Lemma III.5: Let $r_1,r_2>0$ and $F(u,x)$ be a function meromorphic on the polydisc $C(0,r_1)\times C(0,r_2)$. For any $v\in C(0,r_1)$ such that the function F is holomorphic at $(v,y)(y\in C(0,r_2))$, the function $F(v,x)$ is meromorphic on $C(0,r_2)$.

Proof: Because the polydisc $C(0,r_1)\times C(0,r_2)$ is Stein and $H^2(C(0,r_1)\times C(0,r_2),\mathbb{Z})=0$, the sharp form of the Poincaré theorem is valid on $C(0,r_1)\times C(0,r_2)$. (See, for example, Chap. V, Sec. 2 in Ref. 16 and Secs. I and K in Ref. 17.) Then there exist two functions g and h holomorphic on $C(0,r_1)\times C(0,r_2)$ such that h is not identically zero, $F(u,x)=g(u,x)/h(u,x)$, and the functions g and h are coprime locally. Since the function F is holomorphic at (v,y), we have $h(v,y)\neq 0$, which implies $h(v,x)\not\equiv 0$ on $C(0,r_2)$. Thus the function $g(v,x)/h(v,x)$ is meromorphic on $C(0,r_2)$. For any $x\in C(0,r_2)$ such that $h(v,x)\neq 0$, $F(v,x)=g(v,x)/h(v,x)$. This completes the proof of the lemma. □

Let $u_0,\ v_0\in C(u_1,r_1)$. Because of Lemmas III.3 (2) and III.4, we can apply the method introduced in Sec. II B to Eq. (10) for $u:=u_0$ and $v:=v_0$. That is to say, there exists $C(x_0,r_0)\subset C(x_1,r_1)$ such that $\phi_1(x):=B(v_0,x)$ defined on $C(2x_0,2r_0)$, $\phi_2(x):=B(u_0,-x)B(u_0+v_0,x)$, $\phi_3(x):=B(v_0,x)$, $\phi_4(x):=A(x)A(-x)$, and $\phi_5(x)\equiv 1$ defined on $C(x_0,r_0)$ satisfy the conditions (a)–(c) in Sec. II B.

From Theorems II.1 and II.5, the function $\alpha(x)=\tilde{\xi}_2(x)/\tilde{\xi}_1(x)$ defined near the origin is one of the following.

$$(0)\quad \alpha(x)=C\exp(\rho x),$$

$$(\mathrm{I})\quad \alpha(x)=\exp(\rho x)\frac{\sigma(\mu;\tau_1,\tau_2)\sigma(x+\nu;\tau_1,\tau_2)}{\sigma(\nu;\tau_1,\tau_2)\sigma(x+\mu;\tau_1,\tau_2)},$$

$$(\mathrm{II})\quad \alpha(x)=\exp(\rho x)\frac{a(e^{2x/\lambda}-1)+b}{c(e^{2x/\lambda}-1)+b},$$

$$(\mathrm{III})\quad \alpha(x)=\exp(\rho x)\frac{ax+b}{cx+b}.$$

Lemma III.6: $\alpha(x)\neq C\exp(\rho x)$.

Proof: The proof is by contradiction. Assume the assertion were false. With the aid of Theorem II.5, we get $\alpha(0)=1$, and, consequently, $B(v_0,x)=c^{-1}\exp((\rho-\lambda_1+\lambda_2)(x-2x_0))$ near $2x_0$. Here the constant c was defined in Lemma II.2. From Lemma III.5 and the identity theorem for the meromorphic functions, the above equation is also valid on $C(0,r)$, which implies a contradiction of Assumption 1 (1) by virtue of Eq. (8). □

From this lemma, the function φ is uniquely determined by the function α and so are the functions $\tilde{\xi}_1$ and $\tilde{\xi}_2$.

Proof of Theorem III.1 (1): We first note that Assumption 1 implies the condition $a_1a_4-a_2a_3\neq 0$.

By means of $\phi_5(x)\equiv 1$, we have $\tilde{\phi}_5(x)\equiv 1$ and $\gamma_2(x)=\xi_2'(x)$, and $\tilde{\phi}_4(x)=\xi_2(x)/\xi_2'(x)$ as a result. By the definition in Lemma II.2,

$$A(x)A(-x)$$
$$=\begin{cases}\phi_4(x_0)+\dfrac{\phi_4'(x_0)}{\zeta(x-x_0)-\zeta(x-x_0+\nu)+\lambda_2+\zeta(\nu)}, & \text{(I)}\\ \phi_4(x_0)\\ \quad+\dfrac{\phi_4'(x_0)\left(\exp\left(\dfrac{2(x-x_0)}{\lambda}\right)-1\right)\left\{c\left(\exp\left(\dfrac{2(x-x_0)}{\lambda}\right)-1\right)+1\right\}}{\left(\lambda_2+\dfrac{2c-1}{\lambda}\right)\left(\exp\left(\dfrac{2(x-x_0)}{\lambda}\right)-1\right)\left\{c\left(\exp\left(\dfrac{2(x-x_0)}{\lambda}\right)-1\right)+1\right\}+\dfrac{2}{\lambda}\exp\left(\dfrac{2(x-x_0)}{\lambda}\right)}, & \text{(II)}\\ \phi_4(x_0)+\dfrac{\phi_4'(x_0)(x-x_0)\{c(x-x_0)+1\}}{(\lambda_2+c)(x-x_0)\{c(x-x_0)+1\}+1}, & \text{(III)}\end{cases}$$

near x_0, where $\zeta(x)=\zeta(x;\tau_1,\tau_2)$ is the Weierstrass zeta function $\zeta(x;\tau_1,\tau_2)=\sigma'(x;\tau_1,\tau_2)/\sigma(x;\tau_1,\tau_2)$. With the aid of the identity theorem for the meromorphic functions, the equation above is valid on $C(0,r)$. Because $A(x)A(-x)$ is an even function on $C(0,r)$, we obtain the desired result. □

Now we prove Theorem III.1 (2).

Proposition III.7: Let $u_0\in C(u_1,r_1)$. For any $v_0\in C(u_1,r_1)$, there exist $x_0(v_0)\in C(x_1,r_1)$ and $r_2(v_0)(>0)$ such that the function $B(v_0,x)$ is one of the following: For all $x\in C(2x_0(v_0),r_2(v_0))$,

$$\textit{elliptic:}\quad B(v_0,x)=\exp(\rho(v_0)x)b(v_0)\frac{\sigma(x+a(v_0);\tau_1,\tau_2)}{\sigma(x;\tau_1,\tau_2)},$$

$$\textit{trigonometric:}\quad B(u,x)=\exp(\rho(u)x)\tilde{b}(u)\times\frac{c(u)(\exp((x+2\tilde{a}(u))/\lambda)-\exp(-x/\lambda))+\exp(-x/\lambda)}{\sinh(x/\lambda)},$$

$$\textit{rational:}\quad B(v_0,x)=\exp(\rho(v_0)x)\frac{b(v_0)+a(v_0)x}{x},$$

where $\rho(v_0)$, $a(v_0)$, $b(v_0)\in\mathbb{C}$.

Proof: For the sake of brevity, we only show the elliptic case. For any $v_0\in C(u_1,r_1)$, there exists $C(x_0(v_0),r_0(v_0))\subset C(x_1,r_1)\backslash(\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$ such that $\phi_1(x):=B(v_0,x)$ defined on $C(2x_0(v_0),\ 2r_0(v_0))$, $\phi_2(x):=B(u_0,-x)B(u_0+v_0,x)$, $\phi_3(x):=B(v_0,x)$, $\phi_4(x):=A(x)A(-x)$, and $\phi_5(x)\equiv 1$ defined on $C(x_0(v_0),r_0(v_0))$ satisfy the conditions (a)–(c) in Sec. II B by means of Lemma III.4. Thus we deduce

$$\tilde{\xi}_2(x)=\exp(\zeta(2x_0(v_0);\tau_1,\tau_2)x)\frac{\sigma(2x_0(v_0);\tau_1,\tau_2)\sigma(x;\tau_1,\tau_2)}{\sigma(x+2x_0(v_0);\tau_1,\tau_2)},\tag{11}$$

where τ_1 and τ_2 are in Theorem III.1 (1).

Lemma III.8: $\alpha(x)\neq 0$, $\exp(\rho x)$.

The proof is quite similar to that of Lemma III.6, so we omit it. Equation (11) tells us that the zeroes of the function $\tilde{\xi}_2$ are $\mathbb{Z}\tau_1+\mathbb{Z}\tau_2$. Hence the function α is an elliptic solution of Eq. (4) by means of Lemma III.8, and the periods of the Weierstrass sigma function σ in the function α are τ_1 and τ_2 as a consequence. (See Secs. 3 and 4 in Ref. 14.) Thus there exists $(0<)r_2<2r_1$ such that

$$\tilde{\xi}_1(x)=\exp(\zeta(\mu;\tau_1,\tau_2)x)\,\frac{\sigma(\mu;\tau_1,\tau_2)\sigma(x;\tau_1,\tau_2)}{\sigma(x+\mu;\tau_1,\tau_2)}$$

on $C(0,r_2)$. From Lemma II.2, Theorem II.5, Eq. (11) and $\phi_1(x)=B(v_0,x)$, we have proved the proposition. □

Proof of Theorem III.1 (2): For the sake of brevity, we only prove the elliptic case. For any $v_0\in C(u_1,r_1)$, the function $B(v_0,x)$ is meromorphic on $C(0,r)$ by Lemma III.5. On the other hand, by Proposition III.7,

$$B(v_0,x)=\exp(\rho(v_0)x)b(v_0)\,\frac{\sigma(x+a(v_0))}{\sigma(x)}$$

on some small disk in $C(0,r)$. Because the right hand side of the equation above is meromorphic on $C(0,r)$, we have proved the theorem. □

IV. ELLIPTIC CASE

This section presents the solutions A and B of Eqs. (8) and (9) in the elliptic case of Theorem III.1.

Lemma IV.1: For all $u\in C(u_1,r_1)$, $\sigma(a(u))\neq 0$ *and* $b(u)\neq 0$.

Proof: We only show that $\sigma(a(u))\neq 0$ for all $u\in C(u_1,r_1)$. The proof is by contradiction. Assume the assertion were false. Then there would exist $u\in C(u_1,r_1)$ such that $\sigma(a(u))=0$. By means of Eq. (6), there exist functions $\tilde{\rho}$ and $\tilde{b}$ such that $B(u,x)=\exp(\tilde{\rho}(u)x)\tilde{b}(u)$ for all $x\in C(x_1,r_1)\backslash(\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$, and this equation is also valid on $C(0,r)$ from Lemma III.5. By Eq. (8), this contradicts Assumption 1 (1). □

By virtue of Eqs. (5), (6), (8) and the lemma above, we conclude Lemma IV.2.

Lemma IV.2: We have $a_3=0$, *that is to say,* $A(x)A(-x)=\tilde{a}_1\wp(x)+\tilde{a}_2$ *on* $C(0,r)$, *where* $\tilde{a}_1=a_1/a_4$ *and* $\tilde{a}_2=a_2/a_4$.

We note that the relation $a_1a_4-a_2a_3\neq 0$ implies $\tilde{a}_1\neq 0$. It follows from the Lemma IV.2 and Eq. (8) that $b(u)^2\sigma^2(a(u))=-\tilde{a}_1$ for all $u\in C(u_1,r_1)$.

Lemma IV.3: There exist $c\in\mathbb{C}\backslash\{0\}$ *and* $C(u_2,r_2)\subset C(u_1,r_1)$ *such that* $b(u)\sigma(a(u))=c$ *for all* $u\in C(u_2,r_2)$, *and*

$$B(u,x)=c\,\exp(\rho(u)x)\,\frac{\sigma(x+a(u))}{\sigma(a(u))\sigma(x)}$$

for all $(u,x)\in D_1\cap D^e\cap(C(u_2,r_2)\times C(0,r))$ *as a consequence.*

For the proof, it suffices to show the following lemma.

Lemma IV.4: There exists $C((u_2,0),r_2)\subset C(u_1,r_1)\times C(0,r)$ *such that the function* $B(u,x)\sigma(x)$ *is holomorphic on* $C((u_2,0),r_2)$.

Proof: Since the sharp form of the Poincaré theorem is valid on $C((0,0),r)$, there exist two functions g and h holomorphic on $C((0,0),r)$ such that h is not identically zero, $B(u,x)\sigma(x)=g(u,x)/h(u,x)$, and the functions g and h are coprime locally. By Eq. (6), $g(u,x)=\exp(\rho(u)x)b(u)\sigma(x+a(u))h(u,x)$ for all $(u,x)\in D_1\cap D^e\cap(C(u_1,r_1)\times C(0,r))$.

We fix any $u\in C(u_1,r_1)$. Because the function $\exp(\rho(u)x)b(u)\sigma(x+a(u))$ is holomorphic on $C(0,r)$ and $g(u,x)=\exp(\rho(u)x)b(u)\sigma(x+a(u))h(u,x)$ for all $x\in C(x_1,r_1)\backslash(\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$, we have $g(u,x)=\exp(\rho(u)x)b(u)\sigma(x+a(u))h(u,x)$ for all $x\in C(0,r)$. Thus $g(u,0)=b(u)\sigma(a(u))h(u,0)$, which tells us that $(u,0)$ is not a pole of the function $B(u,x)\sigma(x)$ for all $u\in C(u_1',r_1')$. Since the set of points of indeterminacy of the meromorphic function of two variables is isolated, there exists a regular point $(u_2,0)\in C(u_1',r_1')\times C(0,r)$ of the function $B(u,x)\sigma(x)$. We have thus proved the lemma. □

Using Eq. (8), we are led to the following theorem.

Theorem IV.5: *The elliptic solution* $A(x)$ *defined on* $C(0,r)$ *is*

$$A(x)=c\cdot h(x)\frac{\sigma(x+s)}{\sigma(x)\sigma(s)},$$

where $h(x)$ *is a meromorphic function defined on* $C(0,r)$ *satisfying the relation* $h(x)h(-x)=1$ *and* s *is a complex constant such that* $\wp(s)=-\tilde{a}_2/\tilde{a}_1$.

In the sequel, we determine the function B.

Proposition IV.6: There exists $C(u_3',\delta')\subset C(u_2,r_2)$ *such that*

$$B(u,x)=\exp(\tilde{\rho}(u)x)\frac{\sigma(x+a_1(u))}{\sigma(a_1(u))\sigma(x)}$$

for all $(u,x)\in D_1\cap D^e\cap(C(u_3',\delta')\times C(0,r))$, *where the function* a_1 *is holomorphic on* $C(u_3',\delta')$.

We only give the proof in the case that there exists $v_1\in C(u_2,r_2)$ such that $\wp'(a(v_1))\neq 0$ because the proof is rather simple in the case that $\wp'(a(u))\equiv 0$ on $C(u_2,r_2)$. The function $\wp(x)$ is holomorphic at $x=a(v_1)$ by using Lemma IV.1, and the function $\wp$ has a holomorphic inverse g near $a(v_1)$ as a result. (See, for example, p. 215 of Ref. 18.) Then there exists $C(v_1,\delta)\subset C(u_2,r_2)$ such that $\wp(a(u))$ is in the domain of the function g for all $u\in C(v_1,\delta)$. Define a function $\tilde{a}$ holomorphic on $C(v_1,\delta)$ as $\tilde{a}(u)=g(\wp(a(u)))$. There exists a function $\epsilon(u)\in\{0,1\}$ such that $a(u)\equiv(-1)^{\epsilon(u)}\tilde{a}(u)\ (\mathrm{mod}\,\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$ for all $u\in C(v_1,\delta)$, and consequently

$$B(u,x)=\exp(\tilde{\rho}(u)x)(-1)^{\epsilon(u)}\frac{\sigma(x+(-1)^{\epsilon(u)}\tilde{a}(u))}{\sigma(\tilde{a}(u))\sigma(x)}$$

for all $(u,x)\in D_1\cap D^e\cap(C(v_1,\delta)\times C(0,r))$, where $\tilde{\rho}(u)\in\mathbb{C}$.

Proposition IV.6 now follows from the following lemma.

Lemma IV.7: There exist $C(v_1',\delta')\subset C(v_1,\delta)$ *such that* $a(u)\equiv\tilde{a}(u)(\mathrm{mod}\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$ *for all* $u\in C(v_1',\delta')$ *or* $a(u)\equiv-\tilde{a}(u)(\mathrm{mod}\,\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)$ *for all* $u\in C(v_1',\delta')$.

To prove this lemma, it suffices to give the proof in the case that, for all $C(u,\delta_1)\subset C(v_1,\delta)$, there exist $v,w\in C(u,\delta_1)$ such that $\epsilon(v)\neq\epsilon(w)$. By the sharp form of the Poincaré theorem, there exist two functions g and h holomorphic on $C((0,0),r)$ such that h is not identically zero, $B(u,x)\sigma(x)=g(u,x)/h(u,x)$, and the functions g and h are coprime locally. We omit the proof of the lemma below because it is similar to that of Lemma IV.4.

Lemma IV.8: There exists $C(u_3',\delta')\subset C(v_1,\delta)$ *satisfying the following conditions.*

(1) *The function* $B(u,x)\sigma(x)$ *is holomorphic on* $C((u_3',0),\delta')$.
(2) *For all* $(u,x)\in C((u_3',0),\delta')$,

$$c\exp(\tilde{\rho}(u)x)(-1)^{\epsilon(u)}\frac{\sigma(x+(-1)^{\epsilon(u)}\tilde{a}(u))}{\sigma(\tilde{a}(u))}h(u,x)=g(u,x).$$

By means of Lemma IV.8,

$$\exp(\tilde{\rho}(u)x)(-1)^{\epsilon(u)}\sigma(x+(-1)^{\epsilon(u)}\tilde{a}(u))=c^{-1}B(u,x)\sigma(x)\sigma(\tilde{a}(u))$$

for all $(u,x)\in C((u_3',0),\delta')$. Since the function $\tilde{a}(u)$ is holomorphic on $C(u_3',\delta')$, the function $f(u,x):=c^{-1}B(u,x)\sigma(x)\sigma(\tilde{a}(u))$ is holomorphic on $C((u_3',0),\delta')$. The function $(\partial f/\partial x)(u,0)$ is consequently holomorphic on $C(u_3',\delta')$, and

$$\frac{\partial f}{\partial x}(u,0)=\tilde{\rho}(u)\sigma(\tilde{a}(u))+(-1)^{\epsilon(u)}\sigma'(\tilde{a}(u)) \tag{12}$$

for all $u\in C(u_3',\delta')$.

By $B\not\equiv 0$ and Lemma IV.1, we conclude the following.

Lemma IV.9: There exists $C((u_3'',x_3''),\delta'')\subset C((u_3',0),\delta')$ *satisfying the following conditions.*

(1) $C(x_3'',\delta'')\not\ni 0$.
(2) $f(u,x)\neq 0$ *for all* $(u,x)\in C((u_3'',x_3''),\delta'')$.
(3) $\sigma(x-\tilde{a}(u))\neq 0$ *for all* $(u,x)\in C((u_3'',x_3''),\delta'')$.
(4) $\sigma(x+\tilde{a}(u))\neq 0$ *for all* $(u,x)\in C((u_3'',x_3''),\delta'')$.

Lemma IV.7 follows from Lemma IV.10 immediately.

Lemma IV.10: For all $u\in C(u_3'',\delta'')$, $2\tilde{a}(u)\in\mathbb{Z}\tau_1+\mathbb{Z}\tau_2$.

Proof: To prove this lemma, we show

$$-\frac{\sigma(x_3+\tilde{a}(u_3))}{\sigma(x_3-\tilde{a}(u_3))}=\exp(2x_3\zeta(\tilde{a}(u_3)))$$

for all $(u_3,x_3)\in C((u_3'',x_3''),\delta'')$. From Lemma IV.9, the functions $-f(u,x)/\sigma(x-\tilde{a}(u))$ and $f(u,x)/\sigma(x+\tilde{a}(u))$ are holomorphic on $C((u_3'',x_3''),\delta'')$ and satisfy $-f(u,x)/\sigma(x-\tilde{a}(u))\neq 0$ and $f(u,x)/\sigma(x+\tilde{a}(u))\neq 0$ for all $(u,x)\in C((u_3'',x_3''),\delta'')$. For any $(u_3,x_3)\in C((u_3'',x_3''),\delta'')$, let $\mathrm{Log}^{(1)}(x)$ and $\mathrm{Log}^{(2)}(x)$ be branches of the logarithm defined on open connected sets $V_1,V_2\subset\mathbb{C}$ such that $\exp(\tilde{\rho}(u_3)x_3)\in V_1$ and $(-1)^{\epsilon(u_3)+1}f(u_3,x_3)/\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(u_3))\in V_2$, respectively. Because the function $(-1)^{\epsilon(u_3)+1}f(u,x)/\sigma(x+(-1)^{\epsilon(u_3)+1}\tilde{a}(u))$ is continuous at $(u,x)=(u_3,x_3)$, there exist $\tilde{\epsilon}>0$ and $\tilde{\delta}>0$ satisfying the following conditions.

(1) $C((-1)^{\epsilon(u_3)+1}f(u_3,x_3)/\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(u_3)),\tilde{\epsilon})\subset V_2$.
(2) $C((u_3,x_3),\tilde{\delta})\subset C((u_3'',x_3''),\delta'')$.
(3) For all $(u,x)\in C((u_3,x_3),\tilde{\delta})$

$$\frac{(-1)^{\epsilon(u_3)+1}f(u,x)}{\sigma(x+(-1)^{\epsilon(u_3)+1}\tilde{a}(u))}\in C\left(\frac{(-1)^{\epsilon(u_3)+1}f(u_3,x_3)}{\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(u_3))},\tilde{\epsilon}\right).$$

Let $N\in\mathbb{N}$ such that $1/N<\tilde{\delta}$. For all $n\geqslant N$, there exists $\tilde{u}_n\in C(u_3,1/n)$ such that $\epsilon(\tilde{u}_n)\neq\epsilon(u_3)$. (This is the case which we now consider.) Then we have $\epsilon(\tilde{u}_n)\equiv\epsilon(u_3)+1\ (\mathrm{mod}\ 2)$, $\lim_{n\to\infty}\tilde{u}_n=u_3$, and $(-1)^{\epsilon(u_3)+1}f(\tilde{u}_n,x_3)/\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(\tilde{u}_n))\in V_2$ for all $n\geqslant N$. By the conditions (1) and (2) above, $\exp(\tilde{\rho}(\tilde{u}_n)x_3)\in V_2$ for all $n\geqslant N$, and, consequently,

$$\tilde{\rho}(\tilde{u}_n)x_3=\mathrm{Log}^{(2)}\left(\frac{(-1)^{\epsilon(u_3)+1}f(\tilde{u}_n,x_3)}{\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(\tilde{u}_n))}\right)$$

for all $n\geqslant N$. On account of Eq. (12),

$$\begin{aligned}\frac{\partial f}{\partial x}(u_3,0)&=\lim_{n\to\infty}\frac{\partial f}{\partial x}(\tilde{u}_n,0)\\&=\frac{1}{x_3}\mathrm{Log}^{(2)}\left(\frac{(-1)^{\epsilon(u_3)+1}f(u_3,x_3)}{\sigma(x_3+(-1)^{\epsilon(u_3)+1}\tilde{a}(u_3))}\right)\sigma(\tilde{a}(u_3))+(-1)^{\epsilon(u_3)+1}\sigma'(\tilde{a}(u_3)).\end{aligned}$$

Because of $\exp(\tilde{\rho}(u_3)x_3)\in V_1$,

$$\frac{\partial f}{\partial x}(u_3,0)=\frac{1}{x_3}\mathrm{Log}^{(1)}\left(\frac{(-1)^{\epsilon(u_3)}f(u_3,x_3)}{\sigma(x_3+(-1)^{\epsilon(u_3)}\tilde{a}(u_3))}\right)\sigma(\tilde{a}(u_3))+(-1)^{\epsilon(u_3)}\sigma'(\tilde{a}(u_3)).$$

By the straightforward calculation, we obtain the desired result, thereby completing the proof of Proposition IV.6. □

Proposition IV.11: There exists $C(u_3,r_3)\subset C(u_1,r_1)$ *such that*

$$B(u,x)=\exp(\rho_1(u)x)\,\frac{\sigma(x+a_1(u))}{\sigma(a_1(u))\sigma(x)} \tag{13}$$

as meromorphic functions on $C(u_3,r_3)\times C(0,r)$, *where the functions* ρ_1 and a_1 *are holomorphic on* $C(u_3,r_3)$.

Proof: It is enough to show that the function $\tilde{\rho}$ in Proposition IV.6 is holomorphic locally. Define $f_1(u,x):=e^{\tilde{\rho}(u)}\sigma(x+a_1(u))$. Since the function f_1 is expressed as $f_1(u,x)=c^{-1}B(u,x)\sigma(x)\sigma(a_1(u))$, there exists $C((u_3'',0),\delta'')\subset C((u_3',0),\delta')$ such that the function f_1 is holomorphic on $C((u_3'',0),\delta'')$ (see Lemma IV.4), and $(\partial f/\partial x)(u,0)=\tilde{\rho}(u)\sigma(a_1(u))+\sigma'(a_1(u))$ on $C(u_3'',\delta'')$ as a result. By Lemma IV.1, we are led to $\sigma(a_1(u))\neq 0$ on $C(u_3'',\delta'')$, thereby completing the proof. □

Proposition IV.12: We have $\rho_1(u)=\rho u+\rho_3$ *and* $a_1(u)=au+a_3$, *where* ρ, ρ_3, a, $a_3\in\mathbb{C}$. For the proof, we need the following.

Lemma IV.13: There exist $C(u_4,r_4)\subset C(u_3,r_3)$ *and a function* a_4 *holomorphic on* $C(u_4,r_4)$ *such that* $\sigma(a_4(u)+a_1(v))\neq 0$ *for all* $u,v\in C(u_4,r_4)$ *and* $\sigma(a_4(u))\neq 0$ *for all* $u\in C(u_4,r_4)$.

Proof: If $\sigma(2a_1(u))\not\equiv 0$ on $C(u_3,r_3)$, put $a_4:=a_1$. The proof in the case that $\sigma(2a_1(u))\equiv 0$ on $C(u_3,r_3)$ is simple, so we omit it. □

We take $C(\tilde{x}_1,\tilde{r}_1)\subset(C(x_1,r_1)\backslash(\mathbb{Z}\tau_1+\mathbb{Z}\tau_2))$ such that $C(2\tilde{x}_1,2\tilde{r}_1)\cap(\mathbb{Z}\tau_1+\mathbb{Z}\tau_2)=\emptyset$. From Theorem IV.5 and the three term identity of σ (see, for example, p. 377 of Ref. 19 and p. 461 of Ref. 20),

$$\begin{aligned}&\frac{B(v,x+y)(A(x)A(-x)-A(y)A(-y))}{B(v,x)B(v,y)}\\&\quad=\frac{c\sigma(a_1(v))}{\sigma(a_4(u))\sigma(a_4(u)+a_1(v))}\\&\qquad\times\left(\frac{\sigma(x+a_4(u)+a_1(v))\sigma(x-a_4(u))}{\sigma(x)\sigma(x+a_1(v))}-\frac{\sigma(y+a_4(u)+a_1(v))\sigma(y-a_4(u))}{\sigma(y)\sigma(y+a_1(v))}\right)\end{aligned}$$

for all $u,v\in C(u_4,r_4)$ and $x,y\in C(\tilde{x}_1,\tilde{r}_1)$. By virtue of Eq. (10), for all $u,v\in C(u_4,r_4)$, there exists a constant $\gamma(u,v)\in\mathbb{C}$ such that

$$\frac{B(u,-x)B(u+v,x)}{B(v,x)}=\frac{c\sigma(a_1(v))\sigma(x+a_4(u)+a_1(v))\sigma(x-a_4(u))}{\sigma(x)\sigma(x+a_1(v))\sigma(a_4(u))\sigma(a_4(u)+a_1(v))}+\gamma(u,v) \tag{14}$$

for all $x,y\in C(\tilde{x}_1,\tilde{r}_1)$.

From Lemma III.3 and $C((2u_4,2x_1),2r_4)\subset C((0,0),r/2)$, there exist $(u_1',x_1')\in C((2u_4,2x_1),2r_4)$ and $r_1'(>0)$ such that the conditions in Lemma III.3 hold. The proof of Lemma IV.14 is similar to that of Proposition IV.11, so we omit it.

Lemma IV.14: There exists $C(u_3',r_3')\subset C(u_1',r_1')$ *such that*

$$B(u,x)=\pm c\,\exp(\rho_2(u)x)\,\frac{\sigma(x+a_2(u))}{\sigma(x)\sigma(a_2(u))} \tag{15}$$

as meromorphic functions on $C(u_3',r_3')\times C(0,r)$ *with the functions* ρ_2 *and* a_2 *holomorphic on* $C(u_3',r_3')$.

Proof of Proposition IV.12: By Eqs. (13)–(15),

$$\pm\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)\sigma(x-a_1(u))\sigma(x+a_2(u+v))$$
$$\times\sigma(a_1(v))\sigma(a_4(u))\sigma(a_4(u)+a_1(v))$$
$$=\sigma(a_1(v))\sigma(x+a_4(u)+a_1(v))\sigma(x-a_4(u))\sigma(a_1(u))\sigma(a_2(u+v))$$
$$+\gamma(u,v)\sigma(a_4(u))\sigma(x)\sigma(a_2(u+v))\sigma(x+a_1(v))\sigma(a_4(u)+a_1(v))$$

for any $x\in C(\tilde{x}_1,\tilde{r}_1)$ and $u,v\in C(u_3'/2,r_3'/2)$. We note that the equation above is valid on $\mathbb{C}$ $(\ni x)$ also by means of the identity theorem for the holomorphic functions. Since the both sides of the equation above are quasi-periodic with the periods τ_1 and $\tau_2, a_2(u+v)-a_1(u)-a_1(v)\in\mathbb{Z}\tau_1+\mathbb{Z}\tau_2$. Because the functions a_1 and a_2 are holomorphic and the set $\mathbb{Z}\tau_1+\mathbb{Z}\tau_2$ is discrete, the function $a_2(u+v)-a_1(u)-a_1(v)$ is constant on $C((u_3'/2,u_3'/2),r_3'/2)$ and so is the function $\rho_2(u+v)-\rho_1(u)-\rho_1(v)$. Hence we get the desired result. □

It is to be noted that $\rho_2(u)=\rho u+\rho_4$ and that $a_2(u)=au+a_4$, where $\rho_4,a_4\in\mathbb{C}$. By the straightforward computation, we deduce the following.

Theorem IV.15: *The elliptic solution $B(u,x)$ of Eqs. (8) and (9) defined on the polydisc $C((0,0),r)$ is*

$$B(u,x)=c\exp(\rho ux)\frac{\sigma(x+au)}{\sigma(x)\sigma(au)},$$

where $a\in\mathbb{C}\backslash\{0\}$ and $\rho\in\mathbb{C}$.

V. TRIGONOMETRIC CASE

In this section, we solve Eqs. (8) and (9) in the trigonometric case of Theorem III.1.

The proof of Lemma V.1 is the same as that of Lemmas IV.1 and IV.2, so we omit the proof.

Lemma V.1: (1) *For all $u\in C(u_1,r_1)$, $c(u)(\exp(2\tilde{a}(u)/\lambda)-1)+1\neq 0$ and $\tilde{b}(u)\neq 0$.*

(2) *We have $a_3=0$, that is to say, $A(x)A(-x)=\tilde{a}_1\sinh^{-2}(x/\lambda)+\tilde{a}_2$ on $C(0,r)$, where $\tilde{a}_1=a_1/a_4$ and $\tilde{a}_2=a_2/a_4$.*

From Eqs. (7), (8) and Lemma V.1 (2),

$$A(x)A(-x)-B(u,x)B(u,-x)=\tilde{a}_2+4\tilde{b}(u)^2\exp\left(\frac{2\tilde{a}(u)}{\lambda}\right)c(u)(1-c(u)) \tag{16}$$

for all $u\in C(u_1,r_1), x\in C(x_1,r_1)\backslash\mathbb{Z}\pi\sqrt{-1}\lambda$.

Lemma V.2: There exists $C(u_1',r_1')\subset C(u_1,r_1)$ such that

$$B(u,x)=\exp(\rho(u)x)b(u)\frac{\sinh(x+a(u))/\lambda}{\sinh(x/\lambda)},\quad \text{or}\quad B(u,x)=\exp(\rho(u)x)b(u)\frac{1}{\sinh(x/\lambda)}$$

for any $(u,x)\in D_1\cap D^t\cap(C(u_1',r_1')\times C(0,r))$.

If there exists $C(u_1',r_1')\subset C(u_1,r_1)$ such that $c(u)-c(u)^2\neq 0$ for all $u\in C(u_1',r_1')$, then there exists $a(u)\in\mathbb{C}$ such that $c(u)=\exp(a(u)/\lambda)/(2\sinh(a(u)/\lambda))$ for all $u\in C(u_1',r_1')$. For the proof of Lemma V.2, it suffices to show the following lemma.

Lemma V.3: If, for all $C(u,\tilde{r})\subset C(u_1,r_1)$, there exists $u_0\in C(u,\tilde{r})$ such that $c(u_0)-c(u_0)^2=0$, then $c(u)=0$ or 1 for all $u\in C(u_1,r_1)$.

Proof: The proof is by contradiction. Assume the assertion were false. Then there would exist $u_0'\in C(u_1,r_1)$ such that $c(u_0')\neq 0, 1$. We take $N\in\mathbb{N}$ such that $C(u_0',1/N)\subset C(u_1,r_1)$. For all $n\geqslant N$, there exists $u_n\in C(u_0',1/n)$ such that $c(u_n)-c(u_n)^2=0$ and, for all $n\geqslant N$,

$$\tilde{a}_2+4\tilde{b}(u_n)^2\exp\left(\frac{2\tilde{a}(u_n)}{\lambda}\right)c(u_n)(1-c(u_n))=\tilde{a}_2$$

as a result. The left hand side of Eq. (16) is holomorphic on $C(u_1,r_1)$ for a fixed $x \in C(x_1,r_1)\backslash\mathbb{Z}\pi\sqrt{-1}\lambda$, so it is continuous. Since $\lim_{n\to\infty} u_n = u_0'$,

$$\tilde{a}_2 + 4\tilde{b}(u_0')^2 \exp\left(\frac{2\tilde{a}(u_0')}{\lambda}\right) c(u_0')(1-c(u_0')) = \tilde{a}_2,$$

which is a contradiction of the choice of u_0' and Lemma V.1 (1). □

The proof of the theorem below is the same as that in Sec. IV, so we omit it.

Theorem V.4: (1) *The trigonometric solution $A(x)$ of Eqs. (8) and (9) defined on the polydisc $C(0,r)$ is*

$$A(x) = c\cdot h(x)\frac{\sinh(x+s)/\lambda}{\sinh(x/\lambda)\sinh(s/\lambda)} \quad or \quad c\cdot h(x)\frac{1}{\sinh(x/\lambda)},$$

where $c \in \mathbb{C}\backslash\{0\}$, $s \in \mathbb{C}\backslash\mathbb{Z}\pi\sqrt{-1}\lambda$ and $h(x)$ is a meromorphic function defined on $C(0,r)$ satisfying the relation $h(x)h(-x)=1$.

(2) *There exists $C(u_3,r_3)\subset C(u_1,r_1)$ such that the trigonometric solution $B(u,x)$ of Eqs. (8) and (9) is expressed as*

$$B(u,x) = c\exp(\rho_1(u)x)\frac{\sinh(x+a_1(u))/\lambda}{\sinh(a_1(u)/\lambda)\sinh(s/\lambda)}, \quad or \quad c\exp(\rho_1(u)x)\frac{1}{\sinh(x/\lambda)}$$

on $C(u_3,r_3)\times C(0,r)$. Here the functions ρ_1 and a_1 are holomorphic on $C(u_3,r_3)$.

(3) *There exist $C(u_4,r_4)\subset C(u_3,r_3)$ and a function a_4 holomorphic on $C(u_4,r_4)$ such that* $\sinh((a_4(u)+a_1(v))/\lambda)\neq 0$ *and* $\sinh(a_4(u)/\lambda)\neq 0$ *for all $u \in C(u_4,r_4)$.*

(4) *There exists $C(u_3',r_3')\subset C(2u_4,2r_4)$ such that the trigonometric solution $B(u,x)$ of Eqs. (8) and (9) is expressed as follows*:

$$B(u,x) = \pm c\exp(\rho_2(u)x)\frac{\sinh(x+a_2(u))/\lambda}{\sinh(a_2(u)/\lambda)\sinh(x/\lambda)} \quad or \quad \pm c\exp(\rho_2(u)x)\frac{1}{\sinh(x/\lambda)}$$

on $C(u_3',r_3')\times C(0,r)$. Here the functions ρ_2 and a_2 are holomorphic on $C(u_3',r_3')$.

We take $C(\tilde{x}_1,\tilde{r}_1)\subset(C(x_1,r_1)\backslash\mathbb{Z}\pi\sqrt{-1}\lambda)$ as $C(2\tilde{x}_1,2\tilde{r}_1)\cap\mathbb{Z}\pi\sqrt{-1}\lambda=\emptyset$, and fix any $u,v \in C(u_3'/2,r_3'/2)$. From Eq. (10) there exists $\gamma(u,v)\in\mathbb{C}$ such that

$$\frac{B(u,-x)B(u+v,x)}{B(v,x)} = \begin{cases} \dfrac{c\sinh(a_1(v)/\lambda)\sinh((x+a_4(u)+a_1(v))/\lambda)\sinh(x-a_4(u))/\lambda}{\sinh((a_4(u)+a_1(v))/\lambda)\sinh((a_4(u)/\lambda)\sinh(x/\lambda)\sinh((x+a_1(v))/\lambda)} + \gamma(u,v), \\ \dfrac{-c\exp(-x/\lambda)}{\sinh(x/\lambda)} + \gamma(u,v), \end{cases} \tag{17}$$

for all $x \in C(\tilde{x}_1,\tilde{r}_1)$, and, as a result, we are led to the four cases below:

$$\mp\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)\times\frac{\sinh((x+a_2(u+v))/\lambda)\sinh((-x+a_1(u))/\lambda)\sinh(a_1(v)/\lambda)}{\sinh(a_2(u+v)/\lambda)\sinh(a_1(u)/\lambda)}$$
$$=\frac{c\sinh(a_1(v)/\lambda)\sinh((x+a_4(u)+a_1(v))/\lambda)\sinh((x-a_4(u))/\lambda)}{\sinh((a_4(u)+a_1(v))/\lambda)\sinh(a_4(u)/\lambda)}+\gamma(u,v)\sinh\frac{x}{\lambda}\sinh\frac{x+a_1(v)}{\lambda},\tag{18}$$

$$\mp\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)\frac{\sinh((-x+a_1(u))/\lambda)\sinh(a_1(v)/\lambda)}{\sinh(a_1(u)/\lambda)}$$
$$=\frac{c\sinh(a_1(v)/\lambda)\sinh((x+a_4(u)+a_1(v))/\lambda)\sinh((x-a_4(u))/\lambda)}{\sinh((a_4(u)+a_1(v))/\lambda)\sinh(a_4(u)/\lambda)}+\gamma(u,v)\sinh\frac{x}{\lambda}\sinh\frac{x+a_1(v)}{\lambda},\tag{19}$$

$$\mp c\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)\frac{\sinh((x+a_2(u+v))/\lambda)}{\sinh(a_2(u+v)/\lambda)}=-c\exp\left(-\frac{x}{\lambda}\right)+\gamma(u,v)\sinh\frac{x}{\lambda},\tag{20}$$

$$\mp c\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)=-c\exp\left(-\frac{x}{\lambda}\right)+\gamma(u,v)\sinh\frac{x}{\lambda},\tag{21}$$

for any $x\in C(\tilde{x}_1,\tilde{r}_1)$. We note that the equations above are valid on $\mathbb{C}$. Substitution of 0 in x yields that all the signatures of Eqs. (18)–(21) are -1. From the periodicity of Eqs. (18)–(21),

$$\mp\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))\pi\sqrt{-1}\lambda)=1,\tag{22}$$

and consequently, we have the following.

Lemma V.5: There exist $\rho,\rho_3,\rho_4\in\mathbb{C}$ *such that* $\rho_1(u)=\rho u+\rho_3$ *for all* $u\in C(u_3,r_3)$ *and* $\rho_2(u)=\rho u+\rho_4$ *for all* $u\in C(u_3',r_3')$.

In the case of (20), we can express the function B in two ways

$$B(u,x)=c\exp((\rho u+\rho_3)x)\frac{1}{\sinh(x/\lambda)},c\exp((\rho u+\rho_4)x)\frac{\sinh((x+a_2(u))/\lambda)}{\sinh(a_2(u)/\lambda)\sinh(x/\lambda)}.$$

This is a contradiction. In the case of (19), we deduce a contradiction in a similar fashion.

From Eq. (22) there exists $n\in\mathbb{Z}$ such that $\rho_4-2\rho_3=n/\lambda$, and one can regard Eqs. (18) and (21) as the polynomials of the variable $\exp(x/\lambda)$. Thus we deduce the following.

Proposition V.6: On $C((0,0),r)$

$$B(u,x)=\begin{cases}c\exp((\rho u+\rho_3)x)\dfrac{\sinh((x+au+a_3)/\lambda)}{\sinh(x/\lambda)\sinh((au+a_3)/\lambda)} & \text{for (18)},\\[2ex] c\exp((\rho u+\rho_4)x)\dfrac{1}{\sinh(x/\lambda)} & \text{for (21)},\end{cases}$$

where $a,a_3\in\mathbb{C}$.

From Eq. (17) we get $\rho_3=0$, $\rho_4=\pm 1/\lambda$ and $a_3\in\mathbb{Z}\pi\sqrt{-1}\lambda$, that is to say,

Theorem V.7: *The trigonometric solution $B(u,x)$ of Eqs. (8) and (9) defined on the polydisc $C((0,0),r)$ is*

$$B(u,x)=c\exp(\rho ux)\frac{\sinh(x+au)/\lambda}{\sinh(x/\lambda)\sinh(au/\lambda)},\quad \textit{or}\quad c\exp(\rho ux)\frac{\exp(\pm x/\lambda)}{\sinh(x/\lambda)},$$

where c is in Theorem V.4, *$a\in\mathbb{C}\backslash\{0\}$ and $\rho\in\mathbb{C}$.*

VI. RATIONAL CASE

In this section, we continue solving Eqs. (8) and (9) in the rational case of Theorem III.1.

The proof of Theorem VI.1 is the same as that in Sec. IV, so we omit it.

Theorem VI.1: (1) *The rational solution $A(x)$ of Eqs. (8) and (9) defined on the polydisc $C(0,r)$ is*

$$A(x)=c\cdot h(x)\frac{x+s}{xs},\quad \textit{or}\quad c\cdot h(x)\frac{1}{x},$$

where $c,s\in\mathbb{C}\backslash\{0\}$ and $h(x)$ is a meromorphic function defined on $C(0,r)$ satisfying the relation $h(x)h(-x)=1$.

(2) *There exist $C(u_3,r_3)\subset C(u_1,r_1)$ and $C(u_3',r_3')\subset C(2u_3,2r_3)$ such that the rational solution $B(u,x)$ of Eqs. (8) and (9) is expressed as follows:*

$$B(u,x)=\begin{cases}\exp(\rho_1(u)x)\dfrac{a_1(u)x+c}{x}, & \textit{on}\quad C(u_3,r_3)\times C(0,r),\\[2ex] \exp(\rho_2(u)x)\dfrac{a_2(u)x\pm c}{x}, & \textit{on}\quad C(u_3',r_3')\times C(0,r).\end{cases}$$

Here the functions ρ_1 and a_1 are holomorphic on $C(u_3,r_3)$ and the functions ρ_2 and a_2 are holomorphic on $C(u_3',r_3')$.

We fix any $u,v\in C(u_3'/2,r_3'/2)$. From Eq. (10), there exists $\gamma(u,v)\in\mathbb{C}$ such that

$$\frac{B(u,-x)B(u+v,x)}{B(v,x)}=-\frac{c^2}{x(a_1(v)x+c)}+\gamma(u,v)$$

for all $x\in C(x_1,r_1)\backslash\{0\}$, and consequently

$$\exp((\rho_2(u+v)-\rho_1(u)-\rho_1(v))x)=\frac{c^2}{(-a_1(u)x+c)(a_2(u+v)x\pm c)}-\frac{\gamma(u,v)x(a_1(v)x+c)}{(-a_1(u)x+c)(a_2(u+v)x\pm c)}\tag{23}$$

for all $x\in C(x_1,r_1)\backslash\{0\}$. Since the equation above is valid on $\mathbb{C}$, we obtain the following.

Lemma VI.2: There exist $\rho,\rho_3\in\mathbb{C}$ such that $\rho_1(u)=\rho u+\rho_3$ for all $u\in C(u_3,r_3)$ and $\rho_2(u)=\rho u+2\rho_3$ for all $u\in C(u_3',r_3')$.

From Eq. (23), $a_1(u)a_2(u+v)=(a_1(u)-a_2(u+v))a_1(v)$ for all $u,v\in C(u_3'/2,r_3'/2)$, which implies the following.

Lemma VI.3: The function $a_1(u)$ is identically zero on $C(u_3,r_3)$, or there exists $a,a_3\in\mathbb{C}$ such that

$$\frac{1}{a_1(u)}=\frac{au}{c}+\frac{a_3}{c},\quad \forall u\in C(u_3,r_3),$$

$$\frac{1}{a_2(u)}=\frac{au}{c}+\frac{2a_3}{c},\quad \forall u\in C(u_3',r_3').$$

By the straightforward computation, we deduce the following.

Theorem VI.4: *The rational solution $B(u,x)$ of Eqs. (8) and (9) defined on the polydisc $C((0,0),r)$ is*

$$B(u,x)=c\exp(\rho ux)\frac{x+au}{aux},\ \ \textit{or}\ \ c\exp(\rho ux)\frac{1}{x}.$$

Here c is in Theorem VI.1, *$a\in\mathbb{C}\{0\}$ and $\rho\in\mathbb{C}$.*

VII. SINGULAR CASE

This section describes the solutions A and B of Eqs. (1) and (2) on the assumption that $B\not\equiv 0$ and that $A(x)A(-x)(\not\equiv 0)$ is identically constant. It is to be mentioned that the assumption above and Eqs. (1) and (2) imply Eqs. (9) and

$$B(u,x)B(u,-x)=B(u,y)B(u,-y) \tag{24}$$

on $C((0,0),r)$. Let $D_1,D_2\subset C((0,0),r)$ be the domains of the meromorphic function $B(u,x)$ and $B(u,-x)$, respectively. From Eq. (24), for all $u\in C(0,r)$ such that $(u,x)\in D_1\cap D_2$, there exists $a(u)\in\mathbb{C}$ such that

$$B(u,x)B(u,-x)=a(u)\ \ \forall x\in C(0,r)\text{s.t.}(u,x)\in D_1\cap D_2. \tag{25}$$

It follows immediately that $a(u)$ is holomorphic at $u=u_0$ if $(u_0,y_0)\in D_1\cap D_2$.

Lemma VII.1: If $(u_0,y_0)\in D_1\cap D_2$, then $(u_0,0)$ is not a pole of the function $B(u,x)$.

Proof: The proof is by contradiction. Assume the assertion were false. For all $n\in\mathbb{N}$, there would exist $(u_n',x_n')\in C((0,0),r)$ such that $(u_n',x_n')\in C((u_0,0),1/n)\cap D_1$. Then there exists $r_n'>0$ such that $C((u_n',x_n'),r_n')\subset C((u_0,0),1/n)\cap D_1$. Hence there exists $(u_n,x_n)\in D_2$ such that $(u_n,x_n)\in C((u_n',x_n'),r_n')$. Because $(u_n,x_n)\in C((u_0,0),1/n)\cap D_1\cap D_2$, $\lim_{n\to\infty}u_n=u_0$ and $\lim_{n\to\infty}x_n=0$. Since $(u_0,0)$ is a pole of $B(u,x)$, $\lim_{n\to\infty}|B(u_n,x_n)|=\lim_{n\to\infty}|B(u_n,-x_n)|=\infty$, and $\lim_{n\to\infty}|B(u_n,x_n)B(u_n,-x_n)|=\infty$ as a consequence. As we mentioned earlier, we are led to $\lim_{n\to\infty}a(u_n)=a(u_0)$, which is a contradiction of Eq. (25). □

Thus the point $(u_0,0)$ in Lemma VII.1 is a regular point or a point of indeterminacy of $B(u,x)$.

Lemma VII.2. For any $(0<)r'\leqslant r$, there exists $u_0\in C(0,r')$ such that $(u_0,0)$ is a regular point of $B(u,x)$.

Proof: It suffices to consider the case that $(u_0,0)\in C((0,0),r')$ in Lemma VII.1 is a point of indeterminacy of the function $B(u,x)$.

Because the set of the points of the indeterminacy of the meromorphic function with two variables is isolated, there exists $r_0>0$ such that $B(u,x)$ has no points of indeterminacy in $C((u_0,0),r_0)\backslash\{(u_0,0)\}$ and $C((u_0,0),r_0)\subset C((0,0),r')$. That is to say, for any $u_1\in C(u_0,r_0)\backslash\{u_0\}$, $(u_1,0)$ is not a point of indeterminacy of $B(u,x)$, and there exists $s>0$ such that $C((u_1,0),s)\subset C((u_0,0),r_0)\backslash\{(u_0,0)\}$ as a result.

For $(u_3,y_3)\in D_1\cap D_2\cap(C(u_1,s)\times C(0,r'))$, $(u_3,0)$ is not a pole of $B(u,x)$ by means of Lemma VII.1. From $(u_3,0)\in C((u_1,0),s)$, $(u_3,0)$ is not a point of indeterminacy of $B(u,x)$. This point u_3 is the desired one. □

Proposition VII.3: There exist $r_0(>0)$ and $u_0\in C(0,r)$ satisfying the following conditions.

(1) $C((4u_0,0),4r_0)\subset C((0,0),r)$.
(2) $B(u,x)$ *is holomorphic on* $C((u_0,0),r_0)\cup C((2u_0,0),2r_0)\cup C((4u_0,0),4r_0)$.
(3) $B(u,x)\neq 0$ *for all* $(u,x)\in C((u_0,0),r_0)\cup C((2u_0,0),2r_0)\cup C((4u_0,0),4r_0)$.

Proposition VII.3 follows from Lemma VII.4 immediately.

Lemma VII.4: (1) *If there exists* $C((u_0,0),r_0)\subset C((0,0),r)$ *such that* $B(u,x)$ *is holomorphic on* $C((u_0,0),r_0)$ *and* $C((2u_0,0),2r_0)\subset C((0,0),r)$, *then there exists* $C((u_1,0),r_1)\subset C((u_0,0),r_0)$ *such that* $B(u,x)$ *is holomorphic on* $C((2u_1,0),2r_1)$.

(2) *If there exists* $C((u_0,0),r_0)\subset C((0,0),r)$ *such that* $B(u,x)$ *is holomorphic on* $C((u_0,0),r_0)$, *then there exists* $C((u_1,0),r_1)\subset C((u_0,0),r_0)$ *such that* $B(u,x)\neq 0$ *for all* $(u,x)\in C((u_1,0),r_1)$.

Proof: We prove (1) only. We take $C((u_2,y_2),r_2)\subset(C(2u_0,2r_0)\times C(0,r))\cap D_1\cap D_2$, and, for all $u\in C(u_2,r_2)$, there exists $y\in C(y_2,r_2)$ such that $(u,y)\in D_1\cap D_2$ as a result. By Lemma VII.1, $(u,0)$ is not a pole of $B(u,x)$ for all $u\in C(u_2,r_2)$. Because the set of the points of indeterminacy of the meromorphic function of two variables is isolated and $u/2\in C(u_0,r_0)$ for all $u\in C(u_2,r_2)$, there exists $u_1\in C(u_0,r_0)$ such that $(2u_1,0)\in D_1$. Thus there exists $r_1>0$ such that $C((u_1,0),r_1)\subset C((u_0,0),r_0)$ and $C((2u_1,0),2r_1)\subset D_1$. This completes the proof. □

By Eq. (9), there exists $\gamma(u,v)\in\mathbb{C}$ such that

$$\frac{B(u+v,x)}{B(u,x)B(v,x)}=\gamma(u,v) \tag{26}$$

for all $x\in C(0,r_0/2),u,v\in C(u_0,r_0/2)$, and, consequently, we have the following.

Proposition VII.5: We fix any $u,v\in C(u_0,r_0/2)$ *and put*

$$\alpha(x)=\frac{B(u+v,x)}{B(u,x)},\quad \varphi(x)=\frac{1}{B(u,x)},\quad \psi(x)=a(u)\gamma(u,v)B(u+v,x).$$

Then they satisfy Eq. (4) for all $x,y\in C(0,r_0/4)$.

With the aid of Proposition VII.3, the functions α, φ and ψ are all holomorphic on $C(0,r_0/2)$. Moreover, $\varphi(x)\neq 0$ and $\psi(x)\neq 0$ for all $x\in C(0,r_0/2)$. This tells us that the functions α, φ and ψ are the solutions of Eq. (4) with the conditions $\varphi(0)\neq 0$ and $\alpha(x+y)-\alpha(x)\alpha(y)\neq 0$ for all $x,y\in C(0,r_0/4)$. By virtue of Theorem II.1, we conclude the following.

Proposition VII.6: For $u\in C(u_0,r_0/2)$ *and* $x\in C(0,r_0/4)$,

$$B(u,x)=c_1(u)\exp(\rho_1(u)x),$$

where c_1 *and* ρ_1 *are holomorphic on* $C(u_0,r_0/2)$. *The function* c_1 *satisfies* $c_1(u)\neq 0$ *for all* $u\in C(u_0,r_0/2)$.

We obtain Proposition VII.7 in a similar fashion.

Proposition VII.7: For $u\in C(2u_0,r_0)$ *and* $x\in C(0,r_0/2)$,

$$B(u,x)=c_2(u)\exp(\rho_2(u)x),$$

where c_2 *and* p_2 *are holomorphic on* $C(2u_0,r_0)$. *The function* c_2 *satisfies* $c_2(u)\neq 0$ *for all* $u\in C(2u_0,r_0)$.

By virtue of Eqs. (9) and (26), we deduce Theorem VII.8.

Theorem VII.8: *The singular solutions* $A(x)$ *and* $B(u,x)$ *of Eqs. (1) and (2) defined on the polydiscs* $C(0,r)$ *and* $C((0,0),r)$, *respectively, are as follows*:

$$A(x)=c_1h(x),\quad B(u,x)=c_2\exp(\rho ux)\frac{1}{u}.$$

Here c_1, $c_2 \in \mathbb{C}\setminus\{0\}$, $\rho \in \mathbb{C}$ *and* $h(x)$ *is a meromorphic function defined on* $C(0,r)$ *satisfying the relation* $h(x)h(-x)=1$.

VIII. TRIVIAL CASE

In this section, we solve Eqs. (1) and (2) with $A \equiv 0$ or $B \equiv 0$.

Lemma VIII.1: If the function B is identically zero on $C((0,0),r)$, *then, for any function A meromorphic on* $C(0,r)$, *the functions A and* $B(\equiv 0)$ *satisfy Eqs. (1) and (2).*

In the sequel, we assume that $A \equiv 0$ and $B \not\equiv 0$. From the previous assumption, Eqs. (1) and (2) are equivalent to

$$\frac{B(u+v,x)}{B(u,x)B(v,x)} = \frac{B(u+v,y)}{B(u,y)B(v,y)}$$

on $C((0,0,0,0),r/2)$. By differentiating the equation above in the variable x, we get

$$\frac{(\partial B/\partial x)(u+v,x)}{B(u+v,x)} - \frac{(\partial B/\partial x)(u,x)}{B(u,x)} - \frac{(\partial B/\partial x)(v,x)}{B(v,x)} = 0$$

on $C((0,0,0),r/2)$ and, as a result, $(\partial^2 \tilde{B}/\partial u^2)(u,x)=0$ on $C((0,0),r)$, where $\tilde{B}(u,x)=(\partial B/\partial x)(u,x)/B(u,x)$.

Lemma VIII.2: There exists a function f meromorphic on $C(0,r)$ *such that* $\tilde{B}(u,x)=f(x)u$ *as meromorphic functions on* $C((0,0),r)$ *and the function f is holomorphic at* $x=0$.

Proof: We only show that the function f is holomorphic at $x=0$. Let D_1 be the domain of the meromorphic function B. By means of $B \not\equiv 0$, there exists $C((u_1,x_1),r_1) \subset D_1 \setminus (\{0\} \times C(0,r))$ such that $B(u,x) \neq 0$ for all $(u,x) \in C((u_1,x_1),r_1)$. Hence, for all $u \in C(u_1,r_1)$, $f(x)=(\partial B/\partial x)(u,x)/(uB(u,x))$ is meromorphic on $C(0,r)$. (See Lemma III.5) Laurent's expansions near $x=0$ of the functions f and $(\partial B/\partial x)(u,x)/(uB(u,x))$ are

$$f(x)=\sum_{k_1=l}^{\infty} a_{k_1}x^{k_1}, \quad \frac{(\partial B/\partial x)(u,x)}{uB(u,x)} = \frac{1}{u}\sum_{k_2=-1}^{\infty} b_{k_2}(u)x^{k_2} \quad (l, b_{-1}(u) \in \mathbb{Z}),$$

and we get $l=-1$ and $a_{-1}=b_{-1}(u)/u$ for all $u \in C(u_1,r_1)$ as a result. If $b_{-1}(u_1) \neq 0$, then, for all $u \in C(u_1,r_1)$, $u=(b_{-1}(u)/b_{-1}(u_1))u_1 \in \mathbb{Q}u_1$, which is a contradiction. Thus $b_{-1}(u_1)=0$, and consequently $a_{-1}=0$. We have completed the proof. □

Therefore we deduce the following theorem.

Theorem VIII.3: *There exist* $(0<)r_1(\leqslant r)$, *a function F holomorphic on* $C(0,r_1)$ *and a function G meromorphic on* $C(0,r)$ *such that the function G is not identically zero and* $B(u,x)=\exp(F(x)u)G(u)$ *as meromorphic functions on* $C(0,r)\times C(0,r_1)$.

ACKNOWLEDGMENTS

The author would like to express gratitude to Professor Nariya Kawazumi. The author first gave all the solutions A and B meromorphic on $\mathbb{C}$ and $\mathbb{C}^2$, respectively. Professor Kawazumi pointed out to him that one could solve Eqs.(8) and (9) near the origin. Moreover, Professor Kawazumi suggested the way to solve Eqs. (1) and (2) for $A \equiv 0$. He would like to thank the referee for pointing out redundancies in the original manuscript.

The Hagedorn transition in noncommutative open string theory (NCOS) is relatively simple because gravity decouples. For NCOS theories in no more than five space–time dimensions, the Hagedorn transition is second order, and the high temperature phase involves long, nearly straight fundamental strings separating from the D-brane on which the NCOS theory is defined. Above five spacetime dimensions interaction effects become important below the Hagedorn temperature. Although this complicates studies of the transition, we believe that the high temperature phase again involves long strings liberated from the bound state. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1372176]

I. INTRODUCTION

Just as noncommutative field theories (i.e., quantum field theories on noncommutative spaces) can be obtained as certain limits of D-branes with a background magnetic field,[1] noncommutative open string (NCOS) theories are defined as a special limit of Type II D-branes with a uniform electric field.[2,3] The bosonic part of the world volume action has the standard form

$$S=\int_\Sigma d^2\sigma\left[\frac{1}{4\pi\alpha'}((\partial_a X^0)^2-(\partial_a X^1)^2)-\frac{1}{4\pi\alpha'_t}\sum_{i=2}^{9}(\partial_a X^i)^2\right]+E\oint_{\partial\Sigma}X^0\frac{\partial}{\partial\sigma}X^1. \tag{1}$$

In the NCOS limit the electric field approaches its critical value, $E\to E_c=1/2\pi\alpha'$, and $\alpha'\to 0$ in such a way that the effective tension of an open string stretched along the direction of the electric field remains finite:

$$\alpha'_{\rm eff}=\alpha'\frac{E_c^2}{E_c^2-E^2}. \tag{2}$$

a)Electronic mail: ssgubser@ebenezer.Princeton.edu

There is a similar rescaling of the interaction strength:[4]

$$G_o^2 = g_{\rm str}\sqrt{\frac{E_c^2 - E^2}{E_c^2}}, \tag{3}$$

and the open string coupling G_o is held fixed in the NCOS limit. The inverse-tension parameter for the transverse directions, α_t', is finite from the start and independent of E (it is convenient to set $\alpha_t' = \alpha_{\rm eff}'$). A remarkable property of this limit is that, even though $g_{\rm str}\to\infty$, the closed strings decouple from the open strings.[2,3] Therefore, the NCOS is a nongravitational string theory.

This definition of NCOS theories leads naturally to a space–time where the space and time directions do not commute, i.e., $[X^0, X^i] = i\theta^{0i}$. Unlike the situation in noncommutative Yang–Mills theories, here the noncommutativity scale, $|\theta|$, is intrinsically tied to the string scale. This implies that in order to make sense of the notion of a noncommuting space/time manifold, we would have to first give precise meaning to the notion of Einsteinian spacetimes down at the string scale.

The relation (3) implies that $g_{\rm str}\to\infty$ in the NCOS limit. Therefore, *S*-duality may be used to map NCOS to D-brane systems at weak string coupling.[5,6] A particularly simple example of such duality is $1+1$-dimensional NCOS, which is found to be dual to maximally supersymmetric $U(N)$ gauge theory with one unit of electric flux. The open string coupling is $G_o^2 = 1/N$; it becomes weak in the large N limit. Therefore, the $1+1$-dimensional NCOS provides a new example of duality between large N gauge theory and strings. The fact that we find open strings rather than closed is related to the presence of the electric flux tube which binds the N D-strings. Massive open strings are dual to the excitations of this theory where locally $SU(N)$ is broken to $SU(N-1)\times U(1)$. The massless open strings are dual to the $U(1)$ part of the spectrum (the overall vibrations of the bound state), and the duality with the gauge theory predicts that the massless states decouple. In Ref. 6 this prediction was confirmed by explicit NCOS calculations. A further check on the duality performed in Ref. 6 involves the high-energy behavior of the massive amplitudes: it is found to exhibit the same power-law fall-off as expected from the gauge theory.

Another classic way of subjecting strings to extreme conditions is to heat them up to a high temperature. For conventional superstring theory this was extensively studied in the late 80's[7–9] and afterwards (see for instance Refs. 10, 11, 12). A complicating factor in these papers is that it is difficult to study the thermodynamics of gravitating systems. Nevertheless, a coherent picture has emerged suggesting a first-order phase transition happening well below the Hagedorn temperature.[9]

In this paper we study the thermodynamics of NCOS in various dimensions. Just like any other superstring theory, NCOS theory exhibits a Hagedorn density of states:

$$\rho(m) \sim m^{-9/2} e^{m/T_{\rm H}}, \tag{4}$$

with the scale for the Hagedorn temperature set by $\alpha_{\rm eff}'$:

$$T_{\rm H} = \frac{1}{\sqrt{8\pi^2\alpha_{\rm eff}'}}. \tag{5}$$

In particular, the partition function of NCOS theory appears to diverge above the temperature $T = T_{\rm H}$, where the Hagedorn transition is expected to take place. Our goal is to understand the physics of this transition and describe the thermodynamics of NCOS theory at $T > T_{\rm H}$. Since the NCOS theories are decoupled from gravity, we will not face the usual difficulties associated with gravitational thermodynamics. Furthermore, at least in $1+1$ dimensions the dual gauge theory provides an important guide to what happens at the transition. Here we find that the transition is

to a phase where some finite fraction of the strings are freed from the bound state, i.e., where the theory enters the Higgs branch $SU(N)\to SU(N-K)\times U(1)^K$. A calculation of the free energy below and above the transition shows that it is second order.

Guided by the intuition from the $1+1$-dimensional case we proceed to $p+1$ dimensions. For $p>1$, *S*-duality works differently, but on the NCOS side we may still think of some density of *F*-strings bound to a D*p*-brane. We will show that for all $p<5$ the Hagedorn transition is again second order and is associated with the liberation of strings from the bound state. For $p\geqslant 5$ the entropy of noninteracting open strings (and also the string length) diverges as T approaches $T_{\rm H}$ from below.[13] This suggests that string interaction effects become important already below $T_{\rm H}$. Nevertheless, we will argue that the high-temperature phase again contains a finite fraction of long strings liberated from the bound state. In all these cases the theory slightly above the transition appears to be effectively $1+1$-dimensional, with a preferred direction chosen by the electric field.

In previous work[3] it was suggested that there is a change in the behavior of zero-temperature NCOS at $p=7$, where non-planar amplitudes begin to diverge at $k^2=0$ (k is the momentum flowing in the closed string channel). We calculate a cross-section for graviton production and confirm that NCOS theories do not decouple from gravity for $p\geqslant 7$. Our work further shows that, at finite temperature, there is new physics appearing in the NCOS theory at a lower dimension, $p=5$: interaction effects become important already below $T_{\rm H}$. A special role of $p=5$ in open string thermodynamics was noted earlier in Ref. 13.

Other authors have recently studied phases of NCOS theories and Hagedorn behavior of string theories decoupled from gravity.[14–17] These works focused primarily on results derivable from supergravity. The current work takes the rather different approach of examining the free energy of bound states in a field theory approximation. The relevant temperatures for our analysis are so low that the near-extremal supergravity solutions are highly curved on the string scale and hence unreliable.

There is also an extensive literature on Hagedorn behavior in asymptotically free gauge theories. For important early contributions to the subject, see Refs. 18, 19, 20. In the current work we focus on perturbative string techniques rather than field theory. However, some information about strongly coupled gauge theories may be extracted from our results, particularly in the $1+1$-dimensional case.

II. NCOS THERMODYNAMICS FOR $T<T_{\rm H}$

In order to obtain a reliable picture of the thermodynamics of NCOS theory for $T<T_{\rm H}$ directly from the free string spectrum, two conditions must pertain. First, the open strings should interact weakly with one another. Second, the cubic coupling $\langle\phi\phi\sigma\rangle$ between an incipient thermal tachyon ϕ and the radius σ of the Euclidean time direction, which played a crucial role in the analysis of Ref. 9, is absent. This is because σ represents a closed string (gravitational mode), which decouples according to the arguments of Refs. 2, 3. This is the essential difference between the Hagedorn transition for NCOS theory and for critical string theory.[9] Whereas essentially gravitational effects drive the Hagedorn transition first order in critical string theory, we will see that in NCOS theory the transition remains second order.

The free string analysis proceeds in a similar way regardless of the spatial dimension p in which the open strings live. The calculation of free energy of noninteracting open strings on a D*p*-brane, which is not affected by the noncommutativity, was carried out in Ref. 13. We will largely rederive their results and adapt them for our purposes. The principal result is that the free energy is analytic in T for $T<T_{\rm H}$, and that the leading nonanalytic behavior in the expansion of F around $T=T_{\rm H}$ is

$$F\sim\begin{cases}(\text{analytic in } t)+t^{(7-p)/2}+\ldots, & \text{for } p \text{ even},\\ (\text{analytic in } t)+t^{(7-p)/2}\log t+\ldots, & \text{for } p \text{ odd},\end{cases}\tag{6}$$

where $t=(T_{\rm H}-T)/T_{\rm H}$. There are two equivalent means of obtaining this result. First, one may

directly evaluate the annulus diagram in the Matsubara formalism where the Euclidean time direction is compact with circumference $\beta = T^{-1}$. The one loop free energy for a Dp-brane with an electric field of strength E turned on is [21]

$$Z_{\text{single string}} = -c_1 \int_0^\infty \frac{dt}{(p+3)/2}\, \vartheta_2\left(0 \middle| \frac{i\beta^2}{2\pi^2 \alpha'_{\text{eff}} t}\right) \left[\frac{\vartheta_2(0|it)}{\vartheta_1'(0|it)}\right]^4$$
$$= -\frac{c_1}{(2\pi)^4} \int_0^\infty \frac{d\tau}{\tau^{9-p/2}}\, \vartheta_2\left(0 \middle| \frac{i\beta^2 \tau}{2\pi^2 \alpha'_{\text{eff}}}\right) \left[\frac{\vartheta_2(0|i\tau)}{\vartheta_1'(0|i\tau}\right]^4. \tag{7}$$

In the first line we have used t as the modular parameter of the cylinder. In the second line we substitute $\tau = 1/t$, which is the usual closed string modular parameter. The expressions in (7) are exact even away from the NCOS limit, provided we use the definition (2) and neglect coupling to closed strings. They are identical to the partition function of ordinary open superstrings on a Dp-brane, only with α' replaced by α'_{eff}. The constant c_1 is given as $V\beta\pi^4/2(2\pi)^5(2\pi\alpha'_{\text{eff}})^5$. The reduced Hagedorn temperature for the partition function was noted in Ref. 22.

The nonanalytic behavior arises from a divergence in the modular integral at large τ (the long cylinder limit). Near T_{H}, we can use the large τ asymptotics of the ϑ functions to obtain

$$F_{\text{NCOS}}(T \approx T_{\text{H}}) \sim -\int^\infty \frac{d\tau}{\tau^{(g-p)/2}}\, e^{(1/T_{\text{H}}^2 - 1/T^2)\tau}, \tag{8}$$

from which the claimed analyticity for $T < T_{\text{H}}$ and the leading nonanalyticity quoted in (6) are evident.

An equivalent, ''elementary'' approach to obtain the same result is to plug (4) into the standard formula for a partition function:

$$Z_{\text{single string}} = \sum_{\text{states}} e^{-E/T}$$
$$= \sum_{i \in \mathcal{H}_o^\perp} \int \frac{d^p k}{(2\pi)p}\, e^{-\sqrt{k^2 + m_i^2}/T}$$
$$\sim \int_0^\infty dm\, \rho(m)(mT)^{p/2} e^{-m/T} \sim \int^\infty dm\, m^{(p-9)/2} \exp\left[m\left(\frac{1}{T_{\text{H}}} - \frac{1}{T}\right)\right], \tag{9}$$

where in the third step we have made an approximation to the momentum integration which becomes exact in the limit of large masses m_i.[13] Evaluating the last integral leads again to (6).

Note that the free energy is finite at $T = T_{\text{H}}$ for $p < 7$ and diverges logarithmically for $p = 7$. The entropy, $S = -\partial F/\partial T$, remains finite only for $p < 5$, and diverges logarithmically for $p = 5$. For a single long string, the entropy is proportional to the length of the string. Hence when $t = (T_{\text{H}} - T)/T_{\text{H}}$ is small, the total entropy is proportional to the rms length of the excited open strings, l_{NCOS}, times the average number of these strings per unit volume, ρ_{NCOS}.[23] As $T \to T_{\text{H}}$ from below, we have the scalings

$$\rho_{\text{NCOS}} l_{\text{NCOS}} \sim \begin{cases} (\text{finite}), & \text{for } p < 5, \\ -\log t, & \text{for } p = 5, \\ 1/\sqrt{t}, & \text{for } p = 6, \end{cases} \tag{10}$$

and so on.

The quantity $\rho_{\text{NCOS}} l_{\text{NCOS}}$ is the average density of string at any given point. As long as this quantity remains finite, the effects of interactions may be suppressed by taking G_o sufficiently small. Thus for $p < 5$ one can ensure that string interactions are never significant, but for $p \geqslant 5$

they eventually will be. A figure of merit to measure the strength of string interactions is $\eta = G_o \rho_{\rm NCOS} l_{\rm NCOS}$. We work in units where $\alpha'_{\rm eff}=1$ to make η dimensionless. The free energy for $T<T_{\rm H}$, neglecting interactions, is order G_o^0. Interactions make a contribution of order η^2 to the free energy. Thus interactions become important when $\eta \gtrsim 1$, which is to say $\rho_{\rm NCOS} l_{\rm NCOS} \gtrsim 1/G_o$. One can now use (10) to make a rough estimate of the temperature at which string interactions matter. For $p=5$ this temperature is $t \sim e^{-{\rm const}/G_o}$, while for $p=6$ it is $t \sim G_o^2$.

In the next sections, we will propose that the physics above $T_{\rm H}$ involves the gradual emission of long strings. We will assume that the free string picture is valid up to $T=T_{\rm H}$: thus the discussion seems to be limited to $p<5$. Note however that for $p=5,6$ the entropy of the open string gas at the temperature where interactions become important is of order $1/G_o$. For weak string coupling, this is still much smaller than the entropy in the liberated string phase which, as we show in Sec. IV A, is of order $1/G_o^2$. So we speculate that long string liberation starts taking place near $T_{\rm H}$ for $p=5,6$ as well.

The calculations that we present for $p<5$ are clean because we can work in a limit where free string theory applies. The string liberation transition may still occur away from zero coupling, although it is possible that the transition becomes first order. The additional complication for $p=5,\ 6$ is that there is no limit in which free string theory applies uniformly.

III. TWO-DIMENSIONAL NCOS THEORY AT $T>T_{\rm H}$

In this section we focus on the specific example of the two-dimensional NCOS theory, $p=1$. In this case one can use Type IIB *S*-duality to describe a D1-brane with a near-critical electric field as a $(1,N)$ bound state[24,25] where the number, N, of D1-branes is related to the open string coupling constant, $G_o^2=1/N$. At low energies this system behaves as $SU(N)$ two-dimensional super-Yang–Mills theory with one unit of electric flux and coupling constant,

$$g_{\rm YM}^2 = \frac{N^2}{\alpha'_{\rm eff}}. \tag{11}$$

In this dual picture noncommutative open strings can be identified with excitations corresponding to the Higgsing $SU(N) \to SU(N-1)\times U(1)$. Indeed, to create an island (of size L) of the Higgs phase costs an energy [5,6] of

$$E = L\left(\frac{g_{\rm YM}^2}{4\pi(N-1)} - \frac{g_{\rm YM}^2}{4\pi N}\right) \approx \frac{L g_{\rm YM}^2}{4\pi N^2} = \frac{L}{4\pi\alpha'_{\rm eff}}. \tag{12}$$

In the last equality we used the relation (11) between the Yang–Mills coupling constant and the tension of open strings. In terms of the $(1,N)$ bound state, (12) represents the energy to have a D-string split off from the bound state and run parallel to it for a distance L before rejoining.

At finite temperature, there is a gain in entropy when a string splits off from the bound state, due to small fluctuations of the string. Since a long string in light-cone gauge is described by a free supermultiplet, this entropy is $S=4\pi LT$ [in the dual gauge theory it comes from the $U(1)$ part of the Higgsed gauge group $SU(N-1)\times U(1)$]. The corresponding free energy of these light modes is $F=-2\pi LT^2$. Therefore, the total free energy of a string liberated from the bound state,

$$F_{\text{liberated string}} = L\left(\frac{1}{4\pi\alpha'_{\rm eff}} - 2\pi T^2\right), \tag{13}$$

vanishes precisely at the Hagedorn temperature:

$$T_{\rm H} = \frac{1}{\sqrt{8\pi^2\alpha'_{\rm eff}}} = \frac{1}{\sqrt{8}\pi}\frac{g_{\rm YM}}{N}. \tag{14}$$

We would like to interpret the Hagedorn transition as the liberation of fundamental strings parallel to the electric field from the $(N,1)$ bound state. This interpretation is satisfying in that the Hagedorn transition is generally associated with the temperature at which it is favorable to create long closed strings (see for instance Refs. 10, 11). If we compactify in the direction of the electric field, then the liberated strings are precisely those long closed strings. What is special about the NCOS limit is that in the near-critical electric field, the closed strings are allowed to wind only in one direction. Furthermore, since their tension away from the bound state is α', they are nearly straight: the massless $U(1)$ degrees of freedom represent only slight fluctuations.

A crucial aspect of the analysis is that, once one string has been liberated, the Hagedorn temperature of the NCOS theory on the $(N-1,1)$ bound state is slightly higher: after freeing one string, we have

$$\alpha'^{\text{new}}_{\text{eff}}=\frac{(N-1)^2}{g^2_{\text{YM}}}, \quad T_{\text{H}}^{\text{new}}=\frac{g_{\text{YM}}}{\sqrt{8}\pi}\frac{1}{N-1}. \tag{15}$$

In order to free another fundamental string, we must increase T to $T_{\text{H}}^{\text{new}}$. The analysis in (12) and (13) carries over without change to this case, and the Hagedorn temperature of the bound state increases again. Thus we have good control over the physics above the original T_{H}: the liberated fundamental strings are only slightly fluctuating, and the NCOS strings attached to the bound state remain at or below their Hagedorn transition.

It is possible to summarize the analysis in a way that will generalize easily to other cases. Suppose k out of the N fundamental strings have been liberated, $k\gg 1$. The free energy per unit length of the total system, consisting of the $(N-k,1)$ bound state plus the k liberated strings, is

$$\begin{aligned}\frac{F_k}{L}&=\frac{1}{2\pi\alpha'}\sqrt{(N-k)^2+\frac{1}{g^2_{\text{str}}}}+\frac{k}{2\pi\alpha'}-2\pi kT^2+O(1)\\ &\approx\frac{N-k}{2\pi\alpha'}\left(1+\frac{1}{2g^2_{\text{str}}(N-k)^2}\right)+\frac{k}{2\pi\alpha'}-2\pi kT^2\\ &=\frac{N}{2\pi\alpha'}-2\pi NT^2+\frac{1}{4\pi\alpha' g^2_{\text{str}}(N-k)}+2\pi(N-k)T^2\\ &\geqslant\frac{N}{2\pi\alpha'}-2\pi NT^2+T\sqrt{\frac{2}{\alpha' g^2_{\text{str}}}}.\end{aligned} \tag{16}$$

In the first line of (16), we have summed up the total tension of the $(N-k,1)$ bound state, the total tension of the k liberated strings, the free energy of the fluctuations of those k strings, and the $O(1)$ free energy coming from fluctuating open strings attached to the bound state. [26] The symbol $O(1)$ means, more precisely, that this contribution to the free energy is a finite quantity of order 1 times LT^2. In the second line of (16) we have expanded the square root for $g_{\text{str}}(N-k)\gg 1$, and in the last line we have used the arithmetic–geometric mean inequality. Equality holds in the last line iff

$$N-k=\frac{1}{\sqrt{8\pi^2\alpha' g_{\text{str}}}T}. \tag{17}$$

Transforming to rescaled NCOS variables, we find that the fraction of liberated strings is

$$\nu=\frac{k}{N}=\frac{T-T_{\text{H}}}{T}, \tag{18}$$

where T_H is the original Hagedorn temperature defined in (14).

From (16) we immediately read off the total free energy for $T>T_H$:

$$\frac{F}{L}=\inf_k \frac{F_k}{L}=-2\pi N(T_H)^2+O(1). \tag{19}$$

Another way to arrive at this formula is to note that the entropy of the k liberated strings is

$$S=-\frac{dF}{dT}=4\pi kLT=4\pi NL(T-T_H). \tag{20}$$

Integrating this equation with the boundary condition that F/L is of order 1 at $T=T_H$ reproduces the result (19).

Actually, since k is a discrete variable, $F/L=-2\pi N(T-T_H)^2$ and $\nu=(T-T_H)/T$ only represent an approximation to a series of discrete transitions, from F_0 to F_1 to F_2 and so on. However, since we are operating at large N, the discrete transitions are very closely spaced, and can effectively be regarded as a single continuous transition. At some level, the approach we have taken is only meaningful in the large N limit: we have examined various competing minima of the free energy, corresponding to different numbers of liberated fundamental strings, at a completely classical level, ignoring the fact that in one spatial dimension strong infrared fluctuations smooth out any nonanalyticity in the free energy. What saves the day is large N: when a finite fraction of fundamental strings have been liberated, their fluctuations ''average out'' to an extent such that ν is a good order parameter for the transition. One should not take too seriously the literal picture of a single string peeling off the bound state at $T=T_H$, followed shortly thereafter by another, and then another; rather, the free energy starts as an $O(1)$ quantity for $T<T_H$ and rises to $O(N)$ through a transition in which fundamental strings are collectively liberated. There is *not*, after all, a series of closely spaced first-order transitions—this would be in violation of the general analyticity properties of the free energy in one spatial dimension—instead, the maximally smoothed free energy has the form (19), which indicates a discontinuity $\Delta C=2\pi N$ at $T=T_H$. This is essentially the classic picture of a second-order phase transition, only with integer critical exponents that just barely avoid the typical singularity in the specific heat.

Note that, since the equilibrium condition reads as

$$\frac{g_{YM}^2}{4\pi(N-k)^2}-2\pi T^2=0, \tag{21}$$

the open strings on the $(N-k,1)$ bound state are always at their effective Hagedorn temperature (which depends on k provided that g_{YM} is held fixed). Therefore, their contribution to F/L is aT^2, where a is a constant of order 1 which may be found by evaluating (7) directly at the Hagedorn temperature. It is quite possible that additional $O(1)$ contributions to F arise when one considers interactions of the liberated long strings. Also, the interactions could change the critical exponents by terms of order $G_o^2=1/N$. In principle, the effects of interactions can be studied starting from the maximally supersymmetric Yang–Mills description of the bound state. The liberated strings admit a matrix string description,[27–29] while the bound state represents a confining non-Abelian sector of the theory. As far as we can tell, the total problem is quite formidable, but some progress might be made via a lattice or DLCQ approach.

It is clear that as we increase the temperature, one unit of electric flux in the dual super-Yang–Mills theory becomes unimportant. Already when the temperature is a finite multiple of $T_H \sim g_{YM}/N$ (say $T=2T_H$), the free energy is dominated by the matrix string phase (recall that we are mainly interested in the large N limit). When $T\sim g_{YM}/\sqrt{N}$, the proper description of the system is no longer matrix string theory plus a D1-f1 bound state, but rather a single near-extremal black string solution in type IIB supergravity.[30,31] The considerations of Refs. 30, 31 were applied only to multiple, identical, (nearly) coincident branes, but their conclusions should carry over to

the current circumstance, because at $T=g_{\mathrm{YM}}/\sqrt{N}$, nearly all the D1-branes are in the matrix string phase: $\nu=1-O(N^{-1/2})$. The supergravity regime, then, is described by[30,31]

$$F\sim LN^{3/2}\frac{T^3}{g_{\mathrm{YM}}}, \quad \text{for } \frac{g_{\mathrm{YM}}}{\sqrt{N}}<T<g_{\mathrm{YM}}\sqrt{N}. \tag{22}$$

Finally, as we reach the 't Hooft scale $T\approx g_{\mathrm{YM}}\sqrt{N}$, we end up with a gas of free photons, N^2 in number. This crossover is in the general class of correspondence points studied by Horowitz and Polchinski.[32] At very high temperature the free energy looks like this:

$$F\sim LN^2T^2, \quad \text{for } g_{\mathrm{YM}}\sqrt{N}<T. \tag{23}$$

Historically, the Hagedorn transition was originally expected to be essentially a deconfinement transition. In the NCOS context, we see that there are actually two other phases, or regimes, in between the Hagedorn transition and the free gluon phase. In a superficial matching analysis, the transitions between the matrix string regime, the supergravity regime, and the free gluon regime appear to be first order. It could easily be, however, that there is only a second-order transition, or no sharp transition at all, between these phases. As yet, we know of no method of analysis powerful enough to distinguish among the possibilities. For the transition into the supergravity regime from below, one may hope that the perturbation of the matrix string CFT by the DVV twist operator[27] provides some hint of the formation of a horizon.

In summary, we find four different phases of $1+1$-dimensional NCOS theory. They are illustrated in Fig. 1. In more detail, we have the following.

(i) In the NCOS phase, F/LT^2 is an analytic function of order 1 (that is, no factors of N). String interactions are suppressed by $G_o^2=1/N$. Without an understanding of the gauge theory and the possibility of going to a Higgsed phase $SU(N-k)\times U(1)^k$, this is the only part of the phase diagram we would be able to understand.

(ii) Above $T=T_{\mathrm{H}}$, we gradually liberate more and more fundamental strings from the bound state, so that very soon the system becomes dominated by the matrix string phase. The open strings on the bound state stay at their effective Hagedorn temperature: this temperature adjusts as more strings are liberated. The continuous transition so described is the essential new physics of this paper.

(iii) At $T\approx g_{\mathrm{YM}}/\sqrt{N}$ significant departures from conformal invariance and nontrivial interactions drive us into the black string regime, where the thermodynamics is read off from a regular horizon.

(iv) Above $T\approx g_{\mathrm{YM}}\sqrt{N}$, the N^2 non-Abelian gluons (light D1-branes stretched between fundamental strings) are deconfined.

It is straightforward to extend our discussion to (N, M) bound states corresponding to $SU(N)$ theory with arbitrary number, M, of flux units. In that case, open string coupling constant is given by

$$G_o^2=\frac{M}{N},$$

and effective open string tension reads as

$$\frac{1}{\alpha'_{\mathrm{eff}}}=g_{\mathrm{YM}}^2\frac{M^2}{N^2}.$$

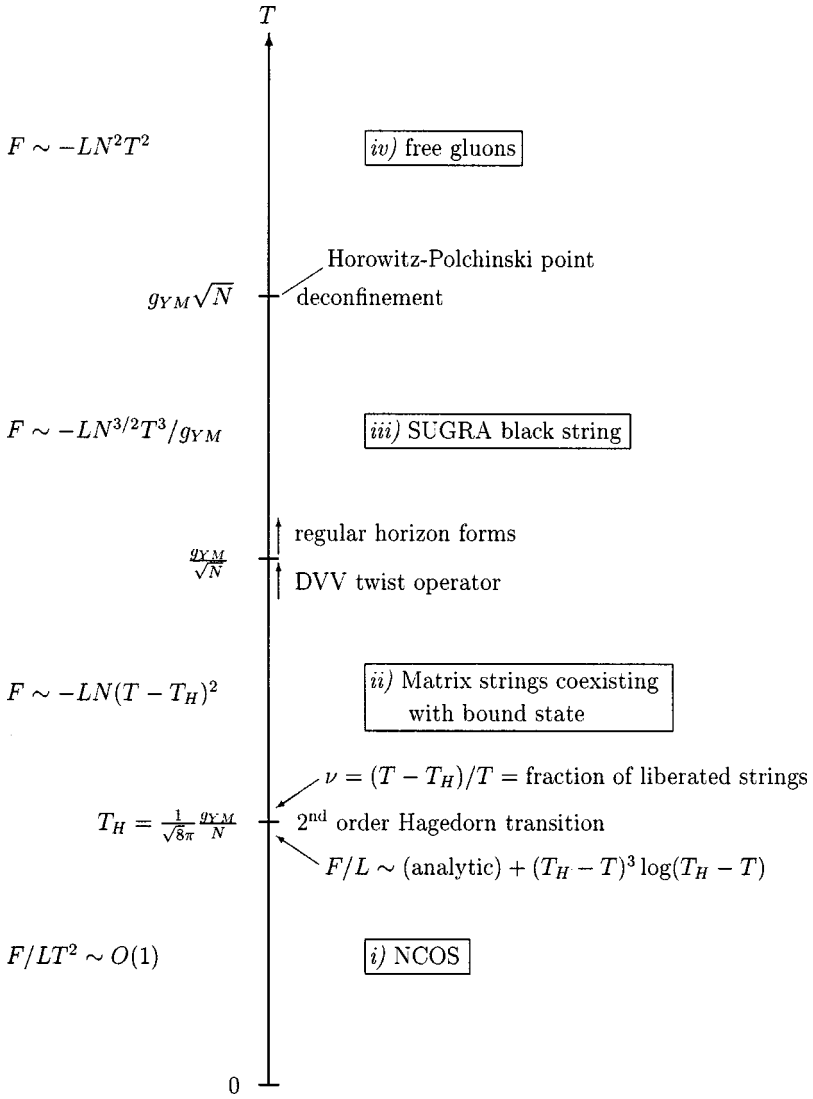

FIG. 1. The four phases of $1+1$-dimensional NCOS theory.

The phase diagram of this system is similar to that of the $(N,1)$ bound state: in particular, the same four phases appear. The only difference is that the phase transitions between phases (i)–(ii)–(iii) occur at different temperatures, greater by a factor of M. For instance, the Hagedorn temperature of such a theory is given by

$$T_{\mathrm{H}}=\frac{g_{\mathrm{YM}}M}{\sqrt{8}\,\pi^2 N}.$$

IV. HIGHER DIMENSIONAL EXAMPLES

Let us now elaborate on extensions of the ideas of the previous section to systems in which the strings are allowed to move in more than one spatial dimension (Sec. IV A), or where not strings but Dp-branes become light (Sec. IV B).

A. Thermodynamics of NCOS theories in higher dimensions

The Hagedorn transition in higher-dimensional NCOS theories (up to $4+1$ dimensions) may be understood in a manner similar to the situation in $1+1$ dimensions. The claim is that finitely above $T_{\rm H}$, a finite fraction of long strings are liberated from the bound state. This process is gradual as in the previous case, and the fraction of long strings that decouple may be computed in a similar fashion. To see this we need the formula for the number of fundamental strings per unit transverse volume bound to a Dp-brane with electric field E:

$$\frac{N}{V_t}\sim(\alpha_t')^{(1-p)/2}\frac{E}{g_{\rm str}\sqrt{E_c^2-E^2}}. \tag{24}$$

One way to get this formula is to consider the Dp-brane to be compactified on a circle of radius L in the direction of the electric field. Then the momentum conjugate to the gauge field is quantized: $P_1=NL$. Equating this to the momentum calculated from the Born–Infeld action, as in Ref. 4, gives (24).

Note that (24) implies

$$G_o^2\sim\frac{V_t(\alpha_t')^{(1-p)/2}}{N}.$$

To fix the precise factor in this expression, consider the BPS formula for the mass of the bound state of N fundamental strings and a Dp-brane wrapped over a transverse torus of volume V_t:

$$\frac{L}{2\pi\alpha'}\sqrt{N^2+\frac{V_t^2}{g_{\rm str}^2(2\pi)^{2p-2}(\alpha_t')^{p-1}}}=\frac{L}{2\pi\alpha'}N\left(1+\frac{V_t^2}{2N^2g_{\rm str}^2(2\pi)^{2p-2}(\alpha_t')^{p-1}}+\ldots\right). \tag{25}$$

Calculating the energy required to free one fundamental string, we get

$$\frac{LV_t^2}{4\pi\alpha' g_{\rm str}^2(2\pi)^{2p-2}(\alpha_t')^{p-1}}\left(\frac{1}{N-1}-\frac{1}{N}\right)\to\frac{LV_t^2}{4\pi\alpha'_{\rm eff}G_o^4N^2(2\pi)^{2p-2}(\alpha_t')^{p-1}}, \tag{26}$$

where we have used

$$\alpha' g_{\rm str}^2=\alpha'_{\rm eff}G_o^4. \tag{27}$$

(26) should be equated to the energy of a closed string wound around the direction of the electric field, which is $L/(4\pi\alpha'_{\rm eff})$.[6] Thus, we find

$$G_o^2=\frac{V_t(\alpha_t')^{(1-p)/2}}{(2\pi)^{p-1}N}. \tag{28}$$

This formula shows that for $p>1$, G_o^{-2} is not quantized, while for $p=1$ it is.

Suppose we start with a Dp-brane with a near-critical electric field E, which loses a fraction of its long strings above $T_{\rm H}$, such that the resulting system is a Dp-brane with a near-critical electric field E' and a bunch of free long strings. Assuming that the resulting brane configuration is right at its effective Hagedorn temperature as before, we find the ratio

$$\frac{T}{T_{\rm H}}=\frac{\sqrt{E_c^2-E'^2}}{\sqrt{E_c^2-E^2}}.$$

Using (24) and the fact that both E and E' are near-critical, we find the relation between temperature and the fraction of strings remaining in the bound state:

$$\frac{N'}{N}=\frac{T_{\mathrm{H}}}{T}. \tag{29}$$

This universal result is in accord with what we found in two-dimensional NCOS theory from its gauge theory dual; cf. (18).

Note that the transverse inverse-tension parameter, α_t', remains fixed for $T>T_{\mathrm{H}}$ because it does not depend on E. Thus, we may simply set $\alpha_t'=\alpha_{\mathrm{eff}}'$. However, the effective parameter governing the 0 and 1 directions starts decreasing as in the $1+1$-dimensional case. From (27) and (28) we find that

$$\alpha_{\mathrm{eff}}'^{\mathrm{new}}=\alpha_{\mathrm{eff}}'\left(\frac{N'}{N}\right)^2.$$

As in $1+1$ dimensions, the condition for equilibrium of long strings at temperature T is

$$\frac{1}{4\pi\alpha_{\mathrm{eff}}'^{\mathrm{new}}}-2\pi T^2=0,$$

from which the relation (29) follows.

One may be concerned that for $T>T_{\mathrm{H}}$ there are two different effective inverse-tension parameters: $\alpha_{\mathrm{eff}}'^{\mathrm{new}}$ for the 01 directions and α_{eff}' for the transverse directions. Which one sets the effective Hagedorn temperature? The answer is that it is $\alpha_{\mathrm{eff}}'^{\mathrm{new}}$, so that T is the effective Hagedorn temperature for $T>T_{\mathrm{H}}$. The dispersion relation for open strings is indeed asymmetric:

$$(k_0^2-k_1^2)-\frac{\alpha_{\mathrm{eff}}'}{\alpha_{\mathrm{eff}}'^{\mathrm{new}}}\sum_{i=2}^{p}k_i^2=\frac{\mathcal{N}}{\alpha_{\mathrm{eff}}'^{\mathrm{new}}},$$

where $\mathcal{N}$ is the excitation level. We see that $\alpha_{\mathrm{eff}}'^{\mathrm{new}}$ determines the mass spectrum. Then following, for instance, the approach in (9) we find that the effective Hagedorn temperature is $(8\pi^2\alpha_{\mathrm{eff}}'^{\mathrm{new}})^{-1/2}=T$. Therefore, the free energy of the gas of open strings on the bound state is a finite (for $p<7$) quantity of order 1, as far as the dependence on G_o is concerned.

For $T>T_{\mathrm{H}}$ the free energy is dominated by that of the $N-N'$ free long strings:

$$F=-2\pi NL(T-T_{\mathrm{H}})^2.$$

Using (28) we observe that this expression is extensive:

$$F=-LV_t(2\pi)^{2-p}(\alpha_{\mathrm{eff}}')^{(1-p)}G_o^{-2}(T-T_{\mathrm{H}})^2. \tag{30}$$

Just as for $p=1$, the free energy is of order G_o^{-2} for $T>T_{\mathrm{H}}$.

Now we are in a position to complete the phase diagram of the higher-dimensional NCOS theories. At very low temperatures, one has the open string phase of the NCOS. This description breaks down at the Hagedorn temperature (5), where one has a phase transition beyond which the tempertively two-dimensional although the free energy remains extensive. The details of the phase transition are dimension dependent. For all $p<5$ the Hagedorn transition is second order. In $p\geqslant 3$ the specific heat diverges as $T\to T_{\mathrm{H}}$ on the open string side.[13]

The free energy of noninteracting open strings becomes more singular with increasing p, and for $p\geqslant 5$ the entropy diverges at the transition. This implies that interaction effects become important already for $T<T_{\mathrm{H}}$. Nevertheless, it is likely that the high-temperature phase again involves liberated long strings. We may argue for this as follows. The free energy of noninteracting open strings is of order G_o^0, and interactions are unlikely to change this scaling. On the other hand, the free energy of liberated strings, (30), is of order G_o^{-2}. Therefore, for weak coupling and for T sufficiently above T_{H}, the system can lower its free energy by liberating long strings from

the bound state. It is not clear, however, whether the transition for $p>4$ is second order; it may be a first-order transition for all values of G_o. Additional ideas on the Hagedorn transition for 5-branes have appeared in Refs. 33, 14, 15.

In fact, one may suspect that for large enough p the Dp-brane does not decouple from gravity in the NCOS limit. In Ref. 3 the nonplanar one-loop amplitude was calculated for 4 open strings, and it was shown that for $p<7$ the amplitude is finite for $k^2=0$ (k is the momentum in the closed string channel). For $p\geqslant 7$ the amplitude blows up for $k^2=0$ which suggests that there is no decoupling from massless bulk modes. In order to check this, we have calculated the cross-section for two massless open strings of energy k_0 colliding along the electric field direction to produce an outgoing graviton. The term in the Born–Infeld action describing this process is

$$\frac{1}{2}\int d^{p+1}x(\partial_0\Phi^i\partial_0\Phi^j-\partial_1\Phi^i\partial_1\Phi^j)(\delta_{ij}+\sqrt{2}\kappa h_{ij}),$$

where we have rescaled the scalar fields so that they are canonically normalized. The cross-section we find,

$$\sigma\sim G_o^4(\alpha'_e)^4k_0^{9-p}(E_c^2-E^2)^{(7-p)/2},$$

vanishes for $p<7$, is finite for $p=7$, and diverges for $p>7$. This result is consistent with the annulus calculation in Ref. 3 and it indicates that nongravitational NCOS theories can exist only for $p<7$. It is interesting to note that $p=7$ is also special from the point of view of the thermodynamics: indeed here the free energy for the low energy phase, computed in Sec. II, diverges logarithmically at $T=T_{\mathrm{H}}$.

To summarize this section, we can draw the general conclusion that the physics of the Hagedorn transition is similar for all NCOS theories with $p<7$, in that above T_{H} the temperature dependence of F is effectively two-dimensional even though F is extensive in p dimensions. This is similar to the answer proposed in Ref. 9, although the justification there was different. In the NCOS case the two-dimensional behavior of the free energy above the Hagedorn temperature has to do with the presence of the electric field.

B. Extension to OD3 theory

In NCOS theory, a critical NS–NS 2-form field in presence of a Dp-brane leads to a decoupling limit in which fundamental strings are light. In certain variants of OM theory, a critical RR $(p+1)$-form field applied to an NS5-brane is associated with a decoupling limit in which Dp-branes become light.[5,16] No computational framework comparable to perturbative quantization of strings has emerged to study light Dp-branes for $p>1$. Indeed, one may wonder if it is logically consistent for higher-dimensional branes ever to be the ''fundamental'' degrees of freedom of a theory.[34] However, it appears from the decoupling arguments of Refs. 5, 16 that there are decoupling limits of string theory where the lightest excitations are indeed open Dp-branes with $p>1$.

It is tempting to adapt the reasoning used for NCOS theories to describe a possible phase transition for various OM-theories. In this section we will make an attempt in this direction, but our arguments will be much more heuristic than in previous sections. We will examine the relatively clean example of OD3-theory, which is the theory of open D3-branes on an NS5-brane in a decoupling limit with a critical 4-form potential turned on. Besides the obvious pitfall that the quantum states of fluctuating open D3-branes are hard to count, there is another interesting effect: fundamental strings living on the NS5-D3 bound state have a substantially reduced tension relative to their tension in flat space, and their Hagedorn behavior competes with the tendency to liberate D3-branes.

An NS5-brane with a near-critical RR 4-form potential can be described as a bound state of many D3-branes and a single NS5, such that the D3-branes make the dominant contribution to the tension. Let ρ be the number density of D3-branes in the two directions orthogonal to the D3-

branes but parallel to the NS5-brane. Then we require $\rho\tau_{\mathrm{D3}} \gg \tau_{\mathrm{NS5}}$. We will see below that this condition turns out to be trivially satisfied in the OD3 limit as defined in Ref. 5.

The tension of the NS5-D3 bound state is $\sqrt{\tau_{\mathrm{NS5}}^2+\rho^2\tau_{\mathrm{D3}}^2}$. The tension of an open D3-brane stuck to the NS5-brane is

$$\begin{aligned}\tau_{\mathrm{OD3}} &= \frac{d}{d(\delta\rho)}\left(\delta\rho\,\tau_{\mathrm{D3}}+\sqrt{\tau_{\mathrm{NS5}}^2+(\rho-\delta\rho)^2\tau_{\mathrm{D3}}^2}\right)\Big|_{\delta\rho=0} \\ &= \tau_{\mathrm{D3}}\left[1-\left(1+\left(\frac{\tau_{\mathrm{NS5}}}{\rho\tau_{\mathrm{D3}}}\right)^2\right)^{-1/2}\right] \approx \frac{1}{2}\left(\frac{\tau_{\mathrm{NS5}}}{\rho\tau_{\mathrm{D3}}}\right)^2\tau_{\mathrm{D3}},\end{aligned} \tag{31}$$

where in the last line we have used $\rho\tau_{\mathrm{D3}} \gg \tau_{\mathrm{NS5}}$. The near-critical scaling limit is described by two parameters:[5] a scale $\tilde{\alpha}'_{\mathrm{eff}}$ and a coupling $G^2_{o(3)}$, which happens to be precisely the closed string coupling g_{str} (this last fact is special to OD3-theory). The precise scaling of the parameters is given as $\tilde{\alpha}' = \sqrt{\epsilon}\tilde{\alpha}'_{\mathrm{eff}}$, the metric in directions transverse to the D3-branes scales as $g_{MN} = \epsilon\delta_{MN}$, and $g_s = G^2_{o(3)}$. The scaling of the metric implies that $\rho = \rho_0/\epsilon$, where ρ_0 is of order unity. This implies $\rho\tau_{\mathrm{D3}} \sim O(\epsilon^{-2})$, while $\tau_{\mathrm{NS5}} \sim O(\epsilon^{-3/2})$, thereby satisfying the aforementioned condition that $\rho\tau_{\mathrm{D3}} \gg \tau_{\mathrm{NS5}}$.

Just as we found in NCOS theory that it is thermodynamically favorable to liberate strings from the bound state at a temperature $T_{\mathrm{H}} \sim \sqrt{\tau_{\mathrm{eff}}}$, so we will find here that it is favorable to liberate D3-branes at a temperature $T_{c,\mathrm{D3}} \sim \tau_{\mathrm{OD3}}^{1/4}$. The argument proceeds along similar lines. First we note that a free $U(1)$ gauge multiplet in a flat-space theory in $p+1$ dimensions and sixteen supercharges has

$$\frac{F}{L^p T^{p+1}} = -c_{\mathrm{D}_p} \equiv -\frac{8\,\mathrm{Vol}\,S^{p-1}}{(2\pi)^p}\left(2-\frac{1}{2^p}\right)\Gamma(p)\zeta(p+1). \tag{32}$$

Here F is the free energy, L^p is the spatial world-volume, and T is the temperature. The low-energy dynamics of the bound state is noncommutative super-Yang–Mills theory in $5+1$ dimensions. Clearly, then, the free energy at low temperatures is order 1 in the sense that it does not grow with a power of the number density ρ. Let us assume that this remains the case up through the temperature where liberating D3-branes becomes thermodynamically favorable. Then the same manipulations that we went through in (16) are justified at large ρ: the free energy after a number density $\delta\rho$ of D3-branes have been liberated is

$$\begin{aligned}\frac{F_{\delta\rho}}{L^5} &= \sqrt{\tau_{\mathrm{NS5}}^2+(\rho-\delta\rho)^2\tau_{\mathrm{D3}}^2}+\delta\rho\,\tau_{\mathrm{D3}}-c_{\mathrm{D3}}\delta\rho T^4 \\ &\approx \rho\tau_{\mathrm{D3}}-c_{\mathrm{D3}}\rho T^4+\frac{\tau_{\mathrm{NS5}}^2}{2(\rho-\delta\rho)\tau_{\mathrm{D3}}}+c_{\mathrm{D3}}(\rho-\delta\rho)T^4 \\ &\geqslant \rho\tau_{\mathrm{D3}}+\tau_{\mathrm{NS5}}\sqrt{2c_{\mathrm{D3}}T^4/\tau_{\mathrm{D3}}}-c_{\mathrm{D3}}\rho T^4,\end{aligned} \tag{33}$$

where we neglect terms which are subleading in ρ. Equality pertains in the last line of (33) if and only if the last two terms in the second line are equal. One reads off the fraction of liberated D3-branes, the free energy, and the critical temperature $T_{c,\mathrm{D3}}$ as

$$\nu \equiv \frac{\delta\rho}{\rho} = \frac{T^2-T_{c,\mathrm{D3}}^2}{T^2},$$

$$\frac{F}{L^5} \approx \rho\tau_{\mathrm{D3}}-c_{\mathrm{D3}}\rho(T^2-T_{c,\mathrm{D3}}^2)^2, \tag{34}$$

$$T_{c,\mathrm{D3}}^2=\frac{\tau_{\mathrm{NS5}}}{\sqrt{2c_{\mathrm{D3}}\tau_{\mathrm{D3}}\rho}}=\sqrt{\tau_{\mathrm{OD3}}/c_{\mathrm{D3}}}=\frac{1}{(2\pi)^{7/2}}\frac{1}{\sqrt{2c_{\mathrm{D3}}}}\frac{1}{g_{\mathrm{str}}^{3/2}\tilde{\alpha}'^2\rho_0}.$$

[Formally, a similar analysis seems to be possible for many D5-branes bound to an NS5-brane. However, in this case, the absence of strong IR dynamics on N coincident D5-branes makes it likely that there are $O(N^2)$ massless degrees of freedom even at low energies. This would overwhelm the $O(N)$ effect due to liberated D5-branes, rendering the whole approach suspect.]

In the case of NCOS theory, it was essentially guaranteed that fundamental strings would start being liberated at the Hagedorn temperature of the noncommutative open strings, because the calculation of the free energy of liberated strings was equivalent to a computation in the light cone formalism of highly excited open strings. In OD3 theory, no analog of the latter computation exists as yet, so to be conservative we should regard $T_{c,\mathrm{D3}}$ as an upper bound on the temperature where some transition must take place. In fact, as we will now show, when $G_{o(3)}\ll 1$, there is a Hagedorn transition for closed fundamental strings living on the NS5-D3 system at a substantially lower temperature than $T_{c,\mathrm{D3}}$. These closed strings are excitations of the NS5-D3 bound state.

There is no net $f1$ charge in the NS5-D3 bound state that we wish to analyze; however, in order to extract the tension of the closed strings which live on the NS5-D3 system, it is convenient to first consider a BPS arrangement where an NS5-brane is oriented in the 012345 directions, ρ D3-branes per unit 45-volume are oriented in the 0123 directions, and ρ_4 fundamental strings per unit 2345-volume are oriented in the 01 directions. The total tension is

$$\tau=\sqrt{(\tau_{\mathrm{NS5}}+\rho_4\tau_{f1})^2+(\rho\tau_{\mathrm{D3}})^2}. \tag{35}$$

The effective tension of a fundamental string bound to the NS5-D3 system is

$$\tau_{f1,\mathrm{eff}}=\left.\frac{\partial\tau}{\partial\rho_4}\right|_{\rho 4=0}=\tau_{f1}\left.\frac{\tau_{\mathrm{NS5}}}{\tau}\right|_{\rho 4=0}\approx\tau_{f1}\frac{\tau_{\mathrm{NS5}}}{\rho\tau_{\mathrm{D3}}}\ll\tau_{f1}, \tag{36}$$

where in the last two steps we have used the fact that most of the mass of the bound state is carried by the D3-branes. Fundamental strings which are orthogonal to the D3-branes but contained in the NS5-branes are much heavier.

Another way to derive the effective tension $\tau_{f1,\mathrm{eff}}$ is to look at the supergravity solution for the NS5-D3 system. The string metric and dilaton are

$$ds_{\mathrm{str}}^2=\frac{1}{\sqrt{h_3}}(-dt^2+dx_1^3+dx_2^2+dx_3^2)+\sqrt{h_3}(dx_4^2+dx_5^2+h_5(dx_6^2+dx_7^2+dx_8^2+dx_9^2)),$$

$$e^{2(\phi-\phi_\infty)}=h_5,\quad h_3=1+\frac{q_3}{r^2},\quad h_5=1+\frac{q_5}{r^2}, \tag{37}$$

$$r^2=x_6^2+x_7^2+x_8^2+x_9^2.$$

In the limit where $\rho\tau_{\mathrm{D3}}\gg\tau_{\mathrm{NS5}}$, we have $q_5/q_3=\tau_{\mathrm{NS5}}/(\rho\tau_{\mathrm{D3}})$. The three-form field strengths need not concern us, except to note that $B_{\mu\nu}^{(NS)}$ may be chosen so that only B_{45} is nonzero. We are considering many D3-branes, but only a single NS5-brane, so the supergravity solution is trustworthy, in the sense that curvatures are sub-stringy, down to a radius $r_{\mathrm{match}}=\sqrt{q_5}$. Following the philosophy of Ref. 32, we assert that the tension and coupling of fundamental strings bound to the NS5-D3 system can be read off, up to factors of order unity, from the properties of a test string located at the matching radius r_{match}. The tension so derived agrees with (36). The advantage of this more heuristic approach is that we can extract the string coupling for the strings bound to the NS5-D3 system: up to a factor of 2 it is just $g_{\mathrm{str}}=G_{o(3)}^2$.

When $G_{o(3)} \ll 1$, we are entitled to use the free string spectrum to predict a Hagedorn temperature for the light fundamental strings whose orientation is within the D3-branes. It is

$$T_{c,f1} \sim \sqrt{\tau_{f1,\mathrm{eff}}} = \frac{1}{(2\pi)^{3/2}} \frac{1}{\sqrt{g_{\mathrm{str}} \tilde{\alpha}'^2 \rho_0}}. \tag{38}$$

From

$$\frac{T_{c,f1}}{T_{c,\mathrm{D3}}} \sim \frac{\sqrt{\tau_{f1,\mathrm{eff}}}}{\tau_{\mathrm{OD3}}^{1/4}} \sim g_{\mathrm{str}}^{1/4} = \sqrt{G_{o(3)}}, \tag{39}$$

we learn that the fundamental string Hagedorn transition happens at a lower temperature when $G_{o(3)} \ll 1$. This supports the view that the most relevant degrees of freedom in OD3-theory with $G_{o(3)} \ll 1$ may be little strings. Before one can ask whether the D3-brane liberation transitions occurs, one must understand what contribution the fundamental strings make to the free energy above $T_{c,f1}$.

When $G_{o(3)} \gg 1$, one can obtain a more natural description of the theory by *S*-dualizing. The scaling limit leading to OD3-theory *S*-dualizes into the zero slope limit used in Ref. 1 to obtain noncommutative Yang–Mills theory.[5] For $G_{o(3)} \gg 1$, this theory is weakly coupled in the sense that $g_{\mathrm{YM}} \ll \sqrt{\theta}$. However, the interacting theory is nonrenormalizable, so it might be inappropriate to regard the quanta of the gauge field as the fundamental degrees of freedom. It was suggested in Ref. 5 that OD3-theory provides an ultraviolet completion of $5+1$-dimensional noncommutative Yang–Mills theory. This is not a very effective description in the absence of a knowledge of how to quantize open D3-branes. It must be admitted that, for $G_{o(3)} \gtrsim 1$, there is neither a natural little string theory description of OD3-theory, nor a renormalizable interacting quantum field theory description. Despite all this uncertainty, the analysis following (33) may still be valid: it only depends on the free energy of the bound state being $O(\rho^0)$ in a $\rho \to \infty$ limit with $G_{o(3)}$ fixed.

[34] It is unquestionable that p-branes on shrinking cycles play a role in gauge symmetry enhancement, as well as in elucidating singularities like the conifold. What seems less certain is whether some theory in noncompact spacetime exists which admits a fundamental description as a theory of fluctuating p-branes, $p>1$.

Noncommutative tachyons and K-theory

(Received 2 January 2001; accepted for publication 13 February 2001)

We show that the relation between D-branes and noncommutative tachyons leads very naturally to the relation between D-branes and K-theory. We also discuss some relations between D-branes and K-homology, provide a noncommutative generalization of the ABS construction, and give a simple physical interpretation of Bott periodicity. In addition, a framework for constructing Neveu–Schwarz five-branes as noncommutative solitons is proposed. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377270]

I. INTRODUCTION

D-branes can be incorporated into open string field theory as solitons of tachyon configurations[1–6] and carry charges which take values in K-theory.[7,2,3] It was recently pointed out[8,9] that the description of D-branes as solitons in the open string tachyon field theory simplifies dramatically when a B field is turned on, thus making the tachyon field theory into a noncommutative field theory with the D-branes appearing as noncommutative solitons.[10]

One point of the following paper is that this description provides another point of view on the relation between D-branes and K-theory. Indeed this point of view makes the relation between D-branes and K-theory manifest.

A second, more speculative point we would like to make is the following. In the discussion below we will encounter some simple C^*-algebras. It is natural to wonder if replacing string field algebras by C^*-algebras leads to some new and interesting string backgrounds, or whether the theory of C^*-algebras should play a more fundamental role in brane physics.

Some observations closely related to this paper have been independently made in Refs. 11, 12. Some of the points below were made in lectures at Strings 2000.[13] Other recent papers suggesting a role of K-homology in D-brane physics include Refs. 14–17.

II. NONCOMMUTATIVE TACHYONS ARE MAPS TO CLASSIFYING SPACES

We first consider noncommutative tachyons in the bosonic string. The basic setup in Ref. 9 is that we consider spacetime to be a product $X\times R^{2n}$, where X is a $26-2n$ manifold. (In Ref. 9, X was taken to be $R^{25-2n,1}$, but the generalization to arbitrary X is easy, and quite important for our point below.)

We now consider open bosonic string field theory with target $X\times R^{2n}$. The action depends on the on-shell background values of the closed string fields $g_{\mu\nu}, g_s, B_{\mu\nu}$, where g_s is the closed string coupling. We take g_s to be small, and assume that the natural generalization of the flat space formulas to curved $g_{\mu\nu}$ applies.

If the tachyon effective action at $B=0$ is

$$S=\frac{C}{g_s}\int_{X\times R^2} d^{26}x\,\sqrt{\det g}\left(\frac{1}{2}f(T)g^{\mu\nu}\,\partial_\mu T\,\partial_\nu T - V(T)+\cdots\right), \tag{2.1}$$

a)Electronic mail: gmoore@physics.rutgers.edu

where C is a constant and T is the tachyon field, then the generalization to $B\neq 0$ is given in terms of a noncommutative field theory:[18–20]

$$S=\frac{C}{G_s}\int_{X\times R^2} d^{26}x\sqrt{\det G}\left(\frac{1}{2}f(T)G^{\mu\nu}D_\mu T D_\nu T - V(T)+\cdots\right), \tag{2.2}$$

where G_s and $G_{\mu\nu}$ are the open string coupling and metric, given by standard formulas.[21,22,20] The effect of B is to transform $g_s\to G_s$, $g_{\mu\nu}\to G_{\mu\nu}$ and commutative products of fields to noncommutative products taken with the Moyal product. In addition, B induces a nonzero coupling of the tachyon to the noncommutative $U(1)$ gauge field.[23]

The tachyon potential is

$$V(T)=V_0-m^2 T*T+\lambda T*T*T+\cdots. \tag{2.3}$$

There are also higher derivative terms in (2.2) that we have ignored.

The construction in Refs. 8, 9 is heavily based on the noncommutative solitons of Ref. 10. According to Ref. 10 the most effective way to think about the tachyon dependence on the noncommutative directions is in terms of operators on Hilbert space. The coordinates x^{2i-1},x^{2i} on the transverse R^{2n} satisfy

$$[x^{2i-1},x^{2i}]:=x^{2i-1}*x^{2i}-x^{2i}*x^{2i-1}=-i\theta_i, \tag{2.4}$$

where the θ^i are the skew eigenvalues of the parameter θ^{ij} appearing in the Moyal product.

Letting x^a denote commutative coordinates along X, x^i, $i=1,...,2n$ denoting the noncommutative coordinates, the tachyon field $T(x^a,x^i)$ is now regarded as an operator valued function of the x^a. What kind of operator can T be? Since T is a real field. T should be a self-adjoint operator. Since we would like to speak of continuous tachyon fields, T should be a map of X into a C^* algebra, and since all such algebras are subalgebras of the algebra of bounded operators on Hilbert space we regard T as a continuous map:

$$T:X\to\mathcal{B}, \tag{2.5}$$

where $\mathcal{B}$ is the C^*-algebra of bounded operators on a Hilbert space $\mathcal{H}$ and we use the norm topology.

In fact, since we wish to have an action, T should have a derivative. (More precisely, T should have a Frechét derivative.) Moreover, the gauge fields should be introduced using unbounded operators $D_i=\theta_{ij}^{-1}\,\mathrm{ad}\,X_j+\mathrm{ad}\,A_i$ on $\mathcal{H}$.

After integrating out the massive string fields the effective action for the tachyon and gauge fields takes the form

$$\begin{aligned}S=\frac{C}{G_s}\int_X d^{26-2n}x\sqrt{\det G}\Bigg(\mathrm{Tr}\Bigg[&\frac{1}{2}f(T)G^{ab}D_aT D_bT+\frac{1}{2}f(T)G^{ij}[D_i,T][T,D_j^\dagger]\\&-V(T)-\frac{1}{4}h(T)G^{ik}G^{jl}F_{ij}F_{kl}-\frac{1}{4}h(T)G^{ac}G^{bd}F_{ab}F_{cd}\Bigg]+\cdots\Bigg).\end{aligned} \tag{2.6}$$

Here Tr is the trace of the operator on Hilbert space; x^a run over the commuting coordinate directions on X. Evidently, in addition to our other criteria, certain combinations of the map T in (2.5) must be trace class in order to have a finite action.

Let us now consider the limit of Ref. 9, $\alpha' B_{ij}\to\infty$, or equivalently, $\theta^{ij}/\alpha'\to 0$, and consider constant tachyon field configurations $\partial_a T=0$. Then by rescaling the coordinates to remove θ_i from the star product one sees that the action reduces to the potential term as $\alpha' B_{ij}\to\infty$ and hence T must satisfy $V'(T)=0$.

As noted by Ref. 10 this can be solved by

$$T=\sum_i \lambda_i P_i, \tag{2.7}$$

where P_i are orthogonal projection operators and λ_i are stationary points for $V(T)$.

In the bosonic string formulated in Witten's open string field theory with a $*$ product, the potential is purely cubic. If we assume that the basic shape of the potential remains unchanged after integrating out massive string fields (recent computations[24,25,6,26] have provided nontrivial evidence that this is correct), then there are two stationary points $\lambda=0$, $\lambda=t_*$. If we choose t_* to correspond to the perturbative open bosonic string vacuum, with $V(t_*)$ given by the tension of the D25-brane, then Sen's conjecture states that $V(0)=0$ represents the closed string vacuum. Therefore, the only nontrivial constant solution to (2.7) is $T=t_* P_n$ where P_n is a rank n projection operator.

Now, in the limit of Ref. 9 the action is proportional to $\mathrm{Tr}\, V(T)=nV(t_*)$ even if the projection operator P_n varies as we move in X. We immediately see the close connection to K-theory. Slowly varying tachyonic field configurations are given by maps from X into the space of rank n projection operators in Hilbert space. This space of projection operators is sometimes denoted $BU(n)$, so we have

$$T: X \to BU(n). \tag{2.8}$$

If we consider a rank $n<k$ projection operator in the finite dimensional Hilbert space C^k then the space of such projection operators is clearly $U(k)/(U(n)\times U(k-n))$. The space $BU(n)$ is defined as the inductive limit of this quotient space as $k\to\infty$.

The space $BU(n)$ is topologically intricate, and if X is topologically nontrivial then the set of homotopy classes of maps $[X,BU(n)]$ can be nontrivial. Indeed, $BU(n)$ is a model for a ''classifying space'' of vector bundles. This means there is an isomorphism,

$$\mathrm{Vect}_n(X)\cong[X,BU(n)], \tag{2.9}$$

where $\mathrm{Vect}_n(X)$ are the isomorphism classes of complex vector bundles on X of rank n. This is explained in detail in Refs. 27, 28. In this way we relate homotopy classes of tachyon field configurations directly to isomorphism classes of vector bundles, and therefore to K-theory classes.

In the bosonic string the physical interpretation of these K-theory classes is less clear than in type II theory since the branes carry no conserved charges and presumably are unstable, even if the K-theory class is nontrivial. Our hypothesis is that these K-theory classes label inequivalent unstable D-brane configurations or boundary states of the bosonic string.

It would be very interesting to extend this discussion to the case of finite θ and to include the effects of second derivatives. Such considerations lead to many new questions beyond the scope of this paper. Some of these considerations indicate the relevance of a nonlinear sigma model with target space $BU(n)$. (Such sigma models have been considered in a superficially different context by Losev, Nekrasov, and Shatashvili.[29])

III. WITTEN'S FACTORIZATION OF THE OPEN STRING * PRODUCT ALGEBRA

We now consider spacetime of the form $X\times R^2$ with X a 24-manifold. We also assume that the metric factorizes and denote the closed string metric on X by g_{ab} and the closed string metric on R^2 by g_{ij}. Witten has observed in Ref. 30 that in the limit of Ref. 9, where the closed string metric g_{ij} is fixed and $\alpha' B_{ij}\to\infty$ (so the open metric $G^{ij}\to 0$) the $*$ algebra of open string field theory factorizes as $\mathcal{A}\to\mathcal{A}_0\otimes\mathcal{A}_1$. Here $\mathcal{A}_0$ is the algebra of the vertex operators in the 26 dimensional open bosonic string with zero momentum in the noncommutative directions and $\mathcal{A}_1$ is the algebra of noncommutative functions on R^2.

We can trivially extend the analysis of Ref. 30 by considering the following two scaling limits. In the first we take $B_{ij}=tB^0_{ij}$ and $g_{ab}=t^2 g^0_{ab}$ and take $t\to\infty$, keeping B^0, g^0_{ab} and g_{ij} fixed.

In this limit the string algebra factorizes as above but with $\mathcal{A}_0$ the algebra of zero momentum vertex operators and $\mathcal{A}_1 = C(X) \otimes C_B(R^2)$ where the first term is the commutative algebra of functions on X and the second is the noncommutative algebra of functions on R^2 defined by the Moyal product. (There is an important question of whether the functions should be compactly supported, or not. We believe that rapid falloff, or compact support is appropriate.) The second scaling limit takes $B_{ij} = 0$ and scales both g_{ab} and g_{ij} as t^2. In this limit the string algebra factorizes with $\mathcal{A}_1 = C(X \times R^2) = C(X) \otimes C(R^2)$ being the algebra of commutative functions on $X \times R^2$.

It is natural to expect that the set of D-branes, or boundary states is somehow connected with a K-theory of the algebra $\mathcal{A}_0 \otimes \mathcal{A}_1$. However, since $\mathcal{A}_0$ is a vertex operator algebra, the meaning of its K-theory definitely requires some explanation. Without answering this question we can at least ask what we can say without knowing too much about $K(\mathcal{A}_0)$.

Our working hypothesis is that $\mathcal{A}_0, \mathcal{A}_1$ behave similar to C^* algebras. In C^*-algebra theory there is a Kunneth-type theorem which implies that, modulo torsion, we may identify $K(\mathcal{A}_0) \otimes K(\mathcal{A}_1)$ with $K(\mathcal{A}_0 \otimes \mathcal{A}_1)$. (See Ref. 31, Theorem 23.1.3.) Therefore, we will focus on the K-theory of the algebra $\mathcal{A}_1$ in the next section.

IV. BOTT PERIODICITY AND NONCOMMUTATIVE SOLITONS

The algebra of functions $\mathcal{A}_1$ is very different for $B = 0$ and for $B \neq 0$. Nevertheless we expect the K-theory classification of branes to be unmodified when we turn on B and scale the metric. We will interpret this statement as a manifestation of Bott periodicity. (See Ref. 32 for a related remark.)

Bott periodicity is usually formulated as

$$K(X) \cong K(X \times S^2) = K_{\mathrm{cpt}}(X \times R^2). \tag{4.1}$$

In Ref. 9, X is R^{23+1} with R^2 as the transverse 2 dimensions to the D23-brane constructed as a noncommutative soliton of the tachyon field theory. Equation (4.1) can be translated into the algebraic setting:

$$K(C(X)) \cong K(C(X) \otimes C_0(R^2)), \tag{4.2}$$

where $C(X)$ is the algebra of continuous functions on X, and $C_0(R^2)$ is the algebra of continuous functions going to zero at infinity.

K-theory is unchanged under ''Morita equivalence.'' Therefore

$$K(C(X)) = K(C(X) \otimes \mathrm{Mat}_N(C)). \tag{4.3}$$

Moreover, the norm-closure of the $N \to \infty$ limit of $\mathrm{Mat}_N(C)$ is the algebra of compact operators $\mathcal{K}$. Since K-theory behaves well under inductive limits,

$$K(C(X)) = K(C(X) \otimes \mathcal{K}). \tag{4.4}$$

If the transverse coordinates satisfy $[x^1, x^2] = -i\theta$ (θ is real) then the Stone–von Neuman theorem says there is a unique irreducible unitary representation $\mathcal{H}$, i.e. the Hilbert space of quantum mechanics. Moreover, to any $f \in \mathcal{S}(R^2)$, the Schwarz space of functions of rapid decrease, the Weyl ordered operators,

$$T(f) = \int dp_1\, dp_2\, \hat{f}(p_1, p_2) \exp[i(p_1 \hat{x}^1 + p_2 \hat{x}^2)], \tag{4.5}$$

where $\hat{f}(p_1,p_2)$ is the Fourier transform, generate the algebra $\mathcal{K}$ of compact operators.[33] If we suppose that the classification of D-branes is unchanged in the limit $B\to 0$ then it follows that $K(C(X)\otimes C_B(R^2))\equiv K(C(X)\otimes\mathcal{K})=K(C(X)\otimes C_0(R^2))$. Combining this with Morita equivalence we obtain the statement of Bott periodicity.

V. K-THEORETIC CLASSIFICATION OF D-BRANES FROM TACHYONS IN TYPE IIB STRINGS

Let us now turn to the tachyon field in the construction of type II D-branes via noncommutative solitons. We will focus on the case of BPS IIB branes. As shown in Ref. 30, the tachyon field must satisfy

$$T\overline{T}T=T, \tag{5.1}$$

where $\overline{T}$ is the Hermitian conjugate of T. Equation (5.1) is the defining equation of a ''partial isometry.'' Moreover, the net brane charge is given by the index of T. In an effective field theory approach the tachyon potential has the form

$$V(T,\overline{T})=U(\overline{T}T-1)+U(T\overline{T}-1). \tag{5.2}$$

(This result could presumably also be derived in string field theory.) To have a finite energy configuration the kernels of both T and $\overline{T}$ must be finite dimensional, thus T should be both a Fredholm operator and a partial isometry.

Once again, we split spacetime as $X\times R_B^{2n}$, where X has dimension $10-2n$ and might be topologically nontrivial. If we consider X-dependent configurations with a finite net number of branes then the tachyon field will give us a map

$$T:X\to\mathcal{F}, \tag{5.3}$$

where $\mathcal{F}$ are the Fredholm operators. But this is exactly one model for K-theory![28,34] Moreover, the map $[X,\mathcal{F}]\to K^0(X)\to 0$ is given by taking the index bundle whose fiber at $x\in X$ is just $\mathrm{Ind}(T)_x:=\mathrm{Ker}(T(x))-\mathrm{Cok}(T(x))$ and we identify this as the K-theory class of the Chan–Paton space of the D-brane. The argument that the map is onto, given in Appendix A of Ref. 28, shows that there is no loss of generality in supposing that the Fredholm operator is in fact a partial isometry. Thus, one recovers in a very straightforward way the classification of type II D-brane charge in terms of K-theory.

A closely related remark has been made (independently) by Witten in Ref. 11 in the type IIA context. Here Witten uses the Fredholm model identifying $K^1(X)$ with $[X,\mathcal{F}^{sa}]$ where $\mathcal{F}^{sa}$ are the self-adjoint Fredholm operators. This model is due to Atiyah and Singer.[35]

VI. TOEPLITZ OPERATORS AND THE ABS CONSTRUCTION

In the explicit solution for the D7-brane as a vortex in the noncommutative plane, explained in Refs. 9, 30, 36 the tachyon operator T is a special kind of partial isometry, namely, a shift operator $T=S$ where S is the shift operator,

$$S:|n\rangle\to|n+1\rangle,\quad n\geq 0, \tag{6.1}$$

in a ''harmonic oscillator'' basis $|n\rangle$, $n\geq 0$, for a separable Hilbert space. Note that $S^*S=1$, but SS^* is not 1, indeed, $SS^*=1-|0\rangle\langle 0|$. The C^* algebra generated by an operator such that $S^*S=1$, but $SS^*\neq 1$ is unique, and known as the ''Toeplitz algebra.'' This algebra can be realized in several ways, and the following is particularly apt for discussing generalizations of noncommutative tachyons.

We consider our Hilbert space to be the Hilbert space of square integrable functions on the circle, $L^2(S^1)$. The functions $1/\sqrt{2\pi}e^{in\theta}$ define a complete orthonormal basis $|n\rangle$ for $n\in\mathbb{Z}$. Given

a continuous function $f(\theta)$ we may associate an operator $M_f:\mathcal{H}\to\mathcal{H}$ simply by multiplying a wavefunction $\psi(\theta)$ by $f(\theta)$. This gives a representation of the commutative C^* algebra $C(S^1)$ on $\mathcal{H}$. Now consider the Dirac operator $D=-id/d\theta$ and split the Hilbert space into the negative and non-negative modes of D. Let P be the orthogonal projection onto the positive subspace H_+ of $L^2(S^1)$ spanned by $|n\rangle$ with $n\geqslant 0$. Equivalently, we could view P as the projection onto the subspace of $L^2(S^1)$ consisting of the boundary values of holomorphic functions. Then given a function $f(\theta)$ on S^1 we can define a Toeplitz operator which maps H_+ to H_+ by $T_f=PM_f$. Note that if f has negative Fourier modes then M_f does not preserve H_+, and hence the projector P acts nontrivially. For example, if $f_l=e^{il\theta}$, then T_{f_l} is just the shift operator S^l for $l>0$, but has a kernel for $l<0$. Quite generally, $(T_f)^\dagger=T_{f^*}$, so $f\to T_f$ preserves the adjoint $*$ action. However, the map f to T_f is not a homomorphism. Indeed, an easy computation shows that

$$T_1-T_{f_l}T_{f_l^*}=P_l \tag{6.2}$$

is the projection operator onto the first l levels in H_+. This is a compact operator, and in general it can be shown that, while $T_fT_g\neq T_{fg}$, the difference $T_fT_g-T_{fg}$ is a compact operator.

In what follows, this construction of Toeplitz operators will be generalized to L^2 functions on odd spheres in order to relate the index of Toeplitz operators to the winding number of ABS configurations.

A. Noncommutative ABS construction

Let us now generalize the construction of T in Refs. 9, 30 allowing for a $2p$-dimensional transverse noncommutative space. (The construction in Ref. 30 includes the possibility of a $2p$ dimensional transverse space for a single D9–anti D9 pair. Here we generalize this to 2^p pairs in order to explain the relation between the index of T and the winding number of the ABS configuration.)

First, we construct the noncommutative tachyon field. Let us skew-diagonalize θ^{ij} and take:

$$[x^{2i-1},x^{2i}]=-i\theta_i \quad \theta_i>0, \quad i=1,...p\,. \tag{6.3}$$

Moreover, we consider the irreducible Clifford representation γ_i for $\mathcal{C}l_{2p}$. These are $2^p\times 2^p$ dimensional complex Hermitian matrices of the form:

$$\gamma_i=\begin{pmatrix} 0 & \Gamma_i \\ \overline{\Gamma_i} & 0 \end{pmatrix}. \tag{6.4}$$

Now we take the noncommutative tachyon to be of the same form as the commutative ABS configuration:[37,2]

$$T=f(r)\Gamma_i x^i, \tag{6.5}$$

except that we now regard the tachyon as an operator,

$$T:\mathcal{H}\otimes S^-\to\mathcal{H}\otimes S^+, \tag{6.6}$$

where the Hilbert space $\mathcal{H}$ is realized as a representation of p oscillators and S^-, S^+ are negative and positive spin representations. To be specific, we will represent $\mathcal{H}$ as the Bargmann quantization,

$$\mathcal{H}_{\mathrm{B}}=\mathrm{Hol}\left(C^p,\exp\left[-2\sum\ \theta_i|z_i|^2\right]dv\right). \tag{6.7}$$

The wavefunctions are holomorphic functions of $z_i = x^{2i-1} + ix^{2i}$, normalizable with respect to the above measure and dv is the standard Euclidean volume element. An orthogonal basis for $\mathcal{H}_B$ is provided by the monomials $z^k := \Pi_i (z_i)^{k_i}$. We will let k stand for a multiindex $k \in (\mathbb{Z}_+)^p$.

We now show that T is a Fredholm operator, and also show how to determine $f(r)$ from the equations $T\overline{T}T = T$, $\overline{T}T\overline{T} = \overline{T}$. The key calculation is

$$\Gamma_i x^i \overline{\Gamma}_j x^j = \sum_{i=1}^{p} 2\theta_i \left(N_i + \frac{1}{2} \right) - i\Sigma_{ij}\theta^{ij},$$
$$\overline{\Gamma}_i x^i \Gamma_j x^j = \sum_{i=1}^{p} 2\theta_i \left(N_i + \frac{1}{2} \right) - i\overline{\Sigma}_{ij}\theta^{ij}. \tag{6.8}$$

Here $\Sigma_{ij} = 1/4(\Gamma_i \vec{\Gamma}_j - \Gamma_j \overline{\Gamma}_i)$, $\overline{\Sigma}_{ij} = 1/4(\overline{\Gamma}_i \Gamma_j - \overline{\Gamma}_j \Gamma_i)$ and $N_i = a_i^\dagger a_i$ is the ith occupation number. The second terms in (6.8) are diagonalized by the spinor weights to be $\Sigma_{i=1}^{p} \pm \theta_i$. Our convention is that in the second equation of (6.8) we have a spinor weight giving $-\Sigma \theta_i$. Therefore, the first operator has no kernel and the second operator has a one dimensional kernel, given by the oscillator ground state times the lowest weight spinor. Thus,

$$\overline{T} = \overline{\Gamma}_i x^i \frac{1}{\sqrt{\Gamma_i x^i \overline{\Gamma}_i x^i}} \tag{6.9}$$

satisfies the equation $T\overline{T}T = T$, has no kernel and is of index -1. We will refer to this as the ''noncommutative ABS construction.'' In order to explain the relation to the ABS construction we would like to make sense of restricting the tachyon field to a sphere in the noncommutative space. Classically, we restrict the field T to the solutions of the equation

$$\sum_i |z_i|^2 = R^2, \tag{6.10}$$

defining the sphere Σ of dimension $2p-1$ and radius R. At the nonzero B field the z_i become noncommuting, so the question arises as to what it means to restrict the operator to a noncommutative sphere. We will now propose one interpretation of what this might mean.

In quantum mechanics, restricting the wavefunctions in the Bargman space $\mathcal{H}_B$ to the sphere produces the Hardy space $\mathcal{H}_\Sigma$. This is the Hilbert subspace of $L^2(\Sigma; d\Omega)$ defined by the boundary values of holomorphic functions. Here $d\Omega$ is the standard round measure on the sphere such that $dv = R^{2p-1}\, dR\, d\Omega$. The projection operator from L^2 to $\mathcal{H}_\Sigma$ is given by

$$(Pf)(z) = \int_\Sigma K_\Sigma(z,w) f(w) d\Omega,$$
$$K_\Sigma(z,w) = (1 - z \cdot \overline{w})^{-p}. \tag{6.11}$$

An orthogonal basis for the Hardy space is again given by $\varphi_k = z^k$. Note that the norm of these states in the Hardy space is

$$(z^k, z^{k'}) = \delta_{k,k'} \frac{2\pi^p \Pi_i (k_i)!}{\Gamma(|k| + p)},$$

where $|k| = \Sigma k_i$ for a multi-index k.

Now let us consider the action of classical coordinates $z_i, \overline{z_i}$ on the Hardy space $\mathcal{H}_\Sigma$. To make sense of this we need to define Toeplitz operators. In general, if $f:\Sigma \to \mathbb{C}$ is any function we define $\mathcal{T}_f := PM_f$ where $M_f:\mathcal{H}_\Sigma \to L^2$ is the operator of multiplication by f. The operators $\mathcal{T}_{z_i}, \mathcal{T}_{\overline{z_i}}$ are easily computed:

$$\begin{aligned} \mathcal{T}_{z_i}\varphi_k &= \varphi_{k+e_i}, \\ \mathcal{T}_{\overline{z_i}}\varphi_k &= 0, \quad \text{if } k_i = 0, \\ &= 2\pi \frac{k_i}{|k|+p-1}\varphi_{k-e_i}, \quad \text{if } k_i > 0, \end{aligned} \tag{6.12}$$

where e_i is the ith unit vector in $(\mathbb{Z}_+)^p$.

By considering the Hilbert space $\mathcal{H}_\Sigma \otimes \mathbb{C}^N$, Toeplitz operators for functions are easily generalized to Toeplitz operators for matrix valued functions $f:\Sigma \to \mathrm{Mat}_N(C)$, and hence we can consider our tachyon operator (6.6) above as a Toeplitz operator:

$$T:\mathcal{H}_\Sigma \otimes S \to \mathcal{H}_\Sigma \otimes S, \tag{6.13}$$

where $S^+ \cong S^- \cong S$ is the irreducible spin representation in odd dimensions. The Toeplitz operator is the projection P_+ composed with matrix multiplication by $\beta:\Sigma \to GL(N,C)$ given, essentially by the ABS construction:

$$\beta(x) = \Gamma_i x^i \frac{1}{\sqrt{x^i x^i + \text{const}}}.$$

The operator T in (6.13) is bounded and Fredholm. Now, although the restriction map $\mathcal{H}_B \to \mathcal{H}_\Sigma$ is *not* unitary it is 1–1 and onto. Therefore, the *index* of T on $\mathcal{H}_B$ will be the same as the index of T on $\mathcal{H}_\Sigma$.

Now, we can invoke the index theorem of Boutet de Monvel,[38] according to which the index is

$$\mathrm{Index}(T|_{\mathcal{H}_\Sigma}) = \int_\Sigma \mathrm{ch}(\beta) Td(T\Sigma). \tag{6.14}$$

Here

$$\mathrm{ch}(\beta) = \beta^* \left(\sum_{j \geqslant 0} (-1)^{j-1} \frac{\omega_{2j-1}}{(j-1)!} \right),$$

and ω_i are standard generators of $H^i(GL(N,C),Q)$. Since $Td(T\Sigma) = 1$ in this case we have a direct connection between the index of the tachyon operator on $\mathcal{H}_B$, and the winding number of the classical ABS tachyon.

VII. REMARKS ON THE RELATION TO K-HOMOLOGY

The noncommutative ABS construction in the previous section leads rather naturally to a relation between D-branes and the work of Brown, Douglas, and Filmore (BDF) on the classification of algebras of essentially normal operators.[39] In this section we will give a brief review of that work, and then explain the relation to D-branes.

A. Brief review of BDF

An expository discussion of Ref. 39 can be found in Refs. 40, 31, 41, 42, 43. For the readers' convenience we give a brief summary here.

In Matrix theory,[44] spacetime emerges from an algebra of commuting operators. Here we will discuss algebras of ''almost commuting'' operators in the belief that these are related to D-branes. Recall that by Gelfand's theorem, C^*-algebras of commuting operators are naturally associated to Hausdorff topological spaces X by considering the algebra of continuous functions $C(X)$. [If X is noncompact, we add the condition that $f\to 0$ at infinity, and correspondingly $C(X)$ does not have a unit. For simplicity of discussion, we henceforth assume X is compact in this subsection.] Isomorphism classes of algebras are in 1–1 correspondence with homeomorphism classes of spaces. We will now consider noncommutative C^*-algebras $\mathcal{A}$ which fit into the short exact sequence:

$$0\to\mathcal{K}\to\mathcal{A}\overset{\beta}{\to}C(X)\to 0, \tag{7.1}$$

for some fixed space X. Note that if T_f denotes some operator in $\mathcal{A}$ mapping to the function f under β, then $T_{f_1}T_{f_2}-T_{f_1f_2}$ is in the kernel of β, and hence is a compact operator. It follows that $[T_{f_1},T_{f_2}]$ is compact and thus the algebra $\mathcal{A}$ is thus ''almost commuting'' in the sense that compact operators are considered to be ''small.'' An example of such an extension is given by the Toeplitz algebra generated by the shift operators, described at the beginning of Sec. VI: $S=T_z\to z$ defines a C^* morphism onto the continuous functions on $X=S^1$.

In Ref. 39, BDF investigated extensions of the form (7.1) for fixed X. To any such extension we can associate a C^*-algebra morphism (called the ''Busby invariant'') $\tau:C(X)\to Q(\mathcal{H})$ where Q is the ''Calkin algebra'' defined by $Q(\mathcal{H}):=B(\mathcal{H})/\mathcal{K}$ where $B(\mathcal{H})$ is the algebra of bounded operators on a separable Hilbert space. Indeed, for any $f\in C(X)$ we choose an operator $T_f\in\mathcal{A}$ projecting to it, and define τ by $\tau(f)=\pi(T_f)$ where $\pi:B(\mathcal{H})\to Q(\mathcal{H})$ is the projection. Since $T_{f_1}T_{f_2}-T_{f_1f_2}$ is a compact operator, τ is an algebra homomorphism. Conversely, given a C^*-algebra morphism $\tau:C(X)\to Q(\mathcal{H})$ one can form an extension (7.1), and, up to a natural notion of isomorphism, τ uniquely characterizes the extension. Full details can be found in Chap. 3 of Ref. 42. Suffice it to say here that, given $\tau:C(X)\to Q(\mathcal{H})$ we can form

$$0\to\mathcal{K}\to\mathcal{A}'\to C(X)\to 0 \tag{7.2}$$

by defining

$$\mathcal{A}':=\{(\mathcal{O},f):\pi(\mathcal{O})=\tau(f)\}\subset B(\mathcal{H})\oplus C(X), \tag{7.3}$$

and that (7.2) is equivalent to (7.1) in the sense that there is an isomorphism $\psi:\mathcal{A}\to\mathcal{A}'$ compatible with the two sequences.

One of the reasons the Busby invariant is useful is that it allows one to define a notion of direct sum of extensions. In order to do this we must first introduce ''unitary equivalence,'' also known as ''strong equivalence.'' Two extensions (7.1) are ''strongly equivalent'' if there is a unitary operator U on $\mathcal{H}$ such that the Busby invariants are related by $\tau_2(f)=\pi(U)\tau_1(f)\pi(U)^*$. Let $\mathbf{Ext}(C(X),\mathcal{K})$ denote the set of strong equivalence classes of extensions of $C(X)$ by $\mathcal{K}$. A direct sum operation on $\mathbf{Ext}(C(X),\mathcal{K})$ can then be defined by taking the extension corresponding to the Busby invariant,

$$\tau_1\oplus\tau_2:C(X)\to Q(\mathcal{H})\oplus Q(\mathcal{H})\to Q(\mathcal{H}\oplus\mathcal{H})\cong Q(\mathcal{H}). \tag{7.4}$$

It turns out that (7.4) defines a semigroup operation on $\mathbf{Ext}(C(X),\mathcal{K})$. Thus far, the theory could have been developed for general extensions $\mathbf{Ext}(A_1,A_2)$ of arbitrary C^*-algebras A_1 by A_2. However, specializing to $A_1=C(X)$ and $A_2=\mathcal{K}$, a number of nice things begin to happen. It turns out that there is a natural zero in the semigroup, corresponding to the ''trivial extensions.'' These are extensions for which the Busby invariant lifts to $B(\mathcal{H})$; equivalently, they are extensions such that the sequence (7.1) splits, and hence we can unambiguously write every operator in $\mathcal{A}$ in the form $T_f=N_f+k$ with $k\in\mathcal{K}$ and $N_{f_1}N_{f_2}=N_{f_1f_2}$. Let $\mathrm{Ext}(C(X),\mathcal{K})$ be the quotient of

Ext$(C(X),\mathcal{K})$ by the trivial extensions. In the above references it is shown that every extension has an inverse (up to the addition of a trivial extension) so that Ext$(C(X),\mathcal{K})$ in fact is an Abelian group. Moreover, Ext$(C(X),\mathcal{K})$ can even be used to define a homology theory on X! Indeed, if we define

$$\begin{aligned} K_1^a(X) &= \mathrm{Ext}(C(X),\mathcal{K}) \\ K_0^a(X) &= \mathrm{Ext}(C(X)\otimes C_0(\mathbb{R}),\mathcal{K}) \end{aligned} \tag{7.5}$$

(the superscript ''a'' is for ''analytic,'' K-homology, as opposed to ''topological'' K-homology), then it turns out that $K_*^a(X)$ is a mod 2 periodic homology theory, dual to K-theory.

One way to make the relation to a homology theory more evident is to introduce the noncommutative spheres $\mathcal{S}^0,\mathcal{S}^1$ with function spaces:

$$\begin{aligned} C(\mathcal{S}^1) &= \left\{ \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} : a_{ij}\in B(\mathcal{H}), a_{12}, a_{21}\in\mathcal{K} \right\}, \\ C(\mathcal{S}^0) &= \left\{ \begin{pmatrix} a_{11} & 0 \\ 0 & a_{22} \end{pmatrix} : a_{11}-a_{22}\in\mathcal{K} \right\}, \end{aligned} \tag{7.6}$$

and then define $K_i(X)$ to be homotopy classes of maps of X into $\mathcal{S}^i$, $K_i(X):=[\mathcal{S}^i,X]$. In the noncommutative setting this amounts to the homotopy classes of $*$-homomorphisms $C(X)\to C(\mathcal{S}^i)$. (The equivalence of this definition to what we described above is hardly obvious. The necessary technical details can be found in Ref. 31, Secs. 15.7 and 15.8.)

B. Algebra extensions associated to IIA-branes

We will now review a contruction from Ref. 41 which may be interpreted as saying that every IIA D-brane naturally provides a nontrivial extension of the algebra of functions on spacetime by compact operators.

Let W be an odd-dimensional Spin^c submanifold of a spacetime X. W is equipped with a complex vector bundle E with connection and inherits a metric from X. We think of W as the IIA-brane worldvolume and E as its Chan–Paton bundle. Using the above data we can form the Hilbert space $\mathcal{H}$ of L^2 spinors with values in $S\otimes E$, where $S\to W$ is the spin bundle. Denote the Dirac operator on $S\otimes E$ by $\not{D}_E$. Assuming the connection and metric are generic, $\not{D}_E$ will have no zero modes and we can decompose the Hilbert space into the positive and negative eigenspaces of $\not{D}_E$: $\mathcal{H}=\mathcal{H}_+\oplus\mathcal{H}_-$. The commutative algebra $C(W)$ is represented on $\mathcal{H}$ by multiplication operators M_f for $f\in C(W)$. In general, M_f does not preserve the subspace $\mathcal{H}_+$, but if we take the ''compression'' of M_f by composing with the projection operator $P_+:\mathcal{H}\to\mathcal{H}_+$ then we can define a Toeplitz operator $T_f=P_+M_f:\mathcal{H}_+\to\mathcal{H}_+$. As in the case $W=S^1$ described previously, it turns out that $T_{f_1}T_{f_2}-T_{f_1f_2}$ is a compact operator and we obtain an extension,

$$0\to\mathcal{K}\to\mathcal{A}\to C(W)\to 0, \tag{7.7}$$

where $\mathcal{A}$ is the C^* algebra generated by the T_f. By using pullback $\phi^*:C(X)\to C(W)$ we obtain an extension of the algebra of functions on all of spacetime. That is, if $\phi:W\to X$ is a continuous map then we can define a Busby invariant $\tau\phi^*:C(X)\to Q(\mathcal{H})$ from which we get an extension:

$$0\to\mathcal{K}\to\tilde{\mathcal{A}}\to C(X)\to 0 \tag{7.8}$$

It is shown in Ref. 41 that all classes in $K_1^a(X)=\mathrm{Ext}(C(X),\mathcal{K})$ can be obtained from the above construction using a suitable triplet (W,E,ϕ). Moreover, if a suitable equivalence relation is put on (W,E,ϕ) then classes in $K_1^a(X)$ are in 1–1 correspondence with classes $[(W,E,\phi)]$. The equivalence relations on (W,E,ϕ) make good physical sense: they include cobordism (i.e., con-

tinuous deformation of the worldvolume and Chan–Paton bundle) and a natural identification of direct sums of Chan–Paton bundles. In addition they include ''vector bundle modification,'' a mathematical construction reminiscent of the Myers dielectric effect.[45]

It is interesting to compare $K_1^q(X)$ with the group of D-brane charges, thought to be given by $K^1(X)$. If X is compact, even dimensional, and spin then, modulo torsion, $K_1(X)$ is isomorphic to $K^1(X)$ by Poincaré duality. However, when we include torsion a puzzling difference emerges. There is a universal coefficient theorem (Ref. 31, Theorem 16.3.3):

$$0 \to \mathrm{Ext}(K^0(X),\mathbb{Z}) \to \mathrm{Ext}(C(X),\mathcal{K}) \to \mathrm{Hom}(K^1(X),\mathbb{Z}) \to O. \tag{7.9}$$

Moreover, the sequence splits, so that the torsion can in principle differ from that of $K^1(X)$. This possible discrepancy in torsion charges deserves to be more thoroughly investigated.

C. The index theorem

We can now put the noncommutative ABS tachyon field of the previous section into its proper mathematical context: The equivalence of IIB D-brane charges in the commutative and noncommutative theory is simply the equality of the analytic and topological index, expressed in the framework of K-homology (as explained in Ref. 41).

In the language of Brown–Douglas–Filmore, the Toeplitz operators on the Hardy space defines an analytic K-homology class,

$$[(\mathcal{H}_\Sigma,\tau)] \in K_{1,a}(\Sigma^{2p-1}), \tag{7.10}$$

where τ is the Busby invariant. That is, the inverse image under $\pi: B(\mathcal{H}) \to Q(\mathcal{H})$ of $\tau(C(\Sigma^{2p-1}))$ in $B(\mathcal{H}_\Sigma)$ defines an algebra of operators $\mathcal{T}$ providing a nontrivial extension by compact operators:

$$0 \to \mathcal{K} \to \mathcal{T} \to C(\Sigma^{2p-1}) \to 0. \tag{7.11}$$

It is explained in Ref. 41 that the K-homology class (7.10) is the same as that determined by the Dirac operator $[\not{D}]$ on Σ using the construction of Sec. VI.2. In particular, the index theorem of Boutet de Monvel follows from the ordinary index theorem.

One usually associates IIB D-brane charge to $K^0(X)$, or for an infinitely extended D-brane with transverse space X_t, to $K^0_{\mathrm{cpt}}(X_t)$. The relation to (7.10) is explained as follows. We consider the exact sequence in K-homology for the pair (D^{2p},Σ^{2p-1}), where D^{2p} is the disk of dimension $2p$ with boundary Σ^{2p-1}. The connecting homomorphism gives an isomorphism,

$$\delta: K_0(D^{2p},\Sigma^{2p-1}) \cong K_1(\Sigma^{2p-1}). \tag{7.12}$$

In this way, the above construction associates an element of analytic K-homology $K_{0,a}$ to the noncommutative tachyon. By Poincare duality $K_0 \cong K^0$, (again, up to torsion) and we produce the same K-theory class we expected to associate to a IIB-brane.

D. Speculations on noncommutative D-branes

The above considerations lead to the idea that it might be fruitful to relax the equivalence relations we have put on the extensions (7.8). As we have discussed, any ''commutative D-brane'' defines a triple (W,E,ϕ) and hence a particular extension. Conversely, given an abstract extension (7.8) could one extract the data of a D-brane? We can easily answer one simple question about such generalized D-branes, namely: ''Where is the brane?'' as follows. The kernel of the Busby invariant $\tau: C(X) \to Q$ defines an ideal, and from the Gelfand corespondence therefore defines a subspace $W \subset X$. Concretely, the ideal is the subalgebra of functions vanishing on W. It would be natural to identify W with the worldvolume of a D-brane. Whether or not one can usefully recover other aspects of the structure of a D-brane, and in particular whether extensions (7.8) which do not come from triples (W,E,ϕ) can be usefully identified with ''noncommutative D-branes'' remains an interesting open question.

In any case, inspired by the result of BDF we would like to define an action whose solutions could be considered to be the set of possible IIA D-branes, generalized in the above sense. The action has some interesting similarities to the IKKT action. On the other hand, we caution the reader at the outset that it remains to be seen if the following action will play any useful role in the computation of any physical quantities.

The action is a function of pairs $(\mathcal{A}, \phi)$, where $\mathcal{A}$ is a C^*-algebra and ϕ is a C^*-algebra morphism $\phi: \mathcal{A} \to C(X) \to 0$, and is given by

$$S(A,\phi) := \sup_{f_1, f_2 \in C(X)} \inf_{\phi(a_i)=f_i} \mathrm{Tr}_{\mathrm{D}}([a_1,a_2][a_1,a_2]^\dagger). \tag{7.13}$$

Here we first take the infimum over all lifts T_f of a pair of functions f. Moreover, Tr_{D} is the Dixmier trace. Roughly speaking, Tr_{D} is defined as follows. Let $\mu_n(T)$ be the eigenvalues of $\sqrt{T^\dagger T}$ arranged in decreasing order. Define

$$\mathrm{Tr}_{\mathrm{D}}(T) := \lim_{N\to\infty} \frac{1}{\log N} \sum_{n=1}^{N} \mu_n(T). \tag{7.14}$$

For the real story, consult the book by Connes.[46]

The action (7.13) is positive semidefinite. So, in any reasonable ''space of $(\mathcal{A}, \phi)$'' the zeros of the action are automatically stationary points of minimal action. The action is identically zero only when, for all $f_1, f_2 \in C(X)$ there are lifts T_{f_1}, T_{f_2} such that the commutator $[T_{f_1}, T_{f_2}]$ has singular values falling off faster than $1/\sqrt{n}$. We may expect the relations (6.12) to give a good approximation to the general behavior of $[T_{f_1}, T_{f_2}]$ on spinors of large energy, and from this we expect that the extensions associated to (W,E,ϕ) described above will be zeros of the action. Conversely, any zero of the action can be used to define an extension of $C(X)$ by compact operators.

It is interesting to compare the action (7.13) with the IKKT model:

$$S = g_{IK} g_{JL} \mathrm{Tr}([X^I, X^J][X^K, X^L]), \tag{7.15}$$

where X^I are $N \times N$ Hermitian matrices and g_{IJ} is a nondegenerate constant metric on $\mathbb{R}^{10}$. If we consider the X^I as generators of the algebra of functions on $\mathbb{R}^9$ then there is a certain similarity between (7.13) and (7.15). However we note the following.

(1) The IKKT action does not generalize easily to curved spaces. Even on $\mathbb{R}^9$ if we attempt to include curved metrics g_{IJ} we run into ordering problems. (See Ref. 47 for the state of the art on this problem.)
(2) When producing D-branes from Matrix theory the solutions have infinite action. Of course, this is physically appropriate for infinitely extended planar branes. Nevertheless, it would be nice to work with finite action quantities when considering compact branes.

VIII. NONZERO H-FIELDS AND 5-BRANES

In this section we will focus on a description of Neveu–Schwarz fivebranes in the framework of Ref. 9. We should first discuss what we mean by an NS fivebrane in open string theory. In the original description[48] NS fivebranes are solutions to the closed string equations of motion with topology $M \times S^3 \times R$ with M the fivebrane worldvolume such that $\int_{S^3} H = Q_5$, H being the NS three-form field and Q_5 the quantized fivebrane charge. Since the tension scales like $1/g_s^2$ with g_s the closed string coupling, these are properly thought of as solitons in the closed string sector rather than the open string sector of the theory where soliton energies scale as $1/g_s$ (as for D-branes). In open string theory we cannot expect to see the detailed form of the closed string solution since closed string states only arise at the loop level in open string theory. We thus define a fivebrane to be a configuration in a ten dimensional spacetime X with $H \in H^3(X,Z)$ a nontrivial integer class.

Given the scaling of the fivebrane tension with g_s, the close connection between the framework of Ref. 9 and Matrix theory,[49] and the well-known difficulties in describing fivebranes in Matrix theory,[50,51] we can anticipate some problems here as well.

To explain the basic idea and the difficulty one expects, consider taking $X=W\times R_B^2$ to be the worldvolume of an unstable D9-brane in IIA with a large B-field on the R^2 component and take $W=R^5\times S^3$. W represents the commutative part of the D9-brane worldvolume. The effective action (2.6) contains gauge fields with gauge group $U(\mathcal{H})$ coupled to the tachyon field in the adjoint representation. Since the $U(1)$ component of $U(\mathcal{H})$ (with A_μ proportional to the identity operator) does not couple to T and has infinite action if its field strength is nonzero, it is more correct to say that the gauge group is $PU(\mathcal{H})\equiv U(\mathcal{H})/U(1)$. Defining more precisely what is meant by the $U(1)$ component when there is nontrivial topology is quite subtle as will be discussed below.

Since $U(\mathcal{H})$ is contractible,[52] $\pi_2(PU(\mathcal{H}))=\pi_1(U(1))=\mathbb{Z}$. Thus we can construct an ''instanton'' configuration of the $PU(\mathcal{H})$ gauge fields on S^3 by patching together gauge fields on the northern and southern hemispheres using a nontrivial element of $\pi_2(PU(\mathcal{H}))$ on the S^2 equator. Our proposal is that such a twisted $PU(\mathcal{H})$ bundle with the tachyon field $T=t_*$ represents a D9-brane in the presence of a NS fivebrane while condensing the tachyon field to $T=0$ removes the D9-brane and leaves an NS fivebrane. More generally, we can use nontrivial projection operators for the tachyon to study lower D-branes in the presence of NS fivebranes.

We can now see one difficulty we expect to encounter. Since the NS fivebrane world volume is six dimensional, it must span $R^5\in W$ and as well have one component in the noncommutative plane R_B^2. As a result, the trace in (2.6) is expected to diverge, i.e. the gauge field fieldstrength-squared for the twisted $PU(\mathcal{H})$ connection is not expected to be trace class. More precisely, we expect that if we cut off the trace by summing over a finite number of modes then the trace will diverge in the mode number cutoff. In fact, an evaluation of the gauge action $\int_W \mathrm{Tr}\, F\wedge *F$ for some examples of smooth nontrivial $PU(\mathcal{H})$ connections shows that the action is in indeed infinite. A proper interpretation of this infinity must be addressed in future work. Here we simply note that since the mode-number cutoff can be interpreted as an infrared cutoff in the noncommutative directions, there is room for an interpretation of the infinite gauge kinetic action as the volume divergence due to the extension of the 5-brane worldvolume in the noncommutative directions.

To see the connection to the fivebrane definition in terms of H, we note that a standard theorem states that principal $PU(\mathcal{H})$ bundles are classified by the Dixmier–Douady class $h\in H^3(W,Z)$. [A quick homotopy-theoretic proof is that $BPU(\mathcal{H})\sim K(\mathbb{Z},3)$ since $\Omega BPU(\mathcal{H})\sim PU(\mathcal{H})\sim K(\mathbb{Z},2)\sim\Omega K(\mathbb{Z},3)$.] This class has been interpreted in Refs. 53, 54, 11 as the cohomology class of the H-field of string theory. In addition to the arguments presented in these papers we would like to point out that the reasoning described by Kapustin in Ref. 55 for the case when h is torsion and in fact can be extended to the case of h nontorsion. This follows because a nontrivial $PU(\mathcal{H})$ bundle defines a nontrivial ''bundle gerbe with connection'' (where we are using the terminology explained in Refs. 56, 57). Then, using the equivalence to the formulation of Brylinski[58] one can argue that the ''holonomy of the $PU(\mathcal{H})$ connection in the fundamental representation'' can be given a concrete definition in terms of a covariantly constant section of a line bundle with connection over loop space LW. The line bundle with connection over LW is constructed using the bundle gerbe associated to the $PU(\mathcal{H})$ bundle with connection A in a way explained in Refs. 58, 56, 57.

In more physical terms, we wish to make sense of the expression

$$\exp\left[i\int_D B\right]\mathrm{Tr}_{\mathcal{H}} P\exp\int_\gamma A, \tag{8.1}$$

in the open string path integral, where D is the disk worldsheet with boundary $\gamma\subset W$, B is the background B-field, and A is a $PU(\mathcal{H})$ connection. In order to define this we must lift A to a compatible $U(\mathcal{H})$ connection $\tilde{A}$. In so doing the field strength acquires a ''$U(1)$ component''

which we denote by $\mathrm{Tr}\,F$, although since we are working with operators not necessarily of trace class this notation should be handled with great care. The essential physical point is that in infinite dimensions the commutator of two Hermitian operators can be proportional to the identity matrix, the standard example being a pair of operators representing the Heisenberg relations. Consequently the commutator term in $\tilde{F}=d\tilde{A}+\tilde{A}^2$ can in fact contribute to the $U(1)$ component of $\tilde{F}$ and in topologically interesting situations it must do so. This in turn means that the Bianchi identity for the $U(1)$ part of $\tilde{F}$ is *not* $d\,\mathrm{Tr}\,F=0$ but rather $d\,\mathrm{Tr}\,F=K$ where K is a globally well-defined 3-form on W. Moreover, by the general results of Ref. 58 it follows that the cohomology class of $K/(2\pi i)$ coincides with the Dixmier–Douady class h. Defining the holonomy of A as a covariantly constant section of a bundle over loopspace one can follow the strategy of Ref. 55 and conclude that the Dixmier–Douady class h must be identified with that of the physical H-field. It is not necessary to assume that h is a torsion class, although in infinite dimensions the trace Tr isolating the $U(1)$ part of the field strength requires an *ad-hoc* definition.[58]

One simple example of a nontrivial $PU(\mathcal{H})$ connection illustrating some of the above general remarks is the following. (This example is a paraphrase of Sec. 4.3 of Ref. 58.) We will take the base space to be the three-manifold $S^2\times S^1$, more appropriate to an H-monopole. A similar (but more elaborate) example applies directly to S^3 and can be extracted from Ref. 57.

We will construct a $PU(\mathcal{H})$ bundle over $S^2\times S^1$ by starting with a $U(1)\times\mathbb{Z}$ bundle over $S^2\times S^1$ and then embedding the $U(1)\times\mathbb{Z}$ transition functions into $PU(\mathcal{H})$. The $U(1)\times\mathbb{Z}$ bundle over $S^2\times S^1$ will simply be $S^3\times\mathbb{R}$ with a rightaction by $U(1)\times\mathbb{Z}$ given by

$$\begin{aligned}(u,x)&\sim(ue^{i\chi\sigma^3/2},x),\\(u,x)&\sim(u,x+1).\end{aligned}\tag{8.2}$$

Here $u\in S^3$ is identified with an $SU(2)$ matrix, the first line is the right $U(1)$ action and the second line is the $\mathbb{Z}$ action on $x\in\mathbb{R}$. Note that the S^3 is not to be thought of as embedded in spacetime. Rather, $W=\mathbb{R}^5\times S^2\times S^1$.

We now consider the Heisenberg algebra generated by operators $\hat{\theta}$, and $\hat{N}$ acting on functions in $L^2(S^1)$. This S^1 should be thought of as the fiber in the Hopf fibration $S^3\to S^2$. Let $\hat{\theta}$ be the position operator and $\hat{N}$ the integrally-quantized angular momentum, so that $[\hat{\theta},\hat{N}]=i$. Using these operators we can form a representation of $U(1)\times\mathbb{Z}$ in $PU(\mathcal{H})$ via

$$(e^{i\chi},n)\to e^{in\hat{\theta}}e^{i\chi\hat{N}}.\tag{8.3}$$

Note that $e^{in\hat{\theta}}$ and $e^{i\hat{\chi}\hat{N}}$ commute up to the phase $e^{in\chi}$ and hence (8.3) is indeed a representation of the commutative group $U(1)\times\mathbb{Z}$ in $PU(\mathcal{H})$. Using (8.3) we convert the transition functions of the $U(1)\times\mathbb{Z}$ bundle $S^3\times\mathbb{R}\to S^2\times S^1$ into $PU(\mathcal{H})$ transition functions. Of course, we can (by construction) lift the transition functions to $U(\mathcal{H})$ over contractible open sets in a good cover of $S^2\times S^1$, but then they will fail to satisfy the cocycle condition.

We now discuss how to isolate the $u(1)$ part. Technically, this is defined in Ref. 58 by the splitting of an exact sequence of bundles of the adjoint representation. Here the relevant Lie algebra of operators is generated by the invariant elements $(\hat{N}-x\mathbf{1})$ and $\mathbf{1}$. Note that $\mathbb{Z}$, being discrete, has no Lie algebra. Therefore, we do not need to include $\hat{\theta}$. Note too that we are forced to choose the combination $(\hat{N}-x\mathbf{1})$ so that $x\sim x+1$ is equivalent to conjugation by $e^{i\hat{\theta}}$. We define ''the $u(1)$ part'' to be the coefficient of $\mathbf{1}$ in this basis.

As an example of a nontrivial $PU(\mathcal{H})$ connection we choose standard Euler angle coordinates (ϕ,θ,ψ) for $u\in S^3$ and x on $\mathbb{R}$. Then we may define the connection using the globally defined Lie algebra valued form on $S^3\times\mathbb{R}$ given by

$$A_+(u,x)=i(d\psi_+ + \tfrac{1}{2}(1-\cos\theta)d\phi)(\hat{N}-x\mathbf{1}),$$
$$A_-(u,x)=i(d\psi_- - \tfrac{1}{2}(1+\cos\theta)d\phi)(\hat{N}-x\mathbf{1}), \tag{8.4}$$

where we have divided S^3 into two hemispheres labeled by $\pm$. One may easily check that $A(u,x+1)=e^{i\hat{\theta}}A(u,x)e^{-i\hat{\theta}}$ so this defines a connection on a bundle over $S^2\times S^1$. According to our definition of the $U(1)$ part of F we have $\mathrm{Tr}(F)=-i\,\mathrm{Ad}\,x$. This is globally defined on $S^3\times S^1$ but is not basic. It is also not closed, as promised, but $K=d\,\mathrm{Tr}(F)\wedge dx=(i/2)\sin\theta\,d\theta\,d\phi\,dx$ is a basic form, giving the globally defined ''gerbe curvature 3-form'' on $S^2\times S^1$ with $\int_{S^2\times S^1}K/(2\pi i)=1$.

In view of the above, we believe that by allowing for twisted $PU(\mathcal{H})$ bundles in the formalism of Ref. 9 we are able to include the effects of NS 5-branes in the picture of Ref. 9. Indeed, if $A\to W$ is a twisted bundle with fiber given by $\mathcal{K}$ and Dixmier–Douady class h then $\Gamma(A)$ is an algebra whose (Grothendieck group of) finitely generated projective modules define $K_{\mathrm{H}}(W)$. In the limit of large noncommutativity the tachyon field still defines a projection operator, hence a projective module for this algebra. In the context of type II strings it is important to note that since $PU(\mathcal{H})$ also acts on Fredholm operators, there is also a Fredholm model for $K_{\mathrm{H}}(W)$.

Obviously, many details need to be worked out in the above proposal. We hope to report on this elsewhere.

ACKNOWLEDGMENTS

We would like to thank E. Diaconescu, E. Martinec, and E. Witten for discussions and comments. We thank I. M. Singer for useful remarks on the manuscript. We are especially grateful to G. B. Segal for many discussions and for some prophetic lectures at the ITP in August, 1999 (Ref. 32). We also recommend lectures by I. M. Singer (Ref. 59). Non-Abelian D-branes and noncommutative geometry

Robert Myers
Department of Physics, McGill University, 3600 University Street, Montréal, Québec H3A 2T8, Canada

(Received 2 January 2001; accepted for publication 13 February 2001)

We discuss the non-Abelian world-volume action which governs the dynamics of N coincident Dp-branes. In this theory, the branes' transverse displacements are described by matrix-valued scalar fields, and so this is a natural physical framework for the appearance of noncommutative geometry. One example is the dielectric effect by which Dp-branes may be polarized into a noncommutative geometry by external fields. Another example is the appearance of noncommutative geometries in the description of intersecting D-branes of differing dimensions, such as D-strings ending on a D3- or D5-brane. We also describe the related physics of giant gravitons. © *2001 American Institute of Physics.*

I. INTRODUCTION

The idea that noncommutative geometry should play a role in physical theories is an old one.[1,2] Suggestions have been made that such noncommutative structure may resolve the ultraviolet divergences of quantum field theories, or appear in the description of space–time geometry at the Planck scale. In the past few years, it has also become a topic of increasing interest to string theorists. From one point of view, the essential step in realizing a noncommutative geometry is replacing the space–time coordinates by noncommuting operators, $x^\mu \to \hat{x}^\mu$. In this replacement, however, there remains a great deal of freedom in defining the nontrivial commutation relations which the operators $\hat{x}^\mu$ must satisfy. Some explicit choices that have appeared in physical problems are as follows:
(i) Canonical commutation relations:

$$[\hat{x}^\mu, \hat{x}^\nu] = i\theta^{\mu\nu} \quad \theta^{\mu\nu} \in \mathbf{C}.$$

Such algebras have appeared in the Matrix theory description of planar D-branes[3]—for a review, see Ref. 4. This work also stimulated an ongoing investigation by string theorists of noncommutative field theories which arise in the low energy limit of a planar D-brane with a constant B-field flux, see, e.g., Refs. 5 6, 7.
(ii) Quantum space relations:

$$\hat{x}^\mu \hat{x}^\nu = q^{-1} R^{\mu\nu}{}_{\rho\tau} \hat{x}^\rho \hat{x}^\tau \quad R^{\mu\nu}{}_{\rho\tau} \in \mathbf{C}.$$

These algebras received some attention from physicists in the early 1990's, see, e.g., Refs. 8 and 9— and have appeared more recently in the geometry of the moduli space of $N=4$ super-Yang–Mills theory.[10]
(iii) Lie algebra relations:

$$[\hat{x}^\mu, \hat{x}^\nu] = i f^{\mu\nu}{}_\rho \hat{x}^\rho \quad f^{\mu\nu}{}_\rho \in \mathbf{C}.$$

Such algebras naturally arise in the description of fuzzy spheres as was discovered in early attempts to quantize the supermembrane.[11,12] These noncommutative geometries have also been

applied in Matrix theory to describe spherical D-branes.[13,14] In string theory, these noncommutative descriptions of spheres also arise in various contexts in the physics of D-branes, as will be discussed below.

For a system of N (nearly) coincident D-branes, the transverse displacements are described by a set of scalar fields, which are matrix-valued in the adjoint representation of U(N). Hence, noncommutative geometries with a Lie-algebra structure appear very naturally in the physics of D-branes. The appearance of a non-Abelian U(N) gauge symmetry in the world-volume theory of N coincident D-branes[15] is, of course, one of the most remarkable aspects of the D-brane story.[16,17] It lies at the heart of such recent developments as the entropy counting of near-BPS black holes[18] and the AdS/CFT correspondence.[19] Progress has recently been made on constructing the world-volume action that controls the dynamics of this non-Abelian theory.[20,21] In particular, one finds that this action includes a wide variety of new nonderivative terms for the world-volume scalars. Amongst these interactions are couplings by which the non-Abelian D-branes can interact with all of the Ramond–Ramond potentials of any form degree. Further, there is an interesting ''dielectric effect'' [20] in which the D-branes are polarized into a higher dimensional noncommutative geometry by nontrivial background fields.

An outline of this paper is as follows: We begin in Sec. II with a discussion of the non-Abelian D-brane action. Section III presents an outline of the dielectric effect for D-branes. Section IV describes the related physical effect by which branes carrying momentum expand in $AdS_m \times S^n$ backgrounds, producing giant gravitons. Finally, Sec. V gives a discussion of how noncommutative geometries can arise in the description of intersecting branes. Sections II and III are essentially a summary of the material appearing in Ref. 20. Section IV describes that in Ref. 22 and Sec. V describes that for Refs. 23 and 24. We direct the interested reader to these papers for a more detailed presentation of the associated works.

II. NON-ABELIAN D-BRANE ACTION

Within the framework of perturbative string theory, a Dp-brane is a $(p+1)$-dimensional extended surface in space–time which supports the end points of open strings.[16,17] The massless modes of this open string theory form a supersymmetric U(1) gauge theory with a vector A_a, $9-p$ real scalars Φ^i and their superpartner fermions—for the most part, the latter are ignored throughout the following discussion. At leading order, the low-energy action corresponds to the dimensional reduction of that for ten-dimensional U(1) super-Yang–Mills theory. However, as usual in string theory, there are higher order $\alpha' = l_s^2$ corrections—l_s is the string length scale. For constant field strengths, these stringy corrections can be resummed to all orders, and the resulting action takes the Born–Infeld form,[25]

$$S_{\rm BI} = -T_p \int d^{p+1}\sigma (e^{-\phi}\sqrt{-\det(P[G+B]_{ab}+\lambda F_{ab})}), \tag{1}$$

where T_p is the Dp-brane tension and λ denotes the inverse of the (fundamental) string tension, i.e., $\lambda = 2\pi l_s^2$. This Born–Infeld action describes the couplings of the Dp-brane to the massless Neveu-Schwarz fields of the bulk closed string theory, i.e., the metric, dilaton and Kalb–Ramond two-form. The interactions with the massless Ramond–Ramond (RR) fields are incorporated in a second part of the action, the Wess–Zumino term,[26–28]

$$S_{\rm WZ} = \mu_p \int P\left[\sum C^{(n)} e^B\right] e^{\lambda F}, \tag{2}$$

where $C^{(n)}$ denotes the n-form RR potentials. Equation (2) shows that a Dp-brane is naturally charged under the $(p+1)$-form RR potential with charge μ_p, and supersymmetry dictates that $\mu_p = \pm T_p$. If the Dp-brane carries a flux of $B+F$, it will also act as a charge source for RR potentials with a lower form degree.[26] Such configurations represent bound states of D-branes of different dimensions.[15]

In both of the expressions above, the symbol $P[\cdots]$ denotes the pullback of the bulk space–time tensors to the D-brane world-volume. Thus the Born–Infeld action (1) has a geometric interpretation, i.e., it is essentially the proper volume swept out by the Dp-brane, which is indicative of the fact that D-branes are actually dynamical objects. This dynamics becomes more evident with an explanation of the static gauge choice implicit in constructing the above action. To begin, we employ space–time diffeomorphisms to position the world-volume on a fiducial surface defined as $x^i=0$ with $i=p+1,\ldots,9$. With world-volume diffeomorphisms, we then match the world-volume coordinates with the remaining spacetime coordinates on this surface, $\sigma^a=x^a$ with $a=0,1,\ldots,p$. Now the world-volume scalars Φ^i play the role of describing the transverse displacements of the D-brane, through the identification

$$x^i(\sigma)=2\pi l_s^2\Phi^i(\sigma) \quad \text{with } i=p+1,\ldots,9. \tag{3}$$

With this identification the general formula for the pullback reduces to

$$P[E]_{ab}=E_{\mu\nu}\frac{\partial x^\mu}{\partial\sigma^a}\frac{\partial x^\nu}{\partial\sigma^b}=E_{ab}+\lambda\, E_{ai}\,\partial_b\Phi^i+\lambda\, E_{ib}\,\partial_a\Phi^i+\lambda^2 E_{ij}\partial_a\Phi^i\partial_b\Phi^j. \tag{4}$$

In this way, the expected kinetic terms for the scalars emerge to leading order in an expansion of the Born–Infeld action (1). Note that our conventions are such that both the gauge fields and world-volume scalars have the dimensions of length^{-1}—hence the appearance of the string scale in Eq. (3).

As N parallel D-branes approach each other, the ground state modes of strings stretching between the different D-branes become massless. These extra massless states carry the appropriate charges to fill out representations under a U(N) symmetry. Hence the $U(1)^N$ of the individual D-branes is enhanced to the non-Abelian group U(N) for the coincident D-branes.[15] The vector A_a becomes a non-Abelian gauge field,

$$A_a=A_a^{(n)}T_n, \quad F_{ab}=\partial_aA_b-\partial_bA_a+i[A_a,A_b], \tag{5}$$

where T_n are N^2 Hermitian generators with $\mathrm{Tr}(T_n\,T_m)=N\,\delta_{nm}$. The scalars Φ^i also transform in the adjoint of U(N) with covariant derivatives,

$$D_a\Phi^i=\partial_a\Phi^i+i[A_a,\Phi^i]. \tag{6}$$

Understanding how to accommodate this U(N) gauge symmetry in the world-volume action is an interesting puzzle. For example, the geometric meaning or even the validity of Eq. (3) seems uncertain when the scalars on the right-hand side are matrix-valued. In fact, this identification does remain roughly correct. Some intuition comes from the case where the scalars are commuting matrices and the gauge symmetry can be used to simultaneously diagonalize all of them. In this case, one interpretes the N eigenvalues of the diagonal Φ^i as representing the displacements of the N constituent D-branes, see, e.g., Ref. 4. Of course, to describe noncommutative geometries, we will be more interested in the case where the scalars do not commute and so cannot be simultaneously diagonalized.

References 20 and 21 recently made progress in constructing the world-volume action describing the dynamics of non-Abelian D-branes. The essential strategy in both of these papers was to construct an action which was consistent with the familiar string theory symmetry of T-duality.[29] Acting on D-branes, T-duality acts to change the dimension of the world-volume.[16,17] The two possibilities are: (i) if a coordinate transverse to the Dp-brane, e.g., $y=x^{p+1}$, is T-dualized, it becomes a D($p+1$)-brane, where y is now the extra world-volume direction; and (ii) if a world-volume coordinate on the Dp-brane, e.g., $y=x^p$, is T-dualized, it becomes a D($p-1$)-brane where y is now an extra transverse direction. Under these transformations, the role of the corresponding world-volume fields change as

$$\text{(i)}\ \ \Phi^{p+1}\to A_{p+1}, \quad \text{(ii)}\ \ A_p\to\Phi^p, \tag{7}$$

while the remaining components of A and scalars Φ are left unchanged. Hence in constructing the non-Abelian action, one can begin with the D9-brane theory, which contains no scalars since the world-volume fills the entire space–time. In this case, the non-Abelian extension of Eqs. (1) and (2) is given by simply introducing an overall trace over gauge indices of the non-Abelian field strengths appearing in the action.[30] Then applying T-duality transformations on $9-p$ directions yields the non-Abelian action for a Dp-brane. Of course, in this construction, one also T-dualizes the background supergravity fields according to the known transformation rules.[29,31–33] As in the Abelian theory, the result for non-Abelian action has two distinct pieces:[20,21] the Born–Infeld term,

$$S_{\rm BI}=-T_p\int d^{p+1}\sigma\, S\,\mathrm{Tr}\Big(e^{-\phi}\sqrt{\det(Q^i{}_j)}\sqrt{-\det(P[E_{ab}+E_{ai}(Q^{-1}-\delta)^{ij}E_{jb}]+\lambda F_{ab})}\Big), \tag{8}$$

with $E_{\mu\nu}=G_{\mu\nu}+B_{\mu\nu}$ $Q^i{}_j\equiv\delta^i{}_j+i\lambda[\Phi^i,\Phi^k]\,E_{kj}$; and the Wess–Zumino term,

$$S_{\rm WZ}=\mu_p\int S\,\mathrm{Tr}\Big(P\Big[e^{i\lambda\, i_\Phi i_\Phi}\Big(\sum C^{(n)}\,e^B\Big)\Big]e^{\lambda F}\Big). \tag{9}$$

Let us enumerate the non-Abelian features of this action.

(1) *Non-Abelian field strength:* The F_{ab} appearing explicitly in both terms is now non-Abelian, of course.

(2) *Non-Abelian Taylor expansion:* The bulk supergravity fields are in general functions of all of the space–time coordinates, and so in the action (8), (9), they are implicitly functionals of the non-Abelian scalars. For example, the metric functional appearing in the D-brane action would be given by a non-Abelian Taylor expansion,

$$\begin{aligned}G_{\mu\nu}&=\exp[\lambda\Phi^i\,\partial_{x^i}]G^0_{\mu\nu}(\sigma^a,x^i)\big|_{x^i=0}\\&=\sum_{n=0}^{\infty}\frac{\lambda^n}{n!}\Phi^{i_1}\cdots\Phi^{i_n}(\partial_{x^{i_1}}\cdots\partial_{x^{i_n}})G^0_{\mu\nu}(\sigma^a,x^i)\big|_{x^i=0}.\end{aligned} \tag{10}$$

(3) *Non-Abelian pullback:* As was noted in Refs. 34 and 35, the pullback of various space–time tensors to the world-volume must now involve covariant derivatives of the non-Abelian scalars in order to be consistent with the U(N) gauge symmetry. Hence Eq. (4) is replaced by

$$P[E]_{ab}=E_{ab}+\lambda E_{ai}D_b\Phi^i+\lambda E_{ib}D_a\Phi^i+\lambda^2E_{ij}D_a\Phi^iD_b\Phi^j. \tag{11}$$

(4) *Non-Abelian interior product:* In the Wess–Zumino term (9), i_Φ denotes the interior product with Φ^i regarded as a vector in the transverse space, e.g., acting on an n-form $C^{(n)}=1/n!\,C^{(n)}_{\mu_1\cdots\mu_n}dx^{\mu_1}\cdots dx^{\mu_n}$, we have

$$i_\Phi i_\Phi C^{(n)}=\frac{1}{2(n-2)!}[\Phi^i,\Phi^j]\,C^{(n)}_{ji\mu_3\cdots\mu_n}dx^{\mu_3}\cdots dx^{\mu_n}. \tag{12}$$

Note that acting on forms, the interior product is an anticommuting operator and hence for an ordinary vector (i.e., a vector v^i with values in $\mathbb{R}^{9-p}$): $i_vi_vC^{(n)}=0$. It is only because the scalars Φ are matrix-valued that Eq. (12) yields a nontrivial result.

(5) *Non-Abelian gauge trace:* As is evident above, both parts of the action are highly nonlinear functionals of the non-Abelian fields, and so Eqs. (8) and (9) would be incomplete without a precise definition for the ordering of these fields under the gauge trace. Above, $S\,\mathrm{Tr}$ denotes a maximally symmetric trace. To be precise, the trace includes a symmetric average over all orderings of F_{ab}, $D_a\Phi^i$, $[\Phi^i,\Phi^j]$, and the individual Φ^k appearing in the non-Abelian Taylor expan-

sions of the background fields. This choice matches that inferred from Matrix theory.[36] Finally, we should note that with this definition an expansion of the Born–Infeld term (1) does agree with the string theory to fourth order in F,[37,38] however, it does not seem to capture the full physics of the non-Abelian fields in the infrared limit.[39] Rather at sixth order, additional terms involving commutators of field strengths must be added to the action.[40]

Some other general comments on the non-Abelian action are as follows: In the Born–Infeld term (8), there are now two determinant factors as compared to one in the Abelian action (1). The second determinant in Eq. (8) is a slightly modified version of that in Eq. (1). One might think of this as the kinetic factor, since to leading order in the low energy expansion, it yields the familiar kinetic terms for the gauge field and scalars. In the same way, one can think of the new first factor as the potential factor, since to leading order in the low energy expansion, it reproduces the non-Abelian scalar potential expected for the super-Yang–Mills theory (see below). Further note that the first factor reduces to simply one when the scalar fields are commuting, even for general background fields.

As mentioned below Eq. (2), an individual Dp-brane couples not only to the RR potential with form degree $n=p+1$, but also to the RR potentials with $n=p-1,p-3,\ldots$ through the exponentials of B and F appearing in the Wess–Zumino action (2). Above in Eq. (9), $i_\Phi i_\Phi$ is an operator of form degree -2, and so world-volume interactions appear in the non-Abelian action (9) involving the higher RR forms. Hence in the non-Abelian theory, a Dp-brane can also couple to the RR potentials with $n=p+3,p+5,\ldots$ through the additional commutator interactions. To make these couplings more explicit, consider the D0-brane action (for which F vanishes),

$$S_{\mathrm{CS}}=\mu_0\int S\,\mathrm{Tr}\Bigg(P\Bigg[C^{(1)}+i\lambda\, i_\Phi i_\Phi(C^{(3)}+C^{(1)}B)-\frac{\lambda^2}{2}(i_\Phi i_\Phi)^2 \times\left(C^{(5)}+C^{(3)}B+\frac{1}{2}C^{(1)}B^2\right)-i\frac{\lambda^3}{6}(i_\Phi i_\Phi)^3\left(C^{(7)}+C^{(5)}B+\frac{1}{2}C^{(3)}B^2+\frac{1}{6}C^{(1)}B^3\right) +\frac{\lambda^4}{24}(i_\Phi i_\Phi)^4\left(C^{(9)}+C^{(7)}B+\frac{1}{2}C^{(5)}B^2+\frac{1}{6}C^{(3)}B^3+\frac{1}{24}C^{(1)}B^4\right)\Bigg]\Bigg). \tag{13}$$

Of course, these interactions are reminiscent of those appearing in Matrix theory.[3,41] For example, Eq. (13) includes a linear coupling to $C^{(3)}$, which is the potential corresponding to D2-brane charge,

$$i\lambda\,\mu_0\int \mathrm{Tr}\,P[i_\Phi i_\Phi C^{(3)}]=i\frac{\lambda}{2}\mu_0\int dt\,\mathrm{Tr}(C^{(3)}_{ijk}(\Phi,t)\,[\Phi^k,\Phi^j]+\lambda C^{(3)}_{ijk}(\Phi,t)\,D_t\Phi^k\,[\Phi^k,\Phi^j]), \tag{14}$$

where we assume that $\sigma^0=t$ in static gauge. Note that the first term on the right-hand side has the form of a source for D2-brane charge. This is essentially the interaction central to the construction of D2-branes in matrix theory with the large N limit.[3,41] Here, however, with finite N, this term would vanish upon taking the trace if $C^{(3)}_{ijk}$ was simply a function of the world-volume coordinate t (since $[\Phi^k,\Phi^j]\in\mathrm{SU}(N)$). However, in general these three-form components are functionals of Φ^i. Hence, while there would be no ''monopole'' coupling to D2-brane charge, nontrivial expectation values of the scalars can give rise to couplings to an infinite series of higher ''multipole'' moments.

Finally we add that by the direct examination of string scattering amplitudes using the methods of Refs. 42 and 43, one can verify at low orders the form of the non-Abelian interactions in Eqs. (8) and (9), including the appearance of the new commutator interactions in the non-Alelian Wess–Zumino action.[44]

III. DIELECTRIC BRANES

In this section, we wish to consider certain physical effects arising from the new non-Abelian interactions in the world-volume action, given by Eqs. (8) and (9). To begin, consider the scalar potential for Dp-branes in flat space, i.e., $G_{\mu\nu}=\eta_{\mu\nu}$ with all other fields vanishing. In this case, the entire scalar potential originates in the Born–Infeld term (8) as

$$V=T_p\,\mathrm{Tr}\sqrt{\det(Q^i{}_j)}=NT_p-\frac{T_p\lambda^2}{4}\mathrm{Tr}([\Phi^i,\Phi^j][\Phi^i,\Phi^j])+\cdots. \tag{15}$$

The commutator-squared term corresponds to the potential for ten-dimensional U(N) super-Yang–Mills theory reduced to $p+1$ dimensions. A nontrivial set of extrema of this potential is given by taking the $9-p$ scalars as constant commuting matrices, i.e.,

$$[\Phi^i,\Phi^j]=0 \tag{16}$$

for all i and j. Since they are commuting, the Φ^i may be simultaneously diagonalized and as discussed above, the eigenvalues are interpreted as the separated positions of N fundamental Dp-branes in the transverse space. This solution reflects the fact that a system of N parallel Dp-branes is supersymmetric, and so they can sit in static equilibrium with arbitrary separations in the transverse space.[16,17]

From the results described in the previous section, it is clear that in going from flat space to general background fields, the scalar potential is modified by new interactions and so one should reconsider the analysis of the extrema. It turns out that this yields an interesting physical effect that is a precise analog for D-branes of the dielectric effect in ordinary electromagnetism. That is when Dp-branes are placed in a nontrivial background field for which the Dp-branes would normally be regarded as neutral, e.g., nontrivial $F^{(n)}$ with $n>p+2$, new terms will be induced in the scalar potential, and generically one should expect that there will be new extrema beyond those found in flat space, i.e., Eq. (16). In particular, there can be nontrivial extrema with noncommuting expectation values of the Φ^i, e.g., with $\mathrm{Tr}\,\Phi^i=0$ but $\mathrm{Tr}(\Phi^i)^2\neq 0$. This would correspond to the external fields ''polarizing'' the Dp-branes to expand into a (higher dimensional) noncommutative world-volume geometry. This is the analog of the familiar electromagnetic process where an external field may induce a separation of charges in neutral materials. In this case, the polarized material will then carry an electric dipole (and possibly higher multipoles). The latter is also seen in the D-brane analog. When the world-volume theory is at a noncommutative extremum, the gauge traces of products of scalars will be nonvanishing in various interactions involving the supergravity fields. Hence at such an extremum, the Dp-branes act as sources for the latter bulk fields.

To make these ideas explicit, we will now illustrate the process with a simple example. We consider N D0-branes in a constant background RR field $F^{(4)}$, i.e., the field strength associated with D2-brane charge. We find that the D0-branes expand into a noncommutative two-sphere which represents a spherical bound state of a D2-brane and N D0-branes.

Consider a background where only RR four-form field strength is nonvanishing with

$$F^{(4)}_{tijk}=-2\,f\varepsilon_{ijk}\quad \text{for } i,j,k\in\{1,2,3\} \tag{17}$$

with f a constant (of dimensions length^{-1}). Since $F^{(4)}=dC^{(3)}$, we must consider the coupling of the D0-branes to the RR three-form potential, which is given above in Eq. (14). If one explicitly introduces the non-Abelian Taylor expansion (10), one finds the leading order interaction may be written as

$$\frac{i}{3}\lambda^2\mu_0\int dt\,\mathrm{Tr}(\Phi^i\Phi^j\Phi^k)F^{(4)}_{tijk}(t). \tag{18}$$

This final form might have been anticipated since one should expect that the world-volume potential can only depend on gauge invariant expressions of the background field. Given that we are considering a constant background $F^{(4)}$, the higher order terms implicit in Eq. (14) will vanish as they can only involve space–time derivatives of the four-form field strength. Combining Eq. (18) with the leading order Born–Infeld potential (15) yields the scalar potential of interest for the present problem,

$$V(\Phi)=NT_0-\frac{\lambda^2 T_0}{4}\mathrm{Tr}([\Phi^i,\Phi^j]^2)-\frac{i}{3}\lambda^2\mu_0\,\mathrm{Tr}(\Phi^i\Phi^j\Phi^k)F^{(4)}_{tijk}(t). \tag{19}$$

Substituting in the background field (17) and $\mu_0=T_0$, $\delta V(\Phi)/\delta\Phi^i=0$ yields

$$0=[[\Phi^i,\Phi^j],\Phi^j]+i\,f\varepsilon_{ijk}[\Phi^j,\Phi^k]. \tag{20}$$

Note that commuting matrices (16) describing separated D0-branes still solve this equation. The value of the potential for these solutions is simply $V_0=NT_0$, the mass of N D0-branes. Another interesting solution of Eq. (20) is

$$\Phi^i=\frac{f}{2}\alpha^i, \tag{21}$$

where α^i are any $N\times N$ matrix representation of the SU(2) algebra,

$$[\alpha^i,\alpha^j]=2i\,\varepsilon_{ijk}\,\alpha^k. \tag{22}$$

For the moment, let us focus on the irreducible representation for which one finds

$$\mathrm{Tr}[(\alpha^i_N)^2]=\frac{N}{3}(N^2-1)\quad\text{for } i=1,2,3. \tag{23}$$

Now evaluating the value of the potential (19) for this new solution yields

$$V_N=NT_0-\frac{T_0\lambda^2 f^2}{6}\sum_{i=1}^{3}\mathrm{Tr}[(\Phi^i)^2]=NT_0-\frac{\pi^2 l_s^3 f^4}{6g}N^3\left(1-\frac{1}{N^2}\right) \tag{24}$$

using $T_0=1/(gl_s)$. Hence the noncommutative solution (21) has lower energy than a solution of commuting matrices, and so the latter configuration of separated D0-branes is unstable towards condensing out into this noncommutative solution. One can also consider reducible representations of the SU(2) algebra (22), however, one finds that the corresponding energy is always larger than that in Eq. (24). Hence it seems that the irreducible representation describes the ground state of the system.

Geometrically, one can recognize the SU(2) algebra as that corresponding to the noncommutative or fuzzy two-sphere.[12,45] The physical size of the fuzzy two-sphere is given by

$$R=\lambda\left(\sum_{i=1}^{3}\mathrm{Tr}[(\Phi^i)^2]/N\right)^{1/2}=\pi l_s^2 fN\left(1-\frac{1}{N^2}\right)^{1/2} \tag{25}$$

in the ground state solution. From the matrix theory construction of Kabat and Taylor,[14] one can infer this ground state is not simply a spherical arrangement of D0-branes rather the noncommutative solution actually represents a spherical D2-brane with N D0-branes bound to it. In the present context, the latter can be verified by seeing that this configuration has a ''dipole'' coupling to the RR four-form. The precise form of this coupling is calculated by substituting the noncommutative scalar solution (21) into the world-volume interaction (18), which yields

$$-\frac{R^3}{3\pi g l_s^3}\left(1-\frac{1}{N^2}\right)^{-1/2}\int dt\, F^{(4)}_{t123} \tag{26}$$

for the ground state solution. Physically this $F^{(4)}$-dipole moment arises because antipodal surface elements on the sphere have the opposite orientation and so form small pairs of separated membranes and antimembranes. Of course, the spherical configuration carries no net D2-brane charge.

Given that the noncommutative ground state solution corresponds to a bound state of a spherical D2-brane and N D0-branes, one might attempt to match the above results using the dual formulation. That is, this system can be analyzed from the point of view of the (Abelian) worldvolume theory of a D2-brane. In this case, one would consider a spherical D2-brane carrying a flux of the U(1) gauge field strength representing the N bound D0-branes, and at the same time, sitting in the background of the constant RR four-form field strength (17). In fact, one does find stable static solutions, but what is more surprising is how well the results match those calculated in the framework of the D0-branes. The results for the energy, radius and dipole coupling are the same as in Eqs. (24), (25), and (26), respectively, except that the factors of $(1-1/N^2)$ are absent.[20] Hence for large N, the two calculations agree up to $1/N^2$ corrections.

One expects that the D2-brane calculations would be valid when $R \gg l_s$ while naively the D0-brane calculations would be valid when $R \ll l_s$. Hence it appears there is no common domain where the two pictures can both produce reliable results. However, a more careful consideration of range of validity of the D0-brane calculations only requires that $R \ll \sqrt{N} l_s$. This estimate is found by requiring that the scalar field commutators appearing in the full non-Abelian potential (15) are small so that the Taylor expansion of the square root converges rapidly. Hence for large N, there is a large domain of overlap where both of the dual pictures are reliable. Note the density of D0-branes on the two-sphere is $N/(4\pi R^2)$. However, even if R is macroscopic it is still bounded by $R \ll \sqrt{N} l_s$ and so this density must be large compared to the string scale, i.e., the density is much larger than $1/l_s^2$. With such large densities, one can imagine the discreteness of the fuzzy sphere is essentially lost and so there is good agreement with the continuum sphere of the D2-brane picture.

Finally note that the Born–Infeld action contains couplings to the Neveu–Schwarz two-form which are similar to that in Eq. (18). From the expansion of $\sqrt{\det(Q)}$, one finds a cubic interaction,

$$\frac{i}{3}\lambda^2 T_0 \int dt\, \mathrm{Tr}(\Phi^i \Phi^j \Phi^k) H_{ijk}(t). \tag{27}$$

Hence the noncommutative ground state, which has $\mathrm{Tr}(\Phi^i \Phi^j \Phi^k) \neq 0$, also acts as a source of the B field with

$$-\frac{R_0^3}{3\pi g l_s^3}\left(1-\frac{1}{N^2}\right)\int dt\, H_{123}. \tag{28}$$

This coupling is perhaps not so surprising given that the noncommutative ground state represents the bound state of a spherical D2-brane and N D0-branes. Explicit supergravity solutions describing D2–D0 bound states with a planar geometry have been found,[46,47] and are known to carry a long-range H field with the same profile as the RR field strength $F^{(4)}$. One can also derive this coupling from the dual D2-brane formulation. Furthermore, we observe that the presence of this coupling (27) means that we would find an analogous dielectric effect if the N D0-branes were placed in a constant background H field.

The example considered above must be considered simply a toy calculation demonstrating the essential features of the dielectric effect for D-branes. A more complete calculation would require analyzing the D0-branes in a consistent supergravity background. For example, the present case could be extended to consider the asymptotic supergravity fields of a D2-brane, where the RR four-form would be slowly varying but the metric and dilaton fields would also be nontrivial. Alternatively, one can find solutions with a constant background $F^{(4)}$ in M-theory, namely the

$AdS_4\times S^7$ and $AdS_7\times S^4$ backgrounds, see, e.g., Ref. 48. In lifting the D0-branes to M-theory, they become gravitons carrying momentum in the internal space. Hence the expanded D2–D0 system considered here correspond to the ''giant gravitons'' of Ref. 49. The analog of the D2–D0 bound state in a constant background $F^{(4)}$ corresponds to M2-branes with internal momentum expanding into AdS_4,[22,50] while that in a constant H field corresponds to the M2-branes expanding on S^4.[49] Alternatively, the dielectric effect has been found to play a role in other string theory contexts, for example, in the resolution of certain singularities in the AdS/CFT correspondence,[51] or in describing D-branes in the space–time background corresponding to a WZW model.[52,53] Further, one can consider more sophisticated background field configurations which through the dielectric effect generate more complicated noncommutative geometries.[54]

IV. GIANT GRAVITONS

From the above discussion, it seems that in the M-theory backgrounds of $AdS_4\times S^7$ or $AdS_7\times S^4$, one will find that an M2-brane carrying internal momentum will expand into a stable spherical configuration. While a matrix theory description of such states in terms of noncommutative geometry is not yet possible, one can instead analyze these configurations in terms of the Abelian world-volume theory of the M2-brane. In fact, the spherical M2-branes expanding into AdS_4 were actually discovered some time ago.[55] It turns out that M5-branes will expand in a similar way for these backgrounds, and further that expanded D3-branes arise in the type IIB supergravity background $AdS_5\times S^5$. A detailed analysis[22,49,50] shows that these expanded branes are BPS states with the quantum numbers of a graviton. In the following, we will discuss the details of the effect for the D3-branes. Most of the discussion applies equally well for the analogous M2- and M5-brane configurations.

The line element for $AdS_5\times S^5$ may be written as

$$ds^2=-\left(1+\frac{r^2}{L^2}\right)dt^2+\frac{dr^2}{1+\frac{r^2}{L^2}}+r^2d\Omega_3^2+L^2(d\theta^2+\cos^2\theta d\phi^2+\sin^2\theta d\tilde{\Omega}_3^2). \tag{29}$$

This background also involves a self-dual RR five-form field strength with terms proportional to the volume forms on the two five-dimensional subspaces, $F^{(5)}=(4/L)[\varepsilon(AdS_5)+\varepsilon(S^5)]$. With the coordinates chosen above, the four-form potential on the the AdS part of the space is

$$C^{(4)}_{\text{electric}}=-\frac{r^4}{L}dt\,\varepsilon(S^3), \tag{30}$$

where $\varepsilon(S^3)$ is the volume form for the three-sphere described by $d\Omega_3^2$. Similarly, the potential on the S^5 is

$$C^{(4)}_{\text{magnetic}}=L^4\sin^4\theta\,d\theta\,d\phi\,\varepsilon(\tilde{S}^3), \tag{31}$$

where $\varepsilon(\tilde{S}^3)$ is the volume form on $d\tilde{\Omega}_3^2$. For the D3-brane configurations of interest, the world-volume action in Eqs. (1) and (2) reduces to

$$S_3=-T_3\int d^4\sigma\sqrt{-\det(P[G])}+T_3\int P[C^{(4)}]. \tag{32}$$

Here, the world-volume gauge field has been set to zero, which will be consistent with the full equations of motion.

Following Ref. 49, one can find solutions where a D3-brane has expanded on the S^5 to a sphere of fixed θ while it orbits the S^5 in the ϕ direction. Our static gauge choice matches the spatial world-volume coordinates with the angular coordinates on $d\tilde{\Omega}_3^2$, and identifies $\sigma^0=t$. Now

we consider a trial solution of the form: $\theta=$constant, $r=0$ and $\phi=\phi(t)$. Substituting this ansatz into the world-volume action (32) and integrating over the angular coordinates, yields the following Lagrangian:

$$\mathcal{L}_3=\frac{N}{L}[-\sin^3\theta\sqrt{1-L^2\cos^2\theta\,\dot{\phi}^2}+L\sin^4\theta\,\dot{\phi}]. \tag{33}$$

Here we have introduced the (large positive) integer N which counts the five-form flux on S^5. This is also, of course, the rank of the U(N) gauge group in the dual super-Yang–Mills theory. Introducing the conjugate angular momentum $P_\phi=\delta\mathcal{L}_3/\delta\dot{\phi}$, we construct the Hamiltonian,

$$\mathcal{H}_3=P_\phi\dot{\phi}-\mathcal{L}_3=\frac{N}{L}\sqrt{p^2+\tan^2\theta\,(p-\sin^2\theta)^2}, \tag{34}$$

where $p=P_\phi/N$. Given that the Hamiltonian is independent of ϕ, the equations of motion will be solved with constant angular momentum (and hence constant $\dot{\phi}$). For fixed p, Eq. (34) can be regarded as the potential that determines the angle θ for equilibrium. Examining $\mathcal{H}_3$ in detail reveals degenerate minima at $\sin\theta=0$ and $\sin^2\theta=p$, and at any of these minima, the energy is $\mathcal{H}_3=P_\phi/L$. The expanded configurations are then the giant gravitons of Ref. 49. An important observation is that the minima at $\sin^2\theta=p$ only exist for $p\leqslant 1$. As p grows beyond $p=1$, the minima at $\theta\neq 0$ are lifted above that at $\sin\theta=0$ and then disappear completely if $p>9/8$.

The discussion above indicates that one can also consider the possibility of a brane expanding into the AdS part of the space–time.[22,50] That is we wish to find solutions where a D3-brane has expanded to a sphere of constant r while it still orbits in the ϕ direction on the S^5. Choosing static gauge, we again identify $\sigma^0=t$ but match the remaining world-volume coordinates with the angular coordinates on $d\Omega_3^2$. The trial solution is now $\theta=0$, $r=$constant, and $\phi=\phi(t)$. Beginning with the same world-volume action (32),[56] one calculates as before and arrives at the following Hamiltonian:

$$\mathcal{H}_3=\frac{N}{L}\left[\sqrt{\left(1+\frac{r^2}{L^2}\right)\left(p^2+\frac{r^6}{L^6}\right)}-\frac{r^4}{L^4}\right], \tag{35}$$

where as before $p=P_\phi/N$. Examining $\partial\mathcal{H}_3/\partial r=0$, one finds minima located at $r=0$ and $(r/L)^2=p$. The energy at each of the minima is $\mathcal{H}_3=P_\phi/L$. In Ref. 22, these expanded configurations were denoted as dual giant gravitons. An essential difference from the previous case, however, is that the minima corresponding to expanded branes persist for arbitrarily large p.

It is interesting to consider the motion of these expanded brane configurations. Evaluating $\dot{\phi}$ for any of the above solutions, remarkably one finds the same result: $\dot{\phi}=1/L$, independent of P_ϕ. Further the center of mass motion for any of the equilibrium configurations in the full ten-dimensional background is along a null trajectory. For example, for the D3-branes expanded on S^5,

$$ds^2=-(1-L^2\cos^2\theta\,\dot{\phi}^2)dt^2=0 \tag{36}$$

when evaluated for $\dot{\phi}=1/L$ and $\theta=0$(=the center of mass position). This is, of course, the expected result for a massless ''pointlike'' graviton, but it applies equally well for both of the expanded brane configurations. However, note that in the expanded configurations, the motion of each element of the sphere is along a timelike trajectory.

From the point of view of five-dimensional supergravity in the AdS space, the stable brane configurations correspond to massive states with $M=P_\phi/L$. Their angular momentum means that these states are also charged under a U(1) subgroup of the SO(6) gauge symmetry in the reduced supergravity theory. With the appropriate normalizations, the charge is $Q=P_\phi/L$, and hence one

finds that these configurations satisfy the appropriate BPS bound.[49] One can therefore anticipate that all of these configurations should be supersymmetric. The latter result has been verified by an explicit analysis of the residual supersymmetries.[22,50]

The $AdS_5 \times S^5$ background is a maximally supersymmetric solution of the type IIB supergravity equations with 32 residual supersymmetries. That is the background fields are invariant under supersymmetries parametrized by 32 independent Killing spinors. These Killing spinors are determined by setting

$$\delta\Psi_M = D_M \epsilon - \frac{i}{480} \Gamma_M^{PQRST} F^{(5)}_{PQRST} \epsilon = 0 \tag{37}$$

as the variations of all of the other type IIB supergravity fields vanish automatically. The solutions take the form $\epsilon = M(x^\mu)\epsilon_0$, where ϵ_0 is an arbitrary constant complex Weyl spinor.

A supersymmetric extension of the Abelian world-volume action has been constructed for D3-branes (and all other Dp-branes) in a General supergravity background.[57,58] This action can be viewed as a four-dimensional nonlinear sigma model with a curved superspace as the target space. Hence the theory is naturally invariant under the target-space supersymmetry. Further however, formulating the action with manifest ten-dimensional Lorentz invariance, requires an additional fermionic invariance on the world-volume called κ-symmetry. For a test brane configuration where both the target space and world-volume fermions vanish, residual supersymmetries may arise provided there are Killing spinors which satisfy a combined target-space supersymmetry and κ-symmetry transformation. The latter amounts to imposing a constraint $\Gamma\epsilon = \epsilon$, where

$$\Gamma = -\frac{i}{4!} \varepsilon^{i_1 \cdots i_4} \partial_{i_1} X^{M_1} \cdots \partial_{i_4} X^{M_4} \Gamma_{M_1 \cdots M_4}. \tag{38}$$

Of course, this constraint is only evaluated on the D3-brane world-volume. For all of the minima of the potentials in both Eqs. (34) or (35), this constraint reduces to imposing the same projection

$$(\Gamma^{t\phi} + 1)\epsilon_0 = 0. \tag{39}$$

Hence not only are the expanded branes and the pointlike states all BPS configurations, all of these configurations preserve precisely the same supersymmetries. Note that this projection is what one might have expected for a massless particle moving along the ϕ direction, e.g., one can compare to the supersymmetries gravitational waves propagating in flat space.[59]

Much of the interest in giant gravitons comes from an intriguing suggestion[49] that they may be related to the ''stringy exclusion principle.''[60–63] The latter arises in the AdS/CFT correspondence,[19] where it is easily understood in the conformal field theory. A family of chiral primary operators in the $N=4$ super-Yang–Mills theory terminates at some maximum weight because the U(N) gauge group has a finite rank. In terms of the dual AdS description, these operators are associated with single particle states carrying angular momentum on the internal five-sphere. So the appearance of an upper bound on the angular momentum seems mysterious from the point of view of the supergravity theory. The suggestion of McGreevy, Susskind, and Toumbas[49] is that if the dual single particle states are identified with the giant gravitons, the D3-branes expanded on the S^5, then the upper bound is produced by the fact that these BPS states only exist for $p \leqslant 1$. In fact, this exactly reproduces the desired upper bound on the angular momentum: $P_\phi \leqslant N$.

Unfortunately this interpretation is not entirely clear because rather than a unique candidate for the graviton state, there are *three* different ones, including the giant gravitons which expand on S^5, the dual giant gravitons which expand on AdS_5, and the pointlike states. All of these configurations have the same angular momentum and energy, and preserve precisely the same supersymmetries. Unfortunately the latter two of the candidates display no upper bound on the angular momentum, and so there is some uncertainty about the proposed mechanism for the stringy exclusion principle.

One tentative suggestion[22] is that the exclusion principle may be realized through the quantum mechanical mixing of these different states. One can find instanton configurations describing tunneling between the pointlike states and either of the expanded branes,[22,50] but not between the two expanded D3-brane solutions.[64] The suggestion is then that this mixing may spontaneously break supersymmetry in the regime $P_\phi > N$ where there are only two potential graviton states.

Reference 50 has done some interesting calculations in the context of the dual CFT. They seem to be able to identify certain classical field configurations with same properties as the dual giant gravitons. Further these calculations seem to indicate that the minimum corresponding to the pointlike graviton is lifted due to strong coupling effects. This then suggests a picture where the D3-branes expanded on AdS_5 are dual to coherent states in the $N=4$ super-Yang–Mills theory, and so do not directly correspond to the chiral primary operators considered in the stringy exclusion principle.

V. INTERSECTING BRANES

One interesting aspect of the (Abelian) Born–Infeld action (1) is that it supports solitonic configurations describing lower-dimensional branes protruding from the original D-brane.[65–67] For example, in the case of a D3-brane, one finds spike solutions, known as ''bions,'' corresponding to fundamental strings and/or D-strings extending out of the D3-brane. In these configurations, both the world-volume gauge fields and transverse scalar fields are excited. The gauge field corresponds to that of a point charge arising from the end point of the attached string, i.e., an electric charge for a fundamental string and a magnetic monopole charge for a D-string. The scalar field describes the deformation of the D3-brane geometry caused by attaching the strings. These solutions seem to have a surprisingly wide range of validity, even near the core of the spike where the fields are no longer slowly varying. In fact, one can show that the electric spike corresponding to a fundamental string is a solution of the full string theory equations of motion.[68] Further the dynamics of these solutions, as probed through small fluctuations, agrees with the expected string behavior.[69–72] In part, these remarkable agreements are probably related to the fact that these are supersymmetric configurations.

For the system of N D-strings ending on a D3-brane, there is also a dual description in terms of the non-Abelian world-volume theory of the N D-strings. There one finds solutions which have an interpretation, in terms of noncommutative geometry, as describing the D-strings expanding out in a funnel to become an orthogonal D3-brane. In fact, there is an extensive discussion of this system in the literature—see, e.g., Refs. 73–80—where the emphasis was on the close connection[73] of the D-string equations to the Nahm equations for BPS monopoles.[81] In Ref. 23, our emphasis was on the interpretation of these solutions in terms of noncommutative geometry and the remarkable agreement that one finds with the D3-brane spikes in the large N limit.

For N D-strings in flat space, the dynamics is determined completely by the Born–Infeld action (8) which reduces to[20,38]

$$S = -T_1 \int d^2\sigma\, S\, \mathrm{Tr}\sqrt{-\det(\eta_{ab} + \lambda^2 \partial_a \Phi^i Q^{-1}_{ij} \partial_b \Phi^j)\, \det(Q^{ij})}, \tag{40}$$

where

$$Q^{ij} = \delta^{ij} + i\lambda[\Phi^i, \Phi^j]. \tag{41}$$

Implicitly here, the world-volume gauge field has been set to zero, which will be a consistent truncation for the configurations considered below. With the usual choice of static gauge, we set the world-volume coordinates, $\tau = t = x^0$ and $\sigma = x^9$. For simplicity, one might consider the leading-order (in λ) equations of motion coming from this action,

$$\partial^a \partial_a \Phi^i = [\Phi^j, [\Phi^j, \Phi^i]]. \tag{42}$$

Of course, a simple solution of these equations are constant commuting matrices, as in Eq. (16). As discussed in the previous section, such a solution describes N separated parallel D-strings sitting in static equilibrium.

To find a dual description of the bion solutions of the D3-brane theory,[65,66] one needs a static solution which represents the D-strings expanding into a D3-brane. The corresponding geometry would be a long funnel where the cross section at fixed σ has the topology of a two-sphere. In this context, the latter cross section naturally arises as a fuzzy two-sphere[12,45] if the scalars have values in an $N\times N$ matrix representation of the SU(2) algebra (22). Hence one is lead to consider the ansatz,

$$\Phi^i=\frac{R(\sigma)}{\lambda\sqrt{N^2-1}}\alpha^i,\quad i=1,2,3, \tag{43}$$

where we will focus on case where the α^i are the irreducible $N\times N$ SU(2) matrices. Then with the normalization in Eq. (43), the function $|R(\sigma)|$ corresponds precisely to the radius of the fuzzy two-sphere,

$$R(\sigma)^2=\frac{\lambda^2}{N}\sum_{i=1}^{3}\mathrm{Tr}[\Phi^i(\sigma)^2]. \tag{44}$$

Substituting the ansatz (43) into the matrix equations of motion (42) yields a single scalar equation,

$$R''(\sigma)=\frac{8}{\lambda^2(N^2-1)}R(\sigma)^3, \tag{45}$$

for which one simple class of solutions is

$$R(\sigma)=\pm\frac{N\pi l_s^2}{\sigma-\sigma_\infty}\left(1-\frac{1}{N^2}\right)^{1/2}. \tag{46}$$

Given the above analysis, Eqs. (43) and (46) only represent a solution of the leading order equations of motion (42), and so naively one expects that it should only be valid for small radius. However, one can show by direct evaluation[23] that in fact these configurations solve the full equations of motion extremizing the non-Abelian action (40). The latter can also be inferred from an analysis of the world-volume supersymmetry of these configurations. Killing spinor solutions of the linearized supersymmetry conditions will exist provided that the scalars satisfy

$$D_\sigma\Phi^i=\pm\frac{i}{2}\varepsilon^{ijk}[\Phi^j,\Phi^k]. \tag{47}$$

The latter can be recognized as the Nahm equations.[73] Hence the duality between the D3-brane and D-string descriptions gives a physical realization of Nahm's transform of the moduli space of BPS magnetic monopoles. Now inserting the ansatz (43) into Eq. (47) yields

$$R'=\mp\frac{2}{\lambda\sqrt{N^2-1}}R^2, \tag{48}$$

which one easily verifies is satisfied by the configuration given in Eq. (46). Hence, one concludes that the solutions given by Eqs. (43) and (46) are in fact BPS solutions preserving 1/2 of the supersymmetry of the leading order D-string theory. Now in Ref. 82, it was shown that BPS solutions of the leading order theory are also BPS solutions of the full non-Abelian Born–Infeld action (40).

The geometry of the solution, Eqs. (43) and (46), certainly has the desired funnel shape. The fuzzy two-sphere shrinks to zero size as $\sigma \to \infty$ and opens up to fill the $x^{1,2,3}$ hypersurface at $\sigma = \sigma_\infty$. By examining the non-Abelian Wess–Zumino action (9), one can show that the noncommutative solution induces a coupling to the RR four-form potential $C^{(4)}_{t123}$. This calculation confirms then that, with the minus (plus) sign in Eq. (46), the D-strings expand into a(n anti-)D3-brane which fills the $x^{1,2,3}$ directions.[23] Given that the funnel solution of the D-string theory and the bion spike of the D3-brane theory are both BPS, one might expect that there will be a good agreement between these two dual descriptions. The formula for the height of D3-brane spike above the $x^{1,2,3}$ hyperplane is[65]

$$\sigma - \sigma_\infty = \frac{N \pi l_s^2}{R}. \tag{49}$$

Compared to Eq. (46), one finds that for large N the two descriptions are describing the same geometry up to $1/N^2$ corrections. One finds similar quantitative agreement for large N in calculating the energy, the RR couplings and the low energy dynamics in the two dual descriptions.[23] As in the discussion of the dielectric effect, one can argue that the D3-brane description is valid for $R \gg l_s$ while the D-string description is reliable for $R \ll \sqrt{N} l_s$.[23] Hence one can understand the good agreement between these dual approaches for large N since there is a large domain of overlap where both are reliable.

Note that in the configurations considered in this section, there are no nontrivial supergravity fields in the ambient space–time. Hence the appearance of the noncommutative geometry in these solutions is quite distinct from that in the dielectric effect, where the external fields drive the D-branes into a certain geometry in the ground state. In the funnel solutions, the noncommutative geometry was put into the ansatz (43) by hand. An interesting extension of these solutions is then to replace the SU(2) generators by those corresponding to some other noncommutative geometry, i.e., to replace Eq. (43) by

$$\Phi^i = \frac{R(\sigma)}{\lambda \sqrt{C}} G^i, \tag{50}$$

where the G^i are new $N \times N$ constant matrices satisfying $\mathrm{Tr} \Sigma (G^i)^2 = N C$. An interesting feature of such a construction is that near the core of the funnel, the leading order equations of motion will still be those given in Eq. (42). Thus for Eq. (50) to provide a solution, the new generators must satisfy $[G^j,[G^j,G^i]] = 2a^2 G^i$ for some constant a, and then the radius is determined by

$$R'' = \frac{2a^2}{\lambda^2 C} R^3, \tag{51}$$

which still has essentially the same form as Eq. (45) above. Further the funnel solution of this equation also has essentially the same form as Eq. (46) above, i.e.,

$$R = \pm \frac{\lambda \sqrt{C}}{a(\sigma - \sigma_\infty)}. \tag{52}$$

Hence the profile with $R \simeq \lambda/\sigma$ is universal for all funnels on the D-string, independent of the details of the noncommutative geometry that describes the cross-section of the funnel.

This universal behavior is curious. For example, one could consider using this framework to describe a D-string ending on an orthogonal Dp-brane with $p > 3$. However, from the dual Dp-brane formulation, one expects that for large R, solutions will essentially be harmonic functions behaving like $\sigma \propto R^{-(p-2)}$ or $R \propto \sigma^{-1/(p-2)}$. The resolution of this puzzle seems to be that the

two profiles apply in distinct regimes, the first for small R and the second for large R. Hence it must be that the nonlinearity of the full Born–Infeld action will generate solutions which display a transition from one kind of behavior to another.

One particular example that we have examined in detail[24] is the case where G^i in Eq. (50) are chosen to be generators describing a fuzzy four-sphere—these may be found in, e.g., Ref. 14. In this case, the funnel describes the D-strings expanding into a D5-brane. One does find the expected transition in the behavior of the geometry. That is, $\sigma \approx N^{2/3} l_s / R$ for small R in accord with Eq. (52), while at large R, higher order terms in the Born–Infeld action (40) become important yielding $\sigma \approx N^{2/3} l_s^4 / R^3$. The same kind of behavior is also found for the corresponding solutions in the dual D5-brane world-volume theory, although of course in that case the nonlinearities of the Born–Infeld action become important for small R. An interesting feature of the D5-brane spike is that it is also non-Abelian in character. Charge conservation arguments indicate that the D-string acts as a source of the second Chern class in the world-volume of the D5-brane.[83] More precisely, if N D-strings end on a D5-brane, then

$$\frac{1}{8\pi^2} \int_{S^4} \mathrm{Tr}(F \wedge F) = N, \tag{53}$$

for any four-sphere surrounding the D-string end point. Hence both of the dual descriptions have a noncommutative character. Again, we find that the dual constructions seem to agree at large N, however, the details of the solutions are more complex. In part, the latter must be due to the fact that the D5$\perp$D1 system is not supersymmetric.

Superstrings and topological strings at large *N*

Cumrun Vafa
Jefferson Physical Laboratory, Harvard University, Cambridge, Massachusetts 02138

(Received 2 January 2001; accepted for publication 13 February 2001)

We embed the large N Chern–Simons/topological string duality in ordinary superstrings. This corresponds to a large N duality between generalized gauge systems with $N=1$ supersymmetry in four dimensions and superstrings propagating on noncompact Calabi–Yau manifolds with certain fluxes turned on. We also show that in a particular limit of the $N=1$ gauge theory system, certain superpotential terms in the $N=1$ system (including deformations if spacetime is noncommutative) are captured to all orders in $1/N$ by the amplitudes of noncritical bosonic strings propagating on a circle with self-dual radius. We also consider D-brane/anti-D-brane system wrapped over vanishing cycles of compact Calabi–Yau manifolds and argue that at large N they induce a shift in the background to a topologically distinct Calabi–Yau, which we identify as the ground state system of the brane/anti-brane system. © *2001 American Institute of Physics.*

I. INTRODUCTION

The idea that large N gauge theories should have a phase described by perturbative strings, set forth by 't Hooft,[1] has been beautifully realized by various examples. The first example of this kind was found by Kontsevich,[2] which relates the bosonic string theory coupled to certain matter [(1, 2) minimal model, which is equivalent to pure topological gravity formulated by Witten[3]], to a matrix integral with cubic interaction (which can be viewed as a particular gauge theory in zero dimensions). (This is not the same as the old matrix model which discretizes the worldsheet—rather it is the target space description exactly in line with 't Hooft's conjecture.) Many more examples were also found in the context of noncritical bosonic strings. For example, it was found[4] that bosonic strings propagating on a circle with self-dual radius is equivalent to Penner matrix model.[5]

More recently it was recognized that 't Hooft's conjecture is also realized even for much more complicated and physically more interesting gauge theories.[6–8] In particular certain gauge theories at large N are equivalent to superstrings propagating on AdS backgrounds. Another example of a string/large N duality was discovered in Ref. 9, where it was shown that large N limit of Chern–Simons gauge theory on S^3 is equivalent to topological strings on a noncompact Calabi–Yau threefold which is a blow up of the conifold [given by $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$]. This duality was tested to all orders in the $1/N$ expansion including checks at the level of Wilson loop observables of the Chern–Simons theory.[10,11] It is also known[12] that in some limit (large N, fixed Chern–Simons coupling k) this theory has the same partition function as bosonic strings at the self-dual radius.

This paper was motivated by trying to connect the duality discovered in Ref. 9 with the dualities discovered in the context of AdS/CFT correspondences. The basic idea is to consider type IIA superstring propagating in the conifold background (which is symplectically the same as T^*S^3) in the presence of N D6 branes wrapped around S^3 and filling the spacetime. It has been known[13] that the topological string amplitudes for the internal theory on the noncompact Calabi–Yau compute superpotential terms on the left-over R^4 world volume of the D6 brane. On the other hand, it is also known that the internal topological string theory with N D-branes wrapped on S^3 is equivalent to Chern–Simons gauge theory on S^3.[14] Thus the duality found in Ref. 9 suggests that type IIA string on the conifold with N D6 branes is equivalent to the blown up version of the

conifold with no branes left over. At first sight this seems strange, because having no D-branes left would naively suggest a theory with $N=2$ supersymmetry rather than $N=1$. Moreover Ramond fluxes should also be turned on in the blown up geometry corresponding to the flux generated by the D6 brane. The main question was why in the dual topological string theory discovered in Ref. 9 there is no mention of RR fluxes? Indeed it is an ordinary topological string (the A model) on the blown up conifold.

The resolution turns out to be that turning on the RR flux does not affect the topological string amplitudes, and the dual string theory *does* involve RR fluxes. Turning on RR flux, however, does generate an $N=1$ superpotential term,[15,16] which can be computed in terms of the topological string amplitudes. Thus the duality found in Ref. 9 can be viewed as an all order check in the $1/N$ expansion for the $N=1$ superpotential computations in the context of this type IIA superstring/gauge theory duality. One can also consider the mirror symmetry acting on all these statements, which as noted in Ref. 9 give rise to similar dualities. In the superstring realization, the mirror case (in a certain limit) would correspond to considering type IIB string on the blow up of the conifold with N D5 branes wrapped on $\mathbf{P}^1$ and we end up with type IIB on deformed conifold geometry T^*S^3 but with RR flux turned on.

One can also consider wrapped D-brane in the context of compact Calabi–Yau manifolds. However, in this case we also need to put anti-D-branes, in order to have no net D-branes. In this case we conjecture that the large N limit will correspond to having a new Calabi–Yau with fluxes, which can decay as discussed in Ref. 17 to a theory with no fluxes left over and with supersymmetry increased to $N=2$. The effect of the non-BPS states has been to shift the background to a new background. This is a novel way of deforming backgrounds, and as we will suggest later in the paper may have many interesting extensions.

The organization of this paper is as follows: In Sec. II we review aspects of topological string amplitudes and what they compute in the corresponding superstring theory. In Sec. III we revisit the duality of Ref. 9 and embed it in the context of type IIA superstrings. In Sec. IV we apply mirror symmetry to the statements in Sec. III and discuss the equivalent type IIB superstring theory. In Sec. V we discuss possible applications of $c=1$ noncritical bosonic strings to the question of generation of superpotential in the large N limit of $N=1$ supersymmetric gauge theory. In Sec. VI we discuss wrapped brane/anti-brane systems in the context of compact Calabi–Yau manifolds and use the above duality to make new predictions about the shift in the background. In Sec. VII we discuss some generalizations of this work.

While preparing this paper, three papers appeared which have overlaps with different aspects of our work. In particular, Refs. 18 and 19 have some overlap with our work in the context of large N duals of $N=1$ gauge theories in the context of type IIB strings, which we will briefly comment on in Sec. IV. Also the same configuration of wrapped D-branes/anti-D-branes considered in Sec. VI was also studied in Ref. 20 in a different context.

II. TOPOLOGICAL STRINGS AND SUPERSTRINGS

In this section we discuss aspects of topological strings and their relevance for superpotential computations in the corresponding superstring compactifications. We will divide our discussion to two parts: Closed string case (i.e., without D-branes) and open string case (i.e., including D-branes). We also point out the relevance of topological string amplitudes for $N=1$ superpotential computations when RR-fluxes are turned on.

A. Closed topological string and superstring amplitudes in 4D

Consider A model topological strings on a Calabi–Yau manifold K (similar remarks apply to the mirror B model). For simplicity of notation let us assume that the CY manifold has only one Kahler class, parametrized by the complexified Kahler parameter t. Then closed topological string amplitude on K is given by

$$F(t,\lambda_s)=\sum_g \lambda_s^{2g-2}F_g, \tag{2.1}$$

$$F_g = \sum_d F_{d,g} e^{-dt},$$

where, roughly speaking $F_{d,g}$ denote the ''numbers'' (Gromov–Witten invariants) of genus g curves in class d. The topological strings compute certain amplitudes in the corresponding type IIA superstring compactifications on the Calabi–Yau.[13,21,22] In particular they compute terms in the action of the form

$$\int d^4\theta \mathcal{W}^{2g} F_g(t) = g R^2 F^{2g-2} F_g(t) + \cdots,$$

where $\mathcal{W}_{\alpha\beta}$ denotes the graviphoton field strength multiplet, R^2 and F^{2g-2} denote certain contractions of the self-dual part of the Riemann tensor and of the gravi-photon field strength, and t denotes the vector superfield with the vev of the lowest component being the Kahler parameter t. One way to derive this formula is to note that with $2g-2$ insertions of the spin operator, needed to compute the amplitude involving the F^{2g-2}, the ordinary sigma model is topologically twisted. At genus 0 what one gets is

$$\int d^4\theta F_0(t) = \partial^2 F_0(t) F^t \wedge F^t + \cdots,$$

where F^t denotes the (self-dual part of the) U(1) field strength in the same multiplet as t. In the type IIA this arises from the 4-form field strength G by setting it to

$$G = F^t \wedge \omega_t,$$

where ω_t denotes the Kahler form associated to t.

It is natural to ask what changes in the closed topological string computations when we turn on some RR flux in the target space. The choices are the 2-form field strength in the internal space F, 4-form field strength G_{int} along the internal CY directions and the G along the spacetime directions G_4, which we equivalently study in terms of the dual 6-form field strength $G_6 = *G_4$. (We can also include the 0-form field strength dual to 10-form field strength in type IIA, but since we will not deal with it in this paper we will not discuss it. It will give rise to an $N=1$ superpotential of the form $\int G_0 \wedge k^3$.) It turns out that the topological string amplitudes in the presence of RR fields is not modified at all. This is particularly simple to show in the Berkovits formalism.[22–24] Instead of demonstrating it in this way we follow a related idea, which we will need later in this paper, by studying the generation of $N=1$ superpotential terms in the presence of RR fluxes, which we will discuss next.

B. Generation of superpotential due to internal field strength

RR fluxes have been studied in the context of CY compactifications.[25,26,15,16] In particular it has been shown in Refs. 15 and 16 that turning on internal field strength in the CY leads to generation of superpotential terms in 4D $N=1$ theory (see also similar situations considered in Refs. 27 and 28). In the context of type IIA theory with RR fluxes corresponding to F and G_{int} and G_6 discussed above, the superpotential is given by

$$\lambda_s W = \int F \wedge k \wedge k + i \int G \wedge k + \int G_6, \tag{2.2}$$

where k is the complexified Kahler class. To see this one considers the BPS charge in the presence of BPS domain walls which may be partially wrapped over the CY. For example, considering a D6-brane wrapped over 4-cycles of CY gives a domain wall with BPS tension $(1/\lambda_s)\int k \wedge k$ integrated over the internal part of the 6-brane. This in turn shifts the dual F by one unit. This BPS formula should be captured by a ΔW and we can see from the above form of (2.2) that the first

term above precisely captures this term. More precisely what we mean by the formula (2.2) is the *worldsheet quantum corrected* formula for the kahler forms (as is well known in the context of mirror symmetry the mass of the D-branes receives corrections by the worldsheet instantons). In particular if t denotes the complexified area of the basic 2-cycle, then the volumes of the 0-, 2-, 4- and 6-cycles are given by

$$1, t, \frac{\partial F_0}{\partial t}, 2F_0 - t\frac{\partial F_0}{\partial t},$$

where F_0 is the genus zero topological string amplitude. So in particular suppose we have N units of the F flux through the basic 2-cycle, where t denotes the complexified area of this 2-cycle. Then the first term in (2.2) is equivalent to

$$\int F \wedge k \wedge k = N\frac{\partial F_0}{\partial t}.$$

Similarly if we considered D4-branes wrapped over 2-cycles and D2-branes with no wrappings, we deduce the existence of the second and third term in (2.2). In particular if we denote the fluxes of F, G_{int}, G_6 by integers N,L,P relative to integral 2-, 4-, and 6-cycles, we have

$$\lambda_s W = N\frac{\partial F_0}{\partial t} + itL + P. \tag{2.3}$$

Note that Eq. (2.2) can also be written in the form

$$\lambda_s W = \int (F + i*G) \wedge k + \int G_6, \tag{2.4}$$

where again here by $*$ we mean the worldsheet quantum corrected $*$ operation.

Now we come to the discussion of why turning on RR fluxes should not modify the topological amplitudes. We will concentrate on genus 0 amplitudes (similar arguments can be advanced for the higher genus amplitudes as well). The vector superfield with bottom component t has an auxiliary field in the superspace of the form

$$t + \theta^2(F + *iG) + \cdots,$$

where F and G are the usual RR fluxes of the internal Calabi–Yau. (I have greatly benefited from discussions with Nathan Berkovits in connection with the auxiliary field structure of the superfields.) In the usual supersymmetric background they are set to zero. Now suppose we wish to turn them on. Suppose, for example, we wish to turn on N units of F. Consider the topological string amplitude $F_0(t)$. We claim that this already yields the correct structure for the generation of $N=1$ superpotential precisely if F_0 *is unmodified in the presence of* RR *flux*. To see this note that using the expansion of t in terms of the RR field strength auxiliary fields we have

$$\int d^4\theta F_0(t) = \int d^2\theta N\frac{\partial F_0}{\partial t}$$

which is exactly the expected answer if F_0 is unmodified. Similarly turning on the G_{int} flux and using (2.4) we see that the term in (2.2) involving G_{int} will also have the correct structure if F_0 is unmodified.

There is another auxiliary field in the vector multiplet which come from the $NS-NS$ sector which is relevant for us. This corresponds to the field strength associated with the lack of integrability of complex structure. In particular if we write $\bar{D} = \bar{\partial} + A\partial$, where A is an antiholomorphic one form taking values in the tangent bundle, then

$$\bar{D}^2=(\bar{\partial}A+[A,A])\partial=\mathcal{F}\partial,$$

where $\mathcal{F}$ is an antiholomorphic 2-form with values in the tangent bundle which is equivalent, by lowering the vector index by the three form, to a (2,2) form. If this is nonvanishing it also corresponds to making the (3,0) form in the CY not to be annihilated by $\bar{\partial}$. These turn out effectively to add to F and $G_{\rm int}$ complex pieces of the form iF^{NS}/λ_s and $iG^{NS}_{\rm int}/\lambda_s$. A similar NS auxiliary field gives rise effectively to the complex part of $*G_6$. (Turning these fields on is mirror to turning on H_{NS} on the mirror CY.) In other words, even with these fields turned on, the formula (2.3) remains correct but now N,L,P also include imaginary pieces of the form iN_I/λ_s, iL/λ_s, iP/λ_s. We will continue to denote the superpotential as (2.3) and keep in mind that N, L, and P can have complex pieces given by an integer over λ_s.

Turning these vevs on breaks the $N=2$ supersymmetry to $N=1$. The field t is now the bottom component of an $N=1$ chiral multiplet whose auxiliary field descends from another auxiliary field (which also comes from the NS sector) in the original $N=2$ multiplet which is not turned on.

Note also that the higher genus topological amplitudes also give rise to certain $N=1$ superpotential terms when the auxiliary field of the $N=2$ multiplet t takes a vev. In particular with N units of RR flux for F we get

$$\int d^4\theta \mathcal{W}^{2g}F_g(t)\to N\int d^2\theta \mathcal{W}^{2g}\frac{\partial F_g}{\partial t}, \tag{2.5}$$

where we continue to denote by $\mathcal{W}_{\alpha\beta}$ the reduction of the $N=2$ multiplet to an $N=1$ multiplet with the self-dual part of the gravi-photon field strength as its bottom component.

So in conclusion we have learned that the topological string amplitudes are not sensitive to turning on RR field strengths, but they are useful in determining the superpotential terms that will be generated once certain RR and NS fields take a vev. This is captured by Eq. (2.3).

C. Open topological strings and $N=1$ amplitudes in 4D

In the A-model, the open topological string corresponds to studying holomorphic maps from worldsheet with boundaries to the target space where the boundary lies on a three-dimensional Lagrangian subspace of the CY, i.e., the three-dimensional topological version of D-brane.[14] Moreover, it was shown that topological string field theory in this case is just the Chern–Simons gauge theory on the corresponding Lagrangian submanifold (possibly corrected with nontrivial worldsheet instantons). The implications of these theories for superstring amplitudes has been studied as well. In particular if we consider type IIA superstring in the presence of a CY with N D6-branes wrapping a Lagrangian 3-cycle of CY and filling the rest of the spacetime we get an $N=1$ gauge theory with SU(N) gauge group in 4D. Then it was shown in Ref. 13 that, for example, the genus 0 open topological string amplitudes compute corrections of the form

$$\lambda_s W=\sum_h \int d^2\theta F_{0,h}[NhS^{h-1}]+\alpha S+\beta, \tag{2.6}$$

where $F_{0,h}$ is the partition function of the topological string at genus 0 with h holes, and $S=\lambda_s \operatorname{Tr} W^2$ where W_α is the chiral superfield with gaugino as its bottom component. [The coefficient of Nh in front arises because, as discussed in Ref. 13, we have to choose $h-1$ holes to put the $\operatorname{tr} W^2$ fields and this can be done in h ways and also the trace over the hole without a field gives a factor of N. Note also that $\operatorname{Tr} W^2$ which is a fermion bilinear is nilpotent, in the sense that $(\operatorname{Tr} W^2)^k=0$ for $k>N^2$. It is relevant for us precisely because we are considering a large N limit. Thus in the large N limit the gaugino bilinear can even have a classical vev.] Here we have shown explicitly the contribution coming from $h=2$ in the form of αS. This term, coming from annulus, is typically divergent, signifying the RG flow of the coupling constant of the gauge theory and needs regularization. Also we have added a constant β to remind us that we cannot fix that from open topological string considerations. Here h is the number of holes on the sphere and $F_{0,h}$

denotes the topological amplitude on the sphere with h holes. If the target space has some Kahler moduli t they will correspond to chiral fields in the $N=1$ theory in four dimensions and $F_{0,h}$ will depend on t. The case of $h=1$ in the above formula was recently discussed in Refs. 29, 30, and 10. Some superstring implications of higher genus open topological strings, i.e., $F_{g,h}$ with arbitrary g, has also been noted in Ref. 10. In particular they compute terms of the form $\int d^2\theta F_{g,h}\mathcal{W}^{2g}[NhS^{h-1}]$.

Let us define the open topological string amplitude summed over all holes at a fixed genus by

$$F_g^{\text{open}}(r)=\sum_h F_{g,h}r^h.$$

Then, for example, the genus 0 open topological string amplitude computes the following correction to the superpotential:

$$\lambda_s W=N\int d^2\theta\frac{\partial F_0^{\text{open}}(S)}{\partial S}+\alpha S+\beta.$$

This is strikingly similar to the form obtained in (2.3) in the context of closed topological string amplitudes. Similarly the higher genus correction computes terms of the form

$$N\int d^2\theta\,\mathcal{W}^{2g}\frac{\partial F_g^{\text{open}}(S)}{\partial S}$$

which is also similar to the higher genus correction obtained in the closed string context in the presence of flux (2.5). The main difference being that S is an operator for the open string amplitudes but t is a parameter in the closed string setup. Nevertheless we will see in the next section why this is not an accidental similarity and provides the superstring interpretation of the duality found in Ref. 9, when S takes an expectation value equal to t.

III. EMBEDDING LARGE *N* TOPOLOGICAL STRING DUALITY IN SUPERSTRINGS

Consider type IIA strings in a noncompact CY three-fold geometry of the form of the conifold times the Minkowski space M^4: The internal geometry is given by

$$f=x_1^2+\cdots+x_4^2=\rho,$$

where each x_i parametrizes $\mathbf{C}$. The real subspace of the above geometry is S^3 (for real ρ) and the imaginary directions sweep the cotangent direction of S^3. The volume of S^3 in string units is given by ρ (here we are taking the canonical 3-form $\Omega=\Pi dx_i/df$, which scales as ρ to give the volume). Thus symplectically the conifold is T^*S^3. Consider N D6-branes wrapped over the S^3 of the conifold and filling the rest of the spacetime. On the uncompactified world volume of the D-brane we have an $N=1$ supersymmetric SU(N) gauge theory. Note that to leading order the action on the uncompactified world volume of the D-branes is given by the superpotential

$$\frac{1}{\lambda_s}\int d^2\theta\,SY, \tag{3.1}$$

where $S=\lambda_s\,\mathrm{Tr}\,W^2$ and where Y denotes the $N=1$ chiral superfield with its bottom component given by $iC+(\rho/\lambda_s)$, where C is the vev of the 3-form gauge field on IIA (normalized with periodicity 2π) and plays the role of the θ angle for the gauge theory and ρ denotes the volume of the S^3.

The choice of this type IIA geometry is based on the desire to utilize the topological open/closed string duality. In particular, as discussed in the preceding section the open topological string in this case computes corrections to the superpotential of the form

$$\frac{N}{\lambda_s}\int d^2\theta\, \partial_S F_0^{\text{open}}(S).$$

The topological A-model is insensitive to complex structure. In particular F^{open} is independent of ρ except for a linear terms in S (coming from the annulus) written in (3.1), which is related to the ambiguity of open topological string at the level of annulus. There is also a divergence of the annulus amplitude corresponding to the running of the gauge coupling constant, which, in the regularized form, can be viewed as addition of a linear term in S. The corrections above to the simple $YS=Y\,\mathrm{Tr}\,W^2$ involve higher dimension operators (more powers of S) and are captured by the open string amplitude which coincide with the large N expansion of the Chern–Simon amplitudes on S^3. Note also that the fact that they are independent of Y implies that they survive no matter what the size of the S^3 is.

Now we wish to consider the limit where we consider the $N\to\infty$ limit keeping $N\lambda_s$ fixed. In this limit, the analog of 't Hooft coupling for the gauge system is given by

$$\frac{1}{Ng_{\text{YM}}^2}\to\frac{Y}{N\lambda_s},$$

which remains fixed in this limit. We would like to consider the gravity dual of this gauge system. In the spirit of AdS/CFT correspondence we will have to consider the near horizon geometry. What the precise notion of ''near'' horizon geometry in this case should be is more subtle because the expectation value of Y undergoes an RG flow, as noted above, and it will depend at which scale we are probing it. In other words we have to readjust the size of Y depending on how close we are approaching the branes. The limit should be such that the S^3 has zero size when we probe it in the UV of the gravitational side but finite size in the IR. To avoid such subtleties we try to look for a consistent gravitational background which the branes create. In particular we should find an S^2 of finite size emerging, surrounding the S^3, with the D-branes completely disappeared and replaced by the corresponding fluxes. In the case at hand, since we have N D6-branes wrapping the S^3 in the geometry after transition we should get N units of the 2-form RR flux F through the dual S^2. We will now turn to studying this geometry.

A. Type IIA superstring on the blown up geometry

We thus seek the dual large N stringy description of the above gauge system, in the form of the type IIA background with the blown up conifold geometry, i.e., the geometry corresponding to $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$, with N units of 2-form F flux through $\mathbf{P}^1$. However, we must also have internal 4-form and 6-form fluxes (in the form of *NS* and RR fields discussed before).

That there should be an *NS* 4-form flux corresponds to the fact that the size of the S^3 is changing (i.e., that Ω is no longer closed and $\rho=\int_{S^3}\Omega$ changes), inducing a running of the gauge coupling constant. Moreover to preserve $N=1$ supersymmetry for a finite value t of the complexified area of the blown up $\mathbf{P}^1$ we need both 4-form as well as 6-form fluxes. In fact, as discussed in the preceding section and summarized in Eq. (2.3) we have a superpotential of the form

$$W=N\partial_t F_0(t)+itL+P, \tag{3.2}$$

where for the geometry at hand $F_0(t)$ is, up to a cubic polynomial, the tri-logarithm function, given by

$$F_0(t)=\frac{1}{6}t^3-\sum_{n>0}\frac{e^{-nt}}{n^3}+P_2(t) \tag{3.3}$$

[where $P_2(t)$ is a polynomial of order 2 in t and is somewhat ambiguous]. Similarly for higher genus F_g we have

$$F_g(t)=\frac{B_{2g}}{2g(2g-2)!}\sum_{n>0} n^{2g-3}e^{-nt}+\frac{B_{2g}B_{2g-2}}{2g(2g-2)(2g-2)!},\quad g>1,$$

$$F_1(t)=\frac{t}{24}+\frac{1}{12}\log(1-e^{-t}),$$

where B_{2g} denotes the Bernoulli numbers. The terms involving e^{-nt} in the above formula reflects the corrections due to worldsheet instantons wrapping n times over the $\mathbf{P}^1$.

The content of the duality obtained in Ref. 9 is that

$$F_g^{\text{open}}(S)=F_g(t)$$

for all g if we set $S=t$. We now try to interpret this statement in the superstring context. For this we need to study solutions to the gravitational equations.

Typically in physics and mathematics when we try to solve some system of equations, there are topological obstructions that have to be shown to be absent. Once they are shown to be absent then a solution exists. For example, when we are trying to find Ricci-flat metrics on Kahler manifolds we need the first Chern class of the manifold to be zero. In fact this is also sufficient for being able to find a Calabi–Yau metric. Of course explicit solution for the metric has not been possible in almost all cases and in fact the Ricci-flat metric is only an approximate metric which gives rise to a conformal worldsheet theory. In a sense the topological condition, guaranteeing the existence of the solution is more fundamental than the solution itself.

Now we come to the case at hand. To preserve $N=1$ supersymmetry we need $W=dW=0$. Once these are satisfied, we expect physically that there must be a solution to the gravitational system. In fact a very similar example with the same number of supercharges (namely 4) was already studied from this point of view. Namely if we consider M-theory on Calabi–Yau fourfold with G-flux turned on, the gravitational equations have been studied in Ref. 31. The topological conditions they find for the existence of the gravitational solution has been shown to be identical to the condition that $W=dW=0$.[27]

Of course the low energy gravitational equation in the present case can also be studied similar to what was done in Ref. 31 and will involve warped geometries mixing the spacetime with the Calabi–Yau. Even though solving the gravity equations would be interesting, we have to remember that due to worldsheet instantons wrapping the $\mathbf{P}^1$ there are important corrections to the gravity equations, and so at best we can trust the low energy gravity description in the limit of large t. Nevertheless, as already noted above, the superpotential terms *including* the corrected string geometry, can be incorporated to all orders in the W which is computable by topological string amplitudes.

Before even solving the conditions $W=dW=0$ we can already interpret the duality of Ref. 9 in the superstring context. If we compare Eq. (3.2) with the superpotential given in the gauge theory side namely $W=N\partial_S F_0^{\text{open}}(S)+\alpha S+\beta$ we see that they are identical in form with an appropriate identification of α and β with L and P. Therefore, since the vacuum in the gauge theory side, as well as the moduli in the gravity side correspond to $W=dW=0$, and W has the same form for the gauge as well as the gravitational system, this will identify

$$\langle S\rangle=\langle \lambda_s \operatorname{Tr} W^2\rangle=t,\quad F_g^{\text{open}}(S)=F_g(t). \tag{3.4}$$

Thus the condition of vacuum configuration which sets $\langle S\rangle=t$ also translates the duality found in Ref. 9 to the match between amplitudes in the gravity side and the gauge theory side to all orders in $1/N$ at least as far as superpotential terms are concerned.

Note that the idea that $\langle S\rangle\neq 0$, i.e., that we have gaugino condensation, is very natural for the open string theory under discussion as it does have an $N=1$ Yang–Mills theory associated with it. Part of the above check involves, on the gauge theory side, the statement that gaugino condensation generates superpotential terms captured through topological open string amplitudes and in fact

this was already pointed out in Ref. 13. Of course here we have a more refined gauge theory than just the $N=1$ Yang–Mills theory and in particular we have in the open string system, also the higher dimension operators present, which are captured by the topological string amplitude. At any rate, the result of Ref. 9 strongly suggests not only the existence of a large N duality involving this $N=1$ brane system with this closed string background, but also that the gaugino condensation takes place.

We now come to finding solutions to the equations $W=dW=0$ on the gravity side, which should guarantee the existence of a solution. There are four parameters under control: the modulus t and the fluxes N,L,P. The two equations $W=dW=0$,

$$\partial_t W=0\rightarrow NF_0''+iL=0\rightarrow L=iNF_0'',$$

$$W=0\rightarrow P=-NF_0'+NtF_0''$$

imply that two of these four quantities are fixed in terms of the other two. The N is of course fixed for us by the number of D6-branes. As is clear from our description of the dual gauge system the choice of a shift in L is related to a shift in the bare coupling constant of the gauge system. In particular in order to agree with the bare coupling constant of the gauge theory $iL=\rho/\lambda_s$, where ρ is the volume of the S^3 where the D6-branes are wrapped around. Thus the value of t (and also of P) is fixed and from (3.3) and $\partial_t W=0$ the solution for t is given by

$$[c(e^t-1)]^N=\exp(-\rho/\lambda_s). \tag{3.5}$$

The constant c depends on the ambiguities hidden in the $P_2(t)$. As we will argue from the dual gauge theory description, it should be fixed in our case (by a suitable regularization of the one loop divergence of the gauge theory) to be $c\sim N\lambda_s$.

Next we turn to the question of how the dynamics of the gauge system is reflected in the W and the other superpotential terms. What do we expect for the dynamics of the $N=1$ supersymmetric theory living on the D6-brane? If we ignore the higher powers of S in the superspace integral, i.e., if we ignore the higher order operators, as already discussed, the leading term with the lowest number of derivatives, is given by the superpotential term

$$\frac{1}{\lambda_s}\int d^2\theta\, SY,$$

where $S=\lambda_s \operatorname{Tr} W^2$ and $Y=iC+(\rho/\lambda_s)$ where ρ denotes the size of the S^3 in the string frame. In the usual geometric engineering of standard $N=1$ gauge theories, and in particular the ones discussed in Ref. 32 one considers the limit where ρ is large, in which case the field Y gets demoted to a parameter in the Lagrangian (the corresponding D-term involving $Y\overline{Y}$ becomes very large). However, here we are not necessarily interested only in a regime where Y is very large. In other words we consider the field Y to be a dynamical field. Thus we have a nonstandard $N=1$ supersymmetric gauge theory with its coupling constant as a dynamical field. Even though it is somewhat unconventional, as we will now argue some of the basic features of this theory are similar to that of $N=1$ QCD, in the limit where we ignore the higher derivative terms of the form $\int d^2\theta[\operatorname{tr} W^2]^k$. In other words, if we consider the field space where $S=\operatorname{tr} W^2\ll 1$ (in string units) we have a theory which is more or less similar to $N=1$ supersymmetric Yang–Mills theory. Even though we do not have to restrict our attention only to this limit, and the duality with gravity holds regardless of which field configuration in S we consider, it is first instructive to consider the small S region to gain intuition for what this theory is.

