The two approaches are, of course, equivalent. Solving the equation numerically, however, we truncate not only the matrices but also the series in Eq. (4.11). The sequences approximating a given eigenvalue are therefore different. Moreover, in the examples given below we find them monotonous in the opposite sense. The sequences coming from Eq. (4.7) were approaching the limiting values from above, while those obtained from Eq. (4.10) were increasing; in combination this gives a good idea about the numerical stability of the solution.

C. Asymmetric case

Let us pass now to the case when the widths of the ducts are nonequal, $d_1 \neq d_2$. Without loss of generality, we may again suppose that $d_2 \leqslant d_1 = d$. With the mirror symmetry with respect to the y-axis in mind, we shall consider the right-halfplane part of Ω only with the Neumann and Dirichlet condition on the segment $\mathscr{W} := [-d_2, d_1]$ of the y-axis.

To expand the sought solution, we need again suitable transverse bases. In the ''connecting part,'' $0 \leqslant x \leqslant a$, we use

$$\eta_k(y) = \sqrt{\frac{2}{D}} \sin[K_k(d_1 - y)], \quad k = 1,2,\ldots, \tag{4.12}$$

where $K_k := kK_1 = k\kappa_1(1+\nu)^{-1}$. On the other hand, for the ducts we choose

$$\chi_j^{(+)}(y) := \sqrt{\frac{2}{d_1}} \sin(\kappa_j y) i_+(y), \quad j = 1,2,\ldots, \tag{4.13}$$

$$\chi_j^{(-)}(y) := -\sqrt{\frac{2}{d_2}} \sin(\kappa_j \nu^{-1} y) i_-(y), \quad j = 1,2,\ldots, \tag{4.14}$$

where $\kappa_j := j\kappa_1$ and $i_\pm$ are the indicator functions of the intervals $\mathscr{D}_+ := [0, d_1]$ and $\mathscr{D}_- := [-d_2, 0]$, respectively.

The union of the two bases is, of course, an orthonormal basis in $L^2(\mathscr{W})$. Since the numerical computation involves a truncation procedure, we need to introduce a proper ordering. For that we arrange the eigenvalues corresponding to Eq. (4.13) to a single nondecreasing sequence. Equivalently, we arrange the numbers $j, k\nu^{-1}$ with $j,k = 1,2,\ldots$ into a nondecreasing sequence (if ν is rational and there is a coincidence, any order can be chosen in the pair); we denote its elements by θ_m,

$$\theta_1 := 1, \quad \theta_2 := \min\{2, \nu^{-1}\}, \quad \text{etc.}$$

The corresponding ordered basis in $L^2(\mathscr{W})$ is

$$\xi_m: \ \xi_m(y) = \begin{cases} \chi_j^{(+)}(y), & \theta_m = j, \\ \chi_j^{(-)}(y), & \theta_m = j\nu^{-1} \end{cases}. \tag{4.15}$$

Consider first the even solutions, i.e., the Neumann condition at $x=0$. A natural Ansatz for a solution of an energy $\epsilon\mu_d$, $(1+\nu)^{-2} \leqslant \epsilon < 1$, is

$$\psi(x,y) := \sum_{k=1}^{\infty} a_k \frac{\cosh(p_k x)}{\cosh(p_k a)} \eta_k(y), \quad 0 \leqslant x \leqslant a,$$

where

$$\psi(x,y) := \sum_{j=1}^{\infty} b_j^{(\pm)} e^{q_j^{(\pm)}(a-x)} \chi_j^{(\pm)}(y), \quad x \geqslant a, \quad y \in \mathscr{D}_{\pm}, \tag{4.16}$$

where

$$p_j := \kappa_1 \sqrt{\left(\frac{j}{1+\nu}\right)^2 - \epsilon}$$

and

$$q_j^{(+)} := \kappa_1 \sqrt{j^2 - \epsilon}, \quad q_j^{(-)} := \kappa_1 \sqrt{\left(\frac{j}{\nu}\right)^2 - \epsilon}.$$

The duct part of Eq. (4.16) can be also written in a unified way as

$$\psi(x,y) = \sum_{m=1}^{\infty} c_m e^{r_m(a-x)} \xi_m(y), \tag{4.17}$$

where

$$c_m := \begin{cases} b_j^{(+)}, & \theta_m = j \\ b_j^{(-)}, & \theta_m = j\nu^{-1}, \end{cases} \quad r_m := \begin{cases} q_j^{(+)}, & \theta_m = j, \\ q_j^{(-)}, & \theta_m = j\nu^{-1}. \end{cases}$$

Using the continuity of the function and its normal derivative at $x=a$ together with the orthonormality of $\{\chi_j^{\pm}\}$, we find conditions for the coefficient sequences,

$$b_j^{(\pm)} = \sum_{k=1}^{\infty} a_k (\chi_j^{(\pm)}, \eta_k), \tag{4.18}$$

$$q_j^{(\pm)} b_j^{(\pm)} + \sum_{k=1}^{\infty} a_k p_k \tanh(p_k a)(\chi_j^{(\pm)}, \eta_k) = 0. \tag{4.19}$$

This can be also written as

$$c_m = \sum_{k=1}^{\infty} a_k (\xi_m, \eta_k), \quad r_m c_m + \sum_{k=1}^{\infty} a_k p_k \tanh(p_k a)(\xi_m, \eta_k) = 0;$$

substituting from the first equation to the second one, we obtain the spectral condition in the form (4.7) with

$$C_{mk} := [r_m + p_k \tanh(p_k a)](\xi_m, \eta_k), \tag{4.20}$$

where the overlap integrals are given by

$$(\chi_j^{(+)}, \eta_k) = \frac{2j}{\pi\sqrt{1+\nu}} \frac{\sin(\pi k/(1+\nu))}{j^2 - (k/(1+\nu))^2},$$

$$(\chi_j^{(-)}, \eta_k) = \frac{2j}{\pi} \sqrt{\frac{\nu}{1+\nu}} \frac{\sin(\pi k/(1+\nu))}{j^2 - (k\nu/(1+\nu))^2}. \tag{4.21}$$

In the odd case, i.e., Dirichlet condition at $x=0$, we get the same equation with tanh replaced by coth in Eq. (4.20).

By a straightforward modification of the above argument, one can check that the coefficient sequences have a faster-than-powerlike decay and the spectral condition can be solved by a sequence of truncations. One can also rewrite the condition in the form analogous to Eq. (4.10), $c + Kc = 0$, where

$$K_{jm} := \frac{1}{r_j} \sum_{k=1}^{\infty} (\xi_j, \eta_k) p_k \tanh(p_k a)(\eta_k, \xi_m). \tag{4.22}$$

V. SCATTERING

The analysis is similar to that of the previous section. The incident wave is supposed to be of the form $\chi_j^{(+)}(y) e^{-ik_j^{(+)}x}$ in the upper channel, where we have introduced

$$k_j^{(+)} := \kappa_1 \sqrt{k^2 - j^2}, \quad k_j^{(-)} := \kappa_1 \sqrt{k^2 - \left(\frac{j}{\nu}\right)^2};$$

we denote by $r_{jj'}^{(\pm)}, t_{jj'}^{(\pm)}$, respectively, the corresponding reflection and transmission amplitudes to the j'th transverse mode in the upper/lower guide. Due to the mirror symmetry, we can again separate the symmetric and antisymmetric situation with respect $x=0$ and to write

$$r_{jj'}^{(\pm)} = \tfrac{1}{2}(\rho_{jj'}^{(s,\pm)} + \rho_{jj'}^{(a,\pm)}), \quad t_{jj'}^{(\pm)} = \tfrac{1}{2}(\rho_{jj'}^{(s,\pm)} - \rho_{jj'}^{(a,\pm)}), \tag{5.1}$$

where $\rho_{jj'}^{(\sigma,\pm)}$, $\sigma = s,a$, are the appropriate reflection amplitudes. In the symmetric case we have the following Ansatz for the solution

$$\psi(x,y) := \sum_{l=1}^{\infty} a_l \frac{\cos(p_l x)}{\cos(p_l a)} \eta_l(y), \quad 0 \leqslant x \leqslant a,$$

$$\psi(x,y) := \sum_{j'=1}^{\infty} (\delta_{jj'} e^{-ik_j^{(+)}(x-a)} + \rho_{jj'}^{(+)} e^{ik_{j'}^{(+)}(x-a)}) \chi_{j'}^{(+)}(y), \quad x \geqslant a, \quad y \in \mathscr{D}_+,$$

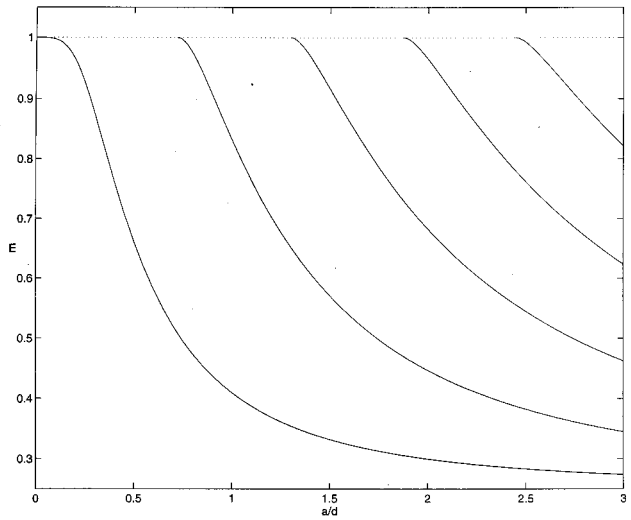

FIG. 2. Bound-state energies vs the window width l in the symmetric case.

$$\psi(x,y) := \sum_{j'=1}^{\infty} \rho_{jj'}^{(-)} e^{ik_{j'}^{(-)}(x-a)} \chi_{j'}^{(-)}(y), \quad x \geqslant a, \quad y \in \mathscr{D}_- . \tag{5.2}$$

The last two relations can be written also as

$$\psi(x,y) = \sum_{m'=1}^{\infty} (\delta_{mm'} e^{-ik_m(x-a)} + \rho_{mm'} e^{ik_{m'}(x-a)}) \xi_{m'}(y),$$

where

$$\rho_{mm'} := \begin{cases} \rho_{jj'}^{(+)}, & \theta_m = j, \quad \theta_{m'} = j', \\ \rho_{jj'}^{(-)}, & \theta_m = j, \quad \theta_{m'} = j' \nu,^{-1} \end{cases} \qquad k_m := \begin{cases} k_j^{(+)}, & \theta_m = j, \\ k_j^{(-)}, & \theta_m = j \nu^{-1}. \end{cases}$$

Matching the functions (5.2) smoothly at $x = a$ we arrive in the same way as above at the equation

$$\sum_{m'=1}^{\infty} [ik_l + p_{m'} \tan(p_{m'} a)](\xi_l, \eta_{m'}) a_{m'} = 2ik_l \delta_{ml}, \tag{5.3}$$

where the index m corresponds to the incident wave and the overlap integrals are given again by Eq. (4.21); in the antisymmetric case one has to replace tan by $-\cot$. The reflection amplitudes are given then by

$$\rho_{ml}^{(\pm)} = -\delta_{ml} + \sum_{m'=1}^{\infty} a_{m'}^{(\pm)}(\xi_l, \eta_{m'}); \tag{5.4}$$

they determine the full S-matrix via Eq. (5.1).

VI. RESULTS

A. Bound states

The results of the mode-matching computation are illustrated on Figs. 2–4. In accordance

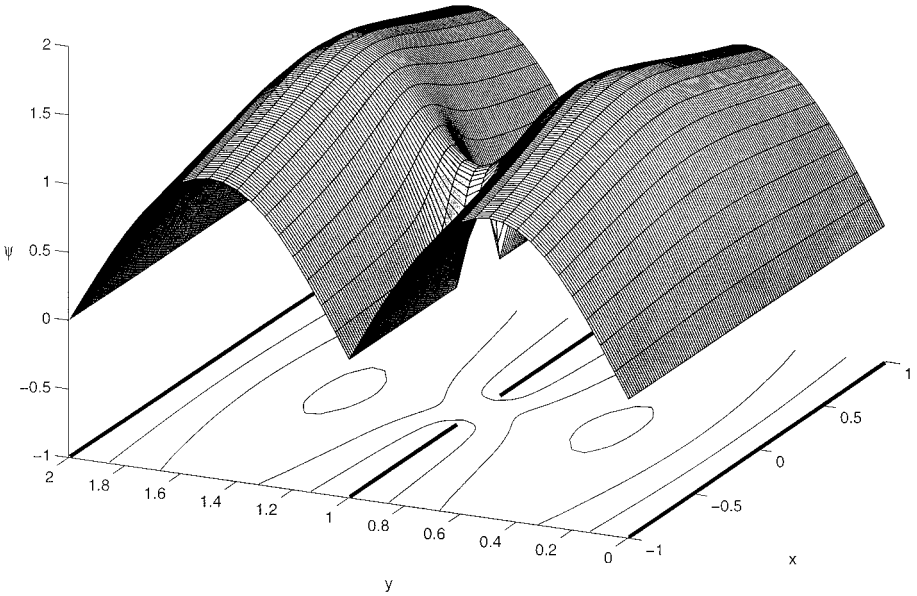

FIG. 3. The ground-state eigenfunction in the symmetric case for $l/d=0.3$.

with the general results of Sec. II the eigenvalues decrease monotonously with the increasing window width and one can sandwich them between the estimates, Eq. (2.5). The eigenfunctions decay exponentially out of the ''interaction'' region. The ground-state wave function is, of course, positive up to a phase factor; the nodal lines of the excited states are parallel to the y-axis. The last feature illustrates once more that apart of the exponential tails in the ducts, the quantum particle ''feels'' the window part as a closed rectangular resonator.

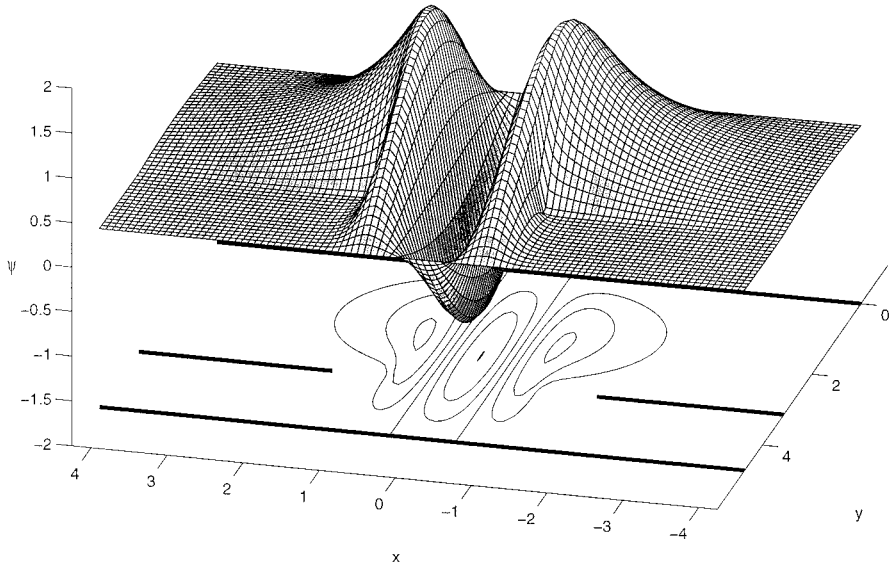

FIG. 4. The eigenfunction of the second excited state in the unsymmetric case, $\nu=1/2$, for $l/d_1=1.08$.

It is also interesting to estimate the rate at which the eigenvalues emerge from the continuum. The results of the mentioned paper[26] together with the Dirichlet bracketing allow us to find a simple upper bound for the ground-state energy by means of a single strip with a ''blister'' whose volume is squeezed to zero. Since the asymptotic formula derived in Ref. 26 applies to ''gentle'' protrusions, it may be employed if the power with which the bump is scaled transversally is larger than the longitudinal one. Hence the gap between the eigenvalue and the continuum for a narrow window is bound from below by $C(\epsilon)l^{4+\epsilon}+\mathcal{O}(l^5)$ for any $\epsilon>0$.

This can be compared with the numerical results. Redrawing the first eigenvalue curve of Fig. 2 and analogous results for $\nu\neq 1$ in the logarithmic scale, we find that the asymptotic behavior is powerlike. The convergence of our method for small l is rather slow; nevertheless, using cutoff dimensions of order 10^3 we get for the power values witnessing clearly that the above bound is saturated,

$$\mu_1(l)=\mu_d-c(\nu)l^4+\mathcal{O}(l^5). \tag{6.1}$$

The numerically found coefficient $c(\nu)$ is monotonous and reaches its maximum value for $\nu=1$; this is the expected behavior as can be seen from a simple bracketing argument. Proving the conjecture (6.1) and finding an analytical expression for $c(\nu)$ remains an open problem; the same can be said about the ''coupling-constant thresholds,'' i.e., the way the other eigenvalues emerge from the continuum.

B. Scattering

The passage of the particle through the window region is determined by the transmission and reflection amplitudes, Eq. (5.1). The physically interesting quantity is the conductivity. If we suppose, for instance, that the particle comes from the upper right guide and leaves through the upper left one, then the conductivity (denoted conventionally as TP and measured in the standard units $2e^2/h$) is given by

$$G(k)=\sum_{j,j'=1}^{[k]} \frac{k_{j'}^{(+)}}{k_j^{(+)}}\,|t_{jj'}^{(+)}(k)|^2, \tag{6.2}$$

and similarly for the other combinations; the summation runs over all open channels. The resonance structure is visible on Fig. 5.

Another insight can be obtained by investigating the probability flow distribution associated with the generalized eigenvector (5.2), which is defined in the standard way,

$$\mathbf{j}(\mathbf{x}):=-i\,\overline{\psi(\mathbf{x})}\,\boldsymbol{\nabla}\psi(\mathbf{x}). \tag{6.3}$$

The flow patterns change with the momentum of the incident particle. They exhibit conspicuous vortices at the resonance energies which represent the ''trapped part'' of the wave function; this phenomenon is illustrated on Fig. 6. It has been argued in the literature that leaky wires similar to those studied here may serve as switching devices.[22] The vortices which emerge in resonance situations lead to the appearance of a magnetic dipole moment, which might be in principle measured experimentally. In this respect situations with a single well developed vortex such as the one illustrated on Fig. 7 are particularly promising.

C. Chaos

Discussing a chaotic behavior of a quantum system, it is useful to start with its classical counterpart, and in particular, its phase space. In the present case of an infinite two-strip ''billiard'' there are no closed classical trajectories with the exception of the obvious zero-measure set;

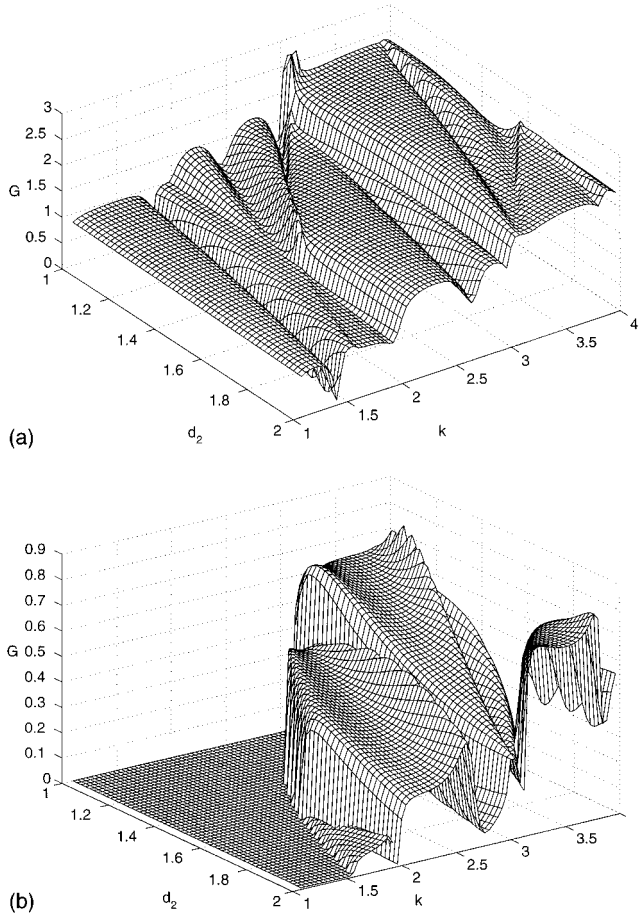

FIG. 5. The conductivity for the particle coming from the right in the upper duct as a function of the momentum k and the width d_2 of the lower tube for $d_1=\pi$, $l=2$. (a) The particle leaves through the upper left channel. A deep resonance is clearly visible. (b) The particle leaves through the lower left channel. The conductivity is zero when there are no propagating modes in the lower part.

hence one has to consider the scattering, i.e., motion of a point particle bouncing its way through the system. The reflection from the walls is supposed be perfectly elastic.

There are two integrals of motion: the longitudinal component of the momentum, $I_1=p_x$, and the modulus of its transverse part, $I_2=|p_y|$. Hence the phase space trajectory of the system is restricted to a two-dimensional manifold (invariant surface) in the four-dimensional phase space. However, due to the singularity of corresponding classical flow at the edges of the connecting window, the topology of this surface is not equivalent to that of a two-dimensional cylinder, but rather of a pair of mutually crossed cylinders; similar systems are usually dubbed pseudo-integrable.[27] The topological structure of the invariant surface has a consequence for the quantum counterpart: the system cannot be quantized semiclassically.

On the other hand, the quantum system of coupled waveguides has in view of our previous arguments bound states, even many of them iff $l\sqrt{\nu}\gg d$. Then one can plot the distribution of the eigenvalue spacing as shown on Fig. 8 for a particular values of ν and l; the character of the distribution does not change as they are varied.

A few comments are due. Since the level statistics depends, in general, on symmetry properties of the corresponding eigenfunction,[28] we have to consider separately bound states of even and

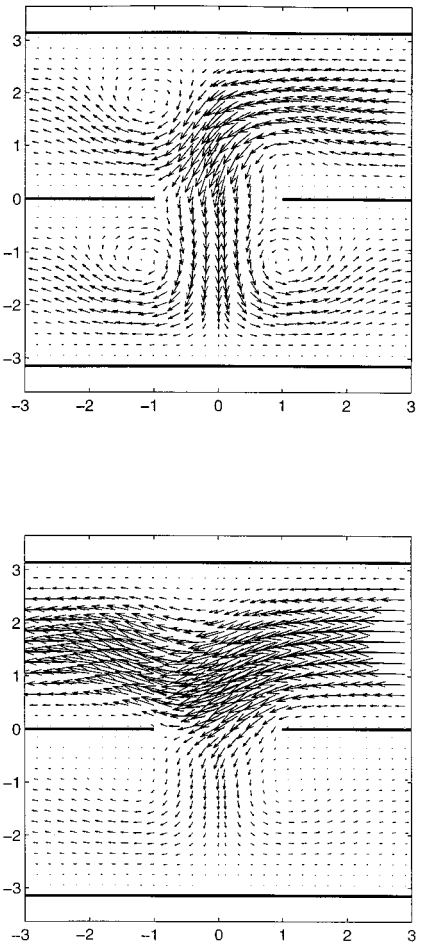

FIG. 6. The quantum probability flow Eq. (6.3), for the symmetric situation, $\nu=1$, in the resonance and nonresonance situation, respectively. The appearance of vortices associated with the resonance scattering is obvious.

odd parity. Furthermore, the inequalities (2.5) show that the energy levels have the same mean spacing if plotted on the scale given by the momentum value $ip_1=\sqrt{\mu_d[\epsilon-(1+\nu)^{-2}]}$. This represents a natural unfolding of our problem; the mean spacing between levels of the same parity then equals $2\pi^2/dl$.

The distributions shown on Fig. 8 differ from typical (unfolded) eigenvalue distributions in billiards, both integrable and chaotic, in the first place due to the existence of the sharp localization around the mean-spacing value. The used statistics (over a thousand eigenvalues in each case) does not allow us to tell what is the behavior around zero; we see, however, that the decay off the peak is at least exponential. This differs substantially from a typical behavior of chaotic systems; however, one should not be surprised because all the corresponding eigenfunctions are dominated transversally by the lowest mode, so the bound-state family in our ''billiard'' is effectively one-dimensional.

It is less trivial whether a chaotic behavior may be manifested in the scattering; recall that spatially restricted pseudo-integrable billiards are known to exhibit the so-called wave chaos.[24] To decide whether a quantum scattering system is chaotic or not, one has to study eigenvalue distribution of the corresponding S-matrix, again properly unfolded, which is expected to conform with that of the Dyson circular ensemble of random matrices[29] in the former case. We have performed

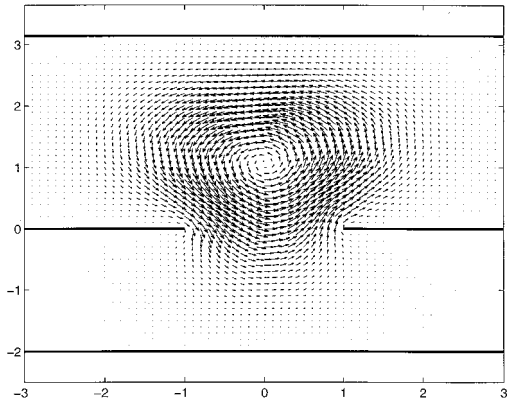

FIG. 7. A single vortex corresponding to the sharp stopping resonance of Fig. 5(a). The conductivity is small in this situation so the waveguide system is closed for the electron transport.

this task for the system under consideration numerically, analyzing the distribution of the spacing between two neighboring eigenvalues of the S-matrix. The result is plotted on Fig. 9; they are compared with the Wigner and the Poissonian distributions peculiar for the chaotic and nonchaotic situation, respectively. It can be seen that the overall shape of this distribution matches the Poissonian distribution for all spacings large enough; on the other hand, the deformation of the distribution near the origin provides a clear sign of nonintegrability of the system. The fact that this nonintegrability differs from a typical chaotic behavior can be attributed to the fact that the scattered particle passes the window region ''only once'' without being bounced to and fro as it is the case of finite billiards.

The absence of the fully developed chaos in the coupled waveguides can also be seen when plotting the coefficients a_l which determine the wave function in the interaction region by Eq. (5.2) as illustrated in Fig. 10. Their distribution remains well localized even for higher energies of

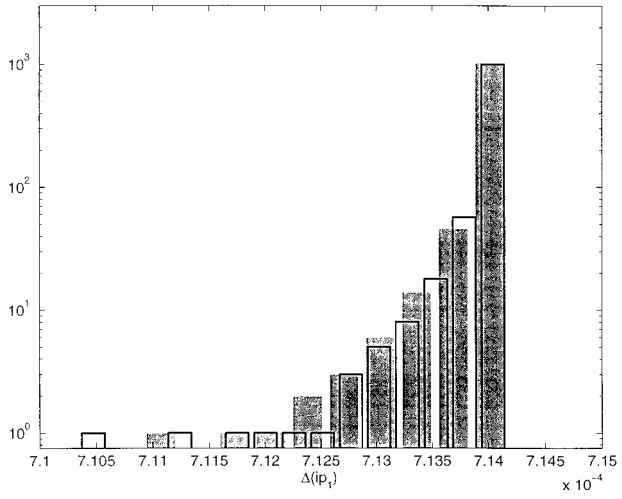

FIG. 8. The unfolded level-spacing distribution of the symmetric and antisymmetric bound states for $d=\pi$, $l=8800$, and $\nu=2(1+\sqrt{5})^{-1}$. The mean momentum distance between eigenvalues of the same parity is 7.1399×10^{-4}. The white and grey boxes correspond to even and odd levels, respectively.

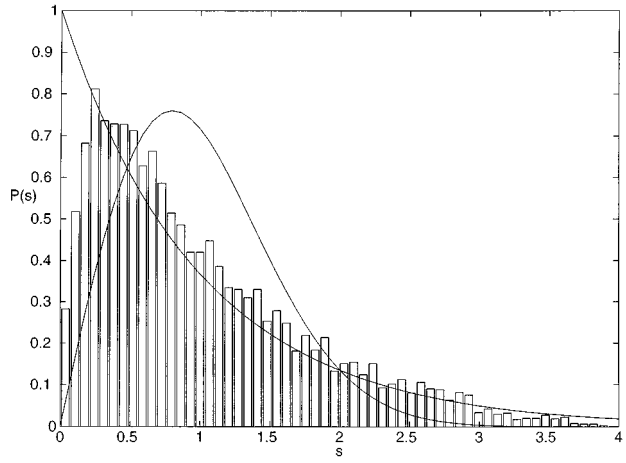

FIG. 9. The unfolded level-spacing distribution for the S-matrix corresponding to $\nu=2/\pi$ and averaged over momentum, in comparison with the Poisson and Wigner distribution.

the incoming particle, its tail being approximately exponential, while in case of an irregular scattering one would expect a slower decay.

VII. TIME EVOLUTION

Up to now we have discussed the coupled waveguide system from the stationary point of view only. Let us look briefly how the window coupling can affect propagation of wave packets in the ducts. This problem has a natural motivation: it has been suggested recently[22,30,31] that coupled electron waveguides provide an analog of the optical directional coupler in the sense that they may switch electrons from one quantum wire to another. Moreover, the authors of Ref. 22 conjectured that the electron switching process should be rather fast due to the direct character of the corresponding resonance, since the electron is not trapped in the interaction region during the resonant switching.

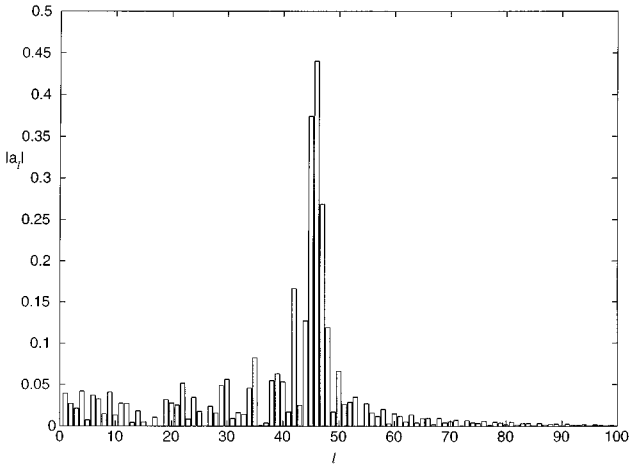

FIG. 10. The absolute value of the coefficients a_l of Eq. (5.2) in the symmetric case for $\nu=2/\pi$ and $k=28.432$; the particle is supposed to be initially in the eighteenth transverse mode.

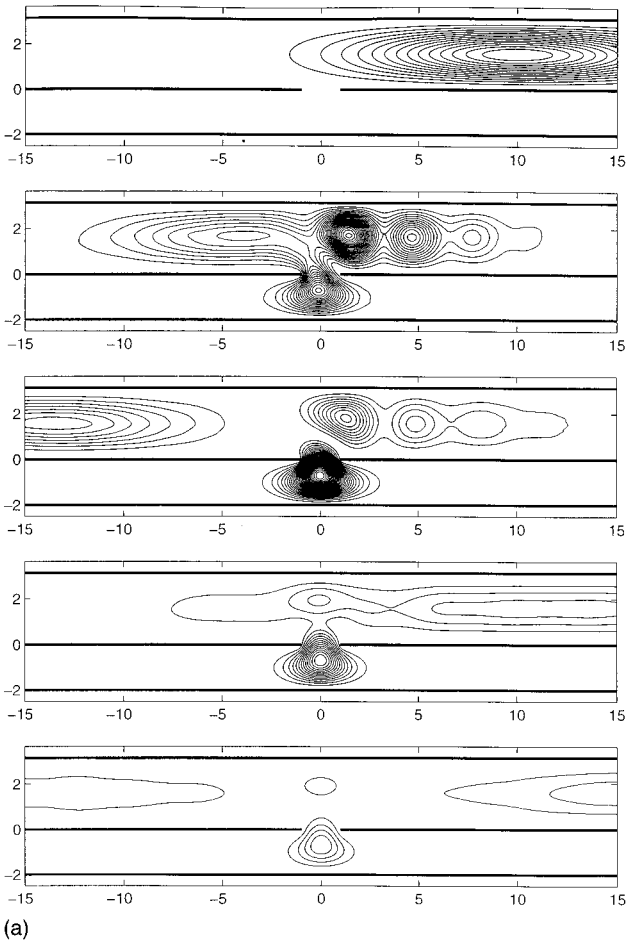
The existence of probability-flow vortices discussed above in the interaction region indicates that this might not be the case, i.e., that the electron dwelling time in the junction may not be generally neglected. To get a better insight we have investigated time evolution of wave packets numerically. This can be achieved by approximating the evolution operator by a Trotter-formula product (see Ref. 12, Sec. VIII.8) with the Dirichlet boundary condition replaced by a very steep and narrow potential barrier localized along the boundary; the latter has been chosen in such a way that the dynamics of the system was equivalent to the dynamics of the true Dirichlet problem for all times taken into account, i.e., that the tunneling leak was negligible during that period.

The kinetic- and potential-part factors of the evolution operator are then multiplication operators in the momentum and coordinate representation, respectively; the passage between the two representations has been realized by means of the two-dimensional fast Fourier transform method[32] with a grid of $2^9\times 2^7$ points. The time evolution of a wave packet approaching the junction through the upper right arm of the structure is plotted on Fig. 11. The incoming wave function was chosen as $\psi(x,y):=g(x)\chi_1^{(+)}(y)$, where $g(x):=\exp\{-a(x-x_0)^2+ikx\}$ with suitably chosen parameters a,x_0.

The difference between the resonant and nonresonant situation is clearly visible. In the first case the electron stays in the junction region and escapes only slowly, while the electron whose



(a)

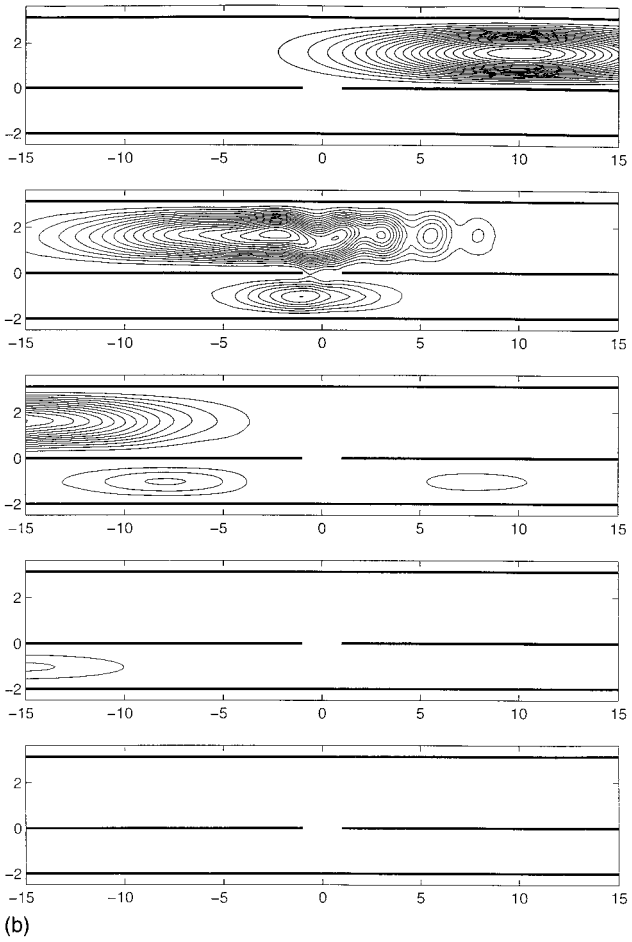

FIG. 11 (*Continued.*)

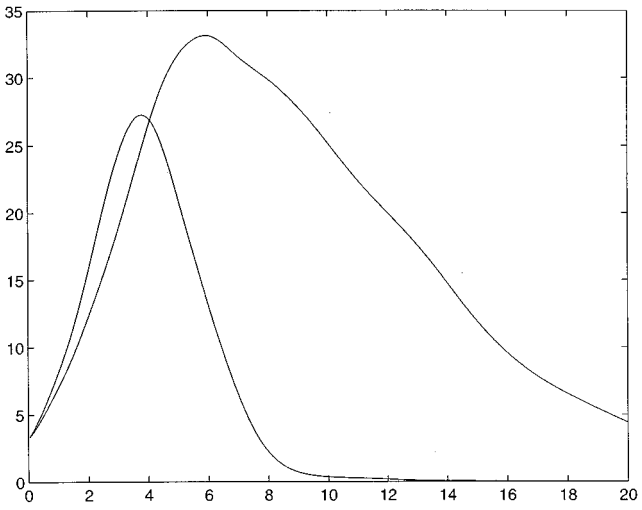

FIG. 12. The probability that the electron will be found within the junction as a function of time evaluated for the same parameters as on Fig. 11.

momentum is localized around a slightly different but nonresonant value of momentum passes the junction ''ballistically.'' Wang and Guo[22] based the mentioned conjecture—which in a realistic situation would lead to ultrashort switching times of a few picoseconds only—on a concept of transmitivity of coupled waveguides leaning on a classical intuition. As we have said in the introduction and demonstrated in the previous sections, this may be a false guide when quantum systems are considered. The example of time evolution offers another illustration. During the resonance-scattering process the evanescent-mode amplitudes inside the quantum wire are considerably enhanced; as a result the electron is trapped temporarily inside the junction. The probability of finding it there in the resonant and nonresonant case, respectively, is shown on Fig. 12. It is desirable to perform the time-delay analysis for the present model, in particular, to confirm that the ''switching time'' of the coupler is inversely proportional to the resonance width.

For a simple model describing the *S*-matrices of open resonators the statistical properties of the resonances are investigated, as well as the wave functions inside the resonator. © *1996 American Institute of Physics.* [S0022-2488(96)00610-X]

I. INTRODUCTION

The properties of ballistic electron transport through a mesoscopic quantum dot are of considerable interest both experimentally and theoretically.[1,2] For the character of the electron motion the shape of the quantum dot is of particular importance. The transport characteristics—such as the conductance fluctuations—are different for shapes which correspond to integrable and chaotic classical motion inside the dot.[3] Similar results have been obtained also in experiments with microwave resonators.[4,5]

The theory accounting for this phenomena is usually based on the so-called stochastic approach, which is able to reproduce the scattering characteristics of the system[6] employing the theory of random matrices. Our aim here is to develop a simple model which will be able to describe not only the corresponding *S*-matrix but also give information about the structure of the wave function inside the cavity.

The system we would like to investigate consists of a cavity (quantum dot, electromagnetic resonator) with attached leads (antenna). The cavity is assumed to be either integrable or fully chaotic. In particular the following characteristics of the system will be of interest for us:

(1) The structure of the *S*-matrix.

(2) Statistical properties of the resonances, including the spacing distribution of the resonance positions and the distribution of the resonance widths.

(3) Statistical properties of the wave function, which is excited inside the cavity by a wave incoming through the waveguide.

We assume that the whole device consists of two different parts. The first part includes ideal leads (waveguides) which couple the device to the measuring apparatus and/or serve as a power

0022-2488/96/37(10)/4888/16/$10.00

supply. The electron/wave moves freely inside these leads, i.e., without scattering by impurities, etc. The second part contains the ''randomizing'' part of the device. Inside this part the electron acquires chaotic features, for instance, through multiple scattering on the boundary of the sample and/or impurities. We shall assume that the dynamics inside this part of the system is chaotic so that its Hamiltonian can be considered as a member of an appropriate random matrix ensemble. We shall also investigate integrable cavities (like a rectangular resonator) and show that the wave transport through it also acquires chaotic features since by connecting such a system to continua one destroys integrability. In the integrable case we shall assume that the internal Hamiltonian is described by a Poisson ensemble.

II. THE MODEL

In this section we shall construct a Hamiltonian describing a resonator coupled to waveguides. Starting with the description of the leads we assume these to support M open channels which are described by one-dimensional Hamiltonians

$$H_l = -\frac{d^2}{dx^2} + \lambda_l, \quad l = 1,\ldots,M. \tag{1}$$

Here λ_l is the threshold energy of the lth channel. Combining these operators into a Hamiltonian H_{ex} for the ''external'' part of the system, i.e., the leads, we get

$$H_{\mathrm{ex}} = -\bigoplus_{l=1}^{M} \frac{d^2}{dx_l^2} + \Lambda. \tag{2}$$

Here Λ is a diagonal matrix describing the threshold energies of the channels,

$$\Lambda = \mathrm{diag}(\lambda_1, \lambda_2, \ldots, \lambda_M). \tag{3}$$

The resonator is described by a Hermitian matrix H_{in} of size $N \times N$, with N much larger than the number of open channels, $N \gg M$. The matrix H_{in} is assumed to belong to the Gaussian orthogonal/unitary ensemble (GOE/GUE) for chaotic resonators and to a Poisson ensemble for integrable ones (see, e.g., Ref. 7 for these concepts). To describe the scattering we couple the resonator and leads by defining the Hamiltonian H of the whole system as

$$H\begin{pmatrix} u \\ u_{\mathrm{in}} \end{pmatrix} = \begin{pmatrix} H_{\mathrm{ex}} u \\ H_{\mathrm{in}} u_{\mathrm{in}} + A u'(0) \end{pmatrix}, \tag{4}$$

where $u = (u_1, \ldots, u_M)$ stands for the wave function inside the leads and u_{in} describes the wave function within the resonator; $u'(0)$ denotes the derivative of the wave functions of the leads at the points of contact with the resonator which are taken as the zeros of the waveguide coordinates, and A is an $N \times M$ coupling matrix. The local character of the coupling in Eq. (4) (a point contact) is justified whenever the diameter of the junction of lead and resonator is smaller than a typical wavelength inside the resonator. The differential operator H_{ex} can be defined on the Sobolev space $W_2^2(R_+, C^M)$ of all complex vector valued square integrable functions on R_+ having two generalized square integrable derivatives. Then the operator H is defined in the Hilbert space $\mathscr{H} = L^2(R^+, C^M) \oplus C^N$ with the scalar product

$$(U, V) = \int_0^\infty \langle u(x), v(x) \rangle_{C^M} dx + \langle u_{\mathrm{in}}, v_{\mathrm{in}} \rangle_{C^N},$$

$\langle \cdot, \cdot \rangle_{C^N}$ denotes the scalar product in the N-dimensional Hilbert space. The domain of the operator H should contain the domain $W_2^2(R_+, C^M) \oplus C^N$ but H is not self-adjoint on the latter domain.

Theorem 1: The operator H defined by formula (4) is self-adjoint on the domain of functions from $W_2^2(R_+,C^M)\oplus C^N$ satisfying the boundary conditions

$$A^\dagger u_{\rm in}=-u(0). \tag{5}$$

Proof: The boundary form of the linear operator H evaluated on the functions $U,V\in W_2^2(R_+,C^M)\oplus C^N$ is given by the following expression

$$\begin{aligned} b[U,V]&=(U,HV)-(HU,V)\\ &=\int_0^\infty \left\langle u(x),-\frac{d^2}{dx^2}\,v(x)+\Lambda v(x)\right\rangle_{C^M} dx+\langle u_{\rm in},H_{\rm in}v_{\rm in}\rangle_{C^N}\\ &\quad+\langle u_{\rm in},Av'(0)\rangle_{C^N}-\int_0^\infty \left\langle -\frac{d^2}{dx^2}\,u(x)+\Lambda u(x),v(x)\right\rangle_{C^M} dx-\langle H_{\rm in}u_{\rm in},v_{\rm in}\rangle_{C^N}\\ &\quad-\langle Au'(0),v_{\rm in}\rangle_{C^N}\\ &=\langle u(0),v'(0)\rangle_{C^M}-\langle u'(0),v(0)\rangle_{C^M}+\langle u_{\rm in},Av'(0)\rangle_{C^N}\\ &\quad-\langle Au'(0),v_{\rm in}\rangle_{C^N}. \end{aligned} \tag{6}$$

The boundary form vanishes if both elements U, V satisfy the boundary conditions (5)

$$\begin{aligned} b[U,V]&=\langle u(0),v'(0)\rangle_{C^M}-\langle u'(0),v(0)\rangle_{C^M}+\langle A^\dagger u_{\rm in},v'(0)\rangle_{C^N}-\langle u'(0),A^\dagger v_{\rm in}\rangle_{C^N}\\ &=\langle u(0),v'(0)\rangle_{C^M}-\langle u'(0),v(0)\rangle_{C^M}-\langle u(0),v'(0)\rangle_{C^M}+\langle u'(0),v(0)\rangle_{C^M}\\ &=0, \end{aligned}$$

where the dagger denotes the adjoint of an operator. This proves that the operator H is symmetric. The self-adjointness of the operator follows from the fact that the range of $H-i$ coincides with the whole Hilbert space $\mathscr{H}$. □

Note: In what follows we shall denote by H the self-adjoint operator defined by formula (4) and the boundary condition (5). The domain of the operator will be denoted by $D(H)$.

Similar models were suggested first in Refs. 8–11. Their main appeal is that they allow for a spectral analysis of the operator H in terms of elementary functions. Moreover, by calculating the eigenfunctions pertaining to the continuous spectrum one may obtain the scattering matrix in terms of the internal Hamiltonian $H_{\rm in}$ and the coupling matrix A. The eigenfunctions

$$\Psi(E)=\begin{pmatrix}\psi(E,x)\\ \psi_{\rm in}\end{pmatrix}$$

corresponding to the energy E solve the equations

$$\begin{pmatrix}-\dfrac{d^2}{dx^2}\,\psi(E,x)+\Lambda\psi(E,x)\\ H_{\rm in}\psi_{\rm in}(E)+A\psi'(E,0)\end{pmatrix}=E\begin{pmatrix}\psi(E,x)\\ \psi_{\rm in}\end{pmatrix}. \tag{7}$$

The second of the foregoing equations leads, together with the boundary condition (5), to the following energy-dependent condition for the external component of the wave function,

$$\psi(E,0)=A^\dagger\,\frac{1}{H_{\rm in}-E}\,A\psi'(E,0). \tag{8}$$

Moreover, the external component is a solution of the free Schrödinger equation. For the energy $E \neq \lambda_j$, $j=1,\ldots,M$, it can be presented in the form

$$\psi(E,x)=\frac{e^{-i\sqrt{E-\Lambda}x}}{\sqrt[4]{E-\Lambda}}\,\mathscr{A}_{\rm inc}-\frac{e^{i\sqrt{E-\Lambda}x}}{\sqrt[4]{E-\Lambda}}\,\mathscr{A}_{\rm out}, \tag{9}$$

where $\mathscr{A}_{\rm inc}$ and $\mathscr{A}_{\rm out}$ are the amplitudes of the incoming and outgoing wave, respectively. For all $E>\max\{\lambda_j\}$ every solution is bounded and the scattering matrix $S(E)$ can easily be defined. The normalization used in Eq. (9) ensures that the S-matrix relates the amplitudes of the incoming and outgoing waves as

$$\mathscr{A}_{\rm out}=S(E).\mathscr{A}_{\rm inc}.$$

The scattering matrix can be calculated substituting the external component of the wave function into the energy-dependent boundary condition (8). The boundary values of the external component at the ''origin,'' i.e., at the coupling points, are equal to

$$\psi(0)=Q(1-S).\mathscr{A}_{\rm inc}, \quad \psi'(0)=iQ^{-1}(-1-S).\mathscr{A}_{\rm inc},$$

where $Q\equiv Q(E)$ denotes the $M\times M$ matrix $Q(E)=(E-\Lambda)^{-1/4}$. For energies above the thresholds the S-matrix can be determined through the following:

Lemma 1: The stationary scattering matrix for the operator H is equal to

$$S(E)=\frac{i+\widetilde{W}^{\dagger}(E-H_{\rm in})^{-1}\widetilde{W}}{i-\widetilde{W}^{\dagger}(E-H_{\rm in})^{-1}\widetilde{W}}, \tag{10}$$

where $E>\max\{\lambda_j\}$ and $\widetilde{W}=AQ^{-1}$.

Similar results were obtained earlier in Ref. 11.

The knowledge of the Hamiltonian of the system enables us to go beyond the standard scattering characteristics and to solve Eq. (7) for the internal-component of the wave function,

$$\psi_{\rm in}=\frac{2}{E-H_{\rm in}}\,\widetilde{W}\,\frac{1}{i-\widetilde{W}^{\dagger}(E-H_{\rm in})^{-1}\widetilde{W}}\,\mathscr{A}_{\rm inc}. \tag{11}$$

In Sec. IV we shall use this formula to evaluate the structure of the wave function in the internal (interaction) part of the system.

Before proceeding further let us shortly comment on the properties of the S-matrix (10). First, we show that the S-matrix (10) can be rewritten in the more familiar form[12]

$$S=I-2\pi i W^{\dagger}\,\frac{1}{E-H_{\rm in}+i\pi WW^{\dagger}}\,W. \tag{12}$$

To prove the equivalence of Eqs. (10) and (12) we use the resolvent equation

$$R(E)=R_0(E)-i\pi R_0(E)P[1+i\pi PR_0(E)P]^{-1}PR_0(E) \tag{13}$$

with $R(E)=(E-H_{\rm in}+i\pi WW^{\dagger})^{-1}$, $R_0(E)=(E-H_{\rm in})^{-1}$, and $P=WW^{\dagger}$. Inserting this into Eq. (12) we obtain after a simple calculation

$$S=\frac{i+\pi W^{\dagger}R_0(E)W}{i-\pi W^{\dagger}R_0(E)W},$$

which is fully equivalent to Eq. (10) provided we identify $\widetilde{W}$ and $\sqrt{\pi}W$. There is, however, one important difference: The coupling matrix $\widetilde{W}$ is energy dependent. This dependence takes into account the threshold effects which are often disregarded in the stochastic approach; it has, however, measurable consequences and leads to the correct high-energy behavior of the S-matrix.[13] We shall come back to this point in Sec. V when we use the model to describe the experimental results obtained for rectangular electromagnetic resonators.

III. RESONANCE DISTRIBUTION

We now propose to study how the distribution of nearest-neighbor spacings between the resonances of our open system differs from the distribution of spacings between eigenenergies of the closed resonator. For simplicity we confine ourselves to the simplest case, that of a single open channel, $M=1$. The original $N\times M$ matrix A becomes then an N-component vector. We shall focus on an integrable resonator rather than a chaotic one since in this case the differences in question turn out to be most drastic: roughly speaking, the opening of the resonator by waveguides destroys the usual spectral signatures of integrability. In what follows we assume that the coupling vector A is normalized as

$$A=ga, \quad \|a\|=1,$$

and that the coupling constant g is large, $g\gg 1$. The resonances of the whole system are the eigenvalues of the effective ''Hamiltonian''

$$H_{\text{eff}}=H_{\text{in}}-i\widetilde{W}\widetilde{W}^{\dagger}=H_{\text{in}}-ig^2aQ^2a^{\dagger}.$$

The ''perturbation'' $-i\widetilde{W}\widetilde{W}^{\dagger}$ of H_{in} is negative imaginary and has rank one. Every eigenfunction of the effective Hamiltonian H_{eff} is a solution to the equation

$$(H_{\text{in}}-ig^2aQ^2a^{\dagger})\psi_{\text{in}}=E\psi_{\text{in}},$$

and comes with a certain resonance energy $E\in\mathbb{C}$. Applying the resolvent of the internal Hamiltonian to the latter equality we get a ''dispersion equation'' for the resonance energy,

$$\frac{1}{g^2\sqrt{\lambda-E}}=a^{\dagger}\,\frac{1}{H_{\text{in}}-E}\,a. \tag{14}$$

Denoting by $F(E)$ the right-hand side (rhs) of Eq. (14) and expressing it in the eigenrepresentation of H_{in} we have

$$F(E)=\sum_{n=1}^{N}\frac{|a_n|^2}{E_n-E}, \tag{15}$$

where E_n are the eigenvalues of the internal Hamiltonian. The function $F(E)$ has a positive imaginary part in the upper half plane and is real on the real axis. Therefore all solutions of Eq. (14) are localized in the lower complex half plane. Consider the case of strong coupling, $g\to\infty$. Then all solutions of the dispersion equation (14) are situated at the zeros of the function $F(E)$. Our aim here is to investigate the distribution of spacings between such zeros (following a method similar to that used in Ref. 14).

It is clear that between two poles there is exactly one zero of $F(E)$. Moreover, two neighboring zeros are locked between three neighboring poles. Since we are interested in the distribution of resonance spacings for small spacings, it suffices to restrict the sum $F(E)$ in Eq. (15) to three terms only, namely, to those whose poles lock up the two colliding zeros of $F(E)$. Let us

label those poles by E_1, E_2, E_3. In order to simplify the expressions (but without loss of generality) we shift the origin of the energy scale to the central pole such that $E_2=0$, whereupon E_1 is negative, $E_1<0$. Then the eigenvalue equation (14) simplifies to

$$\frac{w_1}{E_1-E}-\frac{w_2}{E}+\frac{w_3}{E_3-E}=0 \tag{16}$$

with $w_i=|a_i|^2$, $i=1,2,3$. The two zeros in discussion solve the quadratic equation

$$(w_1+w_2+w_3)E^2-[(w_1+w_2)E_3+(w_2+w_3)E_1]E+w_2E_1E_3=0, \tag{17}$$

and their squared distance $D=s^2$ is given by

$$D=\frac{[(w_1+w_2)E_3+(w_2+w_3)E_1]^2}{(w_1+w_2+w_3)^2}-\frac{w_2E_1E_3}{w_1+w_2+w_3}. \tag{18}$$

Our aim here is to investigate the cumulative probability of these squared spacings, $P(D)=P((z_1-z_2)^2\leqslant D)$, where z_1 and z_2 are the two solutions of Eq. (17) in the case when the internal Hamiltonian H_{in} belongs to the Poisson ensemble, i.e., corresponds to an integrable system. As already announced above that distribution will reveal level repulsion due to the attached waveguides, even though the internal Hamiltonian H_{in} belongs to the Poisson ensemble, i.e., corresponds to an integrable system. Before proceeding further we shall need the following.

Lemma 2: (a) $f(t)\equiv t^\alpha \exp(-t)\leqslant a^\alpha e^{-\alpha}\ \forall t\geqslant 0$, $\alpha>0$. (b) Let $0<\alpha<1$, $b>0$; *then the following estimate is valid*:

$$\int_0^\infty \frac{e^{-br}}{r^{1-\alpha}}\,dr\leqslant\frac{1}{\alpha}+\frac{1}{b}.$$

Proof: (a) holds because f is continuous with maximum at $t=\alpha$. (b) follows from

$$\int_0^\infty \frac{e^{-br}}{r^{1-\alpha}}\,dr=\int_0^1 \frac{e^{-br}}{r^{1-\alpha}}\,dr+\int_1^\infty \frac{e^{-br}}{r^{1-\alpha}}\,dr\leqslant\int_0^1 \frac{1}{r^{1-\alpha}}\,dr+\int_1^\infty e^{-br}dr\leqslant\frac{1}{\alpha}+\frac{1}{b}.$$

□

A. Estimates from above

It follows from Eq. (18) that one can use the following lower estimate for D,

$$D\geqslant -4\,\frac{w_2}{w_1+w_2+w_3}\,E_1E_3. \tag{19}$$

This inequality implies

$$P(D)\leqslant P(X) \tag{20}$$

with $X=-4[w_2/(w_1+w_2+w_3)]E_1E_3$.

Case 1. Constant coupling $w_1=w_2=w_3=1$

Let us assume first that the coefficients w_i are constant and equal, as is not unreasonable when the antenna is attached to a ''symmetry point'' of the resonator and when we restrict ourselves to resonances belonging to one parity class only. For a rectangular resonator this means that we couple the antenna to the geometric center and investigate only resonances which have even–even parity. The probability can be estimated as follows,

$$P(D) \leqslant \int_0^D da \int_{-\infty}^0 dE_1 e^{E_1} \int_0^\infty dE_3 e^{-E_3} \delta(-\tfrac{4}{3} E_1 E_3 - a)$$

$$= -\int_0^D da \int_{-\infty}^0 dE_1 \frac{3}{4E_1} \exp(E_1) \exp\left\{ \frac{3a}{4E_1} \right\}.$$

Thus for any $0<\alpha<1$ we have using Lemmas 2 and 3

$$P(D) \leqslant -\int_0^D da \frac{3}{4} \int_{-\infty}^0 dE_1 \frac{e^{E_1}}{E_1} \left(-\frac{3a}{4E_1} \right)^{-\alpha} \left(-\frac{3a}{4E_1} \right)^{\alpha} \exp\left\{ \frac{3a}{4E_1} \right\}$$

$$\leqslant \left(\frac{3}{4} \right)^{1-\alpha} \int_0^D da \frac{\alpha^\alpha}{a^\alpha} \left(1 + \frac{1}{\alpha} \right) e^{-\alpha}$$

$$= \left(\frac{3}{4} \right)^{1-\alpha} \frac{\alpha^\alpha}{1-\alpha} \left(1 + \frac{1}{\alpha} \right) e^{-\alpha} D^{1-\alpha}$$

$$= C_1(\alpha) D^{1-\alpha}.$$

We note that the latter estimate is valid for any positive value of the parameter α, but the constant $C_1(\alpha)$ tends to infinity when α tends to zero.

Case 2. Poisson distribution of w_i

Another physically relevant case we discuss here is the case when the coupling vector a is complex with coefficients whose real and imaginary parts are independent and normally distributed. Then the w_i are independent random numbers with a χ^2 distribution with two degrees of freedom. Moreover, the sum $w_1+w_2+w_3$ has a χ^2 distribution with 6 degrees of freedom. Having this in mind we obtain that $y=w_2/(w_1+w_2+w_3)$ has a distribution with a density given by $p(y)=2(1-y)$, $y \in [0,1]$. Using Lemma 2 we can estimate $P(D)$ as follows, given by

$$P(D) \leqslant \int_0^D da \int_{-\infty}^0 dE_1 e^{E_1} \int_0^\infty dE_3 e^{-E_3} \int_0^1 dy 2(1-y) \delta(-4yE_1E_3 - a)$$

$$= -\int_0^D da \int_{-\infty}^0 dE_1 e^{E_1} \int_0^1 dy e^{a/4yE_1} \frac{1}{4yE_1} 2(1-y)$$

$$= \int_0^D \frac{da}{a^\alpha} \int_{-\infty}^0 dE_1 e^{E_1} \int_0^1 dy e^{a/4yE_1} \left(-\frac{1}{4yE_1} \right)^{1-\alpha} \left(-\frac{a}{4yE_1} \right)^{\alpha} 2(1-y)$$

$$\leqslant \int_0^D \frac{da}{a^\alpha} \int_0^1 dy 2(1-y) \frac{\alpha^\alpha e^{-\alpha}}{(4y)^{1-\alpha}} \left(\frac{1}{\alpha} + 1 \right) \leqslant C_2(\alpha) D^{1-\alpha}$$

for any $1>\alpha>0$. Similarly as in the previous case $C_2(\alpha)$ is some function of α with $\lim_{\alpha \to 0} C_2(\alpha) = \infty$. Thus we got the same estimate as in the case 1.

A similar estimate is also valid in the case where the components of the vector w are real independent random numbers equally distributed in the interval $[0,1]$.

B. Lower estimates

To obtain a lower estimate for $P(D)$ we use first following upper estimate for the distance between the two zeros:

$$(z_1 - z_2)^2 \leqslant (-E_1 + E_3)^2.$$

Then

$$P(D)\geqslant\int_0^D da\int_{-\infty}^0 dE_1 e^{E_1}\int_0^\infty dE_3 e^{-E_3}\delta((-E_1+E_3)^2-a)$$

$$=\int\int_{-E_1+E_3\leqslant\sqrt{D}} dE_1 dE_3 e^{-(-E_1+E_3)}$$

$$=\frac{1}{2}\int_0^{\sqrt{D}} dx e^{-x}\int_{-x}^{x} dy$$

$$=\int_0^{\sqrt{D}} dx e^{-x}x=1-e^{-\sqrt{D}}(1+\sqrt{D}).$$

Thus the probability $P(D)$ can be approximated from below by a linear function for small values of D,

$$P(D)\geqslant D+o(D)\geqslant BD,$$

where $B\leqslant 1$, $o(D)/D\to 0$ as $D\to 0$.

C. Asymptotic behavior at small spacings

Combining together lower and upper estimates for the probability we can write

$$BD\leqslant P(D)\leqslant C(\alpha)D^{1-\alpha}. \tag{21}$$

A similar estimate can be obtained also for the probability of resonance spacings $\tilde{P}(s)$, $s^2=D$:

$$Bs^2\leqslant\tilde{P}(s)\leqslant C(\alpha)s^{2-2\alpha}. \tag{22}$$

The physically relevant quantity is, however, not the distribution $\tilde{P}(s)$ but the corresponding probability density $p(s)$:

$$\tilde{P}(s)=\int_0^s p(t)dt.$$

Suppose that for small s the probability density has the behavior

$$p(s)\sim ks^\beta+o(s^\beta),$$

with some real constants k and β. Substituting the last asymptotic expansion into the estimate (22) we get for the constants k and β

$$\beta=1,\quad k\geqslant 2B.$$

It follows that the probability density of the spacing s is approximately linear for small values of s. This estimate shows that the presence of the antenna changes the character of the resonance spacing distribution from Poisson to a distribution which displays linear repulsion for small s. For the slope k of the distribution we find $k\geqslant 2$ for small s. This means that the slope k is always larger than the slope of the spacing probability density in a fully chaotic system, which is given by the Wigner distribution with a slope equal to $\pi/2$. The resonance repulsion is therefore always weaker than the level repulsion for a typical GOE matrix.

IV. INTERNAL WAVE FUNCTION

Let us now discuss the properties of the internal wave function (11). To investigate the structure of ψ_{in} in a more detailed way we introduce a coupling constant g and will write $g\widetilde{W}$ for the coupling matrix. The complicated part of this expression is contained in the term

$$\frac{1}{i-g^2T(E)} \tag{23}$$

with the $M\times M$ matrix $T(E)=\widetilde{W}^{\dagger}(E-H_{\text{in}})^{-1}\widetilde{W}$. We solve the spectral problem for the latter matrix:

$$T(E)f_n=\lambda_n(E)f_n \tag{24}$$

[note that for E real $T(E)$ is a symmetric matrix and hence the eigenvalues $\lambda_n(E)$ are real numbers] and use the eigenvectors f_n to define the M vectors ψ_n living in the N-dimensional internal space:

$$\psi_n=(E-H_{\text{in}})^{-1}\widetilde{W}f_n\,. \tag{25}$$

(We shall normalize the vectors f_n, so that $\|f_n\|=1$. This means that the vectors ψ_n are not normalized.)

The vector ψ_n is a solution of the equation

$$\left(H_{\text{in}}+\frac{1}{\lambda_n(E)}\,\widetilde{W}\widetilde{W}^{\dagger}\right)\psi_n=E\psi_n\,. \tag{26}$$

To reveal the usefulness of these vectors we employ the spectral decomposition of the operator (23):

$$\frac{1}{i-g^2T(E)}=\sum_{n=1}^{M}\ \frac{f_nf_n^{\dagger}}{i-g^2\lambda_n(E)} \tag{27}$$

(where $f_nf_n^{\dagger}$ is the projector onto the one-dimensional subspace spanned by the vector f_n). Inserting this into the internal wave function (11) we finally obtain

$$\psi_{\text{in}}=2g\sum_{n=1}^{M}\ \frac{\langle f_n\,,\mathscr{A}_{\text{inc}}\rangle_{C^M}}{i-g^2\lambda_n(E)}\,\psi_n\,. \tag{28}$$

It is most interesting to realize, thus, that internal wave functions (each with N components) can be linearly composed from only M (fewer!) N-component vectors ψ_n.

It can be easily seen that for real energies E the vectors ψ_n are real provided H_{in} and $\widetilde{W}$ are real matrices. The properties of the internal wave function ψ_{in} depend substantially on the structure of these vectors and on the number of terms which contribute to the sum (28). In what follows we shall investigate the structure of ψ_{in} for resonances.

Resonances are defined as poles of the S-matrix in the complex energy plane. Using the above notation the resonances $E_{\text{reson}}=E_r-i\Gamma$ are nothing but the solutions of the following sequence of equations:

$$\lambda_n(E_{\text{reson}})=\frac{i}{g^2},\quad n=1,\ldots,M. \tag{29}$$

(E_r describes the position of the resonance peak, while Γ gives its width.) We shall now assume that the energy E in the incoming wave coincides with the position of some resonance: $E=E_r$. To obtain information about ψ_{in} we insert Eq. (29) into Eq. (26) obtaining for ψ_n

$$(H_{\text{in}}-ig^2\tilde{W}\tilde{W}^{\dagger})\psi_n=E_{\text{reson}}\psi_n\,. \tag{30}$$

It follows therefore that in the resonance case ψ_n are identical with the eigenvectors of the effective Hamiltonian $H_{\text{eff}}=H_{\text{in}}-ig^2\tilde{W}\tilde{W}^{\dagger}$.

For weak coupling ($g\ll 1$) the resonances are localized near the eigenvalues of H_{in} and the resonance widths are small ($\Gamma\ll 1$). Moreover, it follows from Eq. (30) that the vectors ψ_n practically coincide with the eigenvectors of H_{in}. Using the relation $i-g^2\lambda_n(E_r)=-ig^2\Gamma\Lambda_n'(E_r)+O(g^4)$ we obtain from Eq. (28)

$$\psi_{\text{in}}=2i\,\frac{\langle f_{n_0}|\mathscr{A}_{\text{inc}}\rangle_{C^M}}{g\Gamma\lambda_n'(E_r)}\,\psi_{n_0}+O(g)\,, \tag{31}$$

where ψ_{n_0} refers to the appropriate solution of Eq. (30). Consequently, the structure of ψ_{in} coincides with the structure of ψ_{n_0}, which is [up to terms of the order $O(g)$] identical with the corresponding eigenvector of H_{in}.

A similar analysis can be done also for strong coupling ($g\gg 1$). Since $\tilde{W}\tilde{W}^{\dagger}$ is a matrix of rank M the family of resonances can be split into two parts: M resonances are localized deep in the lower complex half plane and have widths $\Gamma\approx g^2$, and the remaining $N-M$ resonances approach the real axis and have widths $\Gamma\approx 1/g^2$. We are interested in the second group of resonances, since they form sharp resonance peaks and are hence easily measurable. A similar analysis as in the weak coupling case gives

$$\psi_{\text{in}}=2i\,\frac{\langle f_{n_0}|\mathscr{A}_{\text{inc}}\rangle_{C^M}}{g\Gamma\lambda_n'(E_r)}\,\psi_{n_0}+O\left(\frac{1}{g}\right). \tag{32}$$

This formula seems to be nearly the same as for weak coupling. There is, however, one deep difference: the position of the resonance E_r does not tend as $g\to\infty$ to some eigenvalue of the internal Hamiltonian H_{in}. This in turn means that the corresponding vector ψ_{n_0} does not coincide with an eigenvector of H_{in}. In fact, for a generic coupling matrix W the vector ψ_{n_0} is a real superposition of all eigenvectors of H_{in}.

For intermediate coupling the resonances overlap and one has to take all terms in Eq. (28) into account. ψ_{in} is in this case a superposition of the vectors ψ_n with complex coefficients.

Let us now discuss the consequences of the above analysis for the statistical properties of the internal wave function ψ_{in}. For weak coupling the properties of ψ_{in} coincide with those of the corresponding eigenfunction of H_{in}. This means that in the GOE case $|\psi_{\text{in}}|^2$ has a Porter–Thomas distribution, similarly for strong coupling. In this case ψ_{in} is proportional to a *real* superposition of the eigenvectors of H_{in}. This means again a Porter–Thomas distribution in the GOE case.

The structure of ψ_{in} becomes interesting in particular for H_{in} describing an integrable system. We know that ψ_{in} becomes a *superposition* of the (integrable) eigenvectors of H_{in}. Hence the internal wave function acquires a structure other than an eigenvector of integrable system. We shall show in the next section that ψ_{in} has features which are similar to the properties of eigenvectors of chaotic quantum systems. This fact supports the finding of the preceding section that opening an integrable system leads to a level repulsion which is typical for the behavior of quantum nonintegrable systems.

It remains to discuss the moderate-coupling case. Here, as already mentioned, the internal vector ψ_{in} becomes a superposition of vectors ψ_n with *complex* coefficients. The consequence is that the statistical properties of ψ_{in} differ from the standard predictions of the random-matrix

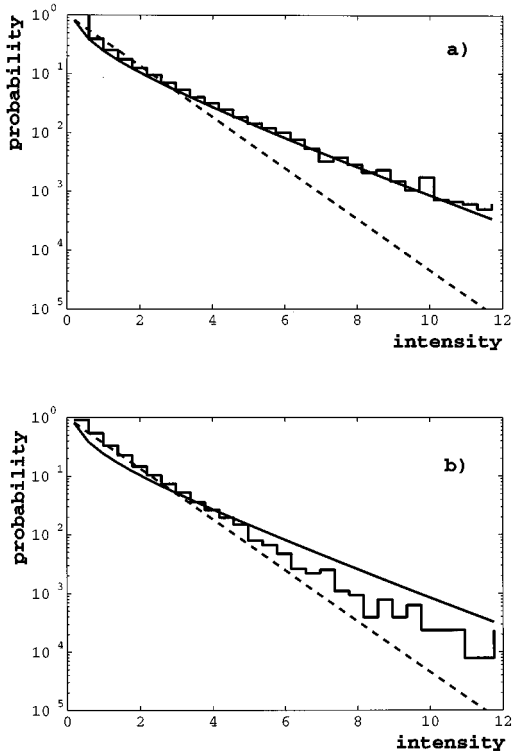

FIG. 1. The intensity distribution $|\psi|^2$ of the internal wave function (11) excited inside the resonator cavity is plotted in a semilogarithmic plot and compared with the Porter–Thomas (dashed line) and the Poisson (Rayleigh) distribution (full line). (a) pertains to one open channel ($M=1$). Good agreement with the Porter–Thomas distribution is visible. (b) shows the result for $M=10$ with a clear shift towards the Poisson distribution.

theory. The complex nature of ψ_{in} moves its statistical properties from a GOE prediction (Porter–Thomas distribution) toward a GUE prediction (Poisson distribution). (Note that ψ_{in} will display a Poisson distribution if its real and imaginary parts are statistically independent and of the same magnitude.) Such a distribution (also known as Rayleigh distribution in the literature[15]) is usually observed when waves excited by a monochromatic source propagate through a random medium—see also Ref. 16. In our case the randomizing effect is due solely to the multiple reflection of the waves inside the resonator. Numerical estimates show that already for $M=3$ the Rayleigh intensity pattern inside the resonator is well developed (see Fig. 1).

V. EXAMPLE

Let us now discuss a rectangular resonator attached to two microwave cables each of which supports one open channel. We assume that the channel threshold energies are set to zero, $\lambda_1=\lambda_2=0$. This system has recently been experimentally investigated in Refs. 4, 5, and 17. The Hamiltonian H_{reson} describing the resonator is given by the two-dimensional Laplace operator

$$H_{\text{reson}}=-\Delta$$

defined on a bounded domain Ω with Dirichlet boundary conditions $f=0$ on the boundary $\partial\Omega$. We shall investigate the statistical properties of the resonances and the structure of the field intensity inside the resonator as excited by waves entering through the microwave cable. Let E_n $[f_n(\mathbf{r}),\mathbf{r}\in\mathbb{R}^2]$ be the eigenvalues [eigenfunctions] of H_{reson}:

$$H_{\text{reson}} f_n(\mathbf{r}) = E_n f_n(\mathbf{r}). \tag{33}$$

Using these solutions let us define the finite-dimensional internal Hamiltonian acting on the space spanned by the first N eigenstates of H_{reson},

$$H_{\text{in}} = \sum_{n=1}^{N} E_n f_n f_n^{\dagger}. \tag{34}$$

The coupling operator A maps the two-dimensional vector

$$\begin{pmatrix} u_1'(0) \\ u_2'(0) \end{pmatrix}$$

into a certain function belonging to the N-dimensional internal space. Let $u_1(x)$ $[u_2(x)]$ denote the first, [second] component of the wave function in the cable. Applying the matrix A to the incoming vector we get

$$A\begin{pmatrix} u_1'(0) \\ u_2'(0) \end{pmatrix} = \alpha_1 d_1^N(\mathbf{r}) u_1'(0) + \alpha_2 d_2^N(\mathbf{r}) u_2'(0),$$

where α_1 and α_2 are the coupling constants and d_l^N, $l=1,2$ are functions spanned by the vectors f_n, $n=1,\ldots,N$. In the experiment the two antennas are coupled to the resonator at the points $\mathbf{r}_1$ and $\mathbf{r}_2$. In order to mimic this local coupling we choose the functions $d_l^N(\mathbf{r})$, $l=1,2$, in a special way, namely, such that they converge to $\delta^2(\mathbf{r}-\mathbf{r}_l)$ when $N\to\infty$, i.e.,

$$d_l^N(\mathbf{r}) = \sum_{i=1}^{N} f_i(\mathbf{r}_l) f_i(\mathbf{r}) \tag{35}$$

such that $\lim_{N\to\infty} d_l^N(\mathbf{r}) = \delta^2(\mathbf{r}-\mathbf{r}_l)$ (in the sense of generalized functions with $\mathbf{r}\in\mathbb{R}^2$).

The Hamiltonian H describing the whole system is self-adjoint on the domain determined by the boundary conditions

$$\langle d_l^N, u_{\text{in}} \rangle = -u_l(0).$$

In the limit $N\to\infty$ the boundary conditions are given by the formula

$$\alpha_l u_{\text{in}}(\mathbf{r}_l) = -u_l(0).$$

For N large enough the S-matrix reads

$$S = \frac{i + T(E)}{i - T(E)} \tag{36}$$

where $T(E)$ is a 2×2 matrix with elements

$$T(E)_{l,m} = \alpha_l \alpha_m \sqrt{E} \sum_{n=1}^{N} \frac{f_n(\mathbf{r}_l) f_m(\mathbf{r}_m)}{E_n - E}. \tag{37}$$

(Implicitly a similar formula has already been used in Ref. 18 in order to evaluate the conductance fluctuation for electrons passing a quantum dot.)

Let us start with the simplest case with one attached antenna only. (The second antenna is easily excluded by choosing the coupling $\alpha_2=0$.) In what follows we shall focus on the statistical properties of the resonances inside such a resonator.

The resonances are identified with the poles of the corresponding S-matrix. In the case of one coupled antenna the resonances are just the solutions of the algebraic equation $T(E)=i$, which is equivalent to

$$\sum_{n=1}^{N} \frac{|f_n(\mathbf{r}_1)|^2}{E_n-E} = \frac{i}{\alpha_1^2\sqrt{E}}. \tag{38}$$

This is an algebraic equation for E which has solutions on the lower complex half plane only. The solutions coincide with the zeros of a certain polynomial of order $2N+1$. One can solve this equation directly using some appropriate numerical method. But before doing this it seems to be helpful to investigate this equation by decoupling it into real and imaginary parts. Let $E=E_r-i\Gamma$ denote a solution with E_r and Γ the position and the width of the resonance, respectively. Assuming that $\Gamma \ll E_r$ we can approximate Eq. (38) by

$$\sum_{n=1}^{N} \frac{|f_n(\mathbf{r}_1)|^2}{E_n-E_r} = 0, \tag{39}$$

whereby the corresponding resonance widths are given by

$$\Gamma = 1 \Big/ \alpha_1^2\sqrt{E_r}\sum_{n=1}^{N} \frac{|f_n(\mathbf{r}_1)|^2}{(E_n-E_r)^2}. \tag{40}$$

This approximation is well justified in particular in the case of strong coupling ($\alpha_1 \gg 1$). In the numerical tests we used this approximate solution as a starting point for a routine searching for the complex roots of Eq. (38).

For the wave function ψ excited inside the resonator we find

$$\psi(\mathbf{r}) = \sum_{k=1}^{2}\sum_{l=1}^{2} 2(E)^{1/4}\alpha_k G(\mathbf{r},\mathbf{r}_k,E)\left(\frac{1}{i-T(E)}\right)_{k,l} \mathscr{A}_{\mathrm{inc},l}, \tag{41}$$

where

$$G(\mathbf{x},\mathbf{x}_k,E) = \sum_{n=1}^{N} \frac{f_n(\mathbf{x})\overline{f_n(\mathbf{x}_k)}}{E_n-E}$$

and $\mathscr{A}_{\mathrm{inc},l}$ denotes the amplitude of the incoming wave in the channel l. It is clear that in the case of a strong coupling to the antenna the structure of the resonance wave function differs substantially from the structure of the original resonator eigenfunction $f_n(x)$.

Let us now apply the above theory to the description of a rectangular resonator with one attached antenna. In the case of a rectangular resonator the eigenvalues E_n and the eigenfunctions f_n are explicitly known. Inserting these solutions into the formulas above we obtain an explicit solution of the perturbed resonator problem. As already mentioned, the resonances of such a system have been measured systematically.[19] In order to enhance the number of measured resonances the results for various rectangular billiards have been combined. In order to reproduce the experimental results we have evaluated resonances for 40 different rectangular billiards. In each billiard we evaluated the first 350 resonances which roughly correspond with the number of experimentally accessible ones. The obtained results have been rescaled (to obtain a mean resonance spacing equal to 1) and divided into three groups: the first group corresponds to resonances

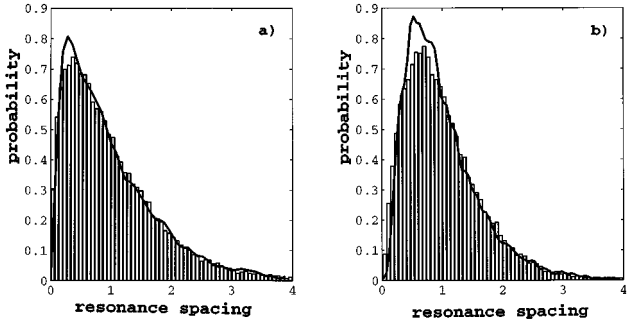

FIG. 2. The distribution of resonance spacings evaluated for a rectangular billiard is plotted (bins) and compared with the experimental results obtained in Ref. 19 (full line). The frequency range used was (a) 5–10 GHz; (b) 10–15 GHz.

measured within the frequency range 5–10 GHz, the second group corresponds to 10–15 GHz, and the third to a frequency range 15–18 GHz. The resonance spacing statistics have been evaluated for each group separately. The coupling constant α_1 has been taken to be equal to 2 in all three cases. The obtained results are plotted in Fig. 2 and compared with the experimental finding. It is worth noting that the theory predicts the effective coupling of the antenna to the resonator to become stronger for higher frequencies. This follows from the fact that the effective coupling of the antenna depends on $\alpha_1^2\sqrt{E}$ and hence on the wave frequency ω. (Note that the energy E and the microwave frequency ω are related by $E \approx \omega^2$.)

The distribution of the corresponding resonance widths is plotted in Fig. 3. We have compared this distribution with the recent prediction by Fyodorov and Sommers[20] for fully chaotic systems (resonators) with one open channel. It is interesting to remark that even though the rectangular resonator is originally integrable the distribution of resonance widths resembles closely that of a fully chaotic system. Clearly, then, the antenna represents a strong perturbation of the original integrable system. This perturbation is also responsible for the observed linear resonance repulsion visible in Fig. 2.

The influence of the antenna on the structure of the corresponding resonance function (i.e., on the structure of the electromagnetic field excited inside the resonator) is demonstrated in Fig. 4.

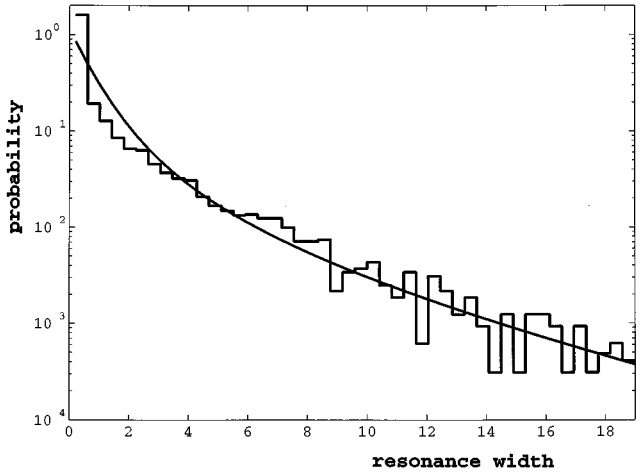

FIG. 3. The distribution of resonance widths evaluated for the frequency range 10–15 GHz is compared with the theoretical prediction for a fully chaotic system with one open channel (Ref. 20).

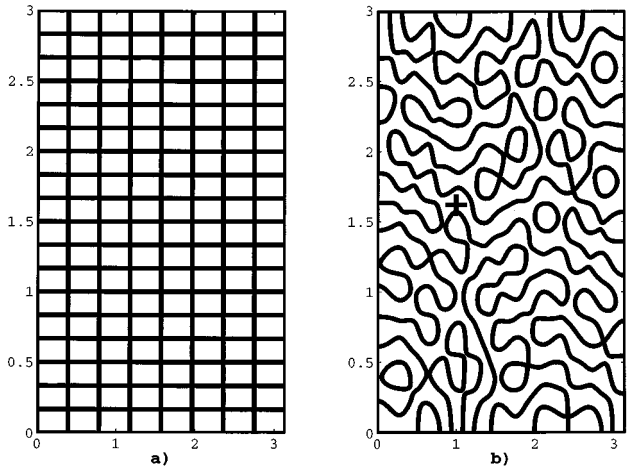

FIG. 4. Nodal lines of the electric field intensity inside a rectangular resonator with sides of lengths π and 3. (a) pertains to the unperturbed 187th state. (b) shows how this nodal line pattern changes after an antenna has been attached at the point marked by a cross.

The figure shows that the structure of the original eigenfunction f_n of the resonator is destroyed.

APPENDIX: PERTURBATION OF THE NEUMANN BOUNDARY CONDITION

The interaction between the external and internal channels can be introduced in a different way. Consider, for example, the operator

$$H_B\begin{pmatrix} u \\ u_{\text{in}} \end{pmatrix} = \begin{pmatrix} H_{\text{ex}}u \\ H_{\text{in}}u_{\text{in}} + Bu(0) \end{pmatrix} \tag{A1}$$

with B being a self-adjoint operator. H_B is self-adjoint on the domain of functions from $W_2^2(R_+, C^M) \oplus C^N$ satisfying the boundary conditions

$$B^\dagger u_{\text{in}} = u'(0).$$

We arrive at the following energy-dependent boundary conditions for the eigenfunctions of the operator H_B:

$$\psi'(E,0) = -B^\dagger (H_{\text{in}} - E)^{-1} B\psi(E,0).$$

Then the scattering matrix above the thresholds is given by

$$S(E) = -\frac{i + \widetilde{W}_B^\dagger (E - H_{\text{in}})^{-1} \widetilde{W}_B}{i - \widetilde{W}_B^\dagger (E - H_{\text{in}})^{-1} \widetilde{W}_B},$$

where $\widetilde{W}_B = BQ$. For the small coupling, $\widetilde{W}_B \to 0$, the scattering matrix tends to -1 and this shows that the model operator constructed here can be considered as a perturbation of the operator H_{ex} with the Neumann boundary conditions at the origin.

(Received 10 April 1996; accepted for publication 9 July 1996)

A diagrammatic method is presented for averaging over the circular ensemble of random-matrix theory. The method is applied to phase-coherent conduction through a chaotic cavity (a ''quantum dot'') and through the interface between a normal metal and a superconductor. © *1996 American Institute of Physics.* [S0022-2488(96)01510-1]

I. INTRODUCTION

The random-matrix theory of quantum transport describes the statistics of transport properties of phase-coherent (mesoscopic) systems in terms of the statistics of random matrices (for reviews, see Refs. 1–4). There exist two separate (but equivalent) approaches: Either the random matrix is used to model the Hamiltonian of the closed system, or it is used to model the scattering matrix of the open system. The second approach is more direct than the first, because the scattering matrix directly determines the conductance through the Landauer formula,

$$G=\frac{2e^2}{h}\,\mathrm{tr}\; tt^\dagger. \tag{1.1}$$

(The transmission matrix t is a submatrix of the scattering matrix.)

Random-matrix theory has been applied successfully to two types of mesoscopic systems: chaotic cavities and disordered wires. Baranger and Mello[5] and Jalabert, Pichard, and Beenakker[6] studied conduction through a chaotic cavity on the assumption that the scattering matrix S is uniformly distributed in the unitary group, restricted only by symmetry. This is the circular ensemble, introduced by Dyson,[7] and shown to apply to a chaotic cavity by Blümel and Smilansky.[8] The symmetry restriction is that $SS^*=1$ in the presence of time-reversal symmetry. (The superscript $*$ indicates complex conjugation if the elements of S are complex numbers; in the presence of spin-orbit scattering, S is a matrix of quaternions, and S^* denotes the quaternion complex conjugate.) For the disordered wire, the circular ensemble applies not to the scattering matrix itself, but to the unitary matrices v, w, v', and w' in the polar decomposition,

$$S=\begin{pmatrix} v & 0 \\ 0 & w \end{pmatrix}\begin{pmatrix} \sqrt{1-T} & i\sqrt{T} \\ i\sqrt{T} & \sqrt{1-T} \end{pmatrix}\begin{pmatrix} v' & 0 \\ 0 & w' \end{pmatrix}. \tag{1.2}$$

The matrix T is a diagonal matrix containing the transmission eigenvalues $T_n \in [0,1]$ on the diagonal. (The T_n's are the eigenvalues of the matrix product $tt^\dagger$.) The distribution of the transmission eigenvalues is governed by a Fokker–Planck equation, the Dorokhov–Mello–Pereyra–Kumar (DMPK) equation.[9,10] The isotropy assumption[10] states that v, v', w, and w' are uniformly and independently distributed in the unitary group, with the restriction $v^*v'=1$, $w^*w'=1$ in the presence of time-reversal symmetry.

The role of the circular ensemble of unitary matrices in the scattering matrix approach is comparable to the role of the Gaussian ensemble of Hermitian matrices in the Hamiltonian approach. However, whereas many computational techniques have been developed for averaging over the Gaussian ensemble,[11–18] the circular ensemble has received less attention. If the dimension N of the unitary matrices is small, the average over the circular ensemble can be done

0022-2488/96/37(10)/4904/31/$10.00

exactly.[19,20] For some applications in the regime of large N, one may regard the elements of the unitary matrix as independent Gaussian variables,[21] and then use the known diagrammatic perturbation theory for the Gaussian ensemble.[12,17] In other applications the Gaussian approximation breaks down.

In this paper we present a diagrammatic technique for integration over the unitary group, which is not restricted to the Gaussian approximation. We discuss two applications: a chaotic cavity coupled to the outside via a tunnel barrier, and a disordered wire attached to a superconductor. In both cases, we calculate the mean and variance of the conductance up to and including terms of order 1. We point out the analogy between the diagrams contributing to the average over the circular ensemble and the diffuson and cooperon diagrams which appear in the theory of weak localization[22,23] and universal conductance fluctuations[24,25] in disordered metals. In the presence of the superconductor a third type of diagrams shows up, which gives rise to the coexistence of weak localization with a magnetic field,[26,27] and to anomalous conductance fluctuations.[28]

The paper starts in Sec. II with a summary of known results[29–31] for the integration over the unitary group of a polynomial function of matrix elements. The diagrammatic technique is explained in Sec. III. Generalizations to unitary symmetric matrices and to unitary quaternion matrices are given in Secs. IV and V, respectively. We then apply the technique to the chaotic cavity (Sec. VI) and the normal-metal–superconductor junction (Sec. VII). Some of the results of Sec. VI have been obtained previously by Iida, Weidenmüller, and Zuk,[1,15] and by Efetov,[32] who used the Hamiltonian approach to quantum transport and the supersymmetry technique. The results of Sec. VII have been published in Refs. 26 and 28, without the detailed derivation presented here. There is some overlap between Sec. VII and a recent work by Argaman and Zee.[33]

II. INTEGRATION OF POLYNOMIALS OF UNITARY MATRICES

In this section we summarize known results[29–31] for the integration of a polynomial function $f(U)$ of the matrix elements of an $N\times N$ unitary matrix U over the unitary group $\mathscr{U}(N)$. We refer to the integration as an ''average,'' which we denote by brackets $\langle\cdots\rangle$,

$$\langle f\rangle \equiv \int dU f(U). \tag{2.1}$$

Here dU is the invariant measure (Haar measure) on $\mathscr{U}(N)$, normalized to unity ($\int dU = 1$). The ensemble of unitary matrices that corresponds to this average is known as the circular unitary ensemble (CUE).[7,34]

We consider a polynomial function $f(U) = U_{a_1 b_1}\ldots U_{a_n b_n} U^*_{\alpha_1\beta_1}\ldots U^*_{\alpha_m\beta_m}$. The average $\langle f(U)\rangle$ is zero unless $n=m$, $\alpha_1,\ldots,\alpha_n$ is a permutation P of $a_1,\ldots,a_n$, and $\beta_1,\ldots,\beta_n$ is a permutation P' of $b_1,\ldots,b_n$. The general structure of the average is

$$\langle U_{a_1 b_1}\ldots U_{a_m b_m} U^*_{\alpha_1\beta_1}\ldots U^*_{\alpha_n\beta_n}\rangle = \delta_{nm}\sum_{P,P'} V_{P,P'}\prod_{j=1}^{n}\delta_{a_j\alpha_{P(j)}}\delta_{b_j\beta_{P'(j)}}, \tag{2.2}$$

where the summation is over all permutations P and P' of the numbers $1,\ldots,n$. The coefficients $V_{P,P'}$ depend only on the *cycle structure* of the permutation $P^{-1}P'$.[30] Recall that each permutation of $1,\ldots,n$ has a unique factorization in disjoint cyclic permutations (''cycles'') of lengths $c_1,\ \ldots\ ,c_k$ (where $n=\sum_{j=1}^{k} c_k$). The statement that $V_{P,P'}$ depends only on the cycle structure of $P^{-1}P'$ means that $V_{P,P'}$ depends only on the lengths $c_1,\ldots,c_k$ of the cycles in the factorization of $P^{-1}P'$. One may therefore write $V_{c_1,\ldots,c_k}$ instead of $V_{P,P'}$.

As an example, we consider the case $n=m=2$ explicitly. The summation over the permutations P and P' extends over the identity permutation $\mathrm{id}=[(1,2)\to(1,2)]$ and the exchange permutation $\mathrm{ex}=[(1,2)\to(2,1)]$. Hence Eq. (2.2) reads

$$\langle U_{a_1b_1}U_{a_2b_2}U^*_{\alpha_1\beta_1}U^*_{\alpha_2\beta_2}\rangle = V_{\mathrm{id,id}}\delta_{a_1\alpha_1}\delta_{b_1\beta_1}\delta_{a_2\alpha_2}\delta_{b_2\beta_2} + V_{\mathrm{ex,id}}\delta_{a_1\alpha_2}\delta_{b_1\beta_1}\delta_{a_2\alpha_1}\delta_{b_2\beta_2} + V_{\mathrm{id,ex}}\delta_{a_1\alpha_1}\delta_{b_1\beta_2}\delta_{a_2\alpha_2}\delta_{b_2\beta_1} + V_{\mathrm{ex,ex}}\delta_{a_1\alpha_2}\delta_{b_1\beta_2}\delta_{a_2\alpha_1}\delta_{b_2\beta_1}. \tag{2.3}$$

The permutation $P^{-1}P'$ that corresponds to $P=P'=\mathrm{id}$ [the first term on the r.h.s. of Eq. (2.3)] is again the identity permutation: $P^{-1}P'=\mathrm{id}=[(1,2)\to(1,2)]$. Its factorization in cyclic permutations is $\mathrm{id}=(1\to1)(2\to2)$, so that $P^{-1}P'$ factorizes in two cyclic permutations of unit length. Hence the cycle structure of $P^{-1}P'$ is $\{1,1\}$, and $V_{\mathrm{id,id}}=V_{1,1}$. The second term on the r.h.s. of Eq. (2.3), corresponding to $P=\mathrm{ex}$, $P'=\mathrm{id}$, has $P^{-1}P'=\mathrm{ex}=[(1,2)\to(2,1)]$, which factorizes in a single cyclic permutation of length two, $\mathrm{ex}=(1\to2\to1)$. Hence the cycle structure of $P^{-1}P'$ is $\{2\}$, and $V_{\mathrm{ex,id}}=V_2$. Treating the remaining two terms of Eq. (2.3) similarly, we obtain

$$\langle U_{a_1b_1}U_{a_2b_2}U^*_{\alpha_1\beta_1}U^*_{\alpha_2\beta_2}\rangle = V_{1,1}\delta_{a_1\alpha_1}\delta_{b_1\beta_1}\delta_{a_2\alpha_2}\delta_{b_2\beta_2} + V_2\delta_{a_1\alpha_2}\delta_{b_1\beta_1}\delta_{a_2\alpha_1}\delta_{b_2\beta_2} + V_2\delta_{a_1\alpha_1}\delta_{b_1\beta_2}\delta_{a_2\alpha_2}\delta_{b_2\beta_1} + V_{1,1}\delta_{a_1\alpha_2}\delta_{b_1\beta_2}\delta_{a_2\alpha_1}\delta_{b_2\beta_1}. \tag{2.4}$$

In general, the coefficient $V_{1,\ldots,1}$ refers to equal permutations $P=P'$, corresponding to a pairwise (Gaussian) contraction of the matrices U and U^*. Coefficients $V_{c_1,\ldots,c_k}$ with some $c_j\neq1$ give non-Gaussian contributions.

The coefficients V are determined by the recursion relation[30]

$$NV_{c_1,\ldots,c_k} + \sum_{p+q=c_1} V_{p,q,c_2,\ldots,c_k} + \sum_{j=2}^{k} c_j V_{c_1+c_j,c_2,\ldots,c_{j-1},c_{j+1},\ldots,c_k} = \delta_{c_1,1}V_{c_2,\ldots,c_k}, \tag{2.5}$$

with $V_0\equiv1$. One can show that the solution $V_{c_1,\ldots,c_k}$ does not depend on the order of the indices $c_1,\ldots,c_k$. Results for V up to $n=5$ are given in the Appendix. The large-N expansion of V is

$$V_{c_1,\ldots,c_k} = \prod_{j=1}^{k} V_{c_j} + \mathcal{O}(N^{k-2n-2}), \tag{2.6a}$$

$$V_c = \frac{1}{c}N^{1-2c}(-1)^{c-1}\binom{2c-2}{c-1} + \mathcal{O}(N^{-1-2c}). \tag{2.6b}$$

(The numbers $c^{-1}\binom{2c-2}{c-1}$ are the Catalan numbers.) For example, $V_{1,\ldots,1}=N^{-n}+\mathcal{O}(N^{-n-2})$. The Gaussian approximation amounts to setting all V's equal to zero except $V_{1,\ldots,1}$, which is set to N^{-n}.

The coefficients $V_{c_1,\ldots,c_k}$ determine the moments of U. Similarly, the coefficients $W_{c_1,\ldots,c_k}$ determine the cumulants of U. The cumulants are obtained from the moments by subsequent subtraction of all possible factorizations in cumulants of lower degree. For example,

$$W_{c_1} = V_{c_1}, \tag{2.7a}$$

$$W_{c_1,c_2} = V_{c_1,c_2} - W_{c_1}W_{c_2}, \tag{2.7b}$$

$$W_{c_1,c_2,c_3} = V_{c_1,c_2,c_3} - W_{c_1}W_{c_2,c_3} - W_{c_2}W_{c_1,c_3} - W_{c_3}W_{c_1,c_2} - W_{c_1}W_{c_2}W_{c_3}. \tag{2.7c}$$

The recursion relation (2.5) for V implies a recursion relation for W,

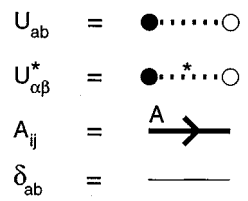

FIG. 1. Substitution rules for the unitary matrices U and U^*, the fixed matrix A and the Kronecker delta.

$$NW_{c_1,\ldots,c_k}+\sum_{p+q=c_1} W_{p,q,c_2,\ldots,c_k}+\sum_{j=2}^{k} c_j W_{c_1+c_j,c_2,\ldots,c_{j-1},c_{j+1},\ldots,c_k}$$
$$+\sum_{p+q=c_1}\sum_{l=1}^{k}\frac{1}{(l-1)!(k-l)!}\sum_{P} W_{p,c_{P(2)},\ldots,c_{P(l)}}W_{q,c_{P(l+1)},c_{P(k)}}=0, \tag{2.8}$$

with $W_0\equiv 1$ and P a permutation of $2,\ldots,k$. To leading order in $1/N$ this equation has the solution,

$$W_{c_1,\ldots,c_k}=2^k N^{-2n-k+2}(-1)^{n+k}\frac{(2n+k-3)!}{(2n)!}\prod_{j=1}^{k}\frac{(2c_j-1)!}{(c_j-1)!^2}+\mathcal{O}(N^{-2n-k}). \tag{2.9}$$

Notice that $W_{c_1,\ldots,c_k}$ decreases with increasing number of cycles k, opposite to the behavior of $V_{c_1,\ldots,c_k}$.

In principle, the recursion relations permit an exact evaluation of the average of any polynomial function of U. In practice, as the number of U's and U^*'s increases, keeping track of the indices and of the Kronecker delta's which connect them becomes more and more cumbersome. It is by the introduction of a diagrammatic technique that one can carry out this bookkeeping problem in a controlled and systematic way.

III. DIAGRAMMATIC TECHNIQUE

The usefulness of diagrams for the bookkeeping problem is well-established for averages over the Gaussian ensemble of Hermitian matrices.[12] Brézin and Zee[17] have developed a diagrammatic method which can be applied to non-Gaussian ensembles as well, as a perturbation expansion in a small parameter multiplying the non-Gaussian terms in the distribution. No such small parameter exists for the circular ensemble. The method presented here deals with non-Gaussian contributions to all orders. Creutz[29] has given a diagrammatic algorithm for integrals over SU(N). Because of the more complicated structure of SU(N), we could not effectively apply his method to integrals over $\mathcal{U}(N)$ in the case of a large number of U's.

The diagrams consist of the building blocks shown in Fig. 1. We represent matrix elements U_{ab} or $U^*_{\alpha\beta}$ by thick dotted lines. The first index (a or α) is a black dot, the second index (b or β) a white dot. A fixed matrix A_{ij} is represented by a directed thick solid line, pointed from the first to the second index. Summation over an index is indicated by attachment of the solid line to a dot. As an example, the functions $f(U)=\mathrm{tr}\,AUBU^\dagger$ and $g(U)=\mathrm{tr}\,AUBUCU^\dagger DU^\dagger$ are represented in Fig. 2.

The average over the matrix U consists of summing over all permutations P and P' in Eq. (2.2). Permutations are generated by drawing thin lines (representing Kronecker deltas) between all black dots attached to U and black dots attached to U^* (one line per dot). Black dots connect

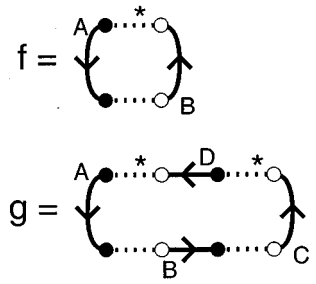

FIG. 2. Diagrammatic representation of the functions $f(U)=\mathrm{tr}\,AUBU^\dagger$ and $g(U)=\mathrm{tr}\,AUBUCU^\dagger DU^\dagger$.

to black dots and white dots to white dots. To find the contribution of the permutations P and P' to $\langle f(U)\rangle$, we need (i) to determine the cycle structure of the permutation $P^{-1}P'$, and (ii) to sum over the indices of the fixed matrices A.

(i) The cycle structure can be read off from the diagrams. A cycle of the permutation $P^{-1}P'$ gives rise to a closed circuit in the diagram consisting of alternating dotted and thin lines. The length c_k of the cycle is half the number of dotted lines contained in the circuit. We call such circuits U-cycles of length c_k.

(ii) The trace over the elements of A is done by inspection of the closed circuits in the diagram which consist of alternating thick and thin lines. We call such circuits T-cycles. A T-cycle containing the matrices $A^{(1)},A^{(2)},\ \ldots\ ,A^{(k)}$ (in this order) gives rise to $\mathrm{tr}\,A^{(1)}A^{(2)}\ldots A^{(k)}$. If the thick line corresponding to a matrix A is traversed opposite to its direction, the matrix should be replaced by its transpose A^{T}.

As an example, let us consider the average of the functions $f(U)=\mathrm{tr}\,AUBU^\dagger$ and $g(U)=\mathrm{tr}\,AUBUCU^\dagger DU^\dagger$. Connecting the dots by thin lines, we arrive at the diagrams of Fig. 3. For f, there is only one diagram. It contains a single U-cycle of length 1 (weight V_1) and two T-cycles (which generate tr A and tr B). We look up the value of $V_1=1/N$ in the Appendix, and find

$$\langle f(U)\rangle = V_1\,\mathrm{tr}\,A\,\mathrm{tr}\,B = N^{-1}\,\mathrm{tr}\,A\,\mathrm{tr}\,B, \tag{3.1}$$

Four diagrams contribute to g. The first diagram contains two U-cycles of length 1, and three T-cycles. Its contribution is $V_{1,1}\,\mathrm{tr}\,A\,\mathrm{tr}\,BD\,\mathrm{tr}\,C$. The second diagram contains two U-cycles of

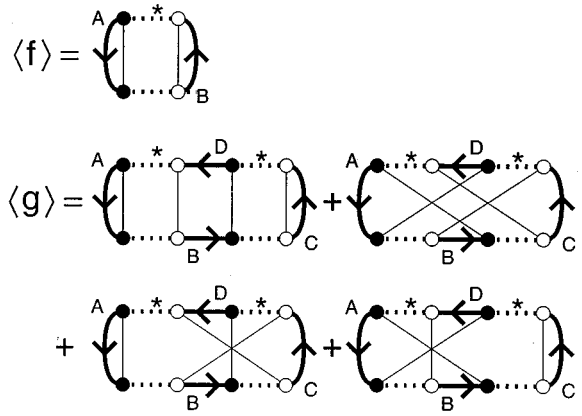

FIG. 3. Diagrammatic representation of the averages of the functions f and g in Fig. 2.

length 1 and a single T-cycle. Its contribution is $V_{1,1}$ tr $ADCB$. The third and fourth diagram each contain a single U-cycle of length 2 and two T-cycles. Their contributions are V_2 tr A tr BDC and V_2 tr ADB tr C. In total we find

$$\begin{aligned}\langle g(U)\rangle &= V_{1,1}(\text{tr } A \text{ tr } BD \text{ tr } C + \text{tr } ADCB) + V_2(\text{tr} A \text{ tr } BDC + \text{tr } ADB \text{ tr } C)\\ &= (N^2-1)^{-1}(\text{tr } A \text{ tr } BD \text{ tr } C + \text{tr } ADCB)\\ &\quad -[N(N^2-1)]^{-1}(\text{tr } A \text{ tr } BDC + \text{tr } ADB \text{tr } C).\end{aligned} \tag{3.2}$$

Whereas each individual T-cycle gives rise to a trace of matrices, it is only the combination of *all* U-cycles together that determines the coefficient $V_{c_1,\ldots,c_k}$. The evaluation of a diagram would be more efficient, if we could attribute a weight to an *individual* U-cycle. We introduced the cumulant expansion of the coefficients V in the coefficients W for this purpose. The leading term $V_{c_1,\ldots,c_k}=\Pi_{p=1}^k W_{c_p}$ of the cumulant expansion attributes a weight W_{c_p} to each individual U-cycle of length c_p. This is sufficient for the calculation of the large-N limit of the average $\langle f\rangle$. The next term $\Sigma_{i<j}^k W_{c_i,c_j}\Pi_{p\neq i,j}^k W_{c_p}$ attributes a weight W_{c_i,c_j} to the pair (i,j) of U-cycles, and the weight W_{c_p} to all others individually. This is sufficient for the variance of f. The general rule is that the jth order cumulant of f in the large-N limit requires the jth order term in the cumulant expansion of the coefficients V, and hence requires consideration of groups of j U-cycles.

Let us summarize the diagrammatic rules:

(1) Draw the diagrams according to the substitution rules of Fig. 1.
(2) Draw thin lines to pair black dots attached to U to black dots attached to U^*. Do the same for the white dots.
(3) Every closed circuit of alternating thick solid lines and thin solid lines (a T-cycle) corresponds to a trace of the matrices A appearing in the circuit. If a thick line is traversed opposite to its direction, the transpose of the matrix appears in the trace.
(4) Every closed circuit of alternating dotted and thin solid lines (a U-cycle) corresponds to a cycle of length c_k equal to half the number of dotted lines. The set of U-cycles in a diagram defines the coefficient $V_{c_1,\ldots,c_k}$, which is the weight of the diagram. The coefficient V can be factorized into cumulants. To determine the cumulant coefficients W, partition the U-cycles into groups. Every group of p U-cycles of lengths $c_1,\ldots,c_p$ contributes a weight $W_{c_1,\ldots,c_p}$.

The diagrammatic rules are exact. In the large-N limit, we may reduce the number of diagrams and partitions that is involved. Let us determine the order in N of a diagram with l T-cycles and k U-cycles of total length n partitioned into g groups. Counting every trace as an order N and using the large-N result (2.9) for the coefficients W, we find a contribution of order $N^{2g+l-k-2n}$. Since $g\leqslant k$, the order is maximal if $g=k$ and the total number of cycles $k+l$ is maximal. Thus, for large N, we may restrict ourselves to diagrams with as many cycles as possible and with a partition of the U-cycles in groups of a single cycle (i.e., we may approximate $V_{c_1,\ldots,c_k}\approx W_{c_1}\cdots W_{c_k}$).

We conclude this section with one more example, which is the calculation of the variance var $f=\langle f^2\rangle-\langle f\rangle^2$ of the function $f(U)=$ tr $AUBU^\dagger$. Diagrammatically, we calculate $\langle f^2\rangle$ as in Fig. 4(a), resulting in

$$\langle f^2\rangle = V_{1,1}[(\text{tr } A)^2(\text{tr } B)^2 + \text{tr } A^2 \text{ tr } B^2] + W_2[\text{tr } A^2(\text{tr } B)^2 + (\text{tr } A)^2 \text{ tr } B^2], \tag{3.3a}$$

$$\begin{aligned}\Rightarrow \text{var } f &= W_{1,1}[(\text{tr } A)^2(\text{tr } B)^2 + \text{tr } A^2 \text{ tr } B^2] + W_1^2 \text{ tr } A^2 \text{ tr } B^2\\ &\quad + W_2[\text{tr } A^2(\text{tr } B)^2 + (\text{tr } A)^2 \text{ tr } B^2].\end{aligned} \tag{3.3b}$$

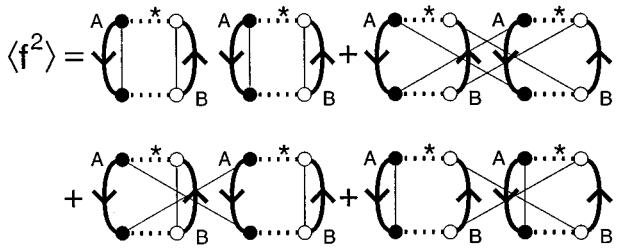

FIG. 4. Diagrammatic representation of $\langle f^2\rangle$.

If we now consider the order in N of the various contributions, we see that the leading $\mathcal{O}(N^2)$ term of $\langle f^2\rangle$ ($l=4$, $g=k=2$, corresponding to 6 cycles and a partition of the U-cycles into two groups of a single cycle), is exactly canceled by $\langle f\rangle^2$. This exact cancelation is possible because the leading contribution of $\langle f^2\rangle$ is *disconnected*: Each T-cycle, and each group of U-cycles belongs entirely to one of the two factors $\mathrm{tr}\, AUBU^\dagger$ of f^2. Only connected diagrams contribute to the variance of f. The connected diagrams are of order 1 ($k+l=4$ and $g=k$ or $k+l=6$ and $g=k-1$). They give the variance

$$\mathrm{var}\, f = W_{1,1}(\mathrm{tr}\, A)^2(\mathrm{tr}\, B)^2 + W_1^2\, \mathrm{tr}\, A^2\, \mathrm{tr}\, B^2 + W_2[\mathrm{tr}\, A^2(\mathrm{tr}\, B)^2 + (\mathrm{tr}\, A)^2\, \mathrm{tr}\, B^2] + \mathcal{O}(N^{-1}). \tag{3.4}$$

IV. INTEGRATION OF UNITARY SYMMETRIC MATRICES

In the presence of time-reversal symmetry the scattering matrix S is both unitary and symmetric: $SS^\dagger=1$, $S=S^{\mathrm{T}}$. The elements of S are complex numbers. (The case of a quaternion S, corresponding to spin-orbit scattering, is treated in the next section.) The ensemble of uniformly distributed unitary symmetric matrices is known as the circular orthogonal ensemble (COE).[7,34] Averages of the unitary symmetric matrix U over the COE can be computed in two ways. One way is to substitute $U=VV^{\mathrm{T}}$, with the matrix V uniformly distributed over the unitary group. This has the advantage that one can use the same formulas as for averages over the CUE, but the disadvantage that the number of unitary matrices is doubled. A more efficient way is to use specific formulas for the COE, as we now discuss.

The average of a polynomial in U and U^* over the COE has the general structure

$$\langle U_{a_1a_2}\cdots U_{a_{2n-1}a_{2n}} U^*_{\alpha_1\alpha_2}\cdots U^*_{\alpha_{2m-1}\alpha_{2m}}\rangle = \delta_{nm}\sum_P V_P \prod_{j=1}^{2n} \delta_{a_j\alpha_{P(j)}}. \tag{4.1}$$

The summation is over permutations P of the numbers $1,\ldots,2n$. We can decompose P as

$$P = \left(\prod_{j=1}^{n} T_j\right) P_{\mathrm{e}} P_{\mathrm{o}} \left(\prod_{j=1}^{n} T'_j\right), \tag{4.2}$$

where T_j and T'_j permute the numbers $2j-1$ and $2j$, and P_{e} (P_{o}) permutes n even (odd) numbers. Because $U_{ab}=U_{ba}$, the moment coefficient V_P depends only on the cycle structure $\{c_1,\ldots,c_k\}$ of $P_{\mathrm{e}}^{-1}P_{\mathrm{o}}$,[35] so that we may write $V_{c_1,\ldots,c_k}$ instead of V_P.

The moment coefficients obey the recursion relation

$$(N+c_1)V_{c_1,\ldots,c_k} + \sum_{p+q=c_1} V_{p,q,c_2,\ldots,c_k} + 2\sum_{j=2}^{k} c_j V_{c_1+c_j,c_2,\ldots,c_{j-1},c_{j+1},\ldots,c_k} = \delta_{c_1 1} V_{c_2,\ldots,c_k}, \tag{4.3}$$

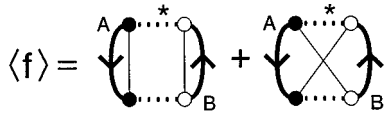

FIG. 5. Diagrammatic representation of $\langle f(U)\rangle$ for $f(U)=\mathrm{tr}\,AUBU^{\dagger}$, where U is a unitary symmetric matrix. The second term arises because of the symmetry constraint.

with $V_0\equiv 1$. The large-N expansion of V is

$$V_{c_1,\ldots,c_k}=\prod_{j=1}^{k} V_{c_j}+\mathcal{O}(N^{k-2n-2}), \tag{4.4a}$$

$$V_c=\frac{1}{c}N^{1-2c}(-1)^{c-1}\binom{2c-2}{c-1}-N^{-2c}(-4)^{c-1}+\mathcal{O}(N^{-1-2c}). \tag{4.4b}$$

Compared with Eq. (2.6) an extra term of order N^{-2c} appears in V_c because of the symmetry restriction. The recursion relation for the cumulant coefficients W is

$$\begin{aligned}(N+c_1)W_{c_1,\ldots,c_k}&+\sum_{p+q=c_1} W_{p,q,c_2,\ldots,c_k}+2\sum_{j=2}^{k} c_j W_{c_1+c_j,c_2,\ldots,c_{j-1},c_{j+1},\ldots,c_k}\\ &+\sum_{p+q=c_1}\sum_{l=1}^{k}\frac{1}{(l-1)!(k-l)!}\sum_{P} W_{p,c_{P(2)},\ldots,c_{P(l)}}W_{q,c_{P(l+1)},c_{P(k)}}=0,\end{aligned} \tag{4.5}$$

with $W_0\equiv 1$ and P a permutation of the numbers $2,\ldots,k$. The solution for large N is

$$W_{c_1,\ldots,c_k}=2^{2k-1}N^{-2n-k+2}(-1)^{n+k}\frac{(2n+k-3)!}{(2n)!}\prod_{j=1}^{k}\frac{(2c_j-1)!}{(c_j-1)!^2}+\mathcal{O}(N^{-2n-k+1}). \tag{4.6}$$

The coefficients $V_{c_1,\ldots,c_k}$ and $W_{c_1,\ldots,c_k}$ are listed in the Appendix for $n=c_1+\cdots+c_k\leqslant 5$.

For the diagrammatic representation, we again use the substitution rules of Fig. 1. The symmetry of U is taken into account by allowing thin lines between black and white dots. Therefore, rule (2) is replaced by

(2) Pair the dots attached to U to the dots attached to U^* by connecting them with thin lines.

As examples, we compute the averages of $f(U)=\mathrm{tr}\,AUBU^{\dagger}$ and $g(U)=\mathrm{tr}\,AUBUCU^{\dagger}DU^{\dagger}$ over the COE. The diagrams for $\langle f(U)\rangle$ are shown in Fig. 5, with the result

$$\langle f(U)\rangle=V_1(\mathrm{tr}\,A\,\mathrm{tr}\,B+\mathrm{tr}\,A^{\mathrm{T}}B)=(N+1)^{-1}(\mathrm{tr}\,A\,\mathrm{tr}\,B+\mathrm{tr}\,A^{\mathrm{T}}B). \tag{4.7a}$$

Similarly, we find that

$$\begin{aligned}\langle g(U)\rangle=&[(N+1)(N+3)]^{-1}(\mathrm{tr}\,A\mathrm{tr}\,BD\,\mathrm{tr}\,C+\mathrm{tr}\,AD^{\mathrm{T}}B^{\mathrm{T}}\,\mathrm{tr}\,C+\mathrm{tr}\,A\,\mathrm{tr}\,BC^{\mathrm{T}}D+\mathrm{tr}\,AD^{\mathrm{T}}CB^{\mathrm{T}}\\ &+\mathrm{tr}\,ADCB+\mathrm{tr}\,AC^{\mathrm{T}}D^{\mathrm{T}}B+\mathrm{tr}\,ADB^{\mathrm{T}}C^{\mathrm{T}}+\mathrm{tr}\,AC^{\mathrm{T}}\,\mathrm{tr}\,BD^{\mathrm{T}})-[(N(N+1)(N+3)]^{-1}\\ &\times(\mathrm{tr}\,A\,\mathrm{tr}\,BDC+\mathrm{tr}\,AC^{\mathrm{T}}D^{\mathrm{T}}B^{\mathrm{T}}+\mathrm{tr}\,A\,\mathrm{tr}\,BD^{\mathrm{T}}C+\mathrm{tr}\,AC^{\mathrm{T}}\,DB^{\mathrm{T}}+\mathrm{tr}\,ADB\,\mathrm{tr}\,C\\ &+\mathrm{tr}\,AD^{\mathrm{T}}B\,\mathrm{tr}\,C+\mathrm{tr}\,ADBC^{\mathrm{T}}+\mathrm{tr}\,AD^{\mathrm{T}}BC^{\mathrm{T}}+\mathrm{tr}\,AD^{\mathrm{T}}B^{\mathrm{T}}C^{\mathrm{T}}+\mathrm{tr}\,AC^{\mathrm{T}}\,\mathrm{tr}\,BD\\ &+\mathrm{tr}\,AD^{\mathrm{T}}\,CB+\mathrm{tr}\,AC^{\mathrm{T}}DB+\mathrm{tr}\,A\,\mathrm{tr}\,BC^{\mathrm{T}}D^{\mathrm{T}}+\mathrm{tr}\,ADCB^{\mathrm{T}}+\mathrm{tr}\,A\,\mathrm{tr}\,BD^{\mathrm{T}}\,\mathrm{tr}\,C\\ &+\mathrm{tr}\,ADB^{\mathrm{T}}\,\mathrm{tr}\,C).\end{aligned} \tag{4.7b}$$

V. INTEGRATION OF MATRICES OF QUATERNIONS

We extend the results of the previous sections for integrals over unitary matrices of complex numbers to integrals over unitary matrices of quaternions. This is relevant to the case that spin-rotation symmetry is broken by spin-orbit scattering.

Let us first recall the definition and basic properties of quaternions.[34] A quaternion q is represented by a 2×2 matrix,

$$q=a_0\mathbb{1}+ia_1\sigma_1+ia_2\sigma_2+ia_3\sigma_3, \tag{5.1}$$

where $\mathbb{1}$ is the 2×2 unit matrix and σ_i is a Pauli matrix,

$$\sigma_1=\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix},\quad \sigma_3=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}. \tag{5.2}$$

The coefficients a_j are complex numbers. The complex conjugate q^* and Hermitian conjugate $q^\dagger$ of a quaternion q are defined as

$$q^*=a_0^*\mathbb{1}+ia_1^*\sigma_1+ia_2^*\sigma_2+ia_3^*\sigma_3,\quad q^\dagger=a_0^*\mathbb{1}-ia_1^*\sigma_1-ia_2^*\sigma_2-ia_3^*\sigma_3. \tag{5.3}$$

The complex conjugate of a quaternion differs from the complex conjugate of a 2×2 matrix, whereas the Hermitian conjugate equals the Hermitian conjugate of a 2×2 matrix. Let Q be an $N\times N$ matrix of quaternions with elements $Q_{kl}=Q_{kl}^{(0)}\mathbb{1}+iQ_{kl}^{(1)}\sigma_1+iQ_{kl}^{(2)}\sigma_2+iQ_{kl}^{(3)}\sigma_3$. The complex conjugate Q^* and Hermitian conjugate $Q^\dagger$ are defined by $(Q^*)_{kl}=Q_{kl}^*$ and $(Q^\dagger)_{kl}=Q_{lk}^\dagger$. The dual matrix Q^{R} is defined by $Q^{\mathrm{R}}=(Q^\dagger)^*=(Q^*)^\dagger$. We call Q unitary if $QQ^\dagger=1$ and self-dual if $Q=Q^{\mathrm{R}}$. A unitary self-dual matrix is defined by $QQ^\dagger=QQ^*=1$. The trace tr Q is defined by tr $Q=\Sigma_j Q_{jj}^{(0)}$, which equals 1/2 the trace of the $2N\times 2N$ complex matrix corresponding to Q. The scattering matrix in zero magnetic field is a unitary self-dual matrix, because of time-reversal symmetry. The ensemble of quaternion matrices which is uniformly distributed over the unitary group is called the circular unitary ensemble (CUE). If the ensemble is restricted to self-dual matrices it is called the circular symplectic ensemble (CSE).[7,34]

The integration of a polynomial function $f(U)$ of an $N\times N$ quaternion matrix U over the CUE or CSE can be related to the integration of a function $\hat{f}(U)$ of an $N\times N$ complex matrix U over the CUE or COE. The translation rule is as follows (a similar rule has been formulated for Gaussian ensembles in Refs. 36 and 37):

(1) $\hat{f}(U)$ is constructed from $f(U)$ by replacing, respectively, the complex conjugates, Hermitian conjugates, and duals of quaternion matrices by complex conjugates, Hermitian conjugates, and transposes of complex matrices. Furthermore, every trace is replaced by $-\frac{1}{2}$ tr, and numerical factors N are replaced by $-\frac{1}{2}N$.
(2) The average $\langle\hat{f}(U)\rangle$ is calculated using the rules for integration of $N\times N$ complex matrices over the CUE or COE.
(3) The average $\langle f(U)\rangle$ over the CUE or CSE is found by replacing, respectively, the complex conjugates, Hermitian conjugates, and transposes of complex matrices by the complex conjugates, Hermitian conjugates, and duals of quaternion matrices. Traces are replaced by -2 tr and numerical factors N by $-2N$.

As examples, we compute the averages of the functions $f(U)=\mathrm{tr}\,AUBU^\dagger$ and $g(U)=\mathrm{tr}\,AUBUCU^\dagger DU^\dagger$ of $N\times N$ quaternion matrices over the CUE and CSE. The first step is to construct the functions $\hat{f}(U)$ and $\hat{g}(U)$ of $N\times N$ complex matrices,

$$\hat{f}(U)=-\tfrac{1}{2}\,\mathrm{tr}\,AUBU^\dagger,\quad \hat{g}(U)=-\tfrac{1}{2}\,\mathrm{tr}\,AUBUCU^\dagger DU^\dagger. \tag{5.4}$$

The second step is to average $\hat{f}$ and $\hat{g}$ over the CUE. The result is in Eqs. (3.1) and (3.2),

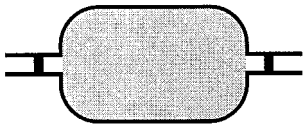

FIG. 6. Chaotic cavity (grey) connected to two leads containing tunnel barriers (black).

$$\langle \hat{f} \rangle_{\rm CUE} = -\tfrac{1}{2} N^{-1} \,{\rm tr}\, A \,{\rm tr}\, B, \tag{5.5a}$$

$$\langle \hat{g} \rangle_{\rm CUE} = -\tfrac{1}{2}(N^2-1)^{-1}({\rm tr}\, A \,{\rm tr}\, BD \,{\rm tr}\, C + {\rm tr}\, ADCB) + \tfrac{1}{2}[N(N^2-1)]^{-1}({\rm tr}\, A \,{\rm tr}\, BDC + {\rm tr}\, ADB \,{\rm tr}\, C). \tag{5.5b}$$

The third step is to translate back to quaternion matrices,

$$\langle f \rangle_{\rm CUE} = N^{-1} \,{\rm tr}\, A \,{\rm tr}\, B, \tag{5.6a}$$

$$\langle g \rangle_{\rm CUE} = (4N^2-1)^{-1}(4\,{\rm tr}\, A \,{\rm tr}\, BD \,{\rm tr}\, C + {\rm tr}\, ADCB) - [N(4N^2-1)]^{-1}({\rm tr}\, A \,{\rm tr}\, BDC + {\rm tr}\, ADB \,{\rm tr}\, C). \tag{5.6b}$$

Similarly, to average of f and g over the CSE we need the average of $\hat{f}$ and $\hat{g}$ over the COE given by Eq. (4.7a), and then translate back to quaternion matrices. For $\langle f(U) \rangle$ we find

$$\langle \hat{f} \rangle_{\rm COE} = -\tfrac{1}{2}(N+1)^{-1}({\rm tr}\, A \,{\rm tr}\, B + {\rm tr}\, A^{\rm T} B),$$

$$\Rightarrow \langle f \rangle_{\rm CSE} = (2N-1)^{-1}(2{\rm tr}\, A \,{\rm tr}\, B - {\rm tr}\, A^{\rm R} B). \tag{5.7a}$$

Similarly, we find for $\langle g(U) \rangle$ the final result

$$\begin{aligned}\langle g \rangle_{\rm CSE} = {} & [(2N-1)(2N-3)]^{-1}(4{\rm tr}\, A \,{\rm tr}\, BD \,{\rm tr}\, C - 2\,{\rm tr}\, AD^{\rm R}B^{\rm R} \,{\rm tr}\, C - 2\,{\rm tr}\, A \,{\rm tr}\, BC^{\rm R}D \\ & + {\rm tr}\, AD^{\rm R}CB^{\rm R} + {\rm tr}\, ADCB + {\rm tr}\, AC^{\rm R}D^{\rm R}B + {\rm tr}\, ADB^{\rm R}C^{\rm R} - 2\,{\rm tr}\, AC^{\rm R} \,{\rm tr}\, BD^{\rm R}) \\ & - [(2N(2N-1)(2N-3)]^{-1}(2\,{\rm tr}\, A \,{\rm tr}\, BDC - {\rm tr}\, AC^{\rm R}D^{\rm R}B^{\rm R} + 2\,{\rm tr}\, A \,{\rm tr}\, BD^{\rm R}C \\ & - {\rm tr}\, AC^{\rm R}DB^{\rm R} + 2\ {\rm tr}\, ADB \,{\rm tr}\, C + 2\,{\rm tr}\, AD^{\rm R}B \,{\rm tr}\, C - {\rm tr}\, ADBC^{\rm R} - {\rm tr}\, AD^{\rm R}BC^{\rm R} \\ & + 2\,{\rm tr}\, A \,{\rm tr}\, BC^{\rm R}D^{\rm R} - {\rm tr}\, ADCB^{\rm R} - 4\,{\rm tr}\, A \,{\rm tr}\, BD^{\rm R} \,{\rm tr}\, C + 2\ {\rm tr}\, ADB^{\rm R} \,{\rm tr}\, C - {\rm tr}\, AD^{\rm R}B^{\rm R}C^{\rm R} \\ & + 2\,{\rm tr}\, AC^{\rm R} \,{\rm tr}\, BD - {\rm tr}\, AD^{\rm R}CB - {\rm tr}\, AC^{\rm R}DB).\end{aligned} \tag{5.7b}$$

VI. APPLICATION TO A CHAOTIC CAVITY

We consider the system shown in Fig. 6, consisting of a chaotic cavity attached to two leads, containing tunnel barriers. The $M \times M$ scattering matrix S is decomposed into $N_i \times N_j$ submatrices s_{ij},

$$S = \begin{pmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{pmatrix}, \tag{6.1}$$

which describe scattering from lead j into lead i ($M = N_i + N_j$). The conductance G is given by the Landauer formula,

$$G/G_0 = {\rm tr}\, s_{12} s_{12}^{\dagger} = {\rm tr}\, C_1 S C_2 S^{\dagger}, \quad G_0 = 2e^2/h. \tag{6.2}$$

The projection matrices C_1 and $C_2=1-C_1$ are defined by $(C_1)_{ij}=1$ if $i=j\leqslant N_1$ and 0 otherwise.

In the absence of tunnel barriers in the leads, S is distributed according to the circular ensemble. The symmetry index $\beta \in \{1,2,4\}$ distinguishes the COE ($\beta=1$), CUE ($\beta=2$), and CSE ($\beta=4$). Calculation of the average and variance of G is straightforward,[5,6]

$$\langle G/G_0\rangle = \frac{\beta N_1 N_2}{\beta M+2-\beta}, \tag{6.3}$$

$$\text{var } G/G_0 = \frac{2\beta N_1 N_2(\beta N_1+2-\beta)(\beta N_2+2-\beta)}{(\beta M+2-2\beta)(\beta M+2-\beta)^2(\beta M+4-\beta)}. \tag{6.4}$$

In the presence of a tunnel barrier in lead i with reflection matrix r_i, the distribution of S is given by the Poisson kernel,[38–41]

$$P(S)\propto \left|\det(1-\overline{S}^{\dagger}S)\right|^{-(\beta M+2-\beta)}, \quad \overline{S}=\begin{pmatrix} r_1 & 0 \\ 0 & r_2 \end{pmatrix}. \tag{6.5}$$

The sub-unitary matrix $\overline{S}$ is the ensemble average of S: $\int dS P(S) S=\overline{S}$. The eigenvalues Γ_j of $1-S\overline{S}^{\dagger}$ are the transmission eigenvalues of the tunnel barriers. The fluctuating part $\delta S\equiv S-\overline{S}$ of S can be parametrized as

$$\delta S = T'(1-UR')^{-1}UT, \tag{6.6}$$

where T, T', and R' are $M\times M$ matrices such that the $2M\times 2M$ matrix

$$\Sigma=\begin{pmatrix} \overline{S} & T' \\ T & R' \end{pmatrix} \tag{6.7}$$

is unitary. The usefulness of the parametrization (6.6) is that U is distributed according the circular ensemble.[21,38,41] In the presence of time-reversal symmetry, we further have $\overline{S}=\overline{S}^{\rm T}$, $T'=T^{\rm T}$, $R'=R'^{\rm T}$, and $U=U^{\rm T}$. Physically, U corresponds to the scattering matrix of the cavity without the tunnel barriers in the leads and Σ corresponds to the scattering matrix of the tunnel barriers in the absence of the cavity.[19,41]

The parametrization (6.6) reduces the problem of averaging S with the Poisson kernel to integrating U over the unitary group. Because the conductance G is a rational function of U, this average cannot be done in closed form for all M. For $N_1, N_2\gg 1$ a perturbative calculation is possible. In this section we will compute the mean and variance of the conductance in the large-N limit, using the diagrammatic technique of the previous sections.

A. Average conductance

According to the Landauer formula (6.2) the average conductance is given by

$$\langle G/G_0\rangle = \langle \text{tr } C_1\delta S C_2 \delta S^{\dagger}\rangle, \tag{6.8}$$

where we have used that $\langle \delta S\rangle=0$. Expansion of the denominator in the parametrization (6.6) of δS yields the series

$$\langle G/G_0\rangle = \sum_{n=1}^{\infty}\langle f_n(U)\rangle, \tag{6.9a}$$

$$f_n(U)=\text{tr } C_1 T'(UR')^{n-1}UTC_2T^{\dagger}U^{\dagger}(R'^{\dagger}U^{\dagger})^{n-1}T'^{\dagger}. \tag{6.9b}$$

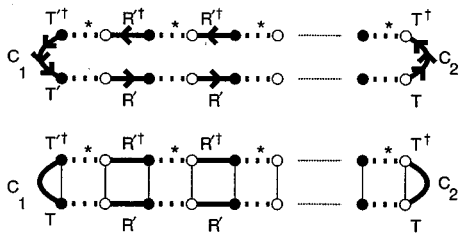

FIG. 7. Top: Diagrammatic representation of the function $f_n(U)$ in Eq. (6.9); Bottom: Ladder diagram with the largest number of cycles, which gives the $\mathcal{O}(N)$ contribution to the average conductance. The arrows are omitted if the direction of the diagram is not ambiguous.

The average of the polynomial function $f_n(U)$ can be calculated diagrammatically. We represent $f_n(U)$ by the top diagram in Fig. 7. The average over the matrix U is done as follows.

The leading contribution, which is of order M, comes from the diagrams with the largest number of T- and U-cycles. For a polynomial of the type (6.8) (all U's are on one side of the $U^\dagger$'s), these diagrams have a ''ladder'' structure (see bottom diagram in Fig. 7). The ladder diagrams contain n U-cycles and $n+1$ T-cycles. Their weight is $W_1^n = M^{-n} + \mathcal{O}(M^{-n-1})$, resulting in

$$\langle f_n(U)\rangle = M^{-n}\,\mathrm{tr}\; T'^{\dagger} C_1 T' (\mathrm{tr}\; R' R'^{\dagger})^{n-1}\,\mathrm{tr}\; T C_2 T^{\dagger} + \mathcal{O}(1). \tag{6.10}$$

Summation of the series (6.9) yields $\langle G\rangle$ to leading order in M,

$$\langle G/G_0\rangle = \frac{(\mathrm{tr}\; T'^{\dagger} C_1 T')(\mathrm{tr}\; T C_2 T^{\dagger})}{M - \mathrm{tr}\; R' R'^{\dagger}} + \mathcal{O}(1) = \frac{(N_1 - \mathrm{tr}\; \overline{S^{\dagger}} C_1 \overline{S})(N_2 - \mathrm{tr}\; \overline{S} C_2 \overline{S^{\dagger}})}{M - \mathrm{tr}\; \overline{S S^{\dagger}}} + \mathcal{O}(1). \tag{6.11}$$

In the second equality we have used the unitarity of the matrix Σ defined in Eq. (6.7).

The weak-localization correction is the $\mathcal{O}(1)$ contribution to $\langle G\rangle$. In general, an $\mathcal{O}(1)$ contribution to the average conductance can have two sources: (i) a higher order contribution to the weight $W_{c_1,\ldots,c_k}$ of the leading-order diagrams, and (ii) higher order diagrams. In the absence of time-reversal symmetry both contributions are absent: (i) $W_1 = M^{-1}$ has no $\mathcal{O}(M^{-2})$ term, and (ii) there are no diagrams of order 1.

The situation is different in the presence of time-reversal symmetry. We discuss the case $\beta = 1$ in which there is no spin-orbit scattering. The case $\beta = 4$ then follows from the translation rule of Sec. V. In the presence of time-reversal symmetry, (i) the coefficient $W_1 = M^{-1} - M^{-2} + \cdots$ has an $\mathcal{O}(M^{-2})$ term, and (ii) there are diagrams of order 1. The first contribution is a correction nM^{-n-1} to the weight M^{-n} in Eq. (6.10). Summation over n yields the first correction to Eq. (6.11),

$$\delta G_1 = -\frac{(\mathrm{tr}\; T'^{\dagger} C_1 T')(\mathrm{tr}\; T C_2 T^{\dagger})}{(M - \mathrm{tr}\; R' R'^{\dagger})^2}. \tag{6.12}$$

The second contribution is from diagrams which are obtained from the ladder diagrams by reversing the order of the contractions in a part of the diagram. The central part of the diagram is ''maximally crossed,'' the left and right ends are ladders (see Fig. 8). In disordered systems, the ladder diagrams are known as diffusons, while the maximally crossed diagrams are known as cooperons. The maximally crossed diagrams are not allowed in the absence of time-reversal

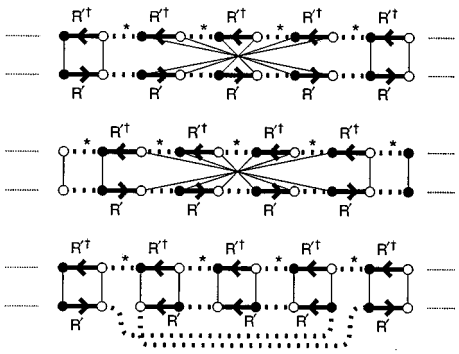

FIG. 8. Top and middle: Two maximally crossed diagrams contributing to the weak-localization correction to the average conductance. The right and left parts of the diagram have a ladder structure; Bottom: The maximally crossed part of the top diagram redrawn as a ladder diagram.

symmetry, because dots of different color are connected by thin lines [violating rule (2) in Sec. III]. A maximally crossed diagram can be redrawn as a ladder diagram by flipping one of the horizontal lines along a vertical axis (bottom diagram in Fig. 8).

In the maximally crossed diagrams all cycles but one have minimum length. The cycle with the exceptional length can be a U-cycle (top diagram in Fig. 8), or a T-cycle (middle diagram). To evaluate these diagrams, we need to introduce some more notation (see Fig. 9). We denote the left and right ladder diagrams by matrices $F_{\rm L}$ and $F_{\rm R}$,

$$F_{\rm L}=T'^{\dagger}C_1T'+\sum_{n=1}^{\infty}M^{-n}(\mathrm{tr}\ T'^{\dagger}C_1T')(\mathrm{tr}\ R'^{\dagger}R')^{n-1}R'^{\dagger}R'$$

$$=T'^{\dagger}C_1T'+\left(\frac{\mathrm{tr}\ T'^{\dagger}C_1T'}{M-\mathrm{tr}\ R'R'^{\dagger}}\right)R'^{\dagger}R', \tag{6.13a}$$

$$F_{\rm R}=TC_2T^{\dagger}+\sum_{n=1}^{\infty}M^{-n}R'R'^{\dagger}(\mathrm{tr}\ R'R'^{\dagger})^{n-1}(\mathrm{tr}\ TC_2T^{\dagger})$$

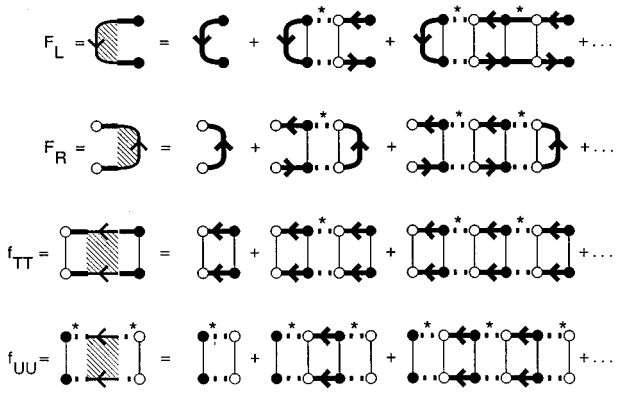

FIG. 9. Diagrammatic representation of Eqs. (6.13) and (6.14).

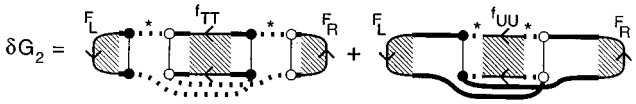

FIG. 10. Diagrammatic representation of the weak-localization correction δG_2 from the maximally crossed diagrams. The total correction $\delta G=\delta G_1+\delta G_2$ contains also a contribution δG_1 from the weight factors [Eq. (6.12)].

$$=TC_2T^\dagger+R'R'^\dagger\left(\frac{\text{tr } TC_2T^\dagger}{M-\text{tr } R'R'^\dagger}\right). \tag{6.13b}$$

The scalars f_{UU} and f_{TT} represent the maximally crossed part of the diagram,

$$f_{TT}=\sum_{n=0}^{\infty} M^{-n}(\text{tr } R'R'^\dagger)^{n+1}=\frac{M \text{ tr } RR'^\dagger}{M-\text{tr } R'R'^\dagger}, \tag{6.14a}$$

$$f_{UU}=\sum_{n=0}^{\infty} M^{-n-1}(\text{tr } R'R'^\dagger)^{n}=\frac{1}{M-\text{tr } R'R'^\dagger}. \tag{6.14b}$$

We used the symmetry of R' to replace R'^{T} by R'. With this notation we may draw the contribution δG_2 to the weak-localization correction from the maximally crossed diagrams as in Fig. 10. It evaluates to

$$\delta G_2=-M^{-3}\,\text{tr } F_{\mathrm{L}}f_{TT}\,\text{tr } F_{\mathrm{R}}+\text{ tr } F_{\mathrm{L}}f_{UU}F_{\mathrm{R}}^{\mathrm{T}}. \tag{6.15}$$

The total weak-localization correction $\delta G=\delta G_1+\delta G_2$ becomes

$$\delta G=-(\text{tr } T^\dagger T)^{-3}[(\text{tr } C_2T^\dagger T)^2\,\text{tr } C_1(T^\dagger T)^2+(\text{tr } C_1T^\dagger T)^2\,\text{tr } C_2(T^\dagger T)^2]. \tag{6.16}$$

Since $T^\dagger T=1-\overline{S^\dagger S}$ has eigenvalues Γ_n, we may write the final result for the average conductance in the form

$$\langle G/G_0\rangle=\frac{g_1g_1'}{g_1+g_1'}+\left(1-\frac{2}{\beta}\right)\frac{g_2g_1'^2+g_2'g_1^2}{(g_1+g_1')^3}+\mathcal{O}(M^{-1}), \tag{6.17}$$

$$g_p=\sum_{n=1}^{N_1}\Gamma_n^p,\quad g_p'=\sum_{n=1+N_1}^{M}\Gamma_n^p. \tag{6.18}$$

(The $\beta=4$ result follows from the translation rule of Sec. V.) The first term in Eq. (6.17) is the series conductance of the two tunnel conductances G_0g_1 and G_0g_1'. The term proportional to $1-2/\beta$ is the weak-localization correction. In the absence of tunnel barriers one has $g_p=N_1$, $g_p'=N_2$, and the large-M limit of Eq. (6.3) is recovered. In the case of two identical tunnel barriers ($N_1=N_2=M/2\equiv N$, $\Gamma_n=\Gamma_{n+N}$ for $n=1,\ldots,N$), Eq. (6.17) simplifies to

$$\langle G/G_0\rangle=\tfrac{1}{2}g_1+\left(1-\frac{2}{\beta}\right)\frac{g_2}{4g_1}+\mathcal{O}(M^{-1}). \tag{6.19}$$

Eq. (6.19) was previously obtained by Iida, Weidenmüller and Zuk[15]. If all Γ_n's are equal to Γ, Eq. (6.19) simplifies further to $\langle G/G_0\rangle=\frac{1}{2}N\Gamma+\frac{1}{4}(1-2/\beta)\Gamma$.

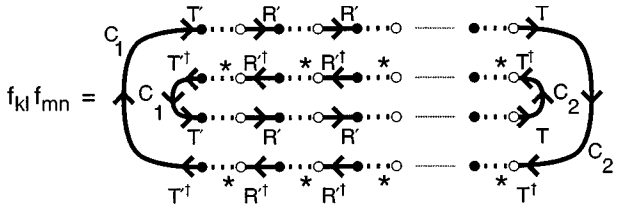

FIG. 11. Diagrammatic representation of a term contributing to G^2, and hence to the variance (6.20) of the conductance.

B. Conductance fluctuations

We seek the effect of tunnel barriers on the variance of the conductance, var $G=\langle G^2\rangle-\langle G\rangle^2$. We consider $\beta=1$ and 2 first, and translate to $\beta=4$ in the end. Using the parametrization (6.6) we write the variance in the form

$$\text{var } G/G_0=\text{var}(\text{tr } C_1\delta S C_2\delta S^\dagger)=\sum_{k,l,m,n\geqslant 1}\text{covar}(f_{kl},f_{mn}), \tag{6.20a}$$

$$f_{kl}=\text{tr } C_1T'(UR')^{k-1}UTC_2T^\dagger U^\dagger(R'^\dagger U^\dagger)^{l-1}T'^\dagger. \tag{6.20b}$$

Since the number U's and U^*'s must be equal for a non-zero average, $\text{covar}(f_{kl},f_{mn})\equiv\langle f_{kl}f_{mn}\rangle-\langle f_{kl}\rangle\langle f_{mn}\rangle=0$ unless $k+m=l+n$. Diagrammatically, we represent $f_{kl}f_{mn}$ by Fig. 11. The diagram consists of an inner loop, corresponding to f_{kl}, and an outer loop, corresponding to f_{mn}. The covariance of f_{kl} and f_{mn} is given by the connected diagrams. We call a diagram ''connected'' if (i) the partition of the U-cycles contains a group which consists of U-cycles from the inner and the outer part, or (ii) the diagram contains a cycle (a U-cycle or a T-cycle) connecting the inner and outer loops.

We first compute the contribution from diagrams which are connected only because of (i), i.e., diagrams in which all U-cycles and T-cycles belong either to the inner or outer loop. The contribution from such a diagram is maximal, if the U-cycles are partitioned in groups which are as small as possible. The optimal partition consists of groups of size 1, except for a single group of size 2, which contains one U-cycle from the inner and one from the outer loop. Furthermore, the total number of cycles is maximal if both the inner and outer loops are ladder diagrams. This requires $k=l$ and $m=n$. The covariance from this diagram is

$$\text{covariance}=km\,\delta_{kl}\delta_{mn}W_{1,1}W_1^{k+m-2}(\text{tr } T'^\dagger C_1T')^2(\text{tr } R'R'^\dagger)^{k+m-2}(\text{tr } TC_2T^\dagger)^2+\mathcal{O}(M^{-1}). \tag{6.21}$$

Summing over k and m we obtain the first contribution to var G/G_0,

$$\text{variance }=M^{-4}(\text{tr } F_{\rm L}\,\text{tr } F_{\rm R})^2. \tag{6.22}$$

The second contribution, consisting of diagrams in which the inner and outer loops are connected by T- or U-cycles, is of maximal order if the partition of the U-cycles involves only groups of size 1. For $\beta=2$ there are 16 connected diagrams of maximal order. They are shown in Fig. 12, and their contribution to var G/G_0 is tabulated in Table I. The shaded areas indicate ladder parts of the diagram (see Figs. 9 and 13). The matrices $F_{\rm L}$ and $F_{\rm R}$, and the scalars f_{UU} and f_{TT} are defined in Eqs. (6.13) and (6.14). The definitions of the matrix H and of the scalars f_{UT} and f_{TU} are

$$f_{UT}=f_{TU}=\sum_{n=0}^{\infty}M^{-n}(\text{tr } R'R'^\dagger)^n=\frac{M}{M-\text{tr } R'R'^\dagger}, \tag{6.23a}$$

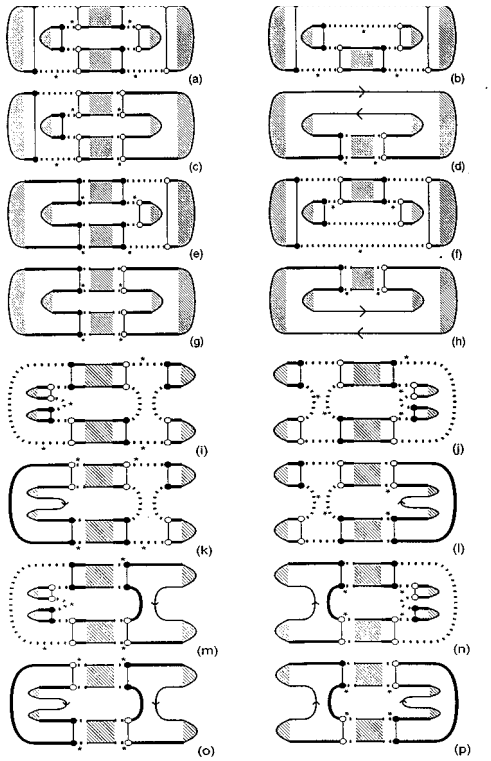

FIG. 12. The 16 connected diagrams which contribute to the variance of the conductance. The shaded parts are defined in Figs. 9 and 13. These diagrams contribute for $\beta=1$ and 2. For $\beta=1$ there are 16 more diagrams, obtained by flipping the inner loop around a vertical axis (diagram a–h) or around a horizontal axis (i–p), so that ladders become maximally crossed.

$$H=M^{-1}(\mathrm{tr}\,F_{\mathrm{R}})R'T'^{\dagger}C_1T'+M^{-1}(\mathrm{tr}\,F_{\mathrm{L}})TC_2T^{\dagger}R'+M^{-2}(\mathrm{tr}\,F_{\mathrm{L}})(\mathrm{tr}\,F_{\mathrm{R}})R'R'^{\dagger}R'. \tag{6.23b}$$

In the presence of time-reversal symmetry ($\beta=1$), the matrix U is symmetric. Diagrammatically, this means that no distinction is made between black and white dots. In addition to the 16 diffuson-like diagrams of Fig. 12, 16 more cooperon-like diagrams contribute. These are obtained from the diagrams of Fig. 12 by flipping the inner loop around a vertical (Figs. 12a–h) or horizontal (Figs. 12i–p) axis, so that segments with a ladder structure become maximally crossed. Their contributions are listed in Table I. The contributions from the individual diffuson-like and cooperon-like diagrams are different. The total contribution to var G from diffuson-like and cooperon-like diagrams is the same.

The final result for the variance of G is

$$\begin{aligned}\mathrm{var}\,G/G_0=2\beta^{-1}(g_1+g_1')^{-6}(&2g_1^4g_1'^2+4g_1^3g_1'^3-4g_1^2g_2g_1'^3+2g_1^2g_1'^4\\&-2g_1g_2g_1'^4+3g_2^2g_1'^4-2g_1g_3g_1'^4+2g_2g_1'^5-2g_3g_1'^5+2g_1^5g_2'-2g_1^4g_1'g_2'\\&-4g_1^3g_1'^2g_2'+6g_1^2g_2g_1'^2g_2'+3g_1^4g_2'^2-2g_1^5g_3'-2g_1^4g_1'g_3').\end{aligned} \tag{6.24}$$

Eq. (6.24) was previously obtained by Efetov.[32] One verifies that the large-N limit of Eq. (6.4) is recovered in the absence of tunnel barriers. For the special case of identical tunnel barriers ($g_p=g_p'$), this simplifies to

p	$\mathrm{tr}\, R'^\dagger H f_{UU}^2\,\mathrm{tr}\, H^\dagger R'$	$\mathrm{tr}\, R'^* H f_{UU}^2\,\mathrm{tr}\, H^* R'$

$$\mathrm{var}\, G/G_0=(8\beta g_1^2)^{-1}(2g_1^2-2g_1g_2+3g_2^2-2g_1g_3), \tag{6.25}$$

in agreement with Ref. 15. Another special case is that of high tunnel barriers, $\Gamma_n \ll 1$ for all n, when Eq. (6.24) simplifies to[42]

$$\mathrm{var}\, G/G_0=4\beta^{-1}(g_1+g_1')^{-4}g_1^2 g_1'^2. \tag{6.26}$$

If all transmission eigenvalues $\Gamma_n \equiv \Gamma$ are equal, one has var $G/G_0=(8\beta)^{-1}[1+(1-\Gamma)^2]$. A high tunnel barrier ($\Gamma \ll 1$) thus doubles the variance.

C. Density of transmission eigenvalues

The transmission eigenvalues $T_n \in [0,1]$ are the N_1 eigenvalues of the matrix product $s_{12}s_{12}^\dagger$. Without loss of generality we may assume that $N_1 \leq N_2$. The matrix product $s_{21}s_{21}^\dagger$ then

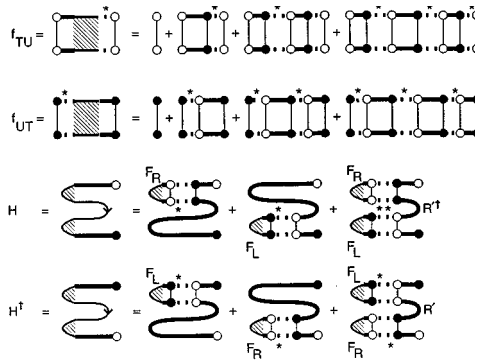

FIG. 13. Diagrammatic representation of Eq. (6.23).

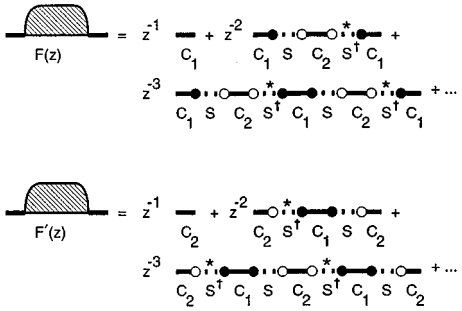

FIG. 14. Diagrammatic representation of the Green functions for the density of transmission eigenvalues.

has the same N_1 eigenvalues as $s_{12}s_{12}^\dagger$, plus N_2-N_1 eigenvalues equal to zero. The N_1 non-zero transmission eigenvalues appear as the diagonal elements of the diagonal matrix T in the polar decomposition of the scattering matrix

$$S=\begin{pmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{pmatrix}=\begin{pmatrix} v & 0 \\ 0 & w \end{pmatrix}\begin{pmatrix} \sqrt{1-T} & 0 & i\sqrt{T} \\ 0 & \mathbb{1} & 0 \\ i\sqrt{T} & 0 & \sqrt{1-T} \end{pmatrix}\begin{pmatrix} v' & 0 \\ 0 & w' \end{pmatrix}. \tag{6.27}$$

Here v and v' (w and w') are $N_1\times N_1$ ($N_2\times N_2$) unitary matrices and $\mathbb{1}$ is the N_2-N_1 dimensional unit matrix. If $N_1=N_2$, Eq. (6.27) simplifies to Eq. (1.2).

So far we have only studied the conductance $G=G_0\Sigma_n T_n$. The leading contribution to the average conductance comes from ladder diagrams. If we wish to average transport properties of the form $A=\Sigma_n a(T_n)$ (so-called linear statistics on the transmission eigenvalues), we need to know the density $\rho(T)$ of the transmission eigenvalues T_n. The leading-order contribution to the transmission-eigenvalue density is given by a larger class of diagrams, as we now discuss.

The density $\rho(T)=\langle\Sigma_{n=1}^{N_1}\delta(T-T_n)\rangle$ of the transmission eigenvalues follows from the matrix Green function $F(z)$:

$$F(z)=\langle C_1(z-SC_2S^\dagger C_1)^{-1}\rangle, \tag{6.28a}$$

$$\rho(T)=-\pi^{-1}\,\mathrm{Im\ tr}\,F(T+i\epsilon), \tag{6.28b}$$

where ϵ is a positive infinitesimal. We first compute $\rho(T)$ in the absence of tunnel barriers, when the result is known from other methods.[4–6,43] Then we include the tunnel barriers, when the result is not known.

In the absence of tunnel barriers, the scattering matrix S is distributed according to the circular ensemble, so that averaging amounts to integrating over the unitary group. We compute $F(z)$ as an expansion in powers of $1/z$,

$$F(z)=\sum_{n=0}^{\infty}\langle C_1 z^{-1}(SC_2S^\dagger C_1 z^{-1})^n\rangle. \tag{6.29}$$

We will also need the Green function

$$F'(z)=\langle C_2(z-S^\dagger C_1 SC_2)^{-1}\rangle=\sum_{n=0}^{\infty}\langle C_2 z^{-1}(S^\dagger C_1 SC_2 z^{-1})^n\rangle. \tag{6.30}$$

The two Green functions F and F' are represented diagrammatically in Fig. 14. A diagram

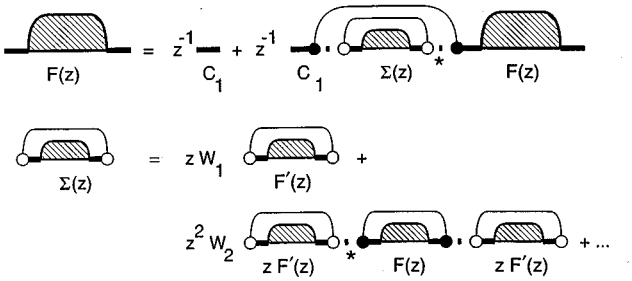

FIG. 15. Diagrammatic representation of the Dyson equation (6.31) for $F(z)$.

contributes to leading order [which is $\mathcal{O}(1)$] if the number of T- and U-cycles is maximal. That is the case if the diagram is *planar*, meaning that the thin lines do not cross. The ladder diagrams are a subset of the planar diagrams. Planar diagrams have been studied in the context of the diagrammatic evaluation of integrals over Hermitian matrices, in particular for the Gaussian ensemble.[12,17] For the Gaussian ensemble, only planar diagrams with U-cycles of unit length have to be taken into account. Summation over all these diagrams results in a self-consistency or Dyson equation for $F(z)$, which solves the problem.[17] For an integral of unitary matrices, U-cycles of arbitrary length need to be taken into account, as is shown diagrammatically in Fig. 15. The corresponding Dyson equation is

$$F(z)=z^{-1}C_1+z^{-1}C_1\Sigma(z)F(z),\quad \Sigma(z)=\sum_{n=1}^{\infty} W_n[z\ \mathrm{tr}\ F'(z)]^n[\mathrm{tr}\ F(z)]^{n-1}, \tag{6.31a}$$

$$F'(z)=z^{-1}C_2+z^{-1}C_2\Sigma'(z)F'(z),\quad \Sigma'(z)=\sum_{n=1}^{\infty} W_n[z\ \mathrm{tr}\ F(z)]^n[\mathrm{tr}\ F'(z)]^{n-1}. \tag{6.31b}$$

In terms of the generating function

$$h(z)=\sum_{n=1}^{\infty} W_n z^{n-1}=\frac{1}{2z}(\sqrt{M^2+4z}-M), \tag{6.32}$$

we may rewrite Eq. (6.31) as

$$F(z)=C_1(z-\Sigma(z)C_1)^{-1},\quad \Sigma(z)=hb(z\ \mathrm{tr}\ F(z)\ \mathrm{tr}\ F'(z)b)z\ \mathrm{tr}\ F'(z), \tag{6.33a}$$

$$F'(z)=C_2(z-\Sigma(z)C_2)^{-1},\quad \Sigma'(z)=hb(z\ \mathrm{tr}\ F(z)\ \mathrm{tr}\ F'(z))z\ \mathrm{tr}\ F(z). \tag{6.33b}$$

In the derivation of Eq. (6.33) we did not use the particular form of the matrices C_1 and C_2. As a check we may choose $C_1=C_2=1$, so that $F(z)=F'(z)=(z-1)^{-1}$, and verify that Eq. (6.33) holds.

The solution of Eq. (6.33) is

$$\mathrm{tr}\ F(z)=\frac{N_1-N_2}{2z}+\frac{\sqrt{M^2z-(N_1-N_2)^2}}{2z\sqrt{z-1}}, \tag{6.34a}$$

$$\mathrm{tr}\, F'(z) = \frac{N_2 - N_1}{2z} + \frac{\sqrt{M^2 z - (N_2 - N_1)^2}}{2z\sqrt{z-1}}. \tag{6.34b}$$

The resulting density of transmission eigenvalues is

$$\rho(T) = \frac{M\sqrt{T - T_{\min}}}{2\pi T\sqrt{1-T}}\,\theta(T - T_{\min}), \quad T_{\min} = \frac{(N_1 - N_2)^2}{M^2}, \tag{6.35}$$

in agreement with Refs. 5, 6, and 43. (The function $\theta(x) = 1$ if $x > 0$ and 0 if $x < 0$.)

The weak-localization correction to $\rho(T)$ follows from the $\mathcal{O}(M^{-1})$ term in the large-M expansion of $F(z)$. As in Sec. VI A, it has two contributions: $\delta F_1(z)$, which is due to the sub-leading order term in the large-M expansion of W_n, and $\delta F_2(z)$, which is due to diagrams of order $\mathcal{O}(M^{-1})$. In the absence of time-reversal symmetry, both contributions are absent. In the presence of time-reversal symmetry, the sub-leading order term $\delta W_n = -M^{-2n}(-4)^{n-1}$ in the large-M expansion of W_n [cf. Eq. (4.4)] yields a sub-leading order contribution δh to the generating function h,

$$\delta h(z) = \sum_{n=1}^{\infty} \delta W_n z^{n-1} = -(M^2 + 4z)^{-1}, \tag{6.36}$$

from which we obtain

$$\mathrm{tr}\ \delta F_1(z) = \tfrac{1}{4}(z - T_{\min})^{-1} - \tfrac{1}{4}(z-1)^{-1}. \tag{6.37}$$

The contribution $\delta F_2(z)$ comes from diagrams in which thin lines connect black and white dots. Each such diagram contains the product $C_1 C_2$, which vanishes. Hence, the $\mathcal{O}(M^{-1})$ contribution to $F(z)$ consists of $\delta F_1(z)$ only. The resulting weak-localization correction to the transmission eigenvalue density is

$$\delta\rho(T) = \frac{2-\beta}{4\beta}[\,\delta(T - T_{\min} - \epsilon) - \delta(T - 1 + \epsilon)], \tag{6.38}$$

in agreement with Refs. 4 and 6.

We now include tunnel barriers in the leads. Motivated by Nazarov's calculation of the density of transmission eigenvalues in a disordered metal,[44] we introduce the $2M \times 2M$ matrices

$$\mathbf{S} = \begin{pmatrix} S & 0 \\ 0 & S^\dagger \end{pmatrix}, \quad \mathbf{C} = \begin{pmatrix} 0 & C_2 \\ C_1 & 0 \end{pmatrix}, \quad \mathbf{F}(z) = \begin{pmatrix} 0 & F'(z) \\ F(z) & 0 \end{pmatrix}, \tag{6.39a}$$

$$\mathbf{T} = \begin{pmatrix} T & 0 \\ 0 & T^\dagger \end{pmatrix}, \quad \mathbf{T}' = \begin{pmatrix} T' & 0 \\ 0 & T'^\dagger \end{pmatrix}, \quad \mathbf{R}' = \begin{pmatrix} R' & 0 \\ 0 & R'^\dagger \end{pmatrix}. \tag{6.39b}$$

Analogous to Eq. (6.6), we decompose $\mathbf{S} = \overline{\mathbf{S}} + \delta\mathbf{S}$, where $\overline{\mathbf{S}} = \langle \mathbf{S} \rangle$ and

$$\delta\mathbf{S} = \mathbf{T}'(1 - \mathbf{U}\mathbf{R}')^{-1}\mathbf{U}\mathbf{T}, \quad \mathbf{U} = \begin{pmatrix} U & 0 \\ 0 & U^\dagger \end{pmatrix} \tag{6.40}$$

is given in terms of a matrix U which is distributed according to the circular ensemble. Because S, C_1, and C_2 commute and $C_1 C_2 = 0$, we may replace S by δS in the expression (6.28a) for $F(z)$. The result for the matrix Green function $\mathbf{F}(z)$ is

$$\mathbf{F}(z)=(2z)^{-1}\sum_{\pm}\langle \mathbf{C}\pm\mathbf{C}\mathbf{T}'[1-\mathbf{U}(\mathbf{R}'\pm\mathbf{T}\mathbf{C}\mathbf{T}'z^{-1/2})]^{-1}\mathbf{U}\mathbf{T}\mathbf{C}z^{-1/2}\rangle$$

$$=(2z)^{-1}\sum_{\pm}[\mathbf{C}\pm\mathbf{A}_{\pm}(\mathbf{F}_{\pm}-\mathbf{X}_{\pm})\mathbf{B}_{\pm}]. \tag{6.41}$$

In the second equation we abbreviated $\mathbf{X}_{\pm}=\mathbf{R}'\pm\mathbf{T}\mathbf{C}\mathbf{T}'z^{-1/2}$, $\mathbf{F}_{\pm}=\langle\mathbf{X}_{\pm}(1-\mathbf{U}\mathbf{X}_{\pm})^{-1}\rangle$, and defined $\mathbf{A}_{\pm}$ and $\mathbf{B}_{\pm}$ such that $\mathbf{A}_{\pm}\mathbf{X}_{\pm}=\mathbf{C}\mathbf{T}'$, $\mathbf{X}_{\pm}\mathbf{B}_{\pm}=\mathbf{T}\mathbf{C}z^{-1/2}$.

After these algebraic manipulations we are ready to compute $\mathbf{F}_{\pm}$ by expanding in planar diagrams. The result is a Dyson equation similar to Eq. (6.31),

$$\mathbf{F}_{\pm}=\mathbf{X}_{\pm}(1+\mathbf{\Sigma}_{\pm}\mathbf{F}_{\pm}),\quad \mathbf{\Sigma}_{\pm}=\sum_{n=1}^{\infty}W_n(\mathscr{P}\mathbf{F}_{\pm})^{2n-1}, \tag{6.42}$$

where the projection operator $\mathscr{P}$ acts on a $2M\times 2M$ matrix $\mathbf{A}$ as

$$\mathbf{A}=\begin{pmatrix}A_{11} & A_{12}\\ A_{21} & A_{22}\end{pmatrix},\quad \mathscr{P}\mathbf{A}=\begin{pmatrix}0 & \mathbb{1}_M\,\mathrm{tr}A_{12}\\ \mathbb{1}_M\,\mathrm{tr}A_{21} & 0\end{pmatrix}, \tag{6.43}$$

$\mathbb{1}_M$ being the $M\times M$ unit matrix. The presence of the projection operator $\mathscr{P}$ in Eq. (6.42) ensures that the planar diagrams contain only contractions between U (the 1,1 block of $\mathbf{U}$) and $U^{\dagger}$ (the 2,2 block of $\mathbf{U}$). In terms of the generating function h we obtain the result

$$\mathbf{F}=(2z)^{-1}\sum_{\pm}(\mathbf{C}\pm\mathbf{C}\mathbf{T}'(1-\mathbf{\Sigma}_{\pm}\mathbf{X}_{\pm})^{-1}\mathbf{\Sigma}_{\pm}\mathbf{T}\mathbf{C}z^{-1/2}), \tag{6.44}$$

$$\mathbf{\Sigma}_{\pm}=(\mathscr{P}\mathbf{X}_{\pm}(1-\mathbf{\Sigma}_{\pm}\mathbf{X}_{\pm})^{-1})h((\mathscr{P}\mathbf{X}_{\pm}(1-\mathbf{\Sigma}_{\pm}\mathbf{X}_{\pm})^{-1})^2). \tag{6.45}$$

It remains to solve the 2×2 matrix equation (6.45). We could not do this analytically for arbitrary Γ_j, but only for the case of two identical tunnel barriers: $N_1=N_2=\frac{1}{2}M\equiv N$, $\Gamma_j=\Gamma_{j+N}$ ($j=1,2,\ldots,N$). The solution of Eq. (6.45) in that case is

$$\mathbf{\Sigma}_{\pm}=\pm(\sqrt{z}-\sqrt{z-1})\begin{pmatrix}0 & \mathbb{1}_M\\ \mathbb{1}_M & 0\end{pmatrix}, \tag{6.46}$$

independent of the Γ_j's. The trace of the Green function is

$$\mathrm{tr}\,F(z)=\sum_{j=1}^{N}\frac{2(1-\Gamma_j)(\sqrt{z}-\sqrt{z-1})+\Gamma_j/\sqrt{z-1}}{2z(1-\Gamma_j)(\sqrt{z}-\sqrt{z-1})+\Gamma_j\sqrt{z}}, \tag{6.47}$$

and the corresponding density of transmission eigenvalues is

$$\rho(T)=\sum_{j=1}^{N}\frac{\Gamma_j(2-\Gamma_j)}{\pi(\Gamma_j^2-4\Gamma_jT+4T)\sqrt{T(1-T)}}. \tag{6.48}$$

As a check, we note that $\rho(T)\to N\delta(T)$ if $\Gamma_j\to 0$ for all j, and $\rho(T)\to N\pi^{-1}[T(1-T)]^{-1/2}$ if $\Gamma_j\to 1$ for all j [in agreement with Eq. (6.35)].

VII. APPLICATION TO A NORMAL-METAL–SUPERCONDUCTOR JUNCTION

As an altogether different application of the diagrammatic technique, we consider a junction between a normal metal (N) and a superconductor (S) (see Fig. 16). At temperatures and voltages

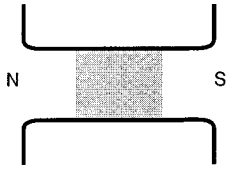

FIG. 16. Conductor consisting of a normal metal (grey) coupled to one normal-metal reservoir (N) and one superconducting reservoir (S). The conductor may consist of a disordered segment or of a quantum dot.

below the excitation gap Δ in S, conduction takes place via the mechanism of Andreev reflection:[45] An electron coming from N with an energy ε (relative to the Fermi energy E_F) is reflected at the NS interface as a hole with energy $-\varepsilon$. The missing charge of $2e$ is absorbed by the superconducting condensate. We calculate the average and variance of the conductance, for the two cases that the NS junction consists of a disordered wire or of a chaotic cavity.

Starting point of the calculation is the relationship between the differential conductance $G_{\rm NS}(eV)=dI/dV$ of the NS junction and the transmission and reflection matrices of the normal region,[46]

$$G_{\rm NS}(\varepsilon)=\frac{4e^2}{h}\,{\rm tr}(t'(\varepsilon)[1+r'(-\varepsilon)^*r'(\varepsilon)]^{-1}t(-\varepsilon)^*)\times(t'(\varepsilon)[1+r'(-\varepsilon)^*r'(\varepsilon)]^{-1}t(-\varepsilon)^*)^\dagger. \tag{7.1}$$

This formula requires $eV\ll\Delta\ll E_F$ and zero temperature. The reflection and transmission matrices are $N\times N$ matrices, which together constitute the $2N\times 2N$ scattering matrix S. Using the polar decomposition (1.2) we may rewrite the conductance formula (7.1) as

$$G_{\rm NS}(\varepsilon)=\frac{4e^2}{h}\,{\rm tr}[T_+(1+u_+\sqrt{1-T_-}u_-^*\sqrt{1-T_+})^{-1}\times u_+T_-u_+^\dagger(1+\sqrt{1-T_+}u_-^{\rm T}\sqrt{1-T_-}u_+^\dagger)^{-1}], \tag{7.2}$$

where $T_\pm=T(\pm\varepsilon)$ and $u_\pm=w'(\pm\varepsilon)w(\mp\varepsilon)^*$. In the presence of spin-orbit scattering, S is a matrix of quaternions, and the transpose should be replaced by the dual. In what follows, we will consider the case of no spin-orbit scattering. Spin-orbit scattering (considered by Slevin, Pichard, and Mello[47]) will be included at the end by means of the translation rule of Sec. V.

Averages are computed in two steps: first over the unitary matrix u, then over the matrix of transmission eigenvalues T. Four cases can be distinguished, depending on the magnitude of the magnetic field B and voltage V relative to the characteristic field B_c for breaking time-reversal symmetry ($\mathscr{T}$) and characteristic voltage E_c/e for breaking electron-hole degeneracy ($\mathscr{D}$):[48]

(1) $eV\ll E_c$, $B\ll B_c\Leftrightarrow\mathscr{T}$ and $\mathscr{D}$ are both present: Then $u_\pm$ may be approximated by the unit matrix, so that one only needs to average over the transmission eigenvalues. This case has been studied extensively[49] and does not concern us here.

(2) $eV\ll E_c$, $B\gg B_c\Leftrightarrow\mathscr{D}$ is present, but $\mathscr{T}$ is broken: Then we may neglect the ε-dependence of S, so that $u_+=u_-\equiv u$. According to the isotropy assumption, u is uniformly distributed in $\mathscr{U}(N)$.

(3) $eV\gg E_c$, $B\ll B_c\Leftrightarrow.\mathscr{T}$ is present, but $\mathscr{D}$ is broken: Then we may consider $S(\varepsilon)$ and $S(-\varepsilon)$ as independent unitary symmetric matrices. Hence $u_+=u_-^\dagger\equiv u$ is uniformly distributed in $\mathscr{U}(N)$.

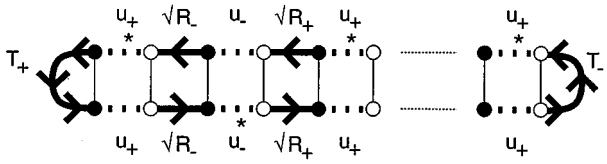

FIG. 17. Ladder diagram for the $\mathcal{O}(N)$ contribution to $\langle G_{\rm NS}\rangle$. We defined $R_\pm = 1 - T_\pm$.

(4) $eV \gg E_c$, $B \gg B_c \Leftrightarrow$ both $\mathcal{T}$ and $\mathcal{D}$ are broken: Then u_+ and u_- are independent, both uniformly distributed in $\mathcal{U}(N)$.

We compute the average and variance of the conductance for cases (2), (3), and (4).

A. Average conductance

We start with the computation of the average conductance $\langle G_{\rm NS}\rangle$. We first perform the average $\langle\cdots\rangle_u$ over $u_\pm$ and then over $T_\pm$. To leading order only ladder diagrams contribute, see Fig. 17. The result is the same for cases (2), (3) and (4):

$$\langle G_{\rm NS}/G_0\rangle_u = 2N \frac{\tau_{1+}\tau_{1-}}{\tau_{1+}+\tau_{1-}-\tau_{1+}\tau_{1-}} + \mathcal{O}(1), \tag{7.3a}$$

$$\tau_{k\pm} = \frac{1}{N}\,\mathrm{tr}\; T_\pm^k = \frac{1}{N}\sum_{j=1}^{N} T_j^k(\pm\varepsilon). \tag{7.3b}$$

The $\mathcal{O}(1)$ contribution $\delta G_{\rm NS}$ is different for the three cases.

Case (2), absence of $\mathcal{T}$ and presence of $\mathcal{D}$. We put $u_\pm = u$, $\tau_{k\pm} = \tau_k$. For normal metals, the $\mathcal{O}(1)$ contribution δG to $\langle G\rangle$ vanishes if $\mathcal{T}$ is broken. However, in the NS junction an $\mathcal{O}(1)$ contribution remains.[26] The diagrams which contribute to $\delta G_{\rm NS}$ have a maximally crossed central part, with contractions between U's and U^*'s on the same side of the diagram (Fig. 18, top). The left and right ends have a ladder structure. In the Hamiltonian approach, a similar maximally crossed diagram has been studied by Altland and Zirnbauer.[27] In total four diagrams contribute to $\delta G_{\rm NS}$, see Fig. 19. The building blocks of the diagram have the algebraic expressions

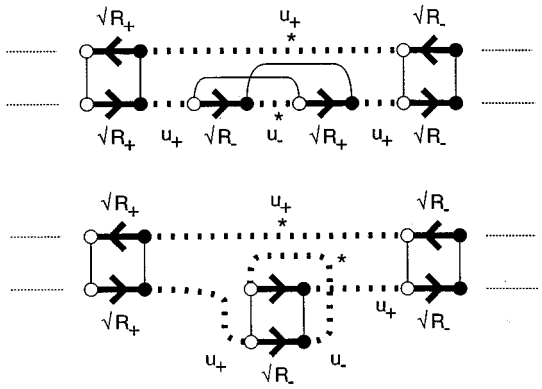

FIG. 18. Maximally crossed diagram for the $\mathcal{O}(1)$ correction to $\langle G_{\rm NS}\rangle$ in the absence of time-reversal symmetry and presence of electron-hole degeneracy (top). The right and left parts of the diagram have a ladder structure. The central part may be redrawn as a ladder diagram (bottom).

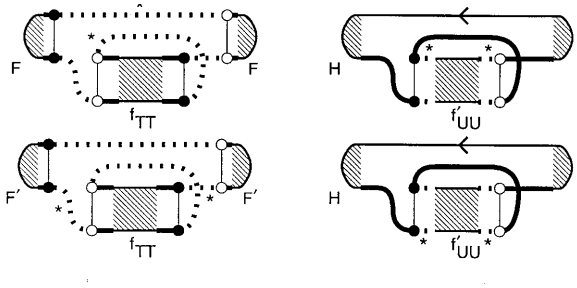

FIG. 19. Diagrams for the $\mathcal{O}(1)$ correction to $\langle G_{\rm NS}\rangle$ in the absence of time-reversal symmetry and presence of electron-hole degeneracy.

$$F_\pm = T_\pm + (1-T_\pm)\ \mathrm{tr}\ T_\pm\ \mathrm{tr}(1-T_\mp)\sum_{j=0}^{\infty} N^{-2j-2}[\ \mathrm{tr}(1-T_+)\ \mathrm{tr}(1-T_-)]^j$$

$$= (\tau_{1\pm} + T_\pm \tau_{1\mp} - \tau_{1+}\tau_{1-})(\tau_{1+} + \tau_{1-} - \tau_{1+}\tau_{1-})^{-1}, \tag{7.4a}$$

$$F'_\pm = -(1-T_\mp)\ \mathrm{tr}\ T_\pm \sum_{j=0}^{\infty} N^{-2j-1}[\ \mathrm{tr}(1-T_+)\ \mathrm{tr}(1-T_-)]^j$$

$$= -(\tau_{1\pm} - \tau_{1\pm}T_\mp)(\tau_{1+} + \tau_{1-} - \tau_{1+}\tau_{1-})^{-1}, \tag{7.4b}$$

$$H_\pm = iN^{-1}T_\pm\sqrt{1-T_\pm}\ \mathrm{tr}\ F_\mp - iN^{-2}(1-T_\pm)\sqrt{1-T_\pm}\ \mathrm{tr}\ F_\mp\ \mathrm{tr}\ F'_\pm, \tag{7.4c}$$

$$f_{TT\pm} = -\ \mathrm{tr}(1-T_\pm)\sum_{j=0}^{\infty} N^{-2j}[\ \mathrm{tr}(1-T_+)\ \mathrm{tr}(1-T_-)]^j = -N(1-\tau_{1\pm})(\tau_{1+} + \tau_{1-} - \tau_{1+}\tau_{1-})^{-1}, \tag{7.4d}$$

$$f_{UU\pm} = -\ \mathrm{tr}(1-T_\pm)\sum_{j=0}^{\infty} N^{-2j-2}[\ \mathrm{tr}(1-T_+)\ \mathrm{tr}(1-T_-)]^j$$

$$= -N^{-1}(1-\tau_{1\pm})[\tau_{1+} + \tau_{1-} - \tau_{1+}\tau_{1-}]^{-1}, \tag{7.4e}$$

$$f'_{UU\pm} = \sum_{j=0}^{\infty} N^{-2j-1}[\ \mathrm{tr}(1-T_+)\ \mathrm{tr}(1-T_-)]^j = N^{-1}(\tau_{1+} + \tau_{1-} - \tau_{1+}\tau_{1-})^{-1}. \tag{7.4f}$$

Capital letters indicate matrices, lower-case letters indicate scalars. The subscripts $\pm$ are omitted from Fig. 19 because of electron-hole degeneracy. The $\mathcal{O}(1)$ correction $\delta G_{\rm NS}$ represented in Fig. 19 equals

$$\delta G_{\rm NS}/G_0 = 8 f'_{UU}\ \mathrm{tr}\ iH\sqrt{1-T} + 4W_2 f_{TT}[(\ \mathrm{tr}\ F)^2 + (\ \mathrm{tr}\ F')^2] = -\frac{8\tau_1 - 4\tau_1^2 + 4\tau_1^3 - 8\tau_2}{\tau_1(2-\tau_1)^3}. \tag{7.5}$$

We still have to average over the transmission eigenvalues. We use that the sample-to-sample fluctuations $\tau_k - \langle\tau_k\rangle$ are an order $1/N$ smaller than the average. (This is a general property of a linear statistics, i.e. of quantities of the form $A = \Sigma_n a(T_n)$, see Ref. 4.) Hence

$$\langle f(\tau_k)\rangle = f(\langle\tau_k\rangle)[1 + \mathcal{O}(N^{-2})], \tag{7.6}$$

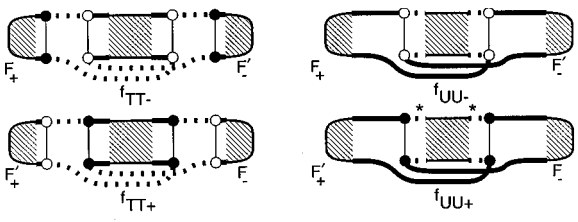

FIG. 20. Diagrams for the $\mathcal{O}(1)$ correction to $\langle G_{\rm NS}\rangle$ in the absence of electron-hole degeneracy and presence of time-reversal symmetry.

which implies that we may replace the average of the rational functions (7.3) and (7.5) of the τ_k's by the rational functions of the average $\langle\tau_k\rangle$. This average has the $1/N$ expansion

$$\langle\tau_k\rangle=\langle\tau_k\rangle_0+\mathcal{O}(N^{-2}), \tag{7.7}$$

where $\langle\tau_k\rangle_0$ is $\mathcal{O}(N^0)$. There is no term of order N^{-1} in the absence of $\mathscr{T}$. The average over T of Eqs. (7.3) and (7.5) becomes

$$\langle G_{\rm NS}/G_0\rangle=\frac{2N\langle\tau_1\rangle_0}{2-\langle\tau_1\rangle_0}-\frac{8\langle\tau_1\rangle_0-4\langle\tau_1\rangle_0^2+4\langle\tau_1\rangle_0^3-8\langle\tau_2\rangle_0}{\langle\tau_1\rangle_0(2-\langle\tau_1\rangle_0)^3}+\mathcal{O}(N^{-1}). \tag{7.8}$$

Case (3), presence of $\mathscr{T}$ and absence of $\mathscr{D}$. We put $u_+=u_-^\dagger\equiv u$. The $\mathcal{O}(1)$ correction comes from the maximally crossed diagrams of Fig. 20,

$$\begin{aligned}\delta G_{\rm NS}/G_0=&\,2W_2\ \mathrm{tr}\ F_+f_{TT-}\ \mathrm{tr}\ F'_-+2W_2\ \mathrm{tr}\ F'_+f_{TT+}\ \mathrm{tr}\ F_-\\&+2\ \mathrm{tr}\ F_+f_{UU-}F'^{\,\mathrm{T}}_-+2\ \mathrm{tr}\ F'_+f_{UU+}F^{\mathrm{T}}_-.\end{aligned} \tag{7.9}$$

Averaging over the transmission eigenvalues amounts to replacing $\tau_{k\pm}$ by its average, $\tau_{k\pm}\to\langle\tau_k\rangle_0+N^{-1}\delta\tau_k+\mathcal{O}(N^{-2})$. (The average of $\tau_{k\pm}$ is the same for $+\varepsilon$ and $-\varepsilon$.) Because $\mathscr{T}$ is not broken there is a term of $\mathcal{O}(N^{-1})$ in this expression. We find for the average conductance

$$\langle G_{\rm NS}/G_0\rangle=\frac{2N\langle\tau_1\rangle_0}{2-\langle\tau_1\rangle_0}+\frac{4\delta\tau_1}{(2-\langle\tau_1\rangle_0)^2}+\frac{4\langle\tau_1\rangle_0^2-4\langle\tau_1\rangle_0^3-4\langle\tau_2\rangle_0+4\langle\tau_1\rangle_0\langle\tau_2\rangle_0}{\langle\tau_1\rangle_0(2-\langle\tau_1\rangle_0)^3}+\mathcal{O}(N^{-1}). \tag{7.10}$$

Case (4), both $\mathscr{T}$ and $\mathscr{D}$ broken. Because u_+ and u_- are independent, there are no diagrams which contribute to order 1. The average conductance is obtained by averaging Eq. (7.3) over the transmission eigenvalues,

$$\langle G_{\rm NS}/G_0\rangle=\frac{2N\langle\tau_1\rangle_0}{2-\langle\tau_1\rangle_0}+\mathcal{O}(N^{-1}). \tag{7.11}$$

From the translation rule of Sec. V one deduces that in the presence of spin-orbit scattering, the leading $\mathcal{O}(N)$ term of the average conductance is unchanged, while the $\mathcal{O}(1)$ correction is multiplied by $-1/2$, in agreement with what was found by Slevin, Pichard and Mello.[47]

The formulas given above apply to any system for which the isotropy assumption holds. We discuss two examples:

(a) A disordered wire (length L, mean free path ℓ, number of transverse modes N), connected to a superconductor. We use the results[50]

$$\langle \tau_1 \rangle_0 = (1+L/\ell)^{-1}, \tag{7.12a}$$

$$\langle \tau_2 \rangle_0 = \tfrac{2}{3}(1+L/\ell)^{-1} + \tfrac{1}{3}(1+L/\ell)^{-4}, \tag{7.12b}$$

$$\delta\tau_1 = -\tfrac{1}{3}(1+\ell/L)^{-3}. \tag{7.12c}$$

We assume $\ell \ll L \ll N\ell$ and neglect terms of order $L/N\ell$ and ℓ/L but retain terms of order 1 and $N\ell^p/L^p (p \geq 1)$. Substitution of Eq. (7.12) into Eqs. (7.8), (7.10), and (7.11) yields

$$\langle G_{\rm NS}/G_0 \rangle = \begin{cases} N(1+L/\ell)^{-1} - 1 + 4/\pi^2 & (\mathscr{D},\mathscr{T}), \\ N(1/2+L/\ell)^{-1} - 1/3 & (\mathscr{D},\ \text{no}\ \mathscr{T}), \\ N(1/2+L/\ell)^{-1} - 2/3 & (\ \text{no}\ \mathscr{D},\mathscr{T}), \\ N(1/2+L/\ell)^{-1} & (\ \text{no}\ \mathscr{D},\ \text{no}\ \mathscr{T}). \end{cases} \tag{7.13}$$

The result in the presence of both $\mathscr{T}$ and $\mathscr{D}$ has been taken from Refs. 51 and 52. In the presence of spin-orbit scattering, the $\mathscr{O}(N)$ term is unchanged, while the $\mathscr{O}(1)$ term is multiplied by $-1/2$.

(b) A chaotic cavity without tunnel barriers in the leads. Lead 1 (with N_1 modes) is connected to a normal metal, lead 2 (with N_2 modes) to a superconductor. An asymmetry between N_1 and N_2 appears because the dimension of u_+ in the polar decomposition (6.27) is $N_2 \times N_2$. The $N_2 \times N_2$ matrix T_+ contains the $\min(N_1,N_2)$ non-zero transmission eigenvalues on the diagonal (remaining diagonal elements being zero). We denote $N_{\rm tot} = N_1 + N_2$ and $N_A = (N_1^2 + 6N_1N_2 + N_2^2)^{1/2}$. The averages $\langle \tau_1 \rangle_0$ and $\langle \tau_2 \rangle_0$ and the correction $\delta\tau_1$ can be computed from the density of transmission eigenvalues [Eqs. (6.35) and (6.38)]. The results are

$$\delta\tau_1 = -N_1N_2N_{\rm tot}^{-2}, \quad \langle \tau_1 \rangle_0 = N_1N_{\rm tot}^{-1}, \quad \langle \tau_2 \rangle_0 = N_1(N_{\rm tot}^2 - N_1N_2)N_{\rm tot}^{-3}. \tag{7.14}$$

Substitution into Eqs. (7.8), (7.10), and (7.11) gives

$$\langle G_{\rm NS}/G_0 \rangle = \begin{cases} N_{\rm tot}(1-N_{\rm tot}/N_A) - 8N_1N_2N_{\rm tot}^2/N_A^4 & (\mathscr{D},\mathscr{T}), \\ 2N_1N_2/(N_{\rm tot}+N_2) - 4N_1N_2N_{\rm tot}/(N_{\rm tot}+N_2)^3 & (\mathscr{D},\ \text{no}\ \mathscr{T}), \\ 2N_1N_2/(N_{\rm tot}+N_2) - 4N_2N_{\rm tot}^2/(N_{\rm tot}+N_2)^3 & (\ \text{no}\ \mathscr{D},\mathscr{T}), \\ 2N_1N_2/(N_{\rm tot}+N_2) & (\ \text{no}\ \mathscr{D},\ \text{no}\ \mathscr{T}). \end{cases} \tag{7.15}$$

The leading order term in Eq. (7.15) has also been obtained by Argaman and Zee.[33] (The case $N_1 = N_2$ was given in Ref. 6).

B. Conductance fluctuations

To compute the variance of the conductance, we average in two steps: $\langle \cdots \rangle = \langle \langle \cdots \rangle_u \rangle_T$, where $\langle \cdots \rangle_u$ and $\langle \cdots \rangle_T$ are, respectively, the average over the unitary matrices u_+ and over the matrices of transmission eigenvalues T_+. It is convenient to add and subtract $\langle \langle G_{\rm NS} \rangle_u^2 \rangle_T$, so that the variance splits up into two parts,

$$\text{var}\, G_{\rm NS} = \langle \langle G_{\rm NS} \rangle_u^2 \rangle_T - \langle \langle G_{\rm NS} \rangle_u \rangle_T^2 + \langle \langle G_{\rm NS}^2 \rangle_u - \langle G_{\rm NS} \rangle_u^2 \rangle_T, \tag{7.16}$$

which we evaluate separately.

The first two terms of Eqs. (7.16) give the variance of $\langle G_{\rm NS} \rangle_u$ over the distribution of transmission eigenvalues. We calculated $\langle G_{\rm NS} \rangle_u$ in Eq. (7.3). Since $\langle G_{\rm NS} \rangle_u$ is a function of the linear statistic τ_{1+} only, we know that its fluctuations are an order $1/N$ smaller than the average. This implies that, to leading order in $1/N$,

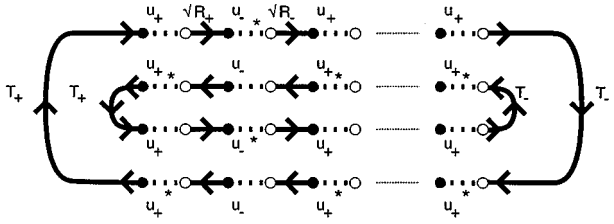

FIG. 21. Diagrammatic representation of $G_{\rm NS}^2$.

$$\langle\langle G_{\rm NS}\rangle_u^2\rangle_T-\langle\langle G_{\rm NS}\rangle_u\rangle_T^2=\sum_{\sigma,\sigma'=\pm}\left\langle\frac{\partial\langle G_{\rm NS}\rangle_u}{\partial\tau_{1\sigma}}\right\rangle_T\left\langle\frac{\partial\langle G_{\rm NS}\rangle_u}{\partial\tau_{1\sigma'}}\right\rangle_T \mathrm{covar}(\tau_{1\sigma},\tau_{1\sigma'})$$
$$=8G_0^2N^2(2-\langle\tau_1\rangle_0)^{-4}\ \mathrm{var}\ \tau_1\times\begin{cases}1 & (\text{without }\mathscr{D}),\\ 2 & (\text{with }\mathscr{D}).\end{cases} \tag{7.17}$$

We now turn to the third and fourth term of Eq. (7.16). These terms involve the variance $\langle G_{\rm NS}^2\rangle_u-\langle G_{\rm NS}\rangle_u^2$ of $G_{\rm NS}$ over $\mathscr{U}(N)$ and subsequently an average over the T_n's. The calculation is similar to that of Sec. VI B. We represent $G_{\rm NS}^2$ by the diagram in Fig. 21. The variance with respect to $u_\pm$ is given by the connected diagrams. We distinguish between two types of connected diagrams: (i) diagrams in which the inner and the outer loop are connected by a T-cycle or by a U-cycle, and (ii) diagrams in which the partition of the U-cycles involves a group which consists of a U-cycle from the inner loop and a U-cycle from the outer loop. The diagrams are similar to those of Fig. 12, and are omitted. The final result is

$$\langle\langle G_{\rm NS}^2\rangle_u-\langle G_{\rm NS}\rangle_u^2\rangle_T=8\,G_0^2(2-\langle\tau_1\rangle_0)^{-6}\langle\tau_1\rangle_0^{-2}(4\langle\tau_1\rangle_0^2-8\langle\tau_1\rangle_0^3+9\langle\tau_1\rangle_0^4-4\langle\tau_1\rangle_0^5+2\langle\tau_1\rangle_0^6$$
$$-4\langle\tau_1\rangle_0\langle\tau_2\rangle_0+2\langle\tau_1\rangle_0^2\langle\tau_2\rangle_0-2\langle\tau_1\rangle_0^3\langle\tau_2\rangle_0-2\langle\tau_1\rangle_0^4\langle\tau_2\rangle_0+6\langle\tau_2\rangle_0^2$$
$$-6\langle\tau_1\rangle_0\langle\tau_2\rangle_0^2+3\langle\tau_1\rangle_0^2\langle\tau_2\rangle_0^2-4\langle\tau_1\rangle_0\langle\tau_3\rangle_0+6\langle\tau_1\rangle^2\langle\tau_3\rangle_0-2\langle\tau_1\rangle_0^3\langle\tau_3\rangle_0)$$
$$\times\begin{cases}2 & (\mathscr{D},\text{ no }\mathscr{T}),\\ 2 & (\mathscr{T},\text{ no }\mathscr{D}),\\ 1 & (\text{ no }\mathscr{D},\text{ no }\mathscr{T}).\end{cases} \tag{7.18}$$

The sum of Eqs. (7.17) and (7.18) equals var $G_{\rm NS}$, according to Eq. (7.16).

In the presence of spin-orbit scattering var $G_{\rm NS}$ is four times as small, according to the translation rule of Sec. V.

We give explicit results for the disordered wire and the chaotic cavity.

(a) For the disordered wire one has[50,53] var $\tau_1=\frac{1}{15}N^{-2}$, $\langle\tau_k\rangle_0=\frac{1}{2}(\ell/L)\Gamma(\frac{1}{2})\Gamma(k)/\Gamma(k+\frac{1}{2}$. Substitution into Eqs. (7.17) and (7.18) yields the variance

$$\mathrm{var}\ G_{\rm NS}/G_0=\begin{cases}16/15-48/\pi^4\approx0.574 & (\mathscr{D},\mathscr{T}),\\ 8/15\approx0.533 & (\mathscr{D},\text{ no }\mathscr{T}),\\ 8/15\approx0.533 & (\mathscr{T},\text{ no }\mathscr{D}),\\ 4/15\approx0.267 & (\text{ no }\mathscr{D},\text{ no }\mathscr{T}).\end{cases} \tag{7.19}$$

The result in the presence of both $\mathscr{T}$ and $\mathscr{D}$ has been taken from Ref. 52 and 54. If both $\mathscr{D}$ and $\mathscr{T}$ are present, breaking $\mathscr{T}$ (or $\mathscr{D}$) reduces the variance by less than 10%.[28,55]

TABLE II. Denominators A_n of the coefficients $V_{c_1,\ldots,c_k}$ for $n=c_1+\ldots+c_k\leqslant 5$.

n	A_n (CUE)	A_n (COE)
1	N	$N+1$
2	$N(N^2-1)$	$N(N+1)(N+3)$
3	$N(N^2-1)(N^2-4)$	$(N-1)N(N+1)(N+3)(N+5)$
4	$N^2(N^2-1)(N^2-4)(N^2-9)$	$(N-2)(N-1)N(N+1)(N+2)(N+3)$ $\times(N+5)(N+7)$
5	$N^2(N^2-1)(N^2-4)(N^2-9)(N^2-16)$	$(N-3)(N-2)(N-1)N(N+1)(N+2)$ $\times(N+3)(N+5)(N+7)(N+9)$

(b) For the chaotic cavity one has var $\tau_1=2N_1^2/\beta N_{\rm tot}^4$ and $\langle\tau_3\rangle_0=N_1(N_{\rm tot}^4-2N_{\rm tot}^2N_1N_2+2N_1^2N_2^2)/N_{\rm tot}^5$ [see Eqs. (6.4) and (6.35)]. In combination with Eq. (7.14) this gives

$$\text{var } G_{\rm NS}/G_0=\begin{cases}128N_1^2N_2^2(N_{\rm tot}^4+2N_1^2N_2^2)(N_{\rm tot}^2+4N_1N_2)^{-4} & (\mathscr{D},\mathscr{T}),\\ 32N_2^2N_{\rm tot}^2(N_{\rm tot}^2-N_1N_2)(N_{\rm tot}+N_2)^{-6} & (\mathscr{D},\text{no }\mathscr{T}),\\ 32N_2^2N_{\rm tot}^2(N_{\rm tot}^2-N_1N_2)(N_{\rm tot}+N_2)^{-6} & (\mathscr{T},\text{no }\mathscr{D}),\\ 16N_2^2N_{\rm tot}^2(N_{\rm tot}^2-N_1N_2)(N_{\rm tot}+N_2)^{-6} & (\text{no }\mathscr{D},\text{no }\mathscr{T}).\end{cases}\tag{7.20}$$

If the coupling between the cavity and the normal metal is weak compared to the coupling to the superconductor ($N_2\gg N_1$), one finds var $G_{\rm NS}(\mathscr{D},\mathscr{T})$/var $G_{\rm NS}(\mathscr{D},\text{no}\,\mathscr{T})=\mathscr{O}(N_1/N_2)^2$. In this case breaking $\mathscr{T}$ greatly enhances the conductance fluctuations. In the opposite case, if the couplings are equal ($N_1=N_2$), one finds var $G_{\rm NS}(\mathscr{D},\mathscr{T})$/var $G_{\rm NS}(\mathscr{D},\text{no}\,\mathscr{T})=2187/2084\approx 1.07$. In this case breaking $\mathscr{T}$ has almost no effect on the conductance fluctuations.

VIII. SUMMARY

We developed a diagrammatic technique for the evaluation of integrals of polynomial functions of unitary matrices over the unitary group $\mathscr{U}(N)$. In the large-N limit the number of relevant diagrams is restricted, which allows for the evaluation of integrals over rational functions. We also considered integrals of unitary symmetric matrices, by means of a slight modification of the diagrammatic rules. A translation rule was given to relate integrals of (self-dual) unitary matrices of quaternions to integrals over (symmetric) unitary matrices of complex numbers.

We discussed two applications: a chaotic cavity (quantum dot) with tunnel barriers in the leads and a normal-metal–superconductor (NS) junction. In both cases, the conductance is a rational function of a unitary matrix. In the large-N limit the average conductance is given by a series of ladder diagrams. The weak-localization correction consists of maximally-crossed diagrams. These two types of diagrams are analogous to the diffuson and cooperon diagrams in the diagrammatic perturbation theory for disordered systems.[22,23] We computed the density of trans-

mission eigenvalues, where the leading order term is given by planar diagrams. Resummation of the diagrams leads to a Dyson equation for the Green function, similar to that encountered in the theory of integrals over Hermitian matrices.[12,17]

For the NS junction, the $\mathcal{O}(1)$ correction to the average conductance is non-zero in the presence of a magnetic field, because of a different type of maximally crossed diagrams. These diagrams are suppressed by a sufficiently large voltage to break electron-hole degeneracy. The new type of maximally crossed diagrams explains the coexistence of weak localization with a magnetic field[26] and the insensitivity of the conductance fluctuations to a magnetic field.[28,55]

APPENDIX: WEIGHT FACTORS FOR POLYNOMIAL INTEGRALS

In Tables II–V we list the weight factors $V_{c_1,\ldots,c_k}$ and $W_{c_1,\ldots,c_k}$ for $n=c_1+\ldots+c_k\leqslant 5$ for the CUE and the COE. (tables of V are also given in Refs. 30, and 31 for the CUE and in Ref. 35 for the COE.) The weight factors are rational functions of the dimension N of the unitary matrix. The denominators A_n and B_n of, respectively, $V_{c_1,\ldots,c_k}$ and $W_{c_1,\ldots,c_k}$ depend only on n. They are tabulated in Tables II and III. The numerators $A_nV_{c_1,\ldots,c_k}$ and $B_nW_{c_1,\ldots,c_k}$ are tabulated in Tables IV and V.

We review the results of a recent study of fluctuations of wave functions in confined chaotic systems. The fluctuations can be due to a random potential or be a consequence of a chaotic scattering by the walls. The entire distribution function of the local amplitudes of the wave functions, f_1, and the joint two-point distribution are calculated in various situations. The computation is performed using the supersymmetry technique and employs the studies of a reduced version of the non-linear supersymmetric σ-model developed especially for investigating the properties of a single eigenstate in a discrete spectrum of a chaotic quantum system. For not very large amplitudes, the complete description can be achieved using the zero-dimensional approximation of the σ-model. The distribution function calculated in the limit of various symmetry classes shows the universal behavior known as the Porter-Thomas statistics, and fluctuations at distant points do not correlate. In the crossover regime between the ensembles, the distribution of local amplitudes shows a somewhat more sophisticated behavior: the fluctuations in this case are correlated over distances exceeding the mean free path. For large amplitudes generated by the states the most affected by the localization (we call them prelocalized), the zero-dimensional approximation is no longer valid. Instead, the statistics of their wave functions is determined by nontrivial vacua of the reduced σ-model which is quite similar to the Liouville model known in conformal field theory. In particular, the vacuum state of the reduced σ-model obeys the Liouville equation, which indicates that in two dimensions the prelocalized states have nearly critical properties: we prove their multifractality and power-law statistically averaged envelope $|\varphi(r)|^2 \propto r^{-2\mu}$ at the intermediate range of distances below the localization length with a spectrum of exponents $\mu<1$, as well as obtain a logarithmically-normal tail of the distribution function f_1. We also find an evidence of prelocalized states in quasi-one-dimensional wires with the length shorter than the localization length: their statistically averaged envelope has power-law asymptotics, $|\varphi(x)|^2 \propto x^{-2}$, and the tail of the distribution function is similar to that describing localized states in the infinite wires. I. INTRODUCTION

The recent progress in semiconductor technology has given an access to the experimental studies of the physics of nanoscale electronic systems. This, in its turn, has generated a number of theoretical problems which did not previously call close enough attention, such as the problem of statistical properties of a single quantum state in a confined chaotic quantum system. Being studied at low temperatures, the small electronic devices are the objects in which the electron motion is coherent and the quantum nature of carriers evidences in many experimental data.[1,2] During the previous decade, the quantum effects in transport have been mainly explored in the

systems where they give small—but nevertheless observable—features in addition to the conductance (inverse resistance) values expected on the basis of a purely classical mechanics analysis. Weak localization effects[3] and mesoscopic conductance fluctuations[1,4,5] are the best known and, maybe, the most spectacular examples of them which can be understood and successfully described on the basis of a semiclassical analysis of quantum mechanics.[4,6,7]

In more recent studies[8] of smaller structures put into a weak (tunneling) contact to the bulk electrodes and cooled down to the temperatures of the order of tens of mK, the resonant tunneling regime of the transport through a single discrete level in a quantum dot has been achieved. Since the value of the resonance tunneling conductance is determined by the amplitudes of the resonance state wave functions in the vicinity of contact, fluctuations and spatial structure of the single-particle eigenstates in a dot become important observables, especially regarding a rich experimental information which is already available in the literature.[9,10]

In small semiconductor structures the capacitance of the dot (filled by a large number of electrons, $N \gg 1$) is so small that the dot charging energy becomes larger than other relevant energy scales in the system. Therefore, if the resistance of contacts of a dot to the external world are much higher than the resistance quantum, h/e^2, the system occurs in the Coulomb blockade regime and the transport through the dot is only possible when a single electron added to the dot does not change its total energy: $E_{N+1}=E_N$, where N is the number of excess electrons. In the semiconductor structures, the condition of such resonance can be controlled by an external gate voltage U_g applied to the dot. Experimentally, this produces a set of conductance peaks at voltages $U_g(N)\approx(N+1/2)e/C$ at which the destruction of the Coulomb blockade makes the transport possible.

Therefore, an important quantity that has become a subject of statistical analysis is the height of the Coulomb blockade peaks. Although the positions of these peaks are periodic, their strengths are quite different depending on current-carrying abilities of those states in the dot that should be filled by the tunneling electrons. Assuming that the level width and the temperature are smaller than the mean-level spacing Δ one may consider only a single single-particle level contribution to each resonance.[11,12] This means that one can use a Breit-Wigner type formula to describe the resonance conductance. Taking into account temperature smearing of the Fermi distribution and assuming that temperature T much exceeds the typical level width γ,[13] one can write the resonance conductance in the form[14,15]

$$g=\frac{e^2}{h}\,\frac{1}{4\pi T}\,\frac{\gamma_L\gamma_R}{\gamma_L+\gamma_R}. \tag{1}$$

In Eq. (1), the level widths $\gamma_{L,R}=A_{L,R}|\varphi_\alpha(\mathbf{r}_{L,R})|^2$ are determined by the wave function amplitudes $|\varphi_\alpha(\mathbf{r}_{L,R})|$ of the resonant state at the coordinates $\mathbf{r}_{L,R}$ of tunnel links to the current leads. The coefficients $A_{L,R}$ depend only on the properties of contacts and, together with temperature T determine the typical conductance values in a specific device, whereas statistics of the heights of conductance peaks are completely controlled by statistics of amplitudes of the electron waves of the confined system near the contact.

At present, it is quite clear that the character of the fluctuations in the conductance peaks series depends on whether the corresponding classical motion of a carrier in quantum dot is chaotic or regular. In the latter case calculation of the wave functions should follow a straightforward procedure, whereas a description of the wave functions in the regime of chaotic dynamics demands considerable effort. By studying experimentally the conductance fluctuations for ''chaotic'' dots, one can check theoretical results for statistics of the amplitudes of the chaotic electron

waves in mesoscopic dots—at least, would a single-particle description work being applied to the system of interacting electrons.

Besides the measurements on the quantum dots, a series of experiments on a completely different object is worth mentioning. These are the experiments on microwave scattering in metallic cavities in which the local amplitudes of electromagnetic waves were measured and their statistics were analyzed.[16,17] Being confined to a thin slab, the electromagnetic waves are strongly polarized and obey the same equation as the Schrödinger equation for the electron. One can make either ballistic cavities where the electromagnetic waves are scattered by the walls or add into the cavity small pieces of a good metal which models impurities. Changing an impurity configuration or sweeping the frequency and passing from one resonance to another, one can collect statistics of the eigenmodes intensities at some fixed point of a sample. In some sense, the microwave cavities represent convenient toy systems for modelling various regimes of quantum chaos, since they have a much higher degree of freedom in changing the parameters (as compared to the experiments on the electronic devices), e.g., the level of disorder, they operate with much better statististics and deliver the direct information about the density distributions of the chaotic electromagnetic waves. At the same time, the single-particle description is completely adequate in this case.

Both types of experiments mentioned above (which can be classified as mesoscopic) provide a good reason for studying in great detail fluctuations of wave functions in chaotic or disordered confined systems. At this point we have to note that the simplest way to produce chaos in a quantum or classical billiard is to fill it with impurities, so that one would expect that all the generic features of quantum chaos may be understood by studying the disordered conductors. Although this expectation is partly true, the physics of disordered systems is even more rich than that. The structure and statistics of eigenstates in the systems where chaos is generated by a large number of impurities is strongly affected by the localization effects, especially in low-dimensional systems. From this point of view, the issue which we intend to answer below is what are the properties of wave functions in disordered systems where localization is expected at long distances that they show being confined by external boundaries below the localization length scale. In the cases when the mean free path is determined mainly by scattering by walls, the localization effects can be ignored, it is reasonable to speak of ''ballistic chaos.''

II. CHOICE OF THE MODEL

Below wave functions of models with disorder will be studied. In all cases consideration is restricted to systems of non-interacting particles in a finite volume. The assumption that the particles do not interact means that, in fact, a one-particle problem is considered. The assumption is very well justified if we consider electromagnetic or sound waves in a box. At the same time, the validity of it is less clear for electrons in a quantum dot where both electron-electron and electron-phonon interactions can be quite important. Nevertheless, at low temperatures the inelastic mean free path can be large and very often the one-particle approximation serves as a good description of interesting physical problems.

To simplify the discussion we will speak about electrons in a box and study solutions of the Schrödinger equation although most of the results obtained below are also applicable to electromagnetic and sound waves.

So, we start with the Schrödinger equation for an electron moving in a limited volume V in the presence of an external potential $U_{dis}(\mathbf{r})$. The potential $U_{dis}(\mathbf{r})$ describes an interaction with impurities. In principle, an external magnetic field H can be applied and the potential $U_{dis}(\mathbf{r})$ can include magnetic and spin-orbit interactions. In the presence of the magnetic and spin-orbit impurities one should take into account electron spin and write two-component wave functions. To avoid complicated formulae, from the beginning we consider first a system without spin interactions. Then, the Schrödinger equation can be written in the form

$$\hat{H}\varphi_\alpha(\mathbf{r})=\epsilon_\alpha\varphi_\alpha(\mathbf{r}), \quad \hat{H}=\hat{H}_0+U_{dis}(\mathbf{r}), \tag{2}$$

where ϵ_α are the eigenenergies of the spectral problem in the dot, Eq. (2), measured off the energy ϵ fixed by an external observer (e.g., the Fermi energy in the bulk electrodes attached to the quantum dot to make an electric measurement); $\varphi_\alpha(\mathbf{r})$ are the corresponding eigenfunctions, and

$$\hat{H}_0 = E_K\left(-i\hbar\nabla - \frac{e}{c}\mathbf{A}\right) - \epsilon, \tag{3}$$

with $E_K(\mathbf{p})$ being the energy of free motion and $\mathbf{A}$ being the vector potential corresponding to the magnetic field $\mathbf{H}=\mathrm{rot}\mathbf{A}$; for the sake of convenience, we use such a gauge that $\mathrm{div}\mathbf{A}=0$ and $\mathbf{An}=0$ at the surface (edge) of the sample. We also assume that fluctuations of U_{dis} are Gaussian and satisfy the following relations:

$$\langle U_{dis}(\mathbf{r})\rangle = 0, \quad \langle U_{dis}(\mathbf{r})U_{dis}(\mathbf{r}')\rangle = \frac{1}{2\pi\nu\tau}\delta(\mathbf{r}-\mathbf{r}'), \tag{4}$$

where τ is the mean free path time and ν is the density of states at the energy ϵ, which are usual notations of condensed matter physics. The angular brackets stand for the averaging procedure.

In principle, the eigenstates problem Eq. (2) should be complemented by the boundary conditions for the wave functions. The fact that the electron is confined in a finite region means that it is located in a quantum well. For our consideration the explicit form of the confining potential is not important. This can be a hard wall model and then the wave functions turn to zero at the boundary or it can be a more general potential resulting in a fast decay of the wave functions at infinity. For calculations presented below it is only important that the spectrum of the eigenenergies is discrete.

The description of quantum chaos by modelling it using the electron motion in a confined disordered system seems to be, in principle, very attractive because of a number of powerful techniques developed during the past two decades in the theory of metals.[1,3] Nevertheless, it remains a non-trivial theoretical problem. This is because the most standard calculational tool—the diagrammatic perturbation theory— fails to work when it is applied to the description of properties of a single discrete quantum level. The perturbation theory calculation consists of the summation of certain classes of diagrams corresponding to terms of an expansion in the impurity concentration. By now, it is well known that the quantum interference is properly described in terms of so called ''cooperons'' and ''diffusons'' which appear as a result of the summation of certain ladder diagrams. To use the perturbation theory, one should start with a ''good metal'' and to assume that the length of the mean free path l is much longer than the electron wavelength λ. But this is only one necessary condition. The reason for a limited power of the perturbation theory with respect to disorder lies in the equivalence of the constraints made for its applicability and those of the semiclassical approximation.[7,18] The semiclassics, in its turn, is able to describe only wave packets composed of a large number of quantum levels, which require any kind of a discrete level broadening γ to be larger than the mean level spacing Δ in the confined quantum dot. The origin of the broadening may be different. It can result from a strong coupling of the dot to external leads, so that the broadening γ is caused by the fast decay of the state due to the particle escape to the bulk electrodes, or this may be a ''homogeneous'' inelastic broadening of the level due to any other relaxation process. That is why the perturbation theory analysis gives reliable results in systems where the contacts of a dot to massive reservoirs have conductances g_c that can be relatively small, as compared to the ''intrinsic'' conductance of the dot, but should be larger than the conductance quantum e^2/h.[19–22] At the same time, the perturbation theory is not an adequate tool to study the properties of a single level in a dot where conductances of contacts are much less than the conductance quantum and where the inelastic broadening γ is much smaller than the mean level spacing.

Another approach to the quantum chaos in disordered conductors is based on the Gorkov and Eliashberg idea[23] to replace the randomness of an impurity configuration in a small piece of metal

by a randomness of a matrix Hamiltonian that describes the specral single-particle problem in it. This enables one to reformulate the issue of statistics of spectra and wave functions in a disordered system in terms of random matrix theory (RMT) the apparatus of which has been developed in many details in nuclear physics.[24,25]

The random matrix theory proved to be a very convenient method and has brought to light some important features of the statistics of conductance fluctuations in chaotic billiards.[14] In particular, depending on the presence or absence of the time reversal invariance in the systems (i.e., of a magnetic field), the eigenstates of the RMT Hamiltonian can be described as either real or complex vectors and have a purely Gaussian distribution of the amplitudes of their projections onto some arbitrarily chosen direction in the basis (Porter-Thomas distribution in the RMT), which is equivalent to the universal distribution of local densities of single-particle wave functions in the ergodic regime of a chaos. The intensive numerical studies of a large number of high-lying eigenstates of confined systems, such as ''quantum billiards'',[26,27] have confirmed the Gaussian distribution of local wave functions amplitudes,[27] and this has been observed directly in the microwave experiments.[16]

On the other hand, although the random matrix theory enables one to catch some part of the physics of quantum chaotic systems, it remains to be a phenomological method which has to be modified each time when broader classes of chaotic systems are involved. The use of the RMT[28] in the studies of the eigenstates problem becomes rather complicated when the crossover regime between different universality classes is studied[29] and is helpless when spatial correlations of the wave functions are called in question.

Another phenomenological approach related to the RMT which also confirms the Gaussian distribution of the wave functions amplitudes has been proposed by Berry. It is based on the assumption that the local structure of the eigenstates can be represented as a superposition of an infinite number of plane waves with random phases and equal wave number.[30] Originally, the applicability of such a conjecture has been justified by classical ergodicity of chaotic systems. For ergodic systems one can assume that relevant classical orbits are the typical ones that pass close to all points on the energy surface corresponding to the energy ϵ of the state with the wave function φ and, in the semiclassical approximation, this leads to random phases. Using this approach, one can describe spatial correlations of the amplitudes of the wave functions of a chaotic billiard[31] which show behavior similar to that of the Friedel oscillations.[32]

However, both the advantage and the disadvantage of this phenomenology are related to the statistical equivalence of eigenstates which is built into the construction of the random matrix substituting the real dynamics, or stands behind Berry's conjecture. This reveals the set of universal features of chaos in the limits where they do exist but hides peculiarities of physically different systems in the cases when universality is broken. In particular, the phenomenolgy can be helpful in the limiting cases of the orthogonal and unitary ensembles corresponding to time reversal invariant systems or to systems where this invariance is completely broken, but not in the crossover regime (quantum billiard in a weak magnetic field). Moreover, they cannot be used in situations where localization effects due to a real disorder become important and the statistical equivalence of the eigenstates is no longer valid.

As a result of the disadvantages of the phenomenological approaches, a derivation of statistics of amplitudes of the wave functions directly from a well defined model without using additional hypotheses (i.e., from the first principles) is desirable, and this requires development of other analytical methods. Fortunately, this goal can be achieved by a modification of the supersymmetry technique originally proposed by one of the present authors (see, e.g., Refs. 33 and 34) for studying the Anderson localization. Within this method, calculation of different physical quantities characterizing, e.g., localization or mesoscopic fluctuations is reduced to the study of a non-linear supermatrix σ-model. At present, this method is well developed and has been used for solving a broad spectrum of quite different problems.[34,35] Models with disorder were the first ones studied by the supersymmetry technique. The zero-dimensional (0D) version of the model corresponds to

the Wigner-Dyson random matrix theory, and, in the simplest cases recovers the RMT results (see Section V). Later on, other versions of the σ-model have been derived from the RMT,[36] from models of random band and sparse matrices[37] and from some models of a ''ballistic chaos''.[38,39]

Below, we demonstrate how the supersymmetry technique can be applied to the problem of the statistics of wave functions in disordered and chaotic confined two-dimensional (2D) and quasi-one-dimensional (Q1D) systems. In this article, we give a complete account of the results[15,40–46] obtained for the disordered models. Most of the methodical part of it (see Sections VI and VII) is devoted to the derivation of a reduced σ-model[41,44] that is adapted for describing the properties of a single eigenstate in the discrete spectrum of a confined chaotic system. The formal derivation we do here is restricted to the usual potential disorder in Eq. (4), but the analysis can also be extended to a broader variety of systems, for example, to the models involving a random gauge or magnetic field.[47] Skipping the details, these models give the same as the analysis of the unitary ensemble, both on the level of perturbation theory analysis[48] and using the nonlinear σ-model approach.[47] Most of the results presented below for the distribution functions of the wave functions have been obtained by the supersymmetry technique and, by now, we know no other way to reproduce them.

III. DEFINITIONS OF THE EIGENSTATES STATISTICS

The most complete information about statistical and correlation properties of the wave functions is implicit to the N-point *joint distribution functions* $f_N(p_1,\ldots,p_N)$ defined as

$$f_N(p_1,\ldots,p_N;\mathbf{r}_1,\ldots,\mathbf{r}_N)=\Delta\left\langle \sum_{\alpha}\ \delta(\epsilon-\epsilon_\alpha)\prod_{n=1}^{N}\ \delta(p_n-|\varphi_\alpha(\mathbf{r}_n)|^2)\right\rangle_{dis}. \tag{5}$$

In Eq. (5) $\Delta=(\nu V)^{-1}$ is the mean level spacing which is finite in a confined system, and $\langle\ldots\rangle_{dis}$ stands for averaging over the random potential configurations. In this definition, we do not take into account spin degrees of freedom. One can find some details on the definition of statistics of a local spin desntity of eigenstates in Ref. 45.

The function $f_N(p_1,\ldots,p_N)$ measures the probability of given amplitudes of the wave function corresponding to the energy ϵ at N different coordinates $\mathbf{r}_n$. When speaking about the problem of a distribution of irradiation in a chaotic cavity, this function describes a probability to detect a given configuration of local electromagnetic field intensities in any resonance. In principle, using the supersymmetry technique one can try to compute the function $f_N(p_1,\ldots,p_N)$ for arbitrary N, but we restrict the analysis below to the functions f_1 and f_2 that are of special importance for physical applications. For example, the conductance g, Eq. (2), and its distribution function can be directly related to f_2, whereas $f_1(p)$ has been directly measured in the microwave experiments.[16] In addition, since f_1 and f_2 can be related as follows:

$$f_1(p,\mathbf{r}_1)=\int_{-\infty}^{\infty} f_2(p,p';\mathbf{r}_1,\mathbf{r}')dp', \tag{6}$$

it would be enough to calculate f_2 alone. Nevertheless, in some cases, it is much easier to analyze f_1, so that below we shall deal with both of them. Knowledge of the distribution function f_1 makes it possible to calculate its moments, the so-called inverse participation numbers (IPN),

$$P_m=\left\langle \sum_{\alpha}\ |\varphi_\alpha(\mathbf{r}_1)|^{2m}\delta(\epsilon-\epsilon_\alpha)\right\rangle_{dis}\equiv\int_0^{\infty} p^m f_1(p,\mathbf{r}_1)dp. \tag{7}$$

A similar definition can be used for introducing the correlation functions

$$K_{nm}(r)=\int_0^\infty dp_1 dp_2 p_1^n p_2^m f_2(p_1,p_2;|\mathbf{r}_1-\mathbf{r}_2|=r)-P_m P_n;$$
$$R(p,r)=\int_0^\infty dp' p' f_2(p,p';|\mathbf{r}_1-\mathbf{r}_2|=r), \tag{8}$$

describing spatial correlations of the wave functions $\varphi_\alpha(\mathbf{r})$. Because of the normalization of wave functions in confined systems, one obtains $P_1\equiv V^{-1}$, and in many cases the correlator K_{22} is the simplest non-trivial one.

To apply the supersymmetry technique to the calculation of physical quantities, one has to express these quantities in terms of retarded G_ϵ^R and advanced G_ϵ^A Green functions. These functions are solutions of equations

$$\left[\hat{H}\pm i\frac{\gamma}{2}\right]G_\epsilon^{R,A}(\mathbf{r},\mathbf{r}')=\delta(\mathbf{r}-\mathbf{r}'). \tag{9}$$

Each of the functions $G_\epsilon^{R,A}(\mathbf{r},\mathbf{r}')$ are analytical in the upper (lower) half plane of complex ϵ, which is controlled by the presence of a finite width of each level γ. The *broadening* γ is introduced here artificially and is assumed to be the same for all quantum levels ϵ_α. The parameter γ allows us to relate the properties of a single quantum state to the Green functions $G^{R,A}$. Indeed, the latter can be represented as

$$G_\epsilon^{R,A}(\mathbf{r},\mathbf{r}')=\sum_\alpha \frac{\varphi_\alpha(\mathbf{r})\varphi_\alpha^*(\mathbf{r}')}{\epsilon-\epsilon_\alpha\pm i\gamma/2}, \tag{10}$$

so that the procedure of taking the *elastic quantum limit* $\gamma\to 0$ becomes a way to pick up a contribution to any expression containing some number of Green functions $G_\epsilon^{R,A}$ taken at the same energy ϵ from a single quantum level in order to study statistical and correlation properties of an individual eigenstate.

The algebraic exercise which shows how one can do this consists in the proof of the following equality:

$$\lim_{\gamma\to 0,\beta\to 1}\int_0^1 dt\frac{d}{d\beta}\left[\beta\frac{(i\gamma\beta t)^m}{(x+i\gamma/2)^m}\frac{(-i\gamma\beta(1-t))^n}{(x-i\gamma/2)^n}\frac{\gamma}{x^2+(\gamma/2)^2}\right]=2\pi\delta(x). \tag{11}$$

To prove Eq. (11), we integrate, first, over t which gives

$$\int_0^1 t^m(1-t)^n dt=\frac{m!n!}{(m+n+1)!}, \tag{12}$$

and then over x, using the formula

$$\gamma^{m+n+1}i^{m-n}\int_{-\infty}^\infty \frac{dx}{(x+i\gamma/2)^{m+1}(x-i\gamma/2)^{n+1}}=2\pi\frac{(m+n)!}{m!n!}. \tag{13}$$

Therefore, recalling the definition of the Green functions $G_\epsilon^{R,A}(\mathbf{r},\mathbf{r}')$, Eq. (10), one can rewrite the distribution function f_2 in the form

$$f_2(p_1,p_2;\mathbf{r}_1,\mathbf{r}_2)=\frac{\Delta}{\pi}\lim_{\gamma\to 0,\beta\to 1}\frac{d}{d\beta}\Big\langle \beta\int_0^1 dt\int d\mathbf{r}\,\mathrm{Im}[G^A_\epsilon(\mathbf{r},\mathbf{r})]$$
$$\times\delta(p_1+iY_AG^A_\epsilon(\mathbf{r}_1,\mathbf{r}_1))\,\delta(p_2-iY_RG^R_\epsilon(\mathbf{r}_2,\mathbf{r}_2))\Big\rangle_{dis}, \tag{14}$$

where $Y_A=\gamma\beta Vt$ and $Y_R=\gamma\beta V(1-t)$.

IV. STATISTICS OF WAVE FUNCTIONS AND NON-LINEAR SUPERMATRIX σ-MODEL

The goal of the manipulations with the distribution functions in the preceding section was to represent these quantities in a form suitable for application of the supersymmetry technique. Following the scheme of calculations developed in Refs. 33 and 34, one should express the function f_N, Eq. (14), in terms of an integral over supervectors ψ containing both commuting s and anticommuting χ elements. To rewrite Eq. (14) in such a form, we expand the δ-functions as a series in the Green functions $G^{R,A}$ and use the representation of the latter in terms of supersymmetric functional integrals. To do this, one can use a 4-component supervector for each of retarded and advanced Green functions, so that the minimal size of the superspace in the theory is 8, Refs. 33 and 34:

$$\psi=\begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix},\quad \psi_m=\begin{pmatrix}\lambda_m\\ S_m\end{pmatrix},\quad \lambda_m=\frac{1}{\sqrt{2}}\begin{pmatrix}\chi^*_m\\ \chi_m\end{pmatrix},\quad S_m=\frac{1}{\sqrt{2}}\begin{pmatrix}s^*_m\\ s_m\end{pmatrix},$$
$$\overline{\psi}=(\overline{\psi_1},-\overline{\psi_2}),\quad \overline{\lambda_m}=\frac{1}{\sqrt{2}}(\chi_m,\chi^*_m),\quad \overline{S_m}=\frac{1}{\sqrt{2}}(s_m,s^*_m),\quad m=1,2. \tag{15}$$

In Eq. (15), the superscripts 1 and 2 relate to the advanced and retarded Green functions, respectively. The components χ and χ^* are anticommuting Grassmann variables whereas s and s^* are conventional complex numbers conjugate with respect to each other.

In principle, to obtain a proper expression for a product of a large number of Green functions related to different energies, one would have to increase the size of the superspace, which would make any further computation extremely difficult. Fortunately, the distribution functions f_N which describe the properties of a single quantum level are all expressed in terms of $G^{R,A}_\epsilon$ taken at exactly the same energy. This enables us to operate in the superspace ψ in Eq. (15) without increasing its dimensions. Within the supersymmetry technique, one uses the Lagrangian L in the form

$$L[\psi]=-\int d\mathbf{r}\,\overline{\psi}(\mathbf{r})\left[\hat{H}_0+U(\mathbf{r})+\frac{i\gamma}{2}\Lambda\right]\psi(\mathbf{r}), \tag{16}$$

where 8×8 supermatrix Λ is

$$\Lambda=\begin{pmatrix}\mathbf{1}_4 & 0\\ 0 & -\mathbf{1}_4\end{pmatrix},\quad \mathbf{1}_4=\mathrm{diag}(1,1,1,1), \tag{17}$$

and represents any product of Green functions which would appear in a formal series expansion of Eq. (14),

$$B_{mn}=\langle G^A_\epsilon(\mathbf{r},\mathbf{r})[G^A_\epsilon(\mathbf{r}_1,\mathbf{r}_1)]^m[G^R_\epsilon(\mathbf{r}_2,\mathbf{r}_2)]^n\rangle_{dis} \tag{18}$$

as

$$m!n!i^{n-m-1}B_{mn}=\left\langle \int \chi_1(\mathbf{r})\chi_1^*(\mathbf{r})|s_1(\mathbf{r}_1)|^{2n}|s_2(\mathbf{r}_2)|^{2m}e^{-iL[\psi]}\mathrm{D}\psi\right\rangle_{dis}, \tag{19}$$

Due to the absence of a weight denominator, the averaging in Eq. (19) can be immediately performed and it leads to the appearance of an effective ''interaction'' $(\psi\psi)^2$ in the Lagrangian. Then, one decouples the interaction using Gaussian integration over 8×8 supermatrices Q with indices $Q^{ij}_{\alpha\beta}$ slowly varying in space. In accordance to the notations of the projections in the supervector space, we distinguish the pair of upper indices $i(j)=1,2$ which indicate from which Green function (advanced or retarded) the corresponding matrix element of Q was originated, and down indices $\alpha,\beta=1.4$ which distinguish between commuting (3,4) and anticommuting (1,2) components of $\psi_{1,2}$. After this, we integrate over ψ with the quadratic (after decoupling) effective Lagrangian

$$L_{\mathrm{eff}}[\psi,Q]=-\int\left[\overline{\psi}(\mathbf{r})\left(\hat{H}_0+\frac{i\gamma}{2}\Lambda+\frac{i}{2\tau}Q\right)\psi(\mathbf{r})\right]d\mathbf{r}. \tag{20}$$

As usual, one can perform the Gaussian integration using the Wick theorem. In principle, not only pairing of the type $\langle\psi_\alpha(\mathbf{r}_n)\underline{\psi}_\alpha(\mathbf{r}_n)\rangle$, such that both ψ's are taken at the same point is possible, but also pairings like $\langle\psi_\alpha(\mathbf{r}_n)\psi_\alpha(\mathbf{r}_m)\rangle$, $n\neq m$, should be taken into account. The latter pairing determines spatial dependence of the correlations of the wave functions. They decay already at distances of the order of wave length and are even exponentially suppressed at distances longer than the mean free path l. As soon as one studies correlations at distances $|\mathbf{r}_1-\mathbf{r}_2|>l$ only the pairings at coinciding points need to be considered and now let us restrict ourselves to this case. Of course, this limits the applicability of this theory to the effects determined by the long-range behavior of the diffusive waves and washes out all features of an electron motion at the short range scale where the specific character of a random potential starts playing an important role. To anticipate a little, the approach we use below enables us to work with zero-dimensional, 2D and quasi-1D systems where the long enough diffusive electron trajectories dominate in forming the structure of quantum states and in localization effects, whereas we cannot use it for studying the localization in three-dimensional (3D) systems.

After these remarks, the Gaussian integration over ψ in Eq. (19) with the Lagrangian L_{eff}, Eq. (20) can be easily performed, and, after collecting all terms B_{nm}, one reduces the function f_2 to the form

$$f_2(p_1,p_2,;|\mathbf{r}_1-\mathbf{r}_2|\gg l)=\lim_{\gamma\to 0,\beta\to 1}\frac{d}{d\beta}\left\langle\frac{\beta}{2V}\int\frac{d\zeta_1 d\zeta_2}{(2\pi)^2}\int_0^1 dt\int d\mathbf{r}(Q^{11}_{11}(\mathbf{r})-Q^{22}_{11}(\mathbf{r}))\right.$$
$$\left.\times\delta\left(p_1-\frac{t\gamma\beta}{2V\Delta}\overline{z_1}Q(\mathbf{r}_1)z_1\right)\delta\left(p_2+\frac{(1-t)\gamma\beta}{2V\Delta}\overline{z_2}Q(\mathbf{r}_2)z_2\right)\right\rangle_Q, \tag{21}$$

where $\langle\cdots\rangle_Q$ stands for the integration[33] over the supermatrices Q with the free energy functional $F[Q]$,

$$F[Q]=\frac{\pi\nu}{8}\mathrm{Str}\int\left[D\left(\nabla Q-\frac{ie}{c\hbar}\mathbf{A}[Q,\tau_3]\right)^2-\gamma\Lambda Q\right]d\mathbf{r},\langle\cdots\rangle_Q=\int DQ\cdots e^{-F[Q]}. \tag{22}$$

Str is supertrace and D is the classical diffusion coefficients. The supermatrix Q obeys the constraint $Q^2=1$ and can be represented in the form

$$Q=U\Lambda\overline{U}, \tag{23}$$

where U is a transformation generating the degeneracy space of graded symmetry group.[49] This field-theoretical model is essentially non-linear, since the matrix U satisfies the condition $\overline{U}U=1$, where an overbar indicates the operation of conjugation defined in Ref. 33 as

$$\overline{U}=CU^TC^T; \quad C=\begin{pmatrix} C_0 & 0 \\ 0 & -C_0 \end{pmatrix}; \quad C_0=\begin{pmatrix} -i\tau_2 & 0 \\ 0 & \tau_1 \end{pmatrix}, \tag{24}$$

where τ_α are the ordinary Pauli matrices and T means the transposition operation.

The transformation U can be imagined as a pseudo-unitary ''rotation'',

$$U=\begin{pmatrix} u_1 & 0 \\ 0 & v \end{pmatrix}\exp\begin{pmatrix} 0 & -iu_2\dfrac{\hat{\theta}}{2} \\ -i\dfrac{\hat{\theta}}{2}\overline{u_2} & 0 \end{pmatrix}, \tag{25}$$

and can be parametrized with an equal number of commuting and anticommuting variables. The second matrix in the product in Eq. (25) is composed only of commuting variables with u_2 an ordinary unitary matrix. All anticommuting variables are collected into matrices u_1 and v_1. The vectors $z_{1,2}$ and $\overline{z_{1,2}}$ have the form determined by

$$\overline{z_1}=(0,0,e^{i\zeta_1},e^{-i\zeta_1},0,0,0,0), \quad \overline{z_2}=(0,0,0,0,0,0,e^{i\zeta_2},e^{-i\zeta_2}). \tag{26}$$

Equations (21–25) completely reduce the problem of computation of the distribution function f_N to functional integration over supermatrices Q within the non-linear σ-model.

The reduction of quantum mechanics of a particle in a disorder medium to the non-linear σ-model has several approximations implicit in the above derivation. First of all, by introducing smoothly varying fields Q, we make a separation between ''fast'' and ''slow'' variables, where the ''fast'' variables have sense only if the particle motion can be everywhere considered as a semiclassical one, that is, the action it takes should be large and real. This excludes from the theory below the effects related to the tunneling through potential barriers—the rare configuration of a random potential which are, nevertheless, possible within the Gaussian model of disorder (but not allowed in the case of the box distribution, for example). At the same time, the procedure[33] which leads to the conjecture $Q^2=1$ and the following gradient expansion we use in determining the effective free energy functional prevents us from discussing features of the wave functions at the length scales shorter than l, and what we are able to describe within the σ-model approach is the structure of quantum states smeared over the volume of a ''Hikami-box'' which is (for the models with short-range scatterers) $\sim\lambda^{d-1}l$. As a result, the localization effects in 3D systems which are dominated by the short-range dynamics of a particle[60] cannot be treated consistently by the σ-model approach we use: they would be systematically underestimated. In 2D and quasi-1D systems, the long-range diffusive trajectories of a particle are important, so that the σ-model approach works, but we cannot speak about densities p higher than $(\lambda^{d-1}l)^{-1}$, and we also cannot anticipate the form of specific configurations of a random potential responsible for forming prelocalized states. We make the latter remark since at short distance (in small volumes) it is possible to imagine rare configurations of scatterers (whose probability to be found strongly depends on the model of disorder) which would appear more efficient being studied beyond the Born approximation.

The same should be repeated concerning the analysis of a somewhat more simple function f_1 which can be expressed in terms of an integral over the supermatrices Q in a similar way starting from Eq. (5):

$$f_1(p,\mathbf{r}_1)=\frac{1}{4V}\int\frac{d\zeta_1 d\zeta_2}{(2\pi)^2}\lim_{\gamma\to 0}\left\langle\int d\mathbf{r}(\overline{z_1}(Q(\mathbf{r})-\Lambda)z_1)\right.$$

$$\left.\times\delta\left(p-\frac{\gamma}{2V\Delta}\overline{z_2}Q(\mathbf{r}_1)z_2\right)\right\rangle_Q. \tag{27}$$

Computation of this function is easier to follow, so that we start the next section from the analysis of this function and study a situation where the σ-model results can be easily compared to those of the RMT.[24]

V. UNIVERSAL EIGENSTATE STATISTICS AND 0D σ-MODEL FOR SYSTEMS WITH BROKEN TIME-REVERSAL SYMMETRY

Disordered systems with the broken time-reversal symmetry represent the simplest ones where the supersymmetric σ-model can be applied and where the results obtained by using this method can be compared with the predictions of the phenomenological approaches. The RMT predicts that the function f_1 describes the Gaussian distribution of wave function amplitudes which, in the case of a broken time-reversal symmetry (unitary ensemble) corresponds to

$$f_1(p;\mathbf{r})=V\exp\{-Vp\}\quad\text{and}\quad P_n=n!V^{-n}. \tag{28}$$

Such a distribution has universal form in the sense that it contains no information about any dynamical parameter such as a mean free path, shape of a cavity or position of the observation point inside it, but only manifests the fact that the density of all eigenstates in the system is normalized by its volume (or area in 2D).

The goal of the analysis presented in this section is to reproduce the result of Eq. (28) using the σ-model calculations. In other words, we have to find an approximation of the complete field theory which would give us the universal statistics. From the explicit form of the free energy functional $F[Q]$ in Eq. (22), it is clear that the only way to omit such a dynamical parameter as the diffusion coefficient D would be to consider the so called zero-dimensional (0D) version of a model, that is, to assume that the only relevant degree of freedom of the field $Q(\mathbf{r})$ is its zero space harmonics $Q(\mathbf{r})=\text{const}=Q_0\equiv Q(\mathbf{r}_1)$.

Physically, the 0D approximation described above neglects any localization effect, which indicates that each wave function is sensitive to boundaries of the sample. The 0D approximation bridges the σ-model to the RMT and, at the same time, drastically simplifies calculations since the functional integration in it is replaced by a definite integral over superspace with a simplified free energy,

$$\langle\ldots\rangle_Q=\int dQ_0 e^{-F_{0D}},\quad F_{0D}[Q]=-\frac{\pi\gamma}{8\Delta}\text{Str}(\Lambda Q). \tag{29}$$

The choice of the unitary ensemble is also motivated by its simplicity. In a strong magnetic field, so called ''cooperon'' degrees of freedom are ''frozen'', and only the part of the supermatrix Q commuting with matrix τ_3 (see the notations in Refs. 33 and 34) gives a contribution. That is why, in the unitary case, the number of independent components of the supermatrix Q is two times smaller than, e.g., in the orthogonal case when the time-reversal symmetry is not broken. The parametrization of the superspace can be made using the invariant representation of Eq. (25), $Q=U_d\Lambda\overline{U_d}$, with group transformations U_d in the form of Eq. (25) where

$$\hat{\theta}=\begin{pmatrix}\theta_d\mathbf{1}_2 & 0\\ 0 & i\theta_{1d}\mathbf{1}_2\end{pmatrix},\quad\begin{matrix}0<\theta_d<\pi,\\ 0<\theta_{1d}<\infty;\end{matrix}\quad\mathbf{1}_2=\begin{pmatrix}1&0\\0&1\end{pmatrix},\quad u_2=\exp\begin{pmatrix}i\varphi_1\tau_3 & 0\\ 0 & i\varphi_2\tau_3\end{pmatrix}, \tag{30}$$

and

$$u_1=\begin{pmatrix} 1-2\hat{\eta}_d\hat{\eta}_d^\dagger & 2\hat{\eta}_d \\ -2\hat{\eta}_d^\dagger & 1+2\hat{\eta}_d\hat{\eta}_d^\dagger \end{pmatrix}, \quad v=\begin{pmatrix} 1+2\hat{\kappa}_d\hat{\kappa}_d^\dagger & 2i\hat{\kappa}_d \\ -2i\hat{\kappa}_d^\dagger & 1-2\hat{\kappa}_d\hat{\kappa}_d^\dagger \end{pmatrix},$$
$$\hat{\eta}_d=\begin{pmatrix} \eta_d & 0 \\ 0 & \eta_d^* \end{pmatrix}, \quad \hat{\kappa}_d=\begin{pmatrix} \kappa_d & 0 \\ 0 & -\kappa_d^* \end{pmatrix}. \tag{31}$$

In this parametrization, the $\theta_{d,1d}$ and $\varphi_{1,2}$ are commuting variables, whereas $\eta_d, \eta_d^*, \kappa_d, \kappa_d^*$ are Grassmann variables. The integration over the superspace in the parametrization Eqs. (30), (31), implies the knowledge of the Jacobian,[33,34]

$$J_d=\frac{d\lambda_{1d}d\lambda_d}{(\lambda_{1d}-\lambda_d)^2}\,\frac{d\eta_d d\eta_d^* d\kappa_d d\kappa_d^*}{16}\,\frac{d\varphi_1 d\varphi_2}{(2\pi)^2}; \quad \lambda_{1d}=\cosh(\theta_{1d}), \quad \lambda_d=\cos(\theta_d). \tag{32}$$

In terms of the variables λ_{1d} and λ_d, the free energy F_{0D} can be reduced to the form

$$F_{0D}=\frac{\pi\gamma}{\Delta}[\lambda_{1d}-\lambda_d]. \tag{33}$$

The pre-exponential factor in Eq. (27) can be simplified as well, since vectors z_1 and z_2 commute with Q, and the integration over the variables ζ_1 and ζ_2 is trivial. As a result, Eq. (27) can be rewritten as

$$f_1(p)=\frac{V}{2}\lim_{\gamma\to 0}\int (Q_{33}^{11}-1)\,\delta\left(p-\frac{\gamma}{\Delta}Q_{33}^{22}\right)e^{-F_{0D}[Q]}dQ, \tag{34}$$

where Q_{33}^{11} and Q_{33}^{22} are matrix elements (the superscripts denote the blocks originating from the presence of both advanced and retarded Green functions and the subscripts—the elements in these blocks).

Note that the combination entering the δ-function in Eq. (34) contains the broadening γ which has to be put to 0. When $\gamma\to 0$, the only possibility to have a finite value of the product $(\gamma/\Delta)Q_{33}^{22}$, which is necessary since p is a finite wave function density in a finite volume, is to take into account the values of Q_{33}^{22} as large as $\Delta/\gamma\to\infty$. We can do it since the degeneracy space of the supersymmetric field theory is non-compact. To be more precise, one has to deal with that part of the superspace where $\lambda_{1d}\sim\Delta/\gamma\to\infty$.

This argument simplifies dramatically our calculus. Indeed, in the leading approximation with respect to γ, it is enough to keep only the pseudo-unitary part in the matrix U_d and even to replace it by an asymptotical expression

$$U_d\to U_\infty=\frac{\sqrt{\lambda_{1d}}}{2}\begin{pmatrix} u_1u_2 & 0 \\ 0 & v \end{pmatrix}\Pi, \quad \overline{U_d}\to\overline{U_\infty}=\frac{\sqrt{\lambda_{1d}}}{2}\overline{\Pi}\begin{pmatrix} \overline{u_2u_1} & 0 \\ 0 & \overline{v} \end{pmatrix},$$
$$\Pi=\begin{pmatrix} \pi_b & \pi_b \\ \pi_b & \pi_b \end{pmatrix}, \quad \overline{\Pi}=\begin{pmatrix} \pi_b & -\pi_b \\ -\pi_b & \pi_b \end{pmatrix}\equiv\Lambda\Pi\Lambda, \quad \pi_b=\begin{pmatrix} 0 & 0 \\ 0 & \mathbf{1}_2 \end{pmatrix}. \tag{35}$$

The matrix U_∞ in Eq. (35) does not belong to the graded symmetry group. It has a sense only as an asymptotical form of parametrization of the ''infinities'' of the superspace in the integrals like in Eq. (21,29,34). Both the Jacobian in Eq. (32) and free energy in Eq. (33) can also be simplified by neglecting a finite $\lambda_d\leqslant 1$ in comparison to infinitely large $\lambda_{1d}\sim\Delta/\gamma$, which finally results in the distribution function in the form of Eq. (28).

Computation of the function $f_2(p_1,p_2;\mathbf{r_1},\mathbf{r_2})$ in the limit of large distances $|\mathbf{r}_1-\mathbf{r}_2|\gg l)$, Eq. (21), can be performed in the same way. At large distances, the distribution function f_2 in the unitary ensemble no longer depends on the coordinates, so they can be omitted. Starting with the expression from Eq. (21), we find that the distribution function has a separable form,

$$f_2(p_1,p_2;|\mathbf{r}_1-\mathbf{r}_2|\gg l)=V^2\ \exp\{-V(p_1+p_2)\}. \tag{36}$$

The separability of the joint density distribution function indicates that, at large distances, the correlations between amplitudes of the wave function are suppressed. To find the law describing their decay with increase of the distance $|\mathbf{r}_1-\mathbf{r}_2|$ (starting from the wavelength scale $\lambda=2\pi k^{-1}$, $\mathbf{k}$ being the wave vector), one has to take into account pairing $\langle\psi_\alpha(\mathbf{r}_n)\psi_\alpha(\mathbf{r}_m)\rangle$ in the derivation of the σ-model in Eqs. (18)–(21). This analysis has been performed by Prigodin.[42] Here we mention the final result re-addressing the reader to Refs. 42 and 43 for technical details. The joint distribution function f_2 in the unitary symmetry class at short distances has the form

$$f_2(p_1,p_2;|\mathbf{r}_1-\mathbf{r}_2|)=\frac{V^2}{1-g^2}\ \exp\left(-\frac{V(p_1+p_2)}{1-g^2}\right)\mathrm{I}_0\left(\frac{2V\sqrt{g^2p_1p_2}}{1-g^2}\right), \tag{37}$$

where $\mathrm{I}_0(x)$ is the modified Bessel function and $g^2(r)$ is the Friedel function[32] ($r=|\mathbf{r}_1-\mathbf{r}_2|$):

$$g=\begin{cases}\mathrm{J}_0(kr)e^{-r/l}, & \text{2D},\\ \sin(kr)e^{-r/l}/(kr), & \text{3D}\cdot\end{cases} \tag{38}$$

From Eqs. (36)–(38) we see that the correlations decay at distances of the order of the wavelength. Absence of distant correlations in wave functions is in so good agreement with a naive expectation coming from the phenomenological models, that one may think that it is the general result which is valid for any chaotic system. However, this is not the case. The suppression of correlations at large distances occurs in the limiting cases of unitary and orthogonal symmetry classes, but does not work in the crossover regime of weak magnetic fields. The correlation of wave functions in the crossover regime will be discussed in detail in the next section.

VI. REDUCED σ-MODEL AND EIGENSTATE STATISTICS BEYOND THE UNIVERSALITY REGIMES: CROSSOVER BETWEEN ORTHOGONAL AND UNITARY ENSEMBLES

Note that the procedure of integration over the ''diffusion'' degrees of freedom in the 0D approximation of the previous section together with the necessity to take the limit $\gamma\to 0$ gives us a result that is free of any level broadening and describes the statistics of a single chaotic eigenstate. Moreover, integration over the zero ''diffusion'' mode in the limit $\gamma\to 0$ can be a good move for any particular realization of the σ-model (e.g., in the case where the magnetic field H is so weak that the magnetic flux through the sample area is small, or when the sample is large enough to expect that the localization effects play an important role). What we obtain after such a manipulation is a *reduced σ-model* which directly describes the statistical properties and spatial structure of a single state in the discrete spectrum of a confined quantum system.

In the general case, the field Q depends on the coordinates and contains more variables. In the crossover regime between the unitary and orthogonal symmetry classes, the presence of the ''cooperon'' degrees of freedom doubles the number of independent parameters, and the transformation U in Eq. (27) can be represented[50] as the product

$$U=U_dU_c;\quad U_c=\begin{pmatrix} u_{1c} & 0\\ 0 & v_c\end{pmatrix}\exp\begin{pmatrix} 0 & -u_{2c}C_0\dfrac{\hat{i}\theta_c}{2}\\ -\dfrac{\hat{i}\theta_c}{2}C_0^{\dagger}\overline{u_{2c}} & 0\end{pmatrix},$$
$$\hat{\theta}_c=\begin{pmatrix}\theta_c\mathbf{1}_2 & 0\\ 0 & i\theta_{1c}\mathbf{1}_2\end{pmatrix},\quad \text{where}\quad \begin{matrix}0<\theta_c<\pi/2,\\ 0<\theta_{1c}<\infty,\end{matrix}. \tag{39}$$

In Eq. (39), C_0 is defined as in Eq. (24), and the matrices $u_{1c,2c}$ and v_c are similar to those in the parametrization of V_d in Eq. (34). The measure of the integration over the ''cooperon'' variables described above is given by

$$dQ_c=\left(\frac{2\lambda_c}{\lambda_{1c}^2-\lambda_c^2}\right)^2\frac{d\lambda_c d\lambda_{1c}}{16}\frac{d\varphi_1' d\varphi_2'}{(2\pi)^2}dR_c,\quad dR_c=d\eta_c d\eta_c^* d\kappa_c^* d\kappa_c, \tag{40}$$

where $\eta_c,\eta_c^*,\kappa_c,\kappa_c^*$ are Grassmann variables.

To derive the reduced σ-model, we represent the supermatrix field $Q(\mathbf{r})$ at any point $\mathbf{r}$ inside the sample in the form

$$Q(\mathbf{r})=U_d(\mathbf{r}_1)\widetilde{Q}(\mathbf{r})\overline{U_d}(\mathbf{r}_1), \tag{41}$$

where $U_d(\mathbf{r}_1)$ is parametrized by Eqs. (33) and (34) and describes the values of the full set of ''diffusion'' variables of the field Q at the observation point $\mathbf{r}_1$. The integration over the zero diffusion mode is equivalent to integration of Eq. (21) over all possible ''directions'' U_d of the superfield in the sample ''as a whole.'' Because of the δ-functional form of the pre-exponential part of the expressions involved, only large $\theta_d(\mathbf{r}_1)$, such that $e^{\theta_d}\sim\Delta/\gamma\to\infty$, contribute to the integrals in Eqs. (21) and (29). So, we use Eq. (35) in the same way as in the previous section.

As a result, the general σ-model transforms into the reduced one with a modified free energy functional. It is easier to follow the derivation calculating the distribution function f_1. In particular, the second term in $F[Q]$ in Eq. (22) containing infinitely small γ, after the integration of $\delta(p-(\gamma/2V\Delta)\overline{z_1}Q(\mathbf{r}_1)z_1)$ over all the variables of $V_d(\mathbf{r}_0)$ converts it into

$$F_2[Q]\to F_2[\widetilde{Q}]=\frac{p}{2\overline{z_1}\Lambda\Pi\widetilde{Q}(\mathbf{r}_1)z_1}\int d\mathbf{r}\,\mathrm{Str}(\Lambda\Pi\widetilde{Q}(\mathbf{r})). \tag{42}$$

The term of Eq. (42) plays the role of an ''external field'' (introduced by the procedure of measurement of the local wave function density) breaking the symmetry between bosonic and fermionic degrees of freedom of the field Q. Note that the above procedure suggests that, the field $\widetilde{Q}(\mathbf{r})$ parametrized as $\widetilde{Q}=\widetilde{U}_d\widetilde{U}_c\Lambda\tilde{\tilde{U}}_c\tilde{\tilde{U}}_d$, corresponds to boundary conditions $U_d(\mathbf{r}_1)=\mathbf{1}$.

On the contrary, the gradient term of the free energy $F[Q]$ in Eq. (22) does not change its form:

$$F_1[Q]\to F_1[\widetilde{Q}]=\frac{D\pi\nu}{8}\int d\mathbf{r}\,\mathrm{Str}\left(\nabla\widetilde{Q}-\frac{ie}{\hbar c}\mathbf{A}[\widetilde{Q},\tau_3]\right)^2. \tag{43}$$

As to the form of the pre-exponential factor in the generating functional of the reduced σ-model, it depends on the index N of the joint distribution and can be sufficiently simplified in several special cases, in particular, when studying the crossover regime between the orthogonal and unitary symmetry classes. Analogously to the derivation of the universal statistics in the

previous section, in a relatively small system we can neglect spatial variations of the field $\widetilde{Q}$, so that $\widetilde{Q}(\mathbf{r})\equiv\widetilde{Q}(\mathbf{r}_1)$. Then the lowest ''cooperon'' mode is described by the expression for the free energy,

$$F_1=-\left(\frac{X}{4}\right)^2\mathrm{Str}([\widetilde{Q},\tau_3]^2)=X^2(\lambda_{1c}^2-\lambda_c^2)X^2=(2\pi)^3\frac{D}{\Delta}\int\frac{d\mathbf{r}}{V}\left(\frac{\mathbf{A}(\mathbf{r})}{\phi_0}\right)^2=\alpha_g\frac{\phi^2}{\phi_0^2}\frac{E_c}{\Delta},$$

where $\phi_0=hc/e$ is the flux quantum, α_g is the sample geometry dependent factor, D is the classical diffusion coefficient, E_c is the Thouless energy equivalent to the inverse time of flight through the system, L^2/D.

The physical meaning of this term arising in the 0D σ-model is that it is related to distribution of the magnetic fluxes encircled by a semiclassical electron trajectory. Due to the Aharonov-Bohm effect,[51] the encircled fluxes determine the phases of the electron wave in a magnetic field,

$$\frac{e}{c\hbar}\oint(\mathbf{A}d\mathbf{r})=\frac{2\pi}{\phi_0}\int\mathbf{H}d\mathbf{S}.$$

In a classical picture of chaos, these phases, as well as the magnetic fluxes, can be arbitrarily large. This is in contrast to the correct semiclassical picture of quantum mechanics where they cannot. The lengths of geometrical paths attributed to classical trajectories in semiclassics should be limited, since the trajectorial description breaks down at the time scale longer than the Heisenberg time, $t_H\sim h/\Delta$. Hence, the values of the encircled magnetic flux are also limited, so that the classical ergodicity does not always lead to the complete randomness of the wave function phases. That is why the crossover between the two limiting symmetry classes extends over a finite region of magnetic fluxes through the sample cross-sectional area, which indicates that there can exist long-range correlations in the chaotic wave function in the entire crossover regime. On the other hand, in classically non-integrable systems, the Heisenberg time is usually much longer than the time flight L^2/D, so that crossover between time-reversal and no-time-reversal symmetry limits occurs at fairly weak magnetic fields.[33,52,53]

In order to establish the presence or absence of the correlations, we study the joint distribution function $f_2(p_1,p_2;\mathbf{r}_1,\mathbf{r}_2)$ at two points separated by the distance $|\mathbf{r}_1-\mathbf{r}_2|$ much larger than the mean free path l and compare it with the single-point distribution function f_1. As discussed in the previous section, the Friedel-type oscillations are dead at these distances, so that the presence of correlations means the non-separability of the joint function $f_2(p_1,p_2)$ into the product $f_1(p_1)f_1(p_2)$.

After some necessary algebra,[41,45] the joint distribution function f_2 and the distribution function f_1 can be represented as

$$f_N(p_1,\ldots,p_N)=V^N\int_0^1 d\lambda_c\int_1^\infty d\lambda_{1c}\exp(-F_\phi)\times\frac{\lambda_c^2}{(\lambda_{1c}^2-\lambda_c^2)^2}$$
$$\times\int\int P\prod_{n=1}^{N}\frac{d\zeta_n}{2\pi}\frac{\exp(-Vp_n/A_n)}{A_n}dR_c, \tag{44}$$

which is a parametrized representation of the reduced σ-model. In Eq. (44), $N=1,2$, and functions P and A_n are defined as

$$P=\lambda_{1c}+2(\eta_c\eta_c^*-\kappa_c\kappa_c^*)(\lambda_{1c}-\lambda_c),\quad A_n=1+\mathrm{Re}\,\frac{Le^{i\zeta_n}}{P},$$

$$L=\sqrt{\lambda_{1c}^2-1}(1+2\eta_c\eta_c^*)(1-2\kappa_c\kappa_c^*)+4\sqrt{1-\lambda_c^2}\eta_c\kappa_c.$$

Skipping further technical details of the algebraic manipulations with Eq. (44), we are able to represent the joint distribution function f_N, $N=1,2$ in the form

$$f_N = V^N \int_1^\infty B(X,x) \prod_{n=1}^{N} M(Vp_n,x)\,dx, \tag{45}$$

where

$$B(X,x) = X^2[(xX^2-1)\Phi_2(X)+\Phi_1(X)]e^{-X^2(x-1)},$$

$$M(q,x) = \sqrt{x}\,\exp(-qx)\mathrm{I}_0(q\sqrt{x^2-x}),$$

Here, $\mathrm{I}_0(z)$ is the modified Bessel function, and

$$\Phi_1(X) = \frac{e^{-X^2}}{X}\int_0^X e^{y^2}dy, \quad \Phi_2(X) = \frac{1-\Phi_1(X)}{X^2}.$$

First of all, let us compare the result obtained by using the σ-model and the predictions of the random matrix theory for the universal statistics. The comparison with the unitary case, $X\to\infty$, may serve as a check of the algebra, since it coincides with the results of Eqs. (30) and (36). In the orthogonal ensemble, $X\to 0$, we also find from Eq. (45) that the joint distribution function is separable at large distances,

$$f_2(p_1,p_2)\to \prod_{n=1,2}\frac{Ve^{-Vp_n/2}}{\sqrt{2\pi Vp_n}}; \quad f_1(p)\to\sqrt{\frac{V}{2\pi p}}\exp\left(-\frac{1}{2}Vp\right). \tag{46}$$

However, the joint distribution function is not separable at any finite magnetic field, which indicates that, even in the limit of large distances between the points $\mathbf{r}_1$ and $\mathbf{r}_2$, the correlations do not vanish. To demonstrate the *existence of a long-range correlation in each individual wave function* in a quantum billiard subjected to a weak magnetic field, we calculate the correlation function $K_{22}(r\gg l)$ defined in Eq. (8). Fig. 1(a) illustrates how the correlations evolve as function of a normalized flux through the sample area. As one can see from Fig. 1(a), the correlations are present all over the crossover regime: from the smallest to the highest values of the normalized flux. Numerically, these correlations are never strong (of the order of one percent), since the maximal value of the correlator $\max(K_{22})\approx 0.05$ has to be compared to the square of the second moment P_2 varying from the value of 3 to 2 between the orthogonal and unitary symmetry classes. The distant correlations in the wave functions can also be traced in the joint probability to find simultaneously two zeros of the wave function $\varphi(\mathbf{r}_{1,2})=0$. At small fluxes corresponding to $X\ll 1$, $[f_1(0)]^2\approx(4\pi/9)X^{-2}$ whereas $f_2(0,0)\approx\frac{5}{3}X^{-2}$, and Fig. 1(b) illustrates the evolution of the distribution function $\varphi(\tau)=2\tau f_1(\tau^2)$ of local amplitudes $\tau=\sqrt{(p)}$ following the variation of a magnetic flux.

Since the pioneering work by Berry,[30] it has been believed that in classically ergodic systems the local wave function density can be imagined as a result of superposition of an infinite number of plane waves with random phases and equal momenta. In the unitary case, this is a complete randomness. In the orthogonal ensemble, the pairs of time-reversed plane waves with wave vectors $\pm\mathbf{k}$ enter this representation with conjugate phases. The randomness of the phases results in the Gaussian randomness of the amplitude φ_α and vanishing of correlations at large distances. Our result in Eq. (45) means that a weak magnetic flux through the sample area introduces some non-local correlations in $\varphi_\alpha(\mathbf{r})$ related to the fact that the Aharonov-Bohm phases taken by an electron moving in a quantum billiard cannot be arbitrarily large and that the phases of the ''plane waves'' in the phenomenological picture are slightly correlated at each point, which has not been

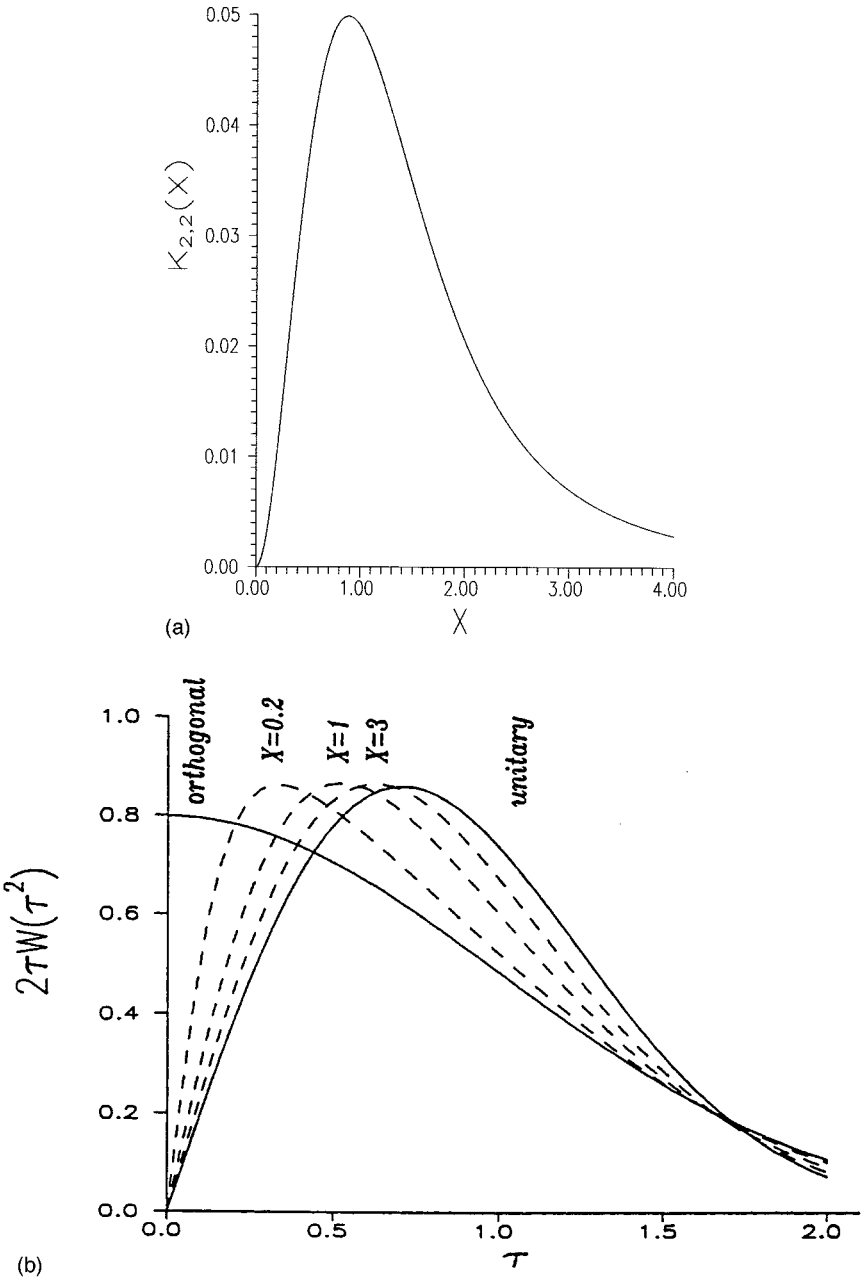

FIG. 1. (a) Two-point correlation function at distant points as a function of a normalized flux. (b) Distribution function of local amplitudes of wave functions (as described in the text) for various values of a normalized magnetic flux through the system.

anticipated in previous semiclassical theories. These correlations are present in the entire crossover regime and can be diminished only by the localization effects which have not been taken into account, yet, but will be considered in the next section.

VII. LOCALIZATION EFFECTS IN THE WAVE FUNCTIONS STATISTICS AND NON-TRIVIAL VACUUM OF THE REDUCED σ-MODEL

To study the localization effects in the wave functions statistics, one has to go beyond the 0D approximation of the σ-model.[33,54–59,44,45] Depending on the system to be studied and problem to be considered, the inhomogeneous field $Q(\mathbf{r})$ can be treated in different ways. In the perturbation theory calculation in the weak localization regime, they appear as non-zero spatial ''cooperon'' modes.[3] In quasi-1D wires, the account for the inhomogeneous $Q(x)$ using the transfer matrix method gives an exact solution of the localization problem in the limit of a weak disorder.[56] Recently, in revising the perturbative results of Ref. 60 on the long-living current relaxation in mesoscopic conductors, Muzykantskii and Khmelnitskii[59] have suggested that an adequate description of anomalous events in the weak localization regime may involve the treatment of the supersymmetric σ-model by using a saddle-point method.

In the studies of the eigenstates statistics in weakly disordered conductors with a size smaller than the localization length,[44,45] the inhomogeneous supermatrix fields appear as a *non-trivial vacuum state of the reduced σ-model.* In this Section, we present all details of the calculus for the unitary symmetry class. That is, regarding to the discussion in Section VI, we assume that the magnetic field applied to the system is large enough (though the classical cyclotron radius is still longer than the mean free path) and formally require that $l/\lambda \gg Hl^2/\phi_0 \gg \sqrt{\lambda/l}$. The unitary symmetry class can be also modeled by a random magnetic or gauge field disorder.[47,48] This allows us to suppress completely the ''cooperon'' degrees of freedom of the Q-field and to deal only with the ''diffusion'' ones. The content of the next few paragraphs repeats the derivation earlier from Ref. 44, and one can find in Ref. 45 its generalization to other fundamental symmetry classes. We also restrict the analysis to the calculation of the single-point distribution function $f_1(p)$ which contains enough information to indicate the existence of *prelocalized states* in a disordered system (the states with an anomalously high local density), and to the correlation function $R(p,r)$ defined in Eq. (8) which tells us about their statistically averaged envelopes. The generating functional of the reduced σ-model equals

$$\Phi_u(p) = \int_{\widetilde{Q}(\mathbf{r}_1)=\Lambda} \mathrm{D}\widetilde{Q}(\mathbf{r}) e^{-F[\widetilde{Q}]}, \tag{47}$$

where the free energy has the form

$$F[\widetilde{Q}] = \int d\mathbf{r} \mathrm{Str}\left[\frac{\pi\nu D}{8}(\nabla\widetilde{Q})^2 - \frac{p}{4}\Lambda\Pi\widetilde{Q}(\mathbf{r})\right], \tag{48}$$

and we are reminded that $\widetilde{Q}(\mathbf{r}_o)=\Lambda$ at the origin and projector Π is that defined in Eq. (35). At the same time, the distribution function f_1 and its moments P_n can be represented (in terms of the generating functional Φ_u) as

$$f_1(p) = \frac{1}{V}\frac{d^2\Phi_u(p)}{dp^2}, \quad P_n = \frac{n(n-1)}{V}\int_0^\infty p^{n-2}\Phi_u(p)dp. \tag{49}$$

As far as other fundamental symmetry classes are concerned, this relation may take various forms (see Ref. 45).

The generating functional in Eq. (47) has several funny features. First, at $p=0$, it has a completely invariant form, and therefore is equal to unity, which corresponds to the normalization of all wave functions,

$$VP_1 = \Phi_u(0) \equiv 1. \tag{50}$$

On the other hand, for any finite p the reduced σ-model has broken symmetry, so that the minimum of the free energy in Eqs. (47) and (48) corresponds to an inhomogeneous $\widetilde{Q}_p(\mathbf{r})$. Indeed, $(p/4)\Lambda\Pi$ in the second term in Eq. (48) resembles a field tending to align the matrix $\widetilde{Q}$ along the non-compact ''direction'' of the Q-space (related to the parameter θ_{1d}), whereas the boundary condition at $\mathbf{r}_0$ together with the gradient term can be viewed as a rigidity attempting to prevent that. The competition between these two tendencies results in a non-trivial minimum configuration of $\widetilde{Q}$. To find this non-trivial vacuum state (saddle-point), we use again the invariance of the Q-space with respect to rotations $\widetilde{U}$ and represent Q as

$$\widetilde{Q}(\mathbf{r})=U_{\mathrm{vac}}(\mathbf{r})\Lambda\frac{1+iP}{1-iP}\overline{U}_{\mathrm{vac}}(\mathbf{r}),\quad P=\begin{pmatrix}0 & B\\ \overline{B} & 0\end{pmatrix}\otimes\mathbf{1}_2, \tag{51}$$

where a weak perturbation P stands for fluctuations around the saddle-point, and the matrices $B,\overline{B}$ can be decomposed into blocks as follows:

$$B=\begin{pmatrix}s_{1,1}\tau_0+is_{1,2}\tau_3 & \hat{\sigma}_1\\ \hat{\sigma}_2^{+} & s_{2,1}\tau_0+is_{2,2}\tau_3\end{pmatrix},\quad \hat{\sigma}_\alpha=\begin{pmatrix}\sigma_\alpha & 0\\ 0 & -\sigma_\alpha^{*}\end{pmatrix}. \tag{52}$$

The parametrization of fluctuation using Eq. (52) is especially convenient from the point of view of the perturbative analysis, since it has a unit value of the Jacobian (Berezian).[34] The form of the saddle-point $\widetilde{Q}_{\mathrm{vac}}=U_{\mathrm{vac}}\Lambda\overline{U}_{\mathrm{vac}}$ follows from the requirement of the absence of linear terms in the expansion of F into the series

$$F[\widetilde{Q}]=F_p+F^{(2)}+F^{(3)}+F^{(4)}+\ldots, \tag{53}$$

in the perturbation $B,\overline{B}$. This selects

$$U_{\mathrm{vac}}=\exp\begin{pmatrix}0 & \frac{1}{2}\theta_p e^{i\chi\tau_3}\pi_b\\ \frac{1}{2}\theta_p e^{-i\chi\tau_3}\pi_b & 0\end{pmatrix}, \tag{54}$$

where the parameter $\theta_t(\mathbf{r})$ satisfies the equation

$$\nabla^2\theta_p(\mathbf{r})=-\frac{p}{\pi\nu D}e^{-\theta_p},\quad \chi=\pi, \tag{55}$$

with the boundary conditions $\theta_p(\mathbf{r}_1)=0$ in the origin and $(\mathbf{n}\nabla)\theta_p=0$ at the surface of the sample. In Eqs. (55) and (54), ∇^2 stands for the Laplacian in the real d-dimensional space, and projection matrix π_b is that defined in Eq. (35).

A similar analysis of the reduced σ-model can also be performed for other symmetry classes and leads us to the same saddle-point equation as in Eq. (55). The difference between the unitary, orthogonal and symplectic (including spin-orbit scattering) ensembles leads only to different values of the coefficient β,

$$\beta_o=\frac{1}{2},\quad \beta_u=1,\quad \beta_s=2, \tag{56}$$

in the expression describing the minimal free energy,

$$F_p = \beta \int d\mathbf{r} \left\{ \frac{\pi \nu D}{2} (\nabla \theta_p)^2 + p e^{-\theta_p} \right\}, \tag{57}$$

and in the higher order terms of the expansion of $F[\widetilde{Q}]$ in the vicinity of the vacuum state $Q_{\rm vac} = U_{\rm vac} \Lambda U_{\rm vac}$.

The optimum (saddle-point) equation in Eqs. (54) and (55) is analogous to the saddle-point equation derived by Muzykantskii and Khmelnitskii[59] when revising the problem of long-living current relaxation in open conductors.[60] Nevertheless, the fact that we started from the reduced σ-model which describes properties of a single quantum state in a confined system results in a different non-linearity in it and different boundary conditions. The *non-trivial vacuum of the reduced σ-model* from Eqs. (51)–(55) *satisfies the Liouville equation*. For those familiar with the conformal theory of quantum gravity,[61] this fact immediately points to the critical properties of the wave functions in two dimensions. The issue of peculiar properties of prelocalized states in 2D conductors will be discussed in more detail in the next section; here we only mention the general difference between the purely conformal quantum Liouville theory[61] and the localization problem. The Liouville equation (55) describes the ''mean field'' distribution of the length scales in the system and is invariant under rescaling $r \to ar$ and $\theta_p \to \theta_p - 2\ln(a)$. Without the above-mentioned boundary conditions, this would give us an infinitely broad distribution of length scales in the structure of the wave functions in two dimensions, and there exist several examples[62–66] when the critical wave functions can be constructed starting from very special models of disorder (e.g., 2D-electrons with g-factor 2 living in a random magnetic field,[62] or 2D relativistic spin-$\frac{1}{2}$ particles in a randon Abelian gauge field).[63] It is amusing to note that the f_1-statistics and some simple correlation functions in the above-mentioned models of disorder may be calculated using the saddle-point method applied to the generating functional analogous to that in Eq. (47).[67]

Although the similarity of the optimum equation, Eq. (55), describing the vacuum state of the reduced σ-model to the Liouville equation and conformal field theory may call helpful analogies,[66] the answers which can be anticipated in this way might be used only as intermediate asymptotics. In conventional models of disorder, there are several relevant length scales in the problem, such as the mean free path l which we keep much smaller than the size of the system L. In our theory, the latter comes to the play through the boundary condition at the edge; the former - through the condition at the origin which has to be replaced by the ''smoothed'' requirement $\theta_p(r_0 \sim l) = 0$. This restricts applicability of the saddle-point calculations by the domain of validity of the σ-model in its standard form: to systems with dimensions lower than three. In 3D systems, the free energy of the non-trivial vacuum state of reduced σ-model is sensitive to the singular behavior of Q-fields at distances shorter than l,[45] and the application of our method to dimension three cannot give an adequate quantitative description of statistics of anomalously high splashes of wave functions and would systematically underestimate the probability of their appearance: As we recently learned from Shklovskii, at short distance (in small volumes), it is possible to construct rare configurations of a random potential which would become more efficient would one go beyond the Born approximation with respect to the random potential implicit to the σ-model approach.

Another difference between precisely conformally invariant Liouville theory and the σ-model description of localization consists in a number of additional degrees of freedom which are present in the supersymmetric order parameter $\widetilde{Q}$. Playing no role in forming the vacuum state, these degrees of freedom become crucially important if the *fluctuations around the non-trivial vacuum* are taken into account. In a complete theoretical construction, they would result in the localized behavior at long distances of all the states we are studying. At present, we are not able to provide a rigorous theoretical treatment of this problem, which seems to require some kind of a functional renormalization group approach. But what we can do here, that is to account for fluctuations perturbatively and to get the lowest order estimation and to control the regime of applicability of the saddle-point method and check the stability of the vacuum.

Since now, we represent the generating functional $\Phi_u(p)$ in the form

$$\Phi_u(p)=J(p)\exp(-F_p). \tag{58}$$

In the conducting regime, the value of the minimal free energy determines the leading term in the exponential of the generating functional, whereas the effect of fluctuations around the non-trivial vacuum is included into the function $J(p)$,

$$J(p)=\int DB\ \exp\{-F^{(2)}-F^{(3)}-F^{(4)}\dots\}. \tag{59}$$

Because of the normalization condition in Eq. (50), the relation $J(0)=1$ holds exactly. The contribution from the fluctuations B at $p=0$ can be calculated by expanding the exponential in the integrand in Eq. (59) in a series in higher order terms $F^{(3,4,\dots)}$ and performing Gaussian integrations over B with the weight $\exp\{-F^{(2)}\}$ determined by the second order correction to the free energy.

The applicability of such a perturbation theory is justified by the fact that the contribution of the higher order terms to the free energy are, at least, by the factor of $(2\pi\nu D)^{-1}\ll 1$ smaller, as compared to what is given by

$$J(p)\approx\int DB\ \exp\{-F^{(2)}[B]\}. \tag{60}$$

The $J(p)$ is the superdeterminant of the Hamiltonian related to the fluctuations around the saddle-point. The value of $J(p)$ differs from unity merely because the symmetry between fermionic and bosonic degrees of freedom is broken by a vacuum state. Since not all projections of the infinitesimal B to the generators of the Lie algebra of the graded symmetry group are equivalently affected by the symmetry breaking, it is convenient to separate in $F^{(2)}$ the terms that perceive the existence of the minimal solution from those that do not. Depending on the physical symmetry class, this involves different sets of variables. Nevertheless, after an appropriate diagonalization, the quadratic form $F^{(2)}$ can be represented uniquely for all symmetry classes:[45]

$$F^{(2)}=F_p^{(2)}+\mathfrak{s}F_0^{(2)},\quad \begin{matrix}\mathfrak{s}_u=0,\\ \mathfrak{s}_{o,s}=1.\end{matrix} \tag{61}$$

The term $F_0^{(2)}$ in Eq. (61) is composed of fields which are not affected by the symmetry breaking,

$$F_0^{(2)}=2\pi\nu D\sum_{\alpha=1,2}\int d\mathbf{r}\{\vec{\nabla}\sigma_\alpha^-\vec{\nabla}(\sigma_\alpha^-)^*+\vec{\nabla}s_\alpha^-\vec{\nabla}(s_\alpha^-)^*\}.$$

This term does not contribute to the function J in the Gaussian approximation, due to the symmetry between boson (s) and fermion σ degrees of freedom incorporated. On the contrary, the first term in Eq.(61) is the sum over those four pairs of dynamical variables which are sensitive to the violation of the boson-fermion symmetry,

$$F_p^{(2)}=2\pi\nu D\int d\mathbf{r}\left\{\sum_{\alpha=1,2}[\nabla\sigma_\alpha\nabla\sigma_\alpha^*+U_\sigma\sigma_\alpha\sigma_\alpha^*]+\sum_{\beta,\alpha=1,2}[(\nabla s_{\alpha,\beta})^2+U_s^{\alpha\beta}s_{\alpha,\beta}^2]\right\}.$$

Therefore, the pre-exponential J can be represented as

$$J=\exp\left\{\frac{1}{2}\sum_n\ln\left(\frac{(\chi_\sigma(n))^4}{\Pi_{\alpha,\beta}\chi_s^{\alpha\beta}(n)}\right)\right\}, \tag{62}$$

where the sum is extended over all eigenvalues $\{\chi\}$ of the spectral problem,

$$[-\Delta+U-\chi]\phi=0, \quad \phi(\mathbf{r}_1)=0, \quad \mathbf{n}\nabla\phi=0|_{edge}. \tag{63}$$

As mentioned, any difference of J from unity is due to the broken symmetry between fermionic and bosonic degrees of freedom in B. The broken symmetry in the Hamiltonian $F_p^{(2)}$ is a consequence of the difference between the effective potentials U_σ and U_s,

$$U_\sigma=\frac{1}{4}(\nabla\theta_p)^2+\frac{p}{2\pi\nu D}e^{-\theta_p}, \quad U_s^{\alpha\beta}=\frac{k_{\alpha,\beta}}{4}(\nabla\theta_p)^2+\frac{pq_{\alpha,\beta}}{2\pi\nu D}e^{-\theta_p}, \tag{64}$$

in the Hamiltonian $F_p^{(2)}$ In Eq. (64), $k_{\alpha,1}=q_{\alpha,1}=0$ and $k_{1,2}=4$, $k_{2,2}=0$, $q_{\alpha,2}=2$. The spectra $\{\chi_\sigma(n)\}$ and $\{\chi_s^{\alpha\beta}(n)\}$ of modes remain gapfull, since all $U>0$. Moreover, because of the sum rule

$$\sum_{\alpha\beta} U_s^{\alpha\beta}=4\sum U_\sigma, \tag{65}$$

their main contribution to J comes from low-lying eigenvalues of Eq. (63). Since the set of U's in Eq. (64) depends on the vacuum state only, the calculation of the correction to the exponent in this order in $(2\pi\nu D)^{-1}$ can be performed for all symmetry classes at once and is small, if the size of the system is shorter than the localization length.

The existence of a non-trivial vacuum of the reduced σ-model and a relatively small contribution from fluctuations in the metallic regime makes it easy to find the form of the cross-correlation function $R(p,r)$ from Eq. (8), too. If we study the envelope of the wave function at sufficiently large distances $r\gg l$ from the position of a high amplitude splash, the reasoning used above can be repeated for $R(p,r)$ with minor modifications, and we arrive at

$$|\varphi_p(r)|^2\sim R(p,r)/f_1(p)\propto pe^{-\theta_p(r)}, \tag{66}$$

so that one can say that the envelope of $|\varphi(r)|^2$ follows the form of the saddle-point configuration of the reduced σ-model.[44,45]

VIII. MULTIFRACTALITY OF EIGENSTATES IN WEAKLY DISORDERED 2D CONDUCTORS

The form of the vacuum state of the reduced σ-model depends on the real dimensionality of the system. In 3D systems, the localization effects are known to be the weakest. Although the distribution function f_1 acquires a broader distribution than the universal one, all its moments P_n (IPN) scale with the inverse integer power of the volume of the system. We, therefore, omit the 3D case, since it gives the results the most resembling the universal ones.[45]

On the contrary, the statistics of eigenstates in quasi-1D wires are the most affected by the localization, and show a clear evidence of prelocalized states. The properties of wires will be discussed in the Section IX, whereas the present chapter is devoted to the most intriguing issue: the statistics of prelocalized wave functions in disordered 2D systems.

The fact is that the 2D disordered systems are very close to the critical ones and, as it has been anticipated by Wegner[54,55] and by Altshuler, Kravtsov and Lerner[60] and confirmed by extensive numerical simulations,[68–73] they possess nearly critical properties in a broad range of distances between the mean free path and the exponentially long localization length. In our calculations, we are after manifestations of very peculiar states which show the behavior similar to that of percolating states at the metal-insulator transition point,[73,74] and it is already commonly believed that the criticality is directly related to the logarithmically-normal statistics and multifractal structure of the objects under investigation.[75,74] Of course, the localization problem in two dimensions is not

really a critical one. The possibility to detect multifractality in the calculations presented below is only because we study finite systems with a size smaller than 2D localization length, and it appears as an approximate intermediate asymptotical result, since the wave functions of critical type are strongly affected by the presence of boundaries, and the evidence about their existence is hidden in the large p tails of the distribution function $f_1(p)$.

To find the distribution function f_1 and the full set of IPN's in a large ($L \gg l$) weakly disordered ($L_c \gg l$) 2D system, one has to solve the optimum equation in Eq. (55) and find the free energy F_p of the vacuum state. For the sake of simplicity, we consider the sample in the form of a disk (with the radius L) and place the observation point $\mathbf{r}_1$ exactly in its center. This choice will be approved by the logarithmic dependences $\ln(L/l)$ we get on the end of calculations. Therefore, we seek a symmetric solution $\theta_p(r)$ of the equation

$$(r^{-1}\partial_r r \partial_r)\theta_p = -\frac{p}{\pi\nu D} e^{-\theta_p}, \quad \theta_p(r_0 \sim l) = 0, \quad \partial_r \theta_p(L) = 0; \quad \rho = \sqrt{\frac{2\pi\nu D}{p l^2}}. \tag{67}$$

This can be done exactly.[76] The solution has the form

$$e^{-\theta_p} = \left[\frac{2(l/r)^{1-A}[\sqrt{(1/A\rho)^2+1}+1]}{[\sqrt{(1/A\rho)^2+1}+1]^2 - (1/A\rho)^2 \left(\frac{r}{l}\right)^{2A}} \right]^2, \tag{68}$$

where A should be found from the boundary condition at the sample edge $r = L$,

$$\sqrt{A^2+\rho^{-2}} + A = \frac{(L/l)^A}{\rho}\sqrt{\frac{1+A}{1-A}}. \tag{69}$$

Substituting the saddle-point solution $\theta_p(r)$ from Eqs. (68) to Eq. (57), we find the minimal free energy,

$$F_p = \beta 4\pi^2 \nu D \left\{ \ln\left(\frac{(L/l)^{(1+A^2)}}{\rho^2[1-A^2]} \right) + 2(1 - \sqrt{A^2+\rho^{-2}}) \right\}.$$

Together with Eq. (69), this can be used for the numerical analysis of the exponential in the distribution function.

The numerical analysis shows that the consistency equation, Eq. (69), has positive roots only if $\rho > \ln(L/l) \gg 1$, which provides a reasonable limitation to the wave function amplitudes we can study using this method. It limits the density p of a splash by the value $\sim(\lambda l)^{-1}$ related to the density of an electron state bound to the forward-and-backward scattered trajectory between two impurities [in fact, we have the restriction $p < p_{\max} \approx (\lambda l)^{-1}/\ln(L/l)$, where λ is the wavelength]. At the same time, in the limit of $\rho > 1$, the roots of Eq. (69) can be approximated by $A = 1 - \mu$, where $\mu < 1$. The same conditions enable us to replace the exact solution in Eq. (68) by

$$e^{-\theta_p} \approx (l/r)^{2\mu}. \tag{70}$$

Prelocalized states which are responsible for the logarithmically-normal tails do not decay exponentially. The statistically averaged envelope of the density of such states can be anticipated from the form of the correlation function $R(p,r)$ in Eqs. (8) and (66) and has power-law asymptotic tails,

$$|\varphi_p(\mathbf{r})|^2 \sim \frac{R(p,r)}{f_1(p)} = e^{-\theta_p(r)} \approx \left(\frac{l}{r}\right)^{2\mu}, \tag{71}$$

with the spectrum of exponents $\{\mu(p)\}$ described by the equation

$$\mu=\frac{(L/l)^{2-2\mu}}{2(1-\mu)\rho^2}\approx\frac{z(T)}{2\ln(L/l)},\quad \text{where } ze^z=T\equiv\frac{pV\ln(L/l)}{2\pi^2\nu D}. \tag{72}$$

For small values of p, $\mu\to 0$, when p grows up to $p_{\max}\sim(l\lambda_F)^{-1}/\ln(L/l)$, μ approaches the limiting value $\mu\approx 1$ which corresponds to $|\varphi_p(r)|^2\propto r^{-2}$. With the same accuracy, the free energy of the vacuum state can be approximated by

$$F_p\approx\beta 4\pi^2\nu D\left\{\mu+\mu^2\ln\frac{L}{l}\right\}, \tag{73}$$

and the applicability of the saddle-point method can be now checked by comparing F_p to the effect of the fluctuations in the lowest order.

The contribution of fluctuations in the environs of the vacuum state can be calculated[45] following the way described in the Section VII. To find the lowest (second) order corrections to the minimal free energy, one has to know the spectrum of fluctuations described by Eqs. (61)–above, this spectrum $\{\chi(n,m)\}$ can be classified by the orbital and radial quantum numbers m and n, respectively, and can be found from the eigenvalues of the Hamiltonian,

$$\hat{H}=-r^{-1}\partial_r(r\partial_r)+m^2r^{-2}+U,$$

where U is determined by Eqs. (64) and (65).

When $U=0$, the spectrum of χ's can be approximated by

$$\chi(0,0)\approx\frac{2L^{-2}}{\ln(L/l)};\quad \chi(n,m)\approx\left(\frac{\pi}{L}\right)^2\left[n+\frac{1}{4}+\frac{m}{2}\right]^2. \tag{74}$$

In the non-trivial vacuum, the fermion-boson symmetry is broken, which induces effective potentials in fermionic sectors and some of bosonic sectors, too. The latter are composed of two terms,

$$\frac{1}{4}k(\partial\theta_p)^2\approx\frac{k\mu^2}{r^2}\quad\text{and}\quad q\frac{p}{2\pi\nu D}e^{-\theta_p}\approx q\mu L^{-2}\left(\frac{L}{r}\right)^{2\mu}.$$

In the above equations, the approximate values are given for the most important range of distances $r\leqslant L\sqrt{z(T)/T}$, and one has to remember that $\mu<1$.

