is the Jacobi Hamiltonian expressed in the three different reference frames. The trace function K is found by integrating the system

$$\tfrac{3}{4}K_{,\bar{w}}+\tilde{R}_{,w}\tilde{G}+2\tilde{R}\tilde{G}_{,w}=0,\quad \tfrac{3}{4}K_{,w}+\bar{\tilde{R}}_{,\bar{w}}\tilde{G}+2\bar{\tilde{R}}\tilde{G}_{,\bar{w}}=0. \tag{38}$$

IV. ARBITRARY ENERGY INVARIANTS

Equation (34) gives the the necessary and sufficient condition for a two-dimensional Riemannian geometry to admit a fourth-rank Killing tensor. If we interpret the geometry according to Eq. (9) as that providing a natural mechanical system, we can derive the additional conditions that make the Killing tensor equations satisfied for every value of the energy E. We use the following form for the Kähler potential,

$$\mathcal{K}=E[z\bar{z}+2\Re\{\Lambda(z)\}]-\Psi, \tag{39}$$

where Λ is a holomorphic function independent of E and the real *prepotential* Ψ is such that

$$\Psi_{,z\bar{z}}=V. \tag{40}$$

In fact, no loss of generality is implied by letting the energy dependence of the Kähler potential be prescribed by Eq. (39) and by taking the function $S_4(z)$ to be energy independent, given that we only take interest in the cases for which the physical invariant I is a quartic polynomial in the momenta. Since the analogous statement was made without proving it for the cubic case,[10] we give a proof here. We begin by noting that the physical invariant I, obtained from the Jacobi invariant I_J of Eq. (36) according to prescription (16), can be written as

$$I=2\Re\{Sp_z^4+Bp_z^3 p_{\bar{z}}\}+C(p_z p_{\bar{z}})^2, \tag{41}$$

where

$$B=2RG^{-1},\quad C=\tfrac{3}{2}KG^{-2}. \tag{42}$$

Since the energy parameter E is now assumed to have been replaced by the physical Hamiltonian $\mathcal{H}$, the functions S, B and C will be dependent on the momenta p_z and $p_{\bar{z}}$, but clearly only through the combination $p_z p_{\bar{z}}$ that appears in $\mathcal{H}$. This implies that all five terms on the right hand side of Eq. (41) have to be quartic polynomials in the momenta since I is quartic by definition. This can be clearly seen by viewing I as a function of the two independent momenta functions $p_z p_{\bar{z}}$ and $p_z/p_{\bar{z}}$, rather than the momenta p_z and $p_{\bar{z}}$ themselves. Indeed, I can be recast into the form

$$I=(p_z p_{\bar{z}})^2 \sum_{k=-2}^{2} Q_k (p_z/p_{\bar{z}})^k, \tag{43}$$

where

$$Q_{-2}=\overline{Q_2}=S, \quad Q_{-1}=\overline{Q_1}=B, \quad Q_0=C. \tag{44}$$

Clearly, with the coefficients of $(p_z/p_{\bar{z}})^k$ only depending on the momenta through $p_z p_{\bar{z}}$, there can be no cancellation of possible nonquartic polynomial dependence in the individual terms. Hence, we conclude that the functions $S p_z^4$, $B p_z^4 p_{\bar{z}}$ and $C(p_z p_{\bar{z}})^2$, as well as the complex conjugates of the first two, must be quartic momenta polynomials. It immediately follows that S, B and C are polynomials in $(p_z p_{\bar{z}})^{-1}$, with coefficients depending only on z and $\bar{z}$, of degree zero, one and two, respectively. This directly proves the part of statement about S having no energy dependence. Moreover, since $G=E-V$ turns into $T=2p_z p_{\bar{z}}$ when E is replaced by $\mathcal{H}=T+V$, it now follows from Eqs. (42) that the functions R and K are restricted to be first respectively second degree polynomials in $p_z p_{\bar{z}}$, which is the same as saying that they must be the same type of polynomials in the energy parameter E, before making the substitution $E\to\mathcal{H}$. Using the second of Eqs. (33) and the conformal transformation formulas given by Eqs. (28) and (31), the function R can be expressed in terms of S and $\mathcal{K}$ according to

$$R=-2(S\mathcal{K}_{,zz}+\tfrac{1}{4}S'\mathcal{K}_{,z}), \tag{45}$$

while Eqs. (38), which notably are form invariant under conformal transformations, give that the trace K is given by integrating

$$\tfrac{3}{4}K_{,\bar{z}}+R_{,z}G+2RG_{,z}=0 \tag{46}$$

and its complex conjugate. Now, there is clearly no loss in generality to write the Kähler potential $\mathcal{K}$ as

$$\mathcal{K}=E[z\bar{z}+2\Re\{\Lambda(E,z)\}]-\Psi(z,\bar{z}), \tag{47}$$

with Λ being analytic in z and Ψ being energy independent. Moreover, since S is energy independent and R is a first degree polynomial in E, it follows from Eq. (45) that we are able to write $\Lambda(E,z)$ as

$$\Lambda(E,z)=\Lambda_0(z)+\Lambda_1(E,z), \tag{48}$$

where $\Lambda_1(E,z)$ does not contribute to Eq. (45). However, since Eq. (46) shows that $\Lambda(z)$ enters into $K_{,\bar{z}}$ only through R, we might as well set $\Lambda_1(E,z)$ to zero, which proves the fact that we could have taken $\Lambda(E,z)$ to be energy independent from the outset. We may finally note that with both R and G being first degree polynomials in E, we find from Eq. (46) that $K_{,\bar{z}}$ is a second degree polynomial in E, which indeed is a necessary and sufficient condition for K to be a second degree polynomial as well, up to addition of an irrelevant integration constant, which in principle can have an arbitrary energy dependence. This completes the proof that the form of the Kähler potential given by Eq. (39) is the most general one which is needed for full generality.

We are now in the position to solve the integrability condition at arbitrary energy. In the original z coordinates, Eq. (34) takes the form

$$\Im\{[S(\mathcal{K}_{,zzz}\mathcal{K}_{,z\bar{z}}+2\mathcal{K}_{,zz\bar{z}}\mathcal{K}_{,zz})+\tfrac{1}{2}S'(\mathcal{K}_{,zzz}\mathcal{K}_{,z}+\tfrac{5}{2}\mathcal{K}_{,zz}\mathcal{K}_{,z\bar{z}})+\tfrac{1}{4}S''\mathcal{K}_{,z\bar{z}}\mathcal{K}_{,z}]_{,z}\}=0. \tag{49}$$

Substituting the ansatz (39) into Eq. (49), this condition provides a second degree polynomial in E:

$$A_2E^2+A_1E+A_0=0. \tag{50}$$

The coefficients A_0, A_1, A_2 must vanish separately if the equation must hold for arbitrary energy. Therefore we obtain the three equations:

$$A_2=\Im\{[\Lambda'''S+\tfrac{5}{4}\Lambda''S'+\tfrac{1}{4}(\bar{z}+\Lambda')S'']_{,z}\}=0, \tag{51}$$

$$\begin{aligned}A_1=\Im\{[&S(\Psi_{,zzz}+2\Lambda'''\Psi_{,z\bar{z}}+2\Lambda''\Psi_{,zz\bar{z}})+\tfrac{1}{2}S'((\bar{z}+\Lambda')\Psi_{,zz\bar{z}}\\&+\tfrac{5}{2}(\Psi_{,zz}+\Lambda''\Psi_{,z\bar{z}}))+\tfrac{1}{4}S''(\Psi_{,z}+(\bar{z}+\Lambda')\Psi_{,z\bar{z}})]_{,z}\}=0,\end{aligned} \tag{52}$$

$$A_0=\Im\{[S(\Psi_{,zzz}\Psi_{,z\bar{z}}+2\Psi_{,zz\bar{z}}\Psi_{,zz})+\tfrac{1}{2}S'(\Psi_{,zzz}\Psi_{,z}+\tfrac{5}{2}\Psi_{,zz\bar{z}}\Psi_{,zz})+\tfrac{1}{4}S''\Psi_{,zz\bar{z}}\Psi_{,z}]_{,z}\}=0. \tag{53}$$

It turns useful to express the system of equations (51)–(53) also in the transformed coordinates since this simplifies the computations when the S function is of higher degree. Using the notation

$$F(w)=H^{-1}(z(w)) \tag{54}$$

for the inverse conformal transformation, the coefficients A_0, A_1, A_2 become

$$A_2=\Im\{[F'''\bar{F}F'\bar{F}'+2(F'')^2\bar{F}\bar{F}'+\Lambda'''F'\bar{F}'+\Lambda''F''\bar{F}']_{,w}\}, \tag{55}$$

$$A_1=\Im\{[(F'''\bar{F}+\Lambda''')\Psi_{,w\bar{w}}+2(F''\bar{F}+\Lambda'')\Psi_{,ww\bar{w}}+F'\bar{F}'\Psi_{,www}+2F''\bar{F}'\Psi_{,ww}]_{,w}\}, \tag{56}$$

$$A_0=\Im\{[\Psi_{,www}\Psi_{,w\bar{w}}+2\Psi_{,ww\bar{w}}\Psi_{,ww}]_{,w}\}. \tag{57}$$

Applying the differential operator

$$\frac{\partial^2}{\partial z\,\partial\bar{z}}$$

to Eq. (51), we get the condition

$$\Im\{S''''(z)\}=0, \tag{58}$$

so that the form allowed to the S function to have integrability at arbitrary energy is

$$S(z)=az^4+\beta z^3+\gamma z^2+\delta z+\epsilon,\quad a\in\mathbb{R},\quad \beta,\gamma,\delta,\epsilon\in\mathbb{C}. \tag{59}$$

In Ref. 2 it has been shown that, to get arbitrary energy quadratic invariants in systems with two degrees of freedom, the function $S(z)$ must satisfy the condition

$$\Im\{S_2''(z)\}=0, \tag{60}$$

that is, it must be a second degree polynomial with real second derivative. Together with the result (58) and the corresponding one obtained in the third-rank case,[10]

$$\Re\{S_3'''(z)\}=0, \tag{61}$$

we can guess that, as a general rule, the analytic function $S(z)$ representing the conformal part of a Killing tensor of arbitrary rank m is required to satisfy the condition

$$\begin{aligned}\Re\left\{\left(\frac{d}{dz}\right)^m S(z)\right\}&=0 \quad (m \text{ odd}),\\ \Im\left\{\left(\frac{d}{dz}\right)^m S(z)\right\}&=0 \quad (m \text{ even}).\end{aligned} \tag{62}$$

As a simple illustration of the solution of the above set of Equations (51)–(53), let us take

$$\Lambda=0, \quad S=b, \quad b\in\mathbb{R}.$$

Equation (51) is automatically satisfied. Equation (52) gives then the equation

$$\Psi_{,xxxy}-\Psi_{,xyyy}=0,$$

whose solution is

$$\Psi_{,xy}=F_1(x+y)+F_2(x-y).$$

Therefore

$$\Psi=f_1(x)+f_2(y)+f_3(x-y)+f_4(x+y).$$

The potential can then be written as

$$V=v_1(x)+v_2(y)+v_3(x-y)+v_4(x+y),$$

where $v_i=f_i''/4$, $i=1,2$ and $v_i=f_i''/2$, $i=3,4$. Equation (53) now gives

$$\begin{aligned}&(v_1''v_4+2v_4''v_1)+3v_1'v_4'-(v_1''v_3+2v_3''v_1)-3v_1'v_3'\\ &\quad-(v_2''v_4+2v_4''v_2)-3v_2'v_4'+(v_2''v_3+2v_3''v_2)-3v_2'v_3'=0.\end{aligned}$$

This equation coincides with that reported in the review of Hietarinta.[9] Its most relevant solutions, together with the expressions of the invariant, are listed in Table II later in this work.

In more general cases Eq. (52) is not as easily solved. The standard approach is to restrict the attention to special cases where $S(z)$ is either a homogeneous polynomial or a nonhomogeneous one which is simply a power of the corresponding function in lower rank cases. Even with such restrictions, many solutions can be obtained. Moreover, in all the solutions found it has turned out that $\Lambda(z)=\lambda z^2$, with λ a complex constant. In this way the coefficient

$$z\bar{z}+2\Re\{\Lambda(z)\}$$

of E in the Kähler potential (39) is always a Hermitian form in z. In the tables included in Sec. VI are listed all the solutions found.

V. STRONG INVARIANTS GENERATED BY LOWER-ORDER WEAK INVARIANTS

In the present section we want to introduce an alternative technique to identify classes of strongly integrable systems. This approach works only in a restricted subclass of systems, but is useful to get insight into the structure of general solutions. The key point of the idea is based on the construction of a generic weak integrable system corresponding to the existence of a second-

rank Killing tensor. Introducing the corresponding simplified Kähler potential in the general set of equations, we try to isolate single systems that satisfy them. The reader more interested in the general approach may wish to skip directly to Sec. VI with the results.

A. Quadratic invariants

The technique devised and applied in Ref. 2 amounts, in short synthesis, in a conformal transformation of the form (25). In the second-rank case, it turns out that it must be generated by an arbitrary holomorphic function $S_2(z)$ via the relation

$$H(z)=\int \frac{dz}{\sqrt{S_2(z)}}. \tag{63}$$

In the new coordinates X, Y, the Jacobi potential $G=E-V$ turns out to be of the form

$$G(X,Y)=\frac{A(X)+B(Y)}{|S_2(X,Y)|}, \tag{64}$$

where A and B are arbitrary functions of their arguments, which can be thought of as the *separation coordinates*. The conformal factor appearing in (64) can be written as

$$|S_2(X,Y)|=\sqrt{S_2(w)\overline{S_2}(\overline{w})}=F'(w)\overline{F'}(\overline{w}). \tag{65}$$

Moreover, we can write the transformation of the momenta in the form

$$p_X=Rp_x+Qp_y, \quad p_Y=-Qp_x+Rp_y, \tag{66}$$

where

$$R=\Re\{F'\}, \quad Q=\Im\{F'\}. \tag{67}$$

We can therefore write the expression of the second invariant in the Jacobi gauge as

$$I_S(p_X,p_Y,X,Y)=\tfrac{1}{2}(p_X^2-p_Y^2)+B(Y)-A(X). \tag{68}$$

As remarked in the Introduction, since to each Jacobi potential G pertains a specific dynamical system, we have that the found invariant is, in general, only a *weak* invariant for the standard Hamiltonian, in the sense that it provides a conserved quantity only at a given value of the energy (perhaps at *zero* energy). In fact, the Poisson bracket of the function (68) with the separated Hamiltonian

$$\mathcal{H}_S=\frac{\tfrac{1}{2}(p_X^2+p_Y^2)-A(X)-B(Y)}{|S_2|} \tag{69}$$

is

$$\{I_S,\mathcal{H}_S\}=\frac{E}{|S_2|}(p_X|S_2|_{,X}-p_Y|S_2|_{,Y}). \tag{70}$$

B. Quartic strong invariants generated by quadratic weak invariants

In Sec. IV, the system of equations (51)–(53) was treated and many nontrivial solutions were found. A general solution is, however, very difficult to find due to the complicated structure of the full system. Here we want instead to exploit the above results to generate new solutions simply starting from the assumption of the existence of a second-rank Killing tensor.

As a foreword to this approach, let us make the following remark. Let us suppose to have made the choice of the S_2 function generating the conformal transformation which gives the second invariant (68) satisfying Eq. (70). Denoting by $\mathcal{H}_0$ the numerator appearing in the expression (69) of the Hamiltonian, the Poisson bracket of a generic higher-order invariant with $\mathcal{H}_S$ can be written as

$$\{I_J,\mathcal{H}_S\}=\frac{1}{|S_2|}\{I_J,\mathcal{H}_0\}-\frac{\mathcal{H}_0}{|S_2|^2}\{I_J,|S_2|\}=\frac{\{I_J,\mathcal{H}_0\}-E\{I_J,|S_2|\}}{|S_2|}. \tag{71}$$

In the case of a second-order invariant in the standard form of (68), this reduces to (70). On the other hand, let us introduce the *null* Hamiltonian

$$\mathcal{H}_\mathcal{N}=(\mathcal{H}_S-E)|S_2|=\mathcal{H}_0-E|S_2|. \tag{72}$$

The Poisson bracket of the invariant with $\mathcal{H}_\mathcal{N}$ is

$$\{I_J,\mathcal{H}_\mathcal{N}\}=\{I_J,\mathcal{H}_0\}-E\{I_J,|S_2|\}. \tag{73}$$

Since $|S_2|$ is a non-null positive function everywhere, Eqs. (71) and (73) are equivalent for what concerns the conservation of I_J. The conceptual difference relies on the fact that, whereas Eq. (73) expresses the conservation of I_J in the dynamics provided by $\mathcal{H}_\mathcal{N}$ at *zero "energy,"* Eq. (71) expresses the conservation of I_J in the dynamics provided by $\mathcal{H}_S$ at *arbitrary* energy. Note that the true energy E enters into $\mathcal{H}_\mathcal{N}$ as an arbitrary parameter.

In the light of this argument, the procedure to look for new integrable systems is the following: regard the null Hamiltonian, written in the form

$$\mathcal{H}_\mathcal{N}=\tfrac{1}{2}(p_X^2+p_Y^2)-\tilde{G}(X,Y), \tag{74}$$

where

$$\tilde{G}(X,Y)=A(X)+B(Y)+E|S_2(X,Y)|, \tag{75}$$

as the system in which to find a new conserved quantity at zero energy. If the search of this new conserved quantity is successful, then *it is a strongly conserved quantity for the original Hamiltonian* $\mathcal{H}_S$, *which is therefore integrable at arbitrary energy*. Going backwards with respect to the previous approach, we take the potential of Eq. (75) and use it to solve the system (33). Once we have the solution, we can write the integrability condition (34) in the form

$$\Im\{R_{,ww}G+3R_{,w}G_{,w}+2RG_{,ww}\}=0. \tag{76}$$

Note that in the remaining part of this section we suppress the "tilde" over $\tilde{G}$ and $\tilde{R}$ to simplify the notation. The solution of this equation provides the explicit form of the functions $A(w+\overline{w})$ and $B(w-\overline{w})$ that allow for the integrability of the system. Finally, the integration of the equations for the trace (38) completes the solution.

In the development of this approach, we find it convenient to use the separating real variables. Equations (33) involving the Kähler potential therefore become

$$\begin{aligned} G(X,Y)&=\tfrac{1}{4}(\mathcal{K}_{,XX}+\mathcal{K}_{,YY}),\\ R(X,Y)&=\tfrac{1}{2}(\mathcal{K}_{,YY}-\mathcal{K}_{,XX})+i\mathcal{K}_{,XY}, \end{aligned} \tag{77}$$

and the integrability condition (76) can be written in the form

$$[(\Im\{R\})_{,XX}-(\Im\{R\})_{,YY}-2(\Re\{R\})_{,XY}]G+3[((\Im\{R\})_{,X}-(\Re\{R\})_{,Y})G_{,X}-((\Re\{R\})_{,X}+(\Im\{R\})_{,Y})G_{,Y}]+2[\Im\{R\}(G_{,XX}-G_{,YY})-2\Re\{R\}G_{,XY}]=0. \tag{78}$$

The system (38) finally becomes

$$\begin{aligned} K_{,X}&=-\tfrac{4}{3}((\Re\{R\})_{,X}+(\Im\{R\})_{,Y}))G-\tfrac{8}{3}(\Re\{R\}G_{,X}+\Im\{R\}G_{,Y}),\\ K_{,Y}&=-\tfrac{4}{3}((\Im\{R\})_{,X}-(\Re\{R\})_{,Y})G-\tfrac{8}{3}(\Im\{R\}G_{,X}-\Re\{R\}G_{,Y}). \end{aligned} \tag{79}$$

To solve system (33), we need only consider the contribution to the potential (75) coming from the conformal factor:

$$G_C=E|S_2(X,Y)|. \tag{80}$$

Recalling the relation (63) between the conformal transformation and the S_2 function in the quadratic case and the definition of the inverse transformation (54), the above source term can also be written as

$$G_C=E\sqrt{S_2(w)\overline{S_2}(\overline{w})}=EF'(w)\overline{F'}(\overline{w}). \tag{81}$$

The solutions of system (33) for this term are

$$\begin{aligned} \mathcal{K}_C&=E(F(w)\overline{F}(\overline{w})+2\Re\{\Lambda(w)\}),\\ R_C&=-2E(F''(w)\overline{F}(\overline{w})+\Lambda''(w)), \end{aligned} \tag{82}$$

so that the complete solution is therefore

$$\begin{aligned} \mathcal{K}&=4\int\left[\int AdX\right]dX+4\int\left[\int BdY\right]dY+E(F(w)\overline{F}(\overline{w})+2\Re\{\Lambda(w)\}),\\ R&=2(B(Y)-A(X))-2E(F''(w)\overline{F}(\overline{w})+\Lambda''(w)). \end{aligned} \tag{83}$$

This solution is subject to the integrability condition (76). In analogy with the general approach, substituting in it the solution (83) we get a second degree polynomial in E of the form (50). This equation must be satisfied for every value of the arbitrary parameter E, so that each coefficient must separately vanish. The three coefficients are in this case

$$\begin{aligned} A_2&=-4i\Im\{(F''''\overline{F}+\Lambda'''')F'\overline{F'}+5F'''F''\overline{F'}\,\overline{F}+3\Lambda'''F''\overline{F'}+2\Lambda''F'''\overline{F'}\},\\ A_1&=4i\Im\{3(B_{,w}-A_{,w})F''\overline{F'}-3(A_{,w}+B_{,w})(F'''\overline{F}+\Lambda''')+2(B-A)F'''\overline{F'}\\ &\quad-2(A_{,ww}+B_{,ww})(F''\overline{F}+\Lambda'')-(A+B)F''''\overline{F}\},\\ A_0&=2i\Im\{6(B_{,w}-A_{,w})(B_{,w}+A_{,w})+4(B-A)(A_{,ww}+B_{,ww})\}. \end{aligned} \tag{84}$$

From the properties of the functions A and B, A_0 is identically zero. Limiting ourselves to the simplest case $\Lambda=0$, the condition that A_2 vanishes turns out to be

$$\Im\{(F''''F'+5F'''F'')\overline{FF'}\}=0, \tag{85}$$

so that it is necessary and sufficient that

$$F''''F'+5F'''F''=6aFF',\quad a\in\mathbb{R}. \tag{86}$$

The general solution is

$$(F')^4 = aF^4 + \gamma F^2 + \delta F + \epsilon, \tag{87}$$

where β, γ, δ, ϵ are complex constants. We see that solution (87) is a subset of the general result (58) so that we can state that the simplified approach presented here consists in choosing a function in the set

$$S_2(z) = \sqrt{az^4 + \gamma z^2 + \delta z + \epsilon}. \tag{88}$$

The equation $A_1 = 0$ then picks the functions A and B that are compatible with strong integrability. The practical advantage with respect to the application of the general technique of Sec. IV is that equation $A_0 = 0$ is automatically satisfied.

C. Class iz^2 systems

To illustrate the simplified approach, in this subsection we present a class of simple systems which are strongly integrable with a quartic invariant and, at zero energy, are separable with a quadratic invariant.

Consider then the function

$$S_2(z) = iz^2. \tag{89}$$

In the solution (87) it corresponds to the choice

$$a = -1, \quad \gamma = \delta = \epsilon = 0. \tag{90}$$

This is the simplest polynomial form which does not satisfy the constraint (60) and therefore gives a potential which is not automatically integrable at arbitrary energy with a quadratic second invariant. The corresponding conformal transformation is given by

$$w = H(z) = \frac{1-i}{\sqrt{2}} \ln z. \tag{91}$$

Using polar coordinates, so that

$$\begin{gathered} z = x + iy = r \exp(i\theta), \\ r = \sqrt{x^2 + y^2}, \quad \theta = \arctan(y/x), \end{gathered} \tag{92}$$

in terms of real variables, we get

$$X = \frac{1}{\sqrt{2}}(\theta + \ln r), \quad Y = \frac{1}{\sqrt{2}}(\theta - \ln r). \tag{93}$$

We point out, in passing, that that in Ref. 2, in Eqs. (102)–(104) corresponding to Eq. (93) above, there is a misprint and the coordinate r must be substituted with its natural logarithm. It follows that the potential given by

$$V(\theta, r) = -\frac{A(\theta + \ln r) + B(\theta - \ln r)}{r^2} \tag{94}$$

is integrable at zero energy for arbitrary functions A and B. The common factor r^{-2} is due to the fact that, from the choice of Eq. (89), we have

$$|S(X,Y)| = r^2 = \mathrm{e}^{\sqrt{2}(X-Y)}. \tag{95}$$

The solutions (83) are

$$\mathcal{K}=4\int\left[\int A dX\right]dX+4\int\left[\int B dY\right]dY+E\mathrm{e}^{\sqrt{2}(X-Y)} \tag{96}$$

and

$$R=2((B(Y)-A(X))-2iE\mathrm{e}^{\sqrt{2}(X-Y)}. \tag{97}$$

The integrability condition (78) becomes

$$4E\mathrm{e}^{\sqrt{2}(X-Y)}[A''-B''+3\sqrt{2}(A'+B')+4(A-B)]=0. \tag{98}$$

This equation splits into

$$A''+3\sqrt{2}A'+4A=c,\quad B''-3\sqrt{2}B'+4B=c, \tag{99}$$

with solutions

$$A(X)=a_1\mathrm{e}^{-\sqrt{2}X}+a_2\mathrm{e}^{-2\sqrt{2}X}+\frac{c}{4},\quad B(Y)=b_1\mathrm{e}^{\sqrt{2}Y}+b_2\mathrm{e}^{2\sqrt{2}Y}+\frac{c}{4}. \tag{100}$$

The potential

$$V(r,\theta)=-\frac{c}{2r^2}-\frac{a_1\mathrm{e}^{-\theta}+b_1\mathrm{e}^{\theta}}{r^3}-\frac{a_2\mathrm{e}^{-2\theta}+b_2\mathrm{e}^{2\theta}}{r^4} \tag{101}$$

is therefore integrable. As a simple concrete example, let us take

$$a_1=b_1=c=0,\quad a_2=b_2=-\tfrac{1}{2}, \tag{102}$$

so that the potential is

$$V=\frac{\mathrm{e}^{2\theta}+\mathrm{e}^{-2\theta}}{2r^4}, \tag{103}$$

which is a known result mentioned in the review by Hietarinta. The second invariant has the form

$$I=p_\theta^4+\mathrm{ch}2\theta p_r^2+2\frac{\mathrm{sh}2\theta}{r}p_r p_\theta+3\frac{\mathrm{ch}2\theta}{r^2}p_\theta^2+2\frac{2-\mathrm{sh}2\theta}{r^4}. \tag{104}$$

VI. CLASSIFICATION OF HAMILTONIANS ADMITTING A QUARTIC INVARIANT AT ARBITRARY ENERGY

In the tables included in this section we present all the solutions we have found of systems admitting an independent invariant quartic in the momenta. Some of them are new. For all cases we present the potential V (up to linear transformations of the coordinates and a linear rescaling of the potential itself) as well as the quartic invariant I, thereby making it possible to compare directly the results with Hietarinta's classification of 1987.[9] For the cases which are superintegrable we also indicate, using the notation of Ref. 9, to which of the real quadratic cases (1), (2), (4) or (7) a given system belongs.

A peculiar property of our solutions is that all but one have a conformal factor generated by function S of even degree in z, with real coefficients. As a consequence of this, the solutions obtained can be expressed in terms of the coordinate systems of separable potentials. In fact, since from (28) and (54), the transformation is

TABLE I. Systems for which $S(z)$ is of zero degree.

$$H(z)=F^{-1}(w(z))=\int dz[S_4(z)]^{-1/4}, \tag{105}$$

with S of the form

$$S_4(z)=\pm(az^2+\beta z+\gamma),\quad a\in\mathbb{R},\quad \beta,\gamma\in\mathbb{C}, \tag{106}$$

we are actually taken back to the coordinate transformations to separable variables given by an S_2 function satisfying the condition (60), for which the transformation is of the form[2]

$$H(z)=\int dz[S_2(z)]^{-1/2}. \tag{107}$$

As an exception to this situation, we have also found a solution with S_4 of third degree in z, by the method of the *coupling constant metamorphosis* (see Ref. 9) which is described in Sec. VI B.

A. Systems for which $S(z)$ is of even degree

The simplest case is that with S_4 of degree zero. This case corresponds simply to rotations and translations of the Cartesian coordinates. In Table I we list the new solutions obtained and, for comparison, the quartic integrable potential of Ref. 13. In Table II the already known solutions of this class are listed together with the proper references. The first sequence of items corresponds to

TABLE II. Systems for which $S(z)$ is of zero degree (continued).

the simple solution sketched at the end of Sec. IV. All solutions are generated by $S_4=\pm 1$: actually, there is nothing fundamental in the choice of sign which has been made only for sake of comparison with already known results.

We then have some solutions with S_4 of degree two and four in z. In Table III, two new interesting classes of integrable systems are presented with S_4 of degree two. They are more conveniently treated using the parabolic coordinates provided by the conformal transformation generated by $S_4=16z^2$. In Table IV, a class of integrable systems generated by $S_4=-z^4$ is presented, generalizing the separability in polar coordinates. Here, the choice of sign is dictated by the transformation used in the simplified approach of Sec. V C above, but to the same system one can also arrive with the general method using the "proper" transformation given by $S_4=z^4$.

B. A system for which $S(z)$ is of degree three

In order to describe how we get this new solution, we briefly recall the method based on the coupling constant metamorphosis.[9] We introduce a null Hamiltonian which, in analogy with Eq. (72), is defined as

$$\mathcal{H}_{\mathcal{N}}=(\mathcal{H}-E)|S_4|^2. \tag{108}$$

TABLE III. Systems for which $S(z)$ is of second degree.

$S(z)=16z^2$

$\mathcal{K}=\frac{2}{3}E(2x^2+y^2)+f(X)+g(Y)+C(XY)^{\alpha}$

$X=\sqrt{\frac{r+x}{2}},\quad Y=\sqrt{\frac{r-x}{2}},\quad r=\sqrt{x^2+y^2}=X^2+Y^2$

$f(X)=-36\,2^{-1/3}cX^{4/3}-\frac{18\,2^{1/3}}{5}aX^{8/3},\quad g(Y)=-36\,2^{-1/3}dY^{4/3}-\frac{18\,2^{1/3}}{5}bY^{8/3},\quad \alpha=4/3$

$V=\frac{a(r+x)^{1/3}+b(r-x)^{1/3}+c(r+x)^{-1/3}+d(r-x)^{-1/3}}{r}+\frac{k}{y^{2/3}},\quad k=-\frac{2^{1/3}C}{36}$

$I=J^2-8ky^{1/3}\left[p_xp_\theta-\frac{y}{r}(a(r+x)^{1/3}+b(r-x)^{1/3}+c(r+x)^{-1/3}+d(r-x)^{-1/3})\right]-8k[a(r-x)^{2/3}+b(r+x)^{2/3}]$

$J=p_yp_\theta+\frac{(r+x)[b(r-x)^{1/3}+d(r-x)^{-1/3}]-(r-x)[a(r+x)^{1/3}+c(r+x)^{-1/3}]}{r}+2\frac{kx}{y^{2/3}}$

$p_\theta=xp_y-yp_x$

$f(X)=\frac{1}{14}CX^8+8a\log X-\frac{1}{10}cX^{-4},\quad g(Y)=\frac{1}{14}CY^8+8b\log Y-\frac{1}{10}dY^{-4},\quad \alpha=4$

$V=\frac{1}{r}\left[\frac{a}{r+x}+\frac{b}{r-x}+\frac{c}{(r+x)^3}+\frac{d}{(r-x)^3}\right]+\frac{1}{2}kr^2,\quad k=-\frac{C}{2}$

$I=J^2-ky^3\left\{p_xp_\theta-\frac{y}{r}\left[\frac{a}{r+x}+\frac{b}{r-x}+\frac{c}{(r+x)^3}+\frac{d}{(r-x)^3}\right]+\frac{1}{4}kx^2y\right\}-k[a(r-x)^2+b(r+x)^2]$

$J=p_yp_\theta+\frac{1}{r}\left\{(r+x)\left[\frac{b}{r-x}+\frac{d}{(r-x)^3}\right]-(r-x)\left[\frac{a}{r+x}+\frac{c}{(r+x)^3}\right]\right\}+\frac{1}{2}kxy^2$

TABLE IV. Systems for which $S(z)$ is of third degree.

$S(z)=64z^3$

$\mathcal{K}=\frac{2}{7}E(4x^2+3y^2)+f(X)+g(Y)-\frac{4}{3}\mu(X^4+Y^4)$

$X=\sqrt{2}r^{1/4}\cos\frac{\theta}{4}=r^{1/4}\sqrt{1+\cos\frac{\theta}{2}},\quad Y=\sqrt{2}r^{1/4}\sin\frac{\theta}{4}=r^{1/4}\sqrt{1-\cos\frac{\theta}{2}}$

$r=\sqrt{x^2+y^2}=(X^2+Y^2)^2/4,\quad \theta=\arctan(y/x)$

$f(X)=32a\log X-\frac{8}{5}cX^{-4},\quad g(Y)=32b\log Y-\frac{8}{5}dY^{-4}$

$V=\frac{\mu}{r}+\frac{a}{r^2(1+\cos\theta/2)}+\frac{b}{r^2(1-\cos\theta/2)}+\frac{c}{r^3(1+\cos\theta/2)^3}+\frac{d}{r^3(1-\cos\theta/2)^3}$

$I=J^2+\Gamma_1\Pi-\Gamma_2$

$J=\Delta+B(Y)-A(X)-\mathcal{H}(X^2-Y^2)^3+4\mu(X^2-Y^2)$

$\Delta=\frac{2}{\sqrt{r}}\left[\cos\frac{\theta}{2}(r^2p_r^2-p_\theta^2)-\sin\frac{\theta}{2}rp_rp_\theta\right]$

$\Pi=\frac{2}{\sqrt{r}}\left[\sin\frac{\theta}{2}(r^2p_r^2-p_\theta^2)+\cos\frac{\theta}{2}rp_rp_\theta\right]$

$\Gamma_1=16\mathcal{H}X^3Y^3$

$\Gamma_2=16\mathcal{H}[\mathcal{H}(2X^6Y^6+3X^4Y^4(X^4+Y^4))-8\mu X^4Y^4-aY^4-bX^4]$

$\mathcal{H}$ is the Hamiltonian of the system, i.e., $\mathcal{H}=\frac{1}{2}\left(p_r^2+\frac{p_\theta^2}{r^2}\right)+V$

$p_\theta=xp_y-yp_x,\quad rp_r=xp_x+yp_y$

TABLE V. Systems for which $S(z)$ is of fourth degree.

$$S(z)=-z^4$$

$$\mathcal{K}=E\mathrm{e}^{\sqrt{2}(X-Y)}+f(X)+g(Y)-k(X^2+Y^2)$$

$$X=\frac{1}{\sqrt{2}}(\theta+\ln r),\quad Y=\frac{1}{\sqrt{2}}(\theta-\ln r)$$

$$A(X)=a_1\mathrm{e}^{-\sqrt{2}X}+a_2\mathrm{e}^{-2\sqrt{2}X},\quad A=f''/4$$

$$B(Y)=b_1\mathrm{e}^{\sqrt{2}Y}+b_2\mathrm{e}^{2\sqrt{2}Y},\quad B=g''/4$$

$$V=\frac{k}{r^2}+\frac{a\mathrm{e}^{\theta}+b\mathrm{e}^{-\theta}}{r^3}+\frac{c\mathrm{e}^{2\theta}+d\mathrm{e}^{-2\theta}}{r^4}$$

$$I=p_\theta^4+(c\mathrm{e}^{2\theta}+d\mathrm{e}^{-2\theta})p_r^2+2\left[a\mathrm{e}^{\theta}-b\mathrm{e}^{-\theta}+\frac{1}{r}(c\mathrm{e}^{2\theta}-d\mathrm{e}^{-2\theta})\right]p_rp_\theta$$
$$+\left[2k+\frac{2}{r}(a\mathrm{e}^{\theta}+b\mathrm{e}^{-\theta})+\frac{3}{r^2}(c\mathrm{e}^{2\theta}+d\mathrm{e}^{-2\theta})\right]p_\theta^2$$
$$+\frac{1}{r^2}[2k(c\mathrm{e}^{2\theta}+d\mathrm{e}^{-2\theta})-(a\mathrm{e}^{\theta}-b\mathrm{e}^{-\theta})^2]$$
$$+\frac{4}{r^3}(bc\mathrm{e}^{\theta}+ad\mathrm{e}^{-\theta})+\frac{1}{r^4}(c^2\mathrm{e}^{4\theta}+d^2\mathrm{e}^{-4\theta}+6cd)$$

The second case of Table III has a null Hamiltonian which, if expressed in the new coordinates, has the form

$$\mathcal{H}_{\mathcal{N}}=\tfrac{1}{2}(p_X^2+p_Y^2)-A(X)-B(Y)+4C(X^2+Y^2)^3-4E(X^2+Y^2). \tag{109}$$

Then, if the term $(X^2+Y^2)^3$ can be identified with the conformal factor associated to a new conformal transformation, we may interpret C as a *new* energy and E as a *new* coupling constant. We get a new potential which is strongly integrable with an invariant of the same nature as before. This is the process known as coupling constant metamorphosis.

In the present instance, we have that the transformation must be still of the form (105) or, equivalently,

$$F'(w)=S_4^{1/4}, \tag{110}$$

where, for simplicity, we still denote the new variable as $w=X+iY$, so that $|w|^2=X^2+Y^2$. Since the conformal factor is assumed to be $(X^2+Y^2)^3$, we get

$$|F'|^2\sim|w|^6. \tag{111}$$

Therefore, $F(w)$ must be of the order w^4, so that

$$w=H(z)\sim z^{1/4}. \tag{112}$$

From (105) we get

$$H'(z)\sim z^{-3/4}, \tag{113}$$

so that, finally,

$$S_4(z)\sim z^3. \tag{114}$$

We end up with a solution of third degree for S which had escaped a previous direct analysis. The new integrable Hamiltonian is

$$\mathcal{H}=\frac{1}{2}\left(p_r^2+\frac{p_\theta^2}{r^2}\right)+\frac{\mu}{r}+\frac{a}{r^2(1+\cos\theta/2)}+\frac{b}{r^2(1-\cos\theta/2)}+\frac{c}{r^3(1+\cos\theta/2)^3}+\frac{d}{r^3(1-\cos\theta/2)^3}$$
$$=\tilde{E}, \tag{115}$$

where $\tilde{E}=C$ is the new energy and $\mu=-E$ is the new coupling constant. Table V reports the form of the coordinate transformation and the expression of the second invariant.

VII. CONCLUSIONS

In this work we have explored the set of natural two-dimensional Hamiltonian systems admitting a second invariant which is a polynomial in the momenta of degree four. The approach is based on the Jacobi geometrization described in Ref. 2, where the linear and quadratic cases were also explored, and in Ref. 10, where the cubic cases were treated. The approach allows a unified treatment of integrability at fixed and arbitrary energy, even if here we have limited ourselves to obtaining the list, as complete as possible, of strongly integrable systems. There are several areas in which this approach can be still useful. The most natural seems to be that of looking for systems admitting higher order invariants of which there exist only a few known examples.

Moreover, other properties of invariants up to degree four are still worth of analysis. In Ref. 14 we have examined the properties of weakly integrable systems with quadratic second invariants and found interesting behaviors both in the integrable regime and in the generic nonintegrable one. One may wonder about the information higher order weak invariants can give on the dynamics of nonintegrable systems. It is reasonable to believe that increasing the order can improve the reliability of these functions when interpreting them as effective invariants approximately conserved in regular portions of phase-space. It would also be interesting to look for other examples of quartic invariants which correspond to lower rank Killing tensors on fixed energy surfaces.

Multisymplectic geometry and multisymplectic Preissman scheme for the KP equation

Tingting Liu[a] and Mengzhao Qin[b]
CCAST (World Laboratory), P.O. Box 8730, Beijing 100080, People's Republic of China and Institute of Computational Mathematics, Academy of Mathematics and Systems Sciences, Chinese Academy of Sciences, P.O. Box 2719, Beijing, 100080, People's Republic of China

(Received 25 July 2001; accepted for publication 17 April 2002)

The multisymplectic structure of the KP equation is obtained directly from the variational principal. Using the covariant De Donder–Weyl Hamilton function theories, we reformulate the KP equation to the multisymplectic form which was proposed by Bridges. From the multisymplectic equation, we can derive a multisymplectic numerical scheme of the KP equation which can be simplified to the multisymplectic 45 points scheme. © *2002 American Institute of Physics.*
[DOI: 10.1063/1.1487444]

I. INTRODUCTION

The generalized Kadomtsev–Petviashvili (GKP) equation is

$$(u_t+\partial_x f(u)+u_{xxx})_x+\sigma u_{yy}=0 \quad (t>0,-\infty<x,y<\infty), \tag{1.1}$$

where σ is a constant, and $f(u)$ is some smooth function. The usually KP equation occurs for $f(u)$ quadratic and it is regarded as a two-dimensional generalization of the Korteweg–de Vries (KdV) equation. It describes the evolution of long water waves of small amplitude if they are weakly two dimensional. In the case of $f(u)=3u^2$ and $\sigma=-3$, Eq. (1.1) is usually called the KPI equation, whereas the KPII equation with $f(u)=3u^2$ and $\sigma=3$. As a soliton equation important from analytical and numerical point of view, the KP equation is one of the few known completely integrable equations in the multidimensional soliton equations. Thus, in the last few years, considerable attention has been paid to the KP equation. Although considerable interest has been focused on the KP equation, the numerical scheme analysis literature for the KP equation is extremely small. As far as we are aware of, Katsis proposed the explicit finite difference method,[1] the results of evolution of the lump solution for the KP equation was given by Minzoni,[2] Wang *et al.* studied the instability of a generalized KP equation,[3] Feng and Mitsui took the linearized implicit method to the KP equation.[4]

In this paper, we try to describe the KP equation in the language of multisymplectic geometry. Recently, for first order field theory, i.e., the Lagrangian density depends on the state variables and their first order derivatives, Marsden, Patrix, and Shkoller[5] derived numerical methods for the first order field theories. However the Lagrangian density of the KP equation is not first-order, therefore MPS theory cannot be applied directly. In Ref. 6, the authors focus their attention on the KdV equation whose Langrangian density is second order. The Langrangian density of the KP equation is truly third-order. In this paper, we give the multisymplectic structure of the KP equation directly from the variational principal. In Ref. 7, the author proposed that the Cartan form is not necessarily unique, and we find it was caused by the higher-order mixed multiple integral in using Stokes' formula in actual calculus variation.

In Lagrange mechanics, we know the Euler–Lagrange equation can be written as

[a]Electronic mail: ttliu@lsec.cc.ac.cn
[b]Electronic mail: qmz@lsec.cc.ac.cn

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}^i}-\frac{\partial L}{\partial q^i}=0. \tag{1.2}$$

Taking the Legendre transform of Lagrange density $L:p^i=\partial L/\partial \dot{q}^i$, we can rewrite Eq. (1.2) as regular Hamilton equation,

$$\begin{cases} \dfrac{dp^i}{dt}=-\dfrac{\partial H}{\partial q^i}, \\ \dfrac{dq^i}{dt}=\dfrac{\partial H}{\partial p^i}, \end{cases} \tag{1.3}$$

where $H=p^i\dot{q}^i-L(q^i,\dot{q}^i,t)$. With the covariant De Donder–Weyl Hamilton function theories[8] we can reformulate the partial differential equation to the following form:

$$\begin{cases} \dfrac{\partial H}{\partial \pi_i^\mu}=\partial_\mu q^i, \\ \dfrac{\partial H}{\partial q^i}=-\partial_\mu \pi_i^\mu, \end{cases} \tag{1.4}$$

where $\pi_i^\mu=\partial L/\partial\partial_\mu q^i$. According to this method, we can rewrite the KP equation to the multisymplectic form that was introduced by Bridges.[9]

Multisymplectic equations have the important multisymplectic conservation laws. In the numerical study, we also hope that the numerical approximations can preserve the multisymplectic conservation laws. Similar to the method,[10] we show that the Preissman scheme is a multisymplectic scheme for the KP equation. Though the Preissman scheme is multisymplectic, it needs more computational memory, so we reduce it to a multisymplectic 45 points scheme. Using the 45 points scheme, we get some numerical results on soliton and solitary waves over long time intervals.

In Sec. II, we describe the multisymplectic geometry of the KP equation entirely in the framework of the variational principal. Section III is devoted to the analysis of the multisymplectic Preissman scheme and reduce it to a multisymplectic 45 points scheme. In Sec. IV, some numerical results on soliton and solitary waves over long time intervals be given.

II. MULTISYMPLECTIC GEOMETRY OF THE KP EQUATION

We now review some aspects of multisymplectic geometry.

Let X be an orientable $(n+1)$-dimensional parameter space (which is usually space–time) and let $\pi_{XY}:Y\to X$ be a fiber over X. Section $\varphi:X\to Y$ of this covariant configuration bundle is the physical fields. Coordinates on X are denoted by x^μ, $\mu=1,2,\ldots,n,0$. In general, x^0 denotes the time coordinate. The parameter n denotes the number of spatial variables. In this paper, we just discuss the case of $n>0$. Adapted coordinates on Y are y^A along the fibers $Y_x=\pi_{XY}^{-1}(x), x\in X$, $A=1,2,\ldots,N$. N denotes the fiber's dimensions. Consider a kth order Lagrangian density L, viewed as a fiber-preserving map $L:J^kY\to\wedge^{n+1}X$. $J^k(Y)$ denotes the kth-order jet bundle over Y which can be induced by $J^1(\cdots(J^1(Y)))$. We let T_xX denote the tangent space of X at x, and denote the derivative of the map π_{XY} in the direction w by $T_{\pi_{XY}}\cdot w$.

At first, we introduce the first jet bundle.

Definition 2.1: The first jet bundle over Y is a fiber bundle denoted by $J^1(Y)$ whose fiber over $y\in Y_x=\pi_{XY}^{-1}(x)$, $x\in X$ consists of those linear mappings $\gamma:T_xX\to T_yY$ satisfying

$$T_{\pi_{XY}}\circ\gamma=\text{Identity}.$$

If $\varphi:X\to Y$ is a section of Y, $j^1(\varphi)$ is a section of $J^1(Y)$ and in coordinates, $j^1(\varphi)$ is given by

$$(x^\mu, \varphi^A(x^\mu), \partial_\mu \varphi^A(x^\mu)), \quad \mu = 1,2,\ldots,n,0.$$

Similarly, higher order jet bundle $J^m(Y)$ is defined by $J^1(J^{m-1}(Y))$.

Definition 2.2: The kth-order jet bundle over Y is a fiber bundle denoted by $J^k(Y)$ whose fiber over $\gamma \in J^{k-1}(Y)_y, y \in Y$ consists of those linear mappings $s: T_x X \to T_\gamma J^{k-1}(Y)$ satisfying

$$T_{\pi_{X, J^{k-1}Y}} \circ s = \text{Identity}.$$

We let $j^k(\varphi) = j^1(\cdots(j^1(\varphi))): x \to T_x j^{k-1}(\varphi)$ denote kth-order jet prolongation of the section $\varphi: X \to Y$, in which $j^{k-1}(\varphi)$ is a section of jet bundle $J^{k-1}(Y)$. Thus, $j^k(\varphi)$ is given in coordinates

$$(x^\mu, \varphi^A(x^\mu), \partial_\mu \varphi^A(x^\mu), \ldots, \partial_{\mu_n} \partial_{\mu_{n-1}} \cdots \partial_{\mu_0} \varphi^A(x^\mu)).$$

Given a kth-order Lagrangian density $L: J^k Y \to \wedge^{n+1} x$, the basis geometric object in the classical calculus of variations is the $(n+1)$-form θ_L on $J^{2k-1}(Y)$, which was called the Cartan form.

The KP equation can be written as

$$(2u_t + 6uu_x + u_{xxx})_x + \sigma u_{yy} = 0. \tag{2.1}$$

The 2 multiplying u_t is added for notational convenience, it can be eliminated by scaling t. In this paper, we consider the KPI equation.

To put the KP equation in the variational frame work, we let $\varphi_{xx} = u$, then φ satisfies equation,

$$2\varphi_{xxxt} + 6\varphi_{xx}\varphi_{xxxx} + 6\varphi_{xxx}^2 + \varphi_{xxxxxx} + \sigma \varphi_{xxyy} = 0. \tag{2.2}$$

The search for a variational principle is equivalent to the inverse problem of the calculus of variations, i.e., the existence and formulation of variational principles for systems of nonlinear partial differential equations. The existence of a variational principle for a differential equation is equivalent to determining whether or not an operator is a potential operator. According to Vainberg theorem,[11] in order that operator N be a potential operator, to summarize, it is necessary and sufficient that the Gateau derivative of the operator N is symmetry. The theorem is stated in terms of the Gateau derivative, but we assume that the Frechet derivative exists in application. Let N be an operator which defined in an appropriate function space E (typically E is Banach space), then N be a potential operator if $N'_u = \tilde{N}'_u$, where

$$N'_u \varphi = \lim_{\varepsilon \to 0} \frac{N(u + \varepsilon\varphi) - N(u)}{\varepsilon} = \left[\frac{\partial}{\partial \varepsilon} N(u + \varepsilon \varphi) \right] \Bigg|_{\varepsilon = 0},$$

and $\tilde{N}'_u$ is the adjoint operator of N'_u. If the operator is a potential operator, the potential F is given by

$$F = \int u \int_0^1 N(\lambda u) d\lambda dV,$$

where $\int dV$ represents integration over the physical domain and $\int_0^1 d\lambda$ represents integration over the scalar variable λ. We test the operator

$$N(\varphi) = 2\varphi_{xxxt} + 6\varphi_{xx}\varphi_{xxxx} + 6\varphi_{xxx}^2 + \varphi_{xxxxxx} + \sigma \varphi_{xxyy}$$

and find $N'_\varphi = \tilde{N}'_\varphi$. Hence,

$$F(\varphi)=\int \varphi\int_0^1 N(\lambda\varphi)d\lambda dV$$

$$=\int \varphi\int_0^1 [2\lambda\varphi_{xxxt}+6\lambda^2\varphi_{xx}\varphi_{xxxx}+6\lambda^2\varphi_{xxx}^2+\lambda\varphi_{xxxxxx}+\sigma\lambda\varphi_{xxyy}]d\lambda dV$$

$$=\int \varphi\left(\varphi_{xxxt}+2\varphi_{xxx}^2+2\varphi_{xx}\varphi_{xxxx}+\tfrac{1}{2}\varphi_{xxxxxx}+\frac{\sigma}{2}\varphi_{xxyy}\right)dV.$$

To obtain $F(u)$ in a more familiar form, integrate by part and discard the integration over the boundary since it has nothing with the Lagrangian density, then we get the potential

$$F(\varphi)=\int\left(\varphi_{xx}\varphi_{xt}-\tfrac{1}{2}\varphi_{xxx}^2+\frac{\sigma}{2}\varphi_{xy}^2+\varphi_{xx}^3\right)dV.$$

We can determine that the Lagrangian density for Eq. (2.2) is

$$L(j^3(\varphi))=\left(\varphi_{xx}\varphi_{xt}-\frac{1}{2}\varphi_{xxx}^2+\frac{\sigma}{2}\varphi_{xy}^2+\varphi_{xx}^3\right)dx\wedge dy\wedge dt.$$

Corresponding to Lagrangian density $L(j^3(\varphi))$, the action function is defined as the following:

$$S(\varphi)=\int_U L(j^3(\varphi)),\quad U \text{ is an open set of } X.$$

Let G be the Lie group of π_{XY} bundle automorphisms η_Y covering η_X. Denote η_Y^λ a smooth path in G such that

$$\overline{\varphi}=\eta_Y^\lambda\circ\varphi\circ(\eta_X^\lambda)^{-1}.$$

The vector field of η_Y^λ is

$$V=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\overline{\varphi}=\begin{bmatrix}V^x\\V^y\\V^t\\V^\varphi\end{bmatrix}.$$

We say that φ is an extremum of S is

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0}S(\overline{\varphi})=0.$$

Now we consider the variation

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0}S(\overline{\varphi})=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_{\eta_X^\lambda U}\left(\overline{\varphi_{xx}}\,\overline{\varphi_{xt}}-\frac{1}{2}\overline{\varphi}_{xxx}^2+\frac{\sigma}{2}\overline{\varphi}_{xy}^2+\overline{\varphi}_{xx}^3\right)d\overline{x}\wedge d\overline{y}\wedge d\overline{t},$$

where

$$\eta_X^\lambda\begin{bmatrix}x\\y\\t\end{bmatrix}=\begin{bmatrix}\overline{x}\\\overline{y}\\\overline{t}\end{bmatrix}.$$

A direct computation shows

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0} S(\overline{\varphi}) = I_1 + I_2,$$

in which

$$I_1 = \int_U -(2\varphi_{xxxt} + 6\varphi_{xx}\varphi_{xxxx} + 6\varphi_{xxx}^2 + \varphi_{xxxxxx} + \sigma\varphi_{xxyy})(V^\varphi - \varphi_x V^x - \varphi_y V^y - \varphi_t V^t)dx\wedge dy\wedge dt, \tag{2.3}$$

$$\begin{aligned} I_2 = \int_{\partial U}\Bigg[&\left(\varphi_{xx}\varphi_{xt} - \frac{1}{2}\varphi_{xxx}^2 + \frac{\sigma}{2}\varphi_{xy}^2 + \varphi_{xx}^3\right)V^t + \varphi_{xx}(V_x^\varphi - \varphi_x V_x^x - \varphi_y V_x^y - \varphi_t V_x^t - \varphi_{xx}V^x - \varphi_{xy}V^y \\ &- \varphi_{xt}V^t)\Bigg]dx\wedge dy\Bigg[-\left(\varphi_{xx}\varphi_{xt} - \frac{1}{2}\varphi_{xxx}^2 + \frac{\sigma}{2}\varphi_{xy}^2 + \varphi_{xx}^3\right)V^y + \sigma\varphi_{xy}(V_x^\varphi - \varphi_x V_x^x - \varphi_y V_x^y - \varphi_t V_x^t \\ &- \varphi_{xx}V^x - \varphi_{xy}V^y - \varphi_{xt}V^t)\Bigg]dx\wedge dt + \Bigg[\left(\varphi_{xx}\varphi_{xt} - \frac{1}{2}\varphi_{xxx}^2 + \frac{\sigma}{2}\varphi_{xy}^2 + \varphi_{xx}^3\right)V^x + (\varphi_{xt} + 3\varphi_{xx}^2 \\ &+ \varphi_{xxxx})(V_x^\varphi - \varphi_x V_x^x - \varphi_y V_x^y - \varphi_t V_x^t - \varphi_{xx}V^x - \varphi_{xy}V^y - \varphi_{xt}V^t) - \varphi_{xxx}(V_{xx}^\varphi - \varphi_x V_{xx}^x - 2\varphi_{xx}V_x^x \\ &- \varphi_y V_{xx}^y - 2\varphi_{xy}V_x^y - \varphi_t V_{xx}^t - 2\varphi_{xt}V_x^t - \varphi_{xxy}V^y - \varphi_{xxt}V^t - \varphi_{xxx}V^x) + (-2\varphi_{xxt} - 6\varphi_{xx}\varphi_{xxx} \\ &- \sigma\varphi_{xyy} - \varphi_{xxxxx})(V^\varphi - \varphi_x V^x - \varphi_y V^y - \varphi_t V^t)\Bigg]dy\wedge dt. \end{aligned} \tag{2.4}$$

In Ref. 7, the author introduced the Lepagean equivalents which is a generalization of the Poincare–Cartan form and proposed the Carton form is not necessarily unique for higher order. The author also pointed out that every Lagrangian density has a Lepagean equivalent on $J^{2k-1}Y$. It turns out that Lepagean equivalents exists on jet bundles of order $2k-1$ or higher, but not necessarily on jet bundle of lower order. The author presented that: As being the principal part of a Lepagean equivalents, the Cartan form always exist and are typically nonunique unless $k=1$. We find it is caused by the higher-order mixed multiple integral in using Stokes' formula in actually calculus of variations. By I_2, we can define a Cartan form,

$$\begin{aligned} \theta_L = &\left(\frac{1}{2}\varphi_{xxx}^2 - \frac{\sigma}{2}\varphi_{xy}^2 + 2\varphi_x\varphi_{xxt} + 6\varphi_x\varphi_{xx}\varphi_{xxx} + \sigma\varphi_x\varphi_{xyy} + \varphi_x\varphi_{xxxxx} - \varphi_{xx}\varphi_{xt} - 2\varphi_{xx}^3 - \varphi_{xx}\varphi_{xxxx}\right)dx\wedge dy\wedge dt \\ &+ (-2\varphi_{xxt} - 6\varphi_{xx}\varphi_{xxx} - \sigma\varphi_{xyy} - \varphi_{xxxxx})d\varphi\wedge dy\wedge dt \\ &+ (\varphi_{xt} + 3\varphi_{xx}^2 + \varphi_{xxxx})d\varphi_x\wedge dy\wedge dt - \varphi_{xxx}d\varphi_{xx}\wedge dy\wedge dt - \sigma\varphi_{xy}d\varphi_x\wedge dx\wedge dt + \varphi_{xx}d\varphi_x\wedge dx\wedge dy. \end{aligned} \tag{2.5}$$

Since

$$j^5(\varphi)^*dx = dx, \quad j^5(\varphi)^*dy = dy, \quad j^5(\varphi)^*dt = dt,$$

$$j^5(\varphi)^*d\varphi = \varphi_x dx + \varphi_y dy + \varphi_t dt,$$

$$j^5(\varphi)^*d\varphi_x = \varphi_{xx}dx + \varphi_{xy}dy + \varphi_{xt}dt,$$

$$j^5(\varphi)^*d\varphi_{xx} = \varphi_{xxx}dx + \varphi_{xxy}dy + \varphi_{xxt}dt,$$

we have

$$I_2 = \int_{\partial U} j^5(\varphi)^*(j^5(V)\rfloor\theta_L).$$

Here $j^5(V)$ is the jet prolongation of the vector field V.[12] The multisymplectic form is the 4-form $\Omega_L=-d\theta_L$. Form θ_L defines a multisymplectic structure on jet bundle $J^5(Y)$.

Now, we consider the Euler–Lagrange equation for the action function $S(\varphi)$.

Since $L(j^3(\overline{\varphi}))=j^5(\overline{\varphi})^*\theta_L$, we have

$$\begin{aligned}\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_{\eta_X^\lambda U}L(j^3(\overline{\varphi}))&=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_{\eta_X^\lambda U}j^5(\overline{\varphi})^*\theta_L\\&=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_{\eta_X^\lambda U}j^5(\eta_Y^\lambda\circ\varphi\circ(\eta_X^\lambda)^{-1})^*\theta_L\\&=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_{\eta_X^\lambda U}((\eta_X^\lambda)^{-1})^*j^5(\varphi)^*j^5(\eta_Y^\lambda)^*\theta_L\\&=\left.\frac{d}{d\lambda}\right|_{\lambda=0}\int_U j^5(\varphi)^*j^5(\eta_Y^\lambda)^*\theta_L=\int_U j^5(\varphi)^*\mathcal{L}_{j^5(V)}\theta_L\end{aligned}$$

in which the symbol $\mathcal{L}$ denotes the Lie derivative.

By the Cartan's Magic formula,[13]

$$\mathcal{L}_{j^5(V)}\theta_L=-j^5(V)\rfloor\Omega_L+d(j^5(V)\rfloor\theta_L).$$

We can obtain

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0}S(\overline{\varphi})=-\int_U j^5(\varphi)^*(j^5(V)\rfloor\Omega_L)+\int_{\partial U}j^5(\varphi)^*(j^5(V)\rfloor\theta_L).$$

If V is a vector field with compact support, we have

$$\int_{\partial U}j^5(\varphi)^*(j^5(V)\rfloor\theta_L)=0.$$

Hence, a necessary condition for φ to be an extremum is that

$$\int_U j^5(\varphi)^*(j^5(V)\rfloor\Omega_L)=0$$

for any V with compact support. Compute the integral and obtain that

$$\begin{aligned}j^5(\varphi)^*(j^5(V)\rfloor\Omega_L)=&(2\varphi_{xxxt}+6\varphi_{xx}\varphi_{xxxx}+6\varphi_{xxx}^2+\varphi_{xxxxxx}+\sigma\varphi_{xxyy})\\&\times(V^\varphi-\varphi_xV^x-\varphi_yV^y-\varphi_tV^t).\end{aligned}\tag{2.6}$$

Remark: We can get the Euler–Lagrange equation from the vertical variation V^φ, and the V^x and V^y directions horizontal variations gives the law of conservation of momentum. The law of conservation of energy can be obtained along time-direction horizontal variation.

Taking the π_{XY}-vertical vector field V and using the standard method from the calculus of variations, we obtain that φ satisfies

$$2\varphi_{xxxt}+6\varphi_{xx}\varphi_{xxxx}+6\varphi_{xxx}^2+\varphi_{xxxxxx}+\sigma\varphi_{xxyy}=0,\tag{2.7}$$

i.e., Eq. (2.2). So, for any vector field V,

$$j^5(\varphi)^*(j^5(V)\rfloor\Omega_L)=0\tag{2.8}$$

holds. A short computation verifies that

$$j^5(\varphi)^*(P\rfloor\Omega_L)=0, \tag{2.9}$$

where $P\in TJ^5(Y)$ and is $T_{\pi_{Y,J^5(Y)}}$-vertical. For any $W\in TJ^5(Y)$, there exists the vector field V, such that

$$W=j^5(V)+P. \tag{2.10}$$

So, by (2.8)–(2.10), if φ is an extremum of S, $j^5(\varphi)^*(W\rfloor\Omega_L)$ mush vanish for any vector field $W\in TJ^5(Y)$, thus, we get the Euler–Lagrange equation,

$$j^5(\varphi)^*(W\rfloor\Omega_L)=0 \tag{2.11}$$

for any vector field $W\in TJ^5(Y)$. In the following part, we consider the multisymplectic form formula and a corollary of the multisymplectic form formula. About the multisymplectic form formula for first order field theories, please refer to Ref. 14.

Theorem 2.3: Let η_Y^λ and ξ_Y^λ demote two one-parameter symmetry groups of Eq. (2.11) and the corresponding vector fields are V and W. Then we have the multisymplectic form formula,

$$\int_{\partial U} j^5(\varphi)^*(j^5(V)\rfloor j^5(W)\rfloor\Omega_L)=0. \tag{2.12}$$

Proof: Since $j^5[W,V]=[j^5(W),j^5(V)]$, from (2.11) we have

$$\begin{aligned}0&=\int_U j^5(\varphi)^*(j^5[W,V]\rfloor\Omega_L)\\&=\int_U j^5(\varphi)^*([j^5(W),j^5(V)]\rfloor\Omega_L)\\&=\int_U j^5(\varphi)^*(\mathcal{L}_{j^5(W)}(j^5(V)\rfloor\Omega_L)-j^5(V)\rfloor\mathcal{L}_{j^5(W)}\Omega_L).\end{aligned} \tag{2.13}$$

Because η_Y^λ and ξ_Y^λ are two one-parameter symmetry groups of Eq. (2.11), so for any vector field $Q\in TJ^5(Y)$, we have

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0} j^5(\eta_Y^\lambda\circ\varphi\circ(\eta_X^\lambda)^{-1})^*(Q\rfloor\Omega_L)=j^5(\varphi)^*\mathcal{L}_{j^5(V)}(Q\rfloor\Omega_L)=0, \tag{2.14}$$

$$\left.\frac{d}{d\lambda}\right|_{\lambda=0} j^5(\xi_Y^\lambda\circ\varphi\circ(\xi_X^\lambda)^{-1})^*(Q\rfloor\Omega_L)=j^5(\varphi)^*\mathcal{L}_{j^5(W)}(Q\rfloor\Omega_L)=0. \tag{2.15}$$

Thus (2.13) becomes

$$\begin{aligned}0&=-\int_U j^5(\varphi)^*(j^5(V)\rfloor\mathcal{L}_{j^5(W)}\Omega_L)\\&=-\int_U j^5(\varphi)^*(j^5(V)\rfloor d(j^5(W)\rfloor\Omega_L))\\&=\int_U j^5(\varphi)^*(j^5(V)\rfloor d(\mathcal{L}_{j^5(W)}\theta_L)).\end{aligned} \tag{2.16}$$

$j^5(V)\rfloor j^5(W)\rfloor\Omega_L$ can be written as

$$j^5(V)\rfloor j^5(W)\rfloor\Omega_L = j^5(V)\rfloor d(j^5(W)\rfloor\theta_L) - j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L$$
$$= \mathcal{L}_{j^5(V)}(j^5(W)\rfloor\theta_L) - j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L - d(j^5(V)\rfloor j^5(W)\rfloor\theta_L). \tag{2.17}$$

So from Stokes' formula we can obtain that

$$\int_{\partial U} j^5(\varphi)^*(j^5(V)\rfloor j^5(W)\rfloor\Omega_L) = \int_{\partial U} j^5(\varphi)^*(\mathcal{L}_{j^5(V)}(j^5(W)\rfloor\theta_L) - j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L - d(j^5(V)\rfloor j^5(W)\rfloor\theta_L))$$
$$= \int_U j^5(\varphi)^* d(\mathcal{L}_{j^5(V)}(j^5(W)\rfloor\theta_L) - j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L)$$
$$= \int_U j^5(\varphi)^*(\mathcal{L}_{j^5(V)}\mathcal{L}_{j^5(W)}\theta_L + \mathcal{L}_{j^5(V)}(j^5(W)\rfloor\Omega_L) - d(j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L)). \tag{2.18}$$

By

$$\mathcal{L}_{j^5(V)}\mathcal{L}_{j^5(W)}\theta_L = j^5(V)\rfloor d(\mathcal{L}_{j^5(W)}\theta_L) + d(j^5(V)\rfloor\mathcal{L}_{j^5(W)}\theta_L), \tag{2.19}$$

we have

$$\int_{\partial U} j^5(\varphi)^*(j^5(V)\rfloor j^5(W)\rfloor\Omega_L) = \int_U j^5(\varphi)^*(j^5(V)\rfloor d(\mathcal{L}_{j^5(W)}\theta_L) + \mathcal{L}_{j^5(V)}(j^5(W)\rfloor\Omega_L)). \tag{2.20}$$

Hence, by (2.14) and (2.16), we obtain

$$\int_{\partial U} j^5(\varphi)^*(j^5(V)\rfloor j^5(W)\rfloor\Omega_L) = 0.$$

Although the covariant Legendre transformation (or complete Legendre transformation) which transform time and space variable simultaneously are not necessarily unique, for this fixed Cartan form θ_L, we can construct corresponding covariant Lengendre transformation of Lagrangian density L. Let $v=\varphi_x$, $u=\varphi_{xx}$, $w=\varphi_{xy}$, $p=\varphi_{xt}$, taking the covariant Legendre transform of Lagrangian density L,

$$p^x = -2\varphi_{xxt} - 6\varphi_{xx}\varphi_{xxx} - \sigma\varphi_{xyy} - \varphi_{xxxxx},$$

$$p^{xx} = \varphi_{xt} + 3\varphi_{xx}^2 + \varphi_{xxxx}, \quad p^{xt} = \varphi_{xx},$$

$$p^{xy} = \sigma\varphi_{xy}, \quad p^{xxx} = -\varphi_{xxx}.$$

According to the covariant De Donder–Weyl Hamilton function theories[8] and the multisymplectic concept introduced by Bridges,[9] the KP equation can be reformulated as a system of ten first-order partial differential equations which can be written in the form,

$$M\mathbb{Z}_t + K\mathbb{Z}_x + L\mathbb{Z}_y = \nabla S(\mathbb{Z}),$$

$$\mathbb{Z} = (\varphi, v, u, w, p, p^x, p^{xx}, p^{xy}, p^{xt}, p^{xxx})^T \in \mathbb{R}^{10}, \tag{2.21}$$

where

$$M=\begin{pmatrix}
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&1&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&-1&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0
\end{pmatrix},$$

$$K=\begin{pmatrix}
0&0&0&0&0&1&0&0&0&0\\
0&0&0&0&0&0&1&0&0&0\\
0&0&0&0&0&0&0&0&0&1\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
-1&0&0&0&0&0&0&0&0&0\\
0&-1&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&-1&0&0&0&0&0&0&0
\end{pmatrix},$$

$$L=\begin{pmatrix}
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&1&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&-1&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0
\end{pmatrix},$$

$$S(\mathbb{Z})=up+\tfrac{1}{2}(p^{xxx})^2+\frac{\sigma}{2}w^2+u^3-p^xv-p^{xx}u-p^{xt}p-p^{xy}w.$$

∇S is the gradient of S with respect to the standard inner product on $\mathbb{R}^{10}$. The system (2.21) is a Hamiltonian formulation of the KP equation on a multisymplectic structure. Although this formulation is not the best, we give a constructive method to get multisymplectic form which was proposed by Bridges.[9] Attention should be paid to (2.21) that it is different from the multisymplectic form of the KP equation in Ref. 15. For Eq. (2.21), there is a conservation law,

$$\partial_t(d\mathbb{Z}\wedge Md\mathbb{Z})+\partial_x(d\mathbb{Z}\wedge Kd\mathbb{Z})+\partial_y(d\mathbb{Z}\wedge Ld\mathbb{Z})=0. \tag{2.22}$$

Substituting M, K, L into (2.22) leads to

$$\begin{aligned}&\frac{\partial}{\partial t}(d\varphi_x\wedge d\varphi_{xx})+\frac{\partial}{\partial x}(d\varphi\wedge(-6\varphi_{xxx}d\varphi_{xx}-6\varphi_{xx}d\varphi_{xxx}-\sigma d\varphi_{xyy}-2d\varphi_{xxt}-d\varphi_{xxxxx})\\&+d\varphi_x\wedge(6\varphi_{xx}d\varphi_{xx}+d\varphi_{xt}+d\varphi_{xxxx})+d\varphi_{xx}\wedge d(-\varphi_{xxx}))+\frac{\partial}{\partial y}(d\varphi_x\wedge d(\sigma\varphi_{xy}))=0.\end{aligned} \tag{2.23}$$

This multisymplectic conservation law (2.22) is consistent with our Theorem 2.3. We can regard the conservation law (2.23) as a corollary of the Theorem 2.3. Let V, W be π_{XY}-vertical and have the expressions $V^\varphi(\partial/\partial\varphi)$, $W^\varphi(\partial/\partial\varphi)$. Thus the corresponding $j^5(V)$ and $j^5(W)$ have the coordinate expressions

$$\begin{aligned}&(V^\varphi,V^\varphi_x,V^\varphi_y,V^\varphi_t,V^\varphi_{xx},V^\varphi_{yy},V^\varphi_{tt},V^\varphi_{xt},V^\varphi_{xy},V^\varphi_{yt},V^\varphi_{xxx},V^\varphi_{xtx},V^\varphi_{xxy},V^\varphi_{xtt},\\&V^\varphi_{xyy},V^\varphi_{ttt},V^\varphi_{yyy},V^\varphi_{tyy},V^\varphi_{tty},V^\varphi_{xxxx},V^\varphi_{xxyy},V^\varphi_{xxtt},V^\varphi_{xxxy},V^\varphi_{xxxt},V^\varphi_{xyyy},V^\varphi_{xttt},\\&V^\varphi_{tttt},V^\varphi_{yyyy},V^\varphi_{tyyy},V^\varphi_{ttyy},V^\varphi_{ttty},V^\varphi_{xxxxx},V^\varphi_{xxxxy},V^\varphi_{xxxxt},V^\varphi_{xxxyy},V^\varphi_{xxxtt},\\&V^\varphi_{xxyyy},V^\varphi_{xxttt},V^\varphi_{xyyyy},V^\varphi_{xtttt},V^\varphi_{yyyyy},V^\varphi_{ttttt},V^\varphi_{yyyyt},V^\varphi_{yyytt},V^\varphi_{yyttt},V^\varphi_{ytttt})\end{aligned}$$

and

$$\begin{aligned}&(W^\varphi,W^\varphi_x,W^\varphi_y,W^\varphi_t,W^\varphi_{xx},W^\varphi_{yy},W^\varphi_{tt},W^\varphi_{xt},W^\varphi_{xy},W^\varphi_{yt},W^\varphi_{xxx},W^\varphi_{xtx},W^\varphi_{xxy},W^\varphi_{xtt},\\&W^\varphi_{xyy},W^\varphi_{ttt},W^\varphi_{yyy},W^\varphi_{tyy},W^\varphi_{tty},W^\varphi_{xxxx},W^\varphi_{xxyy},W^\varphi_{xxtt},W^\varphi_{xxxy}W^\varphi_{xxxt},W^\varphi_{xyyy},W^\varphi_{xttt},\\&W^\varphi_{tttt},W^\varphi_{yyyy},W^\varphi_{tyyy},W^\varphi_{ttyy},W^\varphi_{ttty},W^\varphi_{xxxxx},W^\varphi_{xxxxy},W^\varphi_{xxxxt},W^\varphi_{xxxyy},W^\varphi_{xxxtt},W^\varphi_{xxyyy},\\&W^\varphi_{xxttt},W^\varphi_{xyyyy},W^\varphi_{xtttt},W^\varphi_{yyyyy},W^\varphi_{ttttt},W^\varphi_{yyyyt},W^\varphi_{yyytt},W^\varphi_{yyttt},W^\varphi_{ytttt}).\end{aligned}$$

We can compute

$$\begin{aligned}j^5(\varphi)^*(j^5(V)\rfloor j^5(W)\rfloor\Omega_L)=&(W^\varphi_{xx}V^\varphi_x-W^\varphi_xV^\varphi_{xx})dx\wedge dy+(\sigma W^\varphi_xV^\varphi_{xy}-\sigma W^\varphi_{xy}V^\varphi_x)dx\wedge dt\\&+[W^\varphi_{xx}V^\varphi_{xxx}-W^\varphi_{xxx}V^\varphi_{xx}-W^\varphi_x(V^\varphi_{xt}+6\varphi_{xx}V^\varphi_{xx}+V^\varphi_{xxxx})+V^\varphi_x(W^\varphi_{xt}+6\varphi_{xx}W^\varphi_{xx}+W^\varphi_{xxxx})\\&+V^\varphi(-2W^\varphi_{xxt}-6\varphi_{xx}W^\varphi_{xxx}-6\varphi_{xxx}W^\varphi_{xx}-\sigma W^\varphi_{xyy}-W^\varphi_{xxxxx})\\&+W^\varphi(2V^\varphi_{xxt}+6\varphi_{xx}V^\varphi_{xxx}+6\varphi_{xxx}V^\varphi_{xx}+\sigma V^\varphi_{xyy}+V^\varphi_{xxxxx})]dy\wedge dt.\end{aligned}$$

By the Stokes' formula, we can obtain

$$\begin{aligned}&\int_U\frac{\partial}{\partial t}(W^\varphi_{xx}V^\varphi_x-W^\varphi_xV^\varphi_{xx})dx\wedge dy\wedge dt-\frac{\partial}{\partial y}(\sigma W^\varphi_xV^\varphi_{xy}-\sigma W^\varphi_{xy}V^\varphi_x)dx\wedge dy\wedge dt+\frac{\partial}{\partial x}[W^\varphi_{xx}V^\varphi_{xxx}-W^\varphi_{xxx}V^\varphi_{xx}\\&-W^\varphi_x(V^\varphi_{xt}+6\varphi_{xx}V^\varphi_{xx}+V^\varphi_{xxxx})+V^\varphi_x(W^\varphi_{xt}+6\varphi_{xx}W^\varphi_{xx}+W^\varphi_{xxxx})+V^\varphi(-2W^\varphi_{xxt}-6\varphi_{xx}W^\varphi_{xxx}-6\varphi_{xxx}W^\varphi_{xx}\\&-\sigma W^\varphi_{xyy}-W^\varphi_{xxxxx})+W^\varphi(2V^\varphi_{xxt}+6\varphi_{xx}V^\varphi_{xxx}+6\varphi_{xxx}V^\varphi_{xx}+\sigma V^\varphi_{xyy}+V^\varphi_{xxxxx})]dx\wedge dy\wedge dt=0.\end{aligned}$$

Since U is arbitrary, we get

$$\begin{aligned}&\frac{\partial}{\partial t}(W^\varphi_{xx}V^\varphi_x-W^\varphi_xV^\varphi_{xx})-\frac{\partial}{\partial y}(\sigma W^\varphi_xV^\varphi_{xy}-\sigma W^\varphi_{xy}V^\varphi_x)+\frac{\partial}{\partial x}[W^\varphi_{xx}V^\varphi_{xxx}-W^\varphi_{xxx}V^\varphi_{xx}-W^\varphi_x(V^\varphi_{xt}+6\varphi_{xx}V^\varphi_{xx}+V^\varphi_{xxxx})\\&+V^\varphi_x(W^\varphi_{xt}+6\varphi_{xx}W^\varphi_{xx}+W^\varphi_{xxxx})+V^\varphi(-2W^\varphi_{xxt}-6\varphi_{xx}W^\varphi_{xxx}-6\varphi_{xxx}W^\varphi_{xx}-\sigma W^\varphi_{xyy}-W^\varphi_{xxxxx})\\&+W^\varphi(2V^\varphi_{xxt}+6\varphi_{xx}V^\varphi_{xxx}+6\varphi_{xxx}V^\varphi_{xx}+\sigma V^\varphi_{xyy}+V^\varphi_{xxxxx})]=0.\end{aligned} \tag{2.24}$$

If we let

$$M^t=\begin{pmatrix}0&0&0&0&0&0&0&0&0&0\\0&0&1&0&0&0&0&0&0&0\\0&-1&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\end{pmatrix},$$

$$M^x=\begin{pmatrix}0&0&-6\varphi_{xxx}&0&0&-6\varphi_{xx}&-\sigma&-2&0&-1\\0&0&6\varphi_{xx}&0&1&0&0&0&1&0\\6\varphi_{xxx}&-6\varphi_{xx}&0&0&0&-1&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&-1&0&0&0&0&0&0&0&0\\6\varphi_{xx}&0&1&0&0&0&0&0&0&0\\\sigma&0&0&0&0&0&0&0&0&0\\2&0&0&0&0&0&0&0&0&0\\0&-1&0&0&0&0&0&0&0&0\\1&0&0&0&0&0&0&0&0&0\end{pmatrix},$$

$$M^y=\begin{pmatrix}0&0&0&0&0&0&0&0&0&0\\0&0&0&\sigma&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&-\sigma&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\\0&0&0&0&0&0&0&0&0&0\end{pmatrix},$$

$$M^t(x,y)=x^TM^ty, M^x(x,y)=x^TM^xy, M^y(x,y)=x^TM^yy, \tag{2.25}$$

and set

$$j^5(V)=(V^\varphi,V^\varphi_x,V^\varphi_{xx},V^\varphi_{xy},V^\varphi_{xt},V^\varphi_{xxx},V^\varphi_{xyy},V^\varphi_{xxt},V^\varphi_{xxxx},V^\varphi_{xxxxx}),$$

$$j^5(W)=(W^\varphi,W^\varphi_x,W^\varphi_{xx},W^\varphi_{xy},W^\varphi_{xt},W^\varphi_{xxx},W^\varphi_{xyy},W^\varphi_{xxt},W^\varphi_{xxxx},W^\varphi_{xxxxx}),$$

the other coordinates vanish. Then conservation law (2.24) can be written as

$$\frac{\partial}{\partial t}M^t(j^5(V),j^5(W))+\frac{\partial}{\partial x}M^x(j^5(V),j^5(W))+\frac{\partial}{\partial y}M^y(j^5(V),j^5(W))=0. \tag{2.26}$$

Also, since the translation invariance of the KP equation, we choose $V=W=\varphi$ and take it into (2.26), and conservation law (2.26) becomes

$$\begin{aligned}&\frac{\partial}{\partial t}(d\varphi_x\wedge d\varphi_{xx})+\frac{\partial}{\partial x}(d\varphi\wedge(-6\varphi_{xxx}d\varphi_{xx}-6\varphi_{xx}d\varphi_{xxx}-\sigma d\varphi_{xyy}-2d\varphi_{xxt}-d\varphi_{xxxxx})\\&\quad+d\varphi_x\wedge(6\varphi_{xx}d\varphi_{xx}+d\varphi_{xt}+d\varphi_{xxxx})+d\varphi_{xx}\wedge d(-\varphi_{xxx}))+\frac{\partial}{\partial y}(d\varphi_x\wedge d(\sigma\varphi_{xy}))=0,\end{aligned} \tag{2.27}$$

i.e., the conservation law (2.23).