In the dynamics of $N=1$ supersymmetric gauge theory, a prominent role is played by instantons. Here a similar effect exists: In particular if we consider Euclidean D2-brane instantons wrapping the S^3 the superpotential gets corrected. Moreover this can also be viewed as point-like instantons for the SU(N) gauge theory. To have the right number of fermionic zero modes to lead to a chiral superspace potential we need $1/N$-th of this instanton. Since the action for this instanton

is e^{-Y}, the term that can appear in the action is $e^{-Y/N}$. The coefficient in front of it should be of order N^2 (as argued in Ref. 33). So we must have the effective superpotential given by

$$W=\int d^2\theta\left(\frac{1}{\lambda_s}SY+iN^2\alpha e^{-Y/N}\right), \tag{3.6}$$

where the constant α, by a shift in $Y\to Y+Y_0$, can be identified with a shift in the bare coupling constant of S, i.e.,

$$\alpha=e^{-Y_0/N}. \tag{3.7}$$

(The choice of α is also related to how we regularize the one-loop divergence which corrects the action with a term $a\int d^2\theta S$.)

This effective superpotential has the same structure as that encountered in the proof of mirror symmetry in two dimensions.[34] This same superpotential structure was encountered in Ref. 10 in the context of $N=1$ domain walls in 4D, which we will also need in this paper, and we will discuss further below. Notice that here since Y is a dynamical field, we can integrate it out by setting

$$\partial_Y W=0\to\frac{1}{\lambda_s}S=iN\alpha e^{-Y/N}$$

which leads to

$$Y=\log\left(\frac{S}{iN\alpha\lambda_s}\right)^{-N}$$

plugging it back to the superpotential gives the effective superpotential for S:

$$W_{\text{eff}}(S)=\frac{1}{\lambda_s}\left[S\log\left(\frac{S}{iN\alpha\lambda_S}\right)^{-N}+NS\right].$$

This is the familiar effective superpotential expected for the gaugino bilinear S in the standard $N=1$ supersymmetric gauge theory. Indeed setting $\partial_S W=0$ leads to

$$\left[\frac{S}{iN\alpha\lambda_s}\right]^N=1\to S=iN\alpha\lambda_s e^{2\pi il/N}=iN\lambda_s e^{(-Y_0+2\pi il)/N}. \tag{3.8}$$

Note that we see the N vacua of SU(N) Yang–Mills, in the standard way.

Let us compare the vev we found for $S=\lambda_s\,\mathrm{Tr}\,W^2$ with the gaugino condensate for standard $N=1$ Yang–Mills, which is of the form

$$\mathrm{Tr}\,W^2=iN\Lambda^3 e^{[-1/Ng^2_{\mathrm{YM}}]+(2\pi il/N)}.$$

In comparison with what we have above, note that this is in perfect agreement with (3.8), where Λ corresponds to the string scale and $1/g^2_{\mathrm{YM}}\to Y_0$.

Note that the effective superpotential we have found for S, for small S, also follows from either the open topological string amplitudes in the limit $S\to 0$, or the dual closed topological string amplitude in the limit $S=t\to 0$ which is given by

$$F_0(t)\to-\tfrac{1}{2}t^2\log t+at^2+bt+c$$

and so

$$W(S)=\frac{1}{\lambda_s}[N\partial_S F_0(S)+\alpha S+\beta]=\frac{1}{\lambda_s}(S\log S^{-N}+N\,\text{const}\,S+N\,\text{const})$$

in perfect agreement with expectations based on the gauge theory analysis as well as with the contribution of the Euclidean D2-brane instantons in the string context. This comparison with gauge theory and recalling that $t\leftrightarrow\lambda_s\,\mathrm{Tr}\,W^2$, also fixes the value c in (3.5) to be $c\sim N\lambda_s$. Note that the choice of α, the linear terms in S, on the gravity side is controlled by the 4-form fluxes dual to the $\mathbf{P}^1$, as discussed before.

Having discussed the geometry of the vacua of $N=1$ theory, we now turn to another important feature of $N=1$ theories, namely the domain walls interpolating between various vacua.

B. Domain walls

$N=1$ Yang–Mills theory admits BPS domain walls interpolating between various vacua. As noted in Ref. 33 at large N they behave as D-branes for QCD string. In particular their tension is of the order of N. Since in the present context the QCD string is realized by the fundamental string, ordinary D-branes of string theory should play the role of domain walls. This is indeed the case: On the gravity side we have a blown up $\mathbf{P}^1$. If we consider D4-branes wrapped over $\mathbf{P}^1$ they correspond to domain walls. Their tension goes as

$$T\sim\frac{1}{\lambda_s}|t|=N\frac{|t|}{N\lambda_s}.$$

As discussed before $|N\lambda_s|\sim|t|$ so we obtain the expected behavior. For the QCD domain wall the phase of the S field should change as we go from one vacuum to another. In particular it should shift by $\exp(2\pi i/N)$ for domain walls interpolating adjacent vacua. Let us see how this is realized in the gravity setup. Since we have identified the domain wall with D4-brane wrapped over S^2 we should note that the value of the G flux shifts as we cross the domain wall. Consider in particular the imaginary part of the Y field introduced earlier, which was identified with

$$\mathrm{Im}\,Y=C_{S^3},$$

i.e., the vev of the C field along the S^3. We now discuss how this changes from the left-hand side of the domain wall to the right-hand side. Since the G flux should be equal to one for the $D4$-brane, it implies that $\mathrm{Im}\,Y$ should shift by 2π, i.e.,

$$Y\to Y+2\pi i$$

as we go across the domain wall. In fact we can find the geometry of the BPS domain walls by the usual technique of the LG theory in 2D with $N=2$ susy.[35] In fact for the case at hand similar BPS domain walls were considered in Ref. 36. These domain walls also featured in the discussion of $N=1$ generation of superpotential in Ref. 10. Note that since we have

$$S=\lambda_s N\exp(-(Y+Y_0)/N)$$

this implies that the phase of S changes by $\exp(-2\pi i/N)$ as expected. Of course this is suppressed at large N, in agreement with the fact that classically the wrapped D-brane does not change the value of t.

It is also easy to see from the form of the action (3.6) that the BPS tension, which is given by ΔW, is given by

$$\Delta W=\frac{1}{\lambda_s}S\Delta Y.$$

Since S is identified with t, this corresponds to

$$\Delta W = \frac{2\pi i}{\lambda_s} t$$

as expected for the tension of the BPS wrapped D4-brane.

C. Subleading corrections in the 1/N expansion

So far we have concentrated on the interpretation of the leading corrections in large N. In the context of topological strings also the subleading terms to all orders in $1/N$ were found to agree between the Chern–Simons gauge theory and the closed topological string expansion. What is the interpretation of these higher terms for the gauge theory system?

In the limit of small t the topological string amplitudes is given by

$$F(t) = \sum_g F_g \lambda_s^{2g-2} t^{2-2g},$$

where $F_g = [B_{2g}/2g(2g-2)]$ and B_{2g} are the Bernoulli numbers (F_g turns out to be equal to the Euler characteristic of the moduli space of genus g Riemann surfaces). In this limit the topological string partition function coincides with that of noncritical bosonic strings on a circle with self-dual radius (this connection is well understood and will be reviewed in Sec. V). The $N=2$ amplitude that this computes is given by

$$\int d^4\theta \mathcal{W}^{2g} F_g t^{2-2g} = g R^2 F^{2g-2} F_g t^{2-2g} + \cdots . \tag{3.9}$$

This correction has been physically understood by considering turning on constant gravi-photon field strength in the Minkowski space and computing the effect of wrapped D2-branes on $\mathbf{P}^1$ to the R^2 term.[37] In the present context the wrapped D2-branes correspond to the baryon vertex, as in the usual AdS/CFT correspondence.[38] The baryon fields are charged under the gravi-photon field with charge proportional to their BPS mass t. Thus turning on gravi-photon F effectively turns on a background field strength for F_v, i.e., the $U(1) \subset U(N)$ living on the D6-branes, which can be identified with a global U(1) symmetry (the baryon number symmetry). Let us try to see how this can come about from the gauge theory side.

On the world volume of the D6-branes we have terms of the form

$$\int_{R^4} [G_4 + F \wedge F_v] \left(\int_{S^3} [\mathrm{CS}(\omega) - \mathrm{CS}(A)] \right)$$

where ω denotes the spin connection on S^3 and A is the internal gauge field on S^3. This term arises (by integrating by parts) from the usual inducement of brane charge by gravitational and gauge curvature on the brane (see Ref. 39 and references therein). Thus shifting F effectively shifts F_v. (Note that if we change the G_4 flux this is equivalent to turning on an internal Chern–Simons action for the supersymmetric system on the brane. It should be possible to derive directly the relation between generation of superpotentials on the brane and the Chern–Simons theory on S^3 from this fact.)

There is another term that is also generated from (3.9) when we recall that t has some auxiliary field turned on. In particular this gives rise to the term

$$N \int d^2\theta \mathcal{W}^{2g} \partial_t F_g(t) = N \int d^2\theta F^{2g} \partial_t F_g(t) + \cdots .$$

Recalling that in the gauge theory setup t is replaced by S, the gaugino bilinear superfield, the above term corresponds to the superpotential term

$$\lambda_s W = N \int d^2\theta F^{2g} \partial_S F_g(S) = -N \int d^2\theta \frac{B_{2g}}{2g} F^{2g} S^{1-2g}.$$

So turning on the (self-dual) gravi-photon field strength in four dimensions deforms the superpotential. What is the gauge theory interpretation of this? As noted above turning on F has the effect of turning on the field strength F_v in the $U(1) \in U(N)$, which is also equivalent to turning on B field in spacetime. Thus this seems to be related to considering the noncommutative version of the above gauge system.[40] In particular considering a self-dual noncommutativity in spacetime presumably generates a superpotential, as is predicted from the above formula. Note that this is consistent with the fact that in the UV where S is smaller this modification of the superpotential is a more pronounced effect, and it disappears in the IR where S is larger. It would be interesting to derive this result directly in the context of the noncommutative $N=1$ Yang–Mills theory. Moreover the dependence of the genus g partition function on the noncommutativity parameter is identical (we thank R. Gopakumar for pointing this out to us) to that obtained in Ref. 41. Namely, in the large N expansion, there is no modification at the level of planar diagrams, i.e., at $g=0$. Moreover at genus g the amplitudes are expected (when we have a self-dual noncommutativity) to scale (in the leading order) as $(1/\theta^{4g}) \sim B^{4g}$ which in our case translates to an F^{4g} dependence. This is in agreement with the fact that $|\partial_S W|^2$ indeed scales as F^{4g}.

D. More general values of *S*

So far, in the context of gauge theory discussion we mainly considered the limit where $\langle S \rangle$ is small compared to the string scale. However, the duality we are proposing holds for arbitrary $\langle S \rangle$. If $\langle S \rangle$ is not small, on the gauge theory side we get modification to the form we have written above, which is computed by the Chern–Simons theory on S^3. What kind of gauge theory does this correspond to? The gravity side provides a hint: If we consider wrapped D4-brane domain walls, we have infinitely many species of domain walls. The reason for this is that we can consider the bound state of n D2-branes with the D4-brane manifested through turning on n units of U(1) flux through the S^2 part of the world volume of the D4-brane. This can also be viewed as the effect of changing the B-field on the $\mathbf{P}^1$ by $2\pi i n$. The effect of such domain walls is thus shifting $t = S \to S \exp(2\pi i/N) + 2\pi i n$. In other words we have the vev's of S, not only taking values around a circle about the origin, but also circles about $2\pi i n$ for any integer n. Moreover the BPS tension for such domain walls is given by

$$\Delta W = \frac{1}{\lambda_s}(S + 2\pi i n).$$

The geometry of these domain walls can be recovered from an enlarged field content:[10] We can introduce one variable Y_n for each n, capturing the corresponding domain wall by its shift in the argument, and consider the superpotential

$$W = \int d^2\theta \sum_n \left[(S + 2\pi i n) Y_n + i N^2 \alpha e^{-Y_n/N} \right] \tag{3.10}$$

the domain wall with 1 D4-brane wrapped over $\mathbf{P}^1$ bound to n D2-branes will now correspond to shifting $Y_n \to Y_n + 2\pi i$. Integrating the Y_n's out will give

$$W = \frac{1}{\lambda_s} \sum_n (S + 2\pi i n) \log(S + 2\pi i n)^{-N} + a(S + 2\pi i n) + b$$

which is indeed equal to

$$W = \int d^2\theta \frac{1}{\lambda_s} N \frac{\partial F_0(S)}{\partial S}.$$

The variables Y_n were introduced to incorporate the kinks, but their appearance on the original gauge theory side, except for Y_0 seems mysterious. It would be interesting to see if one can find a direct interpretation of all the Y_n's. We expect that to be related to the possibility of doing large SU(N) gauge transformations on the S^3 part of the world volume of D6-brane.

The higher genus corrections in the case of large S are also similar to the modification at the genus 0 case. In particular we get an infinite sum with S replaced by $S+2\pi in$. This in particular is related to the fact that we can have a new baryon vertex for each wrapped D2-brane with D0-brane turned on.[42]

E. Adding matter

In the context of geometric engineering of $N=1$ supersymmetric gauge theories realized as D6-branes wrapped around S^3 cycles of CY manifolds[32] matter can be realized as extra D6-branes wrapped around other S^3's intersecting the gauge theory S^3 along a circle (where the vev of the Wilson line around the circle on the probe brane plays the role of mass for the matter). How does our duality extend to this case? In fact in the topological string the duality does extend to this case.[10] In particular in computation of Wilson loop observable for the Chern–Simons theory one adds extra topological branes intersecting the original S^3 along a knot, and it was shown that the closed topological string amplitudes agrees with the expected result for knot invariants for Chern–Simons theory. More checks have been made in Ref. 11 for a large number of distinct knots. In the context of embedding the topological string dualities in the superstring what this means is that the dual gravitational system will not only have a blown up S^2 but will also have additional D6-branes (which for algebraic knots will intersect the S^2 along a circle). The fact that the topological computations agree on both sides translates to the statement that the superpotential computations on both sides agree and is further evidence for this duality in the superstring context. Note that for each knot we obtain a different ''matter'' system for this generalized gauge theory, which in the limit of large Y give rise to the same low energy physics, but are distinct theories in the context of generalized gauge theories we have been considering. The gauge theoretic interpretation of these results is currently under investigation.[43]

IV. THE MIRROR TYPE IIB DESCRIPTION

As is well known, type IIA on a CY is equivalent to type IIB on a mirror CY. This implies that everything we have said above in the context of type IIA has a type IIB counterpart.

For example, instead of D6-branes of type IIA wrapped around S^3 we consider D5-branes of type IIB wrapped around S^2. Also turning on even-form fluxes in type IIA is mirror to turning on 3-form H_{RR} and H_{NS} flux in the type IIB side and the superpotential that gets generated in this context is given by

$$W=\frac{1}{\lambda_s}\int \Omega\wedge[H_{RR}+\tau H_{NS}],$$

where τ is the complex coupling constant of type IIB, and Ω is the holomorphic 3-form of the CY. The above integral can be done and yields the formula in terms of the prepotential of the corresponding $N=2$ theory, as discussed in the type IIA case. Note however, that the type IIB system is simpler in that by mirror symmetry the worldsheet instantons that were relevant in the context of type IIA theory in computing the prepotential, are absent for the type IIB case, and classical geometry already captures these corrections. In particular the B-topological theory (known as the Kodaira–Spencer theory of gravity) simply involves aspects of complex geometry of Calabi–Yau.

So as far as writing a classical gravitational background, the type IIB description would be more useful because the worldsheet instanton effects are absent. However, as far as the conformal theory on the string worldsheet, i.e., the large N expansion description of the gauge system, the type IIA and type IIB theories are of course identical.

In the above context we would need to know the mirror of local CY:$O(-1)+O(-1)\rightarrow \mathbf{P}^1$. The mirror of this is known and it is essentially the conifold with one subtlety:[36] The conifold has only one compact 3-cycle, whereas $O(-1)+O(-1)\rightarrow \mathbf{P}^1$ has two compact even cycles, namely 0- and 2-cycle. As was noted in Ref. 36 in the limit where the Kahler class of $\mathbf{P}^1$ approaches zero, i.e., $t\rightarrow 0$, the mirror becomes effectively the conifold (the actual mirror differs from the conifold by having some variables being $\mathbf{C}^*$ variables rather than $\mathbf{C}$ variables). (The actual mirror is given by $x_1+x_2+x_1x_2e^{-t}+1-uv=0$ where x_1,x_2 are $\mathbf{C}^*$ variables and u,v are $\mathbf{C}$ variables.) Similar observations were made in Ref. 44. Even though in principle we can consider the full mirror geometry, since the complex geometry of the conifold is more familiar and better studied we restrict our attention to this case. [In this limit the internal topological theory corresponds to a G/G model on S^2 (coming from the holomorpohic Chern–Simons theory on S^2 (Refs. 14 and 45) which should also be equivalent, by mirror symmetry, to the large N fixed k limit of the Chern–Simons theory. This topological theory should also be equivalent to the Penner matrix model. It would be interesting to verify these equivalences among these topological gauge theories more directly.] This will correspond to a particular limit of our type IIA theory, where we consider only the small $\langle S\rangle$ region. Recall that this was the regime where the theory retained only the leading dimension operators in the action and led to a theory which was similar to the standard $N=1$ supersymmetric gauge theory.

We will be brief for this case, as most of the discussion can be literally borrowed from our discussion in the preceding section. We start with N D5-branes wrapped over the $\mathbf{P}^1$ in the $O(-1)+O(-1)\rightarrow \mathbf{P}^1$ geometry. The large N limit of this, in the limit of shrinking $\mathbf{P}^1$ corresponds to blowing up an S^3 with N units of H_{RR} flux through the S^3. Let us write the conifold geometry as

$$z_1z_2-z_3z_4=\mu.$$

Then the genus 0 prepotential is given as

$$F_0(\mu)=\frac{-1}{2}\mu^2\log\mu+P_2(\mu),$$

where $P_2(\mu)$ is an undetermined polynomial of degree 2 in μ. Now we consider turning on fluxes: The mirror of turning on *NS* 4-form flux corresponds here to turning on H_{NS} and in the cycle dual to S^3. Thus as far as the superpotential is concerned we have

$$W=\frac{1}{\lambda_s}[N\partial_\mu F_0(\mu)+M\mu]=\frac{1}{\lambda_s}[-N\mu\log\mu+a\mu+b],$$

where $M=M_1+\tau M_2$, and the discussion reduces to the small S limit of the discussion in the preceding section.

While this paper was being prepared, two papers[18,19] appeared which are related to this type IIB construction. In particular (among other things) they consider the gravitational background corresponding to $D5$-branes wrapped on 2-cycles of CY and their results are consistent with the superpotential analysis here.

V. $c=1$ NONCRITICAL BOSONIC STRING AND $N=1$ SUPERPOTENTIALS AT LARGE N

As discussed above the type IIA or type IIB near a conifold background with some fluxes turned on can be interpreted as large N limit of certain $N=1$ supersymmetric gauge theories. In particular the string expansion is equivalent to the large N expansion of a gauge theory. Moreover certain superpotential corrections of the gauge theory can be viewed as computations of the corresponding topological strings in the CY background. These are readily computed and thus carry a large amount of information to all orders in $1/N$, for the gauge theories in question. In particular here we will explain how the type IIA superstring near the small blow up of conifold, or

equivalently the type IIB superstrings in the conifold geometry relate the noncritical bosonic string amplitudes with that of the superpotential computations at the large N limit of the corresponding $N=1$ gauge systems.

It was shown in Ref. 46 that the conformal theory near the conifold is given by the same system found in Ref. 47 in connection with noncritical bosonic strings on a circle of self-dual radius. This conformal theory is that of a supersymmetric Kazama–Suzuki coset construction

$$\mathrm{SL}(2)/\mathrm{U}(1)$$

at level $k=3$, and the relation with noncritical bosonic strings is that the topological twisting of this system is equivalent to considering bosonic string propagating on a circle of self-dual radius with the fermions of the coset model playing the role of the ghosts in the bosonic string. This relation between bosonic string on a self-dual circle and the superconformal theory of a conifold is in agreement with the fact[48] that the ground ring of the bosonic string for this background is isomorphic to the holomorphic function on the conifold (which is generated by z_1,z_2,z_3,z_4 subject to the relation $z_1z_2-z_3z_4=\mu$) where the cosmological constant of the bosonic string is mapped to the deformation parameter of the conifold. Moreover, the observables of the $c=1$ theory are mapped to deformations of the conifold geometry:

$$\sum_n \epsilon_n(z_1,z_2,z_3,z_4)+z_1z_2-z_3z_4=\mu,$$

where ϵ_n is a polynomial of degree n is z_i. These deformation parameters get mapped to states of the bosonic string which are indexed by a representation of $\mathrm{SU}(2)_L\times\mathrm{SU}(2)_R$ of this system, viewing z_i as entries of a 2×2 matrix M with the conifold being defined as $\det M=\mu$ and where the $\mathrm{SU}(2)_L$ and $\mathrm{SU}(2)_R$ are realized by left and right multiplication of M with SU(2). In particular the degree n polynomial ϵ_n decomposes into representation of spin $(j_L,j_R)=(n/2,n/2)$ with $|m_L,m_R|\leqslant n/2$. Let us denote the totality of these parameters by μ_i (except for μ). The bosonic string amplitudes compute topological B-twisting of the deformed conifold. (Aspects of this relation has recently been verified and certain results of bosonic strings have been recovered directly using the Calabi–Yau picture and the Kodaira–Spencer theory.[49]) For various aspects of $c=1$ noncritical bosonic string see Ref. 50. As already discussed the genus g partition function will be a function $F_g(\mu,\mu_i)$ of these parameters deforming the conifold background. Recall that in the gauge theory context μ is identified with S and we will thus denote $F_g(S,\mu_i)$. The topological string computes, at genus g, the term in the effective action given by

$$\frac{N}{\lambda_s}\int d^2\theta[\mathcal{W}^2]^g\partial_S F_g(S,\mu_i)=\int d^2\theta F^{2g}\partial_S F_g(S,\mu_i)+\cdots.$$

What is the interpretation of this for the gauge theory? As in the usual AdS/CFT correspondences, we would expect that the μ_i will be related to operators on the gauge theory side, deforming the gauge theory action by terms $\mu_i\mathcal{O}_i$. In fact, in the context of 3-brane probes of the conifold[51] aspects of such deformations for the gravity side have been studied in Ref. 52 and a similar analysis should be extendable to the case at hand. Thus the topological strings compute the response of the system upon such deformations. In particular at genus 0, turning on the μ_i modifies the superpotential for the gaugino superfield. Also turning on F will give rise to $1/N$ correction to the superpotential. It would be extremely interesting to understand the source of these corrections on the gauge theory side.

It would also be interesting to find the conformal theory associated with the RR and NS fluxes turned on in the conifold geometry. This is very interesting in view of the fact that before turning fluxes on we have an exactly solvable conformal theory given by SL(2)/U(1) KS model. It would be very interesting to find the deformation of this theory. It is likely to involve ingredients similar to the ones encountered in Refs. 53 and 54.

VI. WRAPPED *D*-BRANES AND COMPACT CY

Consider type IIA superstrings compactified on a Calabi–Yau threefold. In the above, we considered a situation where we take a large number of D6–branes wrapped over an S^3 in the CY, and taking the analog of the near horizon geometry, to decouple the gravity, and then proposing a dual gravity description for the gauge system.

If we wish to repeat what we did in the preceding sections, by considering D6-branes wrapped on some S^3, which is part of a compact Calabi–Yau, and filling the rest of the spacetime, we immediately run into a problem. We cannot wrap a D6-brane over a 3-cycle as there would be nowhere for the flux to go for compact internal CY. However suppose we consider a CY manifold with some number of S^3's and we wrap D6-branes and anti-D6-branes over them, in such a way that the net D6-brane charge is zero. This is of course a non-supersymmetric situation. (We can also consider the type IIB mirror of this where we consider D5/anti-D5 branes wrapped around vanishing S^2's of the CY.) We expect that the branes will eventually annihilate each other leaving us with an $N=2$ background. If the S^3's are rigid then this annihilation process takes some time, because there is a potential barrier for the wrapped D6-branes to move in the CY (i.e., there is a potential for the scalar corresponding to moving them in the normal direction in the CY).

We now wish to apply the considerations of this paper and propose a large N dual in this context. For the considerations of the gauge theory to be applicable we have to consider the limit where S^3 has shrunk to zero size. This is the analog of $Y_0=0$ in the formula in Sec. III. What we will find is that taking the large N limit induces a transition to a topologically distinct CY, with some fluxes turned on. Moreover the fluxes can disappear as in Ref. 17 leaving us with an $N=2$ supersymmetric vacuum. Thus the effect of the brane annihilation at large N has been to shift the background.

Consider a Calabi–Yau with R vanishing S^3 cycles $[C_i]$ which span a $K<R$ dimensional subspace of H_3. In other words assume

$$\sum Q_{ji}[C_i]=0 \quad \text{for } j=1,...,R-K$$

for some integral matrix Q. Let us consider N_i D6-branes partially wrapped around C_i, where we allow some N_i to be negative, in which case we mean the number of the corresponding anti-branes. The condition that the net D6-brane flux is zero implies that

$$N_i=l_jQ_{ji}$$

for $R-K$ integers l_j. Now, let us consider the limit where the S^3's are vanishingly small. In this limit, applying the discussion of the near horizon geometry, we are naturally led to consider the S^2 blown up geometry where the blowup parameter for the ith sphere is given by

$$t_i=i\lambda_sN_i=i\lambda_sl_jQ_{ji}.$$

Notice that not all the t_i are independent. In particular there are only $R-K$ independent parameters l_j which determine them. This is exactly as it should be for the local geometry to have a blowup. [In fact this shift in the hodge numbers can be understood from the viewpoint of inverse process of Higgsing of $U(1)^{R-K}$ by R charged fields[55] where the charged fields can be viewed as wrapped $D2$-branes in the blown up geometry.] In other words the blowup geometry is a CY with K less dimension of $h^{2,1}$ but $R-K$ more dimensions of $h^{1,1}$. Moreover the condition on the various Kahler classes of the $\mathbf{P}^1$'s is exactly the same as that found above for the t_i. This gives further support for the conjecture that the large N limit of the wrapped brane–anti-brane geometry, when we have no net branes is equivalent to a blown up CY with the Kahler parameters for the blown up spheres given as above. However, here we will also have RR fluxes through the S^2's. In this case the supersymmetry is completely broken[25,26] by the RR fluxes. The fluxes can disappear as recently studied in Ref. 17.

It would be interesting to check this generalized conjecture in the topological string setup: Namely this suggests that the topological open string amplitudes in the context of compact CY manifolds when there is no net topological D-brane, and when the D-branes are wrapped over spheres is easily computable by a related closed string theory computation on the blown up CY with different Hodge numbers.

VII. GENERALIZATIONS

There are many natural generalizations of this work. In particular it is natural to consider transitions among topologically distinct manifolds, going through vanishing cycles, and find a large N-brane system/gravity duals, where the large N gauge system will lie on one side of the transition and the dual gravitational system will lie on the other side (this was in fact the philosophy advocated in Ref. 9). (If we consider a Morse function f on a manifold the critical points of it encode certain topological aspects of the manifold. Near a critical point with p positive and q negative eigenvalues for $\partial_i \partial_j f$, for $f \neq f_{\text{critical}}$ the manifold near the critical point has the geometry of a filled $S^{p-1} \times S^{q-1}$. For $f > f_{\text{critical}}$ the S^{q-1} is filled and for $f < f_{\text{critical}}$ the S^{p-1} is filled. This is the general kind of transition expected for large number of branes replaced by fluxes. If we consider two manifolds in the same cobordism class, and consider a Morse function on the interpolating manifold the above picture suggests that branes can induce the transition. So if the cobordism classes are trivial and we have suitable branes we can interpolate between any two manifolds in this way.) In other words the large N brane systems can be viewed as inducing transitions in the background geometry. For examples there are transitions in the CY which involve the vanishing of certain 3-cycles and blowing up 4 manifolds, such as Del-Pezzo manifolds. In this context it is natural to conjecture the existence of a duality involving a large N limit of wrapped D6-branes about the 3-cycles in the context of type IIA with the four manifold resolution of the singularity on the gravity side, with certain fluxes turned on. (In fact there is already evidence for some such cases based on quotienting the Chern–Simons duality on S^3 by finite groups on both sides.[56] For example Chern–Simons on S^3/Z_2 should be equivalent to $\mathbf{P}^1 \times \mathbf{P}^1$ blow up inside a Calabi–Yau. Some aspects of this predictions have already been checked.) Or in the context of M-theory on fourfolds it is natural to look for transitions involving shrinking S^3's and growing 4-cycles, where we consider a large number of $M5$-branes wrapped over the S^3's and filling the three-dimensional spacetime, which should be dual to the geometry involving the blowup of the 4-cycle with some G flux turned on (in fact in this context the gravity solutions are already worked out in Ref. 31).

It is also natural to extend our results for the case of SU(N) systems to SO and Sp groups by including orientifolds. In fact it has been shown in Ref. 57 that the large N duality of Chern–Simons theory for SU(N) groups extend to the SO and Sp case as well.

Finally, the idea that studying BPS/anti-BPS systems are important for a more fundamental understanding of basic degrees of freedom for string theory as advocated by Sen is in line with the example we have found: We can describe one string background in terms of the ground state of a different one in the presence of D-brane/anti-D-brane systems. In a sense, this idea, combined with the idea that various transitions among manifolds can be induced by large N limit of brane systems, suggests that if we start with any background in string theory, and consider complicated enough configurations of branes and anti-branes, we can effectively be discussing arbitrary backgrounds of string theory.

ACKNOWLEDGMENTS

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 42, NUMBER 7 JULY 2001

D-branes, categories and $\mathcal{N}=1$ supersymmetry

Michael R. Douglas[a)]

(Received 2 January 2001; accepted for publication 13 February 2001)

We show that boundary conditions in topological open string theory on Calabi–Yau (CY) manifolds are objects in the derived category of coherent sheaves, as foreseen in the homological mirror symmetry proposal of Kontsevich. Together with conformal field theory considerations, this leads to a precise criterion determining the supersymmetry preserving branes at any point in CY moduli space, completing the proposal of II-stability. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1374448]

I. INTRODUCTION

Over the last year, the basic elements of a picture of BPS D-branes in weakly coupled type II string theory on general Calabi–Yau (CY) backgrounds have been developed, following the lines described in Ref. 1. Such branes have world-volume theories with $\mathcal{N}=1$, $d=4$ supersymmetry or its equivalent and by analogy with the study of supersymmetric field theory, one might expect to be able to get a good understanding of the observables determined by holomorphic or ''protected'' quantities such as the superpotential and D-flatness conditions; these are the spectrum of BPS branes and their moduli spaces of supersymmetric vacua. By analogy with the study of $\mathcal{N}=2$ compactifications using mirror symmetry, one might even hope to get this understanding and determine the BPS spectrum everywhere in moduli space (i.e., for string scale CYs) from a suitable reinterpretation of large volume results.

In this work, we give a proposal for how to do this, building on the II-stability proposal of Ref. 2 and 3, by combining physical input, notably the theory of boundary conditions in (2,2) superconformal field theory (SCFT) and its topological twistings, with the wealth of relevant mathematics, especially Kontsevich's homological mirror symmetry proposal[4] and the formalism of the derived category.

A longer work with more introductory discussion is in preparation; here we try to give a relatively concise discussion of the ideas and results. In particular, we will not give very precise explanations of the fairly lengthy mathematical background (mostly homological algebra), instead focusing on its physical interpretation. This background can be found in the standard reference 5; we also recommend Ref. 6 for a nice introduction to the derived category.

A good way to identify observables which can be computed in the large volume limit is to consider the topologically twisted world-sheet theory. We will consider sigma models with CY target. These models have two twisted versions, the A twisted model whose observables depend only on (the stringy generalization of) the CY Kähler moduli, and the B twisted model whose observables depend only on the CY complex moduli. Stringy corrections are absent in the B model and thus these observables are computable at large volume; mirror symmetry can then be used to compute A model observables.

For the closed string, the basic ''topological'' observable is the prepotential of the $\mathcal{N}=2$ supergravity obtained by type II compactification on the CY. Equivalent information is the metric on moduli space, or the central charges of BPS states at a general point in moduli space. In the B model these central charges are the periods of the holomorphic three-form and are computable.

[a)]Louis Michel Professor. Electronic mail: mrd@physics.rutgers.edu

For the open string, the basic topological observables are the set of allowed topological boundary conditions (which we could call ''topological D-branes''), and the spectrum of open strings between any pair of topological D-branes. Physically, these correspond to D-brane configurations which solve the F-flatness conditions, and the massless fermionic open strings between any pair of D-branes. Mathematically, this data can be thought of as defining a category of brane configurations, in which the objects are topological D-branes, and the morphisms are open strings.

In principle, this allows computing these observables in the B model at large volume, and extrapolating them to general points in Kähler moduli space. However, this is subtle—the naive extrapolation according to which B branes are holomorphic bundles or coherent sheaves at every point in Kähler moduli space is incorrect.[3]

The source of this contradiction is the following: if one makes a large variation of the Kähler moduli, in general a pair of branes, which has aligned BPS central charges (i.e., with the same phase, so preserving the same $\mathcal{N}=1$ supersymmetry), can vary into a pair with arbitrarily related and even antialigned central charges, as would be the case for a brane and an antibrane. Thus any candidate definition of ''topological D-brane'' which could make sense throughout Kähler moduli space must be able to describe branes and antibranes on the same footing, and thus include more objects than coherent sheaves.

Now there are already natural mathematical candidates for the category of topological D-branes—in the B model, the derived category of coherent sheaves, and in the A model the Fukaya category, as proposed some time ago by Kontsevich.[4] A lot of evidence has accumulated that this is correct, most notably in results of Seidel and Thomas[7] and Horja[8] which we discuss later. Physicists have also suggested various roles for this category.[9–13]

In the present work, we give physical arguments that this is correct. These follow the spirit of Witten's argument that the topological class of a D-brane on the space X is a K theory class on X:[14] we define objects to be bound states of D-branes modulo a relation which equates two configurations which differ by adding cancelling brane-antibrane pairs. However, we will keep track of far more information along the way—essentially, all of the morphisms between objects—and thus the result, the derived category, makes much finer distinctions than K theory. As an example, whereas the K theory class of a D0-brane does not depend on what point it sits at, in the derived category every point is a distinct object.

Technically, this begins with the discussion of topological open string theory as in Ref. 15, but we then generalize the BRST operator to carry additional ''homological'' information associated with the Chan–Paton factors. This will allow treating complexes of boundary states as objects; we will then physically motivate imposing equivalence relations under adding brane-antibrane pairs, under Q-exact variations of the additional data (homotopy equivalence), and under complex gauge transformations, and argue that the result is the derived category formed from the original category of boundary conditions.

Having some understanding of the topological D-branes, we will then discuss their relation to physical D-branes. The primary result in this direction is a flow of the gradings of objects and morphisms under variation of Kähler moduli, for which we give a simple CFT argument as well as explicit examples.

This result allows predicting the masses of bosons in chiral multiplets at arbitrary points in Kähler moduli space, and is thus the key to determining bound state formation and stability. In particular, there is an inconsistency in the CFT interpretation of morphisms of negative degree—they would correspond to operators of negative dimension—which forces certain topological D-branes to drop out of the physical spectrum. This gives a direct CFT argument for the Π-stability condition proposed in Ref. 2.

This agreement suggests that we look for a reformulation of Π-stability which does not require an Abelian category. The direct generalization of subobjects and exact sequences to the derived category is the ''distinguished triangle,'' and we discuss this notion and show how it unifies different versions of the bound state and decay processes involving branes and antibranes.

Combining this with the previous results leads to a proposal for a reformulated stability condition, which, although similar to Π-stability, does not require a preexisting notion of Abelian

category. This appears to be a good candidate for a mathematically precise definition of a BPS brane on a Calabi–Yau manifold, and is quite concrete in simple examples, predicting marginal stability lines and new BPS branes.

II. BPS D-BRANES, GRADING, AND IMAGES

Our starting point will be a (2,2) SCFT such as a sigma model on a Calabi–Yau threefold or a Gepner model, with integrally quantized $U(1)$ charges, so that it can be used to define a type II string compactification with $d=4$, $\mathcal{N}=2$ supersymmetry.

The most basic attributes of a BPS D-brane B (we take it to be a particle in four dimensions for this discussion) are its RR charge $Q(B)$ and its BPS central charge $Z(Q(B))$ or $Z(B)$. These are discussed in many references such as Ref. 16. We will consider B-type branes, for which $Q(B)$ is essentially the K theory class. $Z(B)$ depends on $Q(B)$ and on a point in the stringy Kähler moduli space $\mathcal{M}_k$ (best defined as the complex structure moduli space of the mirror CY).

A quantity which will be particularly important for us is the phase of the BPS central charge. As in Ref. 2, we define the *grade* φ or $\varphi(B)$ of a brane to be this phase normalized so that branes and antibranes have $\varphi(B)-\varphi(\overline{B})=1\,\mathrm{mod}\,2$:

$$\varphi(B)=\frac{1}{\pi}\,\mathrm{Im}\log Z(B). \tag{2.1}$$

We will need to extend this from the circle $[0, 2)$ to a real number; thus there is a $2Z$ ambiguity to be fixed for each brane. If we do this at some point in moduli space, the grades can be defined elsewhere by analytic continuation of Z; we will justify this shortly.

At large volume, BPS branes are either A branes (special Lagrangian manifolds carrying flat connections) or B branes (coherent sheaves carrying Hermitian Yang–Mills connections). The most basic observables in the classical theory are the massless fermion spectrum between a pair of branes. For B branes which fill the CY, these can be obtained by the standard arguments of Kaluza–Klein reduction: the oriented massless fermionic strings from branes carrying the bundle E to branes carrying the bundle F are elements of the complex cohomology group $H^{0,q}(M,E^*\otimes F)$. As we will review, these are the states of the B twisted topological open string theory, so this result does not obtain stringy corrections. The mirror A statement must involve stringy effects as is discussed in Refs. 15, 17 and 18; because of this we prefer the B picture.

A. BPS branes as boundary conditions

In world-sheet terms, a BPS brane corresponds to a boundary condition which preserves an $\mathcal{N}=2$ world-sheet supersymmetry, as discussed in Ref. 19.

For A boundary conditions we have (in the open string channel) $T_L=T_R$, $G_L^{\pm}=G_R^{\mp}$, $J_L=-J_R$, and

$$e^{i(Q_0/2)\phi_L}=e^{i\pi\varphi}e^{-i(Q_0/2)\phi_R}, \tag{2.2}$$

where $J_L=iQ_0\partial\phi_L$ and $J_R=iQ_0\overline{\partial}\phi_R$ define the bosonization of the $U(1)$ current in the (2,2) algebra, $Q_0=\sqrt{\hat{c}}$ and $\hat{c}=3$ for a CY sigma model is the complex dimension of the CY. B boundary conditions are similar to $J_R\to -J_R$ and $\phi_R=-\phi_R$.

The operators in (2.2) are the $\mathcal{N}=2$ spectral flow operators which directly enter the space–time supercharge and thus $e^{i\pi\varphi}$ directly specifies an unbroken $\mathcal{N}=1$ algebra. In sigma model compactification we have

$$e^{iQ_0\phi_L}=\Omega_{ijk}\psi^i\psi^j\psi^k$$

in terms of the world-sheet fermions and so for A boundary conditions φ is precisely as defined in (2.1). This is also true for B boundary conditions, of course. If the two boundary conditions have $\varphi_1-\varphi_2\in 2Z$, there is an overall unbroken $\mathcal{N}=1$ space–time supersymmetry; otherwise not.

From (2.2) we also see that A and B boundary conditions are Dirichlet and Neumann boundary conditions respectively on the boson ϕ, so φ is analogous to a ''position'' for A boundary conditions and a ''position on the T-dual circle'' for B boundary conditions. We will always use the Dirichlet language in which φ is a position and $U(1)$ charge is a ''winding number,'' even though we discuss B branes, just for pictorial convenience.

The massless Ramond sector can be obtained by spectral flow from $\mathcal{N}=2$ primary chiral states, whose $U(1)$ charge q is equal to the grading $H^{0,q}$ of cohomology in the large volume B brane discussion. In this limit the grade φ of all CY-filling branes is the same, and there is an $\mathcal{N}=1$ supersymmetry. Spectral flow can be used even when space–time supersymmetry is broken, but let us postpone discussion of this point.

B. Grading as a real number

We can now explain the extension of φ from a number defined modulo 2 to a real-valued number. The point is that this extension makes no difference for a single brane, but as soon as we consider pairs of branes a relative integer shift of φ in the boundary condition for one of them will modify the spectrum of strings stretched between them.

There is a familiar construction of D-brane world-volume theories on S^1 (or a torus) which is quite analogous.[20,21] Let us take the circumference to be 2 (like our variable φ); the idea is simply to define D-branes on $S^1 \cong \mathbb{R}/2Z$ as the theory of an infinite set of image D-branes in $\mathbb{R}$, located at lattice points $2n+\varphi$ for $n \in Z$, and quotient by a simultaneous shift in space–time and gauge transformation. As is well known, if we start with Dp-branes with world-volume $U(N)$ $p+1$-dimensional super Yang–Mills (SYM) theory, the resulting theory is equivalent to $p+2$-dimensional SYM theory on a circle with the T-dual radius.

In this context, it is clear that the integer part of φ is not a physical quantum number but rather is a gauge degree of freedom. However, open strings, and other quantities relating to a pair of branes, are labeled by an integer, the difference $m-n$ between the positions of the two images. On this point, the analogy with the grade is quite precise.

A difference between the two problems is that the periodicity in the string spectrum is different: for a single D-brane on S^1, the spectrum has the same periodicity as the images, while in $\mathcal{N}=2$ SCFT there is a more complicated correlation between the $U(1)$ sector and the rest of the theory, as discussed in Refs. 22 and 23. The open string partition function factorizes as a sum of products of partition functions in the two factors, say for strings between branes E and F,

$$Z^{(E,F)} = \sum_p \chi_p^{U(1)} \chi_p^{(E,F)_{\text{rest}}},$$

where the structure of the second factor determines the allowed winding numbers.

The spectrum is periodic under the action of the spectral flow operator. A periodicity between space–time bosons is obtained by acting with its square $e^{iQ_0\phi}$, which shifts the grade by $\hat{c}$. In the case at hand of $\hat{c}=3$, the true periodicity is $2\hat{c}$, as the GSO projection reverses sign under odd shifts.

All this does not invalidate the picture of a brane as having integer spaced images, but requires us to distinguish the images. This gives us a convenient way to picture the winding strings corresponding to higher morphisms, which will be reproduced later in the mathematics.

The antibrane of a brane is defined by reversing the open string GSO projection. This can be accomplished by shifting the fermion number by an odd integer, so these images should be interpreted as the antibrane and its images. We will make this precise by requiring the formalism to be invariant under a simultaneous shift of all gradings by 1 and reversal of all K theory classes, and interpreting this as a gauge symmetry.

C. Topologically twisted open string theory

A ''category'' of branes will be considered to be the set of branes themselves (the ''objects'' of the category) and the spectrum of massless fermionic strings between pairs of branes, or ''morphisms'' of the category. This data for BPS branes obeys the mathematical axioms of a category—in particular, the morphisms have an associative multiplication law which in CFT terms is essentially the multiplication law in the open string chiral ring.

By extension, one can consider all of the holomorphic data involving the branes—the space–time vector and chiral multiplets which contain these fermions, and the superpotential—to be part of the ''category'' as well. All of this data has been claimed to be independent of the Kähler class of the CY (for B branes), implicitly in work on topological open string theory and in Kontsevich's homological mirror symmetry proposal, and explicitly in Ref. 24. One can also give a simple space–time argument for this,[25] based on the fact that in type IIb string compactification (in which the branes can be taken to fill $3+1$ Minkowski dimensions) the Kähler moduli are paired under $\mathcal{N}=1$ supersymmetry with RR potentials, which do not have nonderivative couplings in perturbative string theory. (This answers the question of what determines the coordinates on moduli space for which decoupling holds.)

All this should allow determining the category from large volume considerations. To better understand this, we now consider the B twisted topological sigma model with CY target, following Ref. 15. We start with bosonic coordinates Z^i and $\overline{Z^i}$ and their fermionic partners. After twisting, the fermions split into left and right moving scalars $\eta^{\bar{i}}$ and θ_i, and one-forms ρ^i. The simplest boundary conditions are Neumann;[26] they set $\partial_n Z^i = \partial_n \overline{Z^i}$ and $\theta = (*\rho) = 0$. One can also couple to holomorphic bundles, adding a term $\mathrm{Tr} P \int Z^*(A) - i\rho^i F_{i\bar{J}} \eta^{\bar{J}}$ on the boundary.

States in a Hamiltonian quantization of this theory are determined by their dependence on the zero modes of Z and $\eta^{\bar{i}}$, and can thus be regarded as holomorphic p-forms. The BRST operator Q then satisfies $[Q,Z]=0$, $[Q,\overline{Z^i}] = -\eta^{\bar{i}}$ and $\{Q,\eta\}=0$, which means that it can be interpreted as a $\bar{\partial}$ operator coupled to $E^* \otimes F$. Thus, the topological open string Hilbert space with boundary conditions (E,F) is the Q-cohomology, which is $H^*(X, E^* \otimes F)$. The multiplication law is of course wedge product of forms.

In early studies of D-branes it was found that certain pointlike singularities are allowed and are nonsingular in string theory.[27] This motivates allowing more general coherent sheaves as boundary conditions.[28] The entire discussion can be generalized to this case at least formally by replacing $H^p(X, E^* \otimes F)$ with $\mathrm{Ext}^p(E,F)$, which for a pair of holomorphic bundles is equivalent. We will explain and justify this point later; for this reason we switch to use the Ext notation instead of cohomology. We also remind the reader that $\mathrm{Hom}(E,F) \equiv \mathrm{Ext}^0(E,F)$.

The basic topological correlation function is a disk amplitude, nonzero for a combination of states whose charge adds up to $\hat{c}=3$. This is determined by the algebra structure and the integral on $\mathrm{Ext}^3(E,E)$; this integral can also be regarded as a trace and this structure defines a ''Frobenius category.'' We can also use the integral to define Serre duality, which here identifies $\mathrm{Ext}^{3-i}(E,F) \cong \mathrm{Ext}^i(F,E)^*$.

It is known[4,29] that in general topological open string theory can correspond to an A_∞ category,[30] as appeared in Kontsevich's original proposal. An explicit construction of an A_∞ structure on the category of coherent sheaves appears in Refs. 31 and 32; the higher products are essentially correlation functions in holomorphic Chern–Simons theory (the third order product was already discussed in Ref. 15). They are related to the Massey products, which encode the obstruction theory or equivalently the physical superpotential. This structure is very useful in studying deformations, as we will discuss in subsequent work, but we will not need it for our present considerations. In particular, the A_∞ structure defined in Ref. 32 is a ''minimal model,'' i.e., an A_∞ category with $Q=m_1=0$, which satisfies conventional associativity.

III. TOPOLOGICAL D-BRANES AND THE DERIVED CATEGORY

As we discussed in the Introduction, a complete category of ''topological D-branes'' must contain both branes and antibranes. This might be naturally accomplished by introducing a Z_2

grading on the boundary conditions. However, the discussion of the previous section shows that this is contained in a Z grading of the boundary conditions, and that for $\hat{c}>1$ it is better to keep this, because it is related to the degree of morphisms. (One might instead keep a $Z_{2\hat{c}}$ grading, but there is no real advantage to doing this.)

Let us therefore introduce the notation E_n for a boundary condition located at $\varphi=n$, and the notation $E[n]$ for the shift of a boundary condition $(E[n])_m=E_{n+m}$ (the ''translation functor''). At the end of the discussion we will regard the simultaneous translation of all objects by $E \to E[1]$ combined with reversing all the K theory classes as a gauge symmetry, but until we get there, we will regard these as distinct objects.

As usual we can consider the direct sum of a set of boundary conditions to be a new boundary condition, distinguished by ''Chan–Paton factors.'' Let us generalize the preceding notation: if E is such a direct sum, let E_n be the component located at $\varphi=n$.

A map between two such direct sums E and F is a direct sum of components of definite $U(1)$ charge,

$$\mathrm{Ext}^p(E,F)=\oplus_{n,k}\mathrm{Ext}^{p-k}(E_n,F_{n+k}). \tag{3.1}$$

This formula includes a boundary contribution to $U(1)$ charge, by adding the ''distance'' between the images to the fermion number.

Since we now have $U(1)$ charge living on the boundary, we can make a further generalization to put a boundary component in the BRST operator, consistent with it having charge 1. Thus we write

$$Q_{(E,F)}=Q^{(0)}_{(E,F)}+d_E-d_F$$

with

$$d_E\in\oplus_{n,k}\mathrm{Ext}^{1-k}(E_n,E_{n+k})$$

and similarly for d_F. The operator $Q^{(0)}_{(E,F)}$ is the ''original'' BRST operator (not acting on the Chan–Paton factors) and, if we take all of our states to live in its cohomology, can be taken as zero (this could conceivably be generalized). In this case, the condition $Q^2=0$ will be satisfied if

$$\{d_E,d_F\}=0,$$

$$d_E^2=0,$$

$$d_F^2=0.$$

The first equation is conventional, while the other two tell us that (E,d_E) and (F,d_F) are ''complexes'' as defined in homological algebra. The Q-cohomology then consists of maps ϕ in (3.1) such that $d_F\phi=\phi d_E$ (chain maps) modulo the image of $d_F\epsilon-\epsilon d_E$ (homotopic equivalence).[33]

A. Adding brane-antibrane pairs

The main thing we gain from all of this formalism is the ability to describe branes and antibranes on an equal footing. This requires us to be able to identify an object E with an object F related by adding cancelling brane-antibrane pairs.

Now we want a finer equivalence relation than K theory: a pair $A\overline{B}$ will only be considered to cancel if A and B are isomorphic as holomorphic objects, in other words if there is an identity map 1 in $\mathrm{Hom}(A,B)$.[34] We furthermore require that adding the pair does not change the Q cohomology: for every object G, we have $\mathrm{Hom}(E,G)\cong\mathrm{Hom}(F,G)$.

This can be accomplished by adding a pair $B_n\oplus B_{n+1}$ with grades differing by 1, and taking the new BRST operator $Q_{F,G}$ to be the direct sum of the old BRST operator $Q_{E,G}$ with the identity map **1** on morphisms in $\mathrm{Hom}(B,G)$ involving the brane-antibrane pair:

$$Q_{F,G} = Q_{E,G} \oplus \mathbf{1}.$$

This identity map **1** is the composition $\mathrm{Hom}(B,B)\times\mathrm{Hom}(B,G)\to\mathrm{Hom}(B,G)$. If we had considered the (G,F) open string sector, it would act as $\mathrm{Hom}(G,B)\times\mathrm{Hom}(B,B)\to\mathrm{Hom}(G,B)$. This term in Q of course pairs each $\mathrm{Hom}(B_n,G)$ with a $\mathrm{Hom}(B_{n+1},G)$ and removes them from the topological Hilbert space.

By adding brane-antibrane pairs in various degrees to our original objects, we can get a large class of chain complexes. One can understand the main properties of this construction by thinking of the E_n as vector spaces of Chan–Paton factors and the summands of d as matrices. Although at first it looks like we will only get very special d (made up from identity matrices), of course change of basis (complex gauge transformation) and other operations will produce more general complexes.

We now define our category of topological D-branes as the result of identifying any pair of complexes which are related by the following types of morphisms: the morphism which adds brane-antibrane pairs discussed above, complex gauge transformations, morphisms homotopic to the identity (i.e., those of the form $1+Q\epsilon$ which are equivalent to the identity in Q-cohomology), and of course compositions of any of these. Furthermore, we identify two objects E and F if for each there is a morphism in this class mapping it to a third complex R, their ''common refinement.'' The additional identifications we postulated are unavoidable if we do not wish to distinguish objects related by an isomorphism. There is one subtlety in correctly making these identifications which we now explain. In identifying two configurations which differ by adding brane-antibrane pairs, it does not suffice to only identify configurations related by the direct sum we just discussed; a more general identification is required.

Physically, the point is that we want to identify E with $E+X+\overline{X}$ obtained by adding a cancelling brane-antibrane pair, even if E and X (or E and X) themselves were combined in a bound state, say F. To explain the mathematical point, we quote the incorrect argument from the original version, to see where it was wrong. The mathematical description of forming F as a bound state of the branes E and X is a non-split exact sequence:

$$O\to E \overset{f}{\to} F \overset{r}{\to} X\to 0.$$

By definition, the maps satisfy $r\cdot f=0$. A split exact sequence is one for which $F\cong E\oplus X$, in which case F is not physically a bound state. A bound state can be obtained by this by turning on an off-diagonal bosonic mode, breaking the gauge symmetry back to $U(1)$. Such a mode will again be associated to a partner fermionic open string between E and X, and (by general mathematical formalism we will come back to) to an element of $\mathrm{Ext}^1(X,E)$.

Now the point is that physics (crossing symmetry) requires that one can also make a partial annihilation $F+\overline{X}\to E$, and the same exact sequence must also describe this. This will be true if our identifications equate E with the complex $F\overset{r}{\to}X$. The physical identity of these configurations can also be checked in examples, say in large volume.

One can try to do this using a homotopy equivalence $1+Q\varepsilon$, and this is possible if a partial inverse ε to r can be found, satisfying $r\varepsilon=1|X$. However this is precisely the case in which $F=E\oplus X$ is not really a bound state; the open string mode is not turned on.

These considerations lead us to identify all complexes which are related by general quasi-isomorphisms. A quasi-isomorphism is an element of $\mathrm{Hom}(E^{\cdot}, F^{\cdot})$ the Q-cohomology in our previous language) which is an isomorphism when restricted to cohomology. This includes all the morphisms we discussed, but only transformations which add pairs or sequences of objects which cancel out of the cohomology, both of individual objects and of morphisms between objects.

A quasi-isomorphic pair is a pair of complexes each related by quasi-isomorphism to a common refinement; all such pairs are identified. The result of identifying all quasi-isomporphic pairs is the derived category $D(\mathcal{A})$ of the category $\mathcal{A}$ we started with—in our present discussion **Coh** X, the coherent sheaves on the CY X. As discussed in Ref. 5, this is usually done by

localization, i.e., one allows as morphisms formal inverses of all the quasi-isomorphisms, and then shows that one can write any product of morphisms in terms of a single morphism by commuting these inverses through other morphisms (or ''combining denominators''). The result is an associative category, though not abelian (kernels and cokernels need not make sense).

B. Resolutions and Ext

Resolutions are a key tool in homological algebra, and will turn out to give us a mathematical counterpart of the ''images'' we introduced in the previous section.

A free resolution of a complex E is a quasi-isomorphic complex R in which the terms are free. In the context of vector bundles on projective space $\mathbf{P}^n$ this means they are direct sums of line bundles. The point of this is that it means that there are no relations hidden in the definition of the terms; all the relations, and thus the homology, are explicit in the maps d_R.

Free objects or modules are too restrictive for most purposes and one usually discusses the more general concepts of injective and projective resolution. A projective object is a direct summand of a free object, while an injective object can be defined in terms of this by dualizing and reversing arrows. Considerations we mention shortly lead to a more useful criterion: a projective object P has $\mathrm{Ext}^i(P,X)=0\ \forall X$ and $i>0$, while an injective object I $\mathrm{Ext}^i(X,I)=0\ \forall X$ and $i>0$. An injective resolution of F is an exact sequence

$$0\to F\overset{f}{\to} I^0\overset{r_0}{\to} I^1\overset{r_1}{\to} I^2\to\ldots \tag{3.2}$$

where the I^n are injective, and one can similarly define projective resolutions

$$\cdots\to P^1\to P^0\to F\to 0$$

where the P^n are projective. It can be shown that every coherent sheaf on a space M has a resolution whose terms are locally free sheaves on M, i.e., sheaves which in any local region are equivalent to bundles, and thus the use of resolutions allows reducing general computations to those involving bundles. In particular, they can be used to define sheaf cohomology or better its generalization, the Ext groups. We can define $\mathrm{Ext}^k(E,F)$ as the cohomology H^k of the complex

$$0\to\mathrm{Hom}(E,I^0)\to\mathrm{Hom}(E,I^1)\to\mathrm{Hom}(E,I^2)\to\ldots \tag{3.3}$$

or equivalently as homotopy classes of chain maps from E into the resolution. Using the equivalence of F with its resolution in the derived category, this also tells us that

$$\mathrm{Ext}^p(E,F)\cong\mathrm{Hom}(E,F[p]).$$

In other words, an Ext^p is a degree zero map into the pth term of the resolution. This allows us to think of the successive terms in the resolution as providing a concrete picture for the ''images'' we introduced in the previous section.

We define the *length* of a complex to be the number of nonzero terms E_n minus one. For each object, there is a minimal length of the complex required for its free resolution. The maximal such length for a given category is the homological dimension *hd* of the category; for coherent sheaves on a complex manifold this will generally be the dimension of the manifold (it can be less). This is easy to see for bundles if we assume the relation $\mathrm{Ext}^k(E,F)\cong H^k(M,E^*\otimes F)$ and consider (3.3).

The relation between the length of the complex and the highest Ext group which can appear has another consequence, namely that one cannot get all sheaves on a d-fold by using resolutions of length less than d. In particular, the monad construction (which is closely related to this) with a complex of length two and with line bundles as constituents cannot describe all bundles on a generic Calabi–Yau three-fold. It would be interesting and probably quite useful if linear sigma models could be generalized to use longer complexes.

C. Properties of the derived category of coherent sheaves

As we mentioned in the Introduction, the derived category of coherent sheaves contains far more information than the K theory. An illustration of this is the reconstruction theorem of Bondal and Orlov:[35] in certain cases (with ample or anti-ample canonical bundle; this excludes Calabi–Yau), the variety X is determined by $D(\mathbf{Coh}\,X)$. The strategy is to first identify the set of objects corresponding to points; the morphism information can then be used to put a topology on this set and show that it is indeed the expected variety.

Although this result is not literally true for a Calabi–Yau, the reason that it fails is quite interesting and relevant for us. It is that there is not a unique definition of which objects are the points. Indeed, there are ''autoequivalences'' of the derived category—transformations which permute the objects but preserve the structure of the morphisms—which turn the points into other sheaves (or complexes).

These autoequivalences have been much studied in recent mathematical work and all of them can be obtained as Fourier–Mukai transformations (FMTs). A FMT from sheaves on a space X to sheaves on a space Y (possibly the same as X) is defined by specifying a sheaf $\mathcal{F}$ on $Y\times X$ satisfying certain properties; most notably, the restrictions to two points on X $\mathcal{F}_{x_1}$ and $\mathcal{F}_{x_2}$ must satisfy

$$\mathrm{Hom}(\mathcal{F}_{x_1},\mathcal{F}_{x_2})\cong\mathbb{C} \quad \text{if } x_1=x_2;$$

$$=0 \quad \text{if } x_1\neq x_2.$$

The transform of a sheaf E on X is then

$$\hat{E}=R\pi_{Y*}(\mathcal{F}\otimes^L\pi_X^*E). \tag{3.4}$$

The idea expressed by this formula is simple and well explained in Ref. 36: one pulls back E to the product space, tensors with $\mathcal{F}$, and then ''pushes forward'' in the sense that the resulting sheaf can have as local sections any of the local sections of the product sheaf (this construction is referred to as the ''direct image''), but with the dependence on X suppressed—this is the reason for the name ''Fourier,'' as taking all such sections is like integrating over X.

The detailed implementation of this idea requires resolving the sheaves which appear in intermediate steps (this is the meaning of the ''L'' and ''R'' symbols), and is greatly simplified by working with the derived category.

A particularly simple set of FMTs are the ''twist functors'' discussed in detail in Ref. 7. For every sheaf E on X there is a twist functor $\mathcal{T}_E$, which has all the right properties to correspond physically to a monodromy associated to a loop in Kähler moduli space around a point at which $Z(E)=0$, such as a conifold point. Assuming this is so, all of these monodromies preserve the derived category of topological branes and this is fairly strong evidence that any physical construction of a model associated to a CY with a specific complex structure will produce the same derived category of objects.

We will discuss this in more detail elsewhere; here we will motivate the theorem of Beilinson used in Ref. 3 using these ideas. This states that the derived category of sheaves on $\mathbb{P}^n$ is equivalent to the derived category of representations of the quiver-complex $QC(n+1,n+1)$ (to be defined in Sec. V), with $Y=0$.

This comes from a one-to-one correspondence between sheaves, implemented by a FMT in which $\mathcal{F}$ is a sheaf on $\mathbb{P}^n\times\mathbb{P}^n$ which is just the ''delta function'' (or structure sheaf) supported on the diagonal. Such an $\mathcal{F}$ will clearly produce the identity transformation on E.

The nontrivial content of this construction comes when we look at the resolution of this delta function sheaf. This is the ''Koszul resolution'' which is a complex with successive terms

$$\Lambda^n\Omega_Y(n)\times\mathcal{O}_X(-n)\to\ldots\to\Omega_Y(1)\times\mathcal{O}_X(-1)\to\mathcal{O}_Y\times\mathcal{O}_X\to\mathcal{F}.$$

The tensor product appearing in (3.4) is

$$\mathcal{F}\otimes E=\Lambda^n\Omega(n)\otimes E(-n)\rightarrow\ldots\rightarrow\Omega(1)\otimes E(-1)\rightarrow\mathcal{O}\otimes E$$

and, continuing in this vein, one finds that the FMT (which is equivalent to the original object in the derived category) is a complex of the sheaves $\Lambda^p\Omega_Y(p)$ tensored with the cohomologies of the original sheaf $H^m(E(-p))$. If these cohomologies are nonzero in a single degree m, they can be thought of as defining an object in $QC(n+1,n+1)$, providing the correspondence used in Ref. 3, while if they are nonzero in more than one degree, one gets an object in $D(QC(n+1,n+1))$.

IV. KÄHLER MODULI AND FLOW OF GRADING

Having understood the category of boundary conditions in the topological string theory (or-''topological D-branes''), we now can assert with confidence that every physical D-brane corresponds to a unique topological D-brane. We now want to understand why not every topological D-brane corresponds to a physical D-brane.

In particular, let us explore what happens if we start with a BPS configuration of two branes and then vary the Kähler moduli. In general, the grades of the two branes, φ_1 and φ_2, will no longer be equal.

Although open string sectors with $\varphi_1\neq\varphi_2$ bear some resemblance to twisted $\mathcal{N}=2$ sectors, they are not the same. Because a specific $\mathcal{N}=1$ world-sheet supersymmetry is gauged in the open superstring definition, this supersymmetry must still have conventional NS and R boundary conditions on the $\mathcal{N}=1$ supercurrents. Furthermore, it will still admit a GSO projection; two sectors related by a continuous deformation will share the same GSO projection. This is possible because both bosons and fermions in these sectors will have their moding changed; the fermions in a way determined by (2.2) and the bosons in a corresponding way to make NS and R supercurrents possible. A solvable example in which this can be seen is the theory of two three-branes oriented at angles.[37]

As discussed earlier, if we restrict ourselves to Kähler variations, the massless fermion sector will remain unchanged. Now even though these combinations of boundary conditions have broken supersymmetry, we can still identify bosonic partners of the massless fermions as the NS sectors accessible by varying the $U(1)$ charge (spectral flow). Another way to say this is that since the individual boundary CFT's correspond to BPS branes, they each have spectral flow operators, and we can use either of these to define the action of space–time supersymmetry. Depending on which one we use, we will get different results, but these will only differ by a phase. Thus we can still identify a unique NS state as the superpartner.

Let us discuss the various physical states in the CFT we obtain by this construction, and their space–time interpretation. We start with NS states in a sector with $\Delta\theta=0$ and the usual $\mathcal{N}=1$ supersymmetry. Let Q be the $U(1)$ charge in the $\mathcal{N}=2$ algebra; then $Q=q=0$ states are gauge bosons (the standard GSO projection will keep only states $\psi^\mu_{-1/2}|\rangle$ in the space–time CFT) while $Q=q=\pm1$ states are bosons in chiral multiplets ($q=-1$ will be the complex conjugates of the $q=+1$ states).

Varying the relative grading will shift the $U(1)$ charge of all of the states in this list, and preserve the GSO projection. Our conventions are such that the charge shift is equal to the shift in grading, $\Delta q=\Delta(\varphi_1-\varphi_2)$.

Let us write the Ramond vertex operator as a product of internal, bosonized $U(1)$ and space-time factors

$$O_\theta e^{i(q-3/2)\phi}V_{3+1}.$$

As previously discussed, varying φ by only varying the Kähler class keeps the Ramond state massless, and this means that the dimension of O_θ is determined by $h(O_\theta)+(q-3/2)^2/6=\frac{3}{8}$. We can then derive the dimension of the operators related to it by the usual $\mathcal{N}=2$ spectral flow and thus the mass squared of the partner NS states with $U(1)$ charge q. These will be

$$m^2=\frac{3}{8}+\frac{q^2}{6}-\frac{(q-3/2)^2}{6}-\frac{1}{2}$$

$$=\frac{1}{2}(q-1) \tag{4.1}$$

for chiral multiplets. A vector multiplet has $V_{3+1}=\psi^\mu$, so $m^2=q/2$.

The bosons in chiral multiplets come from $q=1$ states, and we see from this that $\Delta\varphi$ enters into their mass squared precisely as a Fayet–Ilipoulos term would. This is the CFT argument for the earlier description of BPS decay by D-term supersymmetry breaking[38,39,2] and indeed these masses can often be modelled by assigning the FI terms associated to the $U(N)$ space–time gauge groups of the two groups of branes the values $\zeta_1=\varphi_1$ and $\zeta_2=\varphi_2$. Starting from an Ext^1 (a massless chiral multiplet), this assignment reproduces (4.1). This explicit $\mathcal{N}=1$ field theory picture has its limitations, however, as seen in Ref. 40 and it is for this reason that, although the formalism and results are very similar to those in $\mathcal{N}=1$ supersymmetric field theory, we have not based our discussion on this similarity but instead on CFT.

We should also mention at this point that in our setup, the precise definition of a theory with tachyonic strings between a pair of branes is to take branes which do not fill Minkowski space (e.g., D0-branes) and separate them in these dimensions. This gives the tachyons large masses and makes the configuration with zero tachyon expectation value stable, while still allowing us to argue that such a configuration of coincident branes would be unstable.

Starting from $q=1$ and making such a flow, m^2 can decrease until we reach $q=0$. At this point, the operator O_θ has dimension zero. Because the world-sheet theory is a (correlated) product of a unitary theory with the bosonized $U(1)$, zero is the minimal possible dimension for O_θ. Thus, if we decrease q further, our assumptions must break down. One also knows from $\mathcal{N}=2$ representation theory that chiral operators must have $0\leqslant q\leqslant\hat{c}$ (for the same reason).

Now the boundary states we are discussing were unstable as soon as we had $q<1$ and a tachyonic open string; we interpret these arguments as showing that, nevertheless, we can treat them as sensible boundary states and use them to define a category of boundary states as discussed earlier, but only as long as $q\geqslant 0$. If $q<0$, the massless Ramond state no longer makes sense in unitary CFT, and must disappear from the theory. Note that it is not becoming massive (in general there is no state for it to pair with) but literally disappearing, which can only happen if one or both of the boundary states also disappear from the theory.

This is the essential subtlety in the relation between topologically twisted open string theory and the physical open string theory. From the point of view of topological theory, there is nothing wrong with these boundary states (since we varied only Kähler moduli, nothing changed). One can even keep track of the $U(1)$ charges in this situation: the same additive conservation laws will hold even though some $U(1)$ charges may be negative. However, any given physical CFT can only realize a subset of these boundary states, chosen so that morphisms of negative degree do not appear.

From our arguments, the choice of which boundary states are realized would be expected to depend on Kähler moduli. Starting from an Ext^1 between a pair of simultaneously BPS branes, one can reach $q=0$ if the relative phase difference reaches π, i.e., if the BPS central charges antialign. In this sense, the phenomenon under discussion has to do with branes turning into antibranes.

A. Special Lagrangian picture

Many of the statements we just made can also be seen from the geometry of the A brane picture.[41] The analog of a coherent sheaf in this picture is an isotopy class of Lagrangian manifolds, while a physical brane is a particular Lagrangian in this class satisfying the ''special'' condition for the chosen complex structure and holomorphic three-form. The morphisms are given by Floer cohomology.

The standard convention for the grading on Floer cohomology agrees with our notations Hom and Ext^1 for vector and chiral multiplets, respectively. To determine this grading, one looks at the

three relative angles $\Delta\theta_i$. There are basically two cases: where these all have the same sign (producing a Hom), or where one sign differs from the other two (producing an Ext). This rule agrees with the physical GSO projection in the branes at angles model of Ref. 37.

In these terms, our grading is $\mathrm{Hom}(A,B[n])$ or $\mathrm{Ext}^1(A,B[n])$ with $n=\Sigma_i\Delta\theta_i$. As one varies the complex structure, the $\Delta\theta_i$ will vary, leading to the flow we just described. In this picture, the reason the gradings cannot flow below zero (or above $\hat{c}$) is that given a pair of Lagrangians which intersect transversely they will continue to intersect transversely under any change of complex structure.

The conclusion is the same, that gradings will flow, but cannot flow below zero for physical objects.

B. Some convenient notation

As we motivated earlier (in terms of resolutions and the derived category), we will denote a morphism with $U(1)$ charge n, i.e., a fermionic string between the brane A and the nth image of the brane B, as an element of $\mathrm{Hom}(A,B[n])$. This group depends only on the difference between the grades: $\mathrm{Hom}(A,B[n])\cong\mathrm{Hom}(A[m],B[n+m])$.

In addition to its other mathematical advantages, this notation makes it simple to express the variation of the $U(1)$ charge of the morphism as we vary the Kähler moduli. It simply comes from varying the grades of the two branes: $\mathrm{Hom}(A,B[n])$ will flow to $\mathrm{Hom}(A[\Delta\varphi(A)],B[n+\Delta\varphi(B)])$.

We now introduce a notation which allows us to keep track of both our new grading and the ''original'' grading (that present in Floer cohomology), since both are needed in string theory. We distinguish the massless fermions leading to chiral and vector multiplets by writing a degree n morphism as $\mathrm{Hom}(A,B[n])$ for a gaugino and $\mathrm{Ext}^1(A,B[n-1])$ (or just Ext) for the fermion in a chiral multiplet. (One motivation for this notation is the observation that the partner boson has m^2 proportional to the quantity in brackets in both cases.)

The two groups Hom and Ext as we defined them are related by double spectral flow, which reverse the GSO projection. This tells us that $\mathrm{Hom}(A,B[n])\cong\mathrm{Ext}(A,B[n+\hat{c}-1])$ and thus Ext is not really independent.

We define the antibrane $\overline{A}$ to a brane A by reversing the GSO projection, so $\overline{A}\cong A[\hat{c}]$. Any simple brane A [with gauge group $U(1)$] will have $\mathrm{Hom}(A,A)\cong\mathbb{C}$, and we can infer the existence of the brane-antibrane tachyon $\mathrm{Ext}(A,\overline{A}[-1])$ from this. More generally one has $\mathrm{Hom}(A,B[n])\cong\mathrm{Ext}(A,\overline{B}[n-1])$.

In the large volume limit, we can use Serre duality to infer the existence of additional morphisms. In the CY theories of prime interest for us, this takes the form $\mathrm{Hom}(A,B[n])\cong\mathrm{Hom}(B,A[\hat{c}-n])^*$. This is a dual relation, not an identification, but can of course be used to relate the dimensions of these spaces. Its most fundamental role in this discussion is that it is the inner product of the topologically twisted open string theory [the shift $\hat{c}$ is the anomalous $U(1)$ charge of the disk].

In our application, this duality also reverses the GSO projection. This is because $\hat{c}$ is odd, so the Serre dual morphism will have opposite parity $U(1)$ charge, and we infer the GSO projection directly from this. This leaves us with the rule

$$\dim\ \mathrm{Hom}(A,B[n])=\dim\ \mathrm{Ext}^1(B,A[\hat{c}-n-1]). \tag{4.2}$$

These rules determine the gradings of morphisms at arbitrary points in Kähler moduli space given the gradings at one point. It is natural to start with the large volume limit as this point. One should note that gradings of morphisms between branes of different dimension (i.e., sheaves with support of different dimension) in our conventions do not agree with the usual grading of cohomology. We can get them either by carefully computing $U(1)$ charges, or masses of partner

bosons in CFT. The latter generally can be obtained from standard D-brane considerations;[42] in particular the lightest NS string between a Dp-brane and a Dq-brane has $m^2=|p-q|/8-\frac{1}{2}$ from the shift of the ground state energy due to ''DN bosons.''

This gives a morphism from a Dp-brane to a Dq-brane degree $n+(p-q)/4$ (one must be careful about orientations in identifying both objects as ''branes''). Taking this rule into account along with the large volume asymptotics for the periods, one finds that morphisms between simultaneously BPS branes (those whose grades differ by integers) will always have integer grading.

Another large volume subtlety we should mention is that one needs to be careful to define the grade in a way which depends smoothly on the Chern classes (the branch of the logarithm cannot jump). This in particular corrects an observation made in Ref. 3—by doing this, one can get the large volume limit of Π-stability to reproduce Gieseker stability in all cases (this comes from the dependence of subleading terms on the higher Chern classes). This is important as otherwise one finds many incorrect predictions—for example, ideal sheaves of points will destabilize the trivial line bundle unless one has Gieseker stability.

V. EXAMPLES OF FLOW OF GRADING

Two classes of examples have been studied in some detail: orbifolds $\mathbb{C}^3/Z_K$, and Gepner models or Landau–Ginzburg orbifolds, which in a certain sense are hypersurfaces in $\mathbb{C}^5/Z_K$ orbifolds. We will not review here the discussion of Refs. 24, 43, 3, and 40, which leads to the following identifications of boundary states and quiver theories, but only cite the results.

For the most recent work on Gepner models, see Refs. 44–46.

A. Quiver-complex theories

Besides defining the quiver theories which will appear in our examples, this subsection defines the quiver Ext groups, which will be compared with their large volume analogs, and illustrates how methods of homological algebra can be helpful in analyzing their moduli spaces of supersymmetric vacua.

Let us consider a theory with p gauge groups, $U(n_1)\times U(n_2)\times\cdots\times U(n_p)$, and a global $U(q)$ symmetry. The matter spectrum is bifundamentals X_i^a in the $(\overline{n_i},n_{i+1})$ for each $1\leqslant i\leqslant p-1$ and in the fundamental of $U(q)$, and bifundamentals $Y_i^{[ab]}$ in the $(\overline{n_{i+2}},n_i)$ for $1\leqslant i\leqslant p-2$ in the antisymmetric $[q-2]$ representation of $U(q)$. For $p>2$ there is a superpotential,

$$W=\sum_{i=1}^{p-2}\mathrm{tr}X_{i+1}^aX_i^bY_i^{[ab]}. \tag{5.1}$$

We will consider the category $QC(p,q)$ whose objects are (classical) solutions of the F-flatness constraints for all of these theories.

The simplest operation we can define for these objects is direct sum, and this allows us to define K theory in the usual way in terms of pairs of objects. Any ''topological'' definition of K theory class will not see the configuration (the X's and Y's can be continuously deformed to zero); thus the K theory class of an object is just the set of integers n_i.

It is also clear that the K theory class is only the most basic invariant of an object; in general the objects come in moduli spaces of finite dimension. For $p=2$, there is an obvious formula for the dimension of this moduli space, valid if the object is simple, i.e., breaks the complexified gauge group to $GL(1)$. It is

$$d=1+qn_1n_2-n_1^2-n_2^2, \tag{5.2}$$

obtained by counting matter fields modulo gauge symmetries. This formula generalizes in an obvious way to any quiver theory with no superpotential.

It turns out that there is no such universal formula which gives the dimension of moduli space just in terms of the K theory class for $p>2$. (There is a formula which works in almost all cases

for $p=3$ and $q\leqslant 3$, but not for higher p or q.) Well-known arguments that such a formula is not to be expected in general $\mathcal{N}=1$ theories are the possibility of lifting arbitrary pairs of chiral multiplets by changing the configuration, and the existence of cases in which the moduli space has several branches of different dimension.

One can, however, go further than these general statements by better understanding the problem. Given a superpotential, one might try to predict the dimension of the moduli space by subtracting the number of relations following from $W'=0$ from the prediction (5.2). Since there is one relation for each matter field, this always leads to a negative dimension and would predict that no solutions exist. In fact solutions can exist, but only when the relations are redundant; these redundancies will depend on the specific configuration.

The redundancies between relations in the quiver complex theory can be understood in homological terms. We start by considering only the configurations with $Y=0$; the relations are then

$$X^a_{i+1}X^b_i = X^b_{i+1}X^a_i\,,$$

which can be expressed (for $q\geqslant p$) as $d^2=0$ on a complex of vector spaces. This complex can be defined in terms of an exterior algebra ΛV where $V\cong\mathbb{C}^q$ has a basis e_a which we think of as anticommuting objects: $e_ae_b+e_be_a=0$. The operator d then acts on an element of $E_i\equiv\mathbb{C}^{n_i}\otimes\Lambda^{i-1}V$ to produce an element of E_{i+1} as multiplication by X^ae_a.

One then defines the ''morphism complex'' as follows. A ''chain map'' $\phi^{(n)}$ of degree n from E to F is a set of linear maps $\phi^{(n)}_i$ from E_i to F_{i+n} which can be written in terms of the e_a; i.e.,

$$\phi^{(n)}_i = \phi^{(n)}_{i,a_1\ldots a_n}e_{a_1}\cdots e_{a_n}.$$

One can then regard d_F-d_E as an operator acting on these chain maps; it squares to zero, so we can define a morphism of degree n as an element of its cohomology. The space of such morphisms will be denoted $\mathrm{Ext}^n(E,F)$ [or $\mathrm{Hom}(E,F)$ for $n=0$].

All of this is very parallel to the discussion we made in Sec. III and the reader may be wondering why we repeated it. The main reason is that while formally it is very parallel, physically its interpretation is rather different: in particular, we do not make the identifications we made in Sec. III, but instead interpret configurations just as we would in supersymmetric gauge theory (identifying only configurations related by complex gauge transformation). The result is (at least mathematically) an Abelian category to which one can then apply the construction of Sec. III, considering complexes of these complexes and forming the corresponding derived category. This is the type of derived category which, according to Beilinson's theorem, will be equivalent to derived categories of coherent sheaves.

Returning to concrete considerations, these definitions lead immediately to a formula for the relative Euler character:

$$\chi(M,N)\equiv\sum_{k=0}^{p}(-1)^k\dim\ \mathrm{Ext}^k(M,N)=\sum_{1\leqslant i\leqslant j\leqslant p}(-)^{i-j}\binom{q}{i-j}m_in_j\,. \tag{5.3}$$

This is proven by showing that $\chi(M,N)$ is ''topological'' (invariant under deformations of the X's), so that one can compute it for $X=0$.

Before going on to the generalization with $Y\neq 0$, let us discuss the physical meaning of this construction. It is not hard to see that elements of $\mathrm{Hom}(E,F)$ correspond to (complex) gauge symmetries which appear when we combine the theories E and F (the cohomology condition says that the matter configuration is preserved by this gauge transformation). Similarly, elements of $\mathrm{Ext}^1(E,F)$ correspond to massless matter multiplets (or linearized moduli): elements of cohomology correspond to deformations which are not lifted by the superpotential and are not pure gauge.

The higher Ext^n's do not admit such an obvious interpretation but clearly have to do with relations between the superpotential relations; when these exist, one cannot derive the dimension of moduli space, which is $\dim \mathrm{Ext}^1(E,E)$, just from the formula (5.3): one needs more information (such as the dimensions of the higher Ext groups).

In the case at hand, there is a second physical interpretation of $\mathrm{Ext}^2(E,F)$: it counts massless deformations of the Y multiplets. This can be seen by considering the ''physical'' inner product on $\mathrm{Ext}^n(E,F)\times\mathrm{Ext}^n(F,E)^*$ defined as

$$(\phi,\psi)=\sum_{i=1}^{p-n}\mathrm{tr}\,\phi^+_{i+n}\psi_i$$

and the adjoint to d defined by

$$(\phi^{(n)},d^*\psi^{(n+1)})=(d\phi^{(n)},\psi^{(n+1)}).$$

Now the F-flatness conditions on Y are linear, $X^aY_{[ab]}=Y_{[ab]}X^b=0$, and in fact are just $d^*Y=0$. The relation to Ext^2 then comes from the usual Hodge-style arguments that we can find a unique representative of each cohomology class satisfying $d^*Y=0$ and that all solutions of these equations arise in this way.

This result is very suggestive of the relation $\mathrm{Ext}^2(E,F)\cong\mathrm{Ext}^1(F,E)^*$ valid on a Calabi–Yau threefold, and indeed one expects such a relation to hold for any quiver theory which arises in this context. Morally speaking, the superpotential (5.1) is a finite dimensional analog of the holomorphic Chern–Simons functional.

Indeed, as explained in Refs. 3 and 40, the case $p=q=3$ is the $\mathbb{C}^3/Z_3$ quiver theory, while $p=q=5$ describes sheaves on the quintic CY, and the other CY theories which arose in Ref. 40 can be treated similarly. Unlike the analogous formula for sheaves on a CY_3, $\chi(E,E)$ can be nonzero; this is because one has separately described deformations which made sense on the ambient projective space (the X's) and those which appear on restriction (the Y's).[47] However, since $\dim \mathrm{Ext}^2$ enters into (5.3) with the wrong sign, one still needs more information than $\chi(E,E)$ to compute the dimension of the moduli space. [In special cases, the situation can be simpler; for example, in the $\mathbb{C}^3/Z_3$ quiver one can show that $\mathrm{Ext}^2(E,E)=0$ except for the D0-brane.]

This is made particularly clear by considering examples in which the moduli space has branches of different dimension; these branches will differ in $\dim \mathrm{Ext}^2$. A simple example of this type is the quiver with $n_1=1$, $n_2=2$ and $n_3=1$ in $QC(3,5)$ which appears as a rational boundary state $|11000\rangle$ in the quintic Gepner model;[24] this moduli space has branches of dimension 5, 7 and 11, distinguished by $\dim \mathrm{Ext}^2=0$, 1 and 3. The last of these must describe the rational boundary state.

These considerations define the morphisms in the quiver categories we are about to discuss; their gradings are always CFT $U(1)$ charges, which agree with the gradings we just defined for the $\mathbb{C}^3$ orbifold example (and in general if the fractional branes are simultaneously BPS), but must instead be taken from CFT in the Gepner model example (since the fractional branes are not simultaneously BPS).

We went into more detail than was required for this, to make the point that these are concrete examples which capture the complexities of categories of sheaves on Calabi–Yaus (and indeed are equivalent to them once one goes to the derived category) but for which computing the dimensions of homology groups (and thus of the local moduli space) is just a problem of linear algebra. Thus such problems, while not as easy as the cases with more supersymmetry, are by no means inaccessible.

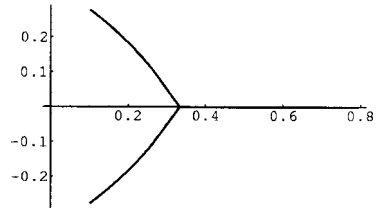

FIG. 1. The evolution of the central charges $Z(B_i)$ for fractional branes in $\mathbb{C}^3/Z_3$ from large volume, where they asymptote to $Q_4(B+iV)^2$, to the orbifold point where they are all equal.

B. The $\mathbb{C}^3/Z_3$ orbifold

This leads to a quiver-complex theory of type $QC(3,3)$. At large volume the orbifold is resolved to $\mathcal{O}_{\mathbb{P}^2}(-3)$ and the three elementary or fractional branes can be identified[43] with the bundles (always on $\mathbb{P}^2$) $B_1 \equiv \mathcal{O}(-1)$, $B_2 \equiv \overline{\Omega}(1)$ (the antibrane to the twisted cotangent bundle) and $B_3 \equiv \mathcal{O}$.

We first discuss the morphisms at the orbifold point. The quiver theory implicitly tells us what these are; since all nine chiral multiplets are massless we see that $\dim \mathrm{Ext}^1(B_i,B_j) = 3\delta_{j\equiv i+1(3)}$.

We next discuss the morphisms at large volume. We can use standard methods to compute morphisms from sheaves to sheaves, and then use the rules in Sec. IV B to infer the morphisms to ''antisheaves'' such as B_2. The elementary morphisms correspond to multiplication by the homogeneous coordinates: we have $\dim \mathrm{Hom}(B_1,B_3)=3$ and (using the Euler sequence) $\dim \mathrm{Hom}(B_1,\overline{B_2}) = \dim \mathrm{Hom}(\overline{B_2},B_3)=3$. Using the rule that $\mathrm{Hom}(A,B)\cong \mathrm{Ext}^1(A,\overline{B}[-1])$ we can also say that $\dim \mathrm{Ext}^1(B_1,B_2[-1]) = \dim \mathrm{Ext}^1(B_2,B_3[-1])=3$. These ''brane-antibrane'' pairs naturally come with tachyonic open strings. Finally, the morphisms $\mathrm{Hom}(B_1,B_3)$ have Serre duals, which according to our previous discussion are $\mathrm{Ext}^1(B_3,B_1[2])$'s.

We can now check that the two limits are related under the flow from large volume to orbifold point. Referring to Fig. 1, we see that $B_1 \to B_1[-1]$, $B_2 \to B_2$, and $B_3 \to B_3[1]$, and all of the morphisms we discussed work. We also see that the superpotential satisfies topological charge conservation, as the sum of the gradings ''around the triangle'' is always 3.

One wants to check that all the morphisms agree, not just these defining ones. This should follow from the equivalence of derived categories established in Ref. 47, which is between representations of the $\mathbb{C}^3/Z^3$ quiver and sheaves with compact support on the resolution $\mathcal{O}^2_{\mathbb{P}}(-3)$. The relation discussed in Ref. 3, between the quiver with some links set to zero and sheaves on $\mathbb{P}^2$, is a subset of this.

From a physical point of view, the difference between sheaves with compact support on $\mathbb{P}^2$ and on $\mathcal{O}^2_{\mathbb{P}}(-3)$ is that a D-brane wrapped on $\mathbb{P}^2$ in the second theory has an extra world-volume field corresponding to the coordinate transverse to $\mathbb{P}^2$, i.e., a chiral multiplet taking values in the line bundle $\mathcal{O}^2_{\mathbb{P}}(-3)$, and the corresponding additional morphisms. Thinking about the D-brane world-volume as a topologically twisted theory[48] shows that the fermion in this multiplet lives in $\mathrm{Ext}^1(E,F\otimes \mathcal{O}_{\mathbb{P}^2}(-3))$. Another way of deducing these morphisms is by using Serre duality twice, first on the total space and then on $\mathbb{P}^2$, which on a Hom amounts to tensoring with this one-form. Because of this, Serre duality on $\mathbb{P}^2$ also leads to relations on the morphisms.

As an example (coming from Ref. 3), we cite $\mathrm{Hom}(\mathcal{O},\mathcal{O}(-3))$ which is nonzero at the orbifold point. Flowing this back produces $\mathrm{Hom}(\mathcal{O}[-1],\mathcal{O}(-3)[1])$ in large volume which indeed agrees with $\dim H^2(\mathcal{O}(-3),\mathbb{P}^2)=1$. The Serre dual to this is the $\mathrm{Ext}^1\mathcal{O}^2_{\mathbb{P}},\mathcal{O}^2_{\mathbb{P}}(-3))$ we just discussed.

C. Gepner models

A product of five $\mathcal{N}=2$ minimal models A_{k_i} with $3=\Sigma_i 1-2/(k_i+2)$, so $\Sigma_i 1/(k_i+2)=1$. Let $K=\mathrm{lcm}(k_i+2)$ and $w_i=K/(k_i+2)$; this corresponds to a Fermat hypersurface in $WP(w_i)$ at a special point in Kähler moduli space with Z_K quantum symmetry.

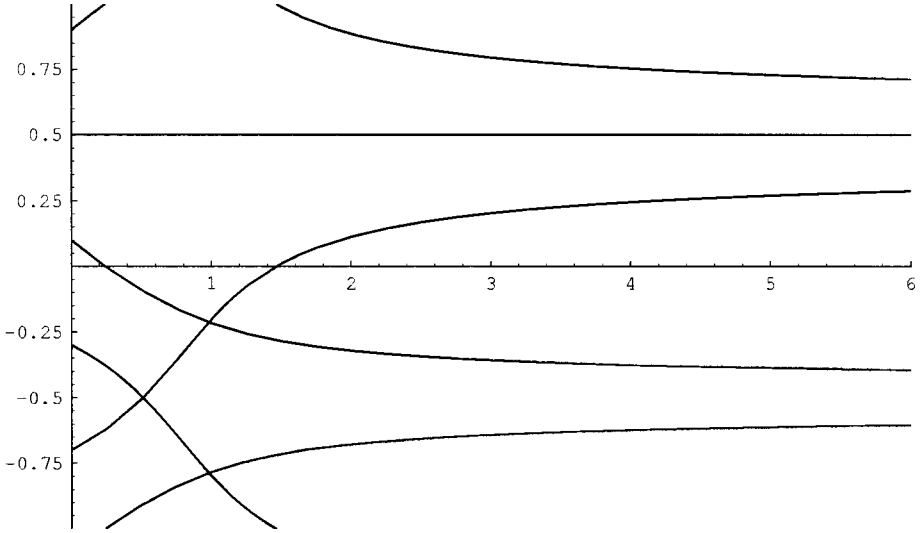

FIG. 2. The evolution of the grades for fractional branes on the quintic from the Gepner point [where $\varphi(B_k)=2k/5-\frac{7}{10}$] to large volume, where they asymptote to $\pm\frac{1}{2}$.

A useful subset of boundary states are the rational $L=0$ states with various M values. Their intersection form (counting massless Ramond strings) is

$$I=\prod_i (1-g^{w_j}). \tag{5.4}$$

The field corresponding to g^{w_j} in this expression (call it X^i) has an NS partner which is nontrivial only in the jth minimal model, where it is the chiral primary $\phi_{(k_i,k_i,0)}$. Thus it has $U(1)$ charge $1-2/(k_i+2)=1-2w_i/K$ and corresponds to a morphism of this degree. The field $Y_{[ij]}$ corresponding to $g^{w_i+w_j}$ is nontrivial in the other three minimal model factors, and has $U(1)$ charge $3-2\Sigma_{l\neq i,j}w_l/K$.

As argued in Ref. 40 the leading term in the superpotential is the cubic term (5.1). The constraints on the k_i guarantee that the degrees of $X^iX^jY_{[ij]}$ add up to 3 and thus this cubic term should correspond directly to the flow of a similar term computed at large volume. Perhaps more interestingly, a product of five fields including one of each X^i also has degree 3. These facts and the direct relation between the gradings of the morphisms and the $\Delta\varphi$ between pairs of branes go a long way towards guaranteeing that the flow will produce sensible large volume gradings; however, there is still something nontrivial to check, namely that the winding numbers of the gradings along the flow are as predicted.

We now consider the quintic with $w_i=1$. The five fractional branes are exterior products of a twisted cotangent bundle on $\mathbb{P}^4$, restricted to the quintic: $B_1=\mathcal{O}(-1)$, $B_2=\overline{\Omega}^3(3)$, $B_3=\Omega^2(2)$, $B_4=\overline{\Omega}(1)$, and $B_5=\mathcal{O}$. Their grades φ are plotted as a function of moduli along the C axis (in the conventions of Ref. 1) in Fig. 2.

The computation of the morphisms at large volume is straightforward as the restriction from $\mathbb{P}^4$ is trivial (it is given by tensoring with the exact sequence

$$0\to\mathcal{O}_{\mathbb{P}^4}(-5)\xrightarrow{f}\mathcal{O}_{\mathbb{P}^4}\to\mathcal{O}_X\to 0,$$

and for the maps we are considering, the first term gives zero). By considerations similar to the previous example, we find $\dim \mathrm{Ext}(B_i,B_{i+1}[-1])=5$ for $1\leqslant i\leqslant 4$, and $\dim \mathrm{Ext}(B_5,B_1[2])=5$.

We also have the composition of two successive Hom's which give $\dim \mathrm{Hom}(B_i, B_{i+2}) = 10$ and its Serre dual $\dim \mathrm{Ext}(B_{i+2}, B_i[2]) = 10$ for $1 \leqslant i \leqslant 3$, and three Hom's giving $\dim \mathrm{Ext}(B_i, B_{i+3}[-1]) = 10$ for $1 \leqslant i \leqslant 2$.

Going to the orbifold point, one has $\Delta(\varphi_{i+1} - \varphi_i) = \frac{3}{5}$ for the pairs $1 \leqslant i \leqslant 4$, leading to the first four degree $\frac{3}{5}$ morphisms X, while $\Delta(\varphi_1 - \varphi_5) = \frac{3}{5} - 3$ (since the sum is zero) leading to the fifth X. The Y morphisms work similarly (since the sum of degrees around each XXY triangle is 3).

VI. PHYSICAL BRANES AS A SUBCATEGORY OF TOPOLOGICAL BRANES

We now address the question of how to identify the physical branes at a specific point in Kähler moduli space $\mathcal{M}_k$.

One approach to this uses the close analogy between general lines of marginal stability, and the ''wall crossing'' associated with variation of μ-stability, which determines whether a holomorphic bundle admits a Hermitian Yang–Mills connection. This idea was developed in Ref. 2 into the proposal that BPS branes are the Π-stable objects. An object E is Π-stable if every subobject E' [i.e., one for which there is an injective $\mathrm{Hom}(E', E)$] satisfies $\varphi(E') < \varphi(E)$. Further discussion of this idea appears in Ref. 49.

Although well motivated, the difficulty in combining this proposal with the present considerations is that the derived category is not an Abelian category and does not have a notion of ''kernel'' or ''subobject.'' The basic reason for this is extremely simple: since we identify A with any combination $AB\overline{B}$ where $B\overline{B}$ is the trivial brane-antibrane bound state (a complex with the identity map), any brane B appears to be a subobject of A.

This point is not just academic, as one can check in examples (as we will do shortly) that the subobject relation is different at different points in $\mathcal{M}_k$.

To better understand this point, we will need to understand what universal structure underlies exact sequences and subobjects in the derived category, and how different Abelian categories can sit in the same derived category.

A. Triangulated categories and bound state formation

In the references, it is shown that derived categories are not Abelian; in particular there is no idea of exact sequence. Since every subobject relation $0 \to E' \to E$ can be completed to an exact sequence, this is the key point in making sense of Π-stability in this general context.

The closest analog to exact sequences are the ''distinguished triangles.'' Let us explain what these are in the context of the derived category $D(\mathcal{A})$ formed from the Abelian category $\mathcal{A}$. (One can axiomatize this structure and talk about triangulated categories which are not necessarily derived in this way, but we will not use that.)

First, for every morphism $A \xrightarrow{f} B$ one has a distinguished triangle

$$\cdots \to C_f[-1] \xrightarrow{\psi} A \xrightarrow{f} B \xrightarrow{\phi} C_f \to \cdots . \tag{6.1}$$

Here C_f is the ''cone'' of f, the quasi-isomorphism class of complexes with terms $A[1] \oplus B$ and differential $\left(\begin{smallmatrix} d_A & 0 \\ f & d_B \end{smallmatrix}\right)$. This is the basic construction we will try to use to represent the ''brane-antibrane bound state'' $\overline{A}B$ produced by condensing the tachyon f.[50] The sequence (6.1) repeats (with a shift of grading) indefinitely to the left and right and this is why it is better thought of as a triangle.

The expression (6.1) appears to single out one arrow as special, the morphism ψ with degree one. Actually this is only a choice of notation: for example we could define $D \equiv A[1]$ and find that the morphism f appeared to have degree one. If one consistently identifies shifted branes $B[2n+1]$ with antibranes $\overline{B}$, then the relation between the K theory classes of the objects is indepen-

dent of this choice. For example, in (6.1), we have $[A]+[C]=[B]$, while in terms of *BCD* we would have had $[B]+[D]=[C]$ which (since $[A]+[D]=0$) is the same. Similarly $[C[-1]]+[B]=[A]$.

The point now is that if we want to base our discussion on the derived category, we cannot talk about exact sequences *a priori* but must instead derive them from the distinguished triangles. If we know that our branes all live in some Abelian category within the derived category, there is a general result which allows us to do this:[51] if and only if three successive objects in the triangle all live in an Abelian subcategory $\mathcal{A}$, that subsequence is a short exact sequence in $\mathcal{A}$. The opposite of this is perhaps easier to see: the cases which do not correspond to exact sequences are those in which C_f has homology in both degrees, and thus is not a member of the Abelian category $\mathcal{A}$. This is interesting for our purposes as there will turn out to be more than one Abelian subcategory of $D(\mathbf{Coh}\,X)$.

Let us discuss this more physically. Suppose in bringing together two objects $\overline{A}$ and B we can form a bound state C, so that $[\overline{A}]+[B]=[C]$. (The choice of notation $\overline{A}$ rather than A is just to get the same K theory relation $[B]=[A]+[C]$ we discussed earlier. We are not assuming any specific relation between central charges yet.) This must start by condensing a tachyonic or massless open string between $\overline{A}$ and B. Let us denote the corresponding morphism (the ''Ext'') with a double arrow $\Rightarrow$, while single arrows denote Hom's (enhanced gauge symmetries).

From the point of view of BPS central charge, $Z_{\overline{A}}=-Z_A$ and Z_B might be aligned, antialigned or not aligned, and the process will look slightly different depending on this. If $Z_{\overline{A}}$ and Z_B are antialigned, there are two further possibilities $|Z_{\overline{A}}|>|Z_B|$ or $|Z_{\overline{A}}|<|Z_B|$, which determine whether the bound state Z_C aligns with $Z_{\overline{A}}$ or Z_B. We now explain how all of these possibilities are contained in the same distinguished triangle (6.1).

If $|Z_B|>|Z_{\overline{A}}|$, the appropriate description is an exact sequence

$$0\to A\overset{f}{\Rightarrow}B\overset{\phi}{\to}C\to 0 \tag{6.2}$$

with maps f and ϕ of degree 0. This is the special case in which C_f has homology only in degree 0, and every such exact sequence corresponds to a distinguished triangle (6.1).

If $|Z_{\overline{A}}|>|Z_B|$, we should use the exact sequence

$$0\to\overline{C}\overset{\psi}{\to}A\overset{f}{\Rightarrow}B\to 0, \tag{6.3}$$

appropriate if C_f has homology only in degree -1. Here we have identified $C[-1]$ with the antibrane $\overline{C}$.

Finally, if $Z_{\overline{A}}$ and Z_B are aligned, we have

$$0\to B\overset{\phi}{\to}C\overset{\psi}{\to}\overline{A}\to 0 \tag{6.4}$$

in which $\overline{A}\overset{f}{\Rightarrow}B[1]$ does not even appear in the exact sequence (it is the ''connecting map'' of the long exact sequence).

The point of all this is to show that the derived category can remain invariant under varying Kähler moduli, while describing somewhat different looking physical processes. The distinction between the processes comes when we identify a specific exact sequence in the triangle. In all three limiting cases (in which central charges align), the exact sequence is the subsequence of (6.1) containing the maps of degree 0, which is the subset of objects which can live in the same Abelian category.

There is some correspondence between our string-inspired notation and the usual mathematical notation and one might try to identify our double arrows $\Rightarrow$ with the special (degree one) morphisms of (6.1). Again, one must recognize that this is only a choice of notation: a single

distinguished triangle admits all three interpretations in which any of the links is a matter field (this could presumably be proven from crossing symmetry of the related BPS algebra).[28] More importantly, the ''special'' morphism in our notation need not have degree 1; this will change under flow.

B. Examples

Let us now look at some examples where we know the interpretations on both sides of a flow.

The simplest situation is illustrated by the brane-antibrane pairs which come out of the Beilinson and generalized McKay constructions. For example, in $\mathbb{C}^3/Z_3$, we have a tachyon $f \in \mathrm{Ext}^1(B_1, B_2[-1])$ at large volume [where $B_1=\mathcal{O}(-1)$ and $B_2=\overline{\Omega}(1)$], which flows to a massless field $f \in \mathrm{Ext}^1(B_1, B_2)$ at the orbifold point.

At large volume, the BPS central charge is dominated by the D4-brane charge (the rank of the bundle). Since $\Omega(1)$ is a rank 2 bundle while $\mathcal{O}(-1)$ has rank 1, at large volume there is a brane-antibrane bound state X, which is an antibrane (D4 charge -1) with these conventions. Its central charge aligns with that of B_2, so the bound state formation is described by the exact sequence

$$0 \to \overline{B}_1 \overset{f}{\Rightarrow} B_2 \overset{\phi}{\to} X \to 0 \tag{6.5}$$

with ϕ a degree zero Hom.

In moving to the orbifold limit, the grade of B_1 decreases by 1, which results in f of degree 1, ψ of degree 0 and ϕ of degree 0. The bound state is still X, but we now want to interpret it as a brane-brane bound state or extension

$$0 \to B_2 \overset{\phi}{\to} X \overset{\psi}{\to} B_1 \to 0 \tag{6.6}$$

with f the connecting map $B_1 \Rightarrow B_2[1]$.

Both come from the distinguished triangle

$$\cdots \to B_1[-1] \overset{f}{\Rightarrow} B_2 \overset{\phi}{\to} X \overset{\psi}{\to} B_1 \to \cdots$$

by specializing to the triple involving maps of degree zero or equivalently whose terms all have the same grade. Note that in the (6.5) interpretation, the object $\overline{B}_1$ has the same K theory class as $B_1[-1]$ (this does not change under flow) but grade zero instead of one.

In the language of Abelian categories, the difference is that at large volume $\overline{B}_1$ and B_2 are both in the Abelian category [justifying the use of (6.5)] while at the orbifold point B_1 and B_2 are in the Abelian category [justifying (6.6)].

We will now try to regard this as a valid description along the flow, where in general the maps will not have integral degree. Of course this is what we expect from the CFT discussion, but it means that we cannot *a priori* rely on the exact sequence interpretation of either (6.5) or (6.6). Nevertheless, physics tells us that we should regard this triangle as describing the formation of a bound state which exists all along the flow. Since the flow is continuous, the grade of X is everywhere determined—this is not something we could take for granted without the triangle, as there is no obvious canonical way to assign gradings to general complexes (they would have to depend on individual homologies, not the total K theory class). Since we have the triangle, we can assign X a grade, and one finds that the gradings of all three morphisms stay within the interval [0, 1] all along the flow. This is consistent with all three objects remaining stable along the flow (in principle they could still be destabilized by other objects).

We next discuss the two-brane, the structure sheaf $\mathcal{O}_\Sigma$ of a two-cycle Σ. There is a simple exact sequence which produces it from the B_i, namely

$$0 \to \mathcal{O}(-1) \overset{f}{\to} \mathcal{O} \overset{g}{\to} \mathcal{O}_\Sigma \to 0,$$

and the corresponding distinguished triangle is

$$\mathcal{O}(-1) \overset{f}{\to} \mathcal{O} \overset{g}{\to} \mathcal{O}_\Sigma \overset{h}{\to} \mathcal{O}(-1)[1] \to \cdots .$$

At large volume this is a perfectly good representation of the 2B; the definition (2.1) leads us (as discussed in Sec. IV) to assign it grade $\frac{1}{2}$ [in conventions where $\varphi(\mathcal{O})=0$] and thus the maps g and h have degree $\frac{1}{2}$. Thus at and near large volume, the 2B can be produced as a bound state of 4B's by condensing a tachyonic open string, as discussed in Ref. 10.

As we flow down, the grade of $\mathcal{O}(-1)$ decreases and the grade of $\mathcal{O}$ increases. Eventually these reach $-\frac{1}{2}$ and $\frac{1}{2}$, respectively, while the 2B remains at $\frac{1}{2}$. At this point, f has degree 1, and g and h have degree 0. If we pass this point, the degree of g goes negative and the 2B goes unstable, while the open string between 4B's becomes massive.

This conclusion basically agrees with that of Ref. 3, where it was justified in terms of Π-stability. However, there was an interesting subtlety noted there; the map g does not look injective when one follows the usual large volume definitions (a map from a sheaf to a sheaf with lower dimensional support could hardly be injective). In the present discussion, since both g and h have degree 0 at the transition, one wants to interpret them as forming an exact sequence at that point, in which case g would ''become'' an injective map. This type of argument can be tested against other known subobject relations at the orbifold point, and seems to work. It suggests a reformulation of Π-stability which we will make below.

By the time we reach the orbifold point, the map f has degree 2 and there is no obvious sign that the 2B ever existed. However, since we can determine that f existed from orbifold considerations (it was an Ext^2 in the quiver-complex formalism), we can run this backwards. From this point of view, we would define $\mathcal{O}_\Sigma$ as a cone C_f in (6.1). Coming back up, the degree of f eventually drops to 1, and it becomes consistent to postulate that this $\mathcal{O}_\Sigma$ becomes stable, with maps g and h of degree 0. Thus we could infer the existence of the 2B elsewhere in moduli space just from information obtained at the orbifold point.

A very similar discussion can be made for the ''mysterious'' bound state $|10000\rangle$ discussed in Refs. 1 and 52, which exists at the Gepner point in the quintic but not at large volume. This is a bound state of $\mathcal{O}(-1)$ and $\mathcal{O}$ and comes about because an $\mathrm{Ext}^3(\mathcal{O},\mathcal{O}(-1))$ at large volume eventually becomes tachyonic near the orbifold point. In this example, one can infer the existence of a bound state which is not a sheaf, just having information about sheaves and about the BPS central charges.

These results demonstrate how we can infer the existence of new BPS branes at distant points in $\mathcal{M}_k$. Given a set of BPS branes, we construct their derived category, including new objects which are candidate BPS branes elsewhere in moduli space. The K theory class of each such object is determined, and this determines the grade of the connecting maps up to an overall $2Z$ ambiguity. If this ambiguity can be fixed in a way that gives all the morphisms non-negative grade, then the object becomes stable.

C. t-structures

There is a mathematical formalism which makes it possible to identify Abelian categories within the derived category, the formalism of t-structures.[51,5] We will not actually use this in the proposal we are about to make, but it illustrates in a clear way how objects which look like complexes from one point of view can be individual objects (not complexes) in a different Abelian category.

A t-structure is defined by prescribing two subcategories $\mathcal{D}^{\geqslant 0}$ and $\mathcal{D}^{\leqslant 0}$ of the derived category $\mathcal{D}$. If $\mathcal{D}$ is derived from an Abelian category $\mathcal{A}$, these would be the categories of complexes

with cohomology only in degrees $n \geqslant 0$ and complexes with cohomology only in degrees $n \leqslant 0$, respectively. The original Abelian category would then be $\mathcal{A} = \mathcal{D}^{\geqslant 0} \cap \mathcal{D}^{\leqslant 0}$.

The nontrivial fact is now that there are a short list of axioms which $\mathcal{D}^{\geqslant 0}$ and $\mathcal{D}^{\leqslant 0}$ must satisfy in order to guarantee that their intersection is an Abelian category. This provides a general way to define new Abelian subcategories. In general, the intersection will contain objects which are complexes from the point of view of the original category; thus these complexes will be regarded as objects in the new category. In this sense, the distinction between ''object'' and ''complex'' is not invariant, and from this point of view it is quite natural to get complexes of coherent sheaves as stable BPS branes at other points in $\mathcal{M}_k$.

A simple way to get new t-structures on $D(\mathbf{Coh}\, X)$ for X Calabi–Yau is to use the Fourier–Mukai transforms discussed earlier. Taking the images of $\mathcal{D}^{\geqslant 0}$ and $\mathcal{D}^{\leqslant 0}$ under the FMT provides a new t-structure whose Abelian category, although isomorphic to the original (for an FMT implementing a monodromy), consists of different objects in $D(\mathbf{Coh}\, X)$. Since these monodromy groups are braid groups this presumably leads to infinitely many t-structures on $D(\mathbf{Coh}\, X)$.

This formalism might be directly usable to produce the Abelian categories which are needed by the original formulation of Π-stability. The basic way this could work would be to move objects between $\mathcal{D}^{\geqslant 0}$ and $\mathcal{D}^{\leqslant 0}$ when their gradings flow across zero.

Indeed, a very concrete example illustrating this idea can be found in work of Bridgeland.[53] In Ref. 53 it is proven that $D(\mathbf{Coh}\, X)$ is invariant under a flop transition, a previously known result,[54] but the interesting point is the way in which this is proven. This uses the theory of so-called perverse sheaves, which can be formulated using t-structures. The basic idea is to consider some submanifold (more generally a stratification of the manifold) and shift the grading of all objects supported on that submanifold in defining the t-structure. The corresponding Abelian category is referred to as a category of ''perverse sheaves.''

In Ref. 53, one considers perverse sheaves defined by shifting the grading of sheaves supported on an appropriate curve C in the CY by -1. Certain of these perverse sheaves can be identified as analogous to points, and it turns out that the moduli space of these ''perverse points'' is isomorphic to the CY X' which is the result of a flop transition on the curve C.

The point of contact with our present considerations is that in terms of periods and BPS central charges, a flop transition simply acts by taking the central charge $Z = B + iV$ of the 2B on the curve C from $V > 0$ to $V < 0$. This indeed shifts the grading of 2B's by ± 1 (the sign depends on the first Chern class) and, by arguments similar to Bridgeland's, might lead to the t-structure appropriate for the flopped CY.

It seems very likely to us that these ideas will be important in future work and more specifically that subcategories of $D(\mathbf{Coh}\, X)$ generated by the stable branes of a given grade on a CY with given moduli will provide a significant generalization of categories of ''perverse sheaves.'' However, we will leave the problem of making this more explicit to future work.

D. A proposal for a stability condition

The stability condition we will propose here builds more simply on the results we already presented and adds some plausible physical input. Unlike Π-stability, it does not provide a way to decide whether a brane is stable at a point in $\mathcal{M}_k$ by just considering that point, but only describes the variation in the set of stable branes as one moves in $\mathcal{M}_k$.

Many of the previous considerations can be summarized by defining a ''stable triangle.'' A distinguished triangle (6.1) involves three morphisms with grades $\alpha + \beta + \gamma = 1$. Let a stable triangle (at a given point in $\mathcal{M}_k$) be a distinguished triangle for which each of the three grades is in $[0, 1]$.

Since if two brane central charges are colinear, the third will be as well, the definitions lead to the constraint that the only stable triangles on the boundary of this region (or ''semistable'' triangles) are those with one grade 1 and the other two 0.

We cannot directly use this to say that a stable object only participates in stable triangles—there will always be lots of extra triangles involving negative morphisms. We only know that

every morphism between stable objects must have non-negative degree. Indeed, there is no physical argument that there should be a canonical definition of grade for unstable objects, and we will not assume that there is.

Let us now suppose that we know the stable objects at some point in $\mathcal{M}_k$, and we move a small distance in this space. The gradings of morphisms will flow: some triangles will become unstable and we must lose objects; others will become stable and we can gain objects.

When a triangle goes unstable, the brane which decays will always be the one sitting between the two morphisms of zero degree. This is because [in all three cases (6.2)–(6.4)] this will always be the heaviest of the three branes. This also means that one only need check lighter branes as possible destabilizing subobjects.

Conversely, when a triangle becomes stable, we will see it by a map f between stable objects having degree coming down through 1. Whenever this happens, we can try to add C_f with grade which gives the other maps degree 0. This uniquely determines the $2Z$ ambiguity in the grading of C_f. We should, however, only add C_f as a stable object if it is not also destabilized by a morphism of negative degree from some preexisting stable object. Once we do this, we might have further candidate bound states involving C_f, so the process must be iterated.

This more or less restates the phenomena we observed in our simple examples but now we must face the question of whether this procedure leads to an unambiguous modified list of stable objects or whether the result depends on the order in which we make these modifications.

One point where such dependence might enter is that we might find that A destabilizes B, but A also decays on the same line. The general result which prevents this type of ambiguity is that the subobject of A responsible for the decay will also be a subobject of B (by composing the Hom's), and typically would be a stable object which will destabilize B. In general it might decay, but this chain must terminate with some stable final product (assuming the spectrum of masses has a gap) which will also be a subobject.

Similarly, we cannot find that adding a new object C_f destabilizes preexisting objects, because there will be a subobject of C_f which already destabilized them before we added C_f.

These considerations suggest that the procedure as we stated it is unambiguous. The main physical assumption we needed was that the spectrum of BPS masses has a finite mass gap, so that we cannot have infinite chains of subobjects and decays.

VII. CONCLUSIONS

In this work, we gave a fundamental picture of BPS D-branes on Calabi–Yau manifolds, based on considerations in conformal field theory and the related topological string theory.

To summarize, we distinguished boundary conditions in topological open string theory or ''topological D-branes'' from BPS boundary conditions in CFT or ''physical D-branes,'' and argued that every physical D-brane had a topological analog but not vice versa. Topological D-branes (in the B model) are more general than holomorphic bundles or coherent sheaves; they can be arbitrary objects of the derived category. The grading of morphisms between topological D-branes depends on the Kähler moduli in a simple way and this is responsible for variation of the spectrum of physical D-branes and lines of marginal stability; branes involved in morphisms of negative degree cannot exist. This provides a CFT derivation of the Π-stability condition of Ref. 2. We went on to discuss the triangulated structure of the derived category, which allows us to dispense with the requirement of a preexisting Abelian category and subobject relation made in the original Π-stability proposal, instead deriving the subobject relations from the gradings and distinguished triangles. All of these points were illustrated in a number of examples; in simple cases these ideas lead directly to explicit predictions for marginal stability lines.

Many new phenomena are clearly possible and can now be studied systematically, such as the formation of branes away from the large volume limit which are not coherent sheaves but more general objects in the derived category.

All of these developments appear rather solid to us and provide a firm basis for further understanding of BPS branes on Calabi–Yau as well as a precise contact with the homological

mirror symmetry proposal of Kontsevich. The ''flow of gradings'' is a new structure in this problem which we believe will be quite important in future developments.

In the final subsection, we went further and stated a definite proposal for how to determine the spectrum of BPS branes at arbitrary points in Kähler moduli space. This proposal is somewhat harder to use than Π-stability in that it requires starting with the spectrum at a single point, say the large volume limit, and following its evolution to the point of interest. (It is not necessary to follow the entire spectrum in order to determine the existence of particular branes, however.) We did not prove that this procedure always leads to unambiguous results, though we did give suggestive arguments for this.

Clearly this proposal requires a great deal of testing and exploration at this point. There are numerous self-consistency checks that it must pass; for example it is not obvious that branes whose periods vanish at nonsingular points of Kähler moduli space will decay before reaching these points (as is required for physical consistency). We did not even prove that monodromies are symmetries of the physical spectrum.

Not having yet performed these basic checks, our main reason for believing in the proposal at present is that it seems to us to be the conceptually simplest proposal which could accomodate the known complexity of these problems as revealed in Ref. 3 and our further studies. Since it is the first such proposal, this point will have to be confirmed by further work as well. Hopefully there is a lot of scope for simplifying its application; ideally one would be able to derive a condition which can be applied at a single point in Kähler moduli space. One might well benefit from using more A model information as well.

We will not get into lengthy discussion of the likely applications of this work here, instead referring to the conclusions of Ref. 3. Perhaps the most direct application would be to provide a simpler invariant of $d=4$, $\mathcal{N}=2$ string compactifications than the explicit spectrum of BPS branes, namely the derived category obtained from this spectrum. The precise sense in which this is simpler is that it does not depend on the BPS central charges or the point in vector multiplet moduli space. Making interesting use of this idea in studying $\mathcal{N}=2$ duality probably requires generalizing the ideas to defining ''derived categories of quantum BPS branes,'' which would have some similarity to BPS algebras[28] but presumably would be independent of vector moduli.

As discussed in the conclusions to Ref. 3, we regard the more important goal of this line of work to be its eventual application to understanding $\mathcal{N}=1$ compactifications of string theory. Building on Ref. 2, in $\mathcal{N}=1$ language we have provided a rather complete discussion of the problem of solving the D-flatness conditions in a certain large class of theories. As will be discussed elsewhere, we believe it will turn out to be possible to get exact superpotentials in Gepner models and perhaps more general CYs as well.

A natural next question in this vein is whether a similar geometric understanding could be developed of non-BPS branes. One should distinguish two cases. The examples we know of are connected to BPS branes or combinations of BPS branes by varying CY moduli, and it seems very likely that these can be understood in the same way, with the non-BPS property arising from spontaneous breaking of space–time $\mathcal{N}=1$ supersymmetry, now involving a competition between D and F flatness conditions. There might be other non-BPS branes not connected to BPS branes by varying moduli; for these it is unclear whether such a picture would apply.

In any case, we believe our present results give further evidence that $\mathcal{N}=1$ string compactification can lead to problems which admit general solutions (not just case by case analysis) and a rich mathematical structure.

[33] Actually, complexes are usually defined in terms of d containing only degree zero maps $\mathrm{Hom}(E_n, E_{n+1})$, and this is all we will need below. The apparent generalization will go away in the final result.
[34] One can make a similiar refinement by making the equivalence $[A]+[C]\cong[B]$ only when there exists an exact sequence $0\to A\to B\to C\to 0$. This leads to analytic K theory, which will distinguish different points in M, for example. However, this does not give the morphism or grading structure of the derived category, which will also be important physically.

Fundamental strings in open string theory at the tachyonic vacuum

Ashoke Sen[a)]
Harish-Chandra Research Institute,[b)] Chhatnag Road, Jhusi, Allahabad 211019, India

(Received 2 January 2001; accepted for publication 13 February 2001)

We show that the world-volume theory on a D-p-brane at the tachyonic vacuum has solitonic string solutions whose dynamics is governed by the Nambu–Goto action of a string moving in $(25+1)$ dimensional space–time. This provides strong evidence for the conjecture that at this vacuum the full $(25+1)$ dimensional Poincaré invariance is restored. We also use this result to argue that the open string field theory at the tachyonic vacuum must contain closed string excitations. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377037]

I. INTRODUCTION AND SUMMARY

It has been conjectured that the tachyonic vacuum in open bosonic string theory on a D-brane describes the closed string vacuum without D-branes, and that various soliton solutions in this theory describe D-branes of lower dimension.[1] Similar conjectures have also been put forward for superstring theories.[2–4] Evidence for these conjectures come from both first[5,6] and second[7–10] quantized string theories.

Given that all D-branes can be regarded as solitons in the open string field theory,[11] one might wonder if the open string field theory could be used for a nonperturbative formulation of string theory.[12] For this one needs to show that not only the D-branes, but other known objects in string theory, namely the fundamental closed strings and the NS five-branes are also present in this open string field theory. Progress in identifying the fundamental string has been made in Refs. 13, 14, 8, 15, and 16. In particular, in Refs. 14, 8, 15, and 16 it was shown that the effective action[17] describing the dynamics of the D-brane around the tachyonic vacuum admits stringlike classical solution whose tension matches that of a fundamental string. It was also established that on a D-25-brane world-volume, the dynamics of these strings is described by that of a Nambu–Goto string moving in $(25+1)$ dimensions.

On the world-volume of a D-p-brane embedded in the $(25+1)$ dimensional space–time, the full $(25+1)$ dimensional Poincaré invariance is spontaneously broken to the product of $(p+1)$ dimensional Poincaré group, and the $(25-p)$ dimensional rotation group. However, if the tachyonic ground state really represents the vacuum without a D-brane, then we expect that in this vacuum the full $(25+1)$ dimensional Poincaré invariance should be restored. Thus the dynamics of the stringlike solutions should be described by a Nambu–Goto action with $(25+1)$ dimensional target space rather than a $(p+1)$ dimensional target space. This is what we shall demonstrate in this paper. (This question was partially addressed in Ref. 15 where it was shown that in the approximation where the contribution to the Hamiltonian is dominated by the electric flux on the D-brane world-volume, there is a symmetry that exchanges the velocity tangential to the D-brane with the velocity transverse to the D-brane.) Since the Nambu–Goto action in $(25+1)$ dimensional target space has full $(25+1)$ dimensional Poincaré invariance, this result provides strong support to the conjecture that at the tachyonic vacuum of the D-p brane the full $(25+1)$ dimensional Poincaré invariance is restored. Earlier string field theory analysis has provided evidence for

[b)]Formerly Mehta Research Institute of Mathematics & Mathematical Physics.

the restoration of the translational invariance along directions transverse to the D-brane world-volume.[18,19]

Since the D-p-brane world-volume is $(p+1)$ dimensional, and the string solution lives on the D-p-brane, it may sound strange at first that this string actually moves in $(25+1)$ dimensions. The reason it can happen is that at the tachyonic vacuum the D-brane has vanishing tension, and hence it does not cost the D-brane any additional energy to adjust its world-volume to contain any given fundamental string world-sheet embedded in $(25+1)$ dimensional space–time. Thus the string world-sheet always lies inside the D-p-brane world-volume, as should be the case. The nontrivial fact here is that the dynamics of the string tangential to the D-brane world-volume, which is described by the gauge fields, and the dynamics transverse to the D-brane world-volume, which is described by the massless scalar fields associated with the transverse motion of the D-brane, are together described by the Nambu–Goto action in the full $(25+1)$ dimensional target space–time.

Although the dynamics of the string soliton constructed this way agrees with that of the fundamental string, there are some caveats. First of all the tension of the string is governed by the total amount of electric flux it carries, and only after properly taking into account the quantization rule for the electric flux one can show that the tension matches that of the fundamental string. Within the classical field theory which we shall be studying, there is no rationale for this quantization law. A related problem is as follows. Although the string solution constructed here has the correct degrees of freedom describing the dynamics of a fundamental string, it also has additional degrees of freedom corresponding to the energy density spreading out in the direction transverse to the original string solution instead of being confined in a thin tube along the string. We show that these problems can be avoided by making the solitonic string driven by an external open string. For this we consider the case where one of the directions transverse to the D-p-brane is compact, and we begin with a configuration of open strings starting on the D-brane, and ending on its image under translation along the compact direction. We then ask what happens when the tachyon on the D-brane rolls down to its ground state. We argue that at the tachyonic vacuum, the two ends of the original open string are connected by a flux line on the D-brane, with the total amount of flux fixed by the source (and the sink) of flux, namely the end points of the original open string on the brane. Furthermore, the condition for minimum energy prevents the flux from spreading, since the source and the sink of flux are pointlike objects on the D-p-brane world-volume. The net result is a single fundamental string winding along the compact direction. Using a T-duality transformation along the compact direction we can then argue that the T-dual D-$(p+1)$-brane at the tachyonic vacuum must contain closed string excitations carrying momentum along the compact direction.

Related earlier work in Ref. 20 analyzed the dynamics of tensionless D-branes in a different formalism and found that the D-brane world-volume is foliated by string world-sheet. It will be interesting to explore the precise relation between these results and the static gauge results of Refs. 14, 8, 15, 16 and the present paper.

The paper is organized as follows. In Sec. II we review the result for the effective action on the D-brane world-volume at the tachyonic vacuum[17] and its Hamiltonian formulation.[15] In Sec. III we show that given any solution of the equations of motion of a Nambu–Goto string moving in $(25+1)$ dimensional space–time, we can construct a solution of the equations of motion of the D-p-brane world-volume theory with energy density localized along the world-sheet of the corresponding Nambu–Goto string solution. This establishes that the D-p-brane world-volume theory admits stringlike soliton solutions whose dynamics is governed by the Nambu–Goto action in $(25+1)$ dimensions. In Sec. IV we use this result to argue that the open string field theory, describing the D-brane world-volume theory at the tachyonic vacuum, must contain closed string excitations.

II. LOW ENERGY EFFECTIVE FIELD THEORY ON THE D-BRANE AT THE TACHYONIC VACUUM

We shall analyze the dynamics of massless fields living on a D-p brane at the tachyonic vacuum in the static gauge. Let us denote by $x^\mu (0 \leqslant \mu \leqslant p)$ the world-volume coordinates on the

D-brane, by A_μ the U(1) gauge field living on the D-brane, and by Y^I $(p+1\leq I\leq 25)$ the massless scalars representing the transverse coordinates of the brane. The action is given by[17]

$$S=-V(T)\int d^{p+1}x\sqrt{-\det(\eta_{\mu\nu}+F_{\mu\nu}+\partial_\mu Y^I\partial_\nu Y^I)}, \tag{2.1}$$

where $V(T)$ is the tachyon potential which vanishes at the tachyonic vacuum $T=T_0$. We shall work in the gauge $A_0=0$, and denote by $\pi^i(x)$ and $p_I(x)$ the momenta conjugate to A_i and Y^I, respectively, for $1\leq i\leq p$. As was shown in Ref. 15, the dynamics of the brane at the tachyonic vacuum is best described in the Hamiltonian formalism, with the Hamiltonian

$$H=\int d^px\mathcal{H}, \tag{2.2}$$

with

$$\mathcal{H}=\sqrt{\pi^i\pi^i+p_Ip_I+(\pi^i\partial_iY^I)^2+b_ib_i}, \tag{2.3}$$

where

$$b_i\equiv F_{ij}\pi^j+\partial_iY^Ip_I. \tag{2.4}$$

$F_{ij}=\partial_iA_j-\partial_jA_i$ is the magnetic field strength. The π^i's satisfy a constraint:

$$\partial_i\pi^i=0. \tag{2.5}$$

In writing down the Hamiltonian (2.2), (2.3) we have taken the tachyon field T to be frozen at its minimum $T=T_0$. Proposals for the effective action including tachyon kinetic term have been put forward in Ref. 21.

Let us denote by $E_i=\partial_0A_i$ the electric field strength. Then the Bianchi identities and the equations of motion derived from the Hamiltonian given in (2.2), (2.3) are given by

$$\partial_{[i}F_{jk]}=0, \quad \partial_0F_{ij}=\partial_iE_j-\partial_jE_i, \tag{2.6}$$

$$E_i=\frac{1}{\mathcal{H}}(\pi^i+\partial_iY^I\pi^j\partial_jY^I-F_{ij}b_j), \tag{2.7}$$

$$\partial_0\pi^i+\partial_j\left(\frac{1}{\mathcal{H}}(\pi_jb_i-\pi_ib_j)\right)=0, \tag{2.8}$$

$$\partial_0Y^I=\frac{1}{\mathcal{H}}(p_I+\partial_iY^Ib_i), \tag{2.9}$$

$$\partial_0p^I=\partial_i\left(\frac{1}{\mathcal{H}}(\pi^i\pi^j\partial_jY^I+b_ip^I)\right). \tag{2.10}$$

For this system, there are conserved Noether currents $T_{\mu\nu}$ and $T_{\mu I}$ $(0\leq\mu,\nu\leq p,\ (p+1)\leq I\leq 25)$ associated with the translation along the spatial coordinates x^μ labeling the D-p-brane world-volume, as well as translation along the coordinates Y^I transverse to the world-volume. These are given by

$$T_{00}=\mathcal{H}, \quad T_{k0}=-b_k, \quad T_{0i}=-b_i, \quad T_{ki}=\frac{1}{\mathcal{H}}(\pi^k\pi^i-b_kb_i), \tag{2.11}$$

$$T_{0I}=p_I, \quad T_{kI}=\frac{1}{\mathcal{H}}(\pi^k\pi^j\partial_j Y^I+b_k p^I),$$

and satisfy

$$\eta^{\mu\nu}\partial_\mu T_{\nu\rho}=0, \quad \eta^{\mu\nu}\partial_\mu T_{\nu I}=0. \tag{2.12}$$

III. FUNDAMENTAL STRING SOLUTION

In this section we shall demonstrate that the equations of motion discussed in Sec. II admit fundamental string solutions whose dynamics is identical to that of a Nambu–Goto string moving in $(25+1)$ dimensional space–time. Using the results of Ref. 22, Ref. 15 showed that if we set the Y^I's to 0, then the dynamics of the solitonic string is described by the Nambu–Goto action in $(p+1)$ dimensional space–time. The new result is the incorporation of the Y^I's. Since the dynamics of a Nambu–Goto string in $(25+1)$ dimensional space–time has full $(25+1)$ dimensional Poincaré invariance, our result gives strong support to the conjecture that the tachyonic vacuum of the D-p-brane represents a configuration where the full $(25+1)$ dimensional Poincaré invariance is restored.

Our strategy will be as follows. We shall show that for every configuration of a Nambu–Goto string satisfying the string equations of motion we can construct a solution of the equations of motion (2.5)–(2.10), with energy density localized along the string. For this we start by writing down the action of the Nambu–Goto string in $(25+1)$ dimensional space–time:

$$S_{\rm NG}=-\int d\tau\, d\sigma \sqrt{-\det(\eta_{MN}\partial_\alpha Z^M\partial_\beta Z^N)}, \tag{3.1}$$

where ξ^α for $\alpha=0,1$ denote the world-volume coordinates of the string: $(\xi^0,\xi^1)\equiv(\tau,\sigma)$, Z^M $(0\leqslant M\leqslant 25)$ denote the space–time coordinates of the string, and η_{MN} is the Minkowski metric diag$(-1,1,1,\ldots,1)$. We shall choose the static gauge: $(Z^0=\tau, Z^1=\sigma)$ and go to the Hamiltonian formalism. If we denote by P_s the momenta conjugate to Z^s for $2\leqslant s\leqslant 25$, the Hamiltonian is given by

$$H_{\rm NG}\equiv\int d\sigma\,\mathcal{H}_{\rm NG}=\int d\sigma\,\sqrt{1+P_sP_s+\partial_\sigma Z^s\partial_\sigma Z^s+(P_s\partial_\sigma Z^s)^2}. \tag{3.2}$$

The equations of motion following from this Hamiltonian are given by

$$\partial_\tau Z^s=\frac{1}{\mathcal{H}_{\rm NG}}(P_s+\partial_\sigma Z^s P_t\partial_\sigma Z^t), \tag{3.3}$$

$$\partial_\tau P_s=\partial_\sigma\left(\frac{1}{\mathcal{H}_{\rm NG}}(\partial_\sigma Z^s+P_sP_t\partial_\sigma Z^t)\right). \tag{3.4}$$

In these equations s and t indices take values $2,3,\ldots,25$. For future use, we shall define

$$P_1=-\sum_{s=2}^{25}P_s\partial_\sigma Z^s, \quad Z^1(\tau,\sigma)=\sigma. \tag{3.5}$$

With these definitions, it is straightforward to verify that Eqs.(3.3) and (3.4) are satisfied also for $s=1$. (The sum over t in these equations still runs from 2 to 25).

Let $(Z^s(\tau,\sigma),P_s(\tau,\sigma))$ for $2\leqslant s\leqslant 25$ be a solution of Eqs. (3.3) and (3.4). Now consider the following field configuration on the D-p-brane:

$$\pi^i(x^0,\ldots,x^p)=\partial_\sigma Z^i(\tau,\sigma)f(x^0,\ldots,x^p)\big|_{(\tau,\sigma)=(x^0,x^1)}, \tag{3.6}$$

$$p_I(x^0,\ldots,x^p)=P_I(\tau,\sigma)f(x^0,\ldots,x^p)|_{(\tau,\sigma)=(x^0,x^1)},$$

where we have used the convention that the indices i,j,k run from 1 to p, the indices I,J,K run from $(p+1)$ to 25, and the indices s,t run from 2 to 25. $f(x^0,\ldots,x^p)$ is an arbitrary function of the variables $(x^m-Z^m(x^0,x^1))$ for $2\leqslant m\leqslant p$, and hence satisfies

$$\partial_\sigma Z^i\partial_i f|_{(\tau,\sigma)=(x^0,x^1)}=0, \quad (\partial_\tau Z^i\partial_i f+\partial_0 f)|_{(\tau,\sigma)=(x^0,x^1)}=0. \tag{3.7}$$

The fields $Y^I(x^0,\ldots,x^p)$ and $F_{ij}(x^0,\ldots,x^p)$ are subject to the following set of conditions:

$$(\partial_\sigma Z^j\partial_j Y^I-\partial_\sigma Z^I)|_{(\tau,\sigma)=(x^0,x^1)}=0, \tag{3.8}$$

and

$$(F_{ij}\partial_\sigma Z^j+\partial_i Y^I P_I+P_i)|_{(\tau,\sigma)=(x^0,x^1)}=0, \tag{3.9}$$

but are otherwise unspecified. Using Eqs. (3.6), (3.8), and (3.9) we can easily verify that for this background,

$$\begin{aligned}
&\mathcal{H}(x^0,\ldots,x^p)=H_{\rm NG}(\tau=x^0,\sigma=x^1)f(x^0,\ldots,x^p),\\
&b_i(x^0,\ldots,x^p)=-P_i(\tau=x^0,\sigma=x^1)f(x^0,\ldots,x^p),\\
&\pi^j\partial_j Y^I(x^0,\ldots,x^p)=\partial_\sigma Z^I(\tau=x^0,\sigma=x^1)f(x^0,\ldots,x^p).
\end{aligned} \tag{3.10}$$

Using Eqs. (3.3)–(3.7) and (3.10) we can now verify that Eqs. (2.5), (2.8), and (2.10) are satisfied by this background. Thus in order to construct a solution of the full set of equations of motion (2.5)–(2.10) we need to show that it is possible to find $F_{\mu\nu}$ and Y^I satisfying the constraints (2.6), (2.7), (2.9), (3.8), and (3.9).

First we shall establish the existence of Y^I's satisfying Eqs. (2.9) and (3.8). [Note that the Eq. (3.9) imposes a constraint on Y^I of the form $\partial_\sigma Z^i(\partial_i Y^I P_I+P_i)|_{(\tau,\sigma)=(x^0,x^1)}=0$, but due to Eq. (3.5), this is automatically satisfied once Eq. (3.8) is satisfied.] Using Eqs. (3.6) and (3.10), we shall now write Eqs. (2.9) and (3.8) as follows:

$$\begin{aligned}
&\partial_0 Y^I=\frac{1}{\mathcal{H}_{\rm NG}}(P_I-\partial_i Y^I P_i),\\
&\partial_1 Y^I=(-\partial_\sigma Z^m\partial_m Y^I+\partial_\sigma Z^I),
\end{aligned} \tag{3.11}$$

where the indices m,n,q run from 2 to p, and it will be understood from now on that τ and σ are to be identified with x^0 and x^1, respectively. We can now treat Eqs. (3.11) as the equations determining the x^0 and x^1 evolution of the functions Y^I. (We replace the $\partial_1 Y^I$ appearing on the right-hand side of the first equation by the right-hand side of the second equation.) Existence of a solution to these equations requires the integrability condition:

$$\partial_1\left(\frac{1}{\mathcal{H}_{\rm NG}}(P_I-\partial_m Y^I P_m+P_1(\partial_\sigma Z^m\partial_m Y^I-\partial_\sigma Z^I))\right)-\partial_0((-\partial_\sigma Z^m\partial_m Y^I+\partial_\sigma Z^I))=0. \tag{3.12}$$

It is a straightforward although tedious exercise to show that once Eqs. (3.3) and (3.4) are satisfied, Eq. (3.12) is satisfied.

Thus it remains to show the existence of a set of $F_{\mu\nu}$ satisfying Eqs. (2.6), (2.7), and (3.9). We begin with the F_{mn}'s $(2\leqslant m,n,q\leqslant p)$. We take them to satisfy the following identities:

$$\partial_{[m}F_{nq]}=0, \tag{3.13}$$

and

$$\partial_1 F_{mn} + \partial_1 Z^q[x^0,x^1]\partial_q F_{mn} = 0,$$
$$\partial_0 F_{mn} + \partial_0 Z^q[x^0,x^1]\partial_q F_{mn} = 0. \tag{3.14}$$

To see that it is possible to choose F_{mn}'s satisfying these conditions, we regard Eq. (3.14) as the evolution equation for F_{mn} in x^0 and x^1 from an initial configuration satisfying the Bianchi identities (3.13). It is easy to verify that the evolution equations (3.14) preserve the Bianchi identities at all values of x^0 and x^1. It is also easy to verify the integrability of Eq. (3.14):

$$\partial_0(\partial_1 Z^q[x^0,x^1]\partial_q F_{mn}) - \partial_1(\partial_0 Z^q[x^0,x^1]\partial_q F_{mn}) = 0. \tag{3.15}$$

Given F_{mn} satisfying (3.13) and (3.14), we can use (3.10) to write Eqs. (2.7) and (3.9) as follows:

$$F_{0i} = \frac{1}{\mathcal{H}_{\rm NG}}(\partial_\sigma Z^i + \partial_i Y^I \partial_\sigma Z^I + F_{ij}P_j), \tag{3.16}$$

and

$$F_{i1} = -F_{in}\partial_\sigma Z^n - \partial_i Y^I P_I - P_i\,. \tag{3.17}$$

If Eq. (3.17) is satisfied for $i=m$, then it is also automatically satisfied for $i=1$ with the help of Eqs. (3.5) and (3.11). Thus the independent equations in (3.17) are

$$F_{m1} = -F_{mn}\partial_\sigma Z^n - \partial_m Y^I P_I - P_m\,. \tag{3.18}$$

This gives F_{m1} in terms of F_{mn} and other known quantities. Replacing the F_{m1}'s appearing on the right-hand side of Eq. (3.16) by the right-hand side of Eq. (3.18), we can now regard Eq. (3.16) as expressions for F_{01} and F_{0m} in terms of F_{mn} and other known quantities.

We now need to check that F_{0i} and F_{m1} defined through Eqs. (3.16) and (3.18), satisfy the remaining Bianchi identities:

$$\partial_0 F_{mn} + \partial_m F_{n0} + \partial_n F_{0m} = 0,$$
$$\partial_1 F_{mn} + \partial_m F_{n1} + \partial_n F_{1m} = 0, \tag{3.19}$$
$$\partial_0 F_{m1} + \partial_m F_{10} + \partial_1 F_{0m} = 0.$$

It is straightforward to verify that all of these identities are consequences of Eqs. (3.3), (3.4), (3.11), (3.13), and (3.14). This completes the construction of a solution of the complete set of equations of motion (2.5)–(2.10) of the D-p-brane world-volume field theory.

We shall now make a special choice of the function f:

$$f(x^0,\ldots,x^p) = \prod_{m=2}^{p} \delta(x^m - Z^m(x^0,x^1)), \tag{3.20}$$

which satisfies Eq. (3.7). Furthermore we take

$$Y^I(x^0,x^1,x^m = Z^m(x^0,x^1)) = Z^I(x^0,x^1), \tag{3.21}$$

which can be seen to be compatible with Eq. (3.11). Indeed, Eqs. (3.11) and (3.14) can be interpreted as the requirement of vanishing of the derivatives of $(Y^I - Z^I)$ and F_{mn} along directions tangential to the string world-sheet. Thus we can solve these equations by taking $Y^I - Z^I$ and F_{mn} to be arbitrary functions g^I and g_{mn}, respectively, of $x^2 - Z^2(x^0,x^1),\ldots x^p - Z^p(x^0,x^1)$. Equation (3.21) can then be satisfied by requiring that $g^I(0,\ldots,0) = 0$. The Bianchi identities (3.13) are satisfied by requiring that the functions g_{mn} satisfy $\partial_{[q}g_{mn]} = 0$.

As can be seen from Eq. (3.10), for the choice of f given in Eq. (3.20), the energy density is localized along the surface $x^m = Z^m(x^0,x^1)$ for $2 \leqslant m \leqslant p$. Using Eq. (3.21) we see that in the full $(25+1)$ dimensional space–time, this describes the surface $x^s = Z^s(x^0,x^1)$ for $2 \leqslant s \leqslant 25$. This is precisely the world-sheet of the string described by the Nambu–Goto action (3.1). Thus our analysis shows that whenever the Nambu–Goto equation has a solution described by $Z^s(\sigma,\tau)$, there is a corresponding solution in the D-p-brane world-volume field theory with energy density localized along the world-sheet of the string. In other words, the D-p-brane world-volume theory contains a solution whose dynamics is exactly that of a Nambu–Goto string in $(25+1)$-dimensions.

Note, however, that the freedom of replacing the δ function by an arbitrary function of $x^m - Z^m(x^0,x^1)$ means that besides the usual degrees of freedom of the fundamental string, our solution has additional degrees of freedom which corresponds to the freedom of spreading out the electric flux in directions transverse to the string. Also the overall normalization on the right-hand side of Eq. (3.20), which fixes the tension/charge of the string, is arbitrary. We shall return to these questions in Sec. IV. There are also additional degrees of freedom stemming from the fact that Eqs. (3.11), (3.13), and (3.14) do not determine Y^I and F_{mn} completely for a given configuration of the Nambu–Goto string. This is analogous to the spurious degeneracy found in Ref. 23. It has been argued in Ref. 24 that this apparent degeneracy is due to the wrong choice of variables in describing the theory, and will disappear once we use the correct set of variables.

We shall end this section by writing down the expressions for the conserved Noether currents for the background described previously. This is a straightforward exercise, and the results are as follows:

$$
\begin{aligned}
&T_{00}(x^0,\ldots,x^p) = \mathcal{H}_{\rm NG}(\tau,\sigma) \prod_{m=2}^{p} \delta(x^m - Z^m(\tau,\sigma))\big|_{(\tau,\sigma)=(x^0,x^1)}, \\
&T_{0k}(x^0,\ldots,x^p) = T_{k0}(x^0,\ldots,x^p) = P_k(\tau,\sigma) \prod_{m=2}^{p} \delta(x^m - Z^m(\tau,\sigma))\big|_{(\tau,\sigma)=(x^0,x^1)}, \\
&T_{ki}(x^0,\ldots,x^p) = \frac{1}{\mathcal{H}_{\rm NG}}(\partial_\sigma Z^k \partial_\sigma Z^i - P_k P_i) \prod_{m=2}^{p} \delta(x^m - Z^m(\tau,\sigma))\big|_{(\tau,\sigma)=(x^0,x^1)}, \qquad (3.22) \\

&T_{kI}(x^0,\ldots,x^p) = \frac{1}{\mathcal{H}_{\rm NG}}(\partial_\sigma Z^k \partial_\sigma Z^I - P_k P_I) \prod_{m=2}^{p} \delta(x^m - Z^m(\tau,\sigma))\big|_{(\tau,\sigma)=(x^0,x^1)}.
\end{aligned}
$$

Verification of the conservation laws (2.12) for $T_{\mu\nu}$ and $T_{\mu I}$ is a straightforward application of Eqs. (3.3) and (3.4). It is also a simple exercise to verify that the corresponding conserved charges $\int d^p x\, T_{00}$, $\int d^p x T_{0i}$ and $\int d^p x\, T_{0I}$ agree with the Noether charges of the Nambu–Goto string associated with translation invariance along x^0, x^i, and x^I directions, respectively.

IV. CLOSED STRINGS IN THE D-BRANE WORLD-VOLUME THEORY

In this section we shall use the results of Sec. III to argue that at the tachyonic vacuum the D-brane world-volume theory must contain closed string excitations. Identification of closed strings as closed flux lines has been discussed earlier in Refs. 13, 14, 8, 15, and 16. The present construction is closely related, but differs in that here part of the closed string is formed by an external open string.

We begin with a thought experiment. Consider three well-separated D-branes A, B, and C, and a state on the world volume of this system consisting of a fundamental string stretched from

A to B, and another fundamental string stretched from B to C. Let us now ask: What happens to this state when the tachyon field on the brane B rolls down to its (local) minimum, but the branes A and C remain unchanged. The D-brane world-volume field theory analysis tells us that the ends of the AB and BC strings are source and sink of one unit of electric flux (measured in natural units) on the world-volume of the brane B. Thus the fate of the system is clear: The final configuration will consist of the AB string, the BC string, and an electric flux line (described by the solution given in Sec. III) on the B-brane world-volume connecting the end point of the AB string to the starting point of the BC string. Note that the condition for minimum energy will prevent the flux from spreading out as its source and sink are point objects. (Of course, one would still need to understand why local fluctuations on the string involving the spreading of the flux is absent. Some discussion on this can be found in Refs. 14 and 8.) Furthermore there is precisely one unit of electric flux and hence its tension is equal to that of a fundamental string.[14] Thus it is natural to interpret the flux line as a fundamental string stretched from the end point of the AB string to the starting point of the BC string. (This string, as well as the external AB and BC strings, can adjust their positions and orientations so as to minimize the energy of the configuration.) Thus the net result of this process is a single open string stretched between A and C. It is as if the tachyon condensation on the world-volume of the brane B joins the ends of the AB and BC strings by a fundamental string. Even before tachyon condensation on the brane B, the ends of AB and BC strings could join to produce an AC string. But there it was a perturbative quantum process, whereas the process described here is a nonperturbative classical process.

Now we consider a different system: Take a single D-brane and an open string with both ends on this D-brane. One can use the same argument to conclude that when the tachyon condenses to its ground state, the two ends of the open string will be connected by a flux line, and once we identify the flux line as the fundamental string, we get a closed string state! This argument can be made more concrete as follows. Take a D-brane with one of its transverse directions compact, and consider an open string stretched from the D-brane to its image under translation along the compact direction. Now let us ask what happens to this open string state when the tachyon on the D-brane condenses to its ground state. Since the original state carries fundamental string winding charge this state cannot disappear. To see what happens it is simplest to go to the infinite cover; in this case we have initially an infinite number of parallel D-branes at regular spacing, and between any two neighboring D-branes we have an open string suspended between the two. Thus on any of the D-branes we have an open string ending and another open string starting giving a source and a sink of electric flux. When the tachyon condenses to its ground state, each D-brane develops a flux line joining the source to the sink. If we identify this flux line as a fundamental string as before, the result is a single infinitely long string. After modding out by the discrete translation symmetry to compactify the direction, this is nothing but a closed string wrapped around the compact direction!

Thus we conclude that if we start with a D-brane with a transverse direction compact, then after tachyon condensation the open string field theory on the D-brane world-volume must contain excitations corresponding to closed string winding states along the compact direction. Let us now make a T-duality transformation along the compact direction. This converts the D-p brane to a D-$(p+1)$ brane, but is otherwise a symmetry of the open string field theory order by order in open string perturbation theory. On the other hand this transforms the closed string winding modes to closed string momentum modes. Thus if we start with a D-brane with one of its tangential directions compact, then after tachyon condensation the corresponding open string field theory will contain excitations corresponding to closed string states carrying momentum along the compact direction.

It will be interesting to see if we can study this phenomenon directly in open string field theory.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 42, NUMBER 7 JULY 2001

Sigma model approach to string theory effective actions with tachyons

A. A. Tseytlin[a)]
Department of Physics, The Ohio State University, Columbus, Ohio 43210-1106

(Received 2 January 2001; accepted for publication 13 February 2001)

Motivated by recent discussions of actions for tachyon and vector fields related to tachyon condensation in open string theory we review and clarify some aspects of their derivation within the sigma model approach. In particular, we demonstrate that the renormalized partition function $Z(T,A)$ of the boundary sigma model gives the effective action for massless vectors which is consistent with the string S-matrix and beta function, resolving an old problem with this suggestion in the bosonic string case at the level of the leading $F^2(dF)^2$ derivative corrections to Born–Infeld action. We give a manifestly gauge invariant definition of $Z(T,A)$ in non-Abelian NSR open string theory and check that its derivative reproduces the tachyon beta function in a particular scheme. We also discuss the derivation of similar actions for tachyon and massless modes in closed bosonic and NSR (type 0) string theories. In the bosonic case the tachyon potential has the structure $-T^2e^{-T}$, but it vanishes in the NSR string case. © *2001 American Institute of Physics.*

I. INTRODUCTION

To try to address the question of the vacuum structure of string theory it is natural to look for a kind of field theory action which would interpolate between possible ground states, e.g., unstable perturbative some stable nonperturbative one. The original S-matrix based method[1] of reconstructing the string effective action order by order in powers of fields from on-shell scattering amplitudes does not in principle allow one to find such an action.

It was suggested in Ref. 2 that a natural framework for an off-shell approach should be a generalized two-dimensional (2-D) sigma model partition function representing a generating functional[3] for correlators of string vertex operators given by the Polyakov path integral.[4] The condensates of string fields are then sigma model couplings, and one may hope to determine the exact structure of the action without expanding in powers of them (e.g., expanding instead in derivatives of the fields). One advantage of this sigma model approach is that off-shell gauge symmetries of low-energy expansions become manifest.

The precise definition of the effective action (see Ref. 5 for a review) should be consistent with the string S-matrix near the perturbative vacuum and should also reproduce the conditions of Weyl invariance of the sigma model as its equations of motion.[6–10] (In critical string theory, where, by definition, one does not integrate over the conformal factor of the 2-D metric, the form of the off-shell action depends on a Weyl symmetry gauge, but that dependence should disappear at the stationary points described by 2-D conformal theories.)

While this sigma model partition function approach was successful for the massless string modes leading to covariant expressions to all orders in powers of gravitons and dilatons in the closed string case and the vector field strength in the open string case,[11] it produced unfamiliar expressions when applied to the tachyon field T. As was observed already in Ref. 2, the expression for the partition function $Z[T]$ computed by expanding in derivatives of T has the following

[a)]Also at Blackett Laboratory, Imperial College, London and Lebedev Physics Institute, Moscow. Electronic mail: tseytlin@mps.ohio-state.edu

structure in the critical bosonic string theory (both in the closed string case on the 2-sphere and the open string case on the disk): $Z=a_0\int d^Dx e^{-T}[1+a_1\alpha'\,\partial^2 T+O(\alpha'^2)]$. [For the closed string case this expression is given in Eqs. (39), (40) in Ref. 2. In the critical open string theory case one is to omit an additional integral over the length of the boundary in the expression following Eq. (54) in Ref. 2.] The constant a_1 was renormalization scheme dependent (logarithmically divergent before subtraction). Introducing $\Phi=e^{-T/2}$ and properly tuning a_1 one was able to reproduce the standard tachyon kinetic term. The meaning of that procedure was, however, unclear.

Indeed, to be able to make a connection with the standard tachyonic amplitudes it was obvious that one should expand in powers of T and not derivatives of T as the tachyon momentum should be close to its mass shell value. The corresponding tachyon beta-function then receives contributions which are nonperturbative in α'[6,12,13] and which are in agreement with the tachyonic terms in the effective action reconstructed directly from string amplitudes. The form of the ''tachyon potential,'' i.e., the zero-momentum part of such action is inherently ambiguous,[14,13] as one can always ''dress'' any factor of T by ∂^2 without changing on-shell amplitudes. Thus one needs some extra principle, not apparent at the level of the string S-matrix, to fix this ambiguity.

One could still hope that such extra input was, in fact, contained in the world-sheet sigma model approach. This was effectively vindicated by the recent derivations of the tachyon potential in the open string theory (which were motivated by the study of tachyon condensation on non-BPS D-branes):[15–18] (For some early studies of tachyon condensation see Ref. 19.) $e^{-T}(1+T)$ in the bosonic string case[20,21] and e^{-T^2} in the NSR string case.[22]

While the discussions in Refs. 20–22 were presented in the framework of Witten's background-independent open string field theory,[23,24] their results can be obtained directly in the context of the sigma model approach as we shall review below.

The idea is to return back to the original boundary sigma model[2] containing only the tachyon and massless vector couplings. This model is renormalizable within the standard derivative (α') expansion, i.e., its set of couplings is closed under perturbative RG flow. While one will certainly need to resum the α' expansion to be able to reproduce correct interaction terms at the standard tachyon vacuum point $T=0$, the low-energy expansion (approximate in ∂T but exact in T) may be useful in order to reveal the existence of a new stationary point invisible in perturbation theory near $T=0$.

As was argued in Refs. 10, 25 the tree level effective action $S[A]$ for the massless vector field should be given simply by the *renormalized* partition function of the boundary sigma model, as originally conjectured in Ref. 2. The renormalization of logarithmic infinities corresponds to subtraction of massless poles[10,6,26], while elimination of power divergences by a shift of the bare tachyon coupling accounts for a contribution of the tachyon poles in the massless amplitudes. When consistently implemented, this renormalization procedure resolves (as we shall explain in Sec. II B) an apparent contradiction between $S[A]=Z[A]$ ansatz and string S-matrix found at the level of the $F^2(\partial F)^2$ terms in Ref. 27.

In the presence of a nonzero (renormalized) tachyon background the $S=Z$ prescription requires a modification in the case of *bosonic* string theory. Indeed, $Z'=\partial Z/\partial T$ does not vanish at the standard vacuum point $T=0$, so one needs to make a subtraction of the derivative term $S[T]=Z[T]-T\cdot Z'[0]+\ldots$. A consistent modification of $S=Z$ satisfying $S[0]=0$ was suggested in the context of the Witten's approach.[23,24] $\hat{S}[T]=Z[T]+\beta^T\cdot Z'[T]$, where β^T is the tachyon β-function. This form of subtraction term is a natural one since it preserves the property of RG invariance of the action. This definition then leads to the expression $e^{-T}(1+T)$ for the open bosonic string tachyon potential.[20] We derive the corresponding low-energy effective action in Sec. II A and also generalize it to the presence of a constant F_{mn} background.

The complication of power divergences and associated shift of the tachyon coupling is absent in the case of world-sheet supersymmetric NSR string, where the $S[A]=Z[A]$ prescription is manifestly consistent[27] and, moreover, should apply also in the case of a nonvanishing tachyon background.[22] [In particular, while in the bosonic string the tachyon couples linearly to the fields of the massless sector, it decouples from them in the NSR case (interaction terms are quadratic in T).] We discuss the NSR case in detail in Sec. III, reproducing some of the results of Ref. 22. We

also give a manifestly gauge invariant definition of the partition function in the general non-abelian case and demonstrate that the second-derivative part of the action $S[T]=Z[T]$ taken in a special scheme has its variation over T proportional to the linear perturbative terms in the tachyon β-function. As in the bosonic case, we generalize this action to the presence of a constant F_{mn} background, when the potential term becomes $e^{-T^2}\sqrt{\det(I+F)}$.

One of the lessons of the application of the sigma model approach to open string theory is that the ''global'' covariant objects defined by the sigma model path integral—partition function or effective action—may contain more information than a set of β-functions (or, more precisely, Weyl anomaly coefficients) computed in a local coordinate patch in field (sigma model coupling) space. Indeed, the information on a metric[8] on the coupling space is effectively encoded in Z. The effective action then may have additional stationary points not seen from the β-functions computed in a ''standard'' coordinate patch. This may happen if the field space metric κ becomes degenerate at these points when described in terms of ''standard'' coordinates. For example, the field space may have a nontrivial topology, and thus may need to be represented by several coordinate patches.

It is natural to expect that the same should be true also in the *closed* string case. In Sec. IV we apply the sigma model approach to discuss the tachyon dependence of the effective actions in *closed* bosonic and NSR string theories. In the closed string theory the effective action for the massless modes is determined by the sigma model partition function on a 2-sphere in the following way:[28,29,5] $S[\lambda]=-(\partial Z/\partial \ln \epsilon)_{\epsilon=1}=\beta^i(\partial Z/\partial\lambda)$, so that $S=\int d^Dx\sqrt{G}e^{-2\phi}(\beta^\phi-1/4G^{mn}\beta^G_{mn})$ $=\int d^Dx\sqrt{G}e^{-2\phi}(D-26+\cdots)$. [The extra derivative over the logarithm of 2-D cutoff (compared to the original $S=Z$ conjecture of Ref. 2) accounts for the subtraction of the volume of the Möbius group which is lorathmically divergent in the 2-sphere case[28] (in both bosonic and fermionic string theories).] We shall suggest that like in the open string case, in the presence of a tachyon background this relation should again be modified by subtracting a term proportional to $\partial S/\partial T$ to satisfy the condition $\hat{S}[0]=0$. The resulting tachyon potential is then $-T^2e^{-T}$.

No such modification is necessary in the closed fermionic NSR (or type 0) string case, where we argue that (the NS–NS part of) the effective action depends on the tachyon field only through $(\partial T)^2$ and $\partial^2 T$, i.e., there appears to be *no* tachyon potential.

II. OPEN BOSONIC STRING

Let us first take a formal approach, forgetting about the possible connection to an on-shell string S-matrix and consider the partition function for the (Euclidean) boundary sigma model with two couplings, $I=\int d\varphi[(1/\epsilon)T(x)+iA_m(x)\dot{x}^m]$. This theory is power counting renormalizable if one expands in powers of derivatives of T and A_m, i.e., is closed under RG with all higher-derivative nonrenormalizable interactions (massive string modes) consistently decoupled. One can then ask which is the functional $S[T,A]$ (the boundary analog[30] of the c-function[8]) that reproduces the corresponding perturbative β-functions in the sense of $\partial S/\partial\lambda^i=\kappa_{ij}(\lambda)\beta^j$, $\lambda^i=(T,A_m)$. If we decouple the tachyon (solve for it in terms of A_m) the result should then be the effective action consistent with the S-matrix for the massless vector mode. More generally, such an ''effective action'' functional $S[T,A]$ may represent a natural off-shell extension, capturing non-trivial behavior of string theory far away from the standard tachyonic mass shell. Remarkably, this is indeed what happens to be true, as indicated by the discussions in Refs. 20 and 21.

It is useful to start by recalling the expression for the partition function (or the generating functional for tachyon and vector amplitudes in open string theory on the disk) in the general non-Abelian case[2,11]

$$Z[T,A,\epsilon]=\left\langle \operatorname{tr} P\exp\left(-\int d\varphi[\epsilon^{-1}T(x)+iA_m(x)\dot{x}^m]\right)\right\rangle, \tag{2.1}$$

where the averaging is done with the free string action in the bulk of the disk and $\varphi\in(0,2\pi)$ parametrizes its boundary. Here T and A_m are Hermitian matrices in the Chan–Paton algebra of

$U(N)$. (We consider the oriented string case relevant in the D-brane context and define the action so that continued to the Minkowski signature it becomes real.) $\epsilon = a/r \to 0$ is a dimensionless UV cutoff, i.e., the ratio of the short-distance cutoff and the radius of the disk. $\langle \cdots \rangle$ depends on ϵ through the propagator [see Eq. (2.5)]. One can make (2.1) more explicit by using the well-known representation[31] of path ordered exponent in terms of the path integral over 1-D anticommuting fields $\eta^a, \overline{\eta}_b$ in the fundamental and antifundamental representations of $U(N)$,

$$Z[T,A,\epsilon] = \left\langle \int [d\eta][d\overline{\eta}] \exp\left(- \int d\varphi [\, \overline{\eta}_a \dot{\eta}^a + \overline{\eta}_a (\epsilon^{-1} T^a_b(x) + i A^a_{bm}(x) \dot{x}^m) \eta^b] \right) \right\rangle. \quad (2.2)$$

The measure of integration is assumed to contain the factor $\overline{\eta}_c(0)\,\eta^c(2\pi)$. In the Abelian case (2.1) is simply

$$Z[T,A,\epsilon] = \langle e^{-\int d\varphi [\epsilon^{-1} T(x) + i A_m(x) \dot{x}^m]} \rangle. \quad (2.3)$$

The standard procedure[2,11,25] to compute Z is to first isolate the constant (''zero mode'') part of x^m and integrate over the internal points of the disk getting an effective 1-D path integral for the boundary theory

$$Z = a_0 \int d^D x\, \epsilon^{-W}, \quad e^{-W} = \langle e^{-I} \rangle = \int [d\xi] e^{-(1/4\pi\alpha') \int \xi G^{-1} \xi - I}, \quad (2.4)$$

$$G(\varphi_1, \varphi_2) = \frac{1}{\pi} \sum_{n=1}^{\infty} \frac{e^{-n\epsilon}}{n} \cos n\varphi_{12}, \quad \varphi_{12} = \varphi_1 - \varphi_2, \quad (2.5)$$

$$I = \int d\varphi \left[\epsilon^{-1} \left(T + \frac{1}{2} \xi^m \xi^k \partial_m \partial_k T + \frac{1}{6} \xi^m \xi^k \xi^l \partial_m \partial_k \partial_l T + \cdots \right) + i \left(\frac{1}{2} \xi^k F_{km} + \frac{1}{3} \xi^k \xi^l \partial_l F_{km} + \cdots \right) \dot{\xi}^m \right]. \quad (2.6)$$

We have shifted $x(\varphi) \to x + \xi(\varphi)$, $\int_0^{2\pi} d\varphi\, \xi(\varphi) = 0$ (so that W contains contributions of 1PI graphs only). In what follows we shall often set the inverse string tension $2\pi\alpha'$ to one, but the dependence on α' is easy to restore on dimensional grounds, $\partial^k T \to (\sqrt{2\pi\alpha'}\partial)^k T$, $\partial^k F_{mn} \to (\sqrt{2\pi\alpha'}\partial)^k (2\pi\alpha' F_{mn})$.

If one ignores all higher than second powers in ξ, i.e., assumes that $\partial_m \partial_n T$ and F_{mn} are constant, the resulting path integral becomes Gaussian and can be computed explicitly, as was done for $T=0$ in Ref. 11 (see also Ref. 32) and including $\partial_m \partial_n T$ in Ref. 33–36.

One may ''resum'' the perturbative expansion by including the $F\xi\xi$ term into the propagator;[37] regularizing the final expression one gets[25,27]

$$G^{mn}(\varphi_1, \varphi_2 | F) = \frac{1}{\pi} \sum_{n=1}^{\infty} \frac{e^{-\epsilon n}}{n} [\mathcal{G}^{mn}(F) \cos n\varphi_{12} - i \mathcal{H}^{mn}(F) \sin n\varphi_{12}], \quad (2.7)$$

$$\mathcal{G}^{mn}(F) \equiv [(I+F)^{-1}]^{(mn)} = [(I-F^2)^{-1}]^{mn} = \delta^{mn} + F^{mk} F^{kn} + \cdots, \quad (2.8)$$

$$\mathcal{H}^{mn} \equiv -[(I+F)^{-1}]^{[mn]} = [F(I-F^2)^{-1}]^{mn} = F^{mk} \mathcal{G}^{kn}.$$

It is then straightforward to compute the leading terms in the expansion of Z in derivatives of T and F but to all orders in F_{mn}.

The model (2.2), (2.3) is renormalizable in the derivative (α') expansion, so that T and A_m in (2.2) or (2.3) should be interpreted as ϵ-dependent bare couplings which cancel all the divergent terms, i.e.,[25]

$$Z[T(\epsilon), A(\epsilon), \epsilon] = Z_R[T_R, A_R], \quad (2.9)$$

where

$$T(\epsilon)=\frac{1}{2\pi}\epsilon[1+h_1(A_R)\ln\epsilon+h_2(A_R)\ln^2\epsilon+\cdots]T_R+[k_1(A_R)+k_2(A_R)\ln\epsilon+\cdots], \quad (2.10)$$

$$A(\epsilon)=A_R+f_1(A_R)\ln\epsilon+f_2(A_R)\ln^2\epsilon+\cdots. \quad (2.11)$$

Here the renormalized fields are defined at point $2\pi r$ and h_i contain differential operators acting on T_R. For example, it is easy to show that in the Abelian case and for the constant F_{mn} background,

$$h_1(A)T=\frac{1}{2\pi}\mathcal{G}^{mn}(F)\partial_m\partial_n T,\ \ [f_1(A)]_k=\frac{1}{2\pi}\mathcal{G}^{mn}(F)\partial_m F_{nk}. \quad (2.12)$$

f_1 represents the ''Born–Infeld'' β-function.[37,38] The inhomogeneous term in (2.10),[25]

$$k_1=-\frac{1}{4\pi}\ln\det(\delta_{mn}+F_{mn})=-\frac{1}{8\pi}F_{mn}^2+O(F^4), \quad (2.13)$$

corresponds to a shift of the bare tachyon needed to be done to absorb the F_{mn}-dependent linear divergence appearing in the computation of Z for $F_{mn}=\text{const}$ leading to the BI action,[11,25]

$$W=b_0\ln\det(\delta_{mn}+F_{mn}),\quad b_0=\sum_{n=1}^{\infty}e^{-2\epsilon n}=\frac{1}{2\epsilon}-\frac{1}{2}+O(\epsilon). \quad (2.14)$$

If one subtracts the term (2.13) from the beginning, it will not appear in the corresponding β^T-function. This is a scheme-dependent[39] property, as one can of course induce a similar term back by a field redefinition, $T\to T+f(F)$. (A similar inhomogeneous term does not appear in the tachyon β-function in the closed string case if one uses the natural scheme in which the general covariance of the theory is manifest.[13]) This scheme is fixed by the requirement that the corresponding effective action with $T=0$ and $F_{mn}=\text{const}$ is given simply by the BI action (which itself is related, via the D-brane action connection, to basic reparametrization symmetry of the underlying string theory). The subtraction of (2.13) to be done in the bare partition function will play an important role in Sec. II B.

The renormalized value of the partition function takes the form (here and in what follows we omit subscripts ''R'' on the renormalized value of Z and the fields)

$$Z=a_0\int d^Dx e^{-T}\sqrt{\det(\delta_{mn}+F_{mn})}[1+a_1\alpha'\mathcal{G}^{mn}(F)\partial_m\partial_n T + \mathcal{F}^{kmnacd}(F)\partial_k F_{mn}\partial_a F_{cd}+O(\partial^4 T,\partial^4 F^k)], \quad (2.15)$$

where $\mathcal{F}^{kmnacd}(F)\sim F^2+F^4+\cdots$[27] and $\alpha'=1/2\pi$ (i.e., $2\pi\alpha'=1$).

The coefficient a_1 is logarithmically divergent before renormalization $[\pi G(\varphi,\varphi)=\Sigma_{n=1}^{\infty}(1/n)e^{-\epsilon n}=-\ln\epsilon+O(\epsilon)]$ and thus is scheme dependent, i.e., its value can be changed by a field redefinition.[39,25]

A. Tachyon action

Let us first set $F_{mn}=0$ and consider the dependence of Z (2.15) on T,

$$Z=a_0\int d^Dx e^{-T}(1+a_1\alpha'\,\partial^2 T+\cdots)=a_0\int d^Dx e^{-T}[1+a_1\alpha'(\partial T)^2+\cdots], \quad (2.16)$$

i.e.,

$$Z = a_0 \int d^D x [\Phi^2 + 4 a_1 \alpha' (\partial \Phi)^2 + \cdots], \quad \Phi \equiv e^{-T/2}. \tag{2.17}$$

This expression which looks like an action for a massive field with $m^2 = (4 a_1 \alpha')^{-1}$ was first found in Ref. 2. However, its derivative does not vanish for $T=0$, i.e., does not reproduce the perturbative tachyon coupling β-function which is given, to all orders in the α' expansion, simply by

$$\beta^T = -T - \alpha' \partial^2 T. \tag{2.18}$$

This suggests that in the *bosonic* open string theory, the definition of the effective action as the renormalized sigma model partition function Z[2,25] needs a modification when the tachyon background is nonzero. The required refinement of the $S=Z$ relation was suggested in Refs. 23, 24: to define an action functional which will be stationary at conformal points one is to add an extra derivative term,

$$\hat{S} = S + \beta^T \cdot \frac{\delta}{\delta T} S = Z + \beta^T \cdot \frac{\delta}{\delta T} Z. \tag{2.19}$$

The second subtraction term is a natural one as it preserves the property of RG invariance of the action. Note that $\hat{S}$ and Z are equal at the stationary points of $\hat{S}$. Also,

$$\hat{S}[T] = S[T + \beta^T] + O((\beta^T)^2) = \epsilon^{\beta^T \cdot \delta / \delta T} Z[T] + O((\beta^T)^2), \tag{2.20}$$

i.e., changing from $S=Z$ to $\hat{S}$ may look like a field redefinition of T. This redefinition is, however, singular in the case of the tachyon coupling.

In general, if for a set of fields (sigma model couplings) λ^i which is closed under the RG one has[23,24]

$$\hat{S} = Z + \beta^i \partial_i Z, \quad \partial_i \hat{S} = \kappa_{ij} \beta^j; \tag{2.21}$$

then

$$\partial_i \hat{S} = \partial_i Z + \partial_i \beta^j \partial_j Z + \beta^j \partial_i \partial_j Z, \tag{2.22}$$

$$(\kappa_{ij} - \partial_i \partial_j Z) \beta^j = (\delta_i^j + \partial_i \beta^j) \partial_j Z, \tag{2.23}$$

so that $\partial_j Z = 0$ may not imply $\beta^j = 0$ if the ''shifted'' matrix of anomalous dimensions $\delta_i^j + \partial_i \beta^j$ is degenerate in some limit (e.g., at low momenta). This is precisely what happens in the tachyon field case [cf. (2.18)], so that the modification (2.19) is important here.

Using (2.16), (2.18) we find that (2.19) is given, to the leading order in derivatives of T, by (cf. Refs. 20, 21)

$$\hat{S} = a_0 \int d^D x e^{-T} [1 + T + (1 - a_1) \alpha' (\partial T)^2 + a_1 \alpha' T (\partial T)^2 + O(\partial^4 T)]. \tag{2.24}$$

Choosing a *special* scheme where

$$a_1 = \tfrac{1}{2}, \tag{2.25}$$

one finally gets

$$\hat{S} = a_0 \int d^D x e^{-T} \left[(1+T) \left(1 + \frac{1}{2} \alpha' \partial^m T \partial_m T \right) + O(\partial^4 T) \right]. \tag{2.26}$$

Then

$$\frac{\delta\hat{S}}{\delta T}=a_0 e^{-T}\Big[-T-\alpha'\,\partial^2 T-\alpha' T\,\partial^2 T+\frac{1}{2}\alpha' T(\partial T)^2+O(\alpha'^2\,\partial^4 T)\Big], \tag{2.27}$$

which is indeed proportional to the β^T-function (2.18) to the leading order in T.[20,21] Here e^{-T} should be interpreted as the field space metric $\kappa_{TT}(T)$ in (2.21) and the nonlinear terms in T should be redefinable away [within α' or derivative expansion (2.18) should be the exact expression for the β^T-function]. Equation (2.27) has two obvious zeros: $T=0$ and $T=\infty$ with the second one related to the tachyon condensation.[16,21] [Another solution $T(x)=a+ux^2$ with finite constants a, u[21] is an artifact of α' expansion (it does not correspond to a conformal 2-D theory).]

Including a $F_{mn}=$const background we get the following generalization of (2.15), (2.24):

$$\hat{S}=a_0\int d^D x e^{-T}\sqrt{\det(\delta_{mn}+F_{mn})}\Big[1+T+\frac{1}{2}\alpha'\mathcal{G}^{mn}(F)\partial_m\partial_n T+\cdots\Big], \tag{2.28}$$

or

$$\hat{S}=a_0\int d^D x e^{-T}\sqrt{\det(\delta_{mn}+2\pi\alpha' F_{mn})}\Big[(1+T)\Big[1+\frac{1}{2}\alpha'\mathcal{G}^{mn}(2\pi\alpha' F)\partial_m T\,\partial_n T\Big] + O(\alpha'^2\,\partial^4 T,\alpha'^2\,\partial^2 F)\Big], \tag{2.29}$$

where we restored the full dependence on α'. The variation of this action is proportional the β^T-function (2.18) with $\partial^2 T$ replaced by $\mathcal{G}^{mn}(F)\partial_m\,\partial_n T$ [in agreement with (2.12)], and which does not contain the inhomogeneous term (2.13).

One may raise the question of why the action (2.29) is consistent with the string S-matrix which contains a nonvanishing tachyon–vector–vector amplitude. The latter can be reproduced by the TF_{mn}^2 term in the effective action but such a term is not present in (2.29). However, the term $-\alpha' F_{mn}^2\,\partial^2 T$ (or $-2\alpha' T\,\partial_k F_{mn}\,\partial_k F_{mn}$) leads to the same on-shell 3-point amplitude since for the on-shell tachyon $\alpha'\,\partial^2 T=-T$. Such a higher derivative term is indeed present in (2.28) or (2.29). The corresponding $\partial_k F_{mn}\,\partial_k F_{mn}$ term in (2.27) or in the tachyon β-function is not visible in the α' expansion but can be reproduced if one expands in powers of the fields instead of powers of derivatives and sums all orders in α' (see Ref. 12). [This case is completely analogous to the RT vs $R_{mnkl}^2 T$ contribution (giving the same on-shell graviton–graviton–tachyon amplitude) in the closed string effective action discussed in Ref. 13].

B. Vector field action

Let us now set T to zero and consider the dependence of Z on the vector field A_m. In view of the arguments given in Refs. 10, 25, 27 the effective action $S[A]$ which reproduces the string S-matrix and is also consistent with the expression for the vector field β^A-function in the boundary sigma model should be given simply by the *renormalized* value of the sigma model partition function,

$$S[A_R]=Z_R[A_R,T_R=0]. \tag{2.30}$$

We shall again omit subscripts ''R'' below.

This relation passes a number of nontrivial tests. In the Abelian case, for $F_{mn}=$const one finds that Z is equal to the BI action[11] whose derivative over A_m is indeed to be proportional to the leading one-loop term $-\alpha'\mathcal{G}^{mn}(F)\partial_m F_{nk}$ in the β^A-function.[37] The F^4 term in the expansion of the BI action is also in agreement with the string 4-point amplitude.[10,40] In the non-Abelian case, the direct computation of $Z(A)$ defined by (2.3) gives, after a renormalization,[25]

$$Z=a_0\int d^Dx\,\mathrm{tr}\Big[1-(2\pi\alpha')^2\Big[\frac{1}{4}F_{mn}^2+\frac{2}{3}\alpha' F_{mn}F_{nk}F_{km}+d_1\alpha'(D_mF_{mn})^2\Big]+O(\alpha'^4)\Big], \tag{2.31}$$

where d_1 is scheme-dependent. This coincides with the non-Abelian F^2+F^3 terms in the action reconstructed from the bosonic string S-matrix.[1,10]

There was, however, a problem with $S=Z$ ansatz (2.30) in the *bosonic* string case pointed out in Ref. 27. The direct computation of the leading derivative ∂F-dependent terms in the Abelian partition function (2.3) gave the following expression $(2\pi\alpha'=1)$:[27]

$$Z=a_0\int d^Dx\Big[1+\frac{1}{4}F_{mn}^2-\frac{1}{8}\Big[(F_{mk}F_{kn})^2-\frac{1}{4}(F_{mn}^2)^2\Big]+b_1F_{kl}F_{kl}\,\partial_aF_{mn}\,\partial_aF_{mn}$$
$$+b_2F_{kl}F_{lm}\,\partial_aF_{mn}\,\partial_aF_{nk}+b_3F_{la}F_{lb}\,\partial_aF_{mn}\,\partial_bF_{mn}+O(\partial^2F^6)\Big], \tag{2.32}$$

where

$$b_1=\frac{1}{24\pi},\quad b_2=-\frac{1}{6\pi},\quad b_3=\frac{1}{12\pi}, \tag{2.33}$$

and we have ignored all terms which have scheme-dependent coefficients (i.e., vanish on $\partial_mF_{mn}=0$). At the same time, both the string 4-point amplitude[27] and the 2-loop sigma model β^A-function calculation[41] led to the action (2.32) with the coefficients

$$b_1=-\frac{1}{48\pi},\quad b_2=-\frac{1}{6\pi},\quad b_3=\frac{1}{12\pi}, \tag{2.34}$$

i.e., with the *same* b_2 and b_3 but with b_1 differing by factor $-1/2$. This apparent disagreement of the $S=Z$ ansatz with the S-matrix and the β^A-function was attributed in Ref. 27 to the presence of the tachyon in the bosonic string. The tachyon poles are formally expanded in momenta in the derivation of the massless field effective action from the string S-matrix, and it was suggested that the corresponding subtraction of power divergences in Z may be hard to implement unambiguously.

This problem has, in fact, a very simple resolution implied by the definition (2.30): a particular ''tachyon-related'' $F^2\,\partial F\,\partial F$ term was missed in Ref. 27 since the tachyon field there was set equal to zero *before* properly subtracting the linearly divergent F-dependent term (2.13). This subtraction effectively accounts for the contribution coming from the expansion of the tachyonic pole in the 4-vector amplitude which is included in the effective action if it is reconstructed from the S-matrix. Once this extra term is added, the agreement between $S[A]$ and $Z[A]$ is indeed restored!

As was stressed above, the effective action should be given by the *renormalized* value of $Z[A]$. The bare partition function has the same structure as (2.15) [with $T\equiv T_R\to(2\pi/\epsilon)T$] but in addition it contains the linearly divergent term in the exponent $e^{(2\pi/\epsilon)k_1}$ [see (2.14), (2.13)]. Shifting the bare tachyon (2.10) to absorb this linear divergence (and then setting $T_R=0$) introduces extra ∂F-dependent terms effectively originating from the ∂^2T term in (2.15). Explicitly, applying the *same* computational scheme [ϵ-regularization in (2.5) plus minimal subtraction] that was used in the original computation of (2.32), (2.33) in Ref. 27 one finds the following expression for $Z(T,A)$ in (2.4), (2.5) $(2\pi\alpha'=1)$, (In the form described below this computation was done by Andreev. It corrects the original version of this argument.)

$$Z=\int d^Dx\,e^{-(2\pi/\epsilon)T}[1+k_1(\epsilon)\partial^2T+k_2(\epsilon)F_{mn}^2+k_3(\epsilon)F_{mn}^2\,\partial^2T+k_4(\epsilon)F^{km}F^{kn}\partial_m\,\partial_nT+O(\partial^4)], \tag{2.35}$$

where

$$k_1=-\epsilon^{-1}I_1(\epsilon),\quad k_2=-\tfrac{1}{2}I_0(2\epsilon),\quad k_3=\tfrac{1}{2}\epsilon^{-1}I_0(2\epsilon)I_1(\epsilon),\quad k_4=\epsilon^{-1}I_1(3\epsilon),\quad (2.36)$$

and

$$I_0(\epsilon)\equiv\sum_{n=1}^{\infty} e^{-\epsilon n}=(e^{\epsilon}-1)^{-1}=\frac{1}{\epsilon}-\frac{1}{2}+\frac{\epsilon}{12}+O(\epsilon^2),\quad (2.37)$$

$$I_1(\epsilon)\equiv\sum_{n=1}^{\infty}\frac{1}{n}e^{-\epsilon n}=-\ln(1-e^{-\epsilon})=-\ln\epsilon+\frac{1}{2}\epsilon+O(\epsilon^2).\quad (2.38)$$

To cancel the leading power divergences in the F_{mn}^2 and $F_{mn}^2\,\partial^2 T$ terms one is to shift $T\to T-(1/8\pi)F_{mn}^2$ in the exponent. Using the *minimal* subtraction to absorb the singular logarithmic parts of the coefficients k_i into the bare couplings T and A_m one is left with the following values for their finite $(\epsilon\to 0)$ parts: $(k_2)_{\rm fin}=1/4$, $(k_3)_{\rm fin}=-1/8$, $(k_4)_{\rm fin}=3/2$. The additional $F^2\partial\partial F^2$ terms coming from (2.35) that should be added to (2.32) are then

$$\Delta Z=a_0\int d^Dx\left(\frac{1}{16\pi}\right)\left[\frac{1}{4}F_{kl}^2\partial^2(F_{mn}^2)-3F_{pq}^2\partial_m\partial_n(F_{mk}F_{nk})\right].\quad (2.39)$$

Using $\partial_{[k}F_{mn]}=0$ and dropping terms proportional to the equations of motion so that $\partial_nF_{mk}\,\partial_mF_{nk}=1/2\partial_kF_{mn}\,\partial_kF_{mn}+O(\partial_mF_{mn})$, we find

$$\Delta Z=a_0\int d^Dx\left(-\frac{1}{16\pi}\right)F_{pq}F_{pq}\,\partial_kF_{mn}\,\partial_kF_{mn}\,.\quad (2.40)$$

Thus this ''tachyonic'' correction contributes only to the coefficient of the first $F^2\,\partial F\,\partial F$ term in (2.32),

$$b_1\to b_1-\frac{1}{16\pi},\quad (2.41)$$

changing it precisely into the b_1 in (2.34). This implies the *equivalence* of the leading ∂F derivative terms in the effective actions obtained (i) from the partition function, (ii) from the string S-matrix, and (iii) from the β^A-function.

III. OPEN NSR STRING

Ignoring first the tachyon, the analog of the partition function (2.3), (2.4) which is the generating functional for massless vector scattering amplitudes is given by[10,42,27]

$$Z(A)=\left\langle \mathrm{tr}P\,\exp\left(-i\int d\varphi\left[\dot{x}^mA_m(x)-\frac{1}{2}\psi^m\psi^nF_{mn}(x)\right]\right)\right\rangle$$
$$=\int d^Dx\left\langle \mathrm{tr}P\,\exp\left(-i\int d\varphi\left[\dot{\xi}^mA_m(x+\xi)-\frac{1}{2}\psi^m\psi^nF_{mn}(x+\xi)\right]\right)\right\rangle,\quad (3.1)$$

where the averaging is done with the free string propagator restricted to the boundary of the disk, i.e., with the effective 1-D boundary action $I_0=(1/4\pi\alpha')\int(\xi G^{-1}\xi+\psi K^{-1}\psi)$ with periodic $\xi^m(\varphi)$ and antiperiodic $\psi^m(\varphi)$. The bosonic Green's function in (2.5) is now supplemented by the fermionic one,

$$G(\varphi_1,\varphi_2)=\frac{1}{\pi}\sum_{n=1}^{\infty}\frac{e^{-n\epsilon}}{n}\cos n\varphi_{12},\quad K(\varphi_1,\varphi_2)=\frac{1}{\pi}\sum_{r=1/2}^{\infty}e^{-r\epsilon}\sin r\varphi_{12}. \tag{3.2}$$

As discussed in Ref. 27, the $\epsilon\to+0$ regularization preserves underlying 1-D supersymmetry (which is spontaneously broken by the antiperiodic boundary condition on ψ^m, i.e., is an ''asymptotic'' symmetry).

P in (3.1) stands for the standard path ordering. The contact $[A_m,A_n]$ term in F_{mn} implying manifest non-Abelian gauge invariance of the resulting amplitudes can be derived[42,27] from the contact terms in the supersymmetric theta-functions in the manifestly 1-D supersymmetric definition of the path ordering (see also below).

To include the tachyon field, one may start with the standard NS[43] vertex operator $\int d\varphi\psi^m\partial_m T(x)$. This coupling cannot, however, be added directly into the exponent in (3.1) as ψ is Grassmann while T is not (integrating ψ^m out would leave no dependence on T). To get a nonzero answer for the correlators one is to properly order the interaction vertices. A simple way to do that, as suggested in Ref. 44 and elaborated on in Refs. 16, 22, is to introduce a nondynamical 1-D anticommuting, real, antiperiodic field $\zeta(\varphi)$, and to add to the action the following terms $\int d\varphi[\zeta\dot{\zeta}+i\zeta\psi^m\partial_m T(x)]$.

A. General non-Abelian case

More precisely, to automatically include the contact terms which will make the non-Abelian gauge invariance explicit, one is to insist on manifest world-sheet supersymmetry of the sigma model interaction terms.[45,42,27] As in Refs. 46, 27 here this is accomplished by replacing x^m by the 1-D scalar superfields $\hat{x}^m=x^m+\theta\psi^m$, and the $U(N)$ ''quarks'' η^a, $\overline{\eta}_\alpha$ in (2.2) and the new variable ζ by the ''spinor'' superfields $\hat{\eta}^a=\eta^a+\theta\chi^a$, $\hat{\overline{\eta}}_a=\overline{\eta}_a+\theta\overline{\chi}_a$ and $\hat{\zeta}=\zeta+\theta f$. This ensures the 1-D supersymmetry of the path ordering.[42,27] The resulting partition function is given by the path integral over $\hat{x}^m$, $\hat{\eta}$, $\hat{\overline{\eta}}$, $\hat{\zeta}$ similar to (2.2), with the interaction part of the action now being

$$I=-\int d\varphi\, d\theta(\hat{\overline{\eta}}D\hat{\eta}+\hat{\zeta}D\hat{\zeta}+i\hat{\overline{\eta}}[\hat{\zeta}\mathcal{T}(\hat{x})+A_m(\hat{x})D\hat{x}^m]\hat{\eta}), \tag{3.3}$$

where $D\equiv\theta\partial_\varphi-\partial_\theta$ and we suppressed the $U(N)$ indices on $\hat{\eta}^a$, $\hat{\overline{\eta}}_a$ and the fields $\mathcal{T}^a_b$, A^a_{bm}. Here $\mathcal{T}$ is the bare tachyon, i.e., $\mathcal{T}\sim(1/\sqrt{\epsilon})T$.

The component form of (3.3) is

$$\begin{aligned}I=\int d\varphi[&\overline{\eta}\dot{\eta}+\zeta\dot{\zeta}+f^2+\overline{\chi}\chi+i\overline{\eta}(\mathcal{T}\zeta+A_m\psi^m)\chi-i\overline{\chi}(\mathcal{T}\zeta-A_m\psi^m)\eta\\&+i\overline{\eta}[f\mathcal{T}-\zeta\psi^m\partial_m\mathcal{T}+(A_m\dot{x}^m-\psi^m\psi^n\partial_m A_n)]\eta].\end{aligned} \tag{3.4}$$

This action is manifestly 1-D supersymmetric, but its non-Abelian gauge invariance becomes apparent only after integrating over the auxiliary fields χ, $\overline{\chi}$,

$$I=\int d\varphi\left[\overline{\eta}\dot{\eta}+\zeta\dot{\zeta}+f^2+i\overline{\eta}\left[f\mathcal{T}-\zeta\psi^m\mathrm{D}_m\mathcal{T}+\left(A_m\dot{x}^m-\frac{1}{2}\psi^m\psi^nF_{mn}\right)\right]\eta\right], \tag{3.5}$$

where

$$\mathrm{D}_m\mathcal{T}=\partial_m\mathcal{T}+i[A_m,\mathcal{T}],\quad F_{mn}=\partial_mA_n-\partial_nA_m+i[A_m,A_n].$$

Integration over the auxiliary field f gives

$$I=\int d\varphi\left[\overline{\eta}\dot{\eta}+\zeta\dot{\zeta}+\frac{1}{4}(\overline{\eta}\mathcal{T}\eta)^2+i\overline{\eta}\left[-\zeta\psi^m\mathrm{D}_m\mathcal{T}+\left(A_m\dot{x}^m-\frac{1}{2}\psi^m\psi^nF_{mn}\right)\right]\eta\right]. \tag{3.6}$$

Finally, integrating over ζ we find

$$I=\int d\varphi\Big[\overline{\eta}\dot{\eta}+\frac{1}{4}(\overline{\eta}\mathcal{T}\eta)^2-\frac{1}{4}(\psi^m\overline{\eta}D_m\mathcal{T}\eta)\partial_\varphi^{-1}(\psi^n\overline{\eta}D_n\mathcal{T}\eta)+i\overline{\eta}\Big(A_m\dot{x}^m-\frac{1}{2}\psi^m\psi^nF_{mn}\Big)\eta\Big]. \tag{3.7}$$

Here [cf. (3.2)]

$$\partial_\varphi^{-1}(\varphi_1,\varphi_2)=\frac{1}{\pi}\sum_{r=1/2}^{\infty}\frac{1}{r}\sin r\varphi_{12}. \tag{3.8}$$

[Note that the δ-function defined on antiperiodic functions is $\delta^{(-)}(\varphi_1,\varphi_2)=(1/\pi)\Sigma_{r=1/2}^{\infty}\cos r\varphi_{12}$ so that (ignoring regularization; cf. Ref. 27) $K\cdot K=-\delta^{(-)}$ and $\partial_\varphi\cdot\partial_\varphi^{-1}=\delta^{(-)}$, $\partial_{\varphi_1}(\varphi_1,\varphi_2)\equiv\partial_{\varphi_1}\delta^{(-)}(\varphi_1,\varphi_2)=-(1/\pi)\Sigma_{r=1/2}^{\infty}r\sin r\varphi_{12}$. One could think of using the regularized expression $\partial_\varphi^{-1}(\varphi_1,\varphi_2)=(1/\pi)\Sigma_{r=1/2}^{\infty}(e^{-re}/r)\sin r\varphi_{12}$, but that leads to complicated expressions as it should be accompanied by a similar regularization in the f^2 term to preserve 1-D supersymmetry.] The resulting derivative expansion of Z is thus expressed in terms of $\mathcal{T}$, F_{mn} and their covariant derivatives.

In the Abelian $U(1)$ case the integral over η, $\overline{\eta}$ in (3.5) is trivial and the tachyonic part of (3.7) becomes equivalent to the terms originally derived in Refs. 16, 22 [cf. (2.3)]

$$I=\int d\varphi\Big(\frac{1}{4}\mathcal{T}^2(x)-\frac{1}{4}[\psi^m\partial_m\mathcal{T}(x)]\partial_\varphi^{-1}[\psi^n\partial_n\mathcal{T}(x)]+i\Big[A_m(x)\dot{x}^m-\frac{1}{2}\psi^m\psi^nF_{mn}(x)\Big]\Big). \tag{3.9}$$

It is easy to check directly that this action is invariant under 1-D supersymmetry $\delta x^m=\psi^m\epsilon$, $\delta\psi^m=\partial_\varphi x^m\,\epsilon$. Note that if $\mathcal{T}$ is a constant non-Abelian matrix then the path ordering [the integral over η in (3.5)] is not relevant, and integrating over f one gets the potential factor $\mathrm{tr}e^{-(\pi/2)\mathcal{T}}$.[22] In general, however, the non-Abelian generalization of (3.9) consistent with 1-D supersymmetry is obtained by using (3.7) [and not by adding trace with ordinary path ordering to (3.9)].

This 1-D supersymmetric theory defined by (3.2), (3.9),

$$Z[\mathcal{T},A]=\int d^Dx e^{-W},\quad e^{-W}=\langle e^{-I[x+\xi,\psi]}\rangle,$$
$$\langle\cdots\rangle=\int[d\xi][d\psi]e^{-(1/4\pi\alpha')\int(\xi G^{-1}\xi+\psi K^{-1}\psi)}, \tag{3.10}$$

has only logarithmic UV divergences, i.e., all power divergences cancel out.[47,27] This is true in the general non-Abelian case, and also in the presence of supersymmetric higher-derivative interactions, and is implied, e.g., by the nonlocal form of the 1-D supersymmetric lowest-dimension interaction in (3.7), (3.9).

In particular, there is no inhomogeneous F-dependent term (2.13) in the analog of (2.10). Indeed, the coefficient in the analog of (2.14) (i.e., in Z computed for $F_{mn}=\mathrm{const}$) now has both bosonic and fermionic contributions and is finite as a result:[47]

$$b_0=\sum_{n=1}^{\infty}e^{-2\epsilon n}-\sum_{r=1/2}^{\infty}e^{-2\epsilon r}=-\frac{1}{2}+O(\epsilon). \tag{3.11}$$

This cancellation of power divergences makes the NSR string partition function $Z[A,\mathcal{T},\ldots]$ much better defined than in the bosonic string case.

One consequence is that the tachyon field manifestly decouples from the massless vector sector. This follows of course from the conservation of G-parity ($\psi^m\to-\psi^m,\theta\to-\theta$) under

which the tachyonic vertex is odd, while the vector vertex is even. In the S-matrix language, there are no tachyonic poles in the massless NS vector amplitudes (so that the theory has of course consistent superstring truncation). Equivalently, this is obvious from (3.9) where $\mathcal{T}$ appears only quadratically.

As a result, the subtleties like the one discussed in Sec. II B do not appear in the NSR case, and the renormalized partition function $Z[A_R, \mathcal{T}_R=0]$ gives directly the vector field effective action consistent with the string S-matrix and β^A-function.[27] (Renormalization of logarithmic divergences corresponding to the subtraction of massless poles in the string amplitudes is still needed in order to define the effective action.) For example, it was demonstrated in Ref. 27 that the leading derivative correction to the BI term in the partition function Z (3.10), (3.9) which has the structure $F^2(\partial\partial F)^2$ is exactly the same as in the action reconstructed from the 4-point NSR string vector amplitude.

B. Tachyon action and correspondence with β-function

Let us compute the leading $\mathcal{T}$-dependent terms in the Abelian partition function (3.10) using a derivative expansion. Expanding in powers of the quantum fields ξ, ψ one finds

$$I=\frac{1}{4}\int d\varphi[\mathcal{T}^2(x+\xi)-[\psi^m\partial_m\mathcal{T}(x+\xi)]\partial_\varphi^{-1}[\psi^n\partial_n\mathcal{T}(x+\xi)]]$$

$$=\frac{1}{4}\int d\varphi[\mathcal{T}^2+(\mathcal{T}\partial_m\partial_n\mathcal{T}+\partial_m\mathcal{T}\,\partial_n\mathcal{T})\xi^m\xi^n-\psi^m\partial_m\mathcal{T}\,\partial_\varphi^{-1}\psi^n\partial_n\mathcal{T}+O(\xi^3,\psi^2\xi)]. \quad (3.12)$$

The leading one-loop contribution to (3.9) is thus ($2\pi\alpha'=1$)

$$W=\frac{\pi}{2}(\mathcal{T}^2+s_1\mathcal{T}\,\partial^2\mathcal{T}+s_2\partial_m\mathcal{T}\,\partial_m\mathcal{T})+O(\partial^4), \quad (3.13)$$

where

$$s_1=G(\varphi,\varphi)=\frac{1}{\pi}\sum_{n=1}^{\infty}\frac{e^{-\epsilon n}}{n}=-\frac{1}{\pi}\ln\epsilon+O(\epsilon), \quad (3.14)$$

$$s_2=(G+K\cdot\partial_\varphi^{-1})(\varphi,\varphi)=\frac{1}{\pi}\left(\sum_{n=1}^{\infty}\frac{e^{-\epsilon n}}{n}-\sum_{r=1/2}^{\infty}\frac{e^{-\epsilon r}}{r}\right)=-\frac{1}{\pi}\ln 4+O(\epsilon). \quad (3.15)$$

The exact expressions for the sums are[27] $\Sigma_{n=1}^{\infty}(e^{-\epsilon n}/n)=-\ln(1-e^{-\epsilon})$, $\Sigma_{r=1/2}^{\infty}(e^{-\epsilon r}/r)=-\ln[(1-e^{-\epsilon/2})/(1+e^{-\epsilon/2})]$. Thus while the coefficient of $\partial\mathcal{T}\,\partial\mathcal{T}$ term is finite[22] (it may probably depend on a regularization only if the latter break 1-D supersymmetry, cf. Ref. 36), the coefficient of $\mathcal{T}\,\partial^2\mathcal{T}$ term is logarithmically divergent. This divergence is to be renormalized by absorbing it into $\mathcal{T}$. Just as in the bosonic case, this logarithmic divergence determines the derivative term in the tachyon β-function. The coefficient of the logarithmic pole (i.e., the anomalous dimension of the tachyon vertex operator) is of course the same as in the bosonic case, but the dimension of the NS tachyon vertex is half the bosonic one ($\mathcal{T}\sim 1/\sqrt{\epsilon}$). Thus [cf. (2.18)]

$$\beta^{\mathcal{T}}=-\frac{1}{2}\mathcal{T}-\frac{1}{2\pi}\partial^2\mathcal{T}. \quad (3.16)$$

Introducing a constant F_{mn} background means replacing G by $G(F)$ in (2.7) and K in (3.2) by $K(F)$,[48,27]

$$K^{mn}(\varphi_1,\varphi_2|F)=\frac{1}{\pi}\sum_{r=1/2}^{\infty}e^{-\epsilon r}[\mathcal{G}^{mn}(F)\sin r\varphi_{12}+i\mathcal{H}^{mn}(F)\cos r\varphi_{12}]. \quad (3.17)$$

Then one finds again (3.13) but with the flat target space metric replaced by $\mathcal{G}^{mn}(F)$ in (2.8). In particular, then (3.16) takes the form (see also Ref. 36)

$$\beta^{\mathcal{T}}=-\frac{1}{2}\mathcal{T}-\frac{1}{2\pi}\mathcal{G}^{mn}(F)\partial_m\partial_n\mathcal{T}. \tag{3.18}$$

Ignoring first the F_{mn} background and expanding e^{-W} in derivatives of the tachyon field we obtain the renormalized value of the partition function in (3.10). To simplify the expression let us define the renormalized value of the tachyon T by rescaling $\mathcal{T}$ by $\sqrt{\pi/2}$. Then

$$Z[T]=c_0\int d^Dx e^{-T^2}[1-\overline{s_1}T\,\partial^2T-s_2(\partial T)^2+O(\partial^4T)], \tag{3.19}$$

where $\overline{s_1}$ stands for a renormalized value of s_1 in (3.14). The same expression, but without the $\overline{s_1}$ term was found in Ref. 22 where T was taken to be linear in x^m (i.e., ∂^2T was equal to zero).

It is natural to expect that in contrast to the bosonic string case where one needs to shift Z by a derivative term[23,24] to get the action (2.19) reproducing the tachyon beta function, in the NSR string case the (renormalized) partition function is itself the correct action, not only in the massless vector sector[27] but also in the tachyonic one.[22] To demonstrate that $S[T]=Z[T]$ (3.19) does indeed reproduce both terms in the perturbative β-function (3.16) it is crucial to include the $\overline{s_1}$ term in (3.19). The two derivative-dependent terms in (3.19) are closely related through integration by parts [cf. (2.24)]

$$S[T]=Z[T]=c_0\int d^Dx e^{-T^2}[1+c_1\alpha'(\partial T)^2+c_2\alpha' T^2(\partial T)^2+O(\partial^4T)], \tag{3.20}$$

$$c_1=2\pi(\overline{s_1}-s_2),\quad c_2=-4\pi\overline{s_1}. \tag{3.21}$$

Since s_1 was logarithmically divergent before renormalization, its renormalized value $\overline{s_1}$ is, in principle, ambiguous and, as in the bosonic case [see (2.24)–(2.27)] can be tuned to match the variation of $S[T]$ with the β^T-function in (3.16). Indeed, we find

$$\frac{\delta S}{\delta T}=2c_0e^{-T^2}[-T-c_1\alpha'\,\partial^2T-c_2\alpha' T^2\,\partial^2T+(c_1-c_2)\alpha' T(\partial T)^2 + c_2\alpha' T^3(\partial T)^2+O(\alpha'^2\,\partial^4T)]. \tag{3.22}$$

Thus the linear terms here are proportional to (3.16) if $\overline{s_1}=(1/\pi)(1-\ln 4)$, i.e., if

$$c_1=2. \tag{3.23}$$

Then $c_2=4(\ln 4-1)>0$ so that the kinetic term in (3.20) is positive for all T.

While it may seem nonsensical to try to reproduce the correct tachyonic mass plus kinetic terms in the action using the perturbative derivative expansion, the point is that the freedom of field redefinitions allows one to do that, both in the bosonic[20,49] and in the NSR cases. The resulting field space ''metric'' κ is then simplest in such a scheme.

The generalization of the action (3.20) to the presence of a $F_{mn}=$const background is straightforward [cf. (2.29)],

$$S=c_0\int d^Dx e^{-T^2}\sqrt{\det(\delta_{mn}+2\pi\alpha' F_{mn})}[1+c_1\alpha'\mathcal{G}^{mn}(2\pi\alpha' F)\partial_mT\,\partial_nT + c_2\alpha'\mathcal{G}^{mn}(2\pi\alpha' F)T^2\,\partial_mT\,\partial_nT+O(\alpha'^2\,\partial^4T,\alpha'^2\,\partial^2F)]. \tag{3.24}$$

where we restored the dependence on α'. [The partition function for $\partial_m T=\text{const}$, $F_{mn}=\text{const}$ background was computed in Ref. 36; its expansion in ∂T reproduces part of the c_1 term in the expression below which it corresponds to the s_2 term in (3.19).] This action is consistent with (3.18) for $c_1=2$.

The non-Abelian generalization of (3.24) may be obtained, in principle, from the gauge-invariant path integral defined by (3.7).

IV. CLOSED STRING THEORIES

In the bosonic closed string case we start with the sigma model,[2]

$$I=\int d^2z\sqrt{g}\left[\epsilon^{-2}T_0(x)+\frac{1}{4\pi\alpha'}\partial^\mu x^m\,\partial_\mu x^n\,G_{mn}(x)+\frac{1}{4\pi}R^{(2)}\phi(x)\right]. \tag{4.1}$$

(For simplicity, we shall ignore the Kalb–Ramond antisymmetric tensor coupling which is not essential for the present discussion and can be easily included.) This model is renormalizable within an α' expansion. The corresponding bare partition function on a 2-sphere has the form[2]

$$Z[T_0(\epsilon),G(\epsilon),\phi(\epsilon),\epsilon]=d_0\int d^Dx\sqrt{G}e^{-2\phi-\epsilon^{-2}AT_0}e^{-W}, \tag{4.2}$$

where we shifted $x(z)\to x+\xi(z)$ so that [as in (2.4)] W is given by the path integral over the nonconstant fluctuations ξ (see Refs. 2, 10, 29 for details). The coefficient A is the area of fiducial 2-D metric (it can be absorbed into the renormalized value of T_0). The leading logarithmically divergent terms in W are found to be[4,2]

$$\begin{gathered}W=\tfrac{1}{2}\gamma\ln\epsilon+O(\ln^2\epsilon)+\text{finite},\\ \gamma=c_0-\alpha'\mathcal{D}^2(\epsilon^{-2}AT_0)-2\alpha'\,\mathcal{D}^2\phi-\alpha' R+O(\alpha'^2),\quad c_0=\tfrac{1}{2}(D-26).\end{gathered} \tag{4.3}$$

For example, taking the derivative of Z over ϵ reproduces the standard perturbative closed string tachyon β-function,

$$\beta^T=-2T-\tfrac{1}{2}\alpha'\,\mathcal{D}^2T, \tag{4.4}$$

with the corresponding Weyl anomaly coefficient being $\overline{\beta^T}=\beta^T+\alpha'\,\partial^m\phi\,\partial_m T$.

To obtain the effective action for the massless fields $S[G,\phi]$ from the partition function Z one should, as in the open string case, renormalize the logarithmic infinities which corresponds to subtracting massless poles in the string amplitudes.[10] An additional subtlety of the closed string case is that the Möbius group volume has logarithmic divergence, and it should be subtracted, in the RG invariant way, by applying $\partial/\partial\ln\epsilon$ to the bare value of Z.[28] [To compare the formal generating functional Z to massless effective action reconstructed from string amplitudes one needs to subtract both Möbius infinities and massless poles (UV logarithms). While the former are power-like in the open string case, they are also logarithmic in the closed string case. That means that ''extra'' log should be subtracted from Z in the closed string case.] Expressed in terms of renormalized couplings, the effective action is then[28] [$\lambda^i=(T,G,\phi)$]

$$S=-\left(\frac{\partial Z}{\partial\ln\epsilon}\right)_{\epsilon=1}=\beta^i\cdot\frac{\delta Z}{\delta\lambda^i}, \tag{4.5}$$

or, explicitly,

$$S=\int d^Dx\sqrt{G}e^{-2\phi-T}\left(-2T+\frac{1}{2}\gamma\right)$$
$$=\int d^Dx\sqrt{G}e^{-2\phi-T}\left[\frac{1}{2}c_0-2T-\frac{1}{2}\alpha'\,\mathcal{D}^2T-\alpha'\,\mathcal{D}^2\phi-\frac{1}{2}\alpha' R+O(\alpha'^2)\right], \tag{4.6}$$

where T is a renormalized value of the tachyon rescaled by A. [Because of the diffeomorphism invariance; the expression for S can be written also as $S=\overline{\beta}^i\cdot\delta Z/\delta\lambda^i$, where $\overline{\beta}^i=\beta^i+(\delta\lambda^i)_{\alpha'\partial\phi}$ (i.e., $\overline{\beta}^\phi=\beta^\phi+\alpha'\partial^m\phi\,\partial_m\phi$, $\overline{\beta}^G_{mn}=\beta^G_{mn}+2\alpha'\mathcal{D}_m\mathcal{D}_n\phi$, etc.) are the Weyl anomaly coefficients, the vanishing of which should be equivalent to the conditions of stationarity of the action.] Equivalently,

$$S=\int d^Dx\sqrt{G}e^{-2\phi-T}\left(\beta^T+2\beta^\phi-\frac{1}{2}G^{mn}\beta^G_{mn}\right)$$
$$=\int d^Dx\sqrt{G}e^{-2\phi-T}\left(\overline{\beta}^T+2\overline{\beta}^\phi-\frac{1}{2}G^{mn}\overline{\beta}^G_{mn}\right), \tag{4.7}$$

i.e.,

$$S=-\left(\frac{d}{d\ln\epsilon}\mathcal{Z}\right)_{\epsilon=1},\quad \mathcal{Z}=\int d^Dx\sqrt{G}e^{-2\phi-T}. \tag{4.8}$$

Note that [in contrast to the open string case (2.15),(2.16)] the coefficients of derivative terms here are scheme-independent. Setting the tachyon to zero (and integrating by parts) we get the standard closed string effective action consistent with the S-matrix[1] and massless β-functions,[50,7]

$$S=-\frac{1}{2}\int d^Dx\sqrt{G}e^{-2\phi}[-c_0+4\alpha'(\partial\phi)^2+\alpha' R+O(\alpha'^2)]. \tag{4.9}$$

As discussed in Ref. 28, the definition (4.5) in general leads to S given by the space–time integral of the ''central charge'' coefficient.

The functional (4.6) is not, however, the right action for $T\neq 0$: it does not have the standard perturbative vacuum ($D=26$, $T=0$, $\phi=$const, $G_{mn}=\delta_{mn}$) as its stationary point [equivalently, the tachyon tadpole on a 2-sphere does not vanish even after taking the derivative in (4.5)]. Another indication of a problem in (4.6) is that one can almost completely absorb T into the dilaton: introducing $\tilde{\phi}=\phi+1/2T$ one is left with only a linear term in T. Furthermore, the kinetic term of T in (4.6) ($-1/2\alpha'\,\partial^mT\,\partial_mT$ after integration by parts) has apparently the ''wrong'' sign. [We use the Euclidean signature so the correct sign for a scalar kinetic term is plus. This is the sign of the dilaton kinetic term in (4.6) after redefining the metric to decouple the graviton from dilaton (i.e., after going to the Einstein frame). In general, T and ϕ and the graviton are mixed, so that their kinetic matrix is to be diagonalized before discussing the signs (see below).]

As in the open string case, to try to find a consistent action that reproduces $\overline{\beta}^i=0$ conditions for all the three fields one is thus to subtract the tachyon tadpole in an RG invariant way. By analogy with (2.19), let us define

$$\hat{S}=S+\frac{1}{2}\beta^i\cdot\frac{\delta S}{\delta\lambda^i}=\beta^i\cdot\frac{\delta}{\delta\lambda^i}Z+\frac{1}{2}\beta^j\cdot\frac{\delta}{\delta\lambda^j}\left(\beta^i\cdot\frac{\delta}{\delta\lambda^i}Z\right). \tag{4.10}$$

(The coefficient 1/2 accounts for the factor of two difference in dimensions of the open and closed strings tachyons; cf. (2.18), (4.4). Note that since S in (4.5) is RG invariant [$(d/d\ln\epsilon)Z=0\rightarrow(d/d\ln\epsilon)\,(\partial/\partial\ln\epsilon)Z=0$], the same applies to each of the two terms in $\hat{S}$.)

Expanding near the standard flat string vacuum ($D=26$, $G_{mn}=$const, $\phi=$const) one is to keep the dilaton and graviton perturbations in $\hat{S}$ and consistently decouple them from T by field redefi-

nitions. (We are grateful to Frolov for an important discussion of this point.) Observing that for small perturbations near the flat vacuum $\beta^{\phi}=-1/2\alpha'\,\partial^2\phi$, $\beta^G_{mn}=\alpha' R_{mn}$, one finds

$$\hat{S}=S+\frac{1}{2}\left(\beta^T\cdot\frac{\delta}{\delta T}+\beta^{\phi}\cdot\frac{\delta}{\delta\phi}+\beta^G_{mn}\cdot\frac{\delta}{\delta G_{mn}}\right)S$$
$$=\int d^Dx\sqrt{G}e^{-2\phi-T}\left[-2T^2+\frac{1}{2}\alpha'\,\mathcal{D}^2T-\alpha' T\,\mathcal{D}^2T-\frac{1}{2}\alpha'(1+2T)(R+2\,\mathcal{D}^2\phi)+O(\alpha'^2)\right]. \tag{4.11}$$

This action no longer has a tadpole T-term [cf. (4.6)], but to decouple the graviton from scalars we still need, as usual, to redefine the metric. Ignoring ''mixed'' (tachyon-massless) terms which are of higher than quadratic order in the fields we can approximately replace the $e^{-2\phi-T}(1+2T)$ factor in front of R by $\epsilon^{-2\varphi}$, $\varphi\equiv\phi-1/2T$ and set $G_{mn}=e^{4\varphi/(D-2)}g_{mn}$. Then $\int d^{\mathcal{D}}x\sqrt{G}e^{-2\phi-T}(1+2T)(R+2\,\mathcal{D}^2\phi)\to\int d^{\mathcal{D}}x\sqrt{g}[R(g)-[4/(D-2)](\partial\varphi)^2+2\,\partial^mT\,\partial_m\varphi]$. As a result, the action (4.11) takes the form

$$\hat{S}=\int d^Dx\sqrt{g}\left(e^{-2T}[-2T^2e^{4\varphi/(D-2)}+2\alpha'(1-T)(\partial T)^2]\right.$$
$$\left.-\frac{1}{2}\alpha'\left[R(g)-\frac{4}{D-2}(\partial\varphi)^2\right]+O(\alpha'^2)\right). \tag{4.12}$$

(If one does the exact redefinition $(1+2T)e^{-2\phi-T}=e^{-2\psi}$, i.e., $\psi=\phi+(1/2)T-(1/2)\ln(1+2T)$, and thus $G_{mn}=e^{4\psi/(D-2)}g_{mn}$, then one finds the following action:

$$\hat{S}=\int d^Dx\sqrt{g}\left(-\frac{2T^2}{1+2T}e^{4\psi/(D-2)}+\frac{2\alpha'}{(1+2T)^2}(\partial T)^2-\frac{1}{2}\alpha'\left[R(g)-\frac{4}{D-2}(\partial\psi)^2\right]+O(\alpha'^2)\right),$$

which is equivalent to the one above in the quadratic order in T. Introducing $\tilde{T}=(1/2)\ln(1+2T)$ (assuming $T>-1/2$) its tachyonic part becomes simply $\hat{S}=\int d^Dx[-2\sinh^2\tilde{T}+2\alpha'(\partial\tilde{T})^2]$.)

Ignoring the graviton and dilaton terms (decoupled to quadratic order in fluctuations) the tachyon part of the action is thus

$$\hat{S}=\int d^Dxe^{-2T}[-2T^2+2\alpha'(1-T)(\partial T)^2+O(\alpha'^2)]. \tag{4.13}$$

This action has a structure similar to (2.24), but the value of the coefficient of the second kinetic term, though now positive, is not the one needed to reproduce the β^T-function (4.4). It may be that the definition (4.10) still needs some further refinement.

The potential term in (4.13) $V=-2e^{-2T}T^2$ has a tachyonic maximum at $T=0$ and the stable minimum at $T=1$. However, that minimum is not reached as the kinetic term of T changes sign at $T=1$. In general, in discussing the vacuum structure one should take into account a nontrivial mixing of the tachyon with the dilaton and the metric. For example, for a linear dilaton and $D=2$ the tachyon should be massless (as follows from $\overline{\beta}^T=0$), and in this case one should expect to find no potential term. [The exponential potential in (4.13) may be suggesting (by analogy with the open string case) a possibility of T rolling to infinity along some directions, and such behavior should be accompanied by a nonconstant dilaton to preserve the central charge condition (see also Ref. 16 for related remarks).]

In the closed NSR string case the tachyon vertex has the following form (in the 0-ghost picture) $\int d^2z\,\psi^m\overline{\psi}^n\partial_m\partial_nT$. Its 2-D supersymmetric generalization is $\int d^2z\,d^2\theta\,T(\hat{x})$, where $\hat{x}^m=x^m+\theta\psi^m+\overline{\theta\psi}^m+\overline{\theta}\theta f^m$. Combined with the kinetic term $\int d^2z\,d^2\theta\,D\hat{x}^m\,\overline{D}\hat{x}^m$ it leads, after the

elimination of the auxiliary field f^m, to the following tachyon terms in the sigma model action [which are the familiar superpotential terms in $N=1$ supersymmetric scalar 2-D field theory; cf. also (3.9)],

$$\int d^2z[\partial^m T(x)\partial_m T(x)+\psi^m\bar{\psi}^n\partial_m\partial_n T(x)]. \tag{4.14}$$

As in the open NSR string case, the resulting partition function and thus the effective action (4.5) it generates are even in T. As a result, there is no need for an additional subtraction like (4.10). Since the sigma model depends on T only through its derivatives, there is no tachyon potential term in S.

The leading T-dependent logarithmic divergence in Z comes from the expansion of $\partial_m T\,\partial^m T$ term in (4.14) and corresponds to the β-function $(-1-(1/2)\alpha'\mathcal{D}^2)T$. The leading G_{mn} and ϕ-dependent terms in Z and S in the NSR case are the same as in the bosonic case[51] [with the obvious replacement of c_0 in (4.3) by $D-10$]. While the NS–NS part of the effective action generated by the sigma model appears to depend on T only through its derivatives, functions of T may still be present in the R-R sector (where one is to use the ghost -1 tachyon vertex[52]).

(Received 2 January 2001; accepted for publication 13 February 2001)

We define an iterative procedure to obtain a non-Abelian generalization of the Born–Infeld action. This construction is made possible by the use of the severe restrictions imposed by kappa-symmetry. In this paper we will present all bosonic terms in the action up to terms quartic in the Yang–Mills field strength and all fermion bilinear terms up to terms cubic in the field strength. Already at this order the fermionic terms do not satisfy the symmetric trace-prescription. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1374449]

I. INTRODUCTION

One of the most intriguing features of D-branes is their close connection with gauge theories. Indeed, the effective theory describing the worldvolume dynamics of a Dp-brane is a $p+1$-dimensional field theory with, in the static gauge, as bosonic degrees of freedom the transversal coordinates of the brane, appearing as $9-p$ scalar fields, and the massless states of the open strings ending on the brane which appear as a U(1) gauge field. When these fields vary slowly, the effective action governing their dynamics is known to all orders in α'. It is the ten-dimensional Born–Infeld action,[1] dimensionally reduced to $p+1$ dimensions.

Once several D-branes are present, the situation changes. The mass of the strings stretching between two branes is proportional to the shortest distance between the branes. Starting off with n well separated D-branes we end up with a $\mathrm{U}(1)^n$ theory, however, once the n branes coincide additional massless states appear which complete the gauge multiplet to a non-Abelian $\mathrm{U}(n)$-theory.[2] Contrary to the Abelian case, the effective action is not known to all orders in α'. The first term, quadratic in the field strength, is nothing but a dimensionally reduced $\mathrm{U}(n)$ Yang–Mills theory. The next order, which is quartic in the field strength, was obtained from the four-gluon scattering amplitude in open superstring theory[3] and from a three-loop β-function calculation.[4] Based upon these results and other considerations, an all order proposal was formulated for the effective action;[5] the non-Abelian Born–Infeld action assumes essentially the same form as the Abelian one, however, all Lie algebra valued objects have to be symmetrized first before taking the trace. Other trace prescriptions, involving commutators, have been given as well.[6] More recently, it was found that the symmetric trace prescription could not be correct as it did not reproduce the mass spectrum of certain D-brane configurations.[7,8] It was shown in Ref. 9 that by adding commutator terms to the action the problem might be cured. Indeed, as was pointed out in Ref. 1, the notion of an effective action for slowly varying fields is subtle in the non-Abelian case. In the effective action higher derivative terms are dropped. However because of

$$D_iD_jF_{kl}=\frac{1}{2}\{D_i,D_j\}F_{kl}-\frac{i}{2}[F_{ij},F_{kl}], \tag{1.1}$$

this is ambiguous. The analysis of the mass spectrum seems to indicate that the symmetrized product of derivatives acting on a field strength should be viewed as an acceleration term which can safely be neglected, while the anti-symmetrized products should be kept. A systematic study of the F^6 terms[10] showed that using the mass spectrum as a guideline, almost all terms at this order

could be determined. However due to the specific choices of backgrounds made in Ref. 10, certain terms do not contribute to the mass spectrum and as a result can not be fixed in this way. A direct calculation from a six-point open superstring amplitude or a five-loop β-function seems unfeasible, so another approach is called for.

Until now, we ignored the fermionic degrees of freedom in our discussion. The fully covariant worldvolume theory of a single D-brane in a type II theory can be formulated in terms of the following world volume fields: the embedding coordinates $X^\mu(\sigma)$ (of which only the transverse coordinates represent physical degrees of freedom), the Born–Infeld vector field $V_i(\sigma)$, and $N=2$ space–time fermionic fields $\theta(\sigma)$. In a curved background the D-brane can be coupled to the corresponding type II supergravity superfields, and $N=2$ supersymmetry is realized locally. In a flat background there is $N=2$ global supersymmetry. This world volume theory has a local κ-symmetry, which acts on the fermions as

$$\delta\overline{\theta}(\sigma)=\overline{\kappa}(\sigma)(1+\Gamma), \tag{1.2}$$

where Γ, which depends on world volume as well as background fields, satisfies

$$\Gamma^2=1. \tag{1.3}$$

The projection (1.2) makes it possible to gauge away half the fermionic degrees of freedom. The field content then corresponds in a static gauge to that of a supersymmetric Yang–Mills theory in $p+1$ dimensions. There is still $N=2$ supersymmetry, but half of this is realized nonlinearly. These covariant D-brane actions have been constructed in flat,[11] as well as in curved backgrounds.[12,13] This paper examines the suggestion in Ref. 8 that κ-symmetry might teach us something about the orderings appearing in the non-Abelian Born–Infeld action.

D-brane actions consist of the sum of a Born–Infeld term, coupling the world volume fields to the NS–NS sector of the background, and a Wess–Zumino term in which the couplings to the R–R fields occur. Each part is separately supersymmetric, but the two are related, in the Abelian case, by the κ-transformations. The Wess–Zumino term is of a topological nature, and can therefore be formulated in a metric-independent way. Its structure is severely restricted, also in the non-Abelian case. The Born–Infeld term is much more complicated, and consequently its generalization from the Abelian to the non-Abelian case is much more difficult. It is natural to assume that also in the non-Abelian case the Born–Infeld and Wess–Zumino term are related by a κ-symmetry. Our aim is to use the knowledge of the Wess–Zumino term and the properties of κ-symmetry to obtain information about the non-Abelian Born–Infeld term.

To construct this non-Abelian generalization we will use an iteration in the number of Yang–Mills field strengths $F(V)$. In this paper we will obtain all terms in the action up to and including the order F^2. As we discussed above, in the purely bosonic terms the conflict between string theoretic results and the symmetric trace prescription arises only at order F^6, so it is clear that in this paper we will not contribute to the discussion of these bosonic terms. However, we find that in the fermionic sector already at quadratic order some of the fermionic terms do not correspond to a symmetric trace.

This paper is organized as follows: We will discuss our choice of variables in Sec. II. In Sec. III we will define the iterative procedure and illustrate it for the Abelian case. In Secs. IV and V we derive and present our results for the non-Abelian case, and bring them to gauge fixed form in Sec. VI. In Sec. VII we give our conclusions, and point out a number of extensions and applications of this work.

We will end the Introduction by recalling briefly some related work on supersymmetric D-brane actions. In four dimensions the supersymmetrization of the Abelian Born–Infeld action in $N=1$ supersymmetry has been known for a long time.[14] More recently, this work has been extended to the non-Abelian Born–Infeld theory, and to $N=2$ supersymmetry.[15,16] In particular, in Ref. 15 it is remarked that $N=2$ supersymmetry in four dimensions is not sufficient to resolve the ordering ambiguities, several ordering prescriptions give rise to supersymmetric actions. So it

seems that it is indeed necessary (and hopefully sufficient) to consider $N=4$ in $D=4$, or, as in this paper, the ten-dimensional supersymmetric Born–Infeld action action. Several aspects of the ten-dimensional problem have been studied in Refs. 17 and 18. In particular, these authors investigate the dependence of the action on transverse scalars, where these scalars are generated by T-duality starting from the D9-brane action. However, this is in the context of the symmetric trace prescription.

II. WORLD VOLUME FIELDS AND TRANSFORMATIONS

The aim of this work is to obtain the effective action for n overlapping Dp-branes, with U(n) covariance on the world volume. Before embarking on the construction, one has to carefully choose the starting point of the calculation. For general Dp-branes the situation is complicated by the presence of the transverse scalar degrees of freedom, which are in the adjoint representation of the Yang–Mills group. Not only does one have to take commutators of these scalars into account, but also the background fields will depend on these scalars.[19] We avoid these complications by limiting ourselves to the case of n overlapping D9-branes, and by choosing a flat background. Through T-duality D-branes for other values of p can be obtained, the extension to curved backgrounds will be discussed in Sec. VII.

For n overlapping D9-branes the completely gauge fixed result should be the supersymmetric version of the non-Abelian Born–Infeld theory. Since the vector fields $V_i^A(\sigma)$, $A=1,...,n^2$, are in the adjoint representation of U(n), we have to make the same choice for the fermion fields θ. Therefore we start out with fields $\theta^A(\sigma)$, which form a doublet ($N=2$) of Majorana–Weyl spinors for each A, satisfying $\Gamma_{11}\theta^A=\theta^A$. After κ-gauge fixing only half of each doublet will remain, and we have the correct number of degrees of freedom for the supersymmetric Yang–Mills theory.

This requires, that there are as many κ-symmetries as θ's, so that the parameter of the κ transformations will have to be in the adjoint of U(n) as well. Thus the θ^A transform as follows under ordinary supersymmetry (ϵ), κ-symmetry (κ), Yang–Mills transformations (Λ^A), and world volume reparametrizations (ξ^i),

$$\delta\overline{\theta^A}(\sigma)=-\overline{\epsilon^A}+\overline{\kappa^B}(\sigma)(1\!\!1\delta^{BA}+\Gamma^{BA}(\sigma))+f^A{}_{BC}\Lambda^B(\sigma)\overline{\theta^C}(\sigma)+\xi^i(\sigma)\partial_i\overline{\theta^A}(\sigma). \tag{2.1}$$

Here ϵ^A are constant, Γ^{AB} depends on the world volume fields, and therefore on σ. It must satisfy

$$\Gamma^{AB}\Gamma^{BC}=\delta^{AC}1\!\!1. \tag{2.2}$$

We will usually write these transformations in terms of

$$\delta\overline{\theta^A}\equiv\overline{\eta^A}\equiv\overline{\kappa^B}(\sigma)(1\!\!1\delta^{BA}+\Gamma^{BA}(\sigma)). \tag{2.3}$$

Useful information is obtained by considering commutators of these transformations. Because ϵ^A is constant we find from the commutator of Yang–Mills and supersymmetry transformations that

$$f^A{}_{BC}\Lambda^B\epsilon^C=0\rightarrow f_{ABC}\epsilon^C=0. \tag{2.4}$$

Therefore $\epsilon=\epsilon^A T_A$, where T_A are the U(n) generators, must be proportional to the unit matrix, i.e., we can choose a basis in which there is only one nonvanishing ϵ parameter. So only a subset of the θ^A transform under supersymmetry, and there is only one independent supersymmetry parameter. The θ's which are presently inert under supersymmetry will obtain their supersymmetry transformations through κ-gauge fixing, as we shall see in Sec. VI. From the commutator of κ-symmetry and supersymmetry we find $\delta_\epsilon\eta^A=0$. This implies that

$$\delta_\epsilon\Gamma^{AB}=0. \tag{2.5}$$

The only scalars we have are the embedding coordinates $X^\mu(\sigma)$ for world volume directions. There are several options that one could consider for the X^μ:

(1) We could assume that we are in the static gauge, i.e.,
$$X^\mu(\sigma)=\delta^\mu_i\sigma^i, \tag{2.6}$$
from the beginning, so that the X^μ are absent. In this case there are no world volume reparametrizations, i.e., $\xi^i=0$ in (2.1);
(2) We could decide that the X^μ are in the singlet representation of the Yang–Mills group. The idea is that the n branes overlap, there is only one set of world volume coordinates, and the corresponding reparametrization group would be sufficient to gauge fix a singlet set of embedding coordinates;
(3) We could choose the X^μ in the adjoint representation of Yang–Mills in analogy with transverse coordinates for $p<9$. Here one thinks of starting with n separate branes where each has its own world volume and embedding coordinates. When the branes overlap the embedding coordinates ''fill up'' to form elements of the adjoint representation. Clearly this requires a different approach toward the worldvolume reparametrisation invariance, which must then correspond to a sufficiently large symmetry group to gauge fix all these embedding functions.

We have investigated the first two possibilities in the non-Abelian case, and we have found that only the first approach is consistent with the iterative procedure that we employ. In Sec. IV we will point out where the first two choices start to diverge, in Sec. VII we will briefly come back to the third possibility.

The transformation rules of the bosonic fields V_i^A, and, in case of the second choice above, of the X^μ, are determined iteratively by requiring invariance of the action.

A special case of a U(n) invariant non-Abelian D-brane action is of course the truncation to U(1)^n. In this case we know the answer: a κ-invariant action is given by the sum of n Abelian D-brane actions. This special case will be discussed again, since it plays a role in making a choice between the different possibilities for the variables X^μ discussed above.

Throughout this paper we will limit ourselves to terms in the action and transformation rules which are at most quadratic in the fermion fields.

III. THE ITERATIVE PROCEDURE AND THE ABELIAN EXAMPLE

In this section we will set up our iterative procedure and illustrate it for the Abelian case. To do this, we must first give some details of the effective D9-brane action in a flat background.[11] In this case we can use a covariant formulation with embedding coordinates X^μ, space–time fermions θ, and the Born–Infeld vector V_i. They transform under supersymmetry (ϵ), κ-symmetry, world volume reparametrizations (ξ^i), and Maxwell gauge transformations (Λ) as

$$\begin{aligned}
\delta X^\mu &= \tfrac{1}{2}\overline{\epsilon}\Gamma^\mu\theta+\tfrac{1}{2}\overline{\eta}\Gamma^\mu\theta+\xi^i\partial X^\mu,\\
\delta\overline{\theta} &= -\overline{\epsilon}+\overline{\eta}+\xi^i\partial_i\overline{\theta},\\
\delta V_i &= -\tfrac{1}{2}(\overline{\epsilon}+\overline{\eta})\gamma_i\theta+\xi^jF_{ji}+\partial_i(\Lambda+\xi^jV_j),
\end{aligned} \tag{3.1}$$

with

$$\overline{\eta}=\overline{\kappa}(1+\Gamma),\quad (\Gamma)^2=\mathbb{1}, \tag{3.2}$$

and

$$\gamma_i\equiv\Gamma^\mu\partial_iX^\mu. \tag{3.3}$$

The Born–Infeld contribution reads

$$\mathcal{L}_{BI} = -\sqrt{-\det(g+\mathcal{F})}$$
$$= -\sqrt{-\det g}\,(1+\tfrac{1}{4}\mathcal{F}_{ij}\mathcal{F}^{ij}+\cdots), \tag{3.4}$$

where in the second line we expand to second order in $\mathcal{F}$, which is given by

$$\mathcal{F}_{ij} = F_{ij}(V) - B_{ij}\,. \tag{3.5}$$

In a flat background and in the quadratic fermion approximation, B_{ij} is

$$B_{ij} = -\overline{\theta}\sigma_3\gamma_{[i}\partial_{j]}\theta. \tag{3.6}$$

The world volume metric reads

$$g_{ij} = \eta_{ij} + \overline{\theta}\gamma_{(i}\partial_{j)}\theta, \quad \eta_{ij} \equiv \partial_i X^\mu \partial_j X_\mu\,. \tag{3.7}$$

The metric g and $\mathcal{F}$ are invariant under supersymmetry and transform covariantly under κ-transformations. The most useful form for comparison with the non-Abelian case is the expansion of (3.4) to second order in fermions,

$$\mathcal{L}_{BI} = -\sqrt{-\det\eta}\,(1+\tfrac{1}{2}\overline{\theta}\gamma^i\partial_i\theta + \tfrac{1}{2}\overline{\theta}\sigma_3\gamma_{[i}\partial_{j]}\theta F^{ij} + \tfrac{1}{4}F^{ij}F_{ij} + \tfrac{1}{2}\overline{\theta}\gamma_i\partial_j\theta T^{ij} + \cdots), \tag{3.8}$$

where T^{ij} is the energymomentum tensor of the vector field,

$$T^{ij} = F^{ik}F^j_k + \tfrac{1}{4}\eta^{ij}F_{kl}F^{kl}. \tag{3.9}$$

The Wess–Zumino term takes on the following form:

$$\mathcal{L}_{WZ} = e^{i_1\cdots i_{10}} \times \sum_{k=0}^{4} \frac{(-1)^k}{2^{k+1}k!(9-2k)!}\,\overline{\theta}\mathcal{P}_{(k)}\gamma_{i_1\cdots i_{9-2k}}\partial_{i_{10-2k}}\theta(\mathcal{F}^k)_{i_{11-2k}\ldots i_{10}}, \tag{3.10}$$

where

$$\mathcal{P}_{(k)} = \sigma_1 \ \ (\text{for } \ k=0,2,4), \ \ \mathcal{P}_{(k)} = i\sigma_2 (\text{for } \ k=1,3). \tag{3.11}$$

Note that the sum in (3.10) runs only to $k=4$, since the RR-scalar field vanishes in the flat background.

It will be useful, also for the non-Abelian case, to discuss why we make this particular choice for the $\mathcal{P}_{(k)}$. The $\mathcal{P}_{(k)}$ are chosen such that the contributions to the Wess–Zumino term are not total derivatives. For odd k this fixes $\mathcal{P}_{(k)}$ to be $i\sigma_2$. For even k we could also have chosen 1 or σ_3. When we start looking at the iterative procedure later in this Section, we will find that we need

$$\{\mathcal{P}_{(0)}, \mathcal{P}_{(1)}\} = 0, \tag{3.12}$$

which excludes 1 for $k=0$. We have in principle the possibility to have either σ_1 or σ_3 (or both) for $k=0$, and taking σ_1 is a choice of basis for the $N=2$ fermions. Note that σ_3 in (3.6) is correlated with the choice for σ_1 in the Wess–Zumino term: had we chosen $\mathcal{P}_{(0)} = \sigma_3$ we would have found σ_1 in (3.6).

The structure of (3.10) guarantees that the WZ-action transforms into a total derivative under the global supersymmetry transformation $\delta\overline{\theta} = -\overline{\epsilon}$. Since we do not go beyond bilinear fermions we can use F instead of $\mathcal{F}$ in the Wess–Zumino term. The numerical coefficients in (3.10) are determined by κ-symmetry once the normalization of F and θ are fixed in the Born–Infeld term.

Let us now consider the iterative construction of κ-symmetry. The variation of the D-brane action takes on the form,

$$\delta\mathcal{L}=-\overline{\eta}(1-\Gamma)\mathcal{T}. \tag{3.13}$$

It indeed vanishes if η is given by (3.2). These variations have the following source:

$$\delta\mathcal{L}_{BI}=-\overline{\eta}\mathcal{T},\quad \delta\mathcal{L}_{WZ}=\overline{\eta}\Gamma\mathcal{T}. \tag{3.14}$$

The variation of the Wess–Zumino term, together with the information that $\Gamma^2=\mathbb{1}$, is sufficient to determine both Γ and $\mathcal{T}$ iteratively. Since $\mathcal{T}$ determines the variation of the Born–Infeld term this information is sufficient to obtain iteratively the Born–Infeld part of the action.

The iteration is obtained by expanding Γ and $\mathcal{T}$ in F,

$$\begin{aligned}\delta\mathcal{L}&=-\overline{\eta}(1-(\Gamma_0+\Gamma_1+\cdots))(\mathcal{T}_0+\mathcal{T}_1+\cdots)\\&=-\overline{\eta}(\mathcal{T}_0-\Gamma_0\mathcal{T}_0+\mathcal{T}_1-\Gamma_1\mathcal{T}_0-\Gamma_0\mathcal{T}_1+\cdots),\end{aligned} \tag{3.15}$$

where the indices indicate the order in F and the Γ_i satisfy various identities which follow from $\Gamma^2=\mathbb{1}$. Since it will be useful to have the Abelian results at hand for comparison with the non-Abelian calculation in Sec. IV, we will work out the beginning of this iteration in some detail.

Let us start with the order F^0. The contribution from (3.10) is

$$\mathcal{L}_{WZ0}=\frac{1}{2\cdot 9!}\epsilon^{i_1\cdots i_{10}}\overline{\theta}\sigma_1\gamma_{i_1\cdots i_9}\partial_{i_{10}}\theta. \tag{3.16}$$

For the κ-variation we only have to vary θ to obtain

$$\delta\mathcal{L}_{WZ0}=\frac{1}{9!}\epsilon^{i_1\cdots i_{10}}\overline{\eta}\sigma_1\gamma_{i_1\cdots i_9}\delta_{i_{10}}\theta=\sqrt{-\det\eta}\,\overline{\eta}\sigma_1\Gamma^{(0)}\gamma^i\partial_i\theta. \tag{3.17}$$

Here $\Gamma^{(0)}$ is given by

$$\Gamma^{(0)}=\frac{1}{10!\sqrt{-\det g}}\epsilon^{i_1\cdots i_{10}}\gamma_{i_1\cdots i_{10}}, \tag{3.18}$$

which satisfies

$$(\Gamma^{(0)})^2=\mathbb{1}. \tag{3.19}$$

In (3.17) we have used the property

$$\Gamma^{(0)}\gamma^{l_1\cdots l_k}=\frac{(-)^{k(k-1)/2}}{(10-k)!\sqrt{-\det g}}\epsilon^{i_1\cdots i_{10-k}l_1\cdots l_k}\gamma_{i_1\cdots i_{10-k}} \tag{3.20}$$

for $k=1$. From (3.17) we read off that

$$\Gamma_0=\Gamma^{(0)}\sigma_1,\quad \mathcal{T}_0=\gamma^i\partial_i\theta. \tag{3.21}$$

Obviously $\Gamma^2=\mathbb{1}$ to this order.

So the Born–Infeld term should vary into $\mathcal{T}$, which is indeed achieved by setting

$$\mathcal{L}_{BI0}=-\sqrt{-\det\eta}(1+\tfrac{1}{2}\overline{\theta}\gamma^i\partial_i\theta). \tag{3.22}$$

This gives

$$\delta\mathcal{L}_{BI0}=-\sqrt{-\det\eta}\,\overline{\eta}\gamma^i\partial_i\theta, \tag{3.23}$$

where we have used the variation of X^μ as given in (3.1).

A similar analysis can be done for the terms of higher order in F. At the linear level the variation of the Wess–Zumino term is

$$\delta\mathcal{L}_{WZ1}=\tfrac{1}{2}\sqrt{-\det\eta}\,\overline{\eta}(i\sigma_2)\Gamma^{(0)}(\gamma^{jk}F_{jk}\gamma^i\partial_i\theta-2\gamma_i\partial_j\theta F^{ij}). \tag{3.24}$$

The variation of the complete action should be

$$\delta\mathcal{L}_1=-\sqrt{-\det\eta}\,\overline{\eta}\{\mathcal{T}_1-(\Gamma_0\mathcal{T}_1+\Gamma_1\mathcal{T}_0)\}. \tag{3.25}$$

So we read off that

$$\Gamma_1=\Gamma^{(0)}(i\sigma_2)\tfrac{1}{2}\gamma^{kl}F_{kl},\quad \mathcal{T}_1=\sigma_3\gamma_i\partial_j\theta F^{ij}. \tag{3.26}$$

Note that $\Gamma^2=\mathbb{1}$ at this order in F because

$$\{\sigma_1,\Gamma_1\}=0. \tag{3.27}$$

This is a general feature: the condition that $\Gamma^2=\mathbb{1}$ only contains useful information at even orders in the expansion in F. At odd orders it is just a consequence of the properties of $\mathcal{P}_{(k)}$.

The variation under supersymmetry and κ-symmetry of the term linear in F in the Born–Infeld action (3.8) reads

$$\delta\mathcal{L}_{BI1}=-\sqrt{-\det\eta}\,\overline{\eta}\sigma_3\gamma_i\partial_j\theta F^{ij}-\tfrac{1}{2}(\overline{\epsilon}+\overline{\eta})\gamma_i\theta\partial_j\{\sqrt{-\det\eta}F^{ij}\}. \tag{3.28}$$

The first term is the required contribution of $\mathcal{T}_1$. The second term must be cancelled by the variation of V in the F^2 term. The F^2 term gives

$$-\delta V_i\partial_j\{\sqrt{-\det\eta}F^{ij}\}, \tag{3.29}$$

which implies the following variation of V_i:

$$\delta V_i=-\tfrac{1}{2}(\overline{\epsilon}+\overline{\eta})\sigma_3\gamma_i\theta. \tag{3.30}$$

Therefore the combination

$$\mathcal{F}_{ij}=F_{ij}+\overline{\theta}\sigma_3\gamma_{[i}\partial_{j]}\theta \tag{3.31}$$

is supersymmetric and transforms covariantly under κ-symmetry.

At the quadratic level we get

$$\delta\mathcal{L}_{WZ2}=\tfrac{1}{8}\sqrt{-\det\eta}\,\overline{\eta}\sigma_1\Gamma^{(0)}(\gamma_{ijkl}\gamma^m\partial_m\theta-4\gamma_{ijk}\partial_l\theta)F^{[ij}F^{kl]}. \tag{3.32}$$

The order 2 terms in the variation of the total action are

$$\delta\mathcal{L}_2=-\sqrt{-\det\eta}\,\overline{\eta}(-(\Gamma_2\gamma^i\partial_i\theta+\Gamma_1\mathcal{T}_1+\sigma_1\mathcal{T}_2)+\mathbb{1}\mathcal{T}_2), \tag{3.33}$$

where Γ_1 and $\mathcal{T}_1$ were determined at the linear level. On the other hand, from $\Gamma^2=\mathbb{1}$ we have

$$\sigma_1\Gamma_2+\Gamma_2\sigma_1+\Gamma_1\Gamma_1=0, \tag{3.34}$$

from which we obtain (using $\Gamma_2\sim\sigma_1$)

$$\Gamma_2=-\tfrac{1}{2}\sigma_1\Gamma_1\Gamma_1=\Gamma^{(0)}\sigma_1\{\tfrac{1}{8}\gamma_{ijkl}F^{ij}F^{kl}-\tfrac{1}{4}F^{kl}F_{kl}\}. \tag{3.35}$$

Substituting all this in (3.33), we find that

$$\mathcal{T}_2 = \gamma_i \partial_j \theta (F^{ik} F^j_k + \tfrac{1}{4} \eta^{ij} F^{kl} F_{kl}). \tag{3.36}$$

This indeed agrees with the variation of the Born–Infeld action.

There is a feature about the Abelian case which just starts being visible in the quadratic terms. It is obviously possible to write Γ at this order in the form

$$\Gamma = (1 - \tfrac{1}{4} F^{kl} F_{kl}) \Gamma^{(0)} ((\sigma_1 + \tfrac{1}{2}(i\sigma_2) \gamma^{kl} F_{kl} + \tfrac{1}{8} \sigma_1 \gamma_{ijkl} F^{ij} F^{kl}) \tag{3.37}$$

up to terms of higher order in F. In fact, this factorization is a general feature of the Abelian action which is also valid for the complete answer,

$$\Gamma = \frac{\sqrt{-\det g}}{\sqrt{-\det(g+\mathcal{F})}} \Gamma^{(0)} \sum_{k=0}^{5} \frac{1}{2^k k!} \mathcal{P}_{(k)} \gamma^{i_1 \cdots i_{2k}} \mathcal{F}^k_{i_1 \cdots i_{2k}}. \tag{3.38}$$

The iterative procedure will obviously confirm this factorization, as is shown by continuing to higher orders in F. However, in this construction it is not clear why the factorization should occur. This is an issue in the non-Abelian situation where the complete answer is not known. Note that the factor

$$\frac{\sqrt{-\det g}}{\sqrt{-\det(g+\mathcal{F})}} \tag{3.39}$$

in (3.38) contains the inverse of the Born–Infeld action. The idea that Γ provides the explicit form of the Born–Infeld action was part of our motivation to use κ-symmetry as a means of constructing the non-Abelian Born–Infeld action.

From (3.36) it is clear that $\mathcal{T}$, at least at the quadratic level, shows a similar factorization property as Γ. The full answer for $\mathcal{T}$ is of the form,

$$\mathcal{T} = \sqrt{-\det(g+\mathcal{F})} \sum_{k=0}^{\infty} (\sigma_3)^k \gamma_i \partial_j \theta (\mathcal{F}^k)^{ij}, \tag{3.40}$$

where

$$(\mathcal{F}^k)^{ij} = \mathcal{F}^{il_1} \mathcal{F}_{l_1 l_2} \cdots \mathcal{F}^{l_{k-1} j} \quad k > 0,$$

$$(\mathcal{F}^k)^{ij} = g^{ij} \quad k = 0. \tag{3.41}$$

We will see a similar feature in the non-Abelian case.

The Abelian case discussed above can easily be generalized to $\mathrm{U}(1)^n$. Then the κ-symmetric action is just the sum of n actions of the type discussed in this section. For n overlapping branes one would need only one set of embedding coordinates X^μ to describe this truncation of the non-Abelian situation. This would be similar to treating X^μ as a singlet of $\mathrm{U}(n)$ in the non-Abelian case. Note however that this sum of actions is very different from a single Born–Infeld action with world volume metric,

$$g_{ij} = \eta_{ij} + \overline{\theta^A} \gamma_{(i} \partial_{j)} \theta^A, \tag{3.42}$$

summed over the $n\mathrm{U}(n)$ branes. A metric (3.42) would be like taking the trace *inside* the root of the Born–Infeld term, while it is known from open string amplitude calculations that there should be a single trace (with some ordening prescription) which produces in the $\mathrm{U}(1)^n$ case a sum of separate Born–Infeld terms.

IV. THE NON-ABELIAN BORN–INFELD ACTION

For the non-Abelian case we start with the following Wess–Zumino term:

$$\mathcal{L}_{WZ}=\epsilon^{i_1\cdots i_{10}}\sum_{k=0}^{4}\frac{(-1)^k}{2^{k+1}k!(9-2k)!}\overline{\theta}^A\mathcal{P}_{(k)}^{ABC_1\cdots C_k}\gamma_{i_1\cdots i_{9-2k}}\mathcal{D}_{i_{10-2k}}\theta^B F^{C_1}_{i_{11-2k}i_{12-2k}}\cdots F^{C_k}_{i_9 i_{10}}. \tag{4.1}$$

The tensors $\mathcal{P}$ are symmetric in the indices C_i contracted with F. $\mathcal{P}$ also contains the Pauli matrices to specify the $N=2$ structure for the fermions. We have the following possibilites:

$$\begin{array}{lll} k \text{ even:} & 1_2,\sigma_1,\ \sigma_3 & \text{symmetry in } AB,\\ & i\sigma_2 & \text{antisymmetry in } AB,\\ k \text{ odd:} & 1_2,\ \sigma_1,\ \sigma_3 & \text{antisymmetry in } AB,\\ & i\sigma_2 & \text{symmetry in } AB. \end{array} \tag{4.2}$$

This requirement follows from the fact that the bilinear fermions in the action (4.1) should not be a total derivative. The Yang–Mills structure of $\mathcal{P}$ arises from the trace of $k+2$ generators in the fundamental representation of U(n), and will be built from the structure constant f_{ABC} (completely antisymmetric) and from the completely symmetric tensors d_{ABC}. In the Appendix we gather useful properties of these tensors.

The general form of (4.1) follows from the requirement that the Wess–Zumino term is of topological nature, i.e., independent of the metric. The coefficients have been chosen equal to those in the Abelian case, which amounts to a particular normalization of the $\mathcal{P}_{(k)}$. Note that we do not assume a particular ordening in the trace, i.e., there is no a priori symmetry imposed between the indices C_i on the one hand, and A, B on the other hand.

So at order 0 we start with

$$\mathcal{P}_{(0)}^{AB}=\sigma_1\,\mathrm{tr}\,T^AT^B=\sigma_1\delta^{AB}, \tag{4.3}$$

and the variation of the lowest order contribution in (4.1) is

$$\delta\mathcal{L}_{WZ0}=\sqrt{-\det\eta}\,\overline{\eta}^A\sigma_1\Gamma^{(0)}\gamma^i\mathcal{D}_i\theta^A. \tag{4.4}$$

We write the variation of the complete action at this order as

$$\delta\mathcal{L}_0=-\sqrt{-\det\eta}\,\overline{\eta}^A(\delta^{AB}-\Gamma_0^{AB})\mathcal{T}_0^B, \tag{4.5}$$

so that

$$\Gamma_0^{AB}=\Gamma^{(0)}\delta^{AB}\sigma_1,\quad \mathcal{T}_0^A=\gamma^i\mathcal{D}_i\theta^A. \tag{4.6}$$

Cleary $\Gamma^{AC}\Gamma^{CB}=\delta^{AB}$. In the above we considered X^μ to be a singlet under U(n) transformations. To go to the static gauge we would have to set $\det\eta\to-1$.

The Born–Infeld term must reproduce the first term in (4.5). The only choice is to have

$$\mathcal{L}_{BI}=-\sqrt{-\det\eta}(1+\tfrac{1}{2}\overline{\theta}^A\gamma^i\mathcal{D}_i\theta^A). \tag{4.7}$$

We indeed find the correct variation if we set

$$\delta X^\mu=\tfrac{1}{2}\overline{\epsilon}^A\Gamma^\mu\theta^A+\tfrac{1}{2}\overline{\eta}^A\Gamma^\mu\theta^A. \tag{4.8}$$

With this choice of δX the metric (3.42) becomes supersymmetric and covariant under κ-transformations. As we explained at the end of Sec. III this is not the natural metric for the non-Abelian [or for the U$(1)^n$] situation. So the different choices for X^μ start to diverge at this

point. At the linear level there is still no crucial difference between the choice of a singlet X^μ and the static gauge. At the quadratic level, however, the singlet choice will fail.

The variation of the linear contribution to the Wess–Zumino term gives

$$\delta\mathcal{L}_{WZ1}=\tfrac{1}{2}\sqrt{-\det\eta}\,\overline{\eta}^A\mathcal{P}^{ABC}_{(1)}\Gamma^{(0)}(\gamma_{ij}\gamma^k\mathcal{D}_k\theta^B-2\gamma_i\mathcal{D}_j\theta^B)F^{Cij}. \tag{4.9}$$

The first term must correspond to $\Gamma_1\mathcal{T}_0$, from which we read off that

$$\Gamma_1^{AB}=\Gamma^{(0)}\mathcal{P}^{ABC}_{(1)}\,\tfrac{1}{2}\gamma_{ij}F^{ijC}. \tag{4.10}$$

From $\Gamma^2=1$ at linear order we find

$$\{\sigma_1,\Gamma_1^{AB}\}=0, \tag{4.11}$$

so that $\mathcal{P}_{(1)}$ must have the following form:

$$\mathcal{P}^{ABC}_{(1)}=(i\sigma_2)d^{ABC}+c_1\sigma_3 f^{ABC}. \tag{4.12}$$

The coefficient of the *d*-term is chosen to agree with the Abelian case. The coefficient of the *f*-term is arbitrary, and with a field redefinition

$$\theta^A\to\theta^A-\tfrac{1}{4}c_1(i\sigma_2)f^{ABC}\gamma^{kl}\theta^B F^C_{kl}, \tag{4.13}$$

and a corresponding redefinition of the vector field, the *f*-term can be eliminated. This is the choice we will make, because then we stay as close as possible to the Abelian situation.