For any $m\neq 0$, the potential U is relatively small, $U\ll m^2/r^2$, and could be treated perturbatively. Due to the sum rule in Eq. (64), the modes with $m\neq 0$ contribute only in the second order in U, and what they give to the exponential of J is of the order of either $\mu^4\ln(L/l)$ or μ^2. With the accuracy we need here regarding the leading terms in F_p, this contribution can be neglected. The spectrum of low-lying modes $\{\chi(n>0,0)\}$ is given by the expression

$$\chi(n,0)\sim\left(\frac{\pi}{L}\right)^2\left[n+\frac{1}{4}+\sqrt{k}\frac{\mu}{2}\right]^2,\quad 0<n\leqslant\frac{L}{\pi l}. \tag{75}$$

The lesson we learn from the above calculated spectrum of fluctuation is that all the eigenvalues χ are positive and increase as compared to what one would get starting from the trivial vacuum ($\widetilde{Q}=\Lambda$), so that we conclude that the vacuum state Q_{vac} is, at least, locally stable. However, the account for the fluctuations $B,\bar{B}$ in the quadratic approximation does not tell us more than that and is not informative from the point of view of manifestation of real localization expected in 2D systems at larger distances.[77] This would need a higher order perturbation theory

with respect to $B,\overline{B}$ in Eq. (53). The second order terms give just corrections to the minimal free energy which are small, as compared to F_p, when $g \gg 1$. This can be checked by substituting the eigenvalues from Eqs. (74)–(75) to the general equation in Eq. (62):

$$J = 1 + 0(T^2), \quad T \ll 1$$
$$J \propto \mu \exp\left(\mu \ln \frac{L}{l}\right) \sim T, \quad T \gg 1.$$

All this enables us to analyze the distribution function f_1. Below, we extend this analysis up to the leading orders in the exponents. For small amplitudes $p < 2\pi\nu D/[L^2 \ln L/l]$, one obtains

$$f_1 \approx \exp\left(-\beta V p\left[1 - \frac{T}{2} + \ldots\right]\right) \times \begin{cases} \sqrt{\frac{V}{2\pi p}}, o, \\ V, u, \\ 2V, s, \end{cases} . \tag{76}$$

where T and β are defined in Eqs. (72) and (56), respectively.

In the opposite limit, $p > 2\pi\nu D/[L^2 \ln L/l]$, the distribution function takes the form

$$f_1 \sim V \exp\left(-\frac{\beta \pi^2 \nu D}{\ln(L/l)} \ln^2 T\right). \tag{77}$$

Equation (77) demonstrates that for all fundamental symmetries, - orthogonal, symplectic and unitary, - disorder makes the appearance of high-amplitude splashes of wave functions much more probable than one would expect from the Porter-Thomas formula and, as concerns the most extra-ordinary events, the tails take the logarithmically-normal form. When written for the orthogonal ensemble, the logarithmically-normal law in Eq. (77) coincides with the form of the asymptotics of the distribution of the local density of states in open systems found in Ref. 60, although our theory is developed for closed systems and is based on a completely different scheme of calculations.

Inverse participation numbers P_n derived on the basis of Eq. (49) show such a scaling with the size of a system which implies a multifractal structure. To find the moments P_n accurately enough, we have to take into account that although the crossover to the 0D case looks like the formal limit $T(p) \to 0$, the Porter-Thomas statistics fail unless the condition $pV \ll \sqrt{2\pi\nu D}$ is satisfied [see Eq. (63)]. Figure 2 illustrates how the large amplitude tail of the distribution function f_1 develops at higher values of p, and the exponentially large deviation from the Porter-Thomas distribution, we find, an indication that only the first few ratios P_n, $2 \leqslant n \ll \sqrt{2\pi\nu D}$, can be estimated using a finite polynomial expansion of $f_1(p)$ in a series in T. Having been treated in such a way, we reproduce corrections to the universal statistics found pertubatively in Ref. 78. Alternatively, we derive the higher order IPN's from Eqs. (49) using the saddle-point method. The moments P_n calculated in both ways are in a good agreement with each other and, in the leading order, can be represented as

$$P_n \approx \frac{\min\{c(n), [2\pi\nu D/\ln L/l]^n\}}{l^{2\delta} V} \left(\frac{1}{V}\right)^{\tau(n)/2}, \tag{78}$$

where

$$\tau(n) = (n-1) d^*(n), \quad d^*(n) \approx 2 - \frac{\beta^{-1} n}{4\pi^2 \nu D}. \tag{79}$$

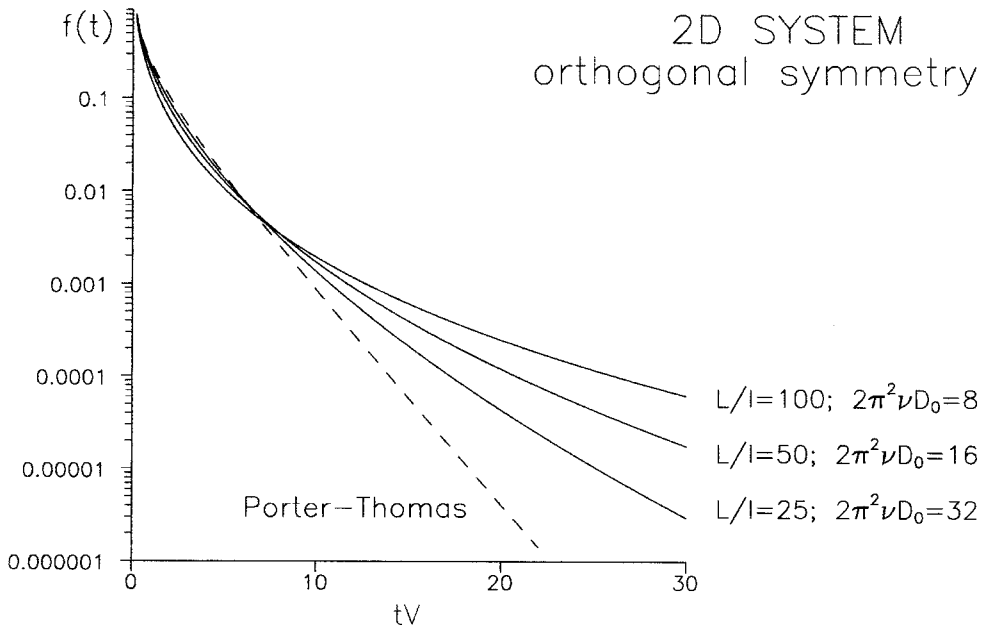

FIG. 2. Distribution function of a local density for 2D disordered system with time reversal symmetry (orthogonal ensemble) calculated for various levels of disorder.

In Eq. (78), $c_u(n)=n!$ in the unitary and $c_o(n)=(2n-1)!!$ in the orthogonal case; β is specified in Eq. (56).

The intermediate asymptotical scaling laws we end up with in Eqs. (78) and (79) manifest the multifractal behavior of quantum states. The set of indices $\tau(n)$ determines the spectrum of fractal (Reny) dimensions $d^*(n)$. In a full agreement with its name, the multifractality indicates that the density of a wave function may be imagined as distributed over some tree whose Hausdorf dimension decreases with increasing the length scale. In truly conformally invariant theories,[66] this property might be traced both by enlarging the system size L for a fixed amplitude of the wave function, or by looking at increasingly growing density peaks for a fixed L. Both ways of moving through the increasing density (p) or length scale (L) would lead to the selection of a ''current'' value of fractal dimension $d^*(n_*)$ determined by a typical n_* which corresponds to the typical wave functions living at this scale. In disordered systems we study in this article, the process of moving along the n-axis of the function $\tau(n)$ cannot last indefinitely, since we should meet one of two obstacles: the limiting value of the density, $p_{\max}\sim(l\lambda)^{-1}/\ln^2 L/l$, or the localization length, and the effective dimensions at large n's should start saturating in order to remain positive, $d^*>0$.

IX. SEMICLASSICAL SOLUTION OF THE TRANSFER-MATRIX METHOD AND PRELOCALIZED STATES IN A SHORT DISORDERED WIRE

The models of disorder in one dimension are explored the most, and there is a lot known about the localization effects in one-dimensional and quasi-one-dimensional (Q1D) wires. In particular, it is well known[79,80] that all quantum states of a particle in a disordered Q1D system are localized, even when disorder is weak. In really one-dimensional objects, the localization length is hardly distinguishable from the classically determined mean free path l. In wires with cross-sectional width w (or area w^2) which is much larger than the wavelength λ (or λ^2), the localization length, L_c, is as large as the number of ''transverse channels'' $N=(w/\lambda)^{d-1}$,[80,56]

$$L_c = \beta 2\pi\nu D \sim (w/\lambda)^{d-1} l \sim Nl, \tag{80}$$

where β is specified by Eq. (56) and the effective 1D density of states ν is determined as the local density of states integrated over the cross-section. In the following, we also redefine the variable p as integrated over the wire cross-section, $p \to w^{d-1}p$, so that it is measured in units of the inverse length. When $w \gg \lambda$, the localization length in Eq. (80) can be much longer than the mean free path l, and the typical (mean value) of the conductance of such a wire, $g = L_c/L$, is large, $g \gg 1$. This allows us to consider short Q1D wires with the length $l < L < L_c$ as typically metallic, and apply to their studies the non-linear σ-model approach. To avoid discussions of a dimensional crossover, we also assume that $w < l$.

It would be a straightforward procedure to use the transfer-matrix method[81] for solving the σ-model in one dimension.[56] It consists in projecting the one-dimensional field theory of the supermatrix $Q(x)$ onto the quantum-mechanical problem of calculation of the Green function of a ''particle'' living on the degeneracy space of the σ-model and an imaginary time ix. To solve such a problem comprehensively, one has to find the full spectrum of ''energies'' and ''eigenstates'' of the corresponding Schrödinger equation determined on the Q-space. Its lowest ''energy'' is nothing but the inverse localization length, L_c^{-1} and the knowledge of the low-lying modes in such a ''quantum mechanics'' is necessary when studying the long-range properties of the system. The problem of statistics of wave functions in disordered quasi-1D wires has been treated in this context by Mirlin and Fyodorov[58] and solved in two asymptotical regimes: of fluctuations with relatively small amplitudes in short wires, and finite-amplitude fluctuations in infinitely long wires. As regarding the statistics of densities $p \sim V^{-1}$ in wires which are much shorter than the localization length, it occurs very close to the universal Porter-Thomas distribution discussed in Eqs. (28) and (46), which is natural to expect for typical states in the metallic regime. For long wires with $L \gg L_c$ and $g \ll 1$, Ref. 58 gives the distribution $f_1(p)$ in the unitary ensemble which is described by the function of a density p normalized by the localization length,

$$f_1(p) \propto \mathrm{K}_1^2(4\sqrt{pL_c}) + \mathrm{K}_0^2(4\sqrt{pL_c}) \propto \sqrt{\frac{L_c}{p}}\,\exp(-4\sqrt{pL_c}), \tag{81}$$

where K_n are modified Bessel functions. Such a scaling law is also naively expected, since it describes behaviour of the states which live at the length scale L_c and have a normalizable density.

What is not that obvious in the problem of statistics of quantum states in disordered wires, is that there exist a small number of prelocalized states even in the metallic regime, when $L \ll L_c$ and $g \gg 1$, which have an anomalously large local amplitude of wave functions. These are described by the asymptotical form of the distribution function which resembles that in the infinite wire: It is dominated by the exponential term in which the density p scales with the localization length and which is independent of the wire length L. In this section, we use the saddle-point method to derive the statistics of such prelocalized states and to describe their spatial structure. Reciting the discussion of two previous paragraphs, the saddle-point calculation in Q1D is nothing but the *''quasiclassical'' solution* of the effective Schrödinger equation on the Q-space[33,56] which appears in the *transfer-matrix method*, and the calculational procedure consists of the steps described by Eqs. (55)–(58),(62) and (66) in Section VII.

First of all, we have to solve the Liouville equation on the vacuum state,

$$\partial_x^2 \theta_p(x) = -\frac{p}{\pi\nu D}\,\exp\{-\theta_p\}, \tag{82}$$

and use its solution $\theta_p(x)$ when calculating the minimal free energy F_p. Due to the condition $\theta_p(x_1) = 0$ at the observation point x_1, the latter splits the wire with the length L into two (not

necessarily equal) intervals $0<x<L_{i=L,R}$. The form of $\theta_p(x)$ can be found separately in each of them. In one dimension, the differential equation in Eq. (82) can be solved exactly,[76] and we represent its general solution in the form

$$e^{-\theta_p}=\left[\frac{A_i}{\cos\{A_i\sqrt{T_i}(1-x/L_i)\}}\right]^2, \quad x>0; i=L,R. \tag{83}$$

The general form of this solution formally contains a singularity at $x_\infty=-L_i[\pi/(2A_i\sqrt{T_i})-1]$ located in the non-physical region $x<0$ which plays a role when one formulates the limitations to our theory. The requirement $x_\infty \gg l$ is related to the limitations on maximal values of gradients permitted by the use of only the lowest order gradient expansion in the free energy functional in Eq. (20). We shall discuss the consequences of this condition at the end of this chapter, assuming for a while that it is satisfied. If so, the consistency equations on the parameters A_i come from the boundary conditions $\partial_x\theta_p(L_i)=0$ at the edges and have the form

$$A_i=\cos(A_i\sqrt{T_i}), \tag{84}$$

where T_i are defined as

$$T_i=\frac{pL_i^2}{2\pi\nu D}. \tag{85}$$

The minimal value of the free energy can be found, in its turn, as

$$F_p=\beta\sum_{i=L,R}\frac{L_i p}{\sqrt{T_i}}[2\sqrt{1-A_i^2}-A_i^2\sqrt{T_i}]. \tag{86}$$

The pre-exponential factor J arising from the fluctuations in the vicinity of the vacuum state can be taken into account as well. As far as the condition $\theta_p=0$ at $x=x_1$ splits the interval $[0,L]$ into two pieces, the spectrum $\{\chi(n)\}$ of fluctuations in Eqs. (63)–(64) can be found in each interval separately, and we represent $J=J_LJ_R$ as a product of contributions from the left- and right-hand-side intervals with lengths $L_{L,R}$. Each of $J_{L,R}$ is determined by the eigenvalues of the Schrödinger equation in Eqs. (63),(64) with the symmetry-breaking potentials

$$U_i=\left[kT_i+q\left(\left[\frac{\sqrt{T_i}\pi/2}{1+\sqrt{T_i}}\right]\Big/\sin\left\{\frac{\sqrt{T_i}\pi/2}{1+\sqrt{T_i}}\frac{x}{L_i}\right\}\right)^2\right]L_i^{-2},$$

where $i=L,R$. When $T\ll 1$ (in the paragraph below, we omit indices L and R), these potentials can be treated perturbatively. Their first order corrections cancel due to the sum rule from Eq. (65), so that $J\approx 1+T^2\approx 1$. When $T\gg 1$, the same cancellation eliminates contributions from the high-excitation eigenvalues $\chi>(\pi/2L)^2T$, so that the important contribution comes from the low-energy part of the spectrum, $\chi<(\pi/2L)^2T$, where one can approximate

$$U\approx(\pi/2L)^2[k+k'/\sin^2(\pi x/2L)], \quad k'=k+q,$$

and the spectral problem can be solved exactly. To find the exact solution, one has to change variables from x to $y=\cot(\pi x/2L)$ and then seek for the eigenstates in the form $P_n(y^2)/(1+y^2)^{\delta(n)}$, where $P_n(y^2)$ are polynomials. This results in the set of eigenvalues $\chi(n)$, $0\leqslant n<T$,

$$\chi(n)=(\pi/2L)^2\{[2n+1/2+\sqrt{k'+1/4}]^2-k\}.$$

Being substituted into Eq. (62), this gives the pre-exponential factor J in the main order in $T_{L,R}$:

$$J \approx \exp\left(\sum_{i=L,R} \frac{1}{4} \ln T_i + \text{ const} \right) \approx C(T_L T_R)^{1/4}. \tag{87}$$

In general, the exact form of F_p in Eq. (86) based on the closed set of equations in Eqs. (83)–(85) can be studied numerically at any value of the parameters included, but a somewhat simpler analytical expression can be written in the asymptotical regions, also because we are able to analyze the effect of fluctuation around the saddle-point mainly for small and large amplitudes separately. First of all, we examine the limit of small amplitudes, $T_i < 1$, where the exact distribution has to match the random matrix theory results. At $T_i < 1$, the results of Eqs. ((84)–(86)) can be expanded into the series in T_i, which gives $A_i \approx 1 - \frac{1}{2} T_i + \frac{13}{24} T_i^2 + \ldots$ and

$$F_p \approx Vp\left(1 - \sum_{i=L,R} \frac{T_i L_i}{3L} + \ldots \right),$$

whereas the contribution from fluctuations can be neglected,[45] and we find that

$$f_1(p) \approx e^{-\beta F_p} \times \begin{cases} V, & u, \\ \sqrt{\dfrac{V}{2\pi p}}, & o. \end{cases} \tag{88}$$

Therefore, the Porter-Thomas formula which describes those amplitudes p which are $p < L^{-1}\sqrt{L_c/L}$. Otherwise, the second term of this expansion, VpT_i, becomes larger than unity and strongly affects the probability to detect a very high splash of the wave function attributed to the prelocalized state.

When

$$T = \frac{pL^2}{2\pi\nu D} \gg 1, \quad \text{i.e.,} \quad p > \frac{2\pi\nu D}{L^2} \sim \frac{g}{L}, \tag{89}$$

$e^{-\theta_p}$ develops at the length scale of $\xi = \sqrt{2\pi\nu D/p} \sim \sqrt{L_c/p}$, where it can be approximated as

$$e^{-\theta_p(x)} \sim (\xi/x)^2, \tag{90}$$

and becomes less sensitive to the presence of the boundaries. Indeed, being an image of a statistically averaged *envelope of the density of the prelocalized wave functions* $\varphi_p(x)$, the vacuum of the σ-model described by Eq. (90) is related to the quantum states with the density integrable at the short range scale,

$$|\varphi_p(x)|^2 \sim \frac{p}{w^{d-1}} e^{-\theta_p} \sim \frac{L_c/w^{d-1}}{x^2} \sim \frac{l/\lambda^2}{x^2}. \tag{91}$$

This behavior very much resembles the localization, with an important difference: It is not a conventional localization with exponential decay $\varphi(x) \propto \exp(-|x|/L_c)$ of the wave functions at large distances $x > L_c$, but only the power-law one.

The asymptotical regime of the distribution function in the limit of $T_i \gg 1$, i.e., of $p > g/L$, is thus described by the minimal free energy

$$F_p = 4\sqrt{\beta L_c p}\{1 - \delta_L - \delta_R\}, \quad \delta_{L(R)} \sim \frac{\pi^2}{8}\left[T_{L(R)}^{-1/2} - \frac{1}{2} T_{L(R)}^{-1} + \ldots \right], \tag{92}$$

and by the pre-exponential factor in Eq. (87). The applicability of the saddle-point method requires that the value of minimal free energy in Eq. (92) dominates over the contribution from fluctuation in Eq. (87), which is satisfied when the conductance of the wire is large, $g \approx L_c/L \gg 1$.

Another limitation to the applicability of the analysis presented above emerges from the requirement of a smoothness of the saddle-point solution, so that its characteristic length scale ξ should be longer than the mean free path, $\xi > l$. Otherwise, the singularity x_∞ of the equation in Eq. (83) comes too close to the physical part of the space. After taking into account that the variable p describes the wave function density integrated over the wire cross-section, we find that $\max[|\varphi_p|^2] \sim p/w^{d-1} < 1/l\lambda^{d-1}$. This restriction is quite natural[45] and is similar to what we wrote about the 2D systems: It limits the density of the wave function by the density of a state bound to a forward and backward scattered trajectory at the length scale of the mean free path (i.e., the inverse volume of the Hikami-box).

Finally, the probability to find an anomalously high splash of a wave function $p > g/L$ related to the power-law prelocalized states has the form

$$f_1(p) \approx C \frac{\sqrt{L_L L_R}}{L} \sqrt{\frac{L_c}{p}} \exp[-4\sqrt{\beta L_c p}\{1-\delta_L-\delta_R\}]. \tag{93}$$

In this asymptotical regime, the distribution function depends on the density normalized by localization length and is insensitive to the systems size, as one gets in the infinite wires.[58] Because of such a coincidence, one may aim to get the asymptotical functional form of f_1 using a less formal heuristic argumentation. We have made this attempt together with Kravtsov and Lerner[82] in the spirit of interpretation of localization results in disordered wires.[80] First of all, we assume that the high splash of the density at the coordinate x_1 is due to a prelocalized state located within the interval $[x_1-\xi, x_1+\xi]$ near this observation point. If so, we describe it as typically metallic in a shorter wire with the length ξ, with a typical occurrence obeying the Porter-Thomas law $A(p,\xi) \sim \exp(-p\xi)$ in such a reduced geometry. On the other hand, the chance to find such a state is very small. To estimate it, we can try to follow the evolution of a locally created wave packet which starts to spread diffusively all over the sample. At the short time scale, its spreading is dominated by the laws of classical random walks, so that the probability of finding a particle inside an interval $[x_1-\xi, x_1+\xi]$ after time $t > \xi^2/D$ passes is $\sim \exp(-tD/\xi^2)$. If a prelocalized state is formed within this interval, it can show up in the wave packet evolution at the time scale of about the Heisenberg time $t_H(\xi) \sim \alpha\hbar/\Delta(\xi) \sim \hbar\nu\xi$ (inverse mean level spacing) related to the length scale ξ, since this is when the classical regime of a progressively spreading particle density changes into quantum limit where the states are already formed in a finite volume ξ. Coming from the classical side, we estimate the expectation value to find a particle inside the interval as $B(\xi) \sim \exp(-t_H(\xi)D/\xi^2)$, which gives us the probability $A(p,\xi)B(\xi)$ to find a high density splash p.

When speaking about typical states in an infinite wire, we take $p \sim \xi^{-1}$ and find that the length scale ξ which we have to choose by assuming that $B \sim 1$ is the localization length $L_c \sim 2\pi\nu D$: that is where the classical diffusion is typically blocked by the quantum interference.[80]

If we study the anomalously dense states in a short wire with the length $L < L_c$, we have to find such a length scale $l \ll \xi < L$ that provides an optimum between two competing exponentially small factors A and B. The optimum corresponds to $\xi = \sqrt{\alpha\nu D/p} \sim \sqrt{L_c/p}$. Since it has any sense only when $\xi < L$, the above reasoning results in the functional form of f_1[82] similar to that in Eq. (93),

$$f_1(p) \sim \min_\xi \left[\exp\left\{ -p\xi - \alpha\frac{D\nu}{\xi} \right\} \right] \sim \exp(-2\sqrt{\alpha p D \nu}), \tag{94}$$

and which is valid in the same asymptotical regime as desribed by Eq. (89).

Note that both in the above-presented scenario of formation of prelocalized states and in the σ-model treatment of the eigenstates statistics, the high amplitude splashes of the density p are produced by the states which extend over the distances $\xi \sim \sqrt{L_c/p}$ larger than $1/p$. This means that, although we are speaking of the localization effects, the localization is not the only reason for the high amplitudes of the wave function. It is quite plausible that the statistics in Eq. (93) detect the rare events of caustics of randomly focused electron waves, whereas the role of localization is to ''return'' the wave ''back'' and to increase the probability of these caustics being formed. This is also the reason that the wire would be linked to bulk ''electrodes'', the statistics of the amplitudes would sufficiently change and take the logarithmically-normal asymptotics[83] with much more suppressed tails of a distribution.

X. CONCLUSIONS

In summary, we review the recent results on the statistical properties and spatial structure of chaotic wave functions in disordered systems obtained using the supersymmetric nonlinear σ-model approach. The use of the σ-model allows us not only to revise and recover the universal statistics of wave functions previously obtained by means of such a phenomenology as the random matrix theory, but also to go far beyond the universality limit. In particular, we give a full account of the properties of chaotic wave functions in the crossover regime between the fundamental symmetry classes (orthogonal and unitary) and in the regime when the localization effects become important. Concerning the latter case, our calculation enables us to find indications of prelocalized states (among the eigenstates of disordered cavities) which exist at any weak disorder and manifest themselves via deformed large-amplitude tails of the distribution function of the local wave functions density, as compared to the universal Porter-Thomas distributions. According to the cross-correlation functions we calculated above, at the short distances below the localization length, the prelocalized states in quasi-one-dimensional wires can be associated with a power-law localization (in contrast to the conventional one which is exponential), whereas in two dimensions they have nearly critical properties and possess all the accessories of multifractal behavior.

The common feature of all the effects discussed in the present article is that they have behind them large random semiclassical phases taken by a particle moving along a chaotic trajectory or undergoing a random walk. On one hand, the ability of a chaotic trajectory to fill the entire isoenergetic surface in the classical phase space predetermines some part of the answers. In unitary or orthogonal fundamental symmetry classes they may be digested just by using the knowledge that the classical counterpart of quantum dynamics is chaotic, whereas the account for localization effects is in many aspects based on the statistical properties of diffusive paths. On the other hand, the deviations from the universal statistics, such as the long-range correlation of the wave functions at low magnetic fields, as well as prelocalized states and multifractality, give us the examples where the application of conventional semiclassics meets restrictions from the discreteness of the spectrum of quantum object. The use of the supersymmetry method enables us to overcome this difficulty and to match the description of a quantum chaos and localization within a unified theoretical approach.

ACKNOWLEDGMENTS

The authors are grateful to B. Altshuler, J. Chalker, M. Janssen, V. Kravtsov, I. Lerner, V. Prigodin, and M. Schreiber for valuable discussions and information, and to A. Chang, C. Marcus, and S. Sridhar for access to their experimental results prior to publication. One of the authors (V.F.) thanks A. Tsvelik, C. Mudry, and Y. Kogan for an exciting introduction to the Liouville theory, B. Shklovskii for relating about quantum traps which are left beyond the σ-model approach, and we both feel obliged to P. Fulde for continuous encouragement during this work. One of us (V.F.) acknowledges financial support from EPSRC and thanks the Max-Planck-Institut in

Stuttgart for hospitality in the early stage of this work; another author (K.F.) thanks Oxford University for making it possible to come and complete the work on this manuscript.

(Received 16 May 1996; accepted for publication 17 June 1996)

This short review is concerned with energy level statistics in weakly disordered metallic grains. In particular, we concentrate on how these statistics deviate from the universal ones. Using a nonperturbative approach we evaluate the large frequency asymptotics of the two-point correlator of the density of states. This allows us to describe the behavior of the system at arbitrary times. © *1996 American Institute of Physics.* [S0022-2488(96)02010-5]

I. INTRODUCTION

A great variety of systems exhibit the phenomenon of quantum chaos. Amongst those most commonly studied are the neutron resonances of atomic nuclei,[1] Rydberg atoms in strong magnetic fields,[2] and electrons in weakly disordered metallic grains (quantum dots).[3] The energy spectrum as a whole is specific for each individual chaotic system. However, in contrast to integrable systems, each eigenstate is characterized only by its energy, rather than by a set of quantum numbers.[4] The variables in the corresponding Schroedinger equation do not separate, which prohibits its analytical solution. Therefore, the only reasonable description of highly excited eigenstates in chaotic systems is a statistical one.

The statistical approach assumes certain averaging. Sometimes, as with disorder, one can think about an ensemble of chaotic systems. In such cases ensemble averaging is sufficient. For an individual chaotic system, such as Rydberg atoms in a magnetic field averaging over a wide energy interval, is the only choice.

The quantities studied in the statistical approach to quantum spectra are various correlators of the density of states (DoS),

$$\nu(E)=\mathrm{Tr}\,\delta(E-H), \tag{1}$$

where H is the Hamiltonian of the system. It is natural to measure the energy difference in units of the mean level spacing Δ. Perhaps the most frequently studied is the dimensionless two-point DoS correlator,

$$R_2(s)=\Delta^2\left\langle \nu\left(E+\frac{s}{2}\Delta\right)\nu\left(E-\frac{s}{2}\Delta\right)\right\rangle -1, \tag{2}$$

where s is the dimensionless energy difference. As has already been mentioned, for disordered

metals the statistical average denoted by $\langle \cdots \rangle$ can be performed over different realizations of the random Hamiltonian, while in general, the average can be taken over a wide energy band.

Associated with each particular chaotic system, there are typically two relevant energy scales. The first, E_c, is associated with the *classical* time scale $t_c = 1/E_c$ on which a density distribution in phase space becomes ergodic, i.e. spreads uniformly over the constant energy shell.[5] On these time scales time averages over a classical trajectory can be substituted by microcanonical averages. In a cavity in which a quantum particle scatters ballistically from a boundary, known as a chaotic billiard, the energy scale E_c is typically set by the frequency of the shortest periodic orbit, or the inverse flight time across the system. In a weakly disordered metallic grain, on the other hand, the classical energy scale is set by the inverse transport time, or Thouless energy $E_c = D/L^2$, where D denotes the classical diffusion constant, and L represents the system size.

The second energy scale is set by the mean energy level spacing $\Delta = 1/t_H$ and defines the Heisenberg time t_H. These energy scales can be combined into the dimensionless ratio,

$$g = E_c/\Delta \gg 1, \tag{3}$$

which represents the ''dimensionless conductance''[6] of a chaotic system. The ergodic time $t_c = 1/E_c$ sets the scale beyond which the details of the classical dynamics of the system become irrelevant (as long as the system is chaotic). Correspondingly for energy scales $s \ll E_c/\Delta = g$ the spectral statistics become universal, independent of the details of the underlying classical dynamics. To a very good approximation they are determined only by the global symmetries of the system, such as T-invariance, and coincide with the universal Wigner–Dyson level statistics of the corresponding random matrix ensembles:[7] Unitary (broken T-invariance), Orthogonal (spinless T-invariant systems), or Symplectic (T-invariant systems with spin-orbit interaction).[8,9] In the semiclassical limit, and in dimensions greater than one, the dimensionless conductance is large, $g \gg 1$, and universal statistics apply in a wide energy interval.

In metals, where the mean free path is much longer than the electron wavelength, the electronic motion can be considered semiclassically, and $g \gg 1$. Thus, the energy interval where the statistics are universal is indeed wide.

The first application of random matrix theory to disordered metals was made by Gorkov and Eliashberg.[10] More than a decade later Efetov[11] provided a microscopic justification for the use of random matrices by showing that spectral statistics in an ensemble of disordered metallic grains in the limit $g \to \infty$ are described by the zero dimensional supersymmetric nonlinear σ-model. The latter has been shown by Verbaarschot, Weidenmueller, and Zirnbauer[12] to be equivalent to random matrix theory.

Remarkably, even with no ensemble averaging (i.e., only energy averaging) spectral statistics of chaotic systems for small energy differences also become universal. This is supported by strong numerical[13,14] as well as recent analytical evidence.[15,16] Thus, universal spectral statistics are a ubiquitous feature of quantum chaos.

For random matrix ensembles, analytic expressions for $R_2(s)$ were obtained for all three ensembles by Dyson:[7]

$$R_2^U(s) = \delta(s) - \frac{1-\cos(2\pi s)}{2\pi^2 s^2}, \tag{4a}$$

$$R_2^O(s) = \delta(s) - \frac{1-\cos(2\pi s)}{2\pi^2 s^2} - \frac{d}{ds}\left(\frac{\sin \pi s}{\pi^2 s}\right)\int_1^\infty \frac{\sin \pi s t}{t}\,dt, \tag{4b}$$

$$R_2^S(s) = \delta(s) - \frac{1-\cos(2\pi s)}{2\pi^2 s^2} + \frac{d}{ds}\left(\frac{\sin \pi s}{\pi^2 s}\right)\int_0^1 \frac{\sin \pi s t}{t}\,dt. \tag{4c}$$

We would like to recall a formal but beautiful connection between energy spectra with universal Wigner–Dyson statistics and one dimensional fermions with interaction inversely proportional to the square of the distance.[17] These models are known as the Calogero–Sutherland models.[18,19] It was shown by Sutherland[18] that each of the two-point correlation functions $R_2(s)$ shown in Eq. (4) coincide with the density-density correlation function of one of the Calogero–Sutherland models if the energy separation s is associated with the spatial separation between quantum particles r. In the Unitary case, after such a substitution, $R_2(s)$ gives the density correlator of noninteracting particles, while the Orthogonal (Symplectic) correlators correspond to those of the fermions that attract (repel) each other with a certain strength. Indeed a similar analogy extends even beyond universality (see the discussion in Sec. VII).

The robust feature of the universal (Wigner–Dyson) level statistics is the rigidity of the energy spectrum which leads to the following characteristic properties:

1 The probability of finding two energy levels separated by a distance $s \ll 1$ vanishes in the limit $s \to 0$.
2 The typical fluctuation of the number of levels inside some window of width $N\Delta$ as measured by the variance scales in proportion to $\ln N$. This contrasts with a linear dependence on N expected for systems in which neighboring levels are uncorrelated.
3 Both the monotonic and the oscillatory parts in the two-point correlator $R_2(s)$ shown in Eq. (4) decay only algebraically.

Spectral rigidity in the dimensionless two level structure factor,

$$S(\tau) = \int_{-\infty}^{\infty} ds e^{is\tau} R_2(s), \tag{5}$$

is manifest in the vanishing of $S(\tau)$ in the limit $\tau \to 0$, while the algebraic decay of the oscillations in $R_2(s)$ leads to a singularity in $S(\tau)$ which appears at the (dimensionless) Heisenberg time, $t_H\Delta$. In the unitary case

$$S(\tau) = \begin{cases} |\tau|/(2\pi), & |\tau| \leqslant 2\pi, \\ 1, & |\tau| > 2\pi; \end{cases} \tag{6}$$

i.e., the derivative of $S(\tau)$ shows a discontinuity at $\tau = 0$ and $\tau = 2\pi$. In the symplectic case $S(\tau)$ itself diverges logarithmically as $\tau \to \pi$, while in the orthogonal case its third derivative is discontinuous at $\tau = 2\pi$.

Note that $S(\tau)$ determines the time evolution in quantum systems. For example, the probability of finding a quantum particle at the original point at a time τ after the start of the evolution is completely determined by $S(\tau)$.[20]

The universal description of spectral statistics of a given chaotic system is far from being exact. Features specific to a given system become more pronounced for large energy separations (which correspond to the short time dynamics). Universality of spectral statistics as well as deviations from it at short times have been the subject of numerous investigations.[13,14,21,22]

In order to understand short time $t \ll t_H$ dynamics one can consider spectral statistics smoothed over a frequency interval of order t^{-1}. For example the structure factor $S(\tau)$ is related to the two-point DoS correlation function $R_2(s)$ averaged over a frequency interval of width $\propto \tau^{-1}$. These smoothed correlation functions were studied in Ref. 23 by making use of a perturbation theory in $1/g$ (see, for example, Refs. 24 and 25). The zeroth order of this perturbation theory was found to coincide with the random matrix theory results of Eqs. (4) when rapidly oscillating terms like $\cos(2\pi s)$ are omitted. The corrections to the universal form of $R_2(s)$, though small in $1/g$, turned out to exceed the universal part for $s > g$.

Recently Kravtsov and Mirlin[26] obtained the corrections, leading order in s/g, to both the smooth and rapidly oscillating part of the two point correlation function at $s \ll g$. In this interval the nonuniversal corrections are small as compared to the universal results of Eqs. (4) [see Eq. (14) below].

In order to understand both the universal and system specific features of level statistics, not only at short times but also at times of the order of t_H, one has to evaluate $R_2(s)$ at arbitrary s without making additional smoothing. This however can not be done in the framework of the perturbation theory [for example, note that $\cos(2\pi s)$ can not be expanded in series in $1/s$].

Here we discuss the field-theoretical scheme that allows an evaluation of the nonperturbative contributions to $R_2(s)$ together with the perturbative ones, as well as a description of the dependence of the two level structure factor on g, and on the geometry of the grains at arbitrary times. This approach allows a generalization to the case of specific quantum systems without disorder. We will discuss this generalization very briefly at the end of the paper.

We would like to mention that Bogomolny and Keating[27] are developing an interesting alternative approach to the energy level statistics beyond universality which is based on the periodic orbit theory. However since this approach is not directly related with the statistics in disordered systems we will not discuss it here.

II. MAIN RESULTS

Here we study the high frequency $s \gg 1$ behavior of $R_2(s)$ retaining the oscillatory terms and monitor how the singularity in $S(\tau)$ that develops at the Heisenberg time is modified by the finite conductance g. To do so we will make use of the nonperturbative field theoretic approach to disordered metals based on the supersymmetric nonlinear σ-model introduced by Efetov.[11] For $s \gg 1$ (the relation between s and g can be arbitrary) we evaluate the σ-model functional integral by a stationary phase approximation. The oscillatory contribution to $R_2(s)$ is associated with a nontrivial saddle-point of the field theory.[28] Associated with this nonperturbative saddle-point are fluctuations which can be treated perturbatively. Their dependence on the same operator that controls the diagrammatic perturbation theory suggests a generality of the results which will be discussed in Sec. VIII.

For $s \gg 1$, $R_2(s)$ separates into a sum of the monotonic perturbative contribution, $R_{\rm p}(s)$ and the oscillatory nonperturbative contribution, $R_{\rm osc}(s)$,

$$R_2(s) = R_{\rm p}(s) + R_{\rm osc}(s). \tag{7}$$

Here the perturbative contribution is given by

$$R_{\rm p}(s,x) = \frac{1}{\alpha \pi^2} \Re \ \mathrm{Tr}\ P(s)^2, \tag{8}$$

where

$$P(s) = \frac{1}{-is - (D/\Delta)\nabla^2} \tag{9}$$

denotes the resolvent of the classical diffuson (Laplace) operator in the grain (D is the classical diffusion constant). The constant α is equal to 1, 2, and 1 for the Orthogonal, Unitary, Symplectic ensembles, respectively.[29]

We will show that the oscillatory terms for the three ensembles are given by[30]

$$R^U_{\rm osc}(s) = -\frac{\cos(2\pi s)}{2\pi^2 s^2} D(s), \tag{10a}$$

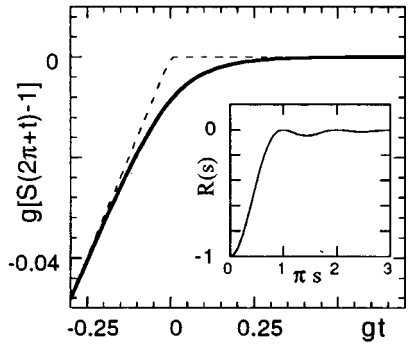

FIG. 1. Structure factor in the quasi-1D case for unitary symmetry (solid line) and the universal structure factor (dashed line). Inset: the two level correlator as a function of level separation.

$$R^{O}_{\mathrm{osc}}(s) = -\frac{\cos(2\pi s)}{2\pi^4 s^4} D^2(s,x), \tag{10b}$$

$$R^{S}_{\mathrm{osc}}(s) = \frac{\cos(\pi s)}{2s} D(s) + \frac{\cos(2\pi s)}{2\pi^4 s^4} D^2(s), \tag{10c}$$

$$D(s) = \prod_{\mu,\epsilon_\mu \neq 0} \left[1 + \left(\frac{s}{\epsilon_\mu} \right)^2 \right]^{-1}, \tag{10d}$$

where ϵ_μ denote the eigenvalues of the dimensionless diffusion operator $(D/\Delta)\nabla^2$. $D(s)$ can be expressed through the regularized determinant of $P(s)$ defined in Eq. (9):

$$D(s) = \left| \frac{\det' P(s)}{\det' P(0)} \right|^2. \tag{11}$$

Here $\det'$ denotes the determinant of the operator, from which the zero eigenvalue has been excluded.[31]

The perturbative part of $R_2(s)$ given by Eq. (8) can be expressed through the spectral determinant $D(s)$ by use of the formula

$$R_{\mathrm{p}}(s) = -\frac{1}{\alpha\pi^2 s^2} - \Re \frac{1}{2\alpha\pi^2} \frac{\partial^2 \ln[D(s)]}{\partial s^2}. \tag{12}$$

For a cubic sample in dimension $d<4$, with closed boundary conditions and $s \gg g$, we obtain the asymptotics

$$D(s) \to \exp\left[-\frac{\pi (s/\pi g)^{d/2}}{\Gamma(d/2) d \sin(\pi d/4)} \right]. \tag{13}$$

This shows that the amplitude of oscillations in $R_2(s)$ decays exponentially as a function of s in contrast to the universal algebraic behavior. This decay removes the singularity in $S(\tau)$ at the Heisenberg time $\tau_H = 2\pi$ and renders the function everywhere *analytic*. The scale of smoothening of the singularity is the inverse dimensionless conductance $1/g$. In real units it is the Thouless time $t_c = L^2/D$. In Figs. 1 and 2 we plot the structure factor around the Heisenberg time for a quasi-one dimensional sample in the unitary and symplectic cases, respectively.

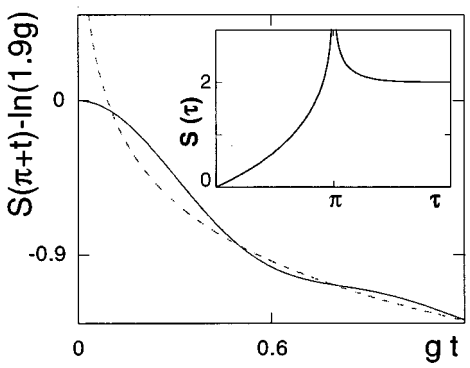

FIG. 2. The structure factor for the symplectic case in quasi-1D (solid line) and the universal result (dashed line). Inset: the universal structure factor.

For $1 \ll s \ll g$ the sums of Eqs. (10) and Eq. (8) provide the leading high frequency asymptotics of the universal result. For $s \gg g$ we recover the perturbative result $R_{\mathrm{p}}(s)$ in Eq. (8) found in Ref. 23.

Taking a closed cubic sample (Dirichlet boundary conditions), the eigenvalues of the dimensionless diffusion operator are given by $\epsilon_\mu = g\pi^2 \vec{n}^2$, where $\vec{n} = (n_1, \ldots, n_d)$ and n_i are nonnegative integers. Then, for frequencies smaller that the dimensionless conductance $1 \ll s \ll g$, the unitary ensemble yields the expression

$$R_2^U(s) = -\frac{\sin^2(\pi s)}{(\pi s)^2}\left[1 - \frac{s^2}{g^2}\sum_{\vec{n}} \frac{1}{(\pi^2\vec{n}^2)^2}\right]. \tag{14}$$

This coincides with the result of Kravtsov and Mirlin[26] who considered nonuniversal corrections to the Wigner-Dyson result of Eq. (4) for $s \ll 1$. In the common domain of applicability, $1 \ll s \ll g$, the two approaches lead to the same results for all three ensembles. These differ from the universal results shown in Eq. (4) by a correction which is as small as $(s/g)^2$. It is interesting to note that Eq. (14) for the unitary case seems to coincide with the result of Ref. 26 even at $s < 1$.

This completes the survey of the main results discussed in more detail below. The rest of paper is organised as follows. In Sec. III we will define the field theoretic construction which describes the statistical properties of weakly disordered metallic grains. We will identify the stationary points of the theory—one generates the standard diagrammatic perturbation theory while others control the dominant nonperturbative contributions. A general scheme to study the fluctuations around each point will be described. In Secs. IV, V, and VI we will obtain the high frequency asymptotics of $R_2(s)$ for the unitary, orthogonal, and symplectic ensembles, respectively. This will allow us to study the behavior of the structure factor near the Heisenberg time. In Sec. VII we make some remarks on our results. Finally, in Sec. VIII we will discuss what implications these results offer to the problem of general quantum chaotic systems.

III. FIELD THEORY OF DISORDERED METALS

As a model to describe the low energy degrees of freedom of electrons propagating in disordered conductors, the functional nonlinear σ-model was first proposed by Wegner.[32] A subsequent generalization by Efetov introduced superfields which obviated the need for replicas.[11] This development was not just convenient but proved to be necessary for describing correlations in the ergodic limit.[33] In this section we will review the microscopic derivation of the nonlinear

σ-model which will serve as the starting point for our investigation of level correlations. Since our aim is not to supplement the many reviews on the foundation of this method but rather to emphasize results that can be obtained from it we will keep the discussion brief and refer to Refs. 11,12, and 34 for a more detailed description.

The model describing a single electron moving in a random impurity potential $V(\vec{r})$ is described by the Hamiltonian

$$H=\frac{1}{2m}\left(\vec{p}-\frac{e}{c}\vec{A}\right)^2+V(\vec{r}), \tag{15}$$

where $\vec{A}(\vec{r})$ denotes the vector potential. For simplicity, we will assume the impurity potential to be δ-correlated and Gaussian distributed with a mean free time τ_{imp}:

$$\langle V(\vec{r})\rangle=0, \quad \langle V(\vec{r})V(\vec{r'})\rangle=\frac{1}{2\pi\nu\tau_{\mathrm{imp}}}\delta(\vec{r}-\vec{r'}). \tag{16}$$

The dimensions of the grain L are assumed to be much larger than the elastic mean free path $\ell\equiv v_F\tau_{\mathrm{imp}}\ll L$ so that the motion of the electron is diffusive.

The starting point is the representation of the generating function of Green functions as a functional integral over the 8-component superfields corresponding to advanced (A) and retarded (R) Green functions,

$$\Psi^p_{gd}(\vec{r})=\begin{pmatrix}\Psi^A_{gd}\\ \Psi^R_{gd}\end{pmatrix}, \quad \Psi^p_{g=1,d}=\begin{pmatrix}\chi^p_d\\ \chi^{p*}_d\end{pmatrix}, \quad \Psi^p_{g=2,d}=\begin{pmatrix}S^p_d\\ S^{p*}_d\end{pmatrix}. \tag{17}$$

Here, following Ref. 35 we introduced block notations. Superscript p refers to retarded/advanced components, subscript g refers to fermionic (F) components $\chi(\vec{r})$ and bosonic (B) components $S(\vec{r})$, and subscript d refers to time-reversal (complex conjugated) components. The introduction of equal numbers of bosonic and fermionic fields is a standard trick which obviates the need to introduce replicas and normalizes the generating function to unity. Expressed as a field integral, the generating function for two-point correlators takes the form

$$\mathcal{Z}(\hat{J})=\int D\Psi\ \exp\left[-\frac{i}{2}\int d\vec{r}\Psi^\dagger(\vec{r})\Lambda\left(\hat{G}^{-1}(\epsilon)-\frac{\hat{J}}{4\Delta}k\Lambda\right)\Psi(\vec{r})\right], \tag{18}$$

where

$$\hat{G}^{-1}(\epsilon)=\epsilon-\frac{s^+\Lambda}{2}-\frac{1}{\Delta}\hat{H}\left(\vec{p}-\frac{e}{c}\tau_3\vec{A}\right), \tag{19}$$

denotes the dimensionless matrix Green function with energy difference s between retarded (R) and advanced (A) blocks and $\hat{J}k\Lambda$ represents the source. Matrices

$$\Lambda=\begin{pmatrix}1&0\\0&-1\end{pmatrix}^p\otimes 1_g\otimes 1_d, \quad k=1^p\otimes\begin{pmatrix}1&0\\0&-1\end{pmatrix}_g\otimes 1_d, \quad \tau_3=1^p\otimes 1_g\otimes\begin{pmatrix}1&0\\0&-1\end{pmatrix}_d, \tag{20}$$

break the symmetry between the advanced/retarded, graded, and conjugate components, respectively. The operations of complex conjugation and transposition of supervectors are defined following Efetov,[11] while STr denotes the trace operation for supermatrices,

$$\mathrm{STr}\ M=\mathrm{Tr}\ M_{FF}-\mathrm{Tr}\ M_{BB}. \tag{21}$$

Equation (18) can be used to represent the two-point correlator of DoS fluctuations. If we choose the source to be a constant $\hat{J}=J$ and perform the ensemble averaging of Eq. (16) we obtain

$$R_2(s)=-\frac{\Delta^2}{\pi^2}\,\Re\,\frac{\partial^2}{\partial J^2}\langle\mathcal{Z}(\hat{J})\rangle_{\epsilon_0}\Big|_{J=0}. \tag{22}$$

Averaging over the disorder potential generates a quartic interaction of the fields $\Psi(\vec{r})$. If the disorder potential is weak, the fields vary only slowly in comparison to the electron wavelength, λ, and the problem can be treated within a semi-classical approximation. In this approximation the interaction can be decoupled by means of a Hubbard–Stratonovich transformation with the introduction of 8×8 supermatrix fields $Q(\vec{r})$ with the symmetry similar to that of the dyadic product $\Psi\otimes\Psi^{\dagger}$. As a result the Ψ integration becomes Gaussian and can be performed.

Further progress is possible within a saddle-point approximation. The manifold of saddle-points is defined by $Q=T^{-1}\Lambda T$, where matrices T occupy the symmetric space $\mathbf{H}=\mathbf{G}/\mathbf{K}$. The groups $\mathbf{G}$ and $\mathbf{K}$ depend on the ensemble.[12] For example, in the unitary ensemble $\mathbf{H}=\mathbf{U(1,1/2)}/\mathbf{U(1/1)}\times\mathbf{U(1/1)}$.[36] Allowing for slow spatial fluctuations of T and expanding to leading order in ℓ/L and $s\Delta\tau_{\rm imp}$, we obtain[11]

$$\langle\mathcal{Z}\rangle=\int d[Q]\exp(-S[Q]), \tag{23a}$$

$$S[Q]=\frac{\pi\nu}{8}\int d\vec{r}\,\mathrm{STr}\left[D\left(\nabla Q+i\frac{e\vec{A}}{c}[\tau_3,Q]\right)^2+2is^{+}\Delta\Lambda Q+iJ\Lambda kQ-\frac{x^2\Delta}{2}(\Lambda Q)^2\right], \tag{23b}$$

where Q matrices obey the nonlinear constraint $Q(\vec{r})^2=1$. Here, we have introduced an additional term containing x^2 into the action which plays the role of a regulator. Its effect will be to stabilise the stationary points which will arise in the evaluation of the integral in Eq. (23b). Ultimately, only after all the integrals have been performed, x^2 should be taken to zero. The integration measure for Q in the functional integral is the invariant measure on $\mathbf{H}$.

The large frequency asymptotics of $R_2(s)$ can be obtained from Eq. (23a) by use of the stationary phase method. Conventional diagrammatic perturbation theory corresponds to integrating over the small fluctuations of Q around Λ.[11] A systematic expansion can be obtained from the explicit parametrisation of the saddle-point manifold,

$$Q=\Lambda(1+iP)(1-iP)^{-1},\quad P=\begin{pmatrix}0 & B\\ \overline{B} & 0\end{pmatrix}, \tag{24}$$

where the matrix P describes deviations of Q from Λ. However, in Ref. 28 two of us showed that $Q=\Lambda$ is not the only stationary point on $\mathbf{H}$. In fact, it is possible to parameterize fluctuations around a general stationary point Q_0, where $Q=Q_0(1+iP_0)(1-iP_0)^{-1}$. Expanding the free energy in Eq. (23b) in powers of P_0 we would obtain the stationarity condition $\partial S/\partial P_0=0$.

This route however is inconvenient since the parameterization of P_0 will depend explicitly on Q_0. Instead it is convenient to perform a global coordinate transformation on $\mathbf{H}$ that maps Q_0 to Λ, $Q_0\to T_0^{-1}Q_0T_0=\Lambda$. Since all points on a symmetric space are equivalent by definition, this coordinate transformation preserves the invariant measure. In particular, let us concentrate on the matrices Λ and $-\Lambda k$ which both belong to $\mathbf{H}$. The corresponding terms in Eq. (23b) can be viewed as symmetry breaking sources. This transformation maps Λ to $Q_\Lambda=T_0^{-1}\Lambda T_0$ and Λk to $Q_{\Lambda k}=T_0^{-1}\Lambda kT_0$. Thus we can employ the parameterization of Eq. (24) with the *same* invariant measure but simply change the sources. As a result, using Eq. (22), we find

$$R_2(s)=\frac{1}{64V^2}\,\Re\int d[Q]\left[\int d\vec{r}\ \mathrm{STr}(Q_{\Lambda k}Q)\right]^2\exp(-S_{Q_\Lambda}[Q]), \tag{25a}$$

$$S_{Q_\Lambda}[Q]=\frac{\pi\nu}{8}\int d\vec{r}\ \mathrm{STr}\left[D\left(\nabla Q+i\frac{e\vec{A}}{c}[\tau_3,Q]\right)^2+2is^+\Delta Q_\Lambda Q-\frac{x^2\Delta}{2}(Q_\Lambda Q)^2\right]. \tag{25b}$$

The stationarity condition,

$$\frac{\partial}{\partial P}S_{Q_\Lambda}[Q]|_{P=0}=0, \tag{26}$$

implies that all the elements of Q_Λ in the AR and RA blocks should vanish [as can be seen from Eq. (24)].

This completes our formulation of the model. For each symmetry class we will find the stationary points of the effective action and generate a perturbative expansion around each point. In principle we could study the transition interval between different universality classes. However, for simplicity we will focus on the ''pure'' symmetry classes. We will begin by studying the Unitary case in some detail.

IV. UNITARY ENSEMBLE

In a strong magnetic field, the components of the $Q(\vec{r})$ matrices that do not commute with τ_3 acquire a mass—the Cooperon gap. For a strong enough field those modes with energies smaller than this gap are frozen out and can be neglected. In the pure unitary ensemble $[\tau_3,Q]=0$ and the magnetic field dependence is removed. In this case we can write an explicit parametrisation for the 4×4 supermatrices B and $\overline{B}$ in the form

$$B=\begin{pmatrix} a & 0 & i\sigma_1 & 0\\ 0 & a^* & 0 & -i\sigma_1^*\\ \sigma_2^* & 0 & ib & 0\\ 0 & \sigma_2 & 0 & ib^*\end{pmatrix},\quad \overline{B}=\begin{pmatrix} a^* & 0 & -\sigma_2 & 0\\ 0 & a & 0 & \sigma_2^*\\ -i\sigma_1^* & 0 & ib^* & 0\\ 0 & -i\sigma_1 & 0 & ib\end{pmatrix}. \tag{27}$$

The zeros in the ''off-diagonal'' elements reflect the absence of the Cooperonic degrees of freedom.

Besides the conventional saddle-point Λ, there is only one other $Q_\Lambda\equiv\widetilde{\Lambda}=-k\Lambda$ ($Q_{k\Lambda}=-\Lambda$) that satisfies the stationarity condition of Eq. (26). All other matrices from the saddle-point manifold contain nonzero elements in the AR and RA blocks. To obtain the high frequency asymptotics of $R_2(s)$ we must take into account both saddle points. Let us first consider the contribution of the usual saddle-point $Q_\Lambda=\Lambda$.

A. Λ point

Instead of calculating the generating function explicitly, we will consider the direct contribution of this point to the two-point correlator of DoS. The stationary point $Q_\Lambda=\Lambda$ is stable, and we set x^2 to zero before taking the integrals over B. Expanding the effective action Eq. (25b) to second order in B we obtain

$$S_\Lambda[Q]=\frac{\pi\nu}{8}\int d\vec{r}\ \mathrm{STr}[D\nabla\overline{B}\nabla B+i2s^+\Delta\overline{B}B]. \tag{28}$$

Employing the parametrisation above and performing the Gaussian integrals we obtain the expression previously found in Ref. 23,

$$R_{\mathrm{p}}(s)=\frac{1}{2\pi^2}\,\Re\ \mathrm{Tr}\ P(s)^2, \tag{29}$$

where $P(s)$ is defined in Eq. (9). For a cubic sample of size L the eigenvalues of the diffusion equation are given by $\epsilon_{\vec{n}}=g\pi^2\vec{n}^2$, where $\vec{n}=(n_1,\ldots,n_d)$, and n_i are non-negative integers.

At large frequencies $s\gg g$ one can substitute the sum by the integral, which gives the result

$$R_{\mathrm{p}}^{U}(s)\propto s^{d/2-2}. \tag{30}$$

B. $\tilde{\Lambda}$ point

Having obtained the contribution to R_2 from the conventional perturbation theory, let us now consider that from the second saddle-point. Substituting $Q_\Lambda=-k\Lambda$ and $Q_{k\Lambda}=\underline{-}\Lambda$ into Eq. (25), expanding both the action and the pre-exponent to the second order in B and $\bar{B}$, and introducing the Fourier components $B_{\vec{q}}$,

$$B(\vec{r})=\sum_{\vec{q}}\ e^{i\vec{q}\vec{r}}B_{\vec{q}}, \tag{31}$$

we obtain

$$\begin{aligned}R_{\mathrm{osc}}^{U}(s)=e^{2\pi i s}\Re\int d[B_{\vec{q}}]\Bigg[\sum_{\vec{q}}\ [a_{\vec{q}}a^{*}_{-\vec{q}}+b_{\vec{q}}b^{*}_{-\vec{q}}-\sigma^{*}_{1,-\vec{q}}\sigma_{1,\vec{q}}+\sigma^{*}_{2,-\vec{q}}\sigma_{2,\vec{q}}]\Bigg]^2\\ \times\exp\Bigg[-2\pi\sum_{\vec{q}}\ (P^{-1}_{\vec{q}}(-s,x^2)a_{\vec{q}}a^{*}_{-\vec{q}}+P^{-1}_{\vec{q}}(s,x^2)b_{\vec{q}}b^{*}_{-\vec{q}}-P^{-1}_{\vec{q}}(0,0)\\ \times[\sigma^{*}_{1,-\vec{q}}\sigma_{1,\vec{q}}-\sigma^{*}_{2,-\vec{q}}\sigma_{2,\vec{q}}])\Bigg].\end{aligned} \tag{32}$$

where $P^{-1}_{\vec{q}}(s,x^2)$ is given by

$$P^{-1}_{\vec{q}}(s,x^2)=-is+2x^2+g(\vec{q}L)^2, \tag{33}$$

and x is the regulator that we introduced in Eq. (23b) to ensure the convergence of the integrations.[37]

Since the action in Eq. (32) contains no Grassmann variables in the zero mode they must come from the pre-exponent. Therefore, out of the whole square of the sum in the pre-exponent only the terms containing all four zero mode Grassmann variables contribute. There are only two such terms. The evaluation of the Gaussian integrals is straightforward and generates products of the determinants of the diffusion operator.

Since the supersymmetry around $\tilde{\Lambda}$ is broken by s, integration over nonuniform modes yields a superdeterminant which differs from unity. The integration measure for Grassmann variables should be defined as

$$\prod_{\vec{q}}\ d\sigma_{1\vec{q}}d\sigma^{*}_{1\vec{q}}d\sigma^{*}_{2\vec{q}}d\sigma_{2\vec{q}}, \tag{34}$$

to enforce the correct sign. (One should keep in mind that the Fourier components with opposite $\vec{q}$ are not independent, and $\vec{q}$ in the product ranges over one half of the total vector space only.) In

an isolated sample the derivative of Q normal to the boundary must vanish, $\nabla Q_{\perp}=0$. For a d-dimensional cubic sample of size L with these boundary conditions we can write $\vec{q}=\pi\vec{n}/L$.

After integration we set x to zero and obtain

$$R^{U}_{\rm osc}(s)=\frac{\cos(2\pi s)}{2\pi^2 s^2}\widetilde{\prod_{\vec{n}\neq\vec{0}}}\left(1+\left(\frac{s}{\pi^2 g\vec{n}^2}\right)^2\right)^{-1}, \tag{35}$$

where the tilde signifies that the product should be taken over one half of the vector space. The product in Eq. (35) can be expressed through the spectral determinant of the diffusion operator.

In the contribution of the conventional saddle-point $Q_{\Lambda}=\Lambda$ the Green function of the same operator appears [see Eq. (29)]. The product (sum) over $\vec{n}$ should be interpreted as the product (sum) over the eigenvalues of the diffusion operator for more complicated boundary conditions.

In quasi-1D the product over momenta can be evaluated exactly.

$$R^{U}_{\rm osc}(s)=\frac{\cos(2\pi s)}{2\pi^2 s^2}\,\frac{s/g}{\sinh^2(\sqrt{s/2g})+\sin^2(\sqrt{s/2g})}. \tag{36}$$

In arbitrary dimensions the product can be evaluated in the limit of high frequency $s\gg g$ and expressed as the sum of logarithms. In the limit $s\gg g$ the sum can be substituted by an integral and we obtain

$$R^{U}_{\rm osc}(s)\to\frac{\cos(2\pi s)}{2\pi^2 s^2}\exp\left(-\frac{1}{2}\left[\frac{s}{\pi^2 g}\right]^{d/2}\int d\vec{t}\ln[1+\vec{t}^{-4}]\right), \tag{37}$$

where $\vec{t}=\pi\vec{n}\sqrt{g/s}$.

The full function $R_2(s)$ is given by the sum of contributions from both saddle-points, Eq. (35) and Eq. (29). At small frequencies $s\ll g$ we can expand the product in Eq. (35) in powers of s/g. Expanding to second order we obtain Eq. (14) which coincides with the result of Ref. 26.

C. Structure factor

The dimensionless two-level structure factor $S^{U}(\tau)$, defined in Eq. (5), has singularities at $|\tau|=2\pi$ and $|\tau|=0$, which are related to the large frequency asymptotics of $R^{U}_{2}(s)$. The former is related to $R^{U}_{\rm osc}(s)$ and the latter to $R^{U}_{\rm p}(s)$. We will address the singularity in $S^{U}(\tau)$ at the Heisenberg time $\tau=2\pi$.

For closed boundary conditions in quasi-1D the contribution to the structure factor from the Λ-point is given by

$$\begin{aligned}S^{U}(\tau)_{\rm p}&=\int_{-\infty}^{+\infty}\sum_{n=0}^{\infty}\frac{ds\ \exp(is\tau)}{(2\pi)^2}\left(\frac{1}{(-is+g\pi^2n^2)^2}+\frac{1}{(is+g\pi^2n^2)^2}\right)\\&=\frac{|\tau|}{2\pi}\sum_{n=0}^{\infty}\exp(-g\pi^2n^2|\tau|).\end{aligned} \tag{38}$$

The contribution from the nonperturbative saddle-point $\widetilde{\Lambda}$-point is given by

$$S^{U}(\tau)_{\rm osc}=\int_{-\infty}^{+\infty}\frac{ds\ \cos(2\pi s)\exp(is\tau)}{2\pi^2 s^2}\,\frac{s/g}{\sin(\sqrt{is/g})\sin(\sqrt{-is/g})}. \tag{39}$$

The integrand has simple poles at $s=\pm ig\pi^2n^2$ for $n=1,2,\ldots$ and a second order pole at $s=0$. Since the expansion of

$$\frac{s/g}{\sin(\sqrt{is/g})\sin(\sqrt{-is/g})} \tag{40}$$

begins at second order in s, the residue of the pole at $s=0$ is unaffected by the fact that g is finite. Therefore this pole always gives the contribution $-|t|/4\pi$, where $t=\tau-2\pi$. The contribution of the other poles can be evaluated straightforwardly and gives

$$\sum_{n=1}^{\infty} \frac{(-1)^n \exp(-\pi^2 n^2 g|t|)}{\pi^2 g n \sinh(\pi n)}. \tag{41}$$

Therefore the structure factor is given by

$$S^U(2\pi+t)_{\rm osc} = -\frac{|t|}{4\pi} + \sum_{n=1}^{\infty} \frac{(-1)^n \exp(-\pi^2 n^2 g|t|)}{\pi^2 g n \sinh(\pi n)}, \tag{42}$$

and is plotted in Fig. 1.

Even though Eq. (42) seems to depend on $|t|$, $S^U(2\pi+t)_{\rm osc}$ depends only on t^2 and is regular at $t=0$.

We can also estimate $S^U(2\pi)_{\rm osc}$ in any dimension. It is proportional to $1/g$ and is given by

$$S^U(2\pi)_{\rm osc} = \frac{1}{g}\int_{-\infty}^{+\infty} \frac{dz}{2\pi^2 z^2} \prod_{\vec{n}\neq\vec{0}} \left(1+\frac{z^2}{\pi^4 n^4}\right)^{-1}. \tag{43}$$

At large times we can keep only the first exponentials in the sums in Eq. (42) and Eq. (38) and obtain the asymptotic expression for the complete structure factor,

$$S(\tau) \approx \frac{|\tau|}{2\pi}\exp(-g\pi^2\tau) - \frac{1}{\pi^2 g \sinh(n)}\exp(-g\pi^2[\tau-2\pi]), \tag{44}$$

which shows the contribution of the $\tilde{\Lambda}$-point to be dominant.

V. ORTHOGONAL ENSEMBLE

Consider now ensembles which respect T-invariance—Orthogonal symmetry. In this case it is necessary to account for both Cooperon as well as diffuson degrees of freedom. However, there are still only two stationary points on the saddle-point manifold: Λ and $\tilde{\Lambda}=-k\Lambda$. To obtain the contribution of the $\tilde{\Lambda}$-point we can use the formula in Eq. (25b) with $Q_\Lambda=\tilde{\Lambda}$ and $Q_{k\Lambda}=-\Lambda$ as well as the parametrization of Efetov for the perturbation theory.[11] The matrices B and $\bar{B}$ are now given by

$$B=\begin{pmatrix} a_1 & a_2 & i\sigma_1 & i\sigma_2 \\ -a_2^* & a_1^* & -i\sigma_2^* & -i\sigma_1^* \\ \sigma_3^* & \sigma_4 & ib_1 & ib_2 \\ \sigma_4^* & \sigma_3 & ib_2^* & ib_1^* \end{pmatrix}, \quad \bar{B}=\begin{pmatrix} a_1^* & -a_2 & -\sigma_3 & -\sigma_4 \\ a_2^* & a_1 & \sigma_4^* & \sigma_3^* \\ -i\sigma_1^* & -i\sigma_2 & ib_1^* & ib_2 \\ -i\sigma_2^* & -i\sigma_1 & ib_2^* & ib_1 \end{pmatrix}. \tag{45}$$

This parametrization implies the following expansion of the action in Eq. (25b),

$$S_{\tilde{\Lambda}}[Q] = -2\pi i s + 2\pi \sum_{\vec{q}} \{P_{\vec{q}}^{-1}(-s,x^2)(a_{1,\vec{q}}a_{1,-\vec{q}}^* + a_{2,\vec{q}}a_{2,-\vec{q}}^*) + P_{\vec{q}}^{-1}(s,x^2)(b_{1,\vec{q}}b_{1,-\vec{q}}^* + b_{2,\vec{q}}b_{2,-\vec{q}}^*)$$

$$+P_{\vec{q}}^{-1}(0,0)(-\sigma^*_{1,-\vec{q}}\sigma_{1,\vec{q}}-\sigma^*_{2,-\vec{q}}\sigma_{2,\vec{q}}+\sigma^*_{3,-\vec{q}}\sigma_{3,\vec{q}}+\sigma^*_{4,-\vec{q}}\sigma_{4,\vec{q}})\}. \tag{46}$$

Once again, since there are no zero mode Grassmann variables in the action, they must come from the prefactor in Eq. (25a). Even though an expansion of the action to higher orders in B will generate Grassmann variables in the zero mode, these terms will contain higher powers of $1/s$ and are smaller than the leading terms at $s \gg 1$. To obtain all eight zero mode Grassmann variables in the prefactor in Eq. (25a) it is necessary to expand it to eighth order in B and $\overline{B}$,

$$[\mathrm{Str}(\Lambda Q)]^2 \approx 16[(\mathrm{STr}(\overline{B}B)^2)^2+2\mathrm{STr}(\overline{B}B)\mathrm{STr}(\overline{B}B)^3]. \tag{47}$$

The second term in this expression does not contribute to the highest weight term in Grassmann variables (it gives only the sixth order) and can be omitted. Then we obtain for the $\widetilde{\Lambda}$-point contribution to the two-point correlator of DoS,

$$R^O_{\mathrm{osc}}(s)=-\frac{\cos(2\pi s)}{2\pi^4 s^4}\widetilde{\prod_{\vec{n}\neq\vec{0}}}\left(1+\left(\frac{s}{\pi^2 g\vec{n}^2}\right)^2\right)^{-2}, \tag{48}$$

where, as before, the product goes over one-half of the total space.

VI. SYMPLECTIC ENSEMBLE

Finally, in the case of the symplectic ensemble there are three types of stationary points which correspond to singularities at $\tau=0$, π, and 2π in the structure factor. The singularity at $\tau=2\pi$ corresponds to $Q_\Lambda=\widetilde{\Lambda}=-k\Lambda$, and its contribution to $R_2(s)$ differs from the one for the Orthogonal case in Eq. (48) only by a minus sign.

The parametrization of the matrices B is and $\overline{B}$ is now given by

$$B=\begin{pmatrix} a_1 & a_2 & i\sigma_1 & i\sigma_2 \\ a_2^* & a_1^* & -i\sigma_2 & i\sigma_1 \\ \sigma_3 & \sigma_4 & ib_1 & -ib_2 \\ -\sigma_4 & \sigma_3 & ib_2^* & ib_1^* \end{pmatrix}, \quad \overline{B}=\begin{pmatrix} a_1^* & a_2 & \sigma_3^* & -\sigma_4^* \\ a_2^* & a_1 & \sigma_4^* & \sigma_3^* \\ -i\sigma_1^* & i\sigma_2^* & ib_1^* & ib_2 \\ -i\sigma_2^* & -i\sigma_1^* & -ib_2^* & ib_1 \end{pmatrix}. \tag{49}$$

Below we concentrate on the singularity at $\tau=\pi$. As we will show, it corresponds to a degenerate set on the saddle-point manifold.

Using Efetov's parametrization[11] we can represent Q_Λ as

$$Q_\Lambda=\hat{U}\begin{pmatrix} \cos\hat{\theta} & i\sin\hat{\theta} \\ -i\sin\hat{\theta} & -\cos\hat{\theta} \end{pmatrix}\widetilde{U},$$
$$\hat{\theta}=\begin{pmatrix} \theta_{11} & 0 \\ 0 & \theta_{22} \end{pmatrix}_g, \quad \theta_{11}=\begin{pmatrix} \theta_1 & \theta_2 \\ \theta_2 & \theta_1 \end{pmatrix}_d, \quad \theta_{22}=\begin{pmatrix} \theta & 0 \\ 0 & \theta \end{pmatrix}_d, \tag{50}$$

and the explicit form of $\hat{U}$ is not important for the present discussion.

The stationarity condition Eq. (26) implies $\sin\hat{\theta}=0$ for Q_Λ, so that terms linear in B in the effective action in Eq. (25b) vanish. It is satisfied if $\theta=0$ and $\theta_1=\pm\pi/2$, $\theta_2=\pm\pi/2$. The matrices $\hat{U}$ in Eq. (50) generate a continuous manifold of stationary points. One such matrix is

$$Q_\Lambda=\widetilde{\Lambda}_1=\Lambda\otimes\begin{pmatrix} \tau_1 & 0 \\ 0 & \mathbb{1} \end{pmatrix}_g, \quad [\tau_1]_d=\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}_d. \tag{51}$$

In Efetov's parametrization it corresponds to $\theta_1=\theta_2=\pi/2$ and all other variables equal to zero. With this source the expression for the effective action, Eq. (25b), becomes

$$S_{\tilde{\Lambda}_1}[Q]=\frac{\pi\nu}{8}\int d\vec{r}\ \mathrm{STr}\left[D(\nabla Q)^2+2is^+\Delta\tilde{\Lambda}_1 Q-\frac{x^2\Delta}{2}(\tilde{\Lambda}_1 Q)^2\right]. \tag{52}$$

In perturbation theory the expression for this effective action can be made more compact by rewriting B and $\bar{B}$ in Eq. (49) in terms of the vectors

$$\begin{gathered}\vec{a}^{\,T}=(a_1,a_1^*,a_2,a_2^*),\ \vec{a}^{\,T}=(b_1,b_1^*,b_2,b_2^*),\\ \vec{\sigma}_{12}^{T}=(\sigma_1,\sigma_1^*,\sigma_2,\sigma_2^*),\quad \vec{\sigma}_{34}^{T}=(\sigma_3,\sigma_3^*,\sigma_4,\sigma_4^*),\end{gathered} \tag{53}$$

and introducing Fourier components as in Eq. (31).

To second order in B, Eq. (52) has the form

$$S_{\tilde{\Lambda}_1}[Q]=-\pi is+\pi\sum_{\vec{q}}\left[\vec{a}_{\vec{q}}^{\dagger}T_{a,\vec{q}}\vec{a}_{\vec{q}}+\vec{b}_{\vec{q}}^{\dagger}T_{b,\vec{q}}\vec{b}_{\vec{q}}+\vec{\sigma}_{12,\vec{q}}^{\dagger}T_{\sigma_{12},\vec{q}}\vec{\sigma}_{12,\vec{q}}+\vec{\sigma}_{34,\vec{q}}^{\dagger}T_{\sigma_{34},\vec{q}}\vec{\sigma}_{34,\vec{q}}\right], \tag{54}$$

where

$$T_{a,\vec{q}}=\begin{pmatrix} P_{\vec{q}}^{-1}(0,x^2/2) & x^2 & -is/2 & -is/2\\ x^2 & P_{\vec{q}}^{-1}(0,x^2/2) & -is/2 & -is/2\\ -is/2 & -is/2 & P_{\vec{q}}^{-1}(0,x^2/2) & x^2\\ -is/2 & -is/2 & x^2 & P_{\vec{q}}^{-1}(0,x^2/2)\end{pmatrix},$$

$$T_{\sigma_{12},\vec{q}}=\begin{pmatrix} P_{\vec{q}}^{-1}(s/2,x^2/2) & 0 & 0 & -is/2-x^2\\ 0 & -P_{\vec{q}}^{-1}(s,x^2/2) & -is/2-x^2 & 0\\ 0 & is/2+x^2 & P_{\vec{q}}^{-1}(s,x^2/2) & 0\\ is/2+x^2 & 0 & 0 & -P_{\vec{q}}^{-1}(s/2,x^2/2)\end{pmatrix},$$

$$T_{b,\vec{q}}=P_{\vec{q}}^{-1}(s,x^2)\otimes\mathrm{diag}(1,1,1,1),\quad T_{\sigma_{34},\vec{q}}=-T_{\sigma_{12},\vec{q}}. \tag{55}$$

The integral over the variables Eq. (53) for each $\vec{q}$ yields

$$\sqrt{\frac{\det T_{\sigma_{12},\vec{q}}\det T_{\sigma_{34},\vec{q}}}{\det T_{a,\vec{q}}\det T_{b,\vec{q}}}}. \tag{56}$$

Evaluating the determinants we obtain

$$\begin{gathered}\det T_{a,\vec{q}}=P_{\vec{q}}^{-1}(s/2,x^2)P_{\vec{q}}^{-1}(-s/2,x^2)(P_{\vec{q}}^{-1}(0,0))^2,\\ \det T_{b,\vec{q}}=(P_{\vec{q}}^{-1}(s/2,x^2))^4,\\ \det T_{\sigma_{12},\vec{q}}=\det T_{\sigma_{34},\vec{q}}=(P_{\vec{q}}^{-1}(s/2,x^2))^2(P_{\vec{q}}^{-1}(0,0))^2.\end{gathered} \tag{57}$$

The integration over the nonuniform modes generates the product of expressions in Eq. (56) for different $\vec{q}$. Taking the limit $x^2 \to 0$ we obtain for this product

$$\prod_{\vec{q}\neq 0} \left[1 + \left(\frac{s\Delta}{D\vec{q}^2} \right)^2 \right]^{-1/2}. \tag{58}$$

The integration over the zero mode variables gives the factor $1/2|s|$. Since $\Im a_1$ and $\Im a_2$ do not enter the the effective action of Eq. (54) in the zero mode,[38] it might appear that the perturbative expansion will diverge. However, this is not so. The degenerate manifold of saddle-points of this type is compact, and the integration over $\Im a_1$ and $\Im a_2$ yields a finite result. The simplest way to obtain it is by making a comparison with the large frequency asymptotics of the Wigner-Dyson distribution. For a cubic sample $\vec{q} = \pi\vec{n}/L$, and we obtain the expression

$$R^S(s)_{\Lambda_1} = \frac{\cos(\pi s)}{2|s|} \widetilde{\prod}_{\vec{n}\neq\vec{0}} \left[1 + \left(\frac{s}{\pi^2 g n^2} \right)^2 \right]^{-1}, \tag{59}$$

where the tilde signifies that the product goes over $\vec{n}$ with non-negative entries only.

In quasi-1D we can obtain the leading contribution to the structure factor $S(\tau)$ around $\tau = \pi$,

$$S^s(t+\pi,0) = \int_0^\infty \frac{-4\sin^2(g|t|z)dz}{\sinh^2\sqrt{z} + \sin^2\sqrt{z}} + \ln(1.9g) + O\left(\frac{1}{g}\right). \tag{60}$$

The result is plotted in Fig. 2. In all dimensions the logarithmic divergence in the zero mode result is now cut off by finite g, and $S^S(\pi,0) \propto \ln g$.

VII. SOME REMARKS

To conclude, let us mention several remarks about these results.

1. The classification of physical systems into the three universality classes (Unitary, Orthogonal, and Symplectic) is, of course, an oversimplification. In practice there is always a time scale which determines the crossover from one ensemble to another. For example if a system is subject to a magnetic field the short time dynamics will appear Orthogonal while the long time behavior is Unitary. The characteristic time is set by the strength of the magnetic field.
   For a disordered metallic grain in a magnetic field this characteristic time is given by ℓ_H^2/D. For frequencies larger than D/ℓ_H^2 the system effectively becomes Orthogonal. This implies that even if we neglect the spatially nonuniform fluctuations of the Q-matrix the cusp in $S(\tau)$ at $\tau = 2\pi$ will be washed out on the scale of $\Delta\ell_H^2/D$ [although there will still remain a jump in the third derivative of $S(\tau)$]. For the system to behave as Unitary for frequencies of order g the magnetic length ℓ_H must be shorter than the size of the system. Spin-orbit interaction that causes the Orthogonal to Symplectic crossover can be considered in a similar way.
2. A rounding off of the singularity in $S(2\pi)$ is also present in the random matrix model with preferred basis.[39,40] However, our results differ from those in Ref. 40 substantially. This means that finite g is not equivalent to finite temperature for the corresponding Calogero-Sutherland model.[17] In fact, the relation of Eq. (12) between the smooth and the oscillatory parts of the two-point correlation function is similar to the one for the density-density correlation function of the Calogero-Sutherland model in a smooth potential $U(E)$ (such that one can neglect back-scattering). Equation (10) can be recovered if the random potential is determined by the correlation function $\langle U(E)U(E+s\Delta)\rangle \propto \Re\Sigma_{\mu\neq 0}(-is+\epsilon_\mu)^{-2}$.

This can be checked from the bosonization of the Calogero-Sutherland Hamiltonian where, in the limit $\epsilon_\mu \gg 1$, the assumption that back-scattering is absent is justified.

VIII. CONCLUSIONS AND PERSPECTIVES

We have described in some detail the calculation of nonuniversal corrections to the two-point density correlation function $R_2(s)$ for an ensemble of disordered metallic grains with the same conductance g and the same geometry. Using ensemble averaging we have evaluated this function for large s: $s \gg 1$. This enabled us to describe the rounding off of the singularity in the structure factor $S(\tau)$ present in the universal limit at $\tau \to 0$ and $\tau \to \tau_H$.

The main conclusion is that this nonuniversal behavior is determined by the spectral properties of the diffusion (Laplace) operator for a given geometry. In particular, the non-oscillatory part of the two-point correlation function is determined by the trace of the resolvent of this operator, while the part that oscillates as $\cos(2\pi s)$ is given by its spectral determinant. As a result, the two parts of $R_2(s)$ are connected by the relation shown in Eq. (12).

The diffusion operator is a purely classical one. Nevertheless, the structure of the supersymmetric σ-model allows us to take into account quantum mechanical interference to some extent. This can be seen from the consideration of T-invariance. The latter is violated by a magnetic field. The magnetic field manifests itself in quantum dynamics through two effects: (1) through the Aharonov-Bohm effect which affects the interference of different Feynman paths and does not alter the classical dynamics, and (2) through the Lorentz force. At weak fields the first effect dominates and governs the crossover of spectral statistics from the orthogonal to unitary ensemble, although classically they are equivalent. In the σ-model formalism T-invariance manifests itself through the additional diffusion mode—the Cooperon. From the semiclassical point of view this difference is due to the fact that, given a trajectory in phase space, the inversion of time transforms it to a different trajectory which in the orthogonal case is characterized by the same Feynman amplitude. This multiplicity of equivalent trajectories can therefore be taken into account by the field theoretic approach.

In general, the σ-model approach seems to be capable of describing systems where the classical limit exists modulo constant degeneracy of Feynman amplitudes. To understand what we mean consider a quantum mechanical return probability. It is given by the double sum over the Feynman paths $\Sigma_{i,j} A_i A_j^*$ where A_i is the Feynman amplitude of the ith path. If the classical limit exists, in the limit when actions are large as compared to $\hbar$ this sum can be substituted by the sum of probabilities $\Sigma_i |A_i|^2$. Discrete symmetries of the system, such as T-invariance, can lead to the fact that the Feynman amplitudes of different paths are degenerate. If this degeneracy is finite and constant for different orbits, like in the case of T-invariance, it could be incorporated into the σ-model.

The results which have been derived here are correct only in the leading order in g^{-1}. There definitely exist quantum corrections which may be referred to as weak localization corrections. It should be mentioned, however, that the sum of these corrections does not reduce to the renormalization of the diffusion constant D.

Here we discussed only the case of an ensemble of disordered quantum dots. Recently it became clear that a similar analysis based on a σ-model approach can be made for individual chaotic systems with a given Hamiltonian H.[28,15,41,16,42] As mentioned earlier, for a given chaotic systems one can use only energy averaging for constructing statistics of energy levels. Nevertheless, a σ-model can be derived for each individual system,[15,16] and results similar to Eq. (10) and Eq. (12) can be obtained.[16,42] The main difference between the general case and that of disorder is that the diffusion operator is substituted by the classical time evolution operator of the system

$$\hat{\mathscr{L}} = \sum_i \left(\frac{\partial H}{\partial p_i} \frac{\partial}{\partial q_i} - \frac{\partial H}{\partial q_i} \frac{\partial}{\partial p_i} \right), \tag{61}$$

where q_i and p_i are, respectively, canonical coordinates and canonical momenta of the system. The eigenvalues of this operator determine the spectral determinant $D(s)$ in Eq. (10d) in the same way as the eigenvalues of the diffusion operator do for a disordered grain.

In common with the diffusion operator in a closed grain, $\hat{\mathscr{L}}$ has a zero eigenvalue which corresponds to the ergodic state and manifests the conservation of the total probability. The nonuniversal part of the two point correlation function R_2 is given by the other (nontrivial) eigenvalues of $\hat{\mathscr{L}}$.

In contrast to the diffusion operator, the operator $\hat{\mathscr{L}}$ acts on the functions defined in phase space rather than in just coordinate space. Moreover, it is very important to realise that $\hat{\mathscr{L}}$ describes *time irreversible* dynamics and its nontrivial eigenvalues acquire a finite real part. This real part appears as a result of the regularization of the operator $\hat{\mathscr{L}}$. Further details of this generalization can be found elsewhere.[42]

Riemannian symmetric superspaces and their origin in random-matrix theory

Martin R. Zirnbauer[a)]

(Received 31 March 1996; accepted for publication 19 June 1996)

Gaussian random-matrix ensembles defined over the tangent spaces of the large families of Cartan's symmetric spaces are considered. Such ensembles play a central role in mesoscopic physics, as they describe the universal ergodic limit of disordered and chaotic single-particle systems. The generating function for the spectral correlations of each ensemble is reduced to an integral over a Riemannian symmetric superspace in the limit of large matrix dimension. Such a space is defined as a pair $(G/H, M_r)$, where G/H is a complex-analytic graded manifold homogeneous with respect to the action of a complex Lie supergroup G, and M_r is a maximal Riemannian submanifold of the support of G/H. © *1996 American Institute of Physics.* [S0022-2488(96)00710-4]

I. INTRODUCTION

The mathematics of supersymmetry, though conceived and developed in elementary particle theory, has been applied extensively to the physics of disordered metals during the past decade. Improving on earlier work by Wegner,[1,2] Efetov[3] showed how to approximately map the problem of calculating disorder averages of products of the energy Green's functions for a single electron in a random potential, on a supersymmetric nonlinear σ model. Later it was shown[4] that the same nonlinear σ model describes the large-N limit of a random-matrix ensemble of the Wigner–Dyson[5] type. Since then, Efetov's method has evolved into a prime analytical tool in the theory of disordered or chaotic mesoscopic single-particle systems. Competing methods are limited either to the diffusive regime (the impurity diagram technique), or to isolated systems in the ergodic regime (the Dyson–Mehta orthogonal polynomial method), or to quasi-one-dimensional systems (the DMPK equation). In contrast, Efetov's method is applicable to isolated and to open systems in the diffusive, ergodic, localized, and even ballistic regime, to both spectral correlations and transport properties, and it can, in principle, be used in any dimension. This versatility has engendered a large body of nontrivial applications, many of which are outside the range of other methods. Of these, let me mention (i) the Anderson transition on a Bethe lattice,[6–8] (ii) localization in disordered wires,[9–13] (iii) multifractality of energy eigenstates in two dimensions,[14–16] (iv) weak localization and conductance fluctuations of chaotic billiards strongly coupled to a small number of scattering channels,[17,18] and, most recently, (v) a theoretical physicist's proof of the Bohigas–Giannoni–Schmit conjecture for chaotic Hamiltonian systems.[19,20]

In spite of these manifest successes, Efetov's supersymmetry method has been ignored (for all that I know) by mathematical physicists. This is rather unfortunate for several reasons. First, an infusion of mathematical expertise is needed to sort out some matters of principle and promote the method to a rigorous tool. Second, various extensions of currently available results seem possible but have been hindered by the lack of mathematical training on the part of the condensed matter theorists applying the method. And third, the geometric structures underlying Efetov's nonlinear σ models are of exquisite beauty and deserve to be studied in their own right. Part of the reason why neither mathematicians nor mathematical physicists have monitored or contributed to the devel-

opment, may be that there does not exist a concise status report that would appeal to a mind striving for clarity and rigor. Hence the first, and very ambitious, motivation for getting started on the present paper was to make an attempt and partially fill the gap.

Another objective is to report on a recent extension of the supersymmetry method to random-matrix theories beyond the standard Wigner–Dyson ones. In her study of Anderson localization in the presence of an A–B sublattice symmetry, Gade[21] noticed that the manifold of the nonlinear σ model is promoted to a larger manifold at zero energy. The same phenomenon occurs in the chiral limit of the QCD Dirac operator at zero virtuality.[22] For several years it remained unclear how to handle this enlargement of the manifold in the supersymmetric scheme. (Gade used the replica trick instead of supersymmetry.) The key to solving the problem can be found in a paper by Andreev, Simons, and Taniguchi,[23] who observed that what one needs to do is to avoid complex conjugation of the anticommuting variables. In the present paper I will elaborate on this observation and cast it in a concise mathematical language. Moreover, I will show that the same technical innovation allows one to treat the random-matrix theories that arose[24,25] in the stochastic modeling of mesoscopic metallic systems in contact with a superconductor.

An outline of the basic mathematical structure is as follows. Consider a homogeneous space G/H, where G and H are complex Lie supergroups, and regard G/H as a complex-analytic (p,q)-dimensional supermanifold in the sense of Berezin–Kostant–Leites.[26,27] To integrate its holomorphic sections, select a closed, oriented, and real p-manifold M_r contained in the support $M=G_0/H_0$ of the supermanifold. The natural (invariant) supergeometry of G/H induces a geometry on M_r by restriction. If this geometry is Riemann and M_r is a symmetric space, the pair $(G/H,M_r)$ is called a Riemannian symmetric superspace. This definition will be shown to be the one needed for the extension of the supersymmetry method beyond Wigner–Dyson. The difficulties disordered single-particle theorists had been battling with were caused by the fact that the exact sequence

$$0\rightarrow \text{nilpotents}\rightarrow G/H\rightarrow M\rightarrow 0,$$

does not, in general, reduce to an exact sequence of sheaves of *real-analytic* sections terminating at the Riemannian submanifold M_r.

When integrating the invariant holomorphic Berezin superform on G/H, one must pay careful attention to its coordinate ambiguity. This subtle point is reviewed in Sec. II A. After a brief reminder of the procedure of Grassmann-analytic continuation (in Sec. II B), the complex Lie supergroups $\mathrm{Gl}(m|n)$ and $\mathrm{Osp}(m|2n)$ (in Sec. II C), and Cartan's symmetric spaces (in Sec. II E), the details of the definition of Riemannian symmetric superspaces are given in Sec. II F. Table II lists the large families of these spaces.

Section III, the largest of the paper, treats the Gaussian random-matrix ensemble defined over the symplectic Lie algebra $\mathrm{sp}(N)$, by an adaptation of Efetov's method. A simple example (Sec. III A) illustrates the general strategy. Details of the method, including a complete justification of all manipulations involved, are presented in Secs. III B–III F. Theorem 3.3 expresses the Gaussian ensemble average of a product of n ratios of spectral determinants as a superintegral. Theorem 3.4 reduces this expression to an integral over the Riemannian symmetric superspace $\mathrm{Osp}(2n|2n)/\mathrm{Gl}(n|n)$ with $M_r=(\mathrm{SO}^*(2n)/\mathrm{U}(n))\times(\mathrm{Sp}(n)/\mathrm{U}(n))$, in the limit $N\rightarrow\infty$.

According to Cartan's list, there exists 11 large families of symmetric spaces. Ten of these correspond to universality classes that are known to describe disordered single-particle systems in the ergodic regime.[24,25] The class singled out for detailed treatment in Sec. III describes mesoscopic normal-superconducting hybrid systems with time-reversal symmetry broken by a weak magnetic field. The remaining nine classes are briefly discussed in Sec. IV. Each of them is related, by the supersymmetry method, to one of the large families of Riemannian symmetric superspaces of Table II. A summary is given in Sec. V.

II. RIEMANNIAN SYMMETRIC SUPERSPACES

A. The Berezin integral on analytic supermanifolds

Let $A(U)$ denote the algebra of analytic functions on an open subset U of p-dimensional real space. By taking the tensor product with the Grassmann algebra with q generators one obtains $A(U)\otimes\Lambda(\mathbb{R}^q)$, the algebra of analytic functions on U with values in $\Lambda(\mathbb{R}^q)$. Multiplication on $\Lambda(\mathbb{R}^q)$ is the exterior one, so the algebra is supercommutative (or graded commutative). The object at hand serves as a model for what is called a real-analytic (p,q)-dimensional supermanifold (or graded manifold[28]) in the sense of Berezin, Kostant, and Leites (BKL);[26,27] which, precisely speaking, is a sheaf of supercommutative algebras $\mathscr{A}$ with an ideal $\mathscr{N}$ (the nilpotents), such that $M\simeq\mathscr{A}/\mathscr{N}$ is an analytic p-manifold and on a domain $U\subset M$, $\mathscr{A}$ splits as $A(U)\otimes\Lambda(\mathbb{R}^q)$. The global sections of the bundle $\mathscr{A}\to M$ are called superfunctions, or functions for short. M is called the underlying space, or base, or support, of the supermanifold. M will be assumed to be orientable and closed ($\partial M=0$).

The calculus on analytic supermanifolds is a natural extension of the calculus on analytic manifolds. Functions are locally expressed in terms of (super-)coordinates $(x;\xi):=(x^1,\ldots,x^p;\xi^1,\ldots,\xi^q)$, where $x^i(\xi^j)$ are even (resp., odd) local sections of $\mathscr{A}$. If $(x;\xi)$ and $(y;\eta)$ are two sets of local coordinates on domains that overlap, the transition functions $y^i=f^i(x;\xi)$ and $\eta^j=\varphi^j(x;\xi)$ are analytic functions of their arguments and are consistent with the $\mathbb{Z}_2$ grading of $\mathscr{A}$.

In what follows the focus is on the theory of integration on analytic supermanifolds. Recall that on p-manifolds the objects one integrates are p-forms and their transformation law is given by

$$dy^1\wedge\cdots\wedge dy^p=dx^1\wedge\cdots\wedge dx^p\,\mathrm{Det}\left(\frac{\partial y^i}{\partial x^j}\right).$$

The obvious (super-)generalization of the Jacobian $\mathrm{Det}(\partial y^i/\partial x^j)$ is the Berezinian[29]

$$\mathrm{Ber}\left(\frac{y,\eta}{x,\xi}\right):=\mathrm{SDet}\begin{pmatrix}\dfrac{\partial y^i}{\partial x^j} & \dfrac{\partial y^i}{\partial \xi^j}\\[2ex] \dfrac{\partial \eta_i}{\partial x^j} & \dfrac{\partial \eta_i}{\partial \xi^j}\end{pmatrix},$$

where SDet is the symbol for superdeterminant. Guided by analogy, one postulates that an integral superform ought to be an object $\widetilde{D}$ transforming according to the law

$$\widetilde{D}(y,\eta)=\widetilde{D}(x,\xi)\mathrm{Ber}(y,\eta/x,\xi). \tag{1}$$

A natural candidate would seem to be

$$D(x,\xi):=dx^1\wedge\cdots\wedge dx^p\otimes\partial_{\xi^1}\cdots\partial_{\xi^q},$$

which is a linear differential operator taking superfunctions f into p-forms $D[f]$ (∂_{ξ^i} denotes the partial derivative with respect to the anticommuting coordinate ξ^i). The p-form $D[f]$ can be integrated in the usual sense to produce a number. However, the transformation law for $D(x,\xi)$ turns out to be not quite (1), but rather

$$D(y,\eta)=D(x,\xi)\mathrm{Ber}(y,\eta/x,\xi)+\beta. \tag{2}$$

An explicit description of the term β on the right-hand side, here referred to as the *anomaly*, was first given by Rothstein.[30] It is nonzero whenever some even coordinate functions are shifted by nilpotent terms. Its main characteristic is that on applying it to a superfunction f, one gets a p-form that is *exact*: $\beta[f]=d(\alpha[f])$.

The existence of an anomaly in the transformation law for $D(x,\xi)$ leads one to consider a larger class of objects, namely, $\Lambda^p(M)\otimes_{\mathscr{A}}\mathscr{D}$, the sheaf of linear differential operators on $\mathscr{A}$ with values in the p-forms on M. [$\Lambda^p(M)\otimes_{\mathscr{A}}\mathscr{D}$ naturally is a right $\mathscr{A}$-module.] To rescue the simple transformation law (1) one usually passes from $\Lambda^p(M)\otimes_{\mathscr{A}}\mathscr{D}$ to its quotient by the anomalies.[30] In order for the integral to be well-defined over the quotient, one must take the functions one integrates to be compactly supported.

Sadly, this last option *is not available to us*. The functions that will be encountered in the applications worked out below, do not ever have compact support but are *analytic* functions instead. When integrating such functions, we need to work with the full transformation law (2), which includes the anomaly.

Another way of avoiding the anomaly is to arrange for the transition functions never to shift the even coordinates by nilpotents, by constructing a restricted subatlas.[31] However, because the concept of a restricted subatlas is somewhat contrived, this approach has been found to be of limited use in the type of problem that is of interest here.

To arrive at a definition of superintegration that is useful in practice, we proceed as follows. The supermanifold is covered by a set of charts with domains U_i and coordinates $(x_{(i)},\xi_{(i)})$ $(i=1,\ldots,n)$. On chart i let $\omega_i:=D(x_{(i)},\xi_{(i)})\circ\widetilde{\omega}_i$ with $\widetilde{\omega}_i$ a local section of $\mathscr{A}$, and let $\alpha_i \in \Lambda^{p-1}(M)\otimes_{\mathscr{A}}\mathscr{D}|_{U_i}$. Partition M into a number of consistently oriented p-cells $D_1,\ldots,D_n$, with D_i contained in U_i. For $i<j$ put $D_{ij}:=\partial D_i\cap\partial D_j$ and, if D_{ij} is nonempty and is a $(p-1)$-cell, fix its orientation by $\partial D_i=+D_{ij}+\cdots$.

Definition 2.1: A collection $\{\omega_i,\alpha_i\}_{i=1,\ldots,n}$ is called a *Berezin measure* ω if the conditions

$$\widetilde{\omega}_i/\widetilde{\omega}_j=\mathrm{Ber}(i/j), \tag{3}$$

$$\omega_i+d\alpha_i=\omega_j+d\alpha_j, \tag{4}$$

are satisfied on overlapping domains. The Berezin integral $f\mapsto\int_M\omega[f]$ is defined as

$$\int_M\omega[f]=\sum_{i=1}^{n}\int_{D_i}\omega_i[f]+\sum_{i<j}\int_{D_{ij}}\alpha_{ij}[f], \tag{5}$$

where $\alpha_{ij}=\alpha_i-\alpha_j$. The quantities ω_i and α_i are called the principal term and the anomaly of the Berezin measure on chart i.

Remark 2.2: The conditions (3) and (4) ensure the existence of a global section $\omega\in\Lambda^p(M)\otimes_{\mathscr{A}}\mathscr{D}$, whose local expression in chart i is $\omega_i+d\alpha_i$. The existence of ω means that the distribution (5) is independent of the coordinate systems and the cell partition chosen. Because (5) depends only on the differences $\alpha_i-\alpha_j$, one can gauge the anomaly to zero on one of the charts without changing the Berezin integral.

Example 2.3: Consider the real supersphere $S^{p|2}$, a $(p,2)$-dimensional supermanifold with support S^p, which is the space of solutions in $(p+1,2)$ dimensions of the quadratic equation

$$\widetilde{x}_0^2+\widetilde{x}_1^2+\cdots+\widetilde{x}_p^2+2\widetilde{\xi}_1\widetilde{\xi}_2=1.$$

Cover S^p by two domains 1 and 2 obtained by removing the South $(\widetilde{x}_0=-1)$ or North Pole $(\widetilde{x}_0=+1)$. Introduce stereographic coordinates $(x_1,\ldots,x_p;\xi_1,\xi_2)$ and $(y_1,\ldots,y_p;\eta_1,\eta_2)$ for $S^{p|2}$ on these domains with transition functions

$$y_1=-\frac{x_1}{R^2},\quad y_i=\frac{x_i}{R^2}\quad (i=2,\ldots,p),\quad \eta_j=\frac{\xi_j}{R^2}\quad (j=1,2),$$

where $R^2=\Sigma_{i=1}^{p}x_i^2+2\xi_1\xi_2$. (The minus sign preserves the orientation.) Consider

$$\omega_1=D(x,\xi)\circ\left(1+\sum x_i^2+2\xi_1\xi_2\right)^{-p+2},$$

$$\omega_2=D(y,\eta)\circ\left(1+\sum y_i^2+2\eta_1\eta_2\right)^{-p+2},$$

$$\alpha_{12}=-\Omega\,\frac{(\Sigma x_i^2)^{(p-2)/2}}{(1+\Sigma x_i^2)^{p-2}}\otimes 2\partial_{\xi_1}\partial_{\xi_2}\circ\xi_1\xi_2,$$

where $\Omega=(\Sigma_j x_j^2)^{-p/2}\Sigma_{i=1}^{p}(-1)^i dx_1\wedge\cdots\wedge dx_{i-1}\wedge x_i dx_{i+1}\wedge\cdots\wedge dx_p$ is the solid-angle $(p-1)$ form in p dimensions. It is not difficult to check by direct calculation that ω_1, ω_2 and $\alpha_1=\alpha_{12}$, $\alpha_2\equiv 0$ obey the relations (3) and (4). Hence, they express a globally defined Berezin measure ω in the sense of Definition 2.1. (The geometric meaning of ω will be specified in Sec. II C.) For $p\geqslant 3$, the anomaly α_{12} scales to zero when $\Sigma x_i^2\to\infty$, so we may shrink cell 2 to a single point (a set of measure zero) and compute the Berezin integral simply from

$$\int_{S^p}\omega[f]=\int_{\mathbb{R}^p}D(x,\xi)\left(1+\sum x_i^2+2\xi_1\xi_2\right)^{-p+2}f(x;\xi).$$

In these cases we can get away with using only a single chart. The situation is different for $p=2$ and $p=1$. In the first case the anomaly is scale-invariant (the solid angle is) and by again shrinking cell 2 to one point [the South Pole $(y_1,y_2)=(0,0)$ on S^2] we get

$$\int_{S^2}\omega[f]=\int_{\mathbb{R}^2}D(x,\xi)f(x;\xi)+4\pi f\Big|_{\text{South Pole}}.$$

In particular, $\int_{S^2}\omega[1]=4\pi$. For $p=1$ the anomaly diverges at $x=0$ and $x=\infty$. In this case the general formula (5) must be used, and one finds $\int_{S^1}\omega[1]=0$.

B. Grassmann-analytic continuation

In the formulation of BKL, the vector fields of a supermanifold do not constitute a module over $\mathscr{A}$ but are constrained to be *even* derivations of $\mathscr{A}$, which is to say that their coordinate expression is of the form

$$\hat{X}=f^i(x;\xi)\,\frac{\partial}{\partial x^i}+\varphi^j(x;\xi)\,\frac{\partial}{\partial\xi^j},$$

where f^i and φ^j are even and odd superfunctions, respectively. Unfortunately, this formulation is too narrow for most purposes. The reason is that in applications one typically deals not with a single supermanifold but with many copies thereof (one per lattice site of a lattice-regularized field theory, for example). So, in addition to the anticommuting coordinates of the one supermanifold that is singled out for special consideration, there exist many more anticommuting variables associated with the other copies of the supermanifold. When the focus is on one supermanifold, these can be considered as ''parameters.'' Often one wants to make parameter-dependent coordinate transformations, leading to coefficients $f_{i_1\cdots i_n}(x)$ in the expansion $f(x;\xi)=\Sigma f_{i_1\cdots i_n}(x)\xi^{i_1}\cdots\xi^{i_n}$ that depend on extraneous Grassmann parameters. (For example, when the

supermanifold is a Lie supergroup, it is natural to consider making left and right translations $g \mapsto g_L g g_R$.) The upshot is that one wants to take $\mathscr{A}$ as a sheaf of graded commutative algebras not over $\mathbb{R}$ but over some (large) parameter Grassmann algebra Λ (the Grassmann algebra generated by the anticommuting coordinates of the ''other'' supermanifolds). Making this extension, which is called ''Grassmann-analytic continuation'' in Ref. 29, one is led to consider the more general class of vector fields of the form

$$\hat{X} = f^i(x,\xi;\beta)\,\frac{\partial}{\partial x^i} + \varphi^j(x,\xi;\beta)\,\frac{\partial}{\partial \xi^j}, \tag{6}$$

where the symbol β stands for the extra Grassmann parameters and the dependences on these are such that f^i and φ^j continue to be even and odd, respectively (the $\mathbb{Z}_2$ grading of $\mathscr{A}$ after Grassmann-analytic continuation is the natural one).

The vector fields (6) still are even derivations of the extended algebra. One can go further by demanding that Der $\mathscr{A}$ be free over $\mathscr{A}$ and including the odd ones, too. When that development is followed to its logical conclusion, one arrives at Rothstein's axiomatic definition[32] of supermanifolds, superseding an earlier attempt by Rogers.[33,34] Although there is no denying the elegance and consistency of Rothstein's formulation, we are not going to embrace it here, the main reason being that odd derivations will not really be needed. For the purposes of the present paper we will get away with considering vector fields of the constrained form (6).

C. The complex Lie supergroups Gl($m|n$) and Osp($m|2n$)

The supermanifolds we will encounter all derive from the complex Lie supergroups[29,28] Gl($m|n$) and Osp($m|2n$), by forming cosets. The definition of Gl($m|n$) rests on the notion of an invertible supermatrix

$$g = \begin{pmatrix} g_{00} & g_{01} \\ g_{10} & g_{11} \end{pmatrix},$$

where g_{00}, g_{01}, g_{10}, and g_{11} are matrices of size $m\times m$, $m\times n$, $n\times m$, and $n\times n$. The supermanifold structure of Gl($m|n$) comes from taking the matrix elements of g_{00} and g_{11} (g_{01} and g_{10}) for the even (resp., odd) coordinates on suitable domains of the base $M = \mathrm{Gl}(m,\mathbb{C})\times\mathrm{Gl}(n,\mathbb{C})$. The Lie supergroup structure derives from the usual law of matrix multiplication.

For $m \neq n$, it is common practice to split off from Gl($m|n$) the Gl(1)-ideal generated by the unit matrix, so as to have an irreducible Lie superalgebra.[35,36] For $m = n$, which turns out to be the case of most interest here, one ends up having to remove two Gl(1)'s, one generated by the unit matrix and the other one by the superparity matrix $\sigma = \mathrm{diag}(1_n, -1_n)$. And even then the Lie superalgebra is not irreducible in a sense, for the Killing form $\mathrm{STr}\,\mathrm{ad}(X)\mathrm{ad}(Y)$ vanishes identically. We therefore prefer to take Gl($m|n$) as it stands (with no ideals removed) and replace the Killing form by the invariant quadratic form $\mathrm{B}(X,Y) = \mathrm{STr}\,XY$, which is nondegenerate in all cases (including $m = n$).

The complex orthosymplectic Lie supergroup Osp($m|2n$) is defined as a connected subgroup of Gl($m|2n$) fixed by an involutory automorphism $g \mapsto \hat{\tau}(g) = \tau g^{-1^{\mathrm{T}}} \tau^{-1}$, where τ is supersymmetric ($\tau = \tau^{\mathrm{T}}\sigma = \sigma\tau^{\mathrm{T}}$).[37] The support of Osp($m|2n$) is $\mathrm{SO}(m,\mathbb{C})\times\mathrm{Sp}(n,\mathbb{C})$.

The action of a Lie supergroup on itself by left and right translations gives rise to right- and left-invariant vector fields. A Berezin measure on a Lie supergroup is said to be invariant, and is called a Berezin–Haar measure, if its Lie derivatives[29] with respect to the invariant vector fields vanish.

Given a Lie supergroup G and a subgroup H, the coset superspace G/H is defined by decreeing that the structure sheaf of the coset superspace is a quotient of sheaves. The action of G

on G/H by left translation gives rise to so-called Killing vector fields. A Berezin measure on G/H is called invariant if its Lie derivatives with respect to the Killing vector fields are zero.

If $\mathrm{Osp}_{\mathbb{R}}(m|2n)$ denotes the orthosymplectic supergroup over the reals, the coset space $\mathrm{Osp}_{\mathbb{R}}(m+1|2n)/\mathrm{Osp}_{\mathbb{R}}(m|2n)$ can be identified with the real supersphere $S^{m|2n}$. The Berezin measure discussed in Example 2.3 is invariant with respect to the action of $\mathrm{Osp}_{\mathbb{R}}(p+1|2)$ on $S^{p|2}$ and can be viewed as the ''volume superform'' of $S^{p|2}$. Hence we can restate the results of that example as follows: $\mathrm{vol}(S^{2|2}) := \int_{S^2}\omega[1] = 4\pi$ and $\mathrm{vol}(S^{1|2}) := \int_{S^1}\omega[1] = 0$.

D. Holomorphic Berezin measures on complex-analytic supermanifolds

To go from real-analytic supermanifolds to complex-analytic ones, one replaces the structure sheaf $\mathscr{A}$ by a sheaf of graded commutative algebras $\mathscr{H}$ over $\mathbb{C}$ such that $M \simeq \mathscr{H}/\mathscr{N}$ is a complex manifold and $\mathscr{H}$ is locally modeled by $H(U)\otimes\Lambda(\mathbb{C}^q)$, where $H(U)$ is the algebra of holomorphic functions on $U\subset M$. The natural objects to consider then are holomorphic superfunctions, i.e., global sections of the bundle $\mathscr{H}\to M$. In local coordinates $z^1,\ldots,z^p$; $\zeta^1,\ldots,\zeta^q$ such sections are written as $f(z;\zeta)$. Grassmann-analytic continuation is done as before when needed. A Berezin measure on a complex-analytic (p,q)-dimensional supermanifold is a linear differential operator ω that takes holomorphic superfunctions f into holomorphic p-forms $\omega[f]$ on M. The statements made in Sec. II A about the anomalous transformation behavior of Berezin measures apply here, too (mutatis mutandi).

To define Berezin's integral in the present context, one more piece of data must be supplied, namely a *real* p-dimensional submanifold $M_r\subset M$ over which the holomorphic p-form $\omega[f]$ can be integrated to produce a complex number. Thus, given ω and M_r, Berezin's integral is the distribution

$$f\mapsto \int_{M_r}\omega[f]. \tag{7}$$

Let me digress and mention that this definition, natural and simple as it is, was not ''discovered'' by the random-matrix and mesoscopic physics community (including myself) until quite recently. With one notable exception,[23] all past superanalytic work on disordered single-particle systems employed some operation of ''complex conjugation'' of the Grassmann generators—namely an adjoint of the first or second kind[29]—to make the treatment of the ordinary (''bosonic'') and anticommuting (''fermionic'') degrees of freedom look as much alike as possible. Presumably this was done because it was felt that such egalitarian treatment is what is required by the principle of ''supersymmetry.'' Specifically, a reality constraint was imposed, not just on the underlying space M (fixing M_r) but on the entire structure sheaf to reduce $\mathscr{H}$ to a sheaf of algebras over $\mathbb{R}$. Although this reduction can be done with impunity in some cases (namely, the classic Wigner–Dyson symmetry classes), it has turned out to lead to insurmountable difficulties in others (the chiral and normal-superconducting symmetry classes). A major incentive of the present paper is to demonstrate that the construction (7) is in fact the ''good'' one to use for the application of supermanifold theory to disordered single-particle systems in general. Although that construction may hurt the physicists' aesthetic sense by ''torturing supersymmetry,'' it should be clear that we are not breaking any rules. Recall that according to Berezin, superintegration is a two-step process: first, the Fermi integral (i.e., differentiation with respect to the anticommuting coordinates) is carried out, and it is only *afterward* that the ordinary (Bose) integrals are done. When the sequential nature of the Berezin integral is taken seriously, there is no compelling reason why one should ever want to ''complex conjugate'' a Grassmann variable. In the present paper, we take the radical step of abandoning complex conjugation of Grassmann variables altogether.

Example 2.4: The simplest nontrivial example[23] is given by $\mathrm{Gl}(1|1)$, the Lie supergroup of regular complex 2×2 supermatrices

$$g=\begin{pmatrix} a & \beta \\ \gamma & d \end{pmatrix}$$

with support $M=\mathrm{Gl}(1,\mathbb{C})\times\mathrm{Gl}(1,\mathbb{C})$. The Berezin–Haar measure on $\mathrm{Gl}(1|1)$ is $\omega=(2\pi i)^{-1}D(ad;\beta\gamma)$, where $D(ad;\beta\gamma)=da\wedge dd\otimes\partial_\beta\partial_\gamma$. Solving the regularity conditions $a\neq 0$ and $d\neq 0$ by parametrizing $\mathrm{Gl}(1|1)$ through its Lie algebra,

$$g=\exp\begin{pmatrix} z_1 & \zeta_1 \\ \zeta_2 & z_2 \end{pmatrix},$$

one finds

$$2\pi i\omega=D(z_1z_2;\zeta_1\zeta_2)\circ\frac{(z_1-z_2)^2}{(1-e^{z_1-z_2})(e^{z_2-z_1}-1)}$$
$$-\left(d\,\ln(e^{z_1}-e^{z_2})-\frac{(z_1-z_2)(dz_1-dz_2)}{(1-e^{z_1-z_2})(e^{z_2-z_1}-1)}\right)\otimes\partial_{\zeta_1}\partial_{\zeta_2}\circ\zeta_1\zeta_2. \tag{8}$$

Note that this expression is holomorphic in a neighborhood of the origin $z_1=z_2=0$. The first term on the right-hand side is the principal term, and the second one is the anomaly of ω in these coordinates. To integrate ω, one might be tempted to choose for M_r the $\mathrm{U}(1)\times\mathrm{U}(1)$ subgroup defined by $\mathrm{Re}(z_1)=0=\mathrm{Re}(z_2)$. However, since the rank-two tensor $\mathrm{STr}\,dg\;dg^{-1}=da\;da^{-1}-dd\;dd^{-1}+\text{nilpotents}=-dz_1^2+dz_2^2+\cdots$ is not Riemann on $\mathrm{U}(1)\times\mathrm{U}(1)$, this will not be the best choice. A Riemannian structure is obtained by taking $M_r=\mathbb{R}^+\times S^1$ defined by $\mathrm{Im}(z_1)=0=\mathrm{Re}(z_2)$. To compute $\int_{\mathbb{R}^+\times S^1}\omega[f]$ we may use a single cell,

$$D:-\infty<x<+\infty,\quad -\pi<y<+\pi,$$

where $x=\mathrm{Re}(z_1)$ and $y=\mathrm{Im}(z_2)$. The boundary ∂D consists of the two lines $y=-\pi$ and $y=\pi$ ($x\in\mathbb{R}$). Using (8), paying attention to the orientation of the boundary, and simplifying terms, one finds the following explicit expression for the integral of ω:

$$\int_{\mathbb{R}^+\times S^1}\omega[f]=\frac{1}{4\pi}\int_{-\infty}^{\infty}dx\int_{-\pi}^{\pi}dy\,\frac{(x-iy)^2}{\cosh(x-iy)-1}\,\partial_{\zeta_1}\partial_{\zeta_2}f\left(\exp\begin{pmatrix} x & \zeta_1 \\ \zeta_2 & iy \end{pmatrix}\right)$$
$$+\frac{1}{2}\int_{-\infty}^{\infty}\frac{dx}{\cosh x+1}\,f\left(\begin{pmatrix} e^x & 0 \\ 0 & -1 \end{pmatrix}\right).$$

By construction, this Berezin integral is invariant under left and right translations $f(g)\mapsto f(g_Lgg_R)$. Evaluation gives $\int_{\mathbb{R}^+\times S^1}\omega[1]=1\neq 0$. The naive guess would have been $\int\omega[1]=(2\pi i)^{-1}\int da\wedge dd\;\partial_\beta\partial_\gamma=0$ due to $\partial_\beta\partial_\gamma\cdot 1=0$. Such reasoning is false because $\int_{\mathbb{R}^+}da=\infty$.

E. Symmetric spaces: A reminder

A Riemannian (globally) symmetric space is a Riemannian manifold M, such that every $p\in M$ is an isolated fixed point of an involutive isometry. (In normal coordinates x^i centered around p, this isometry is given by $x^i\mapsto -x^i$.) This definition implies (cf. Ref. 38) that the Riemann curvature tensor is covariantly constant, so that ''the geometry is the same everywhere.'' The curvature can be positive, negative, or zero, and the symmetric space is said to be of compact, noncompact, or Euclidean type correspondingly.

According to Cartan's complete classification scheme, there exist ten[39] large classes of symmetric spaces. Apart from some minor modifications these are the entries of Table I. The differ-

TABLE I. The large families of symmetry spaces.

Class	Noncompact type	Compact type
A	$\mathrm{Gl}(N,\mathbb{C})/\mathrm{U}(N)$	$\mathrm{U}(N)$
AI	$\mathrm{Gl}(N,\mathbb{R})/\mathrm{O}(N)$	$\mathrm{U}(N)/\mathrm{O}(N)$
AII	$\mathrm{U}^*(2N)/\mathrm{Sp}(N)$	$\mathrm{U}(2N)/\mathrm{Sp}(N)$
$AIII$	$\mathrm{U}(p,q)/\mathrm{U}(p)\times\mathrm{U}(q)$	$\mathrm{U}(p+q)/\mathrm{U}(p)\times\mathrm{U}(q)$
BDI	$\mathrm{SO}(p,q)/\mathrm{SO}(p)\times\mathrm{SO}(q)$	$\mathrm{SO}(p+q)/\mathrm{SO}(p)\times\mathrm{SO}(q)$
CII	$\mathrm{Sp}(p,q)/\mathrm{Sp}(p)\times\mathrm{Sp}(q)$	$\mathrm{Sp}(p+q)/\mathrm{Sp}(p)\times\mathrm{Sp}(q)$
BD	$\mathrm{SO}(N,\mathbb{C})/\mathrm{SO}(N)$	$\mathrm{SO}(N)$
C	$\mathrm{Sp}(N,\mathbb{C})/\mathrm{Sp}(N)$	$\mathrm{Sp}(N)$
CI	$\mathrm{Sp}(N,\mathbb{R})/\mathrm{U}(N)$	$\mathrm{Sp}(N)/\mathrm{U}(N)$
$DIII$	$\mathrm{SO}^*(2N)/\mathrm{U}(N)$	$\mathrm{SO}(2N)/\mathrm{U}(N)$

ence from the standard table[38] is that some of the entries of Table I, namely, the spaces of type A, AI, and AII, are not irreducible. They can be made so by dividing out a factor U(1) ($\mathbb{R}^+$) in the compact (resp., noncompact) cases. Division by such a factor is analogous to removing the center of mass motion from a mechanical system with translational invariance. It turns out that, with a view to superanalytic extensions (cf. Example 2.4), it is preferable not to insist on irreducibility but to ''retain the center of mass motion.''

The next section introduces supergeneralizations of Cartan's symmetric spaces, which have appeared in the theory of mesoscopic and disordered single-particle systems and have come to play an important role in that field.

F. Riemannian symmetric superspaces (definition)

Let G_Λ be a complex Lie supergroup that is realized as a group of supermatrices

$$g=\begin{pmatrix} g_{00} & g_{01} \\ g_{10} & g_{11} \end{pmatrix},$$

with matrix elements that take values in a (sufficiently large) parameter Grassmann algebra $\Lambda=\Lambda_0+\Lambda_1$. If $\mathscr{G}_\mathbb{C}=\mathscr{G}_\mathbb{C}^0+\mathscr{G}_\mathbb{C}^1$ is the Lie superalgebra of G_Λ, the Lie algebra of G_Λ is obtained by taking the even part of the tensor product with Λ: $\mathrm{Lie}\,(G_\Lambda)=\Lambda_0\otimes\mathscr{G}_\mathbb{C}^0+\Lambda_1\otimes\mathscr{G}_\mathbb{C}^1=(\Lambda\otimes\mathscr{G}_\mathbb{C})_0$. Thus, if $\{e_i,\epsilon_j\}$ is a homogeneous basis of complex matrices in $\mathscr{G}_\mathbb{C}$, an element $X\in\mathrm{Lie}(G_\Lambda)$ is expressed by $X=z^ie_i+\zeta^j\epsilon_j$ with $z^i\in\Lambda_0$ and $\zeta^j\in\Lambda_1$.

Let $\theta:G_\Lambda\to G_\Lambda$ be an involutory automorphism and let $H_\Lambda\subset G_\Lambda$ be the subgroup fixed by θ. The decomposition into even and odd eigenspaces of $\theta_*:\mathrm{Lie}(G_\Lambda)\to\mathrm{Lie}(G_\Lambda)$ is written as $\mathrm{Lie}(G_\Lambda)=\mathrm{Lie}(H_\Lambda)+\mathscr{M}_\Lambda$. This decomposition is orthogonal with respect to the $\mathrm{Ad}(G_\Lambda)$-invariant quadratic form $\mathrm{B}:\mathrm{Lie}(G_\Lambda)\times\mathrm{Lie}(G_\Lambda)\to\Lambda_0$, $\mathrm{B}(X,Y):=\mathrm{STr}\,XY$.

Both G_Λ and H_Λ are supermanifolds with underlying spaces that are Lie groups and are denoted by $G_\mathbb{C}$ and $H_\mathbb{C}$. Passing to the coset spaces one obtains a graded commutative algebra $\mathscr{H}=\mathscr{H}_0+\mathscr{H}_1$ of (Grassmann-analytically continued) holomorphic sections of the bundle $G_\Lambda/H_\Lambda\to G_\mathbb{C}/H_\mathbb{C}$. These sections are called (super-)functions (on G_Λ/H_Λ) for short. In local complex coordinates $z^1,\ldots,z^p;\ \zeta^1,\ldots,\zeta^q$ they are written as $f(z^1,\ldots,z^p;\zeta^1,\ldots,\zeta^q)=\Sigma f_{i_1\cdots i_n}(z^1,\ldots,z^p)\zeta^{i_1}\cdots\zeta^{i_n}$, where the coefficients $f_{i_1\cdots i_n}(z^1,\ldots,z^p)$ take values in Λ after Grassmann-analytic continuation. For coordinate-independent calculations the alternative notation $f(gH_\Lambda)$ or $f(g\cdot o)$ is used. In the following $G_\mathbb{C}/H_\mathbb{C}$ is assumed to be connected.

Every $X\in\mathrm{Lie}(G_\Lambda)$ is associated with a vector field (or even derivation) $\hat{X}:\mathscr{H}\to\mathscr{H}$ by

$$(\hat{X}f)(g\cdot o)=\left.\frac{d}{ds}\right|_{s=0} f(e^{-sX}g\cdot o). \tag{9}$$

Here $e^{sX}g$ means the usual product of supermatrices, and the function $f(e^{sX}g\cdot o)$ is determined from $f(g\cdot o)$ by Grassmann-analytic continuation. The Lie algebra of even derivations of $\mathscr{H}$ is a left $\mathscr{H}_0$-module denoted by $\mathrm{Der}_0\,\mathscr{H}$.[40]

A notion of supergeometry on G_Λ/H_Λ is introduced via a left-invariant tensor field $\langle\bullet,\bullet\rangle:\mathrm{Der}_0\,\mathscr{H}\times\mathrm{Der}_0\,\mathscr{H}\to\mathscr{H}_0$. The details are as follows. G_Λ acts on G_Λ/H_Λ by left translation, $T_h^*:f(g\cdot o)\mapsto f((hg)\cdot o)$. The left-translate $dT_h(\hat{X})$ of a vector field $\hat{X}$ is defined by the equation $T_h^*(dT_h(\hat{X})f)=\hat{X}(T_h^*f)$, and one requires

$$T_h^*\langle dT_h(\hat{X}),dT_h(\hat{Y})\rangle=\langle\hat{X},\hat{Y}\rangle.$$

This equation determines $\langle\bullet,\bullet\rangle$ uniquely within a multiplicative constant. For vector fields of the special form (9), one obtains

$$\langle\hat{X},\hat{Y}\rangle(g\cdot o)=c_0\times\mathrm{B}((\mathrm{Ad}(g)^{-1}X)_{\mathscr{M}_\Lambda},(\mathrm{Ad}(g)^{-1}Y)_{\mathscr{M}_\Lambda}),$$

where the subscript $\mathscr{M}_\Lambda$ means projection on the odd eigenspace of θ_*. Note that since $(\mathrm{Ad}(gh)^{-1}X)_{\mathscr{M}_\Lambda}=\mathrm{Ad}(h)^{-1}(\mathrm{Ad}(g)^{-1}X)_{\mathscr{M}_\Lambda}$ for $h\in H_\Lambda$, this is well-defined as a function on G_Λ/H_Λ. The normalization is fixed by choosing $c_0=1$.

The metric tensor $\langle\bullet,\bullet\rangle$ induces a geometry on the ordinary manifold $G_{\mathrm{C}}/H_{\mathrm{C}}$ by restriction (i.e., by setting all anticommuting variables equal to zero). Of course, since the groups G_{C} and H_{C} are complex, this geometry is never Riemann. However, there exist submanifolds in $G_{\mathrm{C}}/H_{\mathrm{C}}$ that are Riemannian symmetric spaces and can be constructed by selecting from the tangent space $T_o(G_{\mathrm{C}}/H_{\mathrm{C}})$ a Lie-triple subsystem $\mathscr{M}$ (i.e., $[\mathscr{M},[\mathscr{M},\mathscr{M}]]\subset\mathscr{M}$), such that the quadratic form B restricted to $\mathscr{M}$ is of definite sign. It is then not hard to show[38] that the image of $\mathscr{M}$ under the exponential map $X\mapsto e^XH_\Lambda$ is Riemann in the geometry given by restriction of $\langle\bullet,\bullet\rangle$. Its completion is a symmetric space.

Definition 2.5: A Riemannian symmetric superspace is a pair $(G_\Lambda/H_\Lambda;M)$, where M is a maximal Riemannian submanifold of the base $G_{\mathrm{C}}/H_{\mathrm{C}}$.

Remark 2.6: The merit of this definition is that it avoids any use of an adjoint (or ''complex conjugation'') of the Grassmann variables. ■

By the complex structure of $G_{\mathrm{C}}/H_{\mathrm{C}}$, the tangent space $\mathscr{M}_{\mathrm{C}}:=T_o(G_{\mathrm{C}}/H_{\mathrm{C}})$ decomposes as $\mathscr{M}_{\mathrm{C}}=\mathscr{M}+i\mathscr{M}$, where $\mathscr{M}$ is taken to be the subspace of $\mathscr{M}_{\mathrm{C}}$ on which the quadratic form B is strictly positive. Now observe that, since an element $g\in G_{\mathrm{C}}$ is of the form $g=\mathrm{diag}(g_{00},g_{11})$, the group G_{C} is a Cartesian product of two factors, and the same is true for H_{C}. Hence, $G_{\mathrm{C}}/H_{\mathrm{C}}$ factors as $G_{\mathrm{C}}/H_{\mathrm{C}}=M_{\mathrm{C}}^0\times M_{\mathrm{C}}^1$, and $\mathscr{M}$ is a sum of two spaces: $\mathscr{M}=\mathscr{M}_0\oplus\mathscr{M}_1$, which are orthogonal with respect to the quadratic form B. (It may happen, of course, that one of these spaces is trivial.) For $Z\in\mathscr{M}$, let the corresponding orthogonal decomposition be written as $Z=X+Y$. Then B restricted to $\mathscr{M}$ is evaluated as

$$\mathrm{B}(Z,Z)=\mathrm{Tr}_0\,X^2-\mathrm{Tr}_1\,Y^2,$$

where the relative minus sign between traces is due to supersymmetry ($\mathrm{STr}=\mathrm{Tr}_0-\mathrm{Tr}_1$). The positivity of B on $\mathscr{M}$ is seen to imply $X=X^\dagger$ and $Y=-Y^\dagger$ (the dagger denotes Hermitian conjugation, i.e. transposition in conjunction with complex conjugation).

Given G_Λ/H_Λ, the condition that M be Riemann and maximal in $G_{\mathrm{C}}/H_{\mathrm{C}}$, fixes M uniquely up to two possibilities: either $T_o(M)=\mathscr{M}$, or $T_o(M)=i\mathscr{M}$. In either case, M is a product of two factors, $M=M_0\times M_1$, both of which are Riemannian symmetric spaces. In the first case, M_0 is of the noncompact type and M_1 is of the compact type, while in the second case it is the other way around. We adopt the convention of denoting the compact space by M_{F} and the noncompact one by M_{B}.

In view of Cartan's list of symmetric spaces (Table I), we arrive at Table II listing the large families of Riemannian symmetric superspaces. Although the entries $A|A$, $BD|C$, and $C|BD$ look

TABLE II. The large families of Riemannian symmetric superspaces.

Class	G_Λ/H_Λ	M_B	M_F
$A\|A$	$\mathrm{Gl}(m\|n)$	A	A

$AII\|AI$	$\mathrm{Gl}(m\|2n)/\mathrm{Osp}(m\|2n)$	AII	AI
$AIII\|AIII$	$\mathrm{Gl}(m_1+m_2\|n_1+n_2)/\mathrm{Gl}(m_1\|n_1)\times\mathrm{Gl}(m_2\|n_2)$	$AIII$	$AIII$
$BD\|C$	$\mathrm{Osp}(m\|2n)$	BD	C
$C\|BD$	$\mathrm{Osp}(m\|2n)$	C	BD
$CI\|DIII$	$\mathrm{Osp}(2m\|2n)/\mathrm{Gl}(m\|n)$	CI	$DIII$
$DIII\|CI$	$\mathrm{Osp}(2m\|2n)/\mathrm{Gl}(m\|n)$	$DIII$	CI
$BDI\|CII$	$\mathrm{Osp}(m_1+m_2\|2n_1+2n_2)/\mathrm{Osp}(m_1\|2n_1)\times\mathrm{Osp}(m_2\|2n_2)$	BDI	CII
$CII\|BDI$	$\mathrm{Osp}(m_1+m_2\|2n_1+2n_2)/\mathrm{Osp}(m_1\|2n_1)\times\mathrm{Osp}(m_2\|2n_2)$	CII	BDI

extraneous because they are groups rather than coset spaces, they fit in the same framework by putting by $G_\Lambda = G\times G$ and $\theta(g_1,g_2)=(g_2,g_1)$, so $H_\Lambda=\mathrm{diag}(G\times G)\simeq G$ and $G_\Lambda/H_\Lambda\simeq G$.

As far as applications to random-matrix theory and disordered single-particle systems are concerned, the most important structure carried by Riemannian symmetric superspaces is their G_Λ-invariant Berezin measure. Such a measure always exists by Definition 2.1 and the existence of local coordinates. To describe it in explicit terms, one introduces a local coordinate system by the exponential map $\mathscr{M}_\Lambda\to G_\Lambda/H_\Lambda$, $Z\mapsto\exp(Z)H_\Lambda$. By straightforward generalization (replace the Jacobian by the Berezinian) of a corresponding calculation (cf. Ref. 38) for ordinary symmetric spaces, one obtains for the principal term of the invariant Berezin measure the expression $DZ\circ J(Z)$, where $DZ = dz^1\wedge\cdots\wedge dz^p\otimes\partial_{\zeta^1}\cdots\partial_{\zeta^q}$ denotes the flat Berezin measure on $\mathscr{M}_\Lambda$, and if $T_Z:\mathscr{M}_\Lambda\to\mathscr{M}_\Lambda$ is the linear operator defined by

$$T_Z=\sum_{n=0}^{\infty}\frac{\mathrm{ad}^{2n}(Z)}{(2n+1)!},$$

the function $J(Z)=\mathrm{SDet}T_Z$. [Note $\Sigma_{n=0}^{\infty}x^{2n}/(2n+1)!=x^{-1}\sinh x$]. A universally valid expression for the anomaly in these coordinates is not available at present.

III. SUPERSYMMETRY APPLIED TO THE GAUSSIAN RANDOM-MATRIX ENSEMBLE OF CLASS *C*

The goal of the remainder of this paper will be to demonstrate that Riemannian symmetric superspaces, as defined in Sec. II F, arise in a compelling way when Gaussian ensemble averages of ratios of spectral determinants for random matrices are considered in the large-N limit. The example to be discussed in detail will be the Gaussian ensemble defined over the symplectic Lie algebra $\mathrm{sp}(N)$, which has recently been identified[24] as a model for the ergodic limit of normal-superconducting mesoscopic systems with broken time-reversal symmetry.

A. The supersymmetry method: A simple example

The pedagogical purpose of this section is to illustrate our strategy at a simple example.[41] If $\mathrm{u}(N)$ is the Lie algebra of the unitary group in N dimensions, consider on $i\mathrm{u}(N)$ (the Hermitian $N\times N$ matrices) the Gaussian probability measure with width $v/\sqrt{N}$. Denoting by H the elements of $i\mathrm{u}(N)$ and by dH a Euclidean measure, we write the Gaussian probability measure in the form $d\mu(H)=\exp(-N\,\mathrm{Tr}\,H^2/2v^2)dH$, $\int d\mu(H)=1$. This measure is called the Gaussian unitary ensemble (GUE) in random-matrix theory. The object of illustration will be the average ratio of spectral determinants,

$$Z(\alpha,\beta)=\int_{iu(N)}\mathrm{Det}\left(\frac{H-\beta}{H-\alpha}\right)d\mu(H),$$

where α,β are complex numbers and α is not in the spectrum of H. Given the generating function Z, the GUE average resolvent is obtained by

$$\int_{iu(N)}\mathrm{Tr}(H-z)^{-1}d\mu(H)=\frac{\partial}{\partial\alpha}\,Z(\alpha,\beta)\bigg|_{\alpha=\beta=z}.$$

We will now show how to compute Z using a formalism that readily generalizes to more complicated situations.

To avoid the introduction of indices and have a basis-independent formulation, we choose to interpret H as a self-adjoint endomorphism $H\in\mathrm{End}(V)$ of N-dimensional complex space $V:=\mathbb{C}^N$ with a Hermitian quadratic form $(x,y)\mapsto\langle\overline{x},y\rangle_V$.

The supersymmetry method starts by introducing ''bosonic space'' $W_\mathrm{B}=W_0=\mathbb{C}$ and ''fermionic space'' $W_\mathrm{F}=W_1=\mathbb{C}$. Auxiliary space is the $\mathbb{Z}_2$-graded sum $W=W_\mathrm{B}\oplus W_\mathrm{F}=\mathbb{C}^{1|1}$. The Cartesian basis of W is denoted by $e_\mathrm{B}=(1,0)$ and $e_\mathrm{F}=(0,1)$. Let $\mathrm{Hom}_\lambda(W,V):=\lambda_0\otimes\mathrm{Hom}(W_\mathrm{B},V)+\lambda_1\otimes\mathrm{Hom}(W_\mathrm{F},V)$, where $\lambda=\lambda_0+\lambda_1$ is the Grassmann algebra with $\dim_\mathbb{C}\mathrm{Hom}(W_\mathrm{F},V)=N$ generators. (Grassmann-analytic continuation will not be needed here.) $\mathrm{Hom}_{\tilde\lambda}(V,W)$ is defined similarly, with another Grassmann algebra $\tilde\lambda$. The key idea is to utilize the Gaussian Berezin integral over the complex-analytic superspace $\mathrm{Hom}_\lambda(W,V)\times\mathrm{Hom}_{\tilde\lambda}(V,W)$. Let $D(\psi,\tilde\psi)$ [with $\psi\in\mathrm{Hom}_\lambda(W,V)$ and $\tilde\psi\in\mathrm{Hom}_{\tilde\lambda}(V,W)$] denote a translation-invariant holomorphic Berezin measure on this linear space. If $\psi_\mathrm{B}(\tilde\psi_\mathrm{B})$ is the restriction of $\psi(\tilde\psi)$ to a map $W_\mathrm{B}\to V$ (resp., $V\to W_\mathrm{B}$), fix a Berezin integral $f\mapsto\int D(\psi,\tilde\psi)f(\psi,\tilde\psi)$ by choosing for the domain of integration the subspace M_r selected by the linear condition $\tilde\psi_\mathrm{B}=\psi_\mathrm{B}$ (the adjoint $\psi_\mathrm{B}^\dagger:\mathbb{C}^N\to\mathbb{C}$ being defined by $\overline{\psi_\mathrm{B}^\dagger z}=\langle\overline{z},\psi_\mathrm{B}\cdot 1\rangle_V$). Because $\mathrm{Hom}_\lambda(W,V)\times\mathrm{Hom}_{\tilde\lambda}(V,W)$ has complex dimension $(2N,2N)$, the integral $\int D(\psi,\tilde\psi)f(\psi,\tilde\psi)$ does not change its value when f is replaced by the rescaled function $f^s(\psi,\tilde\psi)=f(s\psi,s\tilde\psi)$ $(s\in\mathbb{R})$. Now with $\mathrm{End}_0(W)=\mathrm{End}(W_\mathrm{B})\oplus\mathrm{End}(W_\mathrm{F})$ and $\mathrm{End}_1(W)=\mathrm{Hom}(W_\mathrm{B},W_\mathrm{F})\oplus\mathrm{Hom}(W_\mathrm{F},W_\mathrm{B})$, let

$$\mathrm{End}_\Lambda(W):=\Lambda_0\otimes\mathrm{End}_0(W)+\Lambda_1\otimes\mathrm{End}_1(W),$$

where $\Lambda=\Lambda_0+\Lambda_1$ is the Grassmann algebra with $\dim_\mathbb{C}\mathrm{End}_1(W)=2$ generators, and pick $A\in\mathrm{End}(V)$, $B\in\mathrm{End}_\Lambda(W)$. B corresponds to what is called a 2×2 supermatrix in physics. An elementary but useful result is that, if we normalize $D(\psi,\tilde\psi)$ by $\int D(\psi,\tilde\psi)\exp(-s^2\,\mathrm{Tr}\,\tilde\psi\psi)=1$, the identity

$$\int D(\psi,\tilde\psi)\exp(i\,\mathrm{Tr}_V\,A\psi\tilde\psi-i\,\mathrm{STr}_W\,B\tilde\psi\psi)=\mathrm{SDet}_{V\otimes W}(A\otimes 1-1\otimes B)^{-c},\tag{10}$$

holds with $c=1$ provided that the integral exists. (The parameter c is introduced for later convenience.) When A and B are represented by diagonal matrices, verification of (10) is a simple matter of doing one-dimensional Gaussian integrals. The general case follows by the invariance of $D(\psi,\tilde\psi)$ under unitary transformations of V and ''super-rotations'' in W.

Now introduce elements E_BB and E_FF of $\mathrm{End}_0(W)$ by $E_\mathrm{BB}e_\mathrm{B}=e_\mathrm{B}$, $E_\mathrm{FF}e_\mathrm{F}=e_\mathrm{F}$, and $E_\mathrm{BB}e_\mathrm{F}=E_\mathrm{FF}e_\mathrm{B}=0$. By setting $A:=H$ and $B:=\alpha E_\mathrm{BB}+\beta E_\mathrm{FF}=:\omega$, and using

$$\mathrm{SDet}_{V\otimes W}(H\otimes 1-1\otimes\omega)=\mathrm{Det}(H-\alpha)/\mathrm{Det}(H-\beta),$$

we get a Gaussian integral representation of Z:

$$Z(\omega) := Z(\alpha,\beta) = \int \mathrm{SDet}_{V\otimes W}(H\otimes 1 - 1\otimes\omega)^{-c} d\mu(H)$$

$$= \int D(\psi,\tilde{\psi}) \int \exp(i\ \mathrm{Tr}_V\ H\psi\tilde{\psi} - i\ \mathrm{STr}_W\ \omega\tilde{\psi}\psi) d\mu(H). \tag{11}$$

In the next step, the GUE ensemble average is subjected to the following manipulations:

$$\int \exp(i\ \mathrm{Tr}\ H\psi\tilde{\psi}) d\mu(H) = \int_{iu(N)} \exp\left(i\ \mathrm{Tr}\ H\psi\tilde{\psi} - \frac{N\ \mathrm{Tr}\ H^2}{2v^2}\right) dH$$

$$= \exp - \frac{v^2}{2N}\ \mathrm{Tr}_V(\psi\tilde{\psi})^2$$

$$= \exp - \frac{v^2}{2N}\ \mathrm{STr}_W(\tilde{\psi}\psi)^2$$

$$= \int_{\mathbb{R}\times i\mathbb{R}} DQ\ \exp\left(i\ \mathrm{STr}\ Q\tilde{\psi}\psi - \frac{N\ \mathrm{STr}\ Q^2}{2v^2}\right)$$

$$=: \int D\mu(Q) \exp(i\ \mathrm{STr}\ Q\tilde{\psi}\psi). \tag{12}$$

The fourth equality sign decouples the quartic term $\mathrm{STr}_W(\tilde{\psi}\psi)^2$ by introducing an auxiliary integration over $Q \in \mathrm{End}_\Lambda(W)$. In order for this Gaussian integral to converge, the integration domain for the BB part $Q_{\mathrm{BB}}: W_{\mathrm{B}} \to W_{\mathrm{B}}$ (FF part, $Q_{\mathrm{FF}}: W_{\mathrm{F}} \to W_{\mathrm{F}}$), is taken to be the real (resp., imaginary) numbers. By using the relations (10)–(12), we obtain

$$Z(\omega) = \int D(\psi,\tilde{\psi}) \left(\int \exp(i\ \mathrm{Tr}_V\ H\psi\tilde{\psi}) d\mu(H)\right) \exp - i\ \mathrm{STr}_W\ \omega\tilde{\psi}\psi$$

$$= \int D\mu(Q) \int D(\psi,\tilde{\psi}) \exp\ i\ \mathrm{Tr}_V\ \psi(Q-\omega)\tilde{\psi}$$

$$= \int D\mu(Q)\, \mathrm{SDet}_{V\otimes W}(1_N \otimes (Q-\omega))^{-c}$$

$$= \int D\mu(Q)\, \mathrm{SDet}_W(Q-\omega)^{-N}$$

$$= \int_{\mathbb{R}\times i\mathbb{R}} DQ\ \exp - N\ \mathrm{STr}\left(\frac{Q^2}{2v^2} + \ln(Q-\omega)\right). \tag{13}$$

These steps reduce an integral over the $N\times N$ matrix H to an integral over the 2×2 supermatrix Q. The large parameter N now appears in the exponent of the integrand, so that the Q integral can be evaluated by a saddle-point approximation that becomes exact in the limit $N\to\infty$. By solving the saddle-point equation $-Q/v^2 = (Q-\omega)^{-1}$ and doing an elementary calculation, one obtains Wigner's semicircle law for the GUE density of states:[42]

$$\int \mathrm{Tr}\ \delta(E-H) d\mu(H) = \frac{N}{\pi v}\ \sqrt{1 - \left(\frac{E}{2v}\right)^2}, \tag{14}$$

which will be of use later.

B. Definition of the Gaussian ensemble of type *C*

Having run through a simple and well-known example, we now treat in detail a less trivial case where the reduction to a Q-integral representation requires more care.

The ''physical space'' of our model is $V=\mathbb{C}^2\otimes\mathbb{C}^N$. As before, let $x\mapsto\overline{x}$ denote complex conjugation, and fix a symmetric quadratic form $\langle\bullet,\bullet\rangle_V: V\times V\to\mathbb{C}$, such that the corresponding Hermitian quadratic form $\langle\overline{x},y\rangle_V = \overline{\langle\overline{y},x\rangle}_V$ is strictly positive. The transpose and the adjoint of a linear transformation $L\in\mathrm{End}(V)$ are defined by $\langle x,L^{\mathrm{T}}y\rangle_V=\langle Lx,y\rangle_V$ and $\langle\overline{x},L^{\dagger}y\rangle_V = \overline{\langle Lx,y\rangle}_V$, as usual.

Consider now the space, P, of self-adjoint Hamiltonians $H\in\mathrm{End}(V)$ subject to the linear condition

$$H=-\mathscr{C}H^{\mathrm{T}}\mathscr{C}^{-1}, \tag{15}$$

where $\mathscr{C}$ is skew and $\mathscr{C}^2=-1$. Clearly, iP is isomorphic to $\mathrm{sp}(N)=C_N$ (the symplectic Lie algebra in $2N$ dimensions). Introducing an orthonormal real basis of V we can represent H by a $2N\times 2N$ matrix. The explicit form of such a matrix is

$$H=\begin{pmatrix} a & b \\ b^{\dagger} & -a^{\mathrm{T}}\end{pmatrix}, \quad \text{if } \mathscr{C}=\begin{pmatrix} 0 & 1_N \\ -1_N & 0\end{pmatrix},$$

where $a(b)$ is a complex Hermitian (resp., symmetric) $N\times N$ matrix. The Gaussian ensemble to be studied is defined by the probability measure $d\mu(H)=\exp(-N\ \mathrm{Tr}\,H^2/2v^2)dH$, $\int d\mu(H)=1$. For any two $A,B\in\mathrm{End}(V)$,

$$\int_{i\times\mathrm{sp}(N)}\mathrm{Tr}(AH)\mathrm{Tr}(BH)d\mu(H)=\frac{v^2}{2N}\,\mathrm{Tr}(AB-A\mathscr{C}B^{\mathrm{T}}\mathscr{C}^{-1}). \tag{16}$$

The joint probability density for the eigenvalues of H has been given in Ref. 24.

The physical motivation for considering a Gaussian random-matrix ensemble of the above type (type C) comes from the fact[24] that it describes the ergodic limit of mesoscopic normal-superconducting hybrid systems with time-reversal symmetry broken by the presence of a weak magnetic field. To deal with such systems, the Bogoliubov–deGennes (BdG) independent-quasiparticle formalism is used. The first factor in the tensor product $V=\mathbb{C}^2\otimes\mathbb{C}^N$ accounts for the BdG particle-hole degree of freedom, which is introduced for the purpose of treating the pairing field of the superconductor within the formalism of first quantization. The second factor represents the orbital degrees of freedom of the electron. H is the Hamiltonian that enters into the BdG equations, and the relation (15) expresses the particle-hole symmetry of the BdG formalism.

Our goal is to compute the following ensemble average:

$$Z_n(\alpha_1,\ldots,\alpha_n;\beta_1,\ldots,\beta_n)=\int_{i\ \mathrm{sp}(N)}\prod_{i=1}^{n}\mathrm{Det}\left(\frac{H-\beta_i}{H-\alpha_i}\right)d\mu(H). \tag{17}$$

By the particle-hole symmetry of H, Z_n is invariant under a reversal of sign for any pair (α_i,β_j), so no information is lost by restricting all α_i to one-half of the complex plane. For definiteness, we require

$$\mathrm{Im}\ \alpha_i<0 \quad (i=1,\ldots,n). \tag{18}$$

All information about the statistical correlations between the eigenvalues of H can be extracted from Z_n. For example, the probability that, given there is an eigenvalue at E_1, there exist $n-1$ eigenvalues at $E_2,\ldots,E_n$ (regardless of the positions of all other eigenvalues) is equal to

$$R_n(E_1,\ldots,E_n)=\lim_{\epsilon\to 0}\left(\frac{-\epsilon}{\pi}\right)^n \prod_{l=1}^{n}\frac{\partial}{\partial\alpha_{2l}}\bigg|_{\alpha_{2l}=E_l-i\epsilon}\prod_{l=1}^{n}\frac{\partial}{\partial\alpha_{2l-1}}\bigg|_{\alpha_{2l-1}=-E_l-i\epsilon}$$
$$\times Z_{2n}(\alpha_1,\ldots,\alpha_{2n};E_1-i\epsilon,-E_1-i\epsilon,\ldots,E_n-i\epsilon,-E_n-i\epsilon). \tag{19}$$

The function $R_n(E_1,\ldots,E_n)$ is called the n-level correlation function in random-matrix theory.[42]

C. Symmetries of the auxiliary space

To transcribe the supersymmetry method of Sec. III A to the computation of Z_n (which involves n ratios of spectral determinants), a simple and natural procedure would be to enlarge the auxiliary space W by taking the tensor product with $\mathbb{C}^n$. However, on using the formula

$$\int \exp(i\ \mathrm{Tr}\ H\psi\widetilde{\psi})\,d\mu(H)=\exp\left(-\frac{1}{2}\int_{i\ \mathrm{sp}(N)}(\mathrm{Tr}\ H\psi\widetilde{\psi})^2\ d\mu(H)\right),$$

one faces the complication that the second moment $\int(\mathrm{Tr}\,H\psi\widetilde{\psi})^2\,d\mu(H)$ then is a sum of two terms, see the right-hand side of (16). Consequently, one needs *two* decoupling supermatrices Q (one for each term). Although this presents no difficulty of a principal nature, it does lead to rather complicated notations. An elegant remedy is to modify the definition of ψ and $\widetilde{\psi}$ so that $\psi\widetilde{\psi}$ shares the symmetry (15) of the BdG Hamiltonian H. The two terms then combine into a single one:

$$\int (\mathrm{Tr}\ H\psi\widetilde{\psi})^2\ d\mu(H)=\frac{v^2}{N}\,\mathrm{STr}_W(\widetilde{\psi}\psi)^2,$$

which can again be decoupled by a single supermatrix Q. To implement the symmetry (15), we proceed as follows.

We enlarge the auxiliary space $W=W_{\mathrm{B}}\oplus W_{\mathrm{F}}$ in some way (left unspecified for the moment) and fix a rule of supertransposition $\mathrm{Hom}_\lambda(W,V)\to\mathrm{Hom}_\lambda(V,W)$, $\psi\mapsto\psi^{\mathrm{T}}$, and $\mathrm{Hom}_\lambda(V,W)\to\mathrm{Hom}_\lambda(W,V)$, $\widetilde{\psi}\mapsto\widetilde{\psi}^{\,\mathrm{T}}$. Such a rule obeys $\psi^{\mathrm{T}\,\mathrm{T}}=\psi\sigma$ and $\widetilde{\psi}^{\,\mathrm{T}\,\mathrm{T}}=\sigma\widetilde{\psi}$, where $\sigma\in\mathrm{End}_0(W)$ is the operator for superparity, i.e. $\sigma(x+y)=x-y$ for $x+y\in W_{\mathrm{B}}\oplus W_{\mathrm{F}}=W$. It induces a rule of supertransposition $\mathrm{End}_\Lambda(W)\to\mathrm{End}_\Lambda(W)$, $Q\mapsto Q^{\mathrm{T}}$ (no separate symbol is introduced). Combination with complex conjugation gives a rule of Hermitian conjugation $\dagger:\mathrm{End}_0(W)\to\mathrm{End}_0(W)$. Now impose on $\psi\in\mathrm{Hom}_\lambda(W,V)$, $\widetilde{\psi}\in\mathrm{Hom}_\lambda(V,W)$ the linear conditions

$$\psi=\mathscr{C}\widetilde{\psi}^{\mathrm{T}}\gamma^{-1},\quad \widetilde{\psi}=-\gamma\psi^{\mathrm{T}}\mathscr{C}^{-1}, \tag{20}$$

with some invertible even element γ of $\mathrm{End}_0(W)$. The mutual consistency of these equations requires

$$\gamma=\gamma^{\mathrm{T}}\sigma. \tag{21}$$

To see that, insert the transpose of the second equation in (20) into the first one. Using $\psi^{\mathrm{TT}}=\psi\sigma$ you obtain $\psi=-\mathscr{C}\mathscr{C}^{-1^{\mathrm{T}}}\psi\sigma\gamma^{\mathrm{T}}\gamma^{-1}$. Since $\mathscr{C}\mathscr{C}^{-1^{\mathrm{T}}}=-1$ and $\sigma\gamma^{\mathrm{T}}=\gamma^{\mathrm{T}}\sigma$, Eq. (21) follows. The consistency condition can be implemented by taking $W_{\mathrm{B}}=W_{\mathrm{F}}=\mathbb{C}^2\otimes\mathbb{C}^n$, see below. By multiplying the equations (20) we obtain

$$\psi\widetilde{\psi}=-\mathscr{C}(\psi\widetilde{\psi})^{\mathrm{T}}\mathscr{C}^{-1},\quad \widetilde{\psi}\psi=-\gamma(\widetilde{\psi}\psi)^{\mathrm{T}}\gamma^{-1}. \tag{22}$$

The first equation is the desired symmetry relation allowing us to combine terms. To appreciate the consequences of the second equation, note that by the fourth step in (12) the symmetries of $\widetilde{\psi}\psi$ get transferred onto Q, so that the latter is subject to

$$Q = -\gamma Q^{\mathrm{T}} \gamma^{-1}. \tag{23}$$

This symmetry reflects that of the BdG Hamiltonian H, see (15). The linear space $\mathrm{End}_{\Lambda}(W)$, when given a Lie bracket by the commutator, can be identified with $\mathrm{gl}(2n|2n) = \mathrm{Lie}(\mathrm{Gl}(2n|2n))$. As γ is supersymmetric ($\gamma = \gamma^{\mathrm{T}}\sigma$), (23) fixes an $\mathrm{osp}(2n|2n)$ subalgebra.

γ is not unique. For definiteness we choose it as follows. Let $\{E_{ij}\}_{i,j=1,\ldots,M}$ be a canonical basis of $\mathrm{End}(\mathbb{C}^M)$ satisfying $E_{ij}E_{kl} = \delta_{jk}E_{il}$ (here $M=2$ or $M=n$). For $M=2$ define the Pauli spin operators $\sigma_x = E_{12} + E_{21}$, $\sigma_y = -iE_{12} + iE_{21}$, and $\sigma_z = E_{11} - E_{22}$. The usual rule of supertransposition on $\mathrm{End}_{\Lambda}(W)$ is given by ($\mu,\nu = 1,2$ and $i,j = 1,\ldots,n$)

$$\begin{aligned} &(E_{\mathrm{BB}} \otimes E_{\mu\nu} \otimes E_{ij})^{\mathrm{T}} = E_{\mathrm{BB}} \otimes E_{\nu\mu} \otimes E_{ji}, \quad (E_{\mathrm{BF}} \otimes E_{\mu\nu} \otimes E_{ij})^{\mathrm{T}} = -E_{\mathrm{FB}} \otimes E_{\nu\mu} \otimes E_{ji}, \\ &(E_{\mathrm{FB}} \otimes E_{\mu\nu} \otimes E_{ij})^{\mathrm{T}} = E_{\mathrm{BF}} \otimes E_{\nu\mu} \otimes E_{ji}, \quad (E_{\mathrm{FF}} \otimes E_{\mu\nu} \otimes E_{ij})^{\mathrm{T}} = E_{\mathrm{FF}} \otimes E_{\nu\mu} \otimes E_{ji}. \end{aligned}$$

With these conventions, one possible choice for γ is

$$\gamma = E_{\mathrm{BB}} \otimes \gamma_{\mathrm{B}} + E_{\mathrm{FF}} \otimes \gamma_{\mathrm{F}}, \quad \text{where} \quad \gamma_{\mathrm{B}} = \sigma_x \otimes 1_n, \quad \gamma_{\mathrm{F}} = i\sigma_y \otimes 1_n. \tag{24}$$

This is the choice we make.

D. Gaussian Berezin integral

To repeat the steps of Sec. III A and derive a Q-integral representation for the generating function Z_n, we must first generalize the basic identity (10), whose left-hand side is

$$\int D(\psi,\widetilde{\psi}) \exp(i\ \mathrm{Tr}_V\, A\psi\widetilde{\psi} - i\ \mathrm{STr}_W\, B\widetilde{\psi}\psi). \tag{25}$$

By (22) we have

$$\mathrm{Tr}\ A\psi\widetilde{\psi} = \mathrm{Tr}(\psi\widetilde{\psi})^{\mathrm{T}} A^{\mathrm{T}} = \tfrac{1}{2}\mathrm{Tr}(A - \mathscr{C}A^{\mathrm{T}}\mathscr{C}^{-1})\psi\widetilde{\psi},$$

$$\mathrm{STr}\ B\widetilde{\psi}\psi = \mathrm{STr}(\widetilde{\psi}\psi)^{\mathrm{T}} B^{\mathrm{T}} = \tfrac{1}{2}\mathrm{Tr}(B - \gamma B^{\mathrm{T}}\gamma^{-1})\widetilde{\psi}\psi.$$

In view of this we demand that A and B satisfy

$$A = -\mathscr{C}A^{\mathrm{T}}\mathscr{C}^{-1}, \quad B = -\gamma B^{\mathrm{T}}\gamma^{-1}. \tag{26}$$

When carrying out the calculation (11)–(13) we need to apply the identity (10) twice, the first time with $A = H$, $B = \omega$, and the second time with $A = 0$, $B = \omega - Q$. In order for (26) to be satisfied with these identifications, we choose to set

$$\omega = E_{\mathrm{BB}} \otimes \sigma_z \otimes \sum_{i=1}^{n} \alpha_i E_{ii} + E_{\mathrm{FF}} \otimes \sigma_z \otimes \sum_{j=1}^{n} \beta_j E_{jj}.$$

The presence of the factor $\sigma_z = \mathrm{diag}(+1,-1)$ reverses the sign of the α_i and β_j on that subspace where σ_z acts by multiplication with -1. As the imaginary parts of the α_i control the convergence of the integral, this sign reversal affects the correct choice of integration domain for ψ_{B} and $\widetilde{\psi}_{\mathrm{B}}$. To ensure convergence of the integral (25), we require $\mathrm{Im\,STr}\ \omega\widetilde{\psi}\psi \leqslant 0$. This inequality is achieved by imposing the condition $\widetilde{\psi}_{\mathrm{B}} = (\sigma_z \otimes 1_n)\psi_{\mathrm{B}}^{\dagger}$, which is compatible with $\mathscr{C} = i\sigma_y \otimes 1_N$, $\psi_{\mathrm{B}} = \mathscr{C}\widetilde{\psi}_{\mathrm{B}}^{\mathrm{T}}\gamma_{\mathrm{B}}^{-1}$, and $\gamma_{\mathrm{B}} = \sigma_x \otimes 1_n$.

Lemma 3.1: Let $D(\psi,\widetilde{\psi})$ denote a translation-invariant holomorphic Berezin measure on the subspace of $\mathrm{Hom}_\Lambda(W,V)\times\mathrm{Hom}_\Lambda(V,W)$ defined by (20). Fix the integration domain by $\widetilde{\psi}_{\mathrm{B}} = (\sigma_z \otimes 1_n)\psi_{\mathrm{B}}^\dagger$, and normalize $D(\psi,\widetilde{\psi})$ so that $\int D(\psi,\widetilde{\psi})\exp(-s^2\,\mathrm{Tr}\,\psi\widetilde{\psi})=1$ $(s\in\mathbb{R})$. Then if $A\in\mathrm{End}(V)$ and $B\in\mathrm{End}_\Lambda(W)$ are diagonalizable and satisfy the linear conditions (26), the identity (10) holds with $c=1/2$ provided that the integral exists.

Proof: Assume that A and B are represented by diagonal matrices,

$$A=\sigma_z\otimes\sum_{i=1}^{N} x_i E_{ii}\,,\quad B=E_{\mathrm{BB}}\otimes\sigma_z\otimes\sum_{j=1}^{n} z_j E_{jj}+E_{\mathrm{FF}}\otimes\sigma_z\otimes\sum_{j=1}^{n} y_j E_{jj}\,,$$

which conforms with (26). The right-hand side of (10) then reduces to

$$\mathrm{SDet}_{V\otimes W}(A\otimes 1-1\otimes B)^{-1/2}=\prod_{i=1}^{N}\prod_{j=1}^{n}\frac{(x_i-y_j)(x_i+y_j)}{(x_i-z_j)(x_i+z_j)}. \tag{27}$$

To evaluate the left-hand side, write

$$\psi_{\mathrm{B}}=\begin{pmatrix} a & b\\ c & d\end{pmatrix},\quad \psi_{\mathrm{F}}=\begin{pmatrix}\alpha & \beta\\ \gamma & \delta\end{pmatrix},$$

where $a,b,c,d(\alpha,\beta,\gamma,\delta)$ are complex $N\times n$ matrices with commuting (resp., anticommuting) matrix elements. The constraint $\widetilde{\psi}=-\gamma\psi^{\mathrm{T}}\mathscr{C}^{-1}$ results in

$$\widetilde{\psi}_{\mathrm{B}}=\begin{pmatrix}-d^{\mathrm{T}} & b^{\mathrm{T}}\\ -c^{\mathrm{T}} & a^{\mathrm{T}}\end{pmatrix},\quad \widetilde{\psi}_{\mathrm{F}}=\begin{pmatrix}-\delta^{\mathrm{T}} & \beta^{\mathrm{T}}\\ \gamma^{\mathrm{T}} & -\alpha^{\mathrm{T}}\end{pmatrix},$$

and the reality condition $\widetilde{\psi}_{\mathrm{B}} = (\sigma_z\otimes 1_n)\psi_{\mathrm{B}}^\dagger$ means $d=-\overline{a}$ and $c=\overline{b}$. The exponent of the integrand is expressed by

$$\frac{1}{2}\,\mathrm{Tr}\,A\psi\widetilde{\psi}-\frac{1}{2}\,\mathrm{Tr}\,B\widetilde{\psi}\psi=\sum_{i=1}^{N}\sum_{j=1}^{n}\big((x_i-z_j)a_{ij}\overline{a_{ij}}-(x_i+z_j)b_{ij}\overline{b_{ij}}$$
$$+(x_i+y_j)\alpha_{ij}\delta_{ij}-(x_i-y_j)\beta_{ij}\gamma_{ij}\big).$$

Doing the Gaussian integrals one gets a result that is identical to (27), which proves the Lemma for diagonal A and B. The general case follows by the invariance properties of $D(\psi,\widetilde{\psi})$.

Remark: The condition of diagonalizability can of course be weakened but we will not need that here. ∎

To apply Lemma 3.1 to our problem, note

$$\mathrm{SDet}_{V\otimes W}(H\otimes 1-1\otimes\omega)^{1/2}=\prod_{i=1}^{n}\mathrm{Det}_V\left(\frac{(H-\alpha_i)(H+\alpha_i)}{(H-\beta_i)(H+\beta_i)}\right)^{1/2}=\prod_{i=1}^{n}\mathrm{Det}\left(\frac{H-\alpha_i}{H-\beta_i}\right),$$

where in the second step we used the invariance of the ratio of determinants under $H\mapsto -H$, which is due to the particle-hole symmetry $H=-\mathscr{C}H^{\mathrm{T}}\mathscr{C}^{-1}$. Moreover, note

$$\mathrm{SDet}_{V\otimes W}(1\otimes(Q-\omega))^{-1/2}=\mathrm{SDet}_W(Q-\omega)^{-N}.$$

The previous calculation (11)–(13) thus *formally* goes through with $c=1/2$, and $i\mathrm{sp}(N)$ for $i\mathrm{u}(N)$, and we arrive at the following representation of the generating function:

$$Z_n(\omega)=\int DQ\ \exp -N\ \mathrm{STr}\left(\frac{Q^2}{2v^2}+\ln(Q-\omega)\right), \tag{28}$$

where the supermatrix

$$Q=\begin{pmatrix} Q_{\mathrm{BB}} & Q_{\mathrm{BF}} \\ Q_{\mathrm{FB}} & Q_{\mathrm{FF}} \end{pmatrix}$$

is subject to (23). To make this rigorous, we have to specify the integration domain for Q and show that the interchange of the $(\psi,\tilde{\psi})$- and Q-integrations is permitted.

E. Choice of integration domain

If the steps (11)–(13) are to be valid, we must arrange for all integrals to be convergent, at least. This is easily achieved for Q_{FF}, the FF component of Q, but requires substantial labor for ψ_{B}, $\tilde{\psi}_{\mathrm{B}}$, and Q_{BB}. Consider Q_{FF} first. Since $-\mathrm{STr}\,Q^2=-\mathrm{Tr}\,Q_{\mathrm{BB}}^2+\mathrm{Tr}\,Q_{\mathrm{FF}}^2+\text{nilpotents}$, we want $\mathrm{Tr}\,Q_{\mathrm{FF}}Q_{\mathrm{FF}}\leqslant 0$, which leads us to require that Q_{FF} be anti-Hermitian. Combining this with (23) we get

$$Q_{\mathrm{FF}}=-\gamma_{\mathrm{F}}Q_{\mathrm{FF}}^{\mathrm{T}}\gamma_{\mathrm{F}}^{-1}=-Q_{\mathrm{FF}}^{\dagger},$$

where $\gamma_{\mathrm{F}}=i\sigma_y\otimes 1_n$; see (24). The solution space of these equations is $\mathrm{sp}(n)$, the symplectic Lie algebra in $2n$ dimensions. Thus we choose $\mathscr{U}:=\mathrm{sp}(n)$ for the integration domain of Q_{FF}, and, of course, the integration measure is taken to be the flat one.

The choice of integration domain for Q_{BB} is a much more delicate matter and will occupy us for the remainder of this section. Recall, first of all, that the convergence of

$$\int D(\psi,\tilde{\psi})\exp(i\ \mathrm{Tr}\ H\psi\tilde{\psi}-i\ \mathrm{STr}\ \omega\tilde{\psi}\psi)$$

requires taking $\tilde{\psi}_{\mathrm{B}}=\beta\psi_{\mathrm{B}}^{\dagger}$, where $\beta:=\sigma_z\otimes 1_n$ cancels the minus signs that multiply the imaginary parts of the parameters α_i in ω. To ensure the convergence of

$$\int D(\psi,\tilde{\psi})\exp\ i\ \mathrm{Tr}\ \psi(Q-\omega)\tilde{\psi},$$

one is tempted to choose Q_{BB} in such a way that $\mathrm{Re}\,\mathrm{Tr}\,\psi Q\tilde{\psi}=0$. Unfortunately, when this condition is adopted one gets $Q_{\mathrm{BB}}=\beta Q_{\mathrm{BB}}^{\dagger}\beta$, which causes $\mathrm{Tr}\,Q_{\mathrm{BB}}^2=\mathrm{Tr}\,Q_{\mathrm{BB}}\beta Q_{\mathrm{BB}}^{\dagger}\beta$, to be of *indefinite sign*, so that the integral over Q does not exist.

A way out of this difficulty was first described by Schäfer and Wegner[2] in a related context. We are now going to formulate their prescription in a language that anticipates the geometric structure emerging in the large-N limit. To simplify the notation, we put $Q_{\mathrm{BB}}=iZ$. What we need to do is investigate the expression

$$\exp(-N\ \mathrm{Tr}\ Q_{\mathrm{BB}}^2/2v^2+i\ \mathrm{Tr}\ Q_{\mathrm{BB}}\tilde{\psi}_{\mathrm{B}}\psi_{\mathrm{B}})=\exp(N\ \mathrm{Tr}\ Z^2/2v^2-\mathrm{Tr}\ Z\tilde{\psi}_{\mathrm{B}}\psi_{\mathrm{B}}). \tag{29}$$

The conditions on Q_{BB} translate into

$$Z=-\gamma_{\mathrm{B}}Z^{\mathrm{T}}\gamma_{\mathrm{B}}^{-1}=-\beta Z^{\dagger}\beta^{-1}.$$

Because $\gamma_{\mathrm{B}}=\sigma_x\otimes 1_n$ is symmetric, the solution space of the first equation is a complex Lie algebra $\mathscr{G}_{\mathbb{C}}\simeq\mathrm{so}(2n,\mathbb{C})$. The matrix representation of an element $Z\in\mathscr{G}_{\mathbb{C}}$ is of the form

$$\begin{pmatrix} A & B \\ C & -A^{\mathrm{T}} \end{pmatrix},$$

where B and C are skew. The second equation ($Z=-\beta Z^{\dagger}\beta^{-1}$) means $A=-A^{\dagger}$ and $C=B^{\dagger}$, which fixes a real form $\mathcal{G}=\mathrm{so}^*(2n)$ of $\mathcal{G}_{\mathbb{C}}=\mathrm{so}(2n,\mathbb{C})$. This real form is *noncompact* [i.e., $\mathcal{G}=\mathrm{Lie}(G)$ with G a noncompact Lie group], which is what causes all the trouble and is forcing us to work hard. Its maximal compact subalgebra $\mathcal{K}$ is the set of solutions of $X=\beta X\beta^{-1}$ in $\mathcal{G}$. From

$$X=\begin{pmatrix} A & 0 \\ 0 & -A^{\mathrm{T}} \end{pmatrix}$$

and $A=-A^{\dagger}$ we see that $\mathcal{K}\simeq u(n)$.

To display clearly the general nature of the following construction, we introduce a symmetric quadratic form $\mathrm{B}:\mathcal{G}_{\mathbb{C}}\times\mathcal{G}_{\mathbb{C}}\to\mathbb{C}$ by $\mathrm{B}(X,Y)=\mathrm{Tr}\,XY$. The Cartan (orthogonal) decomposition of $\mathcal{G}$ with respect to this quadratic form is written as $\mathcal{G}=\mathcal{K}\oplus\mathcal{M}$. An element Y of $\mathcal{M}$ satisfies $Y=-\beta Y\beta^{-1}$. From this, in conjunction with the equation fixing $\mathcal{K}$ ($X=+\beta X\beta^{-1}$), one deduces the commutation relations

$$[\mathcal{M},\mathcal{M}]\subset\mathcal{K},\quad [\mathcal{K},\mathcal{M}]\subset\mathcal{M},\quad [\mathcal{K},\mathcal{K}]\subset\mathcal{K}. \tag{30}$$

Note that the elements of $\mathcal{M}$ are Hermitian while those of $\mathcal{K}$ are anti-Hermitian. We will also encounter the complexified spaces $\mathcal{K}_{\mathbb{C}}=\mathcal{K}+i\mathcal{K}$ and $\mathcal{M}_{\mathbb{C}}=\mathcal{M}+i\mathcal{M}$. They, too, are orthogonal with respect to B and satisfy the commutation relations (30). The element $\beta=\sigma_z\otimes 1_n$ satisfies $\beta=-\gamma_{\mathrm{B}}\beta^{\mathrm{T}}\gamma_{\mathrm{B}}^{-1}$ and can therefore be regarded as an element of $\mathcal{G}_{\mathbb{C}}$. Moreover, $\beta\in i\mathcal{K}\subset\mathcal{G}_{\mathbb{C}}$.

Now we embed $\mathcal{G}=\mathcal{K}\oplus\mathcal{M}$ into $\mathcal{G}_{\mathbb{C}}$ by a map ϕ_b,

$$\phi_b:\mathcal{K}\times\mathcal{M}\to\mathcal{G}_{\mathbb{C}},$$

$$(X,Y)\mapsto\phi_b(X,Y)=b\times(X+e^{Y}\beta e^{-Y}),$$

where $b\neq 0$ is some constant that will be specified later.

Lemma 3.2: $\phi_b(\mathcal{K}\times\mathcal{M})$ is an analytic manifold without boundary, and is diffeomorphic to $\mathcal{G}$.

Proof: Analyticity is clear. To prove the other properties, we first establish that ϕ_b is injective. For that purpose, we write $e^{Y}\beta e^{-Y}=e^{\mathrm{ad}(Y)}\beta$, where $\mathrm{ad}(Y)\beta=[Y,\beta]$ is the adjoint action on $\mathcal{G}_{\mathbb{C}}$. Decomposing the exponential function according to $\exp=\cosh+\sinh$, we write $\phi_b=\phi_+ +\phi_-$, where

$$\phi_+(X,Y)=b\times(X+\cosh\,\mathrm{ad}(Y)\beta),$$

$$\phi_-(X,Y)=b\times\sinh\,\mathrm{ad}(Y)\beta.$$

From the commutation relations (30) and $\beta\in i\mathcal{K}$, we see that $\phi_{\pm}$ takes values $\phi_+(X,Y)\in\mathcal{K}_{\mathbb{C}}$ and $\phi_-(X,Y)\in\mathcal{M}_{\mathbb{C}}$. Since $\mathcal{G}_{\mathbb{C}}=\mathcal{K}_{\mathbb{C}}\oplus\mathcal{M}_{\mathbb{C}}$ (direct sum), injectivity is equivalent to the regularity of the maps $X\mapsto\phi_+(X,Y)$ (with Y viewed as a parameter) and $Y\mapsto\phi_-(X,Y)$. The function $\phi_+(X,\cdot)=X+\mathrm{const}$ is obviously regular. By $Y=Y^{\dagger}$ the element Y is diagonalizable with real eigenvalues. The regularity of ϕ_- then follows from $\sinh:\mathbb{R}\to\mathbb{R}$ being monotonic and $Y\mapsto\mathrm{ad}(Y)\beta$ being regular. This completes the proof that ϕ_b is injective. The injectivity of ϕ_b means that $\phi_b(\mathcal{K}\times\mathcal{M})$ is diffeomorphic to $\mathcal{G}=\mathcal{K}\oplus\mathcal{M}$. This in turn means that, since $\mathcal{G}$ has no boundary, $\phi_b(\mathcal{K}\times\mathcal{M})$ has no boundary either. ■

We are now going to demonstrate that $\phi_b(\mathscr{K}\times\mathscr{M})$ for any $b>0$ may serve as a mathematically satisfactory domain of integration for the variable Z in (29). We begin by investigating the quadratic form $\mathrm{Tr}\, Z^2=\mathrm{B}(Z,Z)$ on $\phi_b(\mathscr{K}\times\mathscr{M})$. For this we set $Z=Z_+ + Z_-$ with $Z_\pm=\phi_\pm(X,Y)$. Using $\mathrm{B}(Z_+,Z_-)=0$ (recall $\mathscr{K}_\mathbb{C}\perp\mathscr{M}_\mathbb{C}$), $\mathrm{B}(\mathrm{ad}(Y)A,B)=-\mathrm{B}(A,\mathrm{ad}(Y)B)$ and $\cosh^2-\sinh^2=1$, we obtain

$$\mathrm{B}(Z,Z)/b^2=\mathrm{B}(X,X)+2\mathrm{B}(X,\cosh\,\mathrm{ad}(Y)\beta)+\mathrm{B}(\beta,\beta).$$

The antihermiticity of $X\in\mathscr{K}$ gives $\mathrm{B}(X,X)\leqslant 0$. In contrast, $\cosh\,\mathrm{ad}(Y)\beta\in i\mathscr{K}$ is Hermitian, so $\mathrm{B}(X,\cosh\,\mathrm{ad}(Y)\beta)\in i\mathbb{R}$. It follows that $\exp(N\,\mathrm{Tr}\,Z^2/2v^2)=\exp(N\,\mathrm{Tr}\,\phi_b(X,Y)^2/2v^2)$ is decaying with respect to X and oscillatory with respect to Y.

We have not yet made any use of $b>0$ yet. This inequality comes into play when the coupling term

$$-\mathrm{Tr}\, Z\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B}=-\mathrm{B}(Z,\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})=-b\mathrm{B}(X,\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})-b\mathrm{B}(e^Y\beta e^{-Y},\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})$$

is considered. From (22) and $\widetilde{\psi}_\mathrm{B}=\beta\psi_\mathrm{B}^\dagger$ we see that $\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B}$ satisfies

$$\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B}=-\gamma_\mathrm{B}(\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})^\mathrm{T}\gamma_\mathrm{B}^{-1}=+\beta(\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})^\dagger\beta^{-1},$$

so $\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B}\in i\mathscr{G}$. Since B is real valued on $\mathscr{G}\times\mathscr{G}$, the term $\mathrm{B}(X,\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})$ is purely imaginary. The other term,

$$-b\mathrm{B}(e^Y\beta e^{-Y},\widetilde{\psi}_\mathrm{B}\psi_\mathrm{B})=-b\ \mathrm{Tr}(\psi_\mathrm{B}e^{2Y}\psi_\mathrm{B}^\dagger)\leqslant 0,$$

is never positive if $b>0$. Hence the real part of the exponential in (29) is negative semidefinite for $Q=iZ\in i\,\phi_b(\mathscr{K}\times\mathscr{M})$ and $b>0$. As a result, the integrals over Q and $\psi,\widetilde{\psi}$ converge if the integration domain for Q is taken to be $i\,\phi_b(\mathscr{K}\times\mathscr{M})\times\mathscr{U}$ $(b>0)$. Because $i\,\phi_b(\mathscr{K}\times\mathscr{M})\times\mathscr{U}$ is an analytic manifold without boundary and Cauchy's theorem applies, we may perform the shift of integration variables that is implied by the fourth equality sign in (12). Moreover, the presence of the nonvanishing imaginary parts of the parameters α_i in ω ensures *uniform convergence* of the $(\psi,\widetilde{\psi})$ integral with respect to Q, so that we may interchange the order of integration [the second equality sign in (13)]. And finally, any breakdown of diagonalizability of $Q-\omega$ occurs on a set of measure zero, so that the identity (10) (Lemma 3.1) may be used, and all steps leading to (28) are rigorous. In summary, we have proved the following result.

Theorem 3.3: For $V=\mathbb{C}^2\otimes\mathbb{C}^N$ and $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^n$ define the generating function

$$Z_{n,N}(\omega)=\int_{i\times\mathrm{sp}(N)}\mathrm{SDet}_{V\otimes W}(H\otimes 1-1\otimes\omega)^{-1/2}\exp\left(-\frac{N\ \mathrm{Tr}\ H^2}{2v^2}\right)dH,$$

$$\omega=E_\mathrm{BB}\otimes\sigma_z\otimes\sum_{i=1}^n\alpha_iE_{ii}+E_\mathrm{FF}\otimes\sigma_z\otimes\sum_{j=1}^n\beta_jE_{jj}\quad(\mathrm{Im}\ \alpha_i<0).$$

Let DQ denote a translation-invariant holomorphic Berezin measure of the complex-analytic superspace $\mathrm{osp}(2n|2n)$. Then for all $N\in\mathbb{N}$, $n\in\mathbb{N}$ and $b>0$, DQ can be normalized so that

$$Z_{n,N}(\omega)=\int_{i\,\phi_b(\mathscr{K}\times\mathscr{M})\times\mathscr{U}}DQ\ \exp-N\ \mathrm{STr}\left(\frac{Q^2}{2v^2}+\ln(Q-\omega)\right),\tag{31}$$

where $\mathscr{U}=\mathrm{sp}(n)$, $\mathscr{K}\simeq u(n)$, $\mathscr{M}$ is determined by $\mathscr{K}\oplus\mathscr{M}=\mathrm{so}^*(2n)$, and $\phi_b(X,Y)=b(X+\mathrm{Ad}(e^Y)(\sigma_z\otimes 1_n))$. ■

We conclude this section with a comment. In the literature a parametrization of the form $Q=TPT^{-1}$ (cf. Ref. 43) has been very popular. In our language, this factorization amounts to choosing for the integration domain of Q_{BB} the image of $\varphi:\mathscr{G}=\mathscr{K}\oplus\mathscr{M}\to\mathscr{G}$, $X+Y\mapsto e^{Y}Xe^{-Y}$. This is *not* a valid choice as $\varphi(\mathscr{G})$ *does have a boundary*, namely the light cone $\{Z|\mathrm{B}(Z,Z)=0\}$ in $\mathscr{G}$, so that shifting of integration variables is not permitted. (However, it turns out that the error made becomes negligible in the limit $N\to\infty$, so that the final results remain valid if that limit is assumed.)

F. Saddle-point supermanifold

The result (31) holds for all $N\in\mathbb{N}$. We are now going to use the method of steepest descent to show that in the limit $N\to\infty$, the integral on the right-hand side reduces to an integral over a Riemannian symmetric superspace of type $D\mathrm{III}|C\mathrm{I}$.

With our choice of normalization, the mean spacing between the eigenvalues of H scales as N^{-1} for $N\to\infty$; see (14). We are most interested in the eigenvalues close to zero, as their statistical properties describe those of the low-lying Bogoliubov independent-quasiparticle energy levels of mesoscopic normal-superconducting systems.[24] To probe their statistical behavior, what we need to do is keep $\hat{\omega}=N\omega/\pi v$ (i.e., ω scaled by the mean level spacing) fixed as N goes to infinity. In this limit $\omega\sim\mathscr{O}(1/N)$ can be treated as a small perturbation and we may expand $N\ \mathrm{STr}\ln(Q-\omega)=N\ \mathrm{STr}\ln Q-\pi v\ \mathrm{STr}\,Q^{-1}\hat{\omega}+\mathscr{O}(1/N)$ if Q^{-1} exists.

To evaluate the integral (31) by the method of steepest descent, we first look for the critical points of the function $NF(Q)=N\ \mathrm{STr}(Q^2/2v^2+\ln Q)$. These are the solutions of

$$F'(Q)=Q/v^2+Q^{-1}=0,$$

or $Q^2=-v^2$. The solution spaces, the so-called ''saddle-point supermanifolds,'' are nonlinear subspaces of $\mathrm{osp}(2n|2n)$, which can be distinguished by the eigenvalues of Q. Of these supermanifolds, which are the ones to select for the steepest-descent evaluation of the integral (31)?

To tackle this question, we start out by setting all Grassmann variables to zero. The BB part of the saddle-point manifold(s) is uniquely determined by the forced choice of integration domain $i\phi_b(\mathscr{K}\times\mathscr{M})$ and by analyticity. This is because the saddle-point manifold must be deformable (using Cauchy's theorem) into the integration domain without crossing any of the singularities of $\mathrm{SDet}(Q-\omega)^{-N}$; and by inspection one finds that this condition rules out all saddle-point manifolds except for one, which is $i\phi_v(0\times\mathscr{M})$, the subspace of the integration domain $i\phi_b(\mathscr{K}\times\mathscr{M})|_{b=v}$ obtained by dropping from $\mathscr{G}=\mathscr{K}\oplus\mathscr{M}$ the $\mathscr{K}$ degrees of freedom (these are the directions of steepest descent). By an argument given in the proof of Lemma 3.2 we know that $i\phi_v(0\times\mathscr{M})$ is diffeomorphic to $\mathscr{M}$. On general grounds the latter is diffeomorphic to a coset space G/K by the exponential map $\mathscr{M}\to G/K$, $Y\mapsto e^{Y}K$; where in the present case $G=\{g\in\mathrm{Gl}(2n,\mathbb{C})|g=\gamma_{\mathrm{B}}g^{-1^{\mathrm{T}}}\gamma_{\mathrm{B}}^{-1}=\beta g^{-1^{\dagger}}\beta^{-1}\}$, and $K=\{k\in G|k=\beta k\beta^{-1}\}$ (on setting $g=\exp Z$, $k=\exp X$ and linearizing, we recover the conditions $Z=-\gamma_{\mathrm{B}}Z^{\mathrm{T}}\gamma_{\mathrm{B}}^{-1}=-\beta Z^{\dagger}\beta^{-1}$ defining $\mathscr{G}$ and the condition $X=\beta X\beta^{-1}$ fixing the subalgebra $\mathscr{K}$). We already know $\mathscr{G}=\mathrm{so}^*(2n)$ and $\mathscr{K}\simeq\mathrm{u}(n)$, so $G=\exp\mathscr{G}=\mathrm{SO}^*(2n)$ and $K=\exp\mathscr{K}=\mathrm{U}(n)$. Because K is a maximal compact subgroup, the coset space G/K is a Riemannian symmetric space of the noncompact type. In Cartan's notation, $G/K=\mathrm{SO}^*(2n)/U(n)$ is called type $D\mathrm{III}$. For better distinction from its FF analog, we will henceforth denote G/K by G/K_{B}.

We turn to the FF sector. Since $\mathrm{SDet}(Q-\omega)^{-N}$ does not have poles but only has *zeros* as a function of Q_{FF}, analyticity provides *no* criterion for selecting any specific solution space of the saddle-point equation $Q_{\mathrm{FF}}^2=-v^2$. Instead, the determining agent now is the limit $N\to\infty$. From (31) it is seen that integration over the Gaussian fluctuations around the saddle-point manifold produces one factor of $N^{-1}(N^{+1})$ for every commuting (resp., anticommuting) direction of steepest descent. Therefore, the limit $N\to\infty$ is dominated by the saddle-point manifold that has the minimal transverse (super-)dimension $d_{\mathrm{B}}^{\perp}-d_{\mathrm{F}}^{\perp}$. A little thought shows that the transverse dimen-

sion is minimized by choosing Q_{FF} to possess n eigenvalues $+iv$ and n eigenvalues $-iv$. Thus, the dominant saddle-point manifold is unique and contains the special point $q_0 := iv\beta$ ($\beta = \sigma_z \otimes 1_n$ now acts in the fermionic subspace).

Recall that the integration domain for Q_{FF} is a compact Lie algebra $\mathscr{U} = \mathrm{sp}(n)$. The corresponding Lie group $U = \mathrm{Sp}(n)$ operates on $\mathscr{U}$ by the adjoint action $\mathrm{Ad}(u): \mathscr{U} \to \mathscr{U}$, $X \mapsto uXu^{-1}$. Because the saddle-point equation $Q_{\mathrm{FF}} = -v^2 Q_{\mathrm{FF}}^{-1}$ is invariant under this action, the FF part of the (dominant) saddle-point manifold can be viewed as the orbit of the action of $\mathrm{Ad}(U)$ on the special point $q_0 \in \mathscr{U}$. Let K_{F} be the stability group of q_0, i.e., $K_{\mathrm{F}} = \{k \in U | kq_0k^{-1} = q_0\}$. By $\mathrm{Ad}(K_{\mathrm{F}})q_0 = q_0$ the orbit $\mathrm{Ad}(U)q_0$ is diffeomorphic to the coset space U/K_{F}. Arguing in the same way as for the BB sector, one shows that $K_{\mathrm{F}} \simeq K_{\mathrm{B}} \simeq \mathrm{U}(n)$. Hence $U/K_{\mathrm{F}} = \mathrm{Sp}(n)/U(n)$, which in Cartan's notation is a compact Riemannian symmetric space of type CI.

We are finally in a position to construct the full saddle-point *super*manifold. Recall, first of all, that Q is subject to the condition $Q = -\gamma Q^{\mathrm{T}} \gamma^{-1}$, which defines an orthosymplectic complex Lie algebra $\mathscr{G}_\Lambda := \mathrm{osp}(2n|2n)$ in $\mathrm{End}_\Lambda(W)$. The solution spaces in $\mathscr{G}_\Lambda$ of the equation $Q/v^2 + Q^{-1} = 0$ are complex-analytic supermanifolds that are invariant under the adjoint action of the complex Lie supergroup $G_\Lambda := \mathrm{Osp}(2n|2n)$. They can be regarded as $\mathrm{Ad}(G_\Lambda)$ orbits of elements $Q_0 \in \mathrm{Lie}(G_\Lambda)$ that are solutions of $(Q_0)^2 = -v^2$. From the above analysis of the BB and FF sectors, we know that the saddle-point supermanifold that dominates in the large-N limit is obtained by setting $Q_0 = iv\Sigma_z$ where $\Sigma_z = 1_{\mathrm{B|F}} \otimes \beta = (E_{\mathrm{BB}} + E_{\mathrm{FF}}) \otimes \sigma_z \otimes 1_n$. If H_Λ is the stability group of Q_0, the orbit $\mathrm{Ad}(G_\Lambda)Q_0$ is diffeomorphic to the coset space G_Λ/H_Λ. From $\gamma\Sigma_z + \Sigma_z\gamma = 0$ and the equation $h\Sigma_z h^{-1} = \Sigma_z$ (or, equivalently, $h = \Sigma_z h \Sigma_z$) for $h \in H_\Lambda$ one infers $H_\Lambda \simeq \mathrm{Gl}(n|n)$. Hence the unique complex-analytic saddle-point supermanifold that dominates the large-N limit is $G_\Lambda/H_\Lambda \simeq \mathrm{Osp}(2n|2n)/\mathrm{Gl}(n|n)$.

Turning to the integral (31) we note the relations $\mathrm{STr}\, Q_0^2 = -v^2\, \mathrm{STr}\, 1 = 0$ and $\ln \mathrm{SDet} Q_0 = \ln 1 = 0$. These imply that the function $F(Q) = \mathrm{STr}(Q^2/2v^2 + \ln Q)$ vanishes identically on $\mathrm{Ad}(G_\Lambda)Q_0$. Hence the exponent of the integrand in (31) restricted to G_Λ/H_Λ is

$$\pi v\ \mathrm{STr}\ Q^{-1}\hat{\omega}\big|_{G_\Lambda/H_\Lambda} + \mathscr{O}(1/N) = -i\pi \mathrm{B}(\hat{\omega}, \mathrm{Ad}(g)\Sigma_z) + \mathscr{O}(1/N).$$

To complete the steepest-descent evaluation of (31) we need to Taylor expand the exponent of the integrand up to second order and do a Gaussian integral. By the $\mathrm{Ad}(G_\Lambda)$ invariance of the function $NF(Q)$ it is sufficient to do this calculation for one element of the saddle-point supermanifold, say $Q = Q_0$. Putting $Q = Q_0 + Z$ ($Z \in \mathscr{G}_\Lambda$) we get

$$NF(Q_0 + Z) = \frac{N}{2v^2}\, \mathrm{STr}(Z^2 + Z\Sigma_z Z \Sigma_z) + \mathscr{O}(Z^3).$$

Now we make the orthogonal decomposition $\mathscr{G}_\Lambda = \mathrm{Lie}(H_\Lambda) + \mathscr{M}_\Lambda$, $Z = X + Y$, where $Y = -\Sigma_z Y \Sigma_z$ are the degrees of freedom tangent to the saddle-point supermanifold, and $X = +\Sigma_z X \Sigma_z$ are the degrees of freedom transverse to it. The translation-invariant Berezin measure DZ of $\mathscr{G}_\Lambda$ factors as $DZ = DY\ DX$. We thus obtain the transverse Gaussian integral

$$\int DX\ \exp\left(-\frac{N}{v^2}\, \mathrm{STr}\, X^2 + \mathscr{O}(N^0) \right).$$

The integration domain for X is $i\mathscr{K}_{\mathrm{B}} \times \mathscr{K}_{\mathrm{F}} \simeq i\mathrm{u}(n) \times \mathrm{u}(n)$. By $\dim \mathrm{Lie}(H_\Lambda) = (p,q)$ and $p = q$, this integral reduces to a constant independent of N in the limit $N \to \infty$.

What remains is an integral over the saddle-point supermanifold itself. Since DY is the local expression of the invariant Berezin measure of G_Λ/H_Λ at $\mathrm{Ad}(e^Y)Q_0|_{Y=0} = Q_0$ we arrive at the following result.

Theorem 3.4: If Dg_H is a suitably normalized invariant holomorphic Berezin measure of the complex-analytic supermanifold $G_\Lambda/H_\Lambda \simeq \mathrm{Osp}(2n|2n)/\mathrm{Gl}(n|n)$,

$$\lim_{N\to\infty} Z_{n,N}\left(\frac{\pi v\,\hat{\omega}}{N}\right) = \int_{M_{\mathrm{B}}\times M_{\mathrm{F}}} Dg_H \,\exp -i\pi \mathrm{B}(\hat{\omega},\mathrm{Ad}(g)\Sigma_z), \tag{32}$$

where $\Sigma_z = 1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_n$, $M_{\mathrm{B}}\simeq \mathrm{SO}^*(2n)/\mathrm{U}(n)$, and $M_{\mathrm{F}}\simeq \mathrm{Sp}(n)/\mathrm{U}(n)$.

Remark 3.5: This result expresses the generating function for $N\to\infty$ as an integral over a Riemannian symmetric superspace of type $D\mathrm{III}|C\mathrm{I}$ (see Tables I and II) with $m=n$.

In Ref. 44 the n-level correlation function R_n is calculated exactly from (32) for all n.

IV. OTHER SYMMETRY CLASSES

There exist ten known universality classes of ergodic disordered single-particle systems. These are the three classic Wigner-Dyson classes (GOE, GUE, GSE), the three ''chiral'' ones describing a Dirac particle in a random gauge field (chGUE, chGOE, chGSE), and the four classes that can be realized in mesoscopic normal-superconducting (NS) hybrid systems. In Ref. 25 it was noted that there exists a one-to-one correspondence between these universality classes and the large families of symmetric spaces (with the exception of the orthogonal group in odd dimensions). Specifically, the Gaussian random-matrix ensemble over the tangent space of the symmetric space describes the corresponding universality class, in the limit $N\to\infty$. In the notation of Table I the correspondences are $A\leftrightarrow$GUE, $A\mathrm{I}\leftrightarrow$GOE, $A\mathrm{II}\leftrightarrow$GSE, $A\mathrm{III}\leftrightarrow$chGUE, $BD\mathrm{I}\leftrightarrow$chGOE, $C\mathrm{II}\leftrightarrow$chGSE, and the four NS classes correspond to C, D, $C\mathrm{I}$, and $D\mathrm{III}$.

We have shown in detail how to use the supersymmetry method for the Gaussian ensemble over $C_N=\mathrm{sp}(N)$, the tangent space of the symplectic Lie group. There are nine more ensembles to study. We will now briefly run through all these cases, giving only a summary of the essential changes.

A. Class *D*

Recall the definitions given at the beginning of Sec. III B and replace the symplectic unit by $\mathscr{C}=\sigma_x\otimes 1_N$. What you get is a Gaussian random-matrix ensemble over $D_N=\mathrm{so}(2N)$, the orthogonal Lie algebra in $2N$ dimensions. The explicit form of the Hamiltonian is

$$H=\begin{pmatrix} a & b \\ b^\dagger & -a^{\mathrm{T}} \end{pmatrix},$$

where $a(b)$ is complex Hermitian (resp., skew). The treatment of this ensemble closely parallels that of type C. A change first occurs in the consistency condition for γ, which now reads as $\gamma=-\gamma^{\mathrm{T}}\sigma$ (instead of $\gamma=+\gamma^{\mathrm{T}}\sigma$) by $\mathscr{C}\mathscr{C}^{-1^{\mathrm{T}}}=+1$. The extra minus sign can be accommodated by simply exchanging the BB and FF sectors ($\gamma_{\mathrm{B}}\leftrightarrow\gamma_{\mathrm{F}}$). The linear constraint $Q=-\gamma Q^{\mathrm{T}}\gamma^{-1}$ again defines an $\mathrm{osp}(2n|2n)$ Lie algebra, the only difference being that the BB sector is now ''symplectic'' while the FF sector has turned ''orthogonal.'' Everything else goes through as before and we arrive at the statement of Theorem 3.3 with $\mathscr{U}\simeq\mathrm{so}(2n)$, $\mathscr{K}\simeq\mathrm{u}(n)$, and $\mathscr{K}\oplus\mathscr{M}\simeq\mathrm{sp}(n,\mathbb{R})$.

A novel feature arises in the large-N limit, where instead of one dominant saddle-point supermanifold there now emerge *two*. One of them is the orbit with respect to the adjoint action of $\mathrm{Osp}(2n|2n)$ on $Q_0=iv1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_n$ as before, and the other one is the orbit of

$$Q_1 = ivE_{\mathrm{BB}}\otimes\sigma_z\otimes 1_n + ivE_{\mathrm{FF}}\otimes\sigma_z\otimes\left(E_{11}-\sum_{i=2}^{n}E_{ii}\right).$$

[The orbits of Q_0 and Q_1 are disconnected because the Weyl group of $\mathrm{so}(2n)$ is ''too small.''] Consequently, the right-hand side of Theorem 3.4 is replaced by a sum of two terms, one for each of the two saddle-point supermanifolds. The integral is over a Riemannian symmetric superspace of type $C\mathrm{I}|D\mathrm{III}$ ($m=n$) in both cases.

B. Class *CI*

Let $V=\mathbb{C}^2\otimes\mathbb{C}^N$ carry a Hermitian inner product (as always), and consider the space, P, of self-adjoint Hamiltonians $H\in\mathrm{End}(V)$ of the form

$$H=H^{\mathrm{T}}=-\mathscr{C}H^{\mathrm{T}}\mathscr{C}^{-1}=\begin{pmatrix} a & b \\ b & -a \end{pmatrix}, \quad \text{where } \mathscr{C}=i\sigma_y\otimes 1_N=\begin{pmatrix} 0 & 1_N \\ -1_N & 0 \end{pmatrix}.$$

The $N\times N$ matrices a and b are real symmetric. It is easy to see[25] that P is isomorphic to the tangent space of the symmetric space $\mathrm{Sp}(N)/\mathrm{U}(N)$ (type CI). A Gaussian measure $d\mu(H)$ on P is completely specified by its first two moments, $\int_P \mathrm{Tr}(AH)d\mu(H)=0$ and

$$\int_P \mathrm{Tr}(AH)\mathrm{Tr}(BH)d\mu(H)=\frac{v^2}{4N}\,\mathrm{Tr}(A(B+B^{\mathrm{T}})-A\mathscr{C}(B+B^{\mathrm{T}})\mathscr{C}^{-1}).$$

To deal with the random-matrix ensemble defined by this measure, we take $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^n$. Recall $\psi\in\mathrm{Hom}_\Lambda(W,V)$ and $\widetilde{\psi}\in\mathrm{Hom}_{\tilde{\Lambda}}(V,W)$. The symmetries of H are copied to $\psi\widetilde{\psi}$ by imposing the linear conditions

$$\psi=\mathscr{C}\widetilde{\psi}^{\mathrm{T}}\gamma^{-1}, \quad \widetilde{\psi}=-\gamma\psi^{\mathrm{T}}\mathscr{C}^{-1}; \quad \psi=\widetilde{\psi}^{\mathrm{T}}\tau^{-1}, \quad \widetilde{\psi}=\tau\psi^{\mathrm{T}}.$$

In order for these conditions to be mutually consistent, $\tau,\ \gamma\in\mathrm{End}_0(W)$ must satisfy

$$\gamma=\gamma^{\mathrm{T}}\sigma, \quad \tau=\tau^{\mathrm{T}}\sigma, \quad \gamma\tau^{-1}=-\tau\gamma^{-1}.$$

Without loss, we take γ and τ to be orthogonal. The consistency conditions can then be written in the form

$$\gamma^2=\sigma=\tau^2, \quad \gamma\tau+\tau\gamma=0.$$

If $\mathrm{Gl}(W)\simeq\mathrm{Gl}(4n|4n)$ is the Lie supergroup of regular elements in $\mathrm{End}_\Lambda(W)$, the equation $\gamma^2=\sigma$ in conjunction with $g^{\mathrm{TT}}=\sigma g\sigma$ means that the automorphism $\hat{\gamma}:\mathrm{Gl}(W)\to\mathrm{Gl}(W)$ defined by $\hat{\gamma}(g)=\gamma g^{-1^{\mathrm{T}}}\gamma^{-1}$ is involutory. The same is true for $\hat{\tau}$ defined by $\hat{\tau}(g)=\tau g^{-1^{\mathrm{T}}}\tau^{-1}$ and, moreover, $\hat{\gamma}$ and $\hat{\tau}$ commute by $\gamma\tau+\tau\gamma=0$. For definiteness we take

$$\begin{aligned} \gamma&=E_{\mathrm{BB}}\otimes\gamma_{\mathrm{B}}+E_{\mathrm{FF}}\otimes\gamma_{\mathrm{F}}, \quad \gamma_{\mathrm{B}}=\sigma_x\otimes\sigma_z\otimes 1_n, \quad \gamma_{\mathrm{F}}=i\sigma_y\otimes 1_2\otimes 1_n, \\ \tau&=E_{\mathrm{BB}}\otimes\tau_{\mathrm{B}}+E_{\mathrm{FF}}\otimes\tau_{\mathrm{F}}, \quad \tau_{\mathrm{B}}=1_2\otimes\sigma_x\otimes 1_n, \quad \tau_{\mathrm{F}}=\sigma_z\otimes i\sigma_y\otimes 1_n. \end{aligned}$$

(This choice is consistent with $\widetilde{\psi}_B=\beta\psi_B^\dagger$, $\beta=\sigma_z\otimes 1_2\otimes 1_n$.) Let

$$\mathscr{Q}:=\{Q\in\mathrm{End}_\Lambda(W)\,|\,Q=-\gamma Q^{\mathrm{T}}\gamma^{-1}=+\tau Q^{\mathrm{T}}\tau^{-1}\}$$

be the subspace distinguished by the symmetry properties of $\widetilde{\psi}\psi$. The group $\mathrm{Gl}(W)$ acts on $\mathscr{Q}$ by $Q\mapsto gQg^{-1}$. We now ask what is the subgroup G_Λ of $\mathrm{Gl}(W)$ that leaves the symmetries of Q invariant [the normalizer of $\mathscr{Q}$ in $\mathrm{Gl}(W)$].

Lemma 4.1: G_Λ is isomorphic to $\mathrm{Osp}(2n|2n)\times\mathrm{Osp}(2n|2n)$.

Proof: The conditions on $g\in G_\Lambda$ can be phrased as follows:

$$\gamma=g\gamma g^{\mathrm{T}}, \quad \tau=g\tau g^{\mathrm{T}}.$$

Equivalently, G_Λ can be described as the simultaneous ''fixed point set''[45] of the involutory automorphisms $\hat{\gamma}$ and $\hat{\tau}$. We first describe the fixed point set of $\hat{\gamma}\circ\hat{\tau}$, which acts by $(\hat{\gamma}\circ\hat{\tau})(g)=\epsilon g\epsilon^{-1}$, where $\epsilon=-i\gamma\tau^{-1}$. From the explicit expression $\epsilon=1_{B|F}\otimes\sigma_x\otimes\sigma_y\otimes 1_n$ we see that ϵ has $4n$ eigenvalues equal to $+1$, $4n$ eigenvalues equal to -1, and these are equally

distributed over the bosonic and fermionic subspaces. Hence the subgroup of $\mathrm{Gl}(W)$ fixed by $\hat{\gamma}\circ\hat{\tau}$ is isomorphic to $G_+\times G_-$, where $G_+\simeq\mathrm{Gl}(2n|2n)\simeq G_-$. Denote the embedding $G_+\times G_-\to\mathrm{Gl}(W)$ by $\varphi(g_+,g_-)=g$. The group G_Λ is the fixed point set of $\hat{\tau}$ (or, equivalently, of $\hat{\gamma}$) in $\varphi(G_+\times G_-)$ [$\hat{\tau}$ commutes with $\hat{\gamma}\circ\hat{\tau}$ and therefore takes $\varphi(G_+\times G_-)$ into itself]. Note $\epsilon\tau=-\tau\epsilon$, $\epsilon^{-1^{\mathrm{T}}}=-\epsilon$, and for $g\in\varphi(G_+\times G_-)$ do the following little calculation:

$$\epsilon\hat{\tau}(g)=\epsilon\tau g^{-1^{\mathrm{T}}}\tau^{-1}=-\tau\epsilon g^{-1^{\mathrm{T}}}\tau^{-1}=\tau(\epsilon g)^{-1^{\mathrm{T}}}\tau^{-1}=\hat{\tau}(\epsilon g).$$

Combining this with $\epsilon\varphi(g_+,g_-)=\varphi(g_+,-g_-)$ one infers that $\hat{\tau}$ acting on $\varphi(G_+\times G_-)$ is of the form $\hat{\tau}\varphi(g_+,g_-)=\varphi(\hat{\tau}_+(g_+),\hat{\tau}_-(g_-))$. By a short calculation (work in an eigenbasis of ϵ) one sees that the involutory automorphisms $\hat{\tau}_i$: $\mathrm{Gl}(2n|2n)\to\mathrm{Gl}(2n|2n)$ $(i=\pm)$ are expressed by $\hat{\tau}_i(g)=\tau_i g^{-1^{\mathrm{T}}}\tau_i^{-1}$ with supersymmetric $\tau_i(\tau_i=\tau_i^{\mathrm{T}}\sigma)$. It follows that $\hat{\tau}_i$ fixes an orthosymplectic subgroup of $G_i\simeq\mathrm{Gl}(2n|2n)$, so $G_\Lambda\simeq\mathrm{Osp}(2n|2n)\times\mathrm{Osp}(2n|2n)$, as claimed.

Corollary 4.2: The space $\mathscr{Q}$ is isomorphic to the complement of $\mathrm{osp}(2n|2n)\oplus\mathrm{osp}(2n|2n)$ in $\mathrm{osp}(4n|4n)$.

Proof: The solution space in $\mathrm{End}_\Lambda(W)$ of $Q=-\gamma Q^{\mathrm{T}}\gamma^{-1}$ is an $\mathrm{osp}(4n|4n)$ algebra. Implementing the second condition $Q=+\tau Q^{\mathrm{T}}\tau^{-1}$ amounts to removing from $\mathrm{osp}(4n|4n)$ the subalgebra fixed by $X=-\tau X^{\mathrm{T}}\tau^{-1}$. By linearization of the conditions $g=\hat{\gamma}(g)=\hat{\tau}(g)$, this subalgebra is identified as $\mathrm{Lie}(G_\Lambda)\simeq\mathrm{osp}(2n|2n)\oplus\mathrm{osp}(2n|2n)$. ■

The Gaussian integral identity (10) continues to hold, albeit with a different value of $c=1/4$. The proof is essentially the same as before.

Since $\mathscr{Q}$ is not a Lie algebra, the description of the correct choice of integration domain for the auxiliary variable Q is more complicated than before. In the FF sector we take $\mathscr{U}:=\{Q_{\mathrm{FF}}\in\mathscr{Q}_{\mathrm{FF}}|Q_{\mathrm{FF}}=-Q_{\mathrm{FF}}^\dagger\}$. By Corollary 4.2, $\mathrm{sp}(2n)\simeq(\mathrm{sp}(n)\oplus\mathrm{sp}(n))\oplus\mathscr{U}$. To deal with the BB sector we introduce the spaces

$$\mathscr{G}=\{X\in\mathrm{gl}(2n,\mathbb{C})|X=-\gamma_{\mathrm{B}}X^{\mathrm{T}}\gamma_{\mathrm{B}}^{-1}=-\tau_{\mathrm{B}}X^{\mathrm{T}}\tau_{\mathrm{B}}^{-1}=-\beta X^\dagger\beta^{-1}\},$$

$$\mathscr{M}=\{Y\in\mathscr{G}|Y=-\beta Y\beta^{-1}\},\quad \mathscr{P}^\pm=\{X\in\mathscr{Q}_{\mathrm{BB}}|X=-\beta X^\dagger\beta^{-1}=\pm\beta X\beta^{-1}\},$$

where $\beta=\sigma_z\otimes 1_2\otimes 1_n$. The Lie algebra $\mathscr{G}$ is a noncompact real form of the BB part of $\mathrm{Lie}(G_\Lambda)$. By $\beta\in i\mathscr{P}^+$ and the commutation relations $[\mathscr{M},\mathscr{P}^+]\subset\mathscr{P}^-$ and $[\mathscr{M},\mathscr{P}^-]\subset\mathscr{P}^+$, we have an embedding,

$$\phi_b:\mathscr{P}^+\times\mathscr{M}\to\mathscr{Q}_{\mathrm{BB}}=\mathscr{P}^+_{\mathrm{C}}+\mathscr{P}^-_{\mathrm{C}},$$

$$(X,Y)\mapsto b\times(X+e^{\mathrm{ad}(Y)}\beta).$$

Similar considerations as in Sec. III E show that all integrals are rendered convergent by the choice of integration domain $\phi_b(\mathscr{P}^+\times\mathscr{M})\times\mathscr{U}$ $(b>0)$ for Q. With this choice we again arrive at Theorem 3.3.

The large-N limit is dominated by a single saddle-point supermanifold, which can be taken as the orbit of $Q_0=iv\Sigma_z$ (here $\Sigma_z=1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_2\otimes 1_n$) under the adjoint action of G_Λ. This orbit is diffeomorphic to G_Λ/H_Λ, where $H_\Lambda=\{h\in G_\Lambda|h\Sigma_z h^{-1}=\Sigma_z\}$. The stability group H_Λ can equivalently be described as the fixed point set of $\hat{\Sigma}_z:G_\Lambda\to G_\Lambda$, $\hat{\Sigma}_z(g)=\Sigma_z g\Sigma_z$. By the relations $\Sigma_z=\Sigma_z^{\mathrm{T}}=-\gamma\Sigma_z\gamma^{-1}=\tau\Sigma_z\tau^{-1}$ $(\Sigma_z\in\mathscr{Q})$, the element Σ_z anticommutes with $\epsilon=-i\gamma\tau^{-1}$, and $\hat{\Sigma}_z$ commutes with $\hat{\gamma}\circ\hat{\tau}$. These relations are compatible with the existence of an embedding ϕ: $\mathrm{Osp}(2n|2n)\times\mathrm{Osp}(2n|2n)\to\mathrm{Gl}(W)$, such that $(\hat{\Sigma}_z\circ\phi)(g_+,g_-)=\phi(g_-,g_+)$. (Such an embedding is easily constructed.) Hence $H_\Lambda\simeq\mathrm{diag}(\mathrm{Osp}(2n|2n)\times\mathrm{Osp}(2n|2n))\simeq\mathrm{Osp}(2n|2n)$. In this way we arrive at Theorem 3.4 with $G_\Lambda/H_\Lambda\simeq\mathrm{Osp}(2n|2n)$, and the maximal Riemannian submanifold $M_{\mathrm{B}}\times M_{\mathrm{F}}$, where $M_{\mathrm{B}}\simeq\mathrm{SO}(2n,\mathbb{C})/\mathrm{SO}(2n)$ and $M_{\mathrm{F}}\simeq\mathrm{Sp}(n)$ (type $D|C$).[47]

C. Class *D*III

Consider for $V=\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^N$ the linear space

$$P=\{H\in\mathrm{End}(V)\,|\,H=H^\dagger=-\mathscr{C}H^{\mathrm{T}}\mathscr{C}^{-1}=+\mathscr{T}H^{\mathrm{T}}\mathscr{T}^{-1}\},$$

where $\mathscr{C}=\sigma_x\otimes 1_2\otimes 1_N$ and $\mathscr{T}=1_2\otimes i\sigma_y\otimes 1_N$. It has been shown[25] that P is isomorphic to the tangent space of $\mathrm{SO}(4N)/\mathrm{U}(2N)$ (a symmetric space of type *D*III). Introducing an orthonormal real basis of V, we can represent H by a $4N\times 4N$ matrix. If $\mathscr{C}$ and $\mathscr{T}$ are given by

$$\mathscr{C}=\begin{pmatrix} 0 & 0 & 1_N & 0\\ 0 & 0 & 0 & 1_N\\ 1_N & 0 & 0 & 0\\ 0 & 1_N & 0 & 0\end{pmatrix},\quad \mathscr{T}=\begin{pmatrix} 0 & 1_N & 0 & 0\\ -1_N & 0 & 0 & 0\\ 0 & 0 & 0 & 1_N\\ 0 & 0 & -1_N & 0\end{pmatrix},$$

the explicit form of such a matrix is

$$H=\begin{pmatrix} a & b & c & d\\ b^\dagger & a^{\mathrm{T}} & -d^{\mathrm{T}} & -c^\dagger\\ c^\dagger & -d^{\mathrm{T}} & -a^{\mathrm{T}} & b^\dagger\\ d & -c & b & -a\end{pmatrix},$$

where all entries are complex $N\times N$ matrices and $a,d(b,c)$ are Hermitian (skew).

The Gaussian random-matrix ensemble on P is defined by the Gaussian measure $d\mu(H)$ with vanishing first moment, and second moment,

$$\int_P \mathrm{Tr}(AH)\mathrm{Tr}(BH)d\mu(H)=\frac{v^2}{4N}\,\mathrm{Tr}(AB-A\mathscr{C}B^{\mathrm{T}}\mathscr{C}^{-1}+A\mathscr{T}B^{\mathrm{T}}\mathscr{T}^{-1}-A(\mathscr{C}\mathscr{T})B(\mathscr{C}\mathscr{T})^{-1}).$$

Given the auxiliary space $W:=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^n$, we impose on $\psi\in\mathrm{Hom}_\lambda(W,V)$, $\tilde{\psi}\in\mathrm{Hom}_{\tilde{\lambda}}(V,W)$ the linear conditions

$$\psi=\gamma\tilde{\psi}^{\mathrm{T}}\mathscr{C}^{-1},\quad \tilde{\psi}=-\mathscr{C}\psi^{\mathrm{T}}\gamma^{-1},$$
$$\psi=\tau\tilde{\psi}^{\mathrm{T}}\mathscr{T}^{-1},\quad \tilde{\psi}=\mathscr{T}\psi^{\mathrm{T}}\tau^{-1},$$

with some invertible orthogonal elements γ,τ of $\mathrm{End}_0(W)$. Consistency requires $\gamma^2=-\sigma=\tau^2$ and $\gamma\tau+\tau\gamma=0$. A possible choice is

$$\gamma=(E_{\mathrm{BB}}\otimes i\sigma_y\otimes 1_2+E_{\mathrm{FF}}\otimes\sigma_x\otimes\sigma_z)\otimes 1_n,$$

$$\tau=(E_{\mathrm{BB}}\otimes\sigma_z\otimes i\sigma_y+E_{\mathrm{FF}}\otimes 1_2\otimes\sigma_x)\otimes 1_n.$$

Because this differs from class *C*I only by the exchange of the bosonic and fermionic subspaces, the following development closely parallels that for *C*I, and we arrive at another variant of Theorem 3.3.

The large-N limit is dominated by a pair of complex-analytic saddle-point supermanifolds, each being isomorphic to $\mathrm{Osp}(2n|2n)$. [The reason why there are two is that $\mathrm{O}(2n,\mathbb{C})$ has two connected components.] The first one is the orbit under $\mathrm{Ad}(G_\Lambda)$ of $Q_0=iv1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_2\otimes 1_n$, and the second one is the orbit of

$$Q_1 = iv\left(E_{\mathrm{BB}} \otimes \sigma_z \otimes 1_2 \otimes 1_n + E_{\mathrm{FF}} \otimes \left(1_2 \otimes \sigma_x \otimes E_{11} + \sigma_z \otimes 1_2 \otimes \sum_{i=2}^{n} E_{ii} \right) \right).$$

Both saddle-point supermanifolds are Riemannian symmetric superspaces of type $C|D$ with dimensionality $m=2n$ (Table II).[47]

D. Class *AIII*

The tangent space at the origin of $\mathrm{U}(p,q)/\mathrm{U}(p)\times\mathrm{U}(q)$ consists of the matrices of the form

$$H = \begin{pmatrix} 0 & Z \\ Z^\dagger & 0 \end{pmatrix},$$

where Z is complex and has dimension $p\times q$. Such matrices are equivalently described by $H^\dagger = H = -\mathscr{P}H\mathscr{P}^{-1}$, where $\mathscr{P}=\mathrm{diag}(1_p,-1_q)$. For simplicity, we will consider only the case $p=q$ (the general case has not yet been analyzed in the present formalism). The Gaussian ensemble of random matrices H is taken to have second moment

$$\int \mathrm{Tr}(AH)\mathrm{Tr}(BH)\,d\mu(H) = \frac{v^2}{2N}\,\mathrm{Tr}(AB - A\mathscr{P}B\mathscr{P}^{-1}).$$

The physical space is $V=\mathbb{C}^2\otimes\mathbb{C}^p$, and the auxiliary space is $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^n$. The definition of ω is unchanged from class C. To implement the symmetry condition $\psi\widetilde{\psi} = -\mathscr{P}\psi\widetilde{\psi}\mathscr{P}^{-1}$ we set

$$\psi = i\mathscr{P}\psi\pi^{-1}, \quad \widetilde{\psi} = i\pi\widetilde{\psi}\mathscr{P}^{-1},$$

where $\pi = 1_{\mathrm{B|F}}\otimes i\sigma_y\otimes 1_{\mathcal{L}}$. This choice is consistent with the relation $\widetilde{\psi}_{\mathrm{B}} = \beta\psi_{\mathrm{B}}^\dagger$ which ensures convergence of the $(\psi,\widetilde{\psi})$ integration. The auxiliary variable Q ranges over the complex-analytic superspace

$$\mathscr{Q} = \{Q \in \mathrm{End}_\Lambda(W) \,|\, Q = -\pi Q \pi^{-1}\},$$

and the normalizer of $\mathscr{Q}$ in $\mathrm{Gl}(W)$ is

$$G_\Lambda = \{g \in \mathrm{Gl}(W) \,|\, g = \pi g \pi^{-1}\} \simeq \mathrm{Gl}(n|n)\times\mathrm{Gl}(n|n).$$

For the integration domain $\mathscr{M}$ in the FF sector we again take the anti-Hermitian matrices in $\mathscr{Q}_{\mathrm{FF}}$. In the BB sector we set

$$\mathscr{M} = \{Y \in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}}) \,|\, Y = \pi Y \pi^{-1} = -\beta Y \beta^{-1} = Y^\dagger\},$$

$$\mathscr{P}^{\pm} = \{X \in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}}) \,|\, X = -\pi X \pi^{-1} = \pm\beta X \beta^{-1} = \mp X^\dagger\}.$$

The treatment of Sec. III E then goes through as before, leading again to Theorem 3.3.

There is a single dominant saddle-point supermanifold, which is the $\mathrm{Ad}(G_\Lambda)$ orbit of $Q_0 = iv\,1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_n$ and is diffeomorphic to $G_\Lambda/H_\Lambda \simeq \mathrm{Gl}(n|n)$. The integration domain $M_{\mathrm{B}}\times M_{\mathrm{F}}$ is given by $M_{\mathrm{B}}\simeq\mathrm{Gl}(n,\mathbb{C})/\mathrm{U}(n)$ and $M_{\mathrm{F}}=\mathrm{U}(n)$. The invariant Berezin measure of this Riemannian symmetric superspace of type $A|A$ was discussed for $n=1$ in Example 2.4.

E. Class *BD*I

The form of the random-matrix Hamiltonian H for class BDI can be obtained from the preceding case by taking the $p\times q$ matrix Z to be real. Put in formulas, H is subject to $H^\dagger = H = H^{\mathrm{T}} = -\mathscr{P}H\mathscr{P}^{-1}$. We again make the restriction to $p=q$. The basic correlation law of the Gaussian ensemble is

$$\int \mathrm{Tr}(AH)\mathrm{Tr}(BH)\,d\mu(H) = \frac{v^2}{4N}\,\mathrm{Tr}(A(B+B^{\mathrm{T}}) - A\mathscr{P}(B+B^{\mathrm{T}})\mathscr{P}^{-1}).$$

To accommodate the extra symmetry $H=H^{\mathrm{T}}$, auxiliary space is extended to $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^n$. The symmetry conditions on ψ, $\widetilde{\psi}$ are

$$\psi = i\mathscr{P}\psi\pi^{-1}, \quad \widetilde{\psi} = i\pi\widetilde{\psi}\mathscr{P}^{-1}; \quad \psi = \widetilde{\psi}^{\mathrm{T}}\tau^{-1}, \quad \widetilde{\psi} = \tau\psi^{\mathrm{T}},$$

where $\pi = 1_{\mathrm{B|F}}\otimes i\sigma_y\otimes 1_2\otimes 1_n$ and $\tau = (E_{\mathrm{BB}}\otimes 1_2\otimes\sigma_x + E_{\mathrm{FF}}\otimes 1_2\otimes i\sigma_y)\otimes 1_n$. The auxiliary integration space,

$$\mathscr{Q} = \{Q\in \mathrm{End}_\Lambda(W) \,|\, Q = -\pi Q\pi^{-1} = +\tau Q^{\mathrm{T}}\tau^{-1}\},$$

has the symmetry group (or normalizer)

$$G_\Lambda = \{g\in \mathrm{Gl}(W) \,|\, g = \pi g\pi^{-1} = \tau {g^{-1}}^{\mathrm{T}}\tau^{-1}\} \simeq \mathrm{Gl}(2n|2n).$$

For the integration domain $\mathscr{U}$ in the FF sector we once again take the anti-Hermitian matrices in $\mathscr{Q}_{\mathrm{FF}}$. In the BB sector we set

$$\mathscr{M} = \{Y\in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}}) \,|\, Y = \pi Y\pi^{-1} = -\tau Y^{\mathrm{T}}\tau^{-1} = -\beta Y\beta^{-1} = Y^\dagger\},$$

$$\mathscr{P}^{\pm} = \{X\in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}}) \,|\, X = -\pi X\pi^{-1} = +\tau X^{\mathrm{T}}\tau^{-1} = \pm\beta X\beta^{-1} = \mp X^\dagger\}.$$

The treatment of Sec. III E then goes through with modifications as in Sec. IV B.

There is a single dominant saddle-point supermanifold, which is the $\mathrm{Ad}(G_\Lambda)$ orbit of $Q_0 = iv\,1_{\mathrm{B|F}}\otimes\sigma_z\otimes 1_2\otimes 1_n$ and is diffeomorphic to $G_\Lambda/H_\Lambda \simeq \mathrm{Gl}(2n|2n)/\mathrm{Osp}(2n|2n)$. The integration domain $M_{\mathrm{B}}\times M_{\mathrm{F}}$ is given by $M_{\mathrm{B}}\simeq \mathrm{Gl}(2n,\mathbb{R})/\mathrm{O}(2n)$ and $M_{\mathrm{F}} = \mathrm{U}(2n)/\mathrm{Sp}(n)$. This is a Riemannian symmetric superspace of type $AI|AII$ with $m=2n$ (Table II).

F. Class *C*II

The tangent space at the origin of $\mathrm{Sp}(N,N)/\mathrm{Sp}(N)\times\mathrm{Sp}(N)$ (a noncompact symmetric space of type CII) can be described by the equations

$$H^\dagger = H = -\mathscr{P}H\mathscr{P}^{-1} = -\mathscr{T}H^{\mathrm{T}}\mathscr{T}^{-1},$$

where $\mathscr{P} = \sigma_z\otimes 1_2\otimes 1_N$ and $\mathscr{T} = 1_2\otimes i\sigma_y\otimes 1_N$ (the physical space is $V=\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^N$). The explicit form of the matrices is

$$H = \begin{pmatrix} 0 & 0 & a & b \\ 0 & 0 & -\overline{b} & \overline{a} \\ a^\dagger & -b^{\mathrm{T}} & 0 & 0 \\ b^\dagger & a^{\mathrm{T}} & 0 & 0 \end{pmatrix},$$

if

$$\mathscr{P}=\begin{pmatrix} 1_N & 0 & 0 & 0 \\ 0 & 1_N & 0 & 0 \\ 0 & 0 & -1_N & 0 \\ 0 & 0 & 0 & -1_N \end{pmatrix}$$

and

$$\mathscr{T}=\begin{pmatrix} 0 & 1_N & 0 & 0 \\ -1_N & 0 & 0 & 0 \\ 0 & 0 & 0 & 1_N \\ 0 & 0 & -1_N & 0 \end{pmatrix},$$

where a and b are complex and have dimension $N\times N$. The correlation law of the Gaussian random-matrix ensemble of type CII is

$$\int \mathrm{Tr}(AH)\mathrm{Tr}(BH)d\mu(H)=\frac{v^2}{4N}\,\mathrm{Tr}(A-\mathscr{P}A\mathscr{P}^{-1})(B-\mathscr{T}B^{\mathrm{T}}\mathscr{T}^{-1}).$$

As before, $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^n$. The symmetry conditions on ψ, $\widetilde{\psi}$ are

$$\psi=i\mathscr{P}\psi\pi^{-1},\quad \widetilde{\psi}=i\pi\widetilde{\psi}\mathscr{P}^{-1};\quad \psi=\mathscr{T}\widetilde{\psi}^{\mathrm{T}}\tau^{-1},\quad \widetilde{\psi}=\tau\psi^{\mathrm{T}}\mathscr{T}^{-1},$$

where $\pi=1_{\mathrm{B|F}}\otimes i\sigma_y\otimes 1_2\otimes 1_n$ and $\tau=(E_{\mathrm{BB}}\otimes 1_2\otimes i\sigma_y+E_{\mathrm{FF}}\otimes 1_2\otimes\sigma_x)\otimes 1_n$. This differs from class BDI only by the exchange of the bosonic and fermionic subspaces. Once more we arrive at another version of Theorem 3.3.

There is only one complex-analytic supermanifold of saddle-points that dominates for $N\to\infty$. It is isomorphic to that for class BDI. The integration domain $M_{\mathrm{B}}\times M_{\mathrm{F}}$ changes to $M_{\mathrm{B}}\simeq \mathrm{U}^*(2n)/\mathrm{Sp}(n)$ and $M_{\mathrm{F}}\simeq \mathrm{U}(2n)/\mathrm{O}(2n)$ [not $\mathrm{U}(2n)/\mathrm{SO}(2n)$]. This is a Riemannian symmetric superspace of type AII$|A$I with $m=2n$ (Table II). The group $\mathrm{U}^*(2n)$ is defined as the noncompact real subgroup of $\mathrm{Gl}(2n,\mathbb{C})$ fixed by $g=\mathscr{C}\overline{g}\mathscr{C}^{-1}$, where $\mathscr{C}=i\sigma_y\otimes 1_n$.

G. Class A

This class for $n=1$ was used to illustrate our general strategy in Sec. III A. Let us now do the case of arbitrary n,

$$Z_n(\alpha_1,\ldots,\alpha_n;\beta_1,\ldots,\beta_n)=\int_{i\,\mathrm{u}(N)}\prod_{i=1}^{n}\mathrm{Det}\left(\frac{H-\beta_i}{H-\alpha_i}\right)d\mu(H).$$

The classes treated so far (C,D,CI,DIII,AIII,BDI,CII) all share one feature, namely the existence of a particle-hole type of symmetry ($H=-\mathscr{P}H\mathscr{P}^{-1}$ or $H=-\mathscr{C}H^{\mathrm{T}}\mathscr{C}^{-1}$), which allows us to restrict all α_i to one-half of the complex plane. Such a symmetry is absent for the Wigner–Dyson symmetry classes A, AI, and AII, which results in a somewhat different scenario, as it now matters how many α_i lie above or below the real axis. For definiteness let

$$\mathrm{Im}\ \alpha_i<0\quad (i=1,\ldots,n_A),\quad \mathrm{Im}\ \alpha_j>0\quad (j=n_A+1,\ldots,n),$$

and set $n_R=n-n_A$.

Auxiliary space is taken to be $W=\mathbb{C}^{1|1}\otimes\mathbb{C}^n$. The definition of ω changes to

$$\omega = E_{\mathrm{BB}} \otimes \sum_{i=1}^{n} \alpha_i E_{ii} + E_{\mathrm{FF}} \otimes \sum_{j=1}^{n} \beta_j E_{jj} .$$

Recall that the imaginary parts of the α_i steer the convergence of the $(\psi, \widetilde{\psi})$ integration. Since ω couples to $\psi, \widetilde{\psi}$ by $\exp -i\ \mathrm{STr}_W\ \omega \widetilde{\psi} \psi$, convergence forces us to take $\widetilde{\psi}_{\mathrm{B}} = \beta \psi_{\mathrm{B}}^{\dagger}$, where

$$\beta = \sum_{i=1}^{n_A} E_{ii} - \sum_{j=n_A+1}^{n} E_{jj} .$$

There are no further constraints on ψ, $\widetilde{\psi}$, or Q. Thus the complex-analytic auxiliary integration space is $\mathcal{Q} = \mathrm{End}_{\Lambda}(W)$, and $G_{\Lambda} = \mathrm{Gl}(W) \simeq \mathrm{Gl}(n|n)$.

The integration domain for Q in the FF sector is taken to be the anti-Hermitian matrices $\mathcal{U} = \mathrm{u}(n)$. In the BB sector we introduce

$$\mathcal{G} = \{X \in \mathrm{gl}(n, \mathbb{C}) | X = -\beta X^{\dagger} \beta^{-1}\}, \quad \mathcal{K} = \{X \in \mathcal{G} | X = \beta X \beta^{-1}\}.$$

The Lie algebra $\mathcal{G}$ is a noncompact real form $\mathrm{u}(n_A, n_R)$ of $\mathrm{gl}(n, \mathbb{C})$, and $\mathcal{K} = \mathrm{u}(n_A) \oplus \mathrm{u}(n_R)$ is a maximal compact subalgebra. The space $\mathcal{M}$ is defined by the Cartan decomposition $\mathcal{G} = \mathcal{K} \oplus \mathcal{M}$. The integration domain for Q_{BB} is taken to be $i\phi_b(\mathcal{K} \times \mathcal{M})$, where $\phi_b(X, Y) = b(X + e^{\mathrm{ad}(Y)} \beta)$ $(b > 0)$. This gives Theorem 3.3.

By simple power counting, the limit $N \to \infty$ is again dominated by a single complex-analytic saddle-point supermanifold, which is the $\mathrm{Ad}(G_{\Lambda})$-orbit of $Q_0 = iv 1_{\mathrm{B|F}} \otimes \beta$. The stability group H_{Λ} of Q_0 is $H_{\Lambda} = \mathrm{Gl}(n_A|n_A) \times \mathrm{Gl}(n_R|n_R)$, so

$$\mathrm{Ad}(G_{\Lambda}) Q_0 \simeq G_{\Lambda} / H_{\Lambda} = \mathrm{Gl}(n|n) / \mathrm{Gl}(n_A|n_A) \times \mathrm{Gl}(n_R|n_R).$$

The intersection of $\mathrm{Ad}(G_{\Lambda}) Q_0$ with $i\phi_v(\mathcal{K} \times \mathcal{M}) \times \mathcal{U}$ is $M_{\mathrm{B}} \times M_{\mathrm{F}}$, where $M_{\mathrm{B}} \simeq \mathrm{U}(n_A, n_R)/\mathrm{U}(n_A) \times \mathrm{U}(n_R)$ and $M_{\mathrm{F}} \simeq \mathrm{U}(n_A + n_R)/\mathrm{U}(n_A) \times \mathrm{U}(n_R)$. This is a Riemannian symmetric superspace of type $A\mathrm{III}|A\mathrm{III}$ with $m_1 = n_1 = n_A$ and $m_2 = n_2 = n_R$ (see Table II).

H. Class *AI*

The tangent space of $\mathrm{U}(N)/\mathrm{O}(N)$ is the same as (i times) the real symmetric matrices $H^{\dagger} = H = H^{\mathrm{T}}$. It differs from the tangent space of $\mathrm{SU}(N)/\mathrm{SO}(N)$, a symmetric space of type $A\mathrm{I}$ in an inessential way (just remove the multiples of the unit matrix). The Gaussian ensemble over the real symmetric matrices has its second moment given by

$$\int \mathrm{Tr}(AH)\mathrm{Tr}(BH) d\mu(H) = \frac{v^2}{2N} \mathrm{Tr}(AB + AB^{\mathrm{T}}).$$

This ensemble is related to type A in the same way that type $C\mathrm{I}$ is related to type C.

To implement the symmetry $H = H^{\mathrm{T}}$ we set $W = \mathbb{C}^{1|1} \otimes \mathbb{C}^2 \otimes \mathbb{C}^n$ and require $\psi = \widetilde{\psi}^{\mathrm{T}} \tau^{-1}$, $\widetilde{\psi} = \tau \psi^{\mathrm{T}}$, where $\tau = (E_{\mathrm{BB}} \otimes \sigma_x + E_{\mathrm{FF}} \otimes i\sigma_y) \otimes 1_n$. The auxiliary integration space,

$$\mathcal{Q} = \{Q \in \mathrm{End}_{\Lambda}(W) | Q = \tau Q^{\mathrm{T}} \tau^{-1}\},$$

has the symmetry group

$$G_{\Lambda} = \{g \in \mathrm{Gl}(W) | g = \tau g^{-1^{\mathrm{T}}} \tau^{-1}\} \simeq \mathrm{Osp}(2n|2n).$$

The intersection $\mathcal{U}$ of the FF sector $\mathcal{Q}_{\mathrm{FF}}$ with the anti-Hermitian matrices is given by $\mathrm{sp}(n) \oplus \mathcal{U} = \mathrm{u}(2n)$. In the *BB* sector we put

$$\mathscr{M}=\{Y\in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}})\,|\,Y=-\tau Y^{T}\tau^{-1}=-\beta Y\beta^{-1}=Y^{\dagger}\},$$

$$\mathscr{P}^{\pm}=\{X\in \mathrm{End}_{\mathbb{C}}(W_{\mathrm{B}})\,|\,X=+\tau X^{T}\tau^{-1}=\pm\beta X\beta^{-1}=\mp X^{\dagger}\},$$

which leads to yet another version of Theorem 3.3.

The large-N limit is controlled by a single complex-analytic saddle-point supermanifold $\mathrm{Ad}(G_{\Lambda})Q_0\simeq G_{\Lambda}/H_{\Lambda}$, where $H_{\Lambda}\simeq \mathrm{Osp}(2n_A|2n_A)\times\mathrm{Osp}(2n_R|2n_R)$ is the stability group of $Q_0=iv1_{\mathrm{B|F}}\otimes(\Sigma_{i=1}^{n_A}E_{ii}-\Sigma_{j=n_A+1}^{n}E_{jj})$. The intersection of $\mathrm{Ad}(G_{\Lambda})Q_0$ with the integration domain $\phi_v(\mathscr{P}^{+}\times\mathscr{M})\times\mathscr{U}$ is $M_{\mathrm{B}}\times M_{\mathrm{F}}$, where $M_{\mathrm{B}}\simeq \mathrm{SO}(2n_A,2n_R)/\mathrm{SO}(2n_A)\times\mathrm{SO}(2n_R)$ and $M_{\mathrm{F}}\simeq \mathrm{Sp}(n_A+n_R)/\mathrm{Sp}(n_A)\times\mathrm{Sp}(n_R)$. This is a Riemannian symmetric superspace of type $BD\mathrm{I}|C\mathrm{II}$ (Table II) with $m_1=2n_1=2n_A$ and $m_2=2n_2=2n_R$.

I. Class *A*II

Finally, the tangent space of $\mathrm{U}(2N)/\mathrm{Sp}(N)$ [a symmetric space of type *A*II, except for the substitution $\mathrm{SU}(2N)\to\mathrm{U}(2N)$] can be described as ($i$ times) the subspace of $\mathrm{End}(\mathbb{C}^2\otimes\mathbb{C}^N)$ fixed by the linear equations $H^{\dagger}=H=\mathscr{T}H^{\mathrm{T}}\mathscr{T}^{-1}$, $\mathscr{T}=i\sigma_y\otimes 1_N$. The explicit matrix form of H is

$$H=\begin{pmatrix} a & b \\ b^{\dagger} & a^{\mathrm{T}}\end{pmatrix},$$

where b is skew and a is Hermitian.

The conditions $\psi=\mathscr{T}\tilde{\psi}^{\mathrm{T}}\tau^{-1}$ and $\tilde{\psi}=\tau\psi^{\mathrm{T}}\mathscr{T}^{-1}$ are mutually consistent if, say, $\tau=(E_{\mathrm{BB}}\otimes i\sigma_y+E_{\mathrm{FF}}\otimes\sigma_x)\otimes 1_n$. The rest of the manipulations leading up to Theorem 3.3 are the same as for class *A*I, except for the exchange of the bosonic and fermionic subspaces ($\tau_{\mathrm{B}}\leftrightarrow\tau_{\mathrm{F}}$). The large-$N$ limit is controlled by a single saddle-point supermanifold $(G_{\Lambda}/H_{\Lambda},M_{\mathrm{B}}\times M_{\mathrm{F}})$, where

$$G_{\Lambda}/H_{\Lambda}=\mathrm{Osp}(2n|2n)/\mathrm{Osp}(2n_A|2n_A)\times\mathrm{Osp}(2n_R|2n_R),$$

$$M_{\mathrm{B}}=\mathrm{Sp}(n_A,n_R)/\mathrm{Sp}(n_A)\times\mathrm{Sp}(n_R),$$

$$M_{\mathrm{F}}=\mathrm{SO}(2n_A+2n_R)/\mathrm{SO}(2n_A)\times\mathrm{SO}(2n_R),$$

which is a Riemannian symmetric superspace of type $C\mathrm{II}|BD\mathrm{I}$ (Table II) with $m_1=2n_1=2n_A$ and $m_2=2n_2=2n_R$.

V. SUMMARY

When Dyson realized[46] that the random-matrix ensembles he had introduced were based on the symmetric spaces of type *A*, *A*I, and *A*II, he wrote: ''The proof of (the) Theorem... is a mere verification. It would be highly desirable to find a more illuminating proof, in which the appearance of the (final result) might be related directly to the structure of the symmetric space...''. The advent of the supersymmetry method of Efetov and others has improved the situation lamented by Dyson. The present work takes the Gaussian random-matrix ensembles defined over Cartan's large families of symmetric spaces and, going to the limit of large matrix dimension, expresses their spectral correlation functions as integrals over the corresponding Riemannian symmetric superspaces. These correspondences are summarized in Table III. The Riemannian symmetric superspaces that appear there all have superdimension (p,q) with $p=q$. We say that they are ''perfectly graded'' or ''supersymmetric.'' An interesting question for future mathematical research is whether our procedure can be optimized by reducing it to a computation involving no more than the root system of the symmetric space, thereby obviating the space- and time-consuming need to distinguish cases. (Although I have treated all ten cases separately, it is possible, following Efetov,[3] to shorten the derivation by starting from a large ''master ensemble'' of highest symme-

TABLE III. The symmetric-space based random-matrix theories of the first column map onto the Riemannian symmetric superspaces listed in the third column. The notation for the dimensions is taken from Table II.

try and then reducing it by the addition of symmetry-breaking terms. I chose not to follow this route as it involves handling large tensor products, which makes the computations less transparent and the identification of the spaces involved more difficult.)

The great strength of the supersymmetry method, as compared to other methods of mesoscopic physics, stems from the fact that it easily extends beyond the universal random-matrix limit to diffusive and localized systems. What one obtains for these more general systems are field theories of the nonlinear σ model type, with fields that take values in a Riemannian symmetric superspace. The method also extends beyond spectral correlations and allows the calculation of wave function statistics and of transport coefficients such as the electrical conductance (see the literature cited in the Introduction).

Let me end on a provocative note. Mathematicians and mathematical physicists working on supermanifold theory have taken much guidance from developments in such esoteric subjects as supergravity and superstring theory. Would it not be just as worthwhile to investigate the beautiful structures outlined in the present paper, whose physical basis is not speculative but firmly established, and which are of direct relevance to experiments that are currently being performed in physics laboratories all over the world?

(Received 12 April 1996; accepted for publication 19 June 1996)

We consider singularities of the set of energy levels $E_n(\mathbf{X})$ of a quantum Hamiltonian, obtained by varying a set of d parameters $\mathbf{X}=(X_1,..,X_d)$. Singularities such as minima, degeneracies, branch points, and avoided crossings can play an important role in physical applications. We discuss a general method for counting these singularities, and apply it to a random matrix model for the parameter dependence of energy levels. We also show how the density of avoided crossing singularities is related to a non-analyticity of a correlation function describing the energy levels. © *1996 American Institute of Physics.* [S0022-2488(96)01810-5]

I. INTRODUCTION

It is now widely accepted that random matrices provide an excellent model for statistical properties of the spectra of quantum systems for which the energy levels cannot be determined analytically:[1,2] random matrix models have been successfully applied to disordered solids, classically chaotic systems, and many body problems. There are many contexts in which families of Hamiltonians depending smoothly on a set of parameters are of physical importance, for example the parameters could represent the positions of atomic nuclei in the Hamiltonian for the electrons in a molecule, or the Bloch wavevectors of an electron in a periodic potential. Recently the random matrix approach has been extended to describe statistics which characterize the parameter dependence of energy levels.[3–9] One approach to analyzing the parameter dependence is to consider correlation functions; an example which has received attention[6–8] is the correlation function $C(X)$ of the derivatives of energy levels $E_n'=dE_n/dX$:

$$C(X)=\langle E_n'(X+X_0)E_n'(X_0)\rangle. \tag{1.1}$$

An alternative approach is to examine various types of singularity in the spectrum, such as degeneracies[9,10] (where a pair of energy levels become equal at some real valued point in the parameter space), branch points[8] (where energy levels become degenerate at complex parameter values), and avoided crossings[3] (characteristic structures where energy levels come close to degeneracy). These singularities can have direct physical consequences, in determining various aspects of the breakdown of the adiabatic theorem,[11–14,3] and discontinuities of the quantized Hall conductance.[15,16,10]

This paper has two objectives. The first is to explain the strategy for calculating the density of singularities in the parameter space; we will present some new calculations of the density of singularities, as well as reviewing existing results. The second objective is to discuss the implications of these results for the calculation of correlation functions such as (1.1). Guaneri *et al.*[8]

demonstrated that the existence of branch point singularities in the spectrum implies that correlation functions such as $C(X)$ have a non-analytic behavior at $X=0$. We will show how the leading order non-analytic part of this function is obtained from the density of singularities.

This paper is organized as follows. In Sec. II we discuss parameter dependent generalizations of the standard random matrix models. In Sec. III we describe the approach to counting densities of singularities of random functions, using the density of minima as an example. In Sec. IV we review the known results on the density of various types of singularity, and their physical applications. Some of the results in Sec. IV are new, and of these the density of degeneracies for the GUE and GSE ensembles are not easily obtained; these calculations are explained in Sec. V and in an Appendix. Finally in Sec. VI we discuss the implications of the results given in Sec. IV for correlation functions such as (1.1).

In this paper we will discuss a variety of different probability distributions. To avoid naming a multiplicity of different functions describing these distributions, we will introduce the notational convention that $dP=P[X]dX$ is a probability measure for the quantity X.

II. PARAMETER DEPENDENT RANDOM MATRICES

The most fundamental random matrix models are the Gaussian ensembles introduced by Porter and Dyson. These are constructed from real symmetric matrices $\tilde{H}^{(S)}$ and real antisymmetric matrices $\tilde{H}_k^{(A)}$ with independent Gaussian distributed elements; the variance of the ijth element of these matrices is, respectively, $1\pm\delta_{ij}$. There are three Gaussian ensembles, invariant under orthogonal, general unitary, and ''symplectic'' unitary transformations,[1,2] which are constructed from combinations of the symmetric and antisymmetric matrices as follows:

$$[\tilde{H}]_{ij}=\frac{1}{\sqrt{\beta}}\left\{[\tilde{H}^{(S)}]_{ij}\mathbf{e}_0+\sum_{k=1}^{\beta-1}[\tilde{H}_k^{(A)}]_{ij}\mathbf{e}_k\right\}. \tag{2.1}$$

Here $\beta=1,2,4$ for the orthogonal, unitary and symplectic ensembles, respectively, $\mathbf{e}_0$, $\mathbf{e}_1$ are 1, $\sqrt{-1}$, respectively, and the other $\mathbf{e}_k$ are the other bases for the quaternion algebra. In order for these to be useful models for energy level statistics, the dimension N of the matrix should be large.

In order to study singularities of the spectrum, it is necessary to construct a parameter dependent version of these random matrix models. It is convenient to do this in such a way that $\partial\hat{H}/\partial X$ is an independent realization of the same ensemble as $\hat{H}$, and that the distribution of both of these quantities is stationary: this is achieved by writing

$$\hat{H}(X)=\cos X\hat{H}_1+\sin X\hat{H}_2, \tag{2.2}$$

where $\hat{H}_1$ and $\hat{H}_2$ are Hermitean operators represented by independent samples from the same Gaussian symmetry-invariant ensemble defined above. Reference 5 discusses theoretical arguments and numerical results which support the use of (2.2) as a model for parameter dependencies of spectra. In the calculations below, we will require the matrix elements of $d\hat{H}/dX$ in the basis formed by the eigenstates of $\hat{H}$: this is simply an arbitrary unitary transformation of $d\hat{H}/dX$ within the appropriate symmetry class (orthogonal, unitary, or symplectic). Because the Gaussian invariant ensembles are invariant under these unitary transformations, the matrix elements $\partial H_{nm}\equiv\langle\phi_n|d\hat{H}/dX|\phi_m\rangle$ have the same statistical properties as those of the matrix $d\hat{H}/dX$.

In order to compare a random matrix model with the spectrum of a ''real'' physical system in the neighborhood of energy E, we must scale energy levels of the system so that the density of states $\rho(E)$ corresponds to that of the random matrix model. In a parameter dependent system, it is also necessary to adjust another parameter, describing the sensitivity of the energy levels of the system to perturbations: the natural choice is to use either the variance of the off-diagonal matrix elements of $d\hat{H}/dX$ in the eigenbasis,

$$\sigma^2(E)=\langle|\partial H_{nm}|^2\rangle_{\substack{E_n\sim E_m\sim E\\ n\neq m}}, \tag{2.3}$$

or the variance of dE_n/dX: these are related by

$$\mathrm{var}\left[\frac{dE_n}{dX}\right]=\frac{2}{\beta}\sigma^2. \tag{2.4}$$

Equation (2.4) follows from the definition (2.1) for the Gaussian random matrix models, and there are several arguments suggesting that it should also hold for complex quantum systems.[17,18] For the random matrix ensemble (2.2), we have $\sigma=1$.

The model (2.2) can be extended to systems with d parameters in several ways; the simplest is to use $2d$ independent realizations of the random matrices, and write

$$\hat{H}(\mathbf{X})=\sum_{i=1}^{d}\ \cos X_i\hat{H}_{2i-1}+\ \sin X_i\hat{H}_{2i}. \tag{2.5}$$

Now the sensitivity of energy levels to the parameters X_i can be characterized by defining a set of parameters C_{ij} which generalize (2.3):

$$C_{ij}=\langle\partial_i H^*_{nm}\partial_j H_{nm}\rangle_{\substack{E_n\sim E_m\sim E\\ n\neq m}}, \tag{2.6}$$

where $\partial_i H_{nm}\equiv\langle\phi_n|\partial\hat{H}/\partial X_i|\phi_m\rangle$. A change of variables makes the parameter dependence of the energy levels resemble that of the model (2.5). In the many-parameter case the parameter σ characterizing the sensitivity of energy levels is naturally defined in terms of the Jacobean of this transformation: noting that for (2.5) we have $C_{ij}=\delta_{ij}$, the natural definition is

$$\sigma^2=(\det[\widetilde{C}])^{1/d}, \tag{2.7}$$

where $\widetilde{C}$ is a matrix with elements C_{ij}. In order to use the parametrized random matrix models, both the density of states ρ and the sensitivity parameter σ must be estimated. This can always be done numerically calculating an average over energy levels. For systems which exhibit semiclassical behavior, ρ can be estimated using the Weyl formula,[19] and σ^2 can be estimated from the classical correlation function of $\partial H/\partial X$.[20]

III. COUNTING SINGULARITIES

The method which we use for calculating the density of singularities can be viewed as an extension of one described by Rice,[21] who gives an expression for the frequency of zero crossings of a random function $f(x)$, for which the joint probability density of the function and its derivative f' is known. If $\mathscr{D}^{(0)}$ is the density of zeros of the function, the probability of finding a zero in a short interval of length $[x_0,x_0+\delta x]$ at a randomly chosen point x_0 is $\delta P=\mathscr{D}^{(0)}\delta x$. If the point x_0 happens to be close to a zero, the distance from x_0 to this zero crossing is approximately $-f(x_0)/f'(x_0)$, and the probability of the zero crossing lying within δx of x_0 is

$$\delta P\sim\int_{-\infty}^{\infty}df\int_{-\infty}^{\infty}df'\,P[f,f']\chi\left(\frac{-f}{f'\delta x}\right),$$
$$\chi(x)=\begin{cases}1, & 0<x<1,\\ 0, & 0>x>1.\end{cases} \tag{3.1}$$

Dividing by δx and taking the limit $\delta x\to 0$ gives

$$\mathscr{D}^{(0)}=\int_{-\infty}^{\infty}df\int_{-\infty}^{\infty}df'\,P[f,f']\delta\left(\frac{f}{f'}\right)=\int_{-\infty}^{\infty}df'|f'|P[0,f']. \tag{3.2}$$

The same approach is used to determine the density of any point singularity: we use the known statistics of the function to calculate the probability of finding a singularity in a small element centered on a randomly chosen test point, and equate this to the density of singularities multiplied by the volume of the element.

As an elementary example, we can use (3.2) to determine the density of minima $\mathscr{D}^{(\min)}$ of $E_n(X)$ for the random matrix model (2.2). The density of minima might find physical applications, for example in determining the number of possible energetically stable configurations of complex molecules which can be obtained by varying configuration of the nuclei.

The first and second derivatives of $E_n(X)$,

$$E_n'=\frac{dE_n}{dX}=\partial H_{nn}, \quad E_n''=\frac{d^2E_n}{dX^2}=2\sum_{m\neq n}\frac{|\partial H_{nm}|^2}{(E_n-E_m)}-2E_n, \tag{3.3}$$

are independent, because they depend upon different matrix elements. We denote the distributions of the first two derivatives by $P[E']$ and $P[E'']$, respectively. The first derivative E' is Gaussian distributed with variance $2\sigma^2/\beta$, and with a mean value which is zero for the model (2.2), but which may have a non-zero value $\langle E'\rangle$ in physical applications. The distribution of the second derivative is difficult to calculate: when the matrix dimension N is large, an excellent approximation[22] is

$$P[E'']=\frac{C_\beta}{[a_\beta^2+E''^2]^{(\beta+2)/2}}, \tag{3.4}$$

which is also an exact result for the GUE in the limit $N\to\infty$.[23] The constants C_β are given in Refs. 4,5,

$$C_1=2\pi^2\rho^2\sigma^4, \quad C_2=2^4\pi^2\rho^3\sigma^6, \quad C_4=2^8\pi^4\rho^5\sigma^{10}/3, \tag{3.5}$$

and the a_β are then determined by normalizing the distribution: we find $a_1=2\pi\rho\sigma^2$ and $a_1=a_2=a_4$. The density of minima can now be calculated by using (3.2) to calculate the density of zeros of $E_n'(X)$, and dividing by two because half of the extrema of $E_n(X)$ are maxima:

$$\mathscr{D}_\beta^{(\min)}=P[E'=0]\int_0^\infty dE''|E''|P[E'']=C_\beta^{(\min)}\rho\sigma\,\exp\left[\frac{-\beta\langle E'\rangle^2}{4\sigma^2}\right], \tag{3.6}$$

with dimensionless constants

$$C_1^{(\min)}=\frac{\sqrt{\pi}}{2}, \quad C_2^{(\min)}=\sqrt{\frac{2}{\pi}}, \quad C_4^{(\min)}=\frac{4}{3\sqrt{\pi}}. \tag{3.7}$$

These results are exact for the GUE in the limit $N\to\infty$, and at least a very good approximation for the GOE and GSE.

IV. REVIEW OF RESULTS ON DENSITY OF SINGULARITIES

Below we discuss the various other types of singularity of the spectrum which are of interest and their physical significance, and review the existing results on their density. All of the results are exact for the random matrix models introduced in Sec. II in the limit $N\to\infty$.

A. Degeneracies

A degeneracy occurs when two or more energy levels are equal for some real valued point in parameter space; in practice we will only be interested in degeneracies between pairs of levels, because higher order degeneracies have a higher codimension. Generically, two parameters must be varied in a family of real symmetric matrices to create a degeneracy, three parameters in a family of Hermitean matrices, and five parameters in a family of quaternion symmetric matrices.[24] We will therefore consider the density of degeneracies in the model (2.5) with $d=2,3,5$ for the GOE, GUE and GSE versions, respectively.

An interesting example of the importance of degeneracies is given by Simon,[15] who shows that the Chern integers describing the quantized Hall conductance[16] change, typically by ± 1, at degeneracies. Degeneracies can also enable other invariant quantities to change; for example the center of symmetry associated with Wannier functions of a Bloch band can change discontinuously when the band touches a neighboring band at some point in the Brillouin zone.

The density of degeneracies for the parametrized ensembles is defined in a space of $\beta+1$ parameters, and their density is

$$\mathscr{D}_\beta^{(\mathrm{deg})} = C_\beta^{(\mathrm{deg})} (\rho\sigma)^{\beta+1}, \tag{4.1}$$

with dimensionless prefactors

$$C_1^{(\mathrm{deg})} = \frac{\pi}{3}, \quad C_2^{(\mathrm{deg})} = \frac{2\sqrt{\pi}}{3}, \quad C_4^{(\mathrm{deg})} = \frac{16\sqrt{2}\,\pi^{3/2}}{45}; \tag{4.2}$$

$C_1^{(\mathrm{deg})}$ was derived in Ref. 9 and $C_2^{(\mathrm{deg})}$ was quoted in Ref. 10 without a full derivation. An estimate consistent with (4.1) was given in an earlier paper[25] for the special case of billiards, without an accurate value of the prefactor. The derivations of $C_2^{(\mathrm{deg})}$ and $C_4^{(\mathrm{deg})}$ will be given in Sec. V and in an Appendix, respectively.

In the neighborhood of a degeneracy, the separation $\Delta = E_{n+1} - E_n$ of the degenerating levels is given by the square root of a quadratic form; for example in the case of a system such as the GOE, where the Hamiltonian is real, we can write

$$\Delta^2 = A_{11}\delta X_1^2 + A_{22}\delta X_2^2 + 2A_{12}\delta X_1 \delta X_2 + O(\delta X^3). \tag{4.3}$$

This quadratic form can be defined by the orientation, eccentricity, and size of the elliptical level curves of Δ. For the model (2.5), the orientation of the ellipses is random, and the other parameters are defined by the trace $t = A_{11} + A_{22}$ and determinant $d = A_{11}A_{22} - A_{12}^2$ of the matrix which represents the quadratic form. The joint distribution of the trace and determinant has been calculated:[9] it is

$$P[t,d] = \frac{d}{256\sigma^6} \exp\left(\frac{-t}{8\sigma^2} \right), \tag{4.4}$$

within the physically allowed region $t>0$, $d>0$, $d \leqslant \frac{1}{2}t^2$. Other statistics describing the elliptical contours of Δ can be obtained directly from this simple result; for example the distribution of eccentricity e of the ellipses is

$$P[e] = \left(\frac{2e}{2-e^2} \right)^3. \tag{4.5}$$

The distribution of parameters of the quadratic form for the unitary and symplectic ensembles is not known.

B. Avoided crossings

When a single parameter is varied, energy levels of systems without symmetries never cross,[26] but they can approach each other very closely at events called avoided crossings. When the separation of a pair of energy levels is very small compared to their separation from all of the other levels, the structure of these avoided crossings can be understood using degenerate perturbation theory for a two level system: provided the Hamiltonian is a regular function of parameter in the neighborhood of the near-degeneracy, the levels have a hyperbolic form,

$$E_{\pm}(X) \sim B(X-X_0) \pm \frac{1}{2}\sqrt{\epsilon^2 + A^2(X-X_0)^2}. \tag{4.6}$$

The avoided crossing is characterized by four parameters, the gap ϵ, the difference of the asymptotic slopes A, the mean of the asymptotic slopes B, and the position X_0.

Avoided crossings are physically important because they mediate the breakdown of the adiabatic theorem by Landau-Zener transitions,[11,12,3] and in Sec. VI we will show that they determine the form of singular terms in the expansion of correlation functions such as (1.1).

The density of avoided crossings can be defined as follows: $\mathscr{D}_\beta^{(\mathrm{ac})}(A,B,\epsilon)dAdBd\epsilon dX$ is the expected number of avoided crossings between a given pair of successive levels, in an interval of length dX, for which the slope difference, mean slope, and gap parameters all lie in intervals of widths, respectively, dA, dB, $d\epsilon$, centered on the values A, B, ϵ. This statistic is only meaningful for small values of ϵ, because A and B are only defined for avoided crossings with gaps which are very small compared to the mean level separation $1/\rho$. The avoided crossing density is calculated by exactly the same approach as for the density of degeneracies, although the calculation is somewhat more difficult: the result, obtained in Refs. 3 and 5 is

$$\mathscr{D}_\beta^{(\mathrm{ac})}(A,B,\epsilon)dAdBd\epsilon = P[B]dBC_\beta^{(\mathrm{ac})}(\rho/\sigma)^{\beta+1}\epsilon^{\beta-1}d\epsilon A^{\beta+1}\ \exp[-\beta A^2/8\sigma^2]dA, \tag{4.7}$$

where $P[B]dB$ is a Gaussian distribution, with variance σ^2/β, and

$$C_1^{(\mathrm{ac})} = \frac{\pi}{24}, \quad C_2^{(\mathrm{ac})} = \frac{\pi^{3/2}}{12}, \quad C_4^{(\mathrm{ac})} = \frac{8\pi^{7/2}}{135\sqrt{2}}. \tag{4.8}$$

C. Branch points

Degeneracies between levels of the one parameter model (2.2) can occur for complex values of X; these degeneracies have a branch point structure. The branch points are important because they are used to determine the exponents describing the probability of non-adiabatic transitions.[13,14] Branch points can be identified with a particular pair of levels by considering a closed path in the complex X plane which leaves the real axis and loops around one, and only one, branch point. For all but one of the levels indices n, the energy level $E_n(X)$ is single valued when traced around this path, but one level, E_m say, is continuously transformed into another level $E_{m'}$ when traced around this path. The levels with indices m, m' are connected by the branch point.

We define $\mathscr{D}_\beta^{(\mathrm{br})}(Y,N)dY$ to be the frequency with which we encounter branch points involving the nth level and the level $n+N$, with the imaginary part of the parameter X in an interval of width dY centered on Y.

We have only been able to find the density of branch points for $N=1$ and small Y. Branch points very close to the real axis are associated with avoided crossings with very small values of ϵ: the distance of the branch point from the real axis is ϵ/A. The density of these branch points is obtained immediately from (4.7) and (4.8):

$$\mathscr{D}_\beta^{(\mathrm{br})}(Y,1)=\int_0^\infty dA\int_{-\infty}^\infty dB\int_0^\infty d\epsilon\,\mathscr{D}^{(\mathrm{ac})}(A,B,\epsilon)\,\delta\left(\ Y-\frac{\epsilon}{A}\ \right)$$

$$=C_\beta^{(\mathrm{br})}(\rho\sigma)^{\beta+1}Y^{\beta-1}, \tag{4.9}$$

with dimensionless constants

$$C_1^{(\mathrm{br})}=\frac{4\pi}{3},\quad C_2^{(\mathrm{br})}=\frac{16\pi^{3/2}}{3},\quad C_4^{(\mathrm{br})}=\frac{2^{10}\pi^{7/2}}{45\sqrt{2}}. \tag{4.10}$$

Guarneri *et al.*[8] gave an argument for an expression of the form (4.9), but did not obtain the prefactors (4.10).

V. DENSITY OF DEGENERACIES

We now discuss how to determine the density of degeneracies. This has already been described in detail for the Gaussian orthogonal ensemble,[9] and the result for the Gaussian unitary ensemble has also been quoted in an earlier paper.[10] Here we discuss the GUE case in detail, presenting details of the calculation which were omitted in Ref. 10; the calculation for the GSE case is similar, and is discussed in an Appendix.

Following the approach introduced in Sec. III, we select an arbitrary point in parameter space $\mathbf{X}_0$. We assume that this point is close to a degeneracy between levels with indices n and $n+1$. In the neighborhood of this point we represent the Hamiltonian in the basis formed by the eigenfunctions $|\psi_n(\mathbf{X}_0)\rangle$ at $\mathbf{X}_0$, and apply two-state degenerate perturbation theory. The separation of the nearly degenerate levels at a nearby position $\mathbf{X}=\mathbf{X}_0+\delta\mathbf{X}$ is

$$E_{n+1}-E_n\sim\sqrt{\left[\Delta+\sum_i\ (\partial_i H_{n+1\,n+1}-\partial_i H_{nn})\,\delta X_i\right]^2+4\left|\sum_i\ \partial_i H_{nn+1}\delta X_i\right|^2}\quad , \tag{5.1}$$

where $\Delta=E_{n+1}(\mathbf{X}_0)-E_n(\mathbf{X}_0)$. Within this approximation the degeneracy occurs when the discriminant (5.1) vanishes, at a displacement $\delta\mathbf{X}$ from $\mathbf{X}_0$. The components δX_i of this displacement are given by solving a system of linear equations:

$$\sum_{j=1}^3 M_{ij}\delta X_j=\Delta\,\delta_{1j}\,, \tag{5.2}$$

where the elements of the 3×3 matrix $\widetilde{M}=\{M_{ij}\}$ are

$$\begin{aligned} M_{1j}&=\partial_j H_{n+1\,n+1}-\partial_j H_{nn}\,,\\ M_{2j}&=2\ \mathrm{Re}[\partial_j H_{nn+1}],\quad M_{3j}=2\ \mathrm{Im}[\partial_j H_{nn+1}]. \end{aligned} \tag{5.3}$$

Note that the M_{ij} are elements of a real, non-symmetric, random matrix $\widetilde{M}$ with statistically independent elements, all of which are identically Gaussian distributed, with variance $2\sigma^2$ and mean 0.

The distance from the reference point to the degeneracy, $R=|\delta\mathbf{X}|$, is proportional to Δ: we write $R=\Delta f$ where

$$f^2=\sum_{i=1}^3\ [(\widetilde{M}^{-1})_{i1}]^2. \tag{5.4}$$

The probability $P[R]$ that the nearest degeneracy exists at a small distance R can then be written, by analogy with (3.2),

$$P[R]=\int_0^\infty df\int_0^\infty d\Delta P[f]P[\Delta]\delta(R-f\Delta), \tag{5.5}$$

where $P[f]$ is the probability distribution for f, and $P[\Delta]$ is the distribution of neighboring energy level separations: these quantities are independent because of the statistical independence of $\hat{H}$ and $\partial_i\hat{H}$ (note that Δ depends only upon $\hat{H}$ whereas f depends only upon the matrix elements $\partial_i H_{nm}$). The distribution $P[\Delta]$ is the well known level spacing distribution.[1,2] When R is small, the Dirac delta function only supports small values of Δ, for which the level spacing distribution is known analytically[2] in the limit $N\to\infty$:

$$P[\Delta]d\Delta=\left[\frac{1}{3}\pi^2\rho^3\Delta^2+O(\Delta^3)\right]d\Delta, \tag{5.6}$$

where ρ is the density of states. Performing the integrals in (5.5) gives

$$P[R]=\left[\frac{1}{3}\pi^2\rho^3\langle f^{-3}\rangle R^2+O(R^3)\right]dR. \tag{5.7}$$

The expected number of degeneracies in a spherical shell of radius R and thickness dR is $4\pi\mathscr{D}_2^{(\mathrm{deg})}R^2dR$; comparing this with (5.7) gives

$$\mathscr{D}_2^{(\mathrm{deg})}=\frac{1}{12}\pi\rho^3\langle f^{-3}\rangle. \tag{5.8}$$

It remains to evaluate the integral $I=\langle f^{-3}\rangle$, by averaging over the probability density

$$dP=P[\tilde{M}]d\tilde{M}=P[M_{11},M_{12},\ldots,M_{33}]\prod_{ij}dM_{ij}=A\exp\left[-\frac{\mathrm{tr}(\tilde{M}^T\tilde{M})}{4\sigma^2}\right]d\tilde{M}, \tag{5.9}$$

where A is a normalization factor. To facilitate the calculation of the average, the non-symmetric real matrix $\tilde{M}$ is decomposed into a product of two orthogonal matrices $\tilde{O}_1$, $\tilde{O}_2$, and a diagonal matrix $\tilde{D}$:

$$\tilde{M}=\tilde{O}_1^T\tilde{D}\tilde{O}_2. \tag{5.10}$$

This gives a useful simplification of the expression for f:

$$f^2=\sum_{i=1}^3[(\tilde{O}_1^T\tilde{D}\tilde{O}_2)^{-1}]_{i1}^2=\sum_{i=1}^3[\tilde{O}_2^T\tilde{D}^{-1}\tilde{O}_1)_{i1}]^2=\sum_{i=1}^3\lambda_i^{-2}(\tilde{O}_1)_{i1}^2, \tag{5.11}$$

where λ_i is the ith diagonal element of $\tilde{D}$. Also, the trace in (5.9) takes on a simple form when we use (5.10):

$$\mathrm{tr}(\tilde{M}^T\tilde{M})=\mathrm{tr}(\tilde{D}^2)=\sum_{i=1}^3\lambda_i^2. \tag{5.12}$$

We can now calculate $\langle f^{-3}\rangle$ by transforming from the coordinates $\{M_{ij}\}$ to a set of coordinates consisting of the three diagonal elements of $\tilde{D}$, and two sets of three coordinates

$\alpha=\{\alpha_1,\alpha_2,\alpha_3\}$ and $\beta=\{\beta_1,\beta_2,\beta_3\}$ which parametrize the orthogonal matrices $\widetilde{O}_1$ and $\widetilde{O}_2$, respectively. The Jacobian J of the coordinate transformation is defined by

$$d\widetilde{M}=Jd\alpha_1 d\alpha_2 d\alpha_3 d\beta_1 d\beta_2 d\beta_3 d\lambda_1 d\lambda_2 d\lambda_3, \tag{5.13}$$

where $J=|\det\widetilde{j}\,|$ and $\widetilde{j}$ is composed of three, 9×3 blocks:

$$\widetilde{j}=\left(\frac{\partial\widetilde{M}}{\partial\lambda}\,\middle|\,\frac{\partial\widetilde{M}}{\partial\alpha}\,\middle|\,\frac{\partial\widetilde{M}}{\partial\beta}\right). \tag{5.14}$$

In the first block, the elements of the type $\partial M_{ij}/\partial\lambda_k$ are independent of the λ_i. In the second block the elements $\partial M_{ij}/\partial\alpha_k$ are linear in the λ_i; the same applies for the third block. Expanding out the determinant, we find that all the terms which contribute to J are 6th degree polynomials in the λ_i. Furthermore, If $\lambda_i=\pm\lambda_j$ for any i,j, then there exists at least one coordinate for the orthogonal matrices $\widetilde{O}_1$, $\widetilde{O}_2$ which does not affect the matrix $\widetilde{M}$. This implies that the Jacobian J must vanish whenever $\lambda_i=\pm\lambda_j$. These observations lead to a unique form for the Jacobian,

$$J=g(\alpha)g(\beta)\prod_{\substack{i,j=1\\ i>j}}^{3}|\lambda_i^2-\lambda_j^2|, \tag{5.15}$$

where $g(\alpha)d\alpha_1 d\alpha_2 d\alpha_3$ is an invariant measure for the orthogonal group. The probability measure in the transformed coordinates is therefore

$$dP=Ag(\alpha)g(\beta)\prod_{\substack{i,j=1\\ i>j}}^{3}|\lambda_i^2-\lambda_j^2|\exp\left[-\frac{1}{4\sigma^2}\sum_{k=1}^{3}\lambda_k^2\right]\prod_{i=1}^{3}d\alpha_i d\beta_i d\lambda_i. \tag{5.16}$$

We can now use (5.11) and (5.16) to evaluate $\langle f^{-3}\rangle$. The three elements $(\widetilde{O}_1)_{i1}$ in (5.11) are components of a unit vector with random direction, and can easily be represented using polar coordinates θ, ϕ. The required average is then

$$\langle f^{-3}\rangle=I_1/I_2,$$

$$I_1=\int d\lambda P[\lambda]\int_0^{\pi}d\theta\,\sin\,\theta\int_0^{2\pi}d\phi(\lambda_1^{-2}\cos^2\,\theta+\lambda_2^{-2}\sin^2\,\theta\sin^2\,\phi+\lambda_3^{-2}\sin^2\,\theta\cos^2\,\phi)^{-3/2} \tag{5.17}$$

$$I_2=\int d\lambda P[\lambda]\int_0^{\pi}d\theta\,\sin\,\theta\int_0^{2\pi}d\phi,$$

where $P[\lambda]$ is the product of the polynomial and exponential in (5.16). After performing the integrals over θ and ϕ, we find

$$\langle f^{-3}\rangle=\frac{\sqrt{8}\sigma^3\mathscr{I}(1,\frac{1}{2},3)}{\mathscr{I}(\frac{1}{2},\frac{1}{2},3)}, \tag{5.18}$$

where the $\mathscr{I}(\alpha,\gamma,n)$ are integrals obtained from results derived by Selberg[27] and Aomoto,[28] quoted by Mehta,[2]

$$\mathscr{I}(\alpha,\gamma,n)=\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\prod_{i=1}^{n}|x_i|^{2\alpha-1}\prod_{1\leqslant j<i\leqslant n}|x_i^2-x_j^2|^{2\gamma}\exp\left[\frac{-x_i^2}{2}\right]dx_i$$

$$=2^{\alpha n+\gamma n(n-1)}\prod_{j=1}^{n}\frac{\Gamma(1+\gamma j)\Gamma(\alpha+\gamma(j-1))}{\Gamma(1+\gamma)}. \tag{4.29}$$

We find $\mathscr{I}(1,\frac{1}{2},3)=96$, $\mathscr{I}(\frac{1}{2},\frac{1}{2},3)=24\sqrt{2\pi}$, so that $\langle f^{-3}\rangle=8\sigma^3/\sqrt{\pi}$. The density of degeneracies is therefore $\mathscr{D}_2^{(\mathrm{deg})}=\frac{2}{3}\sqrt{\pi}\rho^3\sigma^3$.

VI. SINGULARITIES OF CORRELATION FUNCTIONS

Now we discuss how the singularities of the energy levels are related to singularities of the correlation function $C(X)$ defined in (1.1). Our contribution builds upon work of Guarneri *et al.*,[8] who showed that the Fourier transform of $C(X)$ has a power law decay as $|k|\to\infty$:

$$\widetilde{C}(k)\sim\frac{\alpha_\beta\sigma}{\rho}\left(\frac{\rho\sigma}{|k|}\right)^{\beta+2}, \tag{6.1}$$

where we will define the Fourier transform $\widetilde{f}(k)$ of $f(x)$ as follows:

$$\widetilde{f}(k)=\int_{-\infty}^{\infty}dx f(x)\exp[ikx]. \tag{6.2}$$

Guarneri *et al.* were not able to determine the coefficients α_β; we will show how they can be obtained using the results of Sec. IV B. They showed that the power law decay is caused by avoided crossings with small values of the gap parameter ϵ, and deduced that the algebraic decay of $\widetilde{C}(k)$ implies that $C(X)$ has a non-analytic behavior at $X=0$. Using the generalized Fourier transform pairs,[29]

$$\widetilde{f}(k)=\frac{1}{|k|^3}\Leftrightarrow f(x)=\frac{1}{2\pi}x^2\left(\log|x|+\gamma-\frac{3}{2}\right), \tag{6.3a}$$

$$\widetilde{f}(k)=\frac{1}{k^4}\Leftrightarrow f(x)=\frac{1}{12}|x|^3, \tag{6.3b}$$

$$\widetilde{f}(k)=\frac{1}{k^6}\Leftrightarrow f(x)=-\frac{1}{240}|x|^5, \tag{6.3c}$$

it can be seen that (6.1) implies the existence of non-analytic terms in the expansion of the correlation function about $X=0$. Expressed in terms of the natural dimensionless variable $x=\rho\sigma X$, the behaviour of $C(x)$ up to and including the leading non-analytic term is

$$C(x)=2\sigma^2[1+\gamma_1|x|^2\log|x|+\cdots]\quad(\mathrm{GOE}), \tag{6.4a}$$

$$C(x)=\sigma^2[1+C_2^{(2)}x^2+\gamma_2|x|^3+\cdots]\quad(\mathrm{GUE}), \tag{6.4b}$$

$$C(x)=\tfrac{1}{2}\sigma^2[1+C_4^{(2)}x^2+C_4^{(4)}x^4+\gamma_4|x|^5+\cdots]\quad(\mathrm{GSE}). \tag{6.4c}$$

The coefficients of the power series expansion are obtained by a straightforward application of perturbation theory: the quadratic terms were calculated by Simons and Altshuler,[6] and take the values $C_2^{(2)}=-2\pi^2$ and $C_4^{(2)}=-\frac{4}{3}\pi^2$, respectively; the coefficient $C_4^{(4)}$ could also be determined by the same method. The higher order coefficients of the power series expansion diverge because of the effects of small denominators. We will now calculate the coefficients α_β in (6.1), enabling the coefficients γ_β of the singular terms to be identified.

We will find it convenient to assume that the energy levels are periodic in X, with period L, so that the energy level $E_n(X)$ can be expanded as a Fourier series:

$$E_n(X)=\sum_{m=-\infty}^{\infty} a_m \exp\left[\frac{2\pi i m X}{L}\right]. \tag{6.5}$$

Later we will consider the limit $L\to\infty$. The correlation function $C(X)$ will be defined in terms of an average over the length L, which is conveniently expressed in terms of the Fourier coefficients a_m:

$$C(X)=\frac{1}{L}\int_0^L dX' E_n'(X+X')E_n'(X')=\sum_{m=-\infty}^{\infty}\left(\frac{2\pi m}{L}\right)^2 |a_m|^2 \exp\left[\frac{2\pi i m X}{L}\right]. \tag{6.6}$$

For large m, the Fourier coefficients are determined by singularities of $E_n(X)$ closest to the real axis. These are branch points associated with the avoided crossings with small values of the gap parameter ϵ. In order to calculate the effect of these singularities on the Fourier coefficients, we will assume that the second derivative of the energy can be approximated by a sum of contributions from the avoided crossings:

$$E_n''(X)\sim\sum_j (-1)^{P_j} f(X-X_j,A_j,\epsilon_j), \tag{6.7}$$

where A_j, ϵ_j, and X_j are the parameters of the jth avoided crossing. (It is more convenient to use the second derivative, since this approaches zero at $\pm\infty$.) Here the sum runs over all avoided crossings between 0 and L, P_j is zero if the avoided crossing is with a level below, unity for crossing with a level above, and $f(X,A,\epsilon)$ is the second derivative of the energy associated with a single avoided crossing with slope and gap parameters (A,ϵ) at position $X=0$:

$$f(X,A,\epsilon)=\frac{A^2\epsilon^2}{2(A^2X^2+\epsilon^2)^{3/2}}. \tag{6.8}$$

Using (6.7) to estimate the Fourier coefficients a_m, and we find

$$\begin{aligned} a_m &= -\left(\frac{2\pi m}{L}\right)^{-2}\frac{1}{L}\sum_j (-1)^{P_j}\int_0^L dx f(x-X_j,A_j,\epsilon_j) \\ &\sim -\frac{1}{k^2 L}\sum_j (-1)^{P_j}\exp[ikX_j]\tilde{f}(k,A_j,\epsilon_j), \end{aligned} \tag{6.9}$$

where $k=2\pi m/L$, and $\tilde{f}(k,A,\epsilon)$ is the Fourier transform of $f(X,A,\epsilon)$ with respect to X: in the second relation we have assumed that L is sufficiently large that, for all the avoided crossings except those close to $X_j=0$ or $X_j=L$, the errors associated with taking the limits of integration to infinity can be neglected. Using (6.9) to estimate $|a_m|^2$ gives an expression involving a double sum over pairs of avoided crossings. The positions X_j of the narrowly avoided crossings can be

assumed to be random, implying that the average over off-diagonal terms of the double sum containing the phase factor $\exp[ik(X_j - X_{j'})]$ vanishes. We can therefore write

$$|a_m|^2 \sim \frac{1}{k^4 L^2} \sum_j |\tilde{f}(k, A_j, \epsilon_j)|^2$$

$$\sim \frac{2}{k^4 L} \int_0^\infty dA \int_\infty^\infty dB \int_0^\infty d\epsilon \, \mathscr{D}_\beta^{(\mathrm{deg})}(A,B,\epsilon) |\tilde{f}(k,A,\epsilon)|^2, \tag{6.10}$$

where $\mathscr{D}_\beta^{(\mathrm{deg})}$ is the density of avoided crossings defined in Sec. IV B, and the factor of 2 is included because avoided crossings with both the levels above and below must be considered.

The Fourier transform of (6.8) is

$$\tilde{f}(k,A,\epsilon) = k\epsilon K_1(k\epsilon/A), \tag{6.11}$$

where $K_1(x)$ is the Bessel function with imaginary argument.[30,31] In the limit $L \to \infty$ we can approximate the sum in (6.6) as an integral, and using (6.10) we write

$$C(X) = \frac{1}{2\pi} \int_{-\infty}^\infty dk \, \exp[-ikX] \tilde{C}(k), \tag{6.12}$$

$$\tilde{C}(k) = \frac{2}{k^2} \int_0^\infty dA \int_{-\infty}^\infty dB \int_0^\infty d\epsilon \, \mathscr{D}_\beta^{(\mathrm{deg})}(A,B,\epsilon) |\tilde{f}(k,A,\epsilon)|^2$$

$$= \frac{2 C_\beta^{(\mathrm{ac})}}{k^{(\beta+2)}} \left(\frac{\rho}{\sigma} \right)^{\beta+1} \int_0^\infty dA A^{2\beta+3} \exp\left[\frac{-\beta A^2}{8\sigma^2} \right] \int_0^\infty dx x^{\beta+1} |K_1(x)|^2,$$

where we have used (4.7). Using the integral identity[31]

$$\int_0^\infty dx \, x^\nu |K_1(x)|^2 = \frac{2^{\nu-6}(\nu+1)(\nu-1)^3 [\Gamma(\frac{1}{2}(\nu-1))]^4}{\Gamma(\nu+1)}, \tag{6.13}$$

we find that $\tilde{C}(k)$ is in the form (6.1), with dimensionless constants

$$\alpha_1 = 4\pi^3, \quad \alpha_2 = \frac{256\pi^{3/2}}{3}, \quad \alpha_4 = \frac{2^{14}\sqrt{2}\pi^{7/2}}{45}. \tag{6.14}$$

Expressed in terms of the dimensionless variable $x = \rho\sigma X$, the correlation function, up to and including the first singular term, is therefore

$$C(x) = 2\sigma^2 [1 - \pi^2 x^2 \log|x| + \cdots] \quad \text{(GOE)},$$

$$C(x) = \sigma^2 \left[1 - 2\pi^2 x^2 - \frac{64\pi^{3/2}}{9} |x|^3 + \cdots \right] \quad \text{(GUE)}, \tag{6.15}$$

$$C(x) = \tfrac{1}{2}\sigma^2 \left[1 - \frac{4\pi^2}{3} x^2 + C_4^{(4)} x^4 + \frac{2048\sqrt{2}\pi^{7/2}}{675} |x|^5 + \ldots \right] \quad \text{(GSE)}.$$

ACKNOWLEDGMENTS

We thank Nilanjana Datta for helpful discussions about the calculation in Sec. VI. Much of this paper was written while M.W. and M.J.S. were attending the program ''Chaos and Quantisation'' at the Institut Henri Poincaré, Paris; we thank the organizers for their hospitality.

This work was supported by the EPSRC, Research Grant Reference No. GR/H94337. M.J.S. is supported by a Thalmann fellowship of the Universidad de Buenos Aires, Argentina.

APPENDIX: THE DENSITY OF DEGENERACIES FOR THE GSE

Here we discuss the density of degeneracies $\mathscr{D}_4^{(\mathrm{deg})}$ for a parametrized Gaussian symplectic ensemble. The method employed is the same as that for the GUE, and so can be presented briefly.

The quaternion elements $\mathbf{e}_k$ can be represented by the 2×2 matrices:

$$\mathbf{e}_0=\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix},\quad \mathbf{e}_1=\begin{pmatrix}i & 0\\ 0 & -i\end{pmatrix},\quad \mathbf{e}_2=\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix},\quad \mathbf{e}_3=\begin{pmatrix}0 & i\\ i & 0\end{pmatrix}, \tag{A1}$$

enabling the GSE matrix to be represented by a $2N\times 2N$ real matrix, which has N, 2–fold degenerate eigenvalues: this (Kramer's) degeneracy will be neglected, and we will calculate the density of degeneracies between pairs of these double levels. Five parameters must be varied in order to create these degeneracies.

The condition for a degeneracy between levels n and $n+1$ to be at a distance $\delta\mathbf{X}$ from an arbitrary point can be written in a form analogous to (5.2), where $\widetilde{M}$ is now a 5×5 matrix with elements

$$\begin{aligned} M_{1j}&=[\partial_j\widetilde{H}^{(S)}]_{nn}-[\partial_j\widetilde{H}^{(S)}]_{n+1\,n+1},\\ M_{2j}&=2[\partial_j\widetilde{H}^{(S)}]_{nn+1},\\ M_{ij}&=2[\partial_j\widetilde{H}^{(A)}_{i-2}]_{nn+1},\quad i=3,4,5. \end{aligned} \tag{A2}$$

Again $\widetilde{M}=\{M_{ij}\}$ is a non-symmetric real matrix with independent, Gaussian distributed elements, with mean value zero; the variance is σ^2 in this case.

The Euclidean length of the vector which solves (5.2) is again written $R=\Delta f$, and following the GUE analysis we find the probability $P[R]dR$ that the nearest degeneracy lies in a shell of thickness dR at distance R. Using the fact that for the GSE, the level spacing distribution is $P[\Delta]d\Delta\sim\frac{16}{135}\pi^4\rho^5\Delta^4 d\Delta$ for $\Delta\rho\ll 1$, $N\gg 1$, we find

$$P[R]\sim\frac{16}{135}\pi^4\rho^5R^4\langle f^{-5}\rangle, \tag{A3}$$

which is valid for small R. The expected number of degeneracies in this shell is $P[R]dR=\frac{8}{3}\pi^2R^4\mathscr{D}_4^{(\mathrm{deg})}dR$ implying that the density of degeneracies for the parameterized GSE is

$$\mathscr{D}_4^{(\mathrm{deg})}=\frac{2}{45}\pi^2\rho^5\langle f^{-5}\rangle. \tag{A4}$$

The integral $I=\langle f^{-5}\rangle$ can be evaluated using the same approach as that used for $\langle f^{-3}\rangle$ in Sec. V, using the decomposition of $\widetilde{M}$ given by (5.10). After some algebra, the original 25 dimensional integral over the M_{ij} is reduced to the quotient of two five dimensional integrals:

$$\langle f^{-5}\rangle = \frac{\sigma^5 \mathscr{I}(1,\frac{1}{2},5)}{\mathscr{I}(\frac{1}{2},\frac{1}{2},5)} = \frac{16\sigma^5}{\sqrt{2\pi}}, \tag{A5}$$

where $\mathscr{I}(\alpha,\gamma,n)$ is the integral (5.19). Combining (A4) and (A5), we then find $\mathscr{D}_4^{(\mathrm{deg})} = (16\sqrt{2}\pi^{3/2}/45)\rho^5\sigma^5$.

(Received 9 May 1996; accepted for publication 17 June 1996)

We study the normalized trace $g_n(z)=n^{-1}\,\mathrm{tr}(H-zI)^{-1}$ of the resolvent of $n\times n$ real symmetric matrices $H=[(1+\delta_{jk})W_{jk}\sqrt{n}]_{j,k=1}^{n}$ assuming that their entries are independent but not necessarily identically distributed random variables. We develop a rigorous method of asymptotic analysis of moments of $g_n(z)$ for $|\Im z|\geqslant\eta_0$ where η_0 is determined by the second moment of W_{jk}. By using this method we find the asymptotic form of the expectation $\mathbf{E}\{g_n(z)\}$ and of the connected correlator $\mathbf{E}\{g_n(z_1)g_n(z_2)\}-\mathbf{E}\{g_n(z_1)\}\mathbf{E}\{g_n(z_2)\}$. We also prove that the centralized trace $ng_n(z)-\mathbf{E}\{ng_n(z)\}$ has the Gaussian distribution in the limit $n=\infty$. Based on these results we present heuristic arguments supporting the universality property of the local eigenvalue statistics for this class of random matrix ensembles. © *1996 American Institute of Physics.* [S0022-2488(96)01210-8]

I. INTRODUCTION

Since the pioneer works of Wigner and Dyson random matrix theory (RMT) has been successfully used to describe the energy levels of complex quantum systems: heavy nuclei, quantum chaotic systems, mesoscopic samples, etc. (see, e.g., Refs. 1–5). Another rather broad field of the RMT applications is related to quantum field theory: the large colour limit of QCD, two-dimensional (2D) quantum gravity and bosonic strings (see, e.g., Refs. 6–8).

The phenomenological nature of the RMT approach that may be regarded as its certain drawback on the one hand, provides, on the other hand, the model independent frameworks, that make the approach applicable to a wide variety of systems having different microscopic natures and origins. These frameworks assume a certain amount of ''robustness'' of the RMT models and results. In other words, it is believed that a ''sufficiently large'' number of them should have no dependence or a rather weak one on the random matrix ensemble used. This belief partly explains the fact that the majority of RMT ideas and applications are based on results obtained for the archetype Gaussian ensembles (GE's) and the circular ensembles (CE's). On the other hand, this belief requires a certain justification, in particular extending the results known for the GE's and for the CE's to other classes of ensembles.

The most frequently referred to are the Gaussian orthogonal ensemble (GOE) of random $n\times n$ symmetric matrices and the Gaussian Unitary Ensemble (GUE) of random $n\times n$ Hermitian matrices. The density of the probability distribution in these ensembles has the form

$$P_n(H)=Z_n^{-1}\,\exp[-n\,\mathrm{tr}\,F(H)], \tag{I.1}$$

[a)]On leave from B. I. Verkin Institute for Low Temperature Physics, Kharkov, 310164, Ukraine.

where $F(x)=x^2/4w^2$ and Z_n is the normalization constant.

The probability distribution (I.1) possesses two important properties: (i) it is invariant with respect to either orthogonal or unitary transformations of $\mathbf{R}^n$ or $\mathbf{C}^n$, respectively; and (ii) the matrix elements are independent random variables (modulo the obvious symmetry conditions).

These properties of the GE's determine them uniquely and motivate two classes of generalizations of the GE's.

The first class consists of ensembles having an orthogonal or unitary invariant but not necessarily matrix-element-independent probability distribution. The typical representatives are the ensembles with the probability distribution of the form (I.1) in which $F(x)$ is an arbitrary bounded below and growing fast enough on infinity function. These invariant ensembles can be used to describe physical systems having no preferential basis. They also arose in studying the large-n limit in quantum field theory[6–8] and later found other applications.[3,9,10]

Random matrices with invariant distributions show remarkable ''robustness'' (known as the universality) of spectral properties in the microscopic regime. In this regime one scales the energy so that the mean distance between nearest eigenvalues remains of the order of unity as the dimension of matrices increases.[1,11] Thus one is able to study properties of a finite number of eigenvalues. The universality of the level spacing distribution and other microscopic (local) spectral characteristics has been extensively discussed in recent theoretical physics and mathematical literature. We refer the reader to a number of publications: Refs. 11–16.