In the numerical study, the multisymplectic conservation law can be used to design multisymplectic numerical schemes, i.e., numerical schemes which can preserve the multisymplectic conservation law.

III. MULTISYMPLECTIC PREISSMAN SCHEME FOR THE KP EQUATION

In this section, we consider the multisymplectic Preissman scheme for the KP equation. Equation (2.21) can be reformulated as

$$\begin{cases}\dfrac{\partial p^x}{\partial x}=0,\\[2mm]\dfrac{\partial p^{xx}}{\partial x}+\dfrac{\partial p^{xy}}{\partial y}+\dfrac{\partial p^{xt}}{\partial t}=-p^x,\\[2mm]\dfrac{\partial p^{xxx}}{\partial x}=p+3u^2-p^{xx},\\[2mm]\sigma w-p^{xy}=0,\\[2mm]u-p^{xt}=0,\\[2mm]\dfrac{\partial \varphi}{\partial x}=v,\\[2mm]\dfrac{\partial v}{\partial x}=u,\\[2mm]\dfrac{\partial v}{\partial y}=w,\\[2mm]\dfrac{\partial v}{\partial t}=p,\\[2mm]\dfrac{\partial u}{\partial x}=p^{xxx}.\end{cases} \tag{3.1}$$

For convenience, we assume that the spacing of the grid points in the x,y,t directions is uniform, respectively. We apply the implicit midpoint discretization in time and in space to (3.1),

and obtain

$$
\begin{cases}
\dfrac{p^{x}_{i+1,j+(1/2),k+(1/2)}-p^{x}_{i,j+(1/2),k+(1/2)}}{\Delta x}=0,\\
\dfrac{p^{xx}_{i+1,j+(1/2),k+(1/2)}-p^{xx}_{i,j+(1/2),k+(1/2)}}{\Delta x}+\dfrac{p^{xy}_{i+(1/2),j+1,k+(1/2)}-p^{xy}_{i+(1/2),j,k+(1/2)}}{\Delta y}\\
\quad+\dfrac{p^{xt}_{i+(1/2),j+(1/2),k+1}-p^{xt}_{i+(1/2),j+(1/2),k}}{\Delta t}=-p^{x}_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{p^{xxx}_{i+1,j+(1/2),k+(1/2)}-p^{xxx}_{i,j+(1/2),k+(1/2)}}{\Delta x}=p_{i+(1/2),j+(1/2),k+(1/2)}+3(u_{i+(1/2),j+(1/2),k+(1/2)})^{2}\\
\qquad\qquad-p^{xx}_{i+(1/2),j+(1/2),k+(1/2)},\\
\sigma w_{i+(1/2),j+(1/2),k+(1/2)}=p^{xy}_{i+(1/2),j+(1/2),k+(1/2)},\\
u_{i+(1/2),j+(1/2),k+(1/2)}=p^{xt}_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{\varphi_{i+1,j+(1/2),k+(1/2)}-\varphi_{i,j+(1/2),k+(1/2)}}{\Delta x}=v_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{v_{i+1,j+(1/2),k+(1/2)}-v_{i,j+(1/2),k+(1/2)}}{\Delta x}=u_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{v_{i+(1/2),j+1,k+(1/2)}-v_{i+(1/2),j,k+(1/2)}}{\Delta y}=w_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{v_{i+(1/2),j+(1/2),k+1}-v_{i+(1/2),j+(1/2),k}}{\Delta t}=p_{i+(1/2),j+(1/2),k+(1/2)},\\
\dfrac{u_{i+1,j+(1/2),k+(1/2)}-u_{i,j+(1/2),k+(1/2)}}{\Delta x}=p^{xxx}_{i+(1/2),j+(1/2),k+(1/2)},
\end{cases}
\tag{3.2}
$$

where Δx is the x-direction step, Δy is the y-direction step, Δt is the time step, and $u_{i+(1/2),j+(1/2),k+(1/2)}=u(i\Delta x+(\Delta x/2),j\Delta y+(\Delta y/2),k\Delta t+(\Delta t/2)$, the others are similar.

In fact, the discretization result leads to the Preissman scheme,

$$
\begin{aligned}
&\frac{1}{\Delta}M(\mathbb{Z}_{i+(1/2),j+(1/2),k+1}-\mathbb{Z}_{i+(1/2),j+(1/2),k})+\frac{1}{\Delta x}K(\mathbb{Z}_{i+1,j+(1/2),k+(1/2)}-\mathbb{Z}_{i,j+(1/2),k+(1/2)})\\
&\quad+\frac{1}{\Delta y}L(\mathbb{Z}_{i+(1/2),j+1,k+(1/2)}-\mathbb{Z}_{i+(1/2),j,k+(1/2)})\\
&=\nabla S(\mathbb{Z}_{i+(1/2),j+(1/2),k+(1/2)}).
\end{aligned}
\tag{3.3}
$$

Equation (3.3) preserves the discrete multisymplectic conservation law,

$$
\begin{aligned}
&\frac{dv_{i+(1/2),j+(1/2),k+1}\wedge dp^{xt}_{i+(1/2),j+(1/2),k+1}-dv_{i+(1/2),j+(1/2),k}\wedge dp^{xt}_{i+(1/2),j+(1/2),k}}{\Delta t}\\
&+\frac{dv_{i+(1/2),j+1,k+(1/2)}\wedge dp^{xy}_{i+(1/2),j+1,k+(1/2)}-dv_{i+(1/2),j,k+(1/2)}\wedge dp^{xy}_{i+(1/2),j,k+(1/2)}}{\Delta y}\\
&+\frac{d\varphi_{i+1,j+(1/2),k+(1/2)}\wedge dp^{x}_{i+1,j+(1/2),k+(1/2)}-d\varphi_{i,j+(1/2),k+(1/2)}\wedge dp^{x}_{i,j+(1/2),k+(1/2)}}{\Delta x}
\end{aligned}
$$

$$+\frac{dv_{i+1,j+(1/2),k+(1/2)}\wedge dp^{xx}_{i+1,j+(1/2),k+(1/2)}-dv_{i,j+(1/2),k+(1/2)}\wedge dp^{xx}_{i,j+(1/2),k+(1/2)}}{\Delta x}$$

$$+\frac{du_{i+1,j+(1/2),k+(1/2)}\wedge dp^{xxx}_{i+1,j+(1/2),k+(1/2)}-du_{i,j+(1/2),k+(1/2)}\wedge dp^{xxx}_{i,j+(1/2),k+(1/2)}}{\Delta x}$$

$$=0. \tag{3.4}$$

Although the Preissman scheme (3.3) is multisymplectic, it took many efforts to realize. Hence we elimate the auxiliary variables $\varphi,v,w,p,p^x,p^{xx},p^{xy},p^{xt},p^{xxx}$ by a trivial computation and obtain the following multisymplectic 45 points scheme:

$$\frac{1}{2\Delta x\Delta t}\delta_y^2\Delta_t^0\{u^k_{i+2,j}+2u^k_{i+1,j}-2u^k_{i-1,j}+u^k_{i-2,j}\}+\frac{1}{\Delta x^4}\{\delta_y^2\delta_t^2(u^k_{i+2,j}-4u^k_{i+1,j}+6u^k_{i,j}-4u^k_{i-1,j}$$

$$+u^k_{i-2,j})\}+\frac{\sigma}{4\Delta y^2}\{\delta_t^2\Delta_y^2(u^k_{i+2,j}+4u^k_{i+1,j}+6u^k_{i,j}+4u^k_{i-1,j}+u^k_{i,j})\}$$

$$+\frac{2}{\Delta x^2}(\overline{\delta}f^{k+(1/2)}_{i,j+(1/2)}+\overline{\delta}f^{k+(1/2)}_{i,j-(1/2)}+\overline{\delta}f^{k-(1/2)}_{i,j+(1/2)}+\overline{\delta}f^{k-(1/2)}_{i,j-(1/2)})=0, \tag{3.5}$$

where we denote $u^k_{i,j}=u(i\Delta x,j\Delta y,k\Delta t)$, $f^k_{i,j}=3(u(i\Delta x,j\Delta y,k\Delta t))^2$ and

$$\begin{cases}\Delta_t^0u^k_{i,j}=u^{k+1}_{i,j}-u^{k-1}_{i,j},\ \delta_y^2u^k_{i,j}=u^k_{i,j+1}+2u^k_{i,j}+u^k_{i,j-1},\\ \delta_t^2u^k_{i,j}=u^{k+1}_{i,j}+2u^k_{i,j}+u^{k-1}_{i,j},\ \Delta_y^2u^k_{i,j}=u^k_{i,j+1}-2u^k_{i,j}+u^k_{i,j-1},\\ \overline{\delta}f^k_{i,j}=f^k_{i+(3/2),j}-f^k_{i+(1/2),j}-f^k_{i-(1/2),j}+f^k_{i-(3/2),j}.\end{cases} \tag{3.6}$$

IV. SOME NUMERICAL RESULTS ON SOLITON AND SOLITARY WAVES

In this section, we test the 45 points scheme on soliton and solitary waves over long time intervals.

At first, one line soliton of the KPI equation is considered. We choose the small interval in the y-direction just for computing convenience, and it has nothing to do with the scheme and result. We take the following initial conditions:

$$u(x,y,0)=2\ \mathrm{sech}^2\left(x-\frac{\sqrt{2}}{2}y-6\right) \tag{4.1}$$

and the exact boundary condition. The KPI equation has the theoretic solution,

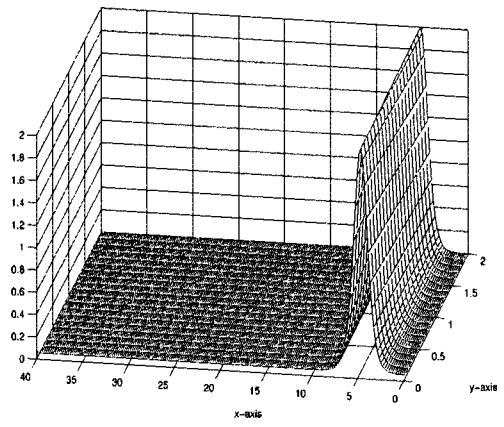

FIG. 1. One soliton at $t=0$.

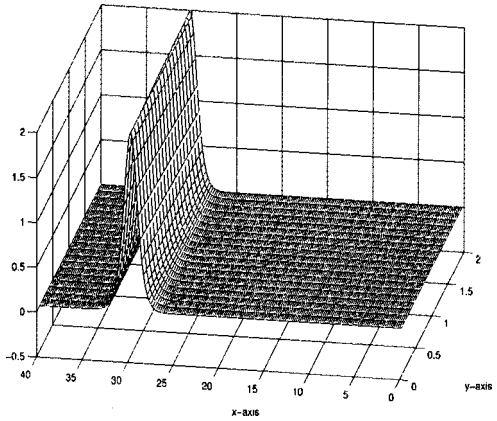

FIG. 2. One soliton at $t=10$.

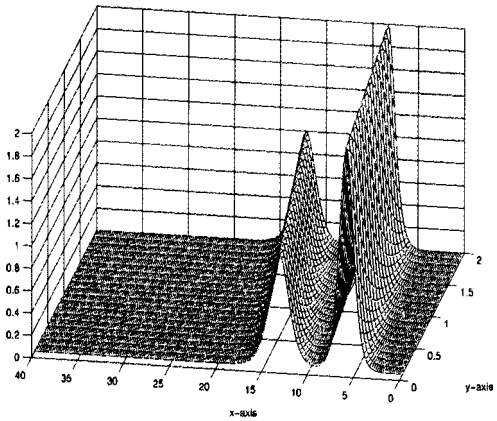

FIG. 3. Soliton interact at $t=0$.

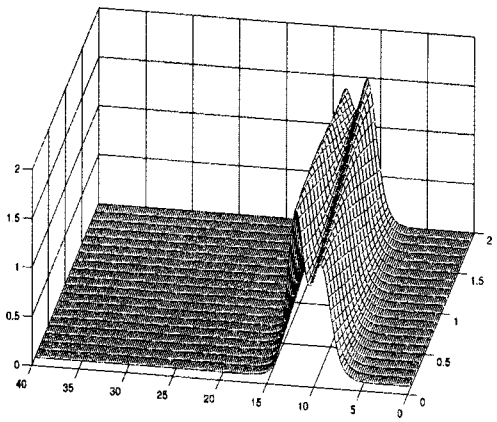

FIG. 4. Soliton interact at $t=1.5$.

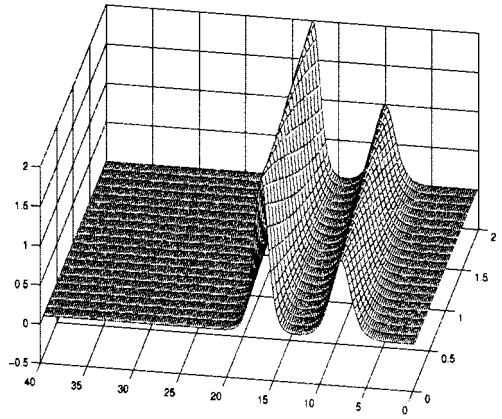

FIG. 5. Soliton interact at $t=3$.

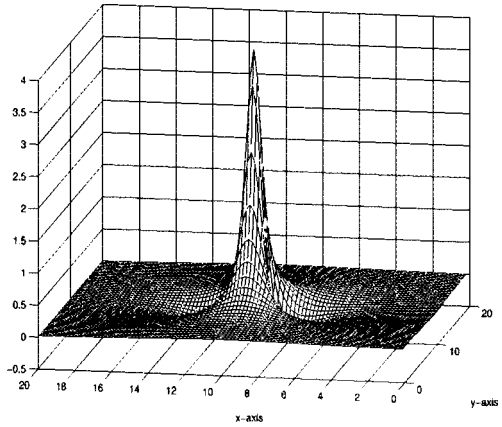

FIG. 6. Lump-type solitary wave at $t=0$.

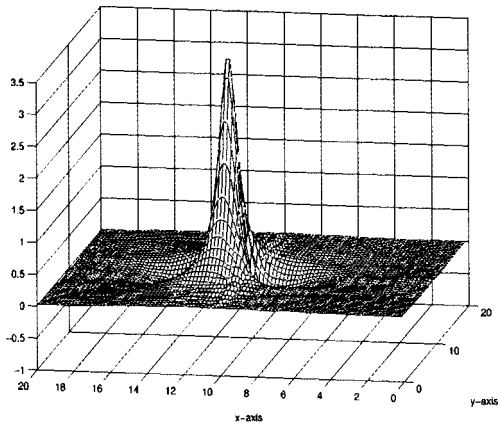

FIG. 7. Lump-type solitary wave at $t=0.5$.

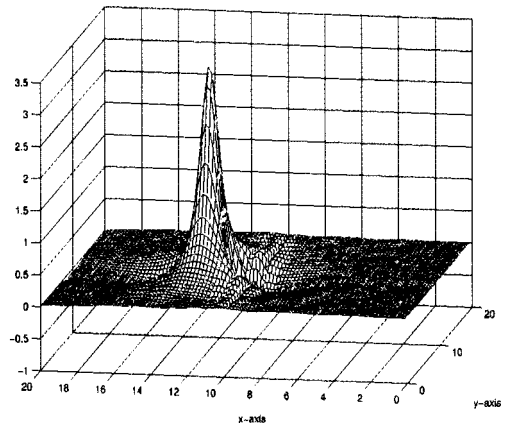

FIG. 8. Lump-type solitary wave at $t=1$.

$$u(x,y,t)=2\,\mathrm{sech}^2\left(x-\frac{\sqrt{2}}{2}y-\frac{5}{2}t-6\right),$$

which represents one line-soliton propagating with the velocity $\frac{5}{2}$ in the direction with the angle of $\tan^{-1}(\sqrt{2})$ to the positive x-axis. We take the test on the domain $[0,40]\times[0,2]$ and choose $\Delta x=0.2$, $\Delta y=0.1$, $\Delta t=0.01$. Figure 1 shows the initial condition and Fig. 2 shows the numerical solution at time $t=10$. In fact, it is the propagating 25-unit distant as we indicated.

Next we try the two line-soliton interaction.

We take the initial condition,

$$u(x,y,0)=2\sum_{i=1}^{2} k_i^2\,\mathrm{sech}^2[k_i(x+\lambda_i y-x_{0,i})], \tag{4.2}$$

where $k_1=1.0$, $k_2=1/\sqrt{2}$, $\lambda_1=-1/\sqrt{3}$, $\lambda_2=-1.0$, and $x_{0.1}=6.0$, $x_{0.2}=11.0$, and the exact boundary condition. The initial condition (4.2) corresponds to two line solitons, each with amplitude $2k_i^2$ placed initially at $x=x_{0,i}$ and moving with velocity $v_i=4k_i^2-3\lambda_i^2$ along the x-axis ($i=1,2$).

We carried out the computation on the domain $[0,40]\times[0,2]$, and choose $\Delta x=0.2$, $\Delta y=0.1$, $\Delta t=0.01$. The initial condition (4.2) is shown in Fig. 3. The larger line-soliton on the right will move with a velocity 3.0 to the positive x-direction and the smaller one on the left will move with a velocity 1.0 in the inverse direction. As time goes on, they will collide with each other, as is shown in Fig. 4. Figure 5 shows that the two line-solitons have separated completely after colliding and restored their original shape by the $t=3$.

We also consider the lump-type solitary waves of the KPI equation. The lump-type initial condition used for the test is

$$u(x,y,0)=4\,\frac{\left(-(x-x_0)^2+\mu^2(y-y_0)^2+\dfrac{1}{\mu^2}\right)}{\left((x-x_0)^2+\mu^2(y-y_0)^2+\dfrac{1}{\mu^2}\right)}, \tag{4.3}$$

where the parameters $\mu^2=1.0$, $x_0=10.0$, $y_0=10.0$, and we adopt the exact boundary condition.

We compute in a rectangle $[0,20]\times[0,20]$ and choose $\Delta x=0.1$, $\Delta y=0.2$, $\Delta t=0.01$. Figure 6 shows the initial condition and Fig. 7 shows the numerical solution at time $t=0.5$. By the time $t=1$, the result is shown in Fig. 8. The lump solution of the KPI equation can be expressed as

$$u(x,y,t)=4\frac{\left(-(x-x_0-3\mu^2t^2)^2+\mu^2(y-y_0)^2+\frac{1}{\mu^2}\right)}{\left((x-x_0-3\mu^2t^2)^2+\mu^2(y-y_0)^2+\frac{1}{\mu^2}\right)}. \tag{4.4}$$

According to (4.4), this lump type solitary wave will move to the positive x-direction with velocity $3\mu^2$. We can see the moving of the lump solitary wave from the graph.

A future task is expected to find a proper numerical boundary condition for collision of the two lump type solitary waves.

(Received 19 February 2002; accepted for publication 22 April 2002)

The $(2+1)$-dimensional $(M+N)$-component AKNS system that is derived from the inner parameter dependent symmetry constraint of the KP equation is studied in detail. First, the Painlevé integrability of the model is proved by using the standard WTC and Kruskal approach. Using the formal series symmetry approach, the generalized KMV symmetry algebra and the related symmetry group are found. The two-dimensional similarity partial differential equation reductions and the ordinary differential equation reductions are obtained from the generalized KMV symmetry algebra and the direct method. Abundant localized coherent structures are revealed by the variable separation approach. Some special types of the localized excitations like the multiple solitoffs, dromions, lumps, ring solitons, breathers and instantons are plotted also. © *2002 American Institute of Physics.*

I. INTRODUCTION

In $(1+1)$-dimensions, the AKNS (Ablowitz–Kaup–Newell–Segur) system[1] is a most important physical model. The $(1+1)$-dimensional AKNS system had been extended in several different directions, say, the $(1+1)$-dimensional $(1+1)$-component AKNS system had been extended to the $(N+N)$-component $(1+1)$-dimensional AKNS system[2] and $(M+N)$-component $(1+1)$-dimensional AKNS system.[3] Several different types of $(2+1)$-dimensional integrable AKNS systems had also been obtained, say, the DS (Davey–Stewartson) type system[4] and the breaking soliton type system.[5] The $(1+1)$-dimensional AKNS system can be obtained from the usual symmetry constraint of the KP (Kadomtsev–Petviashvili) equation.[2] Recently, Lou and Hu had obtained a general $(N+M)$-component $(2+1)$-dimensional AKNS system,

$$ip_{it}+p_{ixx}+p_iu_x=0, \quad i=1,2,\ldots,N, \tag{1}$$

$$-iq_{jt}+q_{jxx}+q_ju_x=0, \quad j=1,2,\ldots,M, \tag{2}$$

$$u_y+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}p_iq_j=0, \tag{3}$$

from the inner parameter dependent symmetry constraints of the KP equation.[3] When we take $y=x$, $N=M=1$, the system (1)–(3) is reduced to the usual $(1+1)$-dimensional AKNS system. If

[a]Mailing address.

q is selected as the complex conjugate and $M=N=1$, then the system (1)–(3) can be considered as the asymmetric part of the DS system. The so-called long-wave–short-wave interaction model is linked with (1)–(3) by $N=M=1$ by

$$p(x,y,t)=L(x,y+it,it)\equiv L(x',y',t'), \quad q(x,y,t)=S(x,y+it,it)\equiv S(x',y',t').$$

The Maccari system[6] is just also a special case of (1)–(3) with $M=N=2$ and $\{q_1=p_1^*,\ q_2=p_2^*\}$.

One of the most powerful methods to prove the integrability of a model is the so-called Painlevé analysis due to WTC (Weiss–Tabor–Carnevale).[7] Furthermore, the Painlevé analysis can also be used to find some exact solutions no matter whether the model is integrable or not. If one only needs to prove the Painlevé property of a model, one may use the Kruskal simplification for the WTC approach.[8] If one hopes to find some more properties of the model, one has to use the original WTC approach or some extended forms.[9–11] In Sec. II of this article, we combine the standard WTC approach and the Kruskal simplification to study the Painlevé integrability of the model. In the symmetry study of the (2+1)-dimensional integrable models like the KP equation, Toda field theory, Davey–Stewartson (DS) equation, dispersive long wave equation, Nizhnik–Novikov–Veselov (NNV) equation, asymmetric DS (ADS) equation, asymmetric NNV (ANNV) equation, KdV-type and AKNS type breaking soliton equations and the Sawada–Kortera (SK) equation, there exist some types of generalized infinitely dimensional Kac–Moody–Virasoro (KMV) type symmetries with a common generalized centerless Virasoro symmetry subalgebra.[12] We had defined the Virasoro integrability if a model possesses an infinite dimensional centerless Virasoro symmetry algebra and a systematic method to construct the Virasoro integrable models was established.[13] Section III is devoted to investigating the Virasoro integrability by means of the formal series symmetry approach. The result shows us that the model possesses an infinite dimensional KMV symmetry algebra with two generalized centerless Virasoro symmetry subalgebra. Starting from the symmetries of a model one may obtain some exact solutions of the model in some different ways. In Sec. IV, we look for the finite transformation (symmetry group) of the related symmetry algebra. Using the finite transformation and any special simple solution, we may obtain a new generalized solution. In Sec. V, we use the general Lie point KMV symmetry algebra and the direct method to obtain the similarity solutions of the model. It is known that the famous inverse scattering transformation (IST) can be considered as an extension of the Fourier transformation in nonlinear physics. The variable separation approach (VSA) is another powerful method in linear physics. However, it is difficult to extend the VSA to nonlinear physics. Recently, two kinds of ''variable separation'' procedures were established. The first method is called the ''formal variable separation approach'' (FVSA),[14] or equivalently the symmetry constraints[2] or nonlinearization of the Lax pairs.[15] The independent variables of a reduced field in FVSA have not totally been separated though the reduced field satisfies some lower-dimensional equations. The second type of variable separation method was established first for the DS equation seven years ago[16] and the method was revisited and developed recently for the NNV equation,[17] ANNV equation,[18] DS equations,[17] ADS equation, dispersive long wave equation (DLWE) and a nonintegrable (2+1)-dimensional KdV equation.[19] In Sec. VI, we will study whether the variable separation approach can be applied to the $(N+M)$-component (2+1)-dimensional AKNS system. The positive result shows us that the (2+1)-dimensional $(N+M)$-component AKNS system possesses also abundant localized coherent structures for the quantity $\Sigma_{i=1,j=1}^{N,M} a_{ij}p_iq_j$. The abundant structures of the model are caused by the appropriate possible selections of the arbitrary functions appearing in the seed solution. Some special types of the localized excitations like the multiple solitoffs, dromions, lumps, ring solitons, breathers and instantons are studied also in this section. It is shown that the interaction between two traveling ring soliton solutions is completely elastic and a ring shape breather may ''breath'' in some different ways. The last section is a summary and discussion.

II. PAINLEVÉ INTEGRABILITY OF THE (2+1)-DIMENSIONAL (M+N) COMPONENT AKNS SYSTEM

According to the standard WTC approach, if the $(2+1)$-dimensional $(M+N)$-component AKNS system (1)–(3) is Painlevé integrable, all the possible solutions of the model can be written as

$$p_i=\sum_{k=0}^{\infty} p_{ik}f^{k+\alpha_i}, \quad i=1,2,\ldots,N, \tag{4}$$

$$q_j=\sum_{k=0}^{\infty} q_{jk}f^{k+\beta_j}, \quad j=1,2,\ldots,M, \tag{5}$$

$$u=\sum_{k=0}^{\infty} u_k f^{k+\gamma}, \tag{6}$$

with sufficient $(2M+2N)$ arbitrary functions among p_{ik}, q_{jk}, u_k in addition to f, where α_i, β_j and γ should all be the negative integers. In other words, all the solutions of the model are single valued about an arbitrary movable singularity manifold f.

To fix the constants α_i, β_j and γ, one may use the standard leading order analysis. By substituting $p_i\sim p_{i0}f^{\alpha_i}$, $q_j\sim q_{j0}f^{\beta_j}$ and $u\sim u_0 f^{\gamma}$ into (1)–(3) and comparing the leading terms for $f\sim 0$, we get the only possible branch with

$$\alpha_i=\beta_j=\gamma=-1, \tag{7}$$

$$u_0=2f_x, \quad \sum_{i=1}^{N}\sum_{j=1}^{M} a_{ij}q_{j0}p_{i0}=2f_xf_y. \tag{8}$$

Substituting (4)–(6) with (7) and (8) into (1)–(3) and vanishing all the coefficients of the powers f^k for different k, we can obtain the recursion relations to determine the functions u_k, p_{ik} and q_{jk}:

$$\begin{pmatrix} A & 0 & \cdots & 0 & 0 & \cdots & 0 & (k-1)f_xp_{10} \\ 0 & A & \cdots & 0 & 0 & \cdots & 0 & (k-1)f_xp_{20} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & A & 0 & \cdots & 0 & (k-1)f_xp_{N0} \\ 0 & 0 & \cdots & 0 & A & \cdots & 0 & (k-1)f_xq_{10} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & \cdots & A & (k-1)f_xq_{M0} \\ B_1 & B_2 & \cdots & B_N & C_1 & \cdots & C_M & (k-1)f_y \end{pmatrix} \begin{pmatrix} p_{1k} \\ p_{2k} \\ \vdots \\ p_{Nk} \\ q_{1k} \\ \vdots \\ q_{Mk} \\ u_k \end{pmatrix} \equiv J\Psi = \begin{pmatrix} P_{1k} \\ P_{2k} \\ \vdots \\ P_{Nk} \\ Q_{1k} \\ \vdots \\ Q_{Mk} \\ U_k \end{pmatrix}, \tag{9}$$

where

$$A\equiv k(k-3)f_x^2,$$

$$B_i\equiv\sum_{j=1}^{M} a_{ij}q_{j0}, \quad (i=1,2,\ldots,N),$$

$$C_j\equiv\sum_{i=1}^{N} a_{ij}p_{i0}, \quad (j=1,2,\ldots,M), \tag{10}$$

$$P_{ik}=-i(p_{i(k-2)t}+(k-2)p_{i(k-1)}f_t)-p_{i(k-2)xx}-2(k-2)p_{i(k-1)x}f_x-(k-2)p_{i(k-1)}f_{xx}$$
$$-\sum_{m=0}^{k-1}u_{mx}p_{i(k-m-1)}-\sum_{m=0}^{k-1}(m-1)f_xu_mp_{i(k-m)}, \tag{11}$$

$$Q_{jk}=i(q_{j(k-2)t}+(k-2)q_{j(k-1)}f_t)-q_{j(k-2)xx}-2(k-2)q_{j(k-1)x}f_x-(k-2)q_{j(k-1)}f_{xx}$$
$$-\sum_{m=0}^{k-1}u_{mx}q_{j(k-m-1)}-\sum_{m=1}^{k-1}(m-1)f_xu_mq_{j(k-m)}, \tag{12}$$

$$U_k=-u_{(k-1)y}-\sum_{m=1}^{k-1}\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}p_{im}q_{j(k-m)} \tag{13}$$

with $p_{ik}=q_{jk}=u_k=0$ for $k<0$. From the matrix equation (9), it is easy to know that if the determinant

$$\Delta\equiv\det J=(k-1)(k(k-3)f_x^2)^{M+N-1}(k+1)(k-4)f_x^2f_y \tag{14}$$

of the coefficient matrix J is not equal to zero, the functions p_{ik}, q_{jk} and u_k can be obtained from (9) uniquely. When

$$k=-1,0,0,\ldots,0,1,3,3,\ldots,3,4, \tag{15}$$

the resonances occur. The resonance at $k=-1$ corresponds to the arbitrary singularity manifold f. If the model is Painlevé integrable, we require $(2N+2M)$ resonance conditions at $k=0$ ($M+N-1$ resonance conditions), $k=1$ (one resonance condition), $k=3$ ($M+N-1$ resonance conditions), and $k=4$ (one resonance condition) are satisfied identically such that other $2M+2N$ arbitrary functions among p_{ik}, q_{jk}, u_k can be introduced into the general series expansion (4)–(6). From the leading order analysis result (8), we know that the $M+N-1$ resonance conditions at $k=0$ are satisfied identically because only one condition exists among $M+N$ functions p_{i0} and q_{j0}. For $k=1$, we can obtain

$$p_{i1}=-\frac{ip_{i0}f_t+2p_{i0x}f_x+p_{i0}f_{xx}}{f_xu_0}, \tag{16}$$

$$q_{j1}=\frac{iq_{j0}f_t-2q_{j0x}f_x-q_{j0}f_{xx}}{f_xu_0}, \tag{17}$$

and the resonance condition

$$2u_{0y}f_x^2-\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(2q_{j0x}f_x+q_{j0}f_{xx})p_{i0}-\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(2p_{i0x}f_x+p_{i0}f_{xx})q_{j0}=0. \tag{18}$$

It is straightforward to see that the resonance condition (18) is satisfied identically because of (8). For $k=2$, (9) with (10)–(13) give us

$$p_{i2}=\frac{1}{12f_x^3f_y}\Bigg\{6f_xf_y(ip_{i0t}+p_{i0xx}+u_{0x}p_{i1}+u_{1x}p_{i0})-2p_{i0}f_x^2\Bigg(u_{1y}+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}q_{m1}p_{n1}\Bigg)$$
$$-p_{i0}\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}[q_{m0}(ip_{n0t}+p_{n0xx}+u_{0x}p_{n1}+2u_{1x}p_{n0})-p_{n0}(iq_{m0t}-q_{m0xx}-u_{0x}q_{m1})]\Bigg\}, \tag{19}$$

$$q_{j2}=\frac{1}{12f_x^3f_y}\left\{6(u_{0x}q_{j1}-iq_{j0t}+u_{1x}q_{j0}+q_{j0xx})f_yf_x-2q_{j0}\left(u_{1y}+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}q_{m1}p_{n1}\right)f_x^2\right.$$
$$\left.-\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}[(u_{0x}p_{n1}+ip_{n0t}+p_{n0xx}+2p_{n0}u_{1x})q_{m0}+(q_{m0xx}+u_{0x}q_{m1}-iq_{m0t})p_{n0}]q_{j0}\right\}, \tag{20}$$

$$u_2=\frac{1}{6f_x^2f_y}\left\{-2f_x^2u_{1y}-\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(2u_{1x}p_{i0}+ip_{i0t}+p_{i0xx}+u_{0x}p_{i1})q_{j0}\right.$$
$$\left.+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}[(-q_{j0xx}+iq_{j0t}-u_{0x}q_{j1})p_{i0}-2f_x^2q_{j1}p_{i1}]\right\}; \tag{21}$$

For $k=3$, the component form of (9) reads ($i=1,2,\ldots,N, j=1,2,\ldots,M$)

$$(2f_xu_3+u_{2x})p_{i0}+(f_{xx}+u_{0x}+if_t)p_{i2}+(u_{1x}+f_xu_2)p_{i1}+2p_{i2x}f_x+ip_{i1t}+p_{i1xx}=0, \tag{22}$$

$$(2f_xu_3+u_{2x})q_{j0}+(f_{xx}+u_{0x}-if_t)q_{j2}+(u_{1x}+f_xu_2)q_{j1}+2q_{j2x}f_x-iq_{j1t}+q_{j1xx}=0, \tag{23}$$

$$u_{2y}+2u_3f_y+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(q_{j2}p_{i1}+q_{j1}p_{i2}+q_{j3}p_{i0}+q_{j0}p_{i3})=0. \tag{24}$$

Now, to verify the remained resonance conditions at $k=3$ and $k=4$, one can use the Kruskal simplification

$$f=x+\psi(y,t),\quad p_{ik}=p_{ik}(y,t),\quad q_{jk}=q_{jk}(y,t),\quad u_k=u_k(y,t) \tag{25}$$

without loss of the generality to prove the Painlevé integrability, where $\psi(y,t)$ is an arbitrary function of $\{y,t\}$. Under the simplification (25), the known results are simplified to

$$u_0=2,\quad q_{j0}p_{i0}=2\psi_y,\quad p_{i1}=-\tfrac{1}{2}ip_{i0}\psi_t,\quad q_{j1}=\tfrac{1}{2}iq_{j0}\psi_t, \tag{26}$$

$$p_{i2}=\frac{1}{12\psi_y}\left[6i\psi_yp_{i0t}-2p_{i0}\left(u_{1y}+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}q_{m1}p_{n1}\right)\right.$$
$$\left.+ip_{i0}\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}(p_{n0}q_{m0t}-q_{m0}p_{n0t})\right], \tag{27}$$

$$q_{j2}=\frac{1}{12\psi_y}i\left[2iq_{j0}\left(u_{1y}+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}q_{m1}p_{n1}\right)\right.$$
$$\left.-6q_{j0t}\psi_y+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}(q_{m0t}p_{n0}-p_{n0t}q_{m0})q_{j0}\right], \tag{28}$$

$$u_2=\frac{1}{6\psi_y}\left(\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}(iq_{m0t}p_{n0}-ip_{n0t}q_{m0})-2u_{1y}-2\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}q_{m1}p_{n1}\right). \tag{29}$$

Using (26)–(29), we can obtain

$$u_3=-\tfrac{1}{4}\psi_{tt} \tag{30}$$

from any one of (22) or (23) for fixed i or j while all the remaining equations of (22) and (23) become resonance conditions which are really satisfied identically because of (26)–(29) and (30). Under the simplification (25), Eq. (24) is simplified to

$$-2\psi_{tt}\psi_y-2\psi_{ty}\psi_t+4u_{2y}+4\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(q_{j0}p_{i3}+4q_{j3}p_{i0})=0, \tag{31}$$

which is the only constraint condition among $M+N$ functions p_{i3} and q_{j3}. In other words, $M+N-1$ resonance conditions satisfy identically at $k=3$, and $N+M-1$ functions of p_{i3} and q_{j3} are arbitrary. For $k=4$, the resonance condition reads

$$u_{3y}+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}\Big[q_{j3}p_{i1}+q_{j1}p_{i3}+q_{j2}p_{i2}+\frac{1}{4}(-u_2q_{j2}+iq_{j2t}+2iq_{j3}\psi_t-2u_3q_{j1})p_{i0}$$
$$+\frac{1}{4}(-u_2p_{i2}-ip_{i2t}-2ip_{i3}\psi_t-2u_3p_{i1})q_{j0}\Big]=0, \tag{32}$$

while p_{i4} and q_{j4} are expressed as

$$p_{i4}=-\tfrac{1}{4}(3u_4p_{i0}+ip_{i2t}+2ip_{i3}\psi_t+2u_3p_{i1}+u_2p_{i2}), \tag{33}$$

$$q_{j4}=\tfrac{1}{4}(iq_{j2t}-3u_4q_{j0}+2iq_{j3}\psi_t-2u_3q_{j1}-u_2q_{j2}) \tag{34}$$

for arbitrary u_4. After substituting (26)–(31) into (32), one can see that the resonance condition (32) is also satisfied identically. So the $(2+1)$-dimensional $(N+M)$-component AKNS system (1)–(3) is Painlevé integrable.

III. GENERALIZED KMV SYMMETRY ALGEBRA OF THE MODEL

In the symmetry study of the $(2+1)$-dimensional integrable models, we have found that there exists a quite universal symmetry algebra, the generalized centerless Virasoro type symmetry algebra (or named Witt algebra).[12] We had defined the Virasoro integrability if a model possesses the generalized centerless Virasoro type symmetry algebra and a system method was established to obtain the Virasoro integrable models.[13] In this section, we are interested in studying the symmetry structure of the $(2+1)$-dimensional AKNS system (1)–(3) at first and then investigating whether the $(2+1)$-dimensional AKNS system (1)–(3) is Virasoro integrable.

There are some different types of methods to find the symmetries of a model, say, the standard classical Lie approach,[20] direct Lie point symmetry ansatz[21] and the formal series symmetry approach.[12] In this article we use the formal series symmetry approach to find the symmetries of the $(2+1)$-dimensional AKNS system (1)–(3). A symmetry of the system (1)–(3) is defined as a solution of the linearized system of (1)–(3),

$$iP_{it}+P_{ixx}+P_iu_x+p_iU_x=0,\quad i=1,2,\ldots,N, \tag{35}$$

$$-iQ_{jt}+Q_{jxx}+Q_ju_x+q_jU_x=0,\quad j=1,2,\ldots,M, \tag{36}$$

$$U_y+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(P_iq_j+p_iQ_j)=0, \tag{37}$$

which means the system (1)–(3) is form invariant under the transformation

$$\{p_1,p_2,\ldots,q_N,q_1,q_2,\ldots,q_M,u\}\to\{p_1,p_2,\ldots,p_N,q_1,q_2,\ldots,q_M,u\}$$
$$+\epsilon\{P_1,P_2,\ldots,P_N,Q_1,Q_2,\ldots,Q_M,U\}, \tag{38}$$

where ϵ is an infinitesimal parameter. To solve the symmetry definition equations (35)–(37), we assume that $\{P_i, Q_j, U\}$ has the form

$$P_i = \sum_{k=0}^{\infty} f^{(-k)} P_i[k], \quad i = 1,2,\ldots,N, \tag{39}$$

$$Q_j = \sum_{k=0}^{\infty} f^{(-k)} Q_j[k], \quad j = 1,2,\ldots,M, \tag{40}$$

$$U = \sum_{k=0}^{\infty} f^{(-k)} U[k], \tag{41}$$

where $f \equiv f(t)$ is an arbitrary function of t, $f^{(k)} = d^k f/dt^k$, $f^{(-1)} = \int^t f \mathrm{d}t$ and the undetermined functions $P_i[k]$, $Q_j[k]$ and $U[k]$ should be determined later.

Substituting (39)–(41) into (35)–(37) and vanishing the coefficients of $f^{(-k)}$ for different k thanks to f being an arbitrary function, we can obtain the recursion relation for the functions $P_i[k]$, $Q_j[k]$ and $U[k]$:

$$P_i[k] = (-\partial_t + i\partial_x^2 + iu_x) P_i[k-1] + ip_i U_x[k-1], \quad i = 1,2,\ldots,N, \tag{42}$$

$$Q_j[k] = (-\partial_t - i\partial_x^2 - iu_x) Q_j[k-1] - iq_j U_x[k-1], \quad j = 1,2,\ldots,M, \tag{43}$$

$$U_y[k] = -\sum_{i=1}^{N} \sum_{j=1}^{M} a_{ij} (P_i[k] q_j + p_i Q_j[k]) \tag{44}$$

with

$$P_1[0] = P_2[0] = \cdots = P_N[0] = Q_1[0] = Q_2[0] = \cdots = Q_M[0] = 0, \quad U[0] = g(x,t), \tag{45}$$

and $g(x,t)$ being an arbitrary function of $\{x,t\}$. Usually the formal series symmetries (39)–(41) with (42)–(45) will not be truncated for the general $g(x,t)$. However, as in other cases (like the KP, DS and Toda equations[12,22]), if we select $g(x,t)$ as some polynomial functions of x, we may obtain some truncated symmetries. It is known that, for some types of $(2+1)$-dimensional integrable models (such as the KP and the Toda equations), one may obtain infinitely many truncated symmetries,[12] while for some other types of $(2+1)$-dimensional integrable models (like the DS and the SK equations), one can obtain only finite numbers of the truncated symmetries.[22] For the $(2+1)$-dimensional $(N+M)$-component AKNS system, we can obtain again only finite numbers of the truncated symmetries. Here are the final results obtained from the selections of the function $g(x,t)$:

$$\sigma_0 = f \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}, \quad \sigma_1 = if \begin{pmatrix} p_1 \\ p_2 \\ \vdots \\ p_N \\ -q_1 \\ -q_2 \\ \vdots \\ -q_M \\ 0 \end{pmatrix} + \dot{f} \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ x \end{pmatrix}, \tag{46}$$

$$\sigma_2=-4f\begin{pmatrix} p_{1x}\\ p_{2x}\\ \vdots\\ p_{Nx}\\ q_{1x}\\ q_{2x}\\ \vdots\\ q_{Mx}\\ u_x\end{pmatrix}+2ix\dot{f}\begin{pmatrix} p_1\\ p_2\\ \vdots\\ p_N\\ -q_1\\ -q_2\\ \vdots\\ -q_M\\ 0\end{pmatrix}+\ddot{f}\begin{pmatrix} 0\\ 0\\ \vdots\\ 0\\ 0\\ 0\\ \vdots\\ 0\\ x^2\end{pmatrix}, \tag{47}$$

$$\sigma_3=-24f\begin{pmatrix} p_{1t}\\ p_{2t}\\ \vdots\\ p_{Nt}\\ q_{1t}\\ q_{2t}\\ \vdots\\ q_{Mt}\\ u_t\end{pmatrix}-6\dot{f}\begin{pmatrix} 2xp_{1x}+p_1\\ 2xp_{2x}+P_2\\ \vdots\\ 2xp_{Nx}+p_N\\ 2xq_{1x}+q_1\\ 2xq_{2x}+q_2\\ \vdots\\ 2xq_{Mx}+q_M\\ 2xu_x+2u\end{pmatrix}+3ix^2\ddot{f}\begin{pmatrix} p_1\\ p_2\\ \vdots\\ p_N\\ -q_1\\ -q_2\\ \vdots\\ -q_M\\ 0\end{pmatrix}+f^{(3)}\begin{pmatrix} 0\\ 0\\ \vdots\\ 0\\ 0\\ 0\\ \vdots\\ 0\\ x^2\end{pmatrix}. \tag{48}$$

Similarly, if we change the function $f\equiv f(t)$ in (39)–(41) as $h\equiv h(y)$, then we can obtain another set of formal series symmetry with two truncated ones:

$$\Sigma_0=-h\begin{pmatrix} p_1\\ p_2\\ \vdots\\ p_N\\ -q_1\\ -q_2\\ \vdots\\ -q_M\\ 0\end{pmatrix},\quad \Sigma_1=-h\begin{pmatrix} p_{1y}\\ p_{2y}\\ \vdots\\ p_{Ny}\\ q_{1y}\\ q_{2y}\\ \vdots\\ q_{My}\\ u_y\end{pmatrix}-\frac{1}{2}\dot{h}\begin{pmatrix} p_1\\ p_2\\ \vdots\\ p_N\\ q_1\\ q_2\\ \vdots\\ q_M\\ 0\end{pmatrix}. \tag{49}$$

All the truncated Lie point symmetries expressed by (46)–(49) can all be obtained by using other types of approaches like the methods described in Ref. 20 and/or in Ref. 21.

It is easy to prove that the symmetries (46)–(48) and (49) constitute the following closed symmetry algebra

$$\begin{aligned}[\sigma_0(f_1),\sigma_0(f_2)]&=[\sigma_0(f_1),\sigma_1(f_2)]=[\sigma_1(f_1),\sigma_1(f_2)]=[\Sigma_0(h_1),\Sigma_0(h_2)]=[\sigma_0(f),\Sigma_0(h)]\\ &=[\sigma_1(f),\Sigma_0(h)]=[\sigma_2(f),\Sigma_0(h)]=[\sigma_3(f),\Sigma_0(h)]=[\sigma_0(f),\Sigma_1(h)]\\ &=[\sigma_1(f),\Sigma_1(h)]=[\sigma_2(f),\Sigma_1(h)]=[\sigma_3(f),\Sigma_1(h)]=0,\end{aligned} \tag{50}$$

$$[\sigma_0(f_1),\sigma_3(f_2)]=12\sigma_0(f_2\dot{f}_1+f_1\dot{f}_2), \tag{51}$$

$$[\sigma_1(f_1),\sigma_2(f_2)]=4\sigma_0(f_2\dot{f}_1), \tag{52}$$

$$[\sigma_1(f_1),\sigma_3(f_2)]=24\sigma_1(f_2\dot{f}_1), \tag{53}$$

$$[\sigma_2(f_1),\sigma_2(f_2)]=8\sigma_1(f_2\dot{f}_1-f_1\dot{f}_2), \tag{54}$$

$$[\sigma_2(f_1),\sigma_3(f_2)]=12\sigma_2(2f_2\dot{f}_1-f_1\dot{f}_2), \tag{55}$$

$$[\sigma_3(f_1),\sigma_3(f_2)]=\sigma_3(f_2\dot{f}_1-f_1\dot{f}_2), \tag{56}$$

$$[\Sigma_1(h_1),\Sigma_0(h_2)]=\Sigma_0(h_1\dot{h}_2), \tag{57}$$

$$[\Sigma_1(h_1),\Sigma_1(h_2)]=\Sigma_1(\dot{h}_1h_2-\dot{h}_2h_1), \tag{58}$$

where the commutator $[A,B]$ $(A\equiv(A_1(p_i,q_j,u),A_2(p_i,q_j,u),\ldots,A_K(p_i,q_j,u))^T,\ K=N+M+1)$ is defined as

$$\begin{aligned}[A,B]=&\begin{pmatrix} A'_{1p_1} & A'_{1p_2} & \cdots & A'_{1p_N} & A'_{1q_1} & A'_{1q_2} & \cdots & A'_{1q_M} & A'_{1u}\\ A'_{2p_1} & A'_{2p_2} & \cdots & A'_{2p_N} & A'_{2q_1} & A'_{2q_2} & \cdots & A'_{2q_M} & A'_{2u}\\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots\\ A'_{Kp_1} & A'_{Kp_2} & \cdots & A'_{Kp_N} & A'_{Kq_1} & A'_{Kq_2} & \cdots & A'_{Kq_M} & A'_{Ku}\end{pmatrix}\begin{pmatrix} B_1\\ B_2\\ \vdots\\ B_K\end{pmatrix}\\ &-\begin{pmatrix} B'_{1p_1} & B'_{1p_2} & \cdots & B'_{1p_N} & B'_{1q_1} & B'_{1q_2} & \cdots & B'_{1q_M} & B'_{1u}\\ B'_{2p_1} & B'_{2p_2} & \cdots & B'_{2p_N} & B'_{2q_1} & B'_{2q_2} & \cdots & B'_{2q_M} & B'_{2u}\\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots\\ B'_{Kp_1} & B'_{Kp_2} & \cdots & B'_{Kp_N} & B'_{Kq_1} & B'_{Kq_2} & \cdots & B'_{Kq_M} & B'_{Ku}\end{pmatrix}\begin{pmatrix} A_1\\ A_2\\ \vdots\\ A_K\end{pmatrix}\end{aligned} \tag{59}$$

and the operators A'_{ig} and B'_{ig}, $(i=1,2,\ldots,K,g=p_i,q_j,u)$ are partial linearized operators, say

$$A'_{kp_i}h\equiv\lim_{\epsilon\to0}\frac{d}{d\epsilon}A_i(p_1,p_2,\ldots,p_k+\epsilon h,p_{k+1},\ldots,p_N,q_1,\ldots,q_M,u). \tag{60}$$

From the symmetry algebra (50)–(58), we see that $\sigma_0(f)$, $\sigma_1(f)$, $\sigma_2(f)$ constitute an infinite dimensional general loop algebra, $\Sigma_0(h)$ constitutes a commute algebra, and $\sigma_3(f)$ and $\Sigma_1(h)$ constitute two centerless generalized Virasoro algebra. So according to Ref. 13, the $(2+1)$-dimensional $(N+M)$-component AKNS system is Virasoro integrable.

IV. FINITE TRANSFORMATIONS

From the symmetry definition equation (38), we know that a symmetry transforms a known solution of the model to a new solution of the same model in infinitesimal form. In order to get some *exact* solutions from known ones, we should find the finite transformations from the obtained symmetries. In other words, we should find a symmetry group from the related symmetry algebra. Now starting from some special solutions and the finite transformations and using the general Lie point symmetries (46)–(49), we can find some interesting solutions. To get the general Lie symmetry group, we should solve the following ''initial'' problem:

$$\frac{\mathrm{d}t'}{\mathrm{d}\epsilon}=-24f_1(t'),\quad t'|_{\epsilon=0}=t, \tag{61}$$

$$\frac{\mathrm{d}y'}{\mathrm{d}\epsilon}=-g_1(y'),\quad y'|_{\epsilon=0}=y, \tag{62}$$

$$\frac{\mathrm{d}x'}{\mathrm{d}\epsilon}=-f_2(t')-12\frac{\mathrm{d}f_1(t')}{\mathrm{d}t'}x',\quad x'|_{\epsilon=0}=x, \tag{63}$$

$$\frac{\mathrm{d}p_i'}{\mathrm{d}\epsilon}=p_i'H(x',y',t'),\quad p'|_{i\epsilon=0}=p_i, \tag{64}$$

$$\frac{\mathrm{d}q_j'}{\mathrm{d}\epsilon}=q_j'R(x',y',t'),\quad q'|_{j\epsilon=0}=q_j, \tag{65}$$

$$\frac{\mathrm{d}u'}{\mathrm{d}\epsilon}=12u'\frac{\mathrm{d}f_1(t')}{\mathrm{d}t'}+S(x',t'),\quad u'|_{\epsilon=0}=u, \tag{66}$$

where $H(x',y',t')$, $R(x',y',t')$, $S(x',t')$ are defined as

$$H(x',y',t')=g_2(y')+\frac{1}{2}\frac{\mathrm{d}g_1(y')}{\mathrm{d}y'}-if_3(t')-3i\frac{\mathrm{d}^2f_1(t')}{\mathrm{d}t'^2}x'^2-2i\frac{\mathrm{d}f_2(t')}{\mathrm{d}t'}x'+6\frac{\mathrm{d}f_1(t')}{\mathrm{d}t'}, \tag{67}$$

$$R(x',y',t')=-H(x',y',t')+12\frac{\mathrm{d}f_1(t')}{\mathrm{d}t'}+\frac{\mathrm{d}g_1(y')}{\mathrm{d}y'}, \tag{68}$$

$$S(x',t')=-x'^3\frac{\mathrm{d}^3f_1(t')}{\mathrm{d}t'^3}-x'^2\frac{\mathrm{d}^2f_2(t')}{\mathrm{d}t'^2}-x'\frac{\mathrm{d}f_3(t')}{\mathrm{d}t'}-f_4(t'). \tag{69}$$

To solve the initial problem (61)–(66), some different situations should be considered:

(a) $f_1=g_1=0$.
(b) $f_1=0,g_1\neq 0$.
(c) $f_1\neq 0,g_1=0$.
(d) $f_1\neq 0,g_1\neq 0$.

In the first case ($f_1=g_1=0$), the general solution of (61)–(66) reads

$$t'=t,\quad y'=y,\quad x'=x-f_2(t)\epsilon, \tag{70}$$

$$p_i'(x',y',t')=[p_i(x,y',t')\exp(\epsilon H_1(\epsilon,x,y',t'))]|_{x=x'+f_2(t')\epsilon}, \tag{71}$$

$$q_j'(x',y',t')=q_j(x'+f_2(t')\epsilon,y',t')\exp(-\epsilon H_1(\epsilon,x'+f_2(t')\epsilon,y',t')), \tag{72}$$

$$u'(x',y',t')=u(x'+f_2(t')\epsilon,y',t')+S_1(\epsilon,x'+f_2(t')\epsilon,t')\epsilon, \tag{73}$$

where

$$\begin{aligned}H_1(\epsilon,x,y,t)\equiv{}&g_2(y)-4if_3(t)x^3-2if_{2t}(t)x+if_2(t)(6f_3(t)x^2+f_{2t}(t))\epsilon\\&-4if_3tf_2^2(t)\epsilon^2+if_3(t)f_2^3(t)\epsilon^3,\end{aligned} \tag{74}$$

$$S_1(\epsilon,x,t)\equiv-f_4(t)-xf_{3t}(t)-x^2f_{2tt}(t)+\tfrac{1}{2}f_2(t)(2xf_{2tt}(t)+f_2(t)f_{3t})\epsilon-\tfrac{1}{3}f_2^2(t)f_{2tt}(t)\epsilon^2. \tag{75}$$

In the second case ($f_1=0,g_1\neq 0$), the related symmetry group has the form

$$t'=t,\quad x'=x-f_2(t)\epsilon, \tag{76}$$

$$y'=G^{-1}(G(y)+\epsilon),\quad G(y)\equiv-\int^y\frac{1}{g_1(y_1)}\mathrm{d}y_1,\quad G^{-1}(G(y))=y, \tag{77}$$

$$p_i'(x',y',t') = [p_i(x,y,t')\exp(H_2(\epsilon,x,y,t'))]\Big|_{\substack{x=x'+f_2(t)\epsilon \\ y=G^{-1}(G(y')-\epsilon)}}, \tag{78}$$

$$q_j'(x',y',t') = \left[\frac{g_1(y)}{g_1(G^{-1}(G(y)+\epsilon))} q_j(x,y,t')\exp(-H_2(\epsilon,x,y,t'))\right]\Big|_{\substack{x=x'+f_2(t)\epsilon \\ y=G^{-1}(G(y')-\epsilon)}}, \tag{79}$$

$$u'(x',y',t') = (u(x,y,t') + S_1(\epsilon,x'+f_2(t)\epsilon,t')), \tag{80}$$

where

$$H_2(x,y,t) \equiv (H_1(\epsilon,x,y,t) - g_2(y))\epsilon + \int_y^{G^{-1}(G(y)+\epsilon)} \left(\frac{g_2(y_1)}{g_1(y_1)} + \frac{g_{1y_1}(y_1)}{g_1(y_1)}\right) \mathrm{d}y_1. \tag{81}$$

For the third case ($g_1 = 0$, $f_1 \neq 0$), the corresponding finite transformation becomes

$$y' = y, \quad t' = F^{-1}(F(t)+\epsilon), \quad F(t) \equiv -\frac{1}{24}\int^t \frac{1}{f_1(t_1)}\mathrm{d}t_1, \quad F^{-1}(F(t)) = t, \tag{82}$$

$$x' = \sqrt{\frac{f_1(t')}{f_1(t)}}x + \frac{\sqrt{f_1(t')}}{24}\int_t^{t'} \frac{f_2(t_1)}{f_1(t_1)^{3/2}}\mathrm{d}t_1 \equiv X_1(t',x,t), \tag{83}$$

$$p_i'(x',y',t') = \left\{ p_i(x,y,t)\exp\left(-\frac{1}{24}\int_t^{t'} \frac{H_3(t_1)}{f_1(t_1)}\mathrm{d}t_1\right)\right\}\Big|_{\substack{t=T(t') \\ y=y' \\ x=X(x',t')}}, \tag{84}$$

$$q_j'(x',y',t') = \left\{ q_j(x,y,t)\sqrt{\frac{f_1(T(t'))}{f_1(t')}}\exp\left(\frac{1}{24}\int_t^{t'} \frac{H_3(t_1)}{f_1(t_1)}\mathrm{d}t_1\right)\right\}\Big|_{\substack{t=T(t') \\ y=y' \\ x=X(x',t')}}, \tag{85}$$

$$u'(x',y',t') = \left\{ u(x,y,t)\frac{\sqrt{f_1(t)}}{\sqrt{f_1(t')}} - \frac{1}{24\sqrt{f_1(t')}}\int_t^{t'} \frac{S(t_1)}{\sqrt{f_1(t_1)}}\mathrm{d}t_1\right\}\Big|_{\substack{t=T(t') \\ y=y' \\ x=X(x',t')}}, \tag{86}$$

where

$$H_3(t_1) \equiv H(x',y',t')|_{t'=t_1,y'=y,x'=X_1(t_1,x,t)}, \tag{87}$$

$$S_3(t_1) \equiv S(x',t')|_{t'=t_1,x'=X_1(t_1,x,t)}, \tag{88}$$

$$T(t') \equiv F^{-1}(F(t')-\epsilon), \tag{89}$$

$$X(x',t') \equiv \sqrt{\frac{f_1(T(t'))}{f_1(t')}}x' - \frac{\sqrt{f_1(T(t'))}}{24}\int_{T(t')}^{t'} \frac{f_2(t_1)}{f_1(t_1)^{3/2}}\mathrm{d}t_1. \tag{90}$$

For the fourth situation, the general solution of (61)–(66) reads

$$t' = F^{-1}(F(t)+\epsilon), \quad F(t) \equiv -\frac{1}{24}\int^t \frac{1}{f_1(t_1)}\mathrm{d}t_1, \quad F^{-1}(F(t)) = t, \tag{91}$$

$$y'=G^{-1}(G(y)+\epsilon),\quad G(y)\equiv-\int^{y}\frac{1}{g_1(y_1)}\mathrm{d}y_1,\quad G^{-1}(G(y))=y, \tag{92}$$

$$x'=\sqrt{\frac{f_1(t')}{f_1(t)}}x+\frac{\sqrt{f_1(t')}}{24}\int_t^{t'}\frac{f_2(t_1)}{f_1(t_1)^{3/2}}\mathrm{d}t_1\equiv X_1(t',x,t), \tag{93}$$

$$p_i'(x',y',t')=\left\{p_i(x,y,t)\exp\left(-\frac{1}{24}\int_t^{t'}\frac{H_4(t_1)}{f_1(t_1)}\mathrm{d}t_1\right)\right\}\Bigg|_{\substack{t=T(t')\\ y=Y(y')\\ x=X(x',t')}}, \tag{94}$$

$$q_j'(x',y',t')=\left\{q_j(x,y,t)\sqrt{\frac{f_1(T(t'))}{f_1(t')}}\frac{g_1(y)}{g_1(y')}\exp\left(\frac{1}{24}\int_t^{t'}\frac{H_4(t_1)}{f_1(t_1)}\mathrm{d}t_1\right)\right\}\Bigg|_{\substack{t=T(t')\\ y=Y(y')\\ x=X(x',t')}}, \tag{95}$$

$$u'(x',y',t')=\left\{u(x,y,t)\frac{\sqrt{f_1(t)}}{\sqrt{f_1(t')}}-\frac{1}{24\sqrt{f_1(t')}}\int_t^{t'}\frac{S_3(t_1)}{\sqrt{f_1(t_1)}}\mathrm{d}t_1\right\}\Bigg|_{\substack{t=T(t')\\ y=Y(y')\\ x=X(x',t')}}, \tag{96}$$

where

$$H_4(t_1)\equiv H(x',y',t')\big|_{t'=t_1,y'=G^{-1}(G(y)+F(t_1)-F(t)),x'=X_1(t_1,x,t)}, \tag{97}$$

$$Y(y')=G^{-1}(G(y')-\epsilon). \tag{98}$$

From the above four situations, we know that if $\{p_i(x,y,t),\ q_j(x,y,t),\ u(x,y,t)\}$ is a solution of the system (1)–(3), then $\{p_i'(x',y',t'),\ q_j'(x',y',t'),\ u'(x',y',t')\}$ shown by (70)–(75), (76)–(80), (82)–(86) and (91)–(96) are all solutions of the same AKNS system (1)–(3) with the replacement $\{x,y,t,p_i,q_j,u\}\to\{x',y',t',p_i',q_j',u'\}$. Because of the entrance of the arbitrary functions $g_1(y),g_2(y),f_1(t),f_2(t),f_3(t),f_4(t)$, abundant localized structures of the (2 +1)-dimensional ($M+N$)-component AKNS system can be obtained from some simple solutions. To exhibit some interesting results explicitly, we discuss only the quantity pq of the simplest case for $M=N=1$, $p\equiv p_1$, $q\equiv q_1$. For the quantity pq, the corresponding finite transformations have the forms

$$p(x,y,t)q(x,y,t)\to p(x+f_2(t)\epsilon,y,t)q(x+f_2(t)\epsilon,y,t) \tag{99}$$

for the first case,

$$p(x,y,t)q(x,y,t)\to pq=\frac{g_1(Y(y))}{g_1(y)}p(x+\epsilon f_2(t),Y(y),t)q(x+\epsilon f_2(t),Y(y),t) \tag{100}$$

for the second case,

$$p(x,y,t)q(x,y,t)\to pq=\sqrt{\frac{f_1(T(t))}{f_1(t)}}p(X(x,t),Y(y),T(t))q(X(x,t),Y(y),T(t)) \tag{101}$$

for the third case and

$$p(x,y,t)q(x,y,t)\to pq=\sqrt{\frac{f_1(T(t))}{f_1(t)}}\frac{g_1(Y(y))}{g_1(y)}p(X(x,t),Y(y),T(t))q(X(x,t),Y(y),T(t)) \tag{102}$$

for the fourth case. In Eqs. (99)–(102), we have dropped out primes because the systems with and without primes are totally the same. Now let us write down some simple solutions of the $(2+1)$-dimensional AKNS system (1)–(3). It is straightforward to see that the system (1)–(3) possesses the n parallel (parallel to the line $x-y/c^2=0$ with constant c) bright soliton and/or n parallel (parallel to the line $x+y/c^2=0$) dark soliton solutions because the system will be reduced to the $(1+1)$-dimensional AKNS system(s):

$$ip_t+p_{\xi_\pm\xi_\pm}\mp c^2p^2q=0, \tag{103}$$

$$-iq_t+q_{\xi_\pm\xi_\pm}\mp c^2q^2p=0, \quad \xi_\pm=x\pm y/c^2. \tag{104}$$

The n dark soliton solutions of (103) and (104) with up sign and the n bright soliton solutions of (103) and (104) with lower sign are known in the literature. Now using the standard n bright soliton solutions of (103) and (104) located at

$$\xi_-=v_kt+x_{k0}, \quad k=1,2,\ldots,n, \tag{105}$$

and the transformation relation (99)–(102), we can obtain many $(2+1)$-dimensional localized structures. For instance, if we take

$$f_1(t)=\text{const.} \tag{106}$$

and $g_1(Y(y))/g_1(y)$ as m straight line (parallel to x axis) solitons, say,

$$\frac{g_1(Y(y))}{g_1(y)}=\sum_{j=1}^{m} Q_j(y-y_{0j}), \tag{107}$$

where $Q_j(y-y_{j0})$ is a straight line soliton located at $y=y_{j0}$, then pq expressed by (102) becomes a special type of $n\times m$ (or even more) dromion solution. All the dromions are located at the cross points and very closed points of the straight line solitons located at $y=y_{0j}$ and the curved line solitons located at

$$X-Y(y)/c^2=v_kt+x_{k0}, \quad k=1,2,\ldots,N, \tag{108}$$

with X and $Y(y)$ being given by (90) and (98), respectively. In high dimensions, the breather solutions may have also abundant structures. For instance, if we take the seed solution as the multi-breather solutions, then (102) with (106) and (107) becomes the breatherlike dromion solutions.

V. SIMILARITY REDUCTIONS

In this section, we try to find the solutions that are invariant under the symmetry group transformations. To find the group transformation invariant solutions of the $(2+1)$-dimensional $(M+N)$-component AKNS system, we should solve the following symmetry constraint equation,

$$\begin{pmatrix} -24f_1(t)p_{it}-(f_2(t)+12f_{1t}x)p_{ix}-g_1(y)p_{iy}+H(x,y,t) \\ -24f_1(t)q_{it}-(f_2(t)+12f_{1t}x)q_{ix}-g_1(y)q_{iy}+R(x,y,t) \\ -24f_1(t)u_t-(f_2(t)+12f_{1t}x)u_x-g_1(y)u_y+S(x,t) \end{pmatrix}=0, \tag{109}$$

at first, where $H(x,y,t)$, $R(x,y,t)$, $S(x,t)$ are given by (67)–(69). One can solve the symmetry constraint equation (109) by solving the characteristic equation

$$\frac{\mathrm{dt}}{-24f_1(t)}=\frac{\mathrm{dx}}{f_2(t)+12f_{1t}x}=\frac{\mathrm{dy}}{-g_1(y)}=\frac{\mathrm{dp_i}}{H(x,y,t)}=\frac{\mathrm{dq_j}}{R(x,y,t)}=\frac{\mathrm{du}}{S(x,t)}, \tag{110}$$

where $H(x,y,t)$, $R(x,y,t)$ and $S(x,t)$ are given by (67)–(69). It is easy to find that all the solutions of the characteristic Eq. (110) have the forms

$$p_i=\pi_i(\xi,\eta)\exp(\pi_0(x,y,t)),\quad \xi\equiv\xi(x,y,t),\quad \eta\equiv\eta(x,y,t), \tag{111}$$

$$q_j=\tau_j(\xi,\eta)\exp(\tau_0(x,y,t)), \tag{112}$$

$$u=\beta(x,y,t)u_1(\xi,\eta)+u_0(x,y,t). \tag{113}$$

The more general results but with the same forms as (111)–(113) can also be obtained by the CK (Clarkson and Kruskal) direct method[23] or the nonclassical Lie approach.[24] So, in the following, we list four general results directly with the forms (111)–(113) instead of solving the characteristic equation (110).

A. Case 1

The simplest case

$$\xi=y,\quad \eta=t,\quad \beta(x,y,t)=1, \tag{114}$$

$$u_0(x,y,t)=U_3(t)x^3+U_2(t)x^2+U_1(t)x, \tag{115}$$

$$\pi_0(x,y,t)=\tfrac{1}{2}(\tfrac{1}{2}\Gamma_1(y,t)-\tfrac{1}{2}\Omega_1(y,t))x^2+F_1(y,t)x, \tag{116}$$

$$\tau_0(x,y,t)=-\pi(x,y,t) \tag{117}$$

is related to the generalization of (110) with $f_1(t)=g_1(y)=0$. The reduction fields $\tau_j(y,t)$, $\pi_i(y,t)$ and $u_1(y,t)$ satisfy the following reduction equations

$$\Gamma_1(y,t)\pi_i(y,t)+i\pi_{it}(y,t)=0, \tag{118}$$

$$\Omega_1(y,t)\tau_j(y,t)-i\tau_{jt}(y,t)=0, \tag{119}$$

$$u_{1y}(y,t)+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}\pi_i(y,t)\tau_j(y,t)=0, \tag{120}$$

where

$$\Omega_1(y,t)=2U_1(t)-\Gamma_1(y,t)+2F_1(y,t)^2, \tag{121}$$

while $F_1(y,t)$ and $\Gamma_1(y,t)$ are determined by

$$F_{1t}(y,t)=2i[\Gamma_1(y,t)F_1(y,t)-F_1(y,t)^3-F_1(y,t)U_1(t)+U_2(t)] \tag{122}$$

and

$$\begin{aligned}\Gamma_{1t}(y,t)=i[&6U_3(t)-2F_1(y,t)^4+4F_1(y,t)U_2(t)-iU_{1t}(t)+2\Gamma_1(y,t)^2\\&-4\Gamma_1(y,t)U_1(t)+2U_1(t)^2],\end{aligned} \tag{123}$$

and $U_1(t)$, $U_2(t)$ and $U_3(t)$ are arbitrary functions of t. When the functions $F_1(y,t)$ and $\Gamma_1(y,t)$ are fixed by (122) and (123), the general solution of the reduction equations (118)–(120) can be obtained by partial integrations:

$$\pi_i=A_i(y)\exp\left(-i\int\Gamma_1(y,t)dt\right), \tag{124}$$

$$\tau_j = B_j(y)\exp\left(i\int \Omega_1(y,t)dt\right), \tag{125}$$

$$u_1(y,t) = -\sum_{i=1}^{N}\sum_{j=1}^{M}\int a_{ij}A_iB_j\exp\left(i\int(\Omega_1(y,t)-\Gamma_1(y,t))dt\right)\mathrm{d}y, \tag{126}$$

with arbitrary functions $A_i(y)$, $i=1,2,\ldots,N$, and $B_j(y)$, $j=1,2,\ldots,M$.

B. Case 2

For the second case, we have

$$\xi = x - f_2(t)G_1(y), \quad \eta = t, \quad \beta(x,y,t)=0, \tag{127}$$

$$\pi_0(x,y,t) = \tfrac{1}{2}if_{2t}(t)G_1(y)x + A_1(y,t), \tag{128}$$

$$\tau_0(x,y,t) = -\tfrac{1}{2}if_{2t}(t)G_1(y)x - A_1(y,t) + A_2(y), \tag{129}$$

$$u_0(x,y,t) = \tfrac{1}{4}f_{2tt}(t)G_1(y)x^2 - iA_{1t}(y,t)x + \tfrac{1}{4}f_{2t}(t)^2G_1(y)^2x + A_0(y,t), \tag{130}$$

and the reduction fields $\tau_j(\xi,t)$, $\pi_i(\xi,t)$ and $u_1(\xi,t)$ satisfy the reduction equations:

$$\pi_{i\xi\xi}(\xi,t) + i\pi_{it}(\xi,t) + u_{1\xi}(\xi,t)\pi_i(\xi,t) = 0, \tag{131}$$

$$\tau_{j\xi\xi}(\xi,t) - i\tau_{jt}(\xi,t) + u_{1\xi}(\xi,t)\tau_j(\xi,t) = 0, \tag{132}$$

$$-u_{1\xi}(\xi,t)f_2(t) + \tfrac{1}{4}f_{2tt}(t)\xi^2 + H_1(t)\xi + H_0(t) + \sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}\pi_i(\xi,t)\tau_j(\xi,t) = 0, \tag{133}$$

where

$$A_0(y,t) = \tfrac{1}{12}f_{2tt}(t)f_2(t)^2G_1(y)^3 - \tfrac{1}{2}H_1(t)f_2(t)G_1(y)^2 + H_0(t)G_1(y) + H_2(t), \tag{134}$$

$$A_{1yt}(y,t) = \tfrac{1}{2}iG_{1y}(y)(-f_{2tt}(t))f_2(t)G_1(y) - f_{2t}(t)^2G_1(y) + 2H_1(t), \tag{135}$$

$$A_2(y) = \ln(G_{1y}(y)), \tag{136}$$

and $H_0(t)$, $H_1(t)$, $H_2(t)$ and $f_2(t)$ are arbitrary functions of t and $G_1(y)$ is an arbitrary function of y.

The reduction system (131)–(133) is equivalent to the $(1+1)$-dimensional $(M+N)$-component AKNS system

$$R_{iXX}(X,T) + iR_{iT}(X,T) + R_i(X,T)\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}R_n(X,T)S_m(X,T) = 0, \tag{137}$$

$$S_{jXX}(X,T) - iS_{jT}(X,T) + S_j(X,T)\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}R_n(X,T)S_m(X,T) = 0, \tag{138}$$

with

$$\pi_i(\xi,t) = R_i(X,T)\exp\left(-i\frac{h_{1t}(t)}{2h_1(t)}\xi^2 - i\frac{h_{2t}(t)}{h_1(t)}\xi + ih_3(t)\right), \tag{139}$$

$$\tau_j(\xi,t)=f_2(t)S_j(X,T)\exp\left(i\frac{h_{1t}(t)}{2h_1(t)}\xi^2+i\frac{h_{2t}(t)}{h_1(t)}\xi-ih_3(t)\right), \tag{140}$$

$$u_1(\xi,t)=\frac{1}{12f_2(t)}[f_{2tt}(t)\xi^3+6H_1(t)\xi^2+12H_0(t)\xi+12f_2(t)^2U(X,T)],$$

and $\{X,\ T,\ h_1,\ h_2,\ h_3\}$ being determined by

$$X=f_2(t)\xi+2\int^t h_{2t}(t)h_1(t)\mathrm{dt},\quad T(t)=\int^t f_2(t)^2\mathrm{dt}, \tag{141}$$

$$h_1(t)^2=f_2(t),\quad h_2(t)=-\int^t f(t')^{-3/2}\int^{t'}H_1(t_1)\mathrm{dt}_1\mathrm{dt}', \tag{142}$$

$$h_3(t)=\int^t\frac{1}{2\,f_2(t')^2}\left[if_2(t')f_{2t'}(t')+2\,f_2(t')H_0(t')-2\left(\int^{t'}H_1(t_1)\mathrm{dt}_1\right)^2\right]\mathrm{dt}'. \tag{143}$$

Actually, the second situation shown by (131)–(133) or equivalently by (137)–(138) is the generalization of that obtained by the classical Lie point symmetry approach of (110) for $f_1(t)=0$, $g_1(y)\neq 0$.