In fact, the whole term linear in F in the Wess–Zumino action can be transformed away by a field redefinition, also in the Abelian case. It is not surprising that these linear terms can be eliminated, since they are part of the supersymmetrization of the bosonic F^3 term, which we know to be absent. The reason we will keep the usual linear term is that in this form the answer in the Abelian case takes on a relatively simple form.[11]

We also find

$$\mathcal{T}_1^A=-\sigma_1\mathcal{P}^{ABC}_{(1)}\gamma_i\mathcal{D}_j\theta^B F^{ijC}, \tag{4.14}$$

so that in analogy with the Abelian case the Born–Infeld term must contain

$$\mathcal{L}_{BI1}=-\sqrt{-\det\eta}\,(-\tfrac{1}{2}\overline{\theta}^A\sigma_1\mathcal{P}^{ABC}_{(1)}\gamma_{[i}\mathcal{D}_{j]}\theta^B F^{ijC}+\tfrac{1}{4}F^{ijA}F^A_{ij}). \tag{4.15}$$

The variation of this term reproduces correctly the $\mathcal{T}_1$ contribution, and the remainder is cancelled by introducing a variation of V_i,

$$\delta V_i^C=+\tfrac{1}{2}(\overline{\epsilon}^A+\overline{\eta}^A)\sigma_{(1)}\mathcal{P}^{ABC}_{(1)}\gamma_i\theta^B. \tag{4.16}$$

We can then define a supersymmetric and κ-covariant $\mathcal{F}^C$ as

$$\mathcal{F}^C_{ij}=F^C_{ij}-\overline{\theta}^A\sigma_1\mathcal{P}^{ABC}_{(1)}\gamma_{[i}\mathcal{D}_{j]}\theta^B. \tag{4.17}$$

This defines the non-Abelian generalization of the NS–NS two-form field, to this order.

At the quadratic level things become more complicated. The variation of the Wess–Zumino term gives

$$\delta\mathcal{L}_{WZ2}=\sqrt{-\det\eta}\,\overline{\eta}^A\mathcal{P}^{ABCD}_{(2)}\Gamma^{(0)}\{\tfrac{1}{8}\gamma_{ijkl}\gamma^m\mathcal{D}_m\theta^B-\tfrac{1}{2}\gamma_{ijk}\mathcal{D}_l\theta^B\}F^{Cij}F^{Dkl}. \tag{4.18}$$

The variations quadratic in F will have to generate the following contributions:

$$\delta\mathcal{L}_2 = -\sqrt{-\det\eta}\,\overline{\eta}^A(-(\Gamma_2^{AB}\gamma^i\mathcal{D}_i\theta^B+\Gamma_1^{AB}\mathcal{T}_1^B+\Gamma_0^{AB}\mathcal{T}_2^B)+\mathbb{1}\mathcal{T}_2^A). \tag{4.19}$$

We can determine Γ_2 from the requirement that $\Gamma^2=\mathbb{1}$ at order 2,

$$\sigma_1\Gamma_2^{AB}+\Gamma_2^{AB}\sigma_1+\Gamma_1^{AC}\Gamma_1^{CB}=0. \tag{4.20}$$

This calculation assumes that $[\Gamma_2,\sigma_1]=0$, and requires the product of the $\mathcal{P}_{(1)}$-tensors. The result is

$$\Gamma_2^{AB}=-\Gamma^{(0)}\sigma_1(\mathcal{S}^{ABCD}(\tfrac{1}{8}\gamma_{ijkl}F^{ijC}F^{klD}-\tfrac{1}{4}F^C_{kl}F^{klD})+\mathcal{A}^{ABCD}\tfrac{1}{2}\gamma_{ij}F^{ikC}F_k^{jD}). \tag{4.21}$$

Here we have defined

$$\mathcal{S}^{ABCD}\equiv\mathcal{P}_{(1)}^{AE(C}\mathcal{P}_{(1)}^{BD)E}=-d^{AE(C}d^{BD)E}, \tag{4.22}$$

$$\mathcal{A}^{ABCD}\equiv\mathcal{P}_{(1)}^{AE[C}\mathcal{P}_{(1)}^{BD]E}=-d^{AE[C}d^{BD]E}, \tag{4.23}$$

where the (anti-)symmetrization is over the indices C and D only. Note that tensors $\mathcal{S}^{ABCD}$ and $\mathcal{A}^{ABCD}$ are then symmetric and antisymmetric, resp., in the index pairs AB and CD.

To solve the remainder of (4.19) we have to make the choice

$$\mathcal{P}_{(2)}^{ABCD}=-\sigma_1\mathcal{S}^{ABCD}. \tag{4.24}$$

We then find the following result for $\mathcal{T}_2$:

$$\mathcal{T}_2^A=-\mathcal{S}^{ABCD}\gamma_{(i}\mathcal{D}_{j)}\theta^B(F^{ikC}F_k^{jD}+\tfrac{1}{4}\eta^{ij}F^C_{kl}F^{klD})+\tfrac{1}{2}\mathcal{A}^{ABCD}\gamma_{ijk}\{\mathcal{D}^k\theta^BF^{ilC}F_l^{jD}-\mathcal{D}_l\theta^BF^{ijC}F^{klD}\}. \tag{4.25}$$

The result (4.25) agrees with the Abelian result (3.36) if we truncate from U(n) to U(1).

The Born–Infeld term now has to reproduce $\mathcal{T}_2$, while remaining contributions may be cancelled by introducing an additional variation of V_i^A. It is at this stage that the choice of X^μ as a Yang–Mills singlet runs into trouble. Contributions to this variation of the Born–Infeld term come from the F^2 term in the action, when the metric η_{ij}, depending on X^μ, is varied. Such variations contain a double sum over U(n) indices, i.e., they would be of the form [using (4.8)]

$$\partial_iX^\mu\partial_j(\eta^A\Gamma_\mu\theta^A)F^{Cik}F^{Cjk}. \tag{4.26}$$

Such terms would have the wrong U$(1)^n$ limit, and cannot be canceled by other contributions. Partial integration does not help, since it produces symmetric second derivatives on X^μ, which do not occur elsewhere. It is at this stage that we should say farewell to the embedding coordinates X^μ, and proceed in the static gauge.

Terms in the Born–Infeld action that might play a role in this analysis are

$$\begin{aligned}\mathcal{L}_{BI2}=-(&\tfrac{1}{4}F^{ijC}F^C_{ij}+\alpha F^{ikA}F_k^{jB}F^C_{ji}f^{ABC}-\tfrac{1}{2}\overline{\theta}^A\mathcal{S}^{ABCD}\gamma_{(i}\mathcal{D}_{j)}\theta^B\{F^{ikC}F_k^{jD}+\tfrac{1}{4}\eta^{ij}F^C_{kl}F^{klD}\}\\&+\tfrac{1}{4}\overline{\theta}^A\mathcal{A}^{ABCD}\gamma_{ijk}\{\mathcal{D}^k\theta^BF^{ilC}F_l^{jD}-\mathcal{D}_l\theta^BF^{ijC}F^{klD}\}).\end{aligned} \tag{4.27}$$

Note that an F^3 term is in principle not excluded in the non-Abelian case.

In the static gauge we know how to deal with these terms. Then we need not vary the F^2 term. In the F^3 term we have to vary F, which gives an F^2 variation with a single γ-matrix. Therefore it does not relate to the $\mathcal{A}$-terms, which have three γ-matrices, and we must choose α equal to zero. In the $\mathcal{S}$-and $\mathcal{A}$-terms we can perform partial integrations to get rid of the ϵ and $\partial\eta$ terms in the variation. These give equations of motion of V, and can be cancelled by new variations of V. The required identities are

$$\mathcal{D}_j(F^{ik(C}F_k^{jD)}+\tfrac{1}{4}\eta^{ij}F_{kl}^{(C}F^{klD)})=F^{ik(C}\mathcal{D}_jF_k^{jD)}, \tag{4.28}$$

$$\mathcal{D}_{[k}(F_i^{l[C}F_{ij]}^{D]})-\mathcal{D}_l(F_{[ij}^{[C}F_{k]}^{lD]})=-F_{[ij}^{[C}\mathcal{D}_lF_{k]}^{lD]}. \tag{4.29}$$

The remaining η terms in the variation give us precisely $\mathcal{T}_2$. This leads to the following new variations of V_i^A,

$$\delta V_i^A=+\tfrac{1}{2}(\bar{\epsilon}^B+\bar{\eta}^B)\mathcal{S}^{BCDA}\gamma_k\theta^CF^{kiD}+\tfrac{1}{4}(\bar{\epsilon}^B+\bar{\eta}^B)\mathcal{A}^{BCDA}\gamma_{ikl}\theta^CF^{klD}. \tag{4.30}$$

Note that the variation of V_i^A no longer agrees with the result given in (3.30). However, now we should compare with the Abelian result in static gauge. This gauge choice requires a compensating world volume coordinate transformation, which, when acting on V_i, produces the Abelian limit of the $\mathcal{S}$-contribution in (4.30). The $\mathcal{A}$-term in (4.30) vanishes in the Abelian limit.

V. SUMMARY

In this section we will summarize the results obtained in the non-Abelian case. The action is the sum of the Born–Infeld and Wess–Zumino terms. The Wess–Zumino term looks as follows:

$$\mathcal{L}_{WZ}=\epsilon^{i_1\cdots i_{10}}\Big\{\frac{1}{2\cdot 9!}\bar{\theta}^A\sigma_1\gamma_{i_1\cdots i_9}\mathcal{D}_{i_{10}}\theta^A-\frac{1}{4\cdot 7!}\bar{\theta}^A\mathcal{P}_{(1)}^{ABC}\gamma_{i_1\cdots i_7}\mathcal{D}_{i_8}\theta^BF_{i_9i_{10}}^C$$
$$+\frac{1}{16\cdot 5!}\bar{\theta}^A(-\sigma_1\mathcal{S}^{ABCD})\gamma_{i_1\cdots i_5}\mathcal{D}_{i_6}\theta^B(F^CF^D)_{i_7\cdots i_{10}}\Big\}. \tag{5.1}$$

The Born–Infeld action is

$$\mathcal{L}_{BI}=-\{1+\tfrac{1}{2}\bar{\theta}^A\gamma^i\mathcal{D}_i\theta^A-\tfrac{1}{2}\bar{\theta}^A\sigma_1\mathcal{P}_{(1)}^{ABC}\gamma_{[i}\mathcal{D}_{j]}\theta^BF^{ijC}+\tfrac{1}{4}F^{ijA}F_{ij}^A-\tfrac{1}{2}\bar{\theta}^A\mathcal{S}_{ABCD}\gamma_{(i}\mathcal{D}_{j)}\theta^B\{F^{ikC}F_k^{jD}$$
$$+\tfrac{1}{4}\eta^{ij}F_{kl}^CF^{klD}\}+\tfrac{1}{4}\bar{\theta}^A\mathcal{A}^{ABCD}\gamma_{ijk}\{\mathcal{D}^k\theta^BF^{ilC}F_l^{jD}-\mathcal{D}_l\theta^BF^{ijC}F^{klD}\}\}. \tag{5.2}$$

In the action we use the following Yang–Mills structures:

$$\mathcal{P}_{(1)}^{ABC}=(i\sigma_2)d^{ABC}, \tag{5.3}$$

$$\mathcal{S}^{ABCD}=\mathcal{P}_{(1)}^{AE(C}\mathcal{P}_{(1)}^{BD)E}=-d^{AE(C}d^{BD)E}, \tag{5.4}$$

$$\mathcal{A}^{ABCD}=\mathcal{P}_{(1)}^{AE[C}\mathcal{P}_{(1)}^{BD]E}=-d^{AE[C}d^{BD]E}. \tag{5.5}$$

The action is invariant under global supersymmetry transformations and local κ-transformations,

$$\delta\bar{\theta}^A=-\bar{\epsilon}^A+\bar{\eta}^A, \tag{5.6}$$

$$\delta V_i^A=\tfrac{1}{2}(\bar{\epsilon}^B+\bar{\eta}^B)\sigma_1\mathcal{P}_{(1)}^{BCA}\gamma_i\theta^C+\tfrac{1}{2}(\bar{\epsilon}^B+\bar{\eta}^B)\mathcal{S}^{BCDA}\gamma_k\theta^CF^{kiD}+\tfrac{1}{4}(\bar{\epsilon}^B+\bar{\eta}^B)\mathcal{A}^{BCDA}\gamma_{ikl}\theta^CF^{klD}, \tag{5.7}$$

where the parameters ϵ^A satisfy the condition,

$$f_{ABC}\epsilon^C=0. \tag{5.8}$$

As explained in the previous sections, the variation of the action under κ-symmetry can be expressed in terms of

$$\Gamma^{AB}=\Gamma^{(0)}\{\sigma_1\delta^{AB}+\mathcal{P}_{(1)}^{ABC}\tfrac{1}{2}\gamma^{kl}F_{kl}^C-\sigma_1\mathcal{S}^{ABCD}(\tfrac{1}{8}\gamma_{ijkl}F^{ijC}F^{klD}-\tfrac{1}{4}F_{kl}^CF^{klD})$$
$$-\sigma_1\mathcal{A}^{ABCD}\tfrac{1}{2}\gamma_{ij}F^{ikC}F_k^{jD}\}, \tag{5.9}$$

$$\mathcal{T}^A = \gamma^i \mathcal{D}_i \theta^A - \sigma_1 \mathcal{P}^{ABC}_{(1)} \gamma_i \mathcal{D}_j \theta^B F^{ijC} - \mathcal{S}^{ABCD} \gamma_{(i} \mathcal{D}_{j)} \theta^B (F^{ikC} F_k^{jD} + \tfrac{1}{4} \eta^{ij} F_{kl}^C F^{klD}) + \tfrac{1}{2} \mathcal{A}^{ABCD} \gamma_{ijk} \{ \mathcal{D}^k \theta^B F^{ilC} F_l^{jD} - \mathcal{D}_l \theta^B F^{ijC} F^{klD} \}. \tag{5.10}$$

VI. GAUGE FIXING

In the κ-symmetric system which we obtained in this paper, the ordinary supersymmetry is hidden in the local κ-symmetry, and to make it explicit, κ-symmetry should be gauge fixed. This analysis is very similar to the one done in the Abelian case in Ref. 11.

To do this analysis it is convenient to write out the $N=2$ doublets explicitly. We write

$$\Gamma = \begin{pmatrix} 0 & \gamma \\ \tilde{\gamma} & 0 \end{pmatrix}, \tag{6.1}$$

with

$$\Gamma^2 = \begin{pmatrix} \gamma\tilde{\gamma} & 0 \\ 0 & \tilde{\gamma}\gamma \end{pmatrix} = 1. \tag{6.2}$$

Here γ, $\tilde{\gamma}$ are 32×32 matrices, with in addition indices AB, where A, B run from 1 to n^2. Then, splitting also the fermions into separate $N=1$ fermions, we write variations as follows:

$$\delta\overline{\theta}_1^A = -\overline{\epsilon}_1^A + \overline{\eta}_1^A, \quad \delta\overline{\theta}_2^A = -\overline{\epsilon}_2^A + \overline{\eta}_2^A. \tag{6.3}$$

The parameters η can be expressed in terms of parameters κ,

$$\overline{\eta} = (\overline{\eta}_1 \quad \overline{\eta}_2) = (\overline{\kappa}_1 + \overline{\kappa}_2 \tilde{\gamma} \quad \overline{\kappa}_2 + \overline{\kappa}_1 \gamma). \tag{6.4}$$

Now we choose a κ-gauge by setting $\overline{\theta}_2 = 0$, which implies that the transformation parameters must satisfy

$$\overline{\kappa}_2 = \overline{\epsilon}_2 - \overline{\kappa}_1 \gamma. \tag{6.5}$$

So after κ-gauge fixing the remaining η is

$$\overline{\eta}_1 = \overline{\epsilon}_2 \tilde{\gamma}, \tag{6.6}$$

and the remaining fermions $\chi^A \equiv \theta_1^A$ transform as

$$\delta\overline{\chi}^A = -\overline{\epsilon}_1^A + \overline{\epsilon}_2^B \tilde{\gamma}^{BA}. \tag{6.7}$$

Let us now look at the gauge fixed action. The Wess–Zumino term vanishes after gauge fixing, since it was off-diagonal in the fermions θ_1 and θ_2. The Born–Infeld term gives

$$\mathcal{L}_{BI} = -\{1 + \tfrac{1}{2}\overline{\chi}^A \gamma^i \mathcal{D}_i \chi^A + \tfrac{1}{2} d_{ABC} \overline{\chi}^A \gamma_{[i} \mathcal{D}_{j]} \chi^B F^{ijC} + \tfrac{1}{4} F^{ijA} F_{ij}^A + \tfrac{1}{2} d^{AEC} d^{BDE} \overline{\chi}^A \gamma_{(i} \mathcal{D}_{j)} \chi^B \{ F^{ikC} F_k^{jD} + \tfrac{1}{4} \eta^{ij} F_{kl}^C F^{klD} \} - \tfrac{1}{4} d^{AE[C} d^{BD]E} \overline{\chi}^A \gamma_{ijk} \{ \mathcal{D}^k \chi^B F^{ilC} F_l^{jD} - \mathcal{D}_l \chi^B F^{ijC} F^{klD} \} \}. \tag{6.8}$$

Note that the terms of the form $\overline{\chi}\partial\chi F^2$ are not symmetric traces of $\mathrm{U}(n)$ generators. The symmetric trace is of the form,

$$\mathrm{tr}\, T_{(A} T_B T_C T_{D)} = \tfrac{1}{3}(d_{ABE} d_{CDE} + d_{CAE} d_{BDE} + d_{BCE} d_{ADE}). \tag{6.9}$$

The second line in (6.8) contains only two of the three contributions needed for the symmetric trace, the last line contains explicit antisymmetrizations and can be rewritten in terms of structure constants,

$$d_{AEC}d_{BDE}-d_{AED}d_{BCE}=f_{ABE}f_{CDE}\,. \tag{6.10}$$

Finally, the linear and nonlinear supersymmetry transformations which leave (6.8) invariant are of the form,

$$\delta\chi^A=-\bar{\epsilon}_1^A-\bar{\epsilon}_2^A+\bar{\epsilon}_2^B\{d^{BAC}\tfrac{1}{2}\gamma^{kl}F^C_{kl}+\mathcal{S}^{BACD}(\tfrac{1}{8}\gamma_{ijkl}F^{ijC}F^{klD}-\tfrac{1}{4}F^C_{kl}F^{klD})\},$$
$$\delta V_i^A=-\tfrac{1}{2}(\bar{\epsilon}_1^B-\bar{\epsilon}_2^B)d^{BCA}\gamma_i\chi^C-\tfrac{1}{4}\bar{\epsilon}_2^B d^{BED}d^{ECA}\gamma_{kl}\gamma_i\chi^C F^{klD}+\tfrac{1}{2}(\bar{\epsilon}_1^B-\bar{\epsilon}_2^B)\mathcal{S}^{BCDA}\gamma_k\chi^C F^{kiD}. \tag{6.11}$$

Note that contributions with $\mathcal{A}$, the antisymmetrized product of two d-tensors, do not appear because of (6.10) and the fact that ϵ must be in the U(1) direction.

VII. CONCLUSIONS

In this paper we have obtained the non-Abelian generalization of the Born–Infeld action up to terms quartic in the Yang–Mills field strength, and including all fermion bilinear terms up to terms cubic in the field strength. The terms of the form $\bar{\chi}\partial\chi F^2$ violate the symmetric trace conjecture.

The κ-symmetric construction of the Born–Infeld action involves the matrix Γ, satisfying $\Gamma^2=\mathbb{1}$, which is used to project away one of the components of the fermion doublet. In the Abelian case Γ factorizes in a part that is polynomial in F, and the inverse of the Born–Infeld action, which expands to an infinite series in F. In the non-Abelian case we are not yet at a stage that such a factorization could be recognized. We see however, that the result (5.9) is consistent with a factorization of the form,

$$\Gamma^{AB}=\Gamma^{(0)}\{\sigma_1\delta^{AC}+\mathcal{P}^{ACF}_{(1)}\tfrac{1}{2}\gamma^{kl}F^F_{kl}-\sigma_1\mathcal{S}^{ACFG}(\tfrac{1}{8}\gamma_{ijkl}F^{ijF}F^{klG})-\sigma_1\mathcal{A}^{ACFG}\tfrac{1}{2}\gamma_{ij}F^{ikF}F_k^{jG}\}$$
$$\times(\delta^{CB}+\mathcal{S}^{CBDE}\tfrac{1}{4}F^D_{mn}F^{mnE}). \tag{7.1}$$

Note that, as in the Abelian case, $\mathcal{T}$ (5.10) contains the inverse of the factor that we find in Γ. Clearly the second factor in the above expression is not a U(n) singlet, and therefore does not correspond to the inverse of the action. Further analysis, which we plan to do at the cubic and quartic level in F, should elucidate in which sense these factors are related to the Born–Infeld action.

It is intriguing that κ-symmetry and worldvolume reparametrization invariance appear to be incompatible. Although for applications such as the construction of non-Abelian BPS states this is not a drawback, issues of superspace and curved background remain unclear in the static gauge. One way to try to resolve the issue of embedding coordinates would be to look in more detail at the transformation rules of V_i^A. If a formulation with world volume reparametrization invariance exists, then our formulation should be its gauge fixed version, and we should recognize the corresponding compensating transformation in the transformation rule of V_i^A. To give an example, let us consider the possibility that the embedding coordinates are in the adjoint of U(n), and transform as

$$\delta X^{\mu A}=d^{ABC}\xi^{iB}\partial_i X^{\mu C}+\delta_\epsilon X^{\mu A}+\delta_\eta X^{\mu A}. \tag{7.2}$$

Let us now gauge fix this extended worldvolume symmetry, by setting $X^A=0$ for all $A\in\mathrm{SU}(n)$, and $X^{\mu 1}=\delta_i^\mu\sigma_i$ for $A=1\in\mathrm{U}(1)$. Then the compensating transformation which preserves this gauge is of the form,

$$\xi^{\mu A}=-\delta_\epsilon X^{\mu A}-\delta_\eta X^{\mu A}. \tag{7.3}$$

Here we have used that $d^{AB1}\sim\delta^{AB}$, in a basis where the U(1) component of U(n) is labeled by $A=1$. Then, if the variation of V_i^A under world volume coordinate transformations is of the form,

$$\delta V_i^A = d^{ABC}\xi^{kB}F_{ki}^C, \tag{7.4}$$

we see that the term proportional to $\mathcal{S}$ in (5.7) has almost the right form to be interpreted as a compensating transformation. However, the Yang–Mills structure in this expression is not quite correct, as the indices of V and F are not on the same d-tensor. We have found that if one chooses in (4.12) $c_1=1$, that then the structure comes out all right, and gives

$$\delta X^{\mu A} \sim d^{ABC}d^{BDE}(\bar{\epsilon}^D+\bar{\eta}^D)\gamma^k\theta^E\partial_k X^{\mu C}. \tag{7.5}$$

It would be interesting to see whether or not the construction of the generalized Born–Infeld action including the worldvolume structure indicated above is possible.

As mentioned above, the generalization to a curved background would be greatly facilitated by a better understanding of the superspace structure of the D-brane action. However, there is also another open issue to consider. Consider the expression (4.17), where we give the non-Abelian generalization of the relation $\mathcal{F}=F+B$ in a flat background. In going to a curved background we have to decide how and where to introduce the NS–NS fields. Should there be a non-Abelian generalization of the NS–NS field B, or do only the U(1) fields on the worldvolume couple effectively to the background fields? Similar questions can be raised about the RR-fields [see (4.1)], whose form in a flat background also suggests that a non-Abelian generalization should be required.

In a future publication,[20] we hope to extend this work to higher order in F, and to apply the results to the construction of non-Abelian BPS states. The simplest situation to think of is the relation between D-branes at angles[21] and overlapping branes through T-duality.[7] As was shown in Ref. 8 the BPS conditions between angles translate to conditions between magnetic fields F which include contributions cubic in F. Therefore we will have to go at least to order F^3 in the supersymmetry transformation rules to be able to compare our results with the predictions implied by Ref. 21. In the Abelian case the relation between κ-symmetric formulations and BPS states was formulated in Ref. 22. In particular, there it was shown that the knowledge of Γ is in fact sufficient to obtain BPS states. It would be interesting to generalize these results to the non-Abelian situation.

Finally, it would be instructive to apply other approaches than the one employed in this paper to find the complete answer. For instance, one could use the superembedding techniques developed in Refs. 23 and 24. Yet another approach could be to extend to the non-Abelian case the analysis of Ref. 25, where it was shown how the super world volume dynamics of superbranes can be obtained from nonlinear realizations.

ACKNOWLEDGMENTS

We like to thank I. Bandos, M. Cederwall, S. Ferrara, S. F. Hassan, E. Ivanov, R. Kallosh, U. Lindström, C. Nappi, A. Peet, V. Periwal, D. Sorokin, J. Troost, and A. Tseytlin for useful discussions. Many of these took place at Strings 2000, and we would like to thank the organizers for providing such a stimulating environment. We are grateful to the Spinoza Institute, Utrecht, halfway between Brussels and Groningen, for the hospitality extended to us. This work is supported by the European Commission RTN program HPRN-CT-2000-00131, in which E.B. and M.d.R. are associated to the university of Utrecht and A.S. is associated to the university of Leuven.

APPENDIX: PROPERTIES OF U(n) GENERATORS, ETC.

In these notes indices $A,B,\ldots$ run from 1,...,n^2. We freely raise and lower these indices.

We use the following conventions for Yang–Mills transformations of the non-Abelian Yang–Mills multiplet:

$$\delta\theta^A = f^A{}_{BC}\Lambda^B\theta^C, \tag{A1}$$

$$\delta V_i^A = -\mathcal{D}_i \Lambda^A, \tag{A2}$$

$$\mathcal{D}_i \theta^A = \partial_i \theta^A + f^A{}_{BC} V_i^B \theta^C, \tag{A3}$$

$$F_{ij}^A = \partial_i V_j^A - \partial_j V_i^A + f^A{}_{BC} V_i^B V_j^C, \tag{A4}$$

$$\mathcal{D}_{[i} \mathcal{D}_{j]} \theta^A = \tfrac{1}{2} f^A{}_{BC} F_{ij}^B \theta^C. \tag{A5}$$

The U(n) generators are Hermitian $n \times n$ matrices. Our normalization for the trace of two U(n)-generators is

$$\mathrm{tr}\, T_A T_B = \delta_{AB}. \tag{A6}$$

In general, we write for the product of two U(n) generators,

$$T_A T_B = +(d_{ABC} + i f_{ABC}) T_C, \tag{A7}$$

where d and f are symmetric and antisymmetric in AB, respectively. We recognize that

$$[T_A, T_B] = 2 i f_{ABC} T_C,$$

$$\{T_A, T_B\} = 2 d_{ABC} T_C. \tag{A8}$$

From this we conclude that

$$\mathrm{tr}[T_A, T_B] T_C = 2 i f_{ABC},$$

$$\mathrm{tr}\{T_A, T_B\} T_C = 2 d_{ABC}. \tag{A9}$$

This tells us that in fact f is completely antisymmetric, and d completely symmetric in ABC.

Then we have the Jacobi identity and its generalizations. These follow from

$$[[T_A, T_B], T_C] + [[T_B, T_C], T_A] + [[T_C, T_A], T_B] = 0,$$

$$[\{T_A, T_B\}, T_C] + [\{T_B, T_C\}, T_A] + [\{T_C, T_A\}, T_B] = 0,$$

$$[T_C, [T_A, T_B]] = \{T_B, \{T_C, T_A\}\} - \{T_A, \{T_B, T_C\}\}. \tag{A10}$$

From these we derive the following identities for the f and d tensors:

$$f_{ABE} f_{ECD} + f_{BCE} f_{EAD} + f_{CAE} f_{EBD} = 0, \tag{A11}$$

$$d_{ABE} f_{ECD} + d_{BCE} f_{EAD} + d_{CAE} f_{EBD} = 0, \tag{A12}$$

$$f_{ABE} f_{ECD} = d_{CAE} d_{BED} - d_{CBE} d_{AED}. \tag{A13}$$

I. THIRTY YEARS OF PROGRESS

Since my topic is the future of string theory, I will discuss issues and problems that are currently unresolved and where there is still confusion, doubt, and uncertainty. However, if I were to do only that, it would give a distorted view of a subject that has undergone tremendous progress over the past thirty years. Therefore, to give a more balanced picture, I have decided to begin by presenting a brief chronology of some of the major developments that have taken place. I think we are entitled to look back on this with considerable pride and satisfaction.

- 1968–70: String theory developed to describe the strong interactions (hadron physics)
- 1971–73: Supersymmetry introduced in string theory and field theory
- 1974: String theory reinterpreted as a unified theory of gravity and other forces
- 1976–78: Supergravity; Montonen–Olive duality
- 1977–83: Superstring theory; path-integral formulation
- 1984: Anomaly cancellation; heterotic strings; Calabi–Yau compactification
- 1985–89: Conformal field theory; superstring perturbation theory; T duality; mirror symmetry; string field theory; matrix models
- 1990–94: S duality; p-branes; Seiberg–Witten theory
- 1995: Topology change; M theory; dualities relating all superstring theories and M theory; D-branes
- 1996: Black-hole entropy; F theory; matrix theory
- 1997–99: Brane configurations; AdS/CFT duality; noncommutative geometry; brane worlds

II. THE ISSUES

Let me now discuss where I think future progress will occur. There are two major fields that string theory ought to illuminate some day: particle physics and cosmology. (A third one is mathematics, but I will not discuss that.) Even though we think of particle physics as addressing the microscopic extreme and cosmology the macroscopic extreme, it is quite natural to consider them together when dealing with a theory that incorporates gravity, as string theory does. Relativists and particle theorists have both identified the important problem of reconciling quantum theory with general relativity. The prospect of achieving this attracts both of them to string theory. It is clear to many of us that string theory really does achieve this reconciliation, but it is also clear that there are important aspects of how this works that are not yet fully understood.

[a)]Electronic mail: jhs@theory.caltech.edu

One such issue concerns the status of quantum mechanics and information loss. In 1976, Hawking argued that the existence of black holes implies that a pure quantum state can evolve into a mixed state, in other words there is a loss of quantum coherence. Were this to happen, it would mean a breakdown of quantum mechanics. I think it is quite clear that string theory respects quantum mechanics, and it might even explain it. It gives unitary evolution without loss of coherence, and it can also describe black holes. Thus, it should be possible to study black holes in string theory and to explain precisely how Hawking's argument breaks down. Despite a great deal of effort, I don't think that this has yet been done in a clear and convincing way. However, I certainly believe that it should be possible.

Let me now turn to the most vexing and far-reaching of the unresolved issues: the cosmological constant.

A. The cosmological constant

The low energy effective theory of gravity contains the standard Einstein–Hilbert term:

$$S_{\mathrm{E}}=\frac{1}{16\pi G}\int \sqrt{-g}R\, d^4x.$$

Theoretically, it is natural to also include a vacuum energy, or cosmological, term,

$$S_{\Lambda}=\int \Lambda\sqrt{-g}\, d^4x.$$

Here, the parameter Λ—called the cosmological constant—can be interpreted as the energy density of the vacuum. Such a term is generically induced by radiative corrections even if it is zero in the classical theory. In particular, it receives contributions from the zero-point energies of all fields in the theory. You need a well-defined quantum theory of gravity, before the vacuum energy becomes something computable. String theory is the only such theory on the market. So it is only with the advent of string theory that proposals for understanding this parameter from a fundamental theoretical viewpoint can be analyzed.

Observationally, the bounds on Λ are exceedingly severe. As a first approximation, one can simply require that the energy in the form of vacuum energy is less than the amount that would give closure of the universe. Using this bound, one finds that Λ, expressed in Planck units, is less than 10^{-122}. This is the best measured approximation to zero of any physical parameter in nature. We do not yet have a convincing way to derive why Λ should be this small in the context of a realistic model. Even so, it seems much more likely that someday we will be able to derive the answer zero than an answer of order 10^{-122}.

In recent years, astrophysicists and cosmologists have settled on a fairly precise inventory of how mass and energy are distributed in the universe. Important constraints come from studies of the cosmic microwave background, large scale structure, and Type Ia supernovas, together with the rest of standard cosmology. Based on this, they have concluded the following: The total mass and energy in the universe give, to within about 10%, the critical closure density. This is the value required by inflation, which gives a flat open universe. It has been clear for some time that an appreciable fraction of the mass of the universe is in the form of *dark matter*, but now it appears that there is a second mysterious component, which could be called *dark energy*. The inventory of mass and energy is roughly as follows: 5% is baryonic matter, 25% is dark matter (mostly cold dark matter, but a small portion could be massive neutrinos), and 70% is dark energy. Cold dark matter is concentrated in the halos of galaxies, whereas dark energy is distributed uniformly throughout the universe.

Each component has an equation of state of the form $p=w\rho$, where p is pressure and ρ is density. Nonrelativistic matter has $w=0$ and radiation has $w=1/3$. To fit the data, the dark energy should have an equation of state with $-1.0\leqslant w<-0.5$. Future observations should determine this

parameter with greater accuracy. The most popular guess, which fits the data well, is that the dark energy is vacuum energy (i.e., a cosmological constant). This gives $w=-1$.

Components of the universe with different values of w evolve differently:

$$\rho \sim R^{-3(1+w)},$$

where R is the scale factor of the universe. Thus the universe was primarily comprised of matter (and radiation) in the distant past and will be more and more comprised of dark energy in the future. This means that the present epoch of the universe is rather special: it is the epoch in which the contributions of matter and dark energy are comparable. This is a surprising coincidence, but it seems to be a fact.

As we have already indicated, if the dark energy is vacuum energy, this corresponds to a value of the cosmological constant that is so small that it seems implausible that we will be able to derive it. Therefore it behooves us to ask whether there are any other candidates for the dark energy.

One alternative to a cosmological constant, which has been discussed quite a bit lately, goes by the name of *quintessence*—a word that originally referred to the human soul. In current usage it is the energy carried by a scalar field, which is not at the minimum of the potential, but is still rolling towards its minimum value. If it rolls sufficiently slowly, the phenomenology becomes very similar to that of a cosmological constant. (This kind of slow-roll mechanism is reminiscent of ''new inflation,'' though at a vastly lower energy scale than in the case of the big bang.) In such a scenario the fundamental value of Λ could be zero, if that is the minimum of the potential that is being approached asymptotically. In this way one avoids the need to explain an exceedingly small cosmological constant, but other equally challenging puzzles arise. For one thing, getting the field to roll slowly enough involves a fine-tuning of parameters that is just about as formidable as that for a tiny cosmological constant.

Such a slowly rolling scalar would correspond to a spin zero particle that is essentially massless, since the curvature of the potential would correspond to a Compton wavelength comparable to the size of the universe. Therefore this scalar could mediate long-range scalar forces. There are many ways in which massless scalar fields can arise in string theory, such as moduli associated with compactification and a dilaton. All of them typically have couplings to ordinary matter that is roughly of gravitational strength. The fact that gravity is observed to be a purely tensor force, to better that one percent accuracy, severely restricts the possibilities for massless scalars. So this seems to me to be a problem for accommodating the quintessence proposal in the context of string theory.

Another issue to be considered is that the values of scalar fields in string theory control observable parameters such as Newton's constant and the fine structure constant. A rolling scalar would therefore be expected to imply that these are changing with time. Observational bounds on such time variation are quite severe, so this is also a problem for the quintessence proposal.

If neither a cosmological constant nor quintessence is the right answer, what other possibilities are there? There has been some discussion of schemes in which the dark energy would be carried by topological defects. For example, domain walls that are solid (i.e., they resist shear) and have certain other special properties could give $w=-2/3$. As it stands, this does not look very convincing. However, neither do any of the alternatives.

So, to conclude this part of the discussion, even if we knew how to prove that the cosmological constant vanishes in string theory, there would still be a serious problem accounting for the cosmological observations. It will be interesting to see whether future high-precision determinations of the cosmological parameters confirm the present picture.

B. What is the role of supersymmetry?

Supersymmetry appears to be an essential feature in string theory and M-theory that is required to ensure mathematical consistency. Therefore it seems pretty clear that supersymmetry should be physically relevant at the fundamental scale, which is either the string scale or the

eleven-dimensional Planck scale. But a crucial question, whose answer is much less certain, is whether supersymmetry is also relevant to the description of physics at the electroweak scale. There are several unrelated arguments that suggest that a supersymmetry is broken near the electroweak scale. Even though none of them is conclusive, it is very impressive that they each lead to roughly the same scale for the typical mass of superpartners.

(1) Supersymmetry provides a solution to the gauge hierarchy problem. The ratio of the electroweak scale to the unification scale or the string scale is around 10^{-14}. In the context of the standard model this is puzzling, since quadratic divergences in the Higgs mass would renormalize the Higgs mass (and hence the electroweak scale) up to the cutoff. Supersymmetry builds in cancellations that softens these divergences to being only logarithmic, thereby protecting the hierarchy from being destroyed by radiative corrections. (This does not explain where the hierarchy comes from in the first place.) This reasoning requires that the energy scale that characterizes supersymmetry breaking should be comparable to the electroweak scale—i.e., around 100 GeV to 1 TeV. This argument is not a proof of supersymmetry, because there could be other solutions to the hierarchy problem. One is known, and there could be others.
(2) The unification of the three gauge couplings at a high energy scale works much better with supersymmetry than without it. In fact, studying the fits with a variable supersymmetry breaking scale one finds that unification of the couplings is achieved for a supersymmetry mass gap less than a few TeV. This is very impressive, but one could certainly imagine that other new physics at intermediate scales could also lead to successful unification.
(3) A neutralino LSP with a mass of about 50–500 GeV is an excellent candidate for cold dark matter. It is not possible to be much more precise than this, because we do not know yet the mixture of gauginos and Higgsinos that makes up the LSP, and that affects the relationship between the LSP mass and the cosmological mass fraction that it provides. If the LSP is the dominant component of cold dark matter, the universe could have five times as much mass in neutralinos as in baryons.
(4) In the context of supersymmetric grand unified models the renormalization group running of Higgs masses can give rise to electroweak symmetry breaking at roughly the right scale. In this way supersymmetry helps in establishing the hierarchy as well as in protecting it from radiative corrections.

Supersymmetry may be relevant to solving the cosmological constant problem. There are many known string theory solutions that give a flat Minkowski spacetime with unbroken supersymmetry. They are unrealistic, of course, since supersymmetry has to be broken. However, for these solutions, supersymmetry ensures that radiative corrections do not generate a cosmological constant. So, at least in the context of unrealistic solutions, there is a symmetry explanation of the vanishing of the cosmological constant. Unfortunately, it seems that this cancellation mechanism only works for solutions with unbroken supersymmetry. When supersymmetry is broken, one expects to get a cosmological constant with a size controlled by the supersymmetry mass gap. Assuming that scale is around 1 TeV, the resulting cosmological constant is still some 56 orders of magnitude too big. That's an improvement on 124 orders of magnitude, but it leaves a lot of room for further progress.

Therefore, I like to pose the problem of the cosmological constant as the following question: *Is there a supersymmetry breaking mechanism that does not generate a cosmological constant?* Such a mechanism is not known, but it seems to me that this is what we need. If one were discovered, that would be very exciting. Generic breaking of supersymmetry in the MSSM introduces over 100 new parameters, which is one of the reasons that it is so difficult to use it to make quantitative predictions. I would expect the ''right'' supersymmetry breaking mechanism to be highly constrained and therefore much more predictive.

Lest I leave you with the wrong impression, I should point out that this problem has received a lot of attention over the years. Ingenious proposals have been put forward by Moore, Witten, Kachru and Silverstein, and others. However, I suspect that the correct solution still remains to be

discovered. It might be that insights gained from AdS/CFT duality will provide a better framework for thinking about the cosmological constant. In any case, the importance of this problem cannot be overstated.

C. What is the theory?

What is the theory? What is the principle on which it is based? What is the best way to formulate it? It is rather striking that after 30 years of enormous progress and effort by many hundreds of the most talented physicists, string theory is not yet fully formulated.

Matrix theory and AdS/CFT duality can be viewed as providing exact nonperturbative definitions of string theory or M-theory for certain classes of solutions. This is a remarkable achievement, but we want more than a new recipe for each solution. We want a single formulation that applies to all possible solutions. When such a formulation is found, it is entirely possible that the name *string theory* will no longer be considered appropriate. I suspect that *M-theory* will not fill the bill either. But this is a secondary issue. Understanding the theory is much more important than naming it.

I do not know what form the theory will take when it is completed. It might, for example, be based on some abstract algebraic structure. The concepts of space and time are likely to emerge as properties of particular solutions rather than as smooth background geometries on which the theory is formulated in the first place. It is hard to begin to formulate a theory without reference to spacetime, since it is so radically different from anything we have dealt with before. The standard recipe would have us introduce quantum fields for particles or strings or whatever, and then formulate an action that describes their propagation in a given spacetime manifold. What we seem to need is a theory for which the particles or the strings, as well as the spacetime manifold, are properties of particular solutions rather than features of the underlying theory itself.

I expect that the optimal formulation of the theory will eventually be found, but I would not wish to attach a time frame to this prediction. One lesson I have learned during my career is that it is very hard to anticipate future developments. String theory has undergone several revolutions that have profoundly changed the way we think about the subject. Each one has caused us to ask new questions that we would not have even posed before. It is not at all clear to me how many more such revolutions are still required before we are in a position to formulate the theory properly. I would guess that the process is finite, and that we will eventually get there, but it is hard to assess how close we are at the present time. Once found, this theory will surely be a thing of great beauty, based on profound physical and mathematical principles. As I mentioned earlier, it will probably be sufficiently different from the present formulations to justify giving the subject a new name. However, I do not think there is yet a good reason to drop the name ''string theory.''

D. What is the right solution?

Formulating the theory is not the whole problem. What is likely to prove to be even harder is the determination of a realistic solution. While I am convinced that the theory should be completely unique, with no adjustable parameters, I suspect that the story for solutions is very different. Every indication is that the theory admits a large number of different solutions, most of which are completely unrealistic. Indeed, the ones that are known are supersymmetric, and therefore certainly unrealistic.

There are a number of obvious questions that need to be answered: Can one completely classify all solutions of the theory? Is there a realistic solution with a Lorentz invariant vacuum, that gives an accurate description of particle physics? Is there a cosmological solution that describes the evolving universe that we observe? Can these two questions be addressed separately or do we need to understand cosmology to give a proper description of particle physics?

For the reasons I discussed earlier, it would probably be better if there were no massless or rolling scalars. An added bonus of this is that it would mean that the quantum effective potential that describes the dynamics of all light scalar fields has an isolated minimum. If such a minimum

could be determined theoretically, the corresponding solution would have no continuously adjustable parameters, and all physical quantities would become computable in principle. This would be a very satisfying outcome.

E. Extra dimensions of space

Besides fermionic dimensions, string theory also requires extra spatial dimensions of a somewhat more conventional type. These have generally been assumed to form a compact space of six or seven dimensions with a size that is roughly comparable to the string scale, which might be some 10^{-32} cm. The details of the geometry of the compact space profoundly influence the physics that is observed in four large dimensions. Thus we can hope to infer the geometry indirectly, even though such small extra dimensions would not be directly accessible by foreseeable experiments.

Some physicists have recently suggested that the extra dimensions could be much larger than previously envisioned, maybe even so large as to be experimentally observable. There is now a rather large community actively exploring possible scenarios of this type. To be honest, I find the idea of large extra dimensions to be rather implausible, since it undermines some of the successful predictions of grand unification, such as unification of the couplings and suppression of proton decay. Nevertheless, I do feel that it is worthwhile to explore these ideas, and to improve the experimental bounds. Who knows what might turn up?

F. The role of experiment

I do not expect the right solution to be found by pure thought alone. Experimental guidance, and the more traditional back and forth between theory and experiment, will be important in this quest. One central issue that experimentalists will settle in the next ten or twenty years is what the new physics is that is responsible for electroweak symmetry breaking and mass generation.

The experiments will surely discover one or more Higgs particles. The bigger question, in my opinion, is whether they will find evidence for supersymmetry that is broken at the electroweak scale. If this is the case, then supersymmetry particles should be discovered experimentally at Fermilab or CERN in the early part of the century. This discovery would have profound theoretical and experimental consequences. It would provide evidence for a nontrivial extension of the known symmetries of space and time, an extension which could be described as the discovery of fermionic dimensions. Also, it would set the agenda for experimental particle physics for several decades. When I want to be sure to be quoted, I tell reporters that the discovery of supersymmetry would be more profound than life on Mars.

In addition to experiments at particle accelerators, there are also important nonaccelerator experiments being carried out. For example, dark matter searches are underway. Over the next few years they are expected to achieve the sensitivity required to cover most of the parameter space that is favored for axions or neutralinos. My guess is that a neutralino LSP will eventually turn up in these searches.

Such discoveries would make it clear that the abstract mathematical musings of the past thirty years can be connected to experimental science. Experimental facts about supersymmetry at the electroweak scale would provide crucial guidance in the quest to understand how to connect the underlying theory to the real world. Maybe it would even guide us to the discovery of a supersymmetry breaking mechanism that does not generate a cosmological constant.

G. The role of communication

The final decade of the old millennium saw the birth—from within particle physics—of a powerful new technology called the World Wide Web, which has been quietly revolutionizing education and bringing young people closer to physics than they could ever get when I was a boy in school. For example, on the Superstringtheory.com web site over Christmas break, the following message appeared posted by a teenager from Canada:

'This was a great site that agreed with many of my own theories of ''strings.'' For the first time in my life it seems that someone seems to know what the heck I ''know.'' (I am in grade 9 so when I bring up the topic of quantum mechanics I usually get a fuzzy stare.) Keep up the excellent work.'

So not only is the next generation of string theorists out there, we have a way to reach them, and they have a way to reach us, that has never existed before in history.

Therefore I would like to predict that the future could look very bright in that direction, if we take full advantage of this new technology.

III. CONCLUSION

In conclusion, string theory has developed into one of the most active areas of theoretical physics in recent years. The last third of the 20th century witnessed the construction of an amazing mathematical edifice, which we are struggling to understand. I expect to see equally striking progress achieved in the first third of the 21st century.

The theory is still not fully understood, but I am optimistic that a deeper formulation, which makes clear that it is a unique theory, will be found. I also think that there is a good chance that we will understand how to find solutions that are able to account for the observations of particle physics and cosmology.

The construction of the standard model arose as a collaborative effort in which theorists and experimentalists both made major contributions. In the case of string theory, the natural energy scale is much higher, and so it is more difficult to make contact with experiment. To date, the interactions with mathematicians have played a bigger role than the ones with experimentalists. In the future, I expect that both will be very important. The subject involves a lot of new and bizarre concepts, much as quantum mechanics did in the first half of the 20th century. Before we are through, it is likely that more of them will be identified. To get it right, we will need the help of our mathematical and experimental friends. It is only fitting that a theory that unifies particles and forces should also unify disciplines.

An exact prediction of $\mathcal{N}=4$ supersymmetric Yang–Mills theory for string theory

Nadav Drukker[a)]
CIT-USC Center for Theoretical Physics, University of Southern California, Los Angeles, California 90089-2535

David J. Gross[b)]
Institute for Theoretical Physics, University of California, Santa Barbara, California 93106

(Received 2 January 2001; accepted for publication 13 February 2001)

We propose that the expectation value of a circular BPS-Wilson loop in $\mathcal{N}=4$ supersymmetric Yang–Mills can be calculated exactly, to all orders in a $1/N$ expansion and to all orders in g^2N. Using the AdS/CFT duality, this result yields a prediction of the value of the string amplitude with a circular boundary to all orders in α' and to all orders in g_s. We then compare this result with string theory. We find that the gauge theory calculation, for large g^2N and to *all* orders in the $1/N^2$ expansion, does agree with the leading string theory calculation, to all orders in g_s and to lowest order in α'. We also find a relation between the expectation value of any closed smooth Wilson loop and the loop related to it by an inversion that takes a point along the loop to infinity, and compare this result, again successfully, with string theory. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1372177]

I. INTRODUCTION

There have been many tests of the conjectured duality of $\mathcal{N}=4$ supersymmetric Yang–Mills theory (SUSYM) with type IIB string theory in an $AdS_5\times S^5$ background. However, since the duality relates gauge theory with coupling g^2 and gauge group of rank N to type IIB string theory in an AdS background with radius $R^2=\sqrt{g^2N}\alpha'$ and string coupling $4\pi g_s=g^2$, the only precise tests have been of quantities so protected by supersymmetry that they receive no perturbative or nonperturbative corrections. It is easy to calculate quantities in the gauge theory for weak coupling—but these yield predictions for string theory in a very curved background, where there do not yet exist methods of computation. Conversely, it is easy to calculate quantities in the string theory for weak coupling (large N) and large curvature (or small α')—but these yield predictions for the gauge theory for large N and large g^2N, for which there are no reliable methods of computation. In neither case, so far, is there a prediction on either side that holds for all N and g^2.

We will suggest, in this paper, that the expectation value of a circular BPS-Wilson loop in $\mathcal{N}=4$ (SUSYM) can be calculated exactly, to all orders in a $1/N$ expansion and to all orders in g^2N. This then yields a prediction of the value of the string amplitude with a circular boundary to all orders in α' and to all orders in g_s. We then compare this result with string theory. We find that the gauge theory calculation, for large g^2N and to *all* orders in the $1/N^2$ expansion, does agree with the leading string theory calculation, to all orders in g_s and to lowest order in α'.

Our result is an extension of a beautiful paper,[1] in which Erickson, Semenoff and Zarembo calculated the contributions of rainbow graphs to the expectation value of a circular Wilson loop in $\mathcal{N}=4$ supersymmetric gauge theory. The result they found was that

$$\langle W\rangle_{\text{rainbow}}=\frac{2}{\sqrt{\lambda}}I_1(\sqrt{\lambda}), \tag{1.1}$$

[a)]Electronic mail: drukker@usc.edu
[b)]Electronic mail: gross@itp.ucsb.edu

where $\lambda = g^2 N$ is the 't Hooft coupling and I_1 is a Bessel function. For large λ (1.1) behaves as

$$\langle W \rangle_{\text{rainbow}} \sim \sqrt{\frac{2}{\pi}} \frac{e^{\sqrt{\lambda}}}{\lambda^{3/4}}. \tag{1.2}$$

The expectation value of Wilson loops can also be calculated using the Maldacena conjecture,[2–4] and for the circular Wilson loop one finds, to leading order in large λ, that[5,6]

$$\langle W \rangle_{\text{circle}} = e^{\sqrt{\lambda}}, \tag{1.3}$$

in agreement with (1.2).

The authors of Ref. 1 conjectured that the rainbow graphs gave the exact large N behavior of the circular Wilson loop and gave some evidence (a 2 loop calculation) to this effect. We will outline a proof that the result (1.1) is indeed exact to all orders in $g^2 N$ for $N=\infty$. We will also generalize this result to all orders in the $1/N^2$ expansion.

How are we able to perform an exact calculation in strongly coupled gauge theory? The reason turns out to be that the circular Wilson loop is totally determined by an anomaly, a conformal anomaly. As in other cases one is able to calculate the anomaly exactly to all orders in the coupling.

To see this recall that the Wilson loop under discussion is the appropriate super-symmetric Wilson loop,

$$W = \frac{1}{N} \mathrm{Tr} \mathcal{P} \exp i \oint (A_\mu \dot{x}^\mu + i \Phi_i |\dot{x}| \theta^i) dt, \tag{1.4}$$

where A_μ and Φ_i are the gauge fields and the scalars that couple to $x^\mu(t)$, parametrizing the circle and to θ^i which is chosen to be some constant unit vector in R^6. This special Wilson loop is locally supersymmetric. If the contour $(x^\mu(t))$ is a straight line then the Wilson line is globally a BPS object whose expectation value is precisely one. A straight line and a circle are related by a conformal transformation. This fact was used by Ref. 5 to find the minimal surface ending along a circle. If the expectation value of a Wilson loop was truly invariant under all conformal transformations then the expectation value of a circular loop would also be one. However, this is not the case. We will show that there are quantum anomalies when one performs the type of global conformal transformations necessary to turn a straight line into a circle. These anomalies are responsible for the very nontrivial $g^2 N$ and $1/N$ behavior of the circular loop, and as often is the case with anomalies, can be calculated exactly.

Accepting for the moment the result of (1.1) (for $N=\infty$), we see that acting on a straight line with a special conformal transformation that changes it to a circle changes its expectation value by a factor of $2I_1(\sqrt{\lambda})/\sqrt{\lambda}$. Since this factor arises from an anomaly, we will be able to argue that this phenomenon is much more general—the same happens for a general Wilson loop. That is

$$\langle W \rangle_{N=\infty} = \frac{2}{\sqrt{\lambda}} I_1(\sqrt{\lambda}) \langle \tilde{W} \rangle, \tag{1.5}$$

where W is any closed smooth Wilson loop and $\tilde{W}$ is the loop related to it by a special conformal transformation that takes a point along W to infinity. Even more, we will generalize this result to all orders in the $1/N^2$ expansion.

The fact that the expectation value of circular Wilson loops and straight line Wilson loops (or more generally closed and open loops related by conformal transformations) are different should not be a surprise. Large conformal transformations, such as an inversion,

$$x^\mu \to \frac{x^\mu}{x^2}, \tag{1.6}$$

are not symmetries of R^4, since they exchange the point at infinity with a point at a finite distance. They are a symmetry of the theory on S^4, which includes the point at infinity. On the sphere there is no distinction between a circle and a line, and the expectation value of either is the same as for a circle on R^4.

There clearly could be a problem with the invariance under global conformal transformations. For example, a conformal transformation of a correlator of n local operators could take one of the points to infinity, and turn it into the correlator of $n-1$ operators. Here we are seeing an analogous statement for Wilson loops, by transforming the circle to the line, one point along the loop is taken to infinity. As such, one might guess that the difference between the line and the circle is the contribution of the fields at a single point. In fact the authors of Ref. 1 pointed out that (1.1) is equal to the Wilson loop of the large N Hermitian matrix model,

$$\frac{2}{\sqrt{\lambda}} I_1(\sqrt{\lambda}) = \left\langle \frac{1}{N} \mathrm{Tr} \exp(N) \right\rangle = \frac{1}{Z} \int \mathcal{D}M \frac{1}{N} \mathrm{Tr} \exp(M) \exp\left(-\frac{2}{g^2} \mathrm{Tr}\, M^2 \right), \tag{1.7}$$

and one could associate the field M with the fluctuations of the fields at the point at infinity.

We will demonstrate how Eq. (1.5), and its finite N generalization, can be proven in Sec. II. The idea for the proof is the following. Under a conformal transformation the gluon propagator is modified by a total derivative. This is analogous to a gauge transformation, and naively does not affect the gauge invariant loop. However the gauge transformation is singular at the point that is taken to infinity. While the perturbative expansion is naively invariant under gauge transformations, we find that this invariance breaks down at the singular point. By calculating the contribution from the singularities we are able to show that it is given by a matrix model. We did not complete the proof that the matrix model is quadratic, but there are many indications that it indeed is. Under that assumption we are able to evaluate the expectation value to all orders in perturbation theory. For large N we will recover (1.5), but our result yields an exact relation for any λ and any N. In the case of a circular loop we derive an exact expression for $\langle W \rangle$.

In Sec. III we compare our results with the dual string theory. We find that at the classical level the minimal area calculation shows the same universal behavior under a conformal transformation. In the case of the circular loop, where we are able to calculate in the gauge theory exactly, we argue that order by order in string perturbation theory, the leading contribution for small α' agrees with the gauge theory predictions. We also show that the agreement extends to large coupling where, after an S-duality transformation, it is given by a D1-brane.

In Sec. IV we generalize the calculation to more general observables in the matrix model. Those correspond to Wilson loops wound multiple times around the circle.

The Appendices contain the details of the explicit evaluation of the matrix model that yields the precise form of our results.

II. THE GAUGE THEORY CALCULATION

We shall explore the invariance of the Wilson loop under large conformal transformations order by order in perturbation theory.

We expand the expectation value of the Wilson loop around some contour C, as defined in (1.4),

$$\begin{gathered} \langle W_C \rangle = \sum_{n=0}^{\infty} A_n \lambda^n, \\ A_0 = 1, \\ A_1 = \frac{1}{2} \oint ds_1 \oint ds_2 \frac{1}{N} \mathrm{Tr}\left(-\dot{x}_1^\mu \dot{x}_2^\nu \langle A_\mu(x_1) A_\nu(x_2) \rangle + |\dot{x}_1| \theta_1^i |\dot{x}_2| \theta_2^j \langle \Phi_i(x_1) \Phi_j(x_2) \rangle \right), \\ A_2 = \cdots . \end{gathered} \tag{2.1}$$

We will work in R^4, where the propagators are translationally invariant and investigate the behavior of $\langle W_C \rangle$ under conformal transformations that take the closed contour C to $\tilde{C}$. We will compare $\langle W_C \rangle$ to

$$\langle \widetilde{W}_{\widetilde{C}} \rangle = \sum_{n=0}^{\infty} \widetilde{A}_n \lambda^n. \tag{2.2}$$

We could instead compare the gauge theory on R^4 to the theory on S^4. In the latter we would use propagators that transform covariantly under inversions. Those were studied in Ref. 7, and are related to the Feynman gauge propagator by a singular gauge transformation. The two computations turn out to be equivalent.

A. Quadratic term

Let us look at the first nontrivial term in the expansion of the Wilson loop and compare $\widetilde{A}_1$ to A_1. First consider the behavior of the propagators under a large conformal transformation. In particular we shall examine the behavior under an inversion about the origin,

$$x^\mu \to \frac{x^\mu}{x^2} = \tilde{x}^\mu. \tag{2.3}$$

All other large conformal transformations can be obtained by a combination of an inversion and small conformal transformations. Under inversion the scalar propagator,

$$G_{ij}^{ab}(x_1,x_2) = \langle \Phi_i^a(x_1)\Phi_j^b(x_2)\rangle = \frac{g^2}{4\pi^2}\frac{\delta_{ij}\delta^{ab}}{(x_1-x_2)^2}, \tag{2.4}$$

transforms to

$$\tilde{G}_{ij}^{ab}(\tilde{x}_1,\tilde{x}_2) = \frac{g^2}{4\pi^2} x_1^2 x_2^2 \frac{\delta_{ij}\delta^{ab}}{(x_1-x_2)^2}. \tag{2.5}$$

Taking into account the fact that under inversion $|\dot{x}| \to |\dot{x}|/x^2$, the one scalar exchange contribution,

$$|\dot{x}_1|\theta_1^i |\dot{x}_2|\theta_2^j \langle \Phi_i(x_1)\Phi_j(x_2)\rangle, \tag{2.6}$$

to the Wilson loop, is invariant under inversion. However, if this was the only term we would have to introduce an ultraviolet cutoff to render the integral finite, and this could spoil the conformal invariance. Indeed, the Wilson loop in a nonsupersymmetric theory exhibits a perimeter law in perturbation theory,

$$W \sim g^2 \frac{L}{\epsilon}, \tag{2.7}$$

which is definitely not invariant under conformal transformations. But the inclusion of both the scalars and the gluons in the Wilson loop exactly cancels this divergence.[6]

The story with the gauge fields is more complicated, since under inversion a vector field (of dimension one) transforms as

$$\widetilde{V}_\mu(\tilde{x}) = x^2 I_{\mu\nu}(x) V^\nu(x), \quad I_{\mu\nu}(x) = g_{\mu\nu} - 2\frac{x_\mu x_\nu}{x^2}. \tag{2.8}$$

This can easily be derived by noting that

$$\frac{\partial}{\partial \tilde{x}^\mu} = x^2 I_{\mu\nu}(x) \frac{\partial}{\partial x^\nu}, \tag{2.9}$$

so that if Φ is a dimensionless scalar field that transforms as $\Phi(\tilde{x})=\Phi(x)$, then the dimension one vector field, $\partial_\mu\Phi(x)$, will transform as above.

Thus the gluon propagator transforms as

$$\langle \tilde{A}^a_\mu(\tilde{x}_1)\tilde{A}^b_\nu(\tilde{x}_2)\rangle = x_1^2 x_2^2 I_{\mu\rho}(x_1) I_{\nu\sigma}(x_2)\langle A^a_\rho(x_1)A^b_\sigma(x_2)\rangle. \tag{2.10}$$

We shall work, for convenience in the Feynman gauge, $\langle A^a_\mu(x_1)A^b_\nu(x_2)\rangle=(g^2/4\pi^2)[g_{\mu\nu}\delta^{ab}/(x_1-x_2)^2]$. Then the transformed propagator is

$$\begin{aligned}\tilde{G}^{ab}_{\mu\nu}(\tilde{x}_1,\tilde{x}_2) &= \frac{g^2\delta^{ab}}{4\pi^2}\frac{x_1^2x_2^2}{(x_1-x_2)^2}\left(g_{\mu\nu}-2\frac{x_1^\mu x_1^\nu}{x_1^2}-2\frac{x_2^\mu x_2^\nu}{x_2^2}+4\frac{x_1\cdot x_2 x_1^\mu x_2^\nu}{x_1^2x_2^2}\right)\\ &= \frac{g^2\delta^{ab}}{4\pi^2}x_1^2x_2^2\left(\frac{g_{\mu\nu}}{(x_1-x_2)^2}+\frac{1}{2}\partial^1_\mu(\ln(x_1-x_2)^2\partial^2_\nu\ln x_2^2)\right.\\ &\quad\left.+\frac{1}{2}\partial^2_\nu(\ln(x_1-x_2)^2\partial^1_\mu\ln x_1^2)-\frac{1}{2}\partial^1_\mu\partial^2_\nu(\ln x_1^2\ln x_2^2)\right).\end{aligned} \tag{2.11}$$

Consequently, while we saw that the contribution of the scalars to the Wilson loop was invariant under inversion, the gluon contribution, $\dot{x}_1^\mu\dot{x}_2^\nu\langle A^a_\mu(x_1)A^b_\nu(x_2)\rangle$, is changed by a total derivative:

$$\begin{aligned}&\frac{g^2\delta^{ab}}{8\pi^2}\dot{x}_1^\mu\dot{x}_2^\nu[\partial^1_\mu(\ln(x_1-x_2)^2\partial^1_\nu\ln x_2^2)+\partial^2_\nu(\ln(x_1-x_2)^2\partial^1_\mu\ln x_1^2)-\partial^1_\mu\partial^2_\nu(\ln x_1^2\ln x_2^2)]\\ &\quad=\frac{g^2\delta^{ab}}{4\pi^2}\dot{x}_1^\mu\dot{x}_2^\nu\partial^1_\mu\left(\ln\frac{(x_1-x_2)^2}{|x_1|}\partial^2_\nu\ln x_2^2\right).\end{aligned} \tag{2.12}$$

Since the modification of the gluon contribution is a total derivative, which is equivalent to a gauge transformation, one might conclude that the inversion is a symmetry of the Wilson loop. This would be the case, except that the gauge transformation in (2.12) has potential singularities. We must therefore reexamine the proof of gauge invariance of the perturbative expansion and see whether it fails.

We are evaluating the integral

$$\tilde{A}_1-A_1=-\frac{1}{16\pi^2}\oint_C dx_1^\mu\oint_C dx_2^\nu\,\partial^1_\mu\left(\ln\frac{(x_1-x_2)^2}{|x_1|}\partial^2_\nu\ln x_2^2\right). \tag{2.13}$$

[Here we have included the contribution from the color indices that gives a factor of $(1/N)\mathrm{Tr}\,T^aT^a=N/2$.] There are two potential singularities that we encounter when doing the x_1 integral, at $x_1=x_2$, and at $x_1=0$. The second singularity only occurs if the point $x^\mu=0$ lies on the contour C. To examine the behavior at the singularities we introduce a cutoff ϵ.

First, consider the case where $x^\mu=0$ lies on the contour C. The contribution from $x_1=0$ is

$$-\frac{1}{16\pi^2}\oint_C dx_2^\nu\ln\frac{(x_2+\epsilon)^2}{(x_2-\epsilon)^2}\partial^2_\nu\ln x_2^2. \tag{2.14}$$

Here ϵ is an infinitesimal vector tangent to the loop at the origin. To perform the x_2 integral, we notice that for large x_2 the integrand is of order ϵ, the integrand can therefore be regarded as a delta function concentrated at $x_2=\pm\epsilon$. A similar term arises from regularizing the singularity at $x_1=x_2$, which is also zero for x_2 far from the origin. So the only contribution comes from the point $x_1=x_2=0$.

To find the contribution from the singular point one can use the expression

$$\int_{\epsilon}^{\infty} dx \frac{1}{x} \ln \frac{x-\epsilon}{x+\epsilon} = -\frac{\pi^2}{4}, \tag{2.15}$$

to find that

$$\tilde{A}_1 - A_1 = -\tfrac{1}{8}. \tag{2.16}$$

On the other hand if $x^\mu = 0$ does not lie on the contour C the integral is not singular enough and it vanishes. Thus in this case $\tilde{A}_1 - A_1 = 0$. Therefore we conclude that under inversion through the origin the quadratic contribution to the Wilson loop is invariant if the original loop does not pass through the origin. Such an inversion transforms a closed contour into another closed contour. On the other hand if C passes through the origin the transformed Wilson loop ($\tilde{C}$) is now extended to infinity, it is an open Wilson line that only meets at the point at infinity. In this case, to quadratic order,

$$\langle \tilde{W}_{\tilde{C}} \rangle - \langle W_C \rangle = -\lambda/8. \tag{2.17}$$

A safer route to the same result is to evaluate the modification to the propagator (2.11) directly, and not use integration by parts. That way one does not encounter any singularities. Let us do this for the two simplest examples. First we look at a circle passing through the origin,

$$x_1(s) = (1+\cos s, \quad \sin s) \quad x_2(t) = (1+\cos t, \sin t). \tag{2.18}$$

Under inversion this is mapped to the straight line: $x(s) = \frac{1}{2}(1, \tan(s/2))$. For this contour the modification of the gluon propagator contributes to $\tilde{W}$ the amount

$$\begin{aligned} &\frac{\lambda}{16\pi^2}\left[\dot{x}_1^\mu \dot{x}_2^\nu \partial_\mu^1 \left(\ln \frac{(x_1-x_2)^2}{|x_1|} \partial_\nu^2 \ln x_2^2 \right) + (x_1 \to x_2) \right] \\ &\quad = \frac{\lambda}{16\pi^2}\left[-\left(\frac{2\sin t}{4\sin^2 \frac{t}{2}} \right)\left(\frac{2\sin s}{4\sin^2 \frac{s}{2}} \right) + \frac{2\sin(s-t)}{4\sin^2\left(\frac{s-t}{2}\right)}\left(\frac{2\sin s}{4\sin^2 \frac{s}{2}} \right)\left(\frac{\sin t}{4\sin^2 \frac{t}{2}} \right) \right] = -\frac{\lambda}{32\pi^2}, \end{aligned} \tag{2.19}$$

which, when integrated over the circle, gives the result of (2.16).

It is even simpler to take a straight line that does not pass through the origin $x(s) = (1,s)$. Under the inversion it is mapped to a circle of radius 1/2 whose origin is at (1/2,0), and the point at infinity is mapped to the origin. Therefore we expect a contribution from the point at infinity that is exactly opposite to the previous calculation. Indeed

$$\begin{aligned} A_1 - \tilde{A}_1 &= -\frac{1}{16\pi^2} \int_{-\infty}^{\infty} ds \int_{-\infty}^{\infty} dt \frac{1}{(s-t)^2}\left(-2\frac{s^2}{s^2+1} - 2\frac{t^2}{t^2+1} + 4\frac{st(st+1)}{(s^2+1)(t^2+1)} \right) \\ &= \frac{1}{8\pi^2} \int_{-\infty}^{\infty} ds \int_{-\infty}^{\infty} dt \frac{1}{(s^2+1)(t^2+1)} = \frac{1}{8}. \end{aligned} \tag{2.20}$$

Finally, we note that the calculation of the quadratic piece of the Wilson loop in the case of the circle and the straight line, which are related by an inversion through the origin, is easy to do directly. For the straight line we automatically get zero, since for a straight line,

$$\dot{x}_1 \cdot \dot{x}_2 - |\dot{x}_1||\dot{x}_2| = 0. \tag{2.21}$$

Thus for a straight line the sum of the gluon and scalar propagators vanishes. The reason for this triviality is the BPS nature of our Wilson loop, which for a straight line ensures that there are no contributions to any order in λ. In the case of the circle the propagators do not cancel, but their sum is a constant, since (for $|x| = |\dot{x}| = 1$)

$$(x_1 - x_2)^2 = -2(\dot{x}_1 \cdot \dot{x}_2 - |\dot{x}_1||\dot{x}_2|). \tag{2.22}$$

Explicitly, for the circle in (2.18),

$$\langle W \rangle = \int_0^{2\pi} ds\, dt \frac{\lambda}{16\pi^2} \frac{-\dot{x}(t)\cdot\dot{x}(s) + |\dot{x}(t)||\dot{x}(s)|}{(x(t)-x(s))^2} = \int_0^{2\pi} ds\, dt \frac{\lambda}{16\pi^2} \frac{1}{2} = \frac{\lambda}{8}. \tag{2.23}$$

So we have learned that to quadratic order the difference between the Wilson loop along an open line $\tilde{C}$ and along the closed contour C obtained by an inversion through the origin is

$$\langle \tilde{W}_{\tilde{C}} \rangle - \langle W_C \rangle = -\lambda/8. \tag{2.24}$$

In the case of the straight line $\langle \tilde{W}_{\tilde{C}} \rangle = 0$ and $\langle W_C \rangle = \lambda/8$. In the following we shall generalize the evaluation of the circle and the relationship (2.24) to all orders in λ.

B. The circle to all orders

It is simple to generalize the calculation of the circle to arbitrary order in perturbation theory. This is because the circle is related by an inversion to the straight line, and the straight line receives no corrections to any order (since it is BPS). So we start with a straight line contour C [say $x(s) = 1/2(1, \tan(s/2))$]. The Wilson loop along this contour is identically equal to one because of supersymmetry. We saw this explicitly to leading order, but the triviality holds to all orders. When we perform the inversion we will get the Wilson loop along the circle, expressed, diagram by diagram, in terms of the diagrams for the straight line loop with the gluon propagators modified according to (2.11). Of course, in addition to propagators and vertices involving the scalars and gluons we will also have to include ghosts—however these, like the scalars, transform covariantly under the inversion.

The modifications of the gluon propagators is of the form of a gauge transformation. Were it not for the fact that this gauge transformation is singular it would have no effect on any of the diagrams of a given order—the boundary terms that one would encounter upon integrating these total derivatives by parts would cancel order by order. This is the regular statement of gauge invariance of the perturbative expansion. Indeed in our case we do not even have to worry, in making these arguments, about the usual short distance singularities that in most theories require regularization and renormalization since the $\mathcal{N}=4$ SUSYM theory is finite when all the diagrams of a given order are included.

However, because of the singularities that occur in the modified propagator at the origin, the point about which the inversion is done, there is another boundary contribution, namely when and only when both ends of a single propagator hits the origin (or the point at infinity). As we saw above, by introducing a cutoff ϵ, when one end of the propagator hits the origin (or the point at infinity), the resulting modification to the propagator is of order ϵ unless the other end of the propagator also hit the origin. Thus it behaves like a one-dimensional delta-function that contributes a finite amount when the other end of the propagator is integrated over the loop. Therefore when both ends of a single propagator approach the origin (or the point at infinity) we get a constant factor of $-1/8$ (1/8).

One should worry about contributions when the other end of the propagator is on an internal vertex that approaches the origin. We think that at least for the $\mathcal{N}=4$ theory those graphs will not contribute, but we were unable to prove that. By using the same regularization as above, it is easy

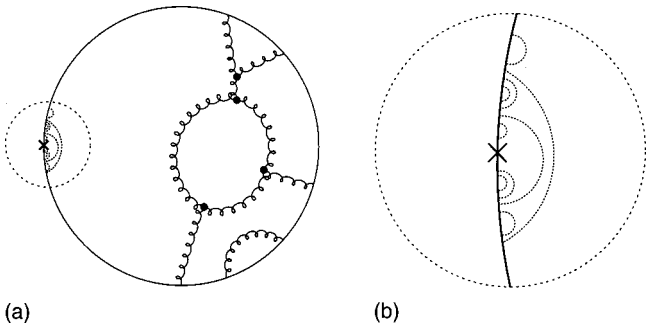

FIG. 1. (a) To go from a straight line to a circle one should include diagrams with some gluon propagators replaced by the total derivatives (dotted lines). Those give a boundary contribution only when all of them hit the point of inversion (marked by an x). (b) Regardless of the rest of the diagram, the anomaly is dependent only on the vicinity of the inversion point and since it lives at one point, is given by the matrix model expression.

to see that the contribution, if any, would come only when all the connected part of the diagram collapses to that point. This means that it can be described by an interaction term in the matrix model. An explicit calculation[1] shows that there is no term of order g^4. It would require a better regulator and a more careful calculation to show that the interaction terms vanish to all orders. The remarkable agreement between our results and the AdS calculation suggests that there are no interactions. In the remainder of the paper we will assume that indeed all the interaction terms vanish, and will provide evidence for that from the comparison to string theory in AdS.

So, ignoring interactions, if we integrate by parts all of the modified gluon propagators we will get nonvanishing contributions from single propagators that are not attached to other parts of the diagram when both ends of a single propagator approach the origin (or the point at infinity). These will yield constant factors times the rest of the diagram, as is illustrated (for a circle) in Fig. 1. But the sum of the rest of the diagrams (to any given order) vanishes in the case of the straight line. Therefore the calculation of the straight line Wilson loop, with modified gluon propagators, reduces to summing all graphs with just noninteracting modified gluon propagators. Each such modified propagator will give a factor as in (2.20). We simply have to add all these terms.

Alternatively we can argue that since the sum of the ordinary gluon and scalar propagators vanishes, we can add these as well. This then is inverted to the Wilson loop for a circle, where we should sum the Feynman diagrams of a noninteracting theory of scalars and vectors. This is a simple calculation to perform, since as we have seen—in the case of the circle—the sum of the gluon (in Feynman gauge) and scalar propagator contributions is a constant[see (2.23)]. Since each propagator just yields a constant, we can perform the sum and account for the factors of N by doing the calculation in a 0-dimension field theory, namely a matrix model. This leads to the expression

$$\langle W_{\text{circle}}\rangle = \left\langle \frac{1}{N}\operatorname{Tr}\exp(M)\right\rangle = \frac{1}{Z}\int \mathcal{D}M\,\frac{1}{N}\operatorname{Tr}\exp(M)\exp\left(-\frac{2N}{\lambda}\operatorname{Tr}\,M^2\right). \tag{2.25}$$

In the Appendix we shall show that this integral can be calculated exactly, in an expansion in powers of $1/N^2$. The result is [where L_n^m is the Laguerre polynomial $L_n^m(x)=1/n!\times\exp[x]x^{-m}(d/dx)^n(\exp[-x]x^{n+m})$]:

$$\begin{aligned}\langle W_{\text{circle}}\rangle &\equiv F(\lambda,N)\\ &= \frac{1}{N}L_{N-1}^1(-\lambda/4N)\exp[\lambda/8N]\\ &= \frac{2}{\sqrt{\lambda}}I_1(\sqrt{\lambda})+\frac{\lambda}{48N^2}I_2(\sqrt{\lambda})+\frac{\lambda^2}{1280N^4}I_4(\sqrt{\lambda})+\frac{\lambda^{5/2}}{9216N^4}I_5(\sqrt{\lambda})+\cdots.\end{aligned} \tag{2.26}$$

To leading order in $1/N$ we recover the result

$$\langle W_{\text{circle}}\rangle_{N=\infty}=\frac{2}{\sqrt{\lambda}}I_1(\sqrt{\lambda})=\sum_{n=0}^{\infty}\frac{(\lambda/4)^4}{n!(n+1)!}, \tag{2.27}$$

in agreement with Ref. 1, where the leading, noninteracting, rainbow graphs (the leading large N graphs) were summed.

Our result is based on a perturbative expansion, but we do not expect corrections due to instantons. We found that the only contributions are from diagrams collapsed to the point of inversion, and since instantons are smooth objects, the singular graphs have measure zero, and will not contribute.

C. Arbitrary loops

As was explained in the preceding section, the contribution to the circular Wilson loop can be localized near a single point. Going from the straight line to the circle, the contribution is from the point at infinity. Since the calculation can be pushed to one point, one would expect that it does not depend on the shape of the curve. Indeed we will see that for any smooth closed curve C and the open curve $\tilde{C}$ related to it by a conformal transformation the appropriate Wilson loops satisfy

$$\langle W_C\rangle=\left\langle\frac{1}{N}\operatorname{Tr}\exp(M)\right\rangle\langle\tilde{W}_{\tilde{C}}\rangle=F(\lambda,N)\langle\tilde{W}_{\tilde{C}}\rangle. \tag{2.28}$$

We will prove this equation below by comparing Feynman diagrams of the two Wilson loops.

First, we will explain one feature of (2.28), the fact that the left hand side has a single trace, while the right hand side has two traces—over $\exp(M)$ and over the open Wilson loop. The reason for this factorization is that the SUSYM fields and the matrix M are independent variables. In general, for two independent Hermitian matrices A and B with independent $U(N)$ invariant measures $\mu(A),\tilde{\mu}(B)$,

$$\begin{aligned}\left\langle\frac{1}{N}\operatorname{Tr}(f(A)g(B))\right\rangle&=\int\mathcal{D}A\mathcal{D}B\mu(A)\tilde{\mu}(B)\frac{1}{N}\operatorname{Tr}(f(A)g(B))\\&=\int\mathcal{D}A\mathcal{D}B\mu(A)\tilde{\mu}(B)\frac{1}{N}\operatorname{Tr}(U^{\dagger}f(A)UV^{\dagger}g(B)V),\end{aligned} \tag{2.29}$$

with arbitrary unitary U, V. Since they are independent, $W=UV^{\dagger}$ can take any value in $U(N)$, and we can integrate over it,

$$\int\mathcal{D}A\mathcal{D}B\frac{\mathcal{D}W}{\operatorname{Vol}[U(N)]}\mu(A)\tilde{\mu}(B)\frac{1}{N}\operatorname{Tr}(AWBW^{\dagger})=\int\mathcal{D}A\mathcal{D}B\mu(A)\tilde{\mu}(B)\frac{1}{N^2}\operatorname{Tr}A\operatorname{Tr}B. \tag{2.30}$$

Using this result,

$$\left\langle\frac{1}{N}\operatorname{Tr}\left[\exp(M)\mathcal{P}\exp i\int_{\tilde{C}}(A_{\mu}\dot{x}^{\mu}+i\Phi_i|\dot{x}|\theta^i)dt\right]\right\rangle=\left\langle\frac{1}{N}\operatorname{Tr}\exp(M)\right\rangle\langle\tilde{W}_{\tilde{C}}\rangle. \tag{2.31}$$

The proof for a general loop is again diagrammatic, order by order in perturbation theory. We write the loops again as

$$\langle W_C\rangle=\sum_{n=0}^{\infty}A_n\lambda^n,\quad\langle\tilde{W}_{\tilde{C}}\rangle=\sum_{n=0}^{\infty}\tilde{A}_n\lambda^n. \tag{2.32}$$

Let us look at a certain diagram Γ of W_C at order g^{2n} which contributes to A_n, and assume it has k vertices on the Wilson loop.

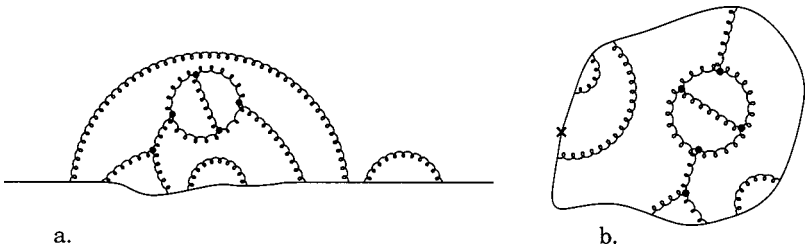

FIG. 2. Two graphs contributing (a) to the open Wilson loop $\langle \tilde{W}_{\tilde{C}} \rangle$ and (b) to the closed loop $\langle W_C \rangle$. The curves are related by a conformal transformation, and the two diagrams differ by total derivatives.

There is a similar diagram $\tilde{\Gamma}$ contributing to the coefficient $\tilde{A}_n$ of $\tilde{W}_{\tilde{C}}$. Those two diagrams are not equal to each other, rather Γ is equal to $\tilde{\Gamma}$ if we replace the gluon propagator by the modified propagator (2.11). Thus Γ is equal to $\tilde{\Gamma}$ plus total derivatives. See Fig. 2.

Exactly as in the case of the circle, the total derivatives terms will cancel unless they hit the origin. When one end hits this point the resulting expression is proportional to a one-dimensional delta-function, forcing the other end to the origin.

So considering $\tilde{\Gamma}$ with l boundary to boundary propagators replaced by the total derivatives will give a contribution from the singular point times the rest of the diagram $\tilde{\Gamma}'$, as in Fig. 3(c). We find the same sub diagram $\tilde{\Gamma}'$ by replacing propagators by total derivatives in other graphs, as illustrated in Fig. 3(d).

Summing all of them we see that the total derivative contribution is exactly the matrix model expression as before. From the example of the circle we know that l total derivatives give the same as the insertion of $[1/(2l)!\lambda^l]M^{2l}$. Since there is only one trace, this should be taken as a matrix multiplying the rest of the diagram. But by the argument above (2.30), the trace breaks in two. Therefore we see that A_n is equal to $\tilde{A}_n$ plus matrix model corrections,

$$A_n = \sum_{l=0}^{n} \left\langle \frac{1}{N(2l)!\lambda^l} \operatorname{Tr} M^{2l} \right\rangle \tilde{A}_{n-l}. \tag{2.33}$$

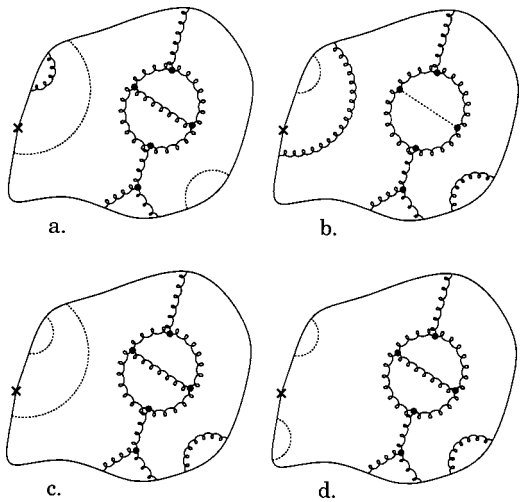

FIG. 3. We show here some diagrams one gets by replacing gluon propagators by total derivatives (dotted lines). Diagrams (a) and (b) will not contribute, since not all the total derivatives hit the inversion point. (c) Does contribute, since all the total derivatives can hit the origin. One gets diagram (d) by doing the same procedure to a sightly different graph. Summing (c), (d) and a few other such graphs gives the matrix model expression at order λ^2 times the rest of the diagram.

Therefore

$$\langle W_C\rangle=\sum_{n=0}^{\infty}A_n\lambda^n=\sum_{n=0}^{\infty}\sum_{l=0}^{n}\left\langle\frac{1}{N(2l)!}\mathrm{Tr}\,M^{2l}\right\rangle\tilde{A}_{n-l}\lambda^{n-1}=\left\langle\frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle\langle\tilde{W}_{\tilde{C}}\rangle. \quad (2.34)$$

The crucial point in the proof is that the total derivative part of the graphs (the matrix model) totally decouple from the rest of the graph. The total derivatives live within an infinitesimal distance from the origin. It is a set of measure zero for any other part of the graph to be in that vicinity, and since the loop is smooth, and the theory is finite, this set of measure zero does not contribute.

The above argument is true for all N, not just planar graphs. Again, one has to note that if the matrix model part has genus p and the rest of the graph is at genus q, the total genus is $p+q$, since those two graphs are totally separated. Also, we assumed here that the matrix model is quadratic, but the statement would be correct regardless of that. Even if the interactions do not vanish, to get a contribution, the entire part of the diagram with interaction has to collapse to the singular point. It would still give a matrix model contribution times the rest of the graph.

III. THE COMPARISON WITH STRING THEORY

The AdS/CFT [2] correspondence allows one to calculate the expectation value of Wilson loops in $\mathcal{N}=4$ SUSYM for large λ from minimal surfaces in AdS space.[3,4] We will now compare our calculation of the ratio of Wilson loops that are related by inversion, as well as the exact expression for a circular Wilson loop, to string theory calculations.

We have shown that a Wilson loop, W_C, along a closed contour C passing through the origin, is related to a Wilson loop, $\tilde{W}_{\tilde{C}}$, along the open line, $\tilde{C}$, obtained by inverting the contour through the origin, by

$$\langle W_C\rangle=F(\lambda,N)\langle\tilde{W}_{\tilde{C}}\rangle. \quad (3.1)$$

We would like to prove the same statement from string theory. A complete proof is beyond our capabilities, since the calculational tools for string perturbation theory in AdS_5 are still undeveloped. However, we are able to give strong evidence from string theory for this relationship, to leading order in $1/\lambda=(l_s/R)^4$, and to all orders in the string coupling, $g_s=\lambda/(4\pi N)$, for arbitrary smooth loops!

A. Circular loops

For circular loops we can perform a precise test of the AdS/CFT correspondence, since we have derived an exact expression for the circular Wilson loop for all λ and N. In string theory, to a given order in $1/N^2$, we expect that the Wilson loop should be given by

$$\langle W_{\mathrm{circle}}\rangle_p=\frac{1}{N^{2p}}e^{-S_p}f_p(\lambda), \quad (3.2)$$

where S_p is the action for a minimal surface ending on the circle with p handles and $f(\lambda)$ would be calculated by evaluating the fluctuations about the minimal surface in powers of α' (or l_s/R, or equivalently $1/\lambda^{1/4}$).

The minimal area surface to leading order in $1/N^2$ can be constructed analytically and yields $S_0=-\sqrt{\lambda}$, it is a smooth, geodesic surface. To higher order in $1/N^2$ we need to find the minimal area surface with handles. It is intuitively obvious that the best we can do is to attach degenerate handles that have no area to the above surface. This is not a smooth surface, but it is the limit of smooth surfaces and has the minimal possible area. If this is the case then $S_p=S_0=-\sqrt{\lambda}$.

To do better than this one would need to evaluate the stringy fluctuations about the minimal surface, in an expansion in α'. This is beyond our capabilities. However, we can determine the overall power of the inverse coupling, $1/(l_s/R)$, that multiplies e^{-S}. We claim that

$$\langle W_{\text{circle}}\rangle_p^{\text{string}} \propto \frac{1}{N^{2p}} \frac{\lambda^{(6p-3)/4}}{p!} e^{\sqrt{\lambda}} \left[1 + O\left(\frac{1}{\sqrt{\lambda}} \right) \right]. \tag{3.3}$$

The factor of $1/p!$ arises since the handles are indistinguishable. We give two arguments for the power of λ in this expression. The string coupling is $g_s^2 \sim \lambda^2/N^2$, but in addition one has to be careful of the contribution of zero modes. The dimension of the moduli space of surfaces of genus p with one boundary is $6p-3$. Since the relevant surfaces are degenerate we have to impose two real constraints for each handle, in addition to the overall 3. Each constraint gives a power of $\lambda^{-1/4}$, from the correct normalization of the zero modes. This gives

$$\left(\frac{\lambda}{N} \right)^{2p} \to \frac{\lambda^{(6p-3)/4}}{N^{2p}}. \tag{3.4}$$

An equivalent calculation comes from the low energy effective supergravity, the degenerate handles are the same as the exchange of supergravity modes. In Ref. 5 the exchange of fields between two widely separated surfaces was calculated. One can redo their calculation for the case at hand, the self interaction of the surface ending on a circle. In their case the coupling of the Kaluza–Klein modes is proportional to $1/N^2$ and the integration over each of the surfaces gives a measure factor of λ.

Therefore the result for well separated surfaces was proportional to λ/N^2. For calculating the self interaction of a single surface we have to use the propagator at short distances, which, in 5 dimensions, has a cubic divergence. Integrating over the surface leaves a linear divergence, which should be cut off at the string scale, giving an extra factor of $R/l_s \sim \lambda^{1/4}$. In addition we should sum over all the KK modes, again imposing a cutoff—the angular momentum cannot exceed R/l_s. This gives the final result $\lambda^{3/2}/N^2$ for each handle.

This power of λ is also confirmed by the *S*-duality argument in the following section.

We can now compare this with the gauge theory result, $\langle W_{\text{circle}}\rangle = F(\lambda, N)$. In Appendix B we examine the large λ behavior of the $1/N^2$ expansion of $F(\lambda, N)$. We show that, order by order in the $1/N^2$ expansion, this function behaves, for large λ, as

$$\langle W_{\text{circle}}\rangle^{\text{gauge}} = F[\lambda, N] = \sum_p \frac{1}{N^{2p}} \frac{e\sqrt{\lambda}}{p!} \sqrt{\frac{2}{\pi}} \frac{\lambda^{(6p-3)/4}}{96^p} \left[1 - \frac{3(12p^2+8p+5)}{40\sqrt{\lambda}} + O\left(\frac{1}{\lambda} \right) \right]. \tag{3.5}$$

Thus we find precise agreement with the string theory calculation, order by order in $1/N^2$, to leading order in $1/\lambda$!

B. *S*-duality

Another very strong test of this expression comes from checking its region of validity. Clearly both the AdS expression (3.3) and the matrix model result (3.5) are valid for $\lambda \gg 1$. If we ignore the $1/\lambda$ correction the matrix model gives

$$\langle W_{\text{circle}}\rangle^{\text{gauge}} \sim \sqrt{\frac{2}{\pi}} \lambda^{-3/4} \exp\left(\sqrt{\lambda} + \frac{\lambda^{3/2}}{96N^2} \right). \tag{3.6}$$

Thus the approximation $\langle W_{\text{circle}}\rangle \sim \exp\sqrt{\lambda}$ is valid as long as $1 \ll \lambda \ll N^2$. The AdS expression is valid only for $\lambda \ll N$, or else string theory is strongly coupled. For $\lambda \gg N$ we should perform an *S*-duality transformation. Under *S*-duality the Wilson loop turns into a 't Hooft loop of the dual theory described by a D1-brane. The action for this configuration is given in terms of the dual couplings $\tilde{g}_s = 1/g_s$ and $\tilde{\lambda} = \lambda/g_s^2$,

$$\langle W_{\text{circle}}\rangle^{\text{dual string}} \sim \exp\frac{\sqrt{\tilde{\lambda}}}{\tilde{g}_s} = \exp\sqrt{\lambda}. \tag{3.7}$$

So the dual D1-brane has the same action as the original fundamental string. This dual description is valid as long as $\tilde{\lambda} \gg 1$, or $\lambda \ll N^2$. We see, therefore, that the range of validity of the two calculations is identical!

This can be regarded as another test of the matrix model expression, and in particular the power of λ accompanying the $1/N^2$ corrections. But it should also be considered a test of *S*-duality in $\mathcal{N}=4$ SUSYM. The matrix model is valid for all values of g, and with the replacement $g \to 4\pi/g$ it gives the value of the 't Hooft loop, which is confirmed by the AdS calculation.

C. Arbitrary loops

This story can be generalized, to some extent, to arbitrary loops. Indeed, a version of this statement for large λ and to lowest order in g_s was made in a footnote in Ref. 8. As shown in Ref. 6, the expectation value of the Wilson loop to leading order in the α' expansion, is

$$\langle W\rangle \propto e^{-S}, \tag{3.8}$$

where the action, *S*, is a Legendre transform of the area of the surface in AdS_5 whose boundary is the loop contour. The Legendre transform removes (for a smooth loop) the divergence in the area. For smooth loops the Legendre transform is equal (asymptotically) to the extrinsic curvature of the boundary κ. Then we can use the Gauss–Bonnet theorem to write the action for the minimal area as

$$S = \frac{\sqrt{\lambda}}{2\pi}\left[\int d^2\sigma\sqrt{g} - \int d\tau\sqrt{\gamma}\kappa\right] = \frac{\sqrt{\lambda}}{2\pi}\int d^2\sigma\sqrt{g}\left(1+\frac{1}{2}R^{(2)}\right) - \sqrt{\lambda}\chi, \tag{3.9}$$

where $R^{(2)}$ is the induced metric and χ the Euler number of the surface (given by this integral expression). It is easy to see that $R^{(2)}$ approaches -2 near the boundary of AdS, so the integral on the right hand side is manifestly convergent.

The action integral is invariant under isometries of AdS including conformal transformations. Since it is manifestly convergent, it is invariant also if the conformal transformation takes a point from finite distance to infinity, or vice versa. What does change in the latter case is the topology of the surface. The Euler number is one for the disk, the appropriate world sheet for a closed Wilson loop W_C. But for the open Wilson loop $\tilde{W}_{\tilde{C}}$ the world sheet is the half plane with Euler number zero. Therefore

$$\langle W_C\rangle = \exp(\sqrt{\lambda})\langle \tilde{W}_{\tilde{C}}\rangle. \tag{3.10}$$

In fact this statement can be generalized to any order in the string coupling, or the $1/N^2$, expansion. This is clearly the case if the minimal surface at higher genus is obtained by adding degenerate handles to the surface of lower genus—the handles do not change the action. But the proof does not require this assumption. To order $1/N^{2p}$ the relevant surface bounding the closed contour is topologically a disk with p handles, for which $\chi = 1-2p$, whereas the surface bounding the open contour is a half plane with p handles, for which $\chi = -2p$. Consequently, to any order in $1/N^2$ and for large λ, we expect from string theory that

$$\langle W_C\rangle = \exp(\sqrt{\lambda}(2p+1-2p))\langle \tilde{W}_{\tilde{C}}\rangle = \exp(\sqrt{\lambda})\langle \tilde{W}_{\tilde{C}}\rangle. \tag{3.11}$$

This is precisely what we find in the gauge theory from (3.1), using the result proved in Appendix B that, to any order in $1/N^2$,

$$F(\lambda,N)\sim e^{\sqrt{\lambda}}, \tag{3.12}$$

for large λ. Thus (3.1) is true to leading order in $1/\lambda$.

Understanding the $1/\lambda$ corrections are more difficult, since we cannot even calculate the expectation value of an arbitrary open loop. Still, the string theory argument leading to (3.3) is general and should apply to any closed curve (as long as there are no new smooth classical solutions at high genus). Therefore we might expect that

$$\langle W_C\rangle_p^{\text{string}}\propto \frac{1}{N^{2p}}\frac{\lambda^{3p/2-3/4}}{p!}e^{-s}\left[1+O\left(\frac{1}{\sqrt{\lambda}}\right)\right]. \tag{3.13}$$

This might look surprising, given that the corresponding open loop $\langle \tilde{W}_{\tilde{C}}\rangle$ is not one. The reason that it works is that the open loop asymptotes to a straight line, so it differs significantly from the BPS straight line only over a compact region. We can expect that the leading behavior of the asymptotically straight line and the true straight line would be the same. If a genus p surface is obtained by adding p degenerate handles, then there is a large probability that they will be attached within the asymptotically straight part of the world sheet, where they will not contribute because of supersymmetry. Therefore, for most of the volume of the moduli space, we will get no enhancement and we might conjecture that to order $1/N^{2p}$,

$$\langle \tilde{W}_{\tilde{C}}\rangle_p^{\text{string}}\propto \frac{1}{N^{2p}}e^{-S-\sqrt{\lambda}}\left[1+O\left(\frac{1}{\sqrt{\lambda}}\right)\right]. \tag{3.14}$$

Under these assumptions, the relation derived from the gauge theory (3.1) will agree with the string theory to all orders in $1/N^2$ for large λ, since

$$\langle W_C\rangle^{\text{string}}\propto\sum_p \frac{1}{N^{2p}}\frac{\lambda^{(6p-3)/4}}{p!}e^{-S}\sim\left[\sum_p \frac{e^{\lambda}}{N^{2p}}\frac{\lambda^{(6p-3)/4}}{p!}\right]\left[\sum_q \frac{1}{N^{2q}}e^{-S-\sqrt{\lambda}}\right]. \tag{3.15}$$

IV. MULTIPLY WOUND LOOPS

The above considerations can be extended to multiply wound Wilson lines or loops. Consider, for example, a Wilson loop consisting of two coincident circles. These can be tied together so that the loop winds twice around a circle, or traced independently. Under an inversion through a point on the circle they go into two coincident parallel straight lines, which are BPS and thus trivial. By the same arguments that we have presented above the evaluation of the multiply wound loops can be expressed in terms of the matrix model.

Consider first two circles on top of each other. If the untraced Wilson loop around the circle is denoted by $\mathcal{W}$, so that the ordinary Wilson loop traced around one circle is $W_1=1/N\langle \mathrm{Tr}\mathcal{W}\rangle$, then the two options for connecting the circles correspond to $W_2=1/N\langle \mathrm{Tr}\mathcal{W}^2\rangle$ and to $W_{1,1}=1/N^2\langle(\mathrm{Tr}\ \mathcal{W})^2\rangle$, respectively. In terms of the matrix model it is clear that

$$W^2=\frac{1}{N}\langle \mathrm{Tr}\exp(2M)\rangle,\quad W_{1,1}=\frac{1}{N^2}\langle[\mathrm{Tr}\exp(M)]^2\rangle. \tag{4.1}$$

The first case, that of a doubly wound loop, is very simple. Scaling $M\to M/2$, we see that the result is the same as the single circle with $\lambda\to 4\lambda$, thus

$$W_2(\lambda,N)=W_1(4\lambda,N)=\frac{1}{N}L_{N-1}^1(-\lambda/N)\exp[\lambda/2N]. \tag{4.2}$$

In the case of the squared singly wound loop we follow the same steps as in Appendix A:

$$W_{1,1}=\frac{1}{Z}\int \mathcal{D}M\left[\frac{1}{N}\mathrm{Tr}\ e^{M}\right]^2 e^{-(2N/\lambda)\mathrm{Tr}\ M^2}$$
$$=\frac{1}{Z}\int dm_i\,\Delta^2(m_i)\left[\frac{1}{N}\sum_i\ e^{m_i}\right]^2 e^{-(2N/\lambda)\Sigma m_i^2}$$
$$=\frac{1}{Z'}\int dm_i\,\Delta^2(m_i)e^{-\Sigma m_i^2}\left[\frac{1}{N}e^{2m_1\sqrt{\lambda/2N}}+\frac{N-1}{N}e^{(m_1+m_2)\sqrt{\lambda/2N}}\right]. \tag{4.3}$$

The first integral is, up to a factor of $1/N$, the same as W_2. The second can be evaluated by expressing, as in Appendix A, the Vandermonde determinant, $\Delta^2(m_i)$, in terms of Hermite polynomials, as

$$\frac{1}{N^2}\int dm\,dm'\sum_{i,j=0}^{N-1}[P_i^2(m)P_j^2(m')-P_i(m)P_j(m)P_i(m')P_j(m')]e^{-(m^2+m'^2)+\sqrt{\lambda/2N}(m+m')}. \tag{4.4}$$

The above integrals can then be done, with the final result being

$$W_{1,1}=\frac{1}{N}W_2+\left(1-\frac{1}{N}\right)(W_1)^2-\frac{2}{N^2}e^{\lambda/4N}\sum_{i=1}^{N-1}\sum_{j=0}^{i-1}\left[L_j^{i-j}\left(-\frac{\lambda}{4N}\right)\right]^2. \tag{4.5}$$

One of the sums in (4.5) can easily be done and the result compared with string theory for large λ. It is trivial to reproduce the correct semiclassical action and it would be interesting to try to account for the factors of λ as well. A similar analysis can be carried out, with increased complication, for loops wound any number of times around the circle. In fact, it does not have to be the exact same circle, one gets the same result from arbitrary loops that are tangent to each other at one point. Under an inversion around the common point they are mapped to a collection of parallel lines which is also a BPS configuration.

These Wilson loops correspond to the most general observables of the matrix model,

$$W_{i_1,i_2,\ldots i_n}\equiv\langle\mathrm{Tr}\exp(i_1M)\mathrm{Tr}\exp(i_2M)\cdots\mathrm{Tr}\exp(i_nM)\rangle, \tag{4.6}$$

and can be used, following the discussion in Refs. 11 and 12, to evaluate the expectation values of Wilson loops in definite representations of $U(N)$. We postpone this analysis for elsewhere.

V. CONCLUSIONS

In this paper we have extended, generalized and outlined a proof for the result of Erickson, Semenoff and Zarembo [1] on the value of the circular Wilson loop in $\mathcal{N}=4$ SUSYM. We showed that the expectation value of a circular BPS-Wilson loop in $\mathcal{N}=4$ SUSYM is determined by an anomaly in the conformal transformation that relates the circular and straight-line loops. As such it can be calculated exactly, to all orders in a $1/N^2$ expansion and to all orders in g^2N. A similar relation was derived between the expectation value of any closed smooth Wilson loop and the loop related to it by an inversion that takes a point along the loop to infinity. Using the AdS/CFT duality, this result yielded a prediction of the value of the string amplitude with a circular boundary to all orders in α' and to all orders in g_s. We then compared this result with string theory, and found that the gauge theory calculation, for large g^2N and to *all* orders in the $1/N^2$ expansion does agree with the leading string theory calculation, to all orders in g_s and to lowest order in α'.

We proved that the anomaly is given by a matrix model, but we leave for future work to complete the proof that all interactions vanish and the matrix model is indeed quadratic. The agreement with the AdS calculation is a very strong indication that the quadratic matrix model is correct, at least for the $\mathcal{N}=4$ theory. In principle the anomaly in other conformal field theories could be described by a more complicated matrix model.

This agreement is remarkable. It is a test of the AdS/CFT correspondence in the regime of strong gauge coupling (small α') and to all orders in $1/N^2$, the string coupling. The result even extends to the S-dual region where the fundamental string is replaced by a D1-brane. This gives strong evidence for the validity of the conjectured AdS/CFT correspondence.

All the calculations in this paper were done for gauge group $U(N)$, but the generalization to $SU(N)$ is trivial. We write the Hermitian matrix M as the sum of a traceless part and the trace times the unit matrix $M=M'+mI_N$. Then

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp M\right\rangle_{U(N)} = \exp\left(\frac{\lambda}{8N^2}\right)\left\langle \frac{1}{N}\mathrm{Tr}\exp M'\right\rangle_{SU(N)}. \tag{5.1}$$

In string theory the difference between $SU(N)$ and $U(N)$ corresponds to the inclusion of some fields that do not have local dynamics, but can be gauged to infinity. In any case the difference is subleading in both N and λ, so it has no consequence on our discussion of the leading behavior for large λ, order by order in $1/N^2$.

It would be very interesting to try to understand the α' corrections to the minimal surface calculation in AdS, in order to compare our exact result with string theory. Consider the leading $N=\infty$ prediction for the circular Wilson loop. Using the asymptotic expansion of the Bessel function, we can write the expectation value of the circular loop as

$$\langle W_{\mathrm{circle}}\rangle^{\mathrm{gauge}} = \sqrt{\frac{2}{\pi}}\frac{e^{\sqrt{\lambda}}}{\lambda^{3/4}}\sum_{k=0}^{\infty}\left(\frac{-1}{2\sqrt{\lambda}}\right)^k\frac{\Gamma(\frac{3}{2}+k)}{k!\Gamma(\frac{3}{2}-k)} - i\sqrt{\frac{2}{\pi}}\frac{e^{-\sqrt{\lambda}}}{\lambda^{3/4}}\sum_{k=0}^{\infty}\left(\frac{1}{2\sqrt{\lambda}}\right)^k\frac{\Gamma(\frac{3}{2}+k)}{k!\Gamma(\frac{3}{2}-k)}. \tag{5.2}$$

The challenge is to reproduce, in an α' expansion, the asymptotic expansion given in (5.2). Note that this asymptotic expansion is not Borel summable. The terms behave as $(k/2\sqrt{\lambda})^k$, to order k. It would be interesting to understand this from the point of view of the world sheet theory. The non-Borel summability, as well as the second term in (5.2), might indicate that there is an instanton contribution to the world sheet amplitude.

Finally, it is interesting that the string theory with a circular boundary is described by the Hermitian matrix model. This model is related to noncritical string theory with $c=-2$.[9] Here it yields a particularly simple observable of the critical superstring theory in the AdS background. It is conceivable that one could derive the matrix model representation of the string amplitude directly, without having to use the duality to gauge theory.

APPENDIX A: MATRIX MODEL CALCULATION

We wish to evaluate

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle = \frac{1}{Z}\int \mathcal{D}M\,\frac{1}{N}\mathrm{Tr}\exp(M)\exp\left(-\frac{2N}{\lambda}\mathrm{Tr}M^2\right). \tag{A1}$$

First, we do the angular integrations, to rewrite the integral in terms of the eigenvalues of M:

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle = \frac{1}{Z}\int \prod dm_i\,\Delta^2(m_i)\,\frac{1}{N}\sum e^{m_i}\exp\left[-\frac{2N}{\lambda}\sum m_i^2\right]$$
$$= \frac{1}{Z}\int \prod dm_i\,\Delta^2(m_i)\exp\left[\sqrt{\frac{\lambda}{2N}}m_1\right]\exp\left[-\sum m_i^2\right], \tag{A2}$$

where $\Delta(m_i)=\Pi_{i<j}(m_i-m_j)=\det[\{m_i^{j-1}\}]$ is the Vandermonde determinant, and we have rescaled the m_i absorbing the normalization into Z.

Now we use the standard trick, Ref. 10, of rewriting this determinant in terms of orthogonal polynomials. It is clear that, in evaluating the determinant of the matrix $\{m_i^{j-1}\}$, we can replace the row m_i^{j-1}, for a given i, by any polynomial in m_i of rank $j-1$, that starts with m_i^{j-1}. We can choose these polynomials to be orthonormal with respect to the measure $\int dm\exp[-m^2]$, thus rendering the resulting integrals easy. The appropriate polynomials are proportional to the Hermite polynomials,

$$H_n(x)=e^{x^2}\left(-\frac{d}{dx}\right)^n e^{-x^2},\quad \int_{-\infty}^{\infty}dx\,e^{-x^2}H_n(x)H_m(x)=\delta_{nm}2^n n!\sqrt{\pi}. \tag{A3}$$

So we choose the polynomials to be the orthonormalized Hermite polynomials [with respect to the measure $dx\exp(-x^2)$],

$$P_n(x)\equiv\frac{H_n(x)}{\sqrt{2^n n!\sqrt{\pi}}}, \tag{A4}$$

and write $\Delta(m_i)\propto\det[\{P_{j-1}(m_i)\}]$, again absorbing the normalization into Z. The integrals over m_i, $i=2\cdots N$, can easily be done leaving us with

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(m)\right\rangle = \frac{1}{N}\int_{-\infty}^{\infty}dm\sum_{j=0}^{N-1}P_j(m)^2\exp\left[-m^2+\sqrt{\frac{\lambda}{2N}}m\right]. \tag{A5}$$

Using the integral,

$$\int_{-\infty}^{\infty}dm\,P_j(m)^2\exp\left[-\left(m-\sqrt{\frac{\lambda}{8N}}\right)^2\right]=L_j(-\lambda/4N), \tag{A6}$$

where L_n^m is the Laguerre polynomial $L_n^m(x)=1/n!\,\exp[x]x^{-m}(d/dx)^n(\exp[-x]x^{n+m})$, $(L_n^0=L_n)$, we obtain

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle = \frac{1}{N}\sum_{j=0}^{N-1}L_j(-\lambda/4N)\exp[\lambda/8N]$$
$$= \frac{1}{N}L_{N-1}^1(-\lambda/4N)\exp[\lambda/8N]$$
$$= \frac{2e^{-\lambda/8N}}{N!\sqrt{\lambda/N}}\int_0^{\infty}dt\,e^{-t}t^{N-1/2}I_1(\sqrt{t\lambda/N}). \tag{A7}$$

In order to exhibit the $1/N$ expansion we write (A7) as a power series in λ,

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle = \exp[\lambda/8N]\sum_{k=0}^{N-1}\binom{N}{k+1}\frac{\lambda^k}{4^k N^{k+1}k!}$$

$$= \sum_{n=0}^{\infty}\frac{\lambda^n}{4^n n!(n+1)!}B(n,N), \tag{A8}$$

where

$$B(n,N)\equiv\sum_{k=0}^{n}\frac{n!(n+1)!2^{k-n}(N-1)!}{k!(k+1)!(n-k)!(N-1-k)!N^n}=\frac{(n+1)!}{(2N)^n}F(-n,1-N;2;2), \tag{A9}$$

and F is the hypergeometric function $[F(\alpha,\beta;\gamma;z)=1+(\alpha\beta/\gamma\cdot 1)z+\{[\alpha(\alpha+1)\beta(\beta+1)/[\gamma(\gamma+1)\cdot 2!]\}z^2+\cdots]$. $B(n,N)$ can easily be expanded in a power series in $1/N^2$ to yield

$$B(n,N)=1+\frac{n(n^2-1)}{12N^2}+\frac{(n+1)!}{(n-4)!}\frac{(5n-2)}{1440N^4}+\frac{(n+1)!}{(n-6)!}\frac{(35n^2-77n+12)}{2^7 3^4 5\cdot 7N^6}$$

$$+\frac{(n+1)!}{(n-8)!}\frac{(175n^3-945n^2+1094n-72)}{2^{11}3^5 5^2 7N^8}+\cdots\ . \tag{A10}$$

Using the definition of the Bessel function: $I_n(2x)=\Sigma_{k=0}^{\infty}[x^{n+2k}/k!(n+k)!]$, we can then use this expansion to derive the asymptotic expansion in powers of $1/N$,

$$\left\langle \frac{1}{N}\mathrm{Tr}\exp(M)\right\rangle = \frac{2}{\sqrt{\lambda}}I_1(\sqrt{\lambda})+\frac{\lambda}{48N^2}I_2(\sqrt{\lambda})+\frac{\lambda^2}{1280N^4}I_4(\sqrt{\lambda})+\frac{\lambda^{5/2}}{9216N^4}I_5(\sqrt{\lambda})+\cdots\ . \tag{A11}$$

APPENDIX B: EXPLICIT 1/*N* EXPANSION

We now present a systematic $1/N^2$ expansion of $F(\lambda,N)$. To this end we use the transformation formula, $F(\alpha,\beta;\gamma;z)=(1-z)^{-\alpha}F(\alpha,\gamma-\beta;\gamma;z/(z-1))$, to rewrite

$$B(n,N)=(-)^n\frac{(n+1)!}{(2N)^n}F(-n,N+1;2;2), \tag{B1}$$

and then we use the Gauss recursion relation,

$$(2\alpha-\gamma-\alpha z+\beta z)F(\alpha,\beta;\gamma;z)+(\gamma-\alpha)F(\alpha-1,\beta;\gamma;z)+\alpha(z-1)F(\alpha+1,\beta;\gamma;z)=0,$$

to derive the recursion relation:

$$B(n+1,N)=B(n,N)+[n(n+1)/4N^2]B(n-1,N). \tag{B2}$$

This recursion relation allows us to derive a systematic expansion of $B(n,N)$ in powers of $1/N^2$, starting with $B(0,N)=1$. It is easy to verify from (B2) that

$$B(n,N)=\sum_{k=0}^{\lfloor n/2\rfloor}\frac{b_k(n)}{N^{2k}},$$

where $b_k(n)$ is a polynomial in n of rank $3k$. It is also easy to see that $b_k(n)=0$ for $n=0,1,2,\ldots,2k-1$. We can therefore expand these polynomials in terms of the k polynomials, $(n+1)!/(n-3k+1+i)!$, that vanish for $n\leqslant 2k-1$:

$$b_k(n)=\sum_{i=0}^{k-1}\frac{(n+1)!}{(n-3k+1+i)!}X_k^i. \tag{B3}$$

To determine the X_k^i we use (B2) to derive

$$4X_k^i=\frac{3k-i-2}{3k-i}X_{k-1}^{i-1}+\frac{1}{3k-i}X_{k-1}^i, \tag{B4}$$

which, together with $X_1^0=1/12$, and $X_k^k=0$, can be used to evaluate the X_k^i's. In particular,

$$X_k^0=\frac{1}{12^k k!};\quad X_k^1=\frac{3}{20}\frac{1}{12^{k-1}(k-2)!}. \tag{B5}$$

The advantage of this expansion is that when we plug (B3) into the expression, (A.8), for $F(\lambda,N)$ the sum over n, order by order in $1/N^2$, can easily be performed to derive

$$F(\lambda,N)=\frac{2}{\sqrt{\lambda}}I_1(\sqrt{\lambda})+\sum_{k=1}^{\infty}\frac{1}{N^{2k}}\sum_{i=0}^{k-1}X_k^i\left(\frac{\lambda}{4}\right)^{(3k-i-1)/2}I_{3k-i-1}(\sqrt{\lambda}). \tag{B6}$$

This expression can then be used to determine the large λ behavior of F, order by order in $1/N^2$,

$$F(\lambda,N)=\sum_p\frac{1}{N^{2p}}e^{\sqrt{\lambda}}\sqrt{\frac{2}{\pi}}\frac{\lambda^{(6p-3)/4}}{96^p p!}\left[1-\frac{3(12p^2+8p+5)}{40\sqrt{\lambda}}+O\left(\frac{1}{\lambda}\right)\right]. \tag{B7}$$

Finite *N* AdS/CFT correspondence for Abelian and non-Abelian orbifolds, and gauge coupling unification

Paul H. Frampton[a)]
Department of Physics and Astronomy, University of North Carolina, Chapel Hill, North Carolina 27599

(Received 2 January 2001; accepted for publication 13 February 2001)

Although the AdS/CFT correspondence is rigorous only for an infinite $N\to\infty$ stack of D3-branes, it can be fruitfully studied for finite N as a source of gauge structures and choices for chiral fermions and complex scalars which solve the hierarchy problem by a conformal fixed point. We emphasize orbifolds $AdS_5\times S^5/\Gamma$ where the resulting GFT has $\mathcal{N}=0$ supersymmetry. The fact that the complex scalars are prescribed by the construction limits the possible spontaneous symmetry breaking. Both Abelian and non-Abelian Γ are illustrated by simple examples. An accurate $\sin^2\theta$ in electroweak unification can be obtained, suggesting that this approach merits further study. © *2001 American Institute of Physics.*

I. INTRODUCTION

It has been a challenge over the last fifteen years to make a connection between superstring theory and the real world. The original attempts[1] to identify massless string modes with the familiar degrees of freedom (quarks, gluons, etc.) did not bear fruit so other ideas to make such identification merit exploration.

A very old idea which is basic to string theory is conformal invariance on the world sheet in two dimensions.[2–6] A more recent idea is that conformal invariance in four spacetime dimensions may guide the sought-for connection of superstring, and hence M theory, to observable physics.

Let us briefly outline the basis for AdS/CFT correspondence to set the scene (for a more complete review; see Ref. 7). Consider the type IIB superstring in flat ten-dimensional Minkowski space, and a number N of parallel D3 branes close to each other, filling a $(3+1)$ subspace of the $(9+1)$ spacetime. The system has two types of perturbative excitations: closed and open strings. Closed strings are the excitations in the bulk and open strings end on the D3-branes. At sufficiently low energies ($\ll l_{\text{string}}^{-1}$, the string scale), only massless states play a role. The massless closed string states form a type IIB supergravity multiplet: the massless open string states form an $\mathcal{N}=4$ vector supermultiplet in $(3+1)$ dimensions with interactions described by an $\mathcal{N}=4$ SU(N) supersymmetric gauge theory.

Next consider the same system but in the background of a D3-brane solution of supergravity:

$$ds^2=f^{-1/2}(-dt^2+dx_1^2+dx_2^2+dx_3^2)+f^{1/2}(dr^2+d\Omega_5), \tag{1}$$

with

$$f=1+(R/r)^4 \quad \text{and} \quad R=4\pi g_{\text{string}}(\alpha'_{\text{string}})^2N. \tag{2}$$

In this case, the energy of an object depends on r: if it is E_r at r then at $r=\infty$ it appears redshifted to $E_\infty=f^{-1/4}E_r$ because of the g_{tt} metric component in Eq. (1). Thus to an observer at infinity, the $r\to 0$ excitations in the ''throat'' appear of lowest energy. There are two types of

a)Electronic mail: frampton@physics.unc.edu

massless excitations. In the bulk is the IIB supergravity multiplet interacting via supergravity: in the near-horizon region of the throat where $r \ll R$ and $f \sim (R/r)^4$ the geometry is that of $AdS_5 \times S^5$:

$$ds^2 = \left(\frac{r^2}{R^2}\right)(-dt^2 + dx_1^2 + dx_2^2 + dx_3^2) + \frac{R^2 dr^2}{r^2} + R^2\, d\Omega_5 . \tag{3}$$

In both backgrounds there are two decoupled theories in the low-energy limit. One theory in both cases is supergravity in flat space. It is natural to identify the other two theories: $\mathcal{N}=4$ SU(N) gauge theory in (3+1) spacetime corresponds to type IIB superstring theory on $AdS_5 \times S^5$.

Let us now step back from M theory and address the needs of a theory of the ''real world.''

In particle phenomenology, the impressive success of the standard theory based on SU(3) $\times$SU(2)$\times U(1)$ has naturally led to the question of how to extend the theory to higher energies. One is necessarily led by weaknesses and incompleteness in the standard theory. If one extrapolates the standard theory as it stands one finds (approximate) unification of the gauge couplings at $\sim 10^{16}$ GeV. But then there is the *hierarchy* problem of how to explain the occurrence of the tiny dimensionless ratio $\sim 10^{-14}$ of the weak scale to the unification scale. Inclusion of gravity leads to a *super-hierarchy* problem of the ratio of the weak scale to the Planck scale, $\sim 10^{18}$ GeV, an even tinier $\sim 10^{-16}$. Although this is obviously a very important problem about which conformality by itself is not informative, we shall discuss first the hierarchy rather than the super-hierarchy.

There are four well-defined approaches to the hierarchy problem:

- 1. Supersymmetry
- 2. Technicolor
- 3. Extra dimensions
- 4. Conformality

Supersymmetry has the advantage of rendering the hierarchy technically natural, that once the hierarchy is put into the Lagrangian it need not be retuned in perturbation theory. Supersymmetry predicts superpartners of all the known particles and these are predicted to be at or below a TeV scale if supersymmetry is related to the electroweak breaking. Inclusion of such hypothetical states improves the gauge coupling unification. On the negative side, supersymmetry does not explain the origin of the hierarchy.

Technicolor postulates that the Higgs boson is a fermion–antifermion composite bound by a new (technicolor) strong dynamics at or below the TeV scale. This obviates the hierarchy problem. On the minus side, no simple convincing model of technicolor has been found.

Extra dimensions can have a range as large as $1(\mathrm{TeV})^{-1}$ and the gauge coupling unification can happen quite differently than in only four spacetime dimensions. This replaces the hierarchy problem with a different fine-tuning question of why the extra dimension is restricted to a distance corresponding to the weak interaction scale. There is also a potentially serious problem with the proton lifetime.

Conformality is inspired by the AdS/CFT correspondence discussed above superstring duality and assumes that the particle spectrum of the standard model is enriched such that there is a conformal fixed point of the renormalization group at the TeV scale. Above this scale the coupling do not run so the hierarchy is nullified. Instead, the couplings $\alpha_1^{-1}, \alpha_2^{-1}, \alpha_3^{-1}$ run from low energy up to the TeV scale then combine to one energy-independent $\alpha_{\mathrm{conformal}}^{-1}$ (in most cases equal to α_3^{-1}). It is important to realize that the observed difference between α_1^{-1}, α_2^{-1} and $\alpha_3^{-1} = \alpha_{\mathrm{conformal}}^{-1}$ arise in this approach from the group theory associated with embedding SU(3)$\times$SU(2) $\times U(1)$ in a semi-simple unifying gauge group.

Conformality is the approach followed in this paper. We shall systematically analyze the compactification of the IIB superstring on $AdS_5 \times S^5/\Gamma$ where Γ is a discrete non-Abelian group designed to break all supersymmetries.

Until very recently, the possibility of testing string theory seemed remote, at best. The advent of the AdS/CFT correspondence suggests this point of view may be too pessimistic, since it could lead to ~TeV evidence for strings. With this thought in mind, we are encouraged to build AdS/CFT models with realistic fermionic structure, and reduce to the standard model below ~1 TeV.

Using AdS/CFT duality, one arrives at a class of gauge field theories of special recent interest. The simplest compactification of a ten-dimensional superstring on a product of an AdS space with a five-dimensional spherical manifold leads to an $\mathcal{N}=4$ SU(N) supersymmetric gauge theory, well known to be conformally invariant.[8] By replacing the manifold S^5 by an orbifold S^5/Γ one arrives at less supersymmetries corresponding to $\mathcal{N}=2$, 1 or 0 depending[9] on whether $\Gamma \subset \mathrm{SU}(2)$, SU(3), or $\not\subset \mathrm{SU}(3)$, respectively, where Γ is in all cases a subgroup of SU(4)~SO(6) the isometry of the S^5 manifold.

It was conjectured in Ref. 10 that such SU(N) gauge theories are conformal in the $N\to\infty$ limit. In Ref. 11 it was conjectured that at least a subset of the resultant nonsupersymmetric $\mathcal{N}=0$ theories are conformal even for finite N and that one of this subset provides the right extension of the standard model. Some first steps to check this idea were made in Ref. 12. Model-building based on Abelian Γ was studied further in Refs. 13, 14, arriving in Ref. 15 at an $\mathrm{SU}(3)^7$ model based on $\Gamma = Z_7$ which has three families of chiral fermions, a correct value for $\sin^2\theta$ and a conformal scale ~10 TeV.

II. ABELIAN ORBIFOLDS

Since, in the context of field-string duality, there has been a shift regarding the relationship of gravity to the standard model of strong and electroweak interactions we shall begin by characterizing how gravity fits in, then to suggest more specifically how the standard model fits in to the string framework.

The descriptions of gravity and of the standard model are contained in the string theory. In the string picture in ten spacetime dimensions, or upon compactification to four dimensions, there is a massless spin-two graviton but the standard model is not manifest in the way we shall consider it. In the conformal field theory extension of the standard model, gravity is strikingly absent. The field-string duality does not imply that the standard model already contains gravity and, in fact, it does not.

In the field theory description[11–14] used in this article, one will simply ignore the massless spin-two graviton. Indeed, since we are using the field theory description only below the conformal scale of ~1 TeV (or, as suggested later in this paper, 10 TeV) and forgoing any requirement of grand unification, the hierarchy between the weak scale and theory-generated scales like M_{GUT} or M_{PLANCK} is resolved. Moreover, seeking the graviton in the field theory description is possibly resolvable by going to a higher dimension and restricting the range of the higher dimension. Here we are looking only at the strong and weak interactions at accessible energies below, say, 10 TeV.

Of course, if we ask questions in a different regime, for example about the scattering of particles with center-of-mass energy of the order M_{PLANCK}, then the graviton will become crucial[16,17] and a string, rather than a field, description will be the viable one.

It is important to distinguish between the holographic description of the five-dimensional gravity in $(\mathrm{AdS})_5$ made by the four-dimensional CFT and the origin of the four-dimensional graviton. The latter could be described holographically only by a lower three-dimensional field theory which is not relevant to the real world. Therefore the graviton of our world can only arise by *compactification* of a higher-dimensional graviton. The introduction of gravity must break conformal invariance and it is an interesting question whether this breaking is related to the mass and symmetry-breaking scales in the low-energy theory. That is all I will say about gravity in the present paper; the remainder is on the standard model and its embedding in a CFT.

An alternative to conformality, grand unification with supersymmetry, leads to an impressively accurate gauge coupling unification.[18,19] In particular it predicts an electroweak mixing angle at the Z-pole, $\sin^2\theta = 0.231$. This result may, however, be fortuitous, but rather than abandon

gauge coupling unification, we can rederive $\sin^2\theta=0.231$ in a different way by embedding the electroweak $SU(2)\times U(1)$ in $SU(N)\times SU(N)\times SU(N)$ to find $\sin^2\theta=3/13\simeq 0.231$.[14] This will be a common feature of the models in this paper.

Actually, it may be premature to dismiss as accidental the success of grand unification with $\sin^2\theta$ since the principal topic here (AdS/CFT) teaches us that quite different theoretical descriptions can be ''dual'' and the same may eventually be understood for conformality and grand unification. For example, conformality is compatible with supersymmetry at low-energy.

The conformal theories will be finite without quadratic or logarithmic divergences. This requires appropriate equal numbers of fermions and bosons which can cancel in loops and which occur without the necessity of space–time supersymmetry. As we shall see in one example, it is possible to combine spacetime supersymmetry with conformality but the latter is the driving principle and the former is merely an option: additional fermions and scalars are predicted by conformality in the TeV range,[13,14] but in general these particles are different and distinguishable from supersymmetric partners. The boson–fermion cancellation is essential for the cancellation of infinities, and will play a central role in the calculation of the cosmological constant (not discussed here). In the field picture, the cosmological constant measures the vacuum energy density.

Here we shall focus on Abelian orbifolds characterized by the discrete group Z_p. Non-Abelian orbifolds will be discussed in the next section.

The steps in building a model for the abelian case (parallel steps hold for non-Abelian orbifolds) are the following:

- (1) Choose the discrete group Γ. Here we are considering only $\Gamma=Z_p$. We define $\alpha=\exp(2\pi i/p)$.
- (2) Choose the embedding of $\Gamma\subset SU(4)$ by assigning $\mathbf{4}=(\alpha^{A_1},\alpha^{A_2},\alpha^{A_3},\alpha^{A_4})$ such that $\Sigma_{q=1}^{q=4}A_q=0(\mathrm{mod}\,p)$. To break $\mathcal{N}=4$ supersymmetry to $\mathcal{N}=0$ (or $\mathcal{N}=1$) requires that none (or one) of the A_q is equal to zero (mod p).
- (3) For chiral fermions one requires that $\mathbf{4}\neq\mathbf{4}^*$ for the embedding of Γ in SU(4). The chiral fermions are in the bifundamental representations of $SU(N)^p$,

$$\sum_{i=1}^{i=p}\sum_{q=1}^{q=4}(N_i,\overline{N}_{i+A_q}). \tag{4}$$

  If $A_q=0$ we interpret $(N_i,\overline{N}_i)$ as a singlet plus an adjoint of $SU(N)_i$.
- (4) The **6** of SU(4) is real $\mathbf{6}=(a_1,a_2,a_3,-a_1,-a_2,-a_3)$ with $a_1=A_1+A_2$, $a_2=A_2+A_3$, $a_3=A_3+A_1$ (recall that all components are defined modulo p). The complex scalars are in the bifundamentals,

$$\sum_{i=1}^{i=p}\sum_{j=1}^{j=3}(N_i,\overline{N}_{i\pm a_j}). \tag{5}$$

  The condition in terms of a_j for $\mathcal{N}=0$ is $\Sigma_{j=1}^{j=3}(\pm a_j)\neq 0(\mathrm{mod}\,p)$.[11]
- (5) Choose the N of $\otimes_i SU(Nd_i)$ (where the d_i are the dimensions of the representations of Γ). For the Abelian case where $d_i\equiv 1$, it is natural to choose $N=3$ the largest $SU(N)$ of the standard model (SM) gauge group. For a non-Abelian Γ with $d_i\neq 1$ the choice $N=2$ would be indicated.
- (6) The p quiver nodes are identified as color (C), weak isospin (W), or a third SU(3) (H). This specifies the embedding of the gauge group $SU(3)_C\times SU(3)_W\times SU(3)_H\subset\otimes SU(N)^p$. This quiver node identification is guided by (7), (8) and (9) below.
- (7) The quiver node identification is required to give three chiral families under Eq. (4). It is sufficient to make three of the $(C+A_q)$ to be W and the fourth H, given that there is only one C quiver node, so that there are three $(3,\overline{3},1)$. Provided that $(\overline{3},3,1)$ is avoided by the $(C-A_q)$ being H, the remainder of the three family trinification will be automatic by chiral

anomaly cancellation. Actually, a sufficient condition for three families has been given; it is necessary only that the difference between the number of $(3+A_q)$ nodes and the number of $(3-A_q)$ nodes which are W be equal to three.

- (8) The complex scalars of Eq. (5) must be sufficient for their vacuum expectation values (VEVs) to spontaneously break $SU(3)^p \to SU(3)_C \times SU(3)_W \times SU(3)_H \to SU(3)_C \times SU(2)_W \times U(1)_Y \to SU(3)_C \times U(1)_Q$.
  Note that, unlike grand unified theories (GUTs) with or without supersymmetry, the Higgs scalars are here prescribed by the conformality condition. This is more satisfactory because it implies that the Higgs sector cannot be chosen arbitrarily.
- (9) Gauge coupling unification should apply at least to the electroweak mixing angle $\sin^2\theta = g_Y^2/(g_2^2+g_Y^2) \simeq 0.231$. For trinification $Y = 3^{-1/2}(-\lambda_{8W}+2\lambda_{8H})$ so that $(3/5)^{1/2}Y$ is correctly normalized. If we make $g_Y^2 = (3/5)g_1^2$ and $g_2^2 = 2g_1^2$ then $\sin^2\theta = 3/13 \simeq 0.231$ with sufficient accuracy.
  In the remainder of this section we answer all these steps for the choice $\Gamma = Z_p$ for successive $p = 2,3,\ldots,$ up to $p=7$, then add some concluding remarks.

- **p=2**
  In this case $\alpha = -1$ and therefore one cannot construct any complex **4** of SU(4) with **4**$\neq$**4***. Chiral fermions are therefore impossible.
- **p=3**
  The only possibilities are $A_q = (1,1,1,0)$ or $A_q = (1,1,-1,-1)$. The latter is real and leads to no chiral fermions. The former leaves $\mathcal{N}=1$ supersymmetry and is a simple three-family model[9] by the quiver node identification C-W-H. The scalars $a_j = (1,1,1)$ are sufficient to spontaneously break to the SM. Gauge coupling unification is, however, missing since $\sin^2\theta = 3/8$, in bad disagreement with experiment.
- **p=4**
  The only complex $\mathcal{N}=0$ choice is $A_q = (1,1,1,1)$. But then $a_j = (2,2,2)$ and any quiver node identification such as C-W-H-H has 4 families and the scalars are insufficient to break spontaneously the symmetry to the SM gauge group.
- **p=5**
  The two inequivalent complex choices are $A_q = (1,1,1,2)$ and $A_q = (1,3,3,3)$. By drawing the quiver, however, and using the rules for three chiral families given in (7) above, one finds that the node identification and the prescription of the scalars as $a_j = (2,2,2)$ and $a_j = (1,1,1)$, respectively, does not permit spontaneous breaking to the standard model.
- **p=6**
  Here we can discuss three inequivalent complex possibilities as follows:
  (6A) $A_q = (1,1,1,3)$ which implies $a_j = (2,2,2)$.
  Requiring three families means a node identification C-W-X-H-X-H where X is either W or H. But whatever we choose for the X the scalar representations are insufficient to break $SU(3)^6$ in the desired fashion down to the standard theory. This illustrates the difficulty of model building when the scalars are not in arbitrary representations.
  (6B) $A_q = (1,1,2,2)$ which implies $a_j = (2,3,3)$.
  Here the family number can be only zero, two or four as can be seen by inspection of the A_q and the related quiver diagram. So (6B) is of no phenomenological interest.
  (6C) $A_q = (1,3,4,4)$ which implies $a_j = (1,1,4)$.
  Requiring three families needs a quiver node identification which is of the form *either* C-W-H-H-W-H *or* C-H-H-W-W-H. The scalar representations implied by $a_j = (1,1,4)$ are, however, easily seen to be insufficient to do the required spontaneous symmetry breaking (S.S.B.) for both of these identifications.
- **p=7**
  Having been stymied mainly by the rigidity of the scalar representation for all $p \leqslant 6$, for

$p=7$ there are the first cases which work. Six inequivalent complex embeddings of $Z_7 \subset \mathrm{SU}(4)$ require consideration.
(7A) $A_q=(1,1,1,4) \Rightarrow a_j=(2,2,2)$
For the required nodes C-W-X-H-H-X-H the scalars are *insufficient* for S.S.B.
(7B) $A_q=(1,1,2,3) \Rightarrow a_j=(2,3,3)$
The node identification C-W-H-W-H-H-H leads to a *successful* model.
(7C) $A_q=(1,2,2,2) \Rightarrow a_j=(3,3,3)$
Choosing C-H-W-X-X-H-H to derive three families, the scalars *fail* in S.S.B.
(7D) $A_q=(1,3,5,5) \Rightarrow a_j=(1,1,3)$
The node choice C-W-H-H-H-W-H leads to a *successful* model. This is Model A of Ref. 14.
(7E) $A_q=(1,4,4,5) \Rightarrow a_j=(1,2,2)$
The nodes C-H-H-H-W-W-H are *successful*.
(7F) $A_q=(2,4,4,4) \Rightarrow a_j=(1,1,1)$
Scalars *insufficient* for S.S.B.

The three successful models (7B), (7D) and (7E) lead to an $\alpha_3(M) \simeq 0.07$. Since $\alpha_3(1\ \mathrm{TeV}) \geqslant 0.10$ this suggests a conformal scale $M \simeq 10\ \mathrm{TeV}$.[14] The above models have less generators than an $E(6)$ GUT and thus $\mathrm{SU}(3)^7$ merits further study. It is possible, and under investigation, that non-Abelian orbifolds will lead to a simpler model.

For such field theories it is important to establish the existence of a fixed manifold with respect to the renormalization group. It could be a fixed line but more likely, in the $\mathcal{N}=0$ case, a fixed point. It is known that in the $N \to \infty$ limit the theories become conformal, but although this 't Hooft limit[20] is where the field-string duality is derived we know that finiteness survives to finite N in the $\mathcal{N}=4$ case[8] and this makes it plausible that at least a conformal point occurs also for the $\mathcal{N}=0$ theories with $N=3$ derived above.

The conformal structure cannot by itself predict all the dimensionless ratios of the standard model such as mass ratios and mixing angles because these receive contributions, in general, from soft breaking of conformality. With a specific assumption about the pattern of conformal symmetry breaking, however, more work should lead to definite predictions for such quantities.

III. NON-ABELIAN ORBIFOLDS

Abelian orbifolds lead us to consider the finite N value $N=3$ guided by trinification $\mathrm{SU}(3)^3$ and the fact that all representations of Abelian groups Z_p are one dimensional.

A non-Abelian orbifold can allow the consideration of finite $N=2$ since for a Γ with doublet and singlet representations can lead to a generalization of a left–right structure of the type $\mathrm{SU}(4) \times \mathrm{SU}(2) \times \mathrm{SU}(2)$.

First we remind the reader of available non-Abelian Γ of low order $g \leqslant 31$.

Of the non-Abelian finite groups, the best known are perhaps the permutation groups S_N (with $N \geqslant 3$) of order $N!$ The smallest non-Abelian finite group is S_3 ($\equiv D_3$), the symmetry of an equilateral triangle with respect to all rotations in a three-dimensional sense. This group initiates two infinite series, the S_N and the D_N. Both have elementary geometrical significance since the symmetric permutation group S_N is the symmetry of the N-plex in N dimensions while the dihedral group D_N is the symmetry of the planar N-agon in 3 dimensions. As a family symmetry, the S_N series becomes uninteresting rapidly as the order and the dimensions of the represention increase. Only S_3 and S_4 are of any interest as symmetries associated with the particle spectrum;[21] also, the order (number of elements) of the S_N groups grow factorially with N. The order of the dihedral groups increases only linearly with N and their irreducible representations are all one- and two-dimensional. This is reminiscent of the representations of the electroweak $\mathrm{SU}(2)_L$ used in nature.

Each D_N is a subgroup of $O(3)$ and has a counterpart double dihedral group Q_{2N}, of order $4N$, which is a subgroup of the double covering $\mathrm{SU}(2)$ of $O(3)$.

With only the use of D_N, Q_{2N}, S_N and the tetrahedral group T (of order 12, the even permutations subgroup of S_4) we find 32 of the 45 non-Abelian groups up to order 31, either as simple groups or as products of simple non-Abelian groups with Abelian groups (Note that $D_6 \simeq Z_2 \times D_3, D_{10} \simeq Z_2 \times D_5$ and $D_{14} \simeq Z_2 \times D_7$):

g	
6	$D_3 \equiv S_3$
8	$D_4, Q = Q_4$
10	D_5
12	D_6, Q_6, T
14	D_7
16	$D_8, Q_8, Z_2 \times D_4, Z_2 \times Q$
18	$D_9, Z_3 \times D_3$
20	D_{10}, Q_{10}
22	D_{11}
24	$D_{12}, Q_{12}, Z_2 \times D_6, Z_2 \times Q_6, Z_2 \times T,$
	$Z_3 \times D_4, Z_3 \times Q, Z_4 \times D_3, S_4$
26	D_{13}
28	D_{14}, Q_{14}
30	$D_{15}, D_5 \times Z_3, D_3 \times Z_5$

There remain thirteen others formed by twisted products of Abelian factors. Only certain such twistings are permissable, namely the following (completing all $g \leqslant 31$).

g	
16	$Z_2 \tilde{\times} Z_8$ (two, excluding D_8), $Z_4 \tilde{\times} Z_4$, $Z_2 \tilde{\times} (Z_2 \times Z_4)$ (two)
18	$Z_2 \tilde{\times} (Z_3 \times Z_3)$
20	$Z_4 \tilde{\times} Z_5$
21	$Z_3 \tilde{\times} Z_7$
24	$Z_3 \tilde{\times} Q$, $Z_3 \tilde{\times} Z_8$, $Z_3 \tilde{\times} D_4$
27	$Z_9 \tilde{\times} Z_3$, $Z_3 \tilde{\times} (Z_3 \times Z_3)$

It can be shown that these thirteen exhaust the classification of *all* inequivalent finite groups up to order thirty-one.[22,23]

Of the 45 non-Abelian groups, the dihedrals (D_N) and double dihedrals (Q_{2N}), of order 2N and 4N, respectively, form the simplest sequences. In particular, they fall into subgroups of $O(3)$ and SU(2), respectively, the two simplest non-Abelian continuous groups.

For the D_N and Q_{2N}, the multiplication tables, as derivable from the character tables, are, in general, simple to express. D_N, for odd N, has two singlet representations $1,1'$ and $m=(N-1)/2$ doublets $2_{(j)}$ $(1 \leqslant j \leqslant m)$. The multiplication rules are

$$1' \times 1' = 1; \quad 1' \times 2_{(j)} = 2_{(j)}, \tag{6}$$

$$2_{(i)} \times 2_{(j)} = \delta_{ij}(1+1') + 2_{(\min[i+j, N-i-j])} + (1-\delta_{ij}) 2_{(|i-j|)}. \tag{7}$$

For even N, D_N has four singlets $1,1',1'',1'''$ and $(m-1)$ doublets $2_{(j)}$ $(1 \leqslant j \leqslant m-1)$ where $m=N/2$ with multiplication rules:

$$1' \times 1' = 1'' \times 1'' = 1''' \times 1''' = 1, \tag{8}$$

$$1' \times 1'' = 1'''; 1'' \times 1''' = 1'; 1''' \times 1' = 1'', \tag{9}$$

$$1' \times 2_{(j)} = 2_{(j)}, \tag{10}$$

$$1'' \times 2_{(j)} = 1''' \times 2_{(j)} = 2_{(m-j)}, \tag{11}$$

$$2_{(j)} \times 2_{(k)} = 2_{|j-k|} + 2_{(\min[j+k, N-j-k])} \tag{12}$$

[if $k \neq j, (m-j)$],

$$2_{(j)} \times 2_{(j)} = 2_{(\min[2j, N-2j])} + 1 + 1' \tag{13}$$

(if $j \neq m/2$),

$$2_{(j)} \times 2_{(m-j)} = 2_{|m-2j|} + 1'' + 1''' \tag{14}$$

(if $j \neq m/2$),

$$2_{m/2}\times 2_{m/2}=1+1'+1''+1'''. \tag{15}$$

This last case is possible only if m is even and hence if N is divisible by *four*.

For Q_{2N}, there are four singlets $1,1',1'',1'''$ and $(N-1)$ doublets $2_{(j)}$ $(1\leqslant j\leqslant(N-1))$.

The singlets have the multiplication rules:

$$1\times 1=1'\times 1'=1, \tag{16}$$

$$1''\times 1''=1'''\times 1'''=1', \tag{17}$$

$$1'\times 1''=1''';1'''\times 1'=1'', \tag{18}$$

for $N=(2k+1)$ but are identical to those for D_N when $N=2k$.

The products involving the $2_{(j)}$ are identical to those given for D_N (N even) above.

This completes the multiplication rules for 19 of the 45 groups. The complete multiplication tables for all the non-Abelian groups with order $g\leqslant 31$ are provided in Appendix A of Ref. 24.

Mathematical theorem: *A* pseudoreal 4 of SU(4) cannot yield chiral fermions

In Ref. 13 it was proved that if the embedding in SU(4) is such that the **4** is real, the resultant fermions are always nonchiral. It was implied there that the converse holds, that if **4** is complex, $\mathbf{4}=\mathbf{4}^*$, then the resulting fermions are necessarily chiral. Actually for $\Gamma\subset$SU(2) one encounters the intermediate possibility that the **4** is *pseudoreal*. In the present section we shall show that if **4** is pseudoreal then the resultant fermions are necessarily nonchiral. The converse now holds: if the **4** is neither real nor pseudoreal then the resultant fermions are chiral.

For $\Gamma\subset$SU(2) it is important that the embedding be consistent with the chain $\Gamma\subset$SU(2)$\subset$SU(4), otherwise the embedding is not a consistent one. One way to see the inconsistency is to check the reality of the $\mathbf{6}=(\mathbf{4}\otimes\mathbf{4})_{\text{antisymmetric}}$. If $\mathbf{6}\neq\mathbf{6}^*$ then the embedding is clearly improper. To avoid this inconsistency it is sufficient to include in the **4** of SU(4) only complete irreducible representations of SU(2).

An explicit example will best illustrate this propriety constraint on embeddings. Let us consider $\Gamma=Q_6$, the dicyclic group of order $g=12$. This group has six inequivalent irreducible representations: $1,1',1'',1''',2_1,2_2$. The 1, $1'$, 2_1 are real. The $1''$ and $1'''$ are a complex conjugate pair, The 2_2 is pseudoreal. To embed $\Gamma=Q_6\subset$SU(4) we must choose from the special combinations which are complete irreducible representations of SU(2) namely 1, $2=2_2$, $3=1'+2_1$ and $4=1''+1'''+2_2$. In this way the embedding either makes the **4** of SU(4) real, e.g., $4=1+1'+2_1$ and the theorem of Ref. 13 applies, and nonchirality results, or the **4** is pseudoreal, e.g., $4=2_2+2_2$. In this case one can check that the embedding is consistent because $(\mathbf{4}\otimes\mathbf{4})_{\text{antisymmetric}}$ is real. But it is equally easy to check that the product of this pseudoreal **4** with the complete set of irreducible representations of Q_6 is again real and that the resultant fermions are nonchiral.

The lesson is the following.

To obtain chiral fermions from compactification on $AdS_5\times S_5/\Gamma$, *the embedding of* Γ *in* SU(4) *must be such that the* 4 *of* SU(4) *is neither real nor pseudoreal.*

Now we are ready for a successful example.[23,24]

Group 24/7; also designated $D_4\times Z_3$

This has twelve singlets $1_1\alpha^i,1_2\alpha^i,1_3\alpha^i,1_4\alpha^i$ $(i=0-2)$ and three doublets $2\alpha^i$ $(i=0-2)$; here $\alpha=\exp(i\pi/3)$. The embedding $\mathbf{4}=(1_1\alpha,1_2,2\alpha)$ was studied in detail in a previous article[23] where it was shown how it can lead to precisely three chiral families in the standard model. For completeness we include the table[24] for the chiral fermions (it was presented in a different equivalent way in Ref. 23):

	1_1	1_2	1_3	1_4	2	$1_1\alpha$	$1_2\alpha$	$1_3\alpha$	$1_4\alpha$	2α	$1_1\alpha^2$	$1_2\alpha^2$	$1_3\alpha^2$	$1_4\alpha^2$	$2\alpha^2$
1_1		×				×				×					
1_2	×						×			×					
1_3				×				×		×					
1_4			×						×	×					
2					×	×	×	×	×	×					
$1_1\alpha$							×				×				×
$1_2\alpha$						×						×			×
$1_3\alpha$									×				×		×
$1_4\alpha$								×						×	×
2α										×	×	×	×	×	×
$1_1\alpha^2$	×				×							×			
$1_2\alpha^2$		×			×						×				
$1_3\alpha^2$			×		×									×	
$1_4\alpha^2$				×	×								×		
$2\alpha^2$	×	×	×	×	×										×

By identifying SU(4) with the diagonal subgroup of $SU(4)_{2,3}$, breaking $SU(4)_1$ to $SU(2)'_L \times SU(2)'_R$, then identifying $SU(2)_L$ with the diagonal subgroup of $SU(2)_{6,7,8}$ and $SU(2)'_L$ and $SU(2)_R$ with the diagonal subgroup of $SU(2)_{10,11,12}$ and $SU(2)'_R$ then leads to a three-family model.

This model is especially interesting because, uniquely among the large number of models examined in this study, the prescribed scalars are sufficient to break the gauge symmetry to that of the standard model with three chiral families.

IV. GAUGE COUPLING UNIFICATION

Most of the research beyond the standard model[25] is motivated by the hierarchy problem and uses the two assumptions of grand unification and low-energy (~TeV) supersymmetry. This is, in turn, driven largely by the successful prediction of one number, $\sin^2\theta$ of the electroweak mixing angle θ. It is proposed to replace the two assumptions of grand unification and low-energy supersymmetry by one assumption, conformality. It therefore is important to show that $\sin^2\theta$ can be derived from conformality alone; that is our principal objective in this section.

Before entering into conformality, let us briefly review the alternative. The experimental data give couplings at the Z pole of[26] $\alpha_3 = 0.118 \pm 0.003, \alpha_2 = 0.0338, \alpha_1 = \frac{5}{3}\alpha'_Y = 0.0169$ (where the

errors on $\alpha_{1,2}$ are less than 1%) and $\sin^2\theta=\alpha_Y'/(\alpha_2+\alpha_Y')=0.231$ with an error of less than 0.001. Note that α_2/α_1 is very nearly two; this will be used later. The RGEs for the supersymmetric grand unification[27,28] are

$$\frac{1}{\alpha_i(M_G)}=\frac{1}{\alpha_i(M_Z)}-\frac{b_i}{2\pi}\ln\left(\frac{M_G}{M_Z}\right). \tag{19}$$

Using the MSSM values $b_i=(6\frac{3}{5},1,-3)$ and substituting $\alpha_{2,3}$ at $M_Z=91.187\,\mathrm{GeV}$ gives $M_G=2.4\times10^{16}\,\mathrm{GeV}$ and $\alpha_{2,3}(M_G)^{-1}=24.305$. Using Eq. (19) with $i=1$ now predicts $\alpha_1(M_Z)=59.172$ and hence $\sin^2\theta=0.231$; this is impressive agreement with experiment and is sometimes presented as the accurate meeting of three straight lines on a $\alpha_i^{-1}(\mu)$ vs the $\ln\mu$ plot.[18,19]

As we have seen above, the relationship of the Type IIB superstring to conformal gauge theory in $d=4$ gives rise to an interesting class of gauge theories. Choosing the simplest compactification[10] on $\mathrm{AdS}_5\times S_5$ gives rise to an $\mathcal{N}=4$ SU(N) gauge theory which is known to be conformal due to the extended global supersymmetry and nonrenormalization theorems. All of the RGE β-functions for this $\mathcal{N}=4$ case are vanishing in perturbation theory. It is possible to break the $\mathcal{N}=4$ to $\mathcal{N}=2,1,0$ by replacing S_5 by an orbifold S_5/Γ where Γ is a discrete group with $\Gamma\subset\mathrm{SU}(2),\subset\mathrm{SU}(3),\not\subset\mathrm{SU}(3)$, respectively.

In building a conformal gauge theory model,[11–13] the steps are the following: (1) Choose the discrete group Γ; (2) embed $\Gamma\subset\mathrm{SU}(4)$; (3) choose the N of SU(N); and (4) embed the standard model $\mathrm{SU}(3)\times\mathrm{SU}(2)\times U(1)$ in the resultant gauge group $\otimes\mathrm{SU}(N)^p$ (quiver node identification). Here we shall look only at Abelian $\Gamma=Z_p$ and define $\alpha=\exp(2\pi i/p)$. It is expected from the string-field duality that the resultant field theory is conformal in the $N\to\infty$ limit, and will have a fixed manifold, or at least a fixed point, for N finite.

Before focusing on $\mathcal{N}=0$ nonsupersymmetric cases, let us first examine an $\mathcal{N}=1$ model first put forward in Ref. 9. The choice is $\Gamma=Z_3$ and the **4** of SU(4) is $\mathbf{4}=(1,\alpha,\alpha,\alpha^2)$. Choosing $N=3$, this leads to the three chiral families under $\mathrm{SU}(3)^3$ trinification,[29]

$$(3,\bar{3},1)+(1,3,\bar{3})+(\bar{3},1,3). \tag{20}$$

In this model it is interesting that the number of families arises as 4-1=3, the difference between the 4 of SU(4) and $\mathcal{N}=1$, the number of unbroken supersymmetries. However this model has no gauge coupling unification; also, keeping $\mathcal{N}=1$ supersymmetry is against the spirit of the conformality approach. We now present three examples, Models A, B and C, which accommodate three chiral families, break all supersymmetries ($\mathcal{N}=0$), and possess gauge coupling unification, including the correct value of the electroweak mixing angle.

Model A. Choose $\Gamma=Z_7$, embed the 4 of SU(4) as $(\alpha^2,\alpha^2,\alpha^{-3},\alpha^{-1})$ and choose $N=3$ to aim at a trinification $\mathrm{SU}(3)_C\times\mathrm{SU}(3)_W\times\mathrm{SU}(3)_H$.

The seven nodes of the quiver diagram will be identified as C-H-W-H-H-H-W.

The behavior of the 4 of SU(4) implies that the bifundamentals of chiral fermions are in the representations

$$\sum_{j=1}^{7}\left[2(N_j,\bar{N}_{j+2})+(N_j,\bar{N}_{j-3})+(N_j,\bar{N}_{j-1})\right]. \tag{21}$$

Embedding the C, W and H SU(3) gauge groups as indicated by the quiver mode identifications then gives the seven quartets of irreducible representations:

$$\begin{aligned}&[3(3,\bar{3},1)+(3,1,\bar{3})]_1+[3(1,1,1+8)+(\bar{3},1,3)]_2+[3(1,3,\bar{3})+(1,1+8,1)]_3\\&\quad+[(2(1,1,1+8)+(1,\bar{3},3)+(\bar{3},1,3)]_4+[2(1,1,1+8)+2(1,\bar{3},3)]_5\\&\quad+[2(\bar{3},1,3)+(1,1,1+8)+(1,\bar{3},3)]_6+[4(1,3,\bar{3})]_7.\end{aligned} \tag{22}$$

Combining terms gives, aside from (real) adjoints and overall singlets,

$$3(3,\overline{3},1)+4(\overline{3},1,3)+(3,1,\overline{3})+7(1,3,\overline{3})+4(1,\overline{3},3). \tag{23}$$

Cancelling the real parts (which acquire Dirac masses at the conformal symmetry breaking scale) leaves under trinification $\mathrm{SU}(3)_C\times\mathrm{SU}(3)_W\times\mathrm{SU}(3)_H$,

$$3[(3,\overline{3},1)+(1,3,\overline{3})+(\overline{3},1,3)], \tag{24}$$

which are the desired three chiral families.

Given the embedding of Γ in SU(4) it follows that the 6 of SU(4) transforms as $(\alpha^4,\alpha,\alpha,\alpha^{-1},\alpha^{-1},\alpha^{-4})$. The complex scalars therefore transform as

$$\sum_{j=1}^{7}[(N_j,\overline{N}_{j\pm4})+2(N_j,\overline{N}_{j\pm1})]. \tag{25}$$

These bifundamentals can by their VEVS break the symmetry $\mathrm{SU}(3)^7=\mathrm{SU}(3)_C\times\mathrm{SU}(3)_W^2\times\mathrm{SU}(3)_H^4$ down to the appropriate diagonal subgroup $\mathrm{SU}(3)_C\times\mathrm{SU}(3)_W\times\mathrm{SU}(3)_H$.

Now to the final aspect of Model A which is its motivation, the gauge coupling unification. The embedding in $\mathrm{SU}(3)^7$ *of* $\mathrm{SU}(3)_C\times\mathrm{SU}(3)_W^2\times\mathrm{SU}(3)_H^4$ *means that the couplings* $\alpha_1,\alpha_2,\alpha_3$ *are in the ratio* $\alpha_1/\alpha_2/\alpha_3=1/2/4$. *Using the phenomenological data given at the beginning, this implies that* $\sin^2\theta=0.231$.

On the other hand, the QCD coupling is $\alpha_3=0.0676$ which is too low unless the conformal scale is at least 10 TeV. We prefer a scale $\sim$1 TeV for conformal breaking where α_3 is nearer to 0.10. This motivates our Models B and C below which have larger α_3 but are otherwise more complicated.

Model B. Choose $\Gamma=Z_{10}$ and embed $Z_{10}\subset\mathrm{SU}(4)$ such that $4=(\alpha^4,\alpha^4,\alpha^{-3},\alpha^{-5})$. The chiral fermions are therefore

$$\sum_{j=1}^{10}[2(N_j,\overline{N}_{j+4})+(N_j,\overline{N}_{j-3})+(N_j,\overline{N}_{j-5})]. \tag{26}$$

To attain trinification we identify the quiver nodes as C-H-H-H-W-W-H-W-H-H and then the chiral fermions are in the ten quartets of irreducible representations.

$$\begin{aligned}&[4(3,\overline{3},1)]_1+[2(1,\overline{3},3)+(1,1,1+8)]_2+[2(1,1,1+8)+(1,\overline{3},3)]_3+[2(1,\overline{3},3)+(\overline{3},1,3)\\&\quad+(1,1,1+8)]_4+[4(1,3,\overline{3})]_5+[3(1,3,\overline{3})+(\overline{3},3,1)]_6+[2(\overline{3},1,3)+(1,1,1+8)]_7\\&\quad+[3(1,3,\overline{3})+(1,1+8,1)]_8+[3(1,1,1+8)+(1,\overline{3},3)]_9+[3(1,1,1+8)+(1,\overline{3},3)]_{10}.\end{aligned} \tag{27}$$

Removing the (real) octets and singlets leaves

$$4(3,\overline{3},1)+(\overline{3},3,1)+3(\overline{3},1,3)+10(1,3,\overline{3})+7(1,\overline{3},3), \tag{28}$$

so that the chiral (complex) part is again

$$3[(3,\overline{3},1)+(1,3,\overline{3})+(\overline{3},1,3)], \tag{29}$$

which are three chiral families.

The 6 of SU(4) transforms under $\Gamma=Z_{10}$ as $6=(\alpha^8,\alpha,\alpha,\alpha^{-1},\alpha^{-1},\alpha^{-8})$ and so the complex scalars are

$$\sum_{j=1}^{10} [(n_j, \overline{N}_{j\pm 8}) + 2(N_j, \overline{N}_{j\pm 1})]. \tag{30}$$

With the given quiver node identification VEVs for these scalars can break $SU(3)^{10} = SU(3)_C \times SU(3)_W^3 \times SU(3)_H^6$ to the diagonal subgroup $SU(3)_C \times SU(3)_W \times SU(3)_H$.

The couplings $\alpha_1, \alpha_2, \alpha_3$ are in the ratio $\alpha_1/\alpha_2/\alpha_3 = 1/2/6$ corresponding to $\sin^2\theta = 0.231$ and $\alpha_3 = 0.101$. This is within the range of a TeV conformal breaking scale. Nevertheless, it is numerically irresistible to notice that the Z-pole values satisfy $\alpha_1/\alpha_2/\alpha_3 = 1/2/7$ which leads naturally to Model C.

Model C. Choose $\Gamma = Z_{23}$ and embed in SU(4) by $4 = (\alpha^6, \alpha^6, \alpha^{-5}, \alpha^{-7})$. Given this embedding the quiver nodes can be chosen as C-C-X-X-X-H-H-W-H-X-X-X-X-X-X-W-H-H-W-X-X-X where the thirteen X's denote any distribution of four W's and nine H's that allows breaking by the complex scalars cited below. The quiver is arranged such that according to the rule of $(3_C - \overline{3}_W)$ minus $(3_W - \overline{3}_C)$ there are three chiral families. [The model in Ref. 13 did not follow this rule and has two families.] Note that because of anomaly cancellation and the occurrence of only bifundamentals the remainder of trinification is automatic and need not be checked in every case.

The chiral families are as in Models A and B.

The 6 of SU(4) transforms as $(\alpha^{12}, \alpha, \alpha, \alpha^{-1}, \alpha^{-1}, \alpha^{-12})$. This implies complex scalars whose VEVs can break $SU(3)^{23} = SU(3)_C^2 \times SU(3)_W^7 \times SU(3)_W^{14}$ to $SU(3)_C \times SU(3)_W \times SU(3)_H$ with a suitable distribution of W and H nodes on the quiver.

With this choice of diagonal subgroups the couplings are in the ratio $\alpha_1/\alpha_2/\alpha_3 = 1/2/7$ corresponding to $\sin^2\theta = 0.231$ and $\alpha_3 = 0.118$ which coincide with the Z-pole values.

In this section, we have given three examples of building conformal models from Abelian Γ with acceptable values of the couplings at the conformal scale, assuming that the SU(3) gauge couplings are all equal at the conformal scale. Model A is the simplest but its α_3 is too small unless the conformal scale is taken up to at least 10 TeV. Models B and C can accommodate a lower conformal scale but are more complicated.

There are two features of conformal models which bear repetition.

(1) Bifundamentals prohibit representations like (8,2) or (3,3) in the standard model consistent with nature.

(2) Charge quantization is incorporated since the Abelian $U(1)_Y$ group has a positive-definite β-function and cannot be conformal until it is embedded in a non-Abelian group.

There are three questions which merit further investigation.

(1) The first question bears on whether there is a fixed manifold (line, plane, ...) with respect to the renormalization group or only a fixed point which is, in any case, sufficient to apply our conformality constraints. In perturbation theory, do the β-functions vanish?

(2) Are the additional particles necessary to render the standard model conformal consistent with the stringent constraints imposed by the precision electroweak data?

(3) Coefficients of dimension-4 operators are prescribed by group theory and all dimensionless properties such as quark and lepton mass ratios and mixing angles are calculable. Do these work and, if not, can one refine the model-building to obtain a best fit?

V. DISCUSSION

String theory has existed for over thirty years and its connection with the real world (at least for ten-/eleven-dimensional versions) is unknown despite a multitude of attempts. The AdS/CFT correspondence offers, in our opinion, the most promising approach presently available to relate string theory to observable physics.

The use of the AdS/CFT correspondence involves the step of, in the first order, dropping the gravitational interaction. In any foreseeable high-energy experiment gravity will be negligible so the approximation is reasonable. On the other hand, if the particles predicted by the conformality

approach discussed in this article were to be discovered in the next (TeV) energy regime, it would provide support for the string approach, including as a theory of quantum gravity.

Whether or not string theory is the correct unifying theory with gravity, it does provide through the AdS/CFT correspondence very promising ideas of how to write conformal theories in four space-time dimensions with particular semi-simple gauge groups, chiral fermions and complex scalars and one of these theories could be the correct direction to proceed.

(Received 2 January 2001; accepted for publication 13 February 2001)

In this paper we study the spectrum of bosonic string theory on AdS_3. We study classical solutions of the SL(2,R) WZW model, including solutions for long strings with nonzero winding number. We show that the model has a symmetry relating string configurations with different winding numbers. We then study the Hilbert space of the WZW model, including all states related by the above symmetry. This leads to a precise description of long strings. We prove a no-ghost theorem for all the representations that are involved and discuss the scattering of the long string. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377273]

I. INTRODUCTION

In this paper we study the spectrum of critical bosonic string theory on $AdS_3 \times \mathcal{M}$ with NS–NS backgrounds, where $\mathcal{M}$ is a compact space. Understanding string theory on AdS_3 is interesting from the point of view of the AdS/CFT correspondence since it enables us to study the correspondence beyond the gravity approximation. Another motivation is to understand string theory on a curved space–time, where the timelike component g_{00} of the metric is nontrivial.

This involves understanding the SL(2,R) WZW model. In this paper, we always consider the case when the target space is the universal cover of the SL(2,R) group manifold so that the timelike direction is noncompact. The states of the WZW model form representations of the current algebras $\widehat{\mathrm{SL}}(2,R)_L \times \widehat{\mathrm{SL}}(2,R)_R$. Once we know which representations of these algebras appear, we can find the physical states of a string in AdS_3 by imposing the Virasoro constraints on the representation spaces. The problem is to find the set of representations that one should consider. In WZW models for compact groups, the unitarity restricts the possible representations.[1] Representations of $\widehat{\mathrm{SL}}(2,R)$, on the other hand, are not unitary except for the trivial representation. Of course this is not a surprise; the physical requirement is that states should have non-negative norms only after we impose the Virasoro constraints. Previous work on the subject[2–10] typically considered representations with L_0 bounded below and concluded that the physical spectrum does not contain negative norm states if there is the restriction $0<j<k/2$ on the SL(2,R) spin j of the representation; the spin of the SL(2,R) is roughly the mass of the string state in AdS_3.

This restriction raises two puzzles. One is that it seems to imply an upper bound on the mass of the string states in AdS_3 so that the internal energy of the string could not be too high. For example, if the compact space $\mathcal{M}$ has a nontrivial 1-cycle, we find that there is an upper bound on the winding number on the cycle. This restriction, which is independent of the string coupling, looks very arbitrary and raises doubts about the consistency of the theory. The second puzzle is that, on physical grounds, we expect that the theory contains states corresponding to the long strings of Refs. 11 and 12. These are finite energy states where we have a long string stretched

a)Electronic mail: malda@pauli.harvard.edu
b)On leave of absence from the University of California, Berkeley; electronic mail: ooguri@theory.caltech.edu

close to the boundary of AdS_3. These states are not found in any representation with L_0 bounded below. In this paper, we propose that the Hilbert space of the WZW model includes a new type of representations, and we show that this proposal resolves both the puzzles. In these new representations, L_0 is not bounded below. They are obtained by acting on the standard representations by elements of the loop group that are not continuously connected to the identity, through an operation called spectral flow. These representations in the SL(2,R) WZW model have also been considered, with some minor variations, in Refs. 13 and 14. The authors of these papers were motivated by finding a modular invariant partition function. They were, however, considering the case when the target space is SL(2,R) group manifold and not its universal cover.

Throughout this paper, we consider AdS_3 in global coordinates, which do not have a coordinate horizon. In these coordinates, the unitarity issue becomes clearer since strings cannot fall behind any horizon. The interested reader could refer to Refs. 15–17 for studies involving AdS_3 in Poincaré coordinates. From the point of view of the AdS/CFT correspondence, it is the spectrum of strings on AdS_3 in the global coordinates that determines the spectrum of conformal dimensions of operators in the boundary CFT, though in principle the same information could be extracted from the theory in Poincare coordinates.

In order to completely settle the question of consistency of the SL(2,R) WZW model, one needs to show that the OPE of two elements of the set of representations that we consider contains only elements of this set. We plan to discuss this issue in our future publication.

The organization of this paper is as follows: In Sec. II, we study classical solutions of the SL(2,R) WZW model and we show that the model has a spectral flow symmetry which relates various solutions. In Sec. III, we do a semiclassical analysis and have the first glimpse of what happens when we raise the internal excitation of the string beyond the upper bound implied by the restriction $j<k/2$. In Sec. IV, we study the full quantum problem and we propose a set of representations that gives a spectrum for the model with the correct semiclassical limits. In Sec. V, we briefly discuss scattering amplitudes involving the long strings. We conclude the paper with a summary of our results in Sec. VI. In Appendix A, we extend the proof of the no-ghost theorem for the representations we introduced in Sec. IV. In Appendix B, we study the one-loop partition function in AdS_3 with the Lorentzian signature metric and show how the sum over spectral flow reproduces the result[18] after taking an Euclidean signature metric, up to contact terms in the modular parameters of the worldsheet.

II. CLASSICAL SOLUTIONS

We start by choosing a parameterization of the SL(2,R) group element as

$$\begin{aligned} g &= e^{iu\sigma_2} e^{\rho\sigma_3} e^{iv\sigma_2} \\ &= \begin{pmatrix} \cos t \cosh\rho + \cos\phi \sinh\rho & \sin t \cosh\rho - \sin\phi \sinh\rho \\ -\sin t \cosh\rho - \sin\phi \sinh\rho & \cos t \cosh\rho - \cos\phi \sinh\rho \end{pmatrix}. \end{aligned} \tag{1}$$

Here $\sigma^i (i=1,2,3)$ are the Pauli matrices $[\sigma_1=\left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$, $\sigma_2=\left(\begin{smallmatrix}0&-i\\i&0\end{smallmatrix}\right)$, and $\sigma_3=\left(\begin{smallmatrix}1&0\\0&-1\end{smallmatrix}\right)]$, and we set

$$u=\tfrac{1}{2}(t+\phi), \quad v=\tfrac{1}{2}(t-\phi). \tag{2}$$

Another useful parameterization of g is

$$g=\begin{pmatrix} X_{-1}+X_1 & X_0-X_2 \\ -X_0-X_2 & X_{-1}-X_1 \end{pmatrix}, \tag{3}$$

with

$$X_{-1}^2+X_0^2-X_1^2-X_2^2=1. \tag{4}$$

This parameterization shows that the SL(2,R) group manifold is a three-dimensional hyperboloid. The metric on AdS_3,

$$ds^2 = -dX_{-1}^2 - dX_0^2 + dX_1^2 + dX_2^2,$$

is expressed in the global coordinates (t, ϕ, ρ) as

$$ds^2 = -\cosh^2\rho dt^2 + d\rho^2 + \sinh^2\rho d\phi^2. \tag{5}$$

We will always work on the universal cover of the hyperboloid (4), and t is noncompact.

Our theory has the WZW action,

$$S = \frac{k}{8\pi\alpha'}\int d^2\sigma\,\mathrm{Tr}(g^{-1}\partial g g^{-1}\partial g) + k\Gamma_{\mathrm{WZ}}. \tag{6}$$

The level k is not quantized since H^3 vanishes for SL(2,R). The semiclassical limit corresponds to large k. We define the right and left moving coordinates on the worldsheet as,

$$x^{\pm} = \tau \pm \sigma, \tag{7}$$

where σ is periodic with the period 2π. This action has a set of conserved right and left moving currents

$$J_R^a(x^+) = k\,\mathrm{Tr}(T^a\partial_+ g g^{-1}),\quad J_L^a(x^-) = k\,\mathrm{Tr}(T^a * g^{-1}\partial_- g), \tag{8}$$

where T^a are a basis for the SL(2,R) Lie algebra. It is convenient to take them as

$$T^3 = -\frac{i}{2}\sigma^2,\quad T^{\pm} = \frac{1}{2}(\sigma^3 \pm i\sigma_1).$$

In terms of our parameterization, the currents are expressed as

$$\begin{aligned} J_R^3 &= k(\partial_+ u + \cosh 2\rho\,\partial_+ v),\\ J_R^{\pm} &= k(\partial_+\rho \pm i\sinh 2\rho\,\partial_+ v)e^{\mp i2u}, \end{aligned} \tag{9}$$

and

$$\begin{aligned} J_L^3 &= k(\partial_- v + \cosh 2\rho\,\partial_- u)\\ J_L^{\pm} &= k(\partial_-\rho \pm i\sinh 2\rho\,\partial_- u)e^{\mp i2v}. \end{aligned} \tag{10}$$

The zero modes of $J_{R,L}^3$ are related to the energy E and angular momentum l in AdS_3 as

$$\begin{aligned} J_0^3 &= \int_0^{2\pi}\frac{dx^+}{2\pi}J_R^3 = \frac{1}{2}(E+l),\\ \overline{J}_0^3 &= \int_0^{2\pi}\frac{dx^-}{2\pi}J_L^3 = \frac{1}{2}(E-l). \end{aligned} \tag{11}$$

The second Casimir of SL(2,R) is

$$c_2 = J^a J^a = \tfrac{1}{2}(J^+J^- + J^-J^+) - (J^3)^2. \tag{12}$$

The equations of motion derived from (6) is $\partial_-(\partial_+ g g^{-1})=0$, namely, that the currents, J_R and J_L, are purely right or left moving as indicated. A general solution of the equations of motion for SL(2,R) is the product of two group elements each of which depends only on x^+ or x^- as

$$g=g_+(x^+)g_-(x^-). \tag{13}$$

Comparing (13) with (1) we can find the embedding of the worldsheet in AdS_3. The requirement that the string is closed under $\sigma\to\sigma+2\pi$ imposes the constraint,

$$g_+(x^++2\pi)=g_+(x^+)M,\ \ g_-(x^--2\pi)=M^{-1}g_-(x^-), \tag{14}$$

with the same $M\in \mathrm{SL}(2,R)$ for both g_+ and g_-. The monodromy matrix M is only defined up to a conjugation by SL(2,R), and classical solutions of the WZW model are classified according to the conjugacy class of M.

For strings on $AdS_3\times\mathcal{M}$, we should impose the Virasoro constraints,

$$T^{\mathrm{total}}_{++}=T^{AdS}_{++}+T^{\mathrm{other}}_{++}=0, \tag{15}$$

and similarly $T^{\mathrm{total}}_{--}=0$, where

$$T^{Ads}_{++}=\frac{1}{k}J^a_R J^a_R$$

is the energy-momentum tensor for the AdS_3 part (In the quantum theory, we will have the same expression but with $k\to k-2$.) and T^{other}_{++} represents the energy-momentum tensor for the sigma-model on $\mathcal{M}$.

Let us analyze some simple classical solutions.

A. Geodesics in AdS_3

Consider a solution

$$g_+=Ue^{iv_+(x^+)\sigma_2},\ \ g_-=e^{iu_-(x^-)\sigma_2}V, \tag{16}$$

where U and V are constant elements of SL(2,R). The energy momentum tensor of this solution is

$$T^{AdS}_{++}=-k(\partial_+ v_+)^2,\ \ T^{AdS}_{--}=-k(\partial_- u_-)^2. \tag{17}$$

Suppose we have some string excitation in the compact part $\mathcal{M}$ of $AdS_3\times\mathcal{M}$, and set $T^{\mathrm{other}}_{\pm\pm}=h$ for some constant $h>0$. We may regard h as a conformal weight of the sigma-model on $\mathcal{M}$. The Virasoro constraints $T^{\mathrm{total}}_{\pm\pm}=0$ implies

$$(\partial_+ v_+)^2=(\partial_- u_-)^2=\frac{h}{k}.$$

Thus we can set $v_+=\alpha x^+/2$ and $u_-=\alpha x^-/2$ where $\alpha=\pm\sqrt{4h/k}$. Substituting this in (13), we obtain

$$g=U\begin{pmatrix}\cos(\alpha\tau) & \sin(\alpha\tau)\\ -\sin(\alpha\tau) & \cos(\alpha\tau)\end{pmatrix}V. \tag{18}$$

Since the solution depends only on τ and not on σ, we interpret that the string is collapsed to a point which flows along the trajectory in AdS_3 parameterized by τ (see Fig. 1). If $U=V=1$, the solution (18) represents a particle sitting at the center of AdS_3,

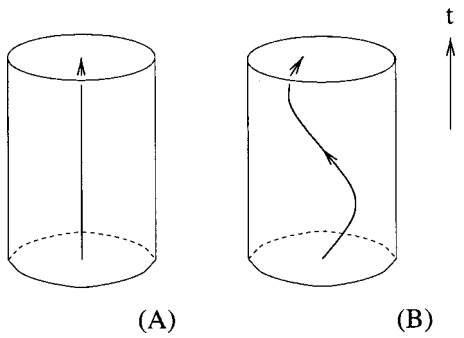

FIG. 1. Timelike geodesic; (A) a solution (18) with $U=V=1$, (B) a general geodesic is obtained by acting the SL(2,R) $\times$SL(2,R) isometry in (A).

$$t=\alpha\tau, \quad \rho=0. \tag{19}$$

A more general solution (18) is given by acting the SL(2,R)$\times$SL(2,R) isometry on (19), and therefore it is a timelike geodesic [In fact, any timelike geodesic can be expressed in the form (18)] in AdS_3. For this solution, the currents are given by

$$J_R^a T^a=\frac{k}{2}\alpha U T^3 U^{-1}, \tag{20}$$

and similarly for J_L. The monodromy matrix M defined by (14) is

$$M=\begin{pmatrix} \cos(\alpha\pi) & \sin(\alpha\pi) \\ -\sin(\alpha\pi) & \cos(\alpha\pi) \end{pmatrix}$$

and belongs to the elliptic conjugacy class SL(2,R).

A solution corresponding to a spacelike geodesic is

$$g=U\begin{pmatrix} e^{\alpha\tau} & 0 \\ 0 & e^{-\alpha\tau} \end{pmatrix}V, \tag{21}$$

with U, $V\in$ SL(2,R). The energy-momentum tensor has a sign opposite of (17)

$$T_{\pm\pm}^{AdS}=\tfrac{1}{4}k\alpha^2. \tag{22}$$

If we choose $U=V=1$, the solution is simply a straight line cutting the spacelike section $t=0$ of AdS_3 diagonally,

$$t=0, \quad \rho e^{i\phi}=\alpha\tau \tag{23}$$

[see Fig. 2(A)]. A general solution (21) is given from this by the action of the isometry, and therefore is a spacelike geodesic. The currents for this solution are

$$J_R^a T^a=\frac{k}{2}\alpha U T^1 U^{-1}, \tag{24}$$

and the monodromy matrix is

$$M=\begin{pmatrix} e^{\alpha\pi} & 0 \\ 0 & e^{-\alpha\pi} \end{pmatrix},$$

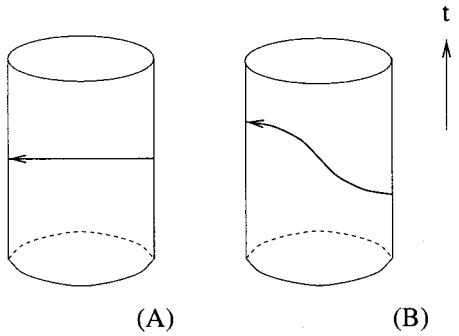

FIG. 2. Spacelike geodesic; (A) a solution (21) with $U=V=1$, (B) a general geodesic is obtained by acting the $SL(2,R)\times SL(2,R)$ isometry in (A).

which belongs to the hyperbolic conjugacy class of $SL(2,R)$.

There is one more class of solutions whose monodromy matrices are in the parabolic conjugacy class of $SL(2,R)$. They correspond to null geodesics in AdS_3.

B. Spectral flow and strings with winding numbers

Given one classical solution $g=\tilde{g}+\tilde{g}_-$, we can generate new solutions by the following operation:

$$g_+=e^{i(1/2)w_R x^+\sigma_2}\tilde{g}_+ \quad g_-=\tilde{g}_- e^{i(1/2)w_L x^-\sigma_2}. \tag{25}$$

Comparing this with the parameterization (1) of $g=g_+g_-$, we see that this operation amounts to

$$\begin{aligned} &t\to t+\tfrac{1}{2}(w_R+w_L)\tau+\tfrac{1}{2}(w_R-w_L)\sigma,\\ &\phi\to\phi+\tfrac{1}{2}(w_R+w_L)\sigma+\tfrac{1}{2}(w_R-w_L)\tau. \end{aligned} \tag{26}$$

The periodicity of the string worldsheet, under $\sigma\to\sigma+2\pi$, on the universal cover of $SL(2,R)$ requires [If the target space is the single cover of $SL(2,R)$, w_R and w_L can be different. In this case (w_R-w_L) gives the winding number along the closed timelike curve on $SL(2,R)$.] $w_R=w_L=w$ for some integer w.

One may regard (25) as an action by an element of the loop group $\widehat{SL}(2,R)\times\widehat{SL}(2,R)$ which is not continuously connected to the identity. [The loop group $\widehat{SL}(2,R)$ has such an element since $\pi_1(SL(2,R))=\mathbb{Z}$. Therefore, in the model whose the target space is the single cover of $SL(2,R)$, the full symmetry group of the model is the loop group of $SL(2,R)\times SL(2,R)$ and its connected components are parametrized by $\mathbb{Z}\times\mathbb{Z}$. In this paper, we are studying the model for the universal cover of $SL(2,R)$. In this case, some of these elements do not act properly on the field space, generating worldsheets which close only modulo time translation. However the ones parametrized by the diagonal $\mathbb{Z}$ are still symmetry of the model. The diagonal $\mathbb{Z}$ parameterizes the spectral flow operation performed simultaneously for both the left and right movers.] This particular symmetry of the theory will also be useful in our analysis of the Hilbert space. Here we see that it generates a new solution from an old solution. Furthermore, the currents (9) change in the following way:

$$J_R^3=\tilde{J}_R^3+\frac{k}{2}w, \quad J_R^\pm=\tilde{J}_R^\pm e^{\mp iwx^+} \tag{27}$$

and a similar expression for J_L^a. Or, in terms of the Fourier modes,

$$J_n^3=\tilde{J}_n^3+\frac{k}{2}w\,\delta_{n,0},\quad J_n^{\pm}=\tilde{J}_{n\mp w}^{\pm}. \tag{28}$$

This means that the stress tensor will change to

$$T_{++}^{AdS}=\tilde{T}_{++}^{AdS}-w\tilde{J}^3-\frac{k}{4}w^2. \tag{29}$$

In the CFT literature, this operation is known as the spectral flow.

Let us study what happens if we act with this symmetry on the solutions corresponding to geodesics, (18) and (21). These solutions depend only on the worldsheet time coordinate τ, and the spectral flow (26) with $w=w_R=w_L$ introduces σ dependence as

$$\begin{aligned} t&=t_0(\tau)+w\tau,\\ \rho&=\rho_0(\tau),\\ \phi&=\phi_0(\tau)+w\sigma. \end{aligned} \tag{30}$$

Here (t_0,ρ_0,ϕ_0) represents the original geodesic solution. So what the spectral flow does is to stretch the geodesic solution in the t-direction (by adding $w\tau$) and rotates it around w-times around the center $\rho=0$ of AdS_3 (by adding $w\sigma$). It is clear that the resulting solution describes a circular string, winding w-times around the center of AdS_3. Since the spectral flow changes the energy-momentum tensor, we need to impose the physical state condition $T_{\pm\pm}^{AdS}+T_{\pm\pm}^{\text{other}}=0$ with respect to the new energy-momentum tensor (29).

C. Short strings as the spectral flow of timelike geodesics

A timelike geodesic in AdS_3 makes a periodic trajectory as shown in Fig. 1, approaching the boundary of AdS_3, then coming back to the center and so on. In particular, when $V=U^{-1}$ in (18), the geodesic periodically passes through the center $\rho=0$ of AdS_3, with the period 2π in the t-coordinate. The spectral flow,

$$t\to t+w\tau,\quad \phi\to\phi+w\sigma,$$

stretches the geodesic in the time direction and rotate it around the center $\rho=0$; it is pictorially clear that the resulting solution describes a circular string which repeats expansion and contraction. This is shown in Fig. 3 in the case of $w=1$. Assuming $T_{\pm\pm}^{\text{other}}=h$ as in the case of geodesics, the Virasoro constraint for the solution is

$$T_{++}^{\text{total}}=\tilde{T}_{++}^{AdS}-w\tilde{J}^3-\frac{k}{4}w^2+T_{++}^{\text{other}}=0. \tag{31}$$

Since

$$\tilde{T}_{++}^{AdS}=-\frac{k}{4}\alpha^2$$

for the timelike geodesic, we find

$$J_0^3=\tilde{J}_0^3+\frac{k}{2}w=\frac{k}{4}w+\frac{1}{w}\left(-\frac{k}{4}\alpha^2+h\right). \tag{32}$$

The space–time energy E of the string is given by $E=2J_0^3$, and is bounded above as

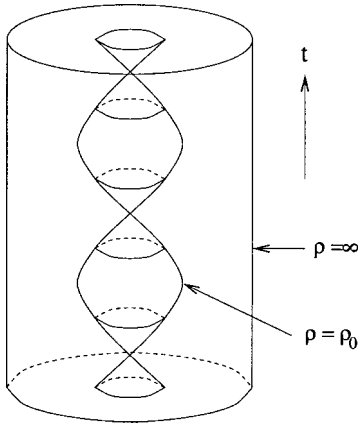

FIG. 3. A classical solution obtained by the spectral flow of a timelike geodesic. The solution repeats expansion and contraction. The maximum size of the string is $\rho=\rho_0$.

$$E=\frac{k}{2}w+\frac{1}{w}(-k\alpha^2+2h)<\frac{k}{2}w+\frac{2h}{w}. \tag{33}$$

It is not difficult to find an explicit form of the solution. When $V=U^{-1}$ in (18), without loss of generality, we can set (A different choice of $U=V^{-1}$ simply results in the shift of ϕ in the solution.) $U=V^{-1}=e^{(1/2)\rho_0\sigma_3}$. The solution (We have been informed that a similar classical solution has also been studied in Refs. 19 and 20.) obtained by the spectral flow of (18) is then

$$\begin{aligned} e^{i\phi}\sinh\rho &= ie^{iw\sigma}\sinh\rho_0\sin\alpha\tau, \\ \tan t &= \frac{\tan w\tau+\tan\alpha\tau/\cosh\rho_0}{1-\tan w\tau\tan\alpha\tau/\cosh\rho_0}. \end{aligned} \tag{34}$$

The currents of this solution are

$$\begin{aligned} J_R^3 &= \frac{k}{2}(\alpha\cosh\rho_0+w), \\ J_R^{\pm} &= \pm i\frac{k}{2}\alpha\sinh\rho_0 e^{\mp iwx^+}, \end{aligned} \tag{35}$$

and similarly for J_L. Comparing this with (32), we find

$$\alpha=\alpha_{\pm}=-w\cosh\rho_0\pm\sqrt{w^2\sinh^2\rho_0+\frac{4h}{k}}. \tag{36}$$

If we choose the branch $\alpha=\alpha_+$, the space–time energy E of the solution is positive and is given by

$$E=2J_0^3=2\bar{J}_0^3=k\left(\cosh\rho_0\sqrt{\frac{4h}{k}+w^2\sin^2\rho_0}-w\sinh^2\rho_0\right). \tag{37}$$

There are several interesting features of this formula for the energy E. Except for the case of $h=kw^2/4$, the energy is a monotonically increasing function of ρ_0, which approaches $E\to kw/2+2h/\omega$ as $\rho_0\to\infty$. One may view that the solution describe a bound state trapped inside of AdS_3.

At the exceptional value of $h=kw^2/4$, we have $\alpha_+=0$ and the energy of the solution becomes $E=kw$, completely independent of the size ρ_0 of the string. The solution in this case is

$$\rho=\rho_0, \quad t=w\tau, \quad \phi=w\sigma, \tag{38}$$

and represents a string staying at the fixed radius $\rho=\rho_0$, neither contracting nor expanding. The fact that we have such a solution at any radius ρ_0 means that the string becomes marginally unstable in AdS_3.

Now let us turn to the case when $U\neq V^{-1}$, or to be more precise, when UV does not commute with $T^3=-(i/2)\sigma^2$. (When UV commutes with T^3, one can shift the value of τ to set $U=V^{-1}$.) In this case, the geodesic does not necessarily pass through the center of AdS_3. Therefore the circular string obtained by its spectral flow does not collapse to a point. Since

$$\tilde{J}^a{}_L T^{*a}=\frac{k}{2}\alpha U T^3 U^{-1}, \quad \tilde{J}^\alpha{}_R T^a=\frac{k}{2}\alpha V^{-1} T^3 V, \tag{39}$$

$\tilde{J}^3_L\neq\tilde{J}^3_R$ unless UV commutes with $T^3=-(i/2)\sigma^2$, and the space–time angular momentum $l=J^3_R-J^3_L=\tilde{J}^3_R-\tilde{J}^3_L$ is nonzero. Thus one may view that the circular string is kept from completely collapsing by the centrifugal force. Since $T^{AdS}_{++}-T^{AdS}_{--}=-w(\tilde{J}^3_R-\tilde{J}^3_L)$, the Virasoro constraint $T^{\text{total}}_{\pm\pm}=0$ requires that the left and right conformal weights (h_L,h_R) of the internal part should be different and that $h_R-h_L=wl$.

D. Long strings as the spectral flow of spacelike geodesics

We have seen in (33) that the space–time energy E of the solution given by the spectral flow of the timelike geodesic is bounded above as $E<kw/2+2h/w$. What will happen if we raise the energy above this value? To understand this, let us look at the spectral flow of the spacelike geodesic. Since $\tilde{T}^{AdS}_{++}=+k\alpha^2/2$ for the spacelike geodesic, the Virasoro constraint (31) gives

$$J^3_0=\tilde{J}^3_0+\frac{k}{2}w=\frac{k}{4}w+\frac{1}{w}\left(\frac{k}{2}\sigma^2+h\right), \tag{40}$$

and the space–time energy is now bounded below,

$$E=2J^3_0>\frac{k}{2}w+\frac{2h}{w}. \tag{41}$$

As an example, let us consider the straight line cutting the spacelike section $t=0$ diagonally (23). The spectral flow with w of this solution is

$$t=w\tau, \quad \rho e^{i\phi}=\alpha\tau e^{iw\sigma}, \tag{42}$$

namely

$$\rho=\frac{\alpha}{w}|t|. \tag{43}$$

The solution starts in the infinite past $t=-\infty$ as a circular string of an infinite radius located at the boundary of AdS_3. The string then collapse, shrinks to a point at $t=0$, and expand away toward the boundary of AdS_3 as $t\to+\infty$. More generally, if we choose $U=V^{-1}=e^{(-1/2)\rho_0\sigma_1}$, the spectral flow of the geodesic (21) gives

$$e^{i\phi}\sinh\rho=e^{iw\sigma}\cosh\rho_0\sinh\alpha\tau, \tag{44}$$

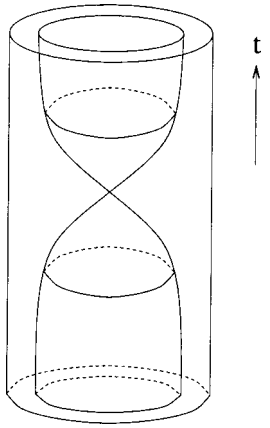

FIG. 4. A long string solution obtained by the spectral flow of a spacelike geodesic. The long string comes from the boundary of AdS_3, collapses to a point, and then expands away to the boundary of AdS_3 again.

$$\tan t = \frac{\tan w\tau + \tanh \alpha\tau \sinh \rho_0}{1 - \tan w\tau \tanh \alpha\tau \sinh \rho_0}.$$

This solution, which we call a long string, is depicted in Fig. 4.

The Virasoro constraint $T^{\text{total}}_{++}=0$ for the long string (44) is

$$T^{AdS}_{++} + T^{\text{other}}_{++} = \frac{k}{4}(\alpha^2 - 2\alpha w \sinh \rho_0 - w^2) + h = 0, \tag{45}$$

with the solutions

$$\alpha = \alpha_{\pm} = w \sinh \rho_0 \mp \sqrt{w^2 \cosh^2 \rho_0 - \frac{4h}{k}}. \tag{46}$$

The space–time energy E of these solutions are

$$E = 2J^2_0 = 2\bar{J}^3_0 = k\left(w \cosh^2 \rho_0 \mp \sinh \rho_0 \sqrt{w^2 \cosh^2 \rho_0 - \frac{4h}{k}} \right). \tag{47}$$

At the critical value $h = kw^2/4$, we have $\alpha_+ = 0$ and the energy for this solution becomes $E = kw$. At this point, the long string solution (44) coincides with (38). Thus we see that, as we increase the value of h to $h = kw^2/4$, the short string solution (34) can turn into the long string solution (44) and escape to infinity.

As explained in Refs. 11 and 12, a string that winds in AdS_3 close to the boundary has finite energy because there is a balance between two large forces. One is the string tension that wants to make the string contract and the other is the NS–NS B field which wants to make the string expand. These forces cancel almost precisely near the boundary and only a finite energy piece is left. The threshold energy for the long string computed in Refs. 11 and 12 is $kw/4$, in agreement with (41) when $h=0$. These strings can have some momentum in the radial direction and that is a degree of freedom α that we saw explicitly above. One may view the long string as a scattering state, while the previous solution (34) is like a bound state trapped inside of AdS_3.

In general, if UV commutes with $T^3 = -(i/2)\sigma^2$, the long string collapses to a point once in its lifetime. If UV does not commute with T^3, the angular momentum $l = J^3_R - J^3_L$ of the solution does not vanish and the centrifugal force keeps the string from collapsing completely. In this case, the Virasoro constraint $T^{\text{total}}_{\pm\pm}=0$ requires $h_R - h_L = wl$ for the conformal weights of the internal sector.

For the long strings, one can define a notion of the S-matrix. In the infinite past, the size of the long string is infinite but its energy is finite. Therefore the interactions between them are expected to be negligible, and one can define asymptotic states consisting of long strings. The strings then approach the center of AdS_3 and are scattered back to the boundary. In this process, the winding number could in principle change.

III. SEMICLASSICAL ANALYSIS

In studying the classical solutions, we were naively identifying the winding number w as associated to the cycle $\phi \to \phi + 2\pi$. But since this cycle is contractible in AdS_3, we should be careful about what we mean by the integer w. The winding number is well-defined when the string is close to the boundary, so we expect that long strings close to the boundary have definite winding numbers. On the other hand, when the string collapses to a point, as shown in Figs. 3 and 4, the winding number is not well-defined. Therefore, if we quantize the string, it is possible to have a process in which the winding number changes. There is however a sense in which string states are characterized by some integer w.

In order to clarify the meaning of w when the string can collapse, let us look at the Nambu action,

$$S = \int dt \frac{d\sigma}{2\pi} [\sqrt{\det g_{\rm ind}} - B_{t\phi}\partial_\sigma \phi], \tag{48}$$

where $g_{\rm ind}$ is the induced metric on the worldsheet, and $B_{t\phi}$ is the NS–NS B-field. We have chosen the static gauge in the time direction $t = \tau$. We assume that initially we have a state with $\rho = 0$, and we want to analyze small perturbations. Since the coordinate ϕ is not well-defined, it is more convenient to use

$$X^1 + iX^2 = \rho e^{i\phi}. \tag{49}$$

Let us compute the components of the induced metric $g_{\rm ind}$. To be specific, we consider the case when the target space $AdS_3 \times S^3 \times T^4$, and consider a string winding around a cycle on T^4. By expanding in the quadratic order in ρ, we find

$$\begin{aligned} g_{\rm ind,00} &= k[-(1+\rho^2) + \partial_0 X^a \partial_0 X^a] + \partial_0 Y^i \partial_0 Y^i, \\ g_{\rm ind,01} &= k\partial_0 X^a \partial_1 X^a + \partial_0 Y^i \partial_1 Y^i, \\ g_{\rm ind,11} &= k\partial_{11} X^a \partial_1 X^a + \partial_1 Y^i \partial_1 Y^i, \quad (a = 1,2), \end{aligned} \tag{50}$$

where Y^i's are coordinates on T^4. For simplicity, we consider purely winding modes on T^4, so that only $\partial_1 Y^i$ is nonzero. For these states, the conformal weight h is given by (One factor of 2 comes from the fact that this includes left and right movers and the other from the fact that the expression for the energy involves $1/2Y'^2$.)

$$4h \oint \frac{d\sigma}{2\pi} G_{ij} \partial_1 Y^i \partial_1 Y^j. \tag{51}$$

Substituting (50) and (51) into the action and expanding to the quadratic order in ρ, we find

$$\begin{aligned} S &= \sqrt{4kh} \int d\sigma^2 \left[1 - \frac{1}{2}(\partial_0 X^a)^2 + \frac{1}{2}\frac{k}{4h}\left(\partial_1 X^a + \epsilon_{ab}\sqrt{\frac{4h}{k}} X^b \right)^2 + \cdots \right] \\ &= \sqrt{4kh} \int d\sigma^2 \left[1 - \frac{1}{2}|\partial_0 \Phi|^2 + \frac{1}{2}\frac{k}{4h}\left| \left(\partial_1 - i\sqrt{\frac{4h}{k}} \right)\Phi \right|^2 + \cdots \right], \end{aligned} \tag{52}$$

where $\Phi = X^1 + iX^2$.

The action (52) is the one for a massless charged scalar field on $\mathbb{R}\times S^1$ coupled to a constant gauge field $A=\sqrt{4h/k}$ around S^1. As we vary A, we observe the well-know phenomenon of the spectral asymmetry. Let us first assume that A is not an integer. A general solution to the equation of motion derived from (52), requiring the periodicity in σ, is

$$\Phi \sim \sum_{n=-\infty}^{\infty} (a_n^\dagger e^{i(n-A)(\tilde{\tau}+\sigma)} + b_n e^{-i(n-A)(\tilde{\tau}-\sigma)}) \frac{e^{iA\sigma}}{n-A}, \tag{53}$$

where $A=\sqrt{4h/k}$ and $\tilde{\tau}=\tau/A$. Upon quantization, the commutation relations are given (modulo a positive constant factor) by

$$[a_n, a_m^\dagger] = (n-A)\delta_{n,m}, \quad [b_n, b_m^\dagger] = (n-A)\delta_{n,m}. \tag{54}$$

Notice that the sign in the right-hand side of (54) determines whether a_n or $a_n^\dagger$ should be regarded as the annihilation operator. Thus, assuming that the Hilbert space is positive definite, the vacuum state is defined by

$$\begin{aligned} a_n|0\rangle = b_n|0\rangle = 0, \quad (n>A), \\ a_n^\dagger|0\rangle = b_n^\dagger|0\rangle = 0, \quad (n<A). \end{aligned} \tag{55}$$

For $\Phi=\rho e^{i\phi}$ given by (53) and $t=A\tilde{\tau}$, we find

$$\begin{aligned} J_R^+ &= k(e^{-it}\partial_+\Phi^* - \Phi^*\partial_+ e^{-it}) \sim -ik\sum_n a_n e^{-in(\tilde{\tau}+\sigma)}, \\ J_R^- &= k(e^{it}\partial_+\Phi - \Phi\partial_+ e^{it}) \sim ik\sum_n a_n^\dagger e^{in(\tilde{\tau}+\sigma)}, \end{aligned} \tag{56}$$

and similarly for $J_L^\pm$. Therefore $J_n^+ = -ika_n$ and $J_n^- = ika_{-n}^\dagger$. The vacuum state $|0\rangle$ defined by (55) then obeys

$$J_n^+|0\rangle = 0 \quad (n>A), \quad J_n^-|0\rangle = 0 \quad (n>-A). \tag{57}$$

Thus the vacuum state $|0\rangle$ is not in a regular highest weight representation of the current algebra $\widehat{\mathrm{SL}}(2,R)$. If we set

$$J_n^\pm = \tilde{J}_{n\mp w}^\pm \tag{58}$$

with the integer w defined by

$$w<A<w+1, \tag{59}$$

then $|0\rangle$ obeys the regular highest weight condition with respect to $\tilde{J}_n^\pm$,

$$\tilde{J}_n^+|0\rangle = 0 \quad (n\geqslant 1), \quad \tilde{J}_n^-|0\rangle = 0 \quad (n\geqslant 0). \tag{60}$$

The change of the basis (58) is nothing but the spectral flow (28) discussed earlier, so we can identify w as the amount of spectral flow needed to transform the string state into a string state which obeys the regular conditions (60). We have found that, for a given value of h, there is a unique integer of w associated to the string state. As we vary the conformal weight h, $A=\sqrt{4h/k}$ will become an integer. At that point, one of the modes of the field Φ will have a vanishing potential. In fact we can check that classically this potential is completely flat. Giving an

expectation value to that mode, we find configurations as in (38). Corresponding to various values of its momentum in the radial direction, we have a continuum of states. So, at this value of h, we do not have a normalizable ground state; instead we have a continuum of states which are δ-function normalizable. If we continue to increase h, we find again normalizable states, but they are labeled by a new integer $(w+1)$. Notice that w is not directly related to the physical winding of the string. In fact by exciting a coherent state of the oscillators a_n or b_n we can find string states that look like expanding and collapsing strings with winding number n around the origin.

One of the puzzles we raised in the Introduction was what happens when we increase the internal conformal weight h of the string beyond the upper bound implied by the restriction $j < k/2$ on the SL(2,R) spin j due to the no-ghost theorem. In this section, we saw a semiclassical version of the puzzle and its resolution. When h reaches the bound, we find that the state can become a long string with no cost in energy. Above the bound, we should consider a Fock space with a different bose sea level. In the fully quantum description of the model given below, we will find a similar situation but with minor corrections.

IV. QUANTUM STRING IN AdS_3

The Hilbert space of the WZW model is a sum of products of representations of the left and the right-moving current algebras generated by

$$J_L^a = \sum_{n=-\infty}^{\infty} J_n^a e^{-inx^-}, \quad J_R^a = \sum_{n=-\infty}^{\infty} \overline{J}_n^a e^{-inx^+}, \tag{61}$$

with $a=3, \pm$, obeying the commutation relations

$$\begin{aligned} [J_n^3, J_m^3] &= -\frac{k}{2} n \delta_{n+m,0}, \\ [J_n^3, J_m^\pm] &= \pm J_{n+m}^\pm, \\ [J_n^+, J_m^-] &= -2J_{n+m}^3 + kn\delta_{n+m,0}, \end{aligned} \tag{62}$$

and the same for $\overline{J}_n^a$. We denote the current algebra by $\widehat{\mathrm{SL}}_k(2,R)$. The Virasoro generator L_n are defined by

$$\begin{aligned} L_0 &= \frac{1}{k-2}\left[\frac{1}{2}(J_0^+ J_0^- + J_0^- J_0^+) - (J_0^3)^2 + \sum_{m=1}^{\infty} (J_{-m}^+ J_m^- + J_{-m}^- J_m^+ - 2J_{-m}^3 J_m^3)\right], \\ L_{n\neq 0} &= \frac{1}{k-2}\sum_{m=1}^{\infty} (J_{n-m}^+ J_m^- + J_{n-m}^- J_m^+ - 2J_{n-m}^3 J_m^3), \end{aligned} \tag{63}$$

and obey the commutation relation,

$$[L_n, L_m] = (n-m)L_{n+m} + \frac{c}{12}(n^3 - n)\delta_{n+m,0}, \tag{64}$$

where the central charge c is given by

$$c = \frac{3k}{k-2}. \tag{65}$$

We will find that the Hilbert space of the WZW model consists of subsectors parameterized by integer w, labeling the amount of spectral flow in a sense to be made precise below. We then

formulate our proposal on how the complete Hilbert space of the WZW model is decomposed into representations of the current algebras and provide evidences for the proposal.

States in a representation of the current algebra are labeled by eigenvalues of L_0 and J_0^3. Since the kinetic term of the WZW model based on SL(2,R) has an indefinite signature, it is possible that the Hilbert space of the model contains states with negative eigenvalues of L_0 as well as states with negative norms, and indeed both types of states appear as we will see below. For the moment, we will consider a representation in which eigenvalues of L_0 is bounded below. We call them *positive energy representations*, or *unflowed* representations. Since the action of $J_n^{3,\pm}$ with $n \geqslant 1$ on a state lowers the eigenvalue of L_0 by n, there has to be a set of states which are annihilated by them. We will call such states the primary states of the positive energy representation. All other states in the representation are obtained by acting $J_{-n}^{3,\pm}(n \geqslant 1)$ on the primary states. The ground states make a representation of SL(2,R) generated by $J_0^{3,\pm}$. So let us review irreducible representations of SL(2,R).

A. Representations of the zero modes

We expect that physical states of a string in AdS_3 have positive norms. Since $J_0^{3,\pm}$ commute with the Virasoro constraints, physical spectrum of the string must be in unitary representations of SL(2,R). Most of the mathematical references on representation theory of SL(2,R) deal with the case with compact time; [For a review of representations of SL(2,R), see, for example, Ref. 21.] we are however interested in the case with noncompact time. A clear analysis from the algebraic point of view is presented in Ref. 22, which we now summarize with some minor changes is notation.

There are the following five types of unitary representations. All the representations are parameterized by j, which is related to the second Casimir $c_2 = \frac{1}{2}(J_0^+ J_0^- + J_0^- J_0^+) - (J_0^3)^2$ as $c_2 = -j(j-1)$.

(1) Principal discrete representations (lowest weight):

A representation of this type is realized in the Hilbert space

$$\mathcal{D}_j^+ = \{|j;m\rangle : m = j,\ j+1,\ j+2, ...\},$$

where $|j;j\rangle$ is annihilated by J_0^- and $|j;m\rangle$ is an eigenstate of J_0^3 with $J_0^3 = m$. The representation is unitarity if j is real and $j > 0$. For representations of the group SL(2,R), j is restricted to be a half-integer. Since we are considering the universal cover of SL(2,R), j can be any positive real number.

(2) Principal discrete representations (highest weight):

A charge conjugation of (1). A representation of this type is realized in the Hilbert space,

$$\mathcal{D}_j^- = \{|j;m\rangle : m = -j,\ -j-1,\ -j-2, ...\},$$

where $|j;j\rangle$ is annihilated by J_0^+ and $|j;m\rangle$ is an eigenstate of J_0^3 with $J_0^3 = m$. The representation is unitary if j is real and $j > 0$.

(3) Principal continuous representations:

A representation of this type is realized in the Hilbert space of

$$\mathcal{C}_j^\alpha = \{|j,\alpha;m\rangle : m = \alpha,\ \alpha \pm 1,\ \alpha \pm 2,\ \ldots\},$$

where $|j,\alpha;m\rangle$ is an eigenstate of J_0^3 with $J_0^3 = m$. Without loss of generality, we can restrict $0 \leqslant \alpha < 1$. The representation is unitary if $j = 1/2 + is$ and s is real. (Strictly speaking the representation with $j = 1/2$, $\alpha = 1/2$ is reducible as the sum of a highest weight and a lowest weight representation with $j = 1/2$.)

(4) Complementary representations:

A representation of this type is realized in the Hilbert space of

$$\mathcal{E}_j^\alpha = \{|j,\alpha;m\rangle : m = \alpha,\ \alpha \pm 1,\quad \alpha \pm 2, ...\},$$

where $|j,\alpha;m\rangle$ is an eigenstate of J_0^3 with $J_0^3 = m$. Without loss of generality, we can restrict $0 \leqslant \alpha < 1$. The representation is unitary if j is real, with $1/2 < j < 1$ and $j - 1/2 < |\alpha - 1/2|$.

(5) Identity representation:

This is the trivial representation with $j = 0$.

The analysis that led to the above representation was completely algebraic and in a particular physical system we can have only a subset of all possible representations. Which of these representations appear in the Hilbert space of the WZW model? As the first approximation, let us consider the $k \to \infty$ limit. If we expand around a short string solutions, i.e., oscillations near geodesics in AdS_3, the WZW model in this limit reduces to the quantum mechanics on AdS_3. The Hilbert space of the quantum mechanical model is the space of square-integrable (Since AdS_3 is noncompact, we consider square-integrability in the delta-function sense.) functions $\mathcal{L}^2(AdS_3)$ on AdS_3. The isometry of AdS_3 is SL(2,R)$\times$SL(2,R), and one can decompose $\mathcal{L}^2(AdS_3)$ into its unitary representations. It is convenient to choose the basis of the Hilbert space in the following way. For each representation $\mathcal{R}$, one can define a function on AdS_3 by $F_{m,\bar{m}}(g) = \langle m|g|\bar{m}\rangle$, where $g \in AdS_3$, i.e., universal cover of SL(2,R), and $|m\rangle$ is an eigenstate of J_0^3 with $J_0^3 = m$. Thus, for a given representation $\mathcal{H}$ of SL(2,R), the function $F_{m,\bar{m}}(g)$ on AdS_3 is in the tensor product of the representations $\mathcal{R}\times\mathcal{R}$ for the isometry group SL(2,R)$\times$SL(2,R).

For a discrete representation $\mathcal{D}_j^\pm$, the wave-function $f(\rho)$ behaves as $f(\rho) \sim e^{-2j\rho}$ for large ρ. Thus $\phi \in \mathcal{L}^2(AdS_3)$ if $j > 1/2$. Notice that in the range $0 < j < 1$ we have two representations with the same value of the Casimir but only one is in $\mathcal{L}^2(AdS_3)$, the one with $1/2 < j < 1$. As explained in Ref. 23, one could modify the norm so that the second solution with $0 < j < 1/2$ becomes normalizable. This modification of the norm is j-dependent. Similarly, supplementary series representations need a j-dependent modification to the norm to render them normalizable.[21] Therefore these representations would appear in nonstandard quantizations of geodesics, quantizations which do not use the $\mathcal{L}^2$ norm on AdS_3. In this paper, we will only consider the standard quantization using the $\mathcal{L}^2$ norm for the zero modes. [Notice however, that even if the primary states have $j > 1/2$, we could have states with smaller values of j_0 for the zero mode SL(2,R) among the descendents, for example, $J_{-1}^-|j\rangle$ with $1 < j < 3/2$, has $j_0 = j - 1 < 1/2$.] Wave-functions in $\mathcal{C}_{j=1/2+is}^\alpha$ are also delta-function normalizable with respect to the $\mathcal{L}^2$ norm. It is known that $\mathcal{C}_{j=1/2+is}^\alpha \times \mathcal{C}_{j=1/2+is}^\alpha$ and $\mathcal{D}_j^\pm \times \mathcal{D}_j^\pm$ with $j > 1/2$ form the complete basis of $\mathcal{L}^2(AdS_3)$.

For discrete lowest weight representations, the second Casimir is bounded above as $c_2 = -j(j-1) \leqslant 1/4$. This corresponds to the well-known Breitenlohner–Freedman bound $(\text{mass})^2 \geqslant -1/4$ for the Klein–Gordon equation. For the principal continuous representation $\mathcal{C}_j^\alpha$ with $j = 1/2 + is$, the second Casimir is $c_2 = 1/4 + s^2$. Therefore an existence of such a particle would violate the Breitenlohner–Freedman bound. In the bosonic string theory, the only physical state of this type is the tachyon. In a perturbatively stable string theory, such particle states should be excluded from its physical spectrum. On the other hand, the continuous representations appear in $\mathcal{L}^2(AdS_3)$ and they are expected to be part of the Hilbert space of the WZW model before the Virasoro constraint is imposed.

B. Representations of the current algebra and no-ghost theorem

Given a unitary representation $\mathcal{H}$ of SL(2,R), one can construct a representation of SL(2,R) by regarding $\mathcal{H}$ as its primary states annihilated by $J_{n\geqslant 1}^{3,\pm}$. The full representation space is generated by acting $J_{n\leqslant -1}^{3,\pm}$ on $\mathcal{H}$. Following the discussion in the previous subsection, we consider the cases when $\mathcal{H} = \mathcal{C}_{j=1/2+is}^\alpha$ and $\mathcal{D}_j^\pm$ with $j > 1/2$. We denote by $\hat{\mathcal{D}}_j^\pm$ and $\hat{\mathcal{C}}_j^\alpha$ the representations of the full current algebra built on the corresponding representations of the zero modes. In Fig. 5, we have shown the weight diagram of the positive energy representation $\hat{\mathcal{D}}_j^+$.

A representation of $\widehat{\text{SL}}_k(2,R)$ in general contains states with negative norms. In order for a string theory on AdS_3 to be consistent, one should be able to remove these negative norm states by imposing the Virasoro constraint,

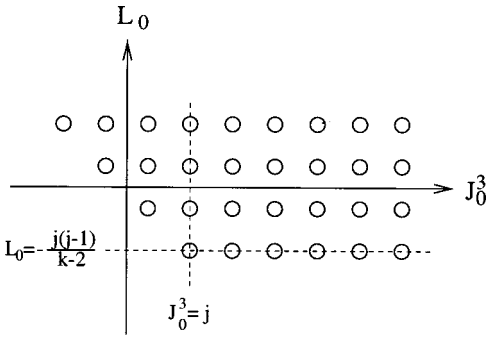

FIG. 5. Weight diagram the representation $\hat{\mathcal{D}}_j^+$, whose the primary states form a discrete lowest weight representation $\hat{\mathcal{D}}_j^+$.

$$(L_n+\mathcal{L}_n-\delta_{n,0})|\text{physical}\rangle=0,\ \ n\geqslant 0, \tag{66}$$

on the Hilbert space for a single string state, where L_n is the Virasoro generator of the SL(2,R)WZW model and $\mathcal{L}_n$ for the sigma-model on $\mathcal{M}$. It has been shown that this no-ghost theorem holds for states in $\hat{\mathcal{C}}^{\alpha}_{j=1/2+is}$ or $\hat{\mathcal{D}}^{\pm}_j$ with $0<j<k/2$.[2,3,6–9,22]

The no-ghost theorem is proven by first showing that all the solutions to the Virasoro constraint (66) can be expressed, modulo null states, as states in the coset SL(2,R)/U(1) obeying

$$J^3_n|\psi\rangle=0,\quad n\geqslant 1. \tag{67}$$

This statement is true for $\hat{\mathcal{C}}^{\alpha}_{1/2+is}$ and $\hat{\mathcal{D}}^{\pm}_j$ with $0<j<k/2$, if the total central charge of the Virasoro generator $L_n+\mathcal{L}_n$ is 26.[2–4,6–9] (We also assume $k>2$.) We review the proof of this statement in Appendix A.1. The second step is to show that the condition (67) removes all negative norm states. This was shown in Ref. 22 for the same class of representations.

The no-ghost theorem suggests that the spectrum of discrete representations has to be truncated for $j<k/2$. As we will see, this truncation is closely related to the existence of the long string states.

C. Spectral flow and the long string

The classical and semiclassical results discussed above indicate that, beyond positive energy representations that we have discussed so far, we have to include others related by spectral flow. To define a quantum version of the spectral flow, we note that, for any integer w, the transformation $J^{3,\pm}_n\to\tilde{J}^{3,\pm}_n$ given by

$$\tilde{J}^3_n=J^3_n-\frac{k}{2}w\,\delta_{n,0},\ \ \tilde{J}^+_n=J^+_{n+w},\ \ \tilde{J}^-_n=J^-_{n-w}, \tag{68}$$

preserves the commutation relations (62). The Virasoro generators $\tilde{L}_n$, which have the standard Sugawara form in terms of $\tilde{J}^a_n$, are different from L_n. They are given by

$$\tilde{L}_n=L_n+wJ^3_n-\frac{k}{4}w^2\delta_{n,0} \tag{69}$$

Of course, they obey the Virasoro algebra with the same central charge c. This is the same formula as saw in the classical counterpart (29) of the spectral flow.

The change of the basis (68) maps one representation into another, and this is called the spectral flow. In the case of a compact group such as SU(2), the spectral flow maps a positive

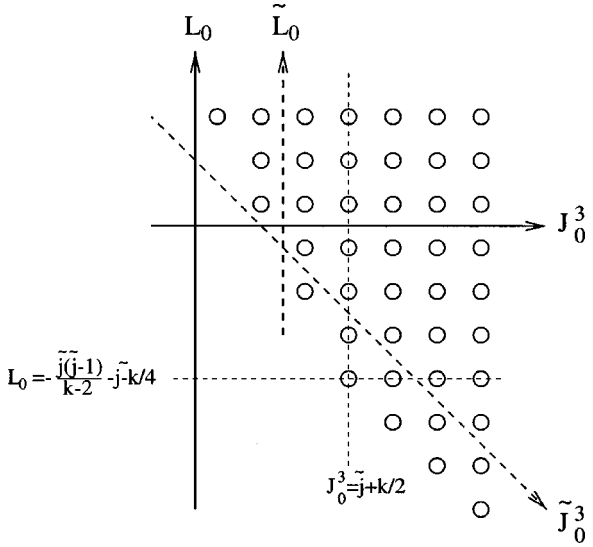

FIG. 6. Weight diagram of the representation $\hat{\mathcal{D}}_j^{+,w=1}$, which is the spectral flow of the diagram 5 with $w=1$. The worldsheet energy L_0 of this representation is not bounded below, but the space–time energy, J_0^3, is bounded below for states obeying the Virasoro constraint $L_0=1$.

energy representation of the current algebra into another positive energy representation. An analogous transformation in the case of the $N=2$ superconformal algebra in two dimensions has been used to construct the spacetime supercharges for superstring.

In the case of SL(2,R), the spectral flow generates a new class of representations. As shown in Fig. 6, the spectral flow with $w=1$ maps the lowest weight representation $\hat{\mathcal{D}}_{\tilde{j}}^{+}$ to a representation in which L_0 is not bounded below. The appearance of negative energy states is not too surprising since the kinetic term of the SL(2,R) model is not positive definite. In general, a spectral flow of $\hat{\mathcal{D}}_{\tilde{j}}^{+}$ with $w\geqslant 1$ or $w\leqslant -2$ gives a new representation in which L_0 is not bounded below. Similarly, the spectral flow of $\hat{\mathcal{C}}^{\alpha}_{j=1/2+is}$ with $w\neq 0$ gives a representation in which L_0 is not bounded below. We denote the resulting representations by $\hat{\mathcal{D}}_{\tilde{j}}^{\pm,w}$ and $\hat{\mathcal{C}}_{\tilde{j}}^{\alpha,w}$, where $\tilde{j}$ labels the SL(2,R) spin before the spectral flow (Fig. 7).

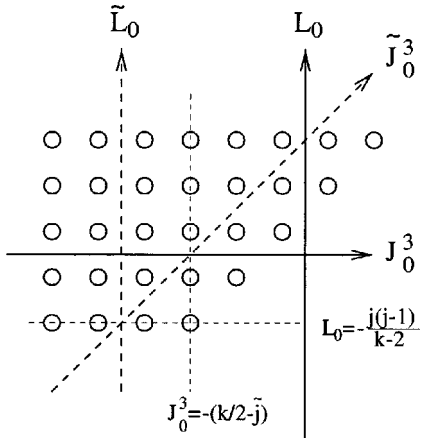

FIG. 7. The spectral flow of the diagram 5 with $w=-1$. $\hat{\mathcal{D}}_j^{+}$ is mapped to $\hat{\mathcal{D}}_j^{+,w=-1}=\hat{\mathcal{D}}_j^{-}$ with $j=k/2-\tilde{j}$. Since $\tilde{j}>1/2$, the resulting $\hat{\mathcal{D}}_j^{-}$ obeys $j<(k-1)/2$. In particular, the unitarity bound $j<k/2$ required by the no-ghost theorem is satisfied.

These representations obtained by the spectral flow also contain negative norm states. In Appendix A.2, we generalize the proof of the no-ghost theorem and show that the Virasoro constraints indeed remove all negative norm states in the representations $\hat{\mathcal{C}}^{\alpha,w}_{j=1/2+is}$ and $\hat{\mathcal{D}}^{\pm,w}_{\tilde{j}}$ with $\tilde{j}<k/2$, for any integer w.

The only case where we get a representation with L_0 bounded below by the spectral flow is $\hat{\mathcal{D}}^{\pm}_{j}$ with $w=\mp 1$. In this case, the representation is mapped to another positive energy representation $\hat{\mathcal{D}}^{\pm,w=\mp 1}_{\tilde{j}}=\hat{\mathcal{D}}^{\mp}_{k/2-\tilde{j}}$. Note that, if we start with the representation with $\tilde{j}>1/2$, the representation one gets after the spectral flow satisfies $j=k/2-\tilde{j}<(k-1)/2$. Conversely, if there were a representation $\hat{\mathcal{D}}^{\pm}_{j}$ with $j>(k-1)/2$ in the Hilbert space, the spectral flow would generate a representation $\hat{\mathcal{D}}^{\pm}_{j}$ with $j<1/2$ in contradiction with the standard harmonic analysis of the zero modes in Sec. IV A. Therefore, if we assume that the spectral flow is a symmetry of the WZW model, the discrete representations $\hat{\mathcal{D}}^{\pm}_{j}$ appearing in the Hilbert space are automatically restricted to be in $1/2<j<(k-1)/2$. In particular, the spectrum of j is truncated below the unitarity bound $j<k/2$ required by the no-ghost theorem. This further restriction on j was discussed in a related context by Ref. 24.

D. Physical spectrum

Let us consider first the spectrum for strings with $w=0$. This is fairly standard. We start from an arbitrary descendent at level N in the current algebra and some operator of the internal CFT with conformal weight h. The L_0 constraint reads

$$(L_0-1)|j,m,N,h\rangle=0\Rightarrow-\frac{j(j-1)}{k-2}+N+h-1=0. \tag{70}$$

If we demand that $1/2\leqslant j\leqslant(k-1)/2$, this equation will have a solution as long as $N+h$ is within the range

$$0\leqslant N+h-1+\frac{1}{4(k-2)}\leqslant\frac{(k-2)}{4}. \tag{71}$$

If we allow j to go all the way to $k/2$ we get $k/4$ on the right-hand side of (71).

To analyze physical states of strings with $w\neq 0$, we start with a positive energy representation $\hat{\mathcal{D}}^{+}_{\tilde{j}}$. After the spectral flow (68), a primary state $|\tilde{j},\tilde{m}\rangle$ of $\hat{\mathcal{D}}^{+}_{\tilde{j}}$, as a state of $\hat{\mathcal{D}}^{+,w}_{\tilde{j}}$, obeys

$$\begin{gathered}J^{+}_{n+w}|\tilde{j},\tilde{m}\rangle=0,\ \ J^{-}_{n-w}|\tilde{j},\tilde{m}\rangle=0,\ \ J^{3}_{n}|\tilde{j},\tilde{m}\rangle=0,\ \ n\geqslant 1,\\ J^{3}_{0}|\tilde{j},\tilde{m}\rangle=\left(\frac{k}{2}w+\tilde{m}\right)|\tilde{j},\tilde{m}\rangle.\end{gathered} \tag{72}$$

Let us look for physical states with respect to the Virasoro generator L_n. From (72), we find the Virasoro constraints are

$$\begin{gathered}(L_0-1)|\tilde{j},\tilde{m}\rangle=\left(-\frac{\tilde{j}(\tilde{j}-1)}{k-2}-w\tilde{m}-\frac{k}{4}w^2+\tilde{N}+h-1\right)|\tilde{j},\tilde{m},\tilde{N},h\rangle=0,\\ L_n|\tilde{j},\tilde{m}\rangle=(\tilde{L}_n-w\tilde{J}^3_n)|\tilde{j},\tilde{m}\rangle=0,\quad n\geqslant 1,\end{gathered} \tag{73}$$

where h is the contribution to the conformal weight from the internal CFT and $\tilde{N}$ is the level inside the current algebra before we take the spectral flow. The state obeys the physical state conditions provided

$$\tilde{m}=-\frac{k}{4}w+\frac{1}{w}\left(-\frac{\tilde{j}(\tilde{j}-1)}{(k-2)}+\tilde{N}+h-1\right). \tag{74}$$

The space–time energy of this state measured by J_0^3 is then

$$J_0^3=\tilde{m}+\frac{k}{2}w=\frac{k}{4}w+\frac{1}{w}\left(-\frac{\tilde{j}(\tilde{j}-1)}{(k-2)}+\tilde{N}+h-1\right). \tag{75}$$

This is the quantum version of the classical formula (32), with the replacement

$$\frac{k}{4}\alpha^2\to\frac{\tilde{j}(\tilde{j}-1)}{k-2}+1.$$

Notice that $\tilde{m}=\tilde{j}+q$ where q is some integer, which could be negative. ($\tilde{m}$ is the total $\tilde{J}^3$ eigenvalue of the state so it can be lowered by applying J^-_{-n} to the highest weight state. So we have the constraint $q\geqslant-\tilde{N}$.) Therefore the physical state condition becomes

$$\tilde{j}=\frac{1}{2}-\frac{k-2}{2}w+\sqrt{\frac{1}{4}+(k-2)\left(h-1+N_w-\frac{1}{2}w(w+1)\right)}. \tag{76}$$

Here

$$N_w=\tilde{N}-wq \tag{77}$$

is the level of the current algebra after the spectral flow by the amount w. Notice that the equation for $\tilde{j}$ is invariant under $\tilde{N}\to\tilde{N}\pm w$, $q\to q\pm1$. This is reflecting the fact that $J_0^{\pm}=\tilde{J}^{\pm}_{\mp w}$ commute with the Virasoro constraints and generate the space–time SL(2,R) multiplets. In particular, we see that the space–time SL(2,R) representations that we get are lowest energy representations, since repeated action of $J_0^-=\tilde{J}_w^-$ will eventually annihilate the state. In fact, it is shown in Appendix A.2 that the only physical state with zero spacetime energy, $J_0^3=0$, is the state $J_{-1}^-|j=1\rangle$, and its complex conjugate. This physical state corresponds to the dilaton field in AdS_3, which played an important role in the analysis of the spacetime Virasoro algebra in Ref. 25. All other states (except the tachyon with $w=0$) have nonzero energy, and form highest/lowest weight representations of SL(2,R) space–time algebra. The negative energy ones are the complex conjugates of the positive energy ones.

By solving the on-shell condition (76) for $\tilde{j}>0$ and substituting it into (75), one finds that the space–time energy of the string is given by

$$\frac{E+l}{2}=J_0^3=q+w+\frac{1}{2}+\sqrt{\frac{1}{4}+(k-2)\left(h-1+N_w-\frac{1}{2}w(w+1)\right)}. \tag{78}$$

Since both N_w and q are integers, the energy spectrum is discrete. This is reasonable since we are considering the string trapped inside of AdS_3. The constraint $1/2<\tilde{j}<(k-1)/2$ translates into the inequality

$$\frac{k}{4}w^2+\frac{w}{2}<N_w+h-1+\frac{1}{4(k-2)}<\frac{k}{4}(w+1)^2-\frac{w+1}{2}. \tag{79}$$

This is the quantum version of the semiclassical formula (59). In fact, if we take $k,h\gg\tilde{N},q,w$, (79) reduces to (59). As in the semiclassical discussion, w is not necessarily related to the physical winding number of the string. It is just an integer labeling the type of representation that the string state is in.

The analysis for the representations coming from the continuous representations for the zero modes is similar. If we do not spectral flow, the only state in the continuous representation is the tachyon. If we do spectral flow, we get Eq. (74), which can be conveniently rewritten as

$$J_0^3=\tilde{m}+\frac{wk}{2}=\frac{kw}{4}+\frac{1}{w}\left(\frac{\frac{1}{4}+s^2}{k-2}+\tilde{N}+h-1\right). \tag{80}$$

For continuous representations w is labeling the physical winding of the string when it approaches the boundary of *AdS*. In this case we do not get an equation like (76) since, for continuous representations, $\tilde{m}$ is not related to j. Comparing with the classical formula (40), we identify s as the momentum α/k of the long string along the radial direction of AdS_3. We clearly see that the energy of this state is above the threshold to produce an excitation that will approach the boundary as a w-times wound string.

We can see that, whenever the value of h is such that it saturates the range (79), we have a continuous representation with the same energy. This is clear for the lower bound in the case of $w=0$ since, for each state in the discrete representation with $j=1/2$, there is one in the continuous representation with the same values of L_0 and J_0^3. By the spectral flow, we see that the same is true for the lower bound in (79) for any w. Indeed we can check explicitly that a state in the discrete representation with parameters $(h,w,q,\tilde{N})$ saturating the lower bound in (79) has the same space–time energy as a state in the continuous representation with parameters $(h,w,s=0,\tilde{N})$. [The parameter α in the continuous representation is fixed by the value of J_0^3 in (80).] Similarly, if we have a state in a discrete representation saturating the upper bound in (79), it has the same spacetime energy as a state in the continuous representation with parameters $(h,w+1,\ s=0,\ \tilde{N}'=\tilde{N}+q)$. Note that, since $q\geqslant-\tilde{N}$ (see the footnote in the previous page), we have $\tilde{N}'\geqslant 0$. In this case, to show that the two states have the same energy, it is useful to identify the state in $\hat{\mathcal{D}}^{+,w}_{\tilde{j}=\tilde{j}}$ as a state in $\hat{\mathcal{D}}^{-,w+1}_{\tilde{j}=k/2-\tilde{j}}$. Since $\tilde{j}\to(k-1)/2$ corresponds to $\tilde{j}\to 1/2$ under this identification, we can apply the above argument for the lower bound to show that we will find a state in the continuous representation. The shift $\tilde{N}'=\tilde{N}+q$ comes from the fact that the identification $\hat{\mathcal{D}}^{+,w}_{\tilde{j}=\tilde{j}}=\hat{\mathcal{D}}^{-,w+1}_{\tilde{j}=k/2-\tilde{j}}$ involves spectral flow one more time.

The above paragraph explains what happens as we change $\tilde{j}$ in a discrete representation and we make it equal to the upper or lower bound: a continuous representation appears. Another question that one could ask is the following. Given a value of h, what is the state with the lowest value of J_0^3 that satisfies the physical state conditions? Let us first look for the lowest energy state in the discrete representations obeying the bound (79). Within this bound, one can show that $\partial J_0^3(h,w,q,\tilde{N})/\partial q\geqslant 0$ and $\partial J_0^3(h,w,q=-\tilde{N},\tilde{N})/\partial\tilde{N}\geqslant 0$. Therefore, if we can set $q=\tilde{N}=0$, it will give the lowest energy state in the discrete representations. This is possible if h is within the range,

$$\frac{k}{4}w^2+\frac{w}{2}<h-1+\frac{1}{4(k-2)}<\frac{k}{4}(w+1)^2-\frac{w+1}{2}. \tag{81}$$

With some more work, one can show that, for h in this range, there is not any state in a continuous representation whose energy is lower than that of the discrete representation state with $\tilde{N}=q=0$. As we saw in the above paragraph, at the upper or lower bound of (81), the energy of the discrete state $(q=0,\ \tilde{N}=0)$ coincides with that of the continuous state with $(s=0,\ \tilde{N}=0)$. Outside this range (81), it is not possible to set $\tilde{N}=q=0$, and the lowest energy state will be in a continuous representation. In our semi-classical discussion in the last section, we found that the discrete representation can decay into the continuous representation at $h=kw^2/4$. Now we see that, in the fully quantum description, the range over which a continuous representation has lower energy has expanded from the point $h=kw^2/4$ to a strip of width w,

$$\frac{k}{4}w^2-\frac{w}{2}<h-1+\frac{1}{4(k-2)}<\frac{k}{4}w^2+\frac{w}{2}. \tag{82}$$

So far we have restricted our attention to right-moving sectors of the Hilbert space. Let us now discuss how the left and right movers are combined together. For the classical solution of the long string, the worldsheet periodicity requires that the spectral flow has to be done simultaneously on both the left and right movers with the same amount. If AdS_3 were not the universal cover of SL(2,R) but its single cover, different amounts of the left and the right spectral flows would have been allowed since the resulting solution is periodic modulo the closed timelike curve of SL(2,R). It is straightforward to identify the corresponding constraint in the quantum theory. Suppose we perform the spectral flows by the amount w_L and w_R on the left and the right-movers. A state with conformal weights (h_L,h_R) and the J_0^3 charge $(\tilde{m}_L,\tilde{m}_R)$ is mapped by this transformation to a state with conformal weights $(h_L-w_L\tilde{m}_L-(k/4)w_L^2,\ h_R-w_R\tilde{m}_W-(k/4)w_R^2)$, according to (69). The worldsheet locality, which is the quantum counterpart of the periodicity of the classical solution, requires that the conformal weights h_L and h_R differ only by an integer. If this is the case before spectral flow, the same requirement after the flow implies

$$w_L\tilde{m}_L+\frac{k}{4}w_L^2=w_R\tilde{m}_R+\frac{k}{4}w_R^2 \ \ (\text{mod integer}). \tag{83}$$

For generic values of $(\tilde{m}_L,\tilde{m}_R)$, the only solution to this constraint is $w_L=w_R$. In this paper, we are considering only the universal cover of SL(2,R) as the target space of the model. In this case, the spectrum of $(\tilde{m}_L,\tilde{m}_R)$ is continuous, and only the left-right symmetric spectral flow $w_L=w_R$ is allowed.

Summary: We propose that the spectrum of the SL(2,R) WZW model [for the universal cover of SL(2,R)] contains the following two types of representations. First, the spectral flow of the continous representations, with the same amount of spectral flow on the left and right, $\hat{\mathcal{C}}^{\alpha,w}_{1/2+is,L}\times\hat{\mathcal{C}}^{\alpha,w}_{1/2+is,R}$. Then the discrete representations $\hat{\mathcal{D}}^{+,w}_{\tilde{j},L}\times\hat{\mathcal{D}}^{+,w}_{\tilde{j},R}$ with the same amount of spectral flow on the left and right and the same value of $\tilde{j}$, with $1/2<\tilde{j}<(k-1)/2$. In the string theory, these representations should be tensored with the states of the internal CFT, and the Virasoro constraints should be imposed.

V. SCATTERING OF THE LONG STRING

When a long string comes in from the boundary of AdS_3 to the center, it will scatter back to the boundary. In this process the winding number could in principle change. In order to study the S-matrix between incoming and outgoing long strings, it is convenient to perform the rotations to Euclidean signature spaces, both on the worldsheet and in space time. Following the standard procedure, we define the hermiticity as is natural in the Lorentzian theory. For this reason we still have the SL(2,R)$_L\times$SL(2,R)$_R$ currents in the Euclidean theory. The relevant conformal field theory, whose target space is the three-dimensional hyperbolic space $H_3=\mathrm{SL}(2,C)/\mathrm{SU}(2)$ has been studied in Refs. 18, 25–30.

A. Vertex operators

To compute the scattering amplitudes, we would like to find vertex operators for all representations considered above. Spectral flow is realized in the vertex operator for malism in the following standard fashion.[31] We bosonize the J^3 currents, introducing left and right moving chiral bosons [Reflecting the hermiticity of the SL(2,R) model, the scalar field ϕ is Hermitian, but with a wrong sign for the two-point function $\langle\phi(z)\phi(z')\rangle=\log(z-z')$.] through

$$J_R^3=-i\sqrt{\frac{k}{2}}\partial\phi(z),\quad J_L^3=-i\sqrt{\frac{k}{2}}\bar{\partial}\phi(\bar{z}). \tag{84}$$

A state with charge m under J_R^3 contains an exponential in $\phi(z)$ of the form $e^{im\sqrt{(2/k)}\phi(z)}$. The other two currents therefore can be expressed as

$$J_R^+ = \psi e^{i\sqrt{(2/k)}\phi(z)}, \quad J_R^- = \psi^\dagger e^{-i\sqrt{(2/k)}\phi(z)}, \tag{85}$$

and similarly for $J_L^\pm$. A primary field $\Phi_{jm\bar{m}}(z,\bar{z})$ of the current algebra can be expressed as

$$\Phi_{jm\bar{m}} = e^{im\sqrt{(2/k)}\phi(z)+i\bar{m}\sqrt{(2/k)}\phi(\bar{z})}\Psi_{jm\bar{m}}, \tag{86}$$

where $\Psi_{jm\bar{m}}$ carries no charges with respect to $J_{R,L}^3$. In the case of the SU(2) model, the field corresponding to Ψ is known as a parafermion. The parafermion for the SL(2,R) model was studied in Ref. 32. The conformal weights of the parafermion field $\Psi_{jm\bar{m}}$ is

$$\begin{aligned} h_{\Psi;jm\bar{m}} &= -\frac{j(j-1)}{k-2} + \frac{m^2}{k}, \\ \bar{h}_{\Psi;jm\bar{m}} &= -\frac{j(j-1)}{k-2} + \frac{\bar{m}^2}{k}. \end{aligned} \tag{87}$$

In the discrete lowest weight representation, $m,\bar{m} = j, j+1, j+2, \ldots$. In particular, when $j=k/2$, the field $\Psi_{j=k/2,m=\bar{m}=k/2}$ has conformal weights $h=\bar{h}=0$. Since the parafermion field lives in the unitary conformal field theory it is natural to assume that it is the identity operator. (Recently we have learned that a similar argument has appeared in unpublished notes by Zamolodchikov. We thank him for having his note available to us.[33]) Here we simply note that the operator,

$$e^{i\sqrt{(k/2)}(\phi(z)+\phi(\bar{z}))}$$

has the correct OPE for the primary field of spin $j=k/2$ with the SL(2,R) currents.

Using the parafermion notation, the operator obtained by the spectral flow by w units is expressed as

$$\Phi^w = e^{i(\tilde{m}+wk/2)\sqrt{(2/k)}\phi(z)+i(\tilde{\bar{m}}+wk/2)\sqrt{(2/k)}\phi(\bar{z})}\Psi_{j\tilde{m}\tilde{\bar{m}}}. \tag{88}$$

It is easy to see that the conformal weight is given by

$$L_0 = \frac{-j(j-1)}{k-2} - mw + kw^2/2. \tag{89}$$

B. Reflection coefficient

We will compute the amplitude, using the formulas obtained in Refs. 34, 35, 26, 33, in the case that the winding number does not change.

The long string states are in the spectral flow of the continuum representation. The corresponding vertex operators are

$$\begin{aligned} \Phi^j_{m\bar{m}} &= e^{m\phi(z)+\bar{m}\phi(\bar{z})}\Psi^j_{\tilde{m}\tilde{\bar{m}}}V_{h\bar{h}}(z,\bar{z}), \\ \tilde{m} = m - wk/2, &\quad \tilde{\bar{m}} = \bar{m} - wk/2, \quad j = \tfrac{1}{2} + is, \end{aligned} \tag{90}$$

where $V_{h\bar{h}}$ is an operator in the internal part with conformal weights $(h,\bar{h})$. The physical energy E and angular momentum l of a state in AdS_3 are given by

$$m = \tfrac{1}{2}(E+l), \quad \bar{m} = \tfrac{1}{2}(E-l). \tag{91}$$

The physical state constraint is (80) with $\tilde{N}=0$. This implies that

$$\tilde{m}=-wk/4+\frac{1}{w}\left[\frac{1/4+s^2}{k-2}+h-1\right]. \tag{92}$$

Now we can now consider the two point function[26,27,33]

$$\langle \Phi^{j}_{m\bar{m}}(z,\bar{z})\Phi^{j'}_{m',\bar{m}'}(z',\bar{z}')\rangle = \frac{\Gamma(1/2+is-\tilde{m})\Gamma(1/2+is+\tilde{m})\Gamma(-2is)\Gamma\left(\frac{2is}{k-2}\right)}{\Gamma(1/2-is-\tilde{m})\Gamma(1/2-is+\tilde{m})\Gamma(2is)\Gamma\left(\frac{-2is}{k-2}\right)} \times \delta(s-s')\,\delta_{N+N'}\,\delta(E+E'). \tag{93}$$

The z dependence is just $1/|z-z'|^4$ coming from the fact that the two operators have weight (1,1). This is the reflection amplitude and the values of $\tilde{m},\tilde{\bar{m}}$ are determined by (92) (notice that m is the physical energy, not $\tilde{m}$).

As explained in Ref. 28 in this context, in string theory we have to integrate over z and divide by the volume of SL(2,C). We can use SL(2,C) invariance to put $z=0$, $z'=\infty$ in the correlator. The volume of the rest of SL(2,C) then gives $\int(d^2z/|z|^2)$, which cancels one of the delta-functions in (93). Notice that $\delta(s-s')\,\delta(E+E')=\delta(s-s')\,\delta(0)$, the volume of SL(2,$C$) cancels the $\delta(0)$ piece.

Now if we study the poles of (93), we find that they are located at $1/2+is-\tilde{m}=-q$ with $q=0,1,2,\ldots$. They come from the first Gamma-function. Taking this condition together with (92) we find that

$$1/2+is+q=\tilde{m}=-wk/4+\frac{1}{w}\left[\frac{1/4+s^2}{k-2}+h-1\right] \tag{94}$$

and this equation is precisely the same as the usual mass shell equation for discrete states if we take $\tilde{j}=1/2+is$. There are similar poles from the second Gamma-function. There are no poles coming from the third factor since they cancel extra poles appearing in the other factors. Notice that the poles appearing in (94) satisfy precisely Eq. (76) for bound states in the representation $\hat{\mathcal{D}}^{+,w}_{\tilde{j}}$ (with $\tilde{N}=0$). There is however, an important difference. In (76) the value of $\tilde{j}$ obeyed the condition

$$\frac{1}{2}<\tilde{j}<\frac{k-1}{2}, \tag{95}$$

while we do not have such a condition in (94). It is interesting to note that if $\tilde{j}$ satisfies (95), then the residue at the pole has the proper sign to be interpreted as coming from a bound state. When $\tilde{j}=(k-1)/2$, i.e., at the upper bound of (95), we find that there is no pole. Moreover, immediately above that value, we have the wrong sign for the pole residue. This might make us worry that the amplitude is not having the right analytic structure. However, in order to have a one-to-one correspondence between poles of the scattering amplitude and bound states, the potential has to decrease sufficiently rapidly at the infinity,[36] a condition that is not met in our case. In such a situation, it is possible to have extra poles that do not correspond to physical states. We plan to analyze the poles and their implications for physical states in a future publication.

C. Relation to the scattering of the two-dimensional black hole

The coset of the SL(2,R) WZW by the U(1) generated by J^3 gives a sigma-model whose target space is the two-dimensional black hole with the Euclidean signature metric.[37] The geom-

etry of the black hole is like a semi-infinite cigar with an asymptotic region in the form of the cylinder $\mathbb{R}\times S^1$. The dilaton field grows as one approaches the center of the black hole, but it remains finite since the geometry is terminated at the tip of the cigar. The string theory on $\mathrm{SL}(2,R)/\mathrm{U}(1)\times(\text{time})\times\mathcal{M}$ is closely related to the string theory on $AdS_3\times\mathcal{M}$ since the physical state conditions for the latter implies $J^3_n|\text{physical}\rangle=0$ for $n\geqslant 1$, as we show in Appendix A. Similarly the superstring theory on $AdS_3\times\mathcal{M}$ is related to the Kazama–Suzuki coset $\mathrm{SL}(2,R)/\mathrm{U}(1)$.

There is however difference between the zero mode sectors of the theories on AdS_3 and on the two-dimensional black hole. In order to construct representations for SL(2)/U(1), we can start from the representations of $\widehat{\mathrm{SL}(2,R)}$ that we described above and impose the condition that $J^3_{n>0}$ annihilate the state and that the total AdS_3 energy vanishes, $J^3_{0,R}+J^3_{0,L}=m+\bar{m}=0$. In terms of the parafermion $\Psi_{j\tilde{m}\bar{\tilde{m}}}$ given in (86) and (88), the condition is $\tilde{m}+\bar{\tilde{m}}=wk$. The locality condition $m-\bar{m}=n$, where n is an integer implies that $\tilde{m}-\bar{\tilde{m}}=n$. These two quantization conditions are the ones in Ref. 38 [see Eq. (3.6) of that paper]. The SL(2)/U(1) theory has been studied recently in connection with ''little'' string theories in Refs. 24 and 39.

VI. CONCLUSION

In this paper, we studied the physical spectrum of bosonic string theory in AdS_3. We proposed that the complete Hilbert space of the $\mathrm{SL}(2,R)$ WZW model consists of the continuous representations and their spectral flow $\hat{\mathcal{C}}^{\alpha,w}_{j=1/2+is}\times\hat{\mathcal{C}}^{\alpha,w}_{j=1/2+is}$, and the discrete representations and their spectral flow $\hat{\mathcal{D}}^{\pm,w}_j\times\hat{\mathcal{D}}^{\pm,w}_j$ with the constraint $1/2<j<(k-1)/2$. The sum over the spectral flow is required if we assume that the Hilbert space realizes the full loop group of $\mathrm{SL}(2,R)$, including its topologically nontrivial elements. We found that this proposal leads to the physical spectrum of the string theory with the correct semiclassical limits.

In particular, we have solved the two puzzles which we mentioned in the Introduction. The no-ghost theorem for $\hat{\mathcal{D}}^{+}_j$ requires the constraint $0<j<k/2$. If we only had the unflowed sector (with $w=0$), it would imply the upper bound on allowed mass of string states, which appears artificial. This was one of the puzzles. We have resolved this puzzle by showing that the upper bound on the mass is removed if we include all the spectral flowed sectors in the Hilbert space. Moreover we showed that the consistency with the spectral flow and the standard harmonic analysis of the zero modes requires the constraint $1/2<j<(k-1)/2$, more stringent than the one required by the no-ghost theorem. The constraint $1/2<j<(k-1)/2$ is found to be consistent with the locations of the poles in the reflection coefficient (with the correct sign for the pole residues; see also Ref. 24 and the modular invariance of the partition function.

Another puzzle was to identify states in the Hilbert space corresponding to the long strings. We found that these states are in the spectral flow of the continuous representations, $\hat{\mathcal{C}}^{\alpha,w}_{j=1/2+is}\times\hat{\mathcal{C}}^{\alpha,w}_{j=1/2+is}$. The integer w, which parametrized the amount of the spectral flow, is identified with the winding number of the long string stretched closed the boundary of AdS_3. The physical spectrum of the long strings obtained from these representations agrees with the expectations from the semiclassical analysis in Refs. 11 and 12.

The resolutions of these puzzles removes the longstanding doubts about the consistency of the model. Moreover it appears that the $\mathrm{SL}(2,R)$ WZW model is exactly solvable, just as WZW models for compact groups, although its Hilbert space structure is significantly different from those of the compact cases. We hope that further study of the model will provide us more useful insights into the AdS/CFT correspondence and strings in curved spaces in general.

ACKNOWLEDGMENTS

We would like to thank A. Zamolodchikov for discussions and for giving us a copy of his unpublished notes. We also thank N. Seiberg, C. Vafa, and E. Witten for discussions. We would like to thank S. Hwang for useful comments on the earlier version of this paper. H.O. would like to thank J. Schwarz and the theory group at Caltech for the kind hospitality while the bulk of this

work was carried out. H.O. also thanks the hospitality of the theory group at Harvard University, where this work was initiated, ICTP, Trieste, and ITP, Santa Barbara, where parts of this work were done. APPENDIX A: NO-GHOST THEOREMS

In this Appendix we would like to extend the proof of the no-ghost theorem to all the representations considered above. We assume $k>2$. The proof of the no-ghost theorem for the standard lowest energy representations.[2–9,22] involves two parts. Part I consists of showing that a physical state can be chosen, up to a null state to be such that $J^3_n|\psi>=0$, for $n\geqslant 1$. This first part uses $0<j<k/2$ for the $\mathcal{D}^{\pm}_j$ representations as well as $c=26$ and the mass shell condition. This was shown in Refs. 2–9. Part II consists in showing that any state that is annihilated by $J^3_{n>0}$ has a non-negative norm. This step also uses $0<j<k/2$ for the $\mathcal{D}^{\pm}_j$ representations. This was done in Ref. 22. Here we will use the same strategy and prove Part I for the all our representations. The no-ghost theorem then follows from Part II.

We first review the proof of Part I for the representations with $w=0$ and then we do Part I for the $w\neq 0$ representations.

1. Proof of part I for unflowed representations

Here we follow the proof in Refs. 2, 3, 6, 7, 9. It has essentially three steps.

Step 1: The first step of the proof is to show that states of the form

$$\begin{gathered} L_{-n_1}L_{-n_2}\cdots L_{-n_N}J^3_{-m_1}J^3_{-m_2}\cdots J^3_{-m_M}|f\rangle, \\ n_1\geqslant n_2\geqslant\cdots\geqslant n_N, \quad m_1\geqslant m_2\geqslant\cdots\geqslant m_M, \\ \text{with } L_n|f\rangle=J^3_n|f\rangle=0 \text{ for } n\geqslant 1, \end{gathered} \tag{A1}$$

are linearly independent and that they form a complete basis of the Hilbert space.

The states $|f\rangle$ are constructed from states in the current algebra times some states in an internal conformal field theory. This internal piece is assumed to be unitary. This step involved separating the piece of L_n involving $L^{(3)}=:J^3J^3:$, defining $\hat{L}_n=L_n-L^{(3)}_n$. One can show that the states (A1) are in one to one correspondence with states of the form,

$$\begin{gathered} L_{-n_1}L_{-n_2}\cdots L_{-n_N}J^3_{-m_1}J^3_{-m_2}\cdots J^3_{-m_M}|f\rangle, \\ n_1\geqslant n_2\geqslant\cdots\geqslant n_N, \quad m_1\geqslant m_2\geqslant\cdots\geqslant m_M. \end{gathered} \tag{A2}$$

Notice that conditions (A1) on $|f\rangle$ are the same as $\hat{L}_{n>0}|f\rangle=J^3_{n>0}|f\rangle=0$. It is easier to show that (A2) is a basis since now we can think of the CFT as a product of a U(1) factor with the rest. The rest is a CFT with $c=25$ and therefore the fact that (A2) is a basis reduces to showing that there are no null states in the Virasoro descendents on a primary field. This will be true if the conformal weight of the rest is positive. This reduces to showing that $c_2/(k-2)+m^2/k+M>0$, where M is the grade in the SL(2,R) piece. For the continuous representations, this is obvious since $c_2>0$. For lowest weight representations, this inequality can be shown by rewriting it as

$$\frac{2j(k/2-j)}{k(k-2)}+\frac{2M}{k}\left(\frac{k}{2}-j\right)+\frac{2j}{k}(-j+m+M)+\frac{1}{k}(j-m)^2>0. \tag{A3}$$

We to use $0<j<k/2$ and also the fact that $m\geqslant j-M$, which is true in general. Notice that the m that appears here is the total J_0^3 value, after we applied $J_{-n}^{\pm}$ any number of times. Notice that in this step we did not use that the states were obeying the mass shell condition, but we used $0<j<k/2$ and that $c=26$.

Step 2: Here we show that a physical state can be chosen so that it involves no L_{-n} when written as (A1).

A physical state can be written as a state with no L_{-n} plus a spurious state. A spurious state is a state with at least one L_{-n}. Then we use the fact that, when $c=26$, $L_n(n\geqslant 1)$ acting on a spurious state which satisfies the $L_0=1$ condition leaves it as a spurious state.[40,41] If $L_{n>0}$ acts on a state of the form (A1) with no L_{-n} then it will not produce any L_{-n}. Together with the fact that (B1) is a basis this implies that the part of the state with no L_{-n} satisfies the physical state condition on its own, and therefore the rest is a null state (a spurious physical state).

Step 3: We show that if the physical state $|\psi\rangle$ involves no L_{-n} when written as in (A1) then $J_n^3|\psi\rangle=0$.

Since there are no L_{-n}'s in the physical state ψ this implies that $L_n^{(3)}\psi=0$ for $n\geqslant 1$. Then we try to show that the only states satisfying this will be states with $J_n^3\psi=0$ for $n\geqslant 1$. This would be true if there are no null states in the $L^{(3)}$ Virasoro descendents of the states $|f\rangle$ we considered above. If $m\neq 0$ then one can show that there is no null state in the Virasoro descendents in the $L^{(3)}$ Virasoro descendents. There are two states with $m=0$ one is in the continuous representation, but the mass shell condition automatically implies that $N=0$ (there are no J_{-n}^a in this state) and therefore the state has positive norm. The other is the state in the lowest weight representation

$$J_{-1}^-|j=1\rangle \tag{A4}$$

(and of course its complex conjugate in the highest weight representation). This state has positive norm. Note that m is the physical energy in AdS_3 of the state in question. Zero energy states, therefore imply that we have a normalizable zero mode. This is the state corresponding to the identity operator in the spacetime boundary conformal field theory, the state $\bar{J}J\Phi_1$ of Ref. 25 which played an important role in the computation of the spacetime Virasoro algebra.