The second class consists of ensembles whose matrix elements in a certain basis are independent random variables, i.e., the ensemble probability distribution factorizes into a product of distributions of the matrix elements in this basis. The corresponding random matrices can be associated with physical systems having a preferential basis and appear, in particular, in condensed matter physics and theory of disordered systems. This second class goes back to Wigner[17] and we shall refer to the corresponding ensembles as Wigner ensembles (or Wigner matrices).

The subject of the present paper is the Wigner ensemble of $n\times n$ real symmetric matrices of the form

$$H=[H_{jk}]_{j,k=1}^{n}, \quad H_{jk}=(1+\delta_{jk})W_{jk}/\sqrt{n}, \tag{I.2}$$

where $W_{jk}, j\leqslant k$ are independent random variables such that

$$\mathbf{E}\{W_{jk}\}=0, \quad \mathbf{E}\{W_{jk}^2\}=w^2. \tag{I.3}$$

Here and thereafter $\mathbf{E}\{\cdot\}$ denotes averaging over all $W_{jk}, j\leqslant k$.

The distributions of W_{jk}'s may depend on (j,k), but we assume that they are independent of n. We make the latter assumption mainly for the sake of technical simplicity. On the other hand, this assumption allows one to consider all W_{jk} on the same probability space and to find an optimal form of a number of important facts related to the Wigner ensembles (for example, the convergence with probability 1 in formulae (I.7) and (I.11) below). If W_{jk}'s are independent Gaussian random variables, then the ensemble (I.2)–(I.3) coincides with the GOE. This justifies the presence of the term with δ_{jk} in Eq. (I.2).

Macroscopic properties of Wigner ensembles are more or less well understood. We call macroscopic the asymptotic regime in which the number of eigenvalues in unit energy interval is proportional to n. Discussing macroscopic properties of random matrices we have to mention first of all the density of states (DOS) which is the simplest macroscopic characteristic of the ensemble eigenvalue statistics. It turns out that under rather natural and mild conditions on the distributions of W_{jk} the DOS in the Wigner ensemble (I.2)–(I.3) does not depend on the form of the distributions of W_{jk}. This DOS is known as the Wigner semi-circle law (see Eq. (I.5) below). Other macroscopic spectral quantities such as the conductivity and the interband light absorption coefficient show the same ''robustness.''[18–20] Definition of these quantities requires some care for Wigner matrices. However, the conductivity and the interband light absorption coefficient can be

defined and computed for the so-called band random matrices and random operators with independent matrix elements that are quite close to the Wigner ensemble (I.2)–(I.3) in their macroscopic properties both technically and by results (see, e.g., Ref. 21). As for the microscopic scale, supersymmetry calculations[22] suggest ''robustness'' (universality) of spectral properties of the Wigner ensemble (I.2)–(I.3) as well but evidence of this has not been rigorously established so far.

Introduce the normalized eigenvalue counting function

$$N_n(E)=n^{-1}\#\{E_j:\ E_j \quad \text{is an eigenvalue of } H \text{ and } E_j\leqslant E\}. \tag{I.4}$$

Wigner at the end of the 1950s proved[17] that in the case of identically distributed W_{jk} having all moments $N_n(E)$ converges in probability as $n\to\infty$ to a non-decreasing function $N_{sc}(E)$ (the semi-circle law) whose derivative (DOS) is

$$\rho(E)=\begin{cases}\dfrac{1}{2\pi w^2}\sqrt{4w^2-E^2}, & |E|\leqslant 2w\\ 0, & |E|>2w.\end{cases} \tag{I.5}$$

The modern formulation of Wigner's result is as follows. Let us consider random matrices (I.2)–(I.3) with mutually independent arbitrary distributed entries defined on a common probability space. Then the condition (the matrix analogue of the Lindeberg condition of probability theory)

$$\lim_{n\to\infty}\frac{1}{n^2}\sum_{j\leqslant k}\int_{|x|>\nu n^{1/2}}x^2\ d\ \mathrm{Prob}[W_{jk}\leqslant x]=0, \quad \text{for any} \quad \nu>0, \tag{I.6}$$

is sufficient[23] and necessary[24] for the following limiting relation

$$\lim_{n\to\infty}N_n(E)=N_{sc}(E) \tag{I.7}$$

to hold for every E with probability 1.[25] If we will not assume that W_{jk} are defined on the same probability space or if their probability distributions depend on n, then the same condition (I.6) will imply the convergence in probability in Eq. (I.7)

As is usual in spectral theory, this result admits a natural reformulation in terms of the resolvent (Green's function). Indeed, the normalized trace of the resolvent

$$g_n(z)=n^{-1}\ \mathrm{tr}\ (H-zI)^{-1} \tag{I.8}$$

is simply the Stieltjes transform of $N_n(E)$:

$$g_n(z)=\frac{1}{n}\sum_{j=1}^{n}\frac{1}{E_j-z}=\int\frac{dN_n(E)}{E-z}. \tag{I.9}$$

Denote the Stieltjes transform of the Wigner law (I.5) by $r(z)$,

$$r(z)=\int\frac{N_{sc}(dE)}{E-z}=\frac{-z+\sqrt{z^2-4w^2}}{2w^2}. \tag{I.10}$$

The obvious condition $\Im r(z)\Im z\geqslant 0$ determines the branch of the square root in Eq. (I.10). Due to the one-to-one correspondence between non-decreasing functions and their Stieltjes transforms[26] Eq. (I.7) is equivalent to the following limiting relation

$$\lim_{n\to\infty} g_n(z)=r(z), \tag{I.11}$$

which holds with probability 1 for any non-real z.

The relation (I.11) and the obvious bound $|g_n(z)|\leqslant|\Im z|^{-1}$ imply that the variance of $g_n(z)$ vanishes as $n\to\infty$ and hence the moments

$$m_n^{(p)}(z_1,\ldots,z_p)=\mathbf{E}\left\{\prod_{l=1}^{p} g_n(z_l)\right\} \tag{I.12}$$

factorize:

$$m_n^{(p)}(z_1,\ldots,z_p)=\prod_{l=1}^{p} m_n^{(1)}(z_l)+o(1), \quad n\to\infty \tag{I.13}$$

This factorization, which follows already from the convergence in probability in Eq. (I.7) or in Eq. (I.11) , is typical for the macroscopic regime and can be found hidden behind many calculations in this regime. It has been known in fact since Refs. 17, 27, 23 and 28.

Since according to Eq. (I.11) $m_n^{(1)}(z)=\mathbf{E}\{g_n(z)\}=r(z)+o(1)$, the leading term of $m_n^{(p)}(z_1,\ldots,z_p)$ is $\Pi_{l=1}^{p} r(z_l)$. It seems interesting from a number of points of view to also find sub-leading terms and their dependence on the probability distributions of matrix elements. For instance these sub-leading terms are important when we would like to go beyond the macroscopic regime, when we are computing connected correlators of $g_n(z)$, etc.

For the Gaussian entries respective corrections were studied in Ref. 29 where the formal perturbation theory with respect to H_{jk} and the respective diagrammatic technique were applied. This approach is an adaptation of the technique developed in Ref. 30 in order to construct the $1/n$ expansion for the random operator describing disordered systems on $\mathbf{Z}^d$ with n orbitals per site.

In Ref. 31 we suggested an approach that allows for the rigorous treatment of this problem in the general case of independent and arbitrary but not necessarily identically distributed matrix elements. Our approach allows us to estimate remainders in respective asymptotic formulae and we show that these estimates are in a sense optimal. The approach is also free to a large extent from the cumbersome combinatorial problem of rearranging diagrams which is necessary in order to carry out various ''dressing'' procedures. In particular, the dressing procedure that replaces the ''bare'' Green function $-1/z$ by $\lim_{n\to\infty}\mathbf{E}\{g_n(z)\}$ is automatic in our approach. Following Ref. 31 one is able to find as many terms in the asymptotic expansion of $m_n^{(p)}(z_1,\ldots,z_p)$ as needed, though the technical difficulties increase with the order.

In the present paper we use the general scheme of Ref. 31 in order to compute first terms in the asymptotic expansion of $\mathbf{E}\{g_n(z)\}$. We also prove that if the distributions of W_{jk} satisfy the Lindeberg condition (I.6) with x^2 in the integral replaced by x^4, and if in addition to Eq. (I.3) the fourth moments of W_{jk} do not depend on (j,k), then

$$F_n(z_1,z_2)=m_n^{(2)}(z_1,z_2)-m_n^{(1)}(z_1)m_n^{(1)}(z_2)=n^{-2}f(z_1,z_2)+o(n^{-2}), \tag{I.14}$$

where

$$f(z_1,z_2)=\frac{2w^2}{[1-w^2r^2(z_1)][1-w^2r^2(z_2)]}\left[\frac{r(z_1)-r(z_2)}{z_1-z_2}\right]^2+\frac{2\sigma r^3(z_1)r^3(z_2)}{[1-w^2r^2(z_1)][1-w^2r^2(z_2)]} \tag{I.15}$$

and $\sigma=\mathbf{E}\{W_{jk}^4\}-3\mathbf{E}^2\{W_{jk}^2\}$ is the excess of W_{jk}. We also establish a limit theorem for the centralized trace $ng_n(z)-\mathbf{E}\{ng_n(z)\}$ of the resolvent.

Unfortunately, our approach gives an estimate for the remainder term in Eq. (I.14) containing a power of $|\Im z_1 \Im z_2|^{-1}$ as a factor. Thus we cannot treat rigorously the microscopic regime which requires $\Im z \propto 1/n$. On the other hand, the first term [Eq. (I.15)] of the asymptotic formula (I.14) is well defined in this regime and coincides with the respective exact expression known for the GOE, provided that the latter is considered for large level spacings and is smoothed over an interval Δ such that $1/n \ll |\Delta| \ll 1$ in proper units (see Section VI). We feel therefore, that by using our procedure of computing corrections, i.e., keeping the imaginary part of energy fixed when n goes to infinity and then letting $\Im z$ go to zero , one may treat energy intervals that are very large on the microscopic scale. On this intermediate scale the second term on the right-hand side (rhs) of Eq. (I.15) which contains the probability distribution excess σ vanishes and the above mentioned universality is restored.

Our article is organized as follows. In Section II we present our basic tools. In Section III we calculate first terms of the asymptotic expansion for $\mathbf{E}\{g_n(z)\}$. In Section IV we give a simple proof of Eqs. (I.14)–(I.15) with $o(n^{-2})$ replaced by $O(n^{-5/2})$ provided that the fifth absolute moment of W_{jk} is uniformly bounded. This result was cited without proof in Ref. 31. In Section V we treat the general case of W_{jk} satisfying the higher order Lindeberg condition mentioned above. We prove that the fluctuations of $ng_n(z)$ around its mean value become Gaussian in the limit $n \to \infty$ and that the covariance of the limiting Gaussian function is $f(z_1, z_2)$, thus proving Eqs. (I.14)–(I.15) in the general case. Section VI contains a discussion of some implications of our results.

II. PRELIMINARIES

In this section we present our basic technical tools.

(i) If ξ is a real-valued random variable such that $\mathbf{E}\{|\xi|^{p+2}\} < \infty$ and if $f(t)$ is a complex-valued function of a real variable such that its first $p+1$ derivatives are continuous and bounded, then

$$\mathbf{E}\{\xi f(\xi)\} = \sum_{a=0}^{p} \frac{\kappa_{a+1}}{a!} \mathbf{E}\{f^{(a)}(\xi)\} + \varepsilon, \tag{II.16}$$

where κ_a are the semi-invariants (cumulants) of ξ, $|\varepsilon| \leqslant C \sup_t |f^{(p+1)}(t)| \mathbf{E}\{|\xi|^{p+2}\}$ and the quantity C depends on p only.

The semi-invariants can be expressed in terms of the moments. If $\mathbf{E}\{\xi\} = 0$ (the case we shall deal with) and $\mu_a = \mathbf{E}\{\xi^a\}$, then a few such first relations are: $\kappa_1 = \mu_1 = 0$, $\kappa_2 = \mu_2$, $\kappa_3 = \mu_3$, $\kappa_4 = \mu_4 - 3\mu_2^2$, $\kappa_5 = \mu_5 - 10\mu_3\mu_2$, $\kappa_6 = \mu_6 - 15\mu_4\mu_2 - 10\mu_3^2 - 30\mu_2^3$, etc. For a Gaussian random variable with zero mean, all semi-invariants but κ_2 vanish and Eq. (II.16) reduces to the exact relation

$$\mathbf{E}\{\xi f(\xi)\} = \mathbf{E}\{\xi^2\} \mathbf{E}\{f'(\xi)\}, \tag{II.17}$$

which can directly be checked integrating the left-hand side (lhs) of Eq. (II.17) by parts. This is only the case when formula (II.16) contains a finite number of terms for non-polynomial f's. Indeed, according to the Marcynkiewicz theorem[32] if all but a finite number of cumulants are zero, then only the first and second can be non-zero.

(ii) For any matrix $A = [A_{\alpha\beta}]_{\alpha,\beta=1}^{n}$

$$\frac{\partial}{\partial A_{jk}} (A^{-1})_{\alpha\beta} = -(A^{-1})_{\alpha j} (A^{-1})_{k\beta}$$

provided A^{-1} exists. For the resolvent G of a real symmetric matrix H this becomes

$$\frac{\partial G_{\alpha\beta}}{\partial H_{jk}}=\begin{cases}-G_{\alpha j}G_{k\beta}, & j=k\\ -G_{\alpha j}G_{k\beta}-G_{\alpha k}G_{j\beta}, & j\neq k.\end{cases} \tag{II.18}$$

(iii) For any two real symmetric matrices and any non-real z the resolvent identity

$$(H_2-zI)^{-1}=(H_1-zI)^{-1}-(H_1-zI)^{-1}(H_2-H_1)(H_2-zI)^{-1} \tag{II.19}$$

is valid. In particular, if $H_2=H$, $H_1=0$ and $G=(H-zI)^{-1}$, then

$$G_{jm}=z^{-1}\delta_{jm}+z^{-1}\sum_{k=1}^{n} G_{jk}H_{km}. \tag{II.20}$$

Let H belong to the Wigner ensemble (I.2)–(I.3). For a fixed complex z consider complex-valued random variable $g_n(z)=n^{-1}\,\mathrm{tr}(H-zI)^{-1}$. Define its variance as

$$\mathbf{E}\{|g_n(z)-\mathbf{E}\{g_n(z)\}|^2\}=F_n(z,z^{\dagger}) \tag{II.21}$$

and define also the domain in the complex plane as follows

$$U_0=\{z\in\mathbf{C}_{\pm}:|\Im z|\geqslant 2w\}. \tag{II.22}$$

We use an asterisk to denote complex conjugate and the sub-index C to indicate centering to zero mean. For instance, $g_n^C(z)=g_n(z)-\mathbf{E}\{g_n(z)\}$ and thus we can rewrite Eq. (II.21) as

$$F_n(z,z^{\dagger})=\mathbf{E}\{|g_n^C(z)|^2\}=\mathbf{E}\{g_n(z)g_n^C(z^{\dagger})\}. \tag{II.23}$$

We will write $O(n^{-p})$ in asymptotic formulae for the remainders having a uniform (with respect $z\in U_0$) upper bound of the form Cn^{-p} where C does not depend on n. In fact the bounds we are able to derive contain $1/(1-|\Im z|^2/2w^2)$ (see, e.g., formula (II.29) below for the simplest case). Thus C is finite for any fixed z satisfying $|\Im z|>\sqrt{2}w$. But we prefer to use $|\Im z|\geqslant 2w$ in favor of uniformity of the bounds with respect to $z\in U_0$.

(iv) Let H belong to the Wigner ensemble (I.2)–(I.3). Assume that the fifth absolute moment of the random variables W_{jk} is uniformly bounded, i.e. $\sup_{j\leqslant k}\mathbf{E}\{|W_{jk}|^5\}<+\infty$, and that $z\in U_0$. Then

$$\mathbf{E}\{|g_n(z)-\mathbf{E}\{g_n(z)\}|^2\}=\mathbf{E}\{|g_n^C(z)|^2\}=O(n^{-2}),\quad \text{as } n\to\infty. \tag{II.24}$$

Let us comment on (i)–(iv). Facts (ii) and (iii) are well known. The ''decoupling'' formula (II.16) is simple to understand in the case when ξ has all moments and $f(x)$ belongs to the Schwartz space. Indeed, by using the Parseval relation for the Fourier transforms we can rewrite the lhs of Eq. (II.16) as

$$\frac{i}{2\pi}\int_{-\infty}^{\infty}\frac{d}{dt}F^{\dagger}(t)\Pi(t)dt=-\frac{i}{2\pi}\int_{-\infty}^{\infty}F^{\dagger}(t)\frac{d}{dt}\Pi(t)dt \tag{II.25}$$

where

$$F(t)=\int_{-\infty}^{\infty}e^{i\xi t}f(\xi)d\xi \quad\text{and}\quad \Pi(t)=\int_{-\infty}^{\infty}e^{i\xi t}dP(\xi)$$

are the Fourier transforms of $f(\xi)$ and of the probability distribution $P(\cdot)$ of ξ, respectively. Now, if we take into account that

$$\Pi(t)=\sum_{a=0}^{\infty}\frac{(it)^a\mu_a}{a!}\quad\text{and}\quad u(t)\equiv\log\,\Pi(t)=\sum_{a=1}^{\infty}\frac{(it)^a\kappa_a}{a!}$$

we can rewrite the rhs of Eq. (II.25) as

$$-\frac{i}{2\pi}\int_{-\infty}^{\infty}F^{\dagger}(t)u'(t)e^{u(t)}dt=-\frac{i}{2\pi}\sum_{a=0}^{\infty}\frac{\kappa_{a+1}}{a!}\int_{-\infty}^{\infty}(it)^{a+1}F^{\dagger}(t)\Pi(t)dt=\sum_{a=0}^{\infty}\frac{\kappa_{a+1}}{a!}\mathbf{E}\{f^{(a)}(\xi)\},$$

where we again used the Parseval relation. The latter formula is obviously Eq. (II.16) for $p=\infty$. The case when ξ has a finite number of moments and $f(\xi)$ has a respective number of derivatives requires certain technicalities which we will not discuss here.

The bound (iv) plays an important role in many questions of random matrix theory and its applications. In fact, it is the simplest of bounds for connected correlators (cumulants) of $g_n(z)$ or, more generally, for cumulants of linear statistics of the eigenvalues (i.e., sums $n^{-1}\Sigma_{j=0}^{n}\,\phi(E_j)$ where $\phi(E)$ is smooth enough). We are going to present a detailed derivation of these bounds and asymptotics (both for the Wigner ensembles and unitary invariant ensembles) in a subsequent publication.

Here we only outline the scheme of the derivation of the bound (iv) considering the simplest case of the GOE and treating it as a representative of the Wigner ensembles, i.e. ensembles with independent entries. Set $r_n(z)=\mathbf{E}\{g_n(z)\}$. Then, according to Eqs. (II.17), (II.18) and (II.20) we have the relation

$$r_n(z)=-\frac{1}{z}-\frac{w^2}{z}\mathbf{E}\{g_n^2(z)\}+\frac{w^2}{n^2z}\mathbf{E}\{\text{ tr }G^2\}. \tag{II.26}$$

Applying similar arguments to $\mathbf{E}\{|g_n^2(z)|\}$ and using Eq. (II.26) we obtain the analogous relation for the variance (II.23)

$$F_n=-\frac{w^2}{z}E\{g_n^2(z)g_n^C(z^{\dagger})\}-\frac{w^2}{n^2z}\mathbf{E}\{[g_n^C(z)]^{\dagger}\text{ tr }G^2\}-\frac{2w^2}{n^3z}\mathbf{E}\{\text{ tr }G(G^*)^2\}, \tag{II.27}$$

where $G^*=(H-z^{\dagger}I)^{-1}$. By using the identity $E\{g_n^2(z)g_n^C(z^{\dagger})\}=E\{(g_n(z)+E\{g_n(z)\})\times|\,g_n^C(z)|^2\}$, the Cauchy–Schwarz inequality and the inequality (III.33) below we can show that the first term on the rhs of Eq. (II.27) is bounded above by $2w^2\eta^{-2}F_n$, where $\eta=|\Im z|$, the second is bounded by $w^2(n\eta^2)^{-1}F_n^{1/2}$ and the third is bounded by $2w^2(n^2\eta^4)^{-1}$. As a result we obtain the following inequality for $\eta^2>2w^2$

$$\left(1-\frac{2w^2}{\eta^2}\right)F_n-\frac{w^2}{n\eta^2}F_n^{1/2}-\frac{2w^2}{n^2\eta^4}\leqslant 0, \tag{II.28}$$

which implies that

$$F_n=\mathbf{E}\{|g_n^C(z)|^2\}\equiv\mathbf{E}\{|g_n(z)-\mathbf{E}\{g_n(z)\}|^2\}\leqslant\frac{C_1}{n^2}, \tag{II.29}$$

where $C_1=\eta^{-2}(\epsilon-1)^{-2}C_1(\epsilon)$, $\epsilon=\eta^2/2w^2$, $1<\epsilon<\infty$ and $C_1(\epsilon)$ is finite for $1\leqslant\epsilon<\infty$ Thus we have obtained Eq. (II.24) for the GOE. This is the simplest but typical bound that can be obtained by our method. In the general case of non-Gaussian W_{jk}'s one has to iterate the resolvent identity (I.20) and use Eq. (I.16) instead of Eq. (I.17), truncating this procedure on the proper step and estimating remainders by variants of arguments presented above.

The bounds (II.29) and (II.26) allow us to prove Eqs. (I.7) and (I.11) for the GOE. Indeed, combining Eq. (II.26) and (II.29) we obtain

$$\left| r_n(z) + \frac{1}{z} + \frac{w^2}{z} r_n^2(z) \right| \leqslant \frac{C_2}{n},$$

where C_2 has same properties as C_1 in Eq. (II.29). The bound and standard compactness arguments show that any limit point $r(z)$ of the sequence $\{r_n(z)\}$ satisfies the equation

$$w^2 r^2(z) + z r(z) + 1 = 0 \tag{II.30}$$

for $|\Im z| \geqslant \eta_0 > 0$. Since this equation has the unique solution (I.10) satisfying $\Im r(z) \Im z \geqslant 0$, we conclude that uniformly in $|\Im z| \geqslant \eta_0 > 0$ $\lim_{n\to\infty} r_n(z) = r(z)$ where $r(z)$ is given by Eq. (I.10). Besides, since the Gaussian W_{jk} satisfying Eq. (I.3) can be defined on the same probability space we conclude from Eq. (II.29) and the Borel–Cantelli lemma that Eqs. (I.11) and (I.7) and are valid.

III. ASYMPTOTIC EXPANSION FOR $E\{g_n(z)\}$

We recall our notation $m_n^{(1)}(z)$ for the mean value of $g_n(z) = n^{-1} \operatorname{tr} (H - zI)^{-1}$. In this section we prove the following

Theorem 1: *Consider the Wigner ensemble of random real symmetric matrices with independent entries defined by Eqs. (I.2)–(I.3). Assume additionally that the third and fourth moments of W_{jk} do not depend on j and k and that $\hat{\mu}_5 = \sup_{j \leqslant k} \mathbf{E}\{|W_{jk}|^5\} < +\infty$.*

Then the following asymptotic formula

$$m_n^{(1)}(z) = r(z) \left\{ 1 + \frac{1}{n} \left[\frac{w^2 r^2(z)}{[1 - w^2 r^2(z)]^2} + \frac{\sigma r^4(z)}{1 - w^2 r^2(z)} \right] \right\} + O(n^{-3/2}) \tag{III.31}$$

holds for any $z \in U_0$ (U_0 is defined in Eq. (II.22)).

Proof: By the resolvent identity (II.19)–(II.20),

$$m_n^{(1)}(z) = -z^{-1} + (zn)^{-1} \sum_{j,m=1}^{n} \mathbf{E}\{G_{jm} H_{mj}\}. \tag{III.32}$$

If we were following the conventional perturbational-diagrammatic approach trying to develop the asymptotic expansion for $\mathbf{E}\{g_n(z)\}$, we would repeatedly iterate the resolvent identity selecting on each step the terms that contribute to the leading and sub-leading terms. The obvious drawback of such an approach is that infinitely many iterations are needed and in the non-Gaussian case, when there is no analogue of the Wick theorem, the diagrammatic approach is rather complicated.

We propose making use of Eq. (II.16) instead of iterating the resolvent identity. For each pair (j,m), G_{jm} is a smooth function of H_{mj} and its derivatives are bounded because of Eq. (II.18) and the inequality

$$|G_{jm}| \leqslant \|G\| \leqslant |\Im z|^{-1}, \tag{III.33}$$

which holds for the resolvent of any real symmetric matrix. In particular, $|D_{mj}^4 G_{jm}| \leqslant C |\Im z|^{-5}$ where C is an absolute constant. Here and thereafter we use the notation D_{mj} for $\partial / \partial H_{mj}$.

According to Eqs. (I.2)–(I.3) and our assumptions, the fifth absolute moment of H_{mj} is of the order $n^{-5/2}$. Thus applying Eq. (II.16) (with $p = 3$) to each of the summands in the rhs of Eq. (III.32) one finds that

$$zm_n^{(1)}(z) = -1 + \sum_{a=1}^{3} \frac{1}{n^{(a+3)/2}} \sum_{j,m=1}^{n} \frac{\kappa_{a+1}(1+\delta_{jm})^{(a+1)/2}}{a!} \mathbf{E}\{D_{mj}^a G_{jm}\} + \varepsilon_n, \qquad \text{(III.34)}$$

where κ_a are the semi-invariants of W_{mj} and

$$|\varepsilon_n| \leqslant \frac{C}{n^{3/2}} \frac{\hat{\mu}_5}{|\Im z|^5}.$$

Obviously, G is a complex symmetric matrix, i.e. $G_{jm} = G_{mj}$. By Eq. (II.18), $D_{mm}^a G_{mm} = a! G_{mm}^{a+1}$ and

$$-D_{mj}^1 G_{jm} = G_{jm}^2 + G_{jj} G_{mm}, \qquad \text{(III.35)}$$

$$D_{mj}^2 G_{jm} = 2G_{jm}^3 + 6G_{jm} G_{jj} G_{mm}, \qquad \text{(III.36)}$$

$$-D_{mj}^3 G_{jm} = 6G_{jm}^4 + 36G_{jm}^2 G_{jj} G_{mm} + 6G_{jj}^2 G_{mm}^2 \qquad \text{(III.37)}$$

for distinct j and m. Let us set $\kappa_2 = w^2$ and $\kappa_4 = \sigma$ in Eq. (III.34). Then, as a consequence of Eqs. (III.35)–(III.37),

$$zm_n^{(1)}(z) = -1 - w^2 m_n^{(2)}(z,z) - n^{-1}[w^2 \mathbf{E}\{c_n(z)\} + \sigma \mathbf{E}\{d_n^2(z)\}] + \varepsilon_n, \qquad \text{(III.38)}$$

where

$$c_n(z) = \frac{1}{n} \sum_{j,m=1}^{n} G_{jm}^2, \quad d_n(z) = \frac{1}{n} \sum_{m=1}^{n} G_{mm}^2 \qquad \text{(III.39)}$$

and

$$|\varepsilon_n| \leqslant \frac{C}{n^{3/2}} \left(\frac{|\kappa_3|}{|\Im z|^3} + \frac{|\kappa_4|}{|\Im z|^4} + \frac{\hat{\mu}_5}{|\Im z|^5} \right). \qquad \text{(III.40)}$$

provided $|\Im z| \geqslant 2w$ and n is large enough.

To infer Eqs. (III.38)–(III.40) from Eq. (III.34), notice first that for the sum over $j = m$ on the rhs of Eq. (III.34) we have the bound

$$\frac{1}{n^{(a+3)/2}} \left| \sum_{m=1}^{n} D_{mm}^a G_{mm} \right| \leqslant \frac{C}{n^{(a+1)/2} |\Im z|^{a+1}} \propto \frac{1}{n^{(a+1)/2}} \leqslant \frac{1}{n^{3/2}}, \quad a = 2,3$$

for all realizations of W_{jk}. Therefore, being interested in the leading-order and $1/n$-order terms of $m_n^{(1)}(z)$ we can omit δ_{jm} from the factor in front of the second and third derivatives. As for the first derivatives, it follows from Eq. (III.35), that for all j and m $(1+\delta_{jm}) D_{jm}^1 G_{jm} = G_{jm}^2 + G_{jj} G_{mm}$ and the term arising from δ_{jm} contributes to $1/n$-order term in the asymptotic expansion of $m_n^{(1)}(z)$.

Now, G_{jm}^2 in the rhs of Eq. (III.35) makes $\mathbf{E}\{c_n(z)\}$ in Eq. (III.38) and $G_{jj} G_{mm}$ does $m_n^{(2)}(z,z)$. The term containing $G_{jj}^2 G_{mm}^2$ in the rhs of Eq. (III.37) leads to $\mathbf{E}\{d_n^2(z)\}$ in Eq. (III.38) and the rest in the rhs of Eqs. (III.36) and (III.37) contributes to ε_n in Eq. (III.38). Corresponding bounds for the terms coming from G_{jm}^3 in Eq. (III.36) and from G_{jm}^4 and $G_{jm}^2 G_{jj} G_{mm}$ in Eq. (III.37) result from the simple inequality

$$n^{-1}\sum_{j,m=1}^{n}|G_{jm}|^p\leqslant|\Im z|^{-p},\quad p\geqslant 2 \tag{III.41}$$

which holds for the resolvent of any real symmetric matrix. Estimating the term coming from $G_{jm}G_{jj}G_{mm}$ in the rhs of Eq. (III.36) requires a longer calculation. Set

$$h_n(z)=\frac{1}{n}\sum_{j,m=1}^{n}G_{jm}G_{jj}G_{mm}. \tag{III.42}$$

Substitute the rhs of Eq. (II.20) for G_{jm} in $h_n(z)$. Then

$$z\mathbf{E}\{h_n(z)\}=-\frac{1}{n}\sum_{m=1}^{n}\mathbf{E}\{G_{mm}^2\}-w^2\mathbf{E}\{g_n(z)h_n(z)\}+O(n^{-1/2}) \tag{III.43}$$

as follows from Eqs. (II.16), (III.35)–(III.37) and simple resolvent bounds like Eq. (III.33) or Eq. (III.41). Here and below we use the notation $O(n^{-p})$ for remainders admitting the upper bound Cn^{-p}, where C does not depend on n for $|\Im z|\geqslant 2w$.

According to Eq. (II.24) the variance of $g_n(z)$ is of order n^{-2} under our assumptions. In other words

$$m_n^{(2)}(z,z)=[m_n^{(1)}(z)]^2+O(n^{-2}) \tag{III.44}$$

if $z\in U_0$. Obviously,

$$\mathbf{E}\{h_n(z)g_n(z)\}-\mathbf{E}\{h_n(z)\}\mathbf{E}\{g_n(z)\}=\mathbf{E}\{h_n(z)[g_n(z)-\mathbf{E}\{g_n(z)\}]\}$$

and by the Cauchy–Schwarz inequality

$$\mathbf{E}\{h_n(z)g_n(z)\}=\mathbf{E}\{h_n(z)\}m_n^{(1)}(z)+O(n^{-1}).$$

Therefore by Eq. (III.43),

$$[z-w^2m_n^{(1)}(z)]\mathbf{E}\{h_n(z)\}=-\frac{1}{n}\sum_{m=1}^{n}\mathbf{E}\{G_{mm}^2\}+O(n^{-1/2}) \tag{III.45}$$

and $\mathbf{E}\{h_n(z)\}$ is of the order of unity. The term we wish to estimate is

$$\frac{2\kappa_3}{n^{5/2}}\sum_{j,m=1}^{n}\mathbf{E}\{G_{jm}G_{jj}G_{mm}\}=\frac{2\kappa_3}{n^{3/2}}\mathbf{E}\{h_n(z)\}$$

and from Eq. (III.45) we see it is of the order of $n^{-3/2}$. This proves Eqs. (III.38)–(III.40).

The calculation above is typical of our approach and uses Eqs. (II.16) and (II.20) combined with simple resolvent bounds on different stages. In what follows we shall often use similar calculations omitting details.

Equations (III.38)–(III.40) and Eq. (III.44) imply that

$$m_n^{(1)}(z)=r(z)+O(n^{-1}), \tag{III.46}$$

where $r(z)$ solves Eq. (II.30). Because of Eq. (I.9) $m_n^1(z)$ as a function of z must satisfy the inequality $\Im r(z)\Im z\geqslant 0$. This restriction fix the branch of the square root in the expression for the solutions of Eq. (II.30). Thus $r(z)$ coincides with the Stieltjes transform (I.10) of the semi-circle law (I.5), as expected.

Once the leading term of $m_n^{(1)}(z)$ is found, we can proceed with finding the sub-leading term. From Eq. (III.38) it is clear that performing this task requires calculating the leading-order terms of $\mathbf{E}\{c_n(z)\}$ and $\mathbf{E}\{d_n^2(z)\}$. Substitute the rhs of Eq. (II.20) for one of G_{jm} in $c_n(z)$ and apply Eq. (II.16). As a result,

$$z\mathbf{E}\{c_n(z)\} = -m_n^{(1)}(z) - 2w^2\mathbf{E}\{c_n(z)g_n(z)\} + O(n^{-1}).$$

By Eq. (II.24),

$$z\mathbf{E}\{c_n(z)\} = -m_n^{(1)}(z) - 2w^2 m_n^{(1)}(z)\mathbf{E}\{c_n(z)\} + O(n^{-1}) \tag{III.47}$$

and in the leading order

$$\mathbf{E}\{c_n(z)\} = -m_n^{(1)}(z)[z + 2w^2 m_n^{(1)}(z)]^{-1}.$$

Taking into account Eqs. (III.46)–(II.30) we conclude that

$$\mathbf{E}\{c_n(z)\} = r^2(z)[1 - w^2 r^2(z)]^{-1} + O(n^{-1}). \tag{III.48}$$

Now, calculate the leading-order term of $\mathbf{E}\{d_n^2(z)\}$. Recall that according to Eq. (II.24) the variance of $g_n(z)$ is of the order of n^{-2}. By Eq. (I.11), $g_n(z) = n^{-1}\Sigma_{m=1}{}^n G_{mm}$ converges almost surely to $r(z)$ as $n \to \infty$. Or, put another way, the Cesaro limit of G_{mm} is $r(z)$. This suggests that the Cesaro limit of G_{mm}^2 should be equal to $r^2(z)$, or in other words $d_n(z)$ should converge almost surely to $r^2(z)$. Therefore $\mathbf{E}\{d_n^2(z)\}$ should converge to $r^2(z)$.

To prove the convergence rigorously and to estimate its rate, we first note that the variance of $d_n(z)$ is of order n^{-1} if $z \in U_0$ (this can be proved following the calculations of Appendix B). Therefore

$$\mathbf{E}\{d_n^2(z)\} = \mathbf{E}\{d_n(z)\}^2 + O(n^{-2}). \tag{III.49}$$

Thus, it suffices to find the leading-order term of $\mathbf{E}\{d_n(z)\}$.

Again, as in the case of $c_n(z)$, substitute the rhs of Eq. (II.20) ($j = m$) for one of G_{mm} in $d_n(z)$ and apply Eq. (II.16). As a result,

$$z\mathbf{E}\{d_n(z)\} = -m_n^{(1)}(z) - w^2\mathbf{E}\{d_n(z)g_n(z)\} + O(n^{-1/2}).$$

By Eq. (II.24),

$$z\mathbf{E}\{d_n(z)\} = -m_n^{(1)}(z) - w^2 m_n^{(1)}(z)\mathbf{E}\{d_n(z)\} + O(n^{-1/2})$$

and

$$\mathbf{E}\{d_n(z)\} = -m_n^{(1)}(z)[z + w^2 m_n^{(1)}(z)]^{-1} + O(n^{-1/2}).$$

Finally by Eqs. (III.46) and (II.30),

$$\mathbf{E}\{d_n(z)\} = r^2(z) + O(n^{-1/2}) \tag{III.50}$$

and by Eq. (III.49),

$$\mathbf{E}\{d_n^2(z)\} = r^4(z) + O(n^{-1/2}). \tag{III.51}$$

Now we are in a position to find the sub-leading term of $m_n^{(1)}(z)$. Collect Eqs. (III.38), (III.44), (III.48) and (III.51) and write

$$zm_n^{(1)}(z) = -1 - w^2[m_n^{(1)}(z)]^2 - \frac{1}{n}\left[\frac{w^2r^2(z)}{1-w^2r^2(z)} + \sigma r^4(z)\right] + O(n^{-3/2}).$$

In view of Eqs. (III.46) and (II.30) this relation is obviously equivalent to the statement of the theorem, i.e. to the asymptotic formula (III.16). The theorem is proved.

Remarks:

1. Our bound for the remainder in Eq. (III.31) is an optimal one. By assuming the sixth absolute moment of W_{jk} to be uniformly bounded and keeping one more term when applying Eq. (II.16), we can find a term of the order of $n^{-3/2}$ in the asymptotic expansion of $m_n^{(1)}(z)$. This term is proportional to $\kappa_3 = \mathbf{E}\{W_{jk}^3\}$

2. If the distributions of W_{jk} are such that $\mathbf{E}\{W_{jk}^3\} = 0$, then the bound $O(n^{-3/2})$ for the remainder in Eq. (III.31) can be strengthened to $O(n^{-2})$. For terms of the order of $n^{-3/2}$ appear in Eq. (III.31) due to the contribution of $\kappa_3 n^{-3/2}\mathbf{E}\{h_n(z)\}$ to ε_n in Eq. (III.38) and also because of Eq. (III.51). If $\mathbf{E}\{W_{jk}^3\} = 0$, then $\kappa_3 = 0$ and we can prove that the remainder in Eq. (III.51) is of the order of n^{-1} (terms of order $n^{-1/2}$ in the rhs of Eq. (III.51) are proportional to κ_3).

3. For Gaussian W_{jk} the excess σ is zero and Eq. (III.31) reduces to the asymptotic formula

$$\mathbf{E}\{g_n(z)\} = r(z)\left[1 + \frac{1}{n}\frac{w^2r^2(z)}{[1-w^2r^2(z)]^2}\right] + O(n^{-2}),$$

which has been derived earlier by the formal diagrammatic approach.[29]

IV. LEADING ORDER OF $F_n(z_1, z_2)$

Let us recall our notation $F_n(z_1, z_2)$ (see Eq. (I.14)) for the covariance function of $g_n(z) = n^{-1}\,\mathrm{tr}(H - zI)^{-1}$,

$$F_n(z_1, z_2) = \mathbf{E}\{g_n^C(z_1)g_n^C(z_2)\} = \mathbf{E}\{g_n(z_1)g_n^C(z_2)\}.$$

In this section we prove the following

Theorem 2: *Consider the Wigner ensemble of random real symmetric matrices with independent entries defined by Eqs. (I.2)–(I.3). Assume additionally that the third and fourth moments of W_{jk} do not depend on j and k and that $\hat{\mu}_5 = \sup_{j \leqslant k}\mathbf{E}\{|W_{jk}|^5\} < +\infty$.*

Let $f(z_1, z_2)$ be the function given by Eqs. (I.15). If z_1 and z_2 belong to U_0 Eq. (II.22), then the following asymptotic relation

$$F_n(z_1, z_2) = n^{-2}f(z_1, z_2) + O(n^{-5/2}) \tag{IV.52}$$

is valid.

Proof: Let us first prove Eq. (IV.52) under the assumption

$$\hat{\mu}_7 = \sup_{j \leqslant k}\mathbf{E}\{|W_{jk}|^7\} < +\infty. \tag{IV.53}$$

Let $G_{jm}(z)$ denote a matrix element of $(H - zI)^{-1}$. By Eq. (II.20),

$$z_1F_n(z_1, z_2) = \frac{1}{n}\sum_{j,m=1}^{n}\mathbf{E}\{H_{mj}G_{jm}(z_1)g_n^C(z_2)\}.$$

For each pair (j, m) $G_{jm}(z_1)g_n^C(z_2)$ is a smooth function of H_{mj} and its derivatives are bounded because of Eq. (III.33). In particular, $|D_{mj}^6[G_{jm}(z_1)g_n^C(z_2)]| \leqslant C(|\Im z_1|^{-1} + (|\Im z_2|^{-1})^8$. Therefore by Eq. (II.16),

$$zF_n(z_1,z_2)=\sum_{a=1}^{5}\frac{1}{n^{(a+3)/2}}\sum_{j,m=1}^{n}\frac{\kappa_{a+1}(1+\delta_{jm})^{(a+1)/2}}{a!}\mathbf{E}\{D_{mj}^{a}[G_{jm}(z_1)g_n^C(z_2)]\}+\varepsilon_n,\tag{IV.54}$$

where κ_a are semi-invariants of W_{mj}, as in Eq. (III.34), and

$$|\varepsilon_n|\leqslant n^{-5/2}C\hat{\mu}_7(|\Im z_1|^{-1}+(|\Im z_2|^{-1})^8.$$

Performing differentiation on the rhs of Eq. (IV.54) one finds that the sums of the fifth, fourth and second derivatives in the rhs of Eq. (IV.54) contribute to $z_1F_n(z_1,z_2)$ terms of order $n^{-9/2}$, $n^{-7/2}$ and $n^{-5/2}$, respectively (corresponding bounds can be obtained using Eqs. (II.24), (III.33) and (III.41)). So, these derivatives give no contribution to the leading-order term of $F_n(z_1,z_2)$. It remains to estimate the contributions coming from the first and third derivatives.

The contribution of third derivatives to $z_1F_n(z_1,z_2)$ consists of several terms which we shall label by integer a and b satisfying $0\leqslant a,b\leqslant 3$ and $a+b=3$. These terms are

$$s_n^{(a,b)}(z_1,z_2)=\frac{\kappa_4}{6n^3}\sum_{j,m=1}^{n}\mathbf{E}\{D_{mj}^{a}G_{jm}(z_1)D_{mj}^{b}g_n^C(z_2)\}.$$

First estimate $s_n^{(3,0)}(z_1,z_2)$. After differentiating it takes the form

$$s_n^{(3,0)}(z_1,z_2)=-n^{-2}\kappa_4\mathbf{E}\left\{n^{-1}\sum_{j,m=1}^{n}G_{jm}^4(z_1)g_n^C(z_2)+6h_n(z_1)g_n^C(z_2)\right\}-n^{-1}\kappa_4\mathbf{E}\{d_n^2(z_1)g_n^C(z_2)\}.\tag{IV.55}$$

($h_n(z)$ and $d_n(z)$ are defined in Eqs. (III.42) and (III.39), respectively). As follows from Eqs. (II.24) and (III.41), the mean value in the rhs of the equation above is $O(n^{-1})$, so

$$s_n^{(3,0)}(z_1,z_2)=-n^{-1}\kappa_4\mathbf{E}\{d_n^2(z_1)g_n^C(z_2)\}+O(n^{-3}).$$

Now we employ the obvious algebraic relation (in the below sub-index C indicates the subtracted mean value)

$$\mathbf{E}\{\eta^2\xi^C\}=2\mathbf{E}\{\eta^C\xi^C\}\mathbf{E}\{\eta\}+\mathbf{E}\{(\eta^C)^2\xi^C\}\tag{IV.56}$$

and write $\mathbf{E}\{d_n^2(z_1)g_n^C(z_2)\}$ as

$$2\mathbf{E}\{d_n^C(z_1)g_n^C(z_2)\}\mathbf{E}\{d_n(z_1)\}+\mathbf{E}\{[d_n^C(z_1)]^2g_n^C(z_2)\}.$$

If $z\in U_0$, variances of $g_n(z)$ and $d_n(z)$ are of order n^{-2}. In addition to this, $d_n(z)$ is bounded in absolute value by $C|\Im z|^{-2}$ for all realizations of W_{jk}. Therefore by the Cauchy–Schwarz inequality, $\mathbf{E}\{d_n^2(z_1)g_n^C(z_2)\}=O(n^{-2})$, provided $z_1,z_2\in U_0$. Thus we have proved that $s_n^{(3,0)}(z_1,z_2)=O(n^{-3})$. A similar argument shows that $s_n^{(0,3)}(z_1,z_2)$ and $s_n^{(2,1)}(z_1,z_2)$ are $O(n^{-3})$, too. The last term we need to estimate is $s_n^{(1,2)}(z_1,z_2)$. It is easy to see that

$$s_n^{(1,2)}(z_1,z_2)=n^{-1}2\kappa_4\mathbf{E}\left\{n^{-1}\sum_{m=1}^{n}G_{mm}(z_1)G_{mm}(z_2)\right\}\mathbf{E}\left\{n^{-1}\sum_{j,m=1}^{n}G_{mm}(z_1)G_{jm}^2(z_2)\right\}+O(n^{-3}).$$

Mean values in the above are calculated in exactly the same way as $\mathbf{E}\{c_n(z)\}$ and $\mathbf{E}\{d_n(z)\}$ have been done. For large n:

$$n^{-1}2\kappa_4\mathbf{E}\left\{n^{-1}\sum_{m=1}^{n}G_{mm}(z_1)G_{mm}(z_2)\right\}=r(z_1)r(z_2)+O(n^{-1/2})$$

and

$$\mathbf{E}\left\{n^{-1}\sum_{j,m=1}^{n}G_{mm}(z_1)G_{jm}^2(z_2)\right\}=r(z_1)r^2(z_2)+O(n^{-1})$$

(compare with Eqs. (III.48) and (III.50)). Thus we conclude that the contribution of third derivatives is

$$-\frac{1}{n^2}\frac{\sigma r^2(z_1)r^3(z_2)}{1-w^2r^2(z_2)}, \tag{IV.57}$$

Eq. (II.17) (we recall using σ for κ_4).

First derivatives in the rhs of Eq. (IV.54) contribute to $z_1F_n(z_1,z_2)$ the term

$$\begin{aligned}t_n(z_1,z_2)=&-w^2\mathbf{E}\{g_n^2(z_1)g_n^C(z_2)\}-n^{-1}w^2\mathbf{E}\{c_n(z_1)g_n^C(z_2)\}\\&-n^{-2}2w^2\mathbf{E}\{n^{-1}\operatorname{tr}(H-z_1I)^{-1}(H-z_2I)^{-2}\}.\end{aligned} \tag{IV.58}$$

By the resolvent identity (II.19)

$$(H-z_1I)^{-1}(H-z_2I)^{-1}=(z_1-z_2)^{-1}[(H-z_1I)^{-1}-(H-z_2I)^{-1}].$$

Thus one reduces $\mathbf{E}\{n^{-1}\operatorname{tr}(H-z_1I)^{-1}(H-z_2I)^{-2}\}$ to

$$(z_1-z_2)^{-1}[(z_1-z_2)^{-1}\mathbf{E}\{g_n(z_1)-g_n(z_2)\}-\mathbf{E}\{c_n(z_2)\}].$$

Now recalling Eqs. (III.46), (III.48) and (II.30),

$$\mathbf{E}\{n^{-1}\operatorname{tr}(H-z_1I)^{-1}(H-z_2I)^{-2}\}=\frac{1}{r(z_1)[1-w^2r^2(z_2)]}\left[\frac{r(z_1)-r(z_2)}{z_1-z_2}\right]^2+O(n^{-1}). \tag{IV.59}$$

Clearly, $\mathbf{E}\{c_n(z_1)g_n^C(z_2)\}=\mathbf{E}\{c_n^C(z_1)g_n^C(z_2)\}$ and the corresponding summand on the rhs of Eq. (IV.58) is $O(n^{-3})$. So it remains to find $\mathbf{E}\{g_n^2(z_1)g_n^C(z_2)\}$.

Use Eq. (IV.56) to write

$$\mathbf{E}\{g_n^2(z_1)g_n^C(z_2)\}=2F_n(z_1,z_2)m_n^{(1)}(z_1)+\mathbf{E}\{[g_n^C(z_1)]^2g_n^C(z_2)\}=2F_n(z_1,z_2)m_n^{(1)}(z_1)+O(n^{-5/2}). \tag{IV.60}$$

The latter equality uses $\mathbf{E}\{[g_n^C(z_1)]^2g_n^C(z_2)\}=O(n^{-5/2})$, the bound which can be obtained following calculations of Appendix B.

Now we are in a position to find the leading order of $F_n(z_1,z_2)$. Collecting Eqs. (IV.57)–(IV.60), we find that

$$\begin{aligned}z_1F_n(z_1,z_2)=&-2w^2F_n(z_1,z_2)m_n^{(1)}(z_1)-\frac{1}{n^2}\frac{\sigma r^2(z_1)r^3(z_2)}{1-w^2r^2(z_2)}\\&-\frac{2w^2}{r(z_1)[1-w^2r^2(z_2)]}\left[\frac{r(z_1)-r(z_2)}{z_1-z_2}\right]^2+O(n^{-5/2}).\end{aligned}$$

As it is clear from Eqs. (III.46) and (II.30),

$$[z_1+2w^2m_n^{(1)}(z_1)]^{-1}=-r(z_1)[1-w^2r^2(z_1)]^{-1}+O(n^{-1})$$

and we end up with Eq. (IV.52).

The standard truncation technique of probability theory allows us to prove Eq. (IV.52) in the case when only the fifth absolute moment of the random variables W_{jk} is uniformly bounded. Calculations using the truncation technique are similar to those used in next section in proof of Theorem 3 and we omit them. Theorem 2 is proved.

One can consider the covariance function $F_n(z_1,z_2)$ for the Wigner ensemble of random Hermitian matrices (see remark 3 after the statement in Theorem 3 in the next section). Repeating almost literally calculations used in the proof of Theorem 2, one can prove that for the Wigner ensemble of Hermitian matrices Eq. (IV.52) is still valid. The only difference is that now $f(z_1,z_2)$ is given by the rhs of Eq. (I.15) multiplied by factor 1/2.

V. GAUSSIAN FLUCTUATIONS OF THE CENTRALIZED TRACE OF THE RESOLVENT

In this section we prove the statement which is analogous to the central limit theorem in the same sense in which the result Eq. (I.11) is analogous to the law of large numbers. Indeed, we can rewrite (I.11) as following limiting relation

$$\lim_{n\to\infty}\frac{1}{n}\sum_{m=1}^{n}G_{mm}=r(z) \tag{V.61}$$

valid with probability 1. Since the lhs here has the form of the arithmetic (Cesaro) mean, this relation is obviously similar to the strong law of large numbers (or more generally to the ergodic theorem). Common wisdom of probability and ergodic theory suggests that Eq. (V.61) should imply that the probability distribution of the random variable

$$n^{1/2}\left[n^{-1}\sum_{m=1}^{n}(G_{mm}-\mathbf{E}\{G_{mm}\})\right]=n^{1/2}[g_n(z)-\mathbf{E}\{g_n(z)\}] \tag{V.62}$$

has the Gaussian form in the limit $n=\infty$. We prove that under rather natural conditions on W_{jk} this is indeed the case provided that we use non-standard normalization, replacing $n^{1/2}$ in Eq. (V.62) by n, i.e., we consider just the centralized trace of the resolvent

$$\gamma^{(n)}(z)=\sum_{m=1}^{n}(G_{mm}-\mathbf{E}\{G_{mm}\})=ng_n(z)-\mathbf{E}\{ng_n(z)\} \tag{V.63}$$

instead of $n^{1/2}\gamma^{(n)}(z)$. This normalization can of course be anticipated from the formula (I.14) giving the order of magnitude (in fact, the asymptotics) of the variance of $g_n(z)$. This decay of the variance, which is ''twice'' as strong than in the standard central limit theorem setting, is rather typical for a number of problems of the theory of disordered systems with non-local interaction and is known as the strong self-averaging property (see e. g. Refs. 28 and 33).

Theorem 3: *Consider the Wigner ensemble of random real symmetric matrices with independent entries defined by Eqs. (I.2)–(I.3) assuming additionally that the fourth moments of W_{jk} exist and are independent of j and k and that the probability distribution functions $P_{jk}(w)$ of W_{jk} satisfy the condition: for any fixed $\nu>0$*

$$\lim_{n\to\infty}\frac{1}{n^2}\sum_{j\leqslant k}\int_{|x|>\nu n^{1/2}}x^4d\ \mathrm{Prob}[W_{jk}\leqslant x]=0. \tag{V.64}$$

Then for any z from $U_0=\{z \in \mathbf{C}_\pm : |\Im z| \geqslant 2w\}$ *the random function* $\gamma^{(n)}(z)$ *[Eq. (V.63)] converges in distribution as* $n\to\infty$ *to the Gaussian random function* $\gamma(z)$ *with zero mean and the covariance function* $f(z_1,z_2)$ *given by Eq. (I.15). In other words, for any integer q and arbitrary collection* $z_1,\ldots,z_q$ *of complex numbers from* U_0 *the joint probability distribution of random variables* $\gamma^{(n)}(z_1),\ldots,\gamma^{(n)}(z_q)$ *converges as* $n\to\infty$ *to the q-dimensional Gaussian distribution with zero mean and the covariance matrix* $[f(z_s,z_t)]_{s,t=1}^q$.

Remarks:

1. Limit theorems concerning $\gamma^{(n)}(z)$ for the Wigner ensemble were established for the first time by Girko (see Ref. 24 and references therein) under the assumption that there exist a positive δ such that

$$\sup_{j\leqslant k}\mathbf{E}|W_{jk}|^{4+\delta}<\infty, \tag{V.65}$$

which is slightly more restrictive than Eq. (V.64). For example in the case of identically distributed W_{jk}, Eq. (V.64) is obviously satisfied if $w_4\equiv\mathbf{E}\{W_{jk}^4\}$ is finite. However, in our opinion, the more important improvement of the result of Ref. 24 is that we calculate the covariance matrix of the limiting Gaussian process in the explicit form while in Ref. 24 this matrix was given in the implicit form as a solution of a system of cumbersome partial differential equations.

2. For the random variables W_{jk} satisfying Eq. (V.65) we can estimate the rate of convergence:

$$\sup_{z_1,z_2\in U_0}|\mathbf{E}\{\gamma^{(n)}(z_1)\gamma^{(n)}(z_2)\}-f(z_1,z_2)|=O(n^{-\delta/2}). \tag{V.66}$$

3. Consider the Wigner ensemble of the $n\times n$ random Hermitian matrices defined as in Eq. (I.2) with $W_{jk}=A_{jk}+iB_{jk}, j\leqslant k$, $W_{jk}=W_{kj}^\dagger$ where A_{jk} and B_{jk} are mutually independent random variables with zero mean, variance $w^2/2$ and excess $\sigma/2$. It can be proved by analogous technique that in this ensemble the fluctuations of the trace of the resolvent around its mean become Gaussian in the limit $n\to\infty$. The corresponding covariance function is given by Eq. (I.15) in which the factor 2 is replaced by 1 in the denominator of both terms.

Proof: We shall work with real-valued variables $\alpha^{(n)}(z)=\Re\gamma^{(n)}(z)$ and $\beta^{(n)}(z)=\Im\gamma^{(n)}(z)$. Then we have to prove that the limiting random functions $\alpha(z)$ and $\beta(z)$ are jointly Gaussian, i.e. if

$$X(z,c)=\begin{cases}\alpha(z) & \text{if } c=\alpha;\\ \beta(z) & \text{if } c=\beta,\end{cases}$$

and

$$(a(c),b(c))=\begin{cases}(1/2,1/2) & \text{if } c=\alpha;\\ (1/2i,1/2i) & \text{if } c=\beta,\end{cases}$$

then $\mathbf{E}\{X(z,c)\}=0$ and for any integer q and arbitrary collections $z_s, s=1,\ldots,q$, $z_s\in U_0$ and $c_s, s=1,\ldots,q$, $c_s\in\{\alpha,\beta\}$ the joint probability distribution of random variables $X(z_1,c_1),\ldots,X(z_q,c_q)$ is the q-dimensional Caussian distribution with zero mean and covariance matrix

$$\begin{aligned}\mathbf{E}\{X(z_s,c_s)X(z_t,c_t)\}=&a(c_s)a(c_t)f(z_s,z_t)+a(c_s)b(c_t)f(z_s,z_t^\dagger)\\&+a(c_t)b(c_s)f(z_s^\dagger,z_t)+b(c_s)b(c_t)f(z_s^\dagger,z_t^\dagger),\end{aligned} \tag{V.67}$$

Let us consider the characteristic function of random variables $X(z_1,c_1),..,X(z_q,c_q)$ which we shall write in the form

$$e_q^{(n)}(T_q,C_q,Z_q)=\mathbf{E}\prod_{s=1}^{q}\exp\{i\tau_s[a(c_s)\gamma^{(n)}(z_s)+b(c_s)\gamma^{(n)}(z_s^\dagger)]\},$$

where $T_q=(\tau_1,\ldots,\tau_q)$, $C_q=(c_1,\ldots,c_q)$, $Z_q=(z_1,\ldots,z_q)$

Recall that we designate the complex conjugate by the symbol an asterisk. Also writing the characteristic function we shall often omit indices indicating its dependence on n and some other variables provided no confusion will arise.

Obviously

$$\frac{\partial}{\partial\tau_s}\mathbf{E}\{e_q(T_q)\}=i\mathbf{E}\{e_q[a(c_s)\gamma^{(n)}(z_s)+b(c_s)\gamma^{(n)}(z_s^\dagger)]\}.$$

Our aim is to show that there exists a set of ''covariance'' coefficients $A_{st}^{(n)}$ $s,t=1,\ldots,q$ such that for each fixed T_q

$$\lim_{n\to\infty}\left|\mathbf{E}\{e_q^{(n)}[a_s\gamma^{(n)}(z_s)+b_s\gamma^{(n)}(z_s^\dagger)]\}-i\sum_{t=1}^{q}\tau_sA_{st}^{(n)}\mathbf{E}\{e_q^{(n)}\}\right|=0,\quad z\in U_0,$$

to show that limits of all these coefficients exist

$$A_{st}=\lim_{n\to\infty}A_{st}^{(n)},\tag{V.68}$$

and correspond to the rhs of Eq. (V.67). Then standard arguments will allow us to prove that the limit characteristic function has the Gaussian form $\exp(-1/2\Sigma_{s,t=1}^{q}A_{st}\tau_s\tau_t)$.

Thus, we have to compute

$$\mathbf{E}\{e_q\gamma^{(n)}(z)\}=\sum_{j=1}^{n}\mathbf{E}\{e_q^C(Z_q)G_{jj}\},$$

for large n (we recall that the sub-index C indicates centering to zero mean). Then putting one of $z_1,\ldots,z_q$ or one of their conjugates in place of z we calculate the limits in Eq. (V.68).

We have complex energies $z,z_1,\ldots,z_q$ and we introduce the notation $G(z_s)$ for the resolvent corresponding to z_s keeping the notation G for the resolvent corresponding to z.

By the resolvent identity Eq. (II.20),

$$\sum_{j=1}^{n}\mathbf{E}\{e_q^CG_{jj}\}=z^{-1}\sum_{j,m=1}^{n}\mathbf{E}\{e_q^CG_{jm}H_{mj}\}.\tag{V.69}$$

We compute the average in the rhs of Eq. (V.69) following the scheme described in Section II. However its direct application requires too strong conditions on the distribution of W_{jk}. Thus, we modify slightly the general scheme and carry out more accurate estimates.

Denote by $\mathbf{E}_{mj}$ the conditional expectation $\mathbf{E}\{\cdot\,|W_{mj}=w\}$ and rewrite the right-hand side of Eq. (V.69) in the form

$$z^{-1}n^{-1/2}\sum_{j,m=1}^{n}\int\mathbf{E}_{mj}\{e_q^CG_{jm}\}w\,dP_{mj}(w).$$

We split the integral into the two ones over sets $\Gamma_1(n)=\{\omega:|W_{mj}|\leqslant\delta n^{1/2}\}$ and $\Gamma_2(n)=\{\omega:|W_{mj}|>\delta n^{1/2}\}$. Now the inequalities

$$\left|n^{-1/2}\sum_{j,m=1}^{n}\int_{\Gamma_2(n)}\mathbf{E}_{mj}\{e_q^C G_{jm}\}wP_{mj}(w)\right|\leqslant\eta^{-1}n^{-1/2}\sum_{j,m=1}^{n}\int_{\Gamma_2(n)}|w|dP_{mj}(w)$$
$$\leqslant\eta^{-1}\nu^{-3}n^{-2}\sum_{j,m=1}^{n}\int_{\Gamma_2(n)}w^4dP_{mj}(w)$$

and the assumption (V.64) imply that only the integrals over $\Gamma_1(n)$ give a non-vanishing contribution to Eq. (V.69).

Following our general scheme, we expand the function $e_q^C G_{jm}$ in powers of random variable $H_{mj}=n^{-1/2}W_{mj}$ restricted to $\Gamma_1(n)$. Since it is bounded by absolute value by ν we can write the relation

$$n^{-1/2}\sum_{j,m=1}^{n}\int_{\Gamma_1}\mathbf{E}_{mj}\{e_q^C G_{jm}\}wdP_{mj}(w)=\sum_{k=1}^{5}S_k(n),\tag{V.70}$$

where

$$S_k(n)=n^{k/2}\sum_{j,m=1}^{n}\mathbf{E}[e_q^C G_{jm}]_{mj}^{(k-1)}\int_{\Gamma_1}w^kdP_{mj}(w),$$

and $[\ldots]_{mj}^{(k)}$ denotes that the kth derivatives with respect to H_{mj} are taken and then H_{mj} is replaced by zero. Let us note also that in S_5 the expression in square brackets is taken at some point $\widetilde{H}_{mj}\in(0,\nu)$.

The term $S_1(n)$ vanishes as $n\to\infty$ due to our assumption [Eq. (V.64)]:

$$|S_1(n)|\leqslant\left|n^{-1/2}\sum_{j,m=1}^{n}\mathbf{E}[e_q^C G_{jm}]_{mj}\int_{\Gamma_1}wdP_{mj}(w)\right|\leqslant\eta^{-1}\nu^{-3}n^{-2}\sum_{j,m=1}^{n}\int_{\Gamma_1}w^4dP_{mj}(w),$$

where $\eta\equiv|\Im z|$.

The term $S_5(n)$ vanishes as $n\to\infty$ because it can be estimated by

$$\frac{B_4(T_p)}{\eta^6n^{5/2}}\sum_{j,m=1}^{n}\int_{\Gamma_1}|w|^5dP_{mj}(w)\leqslant\frac{B_4(T_p)\nu}{\eta^6n^2}\sum_{j,m=1}^{n}\int_{\Gamma_1}w^4dP_{mj}(w),$$

where $B_4(T_p)$ is the upper bound of absolute value of the fourth derivative in Eq. (V.70). For any fixed T_p, $B_4(T_p)$ is finite and recalling Eq. (V.64) we see that $S_5(n)$ goes to zero as $n\to\infty$.

The term $S_3(n)$ also vanishes as $n\to\infty$. We establish this fact at the end of the proof.

The terms $S_2(n)$ and $S_4(n)$ give main contributions to Eq. (V.69). Let us first consider $S_2(n)$. The resolvents $G(z_s)$ and G are complex symmetric matrices and we have:

$$-\sum_{j,m=1}^{n}[e_q^C G_{jm}]_{mj}^{(1)}=[e_q^C G_{jj}G_{mm}]_{mj}+\sum_{j,m=1}^{n}[e_q^C G_{jm}^2]_{mj}+i\sum_{j,m=1}^{n}\left[\sum_{s=1}^{q}2\tau_s(a_s[G^2(z_s)]_{jm}\right.$$
$$\left.+b_s[G^2(z_s^\dagger)]_{jm})G_{jm}e_q\right]_{mj}.\tag{V.71}$$

Each term of the right-hand side of this relation is a function of H in which H_{mj} is replaced by zero and we have to come ''back'' to expressions dependent on the whole matrix H. To this end, we again use the resolvent identity but now in the ''opposite '' direction. We obtain for the first term of Eq. (V.71)

$$w^2 n^{-1} \sum_{j,m=1}^{n} \mathbf{E}\{[e_q^C G_{jj} G_{mm}]_{mj}\} = v^2 n^{-1} \sum_{j,m=1}^{n} \mathbf{E}\{e_q^C G_{jj} G_{mm}\} - w^2 \Psi^{(n)},$$

where

$$\begin{aligned}\Psi^{(n)} = {} & n^{-3/2} \sum_{j,m=1}^{n} \mathbf{E}\{[e_q^C G_{jj} G_{mm}]_{mj}^{(1)}\} \int_{\Gamma_1} w dP_{mj}(w) \\ & - 2^{-1} n^{-2} \sum_{j,m=1}^{n} \mathbf{E}\{[e_q^C G_{jj} G_{mm}]_{mj}^{(2)}\} \int_{\Gamma_1} w^2 dP_{mj}(w) \\ & - 6^{-1} n^{-5/2} \sum_{j,m=1}^{n} \mathbf{E}\{[e_q^C G_{jj} G_{mm}]^{(3)} W_{mj}^3\}.\end{aligned}$$

It is easy to see that the first and the last terms of $\Psi^{(n)}$ vanish as $n \to \infty$ due to our assumption (V.64).

Using Eqs. (V.64) and (III.37), we can rewrite the second term of $\Psi^{(n)}$ in the form

$$\frac{-2iw^2}{n^2} \sum_{j,m=1}^{n} \mathbf{E}\left[e_q \sum_{s=1}^{q} \tau_s (a_s [G^2(z_s)]_{mm} [G(z_s)]_{jj} + b_s [G^2(z_s^\dagger)]_{mm} [G(z_s^\dagger)]_{jj}) G_{jj} G_{mm} \right]_{mj} + \Phi^{(n)},$$

where the remainder $\Phi^{(n)}$ includes terms which have one or more factors G_{jm} or terms of the form

$$n^{-2} \sum_{j,m=1}^{n} \mathbf{E}\{[e_q^C [G(z_s)_{jj}]^2 [G(z_j)_{jj}]^2]_{mj}\}.$$

It is clear that in all these expressions we can remove square brackets $[\ldots]_{mj}$ because this procedure will add terms of order $O(n^{-1/2})$ to the sums under consideration. Using the estimate (III.41), taking into account the self-averaging property

$$\mathbf{E}|g_n^C(z)|^2 = o(n^{-1}), \text{ as } n \to \infty \tag{V.72}$$

(see Lemma 1 of Appendix B for the proof), and the relation

$$\lim_{n\to\infty} \mathbf{E} \left| \left(n^{-1} \sum_j G_{jj}^{\alpha} G_{jj}^{\beta} n^{-1} \sum_j G_{mm}^{\mu} G_{mm}^{\nu} \right)^C \right| = 0 \tag{V.73}$$

with some $\alpha, \beta, \mu, \nu = 0,1,2$ (Lemma 2 of Appendix B), it is easy to prove that $\Phi^{(n)}$ also vanishes as $n \to \infty$.

We finally obtain that among terms coming from the first summand in the right-hand side of Eq. (V.71) only the following

$$w^2 z^{-1}\mathbf{E}\left\{ e_q^C \sum_{j=1}^{n} G_{jj} \right\} g_n(z) - \frac{-2iw_4}{n^2}\mathbf{E}\{e_q\}\sum_{s=1}^{q} \tau_s \mathbf{E}\left\{ \sum_{j,k=1}^{n} (a_s [G^2(z_s)]_{mm}[G(z_s)]_{jj} \right.$$

$$\left. + b_s [G^2(z_s^\dagger)]_{mm}[G(z_s^\dagger)]_{jj}) G_{jj} G_{mm} \right\} \tag{V.74}$$

does not vanish as $n \to \infty$.

The second summand in the rhs of Eq. (V.71) vanishes as $n \to \infty$. This becomes clear after applying the same procedure of removing square brackets $[\dots]_{mj}$ to the expression $n^{-2}\Sigma_{j,m=1}^{n}[e_q^C (G_{jm})^2]_{mj}^{(k)}$ and using the estimates (III.41) and (V.73).

Let us consider the contribution of the last summand in the rhs of Eq. (V.71) for a fixed parameter $z_s, s=1,\dots,q$. Taking into account Eq. (V.64) and repeating the ''returning'' procedure, we obtain for this term

$$\begin{aligned} n^{-1}\sum_{j,m=1}^{n} [[G^2(z_s)]_{jm} G_{mj} e_q]_{mj} = n^{-1}\sum_{j,m=1}^{n} [G^2(z_s)]_{jm} G_{mj} e_q \\ - n^{-3/2}\sum_{j,m=1}^{n} [[G^2(z_s)]_{jm} G_{mj} e_q]_{mj}^{(1)} \int_{\Gamma_1} w dP_{mj}(w) \\ - n^{-2}\sum_{j,m=1}^{n} [[G^2(z_s)]_{jm} G_{mj} e_q]_{mj}^{(2)} \int_{\Gamma_1} w^2 dP_{mj}(w) \\ - n^{-5/2}\sum_{j,m=1}^{n} \mathbf{E}\{[[G^2(z_s)]_{jm} G_{mj} e_q]^{(3)} W_{mj}^3\}. \end{aligned}$$

It is easy to see that in this equality terms with the first and the third derivatives vanish as $n \to \infty$. The second derivative gives

$$2[\{[G^2(z_s)]_{jj} G_{jj} G_{mm} G_{mm} + [G^2(z_s)]_{mm} G_{mm} [G(z_s)]_{jj} G_{jj}\} e_q]_{mj}$$

and 24 terms having a factor of the form $(G^\alpha)_{jm}, \alpha = 1,2$. Omitting brackets $[\dots]_{mj}$ and using Eqs. (V.72)–(V.73), we see that the last term of Eq. (V.71) gives the leading contribution

$$\begin{aligned} \mathbf{E}\{e_q^C\}\sum_{s=1}^{q} \tau_s \mathbf{E}\{a_s n^{-1} \operatorname{tr} G^2(z_s) G + b_s n^{-1} \operatorname{tr} G^2(z_s^\dagger) G\} - iw_4 \mathbf{E}\{e_q^C\} \\ \times \sum_{s=1}^{q} \tau_s \mathbf{E}\left\{ n^{-2}\sum_{j,m=1}^{n} (a_s [G^2(z_s)]_{jj}[G(z_s)]_{mm} + b_s [G(z_s)]_{jj}[G^2(z_s)]_{mm}) G_{jj} G_{mm} \right\}. \end{aligned} \tag{V.75}$$

Consider now the term $S_4(n)$ of Eq. (V.70). The third derivative $[e_q^C G_{jm}]_{mj}'''$ consists of 140 terms. One part of them vanishes as $n \to \infty$ due to the properties (V.72)–(V.73), another part — due to the presence of the factor of the form $(G^\alpha)_{jm}, \alpha = 1,2,3$. Only six terms of the form

$$iw_4 \sum_{s=1}^{q} \mathbf{E}\{e_q^C\}\mathbf{E}\left\{ n^{-2}\sum_{j,m=1}^{n} (a_s [G^2(z_s)]_{jj}[G(z_s)]_{mm} + b_s [G(z_s)]_{jj}[G(z_s)^2]_{mm}) G_{jj} G_{mm} \right\}$$

are non-vanishing in the limit $n\to\infty$. These terms arise when we differentiate G_{jm} once and e_q twice with respect to H_{mj}. Combining these terms with Eqs. (V.74) and (V.75), we finally obtain that

$$\mathbf{E}\{e_q^C \text{ tr } G\} = i\frac{1}{z-2w^2 g_n(z)}\mathbf{E}\{e_q^C\}\sum_{s=1}^{q}\tau_s\Bigg(2w^2 n^{-1}\mathbf{E}\{\text{ tr }(a_s G(z_s)^2 + b_s G(z_s^\dagger)^2)G\} + 2\sigma\mathbf{E}\Bigg\{n^{-2}\sum_{j,m=1}(a_s G^2(z_s)_{jj}G(z_s)_{mm} + b_s G^2(z_s^\dagger)_{jj}G(z_s^\dagger)_{mm})G_{jj}G_{mm}\Bigg\}\Bigg). \tag{V.76}$$

Notice, that the denominator in the first term of the rhs of this expression is bounded away from zero because z belongs to the domain (II.22). Now, combining Eqs. (I.11) and (I.10) with relations

$$\lim_{n\to\infty}\mathbf{E}\Bigg\{n^{-1}\sum_{j=1}^{m}[G^2(z_s)]_{jj}G_{jj}\Bigg\} = r^2(z_s)[1-w^2 r^2(z_s)]^{-1}r(z), \tag{V.77}$$

we derive from Eq. (V.76) the final form of the covariance.

Relation (V.77) can be easily deduced from our proof of Eqs. (V.72)–(V.73).

Let us briefly discuss now the proof of the fact that $S_3(n)$ of Eq. (V.70) vanishes as $n\to\infty$. The second derivative $[e_q^C G_{jm}]_{mj}^{(2)}$ gives terms each having the factor of the form $[(G^\alpha)_{jj}(G^k)_{jm}(G^\beta)_{mm}]_{mj}$. The brackets can be simply omitted because the ''returning'' procedure adds terms of order $O(n^{-1/2})$. Now, regarding $n^{-1/2}(G^\alpha)_{jj}$ as vectors and $(G^m)_{mj}$ as the kernel, we can write inequality

$$\Bigg|n^{-3/2}\sum_{j,m=1}^{n}(G^\alpha)_{jj}(G^m)_{mj}(G^\beta)_{mm}\Bigg| \leqslant \eta^{-\alpha-\beta-m}n^{-1/2}$$

which completes the proof of Theorem 3.

VI. SCALING LIMIT AND UNIVERSALITY CONJECTURE

We have presented above the rigorous derivation of asymptotic corrections (in fact expansions) for moments and more complex quantities constructed from the traces of the Green functions of the Wigner random matrix ensembles. Now we use our result to draw certain non-rigorous conclusions on the form of the leading term of the correlation function $S_n(E_1,E_2)$ of the formal level density $\rho_n(E)=n^{-1}\text{ tr }\delta(H-EI)$. Since $\rho_n(E)=N_n'(E)$ where $N_n(E)$ is defined in Eq. (I.4), then based on the relation (I.7) one can conclude that the number of eigenvalues lying inside the interval (E_1,E_2) with the center at E will be $N(E_2)-N(E_1)\sim n\rho_n(E)(E_2-E_1)$, i.e. that the mean distance between levels is $[n\rho_n(E)]^{-1}$. Thus the scaling $E_2-E_1=O(n^{-1})$ defines the microscopic or local regime in which one deals with a finite numbers of eigenvalues.[1,11]

Consider the density–density correlation function

$$S_n(E_1,E_2)=\mathbf{E}\{\rho_n(E_1)\rho_n(E_2)\}-\mathbf{E}\{\rho_n(E_1)\}\mathbf{E}\{\rho_n(E_2)\}. \tag{VI.78}$$

By using Eqs. (I.8) and (I.9) we obtain from Eqs. (I.14) and (V.63) that the Stieltjes transform of $S_n(E_1,E_2)$

$$F_n(z_1,z_2)=\int\int\frac{S_n(E_1,E_2)}{(E_1-z_1)(E_2-z_2)}dE_1dE_2, \quad \Im z_i\neq 0$$

is

$$F_n(z_1,z_2)=n^{-2}\mathbf{E}\{\gamma^{(n)}(z_1)\gamma^{(n)}(z_2)\}.$$

It follows from the inversion formula for the Stieltjes transform $f(z)=\int(E-z)^{-1}\rho(E)dE$

$$\rho(E)=\pi^{-1}\lim_{\epsilon\downarrow 0}\Im f(E+i\epsilon)\equiv I_{E_1}\{f(z)\} \tag{VI.79}$$

that to find $S_n(E_1,E_2)$, one has to know $F_n(z_1,z_2)$ up to the real axis in both variables because

$$S_n(E_1,E_2)=I_{E_1}\circ I_{E_2}\{F_n(z_1,z_2)\}. \tag{VI.80}$$

On the other hand, we have found the form (I.14) and (I.15) of $F_n(z_1,z_2)$ only in the domain $|\Im z|\geqslant 2w$. However, since the function $f(z_1,z_2)$ given by Eq. (I.15) can obviously be continued up to the real axis with respect to the both variables z_1 and z_2 we can apply to the first term of Eq. (I.14) the operation $I_{E_1}I_{E_2}$, $E_1\neq E_2$ to compute formally the ''leading'' term of the density–density correlation function. This means that we perform first the limit $n\to\infty$ and then the limits $\epsilon_1,\epsilon_2\downarrow 0$. This order of limiting transitions is inverse with respect to that prescribed by the definition of this correlation function.

To make these computations, we use the identity

$$\frac{r_1-r_2}{z_1-z_2}=\frac{r_1r_2}{1-w^2r_1r_2}$$

which follows from Eq. (I.10) or Eq. (II.30). The identity yields the relations $\varepsilon|r(E+i\varepsilon)|^2=\Im r(E+i\varepsilon)(1-w^2|r(E+i\varepsilon)|^2)$ and $|r(E+i0)|^2=w^{-2}$ for E such that $\Im r(E+i0)>0$. Combining these relations with Eq. (I.5), we obtain that

$$w^2[\Re r(E+i0)]^2=\frac{E^2}{4w^2}\quad\text{and}\quad w^2[\Im r(E+i0)]^2=1-\frac{E^2}{4w^2}.$$

Using these equalities, we derive from our results (I.14) and (I.15) and from Eqs. (VI.79) and (VI.80) that

$$\begin{aligned}S_n(E_1,E_2)=&-\frac{1}{\beta\pi^2[n(E_1-E_2)]^2}\,\frac{4w^2-E_1E_2}{(4w^2-E_1^2)^{1/2}(4w^2-E_2^2)^{1/2}}\\&+\frac{\sigma}{2n^2\pi^2w^8}\,\frac{(2w^2-E_1^2)(2w^2-E_2^2)}{(4w^2-E_1^2)^{1/2}(4w^2-E_2^2)^{1/2}}\end{aligned} \tag{VI.81}$$

with $\beta=1$. It can be shown that for the Hermitian matrices with independent entries (see Remark 3 to Theorem 3) the density–density correlator has the same form with $\beta=2$. For the Gaussian orthogonal and unitary ensembles (GOE and GUE) $\sigma=0$, and we recover the result

$$S_n(E_1,E_2)=-\frac{1}{\beta\pi^2[n(E_1-E_2)]^2}\,\frac{4w^2-E_1E_2}{(4w^2-E_1^2)^{1/2}(4w^2-E_2^2)^{1/2}}$$

obtained in Ref. 34 and Ref. 35.

We see that in a general non-Gaussian case the respective expression depends not only on the second moment of entries, but also on their fourth moment via the excess σ.

The remarkable fact is that this dependence vanishes in the microscopic (also called the scaling) limit

$$E_1, E_2 \to E, \quad n(E_2 - E_1) \to s. \tag{VI.82}$$

Indeed, it easy to see that in this limit we obtain from Eq. (VI.81) a very simple expression:

$$\lim_{n(E_2-E_1)\to s} S_n(E_1, E_2) = -\frac{1}{\beta \pi^2 s^2}. \tag{VI.83}$$

According to Wigner and Dyson (see, e.g., Ref. 1), the exact large-s asymptotics for the limiting correlation function of the Gaussian ensembles are: $-1/(\pi^2 s^2)$ (GOE) and $-\sin^2 \pi\rho(E)s/(\pi^2 s^2)$ (GUE). Comparing these expressions with our results, we see that the procedure of computing the correlation function yields for the general case the expression coinciding with the large-s asymptotics of the Gaussian ensembles correlation function smoothed over energy intervals whose length is much smaller than the macroscopic scale $w = \mathbf{E}\{W^2\}^{1/2}$ but much bigger than the microscopic scale given by the mean level spacing $[n\rho(E)]^{-1}$. It is natural to think that in our computations the smoothing has been implemented ''automatically'' due to the non-zero imaginary part of the spectral parameter $\Im z_j$. We notice that the same procedure is widely used in the mesocsopic calculations based on the Kubo formula, weak disorder perturbation theory, etc.

The independence of the scaling limit expressions (VI.83) on the excess σ can be regarded as a support of the universality conjecture for the Wigner ensembles. Let us mention supports of this conjecture for other ensembles.

The first one[22] concerns the so-called sparse (or diluted) random matrices whose entries are independently distributed random variables such that $\Pr\{H_{k,l} = 0\} = p/n$. The authors of Ref. 22 used the Grassman integral technique and found the Wigner–Dyson universal form of the density–density correlator if p is large enough.

The second[36] concerns the ensemble $H = \Sigma_{\mu=1}^{p} \tau_\mu(\cdot, \xi^\mu)\xi^\mu$, where τ_μ and $\xi^\mu = \{\xi_1^\mu, \ldots, \xi_n^\mu\}$ are independent identically distributed random variables (the ensemble was introduced in Ref. 27). For this ensemble, whose entries are dependent random variables, the analogue of Eq. (VI.81) is obtained and it is shown that its scaling limit is the same as above.

The third follows from Appendix A below. We consider there the case of the deformed GOE (see definitions below). For this ensemble the analog of Theorem 3 was proved in Ref. 37. In the appendix we present a short derivation of the density–density correlator and show that in the scaling limit it has the form (VI.83).

We mention also that for the unitary invariant ensembles of the form (I.1) the universality conjecture is rigorously proved in Ref. 16 for a rather broad class of functions $F(x)$.

APPENDIX A: SCALING LIMIT FOR THE DEFORMED GOE

In this Appendix we find the exact form of the leading term of the covariance function $F_n(z_1, z_2)$ [Eq. (I.14)] for the ensemble $H_d = H^{(0)} + H$, where $H^{(0)}$ are $n \times n$ nonrandom matrices such that there exists the ''unperturbed'' IDS

$$N^{(0)}(E) = \lim_{n\to\infty} n^{-1} \#\{e_j : e_j \text{ is an eigenvalue of } H^{(0)} \text{ and } e_j \leqslant E\}$$

and H belongs to the GOE (Eq. (I.1) with $F=x^2/4w^2$). This ensemble is called[2] the deformed GOE. Because of the orthogonal invariance of the GOE distribution, we can restrict our consideration to the case of diagonal $H^{(0)}$. So we assume that $H^{(0)}=[\delta_{jk}e_j]_{j,k=1}^n$ and real numbers e_j are such that the limit

$$g^{(0)}(z)=\lim_{n\to\infty}\frac{1}{n}\sum_{j=1}^{n}\frac{1}{e_j-z} \tag{A1}$$

exists for all non-real z. The function $g^{(0)}(z)$ is the Stieltjes transform of $N^{(0)}(E)$. We shall use the notation $d_j(z)$ for $(e_j-z)^{-1}$ and $g_n(z)$ for the normalized trace of the resolvent of H_d.

Subsequent arguments are quite similar to those used in derivation of Eqs. (II.24) and (II.26) –(II.29) for the GOE. By using Eqs. (II.17) and (II.19) for $H_1=H^{(0)}$ and $H_2=H_d$ one can derive the following two relations (analogues of Eqs. (II.26) and (II.27)) :

$$\mathbf{E}\{G_{jk}(z)\}=d_j(z)\,\delta_{jk}+\mathbf{E}\{g_n(z)G_{jk}(z)\}d_k(z)+n^{-1}\sum_m\mathbf{E}\{G_{jm}(z)G_{km}(z)\}d_k(z), \tag{A2}$$

and

$$\begin{aligned}\mathbf{E}\{g_n^C(z_1)G_{jj}(z_2)\}=&\,w^2\mathbf{E}\{g_n^C(z_1)G_{jj}(z_2)\}\mathbf{E}\{g_n(z_2)\}d_j(z_2)+w^2\mathbf{E}\{g_n^C(z_1)g_n^C(z_2)G_{jj}(z_2)\}d_j(z_2)\\&+w^2n^{-1}\mathbf{E}\{g_n^C(z_1)[G^2(z_2)]_{jj}\}d_j(z_2)\\&+2w^2n^{-2}\sum_m\mathbf{E}\{[G^2(z_1)]_{jm}G_{mj}(z_2)\}d_j(z_2).\end{aligned} \tag{A3}$$

It follows from Eq. (A2) that if for $z\in U_0$ where U_0 is defined in Eq. (II.22)

$$\lim_{n\to\infty}\mathbf{E}\{|g_n(z)-\mathbf{E}\{g_n(z)\}|\}=0, \tag{A4}$$

then $\lim_{n\to\infty}\mathbf{E}\{g_n(z)\}=g(z)$, where $g(z)$ is the unique solution of the functional equation[23]

$$g(z)=g^{(0)}(z+w^2g(z)) \tag{A5}$$

satisfying $\Im g(z)\Im z\geqslant 0$. In the equation above, $g^{(0)}(z)$ is given by Eq. (A1).

It is easy to show that Eqs. (A2) and (A4) imply the relation

$$\sup_{j=1,\ldots,n}|\mathbf{E}\{G_{jj}(z)\}-g_j^{(n)}(z)|=O(n^{-1}),\quad z\in U_0, \tag{A6}$$

where $g_j^{(n)}(z)$ solves the equations

$$g_j^{(n)}(z)=\frac{1}{e_j-z-w^2g^{(n)}(z)},\quad j=1,\ldots,n\quad g^{(n)}(z)=n^{-1}\sum_{m=1}^{n}g_m^{(n)}(z). \tag{A7}$$

Indeed, if $V_j^{(n)}=\mathbf{E}\{g_n^C(z_1)G_{jj}(z_2)\}$ then by Eq. (A3),

$$V_j^{(n)} = w^2 V_j^{(n)} \mathbf{E}\{g_n(z_2) d_j(z_2)\} + n^{-1} \sum_j V_j^{(n)} \mathbf{E}\{g_n(z_2) d_j(z_2)\}$$
$$+ 2w^2 n^{-2} \mathbf{E}\left\{ \sum_j [G^2(z_2)]_{jm} G_{mj}(z_2) d_j(z_2) \right\} + w^2 n^{-1} \mathbf{E}\{g_n^C(z_1)[G^2(z_2)]_{jj}\} d_j(z_2)$$
$$+ w^2 \mathbf{E}\{g_n^C(z_1) g_n^C(z_2)[G_{jj}(z_2)]^C\} d_j(z_2). \tag{A8}$$

Now, repeating arguments used at the end of Section II, we can easily obtain the estimate $n^{-1}\Sigma_j V_j^{(n)} = O(n^{-2})$ which proves Eq. (A6). Using this estimate and considering Eq. (A8) once more, we obtain the estimate

$$\sup_j |V_j^{(n)}| = O(n^{-2}). \tag{A9}$$

It follows from the resolvent identity (II.19) that

$$\sum_j [G^2(z_1)]_{jm} [G(z_2)]_{mj} = \frac{[G^2(z_1)]_{jj}}{z_1 - z_2} - \frac{[G(z_1)]_{jj} - [G(z_2)]_{jj}}{(z_1 - z_2)^2}.$$

Taking into account this relation, Eq. (A6), and Eq. (A9), we obtain that if

$$f_d(z_1, z_2) = \lim_{n \to \infty} n^2 \mathbf{E}\{g^C(z_1) g^C(z_2)\},$$

then

$$\left| n^{-1} \sum_j V_m^{(n)} - f_d(z_1, z_2) \right| = o(n^{-2}), \quad z \in U_0,$$

and as the result

$$f_d(z_1, z_2) = -\frac{2w^2}{(z_1 - z_2)^2} \lim_{n \to \infty} \frac{n^{-1} \Sigma_m [g_m^{(n)}(z_1) - g_m^{(n)}(z_2)] g_m^{(n)}(z_2)}{1 - w^2 n^{-1} \Sigma_j g_m^{(n)}(z_2)^2}$$
$$+ \frac{1}{z_1 - z_2} \lim_{n \to \infty} \frac{n^{-1} \Sigma_j [G^2(z_1)](z_1) g_m^{(n)}(z_2)}{(1 - w^2 n^{-1} \Sigma_j g_m^{(n)}(z_1)^2)(1 - w^2 n^{-1} \Sigma_j g_m^{(n)}(z_2)^2)}. \tag{A10}$$

Since $\lim_{n \to \infty} n^{-1} \Sigma_m \, g_m^{(n)}(z)^2 = \int (E - z - w^2 g_0(z))^{-2} dN_0(E) \equiv \Phi_2$, then the second fraction of the last term of Eq. (A10) is not singular for $z_i = E \pm i0$ with E such that $\Im g(E + i0) > 0$. Thus, this term vanishes in the scaling limit (VI.82).

Consider now the first term of the right-hand side of Eq. (A10). A simple computation shows that

$$n^{-1} \sum_m g_m^{(n)}(z_1) g_m^{(n)}(z_2) = \frac{g^{(n)}(z_1) - g^{(n)}(z_2)}{z_1 - z_2 + w^2 [g^{(n)}(z_1) - g^{(n)}(z_2)]}.$$

Since, according to Eqs. (A4)–(A7) $\lim_{n \to \infty} g^{(n)}(z) = g(z)$ we find for this term

$$-\frac{2w^2}{(z_1 - z_2)^2} \left(\frac{g_0(z_1) - g_0(z_2)}{z_1 - z_2 + w^2 [g_0(z_1) - g_0(z_2)]} - \Phi_2 \right) (1 - w^2 \Phi_2)^{-1} + O(|z_1 - z_2|^{-1}).$$

This relation implies that in the scaling limit (VI.82) we obtain again the simple universal expression (VI.83) .

APPENDIX B: AUXILIARY FACTS

Lemma 1: *Self-averageness property (V.72) holds under assumptions of Theorem 3.*
Proof: We denote

$$F_n(z,z')=\mathbf{E}\{g^C(g')^C\}\equiv\mathbf{E}\{g^Cg'\}, \tag{B1}$$

where $g\equiv g_n(z)$ and $g'\equiv g_n(z')$, $g_n(z)=n^{-1}\,\mathrm{tr}\,(H-zI)^{-1}$ and $g^C=g-\mathbf{E}\{g\}$.

Obviously, $G_{jj}(z^\dagger)=G^\dagger_{jj}(z)$ and $F_n(z,z^\dagger)=\mathbf{E}\{|g^C(z)|^2\}$.

Let us apply the resolvent identity (II.20) to the last factor g' on the right-hand side of Eq. (B1). We obtain the relation

$$F_n(z,z')=\frac{1}{z'n}\sum_{jm}\mathbf{E}\{g^CG'_{jm}H_{mj}\}, \tag{B2}$$

where $G'\equiv G(z')$. Comparing relations (B2) and (V.69), we see that their right-hand sides are similar. The only difference is that the sum in Eq. (B2) has an extra factor n^{-1} and e_q of Eq. (V.69) is replaced by g. Hence, one can compute the average in Eq. (B2) in the same way as it was done for the right-hand side of Eq. (V.69) and come to the expression $F_n(z,z')=\Sigma_{k=1}^5\,T_k(n)$, where $T_k(n)$ are similar to $S_k(n)$, $k=1,..,5$ in Eq. (V.70).

Thus we find that $T_1(n)$ and $T_3(n)$ are of order $o(n^{-1})$, as $n\to\infty$ just as in the case of $S_1(n)$ and $S_3(n)$.

Consider $T_5(n)$ which is analogous to $S_5(n)$ in Eq. (V.70). It contains four derivatives of $G_{kk}G_{jm}$ by H_{mj}. It follows from Eq. (III.37) that the result of differentiating includes at least one factor G_{jm}. Combining Eq. (III.41) with inequalities used to estimate $S_5(n)$, we easily derive that $T_5(n)$ is a quantity of order $O(n^{-3/2})$.

Let us estimate $T_4(n)$ acting in the same way as in the case of $S_4(n)$. As mentioned in Sec. V, the non-vanishing contribution to $S_4(n)$ comes from terms arising from one derivative of G'_{jm} and two derivatives of e_q. The rest of the terms are of order $o(1)$. Thus, in the corresponding terms of $T_4(n)$ we have to take into account only terms with factors G or G' having coincident arguments. It is easy to see that due to extra factor n^{-1} in front of the whole sum and factor n^{-1} in $g(z)$, these terms are of order n^{-2}. Thus, $T_4(n)$ is of order $o(n^{-1})$.

Turning to $T_2(n)$ and taking into account previous arguments, we arrive at the relation

$$F_n(z,z')=-\frac{w^2}{z'n^2}\sum_{j,m}\mathbf{E}\{g^CG'_{jj}G'_{mm}\}-\frac{w^2}{z'n^2}\sum_{j,m}\mathbf{E}\{g^CG'_{jm}G'_{jm}\}+\Phi'(z,z'), \tag{B3}$$

where $\Phi'(z,z')=o(n^{-1})$. Using Eq. (III.41), we easily obtain that

$$\frac{w^2}{n^2}\left|\sum_{j,m}\mathbf{E}\{g^CG'_{jm}G'_{jm}\}\right|\leqslant\frac{w^2}{n^2}\sum_j\mathbf{E}\left\{|g^C|\sum_m|G'_{jm}|^2\right\}\leqslant\frac{w^2}{n|\Im z'|^2}\mathbf{E}^{1/2}\{|g^C|^2\}.$$

Observing that

$$\mathbf{E}\{g^Cg'g'\}=2\mathbf{E}\{g^Cg'\}\mathbf{E}\{g'\}+\mathbf{E}\{g^C[g']^Cg'\},$$

we derive from Eq. (B3) that for $z'=z^\dagger$ and $z\in U_0$ [Eq. (II.22)]:

$$C_1F_n(z,z^\dagger)-C_2n^{-1}|F_n(z,z^\dagger)|^{1/2}-|\Phi'_n|\leqslant O,$$

where C_1 and C_2 are absolute constants (cf. Eq. (II.28)). This inequality implies Eq. (V.72). Lemma proved

Lemma 2: *Under assumptions of Theorem 3 the relation Eq. (V.73) is true.*

Proof: It suffices to show that

$$R_n \equiv \mathbf{E}\{|G_2^C|^2\} = o(1), \quad n \to \infty, \tag{B4}$$

where $G_2 \equiv n^{-1}\Sigma_j G_{jj}^2$. Repeating computations of previous proof, we obtain the following relation

$$R_n = \frac{1}{z'n}\sum_{j,m} \mathbf{E}\{G_2^C G'_{jj} G'_{jm} H_{mj}\}.$$

Comparing again the right-hand side of this equality with those of Eqs. (B2) and (V.69) and repeating the corresponding computation, we conclude that

$$R_n = -\frac{w^2}{z'n^2}\sum_{j,m} \mathbf{E}\{G_2^C G'_{jj} G'_{jj} G'_{mm}\} + \frac{w^2}{z'n^2}\sum_{j,m} \mathbf{E}\{G_2^C G'_{jj} G'_{jm} G'_{mm}\} + \Phi''_n, \tag{B5}$$

where $\Phi''_n = o(1)$ as $n \to \infty$ for $z' = z^\dagger$ and $|\Im z| > 0$. Taking into account Eq. (V.72), we derive from Eq. (B5) that for $z \in U_0$

$$C_3 R_n - C_3 R_n - n^{-1} C_4 |R_n|^{1/2} + o(1) \leqslant 0,$$

where C_3 and C_4 are some absolute constants (cf. Eq. (II.28)). This inequality implies Eq. (B4). Lemma is proved.

Fictitious level dynamics: A novel approach to spectral statistics in disordered conductors

(Received 10 May 1996; accepted for publication 17 June 1996)

We establish a new approach to calculating spectral statistics in disordered conductors, by considering how energy levels move in response to changes in the impurity potential. We use this fictitious dynamics to calculate the spectral form factor in two ways. First, describing the dynamics using a Fokker–Planck equation, we make a physically motivated decoupling, obtaining the spectral correlations in terms of the quantum return probability. Second, from an identity which we derive between two- and three-particle correlation functions, we make a mathematically controlled decoupling to obtain the same result. We also calculate weak localization corrections to this result, and show for two dimensional systems (which are of most interest) that corrections vanish to three-loop order. © *1996 American Institute of Physics.* [S0022-2488(96)01110-3]

I. INTRODUCTION

Numerous properties of quantum systems can be described in terms of their energy spectra. For complex systems an exact determination of energy levels is not feasible, and a statistical description becomes necessary. It turns out that the Wigner–Dyson (WD) statistics[1,2] of eigenvalues of random Hermitian matrices describes energy levels in a wide variety of different systems.[3] The joint distribution of eigenvalues is dominated by level repulsion and is universal in the sense that level correlations depend only upon the symmetry of the Hamiltonian while all specific properties of the system are absorbed into the mean level spacing, Δ. A very important feature of WD statistics is that — by construction of invariant ensembles of random matrices — spectral properties are independent of eigenstate correlations. In real systems such an independence can at best be approximate. It holds, however, in the ergodic regime where the entire phase space of a system is explored. If a non-ergodic regime is of interest, not only is WD statistics inapplicable but the whole concept of the independence of spectral and eigenstate correlations should be re-examined.

Disordered mesoscopic conductors present a natural ensemble for a statistical description - the ensemble of impurity configurations. In this case spectral statistics in the non-ergodic regime are very important for both transport and thermodynamic properties of electrons. Different regimes in disordered conductors are determined by the energy or time scale, as shown in Fig. 1. The ergodic regime involves energy level separations $\varepsilon \lesssim E_c \equiv \hbar/t_{\rm erg}$ where E_c is called the Thouless energy, and $t_{\rm erg} \sim D/L^2$ is the time required for the electronic diffusive motion, with diffusion constant D, to fill all phase space, in a sample of size L. The quantum limit of this regime corresponds to smaller energy separations, $\varepsilon \lesssim \Delta$, where Δ is the mean level spacing, and to longer times $t \gtrsim t_H$, where $t_H \equiv \hbar/\Delta$ is the Heisenberg time. Note that the ratio E_c/Δ is proportional to the dimensionless conductance g (i.e., the conductance measured in the units of $e^2/\hbar$), and is large in the metallic phase. The diffusive regime involves energies $\hbar/t_{\rm erg} \lesssim \varepsilon \lesssim \hbar/t_{\rm el}$, where $t_{\rm el}$ is the mean

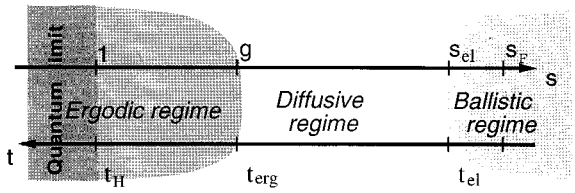

FIG. 1. Regimes of energy and time in a disordered metal; here $s_{\rm el}=\hbar/t_{\rm el}\Delta$ and $s_{_F}=\varepsilon_{_F}/\Delta$.

elastic-scattering time. The largest energies, $\hbar/t_{\rm el}\lesssim\varepsilon\lesssim\varepsilon_{_F}$, (where $\varepsilon_{_F}$ is the Fermi energy) and the shortest times, $t\lesssim t_{\rm el}$, correspond to the ballistic regime in which multiple scattering by impurities is irrelevant.

It was first conjectured by Gor'kov and Eliashberg[4] and then shown by Efetov[5] that spectral correlations in the ergodic regime are described by the random matrix theory (RMT) of Wigner and Dyson. Correlations in the non-ergodic diffusive regime which are important, in particular, for universal conductance fluctuations were analyzed by Altshuler and Shklovskii[6] at leading order in diagrammatic perturbation theory. Their results were later reproduced by Argaman *et al.*[7] within the semiclassical approach, using the diagonal approximation.

We have recently developed[8] an alternative approach to level statistics in the non-ergodic regime which takes into account the inevitable coupling between eigenvalue and eigenstate correlations, and can be extended beyond the region of validity of the perturbative technique. Our approach is based on the idea of parametric motion through the ensemble of disordered Hamiltonians: we treat the energy eigenvalues as particles with fictitious dynamics induced by changing some parameter of the Hamiltonian. This dynamics takes the form of Brownian motion in a fictitious time τ related to the parameter being changed. Originally, this idea was employed by Dyson[9] in the context of RMT. Later, in the context of the semiclassical description, Pechukas[10] used motion along a smooth path in the space of Hamiltonians to generate fictitious dynamics of a different kind. Both Dyson and Pechukas were interested in level dynamics primarily as a way of generating the level distribution. In contrast, a number of recent authors,[11] notably Szafer, Simons and Altshuler,[12,13] have investigated the dynamical problem in its own right, calculating parametric statistics: eigenvalue correlations as a function of position in the space of Hamiltonians.[14] In distinction to our approach, eigenfunction correlations have played no role in previous work,[11–15] an assumption justified only for the ergodic regime.

We have found[8] that a treatment based on Brownian motion through the ensemble of Hamiltonians provides a unified description of all regimes in disordered conductors, except the quantum limit ($t\gtrsim t_{_H}$, or $E\lesssim\Delta$), which is also beyond the scope of diagrammatic and semiclassical approaches. The main result is a new relation explicitly linking the spectral correlation function to the quantum return probability for an expanding wavepacket which, in turn, is related to a certain eigenfuction correlator. The derivation given in Ref. 8 has a limitation: when obtaining a closed Langevin equation describing the Brownian motion, we make use of an uncontrolled, although physically transparent assumption. Thus, within the framework of that calculation it is not possible to establish exactly the region of validity and accuracy.

In this paper, we re-derive the relation between spectral and eigenstate correlation functions using a more explicit procedure: we decouple a certain exact relation between two- and three-level correlation functions using the Kirkwood superposition approximation. Then we examine the accuracy of this decoupling using perturbative diagrammatic techniques. Remarkably, it not only reproduces the results of the diagonal approximation[6,7] but holds well beyond it. We show this to third order in a perturbative expansion in g^{-1}, for two-dimensional systems with or without time-reversal symmetry. We are therefore encouraged to believe that the connection between spectral and eigenstate correlation functions should be useful rather generally, and especially for

problems where the usual diagrammatic technique cannot straightforwardly be applied, such as spectral statistics in the critical regime near the Anderson transition.

II. DEFINITIONS AND MAIN RESULTS

A convenient way to consider spectral correlations is to introduce fictitious level dynamics in response to changing some parameter λ of the Hamiltonian. Thus we parametrize the ensemble of Hamiltonians as follows;

$$H(\lambda)=H_0+\lambda W(\boldsymbol{r}). \tag{2.1}$$

Here both H_0 and $H(\lambda)$ belong to the same symmetry class, and the point $\lambda=0$ corresponds to some arbitrary choice of one of the many members of the same ensemble. We will specify the choice of H_0 and W in the next section.

We consider in this paper the two-level correlation function (TLCF) and its Fourier transform, the spectral form factor, in a disordered conductor described by the Hamiltonian equation (2.1). Let $E_n(\lambda)$ be the energy levels of $H(\lambda)$. We introduce the density of states per unit volume (DoS) as

$$\rho(E,\lambda)=\frac{1}{L^d}\sum_n \delta(E-E_n(\lambda)). \tag{2.2}$$

The mean level spacing, Δ, is then related to the mean DoS, $\rho\equiv\langle\rho\rangle$, by $\Delta=(\rho L^d)^{-1}$. The TLCF is defined as

$$R(s,\lambda)=\rho^{-2}\langle\rho(E+s\Delta,\lambda)\rho(E,0)\rangle-1\,, \tag{2.3}$$

where $\omega=s\Delta$ is the energy difference between two levels. The mean DoS is practically a constant in the entire energy region of interest (as it changes only at scale of order ε_F while we consider energy windows centered at ε_F of width not exceeding $\hbar/t_{\rm el}\ll\varepsilon_F$). We consider only values of λ small enough so that the statistical regime does not change and neither does the mean DoS (for large enough L this nevertheless allows arbitrarily large λ on the scale relevant for parametric correlations). Because of this the TLCF cannot depend on either E, or on the choice of the point H_0 in the ensemble (2.1). We define the (dimensionless) spectral form factor as

$$K(t,\lambda)=\int_{-\infty}^{\infty} e^{-ist/t_H}R(s,\lambda)ds. \tag{2.4}$$

Our main result relates the spectral form factor to the quantum return probability $p(t)$ of a diffusing electron as follows:

$$K(t)=\frac{(2\pi\hbar\rho)^{-1}|t|p(t)}{1+(\pi\hbar\rho)^{-1}\int_{0^+}^{|t|}p(t')dt'}. \tag{2.5}$$

We have obtained this expression for times shorter than the Heisenberg time $t_H\equiv\hbar/\Delta$. Here we define $p(t)$ as the probability density for the wavepacket, originally created in a small volume $V_0\sim\ell^d$, to remain in this volume at the time t (ℓ is the elastic mean free path which is a natural coarse-graining size for the disordered metal; however, we could choose V_0 arbitrarily, provided that $\ell^d\gtrsim V_0\gtrsim\lambda_F^d$ where λ_F is the Fermi wavelength). The ensemble-averaged return probability is related, as we will show later, to the following wave-function correlations:

$$p(t)=\int d^d r\left\langle \sum_l |\psi_n(r)|^2|\psi_{n+l}(r)|^2 e^{-i(E_n-E_{n+l})t/\hbar}\right\rangle. \tag{2.6}$$

It is important to note that, by definition of the wave packet above, the summation here is limited to the number of levels $\mathcal{N}\sim L^d/V_0$ with energies lying within the energy band of width $E_0\sim 1/\rho V_0$.

Equation (2.5) relates the spectral and wave-function correlations. Let us analyze this relation in the metallic phase. In the diffusive regime, $t_{\rm el}\lesssim t\lesssim t_{\rm erg}$, the quantum return probability $p(t)$ reduces at leading order to the *classical* return probability for random walks, multiplied by a symmetry factor $2/\beta$, where $\beta=1, 2$ or 4 is the usual index[3] corresponding to the orthogonal, unitary, and symplectic symmetry ensembles, respectively:

$$p_0(t)=\frac{2}{\beta(4\pi Dt)^{d/2}}. \tag{2.7}$$

Noting that in the ballistic regime, $t\lesssim t_{\rm el}$, $p(t)$ saturates at $p_0(t_{\rm el})\sim 1/\ell^d$, one sees that the integral in the denominator of Eq. (2.5) is of order $(t_{\rm el}/\hbar\rho\ell^d)\sim g_0^{-1}$ for $d>2$, and of order $g_0^{-1}\ln(t/t_{\rm el})$ for $d=2$, where $g_0\gg 1$ is the dimensionless conductance at scale ℓ. It is well known that such an integral describes a weak localization correction to conductance and other physical quantities.[16] On the other hand, the quantum return probability $p(t)$ contains weak localization corrections itself. Neglecting these corrections in both the numerator and denominator of Eq. (2.5), we reduce it to

$$K_0(t)=(2\pi\hbar\rho)^{-1}|t|p_0(t). \tag{2.8}$$

To leading order, this expression is also valid in the ergodic regime, $t_{\rm erg}\lesssim t\ll t_H$, where the classical return probability saturates at $(2/\beta)L^d$ so that the second term in the denominator in Eq. (2.5) is of order $t/t_H\ll 1$ and may be neglected. We should not expect Eq. (2.5) to be correct in the quantum limit, $t\gg t_H$, as we have derived it under the assumption that the opposite inequality holds, as will be seen later. Indeed, in this regime Eq. (2.5) gives the saturation of $K(t)$ at 1/2 instead of the correct limiting value $K(t)=1$.

Equation (2.8) coincides with the result obtained by Argaman *et al.*[7] using the diagonal approximation in semiclassical periodic-orbit theory. The Fourier transform of this expression corresponds to the TLCF obtained originally by Altshuler and Shklovskii.[6] In the diffusive regime, $R(s,0)\sim A_d g^{-d/2}s^{d/2-2}$, where A_d is a numerical coefficient which is zero[17] for $d=2$; and in the ergodic regime,[18] $R(s,0)\sim -1/s^2$.

We also obtain a second relation between $K(t)$ and $p(t)$

$$K(t)+(\pi\hbar\rho)^{-1}\int_{0+}^{|t|}K(t-t')p(t')dt'=(2\pi\hbar\rho)^{-1}|t|p(t), \tag{2.9}$$

which we can see is very similar to Eq. (2.5). The latter is obtained from a diagrammatic analysis discussed in section VI. The new feature is that we have a convolution of $K(t)$ and $p(t)$ which occurs because the decoupling is in ω-space rather than t-space. In 2d, up to 3-loop order in perturbation theory, both these relations correctly reproduce the TLCF. It seems to us quite remarkable that a relation derived from a phenomenological model of energy level dynamics could be exact to 3-loop order. We note that the 2d case is expected to be a good model for the behavior of the system for $d>2$ at the mobility edge. From the point of view of a power-counting analysis of the properties of $K(t)$ at the mobility edge, both Eq. (2.5) and Eq. (2.9) should work equally well.

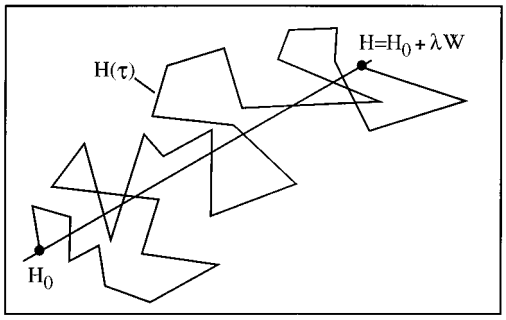

FIG. 2. Smooth $[H(\lambda)]$ and Brownian $[H(\tau)]$ paths through the space of Hamiltonians.

III. RANDOM WALKS THROUGH THE ENSEMBLE OF HAMILTONIANS

We have established elsewhere[8] the relation (2.5), using a Langevin equation to describe the motion of levels on the energy axis in response to a random walk through the ensemble of Hamiltonians. In contrast to eigenvalue statistics in RMT where the Brownian motion ideas were originally applied,[9,15] the Langevin equation for level motion is not closed, and certain assumptions are required to solve it. In the following section, we will re-derive Eq. (2.5) with the help of a different approach based on the decoupling of a certain exact relation between two- and three-level correlation functions. Before doing this, however, it is useful to analyze the Brownian motion picture within the Fokker–Planck scheme. Although the Langevin and Fokker–Planck schemes are in principle equivalent, the assumptions required in order to make the description closed are different. The Langevin scheme of Ref. 8 is physically more transparent. The advantage of the Fokker–Planck scheme which we develop here is that the approximations made are more closely related to those analyzed in subsequent sections.

We consider paths of two types through the ensemble of Hamiltonians (2.1) which, for free electrons in a random potential, have the form

$$H(\lambda) = -\frac{\hbar^2}{2m}\nabla^2 + U(\boldsymbol{r}) + \lambda W(\boldsymbol{r}). \tag{3.1}$$

Here both $U(r)$ and $W(r)$ are chosen to be of Gaussian white-noise form with zero average and

$$\begin{aligned} \langle U(\boldsymbol{r})U(\boldsymbol{r}')\rangle &= \frac{\hbar}{2\pi\rho t_{\mathrm{el}}}\delta(\boldsymbol{r}-\boldsymbol{r}'), \\ \langle W(\boldsymbol{r})W(\boldsymbol{r}')\rangle &= v^2 L^d \delta(\boldsymbol{r}-\boldsymbol{r}'). \end{aligned} \tag{3.2}$$

The first type of path is a straight line through the ensemble, and is generated by varying λ in Eq. (3.1). The second type is a Brownian path through the ensemble, parameterized by the fictitious time τ, generated in the following way:

$$H(\tau) = H_0 + \int_0^\tau d\tau' V(\tau', \boldsymbol{r}). \tag{3.3}$$

We take $V(\tau,\boldsymbol{r})$ to be Gaussian distributed with zero average and

$$\langle V(\tau,\boldsymbol{r})V(\tau',\boldsymbol{r}')\rangle = v^2 L^d \delta(\tau-\tau')\delta(\boldsymbol{r}-\boldsymbol{r}'). \tag{3.4}$$

Referring to Fig 2, one sees that the two ways of exploring the ensemble are equivalent if one

makes the identification $\tau=\lambda^2$.

In our derivation we will use averages over both W or, equivalently, V and then over H_0, and we must here discuss the role of each. The average over all possible perturbations, W, will be necessary to derive the equation of motion of the energy levels, and thence the density of states. We can then obtain correlation functions for energy levels of the system at different parameter values by averaging over the starting point H_0. Such functions should then depend only upon energy and parameter differences by homogeneity.

The first step in our derivation is to obtain the equation of motion for the joint probability density function (JPDF) of energy levels, $P(\{E_n\},\tau)$. We use perturbation theory to second order to calculate the change of $E_n(\tau)$ in response to the evolution from τ to $\tau+\delta\tau$. After averaging over W we obtain

$$\langle \delta E_n(\tau)\rangle=(\delta\tau)v^2\sum_{m\neq n}\frac{c_{nm}(\tau)}{E_n(\tau)-E_m(\tau)}, \tag{3.5a}$$

$$\langle \delta E_n(\tau)\,\delta E_m(\tau)\rangle=(\delta\tau)v^2 c_{nm}(\tau), \tag{3.5b}$$

where

$$c_{nm}(\tau)=L^d\int d^dr\,|\psi_n(\tau,r)|^2|\psi_m(\tau,\mathbf{r})|^2, \tag{3.6}$$

and $\psi_n(\tau,\mathbf{r})$ are the corresponding eigenfunctions of $H(\tau)$. Before we can use the above equations to derive a Fokker–Planck equation for the JPDF, $P(\{E_n\},\tau)$, we must make an assumption. We replace $c_{nm}(\tau)$ by its average over the ensemble of H_0. This amounts to ignoring correlations between eigenvalues and eigenvectors. We take the disorder average to be a function only of the energy difference, $\omega=E_n-E_m$, within the window of interest:

$$\langle c_{nm}(\tau)\rangle\equiv c(\omega). \tag{3.7}$$

Furthermore, we assume that in the Fourier transform of the wavefunction correlator $c(\omega)$ we may neglect the correlations between the eigenvectors and eigenvalues so that

$$C(t)=\left\langle\frac{\Delta}{2\pi\hbar}\sum_l c_{n,n+l}e^{-i\Delta lt/\hbar}\right\rangle=\int_{-\infty}^{\infty}c(\omega)e^{-i\omega t/\hbar}\frac{d\omega}{2\pi\hbar}. \tag{3.8}$$

We can relate $C(t)$ to the return probability of a diffusing electron, Eq. (2.6). To this end, consider a wavepacket made from the eigenstates of $H(\tau)$ and concentrated initially in a volume V_0 of order ℓ^d near the origin (since τ plays no role, we suppress it as a label in the following):

$$\Psi(\mathbf{r},t)=A\sum_n \psi_n(\mathbf{0})^*\psi_n(\mathbf{r})e^{-iE_nt/\hbar}.$$

Here the summation is limited to $\mathcal{N}\sim(L/\ell)^d$ levels with energies $|E_n|\lesssim 1/\rho\ell^d$, and the normalization constant is $A^2=L^d/\mathcal{N}$. The ensemble-averaged return probability $p(t)=\langle|\Psi(\mathbf{0},t)|^2\rangle$ is given by

$$p(t)=A^2\sum_{nm}\langle|\psi_n(0)|^2|\psi_m(0)|^2e^{-i(E_n-E_m)t/\hbar}\rangle=\left\langle\sum_l|\psi_n(0)|^2|\psi_{n+l}(0)|^2e^{-i(E_n-E_{n+l})t/\hbar}\right\rangle,$$

where we have used the fact that the first sum above depends only on the difference $|n-m|$. Noticing also that the ensemble-averaged quantity is spatially homogeneous, we reduce this expression to that given in Eq. (2.6). Comparing this to the definition of c_{nm}, Eq. (3.6), we obtain for $t>0$,

$$p(t)=\frac{1}{L^d}\left\langle \sum_l c_{n,n+l}e^{-i(E_n-E_{n+l})t/\hbar}\right\rangle. \tag{3.9}$$

On the face of it, this coincides, up to a constant factor, with $C(t)$, the Fourier transform of $c_{n,n+l}$, introduced in Eq. (3.8). There is, however, an essential difference: $C(t)$ is defined by the Fourier sum containing all the levels (say, up to ε_F), while the Fourier sum for $p(t)$ contains only the levels within the bandwidth $E_0 \ll \varepsilon_F$. When $|E_n-E_{n+l}| \gtrsim E_0$ the two levels are practically uncorrelated, and $c(\omega)=1$ for $\omega \gtrsim E_0$, so that $C(t)$ contains a δ-like function for t near zero. As we are not interested in an exact description at the ballistic time scale, we can represent the relation between $C(t)$ and $p(t)$ as follows:

$$\begin{aligned} &p(t)=2\pi\hbar\rho C(t), \quad t>0\,; \\ &\int_0^t C(t')dt'=\frac{1}{2}+\frac{1}{2\pi\hbar\rho}\int_{0^+}^t p(t')dt'. \end{aligned} \tag{3.10}$$

We also note that the definition of $H(\tau)$ in Eq. (3.3) causes the energy levels to move away from each other indefinitely as parametric time increases. To overcome this problem we introduce a rescaling term, $-\delta\tau U(E_n)$; to the r.h.s. of Eq. (3.5a). This $U(E_n)$ can be thought of as a Lagrange multiplier, and it will be set later on by the condition that correlation functions can depend only on differences in parametric time.

With these considerations, starting with Eqs. (3.5) we end up with the Fokker–Planck equation for the JPDF:

$$\frac{1}{v^2}\frac{\partial P}{\partial \tau}=-\sum_n \frac{\partial}{\partial E_n}\left(\frac{\partial \mathscr{U}}{\partial E_n}P\right)+\sum_{nm}\frac{\partial^2}{\partial E_n \partial E_m}(c_{nm}P), \tag{3.11}$$

where the drift potential term $\mathscr{U}$ is the sum of one-particle and two-particle potentials,

$$\mathscr{U}(\{E_n\})=\sum_n U(E_n)+\frac{1}{2}\sum_{m\neq n} f(E_n-E_m). \tag{3.12}$$

The one-particle potential arises from the energy rescaling described above, and may be considered as a confinement potential for a one-dimensional gas of fictitious particles interacting via the two-particle potential, $f(\omega)$, which is related to $c(\omega)$ by

$$\frac{\partial f(\omega)}{\partial \omega}=\frac{c(\omega)}{\omega}. \tag{3.13}$$

We see that both the drift potential and the diffusion term in the Fokker–Planck equation are expressed in terms of the function $c(\omega)$, which we have shown to be related to the return probability $p(t)$. The off-diagonal diffusion terms in Eq. (3.11), which are due to eigenfunction correlations, mean that the static solution does not have a simple Gibbs form. In fact we cannot write down its solution in closed form at all. The absence of a simple static solution to the Fokker–Planck equation (3.11) is an important difference between the current problem and the Brownian motion approach to RMT where such a solution yields[9] the exact JPDF. However, the

JPDF contains much more information than we require; for our purposes it is sufficient to study the equation of motion for the density of states, which can be written in the form

$$\rho(E,\tau)=L^{-d}\overline{\sum_n \delta(E-E_n)}, \tag{3.14}$$

where $\overline{\ldots}$ means averaging over the JPDF $P(\{E_n\},\tau)$. Following the procedure of Dyson[19] and Pastur[20] we obtain

$$\frac{1}{v^2}\frac{\partial\rho(E,\tau)}{\partial\tau}=\frac{\partial^2}{\partial E^2}[c(0)\rho(E,\tau)]+\frac{\partial}{\partial E}\left[\frac{\partial U}{\partial E}+L^d\int dE'\rho_2(E,E',\tau)\frac{\partial f(|E-E'|)}{\partial E'}\right], \tag{3.15}$$

where

$$\rho_2(E,E',\tau)=L^{-2d}\overline{\sum_{n\neq m}\delta(E-E_n)\delta(E-E_m)}. \tag{3.16}$$

Since we are only interested in level correlations in energy windows small compared to the scale at which ρ varies, the first term in Eq. (3.15) is negligible. We rewrite the last term in Eq. (3.15) in terms of the static TLCF, $R(E-E')$,

$$\rho_2(E,E',\tau)=\rho(E,\tau)\rho(E',\tau)[1+R(E-E')]. \tag{3.17}$$

After substitution into Eq. (3.15) we see that the integral over $\rho\rho R$ is dominated by a region of relatively small energy differences since the product Rf' falls off rapidly. In this region ρ is roughly constant, and the integral vanishes by oddness of the integrand. We have therefore arrived at the equation

$$\frac{1}{v^2}\frac{\partial\rho(E,\tau)}{\partial\tau}=\frac{\partial}{\partial E}\left[\rho(E,\tau)\frac{\partial}{\partial E}\left(U(E)+L^d\int dE'\rho(E',\tau)f(|E-E'|)\right)\right]. \tag{3.18}$$

This is a non-linear equation, and to proceed further we must linearize it. The static solution of Eq. (3.18) is just the equilibrium density of states, $\rho_{eq}(E)$, and we perform our linearization around by expanding around $\rho_{eq}(E)$, to give the following equation for $\tilde{\rho}(E,\tau)=\rho(E,\tau)-\rho_{eq}(E)$:

$$\frac{1}{v^2}\frac{\partial\tilde{\rho}(E,\tau)}{\partial\tau}=\frac{1}{\Delta}\frac{\partial}{\partial E}\int dE' f(|E-E'|)\frac{\partial}{\partial E'}\,\tilde{\rho}(E',\tau),$$

where we have approximated $\rho_{eq}(E)$ by ρ. Multiplying both sides of this equation by $\rho(E'',0)$ and averaging over the starting point H_0 gives us the evolution equation for the TLCF, $R(E,\tau)$,

$$\frac{\partial}{\partial\tau}R(\omega,\tau)=\frac{\partial}{\partial\omega}\int\frac{d\omega'}{2\pi\hbar}\,f(|\omega-\omega'|)\frac{\partial}{\partial\omega'}\,R(\omega',\tau), \tag{3.19}$$

where we have fixed the units of τ by setting $v^2=\Delta/\pi\hbar$. Equation (3.19) can then be solved by taking the Fourier transform to yield the result for the spectral form factor

$$K(t,\tau)=K(t,0)\exp\left[-\frac{M(t)}{2\hbar^2}|t\tau|\right], \tag{3.20}$$

where $M(t)=2tf(t)$. From the definition of $f(\omega)$, Eq. (3.13), we see that $M(t)$ is related to $C(t)$, the Fourier transform of $c(\omega)$, by

$$M(t)=2\int_0^t C(t')dt'=1+\frac{1}{\pi\hbar\rho}\int_{0^+}^{|t|} p(t')dt. \tag{3.21}$$

Although Eq. (3.20) gives the parametric dependence of $K(t,\tau)$ in terms of a function $M(t)$ related to eigenfunction correlations, we still do not know $K(t,0)$. To relate $K(t,0)$ to eigenfunction correlations we introduce a Ward identity as follows. Similarly to the TLCF, Eq. (2.3), we define the current–current correlation function:

$$\mathscr{C}(s,\lambda)=\Delta^2\sum_{n,m}\langle \dot{E}_n(\lambda)\dot{E}_m(0)\,\delta(E+s\Delta-E_n(\lambda))\,\delta(E-E_m(0))\rangle. \tag{3.22}$$

The assumption that both the correlation functions depend only upon energy and parameter differences leads to the Ward identity

$$\frac{\partial^2\mathscr{C}(\omega,\lambda)}{\partial\omega^2}=\frac{\partial^2 R(\omega,\lambda)}{\partial\lambda^2}, \tag{3.23}$$

and thence to the relation

$$\frac{\partial K(t,\tau)}{\partial\tau}=-\frac{\Delta}{2}\int d\omega\,\mathscr{C}(\omega,0)e^{-i\omega t/\hbar}. \tag{3.24}$$

Finally we can relate $\mathscr{C}(\omega,0)$ to eigenstate correlations assuming, as above, that we can ignore higher order correlations between eigenvalues and eigenstates:

$$\mathscr{C}(\omega,0)=\Delta^2\sum_{n\neq m}\langle W_{nn}W_{mm}\delta(\omega-E_n)\,\delta(E_m)\rangle\approx v^2 c(\omega), \tag{3.25}$$

from which it follows that

$$K(t,0)=\frac{1}{2}\left(\frac{t}{\hbar}\right)^2\frac{C(t)}{M(t)}. \tag{3.26}$$

With allowance for Eqs. (3.10) and (3.21), this is equivalent to the relation (2.5) obtained within the Langevin picture of Ref. 8.

The crucial assumptions used in the Brownian motion approach were in the linearization of appropriate equations, and in the neglection of higher order correlations between eigenvalues and eigenstates. We believe that these assumptions are reasonable provided that one considers only behavior at energy scales much larger than the mean level spacing. However, it is not possible to establish exactly their region of validity and accuracy within the Brownian-motion approach developed here and in Ref. 8. This we will do in the next section using an alternative approach.

IV. EXACT RELATIONS BETWEEN THE RETURN PROBABILITY AND HIGHER ORDER CORRELATION FUNCTIONS

Our aim now is to re-derive Eq. (2.5) using some exact relations which involve the return probability by making only *explicit* assumptions whose region of validity can later be verified. We again consider the ensemble of Hamiltonians, each describing a particular realization of the impurity potential. Now it will be more convenient to use the representation of Eq. (2.1) where the path through the ensemble is a straight line. We define the Fourier transform of the DoS as follows:

$$\mathscr{R}(t,\lambda)=L^d\int_{-\infty}^{\infty}\rho(E,\lambda)e^{-iEt/\hbar}dE=\sum_n\ e^{-iE_n(\lambda)t/\hbar}. \tag{4.1}$$

As all members of the ensemble are statistically equivalent, averaging over realizations should give the same result whatever point along the path has been chosen. Thus one should have

$$\langle\mathscr{R}(t,\lambda).\mathscr{R}(t',\lambda)\rangle=\langle\mathscr{R}(t,0).\mathscr{R}(t',0)\rangle. \tag{4.2}$$

Now we write for small λ;

$$\mathscr{R}(t,\lambda)=\mathscr{R}(t,0)+\lambda.\dot{\mathscr{R}}(t,0)+\frac{1}{2}\lambda^2.\ddot{\mathscr{R}}(t,0)+O(\lambda^3),$$

and substitute this expansion into Eq. (4.2) to obtain

$$2\langle\dot{\mathscr{R}}(t,0).\dot{\mathscr{R}}(t',0)\rangle+\langle\ddot{\mathscr{R}}(t,0).\mathscr{R}(t',0)\rangle+\langle\ddot{\mathscr{R}}(t',0).\mathscr{R}(t,0)\rangle=0\ . \tag{4.3}$$

We will use this identity to derive exact relations between spectral correlation functions. It follows from the definition (4.1) that

$$\begin{aligned}\dot{\mathscr{R}}(t,0)&=-\frac{it}{\hbar}\sum_n\ \dot{E}_n e^{-iE_nt/\hbar},\\ \ddot{\mathscr{R}}(t,0)&=-\frac{it}{\hbar}\sum_n\ \left(\ddot{E}_n-\frac{it}{\hbar}\dot{E}_n^2\right)e^{-iE_nt/\hbar},\end{aligned} \tag{4.4}$$

where

$$\dot{E}_n=\langle n|W|n\rangle,\ddot{E}_n=\sum_m{}'\ \frac{|\langle n|W|m\rangle|^2}{E_n-E_m}.$$

First consider $\langle\dot{\mathscr{R}}(t).\dot{\mathscr{R}}(t')\rangle$. Averaging over W only, we have $\langle\dot{E}_n\dot{E}_{n+l}\rangle_W=v^2c_{n,n+l}$. Hence, averaging also over H_0, we obtain

$$\langle\dot{\mathscr{R}}(t).\dot{\mathscr{R}}(t')\rangle=\frac{2\pi v^2t^2}{\hbar\Delta}\delta(t+t')\left\langle\frac{1}{L^d}\sum_l\ c_{n,n+l}e^{-i(E_n-E_{n+l})t/\hbar}\right\rangle=\frac{2\pi v^2t^2}{\hbar\Delta}p(t), \tag{4.5}$$

where we have used Eqs. (3.9) and (3.10) to relate the average above to the return probability $p(t)$. The crucial assumption in the derivation of Eq. (4.5) was that of homogeneity in energy space which means that $\langle c_{n,n+l}\rangle$ does not depend on n. We expect this assumption to be valid in the whole energy range of interest since the mean density of states is a disorder-independent constant in the energy window centered near ε_F of width $E_0\ll\varepsilon_F$.

Next, consider $\langle\ddot{\mathscr{R}}(t).\mathscr{R}(t')\rangle$, initially averaging only over W. Noting that $\langle\ddot{\mathscr{R}}(t).\mathscr{R}(t')\rangle_W=.\mathscr{R}(t')\langle\ddot{\mathscr{R}}(t)\rangle_W$, as $\mathscr{R}(t')\equiv\mathscr{R}(t',0)$ does not depend on W, and

$$\langle\ddot{E}_n\rangle_W=\frac{2v^2}{L^d}\sum_{l\neq0}\frac{c_{n,n+l}}{E_n-E_{n+l}},$$

we obtain from Eq. (4.4) after rearranging the terms in the summation

$$\langle \ddot{\mathscr{R}}(t)\rangle_W = -\frac{itv^2}{\hbar L^d}\sum_n \left\{ \sum_{l\neq 0} \frac{1-e^{i(E_n-E_{n+l})t/\hbar}}{E_n-E_{n+l}} c_{n,n+l} - \frac{it}{\hbar} c_{nn} \right\} e^{-iE_n t/\hbar}$$

$$= -\frac{tv^2}{\hbar^2 L^d}\sum_{nl} e^{-iE_n t/\hbar} \int_0^t dt'' e^{i(E_n-E_{n+l})t''/\hbar} c_{n,n+l}.$$

Hence, averaging on H_0 as well and using the same assumption as in the derivation of Eq. (4.5), we have

$$\langle \ddot{\mathscr{R}}(t,0).\mathscr{R}(t',0)\rangle = -\frac{2\pi v^2 t}{\hbar\Delta}\delta(t+t')\int_0^t dt'' \left\langle \frac{1}{L^d}\sum_{lm} c_{n,n+l} e^{i(E_n-E_{n+l})t''/\hbar} e^{-i(E_n-E_{n+m})t/\hbar} \right\rangle. \tag{4.6}$$

On exchanging t and t', one gets the same expression.

Now, substituting Eqs. (4.5) and (4.6) into Eq. (4.3), we obtain the following exact relation:

$$tp(t) = Q(t) \equiv \int_0^t dt' \left\langle \frac{1}{L^d}\sum_{lm} c_{n,n+l} e^{i(E_n-E_{n+l})t'/\hbar} e^{-i(E_n-E_{n+m})t/\hbar} \right\rangle, \tag{4.7}$$

where $p(t)$ is the return probability, defined by Eq. (2.6). This exact relation is a starting point to investigate the nature of the approximations needed to obtain our Brownian motion formula, Eq. (2.5). The exact relation involves the higher order correlations, and we need to construct some decoupling procedure. This will be done in the next section. Then we will use the diagrammatic technique to analyze the accuracy of the decoupling.

V. DECOUPLING OF THE HIGHER ORDER CORRELATIONS IN ω-SPACE AND t-SPACE

It is seen from Eq. (2.6) that $p(t)$ involves correlations of two energy levels, whereas, from Eq. (4.7), $Q(t)$ involves correlations of three energy levels. We should therefore assume that $Q(t)$ can be factorized in terms of two-level correlations. In order to see how to factorize Eq. (4.7), let us note that, using homogeneity of the energy space and the definitions of the DoS and TLCF, Eqs. (2.2) and (2.3), one can represent the TLCF (at $\lambda = 0$) as

$$R(\omega) \equiv R(s\Delta) = \Delta \left\langle \sum_m \delta(\omega - E_n + E_{n+m}) \right\rangle - 1 .$$

Then, from the definition (2.4) one obtains the following representation for the form factor:

$$K(t) = \left\langle \sum_m e^{-i(E_n-E_{n+m})t/\hbar} \right\rangle - \frac{2\pi\hbar}{\Delta}\delta(t). \tag{5.1}$$

The δ function above cancels that arising from summation over high levels in Eq. (5.1). Naturally, $K(t)$ defined by Eq. (2.4) as the form factor for the irreducible TLCF, Eq. (2.3), is regular at $t=0$. It is seen now that the natural factorization of Eq. (4.7) is

$$Q(t) \approx 2\int_0^t dt' \left\langle \frac{1}{L^d}\sum_l c_{n,n+l} e^{i(E_n-E_{n+l})t'/\hbar} \right\rangle \left\langle \sum_m e^{-i(E_n-E_{n+m})t/\hbar} \right\rangle. \tag{5.2}$$

The only feature that deserves comment is the factor of 2 on the r.h.s. of Eq. (5.2). To see how this arises we rewrite Eq. (4.7) using the definition of $c_{n,n+l}$,

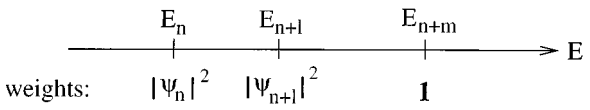

FIG. 3. Structure of the three-level correlation function $Q(t)$. We see that if in factorization we consider the correlation between E_n and E_{n+m}, we must also consider that between E_{n+l} and E_{n+m}.

$$Q(t)=\int_0^t dt' \int d^d r \left\langle \sum_{l,m} |\psi_n(\mathbf{r})|^2 |\psi_{n+l}(\mathbf{r})|^2 e^{i(E_n-E_{n+l})t'/\hbar} e^{i(E_{n+m}-E_n)t/\hbar} \right\rangle .$$

This can be represented on the energy axis in the schematic form shown in Fig. 3. We should allow both for correlations of E_{n+m} with E_n and E_{n+m} with E_{n+l}, since these are equivalent. This is made manifest by changing variable in the integral from t' to $t''=t-t'$,

$$Q(t)=\int_0^t dt'' \int d^d r \left\langle \sum_{l,m} |\psi_n(\mathbf{r})|^2 |\psi_{n+l}(\mathbf{r})|^2 e^{i(E_{n+l}-E_n)t''/\hbar} e^{i(E_{n+m}-E_{n+l})t/\hbar} \right\rangle .$$

We rewrite Eq. (5.2), taking into account that (i) $Q(t)=tp(t)$; (ii) the first average in Eq. (5.2) equals $2\pi\hbar\rho C(t')$, Eq. (3.8); and (iii) the second average is equal to $K(t)$, Eq. (5.1):

$$K(t)=\frac{1}{4\pi\hbar\rho}\frac{tp(t)}{\int_0^t dt' C(t')}, \tag{5.3}$$

which is, with allowance for Eq. (3.10), exactly equivalent to the Brownian motion result of Eq. (2.5). Now it is clear that the assumptions we have made to derive Eq. (2.5) are equivalent to neglecting three-level correlations and keeping only two-level correlations. In the above derivation, we have disregarded the δ function coming from Eq. (5.1), as the exact relation (4.7) has been actually derived from Eqs. (4.5) and (4.6) as $t^2p(t)=tQ(t)$, and this δ function enters in the combination $t\delta(t)$.

For further analysis of the accuracy of Eq. (2.5), it will be useful to see how the factorization (5.2) arises in the energy representation. We begin by representing $Q(t)$ in Eq. (4.7) as follows:

$$Q(t)=\int_0^t dt' \int d\omega \int d\omega' e^{-i\omega' t'/\hbar} e^{i\omega t/\hbar} Q(\omega',\omega), \tag{5.4a}$$

$$Q(\omega',\omega)=L^{-d}\left\langle \sum_{l,m} \delta(E_{n+l}-E_n-\omega')\,\delta(E_{n+m}-E_n-\omega)\,c_{n,n+l} \right\rangle . \tag{5.4b}$$

The function $Q(\omega',\omega)$ can now be related to the three-level correlation function $\mathcal{Q}(E'',E',E)$ defined by

$$\mathcal{Q}(E'',E',E)=L^{-d}\left\langle \sum_{n,l,m} \delta(E''-E_n)\,\delta(E'-E_{n+l})\,\delta(E-E_{n+m})\,c_{n,n+l} \right\rangle , \tag{5.5a}$$

$$=L^d \int d^d r \langle \rho(E'',\mathbf{r})\rho(E',\mathbf{r})\rho(E)\rangle \equiv L^d \int d^d r \mathcal{Q}(E'',E',E;\mathbf{r}), \tag{5.5b}$$

where

$$\rho(E',\mathbf{r}) \equiv \sum_n |\psi_n(\mathbf{r})|^2 \delta(E-E_n) \tag{5.6}$$

is the local density of states (LDoS). Thus the correlation function involves, by definition, correlations of eigenvalues and eigenstates. By the assumption of homogeneity of energy space we see that $\mathcal{Q}(E'',E',E)$ is a function only of energy differences $\omega = E-E''$ and $\omega' = E'-E''$, so that we can put $E''=0$ without loss of generality. Integrating Eq. (5.5a) over E'' prior to and after putting E'' to 0 then yields the following identity:

$$\mathcal{N} Q(\omega',\omega) = E_0 \mathcal{Q}(0,\omega',\omega),$$

where E_0 is energy bandwidth and $\mathcal{N}$ is the total number of energy levels. From this identity and Eq. (5.4b) we obtain the following representation for $Q(\omega',\omega)$:

$$Q(\omega',\omega) = \frac{\Delta}{L^d}\left\langle \sum_{n,l,m} \delta(E_n)\delta(E_{n+l}-E_n-\omega')\delta(E_{n+m}-E_n-\omega)c_{n,n+l}\right\rangle \equiv \Delta \mathcal{Q}(0,\omega',\omega). \tag{5.7}$$

We now apply the Kirkwood approximation[21] to the correlation function, Eq. (5.5b), in the following form:

$$\mathcal{Q}(0,\omega',\omega;\mathbf{r}) = \frac{\langle\rho(0,\mathbf{r})\rho(\omega',\mathbf{r})\rangle\langle\rho(0,\mathbf{r})\rho(\omega)\rangle\langle\rho(\omega',\mathbf{r})\rho(\omega)\rangle}{\rho^3} + B(0,\omega',\omega;\mathbf{r}), \tag{5.8}$$

where the numerator is chosen to incorporate all pairwise correlations, and the denominator ensures the correct limiting value as each energy difference tends to infinity. The correction B is small if the approximation is good, which is expected to be the case unless E'', $E' \equiv E''+\omega'$ and $E \equiv E''+\omega$ are all close together. Now from the definitions of $\rho(E)$ and $\rho(E,r)$, Eqs. (2.2) and (5.6), the averages in Eq. (5.8) can be expressed via the TLCF, $R(\omega)$,

$$\langle\rho(E+\omega,\mathbf{r})\rho(E)\rangle = \langle\rho(E+\omega)\rho(E)\rangle = \rho^2(1+R(\omega)),$$

and the Fourier transform of the return probability, $p(\omega)$,

$$\int d^d r \langle\rho(E+\omega,\mathbf{r})\rho(E,\mathbf{r})\rangle = \frac{1}{2\pi\hbar\Delta}[p(\omega)+2\pi\hbar\rho] = \frac{\rho}{\Delta}c(\omega),$$

where we have taken into account that $p(\omega)$ is expressed via the irreducible part of the LDoS correlation function, and used the relation (3.10).

Thus the Kirkwood approximation of Eq. (5.8) yields the expression

$$Q(\omega',\omega) = \frac{\rho}{\Delta}\{c(\omega')[1+R(\omega)+R(\omega'-\omega)]\} + \frac{\rho}{\Delta}c(\omega')R(\omega)R(\omega'-\omega)$$
$$+ \Delta\int d^d r B(0,\omega',\omega;\mathbf{r}). \tag{5.9}$$

The first line of the above equation represents the terms included in the Brownian motion formula, and the second line is the correction. We can now rewrite the exact relation Eq. (4.7) using Eq. (5.4) and the factorization given by the first line of Eq. (5.9) to obtain

$$K(t) = \left(\frac{1}{4\pi\hbar\rho}\right)\frac{tp(t)-A(t)}{\int_0^t dt'\ C(t')}, \tag{5.10}$$

where the remainder $A(t)$ is given by the Fourier transform in the form (5.4a) of the second line of Eq. (5.9). Note that in deriving Eq. (5.10), we have again neglected a non-integrated $\delta(t)$ function which does not contribute to the final result.

If we ignore the remainder $A(t)$, Eq. (5.10) is equivalent to Eq. (5.3) and thus to the Brownian motion result, Eq. (2.5). We see that the use of the Kirkwood approximation is just a more formal way of doing the factorization discussed previously. The factor of 2 that occurs in Eq. (5.2) emerges naturally, as the two equivalent two-level correlations are automatically taken into account. It is obvious that the second line of Eq. (5.9) could be small only if $|\omega|,|\omega'|,|\omega-\omega'| \gg \Delta$. Thus we could expect $A(t)$ to be small, and Eq. (2.5) to be valid, only outside of the quantum regime, i.e. for $t \lesssim t_H$.

What we would like to be able to do is to find out how big the remainder term $A(t)$ actually is in this non-quantum limit. We can see that $A(t)$ consists of two parts: the first involves a product of three two-level correlation functions, and is the Kirkwood approximation's attempt to represent three-level correlations in terms of two-level correlations; the second is the correction to the approximation itself. To proceed we will introduce diagrammatic perturbation theory in the next section, rewrite our factorization in this language and hence discover what is left over.

VI. DIAGRAMMATIC ANALYSIS

Our aim now is to check the validity of Eq. (2.5) beyond the trivial diagonal approximation in which one can just neglect the t-dependence of the denominator, and substitute the classical limit of $p(t)$ into the numerator of this expression. The simplest way of doing this is to calculate both $K(t)$ and $p(t)$ to higher order in perturbation theory, and to compare directly the r.h.s. and l.h.s. of Eq. (2.5). It is more instructive, however, to analyze diagrammatically the exact relation (4.7) and the decoupling procedure based on Eqs. (5.4) and (5.9). In this way we will not only check the accuracy of Eq. (2.5), but arrive at an alternative factorization given by Eq. (2.9).

Let us note that the role of higher order corrections is different in $d=2$ and $d>2$. In the $2d$ case they are universal in the sense that they are due to diffusive motion of electrons throughout the whole sample and almost insensitive to details of motion at the ballistic scale. In $d>2$, corrections are mainly due to the motion at the ballistic scale, and proportional to powers of an additional small parameter $(t/t_{\mathrm{el}})^{d/2-1}$ (as well as to powers of the standard weak disorder parameter, inverse dimensionless conductance g^{-1}). These corrections are not only small but of no particular interest as they do not drive the system from weak to strong-disorder regime. In contrast to this, the $2d$ corrections do describe crossover from weak to strong disorder, and are widely believed to be more relevant in the vicinity of the metal-insulator transition for $d>2$ than those calculated in the metallic limit directly in $d>2$ dimensions. Moreover, since in the diagonal approximation $K(t) \propto tp(t) \sim$ const for $t \lesssim t_{\mathrm{erg}}$ at $d=2$, the TLCF vanishes in this approximation in the diffusive regime ($E \gtrsim E_c$). Therefore, in this regime the first non-vanishing higher-order contribution governs the main effect rather than describing some correction. For all these reasons, we will consider mainly the $2d$ case in this section.

A. General relations

To be able to work in complete generality we will rewrite the exact equation (4.7) in terms of Green's functions that can then be expanded using standard diagrammatic methods. The form of the diagrams for $K(t)$ is by now well known, but those for $p(t)$ and the three-level correlator $Q(t)$ are less familiar.

We start with the standard expression for DoS in terms of exact Green's functions where, as well as elsewhere in this section, we use the units $\hbar=1$:

$$\rho(E,\boldsymbol{r}) = \frac{i}{2\pi}[G^R(E;\boldsymbol{r},\boldsymbol{r}) - G^A(E;\boldsymbol{r},\boldsymbol{r})]. \tag{6.1}$$

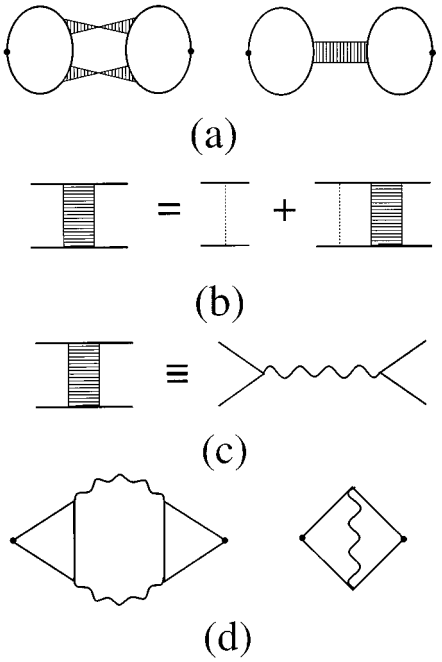

FIG. 4. (a) The two one-loop diagrams for $R(\omega)$ in a disordered metal. The diagram on the left gives the (dominant) Altshuler–Shklovskii contribution; that on the right is smaller by a factor $\Delta t_{\rm el}$, and is usually ignored. (b) Definition of the impurity ladders occurring in (a). (c) Rewriting the impurity ladder as an effective propagator. (d) Rewriting the diagrams in (a) using the notation of (c). The electron Green's function lines end up in the so-called Hikami boxes.

Here the retarded, G^R and advanced G^A Green's functions are defined by

$$G^{R,A}(E;\boldsymbol{r},\boldsymbol{r}')=\sum_n \frac{\psi_n(\boldsymbol{r})\psi_n(\boldsymbol{r}')}{E-E_n\pm i0}. \tag{6.2}$$

For the density–density correlation function we get the formula

$$R(\omega)=\left(\frac{i\Delta}{2\pi}\right)^2\int d^dr\int d^dr'\langle \mathscr{G}(0;\boldsymbol{r},\boldsymbol{r})\mathscr{G}(\omega;\boldsymbol{r}',\boldsymbol{r}')\rangle, \tag{6.3}$$

where $\mathscr{G}=G^R-G^A$. The diagrams for this then consist of two loops, each with an external vertex (with coordinates $\boldsymbol{r}$ and $\boldsymbol{r}'$), as shown in Fig. 4(a). Averaging over the disorder ensemble then leads to the presence of impurity lines both within a loop and across loops. Only the connected diagrams contribute to $R(\omega)$, while the trivial unconnected diagrams are cancelled by the -1 in the definition of $R(\omega)$, Eq. (2.3).

Similarly, $p(\omega)$ is given by

$$p(\omega)=\frac{2\pi}{\rho L^d}\int d^dr\langle\rho(E+\omega,\boldsymbol{r})\rho(E,\boldsymbol{r})\rangle=-\frac{\Delta}{2\pi}\int d^dr\langle\mathscr{G}(\omega;\boldsymbol{r},\boldsymbol{r})\mathscr{G}(0;\boldsymbol{r},\boldsymbol{r})\rangle. \tag{6.4}$$

The difference between the formulae (6.3) and (6.4) is that in the latter the densities of states are evaluated at the same point $\boldsymbol{r}$ in space rather than at different points. In diagrammatic terms this means that $p(\omega)$ consists of two loops connected to a single external point $\boldsymbol{r}$, as shown in Fig. 5.

In the diffusive regime of the disordered metal it is impurity ladders describing diffusive motion which give the important energy dependent contributions. They must have both a R and

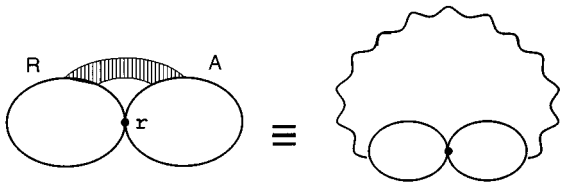

FIG. 5. The one-loop diagram for the quantum return probability $p(\omega)$ in the ladder and Hikami-box representations.

A line – so only RA and AR diagrams can contribute. Since the latter are complex conjugates of each other it follows that we can write the expressions for $R(\omega)$ and $p(\omega)$ in the following form:

$$R(\omega)=\frac{\Delta^2}{2\pi^2}\,\mathfrak{Re}\int d^dr\int d^dr'\langle G^R(\omega;\mathbf{r},\mathbf{r})G^A(0;\mathbf{r}',\mathbf{r}')\rangle, \tag{6.5}$$

$$p(\omega)=\frac{\Delta}{\pi}\,\mathfrak{Re}\int d^dr\langle G^R(\omega;\mathbf{r},\mathbf{r})G^A(0;\mathbf{r},\mathbf{r})\rangle. \tag{6.6}$$

The impurity ladders [Fig. 4(b)] which connect the two loops describe either diffusion or Cooperon propagators and are given in momentum space by

$$D(q;\omega)=\frac{1}{2\pi\rho t_{el}^2}\,\frac{1}{Dq^2-i\omega}. \tag{6.7}$$

We will consider both the cases with and without time-reversal symmetry, referring to them as the orthogonal case ($\beta=1$) and the unitary case ($\beta=2$). Diagrammatically, the latter differs from the former by the absence of the Cooperon contributions which differ from the diffusions by the relative direction of arrows in impurity ladders.

The loops can be connected by an arbitrary number of the ladders. In the lowest order there are the two contributions to $R(\omega)$ shown in Fig. 4(a), and one contribution to $p(\omega)$ (Fig. 5). The dominant contribution to $R(\omega)$ – which is called Altshuler-Shklovskii diagram – has two impurity ladders; the diagram with only one ladder gives a much smaller contribution.

Thus the perturbation order of a diagram is not determined by the number of ladders. A standard way[22,23] to determine this order, and to make the calculation of diagrams more straightforward, is to rewrite them in the form where impurity ladders are represented as propagators [a wavy line in Fig. 4(c)]; this is convenient since the ladders involve small momentum, $q\ell\ll 1$, and energy, $\omega t_{el}\ll 1$. All other Green's function lines are absorbed into effective interactions between propagators (as shown in Figs. 4 and 5) known as Hikami boxes. Then the order of a diagram is the number of independent momenta occurring in the propagators, which is just the number of loops made of the wavy lines. (Each box can be thought of as being contracted into a single node which corresponds to a spatial region of size ℓ; any diagram would then consist of a number of wavy lines joined together at such nodes.) The loop-expansion parameter here is $1/g$ where g is the dimensionless conductance of the sample.

The one-loop diagrams for $R(\omega)$ are shown in Fig. 4(d). The two external vertices may be in separate (odd) boxes, or the same (even) box; we ignore the latter since they are smaller than the former by factor $\Delta t_{\mathrm{el}}\sim(\ell/L)^d$ in the same order of perturbation theory. The remaining Hikami boxes that do not contain an external vertex have an even number of sides.

Rewriting diagrams for $p(\omega)$ in terms of Hikami boxes we find that the external vertex [corresponding to the point $\mathbf{r}$ in Eq. (6.6)] has two boxes connected to it – these can either both be odd boxes, or both be ''2-gons'' (larger even boxes are not allowed since one can always string impurity ladders across them to recover the ''2-gon'' structure). All other boxes have no external

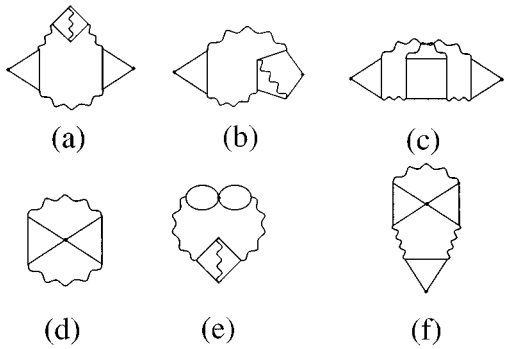

FIG. 6. Two-loop order diagrams to $R(\omega)$ [(a), (b), (c)]; $\tilde{p}(\omega)$ [(d), (e)]; and $\tilde{Q}(\omega)$ (f). All diagrams contribute in the orthogonal case, while only (d) and (f) contribute in the unitary case.

vertex and so have an even number of sides. Note that all the Hikami boxes must be ''dressed,'' i.e. single-impurity lines should connect (without mutual intersection) those *non-adjacent* sides of the boxes which have the same analyticity (both R, or both A).[23] In all diagrams below the boxes are assumed to be dressed. The one-loop contribution to $p(\omega)$ is given in Fig. 5 in both the ladder and Hikami representations. All the two-loop contributions to $p(\omega)$ and $R(\omega)$ are given in the Hikami representation in Fig. 6.

Before comparing the higher order contributions made to Eq. (2.5) by the diagrams for $R(\omega)$ and $p(\omega)$, we consider the three-level correlator $Q(\omega',\omega)$. Starting from Eq. (5.7), and rewriting the densities of states via Eq. (6.1) we get

$$Q(\omega',\omega)=\Delta\left(\frac{i}{2\pi}\right)^3\int d^dr\int d^dr'\langle\mathscr{G}(0;\mathbf{r},\mathbf{r})\mathscr{G}(\omega';\mathbf{r},\mathbf{r})\mathscr{G}(\omega;\mathbf{r}',\mathbf{r}')\rangle. \tag{6.8}$$

Following the procedure used for $R(\omega)$ and $p(\omega)$ above we see that in the ladder representation the diagrams for $Q(\omega',\omega)$ consist of three loops, two of which are joined at the external vertex $\mathbf{r}$, and the third having the external vertex $\mathbf{r}'$. There are now several classes of diagrams that are not fully connected, as shown in Fig. 7(a). (The shaded strips there include symbolically all possible combinations of impurity ladders.) The most trivial has all loops unconnected and yields a constant term. The two others are reducible as they have only two out of the three loops connected by impurity ladders, and contribute terms proportional to $\rho^3R(\omega)$, $\rho^3R(\omega'-\omega)$ and $\rho p(\omega')$. These reducible contributions add up to give

$$Q_{uc}(\omega',\omega)=\left(\frac{\rho L^d}{2\pi}\right)\{2\pi\rho[1+R(\omega)+R(\omega'-\omega)]+p(\omega')\}. \tag{6.9}$$

We see that the r.h.s. of the above is similar , but not identical to, the first line of the r.h.s. of Eq. (5.9). The difference is that the is no $p(\omega')$ multiplying the $R(\omega)$ and $R(\omega'-\omega)$ in Eq. (6.9), only its constant part $2\pi\rho$. If we substitute this term into Eq. (4.7) we obtain $K(t)=(2\pi\hbar)^{-1}tp(t)$. In other words, the reducible diagrams of the three-level correlator Q are enough to reproduce the diagonal approximation of semi-classics. In order to recover our formula, Eq. (2.5), we will need to analyze the irreducible contributions to Q given schematically in Fig. 7(b).

If we look at the irreducible contributions the first thing to note is that each diagram can only have ladders between two of the three *pairs* of loops. This is because ladders are always between an R and an A line, and so in an irreducible diagram either two loops are R and the third A or vice

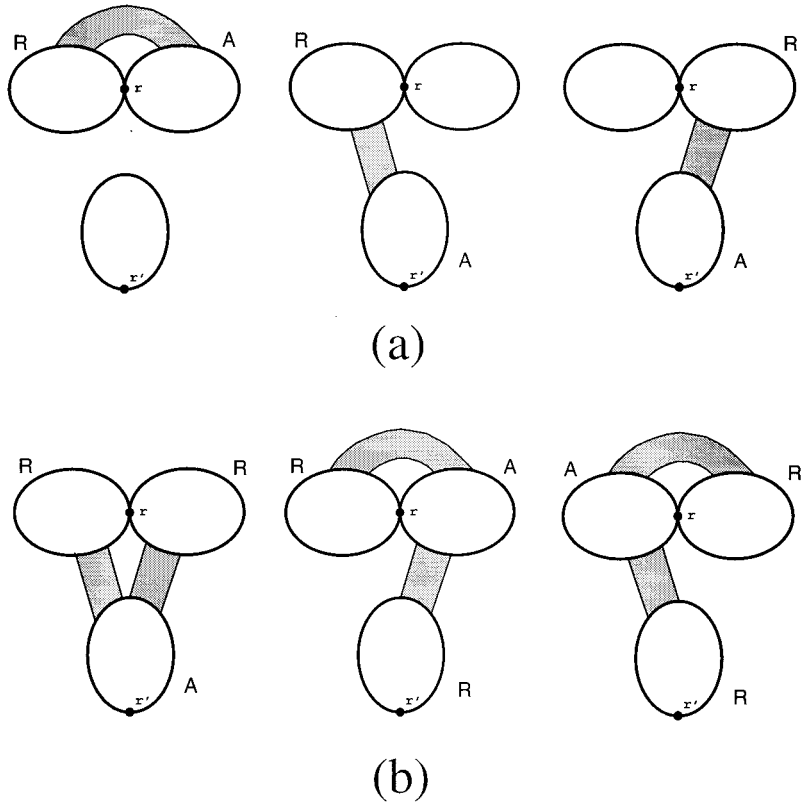

FIG. 7. (a) The reducible contributions to the three-level correlator $Q(\omega',\omega)$. The first diagram yields no contribution to the function $Q(t)$, while the other two yield equal contributions to $Q(t)$ that are proportional to $K(t)$. (b) The irreducible contributions to the three-level correlator $Q(\omega',\omega)$. For analyticity reasons the last two diagrams give no contribution to the function $Q(t)$, so we need consider only diagrams of the first type.

versa. There are therefore 6 possibilities which come in complex conjugate pairs: AAR and RRA; ARA and RAR; RAA and ARR. The irreducible part of $Q(\omega',\omega)$ can then be written in the form

$$Q_c(\omega',\omega)=\frac{1}{4\pi^3\rho L^d}\int d^dr\int d^dr'\,\mathrm{Im}\{\langle G^A(0;\mathbf{r},\mathbf{r})G^A(\omega;\mathbf{r},\mathbf{r})G^R(\omega';\mathbf{r}',\mathbf{r}')\rangle$$
$$+\langle G^A(0;\mathbf{r},\mathbf{r})G^R(\omega;\mathbf{r},\mathbf{r})G^A(\omega';\mathbf{r}',\mathbf{r}')\rangle+\langle G^R(0;\mathbf{r},\mathbf{r})G^A(\omega;\mathbf{r},\mathbf{r})G^A(\omega';\mathbf{r}',\mathbf{r}')\rangle\}. \tag{6.10}$$

When rewritten in the Hikami-box representation the diagrams for Q consist of the two boxes connected to external vertex $\mathbf{r}$ found in $p(\omega)$ diagrams, plus a single odd box connected to external point $\mathbf{r}'$ as found in $R(\omega)$ diagrams; these are then held together by wavy lines and even boxes with no external vertices. Q_{AAR} diagrams cannot have the ''2-gon'' structure in the part connected to external point $\mathbf{r}$ since such a structure ends in ladders, which cannot happen here as both lines of the ladder would be A. Q_{ARA} and Q_{RAA} diagrams can have this ''2-gon'' structure.

If we are to re-derive our main result Eq. (2.5) diagrammatically we will need to show that the connected part of $Q(\omega',\omega)$ factors into a product of R and p. This can be seen by recalling the derivation of Eq. (2.5) via the Kirkwood approximation, where such factorization occurs in the first line of Eq. (5.9). The fact that only two pairs of loops can have ladders between them suggests

a possible reason for this to occur. At this point we note that we are interested not in $Q(\omega',\omega)$ itself but rather in $Q(t)$ which is derived from it by Fourier transforms as in Eq. (5.4a). The analyticity properties of $Q(\omega',\omega)$ diagrams will lead to some types giving no contribution to $Q(t)$. Eventually, a factorization emerges from this analysis which is different to that suggested in Eq. (5.9), but which, remarkably, yields the same spectral form factor in two dimensions, to third-loop order.

B. Analytical properties of the three-level correlation function

First let us prove that only the Q_{AAR} diagrams survive, starting with the formula for $Q(t)$ given by Eq. (5.4),

$$Q(t)=\int_0^t dt' \int d\omega' \int d\omega e^{-i\omega' t'} e^{i\omega t} Q(\omega',\omega)=\int d\omega' \int d\omega \frac{e^{i\omega t}-e^{i(\omega-\omega')t}}{i\omega'} Q(\omega',\omega). \tag{6.11}$$

Taking the Fourier transform of $Q(t)$ then yields

$$\begin{aligned}
&\int dt e^{i\overline{\omega} t} \int d\omega' \int d\omega \frac{e^{i\omega t}-e^{i(\omega-\omega')t}}{i\omega'} Q(\omega',\omega) \\
&\quad = 2\pi \int d\omega' \int d\omega \frac{1}{i\omega'} [\delta(\overline{\omega}+\omega)-\delta(\overline{\omega}+\omega-\omega')] Q(\omega',\omega) \\
&\quad = -2\pi i \int \frac{d\omega'}{\omega'} [Q(\omega',-\overline{\omega})-Q(\omega',\omega'-\overline{\omega})].
\end{aligned} \tag{6.12}$$

Now consider the analyticity properties of the ARR, ARA and AAR, respectively. They can be written in the form

$$\begin{aligned}
Q_{RAA}(\omega',\omega) &= f(-\omega',-\omega), \\
Q_{ARA}(\omega',\omega) &= f(\omega',\omega'-\omega), \\
Q_{AAR}(\omega',\omega) &= f(\omega,\omega-\omega'),
\end{aligned} \tag{6.13}$$

where in each case $f(\omega_1,\omega_2)$ is a function analytic in the u.h.p. for both arguments. For Q_{RAA} Eq. (6.12) gives

$$-2\pi i \int \frac{d\omega'}{\omega'} [f(-\omega',\overline{\omega})-f(-\omega',-\omega'+\overline{\omega})] = -2\pi^2 [f(0,-\overline{\omega})-f(0,-\overline{\omega})] = 0\,, \tag{6.14}$$

since upon closing each term in l.h.p. we only get contributions from the pole at $\omega'=0$, and these cancel. Similarly for Q_{ARA} we get upon closing in the u.h.p.,

$$-2\pi i \int \frac{d\omega'}{\omega'} [f(\omega',\omega'+\overline{\omega})-f(\omega',\overline{\omega})] = 2\pi^2 [f(0,\overline{\omega})-f(0,\overline{\omega})] = 0\,. \tag{6.15}$$

Finally for Q_{AAR} we get

$$-2\pi i \int \frac{d\omega'}{\omega'} [f(-\overline{\omega},-\omega'-\overline{\omega})-f(\omega'-\overline{\omega},-\overline{\omega})] = -(2\pi)^2 f(-\overline{\omega},-\overline{\omega}), \tag{6.16}$$

where we closed first term in l.h.p., second in u.h.p. to yield contributions that add up. The above term can be rewritten in the form $-(2\pi)^2 Q_{AAR}(\omega'=0,-\overline{\omega})$, so it follows that diagrams for Q_{AAR} can yield Fourier transform of $Q(t)$ directly. We have therefore verified our previous assertion, and moreover have derived the contribution to the Fourier transform of $Q(t)$ coming from the Q_{AAR} diagrams. Diagrammatically the above means that all ladders in Q_{AAR} diagrams will have the same energy dependence.

Let us discuss what the above means for our factorization hypothesis. The reason we expected that it would be the Q_{RAR} and Q_{ARR} diagrams that survived is that we can envisage a natural factorization into terms with energy dependence of the form $R(\omega)p(\omega')$ and $R(\omega'-\omega)p(\omega')$, which are exactly what is needed to reproduce Eq. (2.5). The fact that it is Q_{AAR} which survives means that our factorization hypothesis must be altered to have an energy dependence $R(\omega)p(\omega)$, which leads to a convolution in t-space. More precisely, we expect the ω-space factorization to have the form

$$\widetilde{Q}(\omega)=-\frac{(2\pi)^2 i}{\Delta}\widetilde{p}(\omega)\widetilde{R}(\omega). \tag{6.17}$$

Here we have introduced the analytical functions $\widetilde{Q}(\omega),\widetilde{p}(\omega)$ and $\widetilde{R}(\omega)$ as follows:

$$\widetilde{Q}(\omega)\equiv Q_{AAR}(0,\omega);\quad p(\omega)\equiv 2\Re\mathrm{e}\widetilde{p}(\omega);\quad R(\omega)\equiv 2\Re\mathrm{e}\widetilde{R}(\omega). \tag{6.18}$$

Note that diagrammatically we calculate exactly these analytical functions. Before giving the results for higher-loop contributions, note that calculations of $\widetilde{R}(\omega)$ are considerably simplified due to the fact that it can be obtained as the second derivative of ''free energy'' $F(\omega)$:

$$\widetilde{R}(\omega)=-\left(\frac{\Delta}{2\pi}\right)^2\frac{\partial^2}{\partial\omega^2}\,\widetilde{F}(\omega). \tag{6.19}$$

Here $F(\omega)$ is given by the sum of all diagrams that have no external vertices, and the coefficient of proportionality is chosen so as to make $F(\omega)$ dimensionless.

C. Calculation of diagrams up to three-loop order

As a result of the above discussion we can now lay out the diagrammatic program ahead. First, we will calculate the contributions to $\widetilde{F}(\omega)$, $\widetilde{p}(\omega)$ and $\widetilde{Q}(\omega)$ up to three-loop order. Then, we will verify that the exact relation (4.7) is fulfilled with these contributions and check the factorization scheme of Eq. (6.17) which is dictated by the analytical structure described above. This factorization is equivalent to that given by Eq. (2.9). Finally, we will, having verified this factorization up to the three-loop order, check the factorization that comes out of the Kirkwood approximation, Eq. (5.9), and is equivalent to the result of the Brownian-motion model, Eq. (2.5). We will show that up to the third-loop order both the factorizations are identical and exact in $d=2$. Therefore, Eq. (2.5) obtained within the Brownian motion picture turn out to be correct to quite a non-trivial order of perturbation theory.

Let us introduce a notation that is convenient for further analysis:

$$\mathscr{P}_{1\ldots n}\equiv D(\boldsymbol{q}_1+\cdots+\boldsymbol{q}_n)^2-i\omega, \tag{6.20}$$

In particular, $\mathscr{P}_1\equiv Dq_1^2-i\omega$.

Now, two-loop order contributions corresponding to the diagrams in Fig. 8(a) (equivalent to those in Figs. 6(a)–6(c)] and in Figs. 6(d)–6(f) may be written as

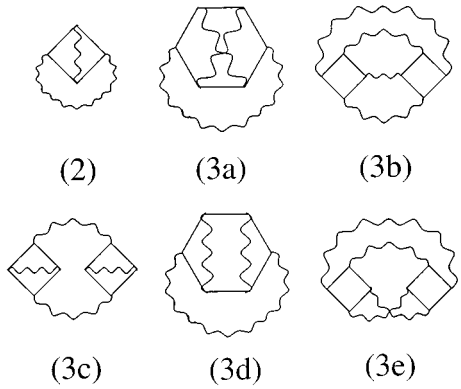

FIG. 8. Two- and three-loop order diagrams for the function $\widetilde{F}(\omega)$. The two-loop diagram is equivalent to those in Figs. 6a–c, and contributes only to the orthogonal case. All 5 three-loop diagrams contribute to the orthogonal case, while only 3a and 3b contribute to the unitary case.

$$\widetilde{F}_2(\omega)=\left(\frac{2-\beta}{\beta}\right)\frac{\Delta}{2\pi}\sum_{q_1,q_2}\frac{\mathscr{P}_1+\mathscr{P}_2+i\omega}{\mathscr{P}_1\mathscr{P}_2};$$

$$\widetilde{p}_2(\omega)=\left(\frac{2}{\beta}\right)\frac{\Delta}{2\pi L^d}\,\mathfrak{Re}\sum_{q_1,q_2}\left\{\frac{1}{\mathscr{P}_1\mathscr{P}_2}+2(2-\beta)\frac{\mathscr{P}_1+\mathscr{P}_2+i\omega}{(\mathscr{P}_1)^2\mathscr{P}_2}\right\}; \tag{6.21}$$

$$\widetilde{Q}_2(\omega)=-i\left(\frac{2}{\beta}\right)^2\frac{\Delta}{L^d}\sum_{q_1,q_2}\frac{1}{(\mathscr{P}_1)^2\mathscr{P}_2}.$$

Here we note the following. The diagrammatic approach could be used both in the diffusive regime, $\omega\gg E_c$, where all the sums above should be replaced by integrals, and in the ergodic regime, $E_c\gg\omega\gg\Delta$, where only the contribution of the zero mode (all $\boldsymbol{q}=0$) survives. In the diffusive regime, regularization of divergent integrals is required. Although we do not explicitly calculate contributions of all diagrams below, in all algebraic manipulations we use dimensional regularization near $d=2$. These manipulations involve dealing with large $q\sim\ell^{-1}$, and so all diagrammatic expressions we give here are not directly valid in the ergodic regime. However, it is straightforward to verify the accuracy of our factorization scheme in the zero-mode regime as well.

The three-loop contributions to $F(\omega)$, $p(\omega)$ and $Q(\omega)$ are shown in Figs. 8, 9 and 10,

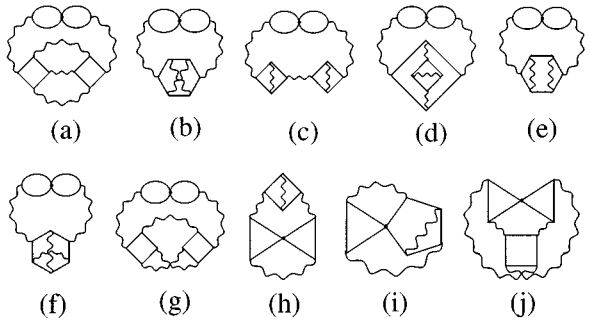

FIG. 9. Three-loop order diagrams for the quantum return probability $\widetilde{p}(\omega)$. All 10 diagrams contribute in the orthogonal case, while only the first 2 contribute in the unitary case.

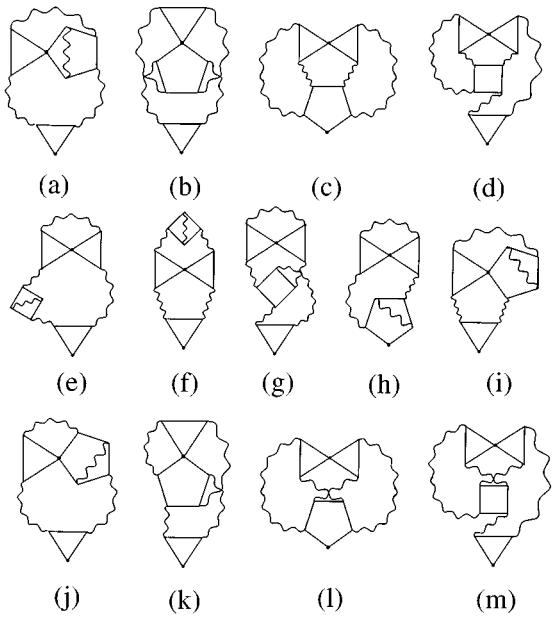

FIG. 10. Three-loop order diagrams for the function $\widetilde{Q}(\omega)$. All 13 diagrams contribute in the orthogonal case, while only the first 4 contribute in the unitary case.

respectively. In Fig. 8(a) we have also drawn the two-loop contribution to $F(\omega)$ which is equivalent to the three two-loop contributions to $R(\omega)$ shown in Fig. 6. Note that in the three-loop order there are 41 diagrams that contribute directly to $R(\omega)$, so that to have instead only the 5 diagrams for $F(\omega)$, as in Fig. 8, is a considerable simplification. Nevertheless, these three-loop results are quite bulky, and we list contributions of each diagram Tables I–III below.

The labels in the tables correspond to those in Figs. 8–10, and in the figure captions we describe which diagrams are made of diffusions only and thus contribute in the unitary ($\beta=2$) case. Obviously, all the diagrams contribute in the orthogonal ($\beta=1$) case. Results for the symplectic symmetry class ($\beta=4$) are practically the same as for the orthogonal case but we do not list them here to avoid complications with the coefficients.

The starting point for our diagrammatic analysis is Eq. (4.7) which we now rewrite as follows. The Fourier transform, Eq. (5.4), of the function $Q(t)$ is split into the reducible and irreducible

TABLE I. Three-loop order contributions to $\widetilde{F}(\omega)$: an overall factor of $(\Delta/2\pi)^2$ should be attached to each contribution.

$3F_a=F_d=-2\Sigma_{q_1,q_2,q_3}\dfrac{2(\mathscr{P}_1+\mathscr{P}_2+\mathscr{P}_3)+3i\omega}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3}$
$F_b=\frac{1}{4}\Sigma_{q_1,q_2,q_3}\dfrac{(\mathscr{P}_{12}+\mathscr{P}_{23})^2}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$
$F_c=2\Sigma_{q_1,q_2,q_3}\dfrac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)(\mathscr{P}_1+\mathscr{P}_3+i\omega)}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3}$
$F_e=\frac{1}{2}\Sigma_{q_1,q_2,q_3}\dfrac{(\mathscr{P}_{12}+\mathscr{P}_{23})(\mathscr{P}_{13}+\mathscr{P}_{32})}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$

TABLE II. Three-loop order contributions to $\tilde{p}(\omega)$: an overall factor of $L^{-d}(\Delta/2\pi)^2$ should be attached to each contribution.

$$p_a=\tfrac{1}{2}p_e=p_f=-2\Sigma_{q_1,q_2,q_3}\frac{2(\mathscr{P}_1+\mathscr{P}_2+\mathscr{P}_3)+3i\omega)}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3}$$

$$p_b=\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_{12}+\mathscr{P}_{23})^2}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$$

$$p_c=4\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)(\mathscr{P}_1+\mathscr{P}_3+i\omega)}{\mathscr{P}_1^3\mathscr{P}_2\mathscr{P}_3}$$

$$p_d=4\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)(\mathscr{P}_2+\mathscr{P}_3+i\omega)}{\mathscr{P}_1^2\mathscr{P}_2^2\mathscr{P}_3}$$

$$p_g=2\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_{12}+\mathscr{P}_{23})(\mathscr{P}_{13}+\mathscr{P}_{32})}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$$

$$p_h=4\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3}$$

$$p_i=-4\Sigma_{q_1,q_2,q_3}\frac{1}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3}$$

$$p_j=\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_{12}+\mathscr{P}_{23})}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$$

parts [Eqs. (6.9) and (6.10), respectively]. As only $\tilde{Q}(\omega)$, Eq. (6.18), contributes to the irreducible part, we obtain

$$\frac{\partial}{\partial(i\omega)}\left[\frac{1}{L^d}\frac{\partial}{\partial(i\omega)}F(\omega)-\tilde{p}(\omega)\right]=\frac{i}{\pi}\tilde{Q}(\omega). \tag{6.22}$$

This is the exact relation which holds to all orders in perturbation theory. It allows us to check the accuracy of our diagrammatics up to three-loop order for both the unitary and orthogonal cases. We do this by first substituting the two-loop results of Eq. (6.21—which is quite straightforward, and then the three-loop data from the tables which requires some significant algebra. We verify that this identity holds with our diagrammatic results which gives us confidence in their accuracy.

TABLE III. Three-loop order contributions to $\tilde{Q}(\omega)$: an overall factor of $(\Delta^2/2\pi L^d)$ should be attached to each contribution.

$$Q_a=2Q_b=Q_h=Q_i=Q_j=Q_k=2i\Sigma_{q_1,q_2,q_3}\frac{1}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3}$$

$$Q_c=Q_l=i\Sigma_{q_1,q_2,q_3}\frac{1}{\mathscr{P}_1\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$$

$$Q_d=Q_m=-2i\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_{12}+\mathscr{P}_{23})}{\mathscr{P}_1^2\mathscr{P}_2\mathscr{P}_3\mathscr{P}_{123}}$$

$$Q_e=-4i\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)}{\mathscr{P}_1^3\mathscr{P}_2\mathscr{P}_3}$$

$$Q_f=-2i\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_3+i\omega)}{\mathscr{P}_1^2\mathscr{P}_2^2\mathscr{P}_3}$$

$$Q_g=-2i\Sigma_{q_1,q_2,q_3}\frac{(\mathscr{P}_1+\mathscr{P}_2+i\omega)}{\mathscr{P}_1^2\mathscr{P}_2^2\mathscr{P}_3}$$

The next step is to see whether our projected ω-space factorization occurs to two- and three-loop order in both the orthogonal and unitary cases. To check Eq. (6.17) up to two-loop order, we calculate both factors in the r.h.s. to the first order only. This is simple and yields

$$\tilde{Q}_2(\omega) = -i\left(\frac{2}{\beta}\right)^2 \sum_{q_1,q_2} \frac{1}{(\mathscr{P}_1)^2 \mathscr{P}_2} = -\frac{i(2\pi)^2}{\Delta} \tilde{p}_1(\omega)\tilde{R}_1(\omega),$$

so that the factorization (6.17) is exact in this order. The reason why this is so simple is that with only two momenta q_1 and q_2 there is no way for the momenta to become ''entangled,'' and so there is only really one possible functional form. The fact that the numerical coefficients match up exactly is the important thing. The three loop case is more involved because now the entanglement can occur, and this leads to the factorization not being exact. For both the unitary and orthogonal cases, however, we get the same functional form in the remainder,

$$Q_3(\omega) + \frac{i(2\pi)^2}{\Delta}[\tilde{R}_1(\omega)\tilde{p}_2(\omega) + \tilde{R}_2(\omega)\tilde{p}_1(\omega)]$$
$$= -\frac{2i\Delta^2}{\pi\beta^2 L^d} \sum_{q_1,q_2,q_3} \left\{ \frac{4}{(\mathscr{P}_1)^2 \mathscr{P}_2 \mathscr{P}_3} - \frac{2(\mathscr{P}_{12}+\mathscr{P}_{23})}{(\mathscr{P}_1)^2 \mathscr{P}_2 \mathscr{P}_3 \mathscr{P}_{123}} + \frac{1}{\mathscr{P}_1 \mathscr{P}_2 \mathscr{P}_3 \mathscr{P}_{123}} \right\}.$$

The remainder can then be algebraically manipulated to give

$$\frac{2\Delta^2}{3\pi\beta^2 L^d} \frac{\partial}{\partial(i\omega)} \sum_{q_1,q_2,q_3} \left\{ \frac{i\omega}{\mathscr{P}_1 \mathscr{P}_2 \mathscr{P}_3 \mathscr{P}_{123}} \right\}. \tag{6.23}$$

At the three-loop level we see that the factorization is not exact, but that the remainder term is simple and its momentum integrals are fully convergent. Certainly for the orthogonal case many terms have been removed to yield this remainder. We next note that in the special case of two dimensions this remainder is zero, and the factorization is exact. This is because for $d=2$ dimensional analysis shows that the term inside the derivative is a constant – it is of the form $(-i\omega)^0$, and no logarithmic singularities are present – and so one gets zero upon taking derivative. Even if the remainder were not able to be written as a derivative, but just as a sum of terms with no logarithmic singularities, it would yield zero. This is because dimensional analysis shows that the result is of the form $a/(-i\omega)$, where a is a real constant. Since we have to take the real part of this to get $R(\omega)$ this would give zero. However in this case there would be a constant contribution to the Fourier transform $K(t)$, because $a/(-i\omega)$ does actually have a real part proportional to $\delta(\omega)$ – this is exactly what happens in the case of the 1-loop contribution in $d=2$. We note that our factorization is exact to 3-loop order in $d=2$ even in the sense of getting the constant term in $K(t)$ correct.

It seems to us that the exactness of factorization up to three-loop order in $d=2$ for both orthogonal and unitary cases is no accident, and we conjecture that this result persists to all orders in perturbation theory. Obviously such a conjecture cannot be proved using order-by-order analysis (although, of course, it could be disproved this way), so any attempt to verify this will require analysis of the structure of $R(\omega)$, $p(\omega)$ and $Q(\omega)$ diagrams.

D. Comparison of the two factorization schemes

In this section we will compare the two factorization schemes that we have introduced in this paper: the t-space scheme that arose from consideration of the Brownian motion model of section III, and the ω-space scheme that arose in the diagrammatic analysis of section VI. We have shown that the ω-space scheme is exact to 2-loop order in all dimensions, and to 3-loop order in the 2d case. We will now examine the validity of the t-space scheme. This involves very little extra work

because most of the algebraic manipulation has already been performed in the ω-space analysis. We first compare the two relations by writing both of them in t-space to yield

$$K(t)-(2\pi\hbar\rho)^{-1}tp(t)=-(\pi\hbar\rho)^{-1}\int_{0+}^{t}dt'K(t')p(t-t'), \tag{6.24a}$$

$$K(t)-(2\pi\hbar\rho)^{-1}tp(t)=-(\pi\hbar\rho)^{-1}K(t)\int_{0}^{t}p(t'), \tag{6.24b}$$

where, of course, we know the region of validity of the first formula. To investigate the t-space factorization we need only compare the r.h.s. of the above equations. In the 2-loop case the $K(t)$ and $p(t)$ in the r.h.s. will both be of 1-loop order, and we know that $p_1(t) \propto t^{-d/2}$ and $K_1(t) \propto t^{1-d/2}$. We find that the two equations above only agree for $d=2$, where $K_1(t)=1$. The t-space factorization is therefore exact to 2-loops only in 2d, and we restrict ourselves to the 2d case from now on.

To look at the t-space scheme to 3-loop order in 2d we note that we can have the combinations K_1, p_2 and K_2, p_1. For the unitary case $K_2(t)=0$, so this leaves only the first contribution, and since $K_1(t)=1$ the two factorizations become the same. For the orthogonal case we have to look at the second contribution. We find that the two equations differ by a constant. For the purpose of calculating the asymptotic behavior of $R(\omega)$, constant terms in $K(t)$ have no effect, so that the t-space factorization works up to 3-loop order in 2d for both orthogonal and unitary cases.

At this point it seems that the ω-space scheme may be perturbatively slightly more accurate than the t-space scheme in that it is correct in 2-loops for all dimensions, and at 3-loop order it gets the constant term in $K(t)$ correct in the orthogonal case. However we are still justified in saying that both schemes are correct to 3-loop order in 2d.

VII. SUMMARY

In this paper we have examined spectral correlations in disordered conductors, starting from the idea [Eq. 4.2] that two samples with impurity configurations differing by an infinitesimal amount should be statistically equivalent. In the first instance, this equivalence yields an identity relating two-point to three-point correlation functions; it is useful only if one can decouple the latter. We argue that a decoupling based on the Kirkwood superposition approximation is physically reasonable provided one is interested only in correlations at scales large compared to the mean level spacing. Within this approximation, we express [Eq. 2.5] both the non-parametric and the parametric spectral form factor in terms of the quantum return probability for a spreading wavepacket. We test the decoupling by calculating corrections, using the standard diagrammatic perturbation theory for disordered conductors to expand about the metallic limit in inverse powers of the dimensionless conductance, g. We show that in two-dimensional systems, the case of greatest interest, there are no corrections to order g^{-3}. We believe that the results we obtain from this approach should be useful rather generally, and especially when a diagrammatic analysis is not straightforward, as at the Anderson transition; the implications of our work in that regime will be discussed elsewhere.

Note added: Since completing this work, we have become aware of an earlier discussion by Wilkinson,[24] in which the effects of eigenfunction correlations on Brownian level dynamics are investigated, using periodic orbit theory to treat the semiclassical limit.

(Received 23 April 1996; accepted for publication 19 June 1996)

We present a semiclassical theory of weak disorder effects in small structures and apply it to the magnetic response of non-interacting electrons confined in integrable geometries. We discuss the various averaging procedures describing different experimental situations in terms of one- and two-particle Green functions. We demonstrate that the anomalously large zero-field susceptibility characteristic of clean integrable structures is only weakly suppressed by disorder. This damping depends on the ratio of the typical size of the structure with the two characteristic length scales describing the disorder (elastic mean-free-path and correlation length of the potential) in a power-law form for the experimentally relevant parameter region. We establish the comparison with the available experimental data and we extend the study of the interplay between disorder and integrability to finite magnetic fields. © *1996 American Institute of Physics.* [S0022-2488(96)01310-2]

I. INTRODUCTION

Electronic mesoscopic systems offer nowadays the possibility of being used as a laboratory for studying quantum chaos. The main question of this novel discipline — the quantum signatures of the underlying classical dynamics — can be addressed in microstructures defined on high mobility semiconductor heterojunctions. This connection presents a considerable challenge to experimentalists since it implies complicated fabrication processes and delicate measurements. The challenge for theoreticians is not any less complicated since semiconductor microstructures are very rich condensed matter systems (involving effects of temperature, confinement, disorder, electron-electron and electron-phonon interactions, etc.) where the applicability and validity of simple models has to be clearly established.

Within the simple model of a particle-in-a-billiard, important differences have been predicted,[1] and later measured,[2,3] in the transport through chaotic and integrable geometries. In the former nearby trajectories diverge exponentially and periodic orbits are usually isolated; the latter are characterized by having as many constants of motion in involution as degrees of freedom, and periodic orbits are organized in families on invariant tori.[4] Chaotic cavities exhibit a universal behavior for the conductance fluctuations and weak-localization, characterized by a single scale. On the contrary, integrable cavities do not show generic behavior presenting more fine-scale fluctuations and a non-Lorentzian line-shape of the low-field magneto resistance. In the case of thermodynamical properties like the magnetic susceptibility, the differences between chaotic and integrable billiards are more spectacular since they involve an order-of-magnitude enhancement of

[a]Permanent address: Division de Physique Théorique, IPN, 91406 Orsay Cedex, France.

the low-field susceptibility of integrable geometries compared to that of chaotic ones.[5–7] Unlike the transport problem, the predicted different behavior according to the integrability of the underlying classical mechanics, has not been experimentally confirmed.

The residual disorder present in actual microstructures plays a special role in the quantum chaos studies. Indeed, any perturbing potential, such as the one provided by the disorder, immediately breaks the integrable character of the classical dynamics. Since small amounts of disorder are unavoidable in actual microstructures, the question of whether or not integrable behavior should be observed, naturally arises. It is then of foremost importance to establish if the differences between chaotic and integrable geometries persist when we go beyond the particle-in-a-box model. This interplay between integrability and disorder is the main subject of this paper.

We start by characterizing the disorder. One limiting case is the absence of it, where the dynamics is determined by the non-random confinement potential (particle-in-a-box or *clean* models). On the other extreme we have the *diffusive* limit where the electron motion is a random walk between the impurities and the confining effects are not important. The strength of the disorder in the diffusive case is characterized by the transport mean free path l_T: the mean distance over which the electron momentum is randomized. When l_T becomes of the order of the typical size a of the microstructure, confinement *and* disorder are relevant. For $l_T > a$ we arrive at the *ballistic* regime where electrons can traverse the structure with a small drift in their momentum (going along almost straight lines), and their dynamics is mainly given by the bounces off the walls of the confining potential. In the ballistic regime the underlying classical mechanics still depends on the geometry and we would like to understand the different role of disorder in integrable and chaotic geometries.

For short range impurity potentials (as typically found in metallic samples) the scattering is isotropic (s-type) and the momentum is randomized after each collision with an impurity. There is therefore only one length scale, namely l_T, characterizing the disorder. For smooth impurity potentials (as typically realized in high-mobility microstructures) the scattering is forward directed and l_T may be significantly larger than the elastic mean free path l associated to the total amplitude diffracted by the disorder.[8] The regime $l_T > a > l$ is particularly interesting because it is ballistic (since the classical mechanics is hardly affected by disorder), but the single particle eigenstates are short lived. In a more technical language that we will precise in the sequel, we have l given by a single-particle Green function and l_T by a two-particle Green function.[9] We will study the interplay between disorder and confinement for physical observables that depend on one- and two-particle Green functions, concentrating on the magnetic susceptibility of individual and ensembles of ballistic microstructures.

The natural tools to attack the interplay between disorder and confinement are semiclassical expansions since they transparently convey at the quantum level the information about the classical mechanics. Supersymmetry[10] and random matrix theories are quite powerful methods that have been widely used in recent studies of quantum chaos and disordered systems,[11–14] but are not applicable to our regime of interest since they deal with the ergodic universal (long time) properties of completely chaotic systems. Diagrammatic perturbation theory for the disorder can describe the diffusive regime,[15] but calculations become exceedingly complicated when the confinement and the detailed nature of the impurity potential has to be considered.

In our semiclassical approach we emphasize the dependence of disorder effects on the ratio between the finite system size a and the disorder correlation length ξ, showing that confined systems exhibit strong deviations from the bulk-behavior. In particular we demonstrate that for integrable geometries the effect of smooth disorder results in a power-law damping of the two-particle Green function properties, and we compare this behavior with that expected in chaotic systems. For completeness of the presentation we first briefly review in Sec. II our work on the magnetic response of clean systems.[5,6] We then develop in detail a treatment of disorder in ballistic microstructures extending some preliminary work.[16] In Sec. III we present the disorder model and some general implications at the level of one- and two-particle Green functions. In

Secs. IV and V we focus on the impurity averaged magnetic susceptibility for individual and ensembles of microstructures.

II. ORBITAL MAGNETISM IN CLEAN SYSTEMS: A BRIEF REVIEW

A. Thermodynamic formalism

In this section we present the basic thermodynamical formalism for obtaining the orbital magnetism within a semiclassical approach. We indicate the main ideas for its application to clean microstructures[5,6] which will be further developed in Secs. IV and V in order to allow for the treatment of static disorder. The principle is to derive thermodynamical expressions for the free energy and the grand potential using a semiclassical approximation for the density of states. This allows us to calculate physical observables such as the magnetic susceptibility for the canonical and grand canonical ensembles.

For a system of electrons confined to an area A at temperature T and subject to a perpendicular magnetic field H, the free energy $F(T,H,\mathbf{N})$ for a fixed number $\mathbf{N}$ of electrons and the grand potential $\Omega(T,H,\mu)$ (representing the coupling to a particle reservoir with chemical potential μ) are related by means of the Legendre transform

$$F(T,H,\mathbf{N})=\mu\mathbf{N}+\Omega(T,H,\mu). \tag{2.1}$$

The canonical (χ) and grand canonical (χ^{GC}) susceptibilities of a confined electron gas are given by

$$\chi=-\frac{1}{A}\left(\frac{\partial^2 F}{\partial H^2}\right)_{T,\mathbf{N}}, \quad \chi^{\mathrm{GC}}=-\frac{1}{A}\left(\frac{\partial^2 \Omega}{\partial H^2}\right)_{T,\mu}. \tag{2.2}$$

The grand potential can be expressed in the form

$$\Omega(T,H,\mu)=-\frac{1}{\beta}\int \mathrm{d}E\, d(E)\, \ln[1+\exp(\beta(\mu-E))] \tag{2.3}$$

(with $\beta=1/k_B T$) in terms of the single-particle density of states $d(E)$ which we decompose into a smooth mean and oscillating part according to

$$d(E)=\overline{d}(E)+d^{\mathrm{osc}}(E). \tag{2.4}$$

As has first been noticed in the context of persistent currents in disordered rings,[17] a distinction between χ and χ^{GC} may be of crucial importance in mesoscopic thermodynamics: Although the number of electrons can be large for a mesoscopic system, the fact that $\mathbf{N}$ is fixed must be taken into account (by working in the canonical formalism) if a disorder or energy averaged magnetic response of an *ensemble* of isolated microsystems is examined. According to Imry[18] a convenient representation for the canonical free energy in terms of grand canonical quantities is obtained by expanding the relationship (2.1) to second order in $\mu-\overline{\mu}$ with a mean chemical potential $\overline{\mu}$ being implicitly defined by accommodating $\mathbf{N}$ charge carriers with the mean number of states

$$\mathbf{N}=N(\mu)=\overline{N}(\overline{\mu}). \tag{2.5}$$

Here

$$N(\mu)=\int_0^\infty \mathrm{d}E\, d(E) f(E-\mu) \tag{2.6}$$

with the Fermi distribution function

$$f(E-\mu)=\frac{1}{1+\exp[\beta(E-\mu)]}. \tag{2.7}$$

$\overline{N}$ is obtained in Eq. (2.5) by replacing $d(E)$ by $\overline{d}(E)$. This finally allows an expansion of the free energy as[17]

$$F(\mathbf{N})\simeq F^0+\Delta F^{(1)}+\Delta F^{(2)}, \tag{2.8}$$

with

$$F^0=\overline{\mu}\mathbf{N}+\overline{\Omega}(\overline{\mu}), \tag{2.9a}$$

$$\Delta F^{(1)}=\Omega^{\mathrm{osc}}(\overline{\mu}), \tag{2.9b}$$

$$\Delta F^{(2)}=\frac{1}{2\overline{d}(\overline{\mu})}(N^{\mathrm{osc}}(\overline{\mu}))^2. \tag{2.9c}$$

The functions $\Omega^{\mathrm{osc}}(\overline{\mu})$ and $N^{\mathrm{osc}}(\overline{\mu})$ are expressed by means of Eqs. (2.3) and (2.6), respectively, upon inserting the oscillating part $d^{\mathrm{osc}}(E)$ of the density of states (2.4). The leading order contribution to F is given by the first two terms $F^0+\Delta F^{(1)}$ yielding the susceptibility calculated in the *grand* canonical case. F^0 gives rise to the (two-dimensional) diamagnetic Landau-susceptibility which for billiard-like systems is expressed as for the bulk as

$$-\chi_L=-\frac{g_s e^2}{24\pi mc^2} \tag{2.10}$$

with $g_s=2$ the spin degeneracy.

B. Semiclassical treatment of susceptibilities

For a semiclassical computation of $\Delta F^{(1)}$ and $\Delta F^{(2)}$ and their derivatives with respect to H we calculate $d^{\mathrm{osc}}(E,H)$ from the trace

$$d(E,H)=-\frac{g_s}{\pi}\,\mathrm{Im}\int d\mathbf{r}\; G_E(\mathbf{r},\mathbf{r}) \tag{2.11}$$

of the semiclassical one-particle Green function. Its contribution to $d^{\mathrm{osc}}(E)$ is given by[4]

$$G_E(\mathbf{r}',\mathbf{r})=\sum_t D_t \exp\left[i\left(\frac{S_t}{\hbar}-\eta_t\frac{\pi}{2}\right)\right], \tag{2.12}$$

as the sum over all classical paths t (of non-zero length) joining $\mathbf{r}$ to $\mathbf{r}'$ at energy E.

$$S_t=\int_{\mathscr{C}_t}\mathbf{p}d\mathbf{q} \tag{2.13}$$

is the classical action integral along the path $\mathscr{C}_t$. The amplitude D_t takes care of the classical probability conservation, and η_t is the Maslov index.

The evaluation of the trace integral (2.11) for chaotic and integrable systems leads to the Gutzwiller[4] and Berry–Tabor[19] periodic-orbit trace formulas, respectively. In order to calculate the magnetic susceptibility at small fields one has to carefully distinguish[6] between the three

possibilities of a chaotic billiard, the special case of an integrable billiard remaining integrable upon inclusion of the H-field, and the more general case where the field acts as a perturbation breaking the integrability of a regular structure.

Since our main interest in Secs. III, IV and V will be devoted to disorder effects on the susceptibility of billiards being integrable at zero H-field we will focus here on the last case. There neither Gutzwiller nor Berry–Tabor-trace formulas are directly applicable and, following Ozorio de Almeida,[20] a uniform treatment of the perturbing H-field is necessary. In the integrable zero-field limit each closed trajectory belongs to a torus $I_{\mathbf{M}}$ and we can replace $\mathbf{r}$ in the trace integral (2.11) by angle coordinates Θ_1 specifying the trajectory within the (one-parameter) family and by the position Θ_2 on the trajectory. For small magnetic field the classical orbits can be treated as essentially unaffected while the field acts merely on the phases in the Green function in terms of the magnetic flux through the area $\mathscr{A}_{\mathbf{M}}(\Theta_1)$ enclosed by each orbit of family $\mathbf{M}$. Evaluating the trace integral (2.11) along Θ_2 for the semiclassical Green function of an integrable system leads in this approximation to a factorization of the density of states

$$d^{\mathrm{osc}}(E)=\sum_{\mathbf{M}\neq 0}\mathscr{C}_{\mathbf{M}}(H)\,d^0_{\mathbf{M}}(E) \tag{2.14}$$

into the contribution from the integrable zero-field limit

$$d^0_{\mathbf{M}}(E)=\widetilde{D}_{\mathbf{M}}\cos\left(k_F L_{\mathbf{M}}-\eta_{\mathbf{M}}\frac{\pi}{2}-\frac{\pi}{4}\right) \tag{2.15}$$

($L_{\mathbf{M}}$ is the length of the orbits of family $\mathbf{M}$ and $\widetilde{D}_{\mathbf{M}}$ the semiclassical weight[19]) and the function

$$\mathscr{C}_{\mathbf{M}}(H)=\frac{1}{2\pi}\int_0^{2\pi}\mathrm{d}\Theta_1\cos\left[2\pi\frac{H.\mathscr{A}_{\mathbf{M}}(\Theta_1)}{\Phi_0}\right] \tag{2.16}$$

containing the H-field dependence ($\Phi_0=hc/e$). Calculating $\Delta F^{(1)}$ from Eq. (2.9b) and taking the derivatives with respect to H gives the grand canonical contribution to the susceptibility at small magnetic field

$$\frac{\chi^{(1)}}{\chi_L}=-\frac{24\pi}{g_s}mA\left(\frac{\Phi_0}{2\pi A}\right)^2\sum_{\mathbf{M}}\frac{R_T(\tau_{\mathbf{M}})}{\tau^2_{\mathbf{M}}}d^0_{\mathbf{M}}(\mu)\frac{d^2\mathscr{C}_{\mathbf{M}}}{dH^2}. \tag{2.17}$$

Here, $\tau_{\mathbf{M}}$ is the period of a closed orbit of family $\mathbf{M}$ and

$$R_T(\tau)=\frac{\tau/\tau_c}{\sinh(\tau/\tau_c)};\quad \tau_c=\frac{\hbar\beta}{\pi} \tag{2.18}$$

is a temperature damping factor which arises from the convolution integral in Eq. (2.3) and gives an exponential suppression of long orbits. This is important from a physical as well as computational point of view, as conceptual difficulties associated with the questions of absolute convergence of semiclassical expansions at zero temperature do not arise.

Eq. (2.17) is the basic equation for the susceptibility of an individual microstructure. When considering ensembles of ballistic microstructures however, an average $\overline{(\cdot)}$ over energy (i.e., k_F) or over the system size a usually has to be performed and leads to variations in the phases (actions $S/\hbar=k_F L_{\mathbf{M}}$) of the density of states (2.15) which are much larger than 2π. Therefore, $\chi^{(1)}$ vanishes upon ensemble average. In order to characterize the orbital magnetism of ensembles we introduce the *typical* susceptibility $\chi^{(\mathrm{t})}=(\overline{\chi^2})^{1/2}$ (the width of the distribution) and the ensemble average $\overline{\chi}$ [its mean value, which is non-zero because of the term $\Delta F^{(2)}$ in the expansion

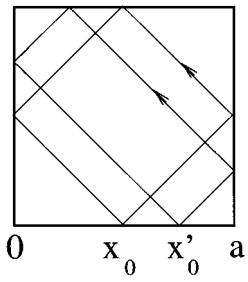

FIG. 1. Two representative periodic orbits characterized by x_0 and x_0' belonging to the family $\mathbf{M}=(1,1)$ (denoting one bounce with each wall) of a square billiard of length a.

Eq. (2.8)]. The typical and ensemble average susceptibilities are of theoretical interest since they are based on two-particle Green functions and are relevant for the description of experiments on ensembles of mesoscopic systems.

If we assume that there are no degeneracies in the lengths of orbits from different families $\mathbf{M}$ we obtain for $\chi^{(t)}$

$$\left(\frac{\chi^{(t)}}{\chi_L}\right)^2=\left(\frac{24\pi}{g_s}mA\right)^2\left(\frac{\Phi_0}{2\pi A}\right)^4\sum_{\mathbf{M}}\frac{R_T^2(\tau_{\mathbf{M}})}{\tau_{\mathbf{M}}^4}\,\overline{d_{\mathbf{M}}^0(\mu)^2}\left(\frac{d^2\mathscr{C}_{\mathbf{M}}}{dH^2}\right)^2. \tag{2.19}$$

In calculating $\overline{\chi}$, the grand canonical contribution $\chi^{(1)}$ from $\Delta F^{(1)}$ vanishes under energy average and the canonical correction $\Delta F^{(2)}$ in Eq. (2.8) gives in semiclassical approximation using Eq. (2.9c)

$$\frac{\overline{\chi}}{\chi_L}\simeq\frac{\overline{\chi^{(2)}}}{\chi_L}=-\frac{24\pi^2}{g_s^2}\hbar^2\left(\frac{\Phi_0}{2\pi A}\right)^2\sum_{\mathbf{M}}\frac{R_T^2(\tau_{\mathbf{M}})}{\tau_{\mathbf{M}}^2}\,\overline{d_{\mathbf{M}}^0(\mu)^2}\,\frac{d^2\mathscr{C}_{\mathbf{M}}^2}{dH^2}. \tag{2.20}$$

Eqs. (2.17)–(2.20) provide the general starting point for a computation of the susceptibility of integrable billiards at small fields.

As an important example, which is also of experimental relevance,[21] we will apply the results to square billiards. At finite temperature χ is essentially given by the family $\mathbf{M}=(1,1)$ of the shortest, flux-enclosing periodic orbits depicted in Fig. 1. A complete treatment including families of longer orbits is given in Ref. 6. Instead of Θ_1 we use the lower reflection point x_0 as orbit parameterization within the family. The orbits (1,1) have the unique length $L_{11}=2\sqrt{2}a$ and enclose a normalized area $\mathscr{A}(x_0)=4\pi x_0(a-x_0)/a^2$. Computation of $d_{11}^0(\mu)$ for the square geometry gives for $\chi^{(1)}$ [Eq. (2.17)]

$$\frac{\chi^{(1)}}{\chi^0}=\int_0^a\frac{dx_0}{a}\,\mathscr{A}^2(x_0)\cos(\varphi\mathscr{A}(x_0))\sin\left(k_FL_{11}+\frac{\pi}{4}\right) \tag{2.21}$$

as a function of the total flux $\varphi=Ha^2/\Phi_0$ with $\Phi_0=hc/e$. The prefactor

$$\chi^0=\chi_L\frac{3}{(\sqrt{2}\pi)^{5/2}}(k_Fa)^{3/2}R_T(L_{11}). \tag{2.22}$$

shows the $(k_Fa)^{3/2}$-dependence typical for (nearly-) integrable systems.

For the square geometry Eqs. (2.19) and (2.20) for the susceptibilities $\chi^{(t)}$ and $\overline{\chi}$ (characterizing different ensemble averages) can be reduced to [including only the dominant contributions from the family (1,1)]

$$\frac{\chi^{(t)}}{\chi^0} \simeq \frac{\sqrt{\overline{\chi^{(1)^2}}}}{\chi^0} = \frac{1}{\sqrt{2}} \int_0^a \frac{dx_0}{a} \mathscr{A}^2(x_0) \cos(\varphi.\mathscr{A}(x_0)) \tag{2.23}$$

and

$$\frac{\overline{\chi}}{\overline{\chi^0}} = \frac{1}{2} \int_0^a \frac{dx_0}{a} \int_0^a \frac{dx_0'}{a} [\mathscr{A}_-^2 \cos(\varphi.\mathscr{A}_-) + \mathscr{A}_+^2 \cos(\varphi.\mathscr{A}_+)] \tag{2.24}$$

with

$$\frac{\overline{\chi^0}}{\chi_L} = \frac{3}{(\sqrt{2}\pi)^3} (k_F a) R_T^2(L_{11}) \tag{2.25}$$

and $\mathscr{A}_\pm = \mathscr{A}(x_0) \pm \mathscr{A}(x_0')$. Although the integrals (2.21), (2.23), and (2.24) can be evaluated analytically in the clean case (leading to Fresnel functions of the magnetic flux[5]), the above expressions serve as suitable starting points for the study of disorder effects on ensembles of microstructures discussed in Secs. IV and V.

III. SEMICLASSICAL APPROACH TO WEAK DISORDER

Disorder is usually studied in terms of the ensemble average over impurity realizations, since it is a perturbation of an electrostatic potential whose detailed nature is unknown. Typically, quantum perturbation theory is followed by the average over the strengths and positions of the impurities. This approach is suited for macroscopic metallic samples (which are self-averaging) or ensembles of mesoscopic samples (where different samples present different impurity configurations). The possibility of measuring a single disordered mesoscopic sample poses a conceptual difficulty since there is not an average process involved. When discussing the effect of disorder on the orbital magnetism of microstructures, it is therefore necessary to distinguish between the behavior of an individual sample and an ensemble.[22]

Moreover, we have to consider the cases where the Fermi energy and size of the microstructures are kept fixed under impurity average and the cases where these parameters change with the different impurity realizations. These various averages, that will be thoroughly discussed in the remainder of the paper, can be expressed in terms of the impurity average of one- and two-particle Green functions. Therefore we perform in this section a general treatment of disorder effects on the basis of semiclassical expansions of Green functions. The Green function formalism, which is useful for a wide range of physical problems, can be applied to thermodynamical quantities like the magnetic susceptibility (Secs. IV and V) as well as to quantum transport problems.

1. Disorder models

Our basic assumptions for the treatment of disorder are the following: We study a spatially random potential $V(\mathbf{r})$ characterized by a correlation function

$$C(|\mathbf{r}-\mathbf{r}'|) = \langle V(\mathbf{r}) V(\mathbf{r}') \rangle \tag{3.1}$$

with a typical correlation length ξ and a mean disorder strength $C^0 = C(0)$. We will make use of a Gaussian correlation

$$C(|\mathbf{r}-\mathbf{r}'|) = C^0 \exp\left(-\frac{(\mathbf{r}-\mathbf{r}')^2}{4\xi^2} \right) \tag{3.2}$$

which allows us to derive analytical expressions for the disorder averages considered below.[23] The disorder correlation function (3.2) can be viewed as being generated by means of a realization i of a two-dimensional Gaussian disorder potential given by the sum

$$V(\mathbf{r})=\sum_{j}^{N_i}\frac{u_j}{2\pi\xi^2}\exp\left\{-\frac{(\mathbf{r}-\mathbf{R}_j)^2}{2\xi^2}\right\} \tag{3.3}$$

of the potentials of N_i *independent* impurities located at points $\mathbf{R}_j$ with uniform probability on an area V. The strengths u_j obey $\langle u_j u_{j'}\rangle = u^2\delta_{jj'}$.The disorder strength [as defined in Eq. (3.2)] is

$$C^0=\frac{u^2 n_i}{4\pi\xi^2} \tag{3.4}$$

with $n_i=N_i/\mathsf{V}$. For $\xi\to 0$ this model yields the white noise case of δ-function scatterers $V(\mathbf{r})=\Sigma_j^{N_i}u_j\delta(\mathbf{r}-\mathbf{R}_j)$. We will use the model of Gaussian disorder for some analytical calculations and for numerical quantum simulations. However, the general results expressed in terms of the correlation function $C(|\mathbf{r}-\mathbf{r}'|)$ will be valid for any kind of disorder.

As we will show, disorder effects depend on several length scales: the elastic mean free path, the Fermi-wavelength λ_F of the electrons, the disorder correlation length ξ and the size a of the microstructure. In the bulk case of an unconstrained two-dimensional electron gas (2DEG) we will distinguish between short range ($\xi<\lambda_F$) and finite range ($\xi>\lambda_F$) disorder potentials. In the case of a microstructure a third, long range regime for $\xi>a>\lambda_F$ has to be considered. The cleanest samples used in today experiments are in the finite range regime $a>\xi>\lambda_F$.[24]

2. Single-particle Green function

If we assume a microstructure with size $a\gg\lambda_F$ (a condition which is always met in lithographically defined samples) and work in the finite range or long range regime, where the disorder potential is smooth on the scale of λ_F, a semiclassical treatment is well justified. A natural starting point is the semiclassical expression (2.12) for the single-particle Green function $G_E(\mathbf{r}',\mathbf{r})$ as a sum over the contributions from classical paths. The classical mechanics of trajectories with length $L_t\ll l_T$ (the transport mean free path) is essentially unaffected by disorder. Therefore the dominant effect on the Green function in Eq. (2.12) results from shifts in the semiclassical phases due to the modification of the actions while the amplitudes D_t and topological indices η_t are nearly unchanged. The first-order approximation to the classical action (2.13) along a path $\mathscr{C}_t$ in a system with weak disorder potential is

$$S_t^d\simeq S_t^c+\delta S_t, \tag{3.5}$$

where the clean action S_t^c is obtained by integrating along the *unperturbed* trajectory $\mathscr{C}_t^c$ without disorder (i.e., $S_t^c=k_F L_t$ in the case of billiards without magnetic field) instead of the actual path $\mathscr{C}_t$. The correction term δS_t is obtained, after expanding $\mathbf{p}=\sqrt{2m[E-V(\mathbf{q})]}$ for small V/E, by the integral

$$\delta S_t=-\frac{1}{v_F}\int_{\mathscr{C}_t^c}V(\mathbf{q})\mathrm{d}q. \tag{3.6}$$

In this approximation an impurity average $\langle\ldots\rangle$ acts only on δS_t and the disorder averaged Green function reads

$$\langle G_E(\mathbf{r}',\mathbf{r})\rangle=\sum_t G_{E,t}^c(\mathbf{r}',\mathbf{r})\left\langle\exp\left[\frac{i}{\hbar}\delta S_t\right]\right\rangle. \tag{3.7}$$

Here $G^c_{E,t}$ is the contribution of the trajectory t to the zero-disorder Green function G^c_E.

For trajectories of length $L_t \gg \xi$ the contributions to δS according to Eq. (3.6) from the disorder potential at trajectory segments separated by a distance larger than ξ are uncorrelated. The related stochastic accumulation of action along the path can therefore be interpreted as determined by a random-walk process, resulting in a Gaussian distribution of $\delta S_t(L_t)$. For larger ξ or shorter trajectories ($L_t \not\gg \xi$), one can still think of a Gaussian distribution of the de-phasing δS_t provided $V(\mathbf{r})$ is generated by a sum of a large number of independent impurity potentials. As a consequence of the Gaussian character of the distribution of $\delta S_t(L_t)$, the disorder contribution involved in Eq. (3.7) is given by

$$\left\langle \exp\left[\frac{i}{\hbar}\delta S_t\right]\right\rangle = \exp\left[-\frac{\langle \delta S_t^2\rangle}{2\hbar^2}\right] \tag{3.8}$$

and therefore entirely specified by the variance

$$\langle \delta S_t^2\rangle = \frac{1}{v_F^2}\int_{\mathscr{C}_t^c} dq \int_{\mathscr{C}_t^c} dq' \langle V(\mathbf{q})V(\mathbf{q}')\rangle, \tag{3.9}$$

which is expressed as the mean of the disorder correlation function $C(|\mathbf{q}-\mathbf{q}'|)$ when the unperturbed orbit is traversed.

If we consider, to start with, an unconstrained 2DEG the sum in Eq. (3.7) is reduced to the direct trajectory joining $\mathbf{r}$ and $\mathbf{r}'$. If $L=|\mathbf{r}-\mathbf{r}'| \gg \xi$ the inner integral in Eq. (3.9) can be extended to infinity and we obtain

$$\langle \delta S^2\rangle = \frac{L}{v_F^2}\int dq\ C(\mathbf{q}). \tag{3.10}$$

The semiclassical average Green function for the bulk exhibits therefore an exponential behavior[16,25] (on a length scale $l_T > L \gg \xi$)

$$\langle G_E(\mathbf{r}',\mathbf{r})\rangle = G^c_E(\mathbf{r}',\mathbf{r})\exp\left(-\frac{L}{2l}\right), \tag{3.11}$$

with the damping governed by an inverse *elastic* mean free path

$$\frac{1}{l} = \frac{1}{\hbar^2 v_F^2}\int dq\ C(\mathbf{q}). \tag{3.12}$$

In the case of Gaussian correlation $C(\mathbf{q})$ is given by Eq. (3.2) and we get

$$l = \frac{\hbar^2 v_F^2}{\xi\sqrt{\pi}C^0}. \tag{3.13}$$

Using the disorder strength (3.4) we have

$$l = \frac{4\sqrt{\pi}\hbar^2 v_F^2 \xi}{u^2 n_i}. \tag{3.14}$$

In the Appendix we discuss the relation between the semiclassical elastic MFPs [Eqs. (3.12)–(3.14)] and the MFP obtained from quantum diagrammatic perturbation theory for the bulk for the disorder model (3.3). The semiclassical and the quantum result [Eq. (A5)] agree asymptotically to

leading order in $k_F\xi$. In the limit of small ξ, especially $\xi<\lambda_F$, our semiclassical approach is no longer applicable.[26] However, Eq. (3.11) still holds, but with l replaced by l_δ given in Eq. (A4).

We now turn from the semiclassical treatment of the bulk to that of a confined system. In the constrained case in the limit $l_T \ll a$ impurity scattering is the dominant process.[27] This gives rise to diffusive motion, and thus there is no essential difference to the bulk for the damping of the Green function. We will treat the ballistic regime $l_T > a$ where both, the confinement *and* the impurities have to be considered. The calculation of l_T in the Appendix shows that for finite ξ the transport MFP l is considerably larger than the elastic one and a ballistic treatment is therefore well justified, even if l is of the order of the system size.

In contrast to the bulk case a disorder averaged confined system is no longer translationally invariant and one has to impose in quantum calculations the correct boundary conditions of the geometry. Confinement implies semi-classically that $G_E^c(\mathbf{r}',\mathbf{r})$ is given as a sum over all direct and multiply reflected paths connecting $\mathbf{r}$ and $\mathbf{r}'$; disorder modifies the corresponding actions according to Eq. (3.6).

In the regimes of short- and finite-range scatterers, the damping of each contribution $\langle G_{E,t}\rangle$ to $\langle G_E\rangle$ is given, analogous to the bulk expression (3.11), [using Eq. (3.10)] by

$$\langle G_E(\mathbf{r}',\mathbf{r})\rangle = \sum_t G_{E,t}^c(\mathbf{r}',\mathbf{r}) \exp\left(-\frac{L_t}{2l}\right). \tag{3.15}$$

Here, L is now replaced by the trajectory length $L_t > a \gg \xi$. This gives an individual damping $\exp(-L_t/2l)$ for each geometry-affected path contributing to $\langle G_E\rangle$.

In the long range regime and for $\xi \sim a$ the correlation integral (3.9) can no longer be approximated (as for $\xi \ll L_t$) by $L\int_{-\infty}^{+\infty} dq\ C(\mathbf{q})$ due to correlations across different sectors of an orbit (with distance smaller ξ). Therefore, the orbit-geometry enters into the correlation integral. For $\xi \gg a$ we can, however, expand $C(|\mathbf{r}-\mathbf{r}'|)$ and obtain in the case of Gaussian disorder (up to first order in ξ^{-2}) $C(|\mathbf{r}-\mathbf{r}'|) \simeq C^0[1-(\mathbf{r}-\mathbf{r}')^2/(4\xi^2)]$. In this approximation the integral (3.9) gives for the Green function damping an exponent

$$\frac{\langle \delta S_t^2\rangle}{2\hbar^2} = \frac{1}{4\sqrt{\pi}} \frac{L_t^2}{l\xi}\left(1-\frac{1}{2}\frac{I_t}{\xi^2}\right). \tag{3.16}$$

$I_t = (1/L_t)\int_{\mathscr{C}_t} \mathbf{r}^2(q)\mathrm{d}q$ can be regarded as the ''moment of inertia'' of the unperturbed trajectory $\mathscr{C}_t$ with respect to its ''center of mass'' $(1/L_t)\int_{\mathscr{C}_t} \mathbf{r}(q)\mathrm{d}q$. Eq. (3.16) shows that the damping in the long range regime depends quadratically on L_t (in contrast to linear behavior in the finite range case or bulk). The length scale of damping is now given by the geometrical mean of the bulk MFP l *and* ξ. The leading damping term does not depend on the specific orbit geometry since it essentially reflects the fluctuation in the mean of the (smooth) potentials of different impurity configurations. Inclusion of higher powers of ξ^{-2} leads to additional contributions from higher moments $\int_{\mathscr{C}_t} r^n(q)\mathrm{d}q$ on the RHS of Eq. (3.16).

3. Two-particle Green function

Density correlation functions in general or the typical [Eq. (2.19)] and ensemble averaged susceptibility [Eq. (2.20)], which will be treated in the subsequent sections, involve the square of the density of states. Writing the latter, Eq. (2.11), in terms of the difference between advanced and retarded Green functions $(G^+ - G^-)$ we are left with products of one-particle Green functions. The terms of most interest are the cross products $G^+(r,r') \times G^-(r,r') = G^+(r,r')G^{+*}(r',r)$, because they survive the energy average and are sensitive to changes in the magnetic field.

Since, in the non-interacting approach we are using, the two-particle Green function factorizes into a product of one-particle Green function[28] we will use the former as a synonym for the latter. The semiclassical average for products of single-particle Green functions will be quantitatively performed for the susceptibility of confined integrable systems in Sec. V, and we discuss here the underlying ideas for the general case.

Considering for instance the product $G(r_1,r_2)G^*(r_1',r_2')$, the effect of the disorder potential can be taken into account perturbatively for each realization of the disorder in the same way as before by Eqs. (3.5)–(3.6). Using the same kind of argument, one can therefore write the disorder average as a double sum over the averaged contributions from trajectories t and t'

$$\langle G_E G_E^* \rangle = \sum_t \sum_{t'} \langle G_{E,t} G_{E,t'}^* \rangle = \sum_t \sum_{t'} G_{E,t}^c G_{E,t'}^{c*} \langle e^{(i/\hbar)(\delta S_t - \delta S_{t'})} \rangle$$
$$= \sum_t \sum_{t'} G_{E,t}^c G_{E,t'}^{c*} \exp\left[- \frac{\langle (\delta S_t - \delta S_{t'})^2 \rangle}{2\hbar^2} \right]. \tag{3.17}$$

It is necessary here, however, to take into account the correlation of the disorder potential between points on trajectories t and t'. One limiting case for instance would be that t and t' are either the same trajectory or the time reversal one of each other. In these cases their contribution acquires exactly the same phase shift and $\langle G_{E,t} G_{E,t}^* \rangle = |G_{E,t}^c|^2$. Within our approximation the diagonal contributions $t=t'$, which, e.g., are responsible for the classical part of the conductivity, remain thus disorder-unaffected, since we assume the trajectories have a length much smaller than l_T. (A semiclassical consideration of these effects for trajectories of length of the order of l_T or larger was performed in Ref. 25 for the bulk, giving a damping of the two-point Green function on the scale of l_T.) At the opposite extreme, if trajectories t,t' are completely uncorrelated, i.e., for long trajectories in classical chaotic systems or trajectories in integrable systems with a spatial distance larger than ξ, the average in Eq. (3.17) factorizes: $\langle G_{E,t} G_{E,t'}^* \rangle = \langle G_{E,t} \rangle \cdot \langle G_{E,t'}^* \rangle$ and lead to single-particle damping behavior.

The double sum Eq. (3.17) may however involve pairs of trajectories which stay within a distance of the order of ξ (as for nearby paths on a torus of an integrable system). In this case the behavior of $\langle G_{E,t} G_{E,t'}^* \rangle$ is more complicated and depends of the confinement geometry of the system under consideration. As a simple illustration of the interplay between disorder correlation and families of orbits, let us consider for the case of the bulk the product of $G(r_1,r_2)$ joining $r_1=(0,0)$ to $r_2=(L,0)$ with $G^*(r_1',r_2')$ joining $r_1=(0,y)$ to $r_2=(L,y)$, with $L \gg \xi$ but y possibly of the order of ξ. Introducing the function

$$K(y) = \int_{-\infty}^{+\infty} C(x,y)\mathrm{d}x \tag{3.18}$$

[for Gaussian correlations Eq. (3.2), $K(y)/K(0) = \exp(-y^2/(4\xi^2))$], the variance of the de-phasing is obtained as

$$\langle (\delta S_t - \delta S_{t'})^2 \rangle = 2L \frac{(K(0)-K(y))}{v_F^2} \tag{3.19}$$

and therefore $\langle G_E G_E^* \rangle = G_E^c G_E^{c*} \tilde{f}(y)$ with

$$\tilde{f}(y) = \exp\left[- \frac{L}{l} \left(1 - \frac{K(y)}{K(0)} \right) \right]. \tag{3.20}$$

The function $\tilde{f}(y)$ expresses in a very simple way that as $y \to 0$, the effect of disorder disappears ($\tilde{f}(0)=1$) while for $y \gg \xi$ the function $\tilde{f}(y)$ behaves as the square of single particle Green function damping.

IV. FIXED-SIZE IMPURITY AVERAGE OF THE MAGNETIC SUSCEPTIBILITY

We consider here a disorder average (which will henceforth be called a fixed-size impurity average) of an ensemble of structures for which the parameters of the corresponding clean system (geometry, size, chemical potential) remain fixed under the change of impurity realizations. In Sec. V, we will then treat the more realistic case of the orbital magnetic response of a *combined* energy (or size) and disorder average.

As shown in the previous section, averages over weak disorder exponentially damp, but do not completely suppress oscillatory contributions (with phase $k_F L_t$) to the single-particle Green function from geometrical paths in confined systems. An observable quantity dependent on these contributions is the disorder averaged susceptibility of an ensemble of billiards of the same size or same clean-system Fermi energy, which will be studied first.

We will treat regular billiards at zero or small magnetic fields, where the integrability is approximately maintained and the density of states has the H-dependence of the formulae (2.14)–(2.16). The general result for $\chi^{(1)}$, Eq. (2.17), formally persists with the replacement of $\mathscr{C}_{\mathrm{M}}$ by

$$\langle \mathscr{C}_{\mathbf{M}}(H) \rangle = \frac{1}{2\pi} \int_0^{2\pi} \mathrm{d}\Theta_1 \, \cos\left[2\pi \frac{H \mathscr{A}_{\mathbf{M}}(\Theta_1)}{\Phi_0} \right] \exp\left[- \frac{\langle (\delta S_{\mathrm{M}}(\Theta_1))^2 \rangle}{2\hbar^2} \right], \tag{4.1}$$

where $\langle \delta S_{\mathrm{M}}^2(\Theta_1) \rangle$ is given by Eq. (3.9) with the integrals performed along the orbits of the family **M** parameterized by Θ_1. In the finite range case (if all orbits of a family **M** are of the same length as in billiards) each family exhibits a unique disorder damping giving a contribution

$$\langle \chi_{\mathrm{M}}^{(1)} \rangle = \chi_{\mathrm{M}}^{(1)} \cdot \exp\left(- \frac{\langle \delta S_{\mathrm{M}}^2 \rangle}{2\hbar^2} \right) \tag{4.2}$$

to the ballistic susceptibility. $\chi_{\mathbf{M}}^{(1)}$ is the contribution of family **M** to the clean susceptibility [Eq. (2.17)] and $\langle \delta S_{\mathrm{M}}^2 \rangle / 2\hbar^2 = L_{\mathrm{M}}/2l$.

In the case of square billiards, where the dominant contribution stems from the family (1,1), we obtain, in analogy with Eq. (2.21),

$$\frac{\langle \chi \rangle}{\chi^0} \simeq \frac{\langle \chi^{(1)} \rangle}{\chi^0} = \int_0^a \frac{\mathrm{d}x_0}{a} \mathscr{A}^2(x_0) \cos(\varphi_{\mathscr{A}}(x_0)) \left\langle \sin\left(k_F L_{11} + \frac{\pi}{4} + \frac{\delta S(x_0)}{\hbar} \right) \right\rangle \tag{4.3}$$

with χ^0 given by Eq. (2.22). For a square billiard $\delta S(x_0)$ is independent of x_0 for the finite- as well as for the long-range regime since $I_{11} = a^2/12$ [entering into Eq. (3.16)] is the same for all orbits (11). Therefore Eq. (4.2) with $\mathbf{M}=(1,1)$ holds for both limiting cases. In the same way as for the damping of the one-particle Green function [Eq. (3.15)] we obtain for square billiards at finite temperature in the finite range regime

$$\langle \chi \rangle \simeq \langle \chi^{(1)} \rangle = \chi_{\mathrm{cl}}^{(1)} \cdot \exp\left(- \frac{L_{11}}{2l} \right), \tag{4.4}$$

where $\chi_{\mathrm{cl}}^{(1)}$ denotes the susceptibility of the system without disorder.

In order to control the validity of our analytical semiclassical approximations we performed numerical quantum calculations by diagonalizing the Hamiltonian for non-interacting particles in a square billiard subject to a uniform perpendicular magnetic field and a random disorder potential of the form of Eq. (3.3). For a given selected correlation length ξ a quantum mechanically

calculated elastic MFP l_{qm} and a fixed Fermi momentum k_F the product of the impurity density and squared mean impurity potential, $n_i u^2$, is determined by Eqs. (A3) and (A4). We found that our numerical results are essentially independent of the choice of n_i (with u^2 adjusted accordingly) for $n_i \geqslant 200$ and used this value for the calculations presented here. The positions $\mathbf{R}_j$ of the impurities were chosen as independently distributed and for the u_j we used a box distribution.

Each impurity configuration α has a self-averaging effect for an *individual* square billiard (for $\xi < a$) due to the differences of the impurity potential $V_\alpha(\mathbf{r})$ across the structure. In an *average* over an ensemble of square billiards, differences in the mean impurity potential $\overline{V_\alpha} = (1/a^2)\int \mathrm{d}\mathbf{r} V_\alpha(\mathbf{r})$ (the integral is taken over the area of the billiard) between different squares lead to an additional damping. It is characterized by the variance

$$\langle \overline{V^2} \rangle = \frac{u^2 n_i}{a^2 \eta^2}\left[\eta\ \mathrm{erf}(\eta) + \frac{1}{\sqrt{\pi}}(e^{-\eta^2} - 1)\right]^2; \quad \eta = \frac{a}{2\xi} \tag{4.5}$$

$$\rightarrow \frac{u^2 n_i}{4\pi\xi^2} \quad \text{for } \xi/a \rightarrow \infty \tag{4.6}$$

$$\rightarrow \frac{u^2 n_i}{a^2} \quad \text{for } \xi \rightarrow 0. \tag{4.7}$$

In the limit of $\xi \gg a$ our numerical calculations showed that the self-averaging effect is negligible (since the impurity potential is essentially flat across the square) and the clean susceptibility of an *individual* structure remains practically unaffected by disorder. In this limit variations in the mean potential V of an ensemble [Eq. (4.6)] dominate the damping. In the limit of short range disorder, fluctuations in the mean V of different samples play a minor role and self-averaging is the predominant process for an integrable system: In semi-classical terms different trajectories of a family of closed orbits are perturbed by white noise disorder in an uncorrelated manner. Therefore we do not observe considerable differences between the susceptibility of a single disordered billiard of integrable geometry and the corresponding ensemble for $\xi \ll a$. In a chaotic billiard this self-averaging effect does not exist (for not too small ξ, see end of Sec. V), since orbits are isolated. Therefore distinct differences between an individual disordered sample and an ensemble of disordered billiards are expected.

To improve the statistics of our numerical ensemble average for square billiards we performed an average over disorder configurations with the same mean V and in addition averaged over V according to Eq. (4.5).[29] Fig. 2 shows results of the numerical quantum simulations for the average susceptibility $\langle \chi \rangle$ of an ensemble of squares with fixed size but different disorder realizations at a temperature $k_B T = 3\mathrm{g}_\mathrm{s}\Delta$, where Δ is the mean level spacing. The characteristic oscillations in $k_F a$ show an interchange between para- and dia-magnetic behavior on a scale $k_F L_{11}$. This indicates that they are dominated by contributions from the shortest flux-enclosing orbits of the family (1,1) [according to Eqs. (2.17) and (4.3)], as has been already shown for the *clean* case in Refs. 5 and 6. Fig. 2 demonstrates the damping of the clean susceptibility (dotted line) with decreasing elastic MFP $l/a = 4, 2, 1, 0.5$ for fixed $\xi/a = 0.1$ (which represents a typical disorder correlation length in experimental realizations). Variations in the mean V lead to a de-phasing of the oscillations in the finite range case on a scale $(\delta k)a \sim (4\pi)^{1/4}\sqrt{\xi/l_{\mathrm{qm}}(\xi)}$ which is, as discussed above, small compared to the self-averaging effect in this regime.

Figure 3 depicts the quantitative comparison between numerical and analytical results: It shows the logarithm of $\langle \chi \rangle$ normalized to the corresponding zero-disorder susceptibility as a function of the inverse MFP for different correlation lengths ξ. The semi-classically predicted exponential damping [Eq. (4.2)] is shown as straight lines for the short range [$\xi \ll a$, Eq. (3.11),

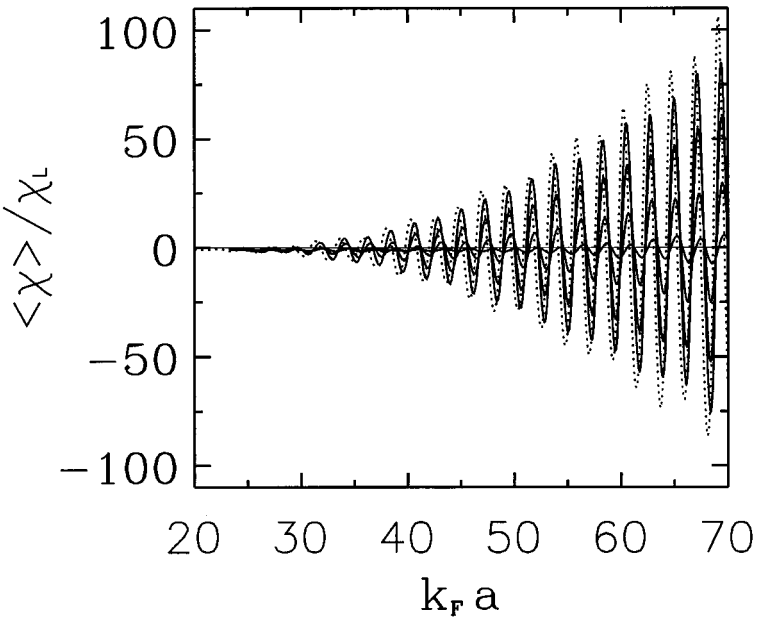

FIG. 2. Magnetic susceptibility $\langle\chi\rangle$ (normalized with respect to the Landau susceptibility χ_L) of a square billiard as a function of $k_F a$ for the clean case (dotted) and for the ensemble average of billiards of fixed size with increasing Gaussian disorder ($\xi/a=0.1$) according to an elastic mean free-path $l/a=4$, 2, 1, 0.5 (solid lines in the order of decreasing amplitude). The susceptibility is calculated for zero magnetic field and at a temperature equal to 6 level spacings.

full line for $\xi=0$] and long range [$\xi>a$, Eq. (3.16), dotted lines for $\xi/a=4$, 2, 1 from the top]. The semiclassical predictions accurately agree with the corresponding quantum results (symbols) for $\xi/a=4$, 2, 1, 0 and fail for intermediate values $\xi/a=0.5$, 0.2 (squares and diamonds) which are off the range of validity of the approximations. The transition from self-averaging dominated ($\xi\to 0$) suppression to damping according to fluctuations in the floor V (for $\xi/a\to\infty$) turns out to be non-monotonic.

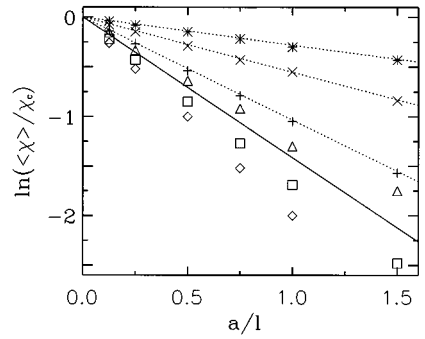

FIG. 3. Logarithm of the ratio $\langle\chi\rangle/\chi_{cl}$ as a function of the inverse elastic MFP a/l. The symbols indicate the numerical quantum results (from the top for $\xi/a=4$, 2, 1, 0, 0.5 and 0.2. The dotted lines show the semiclassical analytical results for $\xi/a=4$, 2, 1 (from above) according to Eq. (3.16). The full line is the semiclassical result for $\xi=0$ [Eq. (3.11)]. The quantum results for $\xi=0.5$ (squares) and 0.2 (diamonds) are beyond the regime of validity of the analytical limits $\xi/a\gg 1$ and $\xi/a\ll 1$.

V. COMBINED IMPURITY- AND ENERGY-AVERAGE OF THE SUSCEPTIBILITY

In currently experimentally realizable structures disorder averages cannot be performed independently from size-averages since the detailed features of the confining potential do not remain unchanged for different impurity configurations. From the basic expressions (2.21) and (4.3) for the susceptibility we see that changes in size a give rise to rapid variations in the phase $k_F a$ (on a quantum scale) and a much slower secular variation through the geometrical factors $\mathscr{A}$. Thus, the effect of small size variations is equivalent to an energy (k_F) average. As discussed in Sec. II for the clean case, variations in k_F lead to vanishing $\chi^{(1)}$. Therefore we have to use the typical and energy averaged susceptibilities [see Eqs. (2.19) and (2.20) for their definition in the clean case]. When disorder is introduced we must consider energy- *and* disorder averages. The typical susceptibility is now defined by $\chi^{(t)}=\langle\overline{\chi^2}\rangle^{1/2}$. It applies to the case of repeated measurements on a given microstructure when different impurity realizations (and simultaneous changes in k_F) are obtained by some kind of perturbation (e.g., cycling to room temperature). From now on we will reserve the term $\chi_{\rm cl}^{(t)}$ for the clean typical susceptibility $(\overline{\chi^2})^{1/2}$. The energy and impurity averaged susceptibility $\langle\overline{\chi}\rangle$ describes the magnetic response of an ensemble of a large number of microstructures with different impurity realizations and variations in size. This is the situation of the experiment of Ref. 21 that we discuss in the sequel.

A. Integrable systems: The square billiard

The semiclassical results for $\chi^{(t)}$ and $\langle\overline{\chi}\rangle$ for a system of integrable geometry are obtained in an analogous way as we proceeded for $\langle\chi\rangle$ in Sec. IV, that is by including in the integral (2.16) for $\mathscr{C}_{\mathbf{M}}$ a Θ_1-dependent disorder-induced phase $\exp(i\delta S(\Theta_1)/\hbar)$ [see Eq. (4.1)]. However, now we have to take the square of $\mathscr{C}_{\mathbf{M}}$ (respectively, $\partial^2\mathscr{C}_{\mathbf{M}}/\partial H^2$) before the impurity average and cross correlations between different paths Θ and Θ' on a torus $\mathbf{M}$ or between different tori have to be considered. We discuss this effect, typical of integrable systems, for the case of a square billiard. For sake of clarity we assume moreover a temperature range such that only the contribution of the shortest closed orbit has to be taken into account. Instead of Eqs. (2.23) and (2.24) which hold for the clean case, the contribution of orbits of topology $\mathbf{M}=(1,1)$ for the typical susceptibility now reads

$$\left(\frac{\chi^{(t)}}{\chi^0}\right)^2=\frac{1}{2}\int_0^a\frac{dx_0}{a}\int_0^a\frac{dx_0'}{a}\mathscr{A}^2(x_0)\mathscr{A}^2(x_0')\cos(\varphi\mathscr{A}(x_0))\cos(\varphi\mathscr{A}(x_0'))f(x_0,x_0'),\tag{5.1}$$

with χ^0 defined as in Eq. (2.22). The function

$$f(x_0,x_0')=\left\langle\exp\left\{\frac{i}{\hbar}(\delta S(x_0)-\delta S(x_0'))\right\}\right\rangle\tag{5.2}$$

$$=\exp\left\{-\frac{1}{2\hbar^2}[\langle\delta S^2(x_0)\rangle+\langle\delta S^2(x_0')\rangle-2\langle\delta S(x_0)\delta S(x_0')\rangle]\right\}\tag{5.3}$$

accounts for the effect of disorder on pairs of orbits x_0 and x_0'. [See Eq. (3.20) for the treatment in the general case]. For the magnetic response of an energy- and disorder-averaged ensemble we find correspondingly

$$\frac{\langle\overline{\chi}\rangle}{\overline{\chi^0}}=\frac{1}{2}\int_0^a\frac{dx_0}{a}\int_0^a\frac{dx_0'}{a}[\mathscr{A}_-^2\cos(\varphi\mathscr{A}_-)+\mathscr{A}_+^2\cos(\varphi\mathscr{A}_+)]f(x_0,x_0')\tag{5.4}$$

with $\overline{\chi^0}$ defined in Eq. (2.25) and $\mathscr{A}_\pm$ as in Eq. (2.24).

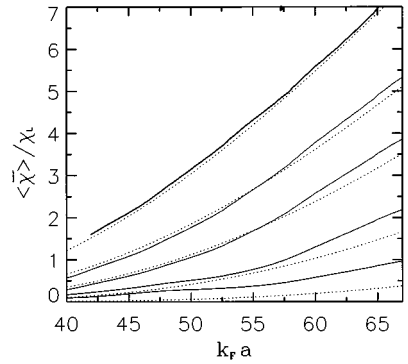

FIG. 4. Averaged magnetic susceptibility (at $H\approx 0$ of an ensemble of square billiards with variations in the size and impurity potential ($\xi=0$) for different disorder strength, i.e., elastic mean free path l_δ. The full curves show the numerical quantum results and the dotted lines the semiclassical predictions from Eq. (5.6) taking into account the variations of l_δ with k_F [see Eq. (A4)]. The two sets of curves correspond to an elastic MFP $l_\delta/a=\infty$, 8, 4, 2, 1 (at $k_F a=65$), (from the top).

1. Short range case

We begin with the discussion of the short range case: Although we reach the border of applicability of our semiclassical approximation for $\xi\to 0$, it shows us that in this limit orbits with $x_0 \neq x_0'$ are disorder-uncorrelated and all such pair contributions are exponentially damped. Using exclusively the family (1,1), one obtains an overall suppression of the typical and average susceptibility at finite temperature according to

$$\lim_{\xi\to 0}\chi^{(t)}=\chi_{\mathrm{cl}}^{(t)}e^{-L_{11}/2l_\delta}, \tag{5.5}$$

$$\lim_{\xi\to 0}\langle\overline{\chi}\rangle=\overline{\chi e}^{-L_{11}/l_\delta}. \tag{5.6}$$

Note that the exponent for $\langle\overline{\chi}\rangle$ differs by a factor 1/2 from that for $\langle\chi\rangle$ [see Eq. (4.2) and subsequent text].

Figure 4 depicts the $k_F a$ dependence of the ensemble averaged susceptibility $\langle\overline{\chi}\rangle$ in the short range case $\xi=0$. The dotted curves showing the semiclassical analytical formula (5.6) are compared with a direct quantum mechanical calculation of $\langle\chi^{(2)}\rangle$ [using the numerically obtained $N^{\mathrm{osc}}(\overline{\mu})$ in Eq. (2.9c)] for disorder ensembles of different impurity strength equivalent to an elastic MFP $l_\delta/a=\infty$, 8, 4, and 1 at $k_F a\sim 65$ (from the top). Note, that the effective MFP decreases along the curves with decreasing k_F [see Eq. (A4)] and the localized regime may eventually be reached for small $k_F a$. At the limit of the ballistic regime at small $l\sim a$ the semiclassical result begins to differ from the quantum one although the functional behavior remains the same. This arising difference may be related to non-ballistic scattering from impurities which is not included here.

2. Finite range case

In the finite range $\lambda_F<\xi\ll a$, the phase shifts $\delta S(x_0)$ and $\delta S(x_0')$ in $f(x_0,x_0')$ are accumulated in a correlated way, if the spatial distance of two orbits x_0 and x_0' is smaller than ξ. To evaluate the product term $2\langle\delta S(x_0)\,\delta S(x_0')\rangle$ in the exponent of $f(x_0,x_0')$ in this regime the integrations are performed as in Eq. (3.9) but with $\mathbf{q}$ and $\mathbf{q}'$ running along paths starting at x_0, respectively, x_0'. Ignoring the additional correlations occuring near the bounces off the boundaries of the billiard, the trajectories x_0 and x_0' (see Fig. 1) can be regarded as straight lines remaining at a

constant distance $y=|x_0-x_0'|/\sqrt{2}$ from another. We can therefore approximate $f(x_0,x_0')$ by $\tilde{f}(|x_0-x_0'|/\sqrt{2})$ with the function $\tilde{f}$ given by Eq. (3.20). For Gaussian correlation we thus have

$$f(x_0,x_0')=\exp\left\{-\frac{L_{11}}{l}\left[1-\exp\left(-\frac{(x_0-x_0')^2}{8\xi^2}\right)\right]\right\}. \tag{5.7}$$

Orbits separated by $|x_0-x_0'|\gg\xi$ are disorder-uncorrelated and exponentially suppressed: $f(x_0,x_0')\simeq\exp(-L_{11}/l)$. For those orbits the random disorder leads to an uncorrelated detuning of the phases. In contrast to that, disorder only weakly affects trajectories separated by $|x_0-x_0'|<\xi$.

The disorder averages in the finite range regime lead, by means of the function f, to a non-exponential damping of the susceptibilities for systems with families of periodic orbits. This behavior becomes obvious for the case of square billiards where at $H=0$ the integrals (5.1) and (5.4) can be evaluated analytically in the limits of $L_{11}\ll l$ (extreme ballistic) and $L_{11}\gg l$ (deep ballistic). We find for the typical and average susceptibility at $H=0$ in the finite range case for $L_{11}\ll l$

$$\left(\frac{\chi^{(t)}}{\chi_{\rm cl}^{(t)}}\right)^2\simeq 1-\frac{L_{11}}{l}\left(1-c_t\frac{\xi}{a}\right), \tag{5.8a}$$

$$\frac{\langle\overline{\chi}\rangle}{\overline{\chi}}\simeq 1-\frac{L_{11}}{l}\left(1-c_a\frac{\xi}{a}\right), \tag{5.8b}$$

and for $L_{11}\gg l$ (by steepest descent)

$$\left(\frac{\chi^{(t)}}{\chi_{\rm cl}^{(t)}}\right)^2\simeq c_t\left(\frac{\xi}{a}\right)\left(\frac{l}{L_{11}}\right)^{1/2}, \tag{5.9a}$$

$$\frac{\langle\overline{\chi}\rangle}{\overline{\chi}}\simeq c_a\left(\frac{\xi}{a}\right)\left(\frac{l}{L_{11}}\right)^{1/2}. \tag{5.9b}$$

The constants in the above equations are $c_t=(20/7)\sqrt{2\pi}$ and $c_a=2\sqrt{2\pi}$. Eqs. (5.8) express the limit of very weak disorder, showing that the small disorder effect is further reduced due to the correlation of the disorder potential. The other limit, Eqs. (5.9), is noticeably more interesting since it shows that disorder correlation effects lead to a replacement of the exponential disorder damping by a power law.

Figure 5 depicts in logarithmic representation our collected results for the disorder averaged typical (a) and averaged (b) susceptibility for square billiards (at $H=0$ and $k_BT=2g_s\Delta$) as a function of the inverse elastic MFP for different disorder correlation lengths. The symbols denote results from numerical quantum simulations described in the previous section and the full curves semiclassical results from numerical integration of the Eqs. (5.1) and (5.4). For the short range case $\xi=0$ they reduce to Eq. (5.6) predicting an exponential decrease with exponent L_{11}/l which is in line with the quantum calculations (circles). The semiclassical results for the finite range are on the whole in agreement with the numerical results for $\xi/a=0.1$ (diamonds), $\xi/a=0.2$ (triangles) and $\xi/a=0.5$ (squares). The semiclassical curves seem to overestimate the damping of the typical susceptibility. The dotted curves (shown for $a/l\geqslant 1$) depict the analytical expressions (5.9) in the regime $L_{11}>l$. Since for finite ξ the transport MFP $l_T>l$ [see Eq. (A6)], this regime can still be considered as (deep) ballistic and our semiclassical assumptions being based on straight-line trajectories remain valid.

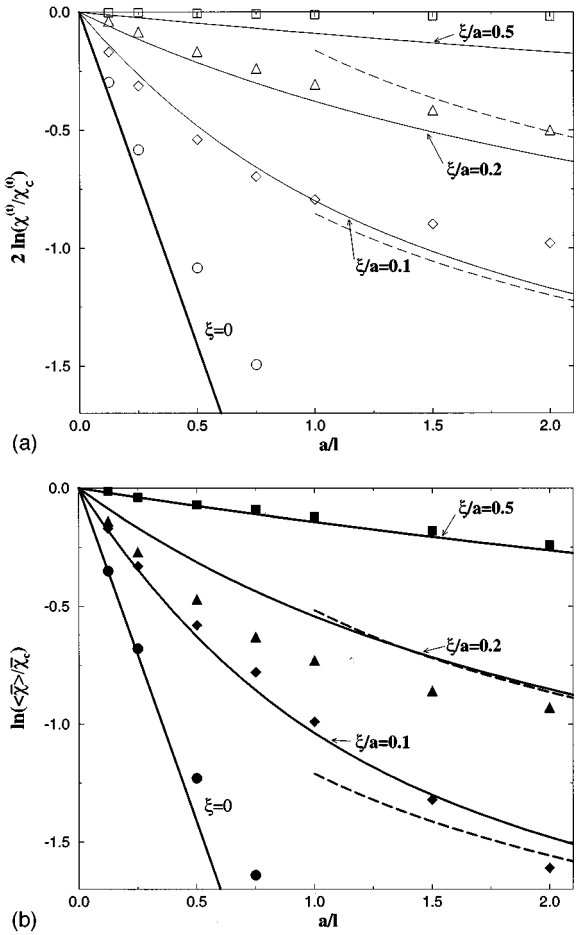

FIG. 5. Logarithm of the ratio between disorder averaged and clean results for (a) typical $\chi^{(t)}$ (b) ensemble averaged $\langle\overline{\chi}\rangle$ susceptibilities as a function of increasing inverse elastic MFP a/l for different values of ξ/a. The symbols denote the numerical quantum results, the solid lines (for $\xi>0$) the semiclassical integrals (5.1) (a) and (5.4) (b) and the dashed lines asymptotic expansions (5.9) of the integrals for large a/l.

As the semiclassical formulae already indicate, the overall disorder behavior of $\langle\overline{\chi}\rangle$ and $\chi^{(t)}$ is quite similar.

3. Long range case

For completeness, we will consider the effect of the disorder for the long range regime: We can use the Eqs. (5.1) and (5.4) but cannot calculate the disorder function $f(x_0,x_0')$ in the same way as for the finite range. We can however, similar as for $\langle\chi\rangle$ in Sec. IV, expand the exponent $-\langle(\delta S(x_0)-\delta S(x_0'))^2\rangle$ of $f(x_0,x_0')$ in Eq. (5.2) for small a/ξ. In the case of the square all orders up to $(a/\xi)^8$ vanish and we find a *very* small overall reduction of the clean averaged susceptibilities [from family (11)] given by

$$\left(\frac{\chi^{(t)}}{\chi_{\mathrm{cl}}^{(t)}}\right)^2 \simeq 1-6.5\cdot 10^{-5}\frac{a}{l}\left(\frac{a}{\xi}\right)^9. \tag{5.10}$$

For square billiards this leading order contribution no longer depends on x_0. The energy- and disorder-average $\langle\overline{\chi}\rangle$ exhibits the same damping as $(\chi^{(t)})^2$. Note that besides the high order in

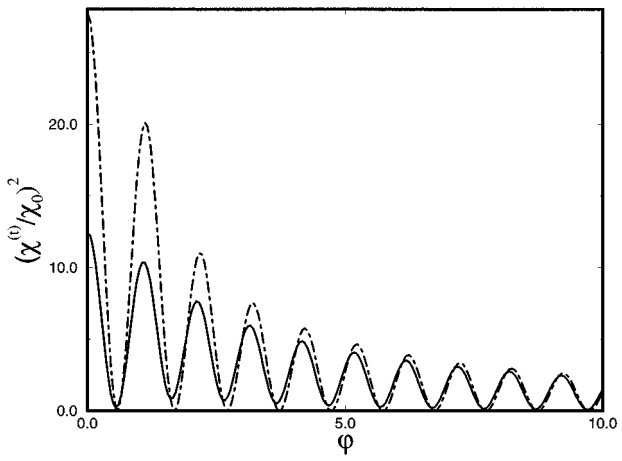

FIG. 6. Typical susceptibility as predicted by Eq. (5.1) as a function of the dimensionless flux $\varphi = Ha^2/\Phi_0$. Dash line: clean case; solid line: $l = a$ and $\xi = 0.1$.

(a/ξ) the prefactor is rather small. This weak suppression of the averaged susceptibilities can be related to the fact that in the long range case, different sectors of the contributing periodic orbits are highly correlated. As seen in Fig. 5(a), the quantum mechanical results (squares) for $\chi^{(t)}$ at $\xi/a = 0.5$, which are closest to the long range case, exhibit already a very weak damping.

B. Disorder effects at finite *H*-field: From integrable to chaotic behavior

In Fig. 6 we compare the ratio $(\chi^{(t)}/\chi^0)^2$ [obtained from calculating the integral in Eq. (5.1)] as a function of the dimensionless flux $\varphi = Ha^2/\Phi_0$ for the clean case and for disorder characterized by $l = a$ and $\xi = 0.1$. This figure shows that the damping due to disorder is maximal at zero field, but that already for $\varphi = 5$ the disorder seems not to affect the magnetic response any further.

The origin of this behavior can be understood readily by observing that as soon as φ is larger than one, the integral Eq. (5.1) is correctly approximated by a stationary phase approximation.[5] The stationary point $x_0^s = a/2$ corresponds to the two periodic orbits of the *perturbed* system, and only the trajectories such that

$$(x_0 - x_0^s)^2 \varphi < 1 \tag{5.11}$$

actually contribute to the integral. The magnetic field causes a de-phasing of the contributions of the various trajectories of the family, thus breaking the integrability of the system. This effect is responsible for the overall decrease of the typical susceptibility as the field increases. In this respect clean and disordered square billiards are not equivalent. In the disordered case, trajectories separated by a distance larger than ξ are already not contributing in phase. Therefore the additional magnetic field affects the magnitude of the susceptibility much less. This remains true up to the point where the condition (5.11) implies $|x_0 - x_0^s| < \xi$ in which case the disorder is not effective anymore, and the two curves coincide.

Therefore the behavior of the disorder damping we discussed in the previous subsection is characteristic for integrable geometries. For chaotic systems diagonal contributions (pair products of the same periodic orbit) are barely affected by disorder. This behavior is similar to that of integrable systems at finite field. When evaluating the contribution to the trace of the Green function in the neighborhood of a periodic orbit by stationary phase approximation, (as for the

derivation of the Gutzwiller trace formula) only orbits extremely close to the periodic orbit under consideration actually contribute. Unless ξ is exceedingly small, all these trajectories will see the same disorder potential.

As a final remark, note that *non-diagonal* contributions (pairs of different paths) are fully damped upon impurity average for chaotic as well as integrable systems, since the disorder potential along two different trajectories is usually not correlated [see also the discussion of the averaged Green function product after Eq. (3.17)]. Therefore non-diagonal contributions, which may be necessary to consider in the clean case,[30] are exponentially suppressed in the presence of disorder. On the contrary, *diagonal* terms which contain orbit correlations on distances ξ, exhibit non-exponential behavior [Eq. (5.7)] as a function of the inverse MFP $1/l$ for integrable geometries and are not affected (within our approximations) by disorder in the chaotic case.

C. Relation to experiment and other theories

Measurements of the orbital magnetism of small microstructures are still rare today. The only experiment on ensembles of ballistic billiards that we are aware of, was performed by Lévy *et al.*[21] and investigated the magnetic susceptibility of an array of about 10^5 ballistic square-like cavities. The size of the squares is on average $a=4.5\mu$m, with a large dispersion (estimated between 10% and 30%) along the array. Each individual square is a mesoscopic ballistic system since the phase-coherence length is estimated to be $L_\Phi=15-40$ μm and the elastic mean-free-path $l=4.5-10$ μm. The potential correlation length can be estimated[24] to be of the order of $\xi/a\simeq 0.1$. Taking the most unfavourable case of $l\simeq a\simeq 4.5$ μm we obtain, with respect to the clean case, a disorder reduction for the averaged susceptibility of $\langle\overline{\chi}\rangle/\overline{\chi}\simeq 0.37$, showing that the features of the clean integrable systems (strong paramagnetic susceptibility at $H=0$) persist upon inclusion of disorder. Since $\overline{\chi}\simeq 100\chi_L$,[5–7] our calculations for the paramagnetic response of the ballistic squares agree quantitatively with the experimental findings (given the experimental uncertainties).

Persistent currents in individual quasi-ballistic rings have recently been measured.[31] A similar setup would be needed for measuring the magnetic response of singly connected geometries, where our typical susceptibility (5.1) should be measured for the integrable case. Since modern lithographic techniques allow one to design chaotic as well as integrable cavities[2,3] and since we have demonstrated that disorder does not mask this difference, an order-of-magnitude effect is expected in the susceptibility according to the shape (chaotic vs. integrable) of the cavity.

In a related theoretical work Gefen *et al.*[32] followed a complementary approach to ours and calculated the disorder-averaged susceptibility for an ensemble of ballistic squares based on long trajectories (strongly) affected by scattering from δ-like impurities. They found that the average susceptibility does not depend on the elastic MFP. These results are not borne out by either our analytical or our semiclassical calculations at temperatures relevant for the experiment, where the exponential damping from Eq. (2.18) makes very long trajectories irrelevant.

VI. SUMMARY

In this work we have studied the interplay between integrability and disorder in the ballistic regime. The integrable property of the confining potential of a microstructure implies a peculiar behavior of its thermodynamical response functions, like the magnetic susceptibility. The disorder effects provided by remote impurity scattering tend to weaken the importance of the boundary scattering (and therefore the relevance of the underlying classical mechanics). Using a semiclassical approach we quantify this damping and show it to be much weaker than previously estimated (power-law suppression instead of exponential damping for the typical and average susceptibility). The disorder damping is decisively affected by finite-size effects since it depends not only on bulk-like characteristics of the disorder (like the elastic mean-free-path), but also on the ratio between the size of the structure and the correlation length of the potential.

TABLE I. Summary of the different average susceptibilities (at $H=0$) considered in the short range ($\xi<\lambda_F<a$), finite range ($\lambda_F<\xi<a$) and long range ($\lambda_F<a<\xi$) regimes. The fixed-size impurity averaged susceptibility $\langle\chi\rangle$ is given by the one-particle Green function, while the typical $\chi^{(t)}$ and average $\langle\overline{\chi}\rangle$ susceptibilities are given by two-particle Green functions and involve impurity and energy averages. The different average susceptibilities are normalized with respect to the corresponding clean counterparts. L_{11} is the length of the shortest flux-enclosing periodic trajectories in the square. In the short range regime the damping is governed by the elastic mean-free-path l_δ given by the quantum mechanical expression (A4). The damping in the finite and long range regimes is governed by the elastic MFP l [whose semiclassical expression is given in Eq. (3.14)], the correlation length ξ of the impurity potential and the size a of the structure. I_t is the moment of inertia of the (11) trajectories [Eq. (3.16)]. The finite-range expressions for $\chi^{(t)}$ and $\langle\overline{\chi}\rangle$ showing a power-law damping hold in the deep ballistic limit $l<L_{11}$. The numerical factors are $c_t=(20/7)\sqrt{2\pi}, c_a=2\sqrt{2\pi}, d_1=1/4\sqrt{\pi}$, and $d_2=6.5\cdot 10^{-5}$.

	Short range	Finite range	Long range
$\langle\chi\rangle/\chi_{cl}$	$\exp(-L_{11}/2l_\delta)$	$\exp(-L_{11}/2l)$	$\exp\{-d_1(L^2/l\xi)[1-I_t/(2\xi^2)]\}$
$(\chi^{(t)}/\chi_{cl}^{(t)})^2$	$\exp(-L_{11}/l_\delta)$	$c_t(\xi/a)(l/L_{11})^{1/2}$	$1-d_2 a/l(a/\xi)^9$
$\langle\overline{\chi}\rangle/\overline{\chi}$	$\exp(-L_{11}/l_\delta)$	$c_a(\xi/a)(l/L_{11})^{1/2}$	$1-d_2 a/l(a/\xi)^9$

Our finding for the weak disorder damping is particularly important due to the large phase coherence effects found for clean integrable structures and to the fact that the difference in the magnetic response between integrable and chaotic geometries has not yet been experimentally demonstrated.

Our calculational tools have been semiclassical expansions, which naturally convey at the quantum level information about the underlying classical mechanics and its sensitivity with respect to disorder. For the weak disorder that we have considered in this work, the lowest order approximation consists of the perturbative modification of the classical actions by the impurity potential. Averages over impurity configurations following our semiclassical calculations, allow us to obtain various ensemble susceptibilities. Our analytical calculations have been checked against numerical quantum simulations performing exact diagonalizations of the corresponding Hamiltonian.

The need to consider different averages is inherent to ballistic nanostructures, which are sufficiently small to be non-self-averaging. These various types of impurity-averaged susceptibilities for integrable systems are summarized in Table I for the three regimes defined by the correlation length of the impurity potential. We have first studied the fixed-size averaged susceptibility, directly obtainable from the disorder average of one-particle Green functions. It corresponds to the case where different impurity configurations of a given sample with a fixed Fermi energy are considered. For the short range regime, where the disorder correlation length $\xi<\lambda_F$, we have an exponential suppression of the clean results governed by the short-range elastic mean-free-path l_δ and the length of the most relevant trajectories. This result also holds in the finite-range ($\lambda_F<\xi\ll a$), but with an elastic mean-free-path that we have evaluated semi-classically. In the long-range regime ($\xi>a$) the fixed-size averaged susceptibility depends exponentially on the product $(L/l)\cdot(L/\xi)$ (where L denotes the typical orbit length) and a correction taking into account the geometry of the periodic trajectories.

For comparison with actual experiments we have to take into account that different impurity realizations are obtained together with a change in the Fermi energy and the size of the structures. We are then led to consider impurity and size averaged susceptibilities, which are expressed in terms of two-particle Green functions. The typical susceptibility is appropriate when considering the magnetic response of an individual sample which is thermally cycled in order to obtain different realizations of the potential. The average susceptibility is obtained from the measurement of an array of microscopically different samples. For the short-range case the only difference between one- and two-point Green function quantities is the factor 1/2 of the exponential damping of the former. In the finite-range regime there appear important differences when considering two-point Green function quantities with respect to the one-particle case. Closed trajectories that

remain closer than the correlation length of the potential result in a weak damping with a power-law dependence on l/L and ξ/a. This is the experimentally relevant situation, and the use of standard parameters led us to conclude that disorder damping in currently realizable microstructures is sufficiently weak in order not to mask the large effects due to integrability. In the long-range case the damping due to disorder is extremely small.

We have further considered the interplay between disorder and magnetic field in integrable geometries. It is interesting to note that both have a similar effect since they produce de-phasing between nearby trajectories. Since the two sources of de-phasing do not superpose, we find that disorder is less effective at finite fields, and reciprocally, disordered samples are less sensitive to magnetic field.

In chaotic geometries periodic trajectories are usually isolated, resulting in smaller oscillations of the density of states and a much smaller magnetic response than integrable systems. Introduction of disorder in chaotic geometries is therefore less dramatic than in integrable systems, since it merely changes the action of the relevant periodic trajectories instead of producing de-phasing within a family. The transition from the ballistic regime (where classical trajectories are essentially unaffected by disorder) to the diffusive regime will be considered in a subsequent publication.

In this work we have started from a system that is physically realizable using modern technology and we have developed a theoretical model with some key ingredients involving integrability and disorder. These are deep theoretical issues that need to be complemented by the consideration of other effects, like interactions, in order to obtain a complete description of the thermodynamics of mesoscopic systems.

APPENDIX: RELATION BETWEEN SEMICLASSICAL AND QUANTUM MECHANICAL RESULTS FOR BULK MEAN FREE PATHS

It is instructive to compare the semiclassical results of Eqs. (3.12)–(3.14) for the ballistic regime with their counterparts obtained from quantum mechanical scattering theory.

In a perturbative diagrammatic approach (treating the related Dyson-equation for scattering within a self-consistent Born approximation) the damping of the disorder-averaged one-particle Green function in a random potential is of the same exponential form as in Eq. (3.11).[9] This is usually obtained by replacing the imaginary part of the self-energy in the Green function after impurity average by the product of the density of states of the unperturbed system and $n{:}u^2$. The resulting quantum mechanical inverse elastic MFP l_{qm}, which appears in Eq. (3.11), is related to the total cross section σ by means of

$$\frac{1}{l_{\mathrm{qm}}} = n_i \sigma, \tag{A1}$$

where n_i is the impurity density and

$$\sigma = \int \mathrm{d}\Theta \, \sigma(\Theta) \tag{A2}$$

with $\sigma(\Theta)$ being the partial cross section for scattering with an angle Θ.

For a Gaussian disorder potential of the form of Eq. (3.3) a calculation of the cross section can be performed analytically and the corresponding inverse MFP gives

$$\frac{1}{l_{\rm qm}}=\frac{1}{l_\delta}I_0[2(k\xi)^2]e^{-2(k\xi)^2}. \tag{A3}$$

Here, I_0 is a modified Bessel function and

$$\frac{1}{l_\delta}=\frac{2\pi}{\hbar}\frac{n_i u^2}{v_{\rm F}}d(\mu)=\frac{n_i u^2}{v_{\rm F}}\frac{m}{\hbar^3} \tag{A4}$$

is the inverse MFP for the white noise case of δ-like scatterers of mean strength u. The $v_{\rm F}$ is the Fermi velocity and $d(\mu)=m/(2\pi\hbar^2)$ the density of states at the Fermi energy of a 2DEG.[9]

In order to compare $l_{\rm qm}$ with our semiclassical result we expand $l_{\rm qm}(k\xi)$ for large $k\xi$ which gives

$$l_{\rm qm}(k\xi)\simeq\sqrt{4\pi}(k\xi)l_\delta\left[1-\frac{1}{16(k\xi)^2}\right]\quad\text{for}\quad k\xi\to\infty. \tag{A5}$$

The leading order term is exactly the semiclassical MFP Eq. (3.14) for the Gaussian disorder model (3.3). The agreement between the semiclassical and diagrammatic approaches for the bulk can be related to the fact that our semiclassical treatment of disorder corresponds to the use of the Eikonal approximation (for each single scattering event) which is known to give the same results as Born approximation for large $k\xi$.

In the limit of $\xi<\lambda_F$ where our semiclassical description is no longer applicable, the mean free path $l_{\rm qm}$ approaches l_δ, which means that Eq. (3.11) can further be used, but with the semiclassical l replaced by l_δ.

The quantum mechanical transport mean free path $l_{\rm T}$ is calculated by including a factor $(1-\cos\Theta)$ in the integral (A2) for the scattering amplitude. It reads for Gaussian disorder

$$\frac{1}{l_{\rm T}}=\frac{1}{l_\delta}(I_0[2(k\xi)^2]-I_1[2(k\xi)^2])e^{-2(k\xi)^2} \tag{A6}$$

$$\simeq\frac{1}{l_{\rm qm}}\frac{1}{4(k\xi)^2}\quad\text{for}\quad k\xi\to\infty. \tag{A7}$$

This relation shows that $l_{\rm T}$ can be considerably larger than $l_{\rm qm}$ for $\lambda_F<\xi$. This shows that in the case of a confined system and smooth disorder, the system may behave ballistically although the elastic MFP l state might be considerably smaller than the system size.

(Received 31 March 1996; accepted for publication 12 July 1996)

We prove that the quantum dynamics of a class of infinite harmonic crystals becomes ergodic and mixing in the following sense: if H_m is the m-particle Schrödinger operator, $\omega_{\beta,m}(A)=\mathrm{Tr}(A\exp-\beta H_m)/\mathrm{Tr}(\exp-\beta H_m)$ the corresponding quantum Gibbs distribution over the observables $A,B,\psi_{m,\lambda}$ the coherent states in the mth particle Hilbert space, $g_{m,\lambda}=(\exp-\beta H_m)\psi_{m,\lambda}$ then $\lim_{t\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}(1/T)\int_0^T\langle e^{iH_nt}Ae^{-iH_nt}\psi_{m,\lambda},\psi_{m,\lambda}\rangle dt=\lim_{m\to\infty}\omega_{\beta,m}(A)$ if the classical infinite dynamics is ergodic, and $\lim_{t\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}\omega_{\beta,m}(e^{iH_nt}Ae^{-iH_nt}B)=\lim_{m\to\infty}\omega_{\beta,m}(A)\lim_{m\to\infty}\omega_{\beta,m}(B)$ if it is in addition mixing. The classical ergodicity and mixing properties are recovered as $\hbar\to0$, and $\lim_{m\to\infty}\omega_{\beta,m}(A)$ turns out to be the average over a classical Gibbs measure of the symbol generating A under Weyl quantization. © *1996 American Institute of Physics.* [S0022-2488(96)01710-0]

I. INTRODUCTION

This paper deals with the ergodic theory of a class of infinite quantum systems, the harmonic crystals. In this introduction we review the relevance of the infinitely many particle limit in detecting chaotic behavior of quantum systems, state the results, and relate why in our opinion it is convenient to examine the problem via pseudodifferential operators.

Let H be the quantization of a Hamiltonian generating a flow S_t on a constant energy manifold $M_E\subset R^m$, $A, B\in\mathscr{L}(\mathscr{H})$ any suitable quantum observable in $\mathscr{H}=L^2(\mathbb{R}^m)$, and let $\sigma(H)$ be discrete and simple, with projections P_n on the eigenvectors $\{u_n: n=0,1,...\}$. If quantum chaotic behavior (if any) is to be characterized in terms of ergodicity and mixing, we have to consider the quantum microcanonical ensemble at energy E, i.e., the application $\omega_{\Delta,E}$ mapping any $A\in\mathscr{L}(\mathscr{H})$ into:

$$\omega_{\Delta,E}(A)=\frac{\mathrm{Tr}\,A\Sigma_{n:E-\Delta<E_n<E}P_n}{\mathrm{Tr}\,\Sigma_{n:E-\Delta<E_n<E}P_n}\equiv\frac{\mathrm{Tr}\,A\delta(H-E)}{\mathrm{Tr}\,\delta(H-E)} \tag{I.1}$$

(see Ref. 1, Sec. 1.3; $\Delta>0$ is arbitrarily small). The quantum evolution $A_H(t)=e^{iHt}Ae^{-iHt}$ of A leaves $\omega_{\Delta,E}(A)$ invariant. Hence the consequent definition of mixing is (see Appendix B for details)

$$\lim_{t\to\infty}\omega_{\Delta,E}(A_H(t)B)=\omega_{\Delta,E}(A)\cdot\omega_{\Delta,E}(B). \tag{I.2}$$

We can always find in $\mathscr{H}$ (see Appendix B for easy verification) a family of normalized vectors $(\psi_\lambda)_{\lambda\in\Lambda},\Lambda=\mathbb{R}^{2m}$ complete for $\omega_{\Delta,E}$, namely,

a)Electronic mail: graffi@dm.unibo.it
b)Electronic mail: martinez@math.univ-paris13.fr

$$\omega_{\Delta,E}(A)=\int_{\Lambda}\langle A\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}d\nu_{\Delta,E}(\lambda),\quad \forall A\in\mathscr{L}(\mathscr{H}) \tag{I.3}$$

for a well-determined probability measure $\nu_{\Delta,E}(\lambda)$ on Λ.[1]
Then Eq. (I.2) becomes

$$\int_{\Lambda}\langle A_H(t)B\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}d\nu_{\Delta,E}(\lambda)\to\int_{\Lambda}\langle A\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}d\nu_{\Delta,E}(\lambda)\int_{\Lambda}\langle B\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}d\nu_{\Delta,E}(\lambda) \tag{I.4}$$

as $|t|\to\infty$. This entails the following representation of the quantum ergodicity notion (again see Appendix B): for any $A\in\mathscr{L}(\mathscr{H})$ and for $d\nu$-almost all $\lambda\in\mathbb{R}^{2m}$,

$$\frac{1}{T}\int_0^T\langle A_H(t)\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}dt\to\int_{\Lambda}\langle A\psi_{\lambda},\psi_{\lambda}\rangle_{\mathscr{H}}d\nu_{\Delta,E}(\lambda)=\omega_{\Delta,E}(A)\quad\text{as}\quad|T|\to\infty. \tag{I.5}$$

On the other hand it is well known (and easy to verify) that

$$\lim_{T\to\infty}\frac{1}{T}\int_0^T\langle\psi,A_H(t)\psi\rangle dt=\sum_{n=0}^{\infty}|\lambda_n|^2\langle u_n,Au_n\rangle. \tag{I.6}$$

Here $\psi=\Sigma_{n=0}^{\infty}\lambda_n u_n$ is any normalized quantum state expanded on the eigenvector basis (u_n). Equation (I.6) is the Von Neumann definition of quantum ergodicity[2] on the microcanonical ensemble. Now the verification of Eq. (I.5) requires H to have a continuous spectrum (Ref. 1, Sec. 1.3), and Eq. (I.6) shows that the time average cannot eliminate the dependence on the initial datum $\psi\equiv\{\lambda_n\}_{n=0}^{\infty}$.

This *a priori* lack of ergodicity, and *a fortiori* of mixing, looks like a manifestation of the so-called ''quantum suppression of classical chaos,'' which however can disappear when the number of particles tends to infinity. This has been noted in different contexts and within different approaches in Refs. 3–6. Hence the quantum counterparts of chaotic systems with infinitely many degrees of freedom (for a recent review see Ref. 6) are the best candidates to look for chaotic behavior. The simplest one is the infinite linear harmonic system

$$\ddot{q}_i=-2\sum_{i,j\in\mathbb{Z}}V_{ij}q_j. \tag{I.7}$$

We prove that, when the couplings V_{ij} generate an infinite dimensional dynamics ϕ_t ergodic with *respect to the (infinite dimensional) Gibbs measure* $d\mu_G(\beta)$,[7–9] the quantum evolution is ergodic, and mixing if ϕ_t is in addition mixing. The averages are now to be computed on the quantum canonical ensemble (the Gibbs state at an inverse temperature β), i.e., the application ω_β mapping any $A\in\mathscr{L}(\mathscr{H})$ into $\omega_\beta(A)=\mathrm{Tr}\,Ae^{-\beta H}/\mathrm{Tr}\,e^{-\beta H}$. More precisely, denote:

$$q_m(x,\xi)=\tfrac{1}{2}|\xi|^2+\langle V_m x,x\rangle,\quad V_m=(V_{i,j})_{\substack{|i|\le m\\|j|\le m}} \tag{I.8}$$

the $(2m+1)$ dimensional Hamiltonian defined on $\Lambda_m=(\mathbb{R}^{2m+1})^2$; $H_m=\mathrm{Op}^W(q_m)$ the operator on $L_m^2\equiv L^2(\mathbb{R}^{2m+1})$ defined by its Weyl quantization, $A=\mathrm{Op}^W(a)$ the operator on L_m^2 quantizing $a\circ\Pi_{m_1}(x,\xi)$ (m_1 fixed) where a is any smooth classical observable on Λ_{m_1}. Here $\Pi_{m_1}(x,\xi)\equiv(x,\xi)_{|i|\le m_1}$.

Then the present results are (see Theorems 2.2, 2.3 and Proposition 5.1 for a sharper version): $\forall\beta>0$ and $m_1\in\mathbb{N}$

$$\lim_{T\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}\frac{1}{T}\int_0^T\langle A_n(t)\psi_{\lambda,m},\psi_{\lambda,m}\rangle_{L^2_m}dt=\lim_{m\to\infty}\int_{\Lambda_\infty}\langle A\psi_{\lambda,m},\psi_{\lambda,m}\rangle_{L^2_m}d\nu_m(\lambda) \tag{I.9}$$

for ν-almost any λ, and

$$\lim_{t\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}\omega_{\beta,m}(A_n(t)B)=\lim_{m\to\infty}\omega_{\beta,m}(A)\cdot\lim_{m\to\infty}\omega_{\beta,m}(B). \tag{I.10}$$

Here

$$\omega_{\beta,m}(A)=\frac{\mathrm{Tr}\,Ae^{-\beta H_m}}{\mathrm{Tr}\,e^{-\beta H_m}};\quad \omega_{\beta,m}(A_n(t)B)=\frac{\mathrm{Tr}\,A_n(t)Be^{-\beta H_m}}{\mathrm{Tr}\,e^{-\beta H_m}}; \tag{I.11}$$

$A_n(t)$ is the Heisenberg observable corresponding to A under the quantum evolution of H_n;

$$\psi_{\lambda,m}=\frac{\exp(-\beta H_m/2)f_{\lambda,m}}{\|\exp(-\beta H_m/2)f_{\lambda,m}\|},\quad \nu_m(\lambda)=\frac{\|\exp(-\beta H_m/2)f_{\lambda,m}\|^2d\lambda}{\int_{\Lambda_m}\|\exp(-\beta H_m/2)f_{\lambda,m}\|^2d\lambda},$$

with $f_{\lambda,m}$ being the Bargmann coherent states (a set of vectors in $L^2(\mathbb{R}^{2m+1})$ indexed by $\lambda\in\Lambda_m$ whose definition is recalled in Appendix B); $\nu(\lambda)=\lim_{m\to\infty}\nu_m(\lambda)$.

Remark 1: The mixing property with respect to the KMS states in the CCR algebra of the infinite harmonic crystal (which has the same W^* closure of the pseudodifferential algebra we use) is proved in Ref. 6, Example 4.46, through the asymptotic abelianess of the Weyl algebra automorphism generated by the dynamics of the infinite crystal, when $\sigma(V)$ is purely absolutely continuous so that classical mixing holds.[7] The asymptotic abelianess may however fail if $\sigma(V)$ is only continuous and the classical system only ergodic. Hence the ergodicity result (I.9) requires in general an independent proof.

Remark 2: The main reason why, in our opinion, an ''analytic'' proof, based on pseudodifferential calculus, is in any case useful is that the notion (I.4) is proved to have the expected classical limit (Appendix B).

Additional reasons are as follows.

(1) One finds the right-hand sides (rhs) of Eqs. (I.9) and (I.10) to be the relevant classical averages:

$$\lim_{m\to\infty}\int_{\Lambda_\infty}\langle A_{m_1}\psi_{\lambda,m},\psi_{\lambda,m}\rangle d\nu_m(\lambda)=\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\hat{\mu}_\beta, \tag{I.12}$$

$$\lim_{m\to\infty}\frac{\mathrm{Tr}\,A_{m_1}e^{-\beta H_m}}{\mathrm{Tr}\,e^{-\beta H_m}}\cdot\frac{\mathrm{Tr}\,B_{m_1}e^{-\beta H_m}}{\mathrm{Tr}\,e^{-\beta H_m}}=\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\hat{\mu}_\beta\cdot\int_{\Lambda_\infty}b\circ\Pi_{m_1}d\hat{\mu}_\beta. \tag{I.13}$$

Here $\hat{\mu}_\beta=\lim_{m\to\infty}\hat{\mu}_{\beta,m}$, where $\hat{\mu}_{\beta,m}$ is the (explicitly constructed) Gibbs measure on Λ whose Weyl quantization yields $e^{-\beta H_m}$. It turns out that $\hat{\mu}_\beta$ depends on $\hbar$ to reduce to $\mu_G(\beta)$ as $\hbar\to 0$, because $e^{-\beta g_m}$ is just the principal symbol of $e^{-\beta H_m}$ realized as a pseudodifferential operator.

(2) If the initial states $\psi_{m,\lambda}$ belong to an explicitly constructed set (the image under $e^{-\beta H_m}$ of ''almost all'' coherent states on Λ_m), the $m\to\infty$ limit can actually eliminate the dependence of the rhs of Eq. (I.9) on the particular state in the set.

(3) Unlike the algebraic proof, the analytic one can, in principle, be extended to systems quantizing nonlinear classical equations. Work in this direction is in progress: it can be proved[10] that in some nonlinear cases the above results are still true in the sense of the formal power series in $\hbar$.

We conclude Sec. I with the remark that the dynamical mechanism generating chaotic behavior, in

the classical case and in the quantum one as well, is but free propagation of the chaotic initial condition: the infinite harmonic crystal indeed goes over (when the spacing goes to zero, and for special choices of V) to the free wave equation (equivalently, there exist coordinates in which the particle motions are free) and the chaotic initial condition is selected by the invariant Gibbs measure. This situation is referred to as kinematic chaos.[11]

The paper is organized as follows: in Sec. II we state assumptions and results, after a brief review of the infinite dimensional classical harmonic dynamics; in Secs. III and IV we prove the quantum ergodicity and the quantum mixing, respectively, in the most general formulation. In Secs. V and VI we prove a sharper formulation of the above results when $\exp-\beta H_m$ is replaced by $\mathrm{Op}^W(\exp-\beta q_m)$ and the family of vectors in L^2_m is specialized to the coherent states. Appendix A contains the proof of some technical lemmas, and Appendix B contains the discussion of our results in light of the existing notions of quantum ergodicity and mixing, together with the verification that they have the expected classical limit.

II. ASSUMPTIONS AND STATEMENT OF THE RESULTS

In the notation of Ref. 7, to which we refer the reader for any further detail on the system of infinitely many oscillators, let $V=(V_{i,j})_{i,j\in\mathbb{z}}$ be an infinite real-symmetric matrix; q_m and V_m are as in Eq. (II.8) and $\Lambda_m=(\mathbb{R}^{2m+1})^2$.

We write $S_m(1)$ for the set of C^∞ functions on Λ_m which are bounded together with all their derivatives, and for $a\in S_m(1)$ we denote $\mathrm{Op}^W(a)$ the Weyl quantization (with $\hbar=1$) of the symbol (equivalently, classical observable) a, explicitly given by the oscillatory integral:

$$\mathrm{Op}^W(a)u(x)=(2\pi)^{-(2m+1)}\int_{\Lambda_m} e^{i\langle (x-y),\xi\rangle}a\left(\frac{x+y}{2},\xi\right)u(y)dy\,d\xi \tag{II.1}$$

for all $u\in\mathscr{S}(\mathbb{R}^{2m+1})$. In particular the Schrödinger operator H_m on $L^2(\mathbb{R}^{2m+1})$

$$H_m:=\mathrm{Op}^W(q_m)=\frac{1}{2}\left(\sum_{j=1}^{2m+1}D_{x_j}^2\right)+\langle V_m x,x\rangle,\quad D_{x_j}=-i\,\frac{\partial}{\partial x_j} \tag{II.2}$$

quantizes the Hamiltonian q_m describing m oscillators coupled through V_m.

We assume from now on

(H1) $$|V_{ij}|=\mathscr{O}(|i-j|^{-\infty}),\quad |i-j|\to+\infty$$

and $\exists 0<\epsilon<M<\infty$ such that $\forall\geqslant 0$, $\sigma(V_m)\subset[\epsilon,M]$.
In particular, $V:l^2(\mathbb{z})\to l^2(\mathbb{Z})$ is bounded and strictly positive, with $\sigma(V)\subset[\epsilon,M]$.
(H2) The operator V acting on $l^2(\mathbb{Z})$ has no point spectrum.
Denote

$$\Lambda_\infty:=\bigcup_{k\in\mathbb{N}}\{(x_j,\xi_j)\};\quad |x_j|+|\xi_j|=\mathscr{O}(|j|^k),\ |j|\to\infty\}:=\bigcup_{k\in\mathbb{N}}\mathscr{H}_k. \tag{II.3}$$

It is proved in Ref. 7 that under condition (H1), Λ_∞ is invariant under the classical evolution of infinitely many degrees of freedom defined as follows:

$$\phi_t(x,\xi)\equiv\phi(t,x,\xi)=e^{tB}(x,\xi),\quad \forall(x,\xi)\in\Lambda_\infty,\quad \forall t\in\mathbb{R}, \tag{II.4}$$

where $B(x,\xi)$ is the infinite-dimensional Hamiltonian vector field generated by q_m when $m\to\infty$

$$B(x,\xi)=\left(\xi_j,-2\sum_{k\in\mathbb{Z}}V_{jk}x_k\right)_{j\in\mathbb{Z}}. \tag{II.5}$$

Moreover, if $\Pi_m:\Lambda_\infty\to\Lambda_m$ denotes the projection

$$\Pi_m(x,\xi)=(x_j,\xi_j)_{|j|\leqslant m} \tag{II.6}$$

for any $(x,\xi)\in\mathscr{H}_k$ one has

$$\phi(t,x,\xi)=\lim_{m\to\infty}\ \phi_{m,t}(\Pi_m(x,\xi))\in\mathscr{H}_k, \tag{II.7}$$

where

$$\phi_{m,t}=\exp\ tH_{q_m},\ \ H_{q_m}=\left(\frac{\partial q_m}{\partial\xi},-\frac{\partial q_m}{\partial x}\right)$$

is the vector field generated by q_m, and the limit is taken with respect to the natural Banach space topology of $\mathscr{H}_k$.

Now by condition (H1) the operator $V^{-1/2}$ exists and is continuous on $l^2(\mathbb{Z})$. This assumption and (H2) allow Lanford and Lebowitz[7] to prove the existence of the infinite dimensional, ergodic Gibbs measure $d\mu_G(\beta)$ on Λ_∞, namely

(1)

$$\int_{\Lambda_\infty}\varphi\circ\Pi_{m_1}d\mu_G(\beta)=\lim_{m\to\infty}\int_{\Lambda_m}\varphi\circ\Pi_{m_1}(x,\xi)e^{-\beta q_m(x,\xi)}\frac{dx\,d\xi}{Z_m},\quad\forall\varphi\in C_b^0(\mathbb{R}^{2m_1+1}) \tag{II.8}$$

where

$$Z_m(\beta)=\int_{\Lambda_m}e^{-\beta q_m(x,\xi)}dx\,d\xi \tag{II.9}$$

is the m-particle partition function

(2) The Gibbs measure is invariant and ergodic with respect to the flow $\phi(t;x,\xi)$, namely the continuous dynamical system $(\Lambda_\infty,\phi_t,d\mu_G(\beta))$ is ergodic.

An example of an infinite matrix satisfying (H1)–(H2) is given by $V=W$ where

$$W_{ij}=0,\quad |i-j|\geqslant 2,\quad W_{ii}=1,\quad W_{i,i+1}=W_{i,i-1}=\alpha \tag{II.10}$$

with $|\alpha|<\frac{1}{2}$, $\alpha\in\mathbb{R}$. The properties (H1), (H2) are proved, e.g., in Ref. 12.

To state our result we need to establish some further notation. For $f\in L^2(\mathbb{R}^{2m+1})$ and $(x,\xi)\in\Lambda_m$, we introduce the Wigner function of f

$$w_f(x,\xi)=\int_{\mathbb{R}^{2m+1}}e^{iu\xi}f\left(x-\frac{u}{2}\right)\overline{f\left(x+\frac{u}{2}\right)}du \tag{II.11}$$

and we restrict our attention to a random set of states f in the following sense: for all $m\in\mathbb{N}$, we consider a measure space (X_m,θ_m) with positive measure θ_m, and a family $(f_\lambda)_{\lambda\in X_m}$ of functions in $L^2(\mathbb{R}^{2m+1})$ such that:

(H3) For $dxd\xi$-almost all $(x,\xi)\in\Lambda_m$ the application $X_m\ni\lambda\mapsto w_{f_\lambda}(x,\xi)$ is in $L^1(X_m,d\theta_m)$ with non-negative values, and the quantity $\int_{X_m}w_{f_\lambda}(x,\xi)d\theta_m(\lambda)$ is ($dxd\xi$-almost everywhere) constant with respect to (x,ξ).