C. Case 3

The third case possesses the solution

$$\xi=F_2(t)x+F_3(t),\quad \eta=y,\quad \beta(x,y,t)=1, \tag{144}$$

$$\pi_0(x,y,t)=-\frac{iF_{2t}(t)}{4F_2(t)}x^2+\frac{iF_{3t}(t)}{2F_2(t)}x+F_1(t)+i\int H_1(y)\mathrm{dy}\int F_2(t)^2\mathrm{dt}, \tag{145}$$

$$\tau_0(x,y,t)=-\pi_0(x,y,t)+\ln(F_2(t)), \tag{146}$$

$$\begin{aligned}u_0(x,y,t)=&\left(-\frac{F_{2tt}(t)}{12F_2(t)}+\frac{1}{6}\frac{F_{2t}(t)^2}{F_2(t)^2}\right)x^3+\left(\frac{1}{4}\frac{F_{3tt}(t)}{F_2(t)}-\frac{1}{2}\frac{F_{3t}(t)F_{2t}(t)}{F_2(t)^2}\right)x^2\\&+\left(\frac{iF_{2t}(t)}{2F_2(t)}+\frac{1}{4}\frac{F_{3t}(t)^2}{F_2(t)^2}-iF_{1t}(t)+F_2(t)^2\int H_1(y)\mathrm{dy}\right)x\\&+F_2(t)\int H_0(y)\mathrm{dy}-F_2(t)F_3(t)\int H_1(y)\mathrm{dy}+F_0(t),\end{aligned} \tag{147}$$

and the reduction fields $\tau_j(\xi,y)$, $\pi_i(\xi,y)$ and $u_1(\xi,y)$ satisfy the reduction equations:

$$\pi_{i\xi\xi}(\xi,y)+u_{1\xi}(\xi,y)\pi_i(\xi,y)=0, \tag{148}$$

$$\tau_{j\xi\xi}(\xi,y)+u_{1\xi}(\xi,y)\tau_j(\xi,y)=0, \tag{149}$$

$$u_{1y}(\xi,y)+H_1(y)\xi+H_0(y)+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}\pi_i(\xi,y)\tau_j(\xi,y)=0, \tag{150}$$

and $F_1(t)$, $F_2(t)$ $F_3(t)$, $F_0(t)$, $H_0(y)$ and $H_1(y)$ are all arbitrary functions of the indicated variables. The third case is the generalization of the solution of (110) with $f_1(t)\neq 0, g_1(y)=0$.

D. Case 4

The fourth case is related to the generalized case of (110) with $f_1(t)\neq 0, g_1(y)\neq 0$. In this case, the general solution has the form

$$\xi = F_2(t)x + F_3(t), \quad \eta = F_1(t) + G_1(y), \tag{151}$$

$$\beta(x,y,t) = F_2(t) = \sqrt{F_{1t}}, \tag{152}$$

$$\pi_0(x,y,t) = -\frac{1}{4F_2(t)}(iF_{2t}(t)x^2 + 2iF_{3t}(t)x - 2g_0(y,t)), \tag{153}$$

$$\tau_0(x,y,t) = \frac{1}{4F_2(t)}(iF_{2t}(t)x^2 + 2iF_{3t}(t)x - 2g_0(y,t) + 4F_2(t)[\ln(G_{1y}(y)\theta_1^{-1}) + \ln(F_2(t))]), \tag{154}$$

$$u_0(x,y,t) = \frac{1}{12F_2(t)^2}((2F_{2t}(t)^2 - F_2(t)F_{2tt}(t))x^3 - (3F_2(t)F_{3tt}(t) - 6F_{3t}(t)F_{2t}(t))x^2 + (-6iF_2(t)g_{0t}(y,t) + 6iF_{2t}(t)(g_0(y,t) + F_2(t)) + 3F_{3t}(t)^2)x + g_1(y,t)F_2(t)^2), \tag{155}$$

and the reduction fields $\tau_j(\xi,\eta)$, $\pi_i(\xi,\eta)$ and $u_1(\xi,\eta)$ satisfy the reduction equations:

$$\pi_{i\xi\xi}(\xi,\eta) + u_{1\xi}(\xi,\eta)\pi_i(\xi,\eta) + i\pi_{i\eta}(\xi,\eta) = 0, \tag{156}$$

$$\tau_{j\xi\xi}(\xi,\eta) + u_{1\xi}(\xi,\eta)\tau_j(\xi,\eta) - i\tau_{j\eta}(\xi,\eta) = 0, \tag{157}$$

$$u_{1\eta}(\xi,\eta)\theta_1 + \theta_{21}(\eta)\xi + \theta_{22}(\eta) + \sum_{i=1}^{N}\sum_{j=1}^{M} a_{ij}\pi_i(\xi,\eta)\tau_j(\xi,\eta) = 0, \tag{158}$$

where

$$g_1(y,t) \equiv g_1(\eta,t) = 12F_2(t)\theta_1^{-1}\int(\theta_{21}(\eta)F_3(t) + \theta_{22}(\eta))\mathrm{d}\eta + F_6(t), \tag{159}$$

$$g_0(y,t) \equiv g_0(\eta,t) = F_4(t) + F_5(\eta)F_2(t) + 2iF_2(t)\theta_1^{-1}\int\int F_2(t)^2\theta_{21}(\eta)\mathrm{d}t\mathrm{d}\eta, \tag{160}$$

while θ_1 is an arbitrary constant and $G_1(y)$, $\theta_{21}(\eta)$, $\theta_{22}(\eta)$, $F_5(\eta)$, $F_1(t)$, $F_3(t)$, $F_4(t)$ and $F_6(t)$ are all arbitrary functions of the indicated arguments.

VI. ORDINARY DIFFERENTIAL EQUATION (ODE) REDUCTIONS

To find the ODE reductions, one may directly study the ODE reductions of the original system (1)–(3) by using the CK direct method as for the KP equation.[25] However, in this section, we treat the problem alternatively. Actually, we have obtained the $(1+1)$-dimensional partial differential equation (PDE) reductions of the system (1)–(3) in the last section. If we reduce these $(1+1)$-dimensional equations further to ODEs, then the ODE reductions of the original system (1)–(3) are found at the same time thanks to the results of the last section.

Because the first type of reduction equation system (118)–(120) had been solved out and the third reduction system (148)–(150) can be considered as a special case of the fourth type of reduction system (156)–(158), we only list the ODE reductions for the $(1+1)$-dimensional systems (137) and (138) and (156)–(158).

A. ODE reductions of (137) and (138)

For the (1+1)-dimensional (M+N)-component AKNS system (137) and (138), using the standard classical and nonclassical Lie group approach and/or the direct method, we can find two types of similarity ODE reductions.

The first type of ODE reduction of the system (137) and (138) reads

$$R_i(X,T)=(T+t_0)^c\exp\left(\frac{i(X+x_0)^2}{4(T+t_0)}-\frac{ic_0(X+x_0)}{\sqrt{T+t_0}}-ic_1\sqrt{T+t_0}\right)r_i(Z), \tag{161}$$

$$S_j(X,T)=(T+t_0)^{-c-1}\exp\left(-\frac{i(X+x_0)^2}{4(T+t_0)}+\frac{ic_0(X+x_0)}{\sqrt{T+t_0}}+ic_1\sqrt{T+t_0}\right)s_j(Z), \tag{162}$$

$$i(Z-4c_0)r_{iZ}+2r_{iZZ}+(i+2ic-2c_0^2+c_0Z)r_i+2r_i\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}r_ns_m=0, \tag{163}$$

$$-i(Z-4c_0)s_{jZ}+2s_{jZZ}+(i+2ic-2c_0^2+c_0Z)s_j+2s_j\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}r_ns_m=0, \tag{164}$$

with

$$Z=\frac{(X+x_0)}{\sqrt{T+t_0}}+\frac{c_1\sqrt{T+t_0}}{c_0} \tag{165}$$

and c, c_0, x_0, t_0 and c_1 being arbitrary constants.

For the second type of ODE reduction, we have

$$R_i(X,T)=\exp\left(\frac{iX^2+4ic_1X}{4(T+t_0)}\right)r_i(T), \tag{166}$$

$$S_j(X,T)=\exp\left(-\frac{iX^2+4ic_1X}{4(T+t_0)}\right)s_j(T), \tag{167}$$

$$ir_{iT}+\left(\frac{c_1^2}{T^2}-\frac{i}{2T}\right)r_i+r_i\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}r_ns_m=0, \tag{168}$$

$$-is_{jT}+\left(\frac{c_1^2}{T^2}+\frac{i}{2T}\right)s_j+s_j\sum_{n=1}^{N}\sum_{m=1}^{M}a_{nm}r_ns_m=0, \tag{169}$$

where c_1 and t_0 are arbitrary constants.

B. ODE reductions of (156)–(158)

For the (1+1)-dimensional system (156)–(158), we can find three types of ODE reductions. The first type of ODE reduction of (156)–(158) reads

$$\pi_i(\xi,\eta)=f_0r_i(Z),\quad Z=\xi+x_0, \tag{170}$$

$$\tau_j(\xi,\eta)=(i\theta_1f_0f_{0\eta\eta}-i\theta_2f_{0\eta}^2-f_0^2\theta_{21}(\eta))\frac{s_j(Z)}{f_0^3a_1}, \tag{171}$$

$$u=u_1(Z)-i\frac{f_{0\eta}}{f_0}\xi+u_0(\eta), \tag{172}$$

$$r_{iZZ}+r_iu_{1Z}=0, \tag{173}$$

$$s_{jZZ}+s_ju_{1z}+iA_1s_j=0, \tag{174}$$

$$a_1Z+a_0+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{ij}r_is_j=0, \tag{175}$$

where a_0, a_1 and A_1 are arbitrary constants and f_0 and u_0 are determined by

$$f_{0\eta\eta\eta}=-A_1\left(f_{0tt}-\frac{f_{0\eta}^2}{f_0}+\frac{if_0\theta_{21}}{\theta_1}\right)-i\frac{f_0\theta_{21\eta}}{\theta_1}+3\frac{f_{0\eta}f_{0\eta\eta}}{f_0}-2\frac{f_{0\eta}^3}{f_0^2} \tag{176}$$

and

$$u_{0\eta}=i(a_0+a_1\xi_0)\left(\frac{f_{0\eta}^2}{a_1f_0^2}-\frac{f_{0\eta\eta}}{a_1f_0}-\frac{i\theta_{21}}{a_1\theta_1}\right)-\frac{\theta_{22}}{\theta_1}. \tag{177}$$

For the second type of similarity reduction of the system (156)–(158), we have

$$\pi_i(\xi,\eta)=e^{-c_2(\eta)\xi^2-c_3(\eta)\xi}r_i(\eta),\quad \tau_j(\xi,\ \eta)=e^{c_2(\eta)\xi^2+c_3(\eta)\xi}s_j(\eta), \tag{178}$$

$$u=\tfrac{1}{3}(ic_{2\eta}-4c_2^2)\xi^3+\tfrac{1}{2}(ic_{3\eta}-4c_2c_3)\xi^2-(2c_2+c_3^2)\xi+u_0(\eta)+\xi u_1(\eta), \tag{179}$$

$$ir_{i\eta}-(4c_2-u_1)r_i=0, \tag{180}$$

$$is_{j\eta}-u_1s_j=0, \tag{181}$$

$$\theta_1u_{0\eta}+\theta_{22}+\sum_{n=1}^{N}\sum_{m=1}^{M}a_{ij}r_is_j=0, \tag{182}$$

where the functions c_2, c_3 and u_1 are given by

$$c_2=-i\frac{c_1}{4}\tanh(c_1(\eta-\eta_0)),\quad c_3=c_5\tanh(c_1(\eta-\eta_0))+c_4\,\mathrm{sech}(c_1(\eta-\eta_0)) \tag{183}$$

and

$$u_{1\eta}=c_1\,\mathrm{sech}(c_1(\eta-\eta_0))\left(2c_4c_5(2\,\mathrm{sech}^2(c_1(\eta-\eta_0))-1)-\frac{i}{2}c_1\,\mathrm{sech}(c_1(\eta-\eta_0))\right)$$

$$+2c_1(c_5^2-c_4^2)\tanh(c_1(\eta-\eta_0))\mathrm{sech}^2(c_1(\eta-\eta_0))-\frac{\theta_{21}}{\theta_1}, \tag{184}$$

and c_1, c_4, c_5 and η_0 are arbitrary constants.

The third type of ODE reduction of the system (156)–(158) has the special form

$$\pi_i=f_0\exp\left(-\frac{i}{4z_1}z_{1\eta}\xi(\xi-2\xi_0)\right)r_i(Z), \tag{185}$$

$$\tau_j=\frac{z_{1\eta}}{f_0A_2}\exp\left(\frac{i}{4z_1}z_{1\eta}\xi(\xi-2\xi_0)\right)s_j(Z), \tag{186}$$

$$u=u_0-\frac{\xi^2(\xi+3\xi_0)}{12z_1^2}(z_1z_{1\eta\eta}-2z_{1\eta}^2)-\left(\frac{if_{0\eta}}{f_0}-\frac{iz_{1\eta}}{2z_1}-\frac{\xi_0^2z_{1\eta}^2}{4z_1^2}\right)\xi, \tag{187}$$

$$Z=z_1(\xi+\xi_0)+Z_0, \tag{188}$$

$$z_1\equiv z_1(\eta)=\sqrt{\frac{c_1}{\exp(c_1(\eta-\eta_0))-A_1}}, \tag{189}$$

$$r_{iZZ}+r_iu_{1Z}=0, \tag{190}$$

$$s_{jZZ}+s_ju_{1Z}+iA_1s_j=0, \tag{191}$$

$$4A_2\theta_1(Z_0-Z)u_{1Z}-4\theta_1A_2u_1-4a_0A_2-4a_1A_2Z-\theta_1Z_0A_2A_1Z^2-4\sum_{n=1}^{N}\sum_{m=1}^{M}a_{ij}r_is_j=0, \tag{192}$$

where the functions $u_0\equiv u_0(\eta)$ and $f_0\equiv f_0(\eta)$ are determined by

$$u_{0\eta}=\frac{z_{1\eta}}{12\theta_1}[-A_1\theta_1(z_1\xi_0-2Z_0)(z_1\xi_0+Z_0)^2+12(a_0+a_1Z_0+a_1z_1\xi_0)]-\frac{\theta_{22}}{\theta_1} \tag{193}$$

and

$$f_{0\eta\eta}=\frac{if_0z_1z_{1\eta}}{4}\left(\frac{4a_1}{\theta_1}+2iA_1+A_1Z_0^2-A_1\xi_0^2z_1^2\right)+\frac{f_{0\eta}^2}{f_0}+\frac{1}{2}iA_1\xi_0^2f_0z_{1\eta}^2-\frac{\theta_{21}f_0}{\theta_1}, \tag{194}$$

while A_1, A_2, a_0, a_1, c_1, η_0, ξ_0 and Z_0 are all arbitrary constants.

VII. EXACT SOLUTIONS OF THE *M+N* COMPONENT AKNS SYSTEM OBTAINED FROM VARIABLE SEPARATION APPROACH

It is well known that the Painlevé analysis can also be used to obtain other interesting properties.[7] For instance, substituting the truncated form of the Painlevé expansion in the original system will lead to its multi-linear form. For the $(M+N)$-component AKNS system (1)–(3), substituting the truncated Painlevé expansion

$$p_i=\frac{P_i}{f}+p_{i0},\quad q_j=\frac{Q_j}{f}+q_{j0},\quad u=\frac{2f_x}{f}+u_0 \tag{195}$$

into the model yields the following bilinear form:

$$(iD_t+D_x^2+u_{0x})P_i\cdot f+p_{i0}D_x^2f\cdot f=0, \tag{196}$$

$$(-iD_t+D_x^2+u_{0x})Q_j\cdot f+q_{j0}D_x^2f\cdot f=0, \tag{197}$$

$$D_xD_yf\cdot f+\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}(P_iQ_j+p_{i0}fQ_j+q_{j0}fP_i)=0, \tag{198}$$

where D_t, D_x and D_y are the standard Hirota's bilinear operator and $\{p_{i0},q_{j0},u_0\}$ is an arbitrary seed solution of the system (1)–(3).

If we select the seed solution as

$$p_{i0}=q_{j0}=0, \quad u_0=u_0(x,t), \tag{199}$$

where $u_0=u_0(x,t)$ is an arbitrary function of x and t, then the bilinear system (196)–(198) can be solved by using the variable separation ansatz

$$f=a_1F(x,t)+a_2G(y,t)+a_3F(x,t)G(y,t), \tag{200}$$

$$P_i=F_{1i}(x,t)G_{1i}(y,t)\exp(iR_{1i}(x,t)+iS_{1i}(y,t)), \tag{201}$$

$$Q_j=F_{2j}(x,t)G_{2j}(y,t)\exp(-iR_{2j}(x,t)-iS_{2j}(y,t)), \tag{202}$$

where the space variables x and y have been totally separated into the functions $\{F,F_{1i},F_{2j},R_{1i},R_{2j}\}$ and $\{G,G_{1i},G_{2j},S_{1i},S_{2j}\}$, respectively.

Substituting the ansatz into (196)–(198) and using the fact that the space variables x and y have been separated into different functions $\{F,F_{1i},F_{2j},R_{1i},R_{2j}\}$ and $\{G,G_{1i},G_{2j},S_{1i},S_{2j}\}$, we can find that

$$G_{1i}=\frac{b_{1i}}{a_{1i}(t)}\sqrt{G_y}, \quad G_{2j}=\frac{b_{2j}}{a_{2j}(t)}\sqrt{G_y}, \tag{203}$$

$$F_{1i}=a_{1i}(t)\sqrt{F_x}, \quad F_{2j}=a_{2j}(t)\sqrt{F_x}, \tag{204}$$

$$S_{1i}=B(t)+s_{1i}(y), \quad S_{2j}=B(t)+s_{2j}(y), \tag{205}$$

$$R_{1ix}=R_{2jx}\equiv R_x=-\frac{1}{2a_1a_2F_x}(a_2^2\alpha_0(t)+a_1a_2F_t+a_2\alpha_2(t)F+\alpha_1F^2), \tag{206}$$

$$G_t=\frac{G^2}{a_1^2}(a_3^3\alpha_0(t)-a_3\alpha_2(t)+\alpha_1(t))+\frac{G}{a_1}(2a_3\alpha_0(t)-\alpha_2(t))+\alpha_0(t), \tag{207}$$

$$\begin{aligned} u_{0x}=&\frac{1}{4a_1^2a_2^2F_x^2}(a_1^2a_2^2F_t^2+2a_1a_2(a_2\alpha_0(t)+a_2\alpha_2(t)F+\alpha_1(t)F^2)F_t\\ &+a_2^2a_1^2(F_{xx}^2-2F_xF_{xxx}+4F_x^2(B_t(t)+R_t))+a_2^2\alpha_2(t)^2F^2\\ &+2a_2\alpha_2(t)F(a_2^2\alpha_0(t)+F^2\alpha_1(t))+(a_2^2\alpha_0(t)+F^2\alpha_1(t))^2), \end{aligned} \tag{208}$$

where b_{1i} and b_{2j} are arbitrary constants and $F(x,t)$,$a_{1i}(t)$, $a_{2j}(t)$, $s_{1i}(y)$, $s_{2j}(y)$, $B(t)$, $\alpha_0(t)$, $\alpha_1(t)$, $\alpha_2(t)$ are all arbitrary functions of the indicated variables with the condition

$$\sum_{i=1}^{N}\sum_{j=1}^{M}a_{ij}b_{1i}b_{2j}\exp(i(s_{1i}(y)-s_{2j}(y)))=2a_1a_2. \tag{209}$$

Hence, for the quantity $v\equiv\Sigma_{i=1}^{N}\Sigma_{j=1}^{M}a_{ij}p_iq_j$, we have

$$v=\frac{2a_1a_2F_xG_y}{(a_1F+a_2G+a_3FG)^2} \tag{210}$$

with F being an arbitrary function of x and t and $G=G(y,t)$ being an arbitrary solution of the Riccati equation (207). It is interesting that the expression (210) is valid for many $(2+1)$-dimensional models like the DS equation, NNV system, ANNV equation and ADS model and the dispersive long wave equation, etc.[4,17–19] Because of the arbitrariness of the functions F

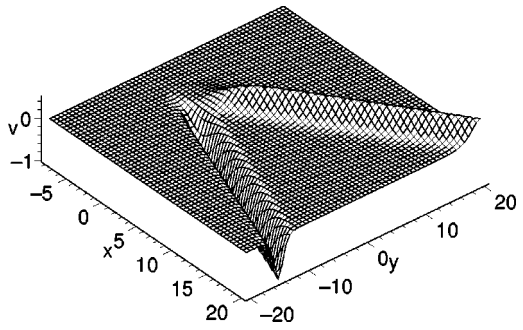

FIG. 1. A special two-solitoff solution for the quantity v shown by (210) with (211) and (212) at time $t=0$.

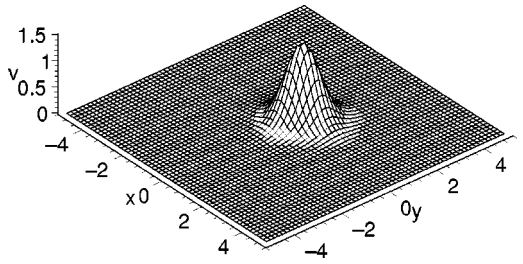

FIG. 2. A single dromion solution for the quantity v shown by (210) with (211) and (213) at time $t=0$.

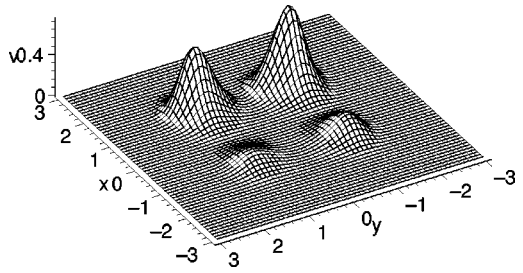

FIG. 3. A special four-dromion solution shown by (210) with (214) and (217) at time $t=0$.

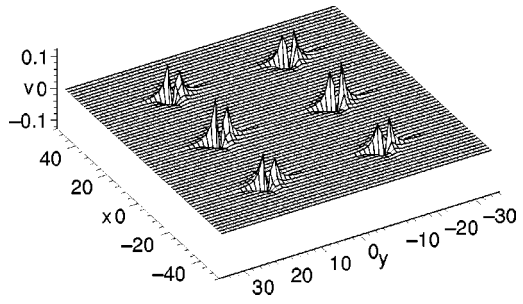

FIG. 4. A special lump solution for (210) with (219) at time $t=0$.

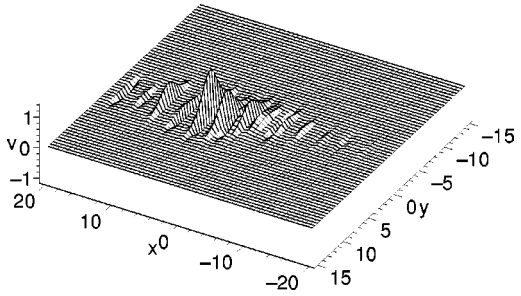

FIG. 5. A special dromion solution with the selection (221) at time $t=0$.

and G included in (210), the quantity v possesses quite rich structures. For instance, as mentioned in Refs. 4 and 17–19, if we select the functions F and G appropriately, we can obtain many kinds of localized solutions like the multi-solitoff solutions, multi-dromion and dromion lattice solutions, multiple ring soliton solutions and so on. Though these types of localized solutions have been discussed for other models, we still write down some special examples for completeness.

Example 1: Multi-solitoff solutions and multi-dromion solutions driven by straight-line solitons. If we restrict the functions F and G of (210) as

$$F=1+\sum_{i=1}^{N}\exp(k_i x+\omega_i t+x_{0i})\equiv 1+\sum_{i=1}^{N}\exp(\xi_i), \tag{211}$$

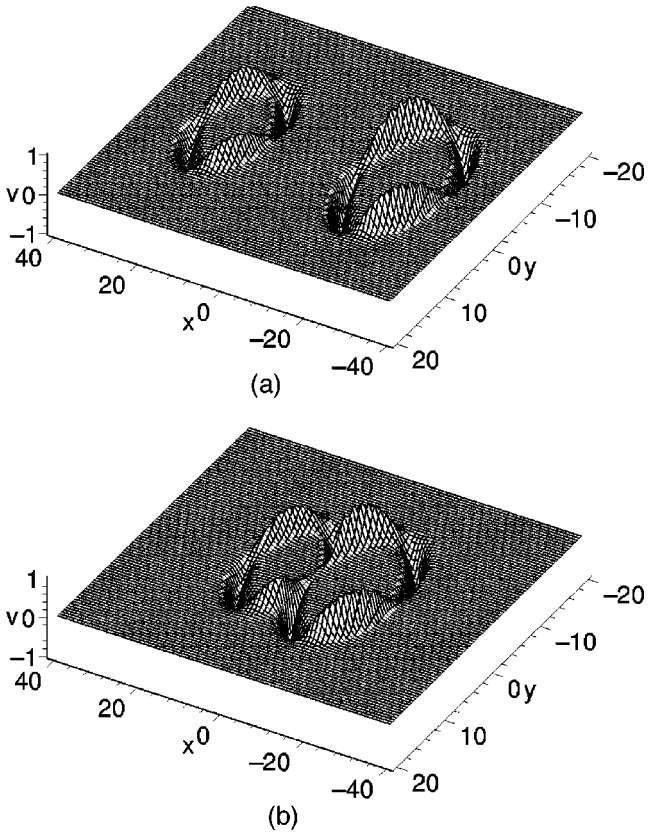

FIG. 6. The evolution of two saddle type ring soliton solution shown by (210) with the selection (222) at the times (a) $t=-1$, (b) $t=-0.4$, (c) $t=0$, (d) $t=0.4$, and (e) $t=1$.

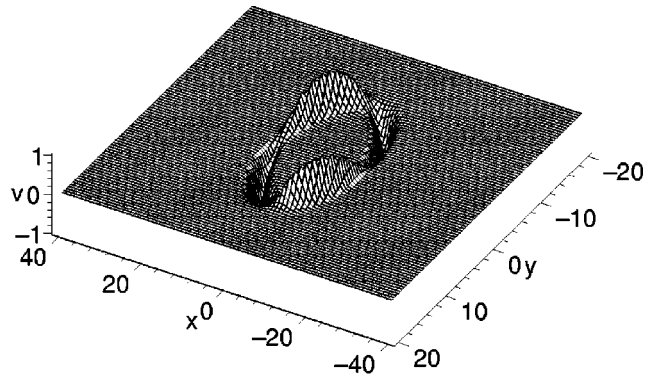

(c)

(e)

FIG. 6. (*Continued.*)

$$G=\sum_{i=1}^{M}\exp(K_{iy}+y_{0i})\sum_{j=1}^{J}\exp(\Omega_j t),$$

where x_{0i}, y_{0i}, k_i, ω_i, K_i and Ω_i are arbitrary constants and M, N and J are arbitrary positive integers, then we have the multi-solitoff solutions (we call a half straight line soliton solution as a

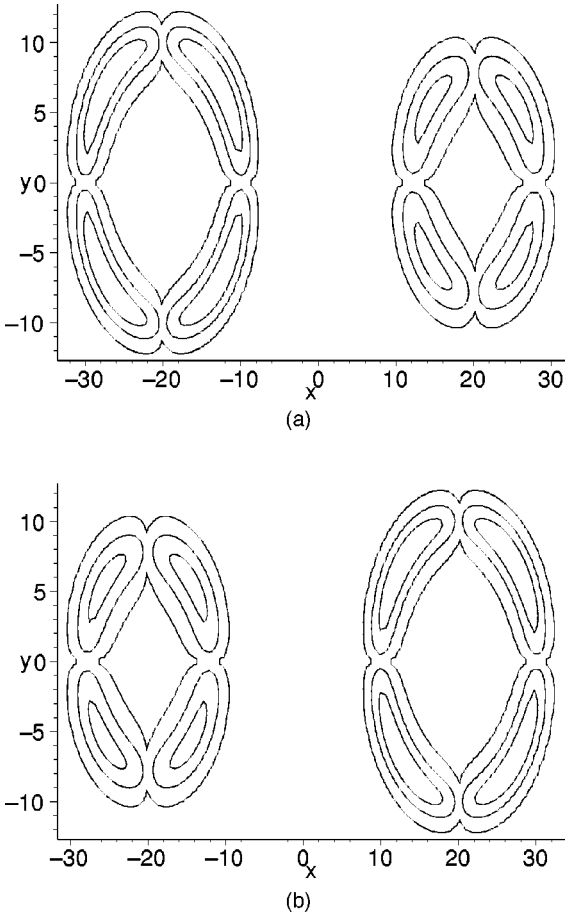

FIG. 7. (a) The contour plot related to Fig. 6(a). (b) The contour plot of Fig. 6(e). The values of the contours in these figures from the outside contours to the inside contours are $|v|=0.01$, $|v|=0.1$, and $|v|=0.4$, respectively.

solitoff which is caused by the resonance condition $a_3=0$) and the first type of special multidromion solutions ($a_3\neq 0$) driven by multiple straight line solitons. The selection (211) corresponds to

$$\alpha_0(t)=0,\quad \alpha_1(t)=a_3\alpha_2(t)=-a_1a_3\frac{\Sigma_{j=1}^{J}\Omega_j\exp(\Omega_j t)}{\Sigma_{j=1}^{J}\exp(\Omega_j t)}.$$

For the solution (211), there is no dispersion relation among k_i, ω_i, K_i and Ω_i.

Figure 1 shows the structure of a two-solitoff solution for the quantity v shown by (210) with (211) and

$$\begin{gathered}M=2,\quad N=1,\quad k_1=K_1=1,\quad K_2=-2,\quad a_1=a_2=1,\quad a_3=0,\\ x_{01}=y_{01}=0,\quad y_{02}=-9\end{gathered}\tag{212}$$

at time $t=0$.

Figure 2 shows the structure of a single dromion solution for the quantity v shown by (210) with (211) and

$$M=1,\quad N=1,\quad k_1=K_1=3,\quad a_1=10,\quad a_2=3,\quad a_3=0,\quad x_{01}=y_{01}=0\tag{213}$$

at time $t=0$.

Example 2: Multi-dromion solutions driven by curved line ghost solitons. Recently, Lou pointed out that for many (2+1)-dimensional models, a dromion may be driven not only by straight line solitons[26] but also by curved line solitons.[27] Actually, (210) can be rewritten as

$$v=\frac{Q_y P_x(a_1a_2)}{2[A_1\cosh\frac{1}{2}(P+Q+C_1)+A_2\cosh\frac{1}{2}(P-Q+C_2)]^2}, \tag{214}$$

where P and Q are related to p and q by $p=b_1\exp(P)$, $q=b_2\exp(Q)$ and

$$A_1=\sqrt{a_3(a_1b_1+a_2b_2+a_3b_1b_2)},\quad A_2=\sqrt{(a_1+a_3b_2)(a_2+a_3b_1)},$$

$$C_2=\ln\frac{a_1+a_3b_2}{a_2+a_3b_2},\quad C_1=\ln\frac{a_3}{a_1b_1+a_2b_2+a_3b_1b_2},$$

with arbitrary constants b_1 and b_2.

So the general multi-dromion solutions of the model expressed by (210) [or equivalently (214)] are driven by two sets of straight line solitons and some curved line solitons. The first set of straight line solitons appears in the factor Q_y, say, one can take

$$Q_y=\sum_{i=1}^{N} Q_i(y-y_{i0}), \tag{215}$$

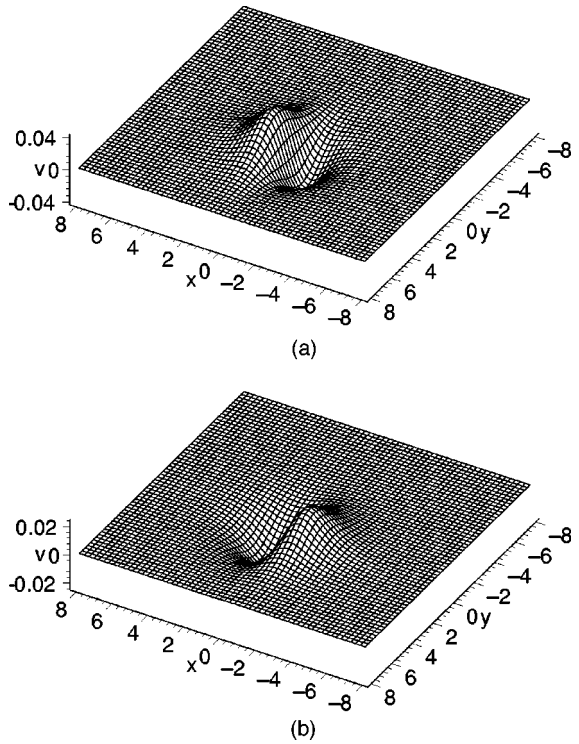

FIG. 8. The plots of the pointlike breather solution (210) with (223) and (224) and the parameters $\omega=\frac{1}{2}$, $a_1=a_2=10$, $a_3=1$, at the times (a) $t=-\pi/4$ and (b) $t=\pi/4$, respectively.

where $Q_i = Q_i(y - y_{i0})$ denotes a straight line soliton which is finite at the line $y = y_{i0}$ and decays rapidly away from the line. Similarly, the second set of straight line solitons appears in the factor P_x. Finally, the curved line solitons are determined by the factors $A_1 \cosh \frac{1}{2}(P+Q+C_1)$ and $A_2 \cosh \frac{1}{2}(P-Q+C_2)$ of (214) and the curves are determined by

$$P + Q + C_1 = \min(P + Q + C_1), \quad P - Q + C_2 = \min(P - Q + C_2), \tag{216}$$

while the number of curved line solitons is determined by the branches of the equations in (216). The dromions are located at the cross points and/or the closed points of the straight and curved lines.

Figure 3 is a plot of a multi-dromion solution driven by the curved line solitons via taking

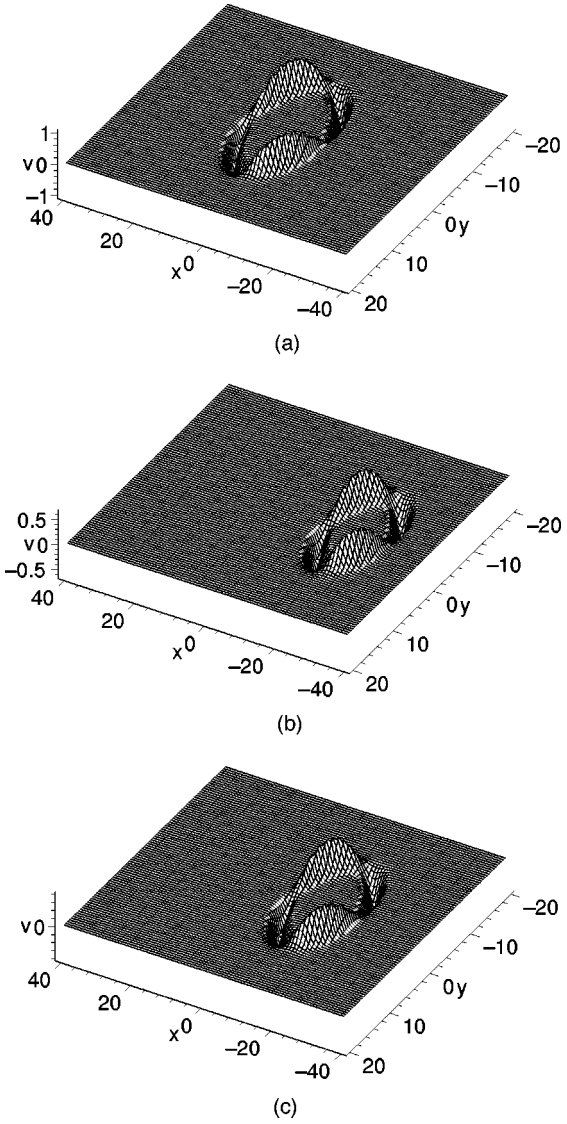

FIG. 9. The evolution of a special ring shape breather solution (210) with the selection (225) at the times (a) $t = -1$, (b) $t = -0.5$, (c) $t = -0.2$, (d) $t = 0$, (e) $t = 0.2$, and (f) $t = 1$, respectively.

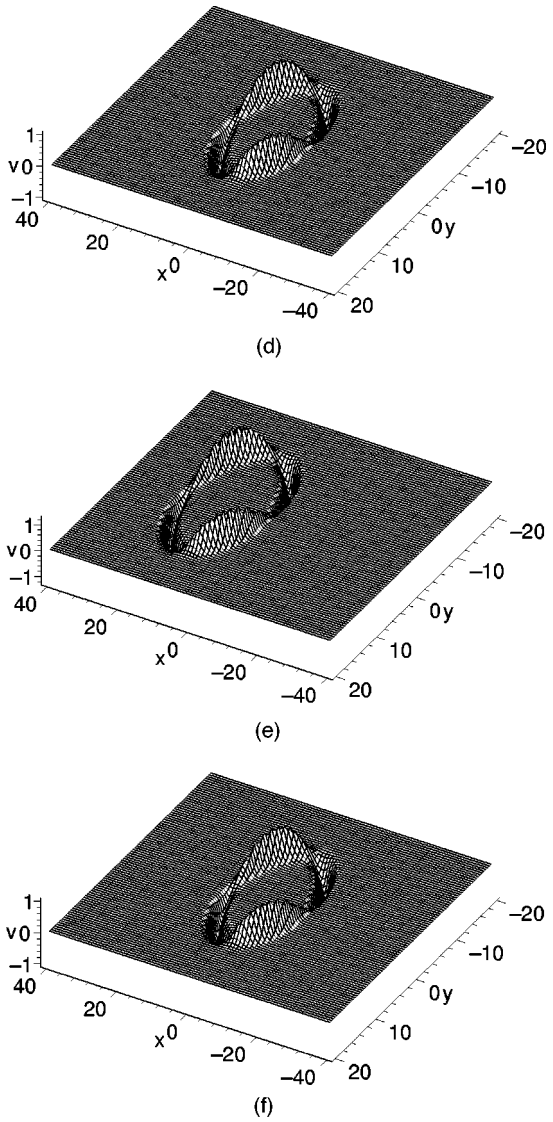

FIG. 9. (*Continued.*)

$$P=(x-v_1t)^3+\frac{x-v_1t}{15},\quad Q=\frac{(y-v_2t)^5}{20}+(y-v_2t)^3+\frac{y-v_2t}{100},$$
$$a_1=a_3=1,\quad a_2=2,b_1=3,\quad b_2=40,\quad t=0. \tag{217}$$

Example 3: Multi-lump solutions. It is also known that in high dimensions, like the KP and DSII equations, a special type of localized structure (called lump solutions) may also be formed by rational functions. Actually, the multi-lump solutions of $(2+1)$-dimensional integrable models can be found by taking the arbitrary functions appropriately.

For the $(M+N)$-component AKNS system, if we select the functions F and G of (210) as any rational functions with the conditions

$$F>0,\ \ G>0,\ \ \forall x,y,t, \tag{218}$$

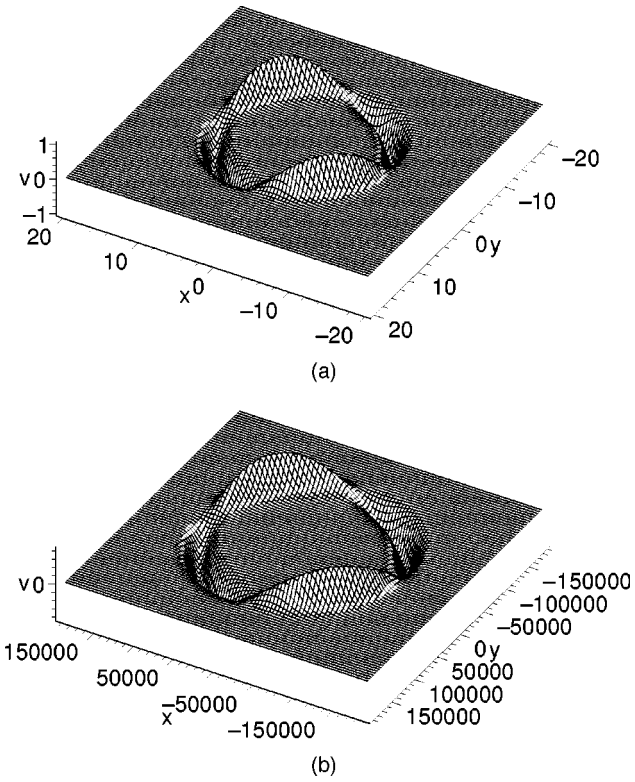

FIG. 10. (a) The evolution plots of the ring type of instanton solution (210) with (226) at the times (a) $t=0$ and (b) $t=10$.

and $a_1>0$, $a_2>0$, $a_3>0$, then we can obtain the nonsingular localized lump solutions. In Fig. 4, we plot a special lump solution (210) with

$$F=1+\frac{1}{1+(x-v_1t-30)^2}+\frac{1}{1+(x-v_2t)^2}+\frac{1}{1+(x-v_3t+30)^2}, \tag{219}$$

$$G=\frac{1}{1+(y-v_4t-15)^2}+\frac{1}{1+(y-v_5t+15)^2}, \quad a_1=10, \quad a_2=10, \quad a_3=1 \tag{220}$$

at time $t=0$.

Example 4: Oscillating dromion solutions. If some periodic functions in space variables are included in the functions p and q, we may obtain some types of multi-dromion solutions with oscillating tails. The oscillated dromion solution in Fig. 5 is related to

$$\begin{gathered} F=1+\exp((x-v_1t)\cos(2(x-v_1t))+\tfrac{5}{4}), \quad G=\exp(y-v_2t), \\ a_1=a_2=10, \quad a_3=1, \quad t=0. \end{gathered} \tag{221}$$

Example 5: Ring soliton solutions. In high dimensions, in addition to the pointlike localized coherent excitations, there may be some other types of physically significant localized excitation. For instance, in $(2+1)$-dimensional cases, there may be some types of ring soliton solutions which are not equal to zero identically at some closed curves and decay exponentially away from the closed curves.[17–19,21] In Figs. 6 and 7, we plot the interaction property of a two traveling saddle type of ring soliton solution with the selection

$$F=\exp\left(-\frac{(x-20t)^2}{10}+5\right)+\exp\left(-\frac{(x+20t)^2}{10}+1\right),\quad G=\exp\left(\frac{y^2}{10}-5\right),\quad a_1=a_2=1,\quad a_3=0. \tag{222}$$

In Fig. 6, we plot the evolution of the two ring soliton solution for the quantity v expressed by (210) with (222) at times (a) $t=-1$, (b) $t=-0.4$, (c) $t=0$, (d) $t=0.4$ and (e) $t=1$, respectively. From Figs. 6(a)–6(e), we can see that the interaction of two ring soliton solutions is elastic. To see more clearly the completely elastic interaction properties between two traveling ring soliton solutions, two counter plots related to Figs. 6(a) and 6(e) are plotted in Fig. 7.

Example 6: Multi-breatherlike soliton solutions. In $(1+1)$-dimensional cases, the breather solutions are another type of important nonlinear excitation. Because of the arbitrariness appearing in the functions F and G of (210), the breather solutions of the $(2+1)$-dimensional models may also have quite rich structures. On one hand, any $(1+1)$-dimensional breather solutions of the $(1+1)$-dimensional integrable models (like the sine-Gordon model and the nonlinear Schrödinger equation) can be used to construct the breather solutions of the higher dimensional models, say, the $(M+N)$-component AKNS system. In Fig. 8, the well known breather solution

$$F=4\arctan\left(\frac{\sqrt{1-\omega^2}\sin(\omega t)}{\omega\cosh(\sqrt{1-\omega^2}x)}\right) \tag{223}$$

of the sine-Gordon model, $F_{xx}-F_{tt}=\sin F$, is taken as the function F of (210) and while G is taken as

$$G=\exp(y) \tag{224}$$

with the parameters $\omega=\frac{1}{2}$, $a_1=a_2=10$, $a_3=1$. On the other hand, one can put any periodic functions of t into the localized excitations as shown in the examples 1–5 to construct more interesting new breatherlike solutions. Figure 9 shows the evolution behavior of a breather-like ring soliton solution shown by (210) with

$$\begin{aligned} F&=\exp\left(-\frac{1}{10}(x-20\sin(\pi t))^2+5(1.1+\sin(\pi t))\right),\\ G&=\exp\left(\frac{y^2}{10}-5+\sin(\pi t)\right),\quad a_1=a_2=1,\quad a_3=0. \end{aligned} \tag{225}$$

From Figs. 9(a)–9(e), we can see that the breatherlike ring soliton solution can ''breath'' in some different ways, say, it can breath not only in its amplitude but also in its shape (like the radius of the loop) and the position.

Example 7: Multiple instanton solution. If some types of decaying functions of time t are included in the solutions (210), then we can find some types of instanton solutions. In Fig. 10, the behavior of a special ring type of instanton solution (210) with

$$\begin{aligned} F&=\exp\left(-\frac{x^2\,\mathrm{sech}^2 t}{10}+5(1.1+\sin(\pi t))\right),\\ G&=\exp\left(\frac{y^2\,\mathrm{sech}^2 t}{10}-5\right),\quad a_1=a_2=1,\quad a_3=0 \end{aligned} \tag{226}$$

is exhibited. From Figs. 10(a) and 10(b), we can see that the amplitude of the ring type of instanton solution (210) with (226) decays rapidly from $|v|\sim 1$ to $|v|\sim 10^{-9}$ as the time increases from $t=0$ to $t=10$.

VIII. SUMMARY AND DISCUSSIONS

In summary, the $(2+1)$-dimensional $(M+N)$-component AKNS system [which is the generalization of the $(1+1)$-dimensional multi-component AKNS system and obtained from the inner parameter dependent symmetry constraints of the KP equation] possesses various interesting properties. The model is Painlevé integrable and Virasoro integrable (possesses infinitely many dimensional KMV type symmetry algebra). The finite transformation (KMV type symmetry group) is also obtained. Using the finite transformation and special seed solutions, one may obtain many types of exact solutions. The group invariant solutions of the model are obtained by means of the CK's direct method and these types of similarity solutions can all be obtained by means of the nonclassical Lie group approach.

In recent studies,[17–19] it was found that a quite universal variable separation solution with some arbitrary functions is valid for many $(2+1)$-dimensional models. For the $(2+1)$-dimensional $(M+N)$-component AKNS system, the universal expression is valid for the quantity $\Sigma_{n=1}^{N}\Sigma_{m=1}^{M}a_{mn}p_nq_m$. Then, by selecting the arbitrary functions appropriately, we may obtain many types of multi-soliton solutions like the solitoffs, dromions, positons, lumps, saddle type ring solitons, breathers, instantons, etc. Some special types of examples of these types of excitations are plotted in Sec. VI. Especially, the complete elastic interaction property between the traveling ring type of solutions is revealed in Figs. 6 and 7.

The Painlevé analysis, symmetry study and the variable separation approaches are three useful methods in the study of the nonlinear science. The idea to form the localized excitations in $(2+1)$-dimensions can be extended to obtain some types of localized excitations in $(3+1)$-dimensions. For instance, a closed camber may be used to construct a bubble like soliton. A closed line which is an intersection of two cambers may be used to form a $(3+1)$-dimensional ring soliton. Some special $(3+1)$-dimensional dromions and ring solitons have been found in some Painlevé and/or Virasoro integrable models.[28] The more about the methods and the model are worthy of studying further.

(Received 16 January 2002; accepted for publication 23 April 2002)

The symmetry properties of a classical N-dimensional harmonic oscillator with rational frequency ratios are studied from a global point of view. A *commensurate* oscillator possesses the same number of globally defined constants of motion as an *isotropic* oscillator. In both cases invariant phase-space functions form the *algebra* su(N) with respect to the Poisson bracket. In the isotropic case, the phase-space flows generated by the invariants can be integrated globally to a set of finite transformations isomorphic to the group SU(N). For a commensurate oscillator, however, the *group* SU(N) of symmetry transformations is found to exist only on a *reduced* phase space, due to unavoidable singularities of the flow in the full phase space. It is therefore crucial to distinguish carefully between local and global definitions of symmetry transformations in phase space. This result solves the long-standing problem of which symmetry to associate with a commensurate harmonic oscillator. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1488672]

I. INTRODUCTION

Harmonic oscillators are ubiquitous in physics. To lowest order, motion close to a stable equilibrium of a classical system is often described by a Hamiltonian of the form

$$H(q,p)=\sum_{n=1}^{N}\frac{\omega_n}{2}(p_n^2+q_n^2),\quad \omega_n\in\mathbb{R}. \tag{1}$$

Here the (appropriately rescaled) canonical coordinates and momenta have Poisson brackets $\{q_n,p_{n'}\}=\delta_{nn'}$, $n,n'=1,...,N$. If the frequencies ω_n are all equal,

$$\omega_n=\omega,\quad n=1,...,N, \tag{2}$$

the Hamiltonian (1) describes an *isotropic* N-dimensional oscillator. This system is invariant under a set of transformations isomorphic to the group SU(N): on the one hand, the quadratic form (1) in $2N$ variables is obviously invariant under proper rotations SO($2N$)—on the other hand, canonical transformations need to be symplectic, hence they are elements of Sp(N). However, any transformation in $\mathbb{R}^{2N}$ which is both (special) orthogonal and symplectic must be (special) unitary:[1] $\mathrm{SU}(N)=\mathrm{SO}(2N)\cap\mathrm{Sp}(N)$. The group SU($N$) is represented by (N^2-1) phase-space functions which, as constants of motion, generate symmetry transformations of the Hamiltonian. In fact, the isotropic oscillator is ''maximally superintegrable'' since it possesses the maximal number of $(2N-1)$ functionally independent constants of motion, exceeding by far the number of N globally defined invariants required for integrability.[2]

Suppose now that the frequency ratios $\omega_n/\omega_{n'}$ are positive rational numbers,

$$\omega_n=\frac{\omega}{m_n}, \quad m_n\in\mathbb{N}_+, \quad \omega>0. \tag{3}$$

This property defines a *commensurate* harmonic oscillator, or **m**-oscillator, with $\mathbf{m}=(m_1,\ldots,m_N)$. As shown below, it also possesses (N^2-1) globally defined phase-space invariants, apart from the Hamiltonian. Their Poisson brackets form the Lie algebra su(N), as for the isotropic oscillator. It is known that in both systems all orbits are closed. Nevertheless, some difference is to be expected, since all orbits of an isotropic oscillator have the same period, while commensurate frequencies allow for closed orbits with different periods. This is easily seen by exciting only individual degrees of freedom with frequencies ω_n.

In the following, the topological and group-theoretical impact of rational frequency ratios (different from one) will be made explicit. First, various papers dealing with commensurate oscillators are reviewed in Sec. II, which is independent of the later developments. The technical part starts with Sec. III, where, for simplicity, the class of two-dimensional **m**-oscillators will be studied in detail. The generalization to $N\geqslant 3$, given in Sec. IV, is *not* straightforward. Finally, the overall picture is summarized and conclusions are drawn. A study of *quantum mechanical* **m**-oscillators, including the classical limit to connect with the present results, will be presented elsewhere.[3]

II. SYMMETRIES OF HARMONIC OSCILLATORS

The equations of motion of N harmonic oscillators can be solved analytically for arbitrary frequency ratios. In spite of this exceptional property many authors have wrestled with the *symmetries* of such systems, the question being how their symmetries depend on the (ir-) rationality of the frequency ratios. Most contributions are fostered by the difficulty to distinguish between local and global properties of phase space. Two-dimensional oscillators with rational or irrational frequency ratios are discussed almost exclusively. Surprising claims have been made in the attempt to generalize properties of the isotropic oscillator in N dimensions.

Jauch and Hill[4] address the problem of ''accidental degeneracy'' of quantum-mechanical energy eigenvalues. The obvious invariance of the three-dimensional harmonic oscillator (as well as the hydrogen atom) under the group of rotations in configuration space is not sufficient to explain the observed degeneracy of the energy levels. They conclude that additional constants of motion must exist which account for extra degeneracies in the quantum mechanical energy spectrum. In fact, (N^2-1) Hermitian operators can be specified which commute with the Hamiltonian of the isotropic harmonic oscillator in N dimensions. Their commutation relations turn out to be those of the algebra su(N). Therefore, the oscillator is said to have the su(N) symmetry—which then leads to the correct degree of degeneracies of energy levels.

Pauli[5] and Klein[6] have pointed out that there is a connection between degeneracies of energy levels and the existence of further constants of motion in the associated *classical* system. Therefore, the result also should be manifest in the corresponding classical isotropic oscillator. Upon ''dequantizing'' the quantum invariants, one obtains indeed (N^2-1) constants of motion which constitute the su(N) algebra with respect to the Poisson bracket. Hence, the classical isotropic oscillator possesses indeed constants of motion other than the angular momentum. Its components generate obvious *geometrical* symmetry transformations while the additional constants are said to generate *dynamical* symmetry transformations. They cannot be visualized in configuration space because they mix coordinates and momenta.

However, to exhibit a set of conserved phase-space functions which form a particular algebra is *not* sufficient in order to prove invariance of the physical system in a global sense, i.e., in the entire phase space. Jauch and Hill assert that the ''system of orbits'' of a classical (m_1,m_2)-oscillator be invariant under a group of transformations isomorphic to the three-dimensional group of proper rotations SO(3). However, this claim cannot be justified by local considerations only. In other words, global invariance under a particular group of transformations does not follow from specifying phase-space functions forming the corresponding algebra.

McIntosh reviews accidental degeneracy in classical and quantum mechanics in Ref. 7. He notes that the phase space of the isotropic harmonic oscillator in two dimensions foliates into hyperspheres, being surfaces of constant energy. A discussion of the canonical transformations generated by three constants of the motion quadratic in the coordinates and momenta follows. It becomes obvious that the group of symmetry transformations is the special unitary group in two dimensions, SU(2)—*not* the group of proper three-dimensional rotations, SO(3), as Jauch and Hill suggested.

Dulock and McIntosh[8] devote a paper to the two-dimensional harmonic oscillator with arbitrary frequency ratio. Using classical variables which mimic quantum mechanical creation and annihilation operators, they write down three constants of motion with Poisson brackets isomorphic to the so(3) algebra relations. A Hopf mapping is performed in order to visualize ''how the rotational symmetry of $\mathcal{S}^2$, which is the three-dimensional rotation group, chances also to be the symmetry group of the harmonic oscillator.'' [8] Formally, this method can be applied to oscillators with *arbitrary* frequency ratio. However, one of the transformations, which is one-to-one in the isotropic case, becomes a multiple-valued map. For rational frequency ratios there is a finite ambiguity, turning to infinite multiple-valuedness if the frequencies ratios are irrationally. In spite of this result, the authors claim that the set of symmetry transformations for *all* types of oscillators investigated is isomorphic to the group SU(2)—irrespective of the multiple-valuedness. Once more, the possibility to write down formal expressions which constitute particular algebraic relations is taken as a proof of the existence of an associated *group* of transformations.

Maiella and Vitale[9] react to the claim that ''every classical system should possess a 'dynamical' symmetry larger than the 'geometrical' one.'' [9] Using action-angle variables, they provide three constants of motion for the two-dimensional oscillator which form the su(2) algebra. However, for irrational frequency ratio the invariants are not single-valued—hence they consider the ''su(2) symmetry'' to be of ''formal value'' only. It is claimed to acquire physical relevance only for commensurate and, *a fortiori*, isotropic oscillators. At the same time, no argument is given which would forbid the existence of the group SU(2) for the irrational oscillator. The authors do not investigate whether, in the commensurate case, the invariants generate indeed finite single-valued phase-space transformations in SU(2).

Maiella[10] extends this discussion to the N-dimensional oscillator and emphasizes that only single-valued constants of the motion generate actual symmetry transformations. Initially, the group of all contact transformations for a given dynamical system is considered. Any subgroup of transformations which is generated by single-valued constants of motion and leaves the Hamiltonian invariant is called an ''invariance group.'' The classical degree of degeneracy determines the number of its generators: each linear relation between the classical frequencies of the system with *rational* coefficients is accompanied by the appearance of a single-valued constant of motion. Subsequently, phase-space functions are given in action-angle variables which realize the algebra su(N) for an isotropic oscillator and the algebra su(n), $2 \leqslant n < N$, for smaller degeneracy. However, it is again not proven explicitly that the generators actually give rise to globally well-defined transformations.

In the late 1960s, successful application of group theoretical concepts in elementary particle physics renewed the interest in symmetries of classical Hamiltonian systems and stimulated more general approaches. The invariance of the three-dimensional Kepler problem under the group of four-dimensional rotations, SO(4), was explicitly shown by Moser[11] in 1970 for the first time. Already in 1965 Bacry, Ruegg and Souriau[12] proved that there exists a set of global symmetry transformations for the Kepler problem being isomorphic to the group SO(4). The transformations presented, however, do not act on variables in phase-space. The transformations of phase-space manifolds are parametrized by the components of angular momentum and of the Runge–Lenz vector. Representing only five independent constants of motion, the time t at which the particle passes the perihelion of the orbit is taken as sixth parameter.

Dulock and McIntosh[13] claim that the Kepler problem has not only the symmetry SO(4) but SU(3). Two papers by Bacry, Ruegg and Souriau[12] and by Fradkin[14] generalize this statement: all classical central potential problems should possess the dynamic symmetries O(4) *and* SU(3). This

surprising statement is subject to the same criticism as the following, even more general claim by Mukunda:[15,16] *all* classical Hamiltonian systems with N degrees of freedom have O(N) and SU(N) symmetries. If this statement were true, then there would exist just one and only one global phase-space structure for systems with N degrees of freedom—the well-established distinction between regular and chaotic systems would have no meaning at all.

Mukunda argues on the basis of a theorem by Eisenhart.[17] Consider, in a Hamiltonian system with N degrees of freedom, $n<N$ independent functions of canonically conjugate variables (subjected to weak conditions). They can always be supplemented by $(2N-n)$ phase-space functions such that N pairs of canonically conjugate variables result which define a symplectic basis of phase space. Hence, starting with the Hamiltonian of the system under consideration one can find (i) a variable being canonically conjugate to the Hamiltonian and (ii) $(N-1)$ additional pairs of phase-space functions with Poisson brackets equal to one, all commuting with the first pair and therefore with the Hamiltonian. Consequently, this theorem is a blueprint to construct $(2N-1)$ independent constants of motion in any Hamiltonian system with N degrees of freedom. The particular form of the Hamiltonian does not even enter into the construction. Next, two different sets of phase-space functions are defined in terms of the $(2N-1)$ functions of this particular basis. Their Poisson brackets realize the relations characteristic of the algebras O(N) and SU(N), respectively. In a footnote, the author restricts the applicability of the results: ''We concern ourselves only with constructing realizations of Lie algebras, not of Lie groups. Even when we talk of invariance under the O(4) group, for example, we really intend invariance under the algebra.''[15] Consequently, ''invariance under the algebra'' is a *local* concept only, so that Mukunda's construction has formal value only. Actually, the phase-space functions written down by Mukunda do not neatly map phase space onto itself: the functions become imaginary if the range of the canonical variables is not restricted artificially. The lesson to be learned is obvious: in order to establish the invariance of a system under a *group* of phase-space transformations it is not sufficient to realize specific Poisson-bracket relations with invariants.

A related position is put forward by Stehle and Han.[18,19] To identify a particular algebra by constants of motion does not guarantee the presence of a ''higher symmetry''—a single-valued, or at most finitely many-valued, realization of the group must exist in phase-space. To show this, they show that a system is classically degenerate if the Hamilton–Jacobi equation of a particular system is separable in a continuous family of coordinate systems. This property is observable. Compare the Fourier series representation of one specific orbit described with respect to two different (continuously connected) coordinate systems. For consistency, the frequencies appearing in its Fourier decomposition must be rationally related, which corresponds to a classical degeneracy. It is important to note that the transformation from one coordinate system to the other be single-valued, otherwise the argument does not hold. Any phase-space function and, consequently, any constant of motion generates a transformation of phase-space onto itself; alternatively, it can be viewed as the generator for a transition to another coordinate system such that the Hamiltonian remains invariant. Only single-valued constants of motion generate global single-valued transformations—infinitely many-valued ''constants of motion'' represent formal expressions only, not necessarily related to the existence of classical degeneracy. Therefore, they do *not* establish a higher symmetry group of the system.

To sum up, the construction of an algebra from constants of motion is only the first step in the proof of the existence of a potential higher symmetry group. It needs to be supplemented by a global investigation of the generated transformations.

III. THE TWO-DIMENSIONAL COMMENSURATE OSCILLATOR

This section deals with the symmetry properties of a two-dimensional commensurate harmonic or (m_1,m_2)-oscillator described by the Hamiltonian

$$H(q_1,q_2,p_1,p_2)=\frac{\omega}{2}\left(\frac{1}{m_1}(p_1^2+q_1^2)+\frac{1}{m_2}(p_2^2+q_2^2)\right),\quad m_1,m_2\in\mathbb{N}_+, \tag{4}$$

where the integers m_1 and m_2 have no common divisor. Two pairs of canonical variables, $q_n, p_n \in (-\infty, \infty), n=1,2$, label points in phase space $\Gamma \sim \mathbb{R}^4$, the only nonvanishing Poisson brackets being given by

$$\{q_1, p_1\} = \{q_2, p_2\} = 1. \tag{5}$$

It will be useful to introduce two other sets of canonical variables. First, combine each pair into a complex variable

$$\alpha_n = \frac{1}{\sqrt{2}}(q_n + i p_n), \quad n=1,2, \tag{6}$$

with nonvanishing brackets

$$\{\overline{\alpha}_1, \alpha_1\} = \{\overline{\alpha}_2, \alpha_2\} = i, \tag{7}$$

where $\overline{\alpha}$ denotes the complex conjugate of α. Second, action-angle variables $I_n \in [0,\infty)$ and $\varphi_n \in [0, 2\pi)$, $n=1,2$, are determined through modulus and phase of $\alpha_n = \sqrt{I_n}\exp[i\varphi_n]$. Their nonzero brackets read

$$\{I_1, \varphi_1\} = \{I_2, \varphi_2\} = 1. \tag{8}$$

These coordinates provide alternative forms of the Hamiltonian,

$$H = \omega\left(\frac{\overline{\alpha}_1 \alpha_1}{m_1} + \frac{\overline{\alpha}_2 \alpha_2}{m_2}\right) = \omega\left(\frac{I_1}{m_1} + \frac{I_2}{m_2}\right). \tag{9}$$

A. Constants of motion and Lie algebras

Commensurate harmonic oscillators possess a large number of constants of motion. The Hamiltonian itself is an invariant as $\{H,H\}=0$. Motion of the system with given energy E is thus restricted to a three-dimensional hyper-surface, an ellipsoid $\mathcal{E}(E)$ in phase space Γ. Further, the actions I_1 and I_2, having zero Poisson brackets with the Hamiltonian and among themselves, render the (m_1,m_2)-oscillator integrable. For fixed values of the actions, Arnold's theorem[2] states that the motion takes place on a two-dimensional torus $\mathcal{T}(I_1,I_2)$. In fact, the *entire* phase space is foliated by tori with radii $\sqrt{I_1}$ and $\sqrt{I_2}$, respectively. According to (9) the Hamiltonian H is a linear function of these invariants.

A third, functionally independent (complex) constant of the motion is given by the expression

$$K = \alpha_2^{m_2}(\overline{\alpha}_1)^{m_1}. \tag{10}$$

As mentioned in Ref. 4, both its real and complex parts are invariant which implies that the phase χ of the function K,

$$\chi = m_2\varphi_2 - m_1\varphi_1 \in [0, 2\pi), \tag{11}$$

is a constant of the motion, too. Considered as a generator of transformations in phase space, it connects energetically degenerate pairs of tori. The existence of a third invariant is expected to reduce the dimensionality of the accessible manifold. Indeed, fixing the values of the three invariants I_1, I_2, and K (or, equivalently, χ) singles out a one-dimensional orbit on the torus $\mathcal{T}$ if the two frequencies are rationally related. Generic orbits, $\alpha_n(t) = \sqrt{I_n}\exp(-i\omega t/m_n + \varphi_n(0))$, $n=1,2$, retrace themselves after a characteristic time $t_{\mathbf{m}} = 2\pi m_1 m_2/\omega$, with winding numbers m_2 for α_1 and m_1 for α_2. However, if the frequency ratio of the motion on the tori were *not* rational, an orbit would cover the torus $\mathcal{T}$ densely—the function K would represent a *formal* constant of the motion only, without any physical impact on the motion of the system. An important difference to the isotropic

oscillator is due to the fact that an **m**-oscillator has different types of orbits with frequencies $\omega/(2\pi m_1)$ and $\omega/(2\pi m_2)$, respectively. This allows one to distinguish experimentally the two cases.

The phase space of an **m**-oscillator has a particular *discrete* symmetry. Combine the variables α_n into a column: now the Hamiltonian is obviously invariant under $m_1 m_2$ finite rotations, $\alpha \to R_1^{r_1} R_2^{r_2} \alpha$, $r_n = 0,...,m_n - 1$, or, explicitly,

$$\begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} \to \begin{pmatrix} e^{-i2\pi r_1/m_1} & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & e^{-i2\pi r_2/m_2} \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix}. \tag{12}$$

These transformations map the phase-space Γ to itself. They form a cyclic group $\mathcal{C}_{m_1 m_2} = \mathcal{C}_{m_1} \times \mathcal{C}_{m_2}$, the direct product of two cyclic groups with m_1 and m_2 elements, respectively. In Ref. 20, $\mathcal{C}_{m_1 m_2}$ has been called *ambiguity group*.

The Poisson bracket of two invariants results in a third invariant. Therefore, the collection of all invariants is a Lie algebra. Typically, it will contain an infinite number of elements, all of which depend functionally on a smaller number of invariants. By an appropriate choice of the invariants, however, algebras with a finite number of elements can be found. The simplest example is given by the three invariants I_1, I_2, K giving rise to the following brackets:

$$\{I_1, K\} = -im_1 K, \quad \{I_2, K\} = im_2 K, \quad \{I_1, I_2\} = 0. \tag{13}$$

The algebra contains three independent elements—it is not possible to find an algebra with fewer elements since the **m**-oscillator has three invariants. It also contains two elements with vanishing Poisson bracket which, in a system with two degrees of freedom, is the maximum number of ''commuting'' functionally independent invariants.

There is an alternative set of four invariants $J = (J_0, \vec{J})$,

$$J_0 = \frac{I_1}{2m_1} + \frac{I_2}{2m_2} = \frac{1}{2\omega} H, \tag{14}$$

$$J_1 = \sqrt{\frac{I_1 I_2}{m_1 m_2}} \cos\chi, \tag{15}$$

$$J_2 = \sqrt{\frac{I_1 I_2}{m_1 m_2}} \sin\chi, \tag{16}$$

$$J_3 = \frac{I_1}{2m_1} - \frac{I_2}{2m_2}. \tag{17}$$

Only three of these invariants are functionally independent because

$$J_0^2 - \vec{J}^2 = 0. \tag{18}$$

This constraint is conveniently rephrased by saying that the ''four vector'' J is ''null'' or ''light like.'' The functions J are particularly interesting since they form the basis of a Lie algebra isomorphic to u(2),

$$\{J_0, J_j\} = 0, \quad \{J_j, J_k\} = \sum_{l=1}^{3} \epsilon_{jkl} J_l, \quad j,k = 1,2,3, \tag{19}$$

which has su(2) as a subalgebra, generated by the components of $\vec{J}$. Equations (19) have been at the origin of many attempts to associate a group SU(2) of symmetry transformations with the two-dimensional **m**-oscillator.

B. Reduced phase space and space of invariants

Consider the complex variables

$$\beta_n = \frac{|\alpha_n|}{\sqrt{m_n}}\left(\frac{\alpha_n}{|\alpha_n|}\right)^{m_n} = \sqrt{\frac{I_n}{m_n}}\exp[i m_n \varphi_n], \quad n=1,2, \tag{20}$$

which satisfy

$$\{\overline{\beta}_n, \beta_{n'}\} = i\delta_{nn'}. \tag{21}$$

In spite of these relations, the variables β_n do *not* define pairs of canonical coordinates of Γ since the map $\alpha \to \beta$ is not a one-to-one transformation. The variables β_n are, however, canonical coordinates in the *reduced* phase space $\Gamma_{\mathbf{m}}$. The reduced space is obtained from identifying those $m_1 m_2$ points of Γ which satisfy $\beta(R_1^{r_1} R_2^{r_2}\alpha) = \beta(\alpha)$, $R_n^{r_n} \in \mathcal{C}_{m_n}$. The definition of the variables (20) is motivated by the invariance of the constants of motion in (14)–(17) under the ambiguity group $\mathcal{C}_{m_1 m_2}$.

The invariants (14)–(17) take a simple form when expressed in terms of the reduced variables,

$$J_0 = \frac{1}{2}(\overline{\beta}_1\beta_1 + \overline{\beta}_2\beta_2), \tag{22}$$

$$J_1 = \frac{1}{2}(\overline{\beta}_1\beta_2 + \overline{\beta}_2\beta_1), \tag{23}$$

$$J_2 = \frac{1}{2i}(\overline{\beta}_1\beta_2 - \overline{\beta}_2\beta_1), \tag{24}$$

$$J_3 = \frac{1}{2}(\overline{\beta}_1\beta_1 - \overline{\beta}_2\beta_2). \tag{25}$$

Using the two-component "Weyl spinor" $\beta = (\beta_1, \beta_2)$, these invariants can be written

$$J_\nu = \frac{1}{2}\overline{\beta}\cdot\sigma_\nu\beta, \quad \nu = 0,...,3, \tag{26}$$

where $\sigma_0 = \mathbf{1}_2$, and the Pauli matrices σ_k, $k=1,2,3$, generate the algebra su(2). Consequently, the invariants, which span the space of invariants, Υ, turn into *sesquilinear* expressions on the reduced phase space $\Gamma_{\mathbf{m}}$. Their structure is similar to those of the isotropic or (1,1)-oscillator: in this case, the reduced phase space and the original one coincide, $\Gamma_{(1,1)} = \Gamma$. In some sense, the non-bijective map $\alpha \to \beta$ "linearizes" the invariants at the expense of accounting for a fraction of phase space only. It will be shown later that the concept of the reduced space $\Gamma_{\mathbf{m}}$ is natural in the present context as it provides appropriate setting to derive global statements about symmetry transformations.

C. Topological aspects

Turn now briefly to the topology of the spaces involved. Consider the nontrivial transformations introduced so far: first, the original phase space has been mapped to the reduced phase space,

$$\psi: \Gamma \to \Gamma_{\mathbf{m}} : \alpha \mapsto \beta(\alpha); \tag{27}$$

second, introducing the invariants J maps the reduced variables to the space of invariants, Υ,

$$\phi:\Gamma_{\mathbf{m}}\to\Upsilon:\beta\mapsto J(\beta), \tag{28}$$

which is an upper cone in $\mathbb{R}^4$ since $J_0=|\vec{J}|$.

The reduced phase space $\Gamma_{\mathbf{m}}$ has the structure of a well-known fiber bundle. To see this, consider an orbit $\alpha(t)$ in phase space Γ. Its image in the reduced space $\Gamma_{\mathbf{m}}$ is given by $\beta(t)=e^{-i\omega t}\beta(0)$. The maps $\beta\to e^{i\gamma}\beta$ form a group U(1) which leaves invariant the map ϕ, $J(e^{i\gamma}\beta)=J(\beta)$, since the phase drops out from the sesquilinear expressions given in Eqs. (26). Therefore, $\Gamma_{\mathbf{m}}$ is indeed a *fiber bundle* $(\Upsilon,\phi,\mathcal{O})$: the invariants Υ form the base, each orbit $\mathcal{O}_{\beta_0}=\{e^{i\gamma}\beta_0\,|\,\gamma\in[0,2\pi)\}$ is a fiber, and the map ϕ is the projection. The global structure of the bundle follows from the fact that the restriction of $\Gamma_{\mathbf{m}}$ to the submanifold $\Gamma_{\mathbf{m}}(E)$ with points $\overline{\beta}\cdot\beta=E/\omega$ is isomorphic to the sphere $\mathcal{S}^3$—as is obvious from the quadratic form (4). Thus, the restriction of the map ϕ to $\Gamma_{\mathbf{m}}(E)$ defines the *Hopf fibration* of $\mathcal{S}^3$. To each orbit $\mathcal{O}_\beta$ in $\mathcal{S}^3$ corresponds a point $\vec{J}(\beta)$ of the sphere of radius $J_0=E/(2\omega)$ and a circle in the tangent space at this point.

It is interesting to look at the space Υ of invariants and the transformations among them from a general perspective. To do so, consider the complex instead of the real Lie algebra su(2) which also leaves invariant the Hamiltonian $H\sim J_0$ in (22) invariant. This is the Lie algebra sl(2,C) associated with the group SL(2,C), the universal covering of the Lorentz group. The Lorentz group induced by SL(2,C) in Υ is the transitivity group of the upper (half-) cone.

The elements of SL(2,C) can be written as $u(\tau,\gamma)=\exp[g(\tau,\gamma)]$, where τ and γ are two real parameters, and each g is a traceless complex matrix,

$$g(\tau,\gamma)=\tfrac{1}{2}(\gamma\vec{\nu}\cdot\vec{\sigma}+i\tau\vec{n}\cdot\vec{\sigma}). \tag{29}$$

The matrices $u(\tau,0)$ belong to the group SU(2). Thus, they generate rotations and infinitesimal transformations which can be written in terms of a Poisson bracket:

$$\frac{d\vec{J}(\tau)}{d\tau}=\vec{n}\wedge\vec{J}(\tau)\equiv\{\vec{J},\vec{n}\cdot\vec{J}\}. \tag{30}$$

The subsets $u(0,\gamma)$ represent Lorentz boosts mapping a point β according to

$$u(0,\gamma)\beta=(\cosh(\gamma/2)+\sinh(\gamma/2)\,\vec{\nu}\cdot\vec{\sigma})\beta\equiv\beta(\gamma). \tag{31}$$

On the invariants, the transformation

$$J_\nu=\overline{\beta}\cdot\sigma_\nu\beta\mapsto J_\nu(\beta)=\overline{\beta(\gamma)}\cdot\sigma_\nu\beta(\gamma) \tag{32}$$

is induced. Hence, the sphere $\mathcal{S}^3$ of radius $J_0=H/(2\omega)$ is mapped to a sphere of radius $J_0(\gamma)$ with

$$\frac{dJ_0}{d\gamma}=\vec{\nu}\cdot\vec{J},\quad \frac{d\vec{J}}{d\gamma}=J_0\vec{\nu}. \tag{33}$$

This is an infinitesimal Lorentz transformation which maps the upper cone $\Upsilon\in\mathbb{R}^4$ to itself as is obvious from $d(J_0(\gamma)^2-\vec{J}(\gamma)^2)/d\gamma=0$ and J_0 remaining positive. Contrary to (30), it is not possible to express the right-hand sides of (33) by means of Poisson brackets. This can be understood from a quantum mechanical point of view. A classical theory can only manage Boltzmann statistics whereas in quantum (field) theory, due to the *anti*commutativity of Weyl spinors, it would be possible to find a commutator to express the derivatives $dJ_\nu/d\gamma$.