One can show, using the mass shell condition, that all other states have $m\neq 0$. The mass shell condition is

$$-\frac{j(j-1)}{k-2}+N+h'-1=0, \tag{A5}$$

where N is the grade in the SL(2,R) part and h' is the conformal weight of the rest, $h'\geqslant 0$. If $0<j<1$ then m is nonzero because it can only change by an integer by the action of the $J_n^{\pm}$ currents. If $j=1$ with $N=1$ and $h'=0$ we find (A4) and states with positive m.

Consider now $j>1$. If we had $m=0$ then we also need $N\geqslant j, j\geqslant 2$ (since $m=0$ only if j is integer) and furthermore

$$-\frac{j(j-1)}{k-2}+N-1\geqslant\frac{(j-1)(k-2-j)}{k-2}>0 \tag{A6}$$

provided $j\leqslant k/2$. Since j has to be at least 2, then $k>4$ and therefore $k-2-k/2>0$. Thus we conclude that (A5) would not be obeyed if $m=0$.

2. Proof of Part I for flowed representations

Now we would like to generalize the above discussion to the spectral flowed representations that we called $\hat{\mathcal{C}}_{1/2+is}^{\alpha,w}$ and $\hat{\mathcal{D}}_{\tilde{j}}^{+,w}$. In the case of discrete representations we want to show that the no ghost theorem holds for $0<\tilde{j}<k/2$, where $\tilde{j}$ labels the representation before we perform the spectral flow operation, i.e., it labels a representation of the current algebra with $\tilde{L}_0$ bounded

below. So we consider the same representations we had above but we modify the physical state conditions. This is equivalent to imposing the usual conditions on the flowed representations. We would like to prove that, given any state built on a lowest weight or continuous representation with respect to $\tilde{J}_n$, the physical state condition $(L_n-\delta_{n,0})|\psi\rangle=0 \quad n\geqslant 0$ with respect to L_n removes non-negative norm states. We only consider spectral flow with $w>1$ on continuous or lowest weight representations $\hat{\mathcal{D}}_j^+$. These and their complex conjugates cover all the representations we needed to consider. We reproduce now the steps in Appendix A.1.

Step 1: In (A1) we need to show that they form a basis with $L_{-n}=\tilde{L}_{-n}-w\tilde{J}^3_{-n}$. We know that they would form a basis if we had an expression like (A1) with $L_{-n}\to\tilde{L}_{-n}$. Fortunately there is an invertible one to one map between these two sets of states, so that they form a basis.

Step 2: It is the same since only $c=26$ is used.

Step 3: If we write a physical state, $|\psi\rangle$, as a state with no L_{-n} then $L_n^{(3)}$ with $n\geqslant 1$ annihilates it. Again we will try to show that $m=\tilde{m}+kw/2$ is nonzero and that will imply that $J^3_{n>0}|\psi\rangle=0$. For this we need to use the new mass shell condition

$$\frac{\tilde{c}_2}{k-2}+\tilde{N}+h'-wm+\frac{kw^2}{4}=1, \tag{A7}$$

where $\tilde{N}$ is the level inside the current algebra before the spectral flow, $\tilde{c}_2$ is the second casimir in terms of $\tilde{j}$ and h' is the conformal weight of state in the internal conformal theory (the internal piece needs not be a primary state, and we only require that the whole combined state needs to be primary). We can assume with no loss of generality that $w\geqslant 1$. Let us start with the spectral flow of a continuous representation, (A7) implies that if $m=0$ then $\tilde{N}=0$ and there are no negative norm states. (The only solution with $m=0$ is in the case of $k=3$ and $\tilde{j}=1/2$.)

Let us turn to lowest weight representations. Thanks to the restriction $0<\tilde{j}<k/2$, we have $\tilde{c}_2/(k-2)>-k/4$. Therefore, if $m=0$, the left-hand side of (A7) is larger than $k/4(w^2-1)$. If $w\geqslant 2$, (A7) cannot be obeyed. If $w=1$, $m=0$ implies $\tilde{m}=-k/2$ and $\tilde{N}$ in (A7) has to be at least $\tilde{N}\geqslant\tilde{j}+k/2$. However, in this case we find $\tilde{c}_2/(k-2)+\tilde{N}+k/4\geqslant k/2+\tilde{j}>1$ (here we used $k>2$) and again (A7) is not satisfied.

So we conclude that all states can be mapped into states obeying $J^3_{n>0}|\psi\rangle=0$.

APPENDIX B: PARTITION FUNCTION

In this Appendix, we discuss the partition function of the SL(2,R) WZW model and its modular invariance.

1. Partition function of the SU(2) model

Before we begin discussing the modular invariance of the SL(2,R) theory, let us review the case of SU(2).

The characters $\chi_l^k(\tau,\theta)$ $(l=0,\frac{1}{2},1,\ldots,k/2)$ of the irreducible representations of the $SU(2)_k$ affine algebra transform under the modular transformation as

$$\chi_l^k(-1/\tau,-\theta/\tau)=\exp\left(2\pi i\frac{k}{4}\frac{\theta^2}{\tau}\right)\sum_{l'}S_{ll'}\chi_{l'}^k(\tau,\theta), \tag{B1}$$

where $S_{ll'}$ is some orthonormal $(k+1)\times(k+1)$ matrix. The diagonal (so-called A_k-type) modular invariant combination is therefore

$$e^{-2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]}\sum_l|\chi_l(\tau,\theta)|^2. \tag{B2}$$

The exponential factor $e^{-2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\tau]}$ is there to cancel the exponential factor in (B1) as

$$\frac{[\mathrm{Im}(-\theta/\tau)]^2}{\mathrm{Im}(-1/\tau)}=\frac{(\mathrm{Im}\,\theta)^2}{\mathrm{Im}\,\tau}+i\frac{\theta^2}{2\tau}-i\frac{\bar{\theta}^2}{2\bar{\tau}}. \tag{B3}$$

It is known that the exponential factor in (B2) is a consequence of the chiral anomaly and therefore of the OPE singularity,

$$J^3(z)J^3(w)\sim\frac{k/2}{(z-w)^2}. \tag{B4}$$

2. Partition function of the SL(2,*C*)/SU(2) model

In string theory, one-loop computations are done after performing the Euclidean rotation on both the target space and the worldsheet (or stay in the Lorentzian signature space and use the $i\epsilon$ prescription). The modular invariance of the partition function is imposed on the Euclidean worldsheet. In our case, the Euclidean rotation of the target space means $\mathrm{SL}(2,R)\to H_3=\mathrm{SL}(2,C)/\mathrm{SU}(2)$. The partition function of the $\mathrm{SL}(2,C)/\mathrm{SU}(2)$ model has been evaluated in Ref. 18 as

$$Z_{\mathrm{SL}(2,C)/\mathrm{SU}(2)}\sim\frac{1}{\sqrt{\mathrm{Im}\,\tau}e^{[-2\pi(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]}|\vartheta_1(\tau,\theta)|^2}. \tag{B5}$$

Note that our definition of the partition function differs from that in Ref. 18 by the factor $e^{2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\tau]}$. It appears that, without this factor, the partition function is not modular invariant. (The puzzle about the apparent lack of the modular invariance was recently resolved in Ref. 42.) One may expect that this partition function is related to the one for the $\mathrm{SL}(2,R)$ model by the Euclidean rotation. In the discussion below, we first evaluate the $\mathrm{SL}(2,R)$ partition function on the Lorentzian torus, and therefore take $\tau,\bar{\tau},\theta,\bar{\theta}$ to be independent real variables. We then analytically continue them to complex values so that (τ,θ) are complex conjugate of $(\bar{\tau},\bar{\theta})$. We will find that, by doing this analytic continuation, and ignoring contact terms, the $\mathrm{SL}(2,R)$ partition function turns into the $\mathrm{SL}(2,C)/\mathrm{SU}(2)$ partition function (B5), provided we impose the constraint $1/2<j<(k-1)/2$ on the discrete representations.

3. Discrete representations of SL(2,*R*)

The character of the discrete representation D_j^+ is

$$\begin{aligned}\chi_j^+(\tau,\theta)&=\mathrm{Tr}(e^{2\pi i\tau(L_0-[k/8(k-2)])}e^{2\pi i\theta J_0^3})\\&=\frac{\exp\left[2\pi i\tau\left(-\frac{j(j-1)}{k-2}-\frac{k}{8(k-2)}\right)+2\pi i\theta j\right]}{(1-e^{2\pi i\theta})\Pi_{n=1}^{\infty}(1-e^{2\pi in\tau})(1-e^{2\pi in\tau}e^{2\pi i\theta})(1-e^{2\pi in\tau}e^{-2\pi i\theta})}\\&=\frac{\exp\left[-\frac{2\pi i\tau}{k-2}\left(j-\frac{1}{2}\right)^2+2\pi i\theta\left(j-\frac{1}{2}\right)\right]}{i\vartheta_1(\tau,\theta)},\end{aligned} \tag{B6}$$

where $\vartheta_1(\tau,\theta)$ is the elliptic theta-function,

$$\vartheta_1(\tau,\theta)=-i\sum_{n=-\infty}^{\infty}(-1)^n\exp\left[\pi i\tau\left(n-\frac{1}{2}\right)^2+2\pi i\theta\left(n-\frac{1}{2}\right)\right]. \tag{B7}$$

The spectral flow,

$$\tilde{L}_0 = L_0 + wJ_0^3 - \frac{k}{4}w^2, \quad \tilde{J}_0^3 = J_0^3 - \frac{k}{2}w, \quad (w = 0, \pm 1, \pm 2, \ldots), \tag{B8}$$

transforms the character χ_j^+ as

$$\begin{aligned}
&\mathrm{Tr}\left(e^{2\pi i\tau(\tilde{L}_0 - [k/8(k-2)])} e^{2\pi i\theta \tilde{J}_0^3}\right) \\
&= \mathrm{Tr}\left(e^{2\pi i\tau(L_0 + wJ_0^3 - (k/4)w^2 - [k/B(k-2)])} e^{2\pi i\theta(J_0^3 - (k/2)w)}\right) \\
&= \frac{\exp\left[-2\pi i\tau\left(\frac{\left(j-\frac{1}{2}\right)^2}{k-2} - w\left(j-\frac{1}{2}\right) + \frac{k}{4}w^2\right) + 2\pi i\theta\left(j-\frac{1}{2}-\frac{k}{2}w\right)\right]}{i\vartheta_1(\tau, \theta + w\tau)} \\
&= (-1)^w \frac{\exp\left[-\frac{2\pi i\tau}{k-2}\left(j-\frac{1}{2}-\frac{k-2}{2}w\right)^2 + 2\pi i\theta\left(j-\frac{1}{2}-\frac{k-2}{2}w\right)\right]}{i\vartheta_1(\tau, \theta)},
\end{aligned} \tag{B9}$$

where we used

$$\vartheta_1(\tau, \theta + w\tau) = (-1)^w \exp(-\pi i\tau w^2 - 2\pi i\theta w)\,\vartheta_1(\tau, \theta). \tag{B10}$$

We have also performed an analytic continuation such as

$$\sum_{n=0}^{\infty} q^n = -\sum_{n=1}^{\infty} q^{-n},$$

ignoring terms like $\Sigma_{n=-\infty}^{\infty} q^n \sim \delta(\tau)$. From here on, we allow $(\tau,\ \theta)$ to take complex values and $(\overline{\tau}, \overline{\theta})$ to be their complex conjugates.

Let us sum over allowed representation. According to our proposal about the Hilbert space of the WZW model, all the representations in the allowed range $1/2 < j < (k-1)/2$ should appear. We also require that the spectrum to be invariant under the spectral flow (B8), so we need to sum over w. The part of the partition function made by discrete representations is then

$$\begin{aligned}
&e^{+2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]} \sum_{w=-\infty}^{\infty} \int_{1/2}^{(k-1)/2} dj \\
&\quad \times \frac{\exp\left[\frac{4\pi\,\mathrm{Im}\,\tau}{k-2}\left(j-\frac{1}{2}-\frac{k-2}{2}w\right)^2 - 4\pi\,\mathrm{Im}\,\theta\left(j-\frac{1}{2}-\frac{k-2}{2}w\right)\right]}{|\vartheta_1(\tau, \theta)|^2} \\
&\quad = e^{+2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]} \int_{-\infty}^{\infty} dt\, \frac{\exp\left[\frac{4\pi\,\mathrm{Im}\,\tau}{k-2}t^2 - 4\pi\,\mathrm{Im}\,\theta t\right]}{|\vartheta_1(\tau, \theta)|^2} \\
&\quad \sim \frac{1}{\sqrt{\mathrm{Im}\,\tau}\, e^{-2\pi[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]} |\vartheta_1(\tau, \theta)|^2}.
\end{aligned} \tag{B11}$$

It is interesting to note that the j-integral over the range $1/2 < j < (k-1)/2$ and the sum over w fit together to give the t-integral over $-\infty < t < \infty$. Since the spectral flow with $w = 1$ maps D_j^+ to $D_{k/2-j}^-$, we do not have to consider the orbit of D_j^- separately. The exponential factor

$e^{+2\pi(k/2)[(\mathrm{Im}\,\theta)^2/(\mathrm{Im}\,\tau)]}$ is due to the chiral anomaly, as in the SU(2) case. The sign in the exponent is opposite here since the sign of the OPE of J^3 is opposite in the SL(2,R) case.

The partition function computed in (B11) is manifestly modular invariant. In fact, it is identical to (B12) computed for the SL(2,C)/SU(2) model. This gives an additional support for our claim that the Hilbert space of the SL(2,R) model contains the discrete representations of $1/2 < j < (k-1)/2$ and their spectral flow.

The construction of the partition function here is closely related to the one given in Ref. 13. There, instead of the integral over j in (B11), the partition function was given by a sum over integral values of j. This is because they considered the string theory on the single cover of the SL(2,R) group manifold with the closed timelike curve. The resulting partition function, after analytic continuation, is also modular invariant and appears to be a correct one for such a model. It is, however, different from the partition function (B15) of the SL(2,C)/SU(2) model, as it should since the Euclidean rotation of the SL(2,C)/SU(2) model is naturally related to the model on the universal cover of SL(2,R) rather than on its single cover.

4. Continuous representations

It is curious that the sum over the discrete representations and their spectral flow alone reproduces the partition function of the SL(2,C)/SU(2) model. In fact, the sum over the continuous representations and their spectral flow, although formally modular invariant by itself, does not contribute to the partition function if we assume the analytic continuation in $\tau, \overline{\tau}, \theta, \overline{\theta}$ and ignore contact terms.

The character of the continuous representation is parametrized by a pair of real numbers (s,α) with $0 \leqslant \alpha < 1$ and s arbitrary. The character is given by

$$\chi_{j=1/2+is,\alpha} = \eta^{-3} e^{2\pi i[s^2/(k-2)]\tau} e^{i\alpha\theta} \sum_n e^{2\pi i n\theta}. \tag{B12}$$

As before, we regard the worldsheet metric to be of the Minkowski signature, and θ is real. So the sum Σ_n in the definition of $\chi_{j,\alpha}$ gives the periodic delta-function,

$$\sum_n e^{2\pi i n\theta} = 2\pi \sum_m \delta(\theta + m). \tag{B13}$$

After the spectral flow (B8), the character becomes

$$\chi_{j=1/2+is,\alpha;w} = \eta^{-3} e^{2\pi i([s^2/(k-2)]+(k/4)w^2)\tau} 2\pi \sum_m e^{2\pi i m(\alpha-(k/2)w)} \delta(\theta + w\tau + m). \tag{B14}$$

Now let us take $|\chi_{1/2+is,\alpha;w}|^2$ and integrate over s and α. The integral over α forces $m_L = m_R$ in the summation in (B14). The integral over s gives the factor $1/\sqrt{\mathrm{Im}\,\tau}$. So we have

$$\int_{-\infty}^{\infty} ds \int_0^1 d\alpha |\chi_{1/2+is,\alpha;w}|^2 = e^{-4\pi\,\mathrm{Im}\,\tau(k/4)w^2} \frac{1}{\sqrt{\mathrm{Im}\,\tau}|\eta|^6} \sum_m \delta^{(2)}(\theta + w\tau + m). \tag{B15}$$

Let us sum this over w. We get a nonzero result only when there is some integer w such that

$$w = -\frac{\mathrm{Im}\,\theta}{\mathrm{Im}\,\tau}. \tag{B16}$$

Therefore

$$e^{+2\pi(k/2)[(\mathrm{Im}\,\theta)^2/\mathrm{Im}\,\tau]}\sum_w \int_{-\infty}^{\infty} ds \int_0^1 d\alpha |\chi_{1/2+is,\alpha;w}|^2 = \frac{1}{\sqrt{\mathrm{Im}\,\tau}|\eta|^6}\sum_{w,m} \delta^{(2)}(\theta + w\tau + m). \tag{B17}$$

This expression is formally modular invariant since $\Sigma_{w,m}$ sums over the modular orbit of the delta-function and $1/|\eta|^4$ cancels its modular weight. If we assume the analytic continuation, terms of this form are all set equal to zero. So, in this sense, the continuous representation does not contribute to the partition function of the SL(2,C)/SU(2) theory after the Euclidean rotation.

(Received 2 January 2001; accepted for publication 13 February 2001)

We consider the one-loop partition function for Euclidean BTZ black hole backgrounds or equivalently thermal AdS_3 backgrounds which are quotients of H_3 (Euclidean AdS_3). The one-loop partition function is modular invariant and we can read off the spectrum which is consistent to that found in hep-th/0001053. We see long strings and discrete states in agreement with the expectations. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377039]

I. INTRODUCTION

In this paper we continue the investigation started in Ref. 1 of the SL(2,R) WZW model describing string theory on $AdS_3 \times \mathcal{M}$. For other work on this model, see Ref. 2. Our motivation is to understand string theories in curved spacetimes where the metric component g_{00} is nontrivial, of which AdS_3 is the simplest example. Moreover, it is possible to construct black hole solutions as quotients of AdS_3,[3] so understanding string theory on AdS_3 would lead to an understanding of strings moving near black hole horizons.

In Ref. 1 the spectrum of the SL(2,R) WZW model was studied, using spectral flow to generate new representations from the standard ones. These new representations include states corresponding to long strings,[5,6] with a continuous energy spectrum, as well as discrete states. The existence of spectral flow as a symmetry of the theory was argued on the basis of classical and semi-classical analysis. Further support was given by the fact that the seemingly arbitrary upper bound on the mass of string states in AdS_3 was removed, thus recovering the infinite tower of masses one expects from string theory. We would like to verify these results by an explicit calculation of the one-loop partition function. As shown in Ref. 4, the Euclidean black hole background is equivalent to the thermal AdS_3 background. So we will consider string theory on AdS_3 at a finite temperature, which is described by strings moving on a Euclidean AdS_3 background with the Euclidean time identified. The calculation of the partition function for this geometry is a minor variation on the calculation of Gawedzki in Ref. 7. From this we can read off the spectrum of the theory in Lorentzian signature by interpreting the result as the free energy of a gas of strings.

This paper is organized as follows. In Sec. II we review the spectrum found in Ref. 1. In Sec. III we compute the one-loop partition function on thermal AdS_3. In Sec. IV we read off the spectrum from the one-loop calculation. First we present a qualitative analysis, which is then followed by a precise calculation. We explain how the different parts of the spectrum arise from

this calculation. We further show how the one-loop result contains information about the SL(2,R) and Liouville reflection amplitudes.

II. THE SPECTRUM

We begin by briefly summarizing the results of Ref. 1, where a concrete proposal for the spectrum of AdS_3 string theory was made. We consider a critical bosonic string theory on $AdS_3 \times \mathcal{M}$. The Hilbert space of the SL(2,R) WZW model is generated by the action of the left-moving and right-moving current algebra $\widehat{\mathrm{SL}(2,R)}_L \times \widehat{\mathrm{SL}(2,R)}_R$, and all the states form representations of this algebra. The simplest representations are built by first choosing representations for the zero modes, then regarding them as the primary states annihilated by $J^{3,\pm}_{n>0}$. The raising operators $J^{3,\pm}_{n<0}$ are then used to generate the representations of the current algebra. From harmonic analysis, i.e. quantum mechanical limit, it is known that the left–right symmetric combinations $\mathcal{C}^{\alpha}_{j=1/2+is} \times \mathcal{C}^{\alpha}_{j=1/2+is}$ and $\mathcal{D}^{\pm}_{j>1/2} \times \mathcal{D}^{\pm}_{j>1/2}$ form a complete basis in $\mathcal{L}^2(AdS_3)$, where $\mathcal{C}^{\alpha}_{j=1/2+is}$ is the principal continuous representation and $\mathcal{D}^{\pm}_{j>1/2}$ the principal discrete representation of SL(2,R). These representations are unitary, but the resulting current algebra representations $\hat{\mathcal{C}}^{\alpha}_{j=1/2+is} \times \hat{\mathcal{C}}^{\alpha}_{j=1/2+is}$ and $\hat{\mathcal{D}}^{\pm}_{j>1/2} \times \hat{\mathcal{D}}^{\pm}_{j>1/2}$, constructed as explained above, are not. This is not a surprise, for even in flat Minkowski space it is not until one imposes the Virasoro constraints,

$$(L_n + \mathcal{L}_n - \delta_{n,0})|\mathrm{physical}\rangle = 0, \quad n \geqslant 0, \tag{1}$$

that a unitary spectrum is obtained. Here $\mathcal{L}_n$ is the Virasoro generator for the internal conformal field theory corresponding to $\mathcal{M}$. The proposal of Ref. 1 is that one should consider not just these representations but also those obtained by the spectral flow

$$\begin{aligned} J^3_n &\to \tilde{J}^3_n = J^3_n - \frac{k}{2} w \delta_{n,0}, \\ J^+_n &\to \tilde{J}^+_n = J^+_{n+w}, \\ J^-_n &\to \tilde{J}^-_n = J^-_{n-w}. \end{aligned} \tag{2}$$

The Virasoro generators, given by the Sugawara form, then become $\tilde{L}_n = L_n + w J^3_n - k/4 w^2 \delta_{n,0}$. Imposing on $\hat{\mathcal{D}}^{\pm}_{j>1/2} \times \hat{\mathcal{D}}^{\pm}_{j>1/2}$ the condition (1) with $\tilde{L}_n$ one finds that these states have a discrete energy spectrum,

$$\begin{aligned} E &= J^3_0 + \overline{J}^3_0 = q + \overline{q} + kw + 2\tilde{j} \\ &= 1 + q + \overline{q} + 2w + \sqrt{1 + 4(k-2)(N_w + h - 1 - \tfrac{1}{2} w(w+1))}; \end{aligned} \tag{3}$$

here N_w is defined to be the level of the current algebra after spectral flow by the amount w, $N_w = \tilde{N} - wq$, and $\tilde{N}$ is the level before spectral flow. The state with energy (3) is obtained from a lowest weight state by acting with the SL(2,R) currents $\Pi \tilde{J}^{\pm}_{n \leqslant 0} |\tilde{j}, \tilde{j}\rangle$, with q the net number of $\pm$ signs in this expression. In other words, q is the number of spacetime energy raising operators J^+_a minus the number of spacetime energy lowering operators J^-_a that we have to apply to the lowest weight, lowest energy state $|\tilde{j}, m = \tilde{j}\rangle$ to get to the state whose spacetime energy is (3). $\overline{q}$ is the corresponding quantity for the generators $\overline{J^{\pm}_a}$. We also have a level matching condition of the form

$$N_w + h = \overline{N}_w + \overline{h}, \tag{4}$$

which implies that the angular momentum in AdS_3, $l=J_0^3-\overline{J}_0^3=q-\overline{q}$, is an integer. We argued in Ref. 1 that $\tilde{j}$ is further restricted to the range

$$\frac{1}{2}<\tilde{j}<\frac{k-1}{2}, \tag{5}$$

which implies

$$\frac{k}{4}w^2+\frac{1}{2}w<N_w+h-1+\frac{1}{4(k-2)}<\frac{k}{4}(w+1)^2-\frac{1}{2}(w+1). \tag{6}$$

A similar analysis on $\hat{\mathcal{C}}^{\alpha}_{j=1/2+is}\times\hat{\mathcal{C}}^{\alpha}_{j=1/2+is}$ yields a continuous spectrum,

$$E=\frac{k}{2}w+\frac{1}{w}\left(\frac{2s^2+\frac{1}{2}}{k-2}+\tilde{N}+h+\tilde{\bar{N}}+\overline{h}-2\right), \tag{7}$$

where s takes values over the real numbers and is interpreted as the momentum in the radial direction for the long strings. These states satisfy the level matching condition

$$\tilde{N}+h=\tilde{\bar{N}}+\overline{h}+w\times(\text{integer}). \tag{8}$$

In the rest of the paper we will do an independent calculation which will reproduce this single string spectrum.

III. ONE-LOOP PARTITION FUNCTION

In this section we compute the worldsheet one-loop partition function. First we explain the relation between various useful coordinate systems. Then we consider thermal $AdS_3=H_3/Z$ and show how the identification of Euclidean time in the global coordinates translates into particular boundary conditions for the target space fields. The partition function is then calculated by an explicit evaluation of the functional integral following Ref. 7.

A. Coordinates on H_3 and thermal AdS_3

The natural metric on H_3 is given by

$$ds^2=\frac{k}{y^2}(dy^2+dw\,d\overline{w}), \tag{9}$$

which is the Euclidean continuation of the Poincaré metric on AdS_3. By the coordinate transformation,

$$w=\tanh\rho e^{t+i\theta},\quad \overline{w}=\tanh\rho e^{t-i\theta},\quad y=\frac{e^t}{\cosh\rho}, \tag{10}$$

we obtain the cylindrical coordinates on Euclidean AdS_3,

$$\frac{ds^2}{k}=\cosh^2\rho\,dt^2+d\rho^2+\sinh^2\rho\,d\theta^2. \tag{11}$$

For the purpose of calculating the partition function, however, it is convenient to use coordinates in which the metric reads[7] as

$$\frac{ds^2}{k}=d\phi^2+(dv+v\,d\phi)(d\overline{v}+\overline{v}\,d\phi), \tag{12}$$

which corresponds to the parametrization of H_3 as

$$g=\begin{bmatrix} e^{\phi}(1+|v|^2) & v \\ \overline{v} & e^{-\phi} \end{bmatrix}. \tag{13}$$

The coordinate transformation from (11) to (12) is

$$\begin{aligned} v &= \sinh\rho e^{i\theta} \\ \overline{v} &= \sinh\rho e^{-i\theta} \\ \phi &= t-\log\cosh\rho. \end{aligned} \tag{14}$$

Thermal AdS_3 is given by the identification

$$t+i\theta\sim t+i\theta+\hat{\beta}, \tag{15}$$

where $\hat{\beta}$ represents the temperature T and the imaginary chemical potential $i\mu$ for the angular momentum,

$$\hat{\beta}=\beta+i\mu\beta=\frac{1}{T}+i\frac{\mu}{T}. \tag{16}$$

The corresponding identifications in the coordinates (12) are

$$\begin{aligned} v &\sim v e^{i\mu\beta} \\ \overline{v} &\sim \overline{v} e^{-i\mu\beta} \\ \phi &\sim \phi+\beta, \end{aligned} \tag{17}$$

which is a consistent symmetry of the WZW action,

$$S=\frac{k}{\pi}\int d^2z(\partial\phi\,\overline{\partial}\phi+(\partial\overline{v}+\partial\phi\,\overline{v})(\overline{\partial}v+\overline{\partial}\phi v)). \tag{18}$$

B. Computation of the partition function on thermal AdS_3

In this subsection we compute the partition function for string theory on thermal AdS_3. We consider a conformal field theory on a worldsheet torus with modular parameter τ ($z\sim z+2\pi\sim z+2\pi\tau$). The two-dimensional conformal field theory on the worldsheet is the sum of three parts: the conformal field theory on H_3, the internal conformal field theory on $\mathcal{M}$, and the (b, c) ghosts. First we start with the computation of the partition function for the conformal field theory describing the three dimensions of thermal AdS_3 and then we will multiply the result by the partition function of the ghosts and the internal conformal field theory.

Due to the identification (17), the string coordinates now satisfy the following boundary conditions:

$$\begin{aligned} &\phi(z+2\pi)=\phi(z)+\beta n, \quad \phi(z+2\pi\tau)=\phi(z)+\beta m, \\ &v(z+2\pi)=v(z)e^{in\mu\beta}, \quad v(z+2\pi\tau)=v(z)e^{im\mu\beta}. \end{aligned} \tag{19}$$

The thermal circle is noncontractible and therefore we get two integers (n,m) characterizing topologically nontrivial embeddings of the worldsheet in spacetime. In order to implement these boundary conditions it is convenient to define new fields $\hat{\phi},\hat{v}$ such that they are periodic:

$$\phi=\hat{\phi}+\beta f_{n,m}(z,\bar{z}),$$
$$v=\hat{v}\,\exp(i\mu\beta f_{n,m}(z,\bar{z})), \tag{20}$$

with

$$f_{n,m}(z,\bar{z})=\frac{i}{4\pi\tau_2}[z(n\bar{\tau}-m)-\bar{z}(n\tau-m)]. \tag{21}$$

When we substitute this into the action (18), we get

$$S=\frac{k\beta^2}{4\pi\tau_2}|n\tau-m|^2+\frac{k}{\pi}\int d^2z\left(|\partial\hat{\phi}|^2+\left|\left(\partial+\frac{1}{2\tau_2}U_{n,m}+\partial\hat{\phi}\right)\hat{\bar{v}}\right|^2\right), \tag{22}$$

where

$$U_{n,m}(\tau)=\frac{i}{2\pi}(\beta-i\mu\beta)(n\bar{\tau}-m). \tag{23}$$

We are interested in the functional integral

$$\mathcal{Z}(\beta,\mu;\tau)=\int \mathcal{D}\phi\,\mathcal{D}\bar{v}\,e^{-S}. \tag{24}$$

This integral is evaluated as explained in Ref. 7. We can first do the integral over $\hat{v},\hat{\bar{v}}$ which is quadratic, giving the determinant

$$\det\left|\partial+\frac{1}{2\tau_2}U_{n,m}+\partial\hat{\phi}\right|^{-2}. \tag{25}$$

We calculate the $\hat{\phi}$ dependence on the determinants by realizing that we can view (25) as an inverse of two fermion determinants. We can then remove $\hat{\phi}$ from the determinants by a chiral gauge transformation and using the formulas for chiral anomalies. The result is

$$\det\left|\partial+\frac{1}{2\tau^2}U_{n,m}+\partial\hat{\phi}\right|^{-2}=e^{2/\pi\int d^2z\,\partial\hat{\phi}\tilde{\partial}\hat{\phi}}\det\left|\partial+\frac{1}{2\tau^2}U_{n,m}\right|^{-2}. \tag{26}$$

The remaining integral over $\hat{\phi}$ gives the usual result for a free boson, except that $k\to k-2$ due to (26). The functional integral for the thermal AdS_3 partition function then gives

$$\begin{aligned}\mathcal{Z}(\beta,\mu;\tau)&=\frac{\beta(k-2)^{1/2}}{8\pi\sqrt{\tau_2}}\\&\quad\times\sum_{n,m}\frac{e^{-k\beta^2|m-n\tau|^2/4\pi\tau_2+2\pi(\mathrm{Im}\,U_{n,m})^2/\tau_2}}{|\sin(\pi U_{n,m})|^2|\Pi_{r=1}^{\infty}(1-e^{2\pi ir\tau})(1-e^{2\pi ir\tau}+2\pi iU_{n,m})(1-e^{2\pi ir\tau-2\pi iU_{n,m}})|^2}\\&=\frac{\beta(k-2)^{1/2}}{2\pi\sqrt{\tau_2}}(q\bar{q})^{-3/24}\sum_{n,m}\frac{e^{-k\beta^2|m-n\tau|^2/4\pi\tau_2+2\pi/(\mathrm{Im}\,U_{n,m})^2/r_2}}{|\vartheta_1(\tau,U_{n,m})|^2},\end{aligned} \tag{27}$$

where ϑ_1 is the elliptic theta function and $q=e^{2\pi i\tau}$. The factor $\beta(k-2)^{1/2}$ comes from the length of the circle in the ϕ direction. This partition function is explicitly modular invariant after summing over (n, m). [In our previous paper, there was a puzzle about the apparent lack of modular invariance of the SL(2,R) partition functions with J^3 insertions (see Appendix B of Ref. 1). Here

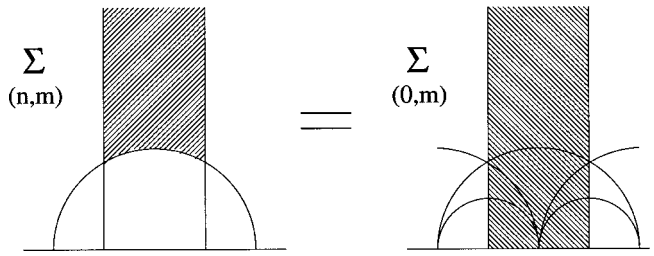

FIG. 1. The sum over n is traded for the sum over copies of the fundamental domain.

we have found that, if we introduce the twist by considering the physical set-up of thermal AdS_3, the result (27) turns out to be manifestly modular invariant. This resolves the puzzle raised in Ref. 1.]

We also need to include the contribution of the (b, c) ghosts and the internal CFT. A partition function of the latter will be of the form

$$\mathcal{Z}_{\mathcal{M}}=(q\bar{q})^{-c_{\rm int}/24}\sum_{h,\bar{h}} D(h,\bar{h})q^h\bar{q}^{\bar{h}}, \tag{28}$$

where $D(h,\bar{h})$ is the degeneracy at left-moving weight h and right-moving weight $\bar{h}$, and $c_{\rm int}$ is the central charge of the internal CFT. Modular invariance requires that $h-\bar{h}\in Z$, a fact which will be useful in the next section. Vanishing of the total conformal anomaly gives

$$c_{\mathrm{SL}(2,R)}+c_{\rm int}=26. \tag{29}$$

We can calculate now the total contribution to the ground state energy. We found a ground state energy of $-3/24$ in (27), the ghosts contribute with $2/24$ and the internal CFT with $-c_{\rm int}/24=(c_{\mathrm{SL}(2,R)}-26)/24$. Using $c_{\mathrm{SL}(2,R)}=3+6/(k-2)$, we find the overall factor,

$$(q\bar{q})^{-(1+c_{\rm int})/24}=e^{4\pi\tau_2(1-1/4(k-2))}. \tag{30}$$

[Note that $c_{\rm int}\geqslant 0$, $k>2$, and (29) imply that there will always be a tachyon in the theory.]

After multiplying (27) by the (b, c) ghosts and the internal CFT partition functions, we should integrate the resulting expression over the fundamental domain F_0 of the modular parameter τ. The computation is much facilitated by the trick invented in Ref. 8 to trade the sum over n in (27) for the sum over copies of the fundamental domain. See Fig. 1. This is possible since (n, m) transforms as a doublet under the modular group $\mathrm{SL}(2,Z)$. If $(n,m)\neq(0,0)$, it can be mapped by an $\mathrm{SL}(2,Z)$ transformation to $(0,m), m>0$. The $\mathrm{SL}(2,Z)$ transformation also maps the fundamental domain into the strip $\mathrm{Im}\,\tau\geqslant 0$, $|\mathrm{Re}\,\tau|\leqslant 1/2$. On the other hand, $(n,m)=(0,0)$ is invariant under the $\mathrm{SL}(2,Z)$ transformation, and the corresponding term still has to be integrated over the fundamental domain F_0. This term represents the zero temperature contribution to the cosmological constant, or the zero temperature vacuum energy. In addition to the usual tachyon divergence of bosonic string theory at large τ_2, it is also divergent due to the $\sin^{-1}$ factor in (27); this divergence can be interpreted as coming from the infinite volume of AdS_3. Since the temperature dependence of this term is trivial we will ignore it from now on. The final result then is that we fix $n=0$ in (27) and we integrate over the entire strip shown in Fig. 1. The one-loop partition function of bosonic string theory on $H_3/Z\times\mathcal{M}$ is then

$$Z(\beta,\mu)=\frac{\beta(k-2)^{1/2}}{8\pi}\int_0^\infty\frac{d\tau_2}{\tau_2^{3/2}}\int_{-1/2}^{1/2}d\tau_1\,e^{4\pi\tau_2(1-1/4(k-2))}\sum_{h,\bar{h}}D(h,\bar{h})q^h\bar{q}^{\bar{h}}$$
$$\times\sum_{m=1}^\infty\frac{e^{-(k-2)m^2\beta^2/4\pi\tau_2}}{|\sinh(m\hat{\beta}/2)|^2}\left|\prod_{n=1}^\infty\frac{1-e^{2\pi in\tau}}{(1-e^{m\hat{\beta}+2\pi in\tau}(1-e^{-m\hat{\beta}+2\pi in\tau})}\right|^2. \tag{31}$$

IV. READING OFF THE SPECTRUM

We will now extract the spectrum of Lorentzian string theory on AdS_3 by interpreting the one-loop partition function in the spacetime theory. The one-loop partition function is the single particle contribution to the spacetime thermal free energy, $Z(\beta,\mu)=-\beta F$. To this each string state makes a contribution $\beta^{-1}\log(1-e^{-\beta(E+i\mu l)})$, where E and l are the energy and the angular momentum of the state. The total free energy is the sum over all such factors:

$$F(\beta,\mu)=\frac{1}{\beta}\sum_{\text{string}\in\mathcal{H}}\log(1-e^{-\beta(E_{\text{string}}+i\mu l_{\text{string}})})=\sum_{m=1}^\infty f(m\beta,m\mu), \tag{32}$$

where

$$f(\beta,\mu)=\frac{1}{\beta}\sum_{\text{string}\in\mathcal{H}}e^{-\beta(E_{\text{string}}+i\mu l_{\text{string}})}. \tag{33}$$

Here $\mathcal{H}$ is the physical Hilbert space of single string states. In both (31) and (32), we have the sums over functions of $(m\beta,m\mu)$. It is therefore sufficient to compare the $m=1$ terms in these expressions. In other words, we want to verify that E_{string} and l_{string} extracted from the identification,

$$f(\beta,\mu)=\sum_{\text{string}\in\mathcal{H}}\frac{1}{\beta}e^{-\beta(E_{\text{string}}+i\mu l_{\text{string}})}$$
$$=\frac{(k-2)^{1/2}}{8\pi}\int_0^\infty\frac{d\rho_2}{\tau_2^{3/2}}\int_{-1/2}^{1/2}d\tau_1\,e^{4\pi\tau_2(1-1/4(k-2))}\sum_{h,\bar{h}}D(h,\bar{h})q^h\bar{q}^{\bar{h}}$$
$$\times\frac{e^{-(k-2)\beta^2/4\pi\tau_2}}{|\sinh(\hat{\beta}/2)|^2}\left|\prod_{n=1}^\infty\frac{1-e^{2\pi in\tau}}{(1-e^{\hat{\beta}+2\pi in\tau})(1-e^{-\hat{\beta}+2\pi in\tau})}\right|^2, \tag{34}$$

agree with the string spectrum found in our previous paper.[1] We will see that the sum over the Hilbert space breaks up into a sum over the discrete states and an integral over the continuous states, with the expressions for the energies that were reviewed in Sec. II. Since the one-loop calculation presented here is independent of the assumptions made in Ref. 1 about strings in Lorentzian AdS_3, we can regard this as a derivation of the spectrum starting from the well-defined Euclidean path integral.

A. Qualitative analysis

In this subsection we will analyze (34) in a qualitative way and explain where the different contributions to the spectrum come from. To keep the notation simple, we set $\mu=0$ in this subsection, leaving the exact computation for the next subsection.

As expected, in (34) there is an exponential divergence as $\tau_2\to\infty$, coming from the tachyon. This is just as in the flat space case, where $(\text{mass})^2<0$ of the tachyon causes its contribution to be weighted with a positive exponential. We will disregard this divergence. [A skeptical reader could think that we are really doing the superstring partition function (the fermions included in the internal CFT, etc.). Then the tachyon divergence will disappear but one would still find the

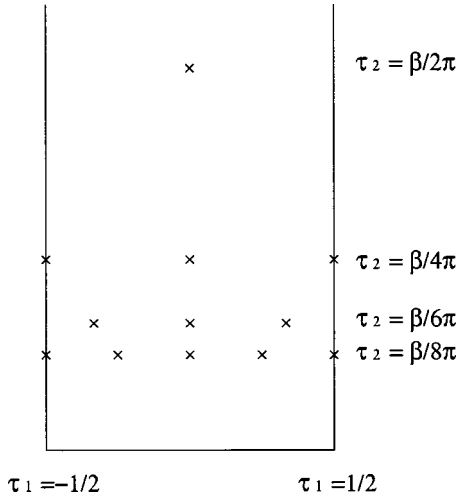

FIG. 2. Poles in the τ-plane, shown for $w=1$ to 4.

divergences that we discuss below. Of course, the one-loop partition function is nonvanishing even in the supersymmetric case since the thermal boundary conditions break supersymmetry.] However, rather unexpectedly, the expression above has additional divergences at finite values of τ. In string theory one might naively expect that divergences come only from the corners of the fundamental domain in the τ-plane, but in this case the divergence is coming from points in the interior of the fundamental domain. Overcoming the initial panic, one realizes that these divergences are related to the presence of long strings. In fact, as with any other string divergence, it can be interpreted as an IR effect. This divergence is due to the fact that long strings feel a flat potential as they go to infinity and therefore we get an infinite volume factor. To see this, note that near the pole (see Fig. 2),

$$\tau=\tau_{\text{pole}}+\epsilon, \tag{35}$$

where

$$\tau_{\text{pole}}=\frac{r}{w}+i\frac{\beta}{2\pi w}, \tag{36}$$

we can expand the partition function and replace τ in all terms by its value at the pole, except in the one term that has the pole. If we integrate (34) near the pole, i.e. in the region $\epsilon<|\tau-\tau_{\text{pole}}|\ll 1$, we find that it diverges as $\log\epsilon$ with the coefficient

$$\frac{1}{\sqrt{w\beta^3}}\exp\left[-\beta\left(\frac{k}{2}w+\frac{1}{w}\left(\tilde{N}+h+\tilde{\bar{N}}+\bar{h}-2+\frac{1}{2(k-2)}\right)\right)+\frac{2\pi i r}{w}(\tilde{N}+h-\tilde{\bar{N}}-\bar{h})\right]. \tag{37}$$

We now sum over r, with $|r/w|\leqslant 1/2$, since these are the ones corresponding to the poles in the strip. (If some poles are on the boundaries of the strip, $\tau_1=\pm 1/2$, then we only count them once.) This sum constrains $\tilde{N}+h-\tilde{\bar{N}}-\tilde{h}$ to be an integer multiple of w, as in (8), and it introduces an additional factor of w in (37). The log divergence in the τ-integral can therefore be expressed as

$$f(\beta,\mu)\sim\frac{1}{\beta}\log\epsilon\int_0^\infty ds\, e^{-\beta E(s)}+\cdots, \tag{38}$$

where $E(s)$ is the energy spectrum given by (7). Note that the s-integral and the sum over r we mentioned above give the factor $\sqrt{w/\beta}$ needed to match the prefactor in (37) to that in (38). This

reproduces the expected contribution from the long strings on the left hand side of (34). The logarithmic divergence should be interpreted as a volume factor due to the fact that the long string can be at any radial position. In the next subsections, we will see more precisely that it is indeed associated to the infinite volume in spacetime by relating ϵ to a long distance cutoff.

Now we would like to calculate the short string spectrum. Since the long string spectrum gives a divergent result, while the short string spectrum gives a finite one, it might appear at first that extracting the contributions due to the short strings from a divergent expression such as (34) will be problematic. Fortunately we can get around this difficulty since the temperature dependence of the long string free energy is different from that of the short string free energy. In the next subsection we will explain how to do this precisely and reproduce the short string spectrum which agrees with Ref. 1. One of the more puzzling aspects of the short string spectrum found there is that there is a cutoff $1/2<\tilde{j}<(k-1)/2$ in the value of the SL(2,R) spin $\tilde{j}$. In the remainder of this section we will explain in a qualitative way how this cutoff arises by doing the calculation for large k.

If we were to evaluate the right hand side of (34) naively (and incorrectly), we would expand the integrand in powers of $q=e^{2\pi i\tau}$ and then perform the τ-integral. If we did this, we would obtain the short string spectrum with $w=0$ and no upper bound on the value of $\tilde{j}$. However this expansion is not correct. How we can expand the integrand in (34) depends on the value of τ_2. When we cross the poles at $\tau_2=\beta/2\pi w$, a different expansion should be used for the denominator:

$$\frac{1}{1-e^{\beta+2\pi i w\tau}}=\sum_{q=0}^{\infty} e^{q(\beta+2\pi i w\tau)}\left(\tau_2>\frac{\beta}{2\pi w}\right),$$
$$=-\sum_{q=0}^{\infty} e^{-(q+1)(\beta+2\pi i w\rho)}\left(\tau_2<\frac{\beta}{2\pi w}\right). \tag{39}$$

When τ_2 is in the range

$$\frac{\beta}{2\pi(w+1)}<\tau_2<\frac{\beta}{2\pi w}, \tag{40}$$

the product over n in the first term in the denominator in (34) is broken up into two factors, a product in $1\leqslant n\leqslant w$ and a product in $w+1\leqslant n$. The first factor is expanded in powers of $e^{(-\beta+2\pi i n\tau)}$ and the second factor is expanded in powers of $e^{\beta+2\pi i n\tau}$. Combining them together with the terms coming from the expansion of the remaining products in (34), we get an exponent of the form[6]

$$-(\tfrac{1}{2}+q+w)\beta+2\pi i\tau(N_w-\tfrac{1}{2}w(w+1)), \tag{41}$$

for some integers q and N_w. [The first term $-\beta/2$ comes from expanding $1/\sinh(\beta/2)$ in (34).] There is a similar term for $\tau\to\bar{\tau}$. We are then to do the τ-integral of the form

$$\int \frac{d^2\tau}{\tau_2^{3/2}}$$
$$\times e^{4\pi\tau_2(1-1/4(k-2))-(k-2)(\beta^2/4\pi\tau_2)-\beta(1+q+\bar{q}+2w)+2\pi i\tau(N_w+h-(1/2)w(w+1))-2\pi i\bar{\tau}(\bar{N}_w+\bar{h}-(1/2)w(w+1))}, \tag{42}$$

over the region (40). The integral over τ_1 produces the level matching condition (4). Now we evaluate the integral over τ_2 using the saddle point approximation. We find that the saddle point is at

$$\tau_{\rm saddle}=\frac{(k-2)\beta}{2\pi\sqrt{1+4(k-2)(N_w+h-1-\frac{1}{2}w(w+1))}}, \tag{43}$$

and the integral gives

$$\frac{1}{\beta}\exp\left[-\beta\left(1+q+\bar{q}+2w+\sqrt{1+4(k-2)\left(N_w+h-1-\frac{1}{2}w(w+1)\right)}\right)\right]. \tag{44}$$

This is the correct form of the contributions due to the short strings on the left hand side of (34). Moreover we obtain the bound on $\tilde{j}$ precisely, because $\tau_{\rm saddle}$ has to be in the range (40) in order for the saddle point approximation to give a nonzero result. By (43), this condition is the same as the bound on the spectrum (6), which is equivalent to $1/2<\tilde{j}<(k-1)/2$. (It is a bit surprising that we get all factors precisely right from the saddle point approximation.) Notice then that the cutoff in $\tilde{j}$ is associated to the fact that we expand the integrand in (34) in different ways depending on the value of τ. The value of τ making the biggest contribution to the integral depends on the values of N and h of the string state.

B. A precise evaluation of the τ-integral

Now let us study the partition function (34) more systematically. In this subsection, we go back to the general case with $\mu\neq 0$. From what we saw in the previous subsection, we expect to find the discrete states from the integral over the range (40), and the continuous states from the poles after a suitable regularization.

In order to evaluate the τ-integral exactly, it is useful to introduce a new variable c by

$$e^{-(k-2)(\beta^2/4\pi\tau_2)}=-\frac{8\pi i}{\beta}\left(\frac{\tau_2}{k-2}\right)^{3/2}\int_{-\infty}^{\infty}dc\;\; ce^{-[4\pi\tau_2/(k-2)]c^2+2i\beta c}. \tag{45}$$

Now suppose τ_2 is in the range

$$\frac{\beta}{2\pi(w+1)}<\tau_2<\frac{\beta}{2\pi w}, \tag{46}$$

and expand the integrand in (34) as explained in the previous subsection. The right hand side of (34) becomes a sum of terms like

$$\frac{4}{\beta(k-2)i}\int_{-\infty}^{\infty}dc\;\; c\int_{\beta/2\pi(w+1)}^{\beta/2\pi w}d\tau_2\int_{-1/2}^{1/2}d\tau_1\exp\left[-\hat{\beta}\left(q+w+\frac{1}{2}\right)-\hat{\bar{\beta}}\left(\bar{q}+w+\frac{1}{2}\right)\right.$$
$$\left.+2\pi i\tau_1(N_w+h-\bar{N}_w-\bar{h})+2ic\beta-2\pi\tau_2\left(h+\bar{h}+N_w+\bar{N}_w+\frac{2c^2+\frac{1}{2}}{k-2}-w(w+1)-2\right)\right]. \tag{47}$$

The integral over τ_1 gives a delta function enforcing $N_w+h=\bar{N}_w+\bar{h}$, which is the level-matching condition (4). Integrating over τ_2 in the range (46) gives

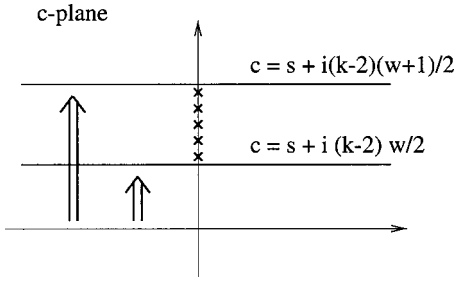

FIG. 3. Shifting the contour of integration picks up the pole residues corresponding to the short string spectrum.

$$\frac{1}{\beta\pi i}\int_{-\infty}^{\infty} dc\ \ c\,\frac{\exp[2ic\beta-\hat{\beta}(q+w+\frac{1}{2})-\hat{\bar{\beta}}(\bar{q}+w+\frac{1}{2})]}{c^2+\frac{1}{4}+(k-2)(N_w+h-1-\frac{1}{2}w(w+1))}$$
$$\times\left\{-\exp\left[-\frac{\beta}{w}\left(2N_w+2h-2+\frac{2c^2+\frac{1}{2}}{k-2}-w(w+1)\right)\right]\right.$$
$$\left.+\exp\left[-\frac{\beta}{w+1}\left(2N_w+2h-2+\frac{2c^2+\frac{1}{2}}{k-2}-w(w+1)\right)\right]\right\}, \tag{48}$$

where we used (4).

Let us first look at the first term (the second line) in (48). We note that the exponent can be expressed in the form of a complete square if we set $c=s+(i/2)(k-2)w$. As it will become clear shortly, it is natural to shift the contour of the c-integral from $\mathrm{Im}\,c=0$ to $\mathrm{Im}\,c=1/2(k-2)w$ so that s becomes real. During this process the contour crosses some poles in the integrand, picking up the residues of the poles in the range $0<\mathrm{Im}\,c<1/2(k-2)w$. See Fig. 3. The poles are located at

$$-\frac{c^2}{(k-2)}=N_w+h-\frac{1}{2}w(w+1)-1+\frac{1}{4(k-2)}<\frac{k-2}{4}w^2. \tag{49}$$

Similarly, for the second exponential term (the third line) in (48) we shift the contour to $c=s+(i/2)(k-2)(w+1)$ with s real. This picks up the poles at

$$-\frac{c^2}{(k-2)}=N_w+h-\frac{1}{2}w(w+1)-1+\frac{1}{4(k-2)}<\frac{k-2}{4}(w+1)^2. \tag{50}$$

It is important to note that the residues of these poles have a sign opposite to that of the residues of the poles obeying (49). So the result is that we are left with only those poles in the range

$$\frac{k-2}{2}w<\mathrm{Im}\,c<\frac{k-2}{2}(w+1), \tag{51}$$

with residues

$$\frac{1}{\beta}\exp[-\hat{\beta}q-\hat{\bar{\beta}}\bar{q}-\beta(1+2w+\sqrt{1+4(k-2)(N_w+h-1-\tfrac{1}{2}w(w+1))})]. \tag{52}$$

This is the expected contribution of the short strings to the right hand side of (34), and we see also that (51) translates into the correct bound on $\tilde{j}$ (5).

It remains to examine the resulting integral over s. Notice that the term coming from just above the pole at $\tau=\hat{\beta}/2\pi w$ has a very similar w dependence in the exponent as that coming from

just below the pole. In other words, we combine the first term of (48) with the second term of an expression similar to (48) but with $w\to w-1$ and we find, after shifting the contours as above,

$$\frac{1}{2\pi i\beta}\int_{-\infty}^{\infty}ds\left(\frac{2s}{w(k-2)}+i\right)\left(\frac{\exp\left[-\hat{\beta}q-\hat{\bar{\beta}}\bar{q}-\beta\left(\frac{k}{2}w+\frac{2}{w}\left(\frac{s^2+1/4}{k-2}+N_{w-1}+h-1\right)\right)\right]}{\frac{1}{2}+is-\frac{k}{4}w+\frac{1}{w}\left(N_{w-1}+h-1+\frac{s^2+1/4}{k-2}\right)}\right.$$
$$\left.-\frac{\exp\left[-\hat{\beta}q-\hat{\bar{\beta}}\bar{q}-\beta\left(\frac{k}{2}w+\frac{2}{w}\left(\frac{s^2+1/4}{k-2}+N_{w}+h-1\right)\right)\right]}{-\frac{1}{2}+is-\frac{k}{4}w+\frac{1}{w}\left(N_{w}+h-1+\frac{s^2+1/4}{k-2}\right)}\right). \tag{53}$$

Let us concentrate for now on the third line of (53). We first note that the sum of such terms over all states gives rise to the log divergence. To see this, it is useful to notice that the combinations

$$\tilde{N}=qw+N_w,\quad \tilde{\bar{N}}=\bar{q}w+\bar{N}_w, \tag{54}$$

that appear in the exponent of the third line of Eq. (53) are the levels before spectral flow. Thus, for a given state $|\psi\rangle$, states of the form $(\tilde{J}_0^+\tilde{\bar{J}}_0^+)^n|\psi\rangle$ all have the same value of $\tilde{N}$ and $\tilde{\bar{N}}$. Acting with $\tilde{J}_0^+\tilde{\bar{J}}_0^+$ on $|\psi\rangle$ does not change the exponent in (53), but it does change the denominator by one. This implies that when we sum over all the states of this type, we will find a divergent sum of the form

$$\sum_{n=0}^{\infty}\frac{1}{A-n}.$$

This divergence has the same origin as the divergence of the right hand side of (34) at the pole $\tau_{\rm pole}=\hat{\beta}/2\pi w$. In fact, if we regularize the τ-integral by removing a small region near the pole as $|\tau-\tau_{\rm pole}|>\epsilon$, we find an additional factor $e^{-n\epsilon}$ in the sum. In the next subsection, we will give the spacetime interpretation of this procedure. With this regularization, the sum behaves as $\log\epsilon$. More precisely we have

$$-\sum_{n=0}^{\infty}\frac{1}{A-n}e^{-n\epsilon}=\log\epsilon+\frac{d}{dA}\log\Gamma(-A)+\mathcal{O}(\epsilon), \tag{55}$$

where

$$A=-\frac{1}{2}+is-\frac{k}{4}w+\frac{1}{w}\left(\frac{s^2+\frac{1}{4}}{k-2}+\tilde{N}+h-1\right). \tag{56}$$

Here we have assumed that

$$\tilde{\bar{N}}+\bar{h}\leqslant\tilde{N}+h, \tag{57}$$

but it can be seen that the other case gives the same result.

Now we turn our attention to the second line of (53). In those terms we have one less unit of spectral flow, as compared to the third line in (53) that we analyzed above. In other words, now we will have that $(w-1)q+N_{w-1}=\tilde{N}'$. These states are in the spectral flow image of $\mathcal{D}_j^+$. Since we want to combine these states with the states coming from the third line in (53) it is convenient to do spectral flow one more time and think of these states as in the spectral flow image of $\mathcal{D}_j^-$ under w units of spectral flow. In this case we find that $q+\tilde{N}'=\tilde{N}$ where now $\tilde{N}$ is the level of the $\mathcal{D}_j^-$

representation before spectral flow. From now on the discussion is very similar to what we had above. The states with $(\tilde{J}_0^- \bar{\tilde{J}}_0^-)^n|\psi\rangle$ all have the same energies but they will contribute to the denominator of the second line in (53) with

$$\sum_{n=0}^{\infty} \frac{1}{B+n} e^{-ne} = \log \epsilon - \frac{d}{dB} \log \Gamma(B) + \mathcal{O}(\epsilon), \tag{58}$$

where

$$B = \frac{1}{2} + is - \frac{k}{4} w + \frac{1}{w} \left(\frac{s^2 + \frac{1}{4}}{k-2} + \bar{\tilde{N}} + \bar{h} - 1 \right). \tag{59}$$

again assuming (57).

After we perform these two sums, we find that (53) can be written in the form

$$\frac{2}{\beta} \int_0^{\infty} ds\, \rho(s) \exp\left[-\beta \left(E(s) + i \frac{\mu}{w} (\tilde{N} + h - \bar{\tilde{N}} - \bar{h}) \right) \right], \tag{60}$$

with $E(s)$ the energy of long strings (7) and $\rho(s)$ the density of states. We will later see that the physical momentum p of a long string in the ρ direction is equal to $p = 2s$. The angular momentum $l = (\tilde{N} + h - \bar{\tilde{N}} - \bar{h})/w$ is an integer since the states in (53) were obeying (4) and the definition (54) ensures that (8) is satisfied. The density of states $\rho(s)$ derived from this analysis is

$$\rho(s) = \frac{1}{2\pi} 2 \log \epsilon + \frac{1}{2\pi i} \frac{d}{2ds} \log \left(\frac{\Gamma(\frac{1}{2} - is + \tilde{m}) \Gamma(\frac{1}{2} - is - \bar{\tilde{m}})}{\Gamma(\frac{1}{2} + is + \tilde{m}) \Gamma(\frac{1}{2} + is - \bar{\tilde{m}})} \right), \tag{61}$$

where

$$\tilde{m} = -\frac{k}{4} w + \frac{1}{w} \left(\frac{s^2 + \frac{1}{4}}{k-2} + \tilde{N} + h - 1 \right), \quad \bar{\tilde{m}} = -\frac{k}{4} w + \frac{1}{w} \left(\frac{s^2 + \frac{1}{4}}{k-2} + \bar{\tilde{N}} + \bar{h} - 1 \right). \tag{62}$$

Note that, despite appearances to the contrary, (61) is actually symmetric under $\tilde{m} \leftrightarrow \bar{\tilde{m}}$ since $\tilde{m} - \bar{\tilde{m}} = l$ is an integer. In the next subsection we will show that this density of states (61) is what is expected from the spacetime meaning of the cutoff ϵ. In going from (53) to (60) we have states which could be interpreted as coming from the spectral flow of the discrete representations $\mathcal{D}_j^+$ and $\mathcal{D}_j^-$, with the zero modes essentially stripped off since they were explicitly summed over in (55) and (58). This implies that the states we have in the end belong to the continuous representation. Note also that the integral over s in (60) has only half the range in (53). We rewrote it in this way using the fact that the exponent is invariant under $s \to -s$, and that is the reason why we have four gamma functions in (61). In going from (53) to (60) we have also used that $d/dA = (1/d/dA(s)/ds)(d/ds)$ in (56) and similarly in (59).

Combining Eqs. (52) and (60), we have, finally,

$$f(\beta,\mu) = \frac{1}{\beta} \sum D(h,\bar{h},\tilde{N},\bar{\tilde{N}},w) \left[\sum_{q,q} e^{-\beta(E + i\mu l)} + \int_0^{\infty} ds \rho(s) e^{-\beta(E(s) + i\mu l)} \right] \tag{63}$$

which is the free energy due to the short strings and the long strings, respectively.

C. The density of long string states

What remains to be shown is the interpretation of $\rho(s)$ given by (61) as the density of long string states. Whenever we have a continuous spectrum the density of states may be calculated by

first introducing a long distance cutoff which will make the spectrum discrete, and then removing the cutoff. If the cutoff is related to the volume of the system then the density of states will have a divergent part, proportional to the volume and dependent only on the bulk physics, and a finite part which encodes information about the scattering phase shift and also has some dependence on the precise cutoff procedure. To see this, let us consider a one-dimensional quantum mechanical model on the half line, $\rho>0$, with a potential $V(\rho)$. We assume that $V(\rho)$ vanishes sufficiently fast for large ρ, and that there is continuous spectrum above a certain energy level. To define the density of states, it is convenient to introduce a long distance cutoff at large ρ so that the spectrum becomes discrete. Let us first consider a cutoff by an infinite wall at $\rho=L$. If L is sufficiently large, an energy eigenfunction $\psi(\rho)$ near the wall can be approximated by the plane wave,

$$\psi(\rho)\sim e^{-ip\rho}+e^{ip\rho+i\delta(p)}, \tag{64}$$

where $\delta(p)$ is the phase shift due to the original potential $V(\rho)$. Imposing Dirichlet boundary condition $\psi(L)=0$ at the wall, we have

$$2pL+\delta(p)=2\pi(n+\tfrac{1}{2}), \tag{65}$$

for some integer n. If L is sufficiently large, there is a unique solution $p=p(n)$ to this equation for a given n. As we remove the cutoff by sending $L\to\infty$, the spectrum of p becomes continuous. We then define the density of states $\rho(p)$ by

$$dn=\rho(p)dp. \tag{66}$$

From (65), we obtain

$$\rho(p)=\frac{1}{2\pi}\left(2L+\frac{d\delta}{dp}\right). \tag{67}$$

Thus the finite part of the density of states is given by the derivative of the phase shift.

Instead of the infinite wall at $\rho=L$, we may consider a more general potential $V_{\text{wall}}(\rho-L)$ which vanishes for $\rho<L$ but rises steeply for $L<\rho$ to confine the particle. Let us denote by $\delta_{\text{wall}}(p)$ the phase shift due to scattering from $V_{\text{wall}}(\rho)$. We then obtain the condition on the allowed values of momenta by matching these two wavefunctions and their derivatives at $\rho=L$ as

$$\psi(\rho)\sim e^{-ip\rho}+e^{ip\rho+i\delta(p)}\sim A[e^{-ip(\rho-L)}+e^{ip(\rho-L)+i\delta_{\text{wall}}(p)}] \quad (\rho\sim L). \tag{68}$$

It follows that

$$pL+\delta(p)=-pL+\delta_{\text{wall}}(p)+2\pi n. \tag{69}$$

In the limit $L\to\infty$, the density of states given by $dn=\rho(p)dp$ is then

$$\rho(p)=\frac{1}{2\pi}\left(2L+\frac{d\delta}{dp}-\frac{d\delta_{\text{wall}}}{dp}\right). \tag{70}$$

When we have the infinite wall, the phase shift due to the wall is independent of $p(\delta_{\text{wall}}=\pi)$, and (70) reduces to (67).

In order to apply this observation to our problem, it is useful to first identify the origin of the logarithmic divergence in the one-loop amplitude $Z(\beta,\mu)$ by examining the functional integral (24) near the boundary of AdS_3. In the cylindrical coordinates (11), the string worldsheet action (18) for large ρ takes the form

$$S\sim\frac{k}{\pi}\int d^2z\left(\partial\rho\,\bar{\partial}\rho+\frac{1}{4}e^{2\rho}|\bar{\partial}(\theta-it)|^2+\cdots\right). \tag{71}$$

Because of the factor $e^{2\rho}$, the functional integral for large ρ restricts (t,θ) to be a harmonic map from the worldsheet to the target space. Since (t,θ) are coordinates on the torus,

$$\theta - it \sim \theta - it + 2\pi n + i\hat{\beta} m \quad (n,m \quad \text{integers}), \tag{72}$$

the harmonic map from the torus to the torus is

$$\begin{aligned}\theta - it &= (2\pi w + i\hat{\beta} m)\sigma^t + (2\pi r + i\hat{\beta} n)\sigma^2 \\ &= [(2\pi w + i\hat{\beta} m)\tau - (2\pi r + i\hat{\beta} n)]\frac{\overline{z}}{2i\tau_2} \\ &\quad - [(2\pi w + i\hat{\beta} m)\overline{\tau} - (2\pi r + i\hat{\beta} n)]\frac{z}{2i\tau_2},\end{aligned} \tag{73}$$

where $z = \sigma^1 + \rho\sigma^2$ is the worldsheet coordinate and (r, w, n, m) are integers. In particular, the map $(\theta - it)$ with $(n,m) = (1,0)$ becomes w–to–1 and *holomorphic* when τ takes the special value

$$\tau_{\text{pole}} = \frac{r}{w} + i\frac{\hat{\beta}}{2\pi w}. \tag{74}$$

On the other hand, if τ is not at one of these points, $\overline{\partial}(\theta - it)$ cannot be set to zero. [For any τ, we also have a trivial holomorphic map $(t,\theta) = \text{const}$. The functional integral around such a map gives a result independent of β and we can neglect it in the following discussion.] This gives rise to an effective potential $e^{2\rho}$ for ρ, which keeps the worldsheet from growing towards the boundary. If τ is near τ_{pole},

$$\tau = \tau_{\text{pole}} + \epsilon, \tag{75}$$

the harmonic map (73) with $(n,m) = (1,0)$ gives

$$|\overline{\partial}(\theta - it)|^2 \sim \left(\frac{2\pi^2 w^2}{\beta}\right)^2 \epsilon^2. \tag{76}$$

Thus the action (71) generates the Liouville potential $\epsilon^2 e^{2\rho}$. When we computed the one-loop amplitude in Secs. IV A and IV B, we regularized the τ-integral by removing a small disk $|\tau - \tau_{\text{pole}}| < \epsilon$ around each of these special points. Near $\tau = \tau_{\text{pole}}$, this is equivalent to adding the infinitesimal Liouville potential $\epsilon^2 e^{2\rho}$ to the worldsheet action. For $|\tau - \tau_{\text{pole}}| \gg \epsilon$, the worldsheet can never grow large enough and the effect of the Liouville term is negligible. To be precise, the Gaussian functional integral of (t,θ) shifts $k \to (k-2)$ as in (26) and the effective action for ρ near $\tau = \tau_{\text{pole}}$ is

$$S_{\text{Liouville}} = \frac{k-2}{\pi}\int d^2z(\partial\rho\,\tilde{\partial}\rho + \epsilon^2 e^{2\rho}). \tag{77}$$

Therefore, we find that our choice of regularization in (55) and (58) amounts to introducing the Liouville wall which prevents the longs strings from going to very large values of ρ. By looking at the potential in (77), we see that the effective length of the interval is $L \sim \log\epsilon$. The central charge of this Liouville theory is such that the $e^{2\rho}$ term has conformal weight one,

$$c_{\text{Liouville}} = 1 + 6\left(b + \frac{1}{b}\right)^2, \quad b \equiv \frac{1}{\sqrt{k-2}}. \tag{78}$$

The finite part of the density of states will be given through (70) by $\delta(s)$, the phase shift in the SL(2,R) model, and $\delta_{\text{wall}}(s)$, the corresponding quantity in Liouville theory. The first one was calculated in Refs. 9 and 10,

$$i\,\delta(s)=\log\left(\frac{\Gamma\left(\frac{1}{2}+is-\tilde{m}\right)\Gamma\left(\frac{1}{2}+is+\tilde{m}\right)\Gamma(-2is)\Gamma\left(\frac{2is}{k-2}\right)}{\Gamma\left(\frac{1}{2}-is-\tilde{m}\right)\Gamma\left(\frac{1}{2}-is+\tilde{m}\right)(2is)\Gamma\left(\frac{-2is}{k-2}\right)}\right), \tag{79}$$

while the second one was obtained in Refs. 11 and 12,

$$i\,\delta_{\text{wall}}(s)=\log\left(\frac{\Gamma(-2is)\Gamma\left(\frac{2is}{k-2}\right)}{\Gamma(2is)\Gamma\left(\frac{-2is}{k-2}\right)}\right). \tag{80}$$

[In order to compare with the expressions in Refs. 11, 12, we use the value of b given in (78) and note that the relevant values of α are $\alpha=Q/2+$isb.] Using these two formulas we can check that indeed the density of states (61) is given by (70). We can view this as an independent calculation of (79) or as an overall consistency check. Notice that the physical momentum p of a long string along the ρ direction is $p=2s$. This can be seen by comparing the energy of a long string (7) with the energy expected from (77) with spacetime momentum p along the radial direction, $p=(k-2)w\dot{\rho}$. We have chosen the variable s since it is conventional to denote by $j=1/2+is$ the SL(2,R) spin of a continuous representation.

Vertex operators for AdS3 with Ramond background

L. Dolan
Department of Physics and Astronomy, University of North Carolina, Chapel Hill, North Carolina 27599-3255

(Received 2 January 2001; accepted for publication 13 February 2001)

This review gives results on vertex operators for the Type IIB superstring in an AdS3×S3 background with Ramond–Ramond flux, which were presented at Strings 2000. Constraint equations for these vertex operators are derived, and their components are shown to satisfy the supergravity linearized equations of motion for the six-dimensional (2, 0) theory of a supergravity and tensor multiplet expanded around AdS3×S3 space-time. © *2001 American Institute of Physics.*

I. INTRODUCTION

The conjectured duality between M-theory or Type IIB string theory on anti-de Sitter (AdS) space and the conformal field theory on the boundary of AdS space may be useful in giving a controlled systematic approximation for strongly coupled gauge theories. Examples with maximal supersymmetry correspond to a set of p-branes whose near horizon geometry looks like $\mathrm{AdS}_{p+2} \times S^{\mathcal{D}-p-2}$, where $\mathcal{D}=10$ or 11 for branes in string or M-theory, and $p=2,3,5$. The formulation of vertex operators and string theory tree amplitudes for the IIB superstring on $\mathrm{AdS}_5 \times S^5$ will allow access to the dual conformal SU(N) gauge field theory CFT_4 at large N, but *small* fixed 't Hooft coupling $x=g_{YM}^2 N$ in the dual picture, as $(g_{YM}^2 N)^{1/2}(4\pi)^{1/2}=R_{sph}^2/\alpha'$. Presently only the large N, and *large* fixed 't Hooft coupling x limit, is accessible in the *CFT*, since only the supergravity limit $(\alpha' \to 0)$ of the correlation functions of the AdS theory is known.

In this article we discuss a case with nonmaximal supersymmetry that is related to a system with a $D1$-brane and a $D5$-brane. Its quantizable worldsheet action[1] describes the IIB string on $\mathrm{AdS}_3 \times S^3 \times M$ with background Ramond–Ramond flux, where M is T^4 or $K3$. The vertex operators for this model can be computed explicitly in the bulk.[2] Correlation functions constructed from these vertex operators, restricted to the boundary of AdS_3, would be those for a two-dimensional space–time conformal field theory. We work to leading order in α', but because of the high degree of symmetry of the model, we expect our result for the vertex operators to be exact. Tree level n-point correlation functions for $n \geqslant 4$ presumably have α' corrections, since the worldsheet theory is not a free conformal field theory. But there may be sufficiently many symmetry currents to determine the tree level correlation functions exactly in α' as well.[3]

In terms of Berkovits–Vafa–Witten worldsheet variables, constraint equations for the vertex operators in the flat space $\mathcal{R}^6$ follow from the physical state conditions coming from an $N=4$ superconformal algebra. We generalize[2] these constraint equations to $\mathrm{AdS}_3 \times S^3$ for the vertex operators of the massless states that are independent of the compactification M. We then solve the constraints and identify the components of the vertex operators as supergravity fields that satisfy the $D=6$, $N=(2,0)$ theory[4] linearized around the $\mathrm{AdS}_3 \times S^3$ background.

Recent work[5,6] discusses covariant ten-dimensional worldsheet variables and extends our analysis to vertex operators on AdS_5 in a spinor formulation.

II. FORMULATING STRINGS ON AdS

In the Ramond–Neveu–Schwarz (RNS) formalism, the worldsheet action for strings on AdS space with background Ramond–Ramond flux involves 2-D spin fields. These violate supercon-

formal worldsheet symmetry, since the worldsheet supercurrents are not local with respect to the spin fields, and their presence makes the worldsheet theory difficult to understand.

For the Type IIB superstring on $AdS_3\times S^3$ case, a sigma model[1] with conventional local interactions (no spin fields in the action) was found using the supergroup PSU(2|2) as target, coupled to ghost fields ρ and σ. The space-time symmetry group is PSU(2|2)×PSU(2|2), acting by left and right multiplication on the group manifold, i.e., by $g\rightarrow agb^{-1}$ where g is a PSU(2|2)-valued field, and $a,b\in$ PSU(2|2) are the symmetry group's Lie algebra elements. The supergroup is generated by the super Lie algebra with 12 bosonic generators forming a subalgebra SO(4)×SO(4) together with 16 odd generators. Hence our model has nonmaximal supersymmetry with 16 supercharges.

The worldsheet field content generalizes the Berkovits–Vafa formalism which provides a manifest Lorentz covariant and supersymmetric quantization on R^6. Its six bosonic fields $x^p(z,\overline{z})$ contain both left- and right-moving modes. In addition there are left-moving fermi fields $\theta^a_L(z),p^a_L(z)$ of spins 0 and 1, together with ghosts $\sigma_L(z),\rho_L(z)$, and right-moving counterparts of all these left-moving fields. These variables allow Ramond–Ramond background fields to be incorporated without adding spin fields to the worldsheet action as follows: in the $AdS_3\times S^3$ case, i.e., after adding RR background fields to the worldsheet action, one can integrate out the p's, so that the model has ordinary conformal fields $x^p,\theta^a,\overline{\theta^a}$ (all now with both left- and right-moving components) as well as the ghosts. The PSU(2|2)-valued field g is given in terms of x, θ, and $\overline{\theta}$, which are identified as coordinates on the supergroup manifold. In addition, type IIB on $AdS_3\times S^3\times M$ has worldsheet variables describing the compactification on the four-dimensional space M. Their Virasoro currents have central charge $c=6$, and will be labeled with a subscript C.

III. $N=4$ SUPER VIRASORO GENERATORS

The holomorphic $N=4$ superconformal generators with $c=6$ are given for flat space by[1]

$$T=-\tfrac{1}{2}\partial x^m\partial x_m-p_a\partial\theta^a-\tfrac{1}{2}\partial\rho\partial\rho-\tfrac{1}{2}\partial\sigma\partial\sigma+\partial^2(\rho+i\sigma)+T_C,$$

$$G^+=-e^{-2\rho-i\sigma}(p)^4+\frac{i}{2}e^{-\rho}p_ap_b\partial x^{ab}$$
$$+e^{i\sigma}\big(-\tfrac{1}{2}\partial x^m\partial x_m-p_a\partial\theta^a-\tfrac{1}{2}\partial(\rho+i\sigma)\partial(\rho+i\sigma)+\tfrac{1}{2}\partial^2(\rho+i\sigma)\big)+G^+_C,$$

$$G^-=e^{-i\sigma}+G^-_C,\quad J=\partial(\rho+i\sigma)+J_C, \tag{1}$$

$$\tilde{G}^+=e^{iH_C}\Big[-e^{-3\rho-2i\sigma}(p)^4+\frac{i}{2}e^{-2\rho-i\sigma}p_ap_b\partial x^{ab}$$
$$+e^{-\rho}\Big(-\frac{1}{2}\partial x^m\partial x_m-p_a\partial\theta^a-\frac{1}{2}\partial(\rho+i\sigma)\partial(\rho+i\sigma)\Big)+\frac{1}{2}\partial^2(\rho+i\sigma)\Big]+e^{-\rho-i\sigma}\tilde{G}^-_C,$$

$$J^+=e^{\rho+i\sigma}J^+_C,\quad J^-=e^{-\rho-i\sigma}J^-_C.$$

These currents are given in terms of the left-moving bosons ∂x^m, ρ, σ, and the left-moving fermionic worldsheet fields p^a,θ^a, where $1\leqslant m\leqslant 6$, $1\leqslant a\leqslant 4$. There are corresponding anti-holomorphic expressions. Both sets of generators are used to implement the physical state conditions on the vertex operators, a procedure which results in a set of string constraint equations.

IV. STRING CONSTRAINT EQUATIONS FOR THE VERTEX OPERATORS

The expansion of the massless vertex operator in terms of the worldsheet fields is

$$V=\sum_{m,n=-\infty}^{\infty} e^{m(i\sigma+\rho)+n(i\bar{\sigma}+\bar{\rho})}V_{m,n}(x,\theta,\bar{\theta}). \tag{2}$$

In flat space, the constraints from the left- and right-moving worldsheet super Virasoro algebra are

$$\begin{gathered}(\nabla)^4V_{1,n}=\nabla_a\nabla_b\partial^{ab}V_{1,n}=0,\\ \tfrac{1}{6}\epsilon^{abcd}\nabla_b\nabla_c\nabla_dV_{1,n}=-i\nabla_b\partial^{ab}V_{0,n},\\ \nabla_a\nabla_bV_{0,n}-\frac{i}{2}\epsilon_{abcd}\partial^{cd}V_{-1,n}=0,\quad \nabla_aV_{-1,n}=0;\end{gathered} \tag{3}$$

$$\begin{gathered}\bar{\nabla}^4V_{n,1}=\bar{\nabla}_{\dot{a}}\bar{\nabla}_{\dot{b}}\bar{\partial}^{\dot{a}\dot{b}}V_{n,1}=0,\\ \tfrac{1}{6}\epsilon^{\dot{a}\dot{b}\dot{c}\dot{d}}\bar{\nabla}_{\dot{b}}\bar{\nabla}_{\dot{c}}\bar{\nabla}_{\dot{d}}V_{n,1}=-i\bar{\nabla}_{\dot{b}}\bar{\partial}^{\dot{a}\dot{b}}V_{n,0},\\ \bar{\nabla}_{\dot{a}}\bar{\nabla}_{\dot{b}}V_{n,0}-\frac{i}{2}\bar{\epsilon}_{\dot{a}\dot{b}\dot{c}\dot{d}}\bar{\partial}^{\dot{c}\dot{d}}V_{n,-1}=0,\quad \bar{\nabla}_{\dot{a}}V_{n,-1}=0;\end{gathered} \tag{4}$$

$$\partial^p\partial_pV_{m,n}=0; \tag{5}$$

for $-1\leqslant m,\ n\leqslant 1$, with the notation $\nabla_a=d/d\theta^a$, $\bar{\nabla}_{\dot{a}}=d/d\bar{\theta}^{\dot{a}}$, and $\partial^{ab}=-\sigma^{pab}\partial_p$. These equations were derived in flat space by requiring the vertex operators to satisfy the physical state conditions

$$\begin{gathered}G_0^-V=\tilde{G}_0^-V=\tilde{G}_0^-V=\bar{\tilde{G}}_0^-V=T_0V=\tilde{T}_0V=0,\\ J_0V=\bar{J}_0V=0,\quad G_0^+\tilde{G}_0^+V=\tilde{G}_0^+\bar{\tilde{G}}_0^+V=0,\end{gathered} \tag{6}$$

where T_n, $G_n^{\pm}$, $\tilde{G}_n^{\pm}$, J_n, $J_n^{\pm}$ and corresponding barred generators are the left and right $N=4$ worldsheet superconformal generators. These conditions further imply $V_{m,n}=0$ for $m>1$ or $n>1$ or $m<1$ or $n<1$, leaving nine nonzero components.

In $\mathrm{AdS}_3\times S^3$ space, we generalize these equations as follows:[2]

$$\begin{gathered}F^4V_{1,n}=F_aF_bK^{ab}V_{1,n}=0,\\ \tfrac{1}{6}\epsilon^{abcd}F_bF_cF_dV_{1,n}=-iF_bK^{ab}V_{0,n}+2iF^aV_{0,n}-E^aV_{-1,n},\\ F_aF_bV_{0,n}-\frac{i}{2}\epsilon_{abcd}K^{cd}V_{-1,n}=0,\quad F_aV_{-1,n}=0;\end{gathered} \tag{7}$$

$$\begin{gathered}\bar{F}^4V_{n,1}=\bar{F}_{\dot{a}}\bar{F}_{\dot{b}}\bar{K}^{\dot{a}\dot{b}}V_{n,1}=0\\ \tfrac{1}{6}\epsilon^{\dot{a}\dot{b}\dot{c}\dot{d}}\bar{F}_{\dot{b}}\bar{F}_{\dot{c}}\bar{F}_{\dot{d}}V_{n,1}=-i\bar{F}_{\dot{b}}\bar{K}^{\dot{a}\dot{b}}V_{n,0}+2i\bar{F}^{\dot{a}}V_{n,0}-\bar{E}^{\dot{a}}V_{n,-1}\\ \bar{F}_{\dot{a}}\bar{F}_{\dot{b}}V_{n,0}-\frac{i}{2}\bar{\epsilon}_{\dot{a}\dot{b}\dot{c}\dot{d}}\bar{K}^{\dot{c}\dot{d}}V_{n,-1}=0,\quad \bar{F}_{\dot{a}}V_{n,-1}=0.\end{gathered} \tag{8}$$

There is also a spin zero condition constructed from the Laplacian

$$(F_a E_a + \tfrac{1}{8}\epsilon_{abcd}K^{ab}K^{cd})V_{n,m} = (\bar{F}_{\bar{a}}\bar{E}_{\bar{a}} + \tfrac{1}{8}\bar{\epsilon}_{\bar{a}\bar{b}\bar{c}\bar{d}}\bar{K}^{\bar{a}\bar{b}}\bar{K}^{\bar{c}\bar{d}})V_{n,m} = 0. \tag{9}$$

We derived[2] the curved space equations (7)–(9) by deforming the equations for the flat case (3)–(5), by requiring invariance under the PSU(2|2) transformations (10) that replace the $D=6$ super Poincare transformations of flat space. The Lie algebra of the supergroup PSU(2|2) contains six even elements $K_{ab} \in \mathrm{SO}(4)$ and eight odd ones E_a, F_a. They generate the infinitesimal symmetry transformations of the constraint equations:

$$\begin{gathered}\Delta_a^- V_{m,n} = F_a V_{m,n}, \quad \Delta_{ab} V_{m,n} = K_{ab} V_{m,n}, \\ \Delta_a^+ V_{1,n} = E_a V_{1,n}, \quad \Delta_a^+ V_{0,n} = E_a V_{0,n} + iF_a V_{1,n}, \quad \Delta_a^+ V_{-1,n} = E_a V_{-1,n} - iF_a V_{0,n}.\end{gathered} \tag{10}$$

We write E_a, F_a, and K_{ab} for the operators that represent the left action of e_a, f_a, and t_{ab} on g. In the above coordinates,

$$\begin{gathered}F_a = \frac{d}{d\theta^a}, \quad K_{ab} = -\theta_a \frac{d}{d\theta^b} + \theta_b \frac{d}{d\theta^a} + t_{Lab}, \\ E_a = \frac{1}{2}\epsilon_{abcd}\theta^b \left(t_L^{cd} - \theta^c \frac{d}{d\theta_d} \right) + h_{a\bar{b}} \frac{d}{d\bar{\theta}_{\bar{b}}},\end{gathered} \tag{11}$$

where we have introduced an operator t_L that generates the left action of SU(2)×SU(2) on h alone, without acting on the θ's. Here

$$g = g(x,\theta,\bar{\theta}) = e^{\theta^a f_a} e^{(1/2)\sigma^{pcd} x_p t_{cd}} e^{\bar{\theta}^{\bar{a}} e_{\bar{a}}} = e^{\theta^a f_a} h(x) e^{\bar{\theta}^{\bar{a}} e_{\bar{a}}}, \tag{12}$$

$$t_{Lab} g = e^{\theta^a f_a}(-t_{ab}) h(x) e^{\bar{\theta}^{\bar{a}} e_{\bar{a}}}, \tag{13}$$

and we found (11) by requiring $F_a g = f_a g$, $E_a g = e_a g$, and $K_{ab} g = -t_{ab} g$. Similar expressions[2] hold for the right-acting generators $\bar{K}_{\bar{a}\bar{b}}$, $\bar{E}_{\bar{a}}$, and $\bar{F}_{\bar{a}}$.

V. SUPERSYMMETRY ALGEBRAS

In flat space, the $D=6$ supersymmetry algebra for the left-movers is given by

$$\begin{gathered}\{q_a^+, q_c^-\} = \tfrac{1}{2}\epsilon_{abcd}P^{cd}, \\ [P_{ab}, P_{cd}] = 0 = [P_{ab}, q_c^\pm] = \{q_a^+, q_b^+\} = \{q_a^-, q_b^-\},\end{gathered} \tag{14}$$

where $P_{ab} \equiv \delta_{ac}\delta_{bd}P^{cd}$ and

$$q_a^- = \oint F_a(z),$$

$$q_a^+ = \oint (e^{-\rho - i\sigma} F_a(z) + iE_a(z)), \tag{15}$$

$$P^{ab} = \oint \partial x_m(z) \sigma^{mab}. \tag{16}$$

In flat space we have $F_a(z) = p_a(z)$ and $E_a(z) = 1/2\epsilon_{abcd}\theta^b(z)\partial x_m(z)\sigma^{mcd}$. We distinguish between the currents and their zero moments E_a, F_a which together with P_{ab} also generate the flat space supersymmetry algebra

$$[P_{ab},P_{cd}]=0=[P_{ab},F_c]=[P_{ab},E_c],$$
$$\{E_a,F_b\}=\tfrac{1}{2}\epsilon_{abcd}P^{cd},\quad \{E_a,E_b\}=\{F_a,F_b\}=0. \tag{17}$$

On $AdS_3\times S^3$, the Poincare supersymmetry algebra (17) is replaced by the PSU(2|2) superalgebra

$$[K_{ab},K_{cd}]=\delta_{ac}K_{bd}-\delta_{ad}K_{bc}-\delta_{bc}K_{ad}+\delta_{bd}K_{ac},$$
$$[K_{ab},E_c]=\delta_{ac}E_b-\delta_{bc}E_a,\quad [K_{ab},F_c]=\alpha_{ac}F_b-\delta_{bc}F_a, \tag{18}$$
$$\{E_a,F_b\}=\tfrac{1}{2}\epsilon_{abcd}K^{cd},\quad \{E_a,E_b\}=0=\{F_a,F_b\}.$$

The generators $q_a^{\pm}$, which generate the AdS transformations (10), still have a form similar to (15) but $E_a(z,\overline{z})$, $F_a(z,\overline{z})$, and $K_{ab}(z,\overline{z})$ are no longer holomorphic and their zero moments with respect to z satisfy (18).

VI. STRING EQUATIONS FOR THE AdS VERTEX OPERATOR COMPONENTS

The AdS supersymmetric constraints (7)–(9) imply[2]

$$F_aF_bK^{ab}V_{1,1}=0,\quad \overline{F}_{\dot a}\overline{F}_{\dot b}\overline{K}^{\dot a\dot b}V_{1,1}i \tag{19}$$

$$\left(F_aE_a+\tfrac{1}{8}\epsilon_{abcd}K^{ab}K^{cd}\right)V_{1,1}=\left(\overline{F}_{\dot a}\overline{E}_{\dot a}+\tfrac{1}{8}\overline{\epsilon}_{\dot a\dot b\dot c\dot d}\overline{K}^{\dot a\dot b}\overline{K}^{\dot c\dot d}\right)V_{1,1}=0. \tag{20}$$

The vertex operators $V_{-1,1},V_{1,-1},V_{0,-1},V_{-1,0},V_{-1,-1}$ can be gauge fixed to zero, and therefore do not correspond to propagating degrees of freedom. Furthermore, this gauge symmetry can be used both to set to zero the components of $V_{1,1}$ with no θ's or no $\overline{\theta}$'s, and to gauge fix all components of $V_{0,1},V_{1,0},V_{0,0}$ that are independent of those of $V_{1,1}$. The physical degrees of freedom of the massless compactification independent vertex operators are thus described by a superfield

$$\begin{aligned}V_{1,1}=&\theta^a\overline{\theta^{\dot a}}V_{a\dot a}^{--}+\theta^a\theta^b\overline{\theta^{\dot a}}\sigma^m_{ab}\overline{\xi}^-_{m\dot a}+\theta^a\overline{\theta^{\dot a}}\overline{\theta^{\dot b}}\sigma^m_{\dot a\dot b}\xi^-_{ma}+\theta^a\theta^b\overline{\theta^{\dot a}}\overline{\theta^{\dot b}}\sigma^m_{ab}\sigma^n_{\dot a\dot b}(g_{mn}+b_{mn}+\overline{g}_{mn}\phi)\\&+\theta^a(\overline{\theta^3})_{\dot a}A_a^{-+\dot a}+(\theta^3)_a\overline{\theta^{\dot a}}A_{\dot a}^{+-a}+\theta^a\theta^b(\overline{\theta^3})_{\dot a}\sigma^m_{ab}\overline{\chi}_m^{+\dot a}\\&+(\theta^3)^a\overline{\theta^{\dot a}}\overline{\theta^{\dot b}}\sigma^m_{\dot a\dot b}\chi_m^{+a}+(\theta^3)_a(\overline{\theta^3})_{\dot a}F^{++a\dot a}.\end{aligned} \tag{21}$$

This has the field content of $D=6$, $N=(2,0)$ supergravity with one supergravity and one tensor multiplet. Further massless multiplets correspond to the compactification degrees of freedom. In flat space, the surviving constraint equations imply that the component fields Φ are all on shell massless fields, that is $\Sigma_{m=1}^6\partial^m\partial_m\Phi=0$ as in (5), and in addition

$$\partial^m g_{mn}=-\partial_n\phi,\quad \partial^m b_{mn}=0,\quad \partial^m\chi_m^{\pm b}=\partial^m\overline{\chi}_m^{\pm\dot b}=0,$$
$$\partial_{ab}\chi_m^{\pm b}=\partial_{\dot a\dot b}\overline{\chi}_m^{\pm\dot b}=0,\quad \partial_{cb}F^{\pm\pm b\dot a}=\partial_{\dot c\dot b}F^{\pm\pm\dot b\dot a}=0, \tag{22}$$

where

$$F^{+-a\dot a}=\partial^{\dot a\dot b}A_{\dot b}^{+-a},\quad F^{-+a\dot a}=\partial^{ab}A_b^{-+\dot a},\quad F^{--a\dot a}=\partial^{ab}\partial^{\dot a\dot b}V_{b\dot b}^{--},$$
$$\chi_m^{-a}=\partial^{ab}\xi^-_{mb},\quad \overline{\chi}_m^{-\dot a}=\partial^{\dot a\dot b}\overline{\xi}^-_{m\dot b}. \tag{23}$$

The equations of motion for the flat space vertex operator component fields describe $D=6$, $N=(2,0)$ supergravity[4] expanded around the six-dimensional Minkowski metric.

In $AdS_3\times S^3$ space corresponding gauge transformations reduce the number of degrees of freedom in a similar fashion, but the Laplacian must be replaced by the AdS Laplacian, and the constraints are likewise deformed. We focus on the vertex operator V_{11} that carries the physical degrees of freedom. We show the string constraint equations are equivalent to the $D=6$, $N=(2,0)$ linearized supergravity equations expanded around the $AdS_3\times S^3$ metric.

For the bosonic field components of the vertex operator the AdS constraint equations result in

$$\Box h_a^g V_{ag}^{--}=-4\sigma_{ab}^m\sigma_{gh}^n\delta^{bh}h_a^g G_{mn}, \tag{24}$$

$$\Box h_a^g h_b^h\sigma_{ab}^m\sigma_{gh}^n G_{mn}=\tfrac{1}{4}\epsilon_{abce}\epsilon_{fghk}\delta^{ch}h_a^f h_b^g F^{++ek}, \tag{25}$$

$$\Box h_g^{\bar a}F^{++ag}=0,\quad \Box h_g^{\bar a}A_a^{-+g}=0,\quad \Box h_a^g A_g^{+-a}=0, \tag{26}$$

$$\epsilon_{eacd}t_L^{cd}h_{\bar a}^b A_b^{+-a}=0,\quad \epsilon_{\bar e\bar a\bar b\bar c\bar d}t_R^{\bar c\bar d}h_{\bar a}^{\bar a}A_{\bar a}^{-+\bar b}=0, \tag{27}$$

$$\epsilon_{eacd}t_L^{cd}h_{\bar b}^{\bar a}F^{++ab}=0,\quad \epsilon_{\bar e\bar b\bar c\bar d}t_R^{\bar c\bar d}h_{\bar a}^{a}F^{++\bar a\bar b}=0, \tag{28}$$

$$t_L^{ab}h_a^g h_b^h\sigma_{ab}^m\sigma_{gh}^n G_{mn}=0,\quad t_R^{\bar a\bar b}h_{\bar a}^{\bar g}h_{\bar b}^{\bar h}\sigma_{\bar g\bar h}^{m}\sigma_{\bar a\bar b}^{n}G_{mn}=0. \tag{29}$$

We have expanded $G_{mn}=g_{mn}+b_{mn}+\bar g_{mn}\phi$. The SO(4) Laplacian is $\Box\equiv 1/8\epsilon_{abcd}t_L^{ab}t_L^{cd}=1/8\epsilon_{\bar a\bar b\bar c\bar d}t_R^{\bar a\bar b}t_R^{\bar c\bar d}$. In order to compare this with supergravity, we need to reexpress the above formulas containing the right- and left-invariant vielbeins t_L^{ab}, $t_R^{\bar a\bar b}$ in terms of covariant derivatives D_p on the group manifold. So we write

$$\mathcal{T}_L^{cd}\equiv-\sigma^{pcd}D_p,\quad \mathcal{T}_R^{\bar c\bar d}\equiv\sigma^{p\bar c\bar d}D_p. \tag{30}$$

Acting on a scalar, $\mathcal{T}_L=t_L$ and $\mathcal{T}_R=t_R$, since both just act geometrically. But they differ in acting on fields that carry spinor or vector indices. For example, on spinor indices,

$$t_L^{ab}V_e=\mathcal{T}_L^{ab}V_e+\tfrac{1}{2}\delta_e^a\delta^{bc}V_c-\tfrac{1}{2}\delta_e^b\delta^{ac}V_c. \tag{31}$$

For $AdS_3\times S^3$ we can write the Riemann tensor and the metric tensor as

$$\bar R_{mnp\tau}=\tfrac{1}{4}(\bar g_{m\tau}\bar R_{np}+\bar g_{np}\bar R_{m\tau}-\bar g_{n\tau}\bar R_{mp}-\bar g_{mp}-\bar R_{n\tau}),\quad \bar g_{mn}=\tfrac{1}{2}\sigma_m^{ab}\sigma_{nab}. \tag{32}$$

The sigma matrices σ^{mab} satisfy the algebra $\sigma^{mab}\sigma_{ac}^n+\sigma^{nab}\sigma_{ac}^m=\eta^{mn}\delta_c^b$ in flat space, where η^{mn} is the six-dimensional Minkowski metric. Sigma matrices with lowered indices are defined by $\sigma_{ab}^m=1/2\epsilon_{abcd}\sigma^{mcd}$, although for other quantities indices are raised and lowered with δ^{ab}, so we distinguish σ_{ab}^m from $\delta_{ac}\delta_{bd}\sigma^{mcd}$. In curved space, η_{mn} is replaced by the $AdS_3\times S^3$ metric $\bar g_{mn}$.

We then find from the string constraints that the six-dimensional metric field g_{rs}, the dilaton ϕ, and the two-form b_{rs} satisfy

$$\begin{aligned}\tfrac{1}{2}D^pD_pb_{rs}=&-\tfrac{1}{2}(\sigma_r\sigma^p\sigma^q)_{ab}\delta^{ab}D_p[g_{qs}+\bar g_{qs}\phi]+\tfrac{1}{2}(\sigma_s\sigma^p\sigma^q)_{ab}\delta^{ab}D_p[g_{qr}+\bar g_{qr}\phi]\\&-R_{\tau rs\lambda}b^{\tau\lambda}-\tfrac{1}{2}\bar R_r^{\tau}b_{\tau s}-\tfrac{1}{2}\bar R_s^{\tau}b_{r\tau}+\tfrac{1}{4}F_{asy}^{++gh}\sigma_r^{ab}\sigma_s^{ef}\delta_{ah}\delta_{be}\delta_{gf},\end{aligned} \tag{33}$$

$$\tfrac{1}{2}D^pD_p(g_{rs}+\overline{g}_{rs}\phi)=-\tfrac{1}{2}(\sigma_r\sigma^p\sigma^q)_{ab}\delta^{ab}D_pb_{qs}+\tfrac{1}{2}(\sigma_s\sigma^p\sigma^q)_{ab}\delta^{ab}D_pb_{rq}-\overline{R}_{\tau rs\lambda}(g^{\tau\lambda}+\overline{g}^{\tau\lambda}\phi)$$
$$-\tfrac{1}{2}\overline{R}^{\tau}_{r}(g_{\tau s}+\overline{g}_{\tau s}\phi)-\tfrac{1}{2}\overline{R}^{\tau}_{s}(g_{r\tau}+\overline{g}_{r\tau}\phi)+\tfrac{1}{4}F^{++gh}_{\rm sym}\sigma_{rga}\sigma_{shb}\delta^{ab}. \tag{34}$$

This is the curved space version of the flat space zero Laplacian condition $\partial^p\partial_pb_{rs}=\partial^p\partial_pg_{rs}=\partial^p\partial_p\phi=0$.

Four self-dual tensor and scalar pairs come from the string bispinor fields F^{++ab}, V^{--}_{ab}, A^{+-a}_{b}, A^{-+b}_{a}. From the string constraint equations they satisfy

$$\sigma^p_{da}D_pF^{++ab}_{\rm asy}=0, \tag{35}$$

$$\tfrac{1}{4}[\,\delta^{Ba}\sigma^r_{ga}D_rF^{++gH}_{\rm sym}-\delta^{Ha}\sigma^r_{ga}D_rF^{++gB}_{\rm sym}]=-\tfrac{1}{4}\epsilon^{BH}{}_{cd}F^{++cd}_{\rm asy}. \tag{36}$$

We also find

$$\tfrac{1}{2}D^pD_pV^{--}_{cd}-\tfrac{1}{2}\delta^{gh}\sigma^p_{ch}D_pV^{--}_{gd}+\tfrac{1}{2}\delta^{gh}\sigma^p_{dh}D_pV^{--}_{cg}+\tfrac{1}{4}\epsilon^{gh}_{cd}V^{--}_{gh}=-4\sigma^m_{ce}\sigma^n_{df}\delta^{ef}G_{mn}. \tag{37}$$

The last constraints can be written as

$$\begin{aligned}
&\epsilon_{eacd}t^{cd}_Lh^{\bar b}_{\bar b}F^{+-ab}=0,\quad \epsilon_{\bar e\bar b\bar c\bar d}t^{\bar c\bar d}_Rh^{\bar a}_{\bar a}F^{+-\bar a\bar b}=0,\\
&\epsilon_{eacd}t^{cd}_Lh^{\bar b}_{\bar b}F^{-+ab}=0,\quad \epsilon_{\bar e\bar b\bar c\bar d}t^{\bar c\bar d}_Rh^{\bar a}_{\bar a}F^{-+\bar a\bar b}=0,
\end{aligned} \tag{38}$$

where

$$F^{+-a\bar a}\equiv\delta^{\bar a\bar b}A^{+-a}_{\bar b}+t^{\bar a\bar b}_RA^{+-a}_{\bar b},\quad F^{-+a\bar a}\equiv\delta^{ab}A^{-+\bar a}_{b}+t^{ab}_LA^{-+\bar a}_{b}, \tag{39}$$

so F^{+-ab} and F^{-+ab} satisfy equations similar to those for F^{++ab}.

Independent conditions on the fermion fields are

$$\begin{aligned}
&\Box h^{\bar g}_{\bar a}\sigma^m_{\bar a\bar b}\bar\xi^-_{mg}=-\sigma^m_{\bar g\bar h}\epsilon_{\bar e\bar d\bar a\bar b}h^{\bar h}_{\bar a}\delta^{\bar g\bar d}\overline{\chi}^{+\bar e}_m,\quad \Box h^{g}_{a}\sigma^m_{ab}\bar\xi^-_{mg}=-\sigma^m_{gh}\epsilon_{edab}h^{h}_{a}\delta^{gd}\chi^{+e}_m,\\
&t^{ab}_Lh^{g}_{a}\sigma^m_{ab}\bar\xi^-_{mg}=0,\quad t^{\bar a\bar b}_Rh^{\bar g}_{\bar a}\sigma^m_{\bar a\bar b}\bar\xi^-_{mg}=0,\\
&t^{ab}_L\sigma^m_{ab}h^{\bar a}_{\bar g}\overline{\chi}^{+g}_m=0,\quad t^{\bar a\bar b}_R\sigma^m_{\bar a\bar b}h^{a}_{\bar g}\chi^{+\bar g}_m=0,\\
&\epsilon_{deab}t^{ab}_Lh^{g}_{a}h^{h}_{b}\sigma^m_{gh}\chi^{+e}_m=0,\quad \epsilon_{\bar d\bar e\bar a\bar b}t^{\bar a\bar b}_Rh^{\bar g}_{\bar a}h^{\bar h}_{\bar b}\sigma^m_{\bar g\bar h}\overline{\chi}^{+\bar e}_m=0.
\end{aligned} \tag{40}$$

VII. COMPARISON WITH LINEARIZED AdS SUPERGRAVITY EQUATIONS

We now show that the $AdS_3\times S^3$ supersymmetric vertex operator constraint equations are equivalent to the linearized supergravity equations for the supergravity multiplet and one tensor multiplet of $D=6$, $N=(2,0)$ supergravity[4] expanded around the $AdS_3\times S^3$ metric and a self-dual three-form. We give the identification of the string vertex operator components in terms of the supergravity fields.

We will see that the two-form b_{mn} is a linear combination of *all* the oscillations corresponding to the five self-dual tensor fields and the anti-self-dual tensor field, *including the oscillation with nonvanishing background*. In flat space, b_{mn} corresponds to a state in the Neveu–Schwarz sector. In our curved space case, the string model describes vertex operators for AdS_3 background with Ramond–Ramond flux. When matching the vertex operator component fields with the supergrav-

ity oscillations, we find that not only the bispinor V^{--}_{ab} (which is a Ramond–Ramond field in the flat space case), but also the tensor b_{mn} include supergravity oscillations with nonvanishing self-dual background.

The linearized supergravity equations are given by

$$D^p D_p \phi^i = \tfrac{2}{3} \overline{H}^i_{prs} g^{6prs}, \tag{41}$$

$$\begin{aligned} &\tfrac{1}{2} D^p D_p h_{rs} - \overline{R}_{\tau rs\lambda} h^{\tau\lambda} + \tfrac{1}{2} \overline{R}^{\tau}_{r} h_{\tau s} + \tfrac{1}{2} \overline{R}^{\tau}_{s} h_{\tau r} - \tfrac{1}{2} D_s D^p h_{pr} - \tfrac{1}{2} D_s D^p h_{pr} + \tfrac{1}{2} D_r D_s h^p_p \\ &\quad = -\overline{H}^i_{r\ pq} g^i_{spq} - \overline{H}^i_{s\ pq} g^i_{rpq} + 2 h^{pt} \overline{H}^i_{rp\ q} \overline{H}^i_{stq}, \end{aligned} \tag{42}$$

$$D^p H_{prs} = -2 \overline{H}^i_{prs} D^p \phi^i + B^i [-\overline{H}^i_{r\ pq} D_p h_{qs} + \overline{H}^i_{s\ pq} D_p h_{qr} + \overline{H}^i_{rs\ q} D^p h_{pq} - \tfrac{1}{2} \overline{H}^i_{rs\ q} D_q h^p{}_p], \tag{43}$$

where we have defined $H_{prs} \equiv g^6_{prs} + B^i g^i_{prs}$ as a combination of the supergravity exact forms $g^6 \equiv db^6$, $g^i \equiv db^i$, since we will equate this with the string field strength $H = db$. We will choose $B^1 = 2$. In zeroth order, the equations are $\overline{R}_{rs} = -\overline{H}^i_{rpq} \overline{H}^i_{s\ pq}$.

We define the vertex operator components in terms of the supergravity fields g^i_{prs}, g^6_{prs}, h_{rs}, ϕ^i, $1 \leqslant i \leqslant 5$ (and $2 \leqslant I \leqslant 5$) as

$$\begin{gathered} H_{prs} \equiv g^6_{prs} + 2 g^1_{prs} + B^I g^I_{prs}, \\ g_{rs} \equiv h_{rs} - \tfrac{1}{6} \overline{g}_{rs} h^\lambda_\lambda, \quad \phi = -\tfrac{1}{3} h^\lambda_\lambda, \\ F^{++ab}_{\text{sym}} = \tfrac{2}{3} (\sigma_p \sigma_r \sigma_s)^{ab} B^I g^I_{prs} + \delta^{ab} \phi^{++}, \\ F^{++ab}_{\text{asy}} = \sigma^{pab} D_p \phi^{++}, \quad \phi^{++} = 4 C^I \phi^I, \end{gathered} \tag{44}$$

which follows from choosing the graviton trace h^λ_λ to satisfy $\phi^1 - h^\lambda_\lambda \equiv -2 C^I \phi^I$, and we have used $H_{prs} \equiv \partial_p b_{rs} + \partial_r b_{sp} + \partial_s b_{pr}$.

The combinations $C^I \phi^I$ and $B^I g^I_{prs}$ reflect the $\mathrm{SO}(4)_{\mathrm{R}}$ symmetry of the $D = 6$, $N = (2,0)$ theory on $\mathrm{AdS}_3 \times S^3$. We relabel $C^I = C^I_{++}$ and $B^I = B^I_{++}$. To define the remaining string components in terms of supergravity fields, we consider linearly independent quantities $C^I_{\mathrm{l}} \phi^I$, $B^I_{\mathrm{l}} g^I_{prs}$, $\mathrm{l} = ++, +-, -+, --$.

$$\begin{gathered} F^{+-ab}_{\text{sym}} = \tfrac{2}{3} (\sigma_p \sigma_r \sigma_s)^{ab} B^I_{+-} g^I_{prs} + \delta^{ab} \phi^{+-}, \\ F^{+-ab}_{\text{asy}} = \sigma^{pab} D_p \phi^{+-}, \quad \phi^{+-} = 4 C^I_{+-} \phi^I, \\ F^{-+ab}_{\text{sym}} = \tfrac{2}{3} (\sigma_p \sigma_r \sigma_s)^{ab} B^I_{-+} g^I_{prs} + \delta^{ab} \phi^{-+}, \\ F^{-+ab}_{\text{asy}} = \sigma^{pab} D_p \phi^{-+}, \quad \phi^{-+} = 4 C^I_{-+} \phi^I. \end{gathered} \tag{45}$$

Here V^{--}_{ab} is given in terms of the fourth tensor/scalar pair $C^I_{--} \phi^I, B^I_{--} g^I_{mnp}$ through

$$D^p D_p V^{--}_{cd} - \delta^{gh} \sigma^p_{ch} D_p V^{--}_{gd} + \delta^{gh} \sigma^p_{dh} D_p V^{--}_{cg} + \tfrac{1}{2} \epsilon^{gh}_{cd} V^{--}_{gh} = -8 \sigma^m_{ce} \sigma^n_{df} \delta^{ef} G_{mn}. \tag{46}$$

These field definitions allow us to identify the string constraint equations for the AdS_3 vertex operators as precisely those which require the vertex operator field components to satisfy the linearized supergravity equations reviewed in this section.

Likewise, the fermion constraints imply the linearized AdS supergravity equations for the gravitinos and spinors, due to the above correspondence for the bosons and the supersymmetry of the two theories.

(Received 2 January 2001; accepted for publication 13 February 2001)

We discuss superparticle and superstring dynamics in $AdS_3 \times S^3$ supported by R–R 3-form background using light-cone gauge approach. Starting with the superalgebra $\mathrm{psu}(1,1|2) \oplus \widetilde{\mathrm{psu}}(1,1|2)$ representing the basic symmetry of this background we find the light-cone superparticle Hamiltonian. We determine the harmonic decomposition of light-cone superfield describing fluctuations of type IIB supergravity fields expanded near $AdS_3 \times S^3$ background and thus the corresponding Kaluza–Klein spectrum. We fix the fermionic and bosonic light-cone gauges in the covariant Green–Schwarz $AdS_3 \times S^3$ superstring action and find the corresponding light-cone string Hamiltonian. We also obtain a realization of the generators of $\mathrm{psu}(1,1|2) \oplus \widetilde{\mathrm{psu}}(1,1|2)$ in terms of the superstring 2-d fields in the light-cone gauge. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377274]

I. INTRODUCTION

Understanding how to quantize superstrings in Ramond–Ramond backgrounds is of topical interest, in particular, in connection with string theory—gauge theory duality.[1,2] The basic example of type IIB Green–Schwarz string in $AdS_5 \times S^5$ with R–R 5-form background[2] was studied, e.g., in. Refs. 3–10. One may hope that a progress towards understanding the spectrum of this theory may be achieved by using a light-cone gauge approach recently developed in Refs. 11, 12 (for an alternative covariant approach, see Ref. 13). To get a better understanding of this light-cone approach it may be useful to consider first a similar but somewhat simpler string model.

An obvious candidate for such simpler model is type IIB string in $AdS_3 \times S^3 \times T^4$ with R–R 3-form background. In what follows we shall ignore the trivial T^4 factor. The $AdS_3 \times S^3 \times T^4$ with NS–NS 3-form background represents the near-horizon limit of NS 5-brane—fundamental string configuration[14] and a fundamental superstring probe in it may be described by the standard $\mathrm{SL}(2,R) \times \mathrm{SU}(2)$ WZW model in the NSR formulation. However, the superstring propagation in S-dual R–R background which is the near-horizon limit of D5–D1 system[15] cannot be studied directly in the usual NSR formalism. The explicit form of the covariant GS string action in this R–R background was found in Refs. 16–18 by applying the same supercoset method which was used in the $AdS_5 \times S^5$ string case in Ref. 3. An alternative ''hybrid'' approach to quantization of superstring in $AdS_3 \times S^3$ R–R background was developed in Ref. 19 (see also Ref. 20).

In this paper we shall discuss several aspects of superstring dynamics in the $AdS_3 \times S^3$ R–R background in the light-cone approach developed for the $AdS_5 \times S^5$ case in Refs. 11, 12. Since the simplest limiting case of superstring is superparticle, we also consider in some detail the light-cone superparticle theory in $AdS_3 \times S^3$, following closely the treatment of the $AdS_5 \times S^5$ case in Ref. 21. First quantization of superparticle determines the spectrum of fluctuations of type IIB supergravity in $AdS_3 \times S^3 \times T^4$ (found directly in component form in Ref. 22) and thus also the ''ground state'' spectrum of the corresponding string theory. In the treatment of the superstring theory our starting point will be the covariant GS action (see Refs. 16–18) where we shall fix the

light-cone-type fermionic (κ-symmetry) and bosonic (2-d diffeomorphism) gauges and derive the light-cone Hamiltonian along the lines of the phase space approach of Ref. 12.

The paper is organized as follows: In Sec. II we review the structure of the underlying symmetry superalgebra of the type IIB superstring theory in $AdS_3\times S^3$ R–R background—$\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ (Ref. 23) and present its (anti)commutation relations in a light-cone basis.

In Sec. III we consider superparticle dynamics in $AdS_3\times S^3$. We find the light-cone superparticle Hamiltonian and a realization of the generators of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ on phase space of (first-quantized) superparticle.

In Sec. IV we develop a manifestly supersymmetric light-cone gauge formulation of type IIB supergravity on $AdS_3\times S^3$ background. The quadratic term in the action for fluctuation fields is written in terms of a single unconstrained scalar light-cone superfield, allowing us to treat all the component fields on an equal footing. We also present a superfield version of S^3 harmonic decomposition and find the corresponding K–K spectra of the supergravity modes propagating in AdS_3.

In Sec. V we find the κ-symmetry light-cone gauge fixed form of the superstring action in $AdS_3\times S^3$. We give the superstring Lagrangian both in the ''Wess–Zumino'' and ''Killing'' parametrizations of the basic coset superspace $[\mathrm{PSU}(1,1|2)\times\widetilde{\mathrm{PSU}}(1,1|2)]/[\mathrm{SO}(2,1)\times\mathrm{SO}(3)]$ on which the superstring is propagating. We also discuss a reformulation of the resulting superstring action in terms of 2-d Dirac world-sheet fermions.

Section VI is devoted to the light-cone phase space approach to superstring theory. We fix the analog of the GGRT bosonic light-cone gauge and derive the phase space analog of the superstring Lagrangian of Sec. V and the corresponding light-cone gauge Hamiltonian.

In Sec. VII we obtain a realization of the generators of the symmetry superalgebra $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ as Noether charges expressed in terms of the 2-d fields which are the coordinates of the $AdS_3\times S^3$ superstring in the light cone gauge.

Some technical details are collected in five Appendices. In Appendix A we summarize our notation and definitions used in this paper and give some relations relevant for a coset description of S^3. In Appendix B we describe correspondence between the ''covariant'' and ''light-cone'' forms of the $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra. In Appendix C we explain the construction of Poincaré supercharges in the case of superparticle. In Appendix D we give some details of computation of the spectrum of type IIB supergravity fluctuations in $AdS_3\times S^3$. In Appendix E we present the expressions for the supercoset Cartan 1-forms which are the basic elements in the construction of the GS superstring action, and describe our procedure of fixing the fermionic light-cone gauge in the string action.

II. $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ SUPERALGEBRA

The symmetry algebra of the $AdS_3\times S^3$ with R–R 3-form background may be represented as a direct sum of two copies of $\mathrm{psu}(1,1|2)$ superalgebra, i.e., as $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra.[23] The even part of this superalgebra consists of the bosonic subalgebras su(1,1), su(2) and $\widetilde{\mathrm{su}}(1,1)$, $\widetilde{\mathrm{su}}(2)$ respectively. su(1,1) and $\widetilde{\mathrm{su}}(1,1)$ combine into so(2,2) algebra while su(2) and $\widetilde{\mathrm{su}}(2)$ form the so(4) algebra. These so(2,2) and so(4) algebras are the isometry algebras of the AdS_3 and S^3 factors, respectively. The odd part of the superalgebra consists of 16 supercharges which correspond to the 16 Killing spinors of $AdS_3\times S^3$ geometry.

The superalgebra $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ will play the central role in our constructions. Let us review its commutation relations in the two forms (''covariant'' and ''light-cone'') we are going to use. In $\mathrm{su}(1,1)\oplus\mathrm{su}(2)$ covariant basis the $\mathrm{psu}(1,1|2)$ superalgebra has the following generators: $m^{\alpha}{}_{\beta}$ and $m^{i}{}_{j}$ which are generators of su(1,1) and su(2) and 8 supercharges q_i^{α}, q^{i}_{α} ($\alpha,\beta=1,2$; $i,j=1,2$). Their (anti)commutation relations have the following well known form,

$$[m^{\alpha}{}_{\beta},m^{\gamma}{}_{\delta}]=\delta^{\gamma}_{\beta}m^{\alpha}{}_{\delta}-\delta^{\alpha}_{\delta}m^{\gamma}{}_{\beta},\quad [m^{i}{}_{j},m^{k}{}_{n}]=\delta^{k}_{j}m^{i}{}_{n}-\delta^{i}_{n}m^{k}{}_{j}, \tag{2.1}$$

$$[m^{\alpha}{}_{\beta},q^{k}_{\gamma}]=-\delta^{\alpha}_{\gamma}q^{k}_{\beta}+\tfrac{1}{2}\delta^{\alpha}_{\beta}q^{k}_{\gamma},\quad [m^{i}{}_{j},q^{k}_{\alpha}]=\delta^{k}_{j}q^{i}_{\alpha}-\tfrac{1}{2}\delta^{i}_{j}q^{k}_{\alpha}, \tag{2.2}$$

$$[m^i{}_j,q_k^\alpha]=-\delta_k^i q_j^\alpha+\tfrac{1}{2}\delta_j^i q_k^\alpha,\quad [m^\alpha{}_\beta,q_k^\gamma]=\delta_\beta^\gamma q_k^\alpha-\tfrac{1}{2}\delta_\beta^\alpha q_k^\gamma, \tag{2.3}$$

$$\{q_\alpha^i,q_j^\beta\}=a(\delta_j^i m^\beta{}_\alpha+\delta_\alpha^\beta m^i{}_j),\quad a^2=-1. \tag{2.4}$$

We assume the following Hermitian conjugation rules:

$$(m^\alpha{}_\beta)^\dagger=-m^\alpha{}_\beta,\quad (m^i{}_j)^\dagger=m^j{}_i,\quad (q_i^\alpha)^\dagger=\epsilon^{\alpha\beta}q_\beta^i,\quad (q_\alpha^i)^\dagger=q_i^\beta\epsilon_{\beta\alpha}, \tag{2.5}$$

where $\epsilon^{\alpha\beta}$ is the Levi-Civita tensor, $\epsilon_{12}=\epsilon^{12}=1$. The $\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra has the same commutation relations but with the constant a in (2.4) replaced by $\tilde{a}(\tilde{a}^2=-1)$ such that its sign is opposite to that of a, i.e., $a\tilde{a}=1$.

It will be useful to decompose the generators according to their light-cone SO(1,1) group transformation properties (we shall call this ''light-cone basis''). In the light-cone basis the generators of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ include translations $P^\pm$, conformal boosts $K^\pm$, Lorentz rotation J^{+-}, dilatation D, R-symmetry generators of su(2) and $\widetilde{\mathrm{su}}(2)$ $J^i{}_j$ and $\tilde{J}^i{}_j$, Poincaré algebra supercharges $Q^{\pm i}$, and conformal algebra supercharges $S^{\pm i}$. To simplify the notation here we use the same type of indices for su(2) and $\widetilde{\mathrm{su}}(2)$. The Hermitian conjugation rules are

$$(P^\pm)^\dagger=P^\pm,\quad (K^\pm)^\dagger=K^\pm,\quad (Q^{\pm i})^\dagger=Q_i^\pm,\quad (S^{\pm i})^\dagger=S_i^\pm, \tag{2.6}$$

$$(J^{+-})^\dagger=-J^{+-},\quad D^\dagger=-D,\quad J^{i\dagger}{}_j=J^j{}_i,\quad \tilde{J}^{i\dagger}{}_j=\tilde{J}^j{}_i. \tag{2.7}$$

The anti(commutation) relations then include (their derivation from the above relations is explained in Appendix B)

$$[P^\pm,K^\mp]=D\mp J^{+-}, \tag{2.8}$$

$$[D,P^\pm]=-P^\pm,\quad [D,K^\pm]=K^\pm,\quad [J^{+-},P^\pm]=\pm P^\pm,\quad [J^{+-},K^\pm]=\pm K^\pm, \tag{2.9}$$

$$[D,Q_i^\pm]=-\tfrac{1}{2}Q_i^\pm,\quad [D,S_i^\pm]=\tfrac{1}{2}S_i^\pm,\quad [J^{+-},Q_i^\pm]=\pm\tfrac{1}{2}Q_i^\pm,\quad [J^{+-},S_i^\pm]=\pm\tfrac{1}{2}S_i^\pm, \tag{2.10}$$

$$[S_i^\mp,P^\pm]=Q_i^\pm,\quad [Q^{\mp i},K^\pm]=S^{\pm i},\quad \{Q^{\pm i},Q_j^\pm\}=\pm P^\pm\delta_j^i,\quad \{S^{\pm i},S_j^\pm\}=\pm K^\pm\delta_j^i, \tag{2.11}$$

$$\{Q^{+i},S_j^-\}=\tfrac{1}{2}(J^{+-}-D)\delta_j^i-\tilde{J}^i{}_j,\quad \{Q^{-i},S_j^+\}=\tfrac{1}{2}(J^{+-}+D)\delta_j^i+J^i{}_j, \tag{2.12}$$

plus Hermitian conjugations of the above ones. The remaining relations can be summarized as follows. The supercharges Q_i^-, Q^{-i}, S^{+i}, S_i^+ transform in the (anti)fundamental representations of su(2)—they are rotated only by $J^i{}_j$, i.e.,

$$[J^i{}_j,Q^{-k}]=\delta_j^k Q^{-i}-\tfrac{1}{2}\delta_j^i Q^{-k},\quad [J^i{}_j,Q_k^-]=-\delta_k^i Q_j^-+\tfrac{1}{2}\delta_j^i Q_k^-, \tag{2.13}$$

and the same for S_i^+, S^{+i}. The remaining supercharges Q^{+i}, Q_i^+, S^{-i}, S_i^- transform in the (anti)fundamental representations of $\widetilde{\mathrm{su}}(2)$—they are rotated only by $\tilde{J}^i{}_j$, i.e.,

$$[\tilde{J}^i{}_j,Q^{+k}]=\delta_j^k Q^{+i}-\tfrac{1}{2}\delta_j^i Q^{+k},\quad [\tilde{J}^i{}_j,Q_k^+]=-\delta_k^i Q_j^++\tfrac{1}{2}\delta_j^i Q_k^+, \tag{2.14}$$

and the same for S^{-i}, S_i^-. The generators $J^i{}_j$, $\tilde{J}^i{}_j$ satisfy the standard relations

$$[J^i{}_j,J^k{}_n]=\delta_j^k J^i{}_n-\delta_n^i J^k{}_j,\quad [\tilde{J}^i{}_j,\tilde{J}^k{}_n]=\delta_j^k\tilde{J}^i{}_n-\delta_n^i\tilde{J}^k{}_j. \tag{2.15}$$

III. SUPERPARTICLE DYNAMICS IN $AdS_3\times S^3$ BACKRGOUND

Before discussing the superstring it is instructive to consider first a superparticle propagating in $AdS_3\times S^3$ space. The covariant Brink–Schwarz κ-symmetric action for a superparticle in $AdS_3\times S^3$ can be obtained, e.g., from the superstring action of Refs. 16–18 by taking the zero slope limit $\alpha'\to 0$. By applying the light-cone gauge fixing procedure (see Ref. 12 and below) one could then obtain the superparticle light-cone gauge fixed action. On the other hand, there is a method[24] which reduces the problem of constructing a new (light-cone gauge) dynamical system to the problem of finding a new solution of the commutation relations of the defining symmetry algebra [in our case $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$]. This method of Dirac was applied to the case of superparticle in $AdS_5\times S^5$ in Ref. 21 (see also Ref. 25) and here we would like to demonstrate how it works for the superparticle in $AdS_3\times S^3$. Quantization of superparticle determines the quadratic part of the action of type IIB supergravity expanded near $AdS_3\times S^3$ background.

In the light-cone formalism the generators of the $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra can be split into the two groups:

$$P^+, K^+, Q^{+i}, Q_i^+, S^{+i}, S_i^+, D, J^{+-}, J^i{}_j, \tilde{J}^i{}_j, \tag{3.1}$$

which we shall refer to as kinematical generators, and

$$P^-, K^-, Q^{-i}, Q_i^-, S^{-i}, S_i^-, \tag{3.2}$$

which we shall refer to as dynamical generators. The kinematical generators have positive or zero J^{+-} (Lorentz) charges, while the dynamical generators have negative J^{+-} charges. It turns out that in the superfield realization the kinematical generators taken at $x^+=0$ are quadratic in the physical fields, while the dynamical generators receive higher-order interaction-dependent corrections. In general, the kinematical generators have the structure $G=G_1+x^+G_2+(x^+)^2G_3$, where G_1 is quadratic but G_2, G_3 contain higher order terms in second-quantized fields. The first step is to find a free (quadratic) superfield representation for the generators of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$. The generators we obtain below will be used for the description of Sec. II B supergravity in $AdS_3\times S^3$ background.

Let us explain step by step how the method of Ref. 24 works in the present case: First, we introduce a light-cone superspace on which we are going to realize the generators of our superalgebra. The superspace coordinates include the position coordinates $x^\pm$, z of AdS_3, a unit vector u^M representing S^3, and the Grassmann coordinates θ^i, η^i. In this parametrization the metric of $AdS_3\times S^3$ is ($M=1,2,3,4$),

$$ds^2=\frac{1}{z^2}(2dx^+dx^-+dz^2)+du^Mdu^M,\quad u^Mu^M=1. \tag{3.3}$$

In formulating our results we shall trade the bosonic coordinate x^- and the Grassmann coordinates θ^i, η^i for the bosonic momentum p^+ and the Grassmann momenta λ_i, ϑ_i.

Let us start with the kinematical generators and consider them on the surface of the initial data $x^+=0$. The kinematical generators which have positive J^{+-}-charge are fixed to be

$$P^+=p^+,\quad K^+=\tfrac{1}{2}z^2p^+, \tag{3.4}$$

$$Q_i^+=\lambda_i,\quad Q^{+i}=p^+\theta^i\quad S_i^+=\frac{1}{\sqrt{2}}z\vartheta_i,\quad S^{+i}=\frac{1}{\sqrt{2}}zp^+\eta^i, \tag{3.5}$$

where the coordinates θ^i, η^i and their momenta λ_i, ϑ_i satisfy the canonical anticommutation relations

$$\{\lambda_i,\theta^j\}=\delta_i^j,\quad \{\vartheta_i,\eta^j\}=\delta_i^j. \tag{3.6}$$

Let us note that in the language of an action based on a supercoset construction the above parametrization of the kinematical generators corresponds to special choices of (i) coset representative and (ii) light-cone gauges for 1-d diffeomorphism symmetry and κ-symmetry. In fact, these choices may be motivated by a simple form of the resulting generators.

Once the above generators are chosen, the remaining kinematical generators which have zero J^{+-}-charge are fixed by the commutation relations of the superalgebra,

$$J^{+-}=\partial_{p^+}p^+-\tfrac{1}{2}\theta\lambda-\tfrac{1}{2}\eta\vartheta+1,\quad D=-\partial_{p^+}p^++z\partial_z+\tfrac{1}{2}\theta\lambda+\tfrac{1}{2}\eta\vartheta-\tfrac{1}{2}, \tag{3.7}$$

$$J^i{}_j=l^i{}_j+\eta^i\vartheta_j-\tfrac{1}{2}\delta^i_j\eta\vartheta,\quad \tilde{J}^i{}_j=\tilde{l}^i{}_j+\theta^i\lambda_j-\tfrac{1}{2}\delta^i_j\theta\lambda, \tag{3.8}$$

where $\partial_{p^+}\equiv\partial/\partial p^+$, $\partial_z\equiv\partial/\partial z$. The orbital parts $l^i{}_j$ and $\tilde{l}^i{}_j$ of the angular momenta $J^i{}_j$ and $\tilde{J}^i{}_j$ are given by

$$l^i{}_j=\tfrac{1}{4}(\sigma^{MN})^i{}_j l^{MN},\quad \tilde{l}^i{}_j=\tfrac{1}{4}(\bar{\sigma}^{MN})^i{}_j l^{MN}, \tag{3.9}$$

where the so(4) orbital momentum l^{MN} can be chosen as

$$l^{MN}=u^M\hat{\partial}^N-u^N\hat{\partial}^M. \tag{3.10}$$

Here $\hat{\partial}^M$ is covariant tangent derivative on S^3 which is fixed by the constraint $u^M\hat{\partial}^M=0$ and by the commutation relations,

$$[\hat{\partial}^M,u^N]=v^{MN},\quad [\hat{\partial}^M,\hat{\partial}^N]=u^M\hat{\partial}^N-u^N\hat{\partial}^N,\quad v^{MN}\equiv\delta^{MN}-u^Mu^N. \tag{3.11}$$

Note that the concrete parametrization of the S^3 part is not very important to us as in the case of the superparticle all the generators are expressed in terms of the orbital part of the angular momentum. The operator $l^i{}_j$ satisfies the following basic relation:

$$l^i{}_k l^k{}_j=\tfrac{1}{2}l^2\delta^i_j+l^i{}_j, \tag{3.12}$$

where $l^2\equiv l^i{}_j l^j{}_i$. The same relation is true for $\tilde{l}^i{}_j$. The Hermitian conjugation rules are

$$\lambda_i^\dagger=p^+\theta^i,\quad \theta^{i\dagger}=\frac{\lambda_i}{p^+},\quad \vartheta_i^\dagger=p^+\eta^i,\quad \eta^{i\dagger}=\frac{\vartheta_i}{p^+},\quad (\partial_{p^+}p^+)^\dagger=-\partial_{p^+}p^++\theta\lambda+\eta\vartheta-2. \tag{3.13}$$

Once the all the kinematical generators are fixed, the dynamical generators are found from the commutation relations of the basic superalgebra (for details see Appendix C)

$$P^-=\frac{1}{2p^+}\left(\partial_z^2-\frac{1}{z^2}A\right), \tag{3.14}$$

$$Q_i^-=\frac{1}{\sqrt{2}p^+}\left(-\vartheta_i\partial_z-\frac{1}{z}(\eta\vartheta)\vartheta_i+\frac{1}{2z}\vartheta_i+\frac{2}{z}(\vartheta l)_i\right), \tag{3.15}$$

$$Q^{-i}=\frac{1}{\sqrt{2}}\left(\eta^i\partial_z-\frac{1}{z}\eta^i(\eta\vartheta)+\frac{1}{2z}\eta^i+\frac{2}{z}(l\eta)^i\right), \tag{3.16}$$

$$K^-=-\bar{S}\frac{1}{p^+}S-\frac{1}{2p^+}(\tilde{l}^2+2\lambda\tilde{l}\theta), \tag{3.17}$$

$$S^{-i}=\theta^i S-(\tilde{l}\,\theta)^i,\quad S_i^-=\lambda_i\bar{S}\frac{1}{p^+}-\frac{1}{p^+}(\lambda\tilde{l})_i, \tag{3.18}$$

where the operators A, S, and $\bar{S}$ are defined by

$$A\equiv X-\tfrac{1}{4},\quad X\equiv 2l^2+4\,\vartheta l\,\eta+(\eta\vartheta-1)^2, \tag{3.19}$$

$$S\equiv-\partial_{p^+}p^+ +\tfrac{1}{2}z\partial_z+\theta\lambda+\tfrac{1}{2}\,\eta\vartheta-\tfrac{3}{4},\quad \bar{S}\equiv\partial_{p^+}p^+ -\tfrac{1}{2}z\partial_z-\tfrac{1}{2}\,\eta\vartheta+\tfrac{3}{4}, \tag{3.20}$$

and we used the notation

$$(\vartheta l)_i\equiv\vartheta_j l^j{}_i,\quad (l\,\eta)^i\equiv l^i{}_j\eta^j,\quad (\lambda\tilde{l})_i\equiv\lambda_j\tilde{l}^j{}_i,\quad (\tilde{l}\,\theta)^i\equiv\tilde{l}^i{}_j\eta^j,\quad (\vartheta l\,\eta)\equiv\vartheta_i l^i{}_j\eta^j, \tag{3.21}$$

$$l^2\equiv l^i{}_j l^j{}_i,\quad \tilde{l}^2\equiv\tilde{l}^i{}_j\tilde{l}^j{}_i,\quad \eta\vartheta\equiv\eta^i\vartheta_i,\quad \theta\lambda\equiv\theta^i\lambda_i. \tag{3.22}$$

In the light-cone approach the operator P^- plays the role of the (minus) Hamiltonian of the superparticle. The expressions for the supercharges can be rewritten as follows:

$$Q_i^-=-\frac{1}{\sqrt{2}p^+}\left(\vartheta_i\partial_z+\frac{1}{2z}[\vartheta_i,A]\right),\quad Q^{-i}=\frac{1}{\sqrt{2}}\left(\eta^i\partial_z+\frac{1}{2z}[\eta^i,A]\right). \tag{3.23}$$

As in Ref. 26 and 27 we shall call A in (3.19) the AdS mass operator. This operator satisfies the following basic relation

$$\{[\eta^i,A],[\vartheta_j,A]\}+2[\eta^i,A]\vartheta_j+2[\vartheta_j,A]\eta^i=-4A\delta^i_j, \tag{3.24}$$

which is useful in checking that $\{Q_i^-,Q^{-j}\}=-\delta_i^j P^-$. Let us note that A is equal to zero only for massless representations which can be realized as irreducible representations of the conformal algebra,[28,27] i.e., of so(3,2) in the case of AdS_3. The values of this operator for various fields are discussed in Ref. 29. Below in Sec. IV B we shall demonstrate that A is not equal to zero for the whole spectrum of the S^3 compactification of type IIB supergravity to AdS_3.

The generators given above were defined on the initial data surface $x^+=0$. In general, they have the structure $G=G(x^+,\mathcal{X}(x^+))$, where $\mathcal{X}$ stands for all of the dynamical variables. Let us use the notation,

$$G|_{x^+=0}\equiv G(0,\mathcal{X}(x^+)). \tag{3.25}$$

The generators $G|_{x^+=0}$ can be obtained from the above expressions by expressing the dynamical variables $\mathcal{X}$ in terms of light-cone time variable x^+ using the Hamiltonian equations of motion which are postulated in our approach. The form of the generators for arbitrary x^+, i.e., $G(x^+,\mathcal{X}(x^+))$, is then found from the conservation laws for the charges,

$$J^{+-}=J^+|_{x^+=0}+x^+P^-,\quad D=D^+|_{x^+=0}+x^+P^-, \tag{3.26}$$

$$K^+=K^+|_{x^+=0}+x^+(D|_{x^+=0}+J^{+-}|_{x^+=0})+x^{+2}P^-, \tag{3.27}$$

$$S_i^+=S_i^+|_{x^+=0}-\mathrm{i}x^+Q_i^-,\quad S^{+i}=S^{+i}|_{x^+=0}+\mathrm{i}x^+Q^{-i}. \tag{3.28}$$

The remaining generators do not have explicit dependence on x^+, i.e., they have the structure $G(x^+,\mathcal{X}(x^+))=G(0,\mathcal{X}(x^+))$.

IV. LIGHT-CONE GAUGE SUPERFIELD FORMULATION OF TYPE IIB SUPERGRAVITY ON $AdS_3\times S^3$

In this section we shall present the light-cone gauge superfield description of type IIB supergravity on $AdS_3\times S^3$ background, implied by the quantization of the superparticle described in the previous section. Linearized equations of motion for fluctuations of supergravity fields in $AdS_3\times S^3\times K3$ background and the corresponding spectrum were found in component form.[22] We shall use instead the light-cone superfield approach.

This analysis can be viewed as a step towards understanding the spectrum of string theory in $AdS_3\times S^3$. As is well known in the case of (super)strings in flat space, reproducing the correct spectrum of the massless modes plays an important role in determining a consistent quantization scheme. The $AdS_3\times S^3$ spectrum we shall find below should be a useful guiding principle in quantising superstrings in this space. In particular, the operator ordering and renormalization scheme should be chosen so that the ground state of the superstring theory in $AdS_3\times S^3$ (with R–R 3-form background) will have the spectrum described below. Note that the selection of R–R as opposed to NS–NS background is predetermined by our choice of the basic superalgebra in Sec. II.

Finding even the quadratic part of the action for fluctuations of the supergravity fields in a curved background is a complicated problem. There are two ways of determining spectra of compactifications of the type II supergravity. The first one uses oscillator construction.[30] The second one is based on the analysis of equations of motion.[22,31] In our construction of the spectrum we shall follow the second approach. A new element which substantially simplifies the analysis is the use of the light-cone superfield formulation.

A. Quadratic light-cone superfield action

We could in principle use the covariant superfield description of type IIB supergavity,[32] starting with linearized expansion of superfileds, imposing light-cone gauge on fluctuations and then solving the constraints to eliminate non-physical degrees of freedom in terms of physical ones. That would be quite tedious. The light-cone gauge method provides a self-contained approach which does not rely upon existence of a covariant description and which gives a much shorter way to arrive to final results. The key idea is that, as in flat space,[33] the superparticle supercharges found in the previous section provide realization of the generators of the basic $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra in terms of the differential operators acting on the scalar supergravity superfield $\Phi(x^{\pm},z,u,\theta,\eta)$. It is convenient to Fourier transform to the momentum space for all of the coordinates except the radial AdS_3 coordinate z and S^3 directions u^M. This means using p^+, λ_i, ϑ_i instead of x^-, θ^i, η^i [λ_i and ϑ_i are in the fundamental representations of $\widetilde{\mathrm{su}}(2)$ and $\mathrm{su}(2)$]. Thus our basic superfield will be $\Phi(x^+,p^+,z,u,\lambda,\vartheta)$ with the following expansion in powers of the Grassmann momenta λ_i and ϑ_i:

$$\Phi(x^+,p^+,z,u,\lambda,\vartheta)=p^+\phi+\lambda_i\psi_1^i+\vartheta_i\psi_2^i+(\epsilon\lambda^2)\phi_1+\lambda_i\vartheta_j\phi_2^{ij}+(\epsilon\vartheta^2)\phi_1^*+\frac{1}{p^+}((\epsilon\lambda)^i(\epsilon\vartheta^2)\psi_1^{i*}+(\epsilon\vartheta)^i(\epsilon\lambda^2)\psi_2^{i*})-\frac{1}{p^+}(\epsilon\lambda^2)(\epsilon\vartheta^2)\phi^*, \tag{4.1}$$

where the coefficients $\phi,\phi_1,\phi_2,\psi_1,\psi_2$ are functions of x^+, the momentum p^+, and the bosonic coordinates z,u^M. We used the notation,

$$(\epsilon\lambda^2)\equiv\tfrac{1}{2}\epsilon^{ij}\lambda_i\lambda_j,\quad (\epsilon\lambda)^i\equiv\epsilon^{ij}\lambda_j, \tag{4.2}$$

and the same for ϑ. The only constraint which this superfield is to satisfy is the reality constraint

$$\Phi(-p^+,z,u,\lambda,\vartheta)=(p^+)^2\int d^2\lambda^\dagger d^2\vartheta^\dagger e^{(\lambda_i\lambda_i^\dagger+\vartheta_i\vartheta_i^\dagger)/p^+}(\Phi(p^+,z,u,\lambda,\vartheta))^\dagger, \tag{4.3}$$

where we assume the convention $(\lambda_1\lambda_2)^\dagger=\lambda_2^\dagger\lambda_1^\dagger$. This reality constraint implies that the component fields ϕ,ϕ_n are related to ϕ^*,ϕ_n^* by the Hermitian conjugation rule for the Fourier components, i.e. $(\phi^*(-p^+))^*=\phi(p^+),(\phi_n^*(-p^+))^*=\phi_n(p^+)$. Equation (4.3) leads also to the following self-duality condition:

$$\phi_2^{ij}(p^+)=-\epsilon^{ik}\epsilon^{jl}\phi_2^{kl*}(-p^+). \tag{4.4}$$

The light-cone action has the following ''noncovariant form:''

$$S=\int dx^+dzdp^+d^3ud^2\lambda d^2\vartheta\,\Phi(-p^+,z,u,-\lambda,-\vartheta)[p^+(i\partial_{x^+}+P^-)]\Phi(p^+,z,u,\lambda,\vartheta), \tag{4.5}$$

where the Hamiltonian density $(-P^-)$ is given by (3.14) and d^3u stands for the S^3 volume element, i.e., $d^4u\,\delta(u^Mu^M-1)$.

Transforming back to the position coordinate x^- this action can be cast into the ''relativistic-invariant'' form,

$$S=\frac{1}{2}\int d^3xd^3ud^2\lambda d^2\vartheta\,\Phi(x,u,-\lambda,-\vartheta)\left(\Box-\frac{1}{z^2}A\right)\Phi(x,u,\lambda,\vartheta), \tag{4.6}$$

where $\Box$ is the flat D'Alembertian $\Box=2\partial_{x^-}\partial_{x^+}+\partial_z^2$, and $d^3x\equiv dx^+dx^-dz$.

As was already mentioned above, the superparticle charges found in Sec. III give the representation of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ in terms of differential operators acting on the supergravity superfield Φ. We can thus write down the ''superfield-theory'' (or ''second-quantized'') realization of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ generators,

$$\hat{G}=\int dp^+dzd^3ud^2\lambda d^2\vartheta\,p^+\Phi(-p^+,z,u,-\lambda,-\vartheta)G\Phi(p^+,z,u,\lambda,\vartheta), \tag{4.7}$$

where G indicates representation of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra in terms of differential operators given in previous section.

B. Harmonic decomposition of the light-cone superfield and the spectrum

The light-cone description given above provides a convenient way to analyze the harmonic decomposition of basic component fields and thus the corresponding spectra of fluctuation modes. A nice feature of this approach is that this can be done at the level of superfields, i.e., in a manifestly supersymmetric way. The action (4.6) gives the following equation of motion for the basic superfield Φ:

$$\left(\Box-\frac{1}{z^2}A\right)\Phi=0. \tag{4.8}$$

To find the spectrum we are thus to decompose Φ into the eigenvectors of the AdS mass operator A defined in (3.19). Let us first make the standard harmonic decomposition (we absorb the coefficients of the expansion in the ''basic'' vectors),

$$\Phi=\sum_{k=0}^{\infty}\Phi_k, \tag{4.9}$$

where Φ_k are the so(4) harmonic superfields, satisfying, by definition,

$$2l^2\Phi_k=k(k+2)\Phi_k. \tag{4.10}$$

In this subsection the index k is used to indicate the Kaluza–Klein modes. We can further expand each Φ_k in power series with respect to the Grassmann momentum ϑ writing

$$\Phi_k=\sum_{\sigma=0}^{2}\Phi_{k,\sigma}, \tag{4.11}$$

where $\Phi_{k,\sigma}$ satisfies

$$2l^2\Phi_{k,\sigma}=k(k+2)\Phi_{k,\sigma}, \quad \eta\vartheta\Phi_{k,\sigma}=(2-\sigma)\Phi_{k,\sigma}. \tag{4.12}$$

These equations tell us that the harmonic superfield $\Phi_{k,\sigma}$ is a polynomial of degree σ in the Grassmann momentum ϑ. From the expression for the operator X (3.19) it is then clear the superfields $\Phi_{k,0}$ are its eigenvectors,

$$X\Phi_{k,0}=(k+1)^2\Phi_{k,0}. \tag{4.13}$$

It is easy to demonstrate that $\Phi_{k,2}$ are also the eigenvectors of X with the same eigenvalues, i.e., $X\Phi_{k,2}=(k+1)^2\Phi_{k,2}$. This gives the following equations of motion determining the part of the mass spectrum corresponding to $\Phi_{k,0},\Phi_{k,2}$:

$$\left(\Box-\frac{(2k+1)(2k+3)}{4z^2}\right)\Phi_{k,0}=0, \quad \left(\Box-\frac{(2k+1)(2k+3)}{4z^2}\right)\Phi_{k,2}=0. \tag{4.14}$$

It turns out that the remaining superfields $\Phi_{k,1}$ are not eigenvectors of X. They can be decomposed, however, into the eigenvectors of this operator as follows (for details see Appendix B)

$$\Phi_{k,1}=\Phi_{k,1}^{(1)}+\Phi_{k,1}^{(2)}, \tag{4.15}$$

where

$$\Phi_{k,1}^{(1)}=\left(\vartheta_i-\frac{2}{k+2}(\vartheta l)_i\right)\Phi_{k,1}^i, \quad k\geqslant 0; \tag{4.16}$$

$$\Phi_{k,1}^{(2)}=\left(\vartheta_i-\frac{2}{k}(\vartheta l)_i\right)\Phi_{k,1}^i, \quad k>0. \tag{4.17}$$

Here $\Phi_{k,1}^i$ does not depend on the Grassmann momentum ϑ but still depend on Grassmann momentum λ. Then,

$$X\Phi_{k,1}^{(1)}=k^2\Phi_{k,1}^{(1)}, \quad X\Phi_{k,1}^{(2)}=(k+2)^2\Phi_{k,1}^{(2)}, \tag{4.18}$$

and this gives the following equations of motion:

$$\left(\Box-\frac{(2k-1)(2k+1)}{4z^2}\right)\Phi_{k,1}^{(1)}=0, \quad \left(\Box-\frac{(2k+3)(2k+5)}{4z^2}\right)\Phi_{k,1}^{(2)}=0, \tag{4.19}$$

determining the spectra of these superfields.

Note that the operator A is equal to zero (i.e., $X=\frac{1}{4}$) only for massless representations which can be realized as irreducible representations of the conformal algebra[27,28] [so(3,2) in the case of AdS_3]. From the above spectra one can see that the mass terms, i.e., the eigenvalues of the operator A, are never equal to zero. That means, in particular, that the fluctuation modes for the compactification of Sec. II B supergravity on S^3 do not satisfy the conformally invariant equations of motion in AdS space.

V. LIGHT CONE SUPERSTRING ACTION IN $AdS_3\times S^3$ R–R BACKGROUND

In this section we shall find the form of the type IIB superstring action in $AdS_3\times S^3$ background with R–R 3-form flux in the light-cone gauge. The Green–Schwarz action for a superstring background was constructed in Refs. 16–18 following a similar construction for the $AdS_5\times S^5$ case in Ref. 3. Our discussion of light-cone gauge fixing will also repeat closely the same steps as in Refs. 11 and 12, where the $AdS_5\times S^5$ case was treated.

In flat space superstring light-cone gauge fixing procedure in flat space consists of the two stages:

(I) fermionic light-cone gauge choice, i.e., fixing the κ-symmetry by $\Gamma^+\theta^I=0$;

(II) bosonic light-cone gauge choice, i.e., using the conformal gauge $\sqrt{g}g^{\mu\nu}=\eta^{\mu\nu}$ and fixing the residual conformal diffeomorphism symmetry by $x^+(\tau,\sigma)=p^+\tau$. Note that we use Minkowski signature 2-d world sheet metric $g_{\mu\nu}$ with $g\equiv-\det g_{\mu\nu}$.

Our fermionic κ-symmetry light-cone gauge will be different from the naive $\Gamma^+\theta^I=0$ but will be related to it in the flat space limit. It will reduce the 16 fermionic coordinates θ^I_α to 8 physical Grassmann variables: ''linear'' θ^i and ''nonlinear'' η^i and their Hermitian conjugates θ_i and η_i. As in the case of the superparticle the 2-d fields θ^i, θ_i, and η^i, η_i transform according to the fundamental representations of $\widetilde{\mathrm{SU}}(2)$ and SU(2), respectively. The superconformal algebra $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ dictates that these variables should be related to the Poincaré and conformal supersymmetry in the light-cone gauge description of the boundary theory. As in the case of superparticle the superstring action and symmetry generators will have simple (quadratic) dependence on θ^i, but complicated (quartic) dependence on η^i. Note that it is these fermionic coordinates that are most suitable for light-cone gauge fixing of kappa symmetry in AdS space, both in the superparticle and superstring cases. These coordinates were introduced in Ref. 21 in the study of light-cone gauge dynamics of superparticle in $AdS_5\times S^5$. Light-cone gauge superstring action in $AdS_5\times S^5$ written in terms of these coordinates was found in Ref. 11. The light-cone gauge action can be found in two related forms. One of them corresponds to the choice of the Wess–Zumino-type gauge in superspace while another is based on the Killing gauge. These ''gauges'' or ''parametrizations'' do not reduce the number of fermionic degrees of freedom but only specialize a choice of fermionic coordinates.

A. Fermionic light-cone gauge action in WZ parametrization

Let us consider first fixing fermionic light-cone gauge in the action written in the WZ parametrization. This action turns out to be more convenient for reformulation of superstring action in terms of 2-*d* Dirac spinors (see next section). Using the parametrization of the basic supercoset $[\mathrm{PSU}(1,1|2)\times\widetilde{\mathrm{PSU}}(1,1|2)]/[\mathrm{SO}(2,1)\times\mathrm{SO}(3)]$ described in Appendix E and fixing a light-cone gauge the $AdS_3\times S^3$ superstring Lagrangian can be written as the sum of the bosonic term, term quadratic in fermions and quartic fermionic term,

$$\mathcal{L}=\mathcal{L}_B+\mathcal{L}_F^{(2)}+\mathcal{L}_F^{(4)}. \tag{5.1}$$

Here,

$$\mathcal{L}_B=-\sqrt{g}g^{\mu\nu}[e^{2\phi}\partial_\mu x^+\partial_\nu x^-+\tfrac{1}{2}\partial_\mu\phi\partial_\nu\phi+\tfrac{1}{2}e^{A'}_\mu e^{A'}_\nu], \tag{5.2}$$

where $e^{A'}_\mu$ is the projection of the vielbein of S^3 which in the special parametrization we will be using is given by

$$e^{A'}_\mu=-\frac{\mathrm{i}}{2}\mathrm{Tr}(\sigma^{A'}\partial_\mu UU^{-1})+\frac{\mathrm{i}}{2}\mathrm{Tr}(\sigma^{A'}\partial_\mu\tilde{U}\tilde{U}^{-1}), \tag{5.3}$$

$$U^i{}_j\equiv(e^y)^i{}_j,\quad \tilde{U}^i{}_j\equiv(e^{-y})^i{}_j,\quad U^\dagger U=I,\quad \tilde{U}^\dagger\tilde{U}=I, \tag{5.4}$$

where the trace is over $i,j=1,2$. The matrices $U\in \mathrm{SU}(2)$, $\tilde{U}\in \widetilde{\mathrm{SU}}(2)$ depends on 3 independent coordinates $y^{A'}$,

$$y^i{}_j \equiv \frac{\mathrm{i}}{2} y^{A'} (\sigma^{A'})^i{}_j, \quad (y^i{}_j)^* = -y^j{}_i, \quad y^i{}_i = 0, \tag{5.5}$$

where $\sigma^{A'}$ are 3 Pauli matrices. The quadratic part of the fermionic action is

$$\mathcal{L}_F^{(2)} = e^{2\phi}\partial_\mu x^+ \left[\frac{\mathrm{i}}{2}\sqrt{g} g^{\mu\nu} (-\theta_i \tilde{\mathcal{D}}_\nu \theta^i - \eta_i \mathcal{D}_\nu \eta^i + \mathrm{i}\eta_i e^i_{\nu j}\eta^j) + \epsilon^{\mu\nu}\eta^i C'_{ij}\tilde{\mathcal{D}}_\nu \theta^j \right] + \text{h.c.} \tag{5.6}$$

The $\epsilon^{\mu\nu}$ dependent (P-odd) term in (5.6) came from the WZ term in the covariant GS action on the supercoset. We used the following notation:

$$\mathcal{D}\eta^i = d\eta^i - \Omega^i{}_j \eta^j, \quad \mathcal{D}\eta_i = d\eta_i + \eta_j \Omega^j{}_i, \quad \tilde{\mathcal{D}}\theta^i = d\theta^i - \tilde{\Omega}^i{}_j \theta^j, \quad \tilde{\mathcal{D}}\theta_i = d\theta_i + \theta_j \tilde{\Omega}^j{}_i, \tag{5.7}$$

$$e^i{}_j \equiv (\sigma^{A'})^i{}_j e^{A'}, \tag{5.8}$$

and $\mathcal{D} = d\sigma^\mu \mathcal{D}_\mu$, $e^i{}_j = d\sigma^\mu e^i_{\mu j}$, where $\sigma^\mu = (\tau,\sigma)$ are 2-d coordinates. $\mathcal{D}$, $\tilde{\mathcal{D}}$ are the generalized spinor derivatives on S^3. They have the structure $\mathcal{D} = d + \Omega^i{}_j J^j{}_i$, $\tilde{\mathcal{D}} = d + \tilde{\Omega}^i{}_j \tilde{J}^j{}_i$ and satisfy the relation $\mathcal{D}^2 = 0$, $\tilde{\mathcal{D}}^2 = 0$. The connections $\Omega^i{}_j$, $\tilde{\Omega}^i{}_j$ are given by

$$\Omega = dUU^{-1}, \quad \tilde{\Omega} = d\tilde{U}\tilde{U}^{-1}, \quad d\Omega - \Omega\wedge\Omega = 0, \quad d\tilde{\Omega} - \tilde{\Omega}\wedge\tilde{\Omega} = 0, \tag{5.9}$$

and can be written in terms of the S^3 spin connection $\omega^{A'B'}$ and the 3-bein $e^{A'}$ as follows:

$$\Omega^i{}_j = -\frac{1}{4}(\sigma^{A'B'})^i{}_j \omega^{A'B'} + \frac{\mathrm{i}}{2}(\sigma^{A'})^i{}_j e^{A'}, \quad \tilde{\Omega}^i{}_j = -\frac{1}{4}(\sigma^{A'B'})^i{}_j \omega^{A'B'} - \frac{\mathrm{i}}{2}(\sigma^A)^i{}_j e^{A'}. \tag{5.10}$$

C'_{ij} is the constant charge conjugation matrix of the SO(3) Dirac matrix algebra (see Appendix A). The Hermitian conjugation rules are $\theta_i^\dagger = \theta^i$, $\eta_i^\dagger = \eta^i$.

The quartic fermionic term in (5.1) depends only on half of the Grassmann variables—on η but not on θ,

$$\mathcal{L}_F^{(4)} = 2\sqrt{g} g^{\mu\nu} e^{4\phi} \partial_\mu x^+ \partial_\nu x^+ (\eta^i \eta_i)^2. \tag{5.11}$$

B. "2-d spinor" form of the action

Like in the flat space case[34] and in the "long string" cases in $AdS_5\times S^5$ (Ref. 9) the resulting action can then be put into the "2-d spinor" form, where the $4+4$ fermionic degrees of freedom are organized into 2 Dirac 2-d spinors, defined in *curved* 2-d geometry (we shall follow similar discussion in $AdS_5\times S^5$ case in Ref. 11). Such action may be useful to establishing a relation to NSR formulation.

In order to do that one needs to impose, addition to fermionic light-cone gauge, the bosonic light-cone gauge. Using the following light-cone gauge:[35]

$$x^+ = \tau, \quad \sqrt{g} g^{\mu\nu} = \mathrm{diag}(-e^{-2\phi}, e^{2\phi}), \tag{5.12}$$

we can write the kinetic term (5.6) as

$$\mathcal{L}_F^{(2)} = \frac{\mathrm{i}}{2}(\theta_i \tilde{\mathcal{D}}_0 \theta^i + \eta_i \tilde{\mathcal{D}}_0 \eta^i - 2\mathrm{i}\eta_i e^i_{0j}\eta^j) + e^{2\phi}\eta^i C'_{ij}\tilde{\mathcal{D}}_1 \theta^j + \text{h.c.}, \tag{5.13}$$

where we used the relation $\mathcal{D}\eta^i=\tilde{\mathcal{D}}\eta^i-\mathrm{i}e^i{}_j\eta^j$ [see (5.10)]. Introducing a 2-d zweibein corresponding to the metric in (5.12),

$$e^m_\mu=\mathrm{diag}(e^{2\phi},1), \quad g_{\mu\nu}=-e^0_\mu e^0_\nu+e^1_\mu e^1_\nu, \tag{5.14}$$

we can put (5.13) in the 2-d form as follows:

$$e^{-1}\mathcal{L}^{(2)}_F=-\frac{\mathrm{i}}{2}\bar{\psi}\varrho^m e^\mu_m\tilde{\mathcal{D}}_\mu\psi+\frac{\mathrm{i}}{2}\bar{\psi}\psi\partial_1\phi-\sqrt{2}\bar{\psi}_i e^i_{0j}\varrho^-\psi^j+\mathrm{h.c.}, \tag{5.15}$$

where ϱ^m are 2-d Dirac matrices,

$$\varrho^0=\mathrm{i}\sigma_2, \quad \varrho^1=\sigma_1, \quad \varrho^3=\varrho^0\varrho^1=\sigma_3, \quad \varrho^\pm\equiv\frac{1}{\sqrt{2}}(\varrho^3\pm\varrho^0), \tag{5.16}$$

$\bar{\psi}_i=(\psi^i)^\dagger\varrho^0$, $\bar{\psi}\psi$ stands for $\bar{\psi}_i\psi^i$, ψ^T denotes the transposition of 2-d spinor and ψ's are related to the original (2-d scalar) fermionic variables θ's and η's by

$$\psi^i=\begin{pmatrix}\psi^i_1\\ \psi^i_2\end{pmatrix}, \quad \psi^i_1=\frac{1}{\sqrt{2}}[\theta^i-\mathrm{i}(C'^{-1})^{ij}\eta_j], \quad \psi^i_2=\frac{1}{\sqrt{2}}[\theta^i+\mathrm{i}(C'^{-1})^{ij}\eta_j]. \tag{5.17}$$

In our notation $\mathrm{i}\bar{\psi}\varrho^m\nabla_m\psi=-\mathrm{i}\psi^\dagger_1(\nabla_0-\nabla_1)\psi_1-\mathrm{i}\psi^\dagger_2(\nabla_0+\nabla_1)\psi_2$, $\nabla_m=e^\mu_m\partial_\mu$. The quartic interaction term (5.11) then takes the following form:

$$e^{-1}\mathcal{L}^{(4)}_F=-(\bar{\psi}_i\varrho^-\psi^i)^2. \tag{5.18}$$

The total action is thus a kind of G/H bosonic sigma model coupled to a Thirring-type 2-d fermionic model in curved 2-d geometry (5.14) (determined by the profile of the radial function of the AdS space), and coupled to some 2-d vector fields. The interactions are such that they ensure the quantum 2-d conformal invariance of the total model.[3]

The mass term $\bar{\psi}\psi\partial_1\phi$ in (5.15) is similar to the one in Ref. 9 (where the background string configuration was non-constant only in the radial ϕ direction) and has its origin in the $\epsilon^{\mu\nu}e^{2\phi}\partial_\mu x^+\partial_\nu\phi\,\eta^iC'_{ij}\theta^j$ term appearing after $\eta\leftrightarrow\theta$ symmetrization of the $\epsilon^{\mu\nu}$ term in (5.6) (its ''noncovariance'' is thus a consequence of the choice $x^+=\tau$). The action is symmetric under shifting $\psi^i\to\psi^i+\varrho^-\epsilon^i$, where ϵ^i is the 2-d Killing spinor. This symmetry reflects the fact that our original action is symmetric under shifting θ^i by a Killing spinor on S^3.

Note also that the 2-d Lorentz invariance is preserved by the fermionic light-cone gauge (original GS fermions θ are 2-d scalars) but is broken by our special choice of the bosonic gauge (5.12) The special form of $g_{\mu\nu}$ in (5.12) implies ''noncovariant'' dependence on ϕ in the bosonic part of the action: the action (5.2) for the field ϕ and the 3-sphere coordinates $y^{A'}$ has the form,

$$\mathcal{L}_B=\tfrac{1}{2}e^{-2\phi}\dot{\phi}^2-\tfrac{1}{2}e^{2\phi}\acute{\phi}^2+\tfrac{1}{2}G_{\mathcal{AB}}(e^{-2\phi}\dot{y}^{\mathcal{A}}\dot{y}^{\mathcal{B}}-e^{2\phi}\acute{y}^{\mathcal{A}}\acute{y}^{\mathcal{B}}), \tag{5.19}$$

where $G_{\mathcal{AB}}$ is the metric of 5-sphere ($y^{\mathcal{A}}$ are coordinates of S^3). A consequence of the unusual $g_{\mu\nu}$ gauge choice in (5.12) compared to the standard conformal gauge is that now the S^3 part of the action is no longer decoupled from the radial AdS_3 direction ϕ.

C. Fermionic light-cone gauge action in the Killing parametrization

Now let us consider the string action in the Killing parametrization. The action is again formulated in terms of 6 bosonic coordinates $(x^\pm,\phi,y^{\mathcal{A}})$ ($\mathcal{A}$ label 3 independent coordinates of S^3) in terms of which the metric of $AdS_3\times S^3$ is

$$ds^2=2e^{2\phi}dx^+dx^-+d\phi^2+G_{\mathcal{AB}}(y)dy^{\mathcal{A}}dy^{\mathcal{B}}, \tag{5.20}$$

and 8 fermionic coordinates (θ^i,θ_i), (η^i,η_i) in the fundamental representations of $\widetilde{\mathrm{SU}}(2)$ and SU(2), respectively. In contrast to the WZ parametrization, the fermions in the Killing parametrization transform in the linear representations of SU(2) and $\widetilde{\mathrm{SU}}(2)$, and thus the covariant derivatives in WZ case (5.7) here will become ordinary derivatives. The Lagrangian is given by the sum of the ''kinetic'' and ''Wess–Zumino'' terms (see Appendices A and B for notation),

$$\mathcal{L}=\mathcal{L}_{\mathrm{kin}}+\mathcal{L}_{\mathrm{WZ}},$$

$$\mathcal{L}_{\mathrm{kin}}=-\sqrt{g}g^{\mu\nu}[e^{2\phi}\partial_\mu x^+\partial_\nu x^-+\tfrac{1}{2}\partial_\mu\phi\partial_\nu\phi+\tfrac{1}{2}G_{\mathcal{AB}}(y)D_\mu y^{\mathcal{A}}D_\nu y^{\mathcal{B}}]-\frac{\mathrm{i}}{2}\sqrt{g}g^{\mu\nu}e^{2\phi}\partial_\mu x^+[\theta^i\partial_\nu\theta_i$$
$$+\theta_i\partial_\nu\theta^i+\eta^i\partial_\nu\eta_i+\eta_i\partial_\nu\eta^i+\mathrm{i}e^{2\phi}\partial_\nu x^+(\eta^2)^2], \tag{5.21}$$

$$\mathcal{L}_{WZ}=\epsilon^{\mu\nu}e^{2\phi}\partial_\mu x^+\,\eta^iC^U_{ij}\partial_\nu\theta^j+\mathrm{h.c.}, \tag{5.22}$$

where

$$D_\mu y^{\mathcal{A}}=\partial_\mu y^{\mathcal{A}}-2\mathrm{i}\,\eta_i(V^{\mathcal{A}})^i{}_j\eta^je^{2\phi}\partial_\mu x^+,\quad C^U_{ij}\equiv U^k{}_iC'_{kl}\tilde{U}^l{}_j. \tag{5.23}$$

Here $G_{\mathcal{AB}}$ and $(V^{\mathcal{A}})^i{}_j$ are the metric tensor and the Killing vectors of S^3, respectively (see Appendix A). This form of the superstring action (which we shall call ''intermediate'') is most convenient for deriving other forms which differ in the way one chooses the bosonic coordinates that parametrize $AdS_3\times S^3$. For example, a useful form of the action is found by introducing a unit 4-vector u^M defined

$$u^{A'}=n^{A'}\sin|y|,\quad u^4=-\cos|y|, \tag{5.24}$$

in terms of which the $AdS_3\times S^3$ metric is

$$ds^2=e^{2\phi}dx^adx^a+d\phi^2+du^Mdu^M,\quad u^Mu^M=1. \tag{5.25}$$

Then the string action takes the form,

$$\mathcal{L}_{\mathrm{kin}}=-\sqrt{g}g^{\mu\nu}\left[e^{2\phi}\partial_\mu x^+\partial_\nu x^-+\frac{1}{2}\partial_\mu\phi\partial_\nu\phi+\frac{1}{2}D_\mu u^MD_\nu u^M\right]-\frac{\mathrm{i}}{2}\sqrt{g}g^{\mu\nu}e^{2\phi}\partial_\mu x^+[\theta^i\partial_\nu\theta_i+\theta_i\partial_\nu\theta^i$$
$$+\eta^i\partial_\nu\eta_i+\eta_i\partial_\nu\eta^i+\mathrm{i}e^{2\phi}\partial_\nu x^+(\eta^2)^2], \tag{5.26}$$

$$\mathcal{L}_{\mathrm{WZ}}=\epsilon^{\mu\nu}e^{2\phi}\partial_\mu x^+(\eta^iy_{ij}\partial_\nu\theta^j+\eta_iy^{ij}\partial_\nu\theta_j), \tag{5.27}$$

where we used the relation $C^U_{ij}=-\mathrm{i}C'_{ik}u^k{}_j$, made the rescalings $\eta^i\to\mathrm{i}\eta^i$, $\eta_i\to-\mathrm{i}\eta_i$ and introduced the following notation:

$$u^i{}_j\equiv(\sigma^M)^i{}_ju^M,\quad y_{ij}\equiv C'_{ik}u^k{}_j,\quad y^{ij}\equiv-u^i{}_k(C'^{-1})^{kj}, \tag{5.28}$$

$$D_\mu u^M=\partial_\mu u^M-2\mathrm{i}\,\eta_i(R^M)^i{}_j\eta^je^{2\phi}\partial_\mu x^+,\quad (R^M)^i{}_j=-\tfrac{1}{2}(\sigma^{MN})^i{}_ju^N, \tag{5.29}$$

with σ^{MN} defined in (A4). Note that $u^i{}_j$, y_{ij}, y^{ij} transform in the fundamental representation of SU(2) with respect to the index i and in fundamental representation of $\widetilde{\mathrm{SU}}(2)$ with respect to the index j. They satisfy

$$y^*_{ij}=-y^{ij},\quad u^i{}^*_j=\bar{u}^j{}_i,\quad \bar{u}^\dagger{}_j\equiv(\bar{\sigma}^M)^i{}_ju^M,\quad \bar{u}^\dagger{}_k(C'^{-1})^{kj}=u^j{}_k(C'^{-1})^{ki}. \tag{5.30}$$

The parametrization based on u^M is the most convenient one for the discussion of the superparticle in $AdS_3\times S^3$ and of the harmonic decomposition of the light-cone superfield of type IIB supergravity into the Kaluza–Klein modes (see Secs. III and IV). We shall use this parametrization in the study of the light-cone superstring Hamiltonian in Sec. VI.

The superstring Lagrangian (5.21), (5.22) taken in any of its forms mentioned above can be represented in the following way:

$$\mathcal{L}=\mathcal{L}_1+\mathcal{L}_2, \tag{5.31}$$

$$\mathcal{L}_1=-h^{\mu\nu}\partial_\mu x^+\partial_\nu x^- +\partial_\mu x^+ A^\mu+\tfrac{1}{2}h^{\mu\nu}\partial_\mu x^+\partial_\nu x^+ B-\tfrac{1}{2}h^{\mu\nu}g_{\mathcal{AB}}D_\mu y^{\mathcal{A}}D_\nu y^{\mathcal{B}}, \tag{5.32}$$

$$\mathcal{L}_2=-\tfrac{1}{2}h^{\mu\nu}e^{-2\phi}\partial_\mu\phi\partial_\nu\phi+T, \tag{5.33}$$

where

$$g_{\mathcal{AB}}\equiv e^{-2\phi}G_{\mathcal{AB}},\quad D_\mu y^{\mathcal{A}}\equiv\partial_\mu y^{\mathcal{A}}+F^{\mathcal{A}}\partial_\mu x^+, \tag{5.34}$$

and $h^{\mu\nu}$ is defined by

$$h^{\mu\nu}\equiv\sqrt{g}g^{\mu\nu}e^{2\phi},\quad h^{00}h^{11}-(h^{01})^2=-e^{4\phi}. \tag{5.35}$$

The decomposition (5.31) is made so that the functions A^μ, B, $F^{\mathcal{A}}$ depend (i) on the anticommuting coordinates and their derivatives with respect to both τ and σ, and (ii) on the bosonic coordinates and their derivatives with respect to the world sheet spatial coordinate σ only. The reason for this decomposition is that below we shall use the phase space description with respect to the bosonic coordinates only, i.e., we shall not make the Legendre transformation with respect to the fermionic coordinates.

In the case of the ''intermediate'' form of the action (5.21),(5.22) these functions are

$$A^\mu=-\frac{\mathrm{i}}{2}h^{\mu\nu}(\theta^i\partial_\nu\theta_i+\eta^i\partial_\nu\eta_i)+\epsilon^{\mu 1}e^{2\phi}\eta^i C^U_{ij}\acute{\theta}^j+\text{h.c.}, \tag{5.36}$$

$$B=e^{2\phi}(\eta^2)^2,\quad F^{\mathcal{A}}=-2\mathrm{i}e^{2\phi}\eta_i(V^{\mathcal{A}})^i{}_j\eta^j,\quad T=-e^{2\phi}\acute{x}^+\eta^i C^U_{ij}\dot{\theta}^j+\text{h.c.} \tag{5.37}$$

VI. LIGHT CONE HAMILTONIAN APPROACH TO THE SUPERSTRING IN $AdS_3\times S^3$

Our next task is to fix the bosonic part of the light-cone gauge. We shall use the generalization of the phase space GGRT approach[36] to a curved AdS-type space described in Ref. 12, fixing the diffeomorphisms in $AdS_3\times S^3$ cases by the *same* gauge condition as in flat space. Most of the discussion below will follow closely to Ref. 12.

A. Phase space lagrangian

Computing the canonical momenta for the bosonic coordinates,

$$\mathcal{P}_a=\frac{\partial\mathcal{L}}{\partial\dot{x}^a},\quad \Pi=\frac{\partial\mathcal{L}}{\partial\dot{\phi}},\quad \mathcal{P}_{\mathcal{A}}=\frac{\partial\mathcal{L}}{\partial\dot{y}^{\mathcal{A}}}, \tag{6.1}$$

we get from (5.31),

$$\Pi=-h^{00}e^{-2\phi}\dot{\phi}^+-h^{01}e^{-2\phi}\acute{\phi}^+, \tag{6.2}$$

$$\mathcal{P}^+=-h^{00}\dot{x}^+-h^{01}\acute{x}^+, \tag{6.3}$$

$$\mathcal{P}^{\mathcal{A}}=-h^{00}\dot{y}^{\mathcal{A}}-h^{01}\acute{y}^{\mathcal{A}}+F^{\mathcal{A}}\mathcal{P}^+, \tag{6.4}$$

$$\mathcal{P}^- = -h^{00}\dot{x}^- - h^{01}\acute{x}^- + A^0 - B\mathcal{P}^+ + \mathcal{P}_{\mathcal{A}}F^{\mathcal{A}}, \tag{6.5}$$

where $\mathcal{P}^{\pm}\equiv\mathcal{P}_{\mp}$, $\mathcal{P}^{\mathcal{A}}\equiv g^{\mathcal{A}\mathcal{B}}\mathcal{P}_{\mathcal{B}}$. By applying the same procedure as in the bosonic case we find then the following phase space Lagrangian $\mathcal{L}=\mathcal{L}_1+\mathcal{L}_2$ (see. Ref. 12):

$$\begin{aligned}\mathcal{L}_1 &= \mathcal{P}^+\dot{x}^- + \mathcal{P}^-\dot{x}^+ + \mathcal{P}_{\mathcal{A}}\dot{y}^{\mathcal{A}} + \frac{1}{2h^{00}}[2\mathcal{P}^+\mathcal{P}^- + 2e^{4\phi}\acute{x}^+\acute{x}^- + g^{\mathcal{A}\mathcal{B}}\mathcal{P}_{\mathcal{A}}\mathcal{P}_{\mathcal{B}} + e^{4\phi}g_{\mathcal{A}\mathcal{B}}D_1y^{\mathcal{A}}D_1y^{\mathcal{B}}\\ &\quad + (\mathcal{P}^{+2} - e^{4\phi}\acute{x}^{+2})B - 2F^{\mathcal{A}}\mathcal{P}_{\mathcal{A}}\mathcal{P}^+] + \frac{h^{01}}{h^{00}}(\mathcal{P}^+\acute{x}^- + \mathcal{P}^-\acute{x}^+ + \mathcal{P}_{\mathcal{A}}\acute{y}^{\mathcal{A}})\\ &\quad - \frac{1}{h^{00}}(\mathcal{P}^+ + h^{01}\acute{x}^+)A^0 + \acute{x}^+A^1,\end{aligned} \tag{6.6}$$

$$\mathcal{L}_2 = \Pi\dot{\phi} + \frac{1}{2h^{00}}e^{2\phi}(\Pi^2 + \acute{\phi}^2) + \frac{h^{01}}{h^{00}}\Pi\acute{\phi} + T. \tag{6.7}$$

Next, we impose the light-cone gauge,

$$x^+ = \tau, \qquad \mathcal{P}^+ = p^+. \tag{6.8}$$

Using these gauge conditions in the action and integrating over $\mathcal{P}^-$ we get the expression for h^{00},

$$h^{00} = -p^+. \tag{6.9}$$

Inserting this into (6.6), (6.7) we get the following general form of the phase space light-cone Lagrangian:

$$\mathcal{L}_1 = \mathcal{P}_{\mathcal{A}}\dot{y}^{\mathcal{A}} - \frac{1}{2p^+}(g^{\mathcal{A}\mathcal{B}}\mathcal{P}_{\mathcal{A}}\mathcal{P}_{\mathcal{B}} + e^{4\phi}g_{\mathcal{A}\mathcal{B}}\acute{y}^{\mathcal{A}}\acute{y}^{\mathcal{B}} + p^{+2}B - 2p^+F^{\mathcal{A}}\mathcal{P}_{\mathcal{A}}) - \frac{h^{01}}{p^+}(p^+\acute{x}^- + \mathcal{P}_{\mathcal{A}}\acute{y}^{\mathcal{A}}) + A^0, \tag{6.10}$$

$$\mathcal{L}_2 = \Pi\dot{\phi} - \frac{1}{2p^+}e^{2\phi}(\Pi^2 + \acute{\phi}^2) - \frac{h^{01}}{p^+}\Pi\acute{\phi}. \tag{6.11}$$

Note that the function T in (5.37) is equal to zero in the light-cone gauge (6.8) This general form of the phase space Lagrangian can be specialized to different choices of bosonic coordinates by using the corresponding functions A^0, B, and $F^{\mathcal{A}}$. For the ''intermediate'' case (5.21),(5.22) these functions are given by (5.36),(5.37) so that we get

$$\begin{aligned}\mathcal{L} &= \mathcal{L}_1 + \mathcal{L}_2\\ &= \Pi\dot{\phi} + \mathcal{P}_{\mathcal{A}}\dot{y}^{\mathcal{A}} + \frac{\mathrm{i}}{2}p^+(\theta^i\dot{\theta}_i + \eta^i\dot{\eta}_i + \theta_i\dot{\theta}^i + \eta_i\dot{\eta}^i) - \frac{e^{2\phi}}{2p^+}[\Pi^2 + \acute{\phi}^2 + 2l^2 + G_{\mathcal{A}\mathcal{B}}\acute{y}^{\mathcal{A}}\acute{y}^{\mathcal{B}}\\ &\quad + p^{+2}(\eta^2)^2 + 4p^+\eta_i l^i{}_j\eta^j] + e^{2\phi}(\eta^iC^U_{ij}\acute{\theta}^j + \eta_iC^{ij}_U\acute{\theta}_j) - \frac{h^{01}}{p^+}\Big[p^+\acute{x}^- + \Pi\acute{\phi} + \mathcal{P}_{\mathcal{A}}\acute{y}^{\mathcal{A}}\\ &\quad + \frac{\mathrm{i}}{2}p^+(\theta^i\acute{\theta}_i + \eta^i\acute{\eta}_i + \theta_i\acute{\theta}^i + \eta_i\acute{\eta}^i)\Big].\end{aligned} \tag{6.12}$$

Here $C^{ij}_U = -(C^U_{ij})^*$, and we used the relation

$$G^{\mathcal{A}\mathcal{B}}\mathcal{P}_{\mathcal{A}}\mathcal{P}_{\mathcal{B}} = 2l^2, \quad l^i{}_j \equiv \mathrm{i}(V^{\mathcal{A}})^i{}_j\mathcal{P}_{\mathcal{A}}, \quad l^2 \equiv l^i{}_jl^j{}_i. \tag{6.13}$$

By applying a coordinate transformation one gets the phase space Lagrangian corresponding to the case (5.26),(5.27) in which the S^3 part is parametrized by the unit 4-vector u^M,

$$\mathcal{L}=\Pi\dot{\phi}+\mathcal{P}_M\dot{u}^M+\frac{\mathrm{i}}{2}p^+(\theta^i\dot{\theta}_i+\eta^i\dot{\eta}_i+\theta_i\dot{\theta}^i+\eta_i\dot{\eta}^i)$$
$$-\frac{e^{2\phi}}{2p^+}[\Pi^2+\acute{\phi}^2+2l^2+\acute{u}^M\acute{u}^M+p^{+2}(\eta^2)^2+4p^+\eta_i l^i{}_j\eta^j]+e^{2\phi}(\eta^i y_{ij}\acute{\theta}^j+\eta_i y^{ij}\acute{\theta}_j)$$
$$-\frac{h^{01}}{p^+}\left[p^+\acute{x}^-+\Pi\acute{\phi}+\mathcal{P}_M\acute{u}^M+\frac{\mathrm{i}}{2}p^+(\theta^i\acute{\theta}_i+\eta^i\acute{\eta}_i+\theta_i\acute{\theta}^i+\eta_i\acute{\eta}^i)\right], \tag{6.14}$$

where $\mathcal{P}_M$ is the canonical momentum for u^M and $l^i{}_j$ in (6.13) has the following explicit form:

$$l^i{}_j=\frac{\mathrm{i}}{2}(\sigma^{MN})^i{}_j u^M\mathcal{P}^N. \tag{6.15}$$

Here and below $l^i{}_j$ is for the classical orbital momentum [note that going to the superparticle limit, after the quantization we get $\mathcal{P}^M=-\mathrm{i}\hat{\partial}^M$ and then the classical orbital momentum $l^i{}_j$ (6.15) becomes the quantum momentum $l^i{}_j$ in (3.9)]. Taking into account the constraint $u^M\mathcal{P}^M=0$ [see (6.32)] we get

$$l^i{}_k l^k{}_j=\tfrac{1}{4}\mathcal{P}^M\mathcal{P}^M\delta^i{}_j, \quad l^2=\tfrac{1}{2}\mathcal{P}^M\mathcal{P}^M. \tag{6.16}$$

The above Lagrangian leads to the following (minus) Hamiltonian:

$$P^-=\int_0^1 d\sigma\mathcal{P}^-, \tag{6.17}$$

where the Hamiltonian density $-\mathcal{P}^-$ is given by

$$\mathcal{P}^-=-\frac{e^{2\phi}}{2p^+}[\Pi^2+\acute{\phi}^2+2l^2+\acute{u}^M\acute{u}^M+p^{+2}(\eta^2)^2+4p^+\eta_i l^i{}_j\eta^j]+e^{2\phi}(\eta^i y_{ij}\acute{\theta}^j+\eta_i y^{ij}\acute{\theta}_j). \tag{6.18}$$

It should be supplemented by the constraint,

$$p^+\acute{x}^-+\Pi\acute{\phi}+\mathcal{P}_M\acute{u}^M+\frac{\mathrm{i}}{2}p^+(\theta^i\acute{\theta}_i+\eta^i\acute{\eta}_i+\theta_i\acute{\theta}^i+\eta_i\acute{\eta}^i)=0. \tag{6.19}$$

As usual, this constraint allows one to express the nonzero modes of the bosonic coordinate x^- in terms of the transverse physical ones.

It is easy to see that in the particle theory limit the superstring Hamiltonian (6.18) reduces to the superparticle one which was found in Sec. III by applying the direct method of constructing relativistic dynamics[24] based on the symmetry algebra. Indeed, the (quantum, operator-ordered) superparticle light-cone Hamiltonian in (3.14),(3.19) can be rewritten as follows:

$$\mathcal{P}^-=-\frac{1}{2p^+}[e^{\phi}\Pi e^{\phi}\Pi+e^{2\phi}(2l^2+(p^+\eta^2-1)^2+4p^+\eta_i l^i{}_j\eta^j)]. \tag{6.20}$$

The string Hamiltonian (6.18) reduces to (6.20) modulo terms ''quantum'' terms proportional to η^2 and a constant (in string Hamiltonian we ignore operator ordering). The derivation of the light-cone string action from the covariant one given above thus provides, in the particle limit, also a self-contained Lagrangian derivation of the light-cone gauge superparticle Hamiltonian (3.14)

(obtained indirectly from the symmetry algebra in Sec. III) from a covariant action. This represents a consistency check on the two different methods used in Sec. III and in the present section.

B. Equations of motion

The equations of motion corresponding to the phase space superstring Lagrangian (6.14) are

$$\dot{\phi}=\frac{e^{2\phi}}{p^+}\Pi, \quad \dot{\Pi}=\frac{1}{p^+}\partial_\sigma(e^{2\phi}\acute{\phi})+2\mathcal{P}^-, \tag{6.21}$$

$$\dot{u}^M=\frac{e^{2\phi}}{p^+}\mathcal{P}^M-\mathrm{i}e^{2\phi}\eta_i(\sigma^{MN})^i{}_j\eta^j u^N, \tag{6.22}$$

$$\dot{\mathcal{P}}^M=-\frac{e^{2\phi}}{p^+}u^M\mathcal{P}^N\mathcal{P}^N+\frac{1}{p^+}v^{MN}\partial_\sigma(e^{2\phi}\acute{u}^N)-\mathrm{i}e^{2\phi}\eta_i(\sigma^{MN})^i{}_j\eta^j\mathcal{P}^N \tag{6.23}$$

$$+e^{2\phi}v^{MN}\eta^i\rho^N_{ij}\acute{\theta}^j+e^{2\phi}v^{MN}\eta_i(\rho^N)^{ij}\acute{\theta}_j, \tag{6.24}$$

$$\dot{\theta}^i=\frac{\mathrm{i}}{p^+}\partial_\sigma(e^{2\phi}\eta_j y^{ji}), \quad \dot{\theta}_i=\frac{\mathrm{i}}{p^+}\partial_\sigma(e^{2\phi}\eta^j y_{ji}), \tag{6.25}$$

$$\dot{\eta}^i=e^{2\phi}\left[\mathrm{i}\eta^2\eta^i-\frac{2\mathrm{i}}{p^+}(l\eta)^i+\frac{\mathrm{i}}{p^+}y^{ij}\acute{\theta}_j\right], \quad \dot{\eta}_i=e^{2\phi}\left[-\mathrm{i}\eta^2\eta_i+\frac{2\mathrm{i}}{p^+}(\eta l)_i+\frac{\mathrm{i}}{p^+}y_{ij}\acute{\theta}^j\right], \tag{6.26}$$

where v^{MN} is given by (3.11) and, as previously, do not distinguish between the upper and lower "S^3" indices M,N, i.e., use the convention $\mathcal{P}_M=\mathcal{P}^M$. These equations can be written in the Hamiltonian form. Introducing the notation $\mathcal{X}$ for the phase space variables $(\Pi,\phi,\mathcal{P}^M,u^M,\theta^i,\theta_i,\eta^i,\eta_i)$, the Hamiltonian equations are

$$\dot{\mathcal{X}}=[\mathcal{X},\mathcal{P}^-], \tag{6.27}$$

where the phase space variables satisfy the (classical) Poisson–Dirac brackets,

$$[\Pi(\sigma),\phi(\sigma')]=\delta(\sigma,\sigma'), \tag{6.28}$$

$$[\mathcal{P}^M(\sigma),u^N(\sigma')]=v^{MN}\delta(\sigma,\sigma'), \quad [\mathcal{P}^M(\sigma),\mathcal{P}^N(\sigma')]=(u^M\mathcal{P}^N-u^N\mathcal{P}^M)\delta(\sigma,\sigma'), \tag{6.29}$$

$$\{\theta_i(\sigma),\theta^j(\sigma')\}=\frac{\mathrm{i}}{p^+}\delta^j_i\delta(\sigma,\sigma'), \quad \{\eta_i(\sigma),\eta^j(\sigma')\}=\frac{\mathrm{i}}{p^+}\delta^j_i\delta(\sigma,\sigma'), \tag{6.30}$$

$$[x_0^-,\theta^i]=\frac{1}{2p^+}\theta^i, \quad [x_0^-,\theta_i]=\frac{1}{2p^+}\theta_i, \quad [x_0^-,\eta^i]=\frac{1}{2p^+}\eta^i, \quad [x_0^-,\eta_i]=\frac{1}{2p^+}\eta_i. \tag{6.31}$$

x_0^- is the zero mode of x^- so that $[p^+,x_0^-]=1$. All the remaining brackets are equal to zero. The structure of (6.29) reflects the fact that in the Hamiltonian formulation the condition $u^Mu^M=1$ should be supplemented by the constraint,

$$u^M\mathcal{P}^M=0. \tag{6.32}$$

These are second class constraints, and the Dirac procedure leads then to the classical Poisson–Dirac brackets (6.29). To derive (6.30) and (6.31) one is to take into account that the Lagrangian (6.14) has the following second class constraints:

$$p_{\theta^i}+\frac{\mathrm{i}}{2}p^+\theta_i=0, \quad p_{\theta_i}+\frac{\mathrm{i}}{2}p^+\theta^i=0, \tag{6.33}$$

where p_{θ^i}, p_{θ_i} are the canonical momenta of fermionic coordinates. The same constraints are found for the fermionic coordinates η^i, η_i. Starting with the Poisson brackets

$$\{p_{\theta^i},\theta^j\}_{\mathrm{P.B.}}=\delta_i^j, \quad \{p_{\theta_i},\theta_j\}_{\mathrm{P.B.}}=\delta_j^i, \quad [p^+,x_0^-]_{\mathrm{P.B.}}=1, \tag{6.34}$$

one gets then the Poisson–Dirac brackets given in (6.30) and (6.31).

VII. NOETHER CHARGES AS GENERATORS OF THE SUPERALGEBRA psu(1,1|2) $\oplus\widetilde{\mathrm{psu}}$(1,1|2)

The Noether charges play an important role in the analysis of the symmetries of dynamical systems. The choice of the light-cone gauge spoils manifest global symmetries, and in order to demonstrate that these global invariances are still present one needs to find the Noether charges which generate them. In what follows ''currents'' and ''charges'' will mean both bosonic and fermionic ones, i.e., will include supercurrents and supercharges. These charges determine the structure of superstring field theory in the light-cone gauge.[37] The first step in the construction of superstring field theory is to find a free (quadratic) superfield representation of the generators of the $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra. The charges we obtain below can be used to obtain (after quantization) these free superstring field charges.

The Noether charges for a superparticle in $AdS_3\times S^3$ were found in Sec. III. These charges are helpful in establishing a correspondence between the bulk fields of type IIB supergravity and the chiral primary operators of the boundary theory in a manifestly supersymmetric way. Superstring Noether charges should thus be important for the study of the AdS/CFT correspondence at the full string-theory level. Our discussion below will be an adaptation to the $AdS_3\times S^3$ case of the results for the currents in the $AdS_5\times S^5$ case given in Ref. 12.

A. Currents for κ-symmetry light-cone gauge fixed superstring action

As usual, symmetry generating charges can be obtained from conserved currents. Since currents themselves may be helpful in some applications, we shall first derive them starting with the κ-symmetry gauge fixed Lagrangian in the form given in (5.26),(5.27) and using the standard Noether method based on the localization of the parameters of the associated global transformations. Let ϵ be a parameter of some global transformation which leaves the action invariant. Replacing it by a function of worldsheet coordinates τ,σ, the variation of the action takes the form,

$$\delta S=\int d^2\sigma\mathcal{G}^\mu\partial_\mu\epsilon, \tag{7.1}$$

where $\mathcal{G}^\mu$ is the corresponding current. Making use of this formula, we shall find below those currents which are related to symmetries that do not involve compensating κ-symmetry transformation. The remaining currents will be found in the next subsection starting from the action (6.14) where both the κ-symmetry and the bosonic light-cone gauges are fixed.

Let us start with the translation invariance $\delta x^a=\epsilon^a$. Applying (7.1) to the Lagrangian (5.26),(5.27) gives the translation currents,

$$\mathcal{P}^{+\mu}=-\sqrt{g}g^{\mu\nu}e^{2\phi}\partial_\nu x^+, \tag{7.2}$$

$$\mathcal{P}^{-\mu}=-\sqrt{g}g^{\mu\nu}(e^{2\phi}\partial_\nu x^-+F^MD_\nu u^M)-\frac{\mathrm{i}}{2}\sqrt{g}g^{\mu\nu}e^{2\phi}(\theta^i\partial_\nu\theta_i+\theta_i\partial_\nu\theta^i+\eta^i\partial_\nu\eta_i+\eta^i\partial_\nu\eta^i$$
$$+2\mathrm{i}e^{2\phi}\partial_\nu x^+(\eta^2)^2)+\epsilon^{\mu\nu}e^{2\phi}(\eta^iy_{ij}\partial_\nu\theta^j+\eta_iy^{ij}\partial_\nu\theta_j), \quad F^M\equiv\mathrm{i}\eta_i(\sigma^{MN})^i{}_j\eta^je^{2\phi}u^N. \tag{7.3}$$

Some of the remaining bosonic currents can be expressed in terms of supercurrents. The invariance with respect to the supertransformations,

$$\delta\theta^i=\epsilon^i,\quad \delta\theta_i=\epsilon_i,\quad \delta x^-=-\frac{\mathrm{i}}{2}\epsilon^i\theta_i-\frac{\mathrm{i}}{2}\epsilon_i\theta^i, \tag{7.4}$$

gives the supercurrents

$$\mathcal{Q}^{+i\mu}=-\sqrt{g}g^{\mu\nu}e^{2\phi}\theta^i\partial_\nu x^+ +\mathrm{i}\epsilon^{\mu\nu}e^{2\phi}\eta_j y^{ji}\partial_\nu x^+, \tag{7.5}$$

$$\mathcal{Q}^{+\mu}_i=-\sqrt{g}g^{\mu\nu}e^{2\phi}\theta_i\partial_\nu x^+ +\mathrm{i}\epsilon^{\mu\nu}e^{2\phi}\eta^j y_{ji}\partial_\nu x^+. \tag{7.6}$$

The invariance of the action (5.26),(5.27) with respect to the rotation of (super) coordinates in the (x^+,x^-) plane,

$$\delta x^\pm=e^{\pm\epsilon}x^\pm,\quad \delta(\theta^i,\theta_i,\eta^i,\eta_i)=e^{-\epsilon/2}(\theta^i,\theta_i,\eta^i,\eta_i), \tag{7.7}$$

leads to

$$\mathcal{J}^{+-\mu}=x^+\mathcal{P}^{-\mu}-x^-\mathcal{P}^{+\mu}+\frac{\mathrm{i}}{2}\theta^i\mathcal{Q}^{+\mu}_i+\frac{\mathrm{i}}{2}\theta_i\mathcal{Q}^{+i\mu}, \tag{7.8}$$

while the invariance with respect to the dilatations,

$$\delta x^a=e^\epsilon x^a,\quad \delta\phi=-\epsilon,\quad \delta(\theta^i,\theta_i,\eta^i,\eta_i)=e^{\epsilon/2}(\theta^i,\theta_i,\eta^i,\eta_i), \tag{7.9}$$

implies conservation of the dilatation current,

$$\mathcal{D}^\mu=x^a\mathcal{P}^{a\mu}+\sqrt{g}g^{\mu\nu}\partial_\nu\phi-\frac{\mathrm{i}}{2}\theta^i\mathcal{Q}^{+\mu}_i-\frac{\mathrm{i}}{2}\theta_i\mathcal{Q}^{+i\mu}. \tag{7.10}$$

The invariances with respect to the SU(2) ($\epsilon^i{}_i=0$) and $\widetilde{\mathrm{SU}}(2)$ rotations ($\tilde\epsilon^i{}_i=0$),

$$\delta y^{ij}=\epsilon^i{}_l y^{lj},\quad \text{i.e.,}\quad \delta u^M=-\tfrac{1}{2}\epsilon^i{}_j(\sigma^{MN})^j{}_i u^N,\quad \delta\eta^i=\epsilon^i{}_j\eta^j,\quad \delta\eta_i=-\eta_j\epsilon^j{}_i, \tag{7.11}$$

$$\delta y^{ij}=\tilde\epsilon^j{}_l y^{il},\quad \text{i.e.,}\quad \delta u^M=-\tfrac{1}{2}\tilde\epsilon^i{}_j(\bar\sigma^{MN})^j{}_i u^N,\quad \delta\theta^i=\tilde\epsilon^i{}_j\theta^j,\quad \delta\theta_i=-\theta_j\tilde\epsilon^j{}_i, \tag{7.12}$$

give the following SU(2) and $\widetilde{\mathrm{SU}}(2)$ currents, respectively:

$$\mathcal{J}^{i\mu}_j=-\mathrm{i}\sqrt{g}g^{\mu\nu}\tfrac{1}{2}(\sigma^{MN})^i{}_j u^M D_\nu u^N+(\eta^i\eta_j-\tfrac{1}{2}\delta^i_j\eta^2)\mathcal{P}^{+\mu}. \tag{7.13}$$

$$\begin{aligned}\tilde{\mathcal{J}}^{i\mu}_j=&-\mathrm{i}\sqrt{g}g^{\mu\nu}\tfrac{1}{2}(\bar\sigma^{MN})^i{}_j u^M D_\nu u^N+(\theta^i\theta_j-\tfrac{1}{2}\delta^i_j\theta^2)\mathcal{P}^{+\mu}-\mathrm{i}\epsilon^{\mu\nu}e^{2\phi}\partial_\nu x^+\\ &\times(\eta^l y_{lj}\theta^i-\tfrac{1}{2}\delta^i_j\eta^k y_{kl}\theta^l)+\mathrm{i}\epsilon^{\mu\nu}e^{2\phi}\partial_\nu x^+(\eta_l y^{li}\theta_j-\tfrac{1}{2}\delta^i_j\eta_k y^{kl}\theta_l).\end{aligned} \tag{7.14}$$

B. Charges for bosonic and κ-symmetry light-cone gauge fixed superstring action

In the previous section we have listed the (super)currents starting with the κ-symmetry light-cone gauge fixed action given in (5.26),(5.27). They can be used to find currents for the action where both the fermionic κ-symmetry and the bosonic reparametrization symmetry are fixed by the light-cone type gauges (6.14). To find the components of currents ($\mathcal{G}^0$) in the world-sheet time direction one needs to use the relations (6.2)–(6.5) for the canonical momenta and to insert the light-cone gauge conditions (6.8) and (6.9) into the expressions for the currents. The charges are then $G=\int d\sigma\mathcal{G}^0$.

Let us start with the kinematical generators (charges) (3.1). The results for the currents imply the following representations:

$$P^+ = p^+, \quad Q^{+i} = \int p^+ \theta^i, \quad Q_i^+ = \int p^+ \theta_i . \tag{7.15}$$

Note that these charges depend only on the zero modes of string coordinates (the integrands are $\mathcal{G}^0$ parts of the corresponding currents in world-sheet time direction: $\mathcal{Q}^{+i0}$, $\mathcal{Q}_i^{+0}$ and $\mathcal{P}^{+0}=p^+$). The remaining kinematical charges depend on nonzero string modes,

$$J^{+-} = \int x^+ \mathcal{P}^- - x^- p^+, \quad D = \int x^+ \mathcal{P}^- + x^- p^+ - \Pi, \tag{7.16}$$

$$J^i{}_j = \int l^i{}_j + p^+ \eta^i \eta_j - \frac{1}{2}\delta^i_j p^+ \eta^2, \quad \tilde{J}^i{}_j = \int \tilde{l}^i{}_j + p^+ \theta^i \theta_j - \frac{1}{2}\delta^i_j p^+ \theta^2, \tag{7.17}$$

where $l^i{}_j$ is given by (6.15) and $\tilde{l}^i{}_j = (\mathrm{i}/2)\,(\bar{\sigma}^{MN})^i{}_j u^M \mathcal{P}^N$. The derivation of the remaining charges follows the procedure described in Appendix D of Ref. 12. The conformal (super)charges are given by (3.27), (3.28), where

$$S_i^+|_{x^+=0} = \int \frac{1}{\sqrt{2}} e^{-\phi} p^+ \eta_i, \quad S^{+i}|_{x^+=0} = \int \frac{1}{\sqrt{2}} e^{-\phi} p^+ \eta^i, \tag{7.18}$$

$$K^+|_{x^+=0} = \int -\frac{1}{2} e^{-2\phi} p^+ . \tag{7.19}$$

The dynamical Poincaré charges Q^{-i}, Q_i^- and the conformal charges S^{-i}, S_i^- are

$$Q_i^- = \int \frac{e^{\phi}}{\sqrt{2}} (\mathrm{i}\eta_i \Pi - p^+ \eta^2 \eta_i + 2\eta_j l^j{}_i + y_{ij}\acute{\theta}^j), \tag{7.20}$$

$$Q^{-i} = \int \frac{e^{\phi}}{\sqrt{2}} (-\mathrm{i}\eta^i \Pi - p^+ \eta^2 \eta^i + 2 l^i{}_j \eta^j - y^{ij}\acute{\theta}_j), \tag{7.21}$$

$$S^{-i} = \int \theta^i S - \tilde{l}^i{}_j \theta^j + \frac{1}{2} e^{-\phi} \partial_\sigma (e^{\phi}\eta_j) y^{ji}, \tag{7.22}$$

$$S_i^- = \int \theta_i \bar{S} - \theta_j \tilde{l}^j{}_i - \frac{1}{2} e^{-\phi} \partial_\sigma (e^{\phi}\eta^j) y_{ji}, \tag{7.23}$$

$$S = \mathrm{i}x^- p^+ - \frac{\mathrm{i}}{2}\Pi + \frac{1}{2} p^+ \theta^2, \qquad \bar{S} = -\mathrm{i}x^- p^+ + \frac{\mathrm{i}}{2}\Pi + \frac{1}{2} p^+ \theta^2 . \tag{7.24}$$

Note that the $G|_{x^+=0}$ parts of the kinematical charges (3.1) can be obtained from the superparticle ones simply by replacing the particle coordinates by the string ones. The remaining dynamical generator K^- can be found by using the expressions found above and applying the commutation relations of $\mathrm{psu}(1,1|2) \oplus \widetilde{\mathrm{psu}}(1,1|2)$ superalgebra.

Our classical charges are normalized so that after the quantization, i.e., the replacement of the classical Poisson–Dirac brackets (6.28)–(6.31) by quantum (anti)commutators

$$[,]_{\mathrm{P.B.}} \to \mathrm{i}[,], \quad \{,\}_{\mathrm{P.B.}} \to \mathrm{i}\{,\}, \tag{7.25}$$

redefinitions $J^{+-}\to -iJ^{+-}$, $D\to -iD$, $K^{\pm}\to -K^{\pm}$, and appropriate operator ordering the charges satisfy the commutation relations of psu(1,1|2) $\oplus$ $\widetilde{\text{psu}}(1,1|2)$ superalgebra given in (2.8)–(2.15).

APPENDIX A: NOTATION AND BASIC DEFINITIONS

In the main part of the paper we use the following conventions for the indices:

$$a,b=0,1 \quad \text{boundary Minkowski space indices,}$$

$$\mathcal{A},\mathcal{B},\mathcal{C}=1,2,3 \quad S^3 \text{ coordinate space indices,}$$

$$A',B',C'=1,2,3 \quad \text{so}(3) \text{ vector indices } (S^3 \text{ tangent space indices),}$$

$$M,N,K,L=1,\ldots,4 \quad \text{so}(4) \text{ vector indices,}$$

$$i,j,k,n=1,2 \quad \text{su}(2) \text{ and } \widetilde{\text{su}}(2) \text{ vector indices,}$$

$$\mu,\nu=0,1 \quad \text{world-sheet coordinate indices.}$$

We decompose x^a into the light-cone coordinates $x^a=(x^+,x^-)$, where $x^{\pm}\equiv(1/\sqrt{2})(x^1\pm x^0)$. We suppress the flat space metric tensor $\eta_{ab}=(-,+)$ in scalar products, i.e., $A^aB^a\equiv\eta_{ab}A^aB^b$. The SO(1,1) vector A^a is decomposed as $A^a=(A^+,A^-)$ so that the scalar product is $A^aB^a=A^+B^-+A^-B^+$. The derivatives with respect to the world-sheet coordinates (τ,σ) are

$$\dot{x}\equiv\partial_\tau x, \quad \acute{x}\equiv\partial_\sigma x. \tag{A1}$$

The world-sheet Levi-Civita $\epsilon^{\mu\nu}$ is defined with $\epsilon^{01}=1$.

The four matrices $(\sigma^M)^i{}_j$, $(\bar{\sigma}^M)^i{}_j$ are off-diagonal blocks of the SO(4) Dirac matrices γ^M in the chiral (Weyl) representation, i.e.,

$$\gamma^M=\begin{pmatrix} 0 & \sigma^M \\ \bar{\sigma}^M & 0 \end{pmatrix}, \quad (\sigma^M)^i{}_k(\bar{\sigma}^N)^k{}_j+(\sigma^N)^i{}_k(\bar{\sigma}^M)^k{}_j=2\,\delta^{MN}\delta^i_j, \tag{A2}$$

$$C'_{ik}(\sigma^M)^k{}_j=C'_{jk}(\bar{\sigma}^M)^k{}_i, \quad (\sigma^M)^i{}_j^*\equiv(\bar{\sigma}^M)^j{}_i, \tag{A3}$$

where C' is a charge conjugation matrix. σ^{MN}, $\bar{\sigma}^{MN}$ are defined by

$$(\sigma^{MN})^i{}_j\equiv\tfrac{1}{2}(\sigma^M)^i{}_k(\bar{\sigma}^N)^k{}_j-(M\leftrightarrow N), \quad (\bar{\sigma}^{MN})^i{}_j\equiv\tfrac{1}{2}(\bar{\sigma}^M)^i{}_k(\sigma^N)^k{}_j-(M\leftrightarrow N). \tag{A4}$$

We use the following explicit form of σ^M, $\bar{\sigma}^M$, and C'_{ij}:

$$\sigma^M=(\sigma^{A'},-iI), \quad \bar{\sigma}^M=(\sigma^{A'},iI), \quad C'_{ij}=c\,\epsilon_{ij}, \quad |c|=1. \tag{A5}$$

We also use the matrices ρ^M defined by

$$\rho^M_{ij}\equiv C'_{ik}(\sigma^M)^k{}_j, \quad (\rho^M)^{ij}\equiv-(\sigma^M)^i{}_k(C'^{-1})^{kj}, \quad (\rho^M_{ij})^*=-(\rho^M)^{ij}. \tag{A6}$$

We assume the following Hermitian conjugation rule for the fermionic coordinates and the notation for their squares,

$$\theta_i^\dagger=\theta^i, \quad \eta_i^\dagger=\eta^i, \quad \theta^2\equiv\theta^i\theta_i, \quad \eta^2\equiv\eta^i\eta_i. \tag{A7}$$

The generators of the su(2) and $\widetilde{\mathrm{su}}(2)$ subalgebras of so(4),

$$[J^{MN},J^{KL}]=\delta^{NK}J^{ML}+3 \text{ terms} \tag{A8}$$

are defined by

$$J^i{}_j=\tfrac{1}{4}(\sigma^{MN})^i{}_jJ^{MN}, \quad \tilde{J}^i{}_j=\tfrac{1}{4}(\bar{\sigma}^{MN})^i{}_jJ^{MN}. \tag{A9}$$

The translation operator $J^{4A'}$ on S^3 is

$$J^{4A'}=\frac{\mathrm{i}}{2}(\sigma^{A'})^j{}_i(J^i{}_j-\tilde{J}^i{}_j). \tag{A10}$$

The coset representative of S^3 defined by $g_y\equiv\exp(y^{A'}J^{4A'})$ takes then the form given in (E6) below. In terms of these coordinates, the 3-sphere interval, metric tensor and vielbein are given by

$$ds^2_{S^3}=d|y|^2+\sin^2|y|ds^2_{S^2}, \quad ds^2_{S^2}=dn^{\mathcal{A}}dn^{\mathcal{A}}, \quad n^{\mathcal{A}}n^{\mathcal{A}}=1, \tag{A11}$$

$$G_{\mathcal{AB}}=e^{\mathcal{A}}_{\mathcal{A}'}e^{\mathcal{A}'}_{\mathcal{B}}, \quad e^{\mathcal{A}'}_{\mathcal{A}}=\frac{\sin|y|}{|y|}(\delta^{\mathcal{A}'}_{\mathcal{A}}-n_{\mathcal{A}}n^{\mathcal{A}'})+n_{\mathcal{A}}n^{\mathcal{A}'}, \tag{A12}$$

$$G_{\mathcal{AB}}=\frac{\sin^2|y|}{|y|^2}(\delta_{\mathcal{AB}}-n_{\mathcal{A}}n_{\mathcal{B}})+n_{\mathcal{A}}n_{\mathcal{B}}, \quad n^{\mathcal{A}}\equiv\frac{y^{\mathcal{A}}}{|y|}, \quad |y|=\sqrt{y^{A'}y^{A'}}. \tag{A13}$$

We use the convention $y^{\mathcal{A}}=\delta^{\mathcal{A}}_{A'}y^{A'}$ and the same for $n^{A'}$. The S^3 Killing vectors $V^{A'}$ and $V^{A'\mathrm{B}'}$ corresponding to the 3 translations and 3 SO(3) rotations are

$$V^{A'}=[|y|\cot|y|(\delta^{A'\mathcal{A}}-n^{A'}n^{\mathcal{A}})+n^{A'}n^{\mathcal{A}}]\partial_{y^{\mathcal{A}}}, \quad V^{A'\mathrm{B}'}=y^{A'}\partial_{y^{\mathrm{B}'}}-y^{\mathrm{B}'}\partial_{y^{A'}}. \tag{A14}$$

They can be collected into the SU(2) combination,

$$(V^{\mathcal{A}})^i{}_j\partial_{y^{\mathcal{A}}}=\frac{1}{4}(\sigma^{A'\mathrm{B}'})^i{}_jV^{A'\mathrm{B}'}+\frac{\mathrm{i}}{2}(\sigma^{A'})^i{}_jV^{A'}. \tag{A15}$$

These relations and (5.24) imply the following relations:

$$G_{\mathcal{AB}}(\eta V^{\mathcal{A}}\eta)(\eta V^{\mathcal{B}}\eta)=(\eta R^M\eta)^2, \qquad G_{\mathcal{AB}}(\eta V^{\mathcal{A}}\eta)dy^{\mathcal{B}}=(\eta R^M\eta)du^M, \tag{A16}$$

where R^M is defined by (5.29), which have been used to transform (5.21)–(5.26).

APPENDIX B: LIGHT-CONE BASIS OF psu(1,1|2)⊕$\widetilde{\mathrm{psu}}$(1,1|2)

Here we explain the relation between the su(1,1)⊕su(2) covariant and light-cone bases of the psu(1,1|2) algebra and define the light-cone basis of psu(1,1|2)⊕$\widetilde{\mathrm{psu}}$(1,1|2). We find it convenient to introduce intermediate basis defined by

$$m^{+-}\equiv-m^1{}_1, \quad m^{+1}\equiv\frac{1}{\sqrt{2}}m^2{}_1, \quad m^{-1}\equiv-\frac{1}{\sqrt{2}}m^1{}_2, \tag{B1}$$

$$q^{+i}\equiv -q_1^i, \quad q^{-i}\equiv q_2^i, \quad q_i^+\equiv q_i^2, \quad q_i^-\equiv q_i^1. \tag{B2}$$

In this basis the Hermitian rules for supercharges take conventional form $(q^{+i})^\dagger = q_i^+$, $(q^{-i})^\dagger = q_i^-$, and for the (anti)commutators one has

$$[m^{+-},m^{\pm 1}]=\pm m^{\pm 1}, \quad [m^{+1},m^{-1}]=-m^{+-}, \quad [m^{+-},q_i^\pm]=\pm\tfrac{1}{2}q_i^\pm, \tag{B3}$$

$$\{q^{\pm i},q_j^\pm\}=-a\sqrt{2}\,\delta_j^i m^{\pm 1}, \quad \{q^{\pm i},q_j^\mp\}=a(\delta_j^i m^{+-}\mp m^i{}_j), \tag{B4}$$

$$[q^{-i},m^{+1}]=-\frac{1}{\sqrt{2}}q^{+i}, \quad [q^{+i},m^{-1}]=\frac{1}{\sqrt{2}}q^{-i}. \tag{B5}$$

The light-cone basis of $\mathrm{psu}(1,1|2)\oplus\widetilde{\mathrm{psu}}(1,1|2)$ superalgebra is defined by

$$P^+=\sqrt{2}\tilde{m}^{+1}, \quad P^-=\sqrt{2}m^{-1}, \quad K^+=\sqrt{2}m^{+1}, \quad K^-=\sqrt{2}\tilde{m}^{-1}, \tag{B6}$$

$$J^{+-}=m^{+-}+\tilde{m}^{+-}, \quad D=m^{+-}-\tilde{m}^{+-}, \quad J^i{}_j=m^i{}_j, \quad \tilde{J}^i{}_j=\tilde{m}^i{}_j, \tag{B7}$$

$$Q^{+i}=\tilde{q}^{+i}, \quad Q_i^+=\tilde{q}_i^+, \quad Q^{-i}=q^{-i}, \quad Q_i^-=q_i^-, \tag{B8}$$

$$S^{-i}=\tilde{a}\tilde{q}^{-i}, \quad S_i^-=\tilde{a}^*\tilde{q}_i^-, \quad S^{+i}=aq^{+i}, \quad S_i^+=a^*q_i^+. \tag{B9}$$

The constants $a,\tilde{a}$ are chosen to be $a=-\mathrm{i}$, $\tilde{a}=\mathrm{i}$. Then the commutation relations are

$$\begin{gathered}
[P^\pm,K^\mp]=D\mp J^{+-},\\
[D,P^\pm]=-P^\pm, \quad [D,K^\pm]=K^\pm, \quad [J^{+-},P^\pm]=\pm P^\pm, \quad [J^{+-},K^\pm]=\pm K^\pm,\\
[D,Q_i^\pm]=-\tfrac{1}{2}Q_i^\pm, \quad [D,S_i^\pm]=\tfrac{1}{2}S_i^\pm, \quad [J^{+-},Q_i^\pm]=\pm\tfrac{1}{2}Q_i^\pm, \quad [J^{+-},S_i^\pm]=\pm\tfrac{1}{2}S_i^\pm,\\
[S_i^\pm,P^\mp]=\mathrm{i}Q_i^\mp, \quad [Q^{\pm i},K^\mp]=-\mathrm{i}S^{\mp i}, \quad \{Q^{\pm i},Q_j^\pm\}=\mp\mathrm{i}P^\pm\delta_j^i,\\
\{S^{\pm i},S_j^\pm\}=\pm\mathrm{i}K^\pm\delta_j^i \quad \{Q^{+i},S_j^-\}=\tfrac{1}{2}(J^{+-}-D)\delta_j^i-\tilde{J}^i{}_j,\\
\{Q^{-i},S_j^+\}=\tfrac{1}{2}(J^{+-}+D)\delta_j^i+J^i{}_j.
\end{gathered} \tag{B10}$$

The supercharges Q_i^-, Q^{-i}, S^{+i}, S_i^+ transform in the fundamental representation of su(2) i.e., they are rotated only by $J^i{}_j$ and satisfy (2.13). The remaining supercharges Q^{+i}, Q_i^+, S^{-i}, S_i^- transform in fundamental representation of $\widetilde{\mathrm{su}}(2)$, i.e., they are rotated only by $\tilde{J}^i{}_j$ and satisfy (2.14). All the generators except K^a and P^a satisfy the Hermitian conjugation rules in (2.6), while K^a and P^a are taken to be anti-Hermitian: $(P^\pm)^\dagger=-P^\pm$, $(K^\pm)^\dagger=-K^\pm$. The light-cone basis for generators described above is used in the calculation of the Cartan forms in Appendix E. Making the substitutions $P^\pm\to\mathrm{i}P^\pm$, $K^\pm\to-\mathrm{i}K^\pm$ we obtain the basis used in Secs. II–IV.

APPENDIX C: DERIVATION OF SUPERCHARGES

Here we would like to demonstrate how the knowledge of kinematical charges and commutation relations of superalgebra allows one to get dynamical charges systematically. Consider, for example, the dynamical supercharges Q^{-i} whose most general form is

$$Q^{-i}=Q^{-i}(p^+,\partial_{p^+},z,\partial_z,\theta,\lambda,\eta,\vartheta), \tag{C1}$$

where a dependence on S^3 is not shown explicitly. From $[P^+,Q^{-i}]=0$ we get

$$Q^{-i}={}^{(1)}Q^{-i}(p^+,z,\partial_z,\theta,\lambda,\eta,\vartheta), \tag{C2}$$

i.e., we learn that Q^{-i} does not depend on ∂_{p^+}. From $\{Q^{-i},Q^{+j}\}=0$ we get

$$^{(1)}Q^{-i}(p^+,z,\partial_z,\theta,\lambda,\eta,\vartheta)=^{(2)}Q^{-i}(p^+,z,\partial_z,\theta,\eta,\vartheta), \tag{C3}$$

i.e., Q^{-i} does not depend on λ. The anticommutator $\{Q^{-i},Q_j^+\}=0$ tell us that Q^{-i} does not depend on θ, i.e.,

$$^{(2)}Q^{-i}(p^+,z,\partial_z,\theta,\eta,\vartheta)=^{(3)}Q^{-i}(p^+,z,\partial_z,\eta,\vartheta). \tag{C4}$$

From $[Q^{-i},K^+]=S^{+i}$ we get

$$^{(3)}Q^{-i}=\frac{1}{\sqrt{2}}\eta^i\partial_z+^{(4)}Q^{-i}(p^+,z,\eta,\vartheta), \tag{C5}$$

i.e.,

$$Q^{-i}=\frac{1}{\sqrt{2}}\eta^i\partial_z+^{(4)}Q^{-i}(p^+,z,\eta,\vartheta), \tag{C6}$$

and from $\{Q^{-i},S^{+j}\}=0$ we get

$$^{(4)}Q^{-i}=-\frac{1}{\sqrt{2}z}\eta^i(\eta\vartheta)+^{(5)}Q^{-i}(p^+,z,\eta), \tag{C7}$$

i.e.,

$$Q^{-i}=\frac{1}{\sqrt{2}}\eta^i\partial_z-\frac{1}{\sqrt{2}z}\eta^i(\eta\vartheta)+^{(5)}Q^{-i}(p^+,z,\eta). \tag{C8}$$

The second anticommutator in (2.12) gives

$$^{(5)}Q^{-i}(p^+,z,\eta)=\frac{1}{2\sqrt{2}z}\eta^i+\frac{2}{\sqrt{2}z}(l\eta)^i+^{(6)}Q^{-i}(p^+,z), \tag{C9}$$

and the su(2) covariance implies $^{(6)}Q^{-i}(p^+,z)=0$. Taking this into account and plugging (C9) into (C8) we get Q_i^- given by (3.16). Using the Hermitian conjugation rule $(Q^{-i})^\dagger=Q_i^-$ we get the expression for Q_i^- in (3.15). The anticommutator $\{Q_i^-,Q^{-j}\}=-P^-\delta_i^j$ determines P^-, i.e., the Hamiltonian. The remaining dynamical generators K^-, S^{-i}, S_i^- can be obtained in a similar way.

APPENDIX D: EIGENVECTORS OF THE *AdS* MASS OPERATOR

Here we would like to explain the procedure of finding the eigenvectors of the AdS mass operator A or the operator X in (3.19) in Sec. IV A. Since the superfield $\Phi_{k,\sigma}$ in (4.11) diagonalizes the operators l^2 and $\eta\vartheta$ we have to diagonalize the operator $\vartheta l\eta\equiv\vartheta_i l^i{}_j\eta^j$, i.e., to find the solution to equation

$$\vartheta l\eta\Phi_{k,1}=m\Phi_{k,1}, \tag{D1}$$

where m is an eigenvalue. We look for the following most general solution:

$$\Phi_{k,1}=(\vartheta_i+c(\vartheta l)_i)\Phi_{k,1}^i, \tag{D2}$$

where Φ^i does not depend on ϑ and c should be determined. Making use of

$$\{(\vartheta l)_j,(l\eta)^i\}=\tfrac{1}{2}(l^2+2\vartheta l\eta)\delta^i_j+(\eta\vartheta-1)l^i{}_j \tag{D3}$$

and $\eta^j\Phi^i_{k,1}=0$ we get

$$(\vartheta l\eta)\Phi_{k,1}=\left((1+c)(\vartheta l)_i+\frac{k(k+2)}{4}c\,\vartheta_i\right)\Phi^i_{k,1}. \tag{D4}$$

From (D1) we then find the equations

$$\frac{k(k+2)}{4}c=m,\quad (1+c)=mc, \tag{D5}$$

which are solved by

$$m^{(1)}=-\frac{k}{2},\quad c^{(1)}=-\frac{2}{k+2};\quad m^{(2)}=\frac{k+2}{2},\quad c^{(2)}=-\frac{2}{k}. \tag{D6}$$

Thus we have the two solution and the two eigenvectors,

$$\Phi^{(1)}_{k,1}=\left(\vartheta_i-\frac{2}{k+2}(\vartheta l)_i\right)\Phi^i_{k,1},\quad \Phi^{(2)}_{k,1}=\left(\vartheta_i-\frac{2}{k}(\vartheta l)_i\right)\Phi^i_{k,1}. \tag{D7}$$

Taking into account the relation

$$2l^2\Phi^{(1,2)}_{k,1}=k(k+2)\Phi^{(1,2)}_{k,1},\quad (\eta\vartheta-1)\Phi^{(1,2)}_{k,1}=0, \tag{D8}$$

and the eigenvalues $m^{(1)}$ and $m^{(2)}$ of $\vartheta l\eta$ given in (D6) we get the following eigenvalues of the operator X:

$$X\Phi^{(1)}_{k,1}=k^2\Phi^{(1)}_{k,1},\quad X\Phi^{(2)}_{k,1}=(k+2)^2\Phi^{(2)}_{k,1}. \tag{D9}$$

APPENDIX E: SUPERSTRING ACTION

The standard kinetic term of superstring action in $AdS_3\times S^3$,[16–18]

$$\mathcal{L}_{\rm kin}=-\tfrac{1}{2}\sqrt{g}g^{\mu\nu}(\hat{L}^A_\mu\hat{L}^A_\nu+L^{A'}_\mu L^{A'}_\nu), \tag{E1}$$

can be rewritten in conformal algebra notation as[11]

$$\mathcal{L}_{\rm kin}=-\tfrac{1}{2}\sqrt{g}g^{\mu\nu}(\hat{L}^a_\mu\hat{L}^a_\nu+L_{D\mu}L_{D\nu}+L^{A'}_\mu L^{A'}_\nu), \tag{E2}$$

where the Cartan 1-forms,

$$\hat{L}^a\equiv L^a_P-\frac{1}{2}L^a_K,\quad L^{A'}\equiv-\frac{\mathrm{i}}{2}(\sigma^{A'})^i{}_jL^j{}_i+\frac{\mathrm{i}}{2}(\sigma^{A'})^i{}_j\tilde{L}^j{}_i, \tag{E3}$$

in the light-cone basis are defined by

$$\begin{aligned}G^{-1}dG=&L^a_PP^a+L^a_KK^a+L_DD+L^{-+}J^{+-}+L^i{}_jJ^j{}_i+\tilde{L}^i{}_j\tilde{J}^j{}_i+L^{-i}_QQ^+_i+L^-_{Q\,i}Q^{+i}+L^{+i}_QQ^-_i\\&+L^+_{Q\,i}Q^{-i}+L^{-i}_SS^+_i+L^-_{S\,i}S^{+i}+L^{+i}_SS^-_i+L^+_{S\,i}S^{-i},\end{aligned} \tag{E4}$$

where the generators are taken in the basis described in Appendix B. To represent the Cartan 1-forms in terms of the even and odd coordinate fields we shall start with the following supercoset representative,

$$G=\exp(x^aP^a+\theta^{-i}Q_i^+ +\theta_i^-Q^{+i}+\theta^{+i}Q_i^- +\theta_i^+Q^{-i})\exp$$
$$\times(\eta^{-i}S_i^+ +\eta_i^-S^{+i}+\eta^{+i}S_i^- +\eta_i^+S^{-i})\, g_y g_\phi , \tag{E5}$$

where g_ϕ and g_y depend on the radial AdS_3 coordinate ϕ and S^3 coordinates $y^{A'}$, respectively,

$$g_\phi \equiv \exp(\phi D), \quad g_y \equiv \exp(y^i{}_j(J^j{}_i-\tilde{J}^j{}_i)), \quad y^i{}_j \equiv \frac{\mathrm{i}}{2}(\sigma^A)^i{}_j y^{A'}. \tag{E6}$$

Choosing the parametrization of the coset representative in the form (E5) corresponds to what is usually referred to as ''Killing gauge'' in superspace. Equation (E4) provides the definition of the Cartan forms in the light-cone basis. Let us further specify them by setting to zero some of the fermionic coordinates which corresponds to fixing a particular κ-symmetry gauge. Namely, we shall fix the κ-symmetry by putting to zero all the Grassmann coordinates which carry positive J^{+-} charge: $\theta^{+i}=\theta_i^+=\eta^{+i}=\eta_i^+=0$. To simplify the notation in what follows we shall set $\theta^i \equiv \theta^{-i}$, $\theta_i \equiv \theta_i^-$, $\eta^i \equiv \eta^{-i}$, $\eta_i \equiv \eta_i^-$. Note that since S^{+i} and Q^{+i} transform in the fundamental representations of su(2) and $\widetilde{\mathrm{su}}(2)$ the corresponding fermionic coordinates η's and θ's also transform in the fundamental representation of su(2) and $\widetilde{\mathrm{su}}(2)$. As a result, the κ-symmetry fixed form of the coset representative (E5) is

$$G_{\mathrm{g.f.}}=\exp(x^aP^a+\theta^iQ_i^+ +\theta_iQ^{+i})\exp(\eta^iS_i^+ +\eta_iS^{+i})g_y g_\phi . \tag{E7}$$

Plugging $G_{\mathrm{g.f.}}$ into (E4) we get the κ-symmetry gauge fixed expressions for the Cartan 1-forms,

$$L_P^+ = e^\phi dx^+, \quad L_P^- = e^\phi\left(dx^- -\frac{\mathrm{i}}{2}\tilde{\theta}^i\tilde{d}\theta_i -\frac{\mathrm{i}}{2}\tilde{\theta}_i\tilde{d}\theta^i\right), \tag{E8}$$

$$L_K^- = e^{-\phi}\left[\frac{1}{4}(\tilde{\eta}^2)^2dx^+ +\frac{\mathrm{i}}{2}\tilde{\eta}^i\tilde{d}\eta_i +\frac{\mathrm{i}}{2}\tilde{\eta}_i\tilde{d}\eta^i\right], \quad L_D=d\phi, \tag{E9}$$

$$L^i{}_j=(dUU^{-1})^i{}_j+\mathrm{i}(\tilde{\eta}^i\tilde{\eta}_j-\tfrac{1}{2}\tilde{\eta}^2\delta^i_j)dx^+, \quad \tilde{L}^i{}_j=(d\tilde{U}\tilde{U}^{-1})^i{}_j, \tag{E10}$$

$$L_Q^{-i}=e^{\phi/2}\tilde{d}\theta^i, \quad ,L_{Qi}^-=e^{\phi/2}\tilde{d}\theta_i, \quad L_Q^{+i}=-\mathrm{i}e^{\phi/2}\tilde{\eta}^idx^+, \quad L_{Qi}^+=\mathrm{i}e^{\phi/2}\tilde{\eta}_idx^+, \tag{E11}$$

$$L_S^{-i}=e^{-\phi/2}\left(\tilde{d}\eta^i+\frac{\mathrm{i}}{2}\tilde{\eta}^2\tilde{\eta}^idx^+\right), \quad L_{Si}^-=e^{-\phi/2}\left(\tilde{d}\eta_i-\frac{\mathrm{i}}{2}\tilde{\eta}^2\tilde{\eta}_idx^+\right), \tag{E12}$$

with all the remaining forms equal to zero. We have introduced the notation

$$\tilde{\eta}^i\equiv U^i{}_j\eta^j, \quad \tilde{\eta}_i\equiv\eta_j(U^{-1})^j{}_i, \quad \tilde{\theta}^i\equiv\tilde{U}^i{}_j\theta^j, \quad \tilde{\theta}_i\equiv\theta_j(\tilde{U}^{-1})^j{}_i, \tag{E13}$$

$$\widetilde{d\eta^i}\equiv U^i{}_jd\eta^j, \quad \widetilde{d\eta_i}\equiv d\eta_j(U^{-1})^j{}_i, \quad \widetilde{d\theta^i}\equiv\tilde{U}^i{}_jd\theta^j, \quad \widetilde{d\theta_i}\equiv d\theta_j(\tilde{U}^{-1})^j{}_i. \tag{E14}$$

The fact that θ^i and η^i are rotated by $\widetilde{\mathrm{SU}}(2)$ and SU(2) is related to the presence of the matrices $\tilde{U}\in\widetilde{\mathrm{SU}}(2)$ and $U\in\mathrm{SU}(2)$ in the definition of $\tilde{\theta}^i$ and $\tilde{\eta}^i$. These matrices defined by (5.4) can be written explicitly as

$$U=\cos\frac{|y|}{2}+\mathrm{i}\sigma^{A'}n^{A'}\sin\frac{|y|}{2}, \quad \tilde{U}=\cos\frac{|y|}{2}-\mathrm{i}\sigma^{A'}n^{A'}\sin\frac{|y|}{2}, \tag{E15}$$

where $|y|$ and $n^{A'}$ are given by (A13).

The S^3 components $L^{A'}$ of the Cartan forms defined by (E3) can be written in the following equivalent ways:

$$L^{A'}=e^{A'}-\tfrac{1}{2}\tilde{\eta}_i(\sigma^{A'})^i{}_j\tilde{\eta}^j dx^+, \quad L^{A'}=e^{A'}_{\mathcal{A}}(dy^{\mathcal{A}}+\mathrm{i}\eta_i(V^{\mathcal{A}})^i{}_j\eta^j dx^+), \tag{E16}$$

where $e^{A'}_{\mathcal{A}}$ and $(V^{\mathcal{A}})^i{}_j$ are defined by (A12) and (A15) and we used the relation,

$$e^{A'}_A(U^\dagger\sigma^{A'}U)^i{}_j=-2\mathrm{i}(V^{\mathcal{A}})^i{}_j, \quad e^{\mathcal{A}\ B'}_{A'\ \mathcal{A}}=\delta^{B'}_{A'}. \tag{E17}$$

Plugging the Cartan 1-forms into the kinetic part of the string Lagrangian (E2) we get

$$\begin{aligned}\mathcal{L}_{\mathrm{kin}}=&-\sqrt{g}g^{\mu\nu}[e^{2\phi}\partial_\mu x^+\partial_\nu x^-+\tfrac{1}{2}\partial_\mu\phi\partial_\nu\phi+\tfrac{1}{2}L^{A'}_\mu L^{A'}_\nu]+\sqrt{g}g^{\mu\nu}\partial_\mu x^+\\&\times\left[\left(e^{2\phi}\left(\frac{\mathrm{i}}{2}\theta^i\partial_\nu\theta_i+\frac{\mathrm{i}}{2}\theta_i\partial_\nu\theta^i\right)+\frac{\mathrm{i}}{4}\eta^i\partial_\nu\eta_i+\frac{\mathrm{i}}{4}\eta_i\partial_\nu\eta^i+\frac{1}{8}(\eta^2)^2\partial_\nu x^+\right)\right].\end{aligned} \tag{E18}$$

In order to get the action in the Killing parametrization one needs to use $L^{A'}$ given by the second expression in (E16) and then make the rescalings,

$$\eta^i\to\sqrt{2}e^{\phi}\eta^i, \quad \eta_i\to\sqrt{2}e^{\phi}\eta_i, \quad x^a\to-x^a. \tag{E19}$$

The action in the WZ parametrization is found by using $L^{A'}$ given by the first expression in (E16) and after the transformation

$$\theta^i\to(\tilde{U}^{-1})^i{}_j\theta^i, \quad \theta_i\to\theta_j\tilde{U}^j{}_i, \quad \eta^i\to\sqrt{2}e^{\phi}(U^{-1})^i{}_j\eta^j, \quad \eta_i\to\sqrt{2}e^{\phi}\eta_j U^j{}_i, \quad x^a\to-x^a, \tag{E20}$$

and use of the Fierz rearrangement rule $(\eta_i(\sigma^{A'})^i{}_j\eta^j)^2=-3(\eta^2)^2$.

The P-odd WZ part of the covariant string Lagrangian $\mathcal{L}_{\mathrm{WZ}}$ (see, e.g., (Refs. 16–18) takes the following form in the light-cone gauge:

$$\mathcal{L}_{\mathrm{WZ}}=-\frac{\mathrm{i}}{\sqrt{2}}\epsilon^{\mu\nu}L^{+i}_{Q\mu}C'_{ij}L^{-j}_{Q\nu}+\mathrm{h.c.} \tag{E21}$$

Plugging in the expressions for the Cartan 1-forms and making the rescalings given above we get $\mathcal{L}_{\mathrm{WZ}}$ in the Killing parametrization (5.22) [see also (5.27)] and in the WZ parametrization [see the $\epsilon^{\mu\nu}$ term in (5.6)].

(Received 2 January 2001; accepted for publication 13 February 2001)

We perform a general analysis of representations of the superconformal algebras OSp(8/4, $\mathbb{R}$) and OSp($8^*/2N$) in harmonic superspace. We present a construction of their highest-weight UIR's by multiplication of the different types of massless conformal superfields (''supersingletons''). In particular, all ''short multiplets'' are classified. Representations undergoing shortening have ''protected dimension'' and may correspond to BPS states in the dual supergravity theory in anti-de Sitter space. These results are relevant for the classification of multitrace operators in boundary conformally invariant theories as well as for the classification of AdS black holes preserving different fractions of supersymmetry. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1374451]

I. INTRODUCTION

Superconformal algebras and their representations play a crucial rôle in the AdS/CFT correspondence because of their dual role of describing the gauge symmetries of the AdS bulk supergravity theory and the global symmetries of the boundary conformal field theory.[1–3]

A special class of configurations which are particularly relevant are the so-called BPS states, i.e., dynamical objects corresponding to representations which undergo ''shortening.''

These representations can only occur when the conformal dimension of a (super)primary operator is ''quantized'' in terms of the R symmetry quantum numbers and they are at the basis of the so-called ''nonrenormalization'' theorems of supersymmetric quantum theories.[4]

There exist different methods of classifying the UIR's of superconformal algebras. One is the so-called oscillator construction of the Hilbert space in which a given UIR acts.[5] Another one, more appropriate to describe field theories, is the realization of such representations on superfields defined in superspaces.[6,7] The latter are ''supermanifolds'' which can be regarded as the quotient of the conformal supergroup by some of its subgroups.

In the case of ordinary superspace the subgroup in question is the supergroup obtained by exponentiating a nonsemisimple superalgebra which is the semidirect product of a super-Poincaré graded Lie algebra with dilatation [SO(1,1)] and the R symmetry algebra. This is the superspace appropriate for non-BPS states. Such states correspond to bulk massive states which can have a ''continuous spectrum'' of the AdS mass (or, equivalently, of the conformal dimension of the primary fields).

BPS states are naturally associated to superspaces with a lower number of ''odd'' coordinates and, in most cases, with some internal coordinates of a coset space G/H. Here G is the R symmetry group of the superconformal algebra, i.e., the subalgebra of the even part which com-

[a)]Electronic mail: sergio.ferrara@cern.ch
[b)]UMR 5108 associée à l'Université de Savoie.

mutes with the conformal algebra of space–time and H is some subgroup of G having the same rank as G.

Such superspaces are called ''harmonic'' [8] and they are characterized by having a subset of the initial odd coordinates θ. The complementary number of odd variables determines the fraction of supersymmetry preserved by the BPS state. If a BPS state preserves K supersymmetries then the θ's of the associated harmonic superspace will transform under some UIR of H_K.

For 1/2 BPS states, i.e., states with maximal supersymmetry, the superspace involves the minimal number of odd coordinates (half of the original one) and H_K is then a maximal subgroup of G. On the other hand, for states with the minimal fraction of supersymmetry H_K reduces to the ''maximal torus'' whose Lie algebra is the Cartan subalgebra of G.

It is our aim in the present paper to give a comprehensive treatment of BPS states related to ''short representations'' of superconformal algebras for the cases which are most relevant in the context of the AdS/CFT correspondence, i.e., the $d=3$ $(N=8)$ and $d=6$ $[N=(2,0)]$. The underlying conformal field theories correspond to world-volume theories of N_c copies of M_2, M_5 and D_3 branes in the large N_c limit[9–13] which are ''dual'' to AdS supergravities describing the horizon geometry of the branes.[14]

The present contribution summarizes the results which have already appeared elsewhere.[15–17] We first carry out an abstract analysis of the conditions for Grassmann (G-)analyticity[18] (the generalization of the familiar concept of chirality[7]) in a superconformal context. We find the constraints on the conformal dimension and R symmetry quantum numbers of a superfield following from the requirement that it does not depend on one or more Grassmann variables. Introducing G-analyticity in a traditional superspace cannot be done without breaking the R symmetry. The latter can be restored by extending the superspace by harmonic variables[19,8,20–24] parametrizing the coset G/H_K. We also consider the massless UIR's (''supersingleton'' multiplets),[25,26] first as constrained superfields in ordinary superspace[27–29] and then, for a part of them, as G-analytic harmonic superfields.[8,24,29] Next we use supersingleton multiplication to construct UIR's of OSp($8^*/2N$) and OSp(8/4, $\mathbb{R}$). We show that in this way one can reproduce the complete classification of UIR's of Ref. 30. We also discuss different kinds of shortening which certain superfields (not of the BPS type) may undergo. We conclude the paper by listing the various BPS states in the physically relevant cases of M_2 and M_5 branes horizon geometry where only one type of supersingleton appears.

Massive towers corresponding to 1/2 BPS states are the K–K modes coming from compactification of M-theory on $AdS_{7/4}\times S_{4/7}$.[31,9] Short representations of superconformal algebras also play a special rôle in determining N-point functions from OPE.[32,33]

Another area of interest is the classification of AdS black holes,[34–37] according to the fraction of supersymmetry preserved by the black hole background.

In a parallel analysis with black holes in an asymptotically flat background,[38] the AdS/CFT correspondence predicts that such BPS states should be dual to superconformal states undergoing ''shortening'' of the type discussed here.

II. THE SIX-DIMENSIONAL CASE

In this section we describe highest-weight UIR's of the superconformal algebras OSp($8^*/2N$) in six dimensions. Although the physical applications refer to $N=1$ and $N=2$, it is worthwhile to carry out the analysis for general N, along the same lines as in the four-dimensional case.[39,40] We first examine the consequences of G-analyticity and conformal supersymmetry and find out the relation to BPS states. Then we will construct UIR's of OSp($8^*/2N$) by multiplying supersingletons. The results exactly match the general classification of UIR's of OSp($8^*/2N$) of Ref. 30.

A. The conformal superalgebra OSp($8^*/2N$) and Grassmann analyticity

The standard realization of the conformal superalgebra OSp($8^*/2N$) makes use of the superspace,

$$\mathbb{R}^{6/8N}=\frac{\mathrm{OSp}(8^*/2N)}{\{K,S,M,D,T\}}=(x^\mu,\theta^{\alpha\ i}), \tag{2.1}$$

where $\theta^{\alpha i}$ is a left-handed spinor carrying an index $i=1,2,...,2N$ of the fundamental representation of the R symmetry group $\mathrm{USp}(2N)$. Unlike the four-dimensional case, here chirality is not an option but is already built in. The only way to obtain smaller superspaces is through Grassmann analyticity. We begin by imposing a single condition of G-analyticity on the superfield defined in (2.1):

$$q^1_\alpha\Phi(x,\theta)=0, \tag{2.2}$$

which amounts to considering the coset

$$\mathbb{A}^{6/4(2N-1)}=\frac{\mathrm{OSp}(8^*/2N)}{\{K,S,M,D,T,Q^1\}}=(x^\mu,\theta^{\alpha\ 1,2,...,2N-1}). \tag{2.3}$$

From the algebra of $\mathrm{OSp}(8^*/2N)$ we obtain

$$m_{\mu\nu}=0, \tag{2.4}$$

$$t^{11}=t^{12}=\cdots=t^{1\ 2N-1}=0, \tag{2.5}$$

$$4t^{1\ 2N}+l=0. \tag{2.6}$$

Equation (2.4) implies that the superfield Φ must be a Lorentz scalar. In order to interpret Eqs. (2.5) and (2.6), we need to split the generators of $\mathrm{OSp}(2N)$ into raising operators (corresponding to the positive roots), $T^{k\ 2N-1}$, $k=1,...,N$, $l=k,\ldots,2N-k$ (simple if $l=k$), $[\mathrm{U}(1)]^N$ charges $H_k=-2T^{k\ 2N-k+1}$, $k=1,...,N$ and lowering operators. The Dynkin labels a_k of a $\mathrm{OSp}(2N)$ irrep are defined as follows:

$$a_k=H_k-H_{k+1},\ \ k=1,...,N-1,\ \ a_N=H_N, \tag{2.7}$$

so that, for instance, the generator Q^1 is the HWS of the fundamental irrep (1, 0, ..., 0).

Now it becomes clear that (2.5) is part of the $\mathrm{USp}(2N)$ irreducibility conditions whereas (2.6) relates the conformal dimension to the sum of the Dynkin labels:

$$l=2\sum_{k=1}^{N}a_k. \tag{2.8}$$

Let us denote the highest-weight UIR's of the $\mathrm{OSp}(8^*/2N)$ algebra by

$$\mathcal{D}(l;J_1,J_2,J_3;a_1,\ldots,a_N),$$

where l is the conformal dimension, J_1, J_2, J_3 are the SU*(4) Dynkin labels and a_k are the $\mathrm{OSp}(2N)$ Dynkin labels of the first component. Then the G-analytic superfields defined above are of the type

$$\Phi(\theta^{1,2,...,2N-1})\Leftrightarrow\mathcal{D}\left(2\sum_{k=1}^{N}a_k;0,0,0;a_1,\ldots,a_N\right). \tag{2.9}$$

From the superconformal algebra it is clear that we can go on in the same manner until we remove half of the θ's, namely $\theta^{N+1},\ldots,\theta^{2N}$. Each time we have to set a new Dynkin label to zero. We can summarize by saying that the superconformal algebra $\mathrm{OSp}(8^*/2N)$ admits the following short UIR's corresponding to BPS states:

$$\frac{p}{2N}\text{BPS:}\quad \mathcal{D}\left(2\sum_{k=p}^{N} a_k;0,0,0;0,...,0,a_p,\ldots,a_N\right),\quad p=1,...,N. \tag{2.10}$$

B. Supersingletons

There exist three types of massless multiplets in six dimensions corresponding to ultrashort UIR's (supersingletons) of OSp(8*/2N) (see, e.g., Ref. 41 for the case $N=2$). All of them can be formulated in terms of constrained superfields as follows.

(i) The first type is described by a superfield $W^{\{i_1\cdots i_n\}}(x,\theta)$, $1\leqslant n\leqslant N$, which is antisymmetric and traceless in the external USp($2N$) indices (for even n one can impose a reality condition). It satisfies the constraint (see Refs. 27 and 42)

$$D_\alpha^{(k_W\{i_1)i_2\ldots i_n\}}=0\Rightarrow\mathcal{D}(2;0,0,0;0,...,0,\ a_n=1,0,...,0). \tag{2.11}$$

The components of this superfield are massless fields. In the case $N=n=1$ this is the on-shell (1, 0) hypermultiplet and for $N=n=2$ it is the on-shell (2, 0) tensor multiplet.[27,28]

(ii) The second type is described by a (real) superfield without external indices, $w(x,\theta)$ obeying the constraint

$$D_{[\alpha}^{(i}D_{\beta]}^{j)}w=0\Rightarrow\mathcal{D}(2;0,0,0;0,...,0). \tag{2.12}$$

(iii) Finally, there exists an infinite series of multiplets described by superfields with n totally symmetrized external Lorentz spinor indices, $w_{(\alpha_1\cdots\alpha_n)}(x,\theta)$ (they can be made real in the case of even n) obeying the constraint

$$D_{[\beta}^{i}w_{(\alpha_1]\ldots\alpha_n)}=0\Rightarrow\mathcal{D}(2+n/2;n,0,0;0,...,0). \tag{2.13}$$

As shown in Ref. 16, the six-dimensional massless conformal fields only carry reps $(J_1,0)$ of the little group SU(2)×SU(2) of a light-like particle momentum. This result is related to the analysis of conformal fields in d dimensions.[43,44] This fact implies that massless superconformal multiplets are classified by a single SU(2) and USp($2N$) R symmetry and are therefore identical to massless super-Poincaré multiplets in five dimensions. Some physical implication of the above circumstance have recently been discussed in Ref. 45 where it was suggested that certain strongly coupled $d=5$ theories effectively become six-dimensional.

C. Harmonic superspace

The massless multiplets (i), (ii) admit an alternative formulation in harmonic superspace (see Refs. 46, 47, 29 for $N=1,2$). The advantage of this formulation is that the constraints (2.11) become conditions for G-analyticity. We introduce harmonic variables describing the coset USp($2N$)/$[\mathrm{U}(1)]^N$:

$$u\in\mathrm{USp}(2N):\ \ u_i^I u_J^i=\delta_J^I,\ \ u_i^I\Omega^{ij}u_j^J=\Omega^{IJ},\ \ u_i^I=(u_I^i)^*. \tag{2.14}$$

Here the indices i, j belong to the fundamental representation of USp($2N$) and I, J are labels corresponding to the $[\mathrm{U}(1)]^N$ projections. The harmonic derivatives,

$$D^{IJ}=\Omega^{K(I}u_i^{J)}\frac{\partial}{\partial u_i^K}, \tag{2.15}$$

form the algebra of USp$(2N)_R$ realized on the indices I, J of the harmonics.

Let us now project the defining constraint (2.11) with the harmonics $u_k^K u_{i_1}^1\cdots u_{i_n}^n$, $K=1,...,n$:

$$D^1_\alpha W^{12\cdots n} = D^2_\alpha W^{12\cdots n} = \ldots = D^n_\alpha W^{12\cdots n} = 0, \tag{2.16}$$

where $D^K_\alpha = D^i_\alpha u^K_i$ and $W^{12\cdots n} = W^{\{i_1\cdots i_n\}} u^1_{i_1} \ldots u^n_{i_n}$. Indeed, the constraint (2.11) now takes the form of a G-analyticity condition. In the appropriate basis in superspace the solution to (2.16) is a short superfield depending on part of the odd coordinates:

$$W^{12\cdots n}(x_A, \theta^1, \theta^2, \ldots, \theta^{2N-n}, u). \tag{2.17}$$

In addition to (2.16), the projected superfield $W^{12\cdots n}$ automatically satisfies the USp($2N$) harmonic irreducibility conditions,

$$D^{K\ 2N-K} W^{12} = 0, \quad K = 1,...,N \tag{2.18}$$

[only the simple roots of USp($2N$) are shown]. The equivalence between the two forms of the constraint follows from the obvious properties of the harmonic products $u^K_{[k} u^K_{i]} = 0$ and $\Omega^{ij} u^K_i u^L_j = 0$ for $1 \leqslant K < L \leqslant n$. The harmonic constraints (2.18) make the superfield ultrashort.

Finally, in case (ii), projecting the constraint (2.12) with $u^I_i u^I_j$ where $I = 1,...,N$ (no summation), we obtain the condition

$$D^I_\alpha D^I_\beta w = 0. \tag{2.19}$$

It implies that the superfield w is *linear* in each projection $\theta^{\alpha I}$.

D. Series of UIR's of OSp(8*/2*N*) and shortening

It is now clear that we can realize the BPS series of UIR's (2.10) as products of the different G-analytic superfields (supersingletons) (2.16).[48] BPS shortening is obtained by setting the first $p-1$ USp($2N$) Dynkin labels to zero:

$$\frac{p}{2N}\text{BPS:}\quad W^{[0,\ldots,0,a_p,\ldots,a_N]}(\theta^1, \theta^2, \ldots, \theta^{2N-p}) = (W^{1\cdots p})^{a_p} \cdots (W^{1\cdots N})^{a_N} \tag{2.20}$$

(note that even if $a_1 \neq 0$ we still have $1/2N$ shortening).

We remark that our harmonic coset USp($2N$)/$[\mathrm{U}(1)]^N$ is effectively reduced to

$$\frac{\mathrm{USp}(2N)}{\mathrm{U}(p) \times [\mathrm{U}(1)]^{N-p}}, \tag{2.21}$$

in the case of $p/2N$ BPS shortening (just as it happened in four dimensions). Such a smaller harmonic space was used in Ref. 29 to formulate the (2, 0) tensor multiplet.

A study of the most general UIR's of OSp(8*/$2N$) [similar to the one of Ref. 50 for the case of SU(2,2/N)] is presented in Ref. 30. We can construct these UIR's by multiplying the three types of supersingletons above:

$$w_{\alpha_1 \ldots \alpha_{m_1}} w_{\beta_1 \ldots \beta_{m_2}} w_{\gamma_1 \ldots \gamma_{m_3}} w^k W^{[a_1,\ldots,a_N]}, \tag{2.22}$$

where $m_1 \geqslant m_2 \geqslant m_3$ and the spinor indices are arranged so that they form an SU*(4) UIR with Young tableau (m_1, m_2, m_3) or Dynkin labels $J_1 = m_1 - m_2$, $J_2 = m_2 - m_3$, $J_3 = m_3$. Thus we obtain four distinct series:

$$\text{(A)}\quad l \geqslant 6 + \frac{1}{2}(J_1 + 2J_2 + 3J_3) + 2\sum_{k=1}^{N} a_k;$$

$$\text{(B)}\quad J_3=0,\qquad l\geqslant 4+\frac{1}{2}(J_1+2J_2)+2\sum_{k=1}^{N}a_k;$$

$$\text{(C)}\quad J_2=J_3=0,\qquad l\geqslant 2+\frac{1}{2}J_1+2\sum_{k=1}^{N}a_k; \tag{2.23}$$

$$\text{(D)}\quad J_1=J_2=J_3=0,\qquad l=2\sum_{k=1}^{N}a_k.$$

The superconformal bound is saturated when $k=0$ in (2.22). Note that the values of the conformal dimension we can obtain are ''quantized'' since the factor w^k has $l=2k$ and k must be a non-negative integer to ensure unitarity. With this restriction Eq. (2.23) reproduces the results of Ref. 30. However, we cannot comment on the existence of a ''window'' of dimensions $2+1/2J_1+2\Sigma_{k=1}^{N}a_k\leqslant l\leqslant 4+1/2J_1+2\Sigma_{k=1}^{N}a_k$ conjectured in Ref. 30 (see also Ref. 49).

In the generic case the multiplet (2.22) is ''long,'' but for certain special values of the dimension some shortening can take place.[30]

III. THE THREE-DIMENSIONAL CASE

In this section we carry out the analysis of the $d=3$ $N=8$ superconformal algebra OSp(8/4, $\mathbb{R}$) in a way similar to the above. Some of the results have already been presented in Ref. 15. As in the previous cases, our results could easily be extended to OSp(N/4,$\mathbb{R}$) superalgebras with arbitrary N. The $N=2$ and $N=3$ cases were considered in Ref. 52.