Here we can notice that, at least formally, condition (H3) is implied by the property [to be compared with Eq. (B10)]:

$$\mathrm{Tr}(A)=\int \langle Af_\lambda, f_\lambda\rangle d\theta_m(\lambda)$$

for any trace-class operator A. Indeed we have $w_{f_\lambda}(x,\xi) = \langle A_{x,\xi}f_\lambda, f_\lambda\rangle$ with $A_{x,\xi}f(y) = e^{2i(y-x)\xi}f(2x-y)$, which actually is not trace-class, but whose distributional kernel $K_{x,\xi}(y,y') = e^{2i(y-x)\xi}\delta(y'+y=2x)$ formally satisfies: $\int K_{x,\xi}(y,y)dy=1$.

In the last section we develop an example (the so-called coherent states) where condition (H3) is satisfied. Note that in any case, $w_f(x,\xi)$ is real and satisfies: $\int w_f(x,\xi)dxd\xi=(2\pi)^{2m+1}\|f\|^2$.

As we shall see, condition (H3) implies among other things that

$$\int_{X_m} \|e^{-\beta H_m/2}f_\lambda\|^2 d\theta_m(\lambda)<+\infty \tag{II.12}$$

so that we can consider the following probability measure on X_m:

$$d\nu_m(\lambda)=\frac{\|e^{-\beta H_m/2}f_\lambda\|^2 d\theta_m(\lambda)}{\int_{X_m}\|e^{-\beta H_m/2}f_\lambda\|^2 d\theta_m(\lambda)}. \tag{II.13}$$

Now let

$$W_\beta=\sqrt{2}V^{-1/2}\tanh\frac{\beta V^{1/2}}{\sqrt{2}} \tag{II.14}$$

(which is well-defined on $l^2(\mathbb{Z})$), and for $\beta>0$, denote $\hat{\mu}_\beta$ the Gaussian probability measure on Λ_∞ with mean zero and covariance given by

$$E[x_ix_j]=\langle(2VW_\beta)^{-1}e_i,e_j\rangle_{l^2(\mathbb{Z})},$$

$$E[\xi_i\xi_j]=\langle W_\beta^{-1}e_i,e_j\rangle_{l^2(\mathbb{Z})},$$

$$E[x_i\xi_j]=0, \tag{II.15}$$

where $e_i = (\delta_{ij})_{j\in\mathbb{Z}}$. Then our first main result is as follows:

Theorem II.1: Assume (H1)–(H3). Then:

(i) *For any $\beta>0$, the dynamical system $(\Lambda_\infty,\phi_t,\hat{\mu}_\beta)$ is ergodic*;

(ii) *For $m_1\in\mathbb{N}$ fixed and $a \in S_{m_1}(1)$, denote*

$$g_{m,\beta,\lambda}=\frac{e^{-1/2\beta H_m}f_\lambda}{\|e^{-1/2\beta H_m}f_\lambda\|}$$

and

$$A(m,n,T,\lambda)=\frac{1}{T}\int_0^T\langle e^{itH_n}\,\mathrm{Op}^W(a\circ\Pi_{m_1})e^{-itH_n}g_{m,\beta,\lambda},g_{m,\beta,\lambda}\rangle_{L^2(\mathbb{R}^{2m+1})}dt.$$

Then one has

$$\lim_{T\to\infty}\limsup_{n\to\infty}\limsup_{m\to\infty}\int_{X_m}\left|A(m,n,T,\lambda)-\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\hat{\mu}_\beta\right|d\nu_m(\lambda)=0.$$

Remarks:

(1) $A(m,n,T,\lambda)$ can be made arbitrarily close to $\int a \circ \Pi_{m_1} d\hat{\mu}_\beta$ in $L^1(X_m, d\nu_m(\lambda))$ by first choosing T, then $n=n(T)$, and finally $m=m(n,T)$ large enough. The *pointwise* convergence of $A(m,n,T,\lambda)$ is proved in Proposition 5.1 below, choosing for f_λ a particular set of coherent states.

(2) Note that $A(m,n,T,\lambda)$ is well-defined since the action of $e^{itH_n}\mathrm{Op}^W(a \circ \Pi_{m_1})e^{-itH_n}$ on $g_{m,\beta,\lambda}$ which is a C^∞ function on $\mathbb{R}^{2m+1}$ is well-defined for $n \leqslant m$.

(3) For small β, we have $W_\beta = \beta I + \mathcal{O}(\beta^3)$ and therefore the covariance of $\hat{\mu}_\beta$ coincides with the one of the usual Gibbs measures $\mu_G(\beta)$ up to a $\mathcal{O}(\beta^3)$-error term. In this sense, we can say that $\hat{\mu}_\beta$ and $\mu_G(\beta)$ are asymptotically equal for small β's (that is for large temperatures).

(4) The measure $\hat{\mu}_\beta$ can be seen as the limit when $m \to +\infty$ of the probability measure on Λ_m obtained by normalizing $e^{-q_{\beta,m}(x,\xi)}dx\,d\xi$, where

$$q_{\beta,m}(x,\xi) = q_m(W_{\beta,m}^{1/2}x, W_{\beta,m}^{1/2}\xi) \tag{II.16}$$

and

$$W_{\beta,m} = \sqrt{2}V_m^{-1/2} \tanh \frac{\beta V_m^{1/2}}{\sqrt{2}}. \tag{II.17}$$

(In fact, one can prove that condition (H1) and the spectral theorem imply that for any continuous function f on $\mathbb{R}$, $\langle f(V_m)e_i, e_j\rangle$ tends to $\langle f(V)e_i, e_j\rangle$ as $m \to \infty$.) This relation between $\hat{\mu}_\beta$ and the usual Gibbs measure reflects the relation between the usual quantum Gibbs measure $e^{-\beta H_m}$ and the Weyl quantization of the classical Gibbs measure $e^{-\beta q_m}$, namely (see Lemma III.1 below):

$$e^{-\beta H_m} = C_{\beta,m}\ \mathrm{Op}^W(e^{-q_{\beta,m}}),$$

where $C_{\beta,m}$ is a constant. In particular, if we denote by # the Weyl composition of symbols, we get (with some other constant $C'_{\beta,m}$):

$$e^{-q_{\beta,m}} \# e^{-q_{\beta,m}} = C'_{\beta,m} e^{-q_{2\beta,m}}, \tag{II.18}$$

which also explains the fact that $\hat{\mu}_\beta$ appears in the result given the above choice of $g_{m,\beta,\lambda}$, dictated by the standard requirement $\mathrm{Tr}\ e^{-\beta H_m} < +\infty$.

To state the mixing property we need two additional assumptions

(H4) The spectrum of V on $l^2(\mathbb{Z})$ is absolutely continuous.

(H5) The matrix $W_{\beta,m} = \sqrt{2}V_m^{-1/2} \tanh \beta V_m^{1/2}/\sqrt{2}$ satisfies:

$$(W_{\beta,m})_{i,j} = \mathcal{O}(|i-j|^{-\infty})$$

uniformly with respect to m, i, and j.

Note that (H5) is satisfied, e.g., for V of the form $V = I + \alpha J$ where J admits only a finite number of nonzero diagonals and $\alpha \in \mathbb{R}$ is chosen small enough. In particular, the example given in Eq. (II.10) satisfies assumption (H1) and assumptions (H4)–(H5) if $|\alpha|$ is small enough. Note also that the absolute continuity of $\sigma(V)$ implies (Ref. 7) that the continuous dynamical system $(\Lambda_\infty, \phi_t, \mu_G)$ enjoys the mixing property. For $m_1 \in \mathbb{N}$ and $a \in S_{m_1}(1)$, we denote $\hat{a} \in \mathcal{S}'(\Lambda_{m_1})$ the usual Fourier transform of a formally given by the integral:

$$\hat{a}(x^*,\xi^*) = \int_{\Lambda_{m_1}} e^{-i\langle (x,\xi),(x^*,\xi^*)\rangle} a(x,\xi)\,dx\,d\xi. \tag{II.19}$$

Then the result is

Theorem II.2: *Assume* (H1) *and* (H4)–(H5). *For* $m_1 \in \mathbb{N}$ *fixed,* $a, b \in S_{m_1}(1)$, *and* $n \geqslant m_1$ *denote*

$$A = \mathrm{Op}^W(a \circ \Pi_{m_1}),$$

$$A_n(t) = e^{itH_n} A e^{-itH_n} = \mathrm{Op}^W(a \circ \Pi_{m_1} \circ \phi_{n,t}) := \mathrm{Op}^W(a_{n,t}),$$

$$B = \mathrm{Op}^W(b \circ \Pi_{m_1}).$$

Then we have

$$\lim_{m\to\infty} \frac{\mathrm{Tr}(Ae^{-\beta H_m})}{\mathrm{Tr}(e^{-\beta H_m})} = \int_{\Lambda_\infty} a \circ \Pi_{m_1} d\hat{\mu}_\beta := \omega_\beta(A) \tag{II.20}$$

and if moreover $\hat{a}$ *and* $\hat{b}$ *are bounded measures on* Λ_{m_1}, *one has:*

$$\lim_{t\to\infty} \lim_{n\to\infty} \omega_\beta(A_n(t)B) = \omega_\beta(A) \cdot \omega_\beta(B). \tag{II.21}$$

Remark: Although this corresponds to the notion of quantum mixing already existing in the framework of W^* dynamical systems, our procedure permits us to completely avoid to realize any algebra of operators on an infinite dimensional space.

Under an additional assumption on V the results of Theorems 2.1 and 2.2 admit a less cumbersome formulation which eliminates the necessity of the double limit with respect to m and n. The further assumption is

(H6) For all $m \geqslant 0$ there exists a $(2m+1)\times(2m+1)$ real-symmetric matrix $\tilde{V}_m$ satisfying the same assumption (H1) as V_m, and such that:

(i) $\forall i,j \in \mathbb{Z}$, $\langle \tilde{V}_m^{-1} e_i, e_j \rangle$ tends to $\langle V^{-1} e_i, e_j \rangle_{l^2}$ as $m \to +\infty$;
(ii) $\forall m,n \in \mathbb{Z}$, the operator $\Pi_m \tilde{V}_n^{-1/2} \Pi_n$ becomes independent of n for $\ddot{n}$ sufficiently large;
(iii) The operator $\tilde{V}_m^{-1/2} \Pi_m \tilde{V}_n^{-1/2} \Pi_n$ tends strongly to the identity on each $\mathscr{H}_k$ ($k \in \mathbb{N}$) as $m \to +\infty$.

It is not very difficult to verify that an example of such V satisfying (H4) (in addition to (H1)–(H2)) is given by $V = W^2$ where W is as in the example (II.10): in this case one can take $\tilde{V}_m = (W_m)^2$ where W_m is extracted from W as in Eq. (I.8).

Under assumption (H6), we define for $0 < \beta < (2M)^{-1/2}$:

$$\tilde{q}_{\beta,m}(x,\xi) = \langle F_{\beta,m}\xi, \xi \rangle + \langle G_{\beta,m}x, x \rangle, \tag{II.22}$$

where (denoting I_m the identity on $\mathbb{R}^{2m+1}$):

$$F_{\beta,m} = \frac{1}{2\beta} \tilde{V}_m^{-1} (I_m - (I_m - 2\beta^2 \tilde{V}_m)^{1/2}), \tag{II.23}$$

$$G_{\beta,m} = 2\tilde{V}_m F_{\beta,m}. \tag{II.24}$$

We also consider on X_m the probability measure:

$$d\tilde{\nu}_m(\lambda) = \frac{\|\mathrm{Op}^W(e^{-\tilde{q}_{\beta,m}}) f_\lambda\|^2 d\theta_m(\lambda)}{\int_{X_m} \|\mathrm{Op}^W(e^{-\tilde{q}_{\beta,m}}) f_\lambda\|^2 d\theta_m(\lambda)}. \tag{II.25}$$

Then the result is:

Theorem II.3: *Assume* (H1)–(H3) *and,* (H6), *and, for* $m_1 \in \mathbb{N}$ *fixed,* $a \in S_{m_1}(1)$ *and* $0 < \beta < (2M)^{-1/2}$, *denote*

$$\widetilde{g}_{m,\beta,\lambda}=\frac{\mathrm{Op}^W(e^{-\widetilde{q}_{\beta/2,m}})f_\lambda}{\|\mathrm{Op}^W(e^{-\widetilde{q}_{\beta/2,m}})f_\lambda\|}$$

and

$$\widetilde{A}(m,T,\lambda)=\frac{1}{T}\int_0^T\langle e^{itH_m}\,\mathrm{Op}^W(a\circ\Pi_{m_1})e^{-itH_m}\widetilde{g}_{m,\beta,\lambda},\widetilde{g}_{m,\beta,\lambda}\rangle_{L^2(\mathbb{R}^{2m+1})}dt.$$

Then one has

(i)

$$\lim_{T\to\infty}\limsup_{m\to\infty}\int_{X_m}\left|\widetilde{A}(m,T,\lambda)-\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\mu_G(\beta)\right|d\widetilde{\nu}_m(\lambda)=0.$$

(ii) *Assume furthermore* (H4). *Then Eq.* (II.20) *becomes*

$$\lim_{m\to\infty}\frac{\mathrm{Tr}\,A\,\mathrm{Op}^W(e^{-\beta q_m})}{\mathrm{Tr}\,\mathrm{Op}^W(e^{-\beta q_m})}=\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\mu_G\beta:=\widetilde{\omega}_\beta(A)\tag{II.26}$$

and if moreover $\hat{a}$ *and* $\hat{b}$ *are bounded measures on* Λ_{m_1}, *Eq.* (II.21) *becomes*:

$$\lim_{t\to\infty}\lim_{m\to\infty}\widetilde{\omega}_\beta(A_m(t)B)=\widetilde{\omega}_\beta(A)\cdot\widetilde{\omega}_\beta(B).\tag{II.27}$$

Remarks:

(1) Here, the choice of the quadratic form $\widetilde{q}_{\beta,m}$ is dictated from the fact that we have (see Lemma V.2 below):

$$e^{-\widetilde{q}_{\beta,m}}\#e^{-\widetilde{q}_{\beta,m}}=C''_{\beta,m}e^{-2\beta\widetilde{q}_m},\tag{II.28}$$

where

$$\widetilde{q}_m(x,\xi)=\tfrac{1}{2}|\xi|^2+\langle\widetilde{V}_m x,x\rangle.$$

In view of assumption (H6) (i), this explains why we get the usual Gibbs measure in the limit $m\to+\infty$. Note that we also have $F_{\beta,m}=\beta/2I_m+\mathcal{O}(\beta^3)$ and $G_{\beta,m}=\beta V_m+\mathcal{O}(\beta^3)$, so that $\widetilde{q}_{\beta,m}$ is asymptotically equal to $\beta\widetilde{q}_m$ as $\beta\to0_+$.

(2) For small β it is possible to compare $\mathrm{Op}^W(e^{-\widetilde{q}_{\beta,m}})$ with $e^{-\beta\widetilde{H}_m}$, where $\widetilde{H}_m=\mathrm{Op}^W(\widetilde{q}_m)=2/1(\Sigma_{j=1}^{2m+1}D_{x_j}^2)+\langle\widetilde{V}_m x,x\rangle$. Actually, denoting $\widetilde{\lambda}_1,\ldots,\lambda_{2m+1}$ the eigenvalues of $\widetilde{V}_m$, we get by standard formulas (see Eq. (III.3) below) that $\mathrm{Op}^W(e^{-\widetilde{q}_{\beta,m}})$ is unitarily equivalent to

$$\bigotimes_{j=1}^{2m+1}\frac{1}{\sqrt{1-\beta^2\widetilde{\lambda}_j/2}}\exp\left[-\frac{1}{2}\left(\ln\frac{1+\beta\sqrt{\widetilde{\lambda}_j/2}}{1-\beta\sqrt{\widetilde{\lambda}_j/2}}\right)(D_{x_j}^2+x_j^2)\right]\tag{II.29}$$

while under the same unitary transformation $e^{-\beta\widetilde{H}_m}$ becomes

$$\bigotimes_{j=1}^{2m+1}e^{-\beta\sqrt{\widetilde{\lambda}_j/2}(D_{x_j}^2+x_j^2)}.\tag{II.30}$$

Since for small β we have:

$$\frac{1}{2}\ln\frac{1+\beta\sqrt{\tilde{\lambda}_j/2}}{1-\beta\sqrt{\tilde{\lambda}_j/2}}=\beta\sqrt{\frac{\tilde{\lambda}_j}{2}}\,(1+\mathcal{O}(\beta))$$

we get from Eqs. (II.29) and (II.30):

$$\mathrm{Op}^W(e^{-\tilde{q}_{\beta,m}})=e^{-\beta\tilde{H}_m(1+\beta R_{\beta,m})}, \tag{II.31}$$

where $[R_{\beta,m},\tilde{H}_m]=0$ and $1/(2m+1)R_{\beta,m}$ is uniformly bounded in (β,m).

(3) The previous remark proves that for small β, $[\mathrm{Op}^W(e^{-\tilde{q}_{\beta,m}}),\tilde{H}_m]=0$. This is true for all positive β, by formula (III.4) below, and the fact that

$$e^{-\tilde{q}_{\beta,m}}\circ\exp tH_{\tilde{q}_m}(x,\xi)=e^{-\tilde{q}_{\beta,m}}\circ\exp tH_{\tilde{q}_{\beta,m}}((2F_{\beta,m})^{-1/2}x,(2F_{\beta,m})^{-1/2}\xi)$$

is constant with respect to $t\in\mathbb{R}$.

(4) Since the choice of the lattice $\mathbb{Z}$ does not play any role at all in our proofs, it can be replaced without modification by any lattice $\Gamma\subset\mathbb{R}^d$ $(d\geqslant 1)$ of the type considered in Ref. 7, in which case the model describes an infinite harmonic crystal in $\mathbb{R}^d$. Also the choice of Λ_m is nonssential, in the sense that any other choice $\Lambda_m'\to\Lambda_\infty$ in a reasonable way leads to the same results.

III. PROOF OF THEOREM 2.1

Now we turn to the proof of Theorem 2.1. The fact that $(\lambda_\infty,\phi_t,\hat{\mu}_\beta)$ is ergodic essentially follows from the arguments of Ref. 7, but, for the sake of completeness, we give a sketch of the proof. First, the invariance of $\hat{\mu}_\beta$ under ϕ_t is a consequence of the commutativity between the operator B defined in Eq. (II.5) and the operator $l^2(\mathbb{Z})\oplus l^2(\mathbb{Z})\ni(x,\xi)\mapsto(W_\beta^{1/2}x,W_\beta^{1/2}\xi)$. Now, denote $\hat{h}_1$ the closure in $L^2(\Lambda_\infty,d\hat{\mu}_\beta)$ of the set of all finite sums of $(a_jx_j+b_j\xi_j)$'s, $(a_j,b_j\in\mathbb{C};j\in\mathbb{Z})$. Then, denoting $d(\mathbb{Z})$ the elements of $l^2(\mathbb{Z})$ with finite support, the application

$$\Theta: d(\mathbb{Z})\oplus d(\mathbb{Z})\to\hat{h}_1,$$

$$a\oplus b\mapsto\sum_j\,(a_jx_j+b_j\xi_j),$$

can be extended into an isomorphism from $D((2VW_\beta)^{-1/2})\oplus D(W_\beta^{-1/2})$ to $\hat{h}_1$ (where $D(A)$ denotes the domain of the operator A). Moreover, identifying $D((2VW_\beta)^{-1/2})\oplus D(W_\beta^{-1/2})$ with $l^2(\mathbb{Z})\oplus l^2(\mathbb{Z})$ in an obvious way, we see that the action of ϕ_t on $\hat{h}_1$ is represented on $l^2(\mathbb{Z})\oplus l^2(\mathbb{Z})$ (via the two previous identifications) by its infinitesimal generator

$$U=\begin{pmatrix}0 & -V^{-1/2}\\ V^{1/2} & 0\end{pmatrix}.$$

Since, by assumption (H2), U has no point spectrum the result (i) follows by an abstract argument (see Ref. 7, Proposition 4.2).

To prove (ii) we first show:

Lemma III.1: There exists a constant $C_{\beta,m}$ such that:

$$e^{-\beta H_m}=C_{\beta,m}\mathrm{Op}^W(e^{-q_{\beta,m}}).$$

Proof: Let $\lambda_1,\ldots,\lambda_{2m+1}$ be the eigenvalues of V_m, and denote $y=(y_1,\ldots,y_{2m+1})$ the coordinates in $\mathbb{R}^{2m+1}$ corresponding to an orthonormal basis of eigenvectors of V_m. Then H_m becomes:

$$H'_m = -\frac{1}{2}\,\Delta_y + \sum_j \lambda_j y_j^2$$

while the operator $K_m = \mathrm{Op}^W(e^{-q_{\beta,m}})$ is transformed into

$$K'_m = \bigotimes_{j=1}^{2m+1} \mathrm{Op}^W\left(\exp -\left(\frac{1}{\sqrt{2\lambda_j}}\tanh\left(\beta\sqrt{\frac{\lambda_j}{2}}\right)\eta_j^2 + \sqrt{2\lambda_j}\tanh\left(\beta\sqrt{\frac{\lambda_j}{2}}\right)y_j^2\right)\right).$$

[Here η is the dual variable of y, and $\xi = ({}^tM)^{-1}\eta = M\eta$ since $x = My$ with M orthogonal.] Then the change of variables

$$y_j \mapsto z_j = (2\lambda_j)^{1/4} y_j$$

transforms H'_m into

$$H''_m = \sum_j \sqrt{\frac{\lambda_j}{2}}\,(D_{z_j}^2 + z_j^2) \tag{III.1}$$

and K'_m into

$$K''_m = \bigotimes_{j=1}^{2m+1} \mathrm{Op}^W\left(\exp\left[\tanh\left(\beta\sqrt{\frac{\lambda_j}{2}}\right)(\zeta_j^2 + z_j^2)\right]\right). \tag{III.2}$$

Next, consider the well known one-dimensional identity valid for $0<a<1$

$$\mathrm{Op}^W(e^{-a(x^2+\xi^2)}) = \frac{1}{\sqrt{1-a^2}}\exp\left(-\frac{a}{2}\,x^2\right)\exp\left(-\frac{a}{1-a^2}\,D_x^2\right)\exp\left(-\frac{a}{2}\,x^2\right),$$

which can be for instance verified by explicit computation of the Weyl symbol on the right-hand side. Then, using the formula (see, e.g., Ref. 13)

$$\exp\left(-\frac{x^2}{2}\right)\exp(-tD_x^2)\exp\left(-\frac{x^2}{2}\right) = \exp\left[-\frac{\ln(z+\sqrt{z^2-1})}{4k\sqrt{z^2-1}}\,(D_x^2 + 4k^2(z^2-1)x^2)\right]$$

with $k = 1/4t$, $z = 2t+1$ $(t>0)$, we get in particular for $0<a<1$:

$$\mathrm{Op}^W(e^{-a(x^2+\xi^2)}) = \frac{1}{\sqrt{1-a^2}}\exp\left[-\frac{1}{2}\left(\ln\frac{1+a}{1-a}\right)(D_x^2 + x^2)\right] \tag{III.3}$$

Taking $a = \tanh(\beta\sqrt{\lambda_j/2})$, the Lemma follows from Eqs. (III.1)–(III.3). □

Now, since the flow generated by q_n defines a linear canonical transformation on Λ_n, we have

$$e^{itH_n}\mathrm{Op}^W(a)e^{itH_n} = \mathrm{Op}^W(a\circ\exp tH_{q_n}), \quad \forall a \in S_n(1). \tag{III.4}$$

This relation [an ''exact Egorov theorem,'' going back at least to Van Hove (see, e.g., Ref. 14)] holds only in the Weyl quantization[15] (Sec. 5.2).

For $n \leqslant m$ and $(x,\xi) \in \Lambda_m$, denote

$$\rho(m,\lambda) = \|e^{-1/2\beta H_m} f_\lambda\|^2, \tag{III.5}$$

$$a_{n,T}(x,\xi)=\frac{1}{T}\int_0^T (a\circ\Pi_{m_1}\circ\exp\, tH_{q_n}\circ\Pi_n)(x,\xi))dt. \tag{III.6}$$

Using Lemma (III.1), (III.4), and (II.11), we get

$$A(m,n,T,\lambda)=\frac{C_{\beta,m}^2}{\rho(m,\lambda)}\int_{\Lambda_m}(e^{-q_{\beta,m}}\#a_{n,T}\#e^{-q_{\beta,m}})(x,\xi)w_{f_\lambda}(x,\xi)dxd\xi, \tag{III.7}$$

where # is the Weyl composition of symbols on Λ_m:

$$(a\#b)(x,\xi)=\pi^{-2(2m+1)}\int_{\Lambda_m^2}a(x+y,\xi+\eta)b(x+z,\xi+\zeta)e^{2i(\zeta y-z\eta)}dyd\eta dzd\zeta. \tag{III.8}$$

Taking advantage of assumption (H3), we get from Eq. (III.7)

$$\int_{X_m}A(m,n,T,\lambda)\rho(m,\lambda)d\theta_m(\lambda)=C_0\int_{\Lambda_m}(e^{-q_{\beta,m}}\#a_{n,T}\#e^{-q_{\beta,m}})(x,\xi)dxd\xi, \tag{III.9}$$

$$\int_{X_m}|A(m,n,T,\lambda)|\rho(m,\lambda)d\theta_m(\lambda)\leqslant C_0\int_{\Lambda_m}|(e^{-q_{\beta,m}}\#a_{n,T}\#e^{-q_{\beta,m}})(x,\xi)|dxd\xi, \tag{III.10}$$

where $C_0=C_0(\beta,m)$ is a constant, which can be computed by taking $a\equiv 1$ in (III.9):

$$C_0=\left(\int e^{-q_{\beta,m}}\#e^{-q_{\beta,m}}dxd\xi\right)^{-1}\int_{X_m}\rho(m,\lambda)d\theta_m(\lambda). \tag{III.11}$$

This also proves Eq. (II.12) so that, using the notation (II.13) we can rewrite Eqs. (III.9)–(III.10) as:

$$\int_{X_m}A(m,n,T,\lambda)d\nu_m(\lambda)=C_1\int_{\Lambda_m}(e^{-q_{\beta,m}}\#a_{n,T}\#e^{-q_{\beta,m}})(x,\xi)dxd\xi, \tag{III.12}$$

$$\int_{X_m}|A(m,n,T,\lambda)|d\nu_m(\lambda)\leqslant C_1\int_{\Lambda_m}|(e^{-q_{\beta,m}}\#a_{n,T}\#e^{-q_{\beta,m}})(x,\xi)|dxd\xi \tag{III.13}$$

with

$$C_1=\left(\int e^{-q_{\beta,m}}\#e^{-q_{\beta,m}}dxd\xi\right)^{-1}.$$

Now we make use of the two following properties of the operation # (valid, e.g., for any a,b,c in $\mathcal{S}(\Lambda_m)$):

$$\int_{\Lambda_m}(a\#b\#c)(x,\xi)dxd\xi=\int_{\Lambda_m}(b\#c\#a)(x,\xi)dxd\xi, \tag{III.14}$$

$$\int_{\Lambda_m}(a\#b)(x,\xi)dxd\xi=\int_{\Lambda_m}a(x,\xi)b(x,\xi)dxd\xi. \tag{III.15}$$

The property (III.14) is just a consequence of the cyclicity of the trace of operators, and Eq. (III.15) comes from a direct computation using Eq. (III.8).

Here our symbol a is not supposed to be in $\mathscr{S}(\Lambda_m)$, but an easy argument of density allows us to deduce from Eq. (III.12) and Eqs. (III.14)–(III.15) [using also Eq. (II.18)]:

$$\int_{X_m} A(m,n,T,\lambda)\,d\nu_m(\lambda) = \int_{\Lambda_m} a_{n,T}(x,\xi)[e^{-q_{\beta,m}(x,\xi)}dx\,d\xi]_N, \tag{III.16}$$

where we have used the notation:

$$\int_E f[d\mu]_N = \frac{1}{\mu(E)} \int_E f\,d\mu \tag{III.17}$$

for any finite positive measure μ on a set E.

Now the problem is to rewrite also Eq. (III.13) in this way, despite the appearance of the modulus. The argument to do this is based upon the following:

Lemma III.2: There exists a positive definite quadratic form $Q_{\beta,m}(x,\xi,y,\eta)$ on Λ_m^2 such that for all $a \in S_m(1)$:

$$e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}} = C'_{\beta,m} \tilde{a} e^{-q_{2\beta,m}},$$

where $C'_{\beta,m}$ is the constant appearing in Eq. (II.18), and

$$\tilde{a}(x,\xi) = \int_{\Lambda_m} a(y,\eta)[e^{-Q_{\beta,m}(x,\xi,y,\eta)}dy\,d\eta]_N.$$

Proof: See Appendix A.

We deduce in particular from Lemma III.2 the existence of a positive C^∞ function $\gamma(x,\xi)$ on Λ_m such that for all $a \in S_m(1)$:

$$\int_{\Lambda_m} (e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}})dx\,d\xi = \int_{\Lambda_m} a(x,\xi)\,\gamma(x,\xi)dx\,d\xi, \tag{III.18}$$

$$\int_{\Lambda_m} |e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}}|dx\,d\xi \leqslant \int_{\Lambda_m} |a(x,\xi)|\,\gamma(x,\xi)dx\,d\xi. \tag{III.19}$$

By Eqs. (III.12), (III.16), and (III.18) we get that γ equals a constant times $e^{-q_{2\beta,m}}$, which by Eqs. (III.13) and (III.19) allows us to conclude that:

$$\int_{X_m} |A(m,n,T,\lambda)|\,d\nu_m(\lambda) \leqslant \int_{\Lambda_m} |a_{n,T}(x,\xi)|[e^{-q_{\beta,m}(x,\xi)}dx\,d\xi]_N. \tag{III.20}$$

Without loss of generality, we can assume from now on that $\int_{\Lambda_\infty} (a \circ \Pi_{m_1})\,d\hat{\mu}_\beta = 0$, and then it remains to estimate the rhs of Eq. (III.20). Since $a_{n,T}(x,\xi)$ depends only on $\Pi_n(x,\xi)$, we can let m go to $+\infty$ in Eq. (III.20) and we get

$$\limsup_{m\to\infty} \int_{X_m} |A(m,n,T,\lambda)|\,d\nu_m(\lambda) \leqslant \int_{\Lambda_\infty} |a_{n,T}(x,\xi)|\,d\hat{\mu}_\beta. \tag{III.21}$$

Then we use Eq. (II.7) to let n go to $+\infty$ in Eq. (III.22). By the dominated convergence theorem, we then obtain

$$\limsup_{n\to\infty}\limsup_{m\to\infty}\int_{X_m}|A(m,n,T,\lambda)|d\nu_m(\lambda)\leqslant\int_{\Lambda_\infty}\left|\frac{1}{T}\int_0^T(a\circ\Pi_{m_1}\circ\phi_t)(x,\xi)dt\right|d\hat{\mu}_\beta. \tag{III.22}$$

Finally, we let T go to $+\infty$. By the ergodicity property, we have that

$$\frac{1}{T}\int_0^T(a\circ\Pi_{m_1}\circ\phi_t)(x,\xi)dt\to\int_{\Lambda_\infty}(a\circ\Pi_{m_1})d\hat{\mu}_\beta=0$$

for $\hat{\mu}_\beta$—almost all (x,ξ) in Λ_∞. Therefore, again applying the dominated convergence theorem, we get from Eq. (III.22):

$$\lim_{T\to+\infty}\limsup_{n\to\infty}\limsup_{m\to\infty}\int_{X_m}|A(m,n,T,\lambda)|d\nu_m(\lambda)\leqslant 0 \tag{III.23}$$

and this completes the proof of Theorem 2.1. □

IV. PROOF OF THEOREM 2.2

Let us now proceed to the proof of Theorem 2.2. Denote

$$\omega_{\beta,m}(A)=\frac{\mathrm{Tr}(Ae^{-\beta H_m})}{\mathrm{Tr}(e^{-\beta H_m})}. \tag{IV.1}$$

Using Lemma III.1 and Eq. (III.15) we see that

$$\omega_{\beta,m}(A)=\int_{\Lambda_m}a\circ\Pi_{m_1}(x,\xi)[e^{-q_{\beta,m}(x,\xi)}dxd\xi]_N \tag{IV.2}$$

so that the first assertion (II.20) of the theorem is obvious.

For $m\geqslant n\geqslant m_1$ we also have:

$$\omega_{\beta,m}(A_n(t)B)=\int_{\Lambda_m}a_{n,t}\#(b\circ\Pi_{m_1})(x,\xi)[e^{-q_{\beta,m}(x,\xi)}dxd\xi]_N. \tag{IV.3}$$

For $X=(x,\xi)$ and $Y=(y,\eta)\in\Lambda_m$, we denote

$$\sigma(X,Y)=\xi y-x\eta \tag{IV.4}$$

the canonical symplectic form on Λ_m. Then by Eq. (III.8) we have:

$$a_{n,t}\#(b\circ\Pi_{m_1})(X)=\pi^{-2(2m+1)}\int_{\Lambda_n^2}(a_{n,t}\circ\Pi_n)(Y)(b\circ\Pi_{m_1})(Z)e^{2i[\sigma(Y,X)+\sigma(Z,Y-X)]}dYdZ. \tag{IV.5}$$

By the Fourier inversion formula and the assumption on a,b, we can write for any $Y_1\in\Lambda_{m_1}$:

$$a(Y_1)=(2\pi)^{-2(2m_1+1)}\int_{\Lambda_{m_1}}e^{\langle Y_1,Y^*\rangle}\hat{a}(Y^*)dY^* \tag{IV.6}$$

and a similar formula for b. Here we have used an abuse of notation by writing $\hat{a}(Y^*)dY^*$ for the (not necessarily Lebesgue absolutely continuous) measure defined by the Fourier transform of a.

In particular, taking $Y_1 = \Pi_{m_1}\phi_{n,t}\Pi_n(Y)$ in Eq. (IV.6) and substituting in Eq. (IV.5), we get

$$a_{n,t}\#(b\circ\Pi_{m_1})(X) = \pi^{-2(2m+1)}(2\pi)^{-4(2m_1+1)} \times \int e^{2i[\sigma(Y,X)+\sigma(Z,Y-X)]+i\langle\phi_{n,t}\Pi_n(Y),Y^*\rangle+i\langle Z,Z^*\rangle} \times \hat{a}(Y^*)dY^*\hat{b}(Z^*)dZ^*dYdZ,$$

where the integration runs over $(Y^*,Z^*,Y,Z) \in \Lambda_{m_1}\times\Lambda_{m_1}\times\Lambda_m\times\Lambda_m$, and Λ_{m_1} has been identified in an obvious way with a subspace of Λ_n and of Λ_m.

Interpreting the integration over (Y,Z) as an oscillatory one, we can first integrate with respect to Z, and we obtain (using the well-known identity $\int_{\mathbb{R}^d} e^{2i(x-y)\xi}d\xi = \pi^d\delta(y=x)$):

$$a_{n,t}\#(b\circ\Pi_{m_1})(X) = (2\pi)^{-4(2m_1+1)}\int e^{i\langle Z^*,X\rangle+i\langle\phi_{n,t}\Pi_n(X+\tilde{Z}^*/2),Y^*\rangle}\hat{a}(Y^*)dY^*\hat{b}(Z^*)dZ^*, \tag{IV.7}$$

where we have denoted $\tilde{Z}^* = (-\zeta^*, z^*)$ if $Z^* = (z^*,\zeta^*)$.

Now, inserting Eq. (IV.7) into Eq. (IV.3), and making the change of variables $X \mapsto X - \tilde{Z}^*/2$, this gives:

$$\omega_{\beta,m}(A_n(t)B) = (2\pi)^{-4(2m_1+1)}\int_{\Lambda_m\times\Lambda_{m_1}^2} e^{i\langle Z^*,X\rangle+i\langle\phi_{n,t}\Pi_n(X),Y^*\rangle} \times [e^{-q_{\beta,m}(X-\tilde{Z}^*/2)}dX]_N\hat{a}(Y^*)dY^*\hat{b}(Z^*)dZ^*$$

and therefore, writing $q_{\beta,m}(X) = \langle Q_{\beta,m}X,X\rangle$ with $Q_{\beta,m}(x,\xi) = (V_mW_{\beta,m}x, W_{\beta,m}\xi)$:

$$\omega_{\beta,m}(A_n(t)B) = (2\pi)^{-4(2m_1+1)}\int_{\Lambda_{m_1}^2}\Gamma_{m,n,t}(Y^*,Z^*)e^{-q_{\beta,m}(\tilde{Z}^*)/4}\hat{a}(Y^*)dY^*\hat{b}(Z^*)dZ^*, \tag{IV.8}$$

where

$$\Gamma_{m,n,t}(Y^*,Z^*) = \int_{\Lambda_m} e^{i\langle Z^*,X\rangle+\langle\tilde{Z}^*,Q_{\beta,m}X\rangle+i\langle\phi_{n,t}\Pi_n(X),Y^*\rangle}[e^{-q_{\beta,m}(X)}dX]_N \tag{IV.9}$$

is of the form

$$\Gamma_{m,n,t}(Y^*,Z^*) = \int_{\Lambda_m} F_{n,t,Y^*,\tilde{Z}^*}(\Pi_{m_1}Q_{\beta,m}X,\Pi_nX))[e^{-q_{\beta,m}(X)}dX]_N \tag{IV.10}$$

with F_{n,t,Y^*,Z^*} smooth and uniformly bounded together with all its derivatives on $\Lambda_{m_1}\times\Lambda_n$. To let m tend to infinity in Eq. (IV.10), we use the following lemma (which is the point where (H5) is used):

Lemma IV.1: Let $F \in C^\infty(\Lambda_{m_1}\times\Lambda_n)$ be uniformly bounded with all its derivatives. Then

$$\int_{\Lambda_m} F(\Pi_{m_1}Q_{\beta,m}X,\Pi_nX))[e^{-q_{\beta,m}(X)}dX]_N \to \int_{\Lambda_\infty} F(\Pi_{m_1}Q_\beta X,\Pi_nX))d\hat{\mu}_\beta \quad (m\to\infty),$$

where $\hat{\mu}_\beta$ is defined in Eq. (II.15), *and Q_β is defined on Λ_∞ by*

$$Q_\beta(x,\xi)=(VW_\beta x, W_\beta \xi), \quad W_\beta=\sqrt{2}V^{-1/2}\tanh\frac{\beta V^{1/2}}{\sqrt{2}}.$$

Proof: See Appendix A.

Now, for any fixed (n,t,Y^*,Z^*), we see on Eqs. (IV.9)–(IV.10) that, as $m\to\infty$, $\Gamma_{m,n,t}(Y^*,Z^*)$ tends to

$$\Gamma_{n,t}(Y^*,Z^*)=\int_{\Lambda_\infty} e^{i\langle Z^*,X\rangle+\langle \tilde{Z}^*,Q_\beta X\rangle+i\langle \phi_{n,t}\Pi_n(X),Y^*\rangle}d\hat{\mu}_\beta \tag{IV.11}$$

which in turn is of the form:

$$\Gamma_{n,t}(Y^*,Z^*)=\int_{\Lambda_\infty} f_{Z^*}(X)g_{Y^*}(\Pi_{m_1}\phi_{n,t}\Pi_n X)d\hat{\mu}_\beta \tag{IV.12}$$

with f_{Z^*} and g_{Y^*} uniformly bounded, and g_{Y^*} continuous on Λ_{m_1}. Then, using Eq. (II.7) and the dominated convergence theorem, we see on Eq. (IV.12) that, as $n\to\infty$, $\Gamma_{n,t}(Y^*,Z^*)$ tends to

$$\Gamma_t(Y^*,Z^*)=\int_{\Lambda_\infty} f_{Z^*}(X)g_{Y^*}(\Pi_{m_1}\phi_t X)d\hat{\mu}_\beta. \tag{IV.13}$$

Now, the same arguments used in the proof of Theorem 2.1 (i) (see the beginning of Sec. III) lead to the fact that under (H4) the classical dynamical system $(\Lambda_\infty,\phi_t,\hat{\mu}_\beta)$ is mixing. As a consequence, we get from Eq. (IV.13)

$$\Gamma_t(Y^*,Z^*)\to\int f_{Z^*}(X)d\hat{\mu}_\beta\cdot\int g_{Y^*}(\Pi_{m_1}X)d\hat{\mu}_\beta \quad \text{as} \quad t\to\infty. \tag{IV.14}$$

Summing up Eqs. (IV.9)–(IV.14), we have proved that for any fixed $(Y^*,Z^*)\in\Lambda_{m_1}^2$, we have

$$\lim_{t\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}\Gamma_{m,n,t}(Y^*,Z^*)=\int_{\Lambda_\infty} e^{i\langle Z^*,X\rangle+\langle\tilde{Z}^*,Q_\beta X\rangle}d\hat{\mu}_\beta(X)\cdot\int_{\Lambda_\infty} e^{i\langle X,Y^*\rangle}d\hat{\mu}_\beta(X) \tag{IV.15}$$

and because of the translation invariance of the Lebesgue measure on Λ_m, and the fact that $\langle Z^*,\tilde{Z}^*\rangle=0$, it is also easy to verify that

$$\int_{\Lambda_\infty} e^{i\langle Z^*,X\rangle+\langle\tilde{Z}^*,Q_\beta X\rangle}d\hat{\mu}_\beta(X)=e^{\langle Q_\beta\tilde{Z}^*,\tilde{Z}^*\rangle/4}\int_{\Lambda_\infty} e^{i\langle Z^*,X\rangle}d\hat{\mu}_\beta(X). \tag{IV.16}$$

Since by assumption $\hat{a}(Y^*)dY^*$ and $\hat{b}(Z^*)dZ^*$ are bounded measures on Λ_{m_1} and $|\Gamma_{m,n,t}(Y^*,Z^*)e^{-q_{\beta,m}(\tilde{Z}^*)/4}|=1$, we can use the dominated convergence theorem in Eq. (IV.8) and conclude from Eqs. (IV.15)–(IV.16) (using also the obvious fact that $q_{\beta,m}(\tilde{Z}^*)$ tends to $\langle Q_\beta\tilde{Z}^*,\tilde{Z}^*\rangle$ as $m\to\infty$) that

$$\lim_{t\to\infty}\lim_{n\to\infty}\lim_{m\to\infty}\omega_{\beta,m}(A_n(t)B)=(2\pi)^{-4(2m_1+1)}\int_{\Lambda_{m_1}\times\Lambda_\infty}e^{i\langle X,Y^*\rangle}\hat{a}(Y^*)dY^*d\hat{\mu}_\beta(X)$$

$$\cdot\int_{\Lambda_{m_1}\times\Lambda_\infty}e^{i\langle Z^*,X\rangle}\hat{b}(Z^*)dZ^*d\hat{\mu}_\beta(X)$$

$$=\int_{\Lambda_\infty}a\circ\Pi_{m_1}d\hat{\mu}_\beta\cdot\int_{\Lambda_\infty}b\circ\Pi_{m_1}d\hat{\mu}_\beta,$$

where the last equality comes again from the Fourier-inversion formula. □

V. PROOF OF THEOREM 2.3

Lemma V.2: For any pair of positive definite real-symmetric matrices F and G on Λ_m, there exists a constant C=C(F,G,m) such that:

$$e^{-(\langle F\xi,\xi\rangle+\langle Gx,x\rangle)}\#e^{-(\langle F\xi,\xi\rangle+\langle Gx,x\rangle)}=Ce^{-2(\langle F(F+G^{-1})^{-1}G^{-1}\xi,\xi\rangle+\langle(F+G^{-1})^{-1}x,x\rangle)}.$$

Proof: See Appendix A.

In particular, taking $F=F_{\beta,m}$ and $G=G_{\beta,m}$ defined in Eqs. (II.23) and (II.24) we easily get Eq. (II.28) from Lemma V.2. Then computations analogous to those of the previous section [Eqs. (III.7)–(III.20)] lead to

$$\int_{X_m}|\widetilde{A}(m,T,\lambda)|d\tilde{\nu}_m(\lambda)\leqslant\int_{\Lambda_m}|a_{m,T}(x,\xi)|[e^{-\beta\tilde{q}_m(x,\xi)}dxd\xi]_N. \tag{V.1}$$

Now on the rhs of Eq. (V.1) we make the change of variables:

$$x=\widetilde{V}_m^{-1/2}y,\quad \xi=\eta,$$

which gives

$$\int_{\Lambda_m}|a_{m,T}(x,\xi)|[e^{-\beta\tilde{q}_m(x,\xi)}dxd\xi]_N=\int_{\Lambda_m}|a_{m,T}(\widetilde{V}_m^{-1/2}y,\eta)|[e^{-\beta(\eta^2+y^2)}dyd\eta]_N. \tag{V.2}$$

Since the quadratic form in the exponent is now diagonal, we can integrate over $n\geqslant m$ variables so that

$$\int_{\Lambda_m}|a_{m,T}(x,\xi)|[e^{-\beta\tilde{q}_m(x,\xi)}dxd\xi]_N=\int_{\Lambda_n}|a_{m,T}(\widetilde{V}_m^{-1/2}\Pi_m y,\Pi_m\eta)|[e^{-\beta(\eta^2+y^2)}dyd\eta]_N \tag{V.3}$$

for any $n\geqslant m$. Coming back to the old variables on Λ_n, this gives

$$\int_{\Lambda_m}|a_{m,T}(x,\xi)|[e^{-\beta\tilde{q}_m(x,\xi)}dxd\xi]_N=\int_{\Lambda_n}|a_{m,T}(\widetilde{V}_m^{-1/2}\Pi_m\widetilde{V}_n^{1/2}x,\Pi_m\xi)|[e^{-\beta\tilde{q}_n(x,\xi)}dxd\xi]_N. \tag{V.4}$$

Now, by assumption (H4) (ii), for n large enough, the function $a_{m,T}(\widetilde{V}_m^{-1/2}\Pi_m V_n^{-1/2}x,\Pi_m\xi)$ depends only on a fixed number of variables independent of n. Then, by assumption (H4) (i) and standard results on the Gaussian measures (see, e.g., Ref. 7), letting n tend to $+\infty$ in Eq. (V.4), we get

$$\int_{\Lambda_m} |a_{m,T}(x,\xi)|[e^{-\beta \tilde{q}_m(x,\xi)} dx d\xi]_N = \int_{\Lambda_\infty} |a_{m,T}(\tilde{V}_m^{-1/2}\Pi_m \tilde{V}_n^{1/2}\Pi_n x, \Pi_m \xi)| d\mu_G(\beta). \quad \text{(V.5)}$$

Finally, using assumption (H4) (iii), Eq. (II.7), and the uniform (with respect to $m \geqslant 0$) continuity of $\exp tH_{q_m} \circ \Pi_m$ on each $\mathscr{K}_k$, we see that for all $(x,\xi) \in \Lambda_\infty$ and $t \in \mathbb{R}$:

$$(a \circ \Pi_{m_1} \circ \exp\, tH_{q_m})(\tilde{V}_m^{-1/2}\Pi_m \tilde{V}_n^{1/2}\Pi_n x, \Pi_m \xi) \to (a \circ \Pi_{m_1} \circ \phi_t)(x,\xi) \quad \text{as} \quad m \to +\infty. \quad \text{(V.6)}$$

It follows from Eqs. (V.6), (V.5), and (V.1) and the dominated convergence theorem that

$$\limsup_{m \to +\infty} \int_{X_m} |\tilde{A}(m,T,\lambda)| d\tilde{\nu}_m(\lambda) \leqslant \int_{\Lambda_\infty} \left| \frac{1}{T} \int_0^T (a \circ \Pi_{m_1} \circ \phi_t)(x,\xi) dt \right| d\mu_G(\beta). \quad \text{(V.7)}$$

Letting T tend to infinity in Eq. (V.7), the ergodicity of the system $[\Lambda_\infty, \phi_t, \mu_G(\beta)]$ and the fact that we can restrict to the case $\int a \circ \Pi_{m_1} d\mu_G(2\beta) = 0$ yield the assertion. □

VI. COHERENT STATES: SHARPENING THE ERGODICITY RESULT

Now we take $X_m = \Lambda_m$, $d\theta_m(\lambda) = d\lambda$, and for $\lambda = (\lambda_x, \lambda_\xi) \in \Lambda_m$ the corehent states defined by

$$f_\lambda(x,\xi) = e^{ix\lambda_\xi - (x-\lambda_x)^2/2}. \quad \text{(VI.1)}$$

Then a direct computation gives

$$w_{f_\lambda}(x,\xi) = 2^{2m+1}\pi^{m+1/2} e^{-(\xi-\lambda_\xi)^2 - (x-\lambda_x)^2} \quad \text{(VI.2)}$$

so that (H3) is obviously satisfied. Therefore the results of Theorems 2.1 and 2.2 hold for V satisfying assumptions (H1)–(H2) [respectively, assumptions (H1), (H2), and (H6)]. The new fact which appears in this situation is

Lemma VI.1: Under Eq. (VI.1), *the two measures* $d\nu_m(\lambda)$ *and* $d\tilde{\nu}_m(\lambda)$, *defined, respectively, by Eqs.* (II.13) *and* (II.25), *are Gaussian probability measures on* $X_m = \Lambda_m$.

Proof: In each case, the measure is of the form $C\|\mathrm{Op}^W(e^{-q}) f_\lambda\|^2 d\lambda$ where C is a constant and q is a positive definite quadratic form on Λ_m. Moreover, by computations analogous, e.g., to those for Eq. (III.7) we have

$$\|\mathrm{Op}^W(e^{-q}) f_\lambda\|^2 = C' \int_{\Lambda_m} (e^{-q} \# e^{-q})(x,\xi) w_{f_\lambda}(x,\xi) dx d\xi, \quad \text{(VI.3)}$$

where C' is another constant. Then the result follows immediately by Eq. (VI.2) and the fact that $e^{-q} \# e^{-q} = C'' e^{-q'}$ where q' is a positive definite quadratic form on Λ_m and C'' is a constant. □

Now denote L_m and $\tilde{L}_m$ the two real-symmetric positive definite $(4m+2) \times (4m+2)$ matrices defined by

$$d\nu_m(\lambda) = [e^{-\langle L_m \lambda, \lambda \rangle} d\lambda]_N, \quad \text{(VI.4)}$$

$$d\tilde{\nu}_m(\lambda) = [e^{-\langle \tilde{L}_m \lambda, \lambda \rangle} d\lambda]_N. \quad \text{(VI.5)}$$

Then for any bounded function $A(\lambda)$ we have

$$\int_{\Lambda_m} A(\lambda) d\nu_m(\lambda) = \int_{\Lambda_m} A(L_m^{-1/2}\lambda)[e^{-|\lambda|^2} d\lambda]_N \quad \text{(VI.6)}$$

and therefore, by an argument similar to the one leading to Eq. (V.21):

$$\int_{\Lambda_m} A(\lambda)d\nu_m(\lambda)=\int_{\Lambda_\infty} A(L_m^{-1/2}\Pi_m\lambda)d\nu_G(\lambda), \tag{VI.7}$$

where $d\nu_G(\lambda)$ is the finite dimensional Gibbs measure obtained by taking the limit of $[e^{-|\lambda|^2}d\lambda]_N$ on Λ_n as $n\to+\infty$. A formula analogous to Eq. (VI.7) is also true for $d\tilde{\nu}_m(\lambda)$, and therefore it follows from Theorems 2.1 and 2.2 that we have in this situation:

$$\lim_{T\to\infty}\ \limsup_{n\to\infty}\ \limsup_{m\to\infty}\int_{\Lambda_\infty}\left|A(m,n,T,L_m^{-1/2}\Pi_m\lambda)-\int_{\Lambda_\infty} a\circ\Pi_{m_1}d\hat{\mu}_\beta\right|d\nu_G(\lambda)=0, \tag{VI.8}$$

$$\lim_{T\to\infty}\ \limsup_{m\to\infty}\int_{\Lambda_\infty}\left|\tilde{A}(m,T,\tilde{L}_m^{-1/2}\Pi_m\lambda)-\int_{\Lambda_\infty} a\circ\Pi_{m_1}d\mu_G(\beta)\right|d\nu_G(\lambda)=0. \tag{VI.9}$$

Finally, using a very standard argument of measure theory, we easily deduce from Eqs. (VI.8) and (VI.9) the following:

Proposition VI.1: Assume (H1)–(H2) *and choose the set of coherent states* (VI.1). *Then there exist sequences* $(T_k)_{k\in\mathbb{N}}$, $(m_k)_{k\in\mathbb{N}}$, $(n_k)_{k\in\mathbb{N}}$ *simultaneously tending to* $+\infty$ *such that for* ν_G*—almost all* $\lambda\in\Lambda_\infty$:

$$\lim_{k\to+\infty} A(m_k,n_k,T_k,L_{m_k}^{-1/2}\Pi_{m_k}\lambda)=\int_{\Lambda_\infty} a\circ\Pi_{m_1}d\hat{\mu}_\beta.$$

If moreover assumption (H3) *is satisfied, there exist sequences* $(T_k)_{k\in\mathbb{N}}$, $(m_k)_{k\in\mathbb{N}}$ *both tending to* $+\infty$ *such that for* ν_G*—almost all* $\lambda\in\Lambda_\infty$:

$$\lim_{k\to+\infty}\tilde{A}(m_k,T_k,\tilde{L}_{m_k}^{-1/2}\Pi_{m_k}\lambda)=\int_{\Lambda_\infty} a\circ\Pi_{m_1}d\mu_G(\beta).$$

Remarks:

(1) An analogous result holds if Eq. (VI.1) is replaced by the more general case $f_\lambda(x,\xi)=e^{ix\lambda_\xi-\langle F_m(x-\lambda_x),x-\lambda_x\rangle}$, F_m being any positive definite symmetric matrix.

(2) Actually, one can replace L_m by any other symmetric matrix L_m' such that $K_m=(L_m')^{-1/2}L_m(L_m')^{-1/2}$ is a diagonal matrix and the measure $[e^{-\langle K_m\lambda,\lambda\rangle}d\lambda]_N$ on Λ_m admits a limit $d\nu_\infty$ as $m\to+\infty$. In this case the ''ν_G—almost all λ'' of the Proposition must be replaced by ''ν_∞—almost all λ.''

ACKNOWLEDGMENTS

We thank G. Jona-Lasinio for many illuminating discussions, and an anonymous referee for pointing out to us the relevant results out of the W^* dynamical systems.

APPENDIX A: PROOF OF THE LEMMAS

Proof of Lemma III.2

Using Eq. (III.8), we see that $e^{-q_{\beta,m}}\#a\#e^{-q_{\beta,m}}$ can be put under the form:

$$(e^{-q_{\beta,m}}\#a\#e^{-q_{\beta,m}})(x,\xi)=C_1\int_{\Lambda_m^4} a(Y_1)e^{-q_1(x,\xi,Y_1,Y_2,Y_3,Y_4)}dY_1dY_2dY_3dY_4, \tag{A1}$$

where all along this proof C_j $(j=1,2...)$ will denote complex constants, q_1 is a complex quadratic form on Λ_m^5, and the integral (A1) is oscillatory. Moreover, a direct computation gives:

$$\int_{\Lambda_m^3} e^{-q_1(x,\xi,Y_1,Y_2,Y_3,Y_4)} dY_2 dY_3 dY_4 = C_2 e^{-Q(x,\xi,Y_1)}, \tag{A2}$$

where $C_2 \in \mathbb{R}$ and Q is a positive definite quadratic form. Actually, this can also be seen without computation in the following way: the existence of the complex constant C_2 and the complex quadratic form Q such that Eq. (A2) holds is clear, and if a is real then $\mathrm{Op}^W(e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}}) = \mathrm{Op}^W(e^{-q_{\beta,m}})\mathrm{Op}^W(a)\mathrm{Op}^W(e^{-q_{\beta,m}})$ is a symmetric operator. As a consequence $e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}}$ must be real for a real, which implies that Ce^{-Q} is real (and hence both C and Q are). Moreover, one can show easily that the application $S_m(1) \ni a \mapsto e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}}$ maps continuously $S_m(1)$ into $\mathscr{S}(\Lambda_m)$, so that Q is necessarily positive definite.

When $a \equiv 1$, we get from Eqs. (II.8), (A1), and (A2):

$$C_1 C_2 \int_{\Lambda_m} e^{-Q(x,\xi,Y_1)} dY_1 = e^{-\tilde{q}_{2\beta,m}}. \tag{A3}$$

Then the result follows from Eqs. (A1), (A2), and (A3) by writing:

$$(e^{-q_{\beta,m}} \# a \# e^{-q_{\beta,m}})(x,\xi) = \left(C_1 C_2 \int_{\Lambda_m} e^{-Q(x,\xi,Y_1)} dY_1 \right) \int_{\Lambda_m} a(Y_1) [e^{-Q(x,\xi,Y_1)} dY_1]_N .$$

□

Proof of Lemma IV.1

Denote $\Delta(m)$ the difference between the two expressions. For any $p,q \in \mathbb{N}$, we write:

$$\Delta(m) = \Delta_1(m,p,q) + \Delta_2(m,p,q) + \Delta_3(m,p) + \Delta_4(p,q) \tag{A4}$$

with

$$\Delta_1(m,p,q) = \int_{\Lambda_m} F(\Pi_{m_1} Q_{\beta,q} \Pi_p X, \Pi_n X)[e^{-q_{\beta,m}(X)} dX]_N - \int_{\Lambda_\infty} F(\Pi_{m_1} Q_{\beta,q} \Pi_p X, \Pi_n X) d\hat{\mu}_\beta ,$$

$$\Delta_2(m,p,q) = \int_{\Lambda_m} (F(\Pi_{m_1} Q_{\beta,m} \Pi_p X, \Pi_n X) - F(\Pi_{m_1} Q_{\beta,q} \Pi_p X, \Pi_n X))[e^{-q_{\beta,m}(X)} dX]_N ,$$

$$\Delta_3(m,p) = \int_{\Lambda_m} (F(\Pi_{m_1} Q_{\beta,m} X, \Pi_n X) - F(\Pi_{m_1} Q_{\beta,m} \Pi_p X, \Pi_n X))[e^{-q_{\beta,m}(X)} dX]_N ,$$

$$\Delta_4(p,q) = \int_{\Lambda_\infty} (F(\Pi_{m_1} Q_{\beta,q} \Pi_p X, \Pi_n X) - F(\Pi_{m_1} Q_\beta X, \Pi_n X)) d\hat{\mu}_\beta .$$

Now, by assumption on F, there exists a positive constant C such that for any m and p:

$$|\Delta_3(m,p)| \leq C \int_{\Lambda_m} \| \Pi_{m_1} Q_{\beta,m} (X - \Pi_p X) \|_{l^\infty} [e^{-q_{\beta,m}(X)} dX]_N \tag{A5}$$

and we have (with obvious notations)

$$\|\Pi_{m_1} Q_{\beta,m}(X-\Pi_p X)\|_{l^\infty} \leqslant \sup_{|i|\leqslant m_1} \sum_{|j|>p} |(Q_{\beta,m})_{i,j} X_j|$$

$$\leqslant \sup_{|i|\leqslant m_1} \left(\sum_{|j|>p} j^2 |(Q_{\beta,m})_{i,j}|^2 \right)^{1/2} \left(1+\sum_{j\neq 0} \frac{X_j^2}{j^2} \right)^{1/2}$$

and therefore, using assumption (H5):

$$\|\Pi_{m_1} Q_{\beta,m}(X-\Pi_p X)\|_{l^\infty} \leqslant \frac{C'}{p} \left(1+\sum_{j\neq 0} \frac{X_j^2}{j^2} \right) \tag{A6}$$

with a constant C' independent of m and p. Since also

$$\int_{\Lambda_m} X_j^2 [e^{-q_{\beta,m}(X)} dX]_N = (Q_{\beta,m}^{-1})_{j,j} \leqslant \|Q_{\beta,m}^{-1}\|_{\mathscr{L}(l^2)} = \mathscr{O}(1) \tag{A7}$$

uniformly with respect to m, we deduce from Eqs. (A5) and (A6):

$$|\Delta_3(m,p)| = \mathscr{O}(p^{-1}) \tag{A8}$$

uniformly with respect to m and p.

In a similar way, using the fact that for fixed p, both finite dimensional matrices $\Pi_{m_1} Q_{\beta,m} \Pi_p$ and $\Pi_{m_1} Q_{\beta,q} \Pi_p$ tend to $\Pi_{m_1} Q_\beta \Pi_p$ as m and q tend to infinity, one can prove that:

$$\Delta_2(m,p,q) \to 0 \quad \text{as} \quad m \quad \text{and} \quad q \to \infty. \tag{A9}$$

Moreover, for any fixed (p,q) we see that

$$\Delta_1(m,p,q) \to 0 \quad \text{as} \quad m \to \infty. \tag{A10}$$

The same arguments also give, substituting Q_β for $Q_{\beta,m}$, that

$$\Delta_4(p,q) \to 0 \quad \text{as} \quad p \quad \text{and} \quad q \to \infty. \tag{A11}$$

Then, choosing $\epsilon > 0$ arbitrarily small, one can first fix p large enough so that $|\Delta_3(m,p)| \leqslant \epsilon$ for all (m,q) and $|\Delta_4(p,q)| \leqslant \epsilon$ for all q sufficiently large, then fix q large enough so that $|\Delta_2(m,p,q)| \leqslant \epsilon$ for all sufficiently large m, and finally get $|\Delta_1(m,p,q)| \leqslant \epsilon$, and thus $|\Delta(m)| \leqslant 4\epsilon$, by taking m large enough. □

Proof of Lemma V.2

From Eq. (III.8) we get easily:

$$e^{-(\langle F\xi,\xi\rangle+\langle Gx,x\rangle)} \# e^{-(\langle F\xi,\xi\rangle+\langle Gx,x\rangle)} = \pi^{-2(2m+1)} \left| \int_{\Lambda_m} e^{2i\zeta y - \langle G(x+y),x+y\rangle - \langle F(\xi+\zeta),\xi+\zeta\rangle} dy d\zeta \right|^2$$

$$= \pi^{-2(2m+1)} |I|^2, \tag{A12}$$

where

$$I = e^{-\langle Gx,x\rangle - \langle F\xi,\xi\rangle} \int e^{iy(2\zeta+2iGx) - \langle Gy,y\rangle - 2\langle F\xi,\zeta\rangle - \langle F\zeta,\zeta\rangle} dy d\zeta. \tag{A13}$$

Making the change of variables $y' = \sqrt{2} G^{1/2} y$ and integrating first with respect to y' we get:

$$I = Ce^{-\langle Gx,x\rangle - \langle F\xi,\xi\rangle} \int e^{-\langle G^{-1}(\zeta + iGx),\zeta + iGx\rangle - 2\langle F\xi,\zeta\rangle - \langle F\zeta,\zeta\rangle} d\zeta, \tag{A14}$$

where C is a constant, and therefore, setting $\zeta' = \sqrt{2}(F + G^{-1})^{1/2}\zeta$, this gives:

$$I = C' e^{-\langle F\xi,\xi\rangle - \langle (F+G^{-1})^{-1}(x - iF\xi),x - iF\xi\rangle}, \tag{A15}$$

where C' is a constant. Then Eqs. (A12) and (A15) yield the result. □

APPENDIX B: REMARKS ON QUANTUM MIXING AND ERGODICITY

The elementary remarks collected here, useful to clarify the subsequent statements, are presumably known but we were unable to locate a precise reference.

We first formulate into an abstract setting the definitions recalled in the introduction. Let H be a positive self-adjoint operator on a separable Hilbert space $\mathscr{H}$ such that $\sigma(H)$ is discrete and simple and $e^{-\beta H}$ is trace class for any positive β. Given $A \in \mathscr{L}(\mathscr{H})$ let $\omega(A)$ be the quantum microcanonical measure defined as in Eq. (I.1) or the corresponding quantum Gibbs measure at inverse temperature β

$$\omega(A) = \frac{\mathrm{Tr}(Ae^{-\beta H})}{\mathrm{Tr}(e^{-\beta H})} \tag{B1}$$

indifferently. Let also $\mathscr{A}$ be a weakly closed sub-algebra of $\mathscr{L}(\mathscr{H})$ invariant under the action of e^{itH}. In this general context we assume (and verify below in our specific case) the existence of a family of normalized states $(\psi_\lambda)_{\lambda \in \Lambda}$ complete for ω on $\mathscr{A}$, in the sense that there is a probability measure $d\nu(\lambda)$ on the set Λ such that

$$\omega(A) = \int_\Lambda \langle A\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda), \quad \forall A \in \mathscr{A}. \tag{B2}$$

Then the quantum mixing property on $\mathscr{A}$, defined as

$$\omega(A_H(t)B) \to \omega(A)\omega(B) \quad \text{as} \quad |t| \to \infty \tag{B3}$$

for any operators $A, B \in \mathscr{A}$ can be rewritten as

$$\int_\Lambda \langle A_H(t)B\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda) \to \int_\Lambda \langle A\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda) \int_\Lambda \langle B\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda). \tag{B4}$$

Remark that Eqs. (I.1), (B1), and (B2) imply the invariance property

$$\int_\Lambda \langle A_H(t)\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda) = \int_\Lambda \langle A\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} d\nu(\lambda) \tag{B5}$$

and by analogy with the classical dynamical systems, a natural possible definition of quantum ergodicity is that for any $A \in \mathscr{A}$:

$$\frac{1}{T}\int_0^T \langle A_H(t)\psi_\lambda, \psi_\lambda\rangle_{\mathscr{H}} dt \to \omega(A) \quad \nu(\lambda) - a.e. \quad \text{as} \quad T \to \infty. \tag{B6}$$

This definition is also motivated from the fact that in most situations the quantum mixing property (B4) implies Eq. (B6). Indeed, still assuming that $\sigma(H)$ is discrete and simple, we see in Eq. (I.6) that for any $A \in \mathscr{A}$ the limit

$$\lim_{T\to\infty}\frac{1}{T}\int_0^T\langle A_H(t)\varphi,\psi\rangle_{\mathscr{H}}dt:=\langle\overline{A}\varphi,\psi\rangle_{\mathscr{H}} \tag{B7}$$

exists for all φ, $\psi\in\mathscr{H}$, and the operator $\overline{A}\in\mathscr{A}$ is invariant under the action of e^{itH}. As a consequence, the definition (B6) of quantum ergodicity is equivalent to the fact that for any $A\in\mathscr{A}$ we have the identity

$$\langle\overline{A}\psi_\lambda,\psi_\lambda\rangle=\omega(A) \tag{B8}$$

for ν—almost every λ. Now it is easy to see that the quantum mixing property implies that for any $A,B\in\mathscr{A}$, $\omega(AB)=\omega(A)\omega(B)$. Therefore, if we assume moreover (which is obviously true in the concrete example discussed below) that for any $A\in\mathscr{A}$, the family $(\omega(AB))_{B\in\mathscr{A}}$ determines $\langle A\psi_\lambda,\psi_\lambda\rangle$ for ν-almost every λ, we deduce immediately that the quantum mixing implies Eq. (B8), and hence quantum ergodicity. Concerning this definition of quantum ergodicity, we remark that it is trivially included in the notion of ergodicity of the W^* dynamical systems[6,16] with respect to the triple $(\mathscr{A},\Theta,\phi)$ where Θ is the automorphism of $\mathscr{A}$ generated by the unitary group e^{iHt} and ϕ is the state defined by the microcanonical or canonical measure.

Let us now turn to an explicit construction, in the particular case $\mathscr{H}=L^2(\mathbb{R}^m)$ ($m<+\infty$ fixed) mentioned in Sec. I of the measures $d\nu(\lambda)$, both in the microcanonical case and in the canonical one as well, through some natural choice of the set $\{\psi_\lambda:\lambda\in\Lambda\}$. This will also enable us to recover the classical definitions of mixing and ergodicity out of Eqs. (B3) and (B6) at the classical limit $h\to 0$.

More precisely, for $\lambda=(\lambda_x,\lambda_\xi)\in\mathbb{R}^{2m}$ consider the Bargmann coherent states defined on $\mathbb{R}^{2m}$:

$$f_\lambda(x)=(\pi h)^{-m/4}e^{ix\lambda_\xi/h-(x-\lambda_x)^2/2h}. \tag{B9}$$

Then it is well known (see, e.g., Ref. 15, Chap. 5) that for any trace class operator A on $L^2(\mathbb{R}^m)$, one has:

$$\int_{\mathbb{R}^{2m}}\langle Af_\lambda,f_\lambda\rangle_{L^2(\mathbb{R}^m)}d\lambda=\mathrm{Tr}(A). \tag{B10}$$

In particular, since $e^{-\beta H}$ is trace class on $L^2(\mathbb{R}^m)$, then

$$\int\|e^{-\beta H/2}f_\lambda\|^2d\lambda=\int\langle e^{-\beta H}f_\lambda,f_\lambda\rangle d\lambda=\mathrm{Tr}(e^{-\beta H})<+\infty.$$

Hence we can consider the following probability measures on $\mathbb{R}^{2m}$:

$$d\nu_m(\lambda)=\frac{\|e^{-\beta H/2}f_\lambda\|^2d\lambda}{\int\|e^{-\beta H/2}f_\lambda\|^2d\lambda},\quad d\nu_{\Delta,E}(\lambda)=\frac{\|\delta(H-E)f_\lambda\|^2d\lambda}{\int\|\delta(H-E)f_\lambda\|^2d\lambda}, \tag{B11}$$

whereas in Sec. I, $\delta(H-E)=\Sigma_{n:E-\Delta<E_n<E}P_n$ with $\Delta>0$ fixed. If we also set

$$\psi_\lambda^c=\frac{e^{-\beta H/2}f_\lambda}{\|e^{-\beta H/2}f_\lambda\|},\quad \psi_\lambda^{mc}=\frac{\delta(H-E)f_\lambda}{\|\delta(H-E)f_\lambda\|}. \tag{B12}$$

then we have the following result [to be compared with Eq. (B2)]:

Lemma B.1: For any bounded operator A on $L^2(\mathbb{R}^m)$, the following identities hold:

$$\frac{\mathrm{Tr}(Ae^{-\beta H})}{\mathrm{Tr}(e^{-\beta H})}=\int\langle A\psi_\lambda^c,\psi_\lambda^c\rangle d\nu_m(\lambda),\quad \frac{\mathrm{Tr}(A\delta(H-E))}{\mathrm{Tr}(\delta(H-E))}=\int\langle A\psi_\lambda^{mc},\psi_\lambda^{mc}\rangle d\nu_{\Delta,E}(\lambda).$$

Proof: Just write

$$\mathrm{Tr}(Ae^{-\beta H}) = \mathrm{Tr}(e^{-\beta H/2} A e^{-\beta H/2}),$$

$$\mathrm{Tr}(A\,\delta(H-E)) = \mathrm{Tr}(\,\delta(H-E) A\,\delta(H-E))$$

and use Eq. (B10). □.

Consider now the particular case where A is the h-Weyl quantization of a classical observable $a = a(x,\xi) \in \mathscr{S}(\mathbb{R}^{2m})$, namely the operator $\mathrm{Op}_h^W(a)$ defined by the oscillatory integral:

$$\mathrm{Op}_h^W(a)u(x) = (2\pi h)^{-m} \int e^{i(x-y)\xi/h} a\left(\frac{x+y}{2}, \xi\right) u(y)\,dy\,d\xi. \tag{B13}$$

A well-known direct application of the stationary phase method yields[16]

$$\lim_{h\to 0} \langle \mathrm{Op}_h^W(a) f_\lambda, f_\lambda \rangle = a(\lambda).$$

As a consequence, if we also have

$$H = \mathrm{Op}_h^W(q)$$

for some symbol $q \in C^\infty(\mathbb{R}^{2m})$, then the semiclassical symbolic and functional calculus of pseudodifferential operators (see Ref. 17) immediately implies:

Lemma B.2: For any $\lambda \in \mathbb{R}^{2m}$,

$$\lim_{h\to 0} \langle \mathrm{Op}_h^W(a) \psi_\lambda, \psi_\lambda \rangle = a(\lambda).$$

Moreover,

$$\lim_{h\to 0} \int_{\mathbb{R}^{2m}} \langle \mathrm{Op}_h^W(a) \psi_\lambda^c, \psi_\lambda^c \rangle d\nu_m(\lambda) = \int a(\lambda) d\mu^c(\lambda),$$

$$d\mu^c(\lambda) = \frac{e^{-\beta q} d\lambda}{\int_{\mathbb{R}^{2m}} e^{-\beta q} d\lambda}$$

and

$$\lim_{h\to 0} \int_{\mathbb{R}^{2m}} \langle \mathrm{Op}_h^W(a) \psi_\lambda^{mc}, \psi_\lambda^{mc} \rangle d\nu_{\Delta,E}(\lambda) = \int_{\mathbb{R}^{2m}} a(\lambda) d\mu^{mc}(\lambda),$$

$$d\mu^{mc}(\lambda) = \frac{\delta(q-E)d\lambda}{\int_{\mathbb{R}^{2m}} \delta(q-E)d\lambda}.$$

Since, by the semiclassical Egorov theorem (Ref. 17, Sec. 5.4) the principal symbol of $e^{itH/h}\mathrm{Op}_h^W(a)e^{-itH/h}$ is given by

$$a_t(x,\xi) = a(\phi_t(x,\xi))$$

where ϕ_t is the Hamiltonian flow generated by q, it follows that for any $a, b \in \mathscr{S}(\mathbb{R}^{2m})$:

$$\lim_{h\to 0} \langle e^{itH/h}\ \mathrm{Op}_h^W(a) e^{-itH/h}\ \mathrm{Op}_h^W(b) \psi_\lambda, \psi_\lambda \rangle = a(\phi_t(\lambda)) b(\lambda). \tag{B14}$$

It has now become clear out of Lemma A.2 and Eq. (A14) that the quantum notions of mixing and ergodicity given by Eqs. (A3) and (A6) formally yield the corresponding classical notions as $h \to 0$.

As a final remark let us mention that if A is a pseudodifferential operator also the Von Neumann definition (I.6) reproduces the classical one at the classical limit if $\langle u_n, Au_n \rangle$ tends to the phase average of the symbol of A, as verified in many instances (see, e.g., Refs. 18–23), in which H is the quantization of a Hamiltonian generating an ergodic flow. Some authors (Refs. 24 and 22) assume this limiting property as the very definition of quantum ergodicity.

Ergodic properties of the quantum ideal gas in the Maxwell–Boltzmann statistics

Marco Lenci[a)]
Dipartimento di Matematica, Università di Bologna, 40127 Bologna, Italy

(Received 10 April 1996; accepted for publication 17 June 1996)

It is proved that the quantization of the Volkovyski–Sinai model of ideal gas (in the Maxwell–Boltzmann statistics) enjoys at the thermodynamical limit the property of quantum mixing in the following sense: $\lim_{|t|\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(e^{iH_m t/\hbar} \times A e^{-iH_m t/\hbar} B) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(A) \cdot \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(B)$. Here H_m is the Schrödinger operator of m free particles moving on a circle of length L; A and B are the Weyl quantization of two classical observables a and b; $\omega^m_{\beta,L}(A)$ is the corresponding quantum Gibbs state. Moreover, one has $\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{\beta,m}(A) = P_{\rho,\beta}(a)$, where $P_{\rho,\beta}(a)$ is the classical Gibbs measure. The consequent notion of quantum ergodicity is also independently proven. © *1996 American Institute of Physics.* [S0022-2488(96)00910-3]

I. INTRODUCTION

The purpose of the present paper is to analyze the quantum ergodic properties of the Volkovyski–Sinai model of ideal gas,[1] quantized according to a Maxwell–Boltzmann statistics (i.e., all particles are distinguishable). This paper represents the companion paper of Ref. 2, where the same result is proved for a strongly analogous system, namely the infinite harmonic chain with suitable restrictions on the normal mode frequencies.

These two systems provide examples of *kinematic quantum chaos*. We borrow the expression *kinematic chaos* from the enlightening paper by Jona-Lasinio and Presilla.[3] By that we mean trivial motion whose chaotic behavior is due to the randomness of the infinite-dimensional initial condition (see, besides Ref. 3 itself, the remark after Theorem III.3). For both the ideal gas and the harmonic chain, this is a classical feature of the system, which works on the quantum level as well because of the *exact Egorov Theorem* (Lemma IV.1). The latter is a fundamental fact here, since it allows us to treat the quantum time evolution as the classical one.

A clear explanation of the motivations for the investigation of the quantum behavior of infinite systems is given in Ref. 2, as well as further references. Here we just sketch what the immediate problems are, concerning the search for *quantum chaos*.

To fix the ideas, let H be a self-adjoint operator acting on $L^2(\Omega)$, $\Omega \in \mathbb{R}^m$, resulting from the quantization of some classical Hamiltonian function $\mathscr{H}$ over $\mathbb{R}^m \times \Omega$. Suppose, as it happens in all interesting cases, that $\sigma(H)$ is discrete. Consider two operators A, $B \in \mathscr{L}(L^2(\Omega))$, which is regarded as our set of observables, and define $\Theta[t](A) := e^{iHt/\hbar} A e^{-iHt/\hbar}$, the Heisenberg evolution. All the physical experiments one can do on such a system imply a certain ''measure'' on the observables is used. In quantum mechanics such measures are *states* over the algebra of the operators. These *quantum ensembles* (see Ref. 4, Sec. 1.3) are typically described as

$$\omega_\varrho(A) = \frac{\operatorname{Tr} A\varrho}{\operatorname{Tr} \varrho}, \tag{I.1}$$

with ϱ a suitable trace-class operator. A suitable definition of mixing would be, then[5,6]

[a)]On leave at the Department of Mathematics, Princeton University, Princeton, New Jersey 08544. Electronic mail: marco@math.princeton.edu

0022-2488/96/37(10)/5136/22/$10.00

$$\lim_{|t|\to\infty} \omega_\varrho(\Theta[t](A),B)=\omega_\varrho(A)\omega_\varrho(B), \quad \forall A,B\in\mathscr{L}(L^2(\Omega)). \tag{I.2}$$

It is easily realized, writing ω_ϱ by means of the matrix elements of the operators, w.r.t. the eigenbasis of H, that such a property can never be verified, *for each underlying classical dynamics*. The same is true for any reasonable definition of ergodicity, as von Neumann's formula[7] shows (see Ref. 2 for details). This is a consequence of the quasiperiodicity of the classical evolution—as long as we have finite degrees of freedom—and it is called ''quantum suppression of classical chaos.''[8,3] Hence the idea of taking the number of degrees of freedom to infinity.

The system we consider is the quantization of the ideal gas in the formulation found in Sinai's book:[9] i.e., m noninteracting particles moving freely on a circle of length L, when m and L are taken to infinity, subject to the finite density requirement $m/L\to\rho$.

For an outline of the ''analytic approach'' we will follow in studying the quantum infinite system in question, the reader is definitely referred to the introduction of Ref. 2, due to the similarities of the two works. There the consequences of such a study are also properly emphasized. In the next paragraph we just point out the structural differences, between the two models, which require nonobvious modifications of the arguments of Graffi and Martinez[2] valid for the harmonic chain. Specifically the following.

(i) The other important classical mechanism which provides the unpredictability (mixing) of the time evolution here, besides the mentioned kinematic effect, is the *symmetry* of the observables under particle exchange. This corresponds to the physical fact that one is not able to distinguish between the particles in a gas. Actually, such a restriction on the observables also has the noticeable outcome to allow the interchange of the time average limit with the thermodynamical limit [see Theorem III.3, Corollary III.4, and relation (III.19)]. The remark after Theorem III.3 will contain more comments. On the quantum side, the symmetry of the observables would entail for a Bose–Einsten or a Fermi–Dirac statistics. Nevertheless, we use Maxwell–Boltzmann for the sake of convenience: see remark 2 in Sec. II B.

(ii) The phase space of any m-particle subsystem is $\mathbb{R}^m\times(LS^1)^m$, with LS^1 denoting henceforth the circle of length L. In other words, the phase space has a cylindrical structure. This has the effect of making necessary a Bloch decomposition of $L^2(\mathbb{R}^m)$, and consequently a direct fiber decomposition of operators, if we want to consider functions on phase space as symbols of operators on a one-to-one correspondence under quantization. Equivalently, $\mathbb{R}^m\times(LS^1)^m$ generates a cylindrical Heisenberg group (see Ref. 10 and Sec. II B) and its only faithful unitary representation is given by a fibered L^2 space.

(iii) The coherent states we use are those adapted to the cylindrical phase space, as presented in the Appendix, Sec. 1 (refer also to Refs. 10 and 11).

(iv) The infinite-particle limit is a true thermodynamic limit, because here not only do we have $m\to\infty$, but also $L\to\infty$ under the constraint of finite density $m/L\to\rho,\rho>0$.

(v) On the other hand, in this model the classical dynamics is just free motion. This entails a simplification: the Weyl symbol of the quantum m-particle Schrödinger operator H_m is obviously the classical Hamiltonian $\mathscr{H}_m=(\frac{1}{2})\Sigma_{i=1}^m p_i^2$, namely $H_m=Op(\mathscr{H}_m)$. Then the Weyl symbol of the (unnormalized here) quantum Gibbs measure is

$$e^{-\beta H_m}=Op(e^{-\beta\mathscr{H}_m}),$$

where, here and above, $Op:=Op^W$ denotes the operation of Weyl quantization of a symbol, whose definition in the present context is recalled in Sec. II B.

Now, as it will be explained in sharper detail in Sec. III A, consider the normalized quantum Gibbs state at inverse temperature β (for a system of m free particles in LS^1), namely the functional

$$\omega^m_{\beta,L}(A) := \frac{\mathrm{Tr}\, A e^{-\beta H_m}}{\mathrm{Tr}\, e^{-\beta H_m}}, \tag{I.3}$$

defined, for instance, over the class of bounded operators A that are ''L-periodic in the coordinate variable'' (refer to Sec. II B). The application Tr is practically the trace over $L^2(\mathbb{R}^m)$ (see Sec. III A for details). Then the main result of the present work, in analogy with Ref. 2, can be stated as

$$\lim_{|t|\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(\Theta^m[t](A)B) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(A) \cdot \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}(B) \tag{I.4}$$

[see also Theorem III.2 and (III.18)]. Here A and B are actually dependent on L and m and represent the operators quantizing two classical observables, a and b, over the Hilbert spaces for m particles in a L circle (square integrable Bloch functions). Also $\Theta^m[t](A) := e^{iH_m t/\hbar} A e^{-iH_m t/\hbar}$. Moreover,

$$\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{\beta,m}(A) = P_{\rho,\beta}(a). \tag{I.5}$$

Formula (I.4) is the quantum mixing property and induces a consistent formulation of the quantum ergodicity: for instance,

$$\lim_{T\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega^m_{\beta,L}((\Xi^m[T](A))^2) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} (\omega^m_{\beta,L}(A))^2, \tag{I.6}$$

if $\Xi^m[T](A) = (1/2T)\int_{-T}^{T} \Theta^m[t](A)\,dt$.

The present model of quantum ideal gas is structurally different from the free Bose gas or the free Fermi gas in the grand canonical ensemble, discussed, e.g., in Ref. 5, Sec. 5.2. The arguments[5,6] yielding the mixing property with respect to the KMS states through the asymptotic abelianess of the CCR (or CAR) automorphisms generated by free dynamics do not apply in this context.

The paper is organized as follows: in the next section we briefly recall the ideal gas model and construct its quantization; in Sec. III we state the results, whose proofs are given in Sec. IV. Finally, in the Appendix we recall the construction of the coherent states on the cylinder[10] with some additional details; we collect two technical lemmas; and we exploit the properties of the convolution over LS^1, as $L\to\infty$, which are crucially used in the proofs.

II. THE CLASSICAL IDEAL GAS AND ITS QUANTIZATION

A. The Volkovyski–Sinai model

To make the exposition self-contained, a brief reminder is here given of the Volkovyski–Sinai model of ideal gas. The reader is referred to Ref. 9, Lecture 8, for details.

Consider a system of m free particles of unit mass constrained to move on a circle of length L. Its Hamiltonian function is

$$\mathscr{H}_m(p,q) = \frac{1}{2}\sum_{j=1}^{m} p_j^2 = \frac{p^2}{2}, \tag{II.1}$$

defined on the phase space $\Lambda_L^m := \mathbb{R}^m \times (LS^1)^m$, which, with a view to the limiting case $L \to \infty$ to be considered below, will be identified with $\mathbb{R}^m \times T_L^m$, $T_L^m := [-L/2, L/2)^m$. The physical intuition is to stretch the circle LS^1 more and more toward a straight line, namely $\mathbb{R}$.

On Λ_L^m the motion is given by the flow map: $\phi_L^m[t](p,q) := (p, q+pt)$. The dynamical system is completely integrable and Λ_L^m is decomposed in a noncountable family of invariant tori: all motions are quasiperiodic. Introducing any ''reasonable'' measure on Λ_L^m (in Ref. 9 the microcanonical measure is used; for reasons that will become clear when quantizing, the natural measure to introduce here is the canonical one) the system is, of course, not even ergodic.

But a suitable thermodynamical limit of it might be. The construction of the infinite dynamical system is based on the idea that the particles should be ''unlabeled.'' More precisely, the phase space for the infinite system is defined as follows:

$$\Lambda_\infty := \{(p,q);\ q \text{ countable subset of } \mathbb{R},\ p: q \to \mathbb{R}\}, \tag{II.2}$$

with the interpretation that $q = \{x_1, x_2, \ldots, x_j, \ldots\}$ contains the positions of the particles, now undistinguishable, and p is a function such that $p(x_j)$ gives the velocity of the particle located at x_j. It may occur that more than one particle—say n—are located at x_j: in this case, with an abuse of notation with respect to definition (II.2), $p(x_j)$ is an n-tuple of velocities. The flow $\phi_\infty[t]: \Lambda_\infty \to \Lambda_\infty$ is defined accordingly: $\phi_\infty[t](p,q) = (p', q')$, where $q' := \{x + p(x)t; x \in q\}$ and $p': q' \to \mathbb{R}$ is $p'(x + p(x)t) := p(x)$.

What we have introduced is the natural limiting object of the spaces $\Lambda_L^m/\mathbb{S}^m$, $\mathbb{S}^m$ being the group of permutations of m coordinates and momenta. Such spaces are expressly defined in Ref. 9 in a way completely analogous to (II.2), i.e., as the collection of all couples (p,q) with $q \subset LS^1$, $\#q \leqslant m$ and $p: q \to \mathbb{R}$ having m values, in the sense specified above. They can be regarded as belonging to Λ_∞, since $q \subset LS^1 \simeq [-L/2, L/2)$. This motivates the above identification.

This remark enables us to consider functions defined on Λ_∞ as having a natural restriction on $\Lambda_L^m/\mathbb{S}^m$. And a function f on $\Lambda_L^m/\mathbb{S}^m$ is simply a totally symmetric function on Λ_L^m, namely $f \circ \Pi_L^m$, where Π_L^m is the natural immersion $\Lambda_L^m \to \Lambda_\infty$:

$$\Pi_L^m(p_1, \ldots, p_m, q_1, \ldots, q_m) := (p: q \to \mathbb{R}, q := \{q_1, \ldots, q_m\}), \tag{II.3}$$

p taking values $p(q_1) = p_1, \ldots, p(q_m) = p_m$. It will be useful in the remainder to notice that

$$\phi_\infty[t] \circ \Pi_L^m = \Pi_L^m \circ \phi_L^m[t]. \tag{II.4}$$

To complete the definition of our infinite dynamical system, we need to specify the measurable functions, i.e., to fix a σ-algebra $\mathscr{A}$ and—after that—a probability measure on it. The answer in Ref. 1 is $\mathscr{A} := \sigma(\gamma(\Delta))_{\Delta \in \mathscr{B}(\mathbb{R})}$. Here Δ runs among the Borel sets in $\mathbb{R}$ and $\gamma(\Delta)$ is the σ-algebra of all subsets of Λ_∞, depending only on the positions and momenta of the *unlabeled* particles in Δ.[12] For the sake of simplicity, we just restrict ourselves to real functions.

Examples of measurable functions are $f_\Delta(p,q) := \#(q \cap \Delta)$, the number of particles of the configuration q located in Δ; or $g_\Delta(p,q) := \Sigma_{x \in \Delta}\, p(x)$, the total momentum of the particles in Δ.

We endow $\mathscr{A}$ with the measure $P_{\rho,\beta}$ defined by the following properties.

(1) The distribution of particles in the configuration space is Poissonian with parameter ρ; that is

$$P_{\rho,\beta}(\{(p,q); f_\Delta(p,q) = n\}) = e^{-\rho|\Delta|}\, \frac{(\rho|\Delta|)^n}{n!}; \tag{II.5}$$

for every $\Delta \in \mathscr{B}(\mathbb{R})$. This implies that the distributions over two disjoint Borel sets Δ_1 and Δ_2 are independent.

(2) The momenta are independent centered Gaussian variables with variance $1/\beta$. This means that, fixed $A \in \mathscr{B}(\mathbb{R}^n)$ and a vector $(x_1,\dots,x_n) \in \mathbb{R}^n$, we have

$$P_{\rho,\beta}(\{(p(x_1),\dots,p(x_n)) \in A\} | \{\{x_1,\dots,x_n\} \subset q\}) = \int_A [e^{-\beta p^2/2}\, dp]_N, \tag{II.6}$$

$[\cdots]_N$ being the normalized measure. This is a Maxwell distribution with inverse temperature β.

This measure has been chosen intentionally as the limit of the canonical measures over the phase spaces of finite numbers of particles.

Proposition II.1: Let a measurable in $\mathscr{A}$. At the thermodynamical limit, i.e., $m,L \to \infty$; $m/L \to \rho$,

$$\int_{\Lambda_L^m} (a \circ \Pi_L^m)(p,q) [e^{-\beta p^2/2}\, dp\ dq]_N \to P_{\rho,\beta}(a).$$

As regards the proof, the statement concerning the distribution of the positions is clearly explained in Ref. 9, while (II.6) trivially holds since the distributions over the momentum spaces for a finite number of particles are given as Maxwellian with inverse temperature β.

We conclude this section formulating the key theorem.

Theorem II.2: *(Ref. 1) The measure $P_{\rho,\beta}$ is invariant under $\phi_\infty[t]$ and the dynamical system $(\Lambda_\infty, \mathscr{A}, P_{\rho,\beta}, \phi_\infty[t])$ is a K flow.*

It may be worth noticing here that the infinite dynamical system just recalled has a nice abstract construction, which is described in Ref. 13 (and shortly in Ref. 6, Example 2.34). It is called the *Poisson system* constructed for a one-dimensional free particle with a Maxwell velocity distribution. Its ergodic properties follow via a general technique, namely the *Bernoulli construction*. This viewpoint shows clearly that $\mathscr{A}$ is generated by the following sets:

$$B^{(n)}_{\Delta,\Gamma} := \{(p,q) \in \Lambda_\infty | \#\{x \in q | x \in \Delta, p(x) \in \Gamma\} = n\}, \tag{II.7}$$

where $\Delta,\Gamma \in \mathscr{B}(\mathbb{R})$. Such a remark will be useful while proving the statements.

Nonetheless, the approach we have chosen has the advantage of constructing the infinite-particle dynamical system through a thermodynamical limit (see above, and in particular Proposition II.1). This fact will be crucial throughout this paper.

B. The quantization

The Hilbert spaces associated to a quantum system of m particles on a circle of length L are denoted by $L^2_{(k)}(T_L^m), k \in [0,1/L)^m$. Each of these is defined as

$$L^2_{(k)}(T_L^m) := \left\{ f \ \text{ on } \ \mathbb{R}^m | \forall j \in \mathbb{Z}^m, f(q+Lj) = e^{2\pi i L k \cdot j} f(q), \int_{T_L^m} |f|^2 < \infty \right\}, \tag{II.8}$$

that is the space of the Bloch functions of parameter k that are square-integrable on a given fundamental domain. Concerning this definition, we remark the following.

(1) The above family of spaces is the familiar one for Schrödinger operators with periodic potential (Ref. 14, Sec. XIII.16). They have to be simultaneously considered for all values of $k \in [0,1/L)^m$, otherwise the quantization application is not well defined since the Schrödinger representation of the Heisenberg group is not faithful: e.g., in one dimension, if we selected only $k=0$, then $T(L,0) = T(0,0) = 1$ (see below).

As a matter of fact, the whole Hilbert space $L^2(\mathbb{R}^m)$ is recovered through the standard direct integral formula[14]

$$\int_{[0,1/L)^m}^{\oplus} L^2_{(k)}(T^m_L)\,dk \simeq L^2(\mathbb{R}^m). \tag{II.9}$$

More details are given in Sec. 1 in the Appendix and in Ref. 10. A basis for $L^2_{(k)}(T^m_L)$ is obviously $e^{(k)}_\alpha := L^{-m/2} e^{2\pi i(\alpha+k)\cdot x}$, with $\alpha \in (\mathbb{Z}/L)^m$.

(2) The choice of the Hilbert spaces in (II.8) corresponds to Maxwell–Boltzmann statistics, since we ask for no wave function symmetry with respect to particle permutations. One could also think of quantizing this system according to Bose–Einstein or Fermi–Dirac statistics. To give a physical explanation, we are considering particles that are, in principle, enumerable, but our observables do not see this enumeration. This approximation makes sense in the semiclassical realm.[15]

A further step toward the definition of the quantization application is the introduction of the Fourier transform and antitransform in Λ^m_L. We define first the dual of the phase space: $(\Lambda^m_L)^* := \mathbb{R}^m \times (T^m_L)^*$, where $(T^m_L)^* := (\mathbb{Z}/L)^m$. Now, if $b \in \mathscr{S}(\Lambda^m_L)$, that is the Schwartz class of functions in Λ^m_L; then for $(\eta,\xi) \in (\Lambda^m_L)^*$, the Fourier transform of b is

$$\hat{b}(\eta,\xi) := \int_{\mathbb{R}^m} \int_{T^m_L} b(p,q) e^{-2\pi i(\eta\cdot p + \xi\cdot q)}\, dq\, dp. \tag{II.10}$$

Correspondingly, the antitransformation is given by

$$b(p,q) := \frac{1}{L^m} \sum_{\xi \in (T^m_L)^*} \int_{\mathbb{R}^m} \hat{b}(\eta,\xi) e^{2\pi i(p\cdot\eta + q\cdot\xi)}\, d\eta. \tag{II.11}$$

The Heisenberg group to be considered in this situation is the naturally induced *cylinder subgroup* of the Heisenberg group on $\mathbb{R}^{2m}\times\mathbb{R}$, namely, $(\Lambda^m_L)^*\times\mathbb{R}$ endowed with the product law

$$(\eta,\xi,\tau)(\eta',\xi',\tau') = (\eta+\eta, \xi+\xi', \tau+\tau' + \tfrac{1}{2}(\eta\cdot\xi' - \xi\cdot\eta')). \tag{II.12}$$

Accordingly,[16] its unitary Schrödinger representation in $L^2(\mathbb{R}^m)$ is defined in the following way:

$$(T(\eta,\xi) f\,)(x) = e^{2\pi i \xi\cdot(\eta/2 + x)} f(x+\eta). \tag{II.13}$$

This can be formally written as $T(\eta,\xi) = e^{2\pi i(\eta\cdot P + \xi\cdot Q)}$, where Q corresponds to the multiplication operator by q, and $P = (2\pi i)^{-1}\nabla_x$. We have therefore taken $\hbar = (2\pi)^{-1}$. It is evident that $T(\eta,\xi)$ preserves $L^2_{(k)}(T^m_L)$: we denote by $T^{(k)}(\eta,\xi)$ its restriction to that space.

We are now in a position to define the quantization application. If b is a pseudodifferential symbol of a given finite order[16,17] on Λ^m_L, then

$$Op(b) := \frac{1}{L^m} \sum_{\xi \in (T^m_L)^*} \int_{\mathbb{R}^m} \hat{b}(\eta,\xi) T(\eta,\xi)\, d\eta; \tag{II.14}$$

with $\hat{b}$ possibly interpreted in a distributional sense.

The restriction of this operator to the invariant space $L^2_{(k)}(T^m_L)$ will be once more denoted by $Op(b)^{(k)}$. The above definition is nothing else than the standard Weyl quantization induced by the cylindrical Heisenberg group and subject to our choice of inverse Fourier transform (II.11). As a matter of fact, elementary algebraic manipulations yield the following explicit formula: for $f^{(k)} \in L^2_{(k)}(T^m_L)$,

$$(Op(b)^{(k)} f^{(k)})(x) = \int_{\mathbb{R}^m} \int_{\mathbb{R}^m} b\left(\frac{x+y}{2}, p\right) e^{2\pi i p\cdot(x-y)} f^{(k)}(y)\, dy\, dp. \tag{II.15}$$

Remark that, since $f^{(k)} \in \mathscr{S}(\mathbb{R}^{2m})$, *a priori* this makes no sense, even as an oscillatory integral. The sense we can give it is, again, distributional, as we know[17] that for pseudodifferential symbols, $Op(b): \mathscr{S}' \to \mathscr{S}'$. Notice also that, as usual, (II.15) implies that if b depends only on one canonical variable, for instance p, then $Op(b) = b(P)$ in the spectral-theoretic sense. In particular, if the quantum Hamiltonian is $H_m := -(1/8\pi^2)\Delta_x = Op(\mathscr{H}_m)$, we have $Op(e^{-\beta \mathscr{H}_m}) = e^{-\beta H_m}$.

We can now calculate the *Weyl composition* $a\#b$ of two symbols a and b, i.e., the (unique) symbol such that $Op(a\#b) = Op(a)Op(b)$. This is done by means of (II.14), remembering that $T(\eta,\xi)$ obeys the multiplication law of the Heisenberg group and that a symbol is obtained by its correspondent operator by substituting $e^{2\pi i(p\cdot\eta + q\cdot\xi)}$ to $T(\eta,\xi)$ when the operator is in the form (II.14)–compare (II.11) with (II.14). The result, after some manipulations of the integrals, is—not surprisingly—an adaptation of the corresponding formula for the Euclidean space case (Ref. 16, Sec. 2.1):

$$\begin{aligned}(a\sharp b)(p,q) &= \frac{1}{L^{2m}} \sum_{\xi_1,\xi_2} \int \hat{a}(\eta_1,\xi_1)\hat{b}(\eta_2,\xi_2) e^{\pi i(\eta_1\cdot\xi_2 - \xi_1\cdot\eta_2)} e^{2\pi i[(\eta_1+\eta_2)\cdot p + (\xi_1+\xi_2)\cdot q]}\, d\eta_1\, d\eta_2 \\ &= \frac{1}{L^{2m}} \sum_{\xi_1,\xi_2} \int a\left(p+\frac{\xi_1}{2}, q+q_1\right) b\left(p+\frac{\xi_2}{2}, q+q_2\right) e^{2\pi i(\xi_2\cdot q_1 - \xi_1\cdot q_2)}\, dq_1\, dq_2 .\end{aligned} \tag{II.16}$$

Notice that the sum is carried over $\xi_1, \xi_2 \in (T_L^m)^*$ and the integration over $q_1, q_2 \in T_L^m$.

By the above formula we deduce that the Weyl composition has a property that may be called the *quasitracial property:*

$$\int_{\Lambda_L^m} (a\#b)(p,q)\,dp\,dq = \int_{\Lambda_L^m} a(p,q)b(p,q)\,dp\,dq, \tag{II.17}$$

even though we cannot hope to have the tracial property for some $L^2_{(k)}(T_L^m)$, i.e., (II.17) with $\mathrm{Tr}_{L^2_{(k)}(T_L^m)} Op(a)Op(b)$ on the lhs, as explained in Ref. 10. Actually, as it will be clear in Sec. III A, what appears on the lhs is something resembling $\mathrm{Tr}_{L^2(\mathbb{R}^m)}$.

Given $f^{(k)}, g^{(k)} \in L^2_{(k)}(T_L^m)$, we define the Fourier–Wigner function relative to those two vectors as $V_{f^{(k)},g^{(k)}}(\eta,\xi) := \langle f^{(k)}, T(\eta,\xi) g^{(k)} \rangle$. This is completely analogous to what is found in Ref. 16. The Wigner function $W_{f^{(k)},g^{(k)}}$ is defined to be the (possibly distributional) Fourier transform of $V_{f^{(k)},g^{(k)}}$ and thus, from (II.14),

$$\langle f^{(k)}, Op(b) g^{(k)} \rangle_{L^2_{(k)}(T_L^m)} = \int_{\Lambda_L^m} b(p,q) W_{f^{(k)},g^{(k)}}(p,q)\,dp\,dq; \tag{II.18}$$

to be understood as $W_{f^{(k)},g^{(k)}}$ being the distribution kernel of $b \mapsto \langle f^{(k)}, Op(b) g^{(k)} \rangle$. Again the standard form for this ''function,''[16] calculated from (II.15) or from its very definition,

$$W_{f^{(k)},g^{(k)}}(p,q) := \int_{\mathbb{R}^m} e^{-2\pi i p\cdot z} \overline{f^{(k)}\left(q - \frac{z}{2}\right)} g^{(k)}\left(q + \frac{z}{2}\right) dz, \tag{II.19}$$

has to be interpreted in the weak sense.

III. STATEMENT OF THE RESULTS

Suppose we have, $\forall L > 0$; $m \in \mathbb{Z}$, $m \geqslant 1$ a measure space $(X_L^m, d\theta)$[18] and a family of states

$$\{f_\lambda\}_{\lambda \in X_L^m} \subset \bigcup_{k \in [0,1/L)^m} L^2_{(k)}(T_L^m), \tag{III.1}$$

labeled by the index λ ranging in X_L^m. Call $w_\lambda(p,q) := W_{f_\lambda,f_\lambda}(p,q)$, the Wigner function corresponding to f_λ.

Hypothesis: We suppose that

$$\int_{X_L^m} w_\lambda(p,q)\,d\theta(\lambda) \equiv 1, \tag{III.2}$$

as a distribution on Λ_L^m.

Remark: Such a family of states represents in this context the quantum substitute for the classical phase space. As a matter of fact, (III.2) says that the $\{f_\lambda\}$ are evenly distributed, as a whole, over Λ_L^m. Hence they play the role of ''points.'' This is clearly seen in the case of the *coherent states*, perhaps the most remarkable example of states fulfilling the above hypothesis. They are introduced in the Appendix, Sec. 1. However, (III.2) can be restated by saying that we are given a set of states complete over all $L^2_{(k)}(T_L^m)$, $k \in [0,1/L)^m$—see Sec. III A.

Since $\|e^{-\beta H_m} f_\lambda\|^2 = \langle f_\lambda, e^{-2\beta H_m} f_\lambda\rangle$,[19] then (III.2) immediately implies

$$\int_{X_L^m} \|e^{-\beta H_m} f_\lambda\|^2 \, d\theta(\lambda) = \int_{\Lambda_L^m} e^{-2\beta \mathscr{H}_m(p)} \, dp \, dq = L^m \left(\frac{\pi}{\beta}\right)^{m/2}. \tag{III.3}$$

We define

$$d\nu(\lambda) := \frac{\|e^{-\beta H_m} f_\lambda\|^2 \, d\theta(\lambda)}{\int_{X_L^m} \|e^{-\beta H_m} f_{\lambda'}\|^2 \, d\theta(\lambda')} \tag{III.4}$$

and

$$g_\lambda := \frac{e^{-\beta H_m} f_\lambda}{\|e^{-\beta H_m} f_\lambda\|} \tag{III.5}$$

be the image under the quantum Gibbs measure of each of our states.

Definition III.1: $a \in \mathscr{A}$ *is said to be an* asymptotic symbol *if* $\exists m_0 \in \mathbb{N}$, $L_0 > 0$ *such that* $\forall m \geqslant m_0$, $L \geqslant L_0$, $a \circ \Pi_L^m$ *is a pseudodifferential symbol over* Λ_L^m.

Remark: Notice that with such a definition, asymptotic symbols are rather rigid objects. In fact, fixed an $m \geqslant m_0$, take $L_0 \leqslant L \leqslant L_1$. Now $\mathrm{Im}(\Pi_L^m) \subseteq \mathrm{Im}(\Pi_{L_1}^m) \subseteq \Lambda_\infty$. So $a \circ \Pi_L^m$ is just the restriction of $a \circ \Pi_{L_1}^m$ to Λ_L^m. But also $a \circ \Pi_L^m$, in order to be a symbol must be C^∞ and T_L^m-periodic. This means that $\forall i = 1,\ldots,m$,

$$(a \circ \Pi_{L_1}^m)(\ldots, -L/2, \ldots) = (a \circ \Pi_{L_1}^m)(\ldots, +L/2, \ldots); \tag{III.6}$$

$$\frac{d}{dq_i}(a \circ \Pi_{L_1}^m)(\ldots, -L/2, \ldots) = \frac{d}{dq_i}(a \circ \Pi_{L_1}^m)(\ldots, +L/2, \ldots), \tag{III.7}$$

where $(\ldots, \pm L/2, \ldots)$ stands for $(p_1,\ldots,p_m,q_1,\ldots,q_{i-1},\pm L/2,q_{i+1},\ldots,q_m)$. Thus, parity arguments imply that for every $|q_i| \geqslant L_0/2$,

$$\frac{d}{dq_i}(a \circ \Pi_{L_1}^m)(\ldots, q_i, \ldots) = 0. \tag{III.8}$$

Hence, for a fixed large m, $(a \circ \Pi^m_{L_1})$ is a constantwise continuation of $(a \circ \Pi^m_{L_0})$, and the former is completely determined by the latter. This also explains why we had to ask for *asymptotic* symbols: one could not request the above property to hold $\forall m \geqslant 0$, $L \geqslant 0$. Examples of such functions are to be found in the families $\mathscr{B}^{(n)}$ defined after Lemma IV.2 in Sec. IV.

We are now ready to state the theorems. For any operator A acting over $L^2(\mathbb{R}^m)$, define

$$\Theta^m[t](A) := e^{2\pi i t H_m} A e^{-2\pi i t H_m}; \tag{III.9}$$

$$\Xi^m[T](A) := \frac{1}{2T} \int_{-T}^{T} \Theta^m[t](A)\, dt. \tag{III.10}$$

The quantum mixing property reads as follows.

Theorem III.2: *Suppose a, b are asymptotic symbols in $L^2(\Lambda_\infty, P_{\rho,2\beta})$ and denote*

$$I(t,L,m) := \int_{X^m_L} \langle g_\lambda, \Theta^m[t](Op(a \circ \Pi^m_L))\, Op(b \circ \Pi^m_L) g_\lambda \rangle\, d\nu(\lambda).$$

Then

$$\lim_{|t|\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} I(t,L,m) = P_{\rho,2\beta}(a) P_{\rho,2\beta}(b).$$

As regards the quantum ergodicity the following is true.

Theorem III.3: *Let a be an asymptotic symbol in $L^2(\Lambda_\infty, P_{\rho,2\beta})$. Let*

$$J(T,L,m) := \int_{X^m_L} \| (\Xi^m[T](Op(a \circ \Pi^m_L)) - P_{\rho,2\beta}(a)) g_\lambda \|^2\, d\nu(\lambda).$$

Then, for all L, m, the operator

$$\Xi^m[\infty](Op(a \circ \Pi^m_L)) := \lim_{T\to\infty} \Xi^m[T](Op(a \circ \Pi^m_L))$$

exists in the domain of $Op(a \circ \Pi^m_L)$ and

$$\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} J(\infty,L,m) = 0.$$

Furthermore, if a is also bounded, then the two limits can be inverted:

$$\lim_{T\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} J(T,L,m) = 0.$$

Remark: The interchange of the time limit with the thermodynamical limit, in the above theorem, is remarkable. The fact that the time average can be taken before the thermodynamical limit can be described saying that the finite-particle system (the ''real'' one) is *quasiergodic*, for very large L and m; that is, the time average of any *decent* function is close, in measure, to a constant. This is a feature of the classical ideal gas, which has nothing to do with quantum mechanics. It is rather a consequence of the kinematic chaos and the restriction to symmetric observables, as anticipated in the Introduction, remark (i). This can be seen quite easily, due to the

integrability of the motion: time averaging means almost averaging everywhere over a torus. The invariant tori here are the sets $\{p\}\times T_L^m \in \Lambda_L^m$, and so the time average of $a(p,q)$ is simply $\int a(p,q)dq$; the invariant functions would depend on p only. Those functions, however, are requested to be symmetric and thus they cannot concentrate around a torus if they do not concentrate around all ''symmetric tori'' as well. An example is

$$a(p_1,\ldots,p_m)=\begin{cases}1 & \text{if } p_i\in\Gamma,\ \forall i=1,\ldots,m;\\ 0, & \text{otherwise,}\end{cases} \tag{III.11}$$

where Γ is a Borel set of $\mathbb{R}$. Now the kinematic chaos effect comes: at the thermodynamical limit, the support of this function, which is the probability to find all the particles having momenta in Γ, is exponentially small.

We can compare this to the situation one has for the harmonic chain, as shown in the companion paper.[2] In that case, there is no requirement on the observables. The fact that they cannot concentrate over invariant tori is due instead to the assumptions on the coupling matrix, which shuffles the tori at the infinite-particle limit.

An even clearer reason for referring to Theorem III.3 as quantum ergodicity comes from the following.

Corollary III.4: Assume a bounded asymptotic symbol. Then, $\forall\epsilon>0$*; set*

$$K(\epsilon,T,L,m):=\nu(\{\lambda\in X_L^m \,|\, |\langle g_\lambda, \Xi^m[T](Op(a\circ\Pi_L^m))g_\lambda\rangle - P_{\rho,2\beta}(a)|>\epsilon\}).$$

Then

$$\lim_{T\to\infty}\ \lim_{\substack{m,L\to\infty\\ m/L\to\rho}} K(\epsilon,T,L,m)=\lim_{\substack{m,L\to\infty\\ m/L\to\rho}}\ \lim_{T\to\infty} K(\epsilon,T,L,m)=0.$$

This can be phrased as follows. Call (T,ϵ)-*exceptional initial states* those states g_λ for which the quantum expectation of the T-time average differs more than ϵ from the classical phase average. Then the claim is that the measure of the (T,ϵ)-exceptional initial states vanishes when the thermodynamical limit and the time limit are performed.

Proof of Corollary III.4: An easy consequence of Theorem III.3, using a Cauchy–Schwartz inequality. Q.E.D.

A. The quantum Gibbs state

The results just formulated can be given a compact form, within the realm of the C^*-dynamical systems theory. It is beyond the purpose of this paper to go deep into that, so we do not outline the main notions of such a theory, hoping that the statements in this section are self-explanatory. However, a brief survey is given in Ref. 2, Appendix 2. Here we just observe that the relations we will write are included in such a general frame. The interested reader is referred to Ref. 5 for complete details, and to Ref. 6 for a recent well-organized review.

Consider $\mathscr{L}_L^m$, the space of all operators on $L^2(\mathbb{R}^m)$ that are invariant and bounded over all the fibers $L^2_{(k)}(T_L^m)$. This is a C^*-algebra when endowed with the usual operator norm. Associated to this algebra we define the Heisenberg dynamics given by $\Theta^m[t](A)$ as in (III.9), and the quantum Gibbs state expressed by

$$\omega_{\beta,L}^m(A):=\frac{\int_{[0,1/L)^m}\mathrm{Tr}_{L,m,k}(Ae^{-\beta H_m})dk}{\int_{[0,1/L)^m}\mathrm{Tr}_{L,m,k}(e^{-\beta H_m})dk}, \tag{III.12}$$

where $\mathrm{Tr}_{L,m,k}$ denotes the trace over $L^2_{(k)}(T_L^m)$. This functional is clearly normalized[20] and invariant for the *-automorphism $\Theta^m[t]$. Actually, it turns out to be a KMS state with parameter β over the W^*-dynamical system $(\mathscr{L}_L^m,\Theta^m[t],\omega_{\beta,L}^m)$.

Now consider, for each value of $k \in [0,1/L)^m$, the standard Fourier basis $\{e_\alpha^{(k)}\}$, as defined in Sec. II A. Next, consider the family of all such vectors, labeled by the index $\lambda := (\alpha,k) \in X_L^m := (T_L^m)^* \times [0,1/L)^m$. Endow X_L^m with the measure

$$d\theta(\alpha,k) := L^m \sum_{\xi \in (T_L^m)^*} \delta(\alpha-\xi)\, d\alpha\, dk. \tag{III.13}$$

Such a family satisfies hypothesis (III.2). In fact, calling $w_{\alpha,k}$ the Wigner function relative to $e_\alpha^{(k)}$, a straightforward computation from (II.19) yields

$$w_{\alpha,k}(p,q) = \frac{1}{L^m}\, \delta(p-(\alpha+k)). \tag{III.14}$$

Integrating this in $d\theta(\alpha,k)$ we obtain (III.2). Thus, define, as it is done in at the beginning of this section, $g_{\alpha,k} := e^{-\beta H_m} e_\alpha^{(k)} / \| e^{-\beta H_m} e_\alpha^{(k)} \|$. By definition (III.12), if $A \in \mathscr{L}_L^m$, we have[21]

$$\omega_{2\beta,L}^m(A) = \frac{\int dk \Sigma_\alpha \langle e^{-\beta H_m} e_\alpha^{(k)}, A e^{-\beta H_m} e_\alpha^{(k)} \rangle}{\int dk \Sigma_\alpha \| e^{-\beta H_m} e_\alpha^{(k)} \|^2} = \int_{X_L^m} \langle g_{\alpha,k}, A g_{\alpha,k} \rangle\, d\nu(\alpha,k), \tag{III.15}$$

with $d\nu$ defined as in (III.4). On the other hand, if one calls in a natural way $A_L^m := Op(a \circ \Pi_L^m)$, then a simple argument that is better explained in the following [see formulas (IV.2) and (IV.3)] gives

$$\omega_{2\beta,L}^m(A_L^m) = \int_{\Lambda_L^m} (a \circ \Pi_L^m)(p,q) [e^{-2\beta \mathscr{H}_m(p)}\, dp\, dq]_N. \tag{III.16}$$

Proposition II.1 immediately yields

$$\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m(A_L^m) = P_{\rho,2\beta}(a). \tag{III.17}$$

Hence, if a,b are asymptotic symbols, we have just proved that Theorem III.2 can be rewritten as

$$\lim_{|t|\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m(\Theta^m[t](A_L^m) B_L^m) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m(A_L^m) \cdot \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m(B_L^m). \tag{III.18}$$

In the same spirit, Theorem III.3 becomes

$$\lim_{T\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m((\Xi^m[T](A_L^m))^2) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m((\Xi^m[\infty](A_L^m))^2) = \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} (\omega_{2\beta,L}^m(A_L^m))^2. \tag{III.19}$$

Remark: We have not defined an algebra of quantum observables for the infinite-particle system, limiting ourselves to deal with finite dimensions and to take a thermodynamical limit afterward (also see Comment 3 below). Had we introduced such a mathematical framework, then relations (III.18) and (III.19), for the state $\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \omega_{2\beta,L}^m$, would be contained in the general set of chaoticity notions in C^*-dynamical system theory (see Ref. 6, Definitions 4.42, 4.43).[22]

Some comments concerning the above reformulation of the theorems as compared to the paper by Graffi and Martinez follow.[2]

(1) (III.18) is completely analogous to statement (1.10) in Ref. 2. That is, the quantum mixing, forbidden in the finite-particle frame by the quasiperiodicity of the Heisenberg evolution, regardless of the dynamics of the classical flow (see the Introduction), is restored at the thermodynamical limit.

(2) A formulation of the ergodicity similar to (1.9) in Ref. 2 has not been chosen in this context because of the technicalities it would require. The coherent states we have here (see the Appendix, Sec. 1) are indexed by $\lambda \in T_L^m \times \mathbb{R}^m \times [0,1/L)_m =: X_L^m$, which is not exactly the classical phase space Λ_L^m. However, one could explicitly calculate $d\nu$ over X_L^m, for particular choices of the coherent states, and find a limit measure space—say—$(X, d\nu)$, but this turns out to be rather cumbersome and possibly misleading. Understandably, though, (III.19) and especially Corollary III.4 carry the same physical meaning as the mentioned result.

(3) As already exploited, we are able to state the ergodicity results here with a commutation of the limits.

(4) As emphasized in Ref. 2, Sec. 1, Remark 2, the techniques we use to prove the quantum ergodic properties at the thermodynamical limit, have the useful outcome to show that the rhs of (III.18) and (III.19) are the expected classical Gibbs averages. This is why we have formulated Theorems III.2 and III.3 in the first place.

(5) More importantly, here, results (III.18) and (III.19) were not known, at least to us.

IV. THE PROOFS

The first key fact is the following.

Lemma IV.1: For every symbol c defined on Λ_L^m,

$$e^{2\pi i t H_m}\, Op(c)\, e^{-2\pi i t H_m} = Op(c \circ \phi_L^m[t]).$$

This is true since we are dealing with a linear flow. This property of linear flows—sometimes referred to as the *exact Egorov Theorem* for the evolution canonical transformation—dates back at least to Van Hove and is valid only for Weyl quantization, whose restriction to L-periodic symbols we are now using. Anyway, for the sake of convenience, a direct proof is found in the Appendix, Sec. 2.

In our case, applying this lemma to $a \circ \Pi_L^m$ and using the remark in formula (II.4), we have

$$e^{2\pi i t H_m}\, Op(a \circ \Pi_L^m)\, e^{-2\pi i t H_m} = Op(a \circ \phi_\infty[t] \circ \Pi_L^m). \tag{IV.1}$$

A. Proof of Theorem III.2

In view of the above relation we call $a_t := a \circ \phi_\infty[t]$. In the rest of this proof, whenever there is no confusion, we denote by a quote the immersion application from Λ_L^m to Λ_∞. Hence $a' := a \circ \Pi_L^m$, and so on. In other words, a' is just our observable a looked at in the finite-dimensional phase space Λ_L^m. By (III.2) and (III.4), the definition of I, in the statement of the theorem, yields

$$I(t,L,m) = \frac{\int_{\Lambda_L^m} (e^{-\beta \mathscr{H}_m} \# a_t' \# b' \# e^{-\beta \mathscr{H}_m})\, dp\, dq}{\int_{\Lambda_L^m} e^{-2\beta \mathscr{H}_m}\, dp\, dq}. \tag{IV.2}$$

Using twice (II.17)—once to permutate cyclically the factors in (IV.2) and once to remove one of the # signs—leads to

$$I(t,L,m) = \int_{\Lambda_L^m} (a_t' \# b')(p,q)\, [e^{-2\beta \mathscr{H}_m(p)}\, dp\, dq]_N, \tag{IV.3}$$

since obviously $e^{-\beta\mathscr{H}_m}\#e^{-\beta\mathscr{H}_m}=e^{-2\beta\mathscr{H}_m}$. We further denote by μ_L^m the classical Gibbs measure (at inverse temperature 2β) over Λ_L^m: $\mu_L^m(p,q):=L^{-m}(\pi/\beta)^{-m/2}e^{-\beta p^2}$, and by $\breve{\mu}^m$ its component in the p space: $\breve{\mu}^m(p):=(\pi/\beta)^{-m/2}e^{-\beta p^2}$.

In view of (II.16), (IV.3) becomes, after some elementary but tedious rearrangements of the nested integrals,

$$I(t,L,m)=\int_{\Lambda_L^m}[a_t'(b'*_L\Phi_L^m)](p,q)\,d\mu_L^m(p,q), \tag{IV.4}$$

where

$$\Phi_L^m(p,q)=e^{\beta p^2}\frac{1}{L^m}\sum_{\xi\in(T_L^m)^*}e^{-\beta(p-\xi/2)^2}e^{2\pi i\xi\cdot q}, \tag{IV.5}$$

and $*_L$ means convolution in the q variable on T_L^m. Particular care must be taken here about this convolution *on a torus*, in order to prevent mistakes: see the Appendix, Sec. 3.

Thus Φ_L^m is completely factorizable, with Φ_L being a natural symbol for each of his factors: if $f(p_1,\ldots,p_m,q_1,\ldots,q_m)=f_1(p_1,q_1)\cdots f_m(p_m,q_m)$, then

$$(f*_L\Phi_L^m)(p,q)=(f_1*_L\Phi_L)(p_1,q_1)\cdots(f_m*_L\Phi_L)(p_m,q_m). \tag{IV.6}$$

This property will be useful in the following. Also, if 1 is the function on Λ_L^m identically equal to 1,

$$1*_L\Phi_L^m=1. \tag{IV.7}$$

We are going to prove the statement of the theorem, starting from (IV.4), for b in a dense subspace of $L^2(\Lambda_\infty,P_{\rho,2\beta})$. To accomplish that we need to make the following construction.

Fix a positive integer n and consider the function $\beta(p,q)\in C_0^\infty(\mathbb{R}^{2n})$,[23] that is, infinitely differentiable functions with compact support. For $m>n$ define the application

$$N_{L,m}^{(n)}(\beta)(p_1,\ldots,p_m,q_1,\ldots,q_m):=\sum_{j_1=1}^m\cdots\sum_{j_n=1}^m\beta(p_{j_1},\ldots,p_{j_n},q_{j_1},\ldots,q_{j_n}). \tag{IV.8}$$

So $N_{L,m}^{(n)}(\beta)$ is a function defined on $\mathbb{R}^{2m}$, and thus, in particular, on Λ_L^m. The use of this application is explained by the following lemma.

Lemma IV.2: If $\beta(p,q)\in\mathscr{S}(\mathbb{R}^{2n})$[24] then there exists a function $b\in L^2(\Lambda_\infty,P_{\rho,2\beta})$ *s.t.* $N_{L,m}^{(n)}(\beta)=b\circ\Pi_L^m$. *Plus, the following properties hold:*

$$\int_{\Lambda_L^m}|(b\circ\Pi_L^m)(p,q)|^2\,d\mu_L^m(p,q)\leqslant m^{2n}\Big(\sup_{(p',q')\in\Lambda_L^n}|\beta(p',q')|\Big)^2; \tag{IV.9}$$

$$\int_{\Lambda_L^m}(b\circ\Pi_L^m)(p,q)\,d\mu_L^m(p,q)=\frac{m!}{L^n(m-n)!}\int_{\Lambda_L^n}\beta(p',q')\,d\breve{\mu}^n(p')\,dq'. \tag{IV.10}$$

Proof of Lemma IV.2: The first inequality simply follows by definition (IV.8), since μ_L^m is a probability measure.

To prove the rest we approximate β with suitably chosen indicator functions over $\mathbb{R}^{2n}$. More precisely, take two sufficiently fine partitions of $\mathbb{R}$, $\{\Gamma_j\},\{\Delta_l\}\subset\mathscr{B}(\mathbb{R})$ with $\sup_{j,l}\{\breve{\mu}(\beta_j),|\Delta_l|\}$ small.[25] Let $\chi_{j_1,\ldots,j_n,l_1,\ldots,l_n}(p',q')$ be the indicator function of the set $\Gamma_{j_1}\times\cdots\times\Gamma_{j_n}\times\Delta_{l_1}\times\cdots\times\Delta_{l_1}$ and approximate β with $\beta_a:=\Sigma c_{j_1,\ldots,l_n}\chi_{j_1,\ldots,l_n}$. So

$$N^{(n)}_{L,m}(\beta_a)(p,q)=\sum_{j_1,\dots,l_n} c_{j_1,\dots,l_n} N^{(n)}_{L,m}(\chi_{j_1,\dots,l_n})(p,q). \tag{IV.11}$$

Since $\chi_{j_1,\dots,l_n}$ is completely factorizable, then it is easy to realize, by definition (IV.8), that $N^{(n)}_{L,m}(\chi_{j_1,\dots,l_n})(p,q) = N^{(1)}_{L,m}(\chi_{\Gamma_{j_1}\times\Delta_{l_1}})\cdots N^{(1)}_{L,m}(\chi_{\Gamma_{j_n}\times\Delta_{l_n}})$. We see that $N^{(1)}_{L,m}(\chi_{\Gamma\times\Delta})(p,q)$ takes integer values between 0 and m. Specifically, it counts the number of particles in the configuration $(p,q)\in\Lambda^m_L$ whose momentum is contained in Γ and whose coordinate in Δ.[26] So $N^{(1)}_{L,m}(\chi_{\Gamma\times\Delta})=N_{\Gamma\times\Delta}\circ\Pi^m_L$, where $N_{\Gamma\times\Delta}:\Lambda_\infty\to\mathbb{N}$ is defined by

$$N_{\Gamma\times\Delta}(p,q):=\#\{x\in q\cap\Delta \,|\, p(x)\in\Gamma\}, \tag{IV.12}$$

where, with sloppy notation, (p,q) denotes a point in Λ_∞. Recalling what we said in Sec. II A, this function obviously belongs to $\mathscr{A}$: see, in particular, (II.7) and comments thereby. Therefore so does every finite product of similar functions. Looking at (IV.11), and subsequent comments, this proves that there exists a $b_a\in\mathbb{A}$, such that $\beta_a=b_a\circ\Pi^m_L$. The analogous statement holds for β as well, by density.

Let us go over to the proof of (IV.10). Fix a sequence $(j,l):=(j_1,\dots,l_n)$ like those we have in formula (IV.11) and fix n integers $k:=(k_1,\dots,k_n)$, such that $k_1+\cdots+k_n\leqslant m$. Now consider the set $A^{(k)}_{j,l}:=\{N^{(1)}_{L,m}(\chi_{\Gamma_{j_i}\times\Delta_{l_i}})=k_i;\forall i=1,\dots,n\}\in\Lambda^m_L$, i.e., the set of the configurations having k_1 particles in $\Gamma_{j_1}\times\Delta_{l_1}$, k_2 particles in $\Gamma_{j_2}\times\Delta_{l_2}$, and so on. Notice that (use some combinatorics)

$$\mu^m_L(A^{(k)}_{j,l})=\frac{m!}{(m-\Sigma k_i)!}\left[\prod_{i=1}^n \frac{1}{k_i!}\left(\frac{|\Delta_{l_i}|}{L}\,\breve{\mu}(\Gamma_{j_i})\right)^{k_i}\right]\left(1-\sum_{i=1}^n \frac{|\Delta_{l_i}|}{L}\,\breve{\mu}(\Gamma_{j_i})\right)^{m-\Sigma k_i}. \tag{IV.13}$$

We have seen that $N^{(n)}_{L,m}(\chi_{j_1,\dots,l_n}) = \Sigma_k k_1\cdots k_n A^{(k)}_{j,l}$. So, when the initially chosen partition is fine, $\mu^m_L(\chi_{j_1,\dots,l_n}) = m!/(L^n(m-n)!)\Pi_i|\Delta_{l_i}|\breve{\mu}(\Gamma_{j_i}) + o(|\Delta_{l_i}|,\breve{\mu}(\Gamma_{j_i}))$. Looking back at (IV.11) this proves that (IV.10) holds with negligible errors for β_a, and thus is exact for β. Q.E.D.

Let us call $\mathscr{B}^{(n)}\in\mathscr{A}$ the space of functions b granted by Lemma IV.2 when $\beta\in C^\infty_0(\mathbb{R}^{2n})$. From now on we will suppose $b\in\mathscr{B}^{(n)}$, so that $b':=b\circ\Pi^m_L=N^{(n)}_{L,m}(\beta)$. In so doing we will be proving Theorem III.2 for $b\in\oplus_{\text{finite}}\mathscr{B}^{(n)}$. But this is dense in $L^2(\Gamma_\infty,P_{\rho,2\beta})$ since, looking at the proof of Lemma IV.2, the closure of $\mathscr{B}^{(n)}$ contains the product of n functions like $N_{\Gamma\times\Delta}$. This means that in the algebra $\overline{(\oplus\mathscr{B}^{(n)})}$ we are able to find the indicator functions of the sets $N^{-1}_{\Gamma\times\Delta}(n),\forall n\in\mathbb{N}$. But these generate $\mathscr{A}$ [look at (II.7) and refer to Refs. 13 and 6].

Under the above assumption, we go back to (IV.4): since $b'=N^{(n)}_{L,m}(\beta)$, then $b'*_L\Phi^m_L=N^{(n)}_{L,m}(\beta*_L\Phi^n_L)$[27] because of the mentioned properties of Φ^m_L [see (IV.5)–(IV.7)]. If we denote by $\gamma_L:=\beta*_L\Phi^n_L$, it is obvious that $\gamma_L\in\mathscr{S}(\mathbb{R}^{2n})$, and so $N^{(n)}_{L,m}(\gamma_L) = c'_L$ for some $c_L\in L^2(\Lambda_\infty,P_{\rho,2\beta})$, by Lemma IV.2. This allows us to rewrite (IV.4) as

$$I(t,L,m)=\langle a'_t,c'_L\rangle_{L^2(\Lambda^m_L,\mu^m_L)}. \tag{IV.14}$$

If we are able to find a limit for c_L then we are done with the cumbersome part of this proof. To this goal, we formulate the following.

Lemma IV.3: There exists a $\gamma_\infty\in\mathscr{S}(\mathbb{R}^{2n})$ such that

$$\sup_{\Lambda^n_L}|\gamma_\infty-\gamma_L|=\mathscr{O}(L^{-\infty}). \tag{IV.15}$$

Furthermore,

$$\int_{\mathbb{R}^{2n}} \gamma_\infty(p',q')d\check{\mu}^n(p')dq' = \int_{\mathbb{R}^{2n}} \beta(p',q')d\check{\mu}^n(p')dq'. \tag{IV.16}$$

The proof of this lemma is found in the Appendix, Sec. 4.

In analogy with the above notations we call c_∞ the observable in $L^2(\Lambda_\infty, P_{\rho,2\beta})$ obtained applying Lemma IV.2 to γ_∞. Comparing now (IV.15) in Lemma IV.3 with (IV.9), we deduce that

$$\lim_{\substack{m,L\to\infty \\ m/L\to\rho}} \|c'_\infty - c'_L\|^2_{L^2(\Lambda_L^m,\mu_L^m)} = 0. \tag{IV.17}$$

Dropping for the sake of simplicity the subscript in the scalar product notation, this means that, when $m, L\to\infty$, $m/L\to\rho$,

$$|\langle a'_t, c'_L\rangle - P_{\rho,2\beta}(a_t c_\infty)| \leqslant \|a'_t\|^2\|c'_L - c'_\infty\|^2 + |\mu_L^m(a'_t c'_\infty) - P_{\rho,2\beta}(a_t c_\infty)| \to 0, \tag{IV.18}$$

because of Proposition II.1. Now we use the other main ingredient of this proof, i.e., the classical result, Theorem II.2. We obtain

$$\lim_{|t|\to\infty} \lim_{\substack{m,L\to\infty \\ m/L\to\rho}} I(t,L,m) = P_{\rho,2\beta}(a)P_{\rho,2\beta}(c_\infty). \tag{IV.19}$$

Now, using the integrals of γ_∞ and β to compare the integrals of c_∞ and b [apply (IV.16) into (IV.10)], we see that $\mu_L^m(c'_\infty) = \mu_L^m(b')$. Taking the limits, $P_{\rho,2\beta}(c_\infty) = P_{\rho.2\beta}(b)$, which, together with the last relation, completes the proof.

B. Proof of Theorem III.3

First of all, it has to be noticed that both statements of Theorem III.3 [respectively, relation (III.19)] cannot be derived so trivially from Theorem III.2 [resp., (III.18)]. This will be seen below in each case.

We borrow the notation from the previous proof: so, for example, $a'_t := a \circ \phi_\infty[t] \circ \Pi_L^m$. Also, let $a'_T := (1/2T)\int_{-T}^{T} a'_t \, dt$. Formula (IV.1) proves that

$$\Xi^m[T](A_L^m) = Op(a'_T), \tag{IV.20}$$

where, as in Sec. III A, we call $A_L^m := Op(a')$.

The existence of $\Xi^m[\infty](A_L^m)$ is a trivial consequence of the Heisenberg evolution: we can easily figure it out looking at its matrix elements wrt the bases $\{e_\alpha^{(k)}\} \subset L^2_{(k)}(T_L^m)$. These bases diagonalize the Hamiltonian H_m, as well as any operator function of P only. We call such eigenvalues

$$E_\alpha^{(k)} = \frac{1}{2}(\alpha + k)^2 = \frac{1}{2}\sum_{i=1}^{n}(\alpha_i + k_i)^2. \tag{IV.21}$$

Now it is easy to see that, $\forall k \in [0,1/L)^m, \alpha, \gamma \in (T_L^m)^*$,

$$\langle e_\alpha^{(k)}, \Xi^m[\infty](A_L^m) e_\gamma^{(k)}\rangle = \langle e_\alpha^{(k)}, A_L^m e_\gamma^{(k)}\rangle \delta_{E_\alpha^{(k)}, E_\gamma^{(k)}}, \tag{IV.22}$$

where δ is the Kronecker δ-function. This formula shows that $\Xi^m[\infty](A_L^m)$ is well defined on all vectors in $D(A_L^m)$.

One might think to prove now the statement regarding $J(\infty,L,m)$ by simply substituting the Heisenberg invariant operator $\Xi^m[\infty](A_L^m)$ to $Op(a')$ and $Op(b')$ in Theorem III.2. We cannot quite do this, since such operator is not, in general, pseudodifferential. It is obvious, though, that

it can be approximated to any extent by pseudodifferential operators, and the result would follow by density. However, as remarked in Sec. III A, we have not defined a proper C^*-algebra for the infinite-particle system. Thus, we cannot talk of any density and have to prove the theorem directly.

$\Xi^m[\infty](A_L^m)$, roughly speaking, represents the quantization of $a'_\infty := \lim_{T\to\infty} a'_T$, which is not, in general, a symbol, being possibly not even continuous. But simple considerations based upon the trivial dynamics over Λ_L^m (also see the remark after the statement of this theorem) show that it is almost everywhere [namely, for $p=(p_1,\dots,p_m)$ having rationally independent components] equal to

$$c'(p,q)=c'(p):=\frac{1}{L^m}\int_{T_L^m} a'(p,q)\,dq, \tag{IV.23}$$

which is a symbol. Moreover, we denote it c' since one can straightforwardly find a $c\in\mathscr{A}$ such that $c'=c\circ\Pi_L^m$. The whole idea of this proof is exactly to show that, in some sense, $Op(c')$ is a.e. equal to $\Xi^m[\infty](A_L^m)$, so that the former can be substituted to the latter in the definition of $J(\infty,L,m)$ in order to apply Theorem III.2 [also compare (III.19) and (III.18)].

We first remark some basic properties of $Op(c')$. Since $c'(p,q)=c'(p)$ then $Op(c')$ is diagonal wrt $\{e_\alpha^{(k)}\}$. Its diagonal matrix elements, using (III.14), are found to be

$$\langle e_\alpha^{(k)}, Op(c')e_\alpha^{(k)}\rangle=\frac{c'(\alpha+k)}{\omega t}=\frac{1}{L^m}\int_{T_L^m} a'(\alpha+k,q)\,dq=\langle e_\alpha^{(k)}, A_L^m e_\alpha^{(k)}\rangle. \tag{IV.24}$$

Also (IV.24), together with (IV.22), implies that $Op(c')^{(k)}=(\Xi^m[\infty](A_L^m))^{(k)}$ [28] for those $k\in[0,1/L)^m$ for which $H_m^{(k)}$ is diagonal.

Using (II.19) over a generic f_λ picked up from the set of states satisfying (III.2), one can see that $w_\lambda(p,q)$ contains a (possibly countable) sum of δ-functions in p. This simple argument shows that, in order for $\{f_\lambda\}$ to verify (III.2), a factor of the measure space $(X_L^m, d\theta)$ must be $([0,1/L)^m, d\tau(k))$, with $d\tau$ absolutely continuous wrt the Lebesgue measure.[29] So if we prove that $\sigma(H_m^{(k)})$ is simple for Lebesgue—almost all k's then

$$J(\infty,L,m):=\int_{X_l^m}\|(Op(c')-P_{\rho,2\beta}(a))g\lambda\|^2\,d\nu(\lambda), \tag{IV.25}$$

and we can apply Theorem III.2 with $a=b=c-P_{\rho,2\beta}(a)$, which is time invariant. This would complete the proof of the first claim.

Rescaling (IV.21) by a factor L^m, what we need is equivalent to the following lemma.

Lemma IV.4:

$$|\{k\in[0,1)^m \mid \exists j,n\in\mathbb{Z}^m s.t.(j+k)^2=(n+k)^2\}|=0.$$

Proof of Lemma IV.4:[30] Thinking of it as a geometric problem in $\mathbb{R}^m$, when such j,n exist, then $-k$ lies in the axial hyperplane of the segment joining j to n, i.e., the set of points in the space equally distant from j and n. By their very construction there is only a countable number of such hyperplanes. Q.E.D.

As far as the last statement of Theorem III.3 is concerned, we see again that it cannot be derived as a corollary of the mixing theorem, since we are taking time limits of both operators. But we can give a direct proof using the techniques of Sec. IV A and the classical ergodicity result contained in Theorem II.2.

Exactly as in (IV.2) and (IV.3) we can write

$$J(T,L,m)=\int_{\Lambda_L^m}[(a'_T-P_{\rho,2\beta}(a))\#(a'_T-P_{\rho,2\beta}(a))](p,q)[e^{-2\beta\mathscr{H}_m(p)}\,dp\,dq]_N, \quad \text{(IV.26)}$$

having used (IV.20). We have become familiar with this object in Sec. IV A, and we have seen that integrating—wrt the Gibbs measure—the Weyl composition of two functions means integrating the product of the two functions, one of which is scrambled by a convolution [see (IV.3), (IV.4), and (IV.14)]. At the thermodynamic limit, this amounts to saying that

$$\lim_{\substack{m,L\to\infty\\ m/L\to\rho}} J(T,L,m)=P_{\rho,2\beta}((a_T-P_{\rho,2\beta}(a))c^{(T)}), \quad \text{(IV.27)}$$

where $c^{(T)}$ is the limit of the ''scrambled functions'' constructed upon $(a_T-P_{\rho,2\beta}(a))$. Its existence is granted by Lemmas IV.3 and IV.2, which yielded (IV.17). From the construction we have just recalled it can be seen that if $(a_T-P_{\rho,2\beta}(a))$ is bounded then $c^{(T)}$ is as well.

A remark is in order here: in Sec. IV A we have worked with symbols belonging to $\mathscr{B}^{(n)}$, and those are unbounded by definition, being the limits of functions like $N_{L,m}^{(n)}(\beta)$ defined in (IV.8). But a simple argument shows that a bounded $a\in\mathscr{A}=\sigma(\oplus\mathscr{B}^{(n)})$ remains bounded after the above procedure, since, roughly speaking, it gets deformed in the same way in each of its $\mathscr{B}^{(n)}$-components.

Finally, we can apply Lebesgue dominated convergence in (IV.27) since the integrand function is bounded and tends pointwise to zero as $T\to\infty$. Thus, the T-limit of (IV.27) gives the last statement in Theorem III.3, whence the end of the proof. Q.E.D.

ACKNOWLEDGMENTS

I would like to thank S. Graffi and Ya. G. Sinai for addressing this problem, giving stimulation as well as useful advice. I also wish to thank A. Parmeggiani and A. Martinez for interesting discussions on this subject. A grant from I.N.F.N. is highly acknowledged.

APPENDIX

1. Coherent states for the cylinder

We begin this section by recalling some notions about the Bloch decomposition (II.9), following Refs. 14 and 10. The idea is very simple: given a function $f\in L^2(\mathbb{R}^m)$, and therefore its Fourier transform $\hat{f}(p)$, we pick up from the latter only the terms at $p=\xi+k$, $(\xi\in(T_L^m)^*)$ to construct $f^{(k)}$, which clearly lies in $L^2_{(k)}(T_L^m)$.

In formula:

$$f^{(k)}(x):=\frac{1}{L^m}\sum_{\xi\in(T_L^m)^*}\hat{f}(\xi+k)e^{2\pi i(\xi+k)\cdot x}. \quad \text{(A1)}$$

Considering the scalar products in the dual spaces [respectively, $L^2(\mathbb{R}^m)$ and $l^2((\mathbb{Z}/L)^m+k)$], it is easy to see the decomposition property that justifies (II.9):

$$\langle f,g\rangle_{L^2(\mathbb{R}^m)}=\int_{[0,1/L)^m}\langle f^{(k)},g^{(k)}\rangle_{L^2_{(k)}(T_L^m)}\,dk. \quad \text{(A2)}$$

An explicit formula for $f^{(k)}$, more direct than (A1), is also computable with the aid of the Poisson summation formula:

$$f^{(k)}(x)=\sum_{n\in\mathbb{Z}^m}e^{-2\pi iLn\cdot k}f(x+Ln). \quad \text{(A3)}$$

We can now proceed to the construction of a remarkable example of states satisfying the assumptions of the theorems. Let a family of generalized coherent states for the Euclidean $2m$-dimensional phase space be given,

$$f_{(u,v)} := T(-u,v) f_0, \tag{A4}$$

as constructed in Ref. 11, where $(u,v) \in \mathbb{R}^{2m}$ and $f_0 \in L^2(\mathbb{R}^m)$, usually a Gaussian centered at the origin. According to our preparatory remark, we give the following definition.

Definition A.1:[10] *The family* $f^{(k)}_{(u,v)}$ *where* $(u,v,k) \in X^m_L := T^m_L \times \mathbb{R}^m \times [0,1/L)^m$ *constructed as above is called a set of* coherent states on Λ^m_L.

We endow X^m_L with the measure $d\theta(u,v,k) := du\ dv\ dk$ and check that they verify the hypothesis of the theorem.

We shall work on the Fourier antitransform of w_λ, i.e., on the Fourier–Wigner function relative to the state f_λ,

$$\begin{aligned}
&\int_{\Lambda^m_L} du\ dv \int_{[0,1/L)^m} dk \langle f^{(k)}_{(u,v)}, T^{(k)}(\eta,\xi) f^{(k)}_{(u,v)} \rangle_{L^2_{(k)}(T^m_L)} \\
&\quad = \int_{\Lambda^m_L} du\ dv \langle f_{(u,v)}, T(\eta,\xi) f_{(u,v)} \rangle_{L^2(\mathbb{R}^m)} \\
&\quad = \int_{\Lambda^m_L} du\ dv \langle T(-u,v) f_0, T(-u,v) T(\eta,\xi) f_0 \rangle_{L^2(\mathbb{R}^m)} e^{2\pi i(\eta\cdot v + \xi\cdot u)} \\
&\quad = \int_{\Lambda^m_L} du\ dv \langle f_0, T(\eta,\xi) f_0 \rangle_{L^2(\mathbb{R}^m)}\ e^{2\pi i(\eta\cdot v + \xi\cdot u)} = \langle f_0, T(\eta,\xi) f_0 \rangle_{L^2(\mathbb{R}^m)}\ \delta_\xi \delta(\eta) = \delta_\xi \delta(\eta),
\end{aligned} \tag{A5}$$

which is another way to state (III.2). The first step is justified by (A2) and the third by the commutation relations in the Heisenberg group.

Finally, this set of coherent states is perhaps the most important among the possible collections one could choose. As a matter of fact, such states are indeed introduced to be as *localized* as the Heisenberg principle permits.[10] Had we performed a limit $\hbar \to 0$, exploiting the Wigner function as a measure of the degree of localization of a state, we would have seen that

$$W_{f^{(k)}_{(u,v)}, f^{(k)}_{(u,v)}}(p,q) \to \delta(p-u)\,\delta(q-v), \quad \text{as } \hbar \to 0; \tag{A6}$$

where the dependence on $\hbar$ is implicit in the construction of $f^{(k)}_{(u,v)}$. This is why one can say that such a state is a good analog of a point in the phase space. Therefore we see that the physical meaning of our quantum ergodic properties gets clearer and more classical, of course, in the semiclassical regime.

2. Proof of Lemma IV.1

Let us check that equality on all the matrix elements with respect to the standard basis of $L^2_{(k)}(T^m_L), \{e^{(k)}_\alpha\}_{\alpha \in (T^m_L)^*}$ introduced in Sec. II B. It is easily computed that

$$T^{(k)}(\eta,\xi) e^{(k)}_\alpha = e^{2\pi i \eta\cdot(\xi/2 + \alpha + k)} e^{(k)}_{\alpha+\xi}. \tag{A7}$$

If we now denote $c^t(p,q) := (c \circ \phi^m_L[t]) = c(p, q+pt)$, we can compute its Fourier transform, which turns out to be $\hat{c}^t(\eta,\xi) = \hat{c}(\eta - \xi t, \xi)$. Thus, substituting into (II.14) and changing the variable

$$Op(c^t) := \frac{1}{L^m} \sum_{\xi \in (T_L^m)^*} \int_{\mathbb{R}^m} \hat{c}(\eta, \xi) T(\eta + \xi t, \xi) d\eta. \tag{A8}$$

In order for the statement to hold for every c, it is a necessary and sufficient condition that $\forall \alpha, \gamma \in (T_L^m)^*$,

$$\langle e_\alpha^{(k)}, T(\eta + \xi t, \xi) e_\gamma^{(k)} \rangle = \langle e_\alpha^{(k)}, e^{2\pi i t H_m} T(\eta, \xi) e^{-2\pi i t H_m} e_\gamma^{(k)} \rangle. \tag{A9}$$

Using (A7) we find on the rhs,

$$\langle e_\alpha^{(k)}, T(\eta + \xi t, \xi) e_\gamma^{(k)} \rangle = e^{2\pi i (\eta + \xi t) \cdot (\xi/2 + \gamma + k)} \delta_{\alpha, \gamma + \xi}. \tag{A10}$$

Since $P^{(k)} e_\alpha^{(k)} = (\alpha + k) e_\alpha^{(k)}$, on the lhs, we have

$$\begin{aligned} \langle e_\alpha^{(k)}, e^{2\pi i t H_m} T(\eta, \xi) e^{-2\pi i t H_m} e_\gamma^{(k)} \rangle &= e^{\pi i (\alpha + k)^2 t} e^{-\pi i (\gamma + k)^2 t} e^{2\pi i \eta \cdot (\xi/2 + \gamma + k)} \delta_{\alpha, \gamma + \xi} \\ &= e^{2\pi i ((\xi/2 + \gamma + k) \xi t + (\xi/2 + \gamma + k) \eta)} \delta_{\alpha, \gamma + \xi}, \end{aligned} \tag{A11}$$

where we have substituted for α its value $\gamma + \xi$. This relation finally verifies (A9). Q.E.D.

3. Convolutions over tori and over Euclidean spaces

The purpose of this section is to clarify the meaning of the symbol $*_L$, indicating q-convolution over T_L^m, when applied to functions that are, in principle, defined over larger sets, like the functions $b \circ \Pi_L^m$, for instance. Also, we want to understand how this is related to $*_\infty$, the ordinary convolution on $\mathbb{R}^m$, when $L \to \infty$.

Since the arguments here are essentially descriptive, we specialize to one dimension, without loss of generality. If f is a nice function defined on $\mathbb{R}$, denote by $f^{(L)}$ its *periodic restriction*, i.e., the function, *defined again on* $\mathbb{R}$, which is L-periodic and coincides with f on $[-L/2, L/2)$. Then if g is also a nice function on $\mathbb{R}$, we define

$$(f *_L g)(x) := (f^{(L)} * g^{(L)})(x) = \int_{-L/2}^{L/2} f^{(L)}(y) g^{(L)}(x - y) dy = \int_{-L/2}^{L/2} f(y) g^{(L)}(x - y) dy. \tag{A12}$$

Thus, for instance, $(f *_L g)(x) \neq \int_{-L/2}^{L/2} f(y) g(x - y) dy$. As $L \to \infty$, however, we expect this to be approximately true, at least for a fixed $x \in \mathbb{R}$. As a matter of fact, requiring some properties of f and g, one can prove a useful lemma. Call $S_R := [-R, R]$.

Lemma A.2: Suppose $f \in C_0^\infty(\mathbb{R})$ *and* supp $f \subseteq S_R$. *Assume also that* $|g|$ *vanishes monotonically at infinity. Defining*

$$h(x) = (f *_L g - f *_\infty g)(x),$$

then one has, for sufficiently large L,

$$h(x) \begin{cases} \leq M(|g(-L/2)| + |g(L/2 - R)|), & \text{for } x \in [-L/2, -L/2 + R), \\ = 0, & \text{for } x \in [-L/2 + R, L/2 - R], \\ \leq M(|g(L/2)| + |g(-L/2 + R)|), & \text{for } x \in (L/2 - R, L/2], \end{cases}$$

where $M := R \max |f|$.

Proof of Lemma A.2: Take L so large that $L/2 > R$ and $|g|$ is increasing in $(-\infty, -L/2 + R]$ and decreasing in $[L/2 - R, +\infty)$.

Looking at (A12) and recalling the hypothesis on f, we can write

$$(f*_L g)(x)=\int_{S_R} f(y)g^{(L)}(x-y)dy. \tag{A13}$$

Hence

$$h(x)=\int_{S_R} f(y)(g^{(L)}-g)(x-y)dy. \tag{A14}$$

Now, $g^{(L)}(x-y)$ coincides with $g(x-y)$ when $x-y\in S_{L/2}$, that is, when $y\in[x-L/2,x+L/2]$. So (A14) is rewritten as

$$h(x)=\int_{S_R\setminus(x+S_{L/2})} f(y)(g^{(L)}-g)(x-y)dy. \tag{A15}$$

It is easily seen that if $x\in[-L/2+R,L/2-R]$, then $S_R\subseteq(x+S_{L/2})$, such that $h(x)=0$ and part of the claim is proved. If $x\in[-L/2,-L/2+R]$, making the change of variable $z=x-y$, (A14) gives

$$|h(x)|=\left|\int_{x-R}^{-L/2} f(x-z)(g^{(L)}-g)(z)dz\right|\leqslant\max|f|\int_{-L/2-R}^{-L/2}(|g^{(L)}(z)|+|g(z)|)dz. \tag{A16}$$

Since by definition, for $z<-L/2$, $g^{(L)}(z)=g(z+L)$, the monotonicity property of g gives the first case in the statement of the lemma. The third case is, of course, analogous. Q.E.D

4. Proof of Lemma IV.3

Before even getting started, let us agree upon denoting, throughout this proof, by (p,q) all momentum-coordinate variables, be they defined on Λ_L^m or on $\mathbb{R}^{2n}$ or on Λ_L^1. Notice that, in the proof of Theorem III.2, we referred to n-dimensional variables as (p',q').

The whole idea here is to realize that, if n is fixed, the function Φ_L^n defined as in (IV.5), gets closer and closer, in Λ_L^n, to

$$\Phi_\infty^n(p,q)=e^{\beta p^2}\int_{\mathbb{R}^n} d\xi e^{-\beta(p-\xi/2)^2}e^{2\pi i\xi\cdot q}=e^{\beta p^2}e^{4\pi ip\cdot q}\left(\frac{4\pi}{\beta}\right)^{n/2}e^{-(4\pi^2/\beta)q^2}=e^{\beta p^2}e^{4\pi ip\cdot q}v^n(q), \tag{A17}$$

where $v(q):=\sqrt{4\pi/\beta}e^{-(4\pi^2/\beta)q^2}$. In the following we will use repeatedly the asymptotic estimate $v(L/2)=\mathcal{O}(L^{-\infty})$.

Anyway, Φ_∞^n is defined by the fact that it has the same Fourier spectrum of Φ_L^n, suitably extended to all of $\mathbb{R}^n$. If we denote by $\tilde{\cdot}$ the q-Fourier transform over T_L^n, then this amounts to saying that, for $\xi\in(T_L^n)^*=(\mathbb{Z}/L)^n$,

$$\int_{\mathbb{R}^n}\Phi_\infty^n(p,q)e^{-2\pi i\xi\cdot q}dq=e^{\beta p^2}e^{-\beta(p-\xi/2)^2}=:\tilde{\Phi}_L^n(p,\xi). \tag{A18}$$

So the best candidate for γ_∞ is $\beta*_\infty\Phi_\infty^n$. The symbol $*_\infty$ designates the q convolution over $\mathbb{R}^n$, as explained in Sec. 3 of this appendix. First of all, such a γ_∞ verifies (IV.16): this is a consequence of the fact that $\int_{\mathbb{R}^n}\Phi_\infty^n=1$, which is easily verified. Let us proceed to the proof of (IV.15).

Recalling the warning in Sec. 3 of this appendix, the main inequality will be

$$\sup_{\Lambda_L^n}|\gamma_L-\gamma_\infty|=\sup_{\Lambda_L^n}|\beta*_L\Phi_L^n-\beta*_\infty\Phi_\infty^n|\leqslant\sup_{\Lambda_L^n}|\beta*_L(\Phi_L^n-\Phi_\infty^n)|+\sup_{\Lambda_L^n}|\beta*_L\Phi_\infty^n-\beta*_\infty\Phi_\infty^n|. \tag{A19}$$

The rightmost term can be worked out easily, using (A17) and Lemma A.2 of Sec. 3 of this appendix. If $(p,q)\in\Lambda_L^n$,

$$|(\beta *_L \Phi_\infty^n - \beta *_\infty \Phi_\infty^n)(p,q)| \leqslant M v^n\left(\frac{L}{2}-R\right) = \mathscr{O}(L^{-\infty}), \tag{A20}$$

where $M \simeq \max(|\beta(p,q)|e^{\beta p^2})$ and R is the radius of the ball containing supp β. To work out the other term in (A19) we employ the ideas stated at the beginning of this section about Φ_∞^n. We start by noticing that $\|\cdot\|_{L^1(T_L^n,dq)} \leqslant L^{n/2}\|\cdot\|_{L^2(T_L^n,dq)}$. We have

$$\sup_{q\in T_L^n} |\beta *_L (\Phi_L^n - \Phi_\infty^n)(p,q)| \leqslant \sup_{q\in T_L^n} |\beta(p,q)| L^{n/2} \|(\Phi_L^n - \Phi_\infty^n)(p,\cdot)\|_{L^2(T_L^n,dq)}. \tag{A21}$$

Notice that β is compactly supported. We also see that

$$\|(\Phi_L^n - \Phi_\infty^n)(p_1,\ldots,p_n,\cdot)\|^2_{L^2(T_L^n,d)} = \prod_{i=1}^n \|(\Phi_L - \Phi_\infty)(p_i,\cdot)\|^2_{L^2(T_L,dq_i)}, \tag{A22}$$

since Φ_L^n and Φ_∞^n are completely factorizable: we call, obviously, Φ_L and Φ_∞ their one-dimensional versions, on which we are immediately going to work. As anticipated at the beginning of this section, we will be a little imprecise and use again the label (p,q) for (p_i,q_i). Now

$$\|(\Phi_L - \Phi_\infty)(p,\cdot)\|^2_{L^2(T_L)} = \frac{1}{L}\sum_{\xi\in(\mathbb{Z}/L)} |\tilde{\Phi}_L(p,\xi) - \tilde{\Phi}_\infty(p,\xi)|^2, \tag{A23}$$

with $\tilde{\Phi}_\infty(p,\xi) = \int_{-L/2}^{L/2} \Phi_\infty(p,q) e^{-2\pi i\xi q}\, dq$. Looking back at (A18) and using definition (A17), we can write

$$\begin{aligned}
|\tilde{\Phi}_L(p,\xi) - \tilde{\Phi}_\infty(p,\xi)| &= \left| \int_{\mathbb{R}\setminus T_L} \Phi_\infty(p,q) e^{-2\pi i\xi q}\, dq \right| \\
&= 2e^{\beta p^2} \left| \int_{L/2}^{+\infty} v(q)\cos(2\pi(\xi-2p)q) dq \right| \\
&= 2e^{\beta p^2} \left| \left[\frac{v(q)\sin(2\pi(\xi-2p)q)}{2\pi(\xi-2p)} \right]_{L/2}^{+\infty} - \int_{L/2}^{+\infty} \frac{v'(q)\sin(2\pi(\xi-2p)q)}{2\pi(\xi-2p)}\, dq \right| \\
&\leqslant e^{\beta p^2} g(\xi-2p) v(L/2),
\end{aligned} \tag{A24}$$

where $g(x)$ is a continuous function defined on $\mathbb{R}$ behaving like $|x|^{-1}$ for large values of $|x|$. Note that, as $L\to\infty$, $(1/L)\Sigma_{\xi\in(\mathbb{Z}/L)} g^2(\xi - 2p) \to \int_{\mathbb{R}} g^2(\xi) d\xi =: K$, *uniformly* for p in a compact set. So, looking at (A21), and merging up (A22), (A23), and (A24), we have

$$\begin{aligned}
\sup_{(p,q)\in\Lambda_L^n} |\beta *_L (\Phi_L^n - \Phi_\infty^n)(p,q)| &\leqslant L^{n/2} \sup_{(p,q)\in\Lambda_L^n} |\beta| \sup_{|p|<R} \|(\Phi_L^n - \Phi_\infty^n)(p,\cdot)\|_{L^2(T_L^n,dq)} \\
&\leqslant (e^{2\beta R^2}(K+1) v^2(L/2) L)^{n/2} \sup|\beta| = \mathscr{O}(L^{-\infty}),
\end{aligned} \tag{A25}$$

since β has compact support. Inserting (A20) and (A25) into the fundamental inequality (A19) the proof is completed.

[14] M. Reed and B. Simon, *Methods of Modern Mathematical Physics IV: Analysis of Operators* (Academic, New York, 1978).
[15] On the other hand, we stress that this paper does not involve any kind of semiclassical limit.
[16] G. Folland, *Harmonic Analysis in Phase Space* (Princeton University Press, Princeton, NJ, 1988).
[17] A. M. Shubin, *Pseudodifferential Operators and Spectral Theory* (Springer-Verlag, Berlin, 1987).
[18] We are intentionally a little informal here, in order to keep the notation not to be cumbersome. A better label for $d\theta$ would be $d\theta_L^m$. The same for $d\nu$ in the following.
[19] Again a remark about the notation. A more formal symbol for the scalar product would be $\langle \cdot\,, \cdot \rangle_{L^2_{(k)}(T_L^m)}$, where $k = k(\lambda)$ is the uniquely determined $k \in [0,1/L)^m$, such that the arguments are in $L^2_{(k)}(T_L^m)$. Since the scalar products have the same structure on each $L^2_{(k)}(T_L^m)$ we will drop that subscript.
[20] Here normalized means $\omega^m_{\beta,L}(1) = 1$.
[21] Notice that we are using 2β instead of β in the remainder.
[22] We are not granted, in principle, all the equivalent ergodicity and mixing properties recalled in that reference, since we have not proved asymptotic commutativity.
[23] Not to be confused with the inverse temperature β, a fixed parameter throughout this paper.
[24] $\mathscr{S}(\cdot)$ denotes the Schwartz class.
[25] $|\cdot|$ denotes the Lebesgue measure.
[26] This explains why we have chosen such a notation for $N^{(n)}_{L,m}$.
[27] This time $*_L$ means convolution in the q-variable over T_L^n. We warn the reader again about the possible confusion arising from the fact that $\beta(p,q)$ is defined on $\mathbb{R}^{2n}$. When in a $*_L$-convolution, it has to be considered as restricted to $[-L/2, L/2)^n$ and periodic according to the identification $[-L/2, L/2)^n \simeq T_L^n$. See again Sec. 3 of the Appendix.
[28] Remember that with $A^{(k)}$ we denote $A_{|L^2_{(k)}(T_L^m)}$ as explained in Sec. II B.
[29] This is a manifestation of the fact that all fibers $L^2_{(k)}(T_L^m)$ need to be taken into account, as mentioned in Sec. II B, Remark 1. We can convince ourselves of this also looking at the two examples of $\{f_\lambda\}$ we have explicitly written: the Fourier basis in Sec. III A and the coherent states in the appendix, Sec. 1. In both cases $(X_L^m, d\theta) = ([0,1/L)^m, dk)) \times$some measure.
[30] I thank D. Dolgopyat for this simple proof.

A mean field theory for arrays of Josephson junctions

I present here some results on the mean field theory approach to the statistical mechanics of a D-dimensional array of Josephson junctions in the presence of a magnetic field. The mean field theory equations are obtained by computing the thermodynamical properties. In the high temperature region in the limit $D\to\infty$, where the problem is simplified, this limit defines the mean field approximation. Close to the transition point the system behaves very similar to a particular form of spin glasses, i.e., to gauge glasses. We have noticed that in this limit the evaluation of the coefficients of the high temperature expansion may be mapped onto the computation of some matrix elements for the q-deformed harmonic oscillator. The same arguments can be used to predict the thermodynamical properties in the mean field limit. These results can be extended to the low temperature phase using a conjecture on the equivalence of some system without disorder with appropriate random systems.

I. INTRODUCTION

In this article I am interested to study the statistical mechanics of arrays of Josephson junctions in D-dimensions in the limit where $D\to\infty$. Here I will show how to obtain the results for the thermodynamics in the framework of the mean field approximation. In order to obtain a consistent mean field theory approach I will show how to perform the limit of infinite dimension.

The main motivation for this enterprise would be to have a starting point which could be used as a starting point to predict the behavior of the system in more realistic situations. Here I will report mainly the results of Refs. 1 and 2, which are an extension to these systems of previous results obtained in Ref. 3.

The model has been extensively studied in two dimensions, especially in the low temperature region.[4,5] It is possible that something has been done to study the three-dimensional extension of the model, but no results are known in very high dimensions.

The article is organized as follows. After this introduction I will describe in detail the model. In Sec. III will describe the computation of the high temperature expansion in the mean field limit for the Gaussian model. In Sec. IV I will show how to extend these results to real spins. In Sec. V I will present the general conjecture which allows us to extend these results to the lower temperature region. In Sec. VI I will discuss the correctness of this conjecture on the equivalence of some system without disorder with appropriate random systems. In Sec. VI I will show how to apply the general conjecture to this case. In Sec. VII I will present a comparison with the numerical simulations.

II. THE MODEL

The model we consider is described by the Hamiltonian:

$$H=-c(D)\sum_{j,k}\ \overline{\phi_j}U_{j,k}\phi_k+\text{h.c.} \tag{1}$$

0022-2488/96/37(10)/5158/13/$10.00

Here $c(D)\equiv(2D)^{-1}$ is a normalization constant, which will be useful later to rescale the Hamiltonian in order to obtain a nontrivial limit when D goes to infinity. The spins ϕ_j are defined on a D-dimensional hypercubic lattice.

We will consider three possibilities:

• The spins ϕ_j are constrained to be of modulus one.

• The spins ϕ_j have modulus one in the average at $\beta=0$: in this limit they have a Gaussian distribution.

• The spins satisfy the constraint $\Sigma_i\,|\phi_i|^2=N$. This is the spherical model which is intermediate among the two previous models.[6]

In the limit where the dimension D goes to infinity the properties of the first model and of the third model can be obtained from that of the Gaussian model. We will concentrate our attention on the Gaussian case and we will later study the other cases.

The couplings U are nonzero only for nearest neighbor sites. They are complex numbers of modulus one and they satisfy the relation

$$U_{k,j}=\overline{U_{j,k}}. \tag{2}$$

In other words the couplings U are the links variables of an $U(1)$ lattice gauge field.

We will select the couplings U to give a constant magnetic field. Many different orientations of the magnetic field can be chosen. For simplicity we restrict our computation to the case where the flux through each elementary plaquette is given by B (or $-B$) independently from the plane to which the plaquette belongs. This corresponds to constant uniform frustration on all the plaquettes. In the extreme case ($B=\pi$) we obtain a fully frustrated model, while for $B=0$ we recover the ferromagnetic case. Random point dependent B values corresponds to a particular form of spin glasses, i.e., to gauge glasses.[7–10]

More precisely we set

$$B_{\alpha,\beta}=S_{\alpha,\beta}B, \tag{3}$$

where $S_{\alpha,\beta}$ may take the values 1 or -1, $B_{\alpha,\beta}$ is the antisymmetric tensor corresponding to the magnetic field, which in the continuum limit is given by $\partial_\alpha A_\beta-\partial_\beta A_\alpha$. The ordered product of the four links of a plaquette in the α,β plane is equal to $\exp(iB_{\alpha,\beta})$.

We must now specify $S_{\alpha,\beta}$, i.e., the sign of $B_{\alpha,\beta}$. A possible choice would be to take

$$S_{\alpha,\beta}=1 \quad \text{for } \alpha>\beta, \tag{4}$$

which implies $B_{\alpha,\beta}=B$ for $\alpha>\beta$.

In two and in three dimensions this choice is equivalent to any other possible choice of the sign. In three dimensions the magnetic field is a vector and all the vectors corresponding to different choices of the sign may be obtained one from the other with a rotation. The choice of S does not influence the thermodynamics.

In more than three dimensions different choices of the matrix S are not equivalent and we must select one among all the possible ones. In this note we consider the case in which the matrix S is a generic one, i.e., the signs of B are randomly chosen. The system is translation invariant and the randomness appears in only in the relative orientation of the magnetic field with the crystal axis.

In the two-dimensional case we recover the usual description for an XY system (or equivalently an array of Josephson junctions) in constant magnetic field.

In order to compute the statistical properties of this model in the mean field approximation in the high temperature region we must find the spectral properties of the lattice discretized Laplacian in presence of a magnetic field. The lattice Laplacian is defined as

$$(\Delta f)_j = \sum_k U_{j,k} f_k . \tag{5}$$

The spectral properties of the lattice Laplacian in two dimension have been carefully studied. They depend on the arithmetic properties of the B/π, i.e., different results are obtained for rational and irrational B/π.[5]

The study of the lattice Laplacian in higher dimensions is much less developed. In any dimension the explicit construction of the field U shows that for rational B/π, of the form $B=2\pi r/s$, with both r and s integers, there is a gauge in which the U couplings are periodic functions of the position, with period s. In this case the spectrum of the Laplacian has the typical band form, the edges of the bands being related to the eigenvalues of a $s^D \times s^D$ matrix. When both s and D are large, a direct study of the eigenvalues is rather complex.

We will study this problem in the limit of an infinite number of dimensions. We will find some unexpected relations with the properties of the q-deformed harmonic oscillator. At the end the behavior of the model will come out very similar to that of spin glasses. The reader should notice that the properties of the model in high dimensions may be quite different from that of the two-dimensional model.

A simplified model (the *single cell* model) can be constructed if we restrict the spins to belong to a single hypercubic cell of size $L=2$ and volume $N=2^D$. The advantage of this simplified model is to allow a simpler computation of the behavior of the system in the low temperature phase. Moreover it is the only case in which numerical simulations can be done for high values of D. The difference of the two models should be small when the dimension of the space D goes to infinity. Indeed in many cases the infinite dimensions limit does not depend on the size (L) of the box, provided that $L>1$.

III. ON THE HIGH TEMPERATURE EXPANSION

A. General considerations

There are two extreme cases for the U which are very well studied for the Hamiltonian (1):

• We set

$$U_{j,k}=1. \tag{6}$$

In this way we obtain the usual ferromagnetic XY model. There is a ferromagnetic transition at $\beta=1$ in the limit $D\to\infty$, if we set $c(D)=1/2D$, i.e., $c(D)$ has to be equal to the inverse of the coordination number of the hypercubic lattice.

• We set

$$U_{j,k}=\exp(i r_{j,k}), \tag{7}$$

where r are random numbers belonging to the interval $0-2\pi$, such that the symmetry condition Eq. (2) is satisfied.

In this way be obtain a spin glass model of the XY type, which is called a gauge glass. The transition temperature is $\beta=1$ in the limit $D\to\infty$, if we set $c(D)=(2D)^{-1/2}$, i.e., $c(D)$ is equal to the inverse of the square root of the coordination number.

The model we study is intermediate among the previous two problems. In order to define it properly, it is convenient to introduce the so-called Wilson loop. Let us consider a closed oriented circuit (C) on the lattice, which goes from the point j to the same point j and let us define $W(C)$ as the product of the U's along the circuit. The Wilson loop $W(C)$ is a gauge invariant. The knowledge of $W(C)$ for any C gives all gauge invariant information concerning the gauge field.

In the continuum limit we have

$$W(C)=\exp\left(i\int_C dx^\mu\, A_\mu(x)\right)=\exp(i\Phi(C)), \tag{8}$$

where $\Phi(C)$ is the magnetic flux entangled within C.

In 2 dimensions in presence of a constant magnetic field the Wilson loop is given by

$$W(C)=\exp(iBS(C)). \tag{9}$$

where $S(C)$ is the signed area of the loop C.

In D dimensions there are $D(D-1)/2$ planes oriented in the directions of the lattice. The choice of the magnetic field we study here is

$$W(C)=\exp(i\Phi(C)),$$

$$\Phi(C)=\sum_{\nu,\mu=\nu<\mu} S_{\nu,\mu}(C)B_{\nu,\mu}, \tag{10}$$

where the indices ν and μ denote one of the D possible different directions and $S_{\nu,\mu}$ is the signed area of the projection of the curve C on the ν, μ plane.

As a consequence of gauge invariance there are infinite many choices of the U which correspond to these Wilson loops. All these choice are physically equivalent. In two dimensions we could set

$$U_1(j)=1, \quad U_2(j)=\exp(iBj_1),$$

where j_ν is the νth component of the vector j and we have introduced the short-hand notation

$$U_\nu(j)=U(j,j+n_\nu), \tag{11}$$

n_ν being the unit vector in the ν direction.

This construction can be generalized to the D-dimensional case. For example in 4 dimensions one obtains

$$U_1(j)=1, \quad U_2(j)=\exp(iB_{2,1}j_1),$$

$$U_3(j)=\exp(i(B_{3,1}j_1+B_{3,2}j_2)), \quad U_4(j)=\exp(i(B_{4,1}j_1+B_{4,2}j_2+B_{4,3}j_3)). \tag{12}$$

Our main task will be the study of the associated Gaussian model, where the Hamiltonian is given

$$H=-c(D)\sum_{j,k}\ \overline{\phi_j}U_{j,k}\phi_k+\text{h.c.}-1/2\sum_k\ |\phi_k|^2. \tag{13}$$

The solution of this associated Gaussian model is a crucial step in the computation of the properties of the high temperature expansion.

B. The high temperature expansion for the Gaussian model

In the case of the Gaussian model the free-energy density can be written as

$$\beta F(\beta)=\sum_C\ W(C)(\beta c(D))^{L/(C)}/L(C), \tag{14}$$

where the sum is done over all the closed lattice circuits with given starting point; $L(C)$ is the length of the circuit.[10]

In a model (like the present one) where gauge invariant quantities are translational invariant, we can chose the origin (and the end) of the circuit at an arbitrary point of the lattice. In other cases, like spin glasses, we must average over all the possible starting points.[11,12]

The previous formula can also be written as

$$\beta F(\beta)=\mathrm{tr}\,\ln(1+c(D)\beta\Delta)=\sum_n \frac{(\beta c(D))^n}{n}\mathcal{N}(n)\langle W(C)\rangle_n, \tag{15}$$

where by $\langle W(C)\rangle_n$ we denote the average over all the circuits of length n and by $\mathcal{N}(n)$ the number of (rooted) closed circuits.

Differentiating the previous formulas we obtain a similar result for the internal energy density:

$$2\beta c(D)U(\beta)=\sum_n (\beta c(D))^n \mathcal{N}(n)\langle W(C)\rangle_n. \tag{16}$$

Here the factor $1/n$ has disappeared. It is easy to show that the coefficients of the high temperature expansions remain finite when $D\to\infty$ if $C(D)=(2D)^{-1}$. From now on we will follow this choice.

C. The results for gauge glasses

In this case we will compute the spectrum of the random Laplacian. This can be done in the infinite dimensions limit since we recover the old problem of computing the spectrum of a random matrix, which is given by a semicircle law.

In this case the U's have zero average and are random elements of the $U(1)$ group. After the average over all the possible starting points. $W(C)$ gets contributions only from those circuits for which for any step going from i to k there is a step going from k to i. In other words we must sum only over *backtracking* circuits.

Let us count the number of these circuits in infinite dimensions. We must to compute

$$G_{2n}=\lim_{D\to\infty}(2D)^{-n}\mathcal{N}(2n)\langle W\rangle_{2n}. \tag{17}$$

The computation of G_n can be thus cast under a graphical form. For each given word, we put its $2n$ letters (two by two equal), on a circle starting from a given point, in the same order of the letters of the corresponding word. We connect those points which have an identical letter by a line and we count the number of intersections of the lines. This number is topological invariant and it does not depend on the point where the letters have been put on the circle, but only on their order.

We can associate to each word the number of intersections. Let us call $I_n(m)$ the number of words which have m intersections ($m\leqslant n(n-1)/2$). It is easy to check that

$$I_n(0)=G_n. \tag{18}$$

Indeed only in the case in which the resulting diagram is planar, the diagram may be reduced to zero by removing consecutively equal letters.

The combinatorial problem of computing $I_n(0)$ has been solved[13] in the past. After a short computation one finds

$$I_n(0)=4^n\frac{\Gamma(n+1/2)}{\Gamma(1/2)\Gamma(n+2)}. \tag{19}$$

We finally find that

$$1+\beta U(\beta)=\sum_n (4\beta^2)^n \frac{\Gamma(n+1/2)}{\Gamma(1/2)\Gamma(n+2)}=\frac{2}{\pi}\int_{-2}^{2} d\lambda \frac{(1-\lambda^2/4)^{1/2}}{(1+\beta\lambda)}. \tag{20}$$

There is a transition at $\beta=1/2$, which is characterized by a singularity of the specific heat of the form $(\beta_c-\beta)^{-1/2}$. In other words the critical exponent α is equal to 1/2.

Equation (20) gives the result for spin glasses in the Gaussian approximation. Starting from it one can obtain the more familiar results for the Ising spin glass or for the spherical spin glass.

D. Josephson junctions in magnetic field

In this case we need at first to compute the function

$$G_n(B)=\lim_{D\to\infty}(2D)^{-n}\mathcal{N}(2n)\langle W\rangle_n. \tag{21}$$

We will follow the strategy of first dividing the circuits into classes corresponding to different words of $2n$ letters (as in the previous case) and to evaluate the contribution of each class.

Let us start by computing $G_2(B)$ (it is trivial that $G_1(B)=1$). The backtracking circuits which correspond to the *planar* diagrams, (the corresponding words are $aabb$ and $abba$) give a contribution 1 each. More generally we can define the area of a circuit as the minimal area of a surface of lattice plaquettes which have that circuit as boundary. Backtracking circuits can be characterized as area zero circuits.

We finally find

$$G_4(B)=2+q, \tag{22}$$

where

$$q=\cos(B). \tag{23}$$

Generally speaking each different word of length $2n$ is associated to $(2D)^n$ circuits having the same area. The signed area of these circuits having the same area (A) is different. In a large number of dimensions (in the generic case where all the independent steps are done in different directions) the projected signed areas $S_{\mu,\nu}$ take only the values 0 or ± 1 and

$$\sum |S_{\mu,\nu}|=A. \tag{24}$$

If we average over all the possible orientations of the lattice the contribution coming from the circuits having the same word, we find that the average value of $\langle W(C)\rangle$ depends only on A and it is given by

$$\langle W(C)\rangle_A=\left(\frac{\exp(iB)+\exp(-iB)}{2}\right)^A=q^A. \tag{25}$$

We finally find that

$$G_n(B)=\sum_w q^{A(w)}, \tag{26}$$

where the sum is taken over all words of $2n$ letters and $A(w)$ is the area associated to each of these words.

It is possible to prove that the area of a of the circuit is exactly equal to the number of intersections of the lines connecting equal letters in the corresponding diagram. In this way we

have transformed the problem of computing the high temperature expansion into a combinatorial problem, although not very easy, which generalize the computation of planar diagrams. The solution of this problem will be presented in the next section.

E. The q-deformed harmonic oscillator plays a role

We have reduced the problem of evaluating the high temperature expansion of the Gaussian model in the presence of a magnetic field to the computation of the number of words of $2n$ letters, two by two equal, such that the number of intersections in the corresponding diagram is equal to a given number.

A detailed recursive combinatorial analysis show that

$$G_n(B)=\sum_w q^{A(w)}=\langle 0|X^{2n}|0\rangle, \tag{27}$$

where

$$X=\mathscr{R}_q+\mathscr{L}_q, \tag{28}$$

and the operators $\mathscr{L}$ and $\mathscr{R}$ satisfy the commutation relation of a q-deformed harmonic oscillator:

$$\mathscr{L}_q\mathscr{R}_q-q.\mathscr{R}_q\mathscr{L}_q=1. \tag{29}$$

[In the case $q=1$ we have Bosonic commutation relations, for $q=1$ we have Fermionic commutation relations and for $q=\exp(i\theta)$ anyonic commutation relations. For $q=0$ we recover the so-called Kunz algebra. Some applications of the anyonic commutation relations can be found in Refs. 14 and 15 and references therein.]

Therefore $\mathscr{L}_q$ may be identified with the destruction operator and R_q with the creation operator for a q-deformed harmonic oscillator. For $q=1$ we recover the ferromagnetic case, for $q=-1$ the fully frustrated case and for $q=0$ the spin glass case.

These operators may be represented as

$$\mathscr{R}_q|m\rangle=[m]_q^{1/2}|m+1\rangle, \quad \mathscr{L}_q|m\rangle=[m-1]_1^{1/2}|m-1\rangle, \tag{30}$$

where

$$[m]_q=(1-q^{m+1})/(1-q), \tag{31}$$

and m ranges in the interval $[0-\infty]$. In the limit $q\to 1$ we obtain the usual Bosonic oscillator and we recover the usual formulas.

Intuitively Eq. (27) tells us that when we use the Wick theorem for q-deformed harmonic oscillators, we must bring together the different terms we contract and for each term we get a factor q to the power of the number of object we have to cross.

If we use this result, we finally find the quite simple formula:

$$1+\beta U(\beta)=\langle 0|\,\frac{1}{1+\beta X}\,|0\rangle_q, \tag{32}$$

which gives a remarkable connection among the high temperature behavior of the Gaussian model and the q-deformed harmonic oscillator.

In this way we have reduced the combinatorial problem of computing the high temperature expansion to an algebraic problem.

F. Near the critical point

The problem now is reduced to the computation of the spectrum of the operator X of the q-deformed harmonic oscillator. The computation is apparently nontrivial. We are however interested to the computation of the spectral density near the largest eigenvalues.

A simple case is $q=1$, where the operator X_q is not bounded and the high temperature expansion is divergent. In this case X has a continuum spectrum and the highest eigenvalues of X are concentrated in the large m region. Let us assume that this feature is valid for q inside the interval $[-1,1]$. One finds that

$$\mathscr{L}_q \sim (1-q)^{-1/2}\mathscr{L}, \quad \mathscr{R}\sim(1-q)^{-1/2}\mathscr{R}. \tag{33}$$

when the operator is applied to a state $|m\rangle$ in the region of large m. ($\mathscr{L}$ and $\mathscr{R}$ are the two shift operators for $q=0$ which are used in the planar case.)

The difference among $\mathscr{L}_q$ and $(1-q)^{-1/2}\mathscr{L}$ can be seen only when the two operators act on a state of low m. It is very reasonable to assume that the spectral radius and the spectral density near the maximum eigenvalues is the same in the two case. We have verified numerically that this conjecture is consistent (at least for q not too close to 1) by estimating the spectral density of X_q in subspaces of various size ($m<M$, with M up to 300).

We find therefore that the critical temperature is given by

$$\beta_c=(1-q)^{1/2}/2, \tag{34}$$

which is the inverse of the spectral value of X, i.e.,

$$|X|^2=4/(1-q). \tag{35}$$

The behavior of the spectral density near the edge is the same as for the random matrix model, i.e., in spin glass. In this way we find the same critical exponents as in spin glasses in the Gaussian approximation.

A possible physical interpretation is the following. In computing the internal energy one has to sum over all the closed circuits. Circuits with large physical area average to zero and only fattened backtracking circuits survive. The situation is very similar to spin glasses, where only backtracking circuits contribute, the only effect being a renormalization of the temperature.

IV. THE HIGH TEMPERATURE EXPANSION

We have explained that we will construct the model based on the random couplings $\hat{U}$ by requiring that the high T expansion is the same than in the original model with complex frustration (and no disorder). Let us remark that both these models, the random one and the deterministic one, are *regular*, i.e., there are no couplings of $O(1)$ when $D\to\infty$. In other words all the U couplings and the $\hat{U}$ ones, after being multiplied times the appropriate $c(D)$ factor, go to zero in this limit. Under this condition the high temperature expansion for the XY model is equal to the one of the spherical model. One can verify this statement by checking that in the two cases (i.e., for the spherical for the XY model) the same diagrams survive in the $D\to\infty$ limit. This condition guarantees the absence of couplings of $O(1)$ which could break the equivalence.

Thanks to this result we will be able to start from computing the high T expansion of the spherical model, in order to work out results valid for the XY model. That will make our task far easier.

We denote the spectral density of the Laplacian operator by $\rho_\Delta(\lambda)$, and we express the trace of its nth moment as

$$2^{-D}\ \mathrm{Tr}(\Delta^n)=\int d\lambda\ \rho_\Delta(\lambda)\lambda^n. \tag{36}$$

Here the trace is taken over a space of dimensionality 2^D, and the normalizing factor 2^{-D} is such that the spectral density of the identity operator $\rho_1(\lambda)$ is $\delta(\lambda-1)$.

We start by remarking that the internal energy density of the Gaussian model is given in terms of $\rho_\Delta(\lambda)$ by

$$E_G=\int d\lambda\ \rho_\Delta(\lambda)\ \frac{\lambda}{1-\beta\lambda}. \tag{37}$$

By using the expression of the Hamiltonian which includes the spherical constraint, we find

$$E_S=\int d\lambda\ \rho_\Delta(\lambda)\ \frac{\lambda}{\mu(\beta)-\beta\lambda}, \tag{38}$$

where μ is a function of β. It is fixed by the condition

$$\int\ d\lambda\ \rho_\Delta(\lambda)\ \frac{1}{\mu(\beta)-\beta\lambda}=1, \tag{39}$$

which tells that $\langle\Sigma_i|\sigma_i|^2\rangle=N$, i.e., that the σ variables satisfy the spherical constraint.

Equations (38) and (39) can be written in a more compact form as

$$\mu(\beta)=R\left(\frac{\beta}{\mu(\beta)}\right), \tag{40}$$

$$E(\beta)=\frac{\mu-1}{\beta}, \tag{41}$$

where the function R is given by

$$R(z)=\int d\lambda\ \rho_\Delta(\lambda)\ \frac{1}{1-z\lambda}. \tag{42}$$

One uses (40) to determine μ, and inserting it in (41) one determines the internal energy density of the system.

The critical temperature β_c^{-1} is fixed by the condition that Eq. (40) does not admit a solution for $\beta>\beta_c$, i.e., is such that

$$z_c R(z_c)=\beta_c, \tag{43}$$

where z_c is the inverse of the largest eigenvalue of Δ.

In the limit $D\to\infty$, the function $R(z)$ has been defined in the previous section:

$$R(z)=\langle 0|\ \frac{1}{1-zX}\ |0\rangle. \tag{44}$$

It can be shown[10] that the function, $R(z)$ has a singularity of the form

$$R(z)=A(z_c^2-z^2)^{1/2}, \tag{45}$$

where

$$z_c=\sqrt{1-q}/2. \tag{46}$$

The critical behavior does not depend on q.

The critical temperature can be found from Eq. (43). A simple computation shows that the specific heat remains finite at the critical temperature.

V. OUR STRATEGY AND THE DEFINITION OF THE RANDOM MODEL

We will use here a strategy we have introduced in Refs. 1 and 2. We start with a model which does not contain quenched disorder, but that is complex enough to make us suspicious of the possible presence of a spin glass like phase for temperatures T low enough. We look for a model which contains quenched disorder, and that is similar enough to the original model to have potentially the same behavior (even in the low T phase, if we are very ambitious). Replica theory allows us to solve the random model, and to try and get information about the deterministic model. Reference 2 discusses successful examples of the use of this strategy.

Here we will adopt the same approach. We will introduce a model containing random quenched disorder. In this new model the new $\hat{U}$ couplings will be chosen at random [as opposed to the original U couplings which are determined by the deterministic equation (12) such to give us the needed complex frustration]. The random values of the $\hat{U}$ will be selected, following Ref. 2, such that the new free energy will have the same high temperature expansion than the original model. We will have a model where the couplings $\hat{U}$ will be distributed according to a probability distribution, determined from the request of finding the same high T expansion than in the original frustrated model. The original model will be this way by construction, a given (hopefully typical) realization of the coupling constants constructed according to this probability distribution.

Because of these remarks, and of our constructive procedure, the deterministic model and the random one coincide in the high T phase. We hope to learn as much as possible about the low T phase, and that the two models are also in this phase very similar.

We will have to start by computing the high temperature expansion for our model with complex frustration. Knowing that we will use a reverse engineering procedure in order to find out the probability distribution of random couplings $\hat{U}$ that have the same high temperature expansion. Finally we will use the replica theory to compute the low temperature behavior of the random model. For sake of simplicity we will present here the computation done under the hypothesis of no replica symmetry breaking. We will compare these analytic results to numerical simulations of the frustrated model.

We will consider a model containing quenched disorder that has the same form of the original model with complex deterministic frustration. In the random model the couplings $\hat{U}$ will be taken randomly among all matrices having the same spectral distribution of the deterministic model. More precisely for finite D we extract a set of 2^D values of the eigenvalues λ, such that

$$2^{-D} \sum_{j=1,2^D} \lambda_j^n \simeq \int d\lambda \ \rho_\Delta(\lambda)\lambda^n, \tag{47}$$

where ρ_Δ is the spectral density of the Laplacian operator, and will be discussed in more detail in next section. We finally set

$$\hat{U}_{i,k} = \sum_{j=1,2^D} V^*_{i,j}\lambda_j V_{j,k}, \tag{48}$$

where V is a random unitary matrix i a 2^D dimensional space.

VI. THE LOW TEMPERATURE REGION

In Sec. V we have discussed the high T region of the deterministic model with complex frustration. Monte Carlo has been done in this region and the data reproduce well (as expected) the

series obtained by computing the Green functions of the q-deformed harmonic oscillator. We also know that in the high T phase the model with quenched disorder coincides by construction with the deterministic model, but we will see that better in the following.

In order to get information about the low T phase we have to use the random model, which we have defined in Eqs. (47) and (48). We will use replica theory to solve it both in the high T phase (where we will find again the same high T series) and in the low T phase. We will try to understand how much the replica formulation of the system is connected to the Monte Carlo data which we will get directly from the deterministic model with complex frustration. This task will be achieved for the *single cell* model, where the computations are much simpler. It is quite possible that similar results can be obtained for the infinite volume model.

Let us solve the random model by using the techniques introduced in Ref. 2. The computation follows quite closely the one of Ref. 2, and we will give here only the main details. One introduces n replicas, where n has to be sent to zero at the end of the computation. The n-dependent free energy is given by

$$f^{(n)}(\beta)\equiv -\lim_{N\to\infty}\frac{1}{\beta N}\frac{\ln\overline{Z_U^n}}{n}, \tag{49}$$

where the bar denotes the average over the random couplings and the replicated partition function Z_U^n depends over the noise and can be written as

$$Z_U^n\equiv\int [d\sigma]\exp\left(-\beta\sum_{a=1}^{n} H_U^a\right). \tag{50}$$

The integration over the unitary group (i.e., the matrix V) can be done explicitly. After some algebra one finds that one has to evaluate the stationary points of the following free energy:

$$A[Q,\Lambda]=-\mathrm{Tr}\ G(\beta Q)+\mathrm{Tr}(\Lambda Q)-F(\Lambda), \tag{51}$$

where Q and Λ are $n\times n$ matrices, the function G is related to the one defined in Eq. (41) by

$$\frac{dG}{dz}\equiv E(z), \tag{52}$$

and

$$F(\Lambda)\equiv\ln\int d[\sigma]\exp\left(\sum_{a,b}\Lambda_{a,b}\sigma^a\sigma^b\right). \tag{53}$$

In the high temperature phase the off-diagonal terms of the two matrices Q and Λ are zero. If we set

$$Q_{a,b}=\delta_{a,b}q,$$

$$\Lambda_{a,b}=\delta_{a,b}\lambda, \tag{54}$$

we find that the stationary equations imply that

$$q=1 \quad \text{and} \quad \lambda=E(\beta). \tag{55}$$

We finally find that in the high temperature phase

$$\frac{\partial F}{\partial \beta} = E(\beta), \tag{56}$$

where $E(\beta)$ is the function defined in (52). In this way we have derived again the equivalence of the model with quenched disorder and the deterministic model with complex frustration in the high temperature phase.

In the low temperature region the off-diagonal terms of the two matrices are nonzero. If we assume that replica symmetry is unbroken, we have that the off-diagonal terms are given by

$$Q_{a,b} = q, \quad \Lambda_{a,b} = \lambda. \tag{57}$$

(We set $Q_{a,a}=1$. The value we choose for $\Lambda_{a,a}$ is irrelevant, and does not change the results.) In this way we find that we have to minimize the free energy

$$G(\beta(1-q)) + \beta q E(\beta(1-q)) - \lambda q + f(\lambda), \tag{58}$$

where the function f is given by

$$\ln\left(\int dh \, \exp(-h^2/2) \right) \ln\left(\int d\sigma_r \, d\sigma_i \, \delta(\sigma_r^2 + \sigma_i^2 - 1) \exp(-\lambda^{1/2} h \sigma_r) \right). \tag{59}$$

The energy turns out to be

$$E(\beta) = G'(\beta(1-q)) - \beta q (1-q) G''(\beta(1-q)). \tag{60}$$

By deriving this expression and evaluating it for $\beta=\beta_c$ we find that

$$C_V(\beta_c^+) = C_V(\beta_c^-) = 1. \tag{61}$$

The critical temperature can also be determined through the relation

$$\beta_c^2 G''(\beta_c) = 1. \tag{62}$$

One also finds that at zero temperature

$$C_V(\infty) = \tfrac{1}{2}, \tag{63}$$

in agreement with the equipartition theorem.

The equations which determine the minimum of such free energy can be solved numerically.

We will show and discuss their solution in Sec. VII, for different q values, together with the Monte Carlo results in the low T phase.

We expect the unbroken replica solution to give rather accurate values for the free energy. In the SK model the error over the correct, replica broken result is smaller than 3%, and it is likely to be even smaller in the present case. It is interesting to note that the replica symmetric solution normally gives a lower bound to the true free energy and to the true internal energy of the system. Numerical simulations show that when we compare numerical simulations of the deterministic model to the replica symmetric solution of the disordered model in the cold phase this is not always the case in our system, pointing to a non complete coincidence of the two models.

VII. COMPUTER SIMULATIONS

We will describe here the numerical simulations of the model with complex frustration, defined with the couplings of Eq. (12), and compare them with the analytic solution of the model with quenched disorder that we have discussed in Sec. III. Here we will mainly focus on the low T phase.

In Ref. 2, systems of size 2 have simulated with D going from 3 to 16, i.e., containing from 8 to 65 536 sites. In the high temperature phase everything is in reasonable agreement with the theoretical predictions.

In the low T phase we will compare the analytic solution of the random model (47) with the numerical simulation of the deterministic model. We will use the replica symmetric solution, which we believe is not too wrong. We shall see that the data are indicative of a strong similarity, but maybe not of a complete equivalence of the two models.

The agreement of Monte Carlo data for the deterministic model and replica symmetric solution of the random model is quite good also in the broken phase, for $T<T_c$. We expect that the solution with broken replica symmetry will have an energy slightly higher than the unbroken one (as we already said, in the general case the replica symmetric energy is a lower bound to the true energy of the physical system). Very small residual finite size effect and this small energy drift to the the breaking of replica symmetry should explain the small discrepancy between the numerical data and the analytic curve. So in the case of the $q=0$ model things seem to go smoothly.

When moving on the side of negative q values things do not change much, and if there is a discrepancy it is very small. This is completely in agreement with the discussion of the behavior of the coefficients of the high T expansion of Sec. VI.

In conclusion, it seems that for $q<0$ and even for small q positive values the replica theory describes the deterministic model with very high accuracy. On the contrary for $q<0$ not so small there is a clear, even if quite small discrepancy between the two models. It is quite possible, although it looks strange, that the discrepancy is due to finite volume effects and to a very slow convergence of the $1/D$ expansion. The computation of the $1/D$ corrections in the low temperature phase would be quite useful to resolve this dilemma.

(Received 10 December 1995; accepted for publication 17 June 1996)

A model of the periodic array of quantum antidots in the presence of a uniform magnetic field is suggested. The model can be conceived as a periodic lattice of resonators (curvilinear triangles) connected through ''infinitely small'' openings at the vertices of the triangles. The model Hamiltonian is obtained by means of operator extension theory in indefinite metric spaces. In the case of rational magnetic flux through an elementary cell of the lattice, the dispersion equation is found in an explicit form with the help of harmonic analysis on the magnetic translation group. It is proved, at least in the case of integer flux, that the spectrum of the model Hamiltonian consists of three parts: (1) Landau levels (they correspond to the classical orbits lying between antidots); (2) extended states that correspond to the classical propagation trajectories; and (3) bound states satisfying the dispersion equation; they correspond to the classical chaotic orbits rotating around single antidots. Among other things, methods of finding the Green's function for some planar domains with curvilinear boundaries are derived. © *1996 American Institute of Physics.* [S0022-2488(96)01410-7]

I. INTRODUCTION

Beginning with the works of Azbel,[1] Hofstadter,[2] and Wannier,[3] unusual spectral properties of two-dimensional periodic systems in a quantizing magnetic field **B** attract ever increasing attention. The most interesting properties of these systems are connected with the presence of two natural geometric scales, namely, the magnetic length and the size of the unit cell of the period lattice. The commensurability (or incommensurability) of the scales leads to such a pecularity of the systems as the transition from the band structure of the spectrum to the fractal one (Hofstadter butterfly).[4,5] This pecularity is important in the theory of the quantum Hall effect (see Refs. 6, 7, and references therein). Nevertheless, because the number η of flux quanta through a unit cell of a crystal lattice is very small for the experimentally accessible values of $B(\eta \sim 10^{-3})$, no energy spectrum of the Hofstadter type is observable in usual quantum Hall systems. Advances in micropatterning of two-dimensional electron systems at semiconductor interfaces have rendered it possible to fabricate a so-called periodic dot array, which is obtained by a laterally periodic modulation of the confining potential of electrons in the system. In the periodic dot array the above-mentioned geometric scales are comparable, and, in consequence, an experimental observation of the Hofstadter butterfly has been made possible.[8] Curiously, Hofstadter himself wrote in 1979 that he ''would be the most surprized person in the world if the butterfly came out of any experiment.'' [9]

A reversed structure to a dot array, i.e., periodic ''antidot'' array is obtained by inducing an periodic array of voids in a two-dimensional electron gas.[10,11] The magnetotransport experiments

with the antidot array show that such a structure can be considered the solide-state realization of a Sinai billiard.[12–16] The experiments unveiled a series of low-B resistance peaks at commensurate B, for which the classical cyclotron orbit encompasses a particular number of antidots. A detailed semiclassical analysis of the transport anomalies in the antidot lattice leads to the conclusion that they stem from electrons trapped on classically chaotic trajectories for commensurate B.[17] The presence of such trajectories should lead to the appearance of bound states in the quantum-mechanical energy spectrum of the system. A numerical investigation of the propagator of a charged particle in a periodic antidot array has been performed by Stratford and Beeby,[18] their results suggest that bound states appear at the condition of the commensurability of the cell size and the magnetic length.

Up to the present there is no complete quantum-mechanical theory of billiard phenomena in the antidot array. In this connection various approximate models are of special interest. The aim of the paper is to construct and study an explicitly solvable model of a periodic antidot array by means of operator extension theory.

Let us describe the basic idea of the construction, introducing simultaneously some notations. Let Γ be a two-dimensional crystal lattice, i.e., $\Gamma=K+\Lambda\equiv\{\kappa+\lambda:\kappa\in K,\ \lambda\in\Lambda\}$, where Λ is a Bravais lattice (a discrete additive subgroup of $\mathbf{R}^2$ with two generators $\mathbf{a}_1$, $\mathbf{a}_2$), and K is a finite subset of the elementary cell $C_\Lambda=\{t_1\mathbf{a}_1+t_2\mathbf{a}_2\colon\ 0\leqslant t_1,\ t_2<1\}$ of Λ; we assume without loss of generality that $0\in K$. We can represent the collection of the voids in the array in the form $V+\Gamma$, where V is a bounded domain in $\mathbf{R}^2$ with the picewise smooth boundary such that $0\in V$ and $(V+\gamma)\cap(V+\gamma')=\varnothing$ if $\gamma,\ \gamma'\in\Gamma,\ \gamma\neq\gamma'$. A realistic quantum-mechanical Hamiltonian of the system should be the operator

$$\hat{H}=(-i\boldsymbol{\nabla}-\mathbf{A})^2, \tag{1}$$

in the domain $G=\mathbf{R}^2\backslash(V+\Gamma)$ with the Dirichlet boundary conditions on ∂G; here $\mathbf{A}$ is the vector potential of the magnetic field. In spite of seeming simplicity, the model with the Hamiltonian $\hat{H}$ is far from being explicitly soluble. It is reasonable in this connection to consider two limiting cases.

(1) *V is small enough.*

In the limit of ''infinitesimal'' V we get the model of periodic point interactions.[19,20] It is known that the energy spectrum of the model contains bound states (namely, unbroadened Landau levels) if η is greater than the number of elements in K. This fact was discovered in numerical experiments by Ando[21] and rigorously proved in Refs. 22 and 23; also see Ref. 24. Nevertheless, it seems likely that the point interaction model is not relevant to the problem in question. The appearance of the bound states in the spectrum of the model is connected with the number of points in K rather than with the sizes of C_Λ and V.

Now let us take up another limiting case.

(2) *V is so large that $V+\gamma$ and $V+\gamma'$ touch one another.*

We restrict our attention to the most interesting case of the honeycomb lattice Γ; in this case $|\mathbf{a}_1|=|\mathbf{a}_2|$, $\widehat{\mathbf{a}_1\mathbf{a}_2}=60°$, $K=\{0,\mathbf{b}\}$, where $\mathbf{b}=2(\mathbf{a}_1+\mathbf{a}_2)/3$ (Fig. 1). At first we suppose that V is a circle, therefore the collection of the voids in the considered array is the densest packing of equal disks (Fig. 2). Hence, $G=\Omega+\Gamma$, where Ω is a curvilinear equilateral triangle with zero angles (Fig. 3). We shall denote in the course of the paper $\Omega_\gamma=\Omega+\gamma$, hence $G=\cup_{\gamma\in\Gamma}\Omega_\gamma$. Obviously, the state space $\mathscr{H}^0$ is isomorphic to the direct sum $\mathscr{H}^0=\Sigma_{\gamma\in\Gamma}\oplus\mathscr{H}^0_\gamma$, where $\mathscr{H}^0_\gamma=L^2(\Omega_\gamma)$, and the Hamiltonian H^0 of the model has the form $H^0=\Sigma_{\gamma\in\Gamma}\oplus H^0_\gamma$, where H^0_γ is defined by the differential expression (1) in the domain Ω_γ and the Dirichlet boundary conditions on $\partial\Omega_\gamma$. The obtained operator corresponds to the absence of any charge transport between domains Ω_γ. To get a nontrivial model Hamiltonian we employ the ''restriction-extension'' procedure.[19,25] Notice that this procedure found use in constructing and studying of explicitly soluble models of crystals[26] and quantum dot arrays.[27,28] Intuitively, we puncture the boundary $\partial\Omega_\gamma$ of every curvilinear tri-

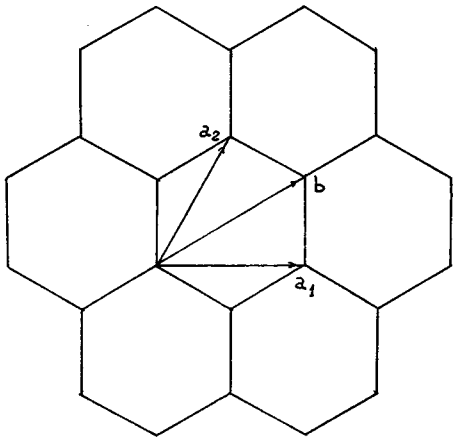

FIG. 1. Honeycomb lattice; $\mathbf{a}_1$, $\mathbf{a}_2$ are basic vectors, $b=2(\mathbf{a}_1+\mathbf{a}_2)/3$.

angle Ω_γ in each vertex to connect the domains Ω_γ with each other.[29,30] From the mathematical point of view we restrict the operator H^0 to the set of smooth functions that vanish near the vertices of the triangles Ω_γ. Nontrivial (i.e., different from H^0) self-adjoint extensions of such a restriction S_0 can be considered as a model Hamiltonian H of the antidot array. Nevertheless, the operator S_0 is essentially self-adjoint, therefore it has no nontrivial self-adjoint extensions in the space $L^2(G)$. Beginning with the Berezin[31] paper on the Lee model of the quantum field theory self-adjoint extensions in Pontryagin or Krein spaces containing $L^2(G)$ are common. A general mathematical formalism for such extensions is elaborated by Shondin,[32] in an easy-to-use form; the formalism is explained in Ref. 33. In Refs. 34 and 35 this method has been used to solve some problems that are similar to those of the present paper. In the cited papers the method of operator extensions in indefinite inner product spaces is developed for Pontryagin spaces only, but in our

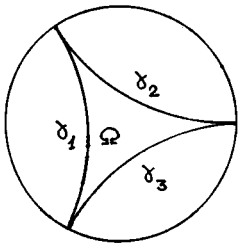

FIG. 3. Curvilinear triangle Ω.

situation we can use this method mutatis mutandis for Krein spaces also.[36] We do not consider the physical status of the state spaces with an indefinite metric, but, seemingly, some comments are necessary. Dirac[37] and Pauli[38] are the first to use the indefinite inner product spaces in some problems of quantum mechanics; also see Ref. 39 and references therein. In Refs. 32, 33, and 40, the physical meaning of the state spaces with indefinite metric and self-adjoint operators in them are discussed in the context of point perturbations.

The paper is organized as follows. To have an explicitly soluble model, we need a description of the Green's function for the domain Ω. Such a description is given in the first part of Sec. II for the case of a curvilinear triangle with zero angles and for the Hamiltonian with zero magnetic field. The description is represented in a convenient form for numerical analysis; such an analysis of our periodic model will be explained elsewhere. Two last parts of Sec. III are devoted to an auxiliary (with relation to our main goal) problem, namely, we show how ''to switch on'' the tunneling between two curvilinear triangles. In this part we offer a method to construct the indefinite inner product space in question. The results of Sec. II are of independent interest also; they describe a model of two coupled quantum dots of a complicated form and generalize some results of Ref. 35.

In Sec. III we present the above-mentioned quantum-mechanical lattice model of a periodic antidot array. The Hamiltonian of the model is invariant with respect to the magnetic translation group.[41] In the case of the rational flux, as it is called, we use the harmonic analysis on the magnetic translation group to represent the model Hamiltonian as a direct integral of finite-dimensional operators. Hence we reduce the spectral problem for the Hamiltonian to an eigenvalue problem of linear algebra, and what is more, in the case of rational flux we obtain the dispersion equation in an explicit form. The formalism used in Sec. III is a generalization of that in Ref. 23 and employs an appropriate modification of the Krein resolvent formula.[42] In conclusion, we prove a main result of the paper, namely, the existence of bound states in the model spectrum that are different from levels of the unperturbed operator H^0. Such states may be considered as quantum-mechanical counterparts of above-mentioned chaotic trajectories. As the final result, we obtain that the spectrum of the model Hamiltonian H_A in the presence of a strong magnetic field consists of three parts: (1) Landau levels that correspond to the classical orbits lying between antidots; (2) extended states that are solutions of the dispersion equation (45); they correspond to the classical propagation trajectories; and (3) bound states that are solutions of Eq. (45) also and correspond to the classical chaotic orbits rotating around a single antidot. The described structure of the spectrum coinsides with that obtained by numerical calculation.[43]

It should be especially stressed that the results of Sec. III do not depend on a particular form of the Green's function of the unperturbed operator H^0, therefore the zero-field restriction of Sec. II does not obstruct the proof of our main result.

II. THE MODEL OF TWO COUPLED TRIANGLES

In this section we show how to find the Green's function of the Laplace–Dirichlet operator in a curvilinear equilateral triangle with zero angles. Then we construct an explicitly soluble model

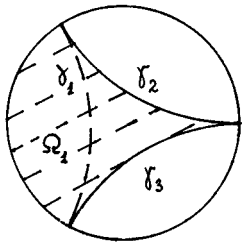

FIG. 4. The auxiliary domain $\hat{\Omega}_1$; γ_i $(i=1,2,3)$ are arcs of a circle (the boundary of the curvilinear triangle Ω).

of two ''quantum dots'' coupled with each other by a small opening; the dots are two curvilinear triangles having only one common point, which is a common vertex of the triangles. The role of such a model in the context of the model of an antidot array is described in the Introduction.

A. Green's function for a curvilinear triangle

Here we consider the most complicated case of a curvilinear triangle with zero angles. At first, we describe the Green's function for the Dirichlet problem in the auxiliary domain $\hat{\Omega}_1$ shown in Fig. 4. Let us map this domain onto a semistrip $\tilde{\Omega}_1$ by a linear-fractional transformation $z=f(\zeta)$. Then the equation for the desired Green's function G_1,

$$-\Delta_z G_1(z,z';\lambda)=\delta(z-z')+\lambda G_1(z,z';\lambda),$$

takes the following form:

$$-\Delta_\zeta \tilde{G}_1(\zeta,\zeta';\lambda)=|f(\zeta)|^{-2}\delta(\zeta-\zeta')+\lambda|f(\zeta)|^{-2}\tilde{G}_1(\zeta,\zeta';\lambda).$$

For the case $\lambda=0$,

$$\tilde{G}_1(\zeta,\zeta';0)=G_{\text{strip}}(\zeta,\zeta';0)-G_{\text{strip}}(\zeta,\zeta'';0),$$

where G_{strip} is the Green's function for the strip, ζ'' is the mirror image of the point ζ' with respect to the end of the semistrip $\tilde{\Omega}_1$.

In the case of nonzero λ we obtain the Lippmann–Shwinger equation for the function $\tilde{G}_1(\zeta,\zeta';\lambda)$:

$$\tilde{G}_1(\zeta,\zeta';\lambda)=\tilde{G}_1(\zeta,\zeta';0)+\lambda|f(\zeta)|^{-2}\int_{\tilde{\Omega}_1}|f(\xi)|^{-2}\tilde{G}_1(\xi,\zeta';0)d\xi.$$

It is essentially a one-dimensional integral equation that can be solved by ordinary methods. In a similar way we can describe the Green's functions for the domains $\tilde{\Omega}_2$ and $\tilde{\Omega}_3$ obtained by the cyclic permutation of γ_1, γ_2, and γ_3. The corresponding Green's functions we denote as G_2 and G_3.

Now we consider the Green's function for the curvilinear triangle Ω (Fig. 2). Let G_0 be the Green's function for the circumscribed circle, v_i $(i=1,2,3)$ be some functions defined on γ_i (densities). We seek the Green's function for Ω in the form

$$G=G_0+P_1(v_2\dot{+}v_3)+P_2(v_3\dot{+}v_1)+P_3(v_1\dot{+}v_2).$$

Here P_i is an integral operator with the Poisson kernel $P_i(x,s)=\partial G_i(x,s)/\partial n_s$, and $v_i \dot{+} v_j$ is the function coinciding with v_i on γ_i and with v_j on γ_j. Bearing in mind the Dirichlet boundary condition, one comes to the following system of integral equations:

$$G|_{\gamma_1}=0=G_0|_{\gamma_1}+P_1(v_2\dot{+}v_3)|_{\gamma_1}+2v_1,$$

$$G|_{\gamma_2}=0=G_0|_{\gamma_2}+P_2(v_3\dot{+}v_1)|_{\gamma_2}+2v_2,$$

$$G|_{\gamma_3}=0=G_0|_{\gamma_3}+P_1(v_1\dot{+}v_2)|_{\gamma_3}+2v_3. \tag{2}$$

Here we take into account that

$$P_2(v_3\dot{+}v_1)|_{\gamma_1}=P_2(v_3)|_{\gamma_1}+P_2(v_1)|_{\gamma_1}=0+v_1,$$

and analogously,

$$P_i(v_j)|_{\gamma_k}=0, \quad \text{if } i,j,k, \text{ are three different indices,}$$
$$P_i(v_j)|_{\gamma_j}=v_j, \quad i\neq j,$$
$$P_i(v_j\dot{+}v_k)|_{\gamma_i}=K_{ij}v_j+K_{ik}v_k, \quad i\neq j,$$

where K_{ij} are integral operators.

Consider the problem of solvability of the system (2). If $\lambda<0$, then one has, in accordance with the maximum principle:

$$|P_i(v_j\dot{+}v_k)|_{\gamma_i}|\leqslant\max\{\|v_j\|_{C(\gamma_j)},\|v_k\|_{C(\gamma_k)}\}. \tag{3}$$

Here $C(\gamma_j)$ is the space of continuous functions on γ_j. The system (2) takes the form

$$G_0|_{\gamma_1}+2v_1+K_{12}v_2+K_{13}v_3=0,$$

$$G_0|_{\gamma_2}+2v_2+K_{23}v_3+K_{21}v_1=0, \tag{4}$$

$$G_0|_{\gamma_3}+2v_3+K_{31}v_1+K_{32}v_2=0.$$

The equations are considered in the space $\widetilde{C}=C(\gamma_1\cup\gamma_2\cup\gamma_3)$. Let K denote the matrix with the elements K_{ij}, where we put $K_{ii}=0$, and let $V=(v_1,v_2,v_3)$. Then the system (4) can be rewritten in the form

$$2^{-1}G_0+V+2^{-1}KV=0, \tag{5}$$

where, in accordance with (3), one get $\|K\|_{\widetilde{C}}\leqslant 1$. Hence it is possible to solve the system by iterations:

$$V=-2^{-1}G_0+2^{-2}KG_0-2^{-3}K^2G_0+\cdots.$$

For $\lambda>0$ the situation is more complicated because there are eigenvalues in this case. Write G_j in the form

$$G_j(\lambda)=G_j(0)+\sum_{k=0}^{n}\lambda^k(G_j(0))^{k+1}+\lambda^{n+1}(G_j(0))^{n+1}G_j(\lambda)$$

(this relation is the iterated Hilbert identity, see, for example, Popov[34]). Let n be so large that the series

$$\sum_{l=1}^{\infty} \frac{|\phi_l\rangle\langle\phi_l|}{\lambda_l^{n+1}(\lambda_l-\lambda)},$$

converges for each λ outside the spectrum of the Dirichlet problem for $\hat{\Omega}_j$. Let λ range over a bounded set. Then this set contains only a finite number of eigenvalues, e.g., $\lambda_1,...,\lambda_N$. Hence the representation of the Green's function G_j takes the form

$$G_j(\lambda)=G_j(0)+\sum_{k=0}^{n}\lambda^k(G_j(0))^{k+1}+\lambda^{n+1}\sum_{l=1}^{N}\frac{|\phi_l\rangle\langle\phi_l|}{\lambda_l^{n+1}(\lambda_l-\lambda)}+\lambda^{n+1}\sum_{l=N+1}^{\infty}\frac{|\phi_l\langle\phi_l|}{\lambda_l^{n+1}(\lambda_l-\lambda)}.$$

We obtain the similar expression for the Poisson kernel:

$$P_j(\lambda)=P_j(0)+\sum_{k=0}^{n}\lambda^k\left(\frac{\partial}{\partial n}G_j(0)\right)^{k+1}+\lambda^{n+1}\sum_{l=1}^{N}\frac{|\phi_l\rangle\langle(\partial/\partial n)\phi_l|}{\lambda_l^{n+1}(\lambda_l-\lambda)}$$
$$+\lambda^{n+1}\sum_{l=N+1}^{\infty}\frac{|\phi_l\langle(\partial/\partial n)\phi_l|}{\lambda_l^{n+1}(\lambda_l-\lambda)}.$$

Note that in this expression $P_j(0)$ is a contracting operator, the second term is smooth with respect to λ, the third term is finite dimensional, and the fourth one is small for an appropriate choice of n and N. Substituting this expression into (4), we represent the operator K in the form

$$K=K_0+K_1+K_2+K_3,$$

where the operator K_0 is a contraction, K_1 is a finite-dimensional operator, K_2 is smooth, and K_3 is an operator with a small norm. Taking into account the character of singularity of the two-dimensional Green's function, one can see that it is possible to choose $n=0$, consequently, there is no smooth term K_2 in the expression

$$K=K_0+K_1+K_3.$$

Hence the equation (5) takes the form

$$2^{-1}G_0+V+2^{-1}K_0V+2^{-1}K_1V+2^{-1}K_3V=0.$$

Since $\|2^{-1}K_0\|\leqslant 2^{-1}$, we have $\|2^{-1}K_0+2^{-1}K_3\|<1$ for an appropriate choice of N. Consequently, the operator $I+2^{-1}K_0+2^{-1}K_3$ is a reversible one. Then we have

$$V+(2I+K_0+K_3)^{-1}K_1V+(2I+K_0+K_3)^{-1}G_0=0.$$

The operator $(2I+K_0+K_3)^{-1}K_1$ is finite dimensional, hence it is reversible for λ different from eigenvalues. Thus we prove that the system (2) is solvable if λ range over a bounded set of half-line containing no eigenvalues.

B. Two coupled curvilinear triangles with nonzero angles

To explain the basic idea of this part we consider at first a planar domain Ω^{in} with the smooth boundary $\partial\Omega^{\text{in}}$. Let $\Omega^{\text{ex}}=\mathbf{R}^2\backslash\overline{\Omega^{\text{in}}}$, $x_0\in\partial\Omega^{\text{in}}$. We shall consider the operator $-\Delta=-(\Delta^{\text{in}}\oplus\Delta^{\text{ex}})$, where Δ^{in} and Δ^{ex} are the Laplace operators with the Neumann boundary conditions in domains Ω^{in} and Ω^{ex}, respectively.

Let us restrict this operator to the set of smooth functions vanishing near the point x_0, then we obtain a symmetric operator S_0 with the deficiency indices (2,2). Therefore S_0 has self-adjoint extensions that are different from $-\Delta$. Each such extension may be considered as a model of an

obstacle Ω^{in} with very small opening around the point x_0. It was shown that one can choose the parameters of the extension in such a way that its Green's function coincides with the leading term of the asymptotics of the Green's function for the obstacle with an opening of small but finite diameter, as the diameter tends to zero.[35] It means that the suggested model of an opening in the obstacle is rather realistic. Furthermore, this model is a solvable one in the following sense: if the solutions of the spectral or scattering problems in the domains Ω^{in} and Ω^{ex} without opening are known, one can obtain the corresponding solutions for the model operator in an explicit form. The described model has also another advantage: the model Green's function and the model solution of scattering problem have the same analytical properties as the corresponding ''realistic'' Green's function and the solution of a ''realistic'' scattering problem.

In a similar way we can proceed in the case of two planar domain Ω^i, $i=1,2$, with the smooth boundaries, having no common interior points but a common point x_0 of their boundaries. The situation changes radicaly in the case of Dirichlet boundary conditions because the singular solutions with the singularity at the point x_0 do not belong to the space L^2 in this case (the singularity is too strong). If Ω^i are curvilinear triangles with a common vertex x_0, some additional obstacles arise connected with singularities of boundaries at the point x_0. We overcome all this difficulties by using operator extension theory in indefinite inner product spaces (see the Introduction).

Let us consider two equal nonoverlapping curvilinear equilateral triangles Ω^1 and Ω^2 having only one common vertex x_0. We shall distinguish two cases: (i) *the angles are equal to* π/p, $p\in\mathbf{N}$; (ii) *the angles are equal to zero.*

The case of zero angles will be discussed in the final part of the section; in what follows we assume that angles are equal to π/p, $p\in\mathbf{N}$. In this case the principal singularity of the Green's function has the order r^p. To construct the nontrivial self-adjoint extensions of the operator S_0 it is necessary to extend the initial state space $L^2(\Omega^1\cup\Omega^2)$ by adding the corresponding pth multipole. More precisely, let $G_p^j(x,k) = Q_p(-\nabla_y)G_D^j(x,y;k)|_{y=x_0}$, where G_D^j is the Green's function for the Dirichlet problem in Ω^j and $Q_p(x)$ is the harmonic polynomial corresponding to the singularity. Let A_p^j be the following set of functions:

$$A_p^j=\left\{ f\in L^2(\Omega^i)\colon \int_{\Omega^j}|f(x)||x-x_0|^{-p-1}\,dx<\infty\right\}.$$

Introduce the chain of functions,

$$h^j_{-p,p}(x)=G_p^j(x,k_0),\quad h^j_{-p+2,p}(x)=(-\Delta^j-\lambda_0)^{-1}h^j_{-p,p},\ldots,$$

$$h^j_{p,p}(x)=(-\Delta^j-\lambda_0)^{-p}h^j_{-p,p}.$$

Here k_0 is a fixed imaginary number such that $\lambda_0=k_0^2$ is a regular point of the Laplace–Dirichlet operator $H_j=-\Delta^j$. Consider the set $\mathscr{H}_p^j$:

$$\mathscr{H}_p^j=\{f^j\colon f^j=f_p^j+C^j_{p,p}h^j_{p,p}+\cdots+C^j_{-p,p}h^j_{-p,p}\},$$

where $f_p^j\in A_p^j$. We define the scalar product in the space $\mathscr{H}_p^j$ in the following way:

$$(f,g)_{\mathscr{H}_p^j}=(f_p,g_p)_{L^2}+\sum_{r=-p}^{p-2}\int_{\Omega^j}f_p(x)\overline{C^j_{r,p}(g)h^j_{r,p}(x)}dx+\sum_{r=-p}^{p-2}\int_{\Omega^j}C^j_{r,p}(f)h^j_{r,p}(x)\overline{g_p(x)}dx$$
$$+\sum_{r,q=-p}^{p-2}C^j_{r,p}(f)\overline{C^j_{q,p}(g)}[h^j_{r,p},h^j_{q,p}],\tag{6}$$

where

$$[h^j_{r,p},h^j_{q,p}]=\begin{cases}\int_{\Omega^j} h^j_{r,p}(x)\overline{h^j_{q,p}(x)}dx, & \text{if the integral converges,}\\ 0, & \text{otherwise.}\end{cases} \tag{7}$$

The set $\mathscr{H}^j_p$ is imbedded as a linear set into the Pontryagin space Π_κ [$\kappa=p/2$ for even p, and $\kappa=(p+1)/2$ for odd p] by the standard way.[31,44]

Define an operator $\widetilde{S}_{p,j}$ in the following way. The domain of the operator is

$$\mathscr{D}(\widetilde{S}_{p,j})=\{f^j\in\mathscr{H}^j_p: f^j_p\in W^2_{2,\mathrm{loc}}(\Omega^j),\quad f_p=f^j_{p+1}+Ch^j_{p,p}\},$$

where f^j_{p+1} belongs to A^j_{p+1} and $(-\widetilde{S}_{p,j}-\lambda_0)f^j_{p+1}\in A^j_p$. On the set A^j_p the operator $\widetilde{S}_{p,j}$ acts by definition as the Laplacian, and on the chain $\{h^j_{r,p}\}$ the operator $(-\widetilde{S}_{p,j}-\lambda_0)$ is the shift operator:

$$(-\widetilde{S}_{p,j}-\lambda_0)h^j_{r,p}=h^j_{r-2,p}.$$

Lemma 2.1: The operator $\widetilde{S}_{p,j}$ is self-adjoint.

Proof: It is easy to check by direct calculations that $\widetilde{S}_{p,j}$ is symmetric. The relation,

$$(-\widetilde{S}_{p,j}-\lambda_0)\mathscr{D}(\widetilde{S}_{p,j})=\mathscr{H}^j_p,$$

implies that it is self-adjoint. ■

Remark: It is worth noting that not only λ_0, but the whole negative half-line, belongs also to the set of regular points of the operator $-\widetilde{S}_{p,j}$. It is simple to show that the space $\mathscr{H}^j_p$ does not depend on the choice of λ_0.

Consider the functional χ_j, defined on the space $\mathscr{D}(\widetilde{S}_{p,j})$ by the relation

$$(f,\chi_j)=((-\widetilde{S}_{p,j}-\lambda_0)f,h^j_{-p,p});$$

this functional is called the generalized deficiency element of the operator $-\widetilde{S}_{p,j}$.[31] Formally we can write

$$\chi_j=(-\widetilde{S}_{p,j}-\lambda_0)h^j_{-p,p}.$$

Restrict the operator $\widetilde{S}_{p,j}$ onto the following set:

$$\mathscr{D}(S^0_{p,j})=\{f\in\mathscr{D}(\widetilde{S}_{p,j}):(f,\chi_j)=0\}.$$

We denote the obtained operator as $S^0_{p,j}$.

Lemma 2.2: The operator $S^0_{p,j}$ is symmetric and has the deficiency indices (1,1).

Proof: Really, for each function f from $\mathscr{D}(S^0_{p,j})$ one has

$$((-\widetilde{S}_{p,j}-\lambda_0)f,h^j_{-p,p})=0.$$

Since $\mathscr{H}^j_p$ is densely imbedded into Π_κ, $S^0_{p,j}$ has no other deficiency elements. ■

Thus the operator $\widetilde{S}_p=\widetilde{S}_{p,j}\oplus\widetilde{S}_{p,2}$ is a self-adjoint one and the operator $S_p=S^0_{p,1}\oplus S^0_{p,2}$ is symmetric with the deficiency indices (2,2). Therefore the operator S_p has self-adjoint extensions. The domain of such an extension is an annihilator subspace of the following ''boundary form'' on $\mathscr{D}(S^*_p)$:

$$J(f,\phi)=((-S^*_p-\lambda_0)f,\phi)-(f;(-S^*_p-\lambda_0)\phi).$$

Now let us describe $\mathscr{D}(S^*_p)$.

Lemma 2.3: The set $\mathscr{D}(S_P^*)$ *consists of all elements* f *from* $\mathscr{D}(\widetilde{S}_p)$ *satisfying the condition* $C^1_{p,p}(f)=C^2_{p,p}(f)=0$.

Proof: Remark that in accordance with the definition (6) of the inner product in the space $\mathscr{H}^j_p$, the relations

$$((-\widetilde{S}_{p,j}-\lambda_0)h^j_{r,p},h^j_{-p,p})=0,\quad j=1,2,$$

hold for each $h^j_{r,p}$, $-p<r<p$. In virtue of the Green's formula we have for each f^j_p from $\mathscr{D}(\widetilde{S}_{p,j})$, $j=1,2$:

$$\int_{\Omega^j}(-\widetilde{S}_{p,j}-\lambda_0)f^j_p(x)\overline{h^j_{-p,p}(x)}dx=\lim_{\epsilon\to 0}\int_{\Sigma^j_\epsilon}\left(f^j_p\frac{\partial\overline{h^j_{-p,p}}}{\partial n}-\overline{h^j_{-p,p}}\frac{\partial f^j_p}{\partial n}\right)dx=C^j_{p,p}(f).$$

Hence

$$((-\widetilde{S}_{p,j}-\lambda_0)f^j_p,h^j_{-p,p})=C^j_{p,p}(f),$$

and the lemma follows from this equality. ■

Note that $C^j_{p,p}(f)$ are the corresponding coefficients of the asymptotics (of the order r^p) of the function f_p near the point x_0 multiplied by a constant that is independent of f.

Lemma 2.3 leads immediately to the following statement.

Lemma 2.4: $\mathscr{D}(S_p^*)=\{f\in\mathscr{H}_p: f_p=f_{p+1}+\alpha h_{p,p},\alpha\in\mathbf{C}\}$. ■

Remark: Lemma 2.4 is equivalent to the assertion

$$\mathscr{D}(S_p^*)=\mathscr{D}(S_p)+\mathscr{N}_{\lambda_0},$$

where $\mathscr{N}_{\lambda_0}$ is the deficiency subspace corresponding to λ_0.

Let us consider the boundary form $J(f,\phi)$ thoroughly:

$$J(f,\phi)=J^1(f,\phi)+J^2(f,\phi),$$

$$\begin{aligned}J^j(f,\phi)=&((-S_p^*-\lambda_0)f^{(0),j},\phi^{(0),j})+((-S_p^*-\lambda_0)f^{(0),j},C^i_{-p,p}(\phi)h^j_{-p,p})\\&-(C^i_{-p,p}(f)h^j_{-p,p},(-S_p^*-\lambda_0)\phi^{(0),j})-(f^{(0),j},(-S_p^*-\lambda_0)\phi^{(0),j}),\end{aligned}$$

where $f^{(0),j},\phi^{(0),j}\in\mathscr{D}(\widetilde{S}_{p,j})$, $j=1,2$. Taking into account the self-adjointness of the operator $\widetilde{S}_{p,j}$, one gets

$$\begin{aligned}J(f,\phi)=&((-S_p^*-\lambda_0)f^{(0),1},C^1_{-p,p}(\phi)h^1_{-p,p})-(C^1_{-p,p}(f)h^1_{-p,p},(-S_p^*-\lambda_0)\phi^{(0),1})\\&+((-S_p^*-\lambda_0)f^{(0),2},C^2_{-p,p}(\phi)h^2_{-p,p})-(C^2_{-p,p}(f)h^2_{-p,p},(-S_p^*-\lambda_0)\phi^{(0),2}).\end{aligned}$$

After brief calculations one obtains

$$J(f,\phi)=C^1_{p,p}(f)\overline{C^1_{-p,p}(\phi)}-C^1_{-p,p}(f)\overline{C^1_{p,p}(\phi)}+C^2_{p,p}(f)\overline{C^2_{-p,p}(\phi)}-C^2_{-p,p}(f)\overline{C^2_{p,p}(\phi)}.$$

To construct a self-adjoint extension it is necessary to study the condition of annihilation of the boundary form. Let us note that the algebraic structure of the form is the same as for conventional zero-width slit model,[35] that is why its analysis is similar to one in the cited paper (the problem now reduces to the problem of linear algebra). The result is the following description of all self-adjoint extensions $H_{A(p)},H_{B(p)}$ of the operator S_p.

Theorem 2.1: *There exist two families* $\{H_{A(p)}\},\{H_{B(p)}\}$ *of self-adjoint extensions of the operator* S_p *which domains consist of all elements from* $\mathscr{D}(S_p^*)$ *satisfying the conditions*

$$\begin{pmatrix} C^1_{p,p} \\ C^2_{p,p} \end{pmatrix} = \begin{pmatrix} a^{(p)}_{11} & a^{(p)}_{12} \\ a^{(p)}_{21} & a^{(p)}_{22} \end{pmatrix} \begin{pmatrix} C^1_{-p,p} \\ C^2_{-p,p} \end{pmatrix} \tag{8}$$

or

$$\begin{pmatrix} C^1_{-p,p} \\ -C^2_{p,p} \end{pmatrix} = \begin{pmatrix} b^{(p)}_{11} & b^{(p)}_{12} \\ b^{(p)}_{21} & b^{(p)}_{22} \end{pmatrix} \begin{pmatrix} C^1_{p,p} \\ C^2_{-p,p} \end{pmatrix}. \tag{9}$$

■

Let us construct the Green's function with the source at the point $Y \in \Omega^2$ for the extended operator (for example, for $-H_{B^{(p)}}$). We seek the function in the form

$$G^p(x,Y;k) = \begin{cases} a^1_p Q_{p-1}(-\nabla_y) \dfrac{\partial}{\partial n} G^1_D(x,y;k)\Big|_{y=x_0}, & x \in \Omega^1, \\ G^{2,p}(x,Y;k) + a^2_p Q_{p-1}(-\nabla_y) \dfrac{\partial}{\partial n} G^2_D(x,y;k)\Big|_{y=x_0}, & x \in \Omega^2, \end{cases}$$

where $G^{2,p}(x,Y;k)$ has the following form in a neighborhood of the point x_0:

$$G^{2,p}(x,Y;k) = Q_{p-1}(-\nabla_y) \frac{\partial}{\partial n} G^2_D(x_0,y;k)\Big|_{y=x_0} Q_p(x-x_0) + o(|x-x_0|^p).$$

Here

$$Q_p(\nabla_y) = Q_{p-1}(-\nabla_y) \frac{\partial}{\partial n}.$$

To satisfy (9) it is necessary to determine $C^1_{-p,p}, C^2_{-p,p}, C^1_{p,p}, C^2_{p,p}$. It is simple to show that

$$C^1_{-p,p} = a^1_p, \quad C^2_{-p,p} = a^2_p.$$

There exist two ways to determine $C^1_{p,p}, C^2_{p,p}$: to investigate the asymptotic expansions of the Green's functions for the operators H_1 and H_2 or to use some operator relations. Let us choose the second way. We start from the Hilbert identity,

$$(H_j - \lambda)^{-1} - (H_j - \lambda_0)^{-1} = (\lambda - \lambda_0)(H_j - \lambda_0)^{-1}(H_j - \lambda)^{-1}.$$

Iterating this identity p times, we obtain

$$\begin{aligned}(H_j - \lambda)^{-1} = (H_j - \lambda_0)^{-1} &+ (\lambda - \lambda_0)(H_j - \lambda_0)^{-1}(H_j - \lambda)^{-1} + \cdots + (\lambda - \lambda_0)^{p-1} \\ &\times (H_j - \lambda_0)^{-p+1}(H_j - \lambda)^{-1} + (\lambda - \lambda_0)^p (H_j - \lambda_0)^{-p}(H_j - \lambda)^{-1}.\end{aligned}$$

After differentiation with respect to y we get

$$\begin{aligned}Q_p(-\nabla_y) G^j_D(x_0,y;k) = Q_p(-\nabla_y) G^j_D(x_0,y;k_0) &+ (\lambda - \lambda_0)(H_j - \lambda_0)^{-1} Q_p(-\nabla_y) G^j_D(x_0,y;k) \\ &+ \cdots + (\lambda - \lambda_0)^{p-1}(H_j - \lambda_0)^{-p+1} Q_p(-\nabla_y) G^j_D(x_0,y;k) \\ &+ (\lambda - \lambda_0)^p (H_j - \lambda_0)^{-p} Q_p(-\nabla_y) G^j_D(x_0,y;k). \end{aligned} \tag{10}$$

It is significant that each iteration of the Hilbert identity rises the smoothness of the last term. Particularly,

$$(H_j-\lambda_0)^{-p}Q_p(-\nabla_y)G_D^j(x_0,y;k)\big|_{y=x_0}\in C^p.$$

The remarkable fact is that the other terms in (10) are elements of the chain $\{h_{r,p}^j\}$. That is why the corresponding coefficient can be simply determined:

$$C_{p,p}^1=\widetilde{C}_{p,p}^1 a_p^1,\quad C_{p,p}^2=\widetilde{C}_{p,p}^2+G_p^2,$$

where

$$\widetilde{C}_{p,p}^j=\lim_{\epsilon\to 0}\int_{\Sigma_\epsilon^j}(\lambda-\lambda_0)^p\left(F_j\,\frac{\partial\overline{h_{-p,p}^j}}{\partial n}-\overline{h_{-p,p}^j}\,\frac{\partial F_j}{\partial n}\right)dx,$$

$$F_j=Q_p(-\nabla_x)(H_j-\lambda_0)^{-p}Q_p(-\nabla_y)G_D^j(x_0,y;k)\big|_{x=x_0,y=x_0},$$

$$G_p^2=\lim_{\epsilon\to 0}\int_{\Sigma_\epsilon^j}\Bigg(Q_p(-\nabla_y)G_D^2(x_0,y;k)\Big|_{y=x_0}Q_p(x-x_0)$$
$$\times\frac{\partial\overline{h_{-p,p}^2}}{\partial n}-\overline{h_{-p,p}^2}\,\frac{\partial}{\partial n}\,(Q_p(-\nabla_y)G_D^2(x_0,y;k)\Big|_{y=x_0}Q_p(x-x_0))\Bigg)dx.$$

C. Two coupled curvilinear triangles with zero angles

Now we consider how to ''switch on'' the interaction through the vertex of a zero angle. In this case the Green's function with the source at the vertex would be a deficiency element. But this function, as has been mentioned above, has an essential singularity at the vertex. Hence there is no finite number n such that nth power of the resolvent maps the function into L^2. Consequently, we cannot realize the above construction of the model in a Pontryagin space. We need to construct a new extension of the initial space such that the determined earlier Green's function belongs to the extended spaces. Let us outline a variant of this procedure. We shall use the following result concerning the asymptotics of the W_2^2 solution of the Dirichlet problem near a vertex of zero angles.[45] Choose Cartesian coordinates (x,y) in the curvilinear triangle Ω^i with zero angles in such a way that the x axis is the common tangent line of two circles forming the zero angle and that the triangle lies in the half-plane $x\geqslant 0$. Then the equation of the boundary line has the asymptotic form $y=cx^2$. The asymptotics of the solution $u(x,y)$ of the Dirichlet problem for the equation $(H_i-\lambda)u=0$ is the following:

$$u(x,y)=C\,\exp(-i\xi_0 x^{-1})\sum_{j=0}^{\infty}\phi_j(x^{-2}y)x^j,$$

where ϕ_j are smooth functions on the cross section θ of the domain by the line $x=1$, ξ_0 is an eigenvalue of the operator $A(\xi)=H_i(d/dy,\xi)$ with the domain $W_2^2(\theta)\cup\mathring{W}_1^2(\theta)$. Here $H_i(\partial/\partial y,\partial/\partial x)$ is the initial operator for the domain Ω^i (see Sec. II B).

In spite of the fact that the described properties of the Green's function are more complicated than ones for the case of nonzero angles, the construction of nontrivial extensions of the operator S_0 is developed formally by the same procedure. Here we start from the set A_∞^i of functions tending exponentially to zero at the vertex, more precisely,

$$A_\infty^i=\{u\in L^2(\Omega^i):\Delta u\in L^2(\Omega^i),\quad u(x,y)\exp(i\xi_0 x^{-1})\to\text{const},\quad \text{as}\ \ x\to 0\}.$$

Then we construct a chain of subspaces, adding step-by-step elements with determined behavior near the vertex $(\phi_j(x^{-2}y)x^j\eta(x,y))$, where $\eta(x,y)$ is a smooth cut-off function, i.e. $\eta(x,y)=1$ for $x^2+y^2<1$ and $\eta(x,y)=0$ for $x^2+y^2>2$. Finally, as above, we add elements χ_i that is proportional to the Green's function for our domain. In the constructed space $\mathscr{H}^i_\infty$ we introduce an inner product $(\cdot,\cdot)_{\mathscr{H}^i_\infty}$. There is some nonessential freedom in the choice of the product. To avoid the ambiguity, we adapt the usual L^2 product on each step of the construction if the corresponding integral converges and suppose the inner product is equal to zero otherwise [see, e.g., Eqs. (7)]. Completing the obtained indefinite metric space, we obtain a Krein space $\mathscr{K}^i$. In this space the considered operators act formally as the corresponding differential expressions. Restrict such an operator on the set of all elements ϕ obeying $(\phi,\chi_i)_{\mathscr{H}^i_\infty}=0$; then we get a symmetric operator $S^0_{\infty,i}$, having self-adjoint extensions, and can introduce the symmetric operator $S_\infty=S^0_{\infty,1}\oplus S^0_{\infty,2}$. In the considered case, the Krein resolvent formula[33,36,42] is a more convenient tool to describe self-adjoint extensions of S_∞ in the Krein space $\mathscr{K}=\mathscr{K}^1\oplus\mathscr{K}^2$. Let us denote by $H_0=H_1\oplus H_2$ the unperturbed operator in the space $L^2(\Omega^1\cup\Omega^2)$ and by $R_0(z)$, $R_0(z)=(H_0-z)^{-1}$, its resolvent. Let $\overline{R_0(z)}$ be the continuous extension of $R_0(z)$ on the space $\mathscr{K}$. In what follows we restrict ourselves to so-called ''transversal'' to H_0 self-adjoint extensions,[46] they are sufficient to our purposes. According to the Krein approach, the resolvent $R(z)$ of a transversal self-adjoint extension of S_∞ has the form

$$R(z)=\overline{R_0(z)}-\sum_{i,j=1}^{2}[Q(z)-A]^{-1}_{ij}\overline{R_0(z)}|\chi_i\rangle\langle\chi_j|\overline{R_0(z)}. \tag{11}$$

Here A is a Hermitian 2×2-matrix that parametrize the extension, and $Q(z)$ is the so-called Krein $\mathscr{Q}$ matrix that has the elements

$$q_{ij}(z)=\tfrac{1}{2}(z-z_0)\langle\chi_i|\overline{R_0(z)R_0(z_0)}|\chi_j\rangle+\tfrac{1}{2}(z-\overline{z_0})\langle\chi_i|\overline{R_0(z)R_0(\overline{z_0})}|\chi_j\rangle, \tag{12}$$

where $z_0\in\mathbf{C}\backslash\sigma(H_0)$ is fixed.

III. MODEL OF A PERIODIC ANTIDOT ARRAY

In this section we consider a periodic system of curvilinear triangles $\Omega_\gamma=\Omega+\gamma$, $\gamma\in\Gamma$; here Ω is a fixed curvilinear equilateral triangle with zero angles or with angles equal to π/p, where $p\geqslant3$ is a fixed positive integer (of course, if $p=3$, this is an ordinary triangle). Thus the typical void V is a circle in the first case and a (in general, curvilinear) triangle in the second one. Instead of condition $0\in V$ it is convenient now to suppose that 0 is the center of the triangle $\Omega=\Omega_0$. (Fig. 2).

As before, the symbol G denotes the domain $\Omega+\Gamma$; remember that $\mathscr{H}^0$ denotes the initial state space $L^2(G)=\Sigma_{\gamma\in\Gamma}{}^{\oplus}\mathscr{H}^0_\gamma$ and $H^0=\Sigma_{\gamma\in\Gamma}{}^{\oplus}H^0_\gamma$ is the unperturbed Hamiltonian of the model (see the Introduction). This Hamiltonian describes a charge carrier in the set of isolated triangles Ω_γ. To switch on the tunneling between the triangles through their vertices by means of operator extension theory, we need three deficiency elements $\chi^{(\gamma)}_i$ in $\mathscr{H}_\gamma$ $(i=1,2,3)$, corresponding to each vertex of the triangle Ω_γ. As a result we obtain an indefinite metric state space containing the space $\mathscr{H}^0_\gamma$ (see Sec. II). It is convenient to proceed in the space $\mathscr{H}^0_0=L^2(\Omega)$ only; this is possible because $\mathscr{H}^0_\gamma$ and $\mathscr{H}^0_0$ are isomorphic. In the absence of magnetic fields an isomorphism is established via translations by vectors from Γ, but in the presence of a magnetic field we must deal with the magnetic translation group.[41] In this connection we begin with some basic concepts related to this group.

A. Magnetic translation group and its lattice representations

Choose some basis vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ of the lattice Λ; if $\mathbf{v}$ is any vector from $\mathbf{R}^2$ we denote by v_1,v_2 the coordinates of $\mathbf{v}$ with respect to the basis $\mathbf{a}_1$, $\mathbf{a}_2$: $\mathbf{v}=v_1\mathbf{a}_1+v_2\mathbf{a}_2$. If $\mathbf{v}$, $\mathbf{v}'\in\mathbf{R}^2$, then the symbol $\mathbf{v}\wedge\mathbf{v}'$ will denote the number $v_1v'_2-v_2v'_1$. It is obvious that $\mathbf{v}\wedge\mathbf{v}'=\mathbf{v}\times\mathbf{v}'/S_\Lambda$, where

$\mathbf{v}\times\mathbf{v}'$ is the standard symplectic product in $\mathbf{R}^2$, and $S_\Lambda=\mathbf{a}_1\times\mathbf{a}_2$ is the oriented area of the elementary cell C_Λ (see the Introduction). Remember that η denotes the number of magnetic flux quanta through the cell C_Λ: $\eta=|S_\lambda(Be/2\pi\hbar c)|$. Let G_η be a subgroup of the multiplicative group $\mathbf{S}^1(\mathbf{S}^1=\{\zeta\in C:|\zeta|=1\})$, consisting of all elements of the form $\exp(\pi i\eta n)$, $n\in\mathbf{Z}$. The symbol W_η will be denote the set $\Lambda\times G_\eta$; W_η become a group structure by defining the multiplication as follows:

$$(\lambda,\zeta)(\lambda',\zeta')=(\lambda+\lambda',\zeta\zeta'\ \exp[\pi i\eta(\lambda\wedge\lambda')]); \tag{13}$$

this group is called the magnetic translation group. It is evident that the definition of W_η does not depend on a choice of basis vectors $\mathbf{a}_1$, $\mathbf{a}_2$.

If a magnetic field is absent, then a quantum-mechanical Hamiltonian H of a charged particle in the lattice system of triangles is invariant with respect to the translations by vectors from Λ. The presence of a magnetic field violates the translation symmetry of the Hamiltonian. Instead of the Λ invariance the Hamiltonian H is invariant under the composition of the translation by a vector $\lambda\in\Lambda$, and the gauge transformation of the vector potential of the magnetic field: $\mathbf{A}\mapsto\mathbf{A}-(\mathbf{B}\times\lambda)/2$. From the mathematical point of view the operator H is invariant with respect to a unitary representation of the group W_η. Under this representation an element $(\lambda,\zeta)\in W_\eta$ corresponds to the unitary operator $[\lambda,\zeta]$, which acts on any function $f\in L^2(G)$ according to the formula

$$([\lambda,\zeta]f\ )(x)=\zeta\ \exp[-\pi i\eta(x\wedge\lambda)]f(x-\lambda). \tag{14}$$

Let us introduce a lattice counterpart of the representation (14). Consider a family $(\mathcal{G}_\gamma)_{\gamma\in\Gamma}$ of complete inner product spaces (Hilbert spaces, Pontryagin spaces, or Krein spaces), such that $\mathcal{G}_{\gamma_1}=\mathcal{G}_{\gamma_2}$ if $\gamma_1\equiv\lambda_2$ (mod Λ). We shall denote

$$\mathcal{G}=\sum_{\gamma\in\Gamma}\oplus\mathcal{G}_\gamma,\quad \mathcal{G}_K=\sum_{\gamma\in K}\oplus\mathcal{G}_\gamma,$$

hence $\mathcal{G}=\Sigma_{\gamma\in\Lambda}\ \oplus\mathcal{G}'_\lambda$, where $\mathcal{G}'_\lambda\simeq\mathcal{G}_K$ for each $\lambda\in\Lambda$. In other words, $\mathcal{G}=\mathcal{G}_K\otimes l^2(\Lambda)$. We shall consider an element $g=(g_\gamma)_{\gamma\in\Gamma}$ of the space $\mathcal{G}$ as a function $g:\Gamma\to\cup_{\gamma\in\Gamma}\mathcal{G}_\lambda$ and write $g(\gamma)$ instead of g_γ. Equation (14) requires that we should define the unitary representation $(\lambda,\zeta)\mapsto[\lambda,\zeta]$ of the group W_η in the space $\mathcal{G}$ in the following way:

$$([\lambda,\zeta]g)(\gamma)=\zeta\ \exp[-\pi i\eta(\gamma\wedge\lambda)]g(\gamma-\lambda). \tag{15}$$

We shall denote the representation (15) as $D^{\mathcal{G}}_\eta$.

We recall that each bounded operator A in the direct sum $\mathcal{G}=\Sigma_{\gamma\in\Gamma}\oplus\mathcal{G}_\gamma$ is represented by the corresponding matrix $(A(\gamma,\gamma'))_{\gamma,\gamma'\in\Gamma}$, where $A(\gamma,\gamma')$ is a bounded operator acting from $\mathcal{G}_{\gamma'}$ into $\mathcal{G}_\gamma$. Namely, let J_γ be the canonical imbedding operator, $J_\gamma:\mathcal{G}_\gamma\hookrightarrow\mathcal{G}$, and let P_γ be the canonical projection, $P_\gamma:\mathcal{G}\to\mathcal{G}_\gamma$. Then $A(\gamma,\gamma')=P_\gamma AJ_{\gamma'}$, and for every $\phi\in\mathcal{G}$ we have

$$(A\phi)(\gamma)=\sum_{\gamma'\in\Gamma}A(\gamma,\gamma')\phi(\gamma'), \tag{16}$$

where the series converges unconditionally in the space $\mathcal{G}$.

Proposition 3.1: The operator A in the space $\mathcal{G}$ is $D^{\mathcal{G}}_\eta$-invariant iff its matrix $(A(\gamma,\gamma'))_{\gamma,\gamma'\in\Gamma}$ satisfies the condition

$$A(\gamma-\lambda,\gamma'-\lambda)=\exp[\pi i\eta((\gamma-\gamma')\wedge\lambda)]A(\gamma,\gamma'), \tag{17}$$

where, γ, $\gamma'\in\Gamma$, $\lambda\in\Lambda$.

Proof: We have from definitions that the relation

$$A[\lambda,1]\phi(\gamma)=[\lambda,1]A(\gamma)$$

($\gamma\in\Gamma$) is equivalent to the following one:

$$\sum_{\gamma'\in\Gamma}A(\gamma,\gamma')\exp[\pi i\,\eta(\lambda\wedge\gamma')]\phi(\gamma'-\lambda)=\sum_{\gamma'\in\Gamma}A(\gamma-\lambda,\gamma')\exp[\pi i\,\eta(\lambda\wedge\gamma)]\phi(\gamma').$$

We can rewrite the relation (17) in the form

$$\sum_{\gamma'\in\Gamma}A(\gamma,\gamma'+\lambda)\exp[\pi i\,\eta(\lambda\wedge(\gamma'-\gamma))]\phi(\gamma')=\sum_{\gamma'\in\Gamma}A(\gamma-\lambda,\gamma')\phi(\gamma'). \tag{18}$$

Taking into account that the linear hull of the set $\cup_{\gamma\in\Gamma}\mathscr{G}_\gamma$ is dense in the space $\mathscr{G}$, we conclude that the validity of the equality (18) is equivalent to the validity of the condition

$$A(\gamma,\gamma'+\lambda)=\exp[\pi i\,\eta((\gamma'-\gamma)\wedge\lambda)]A(\gamma-\lambda,\gamma'),$$

for every $\gamma,\ \gamma'\in\Gamma$ and $\lambda\in\Lambda$. Replacing $\gamma'+\lambda$ by γ', we finish the proof of the proposition. ■

Corollary: The $D^{\mathscr{G}}_\eta$-invariant operator A is fully determined only by the matrix elements $A(\gamma,\kappa')$ ($\gamma\in\Gamma,\ \kappa'\in K$) by the formula

$$A(\gamma,\gamma')=\exp[\pi i\,\eta((\gamma'-\gamma)\wedge\lambda')]A(\gamma-\lambda',\kappa'), \tag{19}$$

where $\lambda'=\gamma'-\kappa',\ \kappa'\in K$. More precisely, let $A(\lambda,\kappa'):\mathscr{G}_{\kappa'}\to\mathscr{G}_\gamma$ ($\gamma\in\Gamma,\ \kappa'\in K$) be a family of bounded operators such that for every $\phi\in\mathscr{G}$ the series (16) unconditionally converges if the operators $A(\gamma,\gamma')$ are defined by the formula (19); then the formula (16) defines a bounded $D^{\mathscr{G}}_\eta$-invariant operator A. ■

Proposition 3.2: In order that the formula (19) gives us a self-adjoint operator A it is necessary and sufficient that the operator family $A(\gamma,\kappa')$ ($\gamma\in\Gamma,\ \kappa'\in K$) satisfies the condition

$$A(\kappa+\lambda,\kappa')=\exp[\pi i\,\eta((\kappa'-\kappa)\wedge\lambda)]A^*(\kappa'-\lambda,\kappa), \tag{20}$$

where $\lambda\in\Lambda,\ \kappa,\ \kappa'\in K$.

Proof: In accordance with (19),

$$A(\gamma,\gamma')=\exp[\pi i\,\eta((\gamma-\gamma')\wedge\mu)]A(\gamma'-\mu,\kappa), \tag{21}$$

where $\gamma,\ \gamma'\in\Gamma,\ \kappa\in K,\ \mu=\gamma-\kappa$. Hence the equality

$$A(\gamma,\gamma')=A^*(\gamma',\gamma), \tag{22}$$

which is equivalent to the self-adjointness of the operator A, takes the form

$$\exp[\pi i\,\eta((\gamma'-\gamma)\wedge\lambda)]A(\gamma-\lambda,\kappa')=\exp[\pi i\,\eta((\gamma'-\gamma)\wedge\mu)]A^*(\gamma'-\mu,\kappa),$$

where $\mu=\gamma-\kappa,\ \lambda=\gamma'-\kappa'$. In the other words, the relation (22) is equivalent to the following one:

$$A(\gamma-\lambda,\kappa')=\exp[\pi i\,\eta((\gamma'-\gamma)\wedge(\mu-\lambda))]A^*(\gamma'-\mu,\kappa),$$

or

$$\begin{aligned}A(\kappa+\mu-\lambda,\kappa')&=\exp[\pi i\,\eta((\kappa'-\kappa+\lambda-\mu)\wedge(\mu-\lambda))]A^*(\kappa'+\lambda-\mu,\kappa)\\&=\exp[\pi i\,\eta((\kappa'-\kappa)\wedge(\mu-\lambda))]A^*(\kappa'+\lambda-\mu,\kappa).\end{aligned}$$

Replacing $\mu-\lambda$ by λ, we obtain (20). ■

The propositions 3.1 and 3.2 allow us to simplify the construction of a model Hamiltonian.

B. Construction of the model

We return to the construction of the model state space and the model Hamiltonian. In our case $K=\{0,\mathbf{b}\}$, where $\mathbf{b}=2(\mathbf{a}_1+\mathbf{a}_2)/3$. We shall identify the space $\mathscr{H}_\gamma^0=L^2(\Omega_\gamma)$ with the space $\mathscr{H}_0^0=L^2(\Omega_0)$ using magnetic translations $[\gamma,1]$ defined in accordance with (14). More precisely, let $\mathscr{H}_\gamma=\mathscr{H}_0$ for every $\gamma\in\Gamma$. We shall identify a function $f\in L^2(G)=L^2(\Omega_0+\Gamma)$ with the family $(f_\gamma)_{\gamma\in\Gamma}\in\mathscr{H}=[|\mathrm{M}|\mathrm{s}_{\gamma\in\Gamma}.\mathscr{H}_\gamma$ by the relation

$$f_\gamma(x)=\exp[\pi i\,\eta x\wedge\gamma]f(x+\gamma),\quad x\in\Omega_0.$$

It is a straightforward matter to establish that the isomorphism $f\mapsto(f_\gamma)_{\gamma\in\Gamma}$ intertwines the unitary representations (13) and (15), i.e., $[\lambda,\zeta](f_\gamma)_{\gamma\in\Gamma}=(([\lambda,\zeta]f_\gamma)_\gamma)_{\gamma\in\Gamma}$ for every $(\lambda,\zeta)\in W_\eta$.

Let us consider now the unperturbed Hamiltonian $H^0=\Sigma_{\gamma\in\Gamma}\oplus H_\gamma^0$, where $H_\gamma^0=H_0^0$ is the operator defined in $L^2(\Omega_0)=\mathscr{H}_0^0$ by the differential expression (1) and Dirichlet boundary conditions. Let S_0^0 be the restriction of H_0^0 to the set of functions from $\mathscr{H}_0^0$ vanishing near of the vertices of the curvilinear triangle Ω_0. We shall denote by χ_i $(i=1,\,2,\,3)$ the generalized deficiency elements of S_0^0 corresponding to the vertices (see Secs. II B and II C). In accordance with the results of Sec. II the operator S_0^0 has nontrivial self-adjoint extensions in an inner product space $\mathscr{H}_0$, which is a Pontryagin or Krein space. Let $R_0(z)$ be the resolvent of the operator H_0^0 in the space $\mathscr{H}_0^0$; as in Sec. II we denote by $\overline{R_0(z)}$ its continuous extension on the space $\mathscr{H}_0$. Let $R^0(z)=\Sigma_{\gamma\in\Gamma}\oplus R^{(\gamma)}(z)$, where $R^{(\gamma)}(z)=\overline{R_0(z)}$ for each $\gamma\in\Gamma$. Now we are able to introduce the state space $\mathscr{H}$ of our model, this is the direct sum $\mathscr{H}=\Sigma_{\gamma\in\Gamma}\oplus\mathscr{H}_\gamma$, where $\mathscr{H}_\gamma=\mathscr{H}_0$ for each $\gamma\in\Gamma$. Let $S^0=\Sigma_{\gamma\in\Gamma}\oplus S_\gamma^0$, where $S_\gamma^0=S_0^0\ \forall\gamma\in\Gamma$. We shall seek the Hamiltonian of our model among self-adjoint extensions of the operator S^0 in the space $\mathscr{H}$. At first, we describe the required extensions using the Krein resolvent formula. To do this, we need three auxiliary objects:[42] the typical deficiency space $\mathscr{G}$, the Krein Γ function $K(z):\mathscr{G}\to\mathscr{H}$, and the Krein $\mathscr{Q}$ function $Q(z):\mathscr{G}\to\mathscr{G}(z\in\mathbf{C}\backslash\sigma(H^0))$. Let us describe them. In our case, the Hilbert space $\mathscr{G}$ is the direct sum $\mathscr{G}=\Sigma_{\gamma\in\Gamma}\oplus\mathscr{G}_\gamma$, where $\mathscr{G}_\gamma$ is the standard three-dimensional Hilbert space $\mathbf{C}^3$ for each $\gamma\in\Gamma$. We shall denote by $Q_\gamma(z)$ $(\gamma\in\Gamma)$ the linear mapping in $\mathbf{C}^3$ with the matrix $q(z)=\|q_{ij}(z)\|$, where the elements $q_{ij}(z)$ are defined by Eq. (12) (now $i,j=1,2,3$). The symbol $Q(z)$ will denote the direct sum $Q(z)=\Sigma_{\gamma\in\Gamma}\oplus\mathscr{Q}_\gamma(z)$. The operator-valued function $Q(z)$ defined on $\mathbf{C}\backslash\sigma(H^0)$ is just the Krein $\mathscr{Q}$ function. Further, denote by $K_\gamma(z)$ the linear mapping from $\mathscr{G}_\gamma=\mathbf{C}^3$ into the space $\mathscr{H}_\gamma=\mathscr{H}_0$ defined on the standard basis vectors $\mathbf{e}_j$ by the formula

$$K_\gamma(z)\mathbf{e}_j=\overline{R_0(z)|\chi_j\rangle}.$$

In our case the Krein Γ function $K(z)$ is the direct sum $K(z)=\Sigma_{\gamma\in\Gamma}\oplus K_\gamma(z)$. Now all the required self-adjoint extensions of the unperturbed Hamiltonian are given by the Krein resolvent formula. Namely, let A be a bounded self-adjoint operator in $\mathscr{G}$ such that the bounded inverse operator exists. Then the operator $R_A(z)$,

$$R_A(z)=R^0(z)-K(z)[Q(z)-A]^{-1}K^*(z),\tag{23}$$

is the resolvent of a self-adjoint extension H_A of the operator H^0 [see Refs. 33 and 36].

The Hamiltonian of our model should be invariant with respect to magnetic translations from W_η. The proposition below provides a condition of the invariance of H_A.

Proposition 3.3: The operator H_A is $D_\eta^{\mathscr{H}}$ invariant-iff the operator A is $D_\eta^{\mathscr{G}}$ invariant.

Proof: We shall use the standard definition of commutation of a bounded operator B with a densely defined closed operator A (see, e.g., Ref. 47): B commutes with A iff $BA\subset AB$, i.e. iff for each $\phi\in\mathscr{D}(A)$ we have $B\phi\in\mathscr{D}(A)$ and $AB\phi=BA\phi$. Taking into account that the operator $R^0(z)$

is $D_\eta^{\mathscr{H}}$ invariant and the operator $Q(z)$ is $D_\eta^{\mathscr{G}}$ invariant, we can finish the proof by reference to Ref. 47, Part III.5.6. ■

We can decompose the operator A into two parts: $A=B+T$, where a bounded self-adjoint operator B parametrizes those extensions H_B which are the model Hamiltonians of arrays consisting of isolated domains Ω_γ, like the operator H^0. The operator T turn on a tunneling between regions Ω_γ. On the one hand, the physical meaning of the operators B and T and on the other the propositions 3.1, 3.2, and 3.3 impose very strong restrictions to the matrices of the operators B and T. Namely, the matrix $B(\gamma,\gamma')$ must be of the form $B(\gamma,\gamma')=B_0\delta_{\gamma,\gamma'}$, where B_0 is a self-adjoint operator in $\mathbf{C}^3$; in other words, B_0 is a Hermitian 3×3 matrix. A detailed physical motivation how to choice the matrix T is presented in Refs. 27 and 28; here we follow the line of the cited papers. To identify an acting in the space $\mathbf{C}^3$ operator $T(\gamma,\gamma')$ with a 3×3 matrix, we enumerate the vertices of the triangle Ω_0 with the numbers 1, 2, 3 in an arbitrary way. Then each triangle Ω_γ acquires the uniquely determined enumeration of vertices by means of the translation of Ω_0 on the vector γ. If Ω_γ and $\Omega_{\gamma'}$ have no common vertex, then, evidently, the equality $T(\gamma,\gamma')=0$ should be valid. Otherwise, the magnitude $|T_{ij}(\gamma,\gamma')|^2$ is proportional to the tunneling probability from a ''infinitesimal neighborhood'' of the ith vertex in Ω_γ to a ''infinitesimal neighborhood'' of the jth vertex in $\Omega_{\gamma'}$. By symmetry, all the nonzero elements T_{ij} must be mutually equal; we shall denote their common value as τ. In virtue of Proposition 3.1 it is sufficient to find the matrices of the form $T(\gamma,0)$ and $T(\gamma,\mathbf{b})$ only. The above arguments show that only the elements of the kind $T(\lambda,\mathbf{b})$ and $T(\mathbf{b}+\lambda,0)$ $(\lambda\in\Lambda)$ may be nonzero. Using Fig. 2 we obtain

$$T(\lambda,\mathbf{b})=\begin{cases}\begin{pmatrix}0&0&\tau\\0&0&0\\0&0&0\end{pmatrix}, & \lambda=\mathbf{a}_1,\\ \begin{pmatrix}0&0&0\\0&0&0\\0&\tau&0\end{pmatrix}, & \alpha=\mathbf{a}_2,\\ \begin{pmatrix}0&0&0\\\tau&0&0\\0&0&0\end{pmatrix}, & \lambda=\mathbf{a}_1+\mathbf{s}_2,\\ \begin{pmatrix}0&0&0\\0&0&0\\0&0&0\end{pmatrix}, & \text{in other cases.}\end{cases} \tag{24}$$

Proposition 3.2 implies that

$$T(\mathbf{b}+\lambda,0)=\exp[\tfrac{2}{3}\pi i\,\eta(\lambda_1-\lambda_2)]T^*(-\lambda,\mathbf{b}). \tag{25}$$

Finally, the operator T is determined by (19) and (20). The construction of the model Hamiltonian is completed, it is the operator H_A with the parametric matrix $A=B+T$ described above. The ''fitting parameters'' of our model are the elements β_{ij} of the Hermitian matrix B and the number τ.

C. Dispersion equation for the model Hamiltonian H_A—the bound states

If the flux η is a rational number: $\eta=N/M$, where N and M are coprime integers, we can use harmonic analysis on the group W_η to reduce the spectral problem for the operator H_A to the eigenvalue problem of linear algebra. Further, we shall write D instead of $D_\eta^{\mathscr{G}}$ for simplicity. The symbol $\mathbf{T}_\eta^2$ will denote the torus,

$$\mathbf{T}^2_\eta=[0,M^{-1})\times[0,1),$$

and we abbreviate $\mathbf{T}^2=\mathbf{T}^2_1=[0,1)\times[0,1)$.

Let us denote by $\widetilde{\mathscr{G}}$ the direct integral,

$$\widetilde{\mathscr{G}}=\int_{\mathbf{T}^2_\eta}\oplus\,\widetilde{\mathscr{G}}(\mathbf{p})d\mathbf{p},$$

where each fiber $\widetilde{\mathscr{G}}(\mathbf{p})$ coincides with the space $\mathbf{C}^M\otimes\mathbf{C}^M\otimes\mathscr{G}_K$. It is evident that

$$\widetilde{\mathscr{G}}=L^2(\mathbf{T}^2_\eta)\otimes\mathbf{C}^M\otimes\mathbf{C}^M\otimes\mathscr{G}_K. \tag{26}$$

Thus, we shall consider the elements ϕ of the space $\widetilde{\mathscr{G}}$ as functions of five variables:

$$\phi=\phi(p_1,p_2,j,m,\kappa)=\phi(\mathbf{p},j,m,\kappa),$$

where $p_1\in[0,M^{-1})$, $p_2\in[0,1)$, $j,\ m\in\{0,\ldots,M-1\}$, $\kappa\in K$.

We define an isomorphism $\mathscr{T}_\eta:\mathscr{G}\to\widetilde{\mathscr{G}}$ in accordance with the formula

$$(\mathscr{T}_\eta\phi)(\mathbf{p};j,m,\kappa)=\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}\phi(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2+\kappa)\exp[\,\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2)$$
$$-2\pi i(\lambda_1p_1+\lambda_2p_2+(\lambda_1\eta/2)(M\lambda_2+m+2j))]. \tag{27}$$

Proposition 3.4: The operator $\mathscr{T}_\eta$ *is a well-defined Hilbert isomorphism.*

Proof: It is easy to prove that the operator $\mathscr{T}_\eta$ is a superposition of the following four operators $\mathscr{T}^{(i)}_\eta$ $(i=1,2,3,4)$.

(1) $\mathscr{T}^{(1)}_\eta$ maps the sequence $\phi\in\mathscr{G}=l^2(\Lambda)\otimes\mathscr{G}_K$ to the sequence $\phi'\in\mathscr{G}=l^2(\mathbf{Z}^2)\otimes\mathbf{C}^M\otimes\mathscr{G}_K$ in accordance with the formula

$$\phi'(\lambda_1,\lambda_2,m,\kappa)=\phi(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2+\kappa).$$

(2) $\mathscr{T}^{(2)}_\eta$ maps the sequence $\phi'\in\mathscr{G}=l^2(\mathbf{Z}^2)\otimes\mathbf{C}^M\otimes\mathscr{G}_K$ to the sequence $\phi''\in\mathscr{G}=l^2(\mathbf{Z}^2)\otimes\mathbf{C}^M\otimes\mathscr{G}_K$ according to the formula

$$\phi''(\lambda_1,\lambda_2,m,\kappa)=\exp[\,\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2)-\pi i\lambda_1\eta(\lambda_2M+m)]\phi'(\lambda_1,\lambda_2,m,\kappa)$$
$$=\exp[\,\pi i\,\eta(\kappa+m\mathbf{a}_2)\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a})-\pi iN\lambda_1\lambda_2]\phi'(\lambda_1,\lambda_2,m,\kappa).$$

(3) $\mathscr{T}^{(3)}_{\mathrm{gh}}$ is the Fourier transform with respect to the variables from $\mathbf{Z}^2$, i.e., $\mathscr{T}^{(3)}_\eta$ maps the sequence $\phi''\in\mathscr{G}=l^2(\mathbf{Z}^2)\otimes\mathbf{C}^M\otimes\mathscr{G}_K$ to the function $\hat{\phi}$ from the space $L^2(\mathbf{T}^2_\eta)\oplus\mathbf{C}^M\oplus\mathscr{G}_K$:

$$\hat{\phi}(\mathbf{p},m,\kappa)=\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}\phi''(\lambda_1,\lambda_2,m,\kappa)\exp[-2\pi i(\lambda_1p_1+\lambda_2p)].$$

(4) $\mathscr{T}^{(4)}_\eta$ has the form $F\otimes I_{\mathbf{C}^M\oplus\mathscr{G}_K}$, where the operator F maps a function $f\in L^2(\mathbf{T}^2)$, to the function $\widetilde{f}\in L^2(\mathbf{T}^2_\eta)\oplus\mathbf{C}^M$ in accordance with the formula

$$\widetilde{f}(p_1,p_2,j)=f(p_1+\{\eta j\},p_2).$$

Here $\{x\}$ is the integer part of the real number x.

Obviously, all the operators $\mathscr{T}^{(i)}_\eta$ $(i=1,\ 2,\ 3,\ 4)$ are Hilbert isomorphisms, hence the operator $\mathscr{T}_\eta$ is an isomorphism too. ∎

Let F be an bounded D-invariant operator in the space $\mathscr{G}$ with the matrix $F(\gamma,\gamma')$, and let $\widetilde{F}$ be the operator $\mathscr{T}_\eta F\mathscr{T}_\eta^{-1}$. Since the operator F is D invariant, the operator $\widetilde{F}$ acts fiberwise. By direct calculation we can obtain that the operator $\widetilde{F}$ in the fiber over a point $\mathbf{p}\in\mathbf{T}^2_\eta$ has the following matrix:

$$\widetilde{F}(\mathbf{p};j,m,\kappa;j',m',\kappa')=\delta_{jj'}\ \exp[-\pi i\,\eta m'\kappa/\!\!\wedge\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2+\kappa;m'\mathbf{a}_2+\kappa')\exp[\pi i\,\eta\kappa/\!\!\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2+(\lambda_1\eta/2)(M\lambda_2+m+2j))]. \tag{28}$$

The formula (28) is equivalent to the following one:

$$\widetilde{F}(\mathbf{p};j,m,\kappa;j',m',\kappa')=\delta_{jj'}\ \exp[-\pi i\,\eta m'\kappa/\!\!\wedge\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+(\lambda_2M+m-m')\mathbf{a}_2+\kappa;\kappa')\exp[\pi i\,\eta\kappa/\!\!\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2+(\lambda_1\eta/2)(M\lambda_2+m+m'+2j))]. \tag{29}$$

Really, in virtue of (17),

$$\begin{aligned}F(\lambda_1\mathbf{a}_1+(\lambda_2M+m)\mathbf{a}_2+\kappa;m'\mathbf{a}_2+\kappa')&=F(\lambda_1\mathbf{a}_1+(\lambda_2M+m-m')\mathbf{a}_2+\kappa;\kappa')\\&\quad\times\exp[-\pi i\,\eta(\lambda_1\mathbf{a}_1+(\lambda_2M+m-m')\mathbf{a}_2+\kappa-\kappa')\\&\quad/\!\!\wedge m'\mathbf{a}_2]\\&=F(\lambda_1\mathbf{a}_1+(\lambda_2M+m-m')\mathbf{a}_2+\kappa;\kappa')\\&\quad\times\exp(-\pi i\,\eta\lambda_1m')\exp[-\pi i\,\eta m'(\kappa-\kappa')/\!\!\wedge\mathbf{a}_2].\end{aligned}$$

Fix a point $\mathbf{p}\in\mathbf{T}^2_\eta$ and consider the operator $\widetilde{F}(\mathbf{p})$ acting in the space $\mathbf{C}^M\otimes\mathbf{C}^M\otimes\mathscr{G}_K$ and having the matrix kernel $\widetilde{F}(\mathbf{p};j,m,\kappa;j',m',\kappa')$. In virtue of (28) the operator $\widetilde{F}(\mathbf{p})$ has a block-diagonal structure with respect to the index j. In other words, let $(\widetilde{F}_{jj'}(\mathbf{p}))$ be the matrix representation of the operator $\widetilde{F}(\mathbf{p})$ [all operators $\widetilde{F}_{jj'}(\mathbf{p})$ act in the space $\mathbf{C}^M\otimes\mathscr{G}_K$], then the matrix $\widetilde{F}_{jj'}(\mathbf{p})$ is a diagonal one:

$$\widetilde{F}_{jj'}(\mathbf{p})=\delta_{jj'}\widetilde{F}_j(\mathbf{p}). \tag{30}$$

Each operator in (30) is defined in an obvious way according to the formula (26).

Let V be a unitary operator in the space $\mathbf{C}^M\otimes\mathscr{G}_K$ having the form

$$V=U\otimes I_{\mathscr{G}_K}, \tag{31}$$

where U is a unitary operator in the space $\mathbf{C}^M$ with a matrix of the form

$$\begin{pmatrix}0 & I_{M-1}\\ \exp(2\pi ip2) & 0\end{pmatrix}$$

(here I_n denotes the $n\times n$ identity matrix). It is evident that U acts onto the vectors $\mathbf{e}_m$ of a standard basis as follows:

$$U\mathbf{e}_m=\exp[2\pi i\,\delta_{m0}p_2]\mathbf{e}_{m\ominus1}, \tag{32}$$

hence

$$U^*\mathbf{e}_m=\exp[-2\pi i\,\delta_{m,M-1}p_2]\mathbf{e}_{m\oplus1}; \tag{33}$$

here $n\oplus m$ and $n\ominus m$ are addition and subtraction modulo M, respectively.

Proposition 3.5: The following relation is valid for each $\mathbf{p}\in\mathbf{T}^2_\eta$:

$$V\widetilde{F}_j(\mathbf{p})V^*=\widetilde{F}_{j\oplus 1}(\mathbf{p}). \tag{34}$$

Proof: In virtue of (32) and (33), we get

$$\begin{aligned}(V\widetilde{F}_jV^*)&(\mathbf{p};m,\kappa;m',\kappa')\\ &=\langle\mathbf{e}_m|U\widetilde{F}_j(\mathbf{p};\kappa,\kappa')U^*\mathbf{e}_{m'}\rangle\\ &=\langle U^*\mathbf{e}_m|\widetilde{F}_j(\mathbf{p};\kappa,\kappa')U^*\mathbf{e}_{m'}\rangle\\ &=\exp[2\pi ip_2(\delta_{m,M-1}-\delta_{m',M-1})]\langle\mathbf{e}_{m\oplus 1}|\widetilde{F}_j(\mathbf{p};\kappa,\kappa')\mathbf{e}_{m'\oplus 1}\rangle\\ &=\exp[2\pi ip_2(\delta_{m,M-1}-\delta_{m',M-1})]\widetilde{F}_j(\mathbf{p};m\oplus 1\kappa;m'\oplus 1,\kappa').\end{aligned}$$

Let us prove that

$$\exp[2\pi ip_2(\delta_{m,M-1}-\delta_{m',M-1})]\widetilde{F}_j(\mathbf{p};m\oplus 1\kappa;m'\oplus 1,\kappa')=\widetilde{F}_{j\oplus 1}(\mathbf{p};m,\kappa;m',\kappa'). \tag{35}$$

This is evident for $m\neq M-1$ and $m'\neq M-1$ [see (29)]. Let $m=M-1$, but $m'\neq M-1$. Then

$$\begin{aligned}\widetilde{F}_j(\mathbf{p};m\oplus 1,\kappa;m'\oplus 1,\kappa')&=\exp[-\pi i\,\eta(m'+1)\kappa\wedge\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+(\lambda_2M-m'-1)\mathbf{a}_2\\ &\quad+\kappa;\kappa')\exp[\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+\lambda_2M\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2+(\lambda_1\eta/2)\\ &\quad\times(M\lambda_2+m'+1+2j))]\\ &=\exp[-\pi i\,\eta m'\kappa\wedge\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+((\lambda_2-1)M+m-m')\mathbf{a}_2\\ &\quad+\kappa;\kappa')\exp[\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+((\lambda_2-1)M+m)\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2\\ &\quad+(\lambda_1\eta/2)(M(\lambda_2-1)+m'+m+2j+2))]\\ &=\exp(-2\pi ip_2)\widetilde{F}_{j\oplus 1}(\mathbf{p};m,\kappa;m',\kappa').\end{aligned}$$

Thus, in this case the equality (34) is proved. Let now $m'=M-1$, but $m\neq M-1$. Then

$$\begin{aligned}\widetilde{F}_j(\mathbf{p};m\oplus 1,\kappa;m'\oplus 1,\kappa')&=\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+(\lambda_2M+m+1)\mathbf{a}_2+\kappa;\kappa')\\ &\quad\times\exp[\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+(\lambda_2M+m+1)\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2\\ &\quad+(\lambda_1\eta/2)(M\lambda_2+m+1+2j))]\\ &=\exp[-\pi i\,\eta m'\kappa\wedge\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+((\lambda_2+1)M+m-m')\mathbf{a}_2\\ &\quad+\kappa;\kappa')\\ &\quad\times\exp[\pi i\,\eta\kappa\wedge(\lambda_1\mathbf{a}_1+((\lambda_2+1)M+m)\mathbf{a}_2)-2\pi i(\lambda_1p_1+\lambda_2p_2\\ &\quad+(\lambda_1\eta/2)(M(\lambda_2+1)+m+m'+2+2j-2M))]\\ &=\exp(2\pi ip_2)\widetilde{F}_{j\oplus 1}(\mathbf{p};m,\kappa;m',\kappa').\end{aligned}$$

Hence, in this case the equality (34) is also valid. If last $m=m'=M-1$, then we get

$$\begin{aligned}\widetilde{F}_j(\mathbf{p};m\oplus 1,\kappa;m'\oplus 1,\kappa')&=\sum_{\lambda_1,\lambda_2\in Z}F(\lambda_1\mathbf{a}_1+\lambda_2 M\mathbf{a}_2+\kappa;\kappa')\exp[\pi i\eta\kappa/\!\backslash(\lambda_1\mathbf{a}_1+\lambda_2 M\mathbf{a}_2)\\&\quad-2\pi i(\lambda_1 p_1+\lambda_2 p_2+(\lambda_1\eta/2)(M\lambda_2+2j))]\\&=\exp[-\pi i\eta m'\kappa/\!\backslash\mathbf{a}_2]\sum_{\lambda_1,\lambda_2\in\mathbf{Z}}F(\lambda_1\mathbf{a}_1+(\lambda_2 M+m-m')\mathbf{a}_2+\kappa;\kappa')\\&\quad\times\exp[\pi i\eta\kappa/\!\backslash(\lambda_1\mathbf{a}_1+(\lambda_2 M+m)\mathbf{a}_2)-2\pi i(\lambda_1 p_1+\lambda_2 p_2\\&\quad+(\lambda_1\eta/2)(M\lambda_2+m+m'+2+2j-2M))]\\&=\widetilde{F}_{j\oplus 1}(\mathbf{p};m,\kappa;m',\kappa').\end{aligned}$$

The proof is complete. ■

Corollary: Let $\mathbf{p}\in\mathbf{T}^2_\eta$ *be fixed. Then the operators* $\widetilde{F}_j(\mathbf{p})$ $(j=0,\ldots,M-1)$ *are mutually unitarily equivalent.* ■

Now we find the matrix $\widetilde{F}(\mathbf{p};j,m,\kappa;j',m',\kappa')$, where $F=Q(z)-A=Q(z)-(B+T)$. In virtue of Proposition 3.5, it is sufficient to determine the matrices $\widetilde{F}_0(\mathbf{p};m,\kappa;m',\kappa')=\widetilde{F}(\mathbf{p};0,m,\kappa;0,m',\kappa')$ only. It is simple to show that

$$\widetilde{Q}_0(\mathbf{p};m,\kappa;m',\kappa')=\begin{cases}q(z), & \text{if } m=m' \text{ and } \kappa=\kappa';\\ 0, & \text{otherwise.}\end{cases}\tag{36}$$

Similarly,

$$\widetilde{B}_0(\mathbf{p};m,\kappa;m',\kappa')=\begin{cases}B_0, & \text{if } m=m' \text{ and } \kappa=\kappa',\\ 0, & \text{otherwise.}\end{cases}\tag{37}$$

To determine the matrix $\widetilde{T}_0$ let us introduce the following notations:

$$L_1=\begin{pmatrix}0&0&\tau\\0&0&0\\0&0&0\end{pmatrix},\quad L_2=\begin{pmatrix}0&0&0\\0&0&0\\0&\tau&0\end{pmatrix},\quad L_3=\begin{pmatrix}0&0&0\\\tau&0&0\\0&0&0\end{pmatrix}.\tag{38}$$

Using (25), we obtain

$$\widetilde{T}_0(\mathbf{p};m,0;m',0)=\widetilde{T}_0(\mathbf{p};m,\mathbf{b};m',\mathbf{b})=0,\quad\forall m,m'.\tag{39}$$

Moreover, the Hermitian symmetry gives us

$$\widetilde{T}_0(\mathbf{p};m,\mathbf{b};m',0)=\widetilde{T}_0^*(\mathbf{p};m',0;m,\mathbf{b}),\quad\forall m,m'.\tag{40}$$

To calculate the nonzero elements of the matrix $\widetilde{T}_0(\mathbf{p})$, we shall deal with three cases.

1. Case M=1

In this case the indices m,m' are equal to zero, and may be omitted from the notations. Simple calculations give us

$$\widetilde{T}_0(\mathbf{p};0,\mathbf{b})=\exp(-2\pi i p_1)L_1+\exp(-2\pi i p_2)L_2+\exp[-2\pi i(p_1+p_2+N/2)]L_3,\tag{41}$$

$$\widetilde{T}_0(\mathbf{p};\mathbf{b},0)=\exp(2\pi i p_1)L_1^*+\exp(2\pi i p_2)L_2^*+\exp[2\pi i(p_1+p_2+N/2)]L_3^*.\tag{42}$$

Considering cases 2 and 3, we shall write $\widetilde{T}^{(0)}_{\kappa\kappa'}(\mathbf{p};m,m')$ instead of $\widetilde{T}^{(0)}(\mathbf{p};m,\kappa;m',\kappa')$. In virtue of (39) and (40), it is sufficient to find the matrix elements $\widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p}m,m')$ only.

2. Case $M=2$

Simple calculations give us

$$\begin{gathered}\widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};0,0)=\exp(-2\pi i p_1)L_1,\\ \widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};1,1)=\exp[-2\pi i(p_1+\eta)]L_1,\\ \widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};1,0)=L_2+\exp[-2\pi i(p_1+\eta/2)]L_3,\\ \widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};0,1)=\exp(-2\pi i p_2)L_2+\exp[-2\pi i(p_1+p_2+3\eta/2)]L_3.\end{gathered} \tag{43}$$

3. Case $M>2$

Only the following three subcases are possible:

$$\text{(i)}\quad \lambda_1=\pm 1, M\lambda_2+m-m'=0;$$

$$\text{(ii)}\quad \lambda_1=0,\quad M\lambda_2+m-m'=1;$$

$$\text{(iii)}\quad \lambda_1=0,\quad M\lambda_2+m-m'=-1.$$

In subcase (i) the number $\lambda_2=(m-m)/M$ should be an integer. Since $0\leqslant m,m'<M$, then $-(M-1)\leqslant m'-m\leqslant M-1$, hence λ_2 is an integer iff $m-m'=0$. Thus the condition (i) may be rewritten in the form

$$\text{(i}')\quad \lambda_1=\pm 1,\quad \lambda_2=0,\quad m=m'.$$

In subcase (ii) the number $\lambda_2=(1+m-m')/M$ should be an integer. Since $-M+2\leqslant 1+m+m'\leqslant M$, then $1+m-m'=0$ or $1+m-m'=M$. Thus we have two possibilities:

$$\begin{aligned}&\text{(ii}')\quad \lambda_1=0,\quad \lambda_2=0,\quad m'=m-1,\\ &\text{(ii}'')\quad \lambda_1=0,\quad \lambda_2=1,\quad m'=M+m-1.\end{aligned}$$

In virtue of the inequality $0\leqslant m'\leqslant M-1$ subcase (ii″) may be reformulated in the following manner:

$$\text{(ii}'')\quad \lambda_1=0,\quad \lambda_2=1,\quad m=0,\quad m'=M-1.$$

The condition (iii) divides into the following two subcases by an analogous way:

$$\begin{aligned}&\text{(iii}')\quad \lambda_1=0,\quad \lambda_2=0,\quad m=m'-,\\ &\text{(iii}'')\quad \lambda_1=0,\quad \lambda_2=-1,\quad m'=0,\quad m=M-1.\end{aligned}$$

Using the relations (i′),...,(iii″), it is easy to find all nonzero elements of the matrix $\widetilde{T}_0(\mathbf{p})$. As a result, we obtain for $M>2$:

$$\widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};m,m)=\exp[-2\pi i(p_1+\eta m)]L_1,$$

$$\widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};m,m-1)=L_2+\exp[-2\pi i(p_1+\eta(2m-1)/2)]L_3,\quad 1\leqslant m\leqslant M-1,$$

$$\widetilde{T}^{(0)}_{0\mathbf{b}}(\mathbf{p};0,M-1)=\exp(-2\pi i p_2)L_2+\exp[-2\pi i(\mathbf{p}_1+p_2+\eta(2M-1)/2)]L_3. \tag{44}$$

Now we describe the spectrum of the Hamiltonian H_A. First, we note that the spectrum of the unperturbed Hamiltonian H_0 coincides (as a set) with the spectrum of H_0^0, which is a discrete one. Hence, the spectrum of H_0 is pure point and consists of infinitely degenerate eigenvalues (Landau levels). A point $E\in\sigma(H_0)$ is contained in the spectrum of H_A as an eigenvalue, if $\eta>1$ (Refs. 23, 27, and 28). Other points of the spectrum $\sigma(H_A)$ are defined by the dispersion equation

$$\det(\widetilde{Q}(E)-\widetilde{T}(\mathbf{p}))=0. \tag{45}$$

The equation (45) determines a multivalued function $E(\mathbf{p})$. The continuous single-valued branches $E_j(\mathbf{p})$ of the function $E(\mathbf{p})$ are called the dispersion laws. The images of the functions $E_j(\mathbf{p})$ are segments that form bands of the spectrum. In virtue of the corollary of Proposition 3.5, each band is M-fold degenerate. As in Ref. 23, the following picture of the spectrum $\sigma(H_A)$ can be established: an eigenvalue of the operator H_0 broadens into a band that lies below the eigenvalue; each band divides into M subbands. It should be emphasized that the bands and the subbands may overlap.

The origin of an eigenvalue $E\in\sigma(H_A)$ that is simultaneously an eigenvalue of the unperturbed operator H_0 is clear: it corresponds to the classical trajectory lying in an area Ω_γ, wholly.[43] The following theorem, which is the main result of the section, shows that there is another possibility of appearance of bound states in the spectrum $\sigma(H_A)$. Namely, a bound state may be arise as a constant solution (independent of the quasimomentum $\mathbf{p}$) of the dispersion equation (45).

Theorem 3.1: *If η is an integer: $\eta=N$, then elements of the ''fitting matrix'' B can be chosen in such a way that the dispersion equation has a solution independent of a quasimomentum $\mathbf{p}\in\mathbf{T}^2$ and the tunneling parameter τ.*

Proof: Let $E_0\in\mathbf{R}\backslash\sigma(H_0)$; we put

$$\beta_{ij}=\begin{cases} q_{ij}(E_0), & \text{if } i=j,\\ q_{ij}(E_0)-1, & \text{if } i\neq j.\end{cases}$$

Evidently, $B=\|\beta_{ij}\|$ is a Hermitian matrix. If τ is not an eigenvalue of $-B$, then the Hamiltonian H_A is well defined. By symmetry, $q_{jj}(z)$ does not depend on j; denote $p(z)=q_{jj}(z)-\beta_{jj}$. After cumbersome algebra, we bring the left-hand side of Eq. (45) for $z=E_0$ to the form

$$p^6+9\tau p^4-4\tau^2p^3+a_2\tau^3p^2+a_1\tau^4p=0, \tag{46}$$

where

$$a_2=-18+2[\cos 2\pi(p_1+N/2)+\cos 2\pi(p_2+N/2)+\cos 2\pi(p_1-p_2)],$$

$$a_1=4[3-\cos 2\pi(p_1+N/2)+\cos 2\pi(p_2+N/2)+\cos 2\pi(p_1-p_2)].$$

The theorem follows from Eq. (46). ■

Remark: The hypothesis of Theorem 3.1 does not exclude the case $N=0$ as well.