IV. GLOBAL INVARIANT VECTOR FIELDS

Each phase-space function generates a flow in phase space Γ, as well as in the reduced phase space $\Gamma_{\mathbf{m}}$, and in the space of invariants Υ. The invariants generate flows which commute with the Hamiltonian vector field. To be more specific, consider any element J_ν, $\nu=0...3$, of the Lie algebra u(2). When acting on an observable f through the Poisson bracket,

$$V_\nu=\{f,J_\nu\}, \quad \nu=0,...,3, \tag{34}$$

it defines a vector field V_ν in Γ. Its integral lines satisfy the differential equation

$$\frac{df}{d\tau}=V_\nu. \tag{35}$$

The solution of this differential equation is a map $f(\tau)$ which will be written in the form

$$f(\tau)=\mathrm{Exp}[\tau J_\nu](f)=\sum_{k=0}^{\infty}\{f,J_\nu\}_k\frac{\tau^k}{k!}, \tag{36}$$

where

$$\{g,h\}_{k+1}=\{\{g,h\}_k,h\}, \quad k=1,2,\ldots, \quad \{g,h\}_0=g, \tag{37}$$

with smooth phase-space functions g and h. In a simplified notation, the solutions (36) are written as

$$S_\nu[\tau]\equiv\mathrm{Exp}[\tau J_\nu], \quad \nu=0,...,3, \quad S_{\vec{n}}[\tau]\equiv\mathrm{Exp}[\tau\vec{n}\cdot\vec{J}], \quad |\vec{n}|=1, \tag{38}$$

each unit vector $\vec{n}$ being associated with a point of the unit sphere $\mathcal{S}^2$.

The crucial question now is to investigate whether the flow (34) and hence the maps (38) are defined everywhere in the space under consideration. Only in this case, the *algebra* formed by the closed set of Poisson brackets among the invariants integrates to a *group* of symmetry transformations. More specifically, one needs to find out whether the invariants (14)–(17) of the **m**-oscillator generate a set of transformations isomorphic to the group SU(2) [or U(2)]. This is only possible if the associated vector fields are well-defined everywhere in the space where they act. The fields will be studied separately for functions f from the spaces Γ, $\Gamma_{\mathbf{m}}$, or Υ.

A. Vector fields in the space of invariants

The simplest case to look at is the orbits generated by the first component of J, which is a multiple of the Hamiltonian, $J_0=H/(2\omega)$. Not surprisingly, one has

$$S_0[\tau](J)=J, \tag{39}$$

that is, all components of J are invariant under the action of J_0. Rotations about the 3-axis, i.e., with an axis passing through the poles $J_3=\pm J_0$, are generated by the invariant $J_3=I_1/(2m_1)-I_2/(2m_2)$,

$$S_3[\tau](J)=(J_0,R_3(\tau)\vec{J}). \tag{40}$$

Each possible orbit in Υ is generated by a linear combination of invariants $\vec{n}\cdot\vec{J}$,

$$S_{\vec{n}}[\tau](J)=(J_0,R_{\vec{n}}(\tau)\vec{J}), \tag{41}$$

where the matrix $R_{\vec{n}}(\tau)$ represents a rotation by an angle τ about an axis parallel to the vector $\vec{n}$. In other words, every point of the sphere $|\vec{J}|=J_0$ is mapped to another point of the same sphere, the energy $E=2\omega J_0$ being conserved.

These results are conveniently summarized by a group theoretical statement. The set

$$\mathcal{R}_J=\{S_{\vec{n}}[\tau]\,|\,0\leqslant\tau<2\pi,\vec{n}\in\mathcal{S}^2\} \tag{42}$$

of maps acting in Υ is a representation of the group SO(3). In other words, there is a subset of all phase-space functions, such that its elements transform according to the group SO(3). Mathematically, this group is the integrated form of the adjoint representation of the algebra (19). Consequently, one can attribute this group as a *symmetry group* to the reduced (m_1,m_2)-oscillator, for any frequency ratio. Note, however, that this symmetry does not act on points in phase space Γ but on points of the space of invariants Υ.

B. Vector fields in the reduced phase space

Again, the action of the generators J_0, J_3, and $\vec{n}\cdot\vec{J}$ will be studied, now with respect to the variables $\beta=(\beta_1,\beta_2)$. It is straightforward to see that

$$S_0[\tau](\beta)=e^{-i\tau/2}\beta, \tag{43}$$

which is just the time evolution with $\tau=2\omega t$. Similarly, the invariant J_3 generates a flow

$$S_3[\tau](\beta)=\begin{pmatrix} e^{-i\tau/2} & 0 \\ 0 & e^{i\tau/2}\end{pmatrix}\beta. \tag{44}$$

Comparison with (20) shows that the function $\chi=m_2\varphi_2-m_1\varphi_1$ is left invariant. Transformation (44) is a special case of the map

$$S_{\vec{n}}[\tau](\beta)=(\sigma_0\cos\tau/2-i\vec{n}\cdot\vec{\sigma}\sin\tau/2)\beta\equiv\beta(\tau). \tag{45}$$

No ambiguities arise when mapping points β under $S_{\vec{n}}[\tau]$, for whatever values of the parameter τ and the directions $\vec{n}$. Therefore, the set

$$\mathcal{R}_\beta=\{S_{\vec{n}}[\tau]|0\leqslant\tau<4\pi,\vec{n}\in\mathcal{S}^2\} \tag{46}$$

of maps faithfully represents the group SU(2) in $\Gamma_{\mathbf{m}}$. Consequently, an **m**-oscillator admits as symmetry not only the three-dimensional rotation group SO(3) in Υ but also the special unitary group SU(2) in $\Gamma_{\mathbf{m}}$.

In this restricted sense, and only in this one, (m_1,m_2)-oscillators are seen to possess both SO(3) and SU(2) as symmetry groups. This statement agrees with the fact that the algebras so(3) *and* su(2) are isomorphic. The next section deals with the question which groups, if any, are represented on the original phase space Γ.

C. Vector fields acting in phase space

It will be shown in this section that the vector fields associated with the invariants J are not defined globally when they act on the variables α which span phase space Γ. Consequently, it is *not* possible to implement the group SU(2) on phase space Γ. More explicitly, it will be shown that the action $S_{\vec{n}}[\tau](\alpha)=(\alpha_1(\tau),\alpha_2(\tau))$ on Γ is nonlinear, and that it is inevitably singular for some parameters $(\vec{n},\tau)$ and initial points α. Contrary to one's intuition the flows can be defined only locally, and they cannot be extended to define a *group* of symmetry transformations.

To begin with, consider the flows generated by J_0 and J_3, respectively. The resulting orbits *are* well-defined for all initial points: they are given by

$$S_0[\tau](\alpha)=\begin{pmatrix} e^{-i\tau/(2m_1)} & 0 \\ 0 & e^{-i\tau/(2m_2)} \end{pmatrix}\alpha, \tag{47}$$

and by

$$S_3[\tau](\alpha)=\begin{pmatrix} e^{-i\tau/(2m_1)} & 0 \\ 0 & e^{i\tau/(2m_2)} \end{pmatrix}\alpha, \tag{48}$$

respectively. Equation (47) describes the time evolution of the point $\alpha\in\Gamma$, hence both the energy $E=2\omega J_0$ and the torus $\mathcal{T}(I_1,I_2)$ are left invariant. Since the values of the actions change according to $I_n(0)\to I_n(\tau)=|\alpha_n(\tau)|^2$, the flow in (48) also conserves the energy while it maps a torus $\mathcal{T}(I_1,I_2)$ to a different one, $\mathcal{T}(I_1(\tau),I_2(\tau))$.

Now consider fields which are generated by *arbitrary* linear combinations of the invariants, $\vec{n}\cdot\vec{J}$. Denote potential solutions of the differential equation

$$\frac{d\alpha}{d\tau}=\{\alpha,\vec{n}\cdot\vec{J}\}\equiv V_{\vec{n}}(\alpha) \tag{49}$$

by $\alpha_{\vec{n}}(\tau)=S_{\vec{n}}[\tau](\alpha(0))$, with some initial point $\alpha(0)\in\Gamma$. Explicitly, the complex two-component field $V_{\vec{n}}$ reads

$$V_{\vec{n}}=\frac{1}{2i}\begin{pmatrix} (\vec{n}\cdot\vec{J}+im_1(\vec{n}\wedge\vec{J})_3+n_3J_0)/\overline{\alpha_1} \\ (\vec{n}\cdot\vec{J}+im_2(\vec{n}\wedge\vec{J})_3-n_3J_0)/\overline{\alpha_2} \end{pmatrix}. \tag{50}$$

It is finite but ill-defined on the hyperplanes $\mathcal{P}_1=\{\alpha|\alpha_1=0,\alpha_2\neq 0\}$ and $\mathcal{P}_2=\{\alpha|\alpha_1\neq 0,\alpha_2=0)\}$. There are points which, when transported by the flow $S_{\vec{n}}[\tau]$, hit the planes $\mathcal{P}_1$ or $\mathcal{P}_2$ for some value of τ. The associated orbits will be called *singular* since they cannot be continued unambiguously across the planes. This is due to the terms in (50) which contain J_1 and J_2,

$$J_1\pm iJ_2=\frac{|\alpha_1||\alpha_2|}{\sqrt{m_1m_2}}\exp[\pm i\chi], \tag{51}$$

while all other terms are zero on $\mathcal{P}_1$ and $\mathcal{P}_2$. Here is a toy example to illustrate the underlying problem. Consider a one-dimensional system with variable $\alpha=\sqrt{I}\exp[i\varphi]$, satisfying $\{I,\varphi\}=1$. The flow generated by $\sqrt{I}$ is ill-defined at the origin,

$$\frac{d\alpha}{d\tau}=\{\sqrt{I},\alpha\}=\frac{i}{2}\exp[i\varphi], \tag{52}$$

as its value depends on the way the point α is approached. If a trajectory were reaching the origin, it would be impossible to continue it unambiguously beyond this point. It is important to realize that this singularity as well as the one encountered in the singular planes is not due to a choice of coordinates but an intrinsic property of the flow.

To visualize the entire set of singular orbits, look at their images in Υ, that is, the orbits $S_{\vec{n}}[\tau](\vec{J})$, $\tau\in\mathbb{R}$. For given energy $E=2\omega J_0$, the points of $\mathcal{P}_1$ correspond to the north pole $(0,0,J_0=|\alpha_1|^2/2m_2)$ of the sphere $\mathcal{S}^2(J_0)$, while those of $\mathcal{P}_2$ are mapped to its south pole, $(0,0,-J_0=-|\alpha_2|^2/(2m_1))$. By $\psi\circ\phi$, an orbit $S_{\vec{n}}[\tau](\alpha)$ goes to a circle $R_{\vec{n}}(\tau)\vec{J}(\alpha)$. *Singular* orbits thus correspond to circles going through either one or both poles of the sphere, while *regular* orbits hit neither of them: for almost all flows, associated with a given vector $\vec{n}$, there exist two ''critical'' circles passing through the north pole and the south pole, respectively. These circles

coalesce into a single one passing through *both* poles if the axis of rotation is in the equatorial plane, $\vec{n}=(n_1,n_2,0)$. They degenerate to points located at the poles if $\vec{n}=\vec{e}_3=(0,0,\pm 1)$. Two conclusions can be drawn from this picture:

(1) for any given unit vector $\vec{n}\neq\pm\vec{e}_3$, the map $S_{\vec{n}}[\tau]$ has at least one singular orbit in Γ;
(2) any point $\alpha\in\Gamma$ can be sent to a singular hyperplane by a map $S_{\vec{n}}[\tau]$ with an appropriately chosen vector $\vec{n}_{\mathcal{P}}$.

In fact, the vectors $\vec{n}_{\mathcal{P}}$ can be chosen from *two* continuous sets: they only need to be in a plane (passing through the origin) which is perpendicular to either of the vectors $\vec{J}(\alpha)\pm J_0(\alpha)\vec{e}_3$, or, explicitly,

$$\vec{n}_{\mathcal{P}}^{\pm}=\frac{c_1(\vec{J}(\alpha)\pm J_0(\alpha)\vec{e}_3)\pm c_2\vec{J}(\alpha)\wedge\vec{e}_3}{|c_1(\vec{J}(\alpha)\pm J_0(\alpha)\vec{e}_3)\pm c_2\vec{J}(\alpha)\wedge\vec{e}_3|}. \tag{53}$$

Regular orbits of $S_{\vec{n}}[\tau]$ are easily computed without solving the differential equation (49). One needs to determine modulus and phase of the variables $\alpha_n, n=1,2$, as a function of τ. It is useful to write down the orbits in the reduced phase space and in the space of the invariants. According to (45), the reduced variables evolve linearly,

$$\beta_1(\tau)=(\cos\tau/2-in_3\sin\tau/2)\beta_1-(in_1+n_2)\sin(\tau/2)\beta_2, \tag{54}$$

$$\beta_2(\tau)=(\cos\tau/2+in_3\sin\tau/2)\beta_2-(in_1-n_2)\sin(\tau/2)\beta_1, \tag{55}$$

while the invariants $\vec{J}=\vec{J}(\beta)$ evolve in Υ as

$$\vec{J}(\tau)=\cos\tau\vec{J}+(1-\cos\tau)\vec{n}\circ\vec{n}\cdot\vec{J}-\sin\tau\,\vec{n}\wedge\vec{J}. \tag{56}$$

Using $|\alpha_n|^2=m_n|\beta_n|^2, n=1,2$, the τ-dependence of the moduli is simply

$$|\alpha_1(\tau)|^2=m_1(j_0+j_3(\tau)),\quad |\alpha_2(\tau)|^2=m_2(j_0-j_3(\tau)). \tag{57}$$

For the evolution of the phases, plug Eqs. (54) into

$$\exp[im_1\varphi_1(\tau)]=\left(\frac{\alpha_n(\tau)}{|\alpha_n(\tau)|}\right)^{m_n}=\frac{\beta_n(\tau)}{|\beta_n(\tau)|},\quad n=1,2, \tag{58}$$

giving

$$\exp[im_1\varphi_1(\tau)]=\frac{(\cos\tau/2-in_3\sin\tau/2)\beta_1-((in_1+n_2)\sin\tau/2)\beta_2}{|(\cos\tau/2-in_3\sin\tau/2)\beta_1-((in_1+n_2)\sin\tau/2)\beta_2|}\equiv\exp[i\Phi_1(\tau)], \tag{59}$$

and a similar equation for $\exp[im_2\varphi_2(\tau)]$. The two phases $\varphi_n(\tau)=\Phi_n(\tau)/m_n, n=1,2$, must be continuous whenever τ reaches the value 4π. They will both have a value which is a multiple of 2π when the parameter τ takes the value $4\pi m_1m_2$. This result seems to suggest that $S[\tau\vec{n}\cdot\vec{J}](\alpha)$ might be an m_1m_2-fold covering of the subgroup $S[\tau\vec{n}\cdot\vec{J}](\beta)$, $0\leqslant\tau<4\pi, \vec{n}\in\mathcal{S}^2$, of the special unitary group, SU(2). Due to the existence of singular orbits, however, this is not possible. Further, it is well-known that the only universal covering of SU(2) is this group itself. Nevertheless, one might describe the situation as a *ramified covering* of SU(2) since the maps $S[\tau\vec{n}\cdot\vec{J}]$ combine according to a group product law.

To visualize the obstruction of a global action of the group SU(2) differently, recall that a given map $S[\tau\vec{n}\cdot\vec{J}]$ sends a torus $\mathcal{T}(I_1,I_2)\in\Gamma$ to a torus $\mathcal{T}(I_1',I_2')$ such that $m_1I_1+m_2I_2=m_1I_1'+m_2I_2'$ holds. For some $\vec{n}$ and τ_0 it happens that one of the actions vanishes, I_1', say. This means that the initial two-dimensional torus $(\mathcal{S}^1\times\mathcal{S}^1)$ is mapped to a *one-dimensional torus*, i.e., a circle

$\mathcal{S}^1$, and, therefore, one of the angle variables has lost its meaning. Once this has happened, it is impossible to unambiguously continue the trajectory which has hit the singular plane, as the missing angle could take any value. The phenomenon is similar to the passage of a spherical wave through a focus.

It will be useful to give a name to the situation encountered here. A system with phase space Γ will be said to have a *faint G symmetry* if it admits a set of globally defined invariants which form an algebra $\mathcal{A}$ while the group G associated with it cannot be realized on Γ but only on a smaller part of it. Thus, all two-dimensional commensurate **m**-oscillators have a faint SU(2) symmetry.

V. THE *N*-DIMENSIONAL COMMENSURATE OSCILLATOR

To describe a commensurate harmonic oscillator in N dimensions, the present notation is straightforward to adapt. Let the label n run from 1 to N: the Hamiltonian of a commensurate **m**-oscillator with $\mathbf{m}=(m_1,\ldots,m_N)$, $m_n \epsilon \mathbb{N}_+$, reads

$$H(q,p)=\frac{\omega}{2}\sum_{n=1}^{N}\frac{1}{m_n}(p_n^2+q_n^2)=\frac{\omega}{2}\sum_{n=1}^{N}\frac{1}{m_n}\overline{\alpha}_n\alpha_n=\frac{\omega}{2}\sum_{n=1}^{N}\frac{1}{m_n}I_n. \tag{60}$$

The complex canonical variables are given by $\alpha_n=(q_n+ip_n)/\sqrt{2}$, $n=1,\ldots,N$, while actions I_n and angles φ_n are defined through $\alpha_n=\sqrt{I_n}\exp[i\varphi_n]$. Thus there are three sets of N pairs of canonical variables to choose from, with brackets

$$\{q_n,p_{n'}\}=\frac{1}{i}\{\overline{\alpha}_n,\alpha_{n'}\}=\{I_n,\varphi_{n'}\}=\delta_{nn'}, \quad n,n'=1,\ldots,N. \tag{61}$$

It will be assumed that the positive integer numbers m_n do not have an overall common divisor. For the discussion to follow, two cases will be distinguished: a commensurate oscillator is said to be *canonical* if *no* pair of numbers m_n and $m_{n'}$, $n\neq n'$, admits a common divisor but one. This class will be studied first. The presence of common divisors among subsets of the frequencies ω_n gives rise to interesting additional complications which will be considered later on.

A. Constants of motion and Lie algebras

In analogy to Eq. (10), each function

$$K_{nn'}=\alpha_n^{m_n}(\overline{\alpha}_{n'})^{m_{n'}}, \quad n,n'=1,\ldots,N, \tag{62}$$

is seen to be an invariant for the commensurate N-oscillator, $\{H,K_{nn'}\}=0$. These N^2 constants of motion depend on only $N(N+1)/2$ real invariants, namely N independent actions $I_n, n=1,\ldots,N$, and $N(N-1)/2$ relative angles

$$\chi_{nn'}=m_n\varphi_n-m_{n'}\varphi_{n'}, \quad 1\leqslant n<n'\leqslant N. \tag{63}$$

As in the two-dimensional case, the range of the functions $\chi_{nn'}$ must be restricted to the interval $[0,2\pi)$ because two values $\chi_{nn'}$ and $(\chi_{nn'}+2\pi)$, respectively, correspond to the *same* orbit. The angles $\chi_{nn'}$ satisfy $(N-1)(N-2)/2$ linear relations,

$$\chi_{nn'}+\chi_{n'n''}+\chi_{n''n}\equiv 0, \quad n,n',n'' \text{ all different.} \tag{64}$$

Therefore, there are no more than $(2N-1)$ functionally independent constants of motion, the maximum number of possibly independent invariants. As independent invariants, one may choose, for example, the N actions I_n and $(N-1)$ relative angles $\chi_{n\,n+1}, n=1,\ldots,N-1$.

The $(2N-1)$- dimensional surface of constant energy $H=E$ is an ellipsoid $\mathcal{E}(E)$ in phase space Γ. It contains the N-dimensional torus $\mathcal{T}(I_1,\ldots,I_N)$ of constant actions I_n as a submanifold. Lines of constant actions and angles are the *orbits* of the motion, winding around a torus $\mathcal{T}$. Each orbit is a one-dimensional closed loop given by

$$\alpha_n(t)=\sqrt{I_n}\exp(-i\omega t/m_n+\varphi_n(0)), \tag{65}$$

where $m_n\varphi_n(0)-m_{n+1}\varphi_{n+1}(0)=\chi_{n,n+1}(0)$. One revolution is completed after a time $t=2\pi M/\omega$, with the number M taking a value such that the *winding numbers* $w_n=M/m_n$ of each subsystem are integer without overall common divisor. In the canonical case, M is equal to $\Pi_1^N m_n$. Here is an example for $N=3$ which illustrates the noncanonical case: let $\mathbf{m}=(km_1',km_2',m_3)$. The number M would then take the value $km_1'm_2'm_3=m_1m_2m_3/k$.

It is important to note that in a canonical (but not isotropic) **m**-oscillator (i.e., all $m_n\neq 1$), there exist orbits with (2^N-1) different periods. There are N orbits corresponding to motion of a single oscillator only; there are $N(N-1)/2$ orbits winding around two-dimensional tori with frequencies $1/m_n$ and $1/m_{n'}$, $1\leqslant n<n'\leqslant N$, etc.

As in the two-dimensional case, the maps $R_n\alpha=(\alpha_1,\ldots,e^{i2\pi/m_n}\alpha_n,\ldots,\alpha_N)$ generate a cyclic group $\mathcal{C}_m=\{R_1^{r_1}\cdots R_N^{r_N}|r_n\in\mathbb{Z}\}$, the ambiguity group of the map ψ:

$$\psi(R_1^{r_1}\cdots R_N^{r_N}\alpha)=\psi(\alpha). \tag{66}$$

B. Reduced phase space and space of invariants

The $(2N-1)$ phase-space functions I_n and $\chi_{n\,n+1}$ form a basis of a Lie algebra commuting with the Hamiltonian H. Since the functions $\chi_{nn'}$ are not continuous on phase space Γ, it is natural to look at appropriate periodic functions of them. Introduce, in analogy to Eq. (20), the set of invariants

$$\beta_n=\frac{|\alpha_n|}{\sqrt{m_n}}\left(\frac{\alpha_n}{|\alpha_n|}\right)^{m_n}=\sqrt{\frac{I_n}{m_n}}\exp[im_n\varphi_n],\quad n=1,...,N. \tag{67}$$

They provide canonical coordinates on the $2N$-dimensional reduced phase space $\Gamma_{\mathbf{m}}$, now with $\mathbf{m}=(m_1,\ldots,m_N)$,

$$\{\overline{\beta}_n,\beta_{n'}\}=i\delta_{nn'}. \tag{68}$$

As before, (67) is a non-bijective map ψ: $\alpha\to\beta(\alpha)$. It is not a projection of the phase space on a subspace but should be thought of as a *ramified* cover of the reduced space $\Gamma_{\mathbf{m}}$.

Not surprisingly, Eqs. (26) have a straightforward generalization. With $\beta=(\beta_1,\ldots,\beta_N)$, one defines (N^2-1) invariants sesquilinear in the coordinates β_n by

$$J^s_{nn'}=\frac{1}{2}\,\overline{\beta}\cdot(E_{nn'}+E_{n'n})\beta=\frac{1}{2}(\overline{\beta}_n\beta_{n'}+\overline{\beta}_{n'}\beta_n),\quad 1\leqslant n<n'\leqslant N, \tag{69}$$

$$J^a_{nn'}=\frac{1}{2}\,\overline{\beta}\cdot\frac{1}{i}(E_{nn'}-E_{n'n})\beta=\frac{1}{2i}(\overline{\beta}_n\beta_{n'}-\overline{\beta}_{n'}\beta_n),\quad 1\leqslant n<n'\leqslant N, \tag{70}$$

$$J^d_{nn}=\frac{1}{2}\,\overline{\beta}\cdot(E_{nn}-E_{n+1\,n+1})\beta=\frac{1}{2}(\overline{\beta}_n\beta_n-\overline{\beta}_{n+1}\beta_{n+1}),\quad n=1,...,N-1. \tag{71}$$

The matrices $E_{nn'}$ are of size $N\times N$ with elements

$$(E_{nn'})_{kk'}=\delta_{nk}\delta_{n'k'},\quad n,n',k,k'=1,...,N, \tag{72}$$

i.e., the only nonzero elements are equal to one at position (n,n'), and they generate the Lie algebra $u(n)$ with respect to the matrix commutator.[21] This property is inherited by the N^2 phase-space functions

$$J_{nn'}=\overline{\beta}\cdot E_{nn'}\beta\equiv\overline{\beta}_n\beta_{n'}; \tag{73}$$

their Poisson brackets,

$$\{J_{nn'},J_{kk'}\}=i(\delta_{nk'}J_{kn'}-\delta_{n'k}J_{nk'}), \tag{74}$$

also realize the algebraic relations of $u(N)$.

It is possible to find (N^2-1) linear combinations of the matrices $E_{nn'}$ which are traceless and Hermitian—hence they provide a basis of the algebra su(N). In fact, these combinations have been introduced already in Eq. (69) when defining $J^s_{nn'}$, $J^a_{nn'}$, and J^d_{nn}. Therefore, these functions form a basis of the algebra su(N) with respect to the Poisson bracket. When supplemented by (a multiple of) the Hamiltonian

$$J_0=\frac{1}{2}\overline{\beta}\cdot\mathbf{1}_N\beta=\frac{1}{2}\sum_{n=1}^{N}\overline{\beta}_n\beta_n\equiv\frac{2}{\omega}H, \tag{75}$$

where $\mathbf{1}_N$ is the N-dimensional unit matrix, the algebra $u(n)$ can be recovered.

C. Vector fields

There is a first group of transformations which acts in the space of invariants Υ. As before, it is the set of finite transformations on the space generated by the real invariants (69)–(71). In other words, it arises from integrating the adjoint representation of the algebra formed by the invariants. As this group will play no role in the following, its discussion is suppressed.

Next, the invariants $J^s_{nn'}$ and $J^a_{nn'}$ generate canonical linear maps in the reduced space $\Gamma_{\mathbf{m}}$,

$$\frac{d\beta_k}{d\tau}=\{\beta_k,J^s_{nn'}\}=\frac{i}{2}(\delta_{kn}\beta_{n'}+\delta_{kn'}\beta_n)\equiv(J^s_{nn'}\beta)_k, \tag{76}$$

$$\frac{d\beta_k}{d\tau}=\{\beta_k,J^a_{nn'}\}=\frac{1}{2}(\delta_{kn}\beta_{n'}-\delta_{kn'}\beta_n)\equiv(J^a_{nn'}\beta)_k, \tag{77}$$

and similar ones follow when taking J^d_{nn} as generator. These linear equations can be integrated in the space $\Gamma_{\mathbf{m}}$ for arbitrary initial values $\beta(0)=\beta_0\in\Gamma_{\mathbf{m}}$,

$$\beta(\tau)=\exp(\tau J^{\varepsilon}_{nn'})\beta_0,\quad \varepsilon=a,s. \tag{78}$$

The solutions are unitary maps of $\Gamma_{\mathbf{m}}$ to itself. In analogy to the two-dimensional case, they will be denoted by

$$\beta(\tau)=\mathrm{Exp}[\tau J^{\varepsilon}_{nn'}](\beta),\quad \varepsilon=a,s, \tag{79}$$

and similarly for finite transformations generated by the invariants J^d_{nn}. Due to the linearity of the equations, no ambiguities arise upon integration. Therefore, the set of transformations in the reduced space $\Gamma_{\mathbf{m}}$ is isomorphic to the group SU(N). In this restricted sense, the **m**-oscillator has the special unitary group in N dimensions as a symmetry group. This group of symmetry transformations is *not* defined in the phase space Γ of the **m**-oscillator but only in $\Gamma_{\mathbf{m}}$.

Finally, a genuine ''pullback'' of SU(N) in phase space Γ does not exist, for the same reasons as in the case $N=2$. In fact, it is sufficient to consider a pair of oscillators with frequencies ω/m_n and $\omega/m_{n'}$, say, in order to see that there are obstructions which prevent the existence of a *global* symmetry group in phase space Γ. This pair of degrees of freedom is equivalent to a two-dimensional $(m_n,m_{n'})$-oscillator, and no set of transformations acting on it can be found which would be isomorphic to SU(2). If, however, the N-dimensional oscillator would have the full symmetry SU(N), a subgroup SU(2) should be associated with this pair of oscillators. Consequently, the group SU(N) cannot be identified as a symmetry group of the canonical N-dimensional commensurate oscillator. In analogy to the two-dimensional commensurate oscillator it is seen to have a *faint* SU(N) symmetry only.

D. The m-oscillator with common divisors

The canonical **m**-oscillator has been shown to be invariant under transformations isomorphic to the group SU(N) in the reduced space $\Gamma_{\mathbf{m}}$. For canonical and isotropic N-dimensional oscil-

lators, subsystems of dimension $N'<N$ are invariant only with respect to a subalgebra $\mathcal{A}_{\mathbf{m}'}$ of the algebra $\mathcal{A}_{\mathbf{m}}=\mathrm{su}(N)$. If the oscillator is neither isotropic nor canonical, other possibilities arise.

A noncanonical oscillator is characterized by frequencies $\mathbf{m}=(m_1,\ldots,m_N)$ with at least one pair (m_k,m_l) having a common integer divisor different from one. Let $N'<N$ frequencies have a common divisor. Then, for the $\mathbf{m}'$-oscillator corresponding to these frequencies, constants of motion do exist which form an algebra $\mathcal{A}_{\mathbf{m}'}=\mathrm{su}(N')$. This algebra, however, is *not* a subalgebra of $\mathcal{A}_{\mathbf{m}}$ as follows immediately from considering the $\mathbf{m}'$-oscillator as an N'-dimensional commensurate oscillator in its own right. Suppose that, after removing the common divisor, the resulting oscillator, characterized by $\mathbf{m}'=(m_1',\ldots,m_{N'}')$, is a canonical one. Then one can construct a group of symmetry transformations $\mathrm{SU}(N')$ in the reduced phase space $\Gamma_{\mathbf{m}'}$, and $\Gamma_{\mathbf{m}'}$ is *not* a subspace of $\Gamma_{\mathbf{m}}$. The Poisson brackets of the generators of $\mathrm{SU}(N')$ acting in $\Gamma_{\mathbf{m}'}$ and those of $\mathrm{SU}(N)$ acting in $\Gamma_{\mathbf{m}}$ will not be linear combinations of the initial ones. Hence, the combination of these two algebras will not close under the Lie product—the resulting algebra will be *infinite*. This property will be important for quantum mechanical commensurate oscillators since it entails additional degeneracies of energy which otherwise appear to be accidental.

Turn these results around: there is no finite algebra to account for all the symmetries of a noncanonical $\mathbf{m}$-oscillator. Obviously, this situation can arise only if $N\geqslant 3$ (if $N=2$ any common divisor can be factored out immediately). In fact, if $m_{n'}'=1$, $n'=1,\ldots,N'$, the subsystem is even an isotropic oscillator, and it has a group $\mathrm{SU}(N')$ of symmetry transformations on phase space Γ.

It is helpful to illustrate this discussion by an exhaustive list of ''classes'' for small values of N.

$\diamond$ $N=2$: A commensurate oscillator is either isotropic or canonical (a common divisor of the frequencies $m_1\neq m_2$ can be factored out).

$\diamond$ $N=3$: Five classes of commensurate oscillators can be identified. An $\mathbf{m}$-oscillator is either isotropic or canonical, or it belongs to one of the three following classes:

(1) a single pair of two frequencies have a common divisor, $\mathbf{m}=(jm_1',jm_2',m_3)$, say;
(2) two pairs have common but different divisors, $\mathbf{m}=(jm_1',jkm_2',km_3')$, say;
(3) all three pairs have common but different divisors, $\mathbf{m}=(jkm_1',klm_2',ljm_3')$, say.

For $N>3$ the number of different classes increases rapidly with N.

Consider an example of type 1 for $N=3$ in detail. The three coordinates β_n of the space $\Gamma_{\mathbf{m}}$ allow one to define eight constants of motion J. In addition, introduce coordinates of the reduced phase space $\Gamma_{\mathbf{m}'}$,

$$\beta_n'=\frac{|\alpha_n|}{\sqrt{m_n'}}\left(\frac{\alpha_n}{|\alpha_n|}\right)^{m_n'},\quad n=1,2. \tag{80}$$

The four functions

$$J_{nn'}'=\overline{\beta}_n'\beta_{n'}',\quad n,n'=1,2, \tag{81}$$

are a different set of constants of motion because the Hamiltonian of the subsystem (1,2) has an overall factor $1/k$. The constants J' are the basis of a Lie algebra $\mathcal{A}_{\mathbf{m}'}$ isomorphic to su(2) (setting aside the fourth commuting invariant), as the subsystem is an $\mathbf{m}'$-oscillator with $N=2$. The resulting algebra $\mathcal{A}_{\mathbf{m}'}$ gives rise to another faint SU(2) symmetry. It is, however, *neither* a subalgebra of the faint $\mathrm{SU}(N)$ symmetry (as it it implemented on a different reduced phase space $\Gamma_{\mathbf{m}'}$) *nor* do the generators of $\mathcal{A}_{\mathbf{m}}$ and $\mathcal{A}_{\mathbf{m}'}$ commute. Consequently, the union of both algebras gives rise to an infinite algebra. Finally, if $m_1'=m_2'=1$, three of the functions J' would generate the group SU(2) on the original phase space Γ. In other words, the faint $\mathrm{SU}(N)$ symmetry of an $\mathbf{m}$-oscillator with common divisors is compatible with the existence of smaller groups acting globally in phase space Γ.

VI. SUMMARY AND OUTLOOK

This article deals with the problem which symmetry group to associate with an N-dimensional *commensurate* harmonic oscillator. Historically, structural similarities to the isotopic oscillator seemed to indicate that the introduction of rational frequency ratios $m_n/m_{n'}$ would not affect the existence of the group SU(N) of symmetry transformations. This suggestion was based on the following observations. Arbitrary rational frequency ratios $m_n/m_{n'}$, are still compatible with the existence of $(2N-1)$ globally defined invariants. In both cases, the invariants confine trajectories to a one-dimensional manifold in phase space, the orbit. Furthermore, the invariants form an algebra su(N) with respect to the Poisson bracket. There is, however, a subtle difference between an isotropic and a commensurate oscillator: isotropy forces all orbits to have the *same* period whereas commensurate frequencies allow for orbits with *different* periods. Consequently, these system *are* distinguishable from an experimental point of view.

It has been shown that the algebra su(N) of the commensurate oscillator cannot be extended globally to a representation of the group SU(N) in phase space. Strictly speaking, it is thus not possible to attribute this group as a symmetry group to the commensurate harmonic oscillator. The group SU(N) is associated with commensurate oscillators in a restricted sense only: to do so, the action of the invariants must be considered in a *reduced* phase space the points of which are no longer in a one-to-one correspondence with the states of the system. The commensurate oscillator is said to have a *faint* SU(N) *symmetry*. Furthermore, if the rationally related frequencies have common divisors, additional sets of symmetry transformations can be found. They are not subgroups of the faint group SU(N), which acts in reduced phase, but they act in different reduced phase spaces.

To conclude, it has been shown that the symmetries of commensurate harmonic oscillators come in a surprisingly rich variety and depend in a subtle way on the frequency ratios. Classical and quantum mechanical oscillators are closely related. Therefore, it will be promising to study the impact of faint symmetries on the Hilbert-space structure of quantum mechanical commensurate oscillators.[3] In particular, a systematic group-theoretical account of their degenerate energy levels is expected to benefit from the concept of faint symmetry.

A low energy bound for static classical solutions in a class of chiral solitonic field theories related to the infrared physics of the SU(N) Yang–Mills theory is established. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1488671]

I. THE MODEL

Consider $N-1$ smooth fields $n_a=n_a(x)$ in space–time taking their values in the Lie algebra of SU(N). The fields are chosen to be commutative $[n_a,n_b]=0$ and orthonormal $(n_a,n_b)=\delta_{ab}$ with respect to the Cartan–Killing form in the Lie algebra. For any two Lie algebra elements ξ and η, the Cartan–Killing form is defined as $(\xi,\eta)=\mathrm{tr}(\hat{\xi}\hat{\eta})$ where the operator $\hat{\xi}$ acts on the Lie algebra as a Lie derivative $\hat{\xi}\eta=[\xi,\eta]$. There can only be $N-1$ mutually commutative and linearly independent elements in the Lie algebra of SU(N) because the rank of SU(N) is $r=N-1$ (the dimension of the Cartan subalgebra). If h_a form an orthonormal basis in the Cartan subalgebra in a matrix representation of SU(N), then

$$n_a(x)=U^{\dagger}(x)h_aU(x), \tag{1}$$

where $U^{\dagger}(x)\in \mathrm{SU}(N)$. In Eq. (1) U($x$) is defined modulo the left multiplication by elements from the Cartan subgroup generated by h_a [the maximal Abelian subgroup $T=U(1)^{N-1}$]. So, in fact, $U(x)\in \mathrm{SU}(N)/T$ since any group element can be represented as a product of an element of T and an element of the quotient $\mathrm{SU}(N)/T$. Under the condition that n_a approaches fixed constant values at the spatial infinity, $n_a(x)\to h_a$, i.e., $U(x)$ approaches the group unity, the fields n_a define a map of a spatial three-sphere $\mathbf{S}^3$ into the manifold $\mathrm{SU}(N)/T$ for every moment of time. The third homotopy group of this map is nontrivial $\pi_3(G/T)\sim Z$, $G=\mathrm{SU}(N)$. When $N=2$, the only field n_1 can be regarded as a unit three-vector. It is a Hopf map: $\mathbf{S}^3\to\mathbf{S}^2\sim \mathrm{SU}(2)/U(1)$. The corresponding topological number is the Hopf invariant which can also be interpreted as a linking number of two curves in $\mathbf{S}^3$ being preimages of two distinct points of $\mathbf{S}^2$. The two-forms $F^a=F^a_{jk}\,dx^j\wedge dx^k$, $j,k=1,2,3$, where

$$F^a_{jk}=iN\sum_b\,(n_a,[\partial_j n_b,\partial_k n_b]) \tag{2}$$

are closed, that is, $F^a_{jk}=\partial_jC^a_k-\partial_kC^a_j$. This is proved at the end of Sec. II. The forms F^a may not be exact. This follows from the fact that the cohomology ring $H^*(G/T)$ is rationally generated by $H^2(G/T)$.[1] The topological number of the map $\mathbf{S}^3\to G/T$ should be constructed out of the two-forms $F^a=iN(n_a,\Sigma_b[dn_b,dn_b])$ on G/T. Introducing the field $B^a_i=1/2\epsilon_{ijk}F^a_{jk}$ with ϵ_{ijk} being the Levi-Chevita tensor, the topological number of the above-mentioned map can be written as

$$Q=(16\pi^2N)^{-1}\int dx\sum_{i,a}\,C^a_iB^a_i\,. \tag{3}$$

a)On leave from Laboratory of Theoretical Physics, JINR, Dubna, Russia; electronic mail: shabanov@phys.ufl.edu

For SU(2), Q is a Hopf invariant. Since $\mathrm{SU}(2)/U(1)\subset G/T$, the normalization coefficient in (3) can be chosen so that Q is an integer when n_a realize a Hopf map.

An explicit realization of the Hopf map by the fields n_a is as follows. Consider the Cartan–Weyl basis in the Lie algebra. Let α be a positive root. For every positive root α, there are two basis elements e_α and $e_{-\alpha}=\overline{e_\alpha}$ such that for any element h from the Cartan subalgebra

$$[h,e_\alpha]=(h,\alpha)e_\alpha, \tag{4}$$

$$[e_\alpha,e_{-\alpha}]=\alpha, \quad [e_\alpha,e_\beta]=N_{\alpha,\beta}e_{\alpha+\beta}, \tag{5}$$

where $N_{\alpha,\beta}\neq 0$ if $\alpha+\beta$ is a root. Note that the elements α, e_α, and $e_{-\alpha}$ form a basis of an SU(2) subalgebra (associated with the root α). Let $U_\omega(x)\in \mathrm{SU}(2)/U(1)\subset \mathrm{SU}(N)/T$ where the subgroup SU(2) is associated with a simple root ω. One can always choose $h_1=N^{1/2}\omega$. The norm of any root of SU(N) is $1/N$ with respect to the Cartan–Killing form (see Sec. II). Then $n_1(x)=N^{1/2}U_\omega^\dagger\omega U_\omega$ is a Hopf map. The other fields realize a trivial map, $n_a=h_a$, $a>1$. Indeed, $U_\omega(x)=\exp[iu_\omega(x)]$ where $u_\omega(x)=\varphi_\omega(x)e_\omega+\overline{\varphi}_\omega(x)e_{-\omega}$. For $a>1$, it follows from (4) that $n_a=U_\omega^\dagger h_a U_\omega=h_a$ because $(\omega,h_a)\sim(h_1,h_a)=0$. Now, if we introduce an orthonormal basis in the SU(2) subgroup, $\tau_1=i(e_\omega-e_{-\omega})/\sqrt{2}$, $\tau_2=(e_\omega+e_{-\omega})/\sqrt{2}$, and $\tau_3=\sqrt{N}\omega$, then $[\tau_j,\tau_k]=iN^{-1/2}\epsilon_{jkn}\tau_n$. Let $\mathbf{n}$ be an isotopic unit three-vector whose components are (τ_j,n_1). It defines the Hopf map by construction. From (2) we infer that $F^a_{jk}=\delta^{a1}\sqrt{N}\mathbf{n}\cdot(\partial_j\mathbf{n}\times\partial_k\mathbf{n})$. Hence our B^a_j and C^a_j contain an extra factor $\sqrt{N}$ when the fields n_a realize a Hopf map associated with an SU(2) subgroup of SU(N). This explains the normalization factor N^{-1} in (3). Since all the roots have the same norm in SU(N), the normalization coefficient in (3) for any SU(2) subgroup has to be the same. The root system is invariant under the Weyl symmetry, and so should be Q. The sum over a in (3) provides this invariance.

The dynamics of the fields n_a is determined by the Lagrangian density

$$\mathcal{L}=m^2\sum_{\mu,a}(\partial_\mu n_a,\partial_\mu n_a)-\frac{g}{4}\sum_{\mu,\nu,a}F^a_{\mu\nu}F^a_{\mu\nu}, \tag{6}$$

$\mu,\nu=0,1,2,3$; and ∂_0 stands for the time derivative. In the case of SU(2), this Lagrangian density describes the Faddeev model[2] for knot solitons. The knot solitons have been extensively studied numerically.[3] The model (6) has been introduced in Ref. 4 and may also have solitonic solutions. The Lagrangian (6) is believed to describe (in a certain approximation) the infrared physics of the SU(N) Yang–Mills theory.[4–6] Recent analytical[7] and lattice[8,9] studies of this correspondence in the SU(2) case look promising.

Due to the Lorentz symmetry of the Langrangian density, a Lorentz transformation of a static solution is a time-dependent solution of the Euler–Lagrange equations for (6). Solutions that describe interacting solitons are not static (even modulo Lorentz transformations). In this paper a low energy bound for static solitons with a topological number Q is established:

$$E\geqslant c_N|Q|^{3/4}, \tag{7}$$

$$c_N=8\pi^2 3^{3/8}\left(\frac{2N^3}{N^2-N-1}\right)^{1/4}\sqrt{m^2 g}, \tag{8}$$

where E is the energy functional

$$E=m^2\int \mathrm{d}x\sum_{j,a}(\partial_j n_a,\partial_j n_a)+\frac{g}{2}\int \mathrm{d}x\sum_{j,a}B^a_jB^a_j \tag{9}$$

$$\equiv\int \mathrm{d}x(\mathcal{E}_2(x)+\mathcal{E}_4(x))\equiv E_2+E_4. \tag{10}$$

For the Faddeev–Hopf knot solitons the low energy bound was found in Ref. 10 and improved in Refs. 11 and 12 (meaning a larger constant c_2). Beyond conventional perturbation theory, the Yang–Mills quantum dynamics can be studied by the large N expansion method with the purpose to establish a relation (duality) to a string theory on some manifold. Therefore it is of interest to investigate the N dependence of the low energy bound for solitons in the model (6).

II. NOTATIONS AND NECESSARY FACTS

We would need the following algebraic inequalities. Let a_i, $b_i \geqslant 0$, $a=\Sigma_i a_i$, $b=\Sigma_i b_i$, and $\gamma \geqslant 1$. Then

$$a_1^\gamma + a_2^\gamma + \cdots + a_r^\gamma \leqslant a^\gamma, \tag{11}$$

$$\sqrt{a} \leqslant \sqrt{a_1} + \sqrt{a_2} + \cdots + \sqrt{a_r} \leqslant \sqrt{r}\sqrt{a}, \tag{12}$$

$$\sum_i a_i^p b_i^q \leqslant a^p b^q, \quad p+q=1. \tag{13}$$

Define $p_i = a_i/a \leqslant 1$. Then $\Sigma_i p_i = 1$. The inequality (11) follows from an obvious inequality $p_i^\gamma \leqslant p_i$ if one takes the sum over i. The second inequality is proved by squaring it and applying the basic algebraic inequality $\sqrt{a_i}\sqrt{a_j} \leqslant 1/2(a_i + a_j)$. The third inequality is an algebraic Hölder inequality (see, e.g., Ref. 13).

An arrow is used to denote vectors in space, e.g., $\vec{\partial}\phi = (\partial_1\phi, \partial_2\phi, \partial_3\phi)$ for the gradient. The scalar product for two vector fields is

$$\langle \vec{u}, \vec{v} \rangle = \int \mathrm{d}x \vec{u} \cdot \vec{v}. \tag{14}$$

The L_p norm of a vector field reads

$$\|\vec{u}\|_p = \left[\int \mathrm{d}x (\vec{u} \cdot \vec{u})^{p/2} \right]^{1/p}. \tag{15}$$

The following functional inequalities are used in the sequel

$$|\langle \vec{u}, \vec{v} \rangle| \leqslant \|\vec{u}\|_p \|\vec{v}\|_q, \quad p^{-1} + q^{-1} = 1, \tag{16}$$

$$\|\vec{u}\|_{6/5} \leqslant \|\vec{u}\|_1^{2/3} \|\vec{u}\|_2^{1/3}, \tag{17}$$

$$\|\vec{u}\|_6 \leqslant \lambda_1 \|\mathrm{curl}\, \vec{u}\|_2, \quad \lambda_1 = (48)^{1/6} (3\pi)^{-2/3}. \tag{18}$$

The first two inequalities are Hölder-type inequalities.[13] The third one follows from Rosen's result for scalar functions[14] (cf. Ref. 11)

$$\|\phi\|_6 \leqslant \lambda_1 \|\vec{\partial}\phi\|_2, \tag{19}$$

where the L_p norm for scalar functions is defined by (15) for one-dimensional vectors. Let $\phi = (\vec{u} \cdot \vec{u})^{1/2}$. We have

$$\vec{\partial}\phi \cdot \vec{\partial}\phi = \phi^{-2} \sum_j (\partial_j \vec{u} \cdot \vec{u})^2 \leqslant \sum_j \partial_j \vec{u} \cdot \partial_j \vec{u}.$$

Making use of this inequality, we infer (18) from (19):

$$\|\vec{u}\|_6=\|\phi\|_6\leqslant\lambda_1\|\vec{\partial}\phi\|_2\leqslant\lambda_1\left[\int dx\sum_{i,j}(\partial_j u_i)^2\right]^{1/2}=\lambda_1\|\mathrm{curl}\,\vec{u}\|_2. \tag{20}$$

The last equality in (20) is true if $\mathrm{div}\,\vec{u}=0$ and $\vec{u}$ decreases sufficiently fast at spatial infinity, which we require in (18). The coefficient λ_1 is the least possible coefficient in inequality (18).[14]

Let ω_a, $a=1,2,\ldots,r$, be simple roots of SU(N). They have the same norm $(\omega_a,\omega_a)\equiv\gamma^2$. The angle between ω_a and $\omega_{a\pm1}$ is $2\pi/3$, and otherwise the roots are perpendicular. Any positive root can be written in the form $\alpha=\omega_a+\omega_{a+1}+\cdots+\omega_{a+q}$ for $a+q\leqslant r$. From this it is easy to deduce that all roots have the same norm with respect to the Cartan–Killing form, $(\alpha,\alpha)=\gamma^2$. To find the actual norm γ, one should compute, say, the matrix $\hat{\omega}_1$ in the Cartan–Weyl basis and take the trace of its square. From (4) it follows that $\hat{\omega}_1$ is block diagonal. The block associated with the Cartan subalgebra is zero because ω_a commute amongst each other. The nontrivial blocks come from the subspaces spanned by e_α and $e_{-\alpha}$ where the positive root α is either equal to ω_1 or contains ω_2 or $\omega_1+\omega_2$. There are $r-1$ roots containing ω_2 and $r-1$ roots containing $\omega_1+\omega_2$. Then $\gamma^2=\mathrm{tr}\,(\hat{\omega}_1^2)=\gamma^4 N$ as is deduced from (4). Hence

$$(\omega_a,\omega_a)=N^{-1}. \tag{21}$$

As a consequence of (21), the following identity holds for any Lie algebra element v:

$$v=\sum_a n_a(n_a,v)+N\sum_a[n_a,[n_a,v]]\equiv v_\parallel+v_\perp. \tag{22}$$

The proof is based on the following observation. Relation (22) is covariant under the adjoint action of SU(N). So, according to (1), n_a can be replaced by h_a after a corresponding adjoint rotation of v. Decomposing v in the Cartan-Weyl basis, one can see that the first term in (22) is the Cartan component of v. The double commutator in the second term can be computed by means of (4) and gives rise to the factor $\Sigma_a(\alpha,h_a)^2=(\alpha,\alpha)=N^{-1}$ for every basis element e_α. Thus the second term in (22) is nothing but a projector onto the subspace orthogonal to the Cartan subalgebra spanned by n_a.

By differentiating (1) one finds

$$\partial_\mu n_a+i[A_\mu,n_a]=0, \tag{23}$$

$$i\partial_\mu U^\dagger U\equiv A_\mu-\sum_a n_a C_\mu^a,\quad (n_a,A_\mu)=0. \tag{24}$$

Equation (23) can be interpreted as: The fields n_a are transported parallel with respect to the connection A_μ. Taking a commutator of (23) with n_a, summing over a and making use of the identity (22), the connection A_μ can be explicitly written via n_a,

$$A_\mu=iN\sum_a[\partial_\mu n_a,n_a]. \tag{25}$$

The connection (25) has been introduced by Cho to study monopoles in the Yang–Mills theory for SU(2) and SU(3).[15] By multiplying (23) by n_b using the Cartan–Killing form, one deduces that the derivatives of n_a are orthogonal to the fields themselves

$$(\partial_\mu n_a,n_b)=0. \tag{26}$$

Now we show that the tensor (2) is an Abelian gauge field tensor (cf. Refs. 4 and 6), that is, the two-forms F^a are closed, $dF^a=0$. Consider the following algebraic transformations:

$$\partial_\mu A_\nu - \partial_\nu A_\mu = 2iN \sum_a [\partial_\nu n_a, \partial_\mu n_a] = 2iN \sum_a [[A_\mu, n_a], [A_\nu, n_a]], \tag{27}$$

$$= 2iN \sum_a \{[A_\nu, [n_a, [n_a, A_\mu]]] + [n_a, [[n_a, A_\mu], A_\nu]]\}, \tag{28}$$

$$= 2i[A_\nu, A_\mu] + iN \sum_a [n_a, [n_a, [A_\mu, A_\nu]]], \tag{29}$$

$$= -i[A_\mu, A_\nu] - i \sum_a n_a (n_a, [A_\mu, A_\nu]). \tag{30}$$

In (27) we have used (25); next, $\partial_\mu n_a$ has been transformed via (23); Eq. (28) follows from the Jacobi identity; to derive (29), the first term in (28) has been transformed by means of the algebraic identity (22), while the second one via the Jacobi identity; finally, by applying the algebraic identity (22) to (29), Eq. (30) has been deduced. Introducing the Yang–Mills field strength tensor

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu], \tag{31}$$

it follows from (30) that

$$F_{\mu\nu} = i \sum_a n_a (n_a, [A_\mu, A_\nu]) = \sum_a n_a F^a_{\mu\nu}. \tag{32}$$

The last equality in (32) is deduced by multiplying (30) and the middle of (27) by n_a using the Cartan–Killing form. Now observe that the field strength (curvature) of the pure gauge connection (24) is zero. Making use of the decomposition (24) of a pure gauge connection we obtain

$$0 = F_{\mu\nu} - \sum_a n_a (\partial_\mu C^a_\nu - \partial_\nu C^a_\mu), \tag{33}$$

where the identity (23) has been used again for algebraic transformations. Thus, $F^a_{\mu\nu} = \partial_\mu C^a_\nu - \partial_\nu C^a_\mu$. Note that (24) allows one to determine C^a_μ via the group element U explicitly. In (3) the vector potential C^a_i can always be chosen to satisfy the Coulomb gauge, $\partial_i C^a_i = 0$, thanks to the gauge freedom $C^a_\mu \to C^a_\mu + \partial_\mu \xi^a$.

III. A KEY ALGEBRAIC INEQUALITY

In this section the following inequality is proved

$$\mathcal{E}_4 \leqslant \kappa_N \mathcal{E}_2^2, \quad \kappa_N = \frac{gN}{4m^4}\left(1 - \frac{1}{N^2 - N}\right). \tag{34}$$

It is used in Sec. IV to establish the low energy bound. Consider the $(N^2-1)\times(N^2-1)$ matrix

$$G = \sum_{i,b} \partial_i n_b \otimes \partial_i n_b .$$

It can be regarded as a linear operator on the Lie algebra, i.e., $G\eta = \Sigma_{i,b}\, \partial_i n_b (\partial_i n_b, \eta)$ for any Lie algebra element η. It has $N-1$ zero eigenvalues because $G n_a = 0$. The matrix G satisfies

$$\operatorname{tr} G^2 \geqslant \frac{1}{N^2 - N} (\operatorname{tr} G)^2. \tag{35}$$

The proof is simple. Let g_k, $k=1,2,\ldots,n=N^2-N$, be nonzero eigenvalues of G. They are real since $G=G^T$ with respect to the Cartan–Killing form. Consider a function of one real variable ξ, $f(\xi)=\Sigma_k(g_k-\xi)^2$. Computing the sum explicitly, one finds that $f(\xi)=\mathrm{tr}\,G^2-2\xi\,\mathrm{tr}\,G+\xi^2 n$. The function attains its absolute minimum at $\xi=\xi_0=\mathrm{tr}\,G/n$. Since $f(\xi)\geqslant 0$ for all ξ's, the inequality (35) follows from $f(\xi_0)\geqslant 0$.

Consider a local Cartan–Weyl basis which is obtained by an adjoint transformation of the basis (4), (5) with the group element $U(x)$ defined in (1). Denoting $n_\alpha=U^\dagger e_\alpha U$ and $n_{-\alpha}=U^\dagger e_{-\alpha}U=\overline{n_\alpha}$ we have

$$[n_a,n_\beta]=(h_a,\beta)n_\beta,\quad [n_\alpha,n_{-\alpha}]=U^\dagger\alpha U\equiv\alpha_U, \tag{36}$$

where $(\alpha_U,n_a)=(\alpha,h_a)$ and $(n_a,n_\beta)=0$, $(n_\alpha,n_{-\alpha})=1$, $(n_\alpha,n_\alpha)=(n_{-\alpha},n_{-\alpha})=0$.

To establish a relation between $\mathcal{E}_4$, $\mathcal{E}_2$ and G, we decompose the connection (25) in the local Cartan–Weyl basis

$$A_i=\sum_{\alpha>0}(A_i^\alpha n_\alpha+\text{c.c.})\equiv H_i+\overline{H}_i. \tag{37}$$

Then we obtain

$$\mathcal{E}_2=m^2\,\mathrm{tr}\,G=-m^2\sum_{i,b}([A_i,n_b],[A_i,n_b])=\frac{m^2}{N}\sum_i(A_i,A_i)=\frac{2m^2}{N}\sum_i(\overline{H}_i,H_i). \tag{38}$$

The second equality follows from (23); the third one is a consequence of (22) and (24). Making use of (32) we also get

$$\mathcal{E}_4=-\frac{g}{4}\sum_{a,i,j}(n_a,[A_i,A_j])^2 \tag{39}$$

$$=-\frac{g}{4}\sum_{\alpha,\beta>0}\sum_{i,j}(A_i^\alpha\overline{A}_j^\alpha-\text{c.c.})(\alpha,\beta)(A_i^\beta\overline{A}_j^\beta-\text{c.c.})$$

$$\leqslant-\frac{g}{4N}\sum_{i,j}[(H_i,\overline{H}_j)-\text{c.c.}]^2. \tag{40}$$

Note that the local Cartan component of $[A_i,A_j]$ can only come from the second commutation relation in (36). Hence the sum over a in (39) yields the factor $\Sigma_a(\alpha,h_a)(h_a,\beta)=(\alpha,\beta)=N^{-1}\cos\theta_{\alpha\beta}\leqslant N^{-1}$ for any two positive roots α and β with the angle $\theta_{\alpha\beta}$ between them. In a similar fashion we derive

$$\mathrm{tr}\,G^2=\sum_{a,b}\sum_{i,j}([A_i,n_a],[A_j,n_b])^2=\sum_{a,b}\sum_{i,j}(n_a,[[n_b,A_i],A_j])^2 \tag{41}$$

$$=\sum_{\alpha,\beta>0}\sum_{i,j}(A_i^\alpha\overline{A}_j^\alpha+\text{c.c.})(\alpha,\beta)^2(A_i^\beta\overline{A}_j^\beta+\text{c.c.})$$

$$\leqslant\frac{1}{N^2}\sum_{i,j}[(H_i,\overline{H}_j)+\text{c.c.}]^2. \tag{42}$$

Combining (42) and (40), we infer

$$4Ng^{-1}\mathcal{E}_4+N^2\,\mathrm{tr}\,G^2\leqslant 4\sum_{i,j}(H_i,\overline{H}_j)(H_j,\overline{H}_i)\leqslant 4\left(\sum_i(H_i,\overline{H}_i)\right)^2=4(\mathrm{tr}\,G)^2, \tag{43}$$

where the Schwartz inequality

$$|(H_i,\overline{H}_j)|^2 \leqslant (H_i,\overline{H}_i)(H_j,\overline{H}_j)$$

has been used. The inequality (34) immediately follows from (43), (38), and (35).

IV. THE LOW ENERGY BOUND

Let $\lambda_0=(16\pi^2 N)^{-1}$. Then Eq. (3) can be written as $Q=\lambda_0\Sigma_a\langle\vec{C}^a,\vec{B}^a\rangle$. Making use of (16) one gets (cf. the case $N=2$ in Ref. 10)

$$|Q| \leqslant \lambda_0 \sum_a \|\vec{C}^a\|_p \|\vec{B}^a\|_{p'} \tag{44}$$

$$\leqslant \lambda_0\lambda_1 \sum_a \|\mathrm{curl}\,\vec{C}^a\|_2 \|\vec{B}^a\|_{6/5} \tag{45}$$

$$= \lambda_0\lambda_1 \sum_a \|\vec{B}^a\|_2 \|\vec{B}^a\|_{6/5}$$

$$\leqslant \lambda_0\lambda_1 \sum_a \|\vec{B}^a\|_2 \|\vec{B}^a\|_2^{1/3} \|\vec{B}^a\|_1^{2/3}. \tag{46}$$

To get (45), Eq. (18) has been used, which dictated the choice $p=6$ in (44), and also $\partial_i C_i^a=0$; then the substitution $\vec{B}^a=\mathrm{curl}\,\vec{C}^a$ has been made; the last inequality (46) is a consequence of (17). The energy can be written as

$$E = m^2 \sum_a \|\vec{\partial}\, n_a\|_2^2 + \frac{g}{2}\sum_a \|\vec{B}^a\|_2^2 = \sum_a (E_{2a}+E_{4a}) = E_2+E_4. \tag{47}$$

Hence, continuing (46) we get

$$|Q| \leqslant \lambda_0\lambda_1 (2/g)^{2/3} \sum_a (E_{4a}^{4/3})^{1/2} (\|\vec{B}^a\|_1^{4/3})^{1/2} \tag{48}$$

$$\leqslant \lambda_0\lambda_1 (2/g)^{2/3} \left[\left(\sum_a E_{4a}\right)^{4/3}\right]^{1/2} \left[\left(\sum_b \|\vec{B}^b\|_1\right)^{4/3}\right]^{1/2} \tag{49}$$

$$= \lambda_0\lambda_1 (2/g)^{2/3} E_4^{2/3} \left[\sum_b \int dx \sqrt{\vec{B}_b\cdot\vec{B}_b}\right]^{2/3}$$

$$\leqslant \lambda_0\lambda_1 g^{-1} (2E_4)^{2/3} (N-1)^{1/3} \left[\int dx \sqrt{2\mathcal{E}_4}\right]^{2/3} \tag{50}$$

$$\leqslant \lambda_0\lambda_1 g^{-1} (2E_4E_2)^{2/3} [2(N-1)\kappa_N]^{1/3} \tag{51}$$

$$\leqslant \lambda_0\lambda_1 g^{-1} 2^{-2/3} [2(N-1)\kappa_N]^{1/3} E^{4/3} \tag{52}$$

$$= c_N^{-4/3} E^{4/3},$$

where the constant c_N is given in (8). To get (49), the Hölder inequality (13) for $p=q=1/2$ and then (11) for $\gamma=4/3$ have been applied; (50) follows from (12); the algebraic inequality (34) has been used to deduce (51); the final result (52), which is equivalent to (7), comes from the basic inequality $E_4E_2\leqslant E^2/4$.

If the Lagrangian (6) defines an effective theory of the SU(N) gauge fields in some approximation, then the coefficients m and g should depend on N, the Yang–Mills coupling constant and a mass scale that determines the energy range in which the approximation is valid.

The result (7) is trivially generalized to the case when the mass scales and coupling constants are different for each mode n_a, that is, m^2 and g are replaced by m_a^2 and g_a, respectively, and inserted into the corresponding sums over a in (6) (cf. Ref. 4). In this case, $m^2=\max_a\{m_a^2\}$ and $g=\max_a\{g_a\}$ in (8). Indeed, all the inequalities in Secs. III and IV still hold as a consequence of $m_a^2\leqslant m^2$ and $g_a\leqslant g$. Equality (38) becomes an inequality $m^2\,\mathrm{tr}\,G\leqslant\mathcal{E}_2$, which, however, does not affect our derivation of (34) from (43).

(Received 9 October 2001; accepted for publication 20 April 2002)

A number of conjectures have been given recently concerning the connection between the antiferromagnetic XXZ spin chain at $\Delta=-1/2$ and various symmetry classes of alternating sign matrices. Here we use the integrability of the XXZ chain to gain further insight into these developments. In doing so we obtain a number of new results using Baxter's Q function for the XXZ chain for periodic, twisted and open boundary conditions. These include expressions for the elementary symmetric functions evaluated at the ground state solution of the Bethe roots. In this approach Schur functions play a central role and enable us to derive determinant expressions which appear in certain natural double products over the Bethe roots. When evaluated these give rise to the numbers counting different symmetry classes of alternating sign matrices. © *2002 American Institute of Physics.*

I. INTRODUCTION

The XXZ Heisenberg spin chain is a central and much studied model in statistical mechanics. It is arguably the best known model solved by means of the Bethe wave function Ansatz.[1] The ground state wave function at the particular anisotropy value $\Delta=-1/2$ has recently been the source of some surprising observations. At this value Razumov and Stroganov[2] observed the appearance of the numbers $A(n)=1,2,7,42,429,\ldots$, which count the number of $n\times n$ alternating sign matrices.[3–5] Here the length of the chain L is odd ($L=2n+1$) with periodic boundary conditions imposed. Alternating sign matrices are matrices whose elements are either $-1,0$ or 1 such that the elements along each row and each column alternate in sign. Furthermore, the entries in each row and column add up to $+1$. The numbers $A(n)$ are well known to enumerative combinatorialists, having appeared in other distinct problems such as the enumeration of plane partitions and generalizations of determinants. The one-to-one correspondence between vertex configurations of the square lattice ice model with domain wall boundary conditions[6] and ASM's has been well documented.[4,5] In particular it led to Kuperberg's alternate proof[7,8] of the alternating sign matrix conjecture.[3,4]

The numbers $A(n)$ appear in the ground state wave function of the XXZ Heisenberg chain at $\Delta=-1/2$ in three ways:[2] (i) as the ratio of the largest and smallest components in the ground state wave function, (ii) in the sum of the components, and (iii) in the sum of the square of the components. These observations at $\Delta=-1/2$ have been extended in a number of directions. Two other known cases are: (i) twisted boundary conditions[9] with L even,[10,11] and (ii) open boundary conditions with appropriate surface fields (the quantum $U_q[sl(2)]$ invariant chain[9,12,13]).[10] For both cases the ground state wave function is complex. Nevertheless, the sums of the wave function components and of their squares are real. The numbers $A(n)$ also appear in the twisted case. However, the open case sees the appearance of other symmetry classes. Here appear $A_V(2n+1)$, the number of $(2n+1)\times(2n+1)$ vertically symmetric alternating sign matrices when L

$=2n$ and $N_8(2n)$, the number of cyclically symmetric transpose complement plane partitions, when $L=2n-1$. The number $N_8(2n)$ is conjectured to be $A_{\mathrm{VH}}(4n+1)/A_{\mathrm{V}}(2n+1)$, where $A_{\mathrm{VH}}(4n+1)$ is the number of $(4n+1)\times(4n+1)$ vertically and horizontally symmetric alternating sign matrices.[14] These various numbers also appear in the corresponding O(1) loop model, for which the ground state wave function is real.[10] Further developments include the combinatorial interpretation[15–17] of the elements of the O(1) loop model wave function and the relation to a one-dimensional Temperley–Lieb stochastic process.[17]

The numerous conjectures made to date for the various ground state wave functions at $\Delta=-1/2$ remain to be proved. In earlier work, Stroganov and co-workers[18–20] have found an expression for Baxter's Q function[21] in each of the above cases. By definition the zeros of the Q function are the Bethe roots. However, little if any use has been made of this function. Here we use the Q function results to obtain closed form expressions for the values of the elementary symmetric functions with the ground state Bethe roots as arguments. This approach also involves the appearance of the Schur function and determinants in a natural way. Ultimately we are led to conjectures for new determinants whose values are related to the alternating sign matrix numbers. These results came from observations on the product of certain combinations of Bethe roots. Although some results can be proved along the way, the evaluation of the determinants, involving the elementary symmetric functions, remains to be done exactly.

The layout of this paper is as follows. In Sec. II we collect some necessary results on the Bethe Ansatz and symmetric polynomials. In Sec. III we give our results for the periodic (L odd), twisted and reflecting boundary cases. Some detailed working is given in the Appendix. The paper concludes with some remarks in Sec. IV.

II. PRELIMINARIES

A. XXZ spin chain and Bethe's Ansatz

We consider the periodic anisotropic quantum XXZ spin chain. A spin variable lives on each site of the chain taking either up or down values. The interaction between two neigboring spins is described in terms of Pauli spin matrices by the well known Hamiltonian,

$$H=-\frac{1}{2}\sum_{j=1}^{L}(\sigma_j^x\sigma_{j+1}^x+\sigma_j^y\sigma_{j+1}^y+\Delta\sigma_j^z\sigma_{j+1}^z), \tag{1}$$

where the anisotropy Δ is parametrized by

$$\Delta=-\tfrac{1}{2}(q+q^{-1}). \tag{2}$$

We denote the position of the ith down spin along the chain by x_i. The Hamiltonian (1) is diagonalized via the Ansatz,[1]

$$\psi(x_1,\ldots,x_n)=\sum_{\pi}A^{\pi_1\cdots\pi_n}\prod_{j=1}^{n}z_{\pi_j}^{x_j} \tag{3}$$

for the form of its eigenvectors. The sum over $\pi=(\pi_1,\ldots,\pi_n)$ denotes a sum over all permutations of the numbers $1,\ldots,n$. Substituting (3) into the eigenvalue equation for H one finds the eigenvalues to be given by

$$E=-\tfrac{1}{2}L\Delta-\sum_{i=1}^{n}(z_i+z_i^{-1}-2\Delta). \tag{4}$$

The amplitudes $A^{\pi_1\cdots\pi_n}$ are also expressed in the variables z_i for which the consistency equations

$$z_i^L=(-)^{n-1}\prod_{j=1}^{n}\frac{1-2\Delta z_i+z_iz_j}{1-2\Delta z_j+z_iz_j} \tag{5}$$

are derived.

It will be convenient to make the change of variables

$$z=\frac{q-w}{qw-1},\quad w=\frac{z+q}{qz+1}, \tag{6}$$

for which the Bethe equations (5) take the form

$$\left(\frac{q-w_i}{qw_i-1}\right)^L+\prod_{j=1}^{n}\frac{w_i-q^2w_j}{q^2w_i-w_j}=0. \tag{7}$$

Up to a normalization, the amplitudes are given by

$$A^{\pi_1\cdots\pi_n}=q^{n(n-1)/2}\prod_{i<j}^{n}\frac{1-2\Delta z_{\pi_i}+z_{\pi_i}z_{\pi_j}}{z_{\pi_i}-z_{\pi_j}}=\prod_{i<j}^{n}\frac{w_{\pi_i}-q^2w_{\pi_j}}{w_{\pi_i}-w_{\pi_j}}. \tag{8}$$

Note that the eigenfunctions (3) are symmetric polynomials in the variables z_i. All properties of the XXZ spin chain can therefore be expressed in symmetric functions of these variables. We will review some of the basic properties of symmetric polynomials in the next section.

From (8) we see that the amplitudes can be written in terms of the generalized Vandermonde product,

$$\det_\lambda(w_i^{n-j})=\det_\lambda(w_j^{i-1})=\prod_{i<j}^{n}(w_i+\lambda w_j), \tag{9}$$

where we have introduced the λ-determinant[22] which can be defined recursively via Dodgson's algorithm for evaluating determinants.[4] If $X^{(1)}=(x_{ij}^{(1)})$ is an $n\times n$ matrix and $Y^{(1)}$ an $(n-1)\times(n-1)$ matrix with each element equal to 1, we define new matrices $X^{(k)}$ and $Y^{(k)}$ recursively by

$$x_{ij}^{(k)}=(x_{ij}^{(k-1)}x_{i+1,j+1}^{(k-1)}+\lambda x_{i+1,j}^{(k-1)}x_{i,j+1}^{(k-1)})/y_{ij}^{(k-1)},\quad i,j=1,\ldots,n-k+1, \tag{10}$$

$$y_{ij}^{(k)}=x_{i+1,j+1}^{(k-1)},\quad i,j=1,\ldots,n-k. \tag{11}$$

The number $X^{(n)}$ thus defined is called the λ-determinant of $X^{(1)}$. For the special value $\lambda=-1$ this procedure evaluates the ordinary determinant $\det X^{(1)}$. Just as the determinant can be written as a sum over the set of permutation matrices, the λ-determinant can be written as a sum over the set of alternating sign matrices,[22]

$$\det_\lambda M=\sum_{A\in\mathcal{A}_n}\lambda^{\mathcal{I}(A)}(1+\lambda^{-1})^{N(A)}\prod_{i,j=1}^{n}m_{ij}^{a_{ij}}, \tag{12}$$

where $\mathcal{A}_n$ is the set of $n\times n$ alternating sign matrices, $\mathcal{I}(A)$ is the inversion number of A and $N(A)$ the number of -1's in A (see e.g., Ref. 4 for the definiton of $\mathcal{I}$). The total number of terms in this sum, or equivalently the number of $n\times n$ alternating sign matrices is given by

$$A(n)=\prod_{j=0}^{n-1}\frac{(3j+1)!}{(n+j)!}=\prod_{i\leqslant j}^{n}\frac{n+i+j-1}{2i+j-1}. \tag{13}$$

We will see later that this and related numbers surprisingly show up in certain combinations of the variables z_i when evaluated at a particular solution of the Bethe equations (5) for $q=e^{i\pi/3}$.

B. Symmetric polynomials

This section is included for the convenience of the reader. The results collected herein can be found in standard textbooks such as Refs. 4 or 23.

A partition μ of k is a nonincreasing set of integers $\mu_1,\ldots,\mu_l$ such that $\mu_1+\cdots+\mu_l=k$. We denote this by $\mu\vdash k$. Partitions define the shape of a semistandard tableau, which is a two-dimensional array of integers with the restriction that these integers are nondecreasing across each row of length μ_j and strictly increasing down columns. An example of a semistandard tableau of shape $(4,4,3,1,1)$ is

$$\begin{array}{cccc} 1 & 1 & 2 & 3 \\ 2 & 3 & 4 & 4 \\ 4 & 4 & 5 & \\ 5 & & & \\ 6 & & & \end{array} .$$

A conjugate partition μ' or conjugate shape is the shape obtained by reflecting the semistandard tableau of shape μ in its main diagonal. For example, the conjugate partition of $(4,4,3,1,1)$ is $(5,3,3,2)$. The integers in the semistandard tableau may be interpreted as indices of variables, and thus to every semistandard tableau is associated a monomial in which the power of each variable is the number of times its index occurs in the tableau, e.g., for the example above the monomial is given by

$$w_1^2 w_2^2 w_3^2 w_4^4 w_5^2 w_6 .$$

Given a tableau T the corresponding monomial is denoted by $\mathbf{w}^T$. In this way one may associate with every tableau of shape μ a polynomial s_μ, called the Schur polynomial, by the definition

$$s_\mu(w_1,\ldots,w_n)=\sum_T \mathbf{w}^T, \tag{14}$$

where the sum is over all semistandard tableaux of shape μ with entries chosen from $\{1,\ldots,n\}$. If $\mu\vdash k$, s_μ is a polynomial of degree k. We will see later that the Schur function is a symmetric function.

The monomial symmetric function of degree k is defined by

$$m_\mu=\sum_\pi{}' \prod_{j=1}^{n} w_j^{\pi_j}, \tag{15}$$

where the sum is over all *distinct* permutations,

$$\pi=(\pi_1,\ldots,\pi_n) \text{ of the numbers } (\mu_1,\ldots,\mu_k,0,\ldots,0).$$

The elementary symmetric function of degree k in n variables is defined as the monomial symmetric function that corresponds to the partition with k 1's,

$$\begin{aligned} e_0&=1 \\ e_1&=w_1+\cdots+w_n, \\ e_2&=w_1w_2+w_1w_3+\cdots w_{n-1}w_n \\ &\vdots \\ e_k&=\sum_{1\leqslant i_1<i_2\cdots<i_k\leqslant n} w_{i_1}\cdots w_{i_k}. \end{aligned} \tag{16}$$

Given a partition μ, this definition is extended to

$$e_\mu = e_{(\mu_1,\ldots,\mu_l)} = e_{\mu_1}\cdots e_{\mu_l}. \tag{17}$$

Finally, the complete symmetric function h_k is defined to be the sum over all monomial symmetric functions of degree k, i.e.,

$$h_k = \sum_{\mu \vdash k} m_\mu . \tag{18}$$

In a similar way as above this is extended to

$$h_\mu = h_{(\mu_1,\ldots,\mu_l)} = h_{\mu_1}\cdots h_{\mu_l}. \tag{19}$$

The following facts are well known concerning the various functions defined above:

(i) The elementary and complete symmetric functions are dual to each other in the sense,

$$e_k = \det(h_{1-i+j})_{i,j=1}^k \tag{20}$$

$$h_k = \det(e_{1-i+j})_{i,j=1}^k, \tag{21}$$

where we put by convention $e_{-k}=h_{-k}=0$ for $k>0$. Their generating functions are given by

$$\sum_{i=0}^{\infty} e_i(w_1,\ldots,w_n)t^i = \prod_{j=1}^{n}(1+w_j t), \tag{22}$$

$$\sum_{i=0}^{\infty} h_i(w_1,\ldots,w_n)t^i = \prod_{j=1}^{n}\frac{1}{1-w_j t}. \tag{23}$$

(ii) The Jacobi–Trudi identity.
Let $\mu=(\mu_1,\ldots,\mu_n)$ be a partition into at most n part, then

$$s_\mu(w_1,\ldots,w_n) = \det(h_{\mu_i+j-i})_{i,j=1}^n. \tag{24}$$

(iii) The Nägelsbach–Kostka identity.
Let μ' be the partition conjugate to μ and k the number of parts in μ', then

$$s_\mu = \det(e_{\mu_i'-i+j})_{i,j=1}^k. \tag{25}$$

(iv) The Schur function is equal to a ratio of Vandermonde determinants,

$$s_{(\mu_1,\ldots,\mu_n)}(w_1,\ldots,w_n) = \frac{\det w_i^{n-j+\mu_j}}{\det w_i^{n-j}}. \tag{26}$$

Usually (26) is taken as the definition of the Schur function.

III. RESULTS FOR $q=e^{i\pi/3}$

We now turn to the XXZ spin chain in the following cases: (i) periodic boundaries and $L=2n+1$, (ii) twisted boundaries with twist angle $\pi/3$ and $L=2n$, and (iii) reflecting boundaries. In these cases the XXZ chain has a trivial ground state energy. It is to be understood that in this section we take $q=e^{i\pi/3}$.