A. The conformal superalgebra OSp(8/4, $\mathbb{R}$) and Grassmann analyticity

The standard realization of the conformal superalgebra OSp(8/4, $\mathbb{R}$) makes use of the superspace

$$\mathbb{R}^{3/16}=\frac{\mathrm{OSp}(8/4,\mathbb{R})}{\{K,S,M,D,T\}}=(x^{\mu},\theta^{\alpha\ i}). \tag{3.1}$$

In order to study G-analyticity we need to decompose the generators Q_{α}^{i} under $[\mathrm{U}(1)]^4\subset\mathrm{SO}(8)$. Besides the vector representation 8_v of SO(8) we are also going to use the spinor ones, 8_s and 8_c. In this context we find it convenient to introduce the four subgroups U(1) by successive reductions: $\mathrm{SO}(8)\to\mathrm{SO}(2)\times\mathrm{SO}(6)\sim\mathrm{U}(1)\times\mathrm{SU}(4)\to[\mathrm{SO}(2)]^2\times\mathrm{SO}(4)\sim[\mathrm{U}(1)]^2\times\mathrm{SU}(2)\times\mathrm{SU}(2)\to[\mathrm{SO}(2)]^4\sim[\mathrm{U}(1)]^4$. Denoting the four U(1) charges by $\pm$, $(\pm)$, $[\pm]$ and $\{\pm\}$, we decompose the three 8-dimensional representations as follows:

$$8_v:\ \ Q^{i}\to Q^{\pm\pm},Q^{(\pm\pm)},Q^{[\pm]\{\pm\}}, \tag{3.2}$$

$$8_s:\ \ \phi^{a}\to\phi^{+(+)\{\pm\}},\phi^{-(-)[\pm]},\phi^{+(-)\{\pm\}},\phi^{-(+)\{\pm\}}, \tag{3.3}$$

$$8_c:\ \ \sigma^{\dot{a}}\to\sigma^{+(+)\{\pm\}},\sigma^{-(-)\{\pm\}},\sigma^{+(-)\{\pm\}},\sigma^{-(+)\{\pm\}}. \tag{3.4}$$

Let us denote a quasi primary superconformal field of the OSp(8/4, $\mathbb{R}$) algebra by the quantum numbers of its HWS:

$$\mathcal{D}(l;J;a_1,a_2,a_3,a_4), \tag{3.5}$$

where l is the conformal dimension, J is the Lorentz spin and a_i are the Dynkin labels (see, e.g., Ref. 53) of the SO(8) R symmetry.

In order to build G-analytic superspaces we have to add one or more projections of Q_{α}^{i} to the coset denominator. In choosing the subset of projections we have to make sure that (i) they anticommute among themselves; (ii) the subset is closed under the action of the raising operators

of SO(8). Then we have to examine the consistency of the vanishing of the chosen projections with the conformal superalgebra. Thus we find the following sequence of G-analytic superspaces corresponding to BPS states:

$$\frac{1}{8}\text{BPS:}\quad \begin{cases} q_\alpha^{++}\Phi=0\rightarrow \\ \Phi(\theta^{++},\theta^{(\pm\pm)},\theta^{[\pm]\{\pm\}}) \\ \mathcal{D}(a_1+a_2+\frac{1}{2}(a_3+a_4);0;a_1,a_2,a_3,a_4) \end{cases} \tag{3.6}$$

$$\frac{1}{4}\text{BPS:}\quad \begin{cases} q_\alpha^{++}\Phi=q_\alpha^{(++)}\Phi=0\rightarrow \\ \Phi(\theta^{++},\theta^{(++)},\theta^{[\pm]\{\pm\}}) \\ \mathcal{D}(a_2+\frac{1}{2}(a_3+a_4);0;0,a_2,a_3,a_4) \end{cases} \tag{3.7}$$

$$\frac{3}{8}\text{BPS:}\quad \begin{cases} q_\alpha^{++}\Phi=q_\alpha^{(++)}\Phi=q_\alpha^{[+]\{+\}}\Phi=0\rightarrow \\ \Phi(\theta^{++},\theta^{(++)},\theta^{[\pm]\{\pm\}},\theta^{[-]\{+\}}) \\ \mathcal{D}(\frac{1}{2}(a_3+a_4);0;0,0,a_3,a_4) \end{cases} \tag{3.8}$$

$$\frac{1}{2}\text{BPS(type I):}\quad \begin{cases} q_\alpha^{++}\Phi=q_\alpha^{(++)}\Phi=q_\alpha^{[+]\{\pm\}}\Phi=0\rightarrow \\ \Phi(\theta^{++},\theta^{(++)},\theta^{[+]\{\pm\}}) \\ \mathcal{D}(\frac{1}{2}(a_3;0;0,0,a_3,0) \end{cases} \tag{3.9}$$

$$\frac{1}{4}\text{BPS(type II):}\quad \begin{cases} q_\alpha^{++}\Phi=q_\alpha^{(++)}\Phi=q_\alpha^{[\pm]\{+\}}\Phi=0\rightarrow \\ \Phi(\theta^{++},\theta^{(++)},\theta^{[\pm]\{+\}}) \\ \mathcal{D}(\frac{1}{2}(a_4;0;0,0,0,a_4) \end{cases} . \tag{3.10}$$

Note the existence of two types of 1/2 BPS states due to the two possible subsets of projections of q^i closed under the raising operators of SO(8).

B. Supersingletons and harmonic superspace

The supersingletons are the simplest OSp(8/4, $\mathbb{R}$) representations of the type (3.9) or (3.10) and correspond to $\mathcal{D}(1/2;\,0;\,0,\,0,\,1,\,0)$ or $\mathcal{D}(1/2;\,0;\,0,\,0,\,0,\,1)$. The existence of two distinct types of $d=3$ $N=8$ supersingletons has first been noted in Ref. 54. Each of them is just a collection of eight Dirac supermultiplets[26] made out of ''Di'' and ''Rac'' singletons.[25]

In order to realize the supersingletons in superspace we note that the HWS in the two supermultiplets above has spin 0 and the Dynkin labels of the 8_s or 8_c of SO(8), correspondingly. Therefore we take a scalar superfield $\Phi_\alpha(x^\mu,\theta_i^\alpha)$ [or $\Sigma_{\dot a}(x^\mu,\theta_i^\alpha)$] carrying an external 8_s index a (or an 8_c index $\dot a$). These superfields are subject to the following on-shell constraints:[55]

$$\text{type I:}\quad D_\alpha^i\Phi_a=\tfrac{1}{8}\gamma^i_{ab}\overline{\gamma}^j_{bc}D_\alpha^j\Phi_c\,; \tag{3.11}$$

$$\text{type II:}\quad D_\alpha^i\sum_{\dot a}=\frac{1}{8}\tilde\gamma^i_{\dot a b}\gamma^j_{b\dot c}D_\alpha^j\sum_{\dot c}\,. \tag{3.12}$$

The two multiplets consist of a massless scalar in the $8_s(8_c)$ and spinor in the $8_c(8_s)$.

The harmonic superspace description of these supersingletons can be realized by taking the harmonic coset,[56]

$$\frac{\mathrm{SO}(8)}{[\mathrm{SO}(2)]^4}\sim\frac{\mathrm{Spin}(8)}{[\mathrm{U}(1)]^4}. \tag{3.13}$$

Since SO(8)~Spin(8) has three inequivalent fundamental representations, $8_s,8_c,8_v$, following Ref. 57 we introduce three sets of harmonic variables:

$$u_a^A, w_{\dot a}^{\dot A}, v_i^I, \tag{3.14}$$

where A, $\dot A$ and I denote the decompositions of an 8_s, 8_c and 8_v index, correspondingly, into sets of four U(1) charges [see (3.2)–(3.4)]. Each of the 8×8 real matrices (3.14) belongs to the corresponding representation of SO(8)~Spin(8). This implies that they are orthogonal matrices [this is a peculiarity of SO(8) due to triality]:

$$u_a^A u_a^B=\delta^{AB}, \qquad w_{\dot a}^{\dot A} w_{\dot a}^{\dot B}=\delta^{\dot A\dot B}, \quad v_i^I v_i^J=\delta^{IJ}. \tag{3.15}$$

Further, we introduce harmonic derivatives [the covariant derivatives on the coset (3.13)]:

$$D^{IJ}=u_a^A(\gamma^{IJ})^{AB}\frac{\partial}{\partial u_a^B}+w_{\dot a}^{\dot A}(\gamma^{IJ})^{\dot A\dot B}\frac{\partial}{\partial w_{\dot a}^{\dot B}}+v_i^{[I}\frac{\partial}{\partial v_i^{J]}}. \tag{3.16}$$

They respect the algebraic relations (3.15) among the harmonic variables and form the algebra of SO(8) realized on the indices $A,\dot A,I$ of the harmonics.

We now use the harmonic variables for projecting the supersingleton defining constraints (3.11), (3.12). It is easy to show that the projections $\Phi^{+(+)[+]}$ and $\Sigma^{+(+)\{+\}}$ satisfy the following G-analyticity constraints:

$$D^{++}\Phi^{+(+)[+]}=D^{(++)}\Phi^{+(+)[+]}=D^{[+]\{\pm\}}\Phi^{+(+)[\pm]}=0, \tag{3.17}$$

$$D^{++}\Sigma^{+(+)\{+\}}=D^{(++)}\Sigma^{+(+)\{+\}}=D^{[+]}\Sigma^{+(+)\{+\}}=0, \tag{3.18}$$

where $D_\alpha^I=v_i^I D_\alpha^i$, $\Phi^A=u_a^A\Phi_a$ and $\Sigma^{\dot A}=w_{\dot a}^{\dot A}\Sigma_{\dot a}$. This is the superspace realization of the 1/2 BPS shortening conditions (3.9), (3.10). In the appropriate basis in superspace $\Phi^{+(+)[+]}$ and $\Sigma^{+(+)\{+\}}$ depend on different halves of the odd variables as well as on the harmonic variables:

$$\text{type I:}\quad \Phi^{+(+)[+]}(x_A,\theta^{++},\theta^{(++)},\theta^{[+]\{+\}},u,w), \tag{3.19}$$

$$\text{type II:}\quad \Sigma^{+(+)\{+\}}(x_A,\theta^{++},\theta(++),\theta^{[\pm]\{+\}},u,w). \tag{3.20}$$

In addition to the G-analyticity constraints (3.17), (3.18), the on-shell superfields $\Phi^{+(+)[+]},\Sigma^{+(+)\{+\}}$ are subject to the SO(8) irreducibility harmonic conditions obtained by replacing the SO(8) raising operators by the corresponding harmonic derivatives. The combination of the latter with Eq. (3.17) is equivalent to the original constraint (3.11).

C. OSp(8/4, $\mathbb{R}$) supersingleton composites

One way to obtain short multiplets of OSp(8/4, $\mathbb{R}$) is to multiply different analytic superfields describing the type I supersingleton. The point is that above we chose a particular projection of, e.g., the defining constraint (3.11) which lead to the analytic superfield $\Phi^{+(+)[+]}$. In fact, we could have done this in a variety of ways, each time obtaining superfields depending on different halves of the total number of odd variables. Leaving out the 8_v lowest weight θ^{--}, we can have four distinct but equivalent analytic descriptions of the type I supersingleton:

$$\begin{aligned}
&\Phi^{+(+)[+]}(\theta^{++},\theta^{(++)},\theta^{[+]\{+\}},\theta^{[+]\{-\}}),\\
&\Phi^{+(+)[-]}(\theta^{++},\theta^{(++)},\theta^{[-]\{+\}},\theta^{[-]\{-\}}),\\
&\Phi^{+(-)\{+\}}(\theta^{++},\theta^{(--)},\theta^{[+]\{+\}},\theta^{[-]\{+\}}),\\
&\Phi^{+(-)\{-\}}(\theta^{++},\theta^{(--)},\theta^{[+]\{-\}},\theta^{[-]\{-\}}).
\end{aligned} \tag{3.21}$$

Then we can multiply them in the following way:

$$(\Phi^{+(+)[+]})^{p+q+r+s}(\Phi^{+(+)[-]})^{q+r+s}(\Phi^{+(-)\{+\}})^{r+s}(\Phi^{+(-)\{-\}})^{s}, \tag{3.22}$$

thus obtaining three series of OSp(8/4, $\mathbb{R}$) UIR's exhibiting 1/8, 1/4 or 1/2 BPS shortening:

$$\begin{aligned}
&\tfrac{1}{8}\text{BPS:}\quad \mathcal{D}(a_1 a_2+\tfrac{1}{2}(a_3+a_4),0;a_1,a_2,a_3,a_4),\quad a_1-a_4=2s\geqslant 0;\\
&\tfrac{1}{4}\text{BPS:}\quad \mathcal{D}(a_2+\tfrac{1}{2}a_3,0;0,a_2,a_3,0);\\
&\tfrac{1}{2}\text{BPS:}\quad \mathcal{D}(\tfrac{1}{2}a_3,0;0,0,a_3,0),
\end{aligned} \tag{3.23}$$

where

$$a_1=r+2s,\quad a_2=q,\quad a_3=p,\quad a_4=r. \tag{3.24}$$

We see that multiplying only one type of supersingletons cannot reproduce the general result of Sec. III B for all possible short multiplets. Most notably, in (3.23) there is no 3/8 series. The latter can be obtained by mixing the two types of supersingletons:

$$[\Phi^{+(+)[+]}(\theta^{++},\theta^{(++)},\theta^{[+]\{\pm\}})]^{a_3}[\Sigma^{+(+)\{+\}}(\theta^{++},\theta^{(++)},\theta[\pm]\{+\})]^{a_4} \tag{3.25}$$

(or the same with Φ and Σ exchanged). Counting the charges and the dimension, we find exact matching with the series (3.8):

$$\tfrac{3}{8}\text{BPS:}\quad \mathcal{D}(\tfrac{1}{2}(a_3+a_4);0;0,0,a_3,a_4). \tag{3.26}$$

Further, mixing two realizations of type I and one of type II supersingletons, we can construct the 1/4 series,

$$[\Phi^{+(+)[+]}]^{a_2+a_3}[\Phi^{+(+)[-]}]^{a_2}[\Sigma^{+(+)\{+\}}]^{a_4}, \tag{3.27}$$

which corresponds to (3.7):

$$\tfrac{1}{4}\text{BPS:}\quad \mathcal{D}(a_2+\tfrac{1}{2}(a_3+a_4);0;0,a_2,a_3,a_4). \tag{3.28}$$

Finally, the full 1/8 series (3.6) [i.e., without the restriction $a_1-a_4=2s\geqslant 0$ in (3.23)] can be obtained in a variety of ways.

D. BPS states of OSp(8/4, $\mathbb{R}$)

Here we give a summary of all possible OSp(8/4, $\mathbb{R}$) BPS multiplets. Denoting the UIR's by

$$\mathcal{D}(l;J;a_1,a_2,a_3,a_4), \tag{3.29}$$

where l is the conformal dimension, J is the spin and a_1,a_2,a_3,a_4 are the SO(8) Dynkin labels, we find four BPS conditions:

3.4.1.

$$\tfrac{1}{8}\text{BPS}: \quad q_\alpha^{++}=0. \tag{3.30}$$

The corresponding UIR's are

$$\mathcal{D}(a_1+a_2+\tfrac{1}{2}(a_3+a_4);0;a_1,a_2,a_3,a_4) \tag{3.31}$$

and the harmonic coset is

$$\frac{\text{Spin}(8)}{[U(1)]^4}. \tag{3.32}$$

If $a_2=a_3=a_4=0$ this coset becomes Spin(8)/U(4).
3.4.2.

$$\tfrac{1}{4}\text{BPS}: \quad q_\alpha^{++}=q_\alpha^{(++)}=0. \tag{3.33}$$

The corresponding UIR's are

$$\mathcal{D}(a_2+\tfrac{1}{2}(a_3+a_4);0;0,a_2,a_3,a_4), \tag{3.34}$$

and the harmonic coset is

$$\frac{\text{Spin}(8)}{[\text{U}(1)]^2\times\text{U}(2)}. \tag{3.35}$$

If $a_3=a_4=0$ this coset becomes Spin(8)/U(1)$\times$[SU(2)]^3.
3.4.3.

$$\tfrac{3}{8}\text{BPS}: \quad q_\alpha^{++}=q_\alpha^{(++)}=q_\alpha^{[+]\{+\}}=0. \tag{3.36}$$

The corresponding UIR's are

$$\mathcal{D}(\tfrac{1}{2}(a_3+a_4);0;0,0,a_3a_4), \tag{3.37}$$

and the harmonic coset is

$$\frac{\text{Spin}(8)}{U(1)\times U(3)}. \tag{3.38}$$

3.4.4.

$$\tfrac{1}{2}\text{BPS(type I)}: \quad q_\alpha^{++}=q_\alpha^{(++)}=q_\alpha^{[+]\{+\}}q_\alpha^{[+]\{\pm\}}=0; \tag{3.39}$$

$$\tfrac{1}{2}\text{BPS(type II)}: \quad q_\alpha^{++}=q_\alpha^{(++)}=q_\alpha^{[+]\{+\}}=q_\alpha^{[\pm]\{+\}}=0. \tag{3.40}$$

The corresponding UIR's are

$$\tfrac{1}{2}\text{BPS(type I)}: \quad \mathcal{D}(\tfrac{1}{2}a_3;0;0,0,a_3,0); \tag{3.41}$$

$$\tfrac{1}{2}\text{BPS(type II)}: \quad \mathcal{D}(\tfrac{1}{2}a_4;0;0,0,0,a_4), \tag{3.42}$$

and the harmonic coset is

$$\frac{\text{Spin}(8)}{U(4)}. \tag{3.43}$$

[55] See also Ref. 29 for the description of a supersingleton related to ours by SO(8) triality. Superfield representations of other OS$p(N/4)$ superalgebras have been considered in Refs. 56,57.
[56] A formulation of the above multiplet in harmonic superspace has been proposed in Ref. 29. The harmonic coset used in Ref. 29 is Spin(8)/U(4). Although the supersingleton itself does indeed live in this smaller coset (see Sec. III B), its residual symmetry U(4) would not allow us to multiply different realizations of the supersingleton. For this reason we prefer from the very beginning to use the coset (3.13) with a minimal residual symmetry.

(Received 2 January 2001; accepted for publication 13 February 2001)

We show that an earlier domain wall solution of type IIB supergravity provides a supersymmetric realization of the Randall–Sundrum brane-world, and give its ten-dimensional interpretation in terms of IIB 3-branes. We also explain how previous no-go theorems are circumvented. In particular, whereas $D=5$ supergravity scalars have AdS_5 energy $E_0 \leqslant 4$ and are unable to support a $D=5$ positive tension brane, our scalar has $E_0=8$, and is the breathing mode of the S^5 compactification. Another essential element of the construction is the implementation of a Z_2 symmetry by patching together compactifications with opposite signs for their 5-form field strengths. This is thus a IIB analog of a previous $D=5$ 3-brane realization of the Hořava–Witten orbifold. A mode-locking phenomenon avoids the appearance of negative energy zero-modes in spite of the necessity of a $D=10$ negative tension brane-source. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1372698]

I. INTRODUCTION

Our purpose in this paper is first to show that the type IIB domain wall solution of Bremer *et al.*[1] provides a supersymmetric realization of the Randall–Sundrum brane-world[2,3] and second to give its ten-dimensional interpretation in terms of IIB 3-branes.

The idea that our universe may be a 3-brane in a higher-dimensional spacetime has a history going back nearly two decades.[4–9] More recently, another viewpoint on this basic idea has grown out of the Hořava–Witten[10,11] model for M-theory/heterotic string duality, based upon an S^1/Z_2 orbifold in $D=11$ spacetime. This orbifold construction was later realized in a $D=5$ compactification by a concrete solution to semiclassical M-theory, i.e., $D=11$ supergravity.[12,13] A key point in this construction was the introduction of flux for the M-theory 4-form field strength $G_{[4]}$ wound around the compact dimensions, which were taken to be a Calabi–Yau 3-fold. The resulting reduced theory is a specific version of matter-coupled $D=5$, $N=2$ supergravity. This dimensionally-reduced theory has a scalar potential arising from the $G_{[4]}$ flux, which rules out flat space or indeed any maximally symmetric space as a solution to the equations of motion. But this $D=5$ reduced theory readily admits domain wall, i.e., 3-brane, solutions. A natural configuration is a pair of two 3-branes in a Z_2 symmetric configuration; projecting the fields of this theory into the subspace of Z_2 invariant configurations then reproduces the Hořava–Witten orbifold. As in the original $D=11/D=10$ discussion, the massless brane-wave excitations of this scenario are not easily deduced by direct analysis of the solution, but one may obtain information about the zero-modes by anomaly inflow arguments. These may either be carried out in $D=10$, leading to the original Hořava–Witten prediction of a $D=10$, $N=1$ super Yang–Mills E_8 gauge multiplet residing on each of the two fixed planes of the orbifold, with the resulting structure subsequently reduced to $D=5$, or one may carry out the anomaly analysis directly in $D=5$, yielding more general possibilities for gauge structure.[14]

a)Electronic mail: jimliu@umich.edu

Another theory in which similar constructions can be made is $D=10$ type IIB supergravity. This has a self-dual 5-form field strength that supports the D3-brane, which is the basis for much recent discussion of the Maldacena conjecture, linking string theory in the near-horizon region of the D3-brane to a Yang–Mills theory quantized on the boundary of the associated asymptotic anti de Sitter space, which is the near-horizon limiting spacetime. In the pure supergravity context, relations between p-branes in higher dimensions and domain walls arising after dimensional reduction on spheres was developed in Ref. 1, including the case of the D3-brane of type IIB theory.

Meanwhile, another development was brewing. Randall and Sundrum[2] proposed a simple model of physics on 3-branes embedded in $D=5$ anti de Sitter space, first in a model with two 3-branes, one of positive and one of negative tension. This model was criticized for the apparent danger of nonphysical modes from the negative tension brane, and also because the modulus related to the distance between the two branes gave another parameter needing fixing in any phenomenological analysis. Subsequently, a revision of this scenario was put forward,[3] in which there was only one 3-brane, of positive tension, essentially obtained from the first scenario by sending the negative tension brane to the Cauchy horizon of anti de Sitter space. The striking result found in this second scenario is that, although the fifth dimension of spacetime is now infinite, the effective gravity theory on the single remaining 3-brane nonetheless has $D=4$ and not $D=5$ leading behavior. The gravitational potential for static sources starts out with a Newtonian $1/r$, corrected by terms of order Λ^{-1}/r^3, where Λ is the $D=5$ cosmological constant. This ''binding of gravity'' to the 3-brane happens when a $D=5$ spacetime has a warped product structure, with the warp factor, i.e., the factor multiplying the $D=4$ submetric, decreasing as one recedes on either side from the single Randall–Sundrum 3-brane. This corresponds in general terms to the 3-brane acting as a positive-tension source on the right-hand side of the Einstein equations. It was not clear, however, whether this scenario could arise from an explicit solution to a supergravity theory.

Links between the Randall–Sundrum model and supergravity were made in Refs. 15–20. In Refs. 17, 18, the $D=5$ 3-brane solutions to the type II theory presented in Ref. 1 were used to make an analogy to the Randall–Sundrum model. The explicit relation between this construction and the specific Randall–Sundrum model was not fully pinned down, however. This perspective was further elaborated in Refs. 19, 20. Despite the existence of these works, there still seems to be some confusion in the literature as to whether the Randall–Sundrum model can in fact be obtained from an explicit supergravity solution. (Note, however, that the equivalence of the graviton propagator calculated from closed loops of the $N=4$ SCFT in the Maldacena picture and that calculated from tree graphs in the Randall–Sundrum picture was already strongly indicative of a supersymmetric Randall–Sundrum brane-world.[21])

Moreover, there are powerful general arguments[22–24] as to why smooth supersymmetric solutions obtained from $D=5$ gauged supergravity coupled to various combinations of $D=5$ matter cannot reproduce a Randall–Sundrum scenario with binding of gravity to the 3-brane. A key word here is ''smooth.'' Although one might well like to replace the Randall–Sundrum scenario, with its delta-function source, by a smooth solution, experience with domain walls in supergravity (i.e., codimension-one brane solutions) shows them always to be based upon a linear harmonic function in the $d=1$ codimension. In order for such a solution to have a localized energy concentration, i.e., a ''brane,'' some kind of ''kink'' must be introduced into the linear harmonic function so as to give a location to the domain wall. Thus, the search for a smooth codimension-one solution looks rather unlikely to be successful. (Some rigorous results along these lines have recently been spelled out in Ref. 25. See also Ref. 26.) Moreover, the remainder of the argument of Refs. 22, 23 concerns the general behavior of renormalization group flows between critical points of coupled supergravity-matter potentials. This gives the impression that even if one were to relax the requirement of smoothness, there would be no solution leading to the binding of gravity to the 3-brane.

In this paper, we shall first explicitly obtain the original (kinked) Randall–Sundrum geometry from type IIB supergravity. This follows from the work of Refs. 1, 17, 20. This construction

makes essential use[17] of the ''breathing mode'' of the S^5 dimensional reduction of type IIB supergravity of Ref. 1. We shall show why this massive mode escapes the constraints on supersymmetric flows by reason of its transforming in a representation with AdS lowest energy $E_0 = 8 > 4$, thus falling outside the scope of the analysis of Refs. 22, 23. The breathing-mode solutions, although Kaluza–Klein consistent in a purely bosonic context containing just the breathing mode and gravity, do not really correspond to a pure $D=5$ supergravity theory. The construction retains an essential memory of its $D=10$ type IIB origin. This is particularly so when one considers the superpartners of the breathing mode, which include massive spin two modes that cannot be retained in a consistent truncation to a finite number of $D=5$ fields.

Another memory of $D=10$ supergravity in the supersymmetric realization of the Randall–Sundrum geometry resides in the Z_2 symmetry of this geometry. This geometry is very similar to the Z_2 symmetric configuration of two M-theory 3-branes in $D=5$ that explicitly realizes the Hořava–Witten construction as an M-theory brane solution.[12,13] In the M-theory solution, the Z_2 symmetry is central to the appearance of the orbifold, and it also plays a critical role in the preservation of unbroken $D=4$ supersymmetry on the brane world-volumes.[13] The same is true in the double 3-brane type IIB solution that we present as the supergravity realization of the Randall–Sundrum geometry: continuity of the unbroken supersymmetry Killing spinor depends on the way the Z_2 symmetry is implemented. In particular, in the M-theory case[13] as well as in the type IIB construction,[27] the constant parameter determining the flux of the relevant underlying form field is Z_2 odd, and so flips sign upon crossing either of the 3-branes; this flip is crucial for the continuity of the unbroken supersymmetry parameter. Accordingly, in the type IIB case as in the M-theory case, the $D=5$ theory is really obtained from a dimensional reduction on a *pair* of Kaluza–Klein ansätze, one on each side of the Z_2 symmetric spacetime. Although this construction requires the presence of brane sources for the form-field flux, it is natural in the context of the higher-dimensional M- or type IIB theory. This split ansatz, however, means that it is much less natural to view the geometry as arising in a single $D=5$ theory.

Having shown how to obtain the Randall–Sundrum model from type IIB supergravity, we next set out to study the brane-wave oscillations of the solution. This analysis is quite natural in the type IIB analog of the M-theory Z_2 symmetric double 3-brane construction.[12,13] Although, as in Ref. 2, this configuration involves both a positive and a negative tension brane, thus leading to concerns about negative energies, we show that there is a ''mode-locking'' phenomenon that reduces the zero-modes to just one (positive energy) $D=4$, $N=4$ Maxwell multiplet in the case of one singly charged brane. This happens because the Z_2-odd modes turn out to be nonzero modes constrained to be related to Kaluza–Klein massive modes by the Bianchi identities for the type IIB 5-form field strength $H_{[5]}$ and for the gravitational curvature. Thus, one does not have to make an explicit projection by hand into a Z_2-invariant subspace of fields: this projection happens spontaneously, by normal Kaluza–Klein dynamical mechanisms freezing out massive Kaluza–Klein modes. The type IIB models considered here have the great advantage that one can carry out more of the Kaluza–Klein analysis explicitly than in the analogous discussion of M-theory reduced on Calabi–Yau spaces.[12,13] But it is to be expected that an analogous mode-locking mechanism will operate there as well. And in that case, the mode-locking can be expected to lead to a spontaneous appearance of $D=4$ chirality, thus generalizing the appearance of chirality by explicit Z_2 projection.

II. SUPERSYMMETRIC DOMAIN WALLS AND RENORMALIZATION GROUP FLOWS

While there are many ways of representing a metric on anti de Sitter space, perhaps the most natural form of the metric from a domain wall point of view is given in terms of Poincaré coordinates,

$$ds^2 = e^{-2gy}\eta_{\mu\nu}dx^\mu dx^\nu + dy^2. \tag{2.1}$$

Written in this manner, the Minkowski signature boundary of AdS is reached when $y \to -\infty$, while the point $y \to \infty$ is instead a null surface, the AdS Killing horizon. In the AdS/CFT corre-

spondence, this metric is viewed as the near-horizon geometry of N coincident D3-branes, which is described by $\mathcal{N}=4$ super Yang–Mills living on the boundary. Furthermore, the distance to the boundary is regarded as an energy; from the bulk point of view $y\to-\infty$ is a flow to the UV, while $y\to\infty$ is a flow to the IR.

The Randall–Sundrum brane-world is obtained by taking two Poincaré patches of AdS, both given by (2.1), and joining them at the brane location $y=0$. The resulting Randall–Sundrum metric has the form

$$ds^2=e^{-2g|y|}\eta_{\mu\nu}\,dx^\mu\,dx^\nu+dy^2, \tag{2.2}$$

and its geometry gives rise to a localized graviton on the ''Planck'' brane. Presented as ''an alternative to compactification,'' much has been made of the fact that this scenario binds gravity even though the y direction has an infinite extent. Nevertheless, it is apparent from the form of (2.2) that the Planck brane only lives in a tiny portion of AdS, and that movement away from the brane flows towards the Killing horizon and not towards the Minkowski boundary of AdS. Had one instead chosen to join together the $y<0$ regions of (2.1), the resulting geometry would preserve the vast majority of the original space, including the entire portion of AdS near the boundary. This then would yield a divergent ''localization'' volume and give rise to a brane of opposite character to the Randall–Sundrum brane, namely one that does not bind gravity.

In fact, the above observation motivated the authors of Ref. 28 to view the Randall–Sundrum geometry as a warped compactification of F-theory on a Calabi–Yau four-fold. In this picture, the warped geometry arises from the presence of D3-branes situated on the elliptically fibered Calabi–Yau manifold. The five-dimensional Randall–Sundrum universe then corresponds to the noncompact four-dimensional spacetime with the addition of a single y coordinate which provides a preferred slicing of the internal space along flows between separated stacks of D3-branes. One thus sees that the Randall–Sundrum brane itself is not identified with any one of the D3-branes, but is instead viewed as an effective geometry that arises in interpolating between the near-horizon locations of the D3-branes. In terms of the parametrization in (2.2), the D3-branes are located at the horizons, $y=\pm\infty$, and the apparent infinite extent of the y coordinate is simply a result of the warping of the compact space by the D3-branes themselves. The localization of gravity is then explained by the compactness of the underlying F-theory construction. Heterotic and M-theory realizations based on warped Calabi–Yau compactifications have been examined in Ref. 29.

Returning to a five-dimensional picture, there have been many attempts to explain the Randall–Sundrum scenario from a supersymmetric domain-wall point of view. The advantage of this approach is that one can generally ignore the added complications of the compactification of the underlying IIB theory, and instead focus only on brane constructions in the resulting $D=5$ gauged supergravity theory. However, as we emphasize below, it is important to realize that there is no reason (other than simplicity) to expect that the relevant degrees of freedom lie only in the massless supergravity sector. In fact, as emphasized in Refs. 22, 23, massless gauged supergravity precludes the localization of gravity on a brane. Thus massive fields are a necessity.

For the Randall–Sundrum picture to be realistic, where the Planck brane is a dynamical object, it would have to be supported by bulk scalar fields. Thus, in the language of bulk renormalization group flow, we seek a brane solution with stable flows to AdS critical points in the IR on both sides of it. This approach has been studied extensively in both the AdS/CFT[30,31] and brane-world[22,23,32,33] pictures, with considerable overlap. Nevertheless, the distinction between flows of massless and massive scalars has not always been made clear, so we wish to do so below.

Since we demand that the flow away from the brane is towards an AdS background, the scalars must reach some fixed values corresponding to a critical point in the potential. Then, independent of any specific model, at that point, we may expand the scalars about their fixed values. However before doing so, it is worth realizing that representations in AdS differ from those in a flat background.

Recall that, for AdS_5, general representations of $SU(2,2)$ may be labeled by $D(E_0,j_1,j_2)$ where E_0 is the lowest energy (which may be given in terms of the natural mass scale of the AdS

background). For scalars, $D(E_0,0,0)$, unitarity requires $E_0 \geqslant 1$ with $E_0=1$ corresponding to the singleton representation. General unitarity bounds for $SU(2,2)$ as well as for the $SU(2,2|N/2)$ superalgebras have been obtained in Refs. 34–39 (see also Ref. 40). For a scalar field in AdS_5, the mass is given in terms of E_0 by $m^2=E_0(E_0-4)$, so that ''massless'' scalars in fact correspond to $E_0=4$. Of course, negative mass squared is not to be feared in an AdS background, provided the Breitenlohner–Freedman bound[41] is satisfied. For this case it corresponds to $m^2 \geqslant -4$, which is saturated for $E_0=2$.

To be specific, we now consider the case of a brane supported by a single scalar coupled to gravity, where the Lagrangian takes the form

$$e^{-1}\mathcal{L}=R-\tfrac{1}{2}\partial\phi^2-V(\phi). \tag{2.3}$$

While one may generalize by including more scalars, this single scalar example is sufficient to bring out our conclusion. The resulting equations of motion have the form

$$R_{MN}=\tfrac{1}{2}\partial_M\phi\,\partial_N\phi+\tfrac{1}{3}g_{MN}V(\phi), \quad \nabla^2\phi=\partial_\phi V(\phi). \tag{2.4}$$

Note that we do not insist that (2.3) necessarily originates from a supersymmetric theory. However, in many cases we are of course interested in supersymmetry. This suggests the identification of a putative ''superpotential'' $W(\phi)$ with

$$V=(\partial_\phi W)^2-\tfrac{2}{3}W^2, \tag{2.5}$$

and the putative ''transformations,''

$$\delta\psi_\mu=\left[\nabla_\mu-\frac{1}{6\sqrt{2}}W\gamma_\mu\right]\epsilon, \quad \delta\lambda=\frac{1}{2}[\gamma\cdot\partial\phi+\sqrt{2}\partial_\phi W]\epsilon. \tag{2.6}$$

Identification of the above transformations with those of an actual supergravity theory requires some care.[42] In particular, from an $N=2$ (i.e., minimal supersymmetry in $D=5$) point of view, the field ϕ may reside in either a vector, tensor or hypermatter multiplet, with possibly different forms of coupling to the fermions. In all cases, the fields $(g_{\mu\nu},\psi_\mu)$ and (ϕ,λ) would be part of a (not necessarily consistent) truncation of the actual supergravity theory.

As emphasized previously in discussions of holographic renormalization group flows, the equations of motion following from a domain-wall ansatz take on a simple form. Starting with the metric

$$ds^2=e^{2A(y)}\eta_{\mu\nu}\,dx^\mu\,dx^\nu+e^{2B(y)}\,dy^2, \tag{2.7}$$

one obtains the following equations:

$$A'^2=\tfrac{1}{24}\phi'^2-\tfrac{1}{12}e^{2B}V, \quad A''-A'B'=-\tfrac{1}{6}\phi'^2, \tag{2.8}$$

$$\phi''+(4A'-B')\phi'=e^{2B}\partial_\phi V,$$

where primes denote y derivatives. The first two equations were obtained by combining components of the Einstein equation. Note that the three equations are not all independent, and we find it convenient to focus only on the first two.

In codimension-one, the second metric factor e^{2B} is redundant, and may be removed by defining a new coordinate $\tilde{y}=\int e^B\,dy$ (keeping in mind that explicit domain wall solutions often have a simpler form when presented in terms of a metric with the e^{2B} factor). We proceed by setting $B=0$, so the equations resulting from (2.8) take the form

$$A''=-\tfrac{1}{6}\phi'^2,\quad A'^2=\tfrac{1}{24}\phi'^2-\tfrac{1}{12}V,\quad \phi''+4A'\phi'=\partial_\phi V. \tag{2.9}$$

As emphasized in Refs. 31, 30, the first of these equations indicates that $A''\leqslant 0$, with saturation of the inequality corresponding to sitting in the pure AdS vacuum. For the present case, this has the consequence that the function $A(y)$ must be concave-down, which is in fact exactly what is needed to support a ''kink-down'' (i.e., positive tension) Randall–Sundrum brane of the form (2.2) with a continuous metric function.

To study the behavior of the flow to the IR fixed point, we may expand about the fixed value, ϕ_*, of the scalar. To quadratic order, the potential then has the form

$$V=-12g^2+\tfrac{1}{2}m^2(\phi-\phi_*)^2+\cdots, \tag{2.10}$$

where the constant factor is chosen to give the conventional normalization of the AdS curvature,

$$R_{MNPQ}=-g^2(g_{MP}g_{NQ}-g_{MQ}g_{NP}). \tag{2.11}$$

While in some cases g may coincide with the coupling constant of gauged supergravity, we only take it to parametrize the AdS background at the specific fixed point in which we are interested.

We now insert (2.10) into the second equation of (2.9) to find that $A(y)\approx\pm gy$, at least up to linear order in ϕ. Thus we recover the expected linear behavior giving rise to an AdS background. Continuing with the ϕ equation of motion, and again working to linear order in ϕ (which amounts to making the substitution $A'\approx\pm g$), we find

$$\phi''\pm 4g\phi'-m^2\phi\approx 0, \tag{2.12}$$

which has in general two solutions:

$$\phi\approx\phi_*+ce^{-E_0A(y)},\quad \text{and}\quad \phi\approx\phi_*+ce^{-(4-E_0)A(y)}, \tag{2.13}$$

where $E_0=2+\sqrt{(m/g)^2+4}\geqslant 2$ is given exactly by the mass/E_0 relation for a scalar field in AdS space. Additionally, for either flow, the metric function behaves like

$$A\approx\pm gy-\tfrac{1}{24}(\phi-\phi_*)^2. \tag{2.14}$$

Finally, this allows us to examine the IR flow, corresponding to the behavior in the direction $A\to-\infty$. We see that IR stability is ensured for $E_0>4$ by taking the second solution of (2.13), while the flow is always unstable for $2\leqslant E_0<4$, and the massless case, $E_0=4$, is marginal.

As a result, the above analysis indicates that $E_0>4$ is a necessary condition for IR stability, and hence for the construction of a Randall–Sundrum brane. Note, furthermore, that this result was derived without having to appeal to supersymmetry. Thus it holds in general for both BPS and non-BPS flows. However, as we see below, BPS flows impose a further condition on the relative signs of the terms in the superpotential. This powerful and completely general result was in fact present, although hidden in the discussion of Refs. 22, 23. However, in Refs. 22, 23, only scalars residing in massless vector multiplets of $N=2$ gauged supergravity (i.e., the $\mathcal{D}(2,0,0,0)$ representation, where the last value denotes the $U(1)_r$ charge) were considered. In particular, the authors of Ref. 22 relied on the relation $(\partial_i\partial_j W)_{\rm cr}=1/3\,g_{ij}W_{\rm cr}$ (in our normalization) arising from very special geometry. Such scalars always have $E_0=2$, yielding the negative reported result. Curiously, while it may not have been appreciated that scalars in the decomposition of an $N=8$ gauged supergravity multiplet reside in $N=2$ tensor and hypermatter multiplets as well as vector multiplets, such $N=8$ scalars all have $E_0=2$, 3 or 4 so that they also do not lead to IR stable branes.

Turning now to the case of a supersymmetric flow, it is straightforward to see from (2.6) that the Killing spinor conditions yield the first order equations,

$$A' = \pm \frac{1}{3\sqrt{2}} e^B W, \quad \phi' = \mp \sqrt{2} e^B \partial_\phi W, \tag{2.15}$$

for a domain wall preserving exactly half of the supersymmetries. This result may in fact also be derived without using the transformations (2.6), but instead by a traditional BPS argument for finding static minimum energy configurations.[30,33] Combining both equations gives rise to a holographic renormalization group flow,

$$\frac{d\phi}{dA} = -6 \frac{\partial_\phi W}{W}, \tag{2.16}$$

consistent with the second order equations (2.8). In this case, we expand the superpotential as

$$W = \pm 3\sqrt{2} g (1 + \tfrac{1}{12} \lambda (\phi - \phi_*)^2 + \cdots), \tag{2.17}$$

corresponding to the potential (2.10), provided λ is identified with either E_0 or $4 - E_0$. Note that this introduces a two-fold ambiguity. However this is in fact somewhat artificial, since knowledge of the actual supersymmetric theory would fully determine the superpotential (but see, e.g., Ref. 43 for a discussion on the relation between V and W without supersymmetry). In contrast to (2.13), the supersymmetric flow condition, (2.16), gives only a single approach to the fixed point,

$$\phi \approx \phi_* + c e^{-\lambda A(y)}. \tag{2.18}$$

As a result, for a BPS flow, not only do we require $E_0 > 4$, but also we learn from the above analysis that $\lambda = 4 - E_0$ must be negative in the superpotential (2.17). The requirement of $\lambda < 0$ was previously noted in Ref. 22.

This connection between E_0 and the behavior of a scalar field in AdS was initially made in investigations of the Maldacena conjecture,[44,45] where E_0 was related to the conformal dimension of appropriate operators on the CFT side of the AdS/CFT conjecture. In this case, (2.12) taken with exact equality is simply the massive scalar equation in the reference AdS background (2.1). This in itself highlights the similarity between the brane-world scenario and the AdS/CFT conjecture. In some sense, the Randall–Sundrum brane, being inserted at some fixed location in AdS, cuts off the flow to the UV and hence may be described by a Maldacena CFT cut off at some energy scale related to the location of the brane.

III. BREATHING MODE DOMAIN WALLS AND THE BRANE-WORLD

Based on the preceding analysis, it is clear that consideration of the massless sector of ($N = 2$, 4 or 8) gauged supergravities alone does not lead to realistic brane-world configurations. However, for a five-dimensional model originating from IIB theory, many other degrees of freedom may come into play. While round S^5 compactifications of IIB supergravity yield $N = 8$ gauged supergravity at the massless level, this is also accompanied by a Kaluza–Klein tower of massive states. In general, consistent truncations of sphere reductions are a delicate matter.[46,47] However it is consistent to include the breathing mode φ in the truncation: although it lives in a massive supermultiplet, it is nevertheless a gauge singlet. Domain walls supported by the breathing mode have been investigated in Refs. 1, 17, 20, and have recently been suggested as possible realizations of the brane-world scenario. Note that we use φ to denote the breathing mode rather than ϕ, in order to emphasize that it is distinct from the $D = 10$ dilaton of the type IIB theory.

To make a connection with the Randall–Sundrum model, we examine type IIB string theory compactified on S^5. This sphere reduction, with the inclusion of a single squashing mode along with the breathing mode, was investigated in Ref. 1. Focusing only on the scalar modes, the resulting five-dimensional Lagrangian is

$$e^{-1} \mathcal{L}_5 = R - \tfrac{1}{2} \partial \tilde{\varphi}^2 - \tfrac{1}{2} \partial \tilde{f}^2 - V(\tilde{\varphi}, \tilde{f}). \tag{3.1}$$

The scalar potential has the form

$$V(\tilde{\varphi},\tilde{f})=8m^2e^{(10/\sqrt{15})\tilde{\varphi}}+e^{(4/\sqrt{15})\tilde{\varphi}}(\mu^2e^{(6/\sqrt{10})\tilde{f}}-R_4e^{(1/\sqrt{10})\tilde{f}}), \tag{3.2}$$

where the constants (m,μ,R_4) are parameters of the compactification.[1]

While this potential may now be expanded in the form of Eq. (2.10), it is perhaps more enlightening to first express it in the form of a ''superpotential'' according to (2.5). We find

$$W=2\sqrt{2}me^{(5/\sqrt{15})\tilde{\varphi}}-e^{(2/\sqrt{15})\tilde{\varphi}}\left(\sqrt{2}\mu e^{(3/\sqrt{10})\tilde{f}}+\frac{R_4}{2\sqrt{2}\mu}e^{-(2/\sqrt{10})\tilde{f}}\right). \tag{3.3}$$

Note that there is a slight sign ambiguity in inverting (2.5); here we have chosen the signs so that W has a critical point at

$$e^{(3/\sqrt{15})\tilde{\varphi}_*}=\frac{\mu}{2m}\left(\frac{R_4}{6\mu^2}\right)^{3/5},\quad e^{(5/\sqrt{10})\tilde{f}_*}=\frac{R_4}{6\mu^2}, \tag{3.4}$$

corresponding to that of V as well. Expansion of W then gives

$$W=-3\sqrt{2}m\left(\frac{\mu}{2m}\right)^{5/3}\left(\frac{R_4}{6\mu^2}\right)\left[1-\frac{1}{3}(\tilde{\varphi}-\tilde{\varphi}_*)^2+\frac{1}{2}(\tilde{f}-\tilde{f}_*)^2+\cdots\right]. \tag{3.5}$$

A comparison with (2.17) then demonstrates explicitly that the breathing mode $\tilde{\varphi}$ has $E_0=8$ while the squashing mode $\tilde{f}$ has $E_0=6$. Curiously, the two modes enter with opposite signs in W. While this $N=8$ symmetric critical point is indeed a minimum of the potential, it is only a saddle point of W.

The consequences for the resulting supersymmetric flow were investigated in the previous section. For supersymmetric flows, this critical point is IR stable for the breathing mode, while it is unstable for the squashing mode. This indicates explicitly that simply having a domain wall supported by a scalar with $E_0>4$ may be insufficient to ensure the stability of a supersymmetric Randall–Sundrum configuration. Nevertheless, we have now seen why use of the massive breathing mode of sphere reductions has been successful in constructing brane-world domain walls,[17,20] avoiding the limitations on supersymmetric flows presented in Refs. 22, 23.

To proceed, we now truncate out the squashing mode by setting $\tilde{f}=0$ and $R_4=6\mu^2=(6/5)R_5$. After dropping tildes, the resulting potential for the breathing mode is simply

$$V(\varphi)=8m^2e^{(10/\sqrt{15})\,\varphi}-R_5e^{(4/\sqrt{15})\,\varphi}, \tag{3.6}$$

and has an AdS minimum at

$$e^{(6/\sqrt{15})\,\varphi_*}=\frac{R_5}{20m^2}. \tag{3.7}$$

Here R_5 is the curvature scalar of the round S^5, arising from the type IIB Kaluza–Klein ansatz,[1]

$$ds_{10}^2=e^{2\alpha\varphi}\,ds_5^2+e^{2\beta\varphi}\,ds^2(S^5),\quad H_{[5]}=4me^{8\alpha\varphi}\epsilon_{[5]}+4m\epsilon_{[5]}(S^5), \tag{3.8}$$

where

$$\alpha=\tfrac{1}{4}\sqrt{\tfrac{5}{2}},\quad \beta=-\tfrac{3}{5}\alpha. \tag{3.9}$$

This also indicates that m is essentially the 5-form flux of the Freund–Rubin compactification. Thus the two parameters m and R_5 of the five-dimensional potential, (3.6), have their origin in the Kaluza–Klein compactification from ten dimensions. Note that the Kaluza–Klein ansatz (3.8) for

the $H_{[5]}$ field strength implies that the Freund–Rubin parameter m must be odd under transformations $y \to -y$. In order for this to be realized as a symmetry of the type IIB theory, this ''lower'' $D=5$ transformation must be accompanied by an orientation-reversing transformation of S^5, so that the self-dual structure of $H_{[5]}$ is preserved, but with $m \to -m$. By the ''skew-whiffing theorem,'' [46] both orientations have the same (maximal) supersymmetry in the case of S^5. For any other compactifying 5-manifold the supersymmetries would not match.

For a complete truncation of the sphere compactification down to $D=5$, in which all Kaluza–Klein modes except for the breathing mode are discarded, the two parameters m and R_5 satisfy trivial Bianchi identities, and hence must be constant. In this case only a single combination of the two is actually physical. The constant parameter R_5 may then be viewed as a necessary dimensionful parameter for measuring coordinate distances on the five sphere (much as one would have to introduce a length scale L for toroidal compactification, where periodic coordinates are identified as $y=y+2\pi L$). The actual invariant (physical) size of the five sphere is then set by the expectation of the breathing mode φ. To see formally how R_5 may be scaled away, consider a shift of φ along with a scaling of m,

$$\varphi \to \varphi + \sqrt{\tfrac{15}{4}} \log \lambda, \quad m \to m\lambda^{-5/4}. \tag{3.10}$$

This transformation has the effect of multiplying R_5 by λ in the potential (3.6), so that an appropriate choice of λ may be used to scale R_5 to any desired value. A particularly natural choice would be to set $R_5=20m^2$, so that the AdS critical point is reached at $\varphi_*=0$. From a ten-dimensional point of view, the transformation (3.10) results in

$$\begin{aligned} ds_{10}^2 &= \lambda^{5/8}[e^{2\alpha\varphi}\, ds_5^2 + e^{2\beta\varphi}\lambda^{-1}\, ds^2(S^5)], \\ H_{[5]} &= \lambda^{5/2}[4me^{8\alpha\varphi}\epsilon_{[5]} + 4m\lambda^{-5/2}\epsilon_{[5]}(S^5)], \end{aligned} \tag{3.11}$$

which is thus a rescaling of S^5 combined with a $D=5$ ''trombone'' symmetry.

However, as we will discuss in the following section, if one no longer truncates out the additional Kaluza–Klein modes, then both m and R_5 no longer need to be taken as constant. In this case, attempts to scale away $R_5(x)$ would result in a dynamical scaling by $\lambda(x)$. In this sense one simply trades one parameter for another, and cannot fully eliminate R_5. With this in mind, we maintain both parameters m and R_5 in the solution below.

Breathing-mode domain wall solutions follow by making the standard ansatz (2.7) and by solving the resulting equations (2.8). As mentioned above, keeping two independent factors in the ansatz, $A(y)$ and $B(y)$, is redundant. For $B=0$, the solution was presented in Ref. 17, while it was originally presented in Ref. 1 with a different choice of coordinates. The advantage of the original choice is its highlighting of a linear harmonic function as a natural feature of codimension-one p-brane solutions. This solution has the basic form[1]

$$e^{-(7/\sqrt{15})\varphi} = H, \quad e^{4A} = e^{-B} = \tilde{b}_1 H^{2/7} + \tilde{b}_2 H^{5/7}, \quad H = e^{-(7/\sqrt{15})\varphi_0} + ky, \tag{3.12}$$

where

$$\tilde{b}_1 = \eta_1 \frac{28m}{3|k|}, \quad \tilde{b}_2 = \eta_2 \frac{14\sqrt{5R_5}}{15|k|}. \tag{3.13}$$

Here $\eta_{1,2}=\pm 1$ are in general independent choices of signs for the solution. For our purposes they are fixed by requiring an appropriate AdS limit for $\varphi \to \varphi_*$. This gives $\eta_2 = -\eta_1$ and η_1 chosen so that $e^{4A}>0$ in order for the metric to be real at a given initial value of y.

The linear harmonic function H is restricted to be nonnegative. Examination of the solution indicates that the AdS horizon is located at $H=H_* \equiv e^{-7\varphi_*/\sqrt{15}}$, where e^{4A} vanishes. For initial $H>H_*$ the five-dimensional space asymptotically flattens out as $H \to \infty$, with a corresponding limit for the scalar field $\varphi \to -\infty$, yielding an asymptotically vanishing scalar potential. This case

is the second branch of Ref. 17, where it was referred to as a hybrid type II and dilatonic domain wall. On the other hand, for initial $H<H_*$, the solution soon runs into a singularity at $H=0$. Note, however, that if one starts with a solution with $H>H_*$ initially and signs $\eta_{1,2}$ chosen so as to make $e^{4A}>0$ initially, but then follows the evolution of H within the spacetime through the $H=H_*$ horizon, the metric in the region with $H<H_*$ becomes complex, so one should really treat the region below the horizon using different, appropriately chosen coordinates. Both the $H>H_*$ and $H<H_*$ cases have a natural interpretation in the lifting of (3.12) to ten dimensions. In the IIB theory, (3.12) lifts directly to the geometry of N coincident D3-branes with total charge $\tilde{k}=m(20/R_5)^{5/2}$.[1] The two regions $H\gtrless H_*$ then correspond to the regions either ''outside'' or ''inside'' the D3-brane horizon. This furthermore demonstrates that the first, $H>H_*$, case is nothing but the conventional near-horizon limit occurring prominently in the Maldacena conjecture. The second, $H<H_*$, case is unphysical as it stands, however, as it sees a different region of the D3-brane geometry containing a singularity.

Neither case by itself provides a suitable framework for a Randall–Sundrum configuration. While in one direction one may reach an AdS horizon, in the other direction one will either run into a singularity or on out into unbounded flat space. One obvious possibility for obtaining an asymptotically AdS space on both sides of a domain wall is to reflect the solution at $y=0$, imposing thus a $y\to -y$ Z_2 symmetry. The resulting two-sided domain wall, supported by an absolute value kink in the linear harmonic function,

$$H=e^{-(7/\sqrt{15})\varphi_0}+k|y|, \tag{3.14}$$

was in fact how the solution was originally presented in Ref. 1. The presence of such a kink is rather natural for a codimension-one object. Supergravity p-brane solutions are generally supported by δ-function sources at the locations of the branes themselves, and this remains true for domain walls. Passing through a domain wall, one jumps through a sheet of charge, and this jump in charge manifests itself in a change in the slope of the linear harmonic function. *A priori*, the slope could take any values on the two sides of the domain wall, but clearly the Z_2 symmetric jump from k to $-k$ is a natural configuration. We shall see that this configuration is distinguished also by preserving unbroken supersymmetry.

For either the plain unkinked (3.12) or the kinked (3.14) solution, the slope k may be scaled away by taking $y\to y/|k|$ and $x^\mu\to x^\mu|k|^{1/4}$. This explains why the apparent domain wall charge k is not directly related to lifted quantities such as the D3-brane charge $\tilde{k}$. However, note that this scaling does not eliminate the sign of k, thus leaving a distinction between the slope-up and slope-down possibilities. For discussions of multiple domain wall configurations or brane fluctuations, it is more convenient to retain k.

If one chooses to restrict the coordinate y in (3.14) to range only over the interval $-y_0\leqslant y\leqslant y_0$, identifying the points y_0 and $-y_0$, then one obtains a Z_2 symmetric solution that can serve as the background for a Z_2 orbifold construction. This orbifold construction is analogous to the treatment of M-theory 3-branes given in Refs. 12, 13 as a brane realization of the Hořava–Witten S^1/Z_2 orbifold, and has also been proposed in the Randall–Sundrum context in Ref. 20. The identification of y_0 and $-y_0$ essentially reproduces the original Randall–Sundrum model[2] with both an attractive and a repulsive brane (if one chooses $k<0$, then the attractive brane is the one located at $y=0$). From the five-dimensional point of view, the $y\to -y$ Z_2 map is a parity flip. As we have mentioned above, however, this alone is not a good symmetry of the underlying type IIB theory. In order for this transformation to be compatible with the round-sphere compactification of the IIB theory, this Z_2 transformation must combine the flip in y with an orientation-reversing transformation[27] of the S^5. For example, an allowable transformation flips all six of the coordinates transverse to the underlying $D=10$ D3-brane. The net effect is to send $m\to -m$ as well as $y\to -y$.

This orientation reversal has important consequences for the supersymmetry transformations (2.6), since the superpotential W also flips, $W\to -W$, under these transformations. Actually, this is what one wants, because if the superpotential were to not to flip in this way, then all supersym-

metries would be broken by the domain wall, and it would then no longer be BPS. To see this, consider for example the $\delta\lambda$ transformation for the solution (3.12) with the linear harmonic function (3.14). By truncating out the squashing mode from (3.3), one arrives at the breathing-mode superpotential:

$$W=\sqrt{2}m\left[2e^{(5/\sqrt{15})\,\varphi}-5\sqrt{\frac{R_5}{20m^2}}\,e^{(2/\sqrt{15})\,\varphi}\right]. \tag{3.15}$$

Written as above, this clearly changes sign as $m\to -m$. On the other hand, If one were to assume instead that W remains invariant, one would find

$$\begin{aligned}\partial_\varphi W&=\frac{2}{3}\sqrt{30}m\left[e^{(5/\sqrt{15})\,\varphi}-\sqrt{\frac{R_5}{20m^2}}\,e^{(2/\sqrt{15})\,\varphi}\right]\\&=\frac{\sqrt{30}}{14}|k|H^{-1}(|\tilde{b}_1|H^{2/7}-|\tilde{b}_2|H^{5/7})\\&=-\frac{1}{\sqrt{2}}|\varphi'|e^{-B},\end{aligned} \tag{3.16}$$

where the signs $\eta_{1,2}$ have been chosen to obtain the outside (i.e., $H>H_*$) AdS solution. Inserting this into (2.6) we would find

$$\delta\lambda=\tfrac{1}{2}e^{-B}(\gamma^{\bar{y}}\varphi'-|\varphi'|)\epsilon, \tag{3.17}$$

where $\bar{y}$ denotes a local Lorentz index. Because of the absolute value in the linear harmonic function (3.14), φ' changes sign on opposite sides of $y=0$. Therefore the assumption of an invariant W would leave no possibility of obtaining a Killing spinor that is consistently defined on both sides of $y=0$. If one were to attempt to patch together separate Killing spinors on both sides of $y=0$, in the case of an invariant W, the $y\gtrless 0$ projections on the supersymmetry parameter would be into mutually orthogonal components, $(1+\gamma^y)\epsilon_+=0$ vs $(1-\gamma^y)\epsilon_-=0$. However, since the superpotential *does* change sign under the Z_2, the absolute value in (3.17) is in fact not present, and we accordingly find global Killing spinors of the form $\epsilon=e^{A/2}(1+\gamma^{\bar{y}})\epsilon_0$. Similar considerations apply at the location of the second kink in the Z_2 invariant background. If one expands the theory in modes about this Z_2 invariant background, keeping only the Z_2 invariant modes, the resulting theory is equivalent to one defined on an S^1/Z_2 orbifold.

As we have just demonstrated, the domain wall solution is always one half supersymmetric, with or without the absolute value kink. In particular, the Z_2 orbifolding has not destroyed any further supersymmetry beyond the original half-BPS solution. On the other hand, there is no restoration of supersymmetry either in the presence of a kink. Consider taking a simultaneous limit $k\to 0$ and $\varphi_0\to\varphi_*$. Without the kink, this limit would yield pure AdS, i.e., the D3-brane near-horizon limit in which full supersymmetry is restored. But with the kink, one obtains instead a Z_2 symmetric patching of AdS, with a Randall–Sundrum brane located, say, at $y=0$. The presence of the orbifold fixed point prevents the full supersymmetry from being restored. However, this is fully expected when a domain wall is present. Although the Z_2 symmetrization introduces an absolute value into functions, the Killing spinor equations are of first order, and so do not see any δ-function singularities. As long as the conditions (2.15) are satisfied, the solution remains supersymmetric.

Of course the second order equations of motion will see the δ-function brane source. For the solution (3.14), we find that the extra source terms at $y=0$ are

$$T^{\text{brane}}_{MN}=\frac{3k}{14}(2\tilde{b}_1^2 e^{(3/\sqrt{15})\,\varphi_0}+5\tilde{b}_2^2 e^{-(3/\sqrt{15})\,\varphi_0}-7|\tilde{b}_1\tilde{b}_2|)\,\delta(y)\,\delta^\mu_M\delta^\nu_N g_{\mu\nu},$$
$$Q^{\text{brane}}=-4\sqrt{\frac{5}{3}}\frac{3k}{14}(\tilde{b}_1^2 e^{(3/\sqrt{15})\,\varphi_0}+\tilde{b}_2^2 e^{-(3/\sqrt{15})\,\varphi_0}-2|\tilde{b}_1\tilde{b}_2|)\,\delta(y), \tag{3.18}$$

assuming $\tilde{b}_1\tilde{b}_2<0$ as indicated above. These ''brane sources'' enter in the equations of motion as

$$R_{MN}-\tfrac{1}{2}g_{MN}R=T^{\varphi}_{MN}+T^{\text{brane}}_{MN},\quad \nabla^2\varphi=\partial_\varphi V(\varphi)+Q^{\text{brane}}, \tag{3.19}$$

where

$$T_{MN}=\tfrac{1}{2}(\partial_M\varphi\partial_N\varphi-\tfrac{1}{2}g_{MN}\partial\varphi^2)-\tfrac{1}{2}g_{MN}V(\varphi). \tag{3.20}$$

Depending on the sign of k, the branes have either positive or negative energy density. However, in both cases the relation between charge and tension is the same, so the branes may be stacked up in BPS configurations.

We have thus seen that the kinks at the brane locations have different consequences for supersymmetry and for the equations of motion. Since the supersymmetry variations and Killing spinor conditions are of first order, the kinks give rise to possibly discontinuous quantities, but no δ-function singularities. On the other hand, the equations of motion will be sensitive to the additional δ-function sources. Although one may view the equations of motion as a composition of two supersymmetries, there is no contradiction in the presence and absence of the δ-function terms since the Killing spinor equations only give rise to a subset of the full equations of motion. To see this consider again for simplicity the $\delta\lambda$ transformation (2.6),

$$\delta\lambda=\tfrac{1}{2}[\,\gamma\cdot\partial_\phi+\sqrt{2}\partial_\varphi W]\epsilon=\tfrac{1}{2}e^{-B}[\,\varphi'\,\bar{\gamma^y}+\sqrt{2}e^B\,\partial_\varphi W]\epsilon. \tag{3.21}$$

Partial breaking of supersymmetry then demands the BPS condition $\varphi'=-\sqrt{2}e^B\,\partial_\varphi W$, relating the scalar to its potential. One may of course choose the other sign if so desired. However this is a global choice, and must be consistent in all patches of space. Similarly, vanishing of the gravitino relates the metric to the scalar potential, $A'=e^B W/3\sqrt{2}$, as given in (2.15). Now consider deriving the second order A'' equation of motion by taking a derivative of $e^{-B}A'$,

$$e^{-B}(A''-A'B')=\frac{1}{3\sqrt{2}}W'. \tag{3.22}$$

For a continuous W, one simply uses the chain rule, $W'=\partial_\varphi W\,\phi'$, and substitutes in the φ' equation to arrive at the A'' equation of motion given in (2.8). However, the assumption of a continuous W is actually too strong. For the Z_2 invariant case, where W changes sign at the brane (say at $y=0$), one would also pick up a source term upon differentiating, resulting in

$$A''-A'B'=-\frac{1}{6}\varphi'^2+\frac{\sqrt{2}}{3}e^B W\delta(y). \tag{3.23}$$

Thus, while supersymmetry implies most of the equations of motion, it does not in fact determine all of them. In fact, for higher codimension branes, there is even more slack between the BPS conditions and the equations of motion. The harmonic function condition, of primary importance in brane constructions, is generally a consequence of the equations of motion, and *not* supersymmetry.[48,49]

IV. D3-BRANES AND THE WORLD IN TEN DIMENSIONS

Until now we have focused almost exclusively on the five-dimensional viewpoint of the Randall–Sundrum scenario. Since the breathing-mode domain wall has its origins in the S^5 compactification of IIB theory, it has a natural interpretation in terms of IIB D3-branes.[1] Following this connection from the brane-world geometry to breathing-mode branes and then to D3-branes, one is led to a realization of the Randall–Sundrum scenario in terms of IIB theory in an appropriate D3-brane background.

While the lifting of the breathing mode brane to patches of the D3 geometry is straightforward, the resulting configuration has unusual features. Following Ref. 1, lifting of the solution given in (3.12) proceeds by identifying a ten-dimensional Schwarzschild coordinate,

$$\rho = \sqrt{\frac{20}{R_5}} H^{3/28}. \tag{4.1}$$

Using the charge relation $\tilde{k} = m(20/R_5)^{5/21}$ and the Kaluza–Klein ansatz (3.8), one finds the resulting ten-dimensional metric,

$$ds_{10}^2 = \tilde{b}_2^{1/2} \left(1 - \frac{\tilde{k}}{\rho^4}\right)^{1/2} dx_\mu^2 + \left(1 - \frac{\tilde{k}}{\rho^4}\right)^{-2} d\rho^2 + \rho^2 \, d\Omega_5^2, \tag{4.2}$$

which is that of N D3-branes of total charge $\tilde{k}$.[8,9] A further change of coordinates, $r^4 = \rho^4 - \tilde{k}$, may be performed to transform this into standard isotropic form,

$$ds_{10}^2 = \sqrt{\tilde{b}_2} H_{D3}^{-1/2} \, dx_\mu^2 + H_{D3}^{1/2} (dr^2 + r^2 \, d\Omega_5^2), \tag{4.3}$$

with a harmonic function $H_{D3} = 1 + \tilde{k}/r^4$. Note that the constant $\tilde{b}_2$ may easily be scaled out of the longitudinal coordinates.

For the Z_2 symmetric configuration, obtained by kinking the linear harmonic function, (3.14), we see that H is a double valued function of y. This has the consequence that the lifting relation (4.1) is similarly double valued; opposite sides of the breathing-mode brane lift to identical ρ values. While the orbifold picture corresponds to a single slice of the D3-brane geometry, $\rho \in [\rho_-, \rho_+]$, the full circle compactification instead corresponds to two copies of the D3-brane geometry patched together at ρ_- and ρ_+. Note that the AdS horizon, located at H_*, lifts to the D3-brane horizon, located at $\rho_* = \tilde{k}^{1/4}$. Thus taking the Randall–Sundrum configuration (kink-down with $H > H_*$) and pushing the second brane off to the Cauchy horizon corresponds in ten dimensions to taking two copies of the near-horizon geometry of N D3-branes, and gluing them together at a value ρ_0 of the Schwarzschild coordinate corresponding to the initial value H_0 of the linear harmonic function.

For this Randall–Sundrum configuration, it is instructive to ''unfold'' the doubled metric (4.3) by defining a new radial coordinate $\xi \in [-r_0, r_0]$ such that $r = r_0 - |\xi|$. After scaling out $\tilde{b}_2$ from (4.3), the lifted Randall–Sundrum metric has the form

$$ds_{10}^2 = \left(1 + \frac{\tilde{k}}{(r_0 - |\xi|)^4}\right)^{-1/2} dx_\mu^2 + \left(1 + \frac{\tilde{k}}{(r_0 - |\xi|)^4}\right)^{1/2} (d\xi^2 + (r_0 - |\xi|)^2 \, d\Omega_5^2). \tag{4.4}$$

The positive tension brane is located at $\xi = 0$, while the negative tension brane is pushed off to the AdS horizon at $\xi = \pm r_0$ (the two values are identified under the Z_2 orbifolding). As seen explicitly here, this act of patching together two stacks of D3-branes essentially compactifies the six-dimensional space transverse to the branes, and also introduces a curvature discontinuity at $\xi = 0$, the location of the patching. Furthermore, this compactification introduces a charge conservation condition, implying that the net D3 charge must vanish. Thus the resulting kink at $\xi = 0$

must include a stack of $2N$ negative tension D3-branes, with $-2N$ units of charge soaking up the $N+N$ units of charge from the two stacks of positive tension D3-branes.

The question arises, however, whether placing this stack of $2N$ negative tension D3-branes at $\xi=0$ is sufficient for generating the kinked Randall–Sundrum geometry. Furthermore, the reduction of D3-brane tension from $D=10$ to $D=5$ yields the simple result $T_{D=5}=T_{D=10}$. In addition to giving rise to the tension discrepancy pointed out in Ref. 27, it also leaves unexplained how positive $D=5$ tension arises from negative $D=10$ tension. As it turns out, the resolution to both issues is the realization that the Z_2 orbifolding, or the doubling of spacetime, itself gives rise to a positive tension contribution at $\xi=0$, the location of the kink. Of course, it is easy to see that the net tension has to be positive, as that is what is required to ''fold up'' or compactify the space transverse to the branes. The resulting picture is one of negative tension D3-branes trapped on a positive tension Z_2 orbifold plane giving rise to a composite description of the Randall–Sundrum configuration.[50]

By starting with a brane-world scenario on a circle, one obviously obtains a compact Kaluza–Klein geometry, corresponding to expanding IIB theory about a $\mathcal{M}^{1,3}\times S_1\times S^5$. The S_1 coordinate y lifts to the radial coordinate ρ, living in a restricted annular range between the two D3 source shells in a double D3-brane background. Of course there is no surprise in starting with a compact geometry and lifting it to another compact scenario. However, by taking the limit of placing the second brane at the Cauchy horizon of AdS, one effectively decompactifies the original Randall–Sundrum geometry of Ref. 2 into the picture of Ref. 3. Nevertheless, from a ten-dimensional point of view, this corresponds to simply extending the range of ρ a finite distance so as to reach the doubled D3-brane horizon: the internal space remains compact (at least if the inside-horizon brane cores are disregarded). By smoothing out the patching of the double D3-brane configuration, one presumably obtains a warped compactification with an internal six-manifold in the spirit of Ref. 28.

To complete this D3-brane picture of the brane-world, we present the limit in which the Z_2 symmetric supergravity solution literally reproduces the Randall–Sundrum configuration of a single positive-tension ''kink-down'' brane between two patches of anti de Sitter space.[3] Starting from the $D=5$ 3-brane metric (3.12) with $\tilde{b}_2>0$, $\tilde{b}_1<0$, $k<0$, we want to take a limit as $k\to 0_-$. However, the inverse power of k in $\tilde{b}_1$ and $\tilde{b}_2$ (3.13) makes this appear singular. The cure for this is to take a coordinated limit as $k\to 0_-$ and $\varphi\to\varphi_*$. We implement this explicitly by taking

$$e^{-(7/\sqrt{15})\,\varphi_0}=\left(\frac{20m^2}{R_5}\right)^{7/6}+\beta|k|,\quad \beta>0. \tag{4.5}$$

Note that for $\beta>0$, one has $e^{-(7/\sqrt{15})\,\varphi_0}>e^{-(7/\sqrt{15})\,\varphi_*}$, i.e., $H_0>H_*$. Accordingly, for finite $k<0$, the harmonic function H decreases from its value H_0, reaching the Cauchy horizon value H_* at $y=y_h$. This is the natural point at which to make an identification $y_h\leftrightarrow -y_h$, putting the second (negative tension) 3-brane at the horizon. For finite k, one thus has a ''semi-interpolating soliton'' in the sense that one of the asymptotic limits of the solution, but not both, corresponds to a vacuum solution of the theory, in this case the AdS space with asymptotic scalar φ_*. At the Randall–Sundrum brane, however, there is no horizon.

Taking the joint limit defined by (4.5) as $k\to 0_-$, the difference between the two harmonic functions in e^{2A} partially cancels, giving an expression proportional to k, which cancels the k in the denominators of $\tilde{b}_1$ and $\tilde{b}_2$. The resulting metric function is then given by

$$e^{4A}=4m\left(\frac{R_5}{20m^2}\right)^{5/6}(\beta-|y|)=\frac{4}{L}(\beta-|y|), \tag{4.6}$$

where $L=m^{-1}(20m^2/R_5)^{5/6}$ and the y coordinate remains restricted to a compact range, $|y|<\beta$. This corresponds to the line element

$$ds^2=\frac{2}{\sqrt{L}}(\beta-|y|)^{1/2}\eta_{\mu\nu}\,dx^\mu\,dx^\nu+\frac{L^2}{16}\frac{dy^2}{(\beta-|y|)^2}. \tag{4.7}$$

The apparent infinite range of the fifth dimension[51] is obtained by making a change of variables,

$$\beta-|y|=\beta e^{-4|\tilde{y}|/L},\quad x^\mu=\left(\frac{L}{4\beta}\right)^{1/4}\tilde{x}^\mu, \tag{4.8}$$

resulting in the five-dimensional metric,

$$ds^2=e^{-2|\tilde{y}|/L}\eta_{\mu\nu}\,d\tilde{x}^\mu\,d\tilde{x}^\nu+d\tilde{y}^2, \tag{4.9}$$

which is literally the Randall–Sundrum solution.[2,3] This sign of the kink ($k<0$) thus corresponds to a binding of gravity to the 3-brane at $y=0$, with a metric corresponding to segments of pure anti de Sitter space everywhere off this brane surface.

In taking the above Randall–Sundrum limit $k\to 0_-$, $\varphi_0\to\varphi_*$, the ten-dimensional coordinate ρ is restricted to a progressively limited range near $\tilde{k}$, or, equivalently, r is progressively restricted to a range near $r=0$. Thus, from a $D=10$ perspective, the ''infinite'' Randall–Sundrum scenario[3] corresponds to shrinking the outer (RS) brane source tightly around the inner horizon brane. Clearly, what is infinite and what is infinitesimal in this subject is frame-dependent.

It is instructive to see in addition the scaling of the ''brane sources'' (3.18) in the Randall–Sundrum limit. Taking $k\to 0_-$, we find

$$T^{\text{brane}}_{MN}=-\frac{24}{L^2}\delta(y/\beta)\,\delta^\mu_M\delta^\nu_N g_{\mu\nu}=2V_*\delta(y/\beta)\,\delta^\mu_M\delta^\nu_N g_{\mu\nu}, \tag{4.10}$$

while $Q^{\text{brane}}=0$. This vanishing of the scalar charge is in fact forced on us since φ decouples from the solution in this limit. This brings up a key observation that it is not so much the breathing mode φ that supports the brane, but rather $H_{[5]}$ flux corresponding to D3 charge. In addition, it is also the behavior of $H_{[5]}$ flux that saves the BPS condition with $Q^{\text{brane}}=0$; the variation $\delta\lambda$ becomes trivial (as it must for a decoupling scalar), while the gravitino transformation becomes that of pure AdS but with a sign flip $W_*\to -W_*$ at $y=0$ (corresponding to a Freund–Rubin compactification with opposite S^5 orientations). This preservation of supersymmetry further supports the D3-brane origin of the Randall–Sundrum brane-world, *via* the double 3-brane configuration that we have presented.

The above successful reproduction of the Randall–Sundrum scenario with a ''kink-down'' (i.e., positive tension) domain wall embedded into $D=5$ anti de Sitter space depends crucially upon use of the breathing mode φ, which we have shown to transform in a necessary $E_0>4$ anti de Sitter representation. Noted as a possibility for a Randall–Sundrum scenario in Refs. 17, 20, this mode escapes the analysis of Refs. 22, 23 because it belongs to a massive spin-two multiplet, and thus does not belong to an intrinsically $D=5$ supergravity theory. This is because the full multiplet of the breathing mode's superpartners cannot be retained in a ''consistent'' Kaluza–Klein reduction, since it involves a massive spin two mode, which never can be kept in a consistent reduction on spheres.[52] With respect to the $D=5$, $N=8$ supersymmetry, the breathing mode belongs to a multiplet containing 20 copies of the following sets of fields: 1 spin 2, 4 spin 3/2, 26 spin 1, 20 spin 1/2, 15 spin 0. With respect to a $D=5$, $N=2$ decomposition, it belongs to a long massive vector supermultiplet[53] which is another way of explaining why it escaped the analysis of Refs. 22, 23. Since the breathing mode is an $SO(6)$ singlet, only the inclusion of the breathing mode's nonsinglet superpartners leads to difficulties with Kaluza–Klein consistency; truncation to the purely bosonic theory involving just $D=5$ gravity and the breathing mode is fully consistent.

V. MODE LOCKING AND SPONTANEOUS REDUCTION TO AN ORBIFOLD

The Z_2 symmetric scenario presented above, with two branes of opposite tension and opposite magnetic charge, corresponding to (3.14), is clearly similar to the brane constructions of Hořava–Witten orbifolds in M-theory given in Refs. 12, 13. The analogous type IIB situation has the great advantage that one can work out explicitly many features of the dynamics, whereas the analogous discussions in M-theory reduced on Calabi–Yau 3-folds must necessarily remain rather implicit. Here, we wish to explore further the properties of this Z_2 symmetric solution, and see to which extent it naturally corresponds to an orbifold compactification.

The orbifold compactification may be viewed as a compactification on a circle with an additional projection of all the fluctuations into Z_2 even states only. In a Kaluza–Klein spirit, however, one can investigate the possibility of removing the enforced Z_2 projection, in order to see what the theory does purely of its own accord when compactified about the double 3-brane background. Thus, we start without making any Z_2 projections, but still shall take the y direction to be a circle. As explained above, from a ten-dimensional point of view, the D3-branes now have no noncompact transverse directions. Thus there is an added cohomology constraint, which demands that there cannot be any nonzero net magnetic charge in the compact transverse space. Unlike general warped compactifications, which allow for additional fields and nontrivial topology, we shall maintain our focus on the round S^5 and the breathing mode of the compactification. Then, the simplest allowed configuration on the circle is to have a simple pair of 3-branes with opposite magnetic charges. Placing the branes at opposite points on the circle gives rise to a Z_2 symmetric configuration. However, without imposing the Z_2 orbifold symmetry, it would appear that the branes are free to move independently. But we shall now demonstrate that this is not the case; instead, there is a mode-locking phenomenon that links the fluctuations of the two 3-branes into a Z_2 invariant combination.

Consider the y coordinate to be periodic with length $2l$, making the identification at $y=\rho_1 \leftrightarrow -\rho_2$. For bosonic fields on this circle, one must impose continuity conditions at both the locations of the 3-branes. Demanding continuity of the scalar field φ and the metric component e^{2A} at $y=0$ and also at $y=\rho_1 \leftrightarrow y=-\rho_2$, one has four continuity conditions to satisfy. In this discussion we shall take the overall periodicity length $2l$ to be fixed, so $\rho_1+\rho_2=2l$. From continuity of the scalar field φ, one simply obtains at $y=0$ that the value φ_0 must be a common limit of φ as one approaches the $y=0$ RS brane either from the left or from the right. Continuity at $y=\rho_1 \leftrightarrow -\rho_2$ implies continuity of the harmonic function H, so one obtains $|k_1|\rho_2=|k_2|\rho_2$, or, using $\rho_1+\rho_2=2l$, that $|k_1/k_2|=2l/\rho_1-1$. Imposing as well the periodicity conditions on the metric function e^{2A} at $y=0$ and $y=\rho_1 \leftrightarrow -\rho_2$, one obtains the continuity conditions

$$\left|\frac{k_2}{k_1}\right| = \frac{|m_2| - \sqrt{\frac{R_{5(2)}}{20}}\, e^{(-3/\sqrt{15})\,\varphi_0}}{|m_1| - \sqrt{\frac{R_{5(1)}}{20}}\, e^{(-3/\sqrt{15})\,\varphi_0}} = \frac{|m_2| - \sqrt{\frac{R_{5(2)}}{20}}\,(e^{(-3/\sqrt{15})\,\varphi_0} + |k_2|\rho_2)}{|m_1| - \sqrt{\frac{R_{5(1)}}{20}}\,(e^{(-3/\sqrt{15})\,\varphi_0} + |k_1|\rho_1)}. \tag{5.1}$$

These conditions are solved by matching relations for m and R_5 between the two regions:

$$m_2 = \left(\frac{2l}{\rho_1} - 1\right)^{-1} m_1, \quad \sqrt{R_{5(2)}} = \left(\frac{2l}{\rho_1} - 1\right)^{-1} \sqrt{R_{5(1)}}. \tag{5.2}$$

Accordingly, if one now makes a standard soliton-physics ansatz by letting the Z_2-odd modulus ρ_1 become dependent upon the $D=4$ coordinates x^μ, then upon substitution back into the field equations, one obtains the effective equation for $\rho_1(x^\mu)$. Because the oscillations of this coordinate are linked by (5.2) to the Kaluza–Klein ansatz parameters m and R_5, however, this specific

modulus has special restrictions on its oscillations. Both m and R_5 are curvature components, and are thus subject to Bianchi identities. To see this for m, consider the Kaluza–Klein ansatz (3.8), together with the Bianchi identity

$$dH_{[5]} + \tfrac{1}{2}\epsilon_{ij}F^i_{[3]}F^j_{[3]} \equiv 0. \tag{5.3}$$

Letting $m \to m(x)$ and substituting the original ansatz (3.8), one obtains directly a suppression of m fluctuations, $\partial_\mu m(x) = 0$. For this reason, parameters entering into generalized Kaluza–Klein ansätze like (3.8) have been sometimes been called ''nonzero modes.'' [13] In order to see the dynamics of such modes in more detail, one should restore the massive Kaluza–Klein modes that are normally set to zero in a compactification. In the case of m, this means replacing the ansatz (3.8) by

$$H_{[5]} = 4m(x)e^{8\alpha\varphi}\epsilon_{[5]} + 4m(x)\epsilon_{[5]}(S^5) + h_{[5]}, \tag{5.4}$$

where $h_{[5]}$ represents the fluctuating massive Kaluza–Klein modes. Re-performing the analysis of the Bianchi identity (5.3) for this generalized ansatz, one now shows that a nonvanishing $\partial_\mu m$ must be proportional to $\epsilon^{z_1 z_2 z_3 z_4 z_5}\partial_{[z_1}h_{|\mu|z_2 z_3 z_4 z_5]}$, where $h_{\mu z_2 z_3 z_4 z_5}$ is a Kaluza–Klein massive mode, with mass determined as usual by the inverse radius of the S^5 internal sphere, i.e., corresponding to the length scale of the $D=5$ anti de Sitter space. Thus, $m(x)$, and hence $\rho_1(x)$ are in fact Kaluza–Klein massive modes, and become ''frozen out'' at energies lower than the AdS scale. Similar considerations apply to the nonzero mode R_5, which is the Ricci scalar of the internal S^5 sphere, upon use of the gravitational curvature Bianchi identity. Specifically, in the simple case with Kaluza–Klein massive modes set to zero, if one sets to zero the $D=5$ Bianchi identity $\nabla^M(R_{MN} - 1/2\, g_{MN}R) = 0$ and uses the dimensionally reduced field equations, one finds, for $R_5 \to R_5(x^\mu)$, the constraint $\partial_\nu R_5 \exp(1/2\sqrt{5/3}\varphi) - m\,\partial_\nu m = 0$, thus locking out the low energy $R_5(x^\mu)$ fluctuations as well.

Given that the Z_2 odd modes are linked *via* Bianchi identities to massive Kaluza–Klein modes, one expects the theory to settle down into a low energy effective theory that is Z_2 symmetric. Strictly speaking, all that has been demonstrated above so far is that the $D=4$ derivatives $\partial_\mu m$, $\partial_\mu R_5$ are locked out at low energies. In order to show that the theory settles down into a Z_2 symmetric lowest energy configuration, one would need either to analyze in detail the energy functional for the compactified theory, or to study in more detail the equations of motion of the massive modes. It is likely that the analysis of Z_2 odd modes can only be done fully consistently if one keeps the entire Kaluza–Klein towers of massive states.

However, one can get an idea of the situation that is obtained with non-Z_2-symmetric configurations if one considers in a little more detail the question of supersymmetry preservation in a patched background with the matching conditions (5.1), (5.2). Locally, in a patch, there is no difficulty in finding a Killing spinor. However, once one declares that the overall compact part of the spacetime is $S^5 \times S^1$, one is required to impose continuity and periodicity conditions both for bosons and for fermions.

In the Z_2 symmetric configuration of the two 3-branes, we have already demonstrated while discussing the unbroken supersymmetry transformation of Sec. III,

$$\delta\lambda = \tfrac{1}{2}e^{-B}(\gamma^{\bar{y}}\varphi' - \varphi')\epsilon, \tag{5.5}$$

that there is a consistently defined and continuous unbroken supersymmetry transformation with a Z_2 even global Killing spinor $\epsilon = e^{A/2}(1+\gamma^{\bar{y}})\epsilon_0$. Now consider the form of the *broken* supersymmetry transformations in the double 3-brane background. As one can see from the supersymmetry algebra the anticommutator $\{Q_{\text{broken}}, Q_{\text{preserved}}\}$ involves a translation in the fifth coordinate y, which is clearly Z_2 odd. Indeed, the broken supersymmetry parameters will have Z_2 odd projection conditions. This Z_2 odd character is canceled, however, in expressions for Goldstone spinor zero modes like (5.5), by the Z_2 odd character of φ'. Combining the Goldstino expression for

$y>0$ with the Z_2 map for $y<0$ amounts to inserting an absolute value sign around φ' in (5.5), taking a broken supersymmetry parameter for ϵ. Thus, overall, the Goldstino zero mode is Z_2 even, as it must be in a consistent truncation. Note that the ''kink'' in the Goldstino expression resulting from (5.5) with the replacement $\varphi' \to |\varphi'|$ corresponds to the sign flip of the superpotential W. That W flips without necessarily passing through zero is what allows the Goldstino mode to be normalizable in the present case, thus circumventing the normalizability problems for Goldstinos described in Ref. 54. Overall, the zero modes of the double 3-brane geometry form a single $D=4$, $N=4$ super Maxwell multiplet.

Now consider what happens if one tries to expand around a non-Z_2-symmetric configuration of 3-branes. For the Killing spinor itself, one may observe that $\epsilon = e^{A/2}(1+\gamma^{\bar{y}})\epsilon_0$ is in fact still continuous and well-behaved in the nonsymmetric case, since the metric function e^{2A} is by construction matched at the branes. However the situation is different for the candidate Goldstinos. For a non-Z_2-symmetric configuration the derivative φ' differs by more than a sign as one crosses a 3-brane: in this case one has $|k_2| \neq |k_1|$, so there is a nonunimodular factor present as well. This prevents one from having continuity both of the unbroken supersymmetry parameter and of the Goldstinos. Thus, although things look locally like one has a BPS configuration with unbroken supersymmetry for a non-Z_2-symmetric configuration, analysis of the putative zero-mode supermultiplets finds them to be inconsistent with the available matching conditions. So, one is led to conclude that only the Z_2 symmetric configuration has a proper unbroken supersymmetry and zero-mode multiplets transforming correctly with respect to it.

The configuration with globally unbroken supersymmetry should be the proper ''vacuum'' in this double 3-brane sector of type IIB theory compactified on S^5. A fuller analysis of this spontaneous reduction to a Z_2 invariant effective theory on the basis of energy functionals and the equations of motion for the Kaluza–Klein massive modes would be desirable. But it is already clear that this double 3-brane model displays a remarkable spontaneous appearance of an orbifold structure. This happens not by insistent projection into a Z_2 invariant sector of the theory, but naturally by virtue of the Kaluza–Klein dynamics of the theory.

Our discussion has indicated that the original Randall–Sundrum model[2] arises naturally when the fifth dimension y direction is taken to be compact, and one may view the model as a system of two D3-branes transverse to the internal $S_1 \times S^5$. From the $D=5$ point of view, there are two branes: one with positive and one with negative tension, constrained by Kaluza–Klein dynamics to live at diametrically opposed points on the circle. While the presence of a negative tension brane might appear troublesome, we have shown that it does not contribute to the naïvely anticipated negative energy modes; these are nonzero modes and mix with higher Kaluza–Klein massive modes. The negative tension 3-brane has the effect of protecting the spacetime from curvature singularities in the geometry that might reside behind the Cauchy horizon. Of the *a priori* two independent types of motion of the 3-branes along the S^1 direction, only the Z_2 even modes, corresponding to an overall ''rotation'' of both branes along the circle, localized in the $D=4$ coordinates x^μ, correspond to genuine zero modes.

VI. CONCLUSIONS

We have found that an appropriately constructed D3-brane configuration provides a supersymmetric and dynamically stable Randall–Sundrum scenario. This is achieved in a solution to the $D=10$ type IIB supergravity equations which can be given a $D=5$ interpretation, but is not fully a $D=5$ solution, for it employs an intrinsically massive Kaluza–Klein mode, the S^5 breathing mode. This mode has AdS energy $E_0=8$, satisfying the bound $E_0>4$ that is required for an asymptotic approach to AdS space from a downwards-facing warp-factor kink in a Randall–Sundrum scenario. There is also a Z_2 flip in the sign of the Freund–Rubin parameter m. This is natural enough in a $D=10$ context where m is a field-strength value, but it is less natural from a $D=5$ viewpoint, where m normally would appear as a parameter. We have found, moreover, that although one can decide to exclude the Z_2 odd modes when expanding the theory around the presented Z_2 invariant background, and thus reproduce an S^1/Z_2 orbifold reduction, it is not

actually necessary to make this projection by hand. Bianchi identities for the curvature values entering in the solution relate the Z_2 odd modes to Kaluza–Klein massive states of the theory, and so they decouple naturally at low energy. Although charge conservation on the circle requires branes to come in oppositely charged pairs, we have seen that one can recover a single brane Randall–Sundrum model by pushing the second brane off to the Cauchy horizon (i.e., by taking $\varphi_1=\varphi_*$ for the second brane). From the $D=10$ point of view, however, this corresponds to shrinking an outer RS shell of D3 brane tightly around an inner ''horizon'' D3 brane of opposite charge and tension. Clearly, an important problem is whether this geometry can be realized in a string theory context.

Note added in proof. As this paper was in the final stages of preparation, a very interesting paper appeared[55] that sheds light on the relationship between constructions such as those of Refs. 12, 13 or the present paper and the supersymmetry scheme of Ref. 56, which was otherwise puzzling. In Ref. 55 supersymmetry in orbifolds, and in particular the $D=5$ case of interest here is discussed. In order to obtain a continuous Killing spinor at orbifold singularities (necessary for the Killing equation to be realized everywhere, including at the singular points), Ref. 55 introduces a 5-form ''theory of nothing'' field strength, which has just a constant as a solution, but allows for this variable to be only piecewise constant. This allows for a Z_2 sign flip in the prepotential that is critical for having a preserved supersymmetry allowing coupling to supermatter. This sign flip was not made in the discussion of Ref. 56, leading to problems with matter coupling. This difficulty of Ref. 56, and the resolution of Ref. 55 was also investigated in Refs. 57, 58 and independently worked out by Ref. 59. We anticipate that a fuller Kaluza–Klein treatment of the type IIB theory, including all fermions and making a careful reduction of the type IIB supersymmetry transformations, will show that the $D=5$ supersymmetry realization adopted in Ref. 55 can also be viewed as the natural dimensional reduction of the type IIB theory using a Z_2 symmetrized ansatz of the type employed in Refs. 12, 13 and the present paper. In particular, we expect that the 5-form ''theory of nothing'' field introduced in Refs. 58, 55 can be identified with the $D=5$ residue of the type IIB self-dual 5-form field strength.

(Received 2 January 2001; accepted for publication 13 February 2001)

We present a systematic study of a new type of consistent ''brane-world Kaluza–Klein reduction,'' which describes fully nonlinear deformations of codimension one objects that arise as solutions of a large class of gauged supergravity theories in diverse dimensions, and whose world-volume theories are described by ungauged supergravities with-one half of the original supersymmetry. In addition, we provide oxidations of these ansätz which are in general related to sphere compactified higher dimensional string theory or M-theory. Within each class we also provide explicit solutions of brane configurations localized on the world-brane. We show that at the Cauchy horizon (in the transverse dimension of the consistently Kaluza–Klein reduced world-brane) there is a curvature singularity for any configuration with a non-null Riemann curvature or a nonvanishing Ricci scalar that lives in the world-brane. Since the massive Kaluza–Klein modes can be consistently decoupled, they cannot participate in regulating these singularities. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377272]

I. INTRODUCTION

The conventional way of extracting an effective lower-dimensional theory from a higher-dimensional one is by performing a Kaluza–Klein reduction in which the extra dimensions are wrapped up into a compact space such as a torus or a sphere. Provided that the scale size of these internal dimensions is sufficiently small in relation to the energy scale of excitations in the lower dimension, then the mass gap separating the massless modes from the massive ones will be sufficient to ensure that the internal dimensions are essentially unobservable, and the world will appear to be effectively lower dimensional.

If an extra dimension were noncompact then seen from the lower-dimensional viewpoint there would usually be a continuum of modes, with masses extending down to zero. One would normally expect that this would mean that the observable world would be the higher-dimensional one, and that one could not usefully describe it in terms of a lower-dimensional viewpoint. (We cannot usefully view our four-dimensional space–time as being effectively three-dimensional simply by shutting our eyes to the existence of the z axis!) However, it has been shown that under suitable circumstances it may be that the continuous mass eigenvalues for the massive lower-dimensional metric perturbations are distributed in such a way that the effects of the nearly-massless modes is suppressed, implying that the world does in fact appear to be lower-dimensional, with only small modifications to the gravitational forced law appropriate to the lower dimension.[1] In its original form this Randall–Sundrum II scenario is realised by starting from pure gravity with a negative

cosmological constant in five dimensions, and patching together two segments of AdS_5. In horospherical coordinates one has

$$d\hat{s}_5^2 = e^{-2k|z|}\,\eta_{\mu\nu}\,dx^\mu\,dx^\nu + dz^2, \tag{1}$$

where the 3-brane is located at $z=0$. (For a review on the global and local space–time structure of the codimension one objects, see Ref. 2.) It was found that gravity is effectively localized on the 3-brane corresponding to the join between the two segments of AdS_5.[1] Specifically, it was shown that the metric fluctuations around the flat Minkowski space–time of the 3-brane are localized near the brane.

More generally, if the flat Minkowski metric on the 3-brane is replaced by any Ricci-flat 4-metric the five-dimensional metric will still, in the bulk, satisfy the Einstein equations with a negative cosmological constant. In other words, one can view

$$d\hat{s}_5^2 = e^{-2k|z|}\,ds_4^2 + dz^2 \tag{2}$$

as a Kaluza–Klein reduction ansatz that gives a consistent embedding of four-dimensional pure Einstein gravity in five-dimensional Einstein gravity with a negative cosmological constant. In fact the construction could be extended to give an embedding of four-dimensional $N=1$ ungauged supergravity in five dimensions, by starting from $N=2$ (i.e., minimal) gauged supergravity in $D=5$. Note, however, that the bosonic sector in $D=4$ would still only comprise the metric, and there would be no Maxwell field that could support charged Reissner–Nordström black holes. In particular, it should be noted that one cannot get a Maxwell field as a standard type of Kaluza–Klein vector by writing $d\hat{s}_5^2 = e^{-2k|z|}\,ds_4^2 + (dz + \mathcal{A}_{(1)})^2$, since $\partial/\partial z$ is not a Killing vector.

In a recent paper, it was shown that if one instead starts with $N=4$ gauged supergravity in five dimensions, then it is possible to construct a consistent Kaluza–Klein reduction ansatz that gives an embedding of four-dimensional ungauged $N=2$ supergravity on the 3-brane.[3] This is a new kind of dimensional reduction, which we shall refer to as ''brane-world Kaluza–Klein reduction.'' It should be emphasized that it is nontrivial that a *consistent* Kaluza–Klein reduction of this sort is possible, (A consistent reduction is one where all the higher-dimensional equations of motion are satisfied provided that the lower-dimensional fields satisfy their equations of motion.) and there is no obvious group-theoretic explanation for why it should work. Two further examples of consistent brane-world Kaluza–Klein reductions were obtained in Ref. 3, describing the embedding of six-dimensional ungauged chiral $N=(1,0)$ supergravity in seven-dimensional SU(2)-gauged $N=2$ supergravity, and the other describing the embedding of five-dimensional ungauged $N=2$ supergravity in six-dimensional SU(2)-gauged $N=2$ supergravity. More generally, it was conjectured that it should be possible to find a consistent brane-world Kaluza–Klein reduction from any gauged supergravity in D dimensions to an ungauged supergravity with half the supersymmetry in $(D-1)$ dimensions.[3]

The purpose of this paper is to provide a systematic construction of consistent brane-world Kaluza–Klein reductions for gauged supergravity theories (with maximal supersymmetry) in diverse dimensions, thus in general leading to the ungauged supergravities with one-half of the original (maximal) gauged supersymmetry. In addition, the studied examples provide compactifications on both AdS and dilatonic codimension one objects. In the first of these examples, in Sec. II, we show that five-dimensional maximal $(N=8)$ SO(6)-gauged supergravity admits a consistent brane-world reduction to four-dimensional ungauged $N=4$ supergravity. Next, in Sec. III, we show that massive type IIA supergravity admits a consistent brane-world reduction to nine-dimensional ungauged $N=1$ supergravity. Next, in Sec. IV we show that eight-dimensional maximal SU(2)-gauged supergravity admits a consistent brane-world reduction to seven-dimensional ungauged $N=2$ supergravity. Then, in Sec. V, we show that seven-dimensional maximal SO(5)-gauged supergravity admits a consistent brane-world reduction to seven-dimensional ungauged $N=(2,0)$ chiral supergravity.

All the brane-world reductions that were constructed in Ref. 3, and the brane-world reductions of five-dimensional maximal SO(6)-gauged supergravity and seven-dimensional maximal SO(5)-

TABLE I. The ungauged supergravities in $(D-1)$ dimensions obtained by brane-world Kaluza–Klein reductions.

D	D-dimensional theory	$(D-1)$-dimensional theory from brane-world reduction
10	Massive IIA	$D=9,\ N=1$
8	SU(2)-gauged $N=2$	$D=7,\ N=2$
7	SO(5)-gauged $N=4$	$D=6,\ N=(2,0)$
6	SU(2)-gauged $N=2$	$D=5,\ N=2$
5	SO(6) gauged $N=8$	$D=4,\ N=4$

gauged supergravity in this paper, are examples where the higher-dimensional theory admits an anti-de Sitter vacuum solution. By contrast, massive type IIA supergravity and the eight-dimensional SU(2)-gauged supergravity that we also consider in this paper do not admit anti-de Sitter solutions, but instead they have dilatonic domain walls as their most symmetric ''vacuum'' solutions. In all the cases, the brane-world Kaluza–Klein reductions can be thought of as fully nonlinear descriptions of deformations around the anti-de Sitter or domain-wall background, in which the $(D-1)$-dimensional Minkowski metric on the $(D-2)$-brane in the D-dimensional AdS or domain-wall vacuum is allowed to become arbitrary, along with the other necessary fields that complete the $(D-1)$-dimensional ungauged supergravity multiplet. (We should emphasize that as with any fully nonlinear Kaluza–Klein ansatz, the reduction is not pinned to any specific solution. Although it may sometimes be convenient to think of the AdS or domain-wall solution as playing a preferred role, it is really just one out of an infinity of solutions of the reduced theory.)

A brane-world type of Kaluza–Klein reduction can also be performed in those cases where the p-brane cannot trap gravity. A classification of domain walls that can and cannot trap gravity was given in Refs. 4 and 5. In these cases, gravity can arise by placing the p-brane on orbifold points[6] à la Hořava–Witten.[7]

At the level of the supergravity theory, the requirement of the consistency of the brane-world Kaluza–Klein reduction does not discriminate between whether or not the brane is capable of trapping gravity. This is analogous to the situation for a standard Kaluza–Klein reduction on S^1; at the level of the massless modes, which are the only ones retained in the consistent truncation, one cannot distinguish between an extra dimension that is a circle or an infinite real line. In particular, we shall usually write the brane-world reduction ansatz, as in (2), with an absolute-value sign for the coordinate z, i.e., insisting on a Z_2 symmetric codimension one ansatz for the transverse dimension. Thus, there is an actual delta function source needed at $z=0$, whose origin lies outside the supergravity Lagrangian description. However, from the mathematical point of view we could perfectly well write the ansatz without the absolute-value sign, thus describing the bulk solution only, which would still correspond to a consistent reduction. In fact now the ansatz will satisfy the equations everywhere, without the need for any external delta-function sources. [However, one would now lose the brane-world interpretation (at $z=0$) of the reduced theory.]

We conclude this Introduction with Table I that summarizes the principal results that we obtain in this paper, and those of Ref. 3.

In addition, we shall consider S^1 reductions of the $D=8$ and $D=7$ gauged supergravities. The former provides a brane-world reduction from $D=7$ that gives the nonchiral $N=(1,1)$ ungauged supergravity in $D=6$, while the latter provides a brane-world reduction from $D=6$ that gives the $N=4$ ungauged theory in $D=5$. The brane-world reduction of the $D=6$ SU(2)-gauged supergravity was obtained in Ref. 3, as were the brane-world reductions of the SU(2)-gauged $N=2$ seven-dimensional supergravity, and the $\mathrm{SU}(2)\times\mathrm{U}(1)$ gauged $N=4$ five-dimensional supergravity. These two cases are contained within reductions with larger supersymmetries that we consider here. It should be noted that an intrinsic feature of brane-world Kaluza–Klein reductions is that the reduced theory never has more than half the maximal supersymmetry that is allowed in that dimension. This is associated with the fact that there is always a halving of supersymmetry on the brane solution of the higher-dimensional gauged or massive supergravity.

II. FOUR-DIMENSIONAL $N=4$ SUPERGRAVITY FROM MAXIMAL FIVE-DIMENSIONAL GAUGED SUPERGRAVITY

A. Direct reduction from type IIB supergravity

In Sec. II B, we shall obtain the brane-world embedding of four-dimensional ungauged $N=4$ supergravity in five-dimensional maximal gauged supergravity, thus providing the brane-world Kaluza–Klein compactification in $D=4$ with the maximal allowed ungauged supersymmetry. However, since this five-dimensional theory is rather complicated, we shall begin in the current section by constructing the brane-world embedding of the four-dimensional $N=4$ theory directly in ten-dimensional type IIB supergravity. This exploits the fact that the five-dimensional gauged theory can itself be obtained via an S^5 reduction from $D=10$. Having done this, we shall then be in a position to re-express our results in terms of a brane-world reduction from $D=5$ to $D=4$. From the five-dimensional viewpoint the fields that we use are the metric, the dilaton and axion [which are singlets under the SO(6) gauge group], and the two sets of six 2-form potentials. Thus in $D=5$ the 15 Yang–Mills gauge fields and the $10+\overline{10}+20'$ of scalars are set to zero.

The bosonic equations of motion of type IIB supergravity can be derived from the Lagrangian,

$$\mathcal{L}_{10}^{\mathrm{IIB}}=\hat{R}\hat{*}\mathbb{1}-\tfrac{1}{2}\hat{*}d\hat{\phi}\wedge d\hat{\phi}-\tfrac{1}{2}e^{2\hat{\phi}}\hat{*}d\hat{\chi}\wedge d\hat{\chi}-\tfrac{1}{4}\hat{*}\hat{F}_{(5)}\wedge\hat{F}_{(5)}-\tfrac{1}{2}e^{-\hat{\phi}}\hat{*}\hat{F}^2_{(3)}\wedge\hat{F}^2_{(3)}-\tfrac{1}{2}e^{\hat{\phi}}\hat{*}\hat{F}^1_{(3)}\wedge\hat{F}^1_{(3)}$$
$$-\tfrac{1}{2}\hat{A}_{(4)}\wedge d\hat{A}^1_{(2)}\wedge d\hat{A}^2_{(2)}, \tag{3}$$

where $\hat{F}^2_{(3)}=d\hat{A}^2_{(2)}$, $\hat{F}^1_{(3)}=d\hat{A}^1_{(2)}-\hat{\chi}\,d\hat{A}^2_{(2)}$, $\hat{F}_{(5)}=d\hat{A}_{(4)}-\frac{1}{2}\hat{A}^1_{(2)}\wedge d\hat{A}^2_{(2)}+\frac{1}{2}\hat{A}^2_{(2)}\wedge d\hat{A}^1_{(2)}$, and we use carets to denote ten-dimensional fields and the ten-dimensional Hodge dual $\hat{*}$. The equations of motion following from the Lagrangian, together with the self-duality condition, are

$$\hat{R}_{MN}=\tfrac{1}{2}\partial_M\hat{\phi}\,\partial_N\hat{\phi}+\tfrac{1}{2}e^{2\hat{\phi}}\partial_M\hat{\chi}\,\partial_N\hat{\chi}+\tfrac{1}{96}\hat{F}^2_{MN}+\tfrac{1}{4}e^{\hat{\phi}}((\hat{F}^1_{(3)})^2_{MN}$$
$$-\tfrac{1}{12}(\hat{F}^1_{(3)})^2\hat{g}_{MN})+\tfrac{1}{4}e^{-\hat{\phi}}((\hat{F}^2_{(3)})^2_{MN}-\tfrac{1}{12}(\hat{F}^2_{(3)})^2\hat{g}_{MN}),$$

$$d\hat{*}d\hat{\phi}=-e^{2\hat{\phi}}\hat{*}d\hat{\chi}\wedge d\hat{\chi}-\tfrac{1}{2}e^{\hat{\phi}}\hat{*}\hat{F}^1_{(3)}\wedge\hat{F}^1_{(3)}+\tfrac{1}{2}e^{-\hat{\phi}}\hat{*}\hat{F}^2_{(3)}\wedge\hat{F}^2_{(3)},$$

$$d(e^{2\hat{\phi}}\hat{*}d\hat{\chi})=e^{\hat{\phi}}\hat{*}\hat{F}^1_{(3)}\wedge\hat{F}^2_{(3)},$$

$$d(e^{\hat{\phi}}\hat{*}\hat{F}^1_{(3)})=\hat{F}_{(5)}\wedge\hat{F}^2_{(3)},\quad d(e^{-\hat{\phi}}\hat{*}\hat{F}^2_{(3)}-\hat{\chi}\,e^{\hat{\phi}}\hat{*}\hat{F}^1_{(3)})=-\hat{F}_{(5)}\wedge(\hat{F}^1_{(3)}+\hat{\chi}\,\hat{F}^2_{(3)}),$$

$$d(\hat{*}\hat{F}_{(5)})=-\hat{F}^1_{(3)}\wedge\hat{F}^2_{(3)},\quad \hat{F}_{(5)}=\hat{*}\hat{F}_{(5)}. \tag{4}$$

The ungauged four-dimensional $N=4$ supergravity that we are seeking to embed in type IIB supergravity is described by the following Lagrangian (Actually this Lagrangian corresponds to a special truncation of toroidally compactified heterotic string theory where the gauge fields of the original heterotic string are turned off and the momentum and winding modes of the NS–NS sector are identified, thus freezing the internal metric and antisymmetric two-form fields of the six-torus):

$$\mathcal{L}_4=R*\mathbb{1}-\tfrac{1}{2}*d\phi\wedge d\phi-\tfrac{1}{2}e^{2\phi}*d\chi\wedge d\chi-\tfrac{1}{2}e^{-\phi}*F^i_{(2)}\wedge F^i_{(2)}-\tfrac{1}{2}\chi\,F^i_{(2)}\wedge F^i_{(2)}, \tag{5}$$

where $1\leqslant i\leqslant 6$, and $F^i_{(2)}=dA^i_{(1)}$.

We find that the following is a consistent reduction ansatz that gives the embedding of the four-dimensional $N=4$ theory in type IIB supergravity,

$$d\hat{s}^2_{10} = e^{-2k|z|}\, ds^2_4 + dz^2 + g^{-2}\, d\Omega^2_5,$$

$$\hat{F}_{(5)} = 4g^{-4}\,\Omega_{(5)} + 4g\, e^{-4k|z|}\,\epsilon_{(4)} \wedge dz,$$

$$\hat{A}^1_{(2)} = \frac{1}{\sqrt{2}} g^{-1}\, e^{-k|z|}\,\mu_i\,(e^{-\phi} * F^i_{(2)} + \chi\, F^i_{(2)}), \tag{6}$$

$$\hat{A}^2_{(2)} = \frac{1}{\sqrt{2}} g^{-1}\, e^{-k|z|}\,\mu_i\, F^i_{(2)},$$

$$\hat{\phi} = \phi, \quad \hat{\chi} = \chi,$$

where $d\Omega^2_5$ is the metric on the unit 5-sphere, which we can write in terms of six coordinates μ_i that are subject to the constraint $\mu_i\,\mu_i = 1$, as $d\Omega^2_5 = d\mu_i\, d\mu_i$. The 5-form $\Omega_{(5)}$ is the volume form of the metric $d\Omega^2_5$, and $\epsilon_{(4)}$ is the volume form of the metric ds^2_4. Note that $\Omega_{(5)}$ can be written as

$$\Omega_{(5)} = \frac{1}{5!}\,\epsilon_{ij_1\cdots j_5}\,\mu_i\, d\mu_{j_1} \wedge \cdots \wedge d\mu_{j_5}. \tag{7}$$

The constant k (which we take to be positive) is related to the gauge-coupling constant g of the five-dimensional theory by $k^2 = g^2$. In fact, to be precise, we must have

$$g = \begin{cases} k, & z > 0, \\ -k, & z < 0. \end{cases} \tag{8}$$

Substituting the ansatz (6) into the equations of motion of type IIB supergravity (4), we find that they are all exactly satisfied if and only if the four-dimensional fields ds^2_4, ϕ, χ, and $F^i_{(2)}$ satisfy the equations of motion of ungauged $N=4$ supergravity, which can be derived from (5). Note in particular that the six abelian gauge fields $F^i_{(2)}$ satisfy the equations of motion,

$$d(e^{-\phi} * F^i_{(2)} + \chi\, F^i_{(2)}) = 0. \tag{9}$$

The following results are useful for verifying the consistency of the reduction ansatz. First, we have from (6) that

$$\hat{F}^1_{(3)} = \frac{1}{\sqrt{2}} g^{-1}\, e^{-k|z|}\, e^{-\phi} * F^i_{(2)} \wedge (d\mu_i - g\,\mu_i\, dz),$$

$$\hat{F}^2_{(3)} = \frac{1}{\sqrt{2}} g^{-1}\, e^{-k|z|}\, F^i_{(2)} \wedge (d\mu_i - g\,\mu_i\, dz). \tag{10}$$

[Here, we have for convenience of presentation already made use of the fact that the $F^i_{(2)}$ satisfy the Bianchi identities $dF^i_{(2)} = 0$ and the field equations (9); they can, of course, be *derived* by substituting the ansatz into the ten-dimensional equations of motion.] Next, we can write the ten-dimensional Hodge duals of these field strengths as follows:

$$
\begin{aligned}
*\hat{F}^1_{(3)} &= \frac{1}{\sqrt{2}} g^{-5} e^{-k|z|} e^{-\phi} F^i_{(2)} \wedge (\mu_i \Omega_{(5)} - g Z_i \wedge dz), \\
*\hat{F}^2_{(3)} &= -\frac{1}{\sqrt{2}} g^{-5} e^{-k|z|} *F^i_{(2)} \wedge (\mu_i \Omega_{(5)} - g Z_i \wedge dz),
\end{aligned}
\tag{11}
$$

where the 4-form Z_i is defined by

$$
Z_i \equiv \frac{1}{4!} \epsilon_{ijk_1\cdots k4} \mu_j d\mu_{k_1} \wedge \cdots \wedge d\mu_{k_4}. \tag{12}
$$

This 4-form is the Hodge dual of $d\mu_i$ in the unit 5-sphere metric, $*_5 d\mu_i = -Z_i$. Note that Z_i has the following properties:

$$
d\mu_i \wedge Z_j = -(\delta_{ij} - \mu_i \mu_j) \Omega_{(5)}, \quad dZ_i = 5 \mu_i \Omega_{(5)}. \tag{13}
$$

It is now straightforward to verify that all the type IIB ten-dimensional equations of motion consistently yield the equations of motion of four-dimensional ungauged $N=4$ supergravity; in particular, all the dependence on the coordinates z and μ_i consistently matches in all the equations.

It is worth noting that the $N=4$ gauged supergravity in the four-dimensional world-volume of the D3-brane has an SL(2,$\mathbb{Z}$) electric/magnetic S-duality, with the two scalars (ϕ,χ) parameterizing the SL(2,$\mathbb{R}$)/O(2) coset. It is easy to see from the reduction ansatz (6) that this SL(2,$\mathbb{Z}$) symmetry of the theory in the world-volume of the D3-brane originates from the SL(2,$\mathbb{Z}$) of the original type IIB theory in $D=10$, which is not an electric/magnetic duality.

It is of interest to see how the brane-world embedding of the four-dimensional $N=4$ supergravity that we have derived here reduces to the $N=2$ supergravity embedding that was constructed in Ref. 3. In the $N=2$ theory there is just one 2-form field strength $F_{(2)}$, and the dilaton ϕ and axion χ are absent. It is easy to see that the equations of motion for ϕ and χ in (5) imply that in order to set $\phi=\chi=0$, we must have

$$
*F^i_{(2)} \wedge F^i_{(2)} = 0, \quad F^i_{(2)} \wedge F^i_{(2)} = 0. \tag{14}
$$

The minimal nontrivial way to satisfy these conditions is by taking all but two of the six field strengths to vanish, and for the remaining ones, say $F^1_{(2)}$ and $F^2_{(2)}$, to be related by $F^2_{(2)} = *F^1_{(2)}$. If we define $F^2_{(2)} = *F^1_{(2)} = -F_{(2)}/\sqrt{2}$, and at the same time we parameterize the six coordinates μ_i that define the 5-sphere as

$$
\mu_1 = \sin\xi \cos\tau, \quad \mu_2 = -\sin\xi \sin\tau, \quad \mu_\alpha = \nu_\alpha \cos\xi, \quad (\alpha = 3,4,5,6), \tag{15}
$$

where $\nu_\alpha \nu_\alpha = 1$, defining a unit 3-sphere, the ansatz for $d\hat{s}^2_{10}$, $\hat{A}^1_{(2)}$, and $\hat{A}^2_{(2)}$ in (6) become

$$
\begin{aligned}
d\hat{s}^2_{10} &= e^{-2k|z|} ds^2_4 + dz^2 + d\xi^2 + \sin^2\xi \, d\tau^2 + \cos^2\xi \, d\Omega^2_3, \\
\hat{A}^1_{(2)} + i\hat{A}^2_{(2)} &= -\tfrac{1}{2} g^{-1} e^{-k|z|} \sin\xi \, e^{-i\tau} (F_{(2)} - i *F_{(2)}).
\end{aligned}
\tag{16}
$$

This is precisely the form of the ansatz found in Ref. 3 for the consistent brane-world embedding of four-dimensional $N=2$ supergravity.

B. Ungauged $D=4$, $N=4$ from gauged $D=5$, $N=8$

In the previous subsection, we considered the reduction from type IIB to the ungauged $N=4$ theory in $D=4$ directly, omitting the intermediate description as a brane-world KK reduction of five-dimensional $N=8$ gauged supergravity on account of the complexity of the five-

dimensional theory. We can now in fact reinterpret our results as a reduction of the maximal five-dimensional gauged theory. However, in order to avoid the full complexity of this theory, we shall work with a truncation of the full set of five-dimensional fields in which just the metric, the dilaton ϕ and axion χ, and the $6+6$ of 2-form potentials are retained. In other words, we set the 15 Yang–Mills SO(6) gauge fields and the $10+\overline{10}+20'$ of scalars to zero. It should be emphasized that this is in general an *inconsistent* truncation of the five-dimensional theory. However, we can still work with it provided that we impose the necessary algebraic constraints on the $6+6$ of 2-form potentials. Of course these constraints are precisely the ones that *are* satisfied by the brane-world KK reduction ansatz, now expressed simply as a reduction from $D=5$ to $D=4$.

We find that the above truncated five-dimensional theory is obtained from $D=10$ by making the following ansatz for the type IIB fields:

$$d\hat{s}^2_{10}=ds^2_5+g^{-2}\,d\Omega^2_5,$$

$$\hat{F}_{(5)}=4g^{-4}\,\Omega_{(5)}+4g\,\epsilon_{(5)},$$

$$\hat{A}^{\alpha}_{(2)}=\mu_i\,A^{i\alpha}_2,$$

$$\hat{\phi}=\phi,\quad \hat{\chi}=\chi, \tag{17}$$

where $\alpha=1,2$. We immediately find from the Bianchi identity for $\hat{F}_{(5)}$ that the following equations must be satisfied:

$$A^{i\alpha}_{(2)}\wedge A^{j\beta}_{(2)}\,\epsilon_{\alpha\beta}=0,\quad dA^{i\alpha}_{(2)}\wedge A^{j\beta}_{(2)}\,\epsilon_{\alpha\beta}=0. \tag{18}$$

These are the algebraic constraints alluded to above. We must impose them because we have set other fields of the maximal five-dimensional theory to zero, which is in general in conflict with the equations of motion of those fields.

Substituting the ansatz (17) into the remaining equations of motion of type IIB supergravity, and making use of the constraints (18), we find that they consistently imply the following five-dimensional equations:

$$dA^{i1}_{(2)}-\chi\,dA^{i2}_{(2)}=-g\,e^{-\phi}*A^{i2}_{(2)},$$

$$dA^{i2}_{(2)}=g\,e^{\phi}*(A^{i1}_{(2)}-\chi\,A^{i2}_{(2)}),$$

$$d(e^{2\phi}*d\chi)=-g^2\,e^{\phi}*(A^{i1}_{(2)}-\chi\,A^{i2}_{(2)})\wedge A^{i2}_{(2)},$$

$$d*d\phi=e^{2\phi}*d\chi\wedge d\chi+\tfrac{1}{2}g^2\,e^{\phi}*(A^{i1}_{(2)}-\chi\,A^{i2}_{(2)})\wedge(A^{i1}_{(2)}-\chi\,A^{i2}_{(2)})-\tfrac{1}{2}g^2\,e^{-\phi}*A^{i2}_{(2)}\wedge A^{i2}_{(2)},$$

$$R_{\mu\nu}=\tfrac{1}{2}\partial_\mu\phi\,\partial_\nu\phi+\tfrac{1}{2}e^{2\phi}\,\partial_\mu\chi\,\partial_\nu\chi+\tfrac{1}{2}g^2\,[e^{\phi}\,(A^{i1}_{\mu\rho}-\chi\,A^{i2}_{\mu\rho})\,(A^{i1\,\rho}_{\nu}-\chi\,A^{i2\,\rho}_{\nu})+e^{-\phi}\,A^{i2}_{\mu\rho}A^{i2\,\rho}_{\nu}]. \tag{19}$$

[$A^{i1}_{(2)}$ and $A^{i2}_{(2)}$ denote $A^{i\alpha}_{(2)}$ with $\alpha=1$ and $\alpha=2$, respectively.] These equations, together with the constraints (18), are precisely equivalent to those of maximal five-dimensional gauged supergravity, after setting the Yang–Mills fields and the $10+\overline{10}+20'$ of scalars to zero. The $6+6$ of 2-form fields $A^{i\alpha}_{(2)}$ satisfy first-order equations of motion, known as ''odd-dimensional self-duality equations.'' These, together with the constraint equations (18), imply that the trace of the 2-form contributions in the energy-momentum tensor vanishes; $e^{\phi}(A^{i1}_{\mu\nu}-\chi\,A^{i2}_{\mu\nu})(A^{i1\,\mu\nu}-\chi\,A^{i2\,\mu\nu})+e^{-\phi}A^{i2}_{\mu\nu}A^{i2\,\mu\nu}=0$. Note that the imposition of the constraints (18) is sufficient to ensure that *all* the type IIB equations of motion are consistently satisfied by the ansatz (17), including the internal and mixed components of the Einstein equations.

It is useful to observe that the equations of motion (19) can be derived from the Lagrangian,

$$\mathcal{L}_5 = R*\mathbb{1} - \tfrac{1}{2}*d\phi\wedge d\phi - \tfrac{1}{2}e^{2\phi}*d\chi\wedge d\chi - \tfrac{1}{2}g^2\,e^{\phi}*(A^{i1}_{(2)}-\chi A^{i2}_{(2)})\wedge(A^{i1}_{(2)}-\chi A^{i2}_{(2)})$$
$$-\tfrac{1}{2}g^2\,e^{-\phi}*A^{i2}_{(2)}\wedge A^{i2}_{(2)} - g\,dA^{i1}_{(2)}\wedge A^{i2}_{(2)} + 12g^2*\mathbb{1}. \tag{20}$$

Finally, we note that the brane-world Kaluza–Klein reduction of the previous subsection, now expressed as a reduction from $D=5$ to $D=4$, is given by

$$ds_5^2 = e^{-2k|z|}\,ds_4^2 + dz^2,$$

$$A^{i1}_{(2)} = \frac{1}{\sqrt{2}}g^{-1}\,e^{-k|z|}\,(e^{-\phi}*F^i_{(2)} + \chi F^i_{(2)}), \tag{21}$$

$$A^{i2}_{(2)} = \frac{1}{\sqrt{2}}g^{-1}\,e^{-k|z|}\,F^i_{(2)},$$

with ϕ and χ just reducing directly. One can easily verify that this reduction ansatz is indeed compatible with the constraints (18).

C. Branes on the D3-brane

One can construct electric and magnetic black holes, strings and instantons in $D=4$, $N=4$ supergravity. They become branes on the D3-brane (in the near-horizon region) when they are lifted back to $D=10$. We analyze these solutions in this section.

Case 1: SL(2,$\mathbb{Z}$) *dyonic black holes on the D3-brane:* We can use one of the six 2-form field strengths to construct an electric or magnetic black hole. As a concrete example, let us consider an electric black hole supported by the field strength $F^1_{(2)}$. Once the solution is lifted back to $D=10$, it becomes

$$d\hat{s}_{10}^2 = e^{-2k|z|}[-H^{-1}\,dt^2 + H(dr^2 + r^2 d\Omega_2^2)] + dz^2 + g^{-2}d\Omega_5^2,$$

$$\hat{F}_{(5)} = 4g^{-4}\Omega_5 + 4g\,e^{-4k|z|}\,r^2 H\,dt\wedge dr\wedge\Omega_2,$$

$$\hat{A}^1_{(2)} = \frac{Q}{\sqrt{2}}g^{-1}\,e^{-k|z|}\,\mu_1\,\Omega_2, \tag{22}$$

$$\hat{A}^2_{(2)} = \frac{1}{\sqrt{2}}g^{-1}\,e^{-k|z|}\,\mu_1\,dt\wedge dH^{-1},$$

$$e^{\phi} = H, \quad H = 1 + \frac{Q}{r},$$

where μ_1 is one of the coordinates μ_i for S^5 appearing in the ansatz (17), corresponding to our choice to consider a black hole supported by $F^1_{(2)}$. Starting with the electric black hole, we can then apply the SL(2,$\mathbb{R}$) symmetry to get a multiplet of dyonic black holes, where the electric and magnetic charges are carried by the same 2-form field strength. The metric of this dyonic solution remains unchanged, but the charge configuration alters.

Case 2: Threshold dyonic black holes on the D3-brane: In $D=4$, $N=4$ supergravity, one can also construct a multicharge black hole solution, where the electric charge is carried by one 2-form field strength, say $F^1_{(2)}$, and the magnetic charge is carried by another, say $F^2_{(2)}$.[8] [Note that the generating technique, as employed, for example, for the four-charge solution[9] of toroidally compactified heterotic string, may allow for a construction of more general dyonic black holes with all the U(1) charges turned on.] Lifting this solution back to $D=10$, it becomes

$$d\hat{s}_{10}^2 = e^{-2k|z|}[-(H_1H_2)^{-1}\,dt^2 + H_1H_2\,(dr^2 + r^2 d\Omega_2^2)] + dz^2 + g^{-2}\,d\Omega_5^2,$$

$$\hat{F}_{(5)} = 4g^{-4}\,\Omega_5 + 4g\,e^{-4k|z|}\,r^2(H_1H_2)\,dt\wedge dr\wedge d\Omega_2,$$

$$\hat{A}^1_{(2)} = \frac{1}{\sqrt{2}}\,g^{-1}\,e^{-k|z|}\,(Q_e\,\mu_1\,\Omega_2 + \mu_2\,dt\wedge dH_2^{-1}),$$

$$\hat{A}^2_{(2)} = \frac{1}{\sqrt{2}}\,g^{-1}\,e^{-k|z|}\,(\mu_1\,dt\wedge dH_1^{-1} + \mu_2\,Q_m\,\Omega_2),$$

$$e^{\phi} = \frac{H_1}{H_2}, \quad H_1 = 1 + \frac{Q_e}{r}, \quad H_2 = 1 + \frac{Q_m}{r}. \tag{23}$$

Case 3: String on the D3-brane: A magnetic string (four-dimensional domain wall), supported by the axion, exists in the four-dimensional supergravity theory. Lifting this solution back to $D = 10$, we have a string living on the D3-brane,

$$d\hat{s}_{10}^2 = e^{-2k|z|}[-dt^2 + dx^2 + H(dr^2 + r^2 d\theta^2)] + dz^2 + g^{-2}d\Omega_5^2,$$

$$\hat{F}_{(5)} = 4g^{-4}\,\Omega_{(5)} + 4g\,e^{-4k|z|}\,rH\,dt\wedge dx\wedge dr\wedge d\theta,$$

$$e^{\hat{\phi}} = H^{-1}, \quad \chi = Q\,\theta,$$

$$H = 1 + Q\log r. \tag{24}$$

This solution is a non-standard intersection of a D3-brane and D7-brane, where there is no overall transverse space. It should be distinguished from the solution describing a D3-brane in the D7-brane, which has a two-dimensional overall transverse space.

Case 4: Instanton on the D3-brane: The axion in the $D=4$ theory also supports a BPS instanton solution when the theory is Euclideanized. The axion χ becomes imaginary under this procedure, the metric ds_4^2 becomes purely flat Euclidean space, and $\hat{F}_{(5)}$ becomes complex, since in ten Euclidean dimensions a real 5-form cannot be self-dual.

III. $N=1$ SUPERGRAVITY IN $D=9$ FROM MASSIVE TYPE IIA

A. D8-brane in massive type IIA theory

The highest dimensional D-brane that can be found in any supergravity theory is the D8-brane in massive type IIA supergravity. This theory was constructed in Ref. 10, but in a formulation where there is not a straightforward massless limit to ordinary type IIA supergravity. However, it is simply a matter of performing a field redefinition to resolve this problem.[11] The Lagrangian for the bosonic sector of the massive type IIA supergravity can then be written as the following differential form:[12]

$$\mathcal{L}_{10} = \hat{R}\,\hat{*}\mathbb{1} - \tfrac{1}{2}\hat{*}d\hat{\phi}\wedge d\hat{\phi} - \tfrac{1}{2}e^{3/2\hat{\phi}}\,\hat{*}\hat{F}_{(2)}\wedge\hat{F}_{(2)} - \tfrac{1}{2}e^{-\hat{\phi}}\,\hat{*}\hat{F}_{(3)}\wedge\hat{F}_{(3)} - \tfrac{1}{2}e^{1/2\hat{\phi}}\,\hat{*}\hat{F}_{(4)}\wedge\hat{F}_{(4)}$$
$$- \tfrac{1}{2}d\hat{A}_{(3)}\wedge d\hat{A}_{(3)}\wedge\hat{A}_{(2)} - \tfrac{1}{6}m\,d\hat{A}_{(3)}\wedge(\hat{A}_{(2)})^3 - \tfrac{1}{40}m^2\,(\hat{A}_{(2)})^5 - \tfrac{1}{2}m^2\,e^{5/2\hat{\phi}}\,\hat{*}\mathbb{1}, \tag{25}$$

where the field strengths are given in terms of potentials by

$$\hat{F}_{(2)} = d\hat{A}_{(1)} + m\,\hat{A}_{(2)}, \quad \hat{F}_{(3)} = d\hat{A}_{(2)},$$

$$\hat{F}_{(4)} = d\hat{A}_{(3)} + \hat{A}_{(1)}\wedge d\hat{A}_{(2)} + \tfrac{1}{2}m\,\hat{A}_{(2)}\wedge\hat{A}_{(2)}. \tag{26}$$

The Bianchi identities for the field strengths are therefore

$$d\hat{F}_{(2)}=m\,\hat{F}_{(3)},\quad d\hat{F}_{(3)}=0,\quad d\hat{F}_{(4)}=\hat{F}_{(2)}\wedge\hat{F}_{(3)}, \tag{27}$$

and the field equations are

$$\begin{aligned} d\hat{F}_{(6)}&=-\hat{F}_{(3)}\wedge\hat{F}_{(4)},\quad d\hat{F}_{(8)}=-\hat{F}_{(3)}\wedge\hat{F}_{(6)},\\ d\hat{F}_{(7)}&=-\tfrac{1}{2}\hat{F}_{(4)}\wedge\hat{F}_{(4)}-m\,\hat{F}_{(8)}-\hat{F}_{(2)}\wedge\hat{F}_{(6)},\\ d\hat{*}d\hat{\phi}&=-\tfrac{1}{4}\hat{F}_{(4)}\wedge\hat{F}_{(6)}-\tfrac{3}{4}\hat{F}_{(2)}\wedge\hat{F}_{(8)}-\tfrac{1}{2}\hat{F}_{(3)}\wedge\hat{F}_{(7)}+\tfrac{5}{4}m^2\,e^{5/2\hat{\phi}}\hat{*}1, \end{aligned} \tag{28}$$

where we have defined the dual field strengths

$$\hat{F}_{(6)}\equiv e^{1/2\hat{\phi}}\hat{*}\hat{F}_{(4)},\quad \hat{F}_{(8)}\equiv e^{3/2\hat{\phi}}\hat{*}\hat{F}_{(2)},\quad \hat{F}_{(7)}\equiv e^{-\hat{\phi}}\hat{*}\hat{F}_{(3)}. \tag{29}$$

This massive type IIA theory supports a ''vacuum'' solution, namely, the D8-brane,

$$d\hat{s}_{10}^2=W^{2/25}\,dx^\mu dx_\mu+dz^2,\quad e^{\hat{\phi}}=W^{-(4/5)}, \tag{30}$$

where the one-dimensional harmonic function is given by

$$W=1+k|z|,\quad k^2=\frac{625}{256}m^2. \tag{31}$$

In fact the sign of m must be opposite on opposite sides of the domain wall,

$$g=\begin{cases} \frac{16}{25}k, & z>0,\\ -\frac{16}{25}k, & z<0, \end{cases} \tag{32}$$

where k is assumed to be positive. This means that one cannot strictly speaking view the domain wall as a solution within the massive type IIA theory as formulated in Ref. 10, since there m is a fixed parameter in the Lagrangian. However, the theory can be re-expressed in a formulation where m is replaced by a 10-form field, with the mass parameter now arising as a constant of integration. It now makes sense for the parameter to be only piecewise constant. In what follows, we shall implicitly assume that we are working with this reformulation of the theory, which allows (32) to hold.

Note that the nine-dimensional flat Minkowskian spacetime $dx^\mu dx_\mu$ of the solution (30) can be replaced by any Ricci-flat Minkowski-signatured space–time.[13] On the other hand, it was observed that domain walls associated with Dp-branes with $p\geqslant 6$ cannot trap gravity. Nevertheless, one can still obtain gravity on the world-volume in such a case by locating the branes at orbifold points, so that the space–time is compact.[6] In this case, we would expect that the resulting theory on the world-volume of the D8-brane would be the ungauged $N=1$, $D=9$ supergravity. We shall prove in the next subsection that this can indeed be obtained from the massive type IIA theory via a consistent brane-world Kaluza–Klein reduction.

B. $N=1$ supergravity in $D=9$ from massive type IIA

We find that the following Kaluza–Klein ansatz for the ten-dimensional massive type IIA fields yields a consistent reduction to nine dimensions,

$$d\hat{s}_{10}^2 = e^{-(5/16)\sqrt{(2/7)}\phi} W^{(2/25)} ds_9^2 + e^{(35/16)\sqrt{(2/7)}\phi} dz^2,$$

$$\hat{A}_{(1)} = 0, \quad \hat{A}_{(2)} = \frac{1}{2m} W^{16/25} F_{(2)}, \quad \hat{A}_{(3)} = \frac{1}{4m} W^{32/25} F_{(3)}, \tag{33}$$

$$e^{\hat{\phi}} = W^{-(4/5)} e^{-(7/8)\sqrt{(2/7)}\phi},$$

where W is given by (31) and g is related to k by (32). Substituting this ansatz into the massive type IIA equations of motion, we find that they are all satisfied provided that the nine-dimensional fields ds_9^2, φ, $F_{(2)} = dA_{(1)}$ and $F_{(3)} = dA_{(2)} - \frac{1}{2} A_{(1)} \wedge F_{(2)}$ satisfy the equations of motion of nine-dimensional ungauged simple supergravity. These equations can be derived from the Lagrangian,

$$\mathcal{L}_9 = R * \mathbb{1} - \tfrac{1}{2} * d\phi \wedge d\phi - \tfrac{1}{2} e^{-\sqrt{(8/7)}\phi} * F_{(3)} \wedge F_{(3)} - \tfrac{1}{2} e^{-\sqrt{(2/7)}\phi} * F_{(2)} \wedge F_{(2)}. \tag{34}$$

C. Branes on the D8-brane

Having consistently embedded the ungauged $N=1$, $D=9$ supergravity in massive type IIA supergravity, we can lift all the solutions of this nine-dimensional theory back to $D=10$. The nine-dimensional theory supports BPS p-branes such as the string, 4-brane, black hole and 5-brane. These solutions are straightforward and well known. When they are lifted back to massive type IIA supergravity using the ansatz (33), they can be viewed as branes living on the D8-brane.

Case 1: String on the D8-brane: The solution of the $D=9$ string lifted back to $D=10$ becomes

$$d\hat{s}_{10}^2 = W^{(2/25)}[H^{-(5/8)}(-dt^2 + dx^2) + H^{3/8}(dr^2 + r^2 d\Omega_6^2)] + H^{-(5/8)} dz^2,$$

$$\hat{A}_{(3)} = \frac{1}{4m} W^{32/25}\, dt \wedge dx \wedge dH^{-1}, \tag{35}$$

$$e^{\hat{\phi}} = W^{-(4/5)} H^{1/4}, \quad H = 1 + \frac{Q}{r^5}.$$

This solution can be viewed as a D2-brane ending on the D8-brane, with the end points forming a string. To see this, it is helpful to introduce a new coordinate y in place of z, defined by $dy = \frac{24}{25} W^{-(1/25)} dz$, and hence

$$W = (1 + k\,|y|)^{25/24}. \tag{36}$$

Using this variable, the y-dependence of the metric is extracted as an overall conformal factor, and we have

$$d\hat{s}_{10}^2 = (1 + k|y|)^{1/12}[H^{-(5/8)}(-dt^2 + dx^2 + dy^2) + H^{3/8}(dr^2 + r^2 d\Omega_6^2)]. \tag{37}$$

Case 2: 4-brane on the D8-brane: The $D=9$ 4-brane solution (the magnetic dual of the string solution), lifted back to $D=10$, becomes

$$d\hat{s}_{10}^2 = W^{2/25}[H^{-(3/8)}\, dx^\mu dx_\mu + H^{5/8}(dr^2 + r^2 d\Omega_3^2)] + H^{5/8} dz^2,$$

$$\hat{A}_{(3)} = \frac{Q}{4m} W^{32/25}\, \Omega_3, \tag{38}$$

$$e^{\hat{\phi}} = W^{-(4/5)} H^{-(1/4)}, \quad H = 1 + \frac{Q}{r^2}.$$

Using the same coordinate transformation (36), the metric can be re-expressed as

$$d\hat{s}_{10}^2=(1+k|y|)^{1/12}[H^{-(3/8)}\,dx^\mu dx_\mu+H^{5/8}(dy^2+dr^2+r^2d\Omega_3^2)]. \tag{39}$$

Thus the solution can be viewed as a D4-brane intersecting with a D8-brane, with the D4-brane uniformly delocalized on the one-dimensional transverse space of the D8-brane.

In Case 1 above, the intersection of the D2-brane and the D8-brane is such that the overall world-volume is a string, and the solution describes a D2-brane ending on the D8-brane. In Case 2, the intersection of the D4-brane and D8-brane is such that the overall world-volume is the entire 4-brane, and so the solution describes a D4-brane living in the D8-brane.

Case 3: Black hole on the D8-brane: The black hole solution of the $D=9$ theory can be lifted to $D=10$, where it becomes

$$d\hat{s}_{10}^2=W^{(2/25)}[-H^{-(13/8)}\,dt^2+H^{3/8}(dr^2+r^2d\Omega_7^2)]+H^{-(5/8)}\,dz^2,$$

$$\hat{A}_{(2)}=\frac{1}{2m}W^{(16/25)}\,dt\wedge dH^{-1},$$

$$e^{\hat{\phi}}=W^{-(4/5)}H^{1/4},\quad H=1+\frac{Q}{r^6}. \tag{40}$$

Using (36), the metric can be cast into the form,

$$d\hat{s}_{10}^2=(1+k|y|)^{1/12}[-H^{-(13/8)}\,dt^2+H^{-(5/8)}\,dy^2+H^{3/8}(dr^2+r^2d\Omega_7^2)]. \tag{41}$$

The solution can be viewed as the intersection of an NS–NS string and a D0-brane with the D8-brane. In particular, the string NS–NS string ends on the D8-brane whilst the D0-brane lives in the D8-brane. To see this, we note that a standard solution for the intersection of a string and a D0-brane would be

$$ds_{10}^2=-H_0^{-(7/8)}H_1^{-(3/4)}\,dt^2+H_0^{1/8}H_1^{-(3/4)}\,du^2+H_0^{1/8}H_1^{1/4}\,d\mathbf{y}^2, \tag{42}$$

where H_0 and H_1 are independent harmonic functions on the eight-dimensional common transverse space of the $\mathbf{y}$ coordinates. If these two harmonic functions are set equal, $H_0=H_1=H$, then we obtain the structure found in (41).

Case 4: 5-brane on the D8-brane: The 5-brane solution (the magnetic dual of the black hole) can be lifted to $D=10$, where it becomes

$$d\hat{s}_{10}^2=W^{2/25}[H^{-(3/8)}\,dx^\mu dx_\mu+H^{13/8}(dr^2+r^2d\Omega_2)]+H^{5/8}\,dz^2,$$

$$\hat{A}_{(2)}=\frac{Q}{2m}W^{16/25}\,\Omega_2, \tag{43}$$

$$e^{\hat{\phi}}=W^{-(4/5)}H^{-(1/4)},\quad H=1+\frac{Q}{r}.$$

Using the redefinition (36), the metric can be cast into the form

$$d\hat{s}_{10}^2=(1+k|y|)^{1/12}(-H^{-(3/8)}\,dx^\mu dx_\mu+H^{5/8}\,dy^2+H^{13/8}(dr^2+r^2d\Omega_2^2)). \tag{44}$$

The solution can be viewed as an intersection of a NS–NS 5-brane and a D6-brane with the D8-brane. In particular, the NS–NS 5-brane lives in the D8-brane, whilst the D6-brane ends on the D8-brane. (The standard solution for the intersection of a 5-brane and a 6-brane would be of the form,

$$ds_{10}^2=H_5^{-(1/4)}H_6^{-(1/8)}\,dx^\mu\,dx_\mu+H_5^{3/4}H_6^{-(1/8)}\,du^2+H_5^{3/4}H_6^{7/8}\,d\mathbf{y}^3, \tag{45}$$

where H_5 and H_6 are independent harmonic functions on the common transverse 3-space of the **y** coordinates. In our case, the two harmonic functions are equal, $H_5=H_6=H$.)

Note that it is straightforward also to construct pp-wave and Taub-NUT solutions on the world-volume of the D8-brane.

IV. REDUCTIONS OF SU(2)-GAUGED $D=8$ SUPERGRAVITY

A. Brane-world reduction to $D=7$

Although there is no gauged supergravity in eight dimensions that admits a maximally-symmetric AdS_8 solution, there *is* a gauged theory that arises from the dimensional reduction of eleven-dimensional supergravity on S^3.[14] Since only the gauge bosons of the left-acting SU(2) of the $SO(4)\sim SU(2)\times SU(2)$ are retained in the truncation, the consistency of this reduction to $D=8$ is guaranteed by the standard group-theoretic arguments of Ref. 15. The theory can also be obtained from the S^2 reduction of type IIA theory, and the SU(2) is the isometry group of the 2-sphere. The eleventh coordinate is the fibre coordinate of the S^3, which can be viewed as a U(1) bundle over S^2.[16] The eight-dimensional theory admits a dilatonic 6-brane domain-wall solution, and this provides a starting-point for the construction of a brane-world Kaluza–Klein reduction to $D=7$.

The bosonic sector of the eight-dimensional theory contains the metric, a dilatonic scalar φ, five further scalars that can be parameterized by a unimodular 3×3 symmetric matrix T_{ij}, the SU(2) Yang–Mills potentials $A^i_{(1)}$, three 2-form potentials $B^i_{(2)}$, and a 3-form potential $A_{(3)}$. The description of the theory is a little involved, but the majority of the complications come from the scalars T_{ij} and the Yang–Mills potentials $A^i_{(1)}$ that will in fact be set to zero in our brane-world Kaluza–Klein reduction to $D=7$. It is not in general consistent in $D=8$ to set $T_{ij}=\delta_{ij}$ and $A^i_{(1)}=0$ while keeping all the other fields nonvanishing, since the retained fields will act as sources for those that are set to zero. However, since in our brane-world reduction to $D=7$ the ansatz for the remaining nonvanishing eight-dimensional fields will be such that these source terms vanish, it is sufficient for our purposes to present the truncated eight-dimensional theory, together with constraints that will be identically satisfied by the brane-world reduction ansatz. These constraints are precisely the conditions that the sources that would have excited the truncated fields should be zero.

It is in fact easy to obtain this truncation of the eight-dimensional gauged theory as an S^3 reduction from $D=11$. The ansatz is given by

$$\begin{aligned} d\hat{s}^2_{11} &= e^{-(1/3)\varphi} ds^2_8 + e^{2/3\varphi} g^{-2} d\Omega^2_3, \\ \hat{A}_{(3)} &= A_3 + \tfrac{1}{2} g^{-1} B^i_{(2)} \wedge \sigma_i . \end{aligned} \tag{46}$$

The quantities σ_i are the three left-invariant 1-forms on the group manifold SU(2), satisfying $d\sigma_i = -\frac{1}{2}\epsilon_{ijk}\sigma_j\wedge\sigma_k$. In terms of these, the unit metric on S^3 can be written as $d\Omega^2_3=\frac{1}{4}\sigma_i\sigma_i$. Substituting the ansatz into the bosonic equations of motion of eleven-dimensional supergravity,

$$d\hat{F}_{(4)} = \tfrac{1}{2}\hat{F}_{(4)}\wedge\hat{F}_{(4)}, \quad \hat{R}_{MN} = \tfrac{1}{12}(\hat{F}^2_{MN} - \tfrac{1}{12}\hat{F}^2_{(4)}\hat{g}_{MN}), \tag{47}$$

we find that the field equation for $\hat{F}_{(4)}$ implies

$$\begin{aligned} d(e^{\varphi} * F_{(4)}) &= -2g\, B^i_{(2)}\wedge G^i_{(3)}, \\ d*G^i_{(3)} &= -4g^2 e^{-\varphi} * B^i_{(2)} - 2g\, F_{(4)}\wedge B^i_{(2)} - g\,\epsilon_{ijk}\, G^j_{(3)}\wedge G^g_{(3)}, \\ F_{(4)}\wedge F_{(4)} &= 0, \end{aligned} \tag{48}$$

where $F_{(4)} \equiv dA_{(3)}$ and $G^i_{(3)} \equiv dB^i_{(2)}$. Note that the last equation in (48) is one of the constraints that results from our having truncated out the T_{ij} and $A^i_{(1)}$ fields. From the Einstein equation in (47), we obtain the following eight-dimensional equations of motion:

$$R_{\mu\nu} = \tfrac{1}{2}\partial_\mu\varphi\,\partial_\nu\varphi - \tfrac{1}{6}\Box\varphi\, g_{\mu\nu} + \tfrac{1}{12}e^{\varphi}[F_{\mu\rho\sigma\lambda}F_{\nu}{}^{\rho\sigma\lambda} - \tfrac{1}{12}F^2_{(4)}\, g_{\mu\nu}]$$
$$+ \tfrac{1}{4}[G^i_{\mu\rho\sigma}G^{i\,\rho\sigma}_{\nu} - \tfrac{1}{9}(G^i_{(3)})^2\, g_{\mu\nu}] + 2g^2 e^{-\varphi}[B^i_{\mu\rho}B^{i\,\rho}_{\nu} - \tfrac{1}{6}(B^i_{(2)})^2\, g_{\mu\nu}],$$

$$\Box\varphi = 6g^2 e^{-\varphi} + \tfrac{1}{48}e^{\varphi}F^2_{(4)} - g^2 e^{-\varphi}(B^i_{(2)})^2, \tag{49}$$

together with the further constraints

$$e^{\varphi}F_{\mu\nu\rho\sigma}G^{i\,\nu\rho\sigma} + 6g\,\epsilon_{ijk}G^j_{\mu\rho\sigma}B^{k\,\rho\sigma} = 0,$$

$$e^{\varphi}G^i_{\mu\nu\rho}G^{j\,\mu\nu\rho} - 12g^2 B^i_{\mu\nu}B^{j\,\mu\nu} = 0. \tag{50}$$

These come from the mixed and the purely internal components of the eleven-dimensional Einstein equation, respectively.

The eight-dimensional equations of motion admit a domain-wall ''ground-state'' solution, where all fields except ds^2_8 and φ are set to zero, and

$$ds^2_8 = W^{2/3}dx\cdot dx + dz^2, \quad e^{\varphi} = W^2, \tag{51}$$

where

$$W = 1 + k|z|, \quad k^2 = \tfrac{9}{4}g^2. \tag{52}$$

Specifically,

$$g = \begin{cases} \tfrac{2}{3}k, & z > 0, \\ -\tfrac{2}{3}k, & z < 0. \end{cases} \tag{53}$$

(As usual, g is allowed to have the necessary sign-change across the domain-wall provided that one thinks of obtaining the eight-dimensional gauged theory as an S^3 reduction from $D=11$, since then g arises as a constant of integration, rather than as a fixed parameter in the eight-dimensional Lagrangian.)

This motivates the construction of the following brane-world reduction ansatz, to give ungauged seven-dimensional $N=2$ supergravity from the gauged eight-dimensional theory,

$$d\hat{s}^2_8 = e^{-(1/2\sqrt{5})\,\phi}W^{2/3}ds^2_7 + e^{(\sqrt{5}/2)\phi}dz^2,$$

$$\hat{B}^i_{(2)} = \frac{1}{2\sqrt{2}}g^{-1}W^{4/3}F^i_{(2)}, \tag{54}$$

$$\hat{A}_{(3)} = A_{(3)}, \quad e^{\hat{\varphi}} = W^2 e^{(\sqrt{5}/2)\phi},$$

where we have now placed hats on all the eight-dimensional fields.

Substituting this ansatz into the equations of motion for the eight-dimensional gauged theory given above, we find that they are satisfied provided that the seven-dimensional fields satisfy the equations of motion of ungauged seven-dimensional $N=2$ supergravity. Specifically, these can be derived from the Lagrangian,

$$\mathcal{L}_7 = R*\mathbb{1} - \tfrac{1}{2}*d\phi\wedge d\phi - \tfrac{1}{2}e^{\sqrt{(8/5)}\phi}*F_{(4)}\wedge F_{(4)} - \tfrac{1}{2}e^{-\sqrt{(2/5)}\phi}*F^i_{(2)}\wedge F^i_{(2)} - \frac{1}{2}F^i_{(2)}\wedge F^i_{(2)}\wedge A_{(3)}\,. \tag{55}$$

It should be noted also that the ansatz (54) identically satisfies the constraint equations in (48) and (50), and so indeed our assumption that these would eventually be satisfied in the brane-world reduction is justified. Note that the theory naturally arises with a 4-form field strength rather than the 3-form field strength that would naturally come from the T^3 reduction of the heterotic theory. This suggests that the former and the latter can be related by a strong/weak duality.

Having obtained the brane-world reduction from eight-dimensional gauged supergravity, we may now lift it back to $D=11$, by using the S^3 reduction ansatz (46). Thus we find that the eleven-dimensional fields are given in terms of seven-dimensional fields by

$$d\hat{s}^2_{11} = e^{-\sqrt{(8/45)}\phi}\,ds^2_7 + e^{\sqrt{(5/18)}\phi}[\,W^{-(2/3)}\,dz^2 + g^{-2}\,W^{4/3}\,d\Omega^2_3], \tag{56}$$

$$\hat{A}_{(3)} = A_{(3)} + \frac{1}{4\sqrt{2}}g^{-2}\,W^{4/3}\,F^i_{(2)}\wedge\sigma_i\,.$$

It is interesting to note that if we perform a coordinate transformation from z to r, defined by $W^{-(1/3)}\,dz = dr$, and hence

$$W = (g\,r)^{3/2}, \tag{57}$$

then this ansatz for the reduction from $D=11$ to $D=7$ becomes

$$\begin{aligned} d\hat{s}^2_{11} &= e^{-\sqrt{8/45}\phi}\,ds^2_7 + e^{\sqrt{5/18}\phi}\,(dr^2 + r^2\,d\Omega^2_3), \\ \hat{A}_{(3)} &= A_{(3)} + \frac{1}{4\sqrt{2}}r^2\,F^i_{(2)}\wedge\sigma_i\,. \end{aligned} \tag{58}$$

This is recognizable as a standard type of Kaluza–Klein reduction on T^4, in which a truncation to the fields of $N=2$ supergravity in $D=7$ has been performed.

B. Brane-world reduction to $D=7$, from type IIA supergravity

Taking the results of the previous subsection, we can perform an additional S^1 Kaluza–Klein reduction on the Hopf fibers of the compactifying 3-sphere that was used in the reduction from $D=11$ to $D=8$, thereby allowing us to obtain a brane-world reduction to $D=7$ that can be viewed as coming from type IIA supergravity compactified first on S^2.

To implement this procedure, we first specialize some results for the Hopf reduction of S^3 that were obtained in Ref. 17. In terms of Euler angles (θ,φ,ψ), the three left-invariant 1-forms of SU(2) can be written as

$$\begin{aligned} \sigma_1 &= \cos\psi\,d\theta + \sin\psi\sin\theta\,d\varphi, \\ \sigma_2 &= -\sin\psi\,d\theta + \cos\psi\sin\theta\,d\varphi, \\ \sigma_3 &= d\psi + \cos\theta\,d\varphi. \end{aligned} \tag{59}$$

Clearly $\partial/\partial\varphi$ is a Killing vector for the 3-sphere metric $d\Omega^2_3 = \frac{1}{4}\sigma_i\,\sigma_i$, and it also leaves the 3-form ansatz in (56) invariant. Let μ_i be three coordinates on $\mathbb{R}^3$ subject to the constraint $\mu_i\,\mu_i = 1$, given in terms of θ and ψ by

$$\mu_1 = \sin\theta\sin\psi, \quad \mu_2 = \sin\theta\cos\psi, \quad \mu_3 = \cos\theta. \tag{60}$$

It is easily seen that in terms of these we can write the left-invariant 1-forms as

$$\sigma_i = -\epsilon_{ijk}\,\mu_j\,d\mu_k + \mu_i\,(d\varphi + \cos\theta\,d\psi). \tag{61}$$

We can now perform a Kaluza–Klein S^1 reduction of the eleven-dimensional expressions (56) on the Hopf fiber coordinate φ, using the standard ansatz,

$$d\hat{s}_{11}^2 = e^{-(1/6)\Phi}\,d\bar{s}_{10}^2 + e^{(4/3)\Phi}\,(d\varphi + \overline{\mathcal{A}}_{(1)})^2,$$

$$\hat{A}_{(3)} = \overline{A}_{(3)} + \overline{A}_{(2)} \wedge (d\varphi + \overline{\mathcal{A}}_{(1)}), \tag{62}$$

where Φ is the type IIA dilaton. Using (61), we therefore obtain the following reduction ansatz for the fields of type IIA supergravity:

$$d\bar{s}_{10}^2 = W^{(1/6)}\,[e^{-(9/8\sqrt{10})\,\phi}\,ds_7^2 + W^{-(2/3)}\,e^{(15/8\sqrt{10})\,\phi}\,dz^2 + \tfrac{1}{4}g^{-2}\,W^{4/3}\,e^{(15/8\sqrt{10})\,\phi}\,d\Omega_2^2],$$

$$\overline{A}_{(3)} = A_{(3)} + \frac{1}{4\sqrt{2}}\,g^{-2}\,W^{4/3}\,\epsilon_{ijk}\,\mu_i\,F_{(2)}^j \wedge d\mu_k,$$

$$\overline{A}_{(2)} = \frac{1}{2\sqrt{2}}\,g^{-1}\,W^{4/3}\,\mu_i\,F_{(2)}^i, \tag{63}$$

$$\overline{\mathcal{A}}_{(1)} = \tfrac{1}{2}g^{-1}\cos\theta\,d\psi,$$

$$e^{\Phi} = W\,e^{(5/4\sqrt{10})\,\phi},$$

where the unit 2-sphere metric $d\Omega_2^2$ is given by

$$d\Omega_2^2 = d\mu_i\,d\mu_i = d\theta^2 + \sin^2\theta\,d\psi^2. \tag{64}$$

The ''vacuum'' solution, corresponding to the metric (63) with $\phi = 0$, can be viewed as the near-horizon limit of a D6-brane.

C. Branes on the D6-brane

The $D=7$, $N=2$ supergravity admits membrane and string solutions supported by electric or magnetic charges for $F_{(4)}$. When lifted back to $D=11$, the membrane becomes an M2-brane delocalised on a 4-hyperplane, whilst the string can be viewed as an M5-brane wrapped on the 4-hyperplane. The seven-dimensional theory also admits black hole and 3-brane solutions, which can be viewed as intersections of two M2-branes, and intersections of two M5-branes, respectively. From the type IIA point of view, they can be viewed as membranes, strings, black holes or 3-branes living in a D6-brane.

V. REDUCTIONS OF GAUGED MAXIMAL $D=7$ SUPERGRAVITY

A. Gauged maximal seven-dimensional supergravity

The bosonic Lagrangian for maximal SO(5)-gauged supergravity in $D=7$ can be written as

$$\mathcal{L}_7 = \hat{R}\,\hat{*}\mathbb{1} - \tfrac{1}{4}T_{ij}^{-1} * DT_{jk} \wedge T_{kl}^{-1}\,DT_{li} - \tfrac{1}{4}T_{ik}^{-1}\,T_{jl}^{-1}\,\hat{*}\hat{F}_{(2)}^{ij} \wedge \hat{F}_{(2)}^{kl} - \tfrac{1}{2}T_{ij}\,\hat{*}\hat{S}_{(3)}^i \wedge \hat{S}_{(3)}^j$$

$$+ \frac{1}{2g}\,\hat{S}_{(3)}^i \wedge \hat{H}_{(4)}^i - \frac{1}{8g}\,\epsilon_{ij_1\cdots j_4}\,\hat{S}_{(3)}^i \wedge \hat{F}_{(2)}^{j_1 j_2} \wedge \hat{F}_{(2)}^{j_3 j_4} + \frac{1}{g}\,\Omega_{(7)} - V\,\hat{*}\mathbb{1}, \tag{65}$$

where

$$\hat{H}^i_{(4)} \equiv D\hat{S}^i_{(3)} = d\hat{S}^i_{(3)} + g\,\hat{A}^{ij}_{(1)} \wedge \hat{S}^j_{(3)}\,. \tag{66}$$

The potential V is given by

$$V = \tfrac{1}{2} g^2 (2T_{ij}\,T_{ij} - (T_{ii})^2), \tag{67}$$

and $\Omega_{(7)}$ is a Chern–Simons-type of term built from the Yang–Mills fields, which has the property that its variation with respect to $\hat{A}^{ij}_{(1)}$ gives

$$\delta\Omega_{(7)} = \tfrac{3}{4}\,\delta^{j_1 j_2 j_3 j_4}_{i_1 i_2 k l}\,\hat{F}^{i_1 i_2}_{(2)} \wedge \hat{F}^{j_1 j_2}_{(2)} \wedge \hat{F}^{j_3 j_4}_{(2)} \wedge \delta\hat{A}^{kl}_{(1)}\,. \tag{68}$$

An explicit expression for $\Omega_{(7)}$ can be found in Ref. 18 Note that the $S^i_{(3)}$ are viewed as fundamental fields in the Lagrangian. The symmetric unimodular SO(5)-valued tensor T_{ij} describes the 14 scalar fields.

Let us now set the SO(5) Yang–Mills potentials $A^{ij}_{(1)}$ to zero, and take the scalars to be trivial also, $T_{ij} = \delta_{ij}$. This is not in general a consistent truncation, since the remaining fields $\hat{S}^i_{(3)}$ would act as sources for the Yang–Mills and scalar fields that have been set to zero. If we impose that these source terms vanish, i.e.,

$$\hat{S}^i_{(3)} \wedge \hat{S}^j_{(3)} = 0, \quad \hat{*}\hat{S}^i_{(3)} \wedge \hat{S}^j_{(3)} = 0, \tag{69}$$

then the truncation will be consistent. (As we shall see below, these sources terms will indeed vanish in the brane-world reduction that we shall be considering.) The remaining equations of motion following from (65) are then

$$\begin{gathered} d\hat{*}\hat{S}^i_{(3)} = 0, \quad d\hat{S}^i_{(3)} = g\,\hat{*}\hat{S}^i_{(3)}\,, \\ \hat{R}_{AB} = \tfrac{1}{4}(\hat{S}^i_{ACD}\,\hat{S}^{i\,CD}_B - \tfrac{2}{15}(S^i_{(3)})^2\,\hat{g}_{AB}) - \tfrac{3}{2} g^2\,\hat{g}_{AB}\,. \end{gathered} \tag{70}$$

B. Chiral $N=(2,0)$ supergravity from $D=7$

We find that the following Kaluza–Klein ansatz for the seven-dimensional fields yields a consistent reduction to six dimensions,

$$\begin{gathered} d\hat{s}^2_7 = e^{-2k|z|}\,ds^2_6 + dz^2, \\ \hat{S}^i_{(3)} = e^{-2k|z|}\,F^i_{(3)}\,, \\ \hat{A}^{ij}_{(1)} = 0, \quad T_{ij} = \delta_{ij}\,, \end{gathered} \tag{71}$$

where the constant k is related to the gauge coupling constant g by

$$g = \begin{cases} -2k, & z > 0\,, \\ +2k, & z < 0. \end{cases} \tag{72}$$

Substituting this ansatz into the field equations of seven-dimensional SO(5)-gauged supergravity, we find that all the equations are consistently satisfied provided that the six-dimensional fields ds^2_6 and $F^i_{(3)}$ satisfy the equations of motion of six-dimensional ungauged $N=(2,0)$ chiral supergravity, namely,

$$F^i_{(3)} = *F^i_3\,, \quad dF^i_{(3)} = 0, \quad R_{\mu\nu} = \tfrac{1}{4} F^i_{\mu\rho\sigma} F^{i\,\rho\sigma}_{\nu}\,. \tag{73}$$

Note that the self-duality of the 3-forms ensures that the constraints (69) are indeed satisfied, since $F^i_{(3)} \wedge F^j_{(3)} = 0$ for any pair of self-dual 3-forms. Of course the self-duality of the $F^i_{(3)}$ fields also implies one cannot write a covariant Lagrangian for this theory.

Since we know the exact embedding of seven-dimensional maximal SO(5)-gauged supergravity in $D=11$, via the S^4 reduction, we can lift the above ansatz to an embedding in eleven-dimensional supergravity. Using the S^4 reduction ansatz, we therefore obtain

$$\begin{aligned} d\hat{s}^2_{11} &= e^{-2k|z|} ds^2_6 + dz^2 + g^{-2} d\mu_i d\mu_i, \\ \hat{F}_{(4)} &= \frac{1}{8g^3} \epsilon_{i_1 \cdots i_5} \mu_{i_1} d\mu_{i_2} \wedge \cdots \wedge d\mu_{i_5} - g^{-1} d(\mu_i e^{-2k|z|} F^i_{(3)}), \end{aligned} \tag{74}$$

where μ_i are coordinates on $\mathbb{R}^5$, subject to the constraint

$$\mu_i \mu_i = 1, \tag{75}$$

which defines the unit 4-sphere.

C. Five-dimensional $N=4$ ungauged supergravity from SO(5)-gauged $D=6$ supergravity

By dimensionally reducing the embedding (74) of six-dimensional chiral $N=(2,0)$ supergravity on a circle in the six-dimensional space–time, we can obtain an embedding of five-dimensional $N=4$ supergravity in type IIA supergravity. Thus we begin by performing a standard S^1 Kaluza–Klein reduction of the six-dimensional fields,

$$\begin{aligned} ds^2_6 &= e^{-2\alpha\phi} d\tilde{s}^2_5 + e^{6\alpha\phi} (dx_5 + \mathcal{A}_{(1)})^2, \\ F^i_{(3)} &= e^{-4\alpha\phi} * \tilde{F}^i_{(2)} + \tilde{F}^i_{(2)} \wedge (dx_5 + \mathcal{A}_{(1)}), \end{aligned} \tag{76}$$

where $\alpha = 1/(2\sqrt{6})$ and $\tilde{F}^i_{(2)} = d\tilde{A}^i_{(1)}$. (Note that the form of the reduction ansatz for the six-dimensional fields $F^i_{(3)}$ is dictated by the fact that they are self-dual.) The theory that results from this dimensional reduction is ungauged $N=4$ supergravity in $D=5$. It is straightforward to show that the equations of motion in $D=5$ that follow from substituting (76) into (73) are derivable from the Lagrangian,

$$\mathcal{L}_5 = \tilde{R} * \mathbb{1} - \tfrac{1}{2} * d\phi \wedge d\phi - \tfrac{1}{2} e^{-4\alpha\phi} * \tilde{F}^i_{(2)} \wedge \tilde{F}^i_{(2)} - \tfrac{1}{2} e^{8\alpha\phi} * \mathcal{F}_{(2)} \wedge \mathcal{F}_{(2)} - \tfrac{1}{2} \tilde{F}^i_{(2)} \wedge \tilde{F}^i_{(2)} \wedge \mathcal{A}_{(1)}, \tag{77}$$

where $\mathcal{F}_{(2)} = d\mathcal{A}_{(1)}$.

We now substitute (76) into (74), and compare it with a standard Kaluza–Klein S^1 reduction from $D=11$ to $D=10$,

$$\begin{aligned} d\hat{s}^2_{11} &= e^{-(1/6)\Phi} ds^2_{10} + e^{(4/3)\Phi} (dx_5 + A_{(1)})^2, \\ \hat{F}_{(4)} &= F_{(4)} + F_{(3)} \wedge (dx_5 + A_{(1)}). \end{aligned} \tag{78}$$

By doing this, we arrive at the ansatz for the embedding of the five-dimensional ungauged $N=4$ supergravity in type IIA supergravity,

$$ds_{10}^2 = e^{-(9/4)\,k|z| - (5/4)\,\alpha\phi}\, d\tilde{s}_5^2 + e^{-(1/4)\,k|z| + (3/4)\,\alpha\phi}\, dz^2 + g^{-2}\, e^{-(1/4)k|z| + (3/4)\,\alpha\phi}\, d\mu_i\, d\mu_i\,,$$

$$F_{(4)} = \frac{1}{8g^3}\,\epsilon_{i_1\cdots i_5}\,\mu_{i_1}\, d\mu_{i_2}\wedge\cdots\wedge d\mu_{i_5} - g^{-1}\, e^{-4\alpha\phi}\, d(\mu_i\, e^{-2k|z|} \hat{*} \widetilde{F}^i_{(2)}),$$

$$F_{(3)} = -g^{-1}\, d(\mu_i\, e^{-2k|z|}\, \widetilde{F}^i_{(2)}), \tag{79}$$

$$F_2 = \mathcal{F}_{(2)}, \quad e^{\Phi} = e^{-(3/4)\,k|z|}\, e^{(9/2)\,\alpha\phi}.$$

D. Chiral $N=(2,0)$ supergravity from type IIA NS5-brane

We showed in Sec. V B that the chiral (2,0) six-dimensional supergravity can be obtained as a brane-world Kaluza–Klein reduction from maximal gauged supergravity in $D=7$, and in turn, this can be obtained as an S^4 reduction from $D=11$. It was shown recently that one can take a singular limit of the S^4 reduction of eleven-dimensional supergravity, in which the 4-sphere degenerates to $S^3\times\mathbb{R}$.[19] The reduction can then be reinterpreted as an S^3 reduction of type IIA supergravity, yielding a maximal SO(4)-gauged supergravity in $D=7$ that admits a domain-wall, but not AdS_7, as a solution. One may refer to this theory as a ''domain-wall'' supergravity.

By applying this limiting procedure in the context of the brane-world reduction to the (2,0) supergravity in $D=6$ that we constructed in Secs. V A and V B, we can now obtain a brane-world reduction of the $D=7$ domain-wall supergravity to the (2,0) theory in $D=6$. Furthermore, we can lift this back, via its S^3 embedding, to an ansatz for type IIA supergravity. Rather than repeating the details of how the singular limit is taken here, we shall simply quote and make use of the general results already obtained in Ref. 19.

We begin by considering the brane-world reduction of the maximal seven-dimensional SO(4)-gauged domain-wall supergravity. As in our previous examples, many of the fields are set to zero in the brane-world reduction, and so rather than presenting the full seven-dimensional theory obtained in Ref. 19, we shall instead give it in an already-truncated form, where all but the participating fields have already been set to zero. As usual, we should add the cautionary remark that one cannot in general consistently set these fields to zero while allowing the remaining fields to take generic configurations. But in anticipation of the fact that the brane-world reduction *will* be consistent, we can make the truncation provided that we take note also of the consequent required constraints, which will be satisfied by the brane-world reduction ansatz.

In this spirit, we therefore set to zero all the fields of the seven-dimensional SO(4)-gauged domain-wall supergravity constructed in Ref. 19 except for the metric, the dilatonic scalar field ϕ, and the 3-forms $S^0_{(3)}$ and $S^\alpha_{(3)}$. Note that $S^0_{(3)}$ is viewed as a 3-form field strength that is derived from a 2-form potential, whilst the four 3-forms $S^\alpha_{(3)}$ are viewed as independent fields in their own right, which satisfy first-order equations of motion. Defining $\gamma=\sqrt{2/5}$, we read off from Ref. 19 that the equations of motion for these remaining fields will be

$$d\hat{*}d\phi = -\gamma\, e^{-2\gamma\phi}\,\hat{*}S^0_{(3)}\wedge S^0_{(3)} + \tfrac{1}{4}\gamma\, e^{(1/2)\,\gamma\phi}\,\hat{*}S^\alpha_{(3)}\wedge S^\alpha_{(3)} - 4\gamma g^2\, e^{\gamma\phi}\,\hat{*}\mathbb{1},$$

$$d(e^{-2\gamma\phi}\,\hat{*}S_{(3)}) = 0, \quad dS^0_{(3)} = 0,$$

$$dS^\alpha_{(3)} = g\, e^{1/2\,\gamma\phi}\,\hat{*}S^\alpha_{(3)}\,, \tag{80}$$

$$\hat{R}_{MN} = \tfrac{1}{2}\partial_M\phi\,\partial_N\phi + \tfrac{1}{4}e^{-2\gamma\phi}[S^0_{MPQ}\,S^{0\,PQ}_N - \tfrac{2}{15}(S^0_{(3)})^2\,\hat{g}_{MN}]$$
$$+ \tfrac{1}{4}e^{(1/2)\,\gamma\phi}[S^\alpha_{MPQ}\,S^{\alpha\,PQ}_N - \tfrac{2}{15}(S^\alpha_{(3)})^2\,\hat{g}_{MN}] - \tfrac{4}{5}g^2\, e^{\gamma\phi}\,\hat{g}_{MN}\,.$$

(Note that we have placed hats on all quantities associated with the seven-dimensional metric, in anticipation of the upcoming brane-world reduction to $D=6$.)

We may first note that these equations of motion admit a domain-wall solution given by $d\hat{s}_7^2 = W^2\, dx\cdot dx + dz^2$, $e^{-\gamma\phi} = W^2$, where $W = 1 + k|z|$ and $k^2 = 4g^2/25$. This provides the basis for the brane-world reduction ansatz to $D=6$. Specifically, we find that all the equations given in (80) are satisfied if we make the following ansatz:

$$d\hat{s}_7^2 = W^2\, ds_6^2 + dz^2\,, \quad e^{-\gamma\phi} = W^2,$$
$$S^0_{(3)} = F^0_{(3)}, \quad S^\alpha_{(3)} = W^{5/2} F^\alpha_{(3)}\,, \tag{81}$$

where the fields ds_7^2 and $F^i_{(3)}$ satisfy the equations of motion of ungauged six-dimensional (2,0) supergravity, as given in (73). Note that here, the index i on $F^i_{(3)}$ runs over the five values $i = (0,\alpha)$.

We can also use the results in Ref. 19 to lift the seven-dimensional fields to those of ten-dimensional type IIA supergravity. For the truncated system that we are considering here, we find that the embedding is simply given by

$$d\bar{s}_{10}^2 = e^{(3/8)\gamma\phi}\, ds_7^2 + g^{-2} e^{-(5/8)\gamma\phi}\, d\Omega_3^2,$$
$$e^{\Phi} = e^{(5/4)\gamma\phi}, \quad \bar{A}_{(1)} = 0,$$
$$\bar{F}_{(4)} = -e^{(1/2)\gamma\phi}\, \mu_\alpha S^\alpha_{(3)} + g^{-1} S^\alpha_{(3)} \wedge d\mu_\alpha\,, \tag{82}$$
$$\bar{F}_{(3)} = 2g^{-3}\,\Omega_{(3)} + g^{-1} S^0_{(3)},$$

where μ_α denote Cartesian coordinates on $\mathbb{R}^4$ subject to the constraint $\mu_\alpha \mu_\alpha = 1$ that defines the unit 3-sphere with metric $d\Omega_3^2$ and volume form $\Omega_{(3)}$. The barred fields are those of type IIA supergravity, with Φ being the type IIA dilaton.

Substituting our brane-world reduction ansatz (81) into this, we obtain the following brane-world embedding of six-dimensional (2,0) supergravity in type IIA supergravity:

$$d\bar{s}_{10}^2 = W^{(5/4)}\,(ds_6^2 + W^{-2}\, dz^2 + g^{-2}\, d\Omega^2_{(3)}),$$
$$e^{\Phi} = W^{-(5/2)}, \quad \bar{A}_{(1)} = 0,$$
$$\bar{F}_{(4)} = -W^{3/2}\, \mu_\alpha F^\alpha_{(3)} + g^{-1} W^{5/2} F^\alpha_{(3)} \wedge d\mu_\alpha\,, \tag{83}$$
$$\bar{F}_{(3)} = 2g^{-3}\,\Omega_{(3)} + g^{-1} F^0_{(3)}.$$

E. Chiral $N=(1,0)$ supergravity from heterotic 5-brane

It was shown in Refs. 20, 21, 19 that one can obtain the chiral $N=(1,0)$ theory from the $N=2$ SU(2)-gauged supergravity in $D=7$ that admits an AdS_7 vacuum solution, via a brane-world Kaluza–Klein reduction. There is also an SU(2)-gauged supergravity in $D=7$ that admits a domain wall instead of AdS_7 as a vacuum solution. This theory can be obtained from the S^3 reduction of $N=1$ supergravity in $D=10$, and its domain-wall solution is therefore the S^3 reduction of the heterotic 5-brane. Clearly it can also obtained from the truncation of the $N=4$ SO(4)-gauged maximal supergravity discussed in the previous subsection. It is straightforward to reduce the seven-dimensional theory or the heterotic theory in $D=10$ on the world-volume of the 5-brane and obtain the chiral $N=(1,0)$ supergravity. The reduction ansatz is identical to that of Sec. V D, but with all the fields that carry the index α set to zero.

Both the (2,0) and (1,0) theories admit a self-dual string solution in $D=6$. This solution can be lifted to $D=11$, where it becomes a self-dual string living in the world-volume of M5-brane,

which can also be viewed as an open membrane ending on the M5-brane.[3] When lifted back to $D=10$ instead, it can be viewed as a self-dual string living in the NS5-brane or the heterotic 5-brane.

F. $N=(1,1)$ supergravity from $D=7$ gauged supergravity

So far, we obtained the chiral ungauged supergravity in $D=6$ from gauged supergravity in $D=7$, which itself can be obtained from S^4 reduction of M-theory, or the S^3 reduction of the type IIA or heterotic theories. There also exist gauged supergravities in $D=7$ that give rise instead to the $N=(1,1)$ nonchiral theory in six dimensions, through a brane-world Kaluza–Klein reduction. One example is the SU(2)-gauged supergravity that is the S^1 reduction of eight-dimensional SU(2)-gauged supergravity, which itself can be obtained from the S^3 reduction of eleven-dimensional supergravity,[14] as we discussed in Sec. IV. This is because the brane-world reduction of the eight-dimensional gauged supergravity gives rise to $N=2$ supergravity in $D=7$. If we perform a further S^1 reduction on a brane-world direction, the bulk gauged-supergravity in $D=8$ becomes a gauged $N=4$ supergravity in $D=7$, whilst the world-volume seven-dimensional ungauged theory becomes the $N=(1,1)$ ungauged theory in $D=6$.

There should also be an SO(4)-gauged supergravity in $D=7$ that gives rise to the $N=(1,1)$ theory in $D=6$. This can be obtained from the S^3 reduction of the type IIB theory. The bulk T-duality of the type IIA and type IIB theories then translates into a T-duality between the $N=(1,1)$ and $N=(2,0)$ theories in the 5-brane world-volume.

VI. CONCLUSION

In this paper, we have constructed several new examples of brane-world Kaluza–Klein reductions. Our focus was to construct the reductions with larger supersymmetry and in diverse dimensions that in general involve consistent Kaluza–Klein reductions with dilatonic codimension one objects, thus extending the results obtained in Ref. 3 in several ways. Specifically, we have shown that it is possible to construct consistent brane-world reductions of five-dimensional $N=8$ SO(6)-gauged supergravity to ungauged $N=4$ supergravity in $D=4$; of massive type IIA supergravity to ungauged $N=1$ supergravity in $D=9$; of eight-dimensional $N=2$ SU(2)-gauged supergravity to ungauged $N=2$ supergravity in $D=7$; and of seven-dimensional $N=4$ SO(5)-gauged supergravity to ungauged $N=2$ supergravity in $D=6$. In all these cases, just as in the original examples constructed in Ref. 3, the degree of ungauged supersymmetry in the lower dimension is one-half of the gauged one in the higher dimension, and in this paper we have focused mainly on the supergravity multiplets.

A simple calculation shows that for any brane-world (codimension one) reduction ansatz of the form

$$d\hat{s}^2 = e^{-2k|z|}\, ds^2 + dz^2, \tag{84}$$

the Riemann tensor $\hat{R}_{ABCD}$ of the D-dimensional metric $d\hat{s}^2$ satisfies

$$\hat{R}_{ABCD}\hat{R}^{ABCD} = e^{4k|z|} R_{abcd} R^{abcd} - 4k^2 e^{2k|z|} R + 2D(D-1)k^4 \tag{85}$$

in the bulk, where R_{abcd} and R are the Riemann tensor and Ricci scalar of the reduced metric ds^2. This implies that any curvature of the lower-dimensional metric for which $R_{abcd}R^{abcd}$ or R is nonzero, no matter how small, will lead to curvature singularities in the higher-dimensional metric on the Cauchy horizons at $z=\pm\infty$. These singularities were discussed in detail for a Schwarzschild black hole on the brane in Ref. 22. In Ref. 23, it was argued that such curvature singularities on the horizons arise as an artifact of considering only the zero-mode of the metric tensor, and that if the massive Kaluza–Klein modes are taken into account they could actually become dominant near the horizons, and may lead to a finite curvature there. The results of Ref. 3 and this paper suggest that the phenomenon of diverging curvature on the Cauchy horizons for the AdS domain wall reductions (or null horizons for the dilatonic domain wall reductions) may be more severe.

Specifically these results show that the brane-world reductions correspond to exact fully nonlinear consistent embeddings in which the massive Kaluza–Klein modes can be consistently decoupled. This implies that there certainly exist exact solutions on the brane-world where Kaluza–Klein modes do not enter the picture, even at the nonlinear level. For these solutions, the curvature will inevitably diverge at the horizons. It becomes necessary, therefore, either to live with these (null) singularities or else to find a principle, perhaps based on the imposition of appropriate boundary conditions, for rejecting the solutions of this type. (Let us also remark that a deviation of the dilatonic domain wall solutions from the flat (BPS)-limit generically introduces naked singularities,[24] again pointing towards difficulties with the interpretation of such solutions within a more realistic set-up.) It should be emphasized, however, that regardless of the physical questions that are prompted by these results, the brane-world Kaluza–Klein reductions remain valid mathematical constructs in their own right. In fact as relatively simple examples of consistent reductions that have no obvious group-theoretic explanation, they can be viewed as precursors of the remarkable examples of consistent reductions on spheres.

Finally, we again emphasize that the absolute-value sign in Eq. (84) for the brane-world metrics in the AdS codimension one brane (as well as dilatonic examples as discussed in the text) actually requires an explicit delta function source to support such a Z_2-symmetric codimension one object that in turn allows for the trapping of gravity on the world-volume of the brane (at $z=0$). The understanding of such delta-function sources in the lower dimension may require a subtle interpretation in terms of fundamental sources, such as D-brane sources of the higher dimensional theory.[25] Nevertheless, the consistency of the Kaluza–Klein reduction in the bulk (for $z\neq 0$) is valid quite independently of the origin of the domain wall sources.

We study supersymmetric domain walls on $S_1/\mathbf{Z}_2$ orbifolds. The supergravity solutions in the bulk are given by the attractor equation associated with Calabi–Yau (CY) spaces and have a naked space–time singularity at some $|y_s|$. We are looking for possibilities to cut off this singularity with the second wall by a stringy mechanism. We use the collapse of the CY cycle at $|y_c|$ which happens before and at a finite distance from the space–time singularity. In our example with three Kähler moduli the second wall is at the end of the moduli space at $|y_c|$ where also the enhancement of SU(2) gauge symmetry takes place so that $|y_e|=|y_c|<|y_s|$. The physics of the excision of a naked singularity via the enhançon in the context of domain wall has an interpretation on the heterotic side related to $R\to 1/R$ duality. The position of the enhançon is given by the equation $R(|y_e|)=1$. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1373424]

The supersymmetric domain wall solutions of $D=5$, $N=2$, U(1) gauged supergravity[1] with brane sources on $S^1/\mathbf{Z}_2$ orbifolds have been described recently in Ref. 2. It has been observed there that in the context of Calabi–Yau (CY) compactifications the collapse of CY cycles may put some restrictions on the distance between the walls.[3,4] In this article we will study this type of domain wall both for $D=5$, $N=2$, U(1) gauged supergravity[1] (GST model) and for Calabi–Yau compactifications of 11-D supergravity with fluxes turned on. The latter is the five-dimensional heterotic M-theory[5,6] obtained by a reduction on a CY threefold of Horava–Witten M-theory[7] on $S^1/\mathbf{Z}_2$ (HW model). The explicit form of the solution with general dependence on the vector multiplets is obtained for both models by solving the generalized attractor equation.[8–11] Since the domain wall solutions[2,6] of the two models behave very similarly, we will discuss them in parallel.

The purpose of this article is to find a possibility to remove the space–time singularity of the domain wall solution via some particular property of the CY space. Specifically we would like to find a situation when the collapse of the CY cycle at $|y_c|$ happens closer to the first wall which is at $y=0$ and at a finite distance from the space–time singularity $|y_s|$, so that

$$|y_c|<|y_s|. \tag{1}$$

In the case of excision of repulson singularities by the enhançon mechanism,[12] the distance between the repulson and enhançon is finite. The hope, therefore, is that also for some domain walls the analogous situation may be possible, particularly if enhancement of gauge symmetry is somehow involved. The finite distance between the naked singularity of the supergravity solution and the position of the collapse of the CY cycle may allow us to use the physics of string theory already at the end of the moduli space which in this case excludes the singularity of the general relativity as unphysical. The generic interest in such a mechanism is supported by some interesting

recent investigations of the brane world scenarios[13] where the naked singularities may be present in solutions of the Einstein equations and need to be removed by a natural stringy-type mechanism.

Our walls are supersymmetric everywhere, including the position of the branes,[2] therefore they do not directly address the problems of the models in Ref. 13. But due to supersymmetry in our model the matching conditions for the solutions are satisfied automatically on both walls. We have more control over the situation and may clearly indicate conditions when a natural mechanism of stringy excision of singularities is available.

We have found that in most cases the singularities of the CY space tend to coincide with the space–time singularity of the domain wall solutions, i.e.,

$$|y_c| = |y_s|. \tag{2}$$

Only in some special cases we will find the singularities in space–time and CY space at some finite distance in the y direction from each other as in Eq. (1). Within the classification of the possible behavior of the CY manifold at the boundary of the Kähler cone[9,14] we consider the special case when a complex divisor D is collapsing to a curve E of A_1 singularities, so that there is an SU(2) enhancement of gauge symmetry at the boundary. The position $|y_c|$ where the cycle collapses therefore corresponds to the position $|y_e|$ of the enhançon. We will find examples where

$$|y_c| = |y_e| < |y_s|. \tag{3}$$

Domain wall solutions of the two models have a metric of the form[15]

$$ds^2 = a^2(y) dx^\mu dx^\nu \eta_{\mu\nu} + a^{2\gamma}(y) dy^2, \tag{4}$$

where $\gamma = -2$ is the GST model and $\gamma = 4$ is the HW model.[16] In both cases the function $a(y)$ and the scalar fields are determined in terms of harmonic functions through generalized attractor equations[9,10] which require that the rescaled variables $\tilde{h}^I \equiv a(y) h^I$ have to satisfy

$$C_{IJK} \tilde{h}^J \tilde{h}^k = H_I(y), \tag{5}$$

where $H_I(y)$ are harmonic functions. Then the physical scalars are given by either solving the hypersurface constraint or by using the the ratios $\tilde{h}^x/\tilde{h}^0$ and the metric is determined by

$$a^3(y) = C_{IJK} \tilde{h}^I \tilde{h}^J \tilde{h}^K = \tilde{h}^I H_I. \tag{6}$$

In the HW model one additional scalar enters nontrivially into the solution. This scalar is the overall volume V, or ''breathing mode'' of the Calabi–Yau space. Since there is no solution with constant V, there are no anti-de Sitter (AdS) vacua in the HW case in contrast to domain walls in 5-D supergravity.[2] For our purpose it is important that V is uniquely determined by the vector multiplet scalars. In fact, V is just some power of a, and therefore a rational function of the harmonic functions:

$$V = a^6 = (C_{IJK} \tilde{h}^I \tilde{h}^J \tilde{h}^K)^2. \tag{7}$$

As a consequence the flow through moduli space is the same as in the GST model. The two models differ in the precise form of the space–time metric and by the fact that a^6 in the HW case is the volume of the internal space.

Following Ref. 2 we consider a setup where the fifth direction is a $S^1/\mathbf{Z}_2$ orbifold with three-branes at the fixed points $y = 0$ and $y = \tilde{y}$, which act as sources for the harmonic functions:

$$\partial_y^2 H_I = -2g q_I [\delta(y) - \delta(y - \tilde{y})], \quad H_I = c_I - 2g q_I |y|. \tag{8}$$

Concerning space–time singularities both models behave very similarly. Components of curvature tensors become singular if either $a=0$ or if its derivatives diverge. The corresponding Ricci scalar is

$$\mathcal{R}=-4a^{-2-2\gamma}((3-2\gamma)(a')^2+2aa''). \tag{9}$$

To find explicit domain wall solutions we consider some CY spaces with three Kähler moduli[17,18] for which the relevant prepotential was identified in 5-D supergravity and the attractor equations have been solved. Many of such solutions are displayed and analyzed in Refs. 9 and 11 for the extended Kähler cone of a CY which is an elliptic fibration over the Hirzebruch surface $\mathcal{F}_1$. The extended Kähler cone consists of two Kähler cones related by a flop transition.[19] We will refer to the two CY compactifications as model III and model II, respectively. Model I forms a particular boundary of the moduli space of the model II. The moduli space of model III has a boundary where SU(2) enhancement occurs in the way described above. Moreover, the metric on the moduli space is finite at this boundary. As explained in Refs. 17 and 18, the region III CY is related to two other CY spaces by deformation of the base of the elliptic fibration into the Hirzebruch surfaces $\mathcal{F}_0$ and $\mathcal{F}_2$, respectively. These models likewise have a boundary with SU(2) enhancement, and the physics close to the boundary is completely isomorphic to the one of the region III $\mathcal{F}_1$ model. Though we will discuss the region III model for definiteness, our results will be automatically valid for these models as well. The M-theory compactifications on the elliptically fibered CY spaces with bases $\mathcal{F}_0$, $\mathcal{F}_1$, $\mathcal{F}_2$ have a dual description by compactifications of the $E_8\times E_8$ heterotic string on $K3\times S^1$ with instanton numbers (12, 12), (13, 11), (14, 10), respectively. To be precise this duality is known to be valid in the absence of G-flux inside the M-theory CY. We will later use the heterotic picture to describe the SU(2) enhancement in a simple way, assuming that the duality is still valid in presence of G-flux. Since switching on G-flux does not interfere with the mechanism underlying gauge symmetry enhancement this is a reasonable assumption.

Let us return to the M-theory compactification on the CY with base $\mathcal{F}_1$. The boundaries of the extended Kähler cone are defined by the collapse of some cycles to zero volume. The whole picture is shown in Fig. 2 of Ref. 9. Some of the boundaries have a vanishing metric of the moduli space, some have an infinite metric. Equations of motion relate the space–time curvature $\mathcal{R}$ with expressions which depend on moduli space metric, $g_{xy}(\phi^x)'(\phi^y)'a^{-2\gamma}$, as well as with expressions depending on the inverse moduli space metric, $W_{,x}g^{xy}W_{,y}$. This indicates that it is likely that the space–time curvature is infinite if the moduli space metric g_{xy} or its inverse g^{xy} are infinite.[20] We have studied several cases explicitly and found that they indeed have coinciding singularities of the space–time and the moduli space.

We proceed therefore directly with the domain walls of the model III, which has a boundary with finite metric. The classical prepotential for this model was derived in Ref. 18. In terms of the variables adapted to the Kähler cone, the prepotential is

$$\mathcal{V}=\tfrac{4}{3}(h^1)^3+\tfrac{3}{2}(h^1)^2h^2+\tfrac{1}{2}h^1(h^2)^2+(h^1)^2h^3+h^1h^2h^3=1, \tag{10}$$

and the Kähler cone is simply $h^I>0$. In the new variables

$$h^1=U,\quad h^2=T-\tfrac{1}{2}U-W,\quad h^3=W-U, \tag{11}$$

the prepotential becomes

$$\mathcal{V}=\tfrac{5}{24}U^3+\tfrac{1}{2}UT^2-\tfrac{1}{2}UW^2+\tfrac{1}{2}U^2W=1. \tag{12}$$

The Kähler cone is $W>U>0$ and $T>W+1/2U$. There are three boundaries when either of h^I vanishes: (*i*) $U=0\Leftrightarrow h^1=0$: here the metric of moduli space becomes singular, (*ii*) $T=W+U/2\Leftrightarrow h^2=0$: the metric of moduli space is regular and one has non-Abelian gauge symmetry enhancement; and (*iii*) $W=U\Leftrightarrow h^3=0$: there is a flop transition, and again the metric is regular. We can solve (12) for T: $T=\sqrt{(2/U)(1-5U^3/24-U^2W/2+UW^2/2)}$ and keep as independent

scalars $\phi^x=(U,W)$. By looking at the resulting moduli space metric g_{xy} with determinant $\det g_{xy}\simeq 12(3-4U^3)/(24U-5U^4-12U^3W+12U^2W^2)$ we recover the picture given in Fig. 2 in Ref. 9: U varies within a finite interval, whereas W varies from 0 to ∞ at $U=0$ and is cutoff by the curves $U=W$ and $T-W-1/2U$ for positive W:

$$0<U<\left(\frac{3}{4}\right)^{1/3}, \quad U<W<\frac{3-U^3}{3U^2}. \tag{13}$$

The stabilization equations (5) are a system of quadratic equations for the rescaled scalars $\tilde{h}^I=a(y)h^I\coloneqq\tilde{U},\tilde{T},\tilde{W}$. For our model they are solved following Ref. 9 by [21]

$$\tilde{U}=\sqrt{\alpha-\sqrt{\alpha^2-\beta}}, \quad \tilde{T}=\frac{H_T}{\tilde{U}}, \quad \tilde{W}=\frac{1}{2}\tilde{U}-\frac{H_W}{2\tilde{U}}, \tag{14}$$

where

$$\alpha=\tfrac{1}{4}(H_U+\tfrac{1}{2}H_W), \quad \beta=\tfrac{1}{8}(H_T^2-H_W^2). \tag{15}$$

One needs to impose that the scalars are real and inside the Kähler cone. Therefore the harmonic functions are subject to the inequalities

$$\tfrac{2}{3}H_U\geqslant H_T\geqslant -H_W\geqslant \tfrac{2}{9}(H_U-\sqrt{H_U^2-\tfrac{9}{4}H_T^2}), \tag{16}$$

which are mutually consistent. The boundary $T=W+U/2$ corresponds to $2H_U=3H_T$, whereas the boundary $W=U$ corresponds to $-H_W=2/9(H_U-\sqrt{H_U^2-9/4H_T^2})$ and the boundary $U=0$ corresponds to $H_T=-H_W$. We would like to mention that the second branch of the attractor equations found in Ref. 11 does not describe a solution inside the Kähler cone, as can be verified by a full analysis of the constraints.

Let us show that for generic values of the parameters of the harmonic functions the collapse of the modulus h^2 is taking place at the point $|y_c|$ which is at a finite distance from the space–time singularity.

First of all we have to find out under which conditions space–time curvature can diverge. Looking at the formula (9) for the Ricci scalar we find that this happens if either $a=0$ or one of its derivatives diverges.[22] The same is true for the components of the Ricci tensor and of the Riemann tensor, which we did not display explicitly. The only point within the extended Kähler cone where a vanishes is $U=W=0$, $T=\infty$. At this point the moduli space metric is infinite. Divergences in the derivatives of a occur when either $\alpha=\sqrt{\alpha^2-\beta}$ or $\alpha^2=\beta$. The first case corresponds to $U=0$, which is a boundary of the Kähler cone on which the moduli space metric diverges. This includes the point where $a=0$ as a subcase. Thus on the boundary $U=0$ one finds the expected coincidence of space–time singularities with moduli space singularities. The only kind of space–time singularities which need to concern us here are the ones related to $\alpha^2=\beta$.

The equation $\alpha^2=\beta$ has no solutions if $9H_T^2<4H_U^2$ which corresponds to $T>W+1/2U$. Therefore no space–time singularity can occur as long as the moduli are inside the Kähler cone. If $9H_T^2>4H_U^2$, then $\alpha^2=\beta$ has two solutions, $H_W=-2/9(H_U\pm\sqrt{8}\sqrt{9/4H_T^2-H_U^2})$. Thus the generic situation is that one *first* crosses the enhancement boundary $T=W+1/2U$ and *then* runs into a space–time singularity at a finite distance. If $9H_T^2=4H_U^2$, which is precisely true on the enhancement boundary, then $\alpha^2=\beta$ has one solution given by $2H_U+9H_W=0$. Thus the only possibility for the space–time singularity to coincide with the boundary of moduli space is when the parameters are fine tuned such that $2H_U(y_c)=3H_T(y_c)=-9H_W(y_c)$. The corresponding point in moduli space is the intersection point of the enhancement boundary $T=W+1/2U$ with the flop boundary $U=W$. At this point the metric on moduli space is degenerate, which nicely fits with our observation that a singularity in moduli space generically induces a singularity in space–time.

The coordinates W, T, U cover both regions of model III and II and allow us to analyze the flop transition in the framework of special geometry, as shown in Ref. 9. It is also interesting to use the description of the region III in STU parametrization. In this parametrization we can also show that the singularities of the space–time and CY space are at finite distance and we will give a numerical example. Moreover, the interpretation of the enhançon-type physics in terms of T-duality is manifest.

After the substitution $W=S'-1/2(T'-U')$, $T=S'+1/2T'$, and $U=U'$, the region III prepotential takes the form

$$\mathcal{V}=S'T'U'+\tfrac{1}{3}U'^3. \tag{17}$$

The original CY Kähler moduli are now related to the heterotic string variables as follows:

$$h^1=U', \quad h^2=T'-U', \quad h^3=S'-\tfrac{1}{2}(T'+U'). \tag{18}$$

The solution in these variables is[23]

$$\tilde{U}'=\frac{1}{2}\sqrt{H'_U-\sqrt{(H'_U)^2-4H'_SH'_T}}, \quad \tilde{T}'=\frac{H'_S}{2\tilde{U}'}, \quad \tilde{S}'=\frac{H'_T}{2U'}. \tag{19}$$

Note that the harmonic functions are now associated with the primed variables. The boundaries of region III are

$$\begin{gathered} U>0\Leftrightarrow U'>0, \\ W>U\Leftrightarrow S'>\tfrac{1}{2}(T'+U'), \\ T>W+\frac{U}{2}\Leftrightarrow T'>U'. \end{gathered} \tag{20}$$

For convenience we drop the primes on moduli and harmonic functions in the rest of the article, denoting moduli simply by S, T, U. One should keep in mind that the T-variables in both parametrizations are different!

Let us look at the moduli space metric. We solve the hypersurface equation $\mathcal{V}=STU+1/3U^3=1$ for $S{:}S=(3-U^3)/3TU$. The determinant of the vector kinetic matrix is $\det G_{IJ}\simeq 1-4/3U^3$. Thus $0\leqslant U\leqslant(3/4)^{1/3}$ as expected, because the U variable is the same in the TUW and STU parametrization. The determinant of the scalar kinetic term is

$$\det g_{xy}\simeq\frac{3-4U^3}{T^2U^2}, \tag{21}$$

implying $0<U<(3/4)^{1/3}$ and $T\neq 0$. Since T is positive for our CY moduli space, the moduli space metric is regular for

$$0<U<(\tfrac{3}{4})^{1/3} \quad \text{and} \quad 0<T. \tag{22}$$

In particular, it becomes singular on $U=0$, which is a boundary from the CY point of view (tensionless strings). On the boundary $U=T$ (symmetry enhancement) it is regular, as long as U takes allowed values. The third boundary (flop) is given by

$$S(T,U)=\tfrac{1}{2}(T+U), \tag{23}$$

which can be solved for T as $T(U)=-1/2U+(\sqrt{3}/6U)\sqrt{24U-5U^4}$. Note that $T(U)$ is positive for all $0<U<(3/4)^{1/3}$. Therefore the moduli space metric is regular along the flop line. The reality of the ''inner'' and ''outer'' roots in (19) imposes

$$H_U^2>4H_SH_T>0. \tag{24}$$

A further look at (19) and (20) tells us that the harmonic functions H_S, H_T, H_U have to be positive. When combining this with (24) then all expressions are real and $U>0$. The other boundaries are $T\geqslant U$ and $S\geqslant 1/2(T+U)$. The condition $T\geqslant U$ takes a very simple form,

$$H_U\geqslant H_S+H_T, \tag{25}$$

which is compatible with (24). We are interested in the limit $H_U\to H_S+H_T$. We still have to implement the constraint that h^3 is positive, which in these variables is $S>1/2(T+U)$. We will impose the stronger constraint $S>T$ which yields a simpler constraint on the harmonic functions and has the additional advantage to guarantee that our solution is also inside the Kähler cones of the related $\mathcal{F}_0$ and $\mathcal{F}_2$ models. For these models the prepotential likewise can be brought to the form (17). However, the boundaries of the Kähler cones are different. For the $\mathcal{F}_2$ model the Kähler cone is defined by $S>T>U>0$, whereas for the $\mathcal{F}_0$ model one has $S,T>U>0$. Note that all models share the $U=T$ boundary, though the other boundaries are different. Moreover, when imposing the strongest constraint $S>T>U>0$ we can discuss the limit $T-U\to 0$ for all three models simultaneously. Now $S>T$ simply implies

$$H_T>H_S. \tag{26}$$

The constraints we found are compatible: evaluating (24), when (26) is saturated, gives $(H_T-H_S)^2\geqslant 0$. Thus the boundary $U=T$ requires that $H_U=H_S+H_T$. This defines its position as

$$|y_c|=\frac{c_U-c_T-c_S}{d_U-d_T-d_S}. \tag{27}$$

A closer inspection of the analytic form of the Ricci scalar $\mathcal{R}$ and of the function a and its space–time derivatives shows that curvature singularity precisely occurs when $H_U^2=4H_SH_T$. Given the inequalities (24)–(26) we see that this can never happen inside the Kähler cone. Moreover, the generic situation is that the space–time singularity is encountered after crossing the $T=U$ boundary. The only possibility to have the space–time singularity coincide with the boundary of moduli space is to fine tune the parameters such that $H_T(y_c)=H_S(y_c)$ coincides with $H_U^2(y_s)=4H_T(y_s)H_U(y_s)$ at $y=y_s=y_c$. At such a point one has $S=T=U$ or $H_U^2(y_c)=4H_S^2(y_c)=4H_T^2(y_c)$. In terms of the parameters in the harmonic function this means that one must arrange $(c_U-c_T-c_S)/(d_U-d_T-d_S)=(c_T-c_S)/(d_T-d_S)\Leftrightarrow|y_c|=|y_s|$. Generically this condition is not satisfied and therefore $|y_c|<|y_s|$.

Now we can set up an example of a solution running into the enhancement boundary. We take care of the constraint $H_T>H_S$ by setting $H_T=2H_S$. It will turn out that this will lead to relatively simple analytic expressions. Note that this choice implies that at the enhancement boundary $U=T$ one has $S=2U$ or in terms of h^I: at $h^2=0$ one has $h^1=h^3$, (see Fig. 2).

The harmonic functions take the form $H_I=c_I-d_I|y|$ dictated by the presence of two space–time boundaries. The constants c_I define the initial condition on the first space–time boundary whereas the slopes d_I determine how the solution flows through moduli space. The c_I are undetermined integration constants, which are only restricted by the fact that all scalars should be inside the Kähler cone at $y=0$ and by the conventional normalization $a=1$ that we impose on the metric at $y=0$. On the other hand, the d_I are, in the context of a Calabi–Yau compactification with flux, determined by the sources of flux put on the boundaries.[4,15] We will choose some values for d_I to simplify the calculations and not try to connect these values to particular sources of fluxes,

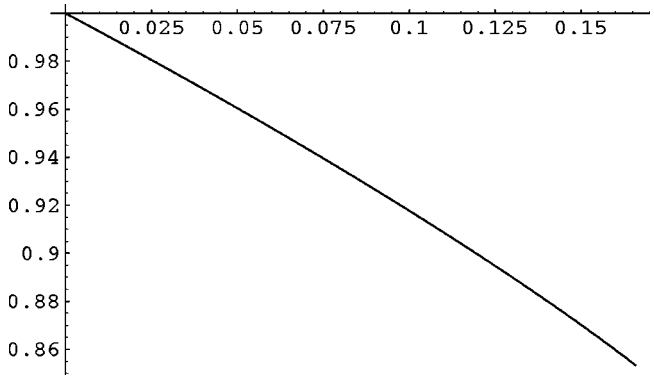

FIG. 1. The function $a(y)$ for $0 \leqslant y \leqslant 0.17$.

since we have shown that the picture is generic. It will not change when taking different slopes, as long as the solution runs into the enhancement boundary without reaching any other boundary of moduli space first.

Now we choose initial data. We have $c_T = 2c_S$ and have to impose $c_U > c_T + c_S = 3c_S$. For definiteness we take $c_U = 4c_S$. Then c_S is fixed by the normalization condition $a(0) = 1$. This can be solved exactly with the result

$$c_S = \left(\frac{45}{49} + \frac{9}{49\sqrt{2}} \right)^{1/3}. \tag{28}$$

Now we have to set the slope. We already decided to take $d_T = 2d_S$. Then the boundary $T = U$ is reached once the inequality

$$|y| \leqslant |y_e| = \frac{C_U - c_T - c_S}{d_U - d_T - d_S} = \frac{c_S}{d_U - 3d_S} \tag{29}$$

is saturated. We are free to choose $d_U > 3d_S$. For definiteness we take $d_U = 10$ and $d_S = 1$. The analytical value of $|y_e|$ is

$$|y_e| = \frac{1}{7} \left(\frac{45}{49} + \frac{9}{49\sqrt{2}} \right)^{1/3} \simeq 0.145\,118. \tag{30}$$

Then $a(|y|)$ is well behaved for $0 \leqslant |y| \leqslant |y_e|$. However, a^3 becomes complex and the scalar curvature $\mathcal{R}$ becomes infinite for some $|y_s| > |y_e|$. Looking at the explicit analytic expressions for a and $\mathcal{R}$ one sees that this happens, independently of our concrete choice of parameters, because $\sqrt{H_U^2 - 4H_S H_T}$ vanishes and then becomes complex.

In our concrete numerical example the equation $H_U^2 - 4H_S H_T = 0$ has two roots, the relevant being

$$|y_s| = \frac{1}{23} \left(8 \left(\frac{45}{49} + \frac{9}{49\sqrt{2}} \right) \right)^{1/3} - 3\sqrt{2} \left(\frac{45}{49} + \frac{9}{49\sqrt{2}} \right)^{1/3} \simeq 0.165\,949, \tag{31}$$

such that indeed $|y_s| > |y_e|$. As we explained earlier, this holds generically for solutions running into the direction of the enhancement boundary. *Whenever the solution runs into the specific boundary of moduli space, where gauge symmetry is enhanced, then it reaches this boundary before the space–time curvature becomes infinite. This is an example where a moduli space boundary shields a space–time singularity.*

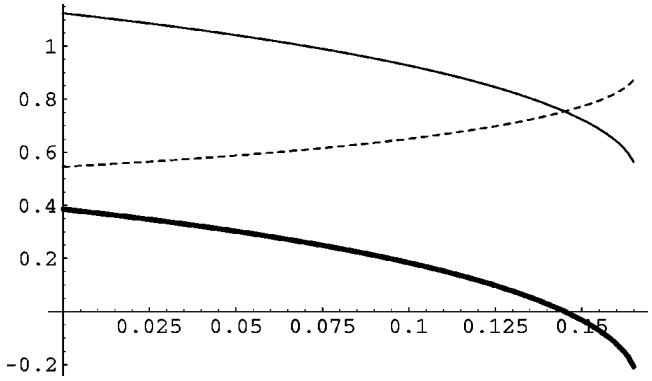

FIG. 2. The Kähler moduli $h^1(y)$ (dashed line), $h^2(y)$ (thick line), and $h^3(y)$ (thin line) for $0 \leqslant y \leqslant 0.17$. At $y=y_c \cong 0.145\,118$ the four-cycle associated to h^2 has collapsed. Note that this happens before the space–time singularity occurs at $y=y_s \cong 0.165\,949$.

The analytical values of a, $\mathcal{R}$ at $|y_e|$ in the example are

$$a(|\tilde{y}|)=\left(\frac{3}{7}\left(\frac{45}{49}+\frac{9}{49\sqrt{2}}\right)\right)^{1/6} \quad \text{and} \quad \mathcal{R}(|\tilde{y}|)=\frac{7}{3}\left(\frac{7}{3}\right)^{1/3}. \tag{32}$$

The analytical expressions of a, $\mathcal{R}$ at $|y_s|$ for our example are complicated and therefore we do not display them. It is, however, instructive to plot various quantities for our specific set of parameters.

We display the metric a in Fig. 1, the moduli h^1, h^2, h^3 which solve the generalized attractor equation in Fig. 2, and the space–time curvature $\mathcal{R}$ in Fig. 3 for $0 \leqslant y \leqslant 0.17$. Clearly, the cycle h^2 collapses at $|y_c|=|y_e| \simeq 0.145\,118...$. At this point the space–time is perfectly regular! Further down at $|y_s| \simeq 0.165\,949...$, where the cycle $h^2 \simeq -0.2527...$ is already negative, i.e., unphysical, the space–time has a naked singularity. *All this follows from the solution of the Einstein equation in the bulk under the condition that we have not yet put the second wall at some* $|\tilde{y}|$.

Note that the GST and HW models show the same qualitative behavior. This is as expected because the singular behavior is due to singularities in the function a and its derivatives.

From the point of view of supergravity nothing special happens along the line $T=U$ in the scalar manifold. A negative value of the scalar field $h^2=T-U$ is as good as a positive one since the metric on the moduli space at $h^2=0$ is regular and there is no reason to consider $T=U$ as a boundary. According to supergravity one can continue the solution to negative $T-U$ and finally

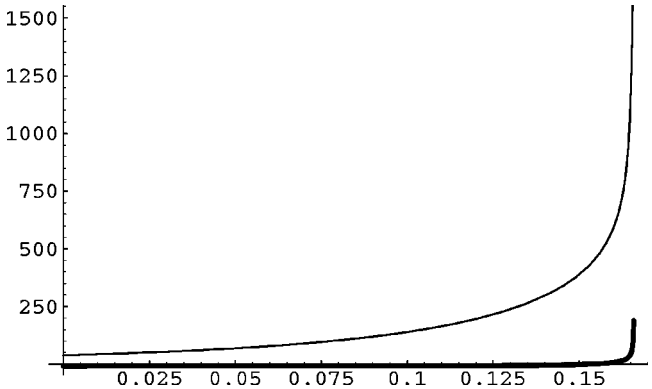

FIG. 3. The Ricci scalar $R(y)$ for $0 \leqslant y \leqslant 0.17$. The thick line refers to the GST model, the thin line to the HW model. In both cases the Ricci scalar diverges at $y=y_s \cong 0.165\,949$.

one encounters a space–time singularity at $|y|=|y_s|$. In order to avoid the singularity one has to put the second brane at some place $|\tilde{y}|<|y_s|$, but there is no distinguished choice of such $|\tilde{y}|$, nor a physical mechanism which excises the singularity. Since our solution is supersymmetric, it has zero energy, as shown in Ref. 2, independently of the position of the second brane.

This is different in M/string theory. In M-theory compactified on CY three-folds h^2 must be positive as a volume of the cycle. $T=U$ is a line of SU(2) gauge symmetry enhancement and $T-U$ is the associated Higgs field. Therefore the moduli space ends at $T=U$, and negative values of $T-U$ are related to positive values by the action of the generator of the Weyl group of SU(2), which is isomorphic to $\mathbf{Z}_2$. This takes a particularly familiar form when using the dual heterotic description, where $R:=\sqrt{T/U}$ is the radius of the sixth dimension. Therefore the Weyl twist acts as T-duality $R\to 1/R$ and SU(2) gauge symmetry enhancement occurs at the self-dual radius, $R=1$.[24,25] Since the gauge symmetry enhancement happens at $y_e<y_s$ it does not make sense to naively continue to $y>y_e$ and in this way the singularity is excised. Moreover, it may be natural to put the second brane precisely at the enhançon point $y=y_e$, defined by the equation

$$R(y_e)=1, \quad R^2(y)\equiv\frac{T(y)}{U(y)}=\frac{h^1+h^2}{h^1}. \tag{33}$$

In this case the $\mathbf{Z}_2$ orbifold symmetry is acting on y and the Weyl twist/T-duality transformation is acting on the moduli coincide. By putting the second wall at the enhançon point $y=y_e$ we enforce the physics to depend on $|T-U|$. When putting the second wall at a different place we would break T-duality spontaneously.

So far we have worked with the prepotential $STU+1/3U^3$ valid inside the Kähler cone. We found that both the resulting theory and the domain wall solutions were regular at $T=U$. However, we had to stop there because we reached a boundary and new physics occurred. One way to capture this new physics is to use the $T\leftrightarrow U$ symmetric form of the prepotential that was found in Ref. 26 in the context of heterotic string theory on $K3\times S^1$:

$$\mathcal{V}=STU+\tfrac{1}{3}U^3\theta(T-U)+\tfrac{1}{3}T^3\theta(U-T). \tag{34}$$

This is now valid for both positive and negative $T-U$. The build-in $T\leftrightarrow U$ symmetry reflects that negative $T-U$ is related to positive $T-U$ by a large gauge transformation. The resulting discontinuities are consequences of the SU(2) gauge symmetry enhancement and reflect the presence of extra massless states at $T=U$. They are analogs of the logarithmic branch cuts one encounters in four dimensions.[26,27]

Earlier we mentioned that it may be natural to put the second wall at the enhançon locus so that $|\tilde{y}|=|y_e|$. We can use the heterotic prepotential (34) to give an additional argument for this. Namely, the presence of the discontinuities in the prepotential automatically causes a δ-function singularity in the space–time geometry of a domain wall which tries to cross the boundary $T=U$. Therefore the enhançon itself acts like a source. Note that this kink singularity is different from the naked singularities of the supergravity solution that we want to excise.

To see this explicitly we first recall that singularities of the Ricci scalar come from singularities of a'', where $'$ is the derivative with respect to y and $a(y)=(\mathcal{V}(\tilde{h}(y)))^{1/3}$. Singularities in a'' can therefore descend from the θ-functions which are present in (34) through application of the chain rule. To work this out we need to be more precise about how $\mathcal{V}$ behaves as a function of $\tilde{T}-\tilde{U}$. Despite the presence of the θ-functions, $\mathcal{V}$ itself is actually continuous, but its derivative with respect to $\tilde{T}-\tilde{U}$ has a finite jump at $\tilde{T}=\tilde{U}$. Consequently the second derivative gives a δ-function: $\partial^2\mathcal{V}/\partial(\tilde{T}-\tilde{U})\partial(\tilde{T}-\tilde{U})=-((\tilde{T}+\tilde{U})/2)^2\delta(\tilde{T}-\tilde{U})+\text{finite}$. This contributes to $a'':a''=1/3\mathcal{V}(\tilde{h})^{-2/3}\mathcal{V}''+\text{finite}\simeq[\partial^2\mathcal{V}/\partial(\tilde{T}-\tilde{U})\partial(\tilde{T}-\tilde{U})][(\tilde{T}-\tilde{U})']^2+\text{finite}$, where we dropped terms, both additive and multiplicative, that stay finite for $\tilde{T}=\tilde{U}$. Since $\tilde{T}-\tilde{U}$ has $y=y_e$ as its only zero we find

$$a'' \sim -\left(\frac{\tilde{T}+\tilde{U}}{2}\right)^2 (\tilde{T}-\tilde{U})' \delta(y-y_e). \tag{35}$$

This would justify our assertion that it is natural to put the second wall at the enhancement point so that $|\tilde{y}|=|y_e|$. Any other position will break the T-duality symmetry.

By five-dimensional heterotic–M-theory duality we expect that the physics of SU(2) enhancement can be equivalently described in the M-theory language. In the context of Calabi–Yau compactifications SU(2) gauge symmetry enhancement (with $g \geqslant 0$ additional hypermultiplets) occurs when a divisor collapses into a (genus g) curve of A_1 singularities. In our case we know from the heterotic analysis that this curve must have genus 0. The Weyl group $\mathbf{Z}_2$ is encoded in the geometry through the local form of the A_1 singularity, $\mathbf{C}^2/\mathbf{Z}_2$. It seems that the Weyl reflections relating positive to negative $T-U$ in the heterotic language correspond to the ''elementary transformations'' discussed in Ref. 28. The extension of the range of moduli as done in (34) presumably corresponds to the procedure of gluing in a reflected Kähler cone at the enhancement boundary, which is described in Ref. 28.

In this article we have shown that there is a stringy mechanism which in certain cases excises space–time singularities which plague supergravity solutions. The mechanism is based on the fact that the stringy moduli space has a boundary on which the moduli space metric is finite. Whereas this boundary does not have a particular meaning in supergravity, so that solutions can be continued beyond until a space-time singularity occurs, one encounters new physics at the boundary in string theory, which makes the space–time singularity unphysical.

This observation leads to a variety of new issues which have to be addressed in the future. Most importantly one would like to understand in detail how the new M/string theory physics modifies space–time geometry and excises the singularity. Since SU(2) gauge symmetry enhancement occurs at the boundary, the situation resembles the enhançon geometry[12] and it would be interesting to explore how far this parallel goes. There are some further facts which might be relevant. In particular at the boundary the tensionless magnetic strings are present in addition to charged massless gauge bosons: it was shown in Ref. 9 that the magnetic string states with charges $\pm(1,-2,1)$ have a vanishing tension. Also one should take into account that the five-dimensional prepotential is purely cubic for five noncompact dimensions. However, in our domain wall setup the fifth dimension is compact and subject to an orbifold projection which reduces the number of unbroken supersymmetries. Thus the new stringy physics at the boundary might be more complex and more interesting than naively expected.

We are very grateful to I. Antoniadis, S. Dimopoulos, S. Kachru, A. Linde, E. Silverstein, L. Susskind, and N. Toumbas for useful discussions. T.M. would like to thank Y. Zunger for help in using Mathematica. This work was supported by NSF Grant No. PHY-9870115.

[19] Recently an extensive study of the flop transition in the context of supersymmetric domain walls was performed in Ref. 4.
[20] The space–time curvature may still be finite if $(\phi^x)'$, $a^{-2\gamma}$, $W_{,x}$ vanish at the singularity of the moduli space.
[21] The harmonic functions $H_I = c_I - d_I|y|$ used here and below are different from the harmonic functions in Ref. 2 and shown in Eq. (8) by a factor of 6. The first term c_I is arbitrary, so we will call it again c_I, the second term is $d_I = 1/3gq_I$. This normalization of the harmonic functions differs by a factor of 2 from the one used in Ref. 11 and more recently in Ref. 4. When comparing to the solution of the attractor equations given in Ref. 9 one should also rescale the charges.
[22] The divergences in a' cancel (for the generic case where $a \neq 0$) as required by the relation $a\dot{a} \sim W$ implied by very special geometry [see equation (6.19) in Ref. 2]. However, a'' is generically singular when $U = 0$.

(Received 2 January 2001; accepted for publication 13 February 2001)

We investigate aspects of the four-dimensional (4D) effective description of brane world scenarios based on warped compactification on anti-de Sitter space. The low-energy dynamics is described by visible matter gravitationally coupled to a ''dark'' conformal field theory. We give the linearized description of the 4D stress tensor corresponding to an arbitrary 5D matter distribution. In particular a 5D falling particle corresponds to a 4D expanding shell, giving a 4D interpretation of a trajectory that misses a black hole only by moving in the fifth dimension. Breakdown of the effective description occurs when either five-dimensional physics or strong gravity becomes important. In scenarios with a TeV brane, the latter can happen through the production of black holes near the TeV scale. This could provide an interesting experimental window on quantum black hole dynamics.

I. INTRODUCTION

It is an old idea that, as an alternative to compactification, the observed Universe instead lives on a brane in a higher-dimensional space. Such ''branification'' scenarios had however until recently been hard to realize, largely because of the difficulty of recovering four-dimensional gravitational dynamics. Two new approaches have changed this and at the same time suggested new views of the origin of the hierarchy of scales in physics. The first, pursued by Ref. 1, is a hybrid of branification and compactification, in which matter is confined to a brane and then large-radius compactification of the extra dimensions yields four-dimensional gravity at long distances.

A more recent approach utilizes warped compactifications to achieve effectively four-dimensional gravitational dynamics. An outline of such a picture has been provided by the RSII model.[2] This utilizes a ''Planck brane'' that serves as the boundary of five-dimensional anti-de Sitter space, and the curvature of anti-de Sitter space effectively ''localizes'' low-energy gravity to the brane. Related models are the RSI model[3] in which AdS is terminated above the horizon by a ''negative tension brane,'' and the model of Lykken and Randall[4] in which visible sector matter lives on a probe brane. None of these are fundamental pictures as they do not provide a microscopic dynamics for the Planck, ''negative-tension,'' and probe branes, but recent work in string theory has begun to provide descriptions of such objects. In particular Ref. 5 has given a geometrical realization of an object akin to a Planck brane, and Refs. 6, 7 have provided geometrical realizations of objects similar to ''negative-tension'' branes. At the same time, these models have been connected to renormalization group flows in four-dimensional gauge theories through the AdS/CFT correspondence.

In providing a new view of the hierarchy problem, either through large radius or other geo-

metrical mechanisms, these scenarios suggest the exciting possibility that quantum gravity effects could be observed at scales far below the usual Planck scale, and perhaps even near the TeV scale. They also suggest the possibility of interesting new gravitational phenomena, particularly in scenarios with infinite extra dimensions (e.g., RSII) and with nontrivial curvature and horizon structure of the resulting spacetime.

Some aspects of this gravitational dynamics has been studied in Refs. 8–11. In particular, in Ref. 11 linearized gravity in the RSII scenario was studied, and both prescriptions for computing propagators and a general picture of the structure of black holes bound to the Planck brane were given. The latter were found to be pancake-like objects, whose transverse sizes are logarithmically smaller than their four-dimensional Schwarzschild radii. Cosmology of these scenarios has also been extensively studied (see, e.g., Refs. 12–15) with suggestions that they offer new approaches to the cosmological constant problem.[16–25]

Many open questions remain, however, in the RSII scenario and its variants. One set of questions centers on the four-dimensional representation of the five-dimensional dynamics. In particular, localization of gravity is not complete and in the RSII scenario there is a gapless spectrum of analogs to Kaluza–Klein modes that are weakly coupled to excitations on the brane. Therefore a four-dimensional low-energy effective field theory does not follow from the usual Kaluza–Klein reasoning, and so one challenge has been to deduce what this effective theory is. It has previously been argued[5,26,27,11,28] that the bulk dynamics can be replaced via the AdS/CFT correspondence by a conformal field theory on the brane, and this suggests an answer, namely that the effective field theory is provided by conformal field theory coupled to the visible sector solely through gravity. In this paper we amplify on this statement, clarify the role of the cutoff, which in RSII is expected to be at the AdS radius scale, and provide one entry in the map between the five-and four-dimensional descriptions by computing a linearized approximation to the four-dimensional stress tensor corresponding to an arbitrary five-dimensional matter distribution. This stress tensor is both conserved and traceless. Corresponding statements should hold for other warped compactification scenarios, using realizations of the AdS/CFT correspondence in more general warped compactifications.

Given the novelties of the gravitational dynamics, for example the above picture of black holes, one is also prodded to investigate whether this field theory has unusual properties. For example, consider the following question:[11] suppose that a particle is launched towards a black hole on the brane with zero four-dimensional impact parameter, but such that it follows a trajectory that misses the black hole through the fifth-dimension. Does this correspond in the four-dimensional perspective to matter that enters a black hole and exists the opposite side? (This question was asked by L. Susskind.) This would surely be a radical departure from usual four-dimensional effective theory!

However, standard AdS/CFT reasoning suggests a more mundane answer. In the UV/IR correspondence outlined in Ref. 29, a state deep in AdS corresponds to a state in the far infrared of the corresponding field theory. This suggests that a falling particle corresponds to a state that spreads. Indeed, using our results for the stress tensor we find that in the four-dimensional description, the falling particle corresponds to an expanding shell of CFT matter. The condition that the five-dimensional trajectory misses the black hole becomes the four-dimensional statement that the shell misses by expanding to a size larger than the black hole.

It is important to emphasize that the CFT description is an effective description, and another interesting set of questions therefore regards breakdown of the effective field theory and the question of whether strong gravitational dynamics—for example black hole formation—is observable at scales far below the four-dimensional Planck scale. We investigate the scales at which scattering experiments would be expected to encounter dynamics beyond the four-dimensional description in the three scenarios outlined, RSII, the probe brane scenario, and terminated AdS. In particular, in the latter scenario with a certain set of assumptions it appears possible to create black holes that decay into observable matter in scattering experiments in the vicinity of the TeV scale. This exciting possibility deserves more theoretical investigation; in particular through construction of concrete models with the required properties.

In an outline, in Sec. II of this paper we discuss conformal field theory as the 4D low-energy effective theory of RSII. In Sec. III we computes the linearized effective stress tensor of bulk matter, as well as solving a corresponding simpler problem of the 4D scalar profile of a five-dimensional scalar source. We also elaborate on the black hole flyby scenario mentioned above. In Sec. IV we then discuss questions of the scale of breakdown for the 4D effective theories, and of the possibility of low-energy black hole production. In Sec. V we close with conclusions.

We have been informed that in related work in progress[30] issues of black hole production and corrections to the effective theory in TeV brane scenarios are also addressed.

II. THE EFFECTIVE THEORY OF RSII

We begin with a quick review of the RSII scenario, and of its transcription into conformal field theory via the AdS/CFT correspondence[26,27,11] in which we will offer some refinements. The upshot of this discussion is that the low-energy effective field theory for the RSII scenario consists of visible 4D matter gravitationally coupled to dark matter described by a cutoff CFT. In subsequent sections we will explore consequences and extensions of this picture.

The RSII scenario is of course just an example of a much broader class of warped compactifications, which have recently been widely studied both in the context of model building, and in the context of string theory and the correspondence between renormalization group flows and supergravity geometries. While many of our comments will be made within the framework of this greatly simplified example (for which the only known microscopic construction is Ref. 5), corresponding arguments should apply to other models including those with stringy realizations. In particular in later sections we will also comment on other variants of the RSII scenario (those with a terminated AdS space or with a probe or ''TeV'' brane) and their possible stringy realizations.

We therefore begin by considering the geometry with a single ''Planck'' brane. Although our central interest is dimension $d=4$, most of the relevant formulas easily generalize and will be given in an arbitrary dimension. We assume that matter fields, denoted by ψ, live only on this Planck brane. The action is

$$S=\int d^{d+1}X\sqrt{-G}(M^{d-1}\mathcal{R}-\Lambda)+\int d^{d}x\sqrt{-\gamma}[\mathcal{L}(\gamma,\psi)-\tau] \tag{2.1}$$

where G, M, $\mathcal{R}$, and Λ are the $d+1$-dimensional metric, Planck mass, curvature scalar, and cosmological constant, respectively, γ is the induced metric on the Planck brane, $\mathcal{L}$ is the action of matter on the brane, and τ is the brane tension. The bulk AdS metric is

$$ds^2=\frac{R^2}{z^2}(dz^2+dx_d^2), \tag{2.2}$$

in $d+1$-dimensional coordinates $X=(x,z)$; here dx_d^2 is the d-dimensional Minkowski metric and the AdS radius R is given by

$$R=\sqrt{\frac{-d(d-1)M^{d-1}}{\Lambda}}. \tag{2.3}$$

The brane tension is fine tuned to the value

$$\tau=\frac{4(d-1)M^{d-1}}{R}, \tag{2.4}$$

in order to maintain a Poincaré invariant Planck brane. We may take the Planck brane to reside at an arbitrary elevation $z=\rho$.

As argued in Refs. 3, 2, 11, at a long distances compared to R, the gravitational dynamics appears d-dimensional. However, there is also a gapless spectrum of weakly-coupled bulk modes.

An obvious question is what serves as a d-dimensional low-energy effective field theory describing the dynamics. Within string theory, an answer to this is provided by the conjectured AdS/CFT correspondence.[26,27,11]

To see this, recall that the AdS/CFT correspondence equates the $d+1$-dimensional bulk gravity (or more precisely, string theory) functional integral to a generating function in the CFT. A regulator is provided by excluding the AdS volume outside $z=\rho$. Suppose that we put the fluctuating metric in a gauge such that near this boundary,

$$ds^2=\frac{R^2}{z^2}[dz^2+g_{\mu\nu}(z,x)dx^\mu dx^\nu]. \tag{2.5}$$

The induced metric γ on the boundary $z=\rho$ is thus

$$ds_d^2=\frac{R^2}{\rho^2}g_{\mu\nu}(\rho,x)dx^\mu dx^\nu\equiv\gamma_{\mu\nu}dx^\mu dx^\nu. \tag{2.6}$$

Define the functional integral over bulk metrics G for fixed boundary metric γ as

$$Z[\gamma,\rho]=\int_\gamma \mathcal{D}G e^{i\int d^{d+1}X\sqrt{-G}(M^{d-1}\mathcal{R}-\Lambda)+2iM^{d-1}\int d^dx\sqrt{-\gamma}K}, \tag{2.7}$$

where K is the extrinsic curvature of the boundary. The AdS/CFT correspondence then states that for small fluctuations about the flat boundary geometry, $g_{\mu\nu}=\eta_{\mu\nu}+h_{\mu\nu}$,

$$\lim_{\rho\to 0} e^{-iS_{\rm grav}[\gamma]}Z[\gamma,\rho]=\langle e^{i\int h_{\mu\nu}T^{\mu\nu}}\rangle_{\rm CFT}. \tag{2.8}$$

Here $S_{\rm grav}$ is a counterterm action formed purely from the induced metric γ,[31,32] in the case $d=4$

$$S_{\rm grav}=\int d^4x\sqrt{-\gamma}\left[\frac{6M^3}{R}+\frac{RM^3}{2}\mathcal{R}(\gamma)-2M^3R^3\log(\rho)\mathcal{R}_2(\gamma)\right], \tag{2.9}$$

where

$$\mathcal{R}_2=-\tfrac{1}{8}\mathcal{R}_{\mu\nu}\mathcal{R}^{\mu\nu}+\tfrac{1}{24}\mathcal{R}^2. \tag{2.10}$$

While the AdS/CFT correspondence was originally stated in terms of small fluctuations, a natural assumption is that it extends to more general boundary geometries. We therefore assume that the CFT generating functional can be written as a functional integral over the CFT degrees of freedom, which we collectively denote χ, in the background metric $g_{\mu\nu}$, and that the correspondence thus becomes

$$\lim_{\rho\to 0} e^{-iS_{\rm grav}[\gamma]}Z[\gamma,\rho]=\int \mathcal{D}\chi\, e^{i\int d^dx\sqrt{-g}\mathcal{L}_{\rm CFT}(g_{\mu\nu},\chi)}. \tag{2.11}$$

Following the ideas of the UV/IR correspondence,[29] we connect this with the RS scenario by extending the conjecture to a statement with a finite cutoff, and assume that

$$e^{-iS_{\rm grav}[\gamma]}Z[\gamma,\rho]=\int [\mathcal{D}\chi]_\rho e^{i\int d^dx\sqrt{-g}\mathcal{L}_{\rm CFT}(g_{\mu\nu},\chi)}, \tag{2.12}$$

where on the RHS ρ provides the cutoff scale for the CFT. While a precise description of this cutoff in the language of the CFT is not known, for the sake of intuition one may imagine that it is for example given by only considering fluctuations on scales Δx such that

$$g_{\mu\nu}\Delta x^\mu \Delta x^\nu > \rho^2. \tag{2.13}$$

In particular, notice that since the only dependence of the CFT on the scale of the metric is through the cutoff, this implies

$$\int [\mathcal{D}\chi]_\rho e^{i\int d^d x\sqrt{-g}\mathcal{L}_{\rm CFT}(g_{\mu\nu},\chi)} = \int [\mathcal{D}\chi]_R e^{i\int d^d x\sqrt{-\gamma}\mathcal{L}_{\rm CFT}(\gamma_{\mu\nu},\chi)}, \tag{2.14}$$

where on the RHS the cutoff is thought of as restricting to fluctuations with

$$\gamma_{\mu\nu}\Delta x^\mu \Delta x^\nu > R^2. \tag{2.15}$$

From (2.12) and (2.14) we therefore see that the integral over the bulk modes can be replaced by a correlator in the CFT, as originally proposed in Refs. 26, 27, 11, with a cutoff given by R. Specifically, d-dimensional dynamics is summarized by a functional integral of the form

$$\int [\mathcal{D}\gamma\,\mathcal{D}\psi\,\mathcal{D}\chi]_R e^{i\int d^d x\sqrt{-\gamma}[(1/2)\mathcal{L}(\gamma,\psi)+\mathcal{L}_{\rm CFT}(\gamma,\chi)+\mathcal{L}_{\rm grav}(\gamma)-\tau]}(\cdots). \tag{2.16}$$

For consistency with the cutoff (2.15) the other modes also presumably should have a corresponding cutoff, as indicated. One consistency check on this approach is cancellation of the brane tension τ by the corresponding term in $S_{\rm grav}$, using (2.4). This indicates that the low-energy effective field theory for the system, up to the scale determined by R, is the theory of brane-matter gravitationally coupled to ''dark'' matter described by the CFT. The d-dimensional Planck mass follows from the d-dimensional version of (2.9), and is given by

$$M_d^{d-2} = \frac{RM^{d-1}}{d-2}. \tag{2.17}$$

III. EFFECTIVE STRESS TENSOR OF BULK MATTER

We now investigate some of the consequences of the above identification of the CFT as the low-energy effective field theory for the RSII scenario. In particular, we start by giving an entry in the bulk to boundary dictionary, by computing a linearized approximation to the CFT stress tensor corresponding to a perturbation in the bulk. We then investigate the particular case of a particle freely falling into the bulk.

Using this calculation, we discuss a test of the AdS/CFT correspondence and of our effective description of RSII: suppose that we shoot a particle towards a black hole with a zero 4D impact parameter, but such that it will miss the black hole through the z direction. How does a 4D observer understand the failure of the black hole to absorb the particle?

A. General results

In this subsection we turn to the problem of deriving the d-dimensional brane stress tensor that corresponds to a general $d+1$-dimensional bulk matter distribution. In general this is a difficult problem, requiring a solution of the bulk Einstein equations, so we will only give a linear treatment.

The basic strategy is as follows. Reference 11 computes the linearized bulk gravitational field of a general matter perturbation. This in particular gives the linearized metric and therefore Einstein tensor induced on the brane. We can then read off the matter stress tensor from the right hand side of the d-dimensional Einstein equations along the brane.

Although the resulting stress tensor has a number of special properties, we have not yet found a particularly illuminating expression for it. However, in the next subsection we specialize to the case of a particle falling into the bulk; in the long distance approximation the corresponding stress tensor simplifies substantially.

In studying gravitational perturbations it proves convenient to introduce the proper ''height'' coordinate y, given by

$$z = \mathrm{Re}^{y/R}, \tag{3.1}$$

in terms of which the linearized metric takes the form

$$ds^2 = dy^2 + e^{-2y/R}(\eta_{\mu\nu} + h_{\mu\nu})dx^\mu dx^\nu. \tag{3.2}$$

Equations (3.20), (3.24), and (3.26) of Ref. 11 then give the linearized bulk Einstein equations in terms of the metric perturbation $\overline{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}h\eta_{\mu\nu}$ as

$$\partial_y(e^{-2y/R}\partial y h) = \frac{1}{(d-1)M^{d-1}}[T^\mu_\mu - (d-2)e^{-2y/R}T^y_y], \tag{3.3}$$

$$\partial_y \partial^\nu h_{\mu\nu} = \partial_y \partial_\mu h + \frac{T^y_\mu}{M^{d-1}}, \tag{3.4}$$

and

$$\Box\overline{h}_{\mu\nu} = \frac{\eta_{\mu\nu}}{2}e^{yd/R}\partial_y(e^{-yd/R}\partial_y h) + e^{2y/R}(-\eta_{\mu\nu}\partial^\lambda\partial^\sigma\overline{h}_{\lambda\sigma} + \partial^\lambda\partial_\mu\overline{h}_{\nu\lambda} + \partial^\lambda\partial_\nu\overline{h}_{\mu\lambda}) - \frac{e^{2y/R}}{M^{d-1}}T_{\mu\nu}. \tag{3.5}$$

The right hand side of (3.5) is determined by the stress tensor and the solutions of Eqs. (3.3), (3.4). This equation can then be solved for $h_{\mu\nu}$ using the scalar Neumann Green function Δ_{d+1}, satisfying

$$\Box\Delta_{d+1}(X,X') = \frac{\delta^{d+1}(X-X')}{\sqrt{-G}},$$

$$\partial_y\Delta_{d+1}(X,X')|_{y=0} = 0, \tag{3.6}$$

and which was derived in Ref. 11. In the present situation we need the retarded propagator rather than the Feynman propagator; the relation between these and approximate expressions for them are given in the Appendix. The resulting expression for the metric has three terms arising from the three lines of (3.5). However, the second term is inessential as a short calculation shows it to be pure gauge on the brane. Therefore its contribution drops when we compute the Einstein tensor on the brane.

One must also specify boundary conditions at the brane; in the case of a surface stress tensor,

$$T^{\mathrm{brane}}_{\mu\nu} = S_{\mu\nu}(x)\delta(y), \quad T^{\mathrm{brane}}_{yy} = T^{\mathrm{brane}}_{y\mu} = 0, \tag{3.7}$$

these become

$$\partial_y(h_{\mu\nu} - \eta_{\mu\nu}h)_{|y=0} = -\frac{S_{\mu\nu}(x)}{2M^{d-1}}. \tag{3.8}$$

In order to simplify the resulting expression for the metric, it is useful to rewrite the scalar Green's function in terms of a new function F as

$$\Delta_{d+1}(y,x;y',x')=e^{(d-2)y'/R}\partial_{y'}[e^{-(d-2)y'/R}F_{y'}(y;x-x')]. \tag{3.9}$$

One nice property of the redefinition is immediate: one readily checks that

$$\int_0^\infty dy'\, e^{(2-d)y'/R}\Delta_{d+1}(X,X')=-F_0(y;x-x') \tag{3.10}$$

satisfies the equation for the d-dimensional Green's function, and so

$$F_0(y;x-x')=-\Delta_d(x,x'). \tag{3.11}$$

Using this and integrating by parts gives the contribution to $\overline{h}_{\mu\nu}$ from the first line in (3.5) as

$$\overline{h}^{(1)}_{\mu\nu}(x,y)=\frac{\eta_{\mu\nu}}{2(d-1)M^{d-1}}\int dV'\,\partial_{y'}F_{y'}(y;x-x')[e^{2y/R}T^\mu_\mu(X')-(d-2)T^y_y(X')]. \tag{3.12}$$

Equation (3.12) combines with the terms induced by the stress tensor and the surface stress (3.7) to give a complete expression of the form

$$\begin{aligned}\overline{h}_{\mu\nu}=&-\frac{1}{M^{d-1}}\int dV'\,e^{dy'/R}\partial_{y'}[e^{-(d-2)y'/R}F_{y'}(y;x-x')]T_{\mu\nu}(X')\\&+\frac{\eta_{\mu\nu}}{2(d-1)M^{d-1}}\int dV'\,\partial_{y'}F_{y'}(y;x-x')[e^{2y/R}T^\mu_\mu(X')-(d-2)T^y_y(X')]+\overline{h}^S_{\mu\nu}+\overline{h}^{\text{gauge}}_{\mu\nu}.\end{aligned} \tag{3.13}$$

Here $\overline{h}^{\text{gauge}}_{\mu\nu}$ is the piece that is pure gauge on the brane, mentioned above, and $\overline{h}^S_{\mu\nu}$ is the contribution due to the surface stress (we will see an example of this shortly).

For simplicity consider a purely bulk distribution ($S_{\mu\nu}=0$). The four-dimensional effective stress tensor is readily computed from (3.13) via Einstein's equations,

$$T^{\text{eff}}_{\mu\nu}=2M_d^{d-2(d)}\mathcal{G}^\mu_\nu=-\frac{RM^{d-1}}{d-2}(\partial^2\overline{h}_{\mu\nu}+\eta_{\mu\nu}\partial^\alpha\partial^\beta\overline{h}_{\alpha\beta}-\partial_\mu\partial^\alpha\overline{h}_{\alpha\nu}-\partial_\nu\partial^\alpha\overline{h}_{\alpha\mu})\big|_{y=0}, \tag{3.14}$$

with $\overline{h}_{\mu\nu}$ given by (3.13). The contribution of $\overline{h}^{\text{gauge}}_{\mu\nu}$ drops out.

One may expand out the expression (3.14) to write it explicitly in terms of the bulk stress tensor $T_{\mu\nu}$:

$$\begin{aligned}T^{\text{eff}}_{\mu\nu}=\frac{R}{d-2}\int dV'\Big\{&e^{dy'/R}\partial_{y'}[e^{-(d-2)y'/R}F_{y'}(0;x-x')](\partial^2T_{\mu\nu}+\eta_{\mu\nu}\partial^\alpha\partial^\beta T_{\alpha\beta}-\partial^\alpha\partial_\mu T_{\alpha\nu}\\&-\partial^\alpha\partial_\nu T_{\alpha\mu})+\frac{1}{d-1}\partial_{y'}F_{y'}(0;x-x')(\partial_\mu\partial_\nu-\eta_{\mu\nu}\partial^2)[e^{2'/R}T^\mu_\mu-(d-2)T^y_y]\Big\}.\end{aligned} \tag{3.15}$$

Note that $T^{\text{eff}}_{\mu\nu}$ satisfies two important properties. First, from its construction and the Bianchi identities, it is conserved:

$$\partial^\mu T^{\text{eff}}_{\mu\nu}=0. \tag{3.16}$$

Second, one may readily verify that it is traceless,

$$\eta^{\mu\nu}T^{\rm eff}_{\mu\nu}=0, \tag{3.17}$$

which accords nicely with its interpretation as arising from a conformal field theory on the brane. Indeed, this easily follows from the (yy) Einstein equation, which states (cf. Ref. 11, Eq. (3.14)]

$${}^{(d)}\mathcal{R}+\frac{(d-1)}{R}\partial_y h\,\epsilon(y)=-\frac{T^y_y}{M^{d-1}}, \tag{3.18}$$

where $\epsilon(y)$ is a step function. On the brane $\partial_y h$ and T^y_y vanish [the former by (3.8)], implying ${}^{(d)}\mathcal{R}(y=0)=0$, and thus $T^{\rm eff}=0$.

Note that in the above discussion we have said nothing about bending of the brane, which was described in Refs. 10, 11. The reason for this is that we are interested in the metric on the brane, and for this it is best to work in a gauge where the brane is straight. In Ref. 11 the resulting metric was computed by first working in the bent gauge, and then transforming back, but an equivalent result is found by working directly in the straight gauge. (For purposes of measurements on the brane, the apparent breakdown of the linearized approximation at $y\to\infty$ may be ignored; for another treatment of these matters see Ref. 33.)

B. Matter on the brane

In order to illustrate this equivalence—and because the result will be used in the next subsection—we will compute the linearized metric and effective stress tensor due to matter on the brane in this approach. Specifically, suppose that there is a surface stress of the form (3.7), but that otherwise $T_{IJ}=0$. The field equations (3.3)–(3.5) should then be solved subject to the boundary conditions (3.8). By tracing the latter can be rewritten in terms of $\overline{h}$, and take the form

$$\partial_y\overline{h}_{\mu\nu}|_{y=0}=-\frac{1}{2M^{d-1}}\left[S_{\mu\nu}-\frac{\eta_{\mu\nu}}{2(d-1)}S\right]. \tag{3.19}$$

By Green's theorem these give a contribution

$$\overline{h}^S_{\mu\nu}(X)=-\frac{1}{2M^{d-1}}\int d^dx'\,\Delta_{d+1}(X;0,x')\left[S_{\mu\nu}(x')-\frac{\eta_{\mu\nu}}{2(d-1)}S(x')\right] \tag{3.20}$$

to the metric. As above, the second term on the RHS of (3.5) is pure gauge, and the third term vanishes, so the remaining contribution comes from the first term. The trace equation (3.3) and the boundary condition (3.8) imply

$$\partial_y h=\frac{e^{2y/R}}{2(d-1)M^{d-1}}S, \tag{3.21}$$

which gives a contribution

$$\overline{h}^{(1)}_{\mu\nu}=\frac{\eta_{\mu\nu}(2-d)}{4(d-1)RM^{d-1}}\int d^dx'\,S(x')\int dy'\,e^{(2-d)y/R}\Delta_{d+1}(X,X'). \tag{3.22}$$

The integral over y' is eliminated by using the identities (3.10) and (3.11), and the combined expressions (3.20) and (3.22) yield

$$\overline{h}_{\mu\nu}(x)=-\frac{1}{2M^{d-1}}\int d^dx'\left\{\Delta_{d+1}(x,0;x',0)S_{\mu\nu}(x')-\eta_{\mu\nu}\left[\Delta_{d+1}(x,0;x',0)-\frac{(d-2)}{R}\Delta_d(x,x')\right]\frac{S^\lambda_\lambda(x')}{2(d-1)}\right\}, \tag{3.23}$$

in agreement with Ref. 11. In particular, this expression may be evaluated for a stress tensor corresponding to a point mass at rest on the brane at $\mathbf{x}=0$,

$$T_{tt}=2m\,\delta^{d-1}(x)\,\delta(y). \tag{3.24}$$

[The extra factor of two is present because of the orbifold boundary conditions, and compensates the 1/2 in (2.16).] Using the long-distance expansion of the propagator,[11]

$$\Delta_{d+1}(x,0;x',0)=\frac{d-2}{R}\,\Delta_d(x,x')\left[1+\left(\frac{R^{d-2}}{r^{d-2}}\right)\right], \tag{3.25}$$

this gives the $d=4$ expression

$$\overline{h}_{tt}=\frac{m}{2\pi RM^3 r}\left[1+\mathcal{O}\left(\frac{R^2}{r^2}\right)\right],\quad \overline{h}_{ij}=\mathcal{O}\left(\frac{mR}{M^3r^3}\right). \tag{3.26}$$

C. The falling particle

The above expression (3.15) for the stress tensor appears rather complicated, but simplifies significantly in the long-distance limit. To illustrate this, we compute the effective stress tensor of a particle falling into the bulk. (The corresponding approximate metric has also been computed by Gregory, Rubakov, and Sibiryakov in Ref. 34.) This case will also apply to our later discussion of black hole flybys; by performing a boost along the brane we get a trajectory that can sail behind a black hole through the extra dimension.

Concretely, consider a particle of mass m that is stuck to the brane at $\mathbf{x}=0$ until time $t=0$ and then released and allowed to freely fall into the bulk. The trajectory for $t>0$ is easily seen to be given by the equation

$$z^2-t^2=R^2. \tag{3.27}$$

For $t<0$ the only nonzero component of the stress tensor is given by (3.24). For $t>0$ the stress tensor is given by the general formula

$$T_{IJ}=m\,\frac{dX_I}{d\tau}\,\frac{dX_J}{dt}\,\frac{\delta^{d-1}(x-x(t))\,\delta(y-y(t))}{\sqrt{-G}}, \tag{3.28}$$

which in the present case gives nonvanishing components,

$$T_{tt}=me^{(d-2)y/R}\,\delta^{d-1}(\mathbf{x})\,\delta(y-y(t)), \tag{3.29}$$

$$T_{yy}=m\,\frac{t^2}{R^2}\,e^{(d-2)y/R}\,\delta^{d-1}(\mathbf{x})\,\delta(y-y(t)), \tag{3.30}$$

and

$$T_{ty}=-m\,\frac{t}{R}\,e^{(d-2)y/R}\,\delta^{d-1}(\mathbf{x})\,\delta(y-y(t)). \tag{3.31}$$

Therefore the contribution to the metric from the trajectory for $t<0$ is a special case of the general surface-stress result of the preceding subsection, (3.23), with

$$S_{tt}=2m\,\delta^{d-1}(x)\,\theta(-t),\quad S_{\mu i}=0. \tag{3.32}$$

The contribution to the metric from the second half of the trajectory is given by our formula (3.13). Specifically, rewriting the $t>0$ stress tensor as

$$T_{IJ}=\mathcal{S}_{IJ}(t,y)\,\delta(y-y(t)), \tag{3.33}$$

we find

$$\overline{h^{>}_{\mu\nu}}(x)=-\frac{1}{M^{d-1}}\int_{t'>0}d^dx'\left\{\partial_y[e^{-(d-2)y/R}F_y(0;x-x')]\mathcal{S}_{\mu\nu}(x',y)\right.$$
$$\left.-\frac{\eta_{\mu\nu}}{2(d-1)}e^{-(d-2)y/R}\partial_yF[\mathcal{S}^\mu_\mu-(d-2)e^{-2y/R}\mathcal{S}^y_y]\right\}\Bigg|_{y=y(t)}+\overline{h}^{\text{gauge}}_{\mu\nu}. \tag{3.34}$$

The expression for the effective stress tensor follows directly from computing the Einstein tensor (3.14) from these expressions for the linearized metric. In order to gain some intuition for this expression, consider the approximation of distances and times much greater than the AdS scale R, which we've seen is the cutoff for the effective theory:

$$x^2-t^2\gg R^2, \tag{3.35}$$

In this limit the Green's function simplifies dramatically (see the Appendix),

$$F_y(0;x-x')\simeq\frac{1}{2\pi}\,\delta(z^2+(x-x')^2)\,\theta(t-t'), \tag{3.36}$$

and the trajectory (3.27) becomes

$$z=\mathrm{Re}^{y/R}\simeq t. \tag{3.37}$$

Defining $r=|x|$, in $d=4$ the approximate metric is then

$$\overline{h}_{\mu\nu}\simeq\frac{m}{2\pi M^3Rr}\,\delta^t_\mu\delta^t_\nu, \tag{3.38}$$

for $r>t$, and

$$\overline{h}_{\mu\nu}\simeq\frac{m}{2\pi M^3R}\left[\left(\frac{3}{2t}-\frac{\mathbf{x}^2}{2t^3}\right)\delta^t_\mu\delta^t_\nu+\frac{t^2-\mathbf{x}^2}{4t^3}\,\eta_{\mu\nu}\right], \tag{3.39}$$

for $r<t$, as in Ref. 34. A straightforward computation shows that the Einstein tensor of both of these metrics vanishes! Thus the effective stress tensor is concentrated on the surface where they match, $r=t$. This stress tensor is

$$T^{\text{eff}}_{\mu\nu}\simeq\frac{m}{4\pi t^2}\,\delta(t-r)u^\mu u^\nu, \tag{3.40}$$

where $u^\mu=x^\mu/t$.

The effective stress tensor of the conformal field theory configuration describing a falling particle is thus concentrated on a thin shell of radius r which expands outward with time, $r=t$. We can estimate the thickness of the shell by investigating the size of the leading corrections in the limit (3.35). One readily sees that the metric is corrected at order $R^2/t^2,R^2/r^2$, both due to corrections to the trajectory and to the Green's function. This suggests that the thickness of the shell of CFT matter is the expected $\mathcal{O}(R)$, the cutoff length scale.

This spreading behavior appears to be quite generic, as one might expect from the IR/UV duality of the AdS/CFT correspondence. Another example of this behavior is provided by a falling charged particle coupled to a bulk gauge field, as investigated in Ref. 35. Indeed, an even simpler example is provided by a falling particle coupled to a bulk scalar field. Specifically, consider a Lagrangian,

$$S=-\int dV\frac{1}{2}(\nabla\phi)^2-q\int d\tau\,\phi(X(\tau)), \tag{3.41}$$

with a coupling of a bulk scalar field ϕ to a particle of scalar charge q falling along a trajectory $X(\tau)$. This determines the scalar field,

$$\phi(X)=q\int d\tau\,\Delta_{d+1}(X,X(\tau)). \tag{3.42}$$

If we assume that the particle again follows the trajectory (3.27) and works at large distances as compared to R and with $d=4$, then the field at $y=0$ takes the approximate form

$$\phi(x,t)\simeq-\frac{q}{2\pi R}\left[\frac{1}{r}\,\theta(r-t)+\frac{4R^2t}{(r^2-t^2)^2}\,\theta(t-r)\right]\left[1+\mathcal{O}\left(\frac{R}{r}\right)^2\right]. \tag{3.43}$$

If we compute the effective source, $J=\Box_4\phi$, we find it vanishes except at $r=t$. Again, subleading $\mathcal{O}(R)$ corrections appear to smooth this into a shell of thickness R.

Note that similar behavior was found by Horowitz and Itzhaki,[36] who investigated the CFT stress tensor corresponding to a particle moving geodesically in the full, infinite AdS. This work also found a shell expanding outward at the speed of light. Indeed, the two calculations are directly related in the infrared limit, as discussed in Appendix B.

This behavior can also be understood directly in terms of the CFT using an argument of Coleman and Smarr,[37] which shows that a stress tensor that is conserved, traceless, and has positive energy density will be localized on the light cone. The basic idea for the proof is to show that the average squared energy radius.

$$\overline{r}(t)^2=\frac{\int d^3x\,r^2T_{00}}{\int d^3x\,T_{00}}, \tag{3.44}$$

satisfies

$$\frac{d^2\overline{r^2}}{dt^2}=2, \tag{3.45}$$

from which it immediately follows that a configuration initially localized at a point will expand on the light cone. Reference 36 argues that the argument extends even to the quantum case, where the energy density may be negative, as long as the total energy is positive.

These results neglect the backreaction of gravity on the outgoing shell. It would be interesting to understand what dynamics results when strong self gravitation of the shell is included.

Vanishing of the Einstein tensor for the metric (3.39) at first sight leads to another puzzle. Specifically, suppose we consider a ''bounce'' trajectory, where the particle follows the trajectory (3.27) for all time. The calculation of the metric above is modified by extending to the trajectory for $t<0$, but still yields a stress tensor that vanishes everywhere. This contradicts our expectation of a shell that collapses and then reexpands. However, note that this computation is not complete. The z coordinates only cover the region outside the AdS horizon, and thus this calculation would miss the contribution of the piece of the trajectory behind the past horizon. If this is not included, energy-momentum conservation is violated at the horizon, and consequently gravity cannot be consistently coupled. A correct calculation includes this piece, but also requires more information about the structure of the Green's function. Specifically, one needs to know what boundary conditions it obeys in the far past. In order to make predictions in the RSII scenario, one needs to understand the physics determining the boundary conditions at the past horizon. Correspondingly, in CFT language on needs to know in what state the CFT sector began.