Asymptotic estimates which relate the diffusion of wave packets on discrete lattices to Hausdorff dimensions of the local density of states are discussed. © *1996 American Institute of Physics.* [S0022-2488(96)01010-9]

I. INTRODUCTION

The basic mathematical objects of this article are a discrete unitary group $\{U^t\}_{t\in\mathbf{Z}}$ in an infinite-dimensional separable Hilbert space $\mathscr{H}$, and a complete Hilbert basis $B=\{e_n\}_{n\in\mathbf{Z}}$. The discrete-time evolution of vectors $\psi\in\mathscr{H}$ is obtained by repeated application of the generator U. Upon expanding vectors $U^t\psi$ on the basis B, vectors in $l^2(\mathbf{Z})$ are obtained, which can be physically depicted as quantum wave packets propagating on a discrete one-dimensional lattice, the sites of which are in one-to-one correspondence to the basis vectors. According to conventional wisdom, long-time wave packet dynamics and spectral structure are qualitatively connected: wave packets will remain essentially confined within a finite region, or will propagate unboundedly, depending on the discrete or continuous nature of the spectrum. The intuitive idea, that the motion of wave packets will be more ''delocalized,'' the more ''continuous'' the spectrum, turns out to have a validity at all points between the extreme cases of discrete and absolutely continuous spectra. It has in fact been turned into rigorous estimates, which relate the asymptotical (in time) wave packet dynamics, to ''spectral'' dimensions of the Hausdorff type, which describe how continuous the spectral measure (local density of states) associated with the vector ψ is. Estimates of this kind make up the subject of this article.

Physical motivation is provided by the increasingly frequent apparition of singular continuous spectra in quantum mechanical models for electron dynamics in solids, where such spectra may have a great influence on quantum transport. This issue has been numerically investigated on several quasiperiodic, incommensurate models. Fractal dimensions which are somehow related to the singular continuous structure of the spectrum have been numerically obtained from a scaling analysis of the band spectra of periodic approximants.[1–4] The results obtained in this way suggest a connection between ''band-scaling'' fractal dimensions and (anomalous) wave packet diffusion. Recourse to more sophisticated concepts of fractal analysis[5,6] now appears necessary, in order to further pursue this line of investigation; a theoretical approach has been proposed.[5]

Further numerical works have investigated the multifractal structure of the spectral measure itself, on different models.[6–8] A comparison of such data with data from numerical simulation of the quantum evolution in time[7,8] confirms a qualitative connection, but at the same time indicates that no simple exact relation exists between diffusion exponents and dimensions of the local density of states.

Rigorous results available to date concern the decay in time of the time-averaged probability of survival in the initial state,[3,9–11] and the algebraic growth of the ''width'' of wave packets, as measured, e.g., by the moments of the associated probability distribution. In the latter case, through successive generalizations the result has been obtained[12–16] that the exponent of growth is bounded from below by the information dimension D_1 of the spectral measure, independently of the choice of the basis B.

No such general *upper* bound is to be expected. The very definition of moments depends on the labeling of the basis vectors, and so do the corresponding growth exponents, independently of

the properties of spectral measures. Thus, although the growth exponents are in all cases subject to the above mentioned lower bound, they do actually depend on the choice of a basis; therefore the ''spatial'' structure of the operator U on the basis B has to be taken into account in order to get upper bounds on growth exponents. For instance, it will be shown in sec. V that a ballistic upper bound is valid as soon as the operator U satisfies a certain ''analyticity'' property with respect to the basis B.

According to empirical evidence, the actual growth exponents can be

significantly different from both the ballistic upper bound and the D_1 lower bound. Getting precise asymptotic estimates on the long-time behavior of wave packets is an open problem that may not be solvable on the level of generality attained by the existing bounds.

In this article a different dynamical characterization of singular continuous spectra is given, based on the growth with time of the dimension of the Hilbert subspace explored by the trajectory of a state ψ. By refining and extending results of Ref. 15, it will be shown that the corresponding growth exponents are related by upper and lower estimates to the fractal and Hausdorff dimensions, respectively, of the spectral measure. These results are presented in sec. IV below. In secs. II and III a survey of some basic definitions and of previous results, which are needed for the elaborations in sec. IV and VI, is given.

Finally, in this article some steps are taken towards a multifractal analysis of the spatial structure of the wave packet, following an idea of Evangelou and Katsanos.[17] Such an analysis is suggested by numerical evidence[15,17] that growth exponents of moments do not scale in a simple way with the order of the moments (*multiscaling*), and so give rise to a nontrivial spectrum of growth exponents. This can be taken as an indication that wave packets develop a sort of multifractal structure in space, which may in turn reflect an analogous structure of eigenfunctions.[1,18] From this viewpoint, estimating growth exponents is but a special aspect of a more general problem: how is this structure related to the multifractal structure of the spectral measures? Some results in this direction, which follow from general lower bound on growth exponents, are presented in sec. VI.

Multiscaling is also a justification for an aspect of the present article, which may appear disturbing to the reader: the proliferation of different quantities, all of which somehow measure the growth of wave packets, but still may behave differently in time. Establishing precise connections between these different definitions would enable reducing their number; however, this as yet unsolved problem is closely related to the problem of upper bounds. Previous general remarks about the latter problem are valid in this case, too.

II. SPECTRAL DIMENSIONS

In the following, the set $\{\lambda \in [0,2\pi]: e^{i\lambda} \in \mathrm{Spec}(U)\}$ will be called ''spectrum.'' The spectral measure of the vector ψ will be supported in this set and is denoted μ_ψ; the label ψ will be usually omitted. The spectral measure μ_ψ is uniquely defined by

$$(\psi, U^t\psi) = \int_0^{2\pi} e^{it\lambda} d\mu_\psi(\lambda)$$

valid at all times t. The distribution of the spectral measure is also called (integrated) *local density of states*, at least in concrete cases in which ψ is an eigenvector of a position operator. In this section we assume $\mu_\psi([0,2\pi]) = \|\psi\|^2 = 1$.

By $d_\mu^-(x), d_\mu^+(x)$ we will denote the lower and upper pointwise dimensions of μ at the point x of the spectrum, defined by

$$d_\mu^-(x) = \lim \inf_{\delta \searrow 0} \frac{\log\, \mu(I_\delta(x))}{\log\, \delta}, \quad d_\mu^+(x) = \lim \sup_{\delta \searrow 0} \frac{\log\, \mu(I_\delta(x))}{\log\, \delta}$$

where $I_\delta(x)$ is an interval of size δ centered at x. If $d_\mu^-(x)=d_\mu^+(x)$, then their common value defines the *local*, or *pointwise*, dimension of the measure μ at the point x. Upper and lower global dimensions of μ will be defined by

$$\dim_H^+(\mu)=\mu\text{-ess sup}d_\mu^-(x)$$
$$\dim_H^-(\mu)=\mu\text{-ess inf}d_\mu^-(x).$$

Note that both definitions involve the *lower* local dimension only. The subscript H stands for Hausdorff; the connection to Hausdorff dimensions is clarified by the following result, where $d_H(A)$ denotes the Hausdorff dimension of a set A.

Theorem 1:

$$\dim_H^+(\mu):=\inf\{d_H(A):\mu(A)=1\};$$
$$\dim_H^-(\mu)=\sup\{\alpha:\mu(A)=0 \quad \text{if} \quad d_H(A)<\alpha\}$$

Proof: These equalities follow from general results of Rodgers and Taylor,[19] compactly reviewed in Refs. 16 and 20. Let $\beta>\mu$ -ess sup$d_\mu^-(x)$; then μ is supported by a set of dimension β,[20] so $\beta\geqslant\dim_H^+(\mu)$ by definition; hence, μ-ess sup$d_\mu^-(x)\geqslant\dim_H^+(\mu)$. Conversely, let $\beta<\mu$-ess sup$d_\mu^-(x)$, and let S be any set supporting μ. Then $d_\mu^-(x)>\beta$ for all x in a set $B\subseteq S$ of positive measure. If χ_B is the characteristic function of B, and $d\mu_B:=\chi_B d\mu$, then the measure μ_B is supported by B, and satisfies $d_{\mu_B}^-(x)\geqslant d_\mu^-(x)>\beta$ for μ_B—almost all x. Any set of Hausdorff dimension less than β must have zero μ_B measure,[20] which entails $d_H(B)\geqslant\beta$, and also $d_H(S)\geqslant\beta$. This holds for any S supporting μ, therefore $\dim_H^+(\mu)\geqslant\beta$; it follows that μ-ess sup$d_\mu^-(x)\leqslant\dim_H^+(\mu)$.

The proof of the second equality is similar. Let $\gamma=\mu$-ess inf$d_\mu^-(x)$. Let us prove $\gamma\leqslant\dim_H^-(\mu)$. If $\gamma=0$ this is obvious. If $\gamma>0$, let $\beta<\gamma$; then $d_\mu{}^-(x)>\beta$ for μ—almost all x, so μ gives zero weight to any set of dimension less than β, which means $\beta\leqslant\dim_H^-(\mu)$. Conversely, if $\beta>\gamma$, then $d_\mu^-(x)<\beta$ on a set S of positive measure. This set S is a subset of the set T_β, defined as

$$T_\beta=\left\{x:\lim\sup_{\delta\searrow 0}\frac{\mu(I_\delta(x))}{\delta^\beta}=+\infty\right\}. \tag{2.1}$$

It is a known result[20] that a set T'_β exists, with $d_H(T'_\beta)\leqslant\beta$, and $\mu(T'_\beta\cap T_\beta)=\mu(T_\beta)$. Therefore, if $S'=S\cap T'_\beta$, then $\mu(S')=\mu(S)>0$, and $d_H(S')\leqslant d_H(T'_\beta)\leqslant\beta$. Hence, $\beta>\dim_H^-(\mu)$. □

If $\dim_H^-(\mu)=\dim_H^+(\mu)=d$ [that is, if $d_\mu{}^-(x)=d$, μ-*a.e.*], the measure is said to have *exact* dimension d. This denomination is not universally agreed upon; for instance, a measure is sometimes[21] said to have exact dimension d if $d_\mu{}^-(x)=d_\mu^+(x)=d$, μ-*a.e.*, that is, if the measure has a well defined constant local dimension μ-*a.e.* A measure with this property will be called here an *exactly scaling* (ES) measure. ES measures also have exact dimension in the sense used here, but the converse is not true—in Ref. 20 examples are given of measures with exact dimension 0 which have $d_\mu^+(x)=1$ μ-*a.e.* Although exceptional on mathematical grounds, in the physical literature the ES property is often assumed of ''smooth multifractal'' measures. On purely empirical grounds, and on the present level of numerical accuracy, this assumption has not shown, so far, any serious inconsistency with numerical data, at least in a few test cases which are relevant to the subject of this article, and which were mentioned in the Introduction. On the other hand, there are certain non generic features in these cases, which enforce great caution in assuming that a likewise smooth structure of spectral measures will be typical, even within the class of quasi-periodic Schrödinger operators.

$\dim_H^+(\mu)$ is known as the Hausdorff dimension of the measure μ. It is also sometimes called the *information dimension* $D_I(\mu)$ of μ,[22] although the latter name is more often given to a

generalized fractal dimension, usually denoted $D_1(\mu)$ [which corresponds to $q=1$ in the set of generalized fractal (box-counting) dimensions $D_q(\mu)$]. For ''smooth'' multifractal measures (as discussed, e.g., in Ref. 23) $D_I(\mu)=D_1(\mu)$, but this is not true in general, not even of exactly dimensional measures.

The *fractal* dimension of μ will instead be defined as

$$\dim_F(\mu)=\sup_{0<\epsilon<1}\inf_K\{d_F(K):\ K\ \text{ compact},\ \ \mu(K)>1-\epsilon\} \tag{2.2}$$

where the fractal dimension $d_F(K)$ of a compact set K is defined by[24]

$$d_F(K)=\lim\ \sup_{\delta\searrow 0}\frac{\log\ N_K(\delta)}{\log(1/\delta)}.$$

Here, $N_K(\delta)$ is the minimum number of closed intervals of size $\leqslant\delta$ which are needed to cover K.

Theorem 2: $\dim_F(\mu)\leqslant\mu$-ess sup $\ d^+_\mu(x)$.

Proof: Let $d^+_\mu(x)<\alpha$ for μ—almost all x; we have to show that $\dim_F(\mu)\leqslant\alpha$. Because

$$\lim_{\delta_0\to 0}\ \sup_{\delta<\delta_0}\frac{\log\ \mu(I_\delta(x))}{\log\ \delta}<\alpha \tag{2.3}$$

for all x in a set of full measure, then, on the strength of the Egorov theorem, we can find a set $J_\epsilon\subset(0,2\pi)$, of measure $\mu(J_\epsilon)>1-\epsilon/2$, in which the monotonic limit on the lhs of (2.3) is uniform, so there is a $\overline{\delta_{\epsilon,\alpha}}$ such that

$$\mu(I_\delta(x))>\delta^\alpha\quad\forall x\in J_\epsilon,\quad\forall\,\delta<\overline{\delta_{\epsilon,\alpha}}. \tag{2.4}$$

Let us fix δ so small that (2.4) holds. The family $\{I_\delta(x)\}_{x\in J_\epsilon}$ is a covering of J_ϵ, from which we can extract a finite or countable covering of the same set with no more than c overlaps, with c a fixed integer (this comes, e.g., from the Besicovitch covering lemma, as formulated in Ref. 25). Denote by $I_1,\ldots$ the intervals in this covering, and let M be their number. From $m\,\delta^\alpha\leqslant\Sigma_1^m\mu(I_j)\leqslant c\,\mu(\cup_1^m I_j)\leqslant c$, which holds for any positive integer $m<M$, it follows that M is finite, $M\leqslant c\,\delta^{-\alpha}$. Finally, choose a compact $K\subset J_\epsilon$, with $\mu(J_\epsilon\backslash K)<\epsilon/2$. For all sufficiently small δ, $N_K(\delta)\leqslant M$, so $d_F(K)\leqslant\alpha$; moreover, $\mu(K)>1-\epsilon$, so, from (2.2), we conclude $\dim_F(\mu)\leqslant\alpha$. □

Remark: Theorem 2 shows that the Hausdorff and the fractal dimensions of ES measures coincide.

III. SPREADING OF WAVE PACKETS

Let $B\equiv\{e_n\}_{n\in\mathbf{Z}}$ an orthonormal set. For any positive integer time t let

$$p_n(t):=\frac{1}{t}\sum_{s=0}^{t-1}|\psi_n(s)|^2 \tag{3.1}$$

where $\psi_n(t):=(e_n,U^t\psi)$. Since time averages like the one in (3.1) appear frequently in the following, the shorthand notation $\langle\cdot\rangle_{t_1}^{t_2}$ will be used for time averages from time t_1 to time t_2-1.

Equation (3.1) defines a finite measure $\mathscr{P}_{t,\psi}$ on subsets A of $\mathbf{Z}$, via $\mathscr{P}_{t,\psi}(A)=\Sigma_{k\in A}p_k(t)$. If B is complete, then the total mass of this measure is just $\|\psi\|^2$. A *minimal ϵ-support* of the measure $\mathscr{P}_{t,\psi}$ will be any finite family $\mathscr{T}_\epsilon\subset\mathbf{Z}$ such that (i) $\mathscr{P}_{t,\psi}(\mathscr{T}_\epsilon)>(1-\epsilon^2)\mathscr{P}_{t,\psi}(\mathbf{Z})$, and (ii)

$\mathscr{P}_{t,\psi}(\mathscr{F}') \leqslant (1-\epsilon^2)\mathscr{P}_{t,\psi}(\mathbf{Z})$ for any other finite family of indices $\mathscr{F}'$ such that $\sharp(\mathscr{F}') < \sharp(\mathscr{F}_\epsilon)$, where $\sharp$ denotes cardinality. The distribution (3.1) may have different minimal ϵ-supports, but they must have the same ''size'' $\sharp(\mathscr{F}_\epsilon)$, which will be denoted by $n_\epsilon(\psi,t,B)$. For simplicity's sake, in the following we shall often omit the complete list of parameters on which n_ϵ, and other quantities, depend, leaving understood those whose specification is not strictly necessary.

If μ_ψ is a purely continuous measure, then it is a classical result that $p_k(t) \to 0$ as $t \to \infty$, $\forall k$, so $\mathscr{P}_{t,\psi}$ gives smaller and smaller weight to any finite set $A \subset \mathbf{Z}$. Thus, if the total mass is constant, or at least bounded away from zero at all times, then n_ϵ diverges in the limit $t \to \infty$. This is true, in particular, when B is complete. It will be shown below that, in the latter case, n_ϵ diverges as soon as μ_ψ has a continuous component. Our aim here is to describe asymptotic bounds on the growth of n_ϵ, in terms of spectral dimensions of μ_ψ, defined in sec. II.

The asymptotic spreading of $\mathscr{P}_{t,\psi}$ can also be quantitatively described by other quantities, e.g. by the moments $m^{(\alpha)}(t)$, which are defined, for $\alpha > 0$, by

$$m^{(\alpha)}(t) := \sum_{k \in \mathbf{Z}} |k|^\alpha p_k(t).$$

The growth of n_ϵ as $t \to \infty$ bounds the growth of $(m^{(\alpha)})^{1/\alpha}$ from below, via a Chebyshev-like inequality. Instead, from the divergence of moments nothing can be inferred about the behavior of n_ϵ; examples are known, in which μ_ψ is pure-point, n_ϵ is bounded in time, but moments diverge algebraically.

A description of the asymptotical growth in time of quantities which in one way or another measure the ''size'' of wave packets is provided by upper and lower growth exponents, which, for a given positive sequence $c \equiv \{c_t\}$, labelled by the discrete time t, will be defined and denoted as follows:

$$\beta^-(c) = \lim \inf_{t \to \infty} \frac{\log c_t}{\log t}, \quad \beta^+(c) = \lim \sup_{t \to \infty} \frac{\log c_t}{\log t}. \tag{3.2}$$

Previous results by the present author[14,15] can be cast in the form of theorem 3 below. These results can be significantly strengthened (see remark 1 below), but the version used here is convenient for the purposes of this article.

Theorem 3: *Let* $\|\psi\| = 1$, $0 < \epsilon < 1$, *and suppose that* B *is complete. Then* $\beta^-(\{n_\epsilon(\psi,t)\}) \geqslant \dim_H^-(\mu)$.

Remark 1: An immediate corollary is $\beta^-(\{m^{(\alpha)}(t)\}) \geqslant \alpha \dim_H^-(\mu)$, because the growth of $n_\epsilon(\psi,t)$ bounds the growth of moments from below. Last[16] has strengthened this result, proving that $m^{(\alpha)}(t) > \text{const} \times t^{\alpha \dim_H^+(\mu)}$ for *any* spectral measure μ (Last's formulation is somewhat different, as it is given in terms of Hausdorff decompositions of μ). A similar generalization of Theorem 3 is also possible, yielding

$$\sup_\epsilon \beta^-(\{n_\epsilon\}) \geqslant \dim_H^+(\mu) \tag{3.3}$$

This step will be explained later.

Remark 2: The result is also true if B is not complete, still $\langle \|P_B \psi(t)\|^2 \rangle_0^t \geqslant \Delta^2 > 0$, $\forall t > 0$, P_B being the projection onto the subspace spanned by B. In this case Theorem 3 holds for $0 < \epsilon < \Delta$. The same is *not* true of the generalization mentioned in remark 1, though.

Remark 3: In Refs. 14 and 15 Theorem 3 was formulated for the case of exactly scaling measures μ. The proof given there is also valid for the present version, without any modification. Other minor differences require no special comment.

Remark 4: Combes and co-workers[13,11] and Last[16] generalize similar results to continuous unitary groups, generated by Schrödinger operators in $L^2(R^n)$.

The following form of Theorem 3 is proven in the same way, and will be used later, in the proof of Proposition 2.

Theorem 3a: *If B is an orthonormal (not necessarily complete) set, and there is a sequence of times $t_k \to \infty$ such that, $\forall k$*

$$\langle \| P_B U^s \psi \|^2 \rangle_{t_k}^{t_{k+1}} \geqslant \Delta^2, \tag{3.4}$$

then, for all sufficiently small positive $\epsilon < \Delta$,

$$\lim \inf_{k \to \infty} \frac{\log n_\epsilon(\psi, t_k)}{\log t_k} \geqslant \dim_H^-(\mu). \tag{3.5}$$

IV. EFFECTIVE DIMENSIONS

For $\psi \neq 0$ consider finite strings $\sigma_{s,t}(\psi) = \{U^s\psi, U^{s+1}\psi, \ldots, U^{s+t-1}\psi\}$ of the orbit of ψ. If μ_ψ has a continuous component, then, $\forall s,t$, $\sigma_{s,t}$ spans a subspace $\Sigma_{s,t}$ of $\mathscr{H}$, of dimension t. Nevertheless it may happen that the ''effective dimension'' of $\sigma_{s,t}$ is significantly smaller, in the sense that some subspace of $\Sigma_{s,t}$, of dimension $\ll t$, exists, such that $U^s\psi, U^{s+1}\psi, \ldots, U^{s+t-1}\psi$ have but a small component outside it. This raises the question, how does the effective dimension of the subspace spanned by a string of length t increase with t?

This question will be formalized as follows. Given $\epsilon \in (0,1)$, let $\theta_\epsilon(\sigma_{s,t}(\psi))$ be the minimum dimension of an orthogonal projector P in $\mathscr{H}$ such that $\|P^\perp U^j \psi\| < \epsilon$ for $s \leqslant j \leqslant s+t-1$. In other words, $\theta_\epsilon(\sigma_{s,t}(\psi))$ is the minimum dimension of a subspace such that the string $\sigma_{s,t}(\psi)$ lies within a distance ϵ of it. Moreover, let $\underline{\theta}_\epsilon(\sigma_{s,t}(\psi))$ be the minimum dimension of a subspace such that the same string lies within ϵ of it *in the average*, that is, $\langle \| P^\perp U^j \psi \|^2 \rangle_s^{s+t} < \epsilon^2$. The mentioned minimal subspaces can be assumed to be subspaces of the subspace spanned by $\sigma_{s,t}(\psi)$. Moreover, since $\sigma_{s,t}(\psi) = U^s(\sigma_{0,t}(\psi))$, all the strings of a given length are unitary images of one another, so $\underline{\theta}_\epsilon(\sigma_{s,t}(\psi))$ and $\theta_\epsilon(\sigma_{s,t}(\psi))$ only depend on t, and will therefore be denoted $\theta_\epsilon(\psi,t)$ and $\underline{\theta}_\epsilon(\psi,t)$. If $\epsilon > \|\psi\|$, then $\theta_\epsilon(\psi,t) = 0$.

Immediate consequences of these definitions are as follows.

Proposition 1:

(i) $\underline{\theta}_\epsilon(\psi,t) \leqslant \theta_\epsilon(\psi,t) \leqslant t$,

(ii) $\theta_\epsilon(\psi, t+s) \leqslant \theta_\epsilon(\psi,t) + \theta_\epsilon(\psi,s)$,

(iii) *if $\psi_1 \in \mathscr{H}_1, \psi_2 \in \mathscr{H}_2$ where $\mathscr{H}_1, \mathscr{H}_2$ are mutually orthogonal subspaces, invariant under U, then*

$$\theta_\epsilon(\psi_1 + \psi_2, t) \geqslant max[\,\theta_\epsilon(\psi_1,t), \theta_\epsilon(\psi_2,t)\,]. \tag{4.1}$$

Moreover, (ii and iii) also hold for $\overline{\theta_\epsilon}$.

Proof: (i) is obvious. (ii) follows from $\theta_\epsilon(\sigma_{0,t} \cup \sigma_{t,s}) \leqslant \theta_\epsilon(\sigma_{0,t}) + \theta_\epsilon(\sigma_{t,s})$. As to (iii), note that $\sigma_{0,t}(\psi_i) \subset \mathscr{H}_i$, and that vectors $\xi_1, \ldots, \xi_t$ exist, which span a subspace of dimension $\theta_\epsilon(\psi_1 + \psi_2, t)$, and satisfy $\|\xi_j - U^j(\psi_1 + \psi_2)\| < \epsilon$ for $j = 0, \ldots, t-1$. Now let projections $P_i \xi_j$ on $\mathscr{H}_i$ span a subspace $\mathscr{S}_i$ of $\mathscr{H}_i$, with $i = 1,2$. On one hand, $\dim(\mathscr{S}_i)$ cannot be larger than $\theta_\epsilon(\psi_1 + \psi_2, t)$, and on the other it cannot be less than $\underline{\theta}_\epsilon(\psi_i, t)$, because $\|P_i \xi_j - U^j \psi_i\| < \epsilon$ for $j = 0, \ldots t-1$. Thus $\theta_\epsilon(\psi_1 + \psi_2, t) \geqslant \underline{\theta}_\epsilon(\psi_i, t)$. For $\overline{\theta_\epsilon}$ the proof proceeds in a similar way. □

At given ϵ, ψ, both $\theta_\epsilon(\psi,t)$ and $\underline{\theta}_\epsilon(\psi,t)$ are positive nondecreasing sequences. Their growth exponents will be presently investigated.

Proposition 2: *If $d_\mu^-(x) > \alpha$, μ-a.e., then, for sufficiently small positive ϵ, $\beta^-(\overline{\theta_\epsilon}) \geqslant \alpha$.*

Proof: Given a sequence of times $t_k \to \infty$, such that

$$\beta^-(\overline{\theta_\epsilon}) = \lim_{k\to\infty} \frac{\log\, \overline{\theta_\epsilon}(\psi, t_k)}{\log\, t_k},$$

let us recursively construct a subsequence $\{t_{k_j}\}$, with $k_1 = 1$, and

$$k_{j+1} = \min\{k: \quad t_k > 2^{l_j}\},$$

where $l_j = \Sigma_{s=1}{}^{j} t_{k_s}$. Let us partition the orbit of ψ into segments $\sigma_j \equiv \{\psi(s), l_j \leqslant s < l_{j+1}\}$; the length of σ_j is thus t_{k_j}. According to the definition of $\overline{\theta_\epsilon}(\psi, t)$ we can find a sequence $\{\varphi_t\}$ of vectors such that, $\forall j$,

$$\langle \| \varphi_s - U^s \psi \|^2 \rangle_{l_j}^{l_{j+1}} < \epsilon^2 \tag{4.2}$$

(so that σ_j lies within an average distance ϵ of the subspace spanned by $\{\varphi_s,\ l_j \leqslant s < l_{j+1}\}$), and, moreover, the subspace spanned by $\{\varphi_s, l_j \leqslant s < l_{j+1}\}$ has exactly dimension $\theta_\epsilon(\psi, t_{k_j})$. On orthonormalizing the sequence $\{\varphi_t\}$ we obtain an orthonormal set B_ϵ with the property that, $\forall j$

$$\langle \| P_{B_\epsilon} U^s \psi \|^2 \rangle_{l_j}^{l_{j+1}} > \| \psi \|^2 - \epsilon^2. \tag{4.3}$$

Therefore we can use Theorem 3a to the effect that, if ϵ is small enough,

$$\lim\ \inf_{j\to\infty} \frac{\log\, n_\epsilon(\psi, B_\epsilon, l_j)}{\log\, l_j} \geqslant \alpha. \tag{4.4}$$

On the other hand, $\psi(0), \ldots, \psi(l_j)$ lie within an average distance ϵ of the subspace spanned by the first l_j vectors φ_t. This subspace has dimension $N(l_j) \leqslant \Sigma_{s=1}^{j} \overline{\theta_\epsilon}(\psi, t_{k_s})$, and is also spanned by the first $N(l_j)$ vectors in B_ϵ. From the definition of a minimal ϵ- support it follows that $n_\epsilon(\psi, B_\epsilon, l_j) \leqslant N(l_j) \leqslant \Sigma_{s=1}{}^{j} \theta_\epsilon(\psi, t_{k_s})$; therefore, using Proposition 1,

$$\frac{\log_2 n_\epsilon(\psi, B_\epsilon, l_j)}{\log_2 l_j} \leqslant \frac{\log_2 \Sigma_{s=1}^{j} \overline{\theta_\epsilon}(\psi, t_{k_s})}{\log_2 l_j} \leqslant \frac{\log_2 \Sigma_{s=1}^{j-1} t_{k_s}}{\log_2 t_{k_j}} + \frac{\log_2 \overline{\theta_\epsilon}(\psi, t_{k_j})}{\log_2 t_{k_j}}$$

$$\leqslant \frac{\log_2 l_{j-1}}{l_{j-1}} + \frac{\log_2 \overline{\theta_\epsilon}(\psi, t_{k_j})}{\log_2 t_{k_j}}$$

Taking the limit $j \to \infty$ and using (4.4) the required result is obtained. □

One further step can be taken, in the spirit of Last's extension of Theorem 3.[16] Recall that $\dim_H^+(\mu) = \mu$-ess $\sup d_\mu^-(x)$. For any small η, let $A_\eta = \{x: d_\mu^-(x) > \dim_H^+(\mu) - \eta\}$; then $\mu(A_\eta) > 0$, and one can write $\psi = \psi_1 + \psi_2$, the spectral decomposition of ψ according to the set A_η and its complement. Then $d\mu_{\psi_1} = \chi_{A_\eta} d\mu$, so $d_{\mu_{\psi_1}}^-(x) \geqslant d_\mu^-(x)$, and $\dim_H^-(\mu_{\psi_1}) \geqslant \dim_H^+ \times (\mu) - \eta$. On account of Proposition 2 and of Proposition 1(iii), $\beta^-(\overline{\theta_\epsilon}) \geqslant \dim_H^+(\mu) - \eta$ if ϵ is smaller than some ϵ_0. The latter depends in general on η, so we can conclude the following.

Proposition 3: *For any $\psi \neq 0$, and for sufficiently small ϵ, $\beta^-(\overline{\theta_\epsilon}(\psi, t)) \geqslant \dim_H^-(\mu)$. Moreover,*

$$\sup_\epsilon \beta^-(\overline{\theta_\epsilon}(\psi, t)) \geqslant \dim_H{}^+(\mu).$$

Remark: This result includes all the versions of Theorem 3 discussed in Remarks 1–3, and inequality (3.3) in particular.

Proposition 4: $\forall \epsilon>0$, $\beta^+(\theta_\epsilon)\leqslant \dim_F(\mu)$ (*the fractal dimension of* μ).

Proof: By spectral equivalence, we can work in the space $\mathscr{L}^2([0,2\pi],\mu)$, where $\psi(t)\equiv e^{itx}$ μ-*a.e.* Choose $\epsilon>0$ and define, for all integer times t, $\delta_t=\epsilon/t\sqrt{2}$. Then, if $\alpha>\dim_F(\mu)$, we can find a compact K with $\mu(K)>1-\epsilon^2/2$, and with a fractal dimension $d_F(K)<\alpha$. For all sufficiently large t, K can be covered by N_t closed intervals I_j of width $\leqslant\delta_t$, with $N_t\leqslant\delta_t^{-\alpha}$. We can assume that the intervals I_j have no more than 2 overlaps; therefore, using their endpoints we can define a covering of K with a number $M_t\leqslant 2N_t\leqslant 2\delta_t^{-\alpha}$ of disjoint intervals of width $\leqslant\delta_t$, which for simplicity will be denoted again by I_j, and which satisfy $\mu(\cup I_j)>1-\epsilon^2/2$. In every interval I_j choose a point x_j and, for $0\leqslant s\leqslant t-1$, define

$$\xi_s(x)\equiv\sum_{j=1}^{M_t} e^{isx_j}\chi_j(x), \quad \text{for } x\in\cup I_j,$$

$$\xi_s(x)\equiv 0, \quad \text{elsewhere},$$

where $\chi_j(x)$ is the characteristic function of I_j. Then

$$\|\psi(s)-\xi_s\|^2=\int_0^{2\pi}|e^{isx}-\xi_s(x)|^2 d\mu(x)\leqslant s^2\delta_t^2+\mu([0,2\pi]\backslash\cup I_j)<t^2\delta_t^2+\frac{\epsilon^2}{2}<\epsilon^2$$

Now ξ_s $(s=0,\ldots,t-1)$ belong by construction in the subspace spanned by $\{\chi_j\}_{1\leqslant j\leqslant M_t}$, which, for sufficiently large t, has dimension $M_t\leqslant 2N_t\leqslant 2(\sqrt{2}t/\epsilon)^\alpha$. Thus, this subspace contains vectors which are $\epsilon-$close to $\psi,\ldots,\psi(t-1)$; therefore, at large times, $\theta_\epsilon(\psi,t)\leqslant 2(\sqrt{2}t/\epsilon)^\alpha$. □

Putting Theorem 2 and propositions 1(i), 2, 3, 4 together, we get

Proposition 5: *If* μ *is exactly scaling, with dimension* d*, then, for sufficiently small* $\epsilon>0$ *the limits*

$$\lim_{t\to\infty}\frac{\log\ \overline{\theta(\epsilon,\psi,t)}}{\log\ t}, \quad \lim_{t\to\infty}\frac{\log\ \theta(\epsilon,\psi,t)}{\log\ t} \tag{4.5}$$

exist, and have the same value $d=\dim_H(\mu)$.

Remark: One may speculate whether Proposition 3, too (hence, Theorem 3 itself) can be proven by a ''box counting'' argument of the kind used in the proof of Proposition 4.

V. A BALLISTIC UPPER BOUND

It is not possible to extract from the above results upper bounds for moments, and not even for the growth of the size of minimal ϵ-supports. Further assumptions are needed, which concern the ''spatial'' structure of the operator U on the basis B. Here a result in this vein is presented. For convenience, we'll say that the spread is *not faster than ballistic* if $[m^{(\alpha)}(t)]^{1/\alpha}$ does not increase faster than linearly with t, $\forall\alpha>0$. In this case, it is easily seen that $n_\epsilon(\psi,t,B)$, too, does not increase faster than linearly.

Proposition 6: *For* $\alpha\geqslant 0$ *let*

$$X_\alpha:=\{\psi\in\mathscr{H} \quad \text{such that} \quad \|\psi\|_\alpha:=\sup_{n\in\mathbf{Z}}|(e_n,\psi)\exp\alpha|n||<\infty\}$$

and suppose that $U(X_\alpha)\subseteq X_\alpha$ for some $\alpha>0$. Then, if $\psi\in X_\alpha$, *the spread is not faster than ballistic. Moreover,* $\forall\psi\in\mathscr{H}$, $n_\epsilon(\psi,t,B)$ *does not increase faster than linearly.*

Proof: Under the stated hypothesis , $U]X_\alpha$ is an everywhere defined linear operator in X_α, which is a Banach space under the norm $\|\cdot\|_\alpha$. Let $\{\psi_n\}$ be a convergent sequence in the

X_α-norm, such that $\{U\psi_n\}$ also converges in that norm, and let $\psi_\infty, \psi'_\infty$ be the corresponding limits. Then $\psi_n \to \psi_\infty$ and $U\psi_n \to \psi'_\infty$ in the weaker Hilbert norm, too; therefore $U\psi_n \to U\psi_\infty$ in the Hilbert norm because U is unitary. It follows that $\psi_\infty{}' = U\psi_\infty$, so $U \restriction X_\alpha$ is a closed operator in X_α. By the Closed Graph Theorem, it must be bounded. Therefore, if $\psi \in X_\alpha$, then $\forall t, n$

$$|\psi_n(t)| \leqslant \|U^t\psi\|_\alpha e^{-\alpha|n|} \leqslant \|U\|_\alpha^t \|\psi\|_\alpha e^{-\alpha|n|}. \tag{5.1}$$

Using (5.1) for $n \geqslant n_t := \alpha^{-1} t \log \|U\|_\alpha + \alpha^{-1} \log \|\psi\|_\alpha$, and $|\psi_n(t)| \leqslant 1$ for $n < n_t$, the announced bound on the growth of moments is immediately obtained. Finally, given any $\psi \in \mathscr{H}$, there is a $\psi' \in X_\alpha$ with $\|\psi - \psi'\| < \epsilon/2$; at any time t, any $\epsilon/2$- support for $U^t\psi'$ is also a ϵ-support for $U^t\psi$. □

Remark 1: Under the hypotheses of Proposition 6, the spread of wave packets in the presence of an absolutely continuous component is exactly ballistic.

Remark 2: Proposition 6 applies in several cases of concrete interest, including tight-binding discrete models and quantum maps like the kicked rotor[26] or the kicked Harper model.[4]

VI. DYNAMICAL DIMENSIONS

In this section, we shall discuss a different characterization of the structure of wave packets, which still makes reference to a specific basis, but, unlike moments, does not depend on the labelling of the basis vectors, or sites. On formal grounds, the construction to be presently described looks like a multifractal analysis of the measure $\mathscr{P}_{t,\psi}$, with the scaling limit defined by $t \to \infty$. It has been proposed, and numerically implemented, on the critical Harper model, in Ref. 17. In the following, $\|\psi\| = 1$, and completeness of B, are always assumed. Let us define the family of *partition functions*

$$Z_q(\psi, t) := \sum_{k \in \mathbf{Z}} p_k^q(t), \tag{6.1}$$

for all values of q such that the series converges at all times t. Such values include a half line $q > q_0$, with $0 \leqslant q_0 \leqslant 1$; for instance, under the assumptions of Proposition 6, Z_q is finite $\forall t$, $\forall\ q > 0$. In the following $q_0 < 1$ is assumed. Generalized entropies are defined, for $q \neq 1$, by

$$S_q := \frac{1}{1-q} \log Z_q$$

and for $q = 1$ by

$$S_1 = \sum_{k \in \mathbf{Z}} \Theta((p_k(t)), \tag{6.2}$$

where $\Theta(x) = -x \log x$ for $0 < x \leqslant 1$, $\Theta(0) = 1$. S_1 is the Shannon entropy of the distribution (3.1). With such definitions, S_q is a continuous function of q. Finally, define the *number of states*

$$\mathscr{N}_q(t) := e^{S_q(t)} = Z_q^{1/(1-q)}(t) \tag{6.3}$$

(the 2nd equality for $q \neq 1$) which, at fixed t, is a nonincreasing function of q.

The growth exponents $\beta^\pm(\mathscr{N}_q) = \mathscr{D}_q^\pm$ will be called here *dynamical dimensions*. From their very definition it follows that

Proposition 7: *$\mathscr{D}_q^\pm$ are nonincreasing functions of q, and $(1-q)\mathscr{D}_q^\pm$ are convex functions of q. Therefore, $\mathscr{D}_q^\pm$ are continuous functions of q, except possibly at $q = 1$.*

Proposition 8: (i) $\mathscr{D}_q^- \geqslant \dim_H^+(\mu)$ for $q < 1$, (ii) $\mathscr{D}_1^- \geqslant \dim_H^-(\mu)$.

Proof: Given $\epsilon>0$, $q<1$, define $\mathscr{A}_{\epsilon,q,t}:=\{k \in \mathbf{Z}: p_k(t)<\epsilon^{1/(1-q)}\mathscr{N}_q(t)^{-1}\}$ and $\mathscr{B}_{\epsilon,q,t}:=\mathbf{Z}\setminus\mathscr{A}_{\epsilon,q,t}$. Then $p_k^{q-1}>\epsilon^{-1}Z_q(t)$ if $k \in A_{\epsilon,q,t}$. From

$$Z_q(t)\geqslant\sum_{k\in\mathscr{A}_{\epsilon,q,t}} p_k(t)p_k^{q-1}(t)\geqslant\epsilon^{-1}Z_q(t)\mathscr{P}_{\psi,t}(\mathscr{A}_{\epsilon,q,t})$$

we obtain $\mathscr{P}_{\psi,t}(\mathscr{B}_{\epsilon,q,t})\geqslant 1-\epsilon$. From the definition of a minimal-support of $\mathscr{P}_{\psi,t}$ it follows that $\sharp(\mathscr{B}_{\epsilon,q,t})\geqslant n_\epsilon(\psi,t)$; therefore,

$$\begin{aligned} Z_q(t)&\geqslant\sum_{k\in\mathscr{B}_{\epsilon,q,t}} p_k^q(t)\\ &\geqslant n_\epsilon(\psi,t)\epsilon^{\frac{q}{1-q}}\mathscr{N}_q(t)^{-q}\\ &= n_\epsilon(\psi,t)\epsilon^{\frac{q}{1-q}}Z_q(t)^{-\frac{q}{1-q}}\end{aligned}$$

which entails $\mathscr{N}_q(t)=Z_q(t)^{1/(1-q)}\geqslant\epsilon^{q/(1-q)}n_\epsilon(\psi,t)$. Since this holds for arbitrarily small ϵ, part (i) of the thesis follows from inequality (3.3).

If $q=1$, let $\mathscr{A}_{\epsilon,t}:=\{k \in Z: p_k(t)<e^{-S_1(t)/\epsilon}\}$, and $\mathscr{B}_{\epsilon,t}=\mathbf{Z}\setminus\mathscr{A}_{\epsilon,t}$. If $k \in \mathscr{A}_{\epsilon,t}$, then $\log\frac{1}{p_k(t)}>[S_1(t)/\epsilon]$, which implies $\mathscr{P}_{\psi,t}(\mathscr{B}_{\epsilon,t})\geqslant 1-\epsilon$, so $\sharp(\mathscr{B}_{\epsilon,t})\geqslant n_\epsilon(\psi,t)$. Now let $\overline{\mathscr{B}}_{\epsilon,t}:=\mathscr{B}_{\epsilon,t}\cap\{k\in\mathbf{Z}: p_k(t)<e^{-1}\}$. Then $\sharp(\overline{\mathscr{B}}_{\epsilon,t})\geqslant n_\epsilon(\psi,t)-3$. Consequently,

$$S_1(t)\geqslant\sum_{k\in\mathscr{B}_{\epsilon,q,t}}\Theta(p_k(t))\geqslant(n_\epsilon(\psi,t)-3)\epsilon^{-1}S_1(t)e^{-S_1(t)/\epsilon}$$

because $\Theta(x)$ is increasing in $(0,e^{-1})$. Now, if $\beta^-(n_\epsilon)=0$, then also $\dim^-(\mu)=0$ by Theorem 3, so (ii) is obvious; if, instead, $\beta^-(n_\epsilon)>0$, then $n_\epsilon>3$ eventually, so, $\mathscr{N}_1\geqslant\epsilon^{-\epsilon}(n_\epsilon(\psi,t)-3)^\epsilon$, and finally $\mathscr{D}_1^-\geqslant\epsilon\beta^-(n_\epsilon)\geqslant\epsilon\dim_H^-(\mu)$ by Theorem 3. Since $\epsilon<1$ is arbitrary, (ii) is proved. □

Remark 1: $\mathscr{D}_1^-\geqslant\dim_H^+(\mu)$ is false in general. If the ''width'' of the wave packet on the basis B is measured by means of the ''informational'' number of states $\mathscr{N}_1$, then the wave packet does not necessarily spread as fast as its fastest component, contrary to what happens with moments. The following elementary example illustrates this and other peculiarities. Let $Ue_k=e_{k+1}$ for $k\neq 0,-1$, and $Ue_{-1}=e_1$, $Ue_0=e_0$. If $\psi=e_0\cos\alpha+e_1\sin\alpha$, then $d\mu_\psi=(\cos^2\alpha)\delta+(\sin^2\alpha)dx$, with δ, and dx the Dirac and Lebesgue measures respectively; so $\dim_H^+(\mu)=1$. On the other hand, $\mathscr{D}_q^\pm=0,\sin^2\alpha,1$ respectively for $q>1, q=1, q<1$. This example shows that, at fixed $\dim_H^+(\mu)$, the value of $\mathscr{D}_1^\pm$ is affected by the weight of different spectral components, and suggests that a discontinuity of $\mathscr{D}_q^\pm$ at $q=1$ may be typical of non-exactly dimensional spectral measures. In particular, such a discontinuity should always appear, in case of coexistence of both a point and a continuous component of the spectral measure.

Remark 2: Inequalities of ''thermodynamic'' type show that $\mathscr{N}_1$ cannot increase faster than $[m^{(\alpha)}(t)]^{1/\alpha}$.

Remark 3: Like moments, $\mathscr{N}_q$ $(q\leqslant 1)$ can, in principle, diverge as $t\to\infty$, even in the absence of a continuous spectrum.

Remark 4: In case μ_ψ has a point component (and only in that case), some at least of the $p_k(t)$ will not converge to 0 as $t\to\infty$; then Z_q will be bounded away from zero at large times, and $\mathscr{N}_q$ will not diverge in the limit $t\to\infty$ if $q>1$. Therefore the presence of a point component of μ_ψ enforces $\mathscr{D}_q^\pm=0$ for $q>1$.

Finding upper bounds for dynamical dimensions appears difficult in general, except in the limit $q\to\infty$, and in the particular case in which ψ is one of the basis vectors, which without loss of generality we may assume to be e_0. Then let

$$\lim\ \inf_{t\to\infty}\frac{\log\, p_0(t)}{\log\, t}=-c^+;\quad \lim\ \sup_{t\to\infty}\frac{\log\, p_0(t)}{\log\, t}=-c^-$$

Now $c^\pm$ can be exactly identified with certain fractal dimensions of μ. Rigorous reformulations of a result by Ketzmerick, Petschel, and Geisel,[3] due to Holschneider,[9] Barbaroux, Combes, and Motcho,[11] and Guerin and Holschneider,[10] show that $c^\pm=D_2^\pm(\mu)$, the upper and lower *correlation dimensions* of the spectral measure (for the exact definition of which the reader is deferred to the quoted papers). In the case when $D_2^+(\mu)=D_2^-(\mu)$, their common value is just called correlation dimension and denoted $D_2(\mu)$. Then, denoting $\mathscr{D}_\infty^\pm$ the $q\to\infty$ limits of the monotonic functions $\mathscr{D}_q^\pm$, we have

Proposition 8: *If* $\psi\in B$, *then* $\mathscr{D}_\infty^-\leqslant D_2^-(\mu)$, *and* $\mathscr{D}_\infty^+\leqslant D_2^+(\mu)$.

Proof: If $q>1$, from $Z_q(t)\geqslant p_0^q(t)\geqslant t^{-(c^++\eta)q}$, which is eventually true (in t) for any small η, we get $\mathscr{D}_q^+\leqslant[q/(q-1)](c^++\eta)$. Analogously, from $Z_q(t)\geqslant p_0^q(t)\geqslant t^{-(c^-+\eta)q}$, which is frequently true, we get $N_q(t)\leqslant t^{q(c^-+\eta)}$ frequently, that is, $\mathscr{D}_q^-\leqslant[q/(q-1)](c^-+\eta)$. □

The above results intuitively fit in a rough qualitative picture of the role of spectral dimensions. The behavior of $Z_q(t)$ at $q<1$ is mainly determined by that part of the probability distribution, which decays faster. This part corresponds to the fastest component of the wave packet, which, according to Theorem 3 [in the form of inequality (3.2)], probes the ''most continuous'' part of the spectrum; this is the sense of Proposition 8. As $q>1$ increases, instead, the slowly propagating part of the wave packet becomes more and more important. This very part also accounts for the tail in the decay of the probability at the initial site, which is determined by a less continuous region of the spectrum, and is in fact described by the correlation dimension(s).

Models of the Hofstadter-type

Ch. Kreft[a] and R. Seiler
Fachbereich Mathematik, Technische Universität Berlin, 10623 Berlin, Germany

(Received 15 May 1996; accepted for publication 17 June 1996)

Spectra and eigenfunctions of discrete Hamiltonians are computed using algebraic, analytic, and numerical tools. In particular, we consider the Hofstadter and the Second Neighbor Square Lattice model, the Triangular Lattice model in an inhomogenous magnetic field, the Doubly-discrete Quantum Pendulum, and the Honeycomb model. Qualitative properties of the spectra are related to symmetries. Semiclassical analysis in the algebraic setting for the Doubly-discrete Quantum Pendulum is shown to match numerical results well. The connection to integrable models is mentioned. © *1996 American Institute of Physics.*

I. INTRODUCTION

The subject of this paper lies on the edge of physics, mathematics, and computer science. It concerns the analysis of some quantum mechanical models for transport phenomena in two-dimensional solids.

For many decades it has been well known that the transport of electrons shows remarkable properties. The collective behavior of particles often leads to situations where charge transport can be described best in terms of quasiparticles. They can have positive, negative, or even noninteger charge. Of particular interest are phenomena that are seen in two-dimensional systems in the presence of large magnetic fields and at low temperature. It is there where integer or fractional quantum Hall conductance is observed.

Such phenomena can be modeled in part by Hamiltonians of the Hofstadter type. These operators have interesting mathematical properties. Their spectra are typically fractal and charge transport is integral.

There are several computational methods for dealing with Hamiltonians of the Hofstadter type. For the computation of spectra Chambers formula (see Sec. V, Theorem 1) is most useful.[1] Dynamics of wave functions can be visualized best in terms of Husimi functions (see Sec. II and Sec. III).

The elementary objects that underlie the construction of all model Hamiltonians are the discrete magnetic translations.[2] We will give a systematic exposition of these operators in terms of Weyl operators in the following section. At this point let us just adopt a pragmatic point of view and discretize the well-known expressions for a charged particle in a constant magnetic field in the most straightforward way.

Let Ψ be a function on $\mathbb{Z}^2$ with values in $\mathbb{C}$ and $\chi=(\chi_1,\chi_2)$ a discrete and real valued vector potential, such that

$$\text{curl } \chi(n) := \partial_1\chi_2 - \partial_2\chi_1 = \Phi. \tag{1}$$

Discrete derivatives are defined by

$$\partial_j F(n) := F(n) - F(n-e_j) \quad (j=1,2), \tag{2}$$

[a]Present address: IVU-Gesellschaft für Informatik, Verkehr und Umweltplanung mbH, 12161 Berlin, Bundesallee 88, Germany.

and magnetic translations as follows:

$$T_1\Psi(n)=e^{i\chi_1(n)}\Psi(n_1-1,n_2), \tag{3}$$

$$T_2\Psi(n)=e^{i\chi_2(n)}\Psi(n_1,n_2-1). \tag{4}$$

[The magnetic translations can be interpreted as connections on the trivial discrete vector bundle $\mathbb{Z}^2\times\mathbb{C}$. Equation (1) defines χ in terms of Φ up to a discrete gradient $(\partial_1\varphi,\partial_2\varphi)$, where φ denotes a function on $\mathbb{Z}^2$ generating a discrete gauge transformation.] They are unitary on $l^2(\mathbb{Z}^2)$. Due to the phase in their definition they have an elementary holonomy,

$$T_1^{-1}T_2^{-1}T_1T_2=e^{i\Phi}. \tag{5}$$

$(1-T_1)$ and $(1-T_2)$ are discrete magnetic momentum operators and give rise to the magnetic discrete Laplacian,

$$\Delta=\sum_{l=1}^{2}(1-T_l)^*(1-T_l), \tag{6}$$

coinciding with the Hofstadter Hamiltonian up to a sign and an additive constant,

$$H_{\mathrm{Hof}}=T_1+T_2+T_1^*+T_2^*. \tag{7}$$

The Hofstadter model has several physical interpretations. The most prominent one is as a tight-binding approximation for electrons bound to atomic sites in a two-dimensional crystal and in a strong external magnetic field. It is a model with two typical frequencies. The first corresponding to the area of the unit cell in the lattice, the second to the flux through a unit cell, which in our notation is Φ.

The history of the Hofstadter model goes back to the work of Peierls[3] on Bloch electrons in metals under the influence of a magnetic field. In the 1950s and 1960s progress was made by Azbel,[4] Harper,[5] Zak,[2] Chambers,[1] and Langbein.[6] They discovered the role of magnetic translations and began a systematic study of the square lattice model.

In 1976, Hofstadter[7] published the famous Hofstadter butterfly (Fig. 3). He found that the figure of the spectral bands versus the magnetic flux exhibits a complicated yet beautiful fractal structure. A detailed study of the square lattice and other models began thereafter. We just mention work by Wilkinson[8] who related the fractal structure to a WKB analysis of tunneling between different lattice cells. This semiclassical approach was put in a rigorous form by Helffer and Sjöstrand[9–13] using pseudodifferential operator calculus. This work was recently simplified and completed by Buslaev and Fedotov[14–18] by means of a WKB approach for difference equations. Since the Hofstadter model turns into Harper's equation by a Bloch-wave ansatz, the spectral analysis of the two models is the same. About the latter and its generalization, the Discrete Mathieu model, detailed results are known. Let us mention just one, the theorem by Last and Wilkinson about the total length of the band spectrum S for the critical value $\lambda=2$ (Harper's equation) and magnetic flux $\phi=2\pi p/q$:[19,20]

$$\frac{2(\sqrt{5}+1)}{q}<S<\frac{8e}{q}. \tag{8}$$

For more details we refer to the recent articles by Last, Jitomirskaya, and Shubin.[21–23] In parallel, the algebraic study was put forward by Bellissard,[24–26] who related the Hofstadter model to the work of Connes[27] on noncommutative geometry.

It was a big surprise at the beginning of the 1990s when it turned out that the Quantum Discrete Sine–Gordon equation[28,29] leads to the Hofstadter model.[29] Presently, Quantum groups and the Bethe Ansatz in the context of the Hofstadter model receive considerable attention.[30–32]

Hamiltonians of the Hofstadter type like the Hofstadter Hamiltonian, the triangular, the hexagonal model, or the Doubly-discrete Quantum Pendulum are the main objects of analysis in this paper. They are all elements of a C^*-algebra generated by the magnetic translations, the so-called rotation algebra, which is a particular case of a Weyl-Heisenberg algebra. Furthermore, they can be understood as pseudodifferential operators on the circle. In this setup the classical symbol of the Hofstadter Hamiltonian is

$$H_{\mathrm{Hof}}(\xi,x)=\cos\ \xi+\cos\ x. \tag{9}$$

It is defined on phase space $S^1\times S^1$ with the natural symplectic structure. For a list of the Hamiltonians discussed in this paper and their symbols, we refer to Table II.

Many of these Hamiltonians allow for a completely different interpretation: they are quantum integrals of a dynamical automorphism of the rotation algebra. Consider, e.g., the Hamiltonian of the Doubly-discrete Quantum Pendulum for $k\in\mathbb{R}\backslash\{0\}$,

$$H_{\mathrm{QP}}=2(T_1+T_2+T_1^*+T_2^*)+k(e^{-i\Phi/2}T_1T_2+e^{i\Phi/2}T_2^*T_1^*)+(1/k)(e^{-i\Phi/2}T_2T_1^*+e^{i\Phi/2}T_1T_2^*). \tag{10}$$

It is invariant under the automorphism generated by the map

$$\alpha:\langle T_1,T_2\rangle\mapsto\left\langle T_2,T_3=T_1^*\left(\frac{k+e^{i\Phi/2}T_2}{1+ke^{i\Phi/2}T_2}\right)^2\right\rangle. \tag{11}$$

This automorphism appeared first in the doubly discrete integrable sine–Gordon theory.[29,28,33]

[In the continuum case the automorphism is generated by Eq. (12) below. It is a special case of the hyperbolic equation,

$$(\partial_t^2-\partial_x^2)\phi(t,x)+g\ \sin\ \phi(t,x)=0. \tag{12}$$

For space-independent solutions $\phi(t)$, one gets the pendulum equation,

$$\partial_t^2\phi(t)+g\ \sin\ \phi(t)=o.] \tag{13}$$

This paper is structured as follows. In the next section we formulate elementary discrete quantum mechanics. The ground state of the elementary Hofstadter Hamiltonian is shown to be unique and invariant under discrete Fourier transformation. All this lays the basics for the ''Kinematics of the Hofstadter Type Models,'' which is the subject of the third section, where there is some overlap with a recent article by Faddeev[34] on the Discrete Heisenberg–Weyl Group and the Modular Group. The discrete analog of the Landau momentum and the Landau velocity is introduced and combined to form generators of the quantum group SL_q. In the fourth section we describe the models and present numerical results. Symmetries are used to understand some qualitative properties of the spectra. The Husimi functions of the Doubly-discrete Quantum Pendulum are shown to be localized at the classical orbits. In the last section we discuss Chambers relation for the Doubly-discrete Quantum Pendulum and comment on semiclassical methods for the computation of spectra. The semiclassical results are shown to approximate the numerical results well. For details on most of the material presented here we refer to Ref. 35.

Quantum group structures appear naturally in the context of the models of the Hofstadter type. It is hoped that this will eventually lead to a better understanding of the complicated and interesting nested structure of their spectra. This has, however, not yet materialized, although we have worked in this direction for several years.

II. ELEMENTARY DISCRETE QUANTUM MECHANICS

The irreducible state space for a discrete quantum system with one degree of freedom and rational Planck constant $\Phi = p/q$, where p and q are relatively prime, is the complex vector space $\mathbb{C}^q$. The canonical position and momentum operators are

$$t_1 = \begin{pmatrix} 0 & 0 & \dots & \dots & 0 & 1 \\ 1 & 0 & & & 0 & 0 \\ \vdots & \ddots & \ddots & & & \\ \vdots & & \ddots & \ddots & & \\ \vdots & & & \ddots & 0 & 0 \\ 0 & \dots & \dots & \dots & 1 & 0 \end{pmatrix} \tag{14}$$

and

$$t_2 = \mathrm{diag}(e^{i\Phi}, e^{2i\Phi}, \dots, e^{iq\Phi}), \quad \Phi = 2\pi\Phi. \tag{15}$$

The operators t_1 and t_2 have simple and remarkable properties listed below.

(1) t_1 and t_2 satisfy the same commutation relations (5) as the magnetic translations T_1 and T_2 defined in the Introduction, formula (3).

(2) They are, however, idempotent,

$$t_1^q = t_2^q = 1. \tag{16}$$

(3) t_1 can be understood as a shift on the q-periodic doubly infinite sequences (which is naturally identified with $\mathbb{C}^q$).

(4) t_1 and t_2 are related by discrete Fourier transformation,

$$\mathscr{F}: \mathbb{C}^q \to \mathbb{C}^q, \quad f(n) \mapsto \hat{f}(n) = \frac{1}{\sqrt{q}} \sum_m e^{inm\Phi} f(m), \tag{17}$$

$$t_2 = \mathscr{F} t_1 \mathscr{F}^{-1}. \tag{18}$$

Note that $\mathscr{F}$ is unitary, $\mathscr{F}^{-1} = \mathscr{F}^*$ and $\mathscr{F}^4 = 1$. Thus

$$\sigma(\mathscr{F}) \subset \{1, -1, i, -i\}. \tag{19}$$

(5) t_1 and t_2 have the same invariants. Particularly for $q > 1$, one gets the equations

$$\det t_1 = \det t_2 = 1, \quad \mathrm{trace}\ t_1 = \mathrm{trace}\ t_2 = 0. \tag{20}$$

The elementary Hofstadter Hamiltonian is the simplest nontrivial self-adjoint operator made out of t_1 and t_2,

$$h = t_1 + t_2 + t_1^* + t_2^*. \tag{21}$$

It is invariant under Fourier transformation. h is the elementary constituent of the Hofstadter Hamiltonian (see Theorem 3, Sec. III and remark 1 thereafter). Furthermore, h (or rather, $4-h$) is the discrete analog of the harmonic oscillator. Unfortunately, its ground state is not expressible in simple terms. Nevertheless, a partial characterization can be given, as the following theorem shows.

Theorem 1:

(i) $4-h$ has a nondegenerate ground state, ω. There is a strictly positive choice for ω.

(ii) ω is invariant under Fourier transformation.

Proof:

(i) The first statement follows from the Perron–Frobenius theorem.[36] Consider the Hamiltonian $h+3$. It has non-negative entries only. Furthermore, for each entry of the matrices the following inequality holds:

$$((h+3)^q)_{i,j} \geqslant ((t_1+t_1^*+1)^q)_{i,j}. \tag{22}$$

Next we replace t_1 by the nilpotent matrix D,

$$D=\begin{pmatrix} 0 & 0 & \dots & \dots & 0 & 0 \\ 1 & 0 & & & 0 & 0 \\ \vdots & \ddots & \ddots & & & \\ \vdots & & \ddots & \ddots & & \\ \vdots & & & \ddots & 0 & 0 \\ 0 & \dots & \dots & \dots & 1 & 0 \end{pmatrix}, \tag{23}$$

and obtain the inequality

$$(t_1+t_1^*+1)^q \geqslant (D+D^*+1)^q \geqslant \sum_{l=1}^{q} (d^l+d^{*l})+1. \tag{24}$$

Hence each entry of the matrix $(h+3)^q$ is larger than one; therefore, $h+3$ is ergodic.

(ii) Since $\mathscr{F}$ commutes with h, there is a choice of ω that is an eigenvector of $\mathscr{F}$ too:

$$\mathscr{F}\omega=\lambda\omega, \tag{25}$$

for some $\lambda \in \{+1,-1,-i,+i\}$.

Consider now the last component in the equation above,

$$\frac{1}{\sqrt{q}} \sum e^{iql\Phi}\omega(l)=\frac{1}{\sqrt{q}} \sum \omega(l)=\lambda\omega(q). \tag{26}$$

Since $\omega(i)$, $i \in \{1,\dots,q\}$, is strictly positive, this is consistent with $\lambda=1$ only.

So it is well motivated to call the ground state ω of h a discrete version of the Gauss function. This is supported by numerical computations (see Fig. 1).

Discrete quantum mechanics can also be formulated in terms of functions on discrete phase space $\mathbb{C}^q \times \mathbb{C}^q$. The transition from one formulation to the other is given by a discrete Bargmann transformation. This formulation is useful—as in the continuous case—for making contact with the corresponding classical theory.

Discrete position and momentum give rise to the Weyl operators $w(m)$, $m \in \mathbb{Z}^2$, defined by

$$\begin{gathered} w(1,0)=t_1, \quad w(0,1)=t_2, \\ w(m+n)=\exp\left[-\frac{i}{2}\Phi\sigma(m,n)\right]w(m)w(n) \quad (m,n \in \mathbb{Z}^2). \end{gathered} \tag{27}$$

$\sigma(m,n)$ denotes the standard discrete sympletic form,

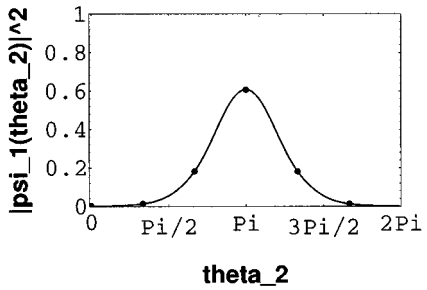

FIG. 1. Ground state of the Discrete Harmonic Oscillator for $q=6$.

$$\sigma(m,n):=m_1n_2-m_2n_1. \tag{28}$$

Note that the discrete Weyl operator w is doubly q-periodic,

$$w(m+qn)=w(m) \quad (m,n\in\mathbb{Z}^2). \tag{29}$$

Fourier transformation acts on w like a rotation by $\pi/2$,

$$\mathscr{F}w(m)\mathscr{F}^{-1}=w(Jm) \quad [m=(m_1,m_2)\in\mathbb{C}^q\times\mathbb{C}^q], \tag{30}$$

where J denotes the discrete complex structure $Jn=(-n_2,n_1)$, $n\in\mathbb{Z}^2$.

In terms of the discrete Weyl operator w and the ground state ω of h, the discrete Bargmann transformation is defined by

$$B:\mathbb{C}^q\to\mathbb{C}^q\times\mathbb{C}^q, \quad \psi\mapsto B_\psi(m):=(\omega,w(Jm)\psi). \tag{31}$$

The action of all relevant operators on the state space $\mathbb{C}^q$ can now easily be transformed to the Bargmann representation.

In order to interpret wave functions in classical terms it is useful to look at the Husimi functions. They are usually defined in terms of Bargmann functions,

$$H_\psi(m)=|B_\psi(m)|^2. \tag{32}$$

Notice, however, that they can also by given in terms of a trace over projectors in the original state space $\mathbb{C}^q$,

$$H_\psi(m)=\mathrm{trace}[p_\psi w(m)p_\omega w^{-1}(m)], \tag{33}$$

where p_ψ and p_ω denote the projectors onto ψ and ω, respectively.

III. KINEMATICS OF HOFSTADTER-TYPE MODELS

Kinematics of the Landau, the Hofstadter model, and their descendents are very close to each other. It is, therefore, natural to develop them in parallel. The basic object in the background of what follows is the Heisenberg group in $2+1$ one dimensions. It gives rise to the following family of unitary Weyl operators on $L^2(\mathbb{C})$:

$$W_\Phi(x)F(y)=\exp\left[\frac{i}{2}\,\Phi\sigma(x,y)\right]F(y-x). \tag{34}$$

σ denotes the natural symplectic quadratic form on $\mathbb{C}$, $\sigma(x,y)=\mathrm{Im}\,\overline{xy}=x_1y_2-x_2y_1$ ($x=x_1+ix_2\in\mathbb{C}$), and Φ is a real parameter that is interpreted to be the magnetic flux through a surface of unit area. Some times it is convenient to identify Φ with a vector $(0,0,\Phi)\in\mathbb{R}^3$.

The Weyl operators W_Φ satisfy the composition law

$$W_\Phi(x)W_\Phi(y)=\exp\left[\frac{i}{2}\,\Phi\sigma(x,y)\right]W_\Phi(x+y), \tag{35}$$

which gives rise to the canonical commutation relation

$$W_\Phi(x)W_\Phi(y)=\exp[i\Phi\sigma(x,y)]W_\Phi(y)W_\Phi(x). \tag{36}$$

Equations (34) and (36) have nice and simple geometric interpretations. [$W_\Phi(x)$ is the integrated connection $\nabla=d+iA$, $dA=\Phi\ dx^1\wedge dx^2$ on $\mathbb{C}\times\mathbb{C}$. Furthermore, W_Φ is a projective representation of the Abelian group $\mathbb{C}$, and at the same time a noncommutative deformation of the characters of $\mathbb{R}^2$.]

The operators $W_{-\Phi}$ commute with the W_Φ's. In fact, it can be proved[23] that the commutand of the von Neumann algebra generated by the W_Φ's is equal to the von Neumann algebra generated by the $W_{-\Phi}$'s and vice versa,

$$\{W_\Phi(x)|x\in\mathbb{C}\}'=\{W_{-\Phi}(x)|x\in\mathbb{C}\}''. \tag{37}$$

The operators W_Φ and $W_{-\Phi}$ form two commuting two-parametric, strongly continuous unitary groups and are, therefore, generated by self-adjoint operators, v and k, as follows:

$$\begin{aligned}
&W_\Phi(x)=\exp\ ix\cdot v, \quad x\cdot v=x_1v_1+x_2v_2,\\
&v_1=i\partial_1-\frac{\Phi}{2}\,y_2, \quad v_2=i\partial_2+\frac{\Phi}{2}\,y_1;\\
&W_{-\Phi}(x)=\exp\ ix\cdot k, \quad x\cdot k=x_1k_1+x_2k_2,\\
&k_1=i\partial_1+\frac{\Phi}{2}\,y_2, \quad k_2=i\partial_2-\frac{\Phi}{2}\,y_1.
\end{aligned} \tag{38}$$

The commutation relations (36) imply

$$[v_1,v_2]=i\Phi, \quad [k_1,k_2]=-i\Phi, \quad [k_m,v_n]=0, \quad m,n\in\{1,2\}. \tag{39}$$

In physical terms, v is the velocity and k the momentum operator. From k, one derives the operator $c=1/\Phi^2\ (k\wedge\Phi)$, which is the operator of the Landau center. (The expectation value of the position operator circles around the expectation value of c according to the dynamics of the Landau Hamiltonian. Furthermore, c is an integral of motion.) It has the commutation relations

$$[c_1,c_2]=-\frac{i}{\Phi}. \tag{40}$$

The magnetic flux Φ plays a role much like Planck's constant in quantum mechanics. This analogy leads naturally to quantization of arbitrary functions on phase space. Let F be an element of the Schwartz test function space and $\hat{F}$ its Fourier transformation. The corresponding quantization is naturally defined by

$$W_\Phi(F)=\left(\frac{1}{2\pi}\right)\int dx\ \hat{F}(x)W_\Phi(x). \tag{41}$$

[The definition below produces a noncommutative Φ-deformation of the algebra of functions on phase space $\mathbb{C}$.] These operators generate a C^* algebra (norm closure) or a von Neumann algebra (weak closure), respectively. According to the von Neumann uniqueness theorem the von Neumann algebra has irreducible constituents that are all equivalent to the standard Schrödinger representation.

Kinematics of the models of the Hofstadter type are a discrete version of the one for the Landau model described above. Consider the discrete phase space $\mathbb{Z}^2$ and the standard discrete symplectic structure σ as defined before (28).

The corresponding Weyl operators on $l^2(\mathbb{Z}^2)$ are defined by

$$W_\Phi(m)F(n)=\exp\left[\frac{i}{2}\,\Phi\sigma(m,n)\right]F(n-m). \tag{42}$$

Again, they satisfy the Weyl relations,

$$W_\Phi(m)W_\Phi(n)=\exp\left[\frac{i}{2}\,\Phi\sigma(m,n)\right]W_\Phi(m+n), \tag{43}$$

$$W_\Phi(m)W_\Phi(n)=\exp[i\Phi\sigma(m,n)]W_\Phi(n)W_\Phi(m) \tag{45}$$

Equations (42) and (43) again have simple geometric interpretations in terms of connections on a discrete complex line bundle over $\mathbb{Z}^2$.

The discrete Weyl operators $W_{-\Phi}$ commute with the W_Φ's and they generate their respective commutant,

$$\{W_\Phi(n)|n\in\mathbb{Z}^2\}'=\{W_{-\Phi}(m)|m\in\mathbb{Z}^2\}''. \tag{46}$$

The operators W_Φ and $W_{-\Phi}$ form 2-parametric, discrete unitary groups. They are generated by the elementary pairs of unitary operators,

$$T_1^{(v)}:=W_\Phi(1,0),\quad T_2^{(v)}:=W_\Phi(0,1), \tag{47}$$

and

$$T_1^{(k)}:=W_{-\Phi}(1,0),\quad T_2^{(k)}:=W_{-\Phi}(0,1), \tag{48}$$

respectively, and satisfy the relations

$$T_1^{(v)}T_2^{(v)}:=e^{i\Phi}T_2^{(v)}T_1^{(v)},\quad T_1^{(k)}T_2^{(k)}=e^{-i\Phi}T_2^{(k)}T_1^{(k)}. \tag{49}$$

In physical terms $T^{(v)}$ is the discrete velocity and $T^{(k)}$ the discrete momenum operator.

Each pair $(T_1^{(v)},T_2^{(v)})$, $(T_1^{(k)},T_2^{(k)})$ generates a rotation algebra. Together they have a natural structure as a quantum group SL_q, $q=e^{i\Phi}$. [Each pair forms a degenerate representation of a quantum group SL_q with the L operators

$$L^{(v)}=\begin{pmatrix} T_1^{(v)} & T_2^{(v)} \\ 0 & T_1^{(v)*}\end{pmatrix},\quad L^{(k)}=\begin{pmatrix} T_2^{(k)} & 0 \\ T_1^{(k)} & T_2^{(k)*}\end{pmatrix}. \tag{50}$$

Since $L^{(v)}$ and $L^{(k)}$ satisfy the Yang–Baxter equation,

$$R_{12}L_1^{(\sigma)}L_2^{(\sigma)}=L_2^{(\sigma)}L_2^{(\sigma)}R_{12} \quad (\sigma\in\{v,k\}), \tag{51}$$

the same is true for their tensor product,

$$L^{(v)}\otimes L^{(k)}=\begin{pmatrix} T_1^{(v)}T_2^{(k)}+T_2^{(v)}T_1^{(k)} & T_2^{(v)}T_2^{(k)*} \\ T_1^{(v)*}T_1^{(k)} & T_1^{(v)*}T_2^{(k)*} \end{pmatrix}. \tag{52}$$

The R-matrix is the canonical one,

$$R=\begin{pmatrix} q & 0 & 0 & 0 \\ 0 & 1 & q-\dfrac{1}{q} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & q \end{pmatrix}. \tag{53}$$

By contruction the q determinant is unity.]

In the following we will mostly use the first pair, $T_1^{(v)}$, $T_2^{(v)}$. To simplify notation we drop the upper index from now on and simply write $T_1:=T_1^{(v)}$, $T_2:=T_2^{(v)}$. Furthermore, we replace $W_\Phi(n)$ by $W(n)$.

Quantization of phase space functions, $f\in C^\infty(T^2)$, where T^2 denotes the two-torus, given by

$$W(f)=\sum \hat{f}(m)W(m) \quad \left(f(x)=\sum \hat{f}(m)e^{imx}\right), \tag{54}$$

leads to the C^*-algebra $\mathscr{C}_\Phi$ and the von Neumann algebra $\mathscr{N}_\Phi$ by norm and weak closures, respectively. To fix the notation, let us call $\mathscr{C}_\Phi$ the rotation algebra and $\mathscr{N}_\Phi$ the Weyl–Heisenberg algebra. [The above definition produces a noncommutative Φ-deformation of the algebra of functions on the torus. In the terminology of Connes this is the quantized torus.] f is the classical symbol of the operator $W(f)$. There is a natural trace on the C^*-algebra generated by the Weyl operators $W(f)$,

$$\text{trace } W(f)=\hat{f}(0). \tag{55}$$

The GNS construction with respect to this trace leads back to the representation (42) we started from.

It is well known that all irreducible representations of the Weyl–Heisenberg algebra $\mathscr{N}_\Phi$ for rational $\Phi=\Phi/2\pi$ can explicitly be written in terms of finite-dimensional matrices.

Theorem 2: Let the magnetic flux be rational, $\Phi=2\pi(p/q)$ and p,q relatively prime. Then all irreducible representations of $\mathscr{N}_\Phi$ are labeled by an element of the torus $S^1\times S^1$. The representation π_θ is, up to unitary conjugation, defined by

$$\pi_\theta(T_1)=e^{i\theta_1}t_1, \quad \pi_\theta(T_2)=e^{i\theta_2}t_2, \tag{56}$$

where t_1 and t_2 are the discrete momentum and the discrete position operators introduced in Sec. II, formulas (14) and (15).

The irreducible representations π_θ have several interesting properties that are, in part, just translations from the corresponding properties of t_1 and t_2.

(1) Representations π_θ, $\theta\in S^1\times S^1$ are not injective since T_1^q and $(e^{iq\theta_1}.\ 1)$ have the same image under the map π_θ.

(2) Two representations, π_θ and $\pi_{\theta'}$ for $\theta\neq\theta'$ and $(\theta,\theta')\in[0,2\pi/q)\times[0,2\pi/q)$, are inequivalent because the spectra of $\pi_\theta(T_l)$ and $\pi_{\theta'}(T_l)$, $l=1,2$, are different.

TABLE I. Useful homomorphisms of the rotational algebra.

No.	Description	Matrix	det(M)	Automorphism	Classical

v	Shear	$\begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}$	1	$T_1 \to T_1$ $T_2 \to e^{i(\Phi/2)} T_1 T_2$	$x_1 \to x_1$ $x_2 \to x_1 + x_2$
vi	Rotation and stretch	$\begin{pmatrix} -1 & 1 \\ -1 & -1 \end{pmatrix}$	2	$T_1 \to e^{-i(\Phi/2)} T_1^* T_2^*$ $T_2 \to e^{i(\Phi/2)} T_1 T_2^*$	$x_1 \to x_1 + x_2$ $x_2 \to x_1 - x_2$
vii	Rotation by $\pi/3$	$\begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}$	1	$T_1 \to T_2$ $T_2 \to e^{-i(\Phi/2)} T_1^* T_2^*$	$x_1 \to x_2$ $x_2 \to -x_1 - x_2$
viii	Reflection at $x = 0$	$\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$	-1	$T_1 \to T_1$ $T_2 \to T_2^*$	$x_1 \to x_1$ $x_2 \to -x_2$
No.	Description	(ζ_1, ζ_2)		Automorphism	
ix	Reverse sign of T's	$(-1,-1)$		$T_1 \to -T_1$ $T_2 \to -T_2$	
x	Reverse sign of T_2	$(1,-1)$		$T_1 \to T_1$ $T_2 \to -T_2$	

(3) If however $\theta' = \theta + (2\pi/q)m$ for $m \in \mathbb{Z}^2$, the two representations $\pi_{\theta'}$ and π_θ are equivalent. The unitary intertwining between $\pi_{\theta'}$ and π_θ is constructed as follows: From the commutation relations of the Weyl operators we conclude that for every $n \in \mathbb{Z}^2$ and $A \in \mathscr{N}_\Phi$,

$$\pi_{\theta + \Phi n}(A) = W(Jn)\, \pi_\theta(A)\, W^{-1}(Jn). \tag{57}$$

Since, furthermore, the Diophantine equation for r, s in $\mathbb{Z}$,

$$pr + qs = 1, \tag{58}$$

has a solution—due to the Euclidean algorithm—we find, for every $m \in \mathbb{Z}^2$, an element $n \in \mathbb{Z}^2$ such that

$$\Phi n = \frac{m}{q} \quad \text{modulo } 1. \tag{59}$$

For rational Φ, the von Neumann algebra $\mathscr{N}_\Phi$ is of Type I_q, where $\Phi = p/q$, p and q relatively prime. This situation changes if $\Phi \notin Q$. In this case the center $\mathscr{N}_\Phi \cap \mathscr{N}_\Phi' = \mathbb{C}1$, hence $\mathscr{N}_\Phi$ is a factor. In fact, $\mathscr{N}_\Phi$ is a II_1 factor because the trace defined by (55) is weakly continuous and strictly positive.[23]

The representation of the Weyl algebra $\mathscr{N}_\Phi$ for rational Φ is reducible. In fact, each irreducible representation appears exactly once. This is the content of the following theorem that we cite with no proof.

Theorem 3: For rational $\Phi = p/q$, p and q relatively prime, there exists a unitary transformation,

TABLE II. Models, Hamiltonians, and classical symbols.

Model	Hamiltonian	Classical symbol
Hofstadter	$H_{\mathrm{Hof}}=T_1+T_2+\mathrm{h.c.}$	$2\cos(x_1)+2\cos(x_2)$
Mathieu	$H_\mu=T_1+\mu T_2+\mathrm{h.c.}$	$2\cos(x_1)+2\mu\cos(x_2)$
Second neighbor	$H_\epsilon=T_1+T_2+\epsilon(T_1^2+T_2^2)+\mathrm{h.c.}$	$2\cos(x_1)+2\cos(x_2)$ $+2\epsilon(\cos(2x)+\cos(2x_2))$
Quantum Pendulum	$H_{\epsilon,k}=\epsilon(T_1+T_2)+ke^{-i(\Phi/2)}T_1T_2$ $+\frac{1}{k}e^{i(\Phi/2)}T_1T_2^*+\mathrm{h.c.}$	$\epsilon(2\cos(x_1)+2\cos(x_2))$ $+2k\cos(x_1+x_2)+(2/k)\cos(x_1-x_2)$
Triangular lattice	$H_\eta=T_1+T_2+e^{-i\eta}T_1T_2+\mathrm{h.c.}$	$\cos(x_1)+\cos(x_2)+\cos(x_1+x_2-\eta+\phi/2)$
Honeycomb lattice	$H_{HC}=\begin{pmatrix}0 & T_1+T_2+e^{-i(\Phi/2)}T_1T_2\\ T_{-1}+T^{-2}+e^{i\Phi/2}T_2^{-1}T_1^{-1} & 0\end{pmatrix}$	none

$$U:l^2(\mathbb{Z}^2)\to\frac{1}{|\mathscr{B}|}\int_{\mathscr{B}}^{\oplus}d^2\theta\ \mathbb{C}^q\otimes\mathbb{C}^q, \tag{60}$$

such that

$$T_\alpha^{(v)}\cong\frac{1}{|\mathscr{B}|}\int_{\mathscr{B}}^{\oplus}d^2\theta\ \pi_\theta(T_\alpha)\otimes\mathbb{1},\quad T_\alpha^{(k)}\cong\frac{1}{|\mathscr{B}|}\int_{\mathscr{B}}^{\oplus}d^2\theta\ \mathbb{1}\otimes\pi_\theta(T_{\alpha+1})\quad(\alpha\in\mathbb{Z}_2). \tag{61}$$

Here, $\cong$ denotes equality up to conjugation by U and $\mathscr{B}$ denotes the magnetic Brillouin torus,

$$\mathscr{B}=\mathbb{R}\left(\mathrm{mod}\ \frac{2\pi}{q}\right)\mathbb{R}\left(\mathrm{mod}\ \frac{2\pi}{q}\right). \tag{62}$$

Theorem 3 has several useful consequences.

(1) The spectral analysis of an element A of $\mathscr{N}_\Phi$ can be reduced to the analysis of its restriction to each individual fiber, since

$$A\cong\frac{1}{|\mathscr{B}|}\int_{\mathscr{B}}^{\oplus}d^2\theta A(\theta)\otimes\mathbb{1}, \tag{63}$$

$$\sigma(A)=\bigcup_{\theta\in\mathscr{B}}\sigma(\pi_\theta(A)). \tag{64}$$

TABLE III. Symmetries of the Mathieu model.

Transformation	Description	Symmetry
No. i	Rotation by $\pi/2$ (Aubry duality)	$\sigma(\mu)=\mu\sigma(1/\mu)$
No. x	Reverse sign of T_2	$\sigma(\mu)=\sigma(-\mu)$
No. ix	Reversion of sign infront of T_j	$\sigma(\mu)=-\sigma(\mu)$
No. viii	Reflection at $x=0$	$\sigma(\Phi)=\sigma(-\Phi)$
$\Phi\to\Phi+2\pi$	Flux periodicity	$\sigma(\Phi)=\sigma(\Phi+2\pi n)$
	Parameter space	$\Phi\in[0,\pi]$
		$\mu\in[0,1]$

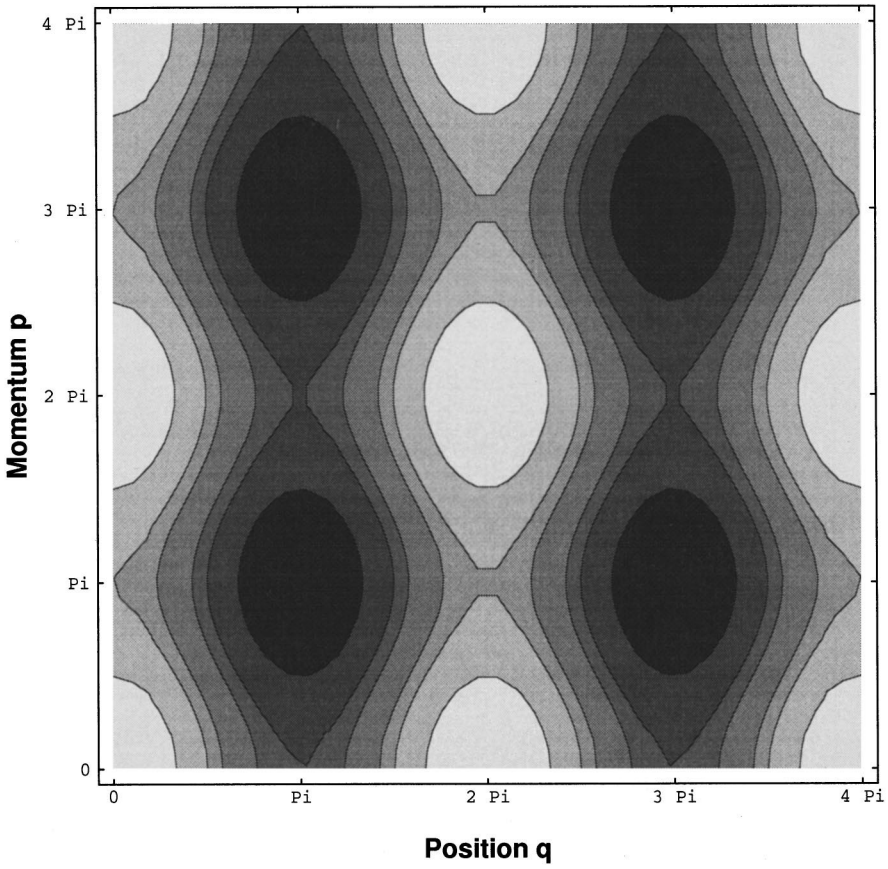

FIG. 2. Classical contour levels the the Discrete Mathieu model for $\mu=0.5$.

This means, in particular, that the spectral analysis of a Hamiltonian of the Hofstadter type is reduced to a matrix problem, e.g.,

$$\sigma(H_{\mathrm{Hof}})=\bigcup_{\theta\in\mathscr{B}}\sigma(H_{\mathrm{Hof}}(\theta)), \tag{65}$$

$$H_{\mathrm{Hof}}(\theta)=e^{i\theta_1}t_1+e^{i\theta_2}t_2+e^{-i\theta_1}t_1^*+e^{-i\theta_2}t_2^*, \tag{66}$$

where we used the notation $H_{\mathrm{Hof}}(\theta)=\pi_\theta(H_{\mathrm{Hof}})$.

(2) The commutand of $\mathscr{N}_\Phi$ is given by the formula

$$\mathscr{N}'_\Phi=\mathrm{End}(L^2(\mathscr{B}))\otimes\mathbb{1}\otimes\mathrm{End}(\mathbb{C}^q), \tag{67}$$

where $\mathrm{End}(L^2(\mathscr{B}))$ and $\mathrm{End}(\mathbb{C}^q)$ denote the spaces of bounded linear operators on $L^2(\mathscr{B})$ and $\mathbb{C}^q$, respectively. [We used the natural identification of $(1/|\mathscr{B}|)\int_{\mathscr{B}}^{\oplus} d^2\theta\ \mathbb{C}^q\otimes\mathbb{C}^q$ with $L^2(\mathscr{B})\otimes\mathbb{C}^q\otimes\mathbb{C}^q$.]

As a last subject in this section we mention a useful property of the Husimi functions. Let $\Psi(\theta)$ be an eigenvector of $H(\theta)=\pi_\theta(H)$, $(\theta\in\mathscr{B})$, where H denotes a Hamiltonian, which by assumption is an element of the von Neumann algebra $\mathscr{N}_\Phi$.

Due to equation (57) one gets for the Husimi function,

$$H_{\Psi(\theta)}(n):=|(w,W(Jn)\Psi(\theta))|^2, \tag{68}$$

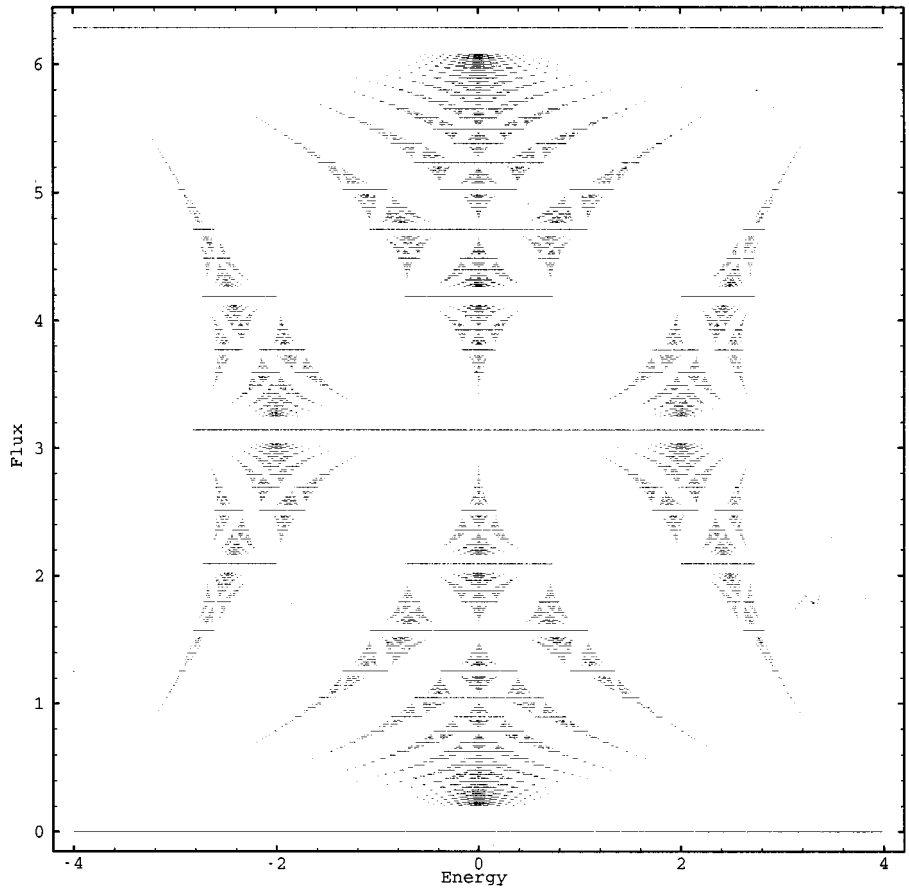

FIG. 3. Hofstadter Butterfly: Spectrum of the Hofstadter Model.

the equation

$$H_{\Psi(\theta)}(n)=H_{\Psi(\theta+\Phi n)}(0) \quad (n\in\mathbb{Z}^2,\theta\in\mathbb{R}^2). \tag{69}$$

It defines a natural interpolation $H_{\Psi(\theta)}(x)$, $x\in\mathbb{R}$, between the discrete values of $H_{\Psi(\theta)}(n)$:

$$H_{\Psi(\theta)}(n)=H_{\Psi(\theta+\Phi n)}(0) \quad (n\in\mathbb{Z}^2,\theta\in\mathbb{R}^2). \tag{70}$$

In particular, one gets the formula

$$H_{\Psi(0)}(\theta)=H_{\Psi(\Phi\theta)}(0) \quad (\theta\in\mathbb{R}^2). \tag{71}$$

IV. THE MODELS

There are many automorphisms of the discrete Weyl–Heisenberg algebra; some are linear others are nonlinear—some are inner others not. We have not studied them systematically. This would be an interesting mathematical problem in itself. However, we will give a list of examples. Many of them will show up later as symmetries of model Hamiltonians.

The simplest class of automorphisms are the linear ones. They may be called discrete Bogoliubov–Valatin transformations.

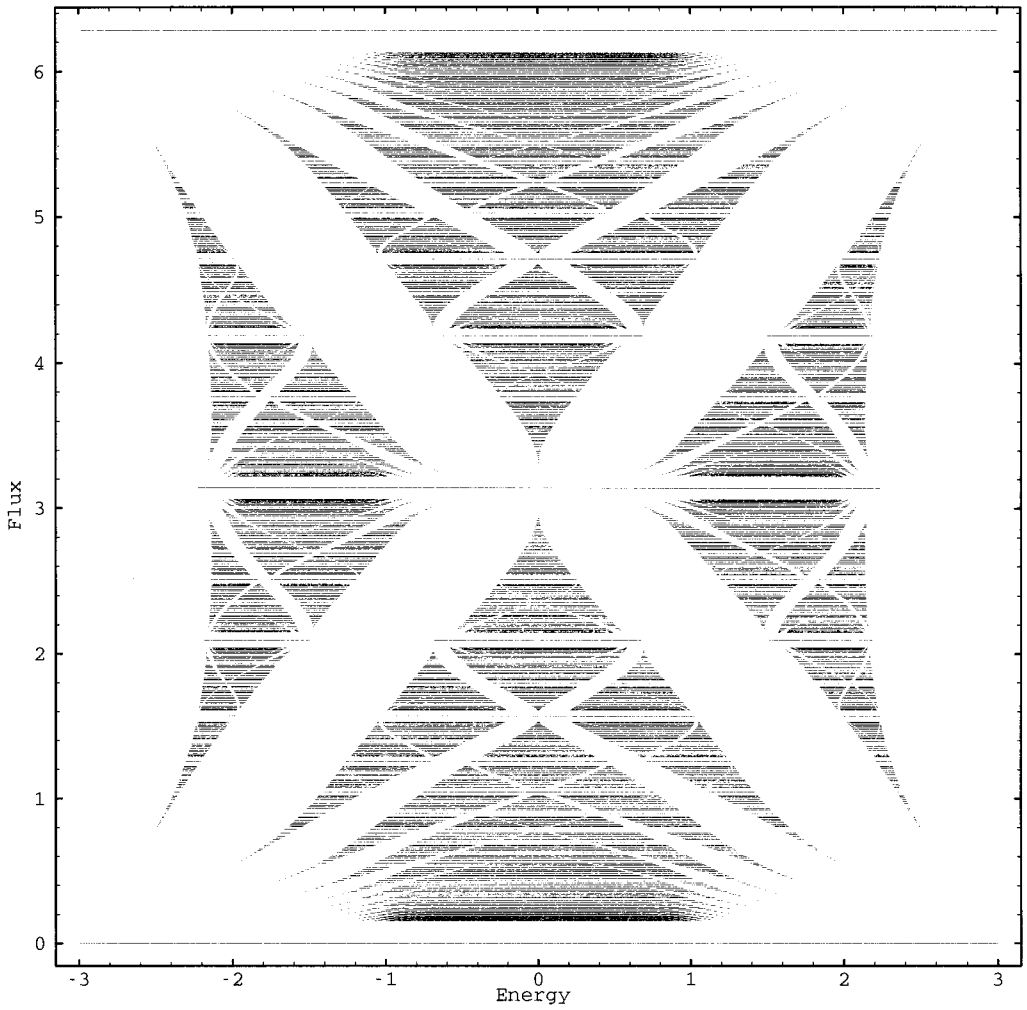

FIG. 4. Spectrum of the Discrete Mathieu Hamiltonian for $\mu=0.5$ and $q<40$.

Proposition: Let M be a 2×2 matrix with integer entries and nonvanishing determinant. Then the map

$$\alpha_M : W(m) \to W(Mm) \quad (m \in \mathbb{Z}^2), \tag{72}$$

generates an algebra homomorphism from $\mathcal{N}_\Phi$ onto $\mathcal{N}_{\det M,\Phi}$.

The statement follows directly from the commutation relations (45). The discrete Fourier transformation implements a special case of a discrete linear automorphism,

$$W(m) = \mathcal{F} W(Jm) \mathcal{F}^{-1}, \tag{73}$$

where J denotes the discrete complex structure introduced before. Others are summarized in Table I.

Nonlinear automorphisms are typically generated by an arbitrary function f that maps the unit circle into itself. In terms of magnetic translations they are defined by the shift

$$\alpha_f : (T_1, T_2) \to (T_2, T_3), \quad T_1 T_3 = f(T_2), \tag{74}$$

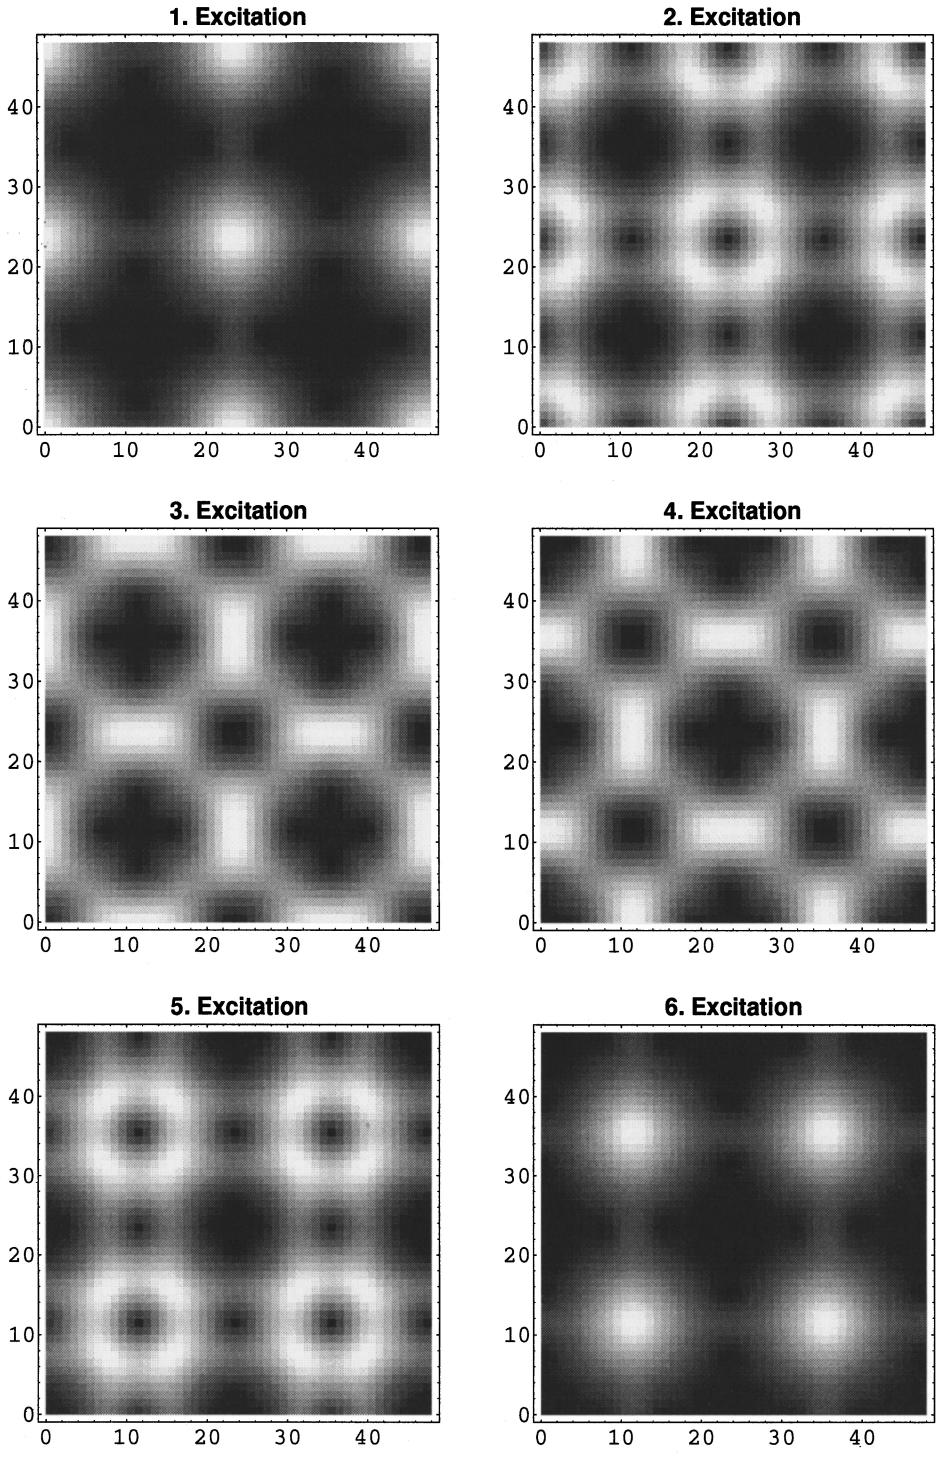

FIG. 5. Continuous Husimi Transformation for Hofstadter model ($p/q=1/6$).

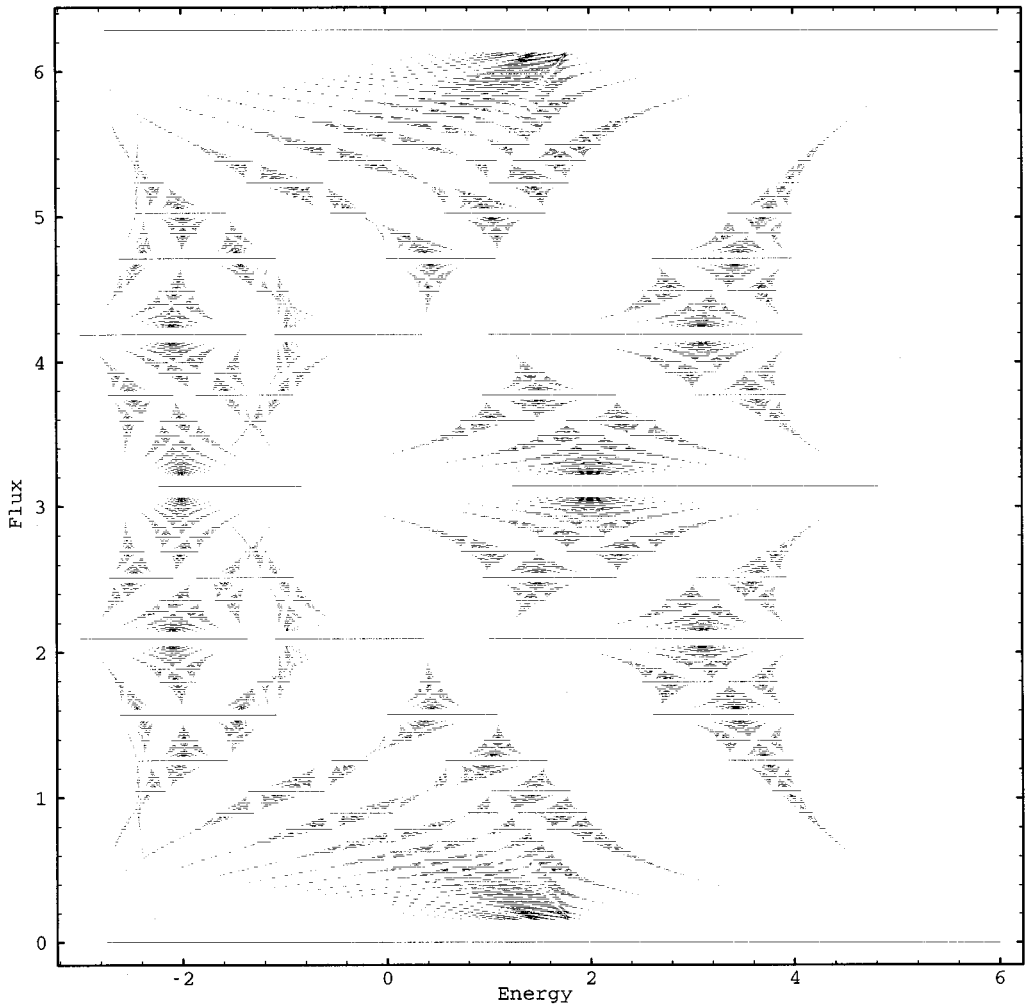

FIG. 6. Spectrum of the Second Neighbor Square Lattice model for $\epsilon=0.25$ and $q<40$.

where T_3 is defined by (74). It is easy to check that α_f is an algebra automorphism as long as all quantities encountered on the way of verification are well defined. (This requires some regularity for f.) A particularly nice example is the one arising from the Doubly-discrete Quantum Pendulum,[29] where

TABLE IV. Symmetries of the second neighbor model.

Transformation	Description	Symmetry
No. iii	Reflection at $x=p$	$\sigma(\Phi)=\sigma(-\Phi)$
No. ix	Reversion of sign infront of T_j	$\sigma(\epsilon)=-\sigma(-\epsilon)$
$\Phi\to\Phi+2\pi$	Flux periodicity	$\sigma(\Phi)=\sigma(\Phi+2\pi n)$
	Parameter space	$\Phi\in[0,\pi]$
		$\epsilon\in[0,\infty)$

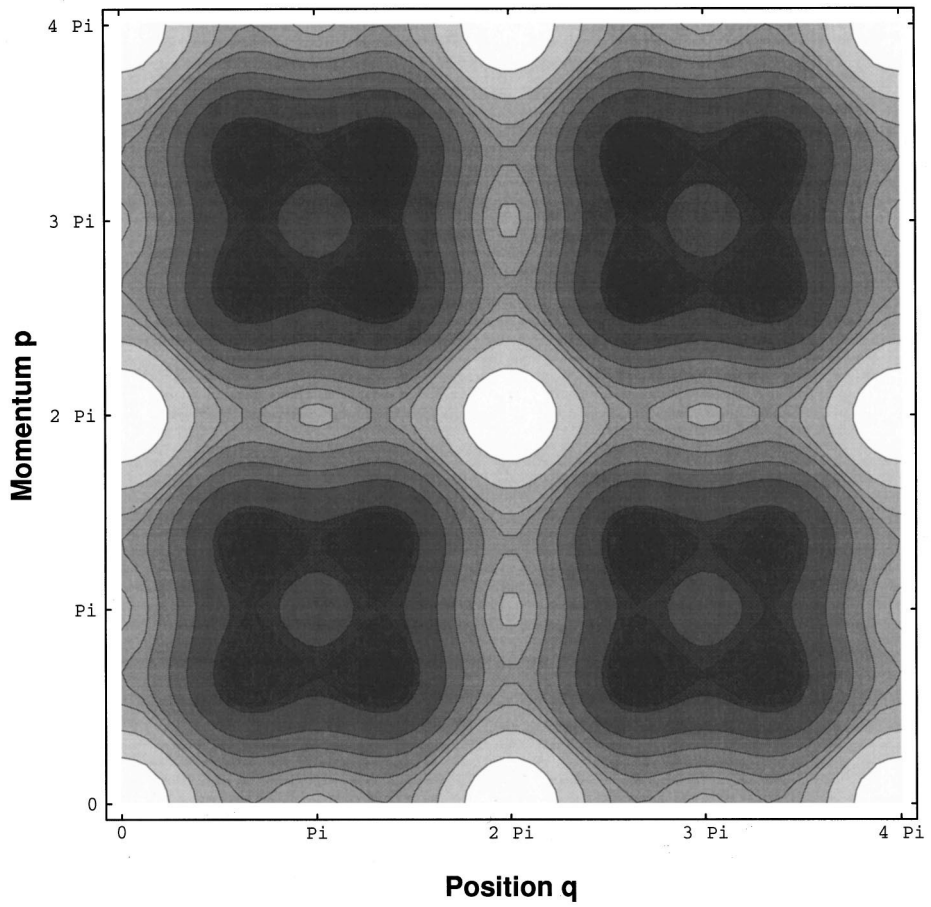

FIG. 7. Classical contour levels in the Second Neighbor Square Lattice model for $\epsilon=0.25$.

$$f_{\mathrm{QP}}(z)=\frac{k+e^{i\phi/2}z}{i+ke^{i\phi/2}z}, \tag{75}$$

k is a real parameter defining the model; it is related to discrete curvature.

The algebra automorphism generated by f_{QP} is a symmetry of the Hamiltonian,

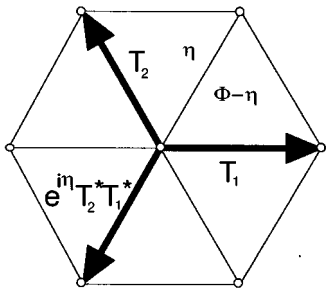

FIG. 8. Hopping interaction in the Triangular Lattice model.

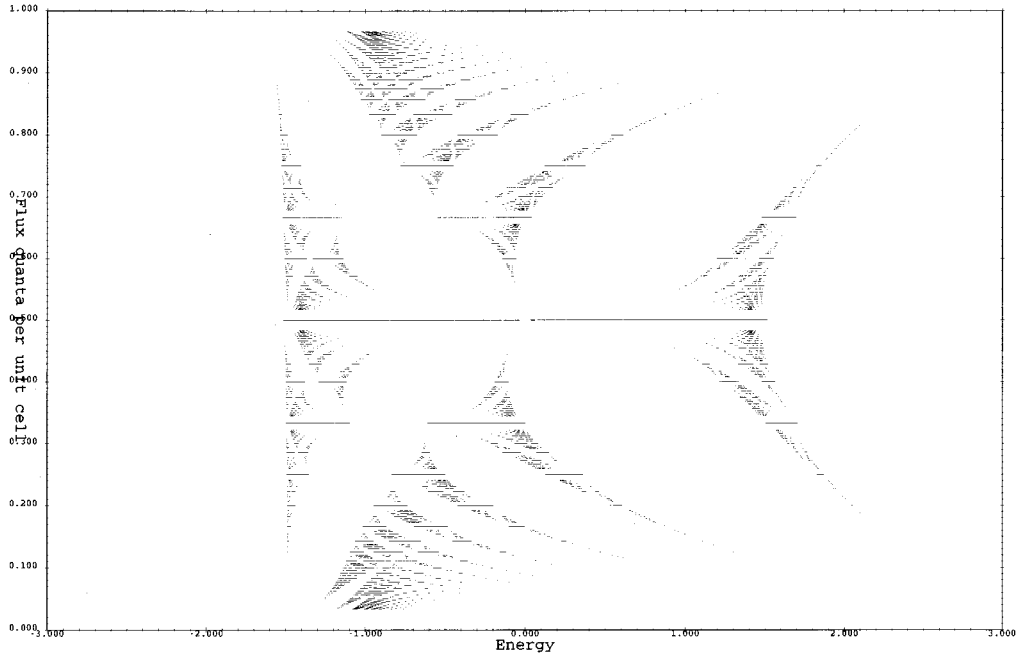

FIG. 9. Spectrum of the Triangular Lattice model for $\eta=0.075$ and $q\leqslant 40$.

$$H_{\mathrm{QP}} := 2\left(W(1,0)+W(1,0)^*+W(0,1)+W(0,1)^*\right)+k\left(W(1,1)+W(1,1)^*\right)+\frac{1}{k}\left(W(1,-1)+W(1,-1)^*\right),$$
$$\alpha_{f_{\mathrm{QP}}}(H_{\mathrm{QP}})=H_{\mathrm{QP}}. \tag{76}$$

Put differently, H_{QP} is a quantum integral of the dynamics generated by $\alpha_{f_{\mathrm{QP}}}$.

In the remaining part of this section we introduce several models of the Hofstadter type and mention their symmetries, from which one can deduce then some qualitative properties of their spectrum and eigenfunctions. Furthermore, we show the results of numerical computations of spectra and eigenfunctions. In Table II the Hamiltonians of all these models are listed, together with their classical symbols.

TABLE V. Symmetries of the triangular lattice model.

Transformation	Description	Symmetry
No. ii	Rotation by π	$\sigma(\eta,\Phi)=\sigma(\eta+\Phi,\Phi)$
No. iii	Reflection at $x_1=x_2$	$\sigma(\eta,\Phi)=\sigma(\eta,-\Phi)$
No. iv	Reflection at $x_1=-x_2$	$\sigma(\eta,\Phi)=\sigma(-\eta,\Phi)$
No. ix	Reversion of sign infront of T_j	$\sigma(\eta)=(-1)^n\sigma(\eta+\pi n)$
$\Phi\to\Phi+2\pi$	Flux periodicity	$\sigma(\Phi)=\sigma(\Phi+2\pi n)$
	Parameter space	$\Phi\in[0,2\pi]$
		$\eta\in[0,\pi]$

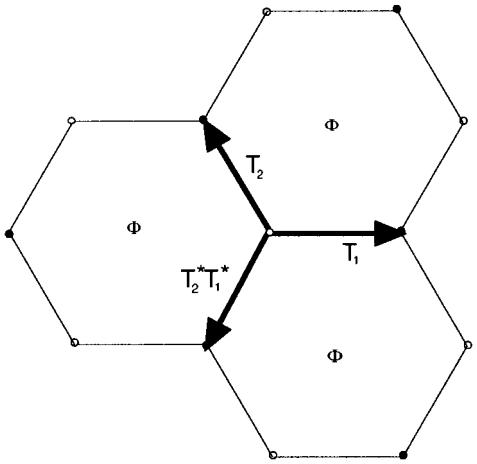

FIG. 10. Interactions in the Honeycomb model.

All numerical computations of the spectra are based on Chamber's relation (see Sec. V). This implies, in particular, that symmetries of classical symbols are reflected in spectral properties [see formula (108) in Sec. V].

A. The discrete Mathieu model

The discrete Mathieu Hamiltonian describes an anisotropic variant of the Hofstadter model. It contains a real parameter μ, which may be interpreted as the relative strength between the hopping interactions in the two lattice directions. The Hamiltonian is given by

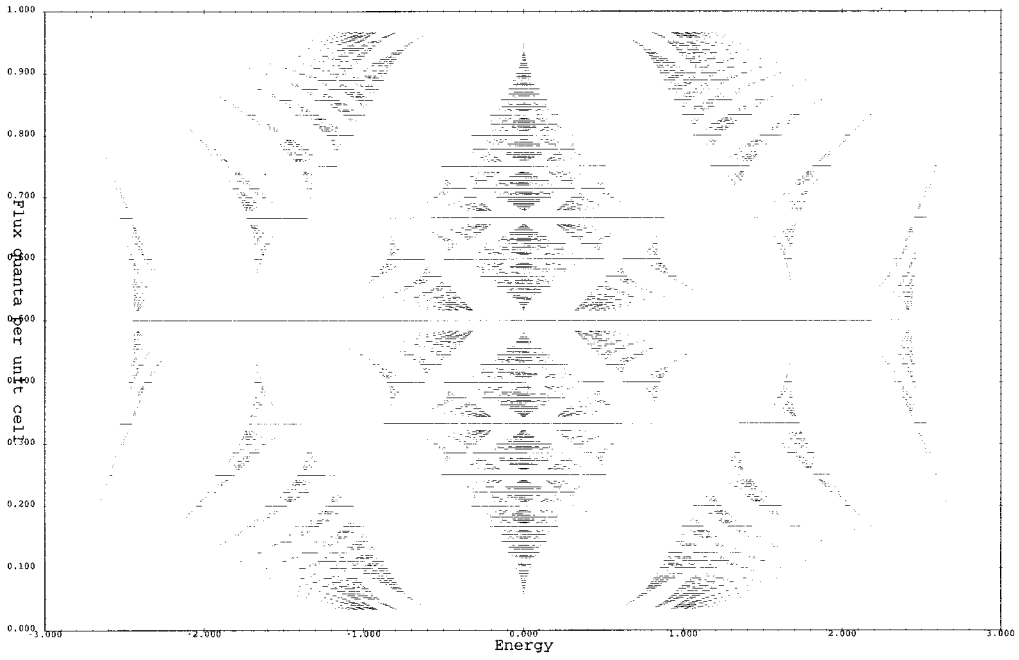

FIG. 11. Spectrum for the Honeycomb model.

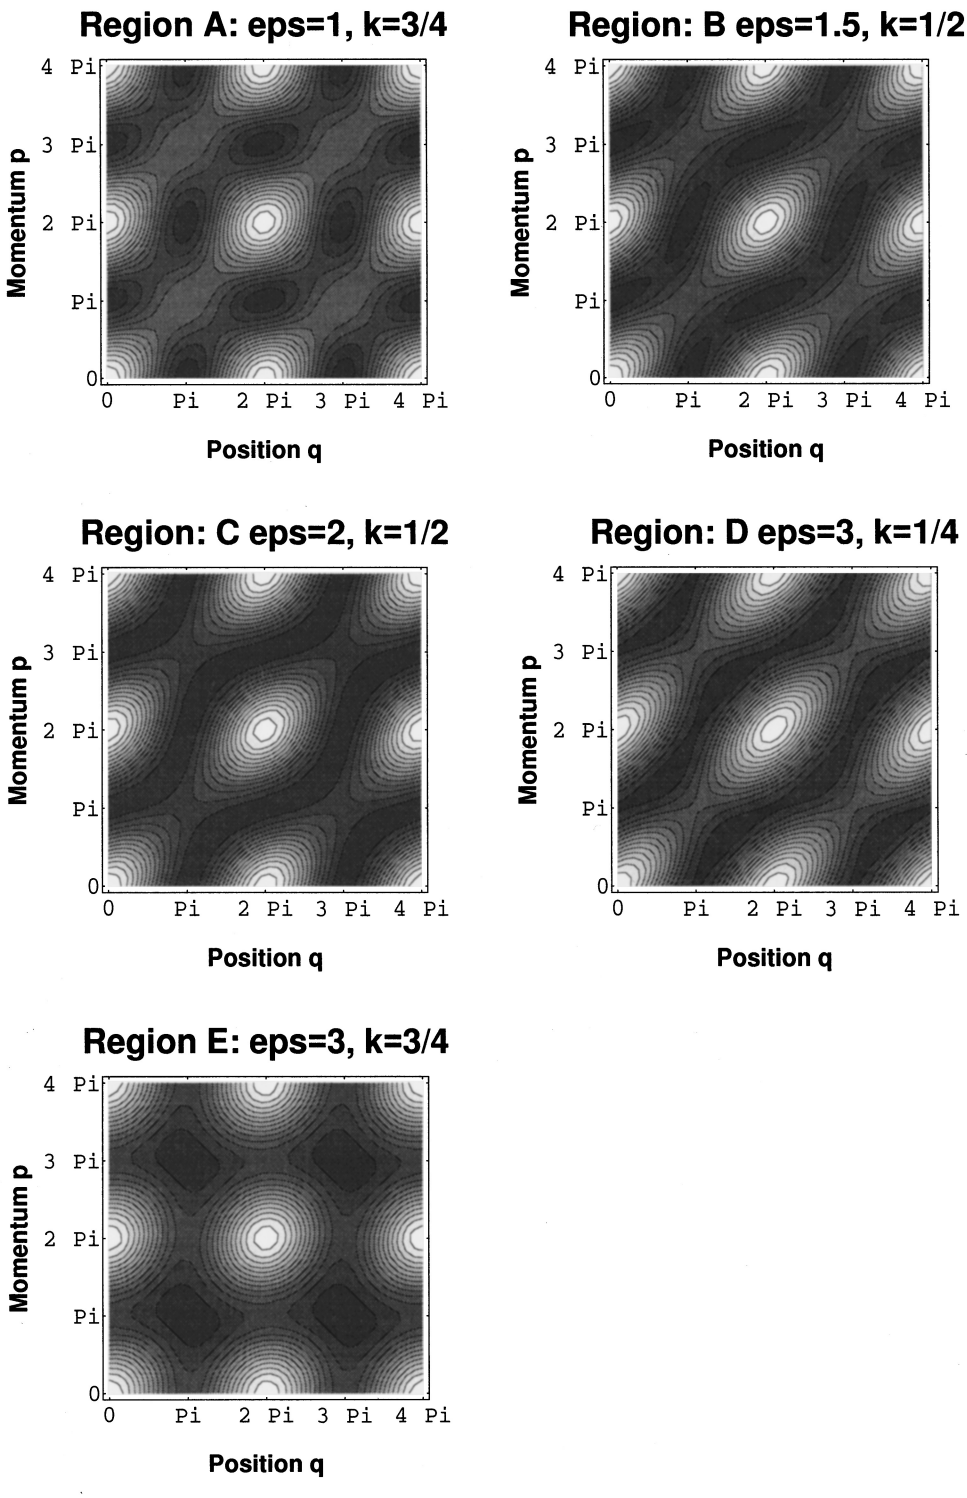

FIG. 12. Examples for classical contour levels in regions A–E for the Doubly-discrete Quantum Pendulum.

No. i	Rotation by $\pi/2$	$\sigma(k)=\sigma(1/k)$
No. iii	Reflection at $x_1=x_2$	$\sigma(\Phi)=\sigma(-\Phi)$
No. ix	Reversion of sign infront of T_j	$\sigma(\epsilon)=-\sigma(-\epsilon)$
	Reversion of energy $H\to -H$	$\sigma(\epsilon,k)=-\sigma(-\epsilon,-k)$
	Derived	$\sigma(k)=-\sigma(-k)$
$\Phi\to\Phi+2\pi$	Flux periodicity	$\sigma(\Phi)=(-1)^n\sigma(\Phi+2\pi n)$
	Parameter space	$\Phi\in[0,2\pi]$
		$k\in(0,1]$
		$\epsilon\in[0,\infty)$

$$H(\mu)=T_1+\mu T_2+T_1^*+\mu T_2^*\,. \tag{77}$$

For $\mu=1$, we recover the Hofstadter Hamiltonian and, for $\mu=0$, the one-dimensional discrete Laplacian, which can be diagonalized explicitly. Hence μ interpolates between these limiting cases; therefore the discrete Mathieu model is a tool to derive properties of the Hofstadter model; e.g., in Ref. 37, the Chern number has been computed in this way. Other properties discussed by that method are the gap labeling,[38] the total gap length, and the spectrum for irrational flux (for recent results see Last[20]).

In Table III the symmetries including the automorphism that gives rise to the Aubry duality are put together. (Notice that in our formulation the Aubry duality transformation is simply the linear automorphism generated by a rotation about the angle $\pi/2$. It is implemented by discrete Fourier transformation.) In the last column of the table, their consequence for the spectrum is

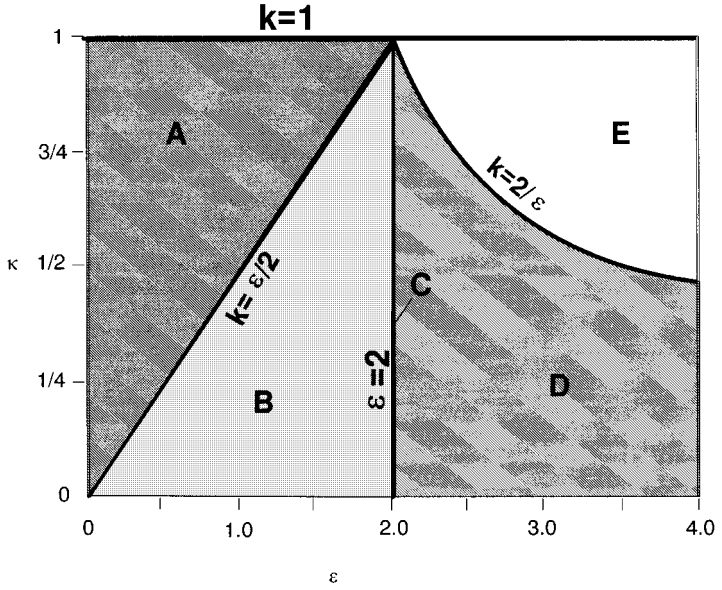

FIG. 13. Regions A–E for critical points in parameter space for the Doubly-discrete Quantum Pendulum.

shown. These symmetries can also be read off from the contour levels of the classical symbol (Fig. 2). The spectra of the Hofstadter and the discrete Mathieu model are shown in Figs. 3 and 4, respectively. In Fig. 5, the Husimi function $H_{\Psi(0)}(n)$ for eigenstates of the Hofstadter model are shown. Small values are dark and large values white. The interpolation between the discrete values of n here and in the sequel are done using Eq. (71) of Sec. III.

B. The second neighbor square lattice model

The model was discussed by Wilkinson already in 1984.[8] Its Hamiltonian is given by the formula

$$H_{\mathrm{SN}}(\varepsilon)=T_1+T_2+\varepsilon(T_1^2+T_2^2)+\mathrm{h.c.}, \tag{78}$$

where ε denotes the relative strength of the coupling to the second neighbor in the lattice. Some qualitative properties of the spectrum (Fig. 6) follow already from the symmetries of the classical symbol (Table IV). Wilkinson's computation of the spectrum showed a splitting of the lowest subband into a braid-type structure (Fig. 6, focus on the point flux=0 and energy -2.4). This has been investigated in Ref. 39, and it was shown that the braid structure can be understood as a phase space tunneling between the four bottom wells in the Brillouin torus (Fig. 7).

C. The triangular lattice model

The triangular model was introduced by Claro and Wannier[40] and describes a hexagonal crystal. They computed the spectrum nummerically and found a nesting structure similar to the one for the Hofstadter model. A semiclassical analysis was presented in Ref. 41. In Ref. 42 the model was generalized to different fluxes in the two classes of triangles (Fig. 8). Its Hamiltonian is

$$H_{\mathrm{TR}}(\eta)=T_1+T_2+e^{-i\eta}T_1T_2+\mathrm{h.c.}. \tag{79}$$

It is remarkable that also in this case the spectrum can be computed in spite of the spatial inhomogeneity of the flux (Fig. 9). This is possible because Chamber's relation still holds (Sec.

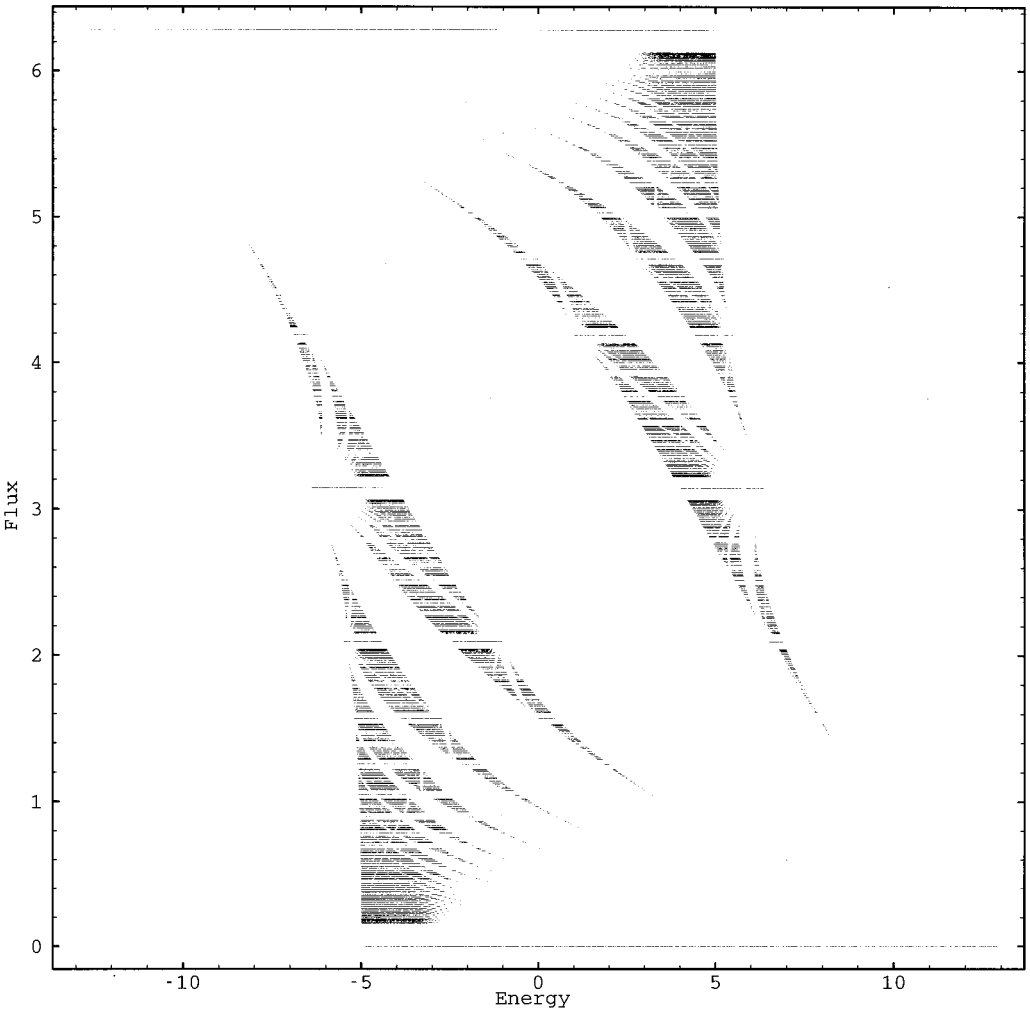

FIG. 14. Spectrum of the Doubly-discrete Quantum Pendulum at $\epsilon=2$ and $k=1/2$ (region C).

V). Numerical computations are in excellent agreement with semiclassical analysis.[42] Several qualitative aspects of the spectrum can already be understood by a simple consideration of symmetries (see Table V).

D. The honeycomb lattice model

This model has been introduced by Rammal[43] and is defined in terms of the Hamiltonian,

$$H_{\mathrm{HC}}=\begin{pmatrix} 0 & T_1+T_2+W(1,1) \\ T_1^*+T_2^*+W(1,1)^* & 0 \end{pmatrix}. \tag{80}$$

He computed the spectrum numerically. The Hamiltonian linkes sites of a bipartite lattice (Fig. 10). This implies that the square of the Hamiltonian is just two independent triangular

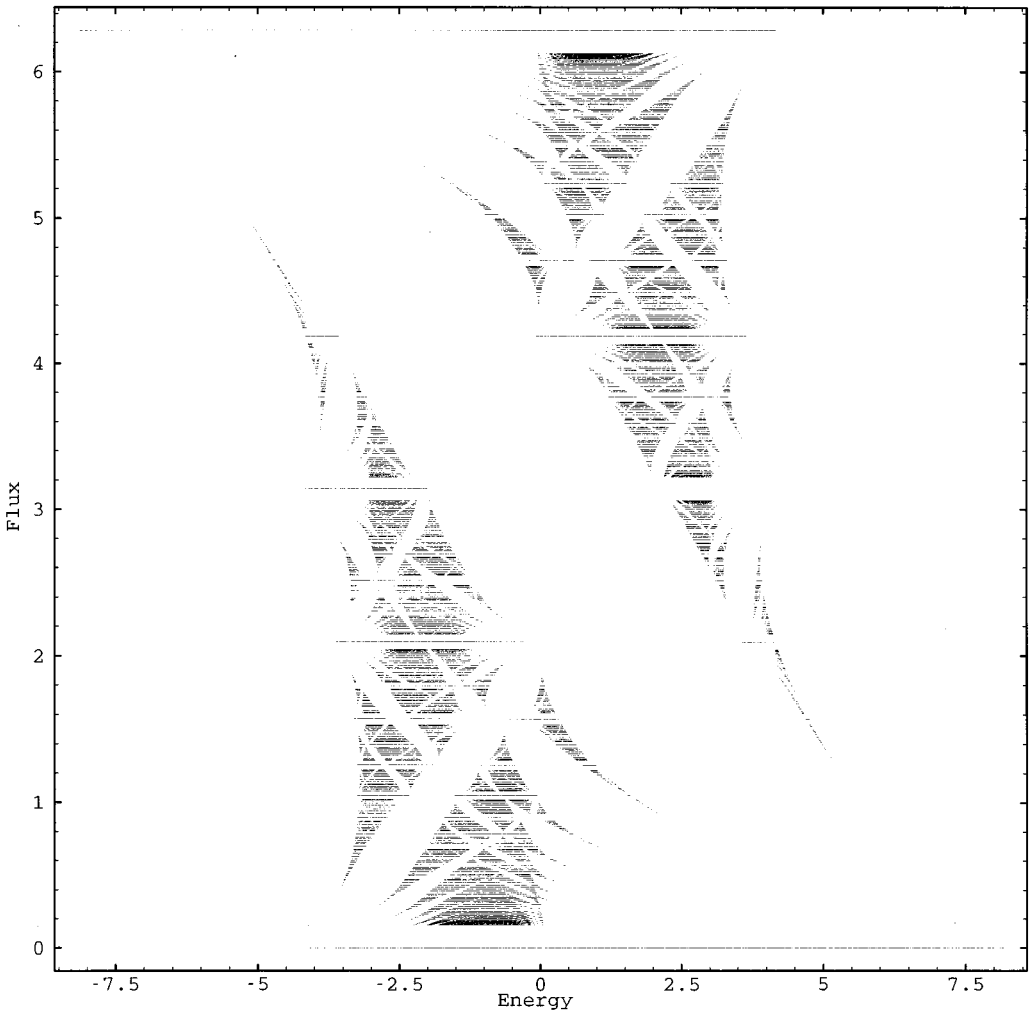

FIG. 15. Spectrum of the Doubly-discrete Quantum Pendulum at $\epsilon=1$ and $k=3/4$ (region A).

lattice models with, as it turns out, flux $\eta=0$. Hence the computation can be reduced to the previous case (Fig. 11).[42]

E. The doubly-discrete quantum pendulum

Recently, Bobenko, Kutz, and Pinkall have introduced a family of Hamiltonians that arises in the analysis of the Doubly-discrete sine-Gordon equation,[29]

$$H_{\mathrm{QP}}(\varepsilon,k)=\varepsilon(T_1+T_2)+kW(1,1)+\frac{1}{k}\,W(1,-1)+\mathrm{h.c.}, \tag{81}$$

where ε and k are real parameters. For $\varepsilon=2$, the Hamiltonian represents a quantum integral with respect to the automorphism defined by the Doubly-discrete sine-Gordon equation in zero spatial dimension [see the Introduction, Eq. (11)]. k is related to curvature.

The Hamiltonian H_{QP} in (81) belongs to the class of the next nearest neighbor Hamiltonians introduced by Hatsugai and Kohomoto.[44]

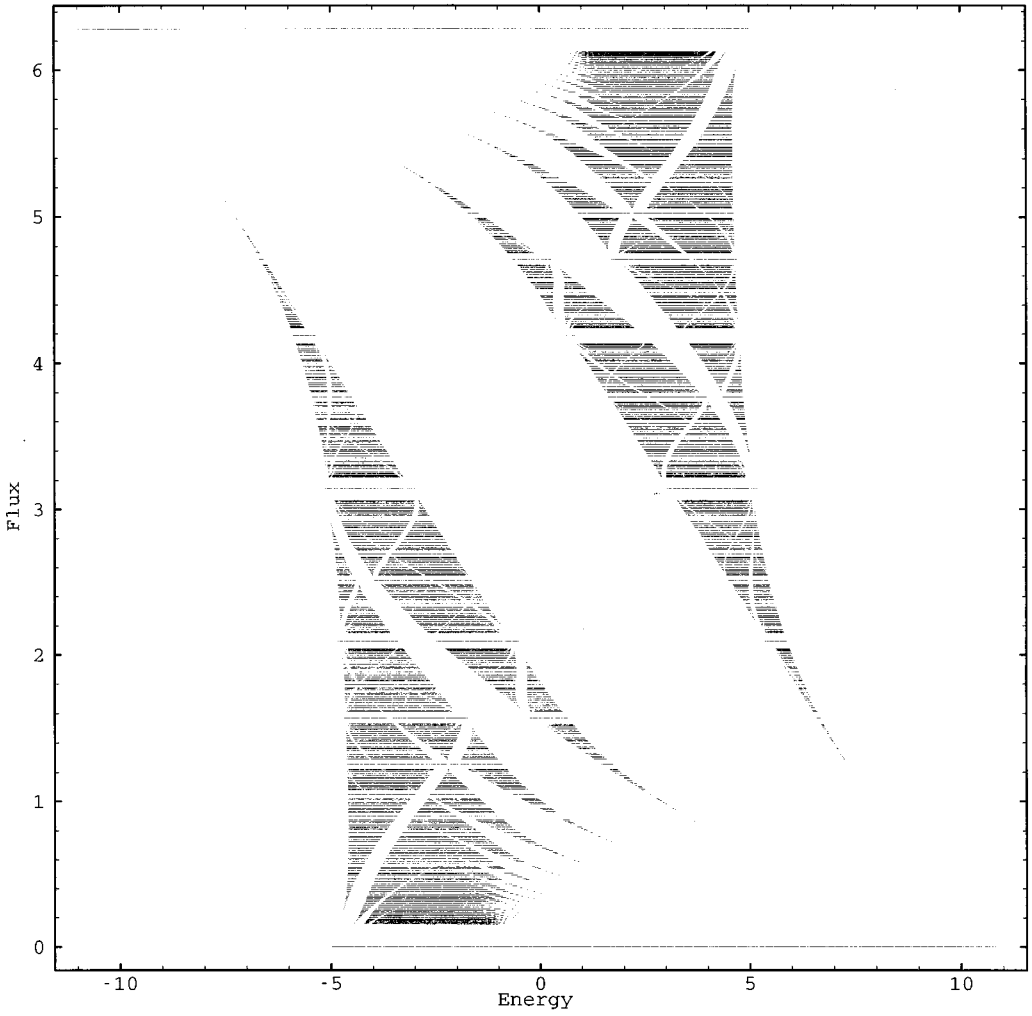

FIG. 16. Spectrum of the Doubly-discrete Quantum Pendulum at $\epsilon=1,5$ and $k=1/2$ (region B).

From the contour levels in classical phase space (Fig. 12), it becomes clear that the model is related to a classical pendulum. In each unit cell of phase space we have closed classical orbits at small energies. At high energies we see extended contours giving rise to rotating solutions. The parameter k is the analog of the gravitational constant in the usual pendulum and controls the onset of rotating solutions. The parameter ε interpolates between the discrete Mathieu model ($\varepsilon=0$) with flux $\Phi'=2\Phi$ and rescaled energy $E'=kE$ and the quantum integral ($\varepsilon=2$). Here, we used the algebra homomorpism

$$\Phi\mapsto 2\Phi, \quad T_1\mapsto e^{i\phi/2}T_2^*T_1^*, \quad T_2\mapsto e^{i\phi/2}T_1T_2^*. \tag{82}$$

In the limit $k\to 0$ the term $1/k$ dominates and the system turns into a discrete Laplacian (up to the factor $1/k$). Finally, if $\varepsilon=k$, the Hamiltonian converges in the limit $\varepsilon\to\infty$ to the Hamiltonian of a triangular lattice model with rescaled energy. Qualitative properties of the spectrum follow again from symmetries of the classical symbol (Table VI) due to the Chambers relation [(108), Sec. V].

The discussion of this model will be continued in the next section.

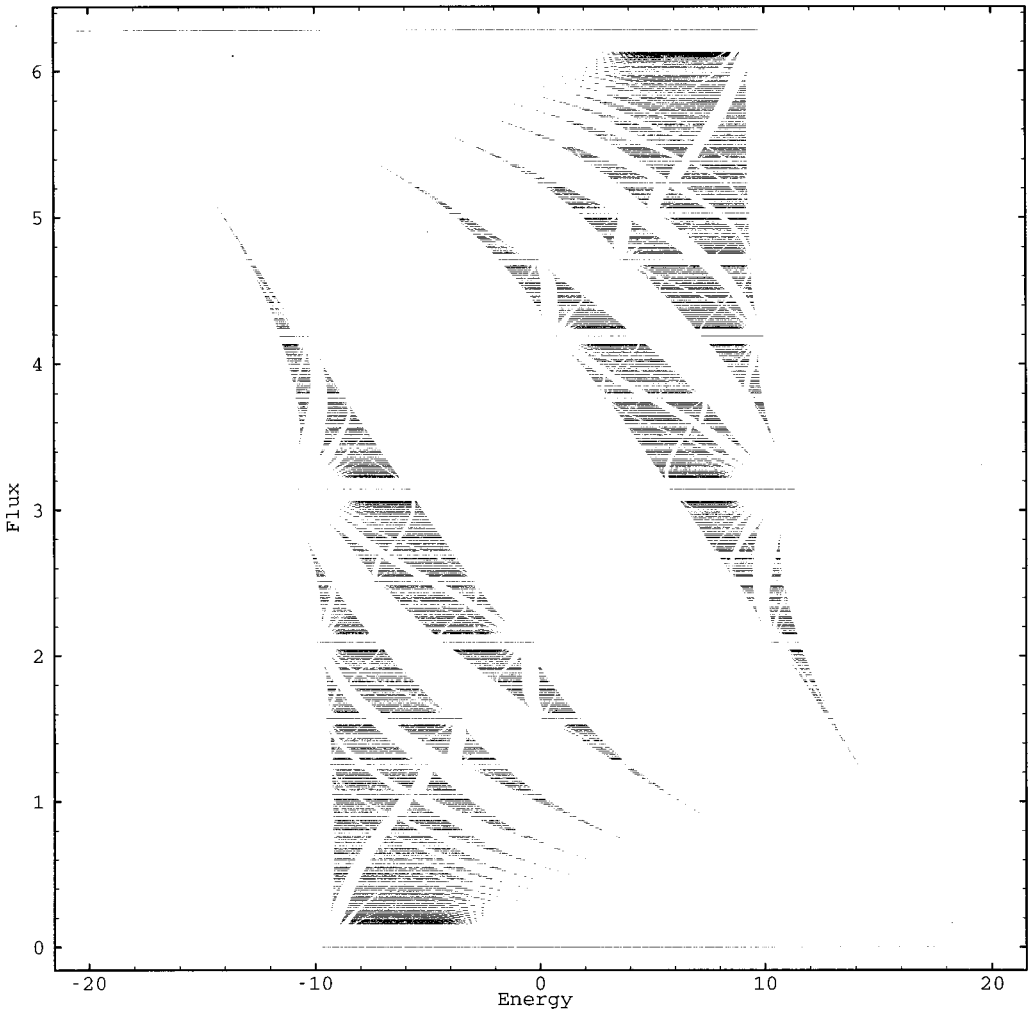

FIG. 17. Spectrum of the Doubly-discrete Quantum Pendulum at $\epsilon=3$ and $k=1/4$ (region D).

V. SPECTRA AND EIGENFUNCTIONS

The analysis of the spectra for Hamiltonians of the Hofstadter-type models is greatly simplified by the Chambers relation. It expresses the fact that the characteristic polynomial of the Hamiltonian restricted to a fiber over the Brillouin torus is the sum of two terms. The first one is a universal polynomial, i.e., it is independent of the coordinate θ of the Brillouin zone, and the second term is the zeroth-order term of the polynomial. It is the only term where the θ dependence enters. This term is furthermore a scaled version of the principal symbol of the Hamiltonian.

We explain Chambers relation for the case of the Doubly-discrete Quantum Pendulum and prove the following result.

Theorem 1: If the flux $\Phi=p/q$ is rational and p,q relatively prime, the secular determinant for the Doubly-discrete Quantum Pendulum is given by Chamber's formula,

$$\det(H_{\mathrm{QP}}(\theta)-z)=p(z)+h_{\mathrm{QP}}(\theta), \tag{83}$$

where $p(z)$ is a polynomial of degree q and

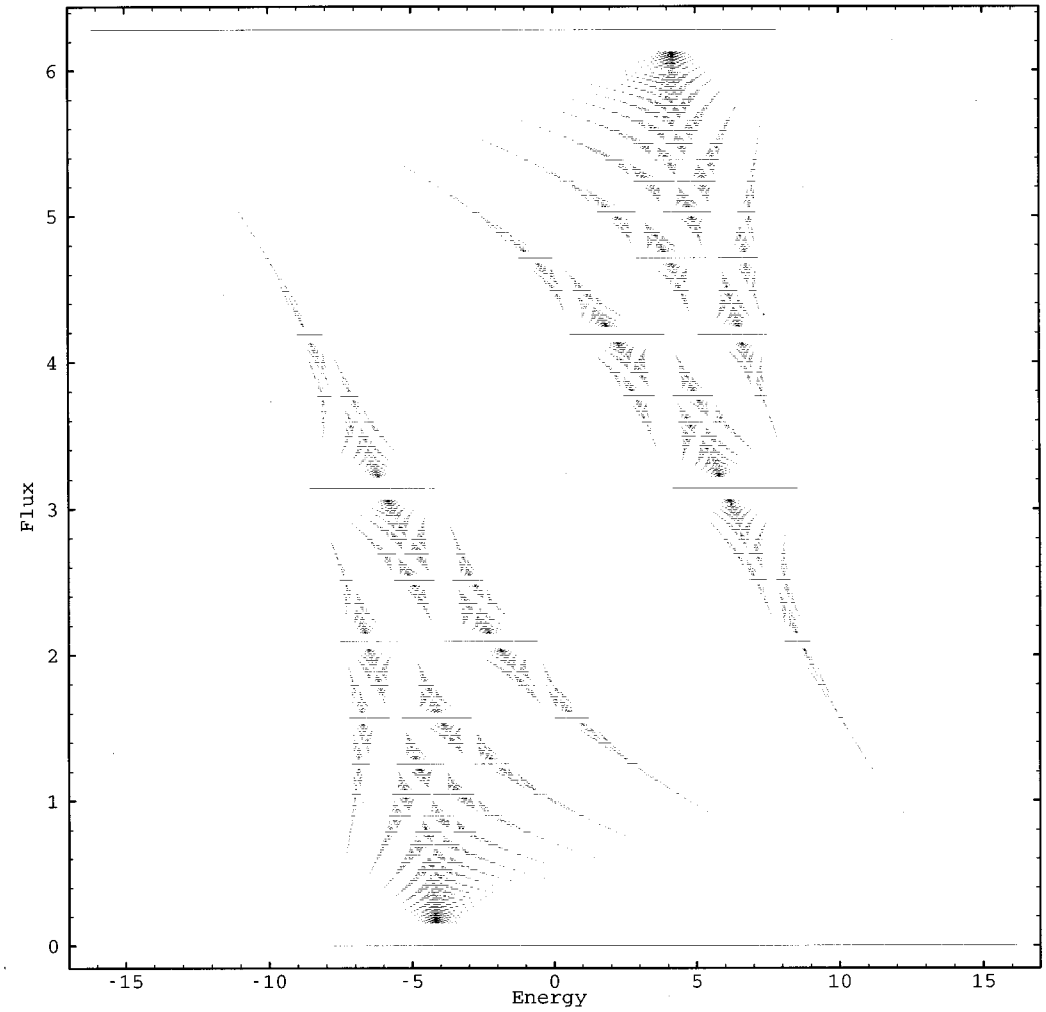

FIG. 18. Spectrum of the Doubly-discrete Quantum Pendulum at $\epsilon=3$ and $k=3/4$ (region E).

$$h_{\mathrm{QP}}(\theta)=-4T_q(-\varepsilon/2)(\cos q\theta_1+\cos q\theta_2)+2(-1)^p\left(k^q\cos q(\theta_1+\theta_2)+\frac{1}{k^q}\cos q(\theta_1-\theta_2)\right). \tag{84}$$

Here T_q denotes the Chebyshev polynomial of degree q, defined by $T_q(\cos x)=\cos qx$ and $T_q(-1)=(-1)^q$.

Chamber's relation is not only very useful to compute spectra. It also shows several conceptually interesting features. The offset function $h_{\mathrm{QP}}(\theta)$—which is almost the classical symbol—generates on the Brillouin torus a Hamiltonian vector field, which gives rise to an isospectral flow.[45] Furthermore, the secular determinant for the Hofstadter model can be factorized at the band edges. This makes it possible to compute the spectral bands algebraically for rather large values of p and q in the field of the cyclotomic extensions of the rationals.[46]

Proof: The characteristic polynomial is a function of $\theta\in\mathscr{B}$ and $z\in\mathbb{C}$,

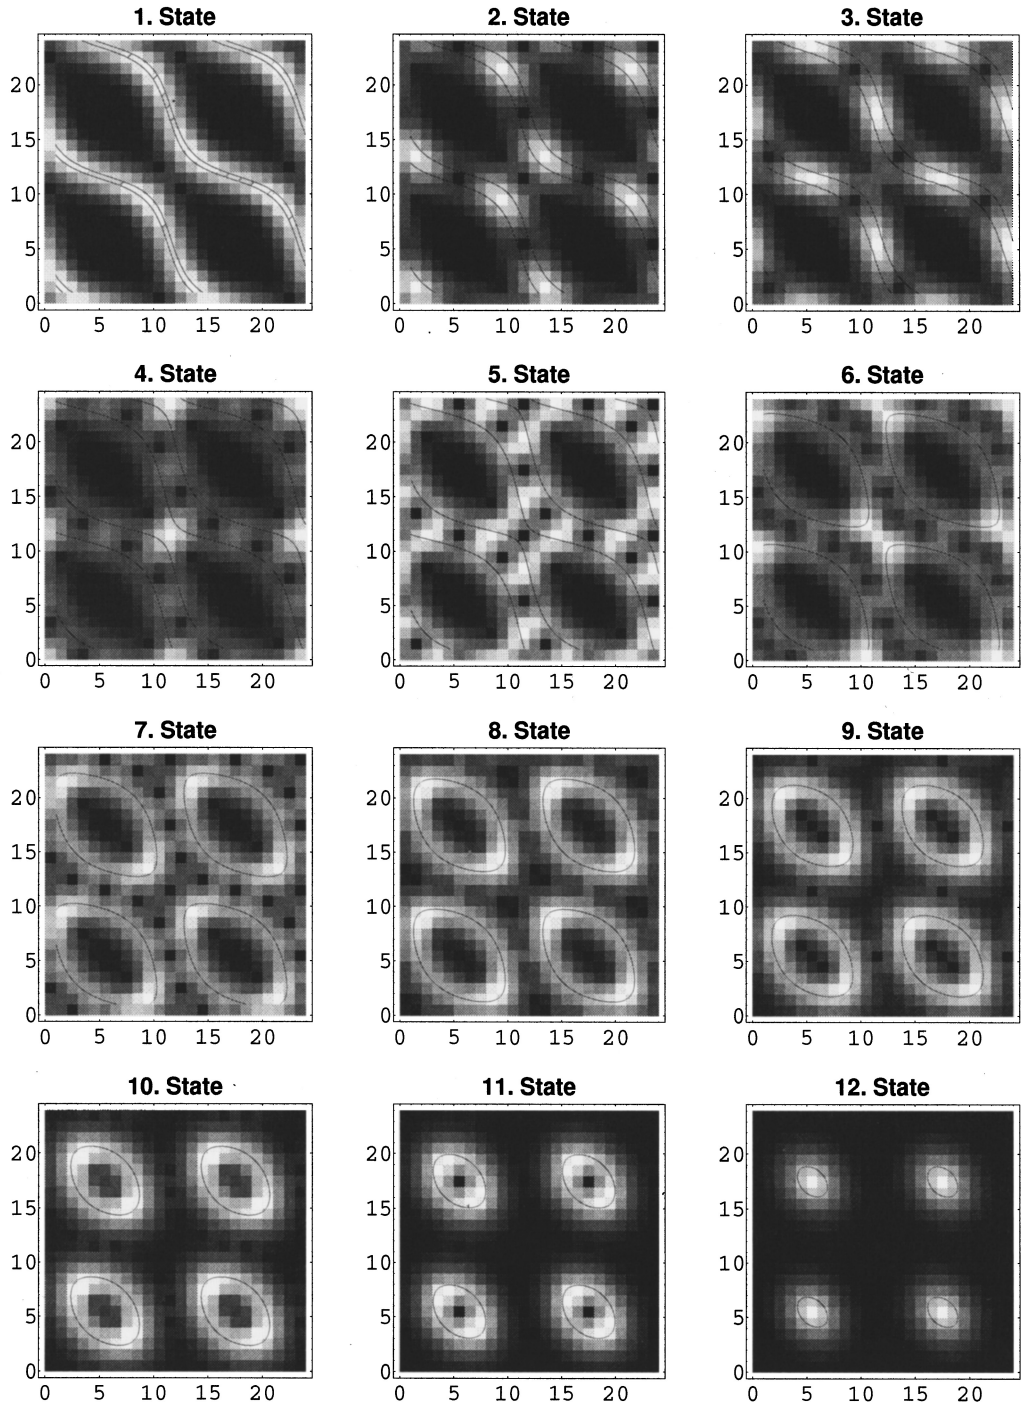

FIG. 19. Husimi transformation for eigenstates of the Quantum Pendulum at $\Phi=2\pi(1/12)$, $\epsilon=2$, $k=1/2$, $\theta=(0,0)$.

$$F(\theta,z):=\det(H_{\mathrm{QP}}(\varepsilon,k,\theta)-z). \tag{85}$$

By definition, it is 2π periodic in the variable θ. Due to Remark 3 after Theorem 2 in Sec. III it is, however, $2\pi/q$-periodic in θ_1 and θ_2. Hence, it can be expressed in terms of a Fourier series as follows:

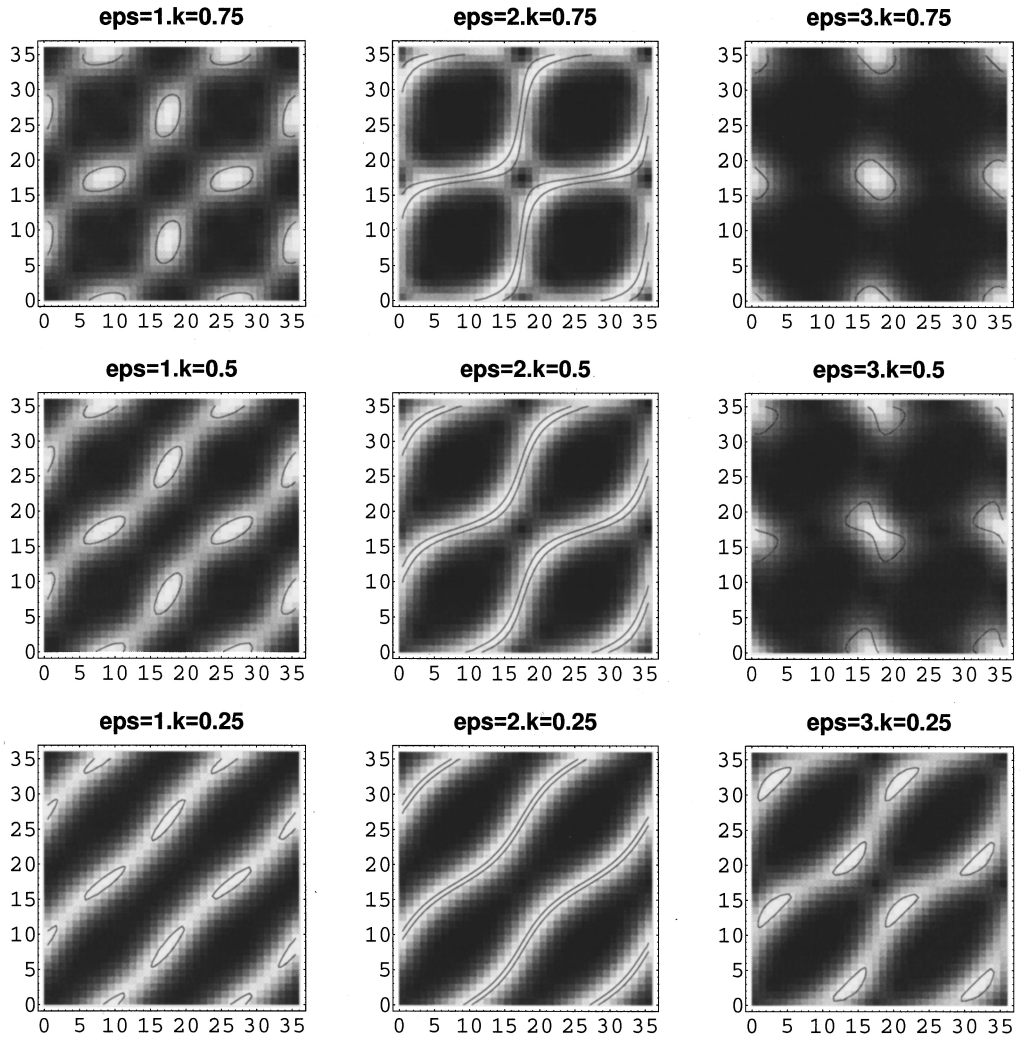

FIG. 20. Husimi transformation of the ground state of the Doubly-discrete Quantum Pendulum for $\Phi=2\pi\frac{1}{9}$.

$$F(\theta,z)=\sum_{n\in\mathbb{Z}^2} F_n(z)\xi_1^{qn_1}\cdot\xi_2^{qn_2}, \tag{86}$$

where we introduced the notation $\xi_1 = e^{i\theta_1}$, $\xi_2 = e^{i\theta_2}$.

Next, we argue that the only nonvanishing terms in the above Fourier series are those for which $|n_1|\leqslant 1$ and $|n_2|\leqslant 1$. This follows from the explicit form of the Hamiltonian,

$$H_{\mathrm{QP}}(\varepsilon,k,\theta)=\varepsilon\left(\xi_1 t_1+\xi_2 t_2+\frac{1}{\xi_1}t_1^*+\frac{1}{\xi_2}t_2^*\right)+k\left(\xi_1\xi_2 W(1,1)+\frac{1}{\xi_1\xi_2}W(1,1)^*\right)$$
$$+\frac{1}{k}\left(\frac{\xi_1}{\xi_2}W(1,-1)+\frac{\xi_2}{\xi_1}W(1,-1)^*\right), \tag{87}$$

and the obvious fact that the determinant is homogeneous of order q in the entries of the $q\times q$ matrix; so we get

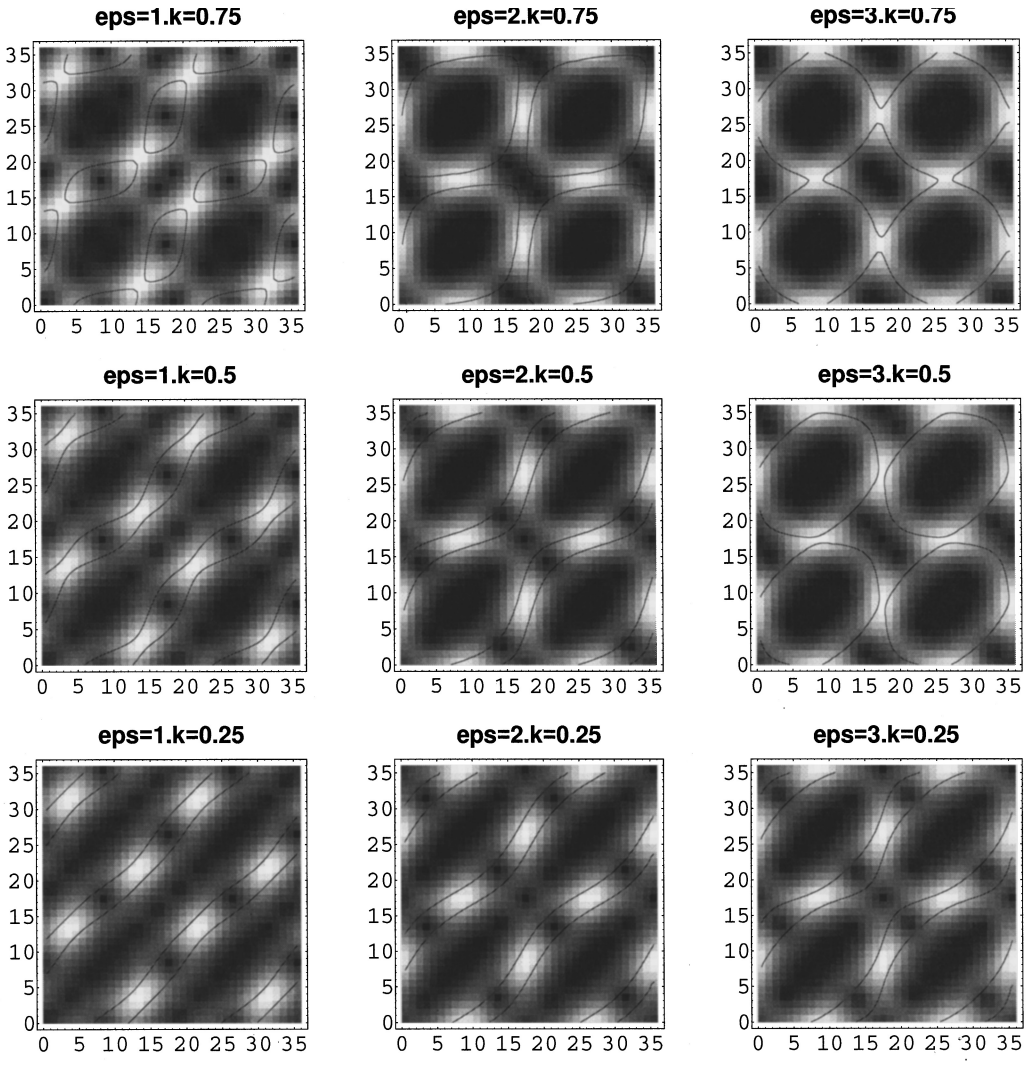

FIG. 21. Husimi transformation of the third state of the Doubly-discrete Quantum Pendulum for $\Phi=2\pi\frac{1}{9}$.

$$F(\theta,z)=\sum_{\substack{|n_1|\leqslant 1\\ |n_2|\leqslant 1}} F_n(z)\xi_1^{qn_1}\xi_2^{qn_2}. \tag{88}$$

The coefficients $F_n(z)$ are now computed by taking limits in this equation to various singular points,

$$\det(H_{\mathrm{QP}}(\varepsilon,k,\theta)-z)=\det\left(\varepsilon\left(\xi_1 t_1+\xi_2 t_2+\frac{1}{\xi_1}t_1^*+\frac{1}{\xi_2}t_2^*\right)+k\left(\xi_1\xi_2 e^{-i\Phi/2}t_1t_2+\frac{1}{\xi_1\xi_2}e^{i\Phi/2}t_2^*t_1^*\right)\right.$$
$$\left.+\frac{1}{k}\left(\frac{\xi_1}{\xi_2}e^{i\Phi/2}t_1t_2^*+\frac{\xi_2}{\xi_1}e^{-i\Phi/2}t_2t_1^*\right)-z\right)=\sum_{\substack{|n_1|\leqslant 1\\ |n_2|\leqslant 1}} F_n(z)\xi_1^{qn_1}\xi_2^{qn_2}. \tag{89}$$

Consider, for instance, the case $\xi_1\to\infty$. It leads to the equation (using $\det t_1=1$)

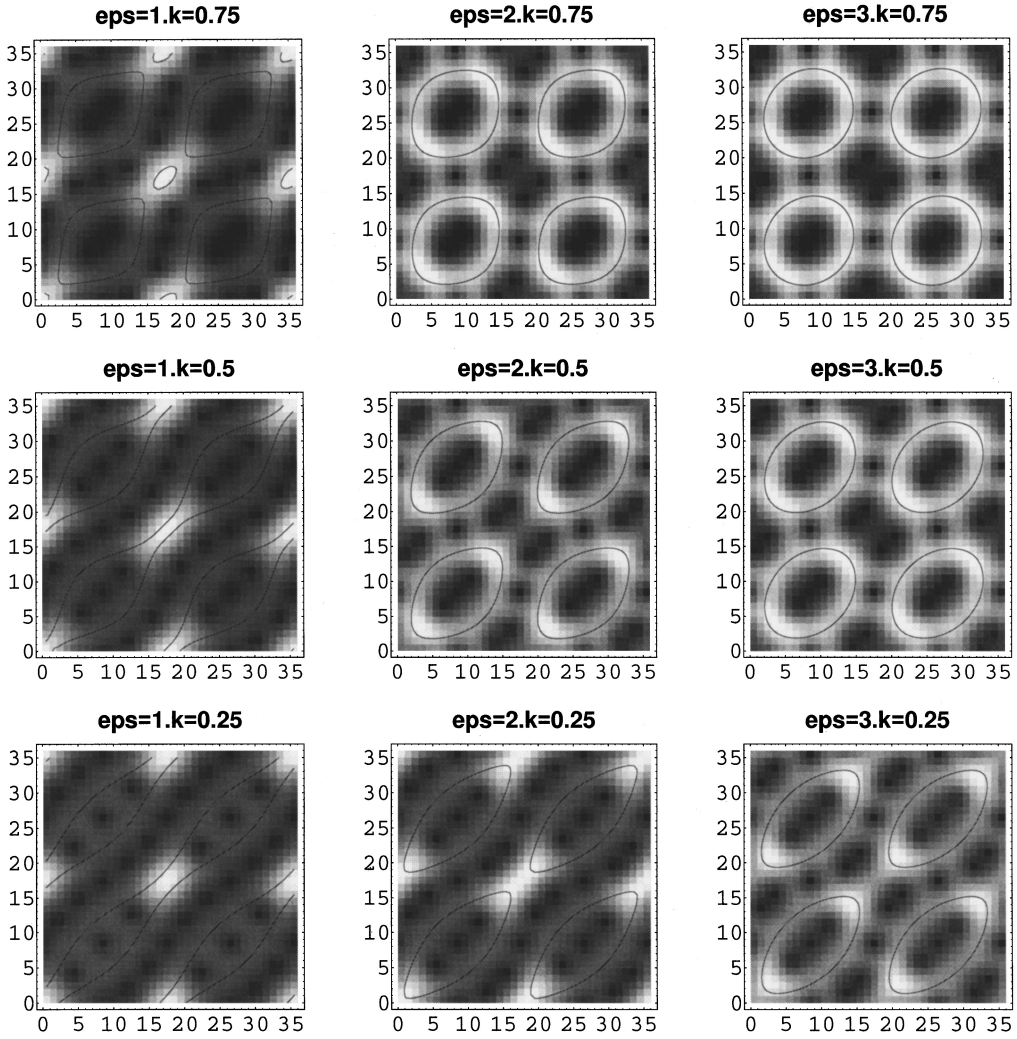

FIG. 22. Husimi transformation of the sixth state excitation of the Doubly-discrete Quantum Pendulum for $\Phi=2\pi\frac{1}{9}$.

$$\det\left(\varepsilon t_1+k\varepsilon_2 e^{-i\Phi/2}t_1t_2+\frac{1}{k\xi_2}\,e^{-i\Phi/2}t_1t_2^*\right)=\det\left(\varepsilon+k\xi_2 e^{-i\Phi/2}t_2+\frac{1}{k\xi_2}\,e^{i\Phi/2}t_2^*\right)$$
$$=F_{1,0}(z)+F_{1,1}(z)\xi_2^q+F_{1,-1}^{(z)}\xi_2^{-q}. \tag{90}$$

A second limiting procedure $\xi_2\to\infty$ leads to

$$\det(ke^{-i\Phi/2}t_2)=F_{1,1}(z). \tag{91}$$

Since $\det(t_1)=\det(t_2)=1$, we get the result

$$F_{1,1}(z)=k^q\cdot e^{-iq\Phi/2}=k^q(-1)^p. \tag{92}$$

If we replace the limit above by $\xi_2\to 0$, we find

$$F_{1,-1}(z)=k^{-q}(-1)^p. \tag{93}$$

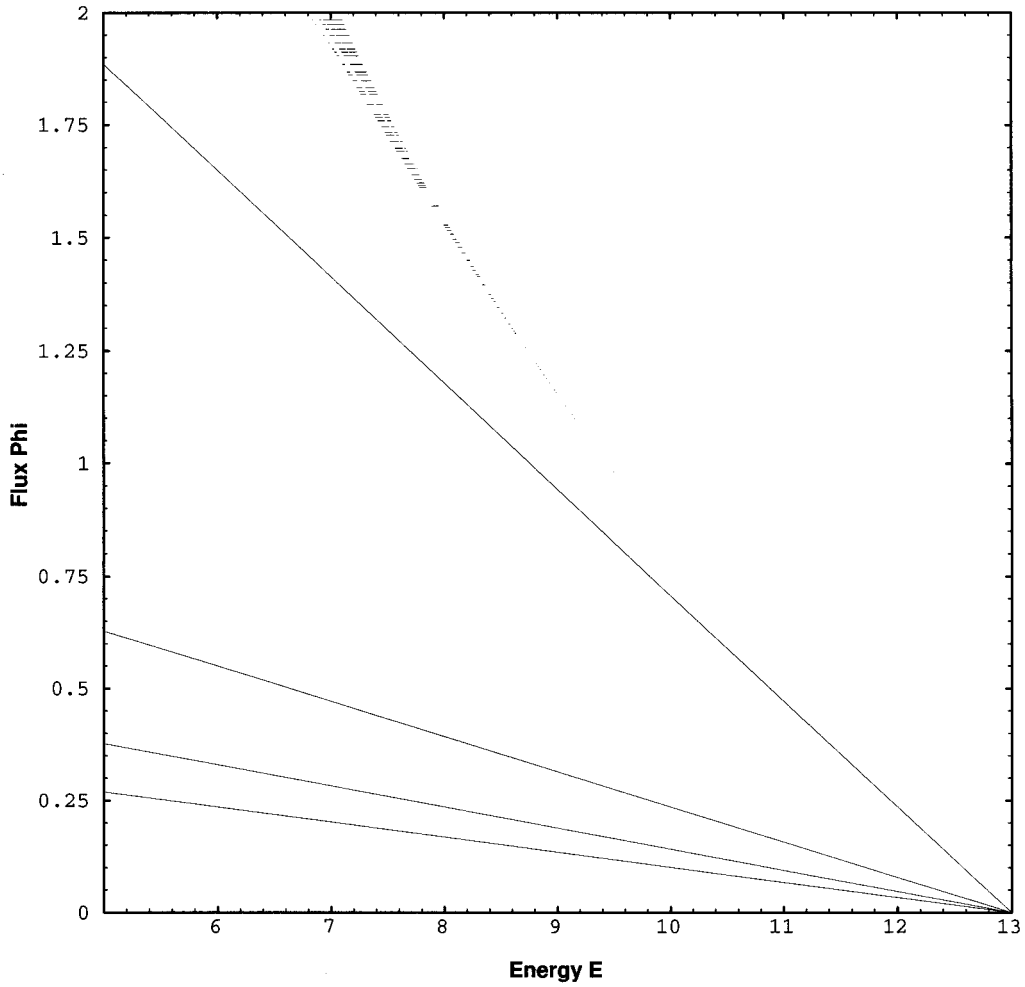

FIG. 23. Exact spectrum and semiclassical Landau levels at $\epsilon=2$, $k=1/2$.

Similarly, we can replace the limit $\xi_1\to\infty$ by $\xi_1\to 0$ followed by $\xi_2\to\infty$ and $\xi_2\to 0$.

This leads to

$$F_{-1,1}(z)=k^{-q}(-1)^p, \quad F_{-1,-1}(z)=k^q(-1)^p. \tag{94}$$

Among the coefficients arising in these equations, only $F_{1,0}(z)$ remains to be computed. This follows easily from the following proposition.

Proposition 2: for any $z\in\mathbb{C}$, $j=1,2$, and $\lambda\in\mathbb{C}\setminus\{0\}$,

$$\det\left(\lambda t_j+\frac{1}{\lambda}\,t_j^*-z\right)=-2T_q\left(\frac{z}{2}\right)+(\lambda^q+\lambda^{-q}), \tag{95}$$

where $T_n(x)=\cos(n\arccos(x))$ is the nth Chebyshev polynomial.

The proof of the proposition uses again the same idea as before. The function $[\lambda t_1 + (1/\lambda)t_1^* - z]$ is a Laurent polynomial in λ of order q and invariant under the substitution $\lambda\to e2\pi i/q\lambda$. Hence, it can be expressed in terms of a Fourier series with three terms only,

$$\det\left(\lambda t_1+\frac{1}{\lambda}\,t_1^*-z\right)=b_0(z)+b_{+1}(z)\lambda^q+b_{-1}(z)\lambda^{-q}. \tag{96}$$

The terms $b_{\pm 1}(z)$ can be computed through the limits $\lambda\to\pm\infty$, from which we infer that $b_\pm(z)=\det t_1^{\pm 1}=1$. So we are left with the computation of the polynomial $b_0(z)$.

By construction, t_1 has the eigenvalue one and is diagonal. Hence, the left-hand side of (96) vanishes if

$$\lambda+\frac{1}{\lambda}-z=0. \tag{97}$$

From this equation and (96) we conclude that

$$b_0\left(\lambda+\frac{1}{\lambda}\right)+\lambda^q+\lambda^{-q}=0, \tag{98}$$

which up to trivial factors, is the functional equation for the Chebyshev polynomial $T_q(x)$,

$$T_q\left(\frac{1}{2}\,(\lambda+\lambda^{-1})\right)-\frac{1}{2}\,(\lambda^q+\lambda^{-q})=0. \tag{99}$$

So, we finally get the result

$$b_0(x)=-2T_q\left(\frac{x}{2}\right). \tag{100}$$

This proves Proposition 2.

Now we are prepared to compute F_{10} from Eq. (90):

$$F_{10}(z)=\det\left(\varepsilon+k\xi_2 e^{-i\Phi/2}t_2+\frac{1}{k\xi_2}\,e^{i\Phi/2}t_2^*\right)-k^q(-1)^p(\xi_2^q+\xi_2^{-q})=-2T_q\left(-\frac{\varepsilon}{2}\right). \tag{101}$$

Analogously, we obtain

$$F_{-1,0}(z)=-2T_q\left(-\frac{\varepsilon}{2}\right). \tag{102}$$

The only term left is $F_{00}(z)$. The results proved so far show that it is the only coefficient among the F_n's, which possibly has an explicit z dependence. All other terms are independent of z. Summarizing, we obtain

$$F(\theta,z)=F_{(0,0)}(z)+\sum_{\substack{|n_1|=1\\|n_2|=1}}(-1)^p k^{n_1n_2q}\xi_1^{n_1q}\xi_2^{n_2q}-2T_q(-\varepsilon/2)((\xi_1^q+\xi_1^{-q})+(\xi_2^q+\xi_2^{-q})). \tag{103}$$

This finishes the proof of Theorem 1.

Similar results hold for many other Hamiltonians of the Hofstadter type; in particular, for all those that are of the form

$$H=\sum_{\substack{|m_1|\leqslant 1\\|m_2|\leqslant 1}}t(m)W(m). \tag{104}$$

This class contains all the models mentioned so far (except the second neighbor square lattice model).

For rational flux the spectrum of the Hamiltonian is computed in terms of band functions, defined as follows. For $\Phi = p/q$, $p \wedge q = 1$, the Hamiltonian H may be expressed in terms of a direct integral (Sec. III, Theorem 3 and Eq. (63)],

$$H \cong \frac{1}{|\mathscr{B}|} \int_{\mathscr{B}}^{\oplus} d^2\theta \; H(\theta) \otimes \mathbb{1}, \tag{105}$$

where $H(\theta)$ is a $q \times q$ matrix operator. Its spectrum is given in terms of the spectra of the fiber Hamiltonians, $H(\theta)$, by

$$\sigma(H) = \bigcup_{\theta \in \mathscr{B}} \sigma(H(\theta)). \tag{106}$$

The latter is computed as the zero set of the secular determinant:

$$\{z | \det(H(\theta) - z) = 0\} = \{E_1(\theta), \ldots, E_q(\theta)\}. \tag{107}$$

$E_1(\theta), \ldots, E_q(\theta)$ are the band functions. Since $H(\theta) = \overline{H(\theta)}^*$ is analytic in θ_1 and θ_2 the band functions are real analytic in both θ_1 and θ_2 separately and continuous jointly in θ_1 and θ_2.[47]

Due to Chambers relation,

$$\det(H(\theta) - z) = P(z) - h(\theta), \tag{108}$$

the band functions are the branches of the relation $P^{-1} \circ h$.

Each band function $E(\theta)$ gives rise to a band $[E_{\min}, E_{\max}] \subset \sigma(H)$, where the band edges are critical points, $dE(\theta_{\min}) = dE(\theta_{\max}) = 0$.

Chamber's relation has another interesting consequence for the critical points of all band functions. Every critical point of the classical symbol $h(\theta)$ is a joint critical point of all band functions, since

$$P'(E(\theta)) \cdot E'(\theta) = h'(\theta). \tag{109}$$

The converse is slightly more subtle. If $E(\theta)$ describes a band that does not touch another one, i.e., $P'(E(\theta)) \neq 0$, for critical points θ of h, the critical points of $E(\theta)$ coincide with those of $h(\theta)$. Degeneracies of spectra occur generically only on a set of codimension 3, hence for discrete points (θ, Φ) in $\mathscr{B} \times \mathbb{R}$ (Neumann and Wigner[48]).

Notice that the fact just mentioned simplifies the computation of spectra considerably since instead of computing all the band functions one merely needs to compute the band edges, i.e., the zeros of the equation

$$P(z) = h(\theta_{\text{crit}}), \tag{110}$$

for all critical points θ_{crit} of h.

Critical points of band functions or of the corresponding classical symbol, respectively, are relevant for the semiclassical analysis of the spectra (see below). They can have a complicated geometrical structure depending on the parameters of the model.

As an example we consider the case of the Doubly-discrete Quantum Pendulum. The parameter space is decomposed into five regions A–E as shown in Fig. 13. In Table VII we list the critical sets in the Brillouin torus $\mathscr{B}$ of the classical symbol. *a* max and *a* min denote absolute maxima and absolute minima, respectively, while max and min refer to local maxima and minima.

In all five regions, there is just one absolute maximum at $(x_1, x_2) = (0,0)$. In a vicinity of this point the Hamiltonian is parabolic and gives rise to oscillating classical solutions. There is one

absolute minimum in all regions except in case C, where $\varepsilon=2$. This case is the one originating from discrete geometry. The absolute minimum is a loop in $\mathscr{B}$, hence a classical orbit.

In the general case, there is a saddle point between the absolute maximum and the absolute minimum. This is clearly seen from the plot of classical contour levels (see Fig. 12).

We have computed numerically the band spectrum of the Doubly-discrete Quantum Pendulum for rational flux by diagonalizing the fiber Hamiltonian $H(\theta)$ at the critical points of the dilated classical symbol h_{QP} defined in (84). These values can be computed easily from the critical points of the classical symbol (Table VII). In Figs. 14–18 we present typical spectra for the regions A–E. In Figs. 19–22, Husimi functions for various parameters and quantum numbers are shown. The figures contain the classical orbits and show that the Husimi functions are localized at their classical counterparts.

Now we present a semirigorous semiclassical analysis of the spectrum of the Doubly-discrete Quantum Pendulum and apply techniques known from the Hofstadter model[8] to the critical points of the classical symbol. If the critical points are not isolated, as is the case for the Doubly-discrete Quantum Pendulum with $\varepsilon=2$, one has to apply technics that are analytically even more involved.[49,50] They go back in spirit to the reaction path method of quantum chemistry.[51,52]

In the case of an isolated critical point there are classically oscillating orbits nearby, giving rise to quasimodes. Their energy can be computed as follows: Consider, e.g., the absolute maximum of the classical symbol at $(x_1,x_2)=(0,0)$, which is unique for all parameter values. Using a semiclassical representation of the Rotation Algebra, namely,

$$T_1=e^{i(x_1+\sqrt{\Phi}K_1)},\quad T_2=e^{i(x_2+\sqrt{\Phi}K_2)},\quad [K_1,K_2]=i, \tag{111}$$

we expand the Hamiltonian in $\sqrt{\Phi}$ around the critical point up to second order and obtain the formal expression

$$H=H_{\mathrm{QP}}(0,0)\pm|\Phi|\sqrt{\det D^2H_{\mathrm{QP}}(0,0)}(K_1^2+K_2^2)+O(|\Phi|^{3/2}). \tag{112}$$

$D^2H_{\mathrm{QP}}(0,0)$ is the Hessian of the classical symbol at the critical point (0,0) where the equation holds:

$$\omega_{\varepsilon,k}=-\sqrt{\det D^2{}_{\mathrm{QP}}(0,0)}=\sqrt{(\varepsilon+2k)(\varepsilon+2/k)}, \tag{113}$$

and, thus, the semiclassical eigenvalues are given by

$$E_n=2(2\varepsilon+k+1/k)-\omega_{\varepsilon,k}(2n+1),\quad (n\in\mathbb{Z}). \tag{114}$$

In physical terms this corresponds to a Bohr–Sommerfeld quantization of classically oscillating solutions.

This approach is oriented toward energies at the top—respectively for isolated critical values of the classical symbol—and small flux. In this case the bands are very short, so one may refer to them as single numbers. As in other Hofstadter-like, models the results match the exact spectrum very well, even for comparatively large values of magnetic flux Φ [see Fig. 23]. For larger flux and smaller energies this changes—due to tunneling—and the bands get longer.

This semiclassical argument does not hold anymore if the energy is close to a classical saddle point, where there are rotating classical solutions.

Except at $\varepsilon=2$ the classical symbol possesses an absolute minimum in phase space, which, again, gives rise to energy levels of the same type as before. This time, however, they emerge from the minimal classical energy. In Fig. 18 (region E) one can easily spot them since the minimal energy is well separated from the separatrix energy, as in the case of the square lattice.

In each region of the parameter space we find rotating solutions for the classical Hamiltonian. In the covering space of phase space they appear as noncompact contours in an energy range

between two distinct saddle points. Except for the trajectory at minimal energy for $\varepsilon=2$, we always find two different rotating solutions at the same energy level. Their semiclassical analysis is more complicated and will not be discussed here.[49,50]

ACKNOWLEDGMENTS

The idea of proof of Chamber's relation (Sec. V) and much more about the Hofstadter model, we learned from Jean Bellissard many years ago, before the discovery of the Doubly-discrete Quantum Pendulum. In particular, he introduced us into the algebraic setting of the Hofstadter Model. We benefitted, furthermore, much from discussions with Ulrich Pinkall and many other members of the SFB ''Differential Geometry and Quantum Physics.'' In particular, the automorphism relating the Hofstadter model to the Doubly-discrete Quantum Pendulum is due to him (Sec. V). We had many stimulating discussions with Ludwig Faddeev. Volker Bach helped us with scientific and linguistic questions alike.

This work is supported in part by the DFG, and the Erwin Schrödinger Institute in Vienna, where we acknowledge useful discussion with Paul Wiegmann and Anton Zabrodin.

(Received 31 May 1996; accepted for publication 17 June 1996)

In this paper we compare the accessible information of quantum communication channels with the entropic content of finite-dimensional matrix algebras with respect to quantum states, as defined by Connes, Narnhofer, and Thirring. In particular, every Abelian $n\times n$ matrix algebra together with a density matrix define the input alphabet of a quantum communication channel whose accessible information equals the entropic content of the algebra with respect to the state. The cases $n=2$ and $n=3$ are concretely examined in connection with the problem of the best estimation. © *1996 American Institute of Physics.* [S0022-2488(96)00110-7]

I. INTRODUCTION

The recent advances in the technology of information transmission[1,2] and the highly stimulating field of quantum computation[3] have greatly enhanced the need of noncommutative generalizations of Shannon's classical information theory.[4]

We will consider idealized communication channels at whose ends Alice is the sender and Bob the receiver. Alice uses quantum means (photons and an optical fiber) to encode a message and to send it to Bob. She might transmit photons in orthogonal, say vertically–horizontally polarized states, each one containing a classical bit of information. Then Bob, by measuring whether the incoming photons are vertically or horizontally polarized, would decode Alice's message.

On the other hand, according to the prescriptions of quantum criptography, possible eavesdroppers will be baffled by Alice using nonorthogonal, say vertical, respectively, 60° right of the vertical, polarized states.[3,5] In this case, however, Bob needs an error correcting code to cope with the fact that he has fixed probabilities of measuring both vertical and horizontal linear polarizations when the incoming photon is not vertically polarized. More photons are to be sent by Alice in order to correct Bob's imperfect distinction between two nonorthogonal photon states, whence the problem of estimating how many *quantum its* in Wheeler's therminology[1] are needed to convey a certain amount of *classical bits*.[6]

In general, Alice might be using a quantum statistical ensemble composed by n quantum (mixed) states $\hat{\rho}_j$ with weights p_j which is thus represented by the density matrix

$$\hat{\rho}=\sum_j p_j\hat{\rho}_j\,. \tag{1}$$

Bob's decoding strategy rests on some set of observables $\hat{e}_k$ he chooses in order to maximize the amount of information he extracts from his measurements. Let the $\hat{e}_k$ be orthogonal, one-dimensional projections such that that $\Sigma_k\hat{e}_k=\hat{1}$. Out of the incoming signal states $\hat{\rho}_j$, Bob will get the $\hat{e}_k$'s eigenstate $|e_k\rangle$ with probability $p_k^e(\hat{\rho}_j):=\mathrm{Tr}\,\hat{\rho}_j\hat{e}_k$, respectively, $p_k^e(\hat{\rho}):=\mathrm{Tr}\,\hat{\rho}\hat{e}_k$ if he happens to measure $\hat{e}_k$ on the whole mixture represented by $\hat{\rho}$. The information content of the (discrete) probability distributions,

$$p^e(\hat{\rho}):=\{p_k^e(\hat{\rho})\},\quad p^e(\hat{\rho}_j):=\{p_k^e(\hat{\rho}_j)\}, \tag{2}$$

a)Electronic mail: Benatti@Trieste.infn.it

0022-2488/96/37(10)/5244/15/$10.00

is measured by the Shannon's entropies:

$$S(p^e(\hat{\rho}))=-\sum_k p_k^e(\hat{\rho})\log p_k^e(\hat{\rho}), \tag{3}$$

$$S(p^e(\hat{\rho}_j))=-\sum_k p_k^e(\hat{\rho}_j)\log p_k^e(\hat{\rho}_j). \tag{4}$$

Since we assumed the $\hat{e}_k$ to be orthogonal, one-dimensional projections, $p^e(\hat{\rho})$, respectively $p^e(\hat{\rho}_j)$, are the spectra of the states resulting from $\hat{\rho}$, respectively $\hat{\rho}_j$, after repeated, nonselective measurements of the observables $\hat{e}_k$:

$$\hat{\rho}^e:=\sum_k p_k^e(\hat{\rho})\hat{e}_k, \quad \text{respectively} \quad \hat{\rho}_j^e:=\sum_k p_k^e(\hat{\rho}_j)\hat{e}_k. \tag{5}$$

Then (3) and (4) coincide with the von Neumann entropies,

$$S(\hat{\rho}^e)=-\mathrm{Tr}\ \hat{\rho}^e\ \log\ \hat{\rho}^e=-\sum_k p_k^e(\hat{\rho})\log p_k^e(\hat{\rho}), \tag{6}$$

$$S(\hat{\rho}_j^e)=-\mathrm{Tr}\ \hat{\rho}_j^e\ \log\ \hat{\rho}_j^e=-\sum_k p_k^e(\hat{\rho}_j)\log p_k^e(\hat{\rho}_j). \tag{7}$$

Notice that from (1) and (2) it follows that $\Sigma_j p_j p_k^e(\hat{\rho}_j)=p_k^e(\hat{\rho})$, whence $p^e(\hat{\rho}_j)$ can be interpreted as the probability of the event $\hat{e}_k$ conditioned upon the occurrence of the event $\hat{\rho}_j$ and

$$\sum_j p_j S(p^e(\hat{\rho}_j)), \tag{8}$$

as the corresponding conditional entropy. Then, Shannon's mutual information is defined as the difference,[2]

$$I_{\hat{\rho}}^e:=S(p^e(\hat{\rho}))-\sum_j p_j S(p^e(\hat{\rho}_j)). \tag{9}$$

In the conventional (classical) setting Alice sends signals to Bob by means of orthogonal photon states $\hat{\rho}_{1,2}$ out of, say, a mixture of them with probabilities p_1 and $p_2=1-p_1$. Then, by measuring the orthogonal projections $\hat{\rho}_{1,2}$, Bob will maximize the amount of information he can extract per measurement. In fact, in this case, the conditional probabilities $p_k^e(\hat{\rho}_j)=0,1$ so that the conditional entropy vanishes and $I_{\hat{\rho}}^e=-p_1\log p_1-p_2\log p_2$ is maximal.

In Sec. IV we will address the corresponding quantum problem, namely the question of the best noncommutative decoding strategy.

Dynamical entropies

The Kolmogorov–Sinai dynamical entropy[1] is, in essence, classical information applied to ergodic theory and provides us with powerful methods to characterize the degree of randomness of classical dynamical systems.

Abstractly, the dynamics is represented by the iterations of a map T on a measure space $\mathscr{X}$, equipped with an invariant measure μ (*a priori* state). Information about the system is gained by assigning the phase point representing the system to one of the disjoint atoms P_j, $1\leqslant j\leqslant n$ of a chosen coarse-grained description (partition) $\mathscr{P}$ of $\mathscr{X}$. The atoms have volumes $\mu(P_j)$ that are probabilities, and the entropy

$$H_\mu(\mathscr{P}) = -\sum_j \mu(P_j)\log\,\mu(P_j) \tag{10}$$

measures the *a priori* information relative to $\mathscr{P}$.

If we get information about the system by means of a different partition $\mathscr{Q} := \{Q_k\}_{k=1}^m$, $\mu_{jk}^Q := \mu(P_j \cap Q_k)/\mu(P_j)$ is the probability of finding the system in the atom Q_k if it is in the atom P_j. The uncertainty removed as a consequence of the assignment of the phase point to any of the atoms Q_k is thus given by

$$H_j^Q := -\sum_j \mu_{jk}^Q \log\,\mu_{jk}^Q, \tag{11}$$

and Shannon's mutual information reads as

$$I_\mu^Q = H_\mu(\mathscr{P}) - \sum_j \mu(P_j) H_j^Q. \tag{12}$$

We can identify the triple $(\mu,\mathscr{P},\mathscr{Q})$ with a classical communication channel by simply thinking of $\mathscr{P}$ as providing a decomposition of the state μ and of $\mathscr{Q}$ as of a decoding procedure. Then, I_Q measures the information capacity of the given classical communication channel and attains its maximum $H_\mu(\mathscr{P})$ when $\mathscr{Q}=\mathscr{P}$. This fits very well with the use of $H_\mu(\mathscr{P})$ as the natural measure of the information content of the partition $\mathscr{P}$ with respect to the state μ. The entropy of a partition is indeed the central notion for the dynamical entropy constructed by Kolmogorov and Sinai.[1]

Any attempt at a quantum generalization of the above considerations encounters a major conceptual problem. In fact, quantum states are generally perturbed by measurement processes. For instance, in (5) $\hat{\rho}_j^e \neq \hat{\rho}_j$, unless $\hat{\rho}_j$ commutes with the $\hat{e}_k$'s. In classical contexts the perturbations of the state due to measurements can always be made negligible, at least in the line of the principle. As a matter of exemplification, in the case of the localization of the phase point within one of the atoms of the partition $\mathscr{P}$, what corresponds to the quantum state $\hat{\rho}$ transforming into the new state $\hat{\rho}^e$ in (5) is the following:

$$\mu \mapsto \mu^P := \sum_j \mu(P_j)\chi_{P_j}, \tag{13}$$

where the χ_{P_j} are the index functions of the various (disjoint) atoms. That $\mu^P = \mu$ can be checked by considering the mean values $\mu(f)$ and $\mu^P(f)$ of any μ-integrable function f.

Intuitively, at the core of the notion of dynamical entropy lies the idea that the more we know about the past of an evolving system, the more confident we are on our predictions about its future. If this is not the case then we have a signature of random behavior. The reliability of our predictions also depends on the degree of accuracy of the observations we performed on the system in order to acquire information about it. In a classical context we can always think of carrying them out without altering the regularity or irregularity of the system, the latter being then intrinsic properties. Quantum mechanically instead, one is very likely to introduce randomness into the system by performing measurements on it. Thus, an observer-independent characterization of quantum chaos based on any meaningful notion of quantum information requires that information be gathered without perturbing the physical state. However, the effects of quantum measurements are inherently quantum mechanical and one is not at all sure that these should not be incorporated in any physical theory of quantum chaos.[7]

In the case of a formulation solely based on the dynamics with respect to which the given state of the system is invariant, what is required is, first, a good notion of ''quantum partition'' and, second, a good measure of the amount of information contained in it with respect to a given

quantum state. In the following, we will be dealing with a proposal of quantum dynamical entropy that tries to fulfill the latter needs, while we refer the reader to Ref. 8 for a formulation that allows for external perturbations of the quantum states.

In the noncommutative setting one usually replaces the measure-theoretic description of classical dynamical systems with an algebraic one. That is, one refers to some algebra $\mathscr{A}$ of bounded operators (C^* or von Neumann algebra) equipped with a dynamical automorphism θ that respects the algebraic relations and preserves a state ω, the latter assigning the expectation values of all the observables of the system.

Finite-dimensional subalgebras $\mathbf{N}\subset\mathscr{A}$ offer themselves as natural substitutes for classical partitions. In Ref. 9 the infinitely many decompositions of any nonpure quantum state are used to construct the *entropy of a subalgebra* $H_\omega(\mathbf{N})$, the quantum generalization of the classical entropy of a partition $H_\mu(\mathscr{P})$ in (10) (also see Ref. 10). We will show that the entropy of an Abelian subalgebra $\mathbf{A}\subset\mathbf{M}_n(\mathbb{C})$ coincides with the accessible information of a specific quantum communication channel. Moreover, a temptative information-geometric interpretation of these optimal decompositions is compared with recent results concerning generic states on $\mathbf{M}_2(\mathbb{C})$ and completely symmetric ones on $\mathbf{M}_3(\mathbb{C})$.[11]

II. ENTROPY OF A SUBALGEBRA

We consider the simplest possible quantum mechanical setting, namely an n-level system the observables, respectively the states, of which are Hermitian $n\times n$ matrices in $\mathbf{M}_n(\mathbb{C})$, respectively density matrices $\hat{\rho}$, with positive eigenvalues ρ_l, $l=1,\ldots,n$ such that $\Sigma_l\rho_l=1$. Any density matrix $\hat{\rho}$ for which $\hat{\rho}^2\neq\hat{\rho}$ is a mixed state and can be arbitrarily decomposed into a convex linear combination of other states $\hat{\rho}_j\in\mathbf{M}_n(\mathbb{C})$ as in (1), with given weights $0\leqslant p_j\leqslant 1$, $\Sigma_j p_j=1$. For our purposes, we will be content with finite linear convex combinations that we will call ''decompositions.''

Two observations are in order at this point: the effect of a quantum measurement on a quantum state is usually described as in (5).[12] The latter amounts to a decomposition if and only if the $\hat{e}_k$ (in general, not orthogonal projections) commute with the state itself. Second, any resolution of the identity, $\Sigma_j\hat{x}_j=\hat{\mathbb{1}}$, by means of positive operators $0\leqslant\hat{x}_j\in\mathbf{M}_n(\mathbb{C})$ gives a decomposition of a state $\hat{\rho}\in\mathbf{M}_n(\mathbb{C})$. As follows:

$$\hat{\rho}=\sum_j \operatorname{Tr}\hat{\rho}\hat{x}_j\,\frac{\sqrt{\hat{\rho}}\hat{x}_j\sqrt{\hat{\rho}}}{\operatorname{Tr}\hat{\rho}\hat{x}_j}. \tag{14}$$

Remark 1: The converse is also true: given a decomposition $\hat{\rho}=\Sigma_j\lambda_j\hat{\rho}_j$, *there exists a set of positive operators* $\hat{x}_j\in\mathbf{M}_n(\mathbb{C})$, $\Sigma_j\hat{x}_j=\hat{\mathbb{1}}$, *such that (14) holds. The clue to it is the so-called GNS construction based on* $\hat{\rho}$ *itself, if it is invertible, otherwise upon restricting to its support projection.*[13]

The information content of quantum states is measured by the von Neumann entropy:

$$S(\hat{\rho})=-\operatorname{Tr}\hat{\rho}\,\log\,\hat{\rho}. \tag{15}$$

Let us now consider a maximally Abelian subalgebra $\mathbf{A}\subset\mathbf{M}_n(\mathbb{C})$ generated by n orthogonal one-dimensional (minimal) projections $\hat{a}_j$ such that $\Sigma_j\hat{a}_j=\hat{\mathbb{1}}$. The restriction $\hat{\rho}\restriction\mathbf{A}$ of any state $\hat{\rho}$ to $\mathbf{A}$ provides us with a discrete probability $P^a_{\hat{\rho}}:=\{p^a_j\}$, $j=1,\ldots,n$ and $p^a_j:=\operatorname{Tr}\hat{\rho}\hat{a}_j$. That is,

$$\hat{\rho}\restriction\mathbf{A}=\sum_j \hat{a}_j\hat{\rho}\hat{a}_j=\sum_j\{\operatorname{Tr}\hat{\rho}\hat{a}_j\}\hat{a}_j \tag{16}$$

and

$$S(\hat{\rho}\restriction\mathbf{A}) = -\sum_j p_j^a \log p_j^a . \tag{17}$$

Now, the map $\hat{\rho}\mapsto\Sigma_j \hat{a}_j\hat{\rho}\hat{a}_j$ is such that $S(\hat{\rho})\leqslant S(\hat{\rho}\restriction\mathbf{A})$ (Ref. 14, Chap. 2), and

$$S(\hat{\rho}) = \min\{S(\hat{\rho}\restriction\mathbf{A}) : \mathbf{A}\subset\mathbf{M}_n(\mathbb{C}) \text{maximally Abelian}\}, \tag{18}$$

the minimum being attained at any maximally Abelian $\mathbf{A}$ containing the spectral projections of $\hat{\rho}$.

The above result makes clear that $S(\hat{\rho}\restriction\mathbf{N})$ is useless as a measure of the information content of a subalgebra $\mathbf{N}\subseteq\mathbf{M}_n(\mathbb{C})$ with respect to the state $\hat{\rho}$. Indeed, we expect that, like finer classical partitions have greater entropy, larger subalgebras contain more information. At the core of the fact that there are subalgebras $\mathbf{N}$ and $\mathbf{M}$ with $\mathbf{N}\subset\mathbf{M}$ and, nevertheless, $S(\hat{\rho}\restriction\mathbf{N})>S(\hat{\rho}\restriction\mathbf{M})$, we find purely quantum reasons (state entanglement): the singlet state of two spin $\frac{1}{2}$ particles is pure and has zero entropy, whereas restricted to the single spin algebra it becomes a mixture of equally distributed spin up and down states with von Neumann entropy log 2.

An entropic-like quantity that is always increasing under embedding is the *relative entropy* of two states $\hat{\rho},\hat{\sigma}$:

$$S(\hat{\rho},\hat{\sigma}) := \mathrm{Tr}\,\hat{\sigma}(\log\,\hat{\sigma} - \log\,\hat{\rho}). \tag{19}$$

Among other properties, $S(\hat{\rho},\hat{\sigma})$ is always positive and vanishes if and only if $\hat{\sigma}=\hat{\rho}$. Moreover, it is monotonic (see Ref. 15):

$$S(\hat{\rho}\restriction\mathbf{N}_1,\hat{\sigma}\restriction\mathbf{N}_1)\leqslant S(\hat{\rho}\restriction\mathbf{N}_2,\hat{\sigma}\restriction\mathbf{N}_2), \quad \text{if } \mathbf{N}_1\subseteq\mathbf{N}_2 . \tag{20}$$

Let a state $\hat{\rho}$, a subalgebra $\mathbf{N}\subseteq\mathbf{M}(\mathbb{C})$ and a decomposition $\hat{\rho}=\Sigma_j p_j\hat{\rho}_j$ be given. Then, we construct the functional

$$H_{\hat{\rho}}(\{p_j\hat{\rho}_j\},\mathbf{N}) := \sum_j p_j S(\hat{\rho}\restriction\mathbf{N},\hat{\rho}_j\restriction\mathbf{N}), \tag{21}$$

$$= S(\hat{\rho}\restriction\mathbf{N}) - \sum_j p_j S(\hat{\rho}_j\restriction\mathbf{N}). \tag{22}$$

The latter equality follows from $\hat{\rho}=\Sigma_j p_j\hat{\rho}_j$ and (19).

Definition 1: The entropy of a subalgebra $\mathbf{N}\subseteq\mathbf{M}_n(\mathbb{C})$ *with respect to a state* $\hat{\rho}$ *is defined*[9] *as*

$$H_{\hat{\rho}}(\mathbf{N}) := \sup\left\{ H_{\hat{\rho}}(\{p_j\hat{\rho}_j\},\mathbf{N}) : \hat{\rho}=\sum_j p_j\hat{\rho}_j \right\}, \tag{23}$$

the supremum being computed over all possible decompositions of $\hat{\rho}$. *The decomposition(s) at which it is attained are called ''optimal decomposition(s).''*

The entropy of a subalgebra has the right monotonicity properties and fulfills the following bounds:

$$\mathbf{M}\subseteq\mathbf{N}\Rightarrow 0\leqslant H_{\hat{\rho}}(\mathbf{M})\leqslant H_{\hat{\rho}}(\mathbf{N})\leqslant S(\hat{\rho}\restriction\mathbf{N}). \tag{24}$$

Some concrete results

We now enumerate a series of known results that mainly stem from Refs. 16 and 11. Four of them are easier to discuss than the others: (0) the state $\hat{\rho}$ is pure, that is, it cannot be decomposed; (1) The subalgebra $\mathbf{N}$ coincides with the whole algebra $\mathbf{M}_n(\mathbb{C})$; (2) $\mathbf{N}$ is a maximally Abelian subalgebra $\mathbf{A}$ commuting with the state $\hat{\rho}$; (3) $\mathbf{N}\subseteq\mathbf{M}_n(\mathbb{C})$ is any subalgebra, but the state $\hat{\rho}$ is the so-called ''tracial state'' (denoted by τ), namely $\tau=\hat{\mathbb{1}}/n$.

Case (0): this case is trivial, namely $H_{\hat{\rho}}(\mathbf{N}) = 0$ for all $\mathbf{N}\subseteq\mathbf{M}_n(\mathbb{C})$.

Case (1): one chooses any decomposition of $\hat{\rho}$ as in (14) with the $\hat{x}_j$ to be one-dimensional projections in $\mathbf{M}_n(\mathbb{C})$. The corresponding $\hat{\rho}_j$ are one-dimensional projections and they obviously equal their restrictions $\hat{\rho}_j\restriction\mathbf{M}_n(\mathbb{C})$. Thus, the entropy $S(\hat{\rho}_j\restriction\mathbf{M}_n(\mathbb{C}))=0$ and the functional in (22) attains its maximum $H_{\hat{\rho}}(\mathbf{M}_n(\mathbb{C})) = S(\hat{\rho})$ at infinitely many optimal decompositions.

Case (2): a generic one-dimensional projection is seen as a mixed state when restricted to $\mathbf{A}$. However, using (14) and the choice $\hat{x}_j=\hat{a}_j$, where the $\hat{a}_j$ are the minimal projections that generate $\mathbf{A}$, one sees that the states

$$\hat{\rho}_j\restriction\mathbf{A}=\frac{\sqrt{\hat{\rho}}\hat{a}_j\sqrt{\hat{\rho}}}{\mathrm{Tr}\,\hat{\rho}\hat{a}_j}\restriction\mathbf{A} \tag{25}$$

are orthogonal, one-dimensional projections, whence $S(\hat{\rho}_j\restriction\mathbf{A})=0$. Therefore, the maximum in (23) equals $H_{\hat{\rho}}(\mathbf{A}) = S(\hat{\rho}\restriction\mathbf{A})$ and is attained at the optimal decomposition $\hat{\rho} = \Sigma_j\sqrt{\hat{\rho}}\hat{a}_j\sqrt{\hat{\rho}}$.

Case 3: one considers any maximally Abelian subalgebra $\mathbf{A}\subseteq\mathbf{N}$, with minimal (in $\mathbf{N}$) projections $\hat{a}_k$ of dimension $\mathrm{Tr}\,\hat{a}_k=d_k\geqslant 1$. Then

$$H_\tau(\mathbf{A})\leqslant H_\tau(\mathbf{N})\leqslant S(\tau\restriction\mathbf{N})\leqslant S(\tau\restriction\mathbf{A}), \tag{26}$$

because of (24) and (18). Let τ be decomposed as $\tau=\Sigma_{j=1}^n\hat{p}_j/n$, where the $\hat{p}_j$, $\Sigma_{j=1}^n\hat{p}_j=\hat{\mathbb{1}}$, are minimal [in $M_n(\mathbb{C})$] projections such that either $\hat{p}_j\hat{a}_k=0$ or $\hat{p}_j\hat{a}_k=\hat{p}_j$. It follows that

$$H_\tau(\mathbf{N})=S(\tau\restriction\mathbf{A})=-\sum_k\ \frac{d_k}{n}\log\frac{d_k}{n}. \tag{27}$$

Obviously, the optimal decompositions correspond to the possible refinements of the orthogonal projections $\hat{a}_k$ into one-dimensional orthogonal ones $\hat{p}_j$.

In more general situations than those discussed above, there are general results concerning $\mathbf{M}_2(\mathbb{C})$.[11,16] Hopes for easy generalizations to higher dimensions are somehow frustrated by a result concerning the entropy of a maximally Abelian subalgebra of $\mathbf{M}_3(\mathbb{C})$ with respect to a particularly symmetric state.[11]

By means of the Pauli matrix $(\hat{\sigma}_x,\hat{\sigma}_y,\hat{\sigma}_z)$ a generic state in $\mathbf{M}_2(\mathbb{C})$ can be written by means of a vector $\mathbf{b}\in\mathbb{R}^3$. As follows:

$$\hat{\rho}=\frac{\hat{1}}{2}+\frac{b_x}{1+b^2}\,\hat{\sigma}_x+\frac{b_y}{1+b^2}\,\hat{\sigma}_y+\frac{b_z}{1+b^2}\,\hat{\sigma}_z,\quad b=|\mathbf{b}|. \tag{28}$$

When $b=1$, $\hat{\rho}$ is a pure state (one-dimensional projection), whereas, if $b=0$, $\hat{\rho}$ is the two-dimensional tracial state τ.

Any proper subalgebra $\mathbf{N}$ of $\mathbf{M}_2(\mathbb{C})$ is a maximally Abelian subalgebra $\mathbf{A}$ that is not restrictive to identify with the one generated by the minimal projections $\hat{a}_\pm:=\hat{\mathbb{1}}/2\pm\hat{\sigma}_z/2$. Setting $\mathbf{n}:=2\mathbf{b}/(1+b^2)$ and $\mathbf{k}:=(0,0,1)$, we shall write

$$\hat{\rho}=\frac{\hat{1}+\mathbf{n}\cdot\hat{\sigma}}{2},\quad \hat{a}_\pm=\frac{\hat{1}\pm\mathbf{k}\cdot\hat{\sigma}}{2}. \tag{29}$$

Let $\mathbf{n}_\perp:=(n_x,n_y,0)$, $\mathbf{n}_\pm^*:=\mathbf{n}_\perp\pm\sqrt{1-\mathbf{n}_\perp^2}\mathbf{k}$ and

$$\hat{\rho}_\pm^*:=\frac{\hat{1}+\mathbf{n}_\pm^*\cdot\hat{\sigma}}{2},\quad p_\pm^*:=\frac{1}{2}\pm\frac{b_z}{\sqrt{(1-b^2)^2+4b_z^2}}. \tag{30}$$

As $\mathbf{n}^*_\pm \cdot \mathbf{n}^*_\pm = 1$, the states $\hat{\rho}^*_\pm$ are one-dimensional projections, but, in general, not orthogonal. The weights $p^*_\pm$ are such that $\hat{\rho} = p^*_+\hat{\rho}^*_+ + p^*_-\hat{\rho}^*_-$. It follows[16,11] that the entropy $H_{\hat{\rho}}(\mathbf{A})$ of $\mathbf{A}$ with respect to $\hat{\rho}$ is attained exactly at this decomposition, that is

$$H_{\hat{\rho}}(\mathbf{A}) = S(\hat{\rho}\restriction\mathbf{A}) - p^*_+ S(\hat{\rho}^*_+\restriction\mathbf{A}) - p^*_- S(\hat{\rho}^*_-\restriction\mathbf{A}). \tag{31}$$

It is easy to check that, when $b=0$ or $\mathbf{b}=(0,0,b)$, the results of the previous cases (2) and (3) are reproduced. Moreover, according to Remark 1, there exist ''observables'' $\hat{e}^*_\pm \in \mathbf{M}_2(\mathbb{C})$, $\hat{e}^*_+ + \hat{e}^*_- = \hat{1}$, namely,

$$\hat{e}^*_\pm = \frac{\hat{\mathbb{1}} \pm \mathbf{e}^* \cdot \hat{\sigma}}{2}, \quad \mathbf{e}^* := \frac{(2b_x b_z, 2b_y b_z, 1-b^2+2b_z^2)}{\sqrt{(1-b^2)^2+4b_z^2}}, \tag{32}$$

that allow us to write

$$\hat{\rho}^*_\pm = \frac{\sqrt{\hat{\rho}}\hat{e}^*_\pm\sqrt{\hat{\rho}}}{\mathrm{Tr}\,\hat{\rho}\hat{e}^*_\pm}. \tag{33}$$

We shall call them ''optimal observables.''

Remark 2: There are some peculiar geometrical symmetries in $\mathbf{M}_2(\mathbb{C})$. *For sake of simplicity and of comparison with Ref. 16, let the vector* $\mathbf{b}$ *identifying the state equal* $(z,0,0)$ *so that*

$$\hat{\rho} = \begin{pmatrix} \frac{1}{2} & z \\ z & \frac{1}{2} \end{pmatrix}.$$

Then, the z*-dependent optimal observables* $\hat{e}^*_\pm(z)$ *remain the same,*

$$\hat{e}^*_\pm(z) = \frac{\hat{\mathbb{1}} \pm \mathbf{k}\cdot\hat{\sigma}}{2} = \hat{a}_\pm, \quad \textit{for all } -1/2 < z < 1/2. \tag{34}$$

Vice versa, let us fix $\mathbf{b}=(b,0,0)$ *(hence the optimal decomposers* $\hat{\rho}^*_\pm$*) and construct the state*

$$\hat{\rho}(t) = t\hat{\rho}^*_+ + (1-t)\hat{\rho}^*_- = \frac{\hat{\mathbb{1}}}{2} + \frac{b}{1+b^2}\,\hat{\sigma}_x + \left(t-\frac{1}{2}\right)\frac{1-b^2}{1+b^2}\,\hat{\sigma}_z, \tag{35}$$

where $0<t<1$. *Then, the optimal observables* $\hat{e}^*_\pm(t)$ *vary, while the optimal decomposers* $\hat{\rho}^*_\pm(t)$ *remain the same, namely* $\hat{\rho}^*_\pm$, *for all* $0<t<1$.

The latter observation is a particular instance of the following general result that we quote from Ref. 11.

Proposition 1: Let $\hat{\rho} = \Sigma_{j\in J} p_j \hat{\rho}_j$ *be an optimal decomposition for a subalgebra* $\mathbf{N}\subseteq\mathbf{M}_n(\mathbb{C})$ *with respect to the state* $\hat{\rho}$. *Let* $\hat{\sigma} = \Sigma_{k\in J}\lambda_k\hat{\rho}_k$ *be any other state obtained as a convex linear combination of (some of) the optimal decomposers* $\hat{\rho}_j$. *Then, this is already an optimal decomposition for* $\mathbf{N}$ *with respect to* $\hat{\sigma}$, *namely*

$$H_{\hat{\sigma}}(\mathbf{N}) = S(\hat{\sigma}\restriction\mathbf{N}) - \sum_k \lambda_k S(\hat{\rho}_k\restriction\mathbf{N}). \tag{36}$$

As to the second geometrical symmetry present in the two-dimensional case, one wonders whether that too holds in greater generality. A clue to this problem comes from considering the maximally Abelian subalgebra $\mathbf{A}\subset\mathbf{M}_3(\mathbb{C})$ generated by

$$\hat{a}_1=\begin{pmatrix}1&0&0\\0&0&0\\0&0&0\end{pmatrix},\quad \hat{a}_2=\begin{pmatrix}0&0&0\\0&1&0\\0&0&0\end{pmatrix},\quad \hat{a}_3=\begin{pmatrix}0&0&0\\0&0&0\\0&0&1\end{pmatrix}. \tag{37}$$

The calculation of its entropy with respect to the symmetric state,

$$\hat{\rho}(z):=\begin{pmatrix}\frac{1}{3}&z&z\\z&\frac{1}{3}&z\\z&z&\frac{1}{3}\end{pmatrix},\quad -\tfrac{1}{6}\leqslant z\leqslant\tfrac{1}{3}, \tag{38}$$

leads to a surprising and intriguing departure from the two-dimensional case.

Let $a:=\sqrt{1+6z}$ and $b:=2\sqrt{1-3z}$. It turns out[11] that $\hat{\rho}(z)$ can be decomposed as

$$\hat{\rho}(z)=\tfrac{1}{3}\,[|\phi^{(1)}_{u,z}\rangle\langle\phi^{(1)}_{u,z}|+|\phi^{(2)}_{u,z}\rangle\langle\phi^{(2)}_{u,z}|+|\phi^{(3)}_{u,z}\rangle\langle\phi^{(3)}_{u,z}|], \tag{39}$$

by means of a one-parameter family of vectors and their cyclic permutations:

$$|\phi^{(1)}_{u,z}\rangle:=\begin{pmatrix}\phi_1(u,z)\\\phi_2(u,z)\\\phi_3(u,z)\end{pmatrix},\quad |\phi^{(2)}_{u,z}\rangle:=\begin{pmatrix}\phi_3(u,z)\\\phi_1(u,z)\\\phi_2(u,z)\end{pmatrix},\quad |\phi^{(3)}_{u,z}\rangle:=\begin{pmatrix}\phi_2(u,z)\\\phi_3(u,z)\\\phi_1(u,z)\end{pmatrix}, \tag{40}$$

$$\phi_1(u,z):=\frac{1}{3}\left[a+b\,\cos\left(u-\frac{\pi}{3}\right)\right], \tag{41}$$

$$\phi_2(u,z):=\frac{1}{3}\left[a+b\,\cos\left(u+\frac{\pi}{3}\right)\right], \tag{42}$$

$$\phi_3(u,z):=\frac{1}{3}\,[a-b\,\cos u]. \tag{43}$$

Proposition 2: There exists a value $z^*<0$ of the real parameter z,

$$z^*=\frac{1}{3}\,\frac{(t^*)^2-4t^*+3}{2(t^*)^2-4t^*+3},\quad \textit{where}\ \ \mathbf{e}^{-t^*}=t^*-1, \tag{44}$$

such that, for $z\geqslant z^*$, the angular parameter $u=\pi/3$ renders the decomposition (39) optimal for the maximally Abelian subalgebra $\mathbf{A}\subset\mathbf{M}_3(\mathbb{C})$ with respect to the state $\hat{\rho}(z)$. When $z<z^*$, there are two possible optimal decompositions corresponding to $u_{\pm}(z)=\pi/3\pm\alpha(z)$.

The proof of this result is partly analytic partly numerical.[11] We examine its consequences.

Proposition 3: The optimal observables $\hat{x}_j(z)$ that, according to Remark 1, correspond to the optimal decompositions of the previous proposition are the minimal projections $\hat{a}_j$ of $\mathbf{A}$ when $z^*\leqslant z<1/3$. Whereas, for $-1/6<z<z^*$, they are one-dimensional, but not orthogonal projections.

Proof: The observables $\hat{e}_j(u,z)$ associated with a given decomposition of the form (39) are given by

$$\tfrac{1}{3}\,|\phi^{(j)}_{u,z}\rangle\langle\phi^{(j)}_{u,z}|=\sqrt{\hat{\rho}(z)}\hat{e}_j(u,z)\sqrt{\hat{\rho}(z)}, \tag{45}$$

whence, via inverting $\hat{\rho}(z)$:

$$\hat{e}_1(u,z)=\frac{1}{9}\begin{pmatrix} C_+^2 & C_+C_- & C_+C \\ C_-C_+ & C_-^2 & C_-C \\ CC_+ & CC_- & C^2 \end{pmatrix}, \quad \begin{cases} C_\pm = 1+\cos u \pm \sqrt{3}\,\sin u, \\ C = 1-2\cos u. \end{cases} \tag{46}$$

$\hat{e}_1(u,z)$ projects onto $|1\rangle := 1/3(C_+, C_-, C)$ and $\hat{e}_2(u,z)$, respectively $\hat{e}_3(u,z)$, project onto $|2\rangle = 1/3(C, C_+, C_-)$, respectively $|3\rangle := 1/3(C_-, C, C_+)$.

According to Proposition 2, for $z^* \leqslant z < 1/3$, $u = \pi/3$ fixes an optimal decomposition and one sees that $|1\rangle = (1,0,0)$, hence $\hat{e}_j^*(\pi/3, z) = \hat{a}_j$.

On the other hand, the scalar products $\langle i|j\rangle$, $i \neq j$, $i,j = 1,2,3$, equal $2\cos^2 u + \cos u - 1$ and vanish for $u = \pi/3$, π only. Therefore, the angular values $u_\pm(z) = \pi/3 \pm \alpha(z)$ fixing two optimal decompositions when $-1/6 < z < z^*$, determine two sets of optimal observables $\hat{e}_j^*(u_\pm(z), z)$ that are one-dimensional, but not orthogonal projections. □

Remark 3: For $z^* \leqslant z < 1/3$ the three- and two-dimensional cases agree (compare Remark 2). However, when $-1/6 < z < z^*$ the situation drastically changes and two different optimal decompositions appear. Moreover, every linear convex combination of optimal decompositions of $\hat{\rho}(z)$ with respect to **A** *is again optimal, and thus, below the critical value z^*, we have infinitely many of them.*[11]

III. ACCESSIBLE INFORMATION

In this section we establish a connection between the concept of entropy of a subalgebra with respect to a given quantum state introduced in the previous section and the notion of information capacity briefly touched upon in the Introduction (see Ref. 17 for the classical case, Ref. 18 and Ref. 15 for the quantum one).

Definition 2: We call ''quantum communication channel'' the couple $\{\mathscr{R}, \mathscr{E}\}$, where $\mathscr{R} := \{p_j, \hat{\rho}_j\}$ is a statistical ensemble of quantum states $\hat{\rho}_j$ with weights p_j, $\Sigma_j p_j = 1$, and $\mathscr{E} := \{\hat{e}_k\}$ is a set of operators $0 \leqslant \hat{e}_k$ such that $\Sigma_k \hat{e}_k = \hat{\mathbb{1}}$.

The quantum state $\hat{\rho} = \Sigma_j p_j \hat{\rho}_j$ is Alice's signal source, or ''input alphabet,'' whereas the observables $\mathscr{E} = \{\hat{e}_k\}$ make up Bob's detection scheme or ''output alphabet.''[17] Notice that, unlike in the Introduction, the $\hat{e}_k$ need not be orthogonal projections. More generally, they define a so-called ''Positive Operator Valued (POV) Measure,'' which generalizes (5) to the following completely positive map[12] on quantum states:

$$\hat{\rho} \mapsto \mathscr{E}(\hat{\rho}) = \sum_k \sqrt{\hat{e}_k}\hat{\rho}\sqrt{\hat{e}_k}. \tag{47}$$

The next almost obvious Lemma establishes a natural connection between certain input alphabets $\mathscr{E}$ and the restrictions $\hat{\rho}\restriction\mathbf{A}$ of quantum states to Abelian subalgebras.

Lemma 1: Given a density matrix $\hat{\rho} \in \mathbf{M}_n(\mathbb{C})$, every (not necessarily maximally) Abelian subalgebra $\mathbf{A} \subset \mathbf{M}_n(\mathbb{C})$ identifies an input alphabet $\mathscr{A}_{\hat{\rho}}$.

Proof: We simply use the projections $\hat{a}_j$, $1 \leqslant j \leqslant n$ [not necessarily minimal in $\mathbf{M}_n(\mathbb{C})$] to decompose the state $\hat{\rho}$ as in (14), whence

$$\mathscr{A}_{\hat{\rho}} := \{p_j^a, \hat{\rho}_j^a\}, \quad p_j^a := \mathrm{Tr}\,\hat{\rho}\hat{a}_j, \quad \hat{\rho}_j^a := \frac{\sqrt{\hat{\rho}}\hat{a}_j\sqrt{\hat{\rho}}}{\mathrm{Tr}\,\hat{\rho}\hat{a}_j}. \tag{48}$$

Given an input, respectively output, alphabet $\mathscr{R} = \{p_j, \hat{\rho}_j\}$, respectively $\mathscr{E} = \{\hat{e}_k\}$, the argument developed in the Introduction for Shannon's mutual entropy (9) leads to associating with the probability measures $p_e(\hat{\rho}) := \{\mathrm{Tr}\,\hat{\rho}\hat{e}_k\}$ and $p^e(\hat{\rho}_j) := \{\mathrm{Tr}\,\hat{\rho}_j\hat{e}_k\}$, the information contents,

$$S(p^e(\hat{\rho})) := -\sum_k \text{Tr}\ \hat{\rho}\hat{e}_k \log \text{Tr}\ \hat{\rho}\hat{e}_k, \tag{49}$$

$$S(p^e(\hat{\rho}_j)) := -\sum_k \text{Tr}\ \hat{\rho}_j\hat{e}_k \log \text{Tr}\ \hat{\rho}_j\hat{e}_k, \tag{50}$$

whence the following[18,19] occurs.

Definition 3: Let a quantum communication channel $\{\mathscr{R},\mathscr{E}\}$ *be given, where* $\mathscr{R}=\{p_j,\hat{\rho}_j\}$ *and* $\mathscr{E}=\{\hat{e}_k\}$*, then the mutual information of the channel is*

$$I(\mathscr{R},\mathscr{E}) := S(p^e(\hat{\rho})) - \sum_j p_j S(p^e(\hat{\rho}_j)). \tag{51}$$

For a given input alphabet $\mathscr{R}$*,*

$$I(\mathscr{R}) := \sup_{\mathscr{E}} I(\mathscr{R},\mathscr{E}), \tag{52}$$

represents the maximal information achievable by varying the detection strategy, namely the output alphabet $\mathscr{E}$*.* $I(\mathscr{R})$ *is called ''accessible information.''*

As we have seen in the previous section any mixed state $\hat{\rho}$ can be decomposed as $\hat{\rho}=\Sigma_j p_j\hat{\rho}_j$ by using whatever decomposition of the identity by means of positive operators we might envisage. From a statistical point of view all these possibilities are equivalent: they all are described by the same density matrix. However, the average relative entropy,

$$\sum_j p_j S(\hat{\rho},\hat{\rho}_j) = S(\hat{\rho}) - \sum_j p_j S(\hat{\rho}_j), \tag{53}$$

we have already encountered [see (21)] is a tool to partially distinguish among them. An important relation between the accessible information of a given statistical mixture $\hat{\rho}=\Sigma_j p_j\hat{\rho}_j$, and the average relative entropy is contained in the so-called Holevo bound.[20] If $\mathscr{R}=\{p_j,\hat{\rho}_j\}$ is Alice's input alphabet, Bob's accessible information must fulfill

$$I(\mathscr{E}) \leqslant S(\hat{\rho}) - \sum_j p_j S(\hat{\rho}_j). \tag{54}$$

Notice that if the $\hat{\rho}_j$ are pure states, then the bound reduces to $S(\hat{\rho})$.

The above considerations point to a close connection between the notion of entropy of a subalgebra and the accessible information of an input alphabet. Indeed, the entropy of an Abelian subalgebra $\mathbf{A}\subset\mathbf{M}_n(\mathbb{C})$ with respect to a state $\hat{\rho}\in\mathbf{M}_n(\mathbb{C})$ equals the accessible information of the input alphabet $\mathscr{A}_{\hat{\rho}}$ determined by $\mathbf{A}$ and $\hat{\rho}$.

Proposition 4: Let $\mathbf{A}\subset\mathbf{M}_n(\mathbb{C})$ *be an Abelian subalgebra generated by orthogonal projections* $\hat{a}_j$, $1\leqslant j\leqslant n$*, and* $\hat{\rho}\in\mathbf{M}_n(\mathbb{C})$ *a given state. Then*

$$H_{\hat{\rho}}(\mathbf{A}) = I(\mathscr{A}_{\hat{\rho}}), \tag{55}$$

where the left-hand side is the entropy of $\mathbf{A}$ *with respect to* $\hat{\rho}$ *as defined in Definition 1, while the right-hand side is the accessible information of the input alphabet associated with* $\mathbf{A}$ *and* $\hat{\rho}$ *as in Lemma 1.*

Proof: Let $\mathscr{A}_{\hat{\rho}} = \{p_j^a, \hat{\rho}_j^a\}$ be the input alphabet as in (48), that is $p_j^a = \mathrm{Tr}\,\hat{\rho}\hat{a}_j$ and $\hat{\rho}_j^a = \sqrt{\hat{\rho}}\hat{a}_j\sqrt{\hat{\rho}}/\mathrm{Tr}\,\hat{\rho}\hat{a}_j$. Let $\mathscr{E} = \{\hat{e}_k\}$ be a given output alphabet and use it to decompose $\hat{\rho}$ as in (14), namely $\hat{\rho} = \Sigma_k p_k^e \hat{\rho}_k^e$, $p_k^e = \mathrm{Tr}\,\hat{\rho}\hat{e}_k$, $\hat{\rho}_k^e = \sqrt{\hat{\rho}}\hat{e}_k\sqrt{\hat{\rho}}/\mathrm{Tr}\,\hat{\rho}\hat{e}_k$. Then, from (22) and (17) (the latter holds independently of the $\hat{a}_j$ being minimal projections),

$$H_{\hat{\rho}}(\{p_k^e\hat{\rho}_k^e\}, \mathbf{A}) = S(\hat{\rho}\restriction\mathbf{A}) - \sum_k p_k^e S(\hat{\rho}_k^e\restriction\mathbf{A}) = -\sum_j p_j^a \log p_j^a + \sum_{j,k} p_k^e\, \mathrm{Tr}\,\hat{\rho}_k^e\hat{a}_j \log \mathrm{Tr}\,\hat{\rho}_k^e\hat{a}_j\,. \tag{56}$$

Using the cyclycity of the trace, we write

$$\mathrm{Tr}\,\hat{\rho}_k^e\hat{a}_j = \frac{p_j^a}{p_k^e}\,\mathrm{Tr}\,\hat{\rho}_j^a\hat{e}_k\,, \tag{57}$$

whence (56) reads as

$$H_{\hat{\rho}}(\{p_k^e\hat{\rho}_k^e\}, \mathbf{A}) = \sum_{j,k} p_j^a\, \mathrm{Tr}\,\hat{\rho}_j^a\hat{e}_k \log \mathrm{Tr}\,\hat{\rho}_j^a\hat{e}_k - \sum_j p_j^a \log p_j^a + \sum_{j,k} \{\mathrm{Tr}\sqrt{\hat{\rho}}\hat{a}_j\sqrt{\hat{\rho}}\hat{e}_k\}\log\frac{p_j^a}{p_k^e} \tag{58}$$

$$= -\sum_k p_k^e \log p_k^e + \sum_{j,k} p_j^a\, \mathrm{Tr}\,\hat{\rho}_j^a\hat{e}_k \log \mathrm{Tr}\,\hat{\rho}_j^a\hat{e}_k = I(\mathscr{A}_{\hat{\rho}}, \mathscr{E}). \tag{59}$$

□

Let us now go back to the two-dimensional case where $\mathbf{A}$ is the Abelian subalgebra generated by projections $\hat{a}_\pm$ of (29) and the state is parametrized as in the same (29). The input alphabet $\mathscr{A}_{\hat{\rho}}$ is formed by the statistical mixture of the pure states,

$$\hat{\rho}_\pm^a := \frac{\sqrt{\hat{\rho}}\hat{a}_\pm\sqrt{\hat{\rho}}}{\mathrm{Tr}\,\hat{\rho}\hat{a}_\pm} = \frac{\hat{\mathbb{1}}}{2} + \frac{\mathbf{n}_\pm}{2}\cdot\hat{\sigma}, \quad \mathbf{n}_\pm := \frac{2\mathbf{b}(1\pm b_z) \pm (1-b^2)\mathbf{k}}{1\pm 2b_z + b^2}, \tag{60}$$

with weights

$$p_\pm^a := \mathrm{Tr}\,\hat{\rho}\hat{a}_\pm = \frac{1+b^2\pm 2b_z}{2(1+b^2)}. \tag{61}$$

In Ref. 19 one finds that this is one of the few cases when the accessible information $I(\mathscr{A}_{\hat{\rho}})$ can be explicitly worked out together with the optimal output alphabet $\mathscr{E}$ at which it is attained. The latter, according to the previous proposition, must consist of the two orthogonal projections $\hat{e}_\pm^*$ in (32). Due to interesting connections with the problem of optimal parameter estimation, the proof of this fact will be postponed to the next section.

Remark 4: From the upper bound in (24) and the previous result we deduce that $I(\mathscr{A}_{\hat{\rho}}) = H_{\hat{\rho}}(\mathbf{A}) \leqslant S(\hat{\rho}\restriction\mathbf{A})$. *On the other, when* $\mathbf{A}$ *is maximally Abelian the states* $\hat{\rho}_j^a$ *in the input alphabet* $\mathscr{A}_{\hat{\rho}}$ *are one-dimensional projections so that the Holevo bound (54) gives* $I(\mathscr{A}_{\hat{\rho}}) \leqslant S(\hat{\rho})$. *This is a better bound than the previous one, as follows from (18).*

IV. OPTIMAL ESTIMATION

In this section we address the question of whether there is any operational interpretation behind the optimal observables giving the accessible information $I(\mathscr{A}_{\hat{\rho}})$, or equivalently, the entropy $H_{\hat{\rho}}(\mathbf{A})$ of the Abelian algebra $\mathbf{A}\subset\mathbf{M}_n(\mathbb{C})$ with respect to the state $\hat{\rho}$. Again, it will turn out that the nice picture that emerges in the two-dimensional case is somewhat misleading. Indeed, the

optimal observables $\hat{e}^*_{\pm}$ in (32) maximize the so-called Fisher information. The latter appears in a lower (Cramer–Rao) bound to the variance of any function X that estimates the parameter t when one deals with a one-parameter family (state path) of classical probability distributions $P(t)$ or quantum states $\hat{\rho}(t)$.[21] Quite interesting are the connections, both in the classical and quantum case, between the best estimation problem and the so-called distinguishability metrics on the state space.[22–24] We will adapt the discussion to the context previously developed in this paper by following Ref. 23.

Let $\hat{\rho}(t)$ be a one-parameter family of quantum states in $\mathbf{M}_n(\mathbb{C})$ such that the ''derivative'' $\hat{\rho}'(t) := d\hat{\rho}(t)/dt$ is well defined. Let $\mathscr{E}=\{\hat{e}_k\}_{k\in K}$ be a set of observables (an output alphabet or POV measure as in Definition 2), that when measured give a (finite) set of results $k\in K$ with probabilities $p^e_k(t) := \mathrm{Tr}\,\hat{e}_k\hat{\rho}(t)$. Out of iterated measurements of $\mathscr{E}$ one tries to estimate the parameter t by means of an estimator function $X^e_N(k_1,\ldots,k_N)$. After N measurements one ends up with a joint probability measure $P^e_N(k_1\cdots k_n;t) := \Pi_{j=1}^N p^e_{k_j}(t)$ and with a mean value $\langle X^e_N\rangle(t) := \Sigma_{k_1\cdots k_n} P^e_N(k_1\cdots k_n;t)X^e_N(k_1\cdots k_n)$ for the estimated parameter t. Let $\Delta^e_N X := X^e_N(k_1\cdots k_n) - \langle X^e_N\rangle(t)$. From the obvious equality $\Sigma_{k_1\cdots k_n} P^e_N(k_1\cdots k_n;t)\Delta^e_N X = 0$ one first derives

$$\frac{d\langle X^e_N\rangle(t)}{dt} = \sum_{k_1\cdots k_n} P^e_N(k_1\cdots k_n;t)\sum_{j=1}^N \frac{d\,\log p^e_{k_j}(t)}{dt}\,\Delta^e_N X. \tag{62}$$

Then, the Cauchy–Schwartz inequality gives the Cramér–Rao lower bound,

$$\langle(\Delta^e_N X)^2\rangle_N(t) \geqslant \frac{1}{NF(t)}\left(\frac{d\langle X^e_N\rangle(t)}{dt}\right)^2, \tag{63}$$

to the variance of the estimator function, where

$$F^e(t) := \sum_{k\in k} p^e_k(t)\left(\frac{d\,\log p^e_k(t)}{dt}\right)^2 \tag{64}$$

is the Fisher information relative to the distribution $p^e(t) := \{p^e_k(t)\}$.

Roughly speaking, in order to diminish the error in the estimate of t one tries to maximize

$$F^e(t) = \sum_{k\in K} (p^e_k)^{-1}(t)\left(\frac{dp^e_k(t)}{dt}\right)^2. \tag{65}$$

Of great help is the so-called logarithmic derivative of $\hat{\rho}'(t)$ at $\hat{\rho}(t)$. The latter, denoted by $\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]$, is defined by Refs. 23 and 24 (also see Ref. 22):

$$\tfrac{1}{2}\{\hat{\rho}(t)\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)] + \mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]\hat{\rho}(t)\} = \hat{\rho}'(t), \tag{66}$$

and allows us to rewrite (65) as follows (Re means real part):

$$F^e(t) = \sum_{k\in K}\{\mathrm{Tr}\,\hat{\rho}\hat{e}_k\}^{-1}[\mathrm{Re}\,\mathrm{Tr}\,\hat{\rho}(t)\mathscr{L}_{\hat{\rho}}[\hat{\rho}(t)]\hat{e}_k]^2. \tag{67}$$

Then, from the cyclicity of the trace and the properties of the Hilbert–Schmidt norm, namely that $|\mathrm{Tr}\,\hat{a}^*\hat{b}|^2 \leqslant \mathrm{Tr}\,\hat{a}^*\hat{a}\,\mathrm{Tr}\,\hat{b}^*\hat{b}$, we get the upper bound,

$$[\mathrm{Re\ Tr}\ \hat{\rho}(t)\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}(t)]\hat{e}_k]^2=[\mathrm{Re\ Tr}\sqrt{\hat{\rho}(t)}\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]\sqrt{\hat{e}_k}\sqrt{\hat{e}_k}\sqrt{\hat{\rho}(t)}]^2$$
$$\leqslant \mathrm{Tr}\ \hat{\rho}(t)\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]\hat{e}_k\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]\mathrm{Tr}\ \hat{\rho}\hat{e}_k. \tag{68}$$

Finally, since $\Sigma_{k\in K}\hat{e}_k=\hat{\mathbb{1}}$,

$$F^e(t)\leqslant \mathrm{Tr}\ \hat{\rho}'(t)\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]. \tag{69}$$

The upper bound is attained at the input alphabet $\mathscr{E}=\{\hat{e}_k\}$, such that

$$\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]\sqrt{\hat{e}_k}=\lambda_k\sqrt{\hat{e}_k},\quad \lambda_k=\frac{\mathrm{Tr}\ \hat{\rho}(t)\hat{e}_k\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]}{\mathrm{Tr}\ \hat{\rho}(t)\hat{e}_k}\in\mathbb{R}, \tag{70}$$

a condition that can always be met by choosing the $\hat{e}_k$ as the eigenprojections of the (self-adjoint) operator $\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]$.

Concretely, we will consider the two-dimensional case by taking as state path $\hat{\rho}(t)$, $0\leqslant t\leqslant 1$, the one-parameter family of density matrices,

$$\hat{\rho}(t):=t\hat{\rho}_+^a+(1-t)\hat{\rho}_-^a=\frac{\hat{\mathbb{1}}}{2}+\frac{\mathbf{n}(t)}{2}\cdot\hat{\sigma}, \tag{71}$$

where, from (60), $\mathbf{n}(t):=t\mathbf{n}_+ +(1-t)\mathbf{n}_-$. Namely, we will deal with the convex hull of the states corresponding to the input alphabet $\mathscr{A}_{\hat{\rho}}$ defined by the Abelian algebra $\mathbf{A}$ of the projections $\hat{a}_\pm$ in (30) and by the state $\hat{\rho}$ in (29).

In order to arrive at an explicit expression of the logarithmic derivative $\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]$, we notice that

$$\hat{\rho}'(t)=\hat{\rho}_+^a-\hat{\rho}_-^a=\mathbf{n}_{+-}\cdot\hat{\sigma},\quad \mathbf{n}_{+-}:=(1-b^2)\,\frac{(1+b^2)\mathbf{k}-2b_z\mathbf{b}}{(1+b^2)^2-4b_z^2}, \tag{72}$$

is a self-adjoint operator and that its logarithmic derivative at $\hat{\rho}(t)$ is self-adjoint, too. We shall then insert

$$\mathscr{L}_{\hat{\rho}(t)}[\hat{\rho}'(t)]=\lambda_+\hat{x}_+ +\lambda_-\hat{x}_-, \tag{73}$$

in (66) and solve for the orthogonal eigenprojections $\hat{x}_\pm$ and the eigenvalues $\lambda_\pm$. After writing $\hat{x}_\pm=\hat{\mathbb{1}}/2\pm\mathbf{x}/2\cdot\hat{\sigma}$, with $\mathbf{x}\cdot\mathbf{x}=1$ (the projection condition), we obtain

$$\lambda_+ +\lambda_- +(\lambda_+ -\lambda_-)\mathbf{n}(t)\cdot\mathbf{x}=0, \tag{74}$$

$$(\lambda_+ -\lambda_-)\mathbf{x}+(\lambda_+ +\lambda_-)\mathbf{n}(t)=4\mathbf{n}_{+-}. \tag{75}$$

From these equations we calculate the unit vector $\mathbf{x}$:

$$\mathscr{N}(t)\mathbf{x}=2\mathbf{b}[(1-b_z)(1+b^2+2b_z)-2t(1+b^2-2b_z^2)]-\mathbf{k}(1-b^2)(1+b^2+2b_z-4tb_z), \tag{76}$$

$$\mathscr{N}(t):=\sqrt{(1+b^2)^2-4b_z^2-16t(1-t)(b^2-b_z^2)}\,\sqrt{(1+b^2)^2-4b_z^2}. \tag{77}$$

The state $\hat{\rho}$ of (29) corresponds to the choice $t=p_+^a$ [see (61)]. Once inserted in the above expression it gives $\mathbf{x}=\mathbf{e}^*$. Therefore we have the following.

Proposition 5: Let $\mathbf{A}\subset\mathbf{M}_2(\mathbb{C})$ *be the subalgebra generated by the projections* $\hat{a}_\pm$ *of (29) and* $\hat{\rho}$ *a given density matrix. Let* $\hat{\rho}(t)$ *the state path in (71). Then, the eigenprojections of the*

logarithmic derivative at $\hat{\rho}(p_+^a)=\hat{\rho}$ *coincide with the observables at which the entropy* $H_{\hat{\rho}}(\mathbf{A})$, *equivalently the accessible information* $I(\mathscr{A}_{\hat{\rho}})$, *is attained. The same optimal observables maximize the Fisher information* $F^e(p_+^a)$ *in (64).*

The above proposition is in agreement with analogous results in Ref. 19, where a proof of the Holevo bound is given by using the logarithmic derivative and in Ref. 2, where the more general question of the optimal measurements in $\mathbf{M}_2(\mathbb{C})$ is addressed.

Optimizing the Fisher information with respect to all possible generalized quantum measurements is essential in constructing a so-called distinguishability metric on the state space. The idea is to provide density matrices with a distance that reasonably discriminates between neighboring states.[23,24] In the symmetric case of Remark 2, that is, for $\mathbf{b}=(b,0,0)$, the logarithmic derivative at $\hat{\rho}(1/2)$ equals

$$\mathscr{L}_{\hat{\rho}(1/2)}\left[\hat{\rho}'\left(\frac{1}{2}\right)\right]=-2\,\frac{1-b^2}{1+b^2}\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}. \tag{78}$$

The projections $\hat{a}_\pm$ can thus be interpreted as the observables that optimally distinguish the symmetric state $\hat{\rho}(1/2)$ from neighboring states $\hat{\rho}(t)$ along the state path (35).

A similar argument does not hold in $\mathbf{M}_3(\mathbb{C})$ for the symmetric state $\hat{\rho}(z)$ in (38). Indeed, one can consider, for instance, the state path

$$\hat{\rho}(t,z)=t\hat{\rho}_1(z)+t\hat{\rho}_2(z)+(1-2t)\hat{\rho}_3(z),\quad \hat{\rho}_j(z)=\frac{\sqrt{\hat{\rho}(z)}\hat{a}_j\sqrt{\hat{\rho}(z)}}{\mathrm{Tr}\,\hat{\rho}(z)\hat{a}_j}, \tag{79}$$

where the $\hat{a}_j$ are the projections in (37), $0\leqslant t\leqslant 1/2$, and $\hat{\rho}(1/3,z)=\hat{\rho}(z)$. After some labor, it turns out that, unless $z=0$, that is, unless $\hat{\rho}(z)$ is the three-dimensional tracial state,

$$\mathscr{L}_{\hat{\rho}(z)}\left[\hat{\rho}'\left(\frac{1}{3},z\right)\right]=\begin{pmatrix}L_1 & L_2 & L_3\\ L_2 & L_1 & L_3\\ L_3 & L_3 & -2L_1\end{pmatrix},\quad \begin{cases} L_1=1+4\,\dfrac{\sqrt{1+3z-18z^2}}{2+3z},\\ L_2=2-4\,\dfrac{\sqrt{1+3z-18z^2}}{2+3z},\\ L_3=1-2\,\dfrac{\sqrt{1+3z-18z^2}}{2+3z}, \end{cases} \tag{80}$$

is not diagonal in the basis in which the $\hat{a}_j$ are diagonal.

Actually, according to Proposition 3, the situation is even more troublesome. In fact, when $z^*\leqslant z<1/3$, the possibility still remains of envisaging a suitable state path, such that the corresponding logarithmic derivative at $\hat{\rho}(1/3,z)$ has the $\hat{a}_j$ as eigenprojections. On the contrary, for $-1/6<z<z^*$, not only are there two sets of optimal observables for the entropy $H_{\hat{\rho}(z)}(\mathbf{A})$ of $\mathbf{A}$ with respect to $\hat{\rho}(z)$, but, above all, the $\hat{e}_j^*(u_\pm(z),z)$ are one dimensional, nonorthogonal projections, therefore they cannot be the spectral projections of a nontrivial logarithmic derivative.

V. CONCLUSIONS

In this paper we have compared two concepts: the accessible information of a quantum communication channel and the entropy of a subalgebra with respect to a quantum state. The first is an important tool to investigate the information content of messages transmitted by quantum carriers; the second aims at generalizing the notion of entropy of a partition of classical ergodic theory. Both find a common ground in the increasingly felt necessity of extending to quantum systems the apparatus of Shannon information theory.

We have pointed out the connections between the two notions, showing that the entropy of a subalgebra corresponds to the accessible information of a particular quantum communication channel, thus giving this seemingly abstract concept a nearly operative concreteness.

On the other hand, the fundamental role of the entropy of a subalgebra in generalizing to the noncommutative realm the dynamical entropy of Kolmogorov and Sinai, opens a wider horizon to the accessible information itself.

In the case of the two-dimensional algebra $\mathbf{M}_2(\mathbb{C})$ we have reviewed results common to both contexts, but apparently unknown to each other. The peculiarity of quantum mechanics, however, shows up when working in $\mathbf{M}_3(\mathbb{C})$, where a recent surprising result renders somehow problematic the promising relationships between the optimal observables and the so-called information geometries or distinguishability metrics that hold in the two-dimensional case.

Comment by R. Landauer

The paper, published in the first volume of the then newly established IBM Journal of Research and Development, is not all that easily located in 1996. As a result the frequent citations to it often assign content to that paper which does not agree with reality. The primary purpose of the paper, conveyed by its title, was to investigate the spatial variation of the transport field, in the presence of highly localized scatterers, and to show that such scatterers were associated with highly localized transport fields. The viewpoint has, since then, been elaborated by a good many other investigators, but has still not become a part of the material widely reflected in texts, review papers and conferences. A second aim of the 1957 paper was to bring a new view to electron transport theory. To the physicist the applied field has always been the source of transport, and the resulting carrier flow is viewed as the response. Electrical engineers, in circuit theory, have had a broader view, allowing for a duality between current sources and voltage sources. My 1957 paper introduced the notion that we can view the carriers introduced at the boundaries of the sample as the source of transport, and then ask how the resulting build-up of carriers produces fields. My 1957 paper is most often cited in connection with the now widely used expressions which relate conductance to the overall transmissive behavior of a sample which transmits carriers in a quantum mechanically coherent and elastic fashion. That result is, however, not contained in the 1957 paper, which is semi-classical and assumes that scatterers act incoherently. It took me several more years to understand that the relation between conductance and transmission is general, and not only applicable to localized plane barriers. It took about another decade after that to get the material accepted by a journal. That history was presented in the introductory paper of a recent conference volume.[1]

Spatial Variation of Currents and Fields Due to Localized Scatterers in Metallic Conduction

Abstract: Localized scatterers can be expected to give rise to spatial variations in the electric field and in the current distribution. The transport equation allowing for spatial variations is solved by first considering the homogeneous transport equation which omits electric fields. The homogeneous solution gives the purely diffusive motion of current carriers and involves large space charges. The electric field is then found, and approximate space charge neutrality is restored, by adding a particular solution of the transport equation in which the electric field is associated only with space charge but not with a current. The presence of point scatterers leads to a dipole field about each scatterer. The spatial average of a number of these dipole fields is the same as that obtained by the usual approach which does not explicitly consider the spatial variation. Infinite plane obstacles with a reflection coefficient r are also considered. These produce a resistance proportional to $r/(1-r)$.

1. Introduction

In the solution of the transport equation in modern treatments of the electrical conductivity process, it is customary to assume that the distribution of electrons in momentum space is the same throughout the specimen (or at best has only a macroscopic variation due to temperature gradients, et cetera). Coupled with this is an assumption that the applied field is uniform. The applied field then produces a motion of the electronic distribution in momentum space. Scattering by lattice waves and obstacles tends to restore the original distribution, and equilibrium is established between the scattering and the accelerating field. The current density is then computed by taking a sum over the states of the undisturbed crystal and weighting the current associated with each state by its probability of occupation. This process ignores the off-diagonal elements of the current matrix. These off-diagonal elements do not contribute to the space average of the current density, but they can represent local fluctuations in the current distribution. The current due to each of the diagonal terms has the periodicity of the crystal. The spatial uniformity of current can, therefore, be regarded as a consequence of the assumed field uniformity and of the neglect of the off-diagonal matrix elements.

We wish to point out that the uniformity of the field and current density are assumptions which may frequently be well justified, but whose validity in general is not apparent. If the intensity of scattering is not uniformly distributed over the material, but is concentrated in well localized scattering centers, as is the case in the residual resistivity caused by impurities at low temperatures, then it seems in fact reasonable that the field should be concentrated near the points where the scattering is actually produced, so as to enable the current to pass around these obstacles. We shall, therefore, in this paper solve the transport equations in two simple cases without neglecting the relevant spatial variations. We shall consider the case of highly localized point scatterers and also the case of scattering by specular reflection at planes of infinite extension.

Despite the fact that the ordinary viewpoint neglects spatial variations it will, in most cases, lead to a correct answer. The quantities which have spatial variations may be characterized by suitably defined average values, which then can be used in the usual formalism. Some care must be exercised in this averaging process. If the averaging is carried out in too naive a manner, incorrect results can be obtained, as will be shown in the case of plane obstacles treated in Section 8.

In constructing our solution we do not wish to assume a uniform field and initially do not know the correct field distribution. It will, instead, be assumed that at the boundaries of the specimen the number of electrons which are moving into the interior of the specimen are so controlled as to maintain the proper current flow in and out of the

material. If there were no scattering in the specimen, the current carriers could move unhampered, and the maintenance of the current at the surfaces of the specimen would not produce a field. An obstacle in the path of the current will result in a pile-up of electrons on one side of the obstacles and a deficit on the other side. This dipole moment will grow until the resultant electric field enables the incident current to pass the obstacle at the same rate at which further charges arrive. It is a superposition of many such dipole fields which will then constitute the electric field associated with the current flow, and it is the space average of these dipole fields which enter into a conductivity measurement.

In the usual discussions of the residual resistivity of metals, the conductivity is evaluated with the aid of the electron acceleration law, $d\mathbf{k}/dt = -e\mathbf{E}/\hbar$. Since the electric field is spatially inhomogeneous and highly concentrated about positions where the periodicity of the lattice potential is disturbed, the use of this relation is questionable. The transport equation, as used in the subsequent discussion, will naturally involve a term closely related to the electron acceleration law. It will be seen, however, that the term can be modified at positions close to the scatterers without affecting our evaluation of the conductivity.

2. General form of treatment

All the complications due to the real crystalline nature of the medium will be neglected in this treatment, and we will assume that our medium is isotropic. Its crystalline nature will be acknowledged only through the fact that the density of states in energy, dn/dU, at the spherical Fermi surface, and the wave number k_0 associated with this Fermi surface, will be taken as independent quantities. Except for the use of Fermi statistics our considerations will be classical, and we shall assume that at each point in space there is a well-defined distribution of electrons in $\mathbf{k}$ space. ($\mathbf{k}$ is the wave vector which determines the wave-function variation in going from cell to cell.) In the presence of a current, the number of electrons per unit volume moving within a solid angle $d\Omega$ about the direction $\boldsymbol{\Omega}$ (a unit vector) will differ from the number that moves in that direction in the undisturbed metal by an amount $N(\boldsymbol{\Omega})d\Omega$. We shall restrict ourselves to sufficiently low temperatures so that the distribution changes represented by $N(\boldsymbol{\Omega})$ are contained in a sufficiently narrow energy range to give all the $N(\boldsymbol{\Omega})$ extra (or deficit) electrons the same velocity and scattering cross sections. The transport equation for the steady state can then be written in the form

$$\partial N(\boldsymbol{\Omega}, r)/\partial t = 0 = -\alpha\boldsymbol{\Omega}\cdot\mathbf{E} - \boldsymbol{\nabla}N\cdot\mathbf{v} + (\partial N/\partial t)_S. \tag{2.1}$$

In this equation the first term on the right-hand side represents the acceleration by the field. In terms of the electronic charge e and the Fermi-surface wave number k_0, we have $\alpha = ek_0^2/4\pi^3\hbar$. The second right-hand term represents spatial gradients, and $\mathbf{v} = \hbar^{-1}\boldsymbol{\Omega}\, dU/dk$. The last term represents the effect of the scatterers which cause the resistance.

Eq. (2.1), considered as an equation for N, is a linear inhomogeneous equation. Such equations can be solved by taking a particular solution and then adding to it solutions of the homogeneous equation to satisfy the boundary conditions. We shall use this procedure and shall use a particularly simple solution of Eq. (2.1) for the particular solution. Eq. (2.1) always has a solution in which the electric field produces spatial variations in electronic density but does not cause a current. This is a solution in which $N(\boldsymbol{\Omega}, \mathbf{r})$ is independent of $\boldsymbol{\Omega}$. In that case, we can expect the term $(\partial N/\partial t)_S$ to vanish. Using $\mathbf{E} = -\boldsymbol{\nabla}V$, we then find for Eq. (2.1) the form

$$\alpha\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}V = v\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}N, \tag{2.2}$$

which has the solution

$$N(\mathbf{r}) = \frac{\alpha}{v}V(\mathbf{r}) + c = \frac{1}{4\pi}\frac{dn}{dU}eV(\mathbf{r}) + c, \tag{2.3}$$

where c is independent of $\mathbf{r}$, and dn/dU is the density of states at the Fermi surface.

The boundary conditions which determine the current entering and leaving the specimen must then be satisfied by a solution of the homogeneous transport equation. The homogeneous equation represents the motion of particles subject only to scattering and therefore gives the purely diffusive motion of the carriers.

3. Neutrality condition

Let $N_D(\boldsymbol{\Omega}, \mathbf{r})$ represent the solution to the homogeneous equation. Let $N_V(\boldsymbol{\Omega}, \mathbf{r})$ be the particular solution as given by Eq. (2.3). N_D will be determined by the boundary conditions and the diffusive motion. To determine N_V and V, we have to use Poisson's equation in addition to Eq. (2.1). This states

$$\nabla^2 V = 4\pi e\int(N_D + N_V)d\boldsymbol{\Omega}. \tag{3.1}$$

Now let

$$n_D = \int N_D d\boldsymbol{\Omega} \quad \text{and} \quad n_V = \int N_V d\boldsymbol{\Omega}. \tag{3.2}$$

If in (2.3) we choose the origin of the potential such that $N(\mathbf{r}) = 0$ where $V(\mathbf{r}) = 0$, it becomes

$$n_V(\mathbf{r}) = \frac{dn}{dU}eV(\mathbf{r}). \tag{3.3}$$

Combining (3.3), (3.2), and (3.1), we find

$$n_V - l^2\nabla^2 n_V = n_D, \tag{3.4}$$

with $1/l^2 = 4\pi e^2 dn/dU$. The distance l is the range to which the electronic screening in this medium permits electric fields to penetrate. In a typical good conductor, if we are concerned with variations existing over a distance of several atomic cells, then we can neglect the term $l^2\nabla^2 n_V$ in Eq. (3.4) and find

$$n_V = -n_D, \tag{3.5}$$

$$(dn/dU)eV = -n_D. \tag{3.6}$$

4. Point scatterer

We shall now analyze in detail the case of a point scatterer embedded in a spatially uniform background scattering. This is immediately suggestive of an impurity embedded in

a material which is scattering thermally. As we shall see later, however, other interpretations are possible.

Before entering into the details of our argument we would like to clear up one frequent misconception concerned with the relative importance of the physical dimensions, e.g., the radius a of a point scatterer and its quantum mechanical scattering cross section σ. We will assume that both a and $\sqrt{\sigma}$ are small compared to the mean free path. The localized obstacle will disturb the otherwise uniform current flow. If we are at a distance several times a from the center of the obstacle, then the disturbances set up there by the obstacle will depend only on the number of electrons that have had their direction changed by the obstacle—i. e., on the differential cross section of the obstacle. The physical size of the obstacle and the potential variation within its physical extension are primarily relevant to an evaluation of the disturbances in the volume of the obstacle itself. These will not concern us, except for some auxiliary discussions.

In solving the problem of the point scatterer, we shall use Eq. (2.1) in the form

$$-\alpha\boldsymbol{\Omega}\cdot\mathbf{E}-\boldsymbol{\nabla}N\cdot\mathbf{v}+(\partial N/\partial t)_B=0, \tag{4.1}$$

where $(\partial N/\partial t)_B$ denotes the background scattering. Eq. (4.1) is then satisfied everywhere except at the obstacle which is taken to be at $\mathbf{r}=0$. We shall satisfy the scattering conditions at $\mathbf{r}=0$ by superposing two solutions of Eq. (4.1). One solution represents the motion of the electrons without the obstacle, and the other represents the corrections due to the changed motion of the carriers after their incidence on the obstacle.

We shall restrict the nature of the scattering, both for the obstacle and for $(\partial N/\partial t)_B$. In both cases the probability of scattering will be taken as a function only of the angle through which the electron is deflected, and not as a function of the incident direction. In that case[1], the usual theory of conductivity which neglects spatial variations permits the background scattering to be characterized by a single conductivity relaxation time τ_B, and also permits the medium which has only a distribution of obstacles to be characterized by a single conductivity relaxation time τ_O. Furthermore, in that case the combined effects of both types of scattering can also be described by a single relaxation time in accordance with Matthiessen's rule.[2]

It is to be particularly noted that the assumption of differential scattering cross sections which are functions only of the angle through which the particle is scattered, leads to a simple timewise exponential relaxation for the disturbance produced by an electric field. For these same scattering cross sections, there will be many other possible disturbances from equilibrium which do not show a relaxation characterized by a single time constant.

In the ensuing discussion we shall use the symbol $\mathbf{i}$ to denote a current measured in numbers of electrons crossing a unit area in unit time. The electrical current $\mathbf{j}$ will then be given by $\mathbf{j}=-e\mathbf{i}$. We shall take the particular situation in which $\mathbf{i}$ far away from the obstacle has only a z component denoted by i_∞. If $v=\hbar^{-1}dU/dk$ is the velocity at the Fermi surface far away from the obstacle, we will have

$$N(\boldsymbol{\Omega})=3i_\infty\cos\theta/4\pi v, \tag{4.2}$$

where θ is the angle between $\boldsymbol{\Omega}$ and the z-axis. This current is accompanied by a field which can be determined from Eq. (4.1). Omitting the second term in Eq. (4.1) gives

$$E_z=-3i_\infty/4\pi v\alpha\tau_B, \tag{4.3}$$

which corresponds to a conductivity

$$\sigma_B=-\frac{ei_\infty}{E_z}=\frac{e^2k_0^2}{3\pi^2\hbar^2}\frac{dU}{dk}\tau_B. \tag{4.4}$$

If $N(\boldsymbol{\Omega})$ and $E(\mathbf{r})$, as given by Eqs. (4.2) and (4.3), are presumed to hold for all $\mathbf{r}$, then Eq. (4.1) is satisfied everywhere. The effect of the localized obstacle will in that case be ignored. Let us assume that the obstacle has a differential scattering cross section, $f^2(\theta)d\Omega$, for scattering through the angle θ into a range $d\Omega$ of solid angle. If Eq. (4.2) is correct in describing the number of electrons incident on the obstacle, then the rate at which electrons are scattered by the obstacle into an angular range $d\Omega$ about the direction $\boldsymbol{\Omega}_f$ is, through the use of (4.2),

$$d\Omega\int f^2(\boldsymbol{\Omega}_f,\boldsymbol{\Omega}_i)N(\boldsymbol{\Omega}_i)v\,d\boldsymbol{\Omega}_i=d\Omega\frac{3i_\infty}{4\pi}\int f^2(\boldsymbol{\Omega}_f,\boldsymbol{\Omega}_i)\cos\theta_i\,d\boldsymbol{\Omega}_i. \tag{4.5}$$

In Eq. (4.5), $f^2(\boldsymbol{\Omega}_f\boldsymbol{\Omega}_i,)$ denotes $f^2(\theta)$ where θ is the angle between the incident direction $\boldsymbol{\Omega}_i$ and the scattered direction $\boldsymbol{\Omega}_f$. θ_i denotes the angle between the direction of incidence and the z-axis. θ_f will similarly locate the scattered direction relative to the z-axis. With a little spherical trigonometry, the right-hand side of Eq. (4.5) can be put into the form

$$d\Omega\frac{3i_\infty}{4\pi}\cos\theta_f\int f^2(\theta)\cos\theta\,d\boldsymbol{\Omega}, \tag{4.6}$$

where the integral is now independent of $\boldsymbol{\Omega}_f$. Expression (4.6) gives the rate at which electrons are scattered into $\boldsymbol{\Omega}_f$, but it has not had subtracted from it the rate at which electrons which were originally moving within a range $d\Omega$ of the direction $\boldsymbol{\Omega}_f$ are scattered out of this range. The latter rate will be

$$d\Omega N(\boldsymbol{\Omega}_f)v\int f^2(\theta)d\boldsymbol{\Omega}=d\Omega\frac{3i_\infty}{4\pi}\cos\theta_f\int f^2(\theta)d\boldsymbol{\Omega}. \tag{4.7}$$

Subtracting the right hand side of Eq. (4.7) from (4.6), we find that the number of electrons per second leaving the obstacle in the range $d\Omega$ exceeds the number specified in Eq. (4.2) by

$$-d\Omega\frac{3i_\infty}{4\pi}(\cos\theta_f)\int f^2(\theta)(1-\cos\theta)d\boldsymbol{\Omega}. \tag{4.8}$$

The integral in (4.8), in which deflections are weighted by the factor $(1-\cos\theta)$, is the scattering cross section found relevant in the usual theory of conductivity and we will label it S_O. Then (4.8) can be written

$$-d\Omega\frac{3i_\infty}{4\pi}(\cos\theta_f)S_O. \tag{4.9}$$

We shall now construct a solution of Eq. (4.1) which has

as its source electrons issuing from the obstacle as specified by (4.9). Furthermore, we shall require that the solution $N_S(\Omega,\mathbf{r})$ generated by this source vanish at infinity. The superposition, then, of N_S on the spatially uniform solution given by Eq. (4.2) and (4.3) satisfies both Eq. (4.1) and the scattering conditions imposed by the obstacle. This is actually not quite correct. The solution N_S contains electrons which can, after some scattering by the background, return again to the obstacle at $\mathbf{r}=0$. Since N_S is a strict solution of Eq. (4.1), it does not take into account scattering by the obstacle when the electron returns to the obstacle a second (or later) time. If, however, the mean free path determined by the background is large compared to the effective dimensions of the scatterer (i. e., the square root of its scattering cross section), the probability of multiple scatterings by the obstacle will be small, and we will therefore restrict our further considerations to this case.

We shall deal with the scattered solution $N_S(\Omega,\mathbf{r})$ by first treating the purely diffusive motion, thus finding $N_{SD}(\Omega,\mathbf{r})$, and then using Eq. (3.6) to find the accompanying field.

5. Diffusive motion about point scatterer

The diffusive motion about a point scatterer is schematized in Fig. 1. Line A shows a direction in which the number of incident carriers exceeds the equilibrium number. Similarly, line B shows a direction in which fewer than the equilibrium number are moving. A and B represent the spatially uniform solution (4.2) which gives the number of electrons incident on the obstacle. Line C shows a direction along which there is an excess of scattered electrons. Along line D there is a deficit. After a number of scatterings by the background the electrons which initially move away from the obstacle along C and D will have their velocity completely randomized. Their motion will then obey the diffusion equation. This diffusion current is schematically indicated by the broad arcs, which finally show the recombination of the electron excess and deficit.

Consider first the diffusion current generated by all the electrons which start their motion away from the scattering center in directions that lie within $d\Omega_f$ of the direction Ω_f. Far away from $\mathbf{r}=0$ at a position in space denoted by (r, ω), where r is the distance from the scattering center and ω is a unit vector pointing from the scatterer to the point involved, the diffusion current will establish a concentration $C(\Omega_f,\omega,r)d\Omega_f$ of electrons, all of which were originally travelling away from $\mathbf{r}=0$ in the direction Ω_f. This concentration obeys the steady state diffusion equation $\nabla^2 C=0$. Up to terms of order $1/r^2$ this has the solution

$$C(\Omega_f,\omega, r)=a/r+\mathbf{p}\cdot\omega/r^2, \tag{5.1}$$

with a and $\mathbf{p}$ arbitrary. The radial current density (in electrons/cm^{2}sec) far from the origin due to the a/r term is $d\Omega_f D_B a/r^2$ where D_B is the diffusion coefficient of electrons in the presence of the background scattering. The integrated flow out of a large sphere is then $4\pi D_B a d\Omega_f$ electrons /sec. The other term $\mathbf{p}\cdot\omega/r^2$ does not contribute to the integrated flow. Equating $4\pi D_B a d\Omega_f$ to (4.9) gives

$$a(\Omega_f)=-\frac{3i_\infty(\cos\theta_f)S_O}{(4\pi)^2 D_B}. \tag{5.2}$$

To terms of order $1/r^2$, the right-hand side of Eq. (5.1) has the form $a/|\mathbf{r}-\mathbf{r}_f|$ with $\mathbf{r}_f=\mathbf{p}/a$. The term $\mathbf{p}\cdot\omega/r^2$ simply serves to displace the effective source away from the origin in the direction of $\mathbf{p}$. The average position of the particles described by Eq. (5.1) is therefore $\mathbf{r}_f=\mathbf{p}/a$. The average position of the particles can also be found by following a beam of particles issuing from $\mathbf{r}=0$ at $t=0$, and initially proceeding along Ω_f. The average position then is:

$$\mathbf{r}_f=\left\langle\int_0^\infty \mathbf{v}dt\right\rangle_{Av}=\int_0^\infty\langle\mathbf{v}\rangle_{Av}dt. \tag{5.3}$$

$\langle\mathbf{v}\rangle_{Av}$ as used in Eq. (5.3) is an average over electrons which initially left $\mathbf{r}=0$ in the direction Ω_f. $\langle\mathbf{v}\rangle_{Av}$ is therefore a function of Ω_f, but for the sake of typographical compactness this will not be explicitly indicated. $\langle\mathbf{v}\rangle_{Av}$ decays with time because of background scattering. The decay is generally not a simple exponential, since the initial velocity distribution, a collimated beam, is not the distribution involved in the usual definition of a relaxation time for the conductivity process. Since $\mathbf{p}=\mathbf{r}_f a$, combining (5.2) and (5.3) gives

$$\mathbf{p}=-\frac{3i_\infty(\cos\theta_f)S_O}{(4\pi)^2 D_B}\int_0^\infty\langle\mathbf{v}\rangle_{Av}dt. \tag{5.4}$$

To find the total concentration of diffused carriers we have to integrate (5.1) over all values of Ω_f. The integration over the a/r terms gives a vanishing result since the total number of carriers emitted at $\mathbf{r}=0$, according to (4.9), is zero. This leaves

$$n_f(\omega, r)=\int d\Omega_f C(\Omega_f,\omega, r)=\int d\Omega_f\mathbf{p}\cdot\omega/r^2$$
$$=-\frac{3i_\infty S_O}{(4\pi)^2 D_B}\frac{1}{r^2}\omega\cdot\int d\Omega_f(\cos\theta_f)\int_0^\infty\langle\mathbf{v}\rangle_{Av}dt. \tag{5.5}$$

After exchange of integrations this becomes

$$n_D(\omega, r)=-\frac{3i_\infty S_O}{(4\pi)^2 D_B}\frac{1}{r^2}\omega\cdot\int_0^\infty dt\int d\Omega_f(\cos\theta_f)\langle\mathbf{v}\rangle_{Av}. \tag{5.6}$$

The values of $\langle\mathbf{v}\rangle_{Av}$ which result from the electrons initially proceeding along Ω_f are now weighted with the factor $\cos\theta_f$. Therefore, Eq. (5.6) represents a timewise integration over a velocity distribution which is initially similar to the distribution produced by an electric field. Hence we can expect $\int d\Omega_f(\cos\theta_f)\langle\mathbf{v}\rangle_{Av}$ to decay as exp $(-t/\tau_B)$, where τ_B is the conductivity relaxation time for the background scattering. At t = 0 we have an initial value

$$d\Omega_f\langle\mathbf{v}\rangle_{Av}\cos\theta_f=\int d\Omega_f\frac{1}{\hbar}\frac{dU}{dk}\Omega_f\cos\theta_f=\frac{4\pi}{3\hbar}\frac{dU}{dk}\mathbf{z}_1, \tag{5.7}$$

with $\mathbf{z}_1$ representing the unit vector in the z-direction. Combining (5.5) with (5.7) gives

$$n_D(\omega,r)=-\frac{i_\infty S_O}{4\pi D_B}\frac{1}{\hbar}\frac{dU}{dk}\frac{1}{r^2}\omega\cdot\mathbf{z}_1\int_0^\infty dte^{-t/\tau_B}$$
$$=-\frac{i_\infty\tau_B}{4\pi D_B}S_O\frac{1}{\hbar}\frac{dU}{dk}\frac{\cos\theta_\omega}{r^2}. \tag{5.8}$$

θ_ω is the angle between ω and the positive z-axis.

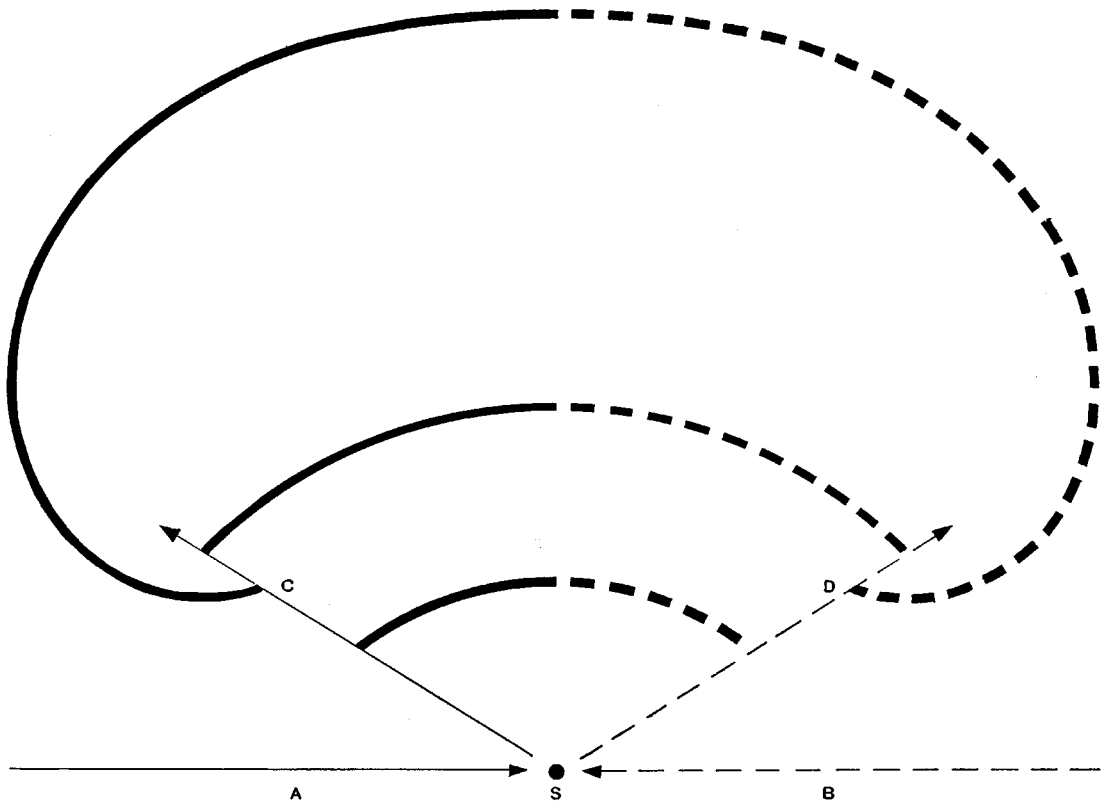

Figure 1 **Schematic representation of current flow disturbed by the scatterer** S.
Electrons in excess numbers are incident along A, then are scattered to C, then scattered by the background. The number of electrons incident along B is less than the equilibrium number. The deficit is scattered to D, then scattered by the background. The excess and deficit diffuse together and recombine along the arcs.

The diffusion coefficient D_B, as determined by the background scattering, and the conductivity σ_B, determined by the same scattering, are not independent. By considering the balance between diffusion currents and conductivity currents, in an equilibrium situation, we arrive at the "Einstein" relation for completely degenerate Fermi statistics in the same way as for semiconductors.[3] The resulting relation is

$$De^2 dn/dU = \sigma. \tag{5.9}$$

For our isotropic band structure and isotropic background scattering the conductivity in (5.9) is given by

$$\sigma_B = \frac{\tau_B}{3\pi^2}\frac{e^2}{\hbar^2}k^2\frac{dU}{dk}. \tag{5.10}$$

Hence we find

$$D_B = \frac{\tau_B}{3\pi^2}\frac{k^2}{\hbar^2}\frac{dU}{dk}\left(\frac{dn}{dU}\right)^{-1}. \tag{5.11}$$

This value for D_B can be introduced into Eq. (5.8) to give

$$n_D(\omega, r) = -\frac{3\pi i_\infty S_0 \hbar}{4k^2}\frac{dn}{dU}\frac{\cos\theta_\omega}{r^2}. \tag{5.12}$$

Eq. (3.6) permits us to go from the above to the potential distribution

$$V = -\frac{n_D}{e}\left(\frac{dn}{dU}\right)^{-1} = \frac{3\pi i_\infty S_0 \hbar}{4k^2 e}\frac{\cos\theta_\omega}{r^2}. \tag{5.13}$$

Eq. (5.1) which we used in the derivation of (5.12) and (5.13) is only an asymptotic expansion, and therefore we cannot on the basis of the above derivation expect (5.13) to be valid close to the scatterer. Consider the electrons close to the scatterer as specified by (4.9) and before they have been appreciably scattered by the background. The density $n_D(\omega, r)$ due to these electrons is easily evaluated and leads again to the expression (5.12). Since (5.12) is correct when we are much closer to the scatterer than a

mean free path, and also when we are many mean free path lengths away from the scatterer, and since furthermore it is easily shown from (4.9) that $n_D(\omega, r)$ must vary as $\cos\theta_\omega$, for all values of r, we can expect that $n_D(\omega, r)$ is closely approximated by (5.12) for all r values. In computing an average field or conductivity, however, it is only the asymptotic behavior of (5.13) that matters, and this has been accurately justified.

Eq. (5.13) gives a potential associated with a dipole of moment

$$p=3\pi i_\infty S_O\hbar/4k^2e. \tag{5.14}$$

If we have a density of $\mathfrak{N}$ obstacles per unit volume which are sufficiently far apart to be non-interacting, there will be a polarization $\mathfrak{N}\mathbf{p}$, and the space average of the dipole fields will be

$$E_z=-4\pi P_z=-3\pi^2 i_\infty S_O\hbar\mathfrak{N}/k^2e. \tag{5.15}$$

The mean free time τ_O as used in the usual conductivity theory, and associated only with scattering by the obstacle is given by

$$\tau_O=1/\mathfrak{N}S_O v. \tag{5.16}$$

This makes the space average field, as given in (5.15), equal to

$$E_z=-3\pi^2 i_\infty\hbar/k^2ev\tau_O. \tag{5.17}$$

In terms of the electric current $j_\infty=-ei_\infty$, we find

$$E_z=\frac{3\pi^2\hbar^2}{k^2e^2\tau_O}\left(\frac{dU}{dk}\right)^{-1}j_\infty, \tag{5.18}$$

which is exactly the field associated with the obstacles, as found by the usual approach [e. g., compare with Eq. (5.10) which gives the connection between σ and τ resulting from the usual considerations]. The field given by (5.18) exists in addition to the background field of Eq. (4.3). Matthiessen's rule is satisfied; (5.18) does not depend on τ_B.

We would like to stress the extreme extent to which these dipole fields are really localized. To do this we must consider how the charges that are responsible for the dipole moment given by (5.14) are actually distributed. Let us assume for the moment that the charge density, in the (spherical) volume of the scatterer is of the form $\rho(r)\cos\theta_\omega$ and vanishes outside the scatterer. In computing an average field for the whole specimen we must evaluate $\int\mathbf{E}d\tau$, where the $\mathbf{E}$ includes the contributions of the particular dipole moment under discussion. Under the conditions specified above, 2/3 of this dipole contribution to $\int\mathbf{E}d\tau$ comes from the volume of the scatterer. Actually, of course, the dipole charges cannot be as well localized as we have assumed. [The screening length l of Eq. (3.4) is finite, the uncertainty principle also prevents an excessively localized charge. Furthermore, Eq. (5.12) is derived from a point model and cannot be expected to hold true up to the actual surface of the scatterer.] Therefore, only perhaps 1/3, instead of 2/3, of the voltage drop associated with the residual resistance is contained in the volume occupied by the impurity atoms.

Since such a large portion of the field is located where the crystalline potential has been disturbed, the use of the usual electron acceleration equation, $d\mathbf{k}/dt=-e\mathbf{E}/\hbar$, becomes questionable. Note that in our arguments the field is found as a result of screening considerations. The exact nature of the screening close to the impurity atom, is not relevant to the evaluation of an average field. That is, the nature of the first term in Eq. (2.1) can be modified, close to the impurity atoms, without appreciably affecting our asymptotic evaluation of the dipole potential. It is only necessary that (dn/dU), in Eq. (3.6) represent the actual density of states, in the dilute alloy, rather than the density in the pure solvent.

6. Interaction of obstacles

The preceding section has been concerned with a localized obstacle of cross section S_O embedded in a medium with a relaxation time τ_B. This is obviously applicable to the case of a single obstacle in a medium which otherwise has only thermal scattering. If we consider a medium which has a density of obstacles such that the obstacle scattering is comparable to the uniform scattering or larger, then we must invoke some supplemental considerations. First of all, the radial current scattered by a particular obstacle, as given by Eq. (4.9), will now be subject to scattering by other obstacles as well as by the uniform background. Let us confine our considerations to the most common case, that in which the mean free path (as determined by the combined scattering) is large compared to the distance between obstacles. Only a small portion of the radial current will then be scattered by any one obstacle and the radial current will therefore see a relaxation time τ_B which depends on both kinds of scattering. Therefore, as the density of obstacles is increased, the effective value of τ_B changes. The value of τ_B, however, does not affect the dipole field brought in with each additional obstacle. As the number of obstacles is increased, therefore, the space average of the electric field changes just as it does in the usual theory.

We have assumed in the preceding section that the electron velocity distribution incident upon the obstacle is equal to the average velocity distribution which exists far away from the obstacle. A localized scatterer disturbs the velocity distribution. Close to the obstacle there are the scattered radial currents as given by Eq. (4.9). Further away there are the diffusion currents. Both of these kinds of currents constitute deviations from the average velocity distribution. A second obstacle placed near the first will be exposed to the deviations caused by the first obstacle. An obstacle, however, will generally see the deviations caused by many obstacles, not just those caused by one. If we add the disturbances due to the many obstacles randomly placed within the vicinity of a given one, then we are doing the same thing as adding the disturbances due to a particular obstacle over many points in its environment, as long as the obstacles are uncorrelated in their positions. The mere fact that the obstacles are finite in extension will give them some correlation. Let us temporarily neglect this. It is easily shown that if we consider the deviations caused by a *single* obstacle, in a *particular* velocity class,

these deviations vanish after integration over all space. Hence, an obstacle which is exposed to the deviations caused by many other obstacles is exposed to the average velocity distribution.

The argument which has just been given relies on an integration which in turn strictly requires a point scatterer, as we have assumed. Let us take a more realistic view and give the scatterer an extension in space. Then the scatterers exclude (or diminish) the current within a small volume, and the average value of the current density at locations which are outside of the excluded regions is larger than the average taken over *all* space. It is this larger current density which an additional scatterer, placed among the previously existing ones, will see. In principle, therefore, one should apply corrections to find the correct "internal" velocity distribution in a manner similar to the use of Lorentz corrections in dielectric theory. If the volume occupied by the scatterers is small, as in a dilute solution, this is presumably a small effect. If the scatterers occupy an appreciable fraction of the volume, these corrections will very likely be overshadowed by the direct effect of the scatterers on the electronic structure of the medium. In the extreme case where the *complete* volume of the metal is occupied by the scatterers, as in the case of high temperature scattering by independently vibrating atoms, then again the incident velocity distribution must be the average velocity distribution.

7. Degree of localization required

The argument we have used in arriving at our dipole field relies upon the localization of the scatterer. Since the quantities entering into the transport equation vary on a scale comparable to the mean free path (associated with the background), it is only necessary that the scatterer be small compared to the mean free path. This condition will generally be satisfied for impurity scattering.

Actually, the localization of the background scattering is as relevant as that of the obstacle scattering. The use of Eq. (4.1) implies that the scattering depends only on the disturbance $N_D(\mathbf{\Omega}, r)$ at the point $\mathbf{r}$ under consideration. Therefore, the obstacle and the background must be "localized" to the same extent. Scattering of electrons by phonons is generally sufficiently localized, since a wave packet of the representative thermally excited phonons is usually short compared to the electronic mean free path. The only apparent exception is the case of electron scattering by phonons at extremely low temperatures in an alloy where the scattering is almost completely determined by the lattice defects. At a sufficiently low temperature, the typical phonon wavelength will then exceed the mean free path. In this case, however, the phonon scattering will be an extremely small portion of the total scattering. Furthermore, this is a case in which any other theory would presumably have difficulties in correctly evaluating the contribution of the phonon scattering.

It might be thought that the spatial variations discussed here must disappear at very low temperatures since the small energy range of the order kT over which the probability of occupation varies from 1 to 0, does not permit the construction of very localized wave packets. This is, however, not relevant. One can, in principle, form stationary states which represent the multiple scattering of electrons by many obstacles, and thus find the probability of directional changes at various points in space. Such a solution specifies the scattered intensity as a function of direction of scattering within a few wavelengths of the scattering center. The relevant dynamic parameters for our theory are thus obtainable from solutions of the time-independent wave equation for a particular energy. (At least this is true for the cases where the time-wise variation of the lattice vibrations is not significant.)

The condition that one can construct highly localized wave packets, small compared to the mean free path, is the condition $\hbar/\tau < kT$, given by Peierls[4] long ago for the validity of the Bloch theory. This criterion was introduced as a consequence of the use of time-dependent perturbation theory and is a criterion only of the validity of time-dependent perturbation theory. If the probability of scattering is known correctly from some other treatment, this criterion has no relevance.

8. Reflecting walls

When there is a current impinging on a reflecting wall one can expect a voltage drop confined to the immediate vicinity of the reflecting plane. This is, in fact, taken for granted in the treatment of the contact resistance at the junction of two metallic conductors.[5] We have in mind a situation in which the current flow is perpendicular to the wall, and assume that the reflection is specular. A density of $\mathfrak{N}$ such planes per cm will be assumed without any additional source of electron scattering. These walls can be considered to be models of grain boundaries or of stacking faults. The reflection coefficient r will be assumed to be a function of the angle, θ, between the wall normal and the direction of incidence. We shall take the wall normal to be in the positive z-direction and θ to be the angle with this direction so that $r(\theta) = r(\pi - \theta)$, and shall first compute the conductivity according to the usual non-local viewpoint.

An electron travelling in a direction at an angle θ with the z-axis will pass $\mathfrak{N}|\cos\theta|$ walls per cm of its travel, and will therefore be incident upon $\mathfrak{N}|\cos\theta|v$ walls per second, where v is the velocity at the Fermi surface. At each of these collisions only a fraction $r(\theta)$ of the electrons are reflected. If there are n_+ electrons per unit volume moving in a certain direction, and n_- electrons in the reflected direction, we can expect that

$$dn_+/dt = -n_+\mathfrak{N}|\cos\theta|r(\theta)|v + n_-\mathfrak{N}|\cos\theta|r(\theta)|v, \tag{8.1}$$

$$dn_-/dt = -n_-\mathfrak{N}|\cos\theta|r(\theta)|v + n_+\mathfrak{N}|\cos\theta|r(\theta)|v. \tag{8.2}$$

If n_0 is the number of electrons travelling in the two directions concerned, in the absence of a current, then symmetry requires

$$n_+ - n_0 = n_0 - n_-. \tag{8.3}$$

If (8.3) is substituted in (8.2) and (8.1), we find

$$\frac{d}{dt}(n_+ - n_0) = -(n_+ - n_0)2\mathfrak{N}|\cos\theta|r(\theta)|v, \tag{8.4}$$

$$\frac{d}{dt}(n_- - n_0) = -(n_- - n_0)2\mathfrak{N}|\cos\theta|r(\theta)|v, \tag{8.5}$$

and therefore a relaxation time $\tau(\theta) = v/2\mathfrak{N}|\cos\theta|r(\theta)$. The usual conductivity theory then gives us a conductivity

$$\sigma = \frac{e^2k^2}{8\pi^3\mathfrak{N}\hbar}\int d\Omega|\cos\theta|r(\theta), \tag{8.6}$$

where the integration is over all directions of motion. Note that this value for the conductivity cannot be exact. As $r(\theta)$ is permitted to approach unity for all θ, all current flow must cease, yet Eq. (8.6) still yields a finite conductivity. This finite conductivity results from a finite relaxation time. The latter, in turn, is a result of the assumption of a uniform field. If the accelerating electric field is taken to be uniform, and the current flow is generated equally at all points in space, then it will take a finite time for portions of this current to reach the nearest reflecting barrier, and this is the relaxation time which can be obtained from (8.4) and (8.5), even if $r = 1$.

Instead of the treatment leading to Eq. (8.6), we can handle the problem by the methods we have already described. This requires that we have an expression for the distribution of electrons incident upon the wall. For any incident velocity distribution we can calculate a scattered current and a compensating charge. In general, however, these will be such that a second plane, parallel to the first, would be exposed to a different incident velocity distribution. We must therefore choose an incident velocity distribution such that the final resultant velocity distribution is the same on both sides of the plane at distances which are more than a screening length away from the plane. This leads, with a little calculation, to a velocity distribution (including incident electrons, reflected electrons, and compensating charge), of the form

$$N(\boldsymbol{\Omega},\mathbf{r}) = \beta\left(\frac{1-r(\theta)}{r(\theta)}\right)\frac{\cos\theta}{|\cos\theta|}, \tag{8.7}$$

where β is independent of θ. The conductivity resulting from the detailed localized treatment is

$$\sigma = \frac{e^2k^2}{8\pi^3\mathfrak{N}\hbar}\int d\Omega|\cos\theta|\frac{1-r(\theta)}{r(\theta)}. \tag{8.8}$$

This differs from (8.6) through the appearance in the integrand of the factor $(1-r(\theta))$. This factor serves to make the conductivity vanish as $r(\theta)$ approaches unity for all θ. The difference between (8.6) and (8.8) is therefore only important if the reflection probability is comparable to unity. In this connection it is interesting to note that some of the calculations for the reflection coefficient of stacking faults predict values for r which are not very small compared to unity.[6]

Note that the velocity distribution (8.7) does not vary with θ as $\cos\theta$. Therefore, there is no single relaxation time for the whole conduction process. If reflecting walls exist simultaneously with thermal scattering, Matthiessen's rule will not be satisfied. Even without thermal scattering, if we have a number of such walls with differing orientations, the scattering probabilities cannot just be added, since each orientation by itself would result in a different shape for the velocity distribution.