A. Periodic boundaries

Consider the function $Q_n(w)$, of which the zeros are the solutions of the Bethe equations (7),

$$Q_n(w) = \prod_{i=1}^{n}(w-w_i) = \sum_{l=0}^{n}(-)^l w^{n-l} e_l , \tag{27}$$

where e_l are the elementary symmetric functions (16) with the variables w_i as arguments. Stroganov showed,[20] using Baxter's T–Q relation[21] that $Q_n(w)$ can be calculated analytically in the case where the w_i are the solution of (7) with $L=2n+1$ corresponding to the lowest value of the energy (4). The answer is given as a rational function in w. Using a binomial coefficient identity, the explicit polynomial form of $Q_n(w)$ is calculated in Appendix A. Comparing expression (A7) now with the formal expansion of $Q_n(w)$ in (27) one can read off the values of the elementary symmetric functions at these particular values of w_i. We find

$$e_l=\binom{n-1/3}{n}^{-1}\sum_{p=0}^{\lfloor l/3\rfloor}\left[\binom{2n-3p+l}{2n}\binom{n-1/3}{n-p}\binom{n+1/3}{p}\right.$$
$$\left.-\binom{2n-3p+l-1}{2n}\binom{n-1/3}{p}\binom{n+1/3}{n-p}\right]. \tag{28}$$

The series in (27) with the coefficients as in (28) in general does not appear to be summable, i.e., cannot be written as a simple product, but it can be verified without too much difficulty that it satisfies the recursion relation

$$(w+1)^2(3n+2)Q_{n+1}(w)=3(w^3-1)(2n+1)Q_n(w)$$
$$-(w^2-w+1)^2(3n+1)Q_{n-1}(w). \tag{29}$$

For special values of w, $Q_n(w)$ simplifies dramatically. The results

$$q^{2n}Q_n(q^{-1})=2^n\prod_{j=1}^{n}\frac{2j-1}{3j-1},\quad Q_n(0)=(-)^n, \tag{30}$$

can for example be calculated easily from (29) when $w=q^{-1}$ and $w=0$. From this we conclude that

$$\prod_{j=1}^{n}(1+z_j+z_j^2)=\left(\frac{3}{4}\right)^n\prod_{j=1}^{n}\left(\frac{3j-1}{2j-1}\right)^2. \tag{31}$$

As another example to derive closed form expressions for symmetric combinations of Bethe roots, we consider the product

$$\prod_{i\neq j}^{n}(1+z_i+z_iz_j)=\prod_{i\neq j}^{n}\frac{\mathrm{i}\sqrt{3}(q^2w_j-w_i)}{(qw_i-1)(qw_j-1)}$$
$$=\prod_{i=1}^{n}\left(\frac{\sqrt{3}q^{-1}}{(w_i-q^{-1})^2}\right)^{n-1}\prod_{i<j}\frac{w_i^3-w_j^3}{w_i-w_j}, \tag{32}$$

where in the last step we recognize the Schur function in the ratio of the two Vandermonde determinants [see Eq. (26)]. Thus we find, using (30),

$$\prod_{i\neq j}^{n}(1+z_i+z_iz_j)=\left(\prod_{j=1}^{n}\frac{\sqrt{3}}{4}\left(\frac{3j-1}{2j-1}\right)^2\right)^{n-1}$$
$$\times s_{(2(n-1),2(n-2),\ldots,2,0)}(w_1,\ldots,w_n). \tag{33}$$

This can be rewritten using the fact that a Schur function can be written as a determinant over the elementary symmetric functions (see (25)). We now have

$$s_{(2(n-1),2(n-2),\ldots,2,0)}(w_1,\ldots,w_n)=\det(e_{n-\lfloor(i+1)/2\rfloor-i+j})_{i,j}^{2(n-1)}, \tag{34}$$

with e_l given by (28). We thus have derived a closed form expression for the product (32). When evaluated explicitly for small values of n we find

$$\prod_{i\neq j}^{n}(1+z_i+z_iz_j)=A(n)^3, \tag{35}$$

where $A(n)$ is the number of $n\times n$ alternating-sign matrices (13). Although we have not been able to evaluate the determinant in (34) analytically, we conjecture that (35) is true for all values of n.

The smallest and largest component of the groundstate wave function are given by $\psi(1,2,\ldots,n)$ and $\psi(1,3,\ldots,2n-1)$ respectively. In Ref. 2 it was conjectured that their ratio is equal to $A(n)$. Using the definitions of Sec. II A, we find by numerical calculation for small n that the smallest and largest component are given by

$$\sum_{\pi}\prod_{i<j}^{n}\frac{1+z_{\pi_i}^{-1}+z_{\pi_j}}{z_{\pi_j}-z_{\pi_i}}=\sum_{\pi}\prod_{i<j}^{n}q^{-1}\frac{qw_{\pi_i}-1}{q-w_{\pi_i}}\frac{w_{\pi_i}-q^2w_{\pi_j}}{w_{\pi_j}-w_{\pi_i}}=A(n), \tag{36}$$

$$\sum_{\pi}\prod_{i<j}^{n}\frac{z_{\pi_i}^{-1}(1+z_{\pi_i}^{-1}+z_{\pi_j})}{z_{\pi_j}-z_{\pi_i}}=\sum_{\pi}\prod_{i<j}^{n}q^{-1}\left(\frac{qw_{\pi_i}-1}{q-w_{\pi_i}}\right)^2\frac{w_{\pi_i}-q^2w_{\pi_j}}{w_{\pi_j}-w_{\pi_i}}=A(n)^2. \tag{37}$$

We conjecture that these equations are true for abitrary values of n. We see that indeed the ratio of these two components is $A(n)$. In fact, using the natural, but otherwise arbitrary, normalization of the amplitudes (8), we find that the smallest component itself is normalized to $A(n)$. Since both functions above are (up to a common factor) symmetric polynomials, we hope that these conjectures can be proven by making use of (28).

B. Twisted boundaries

For twisted boundary conditions,

$$\sigma_{L+1}^{\pm}=(\sigma_{L+1}^{x}\pm i\sigma_{L+1}^{y})=e^{\pm 2i\phi}\sigma_1^{\pm}, \tag{38}$$

the eigenvectors and eigenvalues of H are still given by (3) and (4). The equations for z_i or w_i however are modified and for the special case $\phi=\pi/3$ become

$$\left(\frac{q-w_i}{qw_i-1}\right)^L+q^{-2}\prod_{j=1}^{n}\frac{w_i-q^2w_j}{q^2w_i-w_j}=0. \tag{39}$$

Also for this case $Q_n(w)$ can be calculated analytically when the solution of (39) with $L=2n$ corresponds to the ground state.[18] We find that the elementary symmetric functions now have the values

$$e_l=\binom{n-1/3}{n}^{-1}\sum_{p=0}^{\lfloor l/3\rfloor+1}\left[\binom{2n-3p+l-1}{2n-1}\binom{n-1/3}{n-p}\binom{n-2/3}{p}\right.$$
$$\left.-\binom{2n-3p+l+1}{2n-1}\binom{n-1/3}{p-1}\binom{n-2/3}{n-p}\right]. \tag{40}$$

In a similar way as was done above for the periodic boundaries we can use this expression to evaluate symmetric polynomials in the variables z_i. For example, we find that

$$\prod_{i\neq j}^{n}(1+z_i+z_iz_j)=\left(4\mathrm{e}^{-\mathrm{i}\pi/3}3^{n/2-1}\prod_{j=1}^{n}\left(\frac{3j-1}{n+j}\right)^2\right)^{n-1}\times\det(e_{n-\lfloor(i+1)/2\rfloor-i+j})_{i,j}^{2(n-1)}. \tag{41}$$

When evaluated for small values of n we see this is equal to

$$\prod_{i\neq j}^{n}(1+z_i+z_iz_j)=\mathrm{e}^{-(n-1)\mathrm{i}\pi/3}A(n)A_{\mathrm{HT}}(2n-1), \tag{42}$$

where

$$A_{\mathrm{HT}}(2n+1)=A(n)^2\prod_{k=1}^{n}\frac{3}{4}\left(\frac{3k-1}{2k-1}\right)^2 \tag{43}$$

is the number of $(2n+1)\times(2n+1)$ half-turn symmetric alternating sign matrices. We conjecture that (42) is true for arbitrary values of n.

C. Reflecting boundaries

For the open chain with diagonal, or spin conserving, boundaries, the Hamiltonian is given by

$$H=-\tfrac{1}{2}\sum_{j=1}^{L-1}(\sigma_j^x\sigma_{j+1}^x+\sigma_j^y\sigma_{j+1}^y+\Delta\sigma_j^z\sigma_{j+1}^z+\tfrac{1}{2}(q-q^{-1})(\sigma_j^z-\sigma_{j+1}^z)). \tag{44}$$

The eigenvectors are now

$$\psi(x_1,\ldots,x_n)=\sum_{\pi,\sigma}A_{\sigma_1\cdots\sigma_n}^{\pi_1\cdots\pi_n}\prod_{j=1}^{n}z_{\pi_j}^{\sigma_jx_j}, \tag{45}$$

where the sum runs over all permutations $\pi=(\pi_1,\ldots,\pi_n)$ of the numbers $1,\ldots,n$ and all signs $\sigma_i=\pm1$.[12,24] In this case the energy is given by

$$E=-\tfrac{1}{2}(L-1)\Delta-\sum_{i=1}^{n}(z_i+z_i^{-1}-2\Delta). \tag{46}$$

The Bethe equations become

$$\left(\frac{q-w_i}{qw_i-1}\right)^{2L}-\prod_{\substack{j=1\\j\neq i}}^{n}\left(\frac{q^2w_j-w_i}{w_j-q^2w_i}\right)\left(\frac{q^2-w_iw_j}{1-q^2w_iw_j}\right)=0, \tag{47}$$

where z and w are again related by (6). The amplitudes are up to a normalization given by

$$A_{\sigma_1\cdots\sigma_n}^{\pi_1\cdots\pi_n}=\prod_{i=1}^{n}z_{\pi_i}^{-\sigma_iL}\frac{1+qz_{\pi_i}^{-\sigma_i}}{z_{\pi_i}^{\sigma_i}-z_{\pi_i}^{-\sigma_i}}\prod_{i<l}\frac{(q^2w_{\pi_i}^{-\sigma_i}-w_{\pi_l}^{-\sigma_l})(q^2-w_{\pi_i}^{\sigma_i}w_{\pi_l}^{\sigma_l})}{(w_{\pi_i}-w_{\pi_l})(1-w_{\pi_i}^{-1}w_{\pi_l}^{-1})}. \tag{48}$$

In this case the function Q is defined by

$$Q_n(w)=\prod_{i=1}^{n}(\tilde{w}-\tilde{w}_i)=\sum_{i=0}^{n}(-)^i\tilde{w}^{n-i}e_i(\tilde{w}_1,\ldots,\tilde{w}_n),\quad \tilde{w}=w+w^{-1}. \tag{49}$$

Also for this case $Q_n(w)$ can be given analytically when the solution of (47) corresponds to the lowest value of the energy (46).[18] The explicit polynomial form of $Q_n(w)$ is given in the Appendix, from which the e_i can be read off.

In analogy with the periodic and twisted cases we consider the product

$$\begin{aligned}\prod_{i=1}^{2n}\prod_{\substack{j=1\\ z_j\neq z_i^{\pm 1}}}^{2n}(1+z_i+z_iz_j)&=\prod_{i=1}^{2n}\prod_{\substack{j=1\\ w_j\neq w_i^{\pm 1}}}^{2n}\frac{(q-q^{-1})(q^2w_j-w_i)}{(qw_i-1)(qw_j-1)}\\ &=\prod_{i=1}^{n}\left(\frac{q-q^{-1}}{\tilde{w}_i-q-q^{-1}}\right)^{4(n-1)}\prod_{i\neq j}^{n}\frac{w_i^3+w_i^{-3}-w_j^3-w_j^{-3}}{\tilde{w}_i-\tilde{w}_j}\\ &=\prod_{i=1}^{n}\left(\frac{q-q^{-1}}{\tilde{w}_i-q-q^{-1}}\right)^{4(n-1)}\left(\frac{\det(w_i^{3(n-j)}+w_i^{-3(n-j)})}{\det(w_i^{n-j}+w_i^{-n+j})}\right)^2.\end{aligned} \tag{50}$$

Here we use the convention $w_{i+n}=w_i^{-1}$. The ratio of determinants in (50) is up to a factor a symmetric polynomial in $\tilde{w}_1\cdots\tilde{w}_n$. Unfortunately we have not succeeded in expressing it in the known basis of elementary symmetric functions. Nevertheless, numerical evaluation of (50) leads us to conjecture that

$$\prod_{i=1}^{2n}\prod_{\substack{j=1\\ z_j\neq z_i^{\pm 1}}}^{2n}(1+z_i+z_iz_j)=A_{\mathrm{V}}(2n+1)^2N_8(2n)^4, \tag{51}$$

where $A_{\mathrm{V}}(2n+1)$ is the number of $(2n+1)\times(2n+1)$ vertically symmetric alternating sign matrices (Ref. 8, Theorem 2) given by

$$A_{\mathrm{V}}(2n+1)=\prod_{j=0}^{n-1}(3j+2)\frac{(2j+1)!(6j+3)!}{(4j+2)!(4j+3)!} \tag{52}$$

and $N_8(2n)$ is the number of cyclically symmetric transpose complement plane partitions[4,22] given by

$$N_8(2n)=\prod_{j=1}^{n-1}(3j+1)\frac{(2j)!(6j)!}{(4j)!(4j+1)!}. \tag{53}$$

IV. CONCLUDING REMARKS

We have made a first step towards proving the appearance of certain numbers related to alternating sign matrices in the ground state eigenvector of the XXZ spin chain. Many of the combinatorial results concerning alternating sign matrices have been obtained using the connection with the integrable six-vertex model.[7,8] The XXZ spin chain is closely related to the six-vertex model and the methods used in this paper provide a different application of integrability. The eigenvectors of the XXZ Hamiltonian are given in the form of Bethe's Ansatz as a result of the integrability of the spin chain for each of the different boundary conditions under consideration. In fact, the normalization of the amplitudes (8) ensures that all eigenvectors are symmetric polynomials in the Bethe roots. As is well known, a basis for the space of symmetric polynomials is given by the elementary symmetric functions. Using the results of Stroganov and his collaborators[18–20]

for Baxter's Q-function, we were able to derive explicitly the values that the elementary symmetric functions take at the ground state solution of the Bethe roots. See, e.g., Eqs. (28) and (40) for the periodic and twisted cases. Although in principle possible, we were not able to re-express the ground state in terms of the elementary symmetric functions. However, we could show that certain natural double products over the Bethe roots can be rewritten in this way. Using some results from the theory of symmetric functions we could then derive determinant expressions that when evaluated give rise to the numbers counting different symmetry classes of alternating sign matrices. Our key results (35), (42), and (51) thus remain as conjectures. It is yet to be seen if such products over Bethe roots have any direct combinatorial meaning.

APPENDIX: DETAILS

1. Periodic boundaries

Stroganov's result for $Q_n(w)$ in the case of periodic boundary conditions and odd system size is[20]

$$Q_n(w)=\prod_{i=1}^{n}(w-w_i)=\binom{n-1/3}{n}^{-1}\sum_{k=0}^{n}(-)^k\binom{n-1/3}{k}\times\binom{n+1/3}{n-k}w^{3k+1}\frac{(-1)^n+w^{3n-6k-1}}{(1+w)^{2n+1}}. \tag{A1}$$

We would like to rewrite this in the form

$$Q_n(w)=\sum_{i=0}^{n}(-)^i w^{n-i}e_i, \tag{A2}$$

where the e_i are the elementary symmetric functions with arguments $w_1,\ldots,w_n$. The right-hand side of (A1) can be expanded using

$$\sum_{m=0}^{\infty}(-)^m\binom{2n+m}{m}w^{-2n-m-1}=(1+w)^{-2n-1}. \tag{A3}$$

It follows that Q can be written as

$$Q_n(w)=\binom{n-1/3}{n}^{-1}\sum_{k=0}^{n}\sum_{m=0}^{\infty}(-)^{k+m}w^{n-3k-m}\left[\binom{2n+m}{m}\binom{n-1/3}{n-k}\binom{n+1/3}{k}-\binom{2n+m-1}{m-1}\binom{n-1/3}{k}\binom{n+1/3}{n-k}\right]. \tag{A4}$$

To show that (A4) reduces to a finite sum, we first collect terms of the form $m=3j$, $m=3j+1$ and $m=3j+2$. Then we use the following identity to rewrite (A4):

$$\sum_{k=0}^{n}\sum_{j=0}^{\infty}a_{k,j}=\sum_{l=0}^{n}\sum_{p=0}^{l}a_{l-p,p}+\sum_{l=n+1}^{\infty}\sum_{p=0}^{n}a_{p,l-p}. \tag{A5}$$

To proceed we need the result

$$\sum_{p=0}^{n}\binom{3p-n+s}{2n}\binom{n-1/3}{p}\binom{n+1/3}{n-p}=\sum_{p=0}^{n}\binom{3p-n+s-1}{2n}\binom{n-1/3}{n-p}\binom{n+1/3}{p}. \tag{A6}$$

This identity is proven by first showing that both the left and right hand sides satisfy the same recursion relation in n, i.e., both sums for $n=m+3$ can be expressed in the same sums for $n=m+2,m+1$ and $n=m$. One then shows explicitly that the identity holds for $n=0,1,2$. The recursion relation for (A6) can be easily derived using the Paule and Schorn Mathematica implementation of an algorithm of Zeilberger's.[25]

From (A6) it then follows that the infinite sum in (A5) vanishes and after recollecting terms again we can finally write

$$\begin{aligned}Q_n(w)=&\binom{n-1/3}{n}^{-1}\sum_{l=0}^{n}\sum_{p=0}^{\lfloor l/3\rfloor}(-)^l w^{n-l}\left[\binom{2n-3p+l}{2n}\binom{n-1/3}{n-p}\binom{n+1/3}{p}\right.\\&\left.-\binom{2n-3p+l-1}{2n}\binom{n-1/3}{p}\binom{n+1/3}{n-p}\right],\end{aligned} \tag{A7}$$

the desired result.

2. Twisted boundaries

In this case the result of Fridkin *et al.*[18] for $Q_n(w)$ is

$$\begin{aligned}Q_n(w)=&\binom{n-1/3}{n}^{-1}\frac{1}{(1+w)^{2n}}\sum_{k=0}^{n}(-)^k\binom{n-2/3}{n-k}\\&\times\left((-)^n\binom{n-1/3}{k}w^{3k}-\binom{n-1/3}{k-1}w^{3n-3k+2}\right).\end{aligned} \tag{A8}$$

In analogy with the periodic case we need to rewrite $Q_n(w)$ in powers of w. This can be done along the lines of the previous subsection with the help of the result

$$\sum_{p=0}^{n}\binom{3p-n+s}{2n}\binom{n-1/3}{p}\binom{n-2/3}{n-p}=\sum_{p=0}^{n}\binom{3p-n+s+2}{2n}\binom{n-1/3}{n-p-1}\binom{n-2/3}{p}. \tag{A9}$$

As in the case of (A6), this identity can be proven by showing that both the left and right-hand sides satisfy the same recursion relation in n. We then find

$$\begin{aligned}Q_n(w)=&\binom{n-1/3}{n}^{-1}\sum_{l=0}^{n}(-)^l w^{n-l}\\&\times\sum_{p=0}^{\lfloor l/3\rfloor+1}\left[\binom{2n-3p+l-1}{2n-1}\binom{n-1/3}{n-p}\binom{n-2/3}{p}-\binom{2n-3p+l+1}{2n-1}\binom{n-1/3}{p-1}\binom{n-2/3}{n-p}\right].\end{aligned} \tag{A10}$$

3. Reflecting boundaries

Following Fridkin *et al.*[18] one can prove that Q is given by

$$\binom{2n-2/3}{2n}^{-1}\sum_{k=-n}^{n}(-)^{n+k}\binom{2n+2/3}{n-k}\binom{2n-2/3}{n+k}\frac{w^{3k+1}-w^{-3k-1}}{(w-w^{-1})(2+w+w^{-1})^{2n}}. \tag{A11}$$

Using (A3) and

$$\sum_{p=0}^{\lfloor n/2\rfloor}(-)^p\binom{n-p}{p}(w+w^{-1})^{n-2p}=\frac{w^{n+1}-w^{-n-1}}{w-w^{-1}}, \tag{A12}$$

the expression for Q can be rewritten so that we can read off the values of the elementary symmetric functions with arguments $\tilde{w}_1,\ldots,\tilde{w}_n$, where $\tilde{w}=w+w^{-1}$. Namely,

$$\begin{aligned}Q_n(w)=2^{-3n}\binom{2n-2/3}{2n}^{-1}\sum_{p=0}^{n}(-2)^p\tilde{w}^{n-p}\Bigg[&\binom{3n-p-1}{n-p}\binom{2n+2/3}{n}\binom{2n-2/3}{n}\\&+\sum_{m=0}^{p}\sum_{k=1}^{n}(-)^{\lfloor(k+m+1)/2\rfloor}2^{m-1}(1+(-)^{k+m})\binom{3n-p-m-1}{2n-1}\\&\times\Bigg(\binom{2n+2/3}{n-k}\binom{2n-2/3}{n+k}\binom{\lfloor(3k+m+1)/2\rfloor}{m}\\&+\binom{2n+2/3}{n+k}\binom{2n-2/3}{n-k}\binom{\lfloor(3k+m-1)/2\rfloor}{m}\Bigg)\Bigg].\end{aligned} \tag{A13}$$

Chiral mixtures

Michel Petitjean[a)]
ITODYS (CNRS, ESA 7086), 1 rue Guy de la Brosse, 75005 Paris, France

(Received 22 November 2001; accepted for publication 11 April 2002)

An index evaluating the amount of chirality of a mixture of colored random variables is defined. Properties are established. Extreme chiral mixtures are characterized and examples are given. Connections between chirality, Wasserstein distances, and least squares Procrustes methods are pointed out. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1484559]

I. INTRODUCTION

Classifying a set as symmetric or not has been viewed as a dichotomic yes–no decision process for centuries. Attempts to evaluate the amount of symmetry has received little attention. Grünbaum (1963) noticed the difficulty to elaborate a rational approach of this problem. Physicists and chemists proposed various measures of the amount of chirality: see, for instance, Harris *et al.* (1999), Le Guennec (2000) or references cited by Petitjean (1997). Most methods handle only homogeneous solids, or only discrete sets. Many methods are limited to planar or spatial sets, and continuity properties are often ignored. E.g., for a homogeneous solid, the chiral index of Gilat (1989) is the normalized volume of the symmetric difference between the solid and its inverted image. The volume of the symmetric difference is the distance introduced by Dinghas (1957), this distance being itself the square of the $L2$-norm induced distance between the indicator functions of the solids. In this situation, continuity fails when the set becomes subdimensional. Clearly, functional distances applied to a set and its inverted image have no adequate continuity property because they are applied to densities rather than to distribution functions.

Thus, evaluating the degree of chirality of a random vector X in R^d is possible from some probability metric between the distribution of X and the distribution of its translated and rotated inverted image. The translation and the rotation are denoted respectively t and R. We consider now any two random vectors X and Y in R^d, and we look for a probability metric. For example, F being the distribution function of X, and G being the distribution function of Y, the quantity μ_K [Eq. (1.1)] is issued from the Kolmogorov metric:

$$\mu_K = \mathrm{Inf}_{\{R,t\}}(\mathrm{Sup}_{\{x\}}|F(x)-G(x)|). \tag{1.1}$$

But it was noticed previously (Petitjean, 1997, and 1999a), that some applications require us to consider colored mixtures, i.e., mixtures of colored random variables (see definition in the next section). An example is the algebraic charge density of a molecule or ion, which may be viewed as a mixture of two charge densities, namely the positive one and the negative one. As shown below, the quantity μ_K is not adequate for colored mixtures, because it is not sensitive to colors, and an extension of the Wasserstein distance will be preferred.

II. COLORED MIXTURES AND WASSERSTEIN DISTANCES

The assumption that Y is distributed as a translated and rotated inverted image of X is not used in this section.

A reason to work with the colored model is that, when evaluating the degree of chirality, Y has the distribution of a rotated inverted image of X, and therefore Y is a mixture such that each

a)Electronic mail: petitjean@itodys.jussieu.fr

component $\tilde{Y}$ retains the color of its associated component $\tilde{X}$ and is distributed as the rotated inverted image of $\tilde{X}$. In other words, the mirror (in fact, the inversion operator) sees the colors, e.g., the eight vertices of a cube constitute indeed a chiral figure in R^3 when they have all different colors. Another application needing a probability metric sensitive to colors is the optimal superposition problem (see Sec. II B), the quantitative chirality evaluation being just an instance of this problem.

A. Colored mixtures

When X is a mixture of colored random variables $\tilde{X}$, the more general formulation of its distribution is written in Eq. (2.1) with the mixing distribution P_1, and, similarly, the mixture Y of colored random variables $\tilde{Y}$ is written in Eq. (2.2) with the mixing distribution P_2:

$$F(x) = \int \tilde{F}(x,c) \cdot dP_1(c), \tag{2.1}$$

$$G(y) = \int \tilde{G}(y,c) \cdot dP_2(c). \tag{2.2}$$

When all the components of a mixture have the same color, it means that there is in fact only one colored component, and the colored mixture is an ordinary random vector in R^d. A colored mixture may be viewed as an ordinary mixture of random vectors, for which a supplementary axis has been added (the space of colors), this axis not being of numeric nature.

The joint distribution W of X and Y is expressed with the mixing distribution P operating on the mixed distributions $\tilde{W}$ [Eq. (2.3)]:

$$W(x,y) = \int \int \tilde{W}(x,y,c_1,c_2) \cdot d^2P(c_1,c_2). \tag{2.3}$$

In Eqs. (2.1)–(2.3), the summations are performed over the spaces of the colors. Now, we assume that the two colored mixtures X and Y are defined on the same space of colors. Moreover, the distribution of the colors is assumed to be the same for X and Y, i.e., the respective marginal distributions of X and Y on the space of colors are identical, and therefore can be fully correlated. This correlation is indeed assumed now: $P(c_1,c_2)$ is null when $c_1 \neq c_2$, i.e., $d^2P(c_1,c_2)$ is expressed with the Dirac delta function in Eq. (2.4), and integration over c_2 is performed in (2.3) to give the expression of W in Eq. (2.5), in which P_1 is renamed P and c_1 is renamed C:

$$d^2P(c_1,c_2) = dP_1(c_1) \cdot \delta_{[c_2=c_1]} dc_2, \tag{2.4}$$

$$W(x,y) = \int \tilde{W}(x,y,C) \cdot dP(C). \tag{2.5}$$

Clearly, the independence of the mixtures X and Y cannot be assumed now, except if X has only one colored component. This ''colored model'' is such that coupling the colors of a couple of mixtures X and Y induces constraints on the existence of their joint distributions W [Eq. (2.4)], and the set of joint distributions satisfying Eq. (2.5) is a nonempty subset of the set of the joint distributions of the same couple of mixtures discarding colors.

Equations (2.4) and (2.5) are assumed to stand further.

B. Colored Wasserstein distance and Procrustes methods

A probability metric depending on the joint density is sensitive to the constraints arising from colors [see Eq. (2.5)]. The well known Wasserstein metric (Dobrushin, 1970; Dudley, 1989;

Rachev, 1991) is so. The Wasserstein metric is itself an instance of the Kantorovich functional, which is encountered in the transportation problem (see equation 1.1.25 in Rachev and Rüschendorf, 1998).

The distributions associated respectively to X and Y are P^1 and P^2, and the matricial transposition operator is denoted by the quote. We name here colored Wasserstein distance $C(P^1,P^2)$ the extension of the $L2$ Wasserstein distance μ to colored mixtures, for which the lower bound of the expectation $E[(X-Y)'\cdot(X-Y)]$ is taken for all rotations R, translations t, and joint distributions W satisfying (2.5), i.e., such that each $\tilde{W}$ belongs to the class of all joint distributions of $\tilde{X}$ and $\tilde{Y}$:

$$D^2(W)=E[(X-Y)'\cdot(X-Y)], \tag{2.6}$$

$$\mu(P^1,P^2)=\mathrm{Inf}_{\{W\}}D(W), \tag{2.7}$$

$$C(P^1,P^2)=\mathrm{Inf}_{\{R,t\}}\mu(P^1,P^2). \tag{2.8}$$

In Eq. (2.6), it should be noticed that the expectation is defined through a $2d$-dimensional Lebesgue–Stiltjes integral, rather than a d-dimensional one. On the other hand, for any joint distribution W, computing $E(X'\cdot X)$ with the $2d$-dimensional integral leads to the same value that $E(X'\cdot X)$ computed with the d-dimensional one. The same remark is valid for $E(X)$, $E(Y)$, and $E(Y'\cdot Y)$.

Data analysis methods performing an optimal superposition of a set on another one via a least squares method were named Procrustes methods by Hurley and Cattell (1962), and the sum of the least squares is named the Procrustes distance. These methods are classified with the type of transformation allowed to superpose the moving set on the fixed set: general linear transformation, orthogonal transformation, or pure rotation. The 3D instance of this latter is usually encountered in physics, chemistry and bioinformatics: see references on the RMS algorithm cited in Petitjean (1998). The translation is optional, and it is always shown that the optimal translation is obtained when the mean points are superposed at the origin before further optimizations. The null expectation condition is not required in Procrustes methods.

Clearly, minimizing the $L2$ Wasserstein distance $\mu(P^1,P^2)$ [Eq. (2.7)], for some class of affine transformations of Y, generalizes the Procrustes method, because the usual one is its instance when X and Y are finite mixtures of n colored almost constant vectors, such that there is a one to one correspondence between the n vectors $\tilde{X}_i$ and $\tilde{Y}_i$. In this discrete situation, the unique feasible joint distribution is a bistochastic matrix equal to I/n, I being the identity matrix (colors are supposed to be enumerated in the same order for X and Y), and the Procrustes distance $\mathrm{Min}(D^2)$ is just the minimized sum of the squared distances between the n pairs of vectors. The Procrustes distance is the minimum of the distance induced by the norm itself induced by the scalar product $Tr(Z_X'\cdot Z_Y)$, where Z_X and Z_Y are two (n,d) rectangular matrices. The optimal rotation is analytically known when $d=2$ (see Section 3 in Petitjean, 1997), and when $d=3$ (see appendix in Petitjean, 1999b). The optimal orthogonal transformation is analytically known for any d (Golub and van Loan 1985).

For the noncolored model, i.e., when the n colors are identical, we get the Procrustes method without prefixed correspondence, for which the minimization of D^2 involves the enumeration of at most $n!$ possible correspondences between the two sets. Looking at the probabilistic formulation, the optimal joint distribution exists and is a bistochastic matrix equal to $1/n$ times a permutation matrix, because it is an extreme point of the convex polytope of the feasible solutions of the associated linear programming problem.

To summarize, the Procrustes distance becomes an instance of the $L2$ Wasserstein distance when this latter is extended to colored mixtures and minimized for a class of affine transformations of Y. Using the colored Wasserstein distance C [Eq. (2.8)] assumes that we work in the space of finite inertia colored mixtures, but the finite inertia condition could be relaxed if other adequate Wasserstein distances (see Rachev, 1991) are extended to colored mixtures. For clarity,

we restrict the affine transformations to rotations. In this situation, C is in fact a metric for classes of equivalence of colored mixtures, the colored mixtures being in the same class when their distributions are rotated (and optionally translated) images of one of them. It is pointed out that the colored Wasserstein distance is not defined when the mixtures have different marginal distributions in the space of colors. In this situation, an attempt to work with the ''maximal common substructure'' concept rather than with distances has been done for finite discrete sets (Petitjean, 1998). Of course, when the mixture Y is distributed as $\phi(X)$, ϕ being any transform leaving unchanged the marginal of X in the space of colors, C is indeed defined.

Some immediate properties of $C(P^1,P^2)$ follow.

Let m_{X_i} and m_{Y_i} be the respective expectations of X and Y attached to the i axis, $i \in [1,...,d]$, and σ_{X_i} and σ_{Y_i} be their respective standard deviations. The covariance attached to the i axis is c_i, and the respective inertia are T_X and T_Y. Equation (2.6) is now expandable as

$$D^2 = \sum_i \left[(\sigma_{X_i}^2 + m_{X_i}^2) + (\sigma_{Y_i}^2 + m_{Y_i}^2) - 2(c_i + m_{X_i} m_{Y_i})\right].$$

And, after rearrangement,

$$D^2 = T_X + T_Y + \sum_i \left[(m_{X_i} - m_{Y_i})^2 - 2c_i\right]. \tag{2.9}$$

The inertias and the covariances do not depend on the expectations. Thus the optimal translation t is such that $E(X) = E(Y)$, and the expression of D^2 becomes

$$D^2 = T_X + T_Y - 2\sum c_i. \tag{2.10}$$

Although the optimal joint distribution is not ensured to exist (Rachev and Rüschendorf, 1998), the optimal rotation is shown to exist, but may be not unique (Appendix A). The optimal general transformation and the optimal orthogonal transformation are known (Appendix A).

III. PROPERTIES OF THE CHIRAL INDEX

Let X and Y be colored mixtures in R^d, Y having the distribution of a translated and rotated inverted image of X. W is the joint distribution of the couple X, Y and T is the inertia of X or Y, i.e., $T = E[(X - E(X))' \cdot (X - E(X))]$ and $T = E[(Y - E(Y))' \cdot (Y - E(Y))]$. We define the chiral index χ as follows:

$$\chi = \frac{d}{4T} C^2(P^1,P^2). \tag{3.1}$$

In Eq. (3.1), P^2 being function of P^1, χ depends only on the law of X. In other words, χ is the normalized squared colored Wasserstein distance between the mixtures X and Y, Y being distributed as a translated and rotated inverted image of X. The chiral index is restricted to finite non-null inertia distributions. The situation $T = 0$ arises when X is almost surely equal to some constant x_0, and offers little interest. We neglect it. The chiral index is insensitive to isometries and is size free. As noticed in the preceding section, the optimal translation is obtained when $E(X) = E(Y)$, meaning that X and Y should be centered.

For clarity, we assume without loss of generality that the condition $E(X) = E(Y) = 0$ is satisfied in all this section.

The correlation coefficient attached to the i axis is r_i. Assuming the existence of the correlation coefficients, we get from Eqs. (2.10), (3.1) and (2.8):

$$D^2 = 2T - 2\sum c_i, \tag{3.2}$$

$$\chi = \frac{d}{2}\left(1 - \frac{\mathrm{Sup}_{\{R,W\}}(\Sigma c_i)}{T}\right). \tag{3.3}$$

When $d=1$, $R=1$, Y is distributed as $-X$, and there is only one standard deviation σ, and one correlation coefficient r. Equations (3.2) and (3.3) become

$$D^2 = 2\sigma^2(1-r), \tag{3.4}$$

$$\chi = \frac{1 - \mathrm{Sup}_{\{W\}}(r)}{2}. \tag{3.5}$$

In Eq. (3.5) the chiral index depends on one parameter only. For the noncolored model, this parameter is the maximal correlation of Gebelein (1952), applied to X and $-X$.

Now we return back to the d-dimensional space, and we look for a joint distribution ensured to exist. As noticed in the previous section, the independence of the mixtures X and Y cannot be assumed, except if X has only one colored component. The chiral index is proportional to the colored Wasserstein distance between the colored mixtures X and Y, Y being distributed as a rotated inverted image X (which does not mean that Y is a rotated inverted image of X). When Y is indeed the image of X through rotation R and inversion Q, the joint distribution of (X,Y) expressed from the mixed joint distributions $\tilde{W}(x,y,C)$ in Eq. (3.6) is ensured to exist:

$$d^2\tilde{W}(x,y,C) = d\tilde{F}(x,C)\cdot h_{[y=R\cdot Q\cdot x]}dy. \tag{3.6}$$

In Eq. (3.6), $h_{[y=y_0]}$ denotes the product of the d Dirac delta functions associated to the point y_0. Expression (3.6) is reported in (2.5) for integration over C, and, using Eq. (2.1), the final expression of the joint distribution is, as for a noncolored model:

$$d^2W(x,y) = dF(x)\cdot h_{[y=R\cdot Q\cdot x]}dy. \tag{3.7}$$

Equation (2.6) is expanded for this particular joint distribution to get Eq. (3.8), in which the expectation is calculated through a d-dimensional integral:

$$D^2 = 2T - 2E(X'\cdot R\cdot Q\cdot X). \tag{3.8}$$

The chiral index being insensitive to isometries, we assume now that the covariance matrix of X is diagonal, and that Y is the image of X through the inversion of the coordinate associated to the smallest variance axis. We take $R=I$. The inertia being the sum of the variances, Eq. (3.8) becomes

$$D^2 = 4\sigma_d^2. \tag{3.9}$$

The ratio of the smallest variance to the inertia is upper bounded by $1/d$, thus χ is upper bounded by 1. This bound is the best possible because it is reached for some particular random variables, as shown in Sec. V (see also the colored Bernoulli distribution in Appendix B):

$$0 \leqslant \chi \leqslant 1. \tag{3.10}$$

We consider now the finite discrete situation. The joint distribution is expressed with the square bistochastic matrix of the probabilities W_{ij} of each couple of values $\{x_i, y_j\}$. Using Eq. (2.6), the chiral index is rewritten

$$D^2=\sum_i \sum_j W_{ij}\cdot(x_i-y_j)'\cdot(x_i-y_j), \tag{3.11}$$

$$\chi=\frac{d}{4T}\mathrm{Inf}_{\{W_{ij},R,t\}}D^2. \tag{3.12}$$

Equations (3.11) and (3.12) were proposed previously to evaluate the amount of chirality of a fnite d-dimensional set, and thus our present approach generalizes the previous one [see Eqs. (3) and (4) in Petitjean (2001)]. It was also shown that, for the mass-uniform discrete case, the bistochastic matrix associated to the joint distribution is a permutation matrix. This particular situation means that there is a one-to-one mapping between the points of the set and those of its inverted image. In general, this mapping is not symmetric.

IV. CONVERGENCE

Obtaining the convergence of the chiral index from the convergence of the random variables is desirable to ensure some kind of continuity property of the chiral index. The weakest usual type of convergence possible for random variables is the convergence in law (in distribution), e.g., convergence of densities is a stronger assumption because this latter implies convergence in law [see Scheffé's theorem in Billingsley (1995)].

We consider the noncolored model. Let X_n be a sequence of random vectors converging to X in law. We assume also the convergence of $E[X_n'\cdot X_n]$ to $E[X'\cdot X]$, this latter quantity being finite. Apart from when X is almost surely constant, the convergence properties of the chiral index will arise from the convergence of $\mathrm{Inf}_{\{R\}}(\mu^2(P_n^1,P_n^2))=\mathrm{Inf}_{\{W_n,R\}}(D_n^2)$ to $\mathrm{Inf}_{\{R\}}(\mu^2(P^1,P^2))=\mathrm{Inf}_{\{W,R\}}(D^2)$, where μ denotes the Wasserstein distance [see Eq. (2.7)]. We use the triangle inequality to write

$$\begin{aligned}
&\mu(P^1,P^2)\leqslant\mu(P^1,P_n^1)+\mu(P_n^1,P_n^2)+\mu(P_n^2,P^2),\\
&\mu(P_n^1,P_n^2)\leqslant\mu(P_n^1,P^1)+\mu(P^1,P^2)+\mu(P^2,P_n^2),\\
&|\mu(P_n^1,P_n^2)-\mu(P^1,P^2)|\leqslant\mu(P_n^1,P^1)+\mu(P_n^2,P^2).
\end{aligned} \tag{4.1}$$

The inversion matrix Q being constant, inequation (4.1) stands for any rotation R common to Y_n and Y. For clarity, we name ϵ_n the second member of inequation (4.1). Obviously, ϵ_n does not depend on R. We note respectively $\mu_n(R)=\mu(P_n^1,P_n^2)$ and $\mu_\infty(R)=\mu(P^1,P^2)$. Inequation (4.1) is rewritten

$$|\mu_n(R)-\mu_\infty(R)|\leqslant\epsilon_n. \tag{4.2}$$

Let R_n and R_∞ be optimal rotations (which are shown to exist in Appendix A), respectively associated to D_n^2 and D^2. Inequation (4.2) stands for any R, and then stands for R_n and R_∞:

$$|-\mu_n(R_n)+\mu_\infty(R_n)|\leqslant\epsilon_n, \tag{4.3}$$

$$|\mu_n(R_\infty)-\mu_\infty(R_\infty)|\leqslant\epsilon_n. \tag{4.4}$$

We deduce from addition of (4.3) and (4.4)

$$|[\mu_n(R_\infty)-\mu_n(R_n)]+[\mu_\infty(R_n)-\mu_\infty(R_\infty)]|\leqslant 2\epsilon_n. \tag{4.5}$$

We know from optimality of rotations that each of the two quantities in brackets is nonnegative. Thus both quantities are upper bounded by $2\epsilon_n$:

$$|\mu_n(R_\infty)-\mu_n(R_n)|\leqslant 2\epsilon_n, \tag{4.6}$$

$$|\mu_\infty(R_n)-\mu_\infty(R_\infty)|\leqslant 2\epsilon_n. \tag{4.7}$$

Then, adding (4.3) and (4.7),

$$|\mu_n(R_n)-\mu_\infty(R_\infty)|=|\mu_n(R_n)-\mu_\infty(R_n)+\mu_\infty(R_n)-\mu_\infty(R_\infty)|\leqslant 3\epsilon_n .$$

This inequation is rewritten in terms of Wasserstein distances:

$$|C(P_n^1,P_n^2)-C(P^1,P^2)|\leqslant 3\epsilon_n . \tag{4.8}$$

It was assumed that X_n is converging to X in distribution, and that there was convergence of $E[X_n'\cdot X_n]$ to $E[X'\cdot X]$, with $E[X'\cdot X]<\infty$. These convergences are preserved through affine transformations. Thus, the distribution of Y_n is also converging to that of Y, discarding or not the common rotation used in inequation (4.2), and $E[Y_n'\cdot Y_n]$ is converging to $E[Y'\cdot Y]$ We know from theorem 6.2.1 in Rachev (1991) that the $L2$ Wasserstein distances $\mu(P_n^1,P^1)$ and $\mu(P_n^2,P^2)$ are tending to zero. Then, $\epsilon_n\to 0$, and we get from (4.8) the convergence of $C(P_n^1,P_n^2)$ to $C(P^1,P^2)$.

Looking to the definition of the chiral index in Eq. (3.1) shows that we need also to establish the convergence of the inertia, i.e., the centered two-order moment. The convergence of the two-order moment was assumed, thus it suffices to get the convergence of $E[X_n]$ to $E[X]$. Let A be any almost surely constant random vector, and P^A its distribution. We have from the triangle inequality:

$$|\mu(P_n^1,P^A)-\mu(P^1,P^A)|\leqslant\mu(P_n^1,P^1)$$

and therefore

$$|E[X_n'\cdot X_n]-E[X'\cdot X]-2E[A]'\cdot(E[X_n]-E[X])|\to 0 .$$

Setting the constant successively equal to each of the d canonical base vectors lead to get the desired convergence for each of the d components of the first order moment.

The convergence theorem follows now for the chiral index:

Theorem: *If the sequence* (P_n) *of probability distributions converges to* P *and* $E[X_n'\cdot X_n]\to E[X'\cdot X]<\infty$, *and* $E[(X-E[X])'\cdot(X-E[X])]>0$, *then* $\chi(P_n)\to\chi(P)$.

V. EXTREME CHIRALITY RANDOM VARIABLES

The chiral index maps X onto the interval $[0;1]$. Assuming $E(X)=E(Y)=0$, we look first to the minimum of the chiral index. Let us define a mixture X as achiral when it has the distribution of one of its rotated and inverted images. In this situation, X and Y can be identically distributed, and thus they can be fully correlated, i.e., $E(X'\cdot Y)=E(X'\cdot X)=E(Y'\cdot Y)$, and $\chi=0$. Conversely, when $\chi=0$, X is almost surely equal to Y, Y having the distribution of a rotated inverted image of X, meaning that X is achiral.

Now we look to the maximum of the chiral index. We assume that X has a diagonal covariance matrix, and that Y is the image of X through inversion of the coordinate associated to the smallest variance axis. We reuse the joint distribution in Eqs. (3.7) and (3.8), and $R=I$ is set, such that Eq. (3.9) stands. The ratio of the smallest variance to the inertia being upper bounded by $1/d$; χ cannot be equal to 1 unless all the d variances are equal. Therefore, the covariance matrix of X is proportional to the identity matrix. This covariance matrix is insensitive to isometries, and any rotation R is optimal for the joint distribution. Equation (5.1) expresses thus a necessary condition to get $\chi=1$:

$$E(X\cdot X')=\sigma^2\cdot I. \tag{5.1}$$

The d-dimensional finite mixture of n almost surely constant equiprobable colored variables is such that the joint distribution in Eqs. (3.7) and (3.8) is the only one feasible when all colors are different. It has been shown (Petitjean, 1999b) that the lower bound of D^2 in Eq. (3.8) is indeed that of Eq. (3.9), and the chiral index of the mixture is d times the percentage of inertia associated to the smallest eigenvalue of the covariance matrix of X:

$$\chi = d \cdot \sigma_d^2 \Big/ \sum_i \sigma_i^2. \tag{5.2}$$

Thus, $\chi = 0$ when the set of the n equiprobable points is subdimensional, and $\chi = 1$ when Eq. (5.1) is satisfied. Well-known figures satisfy Eq. (5.1), including regular planar polygons, cube and hypercubes, octahedron and higher dimensional analogs. Regular simplices fall also in this category. It should be pointed out that when the n colors are identical, these mixtures have a null chiral index because there is a symmetry $(d-1)$-hyperplane.

Some maximal chirality random variables can be exhibited for the noncolored model. The joint distribution of the convolution product always exists, and from Eq. (3.3), it comes that the chiral index is upper bounded by $d/2$. When $d = 1$, this bound is optimal, because it cannot be lowered for the Bernoulli distribution (see Appendix B). When $d \geqslant 2$, finding the upper bound for the noncolored model is an open problem. The distribution of three equiprobable points in the plane maximizing χ has been exhibited (Petitjean, 1997).

VI. DISCUSSION AND CONCLUSION

In the definition of χ, the division by the inertia T was needed to get a size free chiral index. Thus the degenerate random variable X with a null inertia has no chiral index, because both D^2 and T are null. Viewing this degenerate situation via the limit of a family of parametrized random variables makes no sense, in general, because the result depends on how the parameters are used to get a null inertia, and because no convergence exists around the singularity $T = 0$.

Conditions under which the convergence theorem (Sec. IV) could be extended to any colored mixture are to be investigated. A consequence of this convergence theorem is that the chiral index associated to the sample converges to that of the random variable. This could be used to get Monte Carlo approximations of χ when the analytical solution is unreachable, but building consistent estimators is outside the scope of this article. Computing the chiral index of a sample is equivalent to compute it in the finite discrete mass-uniform distribution. For the latter, the unidimensional case is solved analytically, and suitable numerical techniques have been built when $d = 2$ and $d = 3$ (Petitjean, 1997, 1999a, b). Computing χ for a general finite discrete distribution is a non linearly constrained optimization problem [see Eqs. (3.11) and (3.12)]. Constraints arising from the joint distribution are linear equalities and inequalities, because the matrix associated to the joint distribution is bistochastic. Constraints arising from the rotation are quadratic, i.e., $R' \cdot R = I$, and there is the polynomial constraint on the determinant of R.

For the noncolored model, when the rotation is fixed, our optimization problem is an instance of the transportation problem, which is a linear programming one. For the latter, solving algorithms and existence conditions of optimal joint distributions have been recently reviewed in Rachev and Rüschendorf (1998) (see also Anderson and Nash, 1987), and numerous results are available in the monodimensional case.

Compared to the noncolored model, the colored model introduces additional constraints on W. These constraints are handled by the $L2$ Wasserstein metric. Extending our present approach to other color sensitive probability metrics potentially gives rise to a family of similarity measures between colored mixtures, which seems not yet to be investigated, and from which the associated family of chiral indices could be derived.

It should be noticed that monodimensional distributions, such as the Gaussian, are confusingly called symmetric in most books. They are in fact achiral. Evaluating the amount of chirality is a different concept from evaluating the amount of direct symmetry. How to extend the present approach to direct symmetry is an open problem.

ACKNOWLEDGMENTS

The author is very grateful to the reviewer, who has done a careful reading and has suggested pertinent corrections, particularly about notations and about the formulation of the convergence theorem.

APPENDIX A: OPTIMAL PROCRUSTES TRANSFORMATIONS

The results in this appendix are valid for colored mixtures, and therefore stand for random vectors. We consider the colored Wasserstein distance $C(P^1,P^2)$ [Eqs. (2.6)–(2.8)], and we look for the lower bound of D^2 when the mixture Y is submitted to a linear transformation A and a translation t:

$$D^2=E[(X-(A\cdot Y+t))'\cdot(X-(A\cdot Y+t))], \tag{A1}$$

$$C^2=\mathrm{Inf}_{\{A,W,t\}}D^2. \tag{A2}$$

The gradient in t is null when $t=E(X)-A\cdot E(Y)$. It means that both mixtures should be centered before looking to the optimal value of A. The optional translation is further ignored, such that all results listed in this appendix remain valid, whether or not X and Y are centered prior any optimization. Now we look to the lower bound of D^2 for A. We have a quadratic expression of A, except if A is orthogonal:

$$D^2=E[(X-A\cdot Y)'\cdot(X-A\cdot Y)], \tag{A3}$$

$$C^2=\mathrm{Inf}_{\{A,W\}}D^2. \tag{A4}$$

1. The optimal general linear transformation

Derivating in (A3), we get:

$$E[2\cdot A\cdot Y\cdot Y'-2\cdot X\cdot Y']=0, \tag{A5}$$

$$A=E[X\cdot Y']\cdot(E[Y\cdot Y'])^{-1}. \tag{A6}$$

When the noncentered covariance matrix of Y is not inversible, we can try to solve by interchanging X and Y. If both noncentered covariance matrices are singular, the problem is in fact subdimensional.

2. The optimal orthogonal transformation

The solution given by Golub and van Loan (1985) is restricted to finite sets of equiprobable points (in a nonprobabilistic context). It is extended here to colored mixtures. For clarity, we set $A=Q$. Equation (A7) shows that D^2 is an affine expression of Q:

$$D^2=E[X'\cdot X+Y'\cdot Y-2\cdot X'\cdot Q\cdot Y]. \tag{A7}$$

Now we look for the upper bound of:

$$E[X'\cdot Q\cdot Y]=Tr(E[Y\cdot X']\cdot Q). \tag{A8}$$

Let us write in Eq. (A9) the singular value decomposition of the square matrix $E[Y\cdot X']$, i.e., S being the diagonal matrix containing the singular values, U being the orthonormal matrix of eigenvalues of $E[X\cdot Y']\cdot E[Y\cdot X']$, and V being the associated orthonormal matrix of eigenvalues of $E[Y\cdot X']\cdot E[X\cdot Y']$, we have

$$E[Y\cdot X']=V\cdot S\cdot U'. \tag{A9}$$

We look for the upper bound of $Tr(V\cdot S\cdot U'\cdot Q)=Tr(U'\cdot Q\cdot V\cdot S)$. The coefficients of the diagonal matrix S are non-negative, thus the trace is maximized when the coefficients of the orthogonal matrix $U'\cdot Q\cdot V$ are all equal to 1, meaning that $U'\cdot Q\cdot V=I$. The optimal matrix Q is

$$Q=U\cdot V'. \tag{A10}$$

When S is nonsingular, the determinant of Q is obtained from (A9) and (A10):

$$\det(Q) = \mathrm{sign}(\det(E[Y \cdot X'])). \tag{A11}$$

The sense of the eigenvectors of U and V are not independant, because the non-normalized matrix of eigenvalues of $E[Y \cdot X'] \cdot E[X \cdot Y']$ (which becomes V after normalization) is equal to $E[Y \cdot X'] \cdot U$. Thus, changing the sense of any eigenvector of U is still possible, but does not affect Q.

The optimal Q is unique, except when S has at least one null diagonal element.

3. The optimal *d*-dimensional rotation

As for the general orthogonal transformation [see Eqs. (A7) and (A8) in which we set $Q = R$ for clarity], we look to the upper bound of $Tr(E[Y \cdot X'] \cdot R)$, which is a linear expression of the unknown rotation. The set of rotations is closed and bounded in R^{d^2}. Our constrained maximization problem of a linear form in R^{d^2} has indeed a solution, but it may be not unique. The general expression of the solution is unknown, except in some particular situations. When $\det(E[Y \cdot X']) > 0$, the optimal rotation is given in Eq. (A10).

4. The optimal planar rotation

The planar rotation matrix is parametrized with the angle r:

$$R = I \cdot \cos(r) + \Pi \cdot \sin(r), \tag{A12}$$

where I is the identity matrix, and Π the antisymmetric matrix associated to the rotation of angle $\pi/2$. Reporting (A12) in (A3) and derivating for r gives the minimum and the maximum of D^2. The minimum is

$$\cos(r) = E[X' \cdot Y]/\mathbf{E}, \tag{A13}$$

$$\sin(r) = E[X' \cdot \Pi \cdot Y]/\mathbf{E}, \tag{A14}$$

$$\mathbf{E} = [(E[X' \cdot Y])^2 + (E[X' \cdot \Pi \cdot Y])^2]^{1/2}, \tag{A15}$$

$$D^2 = E[X' \cdot X] + E[Y' \cdot Y] - 2 \cdot \mathbf{E}. \tag{A16}$$

5. The optimal spatial rotation

The spatial rotation R is parametrized with the unit quaternion q. Its first component is the cosinus of the half rotation angle, and its other three components are the rotation axis, with length equal to the sinus of the half rotation angle. The quaternions q and $-q$ are associated to the same rotation. The optimal quaternion maximizes the quadratic form $q' \cdot B \cdot q$ in Eq. (A17) and the proof is essentially that established in the appendix of Petitjean (1999b) for finite sets of equiprobable points (in a nonprobabilistic context). It is extended here to colored mixtures. The optimal quaternion is the unit eigenvector associated to the highest eigenvalue of the symmetric matrix B:

$$D^2 = D_0^2 - 2 \cdot q' \cdot B \cdot q, \tag{A17}$$

$$D_0^2 = E[(X - Y)' \cdot (X - Y)], \tag{A18}$$

$$B = \begin{pmatrix} 0 & c' \\ c & (Z + Z' - I \cdot Tr(Z + Z')) \end{pmatrix}, \tag{A19}$$

$$Z = E[Y \cdot X'], \tag{A20}$$

$$c = E[Y \wedge X]. \tag{A21}$$

Note that the elements of c are computable from those of Z.

APPENDIX B: THE BERNOULLI DISTRIBUTION

The Bernouilli distribution is translated here to get a null expectation, i.e., the value $1-m$ has probability $P(1-m)=m$ and the value $-m$ has probabilty $P(-m)=1-m$. The rotation $R=1$, and the joint distributions between X and Y distributed as $-X$, are conveniently parametrized by only one parameter $p=P(X=-m\cap Y=m-1)$. Therefore, $P(X=1-m\cap Y=m-1)=m-p$, $P(X=-m\cap Y=m)=1-m-p$, and $P(X=1-m\cap Y=m)=p$. The covariance is $c=p-m(1-m)$, and the maximal correlation coefficient is reached for $p=m$ when $m\in[0;\frac{1}{2}]$, and for $p=1-m$ when $m\in[\frac{1}{2};1]$, i.e., $r=m/(1-m)$ and $r=(1-m)/m$, respectively. According to Eq. (2.1), $\chi=1-(\frac{1}{2})/(1-m)$ when $m\in]0;\frac{1}{2}]$, and $\chi=1-(1/2)/m$ when $m\in[\frac{1}{2};1[$. The chiral index is null when $m=\frac{1}{2}$, and is tending to $\frac{1}{2}$ when m is tending to 0 or to 1. The line $m=\frac{1}{2}$ is a symmetry axis for the graph of the function $\chi(m)$.

The colored Bernoulli distribution is, as for the noncolored one, a mixture of two random variables almost surely constant, with mixing proportions m and $1-m$. As previously, the mixture is translated to get a null expectation. However, the two components of the mixture are colored, and thus $P(X=-m\cap Y=m-1)=0$ and $P(X=1-m\cap Y=m)=0$. Setting now $p=P(X=-m\cap Y=m)$, the covariance is $c=-p\cdot m^2-(1-p)\cdot(1-m)^2$, and the maximal correlation coefficient is reached for $p=1$ when $m\in[0;\frac{1}{2}]$, and for $p=0$ when $m\in[\frac{1}{2};1]$, i.e., $r=-m/(1-m)$ and $r=(m-1)/m$, respectively. According to Eq. (2.1), $\chi=(\frac{1}{2})/(1-m)$ when $m\in]0;\frac{1}{2}]$, and $\chi=1/2m$ when $m\in[\frac{1}{2};1[$. The chiral index is equal to 1 when $m=\frac{1}{2}$, and is tending to $\frac{1}{2}$ when m is tending to 0 or to 1. The line $m=\frac{1}{2}$ is a symmetry axis for the graph of the function $\chi(m)$. This graph is the image of the previous one through the symmetry axis $\chi=\frac{1}{2}$.

(Received 25 January 2002; accepted for publication 2 April 2002)

We give a complete proof of the twisted duality property $\mathcal{M}(\mathfrak{q})' = \tilde{Z}\mathcal{M}(\mathfrak{q}^{\perp})\tilde{Z}^*$ of the (self-dual) CAR-Algebra in any Fock representation. The proof is based on the natural Halmos decomposition of the (reference) Hilbert space when two suitable closed subspaces have been distinguished. We use modular theory and techniques developed by Kato concerning pairs of projections in some essential steps of the proof. As a byproduct of the proof we obtain an explicit and simple formula for the graph of the modular operator. This formula can be also applied to fermionic free nets, hence giving a formula of the modular operator for any double cone. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1483376]

I. INTRODUCTION

Twisted duality is a structural property of the von Neumann algebra obtained from the CAR-Algebra (which is an abstract C*-algebra) in any Fock representation. The (self-dual) CAR-Algebra is uniquely given once a separable Hilbert space $\mathfrak{h}$ and an anti-unitary involution Γ are specified.[3,4] Now for any Γ-invariant subspace $\mathfrak{q}$ of $\mathfrak{h}$ and any Fock state characterized by a so-called basis projection P we can canonically construct a von Neumann algebra $\mathcal{M}(\mathfrak{q})$. Twisted duality means that the equation

$$\mathcal{M}(\mathfrak{q})' = \tilde{Z}\mathcal{M}(\mathfrak{q}^{\perp})\tilde{Z}^* \tag{1}$$

holds, where $\tilde{Z}$ is a certain unitary twist operator to be introduced in the following section and $\mathfrak{q} \oplus \mathfrak{q}^{\perp} = \mathfrak{h}$. Thus in order to formulate duality in the context of the (self-dual) CAR-Algebra one needs to distinguish two closed subspaces $\mathfrak{q}$ and $\mathfrak{p} := P\mathfrak{h}$ in the reference Hilbert space $\mathfrak{h}$. The study of two closed subspaces of a Hilbert space has a long and interesting history in functional analysis (e.g., Refs. 15, 13, 22, 30, 6, 11, and 26) as well as applications in mathematical physics.[5]

We will see how the analysis of the relative position of these subspaces will naturally suggest the strategy of the complete proof of Eq. (1) that we present in this article. Concretely, given $\mathfrak{p}$ and $\mathfrak{q}$ as before we can canonically consider the Halmos decomposition $\mathfrak{h} = \mathfrak{h}_0 \oplus \mathfrak{h}_1$ (cf. Ref. 22), where $\mathfrak{h}_0$ is the maximal subspace on which the orthoprojections corresponding to the closed subspaces commute (Ref. 11 Sec. III). Our proof of (1) in the general case is based on the corresponding property for the generic position situation where $\mathfrak{h}_0 = \{0\}$. The case where $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position allows us to use modular theory[25,12] as well as results of Kato[26] for pairs of projections. In this context we will characterize the bicontinuity of different mappings that naturally appear here, e.g., the Tomita operator restricted to the one-particle Hilbert space. Further, we discuss systematically the relation of an important mapping φ (and the components of its polar decomposition) used by Araki and Dell'Antonio[2,14], to the modular objects given in our case. The mapping φ is introduced by these authors to study the type of certain local von Neumann algebras.

[b]Electronic mail: lledo@iram.rwth-aachen.de

The equation (1) appears naturally in the context of algebraic quantum field theory, in particular in relation with Haag duality, which is one of its central concepts (see e.g., Refs. 16, 17, 31, 21, and 7). Haag duality is a strengthening of Einstein causality for a net of von Neumann algebras indexed by suitable regions in $\mathbb{R}^4$. In the context of the CCR-Algebra (bosonic systems), one usually proceeds in two steps in order to prove this property:[2,18,23,27,29] first one shows the so-called *abstract* duality

$$\mathcal{M}(\mathfrak{m}^{\perp_\sigma}) = \mathcal{M}(\mathfrak{m})',$$

where $\mathcal{M}(\mathfrak{m})'$ is the commutant of the von Neumann algebra $\mathcal{M}(\mathfrak{m})$ which is generated by the Weyl operators associated to a closed real subspace $\mathfrak{m}$ of the one-particle Hilbert space and $\mathfrak{m}^{\perp_\sigma}$ denotes the symplectic complement of $\mathfrak{m}$. This result is then crucially used in a second step in order to reduce the proof of Haag duality to the discussion of certain real subspaces $\mathfrak{m}(\mathcal{O})$ associated to sufficiently regular regions $\mathcal{O}$ in $\mathbb{R}^4$. In the context of the CAR-Algebra (fermionic systems), and taking into account that now the generators of the algebra will anti-commute if the corresponding elements of the reference space are mutually orthogonal, one can adapt the notions of duality [cf. (1)] and Haag duality. (In the following we will avoid the use of the adjective "abstract.") Twisted duality (1) is mentioned (without proof) in Ref. 3, Remark 4.9 and proved in Ref. 20. For the special case of the generic position situation, see also Ref. 32, p. 496. An important difference between the proof we present here and those in Refs. 20 and 32 is that we will use the self-dual approach to the CAR-Algebra[3,4] and will consistently work with *complex* Hilbert subspaces. (For further details about the relation between our proof and those in Refs. 20 and 32 we refer to Remark 5.7 and to Sec. VI.) This is not only a matter of elegance, but only the *explicit* use of a basis projection P in order to specify the Fock states of the CAR-Algebra will allow us to consider the natural Halmos decomposition of the reference Hilbert space. Therefore, the whole strategy of the proof as well as various formulas we prove in Sec. IV (e.g., a simple and explicit expression for the graph of the modular operator as well as a formula for the modular conjugation, cf. Theorem 4.12 and Remark 5.7) will depend on this choice. Finally, the twisted duality property (1) of the CAR-Algebra can be applied to the fermionic free nets defined in Refs. 8, 24, and 28 in order to prove Haag duality for these models. In the mentioned references the authors present a direct way to construct nets of local C*-or von Neumann-algebras associated to massive (resp. massless) models for any half-integer spin (resp. helicity) value. The nets for these models are naturally characterized by a net of local Γ-invariant linear subspaces $\mathcal{O} \mapsto \mathfrak{q}(\mathcal{O})$ of the corresponding reference Hilbert space. Now the formulas for the graph of the modular operator and modular conjugation (cf. Theorem 4.12 and Remark 5.7) can also be applied to the localized CAR-Algebras associated with $\mathfrak{q}(\mathcal{O})$, where $\mathcal{O}$ is a double cone. We will give in Theorem 5.10 the corresponding formulas for the localized modular objects.

The article is structured in seven sections: In Sec. II we will state basic results concerning the CAR-Algebra that will be used later on. In the following section we will consider the Halmos decomposition of a Hilbert space and state necessary and sufficient conditions on the subspaces $\mathfrak{p}$ and $\mathfrak{q}$ in order that the modular theory is well defined for $\mathcal{M}(\mathfrak{q})$ and its Fock vacuum vector Ω. In Sec. IV we will systematically analyze the context defined by two projections: the first one being the orthoprojection Q onto $\mathfrak{q}$ and the other one being the basis projection P. The main goal here is to relate the objects that appear in the polar decomposition of the mapping φ and of the Tomita operator S corresponding to $(\mathcal{M}(\mathfrak{q}),\Omega)$ and restricted to the one-particle space $\mathfrak{p}$. On the way to this goal we will give simple formulas for the graphs of $\varphi^*\varphi$ and the modular operator which show a beautiful symmetry wrt the interchange $P \leftrightarrow Q$ (cf. Theorem 4.12 and Proposition 4.13). These results will be applied in the next section where (1) is proved in the case where $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position. In Sec. VI the relation of the self-dual approach to the real subspace approaches in Refs. 20 and 32 are pointed out. In the last section we give a complete proof of (1) in the most general situation, i.e., for any Γ-invariant closed subspace $\mathfrak{q}$ and any Fock state. The proof is based on the results of the previous two sections.

II. BASIC STRUCTURE OF THE CAR-ALGEBRA

In order to establish our notation we will begin this section collecting some standard results concerning the CAR-Algebra that will be needed later on. For proofs and further results we refer to Refs. 3 and 4. In the following subsections we will also consider additional structure of this algebra necessary for our proof of twisted duality.

Theorem 2.1: *Let* $\mathfrak{h}$ *be a complex Hilbert space with scalar product* $\langle\cdot,\cdot\rangle$ *and let* Γ *be an anti-unitary involution on it, i.e.,* $\langle\Gamma f,\Gamma h\rangle=\langle h,f\rangle$, *for all* $f,h\in\mathfrak{h}$. *Then* $\mathrm{CAR}(\mathfrak{h},\Gamma)$ *denotes the algebraically unique* C*-*algebra generated by* $\mathbb{1}$ *and* $a(f)$, $f\in\mathfrak{h}$, *such that the following relations hold:*

(i) *The mapping* $\mathfrak{h}\ni f\mapsto a(f)$ *is antilinear.*
(ii) *For any* $f\in\mathfrak{h}$ *one has* $a(f)^*=a(\Gamma f)$.
(iii) *For any* $f,h\in\mathfrak{h}$ *the equation* $a(f)a(h)^*+a(h)^*a(f)=\langle f,h\rangle\,\mathbb{1}$ *holds.*

Next we define a class of pure states of the preceding C*-algebra. An orthoprojection P of $\mathfrak{h}$ is called a *basis projection* if it satisfies the relation $P+\Gamma P\Gamma=\mathbb{1}$. These projections uniquely characterize so-called *Fock states* ω_P by means of the equation

$$\omega_P(a(f)^*a(f)):=0 \quad \text{for any} \quad f\in\mathfrak{h} \quad \text{with} \quad Pf=f. \tag{2}$$

The antisymmetric Fock space is given by

$$\mathfrak{F}:=\bigoplus_{n=0}^{\infty}(\wedge^n P\mathfrak{h}). \tag{3}$$

In order to specify the Fock representation $\pi(a(f))$ of the generators $a(f)$ we need to introduce the usual annihilation and creation operators on $\mathfrak{F}$:

$$c(p)\Omega:=0,$$

$$c(p)(p_1\wedge\cdots\wedge p_n):=\sum_{r=1}^{n}(-1)^{r-1}\langle p,p_r\rangle_{\mathfrak{h}}p_1\wedge\cdots\wedge\hat{p}_r\wedge\cdots\wedge p_n,$$

$$c(p)^*\Omega:=p,$$

$$c(p)^*(p_1\wedge\cdots\wedge p_n):=p\wedge p_1\wedge\cdots\wedge p_n,$$

where Ω is the Fock vacuum in the subspace corresponding to $n=0$ in the definition (3) and $p,p_1,\ldots,p_n\in P\mathfrak{h}$. $\hat{p}_r$ means that the vector p_r is omitted in the wedge product. Finally, the Fock representation π is defined by

$$\pi(a(f)):=c(P\Gamma f)^*+c(Pf),\quad f\in\mathfrak{h}.$$

In the rest of the article we assume that a basis projection P is given and when no confusion arises we will also simply write $a(f)$ instead of $\pi(a(f))$. To prove twisted duality in Sec. V we will need an explicit formula for the vector $a(f_n)\cdot\cdots\cdot a(f_1)\Omega$. Let n, k, p be natural numbers with $2p+k=n$ and define the following subset of the symmetric group $\mathfrak{S}_n$:

$$\mathfrak{S}_{n,p}:=\left\{\begin{pmatrix} n & n-1 & \cdots & n-2p+2 & n-2p+1 & k & \cdots & 1\\ \alpha_1 & \beta_1 & \cdots & \alpha_p & \beta_p & j_1 & \ldots & j_k\end{pmatrix}\in\mathfrak{S}_n \,\middle|\, \alpha_1>\cdots>\alpha_p,\alpha_l>\beta_l,\right.$$
$$\left. l=1,\ldots,p \quad \text{and} \quad n\geqslant j_1>j_2>\ldots j_k\geqslant 1\right\}.$$

Note that $\mathfrak{S}_{n,p}$ contains $\binom{n}{n-2p}(2p)!/p!2^p$ elements.

Proposition 2.2: For $f_1,\ldots,f_n\in\mathfrak{h}$ the equation

$$(a(f_n)\cdot\cdots\cdot a(f_1))\Omega=\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\0\leqslant 2p\leqslant n}}(\operatorname{sgn}\pi)\prod_{l=1}^{p}\langle Pf_{\alpha_l},P\Gamma f_{\beta_l}\rangle P\Gamma f_{j_1}\wedge\cdots\wedge P\Gamma f_{j_k}$$

holds, where the indices $\alpha_l,\beta_l,j_1,..,j_k$ are given in the definition of $\mathfrak{S}_{n,p}$ and where for $n=2p$ in the preceding sum one replaces the wedge product by the vacuum Ω.

Proof: See the Appendix. ■

Let Z be the implementation on $\mathfrak{F}$ of the even-oddness automorphism associated to the Bogoljubov unitarity -1 (Ref. 4, p. 76). It satisfies $Z=Z^*=Z^{-1}$ and therefore its spectral decomposition is simply given by

$$Z=E^+-E^-. \tag{4}$$

Let further $X=X_{\text{even}}+X_{\text{odd}}$ be the unique decomposition of any $X\in\mathrm{CAR}(\mathfrak{h},\Gamma)$ into its even and odd parts. The following result will be used in Sec. VII.

Lemma 2.3: Let π be a Fock representation of $\mathrm{CAR}(\mathfrak{h},\Gamma)$ *and $Z=E^+-E^-$ as before. Then for any $X\in\mathrm{CAR}(\mathfrak{h},\Gamma)$ we have*

$$E^+\pi(X_{\text{even}})E^-=E^-\pi(X_{\text{even}})E^+=0,$$

$$E^+\pi(X_{\text{odd}})E^+=E^-\pi(X_{\text{odd}})E^-=0.$$

Proof: Recall that $Z_0\pi(X_{\text{even}})=\pi(X_{\text{even}})Z_0$. Multiplying from the left by E^+ and from the right by E^- we get

$$E^+\pi(X_{\text{even}})E^-=-E^+\pi(X_{\text{even}})E^-,$$

which implies the first two equations. Similarly we obtain the equations corresponding to the odd part. ■

A. Direct sums and tensor products

Let $(\mathfrak{h}_k,\Gamma_k)$, $k=0,1$, be two Hilbert spaces with anti-unitary involutions and let P_k be two basis projections for the corresponding spaces. We denote by π_k the Fock representations of $\mathrm{CAR}(\mathfrak{h}_k,\Gamma_k)$ on the antisymmetric Fock spaces $\mathfrak{F}_k$. Z_k are the implementers of the respective even-oddness automorphisms, $k=0,1$. Motivated by Ref. 14, p. 82 (cf. also Ref. 19, p. 219) we consider the following.

Proposition 2.4: With the preceding notation put $\mathfrak{h}:=\mathfrak{h}_0\oplus\mathfrak{h}_1$ and $\Gamma:=\Gamma_0\oplus\Gamma_1$ and consider $\mathrm{CAR}(\mathfrak{h},\Gamma)$. *The representations defined on $\mathfrak{F}_0\otimes\mathfrak{F}_1$ by*

$$\pi(a(f_0\oplus f_1)):=\pi_0(a(f_0))\otimes 1+Z_0\otimes\pi_1(a(f_1)), \tag{5}$$

$$\pi(a(f_0\oplus f_1)):=\pi_0(a(f_0))\otimes Z_1+1\otimes\pi_1(a(f_1)),\quad f_k\in\mathfrak{h}_k,\ k=0,1, \tag{6}$$

are the Fock representations of $\mathrm{CAR}(\mathfrak{h},\Gamma)$ *wrt the basis projection $P:=P_0\oplus P_1$ on* $(\mathfrak{h},\Gamma)$. *Further, the even-oddness automorphism of* $\mathrm{CAR}(\mathfrak{h},\Gamma)$ *is implemented on $\mathfrak{F}_0\otimes\mathfrak{F}_1$ by $Z:=Z_0\otimes Z_1$.*

Proof: We check first that the definition (5) is compatible with the algebraic structure of $\mathrm{CAR}(\mathfrak{h},\Gamma)$. Indeed, for any $f_k,h_k\in\mathfrak{h}_k$, $k=0,1$,

$$\pi(a(f_0\oplus f_1))^*=\pi_0(a(\Gamma_0 f_0))\otimes 1+Z_0\otimes\pi_1(a(\Gamma_1 f_1))=\pi(a(\Gamma(f_0\oplus f_1)))$$

and

$$
\begin{aligned}
&\pi(a(f_0\oplus f_1))\pi(a(h_0\oplus h_1))^*+\pi(a(h_0\oplus h_1))^*\pi(a(f_0\oplus f_1))\\
&\quad=\pi_0(a(f_0)a(h_0)^*)\otimes\mathbb{1}+\mathbb{1}\otimes\pi_1(a(f_1)a(h_1)^*)\\
&\qquad+\pi_0(a(h_0)^*a(f_0))\otimes\mathbb{1}+\mathbb{1}\otimes\pi_1(a(h_1)^*a(f_1))\\
&\qquad+\underbrace{Z_0\pi_0(a(h_0)^*)\otimes\pi_1(a(f_1))+\pi_0(a(h_0)^*)Z_0\otimes\pi_1(a(f_1))}_{=0}\\
&\qquad+\underbrace{Z_0\pi_0(a(f_0))\otimes\pi_1(a(h_1)^*)+\pi_0(a(f_0))Z_0\otimes\pi_1(a(h_1)^*)}_{=0}\\
&\quad=\langle f_0\oplus f_1,h_0\oplus h_1\rangle\mathbb{1}\otimes\mathbb{1}.
\end{aligned}
$$

Consider next the vector state associated to $\Omega_0\otimes\Omega_1$, where Ω_k are the Fock vacua in $\mathfrak{F}_k$, $k=0,1$. In this case we have

$$
\begin{aligned}
&\langle\Omega_0\otimes\Omega_1,\pi(a(f_0\oplus f_1))^*\pi(a(f_0\oplus f_1))\Omega_0\otimes\Omega_1\rangle\\
&\quad=\|\pi_0(a(f_0))\Omega_0\otimes\Omega_1+\Omega_0\otimes\pi_1(a(f_1))\Omega_1\|^2\\
&\quad=\|P_0\Gamma_0 f_0\|^2+\|P_1\Gamma_1 f_1\|^2=\|(\mathbb{1}-P)(f_0\oplus f_1)\|^2.
\end{aligned}
$$

Thus by the uniqueness of the characterizing condition (2) of a Fock state, together with the fact that the vectors $\pi(a(f_0\oplus f_1))\Omega_0\otimes\Omega_1$, $f_k\in\mathfrak{h}_k$, generate the whole space $\mathfrak{F}_0\otimes\mathfrak{F}_1$, we have that π is actually the Fock representation of CAR$(\mathfrak{h},\Gamma)$ wrt the basis projection P with Fock vacuum $\Omega_0\otimes\Omega_1$.