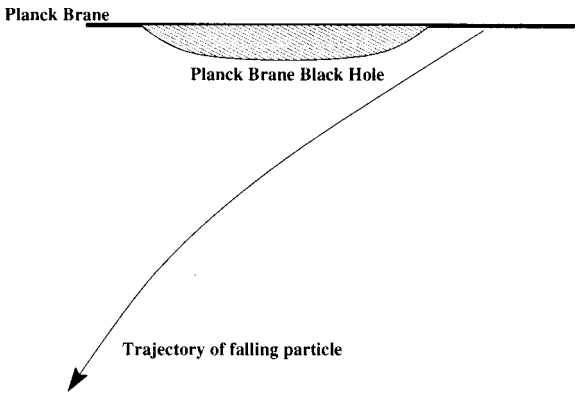

FIG. 1. A particle trajectory that misses a black hole on the brane because of its motion in the extra dimension.

D. Black hole flybys

We now have the necessary tools to discuss particles flying past black holes through the bulk; for simplicity we discuss the four-dimensional case. Specifically, suppose that there is a black hole of mass m located at $\mathbf{x}=0$ and that a particle is shot at it with zero four-dimensional impact parameter, but is allowed to fall in z long enough that it misses the black hole by passing it in the z direction (see Fig. 1). How does a four-dimensional observer describe such an experiment, and in particular does one see radical departures from usual gravitational dynamics, such as matter entering and then escaping a 4D event horizon?

The answer to the latter question is, of course, no. Indeed, a black hole with mass and 4D Schwarzschild radius m has a horizon extending to $z_h \sim m$ in the bulk picture. In order for the particle to miss the black hole, the particle must have $z \gg m$ when $\mathbf{x}=0$. As we have seen above, in the CFT description the particle corresponds to a shell of CFT matter. If it has reached $z \gg m$ by the time it reaches the black hole at $\mathbf{x}=0$, then the shell has expanded to size $r \gg m$ by the time it has reached the black hole, and is continuing to expand outward. No novel physics need be invoked to explain why the shell is not absorbed by the black hole. (Note, however, that a small piece of the shell may be absorbed by the black hole; a quantum treatment of the bulk should yield a corresponding result.) The process has a perfectly adequate four-dimensional effective description in terms of the matter conformal field theory coupled to four-dimensional gravity.

IV. BREAKDOWN OF EFT; CUTOFFS, STRONG GRAVITY, AND BLACK HOLE PRODUCTION

In Sec. II we argued that at low energies the RS scenario is equivalent to coupling ordinary matter to a hidden CFT. In Sec. III we provided illustrations of this statement. An obvious question regards the limitations of this description. At what scale does it fail? Is there any practical advantage or consequence of the five-dimensional description? And what conclusions can one draw about strong gravitational phenomena, such as the production of black holes in high-energy scattering?

In this section we will first consider the scenario with a single Planck brane, and then comment on extensions of the discussion to scenarios with an added probe or ''TeV'' brane or with AdS terminated by a brane-like object are large z (like the ''negative tension'' brane proposal of Ref. 3).

A. Scattering on the Planck brane

The four-dimensional effective action for the scenario with a single Planck brane is given in (2.16). Recall that the fundamental parameters determine the 4D Planck mass by the relation (2.17). We would like to understand what this scenario predicts for high-energy scattering.

The simplest assumption (if one is not trying to solve the hierarchy problem) is that the five-dimensional Planck scale and inverse AdS radius, and hence the four-dimensional Planck scale, are all comparable:

$$M \sim 1/R \approx M_4 . \tag{4.1}$$

In that case all new physics is clearly at the Planck scale. How much can this statement be relaxed? One would expect observable deviations in microgravity experiments—as in the scenario of Ref. 1—for $R \sim 1$ nm. This puts a lower bound of $M \gtrsim 10^8$ GeV on the five-dimensional Planck scale.

Consider now high-energy scattering of particles confined to the brane. From the bulk perspective, we see that at distances $\ll R$ the dynamics is effectively five-dimensional. This is mirrored in the four-dimensional description of (2.16); energies above $1/R$ are past the cutoff and the cutoff CFT description is incomplete.

Does this mean that we can see what a 4D observer would interpret as strong gravitational phenomena at energies just above $1/R$? Clearly not, except when the parameters satisfy $1/R \sim M$, in which case we are at Planckian 4D energies anyway. Consider for example black hole production. There are two types of black holes that one might produce. The first type is the AdS/Schwarzschild black hole, which moves freely in the bulk, and in general will fall towards the AdS horizon once produced. The threshold for producing such black holes is the 5D Planck energy $M \gtrsim 10^8$ GeV. The second type of black hole is bound to the brane, as described in Refs. 38, 11. The horizon radius of such a black hole is $r_h \sim m/M_4^2$; this should be larger than the 5D Planck length which implies $m > RM^2$. Since $RM \gtrsim 1$, the threshold is again at M or above.

From this discussion we see that scattering pushes beyond the cutoff scale at the threshold $1/R$ and in the bulk perspective begins to explore the extra dimension. While this may have visible consequences through the production of the Kaluza–Klein modes, strong gravitational dynamics such as black hole production has a much higher threshold of M, which in the most ''optimistic'' scenario of $M \sim 10^8$ GeV is still a long ways off.

B. Scattering on a probe brane

The preceding Planck-brane scenario is not favored from the viewpoint of low-energy phenomenology in any case, given the expected relation (4.1) between scales. Scenarios which try to generate the hierarchy via the exponential warp factor show more promise. Consider first the probe brane scenario of Ref. 4. Here 4D matter is taken to reside on a ''TeV'' brane at an elevation $z = \rho_T$; the Planck brane is again at $z = \rho$. This brane must be stabilized by a mechanism such as in Refs. 39, 40. The 4D Planck mass is again given by (2.17), but matter on the TeV brane has its energy redshifted by ρ/ρ_T relative to the Planck brane. If $\rho/\rho_T \sim \text{TeV}/M_4$, this gives a mechanism to generate TeV scale effective masses from particles with fundamentally Planckian masses.

To elaborate on these comments, note that in giving a four-dimensional description of the physics it is necessary to specify a reference frame at a definite value of z in terms of which four-dimensional energies are measured. The natural frame to use is that of the Planck brane, as this is where the 4D graviton bound state is supported. Then if we consider an energy E_{prop} as measured by an observer at another value of z, it will be redshifted so that the energy in the frame of the Planck brane is $E = \rho E_{\text{prop}}/z$. In particular, a particle of mass m at rest in the frame at z will have an energy $m\rho/z$ relative to the Planck brane, and that will be interpreted as its four-dimensional mass.

The Lagrangian in this scenario is expected to take the form

$$S = \int d^{d+1}X \sqrt{-G}(M^{d-1}\mathcal{R} - \Lambda + \mathcal{L}_{\text{stab}}) + \int d^d x [\sqrt{-\gamma(x,\rho_T)}\mathcal{L}(\gamma(x,\rho_T),\psi) - \sqrt{-\gamma(x,\rho)}\tau]. \tag{4.2}$$

Here we denote by $\mathcal{L}_{\rm stab}$ the Lagrangian of the stabilizing fields; we assume that beyond stabilizing the brane they do not qualitatively affect our conclusions.

What is the CFT description of this scenario? Here we encounter subtleties beyond the derivation of (2.16). Specifically, the action depends on the metric at $z=\rho_T$. In attempting to relate the bulk functional integral to the boundary CFT we have to confront the nontrivial z-dependence of γ, and in particular give a CFT prescription for computing the metric in the bulk. We have not yet found a convincing prescription to derive such off-shell information from the AdS/CFT correspondence.

In the absence of such a prescription we will consider two approaches to this problem. The first is to work with long-wavelength excitations of the theory such that the simple scaling approximation,

$$\gamma(x,\rho)\simeq\frac{\rho_T^2}{\rho^2}\,\gamma(x,\rho_T), \tag{4.3}$$

holds. We use this equation to replace $\gamma(x,\rho_T)$ by $\gamma(x,\rho)$ in the Lagrangian for matter on the TeV brane. This effectively rescales parameters of dimension δ in that Lagrangian by a factor $(\rho/\rho_T)^\delta$ (cf. Ref. 4). Rewriting the functional integral as in Sec. II produces a 4D effective action analogous to (2.16) in the Planck brane scenario,

$$S_{\rm TeV}=\int d^4x\sqrt{-\gamma}[\mathcal{L}(\gamma,\psi,m\rho/\rho_T)+\mathcal{L}_{\rm CFT}(\gamma,\chi)+\mathcal{L}_{\rm grav}(\gamma)-\tau]. \tag{4.4}$$

Here we have explicitly indicated the rescaling of a typical mass parameter in the matter Lagrangian. Again $\mathcal{L}_{\rm CFT}(\chi)$ represents the Lagrangian of ''dark'' CFT matter, and $\mathcal{L}_{\rm grav}$, given by (2.9), is the gravitational action.

The simple approximation (4.3) fails at short wavelengths, where the z-dependence becomes nontrivial. This effect can be estimated from the long-distance expansion of the propagator,[11]

$$\Delta(x,z;x',z')\sim\frac{1}{Rr^{d-2}}\left[1+\frac{R^{d-2}}{r^{d-2}}+\frac{z^d}{r^d}+\frac{z^{2d}}{r^{2d}}\frac{r^{d-2}}{R^{d-2}}\right]\left[1+\mathcal{O}\left(\frac{z^2}{r^2},\frac{R^2}{r^2}\right)\right]. \tag{4.5}$$

In $d=4$, the correction due to the last term becomes large at distances,

$$r\sim\left(\frac{\rho_T}{\rho}\right)^{4/3}R, \tag{4.6}$$

or at about 10 Fermi for $\rho/\rho_T\sim{\rm TeV}/M$.

In order to understand the origin of corrections at this scale, first let us recall a similar phenomenon in the large scale compactification scenario of Ref. 1. If one for example considers such a compactification with two extra dimensions of size $\mathcal{O}(mm)$, gravitational experiments performed at shorter scales reveal the six-dimensional nature of spacetime: the part of the four-dimensional effective Lagrangian describing the gravitational sector breaks down. One way of understanding this is to note that sources with shorter wavelengths than a millimeter will generically have coupling to the Kaluza–Klein modes that is comparable to the coupling to the gravitational zero mode; summing over these modes produces the six-dimensional gravitational field. While the gravitational part of the 4D effective action breaks down, nonetheless the gauge part of the effective action remains four-dimensional up to scales of order a TeV where gravity itself becomes strongly coupled.

A similar phenomena occurs here. At scales given by (4.6), the couplings of the TeV brane matter to the continuum analogs of the Kaluza–Klein states become comparable to the coupling to the four-dimensional graviton. This means that in the gravitational sector the 4D effective theory

fails, but of course the gauge part of the theory remains four-dimensional up to the TeV scale. The stress tensor of the TeV brane matter acts as the source for these couplings to the Kaluza–Klein modes.

Corresponding statements can be made in the CFT, and will tell us the form of the corrections to the action (4.4) that are responsible for its failure as a 4D effective description. In particular, we expect that corresponding to the couplings to the KK modes, a term is induced in (4.4) in which there is a direct coupling of the stress tensor of the TeV brane matter to the stress tensor of the CFT, and by scaling the coefficient of this should include a factor of $(\rho_T/\rho)^4$. Such terms are responsible for the breakdown of the gravitational part of the 4D effective theory.

A second approach would be to use the holographic renormalization group[41] to evolve the Lagrangian from the Planck brane to the TeV brane. We would expect this to produce similar results, namely a gravitationally coupled CFT with a cutoff scale $\sim$10 MeV. We expect the $T_\chi T_\psi$ terms described above to be present in the Lagrangian at the Planck scale, and then to be rescaled by the renormalization group flow. A better understanding along these lines of the relationship between operators at different z would also clearly be illuminating for our fundamental understanding of holography in the AdS/CFT correspondence.

As in the scenario of Ref. 1, there is a distinction between the scale at which the 5D nature of gravity becomes important and the scale at which gravity becomes strongly coupled. A particularly interesting question is when do we expect to be able to manufacture configurations which would manifest signatures for black holes that we as four-dimensional observers could see?

Within the context of the TeV brane scenario, there are again two kinds of black hole solutions known. The first is the AdS-Schwarzschild black hole. The minimum energy to create these should be $\mathcal{O}(M)$. A collision of TeV brane matter with a proper energy of this magnitude is a collision at the TeV energy scale as measured with respect to the four-dimensional observer. However, it appears that such black holes are not bound to the brane. In the probe-brane limit, where the gravitational backreaction is neglected, this is manifest, but even taking into account the small energy density of the probe brane it seems likely that the binding of the black hole to the brane will be overcome by the gravitational pull of the black hole towards the AdS horizon. (There may be interesting transitory effects—such as stretching and then recoil of the probe brane—that we leave for future investigation.) While a complete analysis of this requires a detailed investigation of stabilized probe brane scenarios, it appears that such a black hole will therefore generically fall towards the AdS horizon, and that the 4D observer will therefore not perceive it as a black hole. In the CFT picture, such black holes will be perceived as complex excitations of the CFT which spread out over time, and it is very unlikely that their signature can be experimentally disentangled from other excitations of the CFT.

The second type of solution is the black hole on the Planck brane. These are truly perceived as 4D black holes. However, given the relation (4.1) between scales, the minimum energy to create such a black hole is again of the order of the Planck energy. The TeV brane scenario does not seem to allow access to what a 4D observer would perceive as strongly coupled gravitational dynamics at lower scales.

In fact, notice the following novelty. A small black hole bound to the Planck brane will not intersect the TeV brane, until its horizon reaches the TeV^{-1} size. Therefore matter moving on the TeV brane may bypass such a black hole, in a close analogy to the black hole flybys discussed in Sec. III B. (See Fig. 2.) In other words, 4D observers made of TeV brane matter have difficulty resolving sub-TeV size black holes. How is this interpreted in four-dimensional language?

To really study this question requires a detailed model of the stabilization and the TeV brane matter. However, a plausible answer to this also comes directly from our earlier discussion. Matter passing a black hole by moving on the TeV brane should be interpreted in the 4D perspective as matter smeared out on the TeV scale. Such matter has a small probability of probing a black hole with a radius much less than 1/TeV.

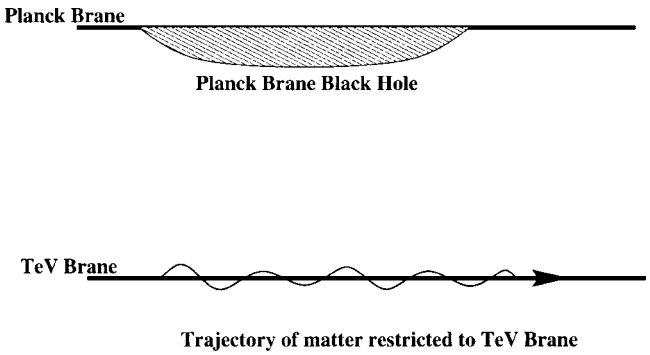

FIG. 2. A particle moving on a probe brane can bypass a small black hole localized on the Planck brane.

C. Terminated AdS scenario

Another interesting possibility is that AdS is terminated at both ends in z. The outlines of such a picture was suggested in Ref. 3 with a idealized lower brane taken to have a finely-tuned negative tension.

Recent developments in string theory have suggested a concrete means to construct geometries with similar properties. Specifically Refs. 6, 7 describe geometries that terminate at a definite value of z. These geometries do not arise from negative tension objects, or even singular branes, but rather are rounded off at the maximal z in a smooth geometry that uses the extra dimensions of string theory in a nontrivial way.

References 6, 7 do not have a simultaneous microscopic construction of the analog of a Planck brane. However, one can envision building such a model by using Verlinde's geometric realization[5] of the Planck brane as a piece of a compactification manifold on the ultraviolet end, and then realize the IR brane as in Refs. 6, 7 or in a variant of these scenarios producing other low-energy dynamics. There may of course be other inequivalent stringy constructions of such doubly-terminated AdS spaces. Constructing detailed models of this kind is an interesting problem for the future.

The models of Refs. 6, 7 have explicit gauge theory duals. If one constructs a model with a geometric ''Planck brane,'' one would expect these to be modified at the UV end and depend on the internal structure of the compactification manifold. Nonetheless, these gauge theories should serve as good effective theories at lower scales, in parallel with our earlier discussion.

Such a scenario—or others with a microscopic realization of an IR brane—may have very interesting consequences for the observability of strong gravitational phenomena. Assume that in such a construction there is a gauge theory sector that we may think of as being truly localized in the vicinity of the maximal z which we take to be $z \simeq \rho_T$. This would then realize what was referred to as matter living on the ''negative tension brane'' of Ref. 3. As explained above, energies at $z \simeq \rho_T$ are redshifted relative to those at the Planck brane, and so if a suitable way is found of stabilizing the separation between the branes, TeV scale scattering corresponds to a proper energy comparable to M, the five-dimensional Planck scale, if the scattering takes place at $z \simeq \rho_T$. Thus scattering at this scale should begin to make black holes. These should be similar to AdS-Schwarzschild solutions, or to the analogous solutions in the new geometry of Refs. 6, 7. (For an explicit formula for the smooth metric in question, see Sec. 5.1 of Ref. 6.)

In the probe-brane picture, these black holes were expected to fall off the brane and into the horizon at $z=\infty$. Now this is not possible since the geometry terminates at $z \simeq \rho_T$. One expects such a black hole to undergo approximately geodesic motion in this vicinity, and ultimately to evaporate.

Note that one may achieve a clean separation of scales in situations where the AdS radius R is larger than the 5D Planck length M^{-1}. In this situation [which can be achieved by taking large 't Hooft parameter g^2M—here only M is the dimension of $SU(M)$—in Ref. 6], there exist black

holes larger than the Planck size but smaller than the AdS radius. These would have an approximately (five-dimensional) Schwarzschild description.

In the probe brane picture, the evaporation of 5D black holes was expected to be nearly exclusively into bulk modes, since the black hole becomes well separated from the TeV brane and so will not couple to its excitations. However, in the present picture, the black hole remains in the vicinity of the analog of the IR brane and this suggests that there is no reason for it to decouple from the matter modes in this vicinity. Indeed, in the idealized ''negative tension brane'' picture, gauge modes on the brane will directly see the black hole metric. Therefore, with this assumption, on general grounds one expects the black hole to Hawking radiate into all available modes, including the visible matter sector modes. As explained in Ref. 42, the radiation in the visible sector is generically expected to be important.

This suggests an interesting scenario in which a black hole could be created at an accelerator operating in the vicinity of the TeV scale. Assuming the black hole is sufficiently coupled to the visible modes, these would provide a channel for the Hawking decay and provide an observational window on this process. One would observe such an object by looking for the characteristic approximately thermal spectrum—with increasing temperature—of the Hawking process.

The basic assumptions that could lead to this possibility being realized are (1) that one has a geometry effectively terminated at a maximal z corresponding to the TeV scale, (2) that one has a description of visible-sector matter localized to the vicinity of this maximal z, and (3) that black holes near the maximal z couple to the visible sector. Whether these assumptions will hold in models based on the ideas of Refs. 6, 7 remains to be seen, but they plausibly do, and there may also be other models with these properties, for which the creation and visible-sector decay of TeV-scale black holes seems a generic prediction.

V. CONCLUSIONS

In this paper we have investigated the interplay between the four- and five-dimensional descriptions of the physics of warped compactifications. In the simplified example of the RSII scenario, at distances long as compared to the AdS radius R there is a four-dimensional effective description of the dynamics given by observable brane matter coupled gravitationally to a sector described by a conformal field theory. At shorter distances the derivation of this description fails. One expects similar 4D effective descriptions for other warped compactification scenarios.

One element of the correspondence between the 4D and 5D descriptions is supplied by the computation of the 4D stress tensor corresponding to a 5D matter distribution. At the linear level we have given a formula for this stress tensor. We have also investigated an amusing scenario that illustrates the interplay between the 4D and 5D descriptions, that of a particle passing a black hole through the fifth dimension, with a corresponding 4D description in terms of a matter distribution expanding into a shell larger than the black hole.

Finally, we have explored situations in which strong gravitational dynamics may give important modifications to the 4D description. In particular, in scenarios where the hierarchy is addressed by visible matter being effectively localized to a large z in AdS space, one potentially has access to strong gravitational dynamics such as black hole formation at TeV energy scales. In probe brane scenarios this may not lead to observable effects since the resulting black hole seems to rapidly decouple from the visible sector by falling off the brane, but scenarios with AdS terminated at this maximal z show much more promise as such a black hole should stay localized in the vicinity of the maximal z. This leads to the possibility of the creation and observable Hawking decay of a black hole in the vicinity of the TeV scale. It would be particularly interesting to find extensions of the work of Ref. 5 and Refs. 6, 7 which give explicit string theory realizations of such terminated AdS scenarios.

Note added in proof. String solutions have now been constructed that realize terminated AdS scenarios.[43]

APPENDIX A: THE RETARDED GREEN'S FUNCTION

In this appendix we describe some properties of the scalar Green's function for the RSII geometry. This was given in Ref. 11 and takes the form

$$\Delta_{d+1}(x,z;x',z') = \frac{i\pi}{2R^{d-1}}(zz')^{d/2}\int \frac{d^d p}{(2\pi)^d} e^{ip(x-x')} \times\left[\frac{J_{d/2-1}(qR)}{H^{(1)}_{d/2-1}(qR)} H^{(1)}_{d/2}(qz)H^{(1)}_{d/2}(qz') - J_{d/2}(qz_<)H^{(1)}_{d/2}(qz_>)\right]. \tag{A1}$$

For the following discussion it is most convenient to use the z coordinate, related to y by (3.1).

The scalar propagator with $d=4$ and one point on the boundary is given by[11]

$$\Delta_{4+1}(x,z;x',R) = \left(\frac{z}{R}\right)^2 \int \frac{d^4 p}{(2\pi)^4} e^{ip(x-x')} \frac{1}{q}\frac{H^{(1)}_2(qz)}{H^{(1)}_1(qR)}, \tag{A2}$$

where $q^2 = -p^2$. As in Eq. (3.9), let us define a function F,

$$\Delta_{4+1}(R,x;z',x') = \frac{z'^3}{R}\partial_{z'}\left[\frac{F_{z'}(R;x-x')}{z'^2}\right]. \tag{A3}$$

Hence, F is given as Fourier transform of Hankel functions,

$$F_{z'}(R;x-x') = -\frac{z'}{R}\int \frac{d^4 p}{(2\pi)^4} e^{ip(x-x')} \frac{1}{q^2}\frac{H^{(1)}_1(qz')}{H^{(1)}_1(qR)}. \tag{A4}$$

In our conventions [given by (3.6)] the Feynman propagator is

$$\Delta_{\mathrm{F}}(X,X') = -i[\,\theta(t-t')\Delta^+(X,X') + \theta(t'-t)\Delta^-(X,X')], \tag{A5}$$

where Δ^+ is the Wightman function $\langle\phi(X)\phi(X')\rangle$ and Δ^- is its Hermitian conjugate. The retarded Green's function is defined as

$$\Delta_R(X,X') = -i\,\theta(t-t')[\Delta^+(X,X') - \Delta^-(X,X')]; \tag{A6}$$

this manifestly vanishes for $t<t'$ and can easily be shown to obey (3.6). We therefore find that

$$\Delta_R(X,X') = 2\,\mathrm{Re}\,\Delta_{\mathrm{F}}(X,X')\,\theta(t-t'). \tag{A7}$$

In order to compute the asymptotic retarded Green's function, note that in the long-distance approximation $(qR\ll 1)$, F reduces to the following form:

$$F_{z'}(R;x-x') \approx -\frac{\pi i z'}{2}\int \frac{d^4 p}{(2\pi)^4} e^{ip(x-x')}\frac{1}{q}H^{(1)}_1(qz'). \tag{A8}$$

We then perform a Euclidean rotation on the above integral, giving

$$F_{z'}(R;x-x') \approx \frac{\pi i z'}{2} \int \frac{d^4p}{(2\pi)^4} e^{ip(x-x')} \frac{1}{p} H_1^{(1)}(ipz')$$

$$\approx \frac{i}{4\pi^2} \frac{1}{(x-x')^2+z^2}. \tag{A9}$$

The Feynman prescription is then to replace $(x-x')^2$ with $(x-x')^2+i\epsilon$. Making this replacement and taking the real part gives

$$F_{z'}^{\mathrm{Ret}}(R;x-x') \approx \frac{1}{2\pi} \delta((x-x')^2+z'^2)\theta(t-t'), \tag{A10}$$

which finally yields the retarded scalar propagator,

$$\Delta_{4+1}(R,x;z',x') \approx \frac{1}{\pi R}[z'^2\delta'((x-x')^2+z'^2) - \delta((x-x')^2+z'^2)]\theta(t-t'). \tag{A11}$$

APPENDIX B: THE INFRARED LIMIT

As we saw in the text, our calculation of the effective source on the boundary produces an expanding shell in the infrared limit. This is true for scalar vector, and graviton fields. This is also the result that Horowitz and Itzhaki found in Ref. 36, using the boundary conditions appropriate for infinite AdS rather than the brane boundary conditions (3.8). In this appendix we sketch the relation between the calculations. For simplicity we only treat the scalar case although the derivation extends to the other cases.

In our calculation with brane boundary conditions, we solve the bulk equation

$$\Box_{d+1}\phi = T, \tag{B1}$$

with the Neumann condition

$$\partial_n \phi|_{z=\rho} = 0. \tag{B2}$$

Here T is the scalar source, in the text given by the falling particle, and ∂_n denotes the normal derivative. The effective boundary source is found by restricting this solution to the boundary and computing its Laplacian:

$$J = \Box_d \phi|_\partial. \tag{B3}$$

Another way to get the same solution is to solve (B1) subject to the Dirichlet boundary condition,

$$\phi|_\partial = \varphi. \tag{B4}$$

The solution is given in terms of the Dirichlet Green's function as

$$\phi(X) = \int dV'\, \Delta_{d+1}^D(X,x')T(X') + \oint_\partial dn'\, \partial_{n'}\Delta_{d+1}^D(X,X')\varphi(x'). \tag{B5}$$

The effective boundary action for φ is computed by evaluating the $d+1$-dimensional action of this solution, which using the bulk equation of motion becomes

$$S[\varphi] = -\frac{1}{2} \oint_\partial dn'\, \varphi\, \partial_{n'}\phi. \tag{B6}$$

The boundary equation of motion for φ then states

$$\partial_n \phi|_\partial = 0. \tag{B7}$$

Thus a solution of the Dirichlet boundary problem such that the boundary field satisfies the boundary equations of motion corresponds to a solution of the Neumann boundary problem.

In the latter approach the effective boundary source can be read off from the boundary equation of motion. Inserting the second term of (B5) into (B7) gives the kinetic operator acting on φ, which becomes $\Box_d$ in the long-distance limit. Thus in this limit (B7) states that

$$J = \Box_d \varphi \sim \partial_z \phi_{\rm D}|_\partial, \tag{B8}$$

where $\phi_{\rm D}$, the first term in (B5), is the solution to (B1) with Dirichlet boundary conditions, $\phi_{\rm D}|_\partial = 0$. In the limit as the cutoff is removed, $\rho \to 0$, this corresponds to the desired solution in infinite AdS. And aside from a rescaling, $\partial_z \phi_{\rm D}$ corresponds to the source on the boundary, which if we had been discussing the metric would be the boundary stress tensor of Ref. 36.

It is also possible to check the relationship to Ref. 36 directly, by acting with $\Box_d$ on (3.42), using Eq. (3.6) to eliminate the d-dimensional Laplacian in favor of y derivatives, and then using the fact that in the infrared limit (A1) is the standard bulk propagator plus a y-independent piece which therefore does not contribute.

(Received 2 January 2001; accepted for publication 13 February 2001)

Intersecting Dp-branes often give rise to chiral fermions living on their intersections. We study the construction of four-dimensional chiral gauge theories by considering configurations of type II D$(3+n)$-branes wrapped on nontrivial n-cycles on $\mathbf{T^{2n}}\times(\mathbf{R^{2(3-n)}}/\mathbf{Z_N})$, for $n=1,2,3$. The gauge theories on the four noncompact dimensions of the brane world-volume are generically chiral and nonsupersymmetric. We analyze consistency conditions (RR tadpole cancellation) for these models, and their relation to four-dimensional anomaly cancellation. Cancellation of $U(1)$ gauge anomalies involves a Green–Schwarz mechanism mediated by RR partners of untwisted and/or twisted moduli. This class of models is of potential phenomenological interest, and we construct explicit examples of $SU(3)\times SU(2)\times U(1)$ three-generation models. The models are nonsupersymmetric, but the string scale may be lowered close to the weak scale so that the standard hierarchy problem is avoided. We also comment on the presence of scalar tachyons and possible ways to avoid the associated instabilities. We discuss the existence of (meta)stable configurations of D-branes on 3-cycles in $(\mathbf{T^2})^3$, free of tachyons for certain ranges of the six-torus moduli. © *2001 American Institute of Physics.*

I. INTRODUCTION

D-branes have turned out to be a key ingredient in our present understanding of the structure of string theory. Interestingly, the fact that D-branes contain gauge fields localized on their world-volume has also suggested new scenarios for string phenomenology and phenomenology beyond the standard model in general (see, e.g., Refs. 1–5). From this point of view, it is important to explore different configurations of branes which can lead to interesting features for phenomenological model building.

An important observation[6] is that intersecting D-branes in flat space may give rise to chiral fermions propagating on the intersection of their world-volumes, arising from open strings stretching between the D-branes. Hence, it is natural to consider the construction of four-dimensional chiral models by compactifications including intersecting D-branes. In this framework, the compactification space can be essentially flat, like a six-torus, since chirality arises from fermions at the intersection of D-brane world-volumes, and does not depend so much on the holonomy group

a)Electronic mail: angel.uranga@cem.ch

of the ambient space. This is in contrast with more familiar compactifications with D-branes, like type IIB orientifolds[7–9] or heterotic string compactifications,[10,11] where chirality arises due to the ambient space being Calabi–Yau threefold.

In this paper we perform a systematic exploration of configurations of $D(3+n)$-branes wrapped on n-cycles in an $2n$-dimensional torus $\mathbf{T^{2n}}$, and sitting at a point in a transverse $6-2n$-dimensional space $\mathbf{B}$. We are interested in configurations leading to chiral four-dimensional gauge theories after reduction on the torus. Chirality is automatically achieved for D6-branes on 3-cycles on $\mathbf{T^6}$. However, for models with D4- or D5-branes, if the point in $\mathbf{B}$ at which the D-branes sit is smooth, the resulting intersection lead to vector-like matter. Chiral matter at the intersections can be obtained by considering branes sitting at singular points in $\mathbf{B}$. We will center on Abelian orbifold singularities, whose local geometry can be modeled as $\mathbf{R^{6-2n}/Z_N}$.

Hence we consider configurations of stacks of $D(3+n)$-branes wrapped on n-cycles in $\mathbf{T^{2n}\times R^{6-2n}/Z_N}$. Each stack of D-branes gives rise to gauge factors, while open strings stretched between them give rise to chiral fermions propagating on the intersections. The resulting four-dimensional gauge theories are of potential phenomenological interest. When the singularity is embedded in a globally compact $(6-2n)$-dimensional variety, one obtains a full-fledged compactification, where gravity is also four-dimensional.

Notice that the case of $n=0$ corresponds to configurations of D3-branes at $\mathbf{R^6/Z_N}$ singularities, which were employed in Ref. 5 to build realistic gauge theories (see Ref. 12 for more formal applications of these systems). Full-fledged compactifications were subsequently obtained by embedding the singularities in global compact geometries. Our approach here is similar in spirit to the bottom-up approach introduced in Ref. 5, although we mainly center on local features in the present paper. The models also present a number of interesting new properties.

The opposite extreme case, $n=3$, corresponds to D6-branes wrapped on 3-cycles in $\mathbf{T^6}$. Configurations of this type have appeared in Ref. 13, but in the presence of an additional orientifold projection. (Other models with branes at angles and orientifold and orbifold projections have appeared in Ref. 14.) This projection is not a necessary ingredient, and it does not improve the phenomenological or theoretical features of the model, hence we choose not to include it. In particular, this allows us to get around the orientifold symmetry constraints in Ref. 13, which prevented the appearance of three-generation models. Without orientifold action, three-family models are easy to build, and we present a specific example.

In this paper we perform a detailed analysis of the configurations for $n=1,2,3$, their construction with explicit examples, and the main features of the resulting four-dimensional theories. We determine the tadpole cancellation conditions, their geometrical interpretation, and their interplay with the cancellation of chiral four-dimensional anomalies. Interestingly, we find that the theories contain several anomalous $U(1)$'s, and that their anomalies are cancelled by a generalized Green–Schwarz mechanism. The fields that mediate this mechanism correspond, for D6-branes wrapped on 3-cycles on $\mathbf{T^6}$, to *untwisted* closed string modes, in contrast with the situation in other string constructions. For $n=1,2$ the exchanged fields correspond to the reduction on $\mathbf{T^{2n}}$ of fields in twisted sectors of $\mathbf{R^{6-2n}/Z_N}$.

The models are generically nonsupersymmetric, even if the orbifold twist is chosen to preserve some bulk supersymmetry. This leads to two important issues. First, although the discussion of more phenomenological aspects in these constructions will appear elsewhere,[15] we would like to mention here the question of scales. Even though models are nonsupersymmetric, it is possible to avoid a hierarchy problem in any realistic application, by lowering the string scale down to a TeV. This is possible, i.e., consistent with a large four-dimensional Planck mass, for models with D4- or D5-branes, in the usual way, by simply taking the transverse $(6-2n)$-dimensional space $\mathbf{B}$ large enough. Notice that the $2n$-torus should remain small (with compactification scale $\approx$ TeV) to avoid too light KK resonances of gauge bosons. Hence, as observed in Ref. 13, for models with D6-branes solving the hierarchy problem by large volume compactification is not possible. It is interesting to consider them, however, in case another mechanism is eventually devised. On the other hand, let us emphasize again that a low string scale is consistent with low-energy physics in models with D4- or D5-branes, with a large transverse volume.

The second comment concerns the generic presence of tachyons at brane intersections, which signal an instability against recombining intersecting branes into a single smooth one. Interestingly, for the case of D6-branes on 3-cycles, there exist brane orientations such that the brane recombination process is not energetically favored, since it implies an increase of the wrapped volume. The corresponding intersection hence does not lead to tachyonic states. Hence it is in principle possible to construct compact models of D6-branes on $\mathbf{T^6}$ where all intersections have this property, and the resulting model is (meta)stable, as we discuss in some detail. In models with D4- or D5-branes, it is possible to construct models where most of the tachyons at intersections are projected out by the $\mathbf{Z_N}$ orbifold twist in the quotient singularity.

In any event, we think it is also interesting to consider models with a small set of tachyons. Recent developments (see Ref. 16 for a review) have suggested that much can be learned by considering unstable configurations in string theory and their decay. On the speculative side, a possible phenomenological application of these ideas would be to interpret the tachyon condensation process as a Higgs mechanism, in which the two gauge factors associated to the intersecting branes break to a smaller subgroup carried by the recombined brane. In fact, it is possible to construct explicit semirealistic models of D4-branes, where the only tachyons have the quantum numbers of Standard Model Higgs multiplets. It is tempting to speculate that the effect of the instability is Higgs breaking of electroweak symmetry (see Ref. 15 for further details).

The paper is organized as follows. In Sec. II we discuss generalities about the configuration of intersecting branes, and the spectrum arising on their world-volume and on their intersections. In Sec. III we discuss the construction of models of D6-branes wrapped on 3-cycles in $\mathbf{T^6}$. We analyze their spectrum, the tadpole cancellation conditions and their interpretation, and cancellation of non-Abelian and mixed $U(1)$ anomalies. We also present several explicit examples, e.g., leading to three-generation Standard Model gauge sectors. We also comment on the possibility of understanding tachyon condensation as symmetry breaking by a Higgs mechanism. A similar analysis is carried out for configurations of D4-branes in Sec. IV, and of D5-branes in Sec. V. Section VI contains our final remarks.

II. INTERSECTING Dp-BRANES

Let us start by considering some generic properties of the spectrum for branes at angles. We start considering D-branes wrapped on d-cycles $\mathbf{T^{2d}}$. We choose a factorizable $\mathbf{T^{2d}}$, product of d two-dimensional rectangular tori $\mathbf{T_I^2}$ parametrized by compact coordinates X_1^I, X_2^I, with radii R_1^I, R_2^I, with $I=1,\ldots,d$. We introduce K different sets of N_a coincident Dp_a-branes, labeled by an index a, $a=1,\ldots,K$. Each set wraps around a 1-cycle Π_a^I, of type (n_a^I, m_a^I), on each of the d two-tori. Namely, it wraps n_a^I times around the X_1^I direction and m_a^I times around the X_2^I direction. The angle of these branes with the X_1^I axis is hence given by

$$\tan \vartheta_a^I = \frac{m_a^I R_2^I}{n_a^I R_1^I}, \tag{2.1}$$

with an obvious modification for skewed two-tori.

The compactification preserves all 32 supersymmetries of type II theory in the closed string sector. The sector of open strings stretching between Dp_a-branes within the same set, preserves 16 supersymmetries, hence giving rise to the corresponding gauge supermultiplet with gauge group $U(N_a)$. [If the wrapping numbers (n,m) are not coprime, $r=\gcd(n,m)\neq 1$, the D-brane is multiwrapped r times over the cycle $(n/r,m/r)$. This state can be equivalently described as r D-branes on $(n/r,m/r)$ with an order r permutation Wilson line turned on. For N such multiwrapped branes, the world-volume gauge group is $U(N)^r$. We thank R. Blumenhagen, B. Körs, and D. Lüst for a discussion on multiwrapped branes.] This piece of the spectrum is non-chiral, so the only source of chiral fields is the sector of open strings stretched between different sets of branes.

The spectrum of such sectors has been studied in Ref. 6. World-sheet bosonic fields for open strings stretching between Dp_a- and Dp_b-branes, at a relative angle $\vartheta^I_{ba}=(\vartheta^I_b-\vartheta^I_a)/\pi$ (given in ''units of π'' for convenience), in the Ith two-torus, satisfy the boundary conditions

$$\begin{aligned}\sin\vartheta^I_a\,\partial_\sigma X^I_1-\cos\vartheta^I_a\partial_\sigma X^I_2=0,\\ \sin\vartheta^I_a\,\partial_t X^I_2-\cos\vartheta^I_a\,\partial_t X^I_1=0,\end{aligned}\tag{2.2}$$

at $\sigma=0$, and a similar equation for $\sigma=\pi$ with $a\to b$. Corresponding equations are satisfied by fermionic coordinates. Such boundary conditions lead to *twisted* mode expansions, with twist given by the relative angle ϑ^I_{ba} between branes. For instance, one obtains world-sheet fermionic modes $\psi^I_{r_-}$, $\psi^I_{r_+}$, with modes $r_\pm=n\pm\vartheta^I_{ba}+\nu$, where n is an integer and $\nu=0,1/2$ for R and NS boundary conditions, respectively. No windings or KK momenta are allowed for nontrivial angles. Antiparticles of states in the ab sector appear in the ba sector.

We are mainly interested in four-dimensional intersections, hence we consider the cases of D$(3+n)$-branes wrapped on n-cycles on $\mathbf{T^{2n}}$, for $n=1,2,3$. As mentioned in the Introduction, configurations $n<3$ would lead to nonchiral intersections, hence we will eventually turn to configurations with singular transverse spaces, namely D$(3+n)$-branes on n-cycles in $\mathbf{T^{2n}\times R^{6-2n}/Z_N}$. Before that, it is convenient to discuss the simpler case of $\mathbf{T^{2n}\times R^{6-2n}}$ in this section, namely D6-branes on $\mathbf{T^6}$, D5-branes on $\mathbf{T^4\times C}$, D4-branes on $\mathbf{T^2\times C^2}$.

The mass operator for strings stretching between branes in the ath and bth set, which make an angle $\vartheta^I\equiv\vartheta^I_{ab}$ on the Ith two-torus is[17,6]

$$\alpha' M^2_{ab}=\frac{Y^2}{4\pi^2\alpha'}\sum_{I=1}^{d}\left[N(\vartheta^I)+\vartheta^I_{ab}\right]-\nu,\tag{2.3}$$

where Y^2 measures the length of the stretched string (minimal distance between branes for minimum winding states), and N_ν is the number operator given by

$$\begin{aligned}N(\vartheta^I)&=\sum_{n>0}\alpha_{-n}\cdot\alpha_n+\sum_{n>0}\alpha^I_{-n_+}\cdot\alpha^I_{n_+}+\sum_{n>0}\alpha^I_{-n_-}\cdot\alpha^I_{n_-}+\alpha^I_{-\vartheta^I}\alpha^I_{\vartheta^I}\\&=+\sum_{n>0}r\psi_{-r}\psi_r+\sum_{n>0}r_+\psi^I_{-r_+}\cdot\psi^I_{r_+}+\sum_{n>0}r_-\psi^I_{-r_-}\cdot\psi^I_{r_-}\\&\quad+\frac{1}{2}\left[(\vartheta^I+\nu)\psi^I_{-(\vartheta^I+\nu)}\cdot\psi^I_{\vartheta^I+\nu}+(-\vartheta^I+\nu)\psi^I_{(\vartheta^I-\nu)}\cdot\psi^I_{-\vartheta^I+\nu}\right].\end{aligned}\tag{2.4}$$

Some comments are in order for the correct use of this expression. We have assumed in its derivation that $0\leqslant\vartheta^I_{ab}\leqslant\frac{1}{2}$, so oscillators modes as above are correctly normal ordered. For negative angles one should replace $\vartheta_I\to|\vartheta_I|$. The ϑ^I_{ab} in the mass equation (2.3) arises from normal ordering of twisted modes.

The spectrum can be described in bosonic language as follows. We introduce a four-dimensional twist vector v_ϑ, whose Ith entry is given by ϑ^I_{ab}. The GSO projected states are labeled by a four-dimensional vector $r+v_\vartheta$, where $r_I\in\mathbf{Z},\mathbf{Z}+\frac{1}{2}$ for NS, R sectors, respectively, and $\Sigma_I r_I=$ odd. The last entry provides four-dimensional Lorentz quantum numbers. The mass of the states is then given by

$$\alpha' M^2=\frac{Y^2}{4\pi^2\alpha'}+N_{\rm bos}(\vartheta)+\frac{(r+v)^2}{2}-\frac{1}{2}+E_{ab},\tag{2.5}$$

with

$$E_{ab}=\sum_I \frac{1}{2}|\vartheta_I|(1-|\vartheta_I|), \tag{2.6}$$

and $N_{\rm bos}(\vartheta)$ is a contribution from bosonic oscillators.

Let us discuss the computation of lowest lying states in the different models. As mentioned above, models for $n<3$ have a nonchiral spectrum, as is easily seen from the fact that all massless states can be made massive in a continuous way by increasing the separation Y^2 in transverse space.

We first consider the case of D4-branes on $\mathbf{T^2\times C^2}$. In the NS sector, the lowest mass state allowed by GSO projection[6] corresponds to $\psi^I_{(\vartheta^1-1/2)}|0>_{\rm NS}$, or $r+v=(-1+\vartheta^1,0,0,0)$ in bosonic language. Its mass is given by

$$\alpha' M_1^2=\frac{Y}{4\pi^2\alpha'}-\frac{1}{2}|\vartheta^1|. \tag{2.7}$$

Thus, a tachyon is generated when D4-branes come closer than the critical distance $Y^2=2\pi^2\alpha'|\vartheta^1|$. The tachyon signals an instability against joining the intersecting branes into a single one, which then wraps a one-cycle in the homology class $[\Pi_a]+[\Pi_b]$, namely a (n_a+n_b,m_a+m_b) cycle on $\mathbf{T^2}$. In Sec. IV we discuss how to use a $\mathbf{Z_N}$ orbifold twist to project out some of these tachyons.

The R groundstate contains four fermions that become massless at zero transverse distance. They are given by

$$\begin{aligned}&(-\tfrac{1}{2}+\vartheta^1,-\tfrac{1}{2},-\tfrac{1}{2},+\tfrac{1}{2});\quad (-\tfrac{1}{2}+\vartheta^1,-\tfrac{1}{2},+\tfrac{1}{2},-\tfrac{1}{2}),\\ &(-\tfrac{1}{2}+\vartheta^1,+\tfrac{1}{2},-\tfrac{1}{2},-\tfrac{1}{2});\quad (-\tfrac{1}{2}+\vartheta^1,+\tfrac{1}{2},+\tfrac{1}{2},+\tfrac{1}{2}).\end{aligned} \tag{2.8}$$

There are two pairs of opposite chirality spinors, so the spectrum is nonchiral. A possibility to obtain a chiral spectrum is to project out some of the above fermions, for instance by locating the D4-branes at $\mathbf{C^2/Z_N}$ singularities in transverse space; see Sec. IV.

In the case of configurations of D5-branes on $\mathbf{T^2\times T^2\times C}$, open strings at intersections have a twist vector $(\vartheta_1,\vartheta_2,0,0)$. In the NS sector, assuming $0<\vartheta_I<1$ the lowest mass NS states correspond to $\psi_{-1/2+\vartheta_1}|0>$, $\psi_{-1/2+\vartheta_2}|0>$, or in bosonic language $(-1+\vartheta_1,0,0,0)$, $(0,-1+\vartheta_2,0,0)$. Their masses are $M_1^2=\frac{1}{2}(\vartheta_2-\vartheta_1)$ and $M_2^2=-\frac{1}{2}(\vartheta_2-\vartheta_1)=-M_1^2$, respectively. Thus, unless $|\vartheta_2|=|\vartheta_1|$, in which case the intersection preserves some supersymmetry, there is always a tachyonic state. The R spectrum contains a set of nonchiral massless fermions, corresponding to the states $(-\frac{1}{2}+\vartheta^1,-\frac{1}{2}+\vartheta^2,-\frac{1}{2},\frac{1}{2})$ and $(-\frac{1}{2}+\vartheta^1,-\frac{1}{2}+\vartheta^2,\frac{1}{2},-\frac{1}{2})$. Again, tachyon elimination and chirality may be obtained by imposing an orbifold projection, namely by considering D5-branes wrapped on $\mathbf{T^4}$ and located at the origin of a $\mathbf{C/Z_N}$ singularity, as we do in Sec. V.

As mentioned, a chiral spectrum is obtained for D6-brane intersections on $\mathbf{T^6}$. The twist vector is now given by $(\vartheta_1,\vartheta_2,\vartheta_3,0)$. In the NS sector, the lowest lying states, for $0\leqslant\vartheta^I\leqslant 1$, are given by $(-1+\vartheta^1,\vartheta^2,\vartheta^3,0)$, $(\vartheta^1,-1+\vartheta^2,\vartheta^3,0)$, $(\vartheta^1,\vartheta^2,-1+\vartheta^3,0)$, and $(-1+\vartheta^1,-1+\vartheta^2,-1+\vartheta^3,0)$. As discussed in more detail in Sec. III, some of them may be tachyonic, but not necessarily. In the R sector, we obtain a single chiral fermion, given by $(-\frac{1}{2}+\vartheta^1,-\frac{1}{2}+\vartheta_2,-\frac{1}{2}+\vartheta_3,+\frac{1}{2})$.

We conclude by emphasizing an important point. Branes wrapped on cycles generically intersect at multiple points, hence the above states in mixed ab sectors appear in several copies, this multiplicity being given by the intersection number of the corresponding wrapped cycles. [If, e.g.,

one of the branes, say the bth, has noncoprime (n,m), the multiplets in the ab sector transform as $\Sigma_{l=1}^{r}\tilde{I}_{ab}(N_a,N_{b,r})$ under the gauge group $U(N_a)\times U(N_b)^r$, and $\tilde{I}_{ab}=I_{ab}/r$.]

III. D6-BRANES WRAPPING AT ANGLES ON $(T^2)^3$

A. Construction

In this section we consider type IIA theory compactified on a factorizable $\mathbf{T^6}$. We consider a configuration containing K stacks of N_a D6-branes, $a=1,\ldots,K$, wrapped on three-cycles Π_a obtained as the product of one-cycles (n_a^I,m_a^I) on each of the three two-tori $I=1,2,3$. [This type of configuration is a particular case of configurations of D6-branes wrapped on special Lagrangian cycles in a Calabi–Yau threefold (see Ref. 18 for recent discussions).] In Ref. 13 these kinds of D6-brane configurations were considered in the presence of an orientifold projection. Since the projection is not required for consistency, we prefer not to impose this restriction and keep our analysis general.

The models admit a T-dual description[6,13] in terms of type IIB compactified on a T-dual torus $\tilde{\mathbf{T}}^6$ (with the Kahler and complex structure on each two-tori exchanged with respect to the original one), with a set of D9-branes (and anti-D9-branes), with wrapping numbers n_a^I and world-volume magnetic flux with charge m_a^I along the Ith two-torus. (Models with such fluxes and orbifold and orientifold projections have appeared in Ref. 19.) Even though we phrase our discussion in D6-brane language, we will find it useful to occasionally turn to this T-dual picture.

The configuration can be described by a free world-sheet CFT, and the consistency conditions (tadpole cancellation conditions) can be analyzed by the usual factorization of one-loop amplitudes. They read as

$$\begin{aligned}
&\sum_a N_a n_a^1 n_a^2 n_a^3=0, \quad \sum_a N_a n_a^1 m_a^2 m_a^3=0,\\
&\sum_a N_a m_a^1 n_a^2 n_a^3=0, \quad \sum_a N_a m_a^1 n_a^2 m_a^3=0,\\
&\sum_a N_a n_a^1 m_a^2 n_a^3=0, \quad \sum_a N_a m_a^1 m_a^2 n_a^3=0,\\
&\sum_a N_a n_a^1 n_a^2 m_a^3=0, \quad \sum_a N_a m_a^1 m_a^2 m_a^3=0.
\end{aligned} \tag{3.1}$$

In the D6-brane picture, they are equivalent to the condition that the homology classes $[\Pi_a]$ of the cycles Π_a wrapped by the D6-branes, counted with multiplicity N_a, add up to zero. Denoting by $[a_I]$, $[b_I]$ the homology classes of the (1,0) and (0,1) basis cycles in the Ith two-torus, we have

$$[\Pi_a]=(n_a^1[a_1]+m_a^1[b_1])\otimes(n_a^2[a_2]+m_a^2[b_2])\otimes(n_a^3[a_3]+m_a^3[b_3]), \tag{3.2}$$

and (3.1) can be recast as

$$\sum_a N_a[\Pi_a]=0. \tag{3.3}$$

The vanishing of the total homology class is required by consistency with the equations of motion for the RR 7-form, under which the D6-branes are electrically charged,

$$d*H_8=\sum_a N_a\delta(\Pi_a), \tag{3.4}$$

where H_8 is the field strength of the 7-form, and $\delta(\Pi_a)$ is a three-form supported at the location of the D6$_a$-branes, the Poincare dual of $[\Pi_a]$. Since $d*H_8$ is exact, the above equation in homology becomes (3.3).

In the language of D9-branes with fluxes, conditions (3.1) receive the following interpretation. In the presence of background magnetic fluxes, D9-branes carry charges under RR forms of all even degrees, due to the WZ world-volume couplings.[20] The above tadpole conditions amount to the cancellation of overall D9-, D7$_I$-, D5$_I$- and D3-brane charges, (where D5$_I$- and D7$_I$-branes, are wrapped on, or transverse to, the Ith two-torus, respectively). This is required for consistency of the equations of motion of the corresponding RR forms, i.e., the T-dual statement to our argument in the D6-brane picture.

From our discussion in Sec. II, the four-dimensional field theory arising after compactification of the D6-branes on the torus contains chiral fermions arising from brane intersections, hence *a priori* have phenomenological interest. They are also nonsupersymmetric, but in principle the existence of a tachyon-free stable configuration is not excluded; see Sec. III D.

Let us obtain the massless (and tachyonic) four-dimensional spectrum. The 6_a6_a sector has unbroken $\mathcal{N}=4$ supersymmetry, and leads, in component fields, to $U(N_a)$ gauge bosons, six real scalars in the adjoint representation and four Majorana fermions in the adjoint as well. In the mixed 6_a6_b and 6_b6_a sectors, the field content appears in general in several replicas, due to the multiple intersection number I_{ab} of the cycles Π_a and Π_b, given by

$$I_{ab}=[\Pi_a]\cdot[\Pi_b]=\prod_i (n_a^i m_b^i - m_a^i n_b^i). \tag{3.5}$$

(In the T-dual picture in terms of D9-branes with magnetic fluxes, the multiplicities arise from the Landau level multiplicities.) In the R sector, we obtain I_{ab} chiral left-handed fermions in the bifundamental representation $(N_a,\overline{N_b})$, with the understanding that a negative multiplicity corresponds to a positive multiplicity of right-handed fermions. In the NS sector, we obtain a set of I_{ab} bifundamental scalars, whose masses are controlled by the angles ϑ_I between the $D6_a$- and the $D6_b$-branes, which depend on the six-torus moduli. Their masses are given by (assuming $0\leqslant\vartheta_i\leqslant 1$)

State	Mass
$(-1+\vartheta_1,\vartheta_2,\vartheta_3,0)$	$\alpha' M^2=\frac{1}{2}(-\vartheta_1+\vartheta_2+\vartheta_3)$,
$(\vartheta_1,-1+\vartheta_2,\vartheta_3,0)$	$\alpha' M^2=\frac{1}{2}(\vartheta_1-\vartheta_2+\vartheta_3)$,
$(\vartheta_1,\vartheta_2,-1+\vartheta_3,0)$	$\alpha' M^2=\frac{1}{2}(\vartheta_1+\vartheta_2-\vartheta_3)$,
$(-1+\vartheta_1,-1+\vartheta_2,-1+\vartheta_3,0)$	$\alpha' M^2=1-\frac{1}{2}(\vartheta_1+\vartheta_2+\vartheta_3)$.

(3.6)

Hence certain intersections may lead to the appearance of tachyons. If present, they signal an instability against joining the intersecting branes into a single smooth one. As observed in Ref. 21, tachyon modes arise precisely in the range of ϑ_I's for which the joining process is energetically favored, namely decreases the 3-cycle volume. In Sec. III D we discuss the construction of models which, for a range of six-torus moduli, do not contain tachyons at brane intersections. Hence the corresponding configurations are protected against recombination by a energy barrier.

In the next section we center robust aspects of the theory, such us the chiral fermion content, and potential gauge anomalies. Hence recall that the gauge group and chiral fermions in the models are

$$\prod_{a=1}^{K} U(N_a), \quad \sum_{a<b} I_{ab}(N_a, \bar{N}_b). \tag{3.7}$$

[In fact, the chiral piece of the spectrum of a set of D6-branes wrapped on 3-cycles in a threefold (not necessarily Calabi–Yau) has this form, and our arguments about the cancellation of four-dimensional anomalies are valid (with some obvious modifications) in this general case.] The spectrum is generically chiral, leading to an interesting set of four-dimensional field theories.

B. Anomaly cancellation

1. Non-Abelian anomalies

Following, Refs. 6, 22, the gauge anomaly induced by the chiral fermions living on each intersection is cancelled by an anomaly inflow mechanism associated to the intersecting branes (see Ref. 23 for string computations of the relevant couplings). Namely, the violation of charge induced by the anomaly is compensated by a charge inflow from the bulk of the intersecting branes. This explanation is sufficient in situations where the branes are infinitely extended. In the compact context, however, within a single brane the charge ''inflowing'' into an intersection must be compensated by charge ''outflowing'' from other intersections. (This anomaly flow picture is analogous to that in Ref. 24.) Consistency of anomaly inflow in a compact manifold imposes global constraints on the configuration.

From the point of view of the compactified four-dimensional effective field theory, which does not resolve the localization of the different chiral fermions, these global constraints correspond to cancellation of triangle gauge anomalies in the usual sense. In fact, the cancellation of cubic non-Abelian anomalies for the gauge factor $SU(N_a)$ in (3.7) reads as

$$\sum_{b=1}^{K} I_{ab} N_b = 0. \tag{3.8}$$

From the ten-dimensional viewpoint, (3.8) expresses the cancellation of inflows from different intersections in the $D6_a$-branes.

By replacing (3.5) in (3.8), one can see that tadpole cancellation conditions imply the cancellation of cubic non-Abelian anomalies. Thus, as usual, string theory consistency conditions imply consistency of the low-energy effective theory. However, tadpole cancellation conditions are in general much stronger than anomaly cancellation conditions (see also Ref. 25), a feature also found in the context of standard type IIB orientifolds[26] (see also Refs. 27, 25).

2. Mixed $U(1)$ anomaly cancellation

Let us turn to mixed $U(1)$ anomalies. Again, anomalies at each intersection are cancelled by the inflow mechanism.[6,22] However, the global consistency of the inflow, or equivalently, cancellation of anomalies from the perspective of the compactified four-dimensional theory, is in this case more intricate, and involves a Green–Schwarz mechanism. (The interplay between the inflow and Green–Schwarz anomaly cancellation mechanisms has been studied in Ref. 28 in a different context.) Using the fermion spectrum in (3.7), the mixed $U(1)_a - SU(N_b)$ triangle anomaly reads as

$$\mathcal{A}_{ab} = \tfrac{1}{2}\delta_{ab} \sum_c N_c I_{bc} + \tfrac{1}{2} N_b I_{ab}. \tag{3.9}$$

The first piece is proportional to the non-Abelian anomaly, and vanishes, while the last piece is generically nonvanishing even after imposing tadpole conditions.

We now show that the residual anomaly is cancelled by a generalized Green–Schwarz mechanism mediated by RR partners of closed string *untwisted* geometric moduli. This situation contrasts with that in type IIB orientifolds, where $U(1)$ anomalies are cancelled through exchange of

closed string *twisted* moduli[29] (see Ref. 30 for the six-dimensional case, and, e.g., Refs. 31, 32 for subsequent work). It also differs from that in heterotic compactifications, in not involving the dilaton multiplet, and in allowing the existence of several anomalous $U(1)$'s.

Let us consider a $D6_a$-brane wrapped on a 3-cycle $[\Pi_a]$. It has several relevant world-volume couplings[20] to the RR 3-form C_3 and its ten-dimensional Hodge dual, the 5-form C_5,

$$\int_{D6_a} C_3 \wedge F_a \wedge F_a ; \quad \int_{D6_a} C_5 \wedge F_a . \tag{3.10}$$

In order to obtain the couplings after a Kaluza–Klein reduction to four dimensions, it is convenient to introduce two basis of homology 3-cycles, $\{[\Sigma_i]\}$, $\{[\Lambda_i]\}$, dual to each other, namely $[\Lambda_i]\cdot[\Sigma_j]=\delta_{ij}$. On these two basis, the $D6_a$-brane 3-cycle $[\Pi_a]$ has the expansions

$$[\Pi_a]=\sum_i r_{ai}[\Sigma_i]; \quad M[\Pi_a]=\sum_i p_{ai}[\Lambda_i]. \tag{3.11}$$

Defining the untwisted RR fields $\Phi_i=\int_{[\Lambda_i]} C_3$; $B_2^i=\int_{[\Sigma_i]} C_5$, which are Hodge duals in the four-dimensional sense, the couplings (3.10) read as

$$\sum_i p_{ai}\int_{M_4}\Phi_i F_a \wedge F_a ; \quad MN_a\sum_i r_{ai}\int_{M_4} B_2^i \wedge F_a , \tag{3.12}$$

where the prefactor N_a arises from normalization of the $U(1)$ generator, as in Ref. 29. These couplings can be combined in a GS diagram where $U(1)_a$ couples to the ith untwisted field, which then couples to F_b^2. The coefficient of this amplitude is (modulo an a, b independent numerical factor)

$$N_a\sum_i r_{ai}p_{bi}=N_a\sum_{i,j} r_{ai}p_{bj}[\Sigma_i]\cdot[\Lambda_j]=N_a[\Pi_a]\cdot[\Pi_b]=N_a I_{ab}, \tag{3.13}$$

precisely of the form required to cancel the residual $U(1)_a-SU(N_b)^2$ anomaly in (3.9).

The same mechanism may be described in the T-dual picture of D9-branes with magnetic fluxes. The couplings on the world-volume of D9-branes to bulk RR fields (the role of these couplings in anomaly cancellation in a different class of models has been suggested in Ref. 19) are of the form (wedge products implied)

$$\begin{gathered}\int_{D9_a} C_0 F_a^5; \quad \int_{D9_a} C_2 F_a^4; \quad \int_{D9_a} C_4 F_a^3, \\ \int_{D9_a} C_6 F_a^2; \quad \int_{D9_a} C_8 F_a ; \quad \int_{D9_a} C_{10}.\end{gathered} \tag{3.14}$$

In order to obtain the four-dimensional version of these couplings, we define

$$C_2^I=\int_{(\mathbf{T^2})_\mathbf{I}} C_4; \quad C_0^I=\int_{(\mathbf{T^2})_\mathbf{I}} C_2,$$

$$B_2^I=\int_{(\mathbf{T^2})_\mathbf{J}\times(\mathbf{T^2})_\mathbf{K}} C_6; \quad B_0^I=\int_{(\mathbf{T^2})_\mathbf{J}\times(\mathbf{T^2})_\mathbf{K}} C_4,$$

$$B_2=\int_{(\mathbf{T^2})_\mathbf{1}\times(\mathbf{T^2})_\mathbf{2}\times(\mathbf{T^2})_\mathbf{2}} C_8; \quad B_0=\int_{(\mathbf{T^2})_\mathbf{1}\times(\mathbf{T^2})_\mathbf{2}\times(\mathbf{T^2})_\mathbf{3}} C_6,$$

where $I\neq J\neq K\neq I$ in the second row. The fields C_2 and C_6, and also C_0 and C_8 are Hodge duals, while C_4 is self-dual. In four dimensions, the duality relations are

$$dC_0=*dB_2;\quad dB_0^I=*dC_2^I,$$

$$dC_0^I=-*dB_2^I;\quad dB_0=-*dC_2.$$

In the dimensional reduction, one should take into account that the integration of F_a along the Ith two-torus yields a factor m_a^I. Also, integrating the pullback of the RR forms on the (multiply wrapped) $D9_a$-brane over the Ith two-torus yields a factor n_a^I. We obtain the couplings

$$N_a\, m_a^1\, m_a^2\, m_a^3\int_{M_4} C_2\wedge F_a;\quad n_b^1\, n_b^2\, n_b^3\int_{M_4} B_0\wedge F_b\wedge F_b,$$

$$N_a\, n_a^I\, m_a^J\, m_a^K\int_{M_4} C_2^I\wedge F_a;\quad n_b^J\, n_b^K\, m_b^I\int_{M_4} B_0^I\wedge F_b\wedge F_b,$$

$$N_a\, n_a^J\, n_a^K\, m_a^I\int_{M_4} B_2^I\wedge F_a;\quad n_b^I\, m_b^J\, m_b^K\int_{M_4} C_0^I\wedge F_b\wedge F_b,$$

$$N_a\, n_a^1\, n_a^2\, n_a^3\int_{M_4} B_2\wedge F_a;\quad m_b^1\, m_b^2\, m_b^3\int_{M_4} C_0\wedge F_b\wedge F_b.$$

As usual, the N_a prefactors arise from $U(1)_a$ normalization.

The GS amplitude where $U(1)_a$ couples to one untwisted field which propagates and couples to two $SU(N_b)$ gauge bosons is proportional to

$$-N_a\, m_a^1 m_a^2 m_a^3 n_b^1 n_b^2 n_b^3+N_a\sum_I\ n_a^I m_a^J m_a^K n_b^J n_b^K m_b^I-N_a\sum_I\ n_a^I n_a^J m_a^K n_b^K m_b^I m_b^J+N_a\, n_a^1 n_a^2 m_a^3 m_b^1 m_b^2 m_b^3$$

$$=N_a\prod_I\ (n_a^I m_b^I-m_a^I n_b^I)=N_a I_{ab}, \tag{3.15}$$

as required to cancel the residual mixed $U(1)$ anomaly in (3.9).

Finally, it is straightforward to check that these theories do not produce mixed $U(1)$ gravitational anomalies.

Due to the linear couplings between the $U(1)$'s and the closed string moduli, anomalous $U(1)$'s become massive with a mass of the order of the string scale. Therefore it is important, for any (phenomenological or not) application of these models, to determine the precise linear combinations becoming massive and those staying massless.

One can advance that since there are eight fields mediating the anomaly cancellation, at most eight $U(1)$ linear combinations can gain mass. Denoting Q_a the generator of the ath $U(1)$, and writing a general linear combination as

$$Q=\sum_{a=1}^{K}\frac{c_a}{N_a}Q_a, \tag{3.16}$$

nonanomalous $U(1)$'s correspond to zero modes of the intersection matrix $\Sigma_a c_a I_{ab}=0$.

We conclude with a brief discussion of Fayet–Iliopoulos terms for the anomalous $U(1)$'s. An important observation is that the standard low-energy field theory arguments relating a GS mechanism with FI terms in Ref. 33 are based on supersymmetry, hence do not directly apply to our models. Notice however that the string theory diagram giving rise to linear couplings between anomalous $U(1)$ and closed string modes is a disk, with boundary on the relevant D6-brane and

a closed string mode insertion. This diagram does not notice the breaking of supersymmetries by other branes, hence yields superpartner interactions, and in particular a FI term, proportional to the NS–NS part of untwisted moduli. As opposed to supersymmetric cases, where the FI terms are not renormalized, in the present nonsupersymmetric situations higher loop contributions are expected.

C. Explicit models

Here we construct an example with a Standard Model gauge group and three quark-lepton families, in order to illustrate how our more general starting point overcomes the difficulty found in Ref. 13 to obtain three generations. Notice that the model, just like the examples in Ref. 13, contains tachyons, but we prefer not to list them since they are moduli dependent (and might even disappear for certain regions in parameter space).

We consider six stacks of D6-branes, $K=6$, with multiplicities and wrapping numbers given by

$$\begin{array}{cccc} \mathbf{N_a} & (\mathbf{n_a^1},\mathbf{m_a^1}) & (\mathbf{n_a^2},\mathbf{m_a^2}) & (\mathbf{n_a^3},\mathbf{m_a^3}) \\ N_1=3 & (1,2) & (1,-1) & (1,-2) \\ N_2=2 & (1,1) & (1,-2) & (-1,5) \\ N_3=1 & (1,1) & (1,0) & (-1,5) \\ N_4=1 & (1,2) & (-1,1) & (1,1) \\ N_5=1 & (1,2) & (-1,1) & (2,-7) \\ N_6=1 & (1,1) & (3,-4) & (1,-5) \end{array} \tag{3.17}$$

This choice satisfies the tadpole conditions. The intersection numbers are

$$\begin{gathered} I_{12}=3,\ I_{13}=-3,\ I_{14}=0,\ I_{15}=0,\ I_{16}=-3, \\ I_{23}=0,\ I_{24}=6,\ I_{25}=3,\ I_{26}=0,\ I_{34}=-6, \\ I_{35}=-3,\ I_{36}=0,\ I_{45}=0,\ I_{46}=6,\ I_{56}=3. \end{gathered} \tag{3.18}$$

The spectrum under $U(3)\times U(2)\times U(1)^4$ is

$$\begin{aligned} &3(3,2)_{[1,-1,0,0,0,0]}+3(\overline{3},1)_{[-1,0,1,0,0,0]}+3(\overline{3},1)_{[-1,0,0,0,0,1]}+6(1,2)_{[0,1,0,-1,0,0]}+3(1,2)_{[0,1,0,0,-1,0]} \\ &+6(1,1)_{[0,0,-1,1,0,0]}+3(1,1)_{[0,0,-1,0,1,0]}+6(1,1)_{[0,0,0,1,0,-1]}+3(1,1)_{[0,0,0,0,1,-1]}, \end{aligned} \tag{3.19}$$

where subindices give $U(1)$ charges. Out the six $U(1)$'s the diagonal linear combination decouples, and two of the remaining are anomalous. A basis of nonanomalous linear combinations (3.16) is provided by the coefficient vectors,

$$\vec{c}=(1,0,0,0,1,0);\quad \vec{c}=(0,1,1,0,0,0);\quad \vec{c}=(0,1,0,0,0,1). \tag{3.20}$$

One can check that the nonanomalous linear combination,

$$Q_Y=-\tfrac{1}{3}Q_1-\tfrac{1}{2}Q_2-Q_3-Q_5, \tag{3.21}$$

can play the role of hypercharge. Indeed, the spectrum, showing only charges under this $U(1)$, is

$$\begin{aligned} &SU(3)\times SU(2)\times U(1)_Y\times 3(3,2)_{1/6}+3(\overline{3},1)_{-2/3}+3(\overline{3},1)_{1/3}+6(1,2)_{-1/2} \\ &+3(1,2)_{1/2}+6(1,1)_1+3(1,1)_0+6(1,1)_0+3(1,1)_{-1}, \end{aligned} \tag{3.22}$$

giving the chiral fermion content of a three-generation standard model [up to charges under additional $U(1)$ symmetries].

This example illustrates that it is relatively easy to do model building in this framework. Unfortunately, as explained in the Introduction, these models suffer a hierarchy problem, since they are not supersymmetric, and it is not possible to lower the string scale by making the six-torus volume large, since this would give rise to too light KK resonances for gauge bosons. However, we cannot exclude that further modifications of the setup improve this aspect. It is conceivable to consider spaces with a small volume region similar to $\mathbf{T^6}$, where D6-branes wrap leading to heavy KK excitation, while the volume of the complete space is much larger. A simple example can be obtained by surgery, taking a small $\mathbf{T^6}$, removing a ball in a region away from the branes, and gluing a throat connecting it to a large volume manifold. Of course, a concrete realization of this would require a much more careful analysis, and our comment is just intended for illustration. In any event, the problem in lowering the string scale is not present in the models of D4- and D5-branes, to be studied in the next sections.

D. Stability and tachyons

The lowest lying states in the NS sector of an open string stretched between intersecting D6-branes are given in (3.6), along with their masses. These can be tachyonic or not, depending on the angles between the D-branes. For instance, for $\vartheta_1 \leqslant \vartheta_2+\vartheta_3$, $\vartheta_2 \leqslant \vartheta_3+\vartheta_1$, $\vartheta_3 \leqslant \vartheta_1+\vartheta_2$, $\vartheta_1+\vartheta_2+\vartheta_3 \leqslant 2$, all states at the intersections have a non-negative mass square. In fact, these are the conditions for the two intersecting 3-cycles to be stable against recombination into a single smooth 3-cycle.[21]

In principle there seems to be no obstruction to the existence of compactifications on $\mathbf{T^6}$ with D6-branes wrapped on 3-cycles, such that every intersection fulfills the above conditions, yielding a four-dimensional nonsupersymmetric chiral theory free of tachyons. Such configurations would be stable against small perturbations, but, carrying no net charges may decay to the vacuum by tunneling through a potential barrier. Such metastable (rather than absolutely stable) non-BPS configurations could however lead to perfectly sensible phenomenological models if their lifetime, exponentially suppressed by the barrier height, is long enough for cosmological standards.

E. Explicit examples of tachyon elimination

In this section we construct specific models where all intersections are tachyon-free for certain regions in the six-torus parameter space, namely the complex structure of the two-tori.

It turns out that it is easier to build such models if the construction includes an orientifold projection ΩR (where $R: z_i \to \overline{z_i}$) as in Ref. 13. The only differences with respect to our configurations above is that the angle between the tori axis is projected out, the $D6_a$-branes wrapped on cycles (n_a^I, m_a^I) must have ΩR orientifold images (denoted $D6a'$-branes) wrapped on cycles (n_a^I, m_a^I), and the first tadpole condition in (3.1) becomes $\Sigma_a N_a\, n_a^1\, n_a^2\, n_a^3 = 16$ (not counting images). The potential tachyon masses are however obtained as above.

The model under consideration is one of the four-dimensional constructions presented in Ref. 13. The sets of D6-branes are given by

N_a	$(\mathbf{n_a^1},\mathbf{m_a^1})$	$(\mathbf{n_a^2},\mathbf{m_a^2})$	$(\mathbf{n_a^3},\mathbf{m_a^3})$
$N_1=3$	(1,0)	(1,0)	(1,1)
$N_2=3$	(1,2)	(1,1)	(1,0)
$N_3=1$	(1,2)	(1,−2)	(1,0)
$N_4=1$	(1,0)	(1,0)	(10,1)

(3.23)

plus their ΩR images. The main advantage in searching tachyon-free models by using constructions with an ΩR orientifold projection, is that, as can be appreciated in (3.23), it allows all

integers n_a^I to be positive. This simplifies the search for tachyon-free regions, since it ensures that taking large ratios R_1/R_2 all angles between branes become small, and states become less tachyonic. For instance, choosing

$$R_2^1/R_1^1=1; \quad R_2^2/R_1^2=3/2; \quad R_2^3/R_1^3=2, \tag{3.24}$$

the masses for the scalars (3.6) at the different intersections are

Intersection	$\alpha'\mathbf{m}_1^2$	$\alpha'\mathbf{m}_2^2$	$\alpha'\mathbf{m}_3^2$	$\alpha'\mathbf{m}_4^2$
$12, 12', 21', 1'2'$	0.16	0.20	0.16	0.49
$13, 13', 31', 1'3'$	0.20	0.15	0.20	0.45
$24, 24', 42', 2'4'$	0.01	0.05	0.30	0.64
$34, 34', 43', 3'4'$	0.05	0.01	0.34	0.59

(3.25)

We can see that they are all positive, hence the intersections are free of tachyons, and the system is stable against recombination of the corresponding cycles.

Pairs of branes with zero intersection number are parallel in some two-torus. In this model, in the nongeneric case that the branes overlap in this two-torus, open strings stretched between them would lead to additional tachyons,

Intersection	$\alpha'\mathbf{m}_1^2$	$\alpha'\mathbf{m}_2^2$	$\alpha'\mathbf{m}_3^2$	$\alpha'\mathbf{m}_4^2$
$11'$	0.35	0.35	-0.35	0.65
$22'$	-0.04	0.04	0.67	0.33
$33'$	0.05	-0.05	0.75	0.25
$44'$	0.06	0.06	-0.06	0.94
$14, 1'4'$	0.14	0.14	-0.14	0.86
$14', 41'$	0.21	0.21	-0.21	0.79
$23, 2'3'$	0.36	-0.36	0.36	0.64
$23', 32'$	-0.31	0.31	0.39	0.61

(3.26)

However, these states are not tachyonic if the branes are separated beyond a critical distance in the corresponding two-torus. It is possible that higher effects, due to brane interactions (one loop in the open string channel), induce a nonzero attractive force between such nonintersecting branes, pushing them to the tachyonic region. In any event, this would be a higher order effect which might be avoided in more complicated models. Our point here is that tachyons and intersections, which appear at tree level and are therefore more dangerous, can be eliminated in some models by a suitable choice of background geometry.

In principle it is possible that this kind of tachyon-free configurations exist in models without the orientifold projection, even though a systematic exploration of parameter space is more difficult. We would like to conclude by pointing out that, since the main difficulty arising from satisfying the tadpole conditions, the above ideas may have a much simpler implementation in other contexts, where such conditions are not relevant. For instance, one may construct a large class of (meta)stable non-BPS states in type IIB theory on $\mathbf{T}^6$, by considering D3-branes wrapped on 3-cycles with tachyon-free intersections.

F. Tachyons and Higgs mechanism

Even if tachyons are present, we would like to point out a quite different perspective on them, which is actually applicable to more general examples (among others, those of D4- and D5-branes in the coming sections). As in the more familiar example of brane–antibrane systems (see, e.g.,

Refs. 16, 34), the condensation of open string tachyons may in certain situations be interpreted as a Higgs mechanism. In our present context, the tachyon is charged under the gauge groups on the intersecting branes, and its condensation reduces the gauge symmetry to that of the recombined brane. From the spacetime viewpoint, it is physically clear that the tachyon has a potential with a minimum, at which the energy of the condensate compensates the difference of tensions between the final and initial states, and at which the tachyon vev breaks the initial gauge symmetry. Adapting Sen's ideas,[16] the intersecting branes with the tachyon condensed to its minimum is *exactly* the final configuration of the recombined brane (stretched along a minimum volume cycle in its homology class). (This is particularly clear in the T-dual picture of D9-branes with magnetic fluxes, where the above process often amounts to annihilation of topological defects on the D9-brane world-volume. Some remarks on tachyon condensation as a Higgs mechanism in this picture have appeared in Ref. 35.)

This idea has an important and interesting caveat, in the interpretation of the inverse process as un-Higgsing. Basically, the final state does not keep track of what initial state it came from. Hence if the system is given energy, it will nucleate not only the W bosons corresponding to the original initial state, but also W bosons of enhanced symmetries associated to all other possible initial states in the same energy range. However, there may be situations where one possible initial state is substantially lighter than the rest. In this situation, a low-energy observer, with a limited range of available energies, would systematically find a single pattern of gauge symmetry enhancement. This situation is close enough to a standard Higgs mechanism, so that tachyons may be interpreted as standard Higgs fields (at least for processes in the appropriate range of energies), even for electroweak symmetry breaking. A more detailed understanding of the tachyon potential and dynamics[34] would help in determining if such a scenario is indeed viable for electroweak or other phenomenological Higgs mechanisms. For the moment, we just point out the tantalizing existence of tachyon fields with the quantum numbers of standard model Higgs fields in some of the models we have explored (see Sec. IV C and Ref. 15 for further details).

IV. D4-BRANES WRAPPING AT ANGLES ON $\mathbf{T^2\times C^2/Z_N}$

A. Construction

As discussed in Sec. II, configurations of D4-branes wrapped on 1-cycles in $\mathbf{T^2\times C^2}$ lead necessarily to nonchiral spectra. In this section we study a simple modification of this basic framework, which leads to generically chiral four-dimensional gauge field theories on the D-brane world-volume.

We consider configurations of D4-branes on $\mathbf{T^2\times(C^2/Z_N)}$, where the D4-branes are distributed in stacks of multiplicity N_a, wrapped along one-cycles Π_a defined by wrapping numbers (n_a,m_a), on $\mathbf{T^2}$ and sitting at the origin in $\mathbf{C^2/Z_N}$. The models admit a T-dual description in terms of type IIB D5-branes on $\mathbf{T^2\times(C^2/Z_N)}$, with nontrivial wrapping numbers and fluxes on $\mathbf{T^2}$. We usually phrase our results in the D4-brane picture, but translation to the D5-brane picture is straightforward, as in the models in Sec. III.

The twist $\mathbf{Z_N}$ is generated by a geometric action θ with a twist vector given by $v=(1/N)(b_1,b_2,0,0)$, where $b_1=b_2$ mod 2 for the variety to be spin. The supersymmetric case is recovered when $b_2=-b_1$ mod N, hence with twist $v=(1/N)(b_1,-b_1,0,0)$. In this case, since b_1 and N must be coprime for a $\mathbf{Z_N}$ action, the orbifold group can be equivalently generated by the twist θ^k, with $kb_1=1$ mod N, which has the more familiar twist vector $v=(1/N)(1,-1,0,0)$.

We would like to emphasize that we imagine this framework as a local description of the configuration near the location of the branes. Globally, the local configuration above may be embedded in a spacetime of the form $\mathbf{T^2\times B}$, where $\mathbf{B}$ is a four-dimensional space (not necessarily Calabi–Yau) with a $\mathbf{C^2/Z_N}$ singularity at which the D-branes sit. More generally, the complete space may not be globally a product, but rather a torus bundle over $\mathbf{B}$, or even a torus fibration, as long as singular fibers are away from the D-brane location. Our configuration is a good local description in these cases, and completely controls the structure of the D-brane world-volume gauge theory.

Let us briefly mention another interesting aspect. These configurations admit a seemingly simple lift to M-theory, as a set of M-theory fivebranes sitting at a $\mathbf{C^2/Z_N}$ singularity, and wrapped on a two-cycle in $\mathbf{T^2\times S^1}$. Obviously, a detailed description of the model in M-theory will involve a number of interesting subtleties, on which our analysis may shed some light. Note that the existence of this six-dimensional parent theory, which reduces to the four-dimensional field theory after compactification, is not in contradiction with chirality in the latter. The higher-dimensional theory is not a conventional field theory, and in fact four-dimensional chiral states arise from membranes stretched between M5-branes and wrapped on $\mathbf{S^1}$, i.e., they do not descend by KK reduction from any six-dimensional field.

Let us describe the computation of the spectrum in our configuration. The closed string sector is computed using standard orbifold techniques. In the supersymmetric case, it gives rise to an $D=4$ $\mathcal{N}=4$ $U(1)^{N-1}$ gauge multiplet. In the nonsupersymmetric case, the main feature is that it leads to tachyons in the NS–NS sector. Their interpretation is, as usual with closed string tachyons, not understood, and we will have nothing new to say about them. Nevertheless, we choose to study these models and in particular their open string spectrum even for nonsupersymmetric singularities.

The $\mathbf{Z_N}$ action may be embedded in the $U(N_a)$ gauge degrees of freedom of the ath stack of D4-branes, through a unitary matrix of the form

$$\gamma_{\theta,a}=\mathrm{diag}(\mathbf{1}_{N_a^0},e^{2\pi i\,(1/N)}\mathbf{1}_{N_a^1},\ldots,e^{2\pi i\,[(N-1)/N]}\mathbf{1}_{N_a^{N-1}}), \tag{4.1}$$

with $\Sigma_i N_a^i=N_a$.

Let us compute the spectrum in the open string sector. In the 4_a4_a sector, the massless states surviving the GSO projection, along with their behavior under the $\mathbf{Z_N}$ twist, are

NS State	$\mathbf{Z_N}$ phase	R State	$\mathbf{Z_N}$ phase
$(\pm 1,0,0,0)$	$e^{\pm 2\pi i\,(b_1/N)}$	$\pm\frac{1}{2}(-,+,+,+)$	$e^{\mp\pi i\,[(b_1-b_2)/N]}$
$(0,\pm 1,0,0)$	$e^{\mp 2\pi i\,(b_2/N)}$	$\pm\frac{1}{2}(+,-,+,+)$	$e^{\pm\pi i\,[(b_1-b_2)/N]}$
$(0,0,\pm 1,0)$	1	$\pm\frac{1}{2}(+,+,-,+)$	$e^{\pm\pi i\,[(b_1+b_2)/N]}$
$(0,0,0,\pm 1)$	1	$\pm\frac{1}{2}(+,+,+,-)$	$e^{\pm\pi i\,[(b_1+b_2)/N]}$

(4.2)

The open string spectrum is obtained by keeping states invariant under the combined geometric plus Chan–Paton $\mathbf{Z_N}$ action.[36] After the $\mathbf{Z_N}$ projections, the resulting gauge group and matter fields are

$$\begin{aligned}
&\text{Gauge bosons} \quad \prod_{a=1}^{K}\prod_{i=1}^{N} U(N_a^i),\\
&\text{Cmplx. scalars} \quad \sum_{a=1}^{K}\sum_{i=1}^{N}\left[\,(N_a^i,\overline{N_a^{i+b_1}})+(N_a^i,\overline{N_a^{i+b_2}})\right],\\
&\text{Left fermion} \quad \sum_{a=1}^{K}\sum_{i=1}^{N}\left[(N_a^i,\overline{N_a^{i+(b_1-b_2)/2}})+(N_a^i,\overline{N_a^{i-(b_1-b_2)/2}}),\right.\\
&\text{Right fermion} \quad \sum_{a=1}^{K}\sum_{i=1}^{N}\left[(N_a^i,\overline{N_a^{i+(b_1+b_2)/2}})+(N_a^i,\overline{N_a^{i-(b_1+b_2)/2}}).\right.
\end{aligned} \tag{4.3}$$

Notice that this piece of the spectrum is generically nonsupersymmetric, and always nonchiral. In the supersymmetric case, $v=(1,-1,0,0)/N$, this sector preserves $\mathcal{N}=2$ supersymmetry in the four-dimensional field theory. The above fields form the multiplets,

$$\mathcal{N}=2 \quad \text{vector} \quad \prod_{a=1}^{K}\prod_{i=1}^{N} U(N_a^i),$$
$$\mathcal{N}=2 \quad \text{hyper} \quad \sum_{a=1}^{K}\sum_{i=1}^{N} (N_a^i,\overline{N}_a^{i+1}). \tag{4.4}$$

In the 4_a4_b sector, open strings are twisted by the angle formed by the branes, denoted ϑ, resulting in a sector twisted by the shift $(\vartheta,0,0,0)$. Assuming $0\leqslant\vartheta\leqslant 1$, tachyonic and massless states, along with their $\mathbf{Z_N}$ phases, are

Sector	State	$\mathbf{Z_N}$ phase
NS	$(-1+\vartheta,0,0,0)$	1
R	$(-\frac{1}{2}+\vartheta,-\frac{1}{2},-\frac{1}{2},+\frac{1}{2})$	$e^{-2\pi i[(b_1+b_2)/2N]}$
	$(-\frac{1}{2}+\vartheta,-\frac{1}{2},+\frac{1}{2},-\frac{1}{2})$	$e^{-2\pi i[(b_1-b_2)/2N]}$
	$(-\frac{1}{2}+\vartheta,+\frac{1}{2},-\frac{1}{2},-\frac{1}{2})$	$e^{2\pi i[(b_1-b_2)/2N]}$
	$(-\frac{1}{2}+\vartheta,+\frac{1}{2},+\frac{1}{2},+\frac{1}{2})$	$e^{2\pi i[(b_1+b_2)/2N]}$

(4.5)

This piece of the spectrum is nonsupersymmetric, even for supersymmetric $\mathbf{Z_N}$ twists. The NS states are tachyonic, with $\alpha' M^2$ equal to $-\frac{1}{2}|\vartheta|$, and signal an instability against recombining intersecting D4-branes with the same Chan–Paton eigenvalue. Hence, they may be avoided by suitable choices of the $\mathbf{Z_N}$ actions $\gamma_{\theta,4_a}$. A different possibility is to interpret these tachyons as triggering breaking of gauge symmetries by a Higgs mechanism, as mentioned in Sec. III D. The R states are massless, and provide a set of chiral fermions in the model. Notice that the antiparticles of these states appear in the 4_b4_a sector, which is twisted by $(-\vartheta,0,0,0)$.

In these sectors the spectrum generically appears in several replicas, whose number is given by the intersection number I_{ab} of the one-cycles Π_a and Π_b in $\mathbf{T^2}$,

$$I_{ab}=n_am_b-m_an_b\,. \tag{4.6}$$

The spectrum after the Chan–Paton projections is given by

$$\text{Cmplx. tachyons} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times(N_a^i,\overline{N}_b^i),$$
$$\text{Left fermion} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times[(N_a^i,\overline{N}_b^{i+(b_1+b_2)/2}+(N_a^i,\overline{N}_b^{i-(b_1+b_2)/2}], \tag{4.7}$$
$$\text{Right fermion} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times[(N_a^i,\overline{N}_b^{i+(b_1-b_2)/2}+(N_a^i,\overline{N}_b^{i-(b_1-b_2)/2}],$$

which is nonsupersymmetric and generically chiral. Therefore the resulting field theories may lead to phenomenologically interesting models. In fact, in Sec. IV C we construct an explicit example with a Standard Model group and three quark lepton generations.

B. Tadpoles and anomalies

1. Tadpole cancellation conditions

The consistency conditions (RR tadpole cancellation conditions) for these configurations are easily computed, and read as

$$\prod_{r=1,2} \sin(\pi k b_r/N) \sum_{a=1}^{K} n_a \mathrm{Tr}\gamma_{\theta^k,4_a} = 0,$$

$$\prod_{r=1,2} \sin(\pi k b_r/N) \sum_{a=1}^{K} m_a \mathrm{Tr}\gamma_{\theta^k,4_a} = 0,$$

for $k=1,\ldots,N-1$.

There is no constraint associated to $k=0$, since the untwisted tadpole is associated to a flux that can escape along the noncompact dimensions of $\mathbf{C}^2/\mathbf{Z}_\mathbf{N}$.

These conditions can be interpreted geometrically, at least for supersymmetric singularities, by regarding the fractional[37] $D4_a^s$-branes (i.e., the set of $D4_a$ branes associated to the phase $e^{2\pi i (s/N)}$ in $\gamma_{\theta,4_a}$) as D6-branes wrapped on the 1-cycle $[\Pi_a]=n_a[a]+m_a[b]$ in $\mathbf{T}^2$ times the sth collapsed two-cycle $[\Sigma_s]$ in the singularity. The conditions above amount to the vanishing of the total homology class,

$$\sum_{a=1}^{K} \sum_{s=0}^{N-1} N_a^s [\Pi_a] \otimes [\Sigma_s] = 0. \tag{4.8}$$

Since $\Sigma_{s=0}^{N-1}[\Sigma_s]=0$, one can increase the N_a^s by an s-independent (but possibly a-dependent) amount and still satisfy the homological condition. Hence, the Chan–Paton matrices for $k=0$ are unconstrained. Note that regarding branes at singularities as branes wrapped on collapsed cycles, our models of D4-branes become a degenerate version of D6-branes wrapped on 3-cycles in a curved ambient space, and our results here are reminiscent of those in Sec. III B.

2. Anomaly cancellation

The spectrum of the model is generically chiral, and has potential gauge anomalies. In analogy with the case of D6-branes on $\mathbf{T}^6$, cancellation of the anomalies due to chiral fermions at each intersection would be achieved by an inflow mechanism. Since the intersections sit at the singularity in transverse space, this inflow mechanism would be more involved and interesting, but still tractable. Leaving aside its study, we prefer to center on the compactified effective four-dimensional description of anomaly cancellation.

The cancellation of cubic non-Abelian anomalies for $SU(N_a^i)$ gives the conditions

$$\sum_{b=1}^{K} I_{ab}(-N_b^{i+(b_1+b_2)/2} - N_b^{i-(b_1+b_2)/2} + N_b^{i+(b_1-b_2)/2} + N_b^{i-(b_1-b_2)/2}) = 0. \tag{4.9}$$

These conditions should follow from the tadpole cancellation conditions. In fact, using (4.1) we can rewrite

$$N_b^i = \frac{1}{N} \sum_{k=0}^{N-1} e^{-2\pi i (ki/N)} \mathrm{Tr}\gamma_{\theta^k,4_b}, \tag{4.10}$$

as in Ref. 38, and the anomaly cancellation conditions read as

$$\prod_{r=1,2} \sin(\pi k b_r/N) \sum_{b=1}^{K} I_{ab} \mathrm{Tr}\gamma_{\theta^k,4_b} = 0. \tag{4.11}$$

These conditions are indeed guaranteed by the tadpole conditions (4.8), but, as usual, are much milder than the latter.

Let us consider cancellation of mixed $U(1)$ anomalies, which involves a generalized Green–Schwarz mechanism, mediated by $2(N-1)$ fields, corresponding to the integration of $N-1$ twisted RR-fields along the two independent 1-cycles in the $\mathbf{T}^2$.

In fact, one can compute the mixed anomaly between the $U(1)_{ai}$ and $SU(N_b^j)$ using the chiral piece of the spectrum (4.7). After removing a vanishing piece proportional to the non-Abelian anomaly, there remains

$$\mathcal{A}_{ai,bj}=\tfrac{1}{2}N_a^i I_{ab}(\delta_{j,i+(b_1+b_2)/2}+\delta_{j,i-(b_1+b_2)/2}-\delta_{j,i+(b_1-b_2)/2}-\delta_{j,i-(b_1-b_2)/2}). \tag{4.12}$$

Substituting the discrete Fourier transform representation of the Kronecker deltas, as in Ref. 29, the anomaly acquires the nice factorized form

$$A_{ai,bj}=iN_a^i I_{ab}\frac{1}{N}\sum_{k=1}^{N-1}4\prod_{r=1,2}\sin(\pi k b_r/N)e^{2\pi i(ki/N)}e^{-2\pi i(kj/N)}. \tag{4.13}$$

The anomaly may therefore be cancelled by exchange of the four-dimensional fields obtained by integrating over the two one-cycles in $\mathbf{T^2}$ the RR twisted forms, which give the four-dimensional couplings:

$$c_k N_a^i n_a\int_{M_4}\mathrm{Tr}(\gamma_{\theta^k,4_a}\lambda_i)\,C_2^{(k)}\wedge\mathrm{tr}F_{a,i};\quad c_k m_b\int_{M_4}\mathrm{Tr}(\gamma_{\theta^k,4_b}\lambda_j^2)\,C_0^{(k)}\wedge\mathrm{Tr}F_{b,j}^2,$$

$$-c_k N_a^i m_a\int_{M_4}\mathrm{Tr}(\gamma_{\theta^k,4_a}\lambda_i)\,B_2^{(k)}\wedge\mathrm{tr}F_{a,i};\quad c_k n_b\int_{M_4}\mathrm{Tr}(\gamma_{\theta^k,4_b}\lambda_j^2)\,B_0^{(k)}\wedge\mathrm{Tr}F_{b,j}^2,$$

where λ denotes the CP wavefunction of the gauge boson state. The prefactors $c_k=[\Pi_r\sin(\pi k b_r/N)]^{1/2}$ can be thought of as arising from $\hat{A}^{1/2}$ in D-brane couplings,[20] and have been explicitly computed in string theory in, e.g., Refs. 31, 32. Since B_2 and B_0, and C_2 and C_0 are Hodge dual in four dimensions, the sum over GS diagrams has the structure (4.13). The GS mechanism is analogous to that for D6-branes on $\mathbf{T^6}$, as is manifest from the appearance of the intersection number, the main difference being that the exchanged fields belong to twisted sectors of the $\mathbf{C^2/Z_N}$ factor.

The above results can be interpreted geometrically by regarding the fractional $D4_a$-branes as D6-branes wrapped on collapsed cycles Σ_s of the singularity and the one-cycle Π_a in $\mathbf{T^2}$. This is simplest in the more familiar supersymmetric case where the anomaly is given by

$$A_{ai,bj}=\tfrac{1}{2}N_b^j I_{ab}(2\delta_{j,i}-\delta_{j,i+1}-\delta_{j,i-1}). \tag{4.14}$$

The collapsed two-cycles have intersections given by (minus) the Cartan matrix of the (affine) $\hat{A}_{N-1}$ algebra, $C_{ij}=[\Sigma_i]\cdot[\Sigma_j]=-2\delta_{ji}+\delta_{j,i+1}+\delta_{j,i-1}$. Hence, the intersection number of D6-branes wrapped on cycles $[\Pi_a]\otimes[\Sigma_i]$ and $[\Pi_b]\otimes[\Sigma_j]$ is $I_{ab}C_{ij}$. Introducing a composite index I grouping together indices a and i, we can express the mixed anomaly (4.14) as

$$A_{IJ}=\tfrac{1}{2}N_I\mathcal{I}_{IJ}, \tag{4.15}$$

where $\mathcal{I}_{IJ}$ denotes the 3-cycle intersection form. The situation is hence analogous to that in Sec. III B. As suggested, the GS cancellation mechanism in Sec. III B can be directly translated, with the obvious modifications, reproducing the cancellation of anomalies in the present context. Since here the wrapped 3-cycles are exceptional divisors of the singularity, the forms mediating the GS mechanism arise as twisted states in string theory. The above geometric interpretation follows also for nonsupersymmetric $\mathbf{Z_N}$ twist, by using the corresponding intersection matrix, obtained from (4.12).

As in Sec. III B, anomalous $U(1)$'s get a mass of the order of the string scale. To find nonanomalous $U(1)$'s, we consider linear combinations,

$$Q=\sum_{a=1}^{K}\sum_{j=0}^{N-1}\frac{c_{a,j}}{N_a^j}Q_{a,j} \tag{4.16}$$

(we choose $c_{b,i}=0$ if the corresponding group is not present, namely if $N_a^i=0$). Nonanomalous $U(1)$'s can again be found as zero modes of the (generalized) intersection matrix. In fact, we can be slightly more explicit. Taking the supersymmetric singularity case for concreteness, and using the expression (4.13), anomaly-free linear combinations satisfy

$$\frac{1}{N}\sum_{k=1}^{N-1}e^{-2\pi i\,(kj/N)}\sin^2(\pi k/N)\sum_{a=1}^{K}I_{ab}\sum_{i=0}^{N-1}e^{2\pi i\,(ki/N)}c_{a,i}=0, \tag{4.17}$$

for each $b=1,\ldots,K$ and $j=0,\ldots,N-1$. A useful trick is to perform the change of coordinates[5] $r_{a,k}=\Sigma_{i=0}^{N-1}e^{2\pi i\,(ki/N)}c_{a,i}$, and obtain the conditions

$$\sin^2(\pi k/N)\sum_{a=1}^{K}I_{ab}\,r_{a,k}=0. \tag{4.18}$$

A set of solutions is given by choosing, for a fixed a, $r_{a,k}=\delta_{k,0}$, and $r_{b,k}=0$ for $b\neq a$. The resulting generator is

$$Q_a=\sum_{i=0}^{N-1}\frac{Q_{a,i}}{N_a^i}. \tag{4.19}$$

Another combination is obtained by choosing $c_{a,i}=N_a^i$, or equivalently by $r_{a,k}=\mathrm{Tr}\,\gamma_{\theta^k,4_a}$, namely

$$Q=\sum_{a=1}^{K}\sum_{i=0}^{N-1}Q_{a,i}. \tag{4.20}$$

Depending on the details of the orbifold group, there may be additional nonanomalous $U(1)$'s. These are most easily determined by directly computing the zero modes of the anomaly matrix in each case.

C. Explicit models

In the present context it is not possible to get rid of all the tachyons while maintaining a chiral fermion spectrum. A general argument goes as follows. Since tachyons arise in $4_a4_b+4_b4_a$ sectors from strings stretching between D4-branes with the same Chan–Paton phase, to avoid tachyons we must consider models where any two intersecting branes have no common Chan–Paton eigenvalues. Consider models with N stacks of $\mathrm{D4}_a$-branes, hence $K=N$, at a $\mathbf{C^2/Z_N}$ singularity, with twist, e.g., $v=(1,-1)/N$, and wrapped on arbitrary 1-cycles Π_a on $\mathbf{T^2}$, and choose the Chan–Paton embeddings,

$$\gamma_{\theta,4_a}=e^{2\pi i\,(a/N)}\mathbf{1}_{N_a}, \tag{4.21}$$

hence $N_a^i=N_a\delta_{a\,i}$ (more general choices can be treated analogously). The spectrum one naively obtains seems chiral, but the tadpole conditions,

$$\sum_{a=1}^{N}e^{2\pi i\,(ka/N)}N_a[\Pi_a]=0,\quad \text{for } k=1,\ldots,N-1, \tag{4.22}$$

turn out to be very constraining. By discrete Fourier transforming, they imply that all $[\Pi_a]$ are actually identical, so all D4-branes are parallel, leading to nonchiral spectra.

Allowing a nonsupersymmetric singularity may relax the tadpole conditions, but introduces (closed string) tadpoles. Also, the case $K<N$ reduces to the above with some $N_a=0$, while additional branes ($K>N$) necessarily repeat eigenvalues and must be nonintersecting, i.e., parallel, to the existing ones to avoid tachyons.

Allowing for some tachyons in the model, however, one can obtain large classes of models with a chiral spectrum, which moreover can be quite close to realistic models. Let us discuss a simple explicit model, which illustrates a possible model building strategy.

Since $\mathbf{Z_2}$ leads to vector-like models, let us consider sets of D4-branes at $\mathbf{T^2\times C^2/Z_3}$, with twist $v=(1,-1,0,0)/3$. A typical tachyon-free and hence nonchiral model would have three stacks of D4-branes, with $\gamma_{\theta,4_a}=e^{2\pi i\, a/3}\mathbf{1}$, and parallel cycles. Consider, e.g., the stack with $\gamma_\theta=\mathbf{1}$ with multiplicity 3 and cycle (1,0), and the remaining two with multiplicity 1 and cycle (3,0), yielding a gauge group $U(3)\times U(1)\times U(1)$ with vector-like matter. To get chirality, we must allow one of these sets to split into several intersecting stacks, a process which also implies the appearance of tachyons (which would trigger the recombination to the original configuration). Let us build this enlarged model with a Standard Model gauge group, namely including a stack with group $U(2)$, and with triplicated intersections. A possible choice is to split the brane with $\gamma_\theta=e^{2\pi i/3}$ wrapped on (3,0), into two branes wrapped on (1,3), one brane on $(0,-3)$ and one brane on $(1,-3)$. Hence we end up with

Multiplicity	Cycle	CP phase
$N_1=3$	(1,0)	1
$N_2=2$	(1,3)	$e^{2\pi i/3}$
$N_3=1$	$(0,-3)$	$e^{2\pi i/3}$
$N_4=1$	$(1,-3)$	$e^{2\pi i/3}$
$N_5=1$	(3,0)	$e^{2\pi i\, 2/3}$

(4.23)

The chiral spectrum contains left-handed fermions transforming under $U(3)\times U(2)\times U(1)_3^3\times U(1)_4\times U(1)_5^3$ as

$$\begin{aligned}&3(3,2)_{[1,-1,(0^3),0,(0^3)]}+(\overline{3},1)_{[-1,0,\underline{1,0,0},0,(0^3)]}+3(\overline{3},1)_{[-1,0,(0^3),1,(0^3)]}\\&\quad+2(1,2)_{[0,1,\underline{-1,0,0},0,(0^3)]}+12(1,2)_{[0,1,(0^3),-1,(0^3)]}+3(1,2)_{[0,-1,(0^3),0,\underline{1,0,0}]}\\&\quad+2(1,1)_{[0,0,\underline{-1,0,0},1,(0^3)]}+(1,1)_{[0,0,\underline{1,0,0},0,\underline{-1,0,0}]}+3(1,1)_{[0,0,(0^3),1,\underline{-1,0,0}]},\end{aligned}\tag{4.24}$$

where underlining means permutation. Besides the diagonal combination, which decouples, there are six nonanomalous $U(1)$ linear combinations. One of them, given by

$$Q_Y=-\tfrac{1}{3}Q_1-\tfrac{1}{2}Q_2-Q_4-(Q_5^{(1)}+Q_5^{(2)}+Q_5^{(3)}),\tag{4.25}$$

provides the correct hypercharge assignments for the above theory, which therefore has the chiral content of a three-generation standard model. Indeed, highlighting the charges under this $U(1)$, the fermion spectrum is

$$3(3,2)_{1/6}+3(\overline{3},1)_{1/3}+3(\overline{3},1)_{-2/3}+15(1,2)_{-1/2}+12(1,2)_{1/2}+6(1,1)_{-1}+9(1,1)_1+9(1,1)_0.\tag{4.26}$$

Further properties of these models will be discussed in Ref. 15. Here let us simply point out that, in models constructed using the above strategy, the tachyons trigger the recombination of branes involving the $U(2)$ factor, and therefore have the gauge quantum numbers of standard

model Higgs fields. These models therefore illustrate that tachyonic modes may be phenomenologically interesting (to trigger electroweak or other extended symmetry breakings), and that in this class of models they are linked to the existence of chiral fermions.

As mentioned in the Introduction, even though the models are nonsupersymmetric, the hierarchy problem is avoided by considering a low string scale and a compactification with large volume for the space transverse to the two-torus.

V. D5-BRANES WRAPPING AT ANGLES ON $(T^2)^2 \times C/Z_N$

A. Construction

For completeness, in this section we center on a last type of configuration, similar to those in the preceding section, and also leading to four-dimensional chiral theories. We consider configurations of D5-branes in $\mathbf{T^4}\times(\mathbf{C}/\mathbf{Z_N})$, where the D5-branes sit at the origin in $\mathbf{C}/\mathbf{Z_N}$, and are grouped in stacks of multiplicity N_a wrapped on 2-cycles defined by (n_a^I, m_a^I), with $I=1,2$, in a factorizable $\mathbf{T^4}$.

The $\mathbf{Z_N}$ action on the third dimension is encoded in the twist vector of the form $v = (1/N)\,(0,0,2,0)$ for the variety to be spin. The closed string sector necessarily contains tachyons in its twisted sector, whose interpretation is unclear. Nevertheless, we proceed studying these models. The Chan–Paton twist matrices have the general form

$$\gamma_{\theta,a} = \mathrm{diag}(\mathbf{1}_{N_a^0}, e^{2\pi i\,(1/N)}\mathbf{1}_{N_a^1}, \ldots, e^{2\pi i\,[(N-1)/N]}\mathbf{1}_{N_a^{N-1}}), \tag{5.1}$$

with $\Sigma_i N_a^i = N_a$. The lowest lying states in the 5_a5_a open string NS and R sectors, along with their $\mathbf{Z_N}$ phases, are

NS state	$\mathbf{Z_N}$ phase;	R State	$\mathbf{Z_N}$ phase
$(\pm 1,0,0,0)$	1	$\pm\frac{1}{2}(-,+,+,+)$	$e^{\pm 2\pi i\,(1/N)}$
$(0,\pm 1,0,0)$	1	$\frac{1}{2}(+,-,+,+)$	$e^{\pm 2\pi i\,(1/N)}$
$(0,0,\pm 1,0)$	$e^{\pm 4\pi i\,(1/N)}$	$\pm\frac{1}{2}(+,+,-,+)$	$e^{\mp 2\pi i\,(1/N)}$
$(0,0,0,\pm 1)$	1	$\pm\frac{1}{2}(+,+,+,-)$	$e^{\pm 2\pi i\,(1/N)}$

(5.2)

The spectrum is nonsupersymmetric. The fourth NS state leads to $\Pi_{a=1}^K \Pi_{i=1}^N U(N_a^i)$ gauge bosons, while the remaining give a set of scalars in bifundamental or adjoint representations. In the R sector, no state is invariant under $\mathbf{Z_N}$, and the model contains no gauginos. On the other hand, it contain a nonchiral set of fermions in diverse bifundamental representations. Summarizing, the spectrum contains the following fields:

$$\begin{aligned}
&\text{Gauge bosons} \quad \prod_{a=1}^{K}\prod_{i=1}^{N} U(N_a^i),\\
&\text{Real scalars} \quad \sum_{a=1}^{K}\sum_{i=1}^{N} [(N_a^i, \overline{N}_a^{i+2}) + 2\times \mathrm{Adj}_{a,i}],\\
&\text{Right fermion} \quad \sum_{a=1}^{K}\sum_{i=1}^{N} (N_a^i, \overline{N}_a^{i+1}),\\
&\text{Left fermion} \quad \sum_{a=1}^{K}\sum_{i=1}^{N} (\overline{N}_a^{i+1}, N_a^i).
\end{aligned} \tag{5.3}$$

In the 5_a5_b sector, open strings are twisted by the angle formed by the branes in the two-tori, encoded in a twist vector $(\vartheta_1,\vartheta_2,0,0)$. The lowest lying states, along with their behavior under $\mathbf{Z_N}$, are (assuming $0\leqslant\vartheta_I\leqslant 1$)

Sector	State	$\mathbf{Z_N}$ phase
NS	$(-1+\vartheta_1,0,0,0)$	1
	$(0,-1+\vartheta_2,0,0)$	1
R	$(-\frac{1}{2}+\vartheta_1,-\frac{1}{2}+\vartheta_2,+\frac{1}{2},-\frac{1}{2})$	$e^{2\pi i\,1/N}$
	$(-\frac{1}{2}+\vartheta_1,-\frac{1}{2}+\vartheta_2,-\frac{1}{2},+\frac{1}{2})$	$e^{-2\pi i\,(1/N)}$

Recall that at most one of the two NS states is tachyonic (both are massless for $|\vartheta_1|=|\vartheta_2|$), while fermions are massless.

The spectrum of tachyonic and massless states, after the Chan–Paton projections, and taking into account the multiplicity due to the intersection numbers,

$$I_{ab}=I^1_{ab}I^2_{ab}=(n^1_am^1_b-m^1_an^2_b)(n^2_am^2_b-m^2_an^2_b), \tag{5.4}$$

is given by

$$\begin{aligned}
&\text{Cmplx. Tachyons} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times(N^i_a,\overline{N^i_b}),\\
&\text{Left fermion} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times(N^i_a,\overline{N^{i+1}_b}),\\
&\text{Right fermion} \quad \sum_{a<b}\sum_{i=1}^{N} I_{ab}\times(N^i_a,\overline{N^{i-1}_b}).
\end{aligned} \tag{5.5}$$

In the case $|\vartheta_2|=|\vartheta_1|$ we would have two bosonic massless states instead of the above tachyon.

B. Tadpoles and anomalies

The analysis of tadpole and anomaly cancellation is similar to that for configurations in Sec. IV B, hence our discussion is more sketchy.

Tadpole cancellation conditions read as

$$\begin{aligned}
&\sin(4\pi k/N)\,n^1_a\,n^2_a\,\mathrm{Tr}\,\gamma_{\theta^k,4_b}=0; \quad \sin(4\pi k/N)\,m^1_a\,n^2_a\,\mathrm{Tr}\,\gamma_{\theta^k,4_b}=0,\\
&\sin(4\pi k/N)\,n^1_a\,m^2_a\,\mathrm{Tr}\,\gamma_{\theta^k,4_b}=0; \quad \sin(4\pi k/N)\,m^1_a\,ma^2\,\mathrm{Tr}\,\gamma_{\theta^k,4_b}=0,
\end{aligned} \tag{5.6}$$

and clearly have the interpretation of the cancellation of charges analogous to that for Eqs. (4.8).

These conditions must ensure the consistency of the low-energy four-dimensional field theory on the D-brane world-volume. In particular, the cancellation of cubic non-Abelian chiral anomalies for $SU(N^i_a)$ reads as

$$\sum_{b=1}^{K} I_{ab}(N^{i+1}_b-N^{i-1}_b)=0, \tag{5.7}$$

or, equivalently, by performing the discrete Fourier transform (4.10),

$$\sin(4\pi k/N)I_{ab}\mathrm{Tr}\,\gamma_{\theta^k,5_b}=0. \tag{5.8}$$

By substituting (5.4) in this equation, we see that it is implied by the tadpole constraints.

Using the spectrum (5.3) it is easy to compute the mixed anomalies between $U(1)_{ai}$ and $SU(N_{bj})$. We obtain

$$A_{ai,bj}=\frac{1}{2}N_a^j I_{ab}(\delta_{j,i+1}-\delta_{j,i-1})=i\,N_a^i I_{ab}\frac{1}{N}\sum_{k=1}^{N-1}\sin(2\pi k/N)\,e^{2\pi i\,(ki/N)}\,e^{-2\pi i\,(kj/N)}, \quad (5.9)$$

where, again, the second equality shows the residual anomaly has a factorized structure, which can be cancelled by a GS mechanism mediated by four-dimensional fields obtained by integrating twisted RR fields on diverse two-cycles in $\mathbf{T^4}$.

The existence and form of nonanomalous (and therefore massless) $U(1)$ linear combinations can be carried out in complete analogy with that in Sec. IV B 2.

VI. FINAL COMMENTS AND OUTLOOK

In this paper we have studied the construction of four-dimensional chiral string compactifications with a gauge sector localized on D-branes wrapped on nontrivial cycles in the internal space. Specifically, we have studied configurations of D$(3+n)$-branes wrapped on n-cycles in $\mathbf{T^{2n}\times C^{3-n}/Z_N}$, where the last factor should be understood as a local model of a singularity within a compact $(6-2n)$-dimensional variety, so that correct four-dimensional gravity is recovered. Several properties (like the anomaly cancellation mechanisms) however hold in more general setups.

The configurations allow a bottom-up approach to embedding realistic gauge sectors in string theory models, in the sense explained in Ref. 5. In fact, the configurations are a natural extension of the work on D3-branes at threefold singularities (e.g., $\mathbf{C^3/Z_N}$) in Ref. 5. However, we have found a number of interesting differences, and original features in the configurations considered in this paper.

Our results in this paper extend the early results in Ref. 6 on intersecting branes to the context of compact models, leading to a large class of nonsupersymmetric chiral four-dimensional models. We have provided a simple set of rules to construct explicit models, and there studied general features. One amusing feature is that, as observed in Ref. 13, compact models of intersecting branes lead naturally to replication of the chiral fermion content, due to the multiple intersections between different wrapped branes. In fact, we have used this property to construct explicit three-generation models with realistic gauge groups.

In analogy with other string compactifications, we have found a rich structure of mixed $U(1)$ anomalies. We have shown that they are cancelled by a generalized GS mechanism mediated by untwisted or twisted RR fields. While the GS mediation by the latter is familiar from type IIB orientifolds,[30,29] the former (valid for D6-brane models) is rather unusual and interesting. We expect it to have relevant phenomenological applications.

Finally, we have discussed that although the models are nonsupersymmetric, they can be used for phenomenological purposes without a hierarchy problem, by simply lowering the string scale, and enlarging the volume transverse to the D-branes. A lack of supersymmetry also induces the appearance of tachyons, for which we have suggested an elimination mechanism, and a tantalizing phenomenological application in certain regimes.

Leaving further phenomenological properties of these configurations for a discussion in Ref. 15, we conclude hoping these results are helpful in the construction of new open string vacua, and in their phenomenological application in the brane-world scenario.

Nonrelativistic closed string theory

Jaume Gomis[a] and Hirosi Ooguri[b]
California Institute of Technology 452-48, Pasadena, California 91125
and Caltech—USC Center for Theoretical Physics, Los Angeles, California

(Received 2 January 2001; accepted for publication 13 February 2001)

We construct a Galilean invariant nongravitational closed string theory whose excitations satisfy a nonrelativistic dispersion relation. This theory can be obtained by taking a consistent low energy limit of any of the conventional string theories, including the heterotic string. We give a finite first order worldsheet Hamiltonian for this theory and show that this string theory has a sensible perturbative expansion, interesting high energy behavior of scattering amplitudes and a Hagedorn transition of the thermal ensemble. The strong coupling duals of the Galilean superstring theories are considered and are shown to be described by an eleven-dimensional Galilean invariant theory of light membrane fluctuations. A new class of Galilean invariant nongravitational theories of light-brane excitations are obtained. We exhibit dual formulations of the strong coupling limits of these Galilean invariant theories and show that they exhibit many of the conventional dualities of M theory in a nonrelativistic setting. © *2001 American Institute of Physics.*

I. INTRODUCTION

One of the legacies of the second superstring revolution is the realization that the different superstring theories describe very special corners of the space of vacua of a single hypothetical structure dubbed M Theory. Another important lesson that has emerged is that there are regions of the space of vacua describable by a theory without gravity. Two beautiful examples of such theories are Matrix Theory[1] and Maldacena's conjecture.[2] The realization that there are consistent limits of M Theory without gravity has led to a geometrical understanding of some field theory dualities and to new, hitherto unknown, field theories in higher dimensions.

The nongravitational limits studied thus far involve considering certain low energy limits of M Theory in the presence of branes. Typically, these limits lead to a theory where the appropriate effective description is given in terms of the massless degrees of freedom propagating on the branes. Such low energy limits lead, for example, to gauge theories in various dimensions. In such examples, the massive open string states on the branes and the entire closed string spectrum decouple from the low energy physics and the truncation to the theory of the massless fluctuations is consistent. These low energy theories are described by field theories.

Recently, very interesting generalizations have been found in which closed strings decouple but the massive open string excitations on the branes need to be taken into account for physical processes.[3,4] These theories appear in low energy limits of branes in near critical electric field backgrounds and are not conventional field theories due to the presence of a tower of massive excitations. Since massive states cannot be neglected, the field theory truncation is not unitary.[5–7] These nongravitational theories describe all the fluctuations on the branes. For example, one can obtain a consistent open string theory without any closed string states. Such theories arise from studying D-branes in a background electric field (NCOS),[3,4] M5-branes in a three-form background (OM)[8] and Neveu–Schwarz five-branes in various constant Ramond–Ramond *p*-form backgrounds (OD).[8–10]

[b]Electronic mail: ooguri@theory.caltech.edu

In this paper we find that there are corners of the moduli space of vacua of M Theory without branes that are described by nongravitational theories whose excitations live in space–time. These massive excitations satisfy a nonrelativistic dispersion relation and the theory that describes their dynamics is unitary and has a sensible perturbative description (whenever one is available). Since background branes are not required to define these nonrelativistic theories, they can be obtained by taking certain low energy limits of all five superstring theories, including the heterotic string. We will call these theories nonrelativistic closed string theories (NRCS).

The simplest limit leading to NRCS is obtained by considering string theory in the presence of a near critical NS–NS two-form field without any D-brane (when the NS–NS two-form exceeds the critical value, the space–time energy of a closed string becomes unbounded below and can become indefinitely negative as we increase the winding number). In the context of $(1+1)$-dimensional NCOS, Klebanov and Maldacena[11] observed that when the spatial direction is compactified on a circle, that there are finite energy winding closed string states that do not decouple from the open strings. An example of NRCS can be obtained by considering precisely the NCOS limit without any D-brane. Naively, one might think that, in the absence of D-branes, that a constant NS–NS two-form can be gauged away and that one ends up getting a conventional relativistic closed string theory. This is obviously true in noncompact space. However, in the presence of a circle, the background NS–NS field modifies the spectrum, which remains relativistic. Once the NCOS limit is taken, there is a truncation of the low energy spectrum and one obtains a new theory with a Galilean invariant Hamiltonian. Perhaps surprisingly, the closed string theory in the NCOS limit without any D-brane has a well-behaved perturbative expansion, described by the Lagrangian in Sec. III. It is also interesting to study the worldsheet theory we propose when the worldsheet has a boundary. Then, our formalism reproduces the relativistic open string spectrum of NCOS and its interactions.

In Sec. III, we give a worldsheet Lagrangian for NRCS, which has Galilean invariance and from which we derive the nonrelativistic spectrum of closed strings and their interactions. The Lagrangian we propose can be derived from the conventional Polyakov path integral quantization of the relativistic string by rewriting it in variables that are conducive to taking the low energy limit that defines NRCS (see Sec. III for details of the limit). We explicitly solve the Virasoro constraints, thus yielding the spectrum, show that the theory is unitary and that it has a sensible perturbative expansion. The string spectrum, being nonrelativistic, does not contain a massless graviton and it is thus nongravitational in nature. However, there is an instantaneous Newtonian potential between the massive strings. This string theory exhibits interesting properties such as an unusual high energy behavior of scattering amplitudes and a Hagedorn transition of the thermal ensemble.

NRCS depends on two parameters, the effective string scale α'_{eff} and the effective string coupling constant g. One may ask what is the strong coupling dual of these theories. For the superstrings, this can be reliably answered. We find that the strong coupling limits of supersymmetric NRCS are given by a Galilean invariant eleven-dimensional theory of light membranes which we call GM (Galilean membrane theory). This eleven-dimensional theory has a unique dimensionful parameter l_{eff} which is the effective Planck length. The relation between the NRCS superstrings and GM is reminiscent to the relation between the conventional superstrings and M theory. For example, Type IIA NRCS with coupling g and string scale α'_{eff} is equivalent to GM on a circle of radius R such that $R=g\sqrt{\alpha'_{\text{eff}}}$ and $l_{\text{eff}}=g^{1/3}\sqrt{\alpha'_{\text{eff}}}$. The conventional dualities and relations with M theory still hold, such that, for example. Type IIB NRCS has an $SL(2,Z)$ symmetry. We discuss these relations in Sec. VII. It is interesting that duality symmetries in string theories do not rely on relativistic invariance nor the presence of gravity.

There are many interesting generalizations that can be made that lead to nonrelativistic, nongravitational theories. The construction of such theories is quite general. The basic idea is to study the low energy limit of M Theory vacua in the presence of any of the many possible gauge fields available. Then, one can take a low energy, near critical limit such that all states of M Theory become infinitely massive, and thus decouple, except for those states that couple to the constant near critical background gauge field. Tuning to the critical value, defined such that that

energy coming from the background field precisely cancels the rest energy of the states in question, ensures that even though we are taking a low energy limit, that there are states that survive and satisfy a nonrelativistic dispersion relation. For example, if we tune the background NS–NS B field to its critical value, then one obtains finite energy nonrelativistic fluctuations of strings winding around the circle. Clearly, such NRCS can be defined in Type II, Type I and heterotic theories. Moreover, if one considers, for example, a near critical R–R gauge field C_{p+1} and takes a low energy limit, then there are light Dp-branes (in order for the constant background C_{p+1} field to affect the energy of a Dp-brane, the brane has to be wrapped on a p-cycle, otherwise the gauge field can be gauged away without changing the energetics) which are nonrelativistic that decouple from all the rest of the modes and lead to decoupled Galilean invariant theories which we will call GDp (Galilean Dp-brane theories). The myriad of gauge fields that exist in M Theory vacua can be used to define new nongravitational Galilean invariant theories. We study such theories in Sec. VII. The dualities of the underlying relativistic M Theory, lead to interesting webs of dualities for these nonrelativistic theories. These nonrelativistic theories may be a promising ground in which to address some of the important questions of M Theory without the complication of gravity.

The rest of the paper is organized as follows.

In Sec. II a very general low energy limit is presented which yields a finite nonrelativistic dispersion relation from the spectrum of a charged relativistic brane. The limit, when applied to the fundamental closed string, yields the spectrum of NRCS. Generalizations to other relativistic objects in M Theory are briefly described.

In Sec. III we find the worldsheet theory of NRCS. We quantize the Galilean invariant, first order Hamiltonian and find under what conditions there is a physical closed string spectrum. We then reproduce the NRCS spectrum in Sec. II within our Hamiltonian formalism. We compute the BRST cohomology of the string and show that there are no ghosts in the spectrum. The possibility of adding a boundary to the worldsheet is considered. The formalism of Sec. III results in the spectrum and worldsheet correlation functions of NCOS. Using this formalism, it is straightforward to prove the decoupling of the massless open string states on worldsheets with any number of handles and holes when the longitudinal direction is noncompact. This extends the result of Ref. 11 to all orders in the perturbative expansion.

Section IV is devoted to performing tree level computations in NRCS. We show that scattering amplitudes have the correct pole structure required by unitarity and have a peculiar behavior of high energy fixed angle scattering amplitudes in NRCS. Despite the absence of gravity in this theory, we exhibit a Newtonian potential among the nonrelativistic strings.

In Sec. V we compute loop amplitudes and show that NRCS is a sensible theory in perturbation theory. We evaluate the Helmholtz free energy at one loop and reproduce from it the spectrum of NRCS found in Sec. II. We find that NRCS behaves similarly to the long string near the boundary of AdS_3.[12] We exhibit the existence of a Hagedorn temperature in NRCS and sketch higher loop computations. We also study in some detail N-point loop amplitudes and show that the amplitudes are finite.

In Sec. VI we elucidate the relation between NRCS and the discrete light-cone quantization (DLCQ) of closed string theory. NRCS is related by T-duality to the discrete light-cone quantization (DLCQ) of closed string theory. Therefore, the formalism developed in this paper provides a useful description of DLCQ string theories as well.

In Sec. VII we study Galilean invariant theories of light branes and some of their dualities. In eleven dimensions we study the Galilean invariant theory of membrane fluctuations (GM) and five-brane fluctuations (GF). In ten dimensions we discuss the theory of nonrelativistic light Dp-branes (GDp) and light Neveu–Schwarz five-branes (GNS). These theories lie in the same moduli space and exhibit the same dualities that the underlying relativistic M theory possesses. In particular we show that the strong coupling limits of some NRCS have an eleven-dimensional description in terms of light-brane excitations.

II. NONRELATIVISTIC LIMIT

In this section we show that by taking a low energy limit of the theory of a relativistic p-brane and by tuning the $p+1$ gauge field that couples to it, that one can obtain an exact nonrelativistic dispersion relation. The idea is to study the low energy spectrum in a scaling limit in which the background gauge field cancels the rest energy of the brane and such that the nonrelativistic approximation becomes exact. In this limit, all the states of the theory decouple, except the light p-brane excitations. We present the truncation to a nonrelativistic theory in a very simple toy model which captures the essence of the limit which defines NRCS and the other generalizations we describe in this paper.

For simplicity, consider a relativistic charged point particle of mass m and charge e coupled to a gauge field A_μ propagating in a geometry with metric components $g_{00}=-1$ and g_{ij} arbitrary with $i, j \neq 0$. The Lagrangian which describes its motion is given by

$$L=-m\sqrt{-\dot{x}^2}+eA_\mu \dot{x}^\mu. \tag{2.1}$$

Worldline reparametrization invariance implies Einstein's dispersion relation,

$$p_0=\sqrt{m^2+g^{ij}(p_i-eA_i)(p_j-eA_j)}+eA_0. \tag{2.2}$$

Consider the following low energy limit:

$$g_{ij}=\frac{m_{\text{eff}}}{m}\delta_{ij}, \quad eA_0=-m+e\hat{A}_0, \tag{2.3}$$

as $m\to\infty$. In this limit, Einstein's relation (2.2) reduces to the following nonrelativistic dispersion law:

$$p_0=\frac{1}{2m_{\text{eff}}}(p_i-eA_i)^2+e\hat{A}_0. \tag{2.4}$$

Although a constant gauge field can be locally gauged away and does not affect the equations of motion, it changes the energy spectrum in the sector of the theory carrying electric charge. In fact, the shift in the energy due to the gauge field precisely cancels the rest mass of the particle and ensures that the energy remains finite in the limit (2.3). Turning on a background field and tuning it to the critical value is an efficient way of rearranging the spectrum of the theory such that only states charged under the gauge field have finite energy, the neutral states acquire infinite proper energy.

The charged point particle model can also be used to show that the there are finite energy, nonrelativistic winding closed string states in the NCOS limit whenever the near critical NS–NS B_{01}-field is along a compact spatial direction. The mass of a closed string winding w-times around a circle of radius R is

$$m^2=\left(\frac{wR}{\alpha'}\right)^2+\frac{2(N+\tilde{N})}{\alpha'}, \tag{2.5}$$

where N and $\overline{N}$ are the amounts of stringy excitations in the left and the right mover oscillators of the string. Moreover, the winding string states are charged under the $U(1)$ gauge field obtained by reducing the NS–NS B-field along the circle. The charge is given by

$$eA_0=-2\pi R w B_{01}. \tag{2.6}$$

We now take the NCOS limit[3,4] in the point particle analogy (2.4),

$$g_{ij}=\frac{\alpha'}{\alpha'_{\rm eff}}\delta_{ij}, \quad eA_0=-\frac{wR}{\alpha'}\left(1-\frac{\alpha'}{2\alpha'_{\rm eff}}\right). \tag{2.7}$$

Taking $\alpha'\to 0$ results in the following nonrelativistic spectrum:

$$p_0=\frac{wR}{2\alpha'_{\rm eff}}+\frac{\alpha'_{\rm eff}k^2}{2wR}+\frac{N+\tilde{N}}{wR}. \tag{2.8}$$

Thus the NCOS limit can be thought of an example of the nonrelativistic limit (2.3). Note that demanding positive energy states selects strings winding only in a particular direction. Indeed, the closed string spectrum (2.8) coincides with the one found by Maldacena and Klebanov in Ref. 11. In the next section we give a Galilean invariant, finite first order Hamiltonian that describes these closed strings and verify that there is a consistent perturbative expansion.

The nonrelativistic limit we found in (2.3) can also be generalized to any state of M Theory which is charged under a gauge field. If one considers winding fundamental closed strings in the near critical NS–NS B_{0i} background of any of the known string theories, one obtains NRCS theories. But we could have considered any of the branes of M Theory. One could, for example, consider a wrapped membrane of M Theory on any two-cycle (say on a two-torus or a two-cycle of a Calabi–Yau) in a critical three-form background. Then, the membrane is charged under a gauge field A_0 obtained by reducing the three-form on the two-cycle. In the limit (2.3) one obtains a nonrelativistic theory without gravity. Likewise, for any other brane. Just like in NCOS, positivity of the energy selects only those states which are wrapped in a particular direction, states of opposite orientation are unphysical. In Sec. VII we will find low energy limits leading to Galilean theories of branes and study their strong coupling duals.

III. LAGRANGIAN AND QUANTIZATION

In this section we construct the worldsheet theory of NRCS and analyze its spectrum and interactions. We consider a certain low energy limit of string theory in a near critical NS–NS B-field. The bosonic worldsheet action which describes this background is given by (here the worldsheet and target space metric are taken to be of Lorentzian signature)

$$S_0=-\frac{1}{4\pi\alpha'}\int d^2\sigma(g_{MN}\,\partial_a X^M\,\partial^a X^N-2\pi\alpha' B_{MN}\epsilon^{ab}\,\partial_a X^M\,\partial_b X^N), \tag{3.1}$$

where $M, N=0,...,9$ and $a, b=0,1$. NRCS is obtained by choosing the B-field with a time-like and a space-like component. Without loss of generality we consider a $B_{01}\equiv B$ background. NRCS is obtained by taking the following zero slope, near critical field limit (this is precisely the NCOS limit of Refs. 3, 4 but without any D-brane),

$$2\pi\alpha' B_{01}=1-\frac{\alpha'}{2\alpha'_{\rm eff}}, \quad g_{\mu\nu}=\eta_{\mu\nu}, \quad g_{ij}\frac{\alpha'}{\alpha'_{\rm eff}}\delta_{ij}, \quad g_s=g\sqrt{\frac{\alpha'_{\rm eff}}{\alpha'}}, \tag{3.2}$$

as $\alpha'\to 0$ where $\mu, \nu=0,1$ and $i,j=2,...9$, and $\alpha'_{\rm eff}$ is the finite effective string scale of NRCS and g its effective coupling constant.

Using

$$\gamma=X^0+X^1, \quad \overline{\gamma}=-X^0+X^1, \tag{3.3}$$

for the target space coordinates,

$$z=e^{i(\sigma^0+\sigma^1)}, \quad \overline{z}=e^{i(\sigma^0-\sigma^1)}, \tag{3.4}$$

for the worldsheet coordinates, and the background given in (3.2), the action (3.1) can be written for finite α' as

$$S_0 = -\frac{1}{4\pi\alpha'}\int d^2z(\partial\gamma\bar{\partial}\bar{\gamma}+\partial\bar{\gamma}\bar{\partial}\gamma-2\pi\alpha' B(\partial\gamma\bar{\partial}\bar{\gamma}-\partial\bar{\gamma}\bar{\partial}\gamma)+2g_{ij}\partial X^i\bar{\partial}X^j). \tag{3.5}$$

We now perform a Euclidean rotation in both the worldsheet and target space such that the Euclidean action is

$$S_0 = \frac{1}{4\pi\alpha'}\int d^2z(\partial\lambda\,\bar{\partial}\bar{\gamma}+\partial\bar{\gamma}\bar{\partial}\gamma-2\pi\alpha' B(\partial\gamma\bar{\partial}\bar{\gamma}-\partial\bar{\gamma}\bar{\partial}\gamma)+2g_{ij}\partial X^i\bar{\partial}X^j). \tag{3.6}$$

Note that, unlike the case of a *B*-field with only space-like components, there is no factor of *i* in the term in the Euclidean action depending on *B*.

In order to obtain a finite worldsheet description in the NRCS limit, it is convenient to introduce Lagrange multipliers β and $\bar{\beta}$. In these variables the worldsheet theory (3.6) is given by

$$S_1 = \int\frac{d^2z}{2\pi}\left(\beta\bar{\partial}\gamma+\bar{\beta}\bar{\partial}\bar{\gamma}-\frac{2\alpha'}{1+2\pi\alpha' B}\beta\bar{\beta}+\frac{1+2\pi\alpha' B}{2\alpha'}\partial\gamma\bar{\partial}\bar{\gamma}+\frac{1}{\alpha'}g_{ij}\partial X^i\bar{\partial}X^j\right), \tag{3.7}$$

where (3.6) is reproduced by integrating out β and $\bar{\beta}$. Therefore, in the strict decoupling limit (3.2), one has the following Lagrangian description of NRCS:

$$S_1 = \int\frac{d^2z}{2\pi}\left(\beta\bar{\partial}\gamma+\bar{\beta}\bar{\partial}\bar{\gamma}+\frac{1}{4\alpha'_{\rm eff}}\partial\gamma\bar{\partial}\bar{\gamma}+\frac{1}{\alpha'_{\rm eff}}\partial X^i\bar{\partial}X_i\right). \tag{3.8}$$

We note that the worldsheet theory of NRCS is defined in terms of more variables than a conventional critical string theory since we have extra β and $\bar{\beta}$ variables. However, the CFT defined by (3.8) has the correct Virasoro central charge to define a consistent string action (see the next subsection for more details). It is interesting to note that the Lagrangian (3.8) is invariant under the Galilean group in the transverse coordinates. This is consistent with the nonrelativistic spectrum that we will find for NRCS. It is crucial, for this symmetry to be realized, that the description has the extra variables β and $\bar{\beta}$.

We will concentrate on the conformal field theory of β, $\bar{\beta}$ and γ, $\bar{\gamma}$ since the transverse coordinates lead to familiar contributions. The equations of motion force β and γ to be holomorphic and $\bar{\beta}$ and $\bar{\gamma}$ to be antiholomorphic. The Lagrange multiplier β forces γ to be a holomorphic map from the worldsheet to the $(1+1)$-dimensional part of the target space parameterized by coordinates X^0 and X^1. Therefore, it describes a worldsheet instanton and the third term in the Lagrangian (3.8) $(1/8\pi\alpha'_{\rm eff})\partial\gamma\bar{\partial}\bar{\gamma}$ is the instanton action. We will show in the rest of this section that this Lagrangian reproduces the spectrum in (2.8). Moreover, we will see that if the string worldsheet has a boundary that (3.8) reproduces the open string spectrum of NCOS and string interactions. In our formalism, one can show that the decoupling of the massless open string modes exhibited by Ref. 11 at the disk level can be extended to all orders in perturbation theory. Thus, (3.8) can be used to perform manifestly finite worldsheet computations for NCOS theories. In the later sections, we will use this Lagrangian to describe amplitudes involving closed strings and higher loops.

A. Closed string spectrum

Here we consider a worldsheet without boundaries. The equations of motion of (3.8) imply that $\beta(z)$ and $\gamma(z)$ are holomorphic and that $\bar{\beta}(\bar{z})$ and $\bar{\gamma}(\bar{z})$ are antiholomorphic. Their OPE's are given by

$$\beta(z)\gamma(w)\sim\frac{-1}{z-w},\quad \overline{\beta}(\overline{z})\overline{\gamma}(\overline{w})\sim\frac{-1}{\overline{z}-\overline{w}},$$

$$\gamma(z)\beta(w)\sim\frac{1}{z-w},\quad \overline{\gamma}(\overline{z})\overline{\beta}(\overline{w})\sim\frac{1}{\overline{z}-\overline{w}},\tag{3.9}$$

$$\gamma(z)\overline{\gamma}(\overline{w})\sim\text{regular},\quad \beta(z)\overline{\beta}(w)\sim\frac{-\pi}{2\alpha'_{\text{eff}}}\delta^{(2)}(z-w).$$

The variables β and γ behave analogously to the bosonic ghost system, except for the contact term in $\beta(z)\overline{\beta}(\overline{w})$. The conformal dimension of γ is (0, 0) while the conformal dimension of β is (1, 0). Moreover, their contribution to the Virasoro central charge takes the required value $c=2$. Note that although it seems that we have added more degrees of freedom to the description, the worldsheet degrees of freedom are identical to those of two worldsheet scalars. A similar story holds for the $\overline{\beta}$ and $\overline{\gamma}$ system.

We will first consider the case when the x^1 coordinate is noncompact. Then we can expand the operators as

$$\gamma(z)=\sum_{n=-\infty}^{\infty}\gamma_n z^{-n},\quad \beta(z)=\sum_{n=-\infty}^{\infty}\beta_n z^{-n-1}.\tag{3.10}$$

Since γ is holomorphic and x^1 is noncompact the standard space–time momentum term in γ is not allowed. Otherwise, γ would be multi-valued function of σ, which is only possible if the string is winding. The oscillator modes satisfy the following commutation relation:

$$[\gamma_n,\beta_m]=\delta_{n+m,0}.\tag{3.11}$$

We now study the Virasoro constraints for NRCS. The energy momentum tensor is given by

$$T(z)=-\beta\,\partial\gamma,\tag{3.12}$$

and the Virasoro generators are

$$L_n=\sum_m m\beta_{n-m}\gamma_m.\tag{3.13}$$

In particular, L_0 is the excitation level of the (β, γ) system, whose spectrum is positive definite. Therefore the Virasoro constraint $L_0+\tilde{L}_0=1$ has no solutions (except for the tachyon, which is projected out in supersymmetric theories), where $\tilde{L}_0$ is the Virasoro generator for the rest of the system, which we assume to be positive definite. Thus, the closed string has no physical states. This can be easily understood. If all coordinates are noncompact the background NS–NS B-field can be gauged away without changing the Hamiltonian of the theory and the closed string spectrum is the usual one. Therefore, in the NRCS limit (3.2), all the closed strings acquire infinite proper energy and thus are unphysical.

When the x^1 direction is compactified on a circle of radius R, there is a nonzero winding sector in $\gamma(z)$. The mode expansion now reads as

$$\gamma(z)=iwR\log z+\sum_{n=-\infty}^{\infty}\gamma_n z^{-n},\tag{3.14}$$

and the Virasoro generator is then given by

$$L_n = -i\beta_n wR + \sum_m m\beta_{n-m}\gamma_m . \tag{3.15}$$

Now the Virasoro constraint $L_0+\tilde{L}_0=1$ has a solution. As we will show later, all physical states are in the vacuum of the (β, γ)-system. Thus the solution to the Virasoro constraint is of the form

$$i\beta_0 = \frac{N}{wR} + \frac{\alpha'_{\rm eff}k^2}{4wR}, \tag{3.16}$$

where N is the conformal weight of the rest of the system (N includes -1 for the bosonic string and $-1/2$ for the NS sector of superstring) and k is the transverse momentum of the string. According to the Lagrangian (3.8), the canonical momentum P conjugate to γ is not equal to β, but in the winding sector it is shifted by an amount proportional to $\bar{\partial}\bar{\gamma}$ as in

$$\frac{1}{2}(P_0+P_1) = \frac{\beta}{2\pi} - \frac{1}{8\pi\alpha'_{\rm eff}}\bar{\partial}\bar{\gamma}, \quad \frac{1}{2}(P_0-P_1) = \frac{\bar{\beta}}{2\pi} - \frac{1}{8\pi\alpha'_{\rm eff}}\partial\gamma. \tag{3.17}$$

Taking the zero mode parts of these equations, one finds that the total energy p_0 and momentum p_1 of the closed string are given by

$$\frac{1}{2}(p_0+p_1) = i\beta_0 + \frac{1}{4\alpha'_{\rm eff}}wR, \quad \frac{1}{2}(p_0-p_1) = i\bar{\beta}_0 + \frac{1}{4\alpha'_{\rm eff}}wR. \tag{3.18}$$

Since x^1 is periodic, its conjugate momentum is quantized as

$$p_1 = \frac{n}{R}. \tag{3.19}$$

Thus we find

$$p_0 = \frac{wR}{2\alpha'_{\rm eff}} + \frac{\alpha'_{\rm eff}k^2}{2wR} + \frac{N+\bar{N}}{wR}, \tag{3.20}$$

with the level matching condition $N-\bar{N}=wn$. In this way, we have recovered the nonrelativistic spectrum in (2.8).

It is straightforward to prove the no-ghost theorem in this case. We introduce the (b, c) ghost and write the BRST operator $Q_{\rm BRST}$ as

$$Q_{\rm BRST} = Q_{-1} + Q_0, \tag{3.21}$$

where

$$Q_{-1} = wR\sum_n \beta_{-n}c_n, \tag{3.22}$$

and Q_0 is defined as the remainder. They obey

$$Q_{-1}^2 = Q_0^2 = \{Q_{-1}, Q_0\} = 0. \tag{3.23}$$

Following the use of the BRST operator in Ref. 13 (see also Sec. 4.4 of Ref. 14), one can show that the cohomology of $Q_{\rm BRST}$ is isomorphic to that of Q_{-1}. The cohomology of the quadratic

operator Q_{-1} is easy to evaluate[15] and it is spanned by the vacuum state $|0\rangle_{\beta\gamma}\otimes|0\rangle_{bc}$ of (β, γ) and (b, c), times any states in the rest of the system. Assuming that the rest of the system is unitary, this proves the no-ghost theorem of NRCS.

B. Open string spectrum

It is possible to consider D-branes in NRCS, and what one gets is of course NCOS. Here we show that the open string spectrum of NCOS is reproduced in this way. Suppose the worldsheet is the upper half plane with the boundary located at $\sigma^1=0$. In the bulk, γ and β are still holomorphic. The equation of motion at the boundary gives

$$\delta\gamma\left(\beta+\frac{1}{4\alpha'_{\rm eff}}\bar{\partial}\bar{\gamma}\right)=0, \quad \delta\bar{\gamma}\left(\bar{\beta}+\frac{1}{4\alpha'_{\rm eff}}\partial\gamma\right)=0. \tag{3.24}$$

For a Dp-brane with $p\geqslant 1$, the boundary values of $(\gamma,\bar{\gamma})$ are not fixed. Therefore

$$\beta=-\frac{1}{4\alpha'_{\rm eff}}\bar{\partial}\bar{\gamma}, \quad \bar{\beta}=-\frac{1}{4\alpha'_{\rm eff}}\partial\gamma, \tag{3.25}$$

at the boundary. This suggests that we analytically continue (γ,β) to $\sigma^1<0$ and use (3.25) to identify (γ, β) on $\sigma^1\geqslant 0$ to $(\bar{\gamma},\bar{\beta})$ in $\sigma^1\leqslant 0$. Since

$$\beta(z)\gamma(w)\sim-\frac{1}{z-w}, \quad \bar{\beta}(\bar{z})\bar{\gamma}(\bar{w})\sim-\frac{1}{\bar{z}-\bar{w}}, \tag{3.26}$$

we find

$$\gamma(z)\bar{\gamma}(\bar{w})\sim 4\alpha'_{\rm eff}\log(z-\bar{w}). \tag{3.27}$$

For points on the real axis this reproduces the correct propagator for open strings in NCOS.

To compute the open string spectrum, we consider a worldsheet that is a strip $-\pi\leqslant\sigma^1\leqslant\pi$, we identify (γ, β) on $0\leqslant\sigma^1\leqslant\pi$ to $(\bar{\gamma},\bar{\beta})$ on $-\pi\leqslant\sigma^1\leqslant 0$ according to (3.25). Thus we have the expansion of these fields as

$$\begin{aligned}
&\beta=\frac{1}{2\sqrt{\alpha'_{\rm eff}}}\sum_n \bar{\alpha}_n\bar{z}^{-n-1}, \quad \gamma=x+4ip\alpha'_{\rm eff}\log z+2\sqrt{\alpha'_{\rm eff}}\sum_{n\neq 0}\frac{\alpha_n}{n}z^{-n},\\
&\bar{\beta}=\frac{1}{2\sqrt{\alpha'_{\rm eff}}}\sum_n \alpha_n z^{-n-1}, \quad \bar{\gamma}=\bar{x}+4i\bar{p}\alpha'_{\rm eff}\log\bar{z}+2\sqrt{\alpha'_{\rm eff}}\sum_{n\neq 0}\frac{\bar{\alpha}_n}{n}\bar{z}^{-n},
\end{aligned} \tag{3.28}$$

and nonzero commutators are

$$[\alpha_n,\bar{\alpha}_m]=n\delta_{n+m,0}, \quad [x,\bar{p}]=[\bar{x},p]=i. \tag{3.29}$$

Note that, unlike the case of closed string, the space–time momentum term $4ip\,\alpha'_{\rm eff}\log z$ is allowed in γ even when x^1 is noncompact. This is because we can choose the branch cut of $\log z$ to be away from the worldsheet. The Virasoro generators are then

$$L_n=\sum_m \bar{\alpha}_{n-m}\alpha_m. \tag{3.30}$$

Thus we reproduce the standard open string spectrum.

C. Free the $U(1)$ to all order

In Ref. 11, it was shown that any tree level amplitude containing a massless open string state in $NCOS_2$ vanishes when the longitudinal direction is noncompact. This is what is expected from the point of view of the S-dual theory, where the massless open strings correspond to the free $U(1)$ gauge fields and their superpartners in the $(1+1)$-dimensional $U(N)$ gauge theory. Using the formalism developed here, it is straightforward to generalize this result to all orders in perturbation theory. The open string amplitude on a worldsheet with h holes and g handles is computed by considering a closed Riemann surface of genus $2g$ with a complex conjugate involution such that the fixed point set of the involution gives the boundaries of the open string worldsheet. Since there is no vertex operator inserted away from the boundary (when the longitudinal direction is noncompact there is no closed string physical state), $\gamma(z)$ is holomorphic everywhere except at the boundaries. Moreover, the vertex operator for a massless open string state is also holomorphic (vertex operators for massive states are not holomorphic; they also depend on $\overline{\gamma}$). Since the sum of the boundaries of the h holes obtained as the fixed point set of the involution is homologically trivial on the genus $2g$ surface, the contour integral of the vertex operator can be deformed away through the middle of the Riemann surface. This proves the decoupling of the massless open string states to all order in the perturbation theory.

IV. TREE AMPLITUDES

In this section we will compute the scattering amplitude of four physical closed string states and show that it factorizes properly into nonrelativistic closed string poles. Moreover, we will see that the truncated closed string scattering amplitudes have a different high energy behavior than in conventional string theory.

For simplicity, we will compute the 4-tachyon amplitude. Since all the physical states are in the vacuum of the (β, γ)-system as we saw in the last section, the essential novelty of NRCS is captured by the tachyon amplitude. The vertex operator for a closed string tachyon is given by (we will not include the cocycles which only change relative signs between amplitudes; the factor $\sqrt{w}$ is included for later convenience)

$$V(v,\overline{v},k;z,\overline{z}) = g\sqrt{w}:e^{i\overline{v}\gamma(z)+iwR\int^z\beta+iv\overline{\gamma(z)}+iwR\int^{\overline{z}}\overline{\beta}+ik\cdot X(z,\overline{z})}:. \tag{4.1}$$

Since

$$\begin{aligned} \gamma(z)V(z') &\sim iwR\log(z-z')V(z'), \\ \beta(z)V(z') &\sim \frac{-i\overline{v}}{z-z'}V(z'), \end{aligned} \tag{4.2}$$

the vertex operator carries $(\beta_0,\overline{\beta}_0)$ eigenvalues of $(-i\overline{v},-iv)$ and winding number w. Thus, according to (3.18), the energy ϵ and the longitudinal momentum n/R of the tachyon state are given by

$$\epsilon = v+\overline{v}+\frac{1}{2\alpha'_{\text{eff}}}wR, \quad \frac{n}{R}=\overline{v}-v. \tag{4.3}$$

Let us evaluate the 4-point amplitude on the sphere, $\langle V_1(z_1)V_2(z_2)V_3(z_3)V_4(z_4)\rangle$, by performing the functional integral with the Lagrangian (3.8). The extremum of the functional integral is given by

$$\gamma(z) = i\sum_{a=1}^{4} w_a R\log(z-z_a), \quad \beta(z) = -i\sum_{a=1}^{4}\frac{\overline{v}_a}{z-z_a}. \tag{4.4}$$

For closed string amplitudes, the winding number has to be conserved (the winding number is not conserved when one considers worldsheet with boundaries), such that $\Sigma_a w_a = 0$. Since the action is free, we can evaluate the amplitude by substituting (4.4) back into the integrand [as is always the case with the Gaussian integral; the same result is obtained by substituting the extremal value (4.4) into the product of the vertex operators $V_1V_2V_3V_4$ alone and by taking its square root]. The amplitude is given by

$$\begin{aligned}
&\langle V_1(z_1)V_2(z_2)V_3(z_3)V_4(z_4)\rangle \\
&\quad = \sqrt{w_1\cdots w_4}\prod_{a\neq b}(z_a-z_b)^{-\bar{v}_a w_b R}(\bar{z}_a-\bar{z}_b)^{-v_a w_b R}|z_a-z_b|^{(\alpha'_{\rm eff}/2)k_a k_b} \\
&\quad = \sqrt{w_1\cdots w_4}\prod_{a<b}|z_a-z_b|^{-(\epsilon_a+\epsilon_b)(w_a+w_b)R+(R^2/2\alpha'_{\rm eff})(w_a+w_b)^2+(\alpha'_{\rm eff}/2)(k_a+k_b)^2-4}. \quad (4.5)
\end{aligned}$$

Here we used the on-shell condition for the tachyon,

$$\begin{aligned}
\epsilon_a &= \frac{w_a R}{2\alpha'_{\rm eff}} + \frac{\alpha'_{\rm eff}k_a^2}{2w_a R} - \frac{2}{w_a R}, \\
v_a &= \bar{v}_a \quad (a=1,\ldots,4).
\end{aligned} \tag{4.6}$$

It is a good test of our formalism to compute the same correlation function using the standard closed string theory and then take the NCOS limit (3.2). One can verify that (4.5) is reproduced in the limit. The tachyon scattering amplitude is then given by

$$\mathcal{A} = ig^4 C_{\rm sphere}\int d^2z\langle V_1(0)V_2(z)V_3(1)V_4(\infty)\rangle. \tag{4.7}$$

Here g is the closed string coupling constant and $C_{\rm sphere}$ is the normalization constant that normalizes the path integral of the string when the topology of the worldsheet is the sphere. The normalization constant can be found by unitarity. Namely, the amplitude in (4.7) has poles associated with intermediate closed string states and a straightforward application of the optical theorem determines it. Therefore, by repeating the analysis in, for example, Sec. 6.6 of Ref. 14, we find

$$C_{\rm sphere} = \frac{2\pi}{g^2 R}. \tag{4.8}$$

This means that even though the theory is defined in the $g_s\to\infty$ limit, that the closed string theory has a sensible perturbation expansion in powers of g. This is consistent with the observation made in Ref. 4 regarding closed string loop diagrams in NCOS.

The amplitude given by (4.5) and (4.7) is very similar to the familiar Virasoro–Shapiro amplitude. It has poles in the energies in the intermediate channels, and they are located at

$$\epsilon_a+\epsilon_b = \frac{(w_a+w_b)R}{2\alpha'_{\rm eff}} + \frac{\alpha'_{\rm eff}(k_a+k_b)^2}{2(w_a+w_b)R} + \frac{2n-2}{(w_a+w_b)R} \quad (n=0,1,2,\ldots). \tag{4.9}$$

This is precisely the closed string spectrum of NRCS, as required by unitarity. From (4.7) we can also see that NRCS exhibits a different behavior of high energy, fixed-angle scattering amplitudes. Since the mass-shell condition of the strings is nonrelativistic, the dependence of the amplitude on energy E is $\mathcal{A}\sim e^{-E}$, as opposed to the conventional dependence $\mathcal{A}\sim e^{-E^2}$.

Although there are no physical states in the sector with 0-winding number and in particular no graviton in the spectrum, there is an instantaneous Newtonian potential between winding strings.

To see this, let us consider the process in which the winding number is not exchanged among strings, i.e., $w_1+w_3=0$ and $w_2+w_4=0$. In this case, the correlation function (4.5) becomes

$$\begin{aligned}
&\langle V_1(z_1)V_2(z_2)V_3(z_3)V_4(z_4)\rangle \\
&\quad = w_1 w_2 (|z_1-z_3||z_2-z_4|)^{\alpha'_{\rm eff}(k_1+k_3)^2-4} \\
&\qquad \times (|z_1-z_2||z_3-z_4|)^{-(\epsilon_1+\epsilon_2)(w_1+w_2)R+(R^2/2\alpha'_{\rm eff})(w_1+w_2)^2+(\alpha'_{\rm eff}/2)(k_1+k_2)^2-4} \\
&\qquad \times (|z_1-z_4||z_2-z_3|)^{-(\epsilon_1+\epsilon_4)(w_1-w_2)R+(R^2/2\alpha'_{\rm eff})(w_1-w_2)^2+(\alpha'_{\rm eff}/2)(k_1+k_4)^2-4}. \qquad (4.10)
\end{aligned}$$

Since the winding number along the (k_1+k_3)-channel is 0, no physical states are propagating in this channel. Nevertheless, after doing the z-integral in (4.7), one finds that there are contributions from the exchange of off-shell states in the 0-winding number sector. In particular, the leading long-range contribution to the 4-point amplitude contains $\sim(k_1+k_3)^{-2}$, corresponding to the Newtonian potential. Thus, even though the theory contains no gravitons, there is an instantaneous gravitational force between winding strings.

V. LOOP AMPLITUDES

In this section, we will compute the one-loop free energy at finite temperature and one-loop corrections to N-point functions of winding states. We will also examine the general structure of higher loop amplitudes and demonstrate that there is a sensible perturbative expansion of NRCS.

On a genus-g surface, the β-field [the (1, 0)-form we introduced in Sec. III as a Lagrangian multiplier] has g zero modes. If we were quantizing the bosonic ghost system, we would introduce delta-functions in the path integral to absorb these zero modes. However, one can show that the rules of the NRCS perturbation theory deduced from the factorization conditions do not call for these delta-functions. Thus one may naively think that zero mode integrals are divergent in NRCS. This would be similar to the problem in DLCQ of field theory,[16,17] where integrals over states carrying zero longitudinal momentum pose difficulties in evaluating loop amplitudes.[18]

It turns out that, whenever we evaluate physical observables such as the temperature dependent part of the free energy and scattering amplitudes of closed strings with nonzero winding numbers, the amplitudes contain terms of *stringy nature* which depend on all the g zero modes of β, so that the zero-mode integrals are convergent. It is easy to understand where these terms come from; they appear because β is a Lagrange multiplier which constrains γ to be a holomorphic map from the worldsheet to the $(1+1)$-dimensional part of the target space. If vertex operators for winding states are inserted on the worldsheet, a holomorphic map γ, if it exists, has to be a nontrivial one since the image of the worldsheet has to wind around each of the vertex operators. As we will show below, a nontrivial holomorphic map from the worldsheet to the $(1+1)$-dimensional part of the target space, which is a cylinder, exists only in a subspace of codimension g of the moduli space of a genus-g Rieman surface. The integral over the g zero modes of β gives a delta-function which exactly picks up the subspace where the holomorphic maps exist.

On the other hand, if we consider amplitudes which do not contain winding strings, such as the vacuum amplitude at zero temperature, then the zero-mode integral gives a divergence. In this case, γ can be a *trivial* map which maps the worldsheet to a point in the target space. Such a map exists everywhere on the moduli space of the worldsheet, and therefore the worldsheet amplitude is independent of the g zero modes of β. The integral over these zero modes is then flatly divergent. If one traces through the NCOS limit in Sec. III, one finds that it is exactly the type of divergence that was pointed out in Ref. 18. Fortunately all the physical states in NRCS have a nonzero winding number, and these divergent amplitudes have no physical meaning and can be safely ignored.

We will demonstrate these points by computing one-loop amplitudes and show how they are generalized to higher loops.

A. Free energy

The one-loop free energy at temperature T is evaluated by performing a Euclidean rotation of the target space–time coordinate and periodically identifying $X^0 \sim X^0 + T^{-1}$. The path integral then involves a sum over maps $(\gamma, \overline{\gamma})$ from the worldsheet torus of modulus τ to the target space torus of periods $(T^{-1}, 2\pi R)$.

The zero-mode dependence of the free energy can be computed by performing the path integral over the maps from the worldsheet to space–time. Thus we write

$$\gamma = \left(2\pi n R + i\frac{m}{T}\right)\frac{\sigma^0}{2\pi} + \left(2\pi w R + i\frac{s}{T}\right)\frac{\sigma^1}{2\pi} + (\text{periodic}), \tag{5.1}$$

where $0 \leqslant \sigma^0$, $\sigma^1 < 2\pi$ and (n, m, w, s) are integers labeling the different winding sectors. For this γ,

$$\overline{\partial}\gamma = \frac{i}{4\pi\,\mathrm{Im}\,\tau}\left[2\pi n R + i\frac{m}{T} - \tau\left(2\pi w R + i\frac{s}{T}\right)\right] + \overline{\partial}(\text{periodic}). \tag{5.2}$$

On the other hand, β can be written as $\beta = \beta_0 + \partial(\text{periodic})$, where β_0 is the zero mode. The worldsheet action depends on β_0 as

$$S = i\beta_0\left[2\pi n R + i\frac{m}{T} - \tau\left(2\pi w R + i\frac{s}{T}\right)\right] + \cdots. \tag{5.3}$$

Thus the integral over β_0 gives a delta-function which fixes the worldsheet modulus τ at

$$\tau = \frac{2\pi n R + i m\dfrac{1}{T}}{2\pi w R + i s\dfrac{1}{T}}. \tag{5.4}$$

Thus the τ-integral becomes a sum over these special points on the worldsheet moduli space. These are the points at which there are holomorphic maps from the worldsheet to the target space.

The one-loop free energy is obtained by a sum over the integers (n, m, w, s) such that τ is in the fundamental domain of the moduli space. To do the summation, it is convenient to use the trick invented in Ref. 19 to trade the sum over s for the sum over copies of the fundamental domain. If $(m,s) \neq (0,0)$, there is an $SL(2,Z)$ transformation which sends (m, s) to $(m, 0)$ with $m > 0$, and it also maps the fundamental domain of τ into the strip, $|\mathrm{Re}\,\tau| \leqslant 1/2$, in the upper half-plane $\mathrm{Im}\,\tau \geqslant 0$. The sum over s covers the strip exactly once by copies of the fundamental domain. On the other hand, the $(m,s) = (0,0)$ term is independent of the temperature T and corresponds to the zero temperature vacuum energy. We will ignore this contribution since it has no physical meanings in NRCS and it vanishes in supersymmetric theories anyway. Thus we have

$$\tau = \frac{2\pi n R + i m\dfrac{1}{T}}{2\pi w R}, \tag{5.5}$$

and we sum over integers (n, m, w). Since $m > 0$ and τ must be in the strip in the upper half-plane, we require $w > 0$ and $|n| \leqslant w/2$ (n at the boundary $n = \pm w/2$ is counted with a factor 1/2).

We can now evaluate the path integral over γ and $\overline{\gamma}$. The zero mode piece is obtained by evaluating the instanton action. Therefore, substituting (5.1) (with $s = 0$) into the action (3.8) and evaluating it at the points (5.5) of the moduli space, we find that the zero mode part of the action is

$$S=\int d^2z\left(\frac{1}{8\pi\alpha'_{\rm eff}}\partial\gamma\bar{\partial}\bar{\gamma}+\cdots\right)=\frac{mwR}{2\alpha'_{\rm eff}T}+\cdots. \tag{5.6}$$

As usual, the contribution from the nonzero modes of (β,γ) is canceled by the determinant of the (b,c) ghost system. Therefore, the one-loop contribution to the free energy takes the form

$$F(T)=-\sum_{n,m,w}\frac{T}{wm}\sum_{h,\bar{h}}D(h,\bar{h})\exp\left[-\frac{m}{T}\left(\frac{wR}{2\alpha'_{\rm eff}}+\frac{h+\bar{h}}{wR}\right)+2\pi i\frac{n}{w}(h-\bar{h})\right]. \tag{5.7}$$

This is obtained by evaluating the partition function of the worldsheet theory at the special points (5.5) on the moduli space. Here $(h,\bar{h})$ are the conformal weights coming from the transverse excitations of the string and $D(h,\bar{h})$ is their multiplicity. To simplify the expression in (5.7), we have included in h the contribution from the transverse momenta k. Thus, in comparison with the notion in Sec. III, h and $\bar{h}$ are defined as

$$h=\frac{\alpha'_{\rm eff}}{4}k^2+N,\quad \bar{h}=\frac{\alpha'_{\rm eff}}{4}k^2+\bar{N}. \tag{5.8}$$

The factor $-T/wm$ in (5.7) is determined as follows. The β_0 integral with the action (5.3) gives a factor $(2\pi wR)^{-2}$ times the delta-function for τ [we set $s=0$ in (5.3)]. The measure for the τ-integral contains the factor

$$\frac{1}{{\rm Im}\,\tau}=\frac{2\pi wRT}{m}. \tag{5.9}$$

The zero-mode integral of γ gives the volume $2\pi R/T$ of the target space. Finally, the definition of the one-loop free energy is $F=-TZ(T)$, where $Z(T)$ is the one-loop vacuum amplitude at temperature T. Combining these factors together, we obtain

$$\frac{1}{(2\pi wR)^2}\frac{2\pi wRT}{m}\frac{2\pi R}{T}(-T)=-\frac{T}{wm}, \tag{5.10}$$

as in (5.7).

The sum over n in $|n|\leqslant w/2$ gives the constraint $h-\bar{h}\equiv 0 \pmod{w}$, which we recognize as the level matching condition. After summing over m, the free energy given by (5.7) becomes

$$F(T)=T\sum_{w=1}^{\infty}\sum_{h,\bar{h}}D(h,\bar{h})\log(1-e^{E(w,h,\bar{h})/T}). \tag{5.11}$$

This is the conventional expression for the one-loop free energy of quantum field theory. Here

$$E(w,h,\bar{h})=\frac{wR}{2\alpha'_{\rm eff}}+\frac{h+\bar{h}}{wR}=\frac{wR}{2\alpha'_{\rm eff}}+\frac{\alpha'_{\rm eff}k^2}{2wR}+\frac{N+\bar{N}}{wR}. \tag{5.12}$$

With the level matching condition for $(h,\bar{h})$, the expression for $E(w,h,\bar{h})$ precisely agrees the energy spectrum of closed strings in NRCS computed in Sec. III, with the correct multiplicity factor.

The computation of the free energy described here is similar to the one for string in AdS_3 discussed in Ref. 12. In that case, the one-loop amplitude has poles exactly at the special points in (5.4), and they are due to the presence of long strings winding near the boundary of AdS_3. Here we have delta-functions at these points and they correspond to the closed strings winding in the x^1 direction.

We now study the high temperature behavior of the free energy. It is clear that, for a fixed winding number w, that the free energy is convergent for any temperature T. However, there might be a divergence when one performs the sum over winding modes. To see whether the sum over w gives a divergence, we use the Cardy's formula,

$$\sum_{h,\bar{h}} D(h,\bar{h})\exp(2\pi i\tau h - 2\pi i\bar{\tau}\bar{h}) \sim \exp\left[\frac{2\pi i c}{24}\left(\frac{1}{\tau}\,\frac{1}{\bar{\tau}}\right)\right], \tag{5.13}$$

for Im $\tau\to 0$. Here c is the central charge of the rest of the system, and $c=12$ for a Type II superstring. Therefore, the high temperature behavior of NRCS is given by

$$\sum_{|n|\leqslant w/2}\sum_{h\bar{h}} D(h,\bar{h})\exp\left[-\frac{m}{T}\left(\frac{wR}{2\alpha'_{\rm eff}}+\frac{h+\bar{h}}{wR}\right)+2\pi i\,\frac{n}{w}(h-\bar{h})\right] \sim \exp\left[2\pi wR\left(\frac{\pi cT}{6m}-\frac{m}{4\pi\alpha'_{\rm eff}T}\right)\right], \tag{5.14}$$

for large w. Therefore, the sum over winding states will be divergent whenever $T\geqslant T_{\rm H}$, where

$$T_{\rm H}=\frac{1}{2\pi}\sqrt{\frac{6}{\alpha'_{\rm eff}c}}. \tag{5.15}$$

This gives the Hagedorn temperature of NRCS. For Type II NRCS we find that $T_{\rm H}=1/2\pi\sqrt{2\alpha'_{\rm eff}}$. It coincides with the location of the Hagedorn transition of NCOS studied in Refs. 11, 20. Just like in conventional string theory, the Hagedorn temperature $T_{\rm H}$ is the temperature at which the tachyonic mode which appears in the spectrum (5.12) due to the finite temperature GSO projection becomes massless. It would be interesting to study the behavior of the closed strings of NRCS above the Hagedorn temperature. In NRCS, the breakdown of the thermal ensemble may not occur unlike for relativistic closed string theories since there is no graviton and the Hamiltonian is positive definite. However, there can be a Jeans instability.

We have demonstrated explicitly that the β zero-mode integral is convergent when one computes the one-loop free energy. As a result of the β zero-mode integral, the integral over τ is localized to a sum over the special points in the moduli space of the worldsheet torus where there is a holomorphic map from the worldsheet to the target space torus. It is straightforward to generalize this observation to higher loops. A simple computation shows that a map from a genus g worldsheet to the target space torus exists only on a $(2g-3)$-dimensional subspace. Such a holomorphic map exists whenever the following condition on the worldsheet period matrix Ω_{ij} $(i,j=1,\ldots,g)$ is satisfied:

$$G_i(\Omega)=\sum_{j=1}^{g}\Omega_{ij}\left(2\pi w^j R+i\,\frac{s^j}{T}\right)+2\pi n_i R+i\,\frac{m_i}{T}=0, \tag{5.16}$$

for some integers (n_i,m_i,w^i,s^i). This generalizes (5.4) for $g=1$. On a genus-g surface, β has g linearly independent zero modes, and their integrals give delta-functions imposing the constraints $G_i=0$ $(i=1,\ldots,g)$.

B. *N*-point amplitudes

Here we analyze the effects of the β zero-mode integrals on the scattering amplitudes. We will discuss the N-point tachyon amplitudes for simplicity, but a generalization to amplitudes involving arbitrary external states is straightforward. As in the case of the tree amplitudes discussed in the last section, the computation of $\langle \pi_{i=1}^{n} e^{i\bar{v}_a\gamma(u_a)+v_a\overline{\gamma(x_a)}}\rangle$ requires finding (β,γ) which are holomorphic away from u_a's and behave near $z=u_a$ as

$$\gamma(z)\sim iw_aR\log(z-u_a),$$
$$\beta(z)\sim\frac{-i\bar{v}_a}{z-u_a}\quad(z\to u_a), \tag{5.17}$$

where w_a is the winding number for the i-th external state. The functional integral is nonzero only when such β and γ exist. As for $\beta(z)$, there is always a meromophic one-form given by

$$\beta(z)=-i\sum_{a=1}^{N}\bar{v}_a\partial_z\log\vartheta_1(z-u_a)+\text{const}, \tag{5.18}$$

where $\vartheta_1(z)$ is the elliptic theta function. This β is single-valued on the worldsheet torus as far as momentum is conserved, $\Sigma_a v_a=0$. On the other hand, $\gamma(z)$ obeying (5.17) does not always exist. To see this, let us try

$$\gamma(z)=i\sum_{a=1}^{N}w_aR\log\vartheta_1(z-u_a)+cz, \tag{5.19}$$

for some constant c. Due to the quasi-periodicity of the elliptic function, we find

$$\gamma(z+2\pi)=\gamma(z)+2\pi c,$$
$$\gamma(z+2\pi r)=\gamma(z)+2\pi\left(-R\sum_{a=1}^{N}w_au_a+c\tau\right), \tag{5.20}$$

where we assumed that the winding number is conserved, $\Sigma_a w_a=0$. By requiring that $\gamma(z)$ is periodic modulo the target space periodicity $\gamma\sim\gamma+2\pi R$, we find that c must be of the form $c=mR$ for some integer m and

$$\sum_{a=1}^{N}w_au_a=n+m\tau, \tag{5.21}$$

for some integer n. This gives a condition on the locations of the N points. Thus we find that, rather than being divergent, the integral over the zero mode of β imposes the condition (5.21) on the locations of the vertex operators on the worldsheet.

High loops

It is straightforward to generalize this result to higher loops. On a genus-g worldsheet, the holomorphic map $\gamma(z)$ winding w_a-times at $z=u_a$ should be of the form

$$\gamma(z)=i\sum_{a=1}^{N}w_aR\log E(z,u_a)+\sum_{i=1}^{g}c^i\int^z\omega_i, \tag{5.22}$$

for some constants c_i, where ω_i are holomorphic one-forms, and $E(z,w)$ is the prime form, a $(-1/2)$-differential with respect to z and w that vanishes linearly on the diagonal $z=w$ only (see, for example, Sec. IIIb.1 of Ref. 21). The periodicity of γ in the α-cycles of the worldsheet requires that c^i must be of the form $c^i=2\pi m^iR$ for some integers m^i, and the periodicity around the β-cycles requires

$$G_i=\sum_{a=1}^{N}w_a\int^{u_a}\omega_i-\left(n_i+\sum_{j=1}^{g}\Omega_{ij}m^j\right)=0, \tag{5.23}$$

for some integers n_i. This imposes g conditions on the $(3g-3+N)$-dimensional moduli space of the genus-g worldsheet with N points. To verify that the g conditions $G_i=0$ are independent of

each other and pick up a codimension g subspace, we need to compute their partial derivatives with respect to the worldsheet moduli y_I $(I=1,\ldots,3g-3)$ and the vertex operator locations u_a. They are given by

$$\frac{\partial G_i}{\partial u_a}=\omega^i(u_a)w_a,$$
$$\frac{\partial G_i}{\partial y_I}=\int d^2z\,\omega_i(z)\,\eta^I(z,\overline{z})\left(\sum_{a=1}^{N} w_a\partial_z \log E(z,u_a)-2\pi i\sum_{j=1}^{g} m^j\omega_j(z)\right), \tag{5.24}$$

where η^I are the Beltrami differentials associated to the moduli y_I. Note that the partial derivatives of G_i are all of the form, $\int d^2z\,\omega_i(z)\,\nu(z,\overline{z})$ for some differential ν. Since

$$\det_{i,j=1,\cdots g}(\omega_i(z_j))\neq 0, \tag{5.25}$$

for generic g points z_i, it is clear that the rank of the $(3g-3+N)\times g$ matrix $(\partial_{u_a}G_i,\partial_{y_I}G_i)$ is generically g. Thus the integral over the g zero modes of β exactly pick up the subspace of the moduli space where the holomorphic map $\gamma(z)$ exists.

VI. RELATION TO DLCQ

In this section we show that the NRCS limit we have studied is related by T-duality to the DLCQ limit of string theory. This follows by performing T-duality along the circle of radius R where the B-field lies. After T-duality, we get string theory without any background B-field, with a metric

$$g_{\mu\nu}=\begin{pmatrix} -1+(2\pi\alpha' B)^2 & 2\pi\alpha' B \\ 2\pi\alpha' B & 1 \end{pmatrix}, \tag{6.1}$$

and where the radius of the circle is α'/R. In the NRCS limit the metric is given by

$$ds^2=-\frac{\alpha'}{\alpha'_{\rm eff}}(dx^0)^2+2\,dx^0\,dx^1+(dx^1)^2. \tag{6.2}$$

We now rescale coordinates such that $x^1\to(\alpha'/\alpha'_{\rm eff})x^1$. In the NRCS $(\alpha'\to 0)$ limit the metric in these coordinates is

$$\frac{1}{\alpha'}ds^2=\frac{1}{\alpha'_{\rm eff}}[-(dx^0)^2+2\,dx^0\,dx^1], \tag{6.3}$$

and the periodicity of the compact direction is given by

$$x^1\sim x^1+2\pi\frac{\alpha'_{\rm eff}}{R}. \tag{6.4}$$

Since in this limit the x^1 coordinate is light-like, we see that DLCQ of closed string theory with string scale $\alpha'_{\rm eff}$ and null radius $\alpha'_{\rm eff}/R$ is T-dual to NRCS.

Because of the relation between NRCS and DLCQ, the formalism developed in this paper gives a useful description of DLCQ closed string theory also. In Refs. 22, 23, loop amplitudes of DLCQ closed string theory were studied to address the issue of divergence due to the longitudinal zero modes.[16–18] In particular, it was found in Ref. 22 that one-loop scattering amplitudes, when external strings carry nonzero longitudinal momenta, have finite DLCQ limits and that the positions of the vertex operators are constrained in the limit. These constraints can be viewed as the T-dual of (5.21) in NRCS. The description of NRCS developed here does not involve the process

of taking the NCOS limit, and thus loop amplitudes are manifestly finite. In fact, the one-loop observation in Ref. 22 has a straightforward generalization to higher loops, as we saw in (5.23). Evidently, unlike in ordinary field theories, the longitudinal zero modes do not cause a problem in DLCQ closed string theory. In the case of Type IIA string theory, this is related, via the hypothetical 11-dimensional Lorentz invariance of M theory, to the existence of the smooth DLCQ limit of M Theory described by the finite N Matrix Theory.[24–26]

For closed strings, the relation between NRCS and DLCQ provides another way to understand the origin of the nonrelativistic dispersion relation. The nonrelativistic limit described in Sec. II, however, is much broader and includes cases that are not related to DLCQ, as we will see in the next section.

VII. GALILEAN THEORIES

In this section we find new theories whose excitations satisfy a nonrelativistic dispersion relation. The light degrees of freedom that survive the low energy limit are light-branes (these theories do not have background branes, unlike the theories discussed in Ref. 8). Depending on which background gauge field one tunes to its critical value, different brane states are light while the rest of the states in M Theory decouple.

We will first consider M Theory limits where the light degrees of freedom are membranes and five-branes. We will call these theories GM (Galilean membrane) and GF (Galilean five-brane), respectively. The first one is obtained by tuning to the critical value the background three-form and the second one by turning on the background six-form of M Theory. The low energy limit is taken such that the terms in the world volume action depending on the transverse coordinates to the background remain finite in the limit. Just as for NRCS, the spectrum is modified if the brane directions are compactified, otherwise there are no finite energy physical excitations surviving the limit.

Therefore, the low energy limit leading to GM is given by (throughout the rest of the paper we will have in mind compactification on tori; it is straightforward to generalize the decoupling limits when branes wrap curved geometries)

$$\begin{aligned} g_{\mu\nu} &= \eta_{\mu\nu} \quad \mu,\nu = 0,1,2, \\ g_{ij} &= \frac{l_p^3}{l_{\text{eff}}^3}\delta_{ij} \quad i,j = 3,\ldots,10, \\ C_{012} &= T_{\text{M2}} - T_{\text{eff}}, \end{aligned} \tag{7.1}$$

with the eleven-dimensional Planck scale $l_p \to 0$ while the effective length scale l_{eff} is kept finite. Here $T_{\text{M2}} = 1/4\pi^2 l_p^3$ is the membrane tension and $T_{\text{eff}} = 1/4\pi^2 l_{\text{eff}}^3$ is the finite effective tension of the light membranes that survive the limit. Note that GM has no coupling constant and it contains a unique dimensionful parameter l_{eff}. This is reminiscent of some of the properties of eleven-dimensional M Theory.

The decoupling limit giving rise to GF is given by

$$\begin{aligned} g_{\mu\nu} &= \eta_{\mu\nu}, \quad \mu,\nu = 0,1,\ldots,5, \\ g_{ij} &= \frac{l_p^6}{l_{\text{eff}}^6}\delta_{ij}, \quad i,j = 6,\ldots,10, \\ C_{012345} &= T_{\text{M5}} - T_{\text{eff}}, \end{aligned} \tag{7.2}$$

with $l_p \to 0$ while the effective length scale l_{eff} is kept finite. Here T_{eff} denotes the effective tension of the light five-brane excitations. Just as GM, GF has no coupling constant and l_{eff} is the unique dimensionless parameter of the theory.

Similar theories can be obtained from light Dp-branes, which we will call GDp (Galilean D-p-branes). As we will now see, these theories are connected by dualities which are reminiscent of the dualities of the fully relativistic theories from which we obtain these Galilean theories. We first discuss the relation between supersymmetric Type IIA NRCS and the eleven-dimensional theory GM.

Here we will show that in fact the strong coupling dual to Type IIA NRCS is described by eleven-dimensional GM such that the parameters of the two theories are related to each other in a similar fashion to the usual relation in the relativistic setting.

Consider GM theory (7.1) compactified on a circle of proper radius R. The background critical three-form potential reduces to a NS–NS two-form potential,

$$B_{01}=2\pi R C_{012}. \tag{7.3}$$

Using the usual relation of parameters between M theory and Type IIA superstring theory,

$$R=g_s\sqrt{\alpha'}, \quad l_p=g_s^{1/3}\sqrt{\alpha'}, \tag{7.4}$$

we can write R and l_p in the limit (3.2) which defines NRCS, so that

$$R=g\sqrt{\alpha'_{\rm eff}}, \quad l_p=g^{1/3}\alpha'^{1/6}_{\rm eff}\alpha'^{1/3}, \tag{7.5}$$

as $\alpha'\to 0$.

Substituting the eleven-dimensional limit (7.1) in (7.3) we see that the background NS–NS two-form potential is given by

$$2\pi\alpha' B_{01}=1-\frac{l_p^3}{l_{\rm eff}^3}. \tag{7.6}$$

Using (7.5) and comparing with the limit defining NRCS in (3.2), we see that NRCS with coupling constant g and effective string scale $\alpha'_{\rm eff}$ is equivalent to GM theory on a circle of radius R and effective Planck scale $l_{\rm eff}$. The parameters are related by

$$R=g\sqrt{\alpha'_{\rm eff}}, \quad l_{\rm eff}=g^{1/3}\sqrt{\alpha'_{\rm eff}}. \tag{7.7}$$

A. GDp and GNSF theories

In this subsection we present some generalizations to the construction we made for perturbative closed strings in a near critical NS–NS B-field to Dp-branes in a near critical Ramond–Ramond $p+1$-form background. In order for the background to affect the Hamiltonian, the spatial directions of the brane have to be compactified on an orientable p-cycle of space–time. In this case, the winding number plays the role of electric charge in the discussion in (2.4) and again positivity of the energy allows only wrapping in one orientation.

The nonrelativistic limit that needs to be taken requires keeping finite the terms in the world volume action depending on the transverse coordinates to the brane and tuning the background field to the tension of the D-brane (this is the analog of the NRCS limit. There, we scaled α' and the metric in the transverse directions to the B-field such that terms of the string worldsheet action depending on the transverse coordinates are kept finite). The limit is given by

$$\begin{aligned} g_{\mu\nu}&=\eta_{\mu\nu}, \quad \mu,\nu=0,1,\ldots,p,\\ g_{ij}&=\left(\frac{\alpha'}{\alpha'_{\rm eff}}\right)^2\delta_{ij}, \quad i,j=p+1,\ldots,9,\\ g_s&=\left(\frac{\alpha'}{\alpha'_{\rm eff}}\right)^{(3-p)/2} g_p, \end{aligned} \tag{7.8}$$

$$C_{01\cdots p}=T_p-T_p^{\rm eff},$$

as $\alpha'\to 0$. Here T_p is the tension of the D-brane (which is infinite in the limit),

$$T_p=\frac{1}{(2\pi)^p g_s \alpha'^{(p+1)/2}}. \tag{7.9}$$

$T_p^{\rm eff}$ is the finite scale of the nonrelativistic theory and g_p the coupling of the theory. The effective tension is given by

$$T_p^{\rm eff}=\frac{1}{(2\pi)^p g_p \alpha_{\rm eff}^{(\prime p+1)/2}}. \tag{7.10}$$

In the limit (7.8) all states of string theory decouple except the light Dp-branes that have finite proper energy excitations. In particular, open and closed strings decouple from the low energy spectrum.

There is a very simple explanation for the limit we take in (7.8). Except for the presence of the background gauge field $C_{01\cdots p}$, (7.8) is the conventional low energy limit that results in a gauge theory on a Dp-brane.[27] This can be easily recognized by noting that the Yang–Mills coupling constant is given by $g_{\rm YM}^2\sim g_p\alpha_{\rm eff}'^{(p-3)/2}$ and that the limit (7.8) keeps the coupling finite. Moreover, the metric for the transverse coordinates X^i to the brane is given as in (7.8) whenever we express them in terms of the Higgs field Φ^i of the gauge theory as $X^i=\alpha'\Phi^i$ and require that the metric for Φ^i remains finite. The low energy limit is supplemented by turning a near critical background gauge field which results in light Dp-brane fluctuations.

There is one more theory we can define by tuning a massless gauge field of string theory, namely the one where the light excitations are NS five-branes. We will call these theories GNSF (Galilean Neveu–Schwarz five-brane). Just like NRCS, these theories can be obtained as a low energy limit of the different superstring theories. This low energy limit can also be motivated by considering the low energy limit on NS five-branes which yields the little string theories.[28] The nonrelativistic limit is given by

$$\begin{aligned} &g_{\mu\nu}=\eta_{\mu\nu}, \quad \mu,\nu=0,1,...,5,\\ &g_{ij}=\left(\frac{g_s}{G}\right)^2\delta_{ij}, \quad i,j=6,...,9,\\ &B_{012345}=T_5-T_5^{\rm eff}, \end{aligned} \tag{7.11}$$

as $g_s\to 0$ while keeping the string scale α' finite in the limit. Now the effective tension of the light NS five-branes is given by

$$T_5^{\rm eff}=\frac{1}{(2\pi)^5 G^2 \alpha_{\rm eff}'^3}. \tag{7.12}$$

Thus, (7.11) defines a nonrelativistic theory GNSF of light fluctuations of NS five-branes.

We will now briefly describe the theory one obtains for different values of p.

1. Zero-branes

For GD0, one may lift the description to M Theory (for a lift to eleven dimensions of a similar limit see Ref. 8). After a suitable rescaling of energy scales in M Theory, the M Theory circle goes from a space-like circle to a light-like circle of finite radius $R=g_0\sqrt{\alpha'_{\rm eff}}$. Then, if we consider the limit (7.8) for N D0-branes one obtains a DLCQ description of M Theory with eleven-dimensional Planck length $l_p=g_0^{1/3}\sqrt{\alpha'_{\rm eff}}$ in a sector with N units of longitudinal momentum.

2. One-branes

For $p=1$, the light states are D1-branes. The strong coupling dual of the theory of light D1-branes can be found by using Type IIB S-duality. S-duality maps the critical R–R background C_{01} to a critical NS–NS background B_{01}. The parameters $\tilde{g}_s$ and $\tilde{\alpha}'$ of the S-dual theory are given by

$$\tilde{g}_s=\frac{1}{g_s}, \quad \tilde{\alpha}'=\alpha' g_s. \tag{7.13}$$

Writing the limit (7.8) for $p=1$ in terms of the S-dual variables and comparing with (3.2) shows that the S-dual of GD1 is given precisely by NRCS if the parameters of the two theories are related by

$$g=\frac{1}{\tilde{g}}, \quad \alpha'_{\text{eff}}=\tilde{g}\tilde{\alpha}'_{\text{eff}}. \tag{7.14}$$

Thus Type IIB NRCS is related to GD1 by a strong–weak coupling duality which takes the same form as the conventional Type IIB S-duality. At the end of this section we will realize S-duality of Type IIB NRCS by studying GM theory compactified on a two-torus.[29,30]

3. Two-branes

GD2 can also be lifted to an eleven-dimensional picture. The D2-branes lift to M2-branes and the parameters (the eleventh-dimensional proper radius R and the Planck length l_p) of M Theory are related to those of GD2 by

$$R=\frac{\alpha'}{\sqrt{\alpha'_{\text{eff}}}}g_2, \quad l_p=g_2^{1/3}\frac{\alpha'^{2/3}}{\alpha'^{1/6}_{\text{eff}}}. \tag{7.15}$$

Moreover, the near critical R–R background lifts to a near critical background for the three-form of eleven-dimensional supergravity. Therefore, GD2 can be identified with GM on a transverse circle. Using the parameters in (7.1) we see that GM with an effective Planck scale l_{eff} on a transverse circle of coordinate size L is GD2 with coupling g_2 and effective string scale α'_{eff}. The parameters are related by

$$L=g_2\sqrt{\alpha'_{\text{eff}}}, \quad l_{\text{eff}}=g_2^{1/3}\sqrt{\alpha'_{\text{eff}}}. \tag{7.16}$$

Thus, the relation between GD2 and GM is reminiscent of the conventional duality between Type IIA and M Theory.

4. Three-branes

In order to get light D3-branes one must turn on a critical RR four-form. We can analyze the strong coupling dual of GD3. In fact, GD3 is self-dual, since S-duality of the underlying string theory maps the limit (7.8) to an analogous limit but with a different coupling constant and effective string scale. Therefore, GD3 with parameters g_3 and α'_{eff} is dual to GD3 with parameters $\tilde{g}_3$ and $\tilde{\alpha}'_{\text{eff}}$. The parameters are related by

$$\tilde{g}_3=\frac{1}{g_3}, \quad \tilde{\alpha}'_{\text{eff}}=g_3\alpha'_{\text{eff}}. \tag{7.17}$$

At the end of this section we realize the S-duality of CD3 from an eleven-dimensional perspective.

5. Four-branes

The GD4 limit can also be lifted to M Theory. The main difference here is that $g_s \to \infty$ in the limit. Therefore, it is required to analyze the configuration in eleven dimensions. The D4-branes lift to M5-branes wrapped on the M Theory circle. The proper size of the circle and the corresponding eleven-dimensional Planck length are given by

$$R = g_4 \sqrt{\alpha'_{\rm eff}}, \quad l_p = g_4^{1/3} \alpha'^{1/3} \alpha'^{1/6}_{\rm eff}. \tag{7.18}$$

Since the background RR five-form lifts to a near critical six-form of eleven-dimensional supergravity, one sees that the strong coupling dual to GD4 is given by GF. Comparing the parameters in (7.18) with those that define GF (7.2) one finds that the parameters of the two theories are related by

$$R = g_4 \sqrt{\alpha'_{\rm eff}}, \quad l_{\rm eff} = g_4^{1/3} \sqrt{\alpha'_{\rm eff}}. \tag{7.19}$$

6. Five-branes

We now consider the OD5 theory. For $p=5$, one also has to perform S-duality since in the decoupling limit $g_s \to \infty$. S-duality maps the D5-branes to NS five-branes. Moreover, the critical RR field gets mapped to a critical NS–NS electric field for the NS five-branes. Thus we are led to studying NS five-branes in a critical field. Type IIB S-duality maps the limit (7.8) for $p=5$ to a theory with string scale and string coupling given by

$$\tilde{\alpha}' = g_s \alpha' = g_5 \alpha'_{\rm eff}, \quad \tilde{g}_s = \frac{1}{g_s} = \frac{\alpha'}{\alpha'_{\rm eff}} \frac{1}{g_5}. \tag{7.20}$$

Note that the string scale of the S-dual theory is finite while the string coupling vanishes. This is precisely the limit that defines Type IIB GNSF (7.11). The parameters of GD5 $(g_5, \alpha'_{\rm eff})$ are related to those of GNSF $(G, \tilde{\alpha}')$ by

$$\alpha'_{\rm eff} = G \tilde{\alpha}', \quad G = \frac{1}{g_5}. \tag{7.21}$$

In the limit that defines GD5, apart from having low energy D5-brane excitations, there are also finite energy D1-string excitations. These are identified in the Type IIB GNSF theory with strings of tension $\tilde{\alpha}'^{-1}$ fluctuating inside the five-branes.

7. Type IIA Neveu–Schwarz five-branes

Type IIA GNSF has an interesting strong coupling dual. The limit in (7.11) can be realized by considering the decoupled theory of light fluctuating five-branes of M Theory on a transverse circle of proper size R. The near critical six-form background of eleven-dimensional supergravity becomes a near critical RR six-form of Type IIA string theory and the M5-brane becomes a NS five-brane on a transverse circle of proper radius R. The parameters of the two theories are related by

$$R = g_s \sqrt{\alpha'}, \quad l_p = g_s^{1/3} \sqrt{\alpha'}. \tag{7.22}$$

By comparing the scaling limit (7.2) with (7.11) and using (7.22) one finds the following relation between the effective length scales of the two theories,

$$l_{\rm eff} = G^{1/3} \sqrt{\alpha'_{\rm eff}}. \tag{7.23}$$

Moreover, the NS five-branes now sit at a point in the transverse circle, whose coordinate length is given by

$$L = G\sqrt{\alpha'}. \tag{7.24}$$

We see that the Galilean theories we have found sit on the same moduli space and satisfy many of the properties of the parent theories from which we define them by taking a low energy limit. The reduced number of degrees of freedom that these theories have can be an interesting avenue in which to study in a simplified setting M Theory dualities.

8. S-duality of Type IIB NRCS from GM

We first notice that Type IIB NRCS can be obtained by considering eleven-dimensional GM theory compactified on a two-torus, where one circle is along the membrane and the other is transverse to it, and then shrinking the torus.

Let us consider GM theory compactified on a rectangular torus of coordinate size radii R_1 and R_2. We will take the circle of radius R_1 to be along the background three-form of supergravity and the circle of radius R_2 to be transverse to it. If we reduce GM on R_1 one gets Type IIA NRCS. The string coupling is given by

$$g_s = \frac{R_1}{\sqrt{\alpha'}}. \tag{7.25}$$

We now perform T-duality along the circle of radius R_2. This maps the limit to a Type IIB set-up. T-duality inverts the proper size of the circle one T-duals along and changes the dilaton in the conventional fashion. The new string coupling is given by

$$g_s' = \frac{R_1}{R_2}\sqrt{\frac{\alpha'_{\text{eff}}}{\alpha'}}. \tag{7.26}$$

Therefore, comparing with (3.2) we see that this compactification of GM leads to Type IIB NRCS with coupling constant

$$g = \frac{R_1}{R_2}, \tag{7.27}$$

compactified on a transverse circle of coordinate size α'_{eff}/R_2. Therefore, one gets Type IIB NRCS from GM in the limit that the coordinate area of the torus vanishes at fixed ratio R_1/R_2.

However, one could have chosen to reduce GM on the circle of coordinate radius R_2. As we showed, this leads to CD2 theory on a parallel circle of coordinate size R_1. The Type IIA coupling is given by

$$\tilde{g}_s = \frac{\sqrt{\tilde{\alpha}'}}{\tilde{\alpha}'_{\text{eff}}} R_2. \tag{7.28}$$

One can perform a T-duality transformation along the circle of radius R_1 such that we get a low energy limit in the Type IIB superstring where the string coupling is given by

$$\tilde{g}_s' = \frac{\tilde{\alpha}'}{\tilde{\alpha}'_{\text{eff}}}\frac{R_2}{R_1} \tag{7.29}$$

and the circle is of coordinate size $\tilde{\alpha}'_{\text{eff}}/R_1$. Thus, by looking at (7.8) for $p=1$ we see that one gets CD1 theory with coupling,

$$\tilde{g}_1 = \frac{R_2}{R_1}. \tag{7.30}$$

Therefore, S-duality of Type IIB NRCS can be understood from an eleven-dimensional perspective as the symmetry that exchanges the two circles when one considers GM theory compactified on a two-torus.[29,30]

9. S-duality of GDS from GF

Consider a single M5 brane compactified on a rectangular two-torus of radii R_1 and R_2 along the background directions in the decoupling limit (7.2). If we treat the circle of radius R_1 to be the one that results in GD4, then the parameters of GD4 are given by

$$R_1 = g_4 \sqrt{\alpha'_{\text{eff}}}, \quad l_{\text{eff}} = g_4^{1/3} \sqrt{\alpha'_{\text{eff}}}. \tag{7.31}$$

One may perform T-duality along the circle of radius R_2. Then, we obtain the Galilean theory of light D3-branes. The string coupling after T-duality is given by

$$g'_s = g_s \frac{\sqrt{\alpha'}}{R_2} = g_4 \sqrt{\frac{\alpha'_{\text{eff}}}{R_2}}. \tag{7.32}$$

Comparing (7.32) with (7.8) for $p=3$ and using (7.31) one finds that the effective coupling of the theory of light D3-branes is

$$g_3 = \frac{R_1}{R_2}, \tag{7.33}$$

which is reminiscent of the relation between M Theory on a two-torus and Type IIB string theory.

If one reduces first on the circle of radius of R_2 and then performs T-duality along the circle of radius R_1 one again obtains GD3 but with the inverse coupling. Therefore, S-duality of GD3 follows from the interchange of the two circles of the two-torus in the GF realization of GD3.

Bosonic M theory

Gary T. Horowitz

(Received 2 January 2001; accepted for publication 13 February 2001)

We conjecture that there exists a strong coupling limit of bosonic string theory which is related to the 26 dimensional theory in the same way that 11 dimensional M theory is related to superstring theory. More precisely, we believe that bosonic string theory is the compactification on a line interval of a 27 dimensional theory whose low-energy limit contains gravity and a three-form potential. The line interval becomes infinite in the strong coupling limit, and this may provide a stable ground state of the theory. We discuss some of the consequences of this conjecture.
 [DOI: 10.1063/1.1376160]

I. INTRODUCTION

There is growing evidence that all the known perturbative ten-dimensional superstring theories are limits of an eleven dimensional theory called M theory.[1–3] In particular, the ubiquitous dilaton which controls the string coupling is simply related to the size of the extra dimension. The 26 dimensional bosonic string has not been included in these developments mostly due to the widespread belief that the existence of the tachyon indicates that the theory is ill defined. (The strong coupling limits of the ten-dimensional bosonic Type 0 theories have been discussed in Ref. 4, and other nonsupersymmetric theories have been considered in Ref. 5.) However, during the past year the significance of the open string tachyon has been understood. Rather than indicating that the theory is sick, it just shows that the usual vacuum is unstable. As Sen first proposed,[6] this vacuum can be viewed as a closed string vacuum together with an unstable D 25-brane. There is increasing evidence that there is a stable minimum of the open string tachyon potential at a value equal to minus the tension of a D 25-brane, and about this minimum there are no open string excitations. This raises the possibility that the closed string tachyon can similarly be removed by appropriately shifting to a new ground state. However, there are good arguments that the closed string tachyon cannot be removed by direct analogy to the open string case. There is probably no stable minimum of the closed string tachyon potential.[7] Something more dramatic is needed.

In this paper we study the strong coupling limit of bosonic string theory and argue that the tachyon instability may be removed in this limit. Unfortunately we have very little firm ground to stand on when trying to determine the strong coupling limit of a theory without supersymmetry. In this paper we make a guess based on the assumption that bosonic string theory is not wholly dissimilar to IIA and heterotic string theory.

The main clue motivating our guess comes from the existence of the dilaton and its connection to the coupling constant. The action for the massless sector of bosonic string theory is

$$S=\int d^{26}x\sqrt{-g}e^{-2\phi}\left[R+4\nabla_\mu\phi\nabla^\mu\phi-\frac{1}{12}H_{\mu\nu\rho}H^{\mu\nu\rho}\right]. \tag{1.1}$$

Evidently, as in IIA string theory, the dilaton enters the action just as it would if it represented the compactification scale of a Kaluza–Klein theory. We propose to take this seriously and try to interpret bosonic string theory as a compactification of a 27 dimensional theory. We will refer to

this theory as bosonic M theory. (The possibility that the bosonic string has a 27 dimensional origin was also briefly discussed in Ref. 8, in the context of a proposed matrix string formulation.)

In the case of IIA string theory there was a second clue that led to its interpretation as a Kaluza–Klein compactification of an 11 dimensional theory; the existence of a vector boson in the string spectrum. Closed bosonic string theory does not have a massless vector. This means it cannot be a compactification on an S^1. In this respect the situation is more analogous to that of heterotic string theory. The solution to the strong coupling problem in that case is a compactification of M theory on a line interval, or more exactly on the orbifold S^1/Z_2.[9] The absence of a $U(1)$ symmetry means that there is no massless gauge boson. Accordingly, we propose that closed bosonic string theory is a compactification of 27 dimensional bosonic M theory on S^1/Z_2. In the supersymmetric case, to cancel anomalies one had to add E_8 gauge fields at each end of the line interval. In the bosonic case, since there are no fermions or chiral bosons, there are no anomalies to cancel. So there are no extra degrees of freedom living at the fixed points.

As in the case of the M theory–heterotic connection, the weakly coupled string theory is the limit in which the compactification length scale becomes much smaller than the 27 dimensional Planck length and the strong coupling limit is the decompactification limit. The 27 dimensional theory should contain membranes but no strings, and would not have a dilaton or variable coupling strength. The usual bosonic string corresponds to a membrane stretched across the compactification interval.

Some support for bosonic M theory comes from the following simple observation. The left moving modes of the heterotic string are precisely those of the 26 dimensional bosonic string. It has been argued[10] that at least perturbatively, the right moving modes of the bosonic string can be embedded in the right moving modes of the heterotic string. So the entire bosonic string is contained in the heterotic string. Since we now know that nonperturbatively the heterotic string grows an extra dimension, it is plausible that the bosonic string will similarly gain an extra dimension at strong coupling.

II. THE LOW-ENERGY THEORY

In this section we study the low-energy limit of bosonic M theory which is a gravity theory in 27 dimensions. Without the powerful tool of supersymmetry it is difficult to give rigorous arguments. Nevertheless there are some plausible guesses that we can make about the form of the low-energy action, using the fact that it must reduce to the usual bosonic string theory in the weak coupling limit. After deriving the low-energy action, we show how the tachyon instability may be removed in the strong coupling limit, and then study branes in this theory.

A. Motivation from weak coupling limit

In order to reproduce the known spectrum of weakly coupled bosonic string theory, bosonic M theory will have to contain an additional field besides the 27 dimensional gravitational field, namely a three-form potential $C_{\mu\nu\rho}$. Let us consider the various massless fields that would survive in the weak coupling limit. First of all, there would be the 26 dimensional graviton. As usual, general covariance in 26 dimensions would insure that it remains massless. The component of the 27 dimensional gravitational field $g_{27,27}$ is a scalar in the 26 dimensional theory. It is of course the dilaton. No symmetry protects the mass of the dilaton. In fact we know that at the one loop level a dilaton potential is generated that lifts the dilatonic flat direction. Why the mass vanishes in the weak coupling limit is not clear.

Massless vectors have no reason to exist since there is no translation symmetry of the compactification space. This is obvious if we think of this space as a line interval. If we think of it as S^1/Z_2 then the two fixed points of the orbifold break the symmetry.

The three-form gauge field $C_{\mu\nu\sigma}$ gives some massless fields. If one of the indices of the three-form is in the compact 27th direction, the resulting 26 dimensional field is the two-form $B_{\mu\nu}$ which is well known in bosonic string theory. It remains massless due to its gauge invariance. The components of $C_{\mu\nu\sigma}$ in which all three components are in the 26 dimensional subspace give a three-form which is absent in the usual bosonic string spectrum. Once again we take a hint from

heterotic string theory. In that case the the three-form that would be inherited from the 11 dimensional origin of heterotic string theory is projected away by the Z_2 identification. This is because M theory includes a Chern–Simons term which implies that the action is invariant under Z_2 only if C is odd under this identification. In the present case we will also assume that C is odd under the Z_2. [If y is the coordinate along the S^1, the fact that the basis vector $\partial/\partial y$ points away from the fixed point $y=0$, means that it also must change sign under the Z_2. This means that the components C_{yij} are even under $y\to -y$, while C_{ijk} are odd (where i,j,k denote all directions other than y)]. Given our limited knowledge of the theory, we do not know if this is required by a symmetry of the action or not.

We are thus led to the following low-energy action for bosonic M theory:

$$S=\int d^{27}x\sqrt{-\hat{g}}\left[R(\hat{g})-\frac{1}{48}F_{\mu\nu\rho\sigma}F^{\mu\nu\rho\sigma}\right], \tag{2.1}$$

where $F=dC$. To see the relation to (1.1), we set

$$\hat{ds}^2=e^{2\sigma}dy^2+e^{-\sigma}g_{\mu\nu}dx^\mu dx^\nu, \tag{2.2}$$

where σ and $g_{\mu\nu}$ are functions of x^μ but independent of y, and set

$$H_{\mu\nu\rho}=F_{y\mu\nu\rho}. \tag{2.3}$$

The coordinate y takes values $-1\leqslant y\leqslant 1$ and we identify y with $-y$. This prevents a term like $A_\mu dy dx^\mu$ from appearing in (2.2). Substituting into the action and integrating by parts yields

$$S=\int d^{26}x\sqrt{-g}e^{-11\sigma}[R(g)+125\nabla_\mu\sigma\nabla^\mu\sigma-\tfrac{1}{12}H_{\mu\nu\rho}H^{\mu\nu\rho}]. \tag{2.4}$$

There is no four-form in 26 dimensions since, as we have just explained, it is projected out by the identification on y. If we now define $2\phi\equiv 11\sigma$, this becomes the standard action for bosonic string theory (1.1) except that the coefficient of the $(\nabla\phi)^2$ is off by a factor of 125/121. So we recover the right fields and interactions, but one numerical coefficient is slightly off. This is not a contradiction since the action (2.1) is only valid on scales larger than the 27 dimensional Planck length, and to recover (1.1) we need to take a limit where one direction becomes much smaller than this. Without supersymmetry to protect coefficients, they can change as the coupling increases. In this respect, the factor of 125/121 may be analogous to the factor of 3/4 which arises in comparing the entropy of weakly coupled $3+1$ Yang–Mills with the near extremal three-brane.[11]

The relation between the 27 dimensional Planck length l_p and the 26 dimensional string length l_s and coupling $g=e^\phi$, follows from the relation between σ and ϕ. Since $g^2 l_s^{24}=G_{26}=G_{27}/e^\sigma l_p$ we get

$$g^{1/11}l_s=l_p. \tag{2.5}$$

Since $g=e^{11\sigma/2}$, weak coupling corresponds to a small distance in the extra dimension, as expected.

There is a possibility of adding a cosmological constant to the action (2.1). Indeed, in the absence of supersymmetry, it would appear inevitable that one is generated. We will discuss this in Sec. IV, but for now, we will assume the cosmological constant is zero.

B. Tachyon

We now consider the fate of the closed string tachyon at strong coupling. The trivial solution to (2.1) consisting of $F=0$ and flat spacetime compactified on S^1/Z_2 has a nonperturbative instability. This is analogous to the instability of the Kaluza–Klein vacuum found by Witten,[12] and

very similar to its application to heterotic–M theory in Ref. 13. The process that destabilizes the space is mediated by an instanton in which the two ends of the world (ends of the compactification interval) come together and produce a ''hole'' in space. In Minkowski space the hole rapidly grows and eats the entire space.

The appropriate instanton is (a projection of) the 27 dimensional euclidean Schwarzschild metric.

$$ds^2=\left[1-\left(\frac{r_0}{r}\right)^{24}\right]dy^2+\left[1-\left(\frac{r_0}{r}\right)^{24}\right]^{-1}dr^2+r^2(d\theta^2+\sin^2\theta d\Omega_{24}). \tag{2.6}$$

The coordinate y is periodic with period $P=\pi r_0/6$. To apply it to our case, we identify y and $-y$. So the size of the extra dimension at infinity is $\pi r_0/12$. To obtain the Lorentzian evolution, one analytically continues $\theta\to(\pi/2)+it$. To picture this evolution, consider the surfaces at the ends of the interval, $y=0,\pi r_0/12$. The separation between these surfaces goes to zero smoothly at $r=r_0$, so the two surfaces are really one surface with the shape of a wormhole. At the initial time, $t=0$, the proper size of the wormhole is r_0, but as time evolves, it grows exponentially.

This instanton description is only valid for $r_0\gg l_p$. However similar instabilities occur in various nonsupersymmetric D–brane systems. A typical example is a D–brane anti D–brane system. If the distance between the branes is larger than the string scale, an instanton process bridging the two branes can again lead to a runaway hole eating the branes.[14] When the branes are closer than the string scale the same process can take place by a perturbative mechanism. At a critical point the lightest string connecting the branes becomes massless and then tachyonic.[15,16] This pattern is seen in several examples and leads to the following conjecture:

When the two ends of the world are closer than the 27 dimensional Planck length a tachyon appears in the spectrum. This is just the closed string tachyon found in string perturbation theory.

The action for the instanton (2.6) is proportional to $(r_0/l_p)^{25}$. So in the limit of strong string coupling, $r_0\to\infty$, this nonperturbative instability is suppressed. Uncompactified 27 dimensional flat space may be a stable ground state of bosonic M theory.

C. Branes

In the absence of supersymmetry, there are no BPS states. Nevertheless, there are stable brane configurations. In terms of the low energy action (2.1) they arise as the extremal limit of black brane solutions. Since the charge must be carried by a four-form, there are 2-branes which are electrically charged and 21-branes which are magnetically charged. It is natural to assume that there are fundamental 2-branes and 21-branes with Planck tension, and these black brane solutions describe the gravitational field of a stack of parallel branes. A nontrivial check of this idea is to compute the tension of a fundamental 2-brane stretched across the extra dimension. It is given by $T=e^{\sigma}/l_p^2$. Using (2.5), and the relation between σ and ϕ we get $T=1/l_s^2$ which is the right answer for a fundamental string. Similarly, the tension of a 21-brane which is not oriented along the extra dimension is $T_{21}=1/l_p^{22}=1/(g^2 l_s^{22})$ which again is the right answer for a solitonic 21-brane in string theory.

The black brane solutions can be read off from the general discussion of nondilatonic black branes in Ref. 17. The black 2-brane is given by

$$\begin{aligned}ds^2=&-\left[1-\left(\frac{r_+}{r}\right)^{22}\right]\left[1-\left(\frac{r_-}{r}\right)^{22}\right]^{-1/3}dt^2+\left[1-\left(\frac{r_-}{r}\right)^{22}\right]^{2/3}dx_i dx^i\\&+\left[1-\left(\frac{r_+}{r}\right)^{22}\right]^{-1}\left[1-\left(\frac{r_-}{r}\right)^{22}\right]^{-1}dr^2+r^2d\Omega_{23},\end{aligned} \tag{2.7}$$

with four-form

$$*F=Nl_p^{22}\epsilon_{23}, \tag{2.8}$$

where ϵ_{23} is the volume form on a unit S^{23}. The charge N is the number of fundamental two branes, and is related to the two free parameters $r_\pm$ via

$$N^2=\frac{1100}{3}\left(\frac{r_+r_-}{l_p^2}\right)^{22}. \tag{2.9}$$

There is an event horizon at $r=r_+$ and a curvature singularity at $r=r_-$. The Hawking temperature of this black 2-brane is

$$T=\frac{11}{2\pi r_+}\left[1-\left(\frac{r_-}{r_+}\right)^{22}\right]^{1/3}. \tag{2.10}$$

If we compactify the two directions along the brane on a torus with side L, then the horizon area is

$$A=r_+^{23}\Omega_{23}L^2\left[1-\left(\frac{r_-}{r_+}\right)^{22}\right]^{2/3}, \tag{2.11}$$

where Ω_{23} is the area of a unit S^{23}. In the extremal limit, $r_+=r_-$, (2.7) takes a simpler form by setting $\rho^{22}=r^{22}-r_-^{22}$

$$ds^2=f(\rho)^{-2/3}[-dt^2+dx_i dx^i]+f(\rho)^{1/11}[d\rho^2+\rho^2 d\Omega_{23}], \tag{2.12}$$

where

$$f(\rho)=1+\left(\frac{r_-}{\rho}\right)^{22}. \tag{2.13}$$

This extremal brane has zero Hawking temperature and is quantum mechanically stable. The surface $\rho=0$ is a smooth horizon. There is no force between two parallel extremal branes. Static, multibrane solutions can be obtained by replacing f with a more general solution of Laplace's equation.

We now turn to the black 21-brane. The metric is

$$\begin{aligned}ds^2=&-\left[1-\left(\frac{r_+}{r}\right)^3\right]\left[1-\left(\frac{r_-}{r}\right)^3\right]^{-10/11}dt^2+\left[1-\left(\frac{r_-}{r}\right)^3\right]^{1/11}dx_i dx^i\\&+\left[1-\left(\frac{r_+}{r}\right)^3\right]^{-1}\left[1-\left(\frac{r_-}{r}\right)^3\right]^{-1}dr^2+r^2d\Omega_4,\end{aligned} \tag{2.14}$$

and the four-form is $F=Nl_p^3\epsilon_4$, where

$$N^2=\frac{75}{11}\left(\frac{r_+r_-}{l_p^2}\right)^3. \tag{2.15}$$

The Hawking temperature is

$$T=\frac{3}{4\pi r_+}\left[1-\left(\frac{r_-}{r_+}\right)^3\right]^{1/22}, \tag{2.16}$$

and the horizon area is

$$A=r_+^4\Omega_4L^{21}\left[1-\left(\frac{r_-}{r_+}\right)^3\right]^{21/22}, \tag{2.17}$$

where we have again compactified the directions along the brane to have size L. Setting $\rho^3 = r^3 - r_-^3$, the extremal limit is

$$ds^2 = f(\rho)^{-1/11}[-dt^2 + dx_i dx^i] + f(\rho)^{2/3}[d\rho^2 + \rho^2 d\Omega_4], \tag{2.18}$$

where now

$$f(\rho) = 1 + \left(\frac{r_-}{\rho}\right)^3. \tag{2.19}$$

Like the 5-brane of M theory, this 21-brane is completely nonsingular. The space–time behind the horizon $\rho = 0$ is identical to the space–time in front.

We now suppose that one direction of spacetime is compactified on S^1/Z_2, and the four-form F is odd under the Z_2 identification. The situation is similar to the usual heterotic string construction.[18] Recall that, if y is the coordinate in the compact direction, the components F_{yijk} must be even under $y \to -y$, while F_{ijkl} are odd (where i,j,k,l denote all directions other than y). Thus, if y is one of the two directions along the 2-brane, the identification can be done trivially since the solution is invariant. As we have already noted, this corresponds to N bosonic strings in 26 dimensions. If the 2-brane is perpendicular to y, a static solution can still be constructed by putting the 2-brane half way between the two fixed points and adding an anti-2-brane at its image point under the Z_2. (This solution is not known explicitly and will be unstable.) It results in an unstable D2-brane in 26 dimensions. If the 21-brane is perpendicular to y, an invariant solution is obtained by adding another 21-brane (not anti-brane) at its image point under the Z_2. This corresponds to a 21-brane in string theory which is magnetically charged with respect to the three-form H. If y is one of the directions along the 21-brane, then no invariant solution can be constructed, since $F_{ijkl} \neq 0$ at $y = 0$.

As an aside, we note that there is also a brane solution of 26 dimensional bosonic string theory which has both electric and magnetic charge associated with the three-form H. It is a 21-brane with fundamental strings lying in it and smeared over the remaining 20 directions. Dimensionally reducing to six dimensions by compactifying on a small T^{20}, one recovers the usual self dual black string in six dimensions.

III. HOLOGRAPHIC DUALS

In this section we go beyond the low-energy limit, and try to say something about exact bosonic M theory. Since it contains gravity it should be holographic. There are two types of holographic duals that we have become familiar with. The first is Matrix theory which is based on the existence of stable D0-branes in type IIA theory and the existence of a DLCQ quantization of M theory. However, in the present case in which the compactification is on a line interval rather than a circle this type of construction is questionable (but see Ref. 8).

The other type of holographic dual is through AdS/CFT duality.[19] Following the arguments used for the superstring, we consider the near horizon limit of the extreme black brane solutions. As usual, the near horizon limit corresponds to dropping the one in f in the solutions (2.12) and (2.18). Starting with the 2-brane, the resulting space is $AdS_4 \times S^{23}$. From (2.9), the radius of each is proportional to $N^{1/11}$. The CFT dual would be a $2+1$ dimensional conformal field theory with a global SO(24) symmetry. The natural candidate would be the dimensional reduction of 26 dimensional Yang–Mills theory which has 23 scalars in the adjoint representation. This theory has manifest SO(23) symmetry. The mechanism for enhancing the symmetry would have to be similar to the enhancement of SO(7) to SO(8) in the supersymmetric case. However, in the present situation we have no superconformal symmetry to ensure the enhanced symmetry. A strong test of the existence of bosonic M theory is the existence of a conformal fixed point with SO(24) symmetry at least in the $N \to \infty$ limit. In other words, if there does not exist a $2+1$ CFT with SO(24) global symmetry, bosonic M theory would be disproven.

As in the usual AdS/CFT correspondence, thermodynamics of the CFT should be related to the near extremal 2-brane. From (2.9) to (2.11), the entropy of near extremal 2-branes can be expressed

$$S \propto N^{25/22}(LT)^2. \tag{3.1}$$

This looks like the entropy of a $2+1$ field theory. The N dependence is analogous to the $N^{3/2}$ which appears in the usual M 2-brane, and can similarly be viewed as a prediction for the density of states of the theory at strong coupling.

Since there are also solutions of the form $AdS_4 \times K$ where K is any 23 dimensional Einstein space, there may also exist holographic duals of the theory with these boundary conditions. They would be $2+1$ conformal field theories with less symmetry.

Starting with the extreme 21-brane (2.18), the near horizon limit is $AdS_{23} \times S^4$, where the radii of each is proportional to $N^{2/3}$. If the theory exists, its holographic dual will be a 22 dimensional conformal field theory with a global SO(5) symmetry. It follows from (2.15) to (2.17) that in the near extremal limit, the entropy of the black 21-brane can be expressed

$$S \propto N^{25/3}(LT)^{21}. \tag{3.2}$$

Once again, this is consistent with a 22 dimensional field theory with a large number of degrees of freedom.

IV. DISCUSSION

We have proposed that a bosonic version of M theory exists, which is a 27 dimensional theory with 2-branes and 21-branes. One recovers the usual bosonic string by compactifying on S^1/Z_2 and shrinking its size to zero. In particular, a Planck tension 2-brane stretched along the compact direction has the right tension to be a fundamental string. This picture offers a plausible explanation of the tachyon instability and suggests that uncompactified 27 dimensional flat space may be stable. A definite prediction of this theory is the existence of a $2+1$ CFT with SO(24) global symmetry, which should be its holographic dual for $AdS_4 \times S^{23}$ boundary conditions.

The conjecture that bosonic M theory exists raises a number of questions which we now address:

(1) What kind of theory do we get if we compactify bosonic M theory on a circle instead of a line interval? Do we get a weakly coupled string theory in the limit that the circle shrinks to zero? This seems problematic since, whatever the resulting theory is, it should have a massless vector and three-form potential. Of course the open string has a massless vector, but as far as we know, there is no 26 dimensional bosonic string theory with a three-form potential. Instead we believe the limit of bosonic M theory compactified on a circle as the radius $R \to 0$ is the same as the limit $R \to \infty$, i.e., the uncompactified 27 dimensional theory. If we compactify bosonic M theory on $S^1 \times (S^1/Z_2)$, and take the second factor very small, this is a consequence of the usual T-duality of the bosonic string. More generally, it appears to be the only possibility with the right massless spectrum;

(2) must bosonic M theory have a vanishing cosmological constant? If not, what is the sign of the cosmological constant? If it is negative then there should be a 27 dimensional AdS solution. The holographic representation of this theory should be an isolated 26 dimensional conformal field theory. Since it is likely that the cosmological constant would be of order one in Planck units we would not expect classical Einstein gravity to be an accurate description. The best description would be the CFT. If the cosmological constant is positive, how do we make sense out of the theory in de Sitter space? This would be the first example of a de Sitter solution emerging out of string theory.

Even with a cosmological constant Λ, there are solutions of the form $AdS_4 \times S^{23}$. The only difference is that the curvature on the two spaces need not be comparable, and are related to different combinations of the four-form charge N and Λ. If $\Lambda > 0$, there is a particularly

interesting special case in which the solution is a sphere cross four dimensional Minkowski spacetime. This may have phenomenological applications. It is worth emphasizing that this solution exists for any (positive) cosmological constant, as long as F can be chosen appropriately. It would certainly be interesting to find a dynamical mechanism which would require F to cancel Λ in this way. (For a recent discussion of a possible mechanism, see Ref. 20.) In any event, we find it intriguing that four-dimensional space–times arise naturally in this theory;

(3) bosonic string theory contains unstable Dp-branes for all p. What are the analog of these in bosonic M theory? It appears that most of these do not survive the strong coupling limit and do not exist as new degrees of freedom in 27 dimensions. This is not surprising since Type II superstring also has unstable Dp-branes which do not appear to have an analog in M theory. However, some Dp-branes may remain. We already saw a construction of an unstable D2-brane in Sec. II. D0-branes can be identified with modes in the 27th direction. In the theory compactified on S^1/Z_2, these modes are unstable since they bounce off the fixed points, interact with themselves and decay into radiation in the other directions. In the uncompactified limit, they should become stable;

(4) even if 27 dimensional flat space, M_{27}, is a stable vacuum, one might ask what is the ''ground state'' of the theory at finite string coupling, or finite compactification size? Tachyon condensation is not likely to lead back to M_{27}, and there is probably no stable minimum of the tachyon potential in 26 dimensions.[7] Instead, we believe tachyon condensation may lead to an exotic state with zero metric $g_{\mu\nu}=0$. It is an old idea that quantum gravity may have an essentially topological phase with no metric. We have argued that the tachyon instability is related to nucleation of ''bubbles of nothing'' which is certainly reminiscent of zero metric. Further support for this idea comes from some old results on the closed string tachyon. Using modular invariance of the one loop vacuum amplitude, one can relate the existence of a tachyon to the asymptotic density of states. It was shown that the tachyon is absent only if, at high energies, the theory has at most a finite number of fields propagating in two spacetime dimensions.[21] Similar results were found by studying the theory near the Hagadorn transition.[22] If the theory starts in 26 (or 27) dimensions, the only way to get down to two dimensions is to have a highly degenerate metric. The most symmetric state would then be $g_{\mu\nu}=0$, and two dimensional subspaces might arise as excitations.

This raises an interesting question in string field theory. Witten's open bosonic string field theory[23] takes the form

$$S=\int A*QA+\frac{2g}{3}A*A*A, \tag{4.1}$$

where Q is the BRST operator and $*$ is a noncommutative product. Formally, $\int$ and $*$ are independent of the metric and other closed string backgrounds but Q is not. Since an interacting theory of open strings must include closed strings, it is awkward having this explicit background dependence in the action. It was shown in Ref. 24 that (4.1) could be derived from the purely cubic action

$$S=\int \Phi*\Phi*\Phi. \tag{4.2}$$

There is a solution Φ_0 to the equation of motion $\Phi*\Phi=0$ such that expanding about this solution, $\Phi=\Phi_0+g^{1/3}A$, one recovers Witten's action. The natural ground state of the purely cubic action is $\Phi=0$. Since this corresponds to zero BRST operator, it has been interpreted as a state of zero metric. But the purely cubic action can be viewed as the strong coupling limit $g\to\infty$ of (4.1) (we thank S. Shenker for pointing this out). If this is similar to the strong coupling limit of purely closed bosonic string theory, the natural ground state should be M_{27}. Could it be that $\Phi=0$ really

corresponds to M_{27} and the fact that $Q=0$ is just the statement that there are no open string excitations? If so, how can one recover the metric and three-form excitations?

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 42, NUMBER 7 JULY 2001

Extended objects from warped compactifications of M theory

Eva Silverstein
Department of Physics and SLAC, Stanford University, Stanford, California 94305

(Received 2 January 2001; accepted for publication 13 February 2001)

We study the massive spectrum of fully wrapped branes in warped M-theory compactifications, including regimes where these states are parametrically lighter than the Planck scale or string scale. We show that many such states behave classically as extended objects in the noncompact directions in the sense that their mass grows with their size as measured along the Poincare slices making up the noncompact dimensions. On the other hand, these states can be quantized in a nontrivial regime: in particular, their spectrum of excitations in a limited regime can be obtained by a warped Kaluza–Klein reduction from ten dimensions. We briefly discuss scattering processes and loop effects involving these states, and also note the possibility of an exponential growth in the number of bound states of these objects as a function of energy. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1373422]

I. INTRODUCTION

One of the features of the web of M-theory duals is the presence of various limits in which a distinctive spectrum of states emerges as the lightest excitation above the (super-) gravity modes. For example, in some limits strings dominate, in others particles including those coming from wrapped branes.

Compactifications of M theory down to d Poincare-invariant dimensions are generically warped products, with d-dimensional Minkowski space varying over a compact $11-d$-manifold K. That is, the metric is of the form

$$ds^2 = a(y)dx_{\|}^2 + H_{ij}(y)dy^i dy^j, \tag{1.1}$$

where $x_{\|}^{\mu}$, $\mu = 0,...,d-1$ are coordinates along the Poincare slices and y_i, $i = d,\ldots,10$ are coordinates along the internal manifold. In this article we will study basic aspects of the massive spectrum in such compactifications (focusing on two concrete examples: Horava–Witten theory compactified on $K3$,[1] and type I′ theory as studied by Polchinski and Witten[2] compactified on a five-torus).

We will find objects which behave in the noncompact $x_{\|}$ directions in a way that is in some sense intermediate between particles and higher branes. These come from ordinary particles or fully wrapped branes in the 10 or 11-dimensional description of the physics, but ones for which the mass and effective size as measured along the Poincare slices vary over the compactification in such a way that the energy grows as some positive power of the thickness $\delta x_{\|}$. We will refer to such objects as elastic states. By size of the object we will mean its thickness or the size of the short-distance cutoff scale, measured with respect to the $x_{\|}$ coordinates, as probed in appropriate scattering experiments. As we will discuss, in some regimes this is greater than or equal to the Compton wavelength of our excitations so that in these cases this is a classically intuitive accounting of the size scale.

In a general warped geometry of the form (1.1), the size R of an object as measured in the $x_{\|}$ coordinates ($R \equiv \delta x_{\|}$) depends on its characteristic proper size $r_0(y)$ and on the warp factor $a(y)$, via the relation

$$R = \frac{1}{\sqrt{a(y)}} r_0(y). \tag{1.2}$$

The energy of an object depends on $a(y)$ and the metric $H_{ij}(y)$ of the internal space (as well as the profiles of any additional fields with nontrivial VEVs in a given background). As we move the object around K to different values of y_i, its effective size changes and its energy changes. For ordinary point-particle quantum field theory the energy is inversely related to the size at high energies. [In anti-de Sitter (AdS) realizations of quantum field theory one sees membrane-shaped objects when a particle falls toward the horizon in AdS,[3–5] with their energy decreasing as their size increases as opposed to the cases we will focus on here.] We will see in our examples that the size instead grows as some positive power of the energy for certain massive states in warped compactifications. This variation in the size of the object results from a combination of its intrinsic thickness in $11d$ M theory and the warping of the metric involved in measuring its size in the $x_\parallel$ coordinates.

The phenomenon of growth of the size of states with energy is generic at high energies due to the presence of black holes, and is seen in other contexts in many corners of M theory (see Ref. 6 for a recent example and references to earlier ones). One result of our analysis is that warped compactifications provide another place where this intriguing effect emerges. Our analysis uses the basic relations arising from the gravitational redshift in geometries of the form (1.1) that also comes into the UV/IR correspondence developed for AdS space in studying the AdS/CFT correspondence;[7] our work involves in some ways a generalization of those studies to other warped geometries where there is no (evident) field theory dual, but where the energy/size relation can be studied directly in the gravity theory. The wrapped branes we study are in some sense generalizations of the baryon states studied in backgrounds with quantum field theory duals.[8]

Although the elastic states have a growth in size with energy reminiscent of branes, their spectrum and interactions at long distances can be calculated via ordinary Kaluza–Klein reduction in the warped geometry (1.1). This spectrum of states, while growing in number faster with energy than for ordinary unwarped Kaluza–Klein states on a circle, exhibits fewer degrees of freedom than a real brane. In this sense our elastic states are intermediate between particles and branes (and perhaps analogous to elastic solids, hence our nomenclature). However, if we consider the set of potential bound states of any number N of elastic states, we obtain a spectrum with enough degrees of freedom to describe modes of a continuous medium, and we discuss at the end a speculation for using these ideas to construct and quantize real branes using warped compactifications.

Direct couplings of objects of different size in this type of system are suppressed due to their separation in the internal dimensions, much like in similar systems studied in the context of the AdS/CFT correspondence. The size of these objects, however, does manifest itself in the cross sections for scattering processes mediated by electromagnetism and gravity.

One limitation of this approach is that these objects in the regime we study here are heavier than certain Kaluza–Klein (KK) modes of massless 11-D supergravity fields. So in the d-dimensional description, we see one or more extra dimensions before we see the elastic states. As we will see, the elastic states can be made very nearly stable in this same limit, and therefore at least do not decay into the lighter KK modes. (In some circumstances it may transpire that there is an AdS/CFT-like duality between a d-dimensional QFT and the supergravity modes, coupled to the rest of the system including the elastic states. Then the elastic states could be studied consistently in a completely d-dimensional description of the system.)

Another limitation is in our ability to calculate detailed physical quantities at the length scale corresponding to the size of the objects here. In the Horava–Witten (HW) example, the size is determined by the intrinsic thickness of the M2-brane, whose proper size is of order l_{11}. We can ameliorate this problem by considering the classical physics of a large-N collection of such objects, as we discuss in Secs. II and III. To discuss the quantum behavior of systems of this sort,

it might be useful to find an example in which the basic object is a (possibly wrapped) fundamental string, in a perturbative regime.

The article is organized as follows. In Sec. II we will introduce the Horava–Witten example and compute the energy/size relations that arise there (explaining in particular how the size is defined and determined). We will work out the scale of masses and sizes arising from Kaluza–Klein reduction. In Sec. III we work out (in less detail) the same procedure for type I′ theory. In Sec. IV we will provide a preliminary discussion of several interesting aspects and applications of these results. In Sec. IV A we will comment on the similarities and differences with branes, and discuss a possibility for an exponentially growing spectrum of bound states. In Sec. IV B we discuss scattering amplitudes and loop effects in these models. In Sec. IV C we conclude with a discussion of other issues and future directions.

II. HORAVA–WITTEN EXAMPLE

A. Mass-size relation in HW theory

M theory compactified on $S^1/\mathbb{Z}_2\times K3$ has a warped metric[1]

$$ds^2=y^{-1/3}dx_\parallel^2+y^{2/3}\left(dK^2+\frac{V_0^2}{l_{11}^6}dy^2\right), \tag{2.1}$$

where l_{11} is the 11-dimensional Planck length, and $y=c+2\sqrt{2}w$ with

$$w=\frac{\pi\rho_0-x^{11}}{V_0}6\pi\sqrt{2}l_{11}^3(k-12), \tag{2.2}$$

where x^{11} is a coordinate along the $S^1/\mathbb{Z}_2$ direction and k is the number of five-branes at the $x^{11}=0$ end of the interval. In these formulas, $\pi\rho_0$ is the size of the $S^1/\mathbb{Z}_2$ as measured with the coordinate x^{11} and V_0 is the volume of the K3 as measured in the K3 metric dK^2. These along with c are three of the moduli of the solution (the others being the other moduli of the K3 metric dK^2). The result (2.2) is valid in the regime $V_0\gg l_{11}^4$ and $\rho_0\gg V_0^{1/4}$.

Consider an M2-brane held at a point y in the interval, and wrapped on a cycle of the K3 with area $A(y)=A_0y^{2/3}$. Because the interval is very large ($\rho_0\gg l_{11}$), the 11-dimensional three-form gauge potential C_{MNP} has a Kaluza–Klein excitation with a tunably small mass. This means that our wrapped M2-brane can be made stable to a good approximation by taking the interval large enough.

Its energy, taking into account the warping, is

$$E=\sqrt{g_{00}}\,m_0=y^{-1/6}\left(y^{2/3}\frac{A_0}{l_{11}^3}\right)=y^{1/2}\frac{A_0}{l_{11}^3}, \tag{2.3}$$

where $m_0=y^{2/3}A_0/l_{11}^3$ is the proper energy of the wrapped M2-brane.

The extent of this wrapped brane along the $x_\parallel$ directions is, on the other hand, given by (1.2),

$$R=\frac{1}{\sqrt{a(y)}}r_0(y), \tag{2.4}$$

in terms of a characteristic proper size r_0. We will presently argue that this characteristic size is in fact l_{11}. Taking this value, we obtain from (2.4)

$$R=l_{11}y^{1/6}. \tag{2.5}$$

Combining (2.3) and (2.5), we obtain an energy-size relation

$$E=TR^3, \tag{2.6}$$

where the effective tension T is

$$T=\frac{A_0}{l_{11}^6}. \tag{2.7}$$

It is tempting to infer a mass scale for excitations from this relation of the order $\tilde{\mu}\sim T^{1/4}$. However, the scale of the tension is *a priori* not the only one in this problem; the kinetic energy of the elastic state will in general depend on further parameters. Therefore we will have to wait for the KK analysis of Sec. II B to obtain a determination of the scale of excitations of this system.

Now let us fix r_0 for this example. We can do so in two different regimes that will be of interest. First, consider the case where $A(y)\gg l_{11}^2$ for all y relevant to a given process. In this regime the supergravity solution for a wrapped membrane has a profile of characteristic size l_{11},[9] plus small corrections down by powers of l_{11}^2/A. At the scale l_{11}, the supergravity/general relativity approximation breaks down and we expect new structure at this scale. We therefore expect this scale to be seen by appropriate $11d$ supergravity modes in scattering processes, and we take it as a natural choice of the intrinsic proper thickness r_0 of the object.

Let us also consider the case of a regime of the K3 moduli space where dk^2 describes a K3 near an ALE singularity, so that there are two-cycles in the K3 with area $A_0\ll l_{11}^2$, and moreover consider a range of y for which $A(y)\ll l_{11}^2$. [We still take $V_0\gg l_{11}^4$ to be able to continue to use the results (2.1) and (2.2).] Strictly speaking the supergravity analysis[1] does not apply if there are sub-Planckian defects in the manifold, but the warping is caused by excess five-branes on one side of the interval scaling up the volume of the K3, which will presumably still happen in a regime where the K3 has localized ALE singularities. The analogous question has been studied in the Calabi–Yau threefold case in Ref. 10.) The UV cutoff of the gauge theory obtained near an ALE singularity (where the wrapped M2-branes emerge as Higgsed gauge bosons of an ADE gauge theory) is $1/l_{11}$. Therefore l_{11} is the short-distance cutoff of the theory, plus possibly small corrections going like powers of A/l_{11}^2. This is also the scale of the gauge coupling of the nonrenormalizable gauge theory obtained at the ALE singularity. The Coulomb forces between the Higgsed gauge bosons will go like $1/r^4$ for separations r much greater than the cutoff l_{11}. The form factor for scattering of these states will then have a characteristic size of order l_{11}. So in this case also, we will take l_{11} as the proper size r_0 of our M2-brane states.

Finally, for a collection of N M2-branes, we will take r_0 to be $l_{11}N^{1/6}$, which is the characteristic scale appearing in the supergravity solution. In Sec. II C we will study these regimes in more detail given the behavior of the KK wavefunctions we determine in the next subsection.

B. HW Kaluza–Klein analysis

We will now compute the spectrum of Kaluza–Klein modes of the wrapped M2-branes in the geometry (2.1). Let us consider for simplicity here the case of an M2-brane wrapped on a genus zero cycle of K3. For these the normal bundle is the line bundle $\mathcal{O}(-2)$ (which has no sections), so the M2-brane cannot move on the K3 without cost in energy. Here we will focus on the motion of the wrapped branes in the y direction, which dominates over the motion in the K3 in appropriate regimes of moduli. Let us for simplicity also consider the scalar components of the wrapped M2-branes.

In order to calculate the spectrum of excitations of these wrapped M2-branes, we can use a Kaluza–Klein reduction of the action

$$S_{\mathrm{HW}}=\int d^6x_{\|}dy\sqrt{G}[-G^{MN}\partial_M\phi\partial_N\phi-m_0^2(y)\phi^2]. \tag{2.8}$$

Here the indices M, N run over the seven dimensions of the warped interval, and G_{MN} is given by the corresponding components of (2.1), so that $G_{\mu\nu}=\eta_{\mu\nu}y^{-1/3}$ and $G_{yy}=y^{2/3}V_0^2/l_{11}^6$. There no explicit dependence in the action on the y-dependent K3 volume $V(y)=V_0y^{4/3}$ since the curve is isolated; there is dependence on the cycle area $A(y)=A_0y^{2/3}$ through the mass term in (2.8).

The modes are given by solutions of the equation of motion

$$\partial_M(\sqrt{G}G^{MN}\partial_N\phi)=\sqrt{G}m_0^2(y)\phi. \tag{2.9}$$

This becomes, upon plugging in our background,

$$y^{-1/3}\partial_{x_\parallel}^2\phi+\frac{l_{11}^6}{V_0^2}\partial_y(y^{-4/3}\partial_y\phi)=y^{2/3}\frac{A_0^2}{l_{11}^6}\phi. \tag{2.10}$$

Letting $\phi=e^{ik_\parallel x_\parallel}\tilde{\phi}$ we have that $\partial_{x_\parallel}^2\phi=-k_\parallel^2\phi=\mu^2\phi$, where μ is the mass of the excitation in six dimensions.

Defining $\eta=y^{-2/3}\phi$, this becomes

$$\eta''-\left[\frac{10}{9y^2}+ay^2-by\right]\eta=0, \tag{2.11}$$

where

$$a=\frac{A_0^2V_0^2}{l_{11}^{12}},\quad b=\frac{\mu^2V_0^2}{l_{11}^6}. \tag{2.12}$$

This is related to a nonrelativistic quantum mechanics problem with effective potential

$$V(z)=ay^2-by+\frac{10}{9y^2}. \tag{2.13}$$

We are interested in the discrete set of values of μ^2 [which comes into the parameter b (2.12)] for which this quantum mechanics problem has a state with zero energy eigenvalue.

For simplicity let us work in a regime where the last term in (2.13) can be dropped. The problem then reduces to a harmonic oscillator potential. We will be interested in determining the mass scale μ and the locations y_c where the solutions η are peaked. We will then check for self-consistency of this approximation.

In this regime, (2.11) can be rewritten

$$-\eta''+a\left(y-\frac{b}{2a}\right)^2\eta=\frac{b^2}{4a}\eta. \tag{2.14}$$

The energy eigenvalues in the corresponding harmonic oscillator problem are given by

$$E_n=\frac{b_n^2}{4a}=\sqrt{a}\left(n+\frac{1}{2}\right). \tag{2.15}$$

Using this and (2.12) we find a tower of masses

$$\mu_n^2=\frac{2A_0^{3/2}}{V_0^{1/2}l_{11}^3}\sqrt{\left(n+\frac{1}{2}\right)}=\frac{1}{\lambda_C^2}, \tag{2.16}$$

where we have indicated the Compton wavelength determined by this mass scale in the last step.

The nontrivial locations of the peaks of the wavefunction are at the length scale

$$y_n=\frac{b}{a}=\frac{2l_{11}^3\sqrt{n+\frac{1}{2}}}{A_0^{1/2}V_0^{1/2}}. \tag{2.17}$$

The values (2.17) are consistent with our assumption that the $1/y^2$ term in (2.13) could be ignored relative to the linear and quadratic terms for large enough μ^2.

From (2.17) and (2.5), we can determine the effective size of these excitations:

$$R_n \approx y_n^{1/6} l_{11} = \mu_n^{1/3} \frac{l_{11}^2}{A_0^{1/3}}. \tag{2.18}$$

They satisfy a mass-size relation

$$\mu_n \sim T R_n^3 \tag{2.19}$$

with a tension T agreeing with that found in our analysis in Sec. II A.

Since these excitations have a nontrivial size R_n, the point-particle Kaluza–Klein analysis we have done breaks down at this scale, which is to say that the mode solutions of (2.9) apply only for momentum $k_\parallel$ along the Poincare slices which is smaller than the scale $1/R_n$.

Note that these states grow (in number) faster than, for example, Kaluza–Klein modes on a circle. Of course the states of a single elastic state grow much more slowly than those of, say, a perturbative string. In Sec. IV A we will discuss briefly possible bound states of these objects, whose density of states does appear to grow exponentially with some power of the energy.

C. Size scales and regimes of moduli

In order for (2.2) to be reliable, we need $V_0 \gg l_{11}^4$. We can then consider different regimes of area $A(y)$ and M2-brane number N. Our arguments at the beginning of this section fixing $r_0 = l_{11}$ involved assuming $A(y)$ to be either very large or very small relative to l_{11}^2 for the range of y's of interest. Let us check here that that can be arranged for our KK excitations (2.16) and (2.17). At the typical y-values y_n, we have

$$A(y_n) = \frac{2 A_0^{2/3} l_{11}^2 \left(n + \frac{1}{2}\right)^{1/3}}{V_0^{1/3}}. \tag{2.20}$$

Suppose we wish to arrange for $A(y) \gg l_{11}^2$. From (2.20) this requires

$$A_0^{2/3} (n + \tfrac{1}{2})^{1/3} \gg V_0^{1/3}. \tag{2.21}$$

In this regime, the membrane is wrapped on a very large two-cycle, and is therefore heavy and behaves classically. Indeed, the condition (2.21) is the same as the condition that the Compton wavelength be much smaller than the object: $\lambda_C \ll R_n$. When (2.21) is satisfied for all n, the K3 is rather skew in shape, since in particular $(A_0/l_{11}^2) \gg (V_0/l_{11}^4)^{1/2}$. In this regime the elastic states behave classically.

On the other hand, suppose we wish to consider the case where $A(y) \ll l_{11}^2$. Then we need

$$A_0^{2/3} (n + \tfrac{1}{2})^{1/3} \ll V_0^{1/3}. \tag{2.22}$$

For this regime, the Compton wavelength is large compared to the size scale R_n, and the objects behave very quantum mechanically. When the K3 is near an ALE singularity, we argued at the beginning of this section that the cutoff scale and gauge coupling scale l_{11} determines the size of the object in this regime as well.

In both regimes we have studied here, for a small number N of branes the size R we have been discussing is determined by the warping from a fundamental proper size $r_0 = l_{11}$. Although we expect structure at this scale as discussed above, this being the scale of the profile of the supergravity solutions for M-branes for example, we do not have direct control over the details of processes at this scale. [Perhaps a more tractable generalization would be a case involving a (possibly wrapped) perturbative string. In such a case one could calculate reliably scattering

processes at the relevant size scale (l_s).] To study the elastic states' physics in a classical regime where we do have control, we can introduce a large number N of wrapped M2-branes. Then as discussed above, $r_0 \sim N^{1/6} l_{11}$. As in studies of black hole systems (Ref. 11, etc.) the branes then become amenable to a classical analysis in certain regions of the solution.[12]

Of course in adding branes to increase N, we increase both the mass and the size of the object as a function of N. Our point here is that in addition to that well-known effect, at fixed N there is the effect we have identified here: the stretching of the object along $x_\parallel$ due to the warping as one increases its energy. Considering a fixed large N allows us to study the classical physics of the elastic state effect in a regime where the physics at the scale of the object is under control.

We have thus obtained a consistent description of the wrapped M2-branes in the HW geometry which shows that they grow in size as a function of their energy. In this sense they behave like extended objects. We will begin a study in Sec. IV of the question of the extent to which these objects and their bound states might behave as familiar extended objects such as branes.

III. THE TYPE I′ CASE

In this section we will do a similar analysis of NS5-branes in the type I′ geometry derived in Ref. 2. We will work this case out a little more schematically than the last one, since the procedure is hopefully clear, but it is worth exhibiting a second example of the basic effect under consideration.

By some rescalings of the moduli and coordinates defined in Ref. 2 we can write the string-frame metric and dilaton schematically in the form

$$ds^2_{\text{string}} = \frac{\gamma^{5/3}}{(\beta + w)^{1/3}} (dx_\parallel^2 + l_s^2 dw^2), \tag{3.1}$$

$$e^{\phi} = \frac{1}{[\gamma(\beta + w)]^{5/6}}, \tag{3.2}$$

where β and γ are some combinations of the dilaton and radial modulus of the type I′ theory. Here $x_\parallel$ denotes the coordinates along the $9d$ Poincare slices in this geometry.

Let us compactify five of the spatial $x_\parallel$ dimensions on a T^5. For simplicity let us take the simple square shape

$$x_\parallel^{5,\ldots,9} \cong x_\parallel^{5,\ldots,9} + R_0. \tag{3.3}$$

The thickness of N NS5-branes in the remaining $x_\parallel$ directions can be determined in a large N limit from the supergravity solution. This gives[13]

$$r_0 \sim l_s N^{1/2}. \tag{3.4}$$

We can determine the energy-size relation from the warped metric and dilaton as follows. Let us work in terms of a coordinate $y \equiv w + \beta$. Taking into account the variation of the volume of the T^5 and the variation of the dilaton as a function of y, the energy is

$$E = \sqrt{g_{00}} m_0 = \frac{R_0^5}{l_s^6} \gamma^{20/3} y^{2/3}. \tag{3.5}$$

The size is

$$R = \frac{y^{1/6}}{\gamma^{5/6}} l_s N^{1/2}. \tag{3.6}$$

Putting these together leads to a growth in size with energy:

$$E = TR^4, \tag{3.7}$$

with effective tension

$$T = \frac{R_0^5 \gamma^{10}}{l_s^{10} N^2}. \tag{3.8}$$

The Kaluza–Klein analysis in this case can be done similarly to that for the Horava–Witten case.

IV. DISCUSSION: BOUND STATES, SCATTERING, AND OTHER ISSUES

A. Remarks on bound states and branes

Though our elastic states have a growth in size with energy somewhat reminiscent of branes, they each individually only have a Kaluza–Klein theory's worth of states. However, bound states of elastic states might exist (establishing or ruling out this possibility would require a careful analysis such as was done for D0-branes[14]). If so, these could have a much faster (exponential) growth in number with energy.

In the HW case, the wrapped M2-branes experience gravitational attraction and gauge (C_{MNP}) repulsion. Because the $S^1/\mathbb{Z}_2$ direction is compact, the relevant modes of C_{MNP} are slightly massive, as discussed in Sec. II. Therefore at very long distances the different elastic states attract each other. This suggests bound states might be possible, though an analysis of the short-distance structure is required to establish (or rule out) this possibility.

Consider a bound collection of bound states of N_n elastic states at level n in the spectrum (2.16) derived in Sec. II. An upper bound on the energy of such a state (in that it does not take into account the binding energy) is

$$\mu_{\rm tot} \sim \sum_n N_n \mu_n = \sum_n N_n \left(n + \frac{1}{2} \right)^{1/4} \frac{\sqrt{2} A_0^{3/4}}{V_0^{1/4} l_{11}^{3/2}}. \tag{4.1}$$

This spectrum grows exponentially.

If bound states do exist here, it is tempting to speculate that a large number of elastic states could mock up an effective brane (perhaps in a somewhat analogous way to the way D0-branes mock up higher branes in matrix theory[15]). It is further tempting to speculate that this approach can then provide a new way to quantize effective branes and study their interactions in some nontrivial regime.

B. Remarks on scattering amplitudes

Given the growth in size with energy of the objects we have been studying, it is interesting to consider where this effect would arise in scattering amplitudes. Contact interactions between large and small elastic states (which are particles at different points y_1, y_2 in the interval) are suppressed by the separation between y_1 and y_2. As in the case of objects going by each other in the AdS bulk,[16] in the d-dimensional description our objects appear to pass right through each other. (One possibility is that the large objects form a ring instead of a filled-in ball in the $x_\parallel$ dimensions as in some states in AdS.[3,5])

However if we consider the electromagnetic and gravitational interactions of our objects, their size is evident at tree level. In particular, the thickness of the object leads to a form factor with characteristic scale R in gauge and gravity-mediated scattering processes.

It will be interesting to study the effects of elastic states and bound states of elastic states in loops. For example, it will be interesting to calculate the contribution these objects and their bound states make to the vacuum energy. For this we need to know the spectrum of bound states as well

as a controlled prescription for describing their interactions. It may be very useful to consider an analogous case where the elastic states originate as strings (with a warping which amplifies their l_s-scale size).

C. Discussion

There are many issues to explore further with these states (and their many cousins in other warped compactifications). Generalizations which could be important for a potential brane picture include cases where the wrapped branes oscillate in more than one direction of a warped compactification. As discussed above, a case which would give more tractable calculations would be one in which the basic object is a perturbative string whose mass and size get warped by the compactification so as to give an energy-size relation of the kind we have studied here.

One question involves the relevance of AdS/CFT ideas and results to more generic warped compactifications. In some ways the elastic states we have discussed here are a generalization of the baryon states identified in AdS/CFT duals and their generalizations.[8] The growth in size of states with energy is characteristic of gravity in various high-energy regimes, but can also occur for some collective excitations in ordinary quantum field theory (and exponential growth of the density of states can also occur there in certain regimes[17]). It would be interesting to classify the behavior of states at high energy in QFT versus gravity in this regard, and in particular to understand if the class of states studied here is characteristic of gravity or could occur in a theory with a completely quantum field-theoretic dual.

Another interesting application of warped geometries is potentially to cosmology (obtained in appropriate cases by viewing the direction along which the warping appears as time t). In such a situation, the wrapped branes can become zero-action instantons at a singularity occuring at $t=0$ in the cosmology. It would be interesting to understand whether the corresponding instanton sum accounts for (and is related to a resolution of) the initial singularity in this sort of setup.

Particularly in the context of gravity, the effects of nonlocality are potentially important for many problems (see, e.g., Ref. 18 for a recent application). It would be interesting to understand what role, if any, these extended states play in the nonlocality of gravity in warped compactifications.

ACKNOWLEDGMENTS

I would like to thank A. Adams, O. Aharony, N. Arkani-Hamed, T. Banks, M. Berkooz, S. Kachru, A. Lawrence, J. Maldacena, M. Peskin, S. Shenker, and A. Strominger for useful discussions. (Received 2 January 2001; accepted for publication 13 February 2001)

We study the topology change in M theory compactifications on Calabi–Yau threefolds in the presence of G flux (the four form field strength). In particular, we discuss vacuum solutions in strongly coupled heterotic string theory in which the topology change is *inevitable* within a single space–time background. For rather generic choices of initial conditions, the field equations drive the Kähler moduli outside the classical moduli space of a Calabi–Yau manifold. Consistency of the solution suggests that degenerate flop curves—just as wrapped M theory fivebranes—carry magnetic charges under the four form field strength. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1377038]

I. INTRODUCTION

Over the years, several works[1,2] have established definitively that there are physically smooth processes in string theory which result in a change in the topology of space–time. In these studies, as well as studies of topology change in M theory,[3] one considers a one parameter family of vacuum solutions—a one parameter family of space–times—that passes from one Calabi–Yau manifold to another which is topologically distinct. The referenced works succeeded in showing that there is no obstruction to such a topology change, but no dynamics was ascribed to motion through the family. In the present work, we study a variation on this theme of topology change in which dynamics does drive the evolution from one topology to another. Specifically, (a) the topology change occurs within a single (not a family of) space–time background and (b) for generic choices of initial conditions, the dynamics (i.e., the field equations) drive us through a topology change.

To be concrete, we focus our studies on Calabi–Yau compactifications of M theory to five dimensions in the presence of G flux (the four form field strength). As discussed in Refs. 4–7, the effective five-dimensional theory does not admit a flat space vacuum solution. Rather, the space–time metric is warped and the solution is of the domain wall type with one of the five dimensions singled out as the transverse direction. In addition to the effective five-dimensional space–time metric, the moduli of the Calabi–Yau will generically vary along the transverse direction. In this paper, we show that there exist Calabi–Yau compactifications in which the field equations force the Kähler moduli to pass from one Kähler cone into an adjacent cone, while the overall volume of the Calabi–Yau manifold remains large. This implies that the Calabi–Yau manifold undergoes

a flop transition and continues on to a topologically distinct Calabi–Yau manifold as we move along the transverse dimension.

One may think of our work as being complementary to that of Refs. 8–10 in which it was shown that in the presence of certain dyonic black holes, a Calabi–Yau with particular moduli at spatial infinity can be driven by the attractor equations through a flop transition on the way to the black hole's horizon. Here we find vacuum solutions whose structure requires topology change.

One feature of these topology changing solutions is that flop curves appear to be magnetic sources for the G flux. This becomes apparent from the Bianchi identity for the four-form G in the context of strongly coupled heterotic string theory (which we shall henceforth refer to as Horava–Witten theory), i.e., M theory on $S_1/\mathbb{Z}_2$. In this set-up, the orbifold planes provide magnetic sources for the four form G and this requires a modification of the Bianchi identity by a topological source term.[11] As we will see, consistency of the topology changing solutions suggests that the zero-size flop curve provides an additional magnetic source for G.

While we will not pursue it in this paper, the results of the present work may have implications for the ''brane world'' scenario.[11,5,12–15,13] Strongly coupled heterotic string theory is a rich context for the brane-world scenario in which fairly realistic low energy models can be constructed.[5] The class of models of interest, however, is substantially enlarged, as we allow the topology, and not just the metric, of the Calabi–Yau to change from one end of the world to another.

This paper is organized as follows. In Sec. II, we summarize the essential results of M theory and Horava–Witten theory compactified on Calabi–Yau three-folds in the presence of G flux. In Sec. III, we give an explicit example in which the solution to the field equations inevitably drives us through a flop transition. In Sec. IV, we discuss general features of topology changing solutions in Horava–Witten theory, and examine properties of G flux and the Bianchi identity in such geometric backgrounds. We end with some discussion in Sec. V.