9. Multiple reflections by a single obstacle

In the treatment of point obstacles in Sections 4 and 5 we ignored the possibility of repeated reflections by the same localized obstacle, and found that the field associated with the point obstacles was linear in the scattering cross section S_0. In the treatment of plane reflectors in Section 8, our method did not ignore the multiple reflections and the resultant field was not linear in r, but varied as $r/(1-r)$. We shall here give a very rough argument to show that a more careful treatment of the point scatterer, taking into account the possibility of repeated reflection by the same obstacle, also leads to a resistivity which is non-linear in the scattering cross section S_0.

Consider the scattered current as given by Eq. (4.9). The z-component of the scattered current (measured in carriers per sec) is obtained by multiplying (4.9) by $\cos\theta_f$ and integrating over $d\Omega$. The resulting current has only a z-component given by $I_z = -S_0 i_\infty$. This scattered current consists of electrons moving away from the obstacle in a radial direction for a distance of about λ, where λ is the mean free path determined by the background scattering. After moving through this distance λ, the electrons have their velocity randomized and follow a diffusive motion. After this randomization a fraction of them will be scattered again by the original obstacle. This fraction is roughly $S_0/4\pi\lambda^2$.

The total current incident on the obstacle at any one time is due to electrons which are incident for the first time and also due to electrons which have previously been scattered by the obstacle one or more times. The scattered current, integrated over all directions, is therefore of the form

$$\begin{aligned} i_z &= S_0 i_\infty(1 + S_0/4\pi\lambda^2 + (S_0/4\pi\lambda^2)^2 + \ldots) \\ &= S_0 i_\infty/(1 - S_0/4\pi\lambda^2). \end{aligned} \tag{9.1}$$

The diffusion charges, N_D, and the resulting potential will then vary with S_0 as $S_0/(1-S_0/4\pi\lambda^2)$. This is comparable to the factor $r/(1-r)$ in the case of plane reflectors. It seems plausible, then, that in situations in which the mean free path is large enough so that multiple scatterings are negligible, we can expect the resistivity to vary linearly with scattering cross sections and can expect the usual formalism to be applicable. Thus, for example, in the case of highly localized, well separated cylindrical obstacles, we would expect that most of the carriers which are incident upon a given obstacle will be scattered only once by it, and that therefore the usual relations between resistance and scattering cross section are valid.

10. Conclusions

A detailed solution of the transport equation has shown that spatially localized scatterers produce spatially localized electric fields in the presence of current flow. In the case of point scatterers, these localized fields are dipole fields, one for each scatterer. The resistivity calculated on this basis

is the same as that given by the more usual calculations. The resistivity calculation has, however, been put on a more secure footing since the discussion that has been presented does not rely as intimately as the usual theory upon the acceleration law, $d\mathbf{k}/dt = -e\mathbf{E}/\hbar$, which has been proven only for uniform fields in strictly periodic crystals. In the case of a reflecting plane, the resistivity calculated from the localized fields is higher than that calculated from the usual equations, but the difference is significant only if the reflection coefficient is comparable to unity.

(Received 5 February 1996; accepted for publication 2 April 1996)

One may introduce at least three different Lie algebras in any Lagrangian field theory: (i) the Lie algebra of local BRST cohomology classes equipped with the odd Batalin–Vilkovisky antibracket, which has attracted considerable interest recently; (ii) the Lie algebra of local conserved currents equipped with the Dickey bracket; and (iii) the Lie algebra of conserved, integrated charges equipped with the Poisson bracket. We show in this paper that the subalgebra of (i) in ghost number -1 and the other two algebras are isomorphic for a field theory without gauge invariance. We also prove that, in the presence of a gauge freedom, (ii) is still isomorphic to the subalgebra of (i) in ghost number -1, while (iii) is isomorphic to the quotient of (ii) by the ideal of currents without charge. In ghost number different from -1, a more detailed analysis of the local BRST cohomology classes in the Hamiltonian formalism allows one to prove an isomorphism theorem between the antibracket and the extended Poisson bracket of Batalin, Fradkin, and Vilkovisky.

I. INTRODUCTION

The first appearance of an antibracket in the context of Lagrangian field theories can be traced back to the study of the renormalization of Yang–Mills theories when the Ward identities are expressed in terms of the generating functional for one-particle irreducible proper vertices.[1] This antibracket has been developed and generalized in the work of Batalin and Vilkovisky[2] on Lagrangian quantization methods for generic gauge theories. The Batalin–Vilkovisky formalism and the antibracket play, for instance, a fundamental role in the covariant formulation of string field theory.[3] It is therefore of interest to gain a better understanding of the physical significance of this antibracket.

We relate in this paper the Batalin–Vilkovisky antibracket at ghost number -1, both to the bracket introduced by Dickey[4] in the space of local currents, and to the Poisson bracket of conserved charges. More generally, we relate the Batalin–Vilkovisky antibracket for arbitrary values of the ghost number to the extended Poisson bracket appearing in the Hamiltonian formulation of the BRST theory.[5,6]

The paper is organized as follows. In the next section, we review the Batalin–Vilkovisky construction and show that the Batalin–Vilkovisky antibracket naturally induces a well-defined odd Lie bracket $\{\cdot,\cdot\}$ in the cohomolgy classes $H^{*,n}(s|d)$ of the BRST differential s modulo the exterior space–time differential d in form degree n. The algebra $(H^{*,n}(s|d), \{\cdot,\cdot\})$ possesses a subalgebra $\mathscr{S}$, namely $(H^{-1,n}(s|d), \{\cdot,\cdot\})$.

We then define the Dickey algebra of conserved currents j^μ (Sec. III) and show that it

[a)]Aspirant au Fonds National de la Recherche Scientifique (Belgium).
[b)]Also at the Centro de Estudios Científicos de Santiago, Chile.

possesses an ideal, namely the ideal I of nontrivial conserved currents for which the charge $Q=\int d^{n-1}x\ j^0$ is zero on shell. Such currents are trivial (i.e., on shell equal to identically conserved currents) when there is no gauge freedom, so that I is effectively zero in that case. They may, however, be nontrivial otherwise. We introduce furthermore the Lie algebra of integrated conserved charges equipped with the covariant Poisson bracket induced by the Dickey bracket.

Isomorphism theorems between $\mathscr{S}$ and the other two Lie algebras in the case of nondegenerate field theories are proved in Sec. IV. The modification of these theorems for gauge theories are discussed in Sec. V. More precisely, we show that $\mathscr{S}$ is still isomorphic to the Dickey algebra, but this algebra itself is now isomorphic to the Lie algebra of conserved charges only after taking the quotient by the ideal I.

In Sec. VI, we investigate the antibracket map for an arbitrary ghost number. In order to do so, we go to the extended Hamiltonian formalism and use the fact that the local BRST cohomology group and the associated antibracket map are invariant under this change of description of the theory. The advantage of the Hamiltonian formulation is that the equations of motion are in normal form, which allows one to control the antifield dependence of the local BRST cohomology classes. We show that it is always possible to choose representatives that are, at most, linear in the antifields of the Hamiltonian description. This allows one to get the general relationship between the antibracket map and the extended Poisson bracket map of the Hamiltonian BRST formalism.

By applying these results to the case of ghost number -1, we find in particular that I is an Abelian subalgebra and corresponds to a subspace of the characteristic cohomology associated with the Hamiltonian constraint surface.

II. THE ANTIBRACKET MAP INDUCED IN LOCAL BRST COHOMOLOGY

In the Batalin–Vilkovisky formalism for gauge theories, which we consider for notational simplicity to be irreducible, one introduces, besides the original fields ϕ^i of ghost number 0 and the ghosts C^α of ghost number 1 related to the gauge invariance, the corresponding antifields ϕ^*_i and C^*_α of opposite Grassmann parity, and ghost number -1 and -2, respectively.[2,6] It is natural to define an antibracket by declaring that the fields $\phi^A\equiv(\phi^i,C^\alpha)$ and antifields ϕ^*_A are conjugate:

$$(\phi^A(x),\phi^*_B(y))=\delta^A_B\delta^n(x-y). \tag{1}$$

The antibracket is then given for arbitrary functionals A_1 and A_2 by

$$(A_1,A_2)=\int d^nx\left(\frac{\delta^R A_1}{\delta\phi^A(x)}\frac{\delta^L A_2}{\delta\phi^*_A(x)}-\frac{\delta^R A_1}{\delta\phi^*_A(x)}\frac{\delta^L A_2}{\delta\phi^A(x)}\right). \tag{2}$$

The central goal of the formalism is the construction of a proper solution to the master equation,

$$(S,S)=0. \tag{3}$$

The functional S is required to start like the classical action S_0, to which one couples through the antifields the gauge transformations with the gauge parameters replaced by the ghosts:

$$S=\int d^nx\ \hat{\mathscr{L}}=\int d^nx\ \hat{\mathscr{L}}_0+\phi^*_i R^i_\alpha C^\alpha+\cdots. \tag{4}$$

The BRST symmetry is canonically generated in the antibracket through the equation

$$s=(S,\cdot). \tag{5}$$

In order to analyze the properties of the antibracket, it is necessary to have a more precise definition of the functionals to which it applies. We will consider in the following only local functionals. A local functional,

$$A[z^a(x)]=\int_X d^n x\ \hat{a}[z^a], \quad z^a(x)\to 0, \quad \text{for } x\to \partial X, \tag{6}$$

is defined as the integral over an orientable domain X of space–time M^n of a local function $\hat{a}[z^a]$, i.e., a function ^{a} of x^μ, the fields and antifields $z^a \equiv (\phi^A, \phi^*_A)$, and their derivatives up to some finite order, evaluated for field and antifield histories $z^a(x)$, which appropriately vanish at the boundary ∂X. Note that X can be all of Minkowski space M^n, and that a local function corresponds to a function on the finite-dimensional ''jet space'' $M^n \times V^k$ with coordinates $x^\mu, \partial_{(\nu)} z^a, |\nu| \leqslant k$ (see Appendix A for more details). The space of local functionals so defined can be proved (see for instance Refs. 7, 6) to be isomorphic to the space of equivalence classes of local functions $\hat{a}$ modulo total divergences $\partial_\mu j^\mu$, for some arbitrary local current j^μ. The total derivative ∂_μ is defined in multi-index notation by

$$\partial_\mu = \frac{\partial^L}{\partial x^\mu} + \partial_{\mu(\nu)} z^a \frac{\partial^L}{\partial(\partial_{(\nu)} z^a)}. \tag{7}$$

Furthermore one can prove that a local function is a total divergence if and only if its Euler–Lagrange derivatives vanish (see, e.g., Ref. 7).

Turning to form notations, $\hat{a}\to a = d^n x\ \hat{a}$ and introducing the space–time exterior derivative $d = dx^\mu\ \partial_\mu$, the space of local functionals can be identified with the cohomology group $H^n(d)$ of the differential d in form degree n in the space of local, form-valued functions.

It is easy to verify that the antibracket of two local functionals is also a local functional. Thus the antibracket induces a well-defined map in the cohomology group $H^n(d)$,

$$\{\cdot,\cdot\}: H^n(d)\times H^n(d)\to H^n(d). \tag{8}$$

This bilinear map inherits from the antibracket the property of being a true, odd, Lie bracket. If we denote by $[a]$ the cohomological class of the n-form a in $H^n(d)$, one may view the antibracket in $H^n(d)$ as arising from a local antibracket in the space of local functions defined as follows:

$$\{\hat{a}_1, \hat{a}_2\} = \frac{\delta^R \hat{a}_1}{\delta \phi^A}\frac{\delta^L \hat{a}_2}{\delta \phi^*_A} - \frac{\delta^R \hat{a}_1}{\delta \phi^*_A}\frac{\delta^L \hat{a}_2}{\delta \phi^A}, \tag{9}$$

$$\{[a_1],[a_2]\} = [d^n x\{\hat{a}_1, \hat{a}_2\}]. \tag{10}$$

In (9), $\delta/\delta\phi^A$ is the Euler–Lagrange derivative defined by

$$\frac{\delta}{\delta \phi^A} = (-\partial)_{(\nu)} \frac{\partial}{\partial(\partial_{(\nu)}\phi^A)}, \tag{11}$$

with $(-\partial)_{(\nu)} = (-)^{|\nu|}\partial_{(\nu)}$. While the bracket (8) in $H^n(d)$ is a true bracket, the local antibracket (9) in the space of local functions is graded symmetric, but satisfies the graded Leibnitz rule and Jacobi identity only up to total divergences (see Appendix B).

It is clear that the antibracket for the integrands that gives rise to the antibracket in $H^n(d)$ is not unique, but expressions differing from the one in (9) by a total divergence are also admissible. This is the case, for instance, for the following expression (see Appendix B):

$$\{\hat{a}_1,\hat{a}_2\}_{\mathrm{alt}}=\partial_{(\nu)}\left(\frac{\delta^R\hat{a}_1}{\delta\phi^A}\right)\frac{\partial^L\hat{a}_2}{\partial(\partial_{(\nu)}\phi^*_A)}-\partial_{(\nu)}\left(\frac{\delta^R\hat{a}_1}{\delta\phi^*_A}\right)\frac{\partial^L\hat{a}_2}{\partial(\partial_{(\nu)}\phi^A)}, \tag{12}$$

which satisfies a graded Leibnitz rule in the second argument, but is only graded symmetric up to a total divergence.

In the Batalin–Vilkovisky formalism, one introduces additional fields, the ghosts and antifields. Quantities of direct physical interest are recovered by considering the cohomology classes of the BRST differential s. The identification of local functionals with the cohomology group $H^n(d)$ implies that the BRST cohomology for local functionals is given by $H^*(s,H^n(d))$. This last group is isomorphic to the relative cohomology group $H^{*,n}(s|d)$ of s modulo d in form degree n evaluated in the space of form-valued local functions. Due to the fact that the BRST symmetry acting on a local function is canonically generated through the formula

$$s\hat{a}=\{\hat{\mathscr{S}},\hat{a}\}_{\mathrm{alt}}, \tag{13}$$

it is straightforward[b] to verify that the local antibracket induces a well-defined odd Lie bracket in the relative cohomology group of s modulo d:

$$\{\cdot,\cdot\}:H^{g_1,n}(s|d)\times H^{g_2,n}(s|d)\to H^{g_1+g_2+1,n}(s|d),\{[a_1],[a_2]\}=[d^nx\{\hat{a}_1,\hat{a}_2\}]. \tag{14}$$

An inspection of the various possible cases shows that it is only for ghost number -1 that this map associates to two cohomology classes a cohomology class of the same type, i.e., of the same ghost number. The subspace $H^{-1,n}(s|d)$ equipped with the antibracket defines a subalgebra of $H^{*,n}(s|d)$, which we denote by $\mathscr{S}$,

$$\mathscr{S}=(H^{-1,n}(s|d),\{\cdot,\cdot\}). \tag{15}$$

III. THE DICKEY BRACKET

Let Σ_k be the stationary surface, i.e., the surface defined by the equations

$$\partial_{(\lambda)}\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}=0, \tag{16}$$

(with $|\lambda|\leqslant k-2$ for second-order equations) in the spaces $M^n\times F^k$ with coordinates x^μ, $\partial_{(\mu)}\phi^i$, $|\mu|\leqslant k$.

The vector space of (equivalence classes of) inequivalent Lagrangian conservation laws is defined by

$$\{j^\mu,\partial_\mu j^\mu\approx 0,\ \text{modulo the identification}\ j^\mu\sim|_\Sigma\, j^\mu+\partial_\nu S^{[\nu\mu]}\}, \tag{17}$$

where the j^μ are local functions. In form notation, we get equivalence classes $[j]$ of $n-1$ forms whose pullback to the stationary surface is d closed, where two such forms have to be identified if they differ by the exterior derivative of an $n-2$ form on the stationary surface:

$$[j]\in H^{n-1}(d^*,\Omega(\Sigma)). \tag{18}$$

Inequivalent conserved currents belong, by definition, to the so-called characteristic cohomology of the stationary surface in form degree $n-1$.

The standard regularity conditions are that locally in the jet space, the equations $\delta\hat{\mathscr{L}}_0/\delta\phi^i$ and their derivatives can be split into two groups: the ''independent equations,'' which can be taken locally as a new coordinate system on the jet space, replacing some of the fields and their

derivatives; and the ''dependent equations'' which hold as a consequence of the independent ones. One then can prove[7,6] that a function that vanishes on the stationary surface can be written as a linear combination of the equations defining the surface, hence

$$\partial_\mu j^\mu = X^{i(\lambda)} \partial_{(\lambda)} \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^i}, \tag{19}$$

for some local functions $X^{i(\lambda)}$. This equation does not determine $X^{i(\lambda)}$ completely, one is, for instance, free to add functions of the form

$$Y^{i(\lambda)j(\nu)} \partial_{(\nu)} \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^j}, \tag{20}$$

with Y antisymmetric under the exchange of the pairs $i(\lambda)$ and $j(\nu)$[c].

The characteristic[7,4] of the equivalence class of conservation laws described by $[j]$ is defined by the equivalence class of local functions of the form $X^i = (-\partial)_{(\lambda)} X^{i(\lambda)}$, where two sets X^i's of local functions have to be identified if they differ by a function of the form

$$(-\partial_{(\lambda)}) \left[Y^{i(\lambda)j(\nu)} \partial_{(\nu)} \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^j} \right]. \tag{21}$$

It is straightforward to verify that the characteristic does not depend on the choice of the representative for j^μ. Let δ_X be the evolutionary vector field defined by X^i:

$$\delta_X = \partial_{(\lambda)} X^i \frac{\partial}{\partial(\partial_{(\lambda)} \phi^i)}. \tag{22}$$

Note that X^i and δ_X satisfy the equations

$$X^i \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^i} = \partial_\mu j'^\mu, \quad \delta_X \hat{\mathscr{L}}_0 = \partial_\mu j''^\mu, \tag{23}$$

with j'^μ, j''^μ in the same equivalence class as j. This means that the characteristics define variational symmetries, i.e., symmetries of the action. In the nondegenerate case, one can then prove directly that there is a one to one correspondence between inequivalent symmetries of the action and inequivalent conservation laws (Noether's theorem),[7] but we will not do so here because it is also a direct consequence of our analysis in the next section.

The Dickey bracket in the space of inequivalent conservation laws (17) is defined by[4]

$$\{[j_1],[j_2]\}_D = -[\delta_{X_1} j_2]. \tag{24}$$

By using properties of the Euler–Lagrange derivatives, one finds the following equivalent expressions (see Ref. 4 and Appendix B):

$$\begin{aligned}\{[j_1],[j_2]\}_D = [\delta_{X_2} j_1] &= \frac{1}{2}[\delta_{X_2} j_1 - \delta_{X_1} j_2] \\ &= \left[-\frac{(\tilde{\nu})_{\mu_1}+1}{|\nu|+1} \partial_{(\nu)} \left[\delta_{X_2} \left(\frac{\delta \hat{\mathscr{L}}_0}{\delta(\partial_{(\nu)\mu_1}\phi^i)} \right) X_1^i - \delta_{X_1} \left(\frac{\delta \hat{\mathscr{L}}_0}{\delta(\partial_{(\nu)\mu_1}\phi^i)} \right) X_2^i \right] \right. \\ &\quad \left. \times \frac{1}{(n-1)!} \epsilon_{\mu_1 \cdots \mu_n} dx^{\mu_2} \cdots dx^{\mu_n} \right],\end{aligned} \tag{25}$$

where $(\tilde{\nu})_\mu$ denotes the number of occurrences of μ in the multi-index (ν). This last expression corresponds to the contraction of the horizontal $(n-1)$ and vertical 2 form,

$$\Omega = \frac{1}{(n-1)!}\,\epsilon_{\mu_1\cdots\mu_n}\,dx^{\mu_2}\cdots dx^{\mu_n}\,\frac{(\tilde{\nu})_{\mu_1}+1}{|\nu|+1}\,\partial_{(\nu)}\left[d_V\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta(\partial_{(\nu)\mu_1}\phi^i)}\right)d_V\phi^i\right], \tag{26}$$

with the evolutionary vector fields δ_{X_1} and δ_{X_2}. This formula involves the vertical derivatives and the higher-order Euler operators defined, for instance, in Refs. 7, 4 (see also Appendices A and B).

Again, in the nondegenerate case, one can prove directly that the Dickey bracket is a well-defined Lie bracket in the space of inequivalent conserved currents (see Ref. 4); namely, it is unambiguous in the quotient space, antisymmetric, and satisfies the Jacobi identity. Alternatively, these properties follow from the isomorphism theorem proved in the next section.

Among the conserved currents, one may distinguish those for which j^0 is trivial, i.e. of the form $j^0 \approx \partial_m S^{m0}$. The corresponding Noether charge $Q=\int d^{n-1}x\; j^0$ is zero on the stationary surface. These currents form an ideal for the Dickey bracket since $\delta_X j^0$ is trivial if j^0 is trivial. We call this ideal the ideal of ''conserved currents without charge'' and we denote it by I.

As we shall show in the next section, the ideal I is trivial in the absence of gauge symmetry. That is, if a conserved current has a vanishing Noether charge, then, it is trivial, i.e., on shell equal to an identically conserved current. But this may not be so in the presence of gauge freedom, for which there exist nontrivial currents in I.

The third algebra that we shall introduce is the algebra of conserved, integrated charges, $Q=\int d^{n-1}x\; j^0$, $\partial_0 j^0 \approx -\partial_k j^k$ for some spatial current j^k, with the identification of two such charges if they agree on the stationary surface. By using the Hamiltonian formalism, one may equip this algebra with a well-defined even bracket, namely, the standard Hamiltonian Poisson bracket. We denote this algebra by $\mathscr{Q}$. It is clear that $\mathscr{Q}$ is isomorphic as a vector space to the quotient of the space of conserved currents by the ideal I. We shall prove furthermore that the Poisson bracket is just the corresponding induced Dickey bracket.

IV. ISOMORPHISMS IN THE CASE OF NONDEGENERATE LAGRANGIAN FIELD THEORY

In the absence of gauge invariance, the only additional fields in the Batalin–Vilkovisky construction besides the original ϕ^i, which we assume for simplicity to be bosonic, are the antifields ϕ_i^*. The original action $S[\phi^i]=\int d^n x\;\hat{\mathscr{L}}_0[\phi^i]$ is by itself a proper solution of the master equation generating the BRST symmetry,

$$s\phi_i^* = \frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}, \quad s\phi^i = 0, \quad s\partial_\mu = \partial_\mu s, \tag{27}$$

which reduces to the so-called Koszul–Tate differential δ.[6] In the nondegenerate case, the equations of motion and their derivatives can be taken locally as first coordinates in a new coordinate system replacing some of the fields and their derivatives. One can prove[6] that the BRST cohomology in the spaces $C^\infty(\mathbf{R}^n\times F^k)\times\mathbf{R}[\partial_{(\nu)}\phi_i^*]$ (with $|\nu|\leqslant k-2$ for second-order equations) is given by smooth functions defined on the stationary surface[d]: $H^0(\delta)\simeq C^\infty(\mathbf{R}^n\times\Sigma^k)$ and $H^g(\delta)=0$, $g\neq 0$.

In the new coordinate system, where the equations and their derivatives are taken as new coordinates, we denote by $I_0=\{x_a\}$ the set of fields and their derivatives needed to complete the coordinate system. Let us assume that the nondegenerate theory is of Cauchy order 1, meaning that $\partial_k x_a \in I_0$ for $k\geqslant 1$. One can then prove[8] that, apart from $H^{0,n}(s|d)$, which corresponds to local functionals defined on the stationary surface, the only nontrivial local BRST cohomology classes are in ghost number -1 and form degree n.

By integrations by parts, the representatives of $H^{-1,n}(s|d)$ can be assumed to be of the characteristic form

$$a = d^n x \ \phi_i^* X^i[\phi^i], \tag{28}$$

for local functions X^i. The cocycle condition reads as

$$\frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^i} X^i = \partial_\mu j^\mu, \tag{29}$$

and implies that the field variation $\delta\phi^i = X^i$ defines a variational symmetry. Furthermore, to a trivial representative of $H^{-1,n}(s|d)$ corresponds to a variational symmetry that is given by an ''antisymmetric'' combination of the equations of motions as in (21)[e]. The space $H^{-1,n}(s|d)$ is accordingly given by inequivalent variational symmetries or characteristics of inequivalent conservation laws[f].

The local antibracket map for such representatives of $H^{-1,n}(s|d)$ is given by

$$\begin{aligned} &\{[d^n x \ \phi_i^* X_1^i],[d^n x \ \phi_i^* X_2^i]\} = [d^n x \ \phi_i^*[X_1, X_2]_L^i], \\ &[X_1, X_2]_L^i = \frac{\partial X_1^i}{\partial \phi_{(\mu)}^j} \partial_{(\mu)}(X_2^j) - \frac{\partial X_2^i}{\partial \phi_{(\mu)}^j} \partial_{(\mu)}(X_1^j) = \delta_{X_2} X_1^i - \delta_{X_1} X_2^i . \end{aligned} \tag{30}$$

Hence we find that, in ghost number -1, the local antibracket map corresponds to the traditional, even Lie bracket for inequivalent variational symmetries under characteristic form given in Ref. 7. Since the Lie bracket for evolutionary vector fields is induced by the commutator for vector fields, we get the following.

Theorem 1: *The odd Lie algebra* $\mathscr{S} = (H^{-1,n}(s|d), \{\cdot,\cdot\})$ *is isomorphic to the algebra of inequivalent variational symmetries equipped with the bracket induced by the commutator for vector fields.*

Using the acyclicity of $s = \delta$[6] at negative ghost numbers and the triviality of the cohomology of d in form degree $p < n$ [$H^p(d) = \delta_0^p \mathbf{R}$, see, e.g., Ref. 7], we can easily prove the isomorphism

$$H^{-1,n}(\delta|d) \simeq H^{n-1,0}(d|\delta)/\delta_1^n \mathbf{R}. \tag{31}$$

This follows from a general relationship for relative cohomology groups proved in Ref. 9. The last space corresponds to the space of inequivalent conserved currents. Indeed, the cocycle condition implies that representatives must be $n-1$ forms, which restrict to closed forms on the stationary surface, while the coboundary condition requires two such currents to be considered as equivalent if they differ on this surface by the exterior derivative of an $n-2$ form, i.e., the divergence of a ''superpotential'' in dual notation, or by a constant in one dimension.

The above isomorphism is explicitly given by associating to a representative a of the first space the representative j of the second space in the equation $sa + dj = 0$. Furthermore, the antibracket map induces through this isomorphism a well-defined Lie bracket in the space of inequivalent conserved currents. An explicit calculation (Appendix B) shows that the corresponding bracket is just given by the Dickey bracket. Hence the following holds.

Theorem 2: *The odd Lie algebra* $\mathscr{S}$ *is isomorphic to the space of inequivalent conservation laws equipped with the Dickey bracket.*

There is no contradiction in the fact that the isomorphism relates an odd bracket to an even bracket, because there is at the same time a shift in the degree [from odd (-1) to even (0)].

Combining theorems 1 and 2, we get the full Noether theorem.

Corollary 1: There is a Lie algebra isomorphism between inequivalent conservation laws and inequivalent variational symmetries.

The ideal I of currents without charge is trivial. Indeed, the coboundary condition allows us to take all the j^k to depend on the x_a alone. Because $\partial_k x_a$ depends also on x_a and not on equations of motion, one must have $\partial_k j^k=0$ identically, which implies that $j^k=\delta_2^n \mathbf{R}+\partial_m S^{[mk]}$. Hence, the Dickey algebra and the space of inequivalent, integrated conserved charges are isomorphic as vector spaces. That the induced Dickey bracket in the space $\mathcal{Q}$ corresponds to the Poisson bracket in $\mathcal{Q}$ in the Hamiltonian formalism is a consequence of the analysis in Sec. VI. Alternatively, it could be proved directly along the lines of Ref. 10, by taking, furthermore, locality into account. Hence the following is true.

Theorem 3: *In dimensions different from 2, if the theory is of Cauchy order 1, the Dickey algebra of inequivalent conserved currents is isomorphic to the algebra of inequivalent conserved charges equipped with the Poisson bracket.*

V. GAUGE THEORIES. GHOST NUMBER −1

The advantage of the cohomological reformulation of Noether's theorem in Eq. (31) is that one can extend this theorem in a straightforward way to gauge theories, which are not covered by the analysis in Refs. 7, 4. One can prove[8] that the subalgebra $\mathcal{S}$ is isomorphic to the algebra $\mathcal{R}=(H_1^n(\delta|d),\{\cdot,\cdot\}_R)$, where the cohomology group $H_1^n(\delta|d)$ involves only the original fields and the antifields, but no ghosts, δ being the Koszul–Tate part of s and the degree of δ the antighost number, which is minus the ghost number (for a function that does not involve the ghosts). The restricted antibracket map $\{\cdot,\cdot\}_R$ is the antibracket map restricted to the original fields ϕ^i and the antifields ϕ_i^*.

The differential δ acts nontrivially on the antifields of higher order. In the case of irreducible gauge theories, its action on C_a^* is given by

$$\delta\ \partial_{(\lambda)} C_a^* = \partial_{(\lambda)}[R_a^{+i(\nu)}\ \partial_{(\nu)}\phi_i^*], \tag{32}$$

where the operators $R_a^{+i(\nu)}\partial_{(\nu)}$ define the Noether identities of the theory, i.e.,

$$R_a^{+i(\nu)}\partial_{(\nu)}\ \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^i}=0. \tag{33}$$

This additional piece maintains $\delta^2=0$ and guarantees that δ still defines a homological resolution of the functions defined on the constraint surface, implying for instance that Eq. (31) still holds.

If we still want Theorem 1 to hold, the definition of δ requires that we change the notion of a trivial variational symmetry; they have to correspond to X^i's that are ''antisymmetric'' combinations of the equations of motion up to a gauge transformation, where the gauge parameters are replaced by arbitrary local functions:

$$X^i=(-\partial)_{(\lambda)}\left[Y^{i(\lambda)j(\nu)}\partial_{(\nu)}\ \frac{\delta \hat{\mathscr{L}}_0}{\delta \phi^j}\right]+R_a^{i(\nu)}\ \partial_{(\nu)}f^a. \tag{34}$$

The operators $R_a^{i(\nu)}\partial_{(\nu)}$ are the adjoints of the operators defining the Noether identities and define the gauge transformations.

With this modification of the space of inequivalent variational symmetries, Theorems 1, 2 and Corollary 1 hold, as in the case with no gauge invariance.

The ideal I, however, is not trivial in the case of gauge theories, because the theory is no longer of Cauchy order 1. For instance, the current $j^\mu=F^{0\mu}=(0,F^{0k})$ in free Maxwell's theory belongs to I since $\int j^0\ d^{n-1}x=0$, but $F^{0k}\neq\partial_m S^{[km]}$ (even weakly). Theorem 3 becomes the following.

Theorem 4: *The Dickey algebra of conserved currents modulo the ideal I is isomorphic to the algebra of inequivalent conserved charges equipped with the Poisson bracket*.

The proof that the induced Dickey bracket is, in fact, the ordinary Poisson bracket in the Hamiltonian formalism again follows from the reasoning given in the next section.

VI. GAUGE THEORIES. GENERAL ANALYSIS

The previous theorems relate the antibracket and the Poisson bracket at particular values of the ghost number. In order to fully prove them, we shall first put them in a more general setting. Indeed, these theorems can be extended to arbitrary values of the ghost number.

To relate the antibracket and the Poisson bracket for all values of the ghost number, one first uses the invariance of the local BRST cohomology group with respect to the introduction of auxiliary fields and generalized auxiliary fields, as shown in Ref. 8. One proves by an analoguous reasoning that the same is true for the antibracket map induced in cohomology. This implies that one can go to the total Hamiltonian formalism and then to the extended Hamiltonian formalism, which we will assume to be local,[6] and describe the solution of the master equation in terms of the Batalin–Fradkin–Vilkovisky framework.

Let us recall that in this framework, a central object is the extended Poisson bracket $[\cdot,\cdot]_{\mathrm{P}}$ for which the ghosts C^a and the ghost momenta $\mathscr{P}_b$ are considered as conjugate dynamical variables, in addition to the usual fields and their momenta. One then constructs out of the constraints, which we assume for simplicity to be irreducible and first class, the BRST charge $\Omega=\int d^{n-1}x\ \omega$, which is a local functional in space verifying $[\Omega,\Omega]_{\mathrm{P}}=0$. The Hamiltonian $H=\int d^{n-1}x\ h$ verifying $[\Omega,H]_{\mathrm{P}}=0$ is also a local functional in space and these two functionals depend only on the fields $\tilde{\phi}^A\equiv\phi^i,\pi_j,C^a,\mathscr{P}_b$ and their spatial derivatives.

The functionals in space are replaced by spatial functions in the same way as in the space–time case, which leads to a local extended Poisson bracket $\{\cdot,\cdot\}_{\mathrm{P}}$ defined through spatial Euler Lagrange derivatives. The BRST charge Ω generates the symmetry $s_\omega=\{\omega,\cdot\}_{\mathrm{P,alt}}$, where $\{\cdot,\cdot\}_{\mathrm{P,alt}}$ is defined in a way analoguous to $\{\cdot,\cdot\}_{\mathrm{alt}}$ in (12). The local extended Poisson bracket induces a well-defined even Lie bracket, the Poisson bracket map, in the cohomology group of s_ω modulo the spatial exterior derivative $\tilde{d}$.

The symmetry s_ω is only a part of the BRST symmetry, which is isomorphic to the BRST symmetry of the initial Lagrangian system through the elimination of (generalized) auxiliary fields. The complete BRST symmetry is generated through the solution of the master equation in the extended Hamiltonian formalism given by[11,6]

$$S_{\mathrm{H}}[\tilde{\phi}^A,\tilde{\phi}^*_A]=\int dt\ d^{n-1}x\left(-\frac{1}{2}\,\dot{\tilde{\phi}}^A(\sigma^{-1})_{AB}\tilde{\phi}^B-h-\{\tilde{\phi}^*_A\tilde{\phi}^A,\omega\}_{\mathrm{P,alt}}\right),\tag{35}$$

where we have introduced the notation

$$\sigma^{AB}=\begin{pmatrix}0&0&\delta^i_j&0\\0&0&0&-\delta^a_b\\-\delta^i_j&0&0&0\\0&-\delta^a_b&0&0\end{pmatrix}.\tag{36}$$

Explicitly, the BRST symmetry $s_{\mathrm{H}}=\{S_{\mathrm{H}},\cdot\}_{\mathrm{alt}}$ reads as

$$s_{\mathrm{H}}=\partial_{(\mu)}\left(\frac{\tilde{\delta}^R\omega}{\delta\tilde{\phi}^A}\right)\sigma^{AB}\,\frac{\partial^L}{\partial(\partial_{(\mu)}\tilde{\phi}^B)}+\partial_{(\mu)}\mathscr{L}_A\,\frac{\partial^L}{\partial(\partial_{(\mu)}\tilde{\phi}^*_A)},\tag{37}$$

where the tilded Euler–Lagrange derivatives are restricted to spatial derivatives only and

$$\mathscr{L}_A \equiv -\dot{\widetilde{\phi}}^B (\sigma^{-1})_{BA} - \frac{\widetilde{\delta}^R h}{\delta \widetilde{\phi}^A} - \frac{\widetilde{\delta}^R}{\delta \widetilde{\phi}^A} (\{\widetilde{\phi}^*_B \widetilde{\phi}^B, \omega\}_{\mathrm{P,alt}}). \tag{38}$$

Note that in the proper solution S_{H} to the master equation in the extended Hamiltonian formalism, we have made the identification of minus the antifields $-\lambda^*_a$ of the Lagrange multipliers for the first class constraints with the ghost momenta $\mathscr{P}_a$. This implies that in terms of the new antifields, the Koszul–Tate part is now associated to the surface $\mathscr{L}_A(\widetilde{\phi}^*=0)=0$ and not with the gauge-invariant, original, Hamiltonian equations of motion. The part in resolution degree 0, the resolution degree being the degree associated to the Koszul–Tate differential,[6] with respect to the *new* antifields, is given by

$$\gamma = s^0_\omega - \partial_{(\mu)} \frac{\widetilde{\delta}^R}{\delta \widetilde{\phi}^A} (\{\widetilde{\phi}^*_B \widetilde{\phi}^B, \omega\}_{\mathrm{P,alt}}) \frac{\partial L}{\partial(\partial_{(\mu)} \phi^*_A)}, \tag{39}$$

and the BRST differential has no contributions in higher resolution degree, contrary to what may happen in the old resolution degree. Here, s^0_ω is defined by the first term on the right-hand side of Eq. (37) and coincides with s_ω when acting on a function involving no time derivatives of the fields. Evaluating the action of $s^{(0)}_\omega$ on ϕ^i, π_j and putting to zero the ghost momenta $\mathscr{P}_a$ reproduces the gauge transformations of these fields with gauge parameters replaced by the ghosts C^a.

One then investigates the local BRST cohomology groups $H(s_{\mathrm{H}}|d)$. A first step is the following theorem.

Theorem 5: *The ordinary BRST cohomology depending on the fields ϕ^A, the antifields ϕ^*_A, and their derivatives is isomorphic to the cohomology of s_ω depending on the fields $\widetilde{\phi}^A$ and their spatial derivatives*:

$$H(s, [\phi^A, \phi^*_A]) \simeq H(s_{\mathrm{H}}, [\widetilde{\phi}^A, \widetilde{\phi}^*_A]) \simeq H(s_\omega, [\widetilde{\phi}^A]). \tag{40}$$

In other words, in a s_{H} cocycle, one can get rid of the temporal derivatives and of the antifields through the addition of a s_{H} coboundary. For a proof of this theorem, see Appendix C.

Starting from the bottom of the descent equations, one then proves (see again Appendix C) that a nontrivial cocycle modulo d, a, $s_{\mathrm{H}} a + db = 0$, given by $a = \widetilde{a} + dt\, a^0$, where $\widetilde{a}$ does not involve the differential dt, can be characterized by

$$a = dt(-\{\widetilde{\phi}^*_A \widetilde{\phi}^A, \widetilde{b}_0\}_{\mathrm{P,alt}} + a^0_0) + \widetilde{a}_0, \tag{41}$$

verifying

$$s_\omega \widetilde{a}_0 + \widetilde{d} \widetilde{b}_0 = 0, \tag{42}$$

$$s_\omega a^0_0 + \widetilde{d} b^0_0 - \frac{\partial}{\partial t} \widetilde{b}_0 + \{h, \widetilde{b}_0\}_{\mathrm{P,alt}} = 0. \tag{43}$$

Here, $\widetilde{a}_0$, $\widetilde{b}_0$, a^0_0, and b^0_0 contain no antifields and no time derivatives of the fields, while $\widetilde{b}_0$ and b^0_0 satisfy analoguous equations to $\widetilde{a}_0$ and a^0_0 for some $\widetilde{m}_0$, m^0_0. In maximum form degree n, there is, of course, no $\widetilde{a}$ and at the bottom, say n, of the descent equations, $\widetilde{n}_0$ and n^0_0 are s_ω cocycles[g].

In the coboundary condition for such cocycles $a = s_{\mathrm{H}} c + de$, we have

$$c = dt(-\{\widetilde{\phi}^*_A \widetilde{\phi}^A, \widetilde{e}_0\}_{\mathrm{P,alt}} + e^0_0) + \widetilde{a}_0, \tag{44}$$

giving the conditions

$$\tilde{a}_0 = s_\omega \tilde{c}_0 + \tilde{d}\tilde{e}_0, \tag{45}$$

$$a_0^0 = -s_\omega c_0^0 - \tilde{d}e_0^0 + \frac{\partial}{\partial t}\tilde{e}_0 - \{h, \tilde{e}_0\}_{\mathrm{P,alt}}, \tag{46}$$

where $\tilde{c}_0$, $\tilde{e}_0$, c_0^0, and e_0^0 again contain no antifields and no time derivatives of the fields, with analogous equations holding for $\tilde{b}_0$, b_0^0 in terms of $\tilde{e}_0$, e_0^0, $\tilde{f}_0$, f_0^0. In maximum form degree, there is no $\tilde{a}$, $\tilde{c}$ and Eq. (45) is trivially satisfied.

In order to characterize the local BRST cohomology groups $H^{g,k}(s_{\mathrm{H}}|d)$, one can first find a basis for the vector space $H^{g,k}(s_\omega|\tilde{d})$ in the space of antifield and time derivative-independent local forms with only spatial differentials (the most general nontrivial solution for $\tilde{a}_0$). One then finds a basis for $H^{g+1,k-1}(s_\omega|\tilde{d})$ (the most general nontrivial solution for $\tilde{b}_0$). One finally considers the subspace $l[H^{g+1,k-1}(s_\omega|\tilde{d})]$ for which Eq. (43) admits a particular solution $a_{0\mathrm{P}}^0$. The general nontrivial form for a_0^0 is then given by $a_0^0 = a_{0\mathrm{P}}^0 + \overline{a_0^0}$, where $\overline{a_0^0}$ belongs to $r[H^{g,k-1}(s_\omega|\tilde{d})]$, which is the subspace of $H^{g,k-1}(s_\omega|\tilde{d})$ remaining nontrivial under the more general coboundary condition (46).

We thus get the following result on the relationship between the local BRST cohomology groups in Lagrangian and Hamiltonian formalism.

Theorem 6: *The local BRST cohomology groups are isomorphic to the direct sum of the following three local cohomology groups of the Hamiltonian formalism:*

$$H^{g,k}(s|d) \simeq H^{g,k}(s_{\mathrm{H}}|d) \simeq H^{g,k}(s_\omega|\tilde{d}) \oplus l[H^{g+1,k-1}(s_\omega|\tilde{d})] \oplus r[H^{g,k-1}(s_\omega|\tilde{d})]. \tag{47}$$

Note that in maximal form degree n, the first group of the last expression vanishes. This decomposition is, in general, quite difficult to achieve in practice since it requires the resolution of complicated equations. However, it corresponds to the natural resolution of the spatiotemporal descent equations in the Hamiltonian formalism, and it is useful, in principle, since it enables one to relate the bracket and the antibracket.

Remark: The groups with prefix r and l appear also in the covariant analysis of the descent equations in the following way. The descent equations provide a homomorphism $\mathscr{D}: H^{g,k}(s|d) \to H^{g+1,k-1}(s|d)$ with $\mathscr{D}[a] = [b]$ for $sa + db = 0 (\to sb + dc = 0)$. The kernel of $\mathscr{D}$ can easily be shown to consist of the vector space $H^{g,k}(s)$ seen as a subspace of $H^{g,k}(s|d)$, i.e., the equivalence classes of s-cocycles, with the equivalence relation determined by s modulo d exactness. We denote this kernel by $r[H^{g,k}(s)]$.

The image of $\mathscr{D}$ is given by the classes $[b] \in H^{g+1,k-1}(s|d)$, which can be lifted, i.e., such that there exists a with $sa + db = 0$. We denote this space by $l[H^{g+1,k-1}(s|d)]$.

This implies the isomorphism

$$H^{g,k}(s|d) \simeq l[H^{g+1,k-1}(s|d)] \oplus r[H^{g,k}(s)], \tag{48}$$

and, by iteration,

$$H^{g,k}(s|d) \simeq \oplus_{i=0}^{k} l^i r[H^{g+i,k-i}(s)], \tag{49}$$

where in the last space ($i = k$) one can forget the r, because there are no d exact terms in form degree 0. Note that since $H^0(d) = \mathbf{R}$, if $g = -k$, the last space has to be replaced by the space $\{e, se = c, e \sim e + sf + c'; c, c' \in \mathbf{R}\}$, which is isomorphic to $H^0(s)/\mathbf{R}$.

In the Hamiltonian case above, we consider only the part of the descent equations involving the exterior derivative with respect to time: $d^0 = dt(d/dt)$. □

We now use Theorem 6 to derive information on the antibracket from the Poisson bracket induced in $H(s_\omega|\tilde{d})$. On the representatives of the local BRST cohomology groups determined by Eqs. (41)–(46), the local antibracket gives

$$\{\hat{a}_1,\hat{a}_2\}=\{\widetilde{\phi}^*_A\widetilde{\phi}^A,\{\hat{\widetilde{b}}_1,\hat{\widetilde{b}}_2\}_{\mathrm{P}}\}_{\mathrm{P,alt}}-\{\hat{a}^0_1,\hat{\widetilde{b}}_2\}_{\mathrm{P}}-(-)^{\epsilon_{\hat{\widetilde{b}}_1}}\{\hat{\widetilde{b}}_1,\hat{a}^0_2\}_{\mathrm{P}}. \tag{50}$$

Hence, (i) the antibracket map can be entirely rewritten in terms of the local Poisson bracket; and (ii) it is nontrivial only if $l[H^{*,n-1}(s_\omega|\widetilde{d})]$ is nontrivial.

More precisely, according to the split of $H^{*,n}(s|d)$ in (47) to which corresponds the split of a^0 into a^0_{P} and $\overline{a_0}$, we see that the antibracket map (14) is completely determined by the local Poisson bracket map induced in

$$\{\cdot,\cdot\}_{\mathrm{P}}:l[H^{g_1+1,n-1}(s_\omega|\widetilde{d})]\times l[H^{g_2+1,n-1}(s_\omega|\widetilde{d})]\to l[H^{g_1+g_2+2,n-1}(s_\omega|\widetilde{d})], \tag{51}$$

and by the local Poisson bracket map in

$$\{\cdot,\cdot\}_{\mathrm{P}}:l[H^{g_1+1,n-1}(s_\omega|\widetilde{d})]\times r[H^{g_2,n-1}(s_\omega|\widetilde{d})]\to r[H^{g_1+g_2+1,n-1}(s_\omega|\widetilde{d})]. \tag{52}$$

Hence the antibracket map is determined by the following matrix in maximum spatial form degree $n-1$:

$$\begin{pmatrix} \{l[H^{g_1+1}(s_\omega|\widetilde{d})],l[H^{g_2+1}(s_\omega|\widetilde{d})]\}_{\mathrm{P}} & (-)^{\epsilon_{g_1+1}}\{l[H^{g_1+1}(s_\omega|\widetilde{d})],r[H^{g_2}(s_\omega|\widetilde{d})]\}_{\mathrm{P}} \\ \{r[H^{g_1}(s_\omega|\widetilde{d})],l[H^{g_2+1}(s_\omega|\widetilde{d})]\}_{\mathrm{P}} & 0 \end{pmatrix}. \tag{53}$$

Equations (52) and (53) mean, in particular, that $r[H^{*,n-1}(s_\omega|\widetilde{d})]$ is an abelian subalgebra and an ideal in the odd Lie algebra $(H^{*,n}(s|d),\{\cdot,\cdot\})$. We have thus proved the following.

Theorem 7: *The odd Lie algebra* $(H^{*,n}(s|d),\{\cdot,\cdot\})$ *is isomorphic to the semidirect sum of the Abelian Lie algebra* $r[H^{*,n-1}(s_\omega|d)]$ *and the Lie algebra* $(l[H^{*,n-1}(s_\omega|d)],\{\cdot,\cdot\}_{\mathrm{P}})$, *where the action of* $l[H^{*,n+1}(s_\omega|\widetilde{d})]$ *on* $r[H^{*,n-1}(s_\omega|d)]$ *is determined by the Poisson bracket map from one space to the other. By taking the quotient, the following isomorphism is seen to hold:*

$$(H^{*,n}(s|d)/r[H^{*,n-1}(s_\omega|\widetilde{d})],\{\cdot,\cdot\})\simeq(l[H^{*,n-1}(s_\omega|\widetilde{d})],\{\cdot,\cdot\}_{\mathrm{P}}). \tag{54}$$

The consequences of this result in the particular case of conserved currents, i.e., for $g_1=g_2=-1$, $k=n$ are as follows. Using the results of Ref. 8 in both the Lagrangian and the Hamiltonian context, the isomorphism (47) means:

(i) The space of inequivalent Lagrangian conservation laws not belonging to I is isomorphic to the subspace of spatial local functionals in the coordinates and momenta, defined on the constraint surface $\widetilde{\Sigma}$ and gauge invariant on this surface, whose Poisson bracket with the first class Hamiltonian $\widetilde{H}_0$ plus the explicit time derivative vanishes on the constraint surface,

$$\left\{ Q=\int_{t=t_0}\widetilde{b}_0[\phi^i\pi_j]\equiv\int_{t=t_0}d^1x\cdots d^{n-1}x\ \widetilde{j}^0[\phi^i\pi_j],\right.$$
$$\left.[Q,H_0]_{\mathrm{P}}+\frac{\partial}{\partial t}Q=0|_{\widetilde{\Sigma}},Q\sim Q|_{\widetilde{\Sigma}}\right\}, \tag{55}$$

(ii) The space of inequivalent Lagrangian conservation laws belonging to I is isomorphic to a subspace of the characteristic cohomology of the constraint surface in spatial form degree $(n-1)-1$, the space of conservation laws associated to the constraint surface, where two such conservation laws have to be considered to be equivalent if they differ on the constraint surface by a spatial superpotential and the total time derivative of a spatial current,

$$\left\{\widetilde{j}^k,\partial_k\widetilde{j}^k=0|_{\widetilde{\Sigma}},\widetilde{j}^k\sim|_{\widetilde{\Sigma}}\widetilde{j}^k+\partial_j\widetilde{S}^{[jk]}+\frac{\partial}{\partial t}\widetilde{f}^k-\{h_0,\widetilde{f}^k\}_{\mathrm{P,al}}\right\}. \tag{56}$$

For example, the current corresponding to the Lagrangian current $j^\mu = F^{0\mu}$ is given by the momenta π^k in the case of electromagnetism.

The semidirect sum structure holds also for the Lagrangian Dickey algebra, but furthermore, we get from (53) that (i) the algebra of inequivalent conserved charges $\mathcal{Q}$ equipped with the induced Dickey bracket corresponds to the ordinary Poisson bracket algebra of conserved inequivalent charges in the Hamiltonian formalism; and (ii) that the ideal I of conserved currents without charge forms an Abelian subalgebra.

VII. CONCLUSION

We have shown what is the precise relationship between the antibracket map and various Lie algebras existing for local gauge field theories. In the case of conserved currents, where ''covariant'' Poisson brackets are known, a direct comparison has been given.

In the general case, the antibracket map is related to the Poisson bracket of the canonical formalism. The core of this analysis is the relationship of the local BRST cohomologies in the Lagrangian and the Hamiltonian formalisms (i.e., the cohomologies modulo d in the Lagrangian case and modulo $\tilde{d}$ in the Hamiltonian one). This relationship turns out to be somewhat more subtle than for the ordinary cohomologies, or the cohomologies modulo $\tilde{d}$, which are simply isomorphic.

We have shown, in particular, what is the precise analog of the Lie algebra of inequivalent conserved currents in the Hamiltonian framework, which in turn allows some general statements on the structure of this Lie algebra and could be useful for its actual computation.

APPENDIX A: JET SPACES, VARIATIONAL BICOMPLEX, AND KOSZUL–TATE RESOLUTION

In this appendix, we recall briefly the construction of jet bundles and of the variational bicomplex. We will construct a tricomplex containing the horizontal, the vertical, and the Koszul–Tate differentials. The construction enhances the cohomological setup of the variational bicomplex associated to possibly degenerate partial differential equations by implementing the pullback from the free bicomplex to the bicomplex of the surface defined by the equations through the homology of the Koszul–Tate differential. (Different considerations on the Batalin–Vilkovisky formalism in the context of the variational bicomplex are given in Ref. 12.)

Let us first recall some of the ingredients of the variational bicomplex relevant for our purpose (for a review see Refs. 7, 13, and 14 and the references to the original literature therein). As we will not be concerned with global properties, we will work in local coordinates throughout. Consider a trivial fiber bundle,

$$\pi: E = \mathbf{M}^n \times F \to \mathbf{M}^n, \tag{A1}$$

with local coordinates

$$\pi: (x^\mu, \phi^i) \to (x^\mu), \tag{A2}$$

where $\mu = 0,\ldots,n-1$ and $i = 1,\ldots,m$, with F a manifold homeomorphic to $\mathbf{R}^m$ parametrized by the ϕ^i. For simplicity, we assume here that all the ϕ^i are even, but all the considerations that follow could also be done in the case where the original bundle is a superbundle.

The induced coordinates on the infinite jet bundle,

$$\pi^{\infty}: J^{\infty}(E) = \mathbf{M}^n \times F^{\infty} \to \mathbf{M}^n \tag{A3}$$

of jets of sections on $\mathbf{M}^n$ are given by

$$(x^{\mu}, \phi^i, \phi^i_{\mu}, \phi^i_{\mu_1\mu_2}, \ldots,). \tag{A4}$$

Let $\Omega^P(J^{\infty}(E))$ be the local differential forms on $J^{\infty}(E)$. The exterior differential d_T is split into horizontal and vertical differentials: $d_T = d_H + d_V$, with

$$d_H = dx^{\mu}\ \partial_{\mu}, \quad \partial_{\mu} = \frac{\partial^L}{\partial x^{\mu}} + \phi^i_{(\nu)\mu}\ \frac{\partial^L}{\partial \phi^i_{(\nu)}} \tag{A5}$$

and

$$d_V \phi^i_{(\nu)} = d\phi^i_{(\nu)} - dx^{\mu}\ \phi^i_{(\nu)\mu}, \quad d_V x^{\mu} = 0. \tag{A6}$$

Note that everywhere else in the paper, we have omitted the subscript H on the horizontal differential and that we have introduced the more compact notation $\phi^i_{(\nu)} \equiv \partial_{(\nu)}\phi^i$ for the independent coordinates corresponding to the derivatives of the fields.

Furthermore, we have

$$d_H d_V + d_V d_H = d_H^2 = d_V^2 = 0. \tag{A7}$$

A local p-form of $\Omega^p(J^{\infty}(E))$ can then be written as a sum of terms of the form $f[\phi]dx^{\mu_1}\cdots dx^{\mu_r}\ d_V\phi^{i_1}_{(\nu_1)}\cdots d_V\phi^{i_s}_{(\nu_s)}$ of horizontal degree r and vertical degree s with $r+s=p$ and $f[\phi]$ a smooth function of x^{μ}, ϕ^i, and a finite number of their derivatives. The free variational bicomplex is the double complex $(\Omega^{*,*}((J^{\infty}(E)), d_H, d_V)$ of differential forms on $(J^{\infty}(E))$,

$$\begin{array}{ccccccccccccc}
 & & & & \vdots & & & & \vdots & & \vdots & & \\
 & & & & d_V\uparrow & & & & d_V\uparrow & & \delta_V\uparrow & & \\
 & & 0 & \to & \Omega^{0,2}(J^{\infty}(E)) & \stackrel{d}{\to} & \cdots & \stackrel{d}{\to} & \Omega^{n,2}(J^{\infty}(E)) & \stackrel{\int}{\to} & \mathscr{F}^2(J^{\infty}(E)) & \to & 0 \\
 & & & & d_V\uparrow & & & & d_V\uparrow & & \delta_V\uparrow & & \\
 & & 0 & \to & \Omega^{0,1}(J^{\infty}(E)) & \stackrel{d}{\to} & \cdots & \stackrel{d}{\to} & \Omega^{n,1}(J^{\infty}(E)) & \stackrel{\int}{\to} & \mathscr{F}^1(J^{\infty}(E)) & \to & 0 \\
 & & & & d_V\uparrow & & & & d_V\uparrow & & \delta_V\uparrow & & \\
0 & \to & \mathbf{R} & \to & \Omega^{0,0}(J^{\infty}(E)) & \stackrel{d}{\to} & \cdots & \stackrel{d}{\to} & \Omega^{n,0}(J^{\infty}(E)) & \stackrel{\int}{\to} & \mathscr{F}^0(J^{\infty}(E)) & \to & 0 \\
 & & & & \uparrow & & & & \uparrow & & \uparrow & & \\
0 & \to & \mathbf{R} & \to & \Lambda^0(\mathbf{M^n}) & \stackrel{d}{\to} & \cdots & \stackrel{d}{\to} & \Lambda^n(\mathbf{M^n}) & \to & 0 & &
\end{array}$$

The important property of this bicomplex is that all the rows and columns of the above diagram are exact.[7,13,4] The integral sign $\int$ denotes the projection, for each vertical degree s, of horizontal n-forms onto the space of local functional forms $\mathscr{F}^s$, i.e., the space of equivalence classes obtained by identifying exact horizontal n-forms with zero: $\mathscr{F}^s = \Omega^{n,s}/d_H\Omega^{n-1,s}$. δ_V is the induced action of the vertical derivative in $\mathscr{F}^s$: $\delta_V \int \omega^{n,s} = \int d_V \omega^{n,s}$. An evolutionary vector field on E is given by $v_Q = Q^i[\phi]\partial^L/\delta\phi^i$. It prolongation is given by $\delta_Q = \partial_{(\nu)}Q^i\partial^L/\partial\phi^i_{(\nu)}$. Because $[\delta_Q, \partial_{\mu}] = 0$, the contraction of a functional form with the prolongation of evolutionary vector fields is well defined.

A system $\mathscr{R}$ of kth-order partial differential equations on E,

$$\mathscr{R}_a(x^\mu, \phi^i, \phi^i_\mu, \ldots, \phi^i_{\mu_1 \cdots \mu_k}) = 0, \quad a = 1, \ldots, l, \tag{A8}$$

defines a sub-bundle $\mathscr{R} \to \mathbf{R}^n$ of $J^k(E) \to \mathbf{R}^n$. We shall assume that the equations $\mathscr{R}_a = 0$, $\partial_\mu \mathscr{R}_a = 0, \ldots, \partial_{\mu_1 \cdots \mu_1} \mathscr{R}_a = 0$ define, for each x^μ, a smooth surface and provide a regular representation of this surface in the vector spaces F^{s+k} for each s, i.e., the equations can be split into independent equations (L_m), which can be locally taken as first coordinates in a new, regular, coordinate system in the vicinity of the surface defined by the equations, and into dependent ones (L_Δ), which hold as a consequence of the independent ones.

This implies that one can split locally the ϕ^i and their derivatives up to order $s+k$ into independent variables x_A not constrained by the equations and dependent variables z_α in such a way that the equations $\mathscr{R}_a = 0, \ldots, \partial_{\mu_1 \cdots \mu_s} \mathscr{R}_a = 0$ are equivalent to $z_\alpha = z_\alpha(x_A, L_m)$. A local coordinate system adapted to the equations is then given by (x^μ, x_A, L_m) in $J^{s+k}(E)$. How this works in detail for Yang–Mills theory, gravity, or two-form fields is discussed in Ref. 8. The infinite prolongation $\mathscr{R}^\infty$ of $\mathscr{R}$, i.e., the given sets of equations and all their total derivatives, define a sub-bundle in $J^\infty(E)$. In the sequel, by ''stationary surface'' or by ''on shell'' we mean that we are on the sub-bundle defined by $\mathscr{R}_a = 0$ and an appropriate number of its derivatives, depending on the space $J^l(E)$ under consideration.

A consequence of the regularity condition is that any function $f[\phi]$ that vanishes on the stationary surface, $f \approx 0$, can be written as a combination of the equations defining this surface.[7,6]

The knowledge of the split of the equations into dependent and independent ones allows one to find a locally complete set of nontrivial local reducibility operators in $J^l(E)$, i.e., operators $R^{+a(\mu)}_{a_1} \partial_{(\mu)}$ for some local functions $R^{+a(\mu)}_{a_1}[\phi]$ on $J^l(E)$, which do not all vanish on shell, such that

$$R^{+a(\mu)} \partial_{(\mu)} \cdot \mathscr{R}_a = 0, \tag{A9}$$

and verifying the property that if $\lambda^{+a(\mu)} \partial_{(\mu)} \cdot \mathscr{R}_a = 0$ for some local functions $\lambda^{+a(\mu)}[\phi]$ on $J^l(E)$, then

$$\lambda^{+a(\rho)} \partial_{(\rho)} = \lambda^{+a_1(\lambda)} \partial_{(\lambda)} (R^{+a(\mu)}_{a_1} \partial_{(\mu)} \cdot) + \mu^{a(\mu)b(\nu)} (\partial_{(\nu)} \cdot \mathscr{R}_b) \partial_{(\mu)}, \tag{A10}$$

for some local functions $\lambda^{+a_1(\lambda)}[\phi]$, and $\mu^{a(\mu)b(\nu)}$ on $J^l(E)$, where $\mu^{a(\mu)b(\nu)} = -\mu^{b(\nu)a(\mu)}$. Furthermore, the first term of the right-hand side of Eq. (A10) can be assumed to be absent if the functions $\lambda^{+a(\mu)}$ vanish on shell.[6] Such reducibility operators will be called trivial because they exist for any gauge theory.

For simplicity, we will assume here that the reducibility operators are themselves irreducible in the sense that if $\lambda^{+a_1(\lambda)} R^{+a(\mu)} \partial_{(\mu)}$ vanishes on the stationary surface, the functions $\lambda^{+a_1(\lambda)}$ vanish on the stationary surface. All the considerations that follow can be generalized to the case with higher-order reducibility operators at the price of increasing the number of additional generators introduced below like in Ref. 6.

The variational bicomplex $(\Omega^{*,*}(\mathscr{R}^\infty), d_H, d_V)$ of the differential equations $\mathscr{R}$ is the pullback of the variational bicomplex from $J^\infty(E)$ to $\mathscr{R}^\infty$. With the previous assumptions, it is straightforward to verify that $\Omega^{*,*}(\mathscr{R}^\infty)$ is locally isomorphic to the forms in dx^μ and $d_V x_A$ with coefficients that are smooth functions in the x^μ, x_A. The columns of this bicomplex remain exact, because the contracting homotopy,[7] which allows us to prove exactness in the free case, still holds when we consider only $d_V x_A$'s. There exist, however, nontrivial cohomology groups along the rows.

The Koszul–Tate resolution of this bicomplex is obtained by a straightforward generalization of the Koszul–Tate resolution of the stationary surface $\mathscr{R}^\infty$.[6] One considers the superbundle

$$\pi: K = M^n \times (F \oplus \Phi^* \oplus C^*) \to M^n, \tag{A11}$$

and the associated free variational bicomplex $(\Omega^{*,*}(J^\infty(K)), d_H, d_V)$. Φ^* is the vector space with coordinates the Grassmann odd ϕ_a^* and is of dimension l, the number of original equations. C^* is the vector space with coordinates, the Grassmann even $C^*_{a_1}$, and its dimension equals the number of nontrivial reducibility operators $R^{+a(\mu)}_{a_1}\partial_{(\mu)}$. The Koszul–Tate differential δ is defined on $\Omega^{*,*}(J^\infty(K))$ by

$$\delta x^\mu = \delta\, dx^\mu = \delta\phi^i = 0,$$

$$\delta\phi_a^* = \mathscr{R}_a, \quad \delta C^*_{a_1} = R^{+a(\mu)}_{a_1}\partial_{(\mu)}\phi_a^*, \tag{A12}$$

$$\delta d_H + d_H\delta = 0 = \delta d_V + d_V\delta,$$

and is extended as a left antiderivation. The associated grading is obtained from the eigenvalues of the antighost number operator defined by

$$\text{antigh} = \phi^*_{a(\mu)}\frac{\partial^L}{\partial\phi^*_{a(\mu)}} + d_V\phi^*_{a(\mu)}\frac{\partial^L}{\partial d_V\,\phi^*_{a(\mu)}} + 2C^*_{a_1(\mu)}\frac{\partial^L}{\partial C^*_{a_1(\mu)}} + 2\,d_V C^*_{a_1(\mu)}\frac{\partial^L}{\partial\, d_V C^*_{a_1(\mu)}}. \tag{A13}$$

As in Ref. 6, one can then prove that

$$H_0(\delta, \Omega_0^{*,*}(J^\infty(K))) \simeq \Omega^{*,*}(J^\infty(E))/\mathscr{N} \simeq \Omega^{*,*}(\mathscr{R}^\infty), \tag{A14}$$

and that

$$H_k(\delta, \Omega_k^{*,*}(J^\infty(K))) = 0, \quad \text{for } k > 0. \tag{A15}$$

Here, $\mathscr{N}$ is the ideal of forms such that each term contains at least one of the terms $\partial_{(\mu)}\mathscr{R}_a$ or $d_V\,\partial_{(\mu)}\mathscr{R}_a$. Hence, locally, the quotient is isomorphic to the forms in dx^μ and $d_V x_A$ with coefficients that are smooth functions in the x^μ, x_A. By using a partition of unity, we then get the last isomorphism in the above equation. This means that the diagram,

$$\cdots \xrightarrow{\delta} \Omega_k^{*,*}(J^\infty(K)) \xrightarrow{\delta} \Omega_{k-1}^{*,*}(J^\infty(K)) \xrightarrow{\delta} \cdots$$

$$\cdots \xrightarrow{\delta} \Omega_1^{*,*}(J^\infty(K)) \xrightarrow{\delta} \Omega^{*,*}(\mathscr{R}^\infty) \to 0,$$

is exact.

In the three-dimensional grid corresponding to the tricomplex,

$$(\Omega_*^{*,*}(J^\infty(K), d_H, d_V, \delta)), \tag{A16}$$

augmented by the projection on local functionals in the d_H direction and by the projection on the bicomplex for the partial differential equations $(\Omega^{*,*}(\mathscr{R}^\infty), d_H, d_V)$ in the δ direction, except for the rows of this last complex, the sequences are exact in all directions.

The advantage of this cohomological resolution of the variational bicomplex for partial differential equations is that the nontrivial cohomology groups $H^{r,*}(d_H, \Omega^{r,*}(\mathscr{R}^\infty))$ are given by relative cohomology groups in the free tricomplex,

$$H^{r,*}(d_H, \Omega^{r,*}(\mathscr{R}^\infty)) \simeq H_0^{r,*}(d_H|\,\delta, \Omega_0^{r,*}(J^\infty(K))). \tag{A17}$$

Since $H_*^{q,*}(d_H,\Omega_*^{q,*}(J^\infty(K)))=0$ for $0<q<n$ and $H_k^{*,*}(\delta,\Omega_k^{*,*}(J^\infty(K)))=0$ for $k>0$, one can, for instance, apply the method of diagram chasing (or ''snake lemma'') in the horizontal and δ directions to get, for $(r,s)\neq(0,0)$,

$$H_0^{r,s}(d_H|\,\delta,\Omega_0^{r,s}(J^\infty(K)))\simeq H_1^{r+1,s}(d_H|\,\delta,\Omega_1^{r,s}(J^\infty(K)))\simeq\cdots\simeq H_{n-r-1}^{n-1,s}(d_H|\,\delta,\Omega_{n-r-1}^{n-1,s}(J^\infty(K))). \tag{A18}$$

For $(r,s)=(0,0)$, the same chain of isomorphisms remain true if one replaces the first element in the chain by $H^{0,0}(d_H|\delta,\Omega_0^{0,0}(J^\infty(K)))/\mathbf{R}$. Furthermore, like in Ref. 9, one proves that

$$\frac{H_k^{r,*}(d_H|\,\delta,\Omega_k^{r,*}(J^\infty(K)))}{p^\sharp H_k^{r,*}(d_H,\Omega_k^{r,*}(J^\infty(K)))}\simeq\frac{H_{k+1}^{r+1,*}(\delta|d_H,\Omega_{k+1}^{r+1,*}(J^\infty(K)))}{p^\sharp H_{k+1}^{r+1,*}(\delta,\Omega_{k+1}^{r+1,*}(J^\infty(K)))}, \tag{A19}$$

where $p^\sharp$ denotes the natural inclusion of an absolute cohomology group as a relative cohomology group. Using the results on the cohomology of d_H and δ, these relations reduce to

$$H_0^{0,0}(d_H|\,\delta,\Omega_0^{0,0}(J^\infty(K)))/\mathbf{R}\simeq H_1^{1,1}(\delta|d_H,\Omega_1^{1,1}(J^\infty(K))), \tag{A20}$$

$$H_k^{r,*}(d_H|\,\delta,\Omega_k^{r,*}(J^\infty(K)))\simeq H_{k+1}^{r+1,*}(\delta|d_H,\Omega_{k+1}^{r+1,*}(J^\infty(K))),\quad (r,s,k)\neq(0,0,0),\quad r<n. \tag{A21}$$

APPENDIX B: LOCAL BRACKETS AND SURFACE TERMS

In the first part of this appendix, we want to calculate explicitly the total divergences that arise in the Jacobi identity for the local (anti)bracket.

Let $z^a=(\phi^A,\phi_A^*)$ and

$$\zeta^{ab}=\begin{pmatrix}0 & \delta_B{}^A\\ -\delta_B{}^A & 0\end{pmatrix}.$$

Let $(\tilde{\nu})_{\mu_1}$ denote the number of times the index μ appears in the multiindex (ν). The higher Euler operators[7] are uniquely defined by the expression

$$\delta_Q f=\partial_{(\nu)}\left(Q^a\,\frac{\delta^L f}{\delta z^a_{(\nu)}}\right). \tag{B1}$$

Let us furthermore define the ''generalized Hamiltonian vector field:''

$$\overline{a^b}=\left(\frac{\delta^R\hat{a}}{\delta z^a}\right)\zeta^{ab}. \tag{B2}$$

Then the local antibracket in the space of integrands (9) can be rewritten as

$$\{a_1,a_2\}=d^nx\left[\partial_{(\mu)}\left(\frac{\delta^R\hat{a}_1}{\delta z^a}\right)\zeta^{ab}\left(\frac{\partial^L\hat{a}_2}{\partial z^b_{(\mu)}}\right)-\frac{(\tilde{\nu})_\mu+1}{|\nu|+1}\,\partial_{\mu(\nu)}\left(\frac{\delta^R\hat{a}_1}{\delta z^a}\,\zeta^{ab}\,\frac{\delta\hat{a}_2}{\delta z^b_{\mu(\nu)}}\right)\right]\equiv\delta\overline{_{a_1}}a_2-dI\overline{_{a_1}}\,a_2. \tag{B3}$$

This expression implies that the graded Leibnitz rule holds up to a total divergence.

We have pointed out in the text that the local antibracket (B3) does not satisfy the graded Jacobi identity strictly, but only up to a total divergence. Similarly, in the Hamiltonian theory, the Poisson bracket among local functions of the fields, their conjugate momenta, and their derivatives,

$$\{\hat{a}_1,\hat{a}_2\}_{\mathrm{P}}=\frac{\widetilde{\delta}^R\hat{a}_1}{\delta\phi^i}\,\sigma^{ij}\,\frac{\widetilde{\delta}^L\hat{a}_2}{\delta\phi^j}, \tag{B4}$$

satisfies the Jacobi identity $\{\hat{a},\{\hat{b},\hat{c}\}\}+cyclic=0$ only up to a (spatial) total divergence. In Eq. (B4), ϕ^i collectively denotes the fields and their conjugate momenta, the tilde superscript denotes the spatial Euler–Lagrange derivatives, and

$$\sigma^{ij}=\begin{pmatrix} 0 & \delta^i_j \\ -\delta^i_j & 0 \end{pmatrix}.$$

For definiteness, we shall evaluate here explicitly the boundary terms in the Jacobi identity in the Hamiltonian case and assume that the fields ϕ^i and the densities $\hat{a}$, $\hat{b}$, and $\hat{c}$ are all even. We will, however, not write explicitly the tilded superscript to indicate the spatial derivatives. The calculation for the local antibracket or the local extended Poisson bracket is simply a matter of taking care of the sign factors.

We will need the following lemma:

$$(-\partial)_{(\alpha)}\left(f\,\frac{\partial}{\partial\phi^i_{(\alpha)}}\,\partial_\beta g\right)=-(-\partial)_{(\alpha)}\left(\partial_\beta f\,\frac{\partial}{\partial\phi^i_{(\alpha)}}\,g\right). \tag{B5}$$

The proof of this lemma follows from a straightforward extension of the proof of $(\delta/\delta\phi^i)(\partial_\beta g)=0$ in Ref. 15.

A direct calculation, using the analog of (B3) for the Poisson bracket and the fact that the Euler–Lagrange derivatives annihilate total divergences, yields

$$\begin{aligned}\{a,\{b,c\}\}+cyclic&=\{a,\{b,c\}\}-\{b,\{a,c\}\}-\{\{a,b\},c\}\\&=\delta_{\bar{a}}\delta_{\bar{b}}c-\delta_{\bar{b}}\delta_{\bar{a}}c-\delta_{\{\overline{a,b}\}}c,\end{aligned} \tag{B6}$$

$$-dI_{\bar{a}}(\delta_{\bar{b}}c)+dI_{\bar{b}}(\delta_{\bar{a}}c)+dI_{\{\overline{a,b}\}}c. \tag{B7}$$

We have

$$(\delta_{\bar{a}}\delta_{\bar{b}}-\delta_{\bar{b}}\delta_{\bar{a}})c=\delta_{\bar{d}}c, \tag{B8}$$

with

$$\begin{aligned}\overline{d^i}&=\delta_{\bar{a}}\left(\frac{\delta\hat{b}}{\delta\phi^j}\right)\sigma^{ji}-(\hat{a}\leftrightarrow\hat{b})\\&=\frac{\delta}{\delta\phi^j}(\delta_{\bar{a}}\hat{b})\sigma^{ji}-(-\partial)_{(\alpha)}\left[\frac{\partial}{\partial\phi^j_{(\alpha)}}\left(\partial_{(\beta)}\,\frac{\delta\hat{a}}{\delta\phi^k}\right)\sigma^{kl}\,\frac{\partial\hat{b}}{\partial\phi^l_{(\beta)}}\right]\sigma^{ji}-(\hat{a}\leftrightarrow\hat{b})\\&=\frac{\delta}{\delta\phi^j}\{\hat{a},\hat{b}\}\sigma^{ji}-(-\partial)_{(\alpha)}\left[\frac{\partial}{\partial\phi^j_{(\alpha)}}\left(\frac{\delta\hat{a}}{\delta\phi^k}\right)\sigma^{kl}\,\frac{\delta\hat{b}}{\delta\phi^l}\right]\sigma^{ji}-(\hat{a}\leftrightarrow\hat{b})\\&=2\,\frac{\delta}{\delta\phi^j}\{\hat{a},\hat{b}\}\sigma^{ji}-(-\partial)_{(\alpha)}\left[\frac{\partial}{\partial\phi^j_{(\alpha)}}\left(\frac{\delta\hat{a}}{\delta\phi^k}\,\sigma^{kl}\,\frac{\delta\hat{b}}{\delta\phi^l}\right)\right]\sigma^{ji}=\frac{\delta}{\delta\phi^j}\{\hat{a},\hat{b}\}\sigma^{ji}=\{\overline{a,b}\}^i.\end{aligned} \tag{B9}$$

To get the line before last, we have used repeatedly the above-mentioned lemma (B5). Hence,

$$\{a,\{b,c\}\}+cyclic=d(-I_{\bar{a}}(\delta_{\bar{b}}c)+I_{\bar{b}}(\delta_{\bar{a}}c)+I_{\{\overline{a,b}\}}c). \tag{B10}$$

This is the desired formula.[h] □

We now prove that the expressions in Eq. (25) for the Dickey bracket are equivalent to the definition in Eq. (24). Let us write terms that vanish on shell by $\delta(\ )$. By applying the lemma (B5), we find that, if X is the characteristic of a variational symmetry, the following equation holds:

$$\delta_X\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}\right)Y^i\ d^nx=-(-\partial)_{(\mu)}\left[\frac{\partial}{\partial\phi^i_{(\mu)}}\,(\partial_{(\nu)}X^j)\,\frac{\partial\hat{\mathscr{L}}_0}{\partial\phi^j_{(\nu)}}\right]Y^i\ d^nx$$
$$=-(-\partial)_{(\mu)}\left[\frac{\partial}{\partial\phi^i_{(\mu)}}\,(X^j)\,\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^j}\right]Y^i\ d^nx=-\delta_Y(X^j)\,\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^j}\,d^nx+d\,\delta(\ ). \tag{B11}$$

Let us evaluate $d(-\delta_{X_1}j_2)$. Using (B11) twice, we get,

$$d(-\delta_{X_1}j_2)=-\delta_{X_1}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}\,X_2^i\right)d^nx+d\,\delta(\ )$$
$$=-\delta_{X_1}(X_2^i)\,\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}\,d^nx+\delta_{X_2}(X_1^j)\,\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i}\,d^nx+d\,\delta(\ ), \tag{B12}$$

$$=d(\delta_{X_2}j_1)+d\,\delta(\ ). \tag{B13}$$

From this equation it also follows immediately that

$$d(-\delta_{X_1}j_2)=\tfrac{1}{2}\,d(\delta_{X_2}j_1)-d(\delta_{X_1}j_2)+d\,\delta(\ ). \tag{B14}$$

Using the triviality of the cohomology of d in form degree $n-1(>0)$ implies the first two expressions in Eq. (25).

From Eq. (B12), it follows that

$$d(-\delta_{X_1}j_2)=\left[\delta_{[X_1,X_2]_L}\hat{\mathscr{L}}_0-\frac{(\widetilde{\nu})_\mu+1}{|\nu|+1}\,\partial_{\mu(\nu)}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\,[X_1,X_2]_L^i\right)\right]d^nx+d\,\delta(\ ). \tag{B15}$$

But we also have

$$\delta_{[X_1,X_2]}\hat{\mathscr{L}}_0=(\delta_{X_2}\delta_{X_1}-\delta_{X_1}\delta_{X_2})\hat{\mathscr{L}}_0$$
$$=\partial_\mu(\delta_{X_2}j_1^\mu-\delta_{X_1}j_2^\mu)+\frac{(\widetilde{\nu})_\mu+1}{|\nu|+1}\,\partial_{\mu(\nu)}\left[\delta_{X_2}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\,X_1^i\right)-\delta_{X_1}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\,X_2^i\right)\right]. \tag{B16}$$

This implies

$$d(-\delta_{X_1}j_2)=d(\delta_{X_2}j_1-\delta_{X_1}j_2)+\frac{(\widetilde{\nu})_\mu+1}{|\nu|+1}\,\partial_{\mu(\nu)}\left(\delta_{X_2}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\right)X_1^i-\delta_{X_1}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\right)X_2^i\right)d^nx$$
$$+d\,\delta(\ ). \tag{B17}$$

Using (B14), we find the last expression of (25):

$$d(-\delta_{X_1} j_2) = -\frac{(\tilde{\nu})_\mu + 1}{|\nu|+1}\,\partial_{\mu(\nu)}\left(\delta_{X_2}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\right)X_1^i - \delta_{X_1}\left(\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i_{(\nu)\mu}}\right)X_2^i\right)d^n x + d\,\delta(\ ). \quad \text{(B18)}$$

□

In the last part of the appendix, we establish the relationship between the antibracket map and the Dickey bracket. As explained before theorem 2, we have to evaluate $\delta\{a_1,a_2\}$, where $a = d^n x\ \phi_i^* X^i$, with X^i defining a variational symmetry:

$$\delta\{a_1,a_2\} = \left(d^n x\,\frac{\delta X_1^i}{\delta\phi^j}\,X_2^j - \frac{\delta X_2^i}{\delta\phi^j}\,X_1^i\right)\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i} = d^n x(\delta_{X_2}X_1^i - \delta_{X_1}X_2^i)\,\frac{\delta\hat{\mathscr{L}}_0}{\delta\phi^i} + d\,\delta(\ )$$
$$= d(-\delta_{X_1} j_2) + d\,\delta(\ ), \quad \text{(B19)}$$

where we have used (B12) in order to get the last equality. This proves that to the antibracket map of two classes in $H_1^n(\delta|d)$ corresponds to the Dickey bracket of the corresponding currents. □

APPENDIX C: DESCENT EQUATIONS IN THE HAMILTONIAN FORMALISM

We analyze in this appendix, first of all, the relationship between the cohomology of s_{H} defined in Eq. (37) and the cohomology of s_ω, thereby proving Theorem 5. Then we analyze the spatiotemporal descent equations of s_{H} by choosing representatives appropriate to the Hamiltonian formalism, proving Eqs. (41)–(46).

1. Cohomology of s_{H} and s_ω

The cocyle n in $s_{\mathrm{H}} n = 0$ depends on the coordinates $x^\mu, \partial_{(\mu)}\tilde{\phi}^A, \partial_{(\mu)}\tilde{\phi}^*_A$. Consider the change of coordinates, which consists in replacing the time derivatives of the fields and all their derivatives by the $\partial_{(\mu)}\mathscr{L}_A$. In the new coordinates, n depends on $x^\mu, \partial_{(k)}\tilde{\phi}^A, \partial_{(\mu)}\tilde{\phi}^*_A, \partial_{(\mu)}\mathscr{L}_A$. Using $s_\omega\Omega = s_\omega H = 0$ and the identity

$$-s_\omega\{\tilde{\phi}^*_A\tilde{\phi}^A,\cdot\}_{\mathrm{P,alt}} + \partial_{(k)}\,\frac{\tilde{\delta}^R}{\delta\tilde{\phi}^C}\,(\sigma^{CA}\{\tilde{\phi}^*_B\tilde{\phi}^B,\omega\}_{\mathrm{P,alt}})\,\frac{\partial^L}{\partial(\partial_{(k)}\tilde{\phi}^A)} = \{\tilde{\phi}^*_A\tilde{\phi}^A, s_\omega\cdot\}_{\mathrm{P,alt}} \quad \text{(C1)}$$

we find that $s_{\mathrm{H}}\mathscr{L}_A = 0$. This means that in the new coordinate system,

$$s_{\mathrm{H}} = s_\omega + \partial_{(\mu)}\mathscr{L}_A\,\frac{\partial^L}{\partial(\partial_{(\mu)}\tilde{\phi}^*_A)}, \quad \text{(C2)}$$

where s_ω is restricted to spatial derivatives. Introducing the contracting homotopy,

$$\rho = \partial_{(\mu)}\tilde{\phi}^*_A\,\frac{\partial^L}{\partial(\partial_{(\mu)}\mathscr{L}_A)}, \quad \text{(C3)}$$

the anticommutator $\{s_{\mathrm{H}},\rho\} = N = z^\alpha(\partial^L/\partial z^\alpha)$ is the operator counting the number of coordinates, $z^\alpha \equiv \partial_{(\mu)}\tilde{\phi}^*_A, \partial_{(\mu)}\mathscr{L}_A$. The standard argument is then that

$$n = n(z^\alpha = 0) + \int_0^1 \frac{d\lambda}{\lambda}\,(Nn)[\lambda z^\alpha], \quad \text{(C4)}$$

$$= n_0 + s_{\mathrm{H}}\left(\int_0^1 \frac{d\lambda}{\lambda}\,(\rho n)[\lambda z^\alpha]\right). \quad \text{(C5)}$$

The cocycle condition now reduces to $s_\omega n_0=0$, and the coboundary condition $n_0=s_{\mathrm{H}}p$ reduces to $n_0=s_\omega p_0$. Indeed, applying N to the coboundary condition implies that $Ns_{\mathrm{H}}p=0$. Using

$$[N,s_{\mathrm{H}}]=0, \tag{C6}$$

and the same decomposition of p as for n in (C4), this equation implies that $s_{\mathrm{H}}p=s_\omega p_0$.

This proves Theorem 5. □

In order to analyze the spatiotemporal descent equations for s_{H}, we start form the bottom, which we can assume to be of the form n_0, as above. We then want to know under what conditions n_0 can be lifted i.e., what are the conditions for the existence of m, such that $s_{\mathrm{H}}m+dn_0=0$. We will now prove, in particular, the crucial lemma that m can be assumed to be independent of the coordinates $\partial_{(\mu)}\mathscr{L}_A$, with a linear dependence in the antifields $\partial_{(k)}\tilde{\phi}^*_A$ only in the terms involving the differential dt.

2. First lift from the bottom of the descent equations

The spatial exterior differential has the same form in the new coordinate system as it had in the old one. The total time derivative, however, is given by

$$\frac{d}{dt}=\frac{\partial}{\partial t}+\partial_{(k)l+1}\tilde{\phi}^*_A\,\frac{\partial^L}{\partial(\partial_{(k)l}\tilde{\phi}^*_A)}+\partial_{(k)l+1}\mathscr{L}_A\,\frac{\partial^L}{\partial(\partial_{(k)l}\mathscr{L}_A)}$$
$$+\partial_{(k)}\sigma^{CA}\left[-\mathscr{L}_C-\frac{\tilde{\delta}^R h}{\delta\tilde{\phi}^C}-\frac{\tilde{\delta}^R}{\delta\tilde{\phi}^C}\{\tilde{\phi}^*_B\tilde{\phi}^B,\omega\}_{\mathrm{P,alt}}\right]\frac{\partial^L}{\partial(\partial_{(k)}\tilde{\phi}^A)}. \tag{C7}$$

We then decompose m and n_0 into pieces, respectively, containing the differential dt or not (m^0, n_0^0, and $\tilde{m},\tilde{n}_0$). The cocycle condition splits into

$$s_{\mathrm{H}}\tilde{m}+\tilde{d}\tilde{n}_0=0,\quad s_{\mathrm{H}}m^0+\tilde{d}n_0^0-\frac{d}{dt}\,\tilde{n}_0=0 \tag{C8}$$

From the homotopy formula (C4) applied to $\tilde{m}$ and the cocycle condition, we get that $\tilde{m}=\tilde{m}_0+s_{\mathrm{H}}(\ )-\tilde{d}(\int_0^1(d\lambda/\lambda)(\rho\tilde{n}_0)[\lambda z^\alpha)$ because ρ (anti)commutes with $\tilde{d}$ and $\tilde{d}$ is homogeneous of degree 0 in z^α. The last expression vanishes since $\rho\tilde{n}_0=0$. Injecting the remaining expression into the cocycle condition, we get

$$s_\omega\tilde{m}_0+\tilde{d}\tilde{n}_0=0. \tag{C9}$$

The homotopy formula (C4) applied to m^0, together with the cocycle condition, implies that

$$m^0=m_0^0+s_{\mathrm{H}}(\ )+\tilde{d}\left(\int_0^1\frac{d\lambda}{\lambda}\,(\rho n_0^0)\right)+\int_0^1\frac{d\lambda}{\lambda}\,\rho\sigma^{CA}\partial_{(k)}\left(-\mathscr{L}_C-\frac{\tilde{\delta}^R h}{\delta\tilde{\phi}^C}\right.$$
$$\left.-\frac{\tilde{\delta}^R}{\delta\tilde{\phi}^C}\{\tilde{\phi}^*_B\tilde{\phi}^B,\omega\}_{\mathrm{P,alt}}\right)\frac{\partial^L}{\partial(\partial_{(k)}\tilde{\phi}^A)}\,\tilde{n}_0[\lambda z^\alpha]$$
$$=m_0^0+s_{\mathrm{H}}(\ )-\{\tilde{\phi}^*_A\tilde{\phi}^A,\tilde{n}_0\}_{\mathrm{P,alt}}, \tag{C10}$$

proving in particular the lemma on the dependence of m on the coordinates z^α. Injecting this last expression in the cocycle condition, using $s_\omega n_0^0=0$ and (C1), implies

$$s_\omega m_0^0 + \tilde{d} n_0^0 - \frac{\partial}{\partial t} \tilde{n}_0 + \{h, \tilde{n}_0\}_{\mathrm{P,alt}} = 0. \tag{C11}$$

3. Next steps in the lifting procedure

We then have to try to lift the equivalent representative of m given by

$$m' = dt(-\{\tilde{\phi}_A^* \tilde{\phi}^A, \tilde{n}_0\}_{\mathrm{P,alt}} + m_0^0) + \tilde{m}_0, \tag{C12}$$

i.e., find $l = dt\ l^0 + \tilde{l}$, such that $s_{\mathrm{H}} l + d m' = 0$. This implies

$$s_{\mathrm{H}} \tilde{l} + \tilde{d} \tilde{m}_0 = 0, \quad s_{\mathrm{H}} l^0 + \tilde{d}(-\{\tilde{\phi}_A^* \tilde{\phi}^A, \tilde{n}_0\}_{\mathrm{P,alt}} + m_0^0) - \frac{d}{dt} \tilde{m}_0 = 0. \tag{C13}$$

By exactly the same reasoning as before, the first equation implies that

$$\tilde{l} = \tilde{l}_0 + s_{\mathrm{H}}(\ ), \quad s_\omega \tilde{l}_0 + \tilde{d} \tilde{m}_0 = 0. \tag{C14}$$

The second equation implies as before that

$$l^0 = l_0^0 + s_{\mathrm{H}}(\ ) - \{\tilde{\phi}_A^* \tilde{\phi}^A, \tilde{m}_0\}_{\mathrm{P,alt}}, \tag{C15}$$

because ρ annihilates the supplementary $\tilde{\phi}_A^*$-dependent term, which does not depend on $\mathscr{S}_A$. Injecting into the cocycle condition, we get

$$s_\omega l_0^0 + \tilde{d} m_0^0 - \frac{\partial}{\partial t} \tilde{m}_0 + \{h, \tilde{m}_0\}_{\mathrm{P,alt}} = 0, \tag{C16}$$

the supplementary antifield-dependent term in m^0 cancelling the term coming from (C1) using the fact that $s_\omega \tilde{m}_0 + \tilde{d} \tilde{n}_0 = 0$. This shows that at every step we get the same dependence on the coordinates z^α, i.e., independence on $\partial_{(\mu)} \mathscr{S}_A$, or by going back to the old coordinate system, on the time derivatives of the fields, with a linear dependence in the antifields and their spatial derivatives $\partial_{(k)} \tilde{\phi}_A^*$ only in the terms involving the differential dt. Furthermore, we have proved the set of equations (41)–(43).

4. Coboundary condition

Let us now consider the coboundary condition for l' defined in an analoguous way as m' in (C12). From $l' = s_{\mathrm{H}} r + d u$, we have, by applying s_{H}, that $s_{\mathrm{H}} u + d p = 0$. Hence, u satisfies the same equation as l above, which implies by (C14) and an appropriate modification of r that we can assume $\tilde{u} = \tilde{u}_0$ and $u^0 = u_0^0 - \{\tilde{\phi}_A^* \tilde{\phi}^A, \tilde{p}_0\}_{\mathrm{P,alt}}$.

We have that $\tilde{l}_0 = s_{\mathrm{H}} \tilde{r} + \tilde{d} \tilde{u}$, which implies, by applying the homotopy formula (C4) to r, that we can assume that $\tilde{r} = \tilde{r}_0$, $\tilde{u} = \tilde{u}_0$. The coboundary condition becomes $\tilde{l}_0 = s_\omega \tilde{r}_0 + \tilde{d} \tilde{u}_0$, proving Eq. (45).

By applying the homotopy formula (C4) to r^0, the coboundary condition,

$$-\{\tilde{\phi}_A^* \tilde{\phi}^A, \tilde{m}_0\}_{\mathrm{P,alt}} + l_0^0 = -s_{\mathrm{H}} r^0 - \tilde{d} u^0 + \frac{d}{dt} \tilde{u}_0, \tag{C17}$$

implies

$$-\{\tilde{\phi}^*_A\tilde{\phi}^A,\tilde{n}_0\}_{\mathrm{P,alt}}+l^0_0=-s_\omega r^0_0-s_{\mathrm{H}}\int_0^1\frac{d\lambda}{\lambda}\left(\rho\left(\{\tilde{\phi}^*_A\tilde{\phi}^A,\tilde{m}_0\}_{\mathrm{P,alt}}-l^0_0-\tilde{d}u^0+\frac{d}{dt}\,\tilde{u}_0\right)\right)[\lambda z^\alpha]-\tilde{d}u^0+\frac{d}{dt}\,\tilde{u}_0. \tag{C18}$$

This gives

$$l^0_0=-s_\omega r^0_0-\tilde{d}u^0_0+\frac{\partial}{\partial t}\,\tilde{u}_0-\{h,\tilde{u}_0\}_{\mathrm{P,alt}}, \tag{C19}$$

proving Eq. (46). These coboundary conditions are satisfied by choosing in the equation $l=s_{\mathrm{H}}r+du$, r to be given by $dt(-\{\tilde{\phi}^*_A\tilde{\phi}^A,\tilde{u}_0\}_{\mathrm{P,alt}}+r^0_0)+\tilde{r}_0$ and a similar equation holding for u. This proves (44). □

NOTES

[a]We will not be too precise about the nature of the field dependence of the local functions (polynomiality or smooth dependence). Similarly, we will not specify whether one should consider polynomials or infinite formal series in the antifields and their derivatives,[8] since most aspects we will consider are really independent of these considerations. For simplicity, we will assume, however, that all the fields live on a star-shaped space.

[b]One uses the facts that (i) $\{\cdot,\cdot\}_{\mathrm{alt}}$ differs from $\{\cdot,\cdot\}$ by a total divergence; (ii) that $\{\cdot,\cdot\}$ satisfies the graded Jacobi up to a total divergence; and (iii) that Euler–Lagrange derivatives annihilate total divergences.

[c]This exhausts the arbitrariness of the functions $X^{i(\lambda)}$ only in the case where the equations and their derivatives are independent;[7,6] in the general case, one has to also take care of the Noether identities, as shown below.

[d]One says that the Koszul–Tate differential δ provides a homological resolution of the functions defined on the stationary surface (also see Appendix A).

[e]A trivial variational symmetry vanishes on the stationary surface. Under certain assumptions,[8] one can prove that *vice versa* every variational symmetry that vanishes on the stationary surface corresponds to a trivial representative of $H^{-1,n}(s|d)$, i.e., an ''antisymmetric'' combination of the equations of motion.

[f]This is the formalization in the appropriate jet space of the idea that functions linear in the antifields define tangent vectors,[16] the physically relevant ones here being those that are ''tangent'' to the stationary surface.

[g]These equations have been first used in Ref. 17 to compare anomalies in the Hamiltonian and the Lagrangian formalism.

[h]It also follows from this proof that the alternative bracket given by $\{a,b\}_{\mathrm{alt}}=\delta_a b$ satisfies a strict Jacobi identity under Leibnitz form [defined by the second expression of (B6)], using, furthermore, the fact that $\{\overline{a,b}\}_{\mathrm{alt}}=\{\overline{a,b}\}$.

On Green–Cusson Ansätze and deformed supersymmetric quantum mechanics

J. Beckers[a] and N. Debergh[b]
Theoretical and Mathematical Physics, Institute of Physics (B.5), University of Liège, B-4000-Liege 1, Belgium

(Received 6 October 1995; accepted for publication 1 July 1996)

Supersymmetric quantum mechanics cannot be deformed when the superposition of only a pair of usual bosons and fermions is considered, but it can if nontrivial parabosons and parafermions of the same order p of paraquantization are superposed. We take the simplest case $p=2$ and exhibit reducibility problems in that context by using Green–Cusson Ansätze following Macfarlane methods. Specific representations of the Lie superalgebra osp $(2|2, \mathbb{R})$ play an interesting role in connection with possible deformations. © *1996 American Institute of Physics.* [S0022-2488(96)01411-9]

I. INTRODUCTION

By revisiting the so-called *Green Ansätze*[1] in parastatistical developments,[2,3] Macfarlane[4] has recently pointed out some *''methods allowing various new results for q-deformed (parabose) oscillators to be derived.''* In particular, Fock bases characterized by bilinear (rather than trilinear) structure relations play a very interesting role in such considerations. Here, we plan to exploit the corresponding *Green–Cusson Ansätze*[5,6] in the study of quantum deformations in a fundamental physical theory such as supersymmetric quantum mechanics (SSQM).[7]

Let us recall that quantum deformations[8] have been investigated, developed, and applied in a large number of fields in quantum physics. More recently, different generalizations[9–13] have also been proposed in order to cover a maximum of information through refined methods.

In particular, a specific question has been asked by Spiridonov[14] in connection with the possible deformation of the standard Witten model[7] of SSQM. A few months later, his answer presented as a q-deformation has been shown[15] as resulting only from ordinary SSQM but including q-dependent superpotentials. It is now evident that SSQM [based on the $D^{(1/2)-}$ representation of su$(2,\mathbb{C})$] cannot be deformed although its super-Hamiltonian can.[16] Let us also mention another recent approach[17] containing investigations on links between high-order derivative supersymmetry and q-deformed SSQM but without direct connections with the point of view we want to develop here.

One of the main purposes of this paper is to circumvent this difficulty by using the above-mentioned Green–Cusson Ansätze and by constructing, in the Macfarlane way, a Fock space exploiting the context of the second-order $(p=2)$ of paraquantization in the so-called relative parabosonic (or relative parafermionic) set characterized by Greenberg and Messiah.[3] Through such developments we will show that SSQM can be deformed by exploiting previous results.[6,18]

The contents of this paper are then distributed as follows. In Sec. II we summarize a few properties[18] resulting from supersymmetric developments in connection with parabosons and parafermions (of order 2, but also valid for arbitrary orders), an important one being the existence of an invariance Lie superalgebra of SSQM, i.e., the orthosymplectic Lie superalgebra osp $(2/2,\mathbb{R})$. Section III is then devoted to the construction of an effective Fock basis in the context of the relative parabosonic set when Green–Cusson Ansätze are exploited. The corresponding state

[a]Electronic mail: Jules.Beckers@ulg.ac.be
[b]Institut Interuniversitaire des Sciences Nucléaires, Brussels.

vectors will appear as characterized by a family of six (simultaneously measurable) observables associated with two usual bosons and four usual fermions. They will be classified in three irreducible representations of the above orthosymplectic Lie superalgebra and will allow us to determine the energy superspectrum of such a context. In Sec. IV, we construct the pair of deformed parabosonic and parafermionic operators leading to generalized deformed supercharges in particular, but also to the eight deformed generators of the orthosymplectic Lie superalgebra. In Sec. V we discuss possible deformations of the superalgebra sqm (2) seen as a subalgebra of osp $(2/2,\mathbb{R})$. The conclusion will be that, effectively, SSQM can be deformed.

II. SUMMARY OF SOME PRECEDING RESULTS

After Greenberg–Messiah,[3] we have learned that there exist only two different relative sets of *trilinear* structure relations which are respectively called the *parabosonic* (or *para-Bose*) and *parafermionic* (or *para-Fermi*) sets characterized by typical relations as follows. If we denote by a (and $a^\dagger$) the parabosonic annihilation (and creation) operator(s) and by b (and $b^\dagger$) the parafermionic annihilation (and creation) operator(s), we have for the two sets the *common* structure relations (when only one pair of paraparticles are concerned)

$$\begin{gathered}[a,\{a^\dagger,a\}]=2a, \quad [b,[b^\dagger,b]]=2b,\\ [\{a^\dagger,a\},b]=0, \quad [[b^\dagger,b],a]=0,\\ [\{a,a\},b]=0, \quad [\{a^\dagger,a^\dagger\},b]=0.\end{gathered} \tag{2.1a}$$

They are supplemented by the following ones,

$$\begin{gathered}[\{a,b\},a^\dagger]=-[\{a^\dagger,b\},a]=2b,\\ \{\{a,b^\dagger\},b\}=\{\{a,b\},b^\dagger\}=2a,\\ [\{a,b\},a]=\{\{a,b\},b\}=0,\\ [\{a^\dagger,b\},a^\dagger]=\{\{a,b^\dagger\},b^\dagger\}=0,\end{gathered} \tag{2.1b}$$

when the *relative parabosonic set* is concerned, *and* by

$$\begin{gathered}\{a,[a^\dagger,b]\}=\{a^\dagger,[b,a]\}=2b,\\ [b^\dagger,[b,a]]=[b,[b^\dagger,a]]=2a,\\ [b,[a,b]]=\{a,[b,a]\}=0,\\ [b^\dagger,[a,b^\dagger]]=\{a^\dagger,[b,a^\dagger]\}=0,\end{gathered} \tag{2.1c}$$

when the *relative parafermionic set* is concerned.

From the first and second sets, we have shown[18] that it is possible to define two supercharges in each context such that, with the corresponding Hamiltonian H, they generate the superalgebra of ordinary SSQM, i.e., sqm (2) (Ref. 7) characterized by the structure relations

$$H=\{Q,Q^\dagger\}, \quad \{Q,Q\}=\{Q^\dagger,Q^\dagger\}=0, \quad [H,Q]=[H,Q^\dagger]=0, \tag{2.2}$$

where H is the sum of a (para)bosonic part $\frac{1}{2}\{a,a^\dagger\}$ and a (para)fermionic part $\frac{1}{2}[b^\dagger,b]$ as in SSQM. Indeed, we have defined, for the relative *parabosonic* set (2.1a) and (2.1b), the two supercharges

$$Q_{(1)}=\tfrac{1}{2}\{a,b\},\quad Q_{(1)}^{\dagger}=\tfrac{1}{2}\{b^{\dagger},a^{\dagger}\} \tag{2.3a}$$

and, in correspondence with the relativistic *parafermionic* set (2.1a) and (2.1c), the other two supercharges

$$Q_{(2)}=\tfrac{1}{2}[a,b],\quad Q_{(2)}^{\dagger}=\tfrac{1}{2}[b^{\dagger},a^{\dagger}], \tag{2.3b}$$

each context ensuring the relations (2.2). Physically speaking, these results mean that the superposition of parabosons with parafermions of order $p=2$ [but this is also true for *arbitrary* orders p (Ref. 18) iff the *same* orders of paraquantization are considered] leads to the rich concept of supersymmetry pointed out by superposing usual bosons and fermions. As we want to show and to exploit in the following, this property leads to a large number of ''reducibility problems,'' as mentioned in particular by Macfarlane[4] in his disconnected considerations on parabosons and parafermions. In fact, we will use the Green–Cusson Ansätze (as proposed in the next section) for illustrating this reducibility.

In order to shorten and to simplify our paper, let us immediately inform the reader that we plan, in the following, to limit ourselves to the explicit use of the relative parabosonic set with the characteristics (2.3a). In fact, all the corresponding developments can also be realized with the relative parafermionic set and the characteristics (2.3b), but they lead to the same conclusions, the resulting (para)supersymmetric Hamiltonian,

$$H=\tfrac{1}{2}\{a,a^{\dagger}\}+\tfrac{1}{2}[b^{\dagger},b], \tag{2.4}$$

being a common operator whose properties have already been pointed out.[18]

III. THE CONSTRUCTION OF A FOCK BASIS FROM THE GREEN–CUSSON ANSÄTZE

As SSQM cannot be deformed when only a pair of usual bosons and fermions are superposed (i.e., when one paraboson and one parafermion of order $p=1$ are superposed), let us go to the order $p=2$ of paraquantization, the first nontrivial order characterized by *trilinear* structure relations but maintaining the main properties of SSQM as recalled in the preceding section. Moreover, let us introduce the Green–Cusson Ansätze for $p=2$ parabosons as well as for $p=2$ parafermions, in order to construct an *ad hoc* Fock basis. This will help us in the realization of the corresponding operators (annihilation and creation ones, parasupercharges, etc.) when, as already chosen, we will consider operators belonging to the *relative parabosonic set* characterized by the structure relations (2.1a) and (2.1b).

Inside this set, let us denote as already mentioned $a(a^{\dagger})$ and $b(b^{\dagger})$ the corresponding annihilation (creation) operators for the paraboson and the parafermion, respectively, so that the Green–Cusson Ansätze can be expressed in terms of a pair of *two* (independent) bosonic oscillators [let us call them in the following a_1 and a_2, see Eq. (3.3a)] and of *four* (independent) fermionic ones [let us call then b_1, b_2, b_3, and f, see Eq. (3.3b)], the motivations for these last four ones having to be justified as follows. The relations (2.1a) and (2.1b) are satisfied if we realize the parabosonic and the parafermionic annihilation operators through the following Green–Cusson Ansätze.

$$a=\sum_{\alpha=1}^{p=2}A_{\alpha}\xi_{\alpha},\quad b=\sum_{\beta=1}^{p=2}B_{\beta}\xi_{\beta}, \tag{3.1}$$

respectively, with the relations[6]

$$\{\xi_{\alpha},\xi_{\beta}\}=2\,\delta_{\alpha\beta},\quad \xi_{\alpha}^{\dagger}=\xi_{\alpha},\quad \alpha,\beta=1,2, \tag{3.2a}$$

$$[A_\alpha, A_\beta^\dagger] = \delta_{\alpha\beta}, \quad \{B_\alpha, B_\beta^\dagger\} = \delta_{\alpha\beta}. \tag{3.2b}$$

The simultaneous consideration of (3.1) thus asks for a usual fermionic annihilation operator [let us call it f, $f \equiv \frac{1}{2}(\xi_1 - i\xi_2)$, see Eqs. (3.3) and (3.4)] besides the two usual bosonic operators A_1, A_2 implied by a in Eq. (3.1) and the two usual fermionic operators B_1, B_2 implied by b in Eq. (3.1) also. These two anticommuting [see Eq. (3.2b)] operators can be replaced by three commuting sets of fermions [see Eq. (3.46)] with

$$B_1 + iB_2 = \sqrt{2} b_1 (b_3 + b_3^\dagger)$$

and

$$B_1 - iB_2 = \sqrt{2} b_2 (b_3 - b_3^\dagger).$$

The Fock basis vectors will then be characterized by two ''eigenvalues'' n_1 and n_2 of the bosonic number operators N_1 and N_2 supplemented by four ''eigenvalues'' σ of the four fermionic number operators corresponding to the four types of necessary fermions. We evidently know that n_1, $n_2 = 0,1,2,...,\infty$ while σ takes only the values 0 or 1, so that we are interested in basis vectors labelled in the following way: $|n_1, n_2, \sigma_1, \sigma_2, \sigma_3, \sigma_4\rangle$. Due to the fact that the independent fermion f has to deal with the usual bosons as well as with the usual fermions, we have to take care of precise combinations inside the resulting Green–Cusson Ansätze. In fact, we explicitly have

$$a = \sqrt{2}(a_1 f + a_2 f^\dagger), \tag{3.3a}$$

where

$$a_1 \equiv \frac{1}{\sqrt{2}}(A_1 + iA_2), \quad a_2 \equiv \frac{1}{\sqrt{2}}(A_1 - iA_2),$$

and

$$b = \sqrt{2}[b_1 (b_3 + b_3^\dagger) f + b_2 (b_3 - b_3^\dagger) f^\dagger]. \tag{3.3b}$$

Let us remember that the independent character of these sets of bosons and fermions requires the relations

$$[a_\alpha, a_\alpha^\dagger] = 1, \quad [a_1, a_2] = 0, \quad \{f, f^\dagger\} = 1, \quad [a_\alpha, f] = 0, \quad \alpha = 1,2 \tag{3.4a}$$

and

$$\begin{gathered} \{b_j, b_j^\dagger\} = 1, \quad [b_j, b_k^\dagger] = 0 \quad (j \neq k), \\ [b_j, b_k] = 0, \quad [b_j, f] = 0, \quad [a_\alpha, b_j] = 0, \quad j,k = 1,2,3. \end{gathered} \tag{3.4b}$$

With such expressions (3.3) and their Hermitian conjugates, we can show that the relative parabosonic set is correctly realized when these operators act on the above Fock basis. A final useful refinement consists of distinguishing more specifically the subspaces corresponding to the eigenvalues $\sigma_4 = 0$ and $\sigma_4 = 1$ due to the specific role played by the fermion f with respect to the two bosons associated with a_1 and a_2 [see Eq. (3.3a)].

At this stage, we are thus interested in the action of a, $a^\dagger$, b, and $b^\dagger$ on the two kinds of states $|n_1, n_2, \sigma_1, \sigma_2, \sigma_3, 0\rangle$ and $|n_1, n_2; \sigma_1, \sigma_2, \sigma_3, 1\rangle$. If we recall[19] that usual bosonic operators are such that

$$a_\alpha|n_\alpha\rangle=\sqrt{n_\alpha}|n_\alpha-1\rangle,\quad a_\alpha^\dagger|n_\alpha\rangle=\sqrt{n_\alpha+1}|n_\alpha+1\rangle,\quad \alpha=1,2, \tag{3.5a}$$

while usual fermionic operators are characterized by

$$b_j|0\rangle=0,\quad b_j|1\rangle=|0\rangle,\quad b_j^\dagger|0\rangle=|1\rangle,\quad b_j^\dagger|1\rangle=0,\quad j=1,2,3,4, \tag{3.5b}$$

it is straightforward to get the following information by taking account of the definitions (3.3):

$$a|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=\sqrt{2n_2}|n_1,n_2-1;\sigma_1,\sigma_2,\sigma_3 1\rangle, \tag{3.6a}$$

$$a|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=\sqrt{2n_1}|n_1-1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle, \tag{3.6b}$$

$$a^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=\sqrt{2(n_1+1)}|n_1+1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle, \tag{3.6c}$$

$$a^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=\sqrt{2(n_2+1)}|n_1,n_2+1;\sigma_1,\sigma_2,\sigma_3,0\rangle, \tag{3.6d}$$

$$\begin{aligned} b|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=&\sqrt{2\sigma_2\sigma_3}|n_1,n_2;\sigma_1,\sigma_2-1,\sigma_3-1,1\rangle\\ &-\sqrt{2\sigma_2(\sigma_3+1)}|n_1,n_2;\sigma_1,\sigma_2-1,\sigma_3+1,1\rangle, \end{aligned} \tag{3.6e}$$

$$\begin{aligned} b|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=&\sqrt{2\sigma_1\sigma_3}|n_1,n_2;\sigma_1-1,\sigma_2,\sigma_3-1,0\rangle\\ &+\sqrt{2\sigma_1(\sigma_3+1)}|n_1,n_2;\sigma_1-1,\sigma_2,\sigma_3+1,0\rangle, \end{aligned} \tag{3.6f}$$

$$\begin{aligned} b^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=&\sqrt{2(\sigma_1+1)\sigma_3}|n_1,n_2;\sigma_1+1,\sigma_2,\sigma_3-1,1\rangle\\ &+\sqrt{2(\sigma_1+1)(\sigma_3+1)}|n_1,n_2;\sigma_1+1,\sigma_2,\sigma_3+1,1\rangle \end{aligned} \tag{3.6g}$$

and

$$\begin{aligned} b^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=&\sqrt{2(\sigma_2+1)(\sigma_3+1)}|n_1,n_2;\sigma_1,\sigma_2+1,\sigma_3+1,0\rangle\\ &-\sqrt{2(\sigma_2+1)\sigma_3}|n_1,n_2;\sigma_1,\sigma_2+1,\sigma_3-1,0\}. \end{aligned} \tag{3.6h}$$

Having these relations at our disposal, it is then easy to verify that all the trilinear relations (2.1a) and (2.1b) are satisfied on the Fock space characterized by the above basis

$$\{|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle\}. \tag{3.7}$$

In order to complete the characteristics of SSQM in the context of the relative parabosonic set, we also have to give the action of the two ''supercharges'' (2.3a) and to confirm[6] that this set admits the simple Lie superalgebra osp(2|2,$\mathbb{R}$) as invariance algebra. Here we obtain

$$\begin{aligned} Q_{(1)}|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle=&\sqrt{\sigma_1\sigma_3 n_2}|n_1,n_2-1;\sigma_1-1,\sigma_2,\sigma_3-1,\sigma_4\rangle+\sqrt{\sigma_1(\sigma_3+1)n_2}|n_1,n_2\\ &-1;\sigma_1-1,\sigma_2,\sigma_3+1,\sigma_4\rangle+\sqrt{\sigma_2\sigma_3 n_1}|n_1-1,n_2;\sigma_1,\sigma_2,-1,\sigma_3\\ &-1,\sigma_4\rangle-\sqrt{\sigma_2(\sigma_3+1)n_1}|n_1-1,n_2;\sigma_1,\sigma_2-1,\sigma_3+1,\sigma_4\rangle \end{aligned} \tag{3.8a}$$

and

$$Q_{(1)}^{\dagger}|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle=\sqrt{(\sigma_1+1)\sigma_3(n_2+1)}|n_1,n_2+1;\sigma_1+1,\sigma_2,\sigma_3-1,\sigma_4\rangle$$
$$+\sqrt{(\sigma_1+1)(\sigma_3+1)(n_2+1)}|n_1,n_2+1;\sigma_1+1,\sigma_2,\sigma_3+1,\sigma_4\rangle$$
$$+\sqrt{(\sigma_2+1)(\sigma_3+1)(n_1+1)}|n_1+1,n_2;\sigma_1,\sigma_2+1,\sigma_3+1,\sigma_4\rangle$$
$$-\sqrt{(\sigma_2+1)\sigma_3(n_1+1)}|n_1+1,n_2;\sigma_1,\sigma_2+1,\sigma_3-1,\sigma_4\rangle, \quad (3.8b)$$

leading to the supersymmetric Hamiltonian [cf. Eq. (2.4)]

$$H|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle=\{Q_{(1)},Q_{(1)}^{\dagger}\}|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle$$
$$=(\tfrac{1}{2}\{a,a^{\dagger}\}+\tfrac{1}{2}[b^{\dagger},b])|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle$$
$$=(H_{\mathrm{PB}}+H_{\mathrm{PF}})|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle$$
$$=\{(\sigma_1+1)\sigma_3(n_2+1)+(\sigma_1+1)(\sigma_3+1)(n_2+1)+(\sigma_2+1)(\sigma_3+1)$$
$$\times(n_1+1)+(\sigma_2+1)\sigma_3(n_1+1)+\sigma_1\sigma_3 n_2+\sigma_1(\sigma_3+1)n_2+\sigma_2\sigma_3 n_1$$
$$+\sigma_2(\sigma_3+1)n_1\}|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,\sigma_4\rangle. \quad (3.9)$$

A very simple discussion of the possible values of the four σs leads to 16 sets of eigenvectors labeled by the discrete numbers n_1 and n_2 which can take all non-negative integer values. In correspondence, we also find three parts of the energy spectrum distributed in subspectra characterized by n_1+n_2+2, n_1+n_2+1, and n_1+n_2, the last one ensuring already that we are dealing with an *exact* ''supersymmetry'' due to the possible values $n_1=n_2=0$.

Let us now complete the information on the invariance superalgebra osp$(2|2,\mathbb{R})$ through the five generators complementary to the three above ones called H, $Q_{(1)}$ and $Q_1^{\dagger}$, i.e., the operators

$$H'=\tfrac{1}{2}\{a,a^{\dagger}\}-\tfrac{1}{2}[b^{\dagger},b]=H_{\mathrm{PB}}-H_{\mathrm{PF}}, \quad (3.10a)$$

$$C_{+}=\tfrac{1}{2}\{a^{\dagger},a^{\dagger}\}, \quad C_{-}=\tfrac{1}{2}\{a,a\}, \quad (3.10b)$$

$$S=\tfrac{1}{2}\{b^{\dagger},a\}, \quad S^{\dagger}=\tfrac{1}{2}\{a^{\dagger},b\}, \quad (3.10c)$$

which have also a well-defined action on the basis (3.7). The eight generators of osp$(2|2,\mathbb{R})$ now help us to search for how many of the 16 sets of eigenvectors do survive according also to the well-known typical characteristics of parabosonic[2,20] and parafermionic[2] operators in the $p=2$ context. Effectively, in the parabosonic case, we have to distinguish between even and odd state vectors as follows:

$$a|2n\rangle=\sqrt{2n}|2n-1\rangle, \quad (3.11a)$$

$$a|2n+1\rangle=\sqrt{2n+2}|2n\rangle, \quad (3.11b)$$

while, in the parafermionic case, we have (due to the property $b^3=0$) to point out only three state vectors [remember the $D^{(1)}$ representation of su$(2,\mathbb{C})$]:

$$b|0\rangle=0, \quad b|1\rangle=\sqrt{2}|0\rangle, \quad b|2\rangle=\sqrt{2}|1\rangle. \quad (3.12)$$

Acceptable eigenvectors compatible with Eqs. (3.6e) and (3.12) are, for example, $|n_1,n_2;0,0,0,0\rangle$, $|n_1,n_2;1,0,1,1\rangle$, and $|n_1,n_2;1,1,0,0\rangle$, and the ladder operators Q, $Q^{\dagger}$, S, and $S^{\dagger}$ select *only* five more of the type $|n_1,n_2;1,0,1,0\rangle$, $|n_1,n_2;0,1,1,0\rangle$, $|n_1,n_2;1,1,0,1\rangle$, $|n_1,n_2;0,0,0,1\rangle$, and $|n_1,n_2;0,1,1,1\rangle$, so that such considerations show that there are eight sets of linearly independent

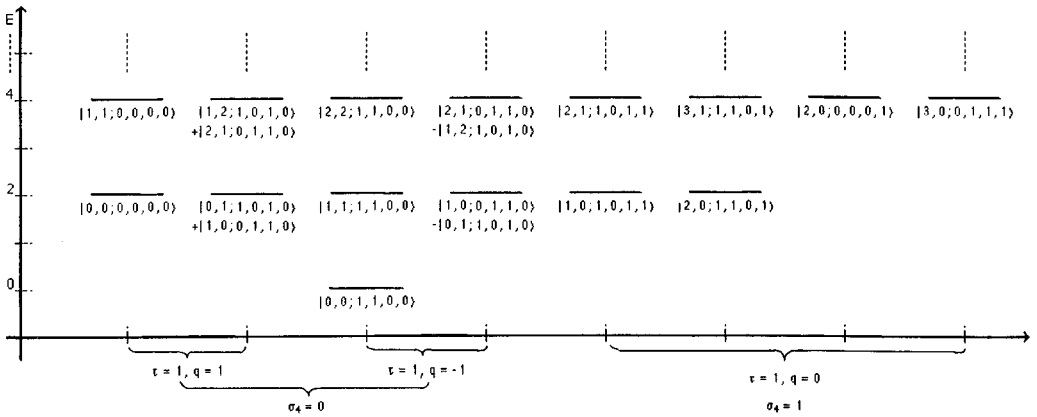

FIG. 1. The three subspectra associated with the three irreducible representations of osp (2/2;$\mathbb{R}$) displayed in our Fock space. The first two columns refer to the atypical ($\tau=1$, $q=1$) representation and the energy eigenvalues $E_n=2n+2$; the third and fourth columns to the atypical ($\tau=1$, $q=-1$) one and $E_n=2n$; the fifth to eighth columns to the typical ($\tau=1$, $q=0$) one and $E_n=2n+2$. The four columns on the left refer to the eigenvalue $\sigma_4=0$ while the four on the right refer to $\sigma_4=1$.

state vectors in the Fock basis (3.7). Moreover, by taking care of the requirements (3.11), we immediately notice that, if $\sigma_4=0$ or 1, the ''even'' vector states always have to be characterized by $n_1=n_2=n$, while the ''odd'' ones are such that $n_1=n+1$ and $n_2=n$.

By collecting all these details, our Fock basis is finally characterized by the following *eight* (families of) vectors ($n=0,1,2,...$),

$$|n,n;0,0,0,0\rangle,|n,n;1,1,0,0\rangle,|n,n+1;1,0,1,0\rangle,|n+1,n;0,1,1,0\rangle,|n+1,n;1,0,1,1\rangle,$$
$$|n+2,n;1,1,0,1\rangle,|n+1,n-1;0,0,0,1\rangle,|n+2,n-1;0,1,1,1\rangle. \tag{3.13}$$

By means of the supercharges (2.3a), the corresponding Hamiltonian (3.9), and its energy eigenvalue problem, it results that there are only three (infinite) irreducible representations of osp(2/2,$\mathbb{R}$) which appear in our Fock space, two of them being *atypical* ones and one being of the *typical* type. These properties are obtained through the study of the Casimir operator of osp(2/2, $\mathbb{R}$) and the well-known properties of the above Lie superalgebra.[16,21] Let us only recall that the Casimir operator here is given by

$$C=H_{\mathrm{PB}}^2-\tfrac{1}{2}\{C_+,C_-\}-H_{\mathrm{PF}}^2-[Q_+,Q_-]+[S_-,S_+] \tag{3.14}$$

and leads to eigenvalues $4(\tau^2-q^2)$. First, we get an *atypical* irreducible representation associated with the values $\tau=1$, $q=1$ (and evidently $C=0$) admitting twofold degeneracies for each energy eigenvalues $E_n=2n+2$, these results being characteristic of the family of eigenvectors $|n,n;0,0,0,0\rangle$. Second, there is another *atypical* one ($\tau=1$, $q=-1$, $C=0$), possible twofold degeneracies, $E_n=2n$ and $|n,n;1,1,0,0\rangle$. Third, there is a *typical* irreducible representation characterized by $\tau=1$, $q=0$ ($C=4$), showing possible fourfold degeneracies, $E_n=2n+2$ and $|n+1,n;1,0,1,1\rangle$. All the states vectors (3.13) are recovered by acting with the ladder operators $Q_{(1)}$ and $Q_{(1)}^{\dagger}$ and the complete spectrum is shown in Fig. 1, pointing out the whole set of eigenvalues and eigenvectors corresponding to $n=0,1,2,...$. Such a spectrum appears as the superposition of the three subspectra: we have only a fundamental state with zero energy (exact supersymmetry), six states with the energy eigenvalue equal to 2, and eight states with energy eigenvalue equal to all the even value 4,6,8,... .

Such results associated with our Fock basis show the reducibility obtained by having realized parabosonic and parafermionic operators through Green–Cusson Ansätze. This reducibility will be exploited in the following sections in order to get possible deformations.

IV. TOWARD DEFORMED PARABOSONIC AND PARAFERMIONIC OPERATORS

Having at our disposal an interesting Fock space, with precise information on its contents with respect to the irreducible representations of the invariance superalgebra osp(2/2, $\mathbb{R}$) of SSQM, let us now polarize our attention on the deformation of the symmetry operators. We notice that we recover here a completely parallel situation with respect to the pioneering contributions[22] for deforming the simple Lie algebra su(2,$\mathbb{C}$).

We want thus to deform more particularly the fundamental operators a and b given by Eqs. (3.1) and, correspondingly, the osp(2/2,$\mathbb{R}$) generators in the relative parabosonic context given by Eqs. (2.3a), (2.4), and (3.10).

Let us first take advantage of the generalized deformed parafermions recently proposed by Quesne.[11] In correspondence with the typical double commutator

$$[b,[b^\dagger,b]]=2b \tag{4.1}$$

contained in the set (2.1a), we propose to associate to the annihilation operator b of parafermion(s) a generalized deformed one—hereafter denoted B—defined by

$$b\rightarrow B=\frac{1}{2\sqrt{2}}\,(\sqrt{F_1}b^\dagger b^2+\sqrt{F_2}b^2b^\dagger), \tag{4.2}$$

where F_1 and F_2 are constants which, except for the particular case $F_1=F_2$, will assign a deformed character to B. We have to remember that, in the $p=2$ context, parafermionic operators are such that

$$b^2b^\dagger+b^\dagger b^2=2b, \quad bb^\dagger b=2b, \tag{4.3}$$

in perfect agreement with Eq. (4.1). When $F_1=F_2$, the two operators b and B are directly proportional and such a case does not interest us.

The second step now consists of the deformation of the parabosonic annihilation operator a. This context is not analogous to the parafermionic one due to the important different behavior of even or odd state vectors as already quoted in Eqs. (3.11). In order to circumvent this difficulty, we propose to introduce functions of the number operator N rather than constants entering into the deformed expression. Here, according to the peculiar relation (2.1a),

$$[a,\{a^\dagger,a\}]=2a, \tag{4.4}$$

and the corresponding $p=2$ property,

$$a^2a^\dagger-a^\dagger a^2=2a, \tag{4.5}$$

we suggest the association

$$a\rightarrow A=\frac{1}{2\sqrt{2}}\,(\sqrt{F_2(N)}a^2a^\dagger-\sqrt{F_1(N)}a^\dagger a^2), \tag{4.6}$$

where the number operator is as usual defined by

$$N=\tfrac{1}{2}\{a,a^\dagger\}-1=H_{\mathrm{PB}}-1 \tag{4.7}$$

characterized in the bosonic context resulting from Sec. III [see Eq. (3.3a), for example] by eigenvalues n_1+n_2 ($n_1,n_2=0,1,2,\ldots$). In passing, let us notice that the case $F_1(N)=F_2(N)$ still corresponds to a deformation in this parabosonic context due to the explicit dependence on N.

By taking care of the specificities introduced in Sec. III for the construction of the Fock basis (3.7), we can apply our new generalized deformed operators A, $A^\dagger$, B, and $B^\dagger$ and obtain the relations corresponding to Eqs. (3.6). By defining the special functions

$$G(n_1,n_2)=[(n_2+1)F_2(n_1+n_2)]^{1/2}(n_1+1)-[(n_2+1)F_1(n_1+n_2)]^{1/2}n_1, \tag{4.8}$$

we get the following information:

$$A|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=G(n_1,n_2-1)|n_1,n_2-1;\sigma_1,\sigma_2,\sigma_3,1\rangle, \tag{4.9a}$$

$$A|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=G(n_2,n_1-1)|n_1-1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle, \tag{4.9b}$$

$$A^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=G(n_2,n_1)|n_1+1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle, \tag{4.9c}$$

$$A^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=G(n_1,n_2)|n_1,n_2+1;\sigma_1,\sigma_2,\sigma_3,0\rangle, \tag{4.9d}$$

$$\begin{aligned}B|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=&[\sigma_1\sigma_3\sqrt{F_1}+(\sigma_1+1)\sigma_3\sqrt{F_2}]\sqrt{\sigma_2\sigma_3}|n_1,n_2;\sigma_1,\sigma_2-1,\sigma_3-1,1\rangle\\&-[\sigma_1(\sigma_3+1)\sqrt{F_1}+(\sigma_1+1)(\sigma_3+1)\sqrt{F_2}]\sqrt{\sigma_2(\sigma_3+1)}\\&\times|n_1,n_2;\sigma_1,\sigma_2-1,\sigma_3+1,1\rangle,\end{aligned} \tag{4.9e}$$

$$\begin{aligned}B|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=&[\sigma_2\sigma_3\sqrt{F_1}+(\sigma_2+1)\sigma_3\sqrt{F_2}]\sqrt{\sigma_1\sigma_3}|n_1,n_2;\sigma_1-1,\sigma_2,\sigma_3-1,0\rangle\\&+[\sigma_2(\sigma_3+1)\sqrt{F_1}+(\sigma_2+1)(\sigma_3+1)\sqrt{F_2}]\sqrt{\sigma_1(\sigma_3+1)}\\&\times|n_1,n_2;\sigma_1-1,\sigma_2,\sigma_3+1,0\rangle,\end{aligned} \tag{4.9f}$$

$$\begin{aligned}B^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,0\rangle=&[\sigma_2\sigma_3\sqrt{F_1}+(\sigma_2+1)\sigma_3\sqrt{F_2}]\sqrt{(\sigma_1+1)\sigma_3}|n_1,n_2;\sigma_1+1,\sigma_2,\sigma_3-1,1\rangle\\&+[\sigma_2(\sigma_3+1)\sqrt{F_1}+(\sigma_2+1)(\sigma_3+1,\sqrt{F_2}]\\&\times\sqrt{(\sigma_1+1)(\sigma_3+1)}|n_1,n_2;\sigma_1+1,\sigma_2,\sigma_3+1,1\rangle,\end{aligned} \tag{4.9g}$$

and

$$\begin{aligned}B^\dagger|n_1,n_2;\sigma_1,\sigma_2,\sigma_3,1\rangle=&[\sigma_1(\sigma_3+1)\sqrt{F_1}+(\sigma_1+1)(\sigma_3+1)\sqrt{F_2}]\sqrt{(\sigma_2+1)(\sigma_3+1)}\\&\times|n_1,n_2;\sigma_1,\sigma_2+1,\sigma_3+1,0\rangle-[\sigma_1\sigma_3\sqrt{F_1}+(\sigma_1+1)\sigma_3\sqrt{F_2}]\\&\times\sqrt{(\sigma_2+1)\sigma_3}|n_1,n_2;\sigma_1,\sigma_2+1,\sigma_3-1,0\rangle.\end{aligned} \tag{4.9h}$$

Let us insist on the fact that these relations are evidently in correspondence with Eqs. (3.6), the resulting state vectors being unchanged up to factors characterizing the deformation. Moreover, through the new deformed supercharges corresponding, for example, to the definitions (2.3a), i.e.,

$$Q_{(1)}=\tfrac{1}{2}\{A,B\},\quad Q_{(1)}^\dagger=\tfrac{1}{2}\{B^\dagger,A^\dagger\}, \tag{4.10}$$

the above relations (4.9) allow us to deduce constraints on the special functions (4.8) in order to discuss possible or impossible deformations of sqm (2), in particular.

So, by applying the operators (4.10) to the Fock state vectors (3.7), it is easy to test the relations (2.2) of the superalgebra sqm (2). An interesting result comes out immediately: by limiting our developments to the acceptable eigenvectors defined after Eqs. (3.12), we have to

mention that the expected nilpotencies ($Q_{(1)}^2 = Q_{(1)}^{\dagger 2} = 0$) are not true in general. They fail when applied to the families of state vectors $|n_1, n_2; 1,1,0,0\rangle$ and $|n_1, n_2; 1,1,0,1\rangle$, but are such that, on these states, we have (also evidently on the others)

$$Q_{(1)}^3 = 0. \tag{4.11}$$

Such a nilpotency calls for analyzing possible deformations in connection with parasupersymmetric developments[23,24] that will be discussed in the following section.

In order to be as complete as possible, let us go now to the eight explicit families of our Fock space subtended by the Lie superalgebra osp (2/2; $\mathbb{R}$) and its atypical and typical irreducible representations pointed out in the previous section.

V. ON POSSIBLE DEFORMATIONS OF sqm (2)

Let us mainly polarize our attention on the superalgebra sqm (2) seen as a subalgebra of osp (2/2; $\mathbb{R}$) in the above deformed context with the operators (4.2) and (4.6) and their actions (4.9). Explicit calculations lead to the results that $Q_{(1)}$, $Q_{(1)}^{\dagger}$, and H still admit only the eight families of state vectors that we have already mentioned in connection with the Casimir operator (3.14) and the atypical and typical representations associated with the spectrum of Fig. 1.

More precisely, let us mention that, on the states belonging to the atypical representation ($\tau = 1$, $q = 1$, $C = 0$), we have

$$\begin{aligned} Q_{(1)}|n,n;0,0,0,0\rangle &= 0, \\ Q_{(1)}(|n,n+1;1,0,1,0\rangle + |n+1,n;0,1,1,0\rangle) &= \sqrt{F_2}\,G(n,n)|n,n;0,0,0,0\rangle, \\ H|n,n;0,0,0,0\rangle &= \frac{F_2}{2}\,G^2(n,n)|n,n;0,0,0,0\rangle, \end{aligned} \tag{5.1}$$

and

$$H(|n,n+1;1,0,1,0\rangle + |n+1,n;0,1,1,0\rangle) = \frac{F_2}{2}\,G^2(n,n)(|n,n+1;1,0,1,0\rangle + |n+1,n;0,1,1,0,\rangle).$$

Double degeneracies are thus present, corresponding to eigenvalues $E_n \approx G^2(n,n)$ leading to a deformed superspectrum but to an undeformed superalgebra sqm (2) always characterized by the structure relations (2.2).

On the states belonging to the other atypical representation ($\tau = 1$, $q = -1$, $C = 0$), we also get relations similar to Eqs. (5.1), but here we have

$$\begin{aligned} Q_{(1)}|n,n;1,1,0,0\rangle &= -\frac{\sqrt{F_1}}{2}\,G(n,n-1)(|n-1,n;1,0,1,0\rangle - |n,n-1;0,1,1,0\rangle), \\ Q_{(1)}(|n-1;n;1,0,1,0\rangle - |n,n-1;0,1,1,0\rangle) &= 0, \\ H|n,n;1,1,0,0\rangle &= \frac{F_1}{2}\,G(n,n-1)|n;1,1,0,0\rangle \end{aligned} \tag{5.2}$$

and

$$H(|n-1,n;1,0,1,0\rangle - |n,n-1;0,1,1,0\rangle) = \frac{F_1}{2}\,G^2(n,n-1)(|n-1,n;1,0,1,0\rangle - |n,n-1;0,1,1,0\rangle).$$

In this case, we point out the existence of a null energy eigenvalue due to the property (4.9a) when $n_1=n_2=n=0$ and its implication $G(0,-1)=0$. Moreover, the other energy eigenvalues are once again doubly degenerated and are such that $E_{n+1}\approx G^2(n+1,n)$. We thus obtain a new deformed superspectrum but an undeformed superalgebra sqm (2).

The third irreducible representation, i.e., the typical ($\tau=1$, $q=0$) one, will happily give us the opportunity to open some possibilities of deformations of sqm (2). Indeed, if we notice that

$$Q_{(1)}|n+2,n-1;0,1,1,1\rangle=\frac{\sqrt{F_2}}{2}\,G(n-1,n+1)|n+1,n-1;0,0,0,1\rangle,$$

$$Q_{(1)}|n+1,n;1,0,1,1\rangle=\frac{\sqrt{F_2}}{2}\,G(n+1,n-1)|n+1,n-1;0,0,0,1\rangle, \tag{5.3}$$

$$Q_{(1)}|n+2,n;1,1,0,1\rangle=\frac{\sqrt{F_1}}{2}\,[G(n+2,n-1)|n+2,n-1;0,1,1,1\rangle-G(n,n+1)|n+1,n;1,0,1,1\rangle],$$

and

$$Q_{(1)}|n+1,n-1;0,0,0,1\rangle=0,$$

we evidently get

$$Q_{(1)}^2|n+2,n;1,1,0,1\rangle=\frac{\sqrt{F_1F_2}}{4}\,[G(n+2,n-1)G(n-1,n+1)-G(n,n+1)G(n+1,n-1)]$$
$$\times|n+1,n-1;0,0,0,1\rangle \tag{5.4}$$

and

$$Q_{(1)}^3|n+2,n;1,1,0,1\rangle=0. \tag{5.5}$$

The nilpotencies of sqm (2) [see Eqs. (2.2)] are thus only ensured iff

$$G(n+2,n-1)G(n-1,n+1)=G(n,n+1)G(n+1,n-1), \tag{5.6}$$

leading once again to a deformed spectrum but to an undeformed structure. In this case, a convenient choice for the functions G ensuring Eq. (5.6) is, for example,

$$G(x,y)=[(y+1)f(y)F_1]^{1/2}\quad\text{for even}\quad|x-y| \tag{5.7a}$$

and

$$G(x,y)=[(y+1)f(y)F_2]^{1/2}\quad\text{for odd}\quad|x-y|. \tag{5.7b}$$

Then, simple calculations lead to a diagonal super-Hamiltonian whose spectrum has the same configuration as the one contained in the four columns on the right of Fig. 1, *but* with the energy eigenvalues given by

$$E_n^{(d)}=nf(n-1)+(n+2)f(n+1),\quad n=0,1,2,\ldots\ . \tag{5.8}$$

the upper index (d) referring to the deformed spectrum. Remembering that this context corresponds to the undeformed eigenvalues $E_n=2n+2$, we understand their relation by noticing that, within our choice, the undeformed function $f(x)$ has to become one.

Let us end this section by coming back on the only context leading to possible deformations of sqm (2), i.e., when Eq. (5.6) is *not* valid, so that we have the constraints (5.4) and (5.5), the last one looking like a nilpotency typical of $p=2$ parastatistical developments.[2] Within our Fock basis and its typical representation ($\tau=1$, $q=0$, $C\neq 0$), the missing information is now only transferred on the corresponding Hamiltonian. *As an example*, let us require *trilinear* relations defining H as it is the case in the parasupersymmetric quantum context[23] but with three unknown complex constants c_i $(i=1,2,3)$, i.e.,

$$c_1 Q_{(1)}^2 Q_{(1)}^\dagger + c_2 Q_{(1)}^\dagger Q_{(1)}^2 + c_3 Q_{(1)} Q_{(1)}^\dagger Q_{(1)} = H Q_{(1)}, \tag{5.9}$$

besides evidently the necessary relations (4.11) and

$$[Q_{(1)}, H]=0, \quad [Q_{(1)}^\dagger, H]=0. \tag{5.10}$$

Now, by defining

$$G(x,y)=[(y+1)f(x)F_1]^{1/2} \quad \text{for even } |x-y| \tag{5.11a}$$

and

$$G(x,y)=[(y+1)f(x)F_2]^{1/2} \quad \text{for odd } |x-y|, \tag{5.11b}$$

and by asking that

$$f(n+2)f(n-1)\neq f(n)f(n+1) \quad \forall n=0,1,2,\ldots, \tag{5.12}$$

we can search for the corresponding spectrum of H in terms of these functions f and the constants c_i $(i=1,2,3)$. In that way, six constraints are put in evidence and lead to a specific discussion not reproduced here for brevity. Let us only point out that, if we choose $c_1=c_2=0$, $c_3=1$, and the following values,

$$f(4n)=-3n, \quad f(4n+1)=n+1, \quad f(4n+2)=3n+2, \quad f(4n+3)=-n-1, \tag{5.13}$$

we can recover the spectrum of the supersymmetric harmonic oscillator but with further degeneracies in comparison with old results.[25] In that way, we can interpret the Rubakov–Spiridonov structure[23] as a deformation of sqm(2). The other case $c_1=c_2=1$, $c_3=0$, is also interesting: it shows that the Beckers–Debergh structure[24] does not appear as a deformation of sqm(2), this property acting once again the nonequivalence of these two approaches of parasupersymmetric quantum mechanics.[23,24]

As a final comment, let us mention that, if we come back to the relations (5.3), it is not difficult to realize the charge $Q_{(1)}$ as a 4×4 matrix and to realize, for example, the Beckers–Debergh structure[24] by constraining the different functions $G(x,y)$ and constants F_1 and F_2. Applied to the particular context of the harmonic oscillator with angular frequency ω, we get the conditions

$$\begin{aligned}
&F_2^{1/2} G(n+1,n-1)=2\sqrt{n\omega}=F_2^{1/2}[(n+2)\sqrt{nF_2(2n)}-(n+1)\sqrt{nF_1(2n)}],\\
&F_1^{1/2} G(n,n+1)=2\sqrt{n\omega}=F_1^{1/2}[(n+1)\sqrt{(n+2)F_2(2n+1)}-n\sqrt{(n+2)F_1(2n+1)}],\\
&G(n+2,n-1)=-2\sqrt{n\omega}=F_1^{1/2}[(n+3)\sqrt{nF_2(2n+1)}-(n+2)\sqrt{nF_1(2n+1)}],
\end{aligned} \tag{5.14}$$

and

$$F_2^{1/2}G(n-1,n+1)=2\sqrt{n\omega}=F_2^{1/2}[n\sqrt{(n+2)F_2(2n)}-(n-1)\sqrt{(n+2)F_1(2n)}],$$

where, besides the constants F_1 and F_2, we have taken care of the relations (4.8) in terms of the deformed functions $F_1(x)$ and $F_2(x)$. Consistency relations impose

$$\begin{gathered}F_1(0)=0,\quad F_2(0)=\frac{\omega}{F_2},\quad F_1(1)=\frac{\omega}{F_1},\quad F_2(1)=0,\\ [F_1(2n)]^{1/2}\geqslant 0,\quad [F_2(2n)]^{1/2}\geqslant 0,\quad [F_1(2n+1)]^{1/2}\geqslant 0,\quad [F_2(2n+1)]^{1/2}\geqslant 0,\end{gathered}\tag{5.15}$$

and the Beckers–Debergh structure will be a deformation of sqm (2) under the following set of final conditions for each $n=0,1,2,...$:

$$\begin{aligned}[F_1(2n)]^{1/2}&=\sqrt{\frac{\omega n}{F_2}}\,(\sqrt{n+2}-\sqrt{n}),\\ [F_2(2n)]^{1/2}&=\frac{1}{n+2}\,\sqrt{\frac{\omega}{F_2}}\,((n+1)\sqrt{n}(\sqrt{n+2}-\sqrt{n})+2),\\ [F_1(2n+1)]^{1/2}&=\sqrt{\frac{\omega}{F_1}}\left(n+1+(n+3)\sqrt{\frac{n}{n+2}}\right),\\ [F_2(2n+1)]^{1/2}&=\sqrt{\frac{\omega n}{F_1}}\,(\sqrt{n+2}+\sqrt{n}).\end{aligned}\tag{5.16}$$

(Received 19 September 1995; accepted for publication 28 May 1996)

We present here the zero curvature formulation for a wide class of field theory models. This formalism, which relies on the existence of an operator δ which decomposes the exterior space–time derivative as a BRS commutator, turns out to be particularly useful in order to solve the Wess–Zumino consistency condition. The examples of the topological theories and of the $B-C$ string ghost system are considered in detail. © *1996 American Institute of Physics.*

I. INTRODUCTION

Nowadays it is an established fact that the search for the possible anomalies and for the counterterms which arise at the quantum level in local field theories can be done in a purely algebraic way[1] by identifying the cohomology classes of the nilpotent Becchi–Rouet–Stora (BRS) operator b in the space of the integrated local polynomials in the fields and their derivatives. This means that one has to look at the nontrivial solutions of the equation

$$b\int \omega_D^G = 0, \tag{1}$$

ω_D^G denoting a local polynomial in the fields of ghost number G and form degree D, D being the dimension of the space–time. The cases $G=0,1$ correspond, respectively, to counterterms and anomalies.

The BRS consistency condition (1), when translated at the nonintegrated level, yields a system of equations usually called descent equations (see Ref. 1 and references therein)

$$\begin{gathered} b\omega_D^G + d\omega_{D-1}^{G+1} = 0, \quad b\omega_{D-1}^{G+1} + d\omega_{D-2}^{G+2} = 0, \\ \cdots \\ \cdots \\ b\omega_1^{G+D-1} + d\omega_0^{G+D} = 0, \quad b\omega_0^{G+D} = 0, \end{gathered} \tag{2}$$

$d = dx^\mu \partial_\mu$ being the exterior space–time derivative and ω_j^{G+D-j} $(0 \leqslant j \leqslant D)$ being the local polynomials of ghost number $(G+D-j)$ and form degree j. The operators b and d obey the algebraic relations

$$b^2 = d^2 = bd + db = 0. \tag{3}$$

It should be remarked that at the nonintegrated level one loses the property of making integration by parts. This implies that the fields and their derivatives have to be considered as independent variables.

0022-2488/96/37(11)/5310/15/$10.00

The problem of solving the descent equations (2) is a problem of cohomology of b modulo d, the corresponding cohomology classes being given by solutions of (2) which are not of the type

$$\omega_m^{G+D-m} = b\,\hat{\omega}_m^{G+D-m-1} + d\,\hat{\omega}_{m-1}^{G+D-m}, \quad 1 \leqslant m \leqslant D,$$
$$\omega_0^{G+D} = b\,\hat{\omega}_0^{G+D-1}, \tag{4}$$

with $\hat{\omega}$'s being local polynomials.

Recently a new method for finding nontrivial solutions of the tower (2) has been proposed by one of the authors[2] and successfully applied to a large number of field models such as Yang–Mills theories,[3] gravity,[4–6] topological field theories,[7–9] string[10] and superstring[11] theories, as well as W_3-algebras.[12] The method relies on the introduction of an operator δ which allows the decomposition of the exterior derivative as a BRS commutator, i.e.,

$$d = -[b,\ \delta]. \tag{5}$$

It is easily proven that, once the decomposition (5) has been found, repeated applications of the operator δ on the polynomial ω_0^{G+D} which solves the last of the equations (2) will give an explicit nontrivial solution for the higher cocycles ω_j^{G+D-j}.

One has to note that solving the last equation of the tower (2) is a problem of local cohomology instead of a modulo-d one. Moreover, the former can be systematically attacked by using several methods such as, for instance, the spectral sequences technique.[13] It is also worth mentioning that the solutions of the descent equations (2) obtained via the decomposition (5) have been proven to be equivalent to those provided by the transgression procedure based on the so-called *Russian Formula*.[14,15]

The aim of the present work is twofold: first, to improve and extend the results obtained in Ref. 2 and, second, to discuss the deep relation between the existence of the operator δ entering the decomposition (5) and the possibility of encoding all the relevant informations (BRS transformations of the fields, BRS cohomology classes, solutions of the descent equations) into a unique equation which takes the form of a generalized zero curvature condition:

$$\tilde{\mathscr{F}} = \tilde{d}.\tilde{\mathscr{A}} - i.\tilde{\mathscr{A}}^2 = 0. \tag{6}$$

The operator $\tilde{d}$ and the generalized gauge connection $\tilde{\mathscr{A}}$ in Eq. (6) turn out to be respectively the δ-transform of the BRS operator b and of the ghost field c corresponding to the Maurer–Cartan form of the underlying gauge algebra

$$\tilde{d} = e^{\delta} b e^{-\delta} = b + d + \cdots, \quad \tilde{d}^2 = 0,$$
$$\tilde{\mathscr{A}} = e^{\delta} c = c + \cdots\ . \tag{7}$$

The main purpose of this work will be that of clarifying the meaning of the generalized gauge connection $\tilde{\mathscr{A}}$ and of the dots $\cdots$ appearing in Eq. (7) with the help of several examples.

In particular, as we shall see, the zero-curvature condition (6) immediately yields the cohomology classes of the generalized operator $\tilde{d}$,[16] the nilpotency of which being a direct consequence of the zero curvature condition (6). The latter turns out to be naturally related to the solutions of the descent equations (2). In other words, once the zero-curvature condition of the model under consideration has been established, the problem of finding the anomalies and the invariant actions becomes straightforward to be solved.

For the sake of completeness and in order to present several detailed models, the paper has been split in two parts, referred as part I and part II. This division corresponds to two different situations, called, respectively, the *complete* and the *noncomplete* ladder case. In the first case the

components of the generalized gauge connection $\tilde{\mathscr{A}}$ form a ladder of fields which span all possible form degrees compatible with the space–time dimension D, i.e., ordering the components of $\tilde{\mathscr{A}}$ according to their increasing form degree p, the allowed interval $0 \leqslant p \leqslant D$, is fully covered. Instead, in the noncomplete ladder case the maximum form degree reached by the components of $\tilde{\mathscr{A}}$ is strictly lower than the space–time dimension D, i.e., $0 \leqslant p < D$. Examples of models belonging to the first case are, for instance, the topological models of the Schwartz type such as the Chern–Simons and the BF models,[17] and the B-C ghost system of the bosonic string theory.[18] On the other hand, the Yang–Mills-type theories can be accommodated in the noncomplete ladder case.

As we shall see in details in the next sections, this means that we shall deal with a generalized gauge connection $\tilde{\mathscr{A}}$ which takes respectively the following forms:

$$\tilde{\mathscr{A}} = \sum_{j=0}^{D} \varphi_j^{1-j} = \varphi_0^1 + \varphi_1^0 + \varphi_2^{-1} + \cdots + \varphi_D^{1-D}, \quad \text{complete ladder case,} \tag{8}$$

and

$$\tilde{\mathscr{A}} = \sum_{j=0}^{q<D} \varphi_j^{1-j} = \varphi_0^1 + \varphi_1^0 + \varphi_2^{-1} + \cdots + \varphi_q^{1-q}, \quad \text{noncomplete ladder case,} \tag{9}$$

where the set $\{\varphi_j^{1-j}\}$ denotes generically the field content which will be used through the work, the indices $(1-j)$ and j identifying respectively the ghost number and the form degree. One has to note that in writing the expressions (8) and (9) we have tacitly assumed that the class of models which we shall consider can be indeed described in terms of the form-valued fields $\{\varphi_j^{1-j}\}$ appearing in Eqs. (8) and (9) and of their exterior derivatives. In other words, we shall assume that the descent equations (2) will be restricted to the functional space of form-valued polynomials in the fields $\{\varphi_j^{1-j}\}$ and their differentials. Of course, the same assumption holds for the decomposition (5).

It is worthwhile to recall here that in the case of the aforementioned topological models this assumption is in fact realized. As it is well known,[7–9,17,19] this is due to the fact that the topological models turn out to be characterized by a set of fields which can be naturally accommodated in a complete ladder.

For where it concerns the Yang–Mills-type theories, it should also be remarked that the use of the space of the form-valued polynomials is not the most general one. Indeed such a functional space does not allow us to obtain all possible Yang–Mills actions,[20] due to the absence of the space–time metric tensor. However, as proven in Refs. 15 and 21, the space of polynomials of forms turns out to be bigger in half to include the anomalies and the Chern–Simons-type actions which, due to their topological character,[14] can be systematically written in terms of differential forms. Therefore also in the noncomplete ladder case, we shall limit ourselves to the algebraic characterization of topological objects like anomalies and Chern–Simons terms.

Even if many properties of the models covered by the complete ladder case have already been investigated,[8,19] their zero curvature formulation still represents a very elegant and interesting aspect. Moreover, in the noncomplete case, the zero curvature condition (6) requires the existence of a set of new operators $(\mathscr{G}_k^{1-k},\ 2 \leqslant k \leqslant D)$ which are in involution, i.e., the operator $\mathscr{G}_k^{1-k}$ is generated by the commutator between $\mathscr{G}_{k-1}^{2-k}$ and the operator δ of (5), according to the recursive formula

$$\mathscr{G}_2^{-1}=\tfrac{1}{2}[\delta,d],$$
$$\mathscr{G}_k^{1-k}=\frac{1}{k}[\delta,\mathscr{G}_{k-1}^{2-k}],\quad k>2. \tag{10}$$

This structure naturally reminds us of the recursive construction of the Lax pair operators of the integrable systems.[22] This is a quite welcome and attractive feature which may signal a deeper relation between the BRS cohomology techniques and the integrability. Needless to say, the zero-curvature condition represents in fact one of the most important chapters of the integrable systems (see also the recent works of Ref. 23).

This paper (referred to as part I) is organized as follows. In Sec. II the general algebraic setup is presented. In Sec. III we discuss the geometrical meaning of the zero-curvature condition. Sections IV and V are devoted, respectively, to the computation of the BRS cohomology and to characterizing the solution of the descent equations. In Sec. VI we deal with the coupling with matter fields in the context of the BF models. Without entering in details, let us briefly comment that, in analogy with the gauge ladder $\tilde{\mathscr{A}}$, the matter fields can be introduced by means of a second complete ladder $\tilde{\mathscr{B}}$ constrained by the requirement of being covariantly constant with respect to the gauge ladder, i.e.,

$$\tilde{\mathscr{D}}\tilde{\mathscr{B}}=\tilde{d}\tilde{\mathscr{B}}-i[\tilde{\mathscr{A}},\tilde{\mathscr{B}}]=0. \tag{11}$$

As we shall see, condition (11) completely characterizes the BRS transformations of the various components of $\tilde{\mathscr{B}}$.

Finally, Sec. VII contains a detailed discussion of the zero-curvature formulation of the $B-C$ string ghost system.

II. THE GENERAL SETUP

In order to present the general algebraic setup, let us begin by fixing the notations. As already said in the Introduction, we shall work in a space–time of dimension D equipped with a set of fields generically denoted by $\{\varphi_q^p\}$, q and p being, respectively, the form degree and the ghost number. The components φ_q^p will be treated as commuting or anticommuting variables according to the fact that their total degree, i.e., the sum $(q+p)$, is even or odd. Otherwise stated, the φ_q^p are Lie algebra valued, $\varphi_q^p=(\varphi_q^p)^a T^a$, T^a being the Hermitian generators of a compact semisimple Lie group G. Moreover, these fields are assumed to be collected into a unique generalized complete field $\tilde{\mathscr{A}}$ of total degree one, i.e.,

$$\tilde{\mathscr{A}}=\sum_{j=0}^{D}\varphi_j^{1-j}=\varphi_0^1+\varphi_1^0+\varphi_2^{-1}+\cdots+\varphi_D^{1-D}. \tag{12}$$

The name complete is due to the fact that the field content of the expansion (12) spans all possible form degrees. In addition, Eq. (12) shows that the generalized field $\tilde{\mathscr{A}}$ contains a zero form with ghost number one φ_0^1, and a one-form with ghost number zero φ_1^0. These fields will be naturally identified with the Faddeev–Popov ghost field and with the gauge connection of the familiar Yang–Mills gauge transformations. Therefore $\tilde{\mathscr{A}}$ will be called the gauge ladder and the components φ_0^1 and φ_1^0 will be denoted, respectively, by c and A, so that

$$\tilde{\mathscr{A}}=c+A+\varphi_2^{-1}+\cdots+\varphi_D^{1-D}. \tag{13}$$

Finally, as already remarked, the functional space $\mathscr{V}$ the BRS operator b acts upon is the space of the form-valued polynomials in the fields φ_j^{1-j} and their differentials, i.e.,

$$\mathscr{V}=\text{polynomials in } (\varphi_j^{1-j}, d\varphi_j^{1-j}; 0\leqslant j\leqslant D), \tag{14}$$

d being the exterior derivative defined as

$$d\eta_p = dx^\mu \partial_\mu \eta_p \tag{15}$$

for any p-form

$$\eta_p = \frac{1}{p!}\ \eta_{i_1\cdots i_p} dx^{i_1}\cdots dx^{i_p}, \tag{16}$$

where a wedge product has to be understood. Observe also that $d\varphi_D^{1-D}$ automatically vanishes, due to the dimension of the space–time.

In order to obtain the BRS transformations of the fields belonging to the gauge ladder (13), we introduce the generalized operator of total degree one (*we recall here that the operators* b *and* d *raise respectively the ghost number and the form degree by one unit*)

$$\tilde{d} = b + d, \tag{17}$$

and we impose the zero curvature condition

$$\tilde{d}\tilde{\mathscr{A}} = i\tilde{\mathscr{A}}^2 = \frac{i}{2}[\tilde{\mathscr{A}}, \tilde{\mathscr{A}}], \tag{18}$$

where $[a,b]=ab-(-1)^{|a||b|}ba$ denotes the graded commutator and $|a|$ is the total degree of a.

Developing equation (18) in components and identifying the terms with the same ghost number and form degree, we obtain the following transformations:

$$bc = ic^2, \quad bA = -dc + i[c,A], \tag{19}$$

$$b\varphi_j^{1-j} = -d\varphi_{j-1}^{2-j} + \frac{i}{2}\sum_{m=0}^{j}[\varphi_m^{1-m}, \varphi_{j-m}^{1-j+m}], \quad 2\leqslant j\leqslant D,$$

which are easily checked to be nilpotent.

$$b^2 = 0. \tag{20}$$

Notice that, as announced, the transformations of the first two components of the ladder $\tilde{\mathscr{A}}$ are nothing but the familiar BRS transformations of the Faddeev–Popov ghost and of the Yang–Mills gauge connection.

Let us introduce now the operator δ defined by (see also Refs. 1, 4, and 8)

$$\tilde{\mathscr{A}} = e^{\delta} c, \tag{21}$$

i.e.,

$$\delta\varphi_j^{1-j} = (j+1)\varphi_{j+1}^{-j}, \quad 0\leqslant j\leqslant D-1, \quad \delta\varphi_D^{1-D} = 0. \tag{22}$$

Its action extends on the differentials $(d\varphi_j^{1-j},\ 0\leqslant j\leqslant D)$ as

$$\begin{aligned} &\delta d\varphi_j^{1-j} = (j+1)d\varphi_{j+1}^{-j}, \quad 0\leqslant j\leqslant D-2, \\ &\delta d\varphi_{D-1}^{2-D} = 0. \end{aligned} \tag{23}$$

It is easily verified then that, on the functional space $\mathscr{V}$, the operators b and δ obey

$$d=-[b,\delta],\quad [d,\delta]=0, \tag{24}$$

i.e., δ allows the decomposition of the exterior derivative as a BRS commutator.

Equations (22) and (23) show that the operator δ increases the form degree by one unit and decreases the ghost number by the same amount, so that it has total degree zero. In particular from Eq. (24) it follows that

$$\tilde{d}=b+d=e^{\delta}be^{-\delta}. \tag{25}$$

III. THE GEOMETRICAL MEANING OF THE ZERO-CURVATURE CONDITION

In the previous section the BRS transformations of the component fields φ_j^{1-j} have been obtained as a consequence of the zero-curvature condition (18).

Conversely, it is very simple to show that, assuming the BRS transformations (19) hold, the zero-curvature condition can be derived as a consequence of the existence of the operator δ. Indeed, applying e^{δ} to the BRS transformation of the ghost field c, i.e.,

$$e^{\delta}be^{-\delta}e^{\delta}c=ie^{\delta}c^2, \tag{26}$$

and making use of Eq. (21) and (25), one gets the zero-curvature condition

$$\tilde{d}\tilde{\mathscr{A}}=i\tilde{\mathscr{A}}^2. \tag{27}$$

This is not surprising since, as it is well known, the ghost field c identifies the so-called Maurer–Cartan form of the gauge group G, and its BRS transformation is nothing but the corresponding Maurer–Cartan equation,[24] which is in fact a zero-curvature condition. This is the geometrical meaning of Eq. (18).

IV. COHOMOLOGY OF THE BRS OPERATOR

Even if the cohomology of the BRS operator in the case of a complete ladder field has already been studied,[8] let us present here a simple derivation which may be useful for the reader.

In order to compute the cohomology of the BRS operator b on the functional space $\mathscr{V}$, we introduce the filtering operator[1,13] $\mathscr{N}$ defined as

$$\begin{aligned}&\mathscr{N}\varphi_j^{1-j}=\varphi_j^{1-j},\quad 0\leqslant j\leqslant D,\\ &\mathscr{N}d\varphi_j^{1-j}=d\varphi_j^{1-j},\end{aligned} \tag{28}$$

according to which the BRS operator b decomposes as

$$b=b_0+b_1, \tag{29}$$

with

$$b_0c=0,\quad b_0\varphi_m^{1-m}=-d\varphi_{m-1}^{2-m},\quad b_0d\varphi_{m-1}^{2-m}=0,\quad 1\leqslant m\leqslant D, \tag{30}$$

and

$$b_0^2=0. \tag{31}$$

The usefulness of the above decomposition relies on a very general theorem on the BRS cohomology.[13] The latter states that the cohomology of the operator b is isomorphic to a subspace of the cohomology of b_0. We focus then on the study of the cohomology of b_0.

In particular, Eq. (30) shows that all the fields $(\varphi_m^{1-m},\ 1\leqslant m\leqslant D)$ with form degree greater than zero and their differentials are grouped in BRS doublets.[1,13,21] It is known that the cohomology does not depend on such variables. Therefore the cohomology classes of b_0 depend only on the ghost field c undifferentiated, i.e., they are given by elements of the type

$$\omega_{i_1\cdots i_n}c^{i_1}\cdots c^{i_n} \tag{32}$$

with $\omega_{i_1\cdots i_n}$ arbitrary coefficients. Moreover, from the previous theorem it follows that the cohomology of b is also given by elements of the form (32) with, in addition, the restriction that the coefficients $\omega_{i_1\cdots i_n}$ are invariant tensors of the gauge group.[15,20,21,25]

In summary, the cohomology of the BRS operator b in the complete ladder case is spanned by invariant polynomials in the ghost field c built up with monomials of the type

$$\mathrm{Tr}\left(\frac{c^{2n+1}}{(2n+1)!}\right),\quad n\geqslant 1. \tag{33}$$

V. SOLUTION OF THE DESCENT EQUATIONS

Having computed the cohomology of the BRS operator b, let us face now the problem of solving the descent equations

$$\begin{gathered} b\omega_{D-j}^{G+j}+d\omega_{D-j-1}^{G+j+1}=0,\quad 0\leqslant j\leqslant D-1,\\ b\omega_0^{G+D}=0. \end{gathered} \tag{34}$$

Introducing the generalized cocycle of total degree $(G+D)$

$$\tilde{\omega}^{G+D}=\sum_{j=0}^{D}\omega_j^{G+D-j}, \tag{35}$$

the descent equations (34) can be cast in the more compact form

$$\tilde{d}\tilde{\omega}^{G+D}=0, \tag{36}$$

$\tilde{d}$ being the nilpotent generalized differential of Eq. (25). Taking into account the zero-curvature condition

$$\tilde{d}\tilde{\mathscr{A}}=i\tilde{\mathscr{A}}^2 \tag{37}$$

and the previous result (33) on the cohomology of the BRS operator b, it follows that the generalized monomials of the type

$$\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!},\quad n\geqslant 1, \tag{38}$$

belongs to the cohomology of $\tilde{d}$,

$$\tilde{d}\left(\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!}\right)=0,\quad \mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!}\neq\tilde{d}\tilde{\mathscr{Q}}^{2n}, \tag{39}$$

for any local polynomial $\tilde{\mathcal{Q}}^{2n}$.

Thus it is apparent that a solution of the descent equations (34) is simply provided by

$$\tilde{\omega}^{G+D}=\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{G+D}}{(G+D)!}, \tag{40}$$

which, of course, is nonvanishing only if its total degree $(G+D)$ is odd. In fact, developing $(\mathrm{Tr}\,\tilde{\mathscr{A}}^{G+D})$ according to the form degree and to the ghost number

$$\left(\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{G+D}}{(G+D)!}\right)=\sum_{j=0}^{D}\omega_j^{G+D-j}, \tag{41}$$

and recalling that $\tilde{d}\tilde{\omega}^{G+D}=0$, it is easily verified that the ω's in Eq. (41) obey

$$\begin{aligned} b\,\omega_{D-j}^{G+j}+d\,\omega_{D-j-1}^{G+j+1}&=0,\\ b\,\omega_0^{G+D}&=0, \end{aligned} \tag{42}$$

i.e., they solve the descent equations.

In addition, from $(\mathrm{Tr}\,\tilde{\mathscr{A}}^{2n+1}\neq\tilde{d}\tilde{\mathcal{Q}}^{2n})$, it follows that they provide a nontrivial solution

$$\begin{aligned} \omega_j^{G+D-j}&\neq b\mathcal{Q}_j^{G+D-1-j}+d\mathcal{Q}_{j-1}^{G+D-j},\quad 1\leqslant j\leqslant D,\\ \omega_0^{G+D}&\neq b\mathcal{Q}_0^{G+D-1}. \end{aligned} \tag{43}$$

In particular, for the zero form ω_0^{G+D} we obtain

$$\omega_0^{G+D}=\mathrm{Tr}\,\frac{c^{G+D}}{(G+D)!}. \tag{44}$$

Let us remark, finally, that as a consequence of the fact that the generalized ladder $\tilde{\mathscr{A}}$ is the δ-transform of the ghost field c, $\tilde{\mathscr{A}}=e^{\delta}c$, the generalized cocycle (38) is the δ-transform of the corresponding ghost cocycle (44), i.e.,

$$\left(\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!}\right)=e^{\delta}\,\mathrm{Tr}\left(\frac{c^{2n+1}}{(2n+1)!}\right). \tag{45}$$

A. Example I: The Chern–Simons theory

For a better understanding of the previous construction let us discuss in detail the case of the three-dimensional Chern–Simons theory, corresponding to $G=0$ and $D=3$. This example will give us the possibility of clarifying the meaning of the negative ghost number components $(\varphi_j^{1-j}$, $2\leqslant j\leqslant D)$ of the gauge ladder $\tilde{\mathscr{A}}$. As we shall see, these fields turn out to be the so-called external BRS sources (*called also antifields in the framework of Batalin–Vilkovsky*[26]) needed in order to properly define[1] the nonlinear transformations of the gauge connection A and of the Faddeev–Popov ghost c. The external sources are then naturally included in the zero-curvature formalism.

In a three-dimensional space–time the complete gauge ladder $\tilde{\mathscr{A}}$ of Eq. (13) takes the following form:

$$\tilde{\mathscr{A}} = c + A + \gamma + \tau, \tag{46}$$

γ and τ identifying, respectively, the negative ghost number components φ_2^{-1} and φ_3^{-2}. From the zero curvature condition (18) one obtains the BRS transformations:

$$\begin{gathered} bc = ic^2, \quad bA = -dc + i[c,\ A], \\ b\gamma = -F + i[c,\ \gamma], \quad b\tau = -d\gamma + i[c,\ \tau] + i[A,\ \gamma], \end{gathered} \tag{47}$$

F being the two-form gauge field strength $F = dA - iA^2$. As explained before, in order to find a solution of the descent equations

$$\begin{gathered} b\omega_{3-j}^{j} + d\omega_{2-j}^{j+1} = 0, \quad 0 \leqslant j \leqslant 2, \\ b\omega_0^3 = 0, \end{gathered} \tag{48}$$

it is sufficient to expand the generalized cocycle of total degree three:

$$\tilde{\omega}^3 = \frac{1}{3!}\ \mathrm{Tr}\ \tilde{\mathscr{A}}^3. \tag{49}$$

After an easy computation we get

$$\frac{1}{3!}\ \mathrm{Tr}\ \tilde{\mathscr{A}}^3 = \omega_3^0 + \omega_2^1 + \omega_1^2 + \omega_0^3, \tag{50}$$

with

$$\begin{gathered} \omega_0^3 = \frac{1}{3!}\ \mathrm{Tr}\ c^3, \quad \omega_1^2 = \frac{1}{2}\ \mathrm{Tr}\ c^2 A, \\ \omega_2^1 = \frac{1}{2}\ \mathrm{Tr}(c^2\gamma + cA^2), \\ \omega_3^0 = \frac{1}{2}\ \mathrm{Tr}\left(c^2\tau + cA\gamma + c\gamma A + \frac{A^3}{3} \right). \end{gathered} \tag{51}$$

From

$$-i\ \mathrm{Tr}(c^2\tau + cA\gamma + c\gamma A) = -\mathrm{Tr}\ AF + b\ \mathrm{Tr}(c\tau + A\gamma) + d\ \mathrm{Tr}\ c\gamma, \tag{52}$$

the three-form ω_3^0 can be rewritten as

$$\omega_3^0 = \frac{-i}{2}\ \mathrm{Tr}\left(AF + i\,\frac{A^3}{3} \right) + \frac{i}{2}\ b\ \mathrm{Tr}(c\tau + A\gamma) + \frac{i}{2}\ d\ \mathrm{Tr}\ c\gamma, \tag{53}$$

yielding thus the invariant action

$$S = i\int \omega_3^0 = \frac{1}{2}\int \mathrm{Tr}\left(AF + i\,\frac{A^3}{3} \right) - \frac{1}{2}\ b\int \mathrm{Tr}(c\tau + A\gamma), \tag{54}$$

which is easily recognized to be the so-called truncated action[1] of the fully quantized Chern–Simons gauge theory. In particular, one sees that the components (γ,τ) of the gauge ladder (46) are the BRS external sources corresponding to the nonlinear transformations of the fields A and c.

VI. COUPLING WITH MATTER FIELDS

The zero-curvature formalism can be extended to include the case in which the gauge fields are coupled to matter fields whose quantization requires the introduction of a complete ladder matter multiplet. A typical example of this kind of coupling is given by the topological BF systems[17,27] whose classical action reads

$$\mathrm{Tr}\int_{\mathscr{M}^D}\mathscr{B}^0_{D-2}F, \tag{55}$$

where F is the two-form gauge curvature, $\mathscr{B}^0_{D-2}$ is a $(D-2)$ form with ghost number zero, and $\mathscr{M}^D$ is a D-dimensional manifold without boundaries.

In the next section we shall discuss another example of matter system, namely the B-C ghost system of the string theory, whose action is not directly given in terms of differential forms. Nevertheless we shall see that this model, although different from the BF systems, actually shares many properties of the latters.

The inclusion of the matter fields goes as follows (see also Ref. 19): we introduce a set of fields $(\mathscr{B}^{D-2}_0, \mathscr{B}^{D-3}_1,\ldots, \mathscr{B}^1_{D-3}, \mathscr{B}^{-1}_{D-1}, \mathscr{B}^{-2}_D)$ which together with the matter field $\mathscr{B}^0_{D-2}$ give rise to a complete ladder $\mathscr{B}$ of total degree $(D-2)$, i.e.,

$$\tilde{\mathscr{B}}=\sum_{j=0}^{D}\mathscr{B}^{D-2-j}_j. \tag{56}$$

The BRS transformations of the various components of this ladder are obtained by requiring that $\tilde{\mathscr{B}}$ is covariantly constant with respect to the generalized covariant derivative $\tilde{\mathscr{D}}=\tilde{d}-i[\tilde{\mathscr{A}},]$,

$$\tilde{\mathscr{D}}\tilde{\mathscr{B}}=\tilde{d}\tilde{\mathscr{B}}-i[\tilde{\mathscr{A}},\ \tilde{\mathscr{B}}]=0. \tag{57}$$

This condition, when expanded in terms of the form degree and of the ghost number, gives in fact the following nilpotent transformations:

$$\begin{aligned} b\mathscr{B}^{D-2}_0&=i[c,\ \mathscr{B}^{D-2}_0],\\ b\mathscr{B}^{D-2-j}_j&=-d\mathscr{B}^{D-1-j}_{j-1}+i\sum_{m=0}^{j}[\varphi^{1-m}_m,\ \mathscr{B}^{D-2-j+m}_{j-m}],\quad 1\leqslant j\leqslant D. \end{aligned} \tag{58}$$

Repeating the same procedure of Sec. IV and making use of the general results of Refs. 15, 20, 21, and 25, one easily checks that with the inclusion of the matter ladder the cohomology of the BRS operator is given by polynomials in the undifferentiated zero form ghosts $(c, \mathscr{B}^{D-2}_0)$ built up with factorized monomials of the type

$$\left(\mathrm{Tr}\,\frac{c^{2n+1}}{(2n+1)!}\right)\cdot\mathrm{Tr}(\mathscr{B}^{D-2}_0)^m,\quad m,n\geqslant 1. \tag{59}$$

In much the same way as the gauge ladder $\tilde{\mathscr{A}}$, the operator δ extends to the matter multiplet $\tilde{\mathscr{B}}$ by means of

$$\tilde{\mathscr{B}} = e^{\delta}.\mathscr{B}_0^{D-2}, \tag{60}$$

i.e.,

$$\begin{gathered}\delta.\mathscr{B}_j^{D-2-j} = (j+1).\mathscr{B}_{j+1}^{D-3-j}, \quad 0 \leqslant j \leqslant D-1, \\ \delta.\mathscr{B}_D^{-2} = 0,\end{gathered} \tag{61}$$

and

$$\begin{gathered}\delta d.\mathscr{B}_j^{D-2-j} = (j+1)d.\mathscr{B}_{j+1}^{D-3-j}, \quad 0 \leqslant j \leqslant D-2, \\ \delta d.\mathscr{B}_{D-1}^{-1} = 0,\end{gathered} \tag{62}$$

so that the algebraic relations

$$d = -[b,\ \delta], \quad [\delta,\ d] = 0, \tag{63}$$

are fulfilled.

For what concerns the cohomology of the generalized operator $\tilde{d}$ of Eqs. (37) and (57), it is immediately seen from Eq. (59) that it is spanned by factorized monomials in the ladders $\tilde{\mathscr{A}}$ and $\tilde{\mathscr{B}}$ of the type

$$\left(\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!}\right)\cdot(\mathrm{Tr}\,\tilde{\mathscr{B}}^{m}). \tag{64}$$

As already discussed in the previous section, the expansion of the above expression (64) in terms of the form degree and of the ghost number yields a solution of the descent equations (34) in the presence of a matter field ladder, reproducing thus the results already established in Ref. 8. Again

$$\left(\mathrm{Tr}\,\frac{\tilde{\mathscr{A}}^{2n+1}}{(2n+1)!}\right)\cdot \mathrm{Tr}\,\tilde{\mathscr{B}}^{m} = e^{\delta}\left(\mathrm{Tr}\,\frac{c^{2n+1}}{(2n+1)!}\right)\cdot(\mathrm{Tr}(.\mathscr{B}_0^{D-2})^{m}), \tag{65}$$

which shows that the cohomology of $\tilde{d}$ is the δ-transform of that of the BRS operator b. Let us conclude this section by remarking that in a space–time of dimension ($D \geqslant 2$) the gauge ladder $\tilde{\mathscr{A}}$ contains $(D-1)$ components of negative ghost number, i.e., $(\varphi_2^{-1},...,\varphi_D^{1-D})$, while the matter ladder $\tilde{\mathscr{B}}$ contains $(D-2)$ components with positive ghost number, i.e., $(\mathscr{B}_0^{D-2}, \mathscr{B}_1^{D-3},...,\mathscr{B}_{D-3}^{1})$, and two components of negative ghost number, namely $(\mathscr{B}_{D-1}^{-1}, \mathscr{B}_D^{-2})$.

These fields turn out to possess the following meaning. The set $(\mathscr{B}_0^{D-2}, \mathscr{B}_1^{D-3},...,\mathscr{B}_{D-3}^{1})$ identifies the well-known tower of ghosts for ghosts needed for the quantization of the *BF* systems. The components $(\varphi_3^{-2},...,\varphi_D^{1-D})$ are then the corresponding $(D-2)$ external sources (or antifields) associated to the nonlinear transformations of the ghosts for ghosts [see Eq. (58)], while φ_2^{-1} is the external source for the $(D-2)$ form $\mathscr{B}_{D-2}^{0}$. Finally $(\mathscr{B}_{D-1}^{-1}, \mathscr{B}_D^{-2})$ are the sources corresponding to the first two components of the gauge ladder, i.e., c and A. We thus see that in the case of the *BF* systems the external sources are exchanged,[8] i.e., the sources for the quantized components of the matter ladder are grouped into the gauge ladder and vice versa.

Let us also recall, for completeness, that the truncated action (including the ghosts for ghosts and the external sources) for the *BF* systems can be cast in the simple form[19]

$$S=\mathrm{Tr}\int_{\mathscr{M}^D}\tilde{\mathscr{B}}(d.\tilde{\mathscr{A}}-i.\tilde{\mathscr{A}}^2)\Big|_D^0=-\mathrm{Tr}\int_{\mathscr{M}^D}\tilde{\mathscr{B}}b.\tilde{\mathscr{A}}\Big|_D^0, \tag{66}$$

where $|_D^0$ means the restriction to terms of ghost number 0 and form degree D. The equality in Eq. (66) stems from the zero-curvature condition (18).

In particular, using Eq. (57), expression (66) is easily proven to be invariant under the action of the operator b,

$$bS=0, \tag{67}$$

this equation expressing the content of the Slavnov–Taylor (or Master Equation) identity.

VII. EXAMPLE II: THE *B*-*C* GHOST SYSTEM

We present here, as another interesting example of matter system, the zero-curvature formulation of the two-dimensional B-C model whose action reads

$$S_{B\text{-}C}=\int dz\, d\bar{z}\, B\, \bar{\partial}C, \tag{68}$$

where the fields $B=B_{zz}$ and $C=C^z$ are anticommuting and carry, respectively, ghost number -1 and $+1$.

It should be noted that, unlike the previous examples, the fields appearing in the action (68) are not naturally associated to differential forms. However, we shall see that, in spite of the fact that these fields do not give rise to a complete ladder structure, this system turns out to possess the same algebraic features of the BF models. The action (68) is recognized to be the ghost part of the quantized bosonic string action which, as it is well known, is left invariant by the following nonlinear BRS transformations

$$\begin{aligned} sC&=C\partial C,\\ sB&=-(\partial B)C-2B\partial C. \end{aligned} \tag{69}$$

The above expression (68) is usually accompanied by its complex conjugate. However, the inclusion of the latter in the present framework does not require any additional difficulty.

In particular, the right-hand side of the BRS transformation of the field B is recognized to be the component T_{zz} of the energy–momentum tensor corresponding to the action (68), this property allowing for a topological interpretation of the model.

Transformations (69) being nonlinear, one needs to introduce two external invariant sources $\mu=\mu_{\bar{z}}^z$ and $L=L_{zz\bar{z}}$ of ghost numbers, respectively, 0 and -2

$$S_{\mathrm{ext}}=\int dz\, d\bar{z}(\mu sB+LsC). \tag{70}$$

The complete action

$$S=S_{B\text{-}C}+S_{\mathrm{ext}} \tag{71}$$

obeys thus the classical Slavnov–Taylor identity

$$\int dz\, d\bar{z}\left(\frac{\delta S}{\delta B}\frac{\delta S}{\delta \mu}+\frac{\delta S}{\delta L}\frac{\delta S}{\delta C}\right)=0=\frac{1}{2}\,bS, \tag{72}$$

b denoting the nilpotent linearized operator

$$b=\int dz\ d\overline{z}\left(\frac{\delta S}{\delta B}\frac{\delta}{\delta\mu}+\frac{\delta S}{\delta\mu}\frac{\delta}{\delta B}+\frac{\delta S}{\delta L}\frac{\delta}{\delta C}+\frac{\delta S}{\delta C}\frac{\delta}{\delta L}\right). \tag{73}$$

The operator b acts on the fields and on the external sources in the following way:

$$bC=sC=C\partial C,\quad b\mu=\overline{\partial C}+(\partial\mu)C-\mu(\partial C), \tag{74}$$

and

$$\begin{aligned} bB&=sB=-(\partial B)C-2B\partial C,\\ bL&=\overline{\partial B}-(2B)\partial\mu-\mu\partial B+(\partial L)C+2L\partial C. \end{aligned} \tag{75}$$

It should be noted that, due to the fact that the BRS transformation of B is the component T_{zz} of the energy-momentum tensor, the differentiation with respect to the external source μ of the Legendre transformation of the complete action (71),

$$Z(j,\mu,L)=S+\int dz\ d\overline{z}(j_C C+j_B B), \tag{76}$$

allows us to obtain the Green's functions with insertion of T_{zz}. In other words, the Slavnov–Taylor identity (72) is the starting point for the algebraic characterization of the energy–momentum current algebra.

Introducing now the two functional operators[10]

$$\mathscr{W}=\int dz\ d\overline{z}\frac{\delta}{\delta C},\quad \overline{\mathscr{W}}=\int dz\ d\overline{z}\left(\mu\frac{\delta}{\delta C}+L\frac{\delta}{\delta B}\right), \tag{77}$$

one easily proves that

$$\delta=dz\mathscr{W}+d\overline{z}\overline{\mathscr{W}} \tag{78}$$

obeys

$$d=-[b,\ \delta],\quad [d,\ \delta]=0, \tag{79}$$

d being the exterior derivative $d=dz\partial+d\overline{z}\overline{\partial}$. We have thus realized the decomposition (24). In order to derive the transformations (74) and (75) from a zero curvature condition we proceed as before and we define the analogue of the gauge ladder (13) as

$$\widetilde{C}^z=e^{\delta}C^z=C^z+dz+d\overline{z}\mu^z_{\overline{z}}. \tag{80}$$

Introducing then the holomorphic generalized vector field $\widetilde{C}=\widetilde{C}^z\partial_z$, it is easily checked that equations (74) can be cast in the form of a zero curvature condition

$$\widetilde{d}\widetilde{C}=\tfrac{1}{2}[\widetilde{C},\ \widetilde{C}]=\mathscr{L}_{\widetilde{C}}\widetilde{C}, \tag{81}$$

where, as usual, $\widetilde{d}$ is the operator

$$\widetilde{d}=e^{\delta}be^{-\delta}=b+d, \tag{82}$$

and $\mathscr{L}_{\widetilde{C}}$ denotes the Lie derivative with respect to the vector field $\widetilde{C}$. Of course, the bracket $[\widetilde{C}, \widetilde{C}]$ in Eq. (82) refers now to the usual Lie bracket of vector fields.

Concerning now the second set of transformations (75), we define the matter ladder $\widetilde{\mathscr{B}}_{zz}$ as

$$\widetilde{\mathscr{B}}_{zz}=e^{\delta}.\mathscr{B}_{zz}=\mathscr{B}_{zz}+d\overline{z}\,L_{zz\overline{z}}. \tag{83}$$

To expression (83) one can naturally associate the generalized holomorphic quadratic differential

$$\widetilde{\mathscr{B}}=\widetilde{\mathscr{B}}_{zz}\,dz\otimes dz. \tag{84}$$

Therefore, transformations (75) can be rewritten as

$$\widetilde{d}.\widetilde{\mathscr{B}}-\mathscr{L}_{\widetilde{C}}\widetilde{\mathscr{B}}=0. \tag{85}$$

This equation is the analogue of the covariantly constant matter condition (57) and together with Eq. (81) completely characterizes the B-C system. One has to remark that, as it happens in the case of the BF models, the external sources (μ, L) are interchanged, i.e., the source μ associated to the nonlinear transformation of B belongs to the gauge ladder $\widetilde{C}$ and vice versa.

Let us consider now the problem of identifying the anomalies which affect the Slavnov–Taylor identity (72) at the quantum level. We look then at the solution of the descent equations

$$b\,\omega_2^1+d\,\omega_1^2=0,\quad b\,\omega_1^2+d\,\omega_0^3=0,\quad b\,\omega_0^3=0. \tag{86}$$

As it has been proven in Refs. 10 and 28, the cohomology of the BRS operator in the sector of the zero forms with ghost number three contains, in the present case, a unique element given by

$$\omega_0^3=C\partial C\partial^2 C. \tag{87}$$

From the zero-curvature condition (81), it follows then that the generalized cocycle of total degree three,

$$\widetilde{\omega}^3=\widetilde{C}\partial\widetilde{C}\partial^2\widetilde{C}, \tag{88}$$

belongs to the cohomology of $\widetilde{d}$. The expansion of $\widetilde{\omega}^3$ will give thus a solution of the ladder (86), i.e.,

$$\widetilde{\omega}^3=\omega_0^3+\omega_1^2+\omega_2^1, \tag{89}$$

with ω_1^2, ω_2^1 given, respectively, by

$$\begin{aligned}\omega_1^2&=(C\partial C\partial^2\mu-C\partial^2 C\partial\mu+\mu\partial C\partial^2 C)d\overline{z}+(\partial C)(\partial^2 C)dz,\\ \omega_2^1&=(-\partial C\partial^2\mu+\partial\mu\partial^2 C)dz\wedge d\overline{z}.\end{aligned} \tag{90}$$

In particular,

$$\int\ \omega_2^1=2\int dz d\overline{z}C\partial^3\mu \tag{91}$$

is recognized to be the well-known two-dimensional diffeomorphism anomaly characterizing the central charge of the energy–momentum current algebra.

Let us conclude by remarking that the complete B-C action (71) can be written, in perfect analogy with Eq. (66) as

$$S=\int \tilde{\mathscr{B}}_{zz}(d\tilde{C}^z-\tilde{C}^z\ \partial\tilde{C}^z)dz\Big|_2^0=-\int \tilde{\mathscr{B}}_{zz}b\tilde{C}^z\ dz\Big|_2^0, \tag{92}$$

showing that the B-C model can be interpreted as a kind of two-dimensional BF system.

VIII. CONCLUSION

The zero curvature formulation of models characterized by means of a complete ladder field can be obtained as a consequence of the existence of the operator δ realizing the decomposition (5). Moreover, the zero curvature condition enables us to encode into a unique equation all the relevant informations concerning the BRS cohomology classes.

I. INTRODUCTION

In the first part of this work[1] (referred to as part I), we have studied the zero-curvature formulation of systems described by means of a complete ladder field, the components of which span all possible form degrees. The present paper is devoted to analyzing the zero-curvature equation in the case in which the completeness condition for the generalized ladder field is relaxed. This means that we shall deal with a gauge ladder $\tilde{\mathscr{A}}$ for which the form degree of the highest component is strictly lower than the space–time dimension D, i.e.,

$$\tilde{\mathscr{A}}=c+A+\varphi_2^{-1}+\cdots+\varphi_q^{1-q}, \quad 1\leqslant q<D. \tag{1}$$

As we shall see in the following, the noncomplete case will display a set of remarkable features which will make it quite different from the previous complete case. The first interesting aspect, as already mentioned in the Introduction of part I, is that the consistency of the zero-curvature condition

$$\tilde{\mathscr{F}}=\tilde{d}.\tilde{\mathscr{A}}-i.\tilde{\mathscr{A}}^2=0 \tag{2}$$

implies now the existence of a set of new operators ($\mathscr{G}_k^{1-k}$, $2\leqslant k\leqslant D$) which are in involution, according to the algebra

$$\begin{aligned}\mathscr{G}_2^{-1}&=\frac{1}{2}[\delta,\ d],\\ \mathscr{G}_k^{1-k}&=\frac{1}{k}[\delta,\ \mathscr{G}_{k-1}^{2-k}], \quad k>2,\end{aligned} \tag{3}$$

δ being the operator which together with the Becchi–Rouet–Stora (BRS) operator b decomposes the exterior space–time derivative d as

$$d=-[b,\ \delta], \tag{4}$$

where, as already remarked in the Introduction of part I, the decomposition (4) has to be understood to hold in the space of form-valued polynomials. This space is in fact the basic functional space of our analysis.

The second interesting feature of the noncomplete case is that the cohomology of the BRS operator b is richer than the corresponding one of the complete case. Indeed, the noncompleteness of $\tilde{\mathscr{A}}$ will allow us to introduce a set of curvatures $(R^{1-m}_{m+1},\ 1\leqslant m\leqslant q)$ which are a generalization of the familiar two-form gauge field strength $F=dA-iA^2$. It follows then that, in addition to the usual ghost cocycles $(\mathrm{Tr}\, c^{2n+1})$ of the complete case (see Sec. IV of part I), the cohomology of b now includes also invariant polynomials in the highest curvature (R^{1-q}_{q+1}).

As a consequence of these new features, the expressions of the polynomials ω^{G+D-j}_j $(0\leqslant j\leqslant D)$ which solve the descent equations

$$\begin{gathered} b\,\omega^{G+j}_{D-j}+d\,\omega^{G+j+1}_{D-j-1}=0, \quad 0\leqslant j\leqslant (D-1), \\ b\,\omega^{G+D}_0=0, \end{gathered} \tag{5}$$

will get modified with respect to the complete case. This modification will result in the appearance of a set of local polynomials Ω^{G+D-j}_j $(q+1\leqslant j\leqslant D)$ in the curvatures (R^{1-m}_{m+1}) which have to be added to the cocycles obtained from the expansion of the generalized terms $(\mathrm{Tr}\,\tilde{\mathscr{A}}^{G+D})$. These polynomials, as already observed in Refs. 2 and 3 in the case of Yang–Mills, turn out to be characterized by a set of consistency conditions involving the operators $\mathscr{G}^{1-k}_k$.

This second part of the work is organized as follows. In Sec. II we present the zero-curvature condition for the noncomplete gauge ladder. Section III is devoted to the study of the cohomology of the BRS operator. In Sec. IV we solve the descent equations. Sections V and VI are finally devoted to the discussion of several examples among which one finds the zero-curvature formulation of the pure Yang–Mills gauge theory.

II. THE ZERO-CURVATURE CONDITION

In part I (cf. Sec. II) the BRS transformations of the various components of the gauge ladder $\tilde{\mathscr{A}}$ have been obtained by constraining the latter to obey a zero-curvature condition. Equivalently, as we have seen in Sec. III of part I, once the BRS transformations of the fields have been given, the zero-curvature condition becomes a consequence of the existence of the operator δ which realizes the decomposition (4). This second procedure will be taken as the starting point for the discussion of the zero-curvature condition in the present noncomplete case. The gauge ladder $\tilde{\mathscr{A}}$ now takes the following form;

$$\tilde{\mathscr{A}}=c+A+\varphi^{-1}_2+\cdots+\varphi^{1-q}_q, \quad 1\leqslant q<D, \tag{6}$$

D being the dimension of the space–time. We will assume therefore that the nilpotent BRS transformations of the components $\varphi^{1-j}_j (0\leqslant j\leqslant q)$ of (6) will be the same as those of the corresponding complete case (see Sec. II of part I), i.e.,

$$\begin{gathered} bc=ic^2, \quad bA=-dc+i[c,\ A], \\ b\varphi^{1-j}_j=-d\varphi^{2-j}_{j-1}+\frac{i}{2}\sum_{m=0}^{j}[\varphi^{1-m}_m,\ \varphi^{1-j+m}_{j-m}], \quad 2\leqslant j\leqslant q, \end{gathered} \tag{7}$$

where, as usual, $[a,\ b]=ab-(-1)^{|a||b|}ba$ denotes the graded commutator and, as done in part I, we shall work in the functional space $\mathscr{V}$ of form-valued polynomials built up with the fields φ^{1-j}_j and their differential $d\varphi^{1-j}_j$, i.e.,

$$\mathscr{V}=\text{polynomials in } (\varphi^{1-j}_j, d\varphi^{1-j}_j; 0\leqslant j\leqslant q). \tag{8}$$

Having assigned the BRS transformations, let us turn to the introduction of the decomposition (4). To this purpose we define the operator δ as

$$\tilde{\mathscr{A}}=e^{\delta}c,$$
$$\delta\varphi_j^{1-j}=(j+1)\varphi_{j+1}^{-j},\quad 0\leqslant j\leqslant q-1, \tag{9}$$
$$\delta\varphi_q^{1-q}=0,$$

and

$$\delta d\varphi_m^{1-m}=(m+1)d\varphi_{m+1}^{-m},\quad 0\leqslant m\leqslant q-2,$$
$$\delta d\varphi_{q-1}^{2-q}=q d\varphi_q^{1-q}-(q+1)\left(d\varphi_q^{1-q}-\frac{i}{2}\sum_{j=1}^{q}[\varphi_j^{1-j},\ \varphi_{q-j+1}^{j-q}]\right), \tag{10}$$
$$\delta d\varphi_q^{1-q}=\frac{i}{2}(q+1)\sum_{j=1}^{q}[\varphi_{q+2-j}^{-1-q+j},\ \varphi_j^{1-j}].$$

One easily checks that, on the functional space $\mathscr{V}$, the operators b and δ realize the decomposition (4), i.e.,

$$d=-[b,\ \delta]. \tag{11}$$

Comparing now Eqs. (9) and (10) the corresponding ones of the complete ladder case (see Sec. II of part I) one sees that, while the action of the operator δ on the components (φ_j^{1-j}) is the same, the transformations of the differentials of higher form degree, i.e., $(d\varphi_{q-1}^{2-q})$ and $(d\varphi_q^{1-q})$, are now nonvanishing. This fact implies that, contrary to the complete case, the operator δ does not commute anymore with the exterior derivative d,

$$[\delta,\ d]\neq 0. \tag{12}$$

In addition, depending on the dimension of the space–time D and on the number q of components of the gauge ladder $\mathscr{A}$, the commutators

$$[\delta,[\delta,[\delta,\ldots,d]]] \tag{13}$$

turn out to be nonvanishing as well.

This algebraic structure, which generalizes that of Refs. 2 and 3, will have important consequences on the zero-curvature condition. The latter, repeating the same argument of Sec. III of part I, is obtained by applying the operator e^{δ} on the BRS transformation of the zero-form ghost field c, i.e.,

$$e^{\delta}be^{-\delta}e^{\delta}c=e^{\delta}ic^2. \tag{14}$$

Recalling now that $\tilde{\mathscr{A}}=e^{\delta}c$ and defining the generalized operator $\tilde{d}$ as

$$\tilde{d}=e^{\delta}be^{-\delta}, \tag{15}$$

we get the zero-curvature condition

$$\tilde{d}\tilde{\mathscr{A}}=i\tilde{\mathscr{A}}^2 \tag{16}$$

for the noncomplete ladder case. Equation (16) is, however, only apparently similar to the corresponding condition of the complete ladder case. In fact, due to Eqs. (12) and (13), the operator $\tilde{d}$ is now given by

$$\tilde{d}=b+d+\sum_{n\geqslant 2}^{D}\frac{1}{n!}\underbrace{[\delta,[\delta,[\delta,\ldots,d]]]}_{(n-1)\text{ times}}, \tag{17}$$

so that, defining the operators

$$\begin{aligned}
\mathcal{G}_2^{\,1}&=\frac{1}{2}[\delta,\,d],\\
\mathcal{G}_3^{\,2}&=\frac{1}{3!}[\delta,[\delta,d]]=\frac{1}{3}[\delta,\,\mathcal{G}_2^{\,1}],\\
\mathcal{G}_4^{\,3}&=\frac{1}{4!}[\delta,[\delta,[\delta,d]]]=\frac{1}{4}[\delta,\mathcal{G}_3^{\,2}],\\
&\cdots,
\end{aligned} \tag{18}$$

we have

$$\tilde{d}=b+d+\sum_{k\geqslant 2}^{D}\mathcal{G}_k^{1-k} \tag{19}$$

with

$$\begin{aligned}
\mathcal{G}_2^{\,1}&=\frac{1}{2}[\delta,\,d],\\
\mathcal{G}_k^{1-k}&=\frac{1}{k}[\delta,\,\mathcal{G}_{k-1}^{2-k}],\quad k>2.
\end{aligned} \tag{20}$$

One thus sees that in the noncomplete case the zero-curvature condition is accompanied by a set of operators $\mathcal{G}_k^{1-k}$ which are in involution, according to Eq. (20). We underline, in particular, that the origin of the operators $\mathcal{G}_k^{1-k}$ actually relies on the noncomplete character of the gauge ladder (6). It is very easy, using Eqs. (9) and (10), to derive the explicit form of the various operators $\mathcal{G}_k^{1-k}$ appearing in Eq. (16). In particular, as we shall show later on in the examples, the number of operators $\mathcal{G}_k^{1-k}$ which do not identically vanish depends both on the dimension D of the space–time and on the number q of components of the gauge ladder $\tilde{\mathcal{A}}$. We also notice that these operators are absent when $q=D$, i.e., they are not present in the case in which the ladder is complete.

Moreover their existence implies that the cohomology of the operator $\tilde{d}$ is no more directly related to that of the operator $(d+b)$. Therefore the cohomology classes of $\tilde{d}$ do not immediately provide solutions of the descent equations (5). It turns out indeed that in order to obtain a solution of the tower (5) we must add to the cohomology classes of $\tilde{d}$, i.e., $\mathrm{Tr}\,\tilde{\mathcal{A}}^{2n+1}$, certain polynomials Ω_j^{G+D-j} $(q+1\leqslant j\leqslant D)$ which obey a set of consistency conditions involving the operator $\mathcal{G}_k^{1-k}$. In other words, the presence of the $\mathcal{G}_k^{1-k}$'s requires a modification of the solution of the descent equations with respect to the complete ladder case (see Sec. V of part I).

Let us conclude this section with the following remark. Instead of having assumed the BRS transformations (7) we could have started directly with the zero-curvature condition (16). It is easily verified then that the introduction of the operators $\mathcal{G}_k^{1-k}$ is needed in order to avoid the appearance of constraints among the components of the noncomplete ladder field $\tilde{\mathcal{A}}$.

III. COHOMOLOGY OF THE BRS OPERATOR

The first step in order to solve the descent equations (5) is that of computing the cohomology of the BRS operator b. This task, due to the noncomplete character of $\mathscr{A}$, will turn out to be simplified by the introduction of the following curvatures R_{m+1}^{1-m} of total degree two:

$$R_{m+1}^{1-m}=d\varphi_m^{1-m}-\frac{i}{2}\sum_{k=1}^{m}[\varphi_k^{1-k},\ \varphi_{m+1-k}^{k-m}];\quad 1\leqslant m\leqslant q. \tag{21}$$

In particular, for $m=1$ the expression (21) reduces to

$$R_2^0=dA-iA^2=F, \tag{22}$$

i.e., one recovers the familiar two-form gauge field strength. We also remark that, for $m>1$, the curvatures R_{m+1}^{1-m} possess the property of having negative ghost number.

The great advantage of working with the curvatures R_{m+1}^{1-m} relies on the fact that they transform covariantly under the action of the BRS operator, i.e.,

$$bR_{m+1}^{1-m}=i[c,\ R_{m+1}^{1-m}]. \tag{23}$$

This feature, following the well-known Yang–Mills case,[4–7] suggests that it is convenient to use the curvatures R_{m+1}^{1-m} as independent variables instead of the differentials $d\varphi_m^{1-m}$, i.e., we replace everywhere the variables $d\varphi_m^{1-m}$ by R_{m+1}^{1-m} making use of Eq. (21). Consequently, for the functional space $\mathscr{V}$ we have

$$\mathscr{V}=\text{polynomials in } (c,A,\varphi_m^{1-m},2\leqslant m\leqslant q;dc,R_{j+1}^{1-j},1\leqslant j\leqslant q), \tag{24}$$

and, for the nilpotent BRS transformations,

$$\begin{aligned}
bc&=ic^2,\\
bA&=-dc+i[c,\ A],\\
b\varphi_m^{1-m}&=i[c,\ \varphi_m^{1-m}]-R_m^{2-m},\quad 2\leqslant m\leqslant q,\\
bdc&=i[c,\ dc],\\
bR_{j+1}^{1-j}&=i[c,\ R_{j+1}^{1-j}],\quad 1\leqslant j\leqslant q.
\end{aligned} \tag{25}$$

Let us turn now to the computation of the cohomology of b. Introducing the filtering operator $\mathscr{N}$

$$\begin{aligned}
&\mathscr{N}c=c,\quad \mathscr{N}A=A,\\
&\mathscr{N}\varphi_m^{1-m}=\varphi_m^{1-m},\quad 2\leqslant m\leqslant q,\\
&\mathscr{N}dc=dc,\quad \mathscr{N}R_{j+1}^{1-j}=R_{j+1}^{1-j},\quad 1\leqslant j\leqslant q,
\end{aligned} \tag{26}$$

the BRS operator decomposes as

$$b=b_0+b_1, \tag{27}$$

with

$$\begin{gathered} b_0 c = 0, \quad b_0 A = -dc, \quad b_0 dc = 0, \\ b_0 \varphi_m^{1-m} = -R_m^{2-m}, \quad b_0 R_m^{2-m} = 0, \quad 2 \leqslant m \leqslant q, \\ b_0 R_{q+1}^{1-q} = 0, \quad b_0^2 = 0. \end{gathered} \tag{28}$$

Equations (28) show that all the variables except the zero-form ghost c and the highest curvature R_{q+1}^{1-q} are grouped in BRS doublets. This implies that the cohomology of b_0 and, in turn, that of the full BRS operator b, depend only on c and R_{q+1}^{1-q}. More precisely, using the general results of Refs. 4–7, it follows that the cohomology of b on the functional space V is spanned by invariant polynomials in the variables (c, R_{q+1}^{1-q}) built up with factorized monomials of the form

$$\left(\mathrm{Tr}\, \frac{c^{2n+1}}{(2n+1)!} \right) \cdot (\mathrm{Tr}(R_{q+1}^{1-q})^m), \quad n, m = 1, 2, \ldots . \tag{29}$$

One sees that in the noncomplete ladder case the cohomology of the BRS operator b, in addition of the usual ghost cocycles $(\mathrm{Tr}\, c^{2n+1})$, includes also polynomials in the highest curvatures R_{q+1}^{1-q}. Notice finally that, being the ghost number of the highest curvature R_{q+1}^{1-q} negative for $q>1$, the cohomology classes of b are nonvanishing in the negative charged sectors.

We conclude this section by remarking that the highest curvature R_{q+1}^{1-q} is actually related to the ghost field c through the action of the operator $\mathscr{G}_{q+1}^{-q}$,

$$\mathscr{G}_{q+1}^{-q} c = (\mathrm{const}) R_{q+1}^{1-q}, \tag{30}$$

the proportionality factor being easily computed by means of Eqs. (9) and (10).

IV. SOLUTION OF THE DESCENT EQUATIONS

Having characterized the cohomology of the BRS operator b, let us focus on the cohomology of b modulo d, i.e., let us try to solve the descent equations

$$\begin{gathered} b\, \omega_{D-j}^{G+j} + d\, \omega_{D-j-1}^{G+j+1} = 0, \quad 0 \leqslant j \leqslant (D-1), \\ b\, \omega_0^{G+D} = 0. \end{gathered} \tag{31}$$

As mentioned before and as already observed in the case of pure Yang–Mills (i.e., $q=1$), the presence of the operators $\mathscr{G}_k^{1-k}$ in the zero-curvature condition (16) requires a slight modification of the climbing procedure presented in the previous complete ladder case (see part I).

Repeating indeed the same argument of Ref. 2, it is easy to convince oneself that, once a solution ω_0^{G+D} of the last equation of (31) has been obtained, an explicit expression for the higher polynomials ω_j^{G+D-j} is provided by the generalized cocycle $\tilde{\omega}^{G+D}$ of total degree $(G+D)$,

$$\begin{gathered} \tilde{\omega}^{G+D} = \sum_{j=0}^{D} \omega_j^{G+D-j}, \\ \tilde{\omega}^{G+D} = e^{\delta} \left(\omega_0^{G+D} + \sum_{j=q+1}^{D} \Omega_j^{G+D-j} \right), \end{gathered} \tag{32}$$

where ω_0^{G+D} is

$$\omega_0^{G+D}=\mathrm{Tr}\,\frac{c^{G+D}}{(G+D)!},\tag{33}$$

and the quantities Ω_j^{G+D-j} are determined recursively by means of the consistency conditions

$$\begin{aligned} b\Omega_j^{G+D-j}&=(j-1)(-1)^j\mathscr{G}_j^{1-j}\omega_0^{G+D}+\sum_{k=2}^{(j-1)}(k-1)(-1)^k\mathscr{G}_k^{1-k}\Omega_{j-k}^{G+D-j+k},\\ \Omega_{j-k}^{G+D-j+k}&=0,\quad \text{if}\quad (j-k)<q+1. \end{aligned}\tag{34}$$

As we shall see, the latter turns out to be easily disentangled by using the results (29) on the BRS cohomology. Moreover, setting $q=1$, Eqs. (34) are seen to reproduce those already met in the pure Yang–Mills case.[1] In particular, from Eqs. (32) and (33), we see that the solution of the tower (31) in the noncomplete case turn out to be deformed with respect to the corresponding solution of the complete ladder case (see Sec. V of part I) by the inclusion of the cocycles Ω_j^{G+D-j}.

V. EXAMPLE I: PURE YANG–MILLS THEORY AS A ZERO-CURVATURE SYSTEM

As a first important example of a noncomplete ladder system, let us present here the zero-curvature formulation of the pure Yang–Mills gauge theory in any space–time dimension, corresponding to a generalized ladder with $q=1$, i.e.,

$$\tilde{\mathscr{A}}=c+A.\tag{35}$$

It is worthwhile to recall that, since the Yang–Mills theories are power-counting nonrenormalizable for space–time dimensions greater than four, the fields A and c, unlike the three-dimensional Chern–Simons case discussed in Part I, are now regarded as unquantized external fields coupled to currents of quantum matter fields. Therefore, the existence of gauge anomalies at the quantum level will correspond to a violation of the conservation law of the matter currents and to the appearance of Schwinger terms in the corresponding current algebra.

It is easily checked that in this case the consistency of the zero-curvature condition (16) requires that only the first operator $\mathscr{G}_2^{-1}$ of Eq. (19) is nonvanishing. Therefore, for the operator $\tilde{d}$ we get

$$\tilde{d}=b+d+\mathscr{G}_2^{-1},\tag{36}$$

and from

$$\tilde{d}.\tilde{\mathscr{A}}=i.\tilde{\mathscr{A}}^2\tag{37}$$

we obtain

$$bc=ic^2,\quad bA=-dc+i[c,\,A],\tag{38}$$

and

$$\begin{aligned} \mathscr{G}_2^{-1}c&=-dA+iA^2=-F,\\ \mathscr{G}_2^{-1}dc&=i[A,\,F],\\ \mathscr{G}_2^{-1}A&=\mathscr{G}_2^{-1}F=0. \end{aligned}\tag{39}$$

From Eqs. (9) and (10), for the operator δ we have

$$\delta c = A, \quad \delta\, dc = -dA + 2iA^2,$$
$$\delta A = 0, \quad \delta dA = 0, \tag{40}$$

and

$$d = -[d,\ \delta], \quad \mathscr{G}_2^{-1} = \tfrac{1}{2}[\delta,\ d],$$
$$[\delta,\ \mathscr{G}_2^{-1}] = [b,\ \mathscr{G}_2^{-1}] = [d,\ \mathscr{G}_2^{-1}] = 0. \tag{41}$$

For what concerns the solutions of the descent equations (31), here we shall limit ourselves only to state the final result, reminding the reader of the detailed discussion and proofs already given in Ref. 2. We underline in particular that, as proven in Ref. 3, the cocycles Ω_j^{G+D-j} appearing in Eq. (32) can be summed up into a unique closed generalized expression which collects both the gauge anomalies and the Chern–Simons terms. The latter are given respectively by

$$\omega_{2n}^1 = \sum_{p=0}^{n} \frac{i^{(n-p)}}{(2n-p+1)!p!} (\mathscr{P}(c, F^p, (A^2)^{n-p}) + i(n-p)\mathscr{P}([c,\ A], F^p, A, (A^2)^{n-p})) \tag{42}$$

and

$$\omega_{2n+1}^0 = \sum_{p=0}^{n} \frac{i^{(n-p)}}{(2n-p+1)!p!} \mathscr{P}(F^p, A, (A^2)^{n-p}), \tag{43}$$

where the integer $n = 1,2,...$ labels the various dimensions of the space–time and $\mathscr{P}(\mathscr{J}_1, \mathscr{J}_2, ..., \mathscr{J}_n)$ denotes the symmetric invariant polynomials defined as

$$\mathscr{P}(\mathscr{J}_1, \mathscr{J}_2, \ldots, \mathscr{J}_n) = \mathscr{J}_1^{a_1} \mathscr{J}_2^{a_2} \cdots \mathscr{J}_n^{a_n} S\ \mathrm{Tr}(T^{a_1} T^{a_2} \cdots T^{a_n}), \tag{44}$$

S Tr being the symmetrized trace[8] and, following Zumino's notations,[9] we have used

$$\mathscr{P}(\mathscr{J}_1, \mathscr{J}_2, \ldots, \mathscr{J}^p) = \mathscr{P}(\mathscr{J}_1, \mathscr{J}_2, \mathscr{J}_3, \underbrace{\mathscr{J}, \ldots, \mathscr{J}}_{p \text{ times}}). \tag{45}$$

It is worthwhile to emphasize that, actually, the formulas (42) and (43) represent one of the most compact expressions for the gauge anomaly and for the Chern–Simons term in any space–time dimension.

VI. EXAMPLE II: THE CASE $D=6$, $G=1$, $q=3$

In order to clarify the role of the operators $\mathscr{G}_k^{1-k}$ and of the generalized curvatures R_{m+1}^{1-m}, let us discuss in this second example the solution of the descent equations (5) in the six-dimensional case $D=6$ with ghost number $G=1$ and a gauge ladder with $q=3$, i.e.,

$$\tilde{\mathscr{A}} = c + A + \varphi_2^{-1} + \varphi_3^{-2}. \tag{46}$$

From Eqs. (25), for the BRS transformations we have

$$\begin{aligned} bc &= ic^2, \\ bA &= -dc + i[c,\ A], \\ b\varphi_2^{-1} &= i[c,\ \varphi_2^{-1}] - R_2^0, \\ b\varphi_3^{-2} &= i[c,\ \varphi_3^{-2}] - R_3^{-1}, \end{aligned} \tag{47}$$

where R_2^0 and R_3^{-1} are the generalized curvatures of Eq. (21) whose expressions are given

$$\begin{aligned} R_2^0 &= F = dA - iA^2, \\ R_3^{-1} &= d\varphi_2^{-1} - i[A,\ \varphi_2^{-1}]. \end{aligned} \tag{48}$$

In particular, for the highest curvature R_4^{-2} we have

$$R_4^{-2} = d\varphi_3^{-2} - i[A,\ \varphi_3^{-2}] - \frac{i}{2}[\varphi_2^{-1},\ \varphi_2^{-1}] \tag{49}$$

and

$$bR_{m+1}^{1-m} = i[c,\ R_{m+1}^{1-m}], \quad 1 \leqslant m \leqslant 3. \tag{50}$$

The curvatures $(R_2^0, R_3^{-1}, R_4^{-2})$ obey the following generalized Bianchi identities:

$$\begin{aligned} dR_2^0 &= i[A,\ R_2^0], \\ dR_3^{-1} &= i[A,\ R_3^{-1}] + i[\varphi_2^{-1},\ R_2^0], \\ dR_4^{-2} &= i[A,\ R_4^{-2}] + i[\varphi_2^{-1},\ R_3^{-1}] + i[\varphi_3^{-2},\ R_2^0]. \end{aligned} \tag{51}$$

They transform under the operator δ of Eqs. (9) and (10) as

$$\begin{aligned} \delta R_2^0 &= 2R_3^{-1}, \\ \delta R_3^{-1} &= -R_4^{-2} - \frac{i}{2}[\varphi_2^{-1},\ \varphi_2^{-1}], \\ \delta R_4^{-2} &= -i\,[\varphi_3^{-2},\ \varphi_2^{-1}]. \end{aligned} \tag{52}$$

For what concerns the operators $\mathscr{G}_k^{1-k}$ of Eq. (20) it is easily seen that in the present example the zero-curvature Equation (16) implies the existence of a set of five nonvanishing operators $(\mathscr{G}_2^{-1}, \mathscr{G}_3^{-2}, \mathscr{G}_4^{3}, \mathscr{G}_5^{4}, \mathscr{G}_6^{5})$. Their action on the fields and on the curvatures is given, respectively, by

$$\begin{aligned} &\mathscr{G}_2^{-1}c = 0, \quad \mathscr{G}_2^{-1}A = 0, \quad \mathscr{G}_2^{-1}\varphi_2^{-1} = -2R_4^{-2}, \\ &\mathscr{G}_2^{-1}\varphi_3^{-2} = 2i[\varphi_3^{-2},\ \varphi_2^{-1}], \\ &\mathscr{G}_2^{-1}dc = 0, \quad \mathscr{G}_2^{-1}R_2^0 = 0, \\ &\mathscr{G}_2^{-1}R_3^{-1} = 2i([\varphi_2^{-1},\ R_3^{-1}] + [\varphi_3^{-2},\ R_2^0]), \\ &\mathscr{G}_2^{-1}R_4^{-2} = 2i[\varphi_3^{-2},\ R_3^{-1}]; \end{aligned} \tag{53}$$

$$\mathcal{G}_3^{-2}c=0,\quad \mathcal{G}_3^{-2}A=\frac{4}{3}R_4^{-2},$$

$$\mathcal{G}_3^{-2}\varphi_2^{-1}=-\frac{4i}{3}[\varphi_3^{-2},\ \varphi_2^{-1}],$$

$$\mathcal{G}_3^{-2}\varphi_3^{-2}=2i[\varphi_3^{-2},\ \varphi_3^{-2}],$$

$$\mathcal{G}_3^{-2}dc=0, \tag{54}$$

$$\mathcal{G}_3^{-2}R_2^0=-\frac{4i}{3}([\varphi_2^{-1},\ R_3^{-1}]+[\varphi_3^{-2},\ R_2^0]),$$

$$\mathcal{G}_3^{-2}R_3^{-1}=4i[\varphi_3^{-2},\ R_3^{-1}],$$

$$\mathcal{G}_3^{-2}R_4^{-2}=0;$$

$$\mathcal{G}_4^{-3}c=-\frac{1}{3}R_4^{-2},\quad \mathcal{G}_4^{-3}A=\frac{i}{3}[\varphi_3^{-2},\ \varphi_2^{-1}],$$

$$\mathcal{G}_4^{-3}\varphi_2^{-1}=-\frac{5i}{2}[\varphi_3^{-2},\ \varphi_3^{-2}],\quad \mathcal{G}_4^{-3}\varphi_3^{-2}=0,$$

$$\mathcal{G}_4^{-3}dc=\frac{i}{3}([A,\ R_4^{-2}]+[\varphi_2^{-1},\ R_3^{-1}]+[\varphi_3^{-2},\ R_2^0]), \tag{55}$$

$$\mathcal{G}_4^{-3}R_2^0=\frac{i}{3}([\varphi_2^{-1},\ R_4^{-2}]-11[\varphi_3^{-2},\ R_3^{-1}]),$$

$$\mathcal{G}_4^{-3}R_3^{-1}=0,\quad \mathcal{G}_4^{-3}R_4^{-2}=0;$$

$$\mathcal{G}_5^{-4}c=0,\quad \mathcal{G}_5^{-4}A=\frac{6i}{5}[\varphi_3^{-2},\ \varphi_3^{-2}],$$

$$\mathcal{G}_5^{-4}\varphi_2^{-1}=0,\quad \mathcal{G}_5^{-4}\varphi_3^{-2}=0,$$

$$\mathcal{G}_5^{-4}dc=\frac{16i}{5}[\varphi_3^{-2},\ R_3^{-1}], \tag{56}$$

$$\mathcal{G}_5^{-4}R_2^0=\mathcal{G}_5^{-4}R_3^{-1}=\mathcal{G}_5^{-4}R_4^{-2}=0;$$

$$\mathcal{G}_6^{-5}c=-\frac{i}{5}[\varphi_3^{-2},\ \varphi_3^{-2}],$$

$$\mathcal{G}_6^{-5}A=\mathcal{G}_6^{-5}\varphi_2^{-1}=\mathcal{G}_6^{-5}\varphi_3^{-2}=0, \tag{57}$$

$$\mathcal{G}_6^{-5}dc=\mathcal{G}_6^{-5}R_2^0=\mathcal{G}_6^{-5}R_3^{-1}=\mathcal{G}_6^{-5}R_4^{-2}=0.$$

Turning now to the descent equations

$$b\omega_{6-j}^{1+j}+d\omega_{5-j}^{2+j}=0, \quad 0\leqslant j\leqslant 5,$$
$$b\omega_0^7=0, \tag{58}$$

we have that, taking into account the result (23) on the cohomology of the BRS operator b and the equation (32), a solution of the ladder (58) is provided by the generalized cocycle of total degree seven

$$\tilde{\omega}^7=e^{\delta}(\omega_0^7+\Omega_4^3+\Omega_5^2+\Omega_6^1) \tag{59}$$

with

$$\omega_0^7=\mathrm{Tr}\,\frac{c^7}{7!}, \tag{60}$$

and $(\Omega_4^3,\Omega_5^2,\Omega_6^1)$ solutions of the equations (34), i.e.,

$$b\Omega_4^3=3\mathscr{I}_4^{-3}\omega_0^7, \tag{61}$$

$$b\Omega_5^2=-4\mathscr{I}_5^{-4}\omega_0^7, \tag{62}$$

$$b\Omega_6^1=\mathscr{I}_2^{-1}\Omega_4^3+5\mathscr{I}_6^{-5}\omega_0^7. \tag{63}$$

This system can be easily solved by using the cohomology of b. Indeed, beginning with the first equation (61), we have from (55)

$$\mathscr{I}_4^{-3}\omega_0^7=-\frac{1}{6!}\,\mathrm{Tr}\,\frac{R_4^{-2}c^6}{3}, \tag{64}$$

so that Ω_4^3 may be identified with

$$\Omega_4^3=-\frac{1}{6!}\,\mathrm{Tr}\,R_4^{-2}c^5. \tag{65}$$

Concerning now the second equation (62), we get from (56) that

$$\mathscr{I}_5^{-4}\omega_0^7=0. \tag{66}$$

Moreover, since the cohomology of b in the sector of form degree five and ghost number two is empty, we may choose Ω_5^2 to be vanishing as well

$$\Omega_5^2=0. \tag{67}$$

Finally for the last equation (63), we get

$$b\Omega_6^1=\frac{2}{6!}\,\mathrm{Tr}([\varphi_3^{-2},\,R_3^{-1}]c^5-i\varphi_3^{-2}\varphi_3^{-2}c^6). \tag{68}$$

However, from

$$b(\mathrm{Tr}\;\varphi_3^{-2}\varphi_3^{-2}c^5)=\mathrm{Tr}([\varphi_3^{-2},\,R_3^{-1}]c^5-i\varphi_3^{-2}\varphi_3^{-2}c^6), \tag{69}$$

we obtain

$$\Omega_6^1=\frac{1}{6!}\,\mathrm{Tr}([\varphi_3^{-2},\varphi_3^{-2}]c^5). \tag{70}$$

Summarizing, an explicit expression for the Ω's is given by

$$\Omega_4^3=-\frac{i}{6!}\,\mathrm{Tr}\,R_4^{-2}c^5,$$

$$\Omega_5^2=0, \tag{71}$$

$$\Omega_6^1=\frac{1}{6!}\,\mathrm{Tr}([\varphi_3^{-2},\varphi_3^{-2}]c^5).$$

Of course, the above expressions are always determined modulo trivial b-cocycles.

Concluding, for the generalized cocycle $\tilde{\omega}^7$ we have

$$\tilde{\omega}^7=\mathrm{Tr}\left(\frac{\tilde{\mathscr{A}}^7}{7!}+\Omega_4^3+\delta\Omega_4^3+\frac{\delta^2}{2}\,\Omega_4^3+\Omega_6^1\right). \tag{72}$$

The expansion of $\tilde{\omega}^7$ in terms of components of different degree and ghost number will give an explicit expression for the cocycles entering the descent equations (58).

VIII. CONCLUSION

We have shown that the Yang–Mills-type theories can be characterized by means of a non-complete gauge ladder field constrained to obey a zero curvature condition, which implies the existence of a set of new operators $\mathscr{F}_k^{1-k}$. These operators give rise together with the BRS operator b to a kind of descent equation which is easily solved using the results on the cohomology of b. These solutions provide a deformation of the cohomology of b modulo d with respect to the corresponding complete ladder case presented in the part I.

(Received 21 March 1996; accepted for publication 8 April 1996)

As has already been pointed out by Birkhoff and von Neumann, quantum logic can be formulated in terms of projective geometry. In three-dimensional Hilbert space, elementary logical propositions are associated with one-dimensional subspaces, corresponding to points of the projective plane. It is shown that, starting with three such propositions corresponding to some basis $\{\mathbf{u},\mathbf{v},\mathbf{w}\}$, successive application of the binary logical operation $(x,y)\mapsto(x \vee y)^{\perp}$ generates a set of elementary propositions which is countable infinite and dense in the projective plane if and only if no vector of the basis $\{\mathbf{u},\mathbf{v},\mathbf{w}\}$ is orthogonal to the other ones. © *1996 American Institute of Physics.* [S0022-2488(96)00309-X]

I. INTRODUCTION

The geometrization of quantum logic was initiated by Birkhoff and von Neumann.[1] In their ''top-down'' approach, the logical entities are identified with Hilbert space entities as follows. Elementary propositions are identified with one-dimensional subspaces or with the vector spanning that subspace. The binary logical operations ''and'' ($\wedge$) and ''or'' ($\vee$) correspond to the set theoretic intersection and to the linear span, respectively. The unary logical operation ''not'' ($^{\perp}$) corresponds to the orthogonal subspace. The proposition which is always false is identified with the null vector. The proposition which is always true is identified with the entire Hilbert space. In that way, the geometry of Hilbert space induces a logical structure which, if Hilbert space quantum mechanics[2] is an appropriate theory of quantum physics, describes correctly the logical structure of measurements (cf. Refs. 3–7).

In what follows, we concentrate on the following question. Assume we start with a set $\{u,v,w\}$ of three elementary quantum mechanical propositions representable as one-dimensional subspaces (spanned by the vectors $\{\mathbf{u}, \mathbf{v}, \mathbf{w}\}$) of three-dimensional Hilbert space. New propositions can be formed from the old ones by the logical operations ''and, or, not.'' In particular, the operation $(x \vee y)^{\perp}$ corresponding to ''not (x or y)'' is just the subspace spanned by the vector product $\mathbf{x}\times\mathbf{y}$. Suppose this operation is carried out recursively. That is, at each step we form the vector product of all (nonparallel) vectors and add the (nonparallel) results to the previous set of vectors. One may ask, what are the conditions for the resulting set (of intersection points with the unit ball) to be dense? Evidently, the set of one-dimensional subspaces spanned by the recursive application of the vector product can at most be countable (cardinality $\aleph_0$). It is less obvious if there can be any regions or ''holes'' formed by the recursively obtained set of one-dimensional subspaces which are unreachable. An answer is given in Theorem 3.

As has been already pointed out by Birkhoff and von Neumann,[1] the structure obtained for three-dimensional Hilbert space is essentially a projective plane. Points of the projective geometry are identified with elementary propositions, and lines are identified with two-dimensional sub-

[b)]Electronic mail: svozil@tph.tuwien.ac.at

spaces. We emphasize this point of view by reformulating the above problem into the geometric language of the real projective plane endowed with the elliptic metric.

The original motivation for this question originates from the consideration of Kochen-Specker type constructions.[8,9] It has been conjectured that every set of three nonorthogonal one-dimensional subspaces generates a Kochen-Specker paradox.[10] More generally, one could ask if any single elementary proposition (corresponding to a one-dimensional subspace of three-dimensional Hilbert space) can be approximated by a logical construction originating from just three propositions (corresponding to nonorthogonal one-dimensional subspaces of three-dimensional Hilbert space).

It has to be kept in mind, however, that a consistent two-valued measure—serving as a classical truth function—will in general not be definable on the set of recursively generated one-dimensional subspaces identifiable with elementary propositions. Indeed, due to complementarity, even for the generating set of three vectors, such an identification of truth functions will only have an operational (physical) meaning if these vectors were mutually orthogonal—a condition which would yield a trivial orthogonal tripod configuration, for which any recursion does not produce any additional vectors.

II. SUBPLANES OF PROJECTIVE PLANES

A *projective plane* is formally a geometric structure $(\mathscr{P},\mathscr{L},I)$ consisting of a set $\mathscr{P}$ of elements called *points*, a set $\mathscr{L}$ of elements called *lines* and a binary relation $I\subset\mathscr{P}\times\mathscr{L}$ called *incidence* satisfying the following axioms.

(P1) Any two distinct points are incident with exactly one common line.

(P2) Any two distinct lines are incident with a common point.

(P3) There are four points, no three of which are incident with a common line.

Instead of $(p,L)\in I$ we also write pIL and use familiar expressions like ''p is on L,'' ''L is running through p,'' etc. A set of points is said to be *colinear*, if all points are on a common line, a *triangle* is a set of three non-colinear points, a *quadrangle* is a set of four points satisfying the condition of axiom (P3). If we are given two distinct points $p_1,p_2\in\mathscr{P}$ then $p_1\vee p_2$ denotes the unique line joining these two points. By (P1) and (P2), two distinct lines $L_1,L_2\in\mathscr{L}$ meet at a unique point which is written as $L_1\wedge L_2$. For basic properties of projective planes see [Ref. 11, Chap. 4], Ref. 12 or Ref. 13.

Let F be a skewfield (division ring). Then F^3 (regarded as left vector space over F) gives rise to a projective plane as follows: Define $\mathscr{P}$ as set of all one-dimensional subspaces of F^3, viz.

$$\mathscr{P}:=\{F\mathbf{a}\,|\,\mathbf{o}\neq\mathbf{a}\in F^3\}, \tag{1}$$

and $\mathscr{L}$ as the set of all two-dimensional subspaces of F^3. Incidence is defined by

$$I:=\{(F\mathbf{a},\mathbf{L})\in\mathscr{P}\times\mathscr{L}\,|\,F\mathbf{a}\subset L\}. \tag{2}$$

We set $(\mathscr{P},\mathscr{L},I)=:\mathrm{PG}(2,F)$. See, e.g., Ref. 14, p. 29, Ref. 15, p. 222 or the textbooks mentioned above for more details.

We remark that there are also projective planes that are not isomorphic to any plane of the form $\mathrm{PG}(2,F)$. Such projective planes are called *Non-Desarguesian* and will not be of interest in this paper.

Suppose that $(\mathscr{P},\mathscr{L},I)$ is a projective plane and that $\widetilde{\mathscr{P}}$ is any subset of $\mathscr{P}$. Put

$$\widetilde{\mathscr{L}}:=\{p_1\vee p_2\,|\,p_1,p_2\in\widetilde{\mathscr{P}},p_1\neq p_2\}\quad\text{and}\quad\widetilde{I}:=I\cap(\widetilde{\mathscr{P}}\times\widetilde{\mathscr{L}}). \tag{3}$$

The substructure $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ is satisfying axiom (P1), but not necessarily (P2) or (P3). If $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ is a projective plane, then it is called a *projective subplane* of $(\mathscr{P},\mathscr{L},I)$. A *degenerate subplane* $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ is satisfying (P2), but not (P3).

All degenerate subplanes are easily described: If $\#\widetilde{\mathscr{L}} \leqslant 1$, then $\widetilde{\mathscr{P}}$ is a set of colinear points. If $\#\widetilde{\mathscr{L}} \geqslant 2$, then $\widetilde{\mathscr{P}}$ is formed by a set of two or more points on a line, say L, plus one more point, say u, off the line L. This L is the only line in $\widetilde{\mathscr{L}}$ not running through u.

In PG(2,F) we may obtain a projective subplane as follows: Let $\{\mathbf{b}_1,\mathbf{b}_2,\mathbf{b}_3\} \subset F^3$ be a basis and let $\widetilde{F} \subset F$ be a sub-skewfield of F. Then set

$$\widetilde{\mathscr{P}} = \left\{ F\mathbf{a} \,\middle|\, \mathbf{a} = \sum_{i=1}^{3} \xi_i \mathbf{b}_i, (0,0,0) \neq (\xi_1,\xi_2,\xi_3) \in \widetilde{F}^3 \right\}, \tag{4}$$

and define $\widetilde{\mathscr{L}}, \widetilde{I}$ according to (3). The verification of (P2) amounts to solving a homogeneous system of linear equations within the sub-skewfield $\widetilde{F}$. A quadrangle in $\widetilde{\mathscr{P}}$ is given by $\{\mathbb{R}\mathbf{b}_1, \mathbb{R}\mathbf{b}_2, \mathbb{R}\mathbf{b}_3, \mathbb{R}(\mathbf{b}_1+\mathbf{b}_2+\mathbf{b}_3)\}$.

The backbone of this article is the following innocently looking result (Ref. 13, p. 266): Any projective subplane of PG(2,F) is of the form (4). (See also Ref. 16, p. 1008.) This allows us to recover an algebraic structure, namely a sub-skewfield of F, from a projective subplane of PG(2,F). Let us add, for the sake of completeness, the following remark: If in (4) the basis $\{\mathbf{b}_1,\mathbf{b}_2,\mathbf{b}_3\}$ is replaced by $\{\alpha\mathbf{b}_1,\alpha\mathbf{b}_2,\alpha\mathbf{b}_3\}$ for some nonzero $\alpha \in F$ and if $\widetilde{F}$ is modified to the sub-skewfield $\alpha\widetilde{F}\alpha^{-1}$, then $\widetilde{\mathscr{P}}$ remains unchanged. Actually, a projective subplane of PG(2,F) determines ''its'' sub-skewfield of F only to within transformation under inner automorphisms of F. Clearly, for a (commutative) field F this means uniqueness.

We confine our attention to the *real projective plane* PG(2,$\mathbb{R}$). The *elliptic metric* on $\mathscr{P}$ is given by

$$d: \mathscr{P}\times\mathscr{P} \to \mathbb{R}, (\mathbb{R}\mathbf{a}, \mathbb{R}\mathbf{b}) \mapsto \arccos\frac{|\mathbf{a}\cdot\mathbf{b}|}{\|\mathbf{a}\|\|\mathbf{b}\|} \in \left[0, \frac{\pi}{2}\right], \tag{5}$$

where $\cdot$ denotes the standard dot product and $\|\ \|$ stands for the Euclidean norm of $\mathbb{R}^3$. The *elliptic distance* $d(\mathbb{R}\mathbf{a}, \mathbb{R}\mathbf{b})$ of two points of PG(2,$\mathbb{R}$) is just the Euclidean angle of the corresponding one-dimensional subspaces through the origin of $\mathbb{R}^3$. It is invariant under transformations (e.g., rotations) which preserve normality. Besides, a connection can be made between the elliptic distance and the more physically motivated *statistical distance*.[17]

For each point $\mathbb{R}\mathbf{a}$ of PG(2,$\mathbb{R}$) there are exactly two unit vectors in $\mathbb{R}\mathbf{a}$. This gives the well-known alternative description of the real projective plane: The ''points'' may be viewed as unordered pairs of opposite points of the unit sphere, the ''lines'' are the great circles and incidence is defined via inclusion. In this interpretation the elliptic distance is equal to the *spherical distance* (Ref. 18, Chap. VI).

If T is a subset of $\mathbb{R}^3$ then $T^{\perp} := \{\mathbf{a} | \mathbf{a}\cdot\mathbf{t} = 0 \text{ for all } \mathbf{t} \in T\}$ is a subspace. In geometric terms $\perp$ is a *polarity* of the projective plane PG(2,$\mathbb{R}$); cf. (Ref. 11, Chap. 17, Ref. 18, p. 52, Ref. 14, p. 110, or Ref. 12, p. 45). Points and lines are interchanged bijectively subject to the rule $\mathbb{R}\mathbf{a} \times (\in\mathscr{P}) \mapsto \mathbf{a}\perp (\in\mathscr{L})$. *The geometric operations of ''join'' ($\vee$) and ''meet'' ($\wedge$) therefore allow a simple algebraic description*: *Given linearly independent vectors* $\mathbf{a},\mathbf{b} \in \mathbb{R}^3$ then

$$\mathbb{R}\mathbf{a} \vee \mathbb{R}\mathbf{b} = (\mathbf{a}\times\mathbf{b})^{\perp}, \tag{6}$$

$$\mathbf{a}^{\perp} \wedge \mathbf{b}^{\perp} = \mathbb{R}(\mathbf{a}\times\mathbf{b}). \tag{7}$$

The following result is essentially ($\widetilde{F} = \mathbb{Q}$) due to Möbius:

Lemma 1: If $(\widetilde{\mathscr{P}}, \widetilde{\mathscr{L}}, \widetilde{I})$ is a projective subplane of $(\mathscr{P},\mathscr{L},I) =$ PG(2,$\mathbb{R}$), then $\widetilde{\mathscr{P}}$ is dense in $\mathscr{P}$.

Proof: Let $\widetilde{\mathscr{P}}$ be given according to (4) with $\widetilde{F} \subset \mathbb{R}$. The field $\mathbb{Q}$ of rational numbers equals the intersection of all subfields of $\mathbb{R}$, whence $\mathbb{Q} \subset \widetilde{F}$. Given a point $\mathbb{R}\mathbf{a} \in \mathscr{P}$ we obtain

$$\mathbf{a}=\xi_1\mathbf{b}_1+\xi_2\mathbf{b}_2+\xi_3\mathbf{b}_3 \quad \text{with} \quad (\xi_1,\xi_2,\xi_3)\in\mathbb{R}^3. \tag{8}$$

There exist three sequences,

$$(\xi_{j,i})_{i\in\mathbb{N}}, \quad \text{with } \xi_{j,i}\in\mathbb{Q}\backslash\{0\} \quad \text{and} \quad \lim_{i\to\infty}\xi_{j,i}=\xi_j \quad (j\in\{1,2,3\}). \tag{9}$$

Defining

$$\mathbf{a}_i:=\xi_{1,i}\mathbf{b}_1+\xi_{2,i}\mathbf{b}_2+\xi_{3,i}\mathbf{b}_3\neq\mathbf{o} \quad (i\in\mathbb{N}) \tag{10}$$

yields a sequence of points $\mathbb{R}\mathbf{a}_i\in\widetilde{\mathscr{P}}$ with $(\mathbb{R}\mathbf{a}_i)_{i\in\mathbb{N}}\to\mathbb{R}\mathbf{a}$, since, by the continuity of dot product and norm,

$$\lim_{i\to\infty}\frac{\mathbf{a}\cdot\mathbf{a}_i}{\|\mathbf{a}\|\|\mathbf{a}_i\|}=\frac{\mathbf{a}\cdot\mathbf{a}}{\|\mathbf{a}\|\|\mathbf{a}\|}=1. \tag{11}$$

This completes the proof. □

The projective subplanes of PG(2,$\mathbb{R}$) belonging to the rational number field are called *Möbius nets*. They allow a simple recursive geometric construction (Ref. 19, p. 140): Starting with a quadrangle one draws all the lines spanned by these points. Next mark all points of intersection arising from these lines. With this set of points the procedure is repeated, and so on. The set of all points that can be reached in a finite number of steps gives then a projective subplane over $\mathbb{Q}$.

III. MAIN THEOREMS

Theorem 1: Let $V_1=\{\mathbf{u},\mathbf{v},\mathbf{w}\}$ be a basis of $\mathbb{R}^3$. Define subsets V_i, V of $\mathbb{R}^3$ as follows:

$$V_{i+1}:=V_i\cup\{\mathbf{r}\times\mathbf{s}|\mathbf{r},\mathbf{s}\in V_i,\mathbf{r}\times\mathbf{s}\neq\mathbf{o}\} \quad (i\in\mathbb{N}), \quad V:=\bigcup_{i=1}^{\infty}V_i. \tag{12}$$

Then

$$\widetilde{\mathscr{P}}:=\{\mathbb{R}\mathbf{a}|\mathbf{a}\in V\} \tag{13}$$

yields a projective or degenerate subplane $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ of PG(2,$\mathbb{R}$) which is ortho-closed. That is, $\mathbb{R}\mathbf{a}\in\widetilde{\mathscr{P}}$ implies $\mathbf{a}^\perp\in\widetilde{\mathscr{L}}$.

Proof: Let $L_1,L_2\in\widetilde{\mathscr{L}}$ be distinct. By (6) and the definition of $\widetilde{\mathscr{L}}$, there are vectors $\mathbf{p}_1,\mathbf{q}_1,\mathbf{p}_2,\mathbf{q}_2\in V$ with

$$L_1=(\mathbf{p}_1\times\mathbf{q}_1)^\perp, \quad L_2=(\mathbf{p}_2\times\mathbf{q}_2)^\perp. \tag{14}$$

Now (7) yields

$$L_1\wedge L_2=\mathbb{R}((\mathbf{p}_1\times\mathbf{q}_1)\times(\mathbf{p}_2\times\mathbf{q}_2))\in\widetilde{\mathscr{P}}. \tag{15}$$

This establishes (P2).

Given a point $\mathbb{R}\mathbf{a}\in\widetilde{\mathscr{P}}$, there exist two vectors in V_1, say **u,v**, such that {**a,u,v**} is a basis of $\mathbb{R}^3$. Then $u\notin\text{span}\{\mathbf{a},\mathbf{v}\}=(\mathbf{a}\times\mathbf{v})^\perp$, but $\mathbf{u}\in(\mathbf{a}\times\mathbf{u})^\perp$. Thus $\mathbb{R}(\mathbf{a}\times\mathbf{v})$ and $\mathbb{R}(\mathbf{a}\times\mathbf{v})$ are distinct points of $\widetilde{\mathscr{P}}$ on the line $\mathbf{a}^\perp$. □

Observe that axiom (P2) may be derived alternatively from the well-known formula

$$(\mathbf{p}_1\times\mathbf{q}_1)\times(\mathbf{p}_2\times\mathbf{q}_2)=\det(\mathbf{p}_1,\mathbf{q}_1,\mathbf{q}_2)\mathbf{p}_2-\det(\mathbf{p}_1,\mathbf{q}_1,\mathbf{p}_2)\mathbf{q}_2=\det(\mathbf{p}_1,\mathbf{p}_2,\mathbf{q}_2)\mathbf{q}_1-\det(\mathbf{q}_1,\mathbf{p}_2,\mathbf{q}_2)\mathbf{p}_1. \tag{16}$$

since linearly dependent vectors yield colinear points.

Theorem 2: The subplane $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ described in Theorem 1 is degenerate if and only if one vector of the basis $\{\mathbf{u},\mathbf{v},\mathbf{w}\}$ is orthogonal to the other ones.

Proof: Let $(\widetilde{\mathscr{P}},\widetilde{\mathscr{L}},\widetilde{I})$ be degenerate. $\{\mathbb{R}\mathbf{u},\mathbb{R}\mathbf{v},\mathbb{R}\mathbf{w}\}$ being a triangle forces $\#\widetilde{\mathscr{L}}\geqslant 3$. We read off from the description of degenerate subplanes in section II that $\widetilde{\mathscr{P}}$ has to consist of one point of this triangle, say $\mathbb{R}\mathbf{u}$, and a subset of points on the line joining $\mathbb{R}\mathbf{v}$ and $\mathbb{R}\mathbf{w}$. The line $\mathbf{u}^{\perp}$ belongs to $\widetilde{\mathscr{L}}$ by Theorem 1. Now $\mathbf{u}\notin\mathbf{u}^{\perp}$ tells us that the point $\mathbb{R}\mathbf{u}$ is off that line. Since $\mathbb{R}\mathbf{u}$ is on all lines of $\widetilde{\mathscr{L}}$ but one, we obtain $\mathbf{v},\mathbf{w}\in\mathbf{u}^{\perp}$.

Conversely, assume that $\mathbf{v},\mathbf{w}\in\mathbf{u}^{\perp}$. Then

$$\widetilde{\mathscr{P}}=\{\mathbb{R}\mathbf{u},\mathbb{R}\mathbf{v},\mathbb{R}\mathbf{w},\mathbb{R}(\mathbf{u}\times\mathbf{v}),\mathbb{R}(\mathbf{u}\times\mathbf{w})\} \tag{17}$$

is a set of five points if $\mathbf{v}\not\perp\mathbf{w}$, and it is a set of just three points if $\mathbf{u},\mathbf{v},\mathbf{w}$ are mutually orthogonal. Thus $\widetilde{\mathscr{P}}$ yields a degenerate subplane. □

Summing up, gives this final result.

Theorem 3: With the settings of Theorem 1 the following assertions are equivalent.

1. The basis $\{\mathbf{u},\mathbf{v},\mathbf{w}\}$ of $\mathbb{R}^3$ does not contain a vector that is orthogonal to the remaining ones.
2. The point set $\widetilde{\mathscr{P}}$ given by (13) is dense in PG$(2,\mathbb{R})$.
3. The point set $\widetilde{\mathscr{P}}$ given by (13) is infinite.

Geometrical interpretation of BRST symmetry in topological Yang–Mills–Higgs theory

Chang-Yeong Lee[a)]
Department of Physics, Sejong University, Seoul 143-747, Korea

(Received 8 April 1996; accepted for publication 5 July 1996)

We study the topological Yang–Mills–Higgs theories in two and three dimensions and the topological Yang–Mills theory in four dimensions in a unified framework of superconnections. In this framework, we first show that a classical action of topological Yang–Mills type can provide all three classical actions of these theories via appropriate projections. Then we obtain the Becchi–Rouet–Stora–Tyutin (BRST) and anti-BRST transformation rules encompassing these three topological theories from an extended definition of curvature and a geometrical requirement of the Bianchi identity. This is an extension of Perry and Teo's work in the topological Yang–Mills case. Finally, comparing this result with our previous treatment in which we used the ''modified horizontality condition,'' we provide a meaning of the Bianchi identity from the BRST symmetry viewpoint and thus interpret the BRST symmetry in a geometrical setting. © *1996 American Institute of Physics.* [S0022-2488(96)01611-8]

I. INTRODUCTION

Soon after Witten[1] constructed the topological Yang–Mills theory to generate the Donaldson invariants of smooth four-manifolds, Baulieu and Singer[2] showed that Witten's topological quantum action could be obtained by gauge fixing the classical topological action

$$I_4=\int_{M_4} \mathrm{Tr}\, F\wedge F \tag{1}$$

in the Becchi–Rouet–Stora–Tyutin (BRST) quantization scheme. Then Perry and Teo[3] argued that the asymmetry of BRST transformation rules that appeared in Baulieu and Singer's work was caused by treating only the BRST symmetry,[4] and not the anti-BRST symmetry.[5] And they obtained symmetric BRST and anti-BRST transformation rules by treating them on an equal footing. They further identified the difference between the ordinary Yang–Mills theory and the topological Yang–Mills theory as follows. In the ordinary Yang–Mills theory, one can impose the so-called ''horizontality condition'' to find BRST symmetry. This is tantamount to requiring that the unphysical components of Yang–Mills field strength (curvature), which contain ghosts, vanish. In the topological case, one cannot impose this vanishing field strength condition along unphysical directions, and one can only impose the Bianchi identity in the extended space where ghosts are included.

Parallel to this development, topological Yang–Mills–Higgs actions in two and three dimensions were also constructed. Following the Baulieu and Singer's approach, Baulieu and Grossman[6] found a topological action for magnetic monopoles by gauge fixing the following classical action in three dimensions:

$$I_3=\int_{M_3} \mathrm{Tr}\, F\wedge D\phi. \tag{2}$$

[a)]Electronic mail: leecy@phy.sejong.ac.kr

0022-2488/96/37(11)/5342/9/$10.00

The two-dimensional case was studied by Chapline and Grossman[7] by gauge fixing the following two-dimensional classical action:

$$I_2=\int_{M_2} \mathrm{Tr}(F[\Phi^\dagger,\ \Phi]-D\Phi^\dagger\wedge D\Phi), \tag{3}$$

and the quantized version of this theory turned out to be connected to the theory of vortices and knots.

In our previous work,[8] we investigated the BRST/anti-BRST symmetry of the above topological Yang–Mills–Higgs theory in two and three dimensions by modifying the horizontality condition in a way that it could account for the topological symmetry in addition to the ordinary Yang–Mills gauge symmetry. This work was done in the superconnection framework so that the scalar and vector gauge fields were treated on the same footing as a connection. Thereby we could find the BRST/anti-BRST transformation rules of the scalar and vector gauge fields immediately in one calculation instead of doing additional and separate calculations.

In this paper, we investigate the BRST/anti-BRST symmetry of these theories through the ''Bianchi identity'' in the same superconnection framework that we used in our previous work. This investigation was motivated by the question of whether Perry and Teo's work could be extended to the topological Yang–Mills–Higgs case where additional ghosts for the scalar field appear. The superconnection framework became a very natural testing ground for this idea. The result of the test is affirmative. By comparing these two approaches—the present work and our previous work—we can further provide a meaning for the Bianchi identity in the extended space from the BRST symmetry view point. This in turn allows a geometrical interpretation of the BRST/anti-BRST symmetry in the extended space.

In Sec. II, we show that the classical actions, $I_4,\ I_3,\ I_2$, can be obtained from a classical action of the topological Yang–Mills type written in superconnection language by appropriate projections depending on the dimensions of spaces to which corresponding theories belong. In Sec. III, we find the BRST/anti-BRST transformation rules of the topological Yang–Mills–Higgs theory from the Bianchi identity in the extended space and an extended definition of curvature expressed in superconnection formalism. In Sec. IV, we compare our present work with the ''horizontality condition'' approach which we adopted in our previous work. From the comparison of these two approaches, we provide a geometrical meaning to the BRST symmetry in the topological Yang–Mills–Higgs theory. In Sec. V, we draw our conclusions.

II. CLASSICAL TOPOLOGICAL ACTION WITH SUPERCONNECTIONS

In 1982, while studying a generalized gauge theory possessing an internal supersymmetry, Thierry-Mieg and Ne'eman[9] constructed a generalized system of connections with arbitrary form degrees hinted from the old idea of Cartan's integrable system.[10] In mathematics, a similar concept was introduced by Quillen in 1985[11] under the notion of superconnections, independently of Thierry-Mieg and Ne'eman's work. Then Ne'eman and Sternberg[12] used Quillen's superconnection concept to study the Higgs mechanism where the Higgs field occurred as the zeroth-order part of the superconnection. Ne'eman and Sternberg's work made it easier for physicists to understand the superconnection concept. It has also shown that the superconnection is not much different from Thierry-Mieg and Ne'eman's generalized connection, except for the existence of zeroth-order connection. In this paper, we follow Ne'eman and Sternberg's presentation of superconnections. In general, the superconnection contains all orders. It contains an even part with odd degree forms and an odd part with even degree forms. However, since the theories we are dealing with have scalar and vector gauge fields only, we shall deal with superconnections which only contain zero-forms and one-forms in this paper. Now, we may write down our superconnection as

$$\mathscr{J}=\begin{pmatrix} A & i\Phi \\ i\Phi^{\dagger} & A \end{pmatrix} \tag{4}$$

where A and Φ are Lie-algebra-valued one-form and zero-form, respectively. The multiplication rule among the elements of total Z_2-graded ''superspace'' is given by[12]

$$\begin{pmatrix} A & C \\ D & B \end{pmatrix}\begin{pmatrix} A' & C' \\ D' & B' \end{pmatrix}=\begin{pmatrix} A\wedge A'+(-1)^{|D'|}C\wedge D' & A\wedge C'+(-1)^{|B'|}C\wedge B' \\ (-1)^{|A'|}D\wedge A'+B\wedge D' & (-1)^{|C'|}D\wedge C'+B\wedge B' \end{pmatrix}, \tag{5}$$

where $A,\ldots,A',\ldots$ are matrices of differential forms, and $|A'|$, $|B'|$, $|C'|$, $|D'|$ denote form degrees of A', B', C', D', respectively.

The ''super'' curvature is defined from superconnection as

$$\mathscr{F}=\mathbf{d}\mathscr{J}+\mathscr{J}\mathscr{J}, \tag{6}$$

where $\mathbf{d}$ denotes a one-form differential operator given by $\mathbf{d}=\left(\begin{smallmatrix} d & 0 \\ 0 & d \end{smallmatrix}\right)$ with d denoting the ordinary one-form exterior derivative times a unit matrix. For brevity, we shall use the term curvature instead of ''super'' curvature from now on. Written in the component form, the curvature is given by

$$\mathscr{F}=\begin{pmatrix} F-\Phi\Phi^{\dagger} & iD\Phi \\ iD\Phi^{\dagger} & F-\Phi^{\dagger}\Phi \end{pmatrix}, \tag{7}$$

where $F=dA+A\wedge A$ and $D\Phi=d\Phi+A\Phi-\Phi A$. Now, we claim our classical topological action as

$$I=\int_M \mathrm{G\,Tr}\,\mathscr{F}\mathscr{F}, \tag{8}$$

and explain ''GTr'' below. In general, we can write down $\mathscr{F}$ as

$$\mathscr{F}=\begin{pmatrix} \mathscr{F}_{ev} & (\mathscr{F}_{od})_1 \\ (\mathscr{F}_{od})_2 & \mathscr{F}_{ev} \end{pmatrix},$$

and $\mathscr{F}\mathscr{F}$ can be written as

$$\mathscr{F}\mathscr{F}=\begin{pmatrix} (\mathscr{F}_{ev})^2-(\mathscr{F}_{od})_1(\mathscr{F}_{od})_2 & \mathscr{F}_{ev}(\mathscr{F}_{od})_1+(\mathscr{F}_{od})_1\mathscr{F}_{ev} \\ (\mathscr{F}_{od})_2\mathscr{F}_{ev}+\mathscr{F}_{ev}(\mathscr{F}_{od})_2 & (\mathscr{F}_{ev})^2-(\mathscr{F}_{od})_2(\mathscr{F}_{od})_1 \end{pmatrix}. \tag{9}$$

In four dimensions, only $(\mathscr{F}_{ev})^2$ terms can contribute since $\mathscr{F}_{ev}$ is either a two-form or zero-form. Thus we take the ordinary trace for ''GTr'' in order to get a meaningful result. In three dimensions, only $\mathscr{F}_{od}\mathscr{F}_{ev}$-type terms can contribute since $\mathscr{F}_{od}$ is a one-form. In this case, ''GTr'' becomes taking the ordinary trace after adding the odd parts of $\mathscr{F}\mathscr{F}$. We denote this procedure as ''QTr'' following the notation of the queer trace defined in Ref. 13. In two dimensions, two types of terms can contribute, $(\mathscr{F}_{ev})^2$ and $\mathscr{F}_{od}\mathscr{F}_{od}$. However, only $\mathscr{F}_{od}\mathscr{F}_{od}$-type terms have second derivative terms and we take ''GTr'' in such a way that these terms do not vanish. Thus we take supertrace in the two-dimensional case. Given this rule, the classical topological action (8) becomes

(a) in four dimensions

$$I=\int_{M_4} \mathrm{Tr}\, \mathscr{F}\mathscr{F}=2\int_{M_4} \mathrm{Tr}\, F\wedge F; \tag{10}$$

(b) in three dimensions

$$I=\int_{M_3} \mathrm{Q}\,\mathrm{Tr}\, \mathscr{F}\mathscr{F}=4i\int_{M_3} \mathrm{Tr}\, F\wedge D\phi, \tag{11}$$

where $\phi=\frac{1}{2}(\Phi^{\dagger}+\Phi)$;

(c) in two dimensions

$$I=\int_{M_2} \mathrm{S}\,\mathrm{Tr}\, \mathscr{F}\mathscr{F}=2\int_{M_2} \mathrm{Tr}(F[\Phi^{\dagger},\,\Phi]-D\Phi^{\dagger}\wedge D\Phi), \tag{12}$$

where we used the anticommuting property of one form $D\Phi$. In this way, we retrieve all three classical actions of the topological Yang–Mills–Higgs theory that appeared in Refs. 2, 6, and 7.

III. CURVATURE, BIANCHI IDENTITY, AND BRST/ANTI-BRST SYMMETRY

In the geometrical BRST quantization scheme, the base space is extended to a (double) fiber bundle space so that it contains unphysical (fiber–gauge orbit) directions, as well as physical (space–time) directions. This scheme was first developed by Thierry-Mieg and Ne'eman[14,15] with the principal fiber bundle structure yielding only the BRST symmetry which is related to the ghost (fiber) direction. It was further developed to yield the BRST and anti-BRST symmetry together. This was yielded by including the antighost direction and employing a double fiber bundle structure.[16] In order to have the antighost direction a double fiber bundle structure must be used. In this scheme, the ghost (antighost) field is obtained from the gauge field by replacing its space–time leg dx^{μ} with $dy^{N}(d\overline{y}^{N})$ where $y,\overline{y}$ represent the fiber coordinates in a double fiber bundle.[9,17–19] If one does not like the interpretation of this extended fiber bundle approach, one can take the superspace interpretation given in Refs. 20 and 21, whose view was taken in Perry and Teo's work.[3] In the superspace approach, the fiber coordinates $y,\overline{y}$ are replaced by a set of anticommuting variables θ and $\overline{\theta}$ which represent the coordinates of an abstract superspace extended from the space–time basemanifold. However, the resultant BRST/anti-BRST transformation rules are exactly the same whichever approach one uses. We do not need to distinguish between the subtle differences of the two approaches because they yield the same result. In the ordinary Yang–Mills theory, the BRST/anti-BRST symmetry is obtained from a condition which is to let the ordinary curvature equal the extended curvature. This is tantamount to requiring the curvature components containing vertical (fiber) directions to vanish, thus only the horizontal components of curvature (physical Yang–Mills field strength) in the extended space survive. For this reason, people gave the name ''horizontality condition''[18] to this condition. In this paper, we denote objects in the extended space with tildes.

Following this geometrical BRST scheme, we first extend the superconnection as

$$\tilde{\mathscr{J}}=\mathscr{J}+\mathscr{C}+\overline{\mathscr{C}}, \tag{13}$$

where $\mathscr{C}$ and $\overline{\mathscr{C}}$ are the first generation ghost and antighost for $\mathscr{J}$, which are given by

$$\mathscr{C}=\begin{pmatrix} c & 0 \\ 0 & c \end{pmatrix}, \quad \overline{\mathscr{C}}=\begin{pmatrix} \overline{c} & 0 \\ 0 & \overline{c} \end{pmatrix}. \tag{14}$$

Here c and $\overline{c}$ denote $c=A_N dy^N$ and $\overline{c}=\overline{A_N}d\overline{y}^{N}$, and represent the ghost and antighost fields, respectively. In this extended space, the curvature is given by

$$\tilde{\mathscr{F}}=\tilde{\mathbf{d}}\tilde{\mathscr{J}}+\tilde{\mathscr{J}}\tilde{\mathscr{J}}, \tag{15}$$

where

$$\tilde{\mathbf{d}}=\mathbf{d}+\mathbf{s}+\overline{\mathbf{s}}. \tag{16}$$

Here, $\mathbf{s}$ and $\overline{\mathbf{s}}$ denote one-form exterior derivative operators acting on ghost and antighost directions expressed in superconnection language. They do the role of $\mathbf{d}$ in space–time. Now, following the spirit of Refs. 2 and 3, we identify the curvature components in unphysical directions with new fields. One thing which is different from the previous works[2,3] is that here we have the first generation ghost and antighost fields which are one-forms in the extended space (having only dy or $d\overline{y}$). This difference was caused by the existence of the one-form curvature components due to the zero-form scalar field in superconnection formalism:

$$\tilde{\mathscr{F}}=\begin{pmatrix} F-\Phi\Phi^{\dagger}+\psi+\tilde{\psi}+m+\lambda+\overline{m} & i(D\Phi+\xi+\overline{\xi}) \\ i(D\Phi^{\dagger}+\xi^{\dagger}+\overline{\xi^{\dagger}}) & F-\Phi^{\dagger}\Phi+\psi+\overline{\psi}+m+\lambda+\overline{m} \end{pmatrix}. \tag{17}$$

Here ψ, $\overline{\psi}$, m, λ, and $\overline{m}$ are the first and second generation ghost and antighost fields for the two form curvature F, and ξ, $\bar{\xi}$ are the first generation ghost and antighost fields for the one form curvature $D\Phi$:

$$\begin{gathered} \psi=\mathscr{F}^{\ 1}_{\mu N}\,dx^{\mu}\,dy^{N}, \quad \overline{\psi}=\mathscr{F}^{\ -1}_{\mu N}\,dx^{\mu}\,d\overline{y}^{N}, \\ m=\mathscr{F}^{\ 2}_{MN}\,dy^{M}\,dy^{N}, \quad \lambda=\mathscr{F}^{\ 0}_{MN}\,dy^{M}\,d\overline{y}^{N}, \\ \overline{m}=\mathscr{F}^{\ -2}_{MN}\,d\overline{y}^{M}\,d\overline{y}^{N}, \\ \xi=\mathscr{F}^{\ 1}_{N}\,dy^{N}, \quad \overline{\xi}=\mathscr{F}^{\ -1}_{N}\,d\overline{y}^{N}, \end{gathered} \tag{18}$$

where upper indices $1,-1,2$, etc., represent ghost numbers. For instance, ψ has ghost number 1 and $\overline{\psi}$ has ghost number -1.

The curvature in the extended space should also satisfy the Bianchi identity:

$$\tilde{\mathbf{d}}\,\tilde{\mathscr{F}}+[\tilde{\mathscr{J}},\,\tilde{\mathscr{F}}]=0. \tag{19}$$

We thus have two conditions now:

(a) We have to equate Eq. (15) with Eq. (17), and
(b) the Bianchi identity, Eq. (19).

The rules of BRST/anti-BRST symmetry are obtained from these two conditions. The BRST/anti-BRST transformation rules for the components of the extended superconnection $\tilde{\mathscr{J}}$ are given by the condition (a):

even part:

$$\begin{gathered} sA+dc+cA+Ac=\psi, \\ \overline{sA}+d\overline{c}+\overline{cA}+A\overline{c}=\overline{\psi}, \\ sc+cc=m, \\ \overline{s\,c}+\overline{c\,c}=\overline{m}, \\ s\overline{c}+\overline{sc}+c\overline{c}+\overline{cc}=\lambda, \end{gathered} \tag{20}$$

odd part:

$$\begin{gathered} s\Phi+c\Phi-\Phi c=\xi, \\ \overline{s\Phi}+\overline{c\Phi}-\Phi\overline{c}=\overline{\xi}. \end{gathered}$$

The condition (b), the Bianchi identity, gives the BRST/anti-BRST transformation rules for the components of the extended curvature $\tilde{\mathcal{F}}$:

even part:

$$\begin{aligned}
&s\psi+dm+Am+c\psi-mA-\psi c=0,\\
&s\overline{\psi}+d\overline{m}+A\overline{m}+c\overline{\psi}-\overline{m}A-\overline{\psi}c=0,\\
&s\psi+s\overline{\psi}+d\lambda+A\lambda+c\psi+c\overline{\psi}-\lambda A-\psi\overline{c}-\overline{\psi}c=0,\\
&sm+cm-mc=0,\\
&s\overline{m}+c\overline{m}-\overline{m}c=0,\\
&s\lambda+sm+c\lambda+cm-m\overline{c}-\lambda c=0,\\
&s\overline{m}+s\overline{\lambda}+c\overline{m}+c\overline{\lambda}-\lambda\overline{c}-\overline{m}c=0,
\end{aligned}\tag{21}$$

odd part:

$$\begin{aligned}
&s\xi+c\xi+\Phi m-m\Phi+\xi c=0,\\
&s\overline{\xi}+c\overline{\xi}+\Phi\overline{m}-\overline{m}\Phi+\xi\overline{c}=0,\\
&s\xi+s\overline{\xi}+c\xi+c\overline{\xi}+\Phi\lambda-\lambda\Phi+\xi\overline{c}+\overline{\xi}c=0.
\end{aligned}$$

As usual, we have to introduce auxiliary fields to completely fix the BRST/anti-BRST transformation rules. We define auxiliary fields as

$$s\overline{c}=b,\quad s\overline{\psi}=-\kappa,\quad s\lambda=\eta,\quad s\overline{m}=\overline{\eta},\quad s\overline{\xi}=\zeta,\tag{22}$$

then we get the following from Eqs. (20) and (21):

$$\begin{aligned}
&\overline{sc}=-b-[c,\overline{c}]+\lambda,\quad \overline{s\psi}=\kappa-D\lambda-[c,\overline{\psi}]-[\overline{c},\psi],\\
&\overline{sm}=-\eta-[c,\lambda]-[\overline{c},m],\quad \overline{s\lambda}=-\overline{\eta}-[c,\overline{m}]-[\overline{c},\lambda],\\
&\overline{s\xi}=-\zeta-[\Phi,\lambda]-[c,\overline{\xi}]-[\overline{c},\xi].
\end{aligned}\tag{23}$$

The nilpotency of BRST/anti-BRST transformation operators, $s^2=\overline{s^2}=0$, determines all the rest:

$$\begin{aligned}
&sb=0,\quad \overline{sb}=[b,\overline{c}]-\overline{\eta},\\
&s\kappa=0,\quad \overline{s\kappa}=-[b,\overline{\psi}]+D\overline{\eta}-[\overline{c},\kappa]+[\overline{m},sA],\\
&s\eta=0,\quad \overline{s\eta}=[b,\lambda]-[c,\overline{\eta}]-[\overline{c},\eta]-[\overline{m},sc],\\
&s\overline{\eta}=0,\quad \overline{s\eta}=[b,\overline{m}]-[\overline{c},\overline{\eta}],\\
&s\zeta=0,\quad \overline{s\zeta}=[b,\overline{\xi}]-[\Phi\ \overline{\eta}]-[\overline{c},\zeta]-[\overline{m},s\Phi].
\end{aligned}\tag{24}$$

Here sA, sc, and $s\Phi$ were given in Eq. (20). The square brackets in Eqs. (23) and (24) denote a graded commutator. For instance, $[c,\overline{c}]=c\overline{c}+\overline{c}c$ and $[b,\overline{c}]=b\overline{c}-\overline{c}b$, since c and $\overline{c}$ are anticommuting fields and b is a commuting field. In this way, we obtain all the transformation rules of the BRST/anti-BRST symmetry of the topological Yang–Mills–Higgs theory in Refs. 3, 6, and 7.

IV. COMPARISON WITH THE ''HORIZONTALITY CONDITION'' APPROACH

The BRST symmetry of the ordinary Yang–Mills theory can be obtained from the so-called horizontality condition.[18] On the other hand, the BRST symmetry of the topological Yang–Mills theory cannot be obtained through a direct application of the horizontality condition. However, it can be obtained through a modified definition of extended curvature, and the Bianchi identity in the extended space.[3] In Ref. 8, we modified the horizontality condition in a way that it yielded the complete BRST symmetry of the topological Yang–Mills–Higgs theory, without relying upon the Bianchi identity. The rationale of this modified horizontality condition approach was the following. In the ordinary Yang–Mills case, the curvature in the extended space has vanishing components along the vertical directions which represent the gauge fiber orbits of classical gauge symmetry. This fact can be expressed as the horizontality condition

$$\tilde{F}=\tilde{d}\tilde{A}+\tilde{A}\tilde{A}=dA+AA=F, \tag{25}$$

where $\tilde{d}=d+s+\overline{s}$ and $\tilde{A}=A+c+\overline{c}$. In the topological case, the symmetry is bigger than the gauge symmetry, and the extra symmetry which cannot be included as gauge symmetry also has to be gauge fixed. This means that we need extra ghosts besides the ordinary ones $(c,\overline{c})$ which are originated from the gauge symmetry. Hence one may modify the horizontality condition by adding ''permissible'' ghosts to the extended curvature so that these additional ghosts account for the extra symmetry of topological nature. For this purpose, we take the modified horizontality condition as

$$\tilde{F}_T=F, \quad \text{where } \tilde{F}_T=\tilde{F}+\tilde{F}', \tag{26}$$

where $\tilde{F}'$ consists of ghosts and antighosts only and satisfies the nilpotency of BRST symmetry, $s^2\tilde{F}'(=\overline{s}^2\tilde{F}')=0$. Furthermore, this $\tilde{F}'$ has to be chosen in a way that it respects $s^2\tilde{A}'(=\overline{s}^2\tilde{A})=0$. In this way, we can obtain the correct BRST/anti-BRST symmetry of the topological Yang–Mills theory in Ref. 3. What we have explained so far is for the topological Yang–Mills case, not including the Higgs field. In order to encompass the topological Yang–Mills–Higgs case,[6,7] what we did in our previous work[8] was to carry out the same procedure in the superconnection framework:

$$\tilde{\mathscr{F}}_T=\mathscr{F}, \quad \text{where } \tilde{\mathscr{F}}_T=\tilde{\mathscr{F}}+\tilde{\mathscr{F}}'. \tag{27}$$

Here, $\mathscr{F}$, $\tilde{\mathscr{F}}$ were given by Eqs. (7) and (15), respectively, and $\tilde{\mathscr{F}}'$ was given by

$$\tilde{\mathscr{F}}'=-\begin{pmatrix} \psi+\overline{\psi}+m+\lambda+\overline{m} & i(\xi+\overline{\xi}) \\ i(\xi^\dagger+\overline{\xi^\dagger}) & \psi+\overline{\psi}+m+\lambda+\overline{m} \end{pmatrix}.$$

Comparing the above approach that we used in our previous work with the Bianchi identity approach that we have carried out in this paper, we note two things. First, the newly defined components of the extended curvature in the Bianchi identity approach correspond to the additional curvature $\tilde{F}'$ (or $\tilde{\mathscr{F}}'$) in the modified horizontality condition approach. Second, the Bianchi identity condition for the newly defined curvature in Eq. (17) is replaced with the BRST/anti-BRST nilpotency condition for the additional curvature, $\tilde{F}'$ (or $\tilde{\mathscr{F}}'$), in the modified horizontality condition approach. Now, the first observation tells us that the newly defined curvature components $(\psi,\psi,m,\lambda,\overline{m},\xi,\xi)$ in Eq. (17) in the Bianchi identity approach are necessitated by the existence of extra symmetry of topological nature, since the ordinary gauge symmetry has been accounted for by the ghost sector of the extended connection $\tilde{A}$ (or $\tilde{\mathscr{A}}$). The second observation tells us that the Bianchi identity in the extended space is simply another expression of the BRST/anti-BRST nilpotency condition for the extra ghost/antighost fields appearing in the newly added

piece of curvature, $\tilde{F}'$ (or $\tilde{\mathscr{F}}'$), in the modified horizontality condition approach. In fact, the last point was already implied in the Bianchi identity approach, since the validity of the Bianchi identity, which is given by

$$\tilde{d}\tilde{F}+[\tilde{A},\ \tilde{F}]=0, \quad \text{where } \tilde{F}=\tilde{d}\tilde{A}+\tilde{A}\tilde{A}, \tag{28}$$

depends on the nilpotency property of the extended exterior derivative $\tilde{d}=d+s+\overline{s}$. Also, the nilpotency of $\tilde{d}$ implies the nilpotency of the BRST symmetry, $s^2=\overline{s}^2=0$. Therefore, in the Bianchi identity approach one does not require the nilpotency condition for the newly introduced ghost degrees of freedom, since this condition is taken care of by the Bianchi identity itself.

Now, the above observations can be summed up as follows. Loosening the horizontality condition is necessary in the topological Yang–Mills-type theories so that new ghost degrees of freedom, which take care of the extra symmetry of topological nature, can be introduced. This point can be implemented either by modifying the definition of the extended curvature in the Bianchi identity approach or by adding a new piece of extended curvature, which is solely consisted of (anti) ghost fields, in the modified horizontality condition approach. The correct behavior of these new ghost fields is then insured by the BRST nilpotency condition in the modified horizontality condition approach, and by the nilpotency property of the extended exterior derivative in the Bianchi identity approach. Hence, in the geometrical setting, the BRST symmetry of topological nature can be expressed by the extended curvature containing all ''permissible'' ghosts whose property is dictated by the Bianchi identity in the extended space. In other words, from the BRST symmetry view point only the extended curvature containing all ''permissible'' ghosts is a geometrically meaningful object in the topological Yang–Mills–Higgs theory.

V. CONCLUSIONS

In this paper, we found the rules for the BRST/anti-BRST symmetry encompassing topological Yang–Mills–Higgs theory in two, three, and four dimensions. This was done in the superconnection framework so that the scalar field is regarded as a part of a connection, as is the vector gauge field. Using the superconnection language, we obtain the classical topological actions in two, three, and four dimensions from a classical action of topological Yang–Mills type through appropriate projections depending on the dimensions of space–times to which corresponding theories belong. In this framework, the BRST/anti-BRST rules for the scalar and vector gauge fields are obtained together rather than separately. This also tells us that the usefulness of the superconnection language when dealing with the scalar and vector gauge fields is greater than in the ordinary treatment, because in the ordinary treatment the BRST/anti-BRST rules for these two fields are obtained separately. In the superconnection language these rules are obtained in one calculation. As a result, we extend the work of Perry and Teo[3] in the topological Yang–Mills case to the topological Yang–Mills–Higgs case in two[7] and three[6] dimensions using the Bianchi identity. Comparing the present work with our previous work of the modified horizontality condition approach, we conclude the following in the topological Yang–Mills–Higgs theory. First, new ghost fields appear due to the existence of topological symmetry, and these fields can be identified as the components of the modified extended curvature in Perry and Teo's work.[3] Second, the symmetry property that these new ghosts should obey is constrained by the Bianchi identity in the extended space, and this requirement is nothing but the nilpotency condition of the BRST symmetry in another guise. Thus in theories with topological symmetry, it can be said that if things are expressed in the extended space, a space which contains the ghost directions, then one can treat the BRST symmetry in a geometrical setting. In this geometrical setting the curvature should contain all the ''permissible'' ghosts, and the BRST symmetry due to the topological symmetry is constrained by the Bianchi identity in this extended space.

Reformulation of QCD in the language of general relativity

F. A. Lunev[a)]
Physical Department, Moscow State University, Moscow, 119899, Russia

(Received 3 October 1995; accepted for publication 29 January 1996)

It is shown that there exists such a collection of variables that the standard QCD Lagrangian can be represented as the sum of usual Palatini Lagrangian for Einstein general relativity and the Lagrangian of matter and some other fields where the tetrad fields and the metric are constructed from initial SU(3) Yang–Mills fields.
 [S0022-2488(96)02309-2]

I. INTRODUCTION

Unified description of all interactions is one of the main goals of modern physics. Partial unification, namely unification of electromagnetic and weak interactions, is achieved in Salam–Weinberg theory and its numerous modifications. More or less satisfactory unification of electromagnetic, weak and strong interactions is achieved in grand unified theories based on various ''large'' gauge groups (SU(5),SO(10), etc.) But the satisfactory unified description of electromagnetic, weak, strong, and gravity interactions is still an open problem.

The origin of the difficulties is clear. Whereas all realistic theories of strong, weak, and electromagnetic interactions are based on Yang–Mills (YM) action

$$S_{\mathrm{YM}}=\int \mathrm{tr}(dA+A\wedge A)\wedge *(dA+A\wedge A), \tag{1}$$

the general relativity is based on Einstein–Hilbert action

$$S_{\mathrm{EH}}=\int dx\sqrt{g}R \tag{2}$$

or, in Palatini formalism, on the action

$$S_P=\int e^a\wedge e^b\wedge(d\Gamma+\Gamma\wedge\Gamma)^{cd}\varepsilon_{abcd}. \tag{3}$$

[We omit inessential overall factors before actions (1)–(3).]

Obviously, the mathematical structure of action (1) and actions (2) or (3) is very different. So the origination of the theory, that reduces to Eqs. (1) and (2) (or Eq. (3)) in certain limiting cases is a very hard problem.

The most direct way to construct unified theory of all interactions is, of course, to replace action (1) by some gravity-like action, or, vice versa, to replace action (2) or (3) by another one, that is more similar to Eq. (1).

The first possibility is realized, for instance, in tensor dominance (or strong gravity) model[1] (see also Ref. 2 for review and further references). The Lagrangian of this model is very similar to a gravitational one, but until now relation of this model and realistic physical models based on YM action is unclear.

The second possibility is realized, for example, in Poincare gauge theories of gravitation (see Refs. 2 and 3 for review), or in SL(6,C) gauge theory of Salam, Isham, and Strathdee[4] and their

[a)]Electronic mail: lunev@hep.phys.msu.su

modifications.[2,5,6] But physical meaning of all above mentioned theories is not quite clear because the corresponding actions are unlike the action of the standard model and it is not obvious that the latter can be considered as some limiting case of the former.

There exist also many other approaches to unification of gravity and YM gauge theories based on different modifications of actions (1)–(3). But, to author's knowledge, all theories proposed are rather far from real physics.

But there exist the third way to unification of general relativity and YM theories. Namely, one can try to find such variables that standard Einstein–Hilbert or Palatini actions written in these variables are transformed in standard YM action (plus, maybe, the action with some supplementary fields), or, vice versa, one can try to transform by change of variables the usual YM action in Einstein–Hilbert or Palatini ones.

During the last 20 years, and especially during last 5 years, the great progress was achieved in both directions.

First of all, the author would like to mention the Ne'eman–Sijacki ''chromogravity'' approach to QCD developed in Ref. 7. Ne'eman and Sijacki showed that there exists the mechanism of appearance of gravity-like forces in infrared limit of QCD. Some speculations in spirit of Ne'eman–Sijacki approach were also given in recent paper of Kuchiev.[8]

But in present paper we will follow another approach, namely the approach proposed in a previous paper.[9]

Let us consider, first, YM theory and general relativity in three dimensional space-time.[10] In this case YM action in the first order formalism can be written in the form

$$S_{\mathrm{YM}}=\int \mathrm{tr}*F\wedge(dA+A\wedge A)+\lambda^2\int \mathrm{tr}*F\wedge F, \tag{4}$$

whereas first order action for gravity is

$$S_{\mathrm{3D}}=\int e^a\wedge(d\Gamma+\Gamma\wedge\Gamma)^{bc}\varepsilon_{abc}. \tag{5}$$

In formula (4) λ means coupling constant and $*$ is the Hodge operator with respect to the space–time metric g_{mn}. (We reserve more usual notations e or g for determinants of the tetrad and the metric, respectively.) Below we will consider the case of Euclidean space–time.

For SU(2) gauge group, forms F and A valued in the space of anti-symmetric 3×3 matrices and so we can write

$$*F^{ab}=-\varepsilon^{abc}*F^c, \tag{6}$$

$$S^{\mathrm{YM}}=\int *F^a\wedge(dA+A\wedge A)^{bc}\varepsilon_{abc}-\lambda^2\int *F^a\wedge F^a. \tag{7}$$

In three dimensions $*F^a$ are 1-forms and so the first term in Eq. (7) coincides with three dimensional Palatini actions (5) up to notations! This fact allows to formulate 3D YM theory in general relativity-like form with the tensor

$$G_{mn}=(*F^a)_m(*F^a)_n \tag{8}$$

as the new space–time metric. In particular, usual YM equations appear to be equivalent to Einstein ones with simple rhs.

The above mentioned results concerning relations between 3D gravity and 3D YM theory were obtained, first, in the author's paper.[9] Independently, analogous results were obtained also in

Ref. 11 in the context of (3+1) dimensional SU(2) YM theory in the gauge $A_0^a=0$. However, in the latter approach YM induced gravity lives only on the three dimensional hyperplanes $x^0=\text{const}$ and so this approach is essentially non-covariant.

Further three dimensional space-time geometry discovered in works 9 and 11 was investigated in Refs. 12–18. In particular, in Ref. 12 solutions of Euclidean 3D YM equations with singularity on the sphere were discovered. These solutions can be also interpreted as stationary solutions of 4D YM equations in the gauge $A_0=0$ and can be considered as analog of Schwarzchild solution in general relativity. Analogous Schwarzchild-like and Kerr-like solutions of Yang–Mills–Higgs equations were recently discovered by Singleton.[19]

It was shown that a quantum particle moving in such a YM field (that is considered as external one) inside this sphere cannot leave it. So, maybe, such solutions can be used for elaborating the black hole or microuniverse (see Ref. 20) mechanism of confinement.

We see that in a three dimensional world, gravity does live inside YM theory. It is easy to understand the origin of such YM induced gravity. Indeed, the usual gravity is described by the triad of covectors e^a defined in each point of the space-time up to SO(3) rotation, and SO(3) connection Γ that defines the parallel transport of tensors in the space-time. All these objects appear naturally in YM theory–1-forms $*F^a$ play the role of the triad and SU(2) YM connection A plays the role of the space-time connection Γ.

But how to generalize this construction for a realistic four dimensional case?[21] Direct generalization is not possible, because, first, $*F$ in four dimensions are 2-forms (rather then 1-forms as in 3D case), and, the second, the structure of 4D Palatini action (3) differs from one of 3D action (5). Nevertheless, such generalization exists. Moreover, this problem was partially solved, in fact, almost 20 years ago in Plebanski's work.[22] But Plebanski obtained his results in absolutely different context (he investigated complex structures in general relativity). Maybe, due to this reason his results have not been used in investigations of YM induced gravity until now.[23]

Let us rewrite the Palatini action (3) in spinor notations

$$S_P=\int e^A_{C'}\wedge e^{BC'}\wedge(d\Gamma_{AB}+\Gamma_{AC}\wedge\Gamma^C_B). \tag{9}$$

(We use the usual isomorphism between the spaces of $O(4)$ vectors and $\mathrm{SU}(2)\times\mathrm{SU}(2)$ spinors.) Sign conventions, normalization factors, etc., are describe in section II below. Further, we omit the part of Palatini action that contains the fields $\Gamma_{A'B'}$. (See, for instance, Refs. 24 and 25, in which it was shown that the using of chiral action (9) is very natural, in particular, in Ashtekar formalism.)

One can note that 1-forms $e^{AA'}$ enter in action only in the combination

$$\Sigma^{AB}=e^A_{C'}\wedge e^{BC'}. \tag{10}$$

So the Palatini action (9) can be represented in the form

$$S_P=\int \Sigma^{AB}\wedge(d\Gamma_{AB}+\Gamma_{AC}\wedge\Gamma^C_B). \tag{11}$$

Of course, the quantities Σ^{AB} in Eq. (11) cannot be considered as the independent dynamical variables. Indeed, due to Eq. (10) the 2-forms Σ^{AB} satisfy the condition

$$\Sigma^{(AB}\wedge\Sigma^{CD)}=0. \tag{12}$$

Further, Plebanski showed that if the conditions (12) are satisfied and

$$\Sigma^{AB}\wedge\Sigma_{AB}\neq 0, \tag{13}$$

then Σ^{AB} can be represented in form (10) with non-degenerate tetrad $e^{AA'}$. So the Palatini action (9) is equivalent to Plebanski action

$$S_{Pl}=\int \Sigma^{AB}\wedge(d\Gamma_{AB}+\Gamma_{AC}\wedge\Gamma^{C}_{B})+\int \phi_{ABCD}\Sigma^{AB}\wedge\Sigma^{CD}. \tag{14}$$

The second term in Eq. (14) with totally symmetric Lagrange multipliers ϕ_{ABCD} is introduced to take into account condition (12).

In action (14) fields Σ^{AB}, Γ_{AB} and ϕ_{ABCD} are independent dynamical variables. The first term in Eq. (14) coincides with the first term in the first order SU(2) YM action

$$S_{\mathrm{YM}}=\int F^{BC}\wedge(dA_{BC}+A_{BD}\wedge A^{D}_{C})+\lambda^{2}\int F^{BC}\wedge *F_{BC} \tag{15}$$

up to notations. But it does not mean that the gravity lives inside SU(2) YM theory as in 3D case, because the analog of the second term in Eq. (14) is absent in Eq. (15) and so we have no analog of Eq. (12) in SU(2) YM theory. But without condition (12) we cannot reconstruct the tetrad $e^{AA'}$.

Let us consider, however, the theory with more large gauge group $G\supset \mathrm{SU}(2)$. One can choose among $N=\dim G$ 2-forms F three forms $F^{AB}=F^{(AB)}$ that are transformed as rank two symmetric spinor under gauge transformations from certain SU(2) subgroup of the group G. Then action (15) will be a piece of the total YM action. Further, if $\dim G\geqslant 8$, then, in general, we can impose, using other gauge degrees of freedom, five SU(2) invariant gauge conditions

$$F^{(AB}\wedge F^{CD)}=0. \tag{16}$$

Conditions (16), that we will call ''the Plebanski gauge,'' coincide with Plebanski conditions (12) up to notations whereas the first term in YM action (15) coincides, up to notations, with the first term in Plebanski action (14). *So we can conclude that gravity lives inside YM theory if the dimension of the gauge group is more or equal to eight.* Indeed, due to Plebanski theorem we can reconstruct the tetrad $e^{AA'}$ and the corresponding metric

$$F^{AB}=e^{A}_{A'}\wedge e^{BA'}, \tag{17}$$

$$G_{mn}=e^{AA'}_{m}e_{AA'n}. \tag{18}$$

After substituting Eq. (17) in the first term of action (15) we obtain the usual Palatini action for gravity (9).

The main idea of the present work is to use of the gauge (16) to reformulate the YM theory in general relativity-like form. Below we will show that the gauge (16) really exists for the gauge group SU(3) and the corresponding gauge theory, the Quantum Chromodynamics, can be formulated in the close analogy with general relativity. But before author would like to give some additional notes concerning 2-forms formalism in general relativity.

Plebanski results allow to use three 2-forms Σ^{AB} instead of metric. In Plebanski's approach these forms satisfy the constraints (12) that play the crucial role in Plebanski's formalism. But later it was shown that this conditions are not necessary. Namely, it appears that, in generic case, any three 2-forms define unique, up to conformal factor, the metric, with respect to which they are (anti)-self-dual. These statement is known now as Urbantke theorem (see Ref. 26. Another proof and some refinements were given in Ref. 27). In particular, in generic case any collection of three 2-forms defined up to SL(3) transformation naturally determine the unique metric. Moreover, later t'Hooft showed[28] that any triple of two forms (with some non-degeneracy condition) natu-

rally defines not only the metric but also certain SL(3) connection and so it is possible to reformulate the general relativity in terms of triples of 2-forms. Similar formalism with GL(3) connection instead of SL(3) ones was proposed also in recent paper.[29]

However, the Lagrangian of t'Hooft and its modifications are reduced to Plebanski's Lagrangian (14) by imposing of gauge conditions that are exactly coincide with Eq. (12). On the other hand, t' Hooft Lagrangian, without the imposing of conditions (12), is quadrilinear and so is not similar to YM one. By these reasons in the present paper we use the old Plebanski formalism rather then its further generalizations.

Clear relations between gravity and YM theory also appear in Ashtekar formalism.[30] An attempt to develop the formalism for unified description of YM and gravity fields in the spirit of Ashtekar phase space approach was done in other works.[31] However, this theory gives the conventional YM theory only in the lowest order in the fields and so it is hard to make consistent its predictions with ones of the Standard Model. Originally discovered,[30] it was very unlike the Plebanski approach. But later it was shown[32] that Ashtekar formalism can be reproduced by (3+1) decomposition of Plebanski Lagrangian.

The paper is organized as follows. In section II we describe our notations. In sections III and IV we formulate QCD in general relativity-like form at classical amd quantum levels respectively. In section V we discuss obtained results.

II. NOTATIONS

Indexes a,b,c,d are frame ones and run over the set $\{0,1,2,3\}$. Indexes m,n,p,q are world ones and run over the same set. Upper case Latin indexes $A,B,C,\ldots$ are SU(2) spinor ones and run over the set $\{0,1\}$. Greek indexes α,β,γ runs over the set $\{1,2,3\}$.

A. SU(2) spinors and O(3) vectors

Lowering and raising of SU(2) spinor indexes are performed by anti-symmetric spinors ε_{AB}, ε^{AB}, $\varepsilon_{01}=\varepsilon^{01}=+1$,

$$\varphi_A=\varphi^B\varepsilon_{BA}, \quad \varphi^B=\varepsilon^{BA}\varphi_A. \tag{19}$$

Hermitian conjugation of SU(2) spinors are defined as

$$(\varphi^\dagger)^{AB\ldots}=\overline{\varphi_{CD\ldots}}\,\varepsilon^{CA}\varepsilon^{DB}\ldots, \tag{20}$$

where quantities $\overline{\varphi_{CD\ldots}}$ are complex conjugated to φ^{CD}. The spaces of symmetric second rank SU(2) spinors and O(3) vectors are isomorphic. The isomorphism is established by the formula

$$S^\alpha\leftrightarrow S^{AB}=-\frac{i}{\sqrt{2}}\,S^\alpha\sigma_\alpha^{AB}, \tag{21}$$

where $\sigma_{\alpha B}^A$ are Pauli matrices. Real vectors correspond to Hermitian spinors,

$$\varepsilon^{\alpha\beta\gamma}U^\alpha V^\beta W^\gamma=\sqrt{2}U^{AB}V_{BC}W_A^C \quad S^\alpha S^\alpha=S^{AB}S_{AB}. \tag{22}$$

Below we will use the convention (21) with one exception: if Γ^α are components of some O(3) connection and

$$R^\alpha=d\Gamma^\alpha+\frac{1}{2}\,\varepsilon^{\alpha\beta\gamma}\Gamma^\beta\wedge\Gamma^\gamma \tag{23}$$

are components of the corresponding curvature form, then

$$\Gamma^{AB}=\frac{1}{2i}\ \sigma_{\alpha}^{AB}\Gamma^{\alpha},\quad R^{AB}=\frac{1}{2i}\ \sigma_{\alpha}^{AB}R^{\alpha}. \tag{24}$$

Using Eq. (24), one can prove that

$$R^{AB}=d\Gamma^{AB}+\Gamma_{C}^{A}\wedge\Gamma^{CB}. \tag{25}$$

B. SU(2)×SU(2) spinors and O(4) vectors

O(4) frame vector indexes are lowered and raised by the tensor δ^{ab}. The spaces of rank (1,1) SU(2)×SU(2) spinors and O(4) vectors are isomorphic. The isomorphism is established by the formula

$$S_{AA'}\leftrightarrow S_a=g_a^{AA'}S_{AA'}, \tag{26}$$

where $g_a^{AA'}$ are Euclidean Infeld–van der Vaerden symbols for flat space

$$(g_a^{AA'})=\left(\frac{1}{\sqrt{2}}\ \delta_{A'}^{A},\ \frac{i}{\sqrt{2}}\ \sigma_{\alpha A'}^{A}\right). \tag{27}$$

Real vectors correspond to Hermitian spinors (Hermitian conjugation of the latter is defined in the previous subsection),

$$S_aS_a=S_{AA'}S^{AA'}. \tag{28}$$

C. O(4) (anti)-self-dual tensors and O(3) vectors

For frame O(4) tensors Hodge operator is defined as usual

$$*M_{ab}=\frac{1}{2}\ \varepsilon_{abcd}M_{cd}. \tag{29}$$

The spaces of the (anti)-self-dual tensors and O(3) vectors are isomorphic. The isomorphism is estublished by the formula

$$^{\pm}M^{\alpha}=\ ^{\pm}\eta_{ab}^{\alpha}\ ^{\pm}M_{ab}, \tag{30}$$

where $^{\pm}\eta_{ab}^{\alpha}$ are t'Hooft symbols

$$^{+}\eta_{ab}^{\alpha}=-\frac{1}{2i}\ \overline{\sigma}_{\alpha B'}^{A'}g_{aAA'}g_{b}^{AB'}, \tag{31}$$

$$^{-}\eta_{ab}^{\alpha}=\frac{1}{2i}\ \sigma_{\alpha B}^{A}g_{aAA'}g_{b}^{BA'}. \tag{32}$$

t'Hooft symbols satisfy the following equations:

$$^{\pm}\eta_{ac}^{\alpha}\ ^{\pm}\eta_{cb}^{\beta}=-\frac{1}{4}\ \delta^{\alpha\beta}\delta_{ab}+\frac{1}{2}\ \varepsilon^{\alpha\beta\gamma}\ ^{\pm}\eta_{ab}^{\gamma} \tag{33}$$

$$^{\pm}\eta^{\gamma}_{ab}\ {}^{\pm}\eta^{\gamma}_{cd}=\frac{1}{4}\ (\delta_{ac}\delta_{bd}-\delta_{ad}\delta_{bc}\pm\varepsilon_{abcd}). \tag{34}$$

Formulas (22), (28), (33), and (34) allow easy translation of any formula from spinor to vector language and vice versa.