We still need to show that $Z_0\otimes Z_1$ implements the even-oddness automorphism of CAR$(\mathfrak{h},\Gamma)$ on $\mathfrak{F}_0\otimes\mathfrak{F}_1$. Note that $\alpha:=\mathrm{ad}(Z_0\otimes Z_1)$ satisfies $\alpha^2=\mathrm{id}$ and it is enough to consider the action of α on the generators:

$$
(Z_0\otimes Z_1)\pi(a(f_0\oplus f_1))(Z_0\otimes Z_1)=Z_0\pi_0(a(f_0))Z_0\otimes Z_1^2+Z_0^3\otimes Z_1\pi_1(a(f_1))Z_1=\pi(-a(f_0\oplus f_1)).
$$

Equation (6) is shown similarly. ■

Corollary 2.5: For $X_0\in\mathrm{CAR}(\mathfrak{h}_0,\Gamma_0)$ *and* $X_1=X_{1,\mathrm{even}}+X_{1,\mathrm{odd}}\in\mathrm{CAR}(\mathfrak{h}_1,\Gamma_1)$ *we have*

$$
\pi(X_0)=\pi_0(X_0)\otimes\mathbb{1}
$$

and

$$
\pi(X_1)=\mathbb{1}\otimes\pi_1(X_{1,\mathrm{even}})+Z_0\otimes\pi_1(X_{1,\mathrm{odd}})=E_0^+\otimes\pi_1(X_1)+E_0^-\otimes Z_1\pi_1(X_{1,\mathrm{odd}})Z_1,
$$

where $Z_0=E_0^+-E_0^-$.

B. The subspace $\mathfrak{q}$ and twisted causality

Let $(\mathfrak{q},\Gamma)$ be as in Theorem 2.1 and denote by $\mathfrak{q}$ a closed Γ-invariant subspace of $\mathfrak{h}$. We can naturally associate with the subspace $\mathfrak{q}$ a von Neumann algebra that acts on the antisymmetric Fock space characterized by the basis projection P:

$$
\mathcal{M}(\mathfrak{q}):=(\{a(q)|q\in\mathfrak{q}\})''\subset\mathcal{L}(\mathfrak{F}). \tag{7}
$$

In order to be able to formulate causality or duality in the context of the CAR-Algebra it is necessary to introduce a so-called *twist operator* $\widetilde{Z}$ on $\mathfrak{F}$. Indeed, this operator allows us to express orthogonality relations of subspaces of $\mathfrak{h}$ in terms of the commutant of a suitable von Neumann algebra. Recalling the definition of Z before Eq. (4) we define the twist operator as usual [Ref. 10, Eq. (26)]:

$$\tilde{Z} := \frac{1}{1+i}(\mathbb{1}+iZ) \quad \text{and} \quad \tilde{Z}a(f)\tilde{Z}^* = iZa(f), \quad f \in \mathfrak{h}. \tag{8}$$

Putting

$$\eta(n) := \begin{cases} 1, & \text{if } n \text{ even}, \\ -i, & \text{if } n \text{ odd}, \end{cases}$$

we may describe the action of $\tilde{Z}$ and $\tilde{Z}^*$ on $\mathfrak{F}$ by $\tilde{Z}(p_1 \wedge \cdots \wedge p_n) = \eta(n)\, p_1 \wedge \cdots \wedge p_n$ and $\tilde{Z}^*(p_1 \wedge \cdots \wedge p_n) = \overline{\eta(n)}\, p_1 \wedge \cdots \wedge p_n$. Further, considering the spectral projections $E^{\pm}$ of Z we also have the relation

$$\tilde{Z} = E^+ - iE^-. \tag{9}$$

The algebra $\tilde{Z}\,\mathcal{M}(\mathfrak{q})\,\tilde{Z}^*$ is usually called "twisted" algebra. It is now immediate to check the following inclusion, which expresses the twisted causality property in the present context.

Proposition 2.6: Let $\mathfrak{q}$ *be a closed* Γ*-invariant subspace of* $\mathfrak{h}$ *as before. Then the inclusion* $\tilde{Z}\,\mathcal{M}(\mathfrak{q}^\perp)\,\tilde{Z}^* \subseteq \mathcal{M}(\mathfrak{q})'$ *holds.*

Remark 2.7: Twisted duality strengthens this relation by turning the preceding inclusion into an equality for *any* closed Γ-invariant subspace $\mathfrak{q}$ of $\mathfrak{h}$.

Remark 2.8: Writing now explicitly the Fock representation and considering Eq. (8) as well as the even-odd grading of the CAR-Algebra we have the following ways of generating the twisted von Neumann algebra:

$$\begin{aligned} \tilde{Z}\,\mathcal{M}(\mathfrak{q}^\perp)\,\tilde{Z}^* &= \{Z\pi(a(q^\perp))\,|\,q^\perp \in \mathfrak{q}^\perp\}'' \\ &= \{\pi(Y_{\text{even}}) + iZ\pi(Y_{\text{odd}}))\,|\,Y = Y_{\text{even}} + Y_{\text{odd}} \in \mathrm{CAR}(\mathfrak{q}^\perp, \Gamma\restriction\mathfrak{q}^\perp)\}''. \end{aligned}$$

III. THE HALMOS DECOMPOSITION OF A HILBERT SPACE

From the preceding subsection we see that to formulate the duality property in the present context one needs to distinguish two closed subspaces of the reference space $\mathfrak{h}$: the subspace $\mathfrak{p}$ (one-particle Hilbert space), which is given by the basis projection P, and the Γ-invariant subspace $\mathfrak{q}$ to which we associate the orthoprojection Q. Therefore, it is natural to consider the Halmos decomposition[22] of $\mathfrak{h}$ wrt $\mathfrak{p}$ and $\mathfrak{q}$, which is given by

$$\mathfrak{h} = \mathfrak{h}_0 \oplus \mathfrak{h}_1, \tag{10}$$

where $\mathfrak{h}_0 = (\mathfrak{p}\cap\mathfrak{q}) \oplus (\mathfrak{p}\cap\mathfrak{q}^\perp) \oplus (\mathfrak{p}^\perp\cap\mathfrak{q}) \oplus (\mathfrak{p}^\perp\cap\mathfrak{q}^\perp)$ and $\mathfrak{h}_1 = \mathfrak{h} \ominus \mathfrak{h}_0$. $\mathfrak{h}_0$ is actually the maximal subspace where P and Q commute (Ref. 11, Sec. III). In $\mathfrak{h}_1$ the subspaces $\mathfrak{p}$ and $\mathfrak{q}$ are said to be in *generic position*,[22] in the sense that the preceding four mutual intersections of the subspaces $\mathfrak{p}$, $\mathfrak{q}$, $\mathfrak{p}^\perp$ and $\mathfrak{q}^\perp$ are equal to $\{0\}$.

In the present context the decomposition (10) is also natural because it allows us to separate the general situation into simpler "pieces" on $\mathfrak{h}_0$ and $\mathfrak{h}_1$:

Lemma 3.1: Consider $(\mathfrak{h},\Gamma)$ *and* P,Q *as before. Further, let* R_0 *be the orthoprojection onto the subspace* $\mathfrak{h}_0$ *in (10). Then we have*

$$R_0P = PR_0, \quad R_0Q = QR_0 \quad \text{and} \quad R_0\Gamma = \Gamma R_0.$$

Proof: The first two equations are clear from the form of $\mathfrak{h}_0$ given after (10) and recall that R_0 is the maximal orthoprojection with the property $R_0\,PQ = R_0\,QP$. Now from

$$\Gamma R_0 \Gamma\, PQ = \Gamma R_0 (\mathbb{1}-P) Q\Gamma = \Gamma R_0 \Gamma\, QP$$

and the maximality of R_0 we must have $\Gamma R_0 \Gamma \leqslant R_0$. Finally, from the Γ-invariance of $\mathfrak{h}$ and since $\Gamma^2 = \mathbb{1}$ we get $R_0 \Gamma = \Gamma R_0$. ■

Remark 3.2: The preceding result allows us to consider the following restrictions:

$$P_k := P \restriction \mathfrak{h}_k, \quad Q_k := Q \restriction \mathfrak{h}_k, \quad \text{and} \quad \Gamma_k := \Gamma \restriction \mathfrak{h}_k, \quad k = 0,1.$$

Further, P_k is a basis projection on $(\mathfrak{h}_k, \Gamma_k)$ characterizing the Fock representation π_k of CAR$(\mathfrak{h}_k, \Gamma_k)$, $k = 0,1$. This possibility to split off the general situation in an Abelian piece and a generic position piece will be essential for the proof of our main theorem in Sec. VII. In this context we will need to split again the Abelian part as $\mathfrak{h}_0 = \mathfrak{h}_{01} \oplus \mathfrak{h}_{02}$, where $\mathfrak{h}_{01} := (\mathfrak{p} \cap \mathfrak{q}^\perp) \oplus \Gamma(\mathfrak{p} \cap \mathfrak{q}^\perp)$ and $\mathfrak{h}_{02} := (\mathfrak{p} \cap \mathfrak{q}) \oplus \Gamma(\mathfrak{p} \cap \mathfrak{q})$.

A. Modular theory

Let $(\mathfrak{h}, \Gamma)$, P and $\mathfrak{q}$ be given as in Sec. II B and denote by $\mathfrak{p} := P\mathfrak{h}$ the corresponding one-particle Hilbert space. We will give in this subsection necessary and sufficient conditions on the subspaces $\mathfrak{p}$ and $\mathfrak{q}$ in order that the Fock vacuum Ω becomes a cyclic and separating vector for the von Neumann algebra $\mathcal{M}(\mathfrak{q})$ (cf. Ref. 19, p. 234). We will see that in the case where the subspaces $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position we can use the results in modular theory[12,25] for the pair $(\mathcal{M}(\mathfrak{q}), \Omega)$. These techniques will be essentially used in the next two sections for the proof of the twisted duality property in the generic position context.

Lemma 3.3: Let $\mathfrak{q} \subset \mathfrak{h}$ be a closed Γ-invariant subspace. Then the following conditions are equivalent:

(i) $q \in \mathfrak{q}$ *and* $Pq = 0$ *implies* $q = 0$.
(ii) $P(\mathfrak{q}^\perp)$ *is a dense submanifold of* $\mathfrak{p}$.
(iii) $\mathfrak{q} \cap \mathfrak{p} = \{0\}$.

Proof: To show $(iii) \Rightarrow (i)$ take $q \in \mathfrak{q}$ with $Pq = 0$. From $\Gamma P \Gamma = \mathbb{1} - P$ and the Γ-invariance of $\mathfrak{q}$ we have that $\Gamma q \in \mathfrak{q} \cap \mathfrak{p} = \{0\}$, thus $q = 0$. The other implications $(i) \Rightarrow (ii) \Rightarrow (iii)$ are checked similarly. ■

Proposition 3.4: Let $\mathfrak{q}$ be a closed Γ-invariant subspace of $\mathfrak{h}$ as before. Then we have the following.

(i) The vacuum vector Ω is cyclic for $\mathcal{M}(\mathfrak{q})$ iff $P\mathfrak{q}$ is a dense submanifold of $\mathfrak{p}$.
(ii) The vacuum vector Ω is separating for $\mathcal{M}(\mathfrak{q})$ iff $P(\mathfrak{q}^\perp)$ is a dense submanifold of $\mathfrak{p}$.

Proof: (i) We assume that Ω is cyclic for $\mathcal{M}(\mathfrak{q})$ and let $p \in \mathfrak{p}$ be a vector satisfying $p \perp P\mathfrak{q}$. From this, from Proposition 2.2 and from the structure of the Fock space $\mathfrak{F}$ [recall Eq. (3)] we have

$$p \perp \operatorname{span}\{a(q_1) \cdots \cdots a(q_n)\Omega \,|\, q_1, \cdots q_n \in \mathfrak{q}, \ n \in \mathbb{N}\},$$

thus

$$p \perp \{A\Omega \,|\, A \in \mathcal{M}(\mathfrak{q})\}.$$

Now since Ω is cyclic for $\mathcal{M}(\mathfrak{q})$ we must have $p = 0$.

Assume now that $P\mathfrak{q} \subset \mathfrak{p}$ is a dense submanifold, so that $\oplus_{n=0}^{\infty}(\overset{n}{\wedge} P\mathfrak{q}) \subset \mathfrak{F}$ is also dense (here $\oplus_{n=0}^{\infty}$ denotes the algebraic direct sum). From Proposition 2.2 we obtain the inclusions

$$\bigoplus_{n=0}^{\infty} (\overset{n}{\wedge} P\mathfrak{q}) \subset \mathcal{M}(\mathfrak{q})\, \Omega \subset \mathfrak{F},$$

which imply that Ω is cyclic for $\mathcal{M}(\mathfrak{q})$.

(*ii*) Suppose now that Ω is a separating vector for $\mathcal{M}(\mathfrak{q})$. We show that this implies part (*i*) of Lemma 3.3. So, let $q \in \mathfrak{q}$ satisfy $Pq=0$. Since $0=Pq=a(\Gamma q)\Omega$ and since Ω is separating for $\mathcal{M}(\mathfrak{q})$ we must have $a(\Gamma q)=0$, which implies $q=0$.

Finally, assume that $P(\mathfrak{q}^\perp)$ is a dense submanifold of $\mathfrak{p}$. By part (*i*) of the present theorem applied to $\mathfrak{q}^\perp$, which is also Γ-invariant, we know that Ω is cyclic for $\mathcal{M}(\mathfrak{q}^\perp)$. Further, since $\tilde{Z}\Omega=\Omega$ we have that Ω is also cyclic for $\tilde{Z}\,\mathcal{M}(\mathfrak{q}^\perp)\,\tilde{Z}^*$ and consequently by Proposition 2.6 also for $\mathcal{M}(\mathfrak{q})' \supseteq \tilde{Z}\,\mathcal{M}(\mathfrak{q}^\perp)\,\tilde{Z}^*$. This shows that Ω is separating for $\mathcal{M}(\mathfrak{q})$. ■

By the preceding result we know that if $\mathfrak{q}$ is a closed Γ-invariant subspace of $\mathfrak{h}$ where $P\mathfrak{q}$ as well as $P(\mathfrak{q}^\perp)$ are dense submanifolds of $\mathfrak{p}$, then the modular theory is well-defined for the pairs $(\mathcal{M}(\mathfrak{q}),\Omega)$ and $(\mathcal{M}(\mathfrak{q}^\perp),\Omega)$. Denote by S and T the Tomita operators corresponding to these pairs respectively. We will next study their action on the submanifolds $P\mathfrak{q}$ and $P(\mathfrak{q}^\perp)$.

Lemma 3.5: With the preceding notation we have for $q \in \mathfrak{q}$ and $q^\perp \in \mathfrak{q}^\perp$

(i) $S(Pq)=P\Gamma q$,
(ii) $T(Pq^\perp)=P\Gamma q^\perp=-S^*(Pq^\perp)$.

Proof: The first two equations follow by direct computation:

$$S(Pq)=S(a(\Gamma q)\,\Omega)=a(\Gamma q)^*\,\Omega=a(q)\,\Omega=P\Gamma q,$$

and similarly for T. To prove the last equation recall that S^* is actually the Tomita operator of $\mathcal{M}(\mathfrak{q})' \supseteq \tilde{Z}\,\mathcal{M}(\mathfrak{q}^\perp)\,\tilde{Z}^*$. Note further that

$$i\,(\tilde{Z}a(\Gamma q^\perp)\tilde{Z}^*)\,\Omega=i\,\tilde{Z}a(\Gamma q^\perp)\,\Omega=i\left(\frac{1-i}{1+i}\right)Pq^\perp=Pq^\perp.$$

From this we can finally check

$$S^*(Pq^\perp)=-i\,S^*(\tilde{Z}a(\Gamma q^\perp)\tilde{Z}^*\,\Omega)=-i\,\tilde{Z}a(q^\perp)\tilde{Z}^*\,\Omega=-P\Gamma q^\perp=-T(Pq^\perp),$$

and the proof is concluded. ■

IV. PAIRS OF PROJECTIONS IN GENERIC POSITION AND THE MAPPING φ

In this section we will consider the mathematically richest situation which appears when the closed subspaces $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position. Let P and Q be the corresponding orthoprojections satisfying as usual the relations $\Gamma P\Gamma=\mathbb{1}-P=P^\perp$ and $Q\Gamma=\Gamma Q$. Motivated by Proposition 3.4 we will also assume here that

$$\mathfrak{p}\cap\mathfrak{q}=\{0\}=\mathfrak{p}\cap\mathfrak{q}^\perp, \quad \text{where} \quad \mathfrak{p}:=P\mathfrak{h}, \tag{11}$$

which directly implies using the basis projection property:

$$\mathfrak{p}^\perp\cap\mathfrak{q}=\{0\}=\mathfrak{p}^\perp\cap\mathfrak{q}^\perp, \quad \text{where} \quad \mathfrak{p}^\perp=P^\perp\mathfrak{h}. \tag{12}$$

Thus in the notation of Sec. III we have the extremal case where $\mathfrak{p}$ and $\mathfrak{q}$ are already in generic position and the Halmos decomposition (10) is trivial in the sense that $\mathfrak{h}_0=\{0\}$.

Note that the properties like $\mathfrak{p}\cap\mathfrak{q}=\{0\}$ can be also expressed by the corresponding projections P and Q, because the orthoprojection onto the intersection $\mathfrak{p}\cap\mathfrak{q}$ is given by

$$\operatorname*{s-lim}_{n\to\infty}(PQ)^n=\operatorname*{s-lim}_{n\to\infty}(QP)^n.$$

Note further that by Lemma 3.3 the intersection assumptions in (11) are equivalent to the density conditions in Proposition 3.4.

Remark 4.1: The following useful density statements are immediate consequences of the assumption that $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position. If $\mathfrak{r}\subseteq\mathfrak{q}$ (or $\mathfrak{r}\subseteq\mathfrak{q}^\perp$) is a dense linear submanifold in $\mathfrak{q}$ (resp. in $\mathfrak{q}^\perp$), then $P\mathfrak{r}$ is dense in $\mathfrak{p}$ and $P^\perp\mathfrak{r}$ is dense in $\mathfrak{p}^\perp$. The same holds if Q and P are interchanged. Thus we have, for example, that $Q\mathfrak{p}^\perp$ is dense in $\mathfrak{q}$, $PQ\mathfrak{p}$ is dense in $\mathfrak{p}$, etc.

We will begin next a systematic analysis of a mapping φ that can be naturally defined in the present context. Put

$$\mathfrak{H}_\varphi := \{(q,q^\perp)\in\mathfrak{q}\times\mathfrak{q}^\perp \,|\, P^\perp(q+q^\perp)=0\},$$

$$\mathfrak{H}_\rho := \{(q,q^\perp)\in\mathfrak{q}\times\mathfrak{q}^\perp \,|\, Pq=Pq^\perp\}.$$

Lemma 4.2: The sets $\mathfrak{H}_\varphi$ and $\mathfrak{H}_\rho$ are graphs of linear, injective and closed mappings $\varphi,\rho:\mathfrak{q}\to\mathfrak{q}^\perp$ with dense domains and dense images. The graphs $\operatorname{gra}\varphi=\mathfrak{H}_\varphi$ *and* $\operatorname{gra}\rho=\mathfrak{H}_\rho$ *can be parametrized by* $\mathfrak{p}$, *resp.* $\mathfrak{p}^\perp$, *as*

$$\begin{aligned}\operatorname{gra}\varphi &:= \{(Qp,Q^\perp p)\,|\,p\in\mathfrak{p}\},\\ \operatorname{gra}\rho &:= \{(Qp^\perp,-Q^\perp p^\perp)\,|\,p^\perp\in\mathfrak{p}^\perp\},\end{aligned} \tag{13}$$

where the domains and images are given explicitly. Moreover, the equation $\rho^{-1}=\varphi^*$ holds.

Proof: We consider first the mapping φ and one can similarly argue for ρ. First note that the assignment $\varphi(q):=q^\perp$ if $P^\perp(q+q^\perp)=0$ is a well-defined linear map. Indeed, if $(q,q_1^\perp)\in\mathfrak{H}_\varphi \ni (q,q_2^\perp)$, then $q_1^\perp=q_2^\perp$, because in this case $q_1^\perp-q_2^\perp\in\mathfrak{q}^\perp\cap\mathfrak{p}=\{0\}$. Injectivity is proved analogously.

Next we show Eq. (13). Let $\mathfrak{p}\ni p=Qp+Q^\perp p$, so that $P^\perp(Qp+Q^\perp p)=0$ and we have $Q\mathfrak{p}\subseteq\operatorname{dom}\varphi$ as well as $Q^\perp\mathfrak{p}\subseteq\operatorname{ima}\varphi$. To show the reverse inclusions take $q_0\in\operatorname{dom}\varphi$, i.e., $P^\perp(q_0+q_0^\perp)=0$ for some $q_0^\perp\in\mathfrak{q}^\perp$. But this implies that $q_0=Q(q_0+q_0^\perp)\in Q\mathfrak{p}$ and $q_0^\perp=Q^\perp(q_0+q_0^\perp)\in Q^\perp\mathfrak{p}$ and Eq. (13) is proved. Note that by the preceding remark the domain and image of φ are dense in $\mathfrak{q}$, resp. $\mathfrak{q}^\perp$, and it is easy to see that $\operatorname{gra}\varphi$ is closed.

Finally, it remains to show that $\rho^{-1}=\varphi^*$. Recall first that

$$\operatorname{gra}\rho^{-1}=\{(Q^\perp p^\perp,-Qp^\perp)\,|\,p^\perp\in\mathfrak{p}^\perp\}.$$

Using the isometric mapping $U:\ \mathfrak{q}\times\mathfrak{q}^\perp\to\mathfrak{q}^\perp\times\mathfrak{q}$ given by $U(q,q^\perp):=(q^\perp,-q)$ we may use the well known formula (see Ref. 1, p. 124)

$$\operatorname{gra}\varphi^*=(\mathfrak{q}^\perp\times\mathfrak{q})\ominus U(\operatorname{gra}\varphi).$$

Therefore $(q^\perp,q)\in\operatorname{gra}\varphi^*$ iff $\langle(q^\perp,q),(Q^\perp p,-Qp)\rangle=0$ for all $p\in\mathfrak{p}$ iff $\langle q^\perp,p\rangle=\langle q,p\rangle$ for all $p\in\mathfrak{p}$ iff $p^\perp:=q^\perp-q\in\mathfrak{p}^\perp$ iff $(q^\perp,q)\in\operatorname{gra}\rho^{-1}$. ∎

Remark 4.3: Note that the preceding lemma depends only on the assumption that P and Q are in generic position (the different role of P and Q wrt Γ, i.e., $Q\Gamma=\Gamma Q$ and $\Gamma P\Gamma=P^\perp$, is not used). This means that the preceding lemma remains true if we do the following replacements:

$$Q\to P \quad\text{and}\quad P\to Q^\perp.$$

Then we obtain the following.

Corollary 4.4: Put

$$\mathfrak{H}_\lambda := \{(p,p^\perp)\in\mathfrak{p}\times\mathfrak{p}^\perp \,|\, Q^\perp p=Q^\perp p^\perp\}.$$

Then $\mathfrak{H}_\lambda$ is the graph of a linear injective closed mapping $\lambda:\mathfrak{p}\to\mathfrak{p}^\perp$ with dense domain and image. $\operatorname{gra}\lambda$ *can be parametrized by* $\mathfrak{q}$:

$$\operatorname{gra}\lambda=\{(Pq,-P^\perp q)\,|\,q\in\mathfrak{q}\}.$$

The parametrization of φ and ρ in terms of $\mathfrak{p}$, resp. $\mathfrak{p}^\perp$, suggests to consider the following mappings:

$$Q:\mathfrak{p}^\perp\to\mathfrak{q}, \tag{14}$$

$$Q^\perp:\mathfrak{p}^\perp\to\mathfrak{q}^\perp, \tag{15}$$

$$Q:\mathfrak{p}\to\mathfrak{q}, \tag{16}$$

$$Q^\perp:\mathfrak{p}\to\mathfrak{q}^\perp, \tag{17}$$

where the first two are related to ρ and the last two are related to φ. For example, the parametrization of ρ in terms of $\mathfrak{p}^\perp$ means that ρ can be seen as the composition of the following mappings:

$$QP^\perp\mathfrak{h}\to P^\perp\mathfrak{h}\to Q^\perp P^\perp\mathfrak{h}.$$

Later we will also need to consider the mappings

$$P:\ \mathfrak{q}^\perp\to\mathfrak{p}, \tag{18}$$

$$P:\ \mathfrak{q}\to\mathfrak{p}. \tag{19}$$

Due to the fact that $\mathfrak{q}$ and $\mathfrak{p}$ are in generic position the mappings (14)–(19) are bounded, injective and their images are dense in the corresponding final subspaces.

We will next give a criterion for the bicontinuity of the mappings (14)–(19). First note that because P is a basis projection

$$\|PQ\|=\|QP\|=\|(\mathbb{1}-P)Q\|=\|Q(\mathbb{1}-P)\|=:\delta$$

and $0<\delta\leqslant 1$. So we can distinguish between the two cases: $\delta<1$ and $\delta=1$.

Proposition 4.5: Let P,Q and δ be given as before. If $\delta<1$, then the mappings (14)–(19) are bicontinuous, in particular their images coincide with the corresponding final spaces. Moreover, the relations

$$\|P-Q\|=\|(\mathbb{1}-Q)P\|=\|(\mathbb{1}-Q)(\mathbb{1}-P)\|=\delta$$

hold.

Proof: This result is a special case of Theorem 6.34 in Ref. 26, p. 56. Note that the second alternative stated in Kato's result cannot appear in the present situation, as a consequence of the fact that $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position. ■

Remark 4.6: This situation corresponds to the case where the index of P and Q is 0 (cf. Ref. 6, Theorem 3.3).

Proposition 4.7: Let P,Q and δ be given as before. If $\delta=1$, then the inverse mappings of (14)–(19) are unbounded and densely defined, i.e., the images of (14)–(19) are nontrivial proper dense sets in the corresponding final subspaces.

Proof: We will only show the assertion for the mapping (19), since one can easily adapt the following arguments to the other cases. Put $A:=QP^\perp Q\restriction\mathfrak{q}\in\mathcal{L}(\mathfrak{q})$, so that $A=A^*$ and $A\geqslant 0$. From

$$\operatorname{spr}A=\|A\|=\|QP^\perp P^\perp Q\|=\|P^\perp Q\|^2=\delta^2=1$$

we obtain $1\in\operatorname{spec}A$. However, 1 is not an eigenvalue of A, because $Aq=q$, $q\in\mathfrak{q}$, implies $\text{s-lim}_{n\to\infty}(QP^\perp)^nq=q$ and this means $q\in\mathfrak{q}\cap\mathfrak{p}^\perp=\{0\}$. Thus $\ker(\mathbb{1}_\mathfrak{q}-A)=\{0\}$ or $(\mathbb{1}_\mathfrak{q}-A)^{-1}$ exists and is unbounded since $1\notin\operatorname{res}A$. Therefore $\vartheta:=\operatorname{dom}(\mathbb{1}_\mathfrak{q}-A)^{-1}$ is a proper dense subset in $\mathfrak{q}$ and this means $\operatorname{ima}(\mathbb{1}_\mathfrak{q}-A)=\vartheta=\operatorname{ima}(Q-QP^\perp Q)=\operatorname{ima}(QPQ)$. Finally, from the polar decomposition of PQ,

$$PQ=\operatorname{sgn}(PQ)\cdot(QPQ)^{1/2},$$

we have that $\operatorname{sgn}(PQ)$ maps $\operatorname{ima}(QPQ)^{1/2}$ isometrically onto $\operatorname{ima}(PQ)=P\mathfrak{q}$. Thus $P\mathfrak{q}$ is a proper dense set in $\mathfrak{p}$, i.e., $P:\mathfrak{q}\to\mathfrak{p}$ is unbounded invertible. ■

Remark 4.8: (*i*) Note that if $\dim\mathfrak{h}<\infty$, then the case $\|PQ\|=1$ is not possible, since the corresponding operators cannot have continuous spectrum. It is easy to show that in this case $\mathfrak{p}\cap\mathfrak{q}=\{0\}$ iff $\|PQ\|<1$.

(*ii*) Note also that $\|(\mathbb{1}-P)Q\|=1$ implies $\|(\mathbb{1}-Q)P\|=1$, because otherwise by Proposition 4.5 $\|(\mathbb{1}-Q)P\|<1$ implies $\|(\mathbb{1}-P)Q\|<1$.

Proposition 4.9: Let the projections P,Q and the mappings φ,ρ be given as before. Then $\varphi,\rho:\mathfrak{q}\to\mathfrak{q}^{\perp}$ are bicontinuous iff $\|PQ\|<1$.

Proof: Suppose that $\|PQ\|<1$, so that by Proposition 4.5 we have that the mappings (14)–(19) are bicontinuous. But as mentioned before we know that φ as well as ρ can be seen as composition of the mappings

$$\varphi:\ QP\mathfrak{h}\to P\mathfrak{h}\to Q^{\perp}P\mathfrak{h},\quad \rho:\ QP^{\perp}\mathfrak{h}\to P^{\perp}\mathfrak{h}\to Q^{\perp}P^{\perp}\mathfrak{h},$$

hence they must be bicontinuous.

In the case that ρ and φ are bicontinuous, then $\operatorname{dom}\rho=\operatorname{dom}\varphi=\mathfrak{q}$ and $\operatorname{ima}\rho=\operatorname{ima}\varphi=\mathfrak{q}^{\perp}$. Finally, Proposition 4.7 implies $\|PQ\|<1$. ■

Motivated by Lemma 3.5 we will analyze next the antilinear mappings defined by the following graphs:

$$\operatorname{gra}\beta:=\{(Pq,P\Gamma q)\in\mathfrak{p}\times\mathfrak{p}\,|\,q\in\mathfrak{q}\},$$

$$\operatorname{gra}\alpha:=\{(Pq^{\perp},-P\Gamma q^{\perp})\in\mathfrak{p}\times\mathfrak{p}\,|\,q^{\perp}\in\mathfrak{q}^{\perp}\}.$$

(Note that the rhs of the preceding equations define indeed graphs of antilinear mappings, because the assignments $q\to Pq$ and $q^{\perp}\to Pq^{\perp}$ are injective.)

Lemma 4.10: The mappings α,β defined by the preceding graphs are antilinear, injective and closed with dense domains and images $\operatorname{dom}\alpha=\operatorname{ima}\alpha=P(\mathfrak{q}^{\perp})$, $\operatorname{dom}\beta=\operatorname{ima}\beta=P\mathfrak{q}$. *Further, we have* $\alpha^2=\mathrm{id}$, $\beta^2=\mathrm{id}$ *on* $P(\mathfrak{q}^{\perp})$, *resp.* $P\mathfrak{q}$ *and* $\alpha=\beta^*$.

Proof: We will only prove the last equation, because the other statements follow immediately from the definition. Now by definition we have $(p_0,p_1)\in\operatorname{gra}\beta^*$ iff $\langle p_0,P\Gamma q\rangle=\langle Pq,p_1\rangle$ for all $q\in\mathfrak{q}$ iff $q^{\perp}:=p_0-\Gamma p_1\in\mathfrak{q}^{\perp}$ iff $(p_0,p_1)\in\operatorname{gra}\alpha$. ■

Remark 4.11: (*i*) Recall Sec. III A and denote by S the Tomita operator associated to $(\mathcal{M}(\mathfrak{q}),\Omega)$. Then from the preceding result we have $S\restriction\mathfrak{p}\supseteq\beta$ and $S^*\restriction\mathfrak{p}\supseteq\alpha$.

(*ii*) Using the mappings (18) and (19) we can now state similarly as in Proposition 4.9 a criterion for the bicontinuity of α,β: the mappings α,β are bicontinuous iff $\|PQ\|<1$.

We introduce next the notation

$$\Delta_{\mathfrak{p}}:=\beta^*\beta,$$

since it will later turn out that $\Delta_{\mathfrak{p}}$ is actually the modular operator restricted to the one-particle Hilbert space $\mathfrak{p}$.

Theorem 4.12: *The mapping $\Delta_{\mathfrak{p}}:\mathfrak{p}\to\mathfrak{p}$ is a densely defined linear positive self-adjoint operator on $\mathfrak{p}$ with graph*

$$\operatorname{gra}\Delta_{\mathfrak{p}}=\{(PQp,PQ^{\perp}p)\,|\,p\in\mathfrak{p}\}.$$

Moreover, $\Delta_{\mathfrak{p}}^{-1}=\beta\beta^*=\alpha^*\alpha$.

Proof: We will compute first the domain of $\beta^*\beta$. Recalling that $\beta^*=\alpha$ we have

$$\begin{aligned}\operatorname{dom}(\Delta_{\mathfrak{p}}) &= \{Pq \mid q \in \mathfrak{q} \text{ and } P\Gamma q \in \operatorname{dom}\alpha = P(\mathfrak{q}^{\perp})\}\\ &= \{Pq \mid q \in \mathfrak{q} \text{ and } P\Gamma q = Pq^{\perp} \text{ for some } q^{\perp} \in \mathfrak{q}^{\perp}\}\\ &= \{Pq \mid q \in \mathfrak{q} \text{ and } \Gamma q \in \operatorname{dom}\rho = Q(\mathfrak{p}^{\perp})\}\\ &= \{Pq \mid q \in \mathfrak{q} \text{ and } q \in \Gamma Q(\mathfrak{p}^{\perp}) = Q(\Gamma\mathfrak{p}^{\perp}) = Q\mathfrak{p}\} = PQ\mathfrak{p} = PQP\mathfrak{h},\end{aligned}$$

which is dense in $\mathfrak{p}$. Furthermore, since $P\Gamma Qp = -PQ^{\perp}\Gamma p$, $p \in \mathfrak{p}$ (recall $P\Gamma p = 0$, $p \in \mathfrak{p}$), we have

$$\Delta_{\mathfrak{p}}(PQp) = \alpha(P\Gamma Qp) = -\alpha(PQ^{\perp}\Gamma p) = P\Gamma Q^{\perp}\Gamma p = PQ^{\perp}p, \quad p \in \mathfrak{p}.$$

The last equations concerning the inverse of $\Delta_{\mathfrak{p}}$ follow from the preceding computation and from the fact that $\alpha^2 = \mathrm{id}$ and $\beta^2 = \mathrm{id}$ on the corresponding domains (recall Lemma 4.10). ■

Note that $\operatorname{dom}\Delta_{\mathfrak{p}} = PQ\mathfrak{p}$ is dense in $\mathfrak{p}$ and that $\Delta_{\mathfrak{p}}^{-1/2} = |\alpha|$, hence $\operatorname{dom}\Delta_{\mathfrak{p}}^{-1/2} = P(\mathfrak{q}^{\perp})$. Next we will calculate the graph of the positive self-adjoint operator $\varphi^*\varphi : \mathfrak{q} \to \mathfrak{q}$.

Proposition 4.13: The graph of $\varphi^*\varphi$ is given by

$$\operatorname{gra}\varphi^*\varphi = \{(QPq, QP^{\perp}q) \mid q \in \mathfrak{q}\}.$$

Proof: We begin computing $\operatorname{dom}(\varphi^*\varphi)$. Since by Lemma 4.2 $\varphi^* = \rho^{-1}$ we have

$$\begin{aligned}\operatorname{dom}(\varphi^*\varphi) &= \{Qp \mid p \in \mathfrak{p} \text{ and } Q^{\perp}p \in \operatorname{dom}\rho^{-1} = Q^{\perp}\mathfrak{p}^{\perp}\}\\ &= \{Qp \mid p \in \mathfrak{p} \text{ and } Q^{\perp}p = Q^{\perp}p^{\perp} \text{ for some } p^{\perp} \in \mathfrak{p}^{\perp}\}\\ &= \{Qp \mid p = Pq \text{ for some } q \in \mathfrak{q}\} = QP\mathfrak{q} = QPQ\mathfrak{h},\end{aligned}$$

where for the third equation we have used Corollary 4.4. Using again this corollary we can calculate

$$\rho^{-1}(\varphi(QPq)) = \rho^{-1}(Q^{\perp}Pq) = \rho^{-1}(Q^{\perp}(-P^{\perp}q)) = QP^{\perp}q, \quad q \in \mathfrak{q},$$

and the proof is concluded. ■

Now we can relate φ and $\varphi^*\varphi$ with $\Delta_{\mathfrak{p}}$ just computing the orthogonal decomposition of $\varphi(q)$, $q \in \operatorname{dom}\varphi$, resp. $\varphi^*\varphi(q)$, $q \in \operatorname{dom}\varphi^*\varphi$, wrt $\mathfrak{h} = \mathfrak{p} \oplus \mathfrak{p}^{\perp}$.

Corollary 4.14: Using the notation before we have the following formulas:

$$\begin{aligned}\varphi(Qp) &= \Delta_{\mathfrak{p}}(PQp) - P^{\perp}Qp, \quad p \in \mathfrak{p},\\ (\varphi^*\varphi)(QPq) &= \Delta_{\mathfrak{p}}(PQPq) + \Gamma\,\Delta_{\mathfrak{p}}^{-1}(P\Gamma QPq), \quad q \in \mathfrak{q}.\end{aligned} \tag{20}$$

Proof: From Lemma 4.2 as well as Theorem 4.12 we have

$$\varphi(Qp) = Q^{\perp}p = PQ^{\perp}p + P^{\perp}Q^{\perp}p = \Delta_{\mathfrak{p}}(PQp) - P^{\perp}Qp, \quad p \in \mathfrak{p}.$$

Further, from the preceding proposition we also have for any $q \in \mathfrak{q}$

$$\begin{aligned}(\varphi^*\varphi)(QPq) = QP^{\perp}q &= PQP^{\perp}q + P^{\perp}QP^{\perp}q\\ &= PQ^{\perp}Pq + \Gamma PQP\Gamma q\\ &= \Delta_{\mathfrak{p}}(PQPq) + \Gamma\,\Delta_{\mathfrak{p}}^{-1}(PQ^{\perp}P\Gamma q)\\ &= \Delta_{\mathfrak{p}}(PQPq) + \Gamma\,\Delta_{\mathfrak{p}}^{-1}(PQP^{\perp}\Gamma q)\\ &= \Delta_{\mathfrak{p}}(PQPq) + \Gamma\,\Delta_{\mathfrak{p}}^{-1}(P\Gamma QPq),\end{aligned}$$

which proves the second formula. ■

We will give the next two formulas in terms of $\Delta_{\mathfrak{p}}^{1/2}$ for the components of the polar decomposition of φ. Denote $\varphi=\operatorname{sgn}\varphi\cdot|\varphi|$, where as usual $|\varphi|:=(\varphi^*\varphi)^{1/2}$. Recall from the results in this section that

$$\operatorname{dom}\varphi=\operatorname{dom}|\varphi|=Q\mathfrak{p}\supseteq QP\mathfrak{q}=\operatorname{dom}(\varphi^*\varphi),$$

$$\operatorname{dom}\beta=\operatorname{dom}|\beta|=P\mathfrak{q}\supseteq PQ\mathfrak{p}=\operatorname{dom}\Delta_{\mathfrak{p}}.$$

Theorem 4.15: *With the notation above we have*

$$|\varphi|(q)=\Delta_{\mathfrak{p}}^{1/2}(Pq)+\Gamma\,\Delta_{\mathfrak{p}}^{-1/2}(P\Gamma q),\quad q\in\operatorname{dom}\varphi^*\varphi=QP\mathfrak{q}, \tag{21}$$

$$\operatorname{sgn}\varphi(q)=\Delta_{\mathfrak{p}}^{1/2}(Pq)-\Gamma\,\Delta_{\mathfrak{p}}^{1/2}(P\Gamma q),\quad q\in\mathfrak{q}. \tag{22}$$

Moreover, $\operatorname{sgn}\varphi$ *is an isometry of* $\mathfrak{q}$ *onto* $\mathfrak{q}^{\perp}$, i.e., $(\operatorname{sgn}\varphi)^*\operatorname{sgn}\varphi=Q$ *and* $\operatorname{sgn}\varphi(\operatorname{sgn}\varphi)^*=Q^{\perp}$.

Proof: From the explicit knowledge of all the domains of the mappings used before it is easily seen that the formulas are well defined. Further, recall Proposition 4.13 and Corollary 4.14 and the fact that the two terms of the rhs of the above formulas correspond to the decomposition of $\mathfrak{h}$ in terms of $P\mathfrak{h}$ and $P^{\perp}\mathfrak{h}$. Applying now for $q\in\operatorname{dom}\varphi^*\varphi$ twice the rhs of (21) we get

$$\begin{aligned}&\Delta_{\mathfrak{p}}^{1/2}P(\Delta_{\mathfrak{p}}^{1/2}(Pq)+\Gamma\,\Delta_{\mathfrak{p}}^{-1/2}(P\Gamma q))+\Gamma\,\Delta_{\mathfrak{p}}^{-1/2}P\Gamma(\Delta_{\mathfrak{p}}^{1/2}(Pq)+\Gamma\,\Delta_{\mathfrak{p}}^{-1/2}(P\Gamma q))\\&\quad=\Delta_{\mathfrak{p}}(Pq)+\Gamma\Delta_{\mathfrak{p}}^{-1}(P\Gamma q)=(\varphi^*\varphi)(q),\end{aligned}$$

which shows the first formula. To prove the second one note first that for $q'=|\varphi|(q)$, $q\in\operatorname{dom}\varphi^*\varphi$, and using Eq. (21) as well as Corollary 4.14 we obtain from a similar calculation as before that

$$(\Delta_{\mathfrak{p}}^{1/2}P-\Gamma\,\Delta_{\mathfrak{p}}^{1/2}P\Gamma)|\varphi|(q')=(\Delta_{\mathfrak{p}}P-P^{\perp})(q')=\varphi(q').$$

Thus the rhs and the lhs of (22) coincide on the dense subspace $\operatorname{ima}\varphi^*\varphi$. Finally, the fact that the rhs is also well defined for all $q\in\mathfrak{q}$ (recall that $\operatorname{dom}\Delta_{\mathfrak{p}}^{1/2}=\operatorname{dom}\beta=P\mathfrak{q}$) and that $\operatorname{sgn}\varphi$ maps isometrically the dense subspace $\operatorname{ima}|\varphi|\subseteq\mathfrak{q}$ onto the dense subspace $\operatorname{ima}\varphi=Q^{\perp}\mathfrak{p}\subseteq\mathfrak{q}^{\perp}$ proves formula (22). Therefore Q is the initial projection of $\operatorname{sgn}\varphi$ and $Q^{\perp}$ is the corresponding final projection. ■

Remark 4.16: Recall that $\operatorname{dom}\varphi^*\varphi$ is a core for $|\varphi|$ and note that the rhs of formula (21) *can not* be extended to the whole $\operatorname{dom}|\varphi|$.

Finally, we consider the mapping

$$\mathfrak{q}\ni q\mapsto Wq:=(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}Pq\in\mathfrak{p}. \tag{23}$$

Lemma 4.17: W is an isometry from $\mathfrak{q}$ *onto* $\mathfrak{p}$.

Proof: First choose $q_1,q_2\in Q\mathfrak{p}$ which is dense in $\mathfrak{q}$. Now using

$$\langle Pq_1,\Delta_{\mathfrak{p}}(Pq_2)\rangle=\langle Pq_1,\beta^*\beta(Pq_2)\rangle=\langle\beta(Pq_2),\beta(Pq_1)\rangle=\langle P^{\perp}q_1,P^{\perp}q_2\rangle$$

we obtain

$$\langle(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}Pq_1,(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}Pq_2\rangle=\langle Pq_1,(\mathbb{1}+\Delta_{\mathfrak{p}})Pq_2\rangle=\langle q_1,q_2\rangle,\ q_1,q_2\in Q\mathfrak{p}.$$

Further, for any $p\in\mathfrak{p}$ we have from Theorem 4.12 that $(\mathbb{1}+\Delta_{\mathfrak{p}})(PQp)=PQp+PQ^{\perp}p=p$. This implies that $\operatorname{ima}(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}=\mathfrak{p}$, since

$$\mathfrak{p}=\operatorname{ima}(\mathbb{1}+\Delta_{\mathfrak{p}})\subseteq\operatorname{ima}(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}\subseteq\mathfrak{p}.$$

Therefore (23) is the isometric extension of $W\restriction Q\mathfrak{p}$. ■

Using now the isometry W we conclude this section showing the unitary equivalence of $|\varphi|$ and $\Delta_{\mathfrak{p}}^{1/2}$.

Theorem 4.18: *With the preceding notation we have*

$$W|\varphi|(q)=\Delta_{\mathfrak{p}}^{1/2}W(q),\quad q\in\mathrm{dom}\,|\varphi|.$$

Proof: For any $q\in\mathrm{dom}\,\varphi^*\varphi$, which is a core of $|\varphi|$, we may use (21) and in this case

$$W|\varphi|(q)=(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}P(\Delta_{\mathfrak{p}}^{1/2}(Pq)+\Gamma\,\Delta_{\mathfrak{p}}^{-1/2}(P\Gamma q))=(\mathbb{1}+\Delta_{\mathfrak{p}})^{1/2}\Delta_{\mathfrak{p}}^{1/2}(Pq)=\Delta_{\mathfrak{p}}^{1/2}W(q).$$

But this implies that $W|\varphi|W^*\subseteq\Delta_{\mathfrak{p}}^{1/2}$ and since the lhs as well as the rhs of the preceding inclusion are self-adjoint operators, we must actually have the equality $W|\varphi|W^*=\Delta_{\mathfrak{p}}^{1/2}$. ■

V. TWISTED DUALITY. THE GENERIC POSITION CASE

We begin the proof of twisted duality considering first one of the extremal cases that may appear in the Halmos decomposition (10). For this assume that $(\mathfrak{h},\Gamma)$, P and Q are given as in the preceding section. In particular $\mathfrak{p}$ and $\mathfrak{q}$ are in generic position, so that by Proposition 3.4 the modular theory is well defined for the pair $(\mathcal{M}(\mathfrak{q}),\Omega)$. Denote as usual by $S=J\Delta^{1/2}$ the polar decomposition of the Tomita operator.

We prove first that the different modular objects leave the n-particle submanifolds $\overset{n}{\wedge}(P\mathfrak{q})$ invariant. This fact is well known in the context of CCR-Algebras,[27] where one can use the so-called exponential vectors which are specially well adapted to the Weyl operators.

Proposition 5.1: Let $q_1,\ldots,q_n\in\mathfrak{q}$ and $q_1^\perp,\ldots,q_n^\perp\in\mathfrak{q}^\perp$. *Then the following equations hold:*

$$S(Pq_1\wedge\cdots\wedge Pq_n)=P\Gamma q_n\wedge\cdots\wedge P\Gamma q_1=S(Pq_n)\wedge\cdots\wedge S(Pq_1),$$

$$S^*(Pq_1^\perp\wedge\cdots\wedge Pq_n^\perp)=S^*(Pq_n^\perp)\wedge\cdots\wedge S^*(Pq_1^\perp).$$

Proof: The proof is done by induction on the number of vectors in the wedge product. For $n=1$ the above equations are trivially satisfied (cf. Lemma 3.5). We will now concentrate on the first formula since one can argue similarly for S^*. Suppose that the first expression holds for a number of vectors $\leqslant n-1$. Then, applying this induction hypothesis as well as Proposition 2.2 we get

$$\begin{aligned}
&S(P\Gamma q_n\wedge\cdots\wedge P\Gamma q_1)\\
&\quad=S\left(a(q_n)\cdot\cdots\cdot a(q_1)\,\Omega-\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\ p\geqslant 1}}(\mathrm{sgn}\,\pi)\prod_{l=1}^{p}\langle Pq_{\alpha_l},P\Gamma q_{\beta_l}\rangle\,P\Gamma q_{j_1}\wedge\cdots\wedge P\Gamma q_{j_k}\right)\\
&\quad=a(\Gamma q_1)\cdot\cdots\cdot a(\Gamma q_n)\,\Omega-\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\ p\geqslant 1}}(\mathrm{sgn}\,\pi)\prod_{l=1}^{p}\langle P\Gamma q_{\beta_l},Pq_{\alpha_l}\rangle\,Pq_{j_k}\wedge\cdots\wedge Pq_{j_1},\qquad(24)
\end{aligned}$$

and recall that the indices specified by $\pi\in\mathfrak{S}_{n,p}$ satisfy $\alpha_1>\cdots>\alpha_p$, $\alpha_l>\beta_l$, $l=1,\ldots,p$ and $n\geqslant j_1>j_2>\cdots>j_k\geqslant 1$. But we can now apply again Proposition 2.2 to the first term of the preceding sum and we get

$$a(\Gamma q_1)\cdot\cdots\cdot a(\Gamma q_n)\,\Omega=Pq_1\wedge\cdots\wedge Pq_n+\sum_{\substack{\pi'\\ p\geqslant 1}}(\mathrm{sgn}\,\pi')\prod_{l=1}^{p}\langle P\Gamma q_{\alpha_l'},Pq_{\beta_l'}\rangle\,Pq_{j_1'}\wedge\cdots\wedge Pq_{j_k'},\qquad(25)$$

where now

$$\pi'=\begin{pmatrix} 1 & 2 & \cdots & 2p-1 & 2p & n-k+1 & \cdots & n \\ \alpha_1' & \beta_1' & \cdots & \alpha_p' & \beta_p' & j_1' & \cdots & j_k' \end{pmatrix}$$

with $\alpha_l'<\beta_l'$, $l=1,\ldots,p$, $1\leqslant j_1'<j_2'<\cdots<j_k'\leqslant n$ and we may reorganize the scalar products such that $\beta_1'<\cdots<\beta_p'$. We can next associate bijectively these permutations with elements in $\mathfrak{S}_{n,p}$ by means of

$$\pi'\mapsto\pi_0=\begin{pmatrix} n & n-1 & \cdots & n-2p+2 & n-2p+1 & k & \cdots & 1 \\ \beta_p' & \alpha_p' & \cdots & \beta_1' & \alpha_1' & j_k' & \cdots & j_1' \end{pmatrix}\in\mathfrak{S}_{n,p}.$$

Since $\operatorname{sgn}\pi'=\operatorname{sgn}\pi_0'$ we have inserting (25) in (24) that all vectors with particle number less than n cancel so that

$$S(P\Gamma q_n\wedge\cdots\wedge P\Gamma q_1)=Pq_1\wedge\cdots\wedge Pq_n$$

and the proof is concluded. ■

Recall from Remark 4.11 (i) $S\restriction\mathfrak{p}\supseteq\beta$ and $S^*\restriction\mathfrak{p}\supseteq\alpha$. We will show next that actually the equality holds. Let P_n denote the projection of $\mathfrak{F}$ onto the n-particle subspace $\overset{n}{\wedge}\mathfrak{p}$. Then the family of orthoprojections $\{P_n\}_{n\in\mathbb{N}}$ is mutually orthogonal and $\Sigma_{n=0}^{\infty}P_n=\mathbb{1}_{\mathfrak{F}}$. Further we define the operator S_{fin} by

$$\operatorname{dom}S_{\text{fin}}:=\operatorname{span}\{a(q_1)\cdot\cdots\cdot a(q_n)\Omega\,|\,q_1,\ldots,q_n\in\mathfrak{q},n\in\mathbb{N}\cup\{0\}\},$$

$$S_{\text{fin}}x:=Sx,\quad x\in\operatorname{dom}S_{\text{fin}}.$$

Lemma 5.2: $\operatorname{dom}S_{\text{fin}}$ *is a core for the Tomita operator* S.

Proof: Put $\mathcal{C}:=\operatorname{dom}S_{\text{fin}}$ and denote by $\mathcal{A}(\mathfrak{q})$ the*-algebra generated by $\{a(q)|q\in\mathfrak{q}\}$, so that $\mathcal{M}(\mathfrak{q})=\mathcal{A}(\mathfrak{q})''$. Further, recall that if $S_0(M\Omega):=M^*\Omega$, $M\in\mathcal{M}(\mathfrak{q})$, then the graph of the Tomita operator $S=\operatorname{clo}S_0$ can be written as

$$\operatorname{gra}S=\operatorname{clo}_w(\operatorname{gra}S_0)=\operatorname{clo}_w\{(M\Omega,M^*\Omega)|M\in\mathcal{M}(\mathfrak{q})\},$$

where clo_w denotes the closure in the weak operator topology. Thus to prove the core property of $\mathcal{C}$, i.e., $\operatorname{clo}(S\restriction\mathcal{C})=S$, we need to show that

$$\operatorname{clo}_w\{(M\Omega,M^*\Omega)|M\in\mathcal{M}(\mathfrak{q})\}=\operatorname{clo}_w\{(A\Omega,A^*\Omega)|A\in\mathcal{A}(\mathfrak{q})\}.$$

Now for each $M\in\mathcal{M}(\mathfrak{q})$ there exists a sequence $\{A_n\}_{n\in\mathbb{N}}\subset\mathcal{A}(\mathfrak{q})$ with $|\langle x,(M-A_n)y\rangle|<\epsilon$ for all $x,y\in\mathfrak{F}$ if n is sufficiently large. This implies that for all $(x,y)\in\mathfrak{F}\times\mathfrak{F}$, we have

$$|\langle(M\Omega,M^*\Omega),(x,y)\rangle-\langle(A_n\Omega,A_n^*\Omega),(x,y)\rangle|=|\langle(M-A_n)\Omega,x\rangle-\langle(M^*-A_n^*)\Omega,y\rangle|\leqslant 2\epsilon,$$

where we have used that in the weak operator topology if $A_n\to M$, then $A_n^*\to M^*$. Therefore if $(M_l\Omega,M_l^*\Omega)\overset{l}{\to}(x_0,y_0)$ weakly, then for each l there exists a sequence $\{A_{(n,l)}\}_{n\in\mathbb{N}}\subset\mathcal{A}(\mathfrak{q})$ such that $(A_{(n,l)}\Omega,A_{(n,l)}^*\Omega)\overset{n}{\to}(M_l\Omega,M_l^*\Omega)$ weakly. Finally, the estimate

$$\begin{aligned}&|\langle(A_{(n,l)}\Omega,A_{(n,l)}^*\Omega),(x,y)\rangle-\langle(x_0,y_0),(x,y)\rangle|\\&\quad\leqslant|\langle(A_{(n,l)}\Omega,A_{(n,l)}^*\Omega),(x,y)\rangle-\langle(M_l\Omega,M_l^*\Omega),(x,y)\rangle|\\&\qquad+|\langle(M_l\Omega,M_l^*\Omega),(x,y)\rangle-\langle(x_0,y_0),(x,y)\rangle|\end{aligned}$$

completes the proof. ■

From Propositions 5.1 and 2.2 we obtain further

$$P_n \operatorname{dom} S_{\mathrm{fin}} \subseteq \operatorname{dom} S_{\mathrm{fin}}, \quad n=0,1,\ldots,$$

$$P_n \operatorname{dom} S_{\mathrm{fin}} \subset P_n \mathfrak{F} \text{ is dense}, \quad n=0,1,\ldots,$$

$$P_n S_{\mathrm{fin}} P_n = S_{\mathrm{fin}} P_n, \quad n=0,1,\ldots.$$

Note that for $x \in \operatorname{dom} S_{\mathrm{fin}}$ the series $x=\Sigma_{n=0}^{\infty} P_n x$ is a finite sum. Further, we consider the operators $S_{\mathrm{fin}}(n): P_n\mathfrak{F} \to P_n\mathfrak{F}$ by $\operatorname{dom} S_{\mathrm{fin}}(n) := P_n \operatorname{dom} S_{\mathrm{fin}}$ and $S_{\mathrm{fin}}(n)x := S_{\mathrm{fin}}x, x \in \operatorname{dom} S_{\mathrm{fin}}(n)$. Recall from Lemma 4.10 that $S_{\mathrm{fin}}(1)=\beta$ is a closed densely defined operator from $\mathfrak{p}=P_1\mathfrak{F}$ into $\mathfrak{p}$ and by the preceding arguments we have

$$S_{\mathrm{fin}} = \bigoplus_{n=0}^{\infty} S_{\mathrm{fin}}(n) \quad \text{(algebraic direct sum)}. \tag{26}$$

We can now state the following.

Proposition 5.3: The Tomita operator S and its adjoint S^* can be restricted to the n-particles subspaces $P_n\mathfrak{F}$. We have

$$S \restriction P_n\mathfrak{F} = \operatorname{clo} S_{\mathrm{fin}}(n) \quad \text{and} \quad S^* \restriction P_n\mathfrak{F} = \operatorname{clo} S_{\mathrm{fin}}^*(n), \quad n=0,1,\ldots.$$

In particular $S \restriction \mathfrak{p} = \beta$ and $S^* \restriction \mathfrak{p} = \alpha$.

Proof: From (26) we obtain immediately that

$$\operatorname{gra} S = \bigoplus_{n=0}^{\infty} \operatorname{clo} \operatorname{gra} S_{\mathrm{fin}}(n) = \mathbb{C}\Omega \oplus \operatorname{gra} S_{\mathrm{fin}}(1) \oplus \sum_{n=2}^{\infty} \operatorname{clo} \operatorname{gra} S_{\mathrm{fin}}(n) \quad \text{(Hilbert sum)}. \tag{27}$$

Note that $\operatorname{clo} \operatorname{gra} S_{\mathrm{fin}}(n) = \operatorname{gra} \operatorname{clo} S_{\mathrm{fin}}(n)$, $n \geqslant 2$, and that now the direct sum (27), in contrast to (26), is the Hilbert sum of these subspaces. Equation (27) implies immediately the assertion that S can be restricted to $P_n\mathfrak{F}$ and that the restriction coincides with $\operatorname{clo} S_{\mathrm{fin}}(n)$, in particular $S \restriction \mathfrak{p} = \beta$. The statements concerning S^* are shown analogously. ■

Corollary 5.4: Let $S = J\Delta^{1/2}$ be the polar decomposition of the Tomita operator. The modular operator $\Delta = S^*S$ and the modular conjugation J can be restricted to the respective n-particle subspaces. In particular we have the following:

(i) Modular operator: $\Delta \restriction \mathfrak{p} = \Delta_{\mathfrak{p}}$ (*recall from the preceding section that* $\Delta_{\mathfrak{p}} = \beta^*\beta$), $\operatorname{dom} \Delta \restriction P_n\mathfrak{F} = \overset{n}{\wedge} \operatorname{dom} \Delta_{\mathfrak{p}}$ and

$$\Delta(p_1 \wedge \cdots \wedge p_n) = (\Delta_{\mathfrak{p}} p_1) \wedge \cdots \wedge (\Delta_{\mathfrak{p}} p_n), \quad p_1,\ldots,p_n \in \operatorname{dom} \Delta_{\mathfrak{p}} = PQ\mathfrak{p}. \tag{28}$$

(ii) Modular conjugation:

$$J(p_1 \wedge \cdots \wedge p_n) = (Jp_n) \wedge \cdots \wedge (Jp_1), \quad p_1,\ldots,p_n \in \mathfrak{p}. \tag{29}$$

Proof: Note first that from Proposition 5.3 and Lemma 4.10 we have $S^*S \restriction \mathfrak{p} = \alpha\beta = \beta^*\beta$. Further, Eq. (28) follows from Propositions 5.1 and 5.3. Next, applying formula (29) to the n-particle vectors $\Delta^{1/2}(p_1 \wedge \cdots \wedge p_n)$, where $p_k := \Delta_{\mathfrak{p}}^{1/2} p_k'$, $p_k' \in \operatorname{dom} \Delta_{\mathfrak{p}}$, $k=1,\ldots,n$, we obtain $S(p_1 \wedge \cdots \wedge p_n)$. Thus Eq. (29) coincides with $J \restriction P_n\mathfrak{F}$ on the dense set $(\operatorname{ima} \Delta_{\mathfrak{p}}) \wedge \cdots \wedge (\operatorname{ima} \Delta_{\mathfrak{p}})$, which concludes the proof. ■

For the next definition recall the formulas concerning $\operatorname{sgn} \varphi$ in Theorem 4.15.

Definition 5.5: Define the following antilinear isometry from $\mathfrak{q}$ onto $\mathfrak{q}^{\perp}$:

$$Vq := -i(\Gamma \operatorname{sgn} \varphi)(q) = i(\Delta_{\mathfrak{p}}^{1/2} P\Gamma q - \Gamma \Delta_{\mathfrak{p}}^{1/2} Pq), \quad q \in \mathfrak{q}.$$

Theorem 5.6: *With the preceding definition we have for any* $q \in \mathfrak{q}$

$$J\,a(q)\,J = \tilde{Z}\,a(Vq)\,\tilde{Z}^*. \tag{30}$$

Proof: Since $\oplus_{n=0}^{\infty} \overset{n}{\wedge} P\mathfrak{q}$ (algebraic direct sum) is dense in $\mathfrak{F}$ and the operators on both sides of Eq. (30) are bounded it is enough to show the preceding relation for the n-particle vectors in $\overset{n}{\wedge} P\mathfrak{q}$. For $q_1,\ldots,q_n \in \mathfrak{q}$ and using Corollary 5.4 (ii) the lhs of the equation reads

$$\begin{aligned}(J\,a(q)\,J)(Pq_1\wedge\cdots\wedge Pq_n) &= Pq_1\wedge\cdots\wedge Pq_n\wedge JP\Gamma q \\ &\quad + \sum_{r=n}^{1} (-1)^{n-r}\,\langle JPq, Pq_r\rangle\, Pq_1\wedge\cdots\wedge\widehat{Pq_r}\wedge\cdots\wedge Pq_n\,.\end{aligned}$$

To compute the rhs recall the definition of the function η in Sec. II B:

$$\begin{aligned}(\tilde{Z}\,a(Vq)\,\tilde{Z}^*)(Pq_1\wedge\cdots\wedge Pq_n) &= -i\,\overline{\eta(n)}\,\tilde{Z}\cdot(-c(\Delta_{\mathfrak{p}}^{1/2}Pq)^*Pq_1\wedge\cdots\wedge Pq_n \\ &\quad + c(\Delta_{\mathfrak{p}}^{1/2}P\Gamma q)Pq_1\wedge\cdots\wedge Pq_n) \\ &= Pq_1\wedge\cdots\wedge Pq_n\wedge\Delta_{\mathfrak{p}}^{1/2}Pq \\ &\quad + \sum_{r=1}^{n} (-1)^{n-r}\,\langle\Delta_{\mathfrak{p}}^{1/2}P\Gamma q, Pq_r\rangle\, Pq_1\wedge\cdots\wedge\widehat{Pq_r}\wedge\cdots\wedge Pq_n\,,\end{aligned}$$

where for the last equation we have used that $-i\,\overline{\eta(n)}\,\eta(n+1) = -i\,\overline{\eta(n)}\,\eta(n-1) = (-1)^{n+1}$. Finally, the equality of both sides follows from the fact that $\Delta_{\mathfrak{p}}^{1/2}Pq = JSPq = JP\Gamma q,\ q \in \mathfrak{q}$. ■

Remark 5.7: As expected we can relate the mapping V defined before with the mapping j (the modular conjugation restricted to the one-particle Hilbert space) used in Ref. 20, p. 738. Indeed, considering the projection onto the one-particle Hilbert space we have the relation

$$J(Pq) = \Delta_{\mathfrak{p}}^{1/2}S(Pq) = \Delta_{\mathfrak{p}}^{1/2}(P\Gamma q) = -iPV(q), \quad q \in \mathfrak{q}.$$

Theorem 5.8: (*Twisted Duality*) *Let* $\mathcal{M}(\mathfrak{q})$ *be the von Neumann algebra given at the beginning of this section. Then*

$$\mathcal{M}(\mathfrak{q})' = \tilde{Z}\,\mathcal{M}(\mathfrak{q}^{\perp})\,\tilde{Z}^*.$$

Proof: From the last theorem and using standard results in modular theory we have

$$\begin{aligned}\mathcal{M}(\mathfrak{q})' &= J\,\mathcal{M}(\mathfrak{q})\,J = J\,\{a(q)\,|\,q \in \mathfrak{q}\}''\,J \\ &= \{J\,a(q)\,J\,|\,q \in \mathfrak{q}\}'' \\ &= \{\tilde{Z}\,a(Vq)\,\tilde{Z}^*\,|\,q \in \mathfrak{q}\}'' \\ &= \tilde{Z}\,\{a(Vq)\,|\,q \in \mathfrak{q}\}''\tilde{Z}^* = \tilde{Z}\,\mathcal{M}(\mathfrak{q}^{\perp})\,\tilde{Z}^*,\end{aligned}$$

where we have used that V is an antilinear isometry from $\mathfrak{q}$ onto $\mathfrak{q}^{\perp}$. ■

Remark 5.9: If one does not want to bother about domain questions, there is possibly an alternative way to show the preceding result. Indeed, one can first prove the statements in this section for finite dimensional subspaces $\mathfrak{q}_n$ of $\mathfrak{q}$ and then apply the AFD-property of $\mathcal{M}(\mathfrak{q})$ as in the proof of Ref. 9, Theorem 15.1.3.

We will finally show that the formulas established in the previous and present sections also apply to the localized algebras that appear in the context of fermionic free nets (cf. Refs. 8 and 28). Let $\mathcal{O} \subset \mathbb{R}^4$ be a double cone in Minkowski space and denote by $\overline{\mathfrak{q}(\mathcal{O})}$ the closure of the

subspaces $\mathfrak{q}(\mathcal{O})$ of the reference Hilbert space $(\mathfrak{h},\Gamma)$. The subspaces $\mathfrak{q}(\mathcal{O})$ are defined in terms of the embeddings that characterize the free nets (essentially Fourier transformation of C^∞ functions with compact support restricted to the positive mass shell/light cone). It is easily shown that $\Gamma\mathfrak{q}(\mathcal{O})=\mathfrak{q}(\mathcal{O})$, hence $\Gamma\overline{\mathfrak{q}(\mathcal{O})}=\overline{\mathfrak{q}(\mathcal{O})}$. Further, the localized C*-algebras are again CAR-algebras, i.e.,

$$\mathcal{A}(\mathcal{O}):=\mathrm{C}^*(\{a(\varphi)\,|\,\varphi\in\mathfrak{q}(\mathcal{O})\})=\mathrm{CAR}(\mathfrak{q}(\mathcal{O}),\Gamma\restriction\mathfrak{q}(\mathcal{O}))=\mathrm{CAR}(\overline{\mathfrak{q}(\mathcal{O})},\Gamma\restriction\overline{\mathfrak{q}(\mathcal{O})})\subset\mathrm{CAR}(\mathfrak{h},\Gamma).$$

For the canonical basis projection P given in the context of free nets (see, e.g., Ref. 28, p. 1157) it is also immediate to check that for double cones

$$\mathfrak{p}\cap\overline{\mathfrak{q}(\mathcal{O})}=\mathfrak{p}\cap\overline{\mathfrak{q}(\mathcal{O})}^{\perp}=\{0\},\quad\text{where }\ \mathfrak{p}=P\mathfrak{h}.$$

This means that $\mathfrak{p}$ and $\overline{\mathfrak{q}(\mathcal{O})}$ are in generic position and we can apply the results and formulas of the previous and present sections to the corresponding localized von Neumann algebras

$$\mathcal{M}(\mathcal{O}):=\{\pi(a(\varphi))\,|\,\varphi\in\overline{\mathfrak{q}(\mathcal{O})}\}''.$$

In particular, from Proposition 5.3 and Corollary 5.4 we have that the modular operator Δ and the modular conjugation J are already characterized by their action on the one-particle Hilbert space. Finally, Theorem 4.12 and Remark 5.7 imply the following theorem.

Theorem 5.10: *Let $\mathcal{O}\subset\mathbb{R}^4$ be a double cone in Minkowski space. Denote by $Q_{\mathcal{O}}$ the orthoprojection onto $\overline{\mathfrak{q}(\mathcal{O})}$ and by P the canonical basis projection given in the context of fermionic free nets. Then the following formulas hold for the modular operator and modular conjugation on the one-particle Hilbert space $\mathfrak{p}$:*

$$\mathrm{gra}\,\Delta_{\mathfrak{p}}=\{(PQ_{\mathcal{O}}(p),PQ^{\perp}_{\mathcal{O}}(p))\,|\,p\in\mathfrak{p}\},$$

$$J(Pq)=\Delta_{\mathfrak{p}}^{1/2}(P\Gamma q),\quad q\in\overline{\mathfrak{q}(\mathcal{O})}.$$

VI. RELATION TO THE REAL SUBSPACE APPROACH

In the present section we will make explicit the relation of the real subspace approach in Refs. 20 and 32 to our consistent use of complex subspaces in the self-dual approach.

The projection $\mathcal{P}$ on the complex Hilbert space H with conjugation γ in Ref. 32 corresponds in the self-dual approach [where $\mathfrak{h}:=H\oplus H$ and $\Gamma:=\left(\begin{smallmatrix}0&\gamma\\ \gamma&0\end{smallmatrix}\right)$] to a diagonal basis projection $\mathfrak{P}:=\left(\begin{smallmatrix}\mathcal{P}&0\\ 0&\gamma\mathcal{P}^{\perp}\gamma\end{smallmatrix}\right)$. Nondiagonal basis projections are not considered in Ref. 32. Further, in that article the author extends by second quantization certain mappings on the one-particle Hilbert space. He has then to verify that these second quantized operators are the modular objects by checking the KMS condition. (In contrast to that we construct the modular objects on the whole antisymmetric Fock space and show that they restrict to the n-particle space.)

The following aspect is that in Ref. 20 (and Ref. 32) real-linear closed manifolds M (resp. K) of the one-particle (complex) space H ($\mathfrak{p}$ in our article) are used, whereas here the subalgebras of the "big" fermion algebra $\mathrm{CAR}(\mathfrak{h},\Gamma)$ are characterized by Γ-invariant complex subspaces of the reference space $\mathfrak{h}$. The relation between the two approaches is given by the following observations: first, the counterpart of the real M in our approach is given by $P(\mathrm{Re}(\mathfrak{q}))$, where $q\in\mathrm{Re}(\mathfrak{q})$ if $\Gamma q=q$. Note that $P(\mathrm{Re}(\mathfrak{q}))$ is a real-linear submanifold of $\mathfrak{p}$ and in general it is *not* closed (see the foregoing considerations). Now we still need to check that $P(\mathrm{Re}(\mathfrak{q}^{\perp}))$ corresponds in the real subspace approach of Ref. 20 to iM'. (Recall that in Ref. 20 one defines M' as the symplectic complement, i.e., $M':=\{x\in H\,|\,\mathrm{Im}\langle x,m\rangle=0,\ m\in M\}\supset M^{\perp}$.) The next result shows that indeed $P(\mathrm{Re}(\mathfrak{q}^{\perp}))$ and iM' generate the same von Neumann algebra.

Lemma 6.1: Put $M:=P(\mathrm{Re}(\mathfrak{q}))$. Then $P(\mathrm{Re}(\mathfrak{q}^{\perp}))$ is dense in (iM').

Proof: We show first that $P(\mathrm{Re}(\mathfrak{q}^{\perp}))\subseteq(iM')$. For any $(q^{\perp}+\Gamma q^{\perp})\in\mathrm{Re}(\mathfrak{q}^{\perp})$, $q^{\perp}\in\mathfrak{q}^{\perp}$, and since

$$iM' := \{p \in \mathfrak{p} | \langle q+\Gamma q, p\rangle + \langle p, q+\Gamma q\rangle = 0,\ \ q \in \mathfrak{q}\},$$

the inclusion follows from

$$\begin{aligned}\langle q+\Gamma q, P(q^\perp+\Gamma q^\perp)\rangle + \langle P(q^\perp+\Gamma q^\perp), q+\Gamma q\rangle &= (\langle q, Pq^\perp\rangle + \langle P\Gamma q^\perp, \Gamma q\rangle)\\ &\quad + (\langle \Gamma q, Pq^\perp\rangle + \langle P\Gamma q^\perp, q\rangle)\\ &\quad + (\langle q, P\Gamma q^\perp\rangle + \langle Pq^\perp, \Gamma q\rangle)\\ &\quad + (\langle \Gamma q, P\Gamma q^\perp\rangle + \langle P\Gamma q^\perp, q\rangle)\\ &= 0,\end{aligned}$$

where for the last equation we have used $\Gamma P + P\Gamma = \Gamma$. Finally, to show the density statement consider $p_0 \in iM'$, i.e.,

$$\langle q+\Gamma q, p_0\rangle + \langle p_0, q+\Gamma q\rangle = 0,\ \ q \in \mathfrak{q}, \tag{31}$$

such that $p_0 \perp P(q^\perp+\Gamma q^\perp)$ for all $q^\perp \in \mathfrak{q}^\perp$. Thus $\langle p_0, P(q^\perp+\Gamma q^\perp)\rangle = 0$, $q^\perp \in \mathfrak{q}^\perp$, and replacing $q^\perp$ by $iq^\perp$ we also obtain $\langle p_0, P(q^\perp-\Gamma q^\perp)\rangle = 0$, $q^\perp \in \mathfrak{q}^\perp$. Hence $\langle p_0, Pq^\perp\rangle = 0$, $q^\perp \in \mathfrak{q}^\perp$, and $p_0 \in \mathfrak{q} \cap \mathfrak{p}$. But according to Eq. (31) we must also have $\langle p_0+\Gamma p_0, p_0\rangle + \langle p_0, p_0+\Gamma p_0\rangle = 0$, which implies $p_0 = 0$. ■

Finally, the conditions $M \cap iM = \{0\}$ and $M + iM$ dense in H in Ref. 20 are equivalent to our conditions $\mathfrak{q} \cap \mathfrak{p} = \{0\} = \mathfrak{q}^\perp \cap \mathfrak{p}$ and the projections P_1, P_2, P_3 in Ref. 20, Proposition 1.5, correspond in the self-dual approach to the orthoprojections onto $\mathfrak{p} \cap \mathfrak{q}^\perp$, $\mathfrak{p} \cap \mathfrak{q}$, $\mathfrak{p} \ominus (\mathfrak{p} \cap \mathfrak{q}^\perp \oplus \mathfrak{p} \cap \mathfrak{q})$, respectively.

VII. TWISTED DUALITY. THE GENERAL CASE

We are now in a position to give the proof of twisted duality in the most general situation. Let $(\mathfrak{h}, \Gamma)$ be a Hilbert space with anti-unitary involution Γ, P *any* basis projection and $\mathfrak{q}$ *any* closed Γ-invariant subspace in $\mathfrak{h}$, to which we associate the orthoprojection Q. We adapt the arguments in Ref. 20, p. 735, to the self-dual approach.

Recall the Halmos decompostion $\mathfrak{h} = \mathfrak{h}_0 \oplus \mathfrak{h}_1$ given in Eq. (10), where $\mathfrak{h}_0 = (\mathfrak{p} \cap \mathfrak{q}) \oplus (\mathfrak{p} \cap \mathfrak{q}^\perp) \oplus (\mathfrak{p}^\perp \cap \mathfrak{q}) \oplus (\mathfrak{p}^\perp \cap \mathfrak{q}^\perp)$. Since $\Gamma(\mathfrak{p} \cap \mathfrak{q}^\perp) = (\mathfrak{p}^\perp \cap \mathfrak{q}^\perp)$ and $\Gamma(\mathfrak{p} \cap \mathfrak{q}) = (\mathfrak{p}^\perp \cap \mathfrak{q})$ it is also natural to consider the previous decomposition as

$$\mathfrak{h} = \mathfrak{h}_{01} \oplus \mathfrak{h}_{02} \oplus \mathfrak{h}_1, \tag{32}$$

where $\mathfrak{h}_{01} := (\mathfrak{p} \cap \mathfrak{q}^\perp) \oplus \Gamma(\mathfrak{p} \cap \mathfrak{q}^\perp)$ and $\mathfrak{h}_{02} := (\mathfrak{p} \cap \mathfrak{q}) \oplus \Gamma(\mathfrak{p} \cap \mathfrak{q})$. In particular, we have

$$Q\mathfrak{h}_{01} = \{0\}, \quad Q\mathfrak{h}_{02} = \mathfrak{h}_{02}, \tag{33}$$

$$Q^\perp \mathfrak{h}_{01} = \mathfrak{h}_{01}, \quad Q^\perp \mathfrak{h}_{02} = \{0\}, \tag{34}$$

as well as

$$\mathfrak{q} = \{0\} \oplus \mathfrak{h}_{02} \oplus Q\mathfrak{h}_1 \quad \text{and} \quad \mathfrak{q}^\perp = \mathfrak{h}_{01} \oplus \{0\} \oplus Q^\perp \mathfrak{h}_1.$$

Theorem 7.1: (*Twisted Duality*) *Let* $(\mathfrak{h}, \Gamma)$, *P and* $\mathfrak{q}$ *be given as in the beginning of this section. Then*

$$\mathcal{M}(\mathfrak{q})' = \tilde{Z}\, \mathcal{M}(\mathfrak{q}^\perp)\, \tilde{Z}^*.$$

Proof: From Proposition 2.6 it is enough to show the inclusion

$$\mathcal{M}(\mathfrak{q})' \subseteq \tilde{Z}\, \mathcal{M}(\mathfrak{q}^\perp)\, \tilde{Z}^*. \tag{35}$$

We can apply now the formulas (5) *and* (6) in Proposition 2.4 to the three-space decomposition in Eq. (32). Indeed, adapting in the obvious way the notation from Proposition 2.4 we get that

$$\pi(a(f_{01}\oplus f_{02}\oplus f_1))=\pi_{01}(a(f_{01}))\otimes Z_{02}\otimes Z_1+1\otimes\pi_{02}(a(f_{02}))\otimes 1+1\otimes Z_{02}\otimes\pi_1(a(f_1)),$$

$f_1\in\mathfrak{h}_1$, $f_{0k}\in\mathfrak{h}_{0k}$, $k=1,2$, specifies a representation of CAR$(\mathfrak{h},\Gamma)$ on the corresponding tensor product of antisymmetric Fock spaces $\mathfrak{F}=\mathfrak{F}_{01}\otimes\mathfrak{F}_{02}\otimes\mathfrak{F}_1$. Now using (33) we obtain

$$\mathcal{M}(\mathfrak{q})=\mathrm{Cl}\otimes\mathcal{L}(\mathfrak{F}_{02})\otimes\mathcal{M}(Q\mathfrak{h}_1),$$

hence

$$\mathcal{M}(\mathfrak{q})'=\mathcal{L}(\mathfrak{F}_{01})\otimes\mathrm{Cl}\otimes\mathcal{M}(Q\mathfrak{h}_1)'.$$

From (34) we also obtain

$$\mathcal{M}(\mathfrak{q}^\perp)=\mathcal{L}(\mathfrak{F}_{01})\otimes\{Z_{02}\}''\otimes\mathcal{M}(Q^\perp\mathfrak{h}_1)=\{L_{01}\otimes Z_{02}\otimes\pi_1(a(f_1))|L_{01}\in\mathcal{L}(\mathfrak{F}_{01}),\quad f_1\in Q^\perp\mathfrak{h}_1\}''.$$

Using now the result stated in Remark 2.8 we have for the twisted von Neumann algebra

$$\begin{aligned}\tilde{Z}\mathcal{M}(\mathfrak{q}^\perp)\tilde{Z}^*&=\{iZ\pi(a(q^\perp))|q^\perp\in\mathfrak{q}^\perp\}''\\&=\{(Z_{01}\otimes Z_{02}\otimes Z_1)\cdot(L_{01}\otimes Z_{02}\otimes\pi_1(a(f_1)))|L_{01}\in\mathcal{L}(\mathfrak{F}_{01}),\quad f_1\in Q^\perp\mathfrak{h}_1\}'',\end{aligned}$$

which immediately implies (35), since we have already proved twisted duality in the generic position case (cf. Theorem 5.8). ■

ACKNOWLEDGMENTS

It is a pleasure to thank Dr. H. Neidhardt for discussions on the subject, in particular on Proposition 4.7 and Theorem 4.18. We would like to acknowledge the remark of a referee (concerning Sec. VII) pointing at the arguments in Ref. 20, p. 735. Finally, one of us (F.L.) wants to thank Dr. C. Binnenhei for a useful conversation in Göttingen.