After the presentation of these results by one of us,[16] M. Wijnholt and S. Zhukov notified us that they had also observed that the Bianchi identity requires modification in the presence of a flop transition.

II. KALUZA–KLEIN REDUCTION OF M THEORY ON A CALABI–YAU THREE-FOLD

Let us briefly summarize the results of the Kaluza–Klein reduction of eleven dimensional supergravity on a manifold with boundaries, that is, strongly coupled heterotic theory on a Calabi–Yau three-fold $\mathcal{M}$. (Many details can be found in the papers,[5,6,17,18] we differ in approach by using a first order formalism for the field strengths; see also Ref. 19. The appropriate Bianchi identities are imposed as an additional field equation.) We concentrate here only on the fields which are relevant to our subsequent discussion. Since we seek solutions with a nontrivial variation of the Kähler moduli, we keep the hypermultiplet scalar V (the Calabi–Yau breathing mode) which couples to the bulk potential terms, the vector multiplet scalars b^i (the Kähler moduli) as well as the axionic field strengths a_i and their dual potentials $\tilde{\lambda}^i$. The 5-dimensional action can be consistently truncated to this reduced field content leading to[5]

$$S_5 = -\frac{L^6}{2l^9}\Bigg[\int_{M_5}\sqrt{-g}\Big(R + G_{ij}(b)\partial_M b^i\,\partial^M b^j + \frac{1}{2}V^{-2}\,\partial_M V\,\partial^M V + \lambda(\mathcal{K}-1)\Big) + \frac{1}{4}V^{-2}G^{ij}(b)a_i\wedge\star a_j + d\tilde{\lambda}^i\wedge a_i\Bigg] - \sum_{n=0}^{N+1}\alpha_i^{(n)}\int_{M_4^{(n)}}\Big(\tilde{\lambda}^i + \frac{b^i}{V}\sqrt{f^*g}\Big). \tag{1}$$

Here λ is a Lagrange multiplier, the a_i arise from the Kaluza–Klein reduction of G with respect to a basis of $H^4(\mathcal{M})$, G_{ij} is the metric on the Kähler moduli space (not the 5-dimensional metric which is denoted by g_{MN}; f^*g is its pullback to the three-brane world-volume) and $\mathcal{K}$ its prepotential;

$$G_{ij}=-\frac{1}{2}\frac{\partial^2}{\partial b_i\,\partial b_j}\ln\mathcal{K},\quad \mathcal{K}\equiv\frac{1}{3!}d_{ijk}b^ib^jb^k, \tag{2}$$

where d_{ijk} are the intersection numbers of the (1,1) forms on $\mathcal{M}$. The gravitational coupling l is that of the original eleven-dimensional theory, and L the length scale of the Calabi–Yau.

The boundary terms include the relevant contributions from N five-branes at *a priori* arbitrary locations, with charges $\alpha_i^{(1)},\ldots,\alpha_i^{(N)}$. In units of the five-brane tension/charge these correspond to the multiplicity or equivalently the winding number of five-branes around the various two-cycles. The first order action includes the Bianchi identity, modified in the presence of five-branes, as the field equation for the dual potential $\tilde{\lambda}^i$,

$$da_i\equiv J_i^{(5)}\Rightarrow\begin{cases}\partial_{11}a_i=\dfrac{2l^9}{L^6}\displaystyle\sum_{k=0}^{N+1}\alpha_i^{(k)}\delta(x^{11}-x_k^{11}),\\ \partial_\mu a_i=0,\end{cases} \tag{3}$$

with the solution[5,6]

$$a_i=\frac{2l^9}{L^6}\left(\sum_k\alpha_i^{(k)}\epsilon(x^{11}-x_k^{11})+c_i\right). \tag{4}$$

The constants $\alpha_i^{(0)}$, $\alpha_i^{(N+1)}$ are the effective M5-brane charges carried by the end-of-the-universe 9-plane domain-walls. On each end-of-the-universe plane, the effective five-brane charge has two constituents, similar to the effective Dp',$(p'<p)$ charge carried by Dp-branes in non-trivial backgrounds. One constituent is the E_8 instanton number, which may be interpreted as M5-branes immersed in the 9-brane;[4,20] the second is the induced five-brane charge due to the nonvanishing curvature of the Calabi–Yau and proportional to $c_2(\mathcal{M})$,[4,5]

$$\alpha_i^{(k)}=\frac{T_5L^2}{8\pi^2}\int_{D_i}\left(\operatorname{tr}F^{(k)}\wedge F^{(k)}-\frac{1}{2}\operatorname{tr}R\wedge R\right),\quad k=0,N+1. \tag{5}$$

Here D_i is a 4-cycle of the Calabi–Yau, and the elementary five-brane charge T_5 equals

$$T_5=\frac{2\pi}{(4\pi)^{2/3}l^6}. \tag{6}$$

In the remainder we set all scales to unity.

The total five-brane charge must vanish on the orbifold interval $S_1/\mathbb{Z}_2$;

$$\sum_{k=1}^{N}\alpha_i^{(k)}+\sum_{j=0,N+1}\int_{D_i}\operatorname{tr}F^{(j)}\wedge F^{(j)}=\int_{D_i}c_2. \tag{7}$$

This is the Kaluza–Klein reduction of the invariant eleven-dimensional statement that the modified Bianchi identity,[11]

$$\begin{aligned}dG=\Bigg(&\left[\operatorname{tr}F_{(1)}\wedge F_{(1)}-\frac{1}{2}\operatorname{tr}R\wedge R\right]\delta(y)\\&+\left[\operatorname{tr}F_{(2)}\wedge F_{(2)}-\frac{1}{2}\operatorname{tr}R\wedge R\right]\delta(y-\pi R_{11})+\sum_i n_5^i\delta_{C^i}\delta(y-y_i)\Bigg)\wedge dy,\end{aligned} \tag{8}$$

due to the presence of boundaries and five-branes is integrable, i.e.,

$$\int_{S_1/\mathbb{Z}_2\times D_i} dG = 0 \quad \forall \quad D_i \in H_4(\mathcal{M}). \tag{9}$$

In (8) $\{C^i\}$ is a basis of $H_2(\mathcal{M})$ dual to the basis $\{D_i\}$ of $H_4(\mathcal{M})$ and δ_{C^i} is the four-form Poincaré dual to the 2-cycle C^i with delta-function support on C^i. Preservation of supersymmetry allows only configurations of instantons and five-branes (or anti-instantons and anti-branes).

If one chooses the standard embedding of the spin connection in the first E_8 gauge group such that

$$\operatorname{tr} F^{(1)} \wedge F^{(1)} = \operatorname{tr} R \wedge R, \tag{10}$$

then $\alpha_i^{(1)} = -\alpha_i^{(2)}$, no additional five-branes are needed and the effective five-brane charge on the Horava–Witten-plane with an unbroken gauge group at $y = \pi R_{11}$ is just the topologically induced charge $\alpha_i^{(2)} = -\frac{1}{2}\int_{D_i} c_2$.

In this formulation the fields a_i appear algebraically and may be integrated out, yielding the 4-dimensional domain-wall action with electric 5-form field-strengths $\mathcal{F}^i = d\tilde{\lambda}^i$;

$$S_5 = -\int_{M_5} \sqrt{-g}\left(R + G_{ij}\partial_M b^i \partial^M b^j + \frac{1}{2} V^{-2} \partial_M V \partial^M V + \lambda(\mathcal{K}-1) \right)$$
$$- V^2 G_{ij}(b) \mathcal{F}^i \wedge * \mathcal{F}^j] - \sum_{n=0}^{N+1} \alpha_i^{(n)} \int_{M_4^{(n)}} \left(\tilde{\lambda}^i + \frac{b^i}{V}\sqrt{f^* g} \right). \tag{11}$$

The supersymmetric domain-wall or three-brane solution to the field equations is given by[5]

$$ds_5^2 = e^{2A} dx_4^2 + e^{8A} dy^2$$

$$V = e^{6A},$$

$$e^{3A} = \left(\frac{1}{3!} d_{ijk} f^i f^j f^k \right),$$

$$b^i = e^{-A} f^i,$$

$$\mathcal{F}^i_{11,\mu\nu\rho\sigma} = \epsilon_{\mu\nu\rho\sigma} e^{-10A}(-\partial_{11} b^i + 2 b^i \partial_{11} A), \tag{12}$$

where the f^i's are defined in terms of one-dimensional harmonic functions,

$$d_{ijk} f^j f^k = H_i, \quad H_i = \sum_n \alpha_i^{(n)} |y - y_n| + c_i \tag{13}$$

$$= \sum_{n=0}^{k} 2\alpha_i^{(n)} y + k_i, y_k < y < y_{k+1}, \tag{14}$$

and the k_i are arbitrary constants of integration.

The solution can be obtained from the supersymmetry variations by searching for a global Killing spinor,[5,18,19]

$$\delta\psi_\mu^A = \gamma_\mu \left((\partial A)\gamma_{11}\epsilon^A - \frac{e^{4A} b^i a_i}{6V} (\tau_3)_B^A \epsilon^B \right),$$

$$\delta\psi_{11}^A = \partial\epsilon^A - \frac{e^{4A} b^i a_i}{12} (\tau_3)_B^A \gamma_{11} \epsilon^B, \tag{15}$$

$$\delta\zeta^A=(\partial \ln V)\,\gamma_{11}\epsilon^A-\frac{e^{4A}b^i a_i}{V}(\tau_3)^A_B\epsilon^B,$$

$$\delta\lambda^{iA}=(\partial b^i)\,\gamma_{11}\epsilon^A+\frac{e^{4A}}{2V}\left(a^i-\frac{2}{3}b^j a_j b^i\right)(\tau_3)^A_B\epsilon^B. \tag{15}$$

The Killing spinor,

$$\epsilon^A=e^A(\delta^A_B+\gamma_{11}(\tau_3)^A_B)\epsilon^B_0, \tag{16}$$

is preserved, provided the following conditions are satisfied:

$$\begin{aligned}\partial A-\frac{e^{-2A}}{6}b^i a_i&=0,\\ \partial b^i+\frac{e^{-2A}}{2}\left(a^i-\frac{2}{3}(b\cdot a)b^i\right)&=0.\end{aligned} \tag{17}$$

These are direct analogs of the attractor equations describing spherically symmetric BPS black-holes in four- and five-dimensional supergravities with eight supercharges.[21–23] By contracting the second equation in (17) with $\partial b^j G_{ji}(b)$, the third term vanishes whereas the first term yields the length (in the moduli space) of the vector tangent to the path the solution follows. Defining a central charge $Z=b^i a_i$, and using the fact that the $a_i=\alpha_i^{(n)}\epsilon(y-y_n)$ are (piecewise) constant, the resulting equation exhibits the monotonic flow of Z,

$$\partial Z=-2e^{2A}\,\partial b^i\,G_{ij}\,\partial b^j\leqslant 0. \tag{18}$$

Alternatively one can define the dimensionful central charge $\tilde{Z}=u^i\alpha_i$ where $u^i=e^{-2A}b^i$. The attractor equation can be written in the form

$$\partial\tilde{Z}=-\tfrac{1}{2}\partial_i\tilde{Z}\,G^{ij}(u)\partial_j\tilde{Z}\leqslant 0, \tag{19}$$

which relates the flow in the target space with the flow in the moduli space. Here,

$$\partial_i\tilde{Z}=\frac{\partial\tilde{Z}}{\partial u^i}. \tag{20}$$

Notice that as in Ref. 5, we are holding the hypermultiplets (which control the complex structure) fixed, and we shall continue to do so throughout this paper. It would be interesting to relax this assumption as one would need to do to study, for example, conifold transitions.

III. AN EXAMPLE

An essential aspect of (12) is that the moduli of the Calabi–Yau manifold will generically vary along the transverse direction y. This raises the question of whether one can find solutions in which the Kähler moduli vary through a Kähler wall in the moduli space; i.e., the Calabi–Yau manifold undergoes a flop transition as we move along y.

Suppose we are able to find such a solution; this will have consequences for the analysis of the action and the field equations in the previous section. Specifically, notice that the equations (12) and (13) depend upon the second Chern numbers through $\alpha_i^{(0)}$ and $\alpha_i^{(N+1)}$, and the intersection numbers d_{ijk} of the Calabi–Yau. These numbers jump when a Calabi–Yau manifold undergoes a flop. Hence, to exhibit an example where topology change occurs, we must search for solutions that (a) pass through a wall of the Kähler moduli space and (b) are a solution to the field equations of the form (12) for values of the topological numbers d_{ijk} and c_2 appropriate to the Calabi–Yau

on *each* side of the wall. Furthermore, in order to trust the supergravity approximation in which we work, we must also ensure that the overall Calabi–Yau volume V stays large.

In this section, through an explicit example involving some fairly tedious algebra, we will show that such topology changing solutions can indeed be found. In this example we will choose the standard embedding for the gauge bundles as this will facilitate our discussion of the Bianchi identity and flop-curves as sources of G-flux, in the next section.

A simple example of a pair of Calabi–Yau manifolds connected by a flop transition are the well studied $(h^{1,1},h^{2,1})=(3,243)$ Calabi–Yau manifolds considered in Refs. 24–26, 8, 9, 21. To investigate whether a flop can occur dynamically, we will attempt to match the solutions to the field equations for each of the Calabi–Yau manifolds across the singular point. We will find that, though the values of the fields can be matched continuously, their first derivatives are discontinuous at the flop. The jumps in the first derivatives of the Kähler moduli imply that there is an additional source of magnetic under the G-flux charge where the solutions are matched together (the flop point), and the Kähler moduli are sensitive to this magnetic source. In the next section, we will discuss the generality of this class of solutions.

Before we proceed, let us collect the essential data of the Calabi–Yau and its flopped cousin.[25] Details can be found in the aforementioned papers. In these works the manifold we denote with $\mathcal{M}$ is known as model III and $\tilde{\mathcal{M}}$ as model II. Both are elliptic fibrations over Hirzebruch surfaces.

(i) *Calabi–Yau manifold* $\mathcal{M}$. The intersection numbers are summarized in the classical prepotential $\mathcal{K}_{\mathcal{M}}=(1/3!)\,d_{ijk}t^it^jt^k$. For $\mathcal{M}$ the prepotential equals

$$\mathcal{K}_{\mathcal{M}}=\frac{1}{3!}(8(t^1)^3+9(t^1)^2t^2+3t^1(t^2)^2+6(t^1)^2t^3+6t^1t^2t^3). \tag{21}$$

The t^i are the components of the Kähler form expanded in a natural basis (a basis in which the Kähler cone is defined by $t^i>0$) of 2-forms ω_i for $H^2(\mathcal{M},\mathbb{Z})$,

$$J=t^i\omega_i\,. \tag{22}$$

Integrating J over an arbitrary 2-cycle C^i shows that the corresponding t^i measures its size.

The moduli t^i are related to the dimensionless fields b^i defined in the previous section by $b^i=V^{-1/3}t^i$. Therefore, the dependence of t^i on the transverse direction y is governed by the one-dimensional harmonic functions $H_i(y)$. The slopes of these harmonic functions are in turn determined by the effective five-brane charges. For the end of the world branes with standard embedding, the slopes are proportional to the periods of the second Chern class; in terms of the divisors $D_i\epsilon H_4(\mathcal{M})$ dual to ω_i, they are

$$c_2(D_1)=92,\quad c_2(D_2)=36,\quad c_2(D_3)=24. \tag{23}$$

(ii) *Flopped Calabi–Yau manifold* $\tilde{\mathcal{M}}$. The intersection numbers of this Calabi–Yau may be determined from its cousin $\mathcal{M}$ with the help of the relation (see, e.g., Ref. 1)

$$(D_{i_1}\cap D_{i_2}\cap D_{i_3})_{\tilde{\mathcal{M}}}=(D_{i_1}\cap D_{i_2}\cap D_{i_3})_{\mathcal{M}}-\sum_{\beta}\prod_{k}(D_{i_k}\cap C^{\beta}). \tag{24}$$

The C^{β} represent the curves that are flopped and the D_i on $\tilde{\mathcal{M}}$ are the proper transforms of the D_i on $\mathcal{M}$. In the present case there is only one such curve, and its intersection with the D_i is $D_i\cap C=\delta_{i3}$. Hence, the only intersection number which changes is d_{333}. It is shifted by -1. Thus, if we choose the D_i and their proper transforms as bases on $\mathcal{M}$ and $\tilde{\mathcal{M}}$ we find that the prepotential of $\tilde{\mathcal{M}}$ is equal to

$$\mathcal{K}_{\tilde{\mathcal{M}}}=\mathcal{K}_{\mathcal{M}}-\frac{(t^3)^3}{6}. \tag{25}$$

The Chern coefficients $\tilde{c}_2(D_i)$ of the flopped Calabi–Yau $\tilde{\mathcal{M}}$ can be calculated from the Tian–Yau theorem in Eq. (60) or using the relation

$$\int_{D_i} c_2 + 2(D_i \cap D_i \cap D_i) = 12\chi(D_i), \tag{26}$$

and noting that the holomorphic Euler characteristic $\chi(D_i)$ is invariant under flops. Hence,

$$\tilde{c}_2(D_1) = 92, \quad \tilde{c}_2(D_2) = 36, \quad \tilde{c}_2(D_3) = 26. \tag{27}$$

(iii) *Solutions to the field equations*. To find the explicit dependence of the moduli $f^i = V^{-1/6} t^i$ on the transverse direction we need to invert the nonlinear relations for $\mathcal{M}$ and $\tilde{\mathcal{M}}$ between f^i and H_i. As mentioned, we consider the case of standard embedding, i.e., $\mathrm{tr}\, F \wedge F = \mathrm{tr}\, R \wedge R$ at $y = 0$ and $\mathrm{tr}\, F \wedge F = 0$ at $y = \pi R_{11}$. In that case the slopes α_i of the harmonic functions H_i are solely proportional to periods of the second Chern class:

$$\alpha_i = \frac{1}{16\pi^2} \int_{D_i} \mathrm{tr}\, R \wedge R = \frac{1}{2} \int_{CY} \omega_i \wedge c_2(CY). \tag{28}$$

First we choose a more convenient basis,[25,8]

$$\begin{aligned} t^1 &= U, \\ t^2 &= T - \tfrac{1}{2} U - W, \\ t^3 &= W - U. \end{aligned} \tag{29}$$

In this basis the respective Kähler cones of $\mathcal{M}$ and $\tilde{\mathcal{M}}$ are defined by the regions

$$\begin{aligned} \mathcal{M}&: W > U > 0, T > \tfrac{1}{2} U + W, \\ \tilde{\mathcal{M}}&: U > W > 0, T > \tfrac{3}{2} U \end{aligned} \tag{30}$$

and the area of the flop curve equals $W - U$.

The relation between the moduli and the harmonic functions can now be straightforwardly inverted.[9] For $\mathcal{M}$ one finds

$$\begin{aligned} T &= \frac{1}{2} \frac{H_T}{U}, \\ U &= \frac{1}{2} \sqrt{\left(H_U + \frac{1}{2} H_W \right)} \pm \sqrt{\left(H_U + \frac{1}{2} H_W \right)^2 + 2H_W^2 - 2H_T^2}, \\ W &= -\frac{1}{2} \frac{H_W}{U} + \frac{1}{2} U, \end{aligned} \tag{31}$$

with

$$\begin{aligned} H_T &= 18|y| + k_T, \\ H_U &= 25|y| + k_U, \\ H_W &= -6|y| + k_W, \end{aligned} \tag{32}$$

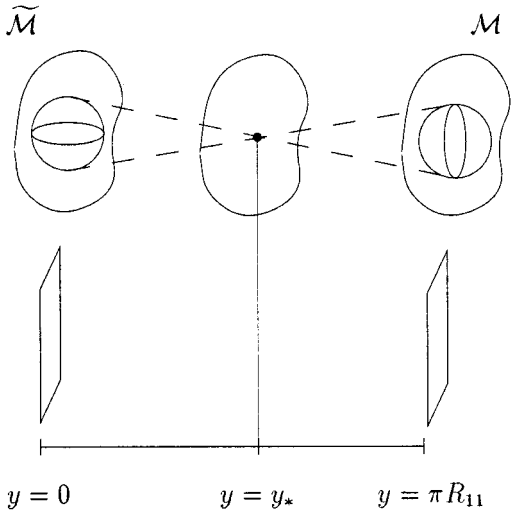

FIG. 1. Calabi–Yau configuration in heterotic M theory which undergoes a flop.

and for $\widetilde{\mathcal{M}}$,

$$T=\sqrt{\frac{1}{2}\tilde{H}_u\pm\frac{1}{2}\sqrt{\tilde{H}_u^2-\frac{9}{4}\tilde{H}_T^2}},$$

$$U=\frac{2}{3}\sqrt{\frac{1}{2}\tilde{H}_u\mp\frac{1}{2}\sqrt{\tilde{H}_u^2-\frac{9}{4}\tilde{H}_T^2}}, \tag{33}$$

$$W=\sqrt{-\tilde{H}_W},$$

with

$$\tilde{H}_T=18|y|+\tilde{k}_T,$$

$$\tilde{H}_U=24|y|+\tilde{k}_U, \tag{34}$$

$$\tilde{H}_W=-5|y|+\tilde{k}_W.$$

Requiring that we are in the correct Kähler cone for $\widetilde{\mathcal{M}}$ selects the positive and negative sign in the expressions for $T_{\tilde{\mathcal{M}}}$ and $U_{\tilde{\mathcal{M}}}$, respectively.

A. Matching the solutions

1. Location of the flop

If the field equations (whose behavior within the framework on each of the Calabi–Yau's we have already deduced) allow for a topology changing transition, it must be possible to match the solutions across the point where the flop-curve $t^3=W-U$ degenerates. As the relation between one of the moduli, W, of the Calabi–Yau $\widetilde{\mathcal{M}}$ and the harmonic functions is rather simple, we will first consider the flop solution from its point of view (see Fig. 1).

From the data in (33) and (34) we see that at the flop point the following quantity must vanish:[9]

$$9\tilde{H}_W^2+4\tilde{H}_U\tilde{H}_W+\tilde{H}_T^2=0. \tag{35}$$

Substituting the harmonic functions we find a quadratic equation for y. This equation has a solution if the discriminant is positive. The latter is a quadratic expression in the three integration constants $\tilde{k}_i$ and vanishes at the two roots:

$$25\tilde{k}_U=\left(45\pm\frac{5\sqrt{69}}{2}\right)\tilde{k}_T+(42\pm 9\sqrt{69})\tilde{k}_W. \tag{36}$$

A brief inspection shows that large $|\tilde{k}_U|$ corresponds to a positive discriminant and for a flop to occur we must therefore tune our integration constants such that

$$25\tilde{k}_U>\left(45\pm\frac{5\sqrt{69}}{2}\right)\tilde{k}_T+(42\pm 9\sqrt{69})\tilde{k}_W, \tag{37}$$

or

$$25\tilde{k}_U<\left(45\pm\frac{5\sqrt{69}}{2}\right)\tilde{k}_T+(42\pm 9\sqrt{69})\tilde{k}_W. \tag{38}$$

Regardless of the flop a necessary condition is that at the location of the brane at $y=0$, we are using the correct Calabi–Yau data. One condition, $2T>3U$, is guaranteed by the choice of solution in (33). The second one, $W>0$, is obeyed by requiring $\tilde{k}_W<0$. The last constraint, $W<U$, yields a lower bound on $\tilde{k}_U$ in terms of $\tilde{k}_T$ and $\tilde{k}_W$

$$\tilde{k}_U<-\frac{9\tilde{k}_W^2+\tilde{k}_T^2}{4\tilde{k}_W}. \tag{39}$$

Third, by requiring that (33) has solutions, we see that $\tilde{H}_U^2>9\tilde{H}_T^2/4$ or $2|\tilde{k}_U|>3|\tilde{k}_T|$. Fourth, in order that the solution to (35) truly corresponds to a point where $U=W$, the lower bound,

$$\tilde{k}_U>\frac{\tilde{k}_W}{2}, \tag{40}$$

must be satisfied. Finally, in order that all divisors also have positive area at $y=0$ one finds an additional constraint $\tilde{k}_T>0$.

The parameter space that obeys all these conditions consists of two regions, and it is quite generic that a flop occurs for some choice of intitial conditions. The two regions correspond to two possible flop scenarios: (a) both roots, y_+ and y_-, of (35) are larger than zero or (b) both roots are less than zero. *A priori*, there is the third possibility that $y_+>0>y_-$. However, this is not allowed because the quadratic (35) is convex and were we to find $y_+>0>y_-$, W would be larger than U at the location of the brane at $y=0$. Hence we would be in the wrong Kähler cone.

Given the explicit values of the roots,

$$y_\pm=\tfrac{1}{69}(10\tilde{k}_U-18\tilde{k}_T-3\tilde{k}_W\pm\sqrt{\mathcal{D}}),$$

$$\mathcal{D}=-612\tilde{k}_W^2-336\tilde{k}_U\tilde{k}_W+108\tilde{k}_T\tilde{k}_W+100\tilde{k}_U^2-360\tilde{k}_U\tilde{k}_T+255\tilde{k}_T^2, \tag{41}$$

the location of the minimum of (35) is

$$y_{\min}=\tfrac{1}{69}(10\tilde{k}_U-18\tilde{k}_T-3\tilde{k}_W). \tag{42}$$

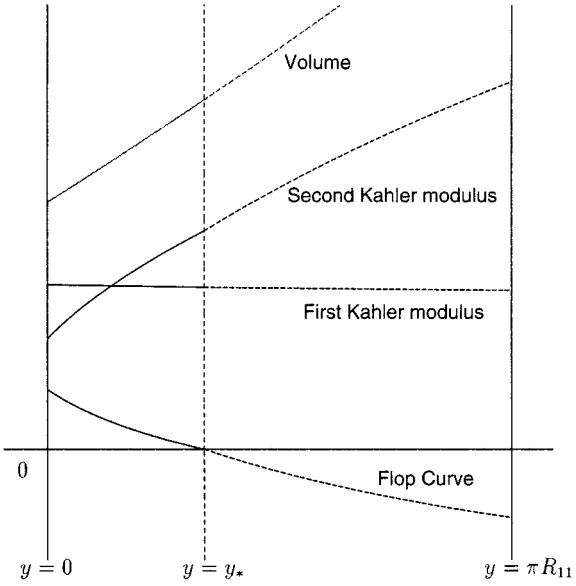

FIG. 2. Profile of the areas of the two cycles and the Calabi–Yau volume along y in a basis appropriate for Calabi–Yau $\tilde{\mathcal{M}}$. Solid lines belong to the validity region $y<y_*$ of the Calabi–Yau $\tilde{\mathcal{M}}$. Dashed lines belong to the Calabi–Yau $\mathcal{M}$ and hold for $y>y_*$.

We will consider the region of parameter space such that $y_{\min}$ is positive. [As it turns out, the field equations do not allow topology changing solutions with standard embedding in scenario (b).] It is easy to see that $y_{\min}>0$ for large $\tilde{k}_U$ provided that the other $\tilde{k}_i$ obey the above constraints (for example, $k_U=100, k_T=30$ and $k_W=1$). This region thus corresponds to scenario (a); the Calabi–Yau manifold at $y=0$ is model II with an $SU(3)$ gauge bundle and that at $y=\pi R$ is model III with no gauge bundle.

2. Continuity

We demand that the solution for the 2-cycles $b^i=V^{-1/6}f^i$ can be matched across the flop at the flop location $y_*\equiv y_-$. This implicitly requires that the harmonic functions match as well; $H_i(y_*)=\tilde{H}_i(y_*)$. As $c_2(D_T)=\tilde{c}_2(D_T)$ this implies that $\tilde{H}_T(y)=H_T(y)$ for all y. Similarly $H_U(y)+H_W(y)=\tilde{H}_U(y)+\tilde{H}_W(y)$. Combining this with the final requirement that $H_U(y_*)-H_W(y_*)=\tilde{H}_U(y_*)-\tilde{H}_W(y_*)$ yields

$$k_T=\tilde{k}_T,$$

$$k_U+k_W=\tilde{k}_U+\tilde{k}_W, \tag{43}$$

$$k_U-k_W=\tilde{k}_U-\tilde{k}_W-\tfrac{1}{2}y_*((c_2(U)-\tilde{c}_2(U))-(c_2(W)-\tilde{c}_2(W))).$$

In order that $U_{\mathcal{M}}(y_*)-W_{\mathcal{M}}(y_*)$ indeed vanishes at the flop point on Calabi–Yau $\mathcal{M}$ with the above values of k_i, we need to choose the negative sign in front of the square root in (31).

It is now straightforward to plot the solutions on both sides of the flop for a particular choice of constants k_i in region (a) and establish the occurrence of a flop transition; see Fig. 2.

3. Discontinuity in the first derivatives

We have seen that the function values of the moduli in the Calabi–Yau manifold $\mathcal{M}$ can be continuously connected to that in the flopped Calabi–Yau $\tilde{\mathcal{M}}$ at the location of the flop. We now check whether the first derivatives are continuous.

In a universal, basis independent, notation the derivatives of the 2-cycles f^i are related to those of the harmonic functions as

$$M_{ij}\,\partial f^j = \partial H_i\,. \tag{44}$$

Here M is the symmetric matrix $M_{ij}=2d_{ijk}f^j$. This equation is nothing but the condition for the existence of a global Killing spinor (17) and therefore a component version of the attractor equation (19). Indeed $M_{ij}\,\partial f^j \sim G_{ij}\,\partial b^j$.

In a natural orthogonal basis such as the t^i where exactly one of the t^i shrinks to zero, one sees immediately that at the flop point M is continuous. The potential source of discontinuity, the jump in the intersection numbers, always multiplies the very cycle which goes to zero. Recalling that the derivative of the harmonic function is just the slope,

$$\partial f^j = (M^{-1})^{ji}\alpha_i\,, \tag{45}$$

continuity of the first derivative of the cycles rests solely on the continuity of the slopes. Here, knowing its relation to the moduli space metric, we assume that the matrix M is invertible. The slopes, of course, are the five-brane charges at each end of the universe. And these jump due to the flop transition:

$$\begin{aligned}\partial f^j(y_*) - \partial \tilde{f}^j(y_*) &= (M^{-1}(y_*))^{ji}\alpha_i - (\tilde{M}(y_*)^{-1})^{ji}\tilde{\alpha}_i \\ &= (M^{-1}(y_*))^{ji}(\alpha_i - \tilde{\alpha}_i).\end{aligned} \tag{46}$$

Since M is generically not (block-)diagonal, the first derivatives of *all* cycles are discontinuous, as is evident in Fig. 2. The reason for the jump is the mismatch in $\int_{D_i} c_2(R)$ on different sides of the flop.

Let us also briefly check the behavior of the volume V of the Calabi–Yau,

$$V = \left(\frac{1}{3!}d_{ijk}f^i f^j f^k\right)^2 = \frac{1}{36}(f^i H_i)^2. \tag{47}$$

It is obviously continuous for the same reason that M is continuous. As for its derivative, it equals

$$\partial V = \frac{\sqrt{V}}{3}(\partial f^i\, H_i + f^i\,\partial H_i). \tag{48}$$

Using the above result for ∂f^i and the implicit relation $f^i = \frac{1}{2}M^{-1}(f(H))H$, this yields

$$6\,\partial\sqrt{V} = (\partial H \cdot M^{-1}\cdot H + \tfrac{1}{2}H\cdot M^{-1}\cdot \partial H) \tag{49}$$

and one recognizes the first Killing spinor equation in (17). Again the expression is simplified at the flop; and one would guess that the volume is discontinuous as well, as $H_i(y)$ and $M^{-1}(y)$ are continuous, but the slopes $\partial H_i(y)$ are not,

$$\partial\sqrt{V} - \partial\sqrt{\tilde{V}} = \tfrac{1}{4}((\alpha - \tilde{\alpha})\cdot M^{-1}\cdot H). \tag{50}$$

However, using the implicit relation, $f^i = \frac{1}{2}M^{-1}H$, once more, this is seen to be equal to

$$\partial\sqrt{V} - \partial\sqrt{\tilde{V}} = \tfrac{1}{2}((\alpha - \tilde{\alpha})\cdot f). \tag{51}$$

The only elements of the charge vector which jump are exactly those parallel to the flopping curve f^i_{flop}, which shrinks to zero. The potential source of discontinuity is therefore absent and ∂V is in fact continuous. This also means that the second derivative of V has no delta-function singularity.

B. Physical properties of the flop point

1. Charge of the flop

In comparing the solutions of the two topologically distinct Calabi–Yau manifolds at the flop, we find that the first derivatives of the Kähler moduli, $\partial_{11} b^i \sim \partial f^i$, are discontinuous.

By virtue of our gluing together solutions whose (piecewise) constant G-fluxes differ in magnitude, there is a jump in G-flux on crossing the flop point, and such a jump will cause a discontinuity in the fields. As we will discuss in more detail in the next section, this is part of why we will associate a magnetic G-charge with the flop point. More generally, though, for the G-flux to be globally defined, we require that

$$\int dG = 0, \tag{52}$$

which implies that the sum of magnetic charges under the four-form G must vanish. If the topology of the Calabi–Yau does not change, this condition is manifest for the standard embedding configuration; the geometrical five-brane charge induced from $\text{tr} R \wedge R$ is cancelled by that of the instanton configuration. However, as the topology of the Calabi–Yau on one ''end of the world'' changes, the global charge conservation constraint is no longer satisfied.

Denoting the induced magnetic charges, $\int_{D_i} G$, associated with the divisors D_i of the Calabi–Yau manifolds by (q_1, q_2, q_3), the brane at $y=0$ reduced over the flopped Calabi–Yau $\tilde{\mathcal{M}}$ has induced geometric charge $\alpha^{y=0}_{\text{geom}} = -\frac{1}{2}\tilde{c}_2(D_1, D_2, D_3) = (-46, -18, -13)$ compensated by the instantons with charge $\alpha^{y=0}_{\text{inst}} \equiv \tilde{c}_2(D_i) = (92, 36, 26)$. The brane at $y = \pi R_{11}$ only has induced geometric charges which equal $\alpha^{y=\pi}_{\text{geom}} = -\frac{1}{2} c_2(D_i) = (-46, -18, -12)$. Adding all contributions we see that we have an excess of $q_{\text{total}} = (0,0,1)$ units of charge.

The question is: what accounts for the missing (0,0,-1) units of magnetic charge? As indicated, a natural candidate is the flop curve which degenerates to zero volume at the flop point. This situation is not completely unfamiliar. There are examples where geometric singularities are magnetic sources (e.g., orbifold singularities in Ref. 27). The singular object in the present setting is the degenerate flop curve. It is therefore natural to conjecture that the flop must in some way be accompanied by $(0,0,-1)$ units of charge to ensure global charge conservation. If this is so, the discontinuities in the solution to the field equations is just a consequence of the fact that the flop carries magnetic charges, thereby inducing a jump in the G-flux.

We will examine in more detail the nature of the charge at the flop point in the next section.

2. Tension of the flop

If the flop point is a charge source, it is natural to inquire as to its possibly being a stress–energy source as well. The tension may be deduced from the curvature singularity. For a metric of the form (12), the nonvanishing components of the Einstein tensor are

$$\begin{aligned} G_{\mu\nu} &= -3e^{-6A}(A'' - 2(A')^2)\eta_{\mu\nu}, \\ G_{11,11} &= -6A'^2. \end{aligned} \tag{53}$$

The delta function singularities of the Einstein tensor, indicating a source of tension, can only come from the term A'', where $e^A = V^{1/6}$. In the previous subsection we showed that the second derivative of V is at most discontinuous. Hence, the tension of the flop point is zero. We note that this is in accord with the tension one would have from a five-brane wrapped around the flopping curve at the flop point.

3. Supersymmetry

Finally, we should check whether the charge of the flop is consistent with supersymmetry. In order that the supersymmetries which are preserved all have the same chirality, the inner products $f^i\alpha_i^{(n)}$ for all charged objects with charges $\alpha_i^{(n)}$ must have the same sign [from the Killing spinor equations, Eqs. (15)]

$$f^i\alpha_i^{(n)} \geqslant 0. \tag{54}$$

This inner product is equivalent to $\int_{\mathrm{CY}} J\wedge c_2(V)$ for vector bundles and $\int_{C^{(n)}} J$ for five-branes wrapping a curve $C^{(n)}$. This gives the well known condition that in order to preserve supersymmetry the bundles must be holomorphic and stable, and that five-branes must wrap around holomorphic curves. See also Ref. 19 for an in depth analysis of the supersymmetry structure.

What about the proposed charge located at the flop curve? As the volume of a flopped curve $\int_C J$ vanishes at a flop point it preserves the global Killing spinor.

Note that since f^i changes sign for the curve which flops, we see from Eq. (54) that a supersymmetric five-brane wrapping around the flopping holomorphic curve on either side of the flop will have *opposite* charge α_i. (Naively, one might think that it is possible to introduce as many 5-branes wrapping around the flopping curve C as possible, provided that we introduce an equal number of 5-branes wrapping around the curve $\tilde{C}$ on the other side of the flop. However, one has to check that the resulting configuration still has a consistent topology changing solution to the field equations.) This can be understood by noting that for a fixed set of divisors D_j, if the flopping holomorphic curve C meets, say, D_i transversely with $C\cap D_i=+1$ in Calabi–Yau manifold $\mathcal{M}$, then the corresponding holomorphic curve $\tilde{C}$ on the flopped Calabi–Yau manifold $\tilde{\mathcal{M}}$ lies inside D_i, with $\tilde{C}\cap D_i=-1$.

IV. TOPOLOGY CHANGING SOLUTIONS

In the above example, we have seen that consistency of the solution suggests that the zero-size flop curve is a source of magnetic charge. The effect of a magnetic charge at the flop is to modify the Horava–Witten Bianchi identity so that G is globally defined. In this section, we discuss this idea in more detail.

Let us begin by considering the global charge constraint anew. For simplicity, let us temporarily ignore the possibility of additional five-branes wrapped on other, nondegenerating, two-cycles in the bulk. In the eleven-dimensional theory on $S_1/\mathbb{Z}_2$, the Bianchi identity for G is modified by boundary sources.[11] We have

$$dG=([\operatorname{tr}F_{(1)}\wedge F_{(1)}-\tfrac{1}{2}\operatorname{tr}R_{(1)}\wedge R_{(1)}]\delta(y)+[\operatorname{tr}F_{(2)}\wedge F_{(2)}-\tfrac{1}{2}\operatorname{tr}R_{(2)}\wedge R_{(2)}]\delta(y-\pi R_{11}))\wedge dy, \tag{55}$$

where we are now taking care to distinguish the curvatures of the different Calabi–Yau spaces at each end of the interval. In the usual case, where $\operatorname{tr}R_{(1)}\wedge R_{(1)}=\operatorname{tr}R_{(2)}\wedge R_{(2)}$, we have the familiar standard embedding solution,

$$\operatorname{tr}F_{(1)}\wedge F_{(1)}=\operatorname{tr}R\wedge R,\quad \operatorname{tr}F_{(2)}\wedge F_{(2)}=0, \tag{56}$$

to the global consistency constraint that

$$\int_{S_1/\mathbb{Z}_2\times D} dG=\int_{S_1/\mathbb{Z}_2\times D} dy\left(\frac{1}{2}\operatorname{tr}R\wedge R\,\delta(y)-\frac{1}{2}\operatorname{tr}R\wedge R\,\delta(y-\pi R_{11})\right)=0. \tag{57}$$

But if $\operatorname{tr}R_{(1)}\wedge R_{(1)}\neq\operatorname{tr}R_{(2)}\wedge R_{(2)}$ (cohomologically) then the mismatch implies that solely embedding either spin connection into the gauge group is no longer a solution.

A natural suggestion, then, is to seek out different holomorphic stable bundles to place at $y=0$ and $y=\pi R_{11}$ with different second Chern classes, so as to find new consistent solutions to the

Bianchi identity. Indeed, one may be able to find appropriate bundles to restore anomaly freedom. However, for a number of reasons, we propose a more general and universal solution. Namely, when $\mathrm{tr}R_{(1)}\wedge R_{(1)}\neq \mathrm{tr}R_{(2)}\wedge R_{(2)}$ because the Calabi–Yau has flopped somewhere along y, there is a new contribution to the Bianchi identity associated with the collapsed flop curves.

To motivate our proposal, notice that given a potential flop solution to (12), *specifically* with standard embedding, we can vary the location in y at which the flop occurs, by varying the integration constants k_i—as we have seen explicitly in the previous section. Imagine now that we have such a solution where a cycle shrinks to zero size but we choose the k_i such that the flop does not occur in the physical range $0\leqslant y\leqslant \pi R_{11}$; rather, it happens formally at $y=\pi R_{11}+\epsilon$. This is just the usual situation in which the topologies of the Calabi–Yau manifolds at $y=0$ and $y=\pi R_{11}$ are identical. Therefore, as expected, the choice of a standard embedding of the spin connection into the gauge group is consistent.

Let's now adjust the k_i so that the flop occurs at $\pi R_{11}-\epsilon$, in the physical range so that the pure standard embedding, with no other charge sources, no longer provides a consistent solution. Where can the necessary other charge sources be? Four natural possibilities are the following: (1) Additional gauge structure at $y=0$; (2) new gauge structure at $y=\pi R_{11}$; (3) new wrapped 5-branes; or (4) magnetic charge associated with the geometrical singularity at y_*. By locality we do not expect to fix the Bianchi identity by adjusting the gauge bundle at $y=0$, as that lies at ''the other end of the universe'' from where the flop occurs, making possibility (1) seem unlikely. Nor do we expect to excite the new nontrivial gauge structure by changing the geometry/topology of the Calabi–Yau at $y=\pi R_{11}$ (where the initial gauge bundle was chosen to be trivial). In fact, as we will see in a moment, possibility (2) seems to be ruled out because the sign of the new magnetic source required to fix the Bianchi identity conflicts with the requirement that the new gauge bundle at $y=\pi R_{11}$ is stable. Possibility (3) immediately raises the following question: where along y_{11} should the purported new 5-brane wrapping C be located? From the discussion of the preceeding section, to contribute the correct charge, it must be located at a point y with $y\leqslant y_*$. Locality, and consistency with the solutions we have constructed in Sec. III in which the flux jumps at the flop point, pick out $y=y_*$. We will come back to this in a moment.

To understand possibility (4) we note that since a flop causes the geometrical G-source contribution $\mathrm{tr}\,R\wedge R$ to change, it is natural to suggest that a compensating magnetic source is provided by the geometrical singularity at the location of the flop itself. Strictly speaking, we are considering M theory compactified on a 7-manifold with boundaries, as the Calabi–Yau moduli are varying over the $S^1/\mathbb{Z}_2$. At the location of the flop, the 7-manifold is also singular—with the singularity of the form of a cone over CP^3 (see, e.g., Ref. 28). (We thank Edward Witten and Chien-Hao Liu for discussions on this point.) Geometrical singularities are known to carry magnetic charges (e.g., orbifold singularities in Ref. 27, and orientifolds). The singular objects in the present setting are the flop curves when they attain zero quantum volume.

To complete the proposal, we need to specify the strength of the charge carried by the flop. A theorem of Tian and Yau, which we will discuss directly below, suggests that, if a flop occurs at $y=y_*$, the gravitational contribution to the Bianchi identity is modified to

$$dG_{\mathrm{grav}}=\left(-\frac{1}{2}\mathrm{tr}\,R_{(1)}\wedge R_{(1)}\delta(y)-\frac{1}{2}\mathrm{tr}\,R_{(2)}\wedge R_{(2)}\delta(y-\pi R_{11})+\sum_{\beta}\delta_{C^\beta}\delta(y-y_*)\right)\wedge dy, \tag{58}$$

where β sums over all the holomorphic curves $\{C^\beta\}$ that flop at $y=y_*$.

This additional gravitional contribution has a close analogy with bulk five-brane sources wrapped on nonsingular curves.[27] The gauge bundle contribution to dG can be augmented by having five-branes wrapped on two-cycles $C^i\subset\mathcal{M}$ at locations $y=y_i$. This causes the matter part of the Bianchi identity to take the form[5] [see Eq. (8)]

$$dG_{\mathrm{matter}}=\left(\mathrm{tr}\,F_{(1)}\wedge F_{(1)}\delta(y)+\mathrm{tr}\,F_{(2)}\wedge F_{(2)}\delta(y-\pi R_{11})+\sum_{i}\delta_{C^i}\delta(y-y_i)\right)\wedge dy, \tag{59}$$

in the case of singly wrapped five-branes on holomorphic curves.

There is, however, an important subtlety in the above expression (58). In the presence of a flop, one has to define precisely what one means by the curves C^β. With respect to a chosen basis of divisors D_i, which (via invoking the proper transform map) can be made universal on both sides of the flop, flopping curves differ in orientation from one side to the other. To be concrete, suppose that the flopping curve C^β and the set of divisors D_i meet transversely on a Calabi–Yau manifold $\mathcal{M}$ with $C^\beta \cap D_i = 1$. In the flopped Calabi–Yau manifold $\tilde{\mathcal{M}}$, as we mentioned earlier, the flopping curve $\tilde{C}^\beta$ is no longer transverse to D_i, but instead lies inside D_i, with $\tilde{C}^\beta \cap D_i = -1$. Therefore, one has to specify in Eq. (58) on which Calabi–Yau manifold the holomorphic curve C^β is collapsing in order that the geometrical data is complete. In fact, this subtlety in assigning magnetic charges when a curve collapses is not intrinsic to the flop point, and is already present when one considers a five-brane wrapped around a collapsing curve. We have discussed this subtlety in the analysis of supersymmetry in the previous section. In the same manner, one has to specify on which Calabi–Yau manifold the curve C_i (that the five-brane wraps) is collapsing. The reason is that with respect to a fixed divisor D_i (and its proper transform), the charge of the five-brane differs by a sign depending on whether one approaches the flop point from one Calabi–Yau or from its flopped cousin.

Let us examine more closely which holomorphic curve C^β one should use in Eq. (58). Recall that our topology changing solution can be obtained, starting from a standard solution in which the topology of the Calabi–Yau does not change in the physical regime $0 \leqslant y \leqslant \pi R_{11}$ (which we call the ''parent'' solution). Subsequently by varying the initial conditions of the two-cycles (the integration constants k_i), while keeping the gauge bundle fixed, we can bring the flop point to $y = \pi R_{11} - \epsilon$. This causes a jump in $\mathrm{tr}\, R \wedge R$, which must be compensated by the flop charge. The question, then, is the following: What is the jump in $\mathrm{tr}\, R \wedge R$ under a flop? A theorem of Tian and Yau[29] states that starting from a Calabi–Yau manifold $\tilde{\mathcal{M}}$ and a collection of holomorphic curves $\{C^\beta\}$ on $\tilde{\mathcal{M}}$, the second Chern numbers of $\tilde{M}$ and its flopped cousin M are related by

$$c_2(\mathcal{M}) = c_2(\tilde{\mathcal{M}}) + 2\sum_\beta \int_D [C^\beta], \tag{60}$$

with D an arbitrary divisor and $[C^\beta] \in H^4(\tilde{\mathcal{M}})$, the Poincare dual of C^β. We therefore see that

$$-\frac{1}{2}\mathrm{tr}_{\mathcal{M}}\, R_{(2)} \wedge R_{(2)} + \sum_\beta \delta_{C^\beta_{(1)}} = -\frac{1}{2}\mathrm{tr}_{\tilde{\mathcal{M}}}\, R_{(1)} \wedge R_{(1)}\,. \tag{61}$$

Hence, the C^β in (58) are holomorphic curves on the Calabi–Yau manifold $\tilde{\mathcal{M}}$ of the ''parent'' solution. The total G-charge, including that carried by the flop, still equals $\mathrm{tr}\, R_{(1)} \wedge R_{(1)}$, which is exactly cancelled by the standard embedding on the brane wrapping $\tilde{\mathcal{M}}$; the charge conservation constraint is satisfied.

Notice that the flop contribution to the Bianchi identity is the same as that of a five-brane wrapping the flopping curve on the Calabi–Yau of the ''parent'' solution (which lies at $y = 0$ in our setup). However due to the fact that supersymmetric five-branes wrapping the ''flopping'' curve on the other ''flopped'' Calabi–Yau, must carry the opposite charge, the missing charge required to satisfy the Bianchi identity *cannot* be carried by a five-brane on the other side of the flop. Nevertheless, this means that the magnetic source contributed by a wrapped 5-brane over the appropriate degeneration of the flop curve is identical to the magnetic source of the singularity at y_* to which we are led by the result of Tian and Yau. Hence, at our level of analysis possibility (3)—realized at y_*— and possibility (4) are indistinguishable. [An argument for possibility (3) is, perhaps, that the above calculation indicates that the form of the local singularity does not uniquely determine the sign of the charge it is required to carry. Namely, as we have phrased the calculation, the additional data of which Calabi–Yau is used in the ''parent'' theory is needed. Equivalently, the sign of the charge depends upon the details of the background G-flux.]

We can now also complete the promised argument that seems to rule out possibility (2). The missing magnetic source for dG in the presence of a single flopped curve is $\delta_C = -\delta_{C'}$ where C lies on the Calabi–Yau to the left of y_* and C' lies on the Calabi–Yau to the right of y_*. The question then is whether there is a stable holomorphic vector bundle V on the Calabi–Yau at $y = \pi R_{11}$ such that

$$c_2(V) = \tfrac{1}{2}(c_2(T_2) - c_2(T_1)) = -\delta_{C'}. \tag{62}$$

But if there were such a bundle, then

$$\int c_2(V) \wedge J = -\int_{C'} J < 0, \tag{63}$$

violating the stability condition on V. Hence, a gauge instanton at $y = \pi R_{11}$ alone cannot account either for the missing charge required to satisfy the Bianchi identity.

We note that the inability of G-charge considerations to distinguish between a five-brane of the ''parent'' solution wrapping the zero-size flop curve and a purely geometrical singularity raises the interesting question whether flop transitions aside from new sources of five-brane charge are also accompanied by the introduction of new low-energy degrees of freedom. (We note that preliminary analysis indicates that we can deform the solutions of Sec. III so that the jump in the G-flux occurs to the left of the flop point, with all quantitites then being smooth across the flop point itself. This would naturally be interpreted as the required G-charge being carried by a 5-brane wrapped on the ''would-be'' flop curve, to the left of the flop point. A further analysis of these solutions would likely help clarify this issue.)

We propose therefore, that in strongly coupled heterotic string theory, the general Bianchi identity for arbitrary gauge bundles at $y = 0$ and $y = \pi R_{11}$, in a space–time background in which the Calabi–Yau undergoes a flop transition at $y = y_*$, together with an arbitrary assortment of 5-branes wrapping two-cycles other than those involved in the flop transition itself, is

$$dG = \Bigg(\left[\operatorname{tr} F_{(1)} \wedge F_{(1)} - \frac{1}{2} \operatorname{tr} R_{(1)} \wedge R_{(1)} \right] \delta(y) + \left[\operatorname{tr} F_{(2)} \wedge F_{(2)} - \frac{1}{2} \operatorname{tr} R_{(2)} \wedge R_{(2)} \right] \times \delta(y - \pi R_{11}) + \sum_i n_5^i \delta_{C^i} \delta(y - y_i) + \delta(y - y_*) \sum_\beta \delta_{C^\beta} \Bigg) \wedge dy, \tag{64}$$

with C^i being holomorphic curves in the Calabi–Yau that the corresponding five-brane wraps, and C^β being the flop curve on the appropriate Calabi–Yau as described above. Of course, the last two contributions can be grouped together, as long as the contribution associated with any degenerating curves is calculated according to the limiting procedure from the correct side of the flop point.

V. CONCLUSION

In this paper, we have studied topology changing solutions in M theory compactifications on Calabi–Yau three-folds with nonzero G-flux. In the presence of G-flux, the field equations do not admit five-dimensional Minkowski space as a vacuum solution. The space–time metric is warped, with the solution of the domain-wall type so that one of the five dimensions is singled out as the transverse direction. In addition to the space–time metric, other moduli of the Calabi–Yau manifold also vary along the transverse directions. We have studied an example in strongly coupled heterotic string theory—the supersymmetric domain wall solution—in which the field equations force us to go through a flop transition as we move from one end of the world to the other. Consistency of the solution suggests that a flop curve—like an ordinary (wrapped) M theory five-brane—carries a single unit of magnetic charge under the G-flux.

We have focused our attention on flop transitions. As in Ref. 5 we have assumed that the hypermultiplets can be consistently decoupled in the five-dimensional effective theory. Especially

in nontrivial geometric situations as presented here, it would be interesting to revisit this issue of decoupling. Moreover, this would allow the study of a more drastic change of topology, such as conifold transitions, in which the hypermultiplets necessarily play a role. As the number of moduli of the Calabi–Yau changes across a conifold transition, it is perhaps more appropriate to treat the compact manifold as a G_2 7-manifold with boundaries which are Calabi–Yau's. The low energy degrees of freedom in the effective four-dimensional theory then correspond to Ricci flat deformations of metric of the 7-manifold. We will leave this investigation for future work. From a phenomenological point of view, it might be interesting to look for more general solutions in which the topology changes also with time. This may have implications for cosmology as well as other physics of the brane world scenario.

(Received 2 January 2001; accepted for publication 13 February 2001)

We find the analog of the Boillat metric of Born–Infeld theory for the M5-brane. We show that it provides the propagation cone of *all* 5-brane degrees. In an arbitrary background field, this cone never lies outside the Einstein cone. An energy momentum tensor for the three-form is defined and shown to satisfy the Dominant Energy Condition. The theory is shown to be well defined for all values of the magnetic field but there is a limiting electric field strength. We consider the strong coupling limit of the M5-brane and show that the corresponding theory is conformally invariant and admits infinitely many conservation laws. On reduction to the Born–Infeld case this agrees with the work of Białynicki-Birula. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1376158]

I. INTRODUCTION

The behavior of the low energy states of the super-string theories in ten dimensions are described by supergravity theories which are uniquely specified by their type of supersymmetry. These theories satisfy a form of the the Equivalence Principle: the characteristics and hence the limiting propagation speeds of all the fields, be they the graviton, the gravitini, p-form fields, scalars and spinors are given universally by the light-cone of the Einstein metric g_{mn}. The characteristics cones determine the paths of null geodesics which are associated with massless particles. Violations of the Weak Equivalence Principal, that is that all freely falling particles, massive or massless, follow geodesics of the Einstein metric, are known to occur for massive particles in string theory, because the former can couple to a background dilaton field Φ. This may be seen by noting that the unique effective actions, that is the maximal supergravity theories in ten dimensions,[1,2] contain different powers of e^{Φ} in front of the field strengths associated with the Neveu–Schwarz⊗Neveu–Schwarz and Ramond⊗Ramond sectors. It is also known that string theory induces higher derivative corrections which may affect the characteristics[3] in a nontrivial background.

The behavior of the states of open string theories are described by Dirac–Born–Infeld type actions provided one discards derivatives acting on field strengths. In a recent paper[4] it was argued that in a nontrivial background these open string states obey a modified form of the Equivalence Principle: the characteristics are universally given by a metric first introduced in nonlinear electrodynamics by Boillat and which is conformal to what is usually referred to as the open string metric.[5]

It was found that the Boillat cone never lies outside the Einstein cone and in general touches it along the two principal null directions of the two-form $\mathcal{F}_{\mu\nu}=F_{\mu\nu}+B_{\mu\nu}$, where $F_{\mu\nu}$ is the Born–Infeld gauge field strength and $B_{\mu\nu}$ is the Kalb–Ramond 2-form gauge field. In the limit of large field strength or equivalently large α', propagation perpendicular to the principal null directions is suppressed.

a)Electronic mail: G.W.Gibbons@damtp.cam.ac.uk

In this paper we shall consider the analog of the Boillat metric for the M-5-brane equations of motion.[6] We shall call this metric C_{mn} Note that the characteristics may be read off from the co-metric C^{mn}. The speed of the rays are read off from its inverse $(C^{-1})_{mn}$ which is traditionally called a metric. If more than one metric is involved one must distinguish carefully between metrics and their inverses, i.e., between metrics and co-metrics. In the context of lattices and elsewhere, the prefix ''co-'' is frequently replaced by the adjective ''reciprocal.'' We prefer ''co-'' because it is shorter. Note that there is no analog of the Boillat co-metric for the M-2-brane because the world volume theory has no gauge fields. We shall find that indeed a modified form of the Equivalence Principal holds for the M-5-brane: the characteristics of fluctuations are given universally by an analog of the Boillat cone which never lies outside the Einstein cone. We will show that if one dimensionally reduces the theory to Born–Infeld theory then the fivebrane metric becomes the Boillat metric of the D4-brane. We shall define an energy momentum tensor for the fivebrane. It satisfies the striking identity,

$$T^{mn}=g^{mn}-C^{mn}, \tag{1}$$

and we show that it obeys the dominant energy condition.

One may show that the fivebrane has a limiting electric field strength beyond which the theory breaks down. By contrast, there is no limiting magnetic field strength. Finally we consider a high energy, or zero tension, limit of the fivebrane which is Weyl invariant and admits infinitely many conservation laws.

The plan of the paper is as follows. In Sec. II we introduce the 5-brane metric and 5-brane Clifford algebra. We show that the 5-brane metric gives the characteristics of the propagating fields whose speeds can never exceed that of light. In Sec. III we show that the two lightcones touch along a circle of null directions. In Sec. IV we introduce the covariantly conserved energy momentum tensor for the three-form and show that it satisfies an identity analogous to Hooke's law in classical elasticity theory. We show that in general its trace is nonvanishing and hence the three-form equations of motion are not invariant under a Weyl rescaling of the Einstein metric. In Sec. V we develop the idea that there is a 5-brane Equivalence Principal. In Sec. VI we show how our metric agrees with the Boillat metric of Born–Infeld theory. In Sec. VIII we show that plane wave solutions of the linear theory are exact solutions of the full nonlinear theory. In Sec. IX we discuss the limiting electric field strength and the behavior the theory near it. In Sec. X we consider this strong coupling limit in detail. We show that the theory is Weyl-invariant in this limit and that it admits infinitely many conserved quantities.

II. THE 5-BRANE METRIC

The equations of motion of the scalars X^N, closed three-form, H_{lmn} and spinors Θ,[6]

$$G^{mn}\nabla_m\nabla_n X^N=0, \tag{2}$$

$$G^{mn}\nabla_m H_{nrs}=0, \tag{3}$$

$$\nabla_m\Theta(1-\Gamma)\Gamma^n m_{mn}=0, \tag{4}$$

where ∇_m is the Levi-Civita covariant derivative with respect to the Einstein metric g_{mn}. To begin with, we consider their characteristics which require only the leading derivative terms. A short calculation shows that the characteristics of the X^N and H_{lmn} fields given by the co-metric G^{mn} which is defined by

$$G^{mn}=m^{mr}g_{rs}m^{sn}=\left(1+\tfrac{2}{3}k^2\right)g^{mn}-4k^{mn}, \tag{5}$$

where G_{mn} which will be defined to be $(G^{-1})_{mn}$, with $G^{mn}=(G)^{mn}$. All indices are raised and lowered using the Einstein metric g_{ab}, which is taken to have signature $-1,+1,+1,+1,+1$,

$+1$, *with the exception of* G_{mn} which will be defined to be $(G^{-1})_{mn}$, with $G^{mn}=(G)^{mn}$. In fact it seems to be possible to avoid explicit use of the covariant form of the metric in all of the equations of motion. Only the contra-variant form is required:

$$m^{mn}=g^{mn}-2k^{mn}, \tag{6}$$

$$k^{mn}=h^{n}{}_{ab}h^{mab}, \tag{7}$$

where h_{abc} is a self-dual three-form,

$$h_{abc}=\tfrac{1}{6}\epsilon_{abcdef}h^{def}, \tag{8}$$

and

$$k^2=k_{ab}k^{ab}. \tag{9}$$

In what follows shall repeatedly use the identities[7,6]

$$g_{ab}k^{ab}=0, \tag{10}$$

and

$$k^{ab}g_{bc}k^{cd}=\tfrac{1}{6}g^{ad}k^2=\tfrac{1}{6}g^{ad}k_{ef}k^{ef}. \tag{11}$$

Thus, for example,

$$C^{mn}=m_a^m m^{an}=2Q^{-1}m^{mn}-g^{mn}. \tag{12}$$

The self-dual field h_{abc} obeys the relations[7]

$$h_{abe}h^{cde}=\delta^{[c}_{[a}k^{d]}_{b]}, \tag{13}$$

and

$$k_a{}^c k_c{}^b=\tfrac{1}{6}\delta^b_a k^2. \tag{14}$$

For later use we define

$$Q=1-\tfrac{2}{3}k^2. \tag{15}$$

The closed three-form H_{abc} is related to the self-dual field h_{abc} by $h_{abc}=m_a{}^e H_{ebc}$, or equivalently by $H_{abc}=(m^{-1})_a{}^e h_{ebc}$ where $m^{-1}=Q^{-1}(1+2k)$. It will be proven useful in what follows to translate the self-duality condition on h_{abc} to one expressed entirely in terms of H_{abc}. This was carried out in Ref. 7 and refined in Ref. 8. Since $k_a{}^e h_{ebc}$ is anti-self-dual we can express

$$H^{+}_{abc}\equiv\frac{1}{2}\left(H_{abc}+\frac{1}{3!}\epsilon_{abcdef}H^{def}\right)=Q^{-1}h_{abc} \tag{16}$$

and

$$H^{-}_{abc}\equiv\frac{1}{2}\left(H_{abc}-\frac{1}{3!}\epsilon_{abcdef}H^{def}\right)=2Q^{-1}k_a{}^e h_{ebc}. \tag{17}$$

Taking the sum and difference we find that

$$H_{abc}=Q^{-1}(1+2k)_a{}^e h_{ebc},\ *H_{abc}=Q^{-1}(1-2k)_a{}^e h_{ebc}. \tag{18}$$

Multipying the second equation by the matrix $(1+2k)^2$ and using the first equation we conclude that

$$*H^a{}_{bc}=Q^{-1}G^{ae}H_{ebc}. \tag{19}$$

Substituting the relation $h_{abc}=m_a{}^eH_{ebc}$ into Eq. (13) we find that

$$H_{abe}H^{cde}=\tfrac{1}{2}\delta^c_{[a}\delta^d_{b]}Q^{-1}(Q^{-1}-1)+2Q^{-2}k^c_{[a}k^d_{b]}+Q^{-2}(2-Q)\,\delta^{[c}_{[a}k^{d]}_{b]}. \tag{20}$$

Taking the trace of this equation we find that

$$k_a{}^c=\frac{Q^2}{(2-Q)}\left((H^2)_a{}^c-\frac{1}{6}\,\delta_a{}^cH^2\right), \tag{21}$$

and tracing again

$$H^2=6Q^{-1}(Q^{-1}-1), \tag{22}$$

where $(H^2)_a{}^c=H_{aef}H^{cef}$.

We may express the last equation as

$$Q=-\frac{3}{H^2}\left(1-\sqrt{1+\frac{2}{3}H^2}\right). \tag{23}$$

It is now straightforward to express the matrix m^2 as

$$(m^2)^{ac}=G^{ac}=\frac{Q^2}{(2-Q)}\left(\eta^{ac}\left(1+\frac{4}{3}H^2\right)-4(H^2)^{ac}\right) \tag{24}$$

and

$$(m^{-2})_{ac}=G_{ac}=\frac{1}{(2-Q)}(\eta_{ac}+4(H^2)_{ac}). \tag{25}$$

Finally, we may express the self-duality of h_{abc} in terms of H_{mnp} by using Eqs. (19) and (20) and find that

$$*H_{abc}=\frac{1}{\sqrt{1+\frac{2}{3}H^2}}\left(\left(1+\frac{4}{3}H^2\right)\delta_a{}^e-4(H^2)_a{}^e\right)H_{ebc}. \tag{26}$$

We now turn briefly to the fermion sector. The projector in the spinor equation of motion is defined by

$$\Gamma=-\tfrac{1}{6}\,\eta^g_{lmnpqr}\Gamma^{lmnpqr}+\tfrac{1}{3}h_{lmn}\Gamma^{lmn}, \tag{27}$$

where η^g_{lmnpqr} is the alternating tensor (not density) constructed from the Einstein metric.

In the case that the scalar and spinors vanish, the covariant equations of motion, when expressed in terms of 5-dimensional language, agree with a particular case of the equations of Ref. 9. The particular case is the one that upon reduction gives Born–Infeld theory. One advantage of the covariant formulation used here is that, not only does it cover the more general case of nonvanishing scalars and spinors, but also the derivation of the characteristics is especially transparent.

The characteristics determine a metric only up to a conformal factor. It turns out that it is more convenient to Weyl rescale the co-metric G^{mn} and we therefore adopt as our definition of the M5-brane metric C^{mn},

$$C^{mn}=Q^{-1}G^{mn}=Q^{-1}m^{mp}g_{pq}m^{qn}. \tag{28}$$

We recall that in the Born Infeld theory the characteristics are given by the Boillat metric[4] up to a conformal factor. The Boillat metric which is proportional to the open string metric has the advantage that it is invariant under electric magnetic duality rotations rather than merely being invariant up to a conformal factor as is the open string metric. In a two recent papers[10] an analog for the fivebrane of the open string metric was proposed. Specifically, it was suggested that the analogous metric should be given by

$$\phi(H_{lpq}H^{lpq})(g_{mn}+4H_{mpq}H_n^{pq}), \tag{29}$$

where the function ϕ should behave like $(H_{lpq}H^{lpq})^{-2/3}$ for large $H_{lpq}H^{lpq}$ in order that, upon reduction, it agrees with the open string metric of string theory in the relevant limit.

The two proposals are both conformally related to the metric in the fivebrane equations. We will see that with our choice of conformal factor we obtain the Boillat metric of the D4-brane upon reduction. Our choice has the additional advantage that in terms of it the equations of motion can be rewritten in a natural way.

We now turn to the characteristics associated with the Dirac equation (4). While the gamma matrices Γ^m give a Dirac square root of the restriction of the bulk Einstein co-metric to the brane,

$$\Gamma^m\Gamma^n+\Gamma^n\Gamma^m=2g^{mn}, \tag{30}$$

the spinor equation of motion contains the 5-brane Gamma matrices $\tilde{\Gamma}^m=n^m{}_n\Gamma^n$, where $n^m{}_n=Q^{-1/2}m^m{}_n$ which give a Dirac square root of the 5-brane co-metric C^{mn},

$$\tilde{\Gamma}^m\tilde{\Gamma}^n+\tilde{\Gamma}^n\tilde{\Gamma}^m=2C^{mn}. \tag{31}$$

One may view the $n^m{}_n$ as a sort of sechbein for the 5-brane metric C_{mn} since

$$C^{mn}=n^m{}_p n^n{}_q g^{pq}. \tag{32}$$

Note that $n_{nm}=g_{ml}n^l{}_m$ is symmetric.

Writing out the Dirac equation in terms of the gamma matrices $\tilde{\Gamma}^m$ reveals that the spinor characteristics are also given by C^{mn}.

In the absence of a background H_{lmn} field, C^{mn} and g^{mn} coincide. Note that there is a *single* G^{mn} and thus a single characteristic cone. That is just as in Born–Infeld theory; there is no bi-refringence: all polarization states travel with the same speed. Since any nonlinear electrodynamic theory, including ones exhibiting bi-refringence can be made $N=1$ supersymmetric, its absence cannot be attributed to just one supersymmetry. However one might imagine that this property is a consequence of maximal superymmetry. In the case of Born–Infeld theory, the absence of bi-refringence, and the exceptional property that the system exhibits no shocks, characterizes the theory uniquely (see Ref. 4 for references). It is an attractive conjecture that the same uniqueness property holds for the M-5-brane equations of motion.

We now establish that the 5-brane co-cone $C_G^\star\in T^\star M$ lies outside or on the Einstein co-cone $T^\star M\supset C_G^\star\supseteq C_g^\star$. The notation here is as follows. $C_g^\star$ consists of timelike co-vectors $p_m\in T^\star M$ such that $g^{mn}p_m p_n\leqslant 0$ and its boundary consists of the lightlike co-vectors l_m for which $g^{mn}l_m l_n=0$. Since passing to the dual space TM reverses inclusions we have that the 5-brane cone lies inside or on the Einstein cone, $TM\supset C_g\supseteq C_G$. In plain language this means that 5-brane

excitations travel with speeds no greater than that of light. Note that the cone $C_G^\star$ depends only on the conformal equivalence class of co-metrics of which G^{mn} is one representative and C^{mn} another.

To establish our basic causality result we consider a co-vector l_a lying on the boundary of $C_g^\star$, i.e., for which

$$g^{mn}l_m l_n = 0. \tag{33}$$

Using (12) we find that

$$C^{mn}l_m l_n = -4Q s_{mn}s^{mn}, \tag{34}$$

where $s_{mn} = -s_{nmb} = h_{mnl}l^l$. Thus

$$s_{mn}l^m = 0. \tag{35}$$

By choice of frame $l^m = (1,0,0,0,0,1)$ and thus $s_{05} = 0$ and $s_{0i} + s_{5i} = 0$, where $i = 1,2,3,4$ are spatial indices. One thus has

$$s_{ab}s^{ab} = s_{ij}s^{ij} \geqslant 0. \tag{36}$$

Thus

$$C^{mn}l_m l_n \leqslant 0. \tag{37}$$

It follows that the boundary of $C_g^\star$ lies inside or on $C_G^\star$ and we are done.

III. PRINCIPAL NULL DIRECTIONS

In the case of Born–Infeld theory in four spacetime dimensions, generically the Boillat and Einstein cones touch along two principal null directions of the electromagnetic two-form $F_{\mu\nu}$.[4] In fact this result holds in all dimensions. The common null direction $l^m = (1,n_i)$ with $n_i n_i = 1$ must satisfy

$$l^n F_{na}F_{mb}g^{ab}l^m = 0. \tag{38}$$

For a generic two-form one may find a frame in which the only nonvanishing components are $F_{01} = -F_{10}, F_{23} = -F_{32}, F_{45} = -F_{54}\cdots$. The touching condition becomes

$$F_{01}^2(1-n_1^2) + F_{23}^2(n_2^2+n_3^2) + F_{45}^2(n_4^2+n_5^2)\cdots = 0. \tag{39}$$

There are only two solutions; $l^m = (1,\pm 1,0,\ldots,0)$.

One may ask what is the analog of this result for the fivebrane with its self-dual three-form h_{lmn} in six spacetime dimensions? In order to answer this question we need to put k_{ab} rather than F_{ab} in standard form by diagonalizing with respect to to g_{ab}. Using (10) and (11) one easily sees that generically k_{ab} takes the form, up to permutations of the spatial axes,

$$k_{ab} = \sqrt{\frac{k^2}{6}}\,\mathrm{diag}(1,1,1,1,-1,-1). \tag{40}$$

The common null directions must be common solutions of

$$-1 + n_1^2 + n_2^2 + n_3^2 + n_4^2 + n_5^2 = 0, \tag{41}$$

and

$$1 + n_1^2 + n_2^2 + n_3^2 - n_4^2 - n_5^2 = 0. \tag{42}$$

There is in general a circle of such directions,

$$l^m=(1,0,0,0,\cos\alpha,\sin\alpha), \tag{43}$$

along which the Einstein and Boillat cones coincide. In all other directions the Boillat cone lies inside the Einstein cone.

IV. THE ENERGY MOMENTUM TENSOR AND HOOKE'S LAW

Following the discussion of the energy momentum tensor in Ref. 11, we shall in this paper define the energy momentum tensor as

$$T^{mn}=g^{mn}-\frac{G^{mn}}{Q}. \tag{44}$$

The main difference from the energy momentum tensor defined in Ref. 11, also used in Ref. 8, is that we have added the metric tensor g_{mn} to the tensor defined there so as to make the energy momentum tensor vanish for zero three-form field $h_{abc}=0$. In fact it is (44) which enters directly into the superysymmetry algebra and hence the Bogomol'nyi bound of the theory.[12] The energy momentum tensor so defined has some important positivity properties which we will explore shortly.

In terms of C^{mn} we have the strikingly simple formula

$$T^{mn}=g^{mn}-C^{mn}. \tag{45}$$

This formula has an interesting interpretation which appears to be closely related to Hooke's law in the classical theory of nonlinear elasticity theory. This is formulated in terms of diffeomorphisms ϕ from the manifold Σ of the elastic body into flat three-dimensional Euclidean space $\mathbb{E}^3$ with metric δ. The relaxed or unstretched state of least energy corresponds to a diffeomorphism ϕ_0. One defines the strain tensor tensor σ_{ij} of a general stretched state corresponding to a diffeomorphism ϕ by

$$\sigma_{ij}=\delta_{\star ij}-\delta_{0ij}, \tag{46}$$

where $\delta_\star$ is the pull-back of the flat Euclidean metric δ under the diffeomorphism ϕ and δ_{0ij} is the pull-back of the flat metric under ϕ_0. For an isotropic medium Hooke's law states that the strain σ_{ij} is proportional to the applied stress T_{ij}. Our formula (1) is similar but not identical because the tensors are contra-variant not co-variant. Thus our case for the analog of $\delta_{\star ij}$ is the pull-back of the bulk closed string co-metric to the M-5-brane world volume. The analog of the unstretched metric δ_{0ij} is the 5-brane co-metric C^{mn}. We believe that it would be worthwhile exploring this analogy further.

Another formula which is similar to one occurring in the Born–Infeld case[4] is the remarkable identity

$$\det C^{mn}=\det g^{mn}. \tag{47}$$

To check conformal invariance we compute the trace of the energy momentum tensor. It is given by

$$T^m_m=-\frac{8k^2}{(1-\frac{2}{3}k^2)}. \tag{48}$$

Thus, the theory is Weyl-invariant in the weak field limit in which the equations of motion become linear. However it is not Weyl-invariant for finite values of the fields. We see shall see later that Weyl invariance is restored in the strong coupling limit.

Later we shall make use of some other identities involving the energy momentum tensor which we derive here. Because the energy momentum tensor is conserved with respect to the Levi-Civita connection,

$$\nabla_m T^{mn}=0, \tag{49}$$

we have, from Hooke's Law, the following identities:

$$\nabla_n C^{mn}=0. \tag{50}$$

These will be used in the next section to establish the M-5-brane Equivalence Principal. Some additional useful identities may be obtained as follows. One defines

$$n^{mn}=Q^{-1/2}m^{mn}=Q^{-1/2}(g^{mn}-2k^{mn}). \tag{51}$$

Thus

$$n^{-1}_{mn}=Q^{-1/2}(g_{mn}+2k_{mn}). \tag{52}$$

We thus have

$$C^{mn}=n^{ma}g_{ab}n^{bn}, \tag{53}$$

and of course,

$$\tilde{\Gamma}^n=n^{na}g_{ab}\Gamma^b. \tag{54}$$

Now one easily finds

$$g_{mn}C^{mn}=\frac{1+\frac{2}{3}k^2}{1-\frac{2}{3}k^2}=g^{mn}C_{mn}. \tag{55}$$

In Ref. 11 an energy momentum tensor was introduced that treated the scalars and three-form in a more symmetric fashion. This tensor is given by

$$S^{mn}=T^{mn}-g^{mn} \tag{56}$$

and is covariantly conserved. Reference 11 also found a tensor density,

$$\mathfrak{G}^{mn}=\sqrt{-g}(T^{mn}-g^{mn}), \tag{57}$$

that was conserved in the sense

$$\partial_m \mathfrak{G}^{mn}=0. \tag{58}$$

In the case that the three-form vanishes, we have $T^{mn}=0$, but $S^{mn}\neq 0$, and so the quantity $\sqrt{-g}g^{mn}$ is a measure of the energy–momentum of the scalars. In fact it is the canonical stress tensor with respect to the flat metric δ_{mn}. It may be obtained from the Lagrangian for the scalars written down in ''static,'' or more accurately ''Monge,'' gauge.

V. THE M5-BRANE EQUIVALENCE PRINCIPLE

It is striking fact that the co-metric C^{mn} rather than the Einstein co-metric g^{mn} enters in the equations of motion of all the 5-brane fields in such a way that it is impossible to determine the Einstein metric by means of observations using 5-brane fields alone. In this respect the situation

resembles attempts to reinterpret General Relativity as a flat space theory by introducing a flat metric $\eta_{\mu\nu}$ into spacetime. The problem is that by the Equivalence Principal no physical measurement can detect the flat metric.

Our aim in this section is to explore further this enhanced version of the Equivalence Principle for the fivebrane. Our claim is that there exists a preferred set of variables to describe the theory that are related in a direct way to the physical observables. In particular, in Sec. II we showed that the characteristics of the fivebrane were given by the metric C_{mn}. This means that the metric can be determined up to a conformal factor by observing the motion of small fluctuations. Another physically relevant variable is the gauge invariant field strength H_{lmn}. This satisfies the Bianchi identity and hence can be written in terms of a two-form potential that couples directly to a twobrane probe. Hence using a twobrane probes allows one to measure the H_{lmn} field.

To illustrate this point we now show how to write the fivebrane equations of motion entirely in terms of the variables C_{mn} and H_{lmn} and X^N. In particular, we will find that the equations of motion for the scalar and the three-form can be written using the Levi-Civita covariant derivative with respect to the metric C_{mn}. The situation is analogous to how the usual Equivalence Principal works in General Relativity. Because all physical equations are writen in terms of the metric C_{mn} the metric g_{mn} is not directly observable.

We begin with the scalar equation of motion. Because G^{mn} is proportional to C^{mn}, this equation can be written as

$$C^{mn}\nabla_m\nabla_n X^N = 0. \tag{59}$$

Following Ref. 11 and using (50) we may re-write this as

$$\nabla_m(C^{mn}\,\partial_n X^N) = \frac{1}{\sqrt{-g}}\partial_m(\sqrt{-g}C^{mn}\,\partial_n X^N) = 0. \tag{60}$$

Now using (47) we have

$$\frac{1}{\sqrt{-C}}\partial_m(\sqrt{-C}C^{mn}\,\partial_n X^N) = \Delta_m(C^{mn}\,\Delta_n X^N) = 0, \tag{61}$$

where Δ_m is the Levi-Civita covariant derivative with respect to the 5-brane metric C_{mn} which is defined by

$$\Delta_m C^{ab} = 0. \tag{62}$$

We see that (61) is just the covariant wave equation with respect to the 5-brane metric C_{mn}.

The closure condition for the three-form H_{lmn},

$$\partial_{[p}H_{qrst]} = 0, \tag{63}$$

clearly requires no metric. The equation of motion of the three-form may be written as

$$C^{mn}\nabla_m(H_{nab}) = 0. \tag{64}$$

Using (50) and the fact that $\nabla_m g^{ab} = 0$, we re-write (64) as

$$\nabla_m(P^{mab}) = 0, \tag{65}$$

where

$$P^{mab} = C^{mn}g^{ac}g^{bd}H_{ncd}. \tag{66}$$

Now the contravariant tensor P^{mab} is totally antisymmetric and satisfies [Ref. 11, Eq. (17)]

$$P^{lmn} = \star_g H^{lmn}, \tag{67}$$

and therefore we may rewrite (64) as

$$\frac{1}{\sqrt{-g}} \partial_m (\sqrt{-g} P^{mab}) = 0. \tag{68}$$

Now using (47) we get

$$\frac{1}{\sqrt{-C}} \partial_m (\sqrt{-C} P^{mab}) = 0. \tag{69}$$

This may now be put in the fivebrane metric covariant form,

$$\Delta_m (\star_C H^{mnp}) = 0. \tag{70}$$

The Hodge operations $\star_g$ and $\star_C$ are taken with respect to the Einstein and 5-brane metric, respectively. However they are related because if η_C^{mabncd} is the contravariant alternating tensor which is covariantly constant with respect to the Levi-Civita connection of the 5-brane metric C_{mn}, we have

$$\sqrt{-C}\, \eta_C^{mabncd} = \sqrt{-g}\, \eta_g^{mabncd}, \tag{71}$$

where η_g^{mabncd} is the contravariant alternating tensor which is covariantly constant with respect to the Levi-Civita connection of the Einstein metric g_{mn}.

Finally we consider the Dirac equation. Following Ref. 11, Eq. (13), this may be written as

$$\nabla_m (\Psi' (1 - \Gamma) \tilde{\Gamma}^m) = 0, \tag{72}$$

where

$$\Psi' = Q^{-1/2} \Theta. \tag{73}$$

Now we must rewrite the projector Γ in terms of the 5-brane gamma-matrices $\tilde{\Gamma}^m$. We have the formula

$$\Gamma = -\tfrac{1}{6} \eta_{C_{lmnrst}} \tilde{\Gamma}^l \tilde{\Gamma}^m \tilde{\Gamma}^n \tilde{\Gamma}^r \tilde{\Gamma}^s \tilde{\Gamma}^t + \tfrac{1}{2} H_{lmn} \tilde{\Gamma}^l \tilde{\Gamma}^m \tilde{\Gamma}^n. \tag{74}$$

The covariant derivative ∇_m is the spinor derivative with respect to the Einstein metric. We expect that one may be able to rewrite this in terms of the spinor covariant derivative Δ_m. This is likely to require a more elaborate redefinition of the spinor than in (73), along the lines of that discussed in Ref. 12.

VI. DIMENSIONAL REDUCTION AND THE RELATION TO THE OPEN STRING METRIC

It is known[7,6] that under double dimensional reduction to five-dimensions the equations of motion of the fivebrane reduce to those of Dirac–Born–Infeld theory. We shall now investigate the relation between the fivebrane metric and the Boillat metric of the D4-brane in this case. We assume that the fields h_{lmn} are independent of the fifth spatial dimension and that

$$H_{mn5} = F_{mn}. \tag{75}$$

Using the results of Ref. 6, Eq. (136)[6] we have (after rescaling F to be consistent with the standard normalization) we find the reduction of fivebrane metric to be given by

$$C^{mn}=Z(1-F^2)^{-1}, \tag{76}$$

where

$$Z=\sqrt{1+2x-y^2}=\sqrt{-\det(g_{mn}-F_{mn})}. \tag{77}$$

The Boillat co-metric is given by

$$C^{mn}_{\text{Boillat}}=Z((1-F^2)^{-1})^{mn}. \tag{78}$$

In other words the two metric coincide.

We now extend the work of Ref. 4 to give an enhanced Equivalence Principle similar to that discussed for the fivebrane earlier. The Born–Infeld equations may be written as

$$\partial_{[l}F_{mn]}=0, \tag{79}$$

and

$$\nabla_m P^{mn}=\frac{1}{\sqrt{-g}}\partial_m(\sqrt{-g}P^{mn})=0. \tag{80}$$

Clearly (79) requires no metric and (80) may be re-written [using (47)] in terms of the Boillat metric as

$$\Delta_m P^{mn}=\frac{1}{\sqrt{-C}}\partial_m(\sqrt{-C}P^{mn})=0. \tag{81}$$

One may check, just as for the 5-brane, that the scalar equations of motion may be written as

$$\Delta_m \Delta^m X^N=0. \tag{82}$$

VII. DOMINANT ENERGY CONDITION

Almost all physically well behaved classical energy momentum tensors satisfy the Dominant Energy Condition. This states that for every pair of future directed casual vectors $p^m, q^m \in C_g^+$ one has

$$T_{mn}p^m q^n \geqslant 0. \tag{83}$$

Note that, if the Dominant Energy Condition holds with respect to the Einstein metric, it necessarily holds with respect to the fivebrane metric, since the lightcone of the former includes that of the latter.

The importance of the Dominant Energy Condition is that it guarantees the classical fields whose energy momentum tensors satisfy the condition propagate causally. It is also an essential ingredient in the Positive Energy Theorems of General Relativity. A theorem of Hawking implies that if the Dominant Energy Condition holds then matter cannot escape from, or enter, a bounded spatial region at a speed faster than light.[13] In particular it guarantees some sort of stability since matter obeying the condition cannot just simply disappear.[13]

Let us evaluate the left hand side of (83) for the fivebrane. Using Eqs. (12), (1) we find that

$$Q^{-1}\left(2k_{mn}p^m q^n+\frac{2}{3}k^2 p\cdot q\right), \tag{84}$$

where

$$p \cdot q = -g_{mn} p^m q^n \geqslant 0. \tag{85}$$

We will now show that the left hand side of the above equation is indeed positive since the quantities k^2 and $k_{mn}p^m q^n$ and are non-negative.

To see that k^2 is positive we introduce an electric two-form in five dimensions by

$$e_{ij} = h_{oij}\,. \tag{86}$$

Self-duality of h_{lmn} implies that

$$e_{ij} = b_{ij} = -\tfrac{1}{6}\epsilon_{ijkrs} h^{krs}. \tag{87}$$

A calculation reveals that

$$k_{ij} = \delta_{ij} e^{pq} e_{pq} - 4 e_{ir} e_j{}^r. \tag{88}$$

From (10) we deduce that

$$k_{00} = e_{rs} e^{rs}, \tag{89}$$

and using (11) we obtain

$$\tfrac{2}{3} k^2 = 16 e_{ij} e^{jk} e_{ks} e^{si} - 4 (e_{ij} e^{ij})^2. \tag{90}$$

Now using $SO(5)$ transformations we can skew-diagonalize the two-form e_{ij}, that is choose a basis in which the only nonvanishing components are $e_{12} = -e_{21} = e_1$ and $e_{34} = -e_{43} = e_2$. In this basis, one finds that

$$k^2 = 24 (e_1^2 - e_2^2)^2. \tag{91}$$

The quantity $k_{mn}p^m q^n$ may be dealt with in a similar way. If p^n is timelike we can choose a six-dimensional Lorentz frame in which $p^m = (p^0,0,0,0,0,0)$. This choice allows us to use the $SO(5)$ freedom to skew diagonalize e_{ij} as above. A short calculation then gives

$$k_{mn} p^p q^n = 2 p^0 q^0 \left(e_1^2 + e_2^2 - 2 \frac{q^5}{q^0} e_1 e_2 \right). \tag{92}$$

Since q^n is causal, $|q^5/q^0| \leqslant 1$ and $e_1^2 + e_2^2 \geqslant 2 e_1 e_2$, we find the desired result, namely $k_{mn} p^m q^n \geqslant 0$.

Interestingly, k^2 vanishes if and only if e_{ij} determines a self- or anti self-dual two-form in the four space orthogonal to its kernel. We also see that $T_{mn} p^m p^n$ is strictly positive for timelike p^n and hence taking the choice $p^n = (p^0,0,0,0,0,0)$ we conclude that T_{00} is strictly positive.

VIII. EXACT PLANE WAVE SOLUTIONS

In this section we shall establish that plane wave solutions of the linearized theory are in fact *exact* solutions of the full nonlinear equations of motion, a property which also holds in Born–Infeld theory (compare Ref. 4) and classical general relativity. We shall suppose that the metric g_{mn} is flat, $g_{mn} = \eta_{mn}$, although one might consider more general cases. We make the ansatz

$$H_{lmn} = H^0{}_{lmn} f(l_n x^n), \tag{93}$$

where H^0_{lmn} is a constant three-form, $f(u)$ is an arbitrary function of its argument and the constant vector l^n is null,

$$\eta_{mn} l^m l^n = 0. \tag{94}$$

The closure condition becomes

$$l_{[l}H^0_{mno]}=0. \tag{95}$$

Thus

$$\epsilon^{pqrstu}l_r H^0_{stu}=0. \tag{96}$$

If we assume that $l_m=(1,1,0,0,0,0)$ and let Greek indices run from 2 to 5, we find that

$$H^0_{\alpha\beta\gamma}=0, \quad H^0_{0\gamma\delta}=H^0_{1\gamma\delta}. \tag{97}$$

This may be written covariantly as

$$H^0_{mnp}=l_{[m}A^0_{np]}, \tag{98}$$

where A^0_{np} is a constant polarization two-form. It is determined only up to

$$A^0_{np}\rightarrow A^0_{np}+l_{[n}A^0_{p]}, \tag{99}$$

where A^0_p is a constant one-form.

We now make the further assumption that

$$l^m H_{mnp}=0. \tag{100}$$

The reason we have to assume (100) is that quantities $H^0_{01\alpha}$ are not constrained by Eq. (96). In order to eliminate this freedom we are in effect assuming that

$$H^0_{01\alpha}=0. \tag{101}$$

Having made this ansatz, i.e., assuming (98), (100), it follows that

$$H_{lmn}H^{lmn}=0. \tag{102}$$

Thus $Q=1$ and hence $C^{mn}=G^{mn}$.

It remains to solve the self-duality condition. Now using (24) we see that the fivebrane metric is of the so-called Kerr–Schild form:

$$G^{mn}=\eta^{mn}-\text{constant}\, f^2 l^m l^n. \tag{103}$$

The constant is positive. To evaluate it we could introduce a (nonunique) null vector n^m, normalized so that

$$\eta_{mn}n^m l^n=-1. \tag{104}$$

One then has

$$\text{constant}=(H^{0^2})_{mn}n^m n^n. \tag{105}$$

Because l^m is null [i.e., from (94)] it follows that

$$G_m{}^q H_{npq}=H_{npm}. \tag{106}$$

Thus the self-duality condition (26) becomes

$$\star H_{lmn}=H_{lmn}, \tag{107}$$

which is the same as the condition for the linear theory.

Using Hooke's Law (1) we deduce that the energy momentum tensor is given by

$$T^{mn} = \text{constant}\, f^2 l^m l^n. \tag{108}$$

Equation (108) is the energy momentum tensor of a fluid of energy density constant moving at the speed of light in the direction l^m. This is often referred to as a null fluid. We shall encounter null fluids again later when we examine the energy momentum tensor in the strong coupling limit.

IX. THE $SO(5)$ COVARIANT FORMALISM AND THE LIMITING FIELD STRENGTH

Born–Infeld theory has a built in upper-bound for the electric field strength. The string theoretic interpretation is that when electric fields approach the limiting field strength, copious pair production of open string states occurs.[14,15] One may ask whether a similar phenomenon takes place in M-Theory.[10]

In Born–Infeld theory one must take care to express the upper-bound in terms of the correct variables. The Lagrangian density is

$$L = 1 - \sqrt{1 - \mathbf{E}^2 + \mathbf{B}^2 - (\mathbf{E}\cdot\mathbf{B})^2}, \tag{109}$$

which shows that the electric field **E** cannot be too big for fixed **B** since then the Lagrangian density becomes complex. However the Hamiltonian density[16] is

$$\mathcal{H} = \sqrt{1 + \mathbf{B}^2 + \mathbf{D}^2 + (\mathbf{B}\times\mathbf{D})^2} - 1. \tag{110}$$

This shows that there is no limit on either the magnetic induction **B** or electric inductions **D**. However the dual Lagrangian[16] is

$$\hat{L} = \sqrt{1 - \mathbf{H}^2 + \mathbf{D}^2 - (\mathbf{D}\cdot\mathbf{H})^2} - 1, \tag{111}$$

which indicates that there is an upper-bound on the magnetic intensity **H**, as there has to be, by electric–magnetic duality invariance. This point is re-enforced by considering the dual Hamiltonian,[16]

$$\hat{H} = 1 - \sqrt{1 - \mathbf{H}^2 - \mathbf{E}^2 + (\mathbf{H}\times\mathbf{E})^2}. \tag{112}$$

In the case of the M5-brane we have a similar range of possible choices of field variables. The fivebrane has a self-duality condition which means that if we define

$$B_{ij} = -\frac{1}{6}\epsilon_{ijklm}H^{klm}, \quad E_{ij} = H_{0ij}, \tag{113}$$

where $i,j,k,.. = 1,2,\ldots,5$, then we can express E_{ij} in terms of B_{ij} and *vice versa*. Thus the energy density $T_{00} = \mathcal{H}$ can be expressed in terms of either variable. To achieve this we will have in effect to solve the self-duality constraint. The self-duality condition on H_{mnp} can be expressed as

$$H^{+}_{mnp} = Q^{-1}h_{mnp}, \quad H^{-}_{mnp} = 2Q^{-1}k_m{}^r h_{rnp}, \tag{114}$$

where $H^{\pm}_{mnp} = \frac{1}{2}(H_{mnp} \pm (1/3!)\,\epsilon_{mnprst}H^{rst})$. In the special frame used above one then finds that

$$B_1 = \frac{e_1}{1 - 4(e_1^2 - e_2^2)}, \quad B_2 = \frac{e_2}{1 + 4(e_1^2 - e_2^2)}, \tag{115}$$

$$E_1 = \frac{e_1}{1 + 4(e_1^2 - e_2^2)}, \quad E_2 = \frac{e_2}{1 - 4(e_1^2 - e_2^2)}. \tag{116}$$

Inverting these equations leads to

$$8e_1=\frac{B_1}{B_2^2-B_1^2}\sqrt{1+16B_2^2}[\sqrt{1+16B_2^2}-\sqrt{1+16B_1^2}], \tag{117}$$

and

$$8e_2=\frac{B_2}{B_1^2-B_2^2}\sqrt{1+16B_1^2}[\sqrt{1+16B_1^2}-\sqrt{1+16B_2^2}]. \tag{118}$$

Note that

$$E_1E_2=B_1B_2. \tag{119}$$

The required solutions of the self-duality constraint are therefore

$$E_1=B_1\sqrt{\frac{1+16B_2^2}{1+16B_1^2}},\quad E_2=B_2\sqrt{\frac{1+16B_1^2}{1+16B_2^2}}, \tag{120}$$

or inversely,

$$B_1=E_1\sqrt{\frac{1-16E_2^2}{1-16E_1^2}},\quad B_2=E_2\sqrt{\frac{1-16E_1^2}{1-16E_2^2}}. \tag{121}$$

Expressing the energy momentum tensor in terms of h_{mnp} and using the relations of section four we find that

$$T_{00}=\frac{1+16(e_1^2-e_2^2)+8(e_1^2+e_2^2)}{1-16(e_2^2-e_1^2)^2}-1. \tag{122}$$

Using the above equations we conclude that

$$T_{00}=\sqrt{(1+16B_1^2)(1+16B_2^2)}-1. \tag{123}$$

The expression for the energy density (123) may be cast in the $SO(5)$ covariant form,

$$\mathcal{H}=\sqrt{\det(\delta_{ij}+4B_{ij})}-1=(\det(\delta_{ij}+16B_{ik}B_{jk}))^{1/4}-1. \tag{124}$$

A Hamiltonian density was derived from the action formulation of the five-brane in Ref. 17 Our $\mathcal{H}$ coincides with that Hamiltonian density.

From (116) and (123) we have

$$E_1=\frac{1}{16}\frac{\partial\mathcal{H}}{\partial B_1},\quad E_2=\frac{1}{16}\frac{\partial\mathcal{H}}{\partial B_2}, \tag{125}$$

which may be cast in the manifestly $SO(5)$-covariant form:

$$E_{ij}=\frac{1}{16}\frac{\partial\mathcal{H}}{\partial B_{ij}}=\frac{(1-8\ \mathrm{Tr}\,B^2)B_{ij}+16B_{ij}^3}{\sqrt{1-8\ \mathrm{Tr}\,B^2+(16)^2W_i^2}}, \tag{126}$$

where

$$W_i=\tfrac{1}{8}\epsilon_{ijrst}B^{jr}B^{st}. \tag{127}$$

Now the Legendre transform of the Hamiltonian density is

$$\hat{\mathcal{H}}=1-\sqrt{(1-16E_1^2)(1-16E_1^2)}=1-\sqrt{\det(\delta_{ij}+4\sqrt{-1}E_{ij})}, \tag{128}$$

so that

$$\hat{\mathcal{H}}+\mathcal{H}=\tfrac{1}{2}E_{ij}B^{ij} \tag{129}$$

and

$$B_{ij}=\frac{1}{16}\frac{\partial\hat{\mathcal{H}}}{\partial E_{ij}}=\frac{(1+8\ \mathrm{Tr}\,E^2)E_{ij}+16E_{ij}^3}{\sqrt{1+8\ \mathrm{Tr}\,E^2+(16)^2U_i^2}}, \tag{130}$$

where

$$U_i=\tfrac{1}{8}\epsilon_{ijrst}E^{jr}E^{st}. \tag{131}$$

In our special frame this equation reduces to (121). For a helpful review of the various formulations of the 5-brane equations of motion which covers some of this material the reader is referred to Ref. 18.

The Hamiltonian density $\mathcal{H}$ is a well defined convex function for all finite values of the magnetic induction B_{ij}. The Legendre transform maps all of B_{ij} space in a one–one fashion onto the open region of E_{ij} space for which the dual Hamiltonian density $\hat{\mathcal{H}}$ is a well defined convex function. That is for which the matrix $\delta_{jk}-16E_{ji}E_{ki}$, which occurs in the dual Hamiltonian, is positive definite. In our special frame, the allowed region is just $4|E_1|<1$ and $4E_2<1$.

The Bianchi identities read as

$$\partial_i B_{ij}=0, \quad \frac{\partial B_{ij}}{\partial t}+\frac{1}{2}\epsilon_{ijkrs}\partial_k E_{rs}=0. \tag{132}$$

Taking the solution (126) for the self-duality condition implies the equations of motion.

X. STRONG COUPLING LIMIT

We are now going to discuss the strong coupling limit of the theory. This is equivalent to taking the tension of the fivebrane to zero and may be thought of as a high energy limit. We shall find that the situation is similar to that of the strong coupling limit of Born–Infeld theory in four spacetime dimensions which has been thoroughly investigated by Białynicki-Birula and called by him UBI theory.[16,19] In that case, the Lagrangian vanishes, but there is a well defined Hamiltonian. Moreover the theory is Lorentz invariant and has the energy momentum tensor of a null fluid. As a consequence there are infinitely many conserved currents in flat spacetime. Because the invariants $F_{\mu\nu}F^{\mu\nu}$ and $F_{\mu\nu}\star F_{\mu\nu}$ both vanish on shell one might speculate that the theory is quantum mechanically finite. As we shall see, there is just as much evidence to warrant a similar speculation about the M-Theory version.

The limit we are considering differs from that discussed in Refs. 10, 20

To proceed we introduce into the Hamiltonian a parameter T with the dimensions of mass cubed. We then take the limit $T\downarrow 0$. The Hamiltonian density is

$$\mathcal{H}=T^2\sqrt{\det\left(1+\frac{4B_{ij}}{T}\right)}-T^2. \tag{133}$$

Letting $T\downarrow 0$, we get the well defined limit

$$\mathcal{H}=16|B_1B_2|. \tag{134}$$

We now evaluate the energy momentum tensor in the strong coupling limit in terms of the variable B_{ij}. In this process we will find quantities that are nonvanishing only when one takes a next to leading contribution in T. One finds that in the limit of small T,

$$e_1\rightarrow \frac{2}{T}\frac{B_1B_2}{B_1+B_2}-\frac{T}{16}\frac{1}{B_1}\frac{B_1-B_2}{B_1+B_2}, \tag{135}$$

$$e_2\rightarrow \frac{2}{T}\frac{B_1B_2}{B_1+B_2}+\frac{T}{16}\frac{1}{B_1}\frac{B_1-B_2}{B_1+B_2}. \tag{136}$$

It follows that

$$e_1^2-e_2^2\rightarrow \frac{1}{4}\frac{B_1-B_2}{B_1+B_2}. \tag{137}$$

Reinstating the coupling constant T, the energy momentum tensor is given by

$$T_{mn}=-T^2\frac{m_{mn}^2}{Q}+T^2g_{mn}. \tag{138}$$

In the small T limit the only nonvanishing components are

$$T_{00}=16|B_1B_2|, \tag{139}$$

$$T_{55}=16|B_1B_2|, \tag{140}$$

$$T_{05}=-16B_1B_2. \tag{141}$$

Thus

$$T_{mm}=\mathcal{H}l_ml_n, \tag{142}$$

with

$$l^m=(1,0,0,0,0,1), \tag{143}$$

and

$$l^ml^ng_{mn}=0. \tag{144}$$

We have been working in a local frame. However, Eqs. (142) and (144) are manifestly covariant and hence hold in a general frame. In particular we have in general, that the null vector l^m is given by

$$l^m=(1,n^i), \tag{145}$$

where n^i is a unit vector in the direction of the Poynting vector T^{0i} and therefore

$$T^{om}=\mathcal{H}l^m. \tag{146}$$

From (142) we see that the trace of the energy momentum tensor vanishes,

$$T_m^m=0. \tag{147}$$

Thus we have shown that the theory is Weyl-invariant in the strong coupling limit. The energy momentum tensor (142) is the same form as the energy momentum tensor of the strong coupling limit of Born–Infeld theory, UBI theory.

Because the energy momentum tensor has the form of a null fluid (see Refs. 16, 19) one may easily check that one has infinitely many conservation laws. The conservation of energy equation $\partial_t T^{00}+\partial_i T^{0i}=0$ may be written covariantly as

$$\nabla_m(\mathcal{H}l^m)=0. \tag{148}$$

The remaining conservation law implies that

$$l^n\nabla_n l^l=0. \tag{149}$$

From (149) it follows that the integral curves tangent to l^m, that is the solutions of

$$\frac{dx^m}{d\lambda}=l^m, \tag{150}$$

are null geodesics with affine parameter λ. In fluid dynamic language (148) corresponds to the conservation of entropy, sometimes thought of as the ''photon'' number. The integral curves are thought of as the world lines of the fluid. In the case of UBI theory[16,19] it turns out[21] (cf. Ref. 22) that the fluid may be thought of as a gas of massless Schild strings.[23] In fluid dynamic language the world-sheets of the strings are the histories of magnetic field lines which are swept out with velocity l^m. We shall turn later to the possible fluid interpretation in the M5-brane case.

It follows from (148) and (149) that the tensors,

$$T^{m_1m_2\cdots m_k}=\mathcal{H}l^{m_1}l^{m_2}\cdots l^{m_k}, \tag{151}$$

satisfy

$$\nabla_m T^{mm_2\cdots m_k}=0, \tag{152}$$

for any positive integer k.

In flat spacetime the divergence identities (152) may be integrated over space to give rise to infinitely many conservation laws.

In order to cast the limiting equations of motion in a manifestly $SO(5)$ covariant form, we recall from (126) and (132) that

$$\frac{\partial B^{ij}}{\partial t}+\frac{1}{2}\epsilon^{ijrst}\partial_r\left\{\frac{(B-8(\mathrm{Tr}\,B^2)B+16B^3)_{st}}{\sqrt{1-8\,\mathrm{Tr}\,B^2+16^2W_i^2}}\right\}=0. \tag{153}$$

One may now re-instate T and then take the limit $T\downarrow 0$ in (153) to obtain

$$\frac{\partial B^{ij}}{\partial t}+\frac{1}{2}\epsilon^{ijrst}\partial_r\left\{\frac{(-\frac{1}{2}(\mathrm{Tr}\,B^2)B+B^3)_{st}}{\sqrt{W_i^2}}\right\}=0. \tag{154}$$

Using the identity

$$(-\mathrm{Tr}\,B^2B+2B^3)^{ij}=\epsilon^{ijklm}W_kB_{lm}, \tag{155}$$

we may show that in the limit, the electric field becomes

$$E^{ij}=\frac{1}{2}\epsilon^{ijrst}\frac{W_r}{\sqrt{W_k^2}}B_{st}, \tag{156}$$

and the field equation becomes

$$\frac{\partial B_{ij}}{\partial t}+\frac{1}{4}\epsilon_{ij}{}^{klm}\partial_k\epsilon_{lmrst}\frac{W^rB^{st}}{\sqrt{W_p^2}}. \tag{157}$$

This is very similar in form to the Born–Infeld case.[16,19] One may also give an $SO(5,1)$ covariant formulation of the 5-brane in the $T\downarrow 0$ limit. It is sufficient to derive the self-duality conditions in this limit as they, together with the Bianchi Identity, imply the field equations.

By multiplying through by m^{-1}, the self-duality condition $*H_{abc}=Q^{-1}(m^2)_a{}^eH_{ebc}$ can be reexpressed as

$$(m^{-1})_a{}^e*H_{ebc}=Q^{-1}(m)_a{}^eH_{ebc} \tag{158}$$

or

$$(1+2k)_a{}^e*H_{ebc}=Q^{-1}(1-2k)_a{}^eH_{ebc}\,. \tag{159}$$

Taking the limit and using the equation for k in terms of H^2 we find that the self-duality condition can be expressed covariantly as

$$(H^2)_a{}^e*H_{ebc}=\left(\tfrac{1}{3}H^2\delta_a^e-(H^2)_a{}^e\right)H_{ebc}\,. \tag{160}$$

In view of the interpretation of the strong coupling limits of Born–Infeld theory as string fluids,[22] it is of interest to consider the detailed structure of the three-form H. Point-wise, i.e. locally, it may be expressed in the general case as

$$H=E_1\,dt\wedge dx^1\wedge dx^2+E_2\,dt\wedge dx^3\wedge dx^4-B_2\,dx^5\wedge dx^1\wedge dx^2-B_1\,dx^5\wedge dx^3\wedge dx^4, \tag{161}$$

$$\star H=E_1\,dx^3\wedge dx^4\wedge dx^5+E_2x^1\wedge dx^2\wedge dx^5+B_2\,dt\wedge dx^3\wedge dx^4+B_1\,dt\wedge dx^1\wedge dx^2. \tag{162}$$

In the strong coupling limit we get the well defined limits,

$$H=(dt-dx^5)\wedge(B_2\,dx^1\wedge dx^2+B_1\,dx^4\wedge dx^5), \tag{163}$$

$$*H=(dt-dx^5)\wedge(B_2\,dx^2\wedge dx^3+B_1\,dx^1\wedge dx^2). \tag{164}$$

By contrast since

$$h=e_1(dt\wedge dx^1\wedge dx^2-dx^5\wedge dx^3\wedge dx^4)+e_2(dt\wedge dx^3\wedge dx^4-dx^5\wedge dx^1\wedge dx^2), \tag{165}$$

the three-form h_{lmn} diverges in the limit of small T,

$$h\rightarrow\frac{2}{T}\frac{B_1B_2}{B_1+B_2}(dt-dx^5)(dx^1\wedge dx^2+dx^3\wedge dx^5). \tag{166}$$

We see that in the limit H and $\star H$ contain a one-dimensional null factor $dt-dx^5=-l_m\,dx^m$, with

$$H_{lmn}l^n=0,\quad \star H_{lmn}l^n=0. \tag{167}$$

It is tempting to give the stress tensor an interpretation in terms of a fluid of p-branes. The null vector l^m clearly provides us with the velocity of the putative fluid and since it is null, we should expect a null fluid analogous to the gas of null or Schild strings[23] considered in Ref. 24 and elaborated in Refs. 25, 26 in four dimensions. In the case of UBI theory[16,19] one has the condition

$$\sqrt{\det(F_{\mu\nu})}=\tfrac{1}{4}F_{\mu\nu}\star F^{\mu\nu}=\mathbf{E}\cdot\mathbf{B}=0. \tag{168}$$

This is equivalent to the simplicity condition

$$F \wedge F = 0, \tag{169}$$

which implies the existence of one-forms a_μ and b_μ such that

$$F_{\mu\nu} = a_\mu b_\nu - a_\nu b_\mu . \tag{170}$$

The co-vectors a_μ and b_μ are not unique; one may choose them such that $a_\mu b^\mu = 0$. Thus, in the tangent space at each point of spacetime, the two-form $F_{\mu\nu}$ is tangent to the two-plane spanned by a_μ and b_μ. The equations of motion imply the integrability condition that these two-planes mesh together to provide a foliation of spacetime by two-surfaces. If

$$F_{\mu\nu} F^{\mu\nu} = 0, \tag{171}$$

then the two-plane is null, and one of the co-vectors, call it a_μ, is null and the other spacelike. Therefore

$$F_{\mu\nu} = l_\mu b_\nu - l_\nu b_\mu . \tag{172}$$

The null vector l_μ satisfies

$$F_{\mu\nu} l^\nu = 0. \tag{173}$$

If (171) then the principal null directions of the two-form $F_{\mu\nu}$ coincide and may be identified with l^μ. One may regard b_μ as the (un-normalized) tangent vector to the magnetic field lines and obtain in this way a picture of the solutions of classical Born–Infeld field theory, subject to the simplicity constraint (168) or (169), as a fluid of strings. This viewpoint is similar to that originally envisaged by Nielsen and Olesen.[27]

In the case of the M5-brane, we have a three-form and one might have thought that some sort of null membrane is involved. However although the three-forms H and and $\star H$ both have a null factor neither quotient two-form, that is neither

$$B_2\, dx^1 \wedge dx^2 + B_1\, dx^4 \wedge dx^5 \quad \text{nor} \quad B_2\, dx^2 \wedge dx^3 + B_1\, dx^1 \wedge dx^2 \tag{174}$$

is simple. Therefore no obvious membrane world volume is picked out.

We observe that this limiting theory admits an infinite number of conserved charges that carry Lorentz indices. Presumably (cf. Ref. 28) the scattering of particlelike excitations is trivial in this limit. It is not obvious whether this is true for 2-branes and 5-branes since they have internal degrees of freedom associated to their world volumes.

(Received 2 January 2001; accepted for publication 13 February 2001)

We show how a recently proposed large N duality in the context of type IIA strings with $\mathcal{N}=1$ supersymmetry in 4 dimensions can be derived from purely geometric considerations by embedding type IIA strings in M-theory. The phase structure of M-theory on G_2 holonomy manifolds and an S^3 flop are the key ingredients in this derivation. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1376159]

I. INTRODUCTION

String propagation in the presence of branes has been studied from many different angles, and has been the intersection point of many fruitful ideas in the context of dualities. A beautiful example of it is in the context of the AdS/CFT correspondence.[1] This idea is a refinement of the statement that if we consider strings in the presence of branes, in certain regime of parameters the system is better described by strings propagating on the gravitational back reaction of light string modes to the presence of branes. This is an example of duality in the sense that two different theories are continuously connected by a change in parameters. On the one end one has a geometry involving branes and on the other extreme the geometry has been deformed and the branes have disappeared.

A recent example of a large N duality in type IIA superstring, was proposed in Ref. 2 based on embedding the large N Chern–Simons/topological gravity duality of Ref. 3 in type IIA superstrings. The duality states that if we consider N D6-branes wrapped on an S^3 in the deformed conifold geometry T^*S^3, then the same system is equivalent to a type IIA geometry where the D-branes have disappeared but where an S^2 has blown up so that the CY geometry is the $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$. [Mathematicians use the terminology ''quadric'' for the deformed conifold and ''quadric cone'' for a singular quadric. The small resolution of conifold is called the small resolution (blow up) of the quadric cone.] In other words, the topology is that of the so called ''small resolution'' of the conifold, where the S^2 has finite size. Moreover there are N units of 2-form field strength flux through $\mathbf{P}^1$, and the complexified Kahler parameter t of $\mathbf{P}^1$ is related to the volume V of the S^3 and the string coupling constant g_s by

$$(e^t-1)^N=a\exp(-V/g_s). \tag{1.1}$$

Note that for large V and when $Ng_{\mathrm{YM}}^2=Ng_s/V\ll 1$, the wrapped D-brane description is good and the blown up description is bad as $t\to 0$, and when $t\gg 0$ where the blown up $\mathbf{P}^1$ description is good the $V\to-\infty$ and the original wrapped D-brane description is bad. In this sense we only really have at most one good description in each regime of parameters and the parameters being related by (1.1). This situation is similar to other cases one encounters in the context of large N string

a)Electronic mail: vafa@string.harvard.edu

dualities. For example with N D3 branes in R^{10} if $Ng_{\rm YM}^2 = Ng_s \ll 1$ the D-brane description ignoring the gravitational backreaction is fine; when $Ng_s \gg 1$ the gravitationally deformed background description without the D-brane is the right description.

Our main aim in this paper is to embed this type IIA duality in M-theory. We find that the statement of this duality in the context of M-theory translates to a simple geometric duality. Turning it around, we can derive the type IIA string duality of Ref. 2 from its relation with M-theory.

The organization of this paper is as follows. In Sec. II we review a perturbative string theory duality which is a good exercise for the M-theory duality of interest. In Sec. III we discuss M-theory in a 7 dimensional background with G_2 holonomy and a simple geometric duality. In Sec. IV we reinterpret the M-theory duality in the context of type IIA strings and obtain the duality of Ref. 2. In the Appendix we discuss some aspects of the G_2 holonomy metric.

The derivation of the large N duality in this case reinforces the philosophy advocated in Refs. 3 and 2 that large N dualities in general correspond to transitions in geometry. It would be interesting to try to understand other large N dualities in the same spirit.

While we were completing this paper we received Ref. 4 which has some overlap with this paper.

II. A STRING THEORY DUALITY

Consider type IIA superstrings propagating on a noncompact CY background given by a $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$. A powerful worldsheet description of this sigma model is in terms of linear sigma model[5] where one considers a (2,2) supersymmetric $U(1)$ gauge theory with four fields $(\Phi_1,\Phi_2,\Phi_3,\Phi_4)$ with charges $(+1,+1,-1,-1)$, with an FI term given by r and a $U(1)\,\theta$ angle. The low energy vacuum of this theory is characterized by

$$\mathcal{V}: |\Phi_1|^2+|\Phi_2|^2-|\Phi_3|^2-|\Phi_4|^2=r. \tag{2.1}$$

The actual vacuum of this theory is given by the gauge inequivalent solutions to (2.1), i.e., one considers $\mathcal{V}/U(1)$. This can be naturally identified with a $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$. If we take $r>0$ the $\mathbf{P}^1$ is identified as the locus $\Phi_3=\Phi_4=0$, and the normal directions are identified with Φ_3 and Φ_4. This space is also called the ''small resolution'' of the conifold, where the S^2 has a finite size.

An important aspect of this theory is its phase structure and in particular what happens as $r \to 0$. In fact the natural phase structure for this theory is parameterized by the *complex* parameter,

$$t = r + i\,\theta.$$

It turns out that both positive and negative r make sense and in fact are smoothly connected if we vary the θ because the only singularity in the moduli space of this theory is at the origin $t=0$. From the equation (2.1) one may naively have thought that there should be some singularity at $r=0$ for all θ, but this is lifted by worldsheet instanton corrections. Of course there is a simple reason why this had to happen. The structure of (2,2) supersymmetry leads to a naturally complex moduli space and it does not allow any real locus singularity in moduli space.

A. A perturbative string duality

From the above description we notice a symmetry: If we replace $t \to -t$ we obtain the same geometry with the role of the $(\Phi_1,\Phi_2) \leftrightarrow (\Phi_3,\Phi_4)$ exchanged. Geometrically this is called a flop. Even though in the geometric setup there is a discontinuity at $r=0$, and one just considers either $r>0$ or $r<0$, the situation in string theory is different because of the θ angle. Both regions are smoothly connected. In particular if we start with $r \gg 0$ and do some computations as a function of t, then an analytic continuation of these quantities by $t \to -t$ should yield the answers for the other side. This in fact was directly checked at the level of instanton computations on both sides.[5,6] In particular the worldsheet instantons at genus 0 (with three points fixed on S^2) have a partition function,

$$\partial_t^3 F_0 = C + \frac{q}{1-q},$$

where $q = e^{-t}$ (the constant term C is somewhat ambiguous and is related to the classical triple intersection of the 4-cycle dual to $\mathbf{P}^1$). This makes sense as an instanton expansion when $r \gg 0$. However if we analytically continue this quantity to $t \to -t$ we obtain in terms of $\tilde{q} = 1/q$,

$$-\partial_t^3 F_0 = 1 - C + \frac{\tilde{q}}{1-\tilde{q}},$$

which is the statement of the symmetry under $t \to -t$. The shift in the constant term is reflecting the geometric fact that under flop the classical triple intersection shifts by one.

Suppose however we consider a modified theory where we mod out the Φ_i's by some discrete group G which does not necessarily act symmetrically under the exchange $(\Phi_1, \Phi_2) \leftrightarrow (\Phi_3, \Phi_4)$. Let us call the resulting theory $Q_G[t]$, exhibiting explicitly the dependence of the theory Q on the choice of the group G as well as the (complexified) size of $\mathbf{P}^1$ given by t. Now we ask what happens when we consider $t \to -t$. In this case in general we do not come back to the same theory because of the asymmetric action of G. We obtain

$$Q_G[-t] = Q_{G'}[t], \tag{2.2}$$

where G' is related to G by conjugation with the element exchanging the pairs,

$$U: (\Phi_1, \Phi_2) \leftrightarrow (\Phi_3, \Phi_4),$$

$$G' = UGU^{-1}.$$

To better appreciate the content of this duality statement let us consider a simple example. Consider the case where G is generated by the element

$$(\Phi_1, \Phi_2, \Phi_3, \Phi_4) \to (\omega \Phi_1, \omega^{-1} \Phi_2, \Phi_3, \Phi_4),$$

where ω is an n-th root of unity (this can also be viewed as introducing an additional Z_n gauge group). Geometrically this corresponds to considering the following action on $O(-1) + O(-1)$ over $\mathbf{P}^1$:

$$(\zeta_1, \zeta_2, z) \to (\omega \zeta_1, \omega \zeta_2, \omega^{-2} z),$$

where z denotes the coordinate of $\mathbf{P}^1$ (say near the north pole) and ζ_i denote the coordinates of the bundle $O(-1) + O(-1)$ over it. Note in particular that modding by this group leads to two orbifold singularities, namely the north and south poles at the origin of the ζ_i. The group G' on the other hand is obtained by conjugating G with U and is generated by

$$(\zeta_1, \zeta_2, z) \to (\omega \zeta_1, \omega^{-1} \zeta_2, z).$$

This is a very different group action from G and in particular it leads to an A_{n-1} singularity over $\mathbf{P}^1$. Thus changing $t \to -t$ has led to a totally new but nevertheless ''dual'' theory. Note that this duality is a perturbative string duality (i.e., can be understood genus by genus in worldsheet expansion).

III. AN M-THEORY DUALITY

We will be interested in compactifications of M-theory on G_2 holonomy manifolds (see Ref. 7 for the construction of some compact 7-manifolds with G_2 holonomy). This leads to $\mathcal{N} = 1$ supersymmetry in $d = 4$. In the compact case, the number of moduli of the Ricci-flat metric is given by the dimension of the third homology of the manifold, i.e. b_3. The point on the moduli

space of Ricci-flat metrics can be characterized by the volume of some basis for 3-cycles. (In the noncompact case there could be additional deformations which change the asymptotic behavior of the metric at infinity.) Physically we know that these should correspond to lowest components of chiral fields in $\mathcal{N}=1$ supersymmetry multiplets. Thus one again expects a complexification of the volumes. In fact this happens because there is a 3-form gauge field C in M-theory and its vev about each 3-cycle leads to the complexification of the volume elements. Moreover the moduli space of M-theory compactifications are given by analytic expressions and thus singularities occur in *complex* codimension 1 and higher. Thus there are in particular no boundary walls in moduli space of M-theory.

Let us now come to the concrete example that we will be interested in. Consider the noncompact 7-manifold given by the spin bundle over S^3. This has the topology of $R^4\times S^3$ and admits a G_2 holonomy metric. We will present the metric later in this section. The topology of the manifold can be viewed as

$$(u_1^2+u_2^2+u_3^2+u_4^2)-(v_1^2+v_2^2+v_3^2+v_4^2)=V,$$

where u_i, v_i are real parameters. For $V>0$ the S^3 is identified as the locus $v_i=0$, and v_i correspond to the R^4 normal directions over S^3. Note that if we consider $V<0$ then the role of the u's and v's have been interchanged and another S^3 blows up, corresponding to $u_i=0$. We can also write this in complex notation by

$$(|z_1|^2+|z_2|^2)-(|z_3|^2+|z_4|^2)=V,$$

where z_i are complex variables. It should be emphasized that the G_2 holonomy manifold does not admit a complex structure (it is odd dimensional) and so there is no intrinsic meaning to writing the equation in terms of complex coordinates, other than for simpler book keeping. We can also use a quaternionic notation and write it as

$$|q_1|^2-|q_2|^2=V.$$

We can view the quaternion as $q_1=\Sigma_i u_i\sigma_i$ and $q_2=\Sigma_i v_i\sigma_i$, where σ_i denotes the realization of quaternionic generators as 2×2 matrices. This way of writing it suggests that one can have $SU(2)^{1,2}_{L,R}$ symmetries, which act on each quaternion, as left and right multiplication by $SU(2)_{L,R}$. This is the same, as the *Spin*(4) action on the u's or on the v's.

A G_2 holonomy metric can be defined on this manifold.[8,9] It is given as

$$ds^2=\alpha^2\,dr^2+\gamma^2(\tilde{w}^a)^2+\beta^2\left(w^a-\tfrac{1}{2}\tilde{w}^a\right)^2, \tag{3.1}$$

with

$$\alpha^{-2}=1-\frac{a^3}{r^3},\quad \beta^2=\frac{r^2}{9}\left(1-\frac{a^3}{r^3}\right),\quad \gamma^2=r^2/12, \tag{3.2}$$

where $\tilde{w}^a$ and w^a are the left invariant one-forms on S^3 and S^3, respectively. The two S^3's are associated to each of the two quaternions at a fixed norm, and the r variable fills one of the S^3's depending on the sign of V. In the form shown above $r\geqslant a$ and it fills the S^3 associated with the left invariant one-forms w^a, while $\tilde{w}^a$ are associated with $\tilde{S}^3$ which is topologically nontrivial. Note that the volume of the $\tilde{S}^3$ is proportional to a^3. This G_2 holonomy metric has an $[SU(2)]^3$ isometry group,

$$SU(2)^1_L\times SU(2)^2_L\times[SU(2)^1_R\times SU(2)^2_R]_D,$$

where $SU(2)^i_{L,R}$ denotes the L, R multiplication of q_i by the $SU(2)$ group and D denotes the diagonal subgroup. This is almost obvious from the above presentation of the metric, where $SU(2)^i_L$ do not act on the left invariant forms and so do not modify the metric. The left invariant

1-forms transform in the adjoint representation of the corresponding $SU(2)_R$. The diagonal combination of $SU(2)_R^i$ leaves the metric invariant [the last term in the metric is what requires choosing the diagonal $SU(2)_R$ as the symmetry group]. To fix notation let us associate $SU(2)^1$ with the $\tilde{S}^3$ sphere and $SU(2)^2$ with the contractible S^3. The space (3.1) is asymptotic to a cone whose base has $\tilde{S}^3 \times S^3$ topology,

$$ds^2 \sim dr^2 + \frac{r^2}{9}[(\tilde{w}^a)^2 + (w^a)^2 - \tilde{w}^a w^a].$$

As we will note later, when we discuss the connection to type IIA string theory we expect a one parameter family of G_2 holonomy metric deformations which breaks the $SU(2)_L^i$ to $U(1)$, for either $i=1$ or $i=2$.

As noted above, in the context of M-theory propagating in this background the moduli space of the theory is parametrized in addition to the volume V of the S^3 by the flux of the C-field through it. Let us denote this complex combination by $V_M = V + iC$. Just as in the case of string propagation on the $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$, the phase structure of M-theory as a function of V_M is expected to have a singularity at most only at the origin and that turning on the C-field should smooth out the singularity where $V=0$ in moduli space. This follows from the number of supersymmetries we are preserving in 4 dimensions and the fact that V_M is the lowest component of a chiral field. A similar situation (with twice as many supersymmetries) in the context of M-theory and type IIA strings on Calabi–Yau threefolds containing an S^3 was analyzed in Ref. 10 where it was shown that Euclidean M2-brane instantons modify the moduli space and in fact remove the singularity at $V=0$. Here also we expect the same to be true, though we do not know how to rigorously argue this. At any rate we can argue, based on supersymmetry alone, that a singularity at most will happen at isolated points in moduli space, and for the theory at hand this means potentially only at $V_M=0$ (in particular $V=0$ and $C\neq 0$ is not a singular point). This observation implies that we can continuously go from regions where the real part of V_M is large and positive to regions where it is large and negative without encountering any singularity. (For a discussion of topology change in the context of G_2 holonomy manifolds see the recent work.[11]) Moreover it is clear that $V_M \to -V_M$ is a flop, and otherwise gives rise to an equivalent ''dual'' M-theory background. Let us denote M-theory in the presence of this background by $Q[V_M]$. Then we have

$$Q[V_M] = Q[-V_M].$$

Notice that for positive V_M, S^3 is contractible in the full geometry and $\tilde{S}^3$ is topologically nontrivial while the opposite is true of negative V_M.

Parallel to our discussion of the string duality in the previous section, we can consider modding out by some group actions which are isometries of the G_2 holonomy manifold. As discussed in the Appendix this leads to manifolds (possibly with singularities) which continue to have G_2 holonomy. In this way we obtain a statement of duality where

$$Q_G[-V_M] = Q_{G'}[V_M],$$

where $G = UG'U^{-1}$ and U is the Z_2 outer automorphism exchanging the u's and the v's, and acts on the $SU(2)$'s as

$$U[SU(2)_{L,R}^{1,2}]U^{-1} = SU(2)_{L,R}^{2,1}.$$

The special case we will be interested in is when G is generated by a Z_N subgroup of $SU(2)_L^2$. In complex coordinates we can view this transformation as

$$g\colon\ (z_1, z_2, z_3, z_4) \to (z_1, z_2, \omega z_3, \omega z_4).$$

Then G' is generated by

$$g':\ (z_1,z_2,z_3,z_4)\to(\omega z_1,\omega z_2,z_3,z_4),$$

and we have an M-theory duality,

$$Q_G[-V_M]=Q_{G'}[V_M]. \tag{3.3}$$

Let us consider $Q_G[V_M]$ when $V\gg 0$. In this case the element g acts with a fixed point: The $\tilde{S}^3$ defined by $z_3=z_4=0$. Moreover the singularity is of the type of A_{N-1} singularity as the normal direction is R^4/Z_N in the usual action of Z_N on R^4. As is well known, this singularity in M-theory gives rise to an $SU(N)$ gauge symmetry on the singular locus. In the present case, taking the number of supersymmetries into account, we have an $\mathcal{N}=1$ supersymmetric $SU(N)$ Yang–Mills gauge theory living on $\tilde{S}^3$ times the Minkowski space. On the other hand when we consider $Q_{G'}[V_M]$ for $V\gg 0$, the g' corresponds to the Z_N action with no fixed points (the would be fixed point locus $z_1=z_2=0$ is not on the manifold for $V\gg 0$).

A. Gauge theoretic interpretation of the duality

From (3.3) we see that M-theory in one background is continuously connected with another one. In particular $Q_G[V_M]$ when $V\gg 0$ contains as light excitations an $\mathcal{N}=1$ Yang–Mills sector in 4 dimensions with the Yang–Mills coupling given by

$$\frac{1}{g^2_{\mathrm{YM}}}+i\theta=V_M,$$

where g^2_{YM} should be viewed as the gauge coupling at the Planck scale. As we know the coupling will start to run. More precisely, the effective coupling constant depends on the scale we probe. Through the above relation we see that V_M itself should run and its value will depend on which scale we measure it at. In particular $V_M(\mu)$ should decrease logarithmically at infrared as

$$V_M(\mu)=V_M+\text{const}\log\frac{\mu}{M_{pl}}.$$

This running should be induced by quantum effects in the presence of the Z_N singularity in measuring the volume of S^3, which is at the singular locus. For small μ, we expect V_M to become small. In fact if we trust the above formula we seem to get a *negative* volume V_M. Even though this is not allowed in the usual gauge theory (negative $1/g^2_{\mathrm{YM}}$ naively does not make sense), here we can make sense of negative V_M as a flop. In fact we are thus led to view the infrared behavior of the same theory at negative and large values of $V\ll 0$. However this theory for negative V is best viewed as the dual theory $Q_G[-V_M]=Q_{G'}[V_M]$, in terms of which there is no singularity in geometry and we obtain an $\mathcal{N}=1$ theory in four dimensions with no sign of $SU(N)$ gauge symmetry. This is exactly what one expects for a confining gauge theory. Moreover we should see N vacua. This is also present here; the G' group corresponds to modding out the S^3 by a Z_N. So the volume of the final S^3 is smaller by a factor of $V\to V/N$. However we also have to decide about the choice of the theta angle. If we change the theta angle by $2\pi k$ on S^3, which in the original $Q_G[V_M]$ corresponds to not changing the theory at all, as we go to negative V_M, it does give rise to a change. Namely quotienting the S^3 by a Z_N gives rise to a fractional change in the C-flux of the quotient theory by $2\pi k/N$. Thus we obtain N choices for the phase of the theory in the infrared. These are the N vacua of $\mathcal{N}=1$ supersymmetric $SU(N)$ Yang–Mills, and we have thus found a purely geometric interpretation of them. One can also identify the domain wall of the $\mathcal{N}=1$ system with the $M5$-brane wrapped over S^3/Z_N.

IV. RE-INTERPRETATION OF THE M-THEORY DUALITY IN TYPE IIA STRING

We now view the same geometry from the type IIA perspective. In order to do this we need to choose the ''11-th'' circle. There are many ways to do this. In order to connect this to the duality of Ref. 2 we identify the 11-th direction with the fibers of the $U(1)$ sitting in $SU(2)_L^2$, where the Z_N that we modded out in the previous section, is a subgroup of it. In other words $Z_N \subset U(1) \subset SU(2)(2)_L^2$. We start with $Q_G[V_M]$ with $V \gg 0$. Kaluza Klein reducing along this circle produces an R^3 fibration over $\tilde{S}^3$ with a singularity at the origin. The singularity at the origin has the interpretation of a $D6$-brane, before modding out by Z_N, or N units of $D6$-branes after modding out. Thus we expect this to correspond to type IIA string theory on the conifold background T^*S^3 with N D6-branes wrapped around S^3. A more precise statement is the following. Suppose we start with the deformed conifold before we put any branes on it. In M-theory we add an extra circle of constant radius so that we have a seven dimensional geometry which is the deformed conifold times a circle. Now we add N D6-branes on $\tilde{S}^3$. At large distances from the D6-branes, the presence of the branes is signaled in IIA theory by the presence of a two-form field strength on the surrounding S^2. When we lift this up to M-theory this means that the eleventh circle S^1 is nontrivially fibered over the S^2. In fact the total topology of this S^1 fibration over S^2 ends up being that of S^3/Z_N. (Notice that for $N=1$ we just have S^3.) For very large r we expect that the dilation will be constant, so that the size of the S^1 fiber is constant, while the size of $S^2 \times \tilde{S}^3$ should grow. For small r, on the other hand, we enter the near horizon region of the six branes. The dilation decreases as we approach the ''core'' of a six-brane. In fact, the near horizon region of N six-branes in flat space lifts up in M-theory to an A_{N-1} singularity and the M-theory circle is just one of the angles on the three-sphere. So when we wrap this on $\tilde{S}^3$ we expect a geometry which is that of the region $r \sim a$ of (3.1). The asymptotics of (3.1) is not what we expect in the IIA situation since the radius of the M-theory circle continues to grow as $r \to \infty$. In fact the geometry (3.1) looks more like the infinite coupling limit of the IIA geometry, where we take the limit in such a way as to keep V_M finite. In principle we expect to find a gravity solution in M-theory that describes more precisely the situation we expect in IIA theory for a finite string coupling constant. That should be a deformation of the above G_2 holonomy metric where the $SU(2)_L^2$ symmetry of (3.1) is broken to $U(1)_L$ so that the circle can have a constant asymptotic size as $r \to \infty$. This deformation should exist for both signs of V_M which means, in terms of (3.1), that we should also find a second deformation where $SU(2)_L^1$ is broken to $U(1)$. This would describe the situation after the transition where, in IIA theory, we have the small resolution of the conifold with N units of F_2 flux. Again, we expect a solution where the string coupling asymptotes to a constant. Assuming this deformation of the metric exists, it is natural to expect that under the flop $V_M \to -V_M$ we get from one kind of deformation to the other. In other words the considerations of Sec. III should also apply to this deformed metric. With this assumption we now rederive the large N type IIA duality, including the identification of parameters on both sides in the geometric regime.

Let us denote the volume of the $\tilde{S}^3$ in the type IIA setup by V_A, and consider N D6-branes wrapped over it. Then from the map between M-theory parameters and type IIA parameters one deduces that

$$V_M = V_A / g_s , \tag{4.1}$$

where g_s is the type IIA coupling constant. Now let us consider the limit where $V_M \ll 0$. In this case the theory is better described by another M-theory background with group modding out by G', and where the volume of the S^3 is $-V_M$. Again we use the same 11-th direction for the circle fibration, which means that we choose G' to be a subgroup of the corresponding $U(1)$. Now the fibration we get gives a geometry which has an S^2 and the M-theory S^3 over it is a quotient of Hopf fibration by Z_N. This means, in the type IIA terminology that we have N units of RR 2-form field strength through S^2. Moreover the volume of the (minimal) S^2 is given, changing the parameters from M-theory to type IIA, as

$$t = -V_M/N. \tag{4.2}$$

This relation is trustable for large t where the supergravity description of M-theory would be adequate. Thus we see that we have a duality which in the type IIA description corresponds to N units of D6-branes wrapping the S^3 of volume V_A and on the other side an S^2 with N units of RR flux through it, with Kahler class t and with the relation [combining (4.1) and (4.2)]

$$t = \frac{-V_A}{Ng_s}. \tag{4.3}$$

This agrees, in the limit of large t, with the result obtained in Ref. 2:

$$(e^t - 1)^N = a \exp(-V_A/g_s). \tag{4.4}$$

The modified relation (4.4) includes the contribution of worldsheet instantons, which is neglected in the identification at the large volume limit given in (4.3). Note that in Ref. 2 the parameter t was identified as the lowest component of the gaugino chiral field $t = g_s \operatorname{Tr} W^2 = S$. Note that in the limit of large V, which corresponds to small t if we include the instanton correction, we deduce a gaugino condensation exactly as one would expect for the $\mathcal{N}=1$ Yang–Mills theory, namely in the form $S^N = \exp(-1/g_{\mathrm{YM}}^2)$ (where the g_{YM} is the Yang–Mills coupling constant at the string scale).

From the relation to M-theory it is natural that the worldsheet instantons know about gaugino condensation. This is similar to the worldsheet instantons for the flopped geometry in the $O(-1)+O(-1)$ over $\mathbf{P}^1$. Thus the worldsheet instantons of the $O(-1)+O(-1)$ theory over $\mathbf{P}^1$ with N units of flux, which in M-theory correspond to superpotential corrections due to Euclidean $M2$-brane instantons, know, by analytic continuation, about the Euclidean $M2$-brane instantons of the flopped geometry, which correspond to the usual gauge theory instantons.

Note that regardless of whether we find the new deformed G_2 holonomy solutions or not, we do not expect to find a geometry that truly decouples from the bulk and which can be interpreted as a decoupled field theory. There is a limit where we expect a decoupled field theory, the large V_M limit, and the region very close to the singularity, but it is not a limit where we expect a weakly coupled geometrical description. This corresponds as we saw above to $t \sim 0$. Though a weakly coupled *string* description is expected for large N. The field theory we have been considering, therefore, has more degrees of freedom than pure $\mathcal{N}=1$ Yang–Mills. In particular, it has the parameter V_M which is not a parameter in $\mathcal{N}=1$ SYM.

It is important to remark that when we talk about the resolved conifold of IIA theory with some units of flux, we are characterizing the space in terms of its topology, but we do not have a complex manifold. So in what sense is the consideration of topological strings as used in Ref. 2 relevant? The answer turns out to be that if we consider the BPS charge measured by the $M2$-brane, when we integrate over the 11-th circle, it leads to a BPS charge seen by the fundamental string, which corresponds to a symplectic form on the quotient geometry, which topologically is $R^4 \times S^2$. The symplectic structure induced from this reduction agrees with the symplectic structure of $O(-1)+O(-1)$ bundle over $\mathbf{P}^1$, as is shown in the Appendix (the corresponding symplectic two form k is obtained by integrating the G2 invariant three form Ω_3 over the 11-th circle, $k = \int_{S^1} \Omega_3$). This implies that we expect to obtain the same results in consideration of topological strings for this reduction of the 7-manifold.

APPENDIX: ASPECTS OF G_2 HOLONOMY METRIC

A G_2 holonomy manifold is a seven dimensional manifold whose holonomy group is the simple group G_2. It can be proven that in such manifolds there is a special harmonic three form Ω, $d\Omega = d^*\Omega = 0$, which is such that it locally determines the reduction of the holonomy group from Spin(7) to G_2. More precisely, at each point the subgroup of GL(7) that leaves Ω invariant is G_2.

It was shown in[9,8] that the following metric (on $R^4 \times S^3$) has G_2 holonomy:

$$ds^2 = \alpha^2\, dr^2 + \gamma^2 (\tilde{w}^a)^2 + \beta^2 \left(w^a - \tfrac{1}{2}\tilde{w}^a \right)^2, \tag{A1}$$

with

$$\alpha^{-2} = 1 - \frac{a^3}{r^3}, \quad \beta^2 = \frac{r^2}{9}\left(1 - \frac{a^2}{r^3}\right), \quad \gamma^2 = r^2/12, \tag{A2}$$

where $\tilde{w}^a$ and w^a are left invariant one-forms on two three-spheres, which we denote as $\tilde{S}^3$ and S^3. We think of S^3 as the $SU(2)$ group manifold. We can use the following formulas:

$$\begin{gathered}
g = e^{i\psi/2\sigma^3} e^{i\theta/2\sigma^1} e^{i\phi/2\sigma^3}, \\
\frac{i}{2} w_R^a \sigma^a = dg\, g^{-1}, \quad \frac{i}{2} w_L^a \sigma^a = g^{-1}\, dg, \\
(w_R^1 + i w_R^2) = e^{-i\psi}(d\theta + i \sin\theta\, d\phi), \quad w_R^3 = d\psi + \cos\theta\, d\phi, \\
(w_L^1 + i w_L^2) = e^{+i\phi}(d\theta - i \sin\theta\, d\psi), \quad w_L^3 = d\phi + \cos\theta\, d\psi, \\
dw_R^a = \tfrac{1}{2}\epsilon^{abc} w_R^b w_R^c, \\
dw_L^a = \tfrac{1}{2}\epsilon^{abc} w_L^b w_L^c .
\end{gathered} \tag{A3}$$

We can see from these definitions that the forms w_L^a are invariant under left multiplications of g, $g \to h_L g$ while they transform in the adjoint representation of $SU(2)$ under right multiplication $g \to g h_R$. We can write the metric of the unit three-sphere as

$$ds^2 = \frac{1}{4}\sum_a (w_L^a)^2 = \frac{1}{4}\sum_a (w_R^a)^2. \tag{A4}$$

We can easily check that the metric (A1) has $SU(2)^3$ isometry. Two $SU(2)$'s arise from left multiplication in each of the $S^3 s$ while the third $SU(2)$ arises from right multiplication on both three-spheres by the same group element. This last fact we can check by noticing that the index a, which transforms in the adjoint of $SU(2)$ is contracted in an $SU(2)$ invariant fashion.

Finally we can write the explicit form of the three-form,

$$\begin{aligned}
\Omega &= \frac{a^3}{12}\frac{1}{6}\epsilon_{abc}\tilde{w}^a\tilde{w}^b\tilde{w}^c - \frac{1}{18}(r^3 - a^3)\epsilon_{abc}(\tilde{w}^a w^b w^c - \tilde{w}^a \tilde{w}^b w^c) + \frac{r^2}{3} dr\, \tilde{w}^a w^a \\
&= \frac{a^3}{12}\frac{1}{6}\epsilon_{abc}\tilde{w}^a\tilde{w}^b\tilde{w}^c + d\left(\frac{r^3 - a^3}{9}\tilde{w}^a w^a\right).
\end{aligned} \tag{A5}$$

From this expression we see that the $SU(2)^3$ isometry group of the metric also leaves the three form invariant. In other words, these symmetries leave the G_2 structure invariant.

The metric (A.1) is asymptotic at large r to

$$ds^2 \sim dr^2 + r^2 \tfrac{1}{9}[(\tilde{w}^a)^2 + (w^a)^2 - w^a \tilde{w}^a]. \tag{A6}$$

The manifold on the right hand side of (A6) is a cone whose base is topologically $\tilde{S}^3 \times S^3$. This cone has a singularity at $r=0$. This singularity is eliminated in (A1) by giving a finite volume to one of the three-spheres, $\tilde{S}^3$. We could similarly consider a situation where we give a finite volume to the other sphere S^3. In that case the manifold we obtain is just given by (A1) with $w^a \leftrightarrow \tilde{w}^a$. These two manifolds are related by a flop. We see from the explicit expression of Ω that we can continuously go from one to the other, passing through a singular manifold at the point where both spheres have zero volume.

If we quotient this manifold by any subgroup of the isometry group described above we will obtain again a G_2 manifold, since the isometry group leaves the three form invariant. We will consider two different quotients.

1. Singular quotient

In this quotient we mod out by $Z_N \subset U(1) \subset SU(2)_L^2$ which acts on the coordinates of S^3. After modding out the metric (A1) by Z_N as above we get a singular space. We get an A_{N-1} singularity wrapped over $\tilde{S}^3$. If we KK reduce over the circle associated to this $U(1)$ and we go to type IIA theory, the singularity looks like the singularity we have in the near horizon region of N sixbranes wrapped on $\tilde{S}^3$. The normal bundle of this S^3 in IIA theory is the same as what we have when we wrap branes on the S^3 of a deformed conifold. In more mathematical notation, it is $T^*\tilde{S}^3$. Notice that in this IIA description, there is a singularity at the position of the branes even for $\mathcal{N}=1$. [Mathematically the point is that when we quotient $R^4=C^2$ by the circle (acting as complex scalars) the resulting space can be naturally identified with R^3 topologically but not differentiably—the identification being singular at the origin. This singularity in type IIA is interpreted as a D6-brane.] As usual, in the near horizon region of six-branes in IIA theory, the dilation is varying and it is approaching zero at the core of the six-branes.[12] The string metric in the directions along the six-brane is also shrinking as we approach the core, but it does so in such a way that $V_M = V_A / g_s$ is constant and equal to the volume of $\tilde{S}^3$ in M-theory. The above remarks about the near horizon region of a six-brane apply close to the singularity at $r=a$, for the region $r-a \ll a$. For large N there is a large region where the IIA description is valid.[12] As we go farther away from the singularity the geometry becomes more and more strongly coupled and the 11 dimensional description becomes better. For large r the dilation goes to infinity. In principle there should be another solution where the dilation goes to a constant.

2. Nonsingular quotient

If we choose $Z_N \subset U(1) \subset SU(2)^1$. This group acts as left multiplication on $\tilde{S}^3$. Since the volume of this three-sphere is nowhere vanishing we conclude that the quotient is nonsingular. We can further Kaluza Klein reduce the metric along this circle. This produces a nonsingular IIA metric on a space which has the topology of the small resolution of the conifold and with N units of two-form flux on S^2. If N is very large, then this IIA geometry is weakly coupled at the origin. When we start moving out in the radial direction the string coupling starts increasing and it becomes infinite asymptotically. In principle there should be another solution where the string coupling does not diverge. If we integrate the three-form (A5) on this S^1 we find the symplectic form on the small resolution of the conifold. It should be noted that, though we get the same two form as the Kahler form of the local CY, the IIA geometry with the flux is not Kahler.

Let us see this more explicitly. The circle in question is parametrized by $\tilde{\psi}$. In order to do the KK reduction it is convenient to define the new one-forms $\hat{w}^a$ and the vector n^a as follows:

$$\tilde{w}_L^a = \tilde{w}^a + n^a \, d\tilde{\psi}. \tag{A7}$$

Notice that $n^a n^a = 1$. We have extracted the dependence on $\tilde{\psi}$ in order to KK reduce. This splitting preserves $SU(2)_R^1$ but breaks $SU(2)_L^1$ to $U(1)_L$.

The IIA dilation, metric and one-form RR potential are

$$e^{4\phi/3} = \frac{1}{N^2}\left[\gamma^2 + \frac{\beta^2}{4}\right],$$

$$ds^2_{\rm str} = e^{2\phi/3}\left[dx_4^2 + \alpha^2\, dr^2 - e^{4\phi/3}A_1^2 + \gamma^2(\hat{w}^a)^2 + \beta^2\left(w^a - \tfrac{1}{2}\hat{w}^a\right)^2\right], \tag{A8}$$

$$A_1 = N\left[\hat{w}^a n^a - \frac{\beta^2}{2(\gamma^2+\beta^2/4)}\, w^a n^a\right],$$

where A_1 is the RR one-form potential.

Similarly we can integrate the three-form over S^1 and we obtain

$$J = \frac{a^3}{12}\frac{1}{2}\epsilon_{abc} n^a \hat{w}^b \hat{w}^c - \left(\frac{r^3}{18} - \frac{a^3}{18}\right)\epsilon_{abc}(n^a w^b w^c - 2 n^a w^b \hat{w}^c) - \frac{r^2}{3} dr\, n^a w^a, \tag{A9}$$

which is closed since Ω was closed.

We can further simplify these expressions by doing a coordinate transformation that amounts to switching from the left invariant one-forms to the right invariant one-forms in $\tilde{S}^3$. This translates into the following replacements:

$$\hat{w}^a \to \check{w}^a_R, \quad n^a \to \check{n}^a_R, \quad w^a \to w^a + \check{w}^a_R, \tag{A10}$$

where now $\check{w}^a_R, \check{n}^a_R$ are defined through,

$$\tilde{w}^a_R|_{\tilde{\psi}=0} = \check{w}^a_R + \check{n}^a_R\, d\tilde{\psi}.$$

In these variables,

$$\check{n}^a_R = \delta^a_3, \quad ,\check{w}^1 = \tilde{\theta}, \quad \check{w}^2 = \sin\tilde{\theta}\, d\tilde{\phi}, \quad \check{w}^3 = \cos\tilde{\theta}\, d\tilde{\phi}.$$

In these variables the two-form (A9) becomes

$$J = \frac{a^3}{12}\sin\tilde{\theta}\, d\tilde{\theta}\, d\tilde{\phi} - d\left(\frac{r^3 - a^3}{9}(w^3 + \cos\tilde{\theta}\, d\tilde{\phi})\right). \tag{A11}$$

This agrees with the two-form of the small resolution of the conifold which is

$$k = t\sin\tilde{\theta}\, d\tilde{\theta}\, d\tilde{\phi} - d(h(\rho)(w^3 + \cos\tilde{\theta} d\tilde{\phi})), \tag{A12}$$

where $h(\rho)$ is some function of the radial coordinate. These two expressions coincide if we identify $h(\rho) = (r^3 - a^3)/9$ which just amounts to a reparametrization of the radial coordinate.

We can also write the IIA metric (A8) and the RR 1-form potential in a more explicit form,

$$ds^2_{\rm str} = e^{2\phi/3}\left[dx_4^2 + \alpha^2\, dr^2 + \gamma^2(d\tilde{\theta}^2 + \sin^2\tilde{\theta}\, d\tilde{\phi}^2) + \beta^2\left[\left(w^1 + \frac{1}{2}d\tilde{\theta}\right)^2 + \left(w^2 + \frac{1}{2}\sin\tilde{\theta}\, d\tilde{\phi}\right)^2 + (w^3 + \cos\tilde{\theta}\, d\tilde{\phi})^2\right] - \frac{\beta^4}{4(\gamma^2+\beta^2/4)}(w^2 + \cos\tilde{\theta}\, d\tilde{\phi})^2\right]$$

$$A_1 = N\left[\cos\tilde{\theta}\, d\tilde{\phi} - \frac{\beta^2}{2(\gamma^2+\beta^2/4)}(w^3 + \cos\tilde{\theta}\, d\tilde{\phi})\right] \tag{A13}$$

Continuous-time histories: Observables, probabilities, phase space structure and the classical limit

Charis Anastopoulos[a)]
Department of Physics, University of Maryland, College Park, Maryland 20742

(Received 29 August 2000; accepted for publication 30 April 2001)

The continuous-time histories program stems from the consistent histories approach to quantum theory and aims to provide a fully covariant formalism for quantum mechanics. In this paper we examine some structural points of the formalism. We demonstrate a general construction of history Hilbert spaces and identify a large class of time-averaged observables. We pay particular attention to the construction of the decoherence functional (the object that encodes probability information) in the continuous-time limit and its relation to the temporal structure of the theory. Phase space observables are introduced, through the study of general representations of the history group, which is the analog of the canonical group in the formalism. We can also define a closed-time-path (CTP) generating functional for each observable, which encodes the information of its correlation functions. The phase space version of the CTP generating functional leads to the implementation of Wigner–Weyl transforms, that gives a description of quantum theory solely in terms of phase space histories. These results allow the identification of an algorithm for going to the classical (stochastic) limit for a generic quantum system. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1383975]

I. INTRODUCTION

A. Canonical vs covariant

Physical systems can be described in two different ways, depending on one's attitude towards time evolution. The first description can be called ''canonical:'' it focuses on properties of a system at a single moment of time and studies how these properties change. It, therefore, provides an evolutionary picture of physical phenomena. The other type is best described as ''covariant:'' its main objects are histories of the physical system. Its main aim is to find criteria that determine which of them are realizable. As such, this description provides a timeless and (in a sense) teleological picture of physical processes.

In classical mechanics the ''canonical'' description is Hamilton's formalism. States of the system correspond to points of the phase space, which is a symplectic manifold. Time evolution is implemented by the action of a one-parameter group of symplectic transformations. Alternatively, one can start from the action principle, which provides the covariant description of classical mechanics. Histories are paths, and the physically realized are the ones that minimize the action subject to fixed boundary conditions.

These two approaches also appear in classical probability theory. A physical system at a moment of time is described by a probability distribution on a space Ω of elementary alternatives. We then study how this distribution evolves in time: the evolution law is a linear partial differential equation, like the Fokker–Planck equation. The ''covariant'' description of probability theory is provided by the theory of stochastic processes. Here, histories are paths on Ω and the physical information is encoded in a probability measure $d\mu$ in the space of all histories; it incorporates information about both initial conditions and dynamics.

a)Electronic mail: charis@physics.umd.edu

Quantum theory was developed in the ''canonical'' framework. The probabilistic information about a system is encoded in a Hilbert space vector, or more generally a density matrix. Its time evolution is given by a one-parameter group of unitary transformations: this is equivalent to Schrödinger's equation. The general structure is very similar to classical probability theory, except for the fact that the observables do not form a commutative algebra.

B. Quantum mechanical histories

When one tries to construct a ''covariant'' description of quantum theory, a problem immediately arises: *the natural probability measure for histories is not additive*. This is due to the fact, that quantum theory is based on amplitudes. When one constructs probabilities out of these amplitudes, interference between histories appears.

In general, a history corresponds to properties of the physical system at successive instants of time. Since in quantum theory a property (or a proposition about it) is represented by a projection operator, a discrete-time history α will correspond to a string $\hat{\alpha}_{t_1},\hat{\alpha}_{t_2},\ldots,\hat{\alpha}_{t_n}$ of projectors, each labeled by an instant of time. From them, one can construct the class operator

$$\hat{C}_\alpha=\hat{U}^\dagger(t_1)\hat{\alpha}_{t_1}\hat{U}(t_1)\cdots\hat{U}^\dagger(t_n)\hat{\alpha}_{t_n}\hat{U}(t_n), \tag{1.1}$$

where $\hat{U}(s)=e^{-i\hat{H}s}$ is the time-evolution operator. The probability for the realization of this history is

$$p(\alpha)=\mathrm{Tr}(\hat{C}_\alpha^\dagger\hat{\rho}_0\hat{C}_\alpha), \tag{1.2}$$

where $\hat{\rho}_0$ is the density matrix describing the system at time $t=0$.

This expression does not define a probability measure in the space of all histories, because the Kolmogorov additivity condition cannot be satisfied: if α and β are exclusive histories and $\alpha\vee\beta$ denotes their conjunction as propositions, then it is not true that

$$p(\alpha\vee\beta)=p(\alpha)+p(\beta). \tag{1.3}$$

The histories formulation of quantum theory does not, therefore, enjoy the status of a genuine probability theory.

1. The consistent histories interpretation

The formalism sketched above was developed as a part of the consistent histories approach to quantum theory, by Griffiths, Omnés, Gell-Mann, and Hartle.[1–4] In this approach, the problem of the nonadditivity of the probability measure is addressed by the remark that an additive probability measure *is* definable, when we restrict to particular sets of histories. These are called *consistent sets*. They are more conveniently defined through the introduction of a new object: the decoherence functional. This is a complex-valued function of a pair of histories given by

$$d(\alpha,\beta)=\mathrm{Tr}(\hat{C}_\alpha^\dagger\hat{\rho}_0\hat{C}_\beta). \tag{1.4}$$

A set of exclusive and exhaustive alternatives is called consistent, if for all pairs of different histories α and β in the set, we have

$$d(\alpha,\beta)=0. \tag{1.5}$$

In that case one can use Eq. (1.2) to assign a probability measure to this set. The consistent histories interpretation then proceeds by postulating that any prediction or retrodiction, we can make based on probabilities *must always make reference to a given consistent set*. This leads to counterintuitive and arguably unphysical situations of getting mutually incompatible predictions, when reasoning within different consistent sets.[5,6] The predictions of this theory are therefore contextual: but in any case, this is a general feature of all realist interpretations of quantum theory.

Even if the formalism of quantum mechanical histories was originally introduced as part of the consistent histories approach, it is conceptually distinct. The same formalism can be viewed in the light of any other interpretational scheme. The Copenhagen interpretation, for instance, would view the nonadditivity of the probability measure in a neutral light. The expression (1.2) describes the statistics of an ensemble of time-ordered sequences of measurements. There would be no *a priori* theoretical reason for the statistics to correspond to a genuine probability measure.

In this paper, we shall focus on the formal aspect of quantum mechanical histories. We do not find it necessary to commit to any particular interpretation: we only assume that all physical information about probabilities and interference of histories is encoded in the decoherence functional, something very explicitly shown by Gell-Mann and Hartle. It is not our aim to insist on how this information can be extracted: both the logic of consistent sets and the Copenhagen stance provide ways of doing this. Perhaps these ways do not exhaust the physical content of the theory—we have argued this in Ref. 7, but each of them is separately adequate to account for all minimal predictions of standard quantum theory.

We view the histories formalism simply as the covariant version of quantum theory. As such, it incorporates features of the covariant formulation of both classical mechanics and probability theory. But interference of probabilities highlights its quantum nature, and for this reason we shall pay particular attention to the structure of the decoherence functional.

2. Temporal logic histories

We shall work in the context of temporal logic histories. This is a scheme initiated by Isham:[8,9] its main point is that the quantum logic is preserved in the histories theory if we represent a history proposition $(\alpha_{t_1},\ldots,\alpha_{t_n})$ by a projection operator on a tensor product of the Hilbert spaces of the canonical theory $\mathcal{V}=\otimes_i H_{t_i}$. This history proposition will then be written as $\alpha=\alpha_{t_1}\otimes\cdots\otimes\alpha_{t_n}$. This construction is completely analogous to the construction of the space of classical histories as a *Cartesian product* of single-time sample spaces.

In this formulation a self-adjoint operator on $\mathcal{V}$ represents a history observable for the physical system. As in any covariant theory, more general observables can be defined. They correspond to time averages and include, for instance, an *action operator*.

One of the great strengths of this formalism is found in its temporal structure. It was shown by Savvidou,[10,11] that one can mathematically distinguish between two qualities of time: its partial ordering properties (the notion of before and after) and its status as a dynamical parameter in the equations of motion.

To see this, examine Eq. (1.1) for the class operator $\hat{C}_\alpha$ entering the expression for the decoherence functional. There, time appears in two places: as an index of the projectors $\hat{\alpha}_t$ and as the argument of the unitary operators $\hat{U}(t)$. In its former status, it is purely a kinematical parameter labelling the moment upon which a proposition is asserted. Its function is to determine the order upon which propositions are asserted, in the sense that if $t_1\leqslant t_2$ the projection operator $\hat{\alpha}_{t_1}$ will appear on the left of the operator $\hat{\alpha}_{t_2}$ in Eq. (1.1) for $\hat{C}_\alpha$. In its latter status as the argument of the unitary operators, time is the parameter of the Heisenberg-type evolution. It, thereby, implements the dynamics of the system.

These two roles of the time parameter are completely disentangled, when we view histories in the tensor product Hilbert space $\mathcal{V}=\otimes_t H_t$. This is an intriguing property, since it allows us to *mathematically distinguish* between the two conceptually distinct roles by which time appears in physical theories: in the form of a causal structure, that determines the order of events and in the form of the parameter by which change is effected in a physical system.

Indeed in the histories formalism there appear two mathematically distinct laws of time transformation. The partial ordering aspect of time is manifested in translations of the form $H_t \rightarrow H_{t+a}$, by which a property asserted at time t is translated to the same property at time $t+a$. At the continuum limit these transformations are generated by the kinematical part of an action operator. Dynamical time transformations are equivalent to a separate unitary transformation for each single-time Hilbert space H_t. They correspond to the Hamiltonian part of the action.

This distinguishing presence of two laws of time transformation is an important physical principle, that will provide a guideline for the construction of history theories, in the case where the canonical formalism does not provide sufficient insight. In retrospect, one can see that this distinction is present in *all* physical theories that are formulated in a covariant (histories) fashion.[11]

C. This paper

Since our aim is to show how histories provide a covariant formulation of quantum theory, we need to go beyond the discrete-time description that is usually effected: time, in physics, is a continuum. Continuous-time histories have been introduced in Ref. 12 and further studied in Refs. 10 and 13–15. This work relied on the use of a Fock space for the history Hilbert space, which is only justified if the Hamiltonian is quadratic.

The first aim of this paper is to explore the nature of continuous time in this framework. In particular, we highlight the structures that arise in the probability assignment. The analogy with stochastic processes is quite helpful in this regard, both at a conceptual and at a technical level.

In Sec. II we explain how a continuous-time Hilbert space with physically interesting observables can be constructed. We then analyze the decoherence functional: we show that it can be decomposed in a way that respects the two laws of time transformation. In fact, its components reflect the distinction between the geometric and the dynamical phase of canonical quantum theory.[16] Finally, we discuss the time-reversal transformations, which are substantially different from the ones of standard quantum theory.

In Sec. III we study the phase space structure of histories. This is incorporated in the quantum theory through the use of the history group, the history analog of the canonical group. The history Hilbert space carries one of its representations. This allows the identification of self-adjoint operators in this Hilbert space with objects that have a classical phase space analog. We explain, how one can construct such representations from the knowledge of the canonical theory.

The analogy with classical probability suggests that one should treat the decoherence functional as the quantum analog of a classical probability measure. In this sense its ''Fourier transform'' yields the analog of the generating function of classical probability: this is the closed-time-path (CTP) generating functional, first introduced by Schwinger.[17] We show how to construct this object for phase space histories. This construction suggests that the Wigner transform is of relevance: it enables us to write the decoherence functional as a complex-valued measure on the space of phase space paths and provides a picture of quantum theory that makes reference only to classical objects. One of the merits of this construction is that it provides an algorithmic procedure for passing into the classical limit of generic quantum theories.

In the final section we review our results. We argue that the formalism is flexible enough to accommodate a large number of applications in different fields. In particular, we stress the importance of our results as part of the developing continuous-time histories program.

Overall, our attitude is to highlight similarities of structures between the histories formalism and more familiar physical formalisms, such as stochastic processes or canonical quantum theory.

1. Notation

In the following, our expressions will make reference to two different types of Hilbert space: canonical ones and history ones. We adopt the following conventions: we will use the braket notation to denote vectors of both types of Hilbert space. But we will insert a subscript in the ket denoting a *canonical* Hilbert space. Hence, for instance, $|\psi_t\rangle_{H_t}$ will denote a vector on the canonical Hilbert space H_t, while $|\psi\rangle$ will denote a vector on a history Hilbert space $\mathcal{V}$.

Also, operators on canonical Hilbert spaces will carry a hat, while the history ones will be unhatted.

As already seen in the introduction, we use the same symbol (small greek letters) to denote both a proposition and the projector that represents it. We let the meaning be determined by the context.

The notation in Sec. III is more complicated, because of the many spaces involved. Points of the (linear) phase space Γ will be denoted as (q,p). But there is also the space $\tilde{\Gamma}$, which is the

vector space dual of Γ and (if Γ is a Hilbert space) isomorphic to it. Points on this space will be denoted as (χ,ξ): they correspond to elements of the canonical group or labels of coherent state vectors. The latter will often be denoted as $|z\rangle$. The inner product in these spaces, will be denoted by a dot: we will write invariably $q\cdot p$ or $q\cdot\xi$, without reference to whether the arguments are elements of Γ or $\tilde{\Gamma}$. In fact, we shall mostly ignore their distinction.

Paths on Γ will be denoted as $(q,p)(\cdot)$, or $t\to(q_t,p_t)$, or simply γ. Paths on $\tilde{\Gamma}$, corresponding to coherent state histories by $(\chi,\xi)(\cdot)$, or $t\to(\chi_t,\xi_t)$, or simply $z(\cdot)$. We will write $(q,\xi)=\int d\mu(t)q_t\xi(t)$. When we want to emphasize that ξ also acts as a smearing function on q_t we will denote the same object as q_ξ.

II. CONTINUOUS-TIME HISTORIES

A. The basic structure

The temporal logic histories scheme is based on ideas from quantum logic. It seeks to represent the set of all history propositions about a physical system with elements of a lattice, that contains the information about the temporal structure.[8]

Let us denote by T the set of all instants of time (this can be either discrete, or the real line $\mathbf{R}$ or a subset of $\mathbf{R}$). Standard quantum theory is recovered, when we consider that history propositions correspond to projection operators on a Hilbert space $\mathcal{V}$, given by the tensor product $\otimes_{t\in T}H_t$. Here H_t is a *copy* of the Hilbert space of the canonical theory indexed by t.

Self-adjoint operators on this Hilbert space correspond to history observables.

As an example, let us consider the case where T is a finite set. Let $\hat{A}$ be a bounded operator on the Hilbert space H of the canonical theory, and let us denote by $\hat{A}_t$ its copy on a Hilbert space H_t. Then we can define the *product operator* $\otimes_{t\in T}\hat{A}_t$ on $\mathcal{V}$.

If $\hat{A}_t$ is unit everywhere, but a single point $t\in T$, then we shall denote the product operator on $\mathcal{V}$ as A_t. If $f:T\to\mathbf{R}$ then we can define the *time-averaged* operator A_f as

$$A_f=\sum_{t\in T}f(t)A_t. \tag{2.1}$$

It corresponds to the average in time of the family $t\to\hat{A}_t$, with a weight given by the function f. We can easily verify the following identity. If $\hat{A}$ is a self-adjoint operator on H, then its time-averaged counterpart on $\mathcal{V}$ satisfies

$$e^{iA_fs}=\otimes_{t\in T}e^{i\hat{A}f(t)s}. \tag{2.2}$$

We shall use this identity to *define* time-averaged operators in the continuous-time case.

Note also that for the case of projection operators, a map $\hat{\alpha}\to\alpha_t$ provides a continuous embedding of the lattice of propositions at a single moment of time to the lattice of history propositions.

The probabilistic content of the theory is contained in the decoherence functional. This is assumed to satisfy the following conditions:

$$\begin{gathered} d(1,1)=1,\\ d(\alpha,\beta)=d^*(\beta,\alpha),\\ d(0,\alpha)=0,\\ d(\alpha+\beta,\alpha')=d(\alpha,\alpha')+d(\beta,\alpha'),\\ d(\alpha,\alpha)\geqslant 0. \end{gathered} \tag{2.3}$$

In general, there exists a class of operators X on $\mathcal{V}\otimes\mathcal{V}$, such that a decoherence functional can be written as[18,19]

$$d(\alpha,\beta)=\mathrm{Tr}_{\mathcal{V}\otimes\mathcal{V}}(X\alpha\otimes\beta). \tag{2.4}$$

When the space T is finite, the construction of the tensor product Hilbert space is straightforward and Eq. (1.4) can be used to construct the decoherence functional. The question arises then, how one deals with continuous time. This is the case when T is a closed subset of the real line. For particular systems the construction of such Hilbert spaces has been carried in Ref. 12. For more general cases, we believe it is instructive to look at the analogous situation in the classical setting.

B. Classical stochastic processes

Let us assume we have a classical system that at a moment of time is described by a sample space Ω. Let us also consider the space T of time instants to be a closed subset of the real line, say $[0,a]$. The space of histories Π is then some suitable subset of the set Ω^T of all measurable maps $\gamma: T\to\Omega$. If Ω is a vector space one can define a norm on Ω^T, and take as Π the subspace of Ω^T, that contains paths with a finite norm.

A function f on Ω defines a family of functions F_t on Π by

$$F_t(\gamma)=f(\gamma(t)). \tag{2.5}$$

As a stochastic process, we usually define a triplet consisting of the space Π, a family F_t, and a measure $d\mu$ on Π. The issue is how to construct physically interesting measures on Π, which is an infinite dimensional function space.

This is effected as follows: Let dx be for brevity a natural integration measure on Ω (say a Lebesque measure). Let $T=[t_0,t_f]$ be an interval and let us also consider a discretization $I=\{t_0,t_1,\ldots,t_n=t_f\}$ of T. Then define the space of discrete time histories $\Omega^I=\times_{t_j\in I}\Omega_{t_j}$, which is a finite dimensional manifold. This admits the measure $\Pi_{t_j\in I}\,dx_{t_j}$. Any probability distribution $p_I(x_{t_1},\ldots,x_{t_n})$ on Ω^I defines a measure $d\mu(x)=p_I(x_{t_1},\ldots,x_{t_n})\Pi_{t_j\in I}\,dx_{t_j}$.

As we consider all possible discretizations I of T, we can encode a choice of probability measure for each discretization in a hierarchy of positive functions

$$\begin{gathered} p_1(x,t),\\ p_2(x_1,t_1;x_2,t_2),\\ \cdots,\\ p_n(x_1,t_1;\ldots;x_n,t_n),\\ \cdots. \end{gathered} \tag{2.6}$$

These have to be symmetric with respect to interchange of their (x,t) arguments.

Now, the fundamental theorem of Kolmogorov asserts the following: If a hierarchy of functions as above, satisfies the *additivity condition*:

$$\int dx_n\, p_n(x_1,t_1;\ldots;x_{n-1},t_{n-1};x_n,t_n)=p_{n-1}(x_1,t_1;\ldots;x_{n-1},t_{n-1}) \tag{2.7}$$

then there exists an essentially unique probability measure $d\mu(\cdot)$ on Ω^T such that it gives the correct discrete time probability measures, i.e., for each partition I, $j_I^*\,d\mu=d\mu_I$, where j_I is the natural injection map $j_I: I\to T$.

Kolmogorov's proof is standard textbook material and is one instance of a general categorical construction of taking the inductive limit. The essential point in the proof is the fact that j_I is a measurable map (with respect to the Borel sets of T) and as such it respects the measurable structure in the definition of $d\mu$.

Hence a probability measure is defined for continuous time, while making reference only to discrete time expressions. This is the theorem that we will try to employ, in order to construct the decoherence functional for continuous-time histories.

C. The continuum limit

1. The Hilbert space

The first objective would be to define a suitable version of the Hilbert space $\mathcal{V}=\otimes_{t\in T}H_t$. This expression cannot be taken literally, for a continuous tensor product of Hilbert spaces leads to a nonseparable Hilbert space. What we will do is a generalization of an idea that has been applied to ''continuous tensor products'' of Fock spaces.[12]

Consider the space $B(T,H)$ of continuous maps $|\psi(\cdot)\rangle$ from T to H. In fact, we can start our construction considering only measurable maps. But since we will later want to define Stieljes integrals, we should impose the restriction that the maps are of *bounded variation*, i.e., they satisfy the following property.

For any finite discretization of T. $\{t_0\leqslant t_1,\leqslant\cdots\leqslant t_i\leqslant\cdots\leqslant t_n\}$, the sum $\Sigma_{i=1}^{n}\|\psi_{t_i}-\psi_{t_{i-1}}\|_H$ is finite.

Assume that T has a measure $d\mu(t)$, which in the standard case should be taken as dt/τ. Here τ is a time parameter that makes the measure dimensionless. If T is compact it can be used to normalize the measure $\mu(T)=1$.

Then define the inner product

$$\langle\psi(\cdot)|\phi(\cdot)\rangle=\prod_{d\mu(t)}\langle\psi_t|\phi_t\rangle:=\exp\left(\int d\mu(t)\log[\langle\psi_t|\phi_t\rangle_{H_t}]\right), \tag{2.8}$$

where it is understood that the inner product vanishes if $\langle\psi_t|\phi_t\rangle_{H_t}=0$ in a subset of T that is not of measure zero, and that the logarithm takes values on the principal branch.

This space then has a norm $\|\psi(\cdot)\|=(\langle\psi(\cdot)|\psi(\cdot)\rangle)^{1/2}$. We identify two elements $\psi_1(\cdot),\psi_2(\cdot)$ of $B(T,H)$, if $\|\psi_1(\cdot)-\psi_2(\cdot)\|=0$. *This identification makes the resulting Hilbert space separable*.

Let us, suggestively, denote the vector space we obtained after identification, as $\times_{t\in T}H_t$. To construct $\otimes_{t\in T}H_t$ we consider the space of all formal linear combinations $\Sigma_i c_i|\psi_i(\cdot)\rangle$. Here i runs over a finite set, $c_i\in\mathbf{C}$, and $\{|\psi_i(\cdot)\rangle\}$ is a finite set of vectors of $\times_{t\in T}H_t$. On the space of these formal linear combinations we define the inner product as

$$\sum_i \overline{c'}_i c_i\langle\psi_i'(\cdot)|\psi_i(\cdot)\rangle \tag{2.9}$$

and close this space with respect to the norm. We have thus defined a Hilbert space $\otimes_{t\in T}H_t$. Note that the time parameter τ enters explicitly into the definition.

The vectors $|\psi(\cdot)\rangle$ form a total set of $\otimes_{t\in T}H_t$. As such, we can define operators on the history Hilbert space by their action on these vectors.

Some properties of this construction are easy to see. For instance,

$$\otimes_t e^{\lambda_t}|\psi_t\rangle_{H_t}=e^{\int d\mu(t)\lambda(t)}|\psi(\cdot)\rangle. \tag{2.10}$$

Also, if T_1 and T_2 are two disjoint subsets of $\mathbf{R}$ with nonzero measure, then

$$\otimes_{t\in T_1\cup T_2}H_t=(\otimes_{t\in T_1}H_t)\otimes(\otimes_{t\in T_2}H_t). \tag{2.11}$$

2. Time-averaged observables

Let $\hat{A}_t$ be a continuous family of bounded operators on H indexed by t. Then one can define the product operator $\otimes_{t\in T}\hat{A}_t$ by its action on $|\psi(\cdot)\rangle$,

$$(\otimes_{t\in T}\hat{A}_t)|\psi(\cdot)\rangle=\otimes_{t\in T}(\hat{A}_t|\psi_t\rangle_{H_t}). \tag{2.12}$$

This definition is extended by linearity to the whole Hilbert space. However, one has to restrict the families $t\to\hat{A}_t$. We have

$$\begin{aligned}\|(\otimes_{t\in T}\hat{A}_t)|\psi(\cdot)\rangle\|^2&=\exp\left(\int d\mu(t)\log(\langle\psi_t|\hat{A}_t^2|\psi_t\rangle_{H_t})\right)\\&\leqslant\exp\left(\int d\mu(t)\log(\|A_t\|^2\langle\psi_t|\psi_t\rangle_{H_t})\right)\\&=e^{\int d\mu(t)\log(\|\hat{A}_t\|^2)}\langle\psi(\cdot)|\psi(\cdot)\rangle,\end{aligned} \tag{2.13}$$

hence one has to demand that $\int d\mu(t)\log(\|\hat{A}_t\|^2)\leqslant\infty$. If T is a compact subset of $\mathbf{R}$, this holds automatically provided the map $t\to\|\hat{A}_t\|$ is measurable. If T is noncompact, e.g., the whole of $\mathbf{R}$, the right-hand side is not finite and one has to additionally demand that $\hat{A}_t=1$ outside some compact subset of $\mathbf{R}$, or that $\|\hat{A}_t-\hat{1}\|_H$ falls to zero sufficiently rapidly.

It is easy to see that

$$\mathrm{Tr}_{\mathcal{V}}(\otimes_{t\in T}\hat{A}_t)=\prod_{t\in T}(\mathrm{Tr}_{H_t}\hat{A}_t)=\exp\left(\int d\mu(t)\log\mathrm{Tr}_{H_t}\hat{A}_t\right). \tag{2.14}$$

Having defined the product operators we can define time-averaged observables, by exploiting Eq. (2.2). Let $\hat{A}$ be a bounded self-adjoint operator on H. We can write the family $t\to\hat{U}_t(s)=e^{i\hat{A}f(t)s}$ of unitary operators and construct the product operator $U_f(s)=\otimes_{t\in T}\hat{U}_t(s)$. This is well-defined if $f(t)\neq 0$ only within a compact subset of $\mathbf{R}$ and corresponds to a one-parameter group of unitary operators on $\mathcal{V}$. By Stone's theorem, if the matrix elements of this operator are continuous functions of s at $s=0$, there exists a self-adjoint operator A_f such that $U_f(s)=e^{iA_fs}$.

It is easy to check that

$$\langle\phi(\cdot)|U_f(s)|\psi(\cdot)\rangle=\exp\left(\int d\mu(t)\log(\langle\phi_t|e^{i\hat{A}f(t)s}|\psi_t\rangle)\right) \tag{2.15}$$

is a continuous function of s at $s=0$, when the operator $\hat{A}$ is bounded. Thus, given suitable functions f, a self-adjoint operator representing the time average of $\hat{A}$ is well defined on $\mathcal{V}$.

3. Unbounded operators

The construction of time-averaged counterparts to unbounded operators on H is more complicated. From Eq. (2.15) we see that even if the matrix elements $\langle\psi_t|e^{i\hat{A}f(t)s}|\phi_t\rangle_{H_t}$ are continuous functions of s, there is no guarantee that so will be the integral.

Also if $\hat{A}$ is unbounded, there exist vectors $|\psi_t\rangle$, for which the action of $\hat{A}_t$ is not defined, hence one cannot write $|\langle\phi_t|e^{i\hat{A}f(t)s}-1|\psi_t\rangle\leqslant c|s|$, which would be sufficient to prove continuity. There is *no guarantee* that the time average of an unbounded operator is definable.

This is unfortunate, because in physical situations we are interested in operators like position, or momentum, or the Hamiltonian, that are typically unbounded. This failure is due to the fact that the Hilbert space $\otimes_{t\in T}H_t$ is still very large. In concrete physical situations one should identify the histories Hilbert space $\mathcal{V}$ with a closed linear subspace of $\otimes_{t\in T}H_t$.

One has to choose this closed linear subspace, in such a way that the tensor product structure is preserved. The simplest way is to restrict the set of vectors that can be used to construct the "paths" $|\psi(\cdot)\rangle$ to a subset $\mathcal{L}$ of H. This set $\mathcal{L}$ has to be sufficiently large to be able to capture all physical information from H (it cannot be a subspace of H), but small enough to allow interesting operators to be definable on the history Hilbert space. A good choice for $\mathcal{L}$ is an overcomplete and continuous family of vectors, like the coherent states.

Having chosen $\mathcal{L}$, the construction proceeds as before, only we substitute $B(T,H)$ with $B(T,\mathcal{L})$: the space of all continuous maps from T to $\mathcal{L}$. It is easy to check that the resulting Hilbert space is a closed linear subspace of $\otimes_{t\in T}H_t$.

If we demand that a particular unbounded operator A exists (time averaged) in our Hilbert space, it would be necessary to take $\mathcal{L}$ consisting of vectors in the domain of A. In that case the matrix elements (2.15) would be a continuous function of s and (by Stone's theorem) A_f would exist. We shall see how this construction works in more detail, in Sec. III. In this section, we shall work with the larger Hilbert space $\otimes_{t\in T}H_t$. All results we obtain will be valid for any of its physically relevant subspaces.

4. The decoherence functional

If T is compact, one can choose $A_t=A$ for all t and therefore interpret A_f as the time average of the quantity associated to A. But, if we try to define an operator on $\mathcal{V}$, that corresponds to an observable at a *sharp* moment of time, we run into problems. Since a point in the real axis is of measure zero, an observable defined at a sharp moment of time can exist only if we can take f to be a delta function. This is unacceptable in our construction. We conclude that one *cannot embed continuously the lattice of single-time propositions into the lattice of history propositions*, in the case of continuous time.

Let us now examine the possibility of defining a decoherence functional for continuous-time histories as a continuous limit of the discrete-time expression (1.4). Let us assume a partition $I=\{t_1,\ldots,t_n\}$ of an interval T of the real line and a proposition $\alpha=\alpha_{t_1}\otimes\ldots\otimes\alpha_{t_n}$ that is a projector operator on $H^I=\otimes_{t_i\in I}H_{t_i}$. Then one can construct the class operator $\hat{C}_\alpha$ defined on one copy of H as in Eq. (1.1). The value of decoherence functional $d_{I,I'}$ between a history on H^I and another on some other discrete-time Hilbert space $H^{I'}$ is given by Eq. (1.4).

The aim is to generalize Kolmogorov's theorem in this histories setting. We want to construct a bilinear, Hermitian, additive map on the space $P(\mathcal{V})\times P(\mathcal{V})$ [by $P(H)$ we mean the lattice of projectors on the Hilbert space H]. If we consider then a pair of discretizations I and I' of T, we can costruct the Hilbert spaces H^I and $H^{I'}$. The point is whether there exist an injection map $j_{I,I'}: H^I\times H^{I'}\to\mathcal{V}\times\mathcal{V}$; if this exists and preserves the lattice structures then Kolmogorov's proof goes through and the decoherence functional d on H^T exists as an inductive limit of the decoherence functional defined on $H^I\times H^{I'}$ for all choices of I and I'. We would also have $d_{I,I'}=j^*_{I,I'}d_T$.

For the map to be lattice preserving it would have to be continuous. But, we showed earlier, that this cannot be true for a single moment of time. The map $j_{I,I'}$ might be continuous in the weak topology, but this is insufficient to define an order preserving map. Recall that the continuity of the Hilbert space enters in a decisive point in the definition of the lattice of propositions: a projection operator corresponds to a *closed* linear subspace. Hence Kolmogorov's theorem does not go through in this case.

But if we restrict to an Abelian sublattice (for instance, to propositions about position) the map $j_{I,I'}$ does not need to be a continuous, linear map, but simply a measurable map from the spectra of the corresponding operators $\mathbf{R}^I\times\mathbf{R}^{I'}$ to $\mathbf{R}^T\times\mathbf{R}^T$. This clearly exists; it is the same as in the case of classical probability theory.

We therefore conclude that *one cannot write the decoherence functional for continuous time, as a limit of discrete-time ones*, unless one restricts to Abelian subalgebras. We might have a continuous-time decoherence functional for each subalgebra, but not one defined on the whole of

$P(\mathcal{V})$. We shall return to this issue again and propose two different ways, by which the decoherence functional can be defined.

D. The structure of the decoherence functional

The presence of two laws of time transformation is an important structural feature of history theories. In this section, we shall show how they are manifested in the probability assignment. We shall see that the decoherence functional for discrete time can be written in such a way, that these two notions of time are distinctly represented. This is a feature, that in the canonical theory is reflected in the distinction between the geometric and dynamical phase.[16] We shall attempt to generalize this feature in the continuous-time case.

For simplicity we shall consider a special class of decoherence functionals. They are of the type (1.4), but with $\hat{\rho}_0$ corresponding to a pure state. This means that we can absorb the projector into the initial state as part of the definition of each history and as such write the decoherence functional in the form

$$d(\alpha,\beta)=\mathrm{Tr}_H(\hat{C}_\alpha^\dagger \hat{C}_\beta). \tag{2.16}$$

Clearly one of the single-time projectors has to be trace-class if the above expression is to be finite. Equation (2.16) can be written as[18]

$$d(\alpha,\beta)=\mathrm{Tr}_{H\otimes H}(Z\hat{C}_\alpha^\dagger\otimes \hat{C}_\beta), \tag{2.17}$$

where Z is an operator on $H\otimes H$ given by

$$Z(|i\rangle\otimes|j\rangle)=|j\rangle\otimes|i\rangle. \tag{2.18}$$

One can write $Z=\Sigma_{rs}\hat{A}^{rs}\otimes\hat{A}^{\dagger rs}$ in terms of a basis on H, where $\hat{A}^{rs}$ is an operator on H with matrix elements

$$\langle k|\hat{A}^{rs}|i\rangle=\delta_{ks}\delta_{ri}. \tag{2.19}$$

Let us now assume that both histories are defined in the same instants of time $t_0,t_1,\ldots,t_n$. Let us for simplicity take $t_0=0$. The corresponding history Hilbert space is then $\mathcal{V}=\otimes_i H_{t_i}$.

Let us also write the *boundary Hilbert space* $\partial\mathcal{V}=H_{t_0}\otimes H_{t_n}$. The indices rs of the operators $\hat{A}^{rs}$ are then indices corresponding to $\partial\mathcal{V}$. It is easy to verify that the expression (2.17) can be written as a trace over the boundary Hilbert space[14]

$$d(\alpha,\beta)=\mathrm{Tr}_{\partial\mathcal{V}}(c(\alpha)c^\dagger(\beta)), \tag{2.20}$$

where $c(\alpha)$ is an operator on $\partial\mathcal{V}$ defined by

$$c(\alpha)=\mathrm{Tr}_H\hat{A}\hat{C}_\alpha^\dagger. \tag{2.21}$$

$\hat{A}$ denotes here a map from H to $\mathcal{V}$. It is easy now to write $c(\alpha)$ as a trace over the history Hilbert space, through the introduction of the *unitary* operator $\mathcal{S}$ on $\mathcal{V}$,

$$\mathcal{S}|v_{t_0}\rangle|v_{t_2}\rangle\cdots|v_{t_n}\rangle=|v_{t_n}\rangle|v_{t_0}\rangle\cdots|v_{t_{n-1}}\rangle. \tag{2.22}$$

Indeed, since $\alpha=\hat{\alpha}_{t_0}\otimes\hat{\alpha}_{t_1}\otimes\cdots\otimes\hat{\alpha}_{t_n}$, we can write

$$c(\alpha)=\mathrm{Tr}_{\mathcal{V}}(\mathcal{A}\mathcal{S}\mathcal{U}^\dagger\alpha\mathcal{U}), \tag{2.23}$$

where

$$\mathcal{U}=\hat{U}(t_0)\otimes\hat{U}(t_1)\cdots\otimes\hat{U}(t_n), \tag{2.24}$$

$$\mathcal{A}=\hat{A}\otimes 1\otimes\cdots\otimes 1. \tag{2.25}$$

This accomplishes the task of writing the decoherence functional in such a way as the two different notions of time are made manifest. The operator $\mathcal{U}$ clearly contains the dynamics. The operator $\mathcal{S}$ induces a transformation that takes from a single-time Hilbert space to the next one. Finally, the operators A incorporate the information about the beginning and the end of the interval. Had we kept the initial density matrix, $\hat{A}$ would explicitly depend upon it. In that case the analog of Eq. (2.19) would be

$$\langle k|\hat{A}^{rs}|i\rangle=\delta_{ks}(\rho_0^{1/2})_{ri}\,. \tag{2.26}$$

E. The continuum limit

Let us now examine whether one can construct these operators in the continuous-time Hilbert space $\otimes_{t\in T}H_t$, which we defined earlier.

The operator $\mathcal{U}$ is relatively easy to define. It would act on a vector $|\psi(\cdot)\rangle$ as

$$\mathcal{U}|\psi(\cdot)\rangle=\otimes_{t\in T}(e^{-i\hat{H}t}|\psi_t\rangle_{H_t}). \tag{2.27}$$

This would have as matrix elements

$$\langle\phi(\cdot)|\mathcal{U}|\psi(\cdot)\rangle=\exp\left(\int d\mu(t)\log\langle\phi_t|e^{-i\hat{H}t}|\psi_t\rangle\right). \tag{2.28}$$

According to our previous analysis this is a genuine unitary operator on $\mathcal{V}$.

1. The geometric phase

The operator $\mathcal{S}$ has an important geometric significance. It incorporates information about the geometric phase[20,21] that is associated to a history. To see this, one has first to recall that a Hilbert space H is a line bundle over the projective Hilbert space PH, i.e., the equivalence class of all vectors that differ by a multiplication with a complex number. We shall denote an element of PH as $[\psi]$. The inner product on H inherits two important geometric structures on PH: a metric

$$ds^2=\|d|\psi\rangle\|^2-|\langle\psi|d|\psi\rangle|^2, \tag{2.29}$$

and a $U(1)$ connection

$$A=-i\langle\psi|d|\psi\rangle. \tag{2.30}$$

When a point of PH evolves along a loop γ, its total phase change consists of a piece that depends upon the dynamics and a piece that is essentially the holonomy of the connection A.[22,23] This is known as the Berry phase and equals

$$e^{i\theta_g[\gamma]}=e^{i\int_\gamma A}=\exp\left(\int\langle\psi|d|\psi\rangle\right). \tag{2.31}$$

The geometric phase can also be defined for open paths. The trick is that any path on the projective Hilbert space can be closed by joining its endpoints with a geodesic, with respect to the natural metric. The geometric phase of the loop thus constructed is then *defined* to equal the geometric phase associated to the open path. Hence if $\gamma=[\psi(\cdot)]$ is a path on PH its associated geometric phase can be found[24]

$$e^{i\theta_g[\gamma]} = \exp\left(\int_{t_i}^{t_f} dt \langle \psi(t) | \dot{\psi}(t) \rangle \right) \langle \psi_i | \psi_f \rangle. \tag{2.32}$$

This expression is defined only if the endpoints are not orthogonal.

Now let us consider a discretized approximation to an element $|\psi(\cdot)\rangle$ of $\mathcal{V}$. Let us write therefore,

$$\alpha = \otimes_{t_j} |\psi_{t_j}\rangle\langle\psi_{s_j}|, \tag{2.33}$$

where $|\psi_{t_j}\rangle$ are normalized vectors on H_{t_j}.

We then calculate

$$\mathrm{Tr}(\mathcal{S}\alpha) = \langle \psi_{t_0} | \psi_{t_n} \rangle \langle \psi_{t_1} | \psi_{t_0} \rangle \langle \psi_{t_2} | \psi_{t_1} \rangle \cdots \langle \psi_{t_n} | \psi_{t_{n-1}} \rangle. \tag{2.34}$$

Let us then assume that $\max|t_j - t_{j-1}| = \delta t$, and we choose the number of time steps n very large, so that $\delta t \sim O(n^{-1})$. Then $|\psi_{t_j}\rangle$ approximates a path $[\psi(t)]$ on PH. Writing formally $\alpha_{\psi(\cdot)}$ for the projector we get

$$\begin{aligned} \log \mathrm{Tr}(\mathcal{S}\alpha_{\psi(\cdot)}) &= \log\langle \psi_{t_0} | \psi_{t_n} \rangle + \sum_{i=1}^{n} \log\langle \psi_{t_i} | \psi_{t_{i-1}} \rangle \\ &= \log\langle \psi_{t_0} | \psi_{t_n} \rangle + \sum_{i=1}^{n} \log(1 - \langle \psi_{t_i} | \psi_{t_i} - \psi_{t_{i-1}} \rangle), \end{aligned} \tag{2.35}$$

which in the limit of large n yields

$$\log \mathrm{Tr}(\mathcal{S}\alpha_{\psi(\cdot)}) = \log\langle \psi_{t_0} | \psi_{t_n} \rangle - \sum_{i=1}^{n} \langle \psi_{t_i} | \psi_{t_i} - \psi_{t_{i-1}} \rangle + O((\delta t)^2). \tag{2.36}$$

As $\delta t \to 0$ the sum in the right-hand side converges to a Stieljes integral $-\int_{t_i}^{t_f} dt \langle \psi(t) | \dot{\psi}(t) \rangle$ and hence

$$\mathrm{Tr}(\mathcal{S}\alpha_{\psi(\cdot)}) = e^{i\theta_g[\psi(\cdot)]}. \tag{2.37}$$

This is the Berry phase associated to the path $\psi(\cdot)$. This implies that $\mathcal{S}$ exists as an operator on $\mathcal{V}$. Its matrix elements can be defined as

$$\langle \phi(\cdot) | \mathcal{S} | \psi(\cdot) \rangle = \langle \phi(t_0) | \psi(t_f) \rangle \exp\left(\int \langle \psi(t) | d | \psi(t) \rangle \right), \tag{2.38}$$

where the integral in the exponential is of the Stieljes type (rather than of the Lebesque, that was used in the definition of $\otimes_{t \in T} H_t$). The Stieljes integral is defined for all measurable functions of bounded variation. Hence the matrix elements of $\mathcal{S}$ are finite. This implies, it is a well-defined bounded operator and it is easy to check that it remains unitary even in the continuous limit.

2. Another attempt to construct the decoherence functional

We have shown that the main operators that form the decoherence functional exist in the continuous limit. Could we then proceed and define a continuous-time decoherence functional from Eq. (2.20)? The answer is no, at least not straightforwardly. The problem is that the analog of the maps $\mathcal{A}$ does not exist in the continuous limit. The reason is the same as before: an embedding of single-time Hilbert spaces to the history Hilbert space fails to be continuous.

Therefore, one has two options. First, it should be noted that an initial and final moment of time is necessary in the decoherence functional, because they incorporate information about the

preparation of the system. From an operational viewpoint, one could then say that the specification of an initial state cannot be sharp in time and as such they should be incorporated in the decoherence functional by an object that is extended in time. This would imply a generalization of expression (2.23), where the map $\mathcal{A}$ is defined from $\mathcal{V}$ not to $\partial\mathcal{V}$, but to some other Hilbert space, which is associated with a finite time subinterval of T. The introduction of such an operator could provide a construction of a continuous decoherence functional in this case. This would be mathematically well defined and operationally meaningful, but would diverge from the standard canonical quantum theory. For this reason, we shall not pursue this further in this paper.

An alternative would be to abandon the effort to define a continuous decoherence functional and assume at most weak continuity.

If we assume two one-dimensional projectors $\alpha_{\psi(\cdot)}$ and $\alpha_{\psi(\cdot)}$ we get an expression for the decoherence functional with zero Hamiltonian

$$d(\alpha_{\psi(\cdot)},\alpha_{\psi(\cdot)}) = \langle\psi(t_i)|\hat{\rho}_0|\psi(t_i)\rangle\langle\psi(t_f)|\psi(t_f)\rangle \times \exp\left(\int_{t_i}^{t_f} dt\langle\psi(t)|\dot{\psi}(t)\rangle - \int_{t_i}^{t_f} dt\langle\dot{\psi}(t)|\psi(t)\rangle\right). \tag{2.39}$$

In the special case where $\hat{\rho}_0 = |\psi(t_i)\rangle\langle\psi(t_i)| = |\psi(t_i)\rangle\langle\psi(t_i)|$ and $|\psi(t_f)\rangle\langle\psi(t_f)| = |\psi(t_f)\rangle\langle\psi(t_f)|$ its value is equal to

$$d(\alpha_{\psi(\cdot)},\alpha_{\psi(\cdot)}) = e^{i\theta_g[\psi(\cdot),\psi(\cdot)]}, \tag{2.40}$$

the Berry phase for the *loop* formed from $\psi(\cdot)$ and $\psi(\cdot)$, since now they have the same endpoints.

More interestingly, when the Hamiltonian is included the decoherence functional becomes

$$d(\alpha_{\psi(\cdot)},\alpha_{\psi(\cdot)}) = \langle\psi(t_i)|\hat{\rho}_0|\psi(t_i)\rangle\langle\psi(t_f)|\hat{\rho}_f|\psi(t_f)\rangle e^{iS[\psi(\cdot)]-iS^*[\psi(\cdot)]}, \tag{2.41}$$

where the action is given by the familiar expression (its variation gives the Schrödinger equation)

$$S[\psi(\cdot)] = \int_{t_i}^{t_f} dt\langle\psi(t)|i\frac{d}{dt} - H|\psi(t)\rangle. \tag{2.42}$$

One might then give Eq. (2.41) as a *definition* of a decoherence functional for pairs of one-dimensional projectors and then extend this definition by finite addition to projectors with finite trace. But there is no *a priori* guarantee that one would thus construct an object taking finite values to a general projector on $\otimes_{t\in T}H_t$. Nonetheless, Eq. (2.41) *highlights the importance of the action as the object relating kinematics, dynamics and the probabilistic structure of quantum theory*.

We shall return to the issue of the definition of a continuous-time decoherence functional in Sec. III E 3.

F. Time reversal

A symmetry on a history Hilbert space is represented either by a unitary or an antiunitary operator. This has been established by Schreckenberg.[25]

Of particular interest are the time-reversal transformations. In discrete time they are defined by[12]

$$\mathcal{T}|v_{t_1}\rangle|v_{t_2}\rangle\cdots|v_{t_n}\rangle = |v_{t_n}\rangle|v_{t_{n-1}}\rangle\cdots|v_{t_1}\rangle. \tag{2.43}$$

Clearly

$$\mathcal{T}\mathcal{T}^\dagger = 1, \tag{2.44}$$

$$\mathcal{T}\mathcal{S}\mathcal{T}^{\dagger}=\mathcal{S}^{\dagger}. \tag{2.45}$$

Also for the operator $\mathcal{U}$ defined by (2.24) we have

$$\mathcal{T}\mathcal{U}\mathcal{T}^{\dagger}=e^{-i\hat{H}t_n}\otimes\cdots\otimes e^{-i\hat{H}t_1} \tag{2.46}$$

and when time runs in the full real line

$$\mathcal{T}\mathcal{U}\mathcal{T}^{\dagger}=\mathcal{U}^{\dagger}. \tag{2.47}$$

Finally for the time-inverted projection operators $\alpha^T=\mathcal{T}\alpha\mathcal{T}^{\dagger}$ (corresponding to homogeneous histories) we have

$$d(\alpha^T,\beta^T)=\mathrm{Tr}(\hat{C}_{\alpha}^{T\dagger}\rho_0\hat{C}_{\beta}^{T}\rho_f), \tag{2.48}$$

where $\hat{C}_{\alpha}^{T}=\hat{\alpha}_{t_1}(t_n)\cdots\hat{\alpha}_{t_n}(t_1)$. In the discrete case this form is not transparent, but when time takes values in all $\mathbf{R}$ the Heisenberg picture operators transform as $\alpha_t(t)\rightarrow\alpha_t(-t)$ and therefore

$$d(\alpha^T,\beta^T)=d(\beta,\alpha)=[d(\alpha,\beta)]^*. \tag{2.49}$$

Of course this later equation does not hold if the Hamiltonian is time dependent and the system is not time homogeneous.

The operator $\mathcal{T}$ is naturally defined also on $\otimes_{t\in\mathbf{R}}H_t$,

$$\mathcal{T}\,|\psi(\cdot)\rangle=\mathcal{T}\,|\psi(-\cdot)\rangle. \tag{2.50}$$

It is important to note that the time-reversal operator is linear rather than antilinear as in canonical quantum mechanics. This has again to do with the presence of two laws of time transformations in history theories; here time reversal implemented by $\mathcal{T}$ corresponds to the causal, kinematical properties of time. The time inversion operator of canonical quantum mechanics is obtained by the study of the Schrödinger equation and as such is clearly associated to the dynamical aspect of time.

Of course we can always define an antilinear time-reversal operator in complete analogy with the canonical case; a complex conjugation on H naturally defines a complex conjugation on $\mathcal{V}$. It would act on the Heisenberg picture operators as $\alpha_t(t)\rightarrow\alpha_t(-t)$.

G. Summary

Let us summarize here the results of this section. We showed how a Hilbert space $\otimes_{t\in T}H_t$ for continuous time histories can be constructed and how time-averaged observables can be defined as operators acting on it. Then we argued that in general we will have to restrict to a particular subset of $\otimes_{t\in T}H_t$. We then showed that the decoherence functional cannot be defined as a limiting case of its discrete-time form.

We then analyzed the structure of the decoherence functional. We identified the pieces out of which it is constructed, in light of the two laws of time transformation of history theories, and showed their relation to the dynamical and geometric phase of canonical quantum theory. We discussed a possible way to construct the continuous-time decoherence functional and finally saw how *unitary* time-reversal transformations are implemented in this scheme.

III. PHASE SPACE HISTORIES

In the preceding section we examined the general structure of continuous-time histories, without making any reference to a particular physical system, or class of systems. In order to do so, we necessarily have to make reference to a corresponding classical system and seeks to

identify operators on the Hilbert space with observables that have a classical analog. This is, in effect, the *quantization* procedure. In this section, we will study how the classical phase space structure is manifested in the histories formalism.

We refer the reader to Sec. I C 1 for explanation of the notations we will use in this section.

A. The canonical group

1. The Weyl group

In quantum theory the information about the corresponding classical theory can be encoded in the *canonical group*. This is classically identified as a group that acts transitively by canonical transformations on the classical phase space Γ.[26] When $\Gamma=\mathbf{R}^{2n}$ the canonical group is the $(2n+1)$-dimensional Weyl group. This is defined whenever the phase space has a vector space structure. It can therefore be infinite dimensional, as in a field theory. For its definition an inner product on Γ has to be assumed, so we usually consider Γ to be a real Hilbert space.

The Weyl group is generated by $q_i, p_i, 1$ and has basic Lie algebra relations

$$\{q_i, q_j\}=0, \tag{3.1}$$

$$\{p_i, p_j\}=0, \tag{3.2}$$

$$\{q_i, p_j\}=\delta_{ij}. \tag{3.3}$$

A generator of the Weyl group reads $\chi\cdot p+\xi\cdot q+c$, in terms of the inner product in Γ, and is labeled by (χ_i,ξ_i,c). The corresponding group element will be denoted as (χ,ξ,c). The group multiplication law is

$$(\chi_1,\xi_1,c_1)\cdot(\chi_2,\xi_2,c_2)=(\chi_1+\chi_2,\xi_1+\xi_2,c_1+c_2+\tfrac{1}{2}(\xi_1\cdot\chi_2-\xi_2\cdot\chi_1)). \tag{3.4}$$

When the canonical group has been identified, the Hilbert space of the theory is constructed through the selection of one of its unitary *irreducible* representations. The criterion for this selection is the existence of self-adjoint operators that correspond to the generators of classical symmetries (e.g., the Hamiltonian, the Lorentz group, etc.).

2. Coherent states

Suppose we have a representation of the canonical group by unitary operators $\hat{U}(g)$ on a Hilbert space. Furthermore, let $\hat{h}$ denote the Hamiltonian of this system and by $|0\rangle_H$ the vacuum, i.e., the Hamiltonian's lowest eigenstate. Then we define the coherent states as the vectors

$$|g\rangle=\hat{U}(g)|0\rangle. \tag{3.5}$$

Now consider the equivalence relation on the canonical group defined as $g\sim g'$ if $|g\rangle$ and $|g'\rangle$ correspond to the same ray. The phase space Γ is identified as the quotient space $G/\sim$ and we can label a coherent state by points $z\in\Gamma$.

Hence the canonical group defines a map $i:\Gamma\to PH$ as $z\to|z\rangle$. As we explained PH has a natural metric and a $U(1)$ bundle structure with a connection. These structures can be pullbacked to Γ with i^*. We have then on Γ a $U(1)$ bundle with a connection A given by

$$A=-i\langle z|d|z\rangle \tag{3.6}$$

and a metric

$$ds^2=\|d|z\rangle\|^2-|\langle z|d|z\rangle|^2, \tag{3.7}$$

where d is the exterior derivative on Γ. The fundamental property of coherent states is that they are an overcomplete basis; i.e., any vector $|\Psi\rangle$ can be written as

$$|\Psi\rangle = \int d\mu(z) f(z) |z\rangle, \tag{3.8}$$

in terms of some complex-valued function f on Γ. Here $d\mu$ denotes some natural measure on Γ. In n dimensions it equals $d^n\overline{z}\,dz/(2\pi)^n$. There is also a decomposition of the unity

$$\int d\mu(z) |z\rangle\langle z| = \hat{1}. \tag{3.9}$$

If the phase space Γ has a vector space structure the canonical group is the Weyl group. Its most usual representation is on $e^{\Gamma_C} = \oplus_{n=1}^{\infty} (\otimes_n H)_S$, the symmetric Fock space generated by the complex vector space Γ_C, a complexification of Γ.[27,28] On the Fock space there exist the unnormalized coherent states $|\exp z\rangle$ that to each $z \in \Gamma_C$ they assign the vector $|\exp z\rangle = \oplus_{n=0}^{\infty} \otimes_n z$. The inner product of such states is given by

$$\langle \exp z' | \exp z \rangle = e^{(z', z)_C}, \tag{3.10}$$

where $(\,,\,)_C$ denotes an inner product on Γ_C (its choice depends upon the way Γ is complexified). The corresponding normalized states are denoted simply as $|z\rangle$, or $|\chi, \xi\rangle$.

3. The overlap kernel

For the finite-dimensional Weyl group, the Stone–von Neumann theorem asserts that all irreducible representations are unitarily equivalent to the Fock one. This is not true in infinite dimensions. In this case, the information about the representation is encoded in the coherent states overlap $\langle \chi' \xi' | \chi \xi \rangle$.

This is determined by the expectation functional $K(\chi, \xi) = \langle 0 | \chi, \xi \rangle$ as a consequence of the group combination law

$$\langle \chi' \xi' | \chi \xi \rangle = e^{i/2(\chi \cdot \xi' - \xi \cdot \chi')} K(\chi - \chi', \xi - \xi'). \tag{3.11}$$

The expectation functional suffices to describe the connection and metric structure on phase space. If we write $K = e^W$, we find

$$A = \xi_i d\chi^i, \tag{3.12}$$

$$ds^2 = -\mathrm{Re}\left(\frac{\partial^2 W}{\partial \chi^i \partial \chi^j} d\chi^i\, d\chi^j + \frac{\partial^2 W}{\partial \xi^i \partial \xi^j} d\xi^i\, d\xi^j + \left(\frac{\partial^2 W}{\partial \chi^i \partial \xi^j} + \frac{\partial^2 W}{\partial \chi^j \partial \xi^i} \right) d\chi^i\, d\xi^j \right). \tag{3.13}$$

In the case of an harmonic oscillator with frequency ω, the functional W reads

$$W(\chi, \xi) = -\tfrac{1}{2}[\omega \chi^2 + \omega^{-1} \xi^2]. \tag{3.14}$$

The knowledge of the overlap suffices to construct the Hilbert space and the representation.[29]

A vector of the Hilbert space can be constructed as a function on phase space of the form $\Psi(\chi, \xi) = \Sigma_l c_l \langle \chi \xi | \chi_l \xi_l \rangle$ for a finite number of complex numbers c_l and χ_l, ξ_l. The inner product between two vectors characterized by c_l, χ_l, ξ_l and c_l', χ_l', ξ_l' is

$$\sum_l c_l'^{*} c_l \langle \chi_l' \xi_l' | \chi_l \xi_l \rangle. \tag{3.15}$$

The Weyl group is then represented by the operators $\hat{U}(\chi, \xi)$, which are defined as

$$(\hat{U}(\chi', \xi')\Psi)(\chi, \xi) = e^{(i/2)(\chi' \cdot \xi - \xi' \cdot \chi)} \Psi(\chi - \chi', \xi - \xi'). \tag{3.16}$$

The above equation is written for the finite-dimensional Weyl group, but with little modification is also valid for the infinite-dimensional case. The only difference is that in finite dimensions the Stone–von Neumann theorem holds: *all irreducible, strongly continuous, unitary representations of the Weyl group, are unitarily equivalent.*

In the infinite-dimensional case the vector space out of which the Weyl group is constructed is a functional space. For field theories in Minkowski spacetime this is a subspace of the space of square integrable functions on $\mathbf{R}^3$. In this case, the group of spatial translations is also represented unitarily on the Hilbert space. If the vacuum is the *unique translationary invariant state* in the representing Hilbert space, then it can be proven that *all unitarily equivalent representations share the same expectation functional*, and conversely, if two representations differ in their expectation functionals, they are unitarily inequivalent.[30] We shall refer to this as the *uniqueness theorem* for the expectation functional.

B. Classical histories

In order to study the phase space structure of quantum mechanical histories, we need to describe histories in classical mechanics in a way that is amenable to a direct comparison. We shall, therefore, reproduce here the main points of this description, referring the reader to Refs. 11 and 15 for details.

Consider the space of classical histories Π viewed as the set of continuous paths on the classical phase space Γ. An element of Π is a path $\gamma: T\to\Gamma$.

For any function f on Γ one can define a family of functions F_t on Π as

$$F_t(\gamma)=f(\gamma(t)). \tag{3.17}$$

Taking for simplicity $\Gamma=\mathbf{R}\times\mathbf{R}=\{(q,p)\}$, we can define q_t and p_t as elements of $C^\infty(\Pi)$ through

$$q_t(\gamma)=q(\gamma(t)), \tag{3.18}$$

$$p_t(\gamma)=p(\gamma(t)). \tag{3.19}$$

Two other functions on Π can be identified

$$V(\gamma)=\int_T dt\, p_t\dot{q}_t(\gamma), \tag{3.20}$$

$$H(\gamma)=\int_T dt\, h(p_t,q_t), \tag{3.21}$$

with h denoting the standard canonical Hamiltonian. If we furthermore equip Π with a symplectic form

$$\omega=\int dt\, dp_t\wedge dq_t, \tag{3.22}$$

corresponding to the Poisson bracket

$$\{q_t,p_{t'}\}=\delta(t,t'), \tag{3.23}$$

we can examine the canonical transformations generated by the functions V and H. These are the generators of the two distinct laws of time transformation that characterize history theories.

The transformations generated by V perform translations of the t argument in a path, that is $\gamma\to\gamma'$ with $\gamma'(t)=\gamma(t+s)$ (s is the affine parameter of the corresponding one-parameter group) or in its induced action on the functions

$$F_t \to F_{t+s}. \tag{3.24}$$

H respects the time labelling of the points of the path. It acts on each point of the path by transforming it (while keeping t fixed) according to Hamilton's equations. This means its action on $C^\infty(\Pi)$ is

$$(q_t, p_t) \to (q_t(s), p_t(s)), \tag{3.25}$$

where $q_t(s)$ is the function that to each path γ assigns the q coordinate of the point obtained by integrating the Hamilton equations from initial point with coordinates (q_t, p_t) to time s; similarly for $p_t(s)$.

In the classical setting this distinction of two laws of time transformation, is nicely related to the least action principle. A path γ is a solution to the classical equations of motions iff it is a fixed point of the canonical transformation generated by the action $S=V-H$. This implies the condition

$$\{q_t, S\}(\gamma) = \{p_t, S\}(\gamma) = 0. \tag{3.26}$$

Hence for the solutions to the equations of motion the laws of time evolution generated by V and H coincide.

C. The history group

The construction of the history Hilbert space through the tensor product of single-time Hilbert spaces suggests a natural generalization; the history Hilbert space has to carry the representation of the history group, the history analog of the canonical group.[12] This is a group that acts by symplectic transformations on the space of phase space histories. For linear phase spaces this is

$$[q^i_t, p^j_{t'}] = i\,\delta^{ij}\delta(t,t'). \tag{3.27}$$

It is clearly an infinite-dimensional Weyl group. Its proper definition involves a choice of smearing functions: we define $q_\xi = \int d\mu(t)\xi_i(t)q^i_t$ and p_χ similarly, and write the commutator as

$$[q_\xi, p_\chi] = i\int d\mu(t)\chi(t)\cdot\xi(t). \tag{3.28}$$

The precise choice of a test-function space depends on the physics of the system, but it definitely has to consist of square-integrable functions, if the right-hand side of (3.28) is to be defined. Here $d\mu$ stands for any measure on the real line, but what is mainly used is the measure employed in the construction of $\otimes_t H_t$, i.e., $d\mu(t) = dt/\tau$.

This history group is an infinite-dimensional Weyl group and admits many unitarily inequivalent representations.

The analysis of the classical histories suggests the criterion for selecting a representation. *There should exist self-adjoint operators in the Hilbert space, that correspond to the functions V and H of the classical theory*. For quadratic Hamiltonians, a Fock representation (that has the structure of a continuous tensor product) can be constructed,[13] in which both the Hamiltonian H_κ and an operator corresponding to V (the Liouville operator) exist. An important feature of this construction is the existence of a Hilbert space vector $|0\rangle$, which is the lowest eigenstate of the Hamiltonian and is left invariant under the action of e^{isV}.[13,10] The projector $|0\rangle\langle 0|$ corresponds to the proposition that at all times the systems is to be found in the ground state.

Another important feature of this construction is the fact that *the continuous tensor product of coherent states of the harmonic oscillator exists as a coherent state in the Fock–Hilbert space*. This is a feature that can be generalized for systems with nonquadratic Hamiltonian. Indeed, it will form the basis of our construction.

1. General representations

Representations cannot be explicitly constructed for nonquadratic Hamiltonians (it is the same situation with the one in canonical quantum field theory). Nonetheless, if we have some information about the canonical theory, we can exploit this to construct representations for the history group.

As we explained in Sec. II C, unbounded operators can be defined on a history Hilbert space, if we start our construction from a subset $\mathcal{L}$ of the Hilbert space. Since we want a Hilbert space that carries a representation of the history group, the natural choice for $\mathcal{L}$ would be the coherent states of the corresponding canonical group. If H carries a representation of the canonical group $\hat{U}(\chi,\xi)$ and $\hat{h}$ is the Hamiltonian with a unique ground state $|0\rangle_H$, we define the canonical coherent states $|z\rangle=|\chi\xi\rangle=\hat{U}(\chi,\xi)|0\rangle_H$. Then the history Hilbert space $\mathcal{V}$ is generated by all vectors

$$|z(\cdot)\rangle=|\chi(\cdot)\xi(\cdot)\rangle:=\otimes_{t\in T}|\chi_t\xi_t\rangle_{H_t}. \tag{3.29}$$

Furthermore, we demand that the vectors $|z(\cdot)\rangle$ on $\mathcal{V}$ are the coherent states associated with the corresponding history group. In this case we shall have a history overlap kernel

$$\langle\chi'(\cdot)\xi'(\cdot)|\chi(\cdot)\xi(\cdot)\rangle=\exp\left(\int d\mu(t)\log(\langle\chi'_t\xi'_t|\chi_t\xi_t\rangle_{H_t})\right). \tag{3.30}$$

The corresponding expectation functional $K_h[\chi(\cdot),\xi(\cdot)]=e^{W_h[\chi(\cdot),\xi(\cdot)]}$ will read in terms of the canonical expectation functional $K(\chi,\xi)=e^{W[\chi,\xi]}$,

$$W_h[\chi(\cdot),\xi(\cdot)]=\int d\mu(t)W[\chi_t,\xi_t]. \tag{3.31}$$

Clearly certain conditions have to be imposed on the admissible paths $(\chi,\xi)(\cdot)$ if the integral is to be finite. (We shall take $T=\mathbf{R}$ without any loss of generality in this section.)

Now, there exists a norm $|\cdot|_\Gamma$ on the phase space [it can be constructed from the metric (3.7) or from the inner product]. This induces a norm in the space of paths $t\to z_t$, which is given by

$$|z(\cdot)|_\Pi=\int d\mu(t)|z_t|_\Gamma. \tag{3.32}$$

Our first restriction, will be to consider only continuous paths with a finite value for the norm. For simplicity we shall assume that the maps $z(\cdot)$ take values (0,0) except within compact subsets of $\mathbf{R}$. But we expect that our results would still be valid, if the paths $x(\cdot)$ converge to (0,0) sufficiently fast (exponentially) outside compact sets.

We shall also assume that the canonical coherent states, viewed as maps from the phase space to H are smooth functions of their arguments. This implies that $W[\chi,\xi]$ is a smooth function of its variables. Since by definition $W[0,0]=0$, the above conditions are sufficient for the integral (3.31) to be finite.

We shall also impose the restriction that the maps $z(\cdot)$ are everywhere *Lifschitz*: in any compact subset U of $\mathbf{R}$, there exists $C>0$, such that for all $t_1,t_2\in U$, $|z_{t_1}-z_{t_2}|_\Gamma<C|t_1-t_2|$. This is a stronger assumption than continuity, but weaker than differentiability and it is necessary for proving existence of the Liouville operator.

If $|\chi(\cdot)\xi(\cdot)\rangle$ are to correspond to coherent states, *they have to be continuous functions of their arguments*. This is proven as follows.

Let us assume that $|z_1(\cdot)-z_2(\cdot)|_\Pi=\delta>0$. Then

$$\||z_1(\cdot)\rangle-|z_2(\cdot)\rangle\|^2_{\mathcal{V}}=2\left(1-\cosh\int d\mu(t)\log\langle z_{1t}|z_{2t}\rangle\right). \tag{3.33}$$

Let us write $|f_t\rangle = |z_{2t}\rangle - |z_{1t}\rangle$. Then we have

$$\| |z_1(\cdot)\rangle - |z_2(\cdot)\rangle \|_{\mathcal{V}}^2 = 2 - 2\cosh \int d\mu(t) \log(1 + \langle z_t | f_t \rangle). \tag{3.34}$$

The finiteness of $|z_1(\cdot) - z_2(\cdot)|_{\Pi}$, implies that except for a set of measure zero, there exists $c \geqslant 0$, such that $|\langle z_t | f_t \rangle| \leqslant \sqrt{\langle f_t | f_t \rangle} < c\delta$. Now, there exist complex numbers c_t, such that $\log(1 + \langle z_t | f_t \rangle) = c_t \langle z_t | f_t \rangle$. By our previous result (except perhaps in a set of measure zero) these c_t satisfy $|c_t| < C$, for $C > 0$. Using this result, we get

$$\| |z_1(\cdot)\rangle - |z_2(\cdot)\rangle \|_{\mathcal{V}}^2 = 2 - 2\cosh\left(\int d\mu(t) c_t \langle z_t | f_t \rangle \right). \tag{3.35}$$

The integral is bounded $|\int d\mu(t) c_t \langle z_t | f_t \rangle| \leqslant C\delta$, so for sufficiently small δ, there exists a constant $C' > 0$ such that

$$\| |z_1(\cdot)\rangle - |z_2(\cdot)\rangle \|_{\mathcal{V}}^2 \leqslant C' \delta^2, \tag{3.36}$$

showing that $|z(\cdot)\rangle$ is a continuous function of $z(\cdot)$.

This implies that W is also a continuous function of $\chi(\cdot), \xi(\cdot)$; so as explained in Sec. III A 3, we define a representation of the history group using Eq. (3.16).

But the representation can also be defined straightforwardly. Indeed, we can write a unitary operator $U(\chi(\cdot), \xi(\cdot))$ as $\otimes_{t \in \mathbf{R}} U(\chi_t, \xi_t)$, i.e., by its action on the coherent state vectors

$$U(\chi(\cdot), \xi(\cdot)) |\chi'(\cdot) \xi'(\cdot)\rangle = e^{(i/2) \int d\mu(t) (\chi_t' \cdot \xi_t - \chi_t \cdot \xi_t')} |\chi(\cdot) + \chi'(\cdot), \xi(\cdot) + \xi'(\cdot)\rangle. \tag{3.37}$$

Therefore time averaged operators for position $q_\xi = \int d\mu(t) q_t \cdot \xi(t)$ and momentum $p_\chi = \int d\mu(t) p_t \chi(t)$ *do exist* on $\mathcal{V}$.

2. Operators

Let us first see how we can define the analog of the Hamiltonian $H_\kappa = \int d\mu(t) h(q_t, p_t)$ in this Hilbert space.

Let $\hat{h}$ be the Hamiltonian on the canonical Hilbert space. We assume that the representation of the Weyl group can be chosen, so that all coherent state vectors lie in the domain of $\hat{h}$. This suffices to show that there exist complex numbers $A(s)$, such that

$$\langle \chi' \xi' | e^{-i\hat{h}s} | \chi \xi \rangle = \langle \chi' \xi' | \chi \xi \rangle (1 - iA(s) h(\chi, \xi; \chi', \xi') s), \tag{3.38}$$

where $h(\chi, \xi; \chi', \xi') = \langle \chi' \xi' | \hat{h} | \chi \xi \rangle / \langle \chi' \xi' | \chi \xi \rangle$, and for each neighborhood of $s = 0$ there exists $C > 0$ such that $|A(s)| \leqslant C$. Let us try to define a version of the operator $U_\kappa(s) = e^{-iH_\kappa s}$ as $\otimes_t e^{-i\hat{h}\kappa(t)s}$. It is easy to show, as in Sec. II C 3, that it is well defined; the issue is to show it is continuous at $s = 0$, for then by Stone's theorem H_κ exists. We have

$$\begin{aligned} |\langle \chi'(\cdot) \xi'(\cdot) | U(s) - 1 | \chi(\cdot) \xi(\cdot) \rangle| &= \left| \exp\left(\int d\mu(t) \log(\langle \chi_t' \xi_t' | e^{-i\hat{h}\kappa(t)s} | \chi_t \xi_t \rangle_{H_t}) \right) - 1 \right| \\ &= \left| \exp\left(\int d\mu(t) \log(1 - iA(s) s \kappa(t) h(\chi_t, \xi_t; \chi_t', \xi_t')) \right) - 1 \right| \\ &\leqslant C \left| \int d\mu(t) \kappa(t) h(\chi_t, \xi_t : \chi_t', \xi_t') \right| |s|. \end{aligned} \tag{3.39}$$

Here C is a real positive number. Therefore $U(s)$ has matrix elements continuous with respect to s if $\int d\mu(t) \kappa(t) h(\chi_t, \xi_t; \chi_t', \xi_t')$ exists. We can take $\kappa(t)$ to be a measurable function that

grows at most polynomially. We have adjusted $\hat{h}$ so that $\hat{h}|0\rangle_H=0$, then it suffices that $h(\chi_t,\xi_t;\chi_t',\xi_t')$ is continuous. We have demanded that $(\chi_t,\xi_t)\to 0$ exponentially fast outside some compact set, hence $h(\chi_t,\xi_t;\chi_t',\xi_t')\to 0$ outside this compact set.

The operator H_κ *can be therefore defined*.

A Liouville operator corresponding to the classical function $\int dt\, p_t\dot{q}_t$ is also defined by its action on coherent states

$$e^{isV}|\chi(\cdot)\xi(\cdot)\rangle\to=|\chi'(\cdot)\xi'(\cdot)\rangle, \tag{3.40}$$

where $(\chi'(t),\xi'(t))=(\chi(t+s),\xi(t+s))$. We need to check that it is continuous at $s=0$. We have

$$\langle\chi(\cdot)\xi(\cdot)|e^{isV}|\chi(\cdot)\xi(\cdot)\rangle=\exp\left(\int d\mu(t)\log\langle\chi_t\xi_t|\chi_{t+s}\xi_{t+s}\rangle_{H_t}\right). \tag{3.41}$$

Since the coherent states are continuous functions of their arguments and the paths $(\chi,\xi)(\cdot)$ have been assumed Lifschitz, there exists a vector $|f_t,s\rangle_{H_t}$ on H such that

$$|\chi_{t+s}\xi_{t+s}\rangle_{H_t}=|\chi_t\xi_t\rangle_{H_t}+s|f_t,s\rangle_{H_t}, \tag{3.42}$$

and $\langle f_t,s|f_t,s\rangle<C_t$ for some constants $C_t>0$. Therefore

$$|\langle\chi(\cdot)\xi(\cdot)|e^{isV}-1|\chi(\cdot)\xi(\cdot)\rangle|=\left|\exp\left(\int d\mu(t)\log(1+s\langle\chi_t\xi_t|f_t,s\rangle)_{H_t}\right)-1\right|\leqslant A|s|\int d\mu(t)C_t, \tag{3.43}$$

for some constant $A>0$. Now, since we assume $(\chi_t,\xi_t)\to(0,0)$ outside compact intervals, C_t can always be chosen to be constant in this compact interval and vanish outside this, thus rendering the integral finite. We therefore establish continuity of the matrix elements of e^{isV} around $s=0$.

The operator V, therefore, exists.

The existence of V and H_κ also implies the existence of an action operator $S_\kappa=V-H_\kappa$.

To summarize, assuming that

(1) the canonical coherent states are smooth functions of their arguments,
(2) they lie in the domain of $\hat{h}$,
(3) $\hat{h}$ has a unique ground state $|0\rangle_H$, in which $\hat{h}|0\rangle_H=0$,
(4) we consider paths $t\to z_t$, that satisfy the Lifschitz condition,

we can define a representation of the history group in a Hilbert space $\mathcal{V}$ in the fashion described, such that the two generators of time transformation are self-adjoint operators on $\mathcal{V}$.

An issue that can be raised at this point is that the choice of paths is restricted to ones that $(\chi_t,\xi_t)\to 0$ as time goes to infinity. These are not sufficient to describe all conceivable phase space motions, as for instance oscillators that oscillate eternally. However, one can consider such properties in an arbitrarily large, but finite, time interval. This restriction is a consequence of the way we have chosen to define the smearing functions for the generators of the history group. A possibility that might lift this difficulty in a natural manner is briefly presented in Sec. IV A.

3. Uniqueness of the representation

As $(\chi_t,\xi_t)\to(0,0)$ for large t, the only vector that is left invariant under the time translations generated by the Liouville operator is the ''vacuum'' vector $|0\rangle=\otimes_{t\in\mathbf{R}}|0\rangle_{H_t}$. (It corresponds to the proposition that the system is on the ground state at all times.) Since the history Weyl group is isomorphic to the Weyl group of a field theory, we can use the uniqueness theorem for the expectation functional, to establish that any two of the representations, we have constructed are unitarily inequivalent, if they have *different expectation functionals*.

This has different implications according to whether the *canonical* Weyl group is finite or infinite dimensional. If it is infinite dimensional and corresponds to a well-behaved quantum field theory (i.e., with a unique translationally invariant vacuum), then the expectation functional of the canonical theory is independent of the representation and unique. Hence, the expectation functional for the history theory, constructed by Eq. (3.30) is also unique. This means for a given representation of the canonical group, we can obtain a representation of the history group, in such a way, that unitarily equivalent representations of the canonical group yield unitarily equivalent representations of the history group. This is, indeed, very satisfactory.

However, for finite-dimensional canonical Weyl group, all representations are unitarily equivalent. Hence different expectation functionals correspond to unitarily equivalent theories. But different expectation functionals canonically, lead to different expectation functionals for the history group. And these give rise to unitarily inequivalent representations. We are then in the unpleasant situation of having many inequivalent history theories corresponding to one canonical theory. There is no remedy for this. But, we should remark that the conditions developed throughout this section, constrain severely the choice of the representation of the canonical group we are allowed to use. The canonical coherent states have to lie in the domain of all operators that we want to also define in the histories theory. Even if this does not guarantee uniqueness, at least it gives a guideline for which type of representations are interesting to use.

4. The decoherence functional

We saw that we have to restrict to paths (χ_t,ξ_t) that fall to zero rapidly at large t. This means that the single-time Hilbert space at $t=\pm\infty$ is essentially one dimensional, consisting only of the vector $|0\rangle$.

We saw that in the construction of the decoherence functional, the main problem came from the operators defined at the boundary Hilbert space. In this construction, when time is taken in the whole of the real line, the boundary Hilbert space is one dimensional and the boundary operator $\mathcal{A}$ is just multiplicative. Hence the decoherence functional splits in the product of two phases:

$$d(\alpha,\beta)=\mathrm{Tr}_{\mathcal{V}}(\mathcal{S}\mathcal{U}^{\dagger}\alpha\mathcal{U})\,\mathrm{Tr}_{\mathcal{V}}(\mathcal{S}^{\dagger}\mathcal{U}^{\dagger}\beta\mathcal{U}). \tag{3.44}$$

The operator $\mathcal{U}$ is easily identified as e^{-iH_κ} for $\kappa(t)=t$.

The construction of the operator $\mathcal{S}$ is more intricate. Complex analyticity of the coherent states makes consideration of the diagonal matrix elements sufficient.

From the basic operation of the Weyl group we get that

$$\langle\chi'\xi'|\chi\xi\rangle=\exp(i/2(\xi\cdot\chi'-\chi\cdot\xi')+W[\chi-\chi',\xi-\xi']). \tag{3.45}$$

Assuming a discetization $t_0,t_1,\ldots,t_n=t_f$ of the interval $[t_i,t_f]$ the definition (2.22) yields

$$\begin{aligned}
&\langle\chi_{t_0},\xi_{t_0};\ldots;\chi_{t_n},\xi_{t_n}|\mathcal{S}|\chi_{t_0},\xi_{t_0};\ldots;\chi_{t_n},\xi_{t_n}\rangle\\
&\quad=\langle\chi_{t_0}\xi_{t_0}|\chi_{t_n}\xi_{t_n}\rangle\prod_i\langle\chi_{t_i}\xi_{t_i}|\chi_{t_{i-1}}\xi_{t_{i-1}}\rangle\\
&\quad=e^{(i/2)(\xi_{t_n}\cdot\chi_{t_0}-\chi_{t_n}\cdot\xi_{t_0})+W[\chi_{t_n}-\chi_{t_0},\xi_{t_n}-\xi_{t_0}]}\\
&\qquad\times\exp\left(\sum_i\frac{i}{2}(\xi_{t_{i-1}}\cdot\chi_{t_i}-\xi_{t_i}\cdot\chi_{t_{i-1}})+W[\chi_{t_{i-1}}-\chi_{t_i},\xi_{t_{i-1}}-\xi_{t_i}]\right)\\
&\quad=e^{(i/2)(\xi_{t_n}\cdot\chi_{t_0}-\chi_{t_n}\cdot\xi_{t_0})+W[\chi_{t_n}-\chi_{t_0},\xi_{t_n}-\xi_{t_0}]}\\
&\qquad\times\exp\left(\sum_i\frac{i}{2}[\xi_{t_i}\cdot(\chi_{t_i}-\chi_{t_{i-1}})-\chi_{t_i}\cdot(\xi_{t_i}-\xi_{t_{i-1}})]\right.\\
&\qquad\left.-\frac{\partial W}{\partial\xi}[\chi_{t_i},\xi_{t_i}](\xi_{t_i}-\xi_{t_{i-1}})-\frac{\partial W}{\partial\chi}[\chi_{t_i},\xi_{t_i}](\chi_{t_i}-\chi_{t_{i-1}})\right).
\end{aligned}\tag{3.46}$$

Hence at the continuous limit we get

$$\begin{aligned}\langle\chi(\cdot)\xi(\cdot)|\mathcal{S}|\chi(\cdot)\xi(\cdot)\rangle &= e^{(i/2)(\xi(t_f)\cdot\chi(t_0)-x(t_f)\cdot\xi(t_0))+W[\chi(t_f)-\chi(t_0),\xi(t_f)-\xi(t_0)]}\\ &\quad\times\exp\left(\int_{t_0}^{t_f}dt\,\frac{i}{2}(\xi\cdot\dot{\chi}-\chi\cdot\dot{\xi})-\int_{W_{t_0}}^{W_{t_f}}dW\right)\\ &=\exp\left(\frac{i}{2}(\xi(t_f)\cdot\chi(t_0)-\chi(t_f)\cdot\xi(t_0))+W[\chi(t_f)-\chi(t_0),\xi(t_f)-\xi(t_0)]\right.\\ &\quad\left.-W[\chi(t_f),\xi(t_f)]+W[\chi(t_0),\xi(t_0)]\right)\\ &\quad\times\exp\left(\frac{i}{2}\int_{t_0}^{t_f}dt(\xi\cdot\dot{\chi}-\chi\cdot\dot{\xi})\right).\end{aligned}\tag{3.47}$$

Clearly as $[t_0,t_f]\to(-\infty,\infty)$ we get

$$\langle\chi(\cdot)\xi(\cdot)|\mathcal{S}|\chi(\cdot)\xi(\cdot)\rangle=\exp\left(i\int_{-\infty}^{\infty}\xi\cdot\dot{\chi}\right).\tag{3.48}$$

In particular, for a pair of coherent-state histories the decoherence functional reads

$$d((\xi,\chi)(\cdot),(\xi',\chi')(\cdot))=e^{iS[\xi(\cdot),\chi(\cdot)]-iS^*[\xi'(\cdot),\chi'(\cdot)]},\tag{3.49}$$

where

$$iS[\xi,\chi]=\langle\xi,\chi|\left(\frac{d}{dt}-iH\right)|\xi,\chi\rangle\tag{3.50}$$

is the classical phase space action.

D. The generating functional

1. N-point functions

A probability theory does not only give probabilities to possible scenaria, it also provides expectation values for observables. In fact, a probability measure can be fully reconstructed from the knowledge of a sufficiently large number of expectation values: these are known as the moments of the distribution or in physics as the N-point functions. We shall write the relevant formulas in the context of stochastic processes, rather than single-time probability theory, for it is the analog of these expressions that we shall attempt to generalize in the quantum context.

Let us denote by x a vector that corresponds to a point of a sample space Ω and Ω^T the space of histories with elements the paths $x(\cdot)$. Let also $d\mu(x(\cdot))$ denote the probability measure in the space of paths. One then defines the N-point functions

$$G^{(n)}(a_1,t_1;\ldots;a_n,t_n)=\int d\mu(x(\cdot))X^{a_1}_{t_1}\cdots X^{a_n}_{t_n},\tag{3.51}$$

where $X^a_t(x(\cdot))=x^a(t)$ is a function on Ω^T.

The information of the N-point functions is encoded in the generating functional

$$Z[J]=\sum_{n=0}^{\infty}\frac{(i)^n}{n!}\int dt_1\cdots dt_n\sum_{a_1\cdots a_n}G^{(n)}(a_1,t_1;\cdots;a_n,t_n)J_{a_1}(t_1)\cdots J_{a_n}(t_n).\tag{3.52}$$

The generating functional is just the Fourier transform of the stochastic measure

$$Z[J(\cdot)]=\int d\mu(x(\cdot))\exp\left(i\int dt\, X_t^a J_a(t)\right). \tag{3.53}$$

The N-point functions (3.51) fully exhaust the physical content of the theory; hence the generating functional (3.53) provides a complete specification of the probability measure. In general, one can define generating functionals containing less complete information, e.g., ones that refer to one single observable. For instance given a function f on Ω we can define

$$Z_f[J(\cdot)]=\int d\mu(x(\cdot))e^{i\int dt\, F_t J(t)} \tag{3.54}$$

which generates the correlation functions of f. Or more generally, one can define generating functionals of time-averaged quantities F (functions on Ω^T) as

$$Z_F(j)=\int d\mu(x(\cdot))e^{iF(x(\cdot))j}, \tag{3.55}$$

for some real number j.

2. The CTP generating functional

Since the decoherence functional is defined through bounded operators on $\mathcal{V}$, its definition can be extended to a bilinear functional over all bounded operators on $\mathcal{V}$: $d: B(\mathcal{V})\times B(\mathcal{V})\to\mathbf{C}$.

We shall first examine the discrete-time case. Let us consider an operator $\hat{A}$ on H. Then if A_t denotes the corresponding single-time operator on $\mathcal{V}$ (see Sec. II A), we can see that

$$d(A_{t_1}\otimes A_{t_2},1)=\Theta(t_1-t_2)\mathrm{Tr}(\hat{\rho}_0\hat{A}(t_1)\hat{A}(t_2))+\Theta(t_2-t_1)\mathrm{Tr}(\hat{\rho}_0\hat{A}(t_2)\hat{A}(t_1)), \tag{3.56}$$

$$d(1,A_{t_1}\otimes A_{t_2})=\Theta(t_2-t_1)\mathrm{Tr}(\hat{\rho}\hat{A}(t_1)\hat{A}(t_2))+\Theta(t_1-t_2)\mathrm{Tr}(\hat{\rho}\hat{A}(t_2)\hat{A}(t_1)), \tag{3.57}$$

where $\hat{A}(t)$ is the Heisenberg picture operator on H: $e^{i\hat{H}t}\hat{A}e^{-i\hat{H}t}$. The right-hand side of (3.56) and (3.57) are the time-ordered and anti-time-ordered two-point function for this observable. Similarly we can construct higher time-ordered and anti-time-ordered functions, respectively, as well as mixed ones, e.g., $d(A_{t_1},A_{t_2}\otimes A_{t_3})$. They are usually denoted by (r,s) correlation functions r denoting the number of time-ordered and s of anti-time-ordered appearances of A in the expectation value. Such N-point functions have been first used in the classic study of quantum Brownian motion by Schwinger.[17] They are obtained by an object known as the closed-time-path (CTP) generating functional.[17,31]

If we want to construct an object that encodes the information about the N-point functions at all times, we need to go to the continuum limit.

Let us by A_f denote the time averaged version of an operator $\hat{A}$ on H, defined in the way we explained in Sec. II C. Then we define the closed-time-path generating functional associated to the operator $\hat{A}$ as a function of a pair of smearing functions J_+ and J_- through

$$Z_{\hat{A}}[J_+(\cdot),J_-(\cdot)]=d(e^{iA_{J_+}},e^{-iA_{J_-}}). \tag{3.58}$$

The signs $+$ and $-$ correspond, respectively, to the part that generates time-ordered, vs anti-time-ordered correlation functions. In general the (r,s) mixed correlation function for A will be given by

$$G_A^{(r,s)}(t_1,\ldots,t_r;t_1',\ldots,t_s')=(-i)^r i^s\frac{\delta^r}{\delta J_+(t_1)\cdots\delta J_+(t_r)}\frac{\delta^s}{\delta J_-(t_1)\cdots\delta J_-(t_s)}Z[J_+,J_-]|_{J_+=J_-=0}. \tag{3.59}$$

When the Hilbert space carries a representation $U(\chi,\xi)=e^{-iq_\xi - ip_\chi}$ of the history Weyl group, there exist time-averaged versions of the position and momentum operators. We can then construct the configuration space CTP generating functional as

$$Z_q[\xi_+,\xi_-]=d(e^{i(q,\xi_+)},e^{-i(q,\xi_-)}). \tag{3.60}$$

This generating functional has been widely used, mainly because it has a convenient path-integral expression. One can construct a corresponding effective action through a Legendre transform of $W=-i\log Z$ (known as the CTP effective action).[32]

But we can also write a generating functional that contains all *phase space* correlation functions. This is simply defined[14] as

$$Z[\xi_+,\chi_+;\xi_-,\chi_-]=d(U(\chi_+,\xi_+),U^\dagger(\chi_-,\xi_-)). \tag{3.61}$$

Since our representation of the history group is irreducible, all physical information about the physical system is contained in the CTP generating functional (3.61). Indeed, it is the quantum analog of the generating functional (3.53) of a general stochastic process.

E. The Wigner–Weyl transform

1. The canonical case

In quantum mechanics a representation $\hat{U}(\chi,\xi)$ of the canonical group enables one to construct a *linear* map that takes a large class of Hilbert space operators to phase space functions. This is known as the Wigner–Weyl transform. It is implemented as follows: If $\hat{A}$ is a trace-class operator on H then, we define the function $F_{\hat{A}}(q,p)$ on phase space as

$$F_{\hat{A}}(q,p)=\int d\chi\, d\xi\, e^{-i\xi\cdot q-i\chi\cdot p}\,\mathrm{Tr}(\hat{U}(\xi,\chi)\hat{A}):=\mathrm{Tr}(\hat{\Delta}(q,p)\hat{A}), \tag{3.62}$$

where $\hat{\Delta}(q,p)=\int d\chi\, d\xi\, e^{-i\xi\cdot q-i\chi\cdot p}\hat{U}(\chi,\xi)$. This operator satisfies

$$\int dq\, dp\, \hat{\Delta}(q,p)=\hat{1}, \tag{3.63}$$

and its matrix elements in a coherent state basis are given by

$$\langle\chi'\xi'|\Delta(q,p)|\chi\xi\rangle=e^{i\xi\cdot(\chi-\chi')+iq\cdot(p-p')+i(\chi\cdot\xi-\chi'\cdot\xi')}\times\tilde{K}\left[p+\frac{\xi+\xi'}{2},q-\frac{\chi+\chi'}{2}\right], \tag{3.64}$$

in terms of the Fourier transform of the expectation functional

$$\tilde{K}[p,q]=\int d\mu(\chi,\xi)e^{-i\chi\cdot p-i\xi\cdot q}K[\chi,\xi]. \tag{3.65}$$

Note that by $dq\,dp$ we denote the standard Lebesque measure on $\Gamma=\mathbf{R}^{2n}$, normalized by a factor of $(2\pi)^{-n}$.

This definition can be extended to bounded operators (at least when the Weyl group is finite dimensional) and to a large class of unbounded ones. The Wigner–Weyl transform of a density matrix is known as the *Wigner function*. There are two important properties of the Wigner transform

$$\int dq\, dp\, F_{\hat{A}}(q,p)=\mathrm{Tr}_H\hat{A}, \tag{3.66}$$

$$\int dq\, dp\, F_{\hat{A}}(q,p)F_{\hat{B}}(q,p)=\mathrm{Tr}_H(\hat{A}\hat{B}). \tag{3.67}$$

The operator commutator induces on the phase the Moyal bracket $\{\,,\}_M$. For a pair of operators $\hat{A}$ and $\hat{B}$ their commutator $\hat{C}=[\hat{A},\hat{B}]$ is associated with the symbol

$$\frac{1}{i}F_{\hat{C}}=\{F_{\hat{A}},F_{\hat{B}}\}_M:=2F_{\hat{A}}\sin\left(\frac{1}{2}\{\,,\}\right)F_{\hat{B}} \tag{3.68}$$

here $\{\,,\}$ is the Poisson bracket on phase space, written as a bilinear operator: $f\{\,,\}g=\{f,g\}$. The sinus in this expression refers to its Taylor series viewed as a function of this bilinear operator.

2. The histories analog

We can proceed similarly in the histories case and to each trace-class operator A on $\mathcal{V}$ associate a function F_A on Π, the space of classical histories as

$$F_A[\gamma]=F_A[q(\cdot),\xi(\cdot)]=\int D\xi(\cdot)D\chi(\cdot)e^{-i(q,\xi)(\gamma)-i(p,\chi)(\gamma)}\,\mathrm{Tr}(U(\xi,\chi)A). \tag{3.69}$$

This expression is only formal, since the measures $D\chi(\cdot)$, etc., do not exist. What is implied is $F_A(\gamma)=\mathrm{Tr}_{\mathcal{V}}(A\Delta(q(\cdot),p(\cdot)))$. By $\Delta(q(\cdot),p(\cdot))$ we denote a linear map that is given by

$$\Delta(q(\cdot),p(\cdot))=\otimes_t\hat{\Delta}(q_t,p_t). \tag{3.70}$$

If the operator A is a product operator $\otimes_t\hat{A}_t$, then using Eq. (2.14) we see that

$$F_{A_f}[q(\cdot),p(\cdot)]=\exp\left(\int d\mu(t)\log F_{\hat{A}_t}(q_t,p_t)\right). \tag{3.71}$$

It is also easy to calculate the symbol for a time averaged operator A_f by constructing the Weyl transform for e^{iA_fs} and expanding around $s=0$. The result is

$$F_{A_f}[q(\cdot),p(\cdot)]=\int d\mu(t)f(t)F_{\hat{A}}(q_t,p_t). \tag{3.72}$$

Such is for instance the case of position, momentum operators, and the Hamiltonian, so that

$$q_f\rightarrow F_{q_f}=\int d\mu(t)q_tf(t), \tag{3.73}$$

$$p_f\rightarrow F_{p_f}=\int d\mu(t)p_tf(t), \tag{3.74}$$

$$H_\kappa\rightarrow F_{H_\kappa}=\int d\mu(t)\kappa(t)h(q_t,p_t), \tag{3.75}$$

where $h(q,p)=F_{\hat{h}}(q,p)$ is the Wigner transform of the canonical Hamiltonian.

For more general operators on $\mathcal{V}$, the Weyl transform is effected by constructing first a suitable discrete-time expression in $\otimes_i H_{t_i}$ and then going to the continuum limit. It is more convenient to employ the decomposition of the unity for the canonical coherent states in order to compute the trace:

$$\mathrm{Tr}_{\mathcal{V}}A=\int\prod_i d\mu(\chi_{t_i},\xi_{t_i})\langle\chi_{t_1}\xi_{t_1};\chi_{t_2}\xi_{t_2}\cdots\chi_{t_n}\xi_{t_n}|A|\chi_{t_1}\xi_{t_1};\chi_{t_2}\xi_{t_2}\cdots\chi_{t_n}\xi_{t_n}\rangle. \tag{3.76}$$

For operators that map coherent states into coherent states, the calculations are easier to perform. Such is, for instance, the operator e^{isV}. We can compute

$$e^{isV}\rightarrow F_{e^{isV}}=\int \prod_t d\mu(\chi_t,p_t)\langle\chi_t\xi_t|\hat{\Delta}(q_t,p_t)|\chi_{t+s}\xi_{t+s}\rangle_{H_t}. \tag{3.77}$$

If we expand this around $s=0$ we find that

$$V\rightarrow F_V=\int dt\, p_t\dot{q}_t, \tag{3.78}$$

where the integral is of a Stieljes type.

Note that Eqs. (3.69) and (3.76) are, as yet, defined for a discretization of the time interval. In order to compute any traces we will always need to check the finiteness of the expressions at the continuum limit. We will return to this later in Sec. III E 3.

3. The decoherence functional

In an analogous manner, one can assign to the decoherence functional a ''function'' on $\Pi\times\Pi$ as

$$\begin{aligned} &W[q(\cdot),p(\cdot)|q'(\cdot),p'(\cdot)]\\ &\quad=W[\gamma|\gamma']\\ &\quad=\int D\xi_+(\cdot)D\chi_+(\cdot)D\xi_-(\cdot)D\chi_-(\cdot)e^{-i(q,\xi_+)-i(p,\chi_+)+i(q',\xi_-)+i(p',\chi_-)}\\ &\qquad\times Z[\xi_+,\chi_+;\xi_-,\chi_-]. \end{aligned} \tag{3.79}$$

Given then some operators (these might be projectors that correspond to a history proposition) A and B on $\mathcal{V}$ we have

$$d(A,B)=\int D\mu(\gamma)D\mu(\gamma')W[\gamma|\gamma']F_A(\gamma)F_B(\gamma'), \tag{3.80}$$

where $D\mu(\gamma)$ is a shorthand for $D\chi(\cdot)D\xi(\cdot)$.

In spite of the general nondefinability of the integration measure, there is a very good sense in which the $W[\gamma|\gamma']$ exists: as the inductive limit of its discrete-time expressions, in complete analogy with the Kolmogorov's construction of the stochastic probability measure. This proceeds as follows.

In standard quantum mechanics one can define objects that correspond to classical multitime probabilities using the Wigner transform.[33] They are of the form

$$W(q_1,p_1,t_1;\ldots;q_n,p_n,t_n)=\mathrm{Tr}(\hat{\rho}_0e^{i\hat{H}t_1}\hat{\Delta}(q_1,p_1)e^{-i\hat{H}t_1}\cdots e^{i\hat{H}t_n}\hat{\Delta}(q_n,p_n)e^{-i\hat{H}t_n}). \tag{3.81}$$

These distributions do not define a probability measure: they are complex and do not satisfy the Kolmogorov additivity condition. Rather they are the building blocks of the decoherence functional. In analogy with the stochastic case if we consider two discretizations $I=\{t_1,\ldots,t_n\}$ and $I'=\{t'_1,\ldots,t'_m\}$ of an interval T, we can define the objects as

$$W_{n,m}[q_1,p_1,t_1;\ldots;q_n,p_n,t_n|q'_1,p'_1,t'_1;\ldots;q'_m,p'_m,t'_m]=\mathrm{Tr}(\hat{C}_n^{\dagger}\hat{\rho}_0\hat{C'}_m), \tag{3.82}$$

where

$$\hat{C}_m=e^{i\hat{H}t_1}\hat{\Delta}(q_1,p_1)e^{-i\hat{H}t_1}\cdots e^{i\hat{H}t_m}\hat{\Delta}(q_m,p_m)e^{-i\hat{H}t_m} \tag{3.83}$$

and similarly for $\hat{C}'_m$.

Let us write Ω^I and $\Omega^{I'}$ as the spaces of discrete-time phase space histories. They can be equipped with the standard Lebesque measure $\Pi_t dq_t\, dp_t$, so that $W_{n,m}$ can be used to define genuine decoherence functionals $d_{I,I'}$ that satisfy properties (2.3). If we denote by Ω^T the space of phase space histories we can consider the injection map $i_{I,I'}: \Omega^n \times \Omega^m \to \Omega^T \times \Omega^T$. These maps are *measurable*. It is easy to check that the hierarchy of functions $W_{n,m}$ satisfies an additivity condition

$$\int dq_{t_1}\, dq_{t_2}\, W_{n,m}[q_1,p_1,t_1;\ldots;q_n,p_n,t_n|q'_1,p'_1,t'_1;\ldots;q'_m,p'_m,t'_m] = W_{n-1,m}[q_2,p_2,t_2;\ldots;q_n,p_n,t_n|q'_1,p'_1,t'_1;\ldots;q'_m,p'_m,t'_m]. \tag{3.84}$$

In complete analogy to Kolmogorov's theorem, the above properties are sufficient to prove the existence of an additive, complex-valued, Hermitian measure on $\Pi \times \Pi$, i.e., a decoherence functional d_Π, such that

$$d_{I,I'} = i^*_{I,I'} d_\Pi. \tag{3.85}$$

It is important to remark that the definition of the decoherence functional on phase space took place with respect to the *measurable subsets* of Π, which define a Boolean algebra. This is clearly distinct from the logic of projectors on the Hilbert space $\mathcal{V}$. This is what enabled us to sidestep the nondefinability of a decoherence functional from the discrete-time expressions.

This construction does not highlight the general structure of the decoherence functional. To see this, it is necessary to compute the Wigner transformations of the operators $\mathcal{S}$ and $\mathcal{U}$.

When the Hamiltonian is quadratic, the coherent states are Gaussians and the calculation of traces reduces to Gaussian integrals. In this case the functional relations of operators is preserved by the Weyl–Wigner transform. For the harmonic oscillator, we get

$$\mathcal{U} \to F_{\mathcal{U}} = e^{-iH\kappa}, \quad \kappa(t) = t, \tag{3.86}$$

$$\mathcal{S} \to F_{\mathcal{S}} = \exp(-\tfrac{1}{2}[\omega(q_{t_f} - q_{t_0})^2 + \omega^{-1}(p_{t_f} - p_{t_0})^2 + i(p_{t_f} \cdot q_{t_0} - q_{t_f} \cdot p_{t_0})]) \times e^{i/2\int_{t_i}^{t_f} dt (p_t \cdot \dot{q}_t - q_t \cdot \dot{p}_t)}. \tag{3.87}$$

In the case of more general Hamiltonians the calculations are more difficult to perform. But if we assume that the interval upon which histories are defined is the whole real line, the boundary condition forces that

$$F_{\mathcal{S}} = e^{i\int dt\, p_t \dot{q}_t}. \tag{3.88}$$

The operator $\mathcal{U}$ is unitary, hence a transformation $A \to \mathcal{U} A \mathcal{U}^\dagger$ preserves the trace. The trace is also preserved by the Weyl–Wigner transform, hence phase space $\mathcal{U}$ corresponds to a trace-preserving automorphism $\mathbf{T}$ of the algebra of functions on the space Π of phase space paths. Explicitly this would be the continuum limit of

$$\mathbf{T} = T_{t_1} \otimes \cdots \otimes T_{t_n}, \tag{3.89}$$

where T_t corresponds to the automorphism of the algebra of single-time functions $A \to T_t[A]$ given by the Moyal bracket version of the Heisenberg equations of motion

$$\frac{\partial}{\partial_t} T_t[A] = \{H, T_t[A]\}_M \tag{3.90}$$

with $T_0[A] = A$.