III. PLEBANSKI GAUGE IN SU(3) YANG-MILLS THEORY

A. Plebanski theorem for real 2-forms

Plebanski showed that three complex 2-forms Σ^{AB}, satisfying conditions (12) and (13), can be represented in form (10). The ''real'' variant of this theorem can be formulated in the following way:

Let S^{α} be three real 2-forms obeying the conditions

$$S^{\alpha}\wedge S^{\beta}=\frac{1}{3}\ \delta^{\alpha\beta}S^{\gamma}\wedge S^{\gamma}, \tag{35}$$

$$S^{\gamma}\wedge S^{\gamma}\neq 0. \tag{36}$$

Let G_{mn} be the Urbantke metric (our definition of the metric (37) differs from the original definition of Urbantke[26] by inessential factor)

$$G_{mn}=-\frac{4}{3}\ [S^{\delta}_{tu}S^{\delta}_{vw}\varepsilon^{tuvw}]^{-1}\varepsilon_{\alpha\beta\gamma}\varepsilon^{pqrs}S^{\alpha}_{mp}S^{\beta}_{qr}S^{\gamma}_{sn}. \tag{37}$$

Then G_{mn} has definite signature, $(++++)$ or $(----)$, and S^{α} can be represented, respectively, as

$$S^{\alpha}=\pm\ ^{-}\eta^{\alpha}_{ab}e^{a}\wedge e^{b}. \tag{38}$$

One notes, that the equations (35) and (36) are nothing but reformulation of Eqs. (12) and (13) in vector language. The spinor analog of Eq. (38) is

$$S^{AB}=\pm\frac{1}{2}\ e^{AC'}\wedge e^{B}_{C'}, \tag{39}$$

where

$$(S^{\dagger})^{AB}=S^{AB},\quad (e^{\dagger})^{AA'}=e^{AA'}. \tag{40}$$

Equation (39) is the analog of Eq. (10).

Let us prove the theorem formulated above. Let

$$M^{\alpha\beta}=\varepsilon^{mnpq}S^{\alpha}_{mn}S^{\beta}_{pq}. \tag{41}$$

Then the matrix $M^{\alpha\beta}$ has a definite signature [see Eq. (35)]. So, due to results of Urbantke[26] and Harnett,[27] the Urbantke metric (37) is non-degenerate, has a definite signature, and 2-forms S^{α} are self-dual or anti-self-dual with respect to Hodge operator corresponding to this metric. Hence, the Urbantke metric can be written as

$$G_{mn}=\pm e^{a}_{m}e^{a}_{n}, \tag{42}$$

whereas 2-forms S^{α} as

$$S^\alpha = C^\alpha_\beta \, {}^- \eta^\beta_{ab} e^a \wedge e^b \tag{43}$$

or

$$S^\alpha = C^\alpha_\beta \, {}^+ \eta^\beta_{ab} e^a \wedge e^b, \tag{44}$$

because the set of three 2-forms ${}^\pm \eta^\alpha_{ab} e^a \wedge e^b$ is a basis in the space of the (anti)-self-dual forms.

One notes, that Eq. (44) can be transformed in Eq. (43). Indeed, 1-forms e^a are defined by Eq. (42) up to transformation

$$e^a \to O^a_b e^b, \quad O \in O(4). \tag{45}$$

Let $O = \mathrm{diag}\{1,-1,-1,-1\}$. Then

$${}^+ \eta^\alpha_{ab} O^a_c O^b_d = - \, {}^- \eta^\alpha_{cd}. \tag{46}$$

So, redefining e^a and C^α_β according to Eqs. (45) and (46), one can transform Eq. (44) in Eq. (43).

One substitutes Eq. (43) in Eq. (35). Using the formulas of the section II C, one obtains

$$C^\alpha_\gamma C^\beta_\gamma = \frac{1}{3} \, \delta^{\alpha\beta} C^\delta_\gamma C^\delta_\gamma. \tag{47}$$

So

$$C^\alpha_\beta = \pm C O^\alpha_\beta, \tag{48}$$

where

$$O \in \mathrm{SO}(3), \quad C = \sqrt{\frac{1}{3} \, C^\delta_\gamma C^\delta_\gamma} > 0. \tag{49}$$

For given $O \in \mathrm{SO}(3)$ there exists the matrix $\widetilde{O} \in \mathrm{SO}(4)$ such that

$${}^- \eta^\alpha_{ab} \widetilde{O}^a_c \widetilde{O}^b_d = (O^{-1})^\alpha_\beta \, {}^- \eta^\beta_{cd}. \tag{50}$$

So, redefining e^a according to Eq. (45) with $O = \widetilde{O}$, and taking into account Eq. (45), one reduces Eq. (43) to

$$S^\alpha = \pm C \, {}^- \eta^\alpha_{ab} e^a \wedge e^b. \tag{51}$$

Finally, substituting Eq. (51) in Eq. (37), one obtains that $C = 1$. The theorem is proved.

B. SU(3) YM action in Plebanski gauge

We start from the usual SU(3) YM action in the first order formalism,

$$S_{\mathrm{YM}} = \int \mathrm{tr}[F \wedge (dA + A \wedge A) + \lambda^2 F \wedge * F], \tag{52}$$

where F and A are considered as independent variables.

The forms F and A valued in the space of 3×3 anti-Hermitian traceless matrices. So we can write

$$A = \Gamma + i\Phi, \quad F = S + iQ, \tag{53}$$

where Γ, Φ, S, and Q valued in the space of real 3×3 matrices, and

$$\Gamma^T=-\Gamma, \quad S^T=-S,$$
$$\Phi^T=\Phi, \quad Q^T=Q, \tag{54}$$
$$\mathrm{tr}\ \Phi=0, \quad \mathrm{tr}\ Q=0,$$

where the superscript T means transposition.

Substituting Eq. (53) in Eq. (52), one obtains

$$S_{\mathrm{YM}}=\int \mathrm{tr}[S\wedge(R-\Phi\wedge\Phi)+Q\wedge D\Phi+\lambda^2 S\wedge *S-\lambda^2 Q\wedge *Q], \tag{55}$$

where

$$R=d\Gamma+\Gamma\wedge\Gamma, \tag{56}$$

$$D\Phi=d\Phi+\Gamma\wedge\Phi+\Phi\wedge\Gamma. \tag{57}$$

Decomposition (53) corresponds to certain embedding of the algebra $\mathrm{su}(2)\approx\mathrm{o}(3)$ in $\mathrm{su}(3)$. So Γ and R can be considered as the forms of connection and curvature corresponding to the subgroup $\mathrm{SU}(2)$ of the gauge group $\mathrm{SU}(3)$ whereas D is covariant derivative defined by the connection Γ.

Due to Eq. (54), one can write

$$S^{\alpha\beta}=-\varepsilon^{\alpha\beta\gamma}S^{\gamma}$$

and to impose the gauge conditions (35) on the 2-forms S^{α}.

Substituting Eq. (39) in Eq. (55), one obtains the action

$$S=2\int e^{A}_{C'}\wedge e^{BC'}\wedge R_{AB}+2\int e^{AC'}\wedge e^{B}_{C'}\wedge\Phi^{CDE}_{A}\wedge\Phi_{BCDE}+\int Q^{ABCD}\wedge D\Phi_{ABCD}$$
$$-\lambda^2\int e^{AC'}\wedge e^{B}_{C'}\wedge *(e^{D'}_{A}\wedge e_{BD'})-\lambda^2\int Q^{ABCD}\wedge *Q_{ABCD}, \tag{58}$$

where R_{AB} is defined by formula (25), Φ^{ABCD} and Q^{ABCD} are the forms Φ, Q written in the spinor language Here we have wrote the YM action in new variables for the upper sign case in Eq. (39). Below we will show that this is enough to formulate quantum version of the theory under consideration.

The first term in Eq. (58) is the Palatini action. So action (58) can be considered as one for gravity coupled with several matter fields. In particular, first three terms in action (58) are invariant under the action of the group of the general coordinate transformations $\mathrm{Diff}(R^4)$—just as in general relativity. But the total action, of course, is not $\mathrm{Diff}(R^4)$ invariant because the last two terms in Eq. (58) depend on fixed space–time metric via Hodge operator.

Action (58) can be rewritten in several equivalent forms. First, one can represent the connection in the form

$$\Gamma=\hat{\Gamma}+K,$$

where $\hat{\Gamma}$ is unique torsionless metric connection and K is contorsion 1-form. Let $\hat{D}$ and $\hat{R}$ are covariant differential and curvature 2-form corresponding to connection $\hat{\Gamma}$. Then

$$\int e^A_{C'} \wedge e^{BC'} \wedge R_{AB} = \int e^A_{C'} \wedge e^{BC'} \wedge (\hat{R}_{AB} + \hat{D}K_{AB} + K_{AC} \wedge K^C_B). \tag{59}$$

But due to torsionless condition

$$\hat{D}e^{AA'} = 0$$

the second term in the rhs of Eq. (59) is total divergence and so can be omitted. Hence, the action (58) can be rewritten as

$$S = 2\int e^A_{C'} \wedge e^{BC'} \wedge (\hat{R}_{AB} + K_{AC} \wedge K^C_B) + 2\int e^{AC'} \wedge e^B_{C'} \wedge \Phi^{CDE}_A \wedge \Phi_{BCDE} + \int Q^{ABCD}$$
$$\wedge (\hat{D}\Phi_{ABCD} + 4K^E_{(A}\Phi_{|E|BCD)}) - \lambda^2 \int e^{AC'} \wedge e^B_{C'} \wedge *(e^{D'}_A \wedge e_{BD'}) - \lambda^2 \int Q^{ABCD} \wedge *Q_{ABCD}. \tag{60}$$

We see that the first term in Eq. (60) is nothing but usual Einstein–Hilbert action. Further, as in usual theories of gravitation with torsion, action (60) depend on torsion quadratically without derivatives. So torsion can be eliminated from action by solving equations of motion. We return to discussion of this point in the last section.

The ''matter'' terms in the action seem rather strange. But they can be rewritten in more familiar form if one eliminates the field Φ from the action by solving the equations

$$\frac{\delta S}{\delta \Phi} = 0. \tag{61}$$

Substituting the solution of Eq. (61) in Eq. (58), one obtains

$$S = 2\int e^A_{C'} \wedge e^{BC'} \wedge R_{AB} + \frac{1}{2}\int DQ^{ABCD} \wedge \star DQ_{ABCD} - \frac{1}{6}\int e^A_{C'} \wedge e^{BC'} \wedge \star DQ^{CDE}_A \wedge \star DQ_{BCDE}$$
$$- \lambda^2 \int Q^{ABCD} \wedge *Q_{ABCD} - \lambda^2 \int e^{AC'} \wedge e^B_{C'} \wedge *(e^{D'}_A \wedge e_{BD'}), \tag{62}$$

where $\star$ denotes Hodge operator with respect to YM metric G_{mn}.

This form of matter action is more recognizable The second and the third terms in Eq. (62) can be interpreted as ''kinetic'' ones whereas the forth term can be considered as ''mass'' term for field Q. The last term in Eq. (62) can be rewritten as

$$S_2 = \int dx \sqrt{g}[g^{mp}g^{nq}G_{mn}G_{pq} - (g^{mn}G_{mn})^2]$$

and so can be considered as ''mass'' term for chromo-gravity field. Terms of such type in the action are already considered in context of strong gravity approach.[20]

We will continue the investigation of SU(3) YM theory in introduced variables in the next section at quantum level. But before we must prove that Plebanski gauge really fixes the gauge up to SU(2) transformations.

C. Investigation of the Plebanski gauge

Any SU(3) matrix U can be written in the form

$$U = e^{i\omega}, \tag{63}$$

where ω is a traceless Hermitian 3×3 matrix. Pure imaginary matrices ω corresponds to generators of the subgroup SU(2), whereas real matrices can be considered as coordinates on the space SU(3)/SU(2). Obviously, the latter satisfy the equations

$$\omega^{\alpha\beta}=\omega^{\beta\alpha}, \quad \omega^{\alpha\alpha}=0. \tag{64}$$

Let us consider the infinitesimal gauge transformations with parameters obeying Eq. (64)

$$\delta A = i d\omega + i[A,\omega], \tag{65}$$

$$\delta F = i[F,\omega]. \tag{66}$$

Comparing Eqs. (65), (66), and (53), one obtains

$$\delta\Gamma = -[\Phi,\omega], \quad \delta\Phi = D\omega, \tag{67}$$

$$\delta S = -[Q,\omega], \quad \delta Q = [S,\omega]. \tag{68}$$

Let

$$T^{ABCD}=*[S^{(AB}\wedge S^{CD)}]. \tag{69}$$

Using Eq. (68), one finds

$$\delta T^{ABCD}=c\varepsilon^{mnpq}e^{(A}_{A'm}e^{B|A'|}_{n}Q^{C}_{EFGpq}\omega^{D)EFG}, \tag{70}$$

where c is irrelevant numerical constant, $e^{AA'}_{m}$ and Q^{ABCD}_{pq} are components of the forms $e^{AA'}$ and Q^{ABCD}, whereas ω^{ABCD} is SU(2) spinor that corresponds to O(3) tensor $\omega^{\alpha\beta}$.

To prove that Plebanski gauge reduces the initial SU(3) YM theory to the SU(2) one, it is sufficient to prove that the equations

$$\delta T^{ABCD}=0 \tag{71}$$

have the only trivial solution $\omega^{ABCD}=0$ for almost all field configurations.

One notes that due to Eq. (64)

$$\omega^{ABCD}=\omega^{(ABCD)}. \tag{72}$$

So Eqs. (71) are the system of five linear homogeneous equations for five unknown ω^{ABCD}.

The system (71) can be rewritten as

$$G^{(ABC}_{EFG}\delta^{D)}_{H}\omega^{EFGH}=0, \tag{73}$$

where

$$G^{ABCEFG}=\varepsilon^{mnpq}e^{A}_{A'm}e^{BA'}_{n}Q^{CEFG}_{pq}. \tag{74}$$

In generic case, the spinor G^{ABCEFG} satisfies the only constraints

$$G^{ABCDEF}=G^{(AB)CDEF}, \quad G^{ABCDEF}=G^{AB(CDEF)}. \tag{75}$$

Now let us consider the field configuration for which the only non-zero components of G^{ABCDEF} are G^{000000}, G^{111111}, and

$$G^{000111}=G^{001011}=G^{001101}=G^{001110}.$$

For such configuration one obtains from Eq. (73)

$$G^{000000}\omega^{0001}+G^{000111}\omega^{1111}=0,$$

$$G^{000000}\omega^{0000}=0, \quad G^{000111}\omega^{0011}=0, \tag{76}$$

$$G^{111111}\omega^{0111}=0, \quad G^{111111}\omega^{1111}=0.$$

Obviously, that the system (76) has the only trivial solution for non-zero G^{000000}, G^{111111}, and G^{000111}.

Let

$$M^{ABCD}_{EFGH}=G^{(ABC}_{(EFG}\delta^{D)}_{H)} \tag{77}$$

the spinor M^{ABCD}_{EFGH} can be considered as some 5×5 matrix M. We have proved that $\det M \neq 0$ for certain field configuration. But $\det M$ is polynomial with respect to fields $e^{AA'}$ and Q^{ABCD}. So $\det M \neq 0$ for almost all field configuration. This means that the system (73) has the only trivial solution for almost all configurations of fields.

IV. QUANTIZATION

We start from usual expression for Euclidean vacuum expectation value of certain Hermitian gauge invariant functional $\mathcal{O}=\mathcal{O}[A,\Psi,\overline{\Psi}]$:

$$\langle\mathcal{O}\rangle=\int dAd\overline{\Psi}d\Psi\mathcal{O}[A,\overline{\Psi},\Psi]\exp\{-S_{\mathrm{YM}}-S_{\mathrm{mat}}\}, \tag{78}$$

where $\overline{\Psi},\Psi$ are matter fields,

$$S_{\mathrm{YM}}[A]=-\frac{1}{4\lambda^2}\int \mathrm{tr}(dA+A\wedge A)\wedge*(dA+A\wedge A), \tag{79}$$

and

$$S_{\mathrm{mat}}=\int dx\sqrt{g}\left\{\sum_{\mathrm{flavors}}(\overline{\Psi}_f\hat{\nabla}\Psi_f-m_f\overline{\Psi}_f\Psi_f)\right\}. \tag{80}$$

Formula (78) can be written as

$$\langle\mathcal{O}\rangle=\int dFdAd\overline{\Psi}d\Psi\mathcal{O}[A,\overline{\Psi},\Psi]\exp\left\{i\int \mathrm{tr}[F\wedge(dA+A\wedge A)]\right\}\exp\left\{-\lambda^2\int \mathrm{tr}F\wedge*F-S_{\mathrm{mat}}\right\} \tag{81}$$

or, finally, as

$$\langle\mathcal{O}\rangle=\int dSdQd\Gamma d\Phi d\overline{\Psi}d\Psi\mathcal{O}[\Gamma+i\Phi,\overline{\Psi},\Psi]$$
$$\times\exp\left\{i\int \mathrm{tr}[S\wedge(R-\Phi\wedge\Phi)+Q\wedge D\Phi]\right\}\exp\left\{\lambda^2\int \mathrm{tr}[S\wedge*S-Q\wedge*Q]\right\}\exp\{-S_{\mathrm{mat}}\}, \tag{82}$$

where variables S, Q, Γ, and Φ are defined by (53).

We will fix the gauge (namely, Plebanski gauge) by usual Faddeev–Popov trick. We insert in Eq. (82) the unit

$$1=\int_{\mathrm{SU}(3)/\mathrm{SU}(2)} d\mu(\omega)\,\delta(*[(S^{\omega})^{(AB}\wedge(S^{\omega})^{CD)}])\Delta_{\mathrm{FP}} \tag{83}$$

where $d\mu(\omega)$ is invariant measure on SU(3)/SU(2), $(S^{\omega})^{AB}$ is a gauge transformation of S^{AB}, and Δ_{FP} is Faddeev–Popov functional. Then, after usual manipulations, one obtains

$$\begin{aligned}\langle\mathscr{O}\rangle=&\int dSdQd\Gamma d\Phi d\overline{\Psi}d\Psi\mathscr{O}[\Gamma+i\Phi,\overline{\Psi},\Psi]\delta(*[S^{(AB}\wedge S^{CD)}])\det M\\&\times\exp\left\{i\int \mathrm{tr}[S\wedge(R-\Phi\wedge\Phi)+Q\wedge D\Phi]\right\}\exp\left\{\lambda^2\int \mathrm{tr}[S\wedge *S-Q\wedge *Q]\right\}\exp\{-S_{\mathrm{mat}}\}.\end{aligned} \tag{84}$$

Here $\det M$ is Faddeev–Popov determinant, where M is 5×5 matrix

$$M^{ABCD}_{EFGH}=*[S^{(AB}\wedge Q^{C}_{(EFG}\delta^{D)}_{H)}]. \tag{85}$$

This matrix coincides, on the surface

$$S^{(AB}\wedge S^{CD)}=0, \tag{86}$$

with the matrix (77). So $\det M\neq0$ for almost all field configurations (see the section III C).

Let $\mathscr{S}_+(\mathscr{S}_-)$ be the set of all 2-forms S^{α} for which Urbantke metric (37) is positive (negative) definite. We can write the integral (84) as the sum of the integrals over $\mathscr{S}_+$ and $\mathscr{S}_-$.

Obviously, that $\mathscr{S}_-$ is mapped onto $\mathscr{S}_+$ by the transformation $S\to-S$, $Q\to-Q$. But the latter is equivalent to the complex conjugation in the integral over $\mathscr{S}_-$. So the integral over $\mathscr{S}_+$ is equal to complex conjugated integral over $\mathscr{S}_-$. Hence,

$$\begin{aligned}\langle\mathscr{O}\rangle=&\mathrm{Re}\int_{\mathscr{S}_+} dSdQd\Gamma d\Phi d\overline{\Psi}d\Psi\mathscr{O}[\Gamma+i\Phi,\overline{\Psi},\Psi]\delta(*[S^{(AB}\wedge S^{CD)}])\det M\\&\times\exp\left\{i\int \mathrm{tr}[S\wedge(R-\Phi\wedge\Phi)+Q\wedge D\Phi]\right\}\exp\left\{\lambda^2\int \mathrm{tr}[S\wedge *S-Q\wedge *Q]\right\}\exp\{-S_{\mathrm{mat}}\}.\end{aligned} \tag{87}$$

We showed in the section III A that the solution of Plebanski gauge conditions (86) for $S\in\mathscr{S}_+$ is given, in vector language, by the formula

$$S^{\alpha}=\bar{}\,\eta^{\alpha}_{ab}e^{a}\wedge e^{b}. \tag{88}$$

So, for $S\in\mathscr{S}_+$,

$$\int\prod_{a,n}de^{a}_{n}\prod_{\substack{\alpha\\m>n}}\delta(S^{\alpha}_{mn}-\bar{}\,\eta^{\alpha}_{ab}e^{a}_{m}e^{b}_{n})=f(S)\prod_{\substack{\alpha\leqslant\beta\\(\alpha,\beta)\neq(3,3)}}\delta\left(*\left[S^{\alpha}\wedge S^{\beta}-\frac{1}{3}\,\delta^{\alpha\beta}S^{\gamma}\wedge S^{\gamma}\right]\right), \tag{89}$$

where the function $f(S)$ to be determined.

It is easy to prove that

$$f=\mathrm{const}. \tag{90}$$

Indeed, $f(S)$ is scalar density with respect to general coordinate transformations and O(3) gauge transformations. So

$$f=f(\varepsilon^{mnpq}S^{\alpha}_{mn}S^{\alpha}_{pq}). \tag{91}$$

But the dimension of f is zero. So the function (91) is a constant.

Inserting Eqs. (89) and (90) in Eq. (87), one obtains

$$\langle\mathscr{O}\rangle=\mathrm{Re}\int dedQd\Gamma d\Phi d\overline{\Psi}d\Psi\mathscr{O}[\Gamma+i\Phi,\overline{\Psi},\Psi]\det M\ \exp\{iS_1-\lambda^2S_2-S_{\mathrm{mat}}\}, \tag{92}$$

where

$$S_1=\int e^A_{C'}\wedge e^{BC'}\wedge R_{AB}+2\int e^{AC'}\wedge e^B_{C'}\wedge\Phi^{CDE}_A\wedge\Phi_{BCDE}+\int Q^{ABCD}\wedge D\Phi_{ABCD},$$

$$S_2=\int dx\sqrt{g}[g^{mp}g^{nq}G_{mn}G_{pq}-(g^{mn}G_{mn})^2]+\int Q^{ABCD}\wedge *Q_{ABCD}, \tag{93}$$

where

$$G_{mn}=e^a_m e^a_n \tag{94}$$

is YM induced metric, det M is Faddeev–Popov determinant,

$$M^{ABCD}_{EFGH}=*[e^{(A|C'|}\wedge e^B_{C'}\wedge Q^C_{(EFG}\delta^{D)}_{H)}] \tag{95}$$

and

$$S_{\mathrm{mat}}=\sum_{\text{flavors}}\int dx\sqrt{g}\{i\overline{\Psi}_{fAB}{}^{(0)}e^n_a\gamma^a D_n\Psi^{AB}_f+i\overline{\Psi}_{fAB}{}^{(0)}e^n_a\gamma^a\Phi^{ABCD}_n\Psi_{fCD}-m_f\overline{\Psi}_{fAB}\Psi^{AB}_f\}.$$

In the latter formula ${}^{(0)}e^n_a$ means the space–time tetrad (that is, $g^{mn}={}^{(0)}e^{m(0)}_a e^n_a$).

The integrand in Eq. (92) is O(4) gauge invariant. To fix this gauge freedom, it is necessary to impose further gauge conditions. The simplest choice is

$$e_{ma}=e_{am}. \tag{96}$$

This gauge entangles space–time and gauge degrees of freedom and so, after imposing of the gauge (96), they must be considered on the equal footing.

It is easy to prove, that Faddeev–Popov determinant, corresponding to gauge (96), is equal to $|e|^{3/2}$. So formula (92) can be written as

$$\langle\mathscr{O}\rangle=\mathrm{Re}\int_{e_{am}=e_{ma}} dedQd\Gamma d\Phi d\overline{\Psi}d\Psi\mathscr{O}[\Gamma+i\Phi,\overline{\Psi},\Psi]|e|^{\frac{3}{2}}\det M\ \exp\{iS_1-\lambda^2S_2-S_{\mathrm{mat}}\}. \tag{97}$$

(It would be remind, that $e^{AA'}_m$ and e_{am} in (97) are connected, according to rules of the section II B, by relation $e^{AA'}_m=g^{aAA'}e_{am}$).

The formula (92) can be also rewritten in manifestly O(4) invariant variables, such as G_{mn},

$$\Phi_{mnpqr}dx^r\equiv\Phi^{\alpha\beta}_r\eta^{\alpha}_{ab}e^a_m e^b_n\eta^{\beta}_{cd}e^c_p e^d_q dx^r,$$

etc. But in such variables the corresponding action in Eq. (92) contains Einstein–Hilbert term $\sqrt{G}R$ and so is not polynomial. So we prefer to consider formulas (92) and (97) as final results of our investigation.

V. DISCUSSION

We have shown that gravity-like interactions live inside QCD. This conclusion is supported by the results of Ne'eman and Sijacki[7] concerning existence of gravity-like interactions in infrared sector of QCD, and vice versa.

Author hopes that the results presented in this paper will be starting point of various new approaches to QCD. Here we will list only some themes of the further investigations.

• Rescaling fields Q^{ABCD} and G_{mn} in Eq. (92), one can rewrite this formula as

$$\langle \mathcal{O} \rangle = \mathrm{Re} \int dedQd\Gamma d\Phi d\overline{\Psi} d\Psi \mathcal{O}[\Gamma + i\Phi, \overline{\Psi}, \Psi] \det M \exp\left\{ \frac{i}{\lambda} S_1 - S_2 - S_{\mathrm{mat}} \right\}. \tag{98}$$

So it is naturally to apply the stationary phase method for expansion of $\langle \mathcal{O} \rangle$ in power series with respect to λ

Such expansion in our theory is absolutely unlike standard perturbative ones in quantum field theory because in our theory one must expend integrand near some non-perturbative (most likely) solution of Einstein–Cartan equations (99) that corresponds to some non-trivial vacuum of the theory under consideration. So the expansion of path integral in power series in λ doesn't mean that interaction is supposed to be weak. So, in particular, there are no contradictions between our results and Ne'eman–Sijacky ones concerning the appearance of gravity-like interactions in infrared limit of QCD in which interaction is strong.

The stationary points are determined by equations

$$\delta S_1 = 0. \tag{99}$$

But Eqs. (99) are nothing but Euclidean Einstein ones. What is the meaning of known exact solutions of Einstein equations (such as gravitational instantons, wormholes, etc.) in the context of QCD?

• In particular, what is the meaning of the flat space solution

$$G_{mn} = c^2 g_{mn}, \quad c = \mathrm{const} \tag{100}$$

of Eq. (99)? How to construct the expansion of the integrand in Eq. (98) near such solution? Does the existence of the flat solutions (100) leads to appearance the vacuum condensates of the gluon fields?

• The action (92) depends on contorsion 1-form quadratically without derivatives. So the contorsion can be integrated out. Obviously, this leads to four-fermion interaction terms in the action (as in usual theories of gravitation with torsion). Recently such four-fermion interaction are intensively investigated at effective low energy theory in the spirit of Nambu–Jona-Lasinio model.[33] It would be very interesting to try to investigate such effective theory in framework of our approach.

• The actions S_1, S_2, and S_{mat} in Eq. (92) are polynomial. So it is possible to derive the corresponding Schwinger equations. What are the solutions of these equations in the usual approximations? Do the solutions exist that correspond to non-zero vacuum condensate of the field G_{mn}?

• The action S_1 in Eq. (92) is invariant with respect to the group $\mathrm{Diff}(R^4)$ of the general coordinate transformations. It is easy to derive the corresponding Ward identities. Obviously, that these identities express nothing but the energy—momentum conservation. Nevertheless, it is interesting to investigate consequences of such Ward identities because in proposed variables they have very unusual form and, most likely, can lead to new interesting results.

Now let us discuss the shortcomings of the proposed approach. First, our formulation is

essencially chiral because left and right SU(2) subgroups of the total $SU(2)\times SU(2)\approx O(4)$ invariance group of the action (58) play the different roles in our formalism. In itself, it is not a difficulty, but after imposing of the gauge conditions that entangle space–time and internal degrees of freedom [as the gauge (96)], one obtains the theory that is not manifestly parity invariant. It is not convenient.

This left–right asymmetry in our approach is connected with the structure of the group SU(3). Indeed, there is no faithful embedding of the group O(4) in SU(3). So it is needed more large gauge group to originate left–right symmetric general relativity-like formalism. Thus

- it is interesting to develop general relativity-like formalism for the grand unified theories based on the groups SU(5),SO(10), etc. Except left–right symmetric formulation, one may hope to find natural spontaneous parity breaking mechanism in electroweak sector of the theory in this way.

Further, our theory is essentially Euclidean and it is unclear how to develop the general relativity-like formulation of YM theory in which YM induced metric has Lorentzian signature in presented approach. This shortcoming again is connected with the structure of the gauge group SU(3). Indeed, the gauge group SU(3) is compact, and so it is impossible to embed in SU(3) neither the non-compact group SO(3,1) nor any its subgroup in a covariant way.

The existence of the only Euclidean formulation of the theory, per se, is not a difficulty. But the formulation of the theory in the Minkowski space is more visual. In particular, the absence of such formulation hampers the investigation of the confinement in our approach. Meanwhile, the results of the works[12,19] indicates that, may be, there exists black hole like mechanism of the confinement. But black holes live in the Lorentzian space rather then in the Euclidean one.

- The author hopes to overcome the above mentioned difficulties by using the formalism developed in Ref. 34 where it was shown that SU(N) YM theory is equivalent to certain GL(N,C) gauge theory in the following sense: classes of the gauge equivalent solutions of the initial SU(N) YM theory are in one-to-one correspondence to classes of the gauge equivalent solutions of the above mentioned GL(N,C) gauge theory. In the QCD case $N=3$, and so Lorentz group SL(2,C) can be embedded in the QCD gauge group in such GL(3,C) formalism. So it is possible to develop the Lorentzian analog of the Euclidean general relativity like formulation of QCD given in the presented work.

On the consistent effect histories approach to quantum mechanics

Oliver Rudolph
II. Institut für Theoretische Physik, Universität Hamburg, Luruper Chaussee 149, D-22761 Hamburg, Germany

(Received 28 May 1996; accepted for publication 4 June 1996)

A formulation of the consistent histories approach to quantum mechanics in terms of generalized observables (POV measures) and effect operators is provided. The usual notion of ''history'' is generalized to the notion of ''effect history.'' The space of effect histories carries the structure of a *D*-poset. Recent results of J. D. Maitland Wright imply that every decoherence functional defined for ordinary histories can be uniquely extended to a bi-additive decoherence functional on the space of effect histories. Omnès' logical interpretation is generalized to the present context. The result of this work considerably generalizes and simplifies the earlier formulation of the consistent effect histories approach to quantum mechanics communicated in a previous work of this author. © *1996 American Institute of Physics.* [S0022-2488(96)00211-3]

I. INTRODUCTION

Nonrelativistic quantum mechanics in its standard formulation is not a theory which describes dynamical processes in time, but it is a theory which gives probabilities to various possible events and measurement outcomes at fixed instants of time. The dynamical law of quantum mechanics, the Schrödinger equation, describes the change of the probability amplitude with time. Quantum mechanics in its usual form does not provide us with a dynamical law which describes the time evolution of events. This can be succinctly summarized by saying that quantum mechanics in its usual form does not provide us with a (naive) model of what is ''actually'' going on on a microscopic level in a quantum system. It is often felt that this is a serious drawback of quantum mechanics. Examples for attempts to modify quantum mechanics to a theory providing us with a model for what is ''actually'' happening are hidden variables theories (see, e.g., Refs. 1–3), the dynamical state vector reduction models (see, e.g., Refs. 4–7), or related models (see, e.g., Ref. 8). The consistent histories formulation of quantum mechanics is another attempt to remedy the situation and to incorporate time sequences of events and—as a special case—sequential measurements into quantum mechanics without providing a naive dynamical model for the microscopic world in the above sense and without altering the basic principles and the basic mathematical structure of Hilbert space quantum mechanics.

The consistent histories approach to nonrelativistic quantum mechanics has been inaugurated in a seminal paper by Griffiths[9] and further developed by Griffiths,[10–12] by Omnès,[13–20] by Isham[21] and Isham and Linden[22,23] and by Isham, Linden, and Schreckenberg[24] and applied to quantum cosmology by Gell-Mann and Hartle[25–30] and Hartle.[31,32] Dowker and Kent have carried out a critical reexamination of the consistent histories approach and particularly of Omnès' notion of truth and of the Gell-Mann–Hartle program (see Refs. 33–35). A critical discussion of the consistent histories approach can also be found in Ref. 36. The consistent histories approach asserts that quantum mechanics provides a realistic description of individual quantum mechanical systems, regardless of whether they are open or closed. The possibility of a quantum mechanical description of single closed systems, which neither interact with their environment nor are exposed to measurements, is denied by the conventional Copenhagen-type interpretations of quantum mechanics.

By contrast, in the logical interpretation developed by Omnès, the notion of measurement is

0022-2488/96/37(11)/5368/12/$10.00

not a key concept. Instead one takes the point of view that the aim of an interpretation is generally to provide us with a systematic and unambiguous language specifying the meaning of the objects in the formalism in terms of real physical objects and specifying what can meaningfully be said about the physical systems described by the theory. We will call this attitude the *semantic* approach to interpretation. Clearly the logical interpretation is a realistic interpretation in the sense that it is presupposed that physical systems really exist and have real properties regardless of whether they are measured or not.

A key notion in the formulation of quantum mechanics is the notion of observable. In the spirit of the logical interpretation the term *speakable* would be more appropriate, but we stick to the usual terminology. In usual Hilbert space quantum mechanics the observables are identified with self-adjoint operators on the Hilbert space and propositions about quantum mechanical systems are identified with projection operators on Hilbert space. There is a one-to-one correspondence between self-adjoint operators on Hilbert space and projection valued (PV) measures on the real line $\mathbb{R}$. To every Borel subset $\mathscr{B}$ of $\mathbb{R}$ there corresponds one projection operator representing the proposition that the value of the considered observable is in the set $\mathscr{B}$. More remarks about observables and propositions in ordinary quantum mechanics can be found in Ref. 37.

The question which objects in the formalism have to be identified with observables (or speakables) is clearly a question belonging to the interpretation of quantum mechanics. Reasonableness and mathematical simplicity are the guiding principles to answer this question. The most general notion of observable compatible with the probabilistic structure of quantum mechanics is that of *positive operator valued (POV) measures*, which contains the ordinary observables represented by PV measures on $\mathbb{R}$ as a subclass. Quantum mechanics is totally consistent without POV measures, but POV measures enrich the language of quantum mechanics and enlarge the measurement theoretical possibilities of quantum mechanics.[38,39] On the other hand, the claim that POV measures represent the observables in quantum mechanics is not only consistent with the mathematical structure of Hilbert space quantum mechanics but furthermore is also reasonable. Many examples can be found in the monograph by Busch *et al.*[40]

In this work we take on the view that POV measures are the observables in quantum mechanics and that all POV measures should be treated on the same footing and that all effects should be identified with the general properties (or speakables or beables) of quantum systems. We further consider *every* effect operator as representative of some sort of reality. Some arguments supporting this view can be found in Ref. 37 and references therein. It is perhaps worthwhile to mention a further simple argument which is essentially due to Ludwig.[41] To this end consider a measuring device $\mathscr{M}$ consisting of a detector $\mathscr{D}$ (designed to measure some property E associated with some projection operator) and some scatterer $\mathscr{S}$. An appropriately prepared incident physical system $\mathscr{T}$ (e.g., a particle) is first scattered by $\mathscr{S}$ and then detected by the detector $\mathscr{D}$. To obtain the property F measured by the device $\mathscr{M}$ one has to apply the unitary transformation given by the S-matrix S of $\mathscr{S}$ to the property measured by $\mathscr{D}$. Let $\varrho_{\mathscr{T}}$ denote the initial state of $\mathscr{T}$ and $\varrho_{\mathscr{S}}$ denote the initial state of $\mathscr{S}$. Then the relation between E and F is given by

$$\mathrm{tr}\big(S(\varrho_{\mathscr{T}}\otimes\varrho_{\mathscr{S}})S^{\dagger}(E\otimes 1)\big)=\mathrm{tr}(\varrho_{\mathscr{T}}F),$$

where the trace on the right-hand side is in the Hilbert space $\mathbb{H}_{\mathscr{T}}$ of $\mathscr{T}$ and the trace on the left-hand side is in the tensor product $\mathbb{H}_{\mathscr{T}}\otimes\mathbb{H}_{\mathscr{S}}$ of the Hilbert spaces $\mathbb{H}_{\mathscr{T}}$ of $\mathscr{T}$ and $\mathbb{H}_{\mathscr{S}}$ of $\mathscr{S}$. The operator F is uniquely determined by this equation. However, realistic physical S-matrices S transform projection operators (according to the above equation) in general to effect operators and only the set of effect operators is invariant under this transformations. Therefore whether a measuring device measures an effect or a property associated with some projection operator may depend on an arbitrary cut between the system and the apparatus. This argument can be formalized (see Ref. 42).

In the consistent histories approach it is claimed that all results of measurement theory also *follow* from the consistent histories approach. In the present work we take seriously this claim and

continue our efforts to formulate the consistent histories formalism for general observables represented by POV measures. This program was first formulated and studied in Ref. 37. We will freely use the notation and terminology from Ref. 37 and review only the bare essentials.

This work is organized as follows: In Sec. II we summarize the consistent histories approach to nonrelativistic Hilbert space quantum mechanics and the logical interpretation of quantum mechanics. In Sec. III we recall basic definitions and results from Ref. 37 and we formulate our generalized (effect) history theory and a generalized logical rule of interpretation for effect histories. Our results are based on an important theorem by Wright.[43] This theorem relies heavily on the recent solution of the Mackey–Gleason problem (see Refs. 44 and 45). The results in Sec. III considerably simplify and generalize the results formulated in Ref. 37. In Sec. IV we present our summary.

As in Ref. 37 it must be emphasized that the representation and the interpretation of the consistent histories approach in this work might not be accepted by the authors cited. The present work solely reflects the inclination and the views of this author.

II. CONSISTENT HISTORIES AND THE LOGICAL INTERPRETATION

We consider a quantum mechanical system $\mathscr{S}$ without superselection rules represented by a separable complex Hilbert space $\mathbb{H}$ and a Hamiltonian operator H. Every physical state of the considered system is mathematically represented by a density operator on $\mathbb{H}$, i.e., a linear, positive, trace-class operator on $\mathbb{H}$ with trace 1. The time evolution is governed by the unitary operator $U(t',t)=\exp(-i(t'-t)H/\hbar)$ which maps states at time t into states at time t' and satisfies $U(t'',t')U(t',t)=U(t'',t)$ and $U(t,t)=1$.

In the familiar formulations of quantum mechanics the observables are identified with (and represented by) the self-adjoint operators on $\mathbb{H}$, and according to the spectral theorem observables can be identified with projection operator valued (PV) measures on the real line; that is, there is a one-to-one correspondence between self-adjoint operators on $\mathbb{H}$ and maps $\mathscr{O}$: $\mathscr{B}(\mathbb{R})\to\mathscr{P}(\mathbb{H})$, such that $\mathscr{O}(\mathbb{R})=1$ and $\mathscr{O}(\cup_i K_i)=\Sigma_i\mathscr{O}(K_i)$ for every pairwise disjoint sequence $\{K_i\}_i$ in $\mathscr{B}(\mathbb{R})$ (the series converging in the ultraweak topology). Here $\mathscr{B}(\mathbb{R})$ denotes the Borel σ-algebra of $\mathbb{R}$ and $\mathscr{P}(\mathbb{H})$ denotes the set of projection operators on $\mathbb{H}$, i.e., self-adjoint operators P satisfying $P=PP$.

A meaningful proposition about the system (also called *physical quality*) is a proposition specifying that the value of some observable $\mathscr{O}$ lies in some set $B\in\mathscr{B}(\mathbb{R})$. This means that to every meaningful proposition about the system under consideration there corresponds one projection operator on $\mathbb{H}$.

In the state represented by the density operator ϱ the probability of a proposition represented by the projection operator P is given by $\mathrm{tr}(\varrho P)$, where tr denotes the trace in $\mathbb{H}$.

Positive and bounded operators F on $\mathbb{H}$, satisfying $0\leqslant F\leqslant 1$, are commonly called *effects* and the set of all effects on the Hilbert space $\mathbb{H}$ will be denoted by $\mathfrak{E}(\mathbb{H})$. We further denote the set of all bounded, linear operators on $\mathbb{H}$ by $\mathscr{B}(\mathbb{H})$.

If $\mathbb{H}$ is an infinite-dimensional Hilbert space, then the set of all projection operators $\mathscr{P}(\mathbb{H})$ on $\mathbb{H}$ is weakly dense in $\mathfrak{E}(\mathbb{H})$.[46]

Generalized observables are now identified with positive operator valued (POV) measures on some measurable space $(\Omega,\mathscr{F})$, i.e., maps $O:\mathscr{F}\to\mathfrak{E}(\mathbb{H})$ with the following properties.

(i) $O(A)\geqslant O(\varnothing)$, for all $A\in\mathscr{F}$.
(ii) Let $\{A_i\}$ be a countable set of disjoint sets in $\mathscr{F}$, then $O(\cup_i A_i)=\Sigma_i O(A_i)$, the series converging ultraweakly.
(iii) $O(\Omega)=1$.

Generalized observables are also called *effect valued measures*. Ordinary observables (associated with self-adjoint operators on $\mathbb{H}$) are then identified with the projection valued measures on the real line $\mathbb{R}$. Generalizing our above terminology, we regard all propositions specifying the value of

some generalized observable as generalized physical qualities. In order to discriminate physical qualities corresponding to ordinary observables from physical qualities corresponding to generalized observables, we will call the former ''ordinary physical qualities'' and the latter ''generalized physical qualities.'' In the generalized approach to every physical quality there corresponds one effect operator.

A *homogeneous history* is a map $h:\mathbb{R}\to\mathscr{P}(\mathbb{H})$, $t\mapsto h_t$. We call $t_i(h):=\min(t\in\mathbb{R}|h_t\neq 1)$ the *initial* and $t_f(h):=\max(t\in\mathbb{R}|h_t\neq 1)$ the *final time* of h, respectively. Furthermore, the *support of h* is given by $\mathfrak{s}(h):=\{t\in\mathbb{R}|h_t\neq 1\}$. If $\mathfrak{s}(h)$ is finite, countable, or uncountable, then we say that h is a *finite, countable*, or *uncountable history*, respectively. The space of all homogeneous histories will be denoted by $\mathscr{H}(\mathbb{H})$, the space of all finite homogeneous histories by $\mathscr{H}_{\text{fin}}(\mathbb{H})$, and the space of all finite homogeneous histories with support S by $\mathscr{H}_S(\mathbb{H})$.

By a *history proposition* we mean a proposition about the system specifying which history will be realized. We use the terms history and history proposition synonymously in this work.

In this work we focus attention on finite histories. If a homogeneous history vanishes for some $t_0\in\mathbb{R}$, i.e., $h_{t_0}=0$, then we say that h is a *zero history*. All zero histories are collectively denoted by 0, slightly abusing the notation.

For every finite subset S of $\mathbb{R}$ we can consider the Hilbert tensor product $\otimes_{t\in S}\mathbb{H}$ and the algebra $\mathscr{B}^{\otimes}_S(\mathbb{H}):=\mathscr{B}(\otimes_{t\in S}\mathbb{H})$ of bounded linear operators on $\otimes_{t\in S}\mathbb{H}$. It has been pointed out by Isham[21] that for any fixed S there is an injective (but not surjective) correspondence σ_S between finite histories with support S and elements of $\mathscr{B}^{\otimes}_S(\mathbb{H})$ given by

$$\sigma_S:\mathscr{H}_S(\mathbb{H})\to\mathscr{B}^{\otimes}_S(\mathbb{H}),\quad h\simeq\{h_{t_k}\}_{t_k\in S}\mapsto\otimes_{t_k\in S}h_{t_k}. \tag{1}$$

The finite homogeneous histories with support S can therefore be identified with projection operators on $\otimes_{t\in S}\mathbb{H}$. The set of all projection operators on $\otimes_{t\in S}\mathbb{H}$ will in the sequel be denoted by $\mathscr{P}^{\otimes}_S(\mathbb{H})$. However, not all projection operators in $\mathscr{P}^{\otimes}_S(\mathbb{H})$ have the form $\sigma_S(h)$ with $h\in\mathscr{H}_S(\mathbb{H})$.

The projection operators in $\mathscr{P}^{\otimes}_S(\mathbb{H})$ are called *finite inhomogeneous histories with support S* and the space $\mathscr{K}_S(\mathbb{H}):=\mathscr{P}^{\otimes}_S(\mathbb{H})$ of projection operators on $\otimes_{t\in S}\mathbb{H}$ is called the *space of finite inhomogeneous histories with support S*. The space of all finite inhomogeneous histories with arbitrary support will be denoted by $\mathscr{K}_{\text{fin}}(\mathbb{H})$ or by $\mathscr{P}^{\otimes}{}_{\text{fin}}(\mathbb{H})$. Furthermore, to every finite homogeneous history $h\in\mathscr{H}_{\text{fin}}(\mathbb{H})$ we associate its *class operator with respect to the fiducial time* t_0 by $C_{t_0}(h):=U(t_0,t_n)h_{t_n}U(t_n,t_{n-1})h_{t_{n-1}}\cdots U(t_2,t_1)h_{t_1}U(t_1,t_0)$. The class operators can be unambiguously extended to finite inhomogeneous histories such that C_{t_0} is additive for orthogonal projectors, i.e., $C_{t_0}(h\vee k):=C_{t_0}(h)+C_{t_0}(k)$ for $h\perp k$. The functional $d_\varrho:\mathscr{K}_{\text{fin}}(\mathbb{H})\times\mathscr{K}_{\text{fin}}(\mathbb{H})\to\mathbb{C}$, $(h,k)\mapsto d_\varrho(h,k):=\text{tr}(C_{t_0}(h)\varrho(t_0)C_{t_0}(k)^\dagger)$ will be called the *consistency functional associated with the state* ϱ. The consistency functional d_ϱ satisfies for all $h,h',k\in\mathscr{K}_{\text{fin}}(\mathbb{H})$

(i) $d_\varrho(h,h)\in\mathbb{R}$ and $d_\varrho(h,h)\geqslant 0$;
(ii) $d_\varrho(h,k)=d_\varrho(k,h)^*$;
(iii) $d_\varrho(1,1)=1$;
(iv) $d_\varrho(h\vee h',k)=d_\varrho(h,k)+d_\varrho(h',k)$, whenever $h\perp h'$;
(v) $d_\varrho(0,h)=0$, for all h.

In Ref. 37 we have used a slightly different terminology: the above consistency functional d_ϱ has been called there ''decoherence functional.'' In this work we want to carefully distinguish biadditive functionals on a Boolean lattice from biadditive functionals defined on a D-poset. Thus, the former are called consistency functionals, whereas we reserve the term ''decoherence functional'' for a biadditive functional defined on a D-poset (see below).

Any collection $\mathscr{C}'$ of histories in $\mathscr{P}^{\otimes}_{\text{fin}}(\mathbb{H})$ is said to be *consistent with respect to the state* ϱ if $\mathscr{C}'$ is a Boolean algebra [with respect to the meet, join, and orthocomplementation in $\mathscr{P}^{\otimes}_{\text{fin}}(\mathbb{H})$ and

with unit $1_{\mathscr{C}'}$] and if $\mathrm{Re}\, d_\varrho(h,k)=0$ for every two disjoint histories $h,k\in\mathscr{C}'$. Here two (possibly inhomogeneous) finite histories h and k are said to be *disjoint* if $h\leqslant\neg k$, where $\leqslant$ is the partial order on $\mathscr{K}_{\mathfrak{s}(h)\cup\mathfrak{s}(k)}(\mathbb{H})$.

It is now easy to see that the consistency functional d_ϱ induces an additive probability measure p_ϱ on every consistent Boolean sublattice $\mathscr{C}\subset\mathscr{P}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. The probability measure p_ϱ is defined by

$$p_\varrho:\mathscr{C}\to\mathbb{R}^+,\quad p_\varrho(h):=\frac{d_\varrho(h,h)}{d_\varrho(1_{\mathscr{C}},1_{\mathscr{C}})}. \tag{2}$$

The probability measure p_ϱ on a consistent Boolean algebra $\mathscr{C}$ of history propositions induced by the consistency functional d_ϱ according to Eq. (2) defines two logical relations in $\mathscr{C}$, namely an implication and an equivalence relation between histories. A history proposition h is said to *imply* a history proposition k if the conditional probability $p_\varrho(k|h)\equiv[p_\varrho(h\wedge_{\mathscr{C}}k)]/p_\varrho(h)$ is well defined and equal to one. Two history propositions h and k are said to be *equivalent* if h implies k and vice versa.

The universal rule of interpretation of quantum mechanics can now be formulated as follows.

Rule 1 (Omnès): Propositions about quantum mechanical systems should solely be expressed in terms of history propositions. Every description of an isolated quantum mechanical system should be expressed in terms of finite history propositions belonging to a common consistent Boolean algebra of histories. Every reasoning relating several propositions should be expressed in terms of the logical relations induced by the probability measure from Eq. (2) in that Boolean algebra.

III. CONSISTENT EFFECT HISTORIES

In Ref. 37 we have motivated and introduced the following notion of homogeneous effect history

Definition 1: A **homogeneous effect history (of the first kind)** *is a map* $u:\mathbb{R}\to\mathfrak{E}(\mathbb{H})$, $t\mapsto u_t$. *The* **support of** u *is given by* $\mathfrak{s}(u):=\{t\in\mathbb{R}|u_t\neq 1\}$. *If* $\mathfrak{s}(u)$ *is finite, countable, or uncountable, then we say that* u *is a* **finite, countable**, or **uncountable effect history**, *respectively. The space of all homogeneous effect histories (of the first kind) will be denoted by* $\mathbb{E}(\mathbb{H})$, *the space of all finite homogeneous effect histories (of the first kind) by* $\mathbb{E}_{\mathrm{fin}}(\mathbb{H})$, *and the space of all finite homogeneous effect histories (of the first kind) with support* S *by* $\mathbb{E}_S(\mathbb{H})$. *All homogeneous effect histories for which there exists at least one* $t\in\mathbb{R}$ *such that* $u_t=0$ *are collectively denoted by* 0, *slightly abusing the notation.*

The class operator C_{t_0} defined above for finite ordinary homogeneous histories can be defined for homogeneous finite effect histories $u\in\mathbb{E}_{\mathrm{fin}}(\mathbb{H})$:

$$C_{t_0}(u):=U(t_0,t_n)\sqrt{u_{t_n}}U(t_n,t_{n-1})\sqrt{u_{t_{n-1}}}\cdots U(t_2,t_1)\sqrt{u_{t_1}}U(t_1,t_0).$$

For every pair u and v of finite homogeneous effect histories (of the first kind) we define the *decoherence weight* of u and v by

$$d_\varrho(u,v):=\mathrm{tr}(C_{t_0}(u)\varrho(t_0)C_{t_0}(v)^\dagger).$$

The functional $d_\varrho:\mathbb{E}_{\mathrm{fin}}(\mathbb{H})\times\mathbb{E}_{\mathrm{fin}}(\mathbb{H})\to\mathbb{C}$, $(u,v)\mapsto d_\varrho(u,v)$, will be called the *decoherence functional associated with the state* ϱ.

The map σ_S given by Eq. (1) can be extended to a map

$$\sigma_{\mathrm{fin}}:\mathbb{E}_{\mathrm{fin}}(\mathbb{H})\to\mathscr{P}^{\otimes}_{\mathrm{fin}}(\mathbb{H}),\quad u\simeq\{u_{t_k}\}_{t_k\in\mathfrak{s}(u)}\mapsto\otimes_{t_k\in\mathfrak{s}(u)}u_{t_k}, \tag{3}$$

where $\mathscr{B}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ denotes the disjoint union of all $\mathscr{B}^{\otimes}_{S}(\mathbb{H})$, $S\subset\mathbb{R}$ finite. The map σ_{fin} is neither injective nor surjective. However, $d_{\varrho}(u,v)$ depends on u and v only through $\sigma_{\mathrm{fin}}(u)$ and $\sigma_{\mathrm{fin}}(v)$. From a mathematical point of view it thus seems to be natural to define the notion of *inhomogeneous* effect history as follows:

Definition 2: Let S be a finite subset of $\mathbb{R}$. *Then we call the space* $\mathfrak{E}^{\otimes}_{S}(\mathbb{H}):=\mathfrak{E}(\otimes_{t\in S}\mathbb{H})$ *of effect operators on* $\otimes_{t\in S}\mathbb{H}$ *the* **space of finite inhomogeneous effect histories with support** S. *The space of all finite inhomogeneous effect histories with arbitrary support will be denoted by* $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. *The elements in* $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ *will also be called* **effect history propositions**.

The homogeneous elements in $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ represent equivalence classes of homogeneous effect histories. In this work we will carefully distinguish between homogeneous effect histories as defined in Definition 1 and homogeneous elements in $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. For clarity of exposition we will call the former *homogeneous effect histories of the first kind* or (where no confusion can arise) simply homogeneous effect histories, whereas the latter will be called *homogeneous effect histories of the second kind*.

In technical terms $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ is the direct limit of the directed system $\{\mathfrak{E}^{\otimes}_{S}(\mathbb{H})|S\subset\mathbb{R}\text{ finite}\}$. All the $\mathfrak{E}^{\otimes}_{S}(\mathbb{H})$, $S\subset\mathbb{R}$, and $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ carry several distinct D-poset structures, as discussed in Ref. 37. For further literature on D-posets and effect algebras, see Refs. 47–54. As in Ref. 37 we use the terms *D-poset* and *effect algebra* synonymously. We refer to the D-poset structure on $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ given by the partial addition $\oplus$, where $E_1\oplus E_2$ is defined if $E_1+E_2\leqslant 1$ by $E_1\oplus E_2:=E_1+E_2$, as the *canonical D-poset structure*. We will denote the canonical partial addition on $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ by $\oplus$ and the canonical partial substraction on $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$ by $\ominus$.

In Ref. 37 we have used a different notion of inhomogeneous effect history, because it was not clear whether the decoherence functional d_{ϱ} defined above on the space of homogeneous effect histories (of the first kind) can be (uniquely) extended to in some appropriate sense a biadditive functional on the space of inhomogeneous effect histories as defined in Definition 2. In Ref. 37 we gave a rather technical definition of the notion of inhomogeneous effect history. Essentially we defined an inhomogeneous effect history to be a member of the free lattice generated by the homogeneous effect histories (of the first kind) by at most finitely many applications of the grammatical connectives ''and'' and ''or,'' to wit, we have viewed inhomogeneous effect histories to be—in essence—propositions in the language of quantum mechanics involving several (but at most finitely many) homogeneous effect histories. In turn only the latter were viewed as the basic *physical* entities in the formalism. We have shown in Ref. 37 that with this definition it is possible to consistently extend the consistent histories formulation of quantum mechanics and to incorporate effect histories. However, this approach involves a rather technical and mathematically by no means canonical definition of the notion of inhomogeneous history. Inhomogeneous effect histories in the sense of Ref. 37 represent only semantical entities without an obvious physical interpretation. In this work the term inhomogeneous effect history is always meant in the sense of Definition 2 unless explicitly otherwise stated.

In this work we use a recent result of J. D. Maitland Wright[43] which implies that the decoherence functional d_{ϱ} as defined above on the space of homogeneous effect histories (of the second kind) can indeed be extended to a functional on the space of inhomogeneous effect histories with the desired properties. We first recall the central result from Ref. 43.

Theorem 1: *Let A be a von Neumann algebra with no type* I_2 *direct summand. Let* $d:\mathscr{P}(A)\times\mathscr{P}(A)\to\mathbb{C}$ *be a decoherence functional. If d is bounded, then d extends to a unique bounded bilinear functional* $\tilde{d}$ *on* $A\times A$. *Furthermore, d is continuous when* $\mathscr{P}(A)$ *is equipped with the topology induced by the norm of A. Also,* $d(u,v)^*=d(v^*,u^*)$.

If A is a von Neumann algebra, let $\mathscr{P}(A)$ denote the set of projectors in A. A function $d:\mathscr{P}(A)\times\mathscr{P}(A)\to\mathbb{C}$ is called a *decoherence functional*, if (i) $d(p_1\oplus p_2,q)=d(p_1,q)+d(p_2,q)$, whenever p_1 and p_2 are mutually orthogonal; (ii) $d(p,q)^*=d(q,p)$; (iii) $d(p,p)\geqslant 0$; and (iv) $d(1,1)=1$.

Since the set $\mathscr{B}(\mathbb{H})$ of bounded operators on a Hilbert space $\mathbb{H}$ with dimension greater than 2

is a von Neumann algebra (of type I), Theorem 1 can be applied to the decoherence functional $d_\varrho : \mathscr{K}_{\text{fin}}(\mathbb{H}) \times \mathscr{K}_{\text{fin}}(\mathbb{H}) \to \mathbb{C}, (h,k) \mapsto d_\varrho(h,k) := \text{tr}(C_{t_0}(h)\varrho(t_0)C_{t_0}(k)^\dagger)$ defined in Sec. II above. Thus for every finite subset $S \subset \mathbb{R}$ there is a unique bounded bilinear functional $\widetilde{d}_{\varrho,S}$ on $\mathscr{B}_S^\otimes(\mathbb{H}) \times \mathscr{B}_S^\otimes(\mathbb{H})$ extending the decoherence functional d_ϱ restricted to $\mathscr{P}_S^\otimes(\mathbb{H}) \times \mathscr{P}_S^\otimes(\mathbb{H})$.

The restriction $\hat{d}_{\varrho,S}$ of $\widetilde{d}_{\varrho,S}$ to $\mathfrak{E}_S^\otimes(\mathbb{H}) \times \mathfrak{E}_S^\otimes(\mathbb{H})$ is a bounded functional which is additive in both arguments with respect to the canonical D-poset structure on $\mathfrak{E}_S^\otimes(\mathbb{H})$. The collection of all such functionals $\hat{d}_{\varrho,S}$ for any finite $S \subset \mathbb{R}$ induces a bounded functional $\hat{d}_\varrho$ on $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H}) \times \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ which is additive in both arguments with respect to the canonical D-poset structure on $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$. The functional $\hat{d}_\varrho$ will be called the *decoherence functional with respect to the state* ϱ *on* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$.

Since $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ is a D-poset, $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ is in particular a partially ordered set. However, for two elements $e_1, e_2 \in \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ the supremum $e_1 \vee e_2$ and the infimum $e_1 \wedge e_2$ not necessarily exist, that is, $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ is not a lattice. But there exists a partially defined join operation denoted by $\vee$ and a partially defined meet operation denoted by $\wedge$. To every element $e \in \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ there exists one unique element $e' \in \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ such that $e \oplus e'$ is well defined and $e \oplus e' = 1$. We refer to $e' = 1 \ominus e$ as to the *complement* of e.

Definition 3: A subset $\mathscr{B} \subset \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *is said to be an* **admissible Boolean lattice of (inhomogeneous) effect histories** *if the following conditions are satisfied.*

(i) *There exist two binary operations on* $\mathscr{B}$*, denoted by* $\vee_{\mathscr{B}}$ *and* $\wedge_{\mathscr{B}}$*, respectively, and one unary operation on* $\mathscr{B}$*, denoted by* $\neg_{\mathscr{B}}$*, such that the operations* $\vee_{\mathscr{B}}$*,* $\wedge_{\mathscr{B}}$*, and* $\neg_{\mathscr{B}}$ *are compatible with the partial order on* $\mathscr{B}$ *induced by the partial order on* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *and such that* $(\mathscr{B}, \vee_{\mathscr{B}}, \wedge_{\mathscr{B}}, \neg_{\mathscr{B}})$ *is a Boolean lattice,* i.e., $\vee_{\mathscr{B}}$ *is the join operation,* $\wedge_{\mathscr{B}}$ *is the meet operation, and* $\neg_{\mathscr{B}}$ *is the complementation operation on* $\mathscr{B}$*. The lattice-operations* $\vee_{\mathscr{B}}$ *and* $\wedge_{\mathscr{B}}$ *coincide with the partially defined meet operation* $\vee$ *and join operation* $\wedge$ *on* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *whenever the latter are well defined, to wit,* $e_1 \wedge_{\mathscr{B}} e_2 = e_1 \wedge e_2$ *and* $e_3 \vee_{\mathscr{B}} e_4 = e_3 \vee e_4$ *for all* $e_1, e_2, e_3, e_4 \in \mathscr{B}$*, whenever the right-hand sides are well defined in* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$*. The lattice operations* $\vee_{\mathscr{B}}$ *and* $\wedge_{\mathscr{B}}$ *are such that a complementation* $\neg_{\mathscr{B}}$ *can be unambiguously defined on* $\mathscr{B}$*.*

(ii) *There exists an injective map* $\mathfrak{M} : \mathscr{B} \to \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$*, which satisfies the following conditions*:

(a) $\mathfrak{M}$ *is a* **positive valuation** *on* $\mathscr{B}$ *with values in* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$*, to wit, a map satisfying the valuation condition* $\mathfrak{M}(b_1 \vee_{\mathscr{B}} b_2) \ominus \mathfrak{M}(b_1) = \mathfrak{M}(b_2) \ominus \mathfrak{M}(b_1 \wedge_{\mathscr{B}} b_2)$*, for all* $b_1, b_2 \in \mathscr{B}$*. This condition means in particular that the left-hand side and the right-hand side are well defined for all* $b_1, b_2 \in \mathscr{B}$;

(b) $\mathfrak{M}$ *preserves decoherence weights, i.e.,* $\hat{d}_\varrho(e_1, e_2) = \hat{d}_\varrho(\mathfrak{M}(e_1), \mathfrak{M}(e_2))$*, for all* $e_1, e_2 \in \mathscr{B}$*.*

An admissible Boolean sublattice of $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *will be briefly denoted by* $(\mathscr{B}, \mathfrak{M})$.

Remark 1: Strictly speaking a **sublattice** $\mathscr{L}$ *of* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *is a subset* $\mathscr{L} \subset \mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *such that* $\mathscr{L}$ *endowed with the restrictions of* $\vee$ *and* $\wedge$ *to* $\mathscr{L}$ *is a lattice. It makes thus sense to speak of sublattices of* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$*. However, it is important to notice that an admissible Boolean sublattice of* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *is not necessarily a sublattice of* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *in this sense.*

Remark 2: Let $\mathscr{L}_1, \mathscr{L}_2$ *be lattices. A map* $\nu : \mathscr{L}_1 \to \mathscr{L}_2$ *is called* **positive** *if* $\nu(p) < \nu(q)$*, whenever* $p < q$*. Since any Boolean lattice is relatively complemented, the condition that the map* $\mathfrak{M}$ *in Definition 3 is positive is actually redundant and follows already from the definition of D-posets and from the valuation condition. In particular* $\mathfrak{M}$ *is order preserving.*

Remark 3: The complement $e' = 1 - e$ *in* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ *of some element* $e \in \mathscr{B}$ *does in general not coincide with the complement* $\neg_{\mathscr{B}} e$ *in* $\mathscr{B}$*. The greatest element* $1_{\mathscr{B}}$ *and the least element* $0_{\mathscr{B}}$ *in* $\mathscr{B}$ *do not necessarily coincide with the greatest element* 1 *and the least element* 0 *in* $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$*, respectively.*

Our target is to generalize Omnès' logical rule and thus to single out the appropriate subsets of $\mathfrak{E}_{\text{fin}}^\otimes(\mathbb{H})$ on which a reasoning involving (inhomogeneous) effect histories compatible with ''common sense'' can be defined. The conditions in Definition 3 are clearly the minimal structure

required. Usually ''common sense'' (compare Ref. 19) is tacitly associated with Boolean lattices. Thus the first condition in Definition 3 that $\mathscr{B}$ is a Boolean lattice is indispensable. We have already mentioned above that the set $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ carries (among others) a canonical D-poset structure, but no lattice structure, and that the decoherence functional $\hat{d}_{\varrho}$ is additive with respect to the D-poset structure on $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$. In the consistent histories approach, however, reasoning is defined on Boolean lattices $\mathscr{B}$ with the help of consistency functionals which are additive with respect to the lattice structure of $\mathscr{B}$. Thus one has to restrict oneself to Boolean lattices $\mathscr{B}\subset\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ such that the lattice structure of $\mathscr{B}$ is exactly mirrored in the D-poset structure of $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ (by the map $\mathfrak{M}$). This leads to the condition that there exists a positive valuation $\mathfrak{M}$ as required in the second condition of Definition 3. The reasoning to be defined should be independent of the map $\mathfrak{M}$ chosen. Thus it is necessary to require that $\mathfrak{M}$ preserves decoherence weights.

Remark 4: The decoherence functional $\hat{d}_{\varrho}$ induces a consistency functional $d_{\varrho,\mathscr{B}}$ on $\mathscr{B}\times\mathscr{B}$ by $d_{\varrho,\mathscr{B}}:\mathscr{B}\times\mathscr{B}\to\mathbb{C}, d_{\varrho,\mathscr{B}}(p_1,p_2):=\hat{d}_{\varrho}(\mathfrak{M}(p_1),\mathfrak{M}(p_2))$, which is additive in both arguments with respect to the Boolean lattice structure on $\mathscr{B}$.

Definition 4: An admissible Boolean lattice $(\mathscr{B},\mathfrak{M})$ is called **consistent wrt** *ϱ if for every pair of disjoint elements $b_1,b_2\in\mathscr{B}$ (i.e., elements satisfying $b_1\wedge_{\mathscr{B}} b_2=0$) the* **consistency condition** $\mathrm{Re}\, d_{\varrho,\mathscr{B}}(b_1,b_2)=0$ *is satisfied.*

Theorem 2: *Let $(\mathscr{B},\mathfrak{M})$ be a consistent admissible Boolean lattice of effect histories. Then the consistency functional $d_{\varrho,\mathscr{B}}$ induces a probability functional $p_{\varrho,\mathscr{B}}$ on $\mathscr{B}$ by $b\mapsto p_{\varrho,\mathscr{B}}(b)\equiv[d_{\varrho,\mathscr{B}}(\mathfrak{M}(b),\mathfrak{M}(b))]/d_{\varrho,\mathscr{B}}(\mathfrak{M}(1_{\mathscr{B}}),\mathfrak{M}(1_{\mathscr{B}}))$.*

Definition 5: An effect history proposition $e_1\in\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ is said to **imply** *an effect history proposition $e_2\in\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ in the state ϱ if there exists a consistent admissible Boolean sublattice $\mathscr{B}$ of $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ containing e_1 and e_2 and if the conditional probability $p_{\varrho,\mathscr{B}}(e_2|e_1)\equiv[p_{\varrho,\mathscr{B}}(e_1\wedge_{\mathscr{B}}e_2)]/p_{\varrho,\mathscr{B}}(e_1)$ is well defined and equal to one. We write $e_{1\Rightarrow\varrho}\,e_2$. Two history propositions e_1 and e_2 are said to be* **equivalent** *if e_1 implies e_2* and *vice versa. We write $e_1\Leftrightarrow_{\varrho}e_2$.*

Remark 5: If $e_1\wedge e_2$ exists in $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$, then it is easy to verify that if $p_{\varrho,\mathscr{B}_0}(e_2|e_1)$ is well defined and equal to one in some consistent admissible Boolean lattice $\mathscr{B}_0$ containing e_1 and e_2, then $p_{\varrho,\mathscr{B}}(e_2|e_1)$ is well defined and equal to one in every consistent admissible Boolean lattice $\mathscr{B}$ containing e_1 and e_2. If $e_1\wedge e_2$ does not exist in $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$, then there may be consistent Boolean lattices $\mathscr{B}_1$ containing e_1 and e_2 such that $p_{\varrho,\mathscr{B}_1}(e_2|e_1)$ is not one or is not well defined. If $e_1\wedge e_2$ does not exist in $\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$, then it seems reasonable to define $e_1\Rightarrow_{\varrho}e_2$ if there exists an admissible Boolean lattice $\mathscr{B}$ containing e_1, e_2 and some further element $e_3\in\mathfrak{E}_{\mathrm{fin}}^{\otimes}(\mathbb{H})$ satisfying $e_1\geqslant e_3$ and $e_2\geqslant e_3$ such that $[p_{\varrho,\mathscr{B}}(e_3,e_3)]/p_{\varrho,\mathscr{B}}(e_1,e_1)$ is well defined in $\mathscr{B}$ and equal to one.

The generalized universal rule of interpretation of quantum mechanics can now simply be formulated as follows.

Rule 3: Propositions about quantum mechanical systems should solely be expressed in terms of effect history propositions. Every description of an isolated quantum mechanical system should be expressed in terms of finite effect history propositions belonging to a common consistent admissible Boolean algebra of effect histories. Every reasoning relating several propositions should be expressed in terms of the logical relations induced by the probability measure from Theorem 2 in that Boolean algebra.

(This rule is numbered ''Rule 3'' in order to distinguish it from Rule 2 stated in Ref. 37.) It is instructive to compare Rule 3 with Rule 2 stated in Ref. 37. It is obvious that Rule 1 is contained in Rule 3 as a special case. A more extensive discussion of the motivation and the philosophy underlying the logical interpretation of quantum mechanics can be found in Refs. 17–19 and 37 and will not be repeated here.

Compared with the treatment in Ref. 37 we have achieved a considerable simplification of the logical interpretation in terms of generalized observables and of the formalism of the consistent effect histories approach to generalized quantum mechanics. From a mathematical point of view, the extension of the ordinary consistent histories approach given in this article is a natural one.

Rule 3 asserts that to every meaningful proposition about a quantum mechanical system there

is an inhomogeneous effect history $e \in \mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. However, homogeneous effect histories of the first kind, which have a direct physical interpretation, are not contained in $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. According to Rule 3, homogeneous effect histories of the first kind can only indirectly be included into a description of a quantum mechanical system by representing every homogeneous effect history of the first kind e by its corresponding homogeneous effect history of the second kind $\sigma_{\mathrm{fin}}(e)$.

It remains to determine the connection of Rule 3 stated above and the generalized logical rule (Rule 2) formulated in Ref. 37. In contrast to Rule 3 above, the propositions about a quantum mechanical system permitted by Rule 2 stated in Ref. 37 contain the homogeneous effect histories of the first kind as a subclass and accordingly a description of a quantum mechanical system and reasoning can be done directly in terms of homogeneous effect histories of the first kind. In the next subsection we will see, however, that in an appropriate sense Rule 3 is a generalization of Rule 2 stated in Ref. 37 and that a description and reasoning (permitted by Rule 2) directly in terms of homogeneous effect histories of the first kind can always be lifted to a description and reasoning (permitted by Rule 3) in terms of the corresponding homogeneous effect histories of the second kind.

A. The connection between admissible and allowed Boolean lattices

In this subsection we will show that Rule 3 formulated above is indeed a generalization of the generalized logical rule as formulated in Ref. 37. In this subsection we will use the notation and terminology introduced in Ref. 37 without further notice. In this subsection the term *homogeneous effect history* is always meant to denote homogeneous effect histories of the first kind.

Consider some homogeneous effect history of order $k>0$ denoted by $w^k_{E_1,\ldots,E_m}$, where $E_1,\ldots,E_m \in \mathfrak{E}(\mathbb{H})$. The corresponding history proposition states that first at k successive times $t_{1,1},\ldots,t_{1,k}$ the appropriately time translated effect $E_1(t_{1,j})=U(t_{1,j},t_{1,1})E_1U(t_{1,j},t_{1,1})^{\dagger}$ $(1\leqslant j\leqslant k)$ is realized and then at k successive times $t_{2,1},\ldots,t_{2,k}$ the effect $E_2(t_{2,j})=U(t_{2,j},t_{1,1})E_2U(t_{2,j},t_{1,1})^{\dagger}$ $(1\leqslant j\leqslant k)$ and so on. [We refer the reader to the discussion following Theorem 4 in Ref. 37; for simplicity we assume that the history w_0 appearing there is the unit history, i.e., $(w_0)_t=1$ for all t.]

Now we first observe that the exact times associated with the effects in some homogeneous effect history are inessential. The only thing that physically matters is the order and sequence of the effects in the homogeneous history. The time points associated with the effect operators in some homogeneous effect history can be changed provided the order remains fixed and provided the effect operators associated with the shifted times are appropriately time translated with the unitary evolution operator U. We say that two homogeneous effect histories related in this way to each other are *shift equivalent*.

If we define $F_j := E_j^{k/2}$, for all $1\leqslant j\leqslant k$, then we see that every homogeneous effect history $w^k_{E_1,\ldots,E_m}$ of order k can be mapped to a homogeneous effect history $w^2_{F_1,\ldots,F_m}$ of order 2. This map preserves decoherence weights. The history $w^2_{F_1,\ldots,F_m}$ is unique up to shift equivalence. That the F_j are effect operators follows from Proposition 2 in Ref. 55. We further recall that $F\oplus_1 F'=F\oplus F'=(E\oplus_{2/k}E')^{k/2}$, where $F=E^{k/2}$ and $F'=(E')^{k/2}$ whenever the expressions are well defined. Now it is easy to see that for every allowed Boolean algebra $(\mathscr{B},\mathrm{B})$ of order k (as defined in Ref. 37) there exists an allowed Boolean algebra $(\mathscr{B}',\mathrm{B}')$ of order 2 and a lattice isomorphism $\varphi:\mathscr{B}\to\mathscr{B}'$ such that $\mathrm{B}=\mathrm{B}'\circ\varphi$. Thus, it suffices to consider allowed Boolean algebras of order 2 in the sequel. In Theorem 3 below $\mathfrak{N}$ denotes the canonical map defined in Remark 15 in Ref. 37.

Theorem 3: *Let $(\mathscr{B},\mathfrak{M})$ be an admissible Boolean lattice in the sense of Definition 3 above and let $(\mathscr{A},\mathfrak{J})$ be an allowed Boolean lattice of effect histories of order k as defined in Ref. 37. Let $\mathscr{A}_0$ denote the set of atoms of $\mathscr{A}$. Then there exists a lattice isomorphism $\psi:\mathscr{A}\to\mathscr{B}$ preserving decoherence weights and satisfying $\mathfrak{J}=\mathfrak{M}\circ\psi$ if an only if $\mathscr{B}$ is atomic, $\mathfrak{M}$ maps the set $\mathscr{B}_0$ of atoms of $\mathscr{B}$ bijectively to $\mathfrak{J}(\mathscr{A}_0)$, and $\mathfrak{M}(0_{\mathscr{B}})=\mathfrak{J}(0_{\mathscr{A}})$.*

Proof: ''⇒:'' trivial. ''⇐:'' $\mathfrak{M}^{-1}\circ\mathfrak{J}$ restricted to $\tilde{\mathscr{A}}:=\mathscr{A}_0\cup\{0_{\mathscr{A}}\}$ can in an obvious way be extended to a lattice isomorphism $\psi:\mathscr{A}\to\mathscr{B}$ by requiring $\psi(\bigvee_{\mathscr{A},i\in I}a_i)=\bigvee_{\mathscr{B},i\in I}\psi(a_i)$ for any $\{a_i\}_{i\in I}\subset\mathscr{A}_0$. Then $\tilde{\mathfrak{J}}:=\mathfrak{M}\circ\psi$ is a positive valuation satisfying the valuation condition and extending the map $\mathfrak{N}_{|\tilde{A}}$ as required in the Definition of the allowed Boolean lattice. Since $(\mathscr{A},\tilde{\mathfrak{J}})$ is an allowed Boolean lattice, $\mathfrak{J}$ is the unique positive valuation with this property and thus $\mathfrak{J}=\tilde{\mathfrak{J}}$. That ψ preserves decoherence weights follows immediately: $d_{\varrho,\mathscr{L}}(a_1,a_2):=d_{\varrho,\mathfrak{E},k}(\mathfrak{J}(a_1),\mathfrak{J}(a_2))=\hat{d}_{\varrho}(\mathfrak{M}\circ\psi(a_1),\mathfrak{M}\circ\psi(a_2))=\hat{d}_{\varrho}(\psi(a_1),\psi(a_2))$, for all $a_1,a_2\in\mathscr{A}$, where $d_{\varrho,\mathfrak{E},k}$ denotes the decoherence functional on $\mathfrak{E}(\mathbb{H})_{2/k,\mathfrak{E}}$ (compare Remark 20 in Ref. 37).

Theorem 4: *For every allowed Boolean lattice* $(\mathscr{A},\mathfrak{J})$ *in the sense of Ref. 37 there is an admissible Boolean lattice* $(\mathscr{B},\mathfrak{M})$ *such that there exists an isomorphism* $\psi:\mathscr{A}\to\mathscr{B}$ *satisfying the conditions from Theorem 3.*

Proof: We denote by $\mathscr{A}_0$ the set of atoms of $\mathscr{A}$. We construct $\mathscr{B}$ inductively. We choose $\mathfrak{J}(\mathscr{A}_0)$ to be the set of atoms of $\mathscr{B}$ and $0_{\mathscr{B}}:=\mathfrak{J}(0_{\mathscr{A}})$. We define $\mathfrak{J}(a_1)\vee_{\mathscr{B}}\mathfrak{J}(a_2):=\mathfrak{J}(a_1\vee_{\mathscr{A}}a_2)$ for all $a_1,a_2\in\mathscr{A}_0$. If $\mathscr{A}_0$ contains more than two elements, then $\mathfrak{J}(a_1)\vee_{\mathscr{B}}\mathfrak{J}(a_2)=\mathfrak{J}(a_1)\oplus\mathfrak{J}(a_2)$ for $a_1\neq a_2$. This definition makes sense since $\mathfrak{J}(a_1)\oplus\mathfrak{J}(a_2)$ is well defined for all $a_1,a_2\in\mathscr{A}_0$ with $a_1\neq a_2$ and since $\mathfrak{J}(a_1)\neq\mathfrak{J}(a_2)$ for all $a_1,a_2\in\mathscr{A}_0$ with $a_1\neq a_2$. If $\mathscr{A}_0$ contains exactly two elements, then $\mathfrak{J}(a_1)\vee_{\mathscr{B}}\mathfrak{J}(a_2)=\mathfrak{J}(a_1)\oplus\mathfrak{J}(a_2)\ominus\mathfrak{J}(0_{\mathscr{A}})$ for $a_1\neq a_2$. This definition makes sense since $\mathfrak{J}(a_1)\oplus\mathfrak{J}(a_2)\ominus\mathfrak{J}(0_{\mathscr{A}})$ is well defined for all $a_1,a_2\in\mathscr{A}_0$ with $a_1\neq a_2$ and since $\mathfrak{J}(a_1)\neq\mathfrak{J}(a_2)$ for all $a_1,a_2\in\mathscr{A}_0$ with $a_1\neq a_2$.

The *full D-posets* also discussed in Ref. 37 are trivially contained in the class of admissible Boolean lattices defined in Definition 3.

From Theorem 4 and our Definition 5 of the implication relation between effect histories it follows immediately that if e_1 and e_2 are homogeneous effect histories such that $e_1\Rightarrow_{\varrho}e_2$ in the sense of Ref. 37, then also $e_1\Rightarrow_{\varrho}e_2$ in the sense of Definition 5.

Thus, Theorem 4 clearly shows that Rule 3 is indeed a generalization of Rule 2 stated in Ref. 37.

IV. SUMMARY

We now summarize our discussion by stating the general axioms for a generalized quantum theory based on our generalized history concept. This subsection parallels the discussion in Ref. 21.

(1) The space $\mathfrak{U}$ of general history propositions.
  (a) The space $\mathfrak{U}$ carries a canonical D-poset structure denoted by $\oplus$.
    (i) In this work $\mathfrak{U}$ is given by $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$.

(2) The space $\mathscr{U}$ of history filters or homogeneous histories.
  (a) $\mathscr{U}$ is the space of the basic physical properties of a physical system with a direct physical interpretation. An element of $\mathscr{U}$ is a time-ordered sequence of one-time propositions about the system. There exists a map F mapping the elements of $\mathscr{U}$ to a D-poset $\mathfrak{E}$. Here $\mathfrak{E}$ can be interpreted as the set of (equivalence classes of) one-time propositions.
    (i) In this work $\mathscr{U}$ equals the space of homogeneous effect histories of the first kind $\mathscr{U}=\mathbb{E}_{\mathrm{fin}}(\mathbb{H})$, cf. Definition 1; $\mathfrak{E}$ is given by $\mathfrak{E}(\mathbb{H})$ and F is given by $F(u)=C_{t_0}(u)^{\dagger}C_{t_0}(u)$.
  (b) $\mathscr{U}$ is a partially ordered set with unit history 1 and null history 0.
  (c) There exists an order preserving map $\tau:\mathscr{U}\to\mathfrak{U}$, i.e., $\tau(\mathscr{U})\subset\mathfrak{U}$.
    (i) In this work τ is given by σ_{fin}.
  (d) $\mathscr{U}$ is a partial semigroup with composition law $\circ$, cf. Ref. 21. Here $a\circ b$ is well-defined if $t_f(a)<t_i(b)$. In this case we say that *a proceeds b* or that *b follows a*. Further, $1\circ a=a\circ 1=a$ and $a\circ 0=0\circ a=0$. If $a\circ b$ is defined, then $a\circ b=a\wedge b$, in particular the right-hand side is well defined.
  (e) The partial ordering on $\mathscr{U}$ induces a partial unary operation $\neg$(complementation) and two

partial binary operations $\wedge$ and $\vee$ (meet and join) on $\mathscr{U}$.

(3) The space of decoherence functionals.
   (a) A decoherence functional is a map $d:\mathfrak{U}\times\mathfrak{U}\to\mathbb{C}$ which satisfies for all $\alpha,\alpha',\beta\in\mathfrak{U}$
      (i) $d(\alpha,\alpha)\in\mathbb{R}$ and $d(\alpha,\alpha)\geqslant 0$;
      (ii) $d(\alpha,\beta)=d(\beta,\alpha)^*$;
      (iii) $d(1,1)=1$;
      (iv) $d(0,\alpha)=0$, for all α;
      (v) $d(\alpha_1\oplus\alpha_2,\beta)=d(\alpha_1,\beta)+d(\alpha_2,\beta)$ for all $\alpha_1,\alpha_2,\beta\in\mathfrak{U}$ for which $\alpha_1\oplus\alpha_2$ is well defined.
   (b) In Ref. 37 it was possible to explicitly construct the decoherence functional on all inhomogeneous effect histories considered. In this work we have no explicit construction of the decoherence functional on $\mathfrak{E}^{\otimes}_{\mathrm{fin}}(\mathbb{H})$. Only its existence is known by Theorem 1.

(4) The physical interpretation.
   (a) The physically interesting subsets of $\mathfrak{U}$ are the ''admissible'' Boolean sublattices $\mathscr{B}$ of $\mathfrak{U}$ (see Definition 3) on which a positive valuation $\mathfrak{M}$ can be defined with values in $\mathfrak{U}$ such that for every $u\in\mathscr{B}$ the value $\mathfrak{M}(u)$ does not depend upon the particular ''admissible'' Boolean lattice $\mathscr{B}$ chosen.
   (b) The map $\mathfrak{M}$ ''lifts'' the lattice structure of $\mathscr{B}$ to the D-poset structure of $\mathfrak{U}$ and every decoherence functional on $\mathfrak{U}$ induces a consistency functional on $\mathscr{B}$.
   (c) The decoherence functional induces a probability measure on the consistent (wrt the decoherence functional) ''admissible'' Boolean sublattices of $\mathfrak{U}$.
   (d) On the ''admissible'' Boolean sublattices of $\mathfrak{U}$ decoherence functional defines a partial logical implication which allows us to make logical inferences.
   (e) The description of a physical system and reasoning in terms of elements of $\mathfrak{U}$ (homogeneous effect histories of the first kind) is only indirectly possible by using the map $\tau:\mathscr{U}\to\mathfrak{U}$.
   (f) While homogeneous effect histories have a direct physical interpretation in terms of time sequences of physical properties, inhomogeneous (effect) histories have no such direct interpretation. We tentatively suggest, however, that they may be interpreted as representatives of *unsharp quantum events*, i.e., events which cannot be associated with some fixed time, but which are smeared out in time.

ACKNOWLEDGMENTS

I would like to thank Professor Frank Steiner for his support of my work.

Financial support given by Deutsche Forschungsgemeinschaft (Graduiertenkolleg für theoretische Elementarteilchenphysik) is also gratefully acknowledged.

(Received 4 December 1995; accepted for publication 2 April 1996)

We use Greechie diagrams to construct finite orthomodular lattices ''realizable'' in the orthomodular lattice of subspaces in a three-dimensional Hilbert space such that the set of two-valued states is not ''large'' (i.e., full, separating, unital, nonempty, resp.). We discuss the number of elements of such orthomodular lattices, of their sets of (ortho)generators and of their subsets that do not admit a ''large'' set of two-valued states. We show connections with other results of this type. © *1996 American Institute of Physics.* [S0022-2488(96)00409-4]

I. INTRODUCTION

Quantum logic, as it has been pioneered by Birkhoff and von Neumann,[1] is usually derived from Hilbert space. There, the logical primitives, such as propositions and the logical operators ''and,'' ''or,'' and ''not'' are defined by Hilbert space entities. For instance, consider the three-dimensional, real Hilbert space $\mathbf{R}^3$ with the usual scalar product $(v,w):=\Sigma_{i=1}^{3}v_i w_i$, $v,w\in\mathbf{R}^3$. There, any proposition is identified with a subspace of $\mathbf{R}^3$. For instance, the zero vector corresponds to a false statement. Any line spanned by a nonzero vector corresponds to the statement that the physical system is in the pure state associated with the vector. Any plane formed by the linear combination of two (noncolinear) vectors v,w corresponds to the statement that the physical system is either in the pure state v or in the pure state w. The whole Hilbert space $\mathbf{R}^3$ corresponds to the tautology (true propositions). The logical ''and'' operation is identified with the set theoretical intersection of two propositions; e.g., with the intersection of two lines. The logical ''not'' operation, or the ''complement,'' is identified with taking the orthogonal subspace; e.g., the complement of a line is the plane orthogonal to that line.

In this top-down approach, one arrives at a propositional calculus that resembles the classical one, but differs from it in several important aspects. It has a non-Boolean, i.e., nondistributive, algebraic structure. Furthermore, as has first been pointed out by Kochen and Specker in the context of partial algebras,[2–4] there exist certain *finite* sets of lines, such that the associated propositional structure cannot be classically embedded. That is, there does not exist any classical, i.e., two-valued, measure that could be interpreted as the fact that propositions are either ''true'' (≡measure value 1) or ''false'' (≡measure value 0). The Kochen and Specker original construction used 117 lines. The number of lines has been subsequently reduced.[5–8] These constructions are examples of propositional structures without any two-valued measures.

In this paper we shall deal with the following questions: which orthomodular structure—finite or infinite—underlies the Kochen–Specker construction. The question can be approached from two different viewpoints: (i) Which *minimal* set of propositions generates some Kochen–Specker-type configurations? By ''generate'' we mean the construction of the propositional structure con-

taining it. (ii) What is the *minimal propositional structure* containing some sort of Kochen–Specker-type configuration? In particular, is it finite or infinite?

II. BASIC NOTIONS

The following definition gives two main concepts of a propositional structure.

Definition 2.1: An *orthomodular poset* is a structure $(P,\leqslant,',0,1)$ fulfilling the following conditions.

(1) $(P,\leqslant)$ is a partial ordered set such that $0\leqslant a\leqslant 1$ for every $a\in P$.

(2) $':P\to P$ is an orthocomplementation, i.e., for every $a, b\in P$: (a) $a''=a$; (b) $a\leqslant b$ implies $b'\leqslant a'$; (c) $a\vee a'=1$.

(3) If $a\leqslant b'$ then the supremum $a\vee b$ exists in P.

(4) If $a\leqslant b$ then there is an element $c\in L$ such that $c\leqslant a'$ and $b=a\vee c$ (the orthomodular law).

An *orthomodular lattice* is an orthomodular poset that is a lattice.

Elements a, b of an orthomodular poset are called *orthogonal* (denoted by $a\perp b$) if $a\leqslant b'$. A subset O of an orthomodular poset is called *orthogonal* if every pair of its elements is orthogonal.

Definition 2.2: Let P_1, P_2 be orthomodular posets. P_1 is *orthorepresentable* in P_2 if there is a mapping (called *orthoembedding*) $h: P_1\to P_2$ such that for every $a, b\in P_1$, (1) $h(0)=0$, (2) $h(a')=h(a)'$, (3) $a\leqslant b$ if and only if $h(a)\leqslant h(b)$, and (4) $h(a\vee b)=h(a)\vee h(b)$ whenever $a\perp b$.

P_1 is *representable* in P_2 if there is a mapping (called *embedding*) $h: P_1\to P_2$ such that h is orthoembedding, and for every $a, b\in P_1$, (4′) $h(a\vee b)=h(a)\vee h(b)$.

The set $h(P_1)$ is then called an *(ortho)representation* of P_1 in P_2.

A *suborthoposet* (*subortholattice*, resp.) is a subset such that the identity mapping is orthoembedding (embedding, resp.).

Boolean subalgebra of an orthomodular poset is a suborthoposet that is a Boolean algebra. *Block* is a maximal Boolean subalgebra.

As we will see later, there are lattices L_1, L_2 such that L_1 is a suborthoposet but not a subortholattice of L_2. On the other hand, a suborthoposet of an orthomodular lattice need not be a lattice.

Definition 2.3: Let L be an orthomodular lattice, G, $\overline{L\subseteq P}$ and let us denote by $L(G)$ [$P(G)$, resp.] the least subortholattice (suborthoposet, resp.) of L containing G. We say that G *generates* (*orthogenerates*, resp.) L if $L\subseteq L(G)$ [$L\subseteq P(G)$, resp.].

$P(G)$ and $L(G)$ can be explicitly defined by the following process: $P(G)=\cup_{n=0}^{\infty}P_n(G)$, $L(G)=\cup_{n=0}^{\infty}L_n(G)$, where $P_0(G)=L_0(G)=G$ and, for every natural number, n:

$$L_{n+1}(G)=\{\vee O;\ O \text{ is a finite subset of } L_n(G)\cup L_n(G)'\},$$

$$P_{n+1}(G)=\{\vee O;\ O \text{ is a finite orthogonal subset of } P_n(G)\cup P_n(G)'\}$$

(M' denotes the set $\{a';a\in M\}$). Hence, every countable set G generates a countable subortholattice and orthogenerates a countable suborthoposet.

A very useful tool for constructing and representing some orthomodular posets is the so-called Greechie diagram.

Definition 2.4: A *diagram* is a pair (V,E), where $V\neq\emptyset$ is a set of *vertices* (usually drawn as points) and $E\subseteq\exp V\setminus\{\emptyset\}$ is a set of *edges* (usually drawn as line segments connecting corresponding points).

Let $n\geqslant 2$ be a natural number. A *loop* of order n in a diagram (V,E) is a sequence $(e_1,\ldots,e_n)\in E^n$ of mutually different edges such that there are mutually different vertices $v_1,\ldots,v_n$ with $v_i\in e_i\cap e_{i+1}$ $(i=1,\ldots,n,\ e_{n+1}=e_1)$.

A *Greechie diagram* is a diagram fulfilling the following conditions.

FIG. 1. Examples of diagrams that are not Greechie diagrams.

(1) Every vertex belongs to at least one edge.
(2) If there are at least two vertices then every edge is at least a two-element.
(3) Every edge that intersects with another edge is at least a three-element.
(4) Every pair of different edges intersects in at most one vertex.
(5) There is no loop of order 3.

Some examples of diagrams that are not Greechie diagrams are given in Fig. 1—these examples violate exactly one of conditions (2)–(5) in the above definition. (We usually do not denote one-element edges.) The condition (4) states that in Greechie diagrams there is no loop of order 2.

Before we present the representation theorem let us recall that an *atom* in an orthomodular poset P is a minimal element of $P\setminus\{\emptyset\}$.

Theorem 2.5: *For every Greechie diagram with only finite edges there is exactly one (up to an isomorphism) orthomodular poset, such that there are one-to-one correspondences between vertices and atoms and between edges and blocks that preserve incidence relations. A Greechie diagram does not contain any loop of order 4 if and only if the corresponding orthomodular poset is a lattice.*

The proof can be found, e.g., in Ref. 9. Let us reserve the notion *Greechie logic* for an orthomodular poset that can be represented by a Greechie diagram with only finite edges. It is easy to see that such an orthomodular poset does not contain any infinite chain, hence every element is a supremum of a finite orthogonal set of atoms.

Let us remark that there are finite orthomodular posets not representable by Greechie diagrams—intersections of blocks might be greater than a four-element Boolean subalgebra, and hence the condition (4) of Definition 2.4 cannot be fulfilled. On the other hand, every orthomodular poset with only finite and at most three atomic blocks (the case we are interested about) is a Greechie logic.

We will have a special interest about the following example.

Definition 2.6: The three-dimensional *Hilbert logic* H_3 is the orthomodular lattice of linear subspaces of $\mathbf{R}^3$. The ordering is given by inclusion and the orthocomplementation is given by $a'=\{v\in\mathbf{R}^3;\ v\perp a\}$ for every $a\in H_3$.

The least element of H_3 is $0=\{(0,0,0)\}$, the greatest element of H_3 is $1=\mathbf{R}^3$. Moreover, $a\wedge b=a\cap b$ and $a\vee b=\mathrm{Sp}(a\cup b)$ for every $a,b\in H_3$, where $\mathrm{Sp}(G)$ is the *span* of G in $\mathbf{R}^3$. [We will usually omit unnecessary parentheses, e.g., Sp(1,0,0) denotes Sp({(1,0,0)}).]

Every element of $H_3\setminus\{0,1\}$ is either an atom or a coatom, every block in H_3 is finite and at most a three-element, every suborthoposet P of H_3 is a Greechie logic and is uniquely determined by the set $A_1(P)$ of its one-dimensional atoms (lines):

$$P=\{0,1\}\cup A_1(P)\cup A_1(P)'.$$

(There might be also two-dimensional atoms in P, e.g., if P is a four-element.) Moreover, for every set G of lines in H_3 the set of lines of the orthomodular lattice $L(G)$ [orthomodular poset $P(G)$, resp.] generated (orthogenerated, resp.) by G can be expressed as follows: $A_1(P(G))=\cup_{n=0}^{\infty}P_n$, $A_1(L(G))=\cup_{n=0}^{\infty}L_n$, where $P_0=L_0=G$ and, for every natural number n,

$$L_{n+1}=L_n\cup\{(a\vee b)';a,b\in L_n\},$$

$$P_{n+1}=P_n\cup\{(a\vee b)';a,b\in P_n,\ \text{such that}\ a\perp b\}.$$

III. TWO-VALUED STATES AND GREECHIE DIAGRAMS

Let us present the main definition.

Definition 3.1: Let P be an orthomodular poset and let $G\subset P$. A *state* s on G is a mapping s: $P\rightarrow[0,1]$, such that

(1) $s(0)=0$,

(2) $s(a)\leqslant s(b)$ whenever $a,b\in G$ with $a\leqslant b$;

(3) $\Sigma_{a\in O}s(a)\leqslant 1$ for every orthogonal set $O\subset G$; and

(4) $\Sigma_{a\in O}s(a)=1$ for every orthogonal set $O\subset G$ with $\vee O=1$.

A *two-valued state* is a state with values in $\{0,1\}$.

If $G=P$ then conditions (1)–(2) follow from conditions (3)–(4) and from the orthomodular law and, moreover, $s(a')=1-s(a)$ for every $a\in P$.

The Kochen–Specker construction gives an example of a propositional structure without any two-valued state. We will use a more general attempt and will ask whether there is a propositional structure without ''enough'' two-valued states. Originally, ''enough'' meant ''at least one.'' We will also use the following properties of state space, which are important in quantum logic theories.

Definition 3.2: Let P be an orthomodular poset and let $G\subseteq P$. A set S of states on G is called *unital* if for every $a\in G\backslash\{0\}$ there is a state $s\in S$ such that $s(a)=1$;

separating if for every $a,b\in G$ with $a\neq b$ there is a state $s\in S$ such that $s(a)\neq s(b)$;

full if for every $a,b\in G$ with $a\not\leqslant b$ there is a state $s\in S$ such that $s(a)>s(b)$.

Existence of a unital set of states means that every proposition that is not a tautology is sometimes false. Existence of a separating set of states means that a different propositions are distinguishable. Existence of a full set of two-valued states means that if some proposition does not imply another, then there is such a state that the first is true while the second is not. These properties are largely studied. An orthomodular poset with a full set of two-valued states is called a *concrete logic* (see, e.g., Ref. 10), an orthomodular poset with a separating set of two-valued states is called a *partition logic*—this notion is within orthomodular posets equivalent to the notion of *automaton logic* (see, e.g., Refs. 11–14).

It is easy to see that a full set of states is separating and that a separating set of two-valued states is unital. Before we give examples demonstrating differences in the above-defined notions let us give some criteria, how we can verify whether an orthomodular poset given by a Greechie diagram has ''enough'' two-valued states.

Definition 3.3: Let P be an orthomodular poset and let A be the set of atoms in P. A *weight* w on A is a mapping w: $A\rightarrow[0,1]$, such that $\Sigma_{a\in O}w(a)=1$ for every maximal orthogonal set $O\subseteq P$. A *two-valued* weight is a weight with values in $\{0,1\}$.

Lemma 3.4: Let P be a Greechie logic and let A be the set of atoms in P. Then there is a one-to-one correspondence between two-valued states s on P and two-valued weights w on A given by $w=s|A$.

Proof: Obvious.

Due to this correspondence we may (and will) identify states and weights and study only the values of states on the set of atoms. Since every maximal orthogonal set of atoms corresponds uniquely to a block, we need only to check that the sum of values of a state on every edge in a Greechie diagram is equal to 1.

Proposition 3.5: Let P be a Greechie logic and let A be the set of atoms in P. Then P has a full set of two-valued states (i.e., P is a concrete logic) if and only if for every pair a_1, $a_2\in$P *of different nonorthogonal atoms there is a two-valued weight w on A such that* $w(a_1)=w(a_2)=1$.

Proof⇒: Let $a_1, a_2 \in A$, such that $a_1 \not\perp a_2$. Then $a_1 \leqslant a_2'$ and there is a two-valued state s on P such that $1 = s(a_1) > s(a_2') = 0$. Hence, $s(a_2)=1$ and, according to Lemma 3.4, it suffices to take $w=s|A$.

⇐*:* Let $b_1, b_2 \in P$ such that $b_1 \not\leqslant b_2$, i.e., $b_1 \not\perp b_2'$. There are orthogonal sets $A_1, A_2 \neq \emptyset$ of atoms in P such that $b_1 = \vee A_1$, $b_2' = \vee A_2$. According to Lemma 3.4, it suffices to prove that there are atoms $a_1 \in A_1$, $a_2 \in A_2'$ and a weight w on A such that $w(a_1)=w(a_2)=1$. Let us suppose first that $A_1 \cap A_2 = \emptyset$. Then there are atoms $a_1 \in A_1$ and $a_2 \in A_2$ such that $a_1 \neq a_2$ and $a_1 \not\perp a_2$ and, due to our assumption, a weight w on A such that $w(a_1)=w(a_2)=1$. Let us suppose now that $A_1 \cap A_2 \neq \emptyset$. Then there is an atom $a_1 \leqslant b_1, b_2'$ and either there is an atom $a_2 \neq a_1$ such that $a_1 \not\perp a_2$, or $a_1 \perp a$ for every atom $a \neq a_1$. In both cases there is a two-valued weight w on A such that $w(a_1)=1$; in the first case due to our assumption and in the second case we can put $w(a)=1$ iff $a=a_1$.

The situation for a separating set of states is much more complicated and we will state a criterion in a special case (which is in our interest here).

Proposition 3.6: Let P be a Greechie logic with, at most three atomic blocks and let A be the set of atoms in P. Then the set of two-valued states on P is separating (i.e., P is a partition logic) if and only if the following conditions hold.

(1) *For every atom $a \in P$ there is a two-valued weight w on A such that $w(a)=1$.*

(2) *For every pair $a_1, a_2 \in$ P of different nonorthogonal atoms there are two-valued weights w_+, w_- on A such that $w_+(a_1)=w_+(a_2)$ and $w_-(a_1) \neq w_-(a_2)$.*

Proof ⇒: Let $a \in A$. Then $a \neq 0$ and there is a two-valued state s on P such that $1=s(a) > s(0)=0$. Let $a_1, a_2 \in A$ such that $a_1 \neq a_2$ and $a_1 \not\perp a_2$. Then also $a_1 \neq a_2'$ and there are two-valued states s_-, s_+ on P such that $1=s_-(a_1) > s_-(a_2)=0$, $1 = s_+(a_1) > s_+(a_2') = 0$, i.e., $s_+(a_1)=s_+(a_2)$. The rest follows from Lemma 3.4.

⇐*:* Let $b_1, b_2 \in P$ such that $b_1 \neq b_2$. Since every element of $P \backslash \{0,1\}$ is either an atom or a coatom, there are atoms $a_1, a_2 \in P$ such that $b_1 \in \{0, a_1, a_1', 1\}$ and $b_2 \in \{0, a_2, a_2', 1\}$. If $a_1 = a_2$ then there are two-valued weights w_+, w_- on A such that $w_+(a_1)=1$ and $w_-(a_1)=0$. If $a_1 \neq a_2$ then there are two-valued weights w_+, w_- on A such that $w_+(a_1)=w_+(a_2)$ and $w_-(a_1) \neq w_-(a_2)$. In both cases there are, according to Lemma 3.4, two-valued states s_+, s_- on P such that either $s_+(b_1) \neq s_+(b_2)$ or $s_-(b_1) \neq s_-(b_2)$.

Let us present a lemma, which might simplify to verify criteria in Proposition 3.6.

Lemma 3.7: Let P be a Greechie logic and let A be the set of atoms in P. If W is an at least three-element set of two-valued weights on A such that $\{w^{-1}(1); w \in W\}$ is a partition of A, then

(1) for every atom $a \in A$ there is a weight $w \in W$ such that $w(a)=1$;

(2) for every pair $a_1, a_2 \in A$ there is a weight $w \in W$ such that $w(a_1)=w(a_2)$.

Proof: Obvious.

Let us remark that in Greechie diagrams it suffices to use the above conditions for every connected subdiagram separately (weights behave independently on nonconnected subgraphs). In terms of orthomodular posets we can use the following important notion.

Definition 3.8: Let $\mathscr{P}$ be a set of orthomodular posets such that $P_1 \cap P_2 = \{0,1\}$ for every P_1, $P_2 \in \mathscr{P}$ with $P_1 \neq P_2$. The *horizontal sum* $\Sigma_{P \in \mathscr{P}} P$ is defined as $(\cup_{P \in \mathscr{P}} P, \cup_{P \in \mathscr{P} \leqslant P}, \cup_{P \in \mathscr{P}} {}'^{P}, 0, 1)$.

More generally, we speak about the horizontal sum of P_i, $i \in I$. It is an abbreviation for saying that we take disjoint representations P_i of P_i (e.g., $\{i\} \times P_i$), identify all 0_i ($i \in I$) and all 1_i ($i \in I$), and take $\Sigma_{i \in I} P_i$. It is easy to see that a horizontal sum of orthomodular posets (orthomodular lattices, resp.) is an orthomodular poset (orthomodular lattice, resp.) and that a set of states is nonempty (unital, separating, full, resp.) on a horizontal sum if and only if it is nonempty (unital, separating, full, resp.) on every horizontal summand.

In a Greechie diagram every connected subdiagram corresponds to a horizontal summand. (In particular, every finite two-atomic block is a horizontal summand.) On the other hand, the horizontal sum of Greechie logics is a Greechie logic with the Greechie diagram, which is a (disjoint)

union of summands with only one exception—we lose isolated vertices (these correspond to the trivial orthomodular poset {0,1}).

The notion of a horizontal sum is a special kind of the notion of *pasting*. We are not interested here in a general setting (see, e.g., Ref. 9), thus we describe only special cases showing how we can obtain a new Greechie logic using this process. Greechie diagram of the *pasting of Greechie logics* P_i $(i\in I)$ *for atoms* $a_i\in P_i$ $(i\in I)$ we obtain as follows: we take the disjoint union of Greechie diagrams of $P_i(i\in I)$, identify vertices corresponding to a_i $(i\in I)$ and, if some a_i $(i\in I)$ belong to a two-atomic block, we delete necessary vertices corresponding to such a_i' such that the condition (3) of Definition 2.4 is fulfilled. Greechie diagram of the *pasting of Greechie logics* P_i $(i\in I)$ *for blocks* $B_i\subseteq P_i$ $(i\in I)$ with the same number of atoms we obtain as follows: we take the disjoint union of Greechie diagrams of P_i $(i\in I)$ and identify edges corresponding to B_i $(i\in I)$ (i.e., we identify also atoms in these blocks.) It is easy to see that such pastings of (lattice) Greechie logics are (lattice) Greechie logics.

The notion of a horizontal sum is also related to the following notion.

Definition 3.9: Let P be an orthomodular poset. The *distance* d on P is a mapping d: $P\times P\to\mathbf{N}\cup\{\infty\}$, defined by

$d(a,b)=\inf\{n\in\mathbf{N}$; there are blocks $B_1,\ldots,B_n$ in P such that $B_i\cap B_{i+1}\neq\{0,1\}$ for $i=0,\ldots,n$, $B_0=\{a\}$, $B_{n+1}=\{b\}\}$.

The distance function defines the largest decomposition of P into horizontal summands—the least summands are maximal subsets of $P\setminus\{0,1\}$ of elements with finite distances joined with $\{0,1\}$.

The following result we will use in the sequel.

Proposition 3.10: Every Greechie logic without any loop has a full set of two-valued states.

Proof: The distance function on P decompose P into the horizontal sum $\Sigma_{i\in I}P_i$, such that the distance of every pair of elements in every summand is finite. It suffices to prove fullness for every summand. According to Proposition 3.5, it suffices, for every $i\in I$ and for every pair a_1, a_2 of different nonorthogonal atoms in P_i, to find a weight w on the set A of atoms in P_i, such that $w(a_1)=w(a_2)=1$. Let us put $A_n=\{a\in A;d(a,a_1)=n\}$ for every natural number n and let us define w by induction.

I. $w(a_1)=1$.

II. Let us suppose that there is a natural number $n\geqslant 0$ such that w is defined on $A_0\cup\cdots\cup A_n$. Every element of A_{n+1} belongs to some block B in P_i such that $B\cap A_n\neq\emptyset$. For every such block B we have $B\cap A_n=\{a_B\}$. If $w(a_B)=1$, we put $w|B\cap A\setminus A_n=0$. If $w(a_B)=0$, we can choose (B has at least three atoms) properly a $b_B\in B\cap A\setminus A_n$ and put $w(b_B)=1$, $w|B\cap A\setminus b_B\}=0$. Properly means that if $n=d(a_2,a_1)-2$ then b_B is chosen such that it does not belong to the same block as a_2 and if $n=d(a_2,a_1)-1$ then $b_B=a_2$.

Let us present examples demonstrating differences in properties of state space.

Proposition 3.11: Let us consider the following conditions.

(1) The set of two-valued states is full.

(2) The set of two-valued states is separating but not full.

(3) The set of two-valued states is unital but not separating.

(4) The set of two-valued states is nonempty but not unital.

(5) The set of two-valued states is empty.

For each of the above conditions there is an orthomodular lattice with only finite three-atomic blocks, which fulfills it.

Proof: (1) See Fig. 2.1. It is a Boolean algebra, which obviously has a full set of two-valued states.

(2) See Fig. 2.2. For every two-valued state s we have $s(a)+s(b)\leqslant(1-s(c_a)+1-s(d_a)+1-s(c_b)+1-s(d_b))/2=(2-s(c)-s(d))/2\leqslant 3/2$. Hence $s(a)+s(b)\leqslant 1$ and, according to Proposition 3.5, this orthomodular lattice has not a full set of two-valued states. The set $S_1=\{s_1,s_2,s_3\}$ of states given in Fig. 3 fulfills conditions of Lemma 3.7. It can be checked that the set of all two-valued states ''symmetric'' to some state from S distinguish different nonor-

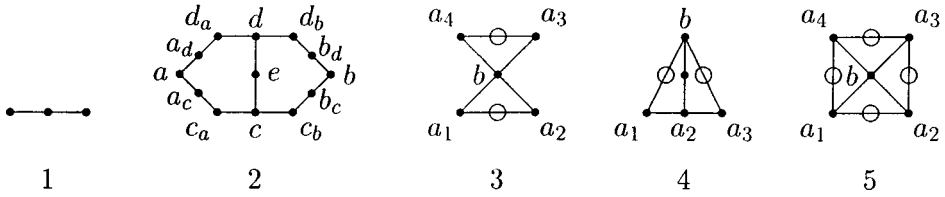

FIG. 2. Greechie diagrams of orthomodular posets with finite three-atomic blocks demonstrating differences of state spaces ($a\!\multimap\!\ominus\!\multimap\!b$ denotes diagram 2).

thogonal atoms. Hence, the set of two-valued states fulfills conditions of Proposition 3.6. A smaller example of a separating set of states is given in Fig. 3. We can express this orthomodular lattice as a partition logic on a six-element set of these states—see Fig. 4.1. (Compare with the representation on the 14-element set of states in Ref. 14).

(3) See Fig. 2.3. Let us use the previous result. For every two-valued state s with $s(a_1)=1$ we obtain $s(a_2)=s(b)=0$, hence $s(a_4)=1$. Using the symmetry we obtain $s(a_1)=s(a_4)$ for every two-valued state, hence the set of two-valued states is not separating. The unitality can be verified routinely.

(4) See Fig. 2.4. For every two-valued state s there is an $i\in\{1,2,3\}$ such that $s(a_i)=1$ and therefore $s(b)=0$. Hence, the set of two-valued states is not unital. Existence of a two-valued state can be verified routinely. (Let us note that if we paste ''sides of the triangle'' not only for b but for the whole block we obtain a smaller example with 25 atoms.)

(5) See Fig. 2.5. According to part (3) of this proof, $s(a_1)=s(a_2)=s(a_3)=s(a_4)$ for every two-valued state s. Hence all these values are equal to 0 and $s(b)=1$. The desired example we obtain by pasting this orthomodular lattice with the orthomodular lattice from Fig. 2.4 for b's or, more effectively, by pasting for blocks containing b's and a_2's.

IV. SUBORTHOLATTICES OF H_3

There are only several types of finite subortholattices of H_3. The following characterization of finite subortholattices of H_3 seems to be in a common knowledge (see, e.g., Ref. 15, Example 1.5.3), but we do not know a proper reference for its proof.

Lemma 4.1: Let L be a subortholattice of H_3 and let lines a_1, a_2, a_3, $b\in L$ be such that a_1, a_2, a_3 are mutually orthogonal and $b\not\perp a_1$, a_2, a_3. Then there is a line $c\in L$ such that $c\not\perp a_3$ and the angle $\angle(c,a_3)$ is greater than $\angle(b,a_3)$.

Proof: Let us choose the system of coordinates such that $a_1=\mathrm{Sp}(1,0,0)$, $a_2=\mathrm{Sp}(0,1,0)$, $a_3=\mathrm{Sp}(0,0,1)$, $b=\mathrm{Sp}(x,y,z)$, such that $x,y,z>0$. Since L is a subortholattice of H_3, the following elements belong to L:

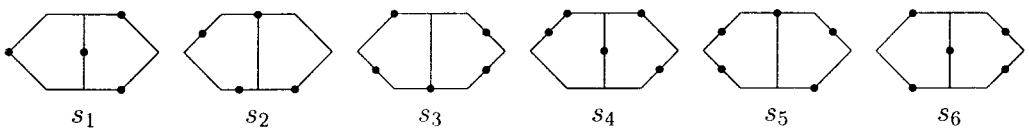

FIG. 3. Separating set of two-valued states on an orthomodular lattice from Fig. 2.2. (only atoms in which the corresponding state is equal to 1 are marked).

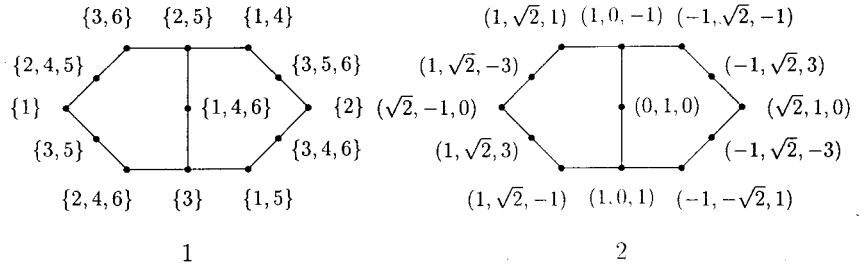

FIG. 4. Various representations of an orthomodular lattice from Fig. 2.2.

$$\overline{b} = (a_1 \vee a_2) \wedge b' = \mathrm{Sp}(y, -x, 0),$$

$$c = (a_1 \vee a_3) \wedge (b \vee \overline{b}) = \mathrm{Sp}(x + y^2/x, 0, z).$$

Hence,

$$0 < \cos\angle(c, a_3) = \frac{z}{\sqrt{(x + y^2/x)^2 + z^2}} < \frac{z}{\sqrt{x^2 + y^2 + z^2}} = \cos\angle(b, a_3).$$

Theorem 4.2: *Let $L \subset H_3$ be a finite orthomodular lattice. Then L is a subortholattice of H_3 if and only if exactly one of the following possibilities is fulfilled.*

(1) *$L = \{0,1\}$, i.e., L is a one-atomic Boolean algebra*;

(2) *$L = \{0, a, a', 1\}$ for some line $a \in H_3$, i.e., L is a two-atomic Boolean algebra.*

(3) *$L = \{0, a_1, a_2, a_3, a_1', a_2', a_3', 1\}$ for some orthogonal set $\{a_1, a_2, a_3\}$ of lines in H_3, i.e., L is a three-atomic Boolean algebra.*

(4) *$L = \{0, a, a', 1\} \cup G \cup G' \cup \{a \vee b; b \in G\} \cup \{a' \wedge b'; b \in G\}$ for some line $a \in H_3$ and some at least two-element set G of mutually nonorthogonal atoms orthogonal to a, i.e., L is a finite pasting of at least two three-atomic Boolean algebras for a given atom.*

Proof: It is easy to see that each of these conditions excludes the others and gives a subortholattice of H_3. Let us suppose that there is a finite subortholattice L of H_3 that fulfills no condition (1)–(4), and seek a contradiction. There are three mutually nonorthogonal lines $a, b, c \in L$. Let $d_3 = (a \vee b)' \in L$. Since L is finite, there is a line $e \in L$ such that $\angle(e, d_3)$ is the greatest among all lines from L nonorthogonal to d_3. Since $a \not\perp b$ there is a $d_1 \in \{a, b\}$ such that $d_1 \not\perp e, e' \wedge d_3'$. Let us put $d_2 = d_1' \wedge d_2' \in L$. Hence, lines d_1, d_2, d_3 are mutually orthogonal and $e \not\perp d_1, d_2, d_3$. According to Lemma 4.1, there is an element $f \in L$ such that $f \not\perp d_3$ and $\angle(f, d_3) < \angle(e, d_3)$—this contradicts the selection of e.

Greechie diagrams of finite subortholattices of H_3 are given in Fig. 5.

Corollary 4.3: Every finite subortholattice of H_3 has a full set of two-valued states.

Proof: It follows from Theorem 4.2 and Proposition 3.10.

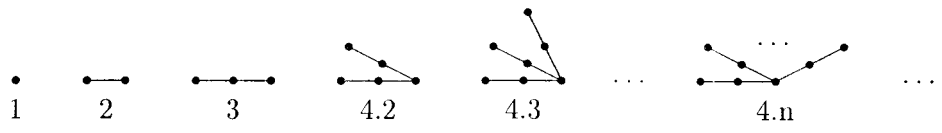

FIG. 5. Greechie diagrams of finite subortholattices of H_3.

As concerns infinite subortholattices of H_3, there is a countable subortholattice of H_3 without any two-valued states (e.g., generated by finite sets without any two-valued state—see Corollary 7.5). On the other hand, there are infinite subortholattices with a full set of two-valued states, e.g. infinite pastings of three-atomic Boolean algebras for a given atom [compare condition (4) of Theorem 4.2]. It seems to be an open problem whether there is an infinite subortholattice of H_3 that is not of this type and that has a two-valued state. Moreover, there might be an interesting connection between the nonexistence of a two-valued state and density in $\mathbf{R}^3$. This might give better insight into the nature of subortholattices of H_3 and the connection with the famous Gleason theorem,[16,10] which (among other things) states that there is no two-valued state on H_3.

It should be noted that Greechie diagrams of subortholattices of H_3 are relatively ''complex''—the distance of every pair of elements is at most 2 (every pair of different lines has a common orthogonal line). Hence, it is usually difficult to give a Greechie diagram of an infinite subortholattice of H_3.

V. REALIZABILITY IN H_3

The study of finite suborthoposets of H_3 is more complicated. We would like to know whether a Greechie logic is orthorepresentable in H_3. The first problem erases with the intrinsic geometrical structure of H_3.

Definition 5.1: Let P be an orthomodular poset. We say that P is *weakly realizable* in H_3 if there is a mapping h: $P\rightarrow H_3$, such that, for every $a,b\in P$,

(1) $h(0)=0$;

(2) $h(a')=h(a)'$,

(3) $h(a)\leqslant h(b)$ whenever $a\leqslant b$; and

(4) $h(a)\neq 0$ whenever $a\neq 0$.

If, moreover, the mapping h fulfills for every $a,b\in P$ the following occurs:

(4′) $h(a)\neq h(b)$ whenever $a\neq b$,

we say that P *is realizable*. The set $h(P)$ is called a (*weak*) *realization* of P in H_3.

Weak realizability means that all orthogonality relations remain true in the images, and, since every nonzero element has a nonzero image, if the set of two-valued states on $G\subseteq P$ is empty (not unital, resp.) then the set of two-valued states on $h(G)$ is empty (not unital., resp.), too. Realizability means that, moreover, the mapping is one to one. Hence, if the set of two-valued states on $G\subseteq P$ is not separating (full, resp.), then the set of two-valued states on $h(G)$ is not separating (full, resp.), too. A realization need not be a suborthoposet because a new orthogonal pairs might appear in the images.

Let us give a characterization of orthomodular posets weakly realizable in H_3.

Lemma 5.2: Let $P_{\mathscr{P}}$ be the pasting of a set $\mathscr{P}$ of orthomodular posets and let there is a mapping h: $P_{\mathscr{P}}\rightarrow H_3$ such that h(P) is a weak realization of P for every $P\in\mathscr{P}$. Then h($P_{\mathscr{P}}$) is a weak realization of $P_{\mathscr{P}}$ in H_3. In particular, every horizontal sum of orthomodular posets weakly realizable in H_3 is weakly realizable in H_3.

Proof: Obvious.

Proposition 5.3: An orthomodular poset is weakly realizable in H_3 if and only if every its block is finite and at most three-atomic.

Proof $\Rightarrow$*:* Every orthogonal set of nonzero elements in an orthomodular poset P corresponds to an orthogonal set of nonzero elements in H_3. Since such a set in H_3 is at most a three-element, every block of P is finite with at most three atoms.

$\Leftarrow$*:* Let P be an orthomodular poset with only finite, at most three-atomic blocks. Let us decompose P into the horizontal sum $\Sigma_{i\in I}P_i$ of minimal horizontal summands. Let us choose a line $l\in H_3$ and let us define a mapping h_i for every $i\in I$ as follows: $h(0)=0$, $h(1)=1$; if P_i is a four element, then let us take an atom $a_i\in P_i$ and put $h(a_i)=l$, $h(a_i')=l'$; if P_i has more than four elements then every block has three atoms, and we put $h(a)=l$, $h(a')=l'$ for every atom

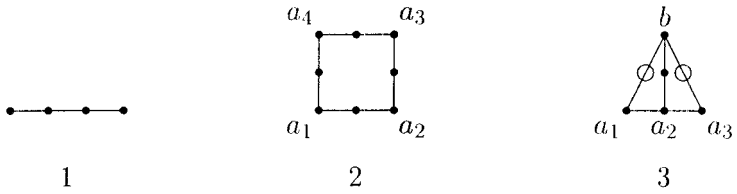

FIG. 6. Greechie diagrams of some orthomodular posets nonrealizable in H_3 (a•⊖•b is an abbreviation of the Greechie diagram in Fig. 2.2).

$a \in P_i$. It is easy to see that $h_i(P_i)$ is a weak realization of P_i in H_3 and that $\cup_{i \in I} h_i(P_i)$ is a weak realization of P in H_3.

The situation with realizability is more difficult and we do not know a characterization of it. Some results we will present in the next section. Let us now present another necessary condition.

Proposition 5.4: Every orthomodular poset realizable in H_3 is a lattice.

Proof: Let us suppose that P is an orthomodular poset with a loop of order 4 realizable in H_3 and seek a contradiction. There are nonzero mutually different elements $a_1 \perp a_2 \perp a_3 \perp a_4 \perp a_1$ in P (see Fig. 6.2). Since for every pair of different nonzero elements there is only one nonzero element in H_3 orthogonal to them, $a_1 = a_3$—a contradiction.

Examples of orthomodular posets nonrealizable in H_3 are given in Fig. 6. The first has a four-atomic block, the second is not a lattice. The third example is much more subtle and depends on the following intrinsic property of H_3.

Lemma 5.5: Let L be a realization of an orthomodular lattice given in Fig. 2.2. *Then $\angle(a,b) \in \langle \arccos 1/3, \pi/2)$. On the other hand, for every $\alpha \in \langle \arccos 1/3, \pi/2)$ there is a realization of L such that $\angle(a,b) = \alpha$.*

Proof [See also Ref. 17]: Let us choose a coordinate system such that $c = \mathrm{Sp}(1,0,0)$, $d = \mathrm{Sp}(0,1,0)$. Hence $e = \mathrm{Sp}(0,0,1)$. Since $c_a \perp c$ and $d_b \perp d$, there are $x, y \in \mathbf{R} \setminus \{0\}$ such that

$$c_a = \mathrm{Sp}(0,y,1), \quad d_b = \mathrm{Sp}(x,0,1).$$

Since $c_b \perp c$, c_a and $d_a \perp d$, d_b, $a \perp c_a$, d_a, and $b \perp c_b$, d_b, we obtain

$$c_b = \mathrm{Sp}(0,-1,y), \quad d_a = \mathrm{Sp}(-1,0,x),$$

$$a = \mathrm{Sp}(xy,-1,y), \quad b = \mathrm{Sp}(-1,xy,x).$$

Thus, using an elementary calculus,

$$\cos\angle(a,b) = \frac{|xy|}{\sqrt{(1+x^2+x^2y^2)(1+y^2+x^2y^2)}} \in \left\langle 0, \frac{1}{3} \right\rangle.$$

For an arbitrary $\alpha \in (\arccos 1/3, \pi/2)$ we can solve this equation and obtain, e.g.,

$$x = y = \sqrt{\frac{1/\cos\,\alpha - 1}{2} - \sqrt{\left(\frac{1/\cos\,\alpha}{2}\right)^2 - 1}}.$$

For $\alpha = \arccos 1/3$ we have exactly one realization (two different solutions given by the symmetry of the Greechie diagram). In Fig. 4.2 there is an example such that symmetries of the

realization are easily seen (with respect to the axis o of a and b and to planes $\mathrm{Sp}\{a,b\}$, $\mathrm{Sp}\{o,a\times b\}$). For $\alpha\in(\arccos 1/3,\pi/2)$ we have two different realizations (each symmetric with respect to the axis of a and b).

The orthomodular lattice given in Fig. 6.3 is not realizable, because for every triple a_1, a_2, $a_3\in H_3$ of mutually orthogonal nonzero elements and for every $b\in H_3$ there is an $i\in\{1,2,3\}$ such that $\angle(b,a_i)\leqslant\arccos 1/\sqrt{3}$.

Let us note that in Ref. 17 the above lemma is also stated for $\alpha=\pi/2$. This is not true, because then either $x=0$ or $y=0$ and we obtain only a weak realization.

VI. SUBORTHOPOSETS OF H_3

We would like to present examples of orthomodular lattices orthorepresentable in H_3. To ensure that an orthomodular lattice is orthorepresentable in H_3 it suffices to find its realization in H_3 such that there are not ordered (orthogonal, resp.) pairs other than it was intended, e.g., it can be easily verified that an orthomodular lattice given in Fig. 2.2 is orthorepresentable in H_3 (see Fig. 4.2). We present partial results that orthomodular lattices are orthorepresentable (realizable, resp.) in H_3. The idea of their proofs is that we can find uncountable many (continuum) weak realizations while only for a countable many of them some images coincide or, in case of orthorepresentability, give a new ordered (orthogonal, resp.) pair.

We show that there is a large class of infinite suborthoposets of H_3 with a full set of two-valued states.

Proposition 6.1: Every horizontal sum of countable many countable orthomodular lattices orthorepresentable (realizable, resp.) in H_3 is orthorepresentable (reliazable, resp.) in H_3.

Proof: It suffices to prove this proposition for two summands (we can proceed by induction). Let L_1, L_2 be their orthorepresentations (realizations, resp.) in H_3. It suffices to prove that we can rotate L_2 to L_2 such that $a_1\not\perp za_2$ and $a_2\not\perp a_1$ for every $a_1\in L_1\backslash\{0,1\}$ and for every $a_2\in L_2\backslash\{0,1\}$, i.e. such that $l\not\perp\cup(L_1\backslash\{1\})$ for every line $l\in L_2$. If $L_2=\{0,1\}$ then the proof is complete. Let us suppose that $L_2\neq\{0,1\}$. Then there is a line $l_0\in L_2$. Since $\cup(L_1\backslash\{1\})\neq\mathbf{R}^3$ there is a line $\overline{l_0}\not\perp\cup(\mathrm{L}_1\backslash\{1\})$ and we can rotate L_2 such that l_0 goes to l_0. Rotating now the image of L_2 around l_0 we obtain an uncountable many possibilities, while for only a countable many of them there is a line $l\in L_2$ such that $l\subseteq\cup(L_1\backslash\{1\})$. Indeed, for every $l\in L_2$ all possible positions of l in a unit sphere $S(0,1)$ in $\mathbf{R}^3$ form a circle C with the center on l_0, while, for every $a\in L_1\backslash\{1\}$, $a\cap S(0,1)$ is either a two-element set (a is a line) or a circle not identical to C; hence $a\cap S(0,1)\cap C$ is at most a two-element.

Proposition 6.2: Every pasting for an atom of a pair of countable orthomodular lattices orthorepresentable (realizable, resp.) in H_3 is orthorepresentable (realizable, resp.) in H_3.

Proof: If we paste for an atom in a two-atomic block then we obtain a horizontal sum and the proof follows from Proposition 6.1. Let us suppose that we paste for atoms in three-atomic blocks. Let L_1, L_2 be orthorepresentations (realizations, resp.) in H_3 of given orthomodular lattices such that $L_1\cap L_2\ni l_0$, where l_0 represents the atom in both L_1, L_2 for which we paste. It suffices to prove that there is a rotation L_2 of L_2 around the line l_0 such that $a_1\not\perp a_2$ and $a_2\not\perp a_1$ for every $a_1\in L_1\backslash\{0,1,l_0,l_0'\}$ and for every $a_2\in L_2\backslash\{0,1,l_0,l_0'\}$, i.e., such that $l\not\perp\cup(L_1\backslash\{1,l_0'\})$ for every line $l\in L_2$. This gives only countable many restrictions to uncountable possible positions of L_2, hence the proof is complete.

Corollary 6.3: Every countable Greechie logic with at most three atomic blocks and without any loop is orthorepresentable in H_3.

Proof: Every countable Greechie logic with only finite at most three atomic blocks is a horizontal sum of subsequent countable pastings of finite three-atomic Boolean algebras for an atom. The rest follows from Theorem 4.2, Proposition 6.2 (using the induction) and Proposition 6.1.

According to Proposition 3.10, Greechie logics from the above Corollary have a full set of two-valued states.

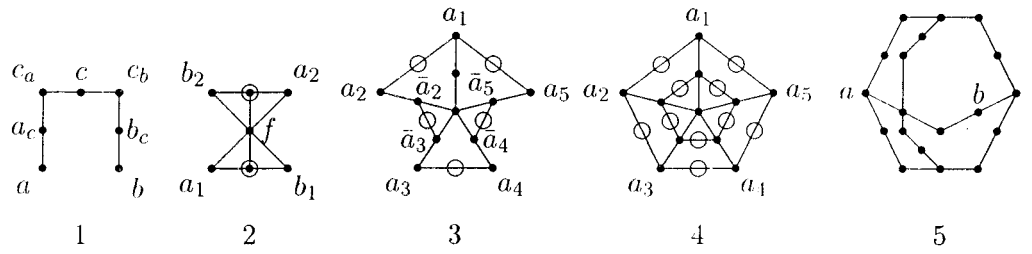

FIG. 7. Greechie diagrams of orthomodular lattices weakly realizable in H_3.

Lemma 6.4: Let L_1 be a countable orthomodular lattice orthorepresentable (realizable, resp.) in H_3 and L_2 be an orthomodular lattice given in Fig. 7.1 such that $L_1 \cap L_2 = \{0,a,b,a',b',1\}$ and $a \neq b$ are nonorthogonal atoms in L_1 (in its realization, resp.). Then the pasting of L_1 and L_2 is orthorepresentable (realizable, resp.) in H_3.

Proof: Let us suppose that L_1 is an orthorepresentation (realization, resp.) in H_3 of a given orthomodular lattice. If a (b, resp.) is a two-dimensional subspace of H_3 then a (b, resp.) is a part of a four-element horizontal summand, and this summand might be considered as a part of L_2. The proof then follows from Proposition 6.2. Let us suppose that a, b are lines. Let us consider all atoms $c_a \leqslant a'$. We have uncountable many possibilities that fill in the unit sphere $S(0,1)$ a circle C_a. Of course, $c_a \leqslant a'$ and $a_c = a' \wedge c_a' \leqslant a'$ but all other ordering of c_a and a_c with elements of $L_1 \backslash \{0,1\}$ can be excluded if we exclude a countable many possibilities. Similarly, if positions of c_a fill a circle C_a then positions of $c_b \perp c_a$, b fill a circle $C_b \subset b'$ ($a \not\perp b$). Again, there is only a countable many positions of c_a for which either c_b or $b_c = b' \wedge c_b'$ is ordered with some element of $L_1 \backslash \{0,1,b'\}$. Finally, it can be shown that positions of c fill a smooth curve on $S(0,1)$, which is not a circle. Hence, there is a possibility to choose c_a such that we obtain the desired orthorepresentation (realization, resp.).

Proposition 6.5: Let $n \geqslant 5$ be a natural number and let $B_1,...,B_n$ be finite three-atomic Boolean algebras such that $B_i \cap B_{i+1} = \{0,a_i,a_i',1\}$ for every $i \in \{1,...,n\}$, where $B_{n+1} = B_1$ and $a_1,...,a_n$ are mutually different atoms. Then the pasting of $\{B_1,...,B_n\}$ (so-called n-cycle) is orthorepresentable in H_3.

Proof: It follows from Proposition 6.2 and from Lemma 6.4.

VII. KOCHEN–SPECKER-TYPE CONFIGURATIONS

We will give several examples of Kochen–Specker-type configurations that arise from Greechie diagrams. Some of these examples has been already used in the literature in the attempt to find a subset of H_3 without a two-valued state. We present the connection to Greechie diagrams (this gives a better geometric insight), show a nonexistence of a ''large'' set of two-valued states for various concepts, and, moreover, we do not stop in proving weak realizability but we discuss the real number of elements.

Proposition 7.1: There is a finite suborthoposet of H_3 such that the set of two-valued states on it is not full.

Proof: Let us consider a suborthoposet L of H_3 given in Fig. 4.2. It is an orthorepresentation of an orthomodular lattice given in Fig. 2.2, it is 28 element (13 atomic), and the set of two-valued states on L is not full [see the proof of Proposition 3.11.(1)]. In fact, in the proof of Proposition 3.11(1) it was shown that there is no two-valued state on the eight-element set $\{a,c_a,d_a,c,d,c_b,d_b,b\}$, such that $s(a)=s(b)=1$ (a reformulation of fullness—see Proposition 3.5). This orthomodular lattice can be orthogenerated, e.g., by the six-element set $\{a,c_a,c_b,b,d_b,d_a\}$ and generated, e.g., by the three-element set $\{a,c_b,d_b\}$.

Proposition 7.2: There is a finite suborthoposet of H_3 such that the set of two-valued states on it is not separating.

Proof: Let us consider an orthomodular lattice given in Fig. 2.3. It is an orthomodular lattice without a separating set of two-valued states [see the proof of Proposition 3.11.(2)]. It has 56 elements (27 atoms) and a 17-element subset without a separating set of states (five marked and six ''hidden'' in every circle). It can be checked that it has the following realization (which forms a suborthoposet of H_3 given in Fig. 7.2—points in the circles denote the middle elements of the diagram from Fig. 2.2): $f=\mathrm{Sp}(0,0,1)$, a_1•⊖•b_1 given by Fig. 4.2; a_2•⊖•b_2 we obtain from the representation on Fig. 4.2 rotating by $\pi/2$ around f. There is a ten-element set of orthogenerators (e.g., $\{a_1,b_1,c_{a1},c_{b1},d_{a1},d_{b1},f,c_2,c_{b2},d_{b2}\}$) and a four-element set of generators (e.g., $\{a_1,c_{b1},d_{b1},c_{b2}\}$).

Let us note that we can take a realization of an orthomodular lattice given in Fig. 2.2, such that we obtain an orthorepresentation of the orthomodular lattice given in Fig. 2.3, but the set of (ortho)generators is larger in this case.

Proposition 7.3: There is a finite suborthoposet of H_3 such that the set of two-valued states on it is not unital.

Proof: Let us consider an orthomodular lattice L given in Fig. 7.3. It is an orthomodular lattice without a unital set of two-valued states. Indeed, for every two-valued state s on L with $s(a_1)=1$ we have $s(f)=s(a_2)=s(a_5)=0$, $s(\overline{a_2})=s(\overline{a_5})=1$, $s(\overline{a_3})=s(\overline{a_4})=0$, $s(a_3)=s(a_4)=1$-a contradiction. It has 132 elements (65 atoms) and a 40-element subset without a unital set of states (six hidden in every circle and all marked a_i's and $\overline{a_i}$'s). Let us find a weak realization of L. It can be done as follows: Put $f=\mathrm{Sp}(0,0,1)$, $a_1=\mathrm{Sp}(1,0,0)$, $\overline{a_1}=\mathrm{Sp}(0,1,0)$, and let $a_k,\overline{a_k}(k=2,\ldots,5)$ be images of $a_1,\overline{a_1}$ in rotations around f about $k\cdot 72°$. Find a realization of the orthomodular lattice given in Fig. 2.2 such that the angle of images of a,b is 72° (see the proof of Lemma 5.5) and rotate this realization to the following pairs of lines: (a_1,a_2), $(\overline{a_2},\overline{a_3})$, (a_3,a_4), $(\overline{a_4},\overline{a_5})$, (a_5,a_1) (i.e., a goes to the first and b to the second line for every pair). It can be checked that an orthomodular poset orthogenerated by this weak realization is finite. (In fact, it is a weak realization of an orthomodular lattice given in Fig. 7.4 by the same way.)

It can be shown that if we take the realization of the orthomodular lattice given in Fig. 2.2 such that the angle between a and b is equal to 72° by the expression given in the proof of Lemma 5.5 as the first copy and if the second and the third copy arise by rotations around the axis of the plane given by a and b such that b coincides with a of the next copy, then some elements coincide:

$$(c_a,c,c_b,b_c,b,b_d,d_b)_1=(d,d_b,d_a,a_d,a,a_c,c_a)_2,$$

$$(c,d_b,d,d_a,e)_1=(c_a,d,c,e,c_b)_3.$$

(The index denotes the number of the copy.) Hence, the weak realization of the orthomodular lattice from the above proof gives a 29-element subset of H_3 without a unital set of two-valued states and the suborthoposet orthogenerated by it has 104 elements (51 atoms), is orthogenerated by a 16-element set and generated by a four-element set (e.g., elements a, c_b, d_b of some $a????b$ and some element from the inner ''pentagon''). The ''almost'' Greechie diagram (20 points that belong to exactly one edge are for simplicity omitted) of this suborthoposet of H_3 (realization of the orthomodular lattice given in Fig. 7.4) is given in Fig. 8, with

$$a_1=\mathrm{Sp}(1,\quad 0,\quad 0),$$

$$a_2=\mathrm{Sp}(\sqrt{3-\sqrt{5}},\quad \sqrt{5+\sqrt{5}},\quad 0),$$

$$a_3=\mathrm{Sp}(-\sqrt{3+\sqrt{5}},\quad \sqrt{5-\sqrt{5}},\quad 0),$$

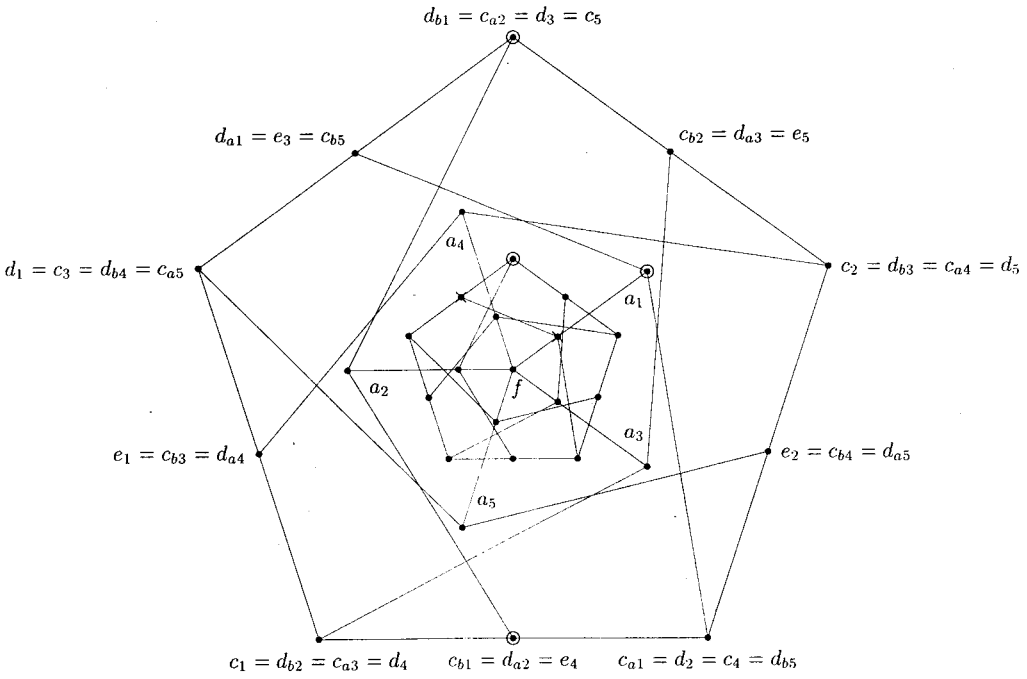

FIG. 8. ''Almost'' Greechie diagram of a suborthoposet of H_3 without a unital set of two-valued states.

$$a_4 = \mathrm{Sp}(-\sqrt{3+\sqrt{5}},\quad -\sqrt{5-\sqrt{5}},\quad 0),$$

$$a_5 = \mathrm{Sp}(\sqrt{3-\sqrt{5}},\quad -\sqrt{5+\sqrt{5}},\quad 0),$$

$$c_{a1} = \mathrm{Sp}(0,-\sqrt{-1+\sqrt{5}},\quad 1),$$

$$d_{a1} = \mathrm{Sp}(0,\quad \sqrt{2},\sqrt{-2+\sqrt{5}}),$$

$$c_1 = \mathrm{Sp}(\sqrt{\sqrt{5}},\quad \sqrt{2+\sqrt{5}},\quad \sqrt{3+\sqrt{5}}),$$

$$d_1 = \mathrm{Sp}(-\sqrt{\sqrt{5}},-\sqrt{-2+\sqrt{5}},\quad \sqrt{2}),$$

$$c_{b1} = \mathrm{Sp}(-\sqrt{5+\sqrt{5}},\quad \sqrt{3-\sqrt{5}},2\sqrt{-2+\sqrt{5}}),$$

$$d_{b1} = \mathrm{Sp}(\sqrt{\sqrt{5}},-\sqrt{-2+\sqrt{5}},\quad \sqrt{2}),$$

$$e_1 = \mathrm{Sp}(\sqrt{\sqrt{5}},\quad -\sqrt{2+\sqrt{5}},\quad \sqrt{3-\sqrt{5}}),$$

$$c_2 = \mathrm{Sp}(-\sqrt{\sqrt{5}},\quad \sqrt{2+\sqrt{5}},\quad \sqrt{3+\sqrt{5}}),$$

$$c_{b2} = \mathrm{Sp}(-\sqrt{\sqrt{5}},\quad -\sqrt{2+\sqrt{5}},\quad \sqrt{3-\sqrt{5}}),$$

$$e_2 = \mathrm{Sp}(\sqrt{5+\sqrt{5}},\quad \sqrt{3-\sqrt{5}},2\sqrt{-2+\sqrt{5}}),$$

$$f = \mathrm{Sp}(0,\quad 0,\quad 1).$$

Elements of the 29-element subset without a unital set of two-valued states are all marked points that are not crossed, a set of orthogenerators is e.g., the set of vertices of both pentagons with a_i's and with the middle point, a set of generators is marked by circles.

It should be noted that in Refs. 8 and 18 there is an example of an 11-element set of lines orthogenerating a 25-element set of lines and a 76-element (37-atomic) suborthoposet of H_3 without a unital set of two-valued states. This suborthoposet is generated by a three-element set. The Greechie diagram of this example does not seem to provide an easy survey, hence we omit it. A more detailed description of this example is given in Sec. VIII.

Proposition 7.4: There is a finite suborthoposet of H_3 such that the set of two-valued states on it is empty.

Proof: Let us consider an orthomodular lattice L, which is the pasting of the orthomodular lattice given in Fig. 7.3 for a_1 and of the orthomodular lattice given in Fig. 7.4 for its middle point. It is an orthomodular lattice without any two-valued state. Indeed, if s is a two-valued state on L then $s(a_1)=0$ (see above). Analogously from the other diagram, $s(a_1)=1$—a contradiction. It has 374 elements (186 atoms) and a 110-element subset without any two-valued state (six ''hidden'' in every circle and all marked except two of them—a_1 and $\overline{a_1}$). According to Proposition 6.2, this orthomodular poset is weakly realizable in H_3.

It can be shown that we can paste for the whole block and obtain a weak realization, which is a union of weak realizations of two copies of an orthomodular lattice given in Fig. 7.4. Hence, this suborthoposet has 200 elements (99 atoms) and a 58-element subset without any two-valued state.

It should be noted that in Ref. 6 there is an example of a 33-element set of lines without any two-valued state. Direction vectors of these lines arise by all permutations of coordinates from (0,0,1), $(0,\pm1,1)$ $(0,\pm1,\sqrt{2})$, and $(\pm1,\pm1,\sqrt{2})$. This set of lines orthogenerates a suborthoposet of H_3 with 116 elements (57 atoms). Direction vectors of remaining lines arise by all permutations of coordinates from $(\pm1,\pm3,\sqrt{2})$. This suborthoposet of H_3 has a 17-element set of orthogenerators (e.g., lines with direction vectors (0,0,1), (0,1,0) and all coordinate permutations from $(0,1,\sqrt{2})$, $(1,\pm1,\sqrt{2})$) and a three-element set of generators [e.g., lines with direction vectors (1,0,0), (1,1,0), $(\sqrt{2},1,1)$]. The ''almost'' Greechie diagram (24 points that belong to exactly one edge are, for simplicity, omitted) of this example is given in Fig. 9 (one edge is denoted by a circle). The above-mentioned three-element set of generators is marked by circles.

Corollary 7.5: There is a three-element set of lines in H_3 such that no subortholattice of H_3 containing it has a two-valued state.

It seems to be an open question whether every three-element set of mutually nonorthogonal lines in H_3 generates a subortholattice without any two-valued state. The least numbers in constructions are given in Table I.

Let us note that the examples in Proposition 7.1 and in Proposition 7.2 appeared in Ref. 17, the example in Fig. 7.4 appeared (not explicitly) in Refs. 17 and 5 as a part of their construction. In Ref. 19 the author uses (not explicitly) the orthomodular lattice given in Fig. 7.3 and paste three copies to distinct atoms of a block obtaining thus an orthomodular lattice without any two-valued state (however, his estimation of lines does not seem to be correct).

In Ref. 7 the author uses weak realizability of an orthomodular lattice in Fig. 7.5 whenever we represent elements a, b by lines in H_3, such that their angle is less than 45°. This leads to the construction of an orthomodular lattice with 392 elements (146 atoms) weakly realizable in H_3 and (at most) 130-element set of lines without any two-valued state.

VIII. DISCUSSION OF PHYSICAL RELEVANCE

In this final section we shall give a brief review of the physical relevance of the above findings. The nonexistence of two-valued measures on certain finite propositional structures in three-dimensional Hilbert spaces has first been explicitly demonstrated by Kochen and Specker.[17] It is strongly recommended that this original account be read. Their result has given rise to a

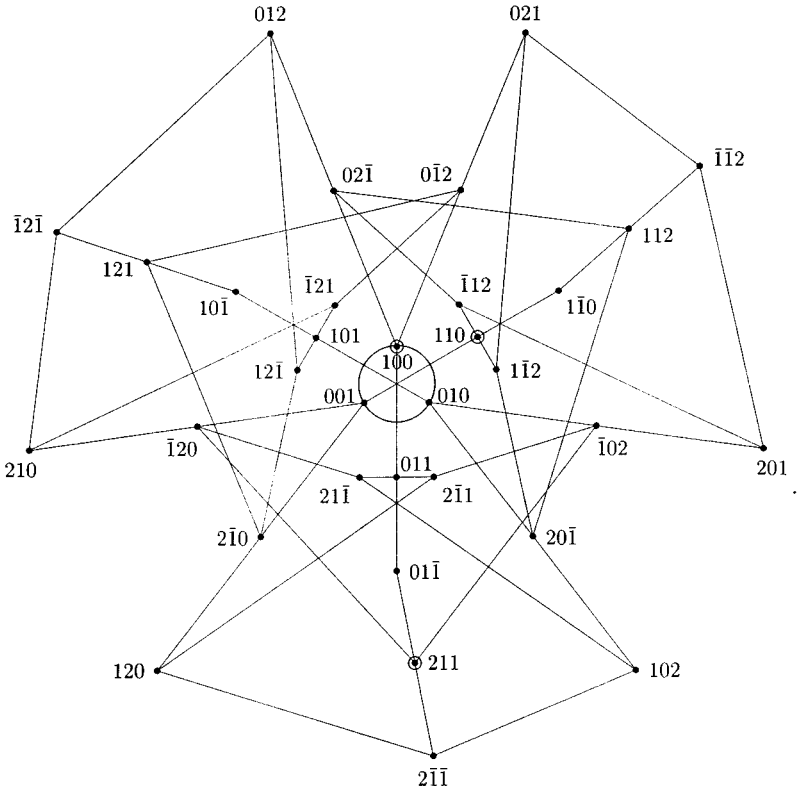

FIG. 9. ''Almost'' Greechie diagram of a suborthoposet of H_3 without any two-valued state [e.g., 1!2 denotes $\mathrm{Sp}(1,-1,\sqrt{2})$].

number of interpretations, by Kochen and Specker and others. A detailed overview of the history of the subject can, for instance, be found in the reviews by Mermin[7] and Brown.[20]

What does it physically mean that *three* nonorthogonal rays in three-dimensional Hilbert space are sufficient to generate a finite system of rays that have no two-valued state? To state the associated Kochen–Specker paradox explicitly, let us associate any one-dimensional subspace $\mathrm{Sp}(v)$ spanned by a nonzero vector v with the proposition that the physical system is in a pure state associated with that subspace. That is,

$$\mathrm{Sp}(1,0,0)=a, \quad \mathrm{Sp}(1,1,0)=b, \quad \mathrm{Sp}(\sqrt{2},1,1)=c,$$

TABLE I. Numbers of elements of constructed propositional structures in H_3 without a ''large'' set of two-valued states.

''Large:''	Full	Separating	Unital		Nonempty
Example (figure)	4.2	7.2	cf. Refs. 8,18	8	9
Elements of a suborthoposet	28	56	76	104	116
Atoms of a suborthoposet	13	27	37	51	57
Lines	8	17	25	29	33
Orthogenerators	6	9	11	16	17
Generators	3	4	3	4	3

where a, b, and c are propositions. If a (similar for b and c) is measured, then we associate the logical value ''true'' or ''false'' with the two-valued state function $s(a)=1$ and $s(a)=0$, respectively. a, b, c generate the propositional structure derived by Peres[6] (cf. also Ref. 21, pp. 186–190). That is, if v and w are two vectors in three-dimensional Hilbert space corresponding to the propositions p_v and p_w, respectively, then the vector product $v\times w$ corresponds to the proposition $(p_v\vee p_w)'$. In particular,

$$\mathrm{Sp}(1,0,0)=a,$$

$$\mathrm{Sp}(1,1,0)=b,$$

$$\mathrm{Sp}(\sqrt{2},1,1)=c,$$

$$\mathrm{Sp}(0,0,1)=(\mathrm{Sp}(1,0,0)\vee\mathrm{Sp}(1,1,0))'=(a\vee b)',$$

$$\mathrm{Sp}(0,1,-1)=(\mathrm{Sp}(1,0,0)\vee\mathrm{Sp}(\sqrt{2},1,1))'=(a\vee c)',$$

$$\mathrm{Sp}(0,1,0)=(\mathrm{Sp}(1,0,0)\vee\mathrm{Sp}(0,0,1))'=(a\vee(a\vee b)')',$$

$$\mathrm{Sp}(0,1,1)=(\mathrm{Sp}(1,0,0)\wedge\mathrm{Sp}(0,1,-1))'=(a\vee(a\vee c)')',$$

$$\mathrm{Sp}(1,-1,0)=(\mathrm{Sp}(1,1,0)\vee\mathrm{Sp}(0,0,1))'=(b\vee(a\vee b)')',$$

$$\mathrm{Sp}(-1,\sqrt{2},0)=(\mathrm{Sp}(\sqrt{2},1,1)\vee\mathrm{Sp}(0,0,1))'=(c\vee(a\vee b)')',$$

$$\mathrm{Sp}(\sqrt{2},-1,-1)=(\mathrm{Sp}(\sqrt{2},1,1)\vee\mathrm{Sp}(0,1,-1))'=(c\vee(a\vee c)')',$$

$$\mathrm{Sp}(-1,0,\sqrt{2})=(\mathrm{Sp}(\sqrt{2},1,1)\vee\mathrm{Sp}(0,1,0))'=(c\vee(a\vee(a\vee b)')')',$$

$$\mathrm{Sp}(\sqrt{2},1,0)=(\mathrm{Sp}(0,0,1)\vee\mathrm{Sp}(-1,\sqrt{2},0))'=((a\vee b)'\vee(c\vee(a\vee b)')')',$$

$$\mathrm{Sp}(1,\sqrt{2},0)=(\mathrm{Sp}(0,0,1)\vee\mathrm{Sp}(\sqrt{2},-1,-1))'=((a\vee b)'\vee(c\vee(a\vee c)'))')',$$

$$\mathrm{Sp}(1,0,\sqrt{2})=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(\sqrt{2},-1,-1))'=((a\vee(a\vee b)')'\vee(c\vee(a\vee c)')')',$$

$$\mathrm{Sp}(\sqrt{2},1,-1)=(\mathrm{Sp}(0,1,1)\vee\mathrm{Sp}(-1,\sqrt{2},0))'=(a\vee(a\vee c)')'\vee(c\vee(a\vee b)'))')',$$

$$\mathrm{Sp}(\sqrt{2},0,1)=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(-1,0,\sqrt{2}))'=((a\vee(a\vee b)')'\vee(c\vee(a\vee(a\vee b)')')')',$$

$$\mathrm{Sp}(\sqrt{2},-1,0)=(\mathrm{Sp}(0,0,1)\vee\mathrm{Sp}(1,\sqrt{2},0))'=((a\vee b)'\vee((a\vee b)'\vee(c\vee(a\vee c)')')')',$$

$$\mathrm{Sp}(\sqrt{2},-1,1)=(\mathrm{Sp}(0,1,1)\vee\mathrm{Sp}(-1,0,\sqrt{2}))'=((a\vee(a\vee c)')'\vee(c\vee(a\vee(a\vee b)')')')',$$

$$\mathrm{Sp}(-1,1,\sqrt{2})=(\mathrm{Sp}(1,1,0)\vee\mathrm{Sp}(\sqrt{2},0,1))'=(b\vee((a\vee(a\vee b)')'\vee(c\vee(a\vee(a\vee b)')')')')',$$

$$\begin{aligned}\mathrm{Sp}(0,\sqrt{2},-1)&=(\mathrm{Sp}(1,0,0)\vee\mathrm{Sp}(-1,1,\sqrt{2}))'\\&=(a\vee(b\vee((a\vee(a\vee b)')'\vee(c\vee(a\vee(a\vee b)')')')')')',\end{aligned}$$

$$\begin{aligned}\mathrm{Sp}(\sqrt{2},0,-1)&=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(1,0,\sqrt{2}))'\\&=((a\vee(a\vee b)')'\vee((a\vee(a\vee b)')'\vee(c\vee(a\vee c)')')')',\end{aligned}$$

$$\mathrm{Sp}(1,-1,\sqrt{2}) = (\mathrm{Sp}(1,1,0) \vee \mathrm{Sp}(-1,1,\sqrt{2}))'$$
$$= (b \vee (b \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')')',$$

$$\mathrm{Sp}(0,1,\sqrt{2}) = (\mathrm{Sp}(1,0,0) \vee \mathrm{Sp}(0,\sqrt{2},-1))'$$
$$= (a \vee (a \vee (b \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')')')',$$

$$\mathrm{Sp}(0,\sqrt{2},1) = (\mathrm{Sp}(1,0,0) \vee \mathrm{Sp}(1,-1,\sqrt{2}))'$$
$$= (a \vee (b \vee (b \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')')')',$$

$$\mathrm{Sp}(-1,-1,\sqrt{2}) = (\mathrm{Sp}(1,-1,0) \vee \mathrm{Sp}(\sqrt{2},0,1))'$$
$$= ((b \vee (a \vee b)')' \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')',$$

$$\mathrm{Sp}(0,-1,\sqrt{2}) = (\mathrm{Sp}(1,0,0) \vee \mathrm{Sp}(0,\sqrt{2},1))'$$
$$= (a \vee (a \vee (b \vee (b \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')')')')',$$

$$\mathrm{Sp}(1,1,\sqrt{2}) = (\mathrm{Sp}(1,-1,0) \vee \mathrm{Sp}(0,\sqrt{2},-1))'$$
$$= ((b \vee (a \vee b)')' \vee (a \vee (b \vee ((a \vee (a \vee b)')' \vee (c \vee (a \vee (a \vee b)')')')')')')',$$

$$\mathrm{Sp}(-1,\sqrt{2},-1) = (\mathrm{Sp}(\sqrt{2},1,0) \vee \mathrm{Sp}(0,1,\sqrt{2}))'$$
$$= (((a \vee b)' \vee (c \vee (a \vee b)')')' (a \vee (a \vee (b \vee ((a \vee (a \vee b)')'$$
$$\vee (c \vee (a \vee (a \vee b)')')')')')')',$$

$$\mathrm{Sp}(-1,\sqrt{2},1) = (\mathrm{Sp}(\sqrt{2},1,0) \vee \mathrm{Sp}(0,-1,\sqrt{2}))'$$
$$= (((a \vee b)' \vee (c \vee (a \vee b)')')' \vee (a \vee (a \vee (b \vee (b \vee ((a \vee (a \vee b)')'$$
$$\vee (c \vee (a \vee (a \vee b)')')')')')')')',$$

$$\mathrm{Sp}(1,\sqrt{2},-1) = (\mathrm{Sp}(\sqrt{2},-1,0) \vee \mathrm{Sp}(0,1,\sqrt{2}))'$$
$$= (((a \vee b)' \vee ((a \vee b)' \vee (c \vee (a \vee c)')')')' \vee (a \vee (a \vee (b \vee ((a \vee (a \vee b)')'$$
$$\vee (c \vee (a \vee (a \vee b)')')')')')')')',$$

$$\mathrm{Sp}(-1,0,1) = (\mathrm{Sp}(0,1,0) \vee \mathrm{Sp}(-1,\sqrt{2},-1))'$$
$$= ((a \vee (a \vee b)')' \vee (((a \vee b)' \vee (\vee (a \vee b)')')'$$

Suppose, for the sake of contradiction, that each one of the above 33 propositions corresponds to an ''element of physical reality''.[22] That is, suppose that its value is either ''true'' (exclusive) or ''false,'' irrespective of whether it has been actually measured or just counterfactually inferred. Let us further assume with Peres[6,21] that—provided these ''elements of reality'' exist—$\mathrm{Sp}(0,0,1) = \mathrm{Sp}(1,0,1) = \mathrm{Sp}(0,1,1) = \mathrm{Sp}(1,-1,\sqrt{2}) = \mathrm{Sp}(1,0,\sqrt{2}) = \mathrm{Sp}(\sqrt{2},1,1) = \mathrm{Sp}(\sqrt{2},0,1) = \mathrm{Sp}(1,1,\sqrt{2}) = \mathrm{Sp}(0,1,\sqrt{2}) = \mathrm{Sp}(1,\sqrt{2},1) =$ ''true.'' One can follow Peres' arguments to show that—provided these ''elements of reality'' exist—all other rays belong to triads that are orthogonal to the above rays. Therefore, these latter rays must correspond to propositions whose value is ''false.'' In particular, $\mathrm{Sp}(1,0,0) = \mathrm{Sp}(0,\sqrt{2},1) = \mathrm{Sp}(0,-1,\sqrt{2}) =$ ''false,'' associate with $s(\mathrm{Sp}(1,0,0)) = s(\mathrm{Sp}(0,\sqrt{2},1)) = s(\mathrm{Sp}(0,-1,\sqrt{2})) = 0$. Thus, $s(\mathrm{Sp}(1,0,0)) + s(\mathrm{Sp}(0,\sqrt{2},1)) + s(\mathrm{Sp}(0,-1,\sqrt{2})) = 0+0+0 = 0$. But $\mathrm{Sp}(1,0,0)$, $\mathrm{Sp}(0,\sqrt{2},1)$, and $\mathrm{Sp}(0,-1,\sqrt{2})$ are mutually orthogonal. This is in contradiction to the assumption that for any orthogonal triad spanning the entire Hilbert space, the sum of the measures should be one [cf. Definition 3.1.(4)]. Notice that in order to arrive at this Kochen–Specker paradox, we had to explicitly assume the existence of the ''elements of reality,'' irrespective of whether they have (or could have) actually been measured or not.

What physical use can be a paradox? How can one measure a contradiction? Indeed, what can actually be measured is merely *one* triplet of propositions corresponding to some of the triads of mutually orthogonal rays. Such a measurement can be performed with the operator discussed by Peres, or with an arrangement of beam splitters discussed by Reck *et al.*[23]

For instance, after c is found to be ''true'' [corresponding to $s(c) = 1$], then measurement of the original values of a or b is no longer possible. However, suppose one would be willing to believe in the existence of ''elements of reality,''[22,24] which could merely be *counterfactually* inferred. Then one could for instance—at least in principle—''measure'' all 16 orthogonal triads by the production of a state with 16 entangled subsystems. On each one of the 16 different entangled subsystems one could measure one of the 16 different orthogonal triads. This is similar to a proposal by Greenberger, Horne, and Zeilinger,[25] which use three particles and eight-dimensional Hilbert space. Indeed, only in such a way—namely by (counterfactually) inferring noncomeasurable propositions—one would encounter a complete Kochen–Specker contradiction.

As has been already proven in the Kochen and Specker original work (cf. Ref. 17, pp. 82–85, Theorem 4), the notion of tautology is connected to a classical (Boolean) imbedding of a partial Boolean algebra. Indeed, there exist propositions that are tautologies in the classical (Boolean) algebra but that are not tautologies in the partial Boolean algebra if and only if the partial Boolean algebra does not have a unital set of two-valued states and thus cannot be imbedded into a classical (Boolean) algebra.

This is true for all partial Boolean algebras, in particular for orthomodular posets. Notice that the above result does not imply that every propositional structure giving rise to a (classical) Boolean tautology that is no quantum tautology also has no two-valued measure (cf. below).

Until now, the lowest number of rays necessary to produce a classical tautology that is not always true quantum mechanically is due to Schütte.[8,18] The 11 rays used by Schütte can also be generated by the three vectors (1,0,0), (1,1,0), and $(\sqrt{2},1,1)$ (corresponding to a, b, and c) used before. Indeed, $d = \mathrm{Sp}(0,1,-1) = (\mathrm{Sp}(1,1,0) \vee \mathrm{Sp}(\sqrt{2},1,1))' = (a \vee c)'$ and

$$a_1 = \mathrm{Sp}(1,0,0) = a,$$

$$a_2 = \mathrm{Sp}(0,1,0) = (\mathrm{Sp}(1,0,0) \vee \mathrm{Sp}(0,0,1))' = (a \vee (a \vee b)')',$$

$$b_1=\mathrm{Sp}(0,1,1)=(Sp(1,0,0)\vee Sp(0,1,-1))'=(a\vee d)',$$

$$b_2=\mathrm{Sp}(1,0,1)=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(-1,1,1))'=((a\vee(a\vee b)')'\vee(b\vee d)')',$$

$$b_3=\mathrm{Sp}(1,1,0)=b,$$

$$c_1=\mathrm{Sp}(1,0,2)=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(2,1,-1))'=((a\vee(a\vee b)')'\vee((a\vee d)'\vee(b\vee(a\vee d)')')')',$$

$$c_2=\mathrm{Sp}(2,0,1)=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(-1,0,2))'=((a\vee(a\vee b)')'\vee((a\vee(a\vee b)')'\vee((a\vee d)'\vee((a\vee d)'\vee(b\vee(a\vee b)')')')')',$$

$$d_1=\mathrm{Sp}(-1,1,1)=(\mathrm{Sp}(1,1,0)\vee\mathrm{Sp}(0,1,-1))'=(b\vee d)',$$

$$d_2=\mathrm{Sp}(1,-1,1)=(\mathrm{Sp}(1,1,0)\vee\mathrm{Sp}(0,1,1))'=(b\vee(a\vee d)')',$$

$$d_3=\mathrm{Sp}(1,1,-1)=(\mathrm{Sp}(0,1,1)\vee\mathrm{Sp}(1,-1,0))'=((a\vee d)'\vee(b\vee(a\vee b)')')',$$

$$d_4=\mathrm{Sp}(1,1,1)=(\mathrm{Sp}(0,1,-1)\vee\mathrm{Sp}(1,-1,0))'=(d\vee(b\vee(a\vee b)')')',$$

where

$$\mathrm{Sp}(2,1,-1)=(\mathrm{Sp}(0,1,1)\vee\mathrm{Sp}(1,-1,1))'=((a\vee d)'\vee(b\vee(a\vee d)')')',$$

$$\mathrm{Sp}(-1,0,2)=(\mathrm{Sp}(0,1,0)\vee\mathrm{Sp}(-2,1,-1))'=((a\vee(a\vee b)')'\vee((a\vee d)'\vee((a\vee d)'\vee(b\vee(a\vee b)')')')')',$$

$$\mathrm{Sp}(2,-1,1)=(\mathrm{Sp}(0,1,1)\vee\mathrm{Sp}(1,1,-1))'=((a\vee d)'\vee((a\vee d)'\vee(b\vee(a\vee b)')')')'.$$

As we have mentioned above, there is not a unital set of two-valued states on a suborthoposet orthogenerated by these rays (e.g., there is no two-valued state s with $s(\mathrm{Sp}(1,0,0))=1$). On the other hand, a two-valued can be defined by $s(\mathrm{Sp}(0,1,0))=s(\mathrm{Sp}(0,1,1))=s(\mathrm{Sp}(1,1,0))=s(\mathrm{Sp}(1,1,1))=s(\mathrm{Sp}(1,1,2))=s(\mathrm{Sp}(1,2,1))=s(\mathrm{Sp}(2,1,1))=s(\mathrm{Sp}(1,2,-1))=s(\mathrm{Sp}(-1,2,1))=s(\mathrm{Sp}(1,5,2))=s(\mathrm{Sp}(2,5,1))=s(\mathrm{Sp}(-1,5,2))=s(\mathrm{Sp}(2,5,-1))=s(\mathrm{Sp}(1,5,-2))=s(\mathrm{Sp}(-2,5,1))=1$ and $s(\mathrm{Sp}(1,0,0))=s(\mathrm{Sp}(0,0,1))=s(\mathrm{Sp}(1,0,1))=s(\mathrm{Sp}(0,1,-1))=s(\mathrm{Sp}(1,0,-1))=s(\mathrm{Sp}(1,-1,0))=s(\mathrm{Sp}(1,1,-1))=s(\mathrm{Sp}(1,-1,1))=s(\mathrm{Sp}(-1,1,1))=s(\mathrm{Sp}(-1,-1,2))=s(\mathrm{Sp}(-1,2,-1))=s(\mathrm{Sp}(2,-1,-1))=s(\mathrm{Sp}(1,-1,2))=s(\mathrm{Sp}(-1,1,2))=s(\mathrm{Sp}(2,1,-1))=s(\mathrm{Sp}(2,-1,1))=s(\mathrm{Sp}(1,0,2))=s(\mathrm{Sp}(2,0,1))=s(\mathrm{Sp}(-1,0,2))=s(\mathrm{Sp}(2,0,-1))=s(\mathrm{Sp}(1,-5,2))=s(\mathrm{Sp}(2,-5,1))=0$.

Consider now the following propositions (notice that any binary operation is either performed by orthogonal rays or by a ray and an orthocomplement of another ray, such that these rays are orthogonal):

$$f_1=d_1\rightarrow b_2'=(d_1\wedge b_2)',$$

$$f_2=d_1\rightarrow b_3'=(d_1\wedge b_3)',$$

$$f_3=d_2\rightarrow a_2\vee b_2=(d_2\wedge(a_2\vee b_2)')',$$

$$f_4=d_2\rightarrow b_3'=(d_2\wedge b_3)',$$

$$f_5=d_3\rightarrow b_2'=(d_3\wedge b_2)',$$

$$f_6 = d_3 \rightarrow (a_1 \vee a_2 \rightarrow b_3) = (d_3 \wedge ((a_1 \vee a_2)' \vee b_3)')',$$

$$f_7 = d_4 \rightarrow a_2 \vee b_2 = (d_4 \wedge (a_2 \vee b_2)')',$$

$$f_8 = d_4 \rightarrow (a_1 \vee a_2 \rightarrow b_3) = (d_4 \wedge ((a_1 \vee a_2)' \vee b_3)')',$$

$$f_9 = (a_2 \vee c_1) \vee (b_3 \vee d_1) = ((a_2 \vee c_1)' \wedge (b_3 \vee d_1)')',$$

$$f_{10} = (a_2 \vee c_2) \vee (a_1 \vee b_1 \rightarrow d_1) = ((a_2 \vee c_2)' \wedge ((a_1 \vee b_1)' \vee d_1)')',$$

$$f_{11} = c_1 \rightarrow b_1 \vee d_2 = (c_1 \wedge (b_1 \vee d_2)')',$$

$$f_{12} = c_2 \rightarrow b_3 \vee d_2 = (c_2 \wedge (b_3 \vee d_2)')',$$

$$f_{13} = (a_2 \vee c_1) \vee [(a_1 \vee a_2 \rightarrow b_3) \rightarrow d_3] = ((a_2 \vee c_1)' \wedge (((a_1 \vee a_2)' \vee b_3)' \vee d_3)')',$$

$$f_{14} = (a_2 \vee c_2) \vee (b_1 \vee d_3) = ((a_2 \vee c_2)' \wedge (b_1 \vee d_3)')',$$

$$f_{15} = c_2 \rightarrow [(a_1 \vee a_2 \rightarrow b_3) \rightarrow d_4] = (c_2 \wedge (((a_1 \vee a_2)' \vee b_3)' \vee d_4)')',$$

$$f_{16} = c_1 \rightarrow (a_1 \vee b_1 \rightarrow d_4) = (c_1 \wedge ((a_1 \vee b_1)' \vee d_4)')',$$

$$f_{17} = (a_1 \rightarrow a_2) \vee b_1 = (a_1' \vee a_2) \vee b_1.$$

The ''implication'' relation has been expressed as $x \rightarrow y \equiv x' \vee y \equiv (x \wedge y')'$.

As can be straightforwardly checked, the proposition formed by

$$F: f_1 \wedge f_2 \wedge \cdots \wedge f_{16} \rightarrow f_{17},$$

is a classical tautology. Nevertheless, F is not valid in three-dimensional (real) Hilbert space $\mathbf{R}^3$, since $f_1, f_2, \ldots, f_{16} = \mathbf{R}^3$, whereas $f_{17} = (\mathrm{Sp}(1,0,0))' = \mathrm{Sp}(0,1,0) \vee \mathrm{Sp}(0,0,1) \neq \mathbf{R}^3$.

The three vectors (1,0,0), (1,1,0), and $(\sqrt{2},1,1)$ generating the Schütte rays are not mutually orthogonal. Therefore, the corresponding propositions a, b, and c are not comeasureable. In the sense of partial algebras, they cannot be combined by logical operations ''or'' ($\vee$), ''and'' ($\wedge$), ''not'' ($'$) to form new expressions. Thus, it would be incorrect to state that there exists a classical tautology in the three variables a, b, and c, which is no quantum tautology. Indeed, Coray proved[26] that all classical tautologies in three variables are tautologies in all partial algebras, in particular in the one associated with the logic of quantum observables.

However, also Schütte's example is counterfactual in nature. Although every operation or relation is solely defined on comeasurable propositions, the entire formula F contains 11 non-comeasurable variables (nonorthogonal rays). In order to be able to evaluate this formula, one would have to know the true value of all these 11 variables in parallel. Since they are not comeasurable, this is possible only by counterfactual inference; in very much the same way as discussed before in the case of the original Kochen–Specker paradox. Indeed, Corey's result shows that *any* classical (Boolean) tautology that is no quantum tautology will have to rely on at least four variables that cannot be mutually orthogonal (in $\mathbf{R}^3$), and therefore must be based upon counterfactual inference.

Finally, let us briefly mention the relevance of these findings to the partition logic of automata. Corollary 4.3 states that every finite subortholattice of $\mathbf{R}^3$ has a full (and thus separating) set of two-valued states. Thus, any finite subortholattice of $\mathbf{R}^3$ can be expressed as an automaton logic. The subortholattices of $\mathbf{R}^3$ that have no two-valued state are infinite.

The canonical form of the Rabi Hamiltonian

M. Szopa,[a] G. Mys, and A. Ceulemans
Department of Quantum Chemistry, University of Leuven, Celestijnenlaan 200F, B-3001 Leuven, Belgium

(Received 29 May 1996; accepted for publication 1 July 1996)

The Rabi Hamiltonian, describing the coupling of a two-level system to a single quantized boson mode, is studied in the Bargmann–Fock representation. The corresponding system of differential equations is transformed into a canonical form in which all regular singularities between zero and infinity have been removed. The canonical or Birkhoff-transformed equations give rise to a two-dimensional eigenvalue problem, involving the energy and a transformational parameter which affects the coupling strength. The known isolated exact solutions of the Rabi Hamiltonian are found to correspond to the uncoupled form of the canonical system. © *1996 American Institute of Physics.* [S0022-2488(96)01211-X]

I. INTRODUCTION

In the study of dynamical problems the harmonic oscillator occupies a prominent place as a prototype of the fundamental unitary symmetry group. The spell of group theory also extends to anharmonic oscillators, which have recently been exposed as mere q-deformations of the unitary group algebra.[1] In contrast dynamical problems which arise in the study of boson–fermion interactions are more reluctant to reveal their hidden symmetries. Such problems are more involved since the actual states of the system are of composite nature with a boson and a fermion part. This results in the appearance of singularities in the corresponding eigenvalue problem. Examples include the Jahn–Teller Hamiltonian in molecular physics and the Rabi Hamiltonian in nuclear physics and quantum optics.

A rather peculiar feature of these systems is the emergence of isolated exact solutions, with eigenvalues that correspond to simple expressions in rational numbers. Such were obtained—in a rather heuristic way—by Judd[2] for the case of the $E\otimes e$ Jahn–Teller Hamiltonian, and by Kuś[3] for the spectrum of a two-level atom coupled to a single quantized mode. It was suggested that the exact solutions probably hint at some dynamical symmetry group, but so far no progress was reported in this direction.

In the present paper we analyze the one-mode Rabi problem in a more rigorous way. First—following Refs. 3 and 4—the dynamical problem is defined in the Bargmann–Fock Hilbert space of entire functions. The resulting system of differential equations is then put into canonical form using a theorem due to Birkhoff. Under this transformation the Kuś exact solutions are found to be mapped onto the levels of a displaced harmonic oscillator. In this way hidden symmetry appears.

II. THE BARGMANN–FOCK REPRESENTATION OF A HILBERT SPACE

Before turning to the actual results we briefly review basic information about the Hilbert space of entire functions introduced by Fock[5] and Bargmann.[6] Let $\mathcal{F}_n$, for n integral, be the set of entire analytic functions $f(z)$, where $z=(z_1,\ldots,z_n)$ and $z_k\in\mathbf{C}$ are complex numbers, $k=1,\ldots,n$. Because $f(z)$ is entire it has an everywhere converging power series

$$f(z)=\sum_{k_1,\ldots,k_n}\alpha_{k_1,\ldots,k_n}z_1^{k_1}\cdot\ \cdots\ \cdot z_n^{k_n}, \tag{1}$$

[a]On leave of the Institute of Physics, University of Silesia, Uniwersytecka 4, 40-007 Katowice, Poland.

0022-2488/96/37(11)/5402/10/$10.00

where summation extends over the whole set of non-negative integers $k_1,\ldots,k_n$ and $\alpha_{k_1,\ldots,k_n}$ are complex coefficients. We define an inner product of two elements f and g of $\mathscr{F}_n$ by

$$(f,g)=\int \overline{f(z)}\cdot g(z)\,d\mu_n(z), \tag{2}$$

where $\overline{f(z)}\cdot g(z)$ is a usual scalar product in $\mathbf{C}^n$,

$$d\mu_n(z)=\frac{1}{\pi^n}\exp(-\overline{z}\cdot z)\prod_{k=1}^{n} dx_k dy_k, \quad z_k=x_k+iy_k, \tag{3}$$

and the integration extends over the whole space $\mathbf{C}^n$. The Bargmann–Fock space $\mathscr{F}_n$ is a set of all entire functions (1), which have a finite norm $(f,f)<\infty$. This is equivalent to the requirement that

$$|f(z)|\leqslant c\,\exp(\tfrac{1}{2}\gamma\overline{z}\cdot z), \tag{4}$$

where c and γ are positive constants with $\gamma<1$. The Bargmann–Fock space $\mathscr{F}_n$ with the inner product defined by (2) is a Hilbert space.

Let us now consider two operators in $\mathscr{F}_n$: multiplication by z_k and differentiation d/dz_k. Since the functions $f(z)$ of $\mathscr{F}_n$ are analytic, $z_k f$ and $(d/dz_k)f$ always exist. The operators satisfy the commutation rules

$$[z_k,z_l]=0, \quad \left[\frac{d}{dz_k},\frac{d}{dz_l}\right]=0, \quad \left[\frac{d}{dz_k},z_l\right]=\delta_{kl}. \tag{5}$$

Furthermore, with respect to the inner product (2), z_k and d/dz_k are Hermitian conjugate

$$(z_k f,g)=\left(f,\frac{d}{dz_k}g\right) \tag{6}$$

whenever $z_k f$ and $(d/dz_k)f$ belong to $\mathscr{F}_n$.

On the other hand, relations (5) and (6) are well-known algebraic relations defining Hermitian conjugate annihilation a_k and creation a_k^+ operators of boson fields in second quantization:

$$[\alpha_k^+,a_l^+]=0, \quad [a_k,a_l]=0, \quad [a_k,a_l^+]=\delta_{kl}. \tag{7}$$

We conclude therefore that within $\mathscr{F}_n$ the annihilation operator a_k is represented by the operation d/dz_k, and the creation operator a_k^+ corresponds to the multiplication by z_k.

As an instructive example let us take a set of n identical uncoupled harmonic oscillators which are described up to a constant by the Hamiltonian $H=\Sigma_{l=1}^n a_l^+ a_l$. The corresponding operator in the Bargmann–Fock space (denoted by $\mathscr{H}$) is $\mathscr{H}=\Sigma_{l=1}^n z_l d/dz_l$ and the corresponding eigenproblem is the system of differential equations

$$\sum_{l=1}^{n} z_l \frac{d}{dz_l} f_k(z)=E_k\, f_k(z). \tag{8}$$

It is easily verified that the eigenfunctions in this case are functions of the type (1), which are homogeneous polynomials of the order k, i.e., in (1) the sum is over $k_1+\cdots+k_n=k$ and the corresponding eigenvalues are $E_k=k$.

III. THE TRANSFORMATION TO A CANONICAL FORM

In the Bargmann–Fock representation of a Hilbert space, quantum mechanical equations for bosons interacting with a manifold of fermion states are represented by a system of linear differential equations in the complex domain.[3,4] The physical solutions (1) of such a system must belong to $\mathscr{F}_n$, i.e., be entire and obey condition (4). In practice the solution of this equation is complicated due to the occurrence of finite regular singularities.

In this section we describe a transformation, due to Birkhoff,[7] which allows us, for a system of linear equations of the first order in one variable, to find a canonical form. To be in the canonical form the system must be transformed in such a way that all its finite singularities reduce to only one singularity at zero, while at the same time preserving the order of the singularity at infinity. Consequently, the transformed system is more likely to be exactly solvable.

The system of m linear differential equations of the first order has a general form

$$\frac{df_r}{dz}=\sum_{s=1}^{m} p_{rs}(z)f_s, \quad r=1,\ldots,m, \tag{9}$$

and we assume that $p_{rs}(z)$ are analytic functions of a complex variable apart from a finite number of regular singularities (even at infinity). Practically it means that, outside the circle $|z|=R$, which includes all the finite singular points, the coefficients may be expanded in a Laurent series

$$p_{rs}(z)=\sum_{k=-\infty}^{q} p_{rs}^{(k)}z^k, \quad p_{rs}^{(k)}\in \mathbf{C}, \tag{10}$$

where $q\geqslant -1$ and $q+1$ is termed the *rank* of the singular point at infinity. In general the system (9) can have m independent sets of solutions $f_s^{(t)}(z)$, where $s=1,\ldots,m$ denotes different solutions within a set $t=1,\ldots,m$. Now we assume a linear transformation of the form

$$f_r(z)=\sum_{s=1}^{m} a_{rs}(z)F_s(z), \tag{11}$$

where the coefficients $a_{rs}(z)$ are analytic at infinity and reduce at infinity to a unit matrix

$$a_{rs}(z)=\sum_{k=0}^{\infty} \frac{a_{rs}^{(k)}}{z^k}, \quad a_{rs}^{(k)}\in \mathbf{C}, \quad a_{rs}^{(0)}=\delta_{rs}. \tag{12}$$

In a sense this $\{a_{rs}(z)\}$ matrix could be said to contain all the finite singularities of the initial system. Under this transformation the original system (9) turns into a system of a slightly different form:

$$z\,\frac{dF_r(z)}{dz}=\sum_{s=1}^{m} P_{rs}(z)F_s(z), \quad r=1,\ldots,m. \tag{13}$$

The coefficients of the transformed system are given by the equation

$$\{P_{rs}(z)\}=z\left(\{a_{rk}^{-1}(z)\}\{p_{kl}(z)\}\{a_{ls}(z)\}-\{a_{rk}^{-1}(z)\}\left\{\frac{d}{dz}\,a_{ks}(z)\right\}\right), \tag{14}$$

where $\{a_{rk}^{-1}(z)\}$ is the matrix inverse to the matrix $\{a_{rk}(z)\}$ and $\{a_{rk}(z)\}\{p_{ks}(z)\}$ denotes the matrix multiplication. Now we are in the position to formulate the Birkhoff theorem—the crucial result in our analysis.

The Birkhoff theorem states that *for every system of the type (9) there exists a transformation matrix (12) such that the coefficients $P_{rs}(z)$ of the transformed system (13) are polynomials of a degree not exceeding $q+1$.*[7]

There are several properties of the above transformation which should be stated here.

(i) All finite singular points of the initial system (9) coalesce to only one singularity at zero [because $P_{rs}(z)$ are polynomials]. This is the most significant property of the transformation and because of it the system (13) may be termed the *canonical* form of the system (9).

(ii) The ranks of the singular points at infinity for both systems (9) and (13) are equal.

(iii) If a given set of solutions $f_s^{(t)}(z)$, $s=1,\ldots,m$, belongs to the Bargmann–Fock space $\mathscr{F}_1$, then the corresponding transformed solutions $F_s^{(t)}(z)$, which are found due to the Birkhoff theorem, also belong to this space. This can easily be shown by adapting the treatment by Birkhoff to the case of entire functions.

The final property allows us to reject all the solutions of the transformed system which do not belong to the Bargmann–Fock space as being nonphysical. However, the inverse of this property is not automatically true, but requires a proper choice of the transformation matrix. We will come back to this point when discussing the actual solutions of the system under investigation.

A useful test to check if the solutions of the transformed system can be entire is given by the indicial equation of the transformed system[8]

$$\det\{c_{rs}-\rho\delta_{rs}\}=0, \tag{15}$$

where $c_{rs}=P_{rs}(0)$, $r,s=1,\ldots,m$. The solutions of (13) depend on the roots $\rho_1,\ldots,\rho_m$ of the indicial equation. There are several rules connected with this equation which indicate the possibility of existence of entire solutions and their degeneracy.

D_0. If none of the roots is a non-negative integer, the equation (13) has no entire solutions (because they are not analytic in the origin).

D_1. If one of the roots ρ_t is a non-negative integer and the remaining roots are either nonintegers or are equal to ρ_t, then there exists exactly one, up to linear dependence, set of analytic solutions of (13) and it is of the form

$$F_s^{(t)}(z)=z^{\rho_t}u_s(z), \quad s=1,\ldots,m, \tag{16}$$

where the $u_s(z)$ are analytic and $u_s(0)\neq 0$. Functions (16) are entire provided their radii of convergence are infinite.

D_2. In the remaining cases if two or more roots of the indicial equation are integers (at least one of them is non-negative), there exists at least one analytic set of solutions of the form (16), where ρ_t is the maximal integral root of (15). The remaining solutions corresponding to other integral roots are usually singular in the origin, but in exceptional cases may also be analytic.

It should be pointed out that the Birkhoff theorem is an existence theorem, which as such does not provide the actual form of the canonical equation nor the transformation matrix. In practice at least the canonical equation can usually be found relatively easy by the use of (14), keeping in mind that the $P_{rs}(z)$ are polynomials of a given degree. To this aim we invert Eq. (14) and express it in terms of the relevant expansion coefficients. This yields, for every integer $l\geqslant 0$, a system of m^2 equations

$$\sum_{i=0}^{l}\left(\{a_{rk}^{(l-i)}\}\{P_{ks}^{(q+1-i)}\}-\{p_{rk}^{(q-i)}\}\{a_{ks}^{(l-i)}\}\right)=(l-q-1)\{a_{rs}^{(l-q-1)}\}, \tag{17}$$

where expansion coefficients for $\{p_{rk}(z)\}$, $\{a_{rk}(z)\}$, and $\{P_{rs}(z)\}$ are defined by (10), (12), and $P_{rs}(z)=\Sigma_{k=0}^{q+1}P_{rs}^{(k)}z^k$, respectively. We assume also that $\{a_{rk}^{(i)}\}$ and $\{P_{rk}^{(i)}\}$ with negative indices i are zero matrices.

This formula can now be used to find the coefficients $P_{rs}(z)$ of the transformed system. In this case we only need the equations corresponding to $l=0,\ldots,q+1$. Here the trivial case with $l=0$ immediately yields

$$\{P_{rs}^{(q+1)}\}=\{p_{rs}^{(q)}\}. \tag{18}$$

For higher l, $1\leqslant l\leqslant q+1$, the resulting expansion coefficients in the transformed system may also depend on the $a_{ks}^{(1)},\ldots,a_{ks}^{(q+1)}$ coefficients in the expansion of the transformation matrix. These coefficients thus may enter the transformed system as extra degrees of freedom, which we will denote as the *parameters* of the transformed equation. The canonical transformation can only be defined up to these parameters. However, in the context of a physical model, their values will be constrained by the requirement that the solution of the initial system belong to the Bargmann–Fock space.

The remaining equations in the system (17), i.e., the formulas corresponding to $l=q+2$, $q+3$, ..., form a set of recurrence equations for the $\{a_{rs}(z)\}$ matrix. This system determines $\{a_{rs}(z)\}$ as a function of the parameters of the transformed system. The procedure of determining the transformation matrix for a given set of parameters is in general infinite and it may be very difficult to find the parameters that lead to solutions in the Bargmann–Fock space. Hence it is conceivable that we know the initial (9) and the transformed (13) systems of equations, without being able to solve the transformation matrix (12). In some cases this still allows us to draw some important conclusions about features of physical interest, such as degeneracies or symmetries.

A special case arises if we assume that the expansion (12) of $\{a_{rs}(z)\}$ in negative powers of z is finite. In this case confinement to the Bargmann–Fock space can indeed easily be guaranteed. If the highest order in the denominators of (12) is not greater than ρ_t from (16), which is the lowest power in the expansion of the $F_s^{(t)}(z)$, then the corresponding solution of the initial system is automatically analytic in the origin. In this case the system (17) also remains finite and can be solved. This procedure precisely leads to the isolated exact solutions of the initial system.

IV. THE SOLUTION OF A TWO-LEVEL SYSTEM COUPLED TO A SINGLE QUANTIZED MODE

A. The canonical form

In this section we derive the canonical form of the dynamical equations for a two-level system coupled to a single quantized mode. The Hamiltonian of such a system, sometimes called Rabi Hamiltonian,[4] is of the form

$$H=\omega a^+a+\mu\sigma_3+\lambda(\sigma^++\sigma^-)(a^++a), \tag{19}$$

where a^+ and a are boson field (7) creation and annihilation operators, $\sigma^{\pm}=\frac{1}{2}(\sigma_1\pm i\sigma_2)$, and σ_1, σ_2, σ_3 are Pauli matrices. The parameter ω is the boson field frequency, 2μ is the atomic level separation, and λ is the atom–boson field coupling constant. We choose the energy unit in such a way that $\omega=1$, and we assume that λ and μ are not vanishing simultaneously.

The first step to solve the system (19) is to make a unitary transformation which replaces operators $\sigma_1\to\sigma_3$, $\sigma_3\to\sigma_1$, and $\sigma_2\to-\sigma_2$. Then we write the stationary Schrödinger equation for the two-component wavefunction in the position variable $\binom{f_1(\xi)}{f_2(\xi)}$. In the second step, by replacing $a^+\to z$ and $a\to d/dz$, we perform a transition to a Bargmann–Fock space. In this space the Schrödinger equation is equivalent to a system of two first-order differential equations for the Bargmann–Fock space functions $f_1(z)$, $f_2(z)\in\mathscr{F}_1$:

$$\frac{d}{dz} f_1(z) = \frac{E-\lambda z}{z+\lambda} f_1(z) - \frac{\mu}{z+\lambda} f_2(z),$$
$$\frac{d}{dz} f_2(z) = -\frac{\mu}{z-\lambda} f_1(z) + \frac{E+\lambda z}{z-\lambda} f_2(z), \tag{20}$$

where E is an eigenenergy of $\mathscr{H}$. Note that in the Schrödinger representation of creation and annihilation operators we have $a^+ \to (1/\sqrt{2})(\xi - ip_\xi)$, $a \to (1/\sqrt{2})(\xi + ip_\xi)$, where ξ and p_ξ are conjugate position and momentum. The system corresponding to (20) in this representation consist of two second-order differential equations in a real variable ξ.

The present Bargmann–Fock space formulation of the problem has been investigated earlier and approximate solutions have been found.[4,9] In addition Kuś has derived some isolated exact solutions, corresponding to degenerate levels.[3]

For our purposes we point out three properties of the system. First, it is of the form (9) with two finite singularities in $z=\lambda,-\lambda$. Second, expanding coefficients of (20) in a Laurent series (10) we find that $q=0$ and therefore the singular point at infinity is of the first rank. Finally, we note the following symmetry: if $\binom{f_1(z)}{f_2(z)}$ is a solution of (20), then $\binom{f_2(-z)}{f_1(-z)}$ is also a solution, corresponding to the same energy value.

The Birkhoff theorem is found to apply to the system in (20). Hence one can claim the existence of a canonical form. With $q=0$, the coefficients of this form will be polynomials of the first degree! They can be obtained from Eqs. (17) and (18), as explained in the previous section. The linear terms of $P_{rs}(z)$ are inferred at once from (18), i.e., $P_{rs}^{(1)}(z) = (-1)^r \lambda \delta_{rs}$. To calculate the remaining four zeroth-order terms of $P_{rs}(z)$ we use Eq. (17) with $l=1$. The canonical form of the system (20) is therefore

$$z \frac{d}{dz} F_1(z) = (E - \lambda z + \lambda^2) F_1(z) + (-\mu - 2\lambda a_{12}^{(1)}) F_2(z),$$
$$z \frac{d}{dz} F_2(z) = (-\mu + 2\lambda a_{21}^{(1)}) F_1(z) + (E + \lambda z + \lambda^2) F_2(z), \tag{21}$$

where $F_1(z)$ and $F_2(z)$ are linearly transformed $f_1(z)$ and $f_2(z)$ (11), and $a_{12}^{(1)}$ and $a_{21}^{(1)}$ are parameters belonging to the transformation matrix (12).

The main feature of the canonical system is that it has only one singularity at $z=0$, and because of that is exactly solvable. Prior to solving it, however, we exploit the symmetry of solutions $\binom{f_1(z)}{f_2(z)}$ of the initial system (20). To preserve this symmetry in the transformed pair, i.e., if $\binom{F_1(z)}{F_2(z)}$ is a solution of (21), then so is $\binom{F_2(-z)}{F_1(-z)}$, we must impose the following symmetry of the transformation matrix

$$a_{ij}(z) = a_{[i+1][j+1]}(-z), \quad i,j = 1,2, \tag{22}$$

where $[\cdot + \cdot]$ denotes an addition modulo 2.

B. Quantization conditions and canonical solutions

Physical constraints require the solutions of (20) belong to the Bargmann–Fock space, i.e., to converge in the entire plane. This leads to quantization conditions, as we will show in this section.

The canonical system contains four parameters λ, μ, E, and $a_{12}^{(1)}$. In the usual perception of the problem λ and μ are external quantities, describing the physics of the system, while E and $a_{12}^{(1)}$ are essentially free parameters, to be determined by the quantum conditions. The indicial equation (15) corresponding to the system (21) is seen to link E and $a_{12}^{(1)}$:

$$\rho = E + \lambda^2 \pm A, \tag{23}$$

where $A = \mu + 2\lambda a_{12}^{(1)}$. For the system (21) to have solutions in the Bargmann–Fock space, at least one value of ρ must be a non-negative integer. The value of A thus determines the whole energy spectrum, but in turn it is controlled by the $a_{12}^{(1)}$ parameter, from which the transformation matrix can be generated via (17). For the time being we will treat it as a free parameter, delineating classes of solutions in the energy spectrum. As we will see later its value will be fixed by the requirement that the solutions of the original system (20) are in the Bargmann–Fock space.

The general solution of (21) can be obtained by transforming it into a second-order form

$$z^2 F_1''(z) + z[1 - 2(E + \lambda^2)]F_1'(z) + [(E + \lambda^2)^2 - A^2 + \lambda z - \lambda^2 z^2]F_1(z) = 0. \tag{24}$$

This equation can be reduced to a confluent hypergeometric (or Kummer) equation. Its general solution is a combination of two functions

$$\begin{aligned} F_1(z) = {} & C_1 \exp(\lambda z)\, {}_1F_1(1 + A, 1 + 2A; -2\lambda z) z^{E + \lambda^2 + A} \\ & + C_2 \exp(\lambda z)\, {}_1F_1(1 - A, 1 - 2A; -2\lambda z) z^{E + \lambda^2 - A}, \end{aligned} \tag{25}$$

with arbitrary C_1 and C_2. The function ${}_1F_1(a, c; z)$ is called confluent series or Kummer function and is defined for all complex a, z and $c \neq -n$, $n = 0,1,2,...$:

$${}_1F_1(a, c; z) = 1 + \frac{a}{c}\frac{z}{1!} + \frac{a(a+1)}{c(c+1)}\frac{z^2}{2!} + \frac{a(a+1)(a+2)}{c(c+1)(c+2)}\frac{z^3}{3!} + \cdots . \tag{26}$$

The Kummer function is entire. The solutions for $F_2(z)$ are of the same general form (25), with however z replaced by $-z$.

The asymptotic behavior of the solution (25) for $|z| \to \infty$ is restricted by the function $z^{\alpha_1} \exp(\lambda z) + z^{\alpha_2} \exp(-\lambda z)$, where α_1 and α_2 are real numbers[10] and therefore the condition (4) is always obeyed. Consequently the solution (25) belongs to the Bargmann—Fock space $\mathscr{F}_1$, provided at least one of the roots of the indicial equation (23) is a non-negative integer.

A particularly simple case occurs if $\lambda = 0$ because then the transformed system (21) coincides with the initial one (20). The transformation matrix reduces in this case to the unit matrix.

Let us now discuss the solutions (25) and their degeneracy for different values of $E + \lambda^2$.

(i) If $E + \lambda^2$ is neither an integer nor a half-integer, then, to get physical solutions, we should take A such that one of the numbers $\rho_1 = E + \lambda^2 + A$ and $\rho_2 = E + \lambda^2 - A$ is a non-negative integer. In this case, according to the general rule D_1, one of the two functions composing $F_1(z)$ can be entire. The corresponding solution for $F_2(z)$ is also one-dimensional and is given by $F_2(z) = (-1)^{\rho_t + t} F_1(-z)$.

(ii) If $E + \lambda^2$ is a half-integer, then we take A also half-integral. Despite the fact that both $E + \lambda^2 + A$ and $E + \lambda^2 - A$ are now integers (rule D_2), the solutions $F_1(z)$ and $F_2(z)$ are still one-dimensional because in this case one of the numbers $1 + 2A$ or $1 - 2A$ is a non-positive integer and the corresponding Kummer function is not defined.

(iii) If $E + \lambda^2$ is an integer, we can take the simple choice $A = 0$. Then, for $E + \lambda^2 \geqslant 0$, each of the solutions is entire and forms a one-dimensional space (rule D_1), but because the system (21) is diagonal we can always take its two linearly independent solutions of the form $\binom{F_1(z)}{F_2(z)}$ and $\binom{F_1(z)}{-F_2(z)}$. Consequently in this case the solutions are degenerate. This class of solutions will comprise the exact solutions found by Kuś.

(iv) If $E + \lambda^2$ is an integer and $E + \lambda^2 > 0$, we can also take A integral, $0 < |A| \leqslant E + \lambda^2$. In this case, although the system (21) is no more diagonal, solutions $F_1(z)$ and $F_2(z)$ become two-dimensional and lead to degenerate solutions. This represents the rarest case of D_2

when two roots of the indicial equation are integral and both corresponding solutions are analytical.

To summarize we conclude that the only case where solutions are degenerate can occur when $E+\lambda^2$ is a non-negative integer.

C. The isolated exact solutions

In the previous section we have shown that the canonical form of the Rabi Hamiltonian can be solved within Bargmann–Fock conditions. This results in a coupling between A and E parameters, which is interesting in its own right, but does not lead to quantized energies. As we have already mentioned, the true quantization condition stems from the requirement that the solutions of the original system belong to the Bargmann–Fock space. This implies that the transformation of the canonical solutions must act within the Bargmann–Fock space. In this way we fix A and hence E.

In general this procedure is nontrivial since the transformation matrix is generated by an infinite system of equations (17), yielding an infinite series of coefficients $a_{rs}^{(k)}$. In this section we will not be concerned with the general case, but only study the exactly solvable class of solutions, which corresponds to $A=0$. We assume that the transformation is nontrivial, i.e., $\lambda\neq 0$.

Let us first consider the simplest possibility $\mu=0$. With $A=0$, and hence $a_{12}^{(1)}=0$, the indicial equation yields that $\rho=E+\lambda^2$ must be a non-negative integer. It is easy to find that the corresponding transformation matrix is diagonal and reads

$$\{a_{rs}(z)\}=\begin{pmatrix} \left(1+\dfrac{\lambda}{z}\right)^{E+\lambda^2} & 0 \\ 0 & \left(1-\dfrac{\lambda}{z}\right)^{E+\lambda^2} \end{pmatrix}, \tag{27}$$

whereas the solutions are generated by

$$F_1(z)=\exp(-\lambda z)z^{E+\lambda^2}, \qquad F_2(z)=\exp(\lambda z)z^{E+\lambda^2}. \tag{28}$$

Note that in this case the expansion (12) in negative powers of both diagonal terms terminate. The last nonzero coefficients are $a_{rs}^{(E+\lambda^2)}$. On the other hand, the lowest power of z in the expansion of the transformed solution (25) is also $E+\lambda^2$. It is then easily verified that the solution of the initial system, which follows from (11), is of form (1) and thus belongs to the Bargmann–Fock space. The energy spectrum is obtained directly from the indicial equation (23) and reads $E_\rho=\rho-\lambda^2$, where $\rho=0,1,2,\ldots$.

In the line of this example we now turn to the more general case $\mu\neq 0$ but keep the $a_{rs}^{(k)}$ matrix finite. As a first example we assume that the expansion (12) of the transformation matrix terminates, and $a_{rs}^{(1)}$ are the only nonzero coefficients. In other words, $a_{rs}^{(2)}=a_{rs}^{(3)}=\cdots=0$. In this case the system (17) is also finite because starting from $l=3$ all the higher-order equations are equivalent to equations corresponding to $l=2$. Taking into account symmetry properties (22) of the matrix, the system reduces to four equations

$$\begin{aligned} &\overline{a_{11}}+2\mu\overline{a_{12}}+2\lambda\overline{a_{12}^2}-\lambda(E+\lambda^2)=0, \qquad 2\mu\overline{a_{11}}+\overline{a_{12}}+2\lambda\overline{a_{11}}\,\overline{a_{12}}+\lambda\mu=0, \\ &(E+\lambda^2)\overline{a_{11}}+\mu\overline{a_{12}}-\lambda(E+\lambda^2)=0, \qquad \mu\overline{a_{11}}+(E+\lambda^2)\overline{a_{12}}+\lambda\mu=0, \end{aligned} \tag{29}$$

where we denote $\overline{a_{kl}}=a_{kl}^{(1)}$ for convenience. Let μ be nontrivial and $0<\mu\leqslant(E+\lambda^2)$. Then, after some algebra, one can show that the system (29) is equivalent to the transformation matrix

$$\{a_{rs}(z)\}=\begin{pmatrix} 1+\dfrac{1+\mu^2}{4\lambda z} & -\dfrac{\mu}{2\lambda z} \\ \dfrac{\mu}{2\lambda z} & 1-\dfrac{1+\mu^2}{4\lambda z} \end{pmatrix} \tag{30}$$

and two other conditions: $E+\lambda^2=1$ and $4\lambda^2+\mu^2=1$. From the $a_{12}(z)$ element in (30) it also follows that $A=\mu+2\lambda a_{12}^{(1)}=0$.

Thus the very assumption that the transformation matrix terminates gave us the form of the matrix, the values of $E+\lambda^2$ and A, showing that they correspond to a degenerate solution of (25). In addition the system has energy $E=1-\lambda^2$ only if the atomic level separation 2μ and the atom–boson field coupling λ obey condition $4\lambda^2+\mu^2=1$. The corresponding eigenfunction $\binom{F_1(z)}{F_2(z)}$ is given by (28) and $\binom{f_1(z)}{f_2(z)}$ can be found by applying (11). One can easily show that $f_1(z)$ and $f_2(z)$ belong to the Bargmann–Fock space. This solution agrees with the first root of the Kuś series.[3]

In an analogous way one can show that if the transformation matrix terminates from the third-order coefficients onwards, $a_{rs}^{(3)}=a_{rs}^{(4)}=\cdots=0$, and $0<\mu\leqslant(E+\lambda^2)$, then the transformation matrix functions are

$$\begin{aligned} a_{11}(z)=a_{22}(-z)&=1+\frac{2\lambda+\dfrac{\mu^2}{2\lambda}}{z}+\frac{\lambda^2+\mu^2+\dfrac{\mu^4-\mu^2}{8\lambda^2}}{z^2}, \\ a_{12}(z)=a_{21}(-z)&=-\frac{\mu}{2\lambda z}+\frac{\mu(6\lambda^2+\mu^2-1)}{4\lambda^2 z^2}, \end{aligned} \tag{31}$$

i.e., again $A=0$ and the remaining conditions are $E+\lambda^2=2$ and $32\lambda^4-32\lambda^2+12\lambda^2\mu^2-5\mu^2+\mu^4+4=0$, which corresponds to the second root of the Kuś series. In this way all solutions of the Rabi Hamiltonian characterized by a terminating $\{a_{rs}(z)\}$ can be generated. They are found to coincide with all known exact solutions.

V. DISCUSSION

The Rabi Hamiltonian describes the coupling between a two-level system and a single mode through a linear interaction term $\lambda\sigma_1(a^+ + a)$. This problem is relevant in quantum optics but also appears in molecular physics as the simplest example of vibronic coupling.[11,12]

In Bargmann–Fock space it can be represented by a system of two first-order differential equations, as shown in (20). For $\mu=0$ this system separates into two independent equations:

$$\begin{aligned} (z+\lambda)\frac{d}{dz}f_1(z)&=(E-\lambda z)f_1(z), \\ (z-\lambda)\frac{d}{dz}f_2(z)&=(E+\lambda z)f_2(z). \end{aligned} \tag{32}$$

This situation corresponds to a highly symmetric case with two uncoupled harmonic oscillators that are displaced to the left and to the right in coordinate space,[9] and cross at the coordinate origin. From this perspective the introduction of the level separation 2μ may be viewed as a symmetry-lowering perturbation, which couples the two oscillators.

If we now compare the original system (20) to the canonical one (21), we still have essentially a set of two displaced oscillators—but now the coupling term no longer corresponds to μ but to $\mu+2\lambda a_{12}^{(1)}$! Hence the canonical transformation provides a degree of freedom that allows us to

perform a displacement in the space of the coupling parameter itself. We can thus adjust $a_{12}^{(1)}$ in such a way that it compensates for the energy gap, by requiring $a_{12}^{(1)}=-\mu/2\lambda$, or $A=0$. System (21) then becomes

$$z\frac{d}{dz}F_1(z)=(E-\lambda z+\lambda^2)F_1(z), \qquad z\frac{d}{dz}F_2(z)=(E+\lambda z+\lambda^2)F_2(z). \tag{33}$$

This system again describes two degenerate harmonic oscillators that are displaced in coordinate space and also underwent a translation in z space over $+$ or $-\lambda$.

We thus have shown that the exact solutions that are found for $A=0$ can be mapped onto the energy spectrum of a degenerate harmonic oscillator. A similar result can also be obtained for the Juddian exact solutions of the $E\otimes e$ Jahn–Teller Hamiltonian.[13]

(Received 24 April 1995; accepted for publication 2 February 1996)

A one-dimensional boson–fermion model with two-body interactions between the two types of chiral fermions is considered. It is shown that the model is exactly soluble and the general Bethe eigenstates are constructed. On the basis of the Bethe ansatz equations, the ground state, the low lying elementary excitations, and the thermodynamics are also given in some closed integral equations. © *1996 American Institute of Physics.* [S0022-2488(96)03305-2]

I. INTRODUCTION

A many-body problem plays a very important role in modern physics, especially in statistical physics and condensed matter physics. After the establishment of quantum mechanics, very many methods had been developed to approach this problem. However, most of the theories are approximate and exact results are still rare. Although many efforts have been done in this aspect, the exact results were only obtained in a few special two-dimensional classical models and one-dimensional quantum models. At present, perhaps the most powerful method to approach one-dimensional quantum soluble models is the Bethe ansatz method. After the elegant work of Bethe,[1] a dozen of models have been solved with his brilliant ansatz. Great achievements have been reached in $1+1$-dimensional quantum field theory[2–4] and condensed matter physics.[5,6] Among the exactly soluble models, there is a special type, i.e., the N wave interaction model[7] in which there are interactions breaking the conservation of the particle numbers. Such interactions put the eigenstates of the Hamiltonian into the coherentlike states. The first Bethe ansatz result of the quantum three wave interaction model was given by Wadati and co-workers after some lengthy calculations.[8] Very recently, a systematic method to approach such interacting systems has been developed by one of the present authors and co-workers.[9]

In this article, we study the boson–fermion model with two-body interactions in one dimension. It is shown that this model is also Bethe ansatz soluble.

The Hamiltonian we shall consider reads

$$H=\int\left\{-i\left[Q_1^\dagger\frac{\partial}{\partial x}Q_1-Q_3^\dagger\frac{\partial}{\partial x}Q_3\right]+\nu Q_2^\dagger Q_2+cQ_1^\dagger Q_3^\dagger Q_3Q_1+g[Q_1^\dagger Q_3^\dagger Q_2+Q_2^\dagger Q_3Q_1]\right\}dx, \tag{1}$$

where the $Q_j^\dagger$s(Q_j's) are particle creation (annihilation) operators. $Q_1^\dagger$ and $Q_3^\dagger$ create spinless chiral fermions with different chiral indices ±1 and $Q_2^\dagger$ creates localized bosons; g is the ''contraction-decay'' coupling constant; c describes the coupling constant between Q_1 and Q_3 particles. Note such an interaction in the Tomonaga model[10] is irrelevant but indeed relevant in the present model as in the Luttinger model;[11] ν is a positive number which denotes the virtual level of the bosons. In our model, we define the bosons being localized. Thus the bosons may describe the bi-polaron

0022-2488/96/37(11)/5412/12/$10.00

states or the dimer states.[13] Although the bosons are static initially, the spontaneous decay into itinerant fermions does allow them to behave itinerantly. The outline of this article is the following. In Sec. II we construct the eigenstates of the model Hamiltonian. Through the consideration of a two-body state, the general eigenstates can be constructed with a theorem. In Sec. III, the ground state or the physical vacuum (Fermi sea) is discussed in a cut-off scheme because the energy spectrum is not bounded from below. Some elementary excitations are given in Sec. IV. It is found that all the four types of elementary excitations fall into the particle-hole scheme with the ''back flow'' of the Fermi sea compensated. The thermodynamics is given in Sec. V by a closed set of integral equations. As checks, some special cases are studied on the basis of the integral equations.

II. CONSTRUCTION OF THE EIGENSTATES

We shall follow the method developed in Ref. 9 to construct the eigenstates of the Hamiltonian (1). Traditionally, the Bethe ansatz method is used to construct the common eigenstates of the Hamiltonian, the total momentum, and the particle number(s). However, the total particle number is not conserved in the present model. Fortunately, the quantities

$$N_1=\int [Q_1^\dagger Q_1+Q_2^\dagger Q_2]dx, \quad N_2=\int [Q_3^\dagger Q_3+Q_2^\dagger Q_2]dx, \tag{2}$$

which we call ''pseudoparticle numbers'' and the total momentum

$$P=-i\int \sum_{j=1}^{3} Q_j^\dagger \frac{\partial}{\partial x} Q_j \, dx \tag{3}$$

are conserved. Therefore, we can specify the eigenstates by $|N_1,N_2\rangle$. To show the procedure clearly, it is convenient to consider first the $N_1=N_2=1$ state. Such a state is the simplest nontrivial state which gives the main information about the general eigenstates. The $|1,1\rangle$ state can be written as

$$|1,1\rangle=\int dx_1\, dx_2\, \Psi(x_1|x_2)Q_1^\dagger(x_1)Q_3^\dagger(x_2)|0\rangle+\int dy\, \Psi_1(y)Q_2^\dagger(y)|0\rangle, \tag{4}$$

where $|0\rangle$ is the vacuum state defined by $Q_j|0\rangle=0$. The Schrödinger equation $H|1,1\rangle=E|1,1\rangle$ leads to

$$\begin{gathered}-i\left[\frac{\partial}{\partial x_1}-\frac{\partial}{\partial x_2}\right]\Psi(x_1|x_2)+[g\Psi_1(x_1)+c\Psi(x_1|x_2)]\delta(x_1-x_2)=E\Psi(x_1|x_2),\\ \nu\Psi_1(y)+g\Psi(y|y)=E\Psi_1(y),\end{gathered} \tag{5}$$

where E is the eigenvalue. To solve the above equations, we make the following ansatz:

$$\begin{gathered}\Psi(x_1|x_2)=\exp[ikx_1+iqx_2][\theta(x_1-x_2)+\theta(x_2-x_1)S(k,q)],\\ \Psi_1(y)=S^+(k,q)\Psi(y|y),\end{gathered} \tag{6}$$

where $\theta(x)$ is the step function with $\theta(0)=\frac{1}{2}$. Other choices of $\theta(0)$ value induce nothing but the renormalization of the coupling constants c and g. The discontinuity of $\Psi(x_1|x_2)$ at $x_1=x_2$ is due to the linear kinetic energy term in the Hamiltonian. Substituting Eq. (6) into Eq. (5) we deduce the two-body S matrix and the contraction matrix S^+ as

$$S(k,q)=S^{-1}(q,k)=e^{i\phi}\,\frac{k-q-\nu+i\mu}{k-q-\nu-i\mu^*},$$
$$S^{+}(k,q)=\frac{g}{k-q-\nu}, \tag{7}$$

with $\mu=g^2/(4+ic)$ and $e^{i\phi}=(4-ic)/(4+ic)$. Then the state $|1,1\rangle$ defined in Eq. (4) is an eigenstate with the eigenenergy $E=k-q$.

Now we turn to construct the general eigenstate with arbitrary N_1 and N_2. Such an eigenstate can be written as

$$\begin{aligned}|N_1,N_2\rangle=&\int\sum_{M=0}^{\min[N_1,N_2]}\Psi_M(x_1,\ldots,x_{N_1-M}|y_1,\ldots,y_{N_2-M}|z_1,\ldots,z_M)\\&\times[M!(N_1-M)!(N_2-M)!]^{-1}\\&\times\prod_{i=1}^{N_1-M}Q_1^{\dagger}(x_i)dx_i\prod_{j=1}^{N_2-M}Q_3^{\dagger}(y_j)dy_j\prod_{l=1}^{M}Q_2^{\dagger}(z_l)dz_l|0\rangle.\end{aligned} \tag{8}$$

Notice that the $Q_1^{\dagger}(x_i)$s and $Q_3^{\dagger}(y_j)$s in the products have a well defined order. That means that if $i<i'$, $Q_1^{\dagger}(x_i)$ must be on the left-hand side of $Q_1^{\dagger}(x_{i'})$. From the Schrödinger equation $H|N_1,N_2\rangle=E|N_1,N_2\rangle$ we get

$$\begin{aligned}&\left\{-i\sum_i\frac{\partial}{\partial x_i}+i\sum_j\frac{\partial}{\partial y_j}+M\nu\right\}\Psi_M+g\sum_{l=1}^{M}\Psi_{M-1}(\ldots,z_l,z_i,\ldots|\ldots,z_{l-1},z_{l+1},\ldots)\\&+g\sum_{i,j}(-1)^{N_1-M-i+j-1}\Psi_{M+1}(\ldots,x_{i-1},x_{i+1},\ldots|\ldots,y_{j-1},y_{j+1},\ldots|x_i,\ldots)\\&\times\delta(x_i-y_j)+c\sum_{i,j}\delta(x_i-y_j)\Psi_M=E\Psi_M.\end{aligned} \tag{9}$$

To give the explicit form of Ψ_M, it is convenient to construct first Ψ_0. We define the color indices of the coordinates x_i and y_j as $\alpha_i=1$ and $\alpha_{N_1+j}=-1$, respectively. Also, we introduce the color indices of the momenta as $\gamma_i=1$ for $\{k_1,\ldots,k_{N_1}\}$ and $\gamma_{N_1+j}=-1$ for $\{q_1,\ldots,q_{N_2}\}$, where k_is and q_js are the momenta carried by the Q_1 and Q_3 particles, respectively. A Q_2 particle may carry a momentum k_i+q_j as shown in Eq. (6). Introduce the notations

$$\{s_1,\ldots,s_N\}=\{k_1,\ldots,k_{N_1};q_1,\ldots,q_{N_2}\},$$
$$\{t_1,\ldots,t_N\}=\{x_1,\ldots,x_{N_1};y_1,\ldots,y_{N_2}\},$$

and then make the following ansatz:

$$\Psi_0(x_1,\ldots,x_{N_1}|y_1,\ldots,y_{N_2})=\sum_{P,Q} A_P(Q)\exp\left[i\sum_{j=1}^{N} s_{P_j}t_{Q_j}\right]$$
$$\times\prod_{j=1}^{N}\delta_{\alpha_{Q_j}}^{\gamma_{P_j}}\theta(t_{Q_1}<\cdots<t_{Q_N})=\sum_{Q,P}\Psi_0[Q,P]. \tag{10}$$

Above we have put $N=N_1+N_2$. P,Q are permutations of (1,..., N) and $A_P(Q)$s are constants which satisfy

$$A_{\ldots,P_i,P_{i+1},\ldots,}(Q)=-A_{\ldots,P_{i+1},P_{i\ldots,}}(Q), \tag{11}$$

due to the antisymmetry of fermion wave functions. The general eigenstates can be constructed by the following theorem.

Theorem: The constants $A_P(Q)$s in Eq. (10) satisfy

$$A_{\ldots,P_i,P_{i+1},\ldots,}(\ldots,Q_i,Q_{i+1},\ldots,)=S(P_i,P_{i+1})A_{\ldots,P_{i+1},P_i,\ldots,}(\ldots,Q_{i+1},Q_i,\ldots), \tag{12}$$

with the S matrix

$$S(P_i,P_j)=e^{i\phi}\frac{s_{P_i}-s_{P_j}-\nu+i\mu}{s_{P_i}-s_{P_j}-\nu-i\mu^*}\quad\text{for}\ \ \gamma_{P_i}=1,\gamma_{P_j}=-1,$$

$$S(P_i,P_j)=e^{-i\phi}\frac{s_{P_i}-s_{P_j}+\nu+i\mu^*}{s_{P_i}-s_{P_j}+\nu-i\mu}\quad\text{for}\ \ \gamma_{P_i}=-1,\gamma_{P_j}=1, \tag{13}$$

$$S(P_i,P_j)=1\quad\text{for}\ \ \gamma_{P_i}=\gamma_{P_j}.$$

Then the wave function (10) is uniquely defined. Ψ_M in Eq. (8) is the M order contraction of Ψ_0. A z_l coordinate corresponds to the contraction of a pair

$$\{x_i=z_l,y_j=z_l|i>N_1-M,\quad j>N_2-M\}.$$

In a given range $[Q,P]$, put

$$x_i=z_l=t_{Q_m},\quad y_j=z_l=t_{Q_{m+1}};\ \ k^{(l)}=s_{P_m},\quad q^{(l)}=s_{P_{m+1}},$$

and

$$\Psi_M[Q,P]=\sum_{Q,P}\prod_{l=1}^{M}S^+(k^{(l)},q^{(l)})(-1)^{N_1-M-i+j-1}\Psi_0[Q,P].$$

Then the state defined in Eq. (8) is an eigenstate with the eigenenergy

$$E=\sum_{i=1}^{N_1}k_i-\sum_{j=1}^{N_2}q_j.$$

Proof: The above theorem can be demonstrated directly from Eq. (9). In a given coordinate and momentum arrangement $[Q,P]$, the corresponding term $\Psi_M[Q,P]$ of Ψ_M can be expressed as

$$\Psi_M[Q,P]=A_M[Q,P]\prod_{i=1}^{N_1-M}\exp(ik_i'x_i)\prod_{j=1}^{N_2-M}\exp(iq_j'y_j)\prod_{l=1}^{M}\exp[i(k^{(l)}+q^{(l)})z_l],$$

k_i' and $k^{(l)}$ belong to $\{k_1,\ldots,k_{N_1}\}$ and q_j' and $q^{(l)}$ belong to $\{q_1,\ldots,q_{N_2}\}$. $A_M[Q,P]$ is a constant. The theorem defines

$$\Psi_{M-1}[Q,P](\ldots,z_l|z_l,\ldots|\ldots,z_{l-1},z_{l+1},\ldots)=\frac{1}{S^+(k^{(l)},q^{(l)})}\Psi_M[Q,P],$$

$$\begin{aligned}&\Psi_{M+1}[Q,P](\ldots,x_{i-1},x_{i+1},\ldots|\ldots,y_{j-1},y_{j+1},\ldots|x_i,\ldots)\\&\quad=(-1)^{N_1-M-i+j-1}S^+(k_i',q_j')\Psi_M[Q,P].\end{aligned}$$

Thus we have

$$\begin{aligned}&M_\nu\Psi_M[Q,P]+g\sum_{l=1}^{M}\Psi_{M-1}[Q,P](\ldots,z_l|z_l,\ldots|\ldots,z_{l-1},z_{l+1},\ldots)\\&\quad=\sum_{l=1}^{M}(k^{(l)}-q^{(l)})\Psi_M[Q,P]\end{aligned}\tag{14}$$

and

$$\begin{aligned}&-i\left\{\sum_{i=1}^{N_1-M}\frac{\partial}{\partial x_i}-\sum_{j=1}^{N_2-M}\frac{\partial}{\partial y_j}\right\}\Psi_M[Q,P]+\sum_{i,j}[c+gS^+(k_i',q_j')]\Psi_M[Q,P]\delta(x_i-y_j)\\&\quad=\left\{\sum_{i=1}^{N_1-M}k_i'-\sum_{j=1}^{N_2-M}q_j'\right\}\Psi_M[Q,P].\end{aligned}\tag{15}$$

Substituting Eqs. (14) and (15) into Eq. (9) we find that Eq. (9) is an identity if $E=\Sigma_{i=1}^{N_1}k_i-\Sigma_{j=1}^{N_2}q_j$. Then the state (8) with the functions Ψ_Ms defined in the theorem is really an eigenstate. (QED)

From the periodic conditions

$$\Psi_M(\ldots,x_i|\ldots,y_j,\ldots)=\Psi_M(\ldots,x_i+L,\ldots)=\Psi_M(\ldots,y_j+L,\ldots)$$

we get the following Bethe ansatz equations:

$$e^{ik_iL}=e^{iN_2\phi}\prod_{j=1}^{N_2}\frac{k_i-q_j-\nu+i\mu}{k_i-q_j-\nu-i\mu^*},\quad e^{iq_jL}=e^{-iN_1\phi}\prod_{i=1}^{N_1}\frac{q_j-k_i+\nu+i\mu^*}{q_j-k_i+\nu-i\mu},\tag{16}$$

where L is the length of the system.

III. PHYSICAL VACUUM

Take the logarithm of Eq. (16),

$$k_i L = 2\pi I_i + \sum_j \Theta(k_i, q_j) + N_2 \phi, \quad q_j L = 2\pi J_j - \sum_i \Theta(k_i, q_j) - N_1 \phi, \tag{17}$$

where I_i and J_j are integers or half-odd integers and

$$\Theta(k,q) = -2 \tan^{-1} \frac{k - q - \nu - \mu_I}{\mu_R}$$

with

$$\mu_R = \mathrm{Re}\ \mu, \mu_I = \mathrm{Im}\ \mu.$$

There are no two I_is or two J_js and then two k_is or two q_js being equal. It can be deduced from Eq. (16) that the present model has no bound state. That means the spectrum of the Hamiltonian must be given in real $\{k,q\}$ sets. A set of $\{I_i, J_j\}$ defines a unique eigenstate of the Hamiltonian and Eq. (17) gives a complete set of the solutions.[12]

Because the energy spectrum is not bounded from below, a cutoff K should be introduced. The cutoffs are defined as $k_i > -K$ and $q_j < K$. In the ground state, all I_is and J_js must be consecutive numbers. Now we consider the thermodynamic limit of the system with $N \to \infty$, $L \to \infty$, and $N/L = D$ keeping finite. Introducing the density functions

$$\rho_0(k) = \frac{1}{L(k_{i+1} - k_i)}, \quad \sigma_0(q) = \frac{1}{L(q_{j+1} - q_j)}, \tag{18}$$

and taking the infinite limit we get

$$\begin{aligned} 1 &= 2\pi\rho_0(k) - \int_0^K \frac{2\mu_R \sigma_0(q)\, dq}{[k - q - \nu - \mu_I]^2 + \mu_{R^2}}, \\ 1 &= 2\pi\sigma_0(q) - \int_{-K}^0 \frac{2\mu_R \rho_0(k)\, dk}{[q - k + \nu + \mu_I]^2 + \mu_{R^2}}. \end{aligned} \tag{19}$$

Here we have put the Fermi level at zero.

The Fermi sea consists thus of all negative k-states and all positive q-states are filled with cutoffs. The density of ground state energy is

$$E_g/L = \int_{-K}^0 k\rho_0(k)\, dk - \int_0^K q\sigma_0(q)\, dq, \tag{20}$$

and the momentum density is

$$P_g/L = \int_{-K}^0 k\rho_0(k)\, dk + \int_0^K q\sigma_0(q)\, dq, \tag{21}$$

with the cutoff K determined by

$$D = \int_{-K}^0 \rho_0(k)\, dk + \int_0^K \sigma_0(q)\, dq. \tag{22}$$

IV. ELEMENTARY EXCITATIONS

The excitations are described by the ''quasiholes'' in the Fermi sea and the ''quasiparticles'' above the Fermi level. There are four types of such excitations. In an isolated system, the number of quasiholes is exactly the same of that of quasiparticles. For an excited state, Eq. (17) shows that the quantum numbers I_is and J_js are also in the same two lattices, but not occupied consecutively. We shall call the empty lattice sites of I_i and J_j holes. Now let

$$\begin{aligned} Lh_1(k) &= kL - N_2\phi - \sum_j \Theta(k,q_j), \\ Lh_2(q) &= qL + N_1\phi + \sum_i \Theta(k_i,q). \end{aligned} \tag{23}$$

Those values of k and q where $Lh_1(k)=2\pi I$ and $Lh_2(q)=2\pi J$ are ks and qs. Those values of k and q where $Lh_1(k)=2\pi I^h$ and $Lh_2(q)=2\pi J^h$ are k^hs and q^hs. Thus

$$\frac{dh_1(k)}{dk}=2\pi[\rho(k)+\rho^h(k)], \quad \frac{dh_2(q)}{dq}=2\pi[\sigma(q)+\sigma^h(q)], \tag{24}$$

where $\rho(k),\sigma(q)$ and $\rho^h(k),\sigma^h(q)$ are the particle and hole densities, respectively, in an excited state. For low lying excitations, there are only few quasiholes in the Fermi sea and few quasiparticles above the Fermi level. We may define the densities of quasihole states in the Fermi sea as

$$\rho^h(k)=\frac{1}{L}\sum \delta(k-k^h), \quad \sigma^h(q)=\frac{1}{L}\sum \delta(q-q^h), \tag{25}$$

and the densities of quasiparticle states above the Fermi level as

$$\frac{1}{L}\sum \delta(k-k^2), \quad \frac{1}{L}\sum \delta(q-q^p), \tag{26}$$

where the symbol Σ denotes the summation of h or p. From Eq. (23) we obtain

$$\begin{aligned} 1 &= 2\pi\rho(k) + \frac{2\pi}{L}\sum \delta(k-k^h) - \int_0^K a(k,q)\sigma(q)dq - \frac{1}{L}a(k,q^p), \\ 1 &= 2\pi\sigma(q) + \frac{2\pi}{L}\sum \delta(q-q^h) - \int_{-K}^0 a(k,q)\rho(k)dk - \frac{1}{L}a(k^p,q). \end{aligned} \tag{27}$$

Above we have put

$$-K<k<0, \quad 0<q<K, \quad a(k,q)=\frac{2\mu_R}{[k-q-\nu-\mu_i]^2+\mu_{R^2}}.$$

Defining

$$F(k)=L[\rho(k)-\rho_0(k)]+\sum \delta(k-k^h),$$
$$H(q)=L[\sigma(q)-\sigma_0(q)]+\sum \delta(q-q^h), \tag{28}$$

then we have

$$2\pi F(k)-\int_0^K a(k,q)H(q)dq=\sum a(k,q^p)-\sum a(k,q^h),$$
$$2\pi H(q)-\int_{-K}^0 a(k,q)F(k)dk=\sum a(k^p,q)-\sum a(k^h,q). \tag{29}$$

The excitation energy is then given by

$$\epsilon=\sum |k^p|+\sum |k^h|+\sum |q^p|+\sum |q^h|+\int_{-K}^0 kF(k)dk-\int_0^K qH(q)dq, \tag{30}$$

where the last two terms are usually called back flow of the Fermi sea. Notice that here $k^p,q^h>0$ and $k^h,q^p<0$. When $\mu\to\infty$, the fermions are too hard to close each other and the system will behave as two noninteracting subsystems. In this case, $a(k,q)\to 0$ and $F(k),H(q)\to 0$. The excitations are exactly described by the quasiparticles and quasiholes. It is just the anticipated result.

V. THERMODYNAMICS

We construct the thermodynamics following the standard method developed by Yang and Yang.[12] At finite temperature, the method used to describe the low lying excitations is inappropriate because the number of quasiparticles and quasiholes becomes a large quantity. Taking the infinite limit of Eq. (17) with Eq. (24) we obtain

$$1=2\pi[\rho(k)+\rho^h(k)]-\int_{-\infty}^K a(k,q)\sigma(q)dq,$$
$$1=2\pi[\sigma(q)+\sigma^h(q)]-\int_{-K}^{\infty} a(k,q)\rho(k)dk. \tag{31}$$

The energy density is

$$E/L=\int_{-K}^{\infty} k\rho(k)dk-\int_{-\infty}^K q\sigma(q)dq \tag{32}$$

and

$$D=\int_{-K}^{\infty}\rho(k)dk+\int_{-\infty}^K \sigma(q)dq. \tag{33}$$

The entropy of the state described by $\rho(k)$ and $\sigma(q)$ is not zero because of the empty sites in the I_i and J_j lattices which allow many wave functions of approximately the same energy to be described by $\rho(k),\rho^h(k)$ and $\sigma(q),\sigma^h(q)$. In an interval dk, the total number of ks and holes is $L(\rho+\rho^h)dk$. Thus the choices of states in dk with given $\rho(k)$ and $\rho^h(k)$ is

$$\frac{[L(\rho+\rho^h)dk]!}{[L\rho dk]![L\rho^h dk]!}.$$

For $\sigma(q)$ and $\sigma^h(q)$ we have the same discussion. Then the density of the total entropy is given by

$$S/L=\int_{-K}^{\infty}[(\rho+\rho^h)\ln(\rho+\rho^h)-\rho\ \ln\ \rho-\rho^h\ \ln\ \rho^h]dk$$
$$+\int_{-\infty}^{K}[(\sigma+\sigma^h)\ln(\sigma+\sigma^h)-\sigma\ \ln\ \sigma-\sigma^h\ \ln\ \sigma^h]dq. \tag{34}$$

The partition function can be written as

$$Z=\int D\sigma\ D\sigma^h\ D\rho\ D\rho^h\ \exp(S-E/T+AN/T), \tag{35}$$

where A is the Lagrange multiplier. At the thermal equilibrium, we should maximize the contribution to the partition function from the states described by ρ,ρ^h and σ,σ^h. The equilibrium values of ρ and σ are then obtained from variation. The above described procedure leads to the following equations for the equilibrium ρ and σ:

$$\begin{aligned} k+T\ \ln\frac{\rho}{\rho^h}-\frac{T}{2\pi}\int_{-\infty}^{K}a(k,q)\ln\left(1+\frac{\sigma}{\sigma^h}\right)dq=A,\\ -q+T\ \ln\frac{\sigma}{\sigma^h}-\frac{T}{2\pi}\int_{-K}^{\infty}a(k,q)\ln\left(1+\frac{\rho}{\rho^h}\right)dk=A. \end{aligned} \tag{36}$$

Introducing the notations $\exp[\epsilon_1(k)/T]=\rho^h(k)/\rho(k)$ and $\exp[\epsilon_2(q)/T]=\sigma^h(q)/\sigma(q)$, we may rewrite Eq. (36) as

$$\begin{aligned} A=k-\epsilon_1(k)-\frac{T}{2\pi}\int_{-\infty}^{K}a(k,q)\ln[1+\exp(-\epsilon_2/T)]dq,\\ A=-q-\epsilon_2(q)-\frac{T}{2\pi}\int_{-K}^{\infty}a(k,q)\ln[1+\exp(-\epsilon_1/T)]dk. \end{aligned} \tag{37}$$

Multiply Eq. (37) by $\rho(k)$ and $\sigma(q)$, respectively, with integral and then sum them to obtain

$$AD=\int_{-K}^{\infty}\rho(k-\epsilon_1)dk+\int_{-\infty}^{K}\sigma(-q-\epsilon_2)dq+T\int_{-\infty}^{K}\left\{\frac{1}{2\pi}-\sigma[1+\exp(\epsilon_2/T)]\right\}$$
$$\times\ln[1+\exp(-\epsilon_2/T)]dq+T\int_{-K}^{\infty}\left\{\frac{1}{2\pi}-\rho[1+\exp(\epsilon_1/T)]\right\}\ln[1+\exp(-\epsilon_1/T)]dk. \tag{38}$$

Now rewriting S/L as

$$S/L=\int_{-K}^{\infty}(\rho+\rho^h)\ln[1+\exp(-\epsilon_1/T)]dk+\frac{1}{T}\int_{-K}^{\infty}\rho\epsilon_1\,dk$$
$$+\int_{-\infty}^{K}(\sigma+\sigma^h)\ln[1+\exp(-\epsilon_2/T)]dq+\frac{1}{T}\int_{-\infty}^{K}\sigma\epsilon_2 dq, \tag{39}$$

we obtain the density of free energy

$$F/L=AD-\frac{T}{2\pi}\left\{\int_{-K}^{\infty}\ln[1+\exp(-\epsilon_1/T)]dk+\int_{-\infty}^{K}\ln[1+\exp(-\epsilon_2/T)]dq\right\}. \tag{40}$$

Below we shall check some special cases.

A. A=Chemical potential

By thermodynamics we have

$$F=-PL+NB, \tag{41}$$

where P and B are the pressure and chemical potential, respectively. The pressure is thus given by

$$P=-N\frac{\partial A}{\partial L}-\frac{N}{2\pi D}\left[\int_{-K}^{\infty}\frac{dk}{1+\exp(\epsilon_1/T)}\frac{\partial\epsilon_1}{\partial A}+\int_{-\infty}^{K}\frac{dq}{1+\exp(\epsilon_2/T)}\frac{\partial\epsilon_2}{\partial A}\right]\frac{\partial A}{\partial L}$$
$$+\frac{T}{2\pi}\left\{\int_{-K}^{\infty}\ln[1+\exp(-\epsilon_1/T)]dk+\int_{-\infty}^{K}\ln[1+\exp(-\epsilon_2/T)]dq\right\}. \tag{42}$$

Differentiating Eq. (37) with respect to A, we obtain

$$1=-\frac{\partial\epsilon_1}{\partial A}+\frac{1}{2\pi}\int_{-\infty}^{K}a(k,q)\frac{\partial\epsilon_2/\partial A}{1+\exp(\epsilon_2/T)}dq,$$
$$1=-\frac{\partial\epsilon_2}{\partial A}+\frac{1}{2\pi}\int_{-K}^{\infty}a(k,q)\frac{\partial\epsilon_1/\partial A}{1+\exp(\epsilon_1/T)}dk. \tag{43}$$

Comparing the above equations with Eq. (31) we get

$$-\frac{\partial\epsilon_1}{\partial A}=2\pi\rho(k)[1+\exp(\epsilon_1/T)],\quad -\frac{\partial\epsilon_2}{\partial A}=2\pi\sigma(q)[1+\exp(\epsilon_2/T)]. \tag{44}$$

Substituting Eq. (44) into Eq. (42) we find

$$P=\frac{T}{2\pi}\left\{\int_{-K}^{\infty}\ln[1+\exp(-\epsilon_1/T)]dk+\int_{-\infty}^{K}\ln[1+\exp(-\epsilon_2/T)]dq\right\}. \tag{45}$$

From Eqs. (40) and (41) with Eq. (45) we conclude that A is the chemical potential.

B. $\mu\to\infty$

In this case, the integrals in Eq. (37) contribute nothing. Thus

$$\epsilon_1(k)=k-A,\quad \epsilon_2(q)=-q-A. \tag{46}$$

From Eq. (31) we deduce

$$\rho(k)=\frac{1}{2\pi\left[1+\exp\left(\frac{k-A}{T}\right)\right]}\,\theta(k+K),$$
$$\sigma(q)=\frac{1}{2\pi\left[1+\exp\left(\frac{-q-A}{T}\right)\right]}\,\theta(K-q). \tag{47}$$

The Lagrange multiplier can be obtained from Eq. (33) as

$$A=T\,\ln[\exp(\pi D/T)-1]-K. \tag{48}$$

Notice that the cutoff K does not depend on temperature. When $T\to 0$, $A\to -K+\pi D$ and from Eq. (22) we obtain

$$K=\pi D,\quad \zeta=e^{A/T}=1-\exp(-K/T). \tag{49}$$

The free energy is given by

$$F/L=TD\,\ln\left[1-\exp\left(-\frac{K}{T}\right)\right]-\frac{T^2}{\pi}\int_{-K/T}^{\infty}\ln[1+\zeta e^{-x}]dx. \tag{50}$$

C. $\mu\to 0$, $\nu\to 0$

As $\mu\to 0$, $\nu\to 0$, $a(k,q)\to 2\pi\delta(k-q)$, so Eq. (37) becomes

$$A=k-\epsilon_1(k)-T\,\ln[1+\exp\{-\epsilon_2(k)/T\}]\,\theta(K-k),$$
$$A=-q-\epsilon_2(q)-T\,\ln[1+\exp\{-\epsilon_1(q)/T\}]\,\theta(q+K). \tag{51}$$

Thus we have

$$\epsilon_1(k)=[k-A]\,\theta(k-K)+\left[\frac{1}{2}\,(k-A)+T\,\ln\sinh\left(-\frac{A}{T}\right)-T\,\ln\cosh\frac{k+A}{2T}\right]\theta(K-|k|) \tag{52}$$

and

$$\epsilon_2(q)=[-q-A]\,\theta(-K-q)+\left[-\frac{1}{2}\,(q+A)+T\,\ln\sinh\left(-\frac{A}{T}\right)-T\,\ln\cosh\frac{A-q}{2T}\right]\theta(K-|q|). \tag{53}$$

From Eq. (31) we have

$$1=2\pi\rho(k)[1+\exp(\epsilon_1/T)]+2\pi\sigma(k)\,\theta(K-k),$$
$$1=2\pi\sigma(q)[1+\exp(\epsilon_2/T)]+2\pi\rho(q)\,\theta(q+K). \tag{54}$$

Thus the thermodynamics can be constructed from Eqs. (33) and (40) with Eqs. (52), (53), and (54).

VI. CONCLUSION

In conclusion, we have established the exact eigenstates of a boson–fermion model with two-body interactions. The physical properties including the ground state, the low lying elementary excitations, and the thermodynamics have been studied in a cut-off scheme. In the present model, the cutoff K is only a parameter which is relevant to the physical data in a concrete system. In fact, we can take the scaling limit $K\to\infty$. In this case, the quantity $F-E_g$ (free energy minus the ground state energy) is indeed convergent. It should be pointed out that the model Hamiltonian is not analytic at $\mu_R=0$ due to the special form of the ''contraction–decay'' interaction which breaks the particle hole symmetry. That means that this type of interactions cannot be turned on adiabatically. This is why the $\mu\to 0$ limit does not give the results of a free fermion system as discussed in the above section.

We would like to point out that even for the particles with arbitrary moving velocities $(v_1\neq v_2\neq v_3)$, the model is also solvable with the same algebra. At first glance, it seems that the linear spectrum of the bosons with a finite moving velocity is ill-defined. However, we notice that the bosons are nothing but the ''fusion'' of two fermions in our model. Thus they behave as hard core bosons. That means the bosons obey Fermi-like statistics rather than Bose statistics. The system has a well defined ground state (Fermi sea) even the velocity of the bosons takes a finite value. Such a result can also be deduced from the Bethe ansatz equations. The energy for a given eigenstate determined uniquely by the two set of real numbers $\{k\}$ and $\{q\}$ which obey the Fermi statistics.

I. INTRODUCTION

In the past few decades, a dozen models have been solved via the Bethe ansatz[1] and the Bethe–Yang ansatz.[2] In this paper, we consider a new Bethe ansatz soluble model, e.g., the Dirac-like Lee model. The Lee model[3] plays an important role in the quantum field theory. Recently, similar models have been proposed to describe the high Tc superconductivity.[4,5]

The Hamiltonian we shall consider reads as

$$\mathbf{H}=\int dx\Big\{-i\sum_{r=\pm} r\Psi_r^\dagger(x)\,\frac{\partial}{\partial x}\,\Psi_r(x)+m[\Psi_+^\dagger(x)\Psi_-(x)+\Psi_-^\dagger(x)\Psi_+(x)]$$
$$+g[\Psi_+^\dagger(x)\Psi_-^\dagger(x)b(x)+b^\dagger(x)\Psi_-(x)\Psi_+(x)]\Big\}, \tag{1}$$

where $\Psi_r^\dagger(x)(\Psi_r(x))$ are the creation (annihilation) operators of the fermions and $b^\dagger(x)(b(x))$ is the creation (annihilation) operator of the bosons. m and g are real constants. The massive term in (1) may be induced by either the electron–phonon $(2k_F)$ interaction or the backward scattering among the electrons. The bosons, however, may represent a variety of physical situations phenomenologically, such as the Cooper-pair-like bound state or the dimer state. We would like to point out that the Hamiltonian (1) is similar to that of the massive Thirring model.[6]

A special feature of the Lee model is that the particle numbers are no longer conserved. It can be easily read off from (1). However, the quantity

$$\mathbf{N}=\int\Big[\sum_{r=\pm}\Psi_r^\dagger(x)\Psi_r(x)+2b^\dagger(x)b(x)\Big]dx, \tag{2}$$

is conserved. Therefore, we can establish the common eigenstates of **H** and **N**.

II. BETHE STATES

To show the procedure clearly, it is convenient to consider the $N=2$ case first. Such a state is the simplest nontrivial state, which gives the main information about the general engenstates. As done in the massive Thirring model,[6] we introduce the operator

$$\Psi_\alpha^\dagger(x)=e^{\alpha/2}\Psi_+^\dagger(x)+e^{-\alpha/2}\Psi_-^\dagger(x), \tag{3}$$

where α takes values in the lines Im $\alpha=0$ and Im $\alpha=\pi$. An $N=2$ eigenstate can be written as

0022-2488/96/37(11)/5424/5/$10.00

$$|\alpha_1,\alpha_2\rangle=\int dx_1\ dx_2\ f(x_1,x_2)\Psi^{\dagger}_{\alpha_1}(x_1)\Psi^{\dagger}_{\alpha_2}(x_2)|0\rangle+\int dy\ h(y)b^{\dagger}(y)|0\rangle, \tag{4}$$

where $|0\rangle$ is the pseudovacuum state defined by $\Psi_r(x)|0\rangle=b(x)|0\rangle=0$. The Schrödinger equation $H|\alpha_1,\alpha_2\rangle=E(\alpha_1,\alpha_2)|\alpha_1,\alpha_2\rangle$ gives

$$\begin{aligned}\int\ dx_1\ dx_2\Bigg\{&\sum_{r=\pm}\left[-ire^{r\alpha_1/2}\frac{\partial}{\partial x_1}+me^{-r\alpha_1/2}\right]f(x_1,x_2)\Psi^{\dagger}_r(x_1)\Psi^{\dagger}_{\alpha_2}(x_2)|0\rangle\\&+\Psi^{\dagger}_{\alpha_1}(x_1)\sum_{r=\pm}\left[-ire^{r\alpha_2/2}\frac{\partial}{\partial x_2}+me^{-r\alpha_2/2}\right]f(x_1,x_2)\Psi^{\dagger}_r(x_2)|0\rangle\Bigg\}+g\int dy\ h(y)\\&\times\Psi^{\dagger}_+(y)\Psi^{\dagger}_-(y)|0\rangle+2g\int dx\ f(x,x)\sinh\frac{\alpha_1-\alpha_2}{2}\,b^{\dagger}(x)|0\rangle=E(\alpha_1,\alpha_2)|\alpha_1,\alpha_2\rangle.\end{aligned} \tag{5}$$

Make the following ansatz:

$$\begin{aligned}f(x_1,x_2)&=\exp\{ix_1m\ \sinh\ \alpha_1+ix_2m\ \sinh\ \alpha_2\}[1+i\lambda(\alpha_1,\alpha_2)\epsilon(x_1-x_2)],\\h(x)&=S^{+}(\alpha_1,\alpha_2)f(x,x),\end{aligned} \tag{6}$$

where $\epsilon(x)=\theta(x)-\theta(-x)$ and $\theta(x)$ is the step function. Substituting (6) into (5), we readily obtain

$$E(\alpha_1,\alpha_2)=m\ \cosh\ \alpha_1+m\ \cosh\ \alpha_2, \tag{7}$$

$$S^{+}(\alpha_1,\alpha_2)=\frac{2g\ \sinh[(\alpha_1-\alpha_2)/2]}{m\ \cosh\ \alpha_1+m\ \cosh\ \alpha_2}, \tag{8}$$

$$\lambda(\alpha_1,\alpha_2)=-\frac{g^2}{4m}\frac{\tanh[(\alpha_1-\alpha_2)/2]}{\cosh\ \alpha_1+\cosh\ \alpha_2}. \tag{9}$$

Through the same procedure, we can establish the general eigenstates with arbitrary N by introducing the ladder wave functions f_M,[7]

$$\begin{aligned}|\alpha_1,\ldots,\alpha_N\rangle=\int&\sum_{M=0}^{[N/2]}\sum_{\{i_k<j_k\}}f_M(x_1,\ldots,x_{i_k-1},x_{i_k+1},\ldots,x_N|x_{i_1}=x_{j_1},\ldots,x_{i_M}=x_{j_M})\\&\times\prod_{\substack{l=1\\l\neq\{i_k,j_k\}}}^{N}\Psi^{\dagger}_{\alpha_l}(x_l)dx_l\prod_{k=1}^{M}b^{\dagger}(x_{i_k})dx_{i_k}|0\rangle,\end{aligned} \tag{10}$$

where $\{i_k<j_k\}$ denotes the choices of i_k's and j_k's with the restrictions $i_k<j_k$ and $i_k\neq i_{k'}$, $j_{k'}$ for $k\neq k'$. After some manipulations we deduce the ladder wave function f_M as

$$\begin{aligned}&f_M(x_1,\ldots,x_{i_k-1},x_{i_k+1},\ldots,x_N|x_{i_1}=x_{j_1},\ldots,x_{i_M}=x_{j_M})\\&=\prod_{l=1}^{N}e^{imx_l\ \sinh\ \alpha_l}\prod_{1\leqslant m<n\leqslant N}[1+i\lambda(\alpha_m,\alpha_n)\epsilon(x_m\end{aligned} \tag{11}$$

$$-x_n)]\prod_{k=1}^{M}\zeta_k\frac{2g\ \sinh[(\alpha_{i_k}-\alpha_{j_k})/2]}{m\ \cosh\ \alpha_{i_k}+m\ \cosh\ \alpha_{j_k}},$$

where $\zeta_k=(-1)^{i_k-j_k+1}$ is induced by the contraction process of two fermions to a boson. It is easy to verify that with f_M defined in (11), the state (10) is really an eigenstate of the Hamiltonian (1) with the eigenenergy and the momentum,

$$E(\alpha_1,\ldots,\alpha_N)=\sum_{l=1}^{N}m\ \cosh\ \alpha_l,\quad P(\alpha_1,\ldots,\alpha_N)=\sum_{l=1}^{N}m\ \sinh\ \alpha_l. \tag{12}$$

Imposing the periodic conditions in f_M's we obtain the following Bethe ansatz equation:

$$e^{iLm\ \sinh\ \alpha_j}=\prod_{i=1}^{N}\frac{\cosh\ \alpha_j+\cosh\ \alpha_i+ic\ \tanh[(\alpha_j-\alpha_i)/2]}{\cosh\ \alpha_j+\cosh\ \alpha_i-ic\ \tanh[(\alpha_j-\alpha_i)/2]}, \tag{13}$$

where L is the length of the system and $c=g^2/4m$. The physical properties of the present model (1) are uniquely determined by the Bethe ansatz equation (13). The physical vacuum or the ground state is the state in which all the α modes in the line Im $\alpha=\pi$ are filled. Suppose $\beta=$Re α. By taking the limit $L\to\infty$ in (13), we deduce that the density of β in the ground state satisfies the following integral equation:

$$m\ \cosh\ \beta=2\pi\rho(\beta)+\int_{-\Lambda}^{\Lambda}\frac{2c}{\cosh[(\beta-\beta')/2]}\frac{\cosh[(\beta+\beta')/2]-\sinh\ \beta\ \sinh[(\beta-\beta')/2]}{(\cosh\ \beta+\cosh\ \beta')^2+c^2\ \tanh^2[(\beta-\beta')/2]}\rho(\beta')d\beta', \tag{14}$$

where $\Lambda\to\infty$ is a cutoff for the modes β that renormalizes the mass m and the velocities of the modes.[6]

III. ELEMENTARY EXCITATIONS

Based on the Bethe ansatz equation (13), we can discuss the excitations of the system. The simplest excitation possible is obtained by moving a mode from $\alpha=\beta+i\pi$ and placing it at $\alpha=\beta'$, where β and β' are real. In free field theory, this particle–hole pair is a state with a fermion and an antifermion. The antifermion (hole) has energy $-m\cosh(\beta+i\pi)=m\cosh\beta$, and the fermion has energy $m\cosh\beta'$. In the interacting system, the energy has the same form to that of the free system. Given a β, we can choose β' arbitrarily to satisfy the Bethe ansatz equation (13) because c is a positive number. This is not the case of the massive Thirring model as described in Ref. 6, where there may be some restriction for the choice of β'.

There are also other possible excitations in the interacting theory. The modes can be put in the complex plane. Generally, we must be careful to place modes symmetrically about the lines Im $\alpha=\pi$ and or Im $\alpha=0$ (mod 2π) to ensure the energy and the momentum to be real. An imaging α ($\alpha\neq n\pi$) introduces the possibility of an exponentially growing wave function in some direction. However, the coefficient of the exponentially growing term vanishes if we choose the complex modes properly. The excitations for the present model have special features because the two-body scattering matrix is not a function of $\alpha_i-\alpha_j$: (i) Only the two strings with position-dependent lengths may exist apart from the origin. The failure of Lorentz invariance in Lee-type models like this one leads to the position dependence of the length of strings; (ii) the n-body bound state corresponds to a bent n string. Here a bent string means that the real parts of the roots are not equal, hence the string is not a straight line parallel to the imaginary axis and may be bent

in the complex plane. A bent $2n$ string is composed by n conjugate pairs and a bent $2n+1$ string is composed by n conjugate pairs plus a mode in the lines Im $\alpha=0,\ \pi$. Below we discuss some special cases.

A. Two-string solutions

The two-string excitation is obtained by moving two modes in the line Im $\alpha=\pi$ to the strip $|\text{Im }\alpha|<\pi$ conjugately. Suppose the two string has the form

$$\alpha_{\pm}=\beta\pm i\Delta(\beta), \tag{15}$$

where β, $\Delta(\beta)$ are real. The complex roots are determined either from the zeros or poles from the right side of the Bethe ansatz equation (13) because of the $L\to\infty$ behavior of the left side. We deduce that

$$\sin\ \Delta(\beta)=\frac{(c^2+16\cosh^2\ \beta)^{1/2}-c}{4\cosh\ \beta}. \tag{16}$$

Obviously, there are two solutions for a given β. One is $\Delta_1=\arcsin\{[(c^2+16\cosh^2\beta)^{1/2}-c]/4\cosh\beta\}$ and the other is $\Delta_2=\pi-\Delta_1$. The length of the string depends on both its position and the constant c. The position of the string is completely determined by the positions of the holes.[6,8]

B. Bent three-strings

One type of the bent three-string is composed by a conjugate pair $\alpha_{\pm}=\beta\pm i\Delta(\beta)$ and a real mode β_0. To meet the Bethe ansatz equation, $\alpha_{\pm}$ and β_0 must satisfy

$$\cosh\ \alpha_{+}+\cosh\ \beta_0+ic\ \tanh\frac{\alpha_{+}-\beta_0}{2}=0,\quad \sin\ \Delta(\beta)>0. \tag{17}$$

For a given β, β_0 and $\Delta(\beta)$ are determined by the following equations:

$$\begin{aligned}\cosh\ \beta\ \cos\ \Delta+\cosh\ \beta_0&=\frac{c\ \sin\ \Delta}{\cosh(\beta-\beta_0)+\cos\ \Delta},\\ \sinh\ \beta\ \sin\ \Delta+\frac{\sinh(\beta-\beta_0)}{\cosh(\beta-\beta_0)+\cos\ \Delta}&=0.\end{aligned} \tag{18}$$

For $\beta=0$, we have $\beta_0=0$. This solution is a normal three-string. The other type of the bent three-string is composed by a conjugate pair $\alpha_{\pm}=\beta\pm i\Delta$ and a mode $\beta_0+i\pi$. β, β_0, and Δ satisfy the equations

$$\begin{aligned}\cosh\ \beta\ \cos\ \Delta-\cosh\ \beta_0&=\frac{c\ \sin\ \Delta}{-\cosh(\beta-\beta_0)+\cos\ \Delta},\\ \sinh\ \beta\ \sin\ \Delta+\frac{\sinh(\beta-\beta_0)}{\cosh(\beta-\beta_0)-\cos\ \Delta}&=0.\end{aligned} \tag{19}$$

C. *n* string on the imaginary axis

Higher strings can be constructed by the same procedures. Any string, consisting of $2s+1$ modes, where s is either an integer or a half-integer, has its modes at α_s, $\alpha_{s-1},\ldots,\alpha_{-s}$, where

$$\cosh\ \alpha_j+\cosh\ \alpha_{j-1}+ic\ \tanh\ \tfrac{1}{2}(\alpha_j-\alpha_{j-1})=0.$$

In the special case where all the modes lie on the imaginary axis, the equation can be simplified. For a $2n$ string,

$$\alpha_{j\pm}=\pm i\Delta_j,\quad j=\frac{1}{2},\ldots,\frac{n}{2}-1, \tag{20}$$

we have the solutions

$$\begin{aligned}&\sin\ \Delta_{1/2}=\frac{(c^2+16)^{1/2}-c}{4},\\ &\cos\ \Delta_{j+1}+\cos\ \Delta_j=c\ \tan\frac{\Delta_{j+1}-\Delta_j}{2},\quad \text{for } j\geqslant\frac{1}{2}.\end{aligned} \tag{21}$$

For a $2n+1$ string,

$$\alpha_0=0,\quad \alpha_{j\pm}=\pm i\Delta_j,\quad j=1,2,\ldots,n, \tag{22}$$

we have the solution

$$\begin{aligned}&1+\cos\ \Delta_1=c\ \tan\frac{\Delta_1}{2},\\ &\cos\ \Delta_{j+1}+\cos\ \Delta_j=c\ \tan\frac{\Delta_{j+1}-\Delta_j}{2},\quad \text{for } j\geqslant 1.\end{aligned} \tag{23}$$

Note by moving the modes by $i\pi$ we can obtain a string symmetric to the line Im $\alpha=\pi$.

IV. CONCLUDING REMARKS

In conclusion, we have established the exact eigenstates of a massive Lee model. The elementary excitations are discussed. It is found that the general complex excitations are bent strings. Some special cases are discussed.

Microcanonical ensemble and algebra of conserved generators for generalized quantum dynamics

Stephen L. Adler and L. P. Horwitz[a)]
School of Natural Sciences, Institute for Advanced Study, Princeton, New Jersey 08540

(Received 6 June 1996; accepted for publication 15 June 1996)

It has recently been shown, by application of statistical mechanical methods to determine the canonical ensemble governing the equilibrium distribution of operator initial values, that complex quantum field theory can emerge as a statistical approximation to an underlying generalized quantum dynamics. This result was obtained by an argument based on a Ward identity analogous to the equipartition theorem of classical statistical mechanics. We construct here a microcanonical ensemble which forms the basis of this canonical ensemble. This construction enables us to define the microcanonical entropy and free energy of the field configuration of the equilibrium distribution and to study the stability of the canonical ensemble. We also study the algebraic structure of the conserved generators from which the microcanonical and canonical ensembles are constructed, and the flows they induce on the phase space. © *1996 American Institute of Physics.* [S0022-2488(96)00511-7]

I. INTRODUCTION

Generalized quantum dynamics[1,2] is an analytic mechanics on a symplectic set of operator-valued variables, forming an operator-valued phase space $\mathscr{S}$. These variables are defined as the set of linear transformations, in general, local (noncommuting) quantum fields, on an underlying real, complex, or quaternionic Hilbert space (Hilbert module), for which the postulates of a real, complex, or quaternionic quantum mechanics are satisfied.[2–6] The dynamical (generalized Heisenberg) evolution, or flow, of this phase space is generated by the total trace Hamiltonian $\mathbf{H}=\mathbf{Tr}\,H$, where for any operator O we have

$$\mathbf{O}\equiv\mathbf{Tr}\;O\equiv\mathrm{Re}\;\mathrm{Tr}(-1)^F O=\mathrm{Re}\sum_n\;\langle n|(-1)^F O|n\rangle, \tag{1.1}$$

H is a function of the operators $\{q_r(t)\},\{p_r(t)\}$, $r=1,2,\ldots,N$ (realized as a sum of monomials, or a limit of a sequence of such sums; in the general case of local noncommuting fields, the index r contains continuous variables), and $(-1)^F$ is a grading operator with eigenvalue $1(-1)$ for states in the boson (fermion) sector of the Hilbert space. Operators are called bosonic or fermionic in type if they commute or anticommute, respectively, with $(-1)^F$; for each r, p_r and q_r are of the same type.

The derivative of a total trace functional with respect to some operator variation is defined with the help of the cyclic property of the **Tr** operation. The variation of any monomial O consists of terms of the form $\mathrm{O}_L\,\delta x_r\mathrm{O}_R$, for x_r one of the $\{q_r\},\{p_r\}$, which, under the **Tr** operation, can be brought to the form

$$\delta\mathbf{O}=\delta\mathbf{Tr}\;O=\pm\,\mathbf{Tr}\;O_R O_L\,\delta x_r\,,$$

so that sums and limits of sums of such monomials permit the construction of

[a)]On sabbatical leave from School of Physics and Astronomy, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Ramat Aviv, Israel, and Department of Physics, Bar Ilan University, Ramat Gan, Israel.

$$\delta\mathbf{O}=\mathbf{Tr}\sum_r \frac{\delta\mathbf{O}}{\delta x_r}\,\delta x_r, \tag{1.2}$$

uniquely defining $\delta\mathbf{O}/\delta x_r$.

Assuming the existence of a total trace Lagrangian[1,2] $\mathbf{L}=\mathbf{L}(\{q_r\},\{\dot{q}_r\})$, the variation of the total trace action

$$\mathbf{S}=\int_{-\infty}^{\infty}\mathbf{L}(\{q_r\},\{\dot{q}_r\})dt \tag{1.3}$$

results in the operator Euler–Lagrange equations

$$\frac{\delta\mathbf{L}}{\delta q_r}-\frac{d}{dt}\frac{\delta\mathbf{L}}{\delta\dot{q}_r}=0. \tag{1.4}$$

As in classical mechanics, the total trace Hamiltonian is defined as a Legendre transform,

$$\mathbf{H}=\mathbf{Tr}\sum_r p_r\dot{q}_r-\mathbf{L}, \tag{1.5}$$

where

$$p_r=\frac{\delta\mathbf{L}}{\delta\dot{q}_r}. \tag{1.6}$$

It then follows from (1.4) that

$$\frac{\delta\mathbf{H}}{\delta q_r}=-\dot{p}_r, \quad \frac{\delta\mathbf{H}}{\delta p_r}=\epsilon_r\dot{q}_r, \tag{1.7}$$

where $\epsilon_r=1(-1)$ according to whether p_r,q_r are of bosonic (fermionic) type.

Defining the generalized Poisson bracket

$$\{\mathbf{A},\mathbf{B}\}=\mathbf{Tr}\sum_r \epsilon_r\left(\frac{\delta\mathbf{A}}{\delta q_r}\frac{\delta\mathbf{B}}{\delta p_r}-\frac{\delta\mathbf{B}}{\delta q_r}\frac{\delta\mathbf{A}}{\delta p_r}\right), \tag{1.8a}$$

one sees that

$$\frac{d\mathbf{A}}{dt}=\frac{\partial\mathbf{A}}{\partial t}+\{\mathbf{A},\mathbf{H}\}. \tag{1.8b}$$

Conversely, if we define

$$\mathbf{x}_s(\eta)=\mathbf{Tr}(\eta x_s), \tag{1.9a}$$

for η an arbitrary, constant operator (of the same type as x_s, which denotes here q_s or p_s), then

$$\frac{d\mathbf{x}_s(\eta)}{dt}=\mathbf{Tr}\sum_r \epsilon_r\left(\frac{\delta\mathbf{x}_s(\eta)}{\delta q_r}\frac{\delta\mathbf{H}}{\delta p_r}-\frac{\delta\mathbf{H}}{\delta q_r}\frac{\delta\mathbf{x}_s(\eta)}{\delta p_r}\right), \tag{1.9b}$$

and comparing the coefficients of η on both sides, one obtains the Hamiltonian equations (1.7) as a consequence of the Poisson bracket relation (1.8b).

The Jacobi identity is satisfied by the Poisson bracket of (1.8a),[7] and hence the total trace functionals have many of the properties of the corresponding quantities in classical mechanics.[8] In particular, canonical transformations take the form

$$\delta \mathbf{x}_s(\eta) = \{\mathbf{x}_s(\eta), \mathbf{G}\}, \tag{1.10a}$$

which implies that

$$\delta p_r = -\frac{\delta \mathbf{G}}{\delta q_r}, \quad \delta q_r = \epsilon_r \frac{\delta \mathbf{G}}{\delta p_r}, \tag{1.10b}$$

with the generator $\mathbf{G}$ any total trace functional constructed from the operator phase space variables. Time evolution then corresponds to the special case $\mathbf{G} = \mathbf{H}\, dt$.

It has recently been shown by Adler and Millard[9] that a canonical ensemble can be constructed on the phase space $\mathscr{S}$, reflecting the equilibrium properties of a system of many degrees of freedom. Since the operator

$$\tilde{C} = \sum_r (\epsilon_r q_r p_r - p_r q_r) = \sum_{r,B} [q_r, p_r] - \sum_{r,F} \{q_r, p_r\}, \tag{1.11}$$

where the sums are over bosonic and fermionic pairs, respectively, is conserved under the evolution (1.7) induced by the total trace Hamiltonian, the canonical ensemble must be constructed taking this constraint into account. This is done by constructing the conserved quantity $\mathbf{Tr}\, \tilde{\lambda}\tilde{C}$, for some given constant anti-Hermitian operator $\tilde{\lambda}$.

In the general case, in the presence of the fermionic sector, the graded trace of the Hamiltonian is not bounded from below, and the partition function may be divergent. When the equations of motion induced by the Lagrangian $\mathbf{L}$ coincide with those induced by the ungraded total trace of the same Lagrangian,

$$\hat{\mathbf{L}} = \mathrm{Re\ Tr}\ L$$

without the factor $(-1)^F$, the corresponding ungraded total trace Hamiltonian $\hat{\mathbf{H}}$ is conserved. It may therefore be included as a constraint functional in the canonical ensemble, along with the new conserved quantity $\hat{\mathbf{Tr}}\, \hat{\tilde{\lambda}}\hat{\tilde{C}}$ (see Appendices 0 and C of Ref. 9), where

$$\hat{\tilde{C}} = \sum_r [q_r, p_r] = \sum_{r,B} [q_r, p_r] + \sum_{r,F} [q_r, p_r]. \tag{1.12}$$

It was argued that the Ward identities derived from the canonical ensemble imply that $\hat{\tilde{\lambda}}$ and $\tilde{\lambda}$ are functionally related, so that they may be diagonalized in the same basis (Appendix F of Ref. 9). It was then shown that, since the ensemble averages depend only on $\tilde{\lambda}$ and $(-1)^F$, the ensemble average of any operator must commute with these operators. Since the ensemble-averaged operator $\langle \tilde{C} \rangle_{AV}$ is anti-self-adjoint, if one furthermore assumes it is completely degenerate (with eigenvalue $i_{\mathrm{eff}}\hbar$), the ensemble average of the theory then reduces to the usual complex quantum field theory. In this paper, we construct a microcanonical ensemble from which the canonical ensemble of Ref. 9 can be obtained following the usual methods of statistical mechanics. This construction gives some insight into the interpretation of the parameters, relates the canonical and microcanonical entropies, and identifies the generalized free energy. It also permits estimates of the statistical fluctuations admitted by the canonical ensemble, and error bounds on the Ward identity which we shall treat elsewhere. We give, in this framework, a self-consistency proof of the

stability of the canonical ensemble. We then go on to discuss the algebraic structure of the canonical generators related to the conserved operators $\tilde{C}$ and $\hat{\tilde{C}}$, and the flows on phase space induced by these generators.

II. THE MICROCANONICAL AND CANONICAL ENSEMBLES

Introducing a complete set of states $\{|n\rangle\}$ in the underlying Hilbert space, the phase space operators are completely characterized by their matrix elements $\langle m|x_r|n\rangle \equiv (x_r)_{mn}$, which have the form

$$(x_r)_{mn} = \sum_A (x_r)^A_{mn} e_A , \tag{2.1}$$

where A takes the values 0,1 for complex Hilbert space, 0,1,2,3 for quaternion Hilbert space (technically, a Hilbert module), and just the one value 0 for real Hilbert space, and the e_A are the associated hypercomplex units (unity, complex, or quaternionic units[2]). The mathematical procedures we establish here are applicable to more general Hilbert modules; arguments are given in Ref. 2, however, for restricting our attention to these three cases, and we shall therefore concentrate on the real, complex, and quaternionic structures in the examination of specific properties. The phase space measure is then defined as

$$d\mu = \prod_A d\mu^A, \quad d\mu^A \equiv \prod_{r,m,n} d(x_r)^A_{mn} , \tag{2.2}$$

where redundant factors are omitted according to adjointness conditions. The measure defined in this way is invariant under canonical transformations induced by the generalized Poisson bracket.[9]

We then define the microcanonical ensemble in terms of the set of states in the underlying Hilbert space which satisfy δ-function constraints on the values of the two total trace functionals $\mathbf{H}$ and $\hat{\mathbf{H}}$ and the matrix elements of the two conserved operator quantities $\tilde{C}$ and $\hat{\tilde{C}}$ discussed in the previous section. The volume of the corresponding submanifold in phase space is given by

$$\Gamma(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}) = \int d\mu\, \delta(E-\mathbf{H})\, \delta(\hat{E}-\hat{\mathbf{H}}) \prod_{n\leqslant m,A} \delta(\nu^A_{nm} - \langle n|(-1)^F \tilde{C}|m\rangle^A)\, \delta(\hat{\nu}^A_{nm} - \langle n|\hat{\tilde{C}}|m\rangle^A), \tag{2.3}$$

where we have used the abbreviations $\tilde{\nu} \equiv \{\nu^A_{nm}\}$ and $\hat{\tilde{\nu}} \equiv \{\hat{\nu}^{\ A}_{nm}\}$ for the parameters in the arguments on the left-hand side. The factor $(-1)^F$ in the term with $\tilde{C}$ is not essential, but convenient in obtaining the precise form given in Ref. 9 for the canonical distribution. The entropy associated with this ensemble is given by

$$S_{\mathrm{mic}}(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}) = \log\, \Gamma(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}). \tag{2.4}$$

As we shall see, it is not possible to associate a temperature to this structure in the usual simple way.

The operators $\tilde{C}$ and $\hat{\tilde{C}}$ are defined in terms of sums over degrees of freedom. In the context of the application to quantum field theory, the enumeration of degrees of freedom includes continuous parameters, corresponding to the measure space of the fields. These operators may therefore be decomposed into parts within a certain (large) region of the measure space, which we denote as b, corresponding to what we shall consider as a *bath*, in the sense of statistical mechanics, and within another (small) part of the measure space, which we denote as s, corresponding to what we shall consider as a *subsystem*. We shall assume that the functionals $\mathbf{H}$ and $\hat{\mathbf{H}}$ may also be

decomposed additively into parts associated with b and s; this assumption is equivalent to the presence of interactions in the Hamiltonian or Lagrangian operators which are reasonably localized in the measure space of the fields (the difference in structure between the Lagrangian and Hamiltonian consists of operators that are explicitly additive), so that the errors in assuming additivity are of the nature of ''surface terms.'' The constraint parameters may then be considered to be approximately additive as well, and we may rewrite the microcanonical ensemble as

$$\begin{aligned}\Gamma(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}) = \int & d\mu_b d\mu_s dE_s d\hat{E}_s (d\nu^s)(d\hat{\nu}^s)\,\delta(E-E_s-\mathbf{H}_b) \\ & \times \delta(E_s-\mathbf{H}_s)\,\delta(\hat{E}-\hat{E}_s-\hat{\mathbf{H}}_b)\,\delta(\hat{E}_s-\hat{\mathbf{H}}_s) \\ & \times \prod_{n\leqslant m,A} \delta(\nu^A_{nm}-\nu^{A,s}_{nm}-\langle n|(-1)^F\tilde{C}_b|m\rangle^A)\,\delta(\nu^{A,s}_{nm}-\langle n|(-1)^F\tilde{C}_s|m\rangle^A) \\ & \times \delta(\hat{\nu}^A_{nm}-\hat{\nu}^{A,s}_{nm}-\langle n|\hat{\tilde{C}}_b|m\rangle^A)\,\delta(\hat{\nu}^{A,s}_{nm}-\langle n|\hat{\tilde{C}}_s|m\rangle^A). \end{aligned} \tag{2.5}$$

We recognize the integrations over $d\mu_s$ and $d\mu_b$ in (2.5) in terms of the corresponding microcanonical subensembles, for the bath b and subsystem s, respectively, i.e., we may write (2.5) as

$$\Gamma(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}) = \int dE_s\; d\hat{E}_s (d\nu^s)(d\hat{\nu}^s)\Gamma_b(E-E_s,\hat{E}-\hat{E}_s,\tilde{\nu}-\tilde{\nu}_s,\hat{\tilde{\nu}}-\hat{\tilde{\nu}}_s)\Gamma_s(E_s,\hat{E}_s,\tilde{\nu}_s,\hat{\tilde{\nu}}_s). \tag{2.6}$$

We now assume that the integrand in (2.6) has a maximum for a large number of degrees of freedom that dominates the integral. In the treatment of the statistical mechanics of classical particles, the number of degrees of freedom generally vastly exceeds the number of variables controlling the constraint hypersurfaces in the phase space; in our case, due to the presence of the constraints imposed by the operators $\tilde{C}$ and $\hat{\tilde{C}}$, there are an infinite number of variables, and the question of the development of a significant maximum may be more delicate. We will demonstrate, however, that due to the semidefinite form of the autocorrelation matrix of the fluctuations, the canonical distribution that we obtain with this assumption is at least locally stable.

Let us, for brevity, define

$$\xi=\{\xi_i\}\equiv\{E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}}\}, \tag{2.7}$$

where the index i refers to the elements of the set of variables, so that (2.6) takes the form

$$\Gamma(\Xi)=\int d\xi_s \Gamma_b(\Xi-\xi_s)\Gamma_s(\xi_s), \tag{2.8a}$$

where Ξ corresponds to the set of total properties for the whole ensemble. A necessary condition for an extremum in all of the variables at $\xi_s=\xi$ is then

$$\frac{\partial}{\partial\xi}[\Gamma_b(\Xi-\xi)\Gamma_s(\xi)]\big|_{\bar{\xi}}=0, \tag{2.8b}$$

which implies that

$$\frac{1}{\Gamma_s(\xi)}\frac{\partial\Gamma_s}{\partial\xi_i}(\xi)\big|_{\bar{\xi}}=\frac{1}{\Gamma_b(\Xi-\xi)}\frac{\partial\Gamma_b}{\partial\Xi_i}(\Xi-\xi)\big|_{\bar{\xi}}. \tag{2.8c}$$

The logarithmic derivatives in (2.8c) define a set of quantities analogous to the (reciprocal) temperature of the usual statistical mechanics, i.e., equilibrium-fixing Lagrange parameters common to the bath and the subsystem. We write these separately as

$$\tau = \frac{\partial}{\partial E} \log \Gamma_s(\xi)|_{\bar{\xi}}, \quad \hat{\tau} = \frac{\partial}{\partial \hat{E}} \log \Gamma_s(\xi)|_{\bar{\xi}},$$
$$\lambda^A_{nm} = -\frac{\partial}{\partial \nu^A_{nm}} \log \Gamma_s(\xi)|_{\bar{\xi}}, \quad \hat{\lambda}^A_{nm} = -\frac{\partial}{\partial \hat{\nu}^A_{nm}} \log \Gamma_s(\xi)|_{\bar{\xi}}. \tag{2.9}$$

According to the definition of entropy (2.4), the bath phase space volume is given by

$$\Gamma_b(\Xi - \xi_s) = e^{S_b(\Xi - \xi_s)} \cong e^{S_b(\Xi)} \exp\left\{ -\sum_i \xi_{i,s} \frac{\partial S_b}{\partial \Xi_i}(\Xi) \right\}. \tag{2.10}$$

Neglecting the small shift in argument $\Xi \to \Xi - \xi_s$, it follows from (2.8a)–(2.8c), (2.9), and (2.10) that

$$\Gamma_b(\Xi - \xi_s) \cong e^{S_b(\Xi)} \exp\left\{ -\tau E_s - \hat{\tau}\hat{E}_s + \sum_{n \leqslant m, A} (\nu^{A,s}_{nm} \lambda^A_{nm} + \hat{\nu}^{A,s}_{nm} \hat{\lambda}^A_{nm}) \right\}. \tag{2.11}$$

We now return to (2.6), replacing the phase space volume of the bath, Γ_b, by the approximate form (2.11), and the subsystem phase space volume Γ_s by the phase space integral over the constraint δ-functions, i.e. (we use the equality henceforth, although it should be understood that we have included just the dominant contribution),

$$\begin{aligned} \Gamma(\Xi) = \int & d\mu_s \, dE_s \, d\hat{E}_s (d\nu^s)(d\hat{\nu}^s) \delta(E_s - \mathbf{H}_s) \delta(\hat{E}_s - \hat{\mathbf{H}}_s) \\ & \times \prod_{n \leqslant m, A} \delta(\nu^{A,s}_{nm} - \langle n | (-1)^F \widetilde{C}_s | m \rangle^A) \delta(\hat{\nu}^{A,s}_{nm} - \langle n | \hat{\widetilde{C}}_s | m \rangle^A) \\ & \times e^{S_b(\Xi)} \exp\left\{ -\tau E_s - \hat{\tau}\hat{E}_s + \sum_{n \leqslant m, A} (\nu^{A,s}_{nm} \lambda^A_{nm} + \hat{\nu}^{A,s}_{nm} \hat{\lambda}^A_{nm}) \right\}. \end{aligned} \tag{2.12}$$

Carrying out the integrals over the parameters, the δ-functions imply the replacement of the parameters E_s, $\hat{E}_s$, $\nu^{A,s}_{nm}$, and $\hat{\nu}^{A,s}_{nm}$ in the exponent by the corresponding phase space quantities. For the product

$$\lambda^A_{nm} \langle n | (-1)^F \widetilde{C}_s | m \rangle^A, \tag{2.13}$$

we note that the anti-self-adjoint property of $\widetilde{C}_s$ implies that

$$\langle n | (-1)^F \widetilde{C}_s | m \rangle = -\langle m | (-1)^F \widetilde{C}_s | n \rangle^*, \tag{2.14}$$

with * denoting conjugation of the hypercomplex units, so that

$$\begin{aligned} \langle n | (-1)^F \widetilde{C}_s | m \rangle^0 &= -\langle m | (-1)^F \widetilde{C}_s | n \rangle^0, \\ \langle n | (-1)^F \widetilde{C}_s | m \rangle^A &= \langle m | (-1)^F \widetilde{C}_s | n \rangle^A, \quad A \neq 0, \end{aligned} \tag{2.15}$$

for all three cases of real, complex, or quaternionic Hilbert spaces. Thus we have

$$\mathrm{Re}\ \lambda_{nm}\langle m|(-1)^F\tilde{C}_s|n\rangle=-\sum_A \lambda^A_{nm}\langle n|(-1)^F\tilde{C}_s|m\rangle^A. \tag{2.16a}$$

Defining the operator $\tilde{\lambda}$ for which the matrix elements are

$$\langle n|\tilde{\lambda}|n\rangle^A=\lambda^A_{nn},\quad \langle n|\hat{\lambda}|m\rangle^A=\tfrac{1}{2}\lambda^A_{nm},\quad n<m, \tag{2.16b}$$

we see that the sum over $n\leqslant m$ of the expression (2.16a) is $\mathbf{Tr}\ \tilde{\lambda}\tilde{C}_s$. A similar result holds for the last term of (2.12) [in this case, since we did not insert the factor $(-1)^F$, we obtain the $\hat{\mathbf{Tr}}$ functional]. The volume in phase space is then

$$\Gamma(\Xi)=e^{S_b(\Xi)}\int d\mu_s\ \exp-\{\tau\mathbf{H}_s+\hat{\tau}\hat{\mathbf{H}}_s+\mathbf{Tr}\ \tilde{\lambda}\tilde{C}_s+\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}_s\}, \tag{2.17}$$

so that the normalized canonical distribution function (with the subscripts s removed) is given by

$$\rho=Z^{-1}\ \exp-\{\tau\mathbf{H}+\hat{\tau}\hat{\mathbf{H}}+\mathbf{Tr}\ \tilde{\lambda}\tilde{C}+\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}\}, \tag{2.18}$$

where

$$Z=\int d\mu\ \exp-\{\tau\mathbf{H}+\hat{\tau}\hat{\mathbf{H}}+\mathbf{Tr}\ \tilde{\lambda}\tilde{C}+\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}\}. \tag{2.19}$$

This formula coincides with that obtained by Adler and Millard.[9] Note that the operators $\tilde{\lambda}$ and $\hat{\tilde{\lambda}}$ appear as an infinite set of inverse ''temperatures,'' i.e., equilibrium Lagrange parameters associated both with the bath and the subsystem, corresponding to the conserved matrix elements of $(-1)^F\tilde{C}$ and $\hat{\tilde{C}}$.

We finally remark that the microcanonical entropy defined in (2.4) provides the Jacobian of the transformation from the integration over the measure of $\mathscr{S}$ in (2.19) to an integral over the parameters defining the microcanonical shells. To see this, we rewrite (2.19) as

$$\begin{aligned}Z=\int d\mu\ dE\ d\hat{E}(d\nu)(d\hat{\nu})\,\delta(E-\mathbf{H})\,\delta(\hat{E}-\hat{\mathbf{H}})\prod_{n\leqslant m,A}\delta(\nu^A_{nm}-\langle n|(-1)^F\tilde{C}|m\rangle^A)\\ \times\delta(\hat{\nu}^A_{nm}-\langle n|\hat{\tilde{C}}|m\rangle^A)\exp-\{\tau E+\hat{\tau}\hat{E}+\mathbf{Tr}\ \tilde{\lambda}\tilde{\nu}+\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{\nu}}\},\end{aligned} \tag{2.20a}$$

where we have defined the anti-self-adjoint parametric operators $\tilde{\nu}$ and $\hat{\tilde{\nu}}$ by

$$\nu^A_{nm}=\langle n|(-1)^F\tilde{\nu}|m\rangle^A,\quad \hat{\nu}^A_{nm}=\langle n|\hat{\tilde{\nu}}|m\rangle^A. \tag{2.20b}$$

The phase space integration over the δ-function factors reproduces the volume of the microcanonical shell associated with these parameters, i.e., the exponential of the microcanonical entropy, so that the partition function can be written as

$$Z=\int dE\ d\hat{E}(d\nu)(d\hat{\nu})e^{S_{\mathrm{mic}}(E,\hat{E},\tilde{\nu},\hat{\tilde{\nu}})}\ \exp-\{\tau E+\hat{\tau}\hat{E}+\mathbf{Tr}\ \tilde{\lambda}\tilde{\nu}+\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{\nu}}\}. \tag{2.21}$$

III. STABILITY AND THERMODYNAMIC RELATIONS

In this section, we study the stability of the canonical ensemble as associated with the dominant contribution to the microcanonical phase space volume. To this end, we formally define the free energy A as the negative of the logarithm of the partition function,

$$Z \equiv e^{-A(\tau,\hat{\tau},\tilde{\lambda},\hat{\tilde{\lambda}})}, \tag{3.1}$$

so that (2.19) can be written as

$$1 = \int d\mu\ e^{A(\tau,\hat{\tau},\tilde{\lambda},\hat{\tilde{\lambda}})} \exp -\{\tau \mathbf{H} + \hat{\tau}\hat{\mathbf{H}} + \mathbf{Tr}\ \tilde{\lambda}\tilde{C} + \hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}\}. \tag{3.2}$$

Differentiating with respect to (the hypercomplex index A should not be confused with the conventional symbol for the free energy) τ, $\hat{\tau}$, and the matrix elements λ^A_{nm}, $\hat{\lambda}^A_{nm}$, we obtain [as in Eqs. (49) of Ref. 9]

$$\frac{\partial A}{\partial \tau} = \langle \mathbf{H} \rangle_{AV}, \tag{3.3}$$

$$\frac{\partial A}{\partial \hat{\tau}} = \langle \hat{\mathbf{H}} \rangle_{AV}, \tag{3.4}$$

and using

$$\begin{aligned} \mathbf{Tr}\ \tilde{\lambda}\tilde{C} &= -\sum_{n \leqslant m, A} \lambda^A_{nm} \langle n|(-1)^F \tilde{C}|m\rangle^A, \\ \hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}} &= -\sum_{n \leqslant m, A} \hat{\lambda}^A_{nm} \langle n|\hat{\tilde{C}}|m\rangle^A, \end{aligned} \tag{3.5}$$

we find

$$\frac{\partial A}{\partial \lambda^A_{nm}} = -\langle\langle n|(-1)^F \tilde{C}|m\rangle^A\rangle_{AV} \equiv -\langle C^A_{nm}\rangle_{AV}, \tag{3.6}$$

$$\frac{\partial A}{\partial \hat{\lambda}^A_{nm}} = -\langle\langle n|\hat{C}|m\rangle^A\rangle_{AV} \equiv -\langle \hat{C}^A_{nm}\rangle_{AV}. \tag{3.7}$$

We now consider the identity

$$0 = \int d\mu (\mathbf{H} - \langle \mathbf{H} \rangle_{AV}) e^{A(\tau,\hat{\tau},\tilde{\lambda},\hat{\tilde{\lambda}})} \exp -\{\tau \mathbf{H} + \hat{\tau}\hat{\mathbf{H}} + \mathbf{Tr}\ \tilde{\lambda}\tilde{C} + \hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}\}. \tag{3.8}$$

Differentiating with respect to τ, one finds

$$0 = \int d\mu \left(\frac{\partial A}{\partial \tau} - \mathbf{H} \right) (\mathbf{H} - \langle \mathbf{H} \rangle_{AV}) e^{A(\tau,\hat{\tau},\tilde{\lambda},\hat{\tilde{\lambda}})} \exp -\{\tau \mathbf{H} + \hat{\tau}\hat{\mathbf{H}} + \mathbf{Tr}\ \tilde{\lambda}\tilde{C} + \hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}\} - \frac{\partial \langle \mathbf{H} \rangle_{AV}}{\partial \tau}, \tag{3.9}$$

so that, from (3.3), we find that (as in Ref. 9)

$$\langle (\mathbf{H} - \langle \mathbf{H} \rangle_{AV})^2 \rangle_{AV} = -\frac{\partial \langle \mathbf{H} \rangle_{AV}}{\partial \tau} = -\frac{\partial^2 A}{\partial \tau^2} \geqslant 0. \tag{3.10}$$

In fact, applying this argument to all of the parameters, we now show that A is a locally convex function. With this result, we will prove the stability of the canonical ensemble.