APPENDIX: PROOF OF PROPOSITION 2.2

We will give in this appendix the proof of Proposition 2.2. Recall the notation and results of Sec. II.

Proposition: For $f_1,\ldots,f_n\in\mathfrak{h}$ the equation

$$(a(f_n)\cdot\cdots\cdot a(f_1))\,\Omega=\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\0\leqslant 2p\leqslant n}}(\mathrm{sgn}\,\pi)\prod_{l=1}^{p}\langle Pf_{\alpha_l},P\Gamma f_{\beta_l}\rangle\,P\Gamma f_{j_1}\wedge\cdots\wedge P\Gamma f_{j_k}$$

holds, where the indices $\alpha_l,\beta_l,j_1,\ldots,j_k$ are given in the definition of $\mathfrak{S}_{n,p}$ and where for $n=2p$ in the preceding sum one replaces the wedge product by the vacuum Ω.

Proof: The proof is done by induction on the number of generators of the CAR-Algebra. For $n=1$ the above formula is immediately verified using the definition of creation and annihilation operators. Assume that it holds for n generators and we prove that it is also true for $n+1$ generators. Take $f_{n+1},f_n,\ldots,f_1\in\mathfrak{h}$ and from the preceding assumption as well as the results stated in Sec. II we have

$$\begin{aligned}&a(f_{n+1})\,(a(f_n)\cdot\cdots\cdot a(f_1)\,\Omega)\\&\quad=(c(P\Gamma f_{n+1})^*+c(Pf_{n+1}))\,(a(f_n)\cdot\cdots\cdot a(f_1)\,\Omega)\\&\quad=\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\0\leqslant 2p\leqslant n}}(\mathrm{sgn}\,\pi)\prod_{l=1}^{p}\langle Pf_{\alpha_l},P\Gamma f_{\beta_l}\rangle\,P\Gamma f_{n+1}\wedge P\Gamma f_{j_1}\wedge\cdots\wedge P\Gamma f_{j_k}\end{aligned}$$

$$+\sum_{\substack{\pi\in\mathfrak{S}_{n,p}\\ 0\leqslant 2p\leqslant n}}\sum_{r=1}^{k}(\operatorname{sgn}\pi)(-1)^{r-1}\langle Pf_{n+1},P\Gamma f_{j_r}\rangle$$

$$\cdot\prod_{l=1}^{p}\langle Pf_{\alpha_l},P\Gamma f_{\beta_l}\rangle\, P\Gamma f_{j_1}\wedge\cdots\wedge\widehat{P\Gamma f}_{j_r}\wedge\cdots\wedge P\Gamma f_{j_k}. \tag{A1}$$

We will determine how many terms with particle number k' appear in the preceding sum. For this let $p'\in\mathbb{N}$ be such that $2p'+k'=n+1$. Now the first term in the above formula contributes by means of expressions where $k=k'-1$ (hence $p=p'$) and there are

$$\binom{n}{n-2p}\frac{(2p)!}{p!\,2^p}=\binom{n}{n-2p'}\frac{(2p')!}{p'!2^{p'}}$$

such summands. Further, the second term contributes by means of expressions where $k=k'+1$ (hence $p=p'-1$) and there are now

$$k\binom{n}{n-2p}\frac{(2p)!}{p!\,2^p}=\binom{n}{n-2p'+1}\frac{(2p')!}{p'!2^{p'}}$$

such summands. Altogether we obtain

$$\binom{n}{n-2p'}\frac{(2p')!}{p'!2^{p'}}+\binom{n}{n-2p'+1}\frac{(2p')!}{p'!2^{p'}}=\binom{n+1}{n+1-2p'}\frac{(2p')!}{p'!2^{p'}}$$

terms with particle number k' and this coincides with the number of elements in $\mathfrak{S}_{n+1,p'}$. To conclude the proof we still need to show that each term in the sum carries the correct sign. For the summands in (A1) this follows from

$$\begin{aligned}
&\operatorname{sgn}\begin{pmatrix} n & n-1 & \cdots & n-2p+2 & n-2p+1 & k & \cdots & 1\\ \alpha_1 & \beta_1 & \cdots & \alpha_p & \beta_p & j_1 & \cdots & j_k\end{pmatrix}\\
&\quad=\operatorname{sgn}\begin{pmatrix} n+1 & n & \cdots & 1\\ n+1 & \alpha_1 & \cdots & j_k\end{pmatrix}\\
&\quad=\operatorname{sgn}\begin{pmatrix} n+1 & n & \cdots & n-2p+3 & n-2p+2 & k+1 & k & \cdots & 1\\ \alpha_1 & \beta_1 & \cdots & \alpha_p & \beta_p & n+1 & j_1 & \cdots & j_k\end{pmatrix}.
\end{aligned}$$

For the remaining terms we have

$$\begin{aligned}
&(-1)^{r-1}\operatorname{sgn}\begin{pmatrix} n & n-1 & \cdots & k & \cdots & k+2-r & k+1-r & k-r & \cdots & 1\\ \alpha_1 & \beta_1 & \cdots & j_1 & \cdots & j_{r-1} & j_r & j_{r+1} & \cdots & j_k\end{pmatrix}\\
&\quad=(-1)^{r-1}\operatorname{sgn}\begin{pmatrix} n+1 & n & \cdots & 1\\ n+1 & \alpha_1 & \cdots & j_k\end{pmatrix}\\
&\quad=\operatorname{sgn}\begin{pmatrix} n+1 & n & n-1 & n-2 & \cdots & k & \cdots & k+1-r & k-r & \cdots & 1\\ n+1 & j_r & \alpha_1 & \beta_1 & \cdots & j_1 & \cdots & j_{r-1} & j_{r+1} & \cdots & j_k\end{pmatrix}.
\end{aligned}$$

Therefore, we have shown that

$$(a(f_{n+1})\cdot\cdots\cdot a(f_1))\,\Omega=\sum_{\substack{\pi\in\mathfrak{S}_{n+1,\,p'}\\ 0\leqslant 2p'\leqslant n+1}}(\operatorname{sgn}\pi)\prod_{l=1}^{p'}\langle Pf_{\alpha_l},P\Gamma f_{\beta_l}\rangle\,P\Gamma f_{j_1}\wedge\cdots\wedge P\Gamma f_{j_k},$$

which concludes the proof. ■

(Received 30 August 2001; accepted for publication 14 February 2002)

A new way of constructing fusion bases (i.e., the set of inequalities governing fusion rules) out of fusion elementary couplings is presented. It relies on a polytope reinterpretation of the problem: the elementary couplings are associated with the vertices of the polytope while the inequalities defining the fusion basis are the facets. The symmetry group of the polytope associated with the lowest rank affine Lie algebras is found; it has order 24 for $\widehat{su}(2)$, 432 for $\widehat{su}(3)$ and quite surprisingly, it reduces to 36 for $\widehat{su}(4)$, while it is only of order 4 for $\widehat{sp}(4)$. This drastic reduction in the order of the symmetry group as the algebra gets more complicated is rooted in the presence of many linear relations between the elementary couplings that break most of the potential symmetries. For $\widehat{su}(2)$ and $\widehat{su}(3)$, it is shown that the fusion-basis defining inequalities can be generated from few (one and two, respectively) elementary ones. For $\widehat{su}(3)$, new symmetries of the fusion coefficients are found. © *2002 American Institute of Physics.*

I. INTRODUCTION

Affine fusion rules give the number of integrable representations $\hat{\nu}$ that appear in the product of two integrable representations $\hat{\lambda}$ and $\hat{\mu}$ for a given affine algebra $\hat{g}$ at fixed level k (see, e.g., Ref. 1, Chap. 16). Fusions are in fact truncated finite Lie algebra tensor products, with the degree of truncation fixed solely by the level. More precisely, fusion rules are completely characterized by the tensor-product coefficients pertaining to the corresponding finite (i.e., nonaffine) representations and the set of threshold levels.[2] The threshold level of a particular coupling representing one of the various copies of the representation $\hat{\nu}$ in the product $\hat{\lambda}\times\hat{\mu}$ is the lowest level at which this coupling appears in this fusion. (Note that only the full set of threshold levels associated with a given triple coupling is an observable; the association of a particular threshold level with a given coupling is basis dependent.)

Even for $\widehat{su}(N)$, no genuine combinatorial methods—analogous to the Littlewood–Richardson rule—have been found. The closest approach to such a goal has been obtained in Ref. 3 in which a new approach to the problem of fusion rules was introduced, centered on the notion of *fusion basis*. A fusion basis is simply a complete set of inequalities, formulated in terms of a complete set of variables needed to describe a tensor product, augmented with an extra variable, the level k. Examples of bases have been constructed for $\widehat{su}(2)$, $\widehat{su}(3)$, $\widehat{su}(4)$, and $\widehat{sp}(4)$.

The idea of the construction in Ref. 3 is the following: one starts from the tensor-product

[a)]Electronic mail: pmathieu@phy.ulaval.ca

elementary couplings, extends this set to a complete set of fusion elementary couplings (using, for instance, the conjectural completeness under outer automorphism—but there exist other possibilities) and from these, construct the inequalities in terms of the basis variables for which the elementary couplings are the elementary solutions.

In Ref. 3, the transition from the elementary couplings to the inequalities uses Farkas' lemma. The aim of this note is to indicate another way of reconstructing the fusion basis given the fusion elementary couplings. This new construction relies on a reinterpretation of the fusion-rule computations in terms of counting points inside a polytope. A polytope can be described by its vertices or its facets. The reconstruction of the facets of a polytope from its vertices is the essential trick we want to adapt to the problem of fusion rules. In our context, the vertices are represented by the fusion elementary couplings and the facets are the inequalities for which the elementary couplings are the elementary solutions. This reformulation is not purely cosmetic: it allows us to use powerful (e.g., computer) techniques developed for the study of polytopes, for instance, for deriving the facets from its vertices.

But this conceptual shift in the description of the fusion basis has an immediate benefit: having constructed a polytope it is natural to look for its symmetries. This means looking for the symmetry group of the fusion basis and organizing the various inequalities into a number of orbits of the group. In this paper we find the symmetry group of the polytopes associated with the known fusion bases.

II. THE $\widehat{su}(2)$ EXAMPLE

As a simple illustrative example we present the $\widehat{su}(2)$ fusion basis:

$$k \geqslant \lambda_1 + n_{11}, \quad n_{12} \geqslant 0, \quad \lambda_1 \geqslant n_{12}, \quad n_{11} \geqslant 0. \tag{2.1}$$

The last three conditions define the Littlewood–Richardson (LR) basis, which is thus recovered from the fusion basis in the infinite level limit ($k \to \infty$). This basis describes the solution set of the fusion $\hat{\lambda} \times \hat{\mu}$ at fixed positive integer level k. The two Dynkin labels of $\hat{\lambda}$ are $\lambda_0 = k - \lambda_1$ and λ_1, with λ_1 being the finite Dynkin label (and we will often use the Dynkin label notation: $\hat{\lambda} = [\lambda_0, \lambda_1]$). Both Dynkin labels are assumed to be non-negative integers. The LR algorithm starts by filling the boxes of the first row of the Young tableau associated to μ with 1's, the second row with 2's, etc. For $su(2)$, μ has only one row, containing μ_1 boxes. These boxes are inserted into the tableau representing λ, which is a row of λ_1 boxes: n_{11} boxes are then added in the first row and n_{12} boxes in the second row. Therefore n_{11} and n_{12} are non-negative integers and $n_{11} + n_{12} = \mu_1$. Moreover, columns with two 1's are not permitted, which forces $\lambda_1 \geqslant n_{12}$. Finally, the tableau associated with the representation ν is read off the resulting LR tableau by taking out the columns of two boxes: $\nu_1 = \lambda_1 + n_{11} - n_{12}$. (For more details on the LR algorithm, see, e.g., Refs. 4–6.)

The elementary solutions of this system of inequalities, written in terms of vectors with entries ordered as $(k, \lambda_1, n_{11}, n_{12})$, are

$$\epsilon_0 = (1,0,0,0), \quad \hat{E}_0 : d$$

$$\epsilon_1 = (1,1,0,1), \quad \hat{E}_1 : dL_1 N_{12} : \ \begin{array}{|c|}\hline \ \\ \hline 1 \\ \hline \end{array}$$

$$\epsilon_2 = (1,1,0,0), \quad \hat{E}_2 : dL_1 : \ \begin{array}{|c|}\hline \ \\ \hline \end{array}$$

$$\epsilon_3 = (1,0,1,0), \quad \bar{E}_3 : dN_{11} : \ \begin{array}{|c|}\hline 1 \\ \hline \end{array} \tag{2.2}$$

We have also presented the corresponding LR tableau at the right and its "exponential" description in between (where the variables k, λ_1, n_{11}, n_{12} appear, respectively, as the exponents of the

dummy variables d, L_1, N_{11}, N_{12}). The problem we consider here is the following: given $\hat{E}_i$, $i=0, 1, 2, 3$, how can we reconstruct the inequalities? In other words, how to go from the vertices (2.2) to the facets (2.1)?

III. THE POLYTOPE INTERPRETATION OF FARKAS' LEMMA

As we just mentioned, for the present work we suppose that the complete set of fusion elementary couplings $\{\hat{\mathcal{E}}_i\}$ is known. These are expressed in terms of a set of variables, denoted collectively as X_j, $j=1,...,n$ (which are the dummy variables d, L_1, N_{11}, N_{12} in the previous example), that furnish a complete description of the fusion rules. These are in fact the variables that describe the tensor products with the addition of the extra variable d that keeps track of the level of the affine algebra under consideration.

A general coupling can always be decomposed into a product of elementary couplings (and that this decomposition may not be unique is irrelevant at this point). This product decomposition can be transferred into a sum decomposition by characterizing an elementary coupling by the exponents ϵ_{ij} in its decomposition in terms of the variables X_j: an elementary coupling is thereby associated with an n-dimensional vector $\boldsymbol{\epsilon}_i$.

Again, our problem is the following: what is the set of linear and homogeneous inequalities for which the $\boldsymbol{\epsilon}_i$ are the elementary solutions? These inequalities will be formulated in terms of the variables x_j, whose exponential versions are the X_j. The set $\{x_i\}$ will typically contain the finite Dynkin labels of the three affine weights entering in the fusion, together with the missing labels appropriate for a complete description of the corresponding tensor product, plus the level k.

Any coupling $\Pi_i X_i^{x_i}$ can thus be decomposed in the form $\Pi_i \hat{\mathcal{E}}_i^{a_i}$. With $\hat{\mathcal{E}}_i=\Pi_j X_j^{\epsilon_{ij}}$, reading off a particular coupling means looking for a choice set of non-negative integers $\{a_i\}$ fixed by

$$\sum_i a_i \epsilon_{ij} = x_j \tag{3.1}$$

in terms of non-negative integers x_j. We are thus searching for the conditions ensuring the existence of such a coupling. This is precisely what Farkas' lemma can do. Quite remarkably, the lemma gives existence conditions in the form of inequalities on the x_j's and these are precisely the inequalities we are looking for.

If we write $V_{ij}=\epsilon_{ji}$ (hence, the columns of the matrix V are the elementary solutions), Farkas' lemma gives existence conditions for solutions of

$$Va = x \tag{3.2}$$

(in matrix form). For instance, for $\widehat{su}(2)$, V takes the form [cf. (2.2)]:

$$V=\begin{pmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{pmatrix}. \tag{3.3}$$

In fact, we are interested in the integer solutions of (3.2).

We should stress that Farkas' lemma is true in general only in the rational case. Sufficient conditions for its application to the integer case are known (see, for instance, Ref. 7), but these are not satisfied by our matrices V. Hence, the analysis has to be completed by a verification step, that is, to check that the elementary solutions of the inequalities obtained are the elementary solutions used at the start (cf. the discussion in Sec. 3 of Ref. 3).

The polytope interpretation of (3.2) is almost immediate (see Sec. IV): modulo renormalization, (3.2) is the equation of a polytope whose vertices v_i are the columns of the matrix V without its first row, hence our elementary couplings without their first entry d.

Now it is a well-known result (the Weyl–Minkowski theorem) that a polytope can be described either in terms of its vertices or its facets. In the present case, we have the vertices; the question is thus: what are the facets of the polytopes whose vertices are our fusion elementary couplings? These facets are the sought for inequalities, which form the fusion basis.

This reformulation is made more formal in Sec. IV. The following sections are devoted to the study of the symmetry group of the fusion polytopes for the simplest affine Lie algebras.

IV. FORMALIZING THE POLYTOPE REINTERPRETATION

To recast the problem in a general setting, let $V \in \mathbb{N}^{n\times m}$ be such that

$$V=(v_1 \ldots v_m)=\begin{pmatrix} w_1 & \cdots & w_m \\ \mathbf{v}_1 & \cdots & \mathbf{v}_m \end{pmatrix}, \tag{4.1}$$

with $v_1,\ldots,v_m$ the fusion elementary couplings and $w_1,\ldots,w_m$ the entries in the first row of V. Also, let $\mathcal{S}$ denote the set of fusion couplings

$$\mathcal{S}=\{x=Va=a_1v_1+\cdots+a_mv_m | a_1,\ldots,a_m \in \mathbb{N}\},$$

which, from our central hypothesis, is the set of non-negative integral combinations of elementary couplings. It is natural to suppose that the fusion couplings are the integral points of a certain geometric object E, that is, the vectors $v_1,\ldots,v_m$ form a Hilbert basis of E. [A finite set of vectors $v_1,\ldots,v_m$ is a Hilbert basis of $C=\text{cone}(a_1,\ldots,a_t)$ if $C\cap\mathbb{Z}^n=\mathbb{N}v_1+\cdots+\mathbb{N}v_m$.] One obvious choice for E, and the one we will make, is the cone generated by $v_1,\ldots,v_m$, that is

$$E=\{x=V\lambda=\lambda_1v_1+\cdots+\lambda_mv_m | \lambda_1,\ldots,\lambda_m \in \mathbb{R}_+\}. \tag{4.2}$$

In general, $v_1,\ldots,v_m$ may or may not be a Hilbert basis of this cone. However, for our examples we find that $v_1,\ldots,v_m$ is indeed a Hilbert basis of E. This checking process is equivalent to the verification step mentioned in Sec. III. The set $\mathcal{S}$ is thus given by

$$\mathcal{S}=E\cap\mathbb{N}^m, \tag{4.3}$$

and the fusion inequalities are simply the facets of the cone E. We can therefore use Farkas' lemma (or any other method) to obtain the facets of E. Now, it turns out that the fusion inequalities are also the facets of a polytope. The remainder of this section is devoted to this reinterpretation.

If we write the vectors $x \in E$ as

$$x=\begin{pmatrix} x_0 \\ \mathbf{x} \end{pmatrix}, \tag{4.4}$$

we have that the fusion couplings at level k are the integral points of the space, $P^{(k)}$, corresponding to the intersection between the hyperplane $x_0=k$ and the cone E. If we drop the x_0 component, which has value k in $P^{(k)}$, we can describe $P^{(k)}$ as

$$P^{(k)}=\left\{\mathbf{x}\middle|\begin{pmatrix} k \\ \mathbf{x} \end{pmatrix}\in E\right\}=\left\{\mathbf{x}\middle|\begin{pmatrix} k \\ \mathbf{x} \end{pmatrix}=V\lambda,\lambda\in\mathbb{R}_+^m\right\}=\left\{\mathbf{x}=\sum_i \mathbf{v}_i\lambda_i\middle|\lambda\in\mathbb{R}_+^m,\sum_i \lambda_i w_i=k\right\}. \tag{4.5}$$

The integral points of $P^{(k)}$ are

$$\mathcal{S}^{(k)}=P^{(k)}\cap\mathbb{N}^{n-1}, \tag{4.6}$$

which are essentially the possible fusion couplings at level k (by adding to the elements of $\mathcal{S}^{(k)}$ an extra component x_0 equal to k, we recover the usual fusion couplings). Because $0<w_i<\infty$, the transformation

$$\lambda_i \to \lambda_i' = \lambda_i(w_i/k), \quad \mathbf{v}_i \to \mathbf{v}_i' = (k/w_i)\mathbf{v}_i, \quad w_i \to w_i' = (k/w_i)w_i = k, \tag{4.7}$$

is well defined, and if we further set

$$V' = \begin{pmatrix} w_1' & \cdots & w_m' \\ \mathbf{v}_1' & \cdots & \mathbf{v}_m' \end{pmatrix} = \begin{pmatrix} k & \cdots & k \\ \mathbf{v}_1' & \cdots & \mathbf{v}_m' \end{pmatrix}, \tag{4.8}$$

$P^{(k)}$ can now be given as

$$P^{(k)} = \left\{ \mathbf{x} = \sum_i \mathbf{v}_i' \lambda_i' \,\middle|\, \lambda' \in \mathbb{R}_+^m, \sum_i \lambda_i' = 1 \right\}, \tag{4.9}$$

which by definition is the *polytope* given by the convex hull of the vertices $\mathbf{v}_i'$, $i = 1,...,m$.

The main theorem of polytope theory[8] tells us that P can be equivalently described as a solution set of a finite system of ℓ linear inequalities (facets), that is

$$P^{(k)} = \{\mathbf{x} | C\mathbf{x} \leqslant -kb\} = \left\{ \mathbf{x} \,\middle|\, C' \begin{pmatrix} k \\ \mathbf{x} \end{pmatrix} \leqslant 0 \right\}, \tag{4.10}$$

where C' is the concatenation (bC) of b and C, with $C \in \mathbb{R}^{\ell \times (n-1)}$ and $b \in \mathbb{R}^{\ell \times 1}$. In the last expression, we have made explicit the fact that the polytope inequalities translate into inequalities that the fusion elements at $x_0 = k$ must satisfy. We have thus obtained that the fusion inequalities are the facets of a polytope.

From a practical point of view, we stress that there exist powerful programs that give the polytope facets from its vertices (and vice-versa). The authors have used the ''cdd'' package of Fukuda[9] for computations in this article. For a description of other methods, we refer the reader to Ref. 8.

V. THE SYMMETRY GROUP OF THE FUSION POLYTOPES: GENERALITIES

The fusion polytope is a geometrical object and so it is natural to look for its symmetry group. However, for a polytope there are several different kinds of symmetry we can consider. For example, consider the polytope E in $\mathbb{R}^2$ with vertices (0,0), (0,2), (1,2), and (1,0) which we label 1, 2, 3, and 4. This polytope is fixed by the reflections in the lines $y = 1$ and $x = 1/2$ and by a 180° rotation about the point (1/2, 1). These are examples of Euclidean (length preserving) symmetries. Except for the identity transformation, there are no other Euclidean symmetries of E. But there are additional symmetries if we consider affine transformations, for example, $x \to 1 - y/2$, $y \to 2 - 2x$ fixes the vertices 2 and 4, while exchanging 1 and 3.

In general, affine symmetries of a polytope E in $\mathbb{R}^{n-1}$ are transformations of the form

$$\overline{\zeta}: \mathbf{x} \to A\mathbf{x} + kb, \tag{5.1}$$

with $A \in \mathbb{R}^{(n-1)\times(n-1)}$ and $b \in \mathbb{R}^{(n-1)\times 1}$, such that

$$\overline{\zeta} E = E. \tag{5.2}$$

If the matrix A is orthogonal then the affine symmetry is also Euclidean.

A convenient method of finding the affine symmetries is to identify $\mathbb{R}^{n-1}$ with the plane $x_0 = k$ in $\mathbb{R}^n$. Then the affine extension of $\overline{\zeta}$, denoted ζ, is given by

$$\zeta: \begin{pmatrix} k \\ \mathbf{x} \end{pmatrix} \to \begin{pmatrix} k \\ A\mathbf{x} + kb \end{pmatrix}, \tag{5.3}$$

or, in matrix form, as

$$\zeta:\begin{pmatrix} k \\ \mathbf{x} \end{pmatrix} \to \begin{pmatrix} 1 & 0 \\ b & A \end{pmatrix} \begin{pmatrix} k \\ \mathbf{x} \end{pmatrix}. \tag{5.4}$$

Now, since any polytope is completely characterized by its vertices or its facets, a transformation that leaves E invariant has to leave its set of vertices and its set of facets invariant. That is, we must have from (4.9) and (4.10) that the action of $\overline{\zeta}$ permutes $\mathbf{v}'_1,\ldots,\mathbf{v}'_m$, so that

$$\overline{\zeta}(\mathbf{v}'_1 \ \cdots \ \mathbf{v}'_m) = (\overline{\zeta}(\mathbf{v}'_1) \ \cdots \ \overline{\zeta}(\mathbf{v}'_m)) = (\mathbf{v}'_1 \ \cdots \ \mathbf{v}'_m)\sigma, \tag{5.5}$$

for some permutation matrix σ. Using V', whose columns are vectors of the type $\binom{k}{\mathbf{x}}$, the requirement (5.5) can be put in matrix form:

$$B(\zeta)V' = V'\sigma, \tag{5.6}$$

where $B(\zeta)$ is the matrix of the transformation ζ defined in (5.4). We shall be mainly interested in finding the affine symmetries of the fusion polytopes and methods for finding these symmetries will be described in Sec. VI.

Note, however, that in general potential symmetries of a polytope can often be ruled out by considering the polytope's combinatorial structure. Consider, for example, the polytope E introduced at the beginning of this section. As mentioned previously, a symmetry of E must permute vertices and facets and so there cannot be a symmetry of any type which exchanges vertices 2 and 3 while fixing vertices 1 and 4, since vertices 1 and 2 are joined by a common edge while 1 and 3 are not.

One type of combinatorial symmetry would be to consider all permutations of the faces of the polyhedron which preserve the face lattice (see, e.g., Ref. 10, p. 128). However, a simpler type of combinatorial symmetry, which is easy to find in our examples, is to look for permutations of vertices and facets which preserve the vertex–facet incidence matrix. This matrix is easy to calculate given the vertices and the inequalities representing the facets: the incidence matrix has an entry 1 in position (i,j) if the ith-vertex saturates (i.e., satisfies with equality) the jth facet inequality and is zero otherwise.

If we label the edges 1–2, 2–3, 3–4, and 4–1 of our example polytope E as 1, 2, 3, and 4, corresponding, respectively, to the inequalities $x \geqslant 0$, $y \leqslant 2$, $x \leqslant 1$, $y \geqslant 0$, we obtain the incidence matrix:

$$\mathcal{I} = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix}. \tag{5.7}$$

If permutations σ and τ of the vertices and the edges, respectively, satisfy $\sigma\mathcal{I}\tau = \mathcal{I}$ then we say that we have an incidence symmetry. If σ and τ are such symmetries then $\sigma\mathcal{I}\tau\tau^{-1}\mathcal{I}^t\sigma^{-1} = \mathcal{I}\mathcal{I}^t$ and so σ commutes with $\mathcal{I}\mathcal{I}^t$. Call any vertex permutation which commutes with $\mathcal{I}\mathcal{I}^t$ a vertex symmetry.

Note that any affine symmetry induces a combinatorial face lattice symmetry and also a combinatorial incidence symmetry and a vertex symmetry. These maps are injective since if an affine symmetry fixes all the vertices of a polytope then it fixes the whole polytope since a polytope is the convex hull of its vertices. Thus we have the inclusions: Euclidean symmetries $\subseteq$ affine symmetries $\subseteq$ combinatorial face lattice symmetries $\subseteq$ combinatorial incidence symmetries $\subseteq$ vertex symmetries. Thus finding the vertex symmetries gives a ''upper bound'' on the other types of symmetries.

For the polytope E we have

$$\mathcal{I}\mathcal{I}^t=\begin{pmatrix} 2 & 1 & 0 & 1 \\ 1 & 2 & 1 & 0 \\ 0 & 1 & 2 & 1 \\ 1 & 0 & 1 & 2 \end{pmatrix}. \tag{5.8}$$

Since any vertex symmetry σ commutes with $\mathcal{I}\mathcal{I}^t$, it must also map eigenvectors to eigenvectors and using this it is not difficult to show that every vertex symmetry of E arises from an affine symmetry.

In general, however, the group of combinatorial symmetries will be much larger than the group of affine symmetries. For example if we take a ''generic'' convex n-gon in $\mathbb{R}^2$, its combinatorial symmetries will be a dihedral group, but there will be no affine symmetries except for the identity transformation.

Perhaps surprisingly, we find that for our examples that every vertex symmetry comes from an affine symmetry and so the most economical method of finding the affine symmetries would be to calculate first the vertex symmetries. However, this is not the usual situation and the only real advantage in our cases turns out to be that the matrices we have to calculate have smaller entries if we use vertex symmetries. So in Sec. VI we give general methods for finding all the affine symmetries for any polytope.

In the rest of this paper we shall only be concerned with finding affine symmetries of our polytopes, and so, unless stated otherwise, by a symmetry we shall mean an affine symmetry. Similarly when we refer to a vertex permutation as being a symmetry we mean that it arises from an affine symmetry as explained at the start of Sec. VI.

VI. THE SYMMETRY GROUP OF THE FUSION POLYTOPES: TECHNICAL TOOLS

In this section we will introduce some tools for finding the affine symmetries of our fusion polytopes introduced in Sec. V. We do this by considering vertex permutations and finding which ones arise from affine symmetries. These tools, however, apply in more generality than these applications and so we start with a more general definition of a symmetry of a matrix:

Definition: Let M be an $n\times m$ matrix. An $m\times m$ permutation matrix σ is a symmetry of M iff $M\sigma=BM$ for some $n\times n$ matrix B.

The set of symmetries of $M\in\mathbb{N}^{n\times m}$ is a subset of the group of permutation matrices which is closed under multiplication, hence is a group. The corresponding set of matrices B does not necessarily form a group, but it does if the rank of M is n.

This definition is inspired by Eq. (5.6) since for the fusions of the affine Lie algebra $\hat{g}$ we will take M to be the matrix V'. So in the terminology of Sec. V, a symmetry of V' is a vertex symmetry of our fusion polytope which comes from an affine symmetry. As explained in Sec. V we will call these vertex symmetries simply symmetries to avoid tedious repetition. The group of symmetries of V' will be denoted by $G[\hat{g}]$. For all our examples the rank of V' turns out to be n, in other words the fusion polytope has ''full-dimension.''

Proposition 1: An $m\times m$ permutation matrix σ is a symmetry of the $n\times m$ matrix M iff $\sigma N(M)=N(M)$ where $N(M)=\{z|Mz=0\}$.

Proof: If $z\in N(M)$ then $M\sigma z=BMz=0$, so $\sigma N(M)\subseteq N(M)$. Also $\sigma^{-1}N(M)\subseteq N(M)$, since σ^{-1} is also a symmetry of M (because the symmetries form a group) and so $\sigma N(M)=N(M)$. Conversely, if $\sigma N(M)=N(M)$ then the matrices M and $M\sigma$ have the same null space. Thus their rows generate the annihilator of $N(M)$. In particular the rows of $M\sigma$ are contained in the span of the rows of M and so there is a matrix B such that $BM=M\sigma$. So σ is a symmetry of M.

When the kernel of M has dimension 0 or 1, this proposition is sufficient to classify the symmetries. As we will show in the following sections, this holds for the fusion polytopes for $\widehat{su}(2)$ and $\widehat{su}(3)$.

If the kernel has larger dimension, we will need another approach. However, to do so we make the additional assumptions that M has real entries and that its rank is n. As noted previously, the fusion polytope matrices V' have these properties.

With these two assumptions, using the Gram–Schmidt procedure, we can find an invertible $n\times n$ matrix L such that the rows of $W=LM$ form an orthonormal basis of the row space of M. Since $M\sigma=BM$ if and only if $W\sigma=LBL^{-1}W$, it is clear that σ is a symmetry of M if and only if σ is a symmetry of W.

Proposition 2: σ is a symmetry of M if and only if $Q\sigma=\sigma Q$, where $Q=W^{\mathsf{T}}W$.

Proof: If σ is a symmetry of M then σ is a symmetry of W and so $W\sigma=TW$ for some $n\times n$ matrix T. Moreover, since σ acts as an orthogonal transformation on the rows of W, T is an orthogonal matrix. Hence, $W\sigma=TW$ implies $\sigma^{-1}W^{\mathsf{T}}=W^{\mathsf{T}}T^{-1}$. So $Q\sigma=W^{\mathsf{T}}W\sigma=W^{\mathsf{T}}TW=\sigma W^{\mathsf{T}}W$ as required. For the converse, note that the matrix Q performs the orthogonal projection onto the row space of M. So if σ commutes with the projection matrix Q then it maps the row space of M to itself and so is a symmetry of M.

Since σ is a permutation, we can read off some of its properties directly from Q. For example a row of Q can be mapped to another row of Q by a symmetry only if the two rows have the same set of entries. A second simplification occurs by observing that if σ is a symmetry and $\sigma u=\lambda u$ for some vector u then $\sigma Qu=Q\sigma u=\lambda Qu$. In particular, if u is fixed by the symmetry group, so is Qu. We will apply these two observations when we compute the symmetries for the $\widehat{sp}(4)$ fusion polytope.

VII. THE SYMMETRY GROUP OF THE $\widehat{su}(2)_k$ POLYTOPE

For $\widehat{su}(2)$, the matrix V' takes the form kV with V given in (3.3); $N(V')$ is thus trivial. Therefore, every permutation is a symmetry. Since $n=m=4$, this gives S_4 as the symmetry group $G[\widehat{su}(2)]$. S_4 is generated by the permutations (1, 2, 3, 4) and (1, 2), where $(i,j,\ldots,k)$ stands for a cyclic permutation of $i,j,\ldots,k$. Since V' is invertible, we can easily find the corresponding transformation ζ acting on $x^{\mathsf{T}}=(k,\lambda_1,n_{11},n_{12})$. It reads:

$$\begin{aligned}(1,2,3,4):&(k,\lambda_1,n_{11},n_{12})\mapsto(k,k-\lambda_1-n_{11}+n_{12},\lambda_1-n_{12},k-\lambda_1-n_{11}),\\(1,2):&(k,\lambda_1,n_{11},n_{12})\mapsto(k,k-n_{11}-n_{12},n_{11},k-\lambda_1-n_{11}).\end{aligned}\tag{7.1}$$

The fusion basis is given in (2.1). Labeling these inequalities from 1 to 4, the symmetries (1, 2, 3, 4) and (1, 2) permute the inequalities. However, the inequalities correspond to the polytope facets, which being dual to the vertices transform by the inverse of the vertex transform. Thus if $x\mapsto Bx$ is the transformation corresponding to the vertices, then $\alpha^{\mathsf{T}}\mapsto\alpha^{\mathsf{T}}B^{-1}$ is the appropriate transformation for the facets. The necessity of this can be seen from the fact that the transformations should preserve the incidence relations of the vertices and facets and that this involves quantities of the form $\alpha^{\mathsf{T}}x$.

From this it follows that the action of (1, 2) is [[1, 2], [3], [4]], i.e., it permutes the first two inequalities and fixes the last two. Similarly the action of (1, 2, 3, 4) is [[1, 2, 3, 4]]. Thus the fusion basis is generated by any one of its inequalities under that action of the symmetry group.

Is there a simple way to understand these symmetries in terms of the symmetries of the fusion coefficients? First, notice that the fusion coefficients are described in terms of a smaller number of labels than those necessary for the complete description of the fusion basis. The complete set of labels can be split into two subsets: the Dynkin labels of the three weights under consideration and the ''missing labels.'' If some symmetries do not involve in an essential way the missing labels, they will project onto fusion-coefficient symmetries. However, if the missing labels are an essential part of the symmetry transformations, the symmetry will disappear in the projection. For instance, tensor-product coefficients can be obtained by projection of the fusion coefficients. The latter require an extra variable for their description, the level k, and fusion coefficients have more symmetries than the tensor-product coefficients. The extra symmetries are the outer automorphisms—see the next paragraph—and these involve the level in an essential way. Let us make the general situation more precise: Denote collectively the finite Dynkin labels $\{\lambda_i,\mu_i,\nu_i\}$ and k by D and the set of missing labels by γ. A facet symmetry is generically of the form $\{D,\gamma\}\to\{D'(D,\gamma),\gamma'(D,\gamma)\}$. This will be a symmetry of the fusion coefficients only when D'

does not depend upon γ. Therefore there is no simple relationship between the symmetries of the facets and the symmetries of the fusion coefficients. In this regard, each algebra has to be studied separately.

The symmetries of the fusion coefficients include those that are level-independent, i.e., the symmetries of the corresponding tensor-product coefficients; these are the conjugation of the three weights, $(\hat{\lambda},\hat{\mu},\hat{\nu})\rightarrow(\hat{\lambda}^*,\hat{\mu}^*,\hat{\nu}^*)$ and the different permutations of $\hat{\lambda}$, $\hat{\mu}$ and $\hat{\nu}^*$. The remaining symmetries are intrinsically affine. These include the outer-automorphism symmetries which take the following form: If A, A' are two arbitrary elements of the outer-automorphism group of $\hat{g}$, the fusion coefficients satisfy

$$\mathcal{N}_{A\hat{\lambda},A'\hat{\mu}}^{(k)\quad AA'\hat{\nu}}=\mathcal{N}_{\hat{\lambda}\hat{\mu}}^{(k)\,\hat{\nu}}. \tag{7.2}$$

For $\widehat{su}(N)$, this group has order N: $A^N=1$. The symmetry group can be larger than that generated by tensor product symmetries and outer automorphisms, see e.g., Refs. 11–13. There are often symmetries which exist for some, but not all levels. The method we present here will not detect this type of symmetry and from this point we will exclude them. In other words, by symmetries of the fusion coefficients we mean symmetries which exist for all levels.

For $\widehat{su}(2)$, there are no missing labels. Hence the symmetry group of the polytope must be identical to the symmetry group of the fusion coefficients which exist for all k and that leave k fixed. This group is isomorphic to the semidirect product $(S_2\times S_2)\colon S_3$. The S_3 factor comes from the permutation of the three weights, while the two factors of S_2 account for the two copies of the outer-automorphism group (one acting on the weight $\hat{\lambda}$, the other acting on $\hat{\mu}$). The conjugation action of S_3 is via the outer automorphisms of $S_2\times S_2$ which permute the nonidentity elements. The group S_4 contains a group $S_2\times S_2$ generated by the cycles of type 2^2. Any of the four S_3 subgroups act on this $S_2\times S_2$ as outer automorphisms by conjugation and so the symmetry group is isomorphic to S_4.

Let us first reexpress all the basis symmetries in terms of the Dynkin labels:

$$\begin{aligned}
&(1,2,3,4)\colon(k,\lambda_1,\mu_1,\nu_1)\rightarrow(k,k-\nu_1,k-\mu_1,\lambda_1),\\
&(1,2)\colon(k,\lambda_1,\mu_1,\nu_1)\rightarrow(k,k-\mu_1,k-\lambda_1,\nu_1),\\
&(2,3)\colon(k,\lambda_1,\mu_1,\nu_1)\rightarrow(k,\lambda_1,\nu_1,\mu_1),\\
&(3,4)\colon(k,\lambda_1,\mu_1,\nu_1)\rightarrow(k,\mu_1,\lambda_1,\nu_1).
\end{aligned} \tag{7.3}$$

(Clearly, the last two symmetries can be obtained from the first two.)

Let us make explicit the correspondence between these symmetries and symmetries of the fusion coefficients. For this, notice first that the multiplicity of the $\widehat{su}(2)_k$ product $\hat{\lambda}\times\hat{\mu}\supset\hat{\nu}$ is the same as that of $\hat{\lambda}\times\hat{\mu}\times\hat{\nu}\supset 0$. Let P_{12} be the operator that permutes the first two weights and similarly for the other permutation operators. Moreover, let a be the $\widehat{su}(2)$ automorphism that interchanges the two simple roots, hence the two Dynkin labels: $a[k-\lambda_1,\lambda_1]=[\lambda_1,k-\lambda_1]$. Therefore, the nontrivial actions on $\hat{\lambda}\times\hat{\mu}\times\hat{\nu}\supset 0$ are simply:

$$a\hat{\lambda}\times a\hat{\mu}\times\hat{\nu}\supset 0,\quad a\hat{\lambda}\times\hat{\mu}\times a\hat{\nu}\supset 0,\quad \hat{\lambda}\times a\hat{\mu}\times a\hat{\nu}\supset 0. \tag{7.4}$$

Denote these actions, respectively, as $(a,a,1)$, $(a,1,a)$, $(1,a,a)$. The fusion basis symmetries can then be related directly to a and P actions as follows:

$$
\begin{aligned}
(1,2,3,4) &\equiv (a,a,1)P_{13},\\
(1,2) &\equiv (a,a,1)P_{12},\\
(2,3) &\equiv P_{23},\\
(3,4) &\equiv P_{12}.
\end{aligned}
\tag{7.5}
$$

"Pure" finite or affine symmetries can be obtained by composition, e.g.,

$$
\begin{aligned}
(2,3,4) &\equiv P_{321},\\
(1,2)(3,4) &\equiv (a,a,1).
\end{aligned}
\tag{7.6}
$$

VIII. THE SYMMETRY GROUP OF THE $\widehat{su}(3)_k$ POLYTOPE

The situation for $\widehat{su}(2)$ is not typical in two ways. First, there are no missing labels; hence any permutation of the vertices is bound to be a symmetry of the fusion coefficients. In addition, there are no linear relations between the elementary solutions. Such relations will induce severe constraints on the possible lifts of the fusion-coefficient symmetries to polytope symmetries.

For $\widehat{su}(3)$, the elementary couplings are (using the notation $\hat{\lambda}=[\lambda_0,\lambda_1,\lambda_2]$ with $\lambda_0+\lambda_1+\lambda_2=k$ and the LR variables—cf. Ref. 3. Note that λ_1 and λ_2 are Dynkin labels and not the partition labels to which they usually refer in the Littlewood–Richardson rule as in Ref. 4, Chap. 1, for example):

$$
\begin{aligned}
\hat{E}_0&: \quad [1,0,0]\times[1,0,0]\supset[1,0,0]: \quad d \qquad (1,0,0,0,0,0,0,0) \quad (1,1)\\
\hat{E}_1&: \quad [0,1,0]\times[0,0,1]\supset[1,0,0]: \quad dL_1N_{12}N_{23} \quad (1,1,0,0,1,0,0,1) \quad (a,a^2)\\
\hat{E}_2&: \quad [0,1,0]\times[1,0,0]\supset[0,1,0]: \quad dL_1 \quad (1,1,0,0,0,0,0,0) \quad (a,1)\\
\hat{E}_3&: \quad [1,0,0]\times[0,1,0]\supset[0,1,0]: \quad dN_{11} \quad (1,0,0,1,0,0,0,0) \quad (1,a)\\
\hat{E}_4&: \quad [0,0,1]\times[0,1,0]\supset[1,0,0]: \quad dL_2N_{13} \quad (1,0,1,0,0,1,0,0) \quad (a^2,a)\\
\hat{E}_5&: \quad [0,0,1]\times[1,0,0]\supset[0,0,1]: \quad dL_2 \quad (1,0,1,0,0,0,0,0) \quad (a^2,1)\\
\hat{E}_6&: \quad [1,0,0]\times[0,0,1]\supset[0,0,1]: \quad dN_{11}N_{22} \quad (1,0,0,1,0,0,1,0) \quad (1,a^2)\\
\hat{E}_7&: \quad [0,1,0]\times[0,1,0]\supset[0,0,1]: \quad dL_1N_{12} \quad (1,1,0,0,1,0,0,0) \quad (a,a)\\
\hat{E}_8&: \quad [0,0,1]\times[0,0,1]\supset[0,1,0]: \quad dL_2N_{11}N_{23} \quad (1,0,1,1,0,0,0,1) \quad (a^2,a^2).
\end{aligned}
\tag{8.1}
$$

Besides each coupling, we have written the "exponential description," the corresponding vector ϵ_i with entries in the order $(k,\lambda_1,\lambda_2,n_{11},n_{12},n_{13},n_{22},n_{23})$, as well as the action of the outer automorphism on the first two weights of $\hat{E}_0$ [in the form (a^n,a^m)] that yields the coupling under consideration.

The corresponding facets (the fusion basis) are found to be

$$
\begin{aligned}
n_{12}&\geqslant 0, \quad \lambda_2+n_{12}-n_{13}-n_{23}\geqslant 0,\\
n_{13}&\geqslant 0, \quad n_{11}-n_{22}\geqslant 0,\\
n_{22}&\geqslant 0, \quad n_{11}+n_{12}-n_{22}-n_{23}\geqslant 0,\\
n_{23}&\geqslant 0, \quad k-\lambda_1-\lambda_2-n_{22}\geqslant 0,\\
\lambda_1-n_{12}&\geqslant 0, \quad k-\lambda_1-\lambda_2-n_{11}+n_{23}\geqslant 0,\\
\lambda_2-n_{13}&\geqslant 0, \quad k-\lambda_1-n_{13}-n_{11}\geqslant 0.
\end{aligned}
\tag{8.2}
$$

This agrees with the system of inequalities obtained in Ref. 3.

For $\widehat{su}(3)$, the matrix V' is 8×9:

$$V'=k\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \tag{8.3}$$

and since the rank of V' is 8, $N(V')$ is one-dimensional and is spanned by

$$w^{\mathsf{T}}=(1\ \ -1\ \ 0\ \ -1\ \ 0\ \ -1\ \ 0\ \ 1\ \ 1). \tag{8.4}$$

The condition on σ is thus $\sigma w=\lambda w$ for some scalar λ and, since the eigenvalues of σ are roots of unity, λ is either 1 or -1. Thus $G[\widehat{su}(3)]$ is isomorphic to $S_3\times(S_3\wr S_2)$. The S_3 permutes the 0's of w and $S_3\wr S_2$ (the wreath product of S_3 and S_2, i.e., the direct product of *two* S_3's with S_2 acting by exchanging them) permutes and exchanges the 1's and -1's.

Let $x^{\mathsf{T}}=(k,\lambda_1,\lambda_2,n_{11},n_{12},n_{13},n_{22},n_{23})$. The action of a set of generators of the symmetry group on the variables is:

$$\begin{aligned}
(3,5,7)&:x^{\mathsf{T}}\mapsto(k,n_{12}+n_{22},\lambda_1+\lambda_2-n_{12}-n_{13},n_{11}+n_{13}-n_{22},n_{12},\lambda_1-n_{12},n_{13},n_{23}),\\
(3,5)&:x^{\mathsf{T}}\mapsto(k,n_{12}+n_{13},\lambda_1+\lambda_2-n_{12}-n_{13},n_{11},n_{12},\lambda_1-n_{12},n_{22},n_{23}),\\
(1,8,9)&:x^{\mathsf{T}}\mapsto(k,k-\lambda_2-n_{11}-n_{12}+n_{23},\lambda_2+n_{12}-n_{23},n_{11}\\
&\quad +n_{12}-n_{23},k-\lambda_1-\lambda_2-n_{11}+n_{23},n_{13},n_{22},n_{12}),\\
(1,8)&:x^{\mathsf{T}}\mapsto(k,k-\lambda_2-n_{11}-n_{12}+n_{23},\lambda_2,n_{11},k-\lambda_1-\lambda_2-n_{11}+n_{23},n_{13},n_{22},n_{23}),
\end{aligned} \tag{8.5}$$

together with

$$\begin{aligned}
(1,2)(4,8)(6,9)&:x^{\mathsf{T}}\mapsto(k,k-\lambda_2-n_{12}-n_{22},\lambda_2,\lambda_2+n_{12}-n_{13}+n_{22}\\
&\quad -n_{23},k-\lambda_1-\lambda_2-n_{22},n_{13},n_{22},k-\lambda_1-n_{13}-n_{11}).
\end{aligned} \tag{8.6}$$

The fusion basis is given by (8.2). Labeling these inequalities successively, column by column, from 1 to 12 (i.e., 8 corresponds to $n_{11}-n_{22}\geqslant 0$), we find that the action of the symmetry group on the inequalities considered as polytope facets is generated by:

$$\begin{aligned}
(3,5,7)&:[[1],[2,3,5],[4],[6],[7],[8],[9],[10],[11],[12]],\\
(3,5)&:[[1],[2,5],[3],[4],[6],[7],[8],[9],[10],[11],[12]],\\
(1,8,9)&:[[1,4,11],[2],[3],[5],[6,12,7],[8,10,9]],\\
(1,8)&:[[1,11],[2],[3],[4],[5],[6],[7,12],[8],[9,10]],\\
(1,2)(4,8)(6,9)&:[[1,10],[2],[3],[4,12],[5],[6],[7,8],[9],[11]],
\end{aligned} \tag{8.7}$$

where as before $[i,j,\ldots,k]$ stands for a cyclic permutation of the inequalities $i,j,\ldots,k$. Thus there are two orbits under the symmetry group. One consisting of the inequalities 2, 3, and 5 and the other consisting of the inequalities 1, 4, 6, 7, 8, 9, 10, 11, and 12. So the fusion basis is generated by the two inequalities $n_{12}\geqslant 0$ and $n_{13}\geqslant 0$ under the action of $G[\widehat{su}(3)]$.

Let us now try to understand these results. As already pointed out, these symmetries must be compatible with the symmetries of the fusion coefficients. But there is a further constraint on the fusion symmetries that has not been spelled out yet: in general there are linear relations among the elementary couplings and the symmetries of the facets must preserve these relations. In the $\widehat{su}(3)$ case, there is only one such linear relation, which is:

$$\hat{E}_0\hat{E}_7\hat{E}_8=\hat{E}_1\hat{E}_3\hat{E}_5. \tag{8.8}$$

This explains the existence of the three S_3 blocks: permutations among the sets $\{\hat{E}_0,\hat{E}_7,\hat{E}_8\}$ and $\{\hat{E}_1,\hat{E}_3,\hat{E}_5\}$ are symmetries that preserve each side of the relation. The third S_3 factor is bound to relate the three remaining vertices. Moreover, the S_2 group generated by (1, 2)(4, 8)(6, 9) is another transformation that leaves the relation unchanged: but instead of leaving each side invariant, it interchanges the two sides of the relation: $\hat{E}_0\leftrightarrow\hat{E}_1$, $\hat{E}_3\leftrightarrow\hat{E}_7$, $\hat{E}_5\leftrightarrow\hat{E}_8$. The occurrence of a linear relation is thus responsible for the fact that the symmetry group is not S_9 but only a subgroup thereof.

Of course, the existence of relations is intimately connected with the matrix V'. In fact, $N(V')$ is precisely the set of generating relations (in the sense of Ref. 3) out of which all the relations can be obtained.

To complete the analysis of the $\widehat{su}(3)_k$ polytope symmetries, let us investigate their explicit relation with symmetries of the fusion coefficients. For this, we first reexpress the symmetry transformations in terms of the Dynkin labels of the three weights plus n_{23}. Thus n_{23} is the missing label. We also reformulate the results in terms of the symmetrized product: $\hat{\lambda}\times\hat{\mu}\times\hat{\nu}\supset 0$. Recall that the multiplicity of $\hat{\lambda}\times\hat{\mu}\supset\hat{\nu}^*$ is the same as that of $\hat{\lambda}\times\hat{\mu}\times\hat{\nu}\supset 0$, where $*$ denotes the finite weight conjugation; for $\widehat{su}(3)$, it amounts to interchanging the two finite Dynkin labels. The precise transformation relations are as follows:

$$\begin{aligned} &n_{11}=L_2-\lambda_1-\lambda_2, \quad n_{12}=L_1-L_2+n_{23},\\ &n_{13}=L_2-\nu_1-\nu_2-n_{23}, \quad n_{22}=\mu_2-n_{23}. \end{aligned} \tag{8.9}$$

With the vector y^{T} defined as $y^{\mathsf{T}}=(k,\lambda_1,\lambda_2,\mu_1,\mu_2,\nu_1,\nu_2,n_{23})$, we can rewrite the symmetries of the fusion basis as

$$\begin{aligned} (3,5,7):&y^{\mathsf{T}}\to(k,L_2-\lambda_2-\nu_2,L_2-\mu_1-\mu_2,L_2-\lambda_2-\mu_2,L_2\\ &-\nu_1-\nu_2,L_2-\mu_2-\nu_2,L_2-\lambda_1-\lambda_2,n_{23}),\\ (3,5):&y^{\mathsf{T}}\to(k,L_1-\nu_1-\nu_2,L_2-\mu_1-\mu_2,L_2-\lambda_2-\mu_2,\mu_2,\nu_1,L_1-\lambda_1-\nu_1,n_{23}),\\ (1,8,9):&y^{\mathsf{T}}\to(k,k-L_1+\lambda_1,L_2-\mu_2-\nu_2,k-L_1+\mu_1,L_2\\ &-\lambda_2-\nu_2,k-L_1+\nu_1,L_2-\lambda_2-\mu_2,L_1-L_2+n_{23}),\\ (1,8):&y^{\mathsf{T}}\to(k,k-L_1+\lambda_1,\lambda_2,k-L_1+\mu_1,\mu_2,k-L_1+\nu_1,\nu_2,n_{23}),\\ (1,2)(4,8)(6,9):&y^{\mathsf{T}}\to(k,k-L_2+\nu_2,\lambda_2,\mu_1,k-L_1+\nu_1,L_2\\ &-\lambda_1-\lambda_2,L_1-\mu_1-\mu_2,n_{23}+k-L_1-\mu_2+\nu_1), \end{aligned} \tag{8.10}$$

where $L_i=(\lambda+\mu+\nu,\omega_i)$ with ω_i the ith fundamental weight. The remarkable feature of these symmetry transformations is that they send $y^{\mathsf{T}}\to y'^{\mathsf{T}}$ such that none of the prime variables except n'_{23} depends upon n_{23}. In other words, the new Dynkin labels, collectively denoted by D', do not depend upon n_{23}. Therefore, these symmetries map a state (i.e., a tableau) of a given fusion to another state of another fusion. The same is necessarily true for the inverted transformations. There is thus a one-to-one correspondence between the two fusions, i.e., they have the same multiplicity! In other words, the symmetries of the fusion basis are symmetries of the fusion coefficients. For instance,

$$
\begin{aligned}
&(3,5,7): \quad \mathcal{N}^{(k)}_{(\lambda_1,\lambda_2)(\mu_1,\mu_2)(\nu_1,\nu_2)} \\
&\qquad = \mathcal{N}^{(k)}_{(L_2-\lambda_2-\nu_2,L_2-\mu_1-\mu_2)(L_2-\lambda_2-\mu_2,L_2-\nu_1-\nu_2)(L_2-\mu_2-\nu_2,L_2-\lambda_1-\lambda_2)}, \\
&(3,5): \quad \mathcal{N}^{(k)}_{(\lambda_1,\lambda_2)(\mu_1,\mu_2)(\nu_1,\nu_2)} = \mathcal{N}^{(k)}_{(L_1-\nu_1-\nu_2,L_2-\mu_1-\mu_2)(L_2-\lambda_2-\mu_2,\mu_2)(\nu_1,L_1-\lambda_1-\nu_1)}, \\
&(1,8,9): \quad \mathcal{N}^{(k)}_{(\lambda_1,\lambda_2)(\mu_1,\mu_2)(\nu_1,\nu_2)} = \mathcal{N}^{(k)}_{(k-L_1+\lambda_1,L_2-\mu_2-\nu_2)(k-L_1+\mu_1,L_2-\lambda_2-\nu_2)(k-L_1+\nu_1,L_2-\lambda_2-\nu_2)}, \\
&(1,8): \quad \mathcal{N}^{(k)}_{(\lambda_1,\lambda_2)(\mu_1,\mu_2)(\nu_1,\nu_2)} = \mathcal{N}^{(k)}_{(k-L_1+\lambda_1,\lambda_2)(k-L_1+\mu_1,\mu_2)(k-L_1+\nu_1,\nu_2)}, \\
&(1,2)(4,8)(6,9): \quad \mathcal{N}^{(k)}_{(\lambda_1,\lambda_2)(\mu_1,\mu_2)(\nu_1,\nu_2)} = \mathcal{N}^{(k)}_{(k-L_2+\nu_2,\lambda_2)(\mu_1,k-L_1+\nu_1)(L_2-\lambda_1-\lambda_2,L_1-\mu_1-\mu_2)}.
\end{aligned}
\tag{8.11}
$$

In this rewriting, the dependence upon the n_{23} variable is dropped.

These are clearly new fusion symmetries as they mix the labels of the three representations. It is simple to verify that they leave the explicit expression of the $\widehat{su}(3)_k$ fusion coefficients (given in Ref. 14) invariant. Here is a numerical illustration: (1, 8) maps

$$
[4,10,12]\times[1,4,11]\times[9,3,4]\supset 0 \leftrightarrow E_0E_1^8E_3^2E_6E_7^2E_8^2, \quad E_1^8E_2E_3^2E_4E_6^2E_7E_8 \tag{8.12}
$$

onto

$$
[5,9,2]\times[2,3,11]\times[10,2,4]\supset 0 \leftrightarrow E_7E_1^8E_3^2E_6E_0^2E_8^2, \quad E_1^8E_2E_3^2E_4E_6^2E_0E_8. \tag{8.13}
$$

Both fusions have two decompositions in terms of elementary couplings, meaning that they have the same multiplicity. This symmetry is manifestly distinct from those already known. It is not a trivial symmetry in that, in terms of the elementary-coupling decompositions, it corresponds to the interchange of E_0 and E_7 in each decomposition.

The usual fusion symmetries can be obtained from various combinations of the above-mentioned symmetries of the fusion basis. For instance,

$$
\begin{aligned}
&(2,4,6)(3,5,7)\equiv P_{123}, \\
&(8,9)(5,7)(2,4)\equiv CP_{13}, \\
&(2,8)(1,4)(6,9)\equiv(1,a,a^2)P_{23},
\end{aligned}
\tag{8.14}
$$

where C is the conjugation:

$$
C\{\hat{\lambda}\times\hat{\mu}\times\hat{\nu}\supset 0\}=\hat{\lambda}^*\times\hat{\mu}^*\times\hat{\nu}^*\supset 0. \tag{8.15}
$$

We thus recover the known symmetries and additional ones.

IX. THE SYMMETRY GROUP OF THE $\widehat{sp}(4)_k$ POLYTOPE

The $\widehat{sp}(4)$ fusion rules are most conveniently described by means of the variables introduced in Ref. 15 and used in Refs. 3 and 6 (with a slight change of notation), namely $\{k,\lambda_1,\lambda_2,\mu_1,\mu_2,r_1,r_2,p,q\}$, with p, q and $r_i/2$ non-negative integers. The Dynkin labels of the third weight are

$$\nu_1=r_2-r_1-2p+\lambda_1+\mu_1, \quad \nu_2=p-q-r_2+\lambda_2+\mu_2. \tag{9.1}$$

In terms of the exponentiated variables, the elementary couplings are $\hat{E}_0=d$, together with

$$\begin{aligned}
&\hat{A}_1=dM_1, && \hat{A}_2=dL_1, && \hat{A}_3=dL_1M_1PQ,\\
&\hat{B}_1=dM_2, && \hat{B}_2=dL_2, && \hat{B}_3=dL_2M_2R_1^2R_2^2,\\
&\hat{C}_1=dL_2M_1Q, && \hat{C}_2=dL_1M_2R_2^2P, && \hat{C}_3=dL_1M_1P,\\
&\hat{D}_1=d^2L_1^2M_2R_2^2P^2, && \hat{D}_2=d^2L_2M_1^2R_1^2, && \hat{D}_3=d^2L_2M_2R_2^2.
\end{aligned} \tag{9.2}$$

Taking these to be the vertices of a polytope, the corresponding facets are found to be:

$$\begin{aligned}
k-\lambda_1-\lambda_2-\mu_2-r_1/2+r_2\geqslant 0, &\quad \mu_1-q\geqslant 0,\\
k-\lambda_1-\lambda_2-\mu_2+r_2/2\geqslant 0, &\quad \mu_1-q-r_1+r_2\geqslant 0,\\
k-\lambda_1-\mu_1-\mu_2+p\geqslant 0, &\quad \mu_1-p-r_1+r_2\geqslant 0,\\
k-\lambda_1-\lambda_2-\mu_1-\mu_2+p+q+r_1/2\geqslant 0, &\quad \mu_2-r_2/2\geqslant 0,\\
\lambda_1-p\geqslant 0, &\quad r_1\geqslant 0,\\
\lambda_2-r_1/2\geqslant 0, &\quad r_2\geqslant 0,\\
\lambda_2-r_1/2-q+p\geqslant 0, &\quad p\geqslant 0,\\
\lambda_2-r_2/2-q+p\geqslant 0, &\quad q\geqslant 0
\end{aligned} \tag{9.3}$$

in agreement with the results obtained in Ref. 3.

We next analyze the symmetries of the $\widehat{sp}(4)$ fusion polytope. The matrix V', with the column ordering $(\hat{E}_0,\hat{A}_1,\ldots,\hat{D}_3)$, reads

$$V'=k\begin{pmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1\\
0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1/2 & 1/2\\
0 & 1 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0\\
0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1/2 & 0 & 1/2\\
0 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 1 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 2 & 0 & 1 & 0 & 1\\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0\\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0
\end{pmatrix}. \tag{9.4}$$

Unfortunately for this case the kernel of V' is not one-dimensional. In fact, $N(V')$ is four-dimensional, which we understand from the fact that there are four generating relations—cf. Ref. 3, Eq. (5.18). As a result, we must study the symmetries of V' via the commutant of the matrix Q that performs the orthogonal projection onto the row space of V' (cf. proposition 2 of Sec. VI). This matrix reads

$$Q=\frac{1}{108}\begin{pmatrix}
82 & 16 & 0 & 18 & 0 & 10 & -2 & -18 & -14 & -20 & 16 & 4 & 16\\
16 & 67 & 0 & -9 & 0 & -20 & -14 & 9 & 10 & 13 & -14 & 28 & 22\\
0 & 0 & 108 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
18 & -9 & 0 & 81 & 0 & -18 & 0 & 27 & 0 & 9 & 18 & 0 & -18\\
0 & 0 & 0 & 0 & 108 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
10 & -20 & 0 & -18 & 0 & 82 & -2 & 18 & -14 & 16 & 16 & 4 & 16\\
-2 & -14 & 0 & 0 & 0 & -2 & 94 & 0 & 10 & -14 & 4 & 28 & 4\\
-18 & 9 & 0 & 27 & 0 & 18 & 0 & 81 & 0 & -9 & -18 & 0 & 18\\
-14 & 10 & 0 & 0 & 0 & -14 & 10 & 0 & 70 & 10 & 28 & -20 & 28\\
-20 & 13 & 0 & 9 & 0 & 16 & -14 & -9 & 10 & 67 & 22 & 28 & -14\\
16 & -14 & 0 & 18 & 0 & 16 & 4 & -18 & 28 & 22 & 40 & -8 & 4\\
4 & 28 & 0 & 0 & 0 & 4 & 28 & 0 & -20 & 28 & -8 & 52 & -8\\
16 & 22 & 0 & -18 & 0 & 16 & 4 & 18 & 28 & -14 & 4 & -8 & 40
\end{pmatrix}. \tag{9.5}$$

As already pointed out in Sec. VI, a row of Q can be mapped to another row by a symmetry transformation σ only if the two rows have the same entries. Hence, from the explicit form of (9.5), we see that any symmetry fixes the sets {1, 6}, {2, 10}, {3, 5}, {4, 8}, {11, 13}, {7}, {9}, and {12}. It is not difficult to see that the permutation (3, 5) is a symmetry.

We can again examine Q to see that a symmetry exchanges rows 1 and 6 iff it exchanges columns 2 and 10. It exchanges rows 2 and 10 iff it exchanges columns 11 and 13 and exchanges rows 11 and 13 iff it exchanges columns 4 and 8.

It is easy to verify that (1,6)(2,10)(11,13)(4,8) is a symmetry. Thus, the symmetries of V' are

$$G[\widehat{sp}(4)]=\{(),(3,5),(1,6)(2,10)(11,13)(4,8),(3,5)(1,6)(2,10)(11,13)(4,8)\} \tag{9.6}$$

isomorphic to $S_2\times S_2$.

With $x^{\mathsf{T}}=(k,\lambda_1,\lambda_2,\mu_1,\mu_2,r_1,r_2,p,q)$, the changes of variables corresponding to the generators of the symmetry group are:

$$\begin{aligned}
&(3,5):x^{\mathsf{T}}\mapsto(k,\mu_2-r_2/2+p,\lambda_2,\mu_1,\lambda_1+r_2/2-p,r_1,r_2,p,q),\\
&(1,6)(2,10)(11,13)(4,8):x^{\mathsf{T}}\mapsto(k,\lambda_1+\mu_1-r_1+r_2-2p,k-\lambda_1-\lambda_2-\mu_1-\mu_2+r_1+p\\
&\qquad +q,\mu_1,\mu_2,r_1,r_2,\mu_1-p-r_1+r_2,q).
\end{aligned} \tag{9.7}$$

The orbits of the symmetries on the inequalities of the fusion basis are [with the inequalities (9.3) labeled consecutively, column by column, from 1 to 16]:

$$\begin{aligned}
&(3,5):[[5,12]],\\
&(1,6)(2,10)(11,13)(4,8):[[1,7],[2,8],[4,6],[11,15]],
\end{aligned} \tag{9.8}$$

where orbits of length 1 have been omitted.

As indicated in the context of the $\widehat{su}(3)$ analysis, the most severe constraints on the symmetries come from the linear relations. There is indeed a large number of relations for $\widehat{sp}(4)$:[3]

$$\begin{gathered}\hat{E}_0\hat{C}_1\hat{C}_2=\hat{A}_3\hat{D}_3,\quad \hat{E}_0\hat{C}_2\hat{C}_3=\hat{A}_1\hat{D}_1,\quad \hat{E}_0\hat{C}_3\hat{C}_1=\hat{A}_1\hat{A}_3\hat{B}_2,\\ \hat{D}_1\hat{D}_2=\hat{E}_0\hat{B}_3\hat{C}_3^2,\quad \hat{D}_2\hat{D}_3=\hat{E}_0\hat{A}_1^2\hat{B}_2\hat{B}_3,\quad \hat{D}_1\hat{D}_3=\hat{E}_0\hat{B}_2\hat{C}_2^2,\\ \hat{C}_1\hat{D}_1=\hat{A}_3\hat{B}_2\hat{C}_2,\quad \hat{C}_2\hat{D}_2=\hat{A}_1\hat{B}_3\hat{C}_3,\quad \hat{C}_3\hat{D}_3=\hat{A}_1\hat{B}_2\hat{C}_2.\end{gathered}\tag{9.9}$$

It is not difficult to check that the symmetries leave these relations invariant. In fact, $(3,5)=(\hat{A}_2,\hat{B}_1)$ (which means the interchange of $\hat{A}_2$ and $\hat{B}_1$) and these two couplings do not appear in the relations. The other symmetry reads $(\hat{E}_0,\hat{B}_2)$ $(\hat{A}_1,\hat{C}_3)$ $(\hat{D}_1,\hat{D}_3)$ $(\hat{A}_3,\hat{C}_1)$.

With the vector y^{T} defined as $y^{\mathsf{T}}=(k,\lambda_1,\lambda_2,\mu_1,\mu_2,\nu_1,\nu_2,p,q)$, we can rewrite the symmetries of the fusion basis as:

$$\begin{gathered}(3,5):y^{\mathsf{T}}\to(k,-\lambda_2/2+\mu_2/2+\nu_2/2+p/2+q/2,\lambda_2,\mu_1,\\ \lambda_1+\lambda_2/2+\mu_2/2-\nu_2/2-p/2-q/2,-\lambda_1-\lambda_2/2+\mu_2/2+\nu_1+\nu_2/2+p/2+q/2,\\ \lambda_1+\lambda_2/2-\mu_2/2+\nu_2/2-p/2-q/2,p,q),\\ (1,6)(2,10)(11,13)(4,8):y^{\mathsf{T}}\to(k,\nu_1,k-\nu_1-\nu_2,\mu_1,\mu_2,\lambda_1,k-\lambda_1-\lambda_2,-\lambda_1+\nu_1+p,q).\end{gathered}\tag{9.10}$$

The first polytope symmetry does not correspond to a fusion-coefficient symmetry. However, the second one is a combination of an outer automorphism and a permutation of two weights:

$$(1,6)(2,10)(11,13)(4,8)=(a,1,a)P_{13}.\tag{9.11}$$

This is not a new symmetry of fusion coefficients.

X. THE SYMMETRY GROUP OF THE $\widehat{su}(4)_k$ POLYTOPE

The whole set of $\widehat{su}(4)$ fusion elementary couplings can all be generated from two couplings that have no elementary finite relative:

$$\hat{E}_0=[1,0,0,0]\times[1,0,0,0]\supset[1,0,0,0],\quad \hat{F}=[0,1,0,1]\times[0,1,0,1]\supset[0,1,0,1]\tag{10.1}$$

by means of the outer-automorphism group. We can thus characterize a coupling by a pair $(a^n,a^m)_i$ where a^n and a^m act on the first and the second weight, respectively, understanding that the action on the third weight is a^{n+m}. Here a permutes the Dynkin labels of an affine $\widehat{su}(4)$ weight as $a[\lambda_0,\lambda_1,\lambda_2,\lambda_3]=[\lambda_3,\lambda_0,\lambda_1,\lambda_2]$ so that $a^4=1$. The subindex i refers to the elementary coupling $\hat{E}_0$ or $\hat{F}$ from which it is obtained; these are labeled respectively as $i=0$, 1. The remaining elementary coupling are thus

$$\begin{gathered}\hat{A}_1=(a^0,a^3)_0,\quad \hat{A}_2=(a^3,a^1)_0,\quad \hat{A}_3=(a^1,a^0)_0,\\ \hat{B}_1=(a^0,a^2)_0,\quad \hat{B}_2=(a^2a^2)_0,\quad \hat{B}_3=(a^2,a^0)_0,\\ \hat{C}_1=(a^0,a^1)_0,\quad \hat{C}_2=(a^1,a^3)_0,\quad \hat{C}_3=(a^3,a^0)_0,\\ \hat{D}_1'=(a^2,a^1)_0,\quad \hat{D}_2'=(a^1,a^1)_0,\quad \hat{D}_3'=(a^1,a^2)_0,\\ \hat{D}_1=(a^2,a^3)_0,\quad \hat{D}_2=(a^3,a^3)_0,\quad \hat{D}_3=(a^3,a^2)_0,\\ \hat{E}_1=(a^0,a^1)_1,\quad \hat{E}_2=(a^1,a^1)_1,\quad \hat{E}_3=(a^1,a^0)_1.\end{gathered}\tag{10.2}$$

(The explicit reexpression of the elementary couplings in terms of the LR variables can be found in Ref. 3).

The reconstruction of the polytope facets out of these vertices reproduce the inequalities obtained in Ref. 3. These are

$$
\begin{aligned}
k-\lambda_1-\lambda_2-\lambda_3-n_{33}\geqslant 0, \quad & \lambda_3+n_{13}-n_{14}-n_{24}\geqslant 0,\\
k-\lambda_1-\lambda_2-n_{11}-n_{14}+n_{34}\geqslant 0, \quad & \lambda_3+n_{13}+n_{23}-n_{14}-n_{24}-n_{34}\geqslant 0,\\
k-\lambda_1-n_{11}-n_{13}-n_{14}\geqslant 0, \quad & n_{11}-n_{22}\geqslant 0,\\
k-\lambda_1-\lambda_2-\lambda_3-n_{22}+n_{34}\geqslant 0, \quad & n_{11}+n_{12}-n_{22}-n_{23}\geqslant 0,\\
k-\lambda_1-\lambda_2-n_{14}-n_{22}\geqslant 0, \quad & n_{11}+n_{12}+n_{13}-n_{22}-n_{23}-n_{24}\geqslant 0,\\
k-\lambda_1-\lambda_2-\lambda_3-n_{11}+n_{24}+n_{34}\geqslant 0, \quad & n_{22}-n_{33}\geqslant 0,\\
k-\lambda_1-\lambda_2-\lambda_3+n_{12}-n_{22}-n_{23}+n_{34}\geqslant 0, \quad & n_{22}+n_{23}-n_{33}-n_{34}\geqslant 0,\\
k-\lambda_1-\lambda_2-n_{14}+n_{13}-n_{22}-n_{24}\geqslant 0, \quad & n_{12}\geqslant 0,\\
k-\lambda_1-\lambda_2-n_{11}-n_{14}+n_{23}\geqslant 0, \quad & n_{13}\geqslant 0,\\
2k-2\lambda_1-2\lambda_2-\lambda_3-n_{14}-n_{22}-n_{11}+n_{34}\geqslant 0, \quad & n_{14}\geqslant 0,\\
\lambda_1-n_{12}\geqslant 0, \quad & n_{23}\geqslant 0,\\
\lambda_2-n_{13}\geqslant 0, \quad & n_{24}\geqslant 0,\\
\lambda_2+n_{12}-n_{13}-n_{23}\geqslant 0, \quad & n_{33}\geqslant 0,\\
\lambda_3-n_{14}\geqslant 0, \quad & n_{34}\geqslant 0.
\end{aligned}
\tag{10.3}
$$

We then look for the symmetry group of the resulting polytope using the commutant of Q. The matrix V', with the column ordering $(\hat{E}_0,\hat{A}_1,\cdots,\hat{D}'_1,\cdots,\hat{D}_3,\hat{E}_1,\hat{E}_2,\hat{E}_3,\hat{F})$, is

$$V' = k \begin{pmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & \frac{1}{2} & 0 & 0 & \frac{1}{2} \\
0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & \frac{1}{2} & 0 & 0 & \frac{1}{2} \\
0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & \frac{1}{2} & 0 & 0 & \frac{1}{2} \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \frac{1}{2} & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & \frac{1}{2} & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & \frac{1}{2} & 0 & \frac{1}{2} \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & \frac{1}{2} & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2}
\end{pmatrix}. \tag{10.4}$$

The matrix $Q' = 3240\, Q$ reads

$$\begin{pmatrix}
2088 & 0 & 0 & 0 & 168 & 168 & 168 & 600 & 600 & 600 & -360 & -360 & -360 & -360 & -360 & -360 & 384 & 384 & 384 & -144 \\
0 & 3240 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

384 & 0 & 0 & 0 & 484 & 484 & -56 & 340 & 340 & -200 & 660 & 120 & -420 & 120 & 660 & -420 & -128 & -128 & 952 & 48 \\
-144 & 0 & 0 & 0 & -384 & -384 & -384 & 480 & 480 & 480 & 360 & 360 & 360 & 360 & 360 & 360 & 48 & 48 & 48 & 792
\end{pmatrix}. \tag{10.5}$$

Again, considering the sets of entries in each row of Q we find that the symmetry group fixes the

sets {1}, {2, 3, 4}, {5, 6, 7}, {8, 9, 10}, {11, 12, 13, 14, 15, 16}, {17, 18, 19}, and {20}. We notice immediately that the permutations of 2, 3, and 4 give an S_3 symmetry that commutes with all the other symmetries.