In general the decoherence functional for phase space paths in a time interval $[t_i,t_f]$ will read

$$d(A,B)=\int_{\Gamma_{t_i}\times\Gamma_{t_f}} dx\,\lambda_x^*(F_A)\lambda_x(F_B), \tag{3.91}$$

where by x we denote points on the boundaries $\Gamma_{t_i}\times\Gamma_{t_f}$. It is then a collective index for $(q_{t_i},p_{t_i},q_{t_f},p_{t_f})$. It is obtained by the Weyl–Wigner transform of the boundary operator with respect to the rs indices in Eq. (2.19). $dx=dq_{t_0}\,dp_{t_0}\,dq_{t_f}\,dp_{t_f}$ is the standard measure on $\Gamma_{t_0}\times\Gamma_{t_f}$. $\lambda_x(\cdot)$ is a family of complex valued measures on the space of paths that have a functional dependence on boundary points x which incorporates the actual initial state of the system. If by $\mathbf{T}$ we denote the automorphism generated by $\mathcal{U}$ then

$$\lambda_x(A)=\int d\mu(\gamma)F_{\mathcal{A}^x\mathcal{S}}(\gamma)\mathbf{T}(A)(\gamma). \tag{3.92}$$

In this equation $F_{\mathcal{A}^x\mathcal{S}}$ is the Weyl symbol associated with the operator $\mathcal{A}^x\mathcal{S}$ of Eq. (2.23). The collective variable x again corresponds to the Weyl–Wigner transform of the indices (r,s) of Eq. (2.19).

In this expression it is very clear that phases appear in the probability assignment solely because of the geometric phase encoded in the operator $\mathcal{S}$. This has been argued in Ref. 16, but in the present context it is clearer, since the automorphism $\mathbf{T}$ makes no reference to complex numbers in its definition. The presence of complex numbers in the decoherence functional is purely due to the presence of a $U(1)$ connection on phase space, as encoded in the function $F_{\mathcal{S}}$.

F. The stochastic limit

Rather than considering the decoherence condition (1.5) as a law of nature, that has to be exactly satisfied (as the consistent histories interpretation does), we can view it as a condition for the approximation of the physical system by a classical probabilistic theory. We remarked how the unequal time pseudoprobability distributions $W_{n,m}$ do not satisfy the Kolmogorov additivity conditions. Perhaps a smeared version would (approximately) satisfy them so that one would get decoherence. So one can try to define smeared pseudoprobability distributions like

$$\begin{aligned}\overline{W}_{n,0}(\overline{q}_1,\overline{p}_1,t_1;\ldots;\overline{q}_n,\overline{p}_n,t_n)\\ =\int dq_1\,dp_1\cdots dq_n\,dp_n\,\chi_{\overline{q}_1\overline{p}_1}(q_1,p_1)\cdots\chi_{\overline{q}_n\overline{p}_n}(q_n,p_n)W_{n,0}(q_1,p_1,t_1;\ldots;q_n,p_n,t_n),\end{aligned} \tag{3.93}$$

Here $\chi_{\overline{\chi}\overline{\xi}}$ denotes a smeared characteristic function of a cell centered around $\overline{\chi}\overline{\xi}$. This will depend on some parameters V which will determine the volume of the cell, within which smearing is effected.

The objects $\overline{W}_{n,0}$ are expectation values. They can be properly normalized if we divide them with the smearing volume. In that case they can be taken as the discrete-time probability densities that might correspond to a measure. If these smeared densities satisfy the Kolmogorov criterion (which is to be expected in many systems given sufficient smearing) they would define a classical probability measure, that would give an effective stochastic description for the quantum system.

1. General operators

The above description is valid for general observables and not only the generators of the canonical group. Indeed if $\hat{A}$ is a self-adjoint operator with continuous spectrum Σ, one defines its

corresponding generating functional $Z_{\hat{A}}[f_+,f_-]$ as in Eq. (3.58). Now if $x\in\mathbf{R}$ denote points of the spectrum of A, we can construct a decoherence functional in the space of histories $x(\cdot):T\rightarrow\Sigma$ by an analogous expression to (3.78),

$$W[x(\cdot)|x'(\cdot)]=\int Df_+(\cdot)Df_-(\cdot)e^{-i(x,f_+)+i(x',f_-)}Z_{\hat{A}}[f_+,f_-]. \tag{3.94}$$

For any two functions F and G on the space of paths, we will have

$$d(F,G)=\int Dx(\cdot)Dx'(\cdot)F[x(\cdot)]G[x'(\cdot)]W[x(\cdot)|x'(\cdot)]. \tag{3.95}$$

The distribution W can again be defined as the inductive limit of the discrete-time distributions $W_{n,m}(x_1,t_1;\ldots;x_n,t_n|x_1',t_1';\ldots;x_n',t_n')$ as in Eq. (3.81), but with the operators

$$\hat{\Delta}(x)=\int dJ\,e^{-ixJ}e^{i\hat{A}J} \tag{3.96}$$

substituting $\hat{\Delta}(p,q)$.

Again one can look for the classical limit by constructing smeared characteristic functions $\chi_{\overline{x}}(x)$ for subsets of Σ. It is convenient to use a Gaussian function for $\chi_{\overline{x}}$. For instance,

$$\chi_{\overline{x}}(x)=\exp\left(-\frac{1}{2\sqrt{V}}(x-\overline{x})^2\right). \tag{3.97}$$

2. Smearing

Let us give a description of how the above prescription for finding the classical limit. We may start with discrete time histories with n time steps, which we shall simply call t and consider the smearing functions $\chi_{\overline{x}}$:

$$\chi_{\overline{x}(\cdot)}=\prod_t \chi_{\overline{x}_t}=\exp\left(-\frac{1}{2\sqrt{V}}\sum_t (x_t-\overline{x}_t)^2\right). \tag{3.98}$$

Then we evaluate the decoherence functional at a pair of χ's (actually their corresponding positive operators) to be

$$\begin{aligned} &d(\chi_{\overline{x}(\cdot)},\chi_{\overline{x}'(\cdot)})\\ &\quad=\int DJ_+\,DJ_-\,Z_{\hat{A}}[J_+,J_-]\left(\int Dx\,Dx'\,\chi_{\overline{x}(\cdot)}[x(\cdot)]\chi_{\overline{x}'(\cdot)}[x'(\cdot)]e^{-i(J_+,x)+i(J_-,x')}\right)\\ &\quad=V^n\int DJ_+\,DJ_-\,Z_{\hat{A}}[J_+/\sqrt{V},J_-/\sqrt{V}]\\ &\qquad\times\exp(-\tfrac{1}{4}(J_+,J_+)-\tfrac{1}{4}(J_-,J_-)-i(\overline{x},J_+)+i(\overline{x}',J_-)). \end{aligned} \tag{3.99}$$

By (J,J') we imply here a discrete sum $\Sigma_t J_t J_t'$. When, we go to the continuous limit it will imply $\int d\mu(t)J_tJ_t'$.

3. The probability measure

Assume now that with sufficient coarse graining we can get approximate satisfaction of the decoherence condition for disjoint $\chi_{\overline{x}(\cdot)}$ and $\chi_{\overline{x}'(\cdot)}$. The next step is to assume that the probabilities $p(\chi_{\overline{x}})=d(\chi_{\overline{x}},\chi_{\overline{x}})$ can be used to define a probability measure

$$p[\overline{x}(\cdot)]=\frac{1}{V^n}d(\chi_{\overline{x}},\chi_{\overline{x}}). \tag{3.100}$$

This is standard practice. It corresponds to the mathematical operation of extending a classical probability measure that is defined in only a part of the lattice of propositions (in this case a semilattice), to the whole of the lattice. This gives then a generating functional (note that $p[\overline{x}(\cdot)]$ has no multiplicative dependence on V^n hence it is safe to go to the continuous limit)

$$\begin{aligned} Z_A[J]&=\int D\overline{x}\,p[\overline{x}(\cdot)]e^{i(\overline{x},J)}\\ &=\int DJ_+\exp(-\tfrac{1}{2}(J_+,J_+)-\tfrac{1}{2}|J-J_+|^2)\times Z[(J_+)/\sqrt{V},(J-J_+)/\sqrt{V}]. \end{aligned} \tag{3.101}$$

This is the generating functional of a stochastic process for a classical observable A, that is obtained as the classical limit of a general quantum mechanical operator $\hat{A}$.

The above construction can be repeated for phase space observables with no modifications. In this case, the representation of the canonical group, provides a *natural metric on phase space*, which can be used in order to construct smearing functions. In this case, a parameter analogous to V plays the role of the volume of the phase space cell (with respect to this metric), within which one smears.

Details on how to obtain the classical stochastic limit of quantum systems with this method, together with a number of examples, are found in Ref. 34.

G. Summary

After giving a brief review of the canonical group construction and the histories version of classical mechanics, we showed how to construct a large class of representations of the history group, using coherent state techniques. A particular nice result was, that for well-behaved quantum field theories the representation of the canonical group uniquely determines one for the history group.

We then showed how to encode the correlation functions for generic observables of the theory into a CTP generating functional. The Wigner–Weyl transform offered a way of representing quantum mechanical objects on the phase space and define a continuous-time decoherence functional as the continuous limit of discrete-time ones.

Finally, we developed a general procedure for taking the classical probability limit of quantum mechanical histories.

IV. DISCUSSION

We shall now discuss a number of topics that explain or put into context the results of the previous two sections.

A. Time averaging

First, we need to address a rather important issue, that we left uncommented. What is the role of the parameter τ that enters the definition of the time integral? It appeared there originally in order to render the measure dimensionless, so that operators A_f would be dimensionally the same with their canonical counterparts $\hat{A}$.

In the case where T is compact, we remarked that τ can be chosen as to normalize the measure to unity. But in the more general case, that $T=\mathbf{R}$, this cannot be done and one would have to accept τ as an additional parameter entering the histories quantum theory. On one hand, it would not appear into the physical predictions of the theory: the values of the decoherence functional are independent of τ. Nonetheless, it would be present in the definition of the time averaged operators and perhaps in the physical correspondence with classical observables.

One possible idea is to substitute all integrals over $d\mu(t)$ with the limit as $\tau\to\infty$ of $(1/\tau)\int_{-\tau/2}^{\tau/2}dt$. Classical quantities of the form

$$q_f=\lim_{\tau\to\infty}\frac{1}{\tau}\int_{-\tau/2}^{\tau/2}dt\, q_t f(t) \tag{4.1}$$

are more naturally interpreted as time-averaged values of the observable q. This implies that we can enlarge the space of possible test functions. It would suffice to demand, that the smearing functions f are *constant* outside a compact set (rather than zero), in order for the integral to be defined.

This could have as immediate consequence, that the boundary Hilbert spaces at infinities would not be one dimensional, as is the case of when f is of compact support.

But this would severely weaken our uniqueness theorem. We need to have a unique translationary invariant ''vacuum'' vector, in order for the uniqueness theorem to hold. This is not any more true, if f is not a function of compact support: any vector $|z(\cdot)\rangle$ with constant values of $z(t)$ would be translationary invariant.

The representation theory for this history group would therefore be very different; in fact, the history group itself is different. Intuitively, one expects that the representation we would obtain from such a construction would be a reducible one: a direct integral of representations like the ones we constructed, each labeled by different boundary conditions for the coherent states as $t\to\pm\infty$.

These considerations will be taken further in another paper.

B. The decoherence functional

We tried various different ways to define a continuous-time decoherence functional. The straightforward analogy with Kolmogorov's construction failed, because we cannot continuously embed the lattice of single-time propositions to the lattice of history ones. We were then left with two choices: one is to incorporate the information about the initial condition in an object that is extended in time, rather than a density matrix as is the case in the canonical approach. This might be operationally meaningful (after all the initial state corresponds to a preparation that takes place in a time interval), but it contradicts our intuition that information about the system can be encoded at a single moment of time, without any need of knowing anything about its past history. (In a sense, such a construction might be considered as the violation of the analog of the Markov condition for stochastic processes.)

The other alternative, is to define the decoherence functional with respect to the structure of propositions about phase space histories. This involves abandoning continuity, but in phase space the natural condition is measurability and using this we can construct a mathematically sensible continuous-time decoherence functional. Operationally it is a very satisfactory construction: phase space measurements exhaust the physical content of quantum theories. But one might raise the objection that we sacrificed the quantum logic structure of history propositions in order to achieve this.

This objection is valid, assuming one considers quantum logic to be a fundamental part of quantum theory. This is however an interpretational attitude towards quantum theory, which we do not feel obliged to adopt. But even should we concede this point, we could still argue, that the true quantum logic is the one corresponding to time-averaged history propositions, and the standard single-time one just an approximation.

It is nonetheless true, that our construction would be conceptually more complete, and aesthetically more satisfying, if we were able to provide a reconstruction theorem: that the knowledge of the decoherence functional on phase space, allows us to uniquely construct the Hilbert space of the theory, the decoherence functional defined as a bilinear functional on the histories Hilbert space and perhaps get some correspondence between phase space symmetries and quantum mechanical unitary operators. This would be an analog of Wightman's reconstruction theorem in

quantum field theory:[35] constructing the Hilbert space, the vacuum and the representations of the history group from the correlation functions. The analogy is very accurate, because the decoherence functional on phase space is equivalent to the CTP generating functional and thus incorporates information about all correlation functions.

So far, we have not been able to find a direct way to prove such a theorem. Of course, one could always proceed indirectly: define the Wightman functions from the CTP generating functional, from them the canonical Hilbert space, the vacuum and the Hamiltonian, and then repeat the construction of Sec. III to construct the history Hilbert space and the representation of the history group. Even though this lends plausibility in the existence of a reconstruction theorem, it does not provide any physical or mathematical insight on the structure of history theories.

C. The classical limit

The identification of the history Hilbert space was based on the representations of the history group. When we have a representation of a group, we inherit all structures associated to it: coherent states, their symbols and the Weyl–Wigner transform. The phase space, then, appears as the most fundamental ingredient of the quantum theory.

Indeed, through the Weyl–Wigner transform we can cast quantum mechanical histories in a language that makes only indirect references to a Hilbert space and is completely based on classical phase space objects. This is important, because on phase space we know how to implement coarse grainings, that are of interest for a wide class of physical systems.

For instance, in many particle systems, one could study coarse grainings of the Boltzmann type (focusing on a description in terms of densities on a single-particle phase space) and derive their stochastic behavior, by the method described in (3.6). This might provide a way to proceed towards a declared aim of the consistent histories scheme: to find how hydrodynamic variables and their quasideterministic evolution laws arise from quantum theory.[3,36–39] In fact, all types of coarse graining of classical statistical mechanics can be implemented for phase space histories.

Another area, where our results are relevant is in the study of back-reaction of quantum fields on geometry. The semiclassical treatment assumes that we can couple the Einstein tensor to the expectation value of a quantum stress-energy tensor.

For quantum fields in curved spacetime, the stress-energy tensor is not defined as an operator or even an operator-valued distribution on the Hilbert space of the theory. This is why it has to be renormalized,[28] but, even so, one cannot remove the divergences from its correlation functions. Our construction suggests that one could first take the stochastic limit for the field in a histories version of the theory, and then construct a *classical* stress-energy tensor from the classicalized field. This would give a fully consistent scheme for dealing with the back-reaction of the matter to geometry, without the dangerous assumptions involved in computing expectation values of stress-energy tensors. This idea has been tentatively developed in Ref. 34.

D. Perturbation theory

In practice, we cannot explicitly construct the Hilbert space of the theory and the basic objects for most interesting physical systems. That is, why we rely on approximation methods, like perturbation theory. In analogy to quantum field theory, we could perhaps develop a perturbation expansion for the decoherence functional, together with a renormalization scheme, in order to adequately treat nonlinear systems

The first problem we would face, is the generic inadequacy of perturbation theory to deal with real-time evolution. In this case we have to expand the operator $e^{-i\hat{H}t}$ in powers of the coupling constant, something that becomes increasingly inaccurate with large values of t. In standard quantum theory, this problem is addressed by performing the perturbation expansion, not to the evolution operator, but to its resolvent $(E-\hat{H})^{-1}$, which is essentially its Fourier transform.

The CTP generating functional plays the same role, since it is a ''Fourier transform'' of the decoherence functional. In the CTP formalism, the perturbation theory is well defined, for instance, in the path integral representation, and its accuracy does not depend on the time t. This

leads to a perturbative evaluation of the decoherence functional, that does not suffer from the problems of real-time perturbation theory. As such, it provides a valuable tool for the construction of powerful approximation schemes in the histories program.

E. The histories quantization program

The main motivation of this paper is to be found in the histories quantization program. This aims to exploit the covariant nature and the richer content of the histories approach, in order to study quantum theories of systems with nontrivial temporal structure. The eventual aim is a theory of quantum gravity.

So far the program has dealt with quantum fields in curved spacetime[14,40] (where, unlike the canonical case, we can construct a theory accepting an instantaneous Hamiltonian) and with constrained systems. The two laws of time transformation have enabled a treatment of parametrized systems[15] (prototypes of general relativity), in which the problem of time does not appear. More recent results involve the more elaborate presence of Poincaré groups in quantum field theory[41] and the appearance of a representation of the spacetime diffeomorphism group in the histories version of general relativity.[42]

The main obstacle to further generalization has been the restriction to Fock representations for the history group, and hence only to quadratic systems. In this paper, we have constructed a larger class of representations and therefore enlarged the domain of applicability of the program. We have also indicated, how a perturbative construction of history theories could be implemented.

This will provide tools for continuation of the program: it will be possible to rigorously construct covariant quantum theories for a large class of systems, at least with the same level of rigor as the canonical approach.

ACKNOWLEDGMENTS

I would like to thank N. Savvidou for many discussions on the histories formalism and its meaning. The research was supported by NSF Grant No. PHY98-00967.

We obtain, through ζ function methods, the one-loop effective action for massive Dirac fields in the presence of a uniform, but otherwise general, electromagnetic background. After discussing renormalization, we compare our ζ function result with Schwinger's proper-time approach. © *2001 American Institute of Physics.*
[DOI: 10.1063/1.1383976]

I. INTRODUCTION

In QED, the effective one-loop Lagrangian describes the effective nonlinear interaction of the electromagnetic fields due to a single fermion loop. In two dimensions, its general form has been obtained both through proper time and ζ function regularizations.[1,2] In four dimensions, on the other hand, only particular field configurations have been studied.

The $3+1$ dimensional problem of constant electromagnetic fields was first studied by Euler and Heisenberg[3] and independently by Weisskopf.[4] These authors obtained an integral expression for the one-loop effective Lagrangian in the framework of the electron-hole theory. Later on, Schwinger rederived this integral representation in a field-theoretical scenario, by making use of proper time techniques.[5] In all these references, explicit results were derived in some limits, the most famous being the weak-field one. This and other particular field configurations were subsequently studied through the proper-time regularization by a number of authors (see, for example, Refs. 6–10).

More recently, the interest in the subject was renewed, and the Euclidean effective action for constant electromagnetic background configurations was studied through ζ function techniques:[11,12] In Ref. 13 analytic expressions were found for the case of purely magnetic fields in any number of dimensions. In this same reference, the case of equal electric and magnetic fields in four Euclidean dimensions was also studied. A step towards more general field configurations was given in Ref. 14, where the authors obtained the effective Lagrangian as a power series in B/E.

It is the aim of this article to obtain, through ζ function methods, an explicit nonperturbative expression for the full one-loop effective action of quantum electrodynamics in four dimensions in the case of constant, but otherwise arbitrary, electromagnetic fields. To this end, we will work in Euclidean space–time, and define the determinant of the relevant Dirac operator $\not{D}$ through the derivative of the ζ function of $\not{D}^\dagger \not{D}$.

The organization of the article is as follows:

After summarizing some well-known generalities in Sec. II, we devote Sec. III to analytically extending the relevant ζ function to the region $\Re s > -2$. (The main point here is the analytic extension of a Barnes ζ function.) Its value at $s=0$ is also given in this section.

In Sec. IV, a complete analytical expression for the effective action in terms of special functions is given, and the renormalization issue is discussed.

Section V contains a comparison between ζ and proper-time regularizations.

The Appendices A and B contain the derivation of some particular limits for the relevant zeta

[a]Fellow FOMEC-UNLP and Fundación Antorchas (Argentina).
[b]Member of CONICET (Argentina). Electronic mail: mariel@obelix.fisica.unlp.edu.ar

and for the effective action, thus allowing for the comparison with previous work on less general field configurations.

II. GENERALITIES

We study the effective action for massive Dirac particles in the presence of uniform, but otherwise arbitrary, electromagnetic background fields. We work in four-dimensional Euclidean space. Then, the effective action in the one-loop approximation is given by

$$S[A_\mu]=S_{\rm cl}[A_\mu]-\log\mathrm{Det}(\not{D}[A_\mu]), \tag{1}$$

where $S_{\rm cl}[A_\mu]$ is the classical Euclidean action and $\not{D}[A_\mu]=\gamma_\mu(\partial_\mu-ieA_\mu)+im$ is the Euclidean Dirac operator, m being the fermion mass.

Note that, even though $\not{D}$ is not self-adjoint, it is normal; so, the functional determinant appearing in the one-loop correction to the action can be defined through ζ function regularization,[11,12] which leads to

$$S_{\rm eff}[A_\mu]=S_{\rm cl}[A_\mu]+S^{(1)}[A_\mu]=S_{\rm cl}[A_\mu]+\frac{1}{2}\frac{\partial}{\partial s}\zeta(s;\not{D}^\dagger\not{D})\big]_{s=0}. \tag{2}$$

In order to evaluate the one-loop correction $S^{(1)}$ in the previous expression, it is necessary to obtain the spectrum of the operator $\not{D}^\dagger\not{D}$, which is well known in the case of uniform fields.[15] In this particular situation, one can always choose a reference frame such that $F_{03}=-F_{30}=E$ and $F_{12}=-F_{21}=B$, while the remaining components of the field tensor vanish. When doing so, the required zeta function turns out to be

$$\begin{aligned}\zeta(s;\not{D}^\dagger\not{D})=\mu^4\Omega\frac{ab}{4\pi^2}\Bigg[&2\sum_{n_a=1}^{\infty}(2n_a a+c)^{-s}+2\sum_{n_b=1}^{\infty}(2n_b b+c)^{-s}\\&+4\sum_{n_a=1}^{\infty}\sum_{n_b=1}^{\infty}(2n_a a+2n_b b+c)^{-s}+c^{-s}\Bigg].\end{aligned} \tag{3}$$

Here, Ω is the volume of the four-dimensional Euclidean space, $a=e|E|/\mu^2$, $b=e|B|/\mu^2$, $c=m^2/\mu^2$, and μ is a parameter with mass dimension, introduced to render the ζ function dimensionless. Note that the series in Eq. (3) are all convergent for $\Re s>2$, where they define an analytic function of s.

III. ANALYTIC EXTENSION OF THE ζ FUNCTION

In this section, we will perform the analytic extension of the relevant ζ function to a region containing $s=0$. In particular, we will show it to be finite at $s=0$ and give its value at this point.

The first two terms in Eq. (3) can be rewritten in terms of Hurwitz' zeta functions, which are well known to be meromorphic functions with a unique simple pole at $s=1$. On the other hand, the third term is a zeta function of the Barnes' type[16,17] (see also Refs. 18 and 19 and references therein). In order to analytically extend this term, we write it in integral form. After doing so, we get

$$\begin{aligned}\zeta(s;\not{D}^\dagger\not{D})=\mu^4\Omega\frac{ab}{4\pi^2}\Bigg\{&\frac{2}{(2a)^s}\zeta\left(s,\frac{c}{2a}+1\right)+\frac{2}{(2b)^s}\zeta\left(s,\frac{c}{2b}+1\right)\\&+\frac{1}{\Gamma(s)}\int_0^\infty dt\,t^{s-1}\frac{4e^{-2at}e^{-2bt}e^{-ct}}{(1-e^{-2at})(1-e^{-2bt})}+c^{-s}\Bigg\}\\=&\,\mathrm{A}(s)+\mathrm{B}(s)+\mathrm{C}(s)+\mathrm{D}(s),\end{aligned} \tag{4}$$

where $\zeta(s,v)$ is Hurwitz' zeta function. This expression (invariant under $a\leftrightarrow b$) is, in principle, well defined for $\Re s>2$. Since the analytic structure of $A(s)$ and $B(s)$ is well known, we will concentrate on the Barnes term $C(s)$, which will be extended to $\Re s>-2$.

To this end, we will use the expansion[20]

$$\frac{1}{e^{at}-e^{-at}}=\frac{1}{2at}+at\sum_{k=1}^{\infty}(-1)^k\frac{1}{(at)^2+(k\pi)^2}, \tag{5}$$

thus obtaining

$$\begin{aligned}C(s)&=2\mu^4\Omega\frac{ab}{4\pi^2}\frac{1}{\Gamma(s)}\left\{\frac{1}{2a}\int_0^\infty dt\,t^{s-2}\frac{e^{-(a+b+c)t}}{e^{bt}-e^{-bt}}\right.\\&\quad\left.+a\int_0^\infty dt\,t^s\frac{e^{-(a+b+c)t}}{e^{bt}-e^{-bt}}\sum_{k=1}^{\infty}(-1)^k\frac{1}{(at)^2+(k\pi)^2}\right\}+a\leftrightarrow b\\&=C_1(s)+C_2(s).\end{aligned} \tag{6}$$

The first term, $C_1(s)$, can be easily seen to be

$$C_1(s)=2\mu^4\Omega\frac{ab}{4\pi^2}\frac{1}{2a}\frac{1}{(s-1)(2b)^{s-1}}\zeta\left(s-1,\frac{a+2b+c}{2b}\right)+a\leftrightarrow b. \tag{7}$$

As all the terms we have analytically extended up to this point, $C_2(s)$ in Eq. (6) involves an integral which diverges at $s=0$. In order to isolate this singularity, we will rewrite this term as

$$\begin{aligned}C_2(s)&=2\mu^4\Omega\frac{ab}{4\pi^2}\frac{1}{\Gamma(s)}a\int_0^\infty dt\,t^s\frac{e^{-(a+b+c)t}}{(e^{bt}-e^{-bt})}\left\{\sum_{k=1}^{\infty}(-1)^k\left[\frac{1}{(at)^2+(k\pi)^2}-\frac{1}{(k\pi)^2}\right]\right.\\&\quad\left.+\sum_{k=1}^{\infty}(-1)^k\frac{1}{(k\pi)^2}\right\}+a\leftrightarrow b\\&=CF_2(s)+CD_2(s).\end{aligned} \tag{8}$$

The integral appearing in $CD_2(s)$ is divergent at $s=0$ but, after performing the sum, this term is easily seen to be

$$CD_2(s)=-\mu^4\Omega\frac{ab}{4\pi^2}\frac{a}{6}\frac{s}{(2b)^{s+1}}\zeta\left(s+1,1+\frac{a+c}{2b}\right)+a\leftrightarrow b. \tag{9}$$

Now, once the difference between brackets is performed, $CF_2(s)$ can be rewritten as

$$CF_2(s)=-2\mu^4\Omega\frac{ab}{4\pi^2}\frac{1}{\Gamma(s)}a^3\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^2}\int_0^\infty dt\,t^{s+2}\frac{e^{-(a+2b+c)t}}{(1-e^{-2bt})}\frac{1}{(at)^2+(k\pi)^2}+a\leftrightarrow b. \tag{10}$$

As is easily seen, this integral converges for $\Re s>-2$. We have thus obtained an analytic extension for the ζ of the operator as a meromorphic function with only simple poles. Such extension is valid for $\Re s>-2$.

Now, the factor $1/[(at)^2+(k\pi)^2]$ can be written as an integral. In fact,

$$\frac{1}{(at)^2+(k\pi)^2}=\frac{-1}{2ik\pi}\left[\frac{1}{at+ik\pi}-\frac{1}{at-ik\pi}\right]=\frac{1}{k\pi}\int_0^\infty du\, e^{-atu}\sin(k\pi u).$$

When replaced in Eq. (10), this gives

$$\mathrm{CF}_2(s)=-2\mu^4\Omega\frac{ab}{4\pi^2}\frac{1}{\Gamma(s)}a^3\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^3}\int_0^\infty dt\, t^{s+2}\frac{e^{-(a+2b+c)t}}{(1-e^{-2bt})}\int_0^\infty du\, e^{-atu}\sin(k\pi u)+a\leftrightarrow b$$

or, after interchanging the integrals

$$\mathrm{CF}_2(s)=-2\mu^4\Omega\frac{ab}{4\pi^2}\frac{a^3}{\Gamma(s)}\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^3}\int_0^\infty du\,\sin(k\pi u)\frac{\Gamma(s+3)}{(2b)^{s+3}}\zeta\left(s+3,\frac{a+2b+c+au}{2b}\right)$$
$$+a\leftrightarrow b.$$

When the ζ function is written in terms of its series development (which is valid for $\Re s>-2$) one has (after interchanging this series and the integral)

$$\mathrm{CF}_2(s)=-2\mu^4\Omega\frac{ab}{4\pi^2}\frac{a^3}{\Gamma(s)}\frac{\Gamma(s+3)}{(2b)^{s+3}}\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^3}\sum_{l=1}^{\infty}\int_0^\infty du\,\sin(k\pi u)\left(l+\frac{a+c+au}{2b}\right)^{-(s+3)}$$
$$+a\leftrightarrow b.$$

Finally, after performing the remaining integral and making use of the functional relations between incomplete gamma functions,[21] one gets

$$\mathrm{CF}_2(s)=i\mu^4\Omega\frac{ab}{4\pi^2}\frac{\Gamma(s+3)}{\Gamma(s)}a^{-s}\frac{1}{s+2}\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^{1-s}}\sum_{l=1}^{\infty}\left[i^{s+2}e^{i(k\pi/a)(2bl+a+c)}\Gamma\left(-s\right.\right.$$
$$\left.\left.-1,i\frac{k\pi}{a}(2bl+a+c)\right)-(-i)^{s+2}e^{-i(k\pi/a)(2bl+a+c)}\Gamma\left(-s-1,-i\frac{k\pi}{a}(2bl+a+c)\right)\right]$$
$$+a\leftrightarrow b. \tag{11}$$

The replacement of Eqs. (7), (9) and (11) into Eq. (4) completes the analytic extension of the relevant ζ function. Its value at $s=0$ can be easily computed, which gives

$$\zeta(0;\mathbb{D}^\dagger\mathbb{D})=\frac{\mu^4\Omega}{4\pi^2}\left\{\frac{1}{2}c^2+\frac{a^2+b^2}{3}\right\}. \tag{12}$$

The agreement with the known results for null and equal fields is shown in Appendix A.

IV. THE EFFECTIVE ACTION AND ITS RENORMALIZATION

This section contains the main result in this article, i.e., the one-loop correction to the Euclidean effective action. According to Eq. (2), to obtain such result, one must perform the derivatives at $s=0$ of the various terms in Eq. (4).

We start from $\mathrm{A}(s)$, which contributes with

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{A}(s)\Big|_{s=0}=\mu^4\Omega\frac{ab}{4\pi^2}\left\{\log(2a)\left(\frac{1}{2}+\frac{c}{2a}\right)+\log\Gamma\left(\frac{c}{2a}+1\right)-\frac{1}{2}\log(2\pi)\right\}. \tag{13}$$

In a completely analogous way, one has

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{B}(s)\Big|_{s=0}=\mu^4\Omega\,\frac{ab}{4\pi^2}\left\{\log(2b)\left(\frac{1}{2}+\frac{c}{2b}\right)+\log\Gamma\left(\frac{c}{2b}+1\right)-\frac{1}{2}\log(2\pi)\right\}. \tag{14}$$

It is also through a direct calculation that one gets

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{C}_1(s)\Big|_{s=0}=\mu^4\Omega\,\frac{ab}{4\pi^2}\,\frac{1}{2a}\left\{2b(-1+\log(2b))\zeta\left(-1,1+\frac{a+c}{2b}\right)\right.$$
$$\left.-2b\,\frac{\partial}{\partial s}\Big|_{s=0}\zeta\left(s-1,1+\frac{a+c}{2b}\right)\right\}+a\leftrightarrow b. \tag{15}$$

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{CD}_2(s)\Big|_{s=0}=\mu^4\Omega\,\frac{ab}{4\pi^2}\,\frac{a}{24b}\left\{\log(2b)+\Psi\left(1+\frac{a+c}{2b}\right)\right\}+a\leftrightarrow b. \tag{16}$$

As regards $\mathrm{CF}_2(s)$, due to the presence of $\Gamma(s)$ in the denominator, the required derivative reduces to the product $\Gamma(s)\,\mathrm{CF}_2(s)$ at $s=0$, i.e.,

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{CF}_2(s)\Big|_{s=0}=-\frac{i}{2}\mu^4\Omega\,\frac{ab}{4\pi^2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k\pi}\sum_{l=1}^{\infty}\left[e^{i(k\pi/a)(2bl+a+c)}\Gamma\left(-1,\frac{ik\pi}{a}(2bl+a+c)\right)\right.$$
$$\left.-e^{-i(k\pi/a)(2bl+a+c)}\Gamma\left(-1,-\frac{ik\pi}{a}(2bl+a+c)\right)\right]+a\leftrightarrow b. \tag{17}$$

Summarizing, the Euclidean effective action is given by the sum of the partial contributions in Eqs. (13)–(17), plus

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{D}(s)\Big|_{s=0}=-\mu^4\Omega\,\frac{ab}{8\pi^2}\log(c). \tag{18}$$

Notice that even though the result is finite, it depends on the arbitrary parameter μ. However, this effective action still admits a finite renormalization. We will perform it by adopting the criterium (used, for instance, in Ref. 22), that a very massive field does not fluctuate. Thus, we will subtract the one loop correction to the effective action in the limit $m\to\infty$. From Eq. (B6) in Appendix B, the effective action in this limit can be seen to be

$$\mu^4\Omega\,\frac{1}{4\pi^2}\left\{\left[\frac{3}{8}-\frac{1}{4}\log(c)\right]c^2-\frac{1}{6}(b^2+a^2)\log(c)\right\}. \tag{19}$$

After doing this subtraction, all dependence on the parameter μ disappears, and the Euclidean effective action is given by

$$S_{\mathrm{eff}}^{\mathrm{Ren}}[A_\mu]=\frac{\Omega\mu^4}{2e^2}(a^2+b^2)+\mu^4\Omega\,\frac{ab}{4\pi^2}\left\{\frac{1}{8}\log\left(\frac{4ab}{c^2}\right)-\frac{1}{24}\,\frac{(a^2+b^2)}{ab}\log\left(\frac{4ab}{c^2}\right)+\frac{c}{4a}\log\left(\frac{a}{b}\right)\right.$$
$$-\frac{c^2}{16ab}\log\left(\frac{4ab}{c^2}\right)+\log\left(\frac{\Gamma(c/2a+1)}{\sqrt{2\pi}}\right)-\frac{b}{a}\zeta\left(-1,1+\frac{a+c}{2b}\right)-\frac{b}{a}\,\frac{\partial}{\partial s}\Big|_{s=0}\zeta\left(s-1,1\right.$$
$$\left.\left.+\frac{a+c}{2b}\right)-\frac{i}{2}\sum_{k=1}^{\infty}\frac{(-1)^k}{k\pi}\sum_{l=1}^{\infty}\left[e^{i(k\pi/a)(2bl+a+c)}\Gamma\left(-1,\frac{ik\pi}{a}(2bl+a+c)\right)\right.\right.$$

$$-e^{-i(k\pi/a)(2bl+a+c)}\Gamma\left(-1,\frac{-ik\pi}{a}(2bl+a+c)\right)\Bigg]$$

$$+\frac{a}{24b}\Psi\left(1+\frac{a+c}{2b}\right)-\frac{3}{16}\frac{c^2}{ab}+a\leftrightarrow b\Bigg\}. \tag{20}$$

The renormalization performed amounts to subtracting the zero field effective action (thus redefining the cosmological constant), and renormalizing the classical action. As a result, one gets the following running charge relationship:

$$\frac{1}{e^2}=\frac{1}{e_0^2}+\frac{1}{12\pi^2}\log\frac{\mu^2}{m^2}. \tag{21}$$

Equivalently, for the fine structure constant one has

$$\alpha=\frac{\alpha_0}{1+(\alpha_0/3\pi)\log\mu^2/m^2}. \tag{22}$$

Note that this expression reduces, in the perturbative limit, to the well known result (see, for example, Ref. 23)

$$\alpha=\alpha_0\left(1-\frac{\alpha_0}{3\pi}\log\frac{\mu^2}{m^2}\right). \tag{23}$$

V. COMPARISON WITH THE PROPER TIME RESULT

In Appendix B we show that, in the weak field limit, our result for the ζ regularized effective action coincides, once renormalized, with the Euclidean version of the well known Schwinger's proper time one.

In this section, we will show that this is also the case for arbitrary field strengths. In fact, Schwinger's integral expression for the one loop correction to the effective action is given, after subtracting the divergent terms, by

$$S_{PT}^{(1)}=\mu^4\Omega\Bigg\{\frac{ab}{8\pi^2}\int_0^\infty dt\,t^{s-1}e^{-ct}\coth(bt)\coth(at)-\frac{1}{8\pi^2}\int_0^\infty dt\,t^{s-3}e^{-ct}$$

$$-\frac{a^2+b^2}{24\pi^2}\int_0^\infty dt\,t^{s-1}e^{-ct}\Bigg\}\Bigg|_{s=0}. \tag{24}$$

Now, performing the integrals in the last two terms and comparing with Eq. (4) (with the Hurwitz's zetas written in integral form), the previous expression can be rewritten as

$$S_{PT}^{(1)}=\frac{1}{2}\left\{\Gamma(s)\zeta(s;\mathcal{D}^\dagger\mathcal{D})-\frac{\mu^4\Omega}{4\pi^2}\left(c^{2-s}\Gamma(s-2)+\frac{a^2+b^2}{3}c^{-s}\Gamma(s)\right)\right\}\Bigg|_{s=0}. \tag{25}$$

After developing around $s=0$, it is easy to see that

$$S_{PT}^{(1)}=S_\zeta^{(1)}-\frac{\mu^4\Omega}{4\pi^2}\left[\frac{3}{8}c^2-\left(\frac{c^2}{4}+\frac{a^2+b^2}{6}\right)\log c\right], \tag{26}$$

where $S_\zeta^{(1)}$ is the ζ-regularized one loop correction to the effective action, as defined in Eq. (2), and the remaining terms are precisely the ones we have subtracted through renormalization. So, the exact agreement between both renormalized effective actions is apparent.

ACKNOWLEDGMENTS

APPENDIX A: THE LIMITS OF NULL AND EQUAL FIELDS

In this section, we will show the agreement of our general ζ function with the results obtained by other authors for some particular cases, i.e., the case of a null electric or magnetic field[13,14] and that of equal electric and magnetic fields.[13]

We will start with the $B\to 0$ limit. It is easy to see that $\lim_{b\to 0}\mathrm{A}(s)=0$. As regards $\lim_{b\to 0}\mathrm{B}(s)$, it can be studied by making use of the asymptotic expansion for Hurwitz' ζ function (see, for example, Ref. 24),

$$\zeta(s,v)=\frac{1}{\Gamma(s)}\left\{v^{1-s}\Gamma(s-1)+\frac{1}{2}v^{-s}\Gamma(s)+\sum_{n=1}^{N}B_{2n}\frac{\Gamma(s+2n-1)}{(2n)!}v^{1-s-2n}\right\}+O(v^{-2N-s-1}), \tag{A1}$$

$$\lim_{b\to 0}\mathrm{B}(s)=\lim_{b\to 0}\left\{\mu^4\Omega\,\frac{ab}{4\pi^2}\,\frac{2}{(2b)^s}\,\frac{\Gamma(s-1)}{\Gamma(s)}\left(\frac{c}{2b}+1\right)^{1-s}\right\}=\frac{\mu^4\Omega}{4\pi^2}\,\frac{a}{s-1}c^{1-s}. \tag{A2}$$

The only contribution to $\mathrm{C}(s)$ in this limit comes from $\mathrm{C}_1(s)$, which gives

$$\lim_{b\to 0}\mathrm{C}(s)=\frac{\mu^4\Omega}{4\pi^2}\,\frac{(2a)^{2-s}}{s-1}\left\{\zeta\left(s-1,\frac{c}{2a}\right)-\left(\frac{c}{2a}\right)^{1-s}\right\}. \tag{A3}$$

Finally, $\mathrm{D}(s)$ vanishes for $b=0$. Then, replacing all these partial results into Eq. (4), one obtains

$$\zeta(s,\mathbb{D}^\dagger\mathbb{D})\rfloor_{b=0}=\frac{\mu^4\Omega}{4\pi^2}\,\frac{(2)^{1-s}}{s-1}a^{2-s}\left\{2\zeta\left(s-1,\frac{c}{2a}\right)-\left(\frac{c}{2a}\right)^{1-s}\right\}, \tag{A4}$$

which is in complete agreement with previous results.[13,14]

Of course, the $E\to 0$ limit gives an analogous expression, which can be obtained by changing $a\to b$ in Eq. (A4).

We will now study the equal fields limit. In this situation, taking $a=b$ in the different terms appearing in the ζ function (4), we have

$$\begin{aligned}\zeta(s;\mathbb{D}^\dagger\mathbb{D})\rfloor_{a=b}=\mu^4\Omega\,\frac{a^2}{4\pi^2}\Bigg\{&\frac{4}{(2a)^s}\zeta\left(s,\frac{c}{2a}+1\right)+c^{-s}+\frac{2^{2-s}a^{-s}}{s-1}\zeta\left(s-1,\frac{3}{2}+\frac{c}{2a}\right)\\&-\frac{1}{6}(2a)^{-s}\,\zeta\left(s+1,\frac{3}{2}+\frac{c}{2a}\right)-i\,2\,a^{-s}(s+1)s\\&\times\sum_{k=1}^{\infty}\frac{(-1)^{k+1}}{(k\pi)^{1-s}}\sum_{l=1}^{\infty}\left[i^{s+2}e^{ik\pi(2l+1+c/a)}\Gamma\left(-s-1,ik\pi\left(2l+1+\frac{c}{a}\right)\right)\right.\end{aligned}$$

$$-(-i)^{s+2}e^{-ik\pi(2l+1+c/a)}\Gamma\left(-s-1,-ik\pi\left(2l+1+\frac{c}{a}\right)\right)\Bigg]\Bigg\}. \tag{A5}$$

In order to compare this expression with the result in Ref. 13, we use the functional relations between incomplete gamma functions once more, thus getting

$$\begin{aligned}\zeta(s;\mathbb{D}^{\dagger}\mathbb{D})\rfloor_{a=b}=\mu^4\Omega\frac{a^2}{4\pi^2}\Bigg\{&\frac{4}{(2a)^s}\zeta\left(s,\frac{c}{2a}+1\right)+c^{-s}+\frac{2^{2-s}a^{-s}}{s-1}\zeta\left(s-1,\frac{3}{2}+\frac{c}{2a}\right)\\&-i\,2\,a^{-s}s\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^{1-s}}\sum_{l=1}^{\infty}\Bigg[i^{s+2}e^{ik\pi(2l+1+c/a)}\Gamma\left(-s,ik\pi\left(2l+1+\frac{c}{a}\right)\right)\\&-(-i)^{s+2}e^{-ik\pi(2l+1+\frac{c}{a})}\Gamma(-s,-ik\pi(2l+1+c/a))\Bigg]\Bigg\}.\end{aligned} \tag{A6}$$

We now use the integral representation for the incomplete gamma function

$$\Gamma(\alpha,x)=\int_x^{\infty}dt\,e^{-t}t^{\alpha-1}.$$

When doing so, and after interchanging the integral and the sum over l, the last term in Eq.(A6) can be written as

$$\begin{aligned}&(2a)^{-s}s\sum_{k=1}^{\infty}\frac{(-1)^k}{(k\pi)^2}\int_0^{\infty}du\,e^{-u}\left[\zeta\left(s+1,\frac{3}{2}+\frac{c}{2a}-\frac{iu}{2k\pi}\right)+\zeta\left(s+1,\frac{3}{2}+\frac{c}{2a}+\frac{iu}{2k\pi}\right)\right]\\&=2(2a)^{-s}\frac{1}{\Gamma(s)}\sum_{k=1}^{\infty}(-1)^k\int_0^{\infty}dt\,t^s\frac{e^{-(3/2+c/2a)t}}{1-e^{-t}}\frac{1}{(k\pi)^2+(t/2)^2}\end{aligned}$$

where we have used the integral form for the Hurwitz's zeta functions, interchanged the integrals and performed the interior one.

Interchanging now the integral with the sum, and using Eq. (5), we obtain

$$\begin{aligned}&2^{2-s}a^{-s}\frac{1}{\Gamma(s)}\int_0^{\infty}dt\,t^{s-1}\frac{e^{-(3/2+c/2a)t}}{1-e^{-t}}\left[\frac{e^{-t/2}}{1-e^{-t}}-\frac{1}{t}\right]\\&=2^{2-s}a^{-s}\left[\zeta\left(s-1,\frac{c}{2a}+1\right)-\left(\frac{c}{2a}+1\right)\zeta\left(s,\frac{c}{2a}+1\right)-\frac{1}{s-1}\zeta\left(s-1,\frac{3}{2}+\frac{c}{2a}\right)\right].\end{aligned}$$

When replaced in (A6), the final result is

$$\begin{aligned}\zeta(s;\mathbb{D}^{\dagger}\mathbb{D})\rfloor_{a=b}&=\mu^4\Omega\frac{a^2}{4\pi^2}\left\{c^{-s}+2^{2-s}a^{-s}\left[\zeta\left(s-1,\frac{c}{2a}+1\right)-\frac{c}{2a}\zeta\left(s,\frac{c}{2a}+1\right)\right]\right\}\\&=\mu^4\Omega\frac{a^2}{4\pi^2}\left\{c^{-s}+4(2a)^{-s}\left(\zeta\left(s-1,\frac{c}{2a}\right)-\frac{c}{2a}\zeta\left(s,\frac{c}{2a}\right)\right)\right\}.\end{aligned} \tag{A7}$$

This expression coincides with the result obtained in Ref. 13 [see Eqs. (5.2.6) and (5.2.4) in that reference].

APPENDIX B: THE WEAK-FIELD LIMIT

An unavoidable test our effective action must resist is its coincidence with the well known result for weak fields.[3,5] In order to check this is the case, we will develop the different contributions to the effective action [Eqs. (13)–(18)] in powers of the fields over the squared mass. In the cases of Eqs. (13)–(16), such development can be obtained by making use of the well known asymptotic expansions[24] for $\log\Gamma(x)$, $\psi(x)$, and $\zeta(s,x)$ [see also our Eq. (A1)]. When doing so, and retaining terms up to the order of squared fields over mass to the fourth, one gets, after a straightforward though tedious calculation,

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{A}(s)\Big|_{s=0} \simeq \mu^4\Omega\,\frac{ab}{4\pi^2}\left\{\frac{1}{6}ac^{-1}+\frac{1}{2}\log(c)+\frac{1}{2a}(\log(c)-1)c\right\}, \tag{B1}$$

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{B}(s)\Big|_{s=0} \simeq \mu^4\Omega\,\frac{ab}{4\pi^2}\left\{\frac{1}{6}bc^{-1}+\frac{1}{2}\log(c)+\frac{1}{2b}(\log(c)-1)c\right\}, \tag{B2}$$

$$\begin{aligned}\frac{1}{2}\frac{\partial}{\partial s}\mathrm{C}_1(s)\Big|_{s=0} \simeq{}& \mu^4\Omega\,\frac{ab}{4\pi^2}\frac{1}{ab}\left\{\left(\frac{1}{4}-\frac{1}{4}\log c+\frac{1}{8}\right)c^2+\left(\frac{1}{2}(a+b)-\frac{1}{2}(a+b)\log c\right)c-\frac{5}{24}(a^2\right.\\ &+b^2)\\ &-\frac{1}{2}ab\log c-\frac{1}{24}(5ba^2+5ab^2+a^3+b^3)c^{-1}\\ &\left.+\left(\frac{1}{24}b^3a+\frac{1}{24}a^3b+\frac{1}{12}b^2a^2+\frac{7}{1440}a^4+\frac{7}{1440}b^4\right)c^{-2}\right\},\end{aligned} \tag{B3}$$

$$\begin{aligned}\frac{1}{2}\frac{\partial}{\partial s}\mathrm{CD}_2(s)\Big|_{s=0} \simeq{}& \mu^4\Omega\,\frac{ab}{4\pi^2}\frac{1}{24}\left\{\left(\frac{a}{b}+\frac{b}{a}\right)\log c+\left(a+b+\frac{a^2}{b}+\frac{b^2}{a}\right)c^{-1}\right.\\ &\left.-\frac{1}{2}\left(2a^2+2b^2+\frac{a^3}{b}+\frac{b^3}{a}+\frac{4}{3}ba\right)c^{-2}\right\}.\end{aligned} \tag{B4}$$

As regards $\frac{1}{2}(\partial/\partial s)\mathrm{CF}_2(s)\rfloor_{s=0}$, one has to use the asymptotic expansions for the incomplete Γ function and for the Hurwitz' zeta functions [Eq. (A1)]. After doing so, one obtains

$$\frac{1}{2}\frac{\partial}{\partial s}\mathrm{CF}_2(s)\Big|_{s=0} \simeq \mu^4\Omega\,\frac{ab}{4\pi^2}\,\frac{7}{1440}\left(\frac{a^3}{b}+\frac{b^3}{a}\right)c^{-2}. \tag{B5}$$

By summing up the contributions in Eqs. (B1)–(B5), plus the one coming from $\frac{1}{2}(\partial/\partial s)\mathrm{D}(s)\rfloor_{s=0}$, the one-loop correction to the effective action is seen to reduce, in this weak-field limit, to

$$S^{(1)}=\mu^4\Omega\,\frac{1}{4\pi^2}\left\{\left[\frac{3}{8}-\frac{1}{4}\log(c)\right]c^2-\frac{1}{6}(b^2+a^2)\log(c)+\left[\frac{7}{90}(ab)^2-\frac{1}{90}(a^2+b^2)^2\right]c^{-2}\right\}. \tag{B6}$$

Now, renormalizing according to the criterium discussed in Sec. IV, one is left with

$$S_{\mathrm{eff}}=\frac{\Omega}{2}(B^2+E^2)+\frac{\Omega e^4}{8\pi^2m^4}\left[\frac{7}{45}(EB)^2-\frac{1}{45}(E^2+B^2)^2\right], \tag{B7}$$

where the definitions of a, b and c given in the paragraph following Eq. (3) were used.

The expression in (B7) is precisely the Euclidean version of the Euler–Heisenberg effective action for weak fields.[3,5]

(Received 22 December 2000; accepted for publication 15 March 2001)

Three-dimensional SO(3) gauged Skyrme models characterized by specific potentials imposing special asymptotic values on the chiral field are considered. These models are shown to support finite energy solutions with nonvanishing magnetic and electrix flux, whose energies are bounded from below by two distinct charges—the magnetic (monopole) charge and a noninteger version of the Baryon charge. Unit magnetic charge solutions are constructed numerically and their properties characterized by the chosen asymptotics and the Skyrme coupling are studied. For a particular value of the chosen asymptotics, charge-2 axially symmetric solutions are also constructed and the attractive nature of the like-monopoles of this system are exhibited. As an indication toward the possible existence of large clumps of monopoles, some consideration is given to axially symmetric monopoles of charges 2,3,4. © *2001 American Institute of Physics.*

I. INTRODUCTION

In the O(4), or usual, Skyrme[1] model in three dimensions, the finite energy conditions uniquely specify the asymptotic value at large distances of the chiral field. Depending on the parametrization, either the SU(2) valued field U or the S^3 valued field ϕ^a, subject to $|\phi^a|^2$, with $a=1,2,3,4$, this asymptotic value is

$$\lim_{r\to\infty} U=\mathbb{1} \qquad \text{or} \qquad \lim_{r\to\infty}\phi^4=1. \tag{1}$$

The fields U and ϕ^a are related through

$$U=\phi^a\sigma^a, \quad U^\dagger=\phi^a\tilde{\sigma}^a, \tag{2}$$

where in terms of the Pauli matrices $\vec{\tau}$, $\sigma^a=(i\tau^i,\mathbb{1})$ and $\tilde{\sigma}^a=(-i\tau^i,\mathbb{1})$.

Often, the static Hamiltonian of the Skyrme system is augmented with a ''pion-mass'' potential

$$V_\pi(\phi^a)=m_\pi(1-\phi^4), \tag{3}$$

consistent with the asymptotics (1). The only practical effect that the inclusion of this potential (3) has is that it renders the asymptotic behavior of the chiral function exponential, where in its absence this would have been a power decay.

a)Electronic mail: hartmann@darkstar.physik.uni-oldenburg.de

The situation is very different when the Skyrme model is gauged in one[2] or other[3] gauging prescription, as a result of which the asymptotic value of the chiral field is not fixed uniquely by finite energy conditions. This feature of three-dimensional gauged Skyrme models was considered and highlighted in Ref. 4.

In the present work, we augment the three-dimensional SO(3) gauged Skyrme model studied in Refs. 5 and 3 with the following potential:

$$V=\lambda(\cos\omega-\phi^4)^2, \quad \pi\geqslant\omega\geqslant 0, \tag{4}$$

whose effect is to specify the asymptotic values of the chiral field uniquely, consistent with finiteness of the energy. Like (3), this potential is also chosen such that it results in the exponential behavior of ϕ^4 asymptotically. The new asymptotics are

$$\lim_{r\to 0}\phi^4=-1, \quad \lim_{r\to\infty}\phi^4=\cos\omega. \tag{5}$$

It is clear from (5) that the volume integral of the density that maps the field space to the configuration space is not going to be an integer except in the case where $\omega=0$. Thus the lower bounds labeled by this charge cannot be identified with the degree of the map, or the topological baryon charge, except when $\omega=0$. Such a noninteger charge, however, does supply a legitimate lower bound on the energy integral. For want of a better name, we shall persist in calling such charges $Q_B(\omega)$, with the understanding that only $Q_B(0)$ is really the baryon charge.

In the generic case $\pi\geqslant\omega\geqslant 0$, there will be an independent lower bound in addition to $Q_B(\omega)$, namely the magnetic monopole flux $\mu(\omega)$, which also depends on ω. These lower bounds will be stated explicitly in the following. The main feature of the dynamics characterized by the potential (4), with $\omega\neq 0$, is that the SO(3) is broken down to U(1), with the residual Maxwell field described by the corresponding 't Hooft-tensor supporting a magnetic flux. Like the charge $Q_B(\omega)$, this magnetic flux $\mu(\omega)$ is integer also only modulo a continuous factor depending on ω, and takes an integer value only when $\omega=\pi/2$. The solutions we have found turn out, as expected, to respect both lower bounds $\mu(\omega)$ and $Q_B(\omega)$.

We have confirmed the existence of finite energy solutions bounded by the charges $\mu(\omega)$ and $Q_B(\omega)$ by numerical construction. An interesting result is that when $\omega\neq 0$, the solution persists even when the Skyrme coupling constant vanishes, i.e., $\kappa_2=0$ in (7) and (8). This is not surprising since the presence of the Yang–Mills term satisfies the (Derrick) scaling requirement independent of the Skyrme term, and in this case, the soliton is bounded from below only by the magnetic flux μ. This will be explained in more detail in Sec. II, where the model is defined and the two said lower bounds will be stated. Then in Sec. III, we study the spherically symmetric solutions for various ω and κ, and find the ranges of these two parameters for which solutions exist by numerical construction. In Sec. IV, we study the axially symmetric magnetic charge-2 solution for the particular value of the parameter $\omega=\pi/2$, with a view to learning whether two like monopoles of that system can be in an attractive or a repulsive phase. We encounter the rather surprising result that even for $\kappa_2=0$ this is *attractive*, and then as expected it becomes even more attractive with increasing $\kappa_2>0$. Section V is devoted to summarizing and discussing our results.

II. THE MODEL AND LOWER BOUNDS

The model is specified by the gauging prescription and is the three-dimensional model used in Refs. 5 and 3, augmented by the potential (4). Usually, we will treat this potential as a *gedanken* entity and will not exploit it save as an agency justifying the asymptotics (5). In terms of the S^3 valued field $\phi^a=(\phi^\alpha,\phi^4)$, $\alpha=1,2,3$, and the SO(3) gauge connection A^α_μ with curvature $F^\alpha_{\mu\nu}$, the covariant derivative is defined by the prescription

$$D_\mu\phi^\alpha=\partial_\mu\phi^\alpha+\varepsilon^{\alpha\beta\gamma}A^\beta_\mu\phi^\gamma, \qquad D_\mu\phi^4=\partial_\mu\phi^4. \tag{6}$$

Since much of the analysis will be almost identical to that in (the relevant) Sec. III of Ref. 3, we will use the same notation here. This will enable us to present some of the new results without the necessity of repeating the detailed analyses leading to them. The model is described by the Lagrangian

$$\mathcal{L}=-\kappa_0^4|F_{\mu\nu}^{\alpha}|^2+\tfrac{1}{2}\kappa_1^2|D_\mu\phi^a|^2-\tfrac{1}{2}\kappa_2^4|D_{[\mu}\phi^a D_{\nu]}\phi^b|^2-V(\phi^4), \tag{7}$$

which in the temporal gauge $A_0^{\alpha}=0$ yields the static Hamiltonian

$$\mathcal{H}=\kappa_0^4|F_{ij}^{\alpha}|^2+\tfrac{1}{2}\kappa_1^2|D_i\phi^a|^2+\tfrac{1}{2}\kappa_2^4|D_{[i}\phi^a D_{j]}\phi^b|^2+V(\phi^4). \tag{8}$$

The potential $V(\phi^4)$ in both (7) and (8) is that given by (4). In our study of the ''monopole,'' we will be mainly concerned with the energy density functional (8), but we give the corresponding Lagrangian (7) too in anticipation of our discussion of the corresponding ''dyon'' solution.

We proceed to state the two distinct lower bounds on the energy, namely the volume integral of (8). Both bounds, the ''magnetic monopole'' charge and the noninteger ''baryon charge,'' pertain to the generic asymptotics (5) with $\omega\neq 0$, dictated by (4).

The first of these follows from the classic Bogomol'nyi inequality

$$\kappa_0^4|F_{ij}^{\alpha}|^2+\tfrac{1}{2}\kappa_1^2|D_i\phi^{\alpha}|^2\geqslant\kappa_0^2\kappa_1\varepsilon_{ijk}\partial_k(\phi^{\alpha}F_{ij}^{\alpha}). \tag{9}$$

It is obvious that the left-hand side of (9) can be replaced by $\mathcal{H}$ of (8), by adding suitable positive definite terms to it, resulting in

$$\mathcal{H}\geqslant\kappa_0^2\kappa_1\varepsilon_{ijk}\partial_k(\phi^{\alpha}F_{ij}^{\alpha}), \tag{10}$$

on the right-hand side of which we recognize the U(1) 't Hooft-tensor, $\phi^{\alpha}F_{ij}^{\alpha}$, of the residual gauge field responsible for the magnetic flux provided that $\omega\neq 0$, so that $|\phi^{\alpha}|\to\sin\omega\neq 0$ asymptotically.

To state the corresponding inequality for the other lower bound, we define the ''baryon charge'' density and its covariantized version, respectively,

$$\varrho_0=\frac{1}{12\pi^2}\varepsilon_{ijk}\varepsilon^{abcd}\partial_i\phi^a\partial_j\phi^b\partial_k\phi^c\phi^d, \tag{11}$$

$$\varrho_G=\frac{1}{12\pi^2}\varepsilon_{ijk}\varepsilon^{abcd}D_i\phi^a D_j\phi^b D_k\phi^c\phi^d. \tag{12}$$

The volume integral of (11) is the noninteger ''baryon charge''

$$\int \mathrm{d}^3x\,\varrho_0=(\pi-\omega)N, \tag{13}$$

except when $\omega=0$, when it is simply the integer N, the degree of the map or the usual baryon charge. The actual gauge invariant charge density which enters the relevant inequality is defined in terms of ϱ_G in (12) by[5,3]

$$\varrho=\varrho_G+3\varepsilon_{ijk}\phi^{\alpha}F_{ij}^{\alpha}D_k\phi^4, \tag{14}$$

whose volume integral turns out to be equal to the ''baryon charge'' (13).

As shown in Ref. 3, it follows that

$$\mathcal{H} \geqslant \frac{\kappa_1 \kappa_2^2}{\sqrt{1+9\left(\frac{\kappa_2}{\kappa_0}\right)^4}} \varrho . \tag{15}$$

We can now conclude from (9) and (15) the two distinct lower bounds on the energy $E = \int \mathrm{d}^3 x \mathcal{H}$, namely the ''magnetic'' and ''baryonic'' lower bounds, following from the asymptotics (5)

$$E \geqslant 4\pi \kappa_0^2 \kappa_1 \sin \omega, \tag{16}$$

$$E \geqslant \frac{12\pi \kappa_1 \kappa_2^2}{\sqrt{1+9\left(\frac{\kappa_2}{\kappa_0}\right)^4}} (\pi - \omega). \tag{17}$$

The two inequalities (16) and (17) signal the possibility of finding finite energy solutions bounded from below, provided that the (Derrick) scaling requirement is satisfied, which for (8) in three dimensions, it is. For the limiting case of $\omega = 0$ considered in Ref. 3, inequality (16) trivializes and (17) then coincides with the lower bound used in Ref. 3. In the other limit when $\omega = \pi$, both (16) and (17) trivialize so we would expect to find no nontrivial solutions in this case. This will be confirmed by our numerical results to be given in the following. For generic values of ω between these two limiting values, both lower bounds are valid independently, and any nontrivial finite energy solution must respect these. This will also be confirmed by our numerical results.

It should perhaps be pointed out that neither of the bounds (10) or (15) can be saturated. As we shall see in Sec. III, for $\omega \neq 0$ finite energy solutions persist also for $\kappa_2 = 0$. But even in that case, the inequality (10) cannot be saturated. Thus in the $\kappa_2 = 0$ model, we have a system which does not saturate a Bogomol'nyi bound and whose stress-energy tensor therefore never vanishes. It follows that the charge-2 monopole of this model is *either* attractive *or* repulsive, a property which it shares with the usual (ungauged) Skyrme model,[1] in the latter case as is well known it being attractive.[6] We shall find in Sec. IV that the model with $\kappa_2 = 0$ supports solutions describing mutually attracting like monopoles. Then as expected, when the Skyrme coupling constant κ_2 is switched on this binding energy will grow further, as is usual with other theories[7] involving Skyrme-like kinetic terms.

III. SPHERICALLY SYMMETRIC SOLUTIONS

In Sec. III A we present the reduced one-dimensional subsystems of (7) and (8), while in Sec. III B we present our numerical results.

A. One-dimensional subsystems

As in Ref. 3, we impose the spherical symmetry thus

$$A_0^\alpha = \kappa_1^{-1} g(r)\, \hat{x}^\alpha, \quad A_i^\alpha = \frac{a(r)-1}{r} \varepsilon_{i\alpha\beta} \hat{x}^\beta, \tag{18}$$

$$\phi^\alpha = \sin f(r) \hat{x}^\alpha, \quad \phi^4 = \cos f(r). \tag{19}$$

The ensuing reduced one-dimensional Lagrange and (static) Hamiltonian, subject to a suitable rescaling $r \to x$ such that all constants but the Skyrme coupling $\kappa_2^4 \equiv \kappa$ are suppressed, are, respectively,

$$L=-2\left(2a'^2+\frac{(a^2-1)^2}{x^2}\right)-\frac{1}{2}(x^2f'^2+2a^2\sin^2 f)$$
$$-2\kappa a^2\sin^2 f\left(2f'^2+\frac{a^2\sin^2 f}{x^2}\right)+x^2g'^2+2a^2g^2, \tag{20}$$

$$H=2\left(2a'^2+\frac{(a^2-1)^2}{x^2}\right)+\frac{1}{2}(x^2f'^2+2a^2\sin^2 f)+2\kappa a^2\sin^2 f\left(2f'^2+\frac{a^2\sin^2 f}{x^2}\right). \tag{21}$$

Note that we have suppressed the potential terms arising from (4) in (20) and (21), since as will be explained in the following, nearly all of numerical constructions will be carried out in the $\lambda=0$ limit.

While (21) is positive definite, (20) is not. The latter will be relevant only in some remarks that follow concerning the dyon solution of this system.

Let us first consider the case of primary interest, namely the monopole solutions of the equations following from the static energy density functional (21). The finite energy conditions require the following asymptotic values:

$$\lim_{x\to 0} f(x)=\pi, \quad \lim_{x\to\infty} f(x)=\omega, \tag{22}$$

$$\lim_{x\to 0} a(x)=1, \quad \lim_{x\to\infty} a(x)=0, \tag{23}$$

as long as $\omega\neq 0$. This is the case of interest in the present work. (The $\omega=0$, which is only a limiting case here, was studied in detail in Ref. 3.)

The behaviors of the functions $f(x)$ and $a(x)$ in the $x\ll 1$ region are independent of the value of λ in (4), and they are

$$f(x)=\pi+F_1x+o(x^3) \quad (x\ll 1), \tag{24}$$

$$a(x)=1+A_1x^2+o(x^4) \quad (x\ll 1). \tag{25}$$

In the $x\gg 1$ region, the asymptotic behavior of the function $a(x)$ is again independent of the value of λ and is

$$a(x)=A\,e^{(-1/2)\,x\sin\omega}, \quad A=\text{const}, \tag{26}$$

while that of the function $f(x)$ does depend on λ. In the limit of vanishing λ and finite λ, these are, respectively, the power and exponential decays,

$$f(x)=\omega-\frac{F}{x}+o\left(\frac{1}{x^2}\right), \tag{27}$$

$$f(x)=\omega-\tilde{F}\frac{e^{-\sqrt{2\lambda}x}}{x}, \tag{28}$$

where F and $\tilde{F}$ are constants which can be evaluated by the numerical process.

Thus, like with the usual (ungauged) Skyrme model, the addition of this potential results in the exponential localization of the chiral function $f(r)$. In the numerical work presented in the following we have used $\lambda=0$ throughout, since the qualitative properties of the solutions are unchanged when $\lambda>0$. This was verified in many typical cases and thereafter the potential (4)

played a *gedanken* role, rather like for the Prasad–Sommerfield limit of the Georgi–Glashow model, except that here the $\lambda=0$ limit is not particularly interesting since it does not lead to the saturation of any Bogomol'nyi bound.

Dyon solution. Before proceeding to describe our numerical results concerning the monopole solutions of this model, we briefly allude to the corresponding dyon solutions. Following Julia and Zee[8] we vary the energy density (20) with respect to the functions $a(r)$, $g(r)$, and $f(r)$. Since (20) is not positive definite, the radial ansatz (18) and (19) is not guaranteed to be consistent with the full Euler–Lagrange equations of this system. It has, however, been verified in Ref. 9 that (18) and (19) are indeed consistent.

The crucial equation that signals the existence of a dyon solution is the $r\gg 1$ asymptotic equation arising from the variation of the function $a(x)$,

$$a''=a\left(\frac{a^2-1}{x^2}-g^2+\sin^2 f+\ldots\right), \tag{29}$$

which in the $x\to\infty$ limit reduces to

$$a''=(\sin^2\omega-g^2)a,$$

which yields acceptable exponentially decaying solutions only when the asymptotic value of $q=\lim_{x\to\infty} g(x)$ satisfies the condition

$$0\leqslant q\leqslant \sin\omega, \tag{30}$$

and otherwise leading to unacceptable oscillatory behavior for the function $a(r)$ asymptotically.

With the asymptotic condition (30), one has the behavior

$$g(x)=q-\frac{c}{x}+o(x^{-2}), \tag{31}$$

in which the constant c is evaluated by the numerical integrations and parametrizes the electric flux of the dyon. We do not repeat here the detailed results of the numerical process as this is identical to that for the dyon[8] of the Georgi–Glashow model, as presented in Ref. 9. The relevant analysis in Sec. V of Ref. 9 can be adapted to the present model, by substituting the condition $0\leqslant q\leqslant 1$ there, by (30).

The only qualitative difference between the dyon of the Georgi–Glashow model and the dyon of the present model is, that unlike in the former case there is no Prasad–Sommerfield limit here.

B. Numerical results

Solving the spherically symmetric equations for numerous values of the parameters $\kappa\in]0,\infty[$ and $\omega\in]0,\pi[$, strongly indicates that they admit at least one regular, finite-energy solution for each choice of these parameters.

The behavior of the solution in the limit $\omega\to 0$ is different according to the value of κ and is strongly influenced by the pattern of solutions occurring in the case $\omega=0$. We briefly recall (see Refs. 3 and 9 for further details) that for $\omega=0$, solutions with $a(\infty)=0$ exist only for $\kappa>\kappa_{\rm cr}$, $\kappa_{\rm cr}\approx 0.697$. For $\kappa\in]0.0,0.697[$ the relevant solution has $a(\infty)=1$.

Let us now describe how the solutions look like for fixed κ, with ω varying. We have found it convenient to characterize the solutions by the value of the asymptotic coefficient F defined in Eq. (27). The evolution of this parameter is reported in Fig. 1 for several values of κ. For $\kappa>\kappa_{\rm cr}$ the solutions are such that the function $f(x)$ [respectively $a(x)$] decreases monotonically from π (respectively, 1) for $x=0$ to ω (respectively, 0) for $x\to\infty$. The parameter F is positive as seen in Fig. 1 for $\kappa=1.0$. The classical energy decreases monotonically when ω increases. In the limit $\omega\to 0$ the classical solutions of Ref. 3 are smoothly approached.

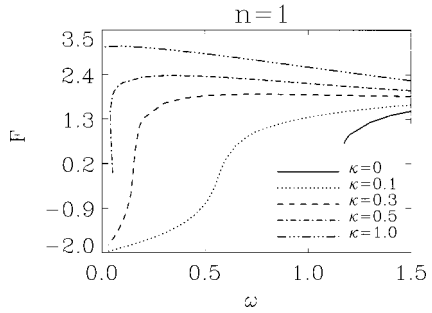

FIG. 1. The quantity F that determines the asymptotic behavior of the Skyrme field function f with $f(x\gg 1)=\omega-F/x+o(1/x^2)$ is shown as a function of ω for $n=1$ and different values of κ.

The behavior of the solutions is more elaborate when $\kappa<\kappa_{\mathrm{cr}}$; this is illustrated in Figs. 1 and 2 for $\kappa=0.1$. One new feature is that the parameter F undergoes a change of sign when ω varies from 0 to π. For large enough values of ω (say, $\omega>\omega_{\max}$, $\omega_{\max}\approx 0.5$ in the case $\kappa=0.1$), the profiles of $f(x)$ and of $a(x)$ monotonically decrease as functions of x and the classical energy decreases for ω increasing. For $\omega<\omega_{\max}$ the function $f(x)$ develops a local minimum at an intermediate value of x and the parameter F defined in Eq. (27) becomes negative. Moreover, the function $a(x)$ develops a local minimum and a local maximum at finite values (say x_m, x_M) of the radial variable. In this region of ω the classical energy increases with ω. When the limit $\omega\to 0$ is considered our numerical analysis indicates that x_m stays finite, x_M increases, and the value $a(x_M)$ approaches $a=1$ in such a way that the corresponding profile of the $\omega=0$ solution is approached on $[0,x_M]$. The corresponding value of the classical energy is also reproduced. These different features are illustrated in Figs. 1 and 2.

Considered as a function of ω, we also observed (see Fig. 2) that the classical energy is maximal at an intermediate value of ω. Our numerical analysis indicates that the maximum is attained precisely for $\omega=\omega_{\max}$, i.e., at the value where the change of sign of the parameter F occurs. The κ dependence of $\omega_{\max}$ is reported in Fig. 3.

As further suggested by Fig. 1, in the region $\kappa\approx 0.5$, $\omega\approx 0.05$ the pattern of the solutions becomes very complicated. We obtained strong numerical evidence that several branches of solutions exist in this region. That is to say, e.g., that we find more than one solution for $\kappa=0.5$, $\omega=0.05$. However these new branches seem to exist on a very small domain of the parameter ω, the numerical analysis is therefore rather difficult in this region. Since the study of such details is not the aim of the present paper, we refrained from further pursuing our numerical analysis in this region.

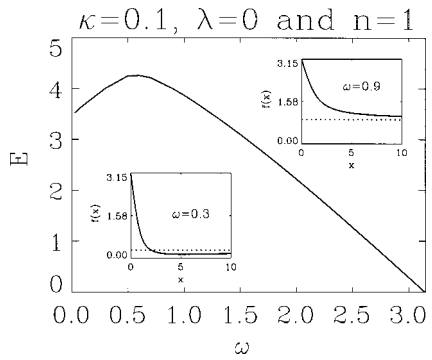

FIG. 2. The energy E of the $n=1$ solution is shown as a function of ω for $\kappa=0.1$ and $\lambda=0$. The two inlets show the Skyrme field function $f(x)$ as function of the radial coordinate x for (a) $\omega=0.3<\omega_{\max}$ and (b) $\omega=0.9>\omega_{\max}$.

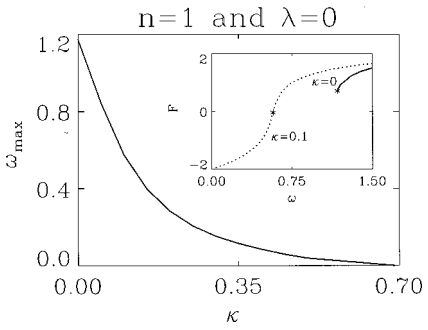

FIG. 3. $\omega_{\max}$, the value of ω at which the energy has its maximum, is shown as a function of κ. The inlet shows the quantity F (see Fig. 1) over ω for $\kappa=0$ and 0.1. The asterisks mark $\omega_{\max}(\kappa)$.

To finish this section, we mention that, choosing $\kappa=0$, we were able to construct numerical solutions for $\omega>1.1729$. The analysis of the solutions in the limit $\kappa\to 0$ (with fixed $\omega<1.1729$), seems to lead to a discontinuity of the function $f(x)$.

IV. AXIALLY SYMMETRIC SOLUTIONS

In Sec. IV A the axially symmetric ansatz and the boundary conditions of the axially symmetric solutions are stated. In Sec. IV B, the numerical results are given.

Our objective in this section is to construct higher magnetic charge solutions, and in the first instance charge-2 axially symmetric solutions, with the aim of discovering whether like monopoles of this model are in an attractive or a repulsive phase. In this framework, we will restrict our analysis to monopole rather than dyon solutions, in the temporal gauge $A_0=0$.

The analysis carried out in this section is less general than that given in Sec. III for the spherically symmetric solutions. There, we studied the detailed dependence of the solutions on the parameter ω specifying the dynamics. Having exposed these properties satisfactorily, we proceed to study the most natural subset of models here, namely those specified by $\omega=\pi/2$, supporting monopoles of *integer* magnetic charges.

Within this $\omega=\pi/2$ subset of models, we consider the models specified by the Skyrme coupling κ_2, or the effective parameter κ for the range $\kappa\geqslant 0$ which includes interestingly the point $\kappa=0$.

A. Ansatz and boundary conditions

With magnetic charge, or azimuthal winding, $n=1,2,3,...$, the axially symmetric ansatz[10] for the gauge field is

$$A_\mu\,\mathrm{d}x^\mu=\frac{1}{2r}[\,\tau_\phi^n(H_1\,\mathrm{d}r+(1-H_2)r\,\mathrm{d}\theta)-n(\tau_r^n H_3+\tau_\theta^n(1-H_4))r\sin\theta\,\mathrm{d}\phi], \tag{32}$$

and for the Skyrme field it is

$$U=\tfrac{1}{2}(\cos f\mathbb{1}+\sin f[(\sin g\sin\theta+\cos g\cos\theta)\tau_r^n+(\sin g\cos\theta-\cos g\sin\theta)\tau_\theta^n]), \tag{33}$$

where H_1,H_2,H_3,H_4,f, and g are functions of the coordinates r and θ. The symbols τ_r^n, τ_θ^n, and τ_ϕ^n denote the dot products of the Cartesian vector of Pauli matrices, $\vec{\tau}=(\tau_x,\tau_y,\tau_z)$, with the spatial unit vectors

$$\vec{e}_r^{\,n}=(\sin\theta\cos n\phi,\sin\theta\sin n\phi,\cos\theta),$$

$$\vec{e}_\theta^{\,n}=(\cos\theta\cos n\phi,\cos\theta\sin n\phi,-\sin\theta), \tag{34}$$

$$\vec{e}_{\phi}^{\,n}=(-\sin n\phi,\cos n\phi,0),$$

respectively.

For $n=1$, $H_1=H_3=0$, $H_2=H_4=a(r)$, $f=f(r)$, and $g=\theta$ the spherically symmetric ansatz of (18) and (19) is recovered.

The residual U(1) gauge degree of freedom[10] is fixed by the condition $r\partial_r H_1-\partial_\theta H_2=0$, which is just the Coulomb gauge in the two-dimensional residual U(1) subsystem resulting from the imposition of radial symmetry in the $x-y$ plane, i.e., with radius $\rho=\sqrt{x^2+y^2}$.

At the origin the boundary conditions for the gauge field functions read

$$H_2|_{r=0}=H_4|_{r=0}=1,\quad H_1|_{r=0}=H_3|_{r=0}=0, \tag{35}$$

and for the Skyrme functions

$$f|_{r=0}=\pi,\quad \partial_r g|_{r=0}=0. \tag{36}$$

For the gauge field to approach the asymptotic configuration of a monopole we choose

$$H_2|_{r=\infty}=H_4|_{r=\infty}=0,\quad H_1|_{r=\infty}=H_3|_{r=\infty}=0, \tag{37}$$

and for the Skyrme field functions

$$f|_{r=\infty}=\omega,\quad g|_{r=\infty}=\theta. \tag{38}$$

The boundary conditions along the ρ and z axes are determined by the symmetries. For the gauge field functions symmetry considerations lead to the boundary conditions

$$\begin{aligned} &H_1|_{\theta=0}=H_3|_{\theta=0}=0,\quad \partial_\theta H_2|_{\theta=0}=\partial_\theta H_4|_{\theta=0}=0,\\ &H_1|_{\theta=\pi/2}=H_3|_{\theta=\pi/2}=0,\quad \partial_\theta H_2|_{\theta=\pi/2}=\partial_\theta H_4|_{\theta=\pi/2}=0 \end{aligned} \tag{39}$$

along the axes, as well as the condition

$$H_2|_{\theta=0}=H_4|_{\theta=0}. \tag{40}$$

Along these axes the Skyrme field functions satisfy the following boundary conditions:

$$\begin{aligned} &\partial_\theta f|_{\theta=0}=0,\quad \partial_\theta g|_{\theta=0}=1,\\ &\partial_\theta f|_{\theta=\pi/2}=0,\quad \partial_\theta g|_{\theta=\pi/2}=1. \end{aligned} \tag{41}$$

B. Numerical results

Solving the set of partial differential equations numerically for the model characterized by $\omega=\pi/2$, and for different values of κ, we find that even for $\kappa=0$ there is only an attractive phase. As shown in Fig. 4, the difference δE of the energy per winding number n between the $n=1$ and $n=2$ increases with increasing κ. This is an indication that in this model two monopole bound states can exist. However, a definitive demonstration of this is well beyond the scope of the present work. (That would involve finding the dependence of the interaction energy on the separation of the two monopoles.)

Moreover, we calculated the energy $E_n(\kappa)$ for different values of κ and n. The values are given in the tables below. Unfortunately the numerical process becomes less reliable with increasing monopole charge n. As a result we restrict our numerical constructions to $n\leqslant 4$ only. For $\kappa=0$, $\kappa=3$, and $\kappa=5$ we find

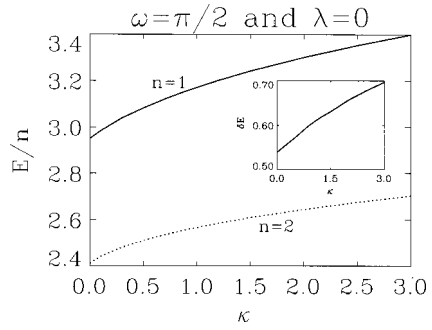

FIG. 4. The energy per winding number E/n is shown as a function of κ for $n=1$ and $n=2$, $\omega=\pi/2$, and $\lambda=0$. The inlet shows the difference of the energy per winding number $\delta E=E(n=1)-E(n=2)/2$ between the $n=1$ and the $n=2$ solution.

n	1	2	3	4
$E_n(0)$	2.95	4.82	6.63	7.56

n	1	2	3	4
$E_n(3)$	3.40	5.40	7.30	8.80

n	1	2	3	4
$E_n(5)$	3.48	5.60	7.50	9.31

From this data we can deduce some quantitative information on the interaction energies of the monopoles leading to the possible formation of lumps of charges $n\leqslant 4$. To this end we define the following ''binding energy'' corresponding to the energy needed to dissociate a charge-n lump into a charge-$n-1$ and a charge-1 lump, divided by the energy of the charge-n lump.

$$\Delta E_n^{\{n-1,1\}}(\kappa)=\frac{[E_{n-1}(\kappa)+E_1(\kappa)]-E_n(\kappa)}{E_n(\kappa)}. \tag{42}$$

The values for different κ and n are given as follows:

n	$\Delta E_n^{\{n-1,1\}}(0)$	$\Delta E_n^{\{n-1,1\}}(3)$	$\Delta E_n^{\{n-1,1\}}(5)$
2	0.22	0.26	0.24
3	0.17	0.21	0.21
4	0.27	0.22	0.18

This table shows that for all three values of κ, $\Delta E_n^{\{n-1,1\}}(\kappa)$ remains positive, which is an indication of the existence of monopole lumps of charges up to $n=4$.

It is hard to extract any reliable conclusion from such meagre data, but the fact that the binding energies do not seem to decrease with increasing n is encouraging from the point of view

of the possibility of finding very large monopole clumps. This question will be investigated elsewhere, using different numerical techniques.

V. SUMMARY AND DISCUSSION

We have studied a particular variant of the Skyrme model gauged according to the prescription (6), equivalent to the commutator gauging with respect to the SU(2) gauge connection $A_i = -(i/2)\vec{A}_i \cdot \vec{\tau}$,

$$D_i U = \partial_i U + [A_i, U], \tag{43}$$

which is augmented by the potential (4). The function of this potential is to fix the boundary value of the Skyrme field at large distances which, unlike in the usual (ungauged) Skyrme model, is not fixed by the requirement of finite energy.[11] Thus we have considered a set of the gauged Skyrme models characterized by the parameter ω appearing in the potential (4). In the usual Skyrme model $\omega = 0$.

The qualitative properties of the solitons, depending on the parameters ω and κ characterizing the models, are studied in the spherically symmetric case.

The main effect of the boundary condition $\omega \neq 0$ is the breaking of the SO(3) gauge symmetry of the solution down to SO(2), asymptotically. This is related to the nonvanishing VEV of the Skyrme field ϕ^α. This can be seen clearly from the second member of (5). In addition to this magnetic charge, a noninteger version of the baryon number given by (13) is also associated with this solution. We have verified the existence of finite energy solutions bounded from below by both these charges for the allowed ranges of ω. The latter (ranges) depend also on the (effective) Skyrme coupling κ of the model. These ranges have been illustrated in Fig. 1.

A surprising if not unexpected property of these models is that the model characterized by $\kappa = 0$ does support a soliton. This could have been expected since in the presence of the Yang–Mills term it is not necessary to have a Skyrme term to satisfy the (Derrick) scaling requirement. We found that the solitons of the $\kappa = 0$ models are generally quite similar to those of the models with $\kappa \neq 0$, with one noticeable qualitative difference. This concerns the restricted range of allowed ω for the $\kappa = 0$ model as seen in Fig. 1 (and in Fig. 3), which in addition to this qualitative feature also illustrates the fact that for small enough κ the profile of the chiral function $f(r)$ sinks below its asymptote ω and approaches it from below.

By contrast when $\omega = 0$, the model with $\kappa = 0$ cannot support a soliton because in that case the lower bound (10) disappears, leaving only the lower bound (13) in place, and the latter trivializes in the $\kappa = 0$ limit. This is also borne out by the graphs in Fig. 1.

After exposing the qualitative features of the solitons in the spherically symmetric case, we studied axially symmetric solutions of the model. Our aim here was to discover if like monopoles of the $\omega \neq 0$ models are in attractive or repulsive phases. For this purpose we restricted ourselves to the $\omega = \pi/2$ model, which has the nice feature of having integer magnetic charge. We did however consider varying values of the (effective) Skyrme parameter κ, including the distinguished case of $\kappa = 0$.

The main interest in the model specified by $\kappa = 0$ in this respect is that, like the usual (ungauged) Skyrme model, it exhibits no free coupling constants that can parametrize the crossover from an attractive to a repulsive phase. Like the latter it also lacks a neutral, or Bogomol'nyi saturated phase, where the (static Euclidean) stress-energy tensor would have vanished leading to noninteracting solitons. Thus the unique phase in which the solitons are supported is of special interest, especially if it were attractive because then the switching on of κ would most likely not result in a crossover to a repulsive phase. We have verified that this is precisely what happens, as illustrated in Fig. 4 for the magnetic charge-2 soliton. An outstanding problem in this context is the calculation of the (attractive) interaction energy of two one-monopoles as a function of their separation. This would demonstrate the existence of bound states definitively.

In addition to verifying that these models support mutually attracting like monopoles, we sought some indications as to whether there is the possibility of forming bound states of monopole

charge greater than 2. (Apart from its intrinsic interest, the formation of very large monopole clumps may be relevant in cosmology.) To this end, axially symmetric solutions with monopole charges $n=2,3,4$, for the $\kappa=0$, $\kappa=3$, and the $\kappa=5$ models were constructed. It was seen that all these solitons remained in attractive phases. While it is expected that these axially symmetric solitons with $n>2$ are not the lowest energy solutions, the latter probably exhibiting (solid) Platonic symmetries[12,13] as in the usual Skyrme model, it is nonetheless true that they give a reliable indication toward the existence of such bound states. To this end we list the binding energies against the dissociation of an axially symmetric charge-n monopole into a charge-$n-1$ and a charge-1 monopole in the last table of Sec. IV. We see that this binding energy stays positive and does not change too much as n increases, at least for $n\leqslant 4$. Unfortunately the numerical process was not reliable much beyond $n=4$.

While in the present work our primary aim has been the qualitative study of the solitons of the gauged Skyrme model characterized by $\omega\neq 0$, and the resulting property of the interaction of like monopoles in these theories, it may be in order to emphasize some physically attractive features of these models. These models combine some attractive features of (a) Higgs models, in this case the Georgi–Glashow model in that they support monopoles, and features of (b) Skyrme models, in this case the usual Skyrme model[1] in that the like-charged solitons are in an attractive phase. Indeed it appears that the attraction properties of these models are considerably more pronounced than those of the Skyrme model.[1]

Apart from the practical consideration of the possibility of supporting large monopole clumps, there are two theoretical properties of the models that deserve mention. One is the physically desirable property of the symmetry breaking from SU(2) to U(1), and the other one is the fact that the $\kappa=0$ model supports solitons with much the same qualitative properties as the generic models. The considerable advantage of this is that we avail of the Skyrme THEORTIC feature of mutually attracting solitons without having to pay the price of featuring a (quartic kinetic) Skyrme term in the Lagrangian, thus avoiding the attendant severe problems of quantization.

ACKNOWLEDGMENTS

We are indebted to B. Kleihaus for his collaboration at the initial stage of this investigation. This work was carried out in the framework of project Nos. SC/96/602 and IC/00/021 of Enterprise–Ireland. We would like to thank the RRZN Hannover for computing time.

[11] Note that in Refs. 3 and 4, unlike here, an explicit potential was not employed. This is because there, *only one* value, $\omega=0$, was used so it was considered reasonable to treat the role of the corresponding potential in a putative capacity. This is justified since, as we have verified here too, the explicit use of a potential only affects the asyptotics of the chiral function $f(r)$ and otherwise leads to no qualitative differences.

(Received 20 February 2001; accepted for publication 20 March 2001)

Standard discussions of Goldstone's theorem based on a symmetry of the action assume constant fields and global transformations, i.e., transformations which are independent of spacetime coordinates. By allowing for arbitrary field distributions in a general representation of the symmetry we derive a generalization of the standard Goldstone's theorem. When applied to gauge bosons coupled to scalars with a spontaneously broken symmetry the generalized theorem automatically imposes the Higgs mechanism, i.e., if the expectation value of the scalar field is nonzero then the gauge bosons must be massive. The other aspect of the Higgs mechanism, the disappearance of the ''would be'' Goldstone boson, follows directly from the generalized symmetry condition itself. We also use our generalized Goldstone's theorem to analyze the case of a system in which scale and conformal symmetries are both spontaneously broken. © *2001 American Institute of Physics.*

I. INTRODUCTION

Symmetry, symmetry breaking, Goldstone bosons and the Higgs mechanism play a very important role in modern physics. (See, for example, Refs. 1–5.) Here we present a more general approach to these ideas which explores the consequences of Goldstone's theorem for spacetime and gauge symmetries and shows that the Higgs mechanism is not as ''mysterious'' or ''miraculous'' as it is sometimes presented to be. We also resolve some old questions regarding the breaking of scale and conformal symmetry.

We consider the physical consequences of actions which have a symmetry or a set of symmetries. Precisely what we mean by this is discussed in detail below. For concreteness we work out the details for the classical action of a set of fields Φ_a, which we denote by $S[\Phi]$. To treat the quantum theory one computes the functional integral over all field configurations (in a given function space) of $\exp(iS[\Phi]+iJ\cdot\Phi)$ to obtain the generating functional $Z[J]$. Here the dot indicates the appropriate inner product over spacetime position, spacetime indices and internal indices. The effective action $\Gamma[\Phi]$,[1–4] defined via a Legendre transformation of $\ln(Z[J])$, is the analog of $S[\Phi]$ but includes all quantum effects. That is, whereas $\delta S/\delta\Phi(x)=0$ is the equation of motion for the classical field configuration $\Phi_C(x)$, $\delta\Gamma/\delta\Phi(x)=0$ is the equation of motion for the vacuum expectation value of the field $\langle\Phi(x)\rangle$. Indeed the nth functional derivative of $\Gamma[\Phi]$ is the n-point quantum Green's function. Generally, but certainly not always, $\Gamma[\Phi]$ will have the same symmetry properties as $S[\Phi]$. To lowest or ''tree'' order the two actions coincide and in a sense $\Gamma[\Phi]$ can be thought of as just a more complicated functional of Φ than $S[\Phi]$. Hence our approach applies to both $S[\Phi]$ and to $\Gamma[\Phi]$ for any given symmetry that holds for either functional. We will generally assume that Φ is classically a commuting field or quantum mechanically

a bosonic field, but the same approach can be applied to classical Grassmann fields or to quantum Fermionic fields yielding similar results with, of course, the requisite care in factor ordering.

II. GENERAL SYMMETRY CONDITION

Consider a Lagrangian density $\mathcal{L}(\Phi(x),\partial\Phi(x))$ which depends on a set of fields Φ_a and their first derivatives, $\partial_\mu\Phi_a$. Here a can be an internal index, a spacetime index or a combination of the two. The action is defined by

$$S[\Phi]=\int d^Dx\,\mathcal{L}(\Phi(x),\partial\Phi(x)), \tag{1}$$

and is taken to be invariant, i.e., $S[\Phi]=S[\Phi']$, under a continuous set of transformations of the fields given by

$$\Phi_a(x)\to\Phi'_a(x)=F(\Phi(x),\partial\Phi(x),\ldots,x)=\Phi_a(x)+\Delta_a(\Phi(x),\partial\Phi(x),\ldots,x)+\cdots, \tag{2}$$

where the last expression is the infinitesimal form of the transformation. In terms of the Lagrangian this symmetry has the form

$$\begin{aligned}\int d^Dx\,\mathcal{L}(\Phi(x),\partial\Phi(x))&=\int d^Dx\,\mathcal{L}(\Phi'(x),\partial\Phi'(x))\\&=\int d^Dx\,\mathcal{L}(F(\Phi(x),\partial\Phi(x),\ldots,x),\partial F(\Phi(x),\partial\Phi(x),\ldots,x)).\end{aligned} \tag{3}$$

We have assumed the change in Φ_a may depend locally on Φ_a and possibly explicitly on x as well. For ease of notation we will abbreviate the Φ dependence of $\mathcal{L}$, F and Δ as

$$\begin{aligned}\mathcal{L}(\Phi(x),\partial\Phi(x))&\equiv\mathcal{L}[\Phi(x)],\\F_a(\Phi(x),\partial\Phi(x),\ldots,x)&\equiv F_a[\Phi(x),x],\\\Delta_a(\Phi(x),\partial\Phi(x),\ldots,x)&\equiv\Delta_a[\Phi(x),x].\end{aligned} \tag{4}$$

Infinitesimally a symmetry is simply the statement that the gradient of the action at any point in function space is perpendicular to the direction defined by Δ_a, i.e.,

$$\int d^Dx\,\frac{\delta S[\Phi]}{\delta\Phi_a(x)}\Delta_a[\Phi(x),x]=0. \tag{5}$$

The symmetry condition expressed in (5) is not an equation for Φ and in fact must hold for all values of Φ. Thus all the functional derivatives of (5) with repect to Φ must vanish. This condition effectively assumes the equivalent of analyticity of $S[\Phi]$ in function space. If the same idea is applied to $\Gamma[\Phi]$, the effective action computed by evaluating a functional integral, then the vanishing of the various functional derivatives yields the generalized Ward–Takahashi identities.

Taking one functional derivative of the symmetry condition (5) and evaluating it at the equation of motion yields, as shown below, what can be seen as a generalized Goldstone theorem:

$$\int d^Dx'\left(\frac{\delta^2S}{\delta\Phi_a(x)\,\delta\Phi_b(x')}\Delta_a[\Phi(x'),x']\right)_{\Phi_C}=0. \tag{6}$$

Substituting (1) and assuming locality of Δ_a as expressed in (4) yields the following after some simple manipulations:

$$\left[-\partial_\alpha\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\alpha\Phi_a)\partial(\partial_\mu\Phi_b)}\partial_\mu\Delta_b\right)-\partial_\alpha\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\alpha\Phi_a)\partial\Phi_b}\Delta_b\right)+\frac{\partial^2\mathcal{L}}{\partial\Phi_a\,\partial(\partial_\mu\Phi_b)}\partial_\mu\Delta_b+\frac{\partial^2\mathcal{L}}{\partial\Phi_a\,\partial\Phi_b}\Delta_b\right]_{\Phi_C}$$
$$=0. \tag{7}$$

In the remainder of the paper we explore some of the consequences of this equation.

III. GOLDSTONE'S THEOREM

There are nominally two consequences of Goldstone's theorem. The primary one is the requirement for the existence of some number of massless bosons, called Goldstone bosons, in the theory if the symmetry is spontaneously broken. The secondary condition is that the Goldstone bosons decouple from the other degrees of freedom in the limit of zero momentum.

Symmetry breaking is based on the additive nature of (2) which indicates that a given field configuration is not invariant under the symmetry transformation. In particular it is often the case that $\Delta_a\equiv 0$ if and only if $\Phi_a=0$ and so for any nonzero field configuration the transformation in (2) is inhomogeneous and the symmetry is spontaneously broken, i.e., a nonzero field configuration is not invariant under the symmetry transformation whereas the zero field configuration is invariant. This is discussed very clearly in Ref. 5.

We begin by reviewing the standard approach to Goldstone's theorem as given for example in the book by Peskin and Schroeder.[1] This form of the derivation proceeds by considering constant fields and field transformations for Lagrangians of the form

$$\mathcal{L}=T(\partial\Phi)-V(\Phi). \tag{8}$$

Specializing to constant fields the equations of motion reduce to

$$\left.\frac{\partial V}{\partial\Phi_a}\right|_{\Phi_C}=0, \tag{9}$$

which shows that the constant field Φ_C is an extremum, commonly a minimum, of V. Expanding V about this miminum yields

$$V(\Phi)=V(\Phi_C)+\frac{1}{2}(\Phi-\Phi_C)_a(\Phi-\Phi_C)_b\left(\frac{\partial^2 V}{\partial\Phi_a\,\partial\Phi_b}\right)_{\Phi_C}+\ldots. \tag{10}$$

The coefficient of the quadratic term is a symmetric matrix, known as the mass matrix, whose eigenvalues are the square of the masses of the various fields obtained from $(\Phi-\Phi_C)_a$ after applying the linear transformation which diagonalizes the matrix. Since the symmetry condition is taken to hold for arbitrary field configurations it holds as well for constant fields in which case the potential V itself is invariant, i.e.,

$$V(\Phi)=V(\Phi+\Delta), \tag{11}$$

which implies

$$\frac{\partial V}{\partial\Phi_a}\Delta_a(\Phi)=0. \tag{12}$$

Now differentiate with respect to Φ_b and evaluate the result at Φ_C to obtain

$$\left(\frac{\partial^2 V}{\partial\Phi_b\,\partial\Phi_a}\right)_{\Phi_C}\Delta_a(\Phi_C)=0. \tag{13}$$

This shows that the mass matrix has a zero eigenvalue for each linearly independent symmetry vector $\Delta(\Phi_C)$ satisfying the above equation. The number of linearly independent nonzero vectors $\Delta(\Phi_C)$ is referred to as the number of broken generators, N_B, and hence there is one Goldstone boson for each broken generator. Our more general result (6) or equivalently (7) yields this same condition as well if we assume Lagrangians of the form given in (8) and set Φ_C to a constant field in Eq. (6) or (7) which can now clearly be seen as a generalization of the above equation.

The decoupling follows from considering a change of variables which diagonalizes the mass matrix. This can be done by writing

$$\Phi_a = \Phi_a(\xi_i, \rho_j), \tag{14}$$

where $i=1,\ldots,N_B$ and $j=1,\ldots,N-N_B$ with ξ_i and ρ_j defined implicitly by choosing $\Phi_a(\xi_i,\rho_j)$ so that

$$\begin{aligned}\begin{pmatrix} \dfrac{\partial^2 V(\Phi(\xi,\rho))}{\partial\xi_i\,\partial\xi_{i'}} & \dfrac{\partial^2 V(\Phi(\xi,\rho))}{\partial\xi_i\partial\rho_{j'}} \\ \dfrac{\partial^2 V(\Phi(\xi,\rho))}{\partial\rho_j\,\partial\xi_{i'}} & \dfrac{\partial^2 V(\Phi(\xi,\rho))}{\partial\rho_j\,\partial\rho_{j'}} \end{pmatrix}_{\Phi_C} &= \begin{pmatrix} \dfrac{\partial\Phi_a}{\partial\xi_i}\dfrac{\partial^2 V}{\partial\Phi_a\,\partial\Phi_b}\dfrac{\partial\Phi_b}{\partial\xi_{i'}} & \dfrac{\partial\Phi_a}{\partial\xi_i}\dfrac{\partial^2 V}{\partial\Phi_a\,\partial\Phi_b}\dfrac{\partial\Phi_b}{\partial\rho_{j'}} \\ \dfrac{\partial\Phi_a}{\partial\rho_j}\dfrac{\partial^2 V}{\partial\Phi_a\,\partial\Phi_b}\dfrac{\partial\Phi_b}{\partial\xi_{i'}} & \dfrac{\partial\Phi_a}{\partial\rho_j}\dfrac{\partial^2 V}{\partial\Phi_a\,\partial\Phi_b}\dfrac{\partial\Phi_b}{\partial\rho_{j'}} \end{pmatrix}_{\Phi_C} \\ &= \begin{pmatrix} 0 & 0 \\ 0 & -(m_j(\Phi_C))^2\delta_{jj'} \end{pmatrix},\end{aligned} \tag{15}$$

where there is no sum on j in the last matrix. The ξ_i are the Goldstone bosons (the $\xi\xi$ sector of the mass matrix vanishes by definition) and the ρ_i are the remaining bosons, i.e., at any given value of Φ_C the ξ_i are tangent to the symmetry directions at that point in function space whereas the ρ_j are perpendicular to these directions. The symmetry transformation (5) becomes $\xi_i \to \xi_i + \delta\xi_i$, $\rho_j \to \rho_j$ for $\Phi_a \to \Phi_a + \Delta_a(\Phi)$ or equivalently,

$$\Delta_a(\Phi) = \frac{\partial\Phi_a}{\partial\xi_i}\delta\xi_i\,. \tag{16}$$

Note that $\delta\xi_i$ must be constant for $\Delta(\Phi)$ constant. The symmetry condition (5) in terms of the new variables yields

$$\begin{aligned} 0 &= \frac{\delta\mathcal{L}[\Phi(\xi,\rho)]}{\delta\xi_i}\delta\xi_i \\ &= \frac{\partial\mathcal{L}[\Phi(\xi,\rho)]}{\partial\xi_i}\delta\xi_i \\ &= \frac{\partial\mathcal{L}'(\xi,\rho)}{\partial\xi_i}\delta\xi_i\,, \end{aligned} \tag{17}$$

where the $\partial_\mu\delta\xi_i$ term vanishes since $\delta\xi_i$ must be constant for the symmetry to hold. Hence $\partial\mathcal{L}'/\partial\xi_i = 0$ and $\mathcal{L}'$ can depend only on $\partial_\mu\xi_i$. Since $\partial_\mu\xi_i$ vanishes in the limit of zero momentum the Goldstone bosons vanish or decouple in this limit.

IV. AUTOMATIC HIGGS

Consider a $U(1)$ gauge model in which a complex scalar field $\phi = \phi_1 + i\phi_2$ with ϕ_i real, $i=1,2$, is coupled in a locally gauge invariant way to a $U(1)$ gauge field, A_μ. In this case,

$$\Phi_a \to (A_\mu, \phi_i), \tag{18}$$

$$\Delta_a \to (\partial_\mu \theta, \varepsilon_{ij}\phi_j \theta),$$

with θ an arbitrary infinitesimal scalar function of position. Note we are working in units with the electric charge $e=1$. Take the Lagrangian to have the form

$$\begin{aligned}\mathcal{L} &= \mathcal{L}_A(\partial_\mu A_\nu) + \mathcal{L}_\phi(\partial_\mu \phi_i, \phi_i) + \mathcal{L}_{A\phi}(A_\mu, \partial_\mu \phi_i, \phi_i) \\ &= -\tfrac{1}{4} F_{\mu\nu}F^{\mu\nu} + \partial_\mu \phi_i\, \partial^\mu \phi_i - V(\phi_i \phi_i) + \mathcal{L}_{A\phi}(A_\mu, \partial_\mu \phi_i, \phi_i),\end{aligned} \tag{19}$$

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ so that $\mathcal{L}_A$ is invariant under gauge transformations and $\mathcal{L}_\phi$ is invariant under $\phi \to e^{i\theta}\phi$ for θ constant. The extra term $\mathcal{L}_{A\phi}$ is explicitly included to "boost" the symmetry from a global one to a local one. It allows for terms of the form $A\phi\,\partial\phi$ and $AA\phi\phi$ which are the lowest order terms with saturated indices. That is for arbitrary, i.e., not necessarily infinitesimal θ the full Lagrangian is required to be symmetric under

$$\begin{aligned}A_\mu &\to A_\mu + \partial_\mu \theta, \\ \phi &\to e^{i\theta}\phi.\end{aligned} \tag{20}$$

We explicitly assume the only $\partial\phi\,\partial\phi$ term in $\mathcal{L}$ is the standard kinetic energy term from $\mathcal{L}_\phi$.

For arbitrary infinitesimal functions θ local gauge invariance yields the following symmetry condition for the action:

$$0 = \int d^D x \frac{\delta S}{\delta A_\beta}\partial_\beta \theta + \int d^D x \frac{\delta S}{\delta \phi_j}\varepsilon_{jk}\phi_k \theta. \tag{21}$$

Note that $\mathcal{L}$ is locally gauge invariant and not just S thus the remaining $\int d^D x$ integration in the above equation can be dropped. The generalized symmetry equation yields two distinct equations since we can take derivatives with respect to A and ϕ:

$$\begin{aligned}0 &= \left(\int d^D x \frac{\delta^2 S}{\delta A_\alpha\, \delta A_\beta}\partial_\beta \theta + \int d^D x \frac{\delta^2 S}{\delta A_\alpha\, \delta \phi_j}\varepsilon_{jk}\phi_k \theta \right)_{\Phi_C} \\ &= -\partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu A_\alpha)\partial(\partial_\mu A_\beta)}\partial_\mu \partial_\beta \theta \right) + \frac{\partial^2 \mathcal{L}}{\partial A_\alpha \partial(\partial_\mu A_\beta)}\partial_\mu \partial_\beta \theta - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu A_\alpha)\partial A_\beta}\partial_\beta \theta \right) \\ &\quad + \frac{\partial^2 \mathcal{L}}{\partial A_\alpha\, \partial A_\beta}\partial_\beta \theta - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu A_\alpha)\partial(\partial_\mu \phi_j)}\partial_\mu \varepsilon_{jk}\,\phi_k \theta \right) + \frac{\partial^2 \mathcal{L}}{\partial A_\alpha \partial(\partial_\mu \phi_j)}\partial_\mu \varepsilon_{jk}\,\phi_k \theta \\ &\quad - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu A_\alpha)\partial \phi_j}\varepsilon_{jk}\phi_k \theta \right) + \frac{\partial^2 \mathcal{L}}{\partial A_\alpha\, \partial \phi_j}\varepsilon_{jk}\phi_k \theta\end{aligned} \tag{22}$$

and

$$\begin{aligned}0 &= \left(\int d^D x \frac{\delta^2 S}{\delta \phi_i\, \delta A_\beta}\partial_\beta \theta + \int d^D x \frac{\delta^2 S}{\delta \phi_i\, \delta \phi_j}\varepsilon_{jk}\phi_k \theta \right)_{\Phi_C} \\ &= -\partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu \phi_i)\partial(\partial_\mu A_\beta)}\partial_\mu \partial_\beta \theta \right) + \frac{\partial^2 \mathcal{L}}{\partial \phi_i \partial(\partial_\mu A_\beta)}\partial_\mu \partial_\beta \theta - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu \phi_i)\partial A_\beta}\partial_\beta \theta \right) \\ &\quad + \frac{\partial^2 \mathcal{L}}{\partial \phi_i\, \partial A_\beta}\partial_\beta \theta - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu \phi_i)\partial(\partial_\mu \phi_j)}\varepsilon_{jk}\partial_\mu(\phi_k \theta) \right) + \frac{\partial^2 \mathcal{L}}{\partial \phi_i \partial(\partial_\beta \phi_j)}\varepsilon_{jk}\partial_\beta(\phi_k \theta) \\ &\quad - \partial_\nu\left(\frac{\partial^2 \mathcal{L}}{\partial(\partial_\nu \phi_i)\partial \phi_j}\varepsilon_{jk}\phi_k \theta \right) + \frac{\partial^2 \mathcal{L}}{\partial \phi_i\, \partial \phi_j}\varepsilon_{jk}\phi_k \theta.\end{aligned} \tag{23}$$

To simplify notation in both equations we have implicitly assumed that the results have been evaluated at a solution to the equations of motion.

In (22) the first term vanishes identically, the second and third terms vanish because we have not allowed for any derivative coupling of the gauge fields. The fifth term and seventh terms vanish since there are no $\phi\,\partial A$ or $\partial A\,\partial\phi$ terms. In (23) the first and second terms vanish. Using the fact that $\partial_\mu\phi_i\,\partial^\mu\phi_i = g^{\mu\nu}\delta_{ij}\,\partial_\mu\phi_i\,\partial_\nu\phi_j$ is the only term quadratic in the derivatives of ϕ and expanding out all the derivatives of product terms we obtain

$$0=\left(\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial A_\beta}+\frac{\partial^2\mathcal{L}}{\partial A_\alpha\partial(\partial_\beta\phi_j)}\varepsilon_{jk}\phi_k\right)\partial_\beta\theta+\left(\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial\phi_j}\varepsilon_{jk}\phi_k+\frac{\partial^2\mathcal{L}}{\partial A_\alpha\partial(\partial_\beta\phi_j)}\varepsilon_{jk}\,\partial_\beta\phi_k\right)\theta \tag{24}$$

and

$$\begin{aligned}0=&-\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}+2g^{\nu\beta}\varepsilon_{ik}\phi_k\right)\partial_\nu\partial_\beta\theta+\left(\begin{array}{c}\dfrac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial A_\beta}-\partial_\nu\left(\dfrac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}\right)-4\varepsilon_{ik}\,\partial^\beta\phi_k\\ +\left(\dfrac{\partial^2\mathcal{L}}{\partial\phi_i\partial(\partial_\beta\phi_j)}-\dfrac{\partial^2\mathcal{L}}{\partial(\partial_\beta\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\phi_k\end{array}\right)\partial_\beta\theta\\ &+\left(\begin{array}{c}-2\varepsilon_{ik}\,\partial^2\phi_k+\left(\dfrac{\partial^2\mathcal{L}}{\partial\phi_i\partial(\partial_\beta\phi_j)}-\dfrac{\partial^2\mathcal{L}}{\partial(\partial_\beta\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\,\partial_\beta\phi_k\\ +\left(\dfrac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial\phi_j}-\partial_\nu\left(\dfrac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial\phi_j}\right)\right)\varepsilon_{jk}\phi_k\end{array}\right)\theta.\end{aligned} \tag{25}$$

Since θ is an arbitrary function the coefficients of $\theta,\partial\theta$ and $\partial\partial\theta$ must vanish independently which yields the following:

$$0=\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial A_\beta}+\frac{\partial^2\mathcal{L}}{\partial A_\alpha\partial(\partial_\beta\phi_j)}\varepsilon_{jk}\phi_k, \tag{26}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial\phi_j}\varepsilon_{jk}\phi_k+\frac{\partial^2\mathcal{L}}{\partial A_\alpha\partial(\partial_\beta\phi_j)}\varepsilon_{jk}\,\partial_\beta\phi_k, \tag{27}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}+2g^{\nu\beta}\varepsilon_{ik}\phi_k, \tag{28}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial A_\beta}-\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}\right)-4\varepsilon_{ik}\,\partial_\beta\phi_k+\left(\frac{\partial^2\mathcal{L}}{\partial\phi_i\partial(\partial_\beta\phi_j)}-\frac{\partial^2\mathcal{L}}{\partial(\partial_\beta\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\phi_k-2\varepsilon_{ik}\partial^2\phi_k, \tag{29}$$

$$0=+\left(\frac{\partial^2\mathcal{L}}{\partial\phi_i\partial(\partial_\beta\phi_j)}-\frac{\partial^2\mathcal{L}}{\partial(\partial_\beta\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\,\partial_\beta\phi_k+\left(\frac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial\phi_j}-\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial\phi_j}\right)\right)\varepsilon_{jk}\phi_k. \tag{30}$$

For a constant solution to the ϕ equations of motion, i.e., $\phi=\text{const}$ but A_μ unspecified, these equations reduce to

$$0=\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial A_\beta}+\frac{\partial^2\mathcal{L}}{\partial A_\alpha\partial(\partial_\beta\phi_j)}\varepsilon_{jk}\phi_k, \tag{31}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial\phi_j}\varepsilon_{jk}\phi_k, \tag{32}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}+2g^{\nu\beta}\varepsilon_{ik}\phi_k, \tag{33}$$

$$0=\frac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial A_\beta}-\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}\right)+\left(\frac{\partial^2\mathcal{L}}{\partial\phi_i\partial(\partial_\beta\phi_j)}-\frac{\partial^2\mathcal{L}}{\partial(\partial_\beta\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\phi_k, \tag{34}$$

$$0=\left(\frac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial\phi_j}-\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial\phi_j}\right)\right)\varepsilon_{jk}\phi_k. \tag{35}$$

Substituting (33) into (31) yields

$$\frac{\partial^2\mathcal{L}}{\partial A_\alpha\,\partial A_\beta}=2g^{\alpha\beta}\phi_i\phi_i,$$

and so for constant nonzero ϕ_i solutions to the equation, the gauge bosons must have a nonzero mass equal to $\sqrt{2\phi_i\phi_i}$. The sign of the gauge boson mass is correct since the Lagrangian for massive vector bosons, the Proca Lagrangian, has the form $-\frac{1}{4}F^2+\frac{1}{2}M^2A^2$. Hence the first part of the Higgs mechanism, the gauge bosons acquire a mass, is automatic and can be seen to be simply a direct requirement of the generalized Goldstone's theorem, Eq. (6) or equivalently (7).

Applying $\varepsilon_{il}\phi_l$ to Eq. (34) and using (32) yields

$$\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial A_\beta}\right)\varepsilon_{il}\phi_l=0, \tag{36}$$

and applying $\varepsilon_{il}\phi_l$ to (35) yields

$$\varepsilon_{il}\phi_l\frac{\partial^2\mathcal{L}}{\partial\phi_i\,\partial\phi_j}\varepsilon_{jk}\phi_k=\varepsilon_{il}\phi_l\partial_\nu\left(\frac{\partial^2\mathcal{L}}{\partial(\partial_\nu\phi_i)\partial\phi_j}\right)\varepsilon_{jk}\phi_k. \tag{37}$$

These two equations along with (32) are automatically satisfied by taking

$$\mathcal{L}_{A\phi}=2A_\mu\varepsilon_{ij}\phi_i\,\partial^\mu\phi_j+\phi_i\phi_iA_\mu A^\mu, \tag{38}$$

which is the standard form.

The second part of the Higgs mechanism, the disappearance of the ''would-be'' Goldstone boson, follows from the symmetry condition (21) itself which after changing variables to ξ and ρ using $\phi=\rho e^{i\xi}$ reads as

$$0=\frac{\partial\mathcal{L}}{\partial(\partial_\mu A_\nu)}\partial_\mu\partial_\nu\theta+\left(\frac{\partial\mathcal{L}}{\partial A_\nu}+\frac{\partial\mathcal{L}}{\partial(\partial_\nu\xi)}\right)\partial_\nu\theta+\left(\frac{\partial\mathcal{L}}{\partial\xi}\right)\theta. \tag{39}$$

Again, since θ is an arbitrary function, each term must vanish separately. The first term vanishes due to the gauge invariance $\mathcal{L}_A$ since $\partial\mathcal{L}/\partial(\partial_\mu A_\nu)=\partial\mathcal{L}_A/\partial(\partial_\mu A_\nu)$. The last term demands $\partial\mathcal{L}/\partial\xi=0$ and so $\mathcal{L}$ may depend only on derivatives of ξ, i.e., $\mathcal{L}(A,\rho,\partial\rho,\xi,\partial\xi)\rightarrow\mathcal{L}(A,\rho,\partial\rho,\partial\xi)$. If we make the change of variables $A_\mu\rightarrow B_\mu=A_\mu-\partial_\mu\xi$, the first and third terms still vanish. The first automatically since for $\mathcal{L}_A$ alone this is just a gauge tranformation and the last still yields the condition $\partial\mathcal{L}/\partial\xi=0$. But now the middle term can be written as

$$0=\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial B_\nu}\right)\frac{\partial B_\nu}{\partial A_\mu}+\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial B_\nu}\right)\frac{\partial B_\nu}{\partial(\partial_\mu\xi)}+\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial(\partial_\nu\xi)}\right)$$

$$=\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial B_\nu}\right)\delta^\mu_\nu+\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial B_\nu}\right)(-\delta^\mu_\nu)+\left(\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial(\partial_\nu\xi)}\right)$$

$$=\frac{\partial\mathcal{L}(B,\rho,\partial\rho,\partial\xi)}{\partial(\partial_\nu\xi)}, \tag{40}$$

and hence $\mathcal{L}$ does not depend on $\partial\xi$ and so the "would-be" Goldstone boson ξ has completely vanished from the model. Effectively it has become the longitudinal component of a now massive gauge boson.

V. SCALE AND CONFORMAL SYMMETRY BREAKING

It has been noted in the literature,[4] see also Ref. 6, that in theories with a spontaneously broken scale and conformal invariance, although five symmetries are broken, only one Goldstone boson appears. A similar thing occurs for broken Lorentz invariance in a class of three dimensional gauge theories as discussed in Ref. 7. In this section we use our more general treatment of Goldstone's theorem to study this question. In particular, we see that our equation predicts only one Goldstone mode, but also imposes four other conditions, not having to do with particle masses, that represent the extra information contained in the spontaneous breakdown of conformal symmetry.

We have in mind a model of the kind considered by Coleman, which contains a scalar and a fermion field, and another scalar, the dilaton, whose role is to implement the broken symmetry. Since we do not consider fermions in this paper, we shall omit them here. Also, we note that the extension of the following discussion to include more than one scalar (but still only one dilaton) is straightforward, but to keep our notation simple we do not put them in explicitly.

Here ϕ_i will be a doublet: $\phi_i=\left[\begin{smallmatrix}\phi\\ \sigma\end{smallmatrix}\right]$, where ϕ is the ordinary scalar field and σ is the dilaton. Under dilations, they transform as

$$\delta\phi=\phi+x^\mu\,\partial_\mu\phi \tag{41}$$

and

$$\delta\sigma=\frac{1}{f}+x^\mu\,\partial_\mu\sigma, \tag{42}$$

where f is a scale characterizing the symmetry breaking. Under special conformal transformations, we have

$$\begin{aligned}\delta^\lambda\phi&=(2x^\lambda x^\rho-g^{\lambda\rho}x^2)\partial_\rho\phi+2x^\lambda\phi,\\ \delta^\lambda\sigma&=(2x^\lambda x^\rho-g^{\lambda\rho}x^2)\partial_\rho\sigma+\frac{2x^\lambda}{f}.\end{aligned} \tag{43}$$

In what follows, we shall assume that translation invariance is not broken. Hence ϕ and σ must be constants. However, one sees that the Δ's will not be constants. We have, in fact,

$$\delta\phi=\phi,\quad \delta\sigma=\frac{1}{f}\quad(\text{dilations}), \tag{44}$$

but

$$\delta^\lambda \phi = 2x^\lambda \phi, \quad \delta^\lambda \sigma = \frac{2x^\lambda}{f} \quad \text{(conformal transfs.)}. \tag{45}$$

Noting further that the spacetime derivatives of the Lagrangian density $\mathcal{L}$ or of its derivatives with respect to the fields will vanish, we obtain from (7),

$$\begin{bmatrix} \frac{\partial^2 \mathcal{L}}{\partial \phi^2} & \frac{\partial^2 \mathcal{L}}{\partial \phi\, \partial \sigma} \\ \frac{\partial^2 \mathcal{L}}{\partial \sigma\, \partial \phi} & \frac{\partial^2 \mathcal{L}}{\partial \sigma^2} \end{bmatrix} \begin{bmatrix} \phi \\ 1/f \end{bmatrix} = 0 \quad \text{(dilations)} \tag{46}$$

and

$$\left(x^\lambda \begin{bmatrix} \frac{\partial^2 \mathcal{L}}{\partial \phi^2} & \frac{\partial^2 \mathcal{L}}{\partial \phi \partial \sigma} \\ \frac{\partial^2 \mathcal{L}}{\partial \sigma\, \partial \phi} & \frac{\partial^2 \mathcal{L}}{\partial \sigma^2} \end{bmatrix} + \begin{bmatrix} 0 & \frac{\partial^2 \mathcal{L}}{\partial \phi \partial(\partial_\lambda \sigma)} - \frac{\partial^2 \mathcal{L}}{\partial \sigma \partial(\partial_\lambda \phi)} \\ \frac{\partial^2 \mathcal{L}}{\partial \sigma \partial(\partial_\lambda \phi)} - \frac{\partial^2 \mathcal{L}}{\partial \phi \partial(\partial_\lambda \sigma)} & 0 \end{bmatrix} \right) \begin{bmatrix} \phi \\ 1/f \end{bmatrix}$$
$$= 0 \quad \text{(conformal transfs.)}. \tag{47}$$

In the second equation, the two terms must separately vanish, because the first is proportional to the variable x^λ and the second is not. But the first term encodes exactly the same information as does Eq. (46). This is the origin of the fact that dilations and special conformal transformations give rise to the same Goldstone boson. There is, however, the second term in (47), which provides an additional set of four constraints:

$$\frac{\partial^2 \mathcal{L}}{\partial \sigma \partial(\partial_\lambda \phi)} = \frac{\partial^2 \mathcal{L}}{\partial \phi \partial(\partial_\lambda \sigma)}. \tag{48}$$

This is, in principle, the ''extra'' information about the Lagrangian (or the effective action, when quantum corrections are considered) that follows from spontaneously broken conformal symmetry.

Let us see how this works at tree level in the specific model considered by Coleman. The Lagrange density is

$$\mathcal{L} = \frac{1}{2} \partial_\mu \phi\, \partial^\mu \phi + \frac{1}{2f^2} \partial_\mu (e^{f\sigma}) \partial^\mu (e^{f\sigma}) - \frac{\mu^2}{2} \phi^2 e^{2f\sigma} - \frac{\lambda}{4!} \phi^4. \tag{49}$$

The equations (46) and (47) imply

$$\begin{bmatrix} 1 + \frac{\lambda}{2\mu^2} \phi^2 e^{-2f\sigma} & 2f\phi \\ 2f\phi & 2f^2\phi^2 \end{bmatrix} \begin{bmatrix} \phi \\ 1/f \end{bmatrix} = 0, \tag{50}$$

which requires $\phi = 0$ and identifies $\left[\begin{smallmatrix} 0 \\ 1/f \end{smallmatrix}\right]$ (i.e., the σ particle) as the Goldstone mode. The extra information furnished in Eq. (47) is trivial in this case, since the relevant terms were set to zero from the beginning.

False vacuum decay: Effective one-loop action for pair creation of domain walls

Óscar J. C. Dias[a] and José P. S. Lemos[b]
CENTRA, Departamento de Física, Instituto Superior Técnico, Av. Rovisco Pais 1, 1096 Lisboa, Portugal

(Received 7 November 2000; accepted for publication 29 March 2001)

An effective one-loop action built from the soliton field itself for the two-dimensional (2D) problem of soliton pair creation is proposed. The action consists of the usual mass term and a kinetic term in which the simple derivative of the soliton field is replaced by a covariant derivative. In this effective action the soliton charge is treated no longer as a topological charge but as a Noether charge. Using this effective one-loop action, the soliton–antisoliton pair production rate $\Gamma/L = A\ \exp[-S_0]$ is calculated and one recovers Stone's exponential factor S_0 and the prefactor A of Kiselev, Selivanov, and Voloshin. The results are also valid straightforwardly to the problem of pair creation rate of domain walls in dimensions $D \geqslant 3$. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1380442]

I. INTRODUCTION

Stone[1] has studied the problem of a scalar field theory in (1+1)D with a metastable vacuum, i.e., with a scalar potential that has a false vacuum, ϕ_+, and a true vacuum, ϕ_-, separated by an energy density difference, ϵ. Stone has noticed that the decay process can be interpreted as the false vacuum decaying into the true vacuum plus a creation of a soliton–antisoliton pair: $\phi_+ \to \phi_- + s + \bar{s}$. The energy necessary for the materialization of the pair comes from the energy density difference between the two vacua. The soliton–antisoliton pair production rate per unit time and length, Γ/L, can then be identified with the decay rate of the false vacuum and is given by ($\hbar = c = 1$):[1]

$$\Gamma/L = A\ e^{-S_0} = Ae^{-\pi m^2/\epsilon}, \tag{1}$$

where m is the soliton mass and prefactor A is a functional determinant whose value was first calculated by Kiselev and Selivanov[2,3] and later by Voloshin.[4] Extensions to this decay problem, such as induced false vacuum decay, have been studied by several authors (for a review and references see, e.g., Refs. 5 and 6).

The method used in Refs. 1–4 is based one the instanton method introduced by Langer in his work about decay of metastable thermodynamical states.[7] This powerful method has been applied to several different studies, namely: Coleman and Callan[8,9] have computed the bubble production rate that accompanies the cosmological phase transitions in a (3+1)D scalar theory (this was indeed previously calculated by other methods by Voloshin, Kobzarev, and Okun[10]); Affleck and Manton[11] have studied monopole pair production in a weak external magnetic field and Affleck, Alvarez, and Manton,[12] have studied e^+e^- boson pair production in a weak external electric field. Recent developments studying pair production of boson and spinorial particles in external Maxwell fields have been performed by several authors using different methods[13–15] and similar results in the Euler–Heisenberg theory, a modified Maxwell theory, have been also obtained.[16] The decay of false vacuum in a condensed matter system providing soliton tunneling has been studied in Refs. 17 and 18.

In this paper we propose an effective one-loop action built from the soliton field itself to study the problem of Stone,[1] Kiselev and Selivanov,[2,3] and Voloshin.[4] The action consists of the usual mass term and a kinetic term in which the simple derivative of the soliton field is replaced by a kind of covariant derivative. In this effective action the soliton charge is treated no longer as a topological charge but as a Noether charge. This procedure of working with an effective action for the soliton field itself has been introduced by Coleman[19] where the equivalence between the Sine–Gordon model and the Thirring model was shown, and by Montonen and Olive[20] who have proposed an equivalent dual field theory for the Prasad–Sommerfield monopole soliton. More connected to our problem, Manton[21] has proposed an effective action built from the soliton field itself which reproduces the soliton physical properties of (1+1)D nonlinear scalar field theories having symmetric potentials with degenerate minima. In this paper we deal instead with a potential with nondegenerate minima in a (1+1)D scalar field theory. Thus, our effective action is new since Manton was not dealing with the soliton pair production process.

Using the effective one-loop action and the method presented in Ref. 12, we calculate the soliton–antisoliton pair production rate, (1). One recovers Stone's exponential factor S_0 (Ref. 1) and the prefactor A of Kiselev and Selivanov[2,3] and Voloshin.[4]

II. EFFECTIVE ONE-LOOP ACTION

In order to present some useful soliton properties let us consider a scalar field theory in a (1+1)D spacetime, whose dynamics is governed by the action (see, e.g., Ref. 22),

$$S[\phi(x,t)]=\int d^2x\left[\frac{1}{2}\partial_\mu\phi\partial^\mu\phi-U(\phi)\right], \tag{2}$$

where U is a generic potential. A particular important case is when U is a symmetric potential, $U=U_s(\phi)$, with two or more degenerate minima. In the ϕ^4 theory the potential is $U_s(\phi)=\frac{1}{4}\lambda(\phi^2-\mu^2/\lambda)^2$, with $\mu\geqslant 0$ and $\lambda\geqslant 0$. Stationarizing the action one obtains the solutions of the theory which have finite and localized energy. The solutions are the soliton

$$\psi\equiv\phi_{\rm sol}=+\frac{\mu}{\sqrt{\lambda}}\tanh\left[\frac{\mu}{\sqrt{2}}\frac{(x-x_0)-vt}{\sqrt{1-v^2}}\right], \tag{3}$$

and the antisoliton $-\psi$. From the Hamiltonian density, $\mathcal{H}=\frac{1}{2}(\partial_x\phi)^2+U_s(\phi)$, one can calculate the mass of the soliton and antisoliton

$$m=\int_{-\infty}^{+\infty}dx\,\mathcal{H}(x)=\frac{2\sqrt{2}}{3}\frac{\mu^3}{\lambda}. \tag{4}$$

One can also define the topological charge, $Q=\frac{1}{2}[\psi(x=+\infty)-\psi(x=-\infty)]$, (conserved in time) which has the positive value $Q_s=+\mu/\sqrt{\lambda}$ in the case of the soliton and the negative value $Q_s^-=-\mu/\sqrt{\lambda}$ in the case of the antisoliton. To this charge one associates the topological current $k^\mu=\frac{1}{2}\varepsilon^{\mu\nu}\partial_\nu\psi$ which is conserved, $\partial_\mu k^\mu=0$, and such that $Q=\int_{-\infty}^{+\infty}dx\,k^0$.

Now, let us consider a nondegenerate potential U in action (2) by adding to U_s a small term that breaks its symmetry:[1,9] $U(\phi)=U_s(\phi)+(\epsilon\sqrt{\lambda}/2\mu)(\phi-\mu/\sqrt{\lambda})$, where ϵ is the energy density (per unit length) difference between the true ($\phi_-=-\mu/\sqrt{\lambda}$) and false ($\phi_+=+\mu/\sqrt{\lambda}$) vacua. As noticed in Refs. 1–3, ϵ is responsible for both the decay of false vacuum and soliton–antisoliton pair creation.

We want to find an effective one-loop action built from the soliton field itself and that describes the above pair creation process. The soliton field should be a charged field since the system admits two charges, Q_s and Q_s^-. Therefore, the action should contain the mass term $m^2\psi\psi^*$, where m is the soliton mass given in Eq. (4), and the kinetic term $(\partial_\mu\psi)(\partial^\mu\psi^*)$. Thus, the free field effective action is $\int d^2x[(\partial_\mu\psi)(\partial^\mu\psi^*)-m^2\psi\psi^*]$. However, if one demands local gauge invariance one has to introduce an "electromagnetic" 2-vector potential A_μ which trans-

forms the common derivative $\partial_\mu\psi$ into a covariant derivative $(\partial_\mu+iQ_sA_\mu)\psi$. As is well known, the field A_μ itself should contribute to the action. This contribution must be gauge invariant since the covariant kinetic term plus the mass term are already gauge invariant. This is achieved by defining the invariant 2-form field, $F_{\mu\nu}=\partial_\mu A_\nu-\partial_\nu A_\mu$. In two dimensions, an antisymmetric field can only be of the form $F_{\mu\nu}=\sigma(t,x)\varepsilon_{\mu\nu}$, where $\varepsilon_{\mu\nu}$ is the Levi-Cevita tensor and $\sigma(t,x)$ is a function. Therefore the effective one-loop action should be $S^{\rm eff}=\int d^2x[(\partial_\nu\psi+iQ_sA_\nu\psi)(\partial^\nu\psi^*-iQ_sA^\nu\psi^*)-m^2\psi\psi^*-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}]$.

Note now that the charged soliton acts also as a source, thus modifying the surrounding field. As a first approximation we shall neglect this effect and assume A_μ fixed by external conditions. This allows us to drop the contribution of the term $F_{\mu\nu}F^{\mu\nu}$ in the effective action. Moreover, the external field responsible for the pair creation is essentially represented by the energy density difference ϵ so we postulate that $F^{\rm ext}_{\mu\nu}=(\epsilon\sqrt{\lambda}/\mu)\,\varepsilon_{\mu\nu}$. Therefore, $A^{\rm ext}_\mu$ is given by $A^{\rm ext}_\mu=\frac{1}{2}(\epsilon\sqrt{\lambda}/\mu)\,\varepsilon_{\mu\nu}x^\nu$.

Finally, if the system is analytically continued to Euclidean spacetime ($t_{\rm min}\to -it_{\rm Euc}$; $A_0\to iA_2$) one obtains the Euclidean effective one-loop action for the soliton pair creation problem

$$S^{\rm eff}_{\rm Euc}=\int d^2x\left[\left|\left(\partial_\mu-\frac{1}{2}\epsilon\,\varepsilon_{\mu\nu}x_\nu\right)\psi\right|^2+m^2|\psi|^2\right]. \tag{5}$$

In the next section this Euclidean effective one-loop action is going to be used to calculate the soliton-antisoliton pair production rate (1). Although the calculations are now similar to those found in Affleck, Alvarez, and Manton pair creation problem,[12] we present some important steps and results since in two dimensions they are slightly different.

III. PAIR PRODUCTION RATE

The soliton–antisoliton pair production rate per unit time is equal to the false vacuum decay rate per unit time

$$\Gamma=-2\ {\rm Im}\,E_0, \tag{6}$$

where the vacuum energy, E_0, is given by the Euclidean functional integral

$$e^{-E_0T}=\lim_{T\to\infty}\int[\mathcal{D}\psi][\mathcal{D}\psi^*]e^{-S^{\rm eff}_{\rm Euc}(\psi;\psi^*)}\ . \tag{7}$$

As it will be verified, E_0 will receive a small imaginary contribution from the negative-mode associated to the quantum fluctuations about the instanton (which stationarizies the action) and this fact is responsible for the decay. Combining (6) and (7) one has

$$\Gamma=\lim_{T\to\infty}\frac{2}{T}{\rm Im}\ln\int[\mathcal{D}\psi][\mathcal{D}\psi^*]e^{-S^{\rm eff}_{\rm Euc}(\psi;\psi^*)}, \tag{8}$$

where $S^{\rm eff}_{\rm Euc}$ is given by (5). Integrating out ψ and ψ^* in (8) one obtains

$$\Gamma=-\lim_{T\to\infty}\frac{2}{T}{\rm Im\,tr}\ln\left[\left(\partial_\mu-\frac{1}{2}\epsilon\,\varepsilon_{\mu\nu}x_\nu\right)^2+m^2\right]. \tag{9}$$

The logarithm in (9) can be written as a "Schwinger proper time integral," $\ln u=-\int_0^\infty(d\mathcal{T}/\mathcal{T})\exp(-\frac{1}{2}u\mathcal{T})$. Taking $u=[(\partial_\mu-\frac{1}{2}\epsilon\,\varepsilon_{\mu\nu}x_\nu)^2+m^2]$, yields

$$\Gamma=\lim_{T\to\infty}\frac{2}{T}{\rm Im}\int_0^\infty\frac{d\mathcal{T}}{\mathcal{T}}e^{-m^2\mathcal{T}/2}\,{\rm tr}\exp\left[-\frac{1}{2}\left(P_\mu-\frac{1}{2}\epsilon\,\varepsilon_{\mu\nu}x_\nu\right)^2\mathcal{T}\right]. \tag{10}$$

Notice that now the trace is of the form $\mathrm{tr}\, e^{-H\mathcal{T}}$, with $H=\frac{1}{2}[P_\mu-\frac{1}{2}\epsilon\ \varepsilon_{\mu\nu}x_\nu]^2$ being the Hamiltonian for a particle subjected to the interaction with the external scalar field in a (2+1)D spacetime, and the proper time playing the role of a time coordinate. One has started with a scalar field theory in a Euclidean 2D spacetime and now one has found an effective theory for particles in a 3D spacetime. It is in this new context that the pair production rate is going to be calculated. The gain in having the trace in the given form is that it can be written as a path integral $\mathrm{tr}\, e^{-H\mathcal{T}}=\int[dx]\exp[-\int d\mathcal{T}L]$, where $L=\frac{1}{2}\dot{x}_\mu\dot{x}_\mu+\frac{1}{2}\epsilon\ \varepsilon_{\mu\nu}x_\nu\dot{x}_\mu$ is the Lagrangian associated with our Hamiltonian. Thus,

$$\Gamma=\lim_{T\to\infty}\frac{2}{T}\,\mathrm{Im}\int_0^\infty\frac{d\mathcal{T}}{\mathcal{T}}e^{-m^2\mathcal{T}/2}\int[dx]\exp\left[-\int_0^{\mathcal{T}}d\mathcal{T}\left(\frac{1}{2}\dot{x}_\mu\dot{x}_\mu+\frac{1}{2}\epsilon\ \varepsilon_{\mu\nu}x_\nu\dot{x}_\mu\right)\right]. \tag{11}$$

Rescaling the proper time variable, $d\mathcal{T}\to d\tau/\mathcal{T}$, and noticing that the path integral is over all the paths, $x_\mu(\tau)$, such that $x_\mu(1)=x_\mu(0)$, one has

$$\Gamma=\lim_{T\to\infty}\frac{2}{T}\,\mathrm{Im}\int[dx]e^{-(\epsilon/2)\oint\varepsilon_{\mu\nu}x_\nu\,dx_\mu}\int_0^\infty\frac{d\mathcal{T}}{\mathcal{T}}\exp\left[-\left(\frac{1}{2}m^2\mathcal{T}+\frac{1}{2\mathcal{T}}\int_0^1 d\tau\,\dot{x}_\mu\dot{x}_\mu\right)\right]. \tag{12}$$

The $\mathcal{T}$ integral can be calculated expanding the function about the stationary point $\mathcal{T}_0^2=\int_0^1 d\tau\,\dot{x}^2/m^2$:

$$\int\frac{d\mathcal{T}}{\mathcal{T}}e^{-f(\mathcal{T})}\sim e^{-f(\mathcal{T}_0)}\frac{1}{\mathcal{T}_0}\sqrt{\frac{\pi}{\frac{1}{2}f''(\mathcal{T}_0)}}\sim e^{-m\sqrt{\int_0^1 d\tau\,\dot{x}^2}}\frac{1}{m}\sqrt{2\pi}\,. \tag{13}$$

Then (12) can be written as

$$\Gamma=\lim_{T\to\infty}\frac{1}{T}\frac{2}{m}\sqrt{2\pi}\,\mathrm{Im}\int[dx]e^{-S_{\mathrm{Euc}}[x_\mu(\tau)]}, \tag{14}$$

where $S_{\mathrm{Euc}}=m\sqrt{\int_0^1 d\tau\dot{x}_\mu\dot{x}_\mu}+\frac{1}{2}\epsilon\oint\varepsilon_{\mu\nu}x_\nu\,dx_\mu$. This integral can be solved using the instanton method. Stationarizing the action, one gets the equation of motion in the (2+1)D spacetime

$$\frac{m\ddot{x}_\mu(\tau')}{\sqrt{\int_0^1 d\tau\dot{x}^2}}=-\epsilon\varepsilon_{\mu\nu}\dot{x}_\nu(\tau')\quad\text{with}\ \ \mu=1,2\ \ \text{and}\ \ \dot{x}_\mu=\frac{dx_\mu}{d\tau}. \tag{15}$$

The instanton, $x_\mu^{\mathrm{cl}}(\tau)$, i.e., the solution of the Euclidean equation of motion that obeys the boundary conditions $x_\mu(\tau=1)=x_\mu(\tau=0)$ is

$$x_\mu^{\mathrm{cl}}(\tau)=R(\cos 2\pi\tau,\sin 2\pi\tau)\quad\text{with}\ \ R=\frac{m}{\epsilon}. \tag{16}$$

The instanton represents a particle describing a loop of radius R in the plane defined by the time x_2 and by the direction x_1. The loop is a thin wall that separates the true vacuum located inside the loop from the false vacuum outside.

The Euclidean action of the instanton is given by $S_0=S_{\mathrm{Euc}}[x_\mu^{\mathrm{cl}}(\tau)]=m2\pi R-\epsilon\pi R^2$. The first term is the rest energy of the particle times the orbital length and the second term represents the interaction of the particle with the external scalar field. The loop radius, $R=m/\epsilon$, stationarizies the instanton action. The action is then $S_0=\pi m^2/\epsilon$.

The second order variation operator is given by

$$M_{\mu\nu}\equiv \left.\frac{\delta^2 S}{\delta x_\nu(\tau')\,\delta x_\mu(\tau)}\right|_{x^{\rm cl}} = \left[-\left(\frac{m\,\delta_{\mu\nu}}{\sqrt{\int_0^1 d\tau \dot{x}^2}}\frac{d^2}{d\tau^2} + \epsilon\ \varepsilon_{\mu\nu}\frac{d}{d\tau}\right)\delta(\tau-\tau') - \frac{m\ddot{x}_\mu(\tau)\ddot{x}_\nu(\tau')}{[\int_0^1 d\tau \dot{x}^2]^{3/2}}\right]_{x^{\rm cl}}$$

$$= -\left[\frac{\epsilon}{2\pi}\delta_{\mu\nu}\frac{d^2}{d\tau^2} + \epsilon\varepsilon_{\mu\nu}\frac{d}{d\tau}\right]\delta(\tau-\tau') - \frac{2\pi\epsilon x_\mu^{\rm cl}(\tau)x_\nu^{\rm cl}(\tau')}{R^2}. \tag{17}$$

The eigenvectors η_μ^n, and the eigenvalues λ_n, associated with the operator $M_{\mu\nu}$ are such that

$$M_{\mu\nu}\ \eta_\nu^n(\tau') = \lambda_n\ \eta_\mu^n(\tau')\ \delta(\tau-\tau'). \tag{18}$$

From this one concludes:

(i) the positive eigenmodes are $(\cos 2n\pi\tau, \sin 2n\pi\tau)$ and $(\sin 2n\pi\tau, -\cos 2n\pi\tau)$ with $\lambda_n = 2\pi\epsilon(n^2-n)$, $n=2,3,4,...$; $(\sin 2n\pi\tau, \cos 2n\pi\tau)$ and $(\cos 2n\pi\tau, -\sin 2n\pi\tau)$ with $\lambda_n = 2\pi\epsilon(n^2+n)$, $n=1,2,3,...$;

(ii) there are two zero-modes associated with the translation of the loop along the x_1 and x_2 directions: $(1,0)$ and $(0,1)$ with $\lambda=0$;

(iii) there is a zero-mode associated with the translation along the proper time, τ: $(\sin 2\pi\tau, -\cos 2\pi\tau) = -\dot{x}_\mu^{\rm cl}/(2\pi R)$ with $\lambda=0$;

(iv) there is a single negative mode associated to the change of the loop radius R: $(\cos 2\pi\tau, \sin 2\pi\tau) = x_\mu^{\rm cl}/R$ with $\lambda_- = -2\pi\epsilon$.

Now, we consider small fluctuations about the instanton, i.e., we do $x_\mu(\tau) = x_\mu^{\rm cl}(\tau) + \eta_\mu(\tau)$. The Euclidean action is expanded to second order so that the path integral (14) can be approximated by

$$\Gamma \simeq \lim_{T\to\infty}\frac{1}{T}\frac{2}{m}\sqrt{\frac{2\pi}{\mathcal{T}_0}}e^{-S_0}\,{\rm Im}\int [d\eta(\tau)]\exp\left[-\frac{1}{2}\int d\tau\, d\tau'\ \eta_\mu(\tau)M_{\mu\nu}\ \eta_\nu(\tau')\right]. \tag{19}$$

The path integral in Eq. (19) is the one-loop factor and is given by $\mathcal{N}(\det M)^{-1/2} = \mathcal{N}\Pi\,(\lambda_n)^{-1/2}$, where λ_n are the eigenvalues of $M_{\mu\nu}$ and $\mathcal{N}$ is a normalization factor that will not be needed. To overcome the problem that arises from having an infinite product of eigenvalues, one compares our system with the free particle system

$$\int [d\eta]\exp\left[-\frac{1}{2}\int d\tau\, d\tau'\ \eta_\mu(\tau)\ M_{\mu\nu}\ \eta_\nu(\tau')\right]$$

$$= \int [d\eta]\exp\left[-\frac{1}{2}\int d\tau\, d\tau'\ \eta_\mu(\tau)\ M^0_{\mu\nu}\ \eta_\nu(\tau')\right]\frac{\Pi\ (\lambda_n)^{-1/2}}{\Pi\ (\lambda_n')^{-1/2}}, \tag{20}$$

where $M^0_{\mu\nu} = -(1/\mathcal{T}_0)\,\delta_{\mu\nu}(d^2/d\tau^2)\,\delta(\tau-\tau')$ is the second variation operator of the free system with eigenvalues $\lambda_n' = 2\pi\epsilon n^2$, $n=0,1,2,3,...$ (each with multiplicity 4). In Eq. (20) the first factor is the path integral of a free particle in a $(2+1)$D Euclidean spacetime

$$\int [d\eta]\exp\left[-\frac{1}{2}\int d\tau\, d\tau'\ \eta_\mu\ M^0_{\mu\nu}\ \eta_\nu\right] = \int [d\eta]\exp\left[-\frac{1}{2\mathcal{T}_0}\int d\tau\ \dot{\eta}_\mu\dot{\eta}_\mu\right] = \frac{1}{2\pi\mathcal{T}_0}. \tag{21}$$

In the productory, one omits the zero eigenvalues, but one has to introduce the normalization factor $(||dx_\mu^{\rm cl}/d\tau||/||\eta_\mu^0||)\sqrt{1/2\pi}=\sqrt{2\pi}R$ which is associated with the proper time eigenvalue. In addition, associated with the negative eigenvalue one has to introduce a factor of 1/2 which accounts for the loops that do expand. The other half contracts (representing the annihilation of recently created pairs) and so does not contribute to the creation rate. So, the one-loop factor becomes

$$\frac{1}{2\pi\mathcal{T}_0}\frac{\Pi\ (\lambda_n)^{-1/2}}{\Pi\ (\lambda_n')^{-1/2}}=\frac{1}{2\pi\mathcal{T}_0}\frac{1}{2}\frac{i}{\sqrt{2\pi\epsilon}}\sqrt{2\pi}R\frac{\Pi_{\lambda>0}\ (\lambda_n)^{-1/2}}{\Pi_{\lambda'>0}\ (\lambda_n')^{-1/2}}=i\frac{1}{2\pi\mathcal{T}_0}\frac{1}{2}\sqrt{2\pi\epsilon}\ \sqrt{2\pi}R\ . \tag{22}$$

Written like this, the one-loop factor accounts only for the contribution of the instanton centered in $(x_1,x_2)=(0,0)$. The translational invariance in the x_1 and x_2 directions requires that one multiplies (22) by the spacetime volume factor $\int dx_2\int dx_1=TL$, which represents the spacetime region where the instanton might be localized. So, the correct one-loop factor is given by

$$\int\ [d\eta(\tau)]\exp\left[-\frac{1}{2}\int d\tau\, d\tau'\ \eta_\mu(\tau)\ M_{\mu\nu}\ \eta_\nu(\tau')\right]=i\frac{LT}{2\pi\mathcal{T}_0}\frac{1}{2}\sqrt{2\pi\epsilon}\ \sqrt{2\pi}R\ . \tag{23}$$

Putting (23) into (19), using $\mathcal{T}_0^2=\int d\tau\,\dot{x}^2/m^2=(2\pi R)^2/m^2$, $R=m/\epsilon$, and $S_0=\pi m^2/\epsilon$, one finally has that the soliton–antisoliton pair production rate per unit time and length is given by

$$\Gamma/L=\frac{\epsilon}{2\pi}e^{-(\pi m^2/\epsilon)}. \tag{24}$$

We have recovered Stone's exponential factor $e^{-\pi m^2/\epsilon}$ (Ref. 1) as well as the prefactor $A=\epsilon/2\pi$ of Kiselev and Selivanov[2,3] and Voloshin.[4]

Note the difference to the 4D problem of Affleck *et al.*[12] and Schwinger,[23] who have found for the factor A the value $(eE)^2/(2\pi)^3$ which is quadratic in eE and not linear, as in our case. This difference has to do with the dimensionality of the problems.

It is well known that a one-particle system in 2D can be transformed straightforwardly to a thin line in 3D and a thin wall in 4D, where now the mass m of the soliton should be interpreted as a line density and surface density, respectively. In fact, a particle in (1+1)D, as well as an infinite line in (2+1)D, can be considered as walls as seen from within the intrinsic space dimension, justifying the use of the name wall for any dimension. Our calculations apply directly to the domain wall pair creation problem in any dimension.

IV. CONCLUSIONS

The equation for the loop of radius R in 2D Euclidean spacetime is given by $x^2+t_E^2=R^2$, where we have put $x=x_1$ and $t_E=x_2$. One can make an analytical continuation of the Euclidean time (t_E) to the Minkowskian time $(t_E=it)$ and obtain the solution in 2D Minkowski spacetime

$$x^2-t^2=R^2. \tag{25}$$

At $t_E=t=0$ the system makes a quantum jump and a soliton–antisoliton pair materializes at $x=\pm R=\pm m/\epsilon$. After the materialization, the soliton and antisoliton are accelerated, driving away from each other, as (25) shows. To check these statements note first that the energy necessary for the materialization of the pair at rest is $E=2m$, where m is the soliton mass. This energy comes from the conversion of false vacuum into true vacuum. Since ϵ is the energy difference per unit length between the two vacua, we conclude that an energy of value $E=2R\epsilon$ is released when this

conversion occurs in the region $(2R)$ within the pair. So, the pair materialization should occur only when R is such that the energy released is equal to the rest energy: $2R\epsilon=2m\Rightarrow R=m/\epsilon$. This value agrees with the one that has been determined in Sec. III.

After the materialization the pair is accelerated so that its energy is now $E=2m/\sqrt{1-v^2}$. Differentiating (25), we get the velocity $v=\sqrt{1-R^2/x^2}$. The energy of the pair is then given by $E=2(m/R)\,|x|=\epsilon\,2|x|$. Notice now that $\epsilon\,2|x|$ is the energy released in the conversion of false vacuum into true vacuum. So, after pair creation, all the energy released in the conversion between the two vacua is used to accelerate the soliton–antisoliton pair.

This discussion agrees with the interpretation of the process as being the false vacuum decaying to the true vacuum plus a creation of a soliton–antisoliton pair. It also justifies the presence of the interaction term $\epsilon\varepsilon_{\mu\nu}x_\nu\psi$ present in the covariant derivative of the proposed effective one-loop action (5), since ϵx is the energy released in the decay and responsible for the creation and acceleration of the pair.

With the proposed effective one-loop action (5) we have recovered Stone's exponential factor S_0 (Ref. 1) of the pair creation rate in (1), and the prefactor A of Kiselev and Selivanov[2,3] and Voloshin.[4] In the proposed effective one-loop action the soliton charge is treated no longer as a topological charge but as a Noether charge. Such an interchange between the topological and the Noether charges was already present in Refs. 19 and 20.

The problem of false vacuum decay coupled to gravity has been introduced in Ref. 24 and recently there has been a renewed interest in it (see, e.g., Refs. 25 and 26). With the proposed effective one-loop action (5) we pretend to further analyze this problem.

Cliffordons

David R. Finkelstein and Andrei A. Galiautdinov[a)]
School of Physics, Georgia Institute of Technology, Atlanta, Georgia 30332-0430

(Received 6 June 2000; accepted for publication 9 April 2001)

At higher energies the present complex quantum theory with its unitary group might expand into a real quantum theory with an orthogonal group, broken by an approximate i operator at lower energies. Implementing this possibility requires a real quantum double-valued statistics. A Clifford statistics, representing a swap (12) by a difference $\gamma_1-\gamma_2$ of Clifford units, is uniquely appropriate. Unlike the Maxwell–Boltzmann, Fermi–Dirac, Bose–Einstein, and para-statistics, which are tensorial and single-valued, and unlike anyons, which are confined to two dimensions, Clifford statistics are multivalued and work for any dimensionality. Nayak and Wilczek such Clifford statistics for the fractional quantum Hall effect. We apply them to toy quanta here. A complex-Clifford example has the energy spectrum of a system of spin-1/2 particles in an external magnetic field. This supports the proposal that the double-valued rotations—spin—seen at current energies might arise from double-valued permutations—swap—to be seen at higher energies. Another toy with real Clifford statistics illustrates how an effective imaginary unit i can arise naturally within a real quantum theory. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1379314]

I. INTRODUCTION: QUANTIFICATION PROCEDURES

Nayak and Wilczek[1] have proposed a startling new statistics for fractional quantum Hall effect carriers. It has great potential for even more fundamental applications to sub-particle structure.[2] To learn its properties we apply it here to some toy models.

The common statistics—Fermi–Dirac (FD), Bose-Einstein (BE), and Maxwell–Boltzmann (MB)—may be regarded as differing prescriptions for constructing the algebra of an ensemble of many individuals from the vector space of one individual. These procedures take qualitative yes-or-no questions about an individual into quantitative how-many questions about an ensemble of similar individuals. Such procedures were termed *quantification*. Now they are sometimes called ''second quantization,'' somewhat misleadingly.

We use a well-known operational formulation of quantum theory. The main point of quantum theory is that mathematical objects may be completely describable, since we make them up, but physical quanta are not. An electron, a physical entity, is not a spinor wave function, a linear operator, or any other mathematical object. But it seems that mathematical objects can usefully represent what we do to an electron. Kets represent input modes (preparation), bras represent outtake modes (registration), operators represent intermediate operations on quantum.[3]

Each of the usual statistics is defined by an associated linear mapping $Q^\dagger$ that maps any one-body initial mode ψ into a many-body creation operator:

$$Q^\dagger: V_I \to \mathcal{A}_S, \quad \psi \mapsto Q^\dagger \psi =: \hat{\psi}. \tag{1}$$

Here V_I is the initial-mode vector space of the individual I and $\mathcal{A}_S = \text{End } V_S$ is the operator (or endomorphism) algebra of the quantified system S. The † in $Q^\dagger$ reminds us that $Q^\dagger$ is contragredient to the initial modes ψ. We write the mapping $Q^\dagger$ to the left of its argument ψ to respect the conventional Dirac order of cogredient and contragredient vectors in a contraction.

a)Electronic mail: gt1570a@prism.gatech.edu

Dually, the final modes $\psi^\dagger$ of the dual space $V_I^\dagger$ are mapped to annihilators in $\mathcal{A}_S$ by the linear operator Q

$$Q: V_I^\dagger \to \mathcal{A}_S, \quad \psi^\dagger \mapsto \psi^\dagger Q =: \hat{\psi}^\dagger. \tag{2}$$

We call the transformation Q the *quantifier* for the statistics. Q and $Q^\dagger$ are tensors of the type

$$Q = (Q^{aB}{}_C), \quad Q^\dagger = (Q^{\dagger C}_{\ \ a\ B}), \tag{3}$$

where a indexes a basis in the one-body space V_I and B,C index a basis in the many-body space V_S.

The basic creators and annihilators associated with an arbitrary basis $\{e_a | a = 1, \ldots, N\} \subset V_I$ and its reciprocal basis $\{e^a |\ a = 1, \ldots, N\} \subset V_I^\dagger$ are then

$$Q^\dagger e_a := \hat{e}_a =: Q^\dagger{}_a \tag{4}$$

and

$$e^a Q := \hat{e}^a =: Q^a. \tag{5}$$

The creator and annihilator for a general initial mode ψ are

$$\begin{aligned} Q^\dagger(e_a \psi^a) &= Q^\dagger{}_a \psi^a, \\ (\phi^\dagger{}_a e^a) Q &= \phi^\dagger{}_a Q^a, \end{aligned} \tag{6}$$

respectively.

We require that quantification respects the adjpoint †. This relates the two tensors Q and $Q^\dagger$

$$\psi^\dagger Q = (Q^\dagger \psi)^\dagger. \tag{7}$$

The rightmost † is the adjoint operation for the quantified system. Therefore,

$$\hat{e}_a^\dagger = M_{ab} \hat{e}^b, \tag{8}$$

with M_{ab} being the metric, the matrix of the adjoint operation, for the individual system.

We now generalize from the common statistics. A *linear statistics* shall be defined by a linear correspondence $Q^\dagger$ called the quantifier

$$Q^\dagger: V_I \to \mathcal{A}_S, \quad \psi \mapsto Q^\dagger \psi =: \hat{\psi}, \tag{9}$$

[compare (1)] from one-body modes to many-body operators, †-algebraically generating the algebra $\mathcal{A}_S := \text{End } V_S$ of the many-body theory. We further require that the quantifier $Q^\dagger$ induce an isomorphism from the one-body unitary group U_I into the many-body unitary group U_S, as described in Sec. IV. This is the *representation principle* for quantifiers.

The representation principle implies bilinear algebraic commutation relations discussed below.

In general $Q^\dagger$ does not produce a creator and Q does not produce an annihilator, as they do in the common statistics.

We construct the quantified algebra $\mathcal{A}_S$ from the individual space V_I in three easy steps:

(1) We form the quantum algebra $\mathcal{A}(V_I)$, defined as the free † algebra generated by (the vectors of) V_I. Its elements are all possible iterated sums and products and †-adjoints of the vectors of V_I. We require that the operations $(+, \times, \dagger)$ of $\mathcal{A}(V_I)$ agree with those of V_I where both are meaningful;
(2) we construct the ideal $\mathcal{R} \subset \mathcal{A}$ of all elements of $\mathcal{A}(V_I)$ that vanish in virtue of the statistics. It is convenient and customary to define $\mathcal{R}$ by a set of expressions **R**, such that the commutation

relations between elements of $\mathcal{A}(V_I)$' have the form $r=0$ with $r\in\mathbf{R}$. Then $\mathcal{R}$ consists of all elements of $\mathcal{A}(V_I)$ that vanish in virtue of the commutation relations and the postulates of a †-algebra.

Let $\mathbf{R}$ be closed under †. Let $\mathcal{R}_0$ be the set of all evaluations of all the expressions in $\mathbf{R}$ when the variable vectors ψ in these expressions assume any values $\psi\in V_I$. Then $\mathcal{R}=\mathcal{A}(V_I)\mathcal{R}_0\,\mathcal{A}(V_I)$;

(3) we form the quotient algebra (actually, a residue algebra)

$$\mathcal{A}_S=\mathcal{A}(V_I)/\mathcal{R}, \tag{10}$$

by identifying elements of $\mathcal{A}(V_I)$ whose differences belong to $\mathcal{R}$.

Then $Q^\dagger$ maps each vector $\psi\in V_I$ into its residue class $\psi+\mathcal{R}$.

Historically, physicists carried out one special quantification first. Since classically one multiplies phase spaces when quantifying, they assumed that quantally one multiplies Hilbert spaces, forming the tensor product

$$V_S=\bigotimes_{p=0}^{N} V_I=V_I^N \tag{11}$$

of N individual spaces V_I. Then in order to improve agreement with experiment they removed degrees of freedom in the tensor product connected with permutations, reducing V_I^N to a subspace PV_I^N invariant under all permutations of individuals. Here P is a projection operator characterizing the statistics. The many-body algebra was then taken to be the algebra of linear operators on the reduced space: $\mathcal{A}_S=\mathrm{End}\ PV_I^N$.

We call a statistics built in that way on a subspace of the tensor algebra over the one-body initial mode space, a *tensorial* statistics. Tensorial statistics represents permutations in a single-valued way. The common statistics are tensorial.

Linear statistics is more general than tensorial statistics, in that the quotient algebra $\mathcal{A}_S=\mathcal{A}-\mathcal{R}$ defining a linear statistics need not be the operator algebra of any subspace of the tensor space $\mathrm{Ten}\,V_I$ and need not be single-valued. Commutation relations permit more general statistics than projection operators do. For example, anyon statistics is linear but not tensorial.

For another example, $\mathcal{A}_S$ may be the endomorphism algebra of a spinor space constructed from the quadratic space V_I. Such a statistics we call a *spinorial statistics*. Clifford statistics, the main topic of this paper, is a spinorial statistics. Linear statistics includes both spinorial and tensorial statistics.

The FD, BE, and MB statistics are readily presented as tensorial statistics. We give their quantifiers next.[3] We then generalize to spinorial, nontensorial, statistics.

II. STANDARD STATISTICS

A. Maxwell–Boltzmann statistics

Classical an MB aggregate is a sequence (up to isomorphism) and $Q=\mathrm{Seq}$, the *sequence*-forming quantifier. The quantum individual I has a Hilbert space $V=V_I$ over the field $\mathbb{C}$. The vector space for the q sequence is the (contravariant) tensor algebra $V_S=\mathrm{Ten}\,V_I$, whose product is the tensor product $\otimes$

$$V_S=\mathrm{Ten}\,V_I, \tag{12}$$

with the natural induced †. The kinematic algebra $\mathcal{A}_S$ of the sequence is the †-algebra of endomorphisms of $\mathrm{Ten}\,V_I$, and is generated by $\psi\in V_I$ subject to the generating relations

$$\hat{\psi}^\dagger\hat{\phi}=\psi^\dagger\phi. \tag{13}$$

The left-hand side is an operator product, and the right-hand side is the contraction of the dual vector $\psi^\dagger$ with the vector ϕ, with an implicit unit element $1 \in \mathcal{A}_S$ as a factor.

B. Fermi–Dirac statistics

Here $Q = \text{Set}$, the *set*-forming quantifier. The kinematic algebra for the quantum set has defining relations

$$\begin{aligned} \hat{\psi}\hat{\phi} + \hat{\phi}\hat{\psi} &= 0, \\ \hat{\psi}^\dagger\hat{\phi} + \hat{\phi}\hat{\psi}^\dagger &= \psi^\dagger\phi. \end{aligned} \tag{14}$$

for all $\psi, \phi \in V_I$.

C. Bose–Einstein statistics

Here $Q = \text{Sib}$, the *sib*-forming quantifier. The sib-generating relations are

$$\begin{aligned} \hat{\psi}\hat{\phi} - \hat{\phi}\hat{\psi} &= 0, \\ \hat{\psi}^\dagger\hat{\phi} - \hat{\phi}\hat{\psi}^\dagger &= \psi^\dagger\phi, \end{aligned} \tag{15}$$

for all $\psi, \phi \in V_I$.

The individuals in each of the discussed quantifications, by construction, have the same (isomorphic) initial spaces. We call such individuals *isomorphic*.

III. RELATION TO THE PERMUTATION GROUP

A statistics is *abelian* if it represents the permutation group S_N on its N individuals by an abelian group of operators in the N-body mode space.

The FD or BE representations are not only abelian but scalar. They represent each permutation by a number, a projective representation of the identity operator. One calls entities with scalar statistics *indistinguishable*. Bosons and fermions are indistinguishable.

Non-abelian statistics describe distinguishable entities.

Nayak and Wilczek[1,4] give a spinorial statistics based on the work on nonabelions of Read and Moore.[5,6] Read and Moore use a subspace corresponding to the degenerate ground mode of some realistic Hamiltonian as the representation space for a nonabelian representation of the permutation group S_{2n} acting on the composite of $2n$ quasiholes in the fractional quantum Hall effect. This statistics, Wilczek showed, represents the permutation group on a spinor space, and permutations by noncommuting spin operators. The quasiholes of Read and Moore and of Wilczek and Nayak are distinguishable, but their permutations leave the ground subspace invariant.

Our own interest in the statistics of distinguishable entitities arises from a study of quantum space–time structure.[2] The dynamical process of any system is composite, it is generally believed, composed of isomorphic elementary actions going on all over, all the time. The first question that has to be answered in setting up an algebraic quantum theory of this composite process is: What statistics do the elementary actions have?

The elementary processes have ordinarily, though implicitly, been assumed to be distinguishable, being addressed by space–time coordinates, and to obey Maxwell–Boltzmann statistics. This repeats the history of particle statistics on the greater field of process statistics.

The Clifford statistics studied below is proposed primarily for the elementary processes of nature. We apply it here to toy models of particles in ordinary space–time to familiarize ourselves with its properties. In our construction, the representation space of the permutation group is the whole (spinor) space of the composite. The permutation group is not assumed to be a symmetry of the Hamiltonian or of its ground subspace any longer. It is used as a dynamical group, not a symmetry group.

IV. NO QUANTIFICATION WITHOUT REPRESENTATION

If we have defined how, for example, one translates individuals, this should define a way to translate the ensemble. We shall require of a quantification that any unitary transformation on an individual quantum entity induces a unitary transformation on the quantified system, defined by the quantifier.

This does not imply that, for example, the actual time-translation of an ensemble is carried out by translating the individuals. This would imply that the Hamiltonians combine additively, without interaction. There is still room for arbitrary interaction. The representation principle means only that there is a well-defined time-translation without interaction. This gives a physical meaning to interaction: it is the difference between the induced time translation generator and the actual one.

Thus we posit that an arbitrary (†-)unitary transformation $U:V_I\to V_I, \psi\mapsto U\psi$ of the individual ket-space V_I, also act naturally on the quantified mode space V_S through an operator $\hat{U}:V_S\to V_S$, defining a representation of the individual unitary group. This is the *representation principle*.

Then U also acts on the algebra $\mathcal{A}_S$ according to

$$\hat{U}:\mathcal{A}_S\to\mathcal{A}_S,\quad \hat{\psi}\mapsto\widehat{U\psi}=\hat{U}\hat{\psi}\hat{U}^{-1}. \tag{16}$$

Every unitary transformation $U:V_I\to V_I$ infinitesimally different from the identity is defined by a *generator* G

$$U=1+G\,\delta\theta, \tag{17}$$

where $G=-G^{\dagger}:V_I\to V_I$ is anti-Hermitian and $\delta\theta$ is an infinitesimal parameter. The infinitesimal anti-Hermitian generators G make up the Lie algebra dU_I of the unitary group U_I of the one-body theory.

By the representation principle, each individual generator G induces a *quantified generator* $\hat{G}\in\mathcal{A}_S$ of the quantified system, defined (up to an added constant) by its adjoint action on $\mathcal{A}_S$

$$\hat{G}:\hat{\psi}\mapsto\widehat{G\psi}=[\hat{G},\hat{\psi}], \tag{18}$$

and (18) and (20) define a representation (Lie homomorphism) $R_Q:dU_I\to dU_S$ of the individual Lie algebra dU_I in the quantified Lie algebra dU_S.

Since

$$G=\sum_{a,b} e_a G^a{}_b e^b, \tag{19}$$

holds by the completeness of the basis e_a and the reciprocal basis e^a, we can express the quantified generator $\hat{G}$ by

$$\hat{G}:=Q^{\dagger}GQ=\sum_{a,b} Q^{\dagger}{}_a G^a{}_b Q^b\equiv\sum_{a,b}\hat{e}_a G^a{}_b\hat{e}^b. \tag{20}$$

The representation principle holds for the usual statistics (MB, FD, BE) and for the Clifford statistics discussed below.

Proposition: If Q is a quantifier for a linear statistics then

$$[\hat{G},Q^{\dagger}\psi]=GQ^{\dagger}\psi, \tag{21}$$

hold for all anti-Hermitian generators G.

Proof: We have

$$
\begin{aligned}
[\hat{G}, Q^\dagger \psi] &= G^a{}_b\,(\hat{e}_a\,\hat{e}^b\,Q^\dagger\psi - Q^\dagger\psi\,\hat{e}_a\,\hat{e}^b) \\
&= G^a{}_b\,(\hat{e}_a\,(e^b\psi + (-1)^\kappa\,Q^\dagger\psi\,\hat{e}^b) - Q^\dagger\psi\,\hat{e}_a\,\hat{e}^b) \\
&= G^a{}_b\,\hat{e}_a\,e^b\psi = G^a{}_b\,\hat{e}_a\,\psi^b = G\,Q^\dagger\psi. \qquad (22)
\end{aligned}
$$

Here $\kappa = 1$ for Fermi statistics and 0 for Bose.

If $\mathcal{A}$ is any algebra, by the *commutator algebra* $\Delta\mathcal{A}$ of $\mathcal{A}$ we mean the Lie algebra on the elements of $\mathcal{A}$ whose product is the commutator $[a,b] = ab - ba$ in $\mathcal{A}$. By the commutator algebra of a quantum system I we mean that of its operator algebra $\mathcal{A}_I$.

In the usual cases of Bose and Fermi statistics, and not in the cases of complex and real Clifford statistics discussed below, the quantification rule (20) defines a Lie isomorphism, $\Delta\mathcal{A}_I \to \Delta\mathcal{A}_S$, from the commutator algebra of the individual to that of the quantified system. Namely, if H and P are two (arbitrary) operators acting on the one-body ket-space, then

$$
\widehat{[H, P]} = [\hat{H}, \hat{P}]. \qquad (23)
$$

Explicitly

$$
\begin{aligned}
[\hat{H}, \hat{P}] &= \hat{H}\hat{P} - \hat{P}\hat{H} \\
&= \hat{e}_r H^r{}_s \hat{e}^s \hat{e}_t P^t{}_u \hat{e}^u - \hat{e}_t P^t{}_u \hat{e}^u \hat{e}_r H^r{}_s \hat{e}^s \\
&= H^r{}_s P^t{}_u (\hat{e}_r \hat{e}^s \hat{e}_t \hat{e}^u - \hat{e}_t \hat{e}^u \hat{e}_r \hat{e}^s) \\
&= H^r{}_s P^t{}_u (\hat{e}_r (\delta^s_t \pm \hat{e}_t \hat{e}^s) \hat{e}^u - \hat{e}_t \hat{e}^u \hat{e}_r \hat{e}^s) \\
&= H^r{}_s P^t{}_u (\hat{e}_r \delta^s_t \hat{e}^u \pm \hat{e}_r \hat{e}_t \hat{e}^s \hat{e}^u - \hat{e}_t \hat{e}^u \hat{e}_r \hat{e}^s) \\
&= H^r{}_s P^t{}_u (\hat{e}_r \delta^s_t \hat{e}^u \pm \hat{e}_t \hat{e}_r \hat{e}^u \hat{e}^s - \hat{e}_t \hat{e}^u \hat{e}_r \hat{e}^s) \\
&= H^r{}_s P^t{}_u (\hat{e}_r \delta^s_t \hat{e}^u \pm \hat{e}_t (\mp \delta^u_r \pm \hat{e}^u \hat{e}_r) \hat{e}^s - \hat{e}_t \hat{e}^u \hat{e}_r \hat{e}^s) \\
&= H^r{}_s P^t{}_u (\hat{e}_r \delta^s_t \hat{e}^u - \hat{e}_t \delta^u_r \hat{e}^s) \\
&= \hat{e}_r (H^r{}_t P^t{}_u - P^r{}_t H^t{}_u) \hat{e}^u \\
&= \widehat{[H, P]}. \qquad (24)
\end{aligned}
$$

This implies that for BE and FD statistics, the quantification rule (20) can be extended from the unitary operators and their anti-Hermitian generators to the whole operator algebra of the quantified system.

V. CLIFFORD QUANTIFICATION

Now let the one-body mode space $V_I = \mathbb{R}^{N_+,N_-} = N_+\mathbb{R} \oplus N_-\mathbb{R}$ be a real quadratic space of dimension $N = N_+ + N_-$ and signature $N_+ - N_-$. Denote the symmetric metric form of V_I by $g = (g_{ab}) := (e_a^\dagger e_b)$. We do not assume that g is positive-definite.

We define *Clifford quantification* (9) by:

(1) the Clifford-like generating relations

$$
\hat{\psi}\hat{\phi} + \hat{\phi}\hat{\psi} = \frac{\zeta}{2}\,\psi^\dagger\phi, \qquad (25)
$$

for all $\phi, \psi \in V_I$, where ζ is a $\pm$ sign that can have either value;

(2) the Hermiticity condition (7)

$$
\hat{e}_a^\dagger = g_{ab}\hat{e}^b, \qquad (26)
$$

(3) a rule for raising and lowering indices

$$
\hat{e}_a := \zeta'\,g_{ab}\hat{e}^b, \qquad (27)
$$

where ζ' is another $\pm$ sign, and

(4) the definition (20) to quantify one-body generators.

Here $\zeta=\pm 1$ covers the two different conventions used in the literature. In Sec. VI we will see that $\zeta=\zeta'$, and that $\zeta=\zeta'=+1$ and $\zeta=\zeta'=-1$ are both allowed physically at the present theoretical stage of development. They lead to two different real quantifications, with either Hermitian or anti-Hermitian Clifford units.

For the quantified basis elements of V_I (25) leads to

$$\hat{e}_a\hat{e}_b+\hat{e}_b\hat{e}_a=\frac{\zeta}{2}g_{ab}\,. \tag{28}$$

The ψ's, which are assigned grade 1 and taken to be either Hermitian or anti-Hermitian, generate a graded †-algebra that we call the *free Clifford †-algebra* associated with $\mathbb{R}^{N_+,N_-}$ and write as $\mathrm{Cliff}(N_+,N_-)\equiv\mathrm{Cliff}(N_\pm)$. $\mathrm{Cliff}(N_\pm)$ contains a double-valued (or projective) representation of the permutation group S_N.

We call quanta obeying Clifford statistics *cliffordons*. Clifford statistics assembles cliffordons individually described by vectors into a composite described by spinors, which we call a *squadron*. We intend the -on suffix to remind us that unlike the common statistics the Clifford statistics has no classical correspondent.

A cliffordon is a hypothetical quantum-physical entity, like an electron, not to be confused with a mathematical object like a spinor or an operator. We cannot describe a cliffordon completely, but we represent our actions on a squadron of cliffordons adequately by operators in a Clifford algebra of operators. One encounters cliffordons only in permuting them, never in creating or annihilating them as individuals.

In assuming a real vector space of quantum modes instead of a complex one, we give up i-invariance but retain quantum superposition $a\psi+b\phi$ with real coefficients. Our theory is nonlinear from the complex point of view. Others considered nonlinear quantum theories, but gave up real superposition as well as i-invariance.[7,8] We are not *that* nonlinear.

VI. QUANTIFYING OBSERVABLES

In the usual statistics, the quantifier Q can be usefully extended from the Lie algebra of the individual to the commutator algebra of the individual; that is, from anti-Hermitian operators to all operators. This is not the case for Clifford quantification. There the quantification of any symmetric operator is a scalar, in virtue of Clifford's law, and so the commutator of any two operators is just the commutator of their antisymmetric parts. A straightforward calculation shows that

$$[\hat{H},\hat{P}]=\hat{H}\hat{P}-\hat{P}\hat{H}=\zeta\,\zeta'(\tfrac{1}{2}[\widehat{H,P}]+\tfrac{1}{4}([\widehat{P,H^\dagger}]+[\widehat{P^\dagger,H}])). \tag{29}$$

The three simplest cases are:

(1) $H=H^\dagger,\ H'=H'^\dagger\Rightarrow[\hat{H},\hat{H}']=0$;
(2) $H=H^\dagger,\ G_1=-G_1^\dagger\Rightarrow[\hat{H},\hat{G}_1]=0$;
(3) $G=-G^\dagger,\ G'=-G'^\dagger\Rightarrow[\hat{G},\hat{G}']=\zeta\,\zeta'\,[\widehat{G,G'}]$.

Thus Clifford quantification respects the commutation relations for anti-Hermitian generators if and only if $\zeta=\zeta'=+1$ or $\zeta=\zeta'=-1$; but not for Hermitian observables, contrary to the Bose and Fermi quantifications, which respect both.

VII. NAYAK–WILCZEK STATISTICS

The *complex* graded algebra generated by the ψ's with the relations (25) is called the *complex Clifford algebra* $\mathrm{Cliff}_{\mathbb{C}}(N)$ over $\mathbb{R}^{N_+,N_-}$. It is isomorphic to the full complex matrix algebra $\mathbb{C}(2^n)\otimes\mathbb{C}(2^n)$ for even $N=2n$, and to the direct sum $\mathbb{C}(2^n)\otimes\mathbb{C}(2^n)\oplus\mathbb{C}(2^n)\otimes\mathbb{C}(2^n)$ for odd $N=2n+1$. We regard $\mathrm{Cliff}_{\mathbb{C}}(N)$ as the kinematic algebra of the complex Clifford composite. As a vector space, it has dimension 2^N.

Schur[9] used complex spinors and complex Clifford algebra to represent permutations some years before Cartan used them to represent rotations. There is a fairly widespread view that spinors may be more fundamental than vectors, since vectors may be expressed as bilinear combinations of spinors. One of us took this direction in much of his work. Clifford statistics support the opposite view. There a vector describes an individual, a spinor an aggregate. Wilczek and Zee[10] seem to have been the first to recognize that spinors represent composites in a physical context, although this is implicit in the Chevalley construction of spinors within a Grassmann algebra.

For dimension $N=3$ spinors have as many parameters as vectors, but for higher N the number of components of the spinors associated with Cliff$(N_\pm)$ grows exponentially with N. The physical relevance of this irreducible double-valued (or projective) representation of the permutation group S_N was recognized by Nayak and Wilczek[1,4] in a theory of the fractional quantum Hall effect. We call the complex statistics based on Cliff$_{\mathbb{C}}(N)$ the *Nayak–Wilczek* or NW statistics.

Clifford statistics, unlike the more familiar particle statistics,[11–13] provides no creators or annihilators. With each individual mode e_a of the quantified system they associate a Clifford unit $\gamma_a = 2Q^\dagger{}_a$.

We may represent any swap (transposition of two cliffordons, say 1 and 2) by the difference of the corresponding Clifford units

$$t_{12} := \frac{1}{\sqrt{2}}(\gamma_1 - \gamma_2), \tag{30}$$

and represent an arbitrary permutation, which is a product of elementary swaps, by the product of their representations. That is, as direct computation shows, this defines a projective homomorphism from S_N into the Clifford algebra generated by the γ_k.

By definition, the number N of cliffordons in a squadron is the dimensionality of the individual initial mode space V_I. N is conserved rather trivially, commuting with every Clifford element. We can change this number only by varying the dimensionality of the one-body space. In one use of the theory, we can do this, for example, by changing the space–time four-volume of the corresponding experimental region. Because our theory does not use creation and annihilation operators, an initial action on the squadron represented by a spinor ξ should be viewed as some kind of spontaneous transition condensation into a coherent mode, analogous to the transition from the superconducting to the many-vertex mode in a type-II superconductor. The initial mode of a set or sib of (FD or BE) quanta can be regarded as a result of possibly entangled creation operations. That of a squadron of cliffordons cannot.

As with (22), let us verify that definition (20) is consistent in the Clifford case:

$$[\hat{G}, Q^\dagger\psi] = G^a{}_b(\hat{e}_a \hat{e}^b Q^\dagger\psi - Q^\dagger\psi \hat{e}_a \hat{e}^b) = \tfrac{1}{2} G^a{}_b(\hat{e}_a \psi^b + \psi_a \hat{e}^b) = G\, Q^\dagger\psi. \tag{31}$$

This shows that $Q^\dagger\psi$ transforms correctly under the infinitesimal unitary transformation of $\mathbb{R}^{N_+,N_-}$ (cf. Ref. 14).

VIII. BREAKING *i* INVARIANCE

Thus we cannot construct useful Hermitian variables of a squadron by applying the quantifier to the Hermitian variables of the individual cliffordon.

This is closely related to fact that the real initial mode space $\mathbb{R}^{N_\pm}$ of a cliffordon has no special operator to replace the imaginary unit i of the standard complex quantum theory. The fundamental task of the imaginary element i in the algebra of complex quantum physics is precisely to relate conserved Hermitian observables H and anti-Hermitian generators G by

$$H = -i\hbar G. \tag{32}$$

To perform this function exactly, the operator i must commute exactly with all observables.

The central operators x and p of classical mechanics are contractions of noncentral operators $\check{x}$ and $\check{p}=-i\hbar\partial/\partial\check{x}$.[2] In the limit of large numbers of individuals organized coherently into suitable condensate modes, the expanded operators of the quantum theory contract into the central operators of the classical theory. Condensations produce nearly commutative variables.

Likewise we expect the central operator i to be a contraction of a noncentral operator $\check{\imath}$ similarly resulting from a condensation in a limit of large numbers. In the simpler expanded theory, $\check{\imath}$, the correspondent of i, is not central.

One clue to the nature of $\check{\imath}$ and the locus of its condensation is how the operator i behaves when we combine separate systems. Since infinitesimal generators $G,G',\ldots$ combine by addition, the imaginaries $i,i',\ldots$ of different individuals must combine by identification

$$i=i'=\cdots, \tag{33}$$

for (32) to hold exactly, and nearly so for (32) to hold nearly. The only other variables in present physics that combine by identification in this way are the time t of clasical mechanics and the space–time coordinates x^μ of field theories. All systems in an ensemble must have about the same i, just as all particles have about the same t in the usual instant-based formulation, and all fields have about the same space–time variables x^μ in field theory. We identify the variables t and x^μ for different systems because they are set by the experimenter, not the system. This suggests that the experimenter, or more generally the environment of the system, mainly defines the operator i. The central operators x,p characterize a small system that results from the condensation of many particles. The central operator i must result from a condensation in the environment; we take this to be the same condensation that forms the vacuum and the spatiotemporal structure represented by the variables x^μ of the standard model.

The existence of this contracted i ensures that at least approximately, every Lie commutation relation between dimensionless anti-Hermitian generators A,B,C of the standard complex quantum theory

$$[A,B]=C, \tag{34}$$

corresponds to a commutation relation between Hermitian variables $-i\hbar A,\ -i\hbar B,\ -i\hbar C$

$$[-i\hbar A,-i\hbar B]=-i\hbar(-i\hbar C). \tag{35}$$

It also tells us that this correspondence is not exact in nature.

Stückelberg[15] reformulated complex quantum mechanics in the real Hilbert space $\mathbb{R}^{2N}$ of twice as many dimensions by assuming a special real antisymmetric operator $J:\mathbb{R}^{2N}\to\mathbb{R}^{2N}$ commuting with all of the variables of the system.

A real † or Hilbert space has no such operator. For example, in $\mathbb{R}^2$ the operator

$$E:=\begin{bmatrix}\varepsilon_1 & 0\\ 0 & \varepsilon_2\end{bmatrix}, \tag{36}$$

is a symmetric operator with an obvious spectral decomposition representing, according to the usual interpretation, two selection operations performed on the system, and cannot be written in the form $G=-(J/\hbar)E$ relating it to some antisymmetric generator G for any real antisymmetric J commuting with E.

On the other hand, if we restrict ourselves to observable operators of the form

$$E':=\begin{bmatrix}\varepsilon & 0\\ 0 & \varepsilon\end{bmatrix}, \tag{37}$$

we can use the operator J

$$J := \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \tag{38}$$

to restore the usual connection between symmetry transformations and corresponding observables. This restriction can be generalized to any even number of dimensions.[15]

IX. BREAKDOWN OF THE EXPECTATION VALUE FORMULA

For a system described in terms of a general real Hilbert space there is no simple relation of the form $G=(i/\hbar)H$ between the symmetry generators and the observables: the usual notions of Hamiltonian and momentum are meaningless in that case. This amplifies our earlier observation that Clifford quantification $A\rightarrow\hat{A}$ respects the Lie commutation relations among anti-Hermitian generators, not Hermitian observables.

Operationally, this means that selective acts of individual and quantified cliffordons use essentially different sets of filters. This is not the case for complex quantum mechanics and the usual statistics. There some important filters for the composite are simply assemblies of filters for the individuals.

Again, in the complex case the expectation value formula for an assembly

$$Av\,X = \psi^\dagger X \psi / \psi^\dagger \psi, \tag{39}$$

is a consequence of the eigenvalue principle for individuals, rather than an independent assumption.[3,16] The argument presented in Refs. 3 and 16 assumes that the individuals over which the average is taken combine with Maxwell–Boltzmann statistics. For highly excited systems this is a good approximation even if the individuals have FD or BE or other tensorial statistics. It is not necessarily a good approximation for cliffordons, which have spinorial, not tensorial, statistics.

X. SPIN-1/2 COMPLEX CLIFFORD MODEL

In this section we present a simplest possible model of a complex Clifford composite. The resulting many-body energy spectrum is isomorphic to that of a sequence of spin-1/2 particles in an external magnetic field.

Recall that in the usual complex quantum theory the Hamiltonian is related to the infinitesimal time-translation generator $G=-G^\dagger$ by $G=iH$. Quantifying H gives the many-body Hamiltonian. In the framework of spinorial statistics, as discussed above, this does not work, and quantification in principle applies to the anti-Hermitian time-translation generator G, not to the Hermitian operator H. Our task now is to choose a particular generator and to study its quantified properties.

We assume an even-dimensional real initial-mode space $V_I=\mathbb{R}^{2n}$ for the quantum individual, and consider the dynamics with the simplest non-trivial time-translation generator

$$G := \varepsilon \begin{bmatrix} \mathbf{0}_n & \mathbf{1}_n \\ -\mathbf{1}_n & \mathbf{0}_n \end{bmatrix}, \tag{40}$$

where ε is a constant energy coefficient.

The quantified time-translation generator $\hat{G}$ then has the form

$$\begin{aligned} \hat{G} &:= \sum_{l,j}^{N} \hat{e}_l G^l{}_j \hat{e}^j = -\varepsilon \sum_{k=1}^{n} (\hat{e}_{k+n}\hat{e}^k - \hat{e}_k \hat{e}^{k+n}) \\ &= +\varepsilon \sum_{k=1}^{n} (\hat{e}_{k+n}\hat{e}_k - \hat{e}_k \hat{e}_{k+n}) \\ &= 2\varepsilon \sum_{k=1}^{n} \hat{e}_{k+n}\hat{e}_k \\ &\equiv \frac{1}{2}\varepsilon \sum_{k=1}^{n} \gamma_{k+n}\gamma_k . \end{aligned} \tag{41}$$

By Stone's theorem, the generator $\hat{G}$ of time translation in the spinor space of the complex Clifford composite of $N=2n$ individuals can be factored into a Hermitian $H^{(N)}$ and an imaginary unit i that commutes strongly with $H^{(N)}$

$$\hat{G}=iH^{(N)}. \tag{42}$$

We suppose that $H^{(N)}$ corresponds to the Hamiltonian and seek its spectrum.

We note that by (41), $\hat{G}$ is a sum of n commuting anti-Hermitian algebraically independent operators $\gamma_{k+n}\gamma_k, k=1,2,\ldots,n$, $(\gamma_{k+n}\gamma_k)^\dagger=-\gamma_{k+n}\gamma_k$, $(\gamma_{k+n}\gamma_k)^2=-1^{(N)}$.

We use the well-known $2^n\times 2^n$ complex matrix representation of the γ-matrices of the complex universal Clifford algebra associated with the real quadratic space $\mathbb{R}^{2n}$ (Brauer and Weyl[17]):

$$\begin{aligned}\gamma_{2j-1}&=\sigma_3\otimes\cdots\otimes\sigma_3\otimes\sigma_1\otimes\mathbf{1}\otimes\cdots\otimes\mathbf{1},\\ \gamma_{2j}&=\sigma_3\otimes\cdots\otimes\sigma_3\otimes\sigma_2\otimes\mathbf{1}\otimes\cdots\otimes\mathbf{1},\\ j&=1,2,3,\ldots,n,\end{aligned} \tag{43}$$

where σ_1, σ_2 occur in the jth position, the product involves n factors, and σ_1, σ_2, σ_3 are the Pauli matrices. The representation of the corresponding permutation group S_{2n} is reducible. We can simultaneously diagonalize the $2^n\times 2^n$ matrices representing the commuting operators $\gamma_{k+n}\gamma_k$, and use their eigenvalues, $\pm i$, to find the spectrum λ of $\hat{G}$, and consequently of $H^{(N)}$.

A simple calculation shows that the spectrum of $\hat{G}$ consists of the eigenvalues

$$\lambda_k=\tfrac{1}{2}\varepsilon(n-2k)i, \quad k=0,1,2,\ldots,n, \tag{44}$$

with multiplicity

$$\mu_k=C_k^n:=\frac{n!}{k!(n-k)!}. \tag{45}$$

The spectrum of eigenvalues of the Hamiltonian $H^{(N)}$ then consists of $n+1$ energy levels

$$E_k=\tfrac{1}{2}(n-2k)\varepsilon, \tag{46}$$

with degeneracy μ_k. Thus E_k ranges over the interval

$$-\tfrac{1}{4}N\varepsilon<E<\tfrac{1}{4}N\varepsilon, \tag{47}$$

in steps of ε, with the given degeneracies.

Thus the spectrum of the structureless N-body complex Clifford composite is the same as that of a system of N spin-1/2 Maxwell–Boltzmann particles of magnetic moment μ in a magnetic field $\mathbf{H}$, with the identification

$$\tfrac{1}{4}\varepsilon=\mu H. \tag{48}$$

Even though we started with such a simple one-body time-translation generator as (40), the spectrum of the resulting many-body Hamiltonian possesses some complexity, reflecting the fact that the units in the composite are distinguishable, and their swaps generate the dynamical variables of the system.

This spin-1/2 model does not tell us how to swap two Clifford units experimentally. Like the phonon model of the harmonic oscillator, the statistics of the individual quanta enters the picture only through the commutation relations among the fundamental operators of the theory.

XI. REAL CLIFFORD STATISTICS

Real Clifford quantification establishes a morphism (20) from the Lie algebra of the individual into that of the composite. The proof for real Clifford statistics parallels that for the complex Clifford case closely.

According to the Periodic Table of the Spinors,[18,19–21] the free (or universal) Clifford algebra $\mathrm{Cliff}_{\mathbb{R}}(N_+,N_-)$ is algebra-isomorphic to the endomorphism algebra of a module $\Sigma(N_+,N_-)$ over a ring $\mathcal{R}(N_+,N_-)$. We give the table to simplify reference to it (here $\zeta=-1$):

N_+ \ N_-	0	1	2	3	4	5	6	7	...
0	$\mathbb{R}$	$\mathbb{R}_2$	$2\mathbb{R}$	$2\mathbb{C}$	$2\mathbb{H}$	$2\mathbb{H}_2$	$4\mathbb{H}$	$8\mathbb{C}$	...
1	$\mathbb{C}$	$2\mathbb{R}$	$2\mathbb{R}_2$	$4\mathbb{R}$	$4\mathbb{C}$	$4\mathbb{H}$	$4\mathbb{H}_2$	$8\mathbb{H}$	...
2	$\mathbb{H}$	$\mathbb{C}_2$	$4\mathbb{R}$	$4\mathbb{R}_2$	$8\mathbb{R}$	$8\mathbb{C}$	$8\mathbb{H}$	$8\mathbb{H}_2$	...
3	$\mathbb{H}_2$	$2\mathbb{H}$	$4\mathbb{C}$	$8\mathbb{R}$	$8\mathbb{R}_2$	$16\mathbb{R}$	$16\mathbb{C}$	$16\mathbb{H}$	...
4	$2\mathbb{H}$	$2\mathbb{H}_2$	$4\mathbb{H}$	$8\mathbb{C}$	$16\mathbb{R}$	$16\mathbb{R}_2$	$32\mathbb{R}$	$32\mathbb{C}$	...
5	$4\mathbb{C}$	$4\mathbb{H}$	$4\mathbb{H}_2$	$8\mathbb{H}$	$16\mathbb{C}$	$32\mathbb{R}$	$32\mathbb{R}_2$	$64\mathbb{R}$	...
6	$8\mathbb{R}$	$8\mathbb{C}$	$8\mathbb{H}$	$8\mathbb{H}_2$	$16\mathbb{H}$	$32\mathbb{C}$	$64\mathbb{R}$	$64\mathbb{R}_2$	...
7	$8\mathbb{R}_2$	$16\mathbb{R}$	$16\mathbb{C}$	$16\mathbb{H}$	$16\mathbb{H}_2$	$32\mathbb{H}$	$64\mathbb{C}$	$128\mathbb{R}$	...
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	

(49)

It shows that the ring of coefficients $\mathcal{R}(N_+,N_-)$ varies periodically with period 8 in each of the dimensionalities N_+ and N_- of V_I, and is a function of signature N_+-N_- alone. In the first cycle, $N_+-N_-=0,1,\ldots,7$, and $\mathcal{R}=\mathbb{R},\mathbb{C},\mathbb{H},\mathbb{H}\oplus\mathbb{H},\mathbb{H},\mathbb{C},\mathbb{R},\mathbb{R}\oplus\mathbb{R}$, respectively. Then the cycle repeats ad infinitum.

In our application the module $\Sigma(N_+,N_-)$, the spinor space supporting $\mathrm{Cliff}_{\mathbb{R}}(N_+,N_-)$, serves as the initial mode space of a squadron of N real cliffordons. $\mathcal{R}(N_\pm)$ we call the *spinor coefficient ring* for $\mathrm{Cliff}_{\mathbb{R}}(N_+,N_-)$.

XII. PERMUTATIONS

In the standard statistics there is a natural way to represent permutations of individuals in the N-body composite. Each N-body ket is constructed by successive action of N creation operators on the special vacuum mode. Any permutation of individuals can be achieved by permuting these creation operators in the product. The identity and alternative representations of the permutation group S_N in the BE and FD cases then follow from the defining relations of Sec. II.

In the case of Clifford statistics, some things are different. There is still an operator associated with each cliffordon; now it is a Clifford unit. Permutations of cliffordons are still represented by operators on a many-body † space. But the mode space on which these operators act is now a spinor space, and its basis vectors are not constructed by creation operators acting on a special ''vacuum'' ket.

The Clifford representation of the permutation group that we have employed is reducible into two irreducible Schur representations. It is a bit easier to write than Schur's because our individual operators γ_i anticommute exactly, corresponding to exactly orthogonal directions in the one-body mode space, like the generators of Dirac's Clifford algebra. In Schur's irreducible representation (slightly simplified) these operators are replaced by their projections normal to the principle diagonal direction $n:=\Sigma\gamma_i/\sqrt{N}$, which is invariant under all permutations. The corresponding angles are those subtended by the edges of a regular simplex of N vertices in $N-1$ dimensions as seen from the center. These angles are all determined by

$$\cos^2\theta = \frac{1}{N-1}. \tag{50}$$

They differ from $\pi/2$ by an angle that vanishes for large N like $1/N$.

XIII. EMERGENCE OF A QUANTUM *i*

The Periodic Table of the Spinors (Sec. XI) suggests another origin for the complex i of quantum theory, and one that is not approximately central but exactly central. Some Clifford algebras $\mathrm{Cliff}_{\mathbb{R}}(N_+,N_-)$ have the spinor coefficient ring $\mathbb{C}$, containing an element i. Multiplication by this i then represents an operator in the center of the Clifford algebra, which we designate also by i. We may use i-multiplication to represent the top element $\gamma^{\uparrow}$ whenever $\gamma^{\uparrow}$ is central and has square -1. This $i \in \mathrm{Cliff}_{\mathbb{R}}(N_{\pm})$ corresponds to the i of complex quantum theory.

$\mathrm{Cliff}_{\mathbb{R}}(1,0)$ contains such an i but is commutative. According to the Periodic Table (with the choice of $\zeta=-1$), the smallest noncommmutative Clifford algebras of Euclidean signature with complex spinor coefficients are $\mathrm{Cliff}_{\mathbb{R}}(0,3)$ with negative Euclidean signature, and $\mathrm{Cliff}_{\mathbb{R}}(5,0)$ with positive Euclidean signature. Triads or pentads of such cliffordons could underlie the physical ''elementary'' particles, giving rise to complex quantum mechanics within the real. We consider these two cases in turn.

$\mathrm{Cliff}_{\mathbb{R}}(0,3)=\mathbb{C}(2)$ has the familiar Pauli representation $\gamma_1 := i\sigma_1$, $\gamma_2 := i\sigma_2$, $\gamma_3 := i\sigma_3$ with $\zeta=-1$. We choose a particular one-cliffordon dynamics of the form

$$G := \begin{bmatrix} 0 & V & 0 \\ -V & 0 & \varepsilon \\ 0 & -\varepsilon & 0 \end{bmatrix}. \tag{51}$$

Quantification (20) of G gives

$$\hat{G} = iH^{(-3)} \tag{52}$$

with the Hamiltonian

$$H^{(-3)} = \frac{1}{2}\begin{bmatrix} V & \varepsilon \\ \varepsilon & -V \end{bmatrix}. \tag{53}$$

This is also the Hamiltonian for a generic two-level quantum-mechanical system (with the energy separation ε) in an external potential field V, like the ammonia molecule in a static electric field discussed in Ref. 22.

$\mathrm{Cliff}_{\mathbb{R}}(5,0)=\mathbb{C}(4)$ has the matrix representation $\gamma_1 := i\sigma_1\otimes\mathbf{1}$, $\gamma_2 := i\sigma_2\otimes\mathbf{1}$, $\gamma_3 := i\sigma_3\otimes\sigma_1$, $\gamma_4 := i\sigma_3\otimes\sigma_2$, $\gamma_5 := i\sigma_3\otimes\sigma_3$, again with $\zeta=-1$. Its top Clifford unit is $\gamma^{\uparrow} := \Pi_k\gamma_k = \gamma^{\uparrow\dagger} = \gamma^{\uparrow -1}$ with eigenvalues ± 1. We choose a specimen dynamics (for the individual cliffordon) in the form

$$G := \begin{bmatrix} 0 & V & 0 & 0 & 0 \\ -V & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \tag{54}$$

Quantification (20) of G gives

$$\hat{G} = iH^{(5)}, \tag{55}$$

with the Hamiltonian

$$H^{(5)}=\frac{1}{2}V\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{bmatrix}. \tag{56}$$

The two examples considered above show how a squadron of several real cliffordons can obey a truly complex quantum theory.

XIV. FERMI AND CLIFFORD STATISTICS

The FD algebra of creators and annihilators is a special case of a Clifford algebra over a quadratic space with neutral quadratic form, called the quantum algebra by Saller[23] and the mother algebra by Doran *et al.*[24] Is FD statistics ever a special case of Clifford statistics? Specifically, are their †-algebras ever isomorphic?

From the N annihilators a_k of the complex FD statistics we can form a sequence of anticommuting hermitian square roots of unity

$$i_k=a_k+a_k^\dagger, \quad i_{k+N}=\frac{a_k-a_k^\dagger}{i}. \tag{57}$$

Moreover, the complex †-algebra that these generate is a Clifford †-algebra Cliff$(2N,0)$. The transformation from the FD generators to the Clifford is invertible. Therefore complex FD statistics and complex Clifford statistics have isomorphic †-algebras.

The graded †-algebras are obviously not isomorphic. The two grade operators do not even commute.

The question is more complicated for the real Fermi and Clifford quantifications. We follow Doran *et al.*,[24] among others.

In the real FD formulation we begin with a real one-fermion n-dimensional space $F\cong n\mathbb{R}$ with no metric or adjoint. The FD quantified algebra $\mathcal{A}$ has the bilinear associative product defined by the FD relations

$$\begin{aligned} f_if_j+f_jf_i&=0,\\ f_if^j+f^jf_i&=\delta_i^j, \end{aligned} \tag{58}$$

and the adjoint defined by

$$f_i^\dagger:=f^i. \tag{59}$$

The f_i are creation and f^j are annihilation operators.

To present $\mathcal{A}$ as a Clifford algebra we form the direct sum

$$W=F\oplus F^\dagger. \tag{60}$$

In a basis $\{f_i, f^i\}_{i=1}^n$ adapted to this direct sum, we define the following GL(V)-invariant metric for W

$$g\sim\begin{bmatrix}0&1/2\\1/2&0\end{bmatrix}, \tag{61}$$

corresponding to

$$f_i \cdot f_j = 0, \quad f^i \cdot f^j = 0, \quad f^i \cdot f_j = \tfrac{1}{2}\delta^i_j . \tag{62}$$

Since F supports a quantum theory it too has a quadratic form $*: F \otimes F \to \mathbb{R}$, which we assume to be Euclidean. We did not use $*$ in the construction of $\mathcal{A}$ and g.

We quantify this fermion by a mapping $Q^\dagger: W \to \mathcal{A}$ into the †-algebra of the composite. For brevity we write f_i for $Q^\dagger f_i$ as is also customary.

The quantification Q has the representation property. In the FD case this means that Q represents the orthogonal group $\mathrm{SO}(F,*)$ in $\mathcal{A}$; in fact it represents the larger group $\mathrm{GL}(F)$, for $*$ has not entered into the definition of Q.

The basis $\{\gamma_i, \tilde{\gamma}_i\}_{i=1}^n$ defined by

$$\gamma_i := f_i + f^i, \quad \tilde{\gamma}_i := f_i - f^i, \tag{63}$$

gives the metric g of W the diagonal form

$$g \sim \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \tag{64}$$

corresponding to

$$\gamma_i \cdot \gamma_j = 1, \quad \tilde{\gamma}_i \cdot \tilde{\gamma}_j = -1, \quad \tilde{\gamma}_i \cdot \gamma_j = 0. \tag{65}$$

That is, $W = E \oplus \tilde{E}$ is a neutral quadratic space, with Eucidean subspace E and anti-Euclidean subspace $\tilde{E}$.

The γ's obey

$$\begin{gathered} \gamma_i \gamma_j + \gamma_j \gamma_i = +2\delta_{ij}, \\ \tilde{\gamma}_i \tilde{\gamma}_j + \tilde{\gamma}_j \tilde{\gamma}_i = -2\delta_{ij}, \\ \tilde{\gamma}_i \gamma_j + \gamma_j \tilde{\gamma}_i = 0. \end{gathered} \tag{66}$$

Therefore the FD algebra (58) is isomorphic to a real Clifford algebra $\mathrm{Cliff}(W,\dagger) = \mathrm{Cliff}(E \oplus \tilde{E})$.

Are the Clifford and FD †-algebras also isomorphic?

With respect to the Fermi adjoint †, half of the Clifford generators (the γ_i) are Hermitian and the other half (the $\tilde{\gamma}_i$) are anti-Hermitian. In a Clifford † algebra, however, all the generators are anti-Hermitian or Hermitian together. Therefore the Clifford-algebra generators $\{\gamma_i, \tilde{\gamma}_i\}_{i=1}^n$ are not Clifford †-algebra generators.

In some cases we construct suitable generators using the top element $\tilde{\gamma}^\uparrow$ of $\tilde{E}$:

If the dimension n of E (and F) is a multiple of 4, then $\overline{\gamma_i} := \tilde{\gamma}^\uparrow \tilde{\gamma}_i$ anticommutes with the γ_j, and is Hermitian like the γ_j. Then the elements $\{\gamma_i, \overline{\gamma_i}\}_{i=1}^n$ generate a Clifford †-algebra with [cf. (66)]

$$\begin{gathered} \gamma_i \gamma_j + \gamma_j \gamma_i = +2\delta_{ij}, \\ \overline{\gamma_i}\,\overline{\gamma_j} + \overline{\gamma_j}\,\overline{\gamma_i} = +2\delta_{ij}, \\ \overline{\gamma_i} \gamma_j + \gamma_j \overline{\gamma_i} = 0, \end{gathered} \tag{67}$$

which is isomorphic to the FD algebra of F. Then the Clifford-quantified †-algebra (the case $\zeta = \zeta' = +1$) is isomorphic to a Fermi-quantified one when $n = 4m$, and the adjoint of the one-cliffordon space is positive definite. The two quantified theories then predict the same transition amplitudes and spectra.

Analogously, when $\zeta=\zeta'=-1$ and all the Clifford generators are anti-Hermitian, and $n=4m$, the FD and Clifford statistics again give isomrphic † algebras.

They still differ in their grades. The FD quantified system has a grade G_F with spectrum $-N,\ldots,0,\ldots,N$, corresponding to the creation and annihilation fermions. The Clifford quantified system has a positive grade operator G_C with spectrum $0,1,\ldots 2N$. The operators G_C and G_F do not even commute. The FD and Clifford graded-algebras are not isomorphic.

This is merely a difference in language. The operators that are said to create and annihilate things in FD statistics are said to permute things in Clifford statistics. In Clifford statistics nothing is created or destroyed.

Becchi–Rouet–Stora–Tyutin formalism and zero locus reduction

M. A. Grigoriev, A. M. Semikhatov,[a] and I. Yu. Tipunin

(Received 4 November 2000; accepted for publication 26 February 2001)

In the Becchi–Rouet–Stora–Tyutin (BRST) quantization of gauge theories, the zero locus $\mathcal{Z}_{\mathbf{Q}}$ of the BRST differential $\mathbf{Q}$ carries an (anti)bracket whose parity is opposite to that of the fundamental bracket. Observables of the BRST theory are in a 1:1 correspondence with Casimir functions of the bracket on $\mathcal{Z}_{\mathbf{Q}}$. For any constrained dynamical system with the phase space $\mathcal{N}_0$ and the constraint surface Σ, we prove its equivalence to the constrained system on the BFV-extended phase space with the constraint surface given by $\mathcal{Z}_{\mathbf{Q}}$. Reduction to the zero locus of the differential gives rise to relations between bracket operations and differentials arising in different complexes (the Gerstenhaber, Schouten, Berezin–Kirillov, and Sklyanin brackets); the equation ensuring the existence of a nilpotent vector field on the reduced manifold can be the classical Yang–Baxter equation. We also generalize our constructions to the bi-*QP* manifolds which from the BRST theory viewpoint correspond to the BRST–anti-BRST-symmetric quantization. © *2001 American Institute of Physics.* [DOI: 10.1063/1.1367867]

I. INTRODUCTION

The Becchi–Rouet–Stora–Tyutin (BRST) quantization of general gauge theories in the Hamiltonian and Lagrangian formalisms includes the Batalin–Fradkin–Vilkovisky (BFV)[1] and Batalin–Vilkovisky (BV)[2] formalisms. From a geometric standpoint, these quantization formalisms deal with an even or odd *QP* manifold $\mathcal{N}$,[3,4] i.e., a symplectic or antisymplectic manifold equipped with a compatible odd vector field $\mathbf{Q}$ such that $\mathbf{Q}^2=0$. This condition is ensured by imposing the *master equation* on the Hamiltonian function of the vector field $\mathbf{Q}$. In the standard physicists' notation, the respective equations are

$$\{\Omega,\Omega\}=0 \quad \text{and} \quad (S,S)=0, \tag{1.1}$$

where Ω (by a widespread abuse of terminology) is the ''BRST generator'' in the Hamiltonian quantization and S is the master action in the Lagrangian quantization.

Under appropriate regularity conditions, the zero locus $\mathcal{Z}_{\mathbf{Q}}\subset\mathcal{N}$ of $\mathbf{Q}=\{\Omega,\cdot\}$ [of $\mathbf{Q}=(S,\cdot)$] is an odd Poisson manifold (respectively, a Poisson manifold),[4,5] whose geometry captures crucial information about the theory on $\mathcal{N}$. In this paper, we mainly concentrate on *even QP* manifolds (which correspond to the BFV quantization and were implicit in Ref. 7) because they have not been considered before; however, we formulate the general facts about the zero-locus reduction such that they apply to both even and odd *QP* manifolds. On an even *QP* manifold, $\mathcal{Z}_{\mathbf{Q}}$ carries an *anti*bracket; we then show that the equivalence classes of observables (the cohomology of $\mathbf{Q}$) are in a 1:1 correspondence with characteristic (Casimir) functions of the antibracket on $\mathcal{Z}_{\mathbf{Q}}$ and gauge symmetries in the BFV theory on $\mathcal{N}$ are Hamiltonian vector fields on $\mathcal{Z}_{\mathbf{Q}}$.

Moreover, the zero locus $\mathcal{Z}_{\mathbf{Q}}$ of the BFV differential on the extended phase space is a proper counterpart of the constraint surface in the following sense. In geometric terms, a first-class constrained system can be specified by its phase space (a symplectic manifold $\mathcal{N}_0$) and the

[a]Author to whom correspondence should be addressed. Electronic mail: asemikha@td.lpi.ac.ru

constraint surface Σ. On the extended phase space $\mathcal{N}$ constructed in the BFV quantization, we can consider the dynamical system whose constraint surface, by definition, is $\mathcal{Z}_{\mathbf{Q}}$ (in local coordinates on $\mathcal{N}$, the constraints can be chosen as the components of $\mathbf{Q}$). Then the constrained systems $(\mathcal{N}_0,\Sigma)$ and $(\mathcal{N},\mathcal{Z}_{\mathbf{Q}})$ *are equivalent*: the respective algebras of the equivalence classes of observables are naturally isomorphic as Poisson algebras.

Beyond the BRST context, algebras of functions on *QP* manifolds, which are differential Poisson algebras (associative supercommutative algebras endowed with a bracket operation and a differential that is a derivation of the bracket) can arise from complexes endowed with a supercommutative associative multiplication and a Gerstenhaber-like multiplication (''*bracket*''); the differential is then interpreted as the $\mathbf{Q}$ structure, and the bracket becomes the P structure [the Poisson or the BV bracket on the dual (super)manifold]. The basic examples are the cohomology complexes of a Lie algebra $\mathfrak{a}$ with coefficients in $\bigwedge\mathfrak{a}$ or $\mathrm{S}\mathfrak{a}$ (the exterior and symmetric tensor algebras); the general case involves L_∞ algebras.[8]

In this algebraic context, reduction to the zero locus can yield relations between different complexes. In certain cases, the zero-locus reduction can be applied *repeatedly*; the equation ensuring the existence of a nilpotent vector field on the reduced manifold at the second step of the reduction can be the classical Yang–Baxter equation (CYBE), in which case the reduction leads to the well-known Sklyanin and Berezin–Kirillov brackets.

In addition to the usual *QP* manifolds, one can consider *bi-QP* manifolds, which are the geometric counterparts of bicomplexes, and in physical terms, originate in the BRST–anti-BRST [Sp(2)-symmetric/triplectic] quantization.[9–12] With two BRST operators represented by two commuting (odd and nilpotent) vector fields, bi-*QP* manifolds might be called *QQP* manifolds; interestingly enough, the corresponding zero-locus reduction (to the submanifold on which both vector fields vanish) results in a ''*PP*'' manifold, i.e., gives rise to a *bi-Hamiltonian* structure. A typical example is obtained by starting with a Lie algebra $\mathfrak{a}$ and deriving the second differential from a *co*algebra structure. Compatibility between two differentials then implies that $(\mathfrak{a},\mathfrak{a}^*,\mathfrak{a}\oplus\mathfrak{a}^*)$ is a Manin triple.[13] There also exists an alternative construction of a bi-*QP* manifold from a *single* Lie algebra structure, which results in non-Abelian triplectic antibrackets[14] on the space of common zeroes of the differentials (and thus, the zero locus reduction leads to a nontrivial relation to the bicomplex used in the extended BRST symmetry).

This paper is organized as follows. In Sec. 2.2, we recall the main points of the zero locus reduction on (odd or even) *QP* manifolds. Symmetries of *QP* manifolds are reviewed in Sec. 2.3. In Sec. 3, we turn to a more detailed analysis of even *QP* manifolds corresponding to the BFV quantization. In Secs. 3.1–3.2, we recall several facts about the BFV formalism in the form that is suitable for what follows. The results given in 3.4 state the relation between objects in the bulk of the phase space and on the zero locus submanifold. We briefly discuss in Sec. 3.5 how these results can be restated for the BV formalism. In Sec. 4, we consider specific brackets resulting from the zero-locus reduction. In Sec. 5, we study *bi-QP* manifolds.

II. GEOMETRY OF *QP* MANIFOLDS AND ZERO LOCUS REDUCTION

Geometric objects underlying the BRST quantization are the *QP* manifolds.

2.1. Definition (Refs. 3 and 4): A QP manifold is a supermanifold $\mathcal{N}$ equipped with a bracket $\{\cdot,\cdot\}$ such that

$$\{F,G\}=-(-1)^{(\mathrm{p}(F)+\kappa)(\mathrm{p}(G)+\kappa)}\{G,F\},$$

$$\{F,GH\}=\{F,G\}H+(-1)^{(\mathrm{p}(F)+\kappa)\mathrm{p}(G)}G\{F,H\}, \tag{2.1}$$

$$\{F,\{G,H\}\}=\{\{F,G\},H\}+\{G,\{F,H\}\}(-1)^{(\mathrm{p}(F)+\kappa)(\mathrm{p}(G)+\kappa)},$$

for F, G, $H\in\mathcal{F}_{\mathcal{N}}$ (smooth functions on $\mathcal{N}$), and with an odd nilpotent vector field $\mathbf{Q}$, $\mathbf{Q}^2=0$, such that

$$\mathbf{Q}\{F,G\}-\{\mathbf{Q}F,G\}-(-1)^{\mathrm{p}(F)+\kappa}\{F,\mathbf{Q}G\}=0, \quad F,G\in\mathcal{F}_{\mathcal{N}} \tag{2.2}$$

[where $p(()\cdot)$ is the Grassmann parity]. QP manifolds with a Poisson bracket ($\kappa=0$) *are called even, and those with an* antibracket ($\kappa=1$), *odd.*

Odd *QP* manifolds arise in the BV quantization, and even ones in the BFV quantization. Odd *QP* manifolds were introduced in Ref. 3 and were studied in Refs. 4 and 5. In most of our definitions, *QP* manifolds can be either even or odd; in Sec. 3, however, we concentrate on even *QP* manifolds, which have not been given enough attention previously.

2.2. The zero locus of $\mathbf{Q}$. In what follows, $\mathcal{Z}_{\mathbf{Q}}$ denotes the zero locus of the odd vector field $\mathbf{Q}$ on a *QP* manifold $\mathcal{N}$. We assume $\mathcal{Z}_{\mathbf{Q}}$ to be a nonempty smooth submanifold and denote by $\mathcal{J}_{\mathcal{Z}_{\mathbf{Q}}}\subset\mathcal{F}_{\mathcal{N}}$ *the ideal of smooth functions vanishing on* $\mathcal{Z}_{\mathbf{Q}}$.

The odd vector field $\mathbf{Q}$ is called *regular* if each function $f\in\mathcal{J}_{\mathcal{Z}_{\mathbf{Q}}}$ can be represented as

$$f=\sum_{\alpha} f_{\alpha}\mathbf{Q}\Gamma^{\alpha}, \tag{2.3}$$

with some f_{α}, $\Gamma^{\alpha}\in\mathcal{F}_{\mathcal{N}}$ (i.e., if the components of $\mathbf{Q}$ generate $\mathcal{J}_{\mathcal{Z}_{\mathbf{Q}}}$). We say that a submanifold $\mathcal{L}\subset\mathcal{N}$ is *coisotropic* if

$$\{\mathcal{J}_{\mathcal{L}},\mathcal{J}_{\mathcal{L}}\}\subset\mathcal{J}_{\mathcal{L}}. \tag{2.4}$$

2.2.1. Lemma: If $\mathbf{Q}$ *is regular,* $\mathcal{Z}_{\mathbf{Q}}$ *is a coisotropic submanifold of the QP manifold* $\mathcal{N}$.

Proof: Let $f, g\in\mathcal{F}_{\mathcal{N}}$ vanish on $\mathcal{Z}_{\mathbf{Q}}$. Using representation (2.3), the Leibnitz rule, Eq. (2.2), and nilpotency of $\mathbf{Q}$, we see that $\{f_{\alpha}(\mathbf{Q}\Gamma^{\alpha}),(\mathbf{Q}\Gamma^{\beta})g_{\beta}\}|_{\mathcal{Z}_{\mathbf{Q}}}=(f_{\alpha}\{\mathbf{Q}\Gamma^{\alpha},\mathbf{Q}\Gamma^{\beta}\}g_{\beta})|_{\mathcal{Z}_{\mathbf{Q}}}=0$. □

In what follows, we assume $\mathcal{Z}_{\mathbf{Q}}$ to be coisotropic even in those cases where $\mathbf{Q}$ is not regular. The algebra $\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}$ of smooth functions on $\mathcal{Z}_{\mathbf{Q}}$ is the quotient $\mathcal{F}_{\mathcal{N}}/\mathcal{J}_{\mathcal{Z}_{\mathbf{Q}}}$. We then have

2.2.2. Lemma: There is a well-defined binary operation given by $\{,\}_{\mathbf{Q}}:\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}\times\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}\to\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}$

$$\{f,g\}_{\mathbf{Q}}=\{F,\mathbf{Q}G\}|_{\mathcal{Z}_{\mathbf{Q}}}, \quad f,g\in\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}, \quad F,G\in\mathcal{F}_{\mathcal{N}}, \quad F|_{\mathcal{Z}_{\mathbf{Q}}}=f, \quad G|_{\mathcal{Z}_{\mathbf{Q}}}=g, \tag{2.5}$$

where F *and* $G\in\mathcal{F}_{\mathcal{N}}$ *are viewed as representatives of functions on* $\mathcal{Z}_{\mathbf{Q}}$. *It makes* $\mathcal{Z}_{\mathbf{Q}}$ *into a Poisson manifold.*

The proof is a straightforward generalization of a proof given in Ref. 5. It is obvious that the parity of the induced bracket on $\mathcal{Z}_{\mathbf{Q}}$ is opposite to the parity of the $\{,\}$ bracket on $\mathcal{N}$. An important characteristic of the differential $\mathbf{Q}$ is the homology of the linear operators $\mathbf{Q}_p:T_p\mathcal{N}\to T_p\mathcal{N}$, $p\in\mathcal{Z}_{\mathbf{Q}}$, defined as follows. We consider the tangent space $T_p\mathcal{N}$ as the quotient of the vector fields $\mathrm{Vect}_{\mathcal{N}}$ modulo those that vanish at p. Then

$$\mathbf{Q}_p(x)=([\mathbf{Q},X])|_p, \quad X\in\mathrm{Vect}_{\mathcal{N}}, \quad x=X_p\in T_p\mathcal{N}. \tag{2.6}$$

This operation is well-defined once $\mathbf{Q}$ vanishes at p.

2.2.3. Definition: A QP manifold $\mathcal{N}$ *is called* proper *if the homology of the linear operator* $\mathbf{Q}_p:T_p\mathcal{N}\to T_p\mathcal{N}$ *is trivial at each point* $p\in\mathcal{Z}_{\mathbf{Q}}$.

This definition is equivalent to the one given in Ref. 4 (and Ref. 5), but uses only invariant notions [in local coordinates Γ^A, we would have $(\mathbf{Q}_p x)^A=(-1)^{p(x)+1}x^B(\partial\mathbf{Q}^A/\partial\Gamma^B)$]. We now have the following proposition.

2.2.4. Proposition (Refs. 4 and 5): Let $\mathcal{N}$ *be a proper QP manifold with a nondegenerate bracket. Then* $\mathcal{Z}_{\mathbf{Q}}$ *is (anti)symplectic with respect to the induced bracket* (2.5).

One can replace $\mathcal{Z}_{\mathbf{Q}}$ with a submanifold that still is coisotropic. As a straightforward generalization of 2.2.2, we have

2.2.5. Theorem: *Let* $\mathcal{N}$ *be a QP manifold and* $\mathcal{L}\subset\mathcal{Z}_{\mathbf{Q}}\subset\mathcal{N}$ *a coisotropic submanifold of* $\mathcal{N}$. *Then* $\mathcal{L}$ *is a Poisson manifold with the Poisson structure given by (by Poisson manifolds, we mean those with either an even Poisson bracket or an antibracket):*

$$\{f,g\}_{\mathbf{Q}}=\{F,\mathbf{Q}G\}|_{\mathcal{L}},\quad f,g\in\mathcal{F}_{\mathcal{L}},\quad F,G\in\mathcal{F}_{\mathcal{N}},\quad F|_{\mathcal{L}}=f,\quad G|_{\mathcal{L}}=g. \tag{2.7}$$

Proof: It is easy to see that (2.7) does not depend on the choice of representatives $F,G\in\mathcal{F}_{\mathcal{N}}$ of $f,g\in\mathcal{F}_{\mathcal{L}}$. The Jacobi identity and the Leibnitz rule follow in the same way as for the bracket in Eq. (2.5), see Ref. 5. □

2.3. Symmetries of QP manifolds (Ref. 5). We now recall several basic facts about symmetries of *QP* structures on a manifold.

2.3.1. Definition: A vector field X on a QP manifold $\mathcal{N}$ is called a symmetry of $\mathcal{N}$ if it commutes with $\mathbf{Q}$ *and is a Poisson vector field, i.e.,*

$$X\{F,G\}-\{XF,G\}-(-1)^{(\mathrm{p}(F)+\kappa)\mathrm{p}(X)}\{F,XG\}=0,\quad F,G\in\mathcal{F}_{\mathcal{N}}. \tag{2.8}$$

Symmetries of the form $X=\{\mathbf{Q}F,\cdot\}$ *(with* $F\in\mathcal{F}_{\mathcal{N}}$*) are called* trivial.

The Lie algebras of symmetries and trivial symmetries behave in a very regular manner under the restriction to $\mathcal{Z}_{\mathbf{Q}}$.

2.3.2. Proposition: Let X be a symmetry of $\mathcal{N}$. Then X restricts to $\mathcal{Z}_{\mathbf{Q}}$ and its restriction x is a Poisson vector field on $\mathcal{Z}_{\mathbf{Q}}$ with respect to the bracket (2.7) on $\mathcal{Z}_{\mathbf{Q}}$, namely

$$x\{F,G\}_{\mathbf{Q}}-\{xF,G\}_{\mathbf{Q}}-(-1)^{(\mathrm{p}(F)+\kappa+1)\mathrm{p}(X)}\{F,xG\}_{\mathbf{Q}}=0,\quad F,G\in\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}. \tag{2.9}$$

If in addition $X=\{\mathbf{Q}H,\cdot\}$ *is a trivial symmetry, x is a Hamiltonian vector field with respect to the* $\{,\}_{\mathbf{Q}}$ *bracket.*

Proof: Any symmetry X restricts to $\mathcal{Z}_{\mathbf{Q}}$ because $XF|_{\mathcal{Z}_{\mathbf{Q}}}=0$ for any F vanishing on $\mathcal{Z}_{\mathbf{Q}}$. Indeed, every such function can be represented as $F=F_\alpha\cdot\mathbf{Q}\Gamma^\alpha$ with some functions F_α and Γ^α, provided $\mathbf{Q}$ is regular. Because $[X,\mathbf{Q}]=0$, we have $XF|_{\mathcal{Z}_{\mathbf{Q}}}=((XF_\alpha)(\mathbf{Q}\Gamma^\alpha))|_{\mathcal{Z}_{\mathbf{Q}}}+(-1)^{p(X)(p(F_\alpha)+1)F_\alpha}(\mathbf{Q}X\Gamma^\alpha)|_{\mathcal{Z}_{\mathbf{Q}}}=0$. Equation (2.9) immediately follows from the definition of the zero locus bracket and the definition of symmetries. If in addition $X=\{\mathbf{Q}H,\cdot\}$ is a trivial symmetry, for any function $f\in\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}$ we have

$$xf=X|_{\mathcal{Z}_{\mathbf{Q}}}f=\{\mathbf{Q}H,F\}|_{\mathcal{Z}_{\mathbf{Q}}}=(-1)^{p(H)+\kappa+1}\{H|_{\mathcal{Z}_{\mathbf{Q}}},f\}_{\mathbf{Q}}, \tag{2.10}$$

where $F\subset\mathcal{F}_{\mathcal{N}}$ is a lift of f (i.e., $f=F|_{\mathcal{Z}_{\mathbf{Q}}}$) and κ is the parity of the $\{,\}$ bracket. Thus, $x=X|_{\mathcal{Z}_{\mathbf{Q}}}$ is a Hamiltonian vector field with respect to the bracket $\{,\}_{\mathbf{Q}}$. □

III. OBSERVABLES, GAUGE SYMMETRIES, AND ZERO LOCUS REDUCTION IN BFV AND BV QUANTIZATIONS

We now consider the embedding of a constrained system into the BFV extended theory with the BRST charge Ω and study the ''on-shell'' gauge symmetries in the two descriptions of the same theory. In the Dirac (''nonextended'') formalism, the on-shell gauge symmetries are those nonvanishing on the constraint surface, and in the BFV extended formalism, these are symmetries nonvanishing on the zero locus $\mathcal{Z}_{\mathbf{Q}}$. We show that the former are mapped into the latter such that the equivalence classes of observables in the original theory are mapped into equivalence classes of observables in the BFV theory (the latter can be considered as gauge invariant functions on $\mathcal{Z}_{\mathbf{Q}}$). In this sense, *the zero locus* $\mathcal{Z}_{\mathbf{Q}}$ *plays the role of a constraint surface in the BFV theory*. We concentrate on the BFV case, where we assume the phase space to be finite-dimensional; reformulation of our results for the BV quantization, although straightforward at the formal level, requires some care because the BV configuration space of any realistic model is infinite-dimensional (see 3.5).

3.1. A reminder on constrained dynamics. We begin with recalling several basic facts about constrained dynamics in the form that will be suitable in what follows.

3.1.1. Basics of the Dirac constrained dynamics. We consider a first-class constrained Hamiltonian system, defined on a phase space (symplectic manifold) $\mathcal{N}_0$ with the *constraints* T_α (functions on $\mathcal{N}_0$) such that

$$\{T_\alpha, T_\beta\} = U^\gamma_{\alpha\beta} T_\gamma, \tag{3.1}$$

where $\{,\}$ is the Poisson bracket on $\mathcal{N}_0$. For simplicity, we assume the first-class constraints T_α to be irreducible. Let Σ denote the *constraint surface* $T_\alpha = 0$. A geometrically invariant way to specify a first-class constrained system is to fix the pair $(\mathcal{N}_0, \Sigma)$ (a symplectic manifold and a coisotropic submanifold). Different choices for T_α then give different generators of the ideal of functions vanishing on Σ.

By definition, an *observable* is a function on $\mathcal{N}_0$ satisfying $\{A, T_\alpha\}|_\Sigma = 0$. Under the standard regularity conditions, each function vanishing on Σ is proportional to the constraints, and therefore,

$$\{A, T_\alpha\} = A^\beta_\alpha T_\beta \tag{3.2}$$

for some functions A^α_β. Observables vanishing on Σ are called *trivial*. Two observables are called *equivalent* if they differ by a trivial observable. The space of equivalence classes of observables is a Poisson algebra, i.e., is closed under multiplication and under the Poisson bracket (these operations are well defined on the equivalence classes via representatives). This algebra can be conveniently thought of as a subalgebra in the algebra of functions on Σ.

Infinitesimal gauge transformations, or gauge symmetries, are the Hamiltonian vector fields $X_0 = \{\phi_0, \cdot\}$, where $\phi_0 = \phi_0^\alpha T_\alpha$ is a trivial observable. Gauge symmetries form a Lie algebra with respect to the commutator. For any observable A and a gauge symmetry $X_0 = \{\phi_0, \cdot\}$, we have

$$X_0 A = \{\phi_0, A\} = \{\phi_0^\alpha T_\alpha, A\} = \phi_0^\alpha \{T_\alpha, A\} + T_\alpha \{\phi_0^\alpha, A\}, \tag{3.3}$$

which vanishes on Σ because A is an observable. Therefore, gauge symmetries preserve equivalence classes of observables.

By the *on-shell gauge symmetries*, we mean the equivalence classes of gauge symmetries modulo those vanishing on the constraint surface Σ. On-shell gauge symmetries can also be viewed as a subalgebra in the algebra of vector fields on Σ. Equivalence classes of observables (viewed as functions on Σ) are then represented by functions annihilated by on-shell gauge symmetries.

3.1.2. Basics of the BFV/BRST approach. In the BFV quantization, the extended phase space $\mathcal{N}$ is an even *QP* manifold whose $\mathbf{Q}$-structure is given by $\mathbf{Q} = \{\Omega, \cdot\}$, where Ω is a function on $\mathcal{N}$ (called the BRST charge) satisfying $\{\Omega, \Omega\} = 0$. In applications, the BFV extended phase space is usually equipped with an additional structure, the ghost charge $G \in \mathcal{F}_\mathcal{N}$. Functions with a definite ghost number are eigenfunctions of the ghost number operator

$$g = \{G, \cdot\}, \tag{3.4}$$

corresponding to integer eigenvalues. The BRST charge is required to have the ghost number 1,

$$\{G, \Omega\} = \Omega. \tag{3.5}$$

We now consider a *QP* manifold $\mathcal{N}$ that is not necessarily constructed via the BFV prescription; however, we refer to the objects on $\mathcal{N}$ as BFV ones because the applications in what follows will be to the case where $\mathcal{N}$ does result from the BFV construction. This also helps to distinguish between observables and symmetries on the *QP* manifold and those in the initial theory (Sec. 3.1.1), with 'BFV' used to refer to the former.

A BFV observable A is a function on the *QP* manifold $\mathcal{N}$ satisfying

$$\mathbf{Q}A = \{\Omega, A\} = 0, \quad \mathrm{gh}(A) = 0. \tag{3.6}$$

TABLE I.

	Dirac (Sec. 3.1.1)	BFV (Sec. 3.1.2)
Observables	$A_0, \{A_0, T_\alpha\} = A_\alpha^\beta T_\beta$	$\mathbf{Q}A = \{\Omega, A\} = 0$, $\mathrm{gh}(A) = 0$
Trivial observables	$(A_0)\vert_\Sigma = 0$	$A = \mathbf{Q}B$
Equivalent observables	$A_0 \sim A_0 + a^\alpha T_\alpha$	$A \sim A + \mathbf{Q}B$
Gauge symmetries	$X_0 = \{\phi_0^\alpha T_\alpha, \cdot\}$	$X = \{\mathbf{Q}H, \cdot\}$, $\mathrm{gh}(X) = 0$

The **Q**-exact BFV observables are called *trivial*. Two BFV observables A and $\tilde{A}$ are equivalent if $A - \tilde{A} = \mathbf{Q}B$ for some function B; the equivalence classes of observables are then the cohomology of **Q** in the ghost number zero. The algebra of BFV observables is a Poisson algebra (multiplication and the Poisson bracket can be defined via representatives).

A vector field X is called a *BFV gauge symmetry* if $X = \{\mathbf{Q}H, \cdot\}$ for some function H with $\mathrm{gh}(X) = \mathrm{gh}(\mathbf{Q}H) = 0$ [these are trivial symmetries (see 2.3.1) of the corresponding *QP* manifold]. In other words, BFV gauge symmetries are the Hamiltonian vector fields generated by trivial BFV observables. If A is an observable and $X = \{\mathbf{Q}H, \cdot\}$ a BFV gauge symmetry, we see that $XA = \{\mathbf{Q}H, A\} = \mathbf{Q}\{H, A\}$ is a trivial observable, i.e., BFV gauge symmetries preserve the equivalence classes of BFV observables.

3.2. From Dirac to the BFV formulation of a constrained system. Formal similarities between the Dirac and BFV formalisms are summarized in Table I. We now make contact between 3.1.1 and 3.1.2 by taking the extended phase space $\mathcal{N}$ and the BRST charge Ω to be those arising in the BFV formalism from a given first-class constrained system $(\mathcal{N}_0, \Sigma)$. As before, the constraints $T_\alpha \in \mathcal{F}_{\mathcal{N}_0}$ are taken to be irreducible; to construct the BFV formalism, one then introduces ghosts c^α, with $\mathrm{gh}(c^\alpha) = 1$, $\mathsf{p}(c^\alpha) = \mathsf{p}(T_\alpha) + 1$ and their conjugate momenta $\mathcal{P}_\alpha$,

$$\{c^\alpha, \mathcal{P}_\beta\} = \delta_\beta^\alpha, \tag{3.7}$$

with $\mathrm{gh}(\mathcal{P}_\alpha) = -1$, $\mathsf{p}(\mathcal{P}_\alpha) = \mathsf{p}(T_\alpha) + 1$. The extended phase space $\mathcal{N}$ is the direct product of $\mathcal{N}_0$ with the superspace spanned by c^α and $\mathcal{P}_\alpha$. The Poisson bracket on $\mathcal{N}$ is the product Poisson bracket of that on $\mathcal{N}_0$ and (3.7). Note that when the constraints are defined *locally*, the extended phase space is a vector bundle over the original phase space, as, for example, in Ref. 16.

One introduces the ghost charge (where we assume the constraints to be bosonic to avoid extra sign factors)

$$G = c^\alpha \mathcal{P}_\alpha, \quad \{G, c^\alpha\} = c^\alpha, \quad \{G, \mathcal{P}_\alpha\} = -\mathcal{P}_\alpha. \tag{3.8}$$

The BRST charge Ω is an odd function defined by the condition that it has the ghost number 1 and satisfies

$$\{\Omega, \Omega\} = 0 \tag{3.9}$$

with the boundary condition

$$\Omega = c^\alpha T_\alpha + \cdots, \tag{3.10}$$

where $\cdots$ means higher-order terms in the ghost momenta. It is well known[1,15,9,17] that under standard assumptions, the BRST charge Ω exists for any constrained system. Up to the first order in $\mathcal{P}_\alpha$, one has

$$\Omega = c^\alpha T_\alpha - \tfrac{1}{2} \mathcal{P}_\gamma U_{\alpha\beta}^\gamma c^\alpha c^\beta + \cdots, \tag{3.11}$$

where the structure functions are those from (3.1).

As regards observables, the following statement is well known[1,15] (see also Ref. 17).

3.2.1. Proposition: The algebra of the equivalence classes of observables on $\mathcal{N}_0$ and the algebra of the equivalence classes of BFV observables (the cohomology of $\mathbf{Q}$ *in the ghost number zero) on the extended phase space $\mathcal{N}$ are isomorphic as Poisson algebras.*

This means that if $A_0 \in \mathcal{F}_{\mathcal{N}_0}$ is an observable of the constrained system on $\mathcal{N}_0$, there exists a BFV observable $A \in \mathcal{F}_{\mathcal{N}}$ with $\mathrm{gh}(A)=0$ such that

$$A|_{\mathcal{N}_0}=A_0. \tag{3.12}$$

Moreover, two BFV observables corresponding to the same observable A_0 differ by a trivial BFV observable. If in addition A_0 is a trivial observable, it follows that $A=\{\Omega,B\}$. The Poisson bracket on $\mathcal{N}$ induces a bracket on the cohomology of $\mathbf{Q}$, and one has

$$\{A,B\}|_{\mathcal{N}_0}=\{A_0,B_0\}. \tag{3.13}$$

The isomorphism between the BRST cohomology in the ghost number zero and the algebra of equivalence classes of observables of the constrained system on $\mathcal{N}_0$ is given by the restriction of representatives to the initial constrained surface $\Sigma \subset \mathcal{N}_0 \subset \mathcal{N}$ (recall that equivalence classes of observables are gauge invariant functions on Σ).

It also follows from 3.2.1 that because gauge symmetries of the initial system $(\mathcal{N}_0,\Sigma)$ are generated by trivial observables, each gauge symmetry can be lifted to a BFV gauge symmetry.

3.3. Zero locus $\mathcal{Z}_{\mathbf{Q}}$ in the BFV theory, the general case. We now consider an even *QP*-manifold $\mathcal{N}$ that is not necessarily constructed by the BFV procedure for a constrained system. We assume $\mathcal{N}$ to be symplectic, and the odd nilpotent vector field $\mathbf{Q}$ to be regular in the sense of 2.3. The zero locus $\mathcal{Z}_{\mathbf{Q}}$ is thus a coisotropic submanifold of $\mathcal{N}$. Because each trivial BFV observable $A=\mathbf{Q}B$ vanishes on $\mathcal{Z}_{\mathbf{Q}}$, each cohomology class uniquely determines a function on $\mathcal{Z}_{\mathbf{Q}}$. Thus, there is a mapping

$$H^0_{\mathbf{Q}} \to \mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}} \tag{3.14}$$

from the space of inequivalent observables to functions on $\mathcal{Z}_{\mathbf{Q}}$.

In what follows, we say that a statement holds locally if it is true in every sufficiently small neighborhood. Mapping (3.14) is locally an embedding in view of the following proposition.

3.3.1. Proposition: Let $\mathbf{Q}=\{\Omega,\cdot\}$ *be regular in the sense of 2.2. Locally, each BFV observable vanishing on $\mathcal{Z}_{\mathbf{Q}}$ is a trivial BFV observable.*

Proof: Let A be an observable vanishing on $\mathcal{Z}_{\mathbf{Q}}$ i.e., $\mathbf{Q}A=0$, $A|_{\mathcal{Z}_{\mathbf{Q}}}=0$. We must show that $A=\mathbf{Q}X$ in a sufficiently small neighborhood U of any point $p \in \mathcal{Z}_{\mathbf{Q}}$. It is well known that locally there exists a coordinate system $p_i,q^j,p_\alpha,q^\beta,c^\alpha,\mathcal{P}_\beta$ on $\mathcal{N}$ such that

$$\Omega=p_i c^i,$$

$$\{q^i,p_j\}=\delta^i_j, \quad \{q^\alpha,p_\beta\}=\delta^\alpha_\beta, \quad \{c^\alpha,\mathcal{P}_\beta\}=\delta^\alpha_\beta. \tag{3.15}$$

Since the function A vanishes on $\mathcal{Z}_{\mathbf{Q}}$, it can be represented as

$$A=A^\alpha p_\alpha + A_\alpha c^\alpha. \tag{3.16}$$

Now the odd vector field $\mathbf{Q}$ becomes

$$\mathbf{Q}=-c^\alpha \frac{\partial}{\partial q^\alpha}+p_\alpha \frac{\partial}{\partial \mathcal{P}_\alpha}, \tag{3.17}$$

and can be considered as the exterior differential under the identification $c^\alpha=-dq^\alpha$, $p_\alpha=d\mathcal{P}_\alpha$, while A becomes a 1-form. The assertion immediately follows from the super analog of the Poincaré lemma in U. □

3.3.2. Embedding $H^0_{\mathbf{Q}}$ into functions on $\mathcal{Z}_{\mathbf{Q}}$. As before, $\mathcal{Z}_{\mathbf{Q}}$ is the zero locus submanifold of $\mathbf{Q}=\{\Omega,\cdot\}$ We recall from 2.3.2 that each BFV gauge symmetry X can be restricted to $\mathcal{Z}_{\mathbf{Q}}$ and the restriction $x=X|_{\mathcal{Z}_{\mathbf{Q}}}$ is a $\{,\}_{\mathbf{Q}}$-Hamiltonian vector field on $\mathcal{Z}_{\mathbf{Q}}$. The image of BFV gauge symmetries under the restriction to $\mathcal{Z}_{\mathbf{Q}}$ is called the algebra of the *on-shell BFV symmetries*. The functions on $\mathcal{Z}_{\mathbf{Q}}$ that are annihilated by the on-shell BFV symmetries are then the characteristic functions of the $\{,\}_{\mathbf{Q}}$ antibracket on $\mathcal{Z}_{\mathbf{Q}}$. We recall that a function f on the (odd) Poisson manifold $\mathcal{N}$ is said to be a characteristic (Casimir) function of an (odd) Poisson bracket $\{,\}$ if $\{f,h\}=0$ for any function h.

Because BFV observables are annihilated by BFV gauge symmetries, the restriction to $\mathcal{Z}_{\mathbf{Q}}$ maps BFV observables into characteristic functions of $\{,\}_{\mathbf{Q}}$. For the equivalence classes of BFV observables (the cohomology of $\mathbf{Q}$), this mapping is certainly an embedding locally. It is also an isomorphism in the important case of a BFV *QP* manifold considered in 3.4. Locally, we choose flat coordinates in some neighborhood U of a point $p\in\mathcal{Z}_{\mathbf{Q}}$ and use explicit form (3.15) of the BRST charge Ω and the Poisson bracket to arrive at

3.3.3. Theorem: *Locally, the equivalence classes of BFV observables (the cohomology of* $\mathbf{Q}$*) are in a 1:1 correspondence with characteristic functions of the* $\{,\}_{\mathbf{Q}}$ *antibracket on* $\mathcal{Z}_{\mathbf{Q}}$.

We note that in one direction, this statement holds in general (i.e., not only locally) because for any observable A, we have

$$\{f,A|_{\mathcal{Z}_{\mathbf{Q}}}\}_{\mathbf{Q}}=\{F,\mathbf{Q}A\}|_{\mathcal{Z}_{\mathbf{Q}}}=0, \tag{3.18}$$

where $F\in\mathcal{F}_{\mathcal{N}}$ is the lift of a function $f\in\mathcal{F}_{\mathcal{Z}_{\mathbf{Q}}}$ and $A|_{\mathcal{Z}_{\mathbf{Q}}}$ is the image of A under (3.14). Thus, $A|_{\mathcal{Z}_{\mathbf{Q}}}$ is a characteristic function of the antibracket $\{,\}_{\mathbf{Q}}$ on $\mathcal{Z}_{\mathbf{Q}}$.

The "$\mathcal{Z}_{\mathbf{Q}}$-based" view on the BFV formalism developed here can be expressed as follows. *Any even QP manifold* $\mathcal{N}$ *gives rise to the constrained system* $(\mathcal{N},\mathcal{Z}_{\mathbf{Q}})$*, i.e., a constrained system whose phase space is* $\mathcal{N}$ *and the constrained surface is* $\mathcal{Z}_{\mathbf{Q}}$. We recall from 3.1.1 that gauge transformations and the algebra of observables can be reconstructed if a first-class constrained system is specified in geometric terms, via its phase space (a symplectic manifold) and the constraint surface (a coisotropic submanifold). We now take this pair to be $(\mathcal{N},\mathcal{Z}_{\mathbf{Q}})$ (with $\mathcal{Z}_{\mathbf{Q}}$ being coisotropic in view of 2.2.1). In local coordinates, the constraints are the components of $\mathbf{Q}$; in a neighborhood $U\subset\mathcal{N}$, the following statement is obvious in the special coordinates in which Ω and $\{,\}_{\mathbf{Q}}$ are given by (3.15).

3.3.4. Theorem: *On a QP manifold* $\mathcal{N}$*, the constrained system* $(\mathcal{N},\mathcal{Z}_{\mathbf{Q}})$ *is locally equivalent to the BFV theory on the extended phase space* $\mathcal{N}$ *with the BRST charge* Ω *(i.e., the respective algebras of equivalence classes of observables are isomorphic as Poisson algebras).*

In a more physical language, the equivalence can be reformulated by saying that the two constrained dynamics are equivalent.

The above considerations show that BFV observables are related to $\mathcal{Z}_{\mathbf{Q}}$ in the same way as observables in the initial theory (Sec. 3.1.1) are related to the constraint surface Σ. This allows us to interpret $\mathcal{Z}_{\mathbf{Q}}$ as the extended constraint surface. In the general case, this correspondence takes place at the local level only.

3.4. Zero locus $\mathcal{Z}_{\mathbf{Q}}$ *in the BFV formulation of a constrained system.* We now concentrate on the important case where the *QP* manifold under consideration is a BFV extended phase space obtained by the BFV procedure from a given constrained system $(\mathcal{N}_0,\Sigma)$.

3.4.1. Proposition: The initial constraint surface $\Sigma\subset\mathcal{N}_0$ *is a submanifold of the zero locus* $\mathcal{Z}_{\mathbf{Q}}\subset\mathcal{N}$ *of the BRST differential* $\mathbf{Q}=\{\Omega,\cdot\}$.

Proof: We restrict ourselves to an irreducible theory with constraints T_α (although the statement is also true for reducible constraints); the structure of the BRST charge is then given by (3.10). Considered as a submanifold in $\mathcal{N}$, the initial phase space $\mathcal{N}_0$ is determined by the equations $c^\alpha=0$ and $\mathcal{P}_\alpha=0$. It follows from (3.10) and from $\mathrm{gh}(\Omega)=1$ that the zero locus $\mathcal{Z}_{\mathbf{Q}}$ is determined by the equations

$$T_\alpha+\cdots=0,\quad \cdots=0, \tag{3.19}$$

where $\cdots$ denotes terms vanishing on $\mathcal{N}_0$. Then the intersection $\mathcal{Z}_\mathbf{Q}\cap\mathcal{N}_0$ (considered as a submanifold in $\mathcal{N}_0$) is determined by the equations $T_\alpha=0$, and therefore, coincides with the initial constraint surface Σ. Thus, Σ is a submanifold in $\mathcal{Z}_\mathbf{Q}$. □

The zero locus can be described somewhat more explicitly if we recall that in the BFV formalism, functions on the extended phase space are formal power series in the ghost variables c^α and $\mathcal{P}_\alpha$. This means that $\mathcal{Z}_\mathbf{Q}$ is actually determined by the equations

$$T_\alpha=0, \quad c^\alpha=0. \tag{3.20}$$

This, in its turn, gives an explicit construction of the antibracket $\{,\}_\mathbf{Q}$ on $\mathcal{Z}_\mathbf{Q}$. Let y^i be local coordinates on Σ. Then y^i and $\mathcal{P}_\alpha$ can be considered as local coordinates on $\mathcal{Z}_\mathbf{Q}$. Evaluating (2.5), we now obtain

$$\{y^i,y^j\}_\mathbf{Q}=0, \quad \{\mathcal{P}_\alpha,y^i\}_\mathbf{Q}=R^i_\alpha(y), \quad \{\mathcal{P}_\alpha,\mathcal{P}_\beta\}_\mathbf{Q}=U^\gamma_{\alpha\beta}(y)\mathcal{P}_\gamma, \tag{3.21}$$

where $R^i_\alpha(y)=\{T_\alpha,y^i\}|_\Sigma$ and $U^\gamma_{\alpha\beta}(y)=U^\gamma_{\alpha\beta}|_\Sigma$ with $U^\gamma_{\alpha\beta}$ from (3.11).

Using the explicit form (3.21) of the antibracket on $\mathcal{Z}_\mathbf{Q}$, it is easy to describe its characteristic functions in terms of the initial constraint surface Σ. The following statement is obvious for irreducible constraints T_α and can be easily generalized to reducible constraints.

3.4.2. Proposition: Characteristic functions of the antibracket $\{,\}_\mathbf{Q}$ *are in a* 1:1 *correspondence with gauge invariant functions on* Σ.

On a *QP* manifold constructed in accordance with the BFV prescription, the relation between the BRST cohomology and the geometry of the extended constrained surface $\mathcal{Z}_\mathbf{Q}$ can be made more precise than in the preceding section. In particular, the respective counterparts of statements 3.3.1, 3.3.3, and 3.3.4 *hold globally*. We first see that (3.14) is an embedding.

3.4.3. Proposition: On a QP manifold $\mathcal{N}$ *constructed in the BFV formalism, each BFV observable that vanishes on* $\mathcal{Z}_\mathbf{Q}\subset\mathcal{N}$ *is a trivial BFV observable.*

Proof: Let A be a BFV observable and $A|_{\mathcal{Z}_\mathbf{Q}}=0$. According to 3.4.1, $\Sigma\subset\mathcal{Z}_\mathbf{Q}$. Then $A|_{\mathcal{Z}_\mathbf{Q}}=0$ implies $A|_\Sigma=0$ (a trivial observable). By 3.2.1, A is a trivial BFV observable. □

We now consider the *QP* manifold constructed in the BFV formalism. Combining 3.4.3 with the argument given after 3.3.3 proves the next theorem in one direction; the other direction follows because each characteristic function on $\mathcal{Z}_\mathbf{Q}$ can be lifted to a BFV observable on $\mathcal{N}$, see 3.2.1 and 3.4.2.

3.4.4. Theorem: *Equivalence classes of BFV observables (the cohomology of* $\mathbf{Q}$ *with the ghost number zero) on the BFV QP manifold are in a 1:1 correspondence with characteristic functions of the zero locus antibracket on* $\mathcal{Z}_\mathbf{Q}$.

As in 3.3.3, we now consider the extended phase space of the BFV formulation as the phase space of a ''new'' constrained system determined by the constraint surface $\mathcal{Z}_\mathbf{Q}$. With $\mathcal{N}$ in its turn obtained from a constrained dynamical system $(\mathcal{N}_0,\Sigma)$ in accordance with the BFV formalism, we have a *global* version of 3.3.4.

3.4.5. Theorem: *Let* $\mathcal{N}$ *be a QP manifold constructed in the BFV formalism. The constrained system determined by the pair* $(\mathcal{N},\mathcal{Z}_\mathbf{Q})$ *is equivalent to the BFV theory on* $\mathcal{N}$ *(i.e., the respective algebras of equivalence classes of observables are isomorphic as Poisson algebras).*

Combining this with 3.2.1, we obtain a remarkable relation between the constrained systems specified by the respective pairs $(\mathcal{N}_0,\Sigma)$ and $(\mathcal{N},\mathcal{Z}_\mathbf{Q})$:

3.4.6. Corollary: The constrained systems $(\mathcal{N}_0,\Sigma)$ *and* $(\mathcal{N},\mathcal{Z}_\mathbf{Q})$ *are equivalent (the respective algebras of inequivalent observables are isomorphic as Poisson algebras).*

We also note a difference between the initial and the extended constraint surfaces Σ and $\mathcal{Z}_\mathbf{Q}$ in that Σ carries an action of the gauge generators $\{T_i,\cdot\}$, while $\mathcal{Z}_\mathbf{Q}$ is equipped with the zero locus antibracket. This is not unnatural, because the on-shell gauge symmetries are Hamiltonian vector fields with respect to the zero-locus antibracket, while inequivalent observables are (identified with) the characteristic functions of the zero-locus antibracket.

The consideration above applies at the classical level. The notion of the initial and the extended constraint surfaces is essentially classical and has no obvious counterparts at the quantum level. At the quantum level, restrictions to the constraint surface should be understood as restriction to some quotient of the full Hilbert space of the quantum system. We do not discuss this very interesting subject here, and refer instead to Ref. 18, where a related problem [19] was considered.

Finally, we note that there is a slightly different point of view on the interpretation of BFV observables in terms of the geometry of $\mathcal{Z}_{\mathbf{Q}}$. Namely, to each (odd) Poisson structure, one can associate the coboundary operator (differential) acting on antisymmetric tensor fields, with the action being the adjoint action of the Poisson bivector with respect to the Schouten–Nijenhuis bracket. Inequivalent observables are then the *zero-degree cohomology* of this differential on $\mathcal{Z}_{\mathbf{Q}}$ (tensors of zero degree are functions).

3.5. Observables, gauge symmetries, and zero-locus reduction in the BV quantization. The above can be reformulated for odd *QP* manifolds/BV quantization. In the BV formulation, the zero locus of $\mathbf{Q}=(S,\cdot)$, where S is the master action, is the stationary surface of S [provided the BV antibracket (,) is nondegenerate]. The BV observables are the cohomology of $\mathbf{Q}$ in the ghost number zero. The BV gauge symmetries are the vector fields of the form

$$X=(QB,\cdot), \tag{3.22}$$

and, thus, are Hamiltonian vector fields generated by trivial observables. Whenever the master action S is constructed via the BV prescription starting from a given initial action S_0, the zero locus of $\mathbf{Q}=(S,\cdot)$ is a certain extension of the stationary surface of the initial action S_0.