The derivative of (3.8) with respect to $\hat{\tau}$ yields, using the second of (3.3),

$$\langle(\mathbf{H}-\langle\mathbf{H}\rangle_{AV})(\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV})\rangle=-\frac{\partial\langle\mathbf{H}\rangle_{AV}}{\partial\hat{\tau}}=-\frac{\partial^2 A}{\partial\tau\partial\hat{\tau}}. \tag{3.11}$$

In the same way that we obtained (3.10), we also find (using $\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV}$ as a factor in the integrand)

$$\langle(\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV})^2\rangle_{AV}=-\frac{\partial\langle\hat{\mathbf{H}}\rangle_{AV}}{\partial\hat{\tau}}=-\frac{\partial^2 A}{\partial\hat{\tau}^2}\geqslant 0. \tag{3.12}$$

We consider next the identity

$$0=\int d\mu(C^A_{nm}-\langle C^A_{nm}\rangle_{AV})e^{A(\tau,\hat{\tau},\tilde{\lambda},\hat{\lambda})}\exp-\{\tau\mathbf{H}+\hat{\tau}\hat{\mathbf{H}}+\mathbf{Tr}\,\tilde{\lambda}\tilde{C}+\hat{\mathbf{Tr}}\,\hat{\tilde{\lambda}}\hat{\tilde{C}}\}. \tag{3.13}$$

Differentiating with respect to $\lambda^B_{n'm'}$ and $\hat{\lambda}^B_{n'm'}$, we find

$$\frac{\partial^2 A}{\partial\lambda^A_{nm}\partial\lambda^B_{n'm'}}=-\langle(C^A_{nm}-\langle C^A_{nm}\rangle_{AV})(C^B_{n'm'}-\langle C^B_{n'm'}\rangle_{AV})\rangle_{AV},$$

$$\frac{\partial^2 A}{\partial\hat{\lambda}^A_{nm}\partial\lambda^B_{n'm'}}=-\langle(\hat{C}^A_{nm}-\langle\hat{C}^A_{nm}\rangle_{AV})(C^B_{n'm'}-\langle C^B_{n'm'}\rangle_{AV})\rangle_{AV},$$

$$\frac{\partial^2 A}{\partial\hat{\lambda}^A_{nm}\partial\hat{\lambda}^B_{n'm'}}=-\langle(\hat{C}^A_{nm}-\langle\hat{C}^A_{nm}\rangle_{AV})(\hat{C}^B_{n'm'}-\langle\hat{C}^B_{n'm'}\rangle_{AV})\rangle_{AV}. \tag{3.14}$$

Finally, we differentiate (3.8) with respect to λ^A_{nm} and $\hat{\lambda}^A_{nm}$ to obtain

$$\frac{\partial^2 A}{\partial\tau\partial\lambda^A_{nm}}=\langle(\mathbf{H}-\langle\mathbf{H}\rangle_{AV})(C^A_{nm}-\langle C^A_{nm}\rangle_{AV})\rangle_{AV} \tag{3.15}$$

and

$$\frac{\partial^2 A}{\partial\tau\partial\hat{\lambda}^A_{nm}}=\langle(\mathbf{H}-\langle\mathbf{H}\rangle_{AV})(\hat{C}^A_{nm}-\langle\hat{C}^A_{nm}\rangle_{AV})\rangle_{AV}, \tag{3.16}$$

as well as the corresponding identity with coefficient $\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV}$ to obtain

$$\frac{\partial^2 A}{\partial\hat{\tau}\partial\lambda^A_{nm}}=\langle(\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV})(C^A_{nm}-\langle C^A_{nm}\rangle_{AV})\rangle_{AV} \tag{3.17}$$

and

$$\frac{\partial^2 A}{\partial\hat{\tau}\partial\hat{\lambda}^A_{nm}}=\langle(\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV})(\hat{C}^A_{nm}-\langle\hat{C}^A_{nm}\rangle_{AV})\rangle_{AV}. \tag{3.18}$$

Combining (3.3)–(3.18), we find that the Taylor expansion of A through second derivatives is given by

$$
\begin{aligned}
&A(\tau+\delta\tau,\hat{\tau}+\delta\hat{\tau},\tilde{\lambda}+\delta\tilde{\lambda},\hat{\tilde{\lambda}}+\delta\hat{\tilde{\lambda}}) \\
&\quad = A(\tau,\hat{\tau},\tilde{\lambda},\hat{\tilde{\lambda}}) + \delta\tau\langle\mathbf{H}\rangle_{AV} + \delta\hat{\tau}\langle\hat{\mathbf{H}}\rangle_{AV} - \sum_{n\leqslant m,A} (\delta\lambda^A_{nm}\langle C^A_{nm}\rangle_{AV} + \delta\hat{\lambda}^A_{nm}\langle\hat{C}^A_{nm}\rangle_{AV}) \\
&\qquad - \frac{1}{2}\left\langle \left[\delta\tau(\mathbf{H}-\langle\mathbf{H}\rangle_{AV}) + \delta\hat{\tau}(\hat{\mathbf{H}}-\langle\hat{\mathbf{H}}\rangle_{AV}) \right.\right. \\
&\qquad \left.\left. - \sum_{m\leqslant n,A} \delta\lambda^A_{nm}(C^A_{nm}-\langle C^A_{nm}\rangle_{AV}) + \delta\hat{\lambda}^A_{nm}(\hat{C}^A_{nm}-\langle\hat{C}^A_{nm}\rangle_{AV}) \right]^2 \right\rangle_{AV} ;
\end{aligned}
\tag{3.19}
$$

the uniform negative sign of the quadratic term in the expansion indicates that A is a locally convex function, and shows that the matrix of second derivatives of A is negative semidefinite.

We now turn to the alternative expression of (2.21) for the partition function, defined in terms of an integral over the parameters of a sequence of microcanonical ensembles. The existence of a maximum in the integrand which dominates the integration assures the stability of the canonical ensemble; we now show that (3.19) implies the self-consistency of our assumption of a maximum.

Returning to (2.21), we see that the conditions for a maximum of the integrand at $\xi=\underline{\xi}$ are that there be a stationary point, i.e., that

$$
\begin{aligned}
&\tau = \frac{\partial}{\partial E} S_{\mathrm{mic}}(\xi)\Big|_{\underline{\xi}}, \quad \hat{\tau} = \frac{\partial}{\partial \hat{E}} S_{\mathrm{mic}}(\xi)\Big|_{\underline{\xi}}, \\
&\lambda^A_{nm} = -\frac{\partial}{\partial \nu^A_{nm}} S_{\mathrm{mic}}(\xi)\Big|_{\underline{\xi}}, \quad \hat{\lambda}^A_{nm} = -\frac{\partial}{\partial \hat{\nu}^A_{nm}} S_{\mathrm{mic}}(\xi)\Big|_{\underline{\xi}},
\end{aligned}
\tag{3.20}
$$

together with the requirement that the integrand should decrease in all directions, so that this point corresponds to a maximum. To make our demonstration of stability more transparent, let us define

$$
\chi = \{\chi_i\} = \{\tau, \hat{\tau}, -\lambda^A_{nm}, -\hat{\lambda}^A_{nm}\}, \tag{3.21}
$$

so that (3.20) takes the form

$$
\chi_i = \frac{\partial S_{\mathrm{mic}}}{\partial \xi_i}\Big|_{\underline{\xi}}, \tag{3.22}
$$

where the indices i are in the correspondence implied by (3.20), together with the requirement that the second derivative matrix

$$
\frac{\partial^2 S_{\mathrm{mic}}}{\partial \xi_i \partial \xi_j} = \frac{\partial \chi_i}{\partial \xi_j} \tag{3.23}
$$

should be positive definite. However, the values of E, $\hat{E}$, ν^A_{nm}, and $\hat{\nu}^A_{nm}$ are equal to $\mathbf{H}$, $\hat{\mathbf{H}}$, C^A_{nm}, and $\hat{C}^A_{nm}$ in the microcanonical ensemble, as seen from (2.3). If the stationary values are those given by (3.3), (3.4), (3.6) and (3.7), then we must have

$$
\xi_i = \frac{\partial A}{\partial \chi_i}, \tag{3.24}
$$

which implies that the matrix inverse to the right-hand side of (3.23) is given by

$$\frac{\partial \xi_j}{\partial \chi_i} = \frac{\partial^2 A}{\partial \chi_i \partial \chi_j}, \tag{3.25}$$

which we have shown to be a negative semidefinite matrix. This in turn implies that the matrix on the right-hand side of (3.23) is negative definite, giving the condition needed to assure that the stationary point in (3.20) is indeed a maximum.

Assuming this maximum dominates the integration, then the logarithm of the integral in (2.21) (up to an additive term which is relatively small for a large number of degrees of freedom) may be approximated by

$$A \cong \tau E + \hat{\tau}\hat{E} + \mathbf{Tr}\ \tilde{\lambda}\tilde{C} + \hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}} - S_{\mathrm{mic}}(E, \hat{E}, \tilde{C}, \hat{\tilde{C}}), \tag{3.26}$$

where the arguments are at the extremal values, giving the analog of the standard thermodynamical result $A = E - TS$ for the free energy.

IV. THE OPERATORS $\tilde{C}$ and $\hat{\tilde{C}}$ AS GENERATORS

The microcanonical ensemble is constructed as a set of elements of $\mathscr{S}$, which satisfy a constraint described by the value of **H**. This subset of $\mathscr{S}$ is invariant to the flow generated by **H**, where we define the flow induced by a functional according to the canonical transformation formulas of (1.10a) and (1.10b). As we have remarked above, the space is further restricted by values of $\hat{\mathbf{H}}$ and, in the canonical ensemble, the values of $\mathbf{Tr}\ \tilde{\lambda}\tilde{C}$ and $\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}}$. Since these four quantities have vanishing Poisson brackets with each other under our present assumptions, the flow generated by all of these functionals lies in the constrained subset of $\mathscr{S}$. In constructing the microcanonical ensemble, we constrain the values of the conserved operators $\tilde{C}$ and $\hat{\tilde{C}}$, i.e., we constrain the values of all total trace functionals constructed by projection from these operators. It is therefore instructive to study the action of general total trace functionals projected from $\tilde{C}$ and $\hat{\tilde{C}}$ as generators of canonical transformations on the phase space.

We first remark that it was pointed out in Ref. 9 that a canonical generator of unitary transformations on the basis of the underlying Hilbert space has the form

$$\mathbf{G}_{\tilde{f}} = -\mathbf{Tr} \sum_r\ [\tilde{f},\ p_r] q_r, \tag{4.1}$$

where $\tilde{f}$ is bosonic. Using (1.11) and the cyclic properties of **Tr**, one sees that

$$\mathbf{G}_{\tilde{f}} = -\mathbf{Tr}\ \tilde{f} \sum_r\ (p_r q_r - \epsilon_r q_r p_r) = \mathbf{Tr}\ \tilde{f}\tilde{C}. \tag{4.2}$$

We thus see that the conserved operator $\tilde{C}$ has the additional role of inducing the action of unitary transformations on the underlying Hilbert space.

That this action preserves the algebraic properties of functionals of the type $\mathbf{G}_{\tilde{f}}$ can be seen by computing the Poisson bracket,

$$\{\mathbf{G}_{\tilde{f}}, \mathbf{G}_{\tilde{g}}\} = \mathbf{Tr} \sum_r\ \epsilon_r \left(\frac{\delta \mathbf{G}_{\tilde{f}}}{\delta q_r} \frac{\delta \mathbf{G}_{\tilde{g}}}{\delta p_r} - \frac{\delta \mathbf{G}_{\tilde{g}}}{\delta q_r} \frac{\delta \mathbf{G}_{\tilde{f}}}{\delta p_r} \right). \tag{4.3a}$$

We use the result that

$$\delta \mathbf{G}_{\tilde{f}} = \mathbf{Tr}\ \tilde{f}\delta\tilde{C} = \mathbf{Tr}\sum_r \{\epsilon_r(\tilde{f}q_r - q_r\tilde{f})\delta p_r - (\tilde{f}p_r - p_r\tilde{f})\delta q_r\} \tag{4.3b}$$

to obtain

$$\frac{\delta \mathbf{G}_{\tilde{f}}}{\delta q_r} = -[\tilde{f},\ p_r], \quad \frac{\delta \mathbf{G}_{\tilde{f}}}{\delta p_r} = \epsilon_r[\tilde{f},\ q_r], \tag{4.4}$$

and hence, expanding out the commutators,

$$\{\mathbf{G}_{\tilde{f}}, \mathbf{G}_{\tilde{g}}\} = -\mathbf{Tr}\sum_r \{p_r\tilde{f}q_r\tilde{g} - p_r\tilde{f}\tilde{g}q_r - \tilde{f}p_rq_r\tilde{g} + \tilde{f}p_r\tilde{g}q_r - p_r\tilde{g}q_r\tilde{f} + p_r\tilde{g}\tilde{f}q_r + \tilde{g}p_rq_r\tilde{f} - \tilde{g}p_r\tilde{f}q_r\}. \tag{4.5}$$

The first and last terms on the right cancel under the **Tr**, as do the fourth and fifth. These cancellations do not depend on the grading under the trace, since they involve only cycling of the bosonic operators $\tilde{f},\tilde{g}$. The remaining terms can be rearranged to the form

$$\{\mathbf{G}_{\tilde{f}}, \mathbf{G}_{\tilde{g}}\} = -\mathbf{Tr}\sum_r [\tilde{f},\ \tilde{g}](p_rq_r - \epsilon_r q_r p_r) = \mathbf{Tr}[\tilde{f},\ \tilde{g}]\tilde{C} = \mathbf{G}_{[\tilde{f},\ \tilde{g}]}. \tag{4.6}$$

These relations, corresponding to the group properties of integrated charges in quantum field theory, can be generalized to a ''local'' algebra. Defining

$$\mathbf{G}_{\tilde{f}r} = \mathbf{Tr}\ \tilde{f}\tilde{C}_r, \tag{4.7a}$$

where

$$\tilde{C}_r = \epsilon_r q_r p_r - p_r q_r, \tag{4.7b}$$

one obtains in the same way that

$$\{\mathbf{G}_{\tilde{f}r}, \mathbf{G}_{\tilde{g}s}\} = \delta_{rs}\mathbf{G}_{[\tilde{f},\ \tilde{g}]r}. \tag{4.8}$$

In studying the flows induced by conserved operators, we shall also need the properties of generators projected from $\hat{\tilde{C}}$. We therefore define

$$\hat{\mathbf{G}}_{\tilde{f}} = \mathbf{Tr}\ \tilde{f}\hat{\tilde{C}}. \tag{4.9}$$

Note that, in terms of this definition,

$$\hat{\mathbf{Tr}}\ \hat{\tilde{\lambda}}\hat{\tilde{C}} = \mathbf{Tr}(-1)^F\hat{\tilde{\lambda}}\hat{\tilde{C}} = \hat{\mathbf{G}}_{(-1)^F\tilde{\lambda}}$$

Substituting (1.12), we find that the operator derivatives of $\hat{\mathbf{G}}_{\tilde{f}}$ with respect to the phase space variables are

$$\begin{aligned} \frac{\delta}{\delta q_r}\hat{\mathbf{G}}_{\tilde{f}} &= -(-1)^F[(-1)^F\tilde{f},\ p_r] = -(\tilde{f}p_r - \epsilon_r p_r\tilde{f}), \\ \frac{\delta}{\delta p_r}\hat{\mathbf{G}}_{\tilde{f}} &= (-1)^F[(-1)^F\tilde{f},\ q_r] = \tilde{f}q_r - \epsilon_r q_r\tilde{f}. \end{aligned} \tag{4.10}$$

Computing Poisson brackets in the same way as above, we find that the algebra of the generators $\mathbf{G}_{\tilde{f}}$ and $\hat{\mathbf{G}}_{\tilde{f}}$ closes,

$$\{\hat{\mathbf{G}}_{\tilde{f}},\hat{\mathbf{G}}_{\tilde{g}}\}=\mathbf{G}_{[\tilde{f},\,\tilde{g}]},\quad \{\hat{\mathbf{G}}_{\tilde{f}},\mathbf{G}_{\tilde{g}}\}=\{\mathbf{G}_{\tilde{f}},\hat{\mathbf{G}}_{\tilde{g}}\}=\hat{\mathbf{G}}_{[\tilde{f},\,\tilde{g}]}, \tag{4.11}$$

giving a structure reminiscent of the vector and axial-vector charge algebra in quantum field theory. Just as the vector and axial-vector charge algebra can be diagonalized into two independent chiral charge algebras, so the algebra of (4.6) and (4.11) can be diagonalized into two independent algebras

$$\mathbf{G}_{\pm\,\tilde{f}}=\tfrac{1}{2}(\mathbf{G}_{\tilde{f}}\pm\hat{\mathbf{G}}_{\tilde{f}}), \tag{4.12}$$

which obey the algebra

$$\{\mathbf{G}_{\pm\,\tilde{f}},\mathbf{G}_{\pm\,\tilde{g}}\}=\mathbf{G}_{\pm[\tilde{f},\,\tilde{g}]},\quad \{\mathbf{G}_{+\,\tilde{f}},\mathbf{G}_{-\,\tilde{g}}\}=0. \tag{4.13}$$

Defining a ''local'' version of $\hat{\mathbf{G}}_{\tilde{f}}$ by

$$\hat{\mathbf{G}}_{\tilde{f}r}=\mathbf{Tr}\;\tilde{\tilde{f}}\hat{\tilde{C}}_r, \tag{4.14}$$

where

$$\hat{\tilde{C}}_r=q_rp_r-p_rq_r, \tag{4.15}$$

the algebras of (4.11) and (4.13) can be converted to local versions analogous to (4.8).

We now turn to the flows associated with $\mathbf{G}_{\tilde{f}}$ and $\hat{\mathbf{G}}_{\tilde{f}}$ when used as canonical generators. Beginning with $\mathbf{G}_{\tilde{f}}$, we consider its action on the function $\mathbf{x}_s(\eta)$ defined in (1.9a), for which $\delta\mathbf{x}_s(\eta)=\mathbf{Tr}\;\eta\delta x_s$. Defining a parameter γ along the motion generated by $\mathbf{G}_{\tilde{f}}$, we choose δx_s as $dx_s/d\gamma$, so that by (1.10a) we have

$$d\mathbf{x}_s(\eta)=\{\mathbf{x}_s(\eta),\mathbf{G}_{\tilde{f}}\}d\gamma. \tag{4.16}$$

Comparing (1.10b) with (4.4) and (4.16) gives

$$\frac{dq_s}{d\gamma}=[\tilde{f},\,q_s],\quad \frac{dp_s}{d\gamma}=[\tilde{f},\,p_s]. \tag{4.17}$$

In both the boson and fermion sectors we see that, as a solution of the differential equations (4.17), $\mathbf{G}_{\hat{f}}$ induces the action of a unitary group generated by $\tilde{f}$,

$$x_s(\gamma)=e^{\tilde{f}\gamma}x_s(0)e^{-\tilde{f}\gamma}. \tag{4.18}$$

The unitary transformation (4.18) preserves the supremum operator norm

$$\|x_s\|=\sup_{\{|n\rangle\}}\frac{|\langle n|x_s|n\rangle|}{|\langle n|n\rangle|}, \tag{4.19}$$

where the supremum is taken over all states $|n\rangle$ in Hilbert space. {The spectrum of x_s may be unbounded; the argument we have given above then applies to all bounded functions of the x_s, for which the operator norm exists. There is, moreover, a possibility that in the unbounded case, a phase space operator may be an eigenfunction of $\tilde{f}$, in the sense that $[\tilde{f},\,x_s]=\sigma_s x_s$ for some real

σ_s. The transformation (4.17) would then correspond to dilation, therefore admitting conformal transformations on some subset of the phase space $\mathscr{S}$ (for which preservation of the operator norm does not form an obstacle).}

We next consider the canonical transformation induced on $\mathbf{x}_s(\eta)$ by the functional $\hat{\mathbf{G}}_{\tilde{f}}$ defined in (4.9). Introducing a parameter $\hat{\gamma}$ along the motion generated by $\hat{\mathbf{G}}_{\tilde{f}}$, we have in this case by (1.10a)

$$d\mathbf{x}_s(\eta)=\{\mathbf{x}_s(\eta),\hat{\mathbf{G}}_{\tilde{f}}\}d\hat{\gamma}. \tag{4.20}$$

Comparing (1.10b) with (4.10) and (4.20) gives

$$\begin{aligned}\frac{dq_s}{d\hat{\gamma}}&=\epsilon_s(-1)^F[(-1)^F\tilde{f},\ q_s]=\epsilon_s\tilde{f}q_s-q_s\tilde{f},\\ \frac{dp_s}{d\hat{\gamma}}&=(-1)^F[(-1)^F\tilde{f},\ p_s]=\tilde{f}p_s-\epsilon_s p_s\tilde{f}.\end{aligned} \tag{4.21}$$

For the bosonic sector, (4.21) can be rewritten as

$$\frac{dq_s}{d\hat{\gamma}}=[\tilde{f},\ q_s],\quad \frac{dp_s}{d\hat{\gamma}}=[\tilde{f},\ p_s], \tag{4.22}$$

and can be integrated as a unitary transformation for both q_s and p_s,

$$x_s(\hat{\gamma})=e^{\tilde{f}\hat{\gamma}}x_s(0)e^{-\tilde{f}\hat{\gamma}}. \tag{4.23}$$

For the fermionic sector, however, the grading index $(-1)^F$ anticommutes with q_s and p_s and $\epsilon_s=-1$; consequently, the differential equations (4.21) in this case take the form

$$\frac{dq_s}{d\hat{\gamma}}=-\{\tilde{f},q_s\},\quad \frac{dp_s}{d\hat{\gamma}}=\{\tilde{f},p_s\}, \tag{4.24}$$

and involve *anticommutators* with the operator $\tilde{f}$, i.e., a graded action. We note, however, that the total trace Lagrangians for which $\tilde{\tilde{C}}$ is conserved are ones in which the fermion fields appear as bosonic bilinears of the form p_rq_s; for these bilinears, and for the reverse ordered bosonic bilinears q_sp_r, we find from (4.24) that

$$\frac{d(p_rq_s)}{d\hat{\gamma}}=[\tilde{f},\ p_rq_s],\quad \frac{d(q_sp_r)}{d\hat{\gamma}}=-[\tilde{f},\ q_sp_r]. \tag{4.25}$$

The solution of these differential equations is the unitary group action

$$(p_rq_s)(\hat{\gamma})=e^{\tilde{f}\hat{\gamma}}(p_rq_s)(0)e^{-\tilde{f}\hat{\gamma}},\quad (q_sp_r)(\hat{\gamma})=e^{-\tilde{f}\hat{\gamma}}(q_sp_r)(0)e^{\tilde{f}\hat{\gamma}}, \tag{4.26}$$

which preserves the supremum operator norm of the bilinears p_rq_s and q_sp_r. However, it is easy to see that for fermionic operators, the supremum operator norm of (4.19) is not preserved by the evolution of (4.24). For example, to lowest order in $\delta\hat{\gamma}$, for the fermionic coordinate variable q_s we have

$$(n,q_s(\delta\hat{\gamma})n)=(n,q_sn)-[(n,\tilde{f}q_sn)+(n,q_s\tilde{f}n)]\delta\hat{\gamma}+O((\delta\hat{\gamma})^2).$$

Now, letting $n=g+h\,\delta\hat{\gamma}$, we obtain

$$(n,q_s(\delta\hat{\gamma})n)=(g,q_sg)+[(h,q_sg)+(g,q_sh)]\delta\hat{\gamma}-[(g,\tilde{f}q_sg)+(g,q_s\tilde{f}g)]\delta\hat{\gamma}+O((\delta\hat{\gamma})^2).$$

Taking $h=\tilde{f}g$, we see that $(g,q_sh)=(g,q_s\tilde{f}g)$ cancels the fifth term on the right, but $(h,q_sg)=(\tilde{f}g,q_sg)=-(g,\tilde{f}q_sg)$ does not cancel the fourth. The action of the diagonalized generators defined in (4.12) is therefore norm preserving on bosonic, but not on fermionic operators.

Finally, it is also useful to define parameters $\gamma_\pm$ along the flows generated by $\mathbf{G}_{\pm\tilde{f}}$ according to

$$d\mathbf{x}_s(\eta)=\{\mathbf{x}_s(\eta),\mathbf{G}_{\pm\tilde{f}}\}d\gamma_\pm, \tag{4.27a}$$

so that

$$\frac{dx_s}{d\gamma_\pm}=\frac{1}{2}\left(\frac{dx_s}{d\gamma}\pm\frac{dx_s}{d\hat{\gamma}}\right). \tag{4.27b}$$

Then taking sums and differences of (4.17), (4.22), and (4.24), we find that for bosons (with x_s either q_s or p_s)

$$\frac{dx_s}{d\gamma_+}=[\tilde{f},\,x_s],\quad \frac{dx_s}{d\gamma_-}=0, \tag{4.28a}$$

which integrate to

$$x_s(\gamma_+)=e^{\tilde{f}\gamma}x_s(0)e^{-\tilde{f}\gamma},\quad x_s(\gamma_-)=x_s(0). \tag{4.28b}$$

Similarly, for fermions we find that

$$\begin{aligned}&\frac{dq_s}{d\gamma_+}=-q_s\tilde{f},\quad \frac{dp_s}{d\gamma_+}=\tilde{f}p_s,\\ &\frac{dq_s}{d\gamma_-}=\tilde{f}q_s,\quad \frac{dp_s}{d\gamma_-}=-p_s\tilde{f},\end{aligned} \tag{4.29a}$$

which integrate to

$$\begin{aligned}&q_s(\gamma_+)=q_s(0)e^{-\tilde{f}\gamma_+},\quad p_s(\gamma_+)=e^{\tilde{f}\gamma_+}p_s(0),\\ &q_s(\gamma_-)=e^{\tilde{f}\gamma_-}q_s(0),\quad p_s(\gamma_-)=p_s(0)e^{-\tilde{f}\gamma_-}.\end{aligned} \tag{4.29b}$$

This identifies $\mathbf{G}_{\pm\tilde{f}}$ as the generators of the one-sided unitary transformations acting on the fermions which are discussed in Refs. 1 and 2.

(Received 9 April 1996; accepted for publication 17 April 1996)

The aim of this paper is to develop the classical lattice models with unbounded spin to the case of nonquadratic polynomial interaction. We demonstrate that the distinct relation between the growths of potentials leads to the uniqueness and the fast decay of correlations for Gibbs measure. © *1996 American Institute of Physics.* [S0022-2488(96)00611-1]

There is an approach initiated in Refs. 1–3 to describe the probability measures on infinite-dimensional spaces in the terms of conditional distributions. This approach has already found its nontrivial applications to the natural construction of the different models in the quantum field theory, mathematical and statistical physics.[4–7]

The effective criteria on the existence and uniqueness of such systems were obtained (see Dobrushin's criterion[1,2,8] and Dobrushin–Shlosman mixing condition[9,10]). In the essence of the Dobrushin-type criteria lie the keen variational estimates on the one-point conditional measures, which admit iteration and application of the fixed point arguments. Moreover, such estimates were used in the applications to the lattice spin systems of the statistical physics to the study of decay of correlations, differentiability of pressure, and the connected questions.[11–17]

In the noncompact spin case the check of Dobrushin's conditions is rather complicated because of the principle unboundedness of interaction potentials. The results in this direction were mainly centered around the regular interactions,[11,18–23] i.e., when the many-point potentials in the Hamiltonian admit the quadratic domination, for example with the quadratic two-point potentials

$$H(x)=\sum_{k\in\mathbb{Z}^d} F(x_k)+\lambda\sum_{k,j\in\mathbb{Z}^d} b_{k-j}(x_k-x_j)^2.$$

On the other hand, a wide class of models with nonregular interaction, associated with massless free lattice field, perturbed by $(\nabla\varphi)^4$,

$$H(x)=\sum_{|k-j|=1}(x_k-x_j)^2+\lambda\sum_{|k-j|=1}(x_k-x_j)^4,$$

has already obtained a detail investigation through various techniques.[24–28] In particular, it was shown that the exponential decay of correlations for such systems does not occur for all $\lambda>0$,[24] i.e., the Dobrushin uniqueness technique does not work for such Hamiltonians.

In this paper we demonstrate that there is a wide class of the Gibbs lattice systems which *do not fulfill* the regularity assumption but have the fast decay of correlations. The aim of this paper is to show that the application of Dobrushin's uniqueness technique for the Hamiltonian

$$H(x)=\sum_{k\in\mathbb{Z}^d} F(x_k)+\lambda\sum_{k,j\in\mathbb{Z}^d} G_{k-j}(x_k-x_j)$$

with polynomials $\{G_j\}$ requires the distinct correlations between the growths of the interaction potentials $\{G_j\}$ and self-action $\{F\}$. This gives us the possibility of treating the problem of the existence, uniqueness, and the *exponentially* fast decay of correlations in the case of *nonquadratic* polynomial interaction. We base our investigation on the scheme of Refs. 1, 2, 8, 12, 13, and 16 and apply the Brascamp–Lieb inequality[29] to obtain estimates on the distance in variations.

Consider $\mathbb{Z}^d$ to be a d-dimensional integer lattice, to each point of which corresponds the linear spin space $\mathbb{R}^1$. Let $\mathcal{G}\{\mu_\Lambda\}$ denote the set of Gibbs measures[1–3] on the product σ-algebra on $\mathbb{R}^{\mathbb{Z}^d}$. It means that the corresponding conditional measures $\{\mu_\Lambda\}$ in the finite volumes of the lattice $\Lambda\subset\mathbb{Z}^d$ are defined by

$$d\mu_\Lambda=\frac{1}{Z_\Lambda}\exp\left\{-\lambda\sum_{\{k,j\}\cup\Lambda\neq\varnothing} G_{k-j}(x_k-x_j)\right\}\times\prod_{k\in\Lambda} e^{-F(x_k)}dx_k, \tag{1}$$

i.e., for all cylinder bounded functions $f\in C_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$ we have $\mu(\mu_\Lambda(f))=\mu(f)$, where $\mu(f)$ denotes the expectation and Z_Λ is a normalization factor.

We put the following conditions on the interactive potentials $\{F,G_j\}$ in the Gibbs measure (1).

(A) Self-action potentials $F\in C^2(\mathbb{R}^1)$, fulfill $F(0)=0$, $\exists\varepsilon>0$ $\inf_{x\in\mathbb{R}}F''(x)\geqslant\varepsilon$ and have no more than the exponential growth on the infinity $\exists c,a\colon\forall x|F(x)|\leqslant ce^{a|x|}$.

(B) Interaction potentials $\{G_j\in C^2(\mathbb{R}^1)\}_{j\in\mathbb{Z}^d\setminus\{0\}}$, fulfill $G_j(0)=0$, $\forall j\in\mathbb{Z}^d\setminus\{0\}\forall x\in\mathbb{R}^1\colon G_j''(x)\geqslant 0$ and $\exists r_0\forall j\colon|j|>r_0\Rightarrow G_j\equiv 0$.

(C) Growth condition $\forall k\in\mathbb{Z}^d|k|\leqslant r_0$

$$\sup_{x_k,x_0\in\mathbb{R}^1}\frac{|G_k''(x_k-x_0)|}{\sqrt{F''(x_k)}\sqrt{F''(x_0)}}<\infty.$$

Immediately remark that condition C states the domination of the one-point potentials over the interaction. It always holds for the quadratic and less than quadratic interaction due to $\sup|G''|\leqslant$const. Actually condition C permits the consideration of the interaction $\{G_j\}$ to be of polynomial type.

The following theorem states the uniqueness and the exponentially fast decay of correlations for the Gibbs measure (1). The existence of such a measure and finiteness of its moments is shown in Theorem 2.

Theorem 1. *Suppose conditions A–C hold and the set of measures $\mu\in\mathcal{G}\{\mu_\Lambda\}$, which satisfy*

$$m_\mu=\sup_{k\in\mathbb{Z}^d}\int_{\mathbb{R}^{\mathbb{Z}^d}}\rho^2(x_k,0)d\mu<\infty,\quad \rho(x,y)=\left|\int_y^x\sqrt{F''(s)}ds\right|, \tag{2}$$

is nonempty. Denote

$$\gamma_d=\sum_{k\in\mathbb{Z}^d} e^{d(k,0)}\sup_{x_k,x_0\in\mathbb{R}^1}\frac{|G''(x_k-x_0)|}{\sqrt{F''(x_k)}\sqrt{F''(x_0)}}$$

for some transitional invariant semimetric $d(k,j)$ on the lattice $\mathbb{Z}^d$.

Then $\forall\lambda\in[0,1/\gamma_d)$ measure $\tilde{\mu}\in\mathcal{G}\{\mu_\Lambda\}$, $m_{\tilde{\mu}}<\infty$, is unique and has exponentially fast decay of correlations, i.e.,

$$\sum_{k\in\mathbb{Z}^d} e^{d(k,0)}|\mathrm{cov}_{\tilde{\mu}}(f,\tau_k g)| \leqslant \frac{1}{1-\lambda\gamma_d}\left(\sum_{k\in\mathbb{Z}^d} e^{d(k,0)}\delta_k(f)\right)\left(\sum_{j\in\mathbb{Z}^d} e^{d(j,0)}\delta_j(g)\right). \tag{3}$$

Above τ_κ is a shift operator on vector $k\in\mathbb{Z}^d$,

$$\delta_k(f)=\sup_{x\in\mathbb{R}^{\mathbb{Z}^d}}\left|\frac{\partial_k f(x)}{\sqrt{F''(x_k)}}\right|, \quad \partial_k f(x)=\frac{\partial f(x)}{\partial x_k}, \quad x=\{x_k\}_{k\in\mathbb{Z}^d}. \tag{4}$$

Inequality (3) is understood on the cylinder bounded differentiable functions $f,g \in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$ such that $\Sigma_{j\in\mathbb{Z}^d} e^{d(j,0)}\delta_j(f)<\infty$.

Proof: We discuss the main tool, which enables us to deal with the polynomial interaction in the Gibbs measure. First note that the usual estimate on the covariance[30,31]

$$\mathrm{cov}_\mu(f,f)\equiv\int_{\mathbb{R}^1}\left(f-\int_{\mathbb{R}^1} f d\mu\right)^2 d\mu \leqslant \frac{1}{\varepsilon}\int_{\mathbb{R}^1}\left|\frac{\partial f}{\partial x}\right|^2 d\mu, \tag{5}$$

for the probability measure $\mu, d\mu=e^{-F(x)}dx$ on the line $\mathbb{R}^1$, holds for *arbitrary* function $F\in C^2(\mathbb{R})$ such that $F''(x)\geqslant\varepsilon>0$ for all $x\in\mathbb{R}^1$. Actually the above inequality (5) is not optimal and in Ref. 29 (Th.4.1) it was found that the next weighted generalization is true:

$$\mathrm{cov}_\mu(f,f)\leqslant\int_{\mathbb{R}^1}\frac{1}{F''(x)}\left|\frac{\partial f}{\partial x}\right|^2 d\mu, \tag{6}$$

with the weight $1/F''$, which in the cases when F'' grows on the infinity improves inequality (5).

Introduce the family of one-point conditional measures $\{\mu_k\}_{k\in\mathbb{Z}^d}$

$$d\mu_k=\frac{1}{Z_k}\exp\left\{-\lambda\sum_{j:j\neq k} G_{k-j}(x_k-x_j)\right\}e^{-F(x_k)}\,dx_k, \tag{7}$$

where Z_k is a normalization factor. Below we also understand the measure μ_k as the operator of conditional expectation

$$\mu_k: C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})\ni f\to\mu_k(f)\overset{\mathrm{def}}{\equiv}\int_{\mathbb{R}^1_k} f d\mu_k\in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d}).$$

The next identity for $j,k\in\mathbb{Z}^d$, $j\neq k$,

$$\partial_j\mu_k(f)=\mu(\partial_j f)-\lambda\,\mathrm{cov}_{\mu_k}(f,\partial_j G_{k-j}(x_k-x_j))$$

leads to

$$\begin{aligned}\delta_j(\mu_k(f))=\sup\left|\frac{\partial_j(\mu_k(f))}{\sqrt{F''}}\right|&=\sup\left|\mu_k\left(\frac{\partial_j f}{\sqrt{F''(x_j)}}\right)-\lambda\,\mathrm{cov}_{\mu_k}\left(f,\frac{\partial_j G_{k-j}(x_k-x_j)}{\sqrt{F''(x_j)}}\right)\right|\\ &\leqslant\delta_j(f)+\lambda\,\sup\left|\mathrm{cov}_{\mu_k}\left(f,\frac{\partial_j G_{k-j}(x_k-x_j)}{\sqrt{F''(x_j)}}\right)\right|.\end{aligned} \tag{8}$$

Using the convexness of G_j we obtain the following consequence of the weighted inequality (6):

$$\mathrm{cov}_{\mu_k}(f,f)\leqslant\int_{\mathbb{R}^1}\frac{|\partial_k f|^2}{F''(x_k)+\Sigma_{j\neq k}G''_{k-j}(x_k-x_j)}\,d\mu_k\leqslant\int_{\mathbb{R}^1}\frac{|\partial_k f|^2}{F''(x_k)}\,d\mu_k\leqslant[\delta_k(f)]^2. \tag{9}$$

Inequality (9) enables us to estimate the second term in (8):

$$\begin{aligned}\sup\left|\mathrm{cov}_{\mu_k}\left(f,\frac{\partial_j G_{k-j}(x_k-x_j)}{\sqrt{F''(x_j)}}\right)\right|&\leqslant\sup\,\mathrm{cov}^{1/2}_{\mu_k}(f,f)\,\mathrm{cov}^{1/2}_{\mu_k}\left(\frac{\partial_j G_{k-j}(x_k-x_j)}{\sqrt{F''(x_j)}},\frac{\partial_j G_{k-j}(x_k-x_j)}{\sqrt{F''(x_j)}}\right)\\&\leqslant\delta_k(f)\left(\int_{\mathbb{R}^1}\frac{|\partial_k\partial_j G(x_k-x_j)|^2}{F''(x_k)F''(x_j)}\,d\mu_k\right)^{1/2}\\&\leqslant\delta_k(f)\sup\frac{|G''_{k-j}(x_k-x_j)|}{\sqrt{F''(x_k)}\sqrt{F''(x_j)}}.\end{aligned}$$

Finally from (8) we obtain that

$$\delta_j(\mu_k(f))\leqslant\delta_j(f)+\lambda C_{kj}\delta_k(f) \tag{10}$$

with

$$C_{kj}=\sup_{x_k,x_j\in\mathbb{R}^1}\frac{|G''_{k-j}(x_k-x_j)|}{\sqrt{F''(x_k)}\sqrt{F''(x_j)}}.$$

The estimate (10) is a key point of the Dobrushin's uniqueness technique and the special structure of the *covariance* matrix C_{kj} permits the polynomiality of $\{G_j\}$ in the interaction.

Below we follow the scheme of Refs. 12, 13, and 16. The principal modification lies in the use of weighted inequality (6) and weighted estimate on covariances (10).

1. Uniqueness of the Gibbs measure. As in Ref. 12 we say that the vector $\{a_j\}_{j\in\mathbb{Z}^d}$ is an estimate for probability measures μ,ν if $\forall f\in C^\infty_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$: $\Sigma_{k\in\mathbb{Z}^d}\delta_k(f)<\infty$ we have

$$\left|\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\mu-\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\nu\right|\leqslant\sum_{j\in\mathbb{Z}^d}a_j\delta_j(f). \tag{11}$$

For any two measures $\mu_1,\mu_2\in\mathcal{G}\{\mu_\Lambda\}$ with property (2) there is an estimate $\tilde{a}=\{\tilde{a}_j\equiv m_0\equiv\mathrm{const}\}_{j\in\mathbb{Z}^d}$ with $m_0=m^{1/2}_{\mu_1}+m^{1/2}_{\mu_2}$. To show this, note first that for $f\in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$ with $\Sigma_{k\in\mathbb{Z}^d}\delta_k(f)<\infty$ we have

$$|f(x)-f(y)|\leqslant\sum_{i\in\mathbb{Z}^d}\delta_i(f)\rho(x_i,y_i)$$

and therefore

$$\begin{aligned}\left|\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\mu_1-\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\mu_2\right|&=\left|\int_{\mathbb{R}^{\mathbb{Z}^d}}(f(x)-f(0))d\mu_1-\int_{\mathbb{R}^{\mathbb{Z}^d}}(f(x)-f(0))d\mu_2\right|\\&\leqslant\sum_{k\in\mathbb{Z}^d}\delta_k(f)\int_{\mathbb{R}^{\mathbb{Z}^d}}\rho(x_k,0)\{d\mu_1(x)+d\mu_2(x)\}\leqslant m_0\sum_{k\in\mathbb{Z}^d}\delta_k(f).\end{aligned} \tag{12}$$

By (10) the operator $f \to \mu_k(f)$ preserves the class of functions $\{f \in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d}): \Sigma_{k\in\mathbb{Z}^d}\delta_k(f) < \infty\}$. From (10) and (12) we have

$$\begin{aligned}|\mu_1(f)-\mu_2(f)| &= |(\mu_1-\mu_2)(\mu_k(f))| \\ &\leqslant \sum_{j\in\mathbb{Z}^d} \tilde{a}_j \delta_j(\mu_k(f)) \\ &\leqslant \sum_{j:j\neq k} \tilde{a}_j \delta_j(f) + \lambda\,\delta_k(f) \sum_{i:i\neq k} \tilde{a}_i C_{ki}. \end{aligned} \tag{13}$$

Iterating the above estimate by choosing some enumeration $k_1,\ldots,k_n$, of the points of lattice $\mathbb{Z}^d$ one can in a purely algebraic way achieve the following estimate (see Ref. 12, Lemma 2.3):

$$|\mu_1(f)-\mu_2(f)| \leqslant \lambda \sum_{k\in\mathbb{Z}^d} \delta_k(f)\left(\sum_{j\in\mathbb{Z}^d} \tilde{a}_j C_{kj}\right),$$

which gives

$$|\mu_1(f)-\mu_2(f)| \leqslant \sum_{k\in\mathbb{Z}^d} (\tilde{a}(\lambda C)^n)_k \delta_k(f)$$

for all $n \geqslant 0$.

Due to

$$\begin{aligned}\|\tilde{a}(\lambda C)^n\|_{l_\infty(\mathbb{Z}^d)} &= m_0 \sup_{k\in\mathbb{Z}^d} \sum_{j\in\mathbb{Z}^d} \{(\lambda C)^n\}_{kj} \\ &= m_0 \sup_{k\in\mathbb{Z}^d} \lambda^n \sum_{j(1)\in\mathbb{Z}^d} \cdots \sum_{j(n-1)\in\mathbb{Z}^d} \sum_{j\in\mathbb{Z}^d} C_{kj(1)}\cdots C_{j(n-1)j} \\ &\leqslant m_0 \left(\sup_{k\in\mathbb{Z}^d} \lambda \sum_{j\in\mathbb{Z}^d} C_{kj}\right)^n \\ &\leqslant m_0(\lambda\gamma_d)^n \to 0, \quad n\to\infty, \end{aligned} \tag{14}$$

we obtain the uniqueness of the Gibbs measure.

2. Decay of correlations. Fix function $g \in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$ such that $\int_{\mathbb{R}^{\mathbb{Z}^d}} g\, d\mu = 1$, $g>0$ and $\Sigma_{k\in\mathbb{Z}^d} e^{d(k,0)}\delta_k(g) < \infty$. Then measure $d\nu = g\, d\mu$ for the unique measure $\mu \in \mathcal{G}\{\mu_\Lambda\}$ with property (2) has the same property

$$\sup_{k\in\mathbb{Z}^d} \int_{\mathbb{R}^{\mathbb{Z}^d}} \rho(x_k,0)\, d\nu(x) \leqslant \|g\|_{C_b} m_\mu^{1/2} < \infty.$$

In analog to (12) this gives the estimate $\tilde{a} = \{\tilde{a}_j \equiv m_\mu^{1/2}(\|g\|_{C_b} + 1)\}_{j\in\mathbb{Z}^d}$ on measures μ and ν

$$|\mu(f)-\nu(f)| \leqslant \sum_{k\in\mathbb{Z}^d} \tilde{a}_k \delta_k(f) = m_\mu^{1/2}(\|g\|_{C_b}+1) \sum_{k\in\mathbb{Z}^d} \delta_k(f).$$

Now we prove that if $\{a_j\}_{j\in\mathbb{Z}^d}$ is an estimate, then $\{\Sigma_{j\in\mathbb{Z}^d} a_j C_{jk} + b_k\}_{k\in\mathbb{Z}^d}$ for $b_k = \delta_k(g)$ is an estimate too. Indeed

$$|\mu(f)-\nu(f)|\leqslant\left|(\mu-\nu)_y\left\{\int_{\mathbb{R}_k} f(\cdot|y)d\mu_k(\cdot|y)\right\}\right|$$
$$+\left|\nu_y\left\{\int_{\mathbb{R}_k} f(\cdot|y)d\mu_k(\cdot|y)-\int_{\mathbb{R}_k} f(\cdot|y)d\nu_k(\cdot|y)\right\}\right|$$
$$=\sum_{j\in\mathbb{Z}^d}\tilde{a}_j\delta_j(\mu_k(f))+\left|\nu_y\left\{\int_{\mathbb{R}_k} f(\cdot|y)d\mu_k(\cdot|y)-\int_{\mathbb{R}_k} f(\cdot|y)d\nu_k(\cdot|y)\right\}\right|. \quad (15)$$

Using (10) the first term in (15) can be estimated by

$$\sum_{j\neq k}\tilde{a}_j\delta_j(f)+\lambda\,\delta_k(f)\left\{\sum_{i\neq k}\tilde{a}_i C_{ik}\right\}.$$

We apply inequality (6) to the second term. We use that $d\nu=g\,d\mu$, so $d\nu_k=[g/\mu_k(g)]d\mu_k$ and obtain

$$\left|\nu_y\left\{\int f\,d\mu_k(\cdot|y)-\int f\,d\nu_k(\cdot|y)\right\}\right|=\left|\nu_y\left\{\int[f-\mu_k(f)]\left(d\mu_k-\frac{g}{\mu_k(g)}\,d\mu_k\right)\right\}\right|$$
$$=\left|\mu_y\left\{\frac{g}{\mu_k(g)}\int(f-\mu_k(f))(g-\mu_k(g))d\mu_k\right\}\right|.$$

The result of integration on $\mathbb{R}_k$ does not depend on variable $x_k\in\mathbb{R}_k$, therefore we continue:

$$\left|\mu_y\left\{\frac{g}{\mu_k(g)}\int(f-\mu_k(f))(g-\mu_k(g))d\mu_k\right\}\right|=\left|\mu\left\{\int_{\mathbb{R}_k}(f-\mu_k(f))(g-\mu_k(g))d\mu_k\right\}\right|$$
$$\leqslant\sup\,\mathrm{cov}^{1/2}_{\mu_k}(f,f)\mathrm{cov}^{1/2}_{\mu_k}(g,g)\leqslant\delta_k(f)\,\delta_k(g)$$
$$=b_k\delta_k(f).$$

Finally we have obtained the estimate on (15):

$$|\mu(f)-\nu(f)|\leqslant\sum_{j\neq k}\tilde{a}_j\delta_j(f)+\delta_k(f)\left\{\sum_{i\neq k}\tilde{a}_i\lambda C_{ik}+b_k\right\}. \quad (16)$$

By iteration of (16) as in Refs. 12, 13, and 16, one achieves that $(\tilde{a}\lambda C+b)$ is an estimate, too:

$$|\mu(f)-\nu(f)|\leqslant\sum_{k\in\mathbb{Z}^d}\{\tilde{a}_i\lambda C_{ik}+b_k\}\,\delta_k(f). \quad (17)$$

The vector $b\Sigma_{n=0}^{\infty}(\lambda C)^n$ is also an estimate because of the following convergence in $l_\infty(\mathbb{Z}^d)$:

$$b\sum_{n=0}^{N}(\lambda C)^n+\tilde{a}(\lambda C)^{N+1}\to b\sum_{n=0}^{\infty}(\lambda C)^n,\quad N\to\infty.$$

Thus we achieve estimate[12,13,16]

$$|\mathrm{cov}_\mu(f,g)|=\left|\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\nu-\int_{\mathbb{R}^{\mathbb{Z}^d}} f\,d\mu\right|\leqslant\sum_{k,j\in\mathbb{Z}^d}D_{kj}\delta_k(f)\,\delta_j(g) \quad (18)$$

for $D=\Sigma_{n=0}^{\infty}(\lambda C)^n$. Therefore

$$|\mathrm{cov}_\mu(f,\tau_i g)|e^{d(i,0)} \leqslant \sum_{k,j\in\mathbb{Z}^d} e^{d(j,k)} D_{jk} e^{d(k,0)} \delta_k(f\,) e^{d(i,j)} \delta_{j-i}(g).$$

Summing up on $i\in\mathbb{Z}^d$ we have the required decay of correlations for $g>0$.

The case of arbitrary $g \in C^1_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$ with $\Sigma_{k\in\mathbb{Z}^d} e^{d(k,0)}\delta_k(g) < \infty$ is obviously due to the identity $\mathrm{cov}_\mu(f,c_1 g + c_2) = c_1\,\mathrm{cov}_\mu(f,g)$ ■

Theorem 2: *Under conditions A–C the set of Gibbs measures $\mathcal{G}\{\mu_\Lambda\}$ with condition*

$$m_\mu = \sup_{k\in\mathbb{Z}^d} \int_{\mathbb{R}^{\mathbb{Z}^d}} \rho^2(x_k,0)\, d\mu(x) < \infty \tag{19}$$

is nonempty.

Moreover, at the coupling interaction constant $\lambda\in[0,1/\gamma_d)$, the Gibbs measure $\tilde{\mu}$ of Theorem 1 fulfills the estimate

$$\sup_{k\in\mathbb{Z}^d} \int_{\mathbb{R}^{\mathbb{Z}^d}} \exp\{a x_k^2\}\, d\tilde{\mu} \leqslant \exp\left(\frac{a}{\epsilon - 2a}\right) \tag{20}$$

for all $a\in[0,\epsilon/2)$.

Proof: Let

$$\mathcal{U}_\Lambda = \sum_{k\in\Lambda} F(x_k) + \lambda \sum_{\{k,j\}\subset\Lambda} G_{k-j}(x_k - x_j)$$

and consider the family of Gibbs measures $\{\mu_\Lambda\}$ with the free boundary conditions in the finite volumes $\Lambda\subset\mathbb{Z}^d$

$$d\mu^0_\Lambda = \frac{1}{Z}\, e^{-\mathcal{U}_\Lambda}\, dx_\Lambda\,.$$

The potentials $(\mathcal{U}_\Lambda)'' \geqslant \epsilon I$ are convex, so the measures μ^0_Λ satisfy inequality (24) in form[30,31]

$$\mathrm{cov}_{\mu^0_\Lambda}(f,f\,) \leqslant \frac{1}{\epsilon} \int_{\mathbb{R}^\Lambda} \sum_{k\in\Lambda} |\partial_k f|^2\, d\mu^0_\Lambda.$$

Substituting $f = x_k$ and using that $\int_{\mathbb{R}^\Lambda} x_k d\mu^0_\Lambda \equiv 0$ by the symmetry of μ^0_Λ, we have that uniformly on Λ and $k\in\Lambda$

$$\sup_{\Lambda\subset\mathbb{Z}^d,\ k\in\Lambda} \int_{\mathbb{R}^\Lambda} x_k^2\, d\mu^0_\Lambda \leqslant 1/\epsilon. \tag{21}$$

The convexness of the potentials $\mathcal{U}_\Lambda$ also implies the Log–Sobolev inequality for the measures $\{\mu^0_\Lambda\}$:[30]

$$\int_{\mathbb{R}^\Lambda} f^2 \ln f^2\, d\mu^0_\Lambda - \int_{\mathbb{R}^\Lambda} f^2\, d\mu^0_\Lambda \ln \int_{\mathbb{R}^\Lambda} f^2\, d\mu^0_\Lambda \leqslant \frac{2}{\epsilon} \int_{\mathbb{R}^\Lambda} \sum_{k\in\Lambda} |\partial_k f(x_\Lambda)|^2\, d\mu^0_\Lambda(x_\Lambda). \tag{22}$$

Fix $\Lambda\subset\mathbb{Z}^d$ and $k\in\Lambda$. Consider increasing on $n\geqslant 1$ sequence of functions:

$$f_n=\begin{cases} -n, & x_k<-n,\\ x_k, & |x_k|\leqslant n,\\ n, & x_k>n. \end{cases}$$

As in Ref. 31 introduce the sequence of functions $h_n(a)=\int_{\mathbb{R}^\Lambda}\exp(af_n^2)d\mu_\Lambda^0\geqslant 1$ on half-line $a\in[0,\infty)$, increasing on both a and n with all derivatives $h_n^{(k)}(a)>0$, $a>0$. Then for $g_n=\exp(af_n^2/2)$ we apply the Log–Sobolev inequality (22):

$$\begin{aligned} ah_n'(a)&=\int_{\mathbb{R}^\Lambda} af_n^2\,\exp(af_n^2)d\mu_\Lambda^0=\int_{\mathbb{R}^\Lambda} g_n^2\,\ln\, g_n^2 d\mu_\Lambda^0\\ &\leqslant\frac{2}{\varepsilon}\int_{\mathbb{R}^\Lambda}\sum_{j\in\Lambda}|\partial_j g_n|^2\,d\mu_\Lambda^0+h_n(a)\ln\, h_n(a)\\ &\leqslant\frac{2}{\varepsilon}\,a^2\int_{\mathbb{R}^\Lambda} f_n^2\,\exp(af_n^2)d\mu_\Lambda^0+h_n(a)\ln\, h_n(a). \end{aligned}$$

Therefore the family $h_n(a)$, increasing on both n and $a\geqslant 0$, $h_n(0)=1$, satisfy the inequality $a(1-2a/\varepsilon)h_n'(a)\leqslant h_n(a)\ln h_n(a)$. To find the major function we must set $h(0)=1$ and take the highest growth of its derivative, so $a(1-2a/\varepsilon)h'(a)=h(a)\ln h(a)$ and

$$h(a)=\exp[aD/(1-2a/\varepsilon)]$$

for some D. The restriction on D we obtain from the highest growth of h_n at zero,

$$h_n'(0)=\int_{\mathbb{R}^\Lambda} f_n^2\,d\mu_\Lambda^0\leqslant\int_{\mathbb{R}^\Lambda} x_k^2\,d\mu_\Lambda^0(x)=D<\infty,$$

and achieve estimate

$$h_n(a)\leqslant\exp\left\{\frac{a}{1-2a/\varepsilon}\int_{\mathbb{R}^\Lambda} x_k^2\,d\mu_\Lambda^0(x)\right\}.$$

Tending $n\to\infty$ we obtain the estimate of the next form at $a\in[0,\varepsilon/2)$,

$$\int_{\mathbb{R}^\Lambda}\exp(ax_k^2)d\mu_\Lambda^0\leqslant\exp\left(\frac{a}{1-2a/\varepsilon}\int_{\mathbb{R}^\Lambda} x_k^2\,d\mu_\Lambda^0\right),$$

which by (21) gives

$$\forall\, a\in[0,\varepsilon/2)\qquad\sup_{\Lambda\subset\mathbb{Z}^d,k\in\Lambda}\int_{\mathbb{R}^\Lambda}\exp(ax_k^2)d\mu_\Lambda^0<\exp\left(\frac{a}{\varepsilon-2a}\right).\tag{23}$$

Compactness of the function $\exp(ax_k^2)$ leads by the Prochorov's theorem[7] to the existence of the weak local limit $\tilde{\mu}$,

$$\lim_{\Lambda\nearrow\mathbb{Z}^d}\int_{\mathbb{R}^\Lambda} f(x_\Lambda)d\mu_\Lambda^0=\int_{\mathbb{R}^{\mathbb{Z}^d}} f(x)d\tilde{\mu},$$

on any cylinder function $f\in C_{b,\mathrm{cyl}}(\mathbb{R}^{\mathbb{Z}^d})$.

Due to the finiteness of the interaction radius (condition B), the limit measure $\tilde{\mu}$ has the conditional measures $\{\mu_\Lambda\}$ in the finite volumes, i.e., $\tilde{\mu}\in\mathcal{G}\{\mu_\Lambda\}$ and the set of the Gibbs measures is nonempty. From (23) we also have that the measure $\tilde{\mu}$ is tempered, i.e.,

$$\sup_{k\in\mathbb{Z}^d}\int_{\mathbb{R}^{\mathbb{Z}^d}}\exp(ax_k^2)d\tilde{\mu}<\exp\left(\frac{a}{\varepsilon-2a}\right),\quad a\in[0,\varepsilon/2),$$

which obviously gives the statement (20). ■

Model 1: Let the potentials be defined by

$$F(x_k)=(1+x_k^2)^{2n+1}\quad\text{and}\quad G_{k-j}(x_k-x_j)=b_{k-j}(x_k-x_j)^{2n+2}$$

and assume that the coefficients $\{b_j\}_{j\in\mathbb{Z}^d}$ satisfy

$$\forall j\in\mathbb{Z}^d\ \ b_j\geqslant 0\ \text{ and }\ \exists r_0\forall|j|>r_0: b_j=0.$$

Then for

$$0\leqslant\lambda<\frac{1}{(n+1)2^{2n+1}\|b\|_d},\quad \|b\|_d=\sum_{j\in\mathbb{Z}^d}b_j e^{d(j,0)}<\infty$$

the statements of Theorems 1 and 2 are valid.

Model 2. Lattice spin system on Riemannian manifold. Denote $M=M_k$, $k\in\mathbb{Z}^d$, a noncompact Riemannian manifold with covariant derivative ∂_k and Ricci curvature tensor Ric_k.

Let potentials $F_k(x_k)$, $G_{kj}(x_k,x_j)$ satisfy

(1) $F_k\in C^2(M)$, $\exists\varepsilon>0\forall x_k\in M_k\ \mathrm{Ric}_k+\partial_k\partial_k F(x_k)\geqslant\varepsilon$;

(2) $G_{kj}\in C^2(M\times M)$, $\exists\alpha\in\mathbb{R}^1\partial_k\partial_k G_{kj}(x_k,x_j)\geqslant-\alpha$, $k,j\in\mathbb{Z}^d$ and $G_{kj}\equiv 0$, for $|k-j|\geqslant r_0$;

(3) $\alpha_{k,j}=\sup_{x\in M^{\mathbb{Z}^d}}\|B^{-1/2}(x_k)B^{-1/2}(x_j)\partial_k\partial_j G_{kj}(x_k,x_j)\|_{TM_k\times TM_j}<\infty$,

where $B(x_k)=\mathrm{Ric}_k(x_k)+\partial_k\partial_k F_k(x_k)$ and $\|\cdot\|_{TM_k\times TM_j}$ is a standard Hilbert norm on tangent space to $M_k\times M_j$.

Then for $\lambda\in[0,\min(\varepsilon/\alpha(2r_0+1)^d,1/\gamma_d))$ the lattice system, described by Hamiltonian

$$H=\sum_{k\in\mathbb{Z}^d}F_k(x_k)+\lambda\sum_{|k-j|\leqslant r_0}G_{kj}(x_k,x_j),$$

has exponentially fast decay of correlations and the Gibbs measure is unique.[32] Above $\gamma_d=\sup_{k\in\mathbb{Z}^d}\Sigma_{j\in\mathbb{Z}^d}e^{d(k,j)}\alpha_{kj}$.

This result is achieved by the scheme of this paper. One needs to consider

$$\delta_k(f)=\sup_{x\in M^{\mathbb{Z}^d}}\|(\mathrm{Ric}_k+\partial_k\partial_k F(x_k))^{-1/2}\partial_k f(x)\|_{TM_k}$$

and apply in corresponding places the following generalization of the Brascamp–Lieb inequality (6) to the case of arbitrary Riemannian manifold:[32] under condition $\exists\varepsilon>0$ $\mathrm{Ric}+\partial\partial F\geqslant\varepsilon$ we have

$$\mathrm{cov}_\mu(f,f)\leqslant\int_M\langle(\mathrm{Ric}+\partial\partial F)^{-1}\partial f,\partial f\rangle d\mu,\quad f\in C_b^1(M),\tag{24}$$

with probability measure $d\mu=e^{-F}\,d\sigma$ (σ denotes Riemannian volume on manifold M) and Riemannian pairing $\langle\cdot,\cdot\rangle$ on tangent space to manifold.

Developing idea of Helffer[28,33] we can shortly explain inequality (24) in the following way. Take $u=\partial H_\mu^{-1}(g-\int g\ d\mu)$ for $H_\mu=\partial_\mu^*\partial$ with dual gradient $\partial_\mu^* v=-\operatorname{div} v+\langle \partial F, v\rangle$. Then $\partial_\mu^* u=H_\mu H_\mu^{-1}(g-\int g\ d\mu)=g-\int g\ d\mu$ and we have

$$\operatorname{cov}_\mu(g,g)=\int g\left(g-\int g\ d\mu\right)d\mu=\int \langle u,\partial g\rangle d\mu$$

$$=\int \langle (H_\mu+\mathrm{Ric}+\partial\partial F)^{-1}\partial g,\partial g\rangle d\mu$$

$$\leqslant \int_M \langle (\mathrm{Ric}+\partial\partial F)^{-1}\partial g,\partial g\rangle d\mu,$$

where we used the positivity of H_μ and $u=(H_\mu+\mathrm{Ric}+\partial\partial F)^{-1}\partial g$ by a simple commutation $\partial g=\partial\partial_\mu^* u=(\partial_\mu^*\partial+\mathrm{Ric}+\partial\partial F)u$.

ACKNOWLEDGMENTS

We wish to sincerely thank Professor S. Albeverio for the attention to the paper, warm hospitality in the BiBoS Research Center, and great help in making Refs. 18 and 21 available for us. We would like to express our appreciation to Professor L. Gross for the invaluable recommendations on Ref. 32 and Professor T. Spencer for the prompt contact with new information on $(\nabla\varphi)^4$ lattice models.

Integration of thermodynamic identities for a relativistic general equation of state

Sankar Chattopadhyay and Dipankar Ray
Department of Mathematics, Jadavpur University, Calcutta-700032, India

(Received 3 December 1993; accepted for publication 23 January 1996)

In a recent paper Mason and Kgathi have integrated some well-known thermodynamic identities for an equation of state $p=nkT$ and thereby have obtained some explicit expressions for the thermodynamic variables concerned. In the present paper we integrate the same identities for a more general equation of state $p=p(n,T)$ and thereby obtain more general expressions for the same thermodynamic variables. © *1996 American Institute of Physics.*
[S0022-2488(96)00608-1]

I. INTRODUCTION

In a recent paper Mason and Kgathi[1] have shown that the well-known thermodynamic identities,

$$d\mu = T\,dS + K\,dn \tag{1a}$$

and

$$\mu = TS + Kn - p, \tag{1b}$$

together can be integrated for an equation of state,

$$p = nkT. \tag{2}$$

Here μ is the total energy density, T is the temperature in Kelvin, S is the entropy per unit volume, n is the particle number density, K is the chemical potential per particle, k is Boltzmann's constant, and p is the pressure. The purpose of the present paper is to integrate equations (1) for a more general equation of state,

$$p = p(n,T). \tag{3}$$

II. SOLUTIONS

Equations (1) and (3) can be combined to give

$$\mu(s,n) = S\,\frac{\partial\mu(S,n)}{\partial S} + n\,\frac{\partial\mu(S,n)}{\partial n} - p(n,T), \tag{4}$$

where

$$T = \frac{\partial\mu(S,n)}{\partial S}, \tag{5a}$$

$$K = \frac{\partial\mu(S,n)}{\partial n}. \tag{5b}$$

Also, by virtue of Eq. (5a), one can rewrite Eq. (4) as

$$\mu(S,n)=S\,\frac{\partial\mu(S,n)}{\partial S}+n\,\frac{\partial\mu(S,n)}{\partial n}-p\left(n,\frac{\partial\mu}{\partial S}\right). \tag{6}$$

Equation (6) is a nonlinear partial differential equation for $\mu(S,n)$ that can be solved as follows.

Differentiating Eq. (6) wrt S while treating n as constant one gets

$$S\,\frac{\partial^2\mu(S,n)}{\partial S^2}+n\,\frac{\partial^2\mu(S,n)}{\partial S\;\partial n}-\frac{p(n,(\partial\mu/\partial S))}{\partial(\partial\mu/\partial S)}\,\frac{\partial^2\mu}{\partial S^2}=0, \tag{7}$$

which by virtue of Eq. (5a) can be rewritten as

$$S\,\frac{\partial T(S,n)}{\partial S}+n\,\frac{\partial T(S,n)}{\partial n}-\frac{\partial p(n,T)}{\partial T}\cdot\frac{\partial T(S,n)}{\partial S}=0. \tag{8}$$

Treating S as a function of n and T, one can rewrite Eq. (8) as

$$S(n,T)-n\,\frac{\partial S(n,T)}{\partial n}=\frac{\partial p(n,T)}{\partial T},$$

which can be easily integrated as

$$S=n\,\frac{\partial}{\partial T}\left(f(T)-\int\frac{1}{n^2}\,p(n,T)dn\right), \tag{9}$$

where $f(T)$ is an arbitrary function of T.

Equation (5a) can now be integrated wrt S by treating n as constant to give

$$\mu=\int T\,dS+\alpha(n)=TS-\int S\,dT+\alpha(n), \tag{10}$$

where $\alpha(n)$ is an arbitrary function of n while $\int S\,dT$ represents an integration of S wrt T, treating n as constant.

From Eqs. (9) and (10) one gets

$$\mu=nT\left[f'(T)-\int\frac{1}{n^2}\,\frac{\partial p(n,T)}{\partial T}\,dn-n\left[f(T)-\int\frac{1}{n^2}\,p(n,T)dn\right]+\alpha(n)\right]. \tag{11}$$

Equations (9) and (11) together give a form for μ as a function of S and n where T is a parameter. Obviously any solution $\mu(S,n)$ of Eq. (6) must be of this form. But any μ of the form given by Eqs. (9) and (11) together may not satisfy Eq. (6), because the equations (9) and (11) are essentially obtained from Eq. (7), which was obtained by differentiation of Eq. (6) wrt S. So putting Eqs. (9) and (11) back into Eq. (6) and using relations like

$$\left(\left.\frac{\partial\mu}{\partial n}\right|_{\substack{S\text{ as}\\ \text{constant}}}\right)=\left(\left.\frac{\partial\mu}{\partial n}\right|_{\substack{T\text{ as}\\ \text{constant}}}\right)-\left(\left.\frac{\partial\mu}{\partial T}\right|_{\substack{n\text{ as}\\ \text{constant}}}\right)\left(\frac{\partial S(n,T)/\partial n}{\partial S(n,T)/\partial T}\right),$$

one gets after a little calculation,

$$n\,\frac{d\alpha(n)}{dn}=\alpha(n),$$

which gives $\alpha(n)=nL$, where L is a constant of integration. Putting this form of $\alpha(n)$ back into Eq. (11), it is easy to see that the constant of integration L can be easily absorbed into $f(T)$. Hence one gets finally

$$\mu=n\left[T\left\{f'(T)-\int \frac{1}{n^2}\frac{\partial p(n,T)}{\partial T}\,dn\right\}-\left\{f(T)-\int \frac{1}{n^2}\,p(n,T)dn\right\}\right]. \tag{12}$$

III. CONCLUSION

In summary, we have integrated the thermodynamic identities given by (1a) and (1b) for any equation of state of the form (3). On integration the total energy density function μ is expressed as a function of other thermodynamic variables n and T, as is given by Eq. (12), the entropy per unit volume S is obtained as a function of n and T, and is given by Eq. (9).

The low activity phase of some Dirichlet series

Pierluigi Contucci[a)]
Department of Mathematics, Kerchof Hall, University of Virginia, Charlottesville, Virginia 22903

Andreas Knauf[b)]
Technische Universität, Fachbereich 3, Mathematik, MA 7-2, Strasse des 17, Juni 135, D-10623 Berlin, Germany

(Received 15 April 1996; accepted for publication 11 June 1996)

We show that a rigorous statistical mechanics description of some Dirichlet series is possible. Using the abstract polymer model language of statistical mechanics and the polymer expansion theory we characterize the *low activity* phase by the suitable exponential decay of the truncated correlation functions. © *1996 American Institute of Physics.* [S0022-2488(96)01511-3]

I. INTRODUCTION

The idea to relate number theory and equilibrium statistical mechanics or, more precisely, zeta functions and partition functions, is now already quite old. One motivation for pursuing this idea lies in the probabilistic aspects of the prime number distribution. Statistical mechanics as an intrinsically probabilistic theory is hoped to be an appropriate language for these phenomena. The book[1] by Kac nicely presents this kind of probabilistic reasoning.

More concretely, the formulation of the famous Lee–Yang theorem was influenced by a paper[2] by Pólya on the Riemann zeta function. In that paper Pólya took the asymptotics of the Fourier transformed zeta function and proved for its inverse Fourier transform the ''Riemann hypothesis,'' saying that the nonreal zeroes have real part $\frac{1}{2}$.

As described by Kac in Ref. 2, the method of Pólya's proof inspired the first version of the Lee–Yang theorem (which says that the partition function of ferromagnetic Ising models has only zeroes on the unit circle of the activity plane).

This led to the natural question whether inversely the Riemann hypothesis or simpler number-theoretical questions could be proven by some statistical mechanics method.

In recent years two approaches have been followed. In one of them the Riemann zeta function $\zeta(s)$ itself was interpreted as partition function of a system of *interacting primes* at inverse temperature s (see Refs. 3–6). In the last-mentioned paper the system was shown to exhibit a phase transition at $s=1$ with type I states (resp. type III) at low (resp. high) temperature.

In the second approach mentioned the quotient $\zeta(s-1)/\zeta(s)$ is interpreted as a partition function at the inverse temperature s (see Refs. 7–13).

It was shown that the partition function described a spin chain with asymptotically translation-invariant long-range ferromagnetic interaction (the *number-theoretical spin chain*). The point $s=2$ corresponds to a phase transition where magnetization jumps from 0 to 1.

Although there exist versions of the Lee–Yang theorem predicting zero-free half-planes in the inverse temperature plane, unfortunately these theorems cannot be applied to the above spin chain, since its interaction includes multi-body terms.

In this paper, using the general polymer model approach of statistical mechanics, we propose a criterium to interpret a large class of Dirichlet series as grand canonical partition functions of hard-core interacting systems.

The criterium involves a finite-volume approximation and a precise notion of activity. We

[a)]Electronic mail address: contucci@virginia.edu
[b)]Electronic mail address: knauf@math.tu-berlin.de

0022-2488/96/37(11)/5458/18/$10.00

present two possible polymerizations: the first is based on the notion of Euler product and works for multiplicative arithmetical functions, the second covers a wider class of cases.

We show that the natural thermodynamical quantities of the polymer model, like correlation functions, carry a deep number-theoretical meaning being the probability of suitable divisibility properties.

In order to control the behavior of the correlation functions we apply the polymer expansion technique by means of the Kirkwood–Salsburg iterative equations: the low activity expansion theory enables us to prove the exponential decay of all the truncated correlation functions and provides, in general, a full analytical control of the low temperature phase.

This shows that the language of polymer models is not only formally but also analytically adequate to describe the considered class of Dirichlet series.

Our approach clarifies the statistical mechanics meaning of the absolute convergence theory for the Dirichlet series and introduces new perspectives on it; moreover, it has the merit to point out the natural limits of each polymerization. The polymerizations treated in this work, like similar techniques in number theory, provide an approximation of the Dirichlet function which works well for the large real part of the complex plane but its results are too nonuniform elsewhere, especially on the critical strip.

We believe that, in order to obtain new analytical results from the number-theoretical point of view, one has to search for different polymerizations, for instance the high temperature ones, or better to explore more subtle strategies like the *rearrangement* procedure for polymer models (see Refs. 14 and 15) which, in some cases, provide a good control of the asymptotic behavior of the correlation functions in the interesting regions of the phase space.

All these ideas can be improved and tested with the study of the number theoretical spin chain: the interacting objects there are not directly related to primes and could suggest different types of polymerization based on groups of spins (see Ref. 13). Moreover the approximant family φ_k (Refs. 7 and 8) of the Euler totient function could really be seen as a systematic way to rearrange the Euler totient function φ thought as a *bare* interaction. We will return to these questions elsewhere.

Notation: Sums (resp. products) over empty sets equal zero (resp. one). We write $\mathbb{N}:=\{1,2,3,...\}$ for the integers, $\mathbb{N}_0:=\mathbb{N}\cup\{0\}$ and $\mathbb{P}\equiv\{2,3,5,...\}$ for the primes. If n divides m, we write $n|m$ and the symbol $\Sigma_{n|m}$ denotes a sum over all the divisors of m; (n,m) is the greatest common divisor of m and n.

II. THE POLYMER EXPANSION

Statistical mechanics seeks to describe the collective behavior of a large number of similar particles. One assumes that these particles are enclosed in a finite region $\Lambda\subset S$ of space S (typically $S=\mathbb{R}^d$ or $S=\mathbb{Z}^d$) and then considers the thermodynamic limit $\Lambda\nearrow S$.

The mutual interaction between the particles in a configuration σ is encoded by their total energy $H_\Lambda(\sigma)$. At inverse temperature s the probability of that configuration is given by $\exp(-sH_\Lambda(\sigma))/Z_\Lambda(s)$,

$$Z_\Lambda(s):=\sum_\sigma \exp(-sH_\Lambda(\sigma)) \tag{1}$$

being the partition function for volume Λ.

So the basic objects of statistical mechanics are the Boltzmann factors $\exp(-sH_\Lambda(\sigma))$ of the configurations.

Whereas the above Gibbs probability measures for the finite volume Λ are real-analytic in the parameter s, in the thermodynamic limit $\Lambda\nearrow S$ nonanalyticities arise which are called phase transitions. Different asymptotic Gibbs measures may then be compatible with a given interaction and inverse temperature.

This phenomenon is typical for random fields, i.e., random functions in several variables, and is of central interest in today's theory of probability.

Thus one basic problem of statistical mechanics consists of determining regions in parameter space (e.g., in the s plane) where intensive quantities like the free energy $|\Lambda|^{-1}\ln(Z_\Lambda(s))$ stay analytic in the thermodynamic limit.

Many of the techniques employed in that context recently turned out to be related, the common ground being the abstract *polymer model* formulation (see Refs. 16–18).

In the abstract setting one starts with a denumerable set $P\equiv\{\gamma_1,\gamma_2,...\}$ whose elements are called *polymers* and with an assigned reflexive symmetric relation of *incompatibility* between each of the two of them.

In the concrete application of a two-dimensional Ising model, the polymers may be the contours enclosing a region of constant spin direction, or the subgraphs of the nearest-neighbor graph, depending on whether one is interested in small or large temperatures; the incompatibility between two of them is simply the mutual overlapping.

Thus one may associate to a *k-polymer* $X:=\{\gamma_1,\ldots,\gamma_k\}\in P^k$ an undirected graph $G(X)=(V(X),E(X))$ with vertex set $V(X):=\{1,\ldots,k\}$, vertices $i\neq j$ being connected by the edge $\{\gamma_i,\gamma_j\}\in E(X)$ if γ_i and γ_j are incompatible. Accordingly the k-polymer X is called connected if $G(X)$ is path connected and (completely) disconnected if it has no edges $[E(X)=\varnothing]$.

The corresponding subsets of P^k are called C^k resp. D^k, with $D^0:=P^0:=\{\varnothing\}$ consisting of a single element. Moreover $P^\infty:=\cup_{k=0}^\infty P^k$ with the subsets $D^\infty:=\cup_{k=0}^\infty D^k$ and $C^\infty:=\cup_{k=1}^\infty C^k$. We write $|X|:=k$ if $X\in P^k$; indicating with $X(\gamma)$ the multiplicity of γ in X it results in $k=\Sigma_i X(\gamma_i)$. It is useful to define the function $c(X):=\Pi_i X(\gamma_i)!$. We will indicate with a hat the Abelianized set: for instance $\hat{P}^\infty$ is the set of Abelian words (which we also call polymer configurations) which arises if one identifies k-polymers $X=\{\gamma_1,\ldots,\gamma_k\}$, $Y=\{\delta_1,\ldots,\delta_k\}\in P^\infty$ if $\delta_{\pi(i)}=\gamma_i$ for some permutation π.

Statistical weights or activities $z:P\to\mathbb{C}$ of the polymers are multiplied to give the activities $z^X:=\Pi_{i=1}^k z(\gamma_i)$ of k-polymers.

The thermodynamical properties of the model are defined through the partition function

$$Z=\sum_{X\in\hat{D}^\infty} z^X. \tag{2}$$

We observe that no multiple occurrence of a polymer is allowed since the incompatibility relation is reflexive; for this reason the sum is finite when P has finite cardinality which corresponds to a finite volume in the concrete cases.

It has to be stressed that the polymer models are not statistical mechanics models in the usual form (1). They are useful devices to study the true models in the *low activity* regime of the phase diagram: for this reason a given model is often mapped into different polymer models according to each different phase regime.

One is mainly interested in the $|P|\to\infty$ limit (thermodynamic limit) for the mean values of the configuration functions h:

$$\langle h\rangle_z=\frac{\Sigma_{X\in\hat{D}^\infty}h(X)z^X}{\Sigma_{X\in\hat{D}^\infty}z^X}, \tag{3}$$

and especially for the correlation functions

$$\rho_z(Y)=\langle\chi_Y\rangle_z, \tag{4}$$

where χ_Y is the characteristic function of Y. Often the dependence of the correlation functions on the activity is studied in terms of parameters such as, for instance in statistical mechanics, the inverse temperature or a magnetic field.

An important quantity to be studied in the thermodynamic limit is the free energy density, or pressure, which turns out to be (see, for instance, Refs. 16 and 19) up to a suitable normalization factor

$$\ln(Z)=\sum_{X\in\hat{P}^{\infty}}\frac{n^{T}(X)}{c(X)}z^{X}, \tag{5}$$

with $n^T(X):=n_+(X)-n_-(X)$, $n_\pm(X)$ being the number of subgraphs of $G(X)$ connecting all the vertices of $G(X)$ with an even (resp. odd) number of edges. The structure of the factors n^T implies that the previous sum is actually supported only on $\hat{C}^{\infty}$.

We notice that, although in the partition sum only compatible configurations of polymer may appear, the free energy contains contribution from all the configuration and also coincident polymers (multiplicities) are allowed.

Formula (5) is important from the conceptional as well as from the analytical point of view. It is complemented by the so-called tree estimate $|n^T(X)|\leqslant|\tau(G(X))|$, where $\tau(G)$ denotes the set of maximal subtrees of the connected graph G. This inequality is useful, since there exist techniques to estimate the number of subtrees. As an example, a theorem by Cayley says that the complete (all edges present) graph $K(k)$ with k vertices contains $|\tau(K(k))|=k^{k-2}$ maximal trees.

It is easy to check that the simplest example $P=\{p\}$, i.e., $Z=1+z$, of a polymer model reduces the formula (5) to the Taylor expansion for the logarithm $\ln(Z)=\Sigma_{k=1}^{\infty}[(-1)^{k-1}/k]z^k$, since $n^T(K(k))=(-1)^{k-1}(k-1)!$ (the last formula showing, by the way, that the tree estimate is nonoptimal).

So even for a finite cardinality of P one needs bounds on the activities to ensure convergence of the free energy. In the statistical mechanics applications such bounds are given in terms of energy (or activity) and entropy bounds.

III. DIRICHLET SERIES

A basic object of analytic number theory is the Dirichlet series consisting of terms of the form $e^{-s\lambda_n}$ whose exponents $\{\lambda_n\}_{n\in\mathbb{N}}$ are a real-valued sequence strictly increasing to $\lim_{n\to\infty}\lambda_n=\infty$.

A formal series of the form

$$\sum_{n=1}^{\infty}a(n)e^{-s\lambda_n} \tag{6}$$

with complex coefficients $a(n)$ and argument s is called a general Dirichlet series. In this context functions $A:\mathbb{N}\to\mathbb{C}$ are called *arithmetical functions*.

Dirichlet series have abscissae $\sigma_a(\sigma_c)$ of *absolute* (resp. *conditional*) convergence. For $\lambda_n:=n$ Eq. (6) is a power series in $x:=e^{-s}$ so that σ_a and σ_c coincide.

For $\lambda_n:=\ln(n)$ Eq. (6) is called an ordinary Dirichlet series, and we write it in the form

$$Z_a(s):=\sum_{n=1}^{\infty}a(n)n^{-s}. \tag{7}$$

In that case $0\leqslant\sigma_a-\sigma_c\leqslant1$.

The simplest choice $a(n):=1$ of coefficients leads to the Riemann zeta function $\zeta(s)=\Sigma_{n=1}^{\infty}n^{-s}$ with inverse $1/\zeta(s)=\Sigma_{n=1}^{\infty}\mu(n)n^{-s}$, with the Möbius function μ (see Appendix A). In that case $\sigma_a=1$ and $\frac{1}{2}\leqslant\sigma_c\leqslant1$, the Riemann hypothesis being $\sigma_c=\frac{1}{2}$.

Many Dirichlet series arising in number theory can be written as a Euler product (see Ref. 20):

$$\sum_{n=1}^{\infty} a(n)n^{-s} = \prod_{p\in\mathbb{P}} f_p(p^{-s}). \tag{8}$$

By the fundamental theorem of arithmetic this is the case exactly if the arithmetical function $n\mapsto a(n)$ is *multiplicative*, that is, it is not identically zero, and

$$a(mn) = a(m)a(n) \quad \text{if gcd } (m,n) = 1.$$

Then $f_p(x) = \Sigma_{k=0}^{\infty}\, a(p^k)x^{-k}$. For example, $\zeta(s) = \Pi_{p\in\mathbb{P}}(1 - p^{-s})^{-1}$.

The product

$$Z_f(s)Z_g(s) = Z_{f*g}(s) \tag{9}$$

of Dirichlet series has coefficients

$$f*g(n) = \sum_{d|n} f(d)g\left(\frac{n}{d}\right), \tag{10}$$

which are given by the Dirichlet convolution product $f*g$ of the arithmetical functions of the factors.

With pointwise addition and Dirichlet multiplication the set of arithmetical functions becomes an associative algebra with unit I, $I(n) = \delta_{1,n}$ (a so-called monoid). It is easy to prove that when $f(1)\neq 0$ a Dirichlet inverse $f^{(-1)}$ exists.

Dirichlet series are used in number theory in order to make use of analytic tools in the theory of prime numbers. As an example, the prime number theorem states that the number $\pi(x) = |\{p\in\mathbb{P}|p\leqslant x\}|$ of primes smaller than x is asymptotic to $x/\ln x$. This can be shown by analyzing $\zeta'(s)/\zeta(s)$ for $\mathrm{Re}(s) = 1$, which is on the line containing the pole.

In order to give a statistical mechanics interpretation of (some) Dirichlet series as polymer partition functions we have to identify the sums (7) and (2). This can be done, of course, in many ways: the main point is that in the partition sum each polymer can only have simple multiplicity.

We propose two types of polymerization: the first works for multiplicative arithmetical functions and is based on the notion of Euler product, the second is more general. We introduce both of them because the first admits a special treatment in the convergence theorems leading to better convergence estimates (see Appendix B).

A. Multiplicative polymerization

(i) If we now interpret $\zeta(s) = \Sigma_{n=1}^{\infty}\, e^{-s\,\ln(n)}$ as a partition function for an infinite system with state space $n\in\mathbb{N}$ and energies $\ln(n)$, then $\zeta'(s)/\zeta(s)$ is minus the expectation of the internal energy. Moreover, in the notation of the previous section,

$$\zeta(s) = \prod_{p\in\mathbb{P}} (1-p^{-s})^{-1} = \sum_{X\in\hat{D}^{\infty}} z_s^X,$$

taking the primes as the polymers ($P := \mathbb{P}$), assuming different primes to be compatible and setting the activities $z_s(p) := 1/(p^s - 1)$; moreover

$$\zeta'(s)/\zeta(s) = \frac{d}{ds}\ln(\zeta(s)) = -\sum_{p\in\mathbb{P}} \ln(p)\cdot z_s(p).$$

(ii) Alternatively one may consider the set $P:=\{p^n | p\in\mathbb{P}, n\in\mathbb{N}\}$ of prime powers as polymers with the activities $z_s(x):=x^{-s}$ for $x\in P$ and call $p_1^{n_1}, p_2^{n_2} \in P$ incompatible iff $p_1=p_2$. Then, again, $\zeta(s)$ can be written as a polymer model (2) and thus its logarithm may be written using formula (5).

Clearly this kind of game can be played with any Dirichlet series having a Euler product (8). Then for the first choice $P=\mathbb{P}$ of polymers the activities are $z_s(p):=f_p(p^{-s})-1$, whereas $z_s(p^k):=a(p^k)p^{-sk}$ in the second case.

It is clear that when the multiplicative arithmetical function $a:\mathrm{N}\to\mathbb{C}$ is a square-free function (that is, it vanishes on integers containing squares), then both polymer model interpretations lead to the same activity $z_s(p) = a(p)e^{-s\ln p}$, $z_s(p^k)=0$ for $k>1$. The function a plays the role of an interaction.

B. General polymerization

1. Square-free case

A large class of *square-free* Dirichlet series admit the interpretation of polymer models where each prime number is considered a polymer. For instance we can consider the family of arithmetical functions $\phi=\omega f$ where f is multiplicative (and possibly positive to have a genuine probabilistic framework) and the function ω is defined as

$$\omega(n)=\begin{cases} 1, & \text{if } n=1,p, \\ \displaystyle\prod_{pp'|n} g(p,p'), & \text{otherwise,} \end{cases} \tag{11}$$

where $g(p,p')$ takes values 0,1 and is a symmetric function vanishing on the diagonal. We stress that the previous conditions define a *class* of matrices [of entries $g(p,p')$] and correspondingly a class of square-free arithmetical functions ϕ not necessarily multiplicative. Two primes with $g(p,p')=0$ are called incompatible; two integers are incompatible if there are two incompatible primes in the respective decomposition.

Some examples of incompatibility are the following: p,p' are compatible polymers when

$-p\neq p'$;

$-|p-p'|>\text{const}$;

$-|p-p'|>\log\sqrt{pp'}$.

The first case corresponds to the square-free function $|\mu|$ (see Appendix A) in which the only interaction is the Fermi statistic; the relative zeta function is $Z_{|\mu|}(s)=\zeta(s)/\zeta(2s)$. The interest of the third case will be clear in the section on convergence.

The fundamental theorem of arithmetic on the unique decomposition of an integer into primes permits the formal identification of the function

$$Z_\phi(s)=\sum_{n\neq\mathbb{N}}\phi(n)n^{-s}, \tag{12}$$

with a partition function of a polymer system in which each prime has activity $z_s(p) = f(p)e^{-s\log p}$ and the function ω play the role of the hard-core interaction.

2. Non-square-free case

An important observation is that to treat the case of non-square-free Dirichlet series we have simply to change the polymer identification: the polymers are now the prime powers

$P:=\{p^n | p\in\mathbb{P}, n\in\mathbb{N}\}\equiv\{2,3,4,5,7,8,9,...\}$ with the activities $z_s(x):=f(x)x^{-s}$ for $x\in P$. The class of arithmetical function treated in this way is defined by $\phi=f\omega$ where f is multiplicative and

$$\omega(n)=\begin{cases}1, & \text{if } n=1,p^k,\\ \displaystyle\prod_{x,x'\in P, xx'|n} g(x,x'), & \text{otherwise,}\end{cases} \tag{13}$$

where $g(x,x')$ takes values 0 and 1 and is a symmetric function vanishing on all the couples $(x,x')=(p^k,p^{k'})$. The previous conditions define a *class* of matrices and correspondingly a class of arithmetical functions ϕ in general not square-free nor multiplicative.

Also in this case there are plenty of examples; for instance, the second and third example of the previous polymerization can be rephrased exactly in this one. The simplest example is just the Riemann zeta function: it corresponds to the element of the previous class in which $f(n)=1$ and $g(x,x')=1$ if $(x,x')\neq(p^k,p^{k'})$ which says that two polymers are incompatible when they are power of the same prime and they are compatible otherwise.

This means that the Riemann zeta function admits the interpretation of the partition function of a hard-core interacting polymer system.

IV. THE HARD-CORE MODELS

Let us consider, for simplicity, the square-free case with $\phi=\omega$. We introduce now a family of approximating functions ω_k depending on an integer k; the meaning of this approximation is just the finite volume approximation in statistical mechanics which manifests itself with a finite number of polymers. The corresponding partition function becomes a finite series for each k and the problem to control the thermodynamical limit for the correlation functions concerns the possibility of obtaining bounds which are uniform in k.

We first define the kth set of square-free integers $\mathbb{N}_k$ as the integers of the form

$$n=p_1^{\alpha_1}p_2^{\alpha_2}\cdots p_k^{\alpha_k}, \quad \text{where } \alpha_i=0 \text{ or } 1, \tag{14}$$

and $p_1,\ldots,p_k$ are the first k prime numbers. Then, for instance, $\mathbb{N}_0=\{1\}$, $\mathbb{N}_1=\{1,2\}$, $\mathbb{N}_2=\{1,2,3,6\}$, $\mathbb{N}_3=\{1,2,3,5,6,10,15,30\}$, etc., and $|\mathbb{N}_k|=2_k$. Now we define

$$\omega_k(n)=\begin{cases}\omega(n), & \text{if } n\in\mathbb{N}_k,\\ 0, & \text{otherwise.}\end{cases} \tag{15}$$

It is easy to prove that

$$\omega_k(n)=\omega(n) \quad \text{for } n\leqslant p_k, \tag{16}$$

and

$$\omega_k(n)=0 \quad \text{for } n>p_1\cdots p_k. \tag{17}$$

The origin of this approximation is quite simple: we consider the natural numbers progressively generated by prime numbers; the nature of the function ω implies that for each generation only a finite quantity of integers gives a contribution.

Remark: The above mechanism induces in general a one-to-one correspondence between the functions of the variable $(\alpha_1,\ldots,\alpha_k)$ and the kth approximation of a square-free arithmetical functions.

It clearly turns out that the approximating zeta function admits the interpretation of a grand canonical partition function for a system of k particles interacting via a hard-core two-body potential:

$$Z_{\omega_k}(s)=\sum_{n\in\mathbb{N}}\omega_k(n)n^{-s}=\sum_{\alpha}\prod_i p_i^{-s\alpha_i}\prod_{i<j}[1+\alpha_i\alpha_j(g(p_i,p_j)-1)], \tag{18}$$

where $\alpha=(\alpha_1,\ldots,\alpha_k)$. A mean values are

$$\langle f\rangle_k(s)=\frac{\Sigma_\alpha f(\alpha)\Pi_i p_i^{-s\alpha_i}\Pi_{i<j}[1+\alpha_i\alpha_j(g(p_i,p_j)-1)]}{Z_{\omega_k}(s)}. \tag{19}$$

The basic objects of our model are the r-points ($r\leqslant k$) correlation functions:

$$\langle\alpha_{i_1}\cdots\alpha_{i_r}\rangle_k(s), \tag{20}$$

with $i_1<i_2<\cdots<i_r$; it is interesting to notice that, by comparing with (20), they represent the probability of divisibility by the integer $p_{i_1}\cdots p_{i_r}$. Without loss we assume $i_1,\ldots,i_r\leqslant k$ because otherwise (20) vanishes.

One of our main problems is to study the limit $k\to\infty$ of the correlation functions, and to prove that they describe, indeed, the equilibrium state of a system of interacting polymers defined by the partition function (18).

There are various approaches in the study of the properties of the polymer models. One of them, the one we consider here, is based on the use of the Kirkwood–Salsburg-type iterative equations to control the analytical behavior of the correlation functions and related quantities. We will follow the ideas of Ref. 19 (see also Refs. 21 and 22) with a different proof of the convergence theorems according to the number theoretical framework which requires a slightly different identification of interaction and activity function.

V. THE ITERATIVE EQUATION FOR THE CORRELATIONS

The analytic control of a polymer model is based on two interrelated axioms carrying a deep statistical mechanics meaning.

Activity Bound: There exists a constant $a<1$ and a positive function $v(\gamma)$ (the volume) such that

$$|z(\gamma)|\leqslant a^{v(\gamma)}. \tag{21}$$

Defining $N(\gamma,x)$ as the number of γ-incompatible polymers for which the function v stay inside the interval $[x,x+1)$, we impose the following.

Entropy Bound: There exists a constant c such that

$$N(\gamma,x)\leqslant v(\gamma)c^x. \tag{22}$$

From an analytic point of view the two requirements are simply saying that the terms we sum have to be not too large and not too many. In our context the activity bound can be naturally fulfilled with the choice $a=e^{-s}$ and $v(p)=\log(p)$ and the entropy bound defines the class of function we are treating. It is easy to see that the three concrete examples of the general polymerization fulfill the entropy axiom for any $c>1$; for each of them one could actually improve the general convergence strategy we are going to present.

Our first goal is to express the correlation function at the temperature s as a zeta function:

$$\langle\alpha_{i_1}\cdots\alpha_{i_r}\rangle_k(s)=\sum_l\langle n\rangle(l)l^{-s}, \tag{23}$$

where $n = p_{i_1}\cdots p_{i_r}$. The algebraic properties of the Dirichlet convolution imply that Eq. (23) can be solved in the arithmetical function $\langle n\rangle$ and the solution is

$$\langle n\rangle = n^{-s}(\omega_k^{(-1)} * D_n\omega_k), \tag{24}$$

where we have introduced the operation D_n as

$$D_n f(k) = f(nk). \tag{25}$$

One immediately realizes that the arithmetic function corresponding to the correlations of a square-free model *is not* square-free. This is because the Dirichlet inverse operation does not conserve the square-free property and it is the main motivation to introduce a formalism able to handle generic polymer configurations with the suitable convolution. Moreover, it also implies that, even for finite k, the correlation's zeta function is no more a finite series; we want to show how it is possible to control its properties in the limit $k\to\infty$ using the statistical mechanics method of the iterative equations. This will provide a statistical mechanics meaning to the limiting correlations and a new point of view in the study of some number theoretical quantities.

The idea, which is a central one in statistical mechanics, is to study the ''interaction'' between one particle and the remaining ones or, in number theoretical terms, to have some control on the nonmultiplicativity of the ω.

Defining the function

$$\Gamma_n := \omega_k^{(-1)} * D_n\omega_k, \tag{26}$$

we consider an integer of the form pn, where p is a prime compatible with n (otherwise $\Gamma_{pn}=0$). By definition we have

$$\Gamma_{pn}(l) = \sum_{d|l} \omega_k^{(-1)}(d)\,\omega_k\left(pn\,\frac{l}{d}\right); \tag{27}$$

indicating $\Sigma_{k\subset n}$ a sum over all the divisors of n counted with multiplicity (see Appendix A), we first observe that

$$\omega_k\left(pn\,\frac{l}{d}\right) = \omega_k\left(n\,\frac{l}{d}\right)\sum_{r\subset l/d}^{p} \lambda(r), \tag{28}$$

where the Σ^p means a sum over all square-free integers build on p-incompatible primes and the function λ is the Liouville function defined by $\lambda(n)=(-1)^{\Omega(n)}$ where Ω is the number of prime factors counted with multiplicity. Since $\omega(p)=1$, the previous formula gives an evaluation of how much the interaction ω deviates from a completely multiplicative function; it can be proved, for instance, observing that the factor $G(p,h)$ defined by

$$\omega(ph) = \omega(h)G(p,h) \tag{29}$$

is

$$G(p,h) = \prod_{p'\subset h} g(p,p') = \prod_{p'\subset h} ((g(p,p')-1)+1) = \sum_{r\subset h}{}^{p}(-1)^{\Omega(r)}, \tag{30}$$

which is the (28) since the integer pn is supposed to be compatible. Substituting the (28) inside the (27) we have

$$\Gamma_{pn}(l)=\sum_{d|l}\ \omega_k^{(-1)}(d)\,\omega_k(p)\,\omega_k\left(n\,\frac{l}{d}\right)\sum_{r\subset l/d}^{p}\ \lambda(r), \tag{31}$$

and interchanging the summation order

$$\Gamma_{pn}(l)=\sum_{r\subset l}^{p}\ \lambda(r)\sum_{d|l/r}\ \omega_k^{(-1)}(d)\,\omega_k\left(\frac{nl}{d}\right), \tag{32}$$

which is, up to renaming the sets,

$$\Gamma_{pn}(l)=\sum_{r\subset l}^{p}\ \lambda(r)\Gamma_{nr}\left(\frac{l}{r}\right). \tag{33}$$

This is the iterative equation we want to consider. In order to control its solutions we observe that, by inspection, it lives naturally as an equation for the *two-variable* arithmetical function Γ; moreover, defining the ''index'' of the quantity $\Gamma_n(l)$ as $\Omega(nl)$, Eqs. (33) can be solved iteratively observing that they allow us to compute the family of index $\Omega(nl)+1$ in terms of that whose index is $\Omega(nl)$. This fact not only makes it possible to study the iterative solutions with the initial condition $\Gamma_1(1)=1$ but it also gives hints on the suitable Banach space structure to be introduced in order to make use of the contraction principle.

VI. THE CONTRACTION REGIME FOR THE ITERATION

In our number-theoretical context we can introduce the seminorms for the family of the $\langle n\rangle(l)$ with $\Omega(nl)=m$, depending on a parameter δ to be optimized at the end,

$$N_m(\delta)=\sup_{n,1\leqslant\Omega(n)\leqslant m}\ \sum_{l,\Omega(nl)=m}\ |\langle n\rangle(l)|l^{-s}n^{(s-\delta)}. \tag{34}$$

We claim that, for suitable values of δ, this norm is contractive for the iterative equations. The proof is along the following lines. Using the (33) we observe that it holds the bound

$$\sum_{l,\Omega(nl)=m}\ |\langle pn\rangle(l)|l^{-s}(pn)^{(s-\delta)}\leqslant\sum_{l,\Omega(nl)=m}\ p^{-s}\sum_{r\subset l}^{p}\ r^{s}|\langle rn\rangle\left(\frac{l}{r}\right)|l^{-s}(pn)^{(s-\delta)}, \tag{35}$$

since the Liouville function is bounded in modulus by one. It follows that

$$\sum_{l,\Omega(nl)=m}\ |\langle pn\rangle(l)|l^{-s}(pn)^{(s-\delta)}\leqslant N_m(\delta)p^{-\delta}\sum_{r}^{p}\ r^{-(s-\delta)}, \tag{36}$$

where the last sum runs over the square-free r build on p-incompatible primes. We also observe that, since r runs over square-free integers,

$$\sum_{r}^{p}\ e^{-(s-\delta)\,\log r}\leqslant\sum_{n=0}^{\infty}\ \frac{1}{n!}\left(\sum_{p'}\ {}^{p}e^{-(s-\delta)\,\log p'}\right)^{n}. \tag{37}$$

Making use of the entropy bound it is possible to control the sum on p-incompatible primes, observing that it can be written as

$$\sum_{v=1}^{\infty} \sum_{p',v\leqslant \log p'<v+1} e^{-(s-\delta)\log p'} = \tag{38}$$

$$\leqslant \log p \sum_{v=1}^{\infty} (ce^{-(s-\delta)})^{v} = \log p \, \frac{ce^{-(s-\delta)}}{1-ce^{-(s-\delta)}}, \tag{39}$$

provided $ce^{-s}<e^{-\delta}$; we notice that the extension of the previous sum up to infinity makes the resulting bound uniform in k. Taking the supremum norm of (35) we obtain

$$N_{m+1}(\delta)\leqslant N_m(\delta)\exp\left(\log 2\left(-\delta+\frac{ce^{-(s-\delta)}}{1-ce^{-(s-\delta)}}\right)\right), \tag{40}$$

which means that we are in the contraction regime when $ce^{-s}<\delta e^{-\delta}/(1+\delta)$. The right-hand side can easily be optimized, observing that it is, on the positive real line, a function with the only maximum reached at the *golden ratio* $\delta=(\sqrt{5}-1)/2$ (see Ref. 23 for a discussion). The previous convergence theorem means that the limit $k\to\infty$ of the correlation functions exists in the range defined by

$$ce^{-s}<\frac{\overline{\delta}e^{-\overline{\delta}}}{1+\delta}\approx e^{-1.58} \tag{41}$$

and describes the equilibrium state of a hard-core interacting polymer system.

An easy corollary to be used in the control of connected correlations functions is that, for all the s defined by the (41), one has the bound

$$N_{m+1}\leqslant N_m e^{-\rho}, \tag{42}$$

where, defining the positive number $\epsilon := \overline{\delta e^{-\overline{\delta}}}/(1+\delta)-ce^{-s}$, one has $\rho=\epsilon e^{\overline{\delta}}\log 2(2+\overline{\delta})$. In particular, it is possible to check that, since $N_1\leqslant 1$, it results that $N_m\leqslant e^{-m\rho}$.

The reader should compare this general result with the one for the multiplicative case (Appendix B), where one has optimal convergence estimates.

VII. THE EXPONENTIAL DECAY OF THE CORRELATIONS

The statistical mechanics theory of the low activity expansion gives a systematic way to obtain bounds for the free energy and for all its derivatives with respect to external parameters. It is well known that those bound are equivalent to the bounds for the truncated correlation function and are usually given in terms of the distance between the polymers.

In our context the convolutory algebra permits a natural rephrasing of all these properties: the bounds we present are given in terms of the volume of each polymer, i.e., $\log p$.

The quantities we are mainly interested in are the generalization of the two-point truncated correlation function

$$\langle \alpha_{i_1},\alpha_{i_2}\rangle^{T}(s) := \langle \alpha_{i_1}\alpha_{i_2}\rangle(s)-\langle \alpha_{i_1}\rangle(s)\langle \alpha_{i_2}\rangle(s). \tag{43}$$

This function represents the deviation from the independence of the two events ''p_{i_1} divides an integer'' and ''p_{i_2} divides an integer.'' As for the simple correlations, an easy computation shows that it is possible to express them as Dirichlet series of a suitable arithmetical function:

$$\langle \alpha_{i_1},\alpha_{i_2}\rangle^{T}(s)=\sum_{l} (p_{i_1}p_{i_2})^{-s}(\Gamma_{p_{i_1}p_{i_2}}-\Gamma_{p_{i_1}}*\Gamma_{p_{i_2}})l^{-s}. \tag{44}$$

We recognize that the two-point truncated expectation is the Dirichlet series of the arithmetical function given by the second order of the formal logarithm of the functions Γ with respect to the *lower variable*:

$$\Gamma^T := \log \Gamma. \tag{45}$$

Let us clarify the geometrical meaning of the operations which naturally appear considering the simple and the truncated correlation functions. First we notice that for the operation D_n it holds (see Ref. 24) the Leibnitz rule with respect to the circle product (see Appendix A):

$$D_n(f \circ g) = D_n f \circ g + f \circ D_n g. \tag{46}$$

From it one can easily prove that the operation ∂_n, defined by

$$\partial_n f(k) = f(nk)\, \frac{c(nk)}{c(k)}, \tag{47}$$

plays the role of a *multiple* derivative with respect to the Dirichlet product since it fulfills the composition rule $\partial_{n_1}\partial_{n_2} = \partial_{n_1 n_2}$ and, when n is a prime number, the Leibnitz rule with respect to the Dirichlet multiplication. This can be seen observing that defining the operation $\mathscr{D}$ from the set of the one-variable to that of the two-variable arithmetical functions by

$$(\mathscr{D} f\ )(n,k) = f(nk)\, \frac{c(nk)}{c(n)c(k)}; \tag{48}$$

it holds for it the important property:

$$\mathscr{D}(f * g) = \mathscr{D} f * \mathscr{D} g, \tag{49}$$

where the convolution on the right-hand side is the two-variable Dirichlet convolution.

In particular it holds the

$$\partial_p \ \mathrm{Exp}\ f = \partial_p f * \mathrm{Exp}\ f, \tag{50}$$

and

$$\partial_p \ \mathrm{Log}\ g = g^{(-1)} * \partial_p g. \tag{51}$$

Since ω is a square-free function $D_n\omega = \partial_n\omega$, we have, with $\omega^T := \mathrm{Log}\ \omega$,

$$\partial_n \omega^T = \Gamma_n^T. \tag{52}$$

Choosing $n = p$ it holds $\partial_p \omega^T = \Gamma_p$, which is

$$\omega^T(pn) = \frac{c(n)}{c(pn)}\, \Gamma_p(n). \tag{53}$$

This relation enables us to obtain a bound, inside our contraction regime, on a quantity which represents the free energy density centered around the prime p:

$$\sum_{l=1, p|l}^{\infty} \omega^T(l) l^{-s}. \tag{54}$$

In fact applying Eq. (53) and the contraction scheme for the norm one has

$$\sum_{l=1,p|l}^{\infty} \omega^T(l) l^{-s} \leqslant \sum_{k=1}^{\infty} \sum_{l,\Omega(pl)=k} |\Gamma_p(l)| p^{-s} l^{-s} \tag{55}$$

$$\leqslant p^{-(s-\overline{\delta})} \sum_{k=1}^{\infty} e^{-\rho k} = e^{-(s-\overline{\delta})\log p} \frac{e^{-\rho}}{1-e^{-\rho}}, \tag{56}$$

which is the claimed exponential decay in terms of the polymer volume (notice that $s > \overline{\delta}$ in the contraction regime). In the same way it is possible to obtain the decay for the multiple truncated correlations functions; let us show it for the two-point case.

From (44) we have

$$|\langle \alpha_{i_1}, \alpha_{i_2} \rangle^T(s)| \leqslant (p_{i_1} p_{i_2})^{-s} \sum_{l=1}^{\infty} (|\Gamma_{p_{i_1} p_{i_2}}(l)| + |\Gamma_{p_{i_1}} * \Gamma_{p_{i+2}}(l)|) l^{-s}. \tag{57}$$

The term with the convolution product on the right-hand side is bounded using the (56) and the multiplicative property of the relative Dirichlet series. For the first terms one has

$$\sum_{l=1}^{\infty} |\Gamma_{p_{i_1} p_{i_2}}(l)| l^{-s} = (p_{i_1} p_{i_2})^{\overline{\delta}} \sum_{k=2}^{\infty} \sum_{l,\Omega(p_{i_1} p_{i_2})=k} \langle p_{i_1} p_{i_2} \rangle(l) l^{-s} (p_{i_1} p_{i_2})^{(s-\overline{\delta})} \tag{58}$$

$$\leqslant (p_{i_1} p_{i_2})^{\overline{\delta}-s} \sum_{k=2}^{\infty} e^{-k\rho} = e^{-(s-\delta)\log(p_{i_1} p_{i_2})} \frac{e^{-2\rho}}{1-e^{-\rho}}. \tag{59}$$

Summing the two contributions we obtain

$$|\langle \alpha_{i_1}, \alpha_{i_2} \rangle^T(s)| \leqslant e^{-(s-\overline{\delta})\log(p_{i_1} p_{i_2})} \left(\frac{e^{-2\rho}}{1-e^{-\rho}} + \frac{e^{-2\rho}}{(1-e^{-\rho})^2} \right), \tag{60}$$

which is the desired result. In the same way one can obtain the same exponential decay for all the other truncated correlation functions.

ACKNOWLEDGMENTS

We thank the Erwin Schrödinger Institute, Wien, for the hospitality and the financial support. One of us (P.C.) thanks Professor D. Brydges for many enlightening discussions on polymer models; during this work P.C. was supported by a NATO-CNR advanced fellowship and, partially, by University of Virginia.

APPENDIX A: SOME ARITHMETICAL FUNCTIONS

Some arithmetical functions considered on this work are the identity for the pointwise multiplication:

$$u(n) = 1 \quad \forall n, \tag{A1}$$

the identity for the Dirichlet product:

$$I(n) = \begin{cases} 1, & \text{if } n = 1, \\ 0, & \text{otherwise,} \end{cases} \tag{A2}$$

the identity map from $\mathbb{N}$ to $\mathbb{N}$:

$$N(n)=n \tag{A3}$$

and the ''square'' function:

$$Q(n)=\begin{cases}1, & \text{if } n \text{ is a square,}\\ 0, & \text{otherwise}\end{cases} \tag{A4}$$

In terms of them it is easy to express other important functions: the Möbius function

$$\mu=u^{-1}, \tag{A5}$$

its absolute value

$$|\mu|=u*Q^{(-1)}. \tag{A6}$$

and the Liouville function

$$\lambda=\mu*Q=|\mu|^{(-1)}. \tag{A7}$$

It can be useful to introduce another convolution product: considering an integer as an unordered sequence of primes $n \equiv \{p_{i_1},\ldots,p_{i_1},p_{i_2},\ldots,p_{i_2},\ldots,p_{i_n}\}$, the natural definition of convolution is the sum over all the subsequences

$$f\circ g(n)=\sum_{d\subset n} f(d)g\left(\frac{n}{d}\right), \tag{A8}$$

where, for instance, the set of subsequences of 4 is {1,2,2,4}. It is easy to see that it is related to the Dirichlet one by

$$f\circ g(n)=\sum_{d|n} f(d)g\left(\frac{n}{d}\right)c\left(d,\frac{n}{d}\right), \tag{A9}$$

where $c(l,m)=c(lm)/c(l)c(m)$ with $c(p_{i_1}^{\alpha_{i_1}}\cdots p_{i_k}^{\alpha_{i_k}}) = \Pi_{j=1}^{k}\alpha_{i_k}!$. This property is equivalent to the fact that the $\circ$-product plays the role of the convolution for the deformed zeta functions with the noncharacter activity $\tilde{z}(n)=n^{-s}/c(n)$;

$$\tilde{Z}_f(s)=\sum_n f(n)\tilde{z}(n), \tag{A10}$$

i.e., it holds

$$\tilde{Z}_f(s)\tilde{Z}_g(s)=\tilde{Z}_{f\circ g}(s). \tag{A11}$$

For both the convolution products it is possible to define the powers of a function and, in some cases, power series like exponential and logarithm: Defining the sets of arithmetical functions $\mathscr{A}_0$ and $\mathscr{A}_1$, respectively, by the conditions $f(1)=0$ and $f(1)=1$ it is possible to construct well-defined power series in the convolution products; in particular, the arithmetical function corresponding to the exponential for $f\in\mathscr{A}_0$ is

$$\text{Exp } f=\sum_{k=0}^{\infty}\frac{f^{(k)}}{k!} \tag{A12}$$

and the logarithm, for $h\in\mathscr{A}_1$ which is, defining $h=I+\tilde{h}$,

TABLE I. Values of some arithmetical functions on the first 10 integers.

Function	1	2	3	4	5	6	7	8	9	10
Q	1	0	0	1	0	0	0	0	1	0
$Q^{(-1)}$	1	0	0	−1	0	0	0	0	−1	0
λ	1	−1	−1	1	−1	1	−1	−1	1	1
μ	1	−1	−1	0	−1	1	−1	0	0	1
ω_3	1	1	1	0	1	1	0	0	0	1
$\omega_3^{(-1)}$	1	−1	−1	1	−1	1	0	−1	1	1
$D_2\omega_3$	1	0	1	0	1	0	0	0	0	0
$\omega_3^{(-1)} * D_2\omega_3$	1	−1	0	1	0	0	0	−1	0	0

$$\mathrm{Log}\, h = \sum_{k=0}^{\infty} (-1)^k \frac{\tilde{h}^{(k)}}{k}. \tag{A13}$$

It is easy to see that the operation Exp: $\mathscr{A}_0 \to \mathscr{A}_1$ and Log: $\mathscr{A}_1 \to \mathscr{A}_0$ are mutually inverse.

From a combinatorial point of view, the main advantage to considering the circle product is that it permits the definition of the exponential of a function as the sum over the *partitions*. Example: the $\circ$-exponential of f in $12 = 2^2 \cdot 3$ is in fact

$$\mathrm{Exp}(f\ )(12) = f(12) + 2\, f(2) f(6) + f(3) f(4) + f(2) f(2) f(3). \tag{A14}$$

On the other hand, the Dirichlet exponential implies the important *formal* property:

$$Z_f(s) = \exp(Z_{\mathrm{Log}\, f}(s)), \tag{A15}$$

which permits us to obtain the *free energy* series expansion starting from the partition function series expansion on a Dirichlet series.

APPENDIX B: CONVERGENCE IN THE MULTIPLICATIVE CASE

First keeping within the context of general polymer models, we set $\psi(X) := \phi(X) z^X$ so that the partition function equals $Z = \Sigma_{X \in \hat{P}^\infty} \psi(X)$. Then the probability that the k-polymer X is present is defined by

$$\rho(X) := \frac{\Sigma_{Y \in \hat{P}^\infty} \psi(Y \cdot X)}{\Sigma_{Y \in \hat{P}^\infty} \psi(Y)} = \sum_{Y \in \hat{P}^\infty} \Delta_X(Y) \tag{B1}$$

with $\Delta_X(Y) = (\psi^{-1} * D_X \psi)(Y)$.

The terms $\Delta_X(Y)$ meet the following recursive equation wrt addition of a polymer $\gamma \in P$ to X:

$$\Delta_{\gamma \cdot X}(Y) = z(\gamma) \sum_{S \subset Y}{}^{\gamma} (-1)^{|S|} \Delta_{X \cdot S}(Y/S). \tag{B2}$$

Here the superscript γ means that summation is restricted to multi-polymers S of Y which are incompatible with γ.

We now express the correlation function

$$\rho_k(X) = \langle \alpha_{i_1} \cdots \alpha_{i_r} \rangle_k(s) = \sum_{Y \in \mathbb{N}} \Delta_X^k(Y)$$

at the inverse temperature s as a series in the activities. By definition $\Delta_X^k(Y) = (\omega_k^{-1} * D_X \omega_k)(Y) \cdot z^X z^Y$, with D_n defined in (25).

Now by (B2) for a prime $p \in \mathbb{P}_k$

$$\Delta_{p\cdot X}^k(Y) = z_s(p) \sum_{S|Y} {}^p(-1)^{|S|} \Delta_{S\cdot X}^k(Y/S) = z_s(p) \sum_{S:p|S|Y} \lambda(S) \Delta_{S\cdot X}^k(Y/S), \tag{B3}$$

since $S \in \mathbb{N}$ is incompatible with $p \in \mathbb{N}$ iff $p|S$. Furthermore, for an integer S of the form $S = \Pi_i p_i^{\alpha_i}$, by definition $|S| = \Sigma_i \alpha_i = \Omega(S)$. Moreover, the Liouville function λ is defined by $\lambda(S) = (-1)^{\Omega(S)}$, showing (B3).

Equations (B3) are the iterative equations we want to consider. Defining the ''index'' of the quantity $\Delta_X^k(Y)$ as $\Omega(XY)$, the equations (B3) can be solved iteratively observing that give the family of index $\Omega(XY)+1$ in terms of that whose index is $\Omega(XY)$. This fact not only makes it possible to study the iterative solutions with the initial condition $\Delta_1^k(1)=1$, but it also gives hints on the suitable Banach space structure to be introduced in order to make use of the contraction principle.

In our number-theoretical context the seminorms N_m^δ have the form

$$N_m^\delta(\rho_k) = \sup_{X \in \mathbb{N}} \sum_{Y \in \mathbb{N}, \Omega(XY)=m} |\Delta_X^k(Y)| e^{-(\ln(a)+\delta)v(X)} = \sup_{X \in \mathbb{N}} \sum_{Y \in \mathbb{N}, \Omega(XY)=m} |\Delta_X^k(Y)| X^{(A'-\delta')} \tag{B4}$$

with $A' - \ln(a)/\ln 2$, $\delta' = \delta/\ln 2$, and $v(X) = \ln(X)/\ln(2)$.

In the multiplicative case $\omega = |\mu|$ we can improve the convergence estimate to the optimal value:

$$\begin{aligned} N_m^\delta(\rho_k) &= \sup_{X \in \mathbb{N}} \sum_{Y \in \mathbb{N}, \Omega(XY)=m} |\omega_k^{-1} * D_X \omega_k(Y)| |z^X z^Y| e^{-(\ln(a)+\delta)v(X)} \\ &= \sup_{X \in \hat{P}_k^\infty} \sum_{Y \in \hat{P}_k^\infty, \Omega(XY)=m} |\omega^{-1} * D_X \omega(Y)| |z^X z^Y| e^{-(\ln(a)+\delta)v(X)}. \end{aligned} \tag{B5}$$

Remember that $\mathbb{P}_k$ consists of the first k primes. So

$$\hat{P}_k^\infty = \{n \in \mathbb{N} | p \in \mathbb{P} \quad \text{and} \quad p|n \Rightarrow p \in \mathbb{P}_k\}.$$

Since we have assumed $\omega = |\mu|$, $\omega^{-1} = \lambda$. So

$$\omega^{-1} * D_X \omega(Y) = \sum_{d|Y} \lambda(Y/d) |\mu|(Xd) = \sum_{d|Y,(d,X)=1} \lambda(Y/d) = \begin{cases} \lambda(Y), & p|Y \Rightarrow p|X (p \in \mathbb{P}) \\ 0, & \text{otherwise} \end{cases}.$$

Now if there is an m-independent bound b on the minimal number of prime factors of an X which attains the supremum in (B4), then $m \mapsto N_m^\delta(\rho_k)$ converges exponentially fast to zero, since then there are only $\mathcal{O}(b^m)$ terms in the sum (B4). Then we are done.

So we can assume wlog that the maximal number of prime factors of the X grows with m. Now since $m+1 \geqslant 2$, the $\widetilde{X} \in \mathbb{N}$ which attain the supremum in $N_{m+1}^\delta(\rho_k)$ are unequal to 1 so that we can write them in the form $\widetilde{X}_0 = pX$ and assume that $p \in \mathbb{P}$ is the largest prime factor. Then we use the recursion relation (B2):

$$N_{m+1}^\delta(\rho_k) = \sup_{\widetilde{X} \in \mathbb{N}} \sum_{Y \in \mathbb{N}, \Omega(\widetilde{X}Y)=m+1} |\Delta_{\widetilde{X}}^k(Y)| \widetilde{X}^{(A'-\delta')}$$

$$
\begin{aligned}
&= \sum_{Y\in\mathbb{N},\ \Omega(XY)=m} |\Delta^k_{pX}(Y)|(pX)^{(A'-\delta')} \\
&= \sum_{Y\in\mathbb{N},\ \Omega(XY)=m} |z_s(p) \sum_{S:p|S|Y} \lambda(S)\Delta^k_{XS}(Y/S)|(pX)^{(A'-\delta')} \\
&\leqslant p^{-\delta'} \sum_{Y\in\mathbb{N},\ \Omega(XY)=m} \ \sum_{S:p|S|Y} |\Delta^k_{XS}(Y/S)|(SX)^{(A'-\delta')} S^{(\delta'-A')} \\
&= p^{-\delta'} \sum_{S:p|S} S^{(\delta'-A')} \sum_{Y:S|Y,\Omega(XY)=m} |\Delta^k_{XS}(Y/S)|(SX)^{(A'-\delta')} \\
&\leqslant p^{-\delta'} \sum_{S:p|S} S^{(\delta'-A')} N^{\delta}_m(\rho_k) \\
&= p^{-A'}\zeta(A'-\delta')N^{\delta}_m(\rho_k). \qquad \text{(B6)}
\end{aligned}
$$

Now we assume that $A'>1$ and $\delta'=\frac{1}{2}(A'-1)$. Then as m and thus p become large, the constant $c:=p^{-A'}\zeta(A'-\delta')$ in

$$N^{\delta}_{m+1}(\rho)\leqslant cN^{\delta}_m(\rho)$$

coming from (B6) is getting strictly smaller than one, implying convergence. In other words, we have absolute convergence if $|z(p)|\leqslant p^{-1-\varepsilon}$ for some $\varepsilon>0$. This is clearly optimal.

A recent criterion for shock waves which predicts the behaviors of the internal energy across the shock is extended to a vapor between two interfaces. We look at the predictions of monotonic or not behavior and at the possible inversion of the internal energy inside the gas. We consider different discrete Boltzmann models, construct new classes of exact solutions (models with a rest particle and models leading to 3×3 Riccati systems), and verify the criteria predictions. © *1996 American Institute of Physics.* [S0022-2488(96)03111-8]

I. INTRODUCTION

Twenty-five years[1] ago a remarkable and paradoxal result was found in the kinetic treatment of slow evaporation/condensation between two parallel liquid surfaces: The temperature of the vapor at the warm interface can be below the one of the cold wall, the so-called ''inverted temperature gradient paradox.'' Experiments and many numerical, analytical, and ''controversial'' studies using the continuous Boltzmann kinetic theory have been performed[2] and, very recently, the discrete kinetic theory.[3]

In the context of the shock waves, a criterion[4] was established to predict, from the knowledge of the two equilibrium states, whether or not the temperature across the shock could present nonmonotonic behavior.

Could the two phenomena be linked in the sense that the criterion for shock waves could be applied to predict the temperature inversion in the vapor between two interfaces? This conjecture is the motivation of the present work. Our tool is discrete kinetic theory with a finite number of velocities and we deal only with internal energy.[5] In fact, the same criterion with a slight modification could be applied to the two phenomena but with an important difference. We try to see whether the change of sign of the derivative of the internal energy which, for shock waves, can be predicted by the macroscopic quantities at the upstream and downstream states, could similarly be predicted from the knowledge of the vapor near the two interfaces. However, for shock waves we cannot have equal masses or pressures in the two equilibrium states. No such restriction applies to the vapor. For the vapor our result is that, in general, the inversion arises after a transition where the masses are equal near the two interfaces. Moreover, before and after this transition the internal energy is monotonic, either increasing or decreasing. We call this effect ''strict inversion.'' On the other hand, for shock waves, we obtain an overshoot with the internal energy increasing and decreasing. In some cases we still find this effect for the gas between two interfaces and we call this ''partial inversion.''

We find two new classes for the exact solutions[6] of the discrete Boltzmann models[7] (DBMs). First, for stationary solutions, the linear differential term of the rest particle density being zero, the sum of the collision terms of the rest particle is also zero. Thus, when a rest particle is present, in addition to the usual nonlinear differential system for the other densities, we must add these identically zero nonlinear terms. For instance, instead of the usual quadratic, cubic, quartic,..., nonlinearities, here we find a ratio of a cubic polynomial by a linear one. Second, we obtain also exact solutions for a 6×6 nonlinear differential system of DBMs. Taking into account the three

0022-2488/96/37(11)/5476/20/$10.00

linear differential conservation laws (that we integrate with three integration constants), we are reduced to a 3×3 Riccati differential system. We seek Riccati scalar-type solutions for the 3×3 system. From the number of parameters and the number of constraints, the surprising result is that we obtain a scaling parameter and exact solutions without any restriction on the coefficients of the nonlinear 3×3 Riccati system.

We recall the criterion for shock waves[4] in one dimension with the variable $\eta=x-\zeta t$. Let us assume for the mass $M(\eta)$, the momentum $J(\eta)$, and the energy $E(\eta)$ the existence of η-dependent ''shock profiles:'' $c_1+c_2/D(\eta)$ with $D(\eta)$ monotonic. Call $M_\pm$, $J_\pm$, and $E_\pm$ the values at the upstream and downstream states and define

$$\begin{aligned}&\lambda_\pm := M_\pm\mu + J_\pm(J_+M_- - J_-M_+),\\ &\mu := M_+E_- - M_-E_+, \quad P_\lambda=\lambda_-\lambda_+ .\end{aligned} \tag{1.1}$$

Depending whether $P_\lambda\geqslant0$ or <0, the internal energy is monotonic or not. In Sec. II we derive the same criterion for a gas between two interfaces, the $M_\pm$,..., being now the states of the gas near the two interfaces, the only change being that the momentum is a constant $J_\pm=j$. The two interfaces being parallel we call z a perpendicular axis. For the connection with classical discrete models and, due to the boundary conditions, for their modification we refer to the thesis of d'Almeida and to Ref. 3. For instance, we recall the Cabannes[3] results for two cubic $10v_i$ models with velocity v_i coordinates (x,y,z):

$$v_i:(\pm\alpha_x,\pm\alpha_y,\pm\alpha_z),\quad (0,0,\pm a),\quad \alpha_x=\alpha_y=\alpha_z=1,\quad a=1,2. \tag{1.2}$$

For the second model with $a=2$ (and for the first one with $a=1$) Cabannes has found inversion effects (and nothing). Here we will study models in $d=2,3$ dimensions (in the paper we write $d^*:=d-1$) which are generalizations and extensions of (1.2). In Sec. II B we construct a class of DBMs such that the velocities have only one projection on the $z>0$ axis and another opposite on $z<0$. Applying the criterion we prove that the internal energy is monotonic and, for exact solutions of two collision terms, without inversion. On the contrary, in Secs. III and IV we study other DBMs (with and without a rest particle) with different projections on the $z>0$ axis (opposite for $z<0$). We verify the predictions given by the criterion and observe partial and strict inversions but in general strict inversion alone.

We explain the determination[2,3] of the macroscopic quantities at the two interfaces or walls: $M_{w,\pm}$ for the masses and $E_{wI,\pm}$ for the internal energies which are associated to isotropic Maxwellians. We apply the following boundary conditions:[2,3] At a given wall we retain only the densities associated to the emitted molecules. More explicitly for any density N_i, associated to a velocity with α_z for z-component, depending whether $\alpha_z>0$ or <0, we retain N_i at the interface with z-component negative or positive.

From the boundary conditions and the geometry of the flow we require that the densities with velocities symmetrical to the z-axis are equal. More explicitly, to any velocity with coordinates $(\alpha_x,\alpha_y,\alpha_z)$ exist other velocities with coordinates $(\pm\alpha_x,\pm\alpha_y,\alpha_z)$. For stationary solutions with a variable η, we assume that the associated densities are equal. The important point is that these associated velocities have both the same speed and the same projection on the z axis. In the standard discrete velocity models we eliminate the velocities parallel to the two interfaces. For the two-dimensional (three) models, with $(x,z)[(x,y,z)]$ coordinates and the interfaces parallel to the x axis [(x,y) plane], we do not consider velocities along the x axis [in the (x,y) plane]. The distinctions between the models become the number of projections of the velocities along the z axis and the fact that the velocities are along the z axis or not.

For the gas near the two interfaces $\eta=\pm\frac{1}{2}$ we define $N_{i,\pm}$, $M_{\pm}$, $E_{\pm}$, and $E_{I\pm}$ for the density N_i, the mass M, the energy E, and the internal energy E_I. We will construct mainly two classes of exact stationary solutions for nonlinear differential systems with quadratic and quartic nonlinearities:

$$D(\eta):=1+\lambda e^{\nu\eta}>0, \quad \eta\in[-\tfrac{1}{2},\tfrac{1}{2}], \tag{1.3a}$$

$$N_i(\eta)=n_{0i}+n_i/D(\eta), \tag{1.3b}$$

$$N_i(\eta)=n_{0i}+n_i/D^{1/3}(\eta). \tag{1.3c}$$

If we find $N_{i,+}=N_{i,-}$, for instance for a transition value, for the monotonic (1.3a)–(1.3c) solutions this means $N_i(\eta)=$const. We can find either $\lambda=0$ or ∞ while before and after the transition, λ changes sign.

II. CRITERIA FOR THE INVERSIONS OF THE INTERNAL ENERGY

Let us call N_i the densities associated to the projection $e_i\neq 0$ of the velocities along the z axis. *We consider stationary solutions with N_i depending only on z*. To N_i we associate the linear differential terms $l_i=e_i\partial_z N_i$, we write the differential mass conservation law, we integrate, and we find that the momentum along the z axis, $J(z)$, is a constant:

$$\Sigma l_i=0\rightarrow J(z)=\Sigma e_i N_i(z)=j=\text{const.}$$

Taking into account the Knudsen number we write η instead of z for the variable.

We study both partial and strict inversions for the internal energy $\tau(\eta)$ defined from the mass, the energy, and the momentum j which is a constant:

$$\tau(\eta)=2E(\eta)/M(\eta)-[j/M(\eta)]^2, \quad \eta\in[-\tfrac{1}{2},\tfrac{1}{2}]. \tag{2.1a}$$

We associate two parameters $\lambda_{\pm}$, which depend on the macroscopic quantities:

$$\lambda_{\pm}:=M_{\pm}\mu+j^2(M_{-}-M_{+}), \quad P_{\lambda}=\lambda_{+}\lambda_{-}, \tag{2.1b}$$

their product with μ written down in (1.1). As we shall see, the derivative $\partial_\eta\tau$ does not change sign if $P_\lambda\geqslant 0$, contrary to the case where $P_\lambda<0$. For this last case, called partial inversion, there exists an extremum for $\tau(\eta)$ and in our examples we find a maximum leading to an overshoot. For the second effect, called strict inversion, at the warm interface with internal energy T_w^+ which can be either at $\eta=\frac{1}{2}$ or $-\frac{1}{2}$, we associate τ^+ for the gas and similarly τ^- at the cold interface $T_w^-<T_w^+$. The strict inversion exists when $\tau^->\tau^+$. We consider a family of $\tau(\eta)$ functions, depending on one arbitrary parameter a. It can happen that for a particular transition value $a=a_0$ both $\lambda_{\pm}=0$ whereas, before and after that value, both $\lambda_{\pm}$ have the same sign which is changing across the transition value while $P_\lambda>0$. As we shall see, the sign of $\tau^--\tau^+$ changes across that value and a strict inversion exists for either $a>a_0$ or $a<a_0$. Of course in the whole interval around a_0, the inequality $T_w^-<T_w^+$ must remain valid.

A. Criterion for partial inversion

We assume (i) *j is a constant*, (ii) *both $M(\eta)$ and $E(\eta)$ are of the type $c_1+c_2/D(\eta)$ with c_i=constants and D is a monotonic η function, without roots for $\eta\in[-\frac{1}{2},\frac{1}{2}]$. We define $D_{\pm}=D(\eta=\pm 1/2)$ and write the energy*:

$$E(\eta)(D_{-}-D_{+})=E_{-}D_{-}-E_{+}D_{+}+D_{+}D_{-}(E_{+}-E_{-})/D(\eta), \tag{2.2}$$

while $M(\eta)$ is obtained with the substitution $E_{\pm}\rightarrow M_{\pm}$. We define α, β, and γ and get the derivative of the internal energy written down in (2.1a):

$$\alpha:=(M_-D_- - M_+D_+)\mu - j^2(M_+ - M_-)(D_-D_+),$$

$$\beta:=\mu(M_+ - M_-)D_+D_-, \quad \gamma:=(DM)^3(D_- - D_+)^2/2D_+D_-, \tag{2.3a}$$

$$\gamma\partial_\eta\tau(\eta)/\partial_\eta D(\eta)=\alpha D(\eta)+\beta.$$

For the sign of the derivative we use

$$D_\pm\alpha+\beta=D_\pm(D_- - D_+)\lambda_\pm,$$

$$(D_+\alpha+\beta)(D_-\alpha+\beta)=D_-D_+(D_+ - D_-)^2\lambda_+\lambda_-, \tag{2.3b}$$

and deduce, for $\eta\in[-\frac{1}{2},\frac{1}{2}]$, that τ is monotonic or not depending on whether $\lambda_+\lambda_-\geqslant 0$ or <0. In the following we study different classes of models differing by their positive projections along the z axis, perpendicular to the interfaces: either the same or different.

B. A class of models without partial inversion

We notice that, for models with $M_\pm=M=$const., Eq. (2.1b) yields

$$\lambda_\pm=M^2(E_- - E_+),$$

$$P_\lambda=\lambda_-\lambda_+=M^4(E_- - E_+)^2\geqslant 0. \tag{2.4}$$

This leads to a monotonic internal energy and partial inversion cannot exist. We construct a simple class of models with v_i in two and three ($d=2,3$) dimensions satisfying $M_+=M_-$. They have two speeds, $4(d-1)+2$ v_i, and generalize the first Cabannes model:

$$v_i:(\pm\alpha_x,\pm\alpha_y,\alpha_z=\pm 1), \quad (0,0,\pm 1), \quad \alpha_y=0 \quad \text{for } d=2. \tag{2.5a}$$

To v_i we associate densities N_i and, from the boundary conditions, all N_i, with associated v_i symmetrical with respect to the z axis, are equal. There remain four independent densities:

$$N_1:(\alpha_x>0,\alpha_y\geqslant 0,1), \quad N_5:(0,0,1),$$

$$N_3:(-\alpha_x,-\alpha_y,-1), \quad N_6:(0,0,-1). \tag{2.5b}$$

We consider stationary z-dependent solutions. In Appendix A 1 we write the three conservation laws, linear combinations of the differential terms $l_i=\alpha_z\partial_\eta N_i$. We integrate the momentum conservation law along the z axis and obtain that the mass is a constant:

$$d^*:=d-1, \quad 2d^*(l_1-l_3)+l_5-l_6=0,$$

$$M(\eta)=2d^*(N_1+N_3)+N_5+N_6=\text{const}=M_\pm. \tag{2.5c}$$

There exist generalizations of these models in $d=2,3$ with $\alpha_z=\pm 1$ and leading to $M_-=M_+$. We must check that the models do not share spurious conservation laws. We present a model with $8(d-1)+2$, velocities, three speeds,

$$1, \quad \sqrt{1+\alpha_x^2+\alpha_y^2}, \quad \sqrt{1+4\alpha_x^2+4\alpha_y^2}, \tag{2.6a}$$

$\alpha_z=\pm 1$ and from the z-axis symmetry, there are only six independent densities:

$$N_1:(\alpha_x>0,\alpha_y>0,1),\quad N_2:(2\alpha_x,2\alpha_y,1),\quad N_3(0,0,1), \tag{2.6b}$$

while N_{i+3}, $i=1,2,3$, are associated to velocities opposite to those of N_i. Collisions not conserving the number of particles with a given speed exist and the models are acceptable:

$$\begin{gathered}4[1+\alpha_x^2+\alpha_y^2]=3[1]+[1+4\alpha_x^2+4\alpha_y^2],\\ N_1^3N_4-N_3^2N_2N_6,\quad N_4^3N_1-N_5N_6^2N_3.\end{gathered} \tag{2.6c}$$

The linear differential momentum conservation law still leads to $M_+=M_-$:

$$2d^*\Sigma(l_i-l_{i+3})=0,\quad i=1,2,3\rightarrow M(\eta)=\text{const.} \tag{2.6d}$$

C. Criterion for strict inversion

Let $E_{wI\pm}$ be the internal energy at the walls. Depending whether

$$Q=(E_{I-}-E_{I+})(E_{wI-}-E_{wI+})<0\quad\text{or}\quad\geqslant 0, \tag{2.7}$$

we have a strict inversion or not. For a strict inversion alone we assume (i) *both* $\lambda_\pm=0$ *for some particular value* a_0 *of one arbitrary parameter* a *building up the solutions of the densities*, (ii) $\lambda_+\lambda_->0$ *for* $a\neq a_0$ *and both* $\lambda_\pm$ *change of sign when* a *crosses the* a_0 *value*. From (2.1b) we deduce for a_0 that both $M_+=M_-$, $E_+=E_-$, and $\tau^+=\tau^-$, whereas for $a\neq a_0$ they are different. From (2.3b) we get that for $a>a_0$ and $a<a_0$ both $D_\pm\alpha+\beta$ have the same sign which are opposite when a crosses the a_0 value. The same property holds for $D\alpha+\beta$ and the derivative $\partial_\eta\tau$ and τ is monotonic but increasing and decreasing when a crosses the a_0 value. Consequently, either for $a>a_0$ or $a<a_0$, necessarily $\tau^->\tau^+$ and the transition value leads to a strict inversion effect. We must verify that the hot and cold interfaces remain at the same interface during the transition where a strict inversion occurs. Later we will illustrate this strict inversion with different examples.

D. Partial proof for a class of models without strict inversion

For the class of models (2.5a)–(2.5c) with ± 1 for the projections of the velocities along the z axis, for different collision terms, we have *numerically not found any strict inversion. We have not a general proof, independent of the choice of the collision terms*, as done in Sec. II B for the partial inversion. For the study, done in Appendix A 1, we first give, for $E_{I\pm}$ and Q defined in (2.7),

$$\begin{gathered}E_{I-}-E_{I+}=c_1(N_{1,-}-N_{1,+}),\\ Q=c_2(N_{1,-}N_{6,+}-N_{3,+}N_{5,-})(N_{1,-}-N_{1,+}),\quad c_i>0\end{gathered} \tag{2.8}$$

without strict inversion if $Q\geqslant 0$. *Second, assuming a binary collision term, we prove* $Q\geqslant 0$ *for the solutions. Third, we add a quaternary collision term and solve the nonlinear equation for a class of exact solutions, proving there is no strict inversion*. More explicitly we show that for $\lambda\leqslant 0$ [defined in (1.3a)] the positivity is violated whereas $Q\geqslant 0$ for $\lambda>0$.

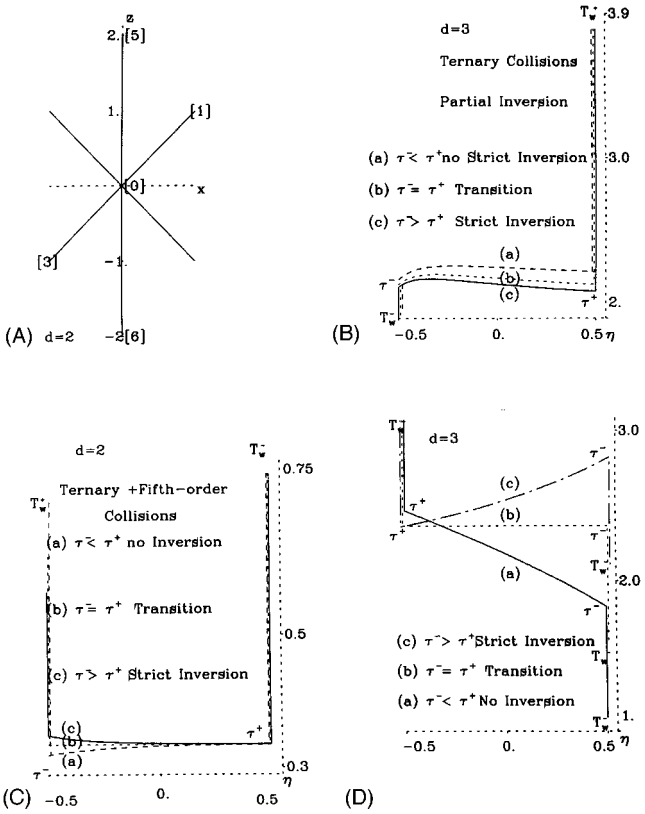

FIG. 1. (A) Models with four and five independent densities. (B) Model with four independent densities: partial and strict Inversions, ternary Collisions. (C) Model with four independent densities: strict inversion, ternary plus fifth-order collisions. (D) Model with five independent densities and a rest particle: strict inversion.

III. MODELS WITH FOUR AND FIVE INDEPENDENT DENSITIES AND TWO $z>0$ VELOCITY PROJECTIONS

We study two classes of models in two dimensions, $d=2$ [cf. Fig. 1(A)], and three dimensions, $d=3$, symmetrical with respect to the z axis. From the boundary conditions there are only four and five (rest particle present) independent densities. In $d=2,3$ we consider models with six and ten velocities (or seven and eleven when a rest particle is present):

$$v_i:(\pm\alpha_x,\pm\alpha_y,\alpha_z=\pm 1),\quad (0,0\pm 2),\quad v_0:(0,0,0)$$
$$\alpha_y=0 \text{ for } d=2,\quad \alpha_x^2+\alpha_y^2=1 \text{ if } v_0 \text{ is present,} \tag{3.1a}$$

generalizing (v_0 absent) the second Cabannes model. To v_i we associate stationary densities $N_i(z)$ and, from the boundary conditions, we write the remaining independent N_i:

$$N_1:(\alpha_x>0,\alpha_y\geqslant 0,1),\quad N_5:(0,0,2),$$
$$N_3:(-\alpha_x,-\alpha_y,-1),\quad N_6:(0,0,-2),\quad N_0:(0,0,0). \tag{3.1b}$$

The difference, with the previous models in Sec. II B, is that the $\alpha_z=\pm 2$ values for N_5 and N_6 are different from ± 1 for N_1 and N_3. It follows that the differential momentum conservation law does not lead to a constant mass. In Appendix A 2 a we write down the three linear differential con-

servation laws (N_0-independent), deduce three differential relations for N_3, N_5, N_6 in terms of N_1, we integrate, and we obtain relations (N_0-independent) for the densities and the momentum j along the z axis, with integration constants a_i:

$$N_3 = N_1 + a_3, \quad N_5 + d^* N_1/2 = a_5 > 0, \quad N_6 + d^* N_1/2 = a_6 > 0, \tag{3.2a}$$

$$j = 2d^*(N_1 - N_3) + 2(N_5 - N_6) = 2(a_5 - a_6 - d^* a_3). \tag{3.2b}$$

All collision terms can be written in terms of $N_1(\eta)$ (with the Knudsen number).

At this stage we discuss models without N_0 and for the connection with the boundary near the interfaces, we write for the gas both the masses and internal energies:

$$\begin{aligned} N_{i,\pm} &:= N_i(\eta = \pm 1/2), \quad M_\pm = 2d^*(N_{1,\pm} + N_{3,\pm}) + N_{5,\pm} + N_{6,\pm}, \\ E_{I\pm} &= [2d^*(1 + \alpha_x^2 + \alpha_y^2)(N_{1,\pm} + N_{3,\pm}) + 4(N_{5,\pm} + N_{6,\pm})]/M_\pm - (j/M_\pm)^2, \end{aligned} \tag{3.3}$$

which can be rewritten with only the $N_{1,\pm}$ values and the constants a_k. For the transition towards a strict inversion we easily write the difference:

$$E_{I+} - E_{I-} = [N_{1,+} - N_{1,-}] F(N_{1,-}, N_{1,+}, a_3, a_5, a_6) \tag{3.4}$$

with $F \neq 0$ for $N_{1,-} = N_{1,+}$. For a transition we have two possibilities:

(i) $N_{1,-} = N_{1,+}$. For monotonic solutions, of the (1.3a)–(1.3c) type, this means that $N_1(\eta)$ is a constant as well as the other densities, the mass, and the internal energy. The transition is characterized by constant microscopic and macroscopic quantities.

(ii) $N_{1,-} \neq N_{1,+}$ and necessarily $F = 0$ in (3.4). In this case the microscopic and macroscopic quantities are not constant at the transition. Adding N_0 (in M), written in terms of N_i or N_1, does not change the discussion of the two (i) and (ii) cases.

At the interfaces or at the walls we associate macroscopic quantities (respectively N_1, N_5 and N_3, N_6 to the interfaces at $\eta = \mp\frac{1}{2}$). At $\eta = -\frac{1}{2}$ we get

$$\begin{aligned} M_{w,-} &= 4d^* N_{1,-} + 2N_{5,-}, \\ E_{wI-} &= [4d^*(1 + \alpha_x^2 + \alpha_y^2) N_{1,-} + 8N_{5,-}]/M_{w,-}, \end{aligned} \tag{3.5}$$

while at $\eta = \frac{1}{2}$ we get $M_{w,+}$ and E_{wI+} with the substitution of $N_{3,+}, N_{6,+}$ to $N_{1,-}, N_{5,-}$.

Finally we define as kinetic temperature (internal energy) T_w^+ at the warm interface and T_w^- at the cold interface satisfying the inequality

$$T_w^+ = \sup(E_{wI+}, E_{wI-}), \quad T_w^- = \inf(E_{wI+}, E_{wI-}). \tag{3.6}$$

This fixes the $\eta = \pm\frac{1}{2}$ value for warmness and coldness. For the gas at the warm and cold interfaces we deduce the masses $M^\pm$ (from $M_\pm$) and we call $\tau^\pm$ the associated limit values of the internal energies ($E_{I\pm}$). If we find solutions with $\tau^- > \tau^+$ we have a strict inversion. We write the internal energy τ and the mass M inside the gas:

$$\begin{aligned} M(\eta) &= 2d^*(N_1 + N_3) + 2(N_5 + N_6) + N_0, \\ \tau(\eta) &= [2d^*(1 + \alpha_x^2 + \alpha_y^2)(N_1 + N_3) + 8(N_5 + N_6)]/M - (j/M)^2. \end{aligned} \tag{3.7}$$

We have a partial inversion if $\tau(\eta)$ is nonmonotonic for $\eta \in [-\frac{1}{2}, \frac{1}{2}]$. In Secs. III A (without rest particle) and III B (with rest particle) we first, with the conservation laws (3.2a), eliminate N_3, N_5

and N_6 and second, solve the nonlinear equation for N_1. We give examples where either both effects exist or only one. At the transition we give examples where either microscopic and macroscopic quantities are constant or not.

A. Models, without rest particle, with four independent densities

We consider ternary and fifth-order collisions with associated parameters θ_3 and θ_5:

$$X:=3(N_3^2N_5-N_1^2N_6), \quad \partial_\eta N_1=(\theta_3+N_1N_3\theta_5)X,$$
$$f_1:=3a_3(2a_5-d^*a_3/2), \quad f_0:=3a_5a_3^2, \tag{3.8}$$
$$\partial_\eta N_1=[3jN_1^2/2+f_1N_1+f_0][\theta_3+\theta_5N_1(N_1+a_3)],$$

and j written down in (3.2b). We get either a quadratic Riccati scalar equation ($\theta_5=0$) or a quartic nonlinear equation. With solutions of the type (1.3a)–(1.3c) in Appendices A 2 b and c, we determine n_{01}, n_1, and γ. Once N_1 is known we deduce, with (3.2a), all n_{0i}, n_i, and N_i.

In all figures of the paper we present three solutions: (a) without strict inversion $\tau^-<\tau^+$, (b) transition $\tau^-=\tau^+$, and (c) with a strict inversion $\tau^->\tau^+$. In Fig. 1(B) ($d=2$, only ternary collisions) we observe both partial and strict inversions with parameter values: Fig. 1(B): $N_{1,-}=0.673$, $N_{3,-}=0.679$, $N_{6,-}=3.107$, $N_{5,-}$ varying in (a)–(c).

Fig. 1(B)	$N_{5,-}$	T_w^-	T_w^+	τ^-	τ^+	M^-	M^+	λ_-	λ_+	λ
(a)	0.081	2.06	<3.8	2.24	<2.29	8.6	>5.13	+	−	−
(b)	0.0315	2.02	<3.8	2.21	$=2.21$	8.54	>5.07	+	−	−
(c)	0.005	2.0	<3.8	2.2	>2.174	8.52	>5.04	+	−	−

(3.9a)

We note that $\lambda_\pm\neq 0$ have opposite signs so that the criterion $\lambda_-\lambda_+<0$ for nonmonotonic $\tau(\eta)$ is always satisfied. The only equality at (b) is $\tau^-=\tau^+$, nevertheless λ, defined in (1.3a) is $\neq 0$, $\neq\infty$, $N_{1,-}\neq N_{1,+}$. *Consequently the transition is of the type (ii) with densities and macroscopic quantities which are η-dependent functions.*

In Fig. 1(C) ($d=3$ and fifth-order collision included) with only a strict inversion, the momentum $j=-4.091$ and two other constants are fixed while λ is varying:

Fig. 1(C)	T_w^-	T_w^+	τ^-	τ^+	M^-	M^+	λ_-	λ_+	λ
(a)	0.7	<0.74	0.318	<0.334	6.24	<6.47	−	−	$+0.075$
(b)	0.62	<0.74	0.33	$=0.33$	6.48	$=6.48$	0	0	0
(c)	0.56	<0.74	0.348	>0.334	6.72	>6.48	+	+	-0.092

(3.9b)

For the transition curve (b) we verify both $\lambda_\pm=0$ and $\lambda=0$ and the changes of signs between (a) and (c). From the criterion $\lambda_-\lambda_+\geqslant 0$ we verify that $\tau(\eta)$ is monotonic. Due to $\lambda_\pm<0$ in (a), >0 in (c), and$=0$ at the transition (b) we see that the curves (a) and (c) are monotonic but either increasing or decreasing. *Due to $\lambda=0$ or $N_{1,-}=N_{1,+}$, the transition is of the (i) type, with constants for all densities and macroscopic quantities.*

B. Models with a rest particle and five independent densities

We add the rest particle density N_0 to the previous models and for N_1 and N_3 the speed of the associated velocities is $\sqrt{2}$. Binary collisions including N_0 of the type [4]+[0]=[2]+[2] are pos-

sible, while for the collisions without N_0, we keep in (3.8) only the ternary X collision term. For the stationary solution there is no differential term associated to the rest particle density N_0. From the sum of the two collision terms including N_0 we get

$$N_0=[N_1^2+N_3^2]/(N_5+N_6)=[2N_1^2+2a_3N_1+a_3^2]/[-d^*N_1+a_5+a_6], \tag{3.10a}$$

leading to an analytic expression of N_0 in terms of N_1, because the relations (3.2a) for N_3, N_5, and N_6 are still valid. In order to distinguish the collisions with and without N_0, we add a cross section θ_2 and substitute (3.10a) for N_0 in the collision term:

$$\begin{aligned}&\partial_\eta N_1=X+\theta_2(N_0N_5-N_1^2),\\ &[-d^*N_1+a_5+a_6]\partial_\eta N_1(\eta)=[3jN_1^2+f_1N_1+f_0][-d^*N_1+a_5+a_6+\theta_2/3].\end{aligned} \tag{3.10b}$$

We finally have a nonlinear differential equation for N_1 alone which is an unusual DBM equation. The study is done in Appendix A 2 d and, except for N_0, we still find solutions of the (1.3a) and (1.3b) type. We start with a_3, a_5, and a_6 as arbitrary parameters and from the coefficients of D^{-q} in (3.10b) we deduce successively n_{01} as a solution of a quadratic equation and θ_2, n_1, and γ. For the masses $M_{w,\pm}$ at the interfaces we can add N_0 or

$$N_{1,-}^2/N_{5,-} \quad \text{at} \quad \eta=-\tfrac{1}{2}, \quad N_{3,+}^2/N_{6,+} \quad \text{at} \quad \eta=\tfrac{1}{2},$$

but we have not found any significant difference concerning the existence of a strict inversion. In Fig. 1(D) we present the three solutions (a), (b), and (c) for $d=3$ (warm interface at $\eta=-\frac{1}{2}$). We give the values of the fixed parameters and λ which is varying:

Fig. 1(D): $N_{1,-}=0.1021$, $N_{3,-}=0.3019$, $N_{5,-}=0.5015$

Fig. 1(D)	T_w^-	T_w^+	τ^-	τ^+	M^-	M^+	λ_-	λ_+	λ
(a)	1.05	<3.07	2.12	<2.36	2.87	>2.38	+	+	$+83.10^{-5}$
(b)	1.6	<3.07	2.36	$=2.36$	2.38	$=2.38$	0	0	0
(c)	2.11	<3.07	2.81	>2.36	1.76	<2.38	−	−	-97.10^{-5}

(3.11)

For the transition curve (b) we find both $\lambda_\pm=0$ and $\lambda=0$, $N_{1,-}=N_{1,+}$, and the changes of signs between (a) and (c). We still have a transition of the (i) type with densities and macroscopic quantities which are constant. Concerning the masses we always notice $M^->M^+$ in Fig. 1(B) while in Fig. 1(C) [contrary to Fig. 1(D)], when there exists a strict inversion the inequality $M^->M^+$ is reversed when there is no inversion. In Figs. 1(B)–1(D) [contrary to Fig. 1(C)] we observe, near and at the two interfaces, the normal pattern: $\tau^->T_w^-$ and $\tau^+<T_w^+$. This was also observed previously.[2,3]

IV. MODELS WITH SIX INDEPENDENT DENSITIES

A. Riccati scalar solutions to a 3×3 Riccati system

We start with a 6×6 differential Riccati system, with only quadratic nonlinear terms, satisfied by six densities X_i, $i=1,..,6$. In DBMs these densities satisfy three linear differential equations for the conservation laws of mass, momentum, and energy:

$$\sum_{j=1}^{6} c_{ij}\partial_\eta X_j=0, \quad i=1,2,3.$$

We rewrite the linear system such that three $\partial_\eta X_k$, $k=4,5,6$, are linear combinations of three other $\partial_\eta X_i$, $i=1,2,3$. We integrate, introducing three constants a_k, $k=4,5,6$, and the three densities X_k are linear combinations of the X_i with the three constants a_k. The three remaining X_i satisfy a 3×3 Riccati system:

$$\partial_\eta X_i=\sum_{j=1}^{3} X_j(a_{ij}X_i+b_{ij})+\sum_{j\neq i,k\neq i,j\leqslant k} a_{ijk}X_jX_k+c_i, \quad i=1,2,3, \tag{4.1}$$

with quadratic and linear terms, a_{ij} and a_{ijk} independent on the integration parameters a_j while the b_{ij} and c_i are respectively linear and quadratic in these parameters. We look at solutions of the scalar Riccati type (1.3a) and (1.3b):

$$X_i(\eta)=x_{0i}+x_i/D(\eta), \quad D(\eta)=1+\lambda e^{\gamma\eta}. \tag{4.2a}$$

We show that such solutions, with ten parameters x_i, x_{0i}, a_i, and γ, satisfying nine relations [coefficients of D^{-k}, $k=0,1,2$ in (4.1)] exist. We define scaled parameters

$$\beta_{ij}=x_j/x_1, \quad \alpha_{1j}=x_{0j}/x_{01}, \quad \lambda_k=a_k/x_{01}, \quad \overline{b_{ij}}=b_{ij}/x_{01}, \quad \overline{c_i}=c_i/x_{01}^2, \tag{4.2b}$$

the $\overline{b_{ij}}$, $\overline{c_i}$ being, respectively, linear and quadratic in λ_k. We will see that x_{01} is finally an arbitrary scaling parameter. First, from the three D^{-2} relations, we get

$$\gamma/x_1=\sum_{j,k} [a_{ij}\beta_{1j}+a_{ijk}\beta_{1k}\beta_{1j}/\beta_{1i}], \quad i=1,2,3. \tag{4.3a}$$

On the rhs we have two independent relations for β_{12}, β_{13}:

$$\sum_j \beta_{1j}\beta_{1l}(a_{1j}-a_{lj})+\sum_{j,k} \beta_{1j}\beta_{1k}(a_{1jk}\beta_{1l}-a_{ljk})=0, \quad l=2,3. \tag{4.3b}$$

We deduce β_{12} and β_{13} as solutions of two coupled polynomials with coefficients a_{ij} and a_{ijk} independent on the a_k. Second, we get from the three D^{-1} relations with $i=1,2,3$

$$\frac{-\gamma}{x_{01}}=\left[\sum_j a_{ij}(\beta_{1j}\alpha_{1i}+\beta_{1i}\alpha_{1j})+\sum_{jk} a_{ijk}(\alpha_{1j}\beta_{1k}+\alpha_{1k}\beta_{1j})+\sum_j \overline{b_{ij}}\beta_{1j}\right] \Big/ \beta_{1i}, \tag{4.4a}$$

On the rhs we have two independent relations, for α_{12} and α_{13} with coefficients $\overline{b_{ij}}$, which are linear in λ_k. We substract the two relations for $i=1,2$ and $i=1,3$:

$$\sum \beta_{1j}(a_{1j}\beta_{1l}-a_{lj}\alpha_{1l})+\beta_{1l}\alpha_{1j}(a_{1j}-a_{lj})+\sum (\beta_{1k}\alpha_{1j}+\beta_{1j}\alpha_{1k})(a_{1jk}\beta_{1l}-a_{ljk})$$

$$=\sum \beta_{1j}(\overline{b_{lj}}-\overline{b_{1j}}\beta_{1l}), \quad l=2,3. \tag{4.4b}$$

The β_{12} and β_{13} are known from (4.3b) and *the two (4.4b) relations* lead to α_{12} and α_{13}, which are linear combinations of b_{ij} or equivalently of λ_k, $k=4,5,6$. Third, we get from the three constant relations D^0 of (4.1)

$$\sum_j a_{ij}\alpha_{1i}\alpha_{1j}+\sum_{jk} a_{ijk}\alpha_{1j}\alpha_{1k}+\sum_j \overline{b_{ij}}\alpha_{1j}+\overline{c_i}=0, \quad i=1,2,3. \tag{4.5}$$

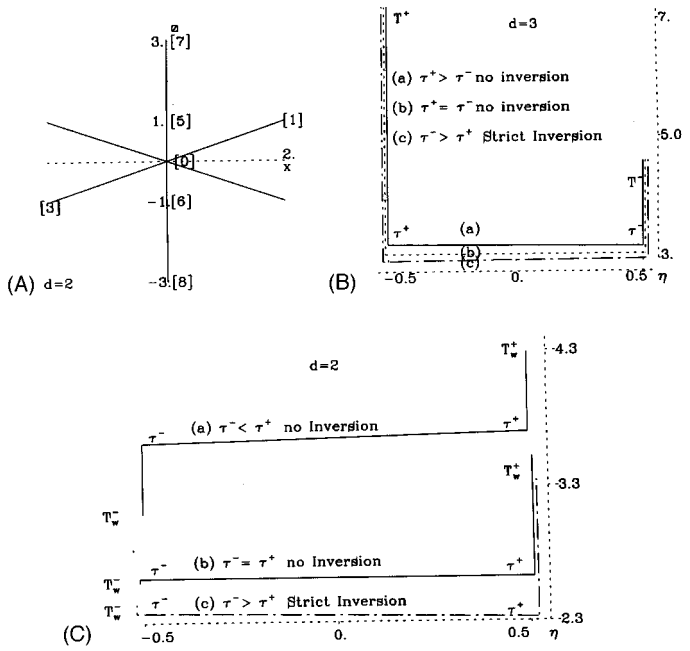

FIG. 2. (A) Models with six independent densities and three speeds. (B) Model with six independent densities, $d=3$, and strict inversion. (C) Model with six independent densities, $d=2$, and strict inversion

We substitute α_{12} and α_{13} given by (4.4b), and which are linear in λ_k, into (4.5). We get three quadratic polynomials in λ_k that we solve and the λ_k and α_{1l} are known. With β_{ij}, α_{1j}, and λ_k known, from (4.3a–4.4a) we deduce γ/x_1, γ/x_{01}, and x_1/x_{01}. Finally we consider x_{01} as a scaling parameter and all ratios of x_i, x_{0i}, γ, and a_k by x_{01} are known.

B. Models with six densities and four velocities along the *z*-axis

We consider models with $8v_i$ in $d=2$ [Fig. 2(A)], coordinates $(x,y=0,z)$ for the velocities, and $12v_i$ in $d=3$ with four velocities along the z axis:

$$v_i:(\pm\alpha_x,\pm\alpha_y,\alpha_z=\pm 1),\quad \alpha_x^2+\alpha_y^2=4,\quad \alpha_y=0\ \ d=2,\quad \alpha_y\neq 0\ \ d=3,$$
$$(0,0,\alpha_z=\pm 1),\quad (0,0,\alpha_z=\pm 3). \tag{4.6a}$$

To the v_i we associate the densities N_i. From the boundary conditions all N_i with associated v_i symmetrical with the z axis are equal. There remain six independent densities:

$$N_1:(\alpha_x>0,\alpha_y\geqslant 0,1),\quad N_5:(0,0,1),\quad N_7:(0,0,3),$$
$$N_3:(-\alpha_x,-\alpha_y,-1),\quad N_6:(0,0,-1),\quad N_8:(0,0,-3). \tag{4.6b}$$

The speeds being 1, 3, and $\sqrt{5}$ it follows that collisions of the type $2[5]=[1]+[9]$ are possible. In Appendix B 1 we write down the differential conservation laws, deduce N_3, N_6, and N_8 as linear combination of N_1, N_5, and N_7 with constants a_k, $k=3,6,8$, write the collision terms leading to an heavy 3×3 Riccati system of the (4.1) type for N_1, N_5, and N_7:

$$\partial_\eta N_5 = N_5^2((d-7)/3+1/d^*)+N_5(6(2-d)+2d^{*2}/3)(N_1+3N_7/d^*)+d^*[(13-4d)N_1^2$$
$$+2(a_6+3a_3)N_1+a_3^2-a_8N_5]+81N_7^2/d^*+18N_1N_7(4-d)+N_5 2a_3(2-d)+18N_7a_3,$$

$$\partial_\eta N_1 = N_1^2(2d-3)-9N_7^2+N_1[3N_5+(11-2d)N_7]+N_5(9N_7+N_5)/d^*+a_6(N_7-N_1)+a_3N_5, \tag{4.6c}$$

$$\partial_\eta 3N_7/d^* = N_1^2+N_7(9N_7+2d^*N_1+a_6).$$

We obtain, for (1.3a) and (1.3b) type of solutions, the ratios of the parameters n_i, n_{0i}, a_k, and γ by n_{01}. Furthermore, we write down $M_{w,\pm}$ and $E_{wI\pm}$ at the two interfaces and for the gas, both the mass and the energy. A sufficient condition that these last quantities, and consequently the internal energy, be equal at the two interfaces is that the three densities N_1, N_5, and N_7 be also equal. For our solution of the (1.3a) and (1.3b) type, we can thus find a transition towards a strict inversion with constant densities and macroscopic quantities for the gas. On the contrary, at the wall, $E_{wI\pm}$ will be different.

In Fig. 2(B) for $d=3$ (warm interface at $\eta=-\frac{1}{2}$) and in Fig. 2(C) for $d=2$ (warm interface at $\eta=\frac{1}{2}$) we still present the three solutions (a), (b), and (c) with a strict inversion. We present the values of the fixed parameters $\beta_{1,l}$ and $\alpha_{1,l}$ and of λ defined in (4.2b) and (1.3a):

Figs.	β_{17}	β_{15}	α_{17}	α_{15}	$N_{1,-}$
2(B)	−0.462	1.387	7.45	0.748	0.215
2(C)	0.0579	1.122	0.0886	3.333	0.015

Figs.	T_w^-	T_w^+	τ^-	τ^+	M^-	M^+	λ_-	λ_+	λ
2(B)(a)	4.593	<7.189	3.17	<3.2	<2.61	<2.63	+	+	−10.0
2(B)(b)	4.592	<7.197	3.04	=3.04	2.81	=2.81	0	0	∞
2(B)(c)	4.59	<7.202	2.95	>2.92	2.97	>2.96	−	−	+13.0
2(C)(a)	3.10	<4.29	3.63	<3.7	2.38	<2.48	−	−	−1.8
2(C)(b)	2.6	<3.52	2.63	=2.63	0.40	=0.40	0	0	∞
2(C)(c)	2.44	<3.34	2.37	>2.33	0.48	>0.475	+	+	+5.0

(4.7)

For the two transition (b) curves we find $\lambda_\pm=0$ and $\lambda=\infty$ or $N_{i,-}=N_{i,+}$ and changes of signs between (a) and (c). *For the gas we still have a transition with constants for the densities and the macroscopic quantities* (contrary to $T_w^\pm$ at the walls which are different). The difference between the two pictures is the fact that $\tau^-<T_w^-$ in Figs. 2(B) and 2(C), curve (c), while the pattern is normal in Fig. 2(c), curves (a) and (b).

C. Models with six densities and two velocities along the *z* axis

For these models with $10v_i$ [$d=2$, Fig. 3(A)] and $18v_i$ ($d=3$), speeds 3 and $\sqrt{3}$, only two velocities are along the z axis with z coordinates ± 3:

$$v_i:(\pm\alpha_x,\pm\alpha_y,\alpha_z=\pm 1),\quad (\pm 2\alpha_x,\pm 2\alpha_y,\alpha_z=\pm 1),\quad (0,0,\alpha_z=\pm 3),$$
$$\alpha_x^2+\alpha_y^2=2,\quad \alpha_y=0 d=2,\quad \alpha_y[\neq]d=3. \tag{4.8a}$$

From the boundary conditions all N_i with v_i symmetrical with respect the z axis are equal. There still remain six independent densities:

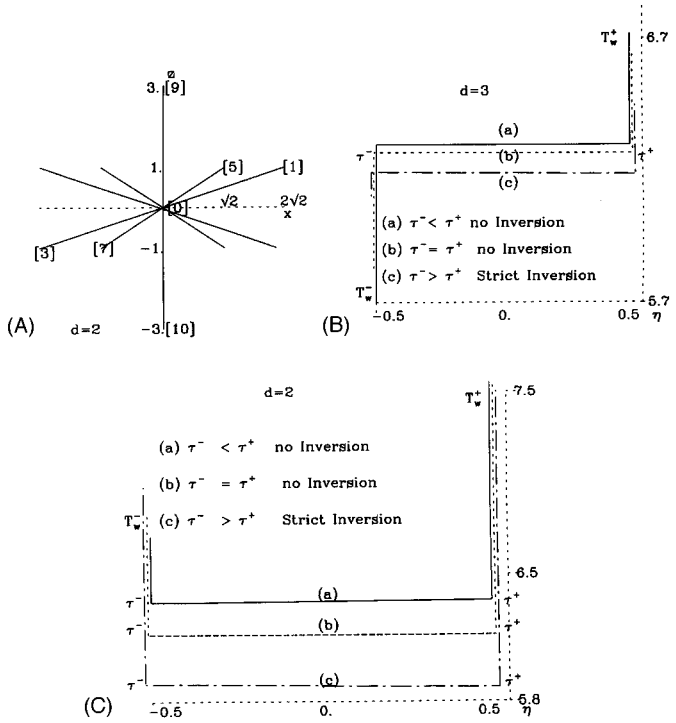

FIG. 3. (A) Models with six independent densities and two speeds. (B) Model with six independent densities, $d=3$, and strict inversion. (C) Model with six independent densities, $d=2$, and strict inversion.

$$N_1:(2\alpha_x>0,2\alpha_y\geqslant 0,1),\quad N_5:(\alpha_x,\alpha_y,1),\quad N_9:(0,0,3),$$
$$N_3:(-2\alpha_x,-2\alpha_y,-1),\quad N_7:(-\alpha_x,-\alpha_y,-1),\quad N_{10}:(0,0,-3). \tag{4.8b}$$

In Appendix B 2 we write the collision terms, the differential conservation laws, deduce N_7, N_3, and N_{10} as a linear combination of N_1, N_5, and N_9 with constants a_k, $k=3,7,10$, leading to a 3×3 Riccati system of the (4.1) type for N_1, N_5, and N_9:

$$\partial_\eta N_1=-2N_1^2-2N_9^2+N_5^2+N_5N_9(1+(27-4d^{*2})/6d^*)-N_1(N_5+N_9(27+4d^{*2})/6d^*+a_3+a_7)$$
$$+N_9(a_7+a_{10})+N_5a_3,$$
$$3\partial_\eta N_9/2d^*=2(N_1^2+N_9^2+N_1N_5)+N_9[(27+4d^{*2})N_1/6d^*+N_5(2d-5)/3-a_7-a_{10}]+N_1a_3, \tag{4.8c}$$
$$\partial_\eta N_5=N_5[2d^*(N_5+N_1)/3+3N_9+a_7-a_{10}]+a_7[3N_1+N_9(2d+7)/2d^*+a_3]$$

with $d^*=d-1$. For solutions of the (1.3a) and (1.3b) type, we find the ratios of the parameters n_i, n_{0i}, a_k, and γ by n_{01}, like for the previous model. We write also $M_{w,\pm}$ and $E_{wI\pm}$ at the two interfaces and both the mass and the energy for the gas. A sufficient condition for the equality of the internal energy at $\eta=\pm\frac{1}{2}$ is the equality of N_1, N_5, and N_7 at $\eta=\pm\frac{1}{2}$. For (1.3a) and (1.3b) type solutions we can find a transition with, for the gas, densities and macroscopic quantities constant (at the walls $E_{wI\pm}$ are different).

In Fig. 3(B) for $d=3$ (warm interface at $\eta=-\frac{1}{2}$) and in Fig. 3(C) for $d=2$ (warm interface at $\eta=1/2$) we still present three solutions with curves (a)–(c), the fixed parameters values, and the three values for λ:

Figs.	β_{19}	β_{15}	α_{19}	α_{15}	$N_{1,-}$
3(B)	5.040	6.374	−0.3684	−0.1489	0.011
3(C)	1.847	2.514	−0.3169	−0.2827	0.025

$$\left|\begin{array}{cccccccccc} \text{Figs.} & T_w^- & T_w^+ & \tau^- & \tau^+ & M^- & M^+ & \lambda_- & \lambda_+ & \lambda \\ 3(B)(a) & 5.7< & 6.72 & 6.294< & 6.296 & 3.52< & 3.54 & - & - & -0.13 \\ 3(B)(b) & 5.83< & 6.25 & 6.26= & 6.26 & 3.17= & 3.17 & 0 & 0 & 0 \\ 3(B)(c) & 6.1< & 6.48 & 6.188> & 6.184 & 2.61> & 2.58 & + & + & +0.28 \end{array}\right|, \quad (4.9)$$

$$\left|\begin{array}{ccccccccc} 3(C)(a) & 6.71< & 7.55 & 6.34< & 6.35 & 0.426< & 0.429 & - & - & -0.11 \\ 3(C)(b) & 6.82< & 7.53 & 6.16= & 6.16 & 0.41= & 0.41 & 0 & 0 & 0 \\ 3(C)(c) & 6.98< & 7.50 & 5.89> & 5.87 & 0.385> & 0.383 & + & + & +0.17 \end{array}\right|.$$

The transition cases (b) still correspond to $\lambda_{\pm}=0$ and $\lambda=0$, their changes of signs between (a) and (c) and, due to $\lambda=0$, to *constant densities* $N_i(\eta)$. *At the transition (b) both the masses and the internal energies are constant while these quantities are different at the two walls*. The difference between the two pictures is still $\tau^- < T_w^-$ in Fig. 3(C) and the opposite in Fig. 3(B). For the masses near the interfaces, in Figs. 2(B), 2(C), 3(B), and 3(C) we notice $M^- > M^+$ when there exists a strict inversion and the reversed inequality when there is no inversion.

V. CONCLUSION

In this paper we have applied and modified, to a vapor between two interfaces, a criterion previously established for shock waves. However, we look at stationary solutions (not shock waves) and we have eliminated the velocities parallel to the two interfaces. Our results confirm, generalize, and extend those of Ref. 3. The two different effects (either partial inversion, where the internal energy between the two interfaces is not monotonic, or strict inversion, where the internal energy of the gas is larger at the cold interface) have been illustrated with different possibilities: either both effects exist or only one or none. Summarizing the results for the nonexistence or existence of at least one effect: (i) no effect when only one $z>0$ projection of the velocities exists and (ii) at least one effect when more than one positive $z>0$ projection exists. With different models we have verified that the distinctions (i) and (ii) hold whatever the number and location of the velocities are, parallel to the z axis or oblique. For models of the type (i) we can prove, without explicit construction of the solutions, that no partial inversion can occur. This is an immediate consequence of the fact that the mass inside the gas remains constant. On the contrary for the nonexistence of a strict inversion, we must construct explicitly the solutions. We have given the proof for two collision terms, verified numerically for some other collisions; however, we have not a general proof independent of the collision terms.

Summarizing the results for the existence of both effects or only one (strict inversion), we find a distinction at the transition where the values of the internal energy at the two interfaces are the same: (i) both the masses and the densities are the same at the two interfaces and only the strict inversion occurs and (ii) they are different and we find both effects. In the first case, due to the fact that our particular solutions (1.3a)–(1.3c) for the densities are monotonic, the densities and all macroscopic quantities of the gas are necessarily constant at the transition. On the contrary, in the second case the microscopic and macroscopic quantities are not constant.

If we want to enlarge the present exact results, we can either introduce rest particles in the models with six independent densities or we can consider more general models with eight, ten,..., densities. However, in these cases, taking into account the fact that the number of linear conservation laws remains three, we are reduced to $5\times5,7\times7,...$, nonlinear systems and the determination of exact solutions becomes more and more difficult. Another possible extension is the deter-

mination of density solutions which are not monotonic. We know that this is possible for Riccati systems.[8] At the transition, the equality at the two interfaces will not necessarily lead to constant solutions. However, these solutions are more difficult to handle. It will be useful to establish the connection between these results of the discrete theory with those of the continuous one. We notice also a recent study[9] of evaporation/condensation in the scope of the Navier–Stokes equations.

ACKNOWLEDGMENT

We thank G. Ripka for the improvement in the presentation.

APPENDIX A: EXACT SOLUTIONS FOR MODELS WITH FOUR AND FIVE DENSITIES

1. No strict inversion for a model with ±1 for the *z*-axis velocities projections

We study the models (2.5a)–(2.5c), like Fig. 1(A) but $\alpha_z=\pm 1$ for N_5 and N_6, with four independent velocities N_1, N_3, N_5, and N_6. We have the three linear differential conservation laws:

$$\begin{gathered} 2d^*(l_1\pm l_3)+l_5\pm l_6=0, \\ d^*:=d-1, \quad 2d^*(1+\alpha_x^2+\alpha_y^2)(l_1+l_3)+(l_5+l_6)=0. \end{gathered} \tag{A1a}$$

We deduce l_3, l_5, and l_6 from l_1, integrate and get N_3, N_5, and N_6 from N_1:

$$N_3-N_1=a_3, \quad N_5+2d^*N_1=a_5>0, \quad N_6+2d^*N_1=a_6>0. \tag{A1b}$$

Taking into account $M_-=M_+$, we get for the gas at $\eta=\pm\frac{1}{2}$ the difference

$$E_{I-}+E_{I+}=2(E_--E_+)/M=c_1(N_{1-}-N_{1+}), \quad c_1>0, \tag{A2a}$$

and for the internal energy at the two interfaces,

$$\begin{gathered} E_{wI-}-E_{wI+}=c_2(N_{1,-}N_{6,+}-N_{1,+}N_{5,-}), \quad c_2>0, \\ j=a_5-a_6-2d^*a_3, \quad E_{wI-}-E_{wI+}=c_2((N_{1,-}-N_{1,+})a_5-jN_{1,-}-a_3a_5). \end{gathered} \tag{A2b}$$

If the product Q of the two differences (2.7) is positive, there is no strict inversion

$$\begin{gathered} Q/c_1c_2:=a_5(N_{1,-}-N_{1,+})^2+\overline{Q}>0 \quad \text{if } \overline{Q}>0, \\ \overline{Q}=-(jN_{1,-}+a_3a_5)(N_{1,-}-N_{1,+}), \end{gathered} \tag{A2c}$$

and $\overline{Q}>0$ *is a sufficient condition for the nonexistence of a strict inversion.*

(i) First, we can prove $Q>0$ for a simple example of a binary collision:

$$\begin{gathered} \partial_\eta N_1(\eta)=N_3N_5-N_1N_6=jN_1(\eta)+a_3a_5, \quad N_1(\eta)=-a_3a_5/j+ce^{j\eta}, \\ c=\text{const}, \quad \overline{Q}=jc^2(1-e^{-j})\geqslant 0. \end{gathered} \tag{A3}$$

(ii) Second, we add a quaternary collision term $\theta_4(N_5^2N_3^2-N_1^2N_6^2)$, $\theta_4>0$,

$$\partial_\eta N_1(\eta)=(jN_1(\eta)+a_3a_5)[1+\theta_4(-4d^*N_1^2(\eta)+(j+2a_6)N_1(\eta)+a_3a_5)]. \tag{A4a}$$

For cubic $j\neq 0$ nonlinearity, we have found two exact solutions with the same $j\gamma<0$:

$$D=1+\lambda e^{\gamma\eta}>0, \quad j\neq 0, \quad N_1=n_{01}+N_1/D^{1/2}. \tag{A4b}$$

Solution 1: $a_3, a_5, \theta_4, N_{1,-}$, arbitrary: $a_6=2d^*a_3+a_5$, $n_{01}=a_5/4d^*$, $n_1^2 4d^*=1/\theta_4+a_6a_5/2d^*$:

$$j=-4d^*a_3, \quad j\gamma=-8d^*(jn_1)^2<0 \tag{A4c}$$

Solution 2: a_3, a_5, a_6 arbitrary: $n_{01}=(j+2a_6)/12d^*-a_3a_5/3j$, $n_1=n_{01}+a_3a_5/j$, $1/\theta_4=4d^*n_{01}^2-n_{01}(j+2a_6)-a_3a_5$.

With $\lambda>0$ we get both sign of $\overline{Q}=j\lambda(e^{-\gamma}-1)>0$ and positivity for θ_4, solutions 1 and 2. We give the proof for solution 1 and notice

$$a_6>0\rightarrow y:=2d^*a_3/a_5>-1, \quad 2\sqrt{2}d^*|n_1|/a_5>\sqrt{1+y}. \tag{A5a}$$

First we assume $\lambda=0$ or $N_{1,-}=N_{1,+}$, find four cases, and with (A1b) for N_3, N_5, and N_6,

$$\begin{gathered}
n_1<0, \quad a_3>0\rightarrow N_1=a_5/4d^*-|n_1|<a_5(1-\sqrt{2})/4d^*<0,\\
n_1<0, \quad a_3<0\rightarrow 4d^*Ns_3/a_5<y+\sqrt{1+y}[\sqrt{1+y}-\sqrt{2}]<0,\\
n_1>0, \quad a_3>0\rightarrow N_5<a_5(1-\sqrt{2})/2<0,\\
n_1>0, \quad a_3<0\rightarrow N_6/a_5<1/2+y-\sqrt{1+y}/\sqrt{2}<0.
\end{gathered} \tag{A5b}$$

Second, for $\lambda<0$, $D(\lambda<0)<D(\lambda=0)=1$, we define $\tilde{N}_i=N_i(\lambda=0)$ with four cases:

$$\begin{gathered}
n_1<0, \quad a_3>0\rightarrow N_1(\lambda)=n_{01}-n_1|\sqrt{D(\lambda)}<\tilde{N}_1<0,\\
n_1<0, \quad a_3<0\rightarrow N_3(\lambda)=\tilde{N}_3+|n_1|(1-1\sqrt{D(\lambda)})<0,\\
n_1>0\rightarrow N_1(\lambda)=n_{01}+|n_1|\sqrt{D(\lambda)}>\tilde{N}_1,\\
n_1>0, \quad a_3>0\rightarrow N_5(\lambda)<-2d^*\tilde{N}_1+a_5=\tilde{N}_5<0,\\
n_1>0, \quad a_3<0\rightarrow N_6(\lambda)<2d^*\tilde{N}_1+a_6=\tilde{N}_6<0.
\end{gathered} \tag{A5c}$$

For $j=0$ *we have found one exact solution* $N_1=n_{01}+n_1/D$:
Solution 3: a_3, a_5, θ_4, $N_{1,-}$ arbitrary: $a_6=a_5-2d^*a_3$, $\gamma=-4d^*\theta_4 n_1 a_3 a_5$,

$$n_{01}^2-n_{01}a_6/2d^*=-n_{01}(n_1+n_{01})=(a_3a_5+1/\theta_4)/4d^* \tag{A5d}$$

$N_i>0$, sign $\overline{Q}=a_3n_1\lambda(e^{-\gamma}-1)>0$ for $\lambda>0$ and positivity violated for $\lambda\leqslant 0$.

2. Models with ±1, ±2 for the *z*-axis velocity projections (Sec. III)

a. Conservation laws for stationary solutions

We call $l_i=e_i\partial_\eta N_i$ with $e_i=\pm 1$ for N_1 and N_3,$=\pm 2$ for N_5 and N_6, and$=0$ for N_0. We have $l_0=0$ and for the three linear differential conservation laws

$$\begin{gathered}
2d^*(1+\alpha_x^2+\alpha_y^2)(l_1+l_3)+4(l_5+l_6)=0,\\
2d^*(l_1\pm l_3)+(3\mp 1)(l_5\pm l_6)/2=0, \quad l_1=-l_3=-l_5/d^*=l_6/d^*.
\end{gathered} \tag{A6}$$

We integrate and, from N_1, find (3.2a) for N_3, N_5, and N_6. *We note that the masses associated to the densities with the same speed satisfy* $N_1+N_3\neq$const. and $N_5+N_6\neq$const.

b. Only ternary collisions for the Sec. III A models with $N_0=0$, $\theta_5=0$

In (3.8) for N_1 solutions (1.3a) and (1.3b), from the coefficients of D^{-q}, $q=0,1,2$ we get

$$3jn_{01}^2/2+f_1n_{01}+f_0=0\rightarrow n_{01}\rightarrow n_1=-2n_{01}-f_1/3j\rightarrow\gamma=n_1 3j/2. \tag{A7}$$

c. Ternary and fifth-order collisions for the Sec. III A models with $N_0=0$

In (3.8), $\theta_5\neq0$, we get a quartic nonlinearity with a_3, a_5, a_6, θ_3, and θ_5 dependent coefficients:

$$\overline{f_1}:=f_1/a_3,\quad \overline{\theta_{35}}=(\theta_3/\theta_5)(j/a_3)^2,\quad A_4=1,\quad A_3=2\,\overline{f_1}/3+j,$$
$$A_2=2j(a_5+\overline{f_1}/3)+\overline{\theta_{35}},\quad A_1=3j^2a_5+\overline{f_1\theta_{35}},\quad A_0=3ja_5\overline{\theta_{35}}, \tag{A8}$$
$$\frac{\partial_\eta N_1(\eta)}{(1.5j\theta_5)}=\sum_{k=0}^{4}A_k\left(\frac{a_3}{j}\right)^{4-k}N_1^k(\eta),$$

For (1.3a)–(1.3c) solutions, with $D^{-q/3}$ coefficients, we get from const, $D^{-2/3}$, and D^{-1}

$$n_{01}=-(a_3/4j)A_3,\quad A_2=3A_3^2/8\rightarrow\overline{\theta_{35}}=-2j(a_5+\overline{f_1}/3)+3A_3^2/8, \tag{A9a}$$
$$3A_3^4/32-2A_1A_3+8A_0=0\rightarrow\overline{\theta_{35}}=\frac{A_3[3A_3^3/32-6a_5j^2]}{[2A_3\overline{f_1}-24ja_5]}.$$

Here $\overline{f_1}$ and j are arbitrary. From (A8) and (A9a) we get, A_3, a_5 (quadratic equation), and $\overline{\theta_{35}}$ and deduce successively a_j, θ_3/θ_5, A_k, and n_{01}. From $D^{-4/3}$ and $D^{-1/3}$ we get γ and n_1:

$$2\gamma/9j=(a_3/j)^3(A_3^3/16-A_1)=n_1^3. \tag{A9b}$$

We know the $N_1(\eta)$ solution (1.3)–(1.3c) and the other N_i with (3.2a).

d. Binary and ternary collisions for the Sec. III B models with $N_0\neq0$

We write the rhs of (3.10b) as a cubic $Z(N_1)$ polynomial with j, f_0, and f_1 defined in (3.2b)–(3.8):

$$b_0:=-d^*f_1+3(a_5+a_6)j/2,\quad c_0:=-d^*f_0+f_1(a_5+a_6),\quad d_0=f_0(a_5+a_6),$$
$$Z(N_1)=-3jd^*N_1^3/2+N_1^2(b_0+\theta_2j/2)+N_1(c_0+\theta_2+f_1/3)+d_0+\theta_2f_0/3, \tag{A10}$$

while the (3.10b) lhs is the product of the derivative by a first-order polynomial. For N_1 solutions of the (1.3a) and (1.3b) type, from D^{-q}, $q=0,1,2,3$, we successively get n_{01}, θ_2, n_1, and γ:

$$\sum_{q=0}^{2}A_qn_{01}^1=0,\quad e_0:=j(a_5+a_6)/2d^*+f_1/3,\quad A_0:=d_0e_0+d^*f_0^2/3,$$

$$A_1 := c_0 e_0 + 2 f_1 f_0 d^*/3 + j d_0/2, \quad A_2 := b_0 e_0 + d^*(j f_0 + f_1^2/3) + c_0 j/2,$$
$$\theta_2 = d^*[3 j n_{01}^2/2 + f_1 n_{01} + f_0]/[j n_{01}/2 + e_0], \tag{A11}$$
$$n_1 = \omega_2/3d^* - 2n_{01} - 2 f_1/3j, \quad \gamma = 3 j n_1/2.$$

With $N_1(\eta)$, from (3.2a) we get all other $N_i(\eta)$ densities and, from (3.10a), $N_0(\eta)$.

APPENDIX B: EXACT SOLUTIONS FOR MODELS WITH SIX INDEPENDENT DENSITIES

1. Scalar Riccati-type solutions for the Sec. IV B models

For stationary solutions we define the differential terms $l_i = e_i \partial_\eta N_i$, $e_i = \pm 1$ for $i = 1, 3, 5$, and $6, = \pm 3$ for N_7 and N_8, write the linear differential conservation laws

$$2d^*(l_1 \pm l_3) + l_5 \pm l_6 + (2 \mp 1)(l_7 \pm l_8) = 0,$$
$$10 d^*(l_1 + l_3) + l_5 + l_6 + 9(l_7 + l_8) = 0, \tag{B1a}$$

deduce l_3, l_6, and l_8 from l_1, l_5, and l_7, integrate, and get N_3, N_6, and N_8 from N_1, N_5, and N_7:

$$N_3 = 3N_1 + (N_5 + 9N_7)/d^* + a_3, \quad N_6 = -2d^* N_1 - 9N_7 + a_6,$$
$$N_8 = -[6N_7 + 2d^* N_1 + N_5]/3 + a_8. \tag{B1b}$$

We write the collision terms and the nonlinear equations for three densities N_1, N_5, and N_7:

$$X_1 = N_3 N_5 - N_1 N_6, \quad X_0 = N_7 N_6 - N_1^2, \quad X_{00} = N_8 N_5 - N_3^2,$$
$$\partial_\eta N_1 = X_0 + X_1, \quad \partial_\eta N_5 = -d^*(2X_1 + X_{00}), \quad 3\partial_\eta N_7 = -d^* X_0. \tag{B2}$$

We substitute (B1b) and get the 3×3 (4.6c) system for N_1, N_5, and N_7. For N_i of the (1.3a) and (1.3b) type, we define $\beta_{1j} = n_j/n_{1,j} = 5,7$, and from the coefficients of D^{-2} we obtain two polynomials of the (4.3b) type and we deduce a polynomial for β_{17}:

$$\beta_{15}\beta_{17}[3 + (\beta_{15} + 9\beta_{17})/d^*] - \beta_{17}^2[5d - 14 + 9\beta_{17}] - (2d^{*2}/3 - 3 + 2d)\beta_{17} - d^*/3 = 0,$$
$$d = 2{:}6075\beta_{17}^4 + 1140\beta_{17}^3 + 116\beta_{17}^2 + 40\beta_{17} - 3 = 0. \tag{B3}$$

As explained in Sec. IV A, n_{01} is a scaling parameter. We define $\lambda_k = a_k/n_{01}$, $\alpha_{1j} = n_{0j}/n_{01}, j = 5,7$, and get from the two constant relations of the N_1 and N_7 collision terms in (4.6c)

$$\lambda_6 = 9\alpha_{17} + 2d^* + 1/\alpha_{17}, \quad \lambda_3 = -3 - 9\alpha_{17} - \alpha_{15}/d^* + 1/\alpha_{17}\alpha_{15}. \tag{B4}$$

From the two D^{-1} relations for the N_1 and N_7 collision terms, substituting λ_6 and λ_3 given by (B4) we obtain a polynomial relation for α_{17}, α_{15}:

$$A\alpha_{15}^2 + B\alpha_{15} + C = 0, \quad A := -(\beta_{15} + 9\beta_{17})/d^* - 3, \quad C := -\beta_{15}/\alpha_{17},$$
$$B := \alpha_{17}[5d^* + 9\beta_{17} + 2d^{*2}/3\beta_{17}] + (4 - d - 3\beta_{17})/3\alpha_{17} + 2(2 - d) - 9\beta_{17} + 2d^*/\beta_{17}. \tag{B5}$$

We start with α_{17} as an arbitrary parameter, we deduce α_{17}, λ_6, and λ_8 from (B5) and (B4), and we see from (4.6c) that a_8 or λ_8 enters only in the collision term for N_5 and linearly in the coefficient of D^{-1}. From the two D^{-1} relations for N_1 and N_5 we deduce λ_8 as a function of α_{17}.

Substituting all parameters deduced from α_{17} into the constant term of the (4.6c) N_5 equation fixes α_{17} and all other values except the scaling parameter n_{01} and λ in $D(\eta)$ of (1.3a). Finally we write the mass and the internal energy at the wall $\eta=-\frac{1}{2}$:

$$M_{w,-}=4d^*N_{1,-}+2N_{5,-}+2N_{7,-},$$
$$E_{wI-}=(20d^*N_{1,-}+2N_{5,-}+18N_{7,-})/M_{w,-}, \tag{B6}$$

while at $\eta=\frac{1}{2}$ we get $M_{w,+}$, E_{wI+} with the substitution of $N_{3,+}$, $N_{6,+}$, $N_{8,+}$ to $N_{1,-}$, $N_{5,-}$, $N_{7,-}$. The hot and cold interfaces are still defined by (3.6). With (B1b) we write the mass M and the energy E in terms of N_1, N_5, N_7:

$$M(\eta)=8(2d^*N_1+N_5+3N_7)/3+2d^*a_3+a_6+a_8,$$
$$2E(\eta)=8(4d^*N_1+N_5+9N_7)+10d^*a_3+a_6+9a_8, \tag{B7}$$
$$N_{i,-}=N_{i,+}, \quad i=1,5,7\rightarrow M^-=M^+, \quad E^-=E^+\rightarrow\tau^-=\tau^+.$$

2. Scalar Riccati-type solutions for the Sec. IV C models

For stationary solutions we define the linear differential terms $l_i=e_i\partial_\eta N_i$, $e_i=\pm1$ for $i=1,5,3,7$, $e_i=\pm3$ for N_9, N_{10}. We write the linear differential conservation laws:

$$2d^*(l_1\pm l_3+l_5\pm l_7)+(2\mp1)(l_9\pm l_{10})=0,$$
$$6d^*(3(l_1+l_3)+l_5+l_7)+9(l_9+l_{10})=0, \tag{B8a}$$

We deduce l_3, l_7, and l_{10} from l_1, l_5, and l_9, we integrate, and we get N_3, N_7, and N_{10} from N_1, N_5, and N_9:

$$N_7=N_5+a_7, \quad N_3=2N_1+N_5+9N_9/2d^*+a_3,$$
$$N_{10}=-2d^*(N_1+N_5)/3-2N_9+a_{10}. \tag{B8b}$$

We write the collision terms and the equations for three densities N_1, N_5, and N_9:

$$X_1=N_9N_{10}-N_1N_3, \quad X_2=N_3N_5-N_1N_7,$$
$$X_3=N_3N_7-N_5N_{10}, \quad X_4=N_1N_5-N_9N_7, \tag{B9}$$
$$\partial_\eta N_1=X_1+X_2-X_3, \quad \partial_\eta N_5=-X_2+X_3-X_4, \quad 3\partial_\eta N_9=2d^*(-X_1+X_3).$$

We substitute (B8b) and get the 3×3 (4.8c) equation for N_1, N_5, and N_9. For N_i of the (1.2a) and (1.2b) type with $D=1+\lambda e^{\gamma\eta}$. We define $\beta_{1j}=n_j/n_{1,j}=5,9$, and, from the coefficients of D^{-2}, we obtain two polynomials of the (4.3) type:

$$d=2,3:3(12d-47)\beta_{19}^2+19(2d+1)\beta_{19}+12(9d-13)=0,$$
$$\beta_{15}(8\beta_{19}/3-4d^*)=(4d-13)\beta_{19}^2+(6d+13)\beta_{19}/3+4d^*; \tag{B10}$$

n_{01} is still a scaling parameter. We define $\lambda_k=a_k/n_{01}$, $\alpha_{1j}=n_{0j}/n_{01}$, $j=5,9$, and from the two constant relations of the N_1 and N_9 collision terms in (4.8c) we get

$$\lambda_3=-\alpha_{15}-1-9\alpha_{19}/2d^*+\lambda_7/\alpha_{15}, \tag{B11}$$

$$\lambda_{10}=(1+\alpha_{15})/\alpha_{19}+2\alpha_{19}+\alpha_{15}(2d-5)/3+\lambda_7(1/\alpha_{15}\alpha_{19}-1).$$

From the three D^{-1} relations for the N_1, N_5, and N_9 collision terms, substituting λ_3 and λ_{10} we obtain two rational fractions of polynomials P_j, Q_j, with α_{19}-dependent coefficients,

$$\lambda_7/\alpha_{19}=P_1(\alpha_{15})/Q_1(\alpha_{15})=S_1(\alpha_{15})/T_1(\alpha_{15}), \tag{B12}$$

linear in α_{15}. *We start with* α_{19} *arbitrary*, we deduce α_{15}, λ_7, λ_3, λ_{10} from (B12) and (B11), all parameters substituted into the constant term of (4.8c) for N_5 fixed α_{19} and all parameters except n_{01}, and λ in $D(\eta)$. Finally we write $M_{w,-}$, E_{wI-} and $M(\eta), E(\eta)$ with (B8b):

$$M_{w,-}=4d^*(N_{1,-}+N_{5,-})+2N_{9,-},$$

$$E_{wI-}=(4d^*(9N_{1,-}+3N_{5,-})+18N_{9,-})/M_{w,-},$$

$$M(\eta)=16d^*(N_1+N_5)/3+8N_9+2d^*(a_3+a_7)+a_{10}, \tag{B13}$$

$$E(\eta)=12d^*(2N_1+N_5)+36N_9+3d^*(3a_3+a_7)+9a_{10}/2,$$

$$N_{i,-}=N_{i,+}, \quad i=1,5,9\rightarrow M^-=M^+, \quad E^-=E^+\rightarrow\tau^-=\tau^+,$$

while we get $M_{w,+}, E_{wI+}$ with the substitution of $N_{3,+}$, $N_{6,+}$, $N_{10,+}$ to $N_{1,-}$, $N_{5,-}$, $N_{9,-}$.

(Received 23 April 1996; accepted for publication 12 July 1996)

One-dimensional time-dependent potentials are considered for which an invariant can be expressed in terms of the potential and the momentum according to the formulation of Giacomini. New solutions of Giacomini's equations are derived. In addition, possibilities are discussed for extending Giacomini's approach to more general systems. © *1996 American Institute of Physics.*

I. INTRODUCTION

Giacomini[1] has presented a formalism for examining Hamiltonian systems in which a one-dimensional potential admits an invariant that can be expressed solely as a function of the potential and the momentum, and he derived some solutions of the associated equations. In Sec. II, we summarize Giacomini's formalism and derive some additional solutions of his equations. In Sec. III, we explore the possibility of extending Giacomini's approach to cases where the invariant cannot be expressed solely as a function of a potential and the momentum. The starting point for that discussion is the work of Lewis *et al.*,[2] who deduced all one-degree-of-freedom Hamiltonians $H(q,p,t)$ for which a specified function of (q,p,t) is an invariant. Certain differential identities that are used in Sec. III are given in the Appendix.

The one-degree-of-freedom Hamiltonian $H(q,p,t)$ under consideration is that associated with a one-dimensional potential $V(q,t)$,

$$H(q,p,t)=\tfrac{1}{2}p^2+V(q,t). \tag{1.1}$$

An invariant for this system is any function $I(q,p,t)$ whose total time derivative vanishes:

$$0=\frac{dI}{dt}=I_t(q,p,t)+[I,\,H]=I_t(q,p,t)+I_q p-I_p V_q\,, \tag{1.2}$$

where $[I,\,H]$ is the Poisson bracket of I with H. Potentials for which (1.2) can be solved analytically to give an invariant are usually identified by invoking some symmetry of the system, or by using a direct method, in which some functional restriction of the potential or the invariant is postulated. For example, it may be possible to apply Noether's theorem,[3–5] or to apply the theory of extended Lie groups.[6] Examples of the use of direct methods can be found in Refs. 7–11.

II. NEW SOLUTIONS OF GIACOMINI'S FORMALISM

Giacomini[1] has developed a theoretical framework that defines exact invariants for a certain class of one-dimensional time-dependent potentials and he used the relevant equations to determine examples of such potentials. Giacomini's result begins with the ansatz that the invariant is expressible as a function of two arguments, $V(q,t)$ and p:

$$I(q,p,t)\rightarrow I[V(q,t),p]=I(v,p) \quad \{v=V(q,t)\}. \tag{2.1}$$

Then (1.2) can be written as

$$\left[\frac{V_t(q,t)}{V_q(q,t)}+p\right]I_v[V(q,t),p]-I_p[V(q,t),p]=0. \tag{2.2}$$

In order for (2.2) to have a solution, $V(q,t)$ must satisfy

$$V_t(q,t)=f[V]V_q(q,t), \tag{2.3}$$

where f is an arbitrary function. The implicit solution of (2.3) is

$$\Phi[V]-t-\frac{q}{f[V]}=0, \tag{2.4}$$

where also Φ is an arbitrary function. As a result, the equation for $I(v,p)$ is

$$[f(v)+p]I_v(v,p)-I_p(v,p)=0, \tag{2.5}$$

whose characteristic equation is

$$\frac{dv}{dp}+f(v)+p=0. \tag{2.6}$$

Giacomini treated the case

$$f(v)=a_1v^2+a_2v+a_3, \tag{2.7}$$

where (a_1,a_2,a_3) are arbitrary constants, analytically in terms of Airy functions.

New solutions of Giacomini's relations (2.5) and (2.6) can be obtained by defining a function $X(v)$ as

$$X(v)=\frac{1}{p+f(v)}, \tag{2.8}$$

where p is to be interpreted as a function of v along a characteristic of (2.5) that is determined by solving (2.6). By differentiating (2.8) with respect to v and using (2.6) we find that $X(v)$ satisfies the Abel equation of the first kind[12]

$$\frac{dX}{dv}=X^3-\frac{df}{dv}X^2. \tag{2.9}$$

By means of the transformation from $X(v)$ to $U(v)$ defined by[12]

$$U(v)=\frac{[X(v)-X_2(v)]}{[X_1(v)]^{1/3}}, \tag{2.10}$$

where

$$X_1(v)=-\frac{1}{3}\frac{d^2f}{dv^2}-\frac{2}{27}\left(\frac{df}{dv}\right)^3, \quad X_2(v)=\frac{1}{3}\frac{df}{dv}, \tag{2.11}$$

(2.9) is transformed to

$$\frac{dU}{dv}=X_1{}^{2/3}\left[1-\left(3X_1{}^{-2/3}X_2^2+\frac{1}{3}X_1{}^{-5/3}\frac{dX_1}{dv}\right)U+U^3\right]. \tag{2.12}$$

We shall use (2.12) for finding solutions to the characteristic equation (2.6).

Equation (2.12) can be solved analytically if it is separable. In order for it to be separable, the coefficient of U must be a constant, which we denote by K. This gives the following condition on $f(v)$:

$$\left[9\frac{d^3f}{dv^3}+15\frac{d^2f}{dv^2}\left(\frac{df}{dv}\right)^2+2\left(\frac{df}{dv}\right)^5\right]^3=\left(\frac{K}{3}\right)^3\left[9\frac{d^2f}{dv^2}+2\left(\frac{df}{dv}\right)^3\right]^5. \tag{2.13}$$

We have found three values of K for which (2.13) can be solved in terms of implicit relations that do not involve integrals; these values are $K=3/2^{2/3}$, $K=3(A^2-6)/[2A(A^2-9)]^{2/3}$ ($A=$const $\neq\pm3$, $\neq0$, $\neq\sqrt{6}$), and $K=0$. In addition, a general partial treatment of (2.13) can be given in terms of implicit relations that involve an indefinite integral. [It has been pointed out by the referee of this paper that (2.13) is formally integrable for all values of K because (2.13) has three Lie point symmetries.]

A. $K=3/2^{2/3}$

This choice of K leads to

$$f(v)=a_2v+a_3, \tag{2.14}$$

where a_2 and a_3 are arbitrary constants. This is a case analyzed by Giacomini (Giacomini's form with $a_1=0$).[1] For $f(v)=a_1v^2+a_2v+a_3$, which is the most general form for which Giacomini solved his equations, (2.13) cannot be satisfied if $a_1\neq0$. This is associated with the fact that (2.6) can only be solved with Airy functions in this case, but Airy functions do not solve $dU/dV=[X_1(V)]^{2/3}(1-KU+U^3)$.

B. $K=3(A^2-6)/[2A(A^2-9)]^{2/3}$, $A=$const$\neq\pm3$

In this case, we find

$$f(v)=A\sqrt{v}. \tag{2.15}$$

It is interesting to note that one is also led to (2.15) by considering the Lie invariance properties of (2.6).[13] The invariant associated with (2.15) is given by

$$I[V(q,t),\,p]=\ln(2V+p^2+A\sqrt{V}p)-A\int^{\sqrt{V}/p}\frac{dy}{(2y^2+Ay+1)} \tag{2.16}$$

and, from (2.4), the potential is determined from

$$\Phi[V]-t-\frac{q}{A\sqrt{V}}=0. \tag{2.17}$$

It is instructive to examine the special case $A=0$. Then $f(v)=0$, (2.3) implies $V(q,t)$ is a function of q only, and (2.16) reduces to $I[V(q,t),\ p]=\ln(2V+p^2)$. Thus, the energy is conserved, as expected.

C. $K=0$

With this choice, (2.13) reduces to

$$9\frac{d^3f}{dv^3}+15\frac{d^2f}{dv^2}\left(\frac{df}{dv}\right)^2+2\left(\frac{df}{dv}\right)^5=0. \tag{2.18}$$

This equation can be integrated completely in terms of three arbitrary constants as follows. Because (2.18) is autonomous and depends only on the derivatives of f, we introduce

$$W=\frac{d^2f}{dv^2} \tag{2.19}$$

and

$$F=\frac{df}{dv}, \tag{2.20}$$

in which case (2.18) is transformed into the first-order differential equation

$$9W\frac{dW}{dF}+15WF^2+2F^5=0. \tag{2.21}$$

This equation can be integrated by changing variable to

$$Z=W/F^3. \tag{2.22}$$

The result is

$$|Z+\tfrac{2}{9}|^{-2}|Z+\tfrac{1}{3}|^3|F|^3=C_1, \tag{2.23}$$

where C_1 is an arbitrary positive constant. Moreover, since by construction we have $W=dF/dv$, we also have $Z=(dF/dv)/F^3$, which can be written in the form

$$dv=\frac{1}{F^3}\frac{dF}{dZ}\frac{dZ}{Z}. \tag{2.24}$$

Using $dF/dZ=-FZ/[3(Z+2/9)(Z+1/3)]$, which is obtained from (2.21) and (2.22), and $|F|=C_1^{1/3}|Z+2/9|^{2/3}/|Z+1/3|$, which is obtained from (2.23), (2.24) becomes

$$dv=-\frac{\varepsilon_1}{3C_1^{2/3}}\frac{(Z+\frac{1}{3})}{|Z+\frac{2}{9}|^{7/3}}\,dZ, \tag{2.25}$$

where ε_1 is the sign of $(Z+\frac{2}{9})$. This relation, which is valid for $C_1\neq 0$, can be integrated to yield

$$v+C_2=C_1^{-2/3}[\varepsilon_1|Z+\tfrac{2}{9}|^{-1/3}+\tfrac{1}{36}|Z+\tfrac{2}{9}|^{-4/3}], \tag{2.26}$$

where C_2 is a constant of integration. Using (2.20), (2.25), and the expression for F in terms of Z, we can obtain

$$df = -\frac{\epsilon_1\epsilon_2\epsilon_3}{3C_1^{1/3}}\frac{dZ}{|Z+\frac{2}{9}|^{5/3}}, \tag{2.27}$$

where ϵ_2 and ϵ_3 are, respectively, the signs of $Z+\frac{1}{3}$ and F. This can be integrated to give f as a function of Z:

$$f + C_3 = \frac{\epsilon_2\epsilon_3}{2C_1^{1/3}}|Z+\tfrac{2}{9}|^{-2/3}, \tag{2.28}$$

where C_3 is a constant of integration.

It is now possible to derive the relation between the function f and the potential V for $K=0$. Combining (2.26) and (2.28), and substituting $v=V(q,t)$ from (2.1), an easy calculation yields

$$V(q,t)+C_2=\epsilon_1\sqrt{2/C_1}\sqrt{\epsilon_2\epsilon_3(f(V)+C_3)}+(f(V)+C_3)^2/9, \quad C_1\neq 0. \tag{2.29}$$

$C_1=0$ and $C_1=\infty$ are interesting special cases. For $C_1=0$, we use (2.23) to get $-\frac{1}{3}=Z=(dF/dv)/F^3$, which can be integrated to give $f(v)=[6(v+k_1)]^{1/2}+k_2$, where k_1 and k_2 are arbitrary constants. If $k_1=k_2=0$, this corresponds to (2.15) of Case B with $A=\sqrt{6}$. For $C_1=\infty$, we may use (2.29) to obtain $f(v)=[3(v+C_2)]^{1/2}-C_3$. If $C_2=C_3=0$, this corresponds to (2.15) with $A=3$, which was excluded in our discussion of Case B.

For $K\equiv 3X_1^{-2/3}X_2^2+(1/3)X_1^{-5/3}(dX_1/dv)=0$, (2.12) can be integrated and the constant of integration equals the invariant that we seek:

$$I[v,p]=\int^U \frac{dU'}{1+U'^3}-\int^v [X_1(v')]^{2/3}\,dv'. \tag{2.30}$$

Here U as defined by (2.10) depends on v; it also depends parametrically on the constant that labels the characteristic. The constant can be expressed as a function of v and p, so that U can in fact be expressed directly in terms of v and p. The result, which can be found by combining (2.8) and (2.10), we denote by $U(v,p)$:

$$U(v,p)=\frac{1-[p+f(v)]X_2(v)}{[p+f(v)][X_1(v)]^{1/3}}. \tag{2.31}$$

Thus, the formula for the invariant in terms of (q,p,t) is

$$I[V(q,t),p]=\int^{U[V(q,t)p]}\frac{dU'}{1+U'^3}-\int^{V(q,t)}[X_1(v')]^{2/3}\,dv'. \tag{2.32}$$

Carrying out the integrations in (2.32) is a lengthy calculation. The result is

$$\begin{aligned} I[V(q,t),p]=\frac{1}{6}&\left\{\ln\left[\frac{(1+U[V(q,t),p])^3}{1+U[V(q,t),p]^3}\right]+\epsilon_2\ln\left[\frac{(1+|f[V(q,t)]+C_3|)^3}{1+|f[V(q,t)]+C_3|^3}\right]\right\}\\ &+\frac{1}{\sqrt{3}}\left[\arctan\left(\frac{2U[V(q,t),p]-1}{\sqrt{3}}\right)+\epsilon_2\arctan\left(\frac{2|f[V(q,t)]+C_3|-1}{\sqrt{3}}\right)\right]. \end{aligned} \tag{2.33}$$

The constants ϵ_1 and ϵ_3 do not appear in this formula because, in the derivation, certain quantities occur raised to fractional powers. In order for those quantities to be positive, ϵ_1 and ϵ_3 are required to have the values $\epsilon_1=1$ and $\epsilon_3=-1$.

D. General treatment of Eq. (2.13)

Introduce functions W and F as in (2.19) and (2.20) so that (2.13) becomes

$$\left(9W\frac{dW}{dF}+15WF^2+2F^5\right)^3=\left(\frac{K}{3}\right)^3(9W+2F^3)^5. \tag{2.34}$$

Then, with Z as defined by (2.22), this can be transformed to

$$9FZ\frac{dZ}{dF}+27Z^2+15Z+2=\frac{K}{3}(9Z+2)^{5/3}, \tag{2.35}$$

$$\frac{9ZdZ}{27Z^2+15Z+2-\frac{K}{3}(9Z+2)^{5/3}}=-\frac{dF}{F}. \tag{2.36}$$

Defining Y by

$$Y=(9Z+2)^{1/3}\Rightarrow dY=3Y^{-2}dZ, \tag{2.37}$$

we can write (2.36) as

$$\frac{(Y^3-2)dY}{Y(Y^3-KY^2+1)}=-\frac{dF}{F}, \tag{2.38}$$

which can be integrated to give

$$\ln(F^4|Y^4-KY^3+Y|)+\int\frac{3KY^2+1}{Y^4-KY^3+Y}\,dY=0. \tag{2.39}$$

From this relation F can be obtained as a function of Y and then of Z. Equation (2.22) gives the relation between F and W, which leads to an equation relating d^2f/dv^2 and df/dv. This equation can be solved in principle to give $f(v)$.

III. AN APPROACH FOR EXTENDING GIACOMINI'S ANSATZ

Attempts to generalize ansatz (2.1), which is the basis of Giacomini's formalism, have not led to equations from which new invariant/potential pairs have been derived. In this section we generalize Giacomini's formalism within the context of the theoretical framework of Lewis *et al.*[2] Although this generalization has not led to new invariant/potential pairs, it is sufficiently general to hold the promise of new results.

A. The result of Lewis *et al.*

Lewis *et al.*[2] showed that all Hamiltonians $H(q,p,t)$ for which a specified function $\tilde{P}(q,p,t)$ is an invariant are given by

$$H(q,p,t)=K(t)-F_t[\tilde{P}(q,p,t),t]-\int^q G_t[q',\tilde{P}(q,p,t),t]dq', \tag{3.1}$$

where $G(q,P,t)$ is the inverse of $\tilde{P}(q,p,t)$,

$$p=G(q,P,t)\leftrightarrow P=\tilde{P}(q,p,t), \tag{3.2}$$

and where $F(P,t)$ and $K(t)$ are arbitrary functions. For a given $H(q,p,t)$, the function $F(P,t)$ can be determined and a canonically conjugate second invariant can be constructed.[14] We note in passing that (3.1) is related to the Hamilton–Jacobi equation through a Type-Two generating function $S(q,P,t)$ for a canonical transformation that is defined by

$$S(q,P,t)=\int^{q} G(q',P,t)dq'+F(P,t)-\int^{t} K(t')dt', \tag{3.3}$$

with $p=S_q(q,P,t)$ and $Q=S_P(q,P,t)$. From (3.3), $G(q,P,t)$ and $S(q,P,t)$ are related by

$$G(q,P,t)=S_q(q,P,t). \tag{3.4}$$

As a result, (3.1) can be written in terms of (q,P,t) as

$$H[q,S_q(q,P,t),t]+S_t(q,P,t)=0, \tag{3.5}$$

which is the Hamilton–Jacobi equation. In the remainder of this paper we shall not use the generating function $S(q,P,t)$.

Equation (3.1) written in terms of the variables (q,P,t) and the function $G(q,P,t)$ is

$$H[q,G(q,P,t),t]=K(t)-F_t(P,t)-\int^{q} G_t(q',P,t)dq'. \tag{3.6}$$

Differentiating (3.6) with respect to q gives

$$H_q[q,G(q,P,t),t]+H_p[q,G(q,P,t),t]G_q(q,P,t)=-G_t(q,P,t), \tag{3.7}$$

where $H_q(q,p,t)$ and $H_p(q,p,t)$ are the derivatives with respect to q and p of $H(q,p,t)$. We now specialize to the case of motion in a time-dependent potential $V(q,t)$,

$$H(q,p,t)=\tfrac{1}{2}p^2+V(q,t). \tag{3.8}$$

Then (3.7) becomes

$$G_t(q,P,t)+G(q,P,t)G_q(q,P,t)=-V_q(q,t), \tag{3.9}$$

which determines the functions $G(q,P,t)$ that are allowable for a given potential $V(q,t)$. If we associate $G(q,P,t)$ with the momentum density as a function of (q,t) of a fluid of particles acted upon by a force density $-V_q(q,t)$, then (3.9) is the equation of motion of that fluid.

Giacomini's ansatz (2.1) is equivalent to demanding that $G(q,P,t)$ be expressible in terms of a function G of two arguments, where the two arguments are $V(q,t)$ and P:

$$G(q,P,t)=\overline{G}[V(q,t),P]. \tag{3.10}$$

Our objective is to explore the consequences of generalizing (3.10) to allow the two arguments to be arbitrary functions of (q,P,t). That is, we assume that $G(q,P,t)$ can be written as

$$G(q,P,t)=\overline{G}(x,y)=\overline{G}[f(q,P,t),h(q,P,t)], \tag{3.11}$$

where the variables x and y are defined in terms of arbitrary functions $f(q,P,t)$ and $h(q,P,t)$ by

$$x=f(q,P,t), \quad y=h(q,P,t). \tag{3.12}$$

The idea is to restrict $f(q,P,t)$ and $h(q,P,t)$ in such a way as to facilitate finding functions $G(q,P,t)$ that solve (3.9) for some new potentials $V(q,t)$. In Sec. III C we shall demonstrate that

Giacomini's equations can be derived easily by choosing $h(q,P,t)=P$ and taking $f(q,P,t)$ to be an arbitrary function of (q,t). With the ansatz (3.11),(3.9) can be written as

$$\overline{G_x}(x,y)f_t(q,P,t)+\overline{G_y}(x,y)h_t(q,P,t)+\overline{G}(x,y)[\overline{G_x}(x,y)f_q(q,P,t)+\overline{G_y}(x,y)h_q(q,P,t)] = -V_q(q,t). \tag{3.13}$$

Equation (3.13) is a very general equation that can be arbitrarily nonlinear. If we were to specify $G(x,y)$, which is a function of only two arguments, then there generally would be solutions, because $f(q,P,t)$ and $h(q,P,t)$ are unspecified functions of three arguments. However, viewed in that way, the equations are too complicated and general to be amenable to analysis. The approach that we adopt is to view (3.13) as an equation for $G(x,y)$. Because $G(x,y)$ is a function of only two arguments, this imposes consistency conditions on $V_q(q,t)$ and on the coefficients of $G(x,y)$ and its derivatives. In the remainder of this paper we examine (3.13) as an equation for $G(x,y)$.

B. Consistency conditions

The derivatives of (3.13) with respect to q, P, and t involve $\overline{G}(x,y)$ and the derivatives of $\overline{G}(x,y)$ with respect to x and y. Thus, (3.13) and the derivatives of (3.13) up to some order with respect to q, P, and t may be viewed as a system of algebraic equations for $G(x,y)$ and those derivatives of $G(x,y)$ that appear up to that order. Equation (3.13) involves three functions of (x,y) [i.e., $G(x,y)$ and its first derivatives]. The four equations comprising (3.13) and its three first derivatives involve six functions of (x,y) [i.e., $G(x,y)$ and its first and second derivatives]. The ten equations comprising (3.13) and its first and second derivatives involve ten functions of (x,y) [i.e., $G(x,y)$ and its first, second, and third derivatives]. The twenty equations comprising (3.13) and its first, second and third derivatives involve 15 functions of (x,y) [i.e., $G(x,y)$ and its first, second, third, and fourth derivatives]. The ten equations comprising (3.13) and its first and second derivatives are unique in that there are exactly the same number of functions of (x,y) as there are equations. Thus, one might consider solving that algebraic system of ten equations for $G(x,y)$ and its first, second, and third derivatives. One would then have the consistency conditions that the algebraically obtained solutions for $G(x,y)$ and its first, second, and third derivatives [in terms of $f(q,P,t),h(q,P,t),V(q,t)$ and their derivatives] would need to satisfy in order to be consistent with one another. For example, if the algebraic solutions for $G(x,y)$ and its first derivatives were given by

$$\overline{G}[f(q,P,t),h(q,P,t)]=\Lambda^{(0)}(q,P,t), \tag{3.14}$$

$$\overline{G_x}[f(q,P,t),h(q,P,t)]=\Lambda^{(1)}(q,P,t), \tag{3.15}$$

$$\overline{G_y}[f(q,P,t),h(q,P,t)]=\Lambda^{(2)}(q,P,t), \tag{3.16}$$

where $\Lambda^{(0)}(q,P,t)$, $\Lambda^{(1)}(q,P,t)$, and $\Lambda^{(2)}(q,P,t)$ were defined as explicit functions of $f(q,P,t),h(q,P,t),V(q,t)$, and their derivatives, then the relation

$$\Lambda^{(0)}_q(q,P,t)=\Lambda^{(1)}(q,P,t)f_q(q,P,t)+\Lambda^{(2)}(q,P,t)h_q(q,P,t) \tag{3.17}$$

would need to hold. Similarly for the P and t derivatives.

Two salient facts are encountered in an attempt to solve the ten equations for $\overline{G}(x,y)$ and its first, second, and third derivatives. First, there is a subsidiary consistency condition that must be satisfied by the three first derivatives of (3.13) in order that they be soluble for the second derivatives of $\overline{G}(x,y)$. Second, proceeding beyond that condition leads to extremely complex equations. We shall not proceed beyond that condition here.

The derivatives of (3.13) with respect to q, P, and t can be viewed as a system of three linear equations for the three second derivatives of $G(x,y)$. In matrix form they are

$$A\begin{pmatrix} \overline{G_{xx}} \\ \overline{G_{xy}} \\ \overline{G_{yy}} \end{pmatrix} = \beta, \tag{3.18}$$

where

$$A = \begin{pmatrix} f_q(f_t+\overline{Gf}_q) & [h_q(f_t+\overline{Gf}_q)+f_q(h_t+\overline{Gh}_q)] & h_q(h_t+\overline{Gh}_q) \\ f_P(f_t+\overline{Gf}_q) & [h_P(f_t+\overline{Gf}_q)+f_P(h_t+\overline{Gh}_q)] & h_P(h_t+\overline{Gh}_q) \\ f_t(f_t+\overline{Gf}_q) & [h_t(f_t+\overline{Gf}_q)+f_t(h_t+\overline{Gh}_q)] & h_t(h_t+\overline{Gh}_q) \end{pmatrix}, \tag{3.19}$$

$$\beta = \begin{pmatrix} -\overline{G_x(f_t+\overline{Gf}_q)_q}-\overline{G_y(h_t+\overline{Gh}_q)_q}-V_{qq} \\ -\overline{G_x(f_t+\overline{Gf}_q)_P}-\overline{G_y(h_t+\overline{Gh}_q)_P} \\ -\overline{G_x(f_t+\overline{Gf}_q)_t}-\overline{G_y(h_t+\overline{Gh}_q)_t}-V_{qt} \end{pmatrix}. \tag{3.20}$$

The matrix A is singular, corresponding to a null vector n of its transpose:

$$\tilde{A}n=0, \quad n=\begin{pmatrix} f_th_P-f_Ph_t \\ -f_th_q+f_qh_t \\ -f_qh_P+f_Ph_q \end{pmatrix}. \tag{3.21}$$

The subsidiary consistency condition for (3.18) is

$$\tilde{n}\beta=0. \tag{3.22}$$

The meaning of this condition can be understood clearly by transforming variables from (q,P,t) to (x,y,t), where x and y are defined by (3.12). Denote the inverse transformation by

$$q=r(x,y,t), \quad P=s(x,y,t). \tag{3.23}$$

Derivatives of $f(q,P,t)$ and $h(q,P,t)$ are related to derivatives of $r(x,y,t)$ and $s(x,y,t)$ by the derivatives of the identities

$$x\equiv f[r(x,y,t),s(x,y,t),t], \quad y\equiv h[r(x,y,t),s(x,y,t),t]. \tag{3.24}$$

Those relations are presented in the Appendix.

Completely in terms of (x,y,t), we can express (3.13) as

$$\overline{G_x}[(r_ys_t-r_ts_y)+s_y\overline{G}]-\overline{G_y}[(r_xs_t-r_ts_x)+s_x\overline{G}]=(r_ys_x-r_xs_y)V_q[r(x,y,t),t]. \tag{3.25}$$

Since $\overline{G}(x,y)$ is not a function of t, the derivative of (3.25) with respect to t is

$$\overline{G_x}[(r_ys_t-r_ts_y)_t+s_{yt}\overline{G}]-\overline{G_y}[(r_xs_t-r_ts_x)_t+s_{xt}\overline{G}]=\{(r_ys_x-r_xs_y)V_q[r(x,y,t),t]\}_t. \tag{3.26}$$

The consistency condition (3.22) is the same as the condition obtained by subtracting the product of $(r_ys_x-r_xs_y)_t$ with (3.25) from the product of $(r_ys_x-r_xs_y)$ with (3.26).

If we view (3.25) and (3.26) as equations for $\overline{G}(x,y)$ given $r(x,y,t)$, $s(x,y,t)$, and $V[r(x,y,t),t]$, three approaches come to mind for performing an analysis. None of them has proven fruitful. The first approach is to eliminate $G(x,y)$ algebraically from (3.25) and (3.26).

Note that the case $(s_y\overline{G_x}-s_x\overline{G_y})=0$ is not of interest. This is because that case would imply $s(x,y,t)=$[function of $G(x,y)$ and t], so that $G(x,y)$ could be expressed as a function of $s(x,y,t)$ and t; in that event, the invariant $\widetilde{P}(q,p,t)$ would have to be a function of p and t alone. The result for $(s_yG_x-s_xG_y)\neq 0$ can be written as

$$\frac{\partial}{\partial t}\left\{\frac{[(r_ys_t-r_ts_y)\overline{G_x}-(r_xs_t-r_ts_x)\overline{G_y}]}{(s_y\overline{G_x}-s_x\overline{G_y})}\right\}=\frac{\partial}{\partial t}\left\{\frac{[(r_ys_x-r_xs_y)V_q]}{(s_y\overline{G_x}-s_x\overline{G_y})}\right\}, \tag{3.27}$$

which can be immediately integrated to give

$$A(x,y)(s_y\overline{G_x}-s_x\overline{G_y})+[(r_ys_t-r_ts_y)\overline{G_x}-(r_xs_t-r_ts_x)\overline{G_y}]=[(r_ys_x-r_xs_y)V_q], \tag{3.28}$$

where $A(x,y)$ is arbitrary. However, comparison with (3.25) shows that

$$A(x,y)=\overline{G}(x,y), \tag{3.29}$$

so that (3.28) is really the same as (3.25).

The second approach is to solve (3.25) and (3.26) algebraically for $\overline{G_x}(x,y)$ and $\overline{G_y}(x,y)$ and then impose the compatibility condition that the cross derivatives must be equal:

$$\overline{G_{xy}}(x,y)=\overline{G_{yx}}(x,y). \tag{3.30}$$

This condition is very complicated and will not be pursued further.

The third approach is to construct a linear combination of (3.25) and (3.26) which does not contain the nonlinear products $G(x,y)G_x(x,y)$ and $G(x,y)G_y(x,y)$. This requires

$$0=s_xs_{yt}-s_ys_{xt}\Rightarrow\frac{\partial}{\partial t}\left(\frac{s_x}{s_y}\right)=0\Rightarrow s(x,y,t)=s_0[u(x,y),t], \tag{3.31}$$

where $s_0[z,t]$ and $u(x,y)$ are arbitrary functions. The linear combination of (3.25) and (3.26) is a linear differential equation that can be solved formally. With that solution, (3.25) can be reduced to another formally soluble linear differential equation. Unfortunately, the formal solutions of the linear differential equations involve arbitrary functions whose occurrence prevents practical use of the formal solutions.

C. A different approach in (x,y,t) space

Let us view (3.25) as an equation for $s(x,y,t)$ given $r(x,y,t)$, $\overline{G}(x,y)$, and $V_q(q,t)$. In that case, it is appropriate to write (3.25) in the form

$$(r_y\overline{G_x}-r_x\overline{G_y})s_t-\{r_yV_q[r(x,y,t),t]-r_t\overline{G_y}+\overline{GG_y}\}s_x+\{r_xV_q[r(x,y,t),t]-r_t\overline{G_x}+\overline{GG_x}\}s_y=0. \tag{3.32}$$

We can recover Giacomini's equations from (3.32) as follows. Assume

$$f(q,P,t)=A(q,t),\quad h(q,P,t)=P, \tag{3.33}$$

which implies that the inverse functions can be written as

$$r(x,y,t)=B(x,t),\quad s(x,y,t)=y. \tag{3.34}$$

Then (3.32) reduces to

$$B_xV_q[B(x,t),t]-B_t\overline{G_x}+\overline{GG_x}=0. \tag{3.35}$$

Differentiation with respect to x gives

$$B_t\overline{G_{xy}}=(\overline{GG_x})_y, \tag{3.36}$$

which implies that $B_t(x,t)$ is a function of x alone:

$$B_t(x,t)=-f(x)\Rightarrow\frac{A_t(q,t)}{A_q(q,t)}=f[A]. \tag{3.37}$$

Applying (3.37) to (3.35) shows that $B_xV_q[B(x,t),t]$ is a function of x alone:

$$\frac{V_q}{A_q}=S'[A(q,t)]\Rightarrow V(q,t)=S[A(q,t)]+\alpha(t), \tag{3.38}$$

where S and α are arbitrary. Without loss of generality, we can take $S(A)=A$ and $\alpha=0$. Then, (3.37) becomes

$$V_t=f(V)V_q, \tag{3.39}$$

which is identical to (2.3). Finally, (3.5) can now be written as

$$1+f(x)\overline{G_x}+\overline{GG_x}=0. \tag{3.40}$$

Equations (3.39) and (3.40) constitute Giacomini's result expressed in terms of (x,y,t). Giacomini expressed (3.40) in terms of an invariant function $I[V(q,t),p]$. Here $I(x,p)$ is the inverse of $G(x,y)$:

$$p=\overline{G}(x,y)\leftrightarrow y=I(x,p). \tag{3.41}$$

Differentiation of the identity

$$y\equiv I[x,\overline{G}(x,y)] \tag{3.42}$$

with respect to x yields

$$\overline{G_x}=-\frac{I_x}{I_p}. \tag{3.43}$$

Combining this with (3.11) gives

$$[f(x)+p]I_x-I_p=0, \tag{3.44}$$

which is the actual equation derived by Giacomini.

In order to obtain a generalization of Giacomini's equations in terms of the variables (x,y,t), we would need to generalize (2.4) and (3.40). Perhaps this could be achieved with the following approach. Assume

$$f_q(q,P,t)=a[f,P]V_q, \quad f_t(q,P,t)=b[f,P]V_q, \tag{3.45}$$

$$h(q,P,t)=P, \quad s(x,y,t)=y. \tag{3.46}$$

From (3.45), $f(q,P,t)$ must satisfy

$$f_t - \frac{b}{a} f_q = 0, \tag{3.47}$$

whose solution is

$$\Omega[f,P] = \frac{b}{a} t + q, \tag{3.48}$$

where Ω is arbitrary. Equation (3.48) is a generalization of (2.4). If we express $a[f,P]$ as

$$a[f,P] = \frac{1}{A_f[f,P]}, \tag{3.49}$$

then (3.45) implies

$$A[f(q,P,t),P] = V(q,t) + \gamma(P,t), \tag{3.50}$$

where γ is arbitrary. As a result of (3.46), (3.32) now reduces to

$$A_f[f,P] + A_f[f,P] b[f,P] \overline{G_x}(x,y) + \overline{G}(x,y) \overline{G_x}(x,y) = 0, \tag{3.51}$$

which is a generalization of (3.40). For (3.48) and (3.51) to be legitimate generalizations of (2.4) and (3.40), it is imperative that (3.47) and (3.49) be satisfied in a way that does not make $V(q,t)$ depend upon P when it is calculated from (3.50).

APPENDIX: RELATIONS AMONG THE DERIVATIVES OF *f*, *h*, *r*, AND *s*

Define the transformation from variables (q,P,t) to variables (x,y,t) by

$$x = f(q,P,t), \quad y = h(q,P,t), \tag{3.12}$$

and define the inverse transformation by

$$q = r(x,y,t), \quad P = s(x,y,t). \tag{3.23}$$

The formulas relating the first derivatives of $f(q,P,t)$ and $h(q,P,t)$ to the first derivatives of $r(x,y,t)$ and $s(x,y,t)$ can be obtained from the first derivatives of the identities

$$x \equiv f[r(x,y,t),s(x,y,t),t], \quad y \equiv h[r(x,y,t),s(x,y,t),t]; \tag{A1}$$

the identities are linear in the derivatives. The relations are

$$f_q = \frac{s_y}{r_x s_y - r_y s_x}, \quad f_p = -\frac{r_y}{r_x s_y - r_y s_x}, \quad f_t = \frac{r_y s_t - r_t s_y}{r_x s_y - r_y s_x}, \tag{A2}$$

$$h_q = -\frac{s_x}{r_x s_y - r_y s_x}, \quad h_p = \frac{r_x}{r_x s_y - r_y s_x}, \quad h_t = \frac{r_t s_x - r_x s_t}{r_x s_y - r_y s_x}, \tag{A3}$$

$$r_x = \frac{h_p}{f_q h_p - f_p h_q}, \quad r_y = -\frac{f_p}{f_q h_p - f_p h_q}, \quad r_t = \frac{f_p h_t - f_t h_p}{f_q h_p - f_p h_q}, \tag{A4}$$

$$s_x = -\frac{h_q}{f_q h_p - f_p h_q}, \quad s_y = \frac{f_q}{f_q h_p - f_p h_q}, \quad s_t = \frac{f_t h_q - f_q h_t}{f_q h_p - f_p h_q}. \tag{A5}$$

(Received 23 April 1996; accepted for publication 12 July 1996)

An explicit formula for a second invariant of a one-degree-of-freedom time-dependent Hamiltonian is derived in terms of the Hamiltonian and an assumed first invariant. If the first invariant is expressed as a function of two canonical functions, a transformation to an autonomous Hamiltonian system is possible. © *1996 American Institute of Physics.* [S0022-2488(96)02411-5]

I. INTRODUCTION

Considerable attention has been paid in recent years to the question of finding invariants for one-degree-of-freedom, time-dependent Hamiltonian systems. In this paper we assume that one invariant is known as an explicit function of two canonically conjugate variables and time, and we derive an explicit formula for a second invariant in terms of the Hamiltonian and the assumed first invariant. The two invariants are canonically conjugate to one another. Then we consider the special case in which the assumed first invariant is expressed as a function of *two* arguments, which are canonically conjugate functions of the canonical variables and time. This is always possible in principle, but such an expression for the invariant may not be known for a particular problem. If it is known, then a related *autonomous* Hamiltonian system can be derived that leads to a simplification of the formula for the second invariant. The related autonomous system is in terms of a new time variable that is defined separately for each value of the assumed first invariant.

By an invariant we mean any function $\tilde{I}(q,p,t)$ whose total time derivative vanishes:

$$0=\frac{d\tilde{I}}{dt}=\tilde{I}_t(q,p,t)+[\tilde{I},H]=\tilde{I}_t(q,p,t)+\tilde{I}_q(q,p,t)H_p(q,p,t)-\tilde{I}_p(q,p,t)H_q(q,p,t), \quad (1.1)$$

where $[\tilde{I},H]$ is the Poisson bracket of $\tilde{I}$ with H, and Hamilton's equations of motion have been taken into account in the evaluation of the total time derivative.

Our starting point is the formulation of Lewis *et al.*,[1] who gave an expression for all Hamiltonians $H(q,p,t)$ for which a specified function $\tilde{I}(q,p,t)$ is an invariant. In addition to the general case in which $\tilde{I}(q,p,t)$ is given explicitly as a function of the *three* arguments (q,p,t), they also treat the special case in which $\tilde{I}(q,p,t)$ is expressed as an explicit function of *two* arguments which are canonically conjugate to one another. The results of Lewis *et al.*[1] allow a simple, elegant derivation of a canonically conjugate second invariant within the framework of canonical transformation theory. A derivation of an equivalent canonically conjugate second invariant from a different point of view was given earlier by Dewisme and Bouquet.[2]

In Sec. II, we derive the general formula for a second invariant in terms of the Hamiltonian and the assumed first invariant. In Sec. III, we consider the special case in which the assumed first invariant is expressed as a function of two canonically conjugate functions and we present an

[a)]Also affiliated with CEA, Centre d'Etudes de Saclay, DRECAM/SPEC, 91191 Gif sur Yvette, Cedex, France.

example. In Appendix A we verify a required mathematical property of a function that is introduced in the derivation of the second invariant. In Appendix B we demonstrate directly that the general expression for a second invariant derived in this paper and the general expression derived by Dewisme and Bouquet[2] both satisfy the equation that defines an invariant and that they both are canonically conjugate to the assumed first invariant.

II. THE GENERAL CASE

Lewis *et al.*[1] showed that all Hamiltonians $H(q,p,t)$ for which a specified function $\tilde{I}(q,p,t)$ is an invariant are given by

$$H(q,p,t)=K(t)-F_t[\tilde{I}(q,p,t),t]-\int_{q_0}^{q}G_t[q',\tilde{I}(q,p,t),t]dq', \tag{2.1}$$

where $G(q,I,t)$ is the inverse of $\tilde{I}(q,p,t)$,

$$p=G(q,I,t)\leftrightarrow I=\tilde{I}(q,p,t), \tag{2.2}$$

and where $F(I,t)$ and $K(t)$ are arbitrary functions and q_0 is a constant. Consider a canonical transformation from variables (q,p,t) to variables (J,I,t),

$$J=\tilde{J}(q,p,t), \quad I=\tilde{I}(q,p,t), \tag{2.3}$$

such that the new Hamiltonian is $K(t)$. Then the functions $\tilde{J}(q,p,t)$ and $\tilde{I}(q,p,t)$ are canonically conjugate invariants of $H(q,p,t)$. A result of Lewis *et al.*[1] is that a Type Two generating function $S(q,I,t)$ for the canonical transformation from variables (q,p,t) to variables (J,I,t) is given by

$$S(q,I,t)=F(I,t)+\int_{q_0}^{q}G(q',I,t)dq'. \tag{2.4}$$

The transformation equations are

$$p=S_q(q,I,t), \quad \tilde{J}(q,p,t)=S_I[q,\tilde{I}(q,p,t),t], \tag{2.5}$$

and

$$K(t)=H(q,p,t)+S_t[q,\tilde{I}(q,p,t),t], \tag{2.6}$$

which is equivalent to (2.1). If we arbitrarily choose $K(t)=0$ and use (2.5) to write (2.6) in terms of (q,I,t), the result is the Hamilton–Jacobi equation for $S(q,I,t)$. There is an analogous result if one of the other generating functions is used mutatis mutandis, but the equation analogous to (2.6) would not normally be called the Hamilton–Jacobi equation.

We assume that both the Hamiltonian $H(q,p,t)$ and a first invariant $\tilde{I}(q,p,t)$ are given. In order to determine the second invariant $\tilde{J}(q,p,t)$, we shall determine a suitable function $F(I,t)$ that occurs in (2.1). Equation (2.1) written in terms of the variables (q,I,t) is

$$H[q,G(q,I,t),t]=K(t)-F_t(I,t)-\int_{q_0}^{q}G_t(q',I,t)dq'. \tag{2.7}$$

Integration of (2.7) with respect to t gives

$$F(I,t)-F(I,t_0)=\int_{t_0}^{t}K(t')dt'-\int_{t_0}^{t}H[q,G(q,I,t'),t']dt'-\int_{q_0}^{q}G(q',I,t)dq'+\int_{q_0}^{q}G(q',I,t_0)dq', \tag{2.8}$$

where t_0 is a constant. That this formula for $F(I,t)$ is indeed independent of q is verified in Appendix A. For that verification and for the remainder of the derivation of the second invariant, we use the following identities that relate the derivatives of $G(q,I,t)$ and $\tilde{I}(q,p,t)$:

$$G_q(q,I,t)=-\frac{\tilde{I}_q[q,G(q,I,t),t]}{\tilde{I}_p[q,G(q,I,t),t]}, \tag{2.9}$$

$$G_I(q,I,t)=\frac{1}{\tilde{I}_p[q,G(q,I,t),t]}, \tag{2.10}$$

$$G_t(q,I,t)=-\frac{\tilde{I}_t[q,G(q,I,t),t]}{\tilde{I}_p[q,G(q,I,t),t]}. \tag{2.11}$$

They can be derived by differentiating the identity

$$I=\tilde{I}[q,G(q,I,t),t] \tag{2.12}$$

with respect to q, I, and t and solving the resulting three equations for the derivatives of $G(q,I,t)$.

Now that we have $F(I,t)$ we can use (2.4) and (2.5) to calculate the second invariant $\tilde{J}(q,p,t)$. Taking $F(I,t_0)=0$, the generating function $S(q,I,t)$ is given by

$$S(q,I,t)=\int_{t_0}^{t}K(t')dt'+\int_{q_0}^{q}G(q',I,t_0)dq'-\int_{t_0}^{t}H[q,G(q,I,t'),t']dt', \tag{2.13}$$

and its derivative with respect to I is

$$S_I(q,I,t)=\int_{q_0}^{q}G_I(q',I,t_0)dq'-\int_{t_0}^{t}H_p[q,G(q,I,t'),t']G_I(q,I,t')dt'$$
$$=\int_{q_0}^{q}\frac{1}{\tilde{I}_p[q',G(q',I,t_0),t_0]}dq'-\int_{t_0}^{t}\frac{H_p[q,G(q,I,t'),t']}{\tilde{I}_p[q,G(q,I,t'),t']}dt'. \tag{2.14}$$

In order to obtain (2.14) we have used the identity (2.10). The second invariant $\tilde{J}(q,p,t)$ is obtained directly from (2.14) by replacing the variable I by the function $\tilde{I}(q,p,t)$.

The expression for the second invariant specified by (2.14) is very similar to, but different than, the expression given by Dewisme and Bouquet in Eq. (2.7) of Ref. 2. That both expressions are indeed invariants canonically conjugate to $\tilde{I}(q,p,t)$ is verified directly in Appendix B.

III. THE FIRST INVARIANT GIVEN AS A FUNCTION OF TWO CANONICALLY CONJUGATE FUNCTIONS

We now suppose that the first invariant, $\tilde{I}(q,p,t)$, is given as a function of two canonically conjugate functions:

$$\tilde{I}(q,p,t)\rightarrow\tilde{I}(x,y), \tag{3.1}$$

where

$$x=\tilde{x}(q,p,t), \quad y=\tilde{y}(q,p,t), \tag{3.2}$$

$$[\tilde{x}(q,p,t),\tilde{y}(q,p,t)]=1. \tag{3.3}$$

As is demonstrated by Lewis *et al.*,[1] a representation in the form (3.1) with canonically conjugate functions $\tilde{x}$ and $\tilde{y}$ is always possible in principle for any invariant. Although a realization of (3.1) may not be available in a particular case, such a representation is a natural generalization of the form of invariants that are quadratic in the momentum for the case of a particle moving in a potential.[3] The treatment leading to a second invariant is analogous to that for the general case, the canonical variables (x,y) replacing (q,p). However, because $\tilde{I}(x,y)$ does not depend on t, the treatment is simpler.

Define $G(x,I)$ as the inverse of $\tilde{I}(x,y)$,

$$y=G(x,I)\leftrightarrow I=\tilde{I}(x,y). \tag{3.4}$$

All Hamiltonians $H(x,y,t)$ for which a specified function $\tilde{I}(x,y)$ is an invariant are given by

$$H(x,y,t)=K(t)-F_t[\tilde{I}(x,y),t], \tag{3.5}$$

where $F(I,t)$ and $K(t)$ are arbitrary functions. Consider a canonical transformation from variables (x,y,t) to variables (J,I,t),

$$J=\tilde{J}(x,y,t), \quad I=\tilde{I}(x,y), \tag{3.6}$$

such that the new Hamiltonian is $K(t)$. Then the functions $\tilde{J}(x,y,t)$ and $\tilde{I}(x,y)$ are canonically conjugate invariants of $H(q,p,t)$. A Type Two generating function $S(x,I,t)$ for the canonical transformation from variables (x,y,t) to variables (J,I,t) is given by

$$S(x,I,t)=F(I,t)+\int_{x_0}^{x} G(x',I)dx', \tag{3.7}$$

where x_0 is a constant. The transformation equations are

$$y=S_x(x,I,t), \quad \tilde{J}(x,y,t)=S_I[x,\tilde{I}(x,y),t], \tag{3.8}$$

and

$$K(t)=H(x,y,t)+S_t[x,\tilde{I}(x,y),t], \tag{3.9}$$

which is equivalent to (3.5).

Equation (2.1) written in terms of the variables (x,I,t) is

$$H[q,G(x,I),t]=K(t)-F_t(I,t). \tag{3.10}$$

Integration of (3.10) with respect to t gives

$$F(I,t)-F(I,t_0)=\int_{t_0}^{t} K(t')dt'-\int_{t_0}^{t} H[x,G(x,I),t']dt', \tag{3.11}$$

where t_0 is a constant. That this formula for $F(I,t)$ is indeed independent of x is verified in Appendix A.

Now that we have $F(I,t)$ we can use (3.7) and (3.8) to calculate the second invariant $\tilde{J}(x,y,t)$. Taking $F(I,t_0)=0$, the generating function $S(x,I,t)$ is given by

$$S(x,I,t)=\int_{t_0}^{t}K(t')dt'+\int_{x_0}^{x}G(x',I)dx'-\int_{t_0}^{t}H[x,G(x,I,t'),t']dt', \tag{3.12}$$

and its derivative with respect to I is

$$\begin{aligned}S_I(x,I,t)&=\int_{x_0}^{x}G_I(x',I)dx'-\int_{t_0}^{t}H_y[x,G(x,I),t']G_I(x,I)dt'\\&=\int_{x_0}^{x}\frac{1}{\tilde{I}_y[x',G(x',I)]}\,dx'-\int_{t_0}^{t}\frac{H_y[x,G(x,I),t']}{\tilde{I}_y[x,G(x,I)]}\,dt'.\end{aligned} \tag{3.13}$$

In order to obtain (3.13) we have used the identity analogous to (2.10). The second invariant $\tilde{J}(x,y,t)$ is obtained directly from (3.13) by replacing the variable I by the function $\tilde{I}(x,y)$.

It is possible to convert the Hamiltonian system in terms of (x,y,t) to an autonomous system by introducing a new time variable T that is defined separately on each level curve of $\tilde{I}(x,y)$. This leads to an elegant expression for $\tilde{J}(x,y,t)$. Hamilton's equations for the Hamiltonian given by (3.5) are

$$\dot{x}(t)=-F_{tI}[\tilde{I}(x,y),t]\tilde{I}_y(x,y),\quad \dot{y}(t)=F_{tI}[\tilde{I}(x,y),t]\tilde{I}_x(x,y). \tag{3.14}$$

Define the new time variable T by

$$T=-F_I(I,t), \tag{3.15}$$

and define $X(T)=x(t)$ and $Y(T)=y(t)$. Then Hamilton's Eqs. (3.14) can be written as an autonomous Hamiltonian system in (X,Y,T),

$$\frac{dX}{dT}=\tilde{I}_y(X,Y)=h_Y(X,Y),\quad \frac{dY}{dT}=-\tilde{I}_x(X,Y)=-h_X(X,Y), \tag{3.16}$$

whose Hamiltonian is

$$h(X,Y)=\tilde{I}(X,Y). \tag{3.17}$$

Thus, a canonically conjugate second invariant written in terms of (X,Y,T) is immediately given by

$$\tilde{\tilde{J}}(X,Y,T)=-T+\int_{X_0}^{X}\frac{1}{h_Y\{X',G[X',h(X,Y)]\}}\,dX', \tag{3.18}$$

and in terms of (x,y,t) by

$$\tilde{J}(x,y,t)=F_I[\tilde{I}(x,y),t]+\int_{x_0}^{x}\frac{1}{\tilde{I}_y\{x',G[x',\tilde{I}(x,y)]\}}\,dx'. \tag{3.19}$$

As an example, we consider the system discussed in Sec. IV C of Ref. 1. The Hamiltonian in terms of (q,p,t) is

$$H(q,p,t)=\tfrac{1}{2}p^2+V(q,t), \tag{3.20}$$

where the potential is

$$V(q,t)=-\frac{1}{2}\left(\frac{\dot{\alpha}_1 q+\dot{\beta}_1}{\alpha_1}\right)^2-\frac{\dot{\alpha}_1}{\alpha_1^2}\left(\frac{1}{2}\,\dot{\alpha}_1 q+\dot{\beta}_1\right)q+\frac{1}{\alpha_1}\left(\frac{1}{2}\,\ddot{\alpha}_1 q+\ddot{\beta}_1\right)q$$
$$-\alpha_1^2\,\ln(\alpha_1 q+\beta_1)-\frac{\alpha_1^2}{2(\alpha_1 q+\beta_1)^2}\int^t \alpha_1^2(t')dt' \tag{3.21}$$

and $\alpha_1(t)$ and $\beta_1(t)$ are two arbitrary functions of time. An invariant for this system is

$$\tilde{I}(x,y)=xy^2+\ln y, \tag{3.22}$$

where x and y are defined by

$$x=\tilde{x}(q,p,t)=\frac{1}{2}\,(\alpha_1 q+\beta_1)^2+\frac{\alpha_1(\alpha_1 q+\beta_1)\int^t\alpha_1^2(t')dt'}{p-\dfrac{\alpha_1}{(\alpha_1 q+\beta_1)}\int^t\alpha_1^2(t')dt'+\dfrac{(\dot{\alpha}_1 q+\dot{\beta}_1)}{\alpha_1}}, \tag{3.23}$$

$$y=\tilde{y}(q,p,t)=\frac{p}{\alpha_1(\alpha_1 q+\beta_1)}+\frac{(\dot{\alpha}_1 q+\dot{\beta}_1)}{\alpha_1^2(\alpha_1 q+\beta_1)}-\frac{1}{(\alpha_1 q+\beta_1)^2}\int^t\alpha_1^2(t')dt'. \tag{3.24}$$

The function $F(I,t)$ is

$$F(I,t)=-\alpha_1^2(t)I, \tag{3.25}$$

and the new time is

$$T=\int^t\alpha_1^2(t')dt'. \tag{3.26}$$

For this example, the new time is independent of I. The autonomous Hamiltonian is

$$h(X,Y)=XY^2+\ln Y \tag{3.27}$$

and Hamilton's equations are

$$\frac{dX}{dT}=2XY+\frac{1}{Y},\quad \frac{dY}{dT}=-Y^2. \tag{3.28}$$

A second invariant canonically conjugate to I is

$$J=-T+\frac{1}{Y}=-\int^t\alpha_1^2(t')dt'+\frac{1}{\tilde{y}(q,p,t)}. \tag{3.29}$$

Direct integration of (3.28) yields

$$X(T)=(T+c_1)^2[c_2+\ln(T+c_1)],\quad Y(T)=(T+c_1)^{-1}, \tag{3.30}$$

where c_1 and c_2 are constants of integration equal to J and I, respectively.

APPENDIX A: VERIFICATION OF THE FUNCTIONAL DEPENDENCE OF $F(I,t)$

In order to verify that the rhs of (2.8) is independent of q, we evaluate its derivative with respect to q:

$$\frac{\partial}{\partial q}\,\mathrm{rhs}(2.8) = -\frac{\partial}{\partial q}\int_{t_0}^{t} H[q,G(q,I,t'),t']dt' - G(q,I,t) + G(q,I,t_0). \tag{A1}$$

The first term can be transformed as follows:

$$\begin{aligned} &-\frac{\partial}{\partial q}\int_{t_0}^{t} H[q,G(q,I,t'),t']dt' \\ &\quad = -\int_{t_0}^{t} \frac{1}{\widetilde{I}_p[q,G(q,I,t'),t']}\{H_q[q,G(q,I,t'),t']\widetilde{I}_p[q,G(q,I,t'),t'] \\ &\qquad - H_p[q,G(q,I,t'),t']\widetilde{I}_q[q,G(q,I,t'),t']\}dt' \end{aligned} \tag{A2}$$

In order to obtain (A2) we have used the identity (2.9). The expression in the curly brackets in (2.10) is minus the Poisson bracket of $\widetilde{I}$ with H. Therefore we may use (1.1) to obtain

$$-\frac{\partial}{\partial q}\int_{t_0}^{t} H[q,G(q,I,t'),t']dt' = -\int_{t_0}^{t} \frac{\widetilde{I}_t[q,G(q,I,t'),t']}{\widetilde{I}_p[q,G(q,I,t'),t']}\,dt' = \int_{t_0}^{t} G_t(q,I,t')dt'. \tag{A3}$$

In order to obtain (A3) we have used the identity (2.11). Finally, by substituting (A3) into (A1), we obtain

$$\frac{\partial}{\partial q}\,\mathrm{rhs}(2.8) = 0, \tag{A4}$$

as is required in order that (2.8) be a valid formula for $F(I,t)$.

The derivative of the rhs of (3.11) with respect to x can be evaluated as follows:

$$\begin{aligned} \frac{\partial}{\partial x}\,\mathrm{rhs}(3.11) &= -\frac{\partial}{\partial x}\int_{t_0}^{t} H[x,G(x,I),t']dt' \\ &= -\int_{t_0}^{t} \frac{1}{\widetilde{I}_y[x,G(x,I),t']}\{H_x[x,G(x,I),t']\widetilde{I}_y[x,G(x,I)] \\ &\quad - H_y[x,G(x,I),t']\widetilde{I}_x[x,G(x,I)]\}dt'. \end{aligned} \tag{A5}$$

In order to obtain (A5) we have used the identity analogous to (2.9). The expression in the curly brackets in (A5) is minus the Poisson bracket of $\widetilde{I}$ with H. Therefore, since $\widetilde{I}(x,y)$ is not an explicit function of t, we obtain

$$\frac{\partial}{\partial x}\,\mathrm{rhs}(3.11) = 0, \tag{A6}$$

as is required in order that (3.11) be a valid formula for $F(I,t)$.

APPENDIX B: DIRECT VERIFICATION OF EQ. (2.14) AND OF THE CORRESPONDING RESULT OF DEWISME AND BOUQUET

The expression for $\widetilde{J}(q,p,t)$ specified by (2.5) and (2.14) is very similar to, but different than, the expression given by Dewisme and Bouquet in Eq. (2.7) of Ref. 2. The two expressions may

differ by a function of the invariant $\tilde{I}(q,p,t)$. Here we verify directly that both expressions are indeed invariants canonically conjugate to $\tilde{I}(q,p,t)$. For that purpose we substitute the expressions into (1.1) and evaluate their Poisson brackets with $\tilde{I}(q,p,t)$.

1. $\tilde{J}(q,p,t)$ specified by Eq. (2.14)

The total time derivative of $\tilde{J}(q,p,t)$ is

$$\frac{d}{dt}\tilde{J}(q,p,t)=\tilde{J}_t(q,p,t)+[J,H]=S_{It}+S_{II}\tilde{I}_t+S_{Iq}H_p+S_{II}[I,H]=S_{It}+S_{Iq}H_p=-\frac{H_p(q,p,t)}{\tilde{I}_p(q,p,t)}$$
$$+\left\{\frac{1}{\tilde{I}_p(q,p,t_0)}-\int_{t_0}^{t}\frac{\partial}{\partial q}\frac{H_p[q,G(q,I,t'),t']}{\tilde{I}_p[q,G(q,I,t'),t']}\,dt'\right\}H_p(q,p,t). \tag{B1}$$

The integral in (B1) can be evaluated by transforming the integrand to a derivative with respect to t holding (q,I) fixed. In order to do that, we use the derivative with respect to p of (1.1),

$$0=\tilde{I}_{tp}+\tilde{I}_{qp}H_p+\tilde{I}_qH_{pp}-\tilde{I}_{pp}H_q-\tilde{I}_pH_{qp}, \tag{B2}$$

along with (2.10), (1.1), and (2.12):

$$\frac{\partial}{\partial q}\frac{H_p[q,G(q,I,t),t]}{\tilde{I}_p[q,G(q,I,t),t]}=\frac{1}{\tilde{I}_p^2}\{[H_{pq}+H_{pp}G_q]\tilde{I}_p-H_p[\tilde{I}_{pq}+\tilde{I}_{pp}G_q]\}$$
$$=\frac{1}{\tilde{I}_p^2}\{\tilde{I}_{tp}+\tilde{I}_{pp}G_t\}=-\frac{\partial}{\partial t}\frac{1}{\tilde{I}_p[q,G(q,I,t),t]}. \tag{B3}$$

Substitution of (B3) into (B1) immediately shows satisfaction of (1.1).

The following evaluation demonstrates that $\tilde{J}(q,p,t)$ and $\tilde{I}(q,p,t)$ are canonically conjugate:

$$[J,I]=\frac{1}{\tilde{I}_p(q,p,t_0)}\tilde{I}_p(q,p,t)-\left\{\int_{t_0}^{t}\frac{\partial}{\partial q}\frac{H_p[q,G(q,I,t'),t']}{\tilde{I}_p[q,G(q,I,t'),t']}\,dt'\right\}\tilde{I}_p(q,p,t)$$
$$=\left\{\frac{1}{\tilde{I}_p(q,p,t_0)}+\int_{t_0}^{t}\frac{\partial}{\partial t'}\frac{1}{\tilde{I}_p[q,G(q,I,t'),t']}\,dt'\right\}\tilde{I}_p(q,p,t)=1. \tag{B4}$$

2. $\tilde{J}(q,p,t)$ as given by Dewisme and Bouquet

The expression for $\tilde{J}(q,p,t)$ given by Dewisme and Bouquet in Eq. (2.7) of Ref. 2, written in the notation of the present paper, is

$$\tilde{J}(q,p,t)=S_I[q,\tilde{I}(q,p,t),t],$$

as in (2.5), but where $S_I(q,I,t)$ is given by

$$S_I(q,I,t)=\int_{q_0}^{q}\frac{1}{\tilde{I}_p[q',G(q',I,t),t]}\,dq'-\int_{t_0}^{t}\frac{H_p[q_0,G(q_0,I,t'),t']}{\tilde{I}_p[q_0,G(q_0,I,t'),t']}\,dt', \tag{B5}$$

instead of by (2.14). The total time derivative of this $\tilde{J}(q,p,t)$ is

$$\frac{d}{dt}\,\widetilde{J}(q,p,t)=-\frac{H_p(q_0,p,t)}{\widetilde{I}_p(q_0,p,t)}+\int_{q_0}^{q}\frac{\partial}{\partial t}\,\frac{1}{\widetilde{I}_p[q',G(q',I,t),t]}\,dq'+\frac{H_p(q,p,t)}{\widetilde{I}_p(q,p,t)}. \tag{B6}$$

The integral in (B6) can be evaluated by using (B3). It follows immediately that (1.1) is satisfied.

Verification of the Poisson bracket relation $[J,I]=1$ is very simple when $S_I(q,I,t)$ is given by (B5).

(Received 25 April 1996; accepted for publication 22 May 1996)

It is shown theoretically for the first time that, depending on its period, amplitude, and initial phase, a periodic parametric modulation can suppress a chaotic escape from a potential well. The instance of the Helmholtz oscillator is used to demonstrate, by means of Melnikov's method, that parametric modulations of the linear or quadratic potential terms inhibit chaotic escape when certain resonance conditions are met. © *1996 American Institute of Physics.* [S0022-2488(96)03709-7]

I. INTRODUCTION

Escape from a potential well is a general problem in the physical sciences. One finds it in very different contexts: the escape of stars from a stellar system,[1] the orbits of a photon near a Schwarzschild black hole,[2] the photodissociation of molecules as described by the driven Morse oscillator,[3] the capsizing of a boat subjected to trains of regular waves,[4] and the stochastic escape of a trapped ion induced by a resonant laser field,[5] to quote a few. All of these systems (except the integrable one of Ref. 2) present a common characteristic: before escape, chaotic transients of unpredictable duration are usually observed for orbits starting from chaotic generic phase space regions (such as those surrounding separatrices), in both Hamiltonian[1,3,5] and dissipative[4] systems. As the application of weak parametric modulations (PMs) is an effective technique for taming chaos arising from such a wide class of dynamical systems,[6] one might conjecture that there would be a similar efficacy for suppressing chaotic escape. The approach is of the nonfeedback type, and is easily implemented in practical systems, where the performance of a specific nonlinear system with a potential well subjected to a periodic excitation would generally be considered optimal if it operates in a periodic mode (i.e., inside the well).

For the sake of clarity, we shall concentrate in this paper on the simplest model for a universal chaotic escape situation—the Helmholtz oscillator.[7] We first added a weak PM of the quadratic term,

$$\ddot{x}=x-\beta[1+\eta\,\sin(\Omega t+\phi)]x^2-\delta\dot{x}+\gamma\,\sin(\omega t), \tag{1}$$

where x is the displacement, Ω, η and ϕ are the normalized frequency, amplitude, and initial phase, respectively, of the PM ($\eta\ll 1$), which will have an inhibitory effect on the chaotic escape of the remaining system ($\delta,\gamma\ll 1$),[8] and ω, δ, and γ are the normalized parameters of frequency, damping coefficient, and driving term amplitude, respectively. We shall then apply instead a PM of the linear term

0022-2488/96/37(11)/5518/6/$10.00

$$\ddot{x}=x[1+\eta' \sin(\Omega' t+\phi')]-\beta x^2-\delta\dot{x}+\gamma \sin(\omega t), \tag{2}$$

where Ω', η', and ϕ' are the normalized frequency, amplitude, and initial phase, respectively, of the PM ($\eta' \ll 1$), and compare the results.

II. MELNIKOV ANALYSIS

Melnikov's method (MM) is the main analytical technique currently available to provide a criterion for the occurrence of homoclinic (and heteroclicic) chaos in a dynamical system, and is today considered standard. As is well known, MM predictions are both approximate (the MM is a first-order perturbative method) and limited (only valid for orbits starting at points sufficiently near the separatrix). However, they are highly valued because of the quite general scarcity of analytical results in the theory of chaos. Since it has been described many times by different authors, we shall not discuss it in detail here, but refer the interested reader to that literature.[9–13]

A. Melnikov function

The application of MM to Eq. (1) involves calculating the Melnikov function,

$$M(t_0)=-\delta\int_{-\infty}^{\infty}\dot{x}_0^2(t)dt+\gamma\int_{-\infty}^{\infty}\dot{x}_0(t)\sin[\omega(t+t_0)]dt-\beta\eta\int_{-\infty}^{\infty}\dot{x}_0(t)x_0^2(t)\sin[\Omega(t+t_0)+\phi]dt, \tag{3}$$

where

$$x_0(t)=\frac{3}{2\beta}\operatorname{sech}^2\left(\frac{t}{2}\right),$$
$$\dot{x}_0(t)=-\frac{3}{2\beta}\operatorname{sech}^2\left(\frac{t}{2}\right)\tanh\left(\frac{t}{2}\right), \tag{4}$$

is the parametric representation of the separatrix of the underlying conservative system ($\delta=\gamma=\eta=0$). After substituting Eq. (4) into Eq. (3) and computing the resulting integrals with the aid of standard integral tables,[14] Eq. (3) can be written as

$$M(t_0)=-C-A\cos(\omega t_0)+B\cos(\Omega t_0+\phi), \tag{5}$$

with

$$C=\frac{6\delta}{5\beta^2},$$
$$A=\frac{6\pi\gamma}{\beta}\omega^2\operatorname{cosech}(\pi\omega), \tag{6}$$
$$B=\frac{3\pi\eta}{5\beta^2}\Omega^2(\Omega^2+1)(\Omega^2+4)\operatorname{cosech}(\Omega\pi).$$

As is well known,[11–13] the Melnikov function $M(t_0)$ measures the distance between the perturbed stable and unstable manifolds in the Poincaré section at t_0. If $M(t_0)$ has a simple zero, then a homoclinic bifurcation occurs, signifying the possibility of chaotic behavior, i.e., only *necessary* conditions for steady chaos are obtained from MM, and therefore one always has the

possibility of finding *sufficient* conditions for the elimination of even transient chaos. Indeed, we shall show in the following that the MM provides, for the system under consideration, sufficient conditions for the inhibition of chaotic escape.

B. Escape Inhibition Theorem (EIT)

Suppose that for $\eta=0$ the system (1) undergoes a chaotic escape for which the associated Melnikov function $M_0(t_0)\equiv -C+A\cos(\omega t_0)$ has simple zeros, i.e., $A-C\equiv d\geqslant 0$, where the equal sign corresponds to the case of tangency between the stable and unstable manifolds. If we now let the PM act on the system ($\eta\neq 0$) in such a way that $B>d$, i.e., $A-B-C<0$, this relationship provides a necessary condition for $M(t_0)$ to always have the same sign, specifically $M(t_0)<0$, which is

$$\eta>\left(1-\frac{C}{A}\right)R, \tag{7}$$

with

$$R=\frac{10\gamma\beta\omega^2}{\Omega^2(\Omega^2+1)(\Omega^2+4)}\left[\frac{\sinh(\pi\Omega)}{\sinh(\pi\omega)}\right]. \tag{8}$$

For general Ω and ϕ ($0\leqslant\phi\leqslant 2\pi$), we shall see that this condition is not sufficient to assure the negativity of $M(t_0)$. In order to achieve such a sufficient condition, we shall first need three lemmas.

Lemma I: Let Ω/ω be irrational. Then there exists an $\overline{t_0}$ such that $B\cos(\Omega\overline{t_0}+\phi)-A\cos(\omega\overline{t_0})>A-B$.

Lemma II: Let $p\omega=q\Omega$ for some positive integers p and q. Then a t_0^* exits such that $\cos(\omega t_0^*)=\cos(\Omega t_0^*+\phi)=-1$ if and only if

$$\frac{p}{q}=\frac{2m-1-\phi/\pi}{2n-1}, \tag{9}$$

for some integers m and n.

Remark: Observe that a requirement for Eq. (9) to be fulfilled for some integers m and n is $\phi=m_1\pi/m_2$, $m_{1,2}$ integers.

Lemma III: Let $g(t;p,q)=[1-\cos(pt/q)]/(1-\cos t)$, t real, p and q integers. Then g is finite if and only if $q=1$. One also has that $0\leqslant g(t;p,1)\leqslant p^2$.

It is obvious that for Eq. (7) to also be a sufficient condition for $M(t_0)$ to be negative for all t_0, one must have

$$A-B\geqslant B\cos(\Omega t_0+\phi)-A\cos(\omega t_0). \tag{10}$$

We now look for the values of ω, Ω, and ϕ, permitting Eq. (10) to be fulfilled for all t_0. From Lemma I, a resonance condition is required: $p\omega=q\Omega$. In such a situation, Lemma II provides a condition for Eq. (10) to be satisfied for an infinity of t_0 values. Thus, let us assume that p, q, and ϕ verify Eq. (9). We can then rewrite Eq. (10) in the form

$$\frac{A}{B}\geqslant\frac{1-\cos(p\tau/q)}{1-\cos\tau}, \tag{11}$$

with $\tau\equiv\omega t_0-(2n-1/2)\pi$. Finally, if $q=1$, Lemma III provides a condition for Eq. (11) to be fulfilled for all τ:

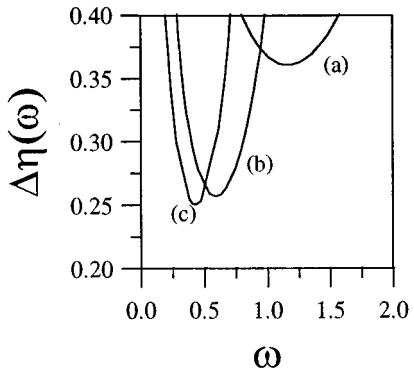

FIG. 1. Function $\Delta\eta(\omega)=\eta_{\max}-\eta_{\min}$ vs ω for δ=const, β=const, γ=const, and $\Omega=p\omega$: (a) $p=1$; (b) $p=2$; (c) $p=3$.

$$\eta \leqslant \frac{R}{p^2}, \tag{12}$$

with R given by (8). The proofs of the lemmas are quite straightforward, so they will not be included here. In brief we have the following.

Escape Inhibition Theorem (EIT): Let $\Omega=p\omega$, p an integer, such that $p=(2m-1-\phi/\pi)/(2n-1)$ is satisfied for some integers m and n. Then $M(t_0)$ always has the same sign, i.e., $M(t_0)<0$, if and only if the following condition is fulfilled:

$$\eta_{\min} < \eta \leqslant \eta_{\max},$$

$$\eta_{\min}=\left(1-\frac{C}{A}\right)R, \tag{13}$$

$$\eta_{\max}=\frac{R}{p^2}.$$

Remarks: First, note that, for a given set of parameters satisfying the theorem's hypothesis, as the resonance order p is increased, the allowed interval $]\eta_{\min},\eta_{\max}]$ for escape inhibition shrinks rapidly. One may therefore expect only the first few resonances to be suitable for suppressing chaotic escape (as, in fact, we observed in numerical experiments). Figure 1 shows the width $\Delta\eta(\omega)=\eta_{\max}-\eta_{\min}$ vs ω for δ,γ=const. There exist a minimum-range frequency for each resonance. Observe that the minimum $\omega_{\min}$ is lower as the resonance order is increased. The asymptotic behavior $\Delta\eta(\omega\to 0,\infty)=\infty$ means that chaotic escape is impossible in these limits. Second, we can test the EIT theoretically by considering the limiting case $\delta=0$. From Eqs. (9) and (13), one has $\phi=0$, $\Omega=\omega$, and $\eta=R$ as a necessary and sufficient condition for eliminating stochastic escape. But this is the obvious result arising from a direct analysis of Eq. (5). Third, the EIT imposes having $\phi=0$ ($\phi=\pi$) for odd (even) values of p. Note that since distinct ϕ values imply different initial conditions for the complete system (1), the above results provide information about the *extension* and *structure* of the basin of attraction of the regularized (periodic) orbits inside the well.

C. Case of a PM of the linear term

We now compare the above results with those corresponding to the application of a PM of the linear term as in Eq. (2). Proceeding similarly to the quadratic case, the Melnikov function corresponding to Eq. (2) is

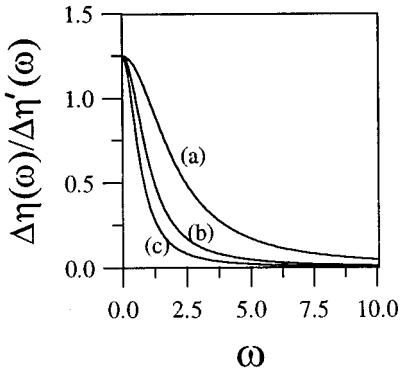

FIG. 2. Function $\Delta\eta(\omega)/\Delta\eta'(\omega)$ [Eq. (17)] vs ω for several values of p: (a) $p=1$; (b) $p=2$; (c) $p=3$.

$$M'(t_0) = -C - A\cos(\omega t_0) + B\cos(\Omega' t_0 + \phi'), \tag{14}$$

with

$$B' = \frac{3\pi\eta'}{\beta^2}\,\Omega'^2(\Omega'^2+1)\,\mathrm{cosech}(\pi\Omega'), \tag{15}$$

and C, A given by Eq. (6). Note that Eqs. (5) and (14) become identical with the substitutions: $B\to B'$, $\Omega\to\Omega'$, $\phi\to\phi'$. Therefore (cf. Sec. II B), one obtains a similar escape inhibition theorem (that we shall denote EIT′): Let $\Omega'=p\omega$, p an integer, such that $p=(2m-1-\phi'/\pi)/(2n-1)$ is satisfied for some integers m and n. Then $M'(t_0)$ always has the same sign, i.e., $M'(t_0)<0$, if and only if

$$\begin{aligned} &\eta'_{\min} < \eta' \leqslant \eta'_{\max}, \\ &\eta'_{\min} = \left(1 - \frac{C}{A}\right) R', \\ &\eta'_{\max} = \frac{R'}{p^2}, \\ &R' = \frac{2\gamma\beta\omega^2}{\Omega'^2(\Omega'^2+1)}\left[\frac{\sinh(\pi\Omega')}{\sinh(\pi\omega)}\right]. \end{aligned} \tag{16}$$

The same remarks hold as for EIT. In order to compare the quadratic and linear cases we set $\Omega=\Omega'$, $\phi=\phi'$ and define $\Delta\eta'(\omega) = \eta'_{\max} - \eta'_{\min}$. We then obtain [cf. Eqs. (13) and (16)]

$$\frac{\Delta\eta(\omega)}{\Delta\eta'(\omega)} = \frac{5}{p^2\omega^2+4}. \tag{17}$$

Figure 2 shows the relative width $\Delta\eta(\omega)/\Delta\eta'(\omega)$ vs ω for several values of p. First, observe that for $\omega=1/p$, $\Delta\eta(\omega)=\Delta\eta'(\omega)$, whereas for $\omega>1/p$ ($\omega<1/p$) one has $\Delta\eta(\omega)<\Delta\eta'(\omega)$ [$\Delta\eta(\omega)>\Delta\eta'(\omega)$], i.e., the effectiveness of the quadratic PM (in the frequency domain) relative to the linear PM rises with decreasing resonance order, and *vice versa*. Second, with fixed p, the asymptotic behavior $[\Delta\eta/\Delta\eta'](\omega\to\infty)=0$ means that a linear PM inhibits chaotic escape much more easily (i.e., for a larger interval of amplitudes) than a quadratic PM for small driving periods

of the primary chaos-inducing modulation. From the other limit $(\Delta\eta/\Delta\eta')(\omega\to 0)=5/4$, we deduce the opposite result for large driving periods, i.e., for resonances with orbits (of the conservative Helmholtz oscillator) very close to the separatrix (for which $T=\infty$).

III. CONCLUSIONS

We have shown here for the first time that the application of periodic PM is an efficient procedure for suppressing chaotic escape from a potential well. Analytical estimates of the ranges of parameters for inhibition were found by means of the Melnikov analysis of the example of the Helmholtz oscillator. The cases of PMs of the linear and quadratic potential terms were studied and compared. It was demonstrated that a PM of the linear (quadratic) term suppress chaotic escape more efficiently than that of the quadratic (linear) term for small (large) driving periods of the primary chaos-inducing modulation.

(Received 9 February 1996; accepted for publication 22 May 1996)

An approach of constructing isospectral flows K_l, nonisospectral flows σ_k and their implicit representations of a general Lax integrable system is proposed. By introducing product function matrices, it is shown that the two sets of flows and of related symmetries both constitute infinite-dimensional Lie algebras with respect to the commutator $[\![\cdot,\cdot]\!]$ given in this paper. Algebraic properties for some well-known integrable systems such as the AKNS system, the generalized Harry Dym system, and the n-wave interaction system are obtained as particular examples. © *1996 American Institute of Physics.* [S0022-2488(96)00311-8]

I. INTRODUCTION

Many (1+1)-dimensional Lax integrable systems, such as the AKNS system, the generalized Harry Dym (HD) system, and the n-wave interaction system, possess a couple of isospectral flows K_l and nonisospectral flows σ_k. For an integrable system with a recursion operator, by using the hereditariness of this operator, an infinite-dimensional Lie algebra constituted by the flows K_l and σ_k can be derived. In recent years, there are some new methods that do not use the concept of hereditary symmetry in the study of the algebraic structure of the flows. On the basis of Fokas–Fuchssteiner's idea of the master symmetry, Cheng *et al.*[1,2] have introduced the notion of semi-product Lie algebra of Lax operator. From here, they have suggested a direct approach to derive the commutator relations of flows for some integrable systems. Following this line and assuming that there exists a recursion operator for flows and some other restrictive conditions, Ma[3] has further given the algebraic structure of Lax operator and corresponding flows for the spectral problem $L\phi=\lambda\phi$. However, the applied scope of Ma's results is very limited. In Refs. 4–6, we have introduced the implicit representations of the flows of some soliton systems by using the zero-curvature equation and have also obtained the algebraic properties of these flows by simple computation.

In this paper, we would like to consider the algebraic properties of an integrable system associated with the general linear problem

$$\phi_x=M(\eta,u)\phi, \tag{1.1a}$$

$$\phi_t=N(t,x,\eta,u)\phi. \tag{1.1b}$$

We first put forward a simple method to derive respectively its isospectral flows K_l, nonisospectral flows σ_k (may be no recursion operator), and their implicit representations. Then we introduce the notion and some Lie commutator equalities of product function matrices which play crucial roles in our theory. As a result, the infinite-dimensional Lie algebraic structures of the flows and related symmetries of the general Lax integrable system can be derived naturally. Finally we shall apply our results to several known integrable systems such as the AKNS system, the generalized HD system, and the n-wave interaction system.

The method used in this paper is universal and can be extended to some high-dimensional Lax integrable systems. Thus it is revealed that there exists a close relationship between infinite-dimensional Lie algebra of flows and Lax integrability of corresponding evolution equations.

0022-2488/96/37(11)/5524/15/$10.00

This paper is organized as follows. Section II gives the notion of the Gateaux derivative and some required derivation formulas. In Sec. III we derive the isospectral flows K_l and nonisospectral flows σ_k of a general integrable system associated with the linear problem (1.1) and their implicit representations. In Sec. IV we introduce product function matrices and related Lie commutator equalities. In Sec. V, we derive Lie algebraic structure of flows K_l and σ_k of the general Lax integrable system. Finally, we apply the results obtained to some classical integrable systems in Sec. VI.

II. GATEAUX DERIVATIVE

Let $x \in R^n$, $u=u(t,x)=(u_1,u_2,\ldots,u_s)^T$, where $u_i=u_i(t,x) \in S(R^n)$ (the space of rapidly decreasing functions). Suppose $f=f(t,x,u)=(f_1,f_2,\ldots,f_m)^T$ with $f_i=f_i(t,x,u,Du,D^2u,\ldots,D^ru)$, in which $D^ru = D_1^{r_1}D_2^{r_2}\cdots D_n^{r_n}u$, $D_iu=\partial u/\partial x_i$, and r is a set of non-negative integers $\{r_1,r_2,\ldots,r_n\}$, is a C^∞ differentiable vector filed with respect to x, u, Du, D^2u,..., and D^ru. By $V^{(m)}$ denote a complex linear space constructed by these vector fields. By $Q^{(m)}$ denote a set composed of all the linear operators [in the form of $T=T(t,x,u)$] acting on the vector field space $V^{(m)}$ and being C^∞ differentiable for x and u as well. Obviously, $Q^{(m)}$ is also a linear space. In addition, by $Q_0^{(m)}$ denote a subspace described by all the $m\times m$ function matrices in $Q^{(m)}$.

Definition 1: Let $f \in V^{(m)}$, $h \in V^{(s)}$, and $T \in Q^{(m)}$. Then

$$f'[h]=f'(u)[h]=\frac{d}{d\varepsilon}\,f(u+\varepsilon h)\big|_{\varepsilon=0} \tag{2.1a}$$

and

$$T'[h]=T'(u)[h]=\frac{d}{d\varepsilon}\,T(u+\varepsilon h)\big|_{\varepsilon=0} \tag{2.1b}$$

are called, respectively, the Gateaux derivatives of the vector field f and linear operator T in the direction h with respect to u, or called the G-derivative for short.

From the definition, we obtain the following.

Lemma 1: Let $f \in V^{(m)}$, $h \in V^{(s)}$, and T, $S \in Q^{(m)}$. Then the Leibniz formulas

$$(Tf\,)'[h]=T'[h]f+Tf'[h] \tag{2.2a}$$

and

$$(TS)'[h]=T'[h]S+TS'[h] \tag{2.2b}$$

are valid.

Clearly, $T' \in Q^{(m)}$, and the G-derivative can also be defined. So we have the following lemma.

Lemma 2: Let $f,g \in V^{(s)}$ and $T \in Q^{(m)}$. Then

$$(T')'[f]g=(T')'[g]f. \tag{2.3}$$

Definition 2: Let $f,g \in V^{(s)}$. Then

$$[\![f,\,g]\!]=f'[g]-g'[f] \tag{2.4}$$

is named the commutator of vector fields f and g.

Lemma 3: Linear space $V^{(s)}$ constitutes a Lie algebra with respect to the commutator operation (2.4).[7]

Lemma 1 together with Lemma 2 immediately implies the following.

Lemma 4: Let $f,g\in V^{(s)}$ and $T\in Q^{(m)}$. Then

$$(T'[f])'[g]-(T'[g])'[f]=T'[[\![f,\ g]\!]]. \tag{2.5}$$

III. ISOSPECTRAL AND NONISOSPECTRAL FLOWS

Let η be a spectral parameter and $\mathscr{S}(Q_0^{(m))}$ be a linear space containing all the polynomials of η on $Q_0^{(m)}$.

Suppose that the couple of function matrices $M=M(\eta,u)$ and $N=N(t,x,\eta,u)$ in the linear problem (1.1) belong to $\mathscr{S}(Q_0^{(m)})$. The compatible condition of (1.1) is

$$M_t-N_x+[M,\ N]=0, \tag{3.1}$$

where $[M,N]=MN-NM$ and $x\in R'$. Usually, (3.1) is called the zero-curvature equation.

From Eq. (3.1), if one can derive a hierarchy of isospectral evolution equations

$$u_t=K_l,\quad K_l\in V^{(s)},\quad l=0,1,2,\ldots, \tag{3.2}$$

or of nonisospectral evolution equations

$$u_t=\sigma_k,\quad \sigma_k\in V^{(s)},\quad k=0,1,2,\ldots\ . \tag{3.3}$$

Then (3.2) or (3.3) are called to be Lax integrable.

In the isospectral case, $M_t=M'[u_t]=M'[K_l]$. It follows that Eq. (3.1) can be written as

$$M'[K_l]=N_{l,x}+[N_l,\ M], \tag{3.4}$$

where $N_l=N_l(t,x,\eta,u)\in\mathscr{S}(Q_0^{(m)})$. While for nonisospectrum, $M_t=M'[\sigma_k]+M_\eta\eta_t$; then Eq. (3.1) implies

$$M'[\sigma_k]=P_{k,x}+[P_k,\ M]-M_\eta\eta^{\alpha k+\beta}, \tag{3.5}$$

where $P_k=P_k(t,x,\eta,u)\in\mathscr{S}(Q_0^{(m)})$, $\eta_t=\eta^{\alpha k+\beta}$, and α, β, and k are all integers. Equations (3.4) and (3.5) are named respectively the implicit representations of the hierarchies of evolution equations (3.2) and (3.3) (or of the flows K_l and σ_k).

In what follows, we shall discuss a sufficient condition under which the above implicit representations are existential and unique. Suppose that for the given function matrix $M=M(\eta,u)\in\mathscr{S}(Q_0^{(m)})$ and vector field $Y=Y(t,x,u)\in V^{(s)}(Y|_{u=0}=0)$, the matrix equation

$$M'[X-\eta^\alpha Y]=N_x+[N,\ M] \tag{3.6}$$

possesses unique solutions $X=X(t,x,u)\in V^{(s)}$ and $N=N(t,x,\eta,u)\in\mathscr{S}(Q_0^{(m)})$ which meet the condition

$$N|_{u=0}=\delta_0 M|_{u=0}\eta^\mu, \tag{3.7a}$$

where $\alpha(\alpha\neq 0)$ and μ are integers and δ_0 is given by

$$\delta_0=\begin{cases}1, & \text{if } Y=0,\\ 0, & \text{if } Y\neq 0.\end{cases} \tag{3.7b}$$

Then for each j there exists a unique vector field $K_j\in V^{(s)}$ with $K_j|_{u=0}=0$ [see (3.16) and (3.17)] and a unique function matrix $U_j\in\mathscr{S}(Q_0^{(m)})$ $(j=0,1,\ldots,l)$, which satisfy in turn the following:

$$M'[K_0]=U_{0,x}+[U_0,\ M],\quad U_0=M|_{u=0}\eta^\mu, \tag{3.8a}$$

$$M'[K_j-\eta^{\alpha}K_{j-1}]=U_{j,x}+[U_j,\ M],\quad U_j|_{u=0}=0\quad (j=1,2,...,l). \tag{3.8b}$$

Equation (3.8) suggests

$$\begin{aligned} M'[K_l]&=M'[K_0]\eta^{\alpha l}+\sum_{j=1}^{l} M'[K_j-\eta^{\alpha}K_{j-1}]\eta^{\alpha(l-j)}\\ &=\sum_{j=0}^{l} U_{j,x}\eta^{\alpha(l-j)}+\left[\sum_{j=0}^{l} U_j\eta^{\alpha(l-j)},\ M\right], \end{aligned} \tag{3.9}$$

that is to say, the vector field K_l possesses a unique implicit representation (3.4) where

$$N_l=\sum_{j=0}^{l} U_j\eta^{\alpha(l-j)}\in Q_0^{(m)},\quad N_l|_{u=0}=M|_{u=0}\eta^{\alpha l+\mu}. \tag{3.10}$$

In the same way, if we suppose that there exist a vector field $\sigma_0\in V^{(s)}$ $(\sigma_0|_{u=0}=0)$ and a function matrix $W_0\in\mathscr{S}(Q^{(m)})$ which satisfy

$$M'[\sigma_0]=W_{0,x}+[W_0,\ M]-M_{\eta}\eta^{\beta} \tag{3.11a}$$

and

$$W_0|_{u=0}=(p_0xM|_{u=0}+A_0)\eta^{\beta-1}, \tag{3.11b}$$

here $p_0=p_0(t)\in Q_0^{(1)}$, $A_0=A_0(t)\in Q_0^{(m)}$, both depend on given spectral problem. Then for each j there also must exist uniquely a vector field σ_j with $\sigma_j|_{u=0}=0$ [see (3.18)] and a function matrix $W_j\in\mathscr{S}(Q_0^{(m)})(j=1,2,\ldots,k)$ which satisfy in turn

$$M'[\sigma_j-\eta^{\alpha}\sigma_{j-1}]=W_{j,x}+[W_j,\ M],\quad W_j|_{u=0}=0\quad (j=1,2,...,k). \tag{3.12}$$

Equation (3.11) coupled with (3.12) yields

$$\begin{aligned} M'[\sigma_k]&=M'[\sigma_0]\eta^{\alpha k}+\sum_{j=1}^{k} M'[\sigma_j-\eta^{\alpha}\sigma_{j-1}]\eta^{\alpha(k-j)}\\ &=\sum_{j=0}^{k} W_{j,x}\eta^{\alpha(k-j)}+\left[\sum_{j=0}^{k} W_j\eta^{\alpha(k-j)},\ M\right]-M_{\eta}\eta^{\alpha k+\beta}. \end{aligned} \tag{3.13}$$

That means the vector field σ_k possesses the implicit representation (3.5) where

$$P_k=\sum_{j=0}^{k} W_j\eta^{\alpha(k-j)}\in\mathscr{S}(Q_0^{(m)}),\quad P_k|_{u=0}=(p_0xM|_{u=0}+A_0)\eta^{\alpha k+\beta-1}. \tag{3.14}$$

It should be noted that if Eq. (3.6) has unique solutions meeting Condition (3.7), then the matrix equation

$$M'[X]=N_x+[N,\ M],\quad N|_{u=0}=0, \tag{3.15}$$

only admits zero solutions $X=0$ and $N=0$. As a result, the solutions σ_0 and W_0 of (3.11) are unique, and so is the implicit representation of σ_k.

From the above note, it is easy to know that if Eq. (3.6) possesses solutions $X\in V^{(s)}$ and $N\in\mathscr{S}(Q_0^{(m)})$ meeting Condition (3.7), the two following propositions are equivalent:

(1) The solutions satisfying Eq. (3.6) and Condition (3.7) are unique.
(2) In (3.15), operator M' is an injective homomorphism and from $N|_{u=0}=0$ it can be deduced that $N=0$.

Furthermore, from (3.8), we have

$$M'[K_0]|_{u=0}=0, \quad M'[K_j-\eta^{\alpha}K_{j-1}]|_{u=0}=0 \quad (j=1,2,...,l). \tag{3.16}$$

Because M' is an injective homomorphism (so is $M'|_{u=0}$), (3.16) suggests