Let us suppose that σ is a symmetry and let τ be the induced permutation of {11, 12, 13, 14, 15, 16}. The submatrix of Q corresponding to rows {11, 12, 13, 14, 15, 16} and columns {5, 6, 7} is

$$U_1=\frac{1}{3240}\begin{pmatrix} -285 & 660 & -15 \\ -15 & -285 & 660 \\ 660 & -15 & -285 \\ -285 & -15 & 660 \\ 660 & -285 & -15 \\ -15 & 660 & -285 \end{pmatrix}, \tag{10.6}$$

while the submatrix for rows {11, 12, 13, 14, 15, 16} and columns {8, 9, 10} is

$$U_2=\frac{1}{3240}\begin{pmatrix} 255 & -420 & 525 \\ 525 & 255 & -420 \\ -420 & 525 & 255 \\ 255 & 525 & -420 \\ -420 & 255 & 525 \\ 525 & -420 & 255 \end{pmatrix}, \tag{10.7}$$

and for rows {11, 12, 13, 14, 15, 16} and columns {17, 18, 19} it is

$$U_3=\frac{1}{3240}\begin{pmatrix} -420 & 120 & 660 \\ 660 & -420 & 120 \\ 120 & 660 & -420 \\ -420 & 660 & 120 \\ 120 & -420 & 660 \\ 660 & 120 & -420 \end{pmatrix}. \tag{10.8}$$

Since each of these matrices have rows with distinct entries, we can deduce the action of σ on each of the sets {5, 6, 7}, {8, 9, 10}, and {17, 18, 19} from τ. Since σ fixes 1 and 20 this determines σ except for its action on 2, 3, and 4, which, as noted previously, is arbitrary.

Thus, to find all symmetries, it suffices to find all possible τ. The submatrix of Q corresponding to rows {11, 12, 13, 14, 15, 16} and columns {11, 12, 13, 14, 15, 16} is

$$K=\frac{1}{3240}\begin{pmatrix} 2550 & 225 & 225 & -45 & -45 & -450 \\ 225 & 2250 & 225 & -450 & -45 & -45 \\ 225 & 225 & 2250 & -45 & -450 & -45 \\ -45 & -450 & -45 & 2250 & 225 & 225 \\ -45 & -45 & -450 & 225 & 2250 & 225 \\ -450 & -45 & -45 & 225 & 225 & 2250 \end{pmatrix}. \tag{10.9}$$

The permutation τ commutes with K and K has an eigenvector $w^{\mathrm{T}}=(-1,-1,-1,1,1,1)$, the corresponding eigenspace being one-dimensional. τ fixes this eigenspace and so either $\tau w=w$ or $\tau w=-w$. The group of all such permutations is $S_3 \wr S_2$ with the two S_3 groups permuting {11, 12,

13} and {14, 15, 16} and the S_2 interchanging them. Thus, every σ gives a τ in $S_3 \wr S_2$, but it is not necessarily true that every element of $S_3 \wr S_2$ extends to a symmetry of V'. In fact, only a subgroup can be extended, as we now show.

By trial and error, we can find two elements

$$\alpha=(11,14)(12,16)(13,15), \quad \beta=(11,12,13)(14,15,16) \tag{10.10}$$

of $S_3 \wr S_2$ which can be extended to the two symmetries

$$(6,7)(9,10)(11,14)(12,16)(13,15)(18,19) \tag{10.11}$$

and

$$(5,6,7)(8,9,10)(11,12,13)(14,15,16)(17,18,19). \tag{10.12}$$

The group generated by α and β turns out to be isomorphic to S_3 (which does not have the standard action).

Thus, we get a group of symmetries isomorphic to $S_3 \times S_3$:

$$\begin{aligned} G[\widehat{su}(4)]=\langle &(2,3),(2,3,4),(6,7)(9,10)(11,14)(12,16)(13,15) \\ &\times(18,19),(5,6,7)(8,9,10)(11,12,13)(14,15,16)(17,18,19)\rangle. \end{aligned} \tag{10.13}$$

There are no other symmetries for the following reason. Suppose that σ is a symmetry and τ is the induced permutation on {11, 12, 13, 14, 15, 16}. Since the group generated by α and β is transitive on {11, 12, 13, 14, 15, 16}, there is some τ' such that $\tau\tau'$ fixes 11. Then, by considering the first row of U_1, $\tau\tau'$ also fixes {5, 6, 7}. Hence $\tau\tau'$ must fix U_1. But this implies $\tau\tau'$ is the identity since U_1 has distinct rows. Thus $\tau^{-1}=\tau'$ and so σ is in the group G.

With $x^{\mathsf{T}}=(k,\lambda_1,\lambda_2,\lambda_3,n_{11},n_{12},n_{13},n_{14},n_{22},n_{23},n_{24},n_{33},n_{34})$, the changes of variables corresponding to the generating symmetries are:

$$\begin{aligned} &(2,3): x^{\mathsf{T}} \mapsto (k,\lambda_1,\lambda_2,\lambda_3-n_{14}+n_{33},n_{11}+n_{14}-n_{33},n_{12},n_{13},n_{33},n_{14}+n_{22}-n_{33},n_{23},n_{24},n_{14},n_{34}), \\ &(2,3,4): x^{\mathsf{T}} \mapsto (k,n_{12}+n_{14},\lambda_2,\lambda_3-n_{14}+n_{33},\lambda_1+n_{11}-n_{12}-n_{33},n_{12},n_{13},n_{33},\lambda_1-n_{12}+n_{22} \\ &\qquad -n_{33},n_{23},n_{24},\lambda_1-n_{12},n_{34}), \\ &(11,14)(12,16)(13,15)(6,7)(18,19)(9,10): \\ &\quad x^{\mathsf{T}} \mapsto (k,\lambda_1+\lambda_3-n_{12}-n_{14},\lambda_2,n_{12}+n_{14},n_{11}+n_{12}+n_{13}-n_{24}-n_{34},\lambda_3-n_{14},\lambda_2 \\ &\qquad -n_{13},n_{14},n_{22}+n_{23}-n_{34},\lambda_3+n_{13}-n_{14}-n_{24},\lambda_2+n_{12} \\ &\qquad -n_{13}-n_{23},n_{33},\lambda_3+n_{13}+n_{23}-n_{14}-n_{24}-n_{34}), \\ &(5,6,7)(8,9,10)(11,12,13)(14,15,16)(17,18,19): \\ &\quad x^{\mathsf{T}} \mapsto (k,\lambda_1+n_{11}+n_{13}-n_{22}-n_{23}-n_{24},n_{22}+n_{23}+n_{24}-n_{33} \\ &\qquad -n_{34},n_{14}+n_{34},\lambda_2+\lambda_3-n_{13}-n_{14}+n_{33},n_{11}+n_{12}+n_{13}-n_{22}-n_{23}-n_{24},n_{22}+n_{23} \\ &\qquad -n_{33}-n_{34},n_{14},\lambda_2-n_{13}+n_{33},n_{11}+n_{12}-n_{22}-n_{23},n_{22}-n_{33},n_{33},n_{11}-n_{22}). \end{aligned} \tag{10.14}$$

Labeling the $\widehat{su}(4)$ fusion inequalities of (10.3) from 1 to 28 (row by row), the orbits on the fusion basis are:

$$
\begin{aligned}
&(2,3):[[24,27]],\\
&(2,3,4):[[11,27,24]],\\
&(11,14)(12,16)(13,15)(6,7)(18,19)(9,10):\\
&\quad [[2,9],[3,6],[4,8],[5,7],[12,23],[13,26],[14,22],[15,25],[16,28],[17,19],[20,21]],\\
&(5,6,7)(8,9,10)(11,12,13)(14,15,16)(17,18,19):\\
&\quad [[1,6,3],[2,5,4],[7,9,8],[12,20,26],[13,21,23],[14,17,28],[15,18,25],[16,19,22]],
\end{aligned}
\tag{10.15}
$$

where the orbits of length 1 have been omitted.

As already indicated, severe constraints on the symmetries come from the linear relations. And in fact there are many such relations in the $\widehat{su}(4)$ case. The full list is:[3]

$$
\begin{aligned}
&\hat{E}_0\hat{D}_j'\hat{D}_k=\hat{C}_i\hat{E}_i, \quad \hat{E}_0\hat{D}_j\hat{D}_k'=\hat{B}_i\hat{C}_j\hat{C}_k, \quad \hat{E}_i\hat{E}_j=\hat{E}_0\hat{B}_k\hat{D}_k\hat{D}_k',\\
&\hat{D}_i\hat{E}_i=\hat{C}_j\hat{B}_k\hat{D}_k, \quad \hat{D}_i'\hat{E}_i=\hat{B}_j\hat{D}_j'\hat{C}_k, \quad \hat{E}_0\hat{F}=\hat{C}_1\hat{C}_2\hat{C}_3
\end{aligned}
\tag{10.16}
$$

with *i, j, k* a cyclic permutation of 1, 2, 3. The large number of relations, and more precisely, the fact that they mix elementary couplings with different threshold levels, is responsible for the absence of symmetries involving the level. All the above-found symmetries leave this set of relations invariant. For instance, the S_3 group generated by (2, 3) and (2, 3, 4) is the permutation group of the three $\hat{A}_i$'s, which do not appear in the relations.

With the vector y^{T} defined as $y^{\mathsf{T}}=(k,\lambda_1,\lambda_2,\lambda_3,\mu_1,\mu_2,\mu_3,\nu_1,\nu_2,\nu_3,n_{12},n_{14},n_{33})$, we can rewrite the symmetries of the fusion basis as:

$$
\begin{aligned}
&(2,3):y^{\mathsf{T}}\to(k,\lambda_1,\lambda_2,\lambda_3-n_{14}+n_{33},\mu_1-n_{14}+n_{33},\mu_2,\mu_3+n_{14}-n_{33},\nu_1+n_{14}\\
&\qquad -n_{33},\nu_2,\nu_3,n_{12},n_{14}n_{33}),\\
&(2,3,4):y^{\mathsf{T}}\to(k,n_{12}+n_{33},\lambda_2,\lambda_1+\lambda_3-n_{12}-n_{14},\lambda_1+\mu_1-n_{12}-n_{14},\mu_2,\mu_3+n_{14}-n_{33},\nu_1+n_{14}\\
&\qquad -n_{33},\nu_2,-\lambda_1+\nu_3+n_{12}+n_{33},n_{12},\lambda_1-n_{12},n_{14}),\\
&\qquad (11,14)(12,16)(13,15)(6,7)(18,19)(9,10):\\
&\qquad\quad y^{\mathsf{T}}\to(k,\lambda_1+\lambda_3-n_{12}-n_{14},\lambda_2,n_{12}+n_{14},\nu_3-\lambda_1+n_{12}\\
&\qquad\qquad +n_{14},\nu_2,\nu_1,\mu_3,\mu_2,\lambda_1+\mu_1-n_{12}-n_{14},\lambda_3-n_{14},n_{14},n_{33}),\\
&(5,6,7)(8,9,10)(11,12,13)(14,15,16)(17,18,19):\\
&\quad y^{\mathsf{T}}\to(k,\lambda_1+\nu_1-n_{12}-n_{33},\nu_2,-\lambda_1+\nu_3+n_{12}+n_{14},n_{12}+n_{14},\lambda_2,\lambda_3-n_{14}+n_{33},\mu_1-n_{14}\\
&\qquad +n_{33},\mu_2,\lambda_1+\mu_3-n_{12}-n_{33},\nu_1-n_{33},n_{14},n_{33}).
\end{aligned}
\tag{10.17}
$$

These symmetries do not correspond to a fusion-coefficient symmetries.

XI. CONCLUSION

In this paper we presented the concept of fusion bases, first introduced in Ref. 3, from a novel point of view as the set of facets of a polytope. This reformulation gives access to the powerful computer programs that have been developed for generating facets out of the vertices. Moreover, by reformulating the problem in a geometrical way, we were led to the study of the affine symmetry group of the fusion polytope, introduced here for the first time. We developed simple

tools for studying this group analytically for the lowest rank affine Lie algebras. We also defined the vertex symmetry group of a polytope and noted that for fusion polytopes the affine and vertex symmetry groups appear to be the same—a property which does not hold for general polytopes.

The order of the vertex symmetry group of the fusion polytope of the lowest rank affine Lie algebras was found to be 24 for $\widehat{su}(2)$, 432 for $\widehat{su}(3)$, 36 for $\widehat{su}(4)$, and 4 for $\widehat{sp}(4)$. Comparing $\widehat{su}(2)$ and $\widehat{su}(3)$, it is natural to see an increase of the order of the group with the rank since the number of vertices increases rapidly. However, it might be surprising to observe this drastic reduction in the order when passing from $\widehat{su}(3)$ to $\widehat{su}(4)$. The reason is that the number of linear relations, which have to be preserved by the symmetry transformations, also increases rapidly with the rank.

We should stress that a fusion polytope is rather special type of polytope in that its vertices are the elementary solutions of the facets, which is far from being a generic property of polytopes.

It is an interesting open problem to try to generate the full set of fusion inequalities, or equivalently, to give a generic description of the fusion polytope, from a general Lie algebraic point of view.

On the other hand, we could ask whether the polytope we have obtained, whose description relies heavily on the LR variables, is the ''genuine'' fusion polytope or whether it is just one among a variety of polytopes. In that vein, we note that Rasmussen and Walton[16] have recently also developed a polytope interpretation of $\widehat{su}(3)$ and $\widehat{su}(4)$ fusion coefficients using a different approach from ours. Prompted by the referee we have investigated the relationship with the polytopes found in this paper. We find, perhaps surprisingly, after removing redundant variables and making a suitable change of coordinates that the two sets of polytopes coincide. This suggests that the polytopes might be in some sense unique.

Finally, concerning the symmetry analysis, we stress that we have restricted our analysis to a special class of symmetries, namely those which exist at all levels. Whether symmetries at particular levels or even symmetries that relate fusion polytopes at different levels can be unraveled by our method remains to be studied.

(Received 15 March 2002; accepted for publication 26 April 2002)

The introduction of a lattice converts a singular boundary-layer problem in the continuum into a regular perturbation problem. However, the continuum limit of the discrete problem is extremely nontrivial and is not completely understood. This article examines two singular boundary-layer problems taken from mathematical physics, the instanton problem and the Blasius equation, and in each case examines two strategies, Padé resummation and variational perturbation theory, to recover the solution to the continuum problem from the solution to the associated discrete problem. Both resummation procedures produce good and interesting results for the two cases, but the results still deviate from the exact solutions. To understand the discrepancy a comprehensive large-order behavior analysis of the strong-coupling lattice expansions for each of the two problems is done. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1490408]

I. INTRODUCTION

In this article we report some major advances in understanding (albeit not a complete solution to) a difficult general class of problems in mathematical physics. We consider here the conversion of a continuum problem into a discrete problem by the insertion of a lattice spacing parameter a, the solution of the continuum problem on the lattice, and the subsequent extremely subtle continuum limit $a\to 0$.

Almost every continuum physics problem is singular as a function of the parameters in the problem. As a result, only rarely does the perturbation series take the form of a Taylor series having a nonzero radius of convergence. As an elementary example, consider the algebraic polynomial equation

$$\epsilon x^3 + x - 1 = 0. \tag{1}$$

This problem is singular in the limit $\epsilon\to 0$. In this limit, the degree of the polynomial changes from three to one and thus two of the roots abruptly disappear. As a consequence, a perturbative solution to this problem [expressing the roots $x(\epsilon)$ as series in powers of ϵ] yields expressions that are more complicated than Taylor series.

A more elaborate example of a singular problem is the time-independent Schrödinger equation

$$-\frac{\hbar^2}{2M}\nabla^2\Psi(\mathbf{x}) + [V(\mathbf{x}) - E]\Psi(\mathbf{x}) = 0. \tag{2}$$

a)Electronic mail: cmb@howdy.wustl.edu
b)Electronic mail: pelster@physik.fu-berlin.de
c)Electronic mail: weisbach@physik.fu-berlin.de

In the classical limit $\hbar \to 0$ this differential equation abruptly becomes an *algebraic* equation, and thus the general solution no longer contains any arbitrary constants or functions and, as a result, it can no longer satisfy the initial conditions. We know that for small $\hbar$ the solution is not Taylor-like but rather is a singular exponential in WKB form:

$$\Psi(\mathbf{x}) \sim e^{S(\mathbf{x})/\hbar} \quad (\hbar \to 0). \tag{3}$$

In the study of quantum field theory, it is well known that infinities appear in the perturbative expansion in powers of the coupling constant. There are two kinds of infinities. The first kind, which is due to the pointlike nature of the interaction, requires the use of renormalization. The second kind, which is due to singularities in the complex-coupling-constant plane, forces the perturbation series to have a zero radius of convergence.

A quantum field theory can be regulated by introducing a lattice spacing. The resulting discrete theory is completely finite and can be studied numerically by using various kinds of numerical methods such as Monte Carlo integration. However, the underlying singular nature of the continuum quantum field theory resurfaces in the continuum limit $a \to 0$. The introduction of a lattice spacing and the singular nature of the continuum limit was investigated in a series of papers by Bender *et al.*[1–9]

A quantum field theory is just one instance in which discretization regulates and eliminates the singular nature of the problem. It is also known that introducing a lattice spacing converts a boundary-layer problem, which is a singular perturbation problem, into a regular perturbation problem.[10–12] A *boundary-layer problem* is a differential-equation-boundary-value problem in which the highest derivative of the differential equation is multiplied by a small parameter ϵ. Consider as an example

$$\epsilon y''(x) + a(x)y'(x) + b(x)y(x) = c(x), \tag{4}$$

where the boundary conditions on the function $y(x)$ typically have a form such as

$$y(0) = A, \quad y(1) = B. \tag{5}$$

This boundary-value problem is singular because in the limit $\epsilon \to 0$ one of the solutions abruptly disappears and the limiting solution is not able to satisfy the two boundary conditions in (5). The usual way to solve the boundary-value problem (4) and (5) is to decompose the interval $0 \leqslant x \leqslant 1$ into two regions, an *outer region*, in which the solution varies slowly as a function of x, and an *inner region* or *boundary-layer region*, in which the solution varies rapidly as a function of x. The boundary-layer region is a narrow region whose thickness is typically of order ϵ or some power of ϵ.[13]

An important example of a boundary-layer problem is the instanton equation

$$\epsilon^2 f''(x) + f(x) - f^3(x) = 0, \tag{6}$$

with the associated boundary conditions

$$f(0) = 0, \quad f(\infty) = 1. \tag{7}$$

The exact solution to this instanton problem is

$$f(x) = \tanh \frac{x}{\epsilon\sqrt{2}}. \tag{8}$$

Note that the solution $f(x)$ varies rapidly at the origin $x = 0$ over a region of thickness ϵ; this is the boundary-layer region. The solution varies slowly (it is approximately 1) outside of this region. The outer region consists of those x not near the origin.

A novel way to solve the instanton problem is to discretize it by introducing a lattice. On the lattice, the differential equation becomes a difference equation that can easily be solved perturbatively. In the continuum limit, as the lattice spacing vanishes, we then obtain a strong-coupling expansion that must be evaluated by means of a Padé or a variational perturbation theory method. To illustrate the approach our objective will be to calculate the slope of the instanton at $x=0$, which from (8) has the value

$$f'(0)=\frac{1}{\epsilon\sqrt{2}}. \tag{9}$$

We introduce a lattice with lattice spacing a so that the real axis is discretized in steps of width a. The spatial coordinate reads $x_n=na$, where the function $f(x)$ assumes the value $f_n=f(x_n)$. On the lattice the second spatial derivative in (6) becomes

$$f''(x)\to\frac{f_{n+1}-2f_n+f_{n-1}}{a^2}. \tag{10}$$

Thus, from the instanton equation (6) we obtain the difference equation

$$\frac{\epsilon^2}{a^2}(f_{n+1}-2f_n+f_{n-1})+f_n-f_n^3=0, \tag{11}$$

where the boundary values follow from (7):

$$f_0=0, \quad f_\infty=1. \tag{12}$$

The natural expansion parameter now is ϵ^2/a^2, to which we assign the name δ:

$$\delta\equiv\frac{\epsilon^2}{a^2}. \tag{13}$$

The singular perturbation problem in the continuum [whose solution $f(x)$ in (8) does not possess a Taylor expansion in powers of ϵ] has become a *regular* perturbation problem. That is, we can now expand the solution f_n to the difference equation (11) as a *Taylor series* in powers of δ:

$$f_n=a_{n,0}+a_{n,1}\delta+a_{n,2}\delta^2+\cdots. \tag{14}$$

We impose the boundary values (12) by requiring that

$$a_{0,0}\equiv 0 \quad \text{and} \quad a_{n,0}\equiv 1 \quad (n\geqslant 1). \tag{15}$$

Inserting the *ansatz* (14) into the difference equation (11), we get the recursion relation[10]

$$a_{n,j}=\frac{1}{2}a_{n+1,j-1}+a_{n,j-1}+\frac{1}{2}a_{n-1,j-1}-\sum_{k=1}^{j-1}a_{n,k}a_{n,j-k}-\frac{1}{2}\sum_{k=1}^{j-1}\sum_{l=1}^{j-k}a_{n,k}a_{n,l}a_{n,j-k-l}. \tag{16}$$

For the first derivative at the origin $x=0$ this leads to the series

$$f'(0)=\lim_{a\to 0}\frac{f_1-f_0}{a}=\lim_{a\to 0}\frac{f_1}{a}=\lim_{a\to 0}\frac{1}{a}\sum_{j=0}^{\infty}a_{1,j}\delta^j=\lim_{a\to 0}\frac{1}{a}\left(1-\frac{\delta}{2}+\frac{\delta^2}{8}+\frac{11\delta^4}{128}+\cdots\right). \tag{17}$$

We have calculated the coefficients $a_{1,j}$ with the help of Maple V R7 up to order $j=200$. The first 20 numbers are given in Table I. A complete list of these coefficients can be found on the

webpage of the author FW.[14] Note that the expansion parameter δ in (17) is not small but rather tends to infinity in the limit as the lattice spacing a approaches zero. Using the parameter δ defined in (13) we rewrite the series (17) as

$$f'(0)=\frac{1}{\epsilon}\lim_{\delta\to\infty}\sqrt{\delta}\left(1-\frac{\delta}{2}+\frac{\delta^2}{8}+\frac{11\delta^4}{128}+\cdots\right). \tag{18}$$

Taking into account the exact result (9), we obtain the identity

$$\frac{1}{\sqrt{2}}=\lim_{\delta\to\infty}\sqrt{\delta}\left(1-\frac{\delta}{2}+\frac{\delta^2}{8}+\frac{11\delta^4}{128}+\cdots\right). \tag{19}$$

The purpose of this article is to examine equations like (19). This equation shows that the singular nature of the instanton problem has resurfaced in the continuum limit $\delta\to\infty$ of the lattice expansion. The expression on the right side of (19) should have the value $1/\sqrt{2}=0.707\,106\,781\,2\ldots$, but it is not at all obvious why this is so, and the objective of this article is to analyze this difficult and subtle limit.

This article is organized as follows. In Sec. II we use Padé techniques to perform the limit in (19). We will see that while the results are not bad (the accuracy is about 1%), better methods are needed. We perform the Padé analysis to much higher order than has ever been done before and we discover a new qualitative behavior that has not yet been observed. In Sec. III we try the use of the variational perturbation theory techniques introduced by Kleinert to perform the sum in (19). These techniques increase the accuracy by a factor of about 10, but they still do not give the exact result. While variational perturbation theory works very well in summing the strong-coupling series for the ground-state energy of the anharmonic oscillator,[15] and for the critical exponents of second-order phase transitions,[16] we show that the series in (19) is at the very edge of validity for Kleinert's methods. We then examine the large-order behavior of the terms of the

sum in (19) in Sec. IV. We show definitively that the Taylor expansion has a nonzero radius of convergence and, thus, on the lattice, the instanton problem is a regular perturbation problem.

In Sec. V we turn to a more difficult singular perturbation problem, namely, the Blasius equation of fluid dynamics. We use the same approach as for the instanton equation. In Secs. VI–VIII we study the summation of the lattice perturbation expansion using Padé and variational methods and we examine the large-order behavior of the lattice perturbation series. We find that Padé methods give good but not excellent results and that variational perturbation theory is better than Padé. Again, the series we need to evaluate in the continuum limit lies at the very edge of validity for Kleinert's methods. We also find that, unlike the lattice perturbation expansion coefficients for the instanton problem, the sign pattern of the Blasius weak-coupling series does not alternate. Rather, it is governed by a cosine function with a frequency different from π.

II. PADÉ RESUMMATION FOR THE INSTANTON EQUATION

In this section we examine what happens if we attempt to evaluate the right side of (19) by using Padé techniques. Padé resummation has already been applied to the instanton problem up to 50th order.[10] However, we have been able to perform the procedures to much higher orders. We have discovered that remarkable and unsuspected new phenomena occur just a few orders beyond what has been computed.

The procedure is as follows. Consider the formal Frobenius series

$$S(\delta)=\delta^M\sum_{n=0}^{\infty} a_n\delta^n, \tag{20}$$

where M is a non-negative number. Raising this series to the power $1/M$, inverting the right hand side and reexpanding, we obtain

$$S^{1/M}(\delta)=\frac{\delta}{\sum_{n=0}^{\infty} b_n\delta^n}, \tag{21}$$

with new expansion coefficients b_n. Assuming we know the first $N+1$ terms of the original power series in (20), we raise Eq. (21) to the power N. We then truncate the summation at $n=N$, finally getting

$$S^{N/M}(\delta)=\frac{\delta^N}{\sum_{n=0}^{N} c_n^{(N)}\delta^n}, \tag{22}$$

where we have reexpanded and obtained new expansion coefficients c_n. In the limit $\delta\to\infty$, only the Nth term in the denominator survives and we obtain the approximant

$$(S_N)^{N/M}\equiv\lim_{\delta\to\infty} S^{N/M}(\delta)=\lim_{\delta\to\infty}\frac{\delta^N}{\sum_{n=0}^{N} c_n^{(N)}\delta^n}=\frac{1}{c_N^{(N)}}. \tag{23}$$

The approximant $S_N=(c_N^{(N)})^{-M/N}$ is the zeroth-order survivor of the limiting process. Also, taking into account the first-order correction we observe that, as in the case of variational perturbation theory (see Sec. III), there is an approach to scaling. In the limit $\delta\to\infty$ the Frobenius series $S(\delta)$ in Eq. (20) converges to a constant C. Additionally, the approach to scaling, following from the Padé resummation (23), reveals how fast it converges:

$$S(\delta)\sim C+C'\delta^{-1}\quad(\delta\to\infty). \tag{24}$$

We now apply this procedure to the boundary-layer problem (11). [Recall that the weak-coupling coefficients for the first 20 coefficients $a_{1,j}$ obtained from (16) are shown in Table I and that more can be found in Ref. 14.] Resumming the series (14) for $n=1$,

TABLE II. The first 20 Padé approximants for the solution to the instanton problem (19).

10	0.712 308 458	20	0.702 349 024

$$f_1 = \sum_{j=0}^{N} a_{1,j}\delta^j, \tag{25}$$

according to the Padé procedure (23) with $M=\frac{1}{2}$ as follows from (19) and evaluating the approximants $S_N=(c_N^{(N)})^{-M/N}$, we get the numbers listed in Table II.

Compared with the numerical solution $1/\sqrt{2}\approx 0.717\,106\,781\,2$, this strong-coupling expansion seems to converge quite well. However, when we go to higher orders, we find that the numbers drop below the exact solution and assume a minimum at $N=24$, where the approximant has the value $S_{24}\approx 0.701\,983\,19$. The approximants then rise again, cross the exact solution at $N=41$ and become complex at $N=52$. The appearance of complex numbers is a consequence of taking the Nth root in Eq. (23) when the coefficients $c_N^{(N)}$ become negative. This phenomenon has not been observed before in the course of using this Padé procedure. The imaginary part then becomes smaller and smaller as N rises. Abruptly, at $N=68$, the approximants become real again. As one can see from the spikes in Fig. 1 this pattern is repeated for higher N. Note that the figure only shows the real part of the Padé approximant S_N.

Apparently, the sequence of approximants S_N does not converge. The singular nature of the instanton equation has the effect of making the Padé approximants behave like the partial sums of a divergent (asymptotic) series; at first the partial sums appear to converge to a limit, and then they veer off. In the case of the Padé's shown in Fig. 1 the approximants approach to within 1% of the

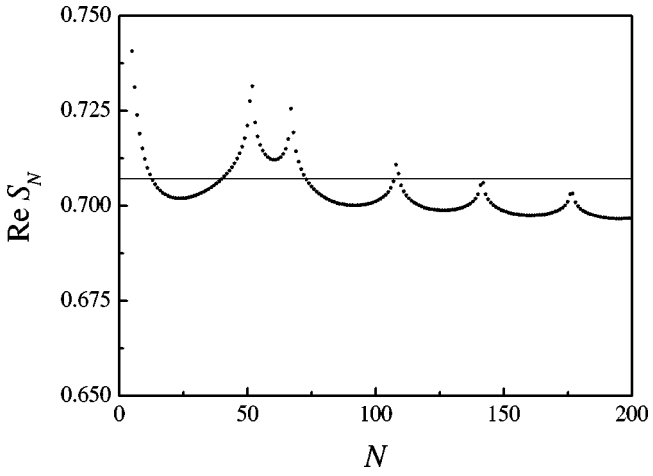

FIG. 1. The real part of the Padé approximants S_N up to 200th order. Note that the approximants do not converge to the exact solution, which is represented by the horizontal solid line. The phases where the approximants become complex are marked by spikes.

correct limit before veering off. It appears that another more powerful resummation technique is needed to treat the expression in (19). In the next section we apply a technique due to Kleinert.

III. VARIATIONAL PERTURBATION THEORY FOR THE INSTANTON EQUATION

Kleinert has developed a technique in the context of the ground-state energy of the anharmonic oscillator[15] and of critical exponents of second-order phase transitions[16] for summing divergent perturbation series. This technique, known as Kleinert's square-root trick, is described below.

Consider a weak-coupling series

$$f_N(\delta)=\sum_{n=0}^{N} f_n \delta^n, \tag{26}$$

which is truncated at order N. Rewrite this weak-coupling expansion by introducing an auxiliary scaling parameter κ:[15,16]

$$f_N(\delta)=\kappa^p \sum_{n=0}^{N} f_n \left(\frac{\delta}{\kappa^q}\right)^n \Bigg|_{\kappa=1}, \tag{27}$$

which is set to $\kappa=1$ later. The square-root trick now reads

$$\kappa \to \sqrt{K^2+\kappa^2-K^2}=K\sqrt{1+\delta r}, \tag{28}$$

where K is a ''dummy'' scaling parameter and

$$r=\frac{1}{\delta}\left(\frac{\kappa^2}{K^2}-1\right). \tag{29}$$

In the case of the anharmonic oscillator, K is the frequency Ω of a trial harmonic oscillator.[15]

Substituting (28) into the truncated weak-coupling series (27), we obtain

$$f_N(\delta)=\sum_{n=0}^{N} f_n K^{p-nq}(1+\delta r)^{(p-nq)/2}\delta^n. \tag{30}$$

The factor $(1+\delta r)^\alpha$ with $\alpha \equiv (p-nq)/2$ is expanded by means of generalized binomials:

$$(1+\delta r)^\alpha=\sum_{k=0}^{N-n}\binom{\alpha}{k}(\delta r)^k \mathcal{O}(\delta^{N-n})=\sum_{k=0}^{N-n}\binom{\alpha}{k}\left(\frac{1}{K^2}-1\right)^k \mathcal{O}(\delta^{N-n}), \tag{31}$$

where we have used (29) and finally have set $\kappa \equiv 1$. The binomial is defined as

$$\binom{\alpha}{k}\equiv \frac{\Gamma(\alpha+1)}{\Gamma(k+1)\Gamma(\alpha-k+1)}. \tag{32}$$

Thus the function $f_N(\delta)$ becomes K dependent and reduces to

$$f_N(\delta,K)=\sum_{n=0}^{N}\left[\sum_{k=0}^{N-n}\binom{\frac{1}{2}(p-nq)}{k}\left(\frac{1}{K^2}-1\right)^k K^{p-nq}\right] f_n \delta^n. \tag{33}$$

To first order this expression reduces to

$$f_1(\delta,K)=\left(1-\frac{p}{2}\right)f_0K^p+\frac{p}{2}f_0K^{p-2}+f_1\delta K^{p-q}. \tag{34}$$

Applying the principle of least sensitivity[17] leaves us with

$$\frac{\partial f_1(\delta,K)}{\partial K}\sim p\left(1-\frac{p}{2}\right)f_0+\frac{p(p-2)}{2}f_0K^{-2}+(p-q)f_1\delta K^{-q}\equiv 0. \tag{35}$$

Next, making the strong-coupling ansatz

$$K^{(1)}(\delta)=\delta^{1/q}(k_0^{(1)}+k_1^{(1)}\delta^{-2/q}+\cdots), \tag{36}$$

we obtain the following equation from (35):

$$p\left(1-\frac{p}{2}\right)f_0+\frac{p(p-2)}{2}f_0(k_0^{(1)}\delta^{1/q})^{-2}+(p-q)f_1\delta(\delta^{1/q}k_0^{(1)})^{-q}=0. \tag{37}$$

The second term is a subleading contribution in the limit as the coupling δ goes to infinity which we can neglect. Solving for $k_0^{(1)}$ we then get

$$k_0^{(1)}=\left(\frac{2f_1}{f_0}\frac{p-q}{p(p-2)}\right)^{1/q}. \tag{38}$$

Assuming that the ansatz (36) for the variational parameter $K(\delta)$ also holds for higher orders we obtain from the function $f_N(\delta,K)$ in (33)

$$f_N(\delta)=\delta^{p/q}[b_0^{(N)}(k_0^{(N)})+b_1^{(N)}(k_0^{(N)},k_1^{(N)})\delta^{-2/q}+\cdots], \tag{39}$$

where the leading strong-coupling coefficient $b_0^{(N)}(k_0^{(N)})$ is given by

$$b_0^{(N)}(k_0^{(N)})=\sum_{n=0}^{N}\sum_{k=0}^{N-n}\binom{\frac{1}{2}(p-nq)}{k}(-1)^k f_n(k_0^{(N)})^{p-nq}. \tag{40}$$

The inner sum can be further simplified, using

$$\sum_{k=0}^{m}(-1)^k\binom{\alpha}{k}=(-1)^m\binom{\alpha-1}{m}. \tag{41}$$

Thus the strong-coupling coefficient (40) reduces to

$$b_0^{(N)}(k_0^{(N)})=\sum_{n=0}^{N}(-1)^{N-n}\binom{\frac{1}{2}(p-nq)-1}{N-n}f_n(k_0^{(N)})^{p-nq}. \tag{42}$$

So, looking at Eq. (39) we see that the fraction p/q tells us the leading power behavior in δ and $2/q$ indicates the approach to scaling:

$$\sum_{j=0}^{\infty}f_j\delta^j\sim\delta^{p/q}(b_0+b_1\delta^{-2/q}+\cdots)\quad(\delta\to\infty). \tag{43}$$

For the instanton equation we can determine the numbers p and q by re-obtaining the differential equation (6) from the difference equation (11). The positive real axis is discretized in steps of width a, so that we let $x_n \equiv na$. The power series expansion for the discrete function $f_n = f(x_n)$ has the form

$$f_{n\pm1} = f(x_n) \pm f'(x_n)a + \tfrac{1}{2}f''(x_n)a^2 \pm \tfrac{1}{6}f'''(x_n)a^3 + \tfrac{1}{24}f''''(x_n)a^4 \pm \cdots . \tag{44}$$

Thus, the numerator of the second derivative (10) becomes

$$f_{n+1} - 2\,f_n + f_{n-1} = f_n'' a^2 + \tfrac{1}{12}f_n''''a^4 + \cdots , \tag{45}$$

so the zeroth-, first-, and third-order contributions cancel. Translating the lattice result for f_n back to the continuous function $f(x_n) = f_n$, the difference equation (11) reads

$$\epsilon^2[f''(x) + \tfrac{1}{12}f''''(x)a^2 + \cdots] + f(x) - f^3(x) = 0. \tag{46}$$

Writing out the power series

$$f(x) = f_0(x) + a^2 f_1(x) + a^4 f_2(x) + \cdots , \tag{47}$$

and comparing even powers of a, we get from Eq. (46) for a^0

$$\epsilon^2 f_0''(x) + f_0(x) - f_0^3(x) = 0, \tag{48}$$

which is just the original instanton equation (6). For a^2 we have

$$\epsilon^2 f_1''(x) + f_1(x)(1 - 3f_0^2(x)) = -\tfrac{1}{12}\epsilon^2 f_0''''(x). \tag{49}$$

The boundary values read

$$f_0(0) = 0, \quad f_0(\infty) = 1, \tag{50}$$

and

$$f_1(0) = f_1(\infty) = 0, \tag{51}$$

respectively. The solution to Eq. (48) with the boundary values (50) is of course

$$f_0(x) = \tanh\frac{x}{\epsilon\sqrt{2}}. \tag{52}$$

So, finally from (47) we get for the derivative at the origin $x = 0$:

$$f'(0) = f_0'(0) + \frac{\epsilon^2}{\delta}f_1'(0) + \cdots = \frac{1}{\epsilon\sqrt{2}} + \frac{\epsilon^2}{\delta}f_1'(0) + \cdots . \tag{53}$$

Comparing Eq. (53) with (18), we resum the weak-coupling series in (18) as

$$1 - \frac{\delta}{2} + \frac{\delta^2}{8} + \cdots = \delta^{-1/2}\left[\frac{1}{\sqrt{2}} + \epsilon^3 f_1'(0)\,\delta^{-1} + \cdots\right]. \tag{54}$$

Also, comparing with (43), we conclude that the leading power and the approach to scaling are given by

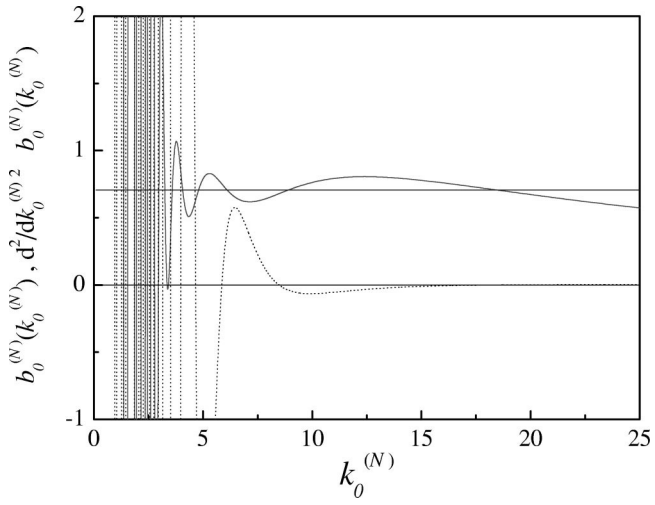

FIG. 2. The function $b_0^{(N)}(k_0^{(N)})$ from (42) for $N=200$ (solid line) and its second derivative with respect to $k_0^{(N)}$ (dotted line). The upper horizontal line equals $1/\sqrt{2}$, the correct limiting value of the instanton problem. All extrema of $b_0^{(N)}$ are far from this value. Only the inflection point on the right-hand side comes close. The value for $k_0^{(N)}$, for which the second derivative vanishes, is $k_0^{(N)}=18.425\,10$. Substituting that number into the function $b_0^{(N)}(k_0^{(N)})$, we obtain in the 200th order $b_0^{(200)}=0.707\,417$. The corresponding Richardson extrapolations can be found in Table IV.

$$\frac{p}{q}=-\frac{1}{2}, \quad \frac{2}{q}=1, \tag{55}$$

respectively. So we identify $p=-1$ and $q=2$.

We now evaluate the leading strong-coupling coefficient b_0 from (43) according to (42) with $p=-1$ and $q=2$. To that end we substitute our 200 weak-coupling coefficients from Ref. 14 into the formula using a computer algebra program. We are now confronted with the following problem: The principle of least sensitivity cannot be unambiguously applied. Optimizing with respect to extrema, inflection points, or higher derivatives does yield converging results for the strong-coupling limit. However, all these strong-coupling series converge to the wrong values.

There is one particularly unpleasant case: The second derivative with respect to $k_0^{(N)}$ for the largest $k_0^{(N)}$ where this derivative exists (see Fig. 2) gives a convergent strong-coupling series. The numbers come extremely close to $1/\sqrt{2}$ as one can see from the 20 numbers in Table III. The 200th leading strong-coupling coefficient is $b_0^{(200)}=0.707\,417\ldots$. However, a Richardson extrapolation[13] based on the first 200 orders then unfortunately shows that variational perturbation theory produces a value slightly smaller than $1/\sqrt{2}$. The first six orders of Richardson extrapola-

6	0.706 399 832 085 884 464 98	increasing

tions are presented in Table IV. Hence, the strong-coupling series $b_0^{(N)}$ does converge, but it converges to the wrong number, only one part per 1000 away from the true value:

$$f_1^{(\mathrm{VPT})} \approx \lim_{\delta\to\infty} \sum_{n=0}^{200} a_{1,n}\delta^n = b_0^{(\infty)} = 0.706\,399\,832\,085\,88\,45 \pm 0.000\,000\,000\,000\,000\,1 \tag{56}$$

compared with $f'(0)=1/\sqrt{2}=0.707\,106\,781\,2\ldots$. The deviation is just 0.099%, but $1/\sqrt{2}$ can unfortunately be ruled out.

Given that $p=-1$ and $q=2$, the failure of variational perturbation theory is not surprising. According to Ref. 16 the fraction $2/q$ must lie within the open interval $(\frac{1}{2},1)$. Otherwise, one cannot prove that variational perturbation theory converges. Thus, *this problem lies exactly on the upper boundary of the region in which the summation method is known to work.*

We can understand the upper edge of the range of the parameter $2/q$ that describes the approach to scaling by looking at the standard deviation from the actual limiting value. It turns out[16] that the deviation in the limit as the perturbative order N goes to infinity assumes the shape

$$\left|\frac{b_0^{(N)}-b_0}{b_0}\right| \sim \exp(-CN^{1-2/q}) \quad (N\to\infty), \tag{57}$$

where C is a constant. So, to obtain exponential convergence for the sequence formed by the $b_0^{(N)}$, we need $1-2/q>0$. In other words, the approach to scaling $2/q$ is bounded and it must be smaller than one. The lower edge is more subtle and is discussed in Ref. 16.

In conclusion, we have applied variational perturbation theory to a case that lies at the very edge of its applicability. We see that variational perturbation theory gives better results by about a factor of 10 than the Padé approximations examined in Sec. II. However, we have not yet found a systematic method for resumming (19) that enables us to perform the continuum limit of the discrete lattice theory. Therefore, we now lay the foundation for further investigations by analyzing the large-order behavior of the instanton series.

IV. LARGE-ORDER BEHAVIOR FOR THE INSTANTON EQUATION

It can be seen from the numerical results in Ref. 14 that the instanton weak-coupling series is of Borel type. That is, it exhibits an alternating sign pattern. From the ratio test we can see that the coefficients $a_{n,j}$ do not grow factorially fast. The large-order behavior of $a_{n,j}$ has the general form

$$a_{n,j} \sim (-1)^{n+j+1} K_n^j j^{A_n} B_n \quad (j\to\infty). \tag{58}$$

The constant A_n can be obtained by evaluating the limit

$$A_n = \lim_{j\to\infty} \frac{\log[a_{n,j+2}\,a_{n,j}/(a_{n,j+1})^2]}{\log[j(j+2)/(j+1)^2]}, \tag{59}$$

TABLE V. Six orders of Richardson extrapolations for the exponent A of the large-order instanton weak-coupling coefficients, based on the first 200 weak-coupling coefficients. The value $A=-\frac{3}{2}$ is quite plausible.

Order	Value for A	Convergence
1	−1.4998	increasing
2	−1.500 017	decreasing
3	−1.500 001 1	decreasing
4	−1.499 998 74	increasing
5	−1.500 000 4	decreasing
6	−1.499 999 893	increasing

and the reciprocal of the radius of convergence is

$$K_n=-\lim_{j\to\infty}\frac{a_{n,j+1}}{a_{n,j}}\left(\frac{j}{j+1}\right)^{A_n}. \tag{60}$$

Also, the overall factor B_n is determined from

$$B_n=\lim_{j\to\infty}\frac{|a_{n,j}|}{K_n^j j^{A_n}}. \tag{61}$$

Using the 200 weak-coupling coefficients, we find that the exponent A_n and the reciprocal radius of convergence K_n are independent of n. The value of $K_2=2.466\,829\,06$ coincides with $K_1=2.466\,829\,06$ for all significant digits. The same is true for $A_1=-1.500\,000$ and $A_2=-1.500\,000$. Thus, it appears that we may omit the subscripts n for K_n and A_n. In contrast, the data suggest that B_n strongly depends on n. B_n is the numerical value associated with the largest uncertainty. In fact, Eq. (61) suggests that small deviations in K and A lead to dramatic changes in the value of B_n. We calculated A, K, B_1, and B_2 up to 200th order with the help of Maple V R7. We then extrapolated these 200 orders to infinity using Richardson extrapolation.[13] We obtained

$$\begin{aligned} A&=-1.500\,000\pm 0.000\,001,\\ K&=2.466\,829\,06\pm 0.000\,000\,1,\\ B_1&=0.0171\pm 0.0001,\\ B_2&=0.1190\pm 0.0001. \end{aligned} \tag{62}$$

Detailed numerical results for the first six Richardson extrapolations for the exponent A, the inverse radius of convergence K, and the overall factors B_1 and B_2 can be found in Tables

TABLE VI. Six orders of Richardson extrapolations for the inverse radius of convergence K of the large-order instanton weak-coupling coefficients, based on the first 200 weak-coupling coefficients under the assumption that $A=-\frac{3}{2}$.

Order	Value for K	Convergence
1	2.466 92	decreasing
2	2.466 828 3	increasing
3	2.466 829 11	decreasing
4	2.466 829 065	decreasing
5	2.466 829 059 7	increasing
6	2.466 829 063 5	decreasing

TABLE VII. Six orders of Richardson extrapolations for the overall factor B_1 of the large-order instanton weak-coupling coefficients, based on the first 200 weak-coupling coefficients under the assumption that $K=2.448\,290\,6$ and $A=-\frac{3}{2}$. The value of B_1 strongly depends on the numerical values for A and K. Changing K in the sixth decimal place influences the third significant figure of B_1. Also, all the Richardson extrapolations are increasing, so, strictly speaking, we only have a lower boundary for B_1. Thus, the accuracy of B_1 may not be very good.

Order	Value for B_1	Convergence
1	0.017 083 7	increasing
2	0.017 086 4	increasing
3	0.017 087	increasing
4	0.017 089 3	increasing
5	0.017 090 8	increasing
6	0.017 092 2	increasing

V–VIII. The calculation of B_1 is extremely delicate; changing the inverse radius of convergence in the sixth decimal place influences the third significant figure of B_1. The same is true of B_2.

Unfortunately, there is no way to derive these values by applying asymptotic analysis to the recursion relation (16). The problem is that the double summation in this equation includes small j, so we cannot let j go to infinity and use the large-order behavior (58). Substituting the *ansatz* (58) into Eq. (16) and taking the limit leads to contradictory results. For $n=1$ we get

$$Kj^A B_1=\frac{1}{2}(j-1)^A B_2+(j-1)^A B_1-\frac{3}{2}B_1^2 K\sum_{k=1}^{j-1}k^A(j-k)^A-\frac{1}{2}B_1^3 K\sum_{k=1}^{j-1}\sum_{l=1}^{j-k}k^A l^A(j-k-l)^A. \tag{63}$$

Pulling out some factors and letting $x\equiv k/j$, we obtain for the first summation

$$\lim_{j\to\infty}\sum_{k=1}^{j}\left(\frac{k}{j}\right)^A\left(1-\frac{k}{j}\right)^A=\int_0^1 dx\,[x(1-x)]^A=\frac{\Gamma^2(A+1)}{\Gamma(2A+2)}, \tag{64}$$

if and only if $A>-1$. For $A<-1$ which is strongly favored by the data we obtain

$$\int_0^1 dx\,[x(1-x)]^A=2\zeta(-A). \tag{65}$$

The double summation reduces to

$$\lim_{j\to\infty}\sum_{k=1}^{j}\sum_{l=1}^{j-k}\frac{k^A l^A}{j^{2A}}\left(1-\frac{k}{j}-\frac{l}{j}\right)=\int_0^1 dx\int_0^1 dy\,[xy(1-x-y)]^A=\frac{\Gamma^3(A+1)}{\Gamma(3A+3)}, \tag{66}$$

where $y\equiv l/j$ and $A>-1$. For $A<-1$ the result is

TABLE VIII. Six orders of Richardson extrapolations for the overall factor B_2 of the large-order instanton weak-coupling coefficients based on the first 200 weak-coupling coefficients and the same assumptions as in the case of B_1 (see Table VII). The value of B_2 depends strongly on A and K.

Order	Value for B_2	Convergence
1	0.119 069	increasing
2	0.119 083	increasing
3	0.119 093	increasing
4	0.119 054 095	increasing
5	0.119 054 125	increasing
6	0.119 054 146	increasing

$$\int_0^1 dx \int_0^1 dy\,[xy(1-x-y)]^A = 3\zeta^2(-A). \tag{67}$$

Substituting the results in (65) and (67) into (63) leads to a contradiction: The inverse radius of convergence then turns out to be

$$K = \frac{1 + B_2/2B_1}{1 + 3\zeta(\frac{3}{2})B_1 + \frac{3}{2}\zeta^2(\frac{3}{2})B_1^2}, \tag{68}$$

which would imply that, given $B_1 = 0.0171$ and $B_2 = 0.1190$, the value of K would be

$$K = 3.940. \tag{69}$$

This result can be ruled out because of the numerical result (62). Also, (68) does not contain the exponent A because all the factors j^A in (63) cancel. So A cannot be determined analytically using this asymptotic analysis.

V. BOUNDARY LAYERS ON THE LATTICE—BLASIUS EQUATION

The Blasius equation[18] arises in the study of fluid dynamics. It is a special limiting case of the Navier–Stokes equation and determines the flow of an incompressible fluid across a semi-infinite flat plate. The equation reads

$$2\epsilon y'''(x) + y(x)y''(x) = 0. \tag{70}$$

Assuming that the tangential velocity $y'(x)$ at the outer limit of the boundary layer is constant, the boundary conditions read[19]

$$y(0) = y'(0) = 0, \quad y'(\infty) = 1. \tag{71}$$

Our objective here is to calculate the second derivative $y''(0)$, which represents the stress on the plate. We discretize the Blasius equation (70) by introducing a lattice spacing a:

$$2\delta(f_{n+1} - 3f_n + 3f_{n-1} - f_{n-2}) + f_n(f_{n+1} - 2f_n + f_{n-1}) = 0, \tag{72}$$

where we define $f_n \equiv y(na)/a$ and $\delta \equiv \epsilon/a^2$. The boundary conditions (71) now read

$$f_0 = f_{-1} = 0, \quad f_n \sim n \quad (n \to \infty). \tag{73}$$

Expanding f_n as a series in powers of δ as in Eq. (14), we obtain the recursion relation[10]

$$\begin{aligned} a_{n+1,j} - 2a_{n,j} + a_{n-1,j} = &-\frac{2}{n}(a_{n+1,j-1} - 3a_{n,j-1} + 3a_{n-1,j-1} - a_{n-2,j-1}) \\ &-\frac{1}{n}\sum_{k=1}^{j-1} a_{n,k}(a_{n+1,j-k} - 2a_{n,j-k} + a_{n-1,j-k}). \end{aligned} \tag{74}$$

The boundary values are

$$\begin{aligned} a_{n,0} &= n \quad (n \geqslant 0), \\ a_{-1,0} &= 0, \\ a_{-n-1,j} &= a_{n,j} \quad (n \geqslant 0). \end{aligned} \tag{75}$$

TABLE IX. The first 20 weak-coupling coefficients for the Blasius recursion relation (74) and (75). Observe that the coefficients $a_{1,j}$ are not of Borel type (they do not alternate in sign). A cosine function with a frequency different from π governs the sign pattern (see Sec. VIII).

j	$a_{1,j}$	j	$a_{1,j}$
1	-2	11	$\frac{30868632383}{5457375}$
2	2	12	$\frac{6325029622}{637875}$
3	$\frac{8}{3}$	13	$-\frac{487693745019181}{13408770375}$
4	-6	14	$-\frac{4774319527974167}{37819608750}$

10	$-\frac{57628622}{99225}$	20	$\frac{121756993154067534451733120837029}{115321796848755734737500 0}$

Equation (74) can be solved order by order by using a computer algebra program. Table IX shows the first 20 weak-coupling coefficients $a_{1,j}$. All coefficients up to the 300th order can be found Ref. 20.

VI. PADÉ RESUMMATION FOR THE BLASIUS EQUATION

We now resum the weak-coupling coefficients using the Padé method (23) with $M=\frac{1}{2}$. This value of M will be derived in Sec. VII in Eq. (82). The exact solution[10] to the Blasius equation (70), obtained numerically up to five digits, is $y''(0)=0.332\,06$. Unfortunately, the sequence formed by the approximants S_N appears to converge, but not to the correct value. According to Table X the sequence becomes very flat and Richardson extrapolation[13] shows that the S_N ap-

TABLE X. The first 20 Padé approximants for the solution to the Blasius equation (70). The sequence formed by the S_N converges extremely slowly.

N	S_N	N	S_N
1	0.5	11	0.357 463 212 1
2	0.420 448 207 6	12	0.356 332 665 1
3	0.394 820 183 0	13	0.355 384 804 8
4	0.381 944 373 2	14	0.354 579 594 4
5	0.374 206 230 9	15	0.353 888 284 2
6	0.369 050 481 1	16	0.353 289 150 9

8	0.362 635 906 0	18	0.352 304 658 8
9	0.360 515 591 5	19	0.351 896 192 9
10	0.358 830 970 7	20	0.351 532 039 9

TABLE XI. Three orders of Richardson extrapolations for the Blasius equation (70), based on the first 70 Padé approximants S_N.

Order	Value of $y''(0)$	Convergence
1	0.3445	decreasing
2	0.3436	decreasing
3	0.3430	oscillating

proach the wrong limiting value (see Table XI). A third-order Richardson gives $S_\infty = 0.3430$, based on the first 70 weak-coupling coefficients. This value is significantly higher than the correct value $y''(0) = 0.33206$, the deviation is 3.3%.

The failure of the Padé resummation is not surprising because the Padé method assumes the approach to scaling δ^{-1} according to (24). However, in the case of the Blasius equation the approach to scaling is $\delta^{-1/2}$, as we will see in Eq. (82) in the next section.

VII. VARIATIONAL PERTURBATION THEORY FOR THE BLASIUS EQUATION

Variational perturbation theory for the Blasius equation fails to converge to the correct answer in the same way as for the instanton problem. We determined the leading strong-coupling term (42) up to 200th order and again it was impossible to find extrema, inflection points, or higher derivatives that yield the correct result. Tables XII and XIII show the last 20 strong-coupling coefficients $b_0^{(N)}$ and six orders of Richardson extrapolation. By determining the values of p and q we show why variational perturbation is likely to fail for this problem.

Consider again the Taylor expansions for $f_{n\pm1}$ in (44) together with the Taylor series for $f_{n-2} = f(x_n - 2a)$, namely,

$$f_{n-2} = f(x_n) - 2\,f'(x_n)a + 2\,f''(x_n)a^2 - \tfrac{4}{3}f'''(x_n)a^3 + \tfrac{2}{3}f''''(x_n)a^4 \pm \cdots . \tag{76}$$

Inserting these expressions into the difference equation for the Blasius problem (72) and translating back to the continuous function $f(x_n) = f_n$, we get

$$2\epsilon(f'''(x)a - \tfrac{1}{2}f''''(x)a^2 + \cdots) + f(x)(f''(x)a^2 + \tfrac{1}{2}f''''(x)a^4 + \cdots) = 0. \tag{77}$$

Next we transform back to the function $y(x) = af(x)$ and assume the Taylor series

$$y(x) = y_0(x) + ay_1(x) + a^2y_2(x) + \cdots . \tag{78}$$

To zeroth order in a we obtain

TABLE XII. The last 20 variational strong-coupling coefficients $b_0^{(N)}$ for the Blasius equation. The very last coefficient is $b_0^{(200)} = 0.336\,959\,312\,377\,13$, as opposed to the correct value $y''(0) = 0.33206$.

N	$b_0^{(N)}$	N	$b_0^{(N)}$
180	0.336 960 177 930 94	190	0.336 959 711 196 46

TABLE XIII. Six orders of Richardson extrapolations for the strong-coupling coefficient $b_0^{(N)}(k_0^{(N)})$ up to $N=200$ for the Blasius equation. The last value is 1.5% away from the correct limiting value $y''(0)=0.33206$.

Order	Value for $b_0^{(N)}$	Convergence
1	0.336 951 8	increasing
2	0.336 955 563	increasing
3	0.336 955 600 539	increasing
4	0.336 955 600 880 3	increasing
5	0.336 955 600 883 462	increasing
6	0.336 955 600 883 492 32	increasing

$$2\epsilon y_0'''(x)+y_0(x)y_0''(x)=0, \tag{79}$$

which is just the Blasius equation (70). The small parameter a, which is the lattice spacing, relates ϵ and δ by $a=\sqrt{\epsilon/\delta}$. Thus, if we evaluate the Taylor series (78) for the second derivative at the origin, we see that

$$y''(0)=y_0''(0)+ay_1''(0)+\cdots=\frac{0.332\,06}{\sqrt{\epsilon}}+\sqrt{\frac{\epsilon}{\delta}}y_1''(0)+\cdots. \tag{80}$$

Comparing this series to the original weak-coupling series

$$y''(0)=\sqrt{\frac{\delta}{\epsilon}}(1-2\delta+2\delta^2+\cdots), \tag{81}$$

we can now determine the leading power p/q and the approach to scaling $2/q$:

$$1-2\delta+2\delta^2+\cdots=\delta^{-1/2}(0.332\,06+\delta^{-1/2}\epsilon y_1''(0)+\cdots), \tag{82}$$

so we obtain $p=-2$ and $q=4$.

Again we find that the approach to scaling $2/q=\frac{1}{2}$ lies just on the boundary of the open interval $(\frac{1}{2}, 1)$, for which the proof of convergence[16] holds. This situation here is the opposite of the instanton case in that it sits at the *lower* boundary of the open interval in which variational perturbation theory works.

VIII. LARGE-ORDER BEHAVIOR FOR THE BLASIUS EQUATION

The Blasius equation exhibits a large-order behavior which is a more subtle than for the instanton problem (58). The Blasius weak-coupling coefficients are not of Borel type; that is, the sign pattern is not alternating. Rather, the sign structure is governed by a cosine function with a frequency that is significantly different from π. Remarkably, it turns out that a pure cosine $\cos(an)$ cannot reproduce all signs correctly. Up to 300th order the sign structure given by $\cos(an)$ is broken twice: The signs at $n=62$ and at $n=212$ are not correct if we optimize with respect to a. So we must consider an additional phase shift $\cos(an+b)$. The parameter b turns out to be slightly smaller than π, but it reproduces all 300 signs correctly.

In order to determine the numerical values of a and b we define

$$f(a,b)\equiv\sum_{n=1}^{N}\frac{\cos(an+b)}{|\cos(an+b)|}\frac{a_{1,n}}{|a_{1,n}|}. \tag{83}$$

The sum ends at $N=300$ because this is as high as we can calculate using Maple; we know the first 300 weak-coupling coefficients $a_{1,j}$. For the correct values of a and b the function $f(a,b)$

TABLE XIV. Examples of the parameters a and b that give the first 300 signs of the Blasius weak-coupling coefficients correctly, assuming that the sign structure of the underlying large-order behavior is of the form $\cos(an+b)$. The last two values for a can be obtained approximately by summing 2π to the first two values.

a	b
1.3941	3.09
1.3939	3.11
7.67830	3.031
7.67686	3.130

must be equal to 300. We then plot the function $f(a,b)$ over the $a-b$ plane and search for peaks. A careful study of the peaks yields values for a and b which allow the function $f(a,b)$ to assume its maximum at 300. These numbers are given in Table XIV.

The large-order behavior of the Blasius weak-coupling coefficients (unlike the large-order behavior of the instanton coefficients) has an additional overall factor $\cos(an+b)$, and we can now see that the remaining structure differs from the structure of the instanton weak-coupling coefficients. Dividing by the cosine, we observe that the coefficients

$$a_j' \equiv \frac{a_{1,j}}{\cos(aj+b)} \tag{84}$$

grow factorially fast. Thus, we also divide by $j!$:

$$b_j \equiv \frac{a_{1,j}}{\cos(aj+b)j!}. \tag{85}$$

The coefficients b_j are unstable under a ratio test. That is, the ratio b_{j+1}/b_j decreases and then begins to oscillate. This is the inaccuracy that results from the delicate sign pattern of the first 300 coefficients $a_{1,j}$.

(Received 28 June 2001; accepted for publication 9 April 2002)

The problem of construction of irreducible representations of quantum A_n^q algebras is solved by explicit integration of the linear (inhomogeneous) system of equations in finite differences in the n-dimensional space. The general solution of this system is given explicitly, and particular solutions corresponding to the irreducible representations are selected. © *2002 American Institute of Physics.*
[DOI: 10.1063/1.1491595]

I. INTRODUCTION

In the author's recent paper,[1] the problem of construction of irreducible representations of the unimodular matrix algebra A_n—the famous result obtained by Gel'fand and Tsetlin[2]—was reformulated through explicit integration of a linear system in finite differences.

It is possible to reduce all the calculations to the solution of a linear system of equations in finite differences (or PDEs in the continuous functional group limit). What is surprising and intriguing in this approach is the fact that the results obtained at the functional group level[3,4] (the Poisson brackets of the classical Hamiltonian formalism) literally pass to those arising in the algebraic calculations. The only thing that is necessary is to replace the Poisson brackets by commutators, and canonically conjugated classical variables by elements of n-dimensional Heisenberg algebras and to choose the correct order of operators involved. All expressions retain their form at both the levels after replacing the operation of usual differentiation in the case of the functional group by discrete difference in the algebra-theoretical case.

In the present paper we apply the method of Ref. 1 to the problem of construction of irreducible representations of the quantum A_n^q algebras. We try to resolve the system of commutation relations between $3n$ generators ($2n$ generators of simple roots $X_i^{\pm}$ and n generators of the Cartan elements h_i)

$$[X_i^+, X_j^-] = \delta_{ij}\phi_i(h_i), \quad [h_i, X_j^{\pm}] = \pm k_{ji} X_j^{\pm}, \tag{1}$$

where ϕ_i are initially arbitrary functions of their arguments.

Using only the ''selection rules'' of the Gel'fand–Tsetlin paper,[2] we find that in the case of $U_q(2)$, A_1^q algebra it is possible to resolve Eq. (1) for an arbitrary function ϕ in a self-consistent way. However, already in the case of $U_q(3)$, A_2^q algebras, the self-consistency of the construction leads to a unique choice of the functions ϕ_i in the standard trigonometrical form.

The notion of coproduct was not used at any step of our construction. We try to literally conserve the text and presentation of the material as in Ref. 1, in order to simplify the comparison between these too very similar papers for the reader.

In Secs. II and III, we consider the simplest cases of $U_q(2)$, $U_q(3)$ quantum algebras with detailed calculations. In Sec. IV, we consider the case of arbitrary $U_q(n+1)$ quantum algebras. In Sec. V, we summarize the results and discuss the perspectives for further investigations.

II. THE CASES OF $A_1^q \approx SU_q(2)$ AND $U_q(2)$

Every section will be divided into two parts: the classical case (the functional group level) and proper algebraic construction (''quantum case''). As remarked in Sec. I, the classical results can be used as good guides in further algebraic (quantum) calculations.

A. The functional algebra case

The functional $U_q(2)$ algebra contains four elements $X^{\pm}$, H, I connected by the Poisson brackets:

$$\{I,X^{\pm}\}=\{I,H\}=0, \quad \{X^{+},X^{-}\}=\phi(H), \quad \{H,X^{\pm}\}=\pm 2X^{\pm}, \tag{2}$$

where ϕ is an arbitrary function of a single argument.

In accordance with the Darboux theorem,[3] of the elements of the $U_q(2)$ functional group[3] it is possible to construct a pair of canonically conjugated variables M,m, $\{M,m\}=1$ and two cyclic variables I,L with the zero Poisson brackets with each other and with all other elements of the $U_q(2)$ functional group (clearly, up to an arbitrary canonical transformation). The explicit expression for them in terms of the functional group elements will be given a bit later.

Let us choose $M=H$ and $m=(1/4)\ln(X^{+}/X^{-})+f(H)$. With the help of Poisson brackets (2) it is not difficult to see that M,m thus constructed are really canonically conjugated variables. Resolving these relations with respect to the functional group elements leads to the following realization in terms of the canonical conjugated coordinate m and momenta M and the two cyclic momenta L_1,L_2:

$$X^{+}=\frac{1}{2}e^{2m}\left(f\left(\frac{L_1-L_2}{2}\right)-f(H)\right), \quad X^{-}=\frac{1}{2}e^{-2m}\left(f\left(\frac{L_1-L_2}{2}\right)+f(H)\right),$$
$$H=M-\frac{L_1+L_2}{2}, \quad \phi(x)=\frac{\mathrm{d}f^2}{\mathrm{d}x}. \tag{3}$$

It is not difficult to verify by direct calculations that (3) is indeed a realization of the functional group (2). If we want to restrict ourselves to the case of quantum A_1^q algebra it is necessary to put $I=L_1+L_2=0$.

B. Quantum algebra case

As always, to pass from the classical expressions to the quantum ones it is necessary to order the operators involved in a certain way and to replace the Poisson brackets by commutators. Equation (3) provides a very tempting possibility to rewrite them as

$$X^{+}=\frac{1}{2}e^{m}\left(f\left(\frac{L_1-L_2}{2}\right)-f(H)\right)e^{m}, \quad X^{-}=\frac{1}{2}e^{-m}\left(f\left(\frac{L_1-L_2}{2}\right)+f(H)\right)e^{-m}, \tag{4}$$

$$H=M-\frac{L_1+L_2}{2}, \quad I=L_1+L_2, \quad L=X^{+}X^{-}+X^{-}X^{+}+\tfrac{1}{4}(f^2(H+1)+f^2(H-1))$$

and consider now M,m as generators of the Heisenberg algebra ($[M,m]=1,[M,1]=0,[m,1]=0$), with L_1,L_2 commuting with all the generators involved in (4). Keeping in mind the operator relation of the Heisenberg algebra: $\exp(\pm x)p\exp(\mp x)=p\mp 1$, we conclude that the generators defined in (4) satisfy the commutation relations (2) of $U_q(2)$ algebra (of course with square brackets instead of the curly ones) and $\phi=1/4(f^2(H+1)-f^2(H-1))$.

Two Casimir operators under realization (4) take the constant values

$$K^{(1}=L_1+L_2, \quad K^{(2}=X^{+}X^{-}+X^{-}X^{+}+\frac{1}{4}(f^2(H+1)+f^2(H-1))=\frac{1}{2}f^2\left(\frac{L_1-L_2}{2}\right), \tag{5}$$

which proves the irreducibility of the constructed representation. In the conclusion of this section, we want to stress the fact that commutation relations themselves give no additional restrictions on the form of the f,ϕ functions.

III. $A_2^q \equiv SU_q(3)$ AND $U_q(3)$ CASES

In this case, the problem consists in resolution of the system of commutation relations

$$\begin{aligned}&[X_1^+,X_1^-]=\phi(h_1),\quad [X_1^+,X_2^-]=0,\quad [h_1,X_1^\pm]=\pm 2X_1^\pm,\quad [h_1,X_2^\pm]=\mp X_2^\pm,\\ &[X_1^+,X_2^-]=0,\quad [X_2^+,X_2^-]=\Phi(h_2),\quad [h_2,X_2^\pm]=\pm 2X_2^\pm,\quad [h_2,X_1^\pm]=\mp X_1^\pm.\end{aligned}\tag{6}$$

We choose the arbitrary functions $\phi(h_1)$, $\Phi(h_2)$ in accordance with the comments at the end of Sec. II.

The selection rules of the GZ paper allow us to try to find a resolution of this problem in the following form:

$$\begin{aligned}&X_1^+=\frac{1}{2}e^m\left(f\left(\frac{L_1-L_2}{2}\right)-f(H)\right)e^m,\quad X_2^+=e^{l_1}f^1e^{l_1}+e^{l_2}f^2e^{l_2},\\ &h_1=M-\frac{L_1+L_2}{2},\\ &X_1^-=\frac{1}{2}e^{-m}\left(f\left(\frac{L_1-L_2}{2}\right)+f(H)\right)e^{-m},\quad X_2^-=e^{-l_1}\overline{f^1}e^{-l_1}+e^{-l_2}\overline{f^2}e^{-l_2},\\ &h_2=-\frac{M}{2}+L_1+L_2-\frac{N_1+N_2+N_3}{2},\end{aligned}\tag{7}$$

where all "structural" functions $f^{1,2}$, $\overline{f}^{1,2}$ depend only on the momentum (capital letters) variables. We intentionally preserve the order of factors to avoid rewriting the same formulas several times.

A. Functional group case

In this case, it is necessary to understand all the above-mentioned relations at the functional group level. The commutators have to be replaced by the Poisson brackets understood as usual:

$$\{A,B\}=\sum_1^3\left(\frac{\partial A}{\partial p_i}\frac{\partial B}{\partial x_i}-\frac{\partial A}{\partial x_i}\frac{\partial B}{\partial p_i}\right),\quad x_i=(m,l_1,l_2),\quad p_i=(M,L_1,L_2).$$

Now all of the objects are commutative, and the order of the factors in (7) is unimportant. As a consequence of the vanishing Poisson brackets $\{X_1^+,X_2^-\}=\{X_2^+,X_1^-\}=0$, we obtain equations determining the explicit dependence of structural functions on the momentum M. Namely

$$\begin{aligned}&(\ln\overline{f^1})_M+\frac{1}{2}\frac{f_1'+f_2'}{f_1-f_2}=0,\quad (\ln\overline{f^2})_M+\frac{1}{2}\frac{-f_1'+f_2'}{f_1-f_2}=0,\\ &(\ln f^1)_M+\frac{1}{2}\frac{f_1'-f_2'}{f_1+f_2}=0,\quad (\ln f^2)_M-\frac{1}{2}\frac{f_1'+f_2'}{f_1+f_2}=0,\end{aligned}$$

where $f_1\equiv f((L_1-L_2)/2)$, $f_2\equiv f(M-(L_1+L_2)/2)$ and the prime means differentiation of the functions f_1,f_2 with respect to their arguments.

The Poisson brackets $\{X_2^+,X_2^-\}=\Phi(h_2)$ have, as their corollary, three additional equations:

$$(\ln \overline{f^1})_{L_2}+(\ln f^2)_{L_1}=0, \quad (\ln \overline{f^2})_{L_1}+(\ln f^1)_{L_2}=0$$
$$-2(f^1\overline{f^1})_{L_1}+2(f^2\overline{f^2})_{L_2}=\Phi(h_2). \tag{8}$$

The condition of self-consistency of the second pair of equations containing $\ln f$, $\ln \overline{f}$ with the first one leads to the functional equation with shifted arguments for a single unknown function ($X \equiv f(x), Y \equiv f(y)$):

$$(X_{xx}X+Y_{yy}Y)(X^2-Y^2)=(X_x^2-Y_y^2)(X^2+Y^2). \tag{9}$$

This equation allows the exact integration, and its general solution has the form (see Appendix A)

$$f(x)=\sqrt{(a+b\cosh(2\epsilon x))}. \tag{10}$$

In what follows, we will use a special choice of parameters (10) such that $f=\sinh \epsilon x$. This choice can be connected with the condition of the correct classical limit (in the sense $\epsilon \to 0$) in which the quantum functional algebra should pass into the functional algebra A_1. In this case, it is possible to perform all the calculations up to explicit expressions.

Resolution of all additional equations, except for (8), gives the following dependence of the structure functions upon the momentum M:

$$f^1=\cosh \epsilon \frac{L_1-M}{2} f^1(L_1,L_2), \quad f^2=\sinh \epsilon \frac{M-L_2}{2} f^2(L_1,L_2),$$
$$\overline{f^1}=\sinh \epsilon \frac{L_1-M}{2} \overline{f^1}(L_1,L_2), \quad \overline{f^2}=\cosh \epsilon \frac{M-L_2}{2} \overline{f^2}(L_1,L_2), \tag{11}$$

where all new structure functions (for which we reserve the same notation) depend only on two arguments $x_1 \equiv L_1, x_2 \equiv L_2$.

For two unknown functions $X^1 \equiv -f^1\overline{f^1}, X^2 \equiv f^2\overline{f^2}$, Eq. (8) (keeping in mind the form of its right-hand side) becomes the system of two equations:

$$(e^{\epsilon x_1}X^1)_{x_1}+(e^{\epsilon x_2}X^2)_{x_2}=e^{\epsilon(2x_1+2x_2-N)}(e^{-\epsilon x_1}X^1)_{x_1}+(e^{-\epsilon x_2}X^2)_{x_2}=e^{-\epsilon(2x_1+2x_2-N)}, \tag{12}$$

where $N \equiv N_1+N_2+N_3$.

In accordance with Ref. 1, we try to find a solution to the last system in the form:

$$X^1=Y^2_{x_2}, \quad X^2=Y^1_{x_1}.$$

Solving the linear algebraic system of equations that arises for the functions $Y^{1,2}$, we are led to the following solution of the initial system:

$$X^1=\frac{1}{4\epsilon^2}\left(\frac{\sinh \epsilon(2x_1+x_2-N)}{\sinh \epsilon(x_1-x_2)}\right)_{x_2}+\left(\coth \epsilon(x_1-x_2)\Theta(x_1)+\frac{\overline{\Theta}(x_2)}{\sinh \epsilon(x_1-x_2)}\right)_{x_2},$$
$$X^2=-\frac{1}{4\epsilon^2}\left(\frac{\sinh \epsilon(x_1+2x_2-N)}{\sinh \epsilon(x_1-x_2)}\right)_{x_1}-\left(\coth \epsilon(x_1-x_2)\overline{\Theta}(x_2)+\frac{\Theta(x_1)}{\sinh \epsilon(x_1-x_2)}\right)_{x_1}. \tag{13}$$

These formulas result from the exact integration of the system (12). The remaining additional conditions follow from the corresponding equations for invariant (in the sense of independence of the momentum M) structural functions. They can be summarized as follows:

$$(\ln X^1)_{x_2}+(\ln X^2)_{x_1}=0. \tag{14}$$

To satisfy them, it is natural to make a special choice of arbitrary functions $\Theta,\overline{\Theta}$ in the general solution (13).

After performing all operations of the differentiation in (13) we obtain for X^1,

$$X^1=\frac{1}{4\epsilon}\left(\frac{\sinh\epsilon(3x_1-N)}{\sinh^2\epsilon(x_1-x_2)}\right)+\frac{\Theta(x_1)}{\sinh^2\epsilon(x_1-x_2)}+\frac{\sinh\epsilon(x_1-x_2)\overline{\Theta}(x_2)_{x_2}+\cosh\epsilon(x_1-x_2)\overline{\Theta}(x_2)}{\sinh^2\epsilon(x_1-x_2)}.$$

If we want to satisfy the auxiliary condition (14), it is natural to find the solution in the form

$$X^{1,2}=\frac{\psi(x_{1,2})}{\sinh^2\epsilon(x_1-x_2)}.$$

Under this kind of assumption, for functions $\Theta,\overline{\Theta}$ we uniquely obtain $\Theta=A\cosh\epsilon x+B\sinh\epsilon x$, $\overline{\Theta}=C\cosh\epsilon x+D\sinh\epsilon x$ where A,B,C,D are arbitrary numerical constants. Finally, for the function ψ that parametrizes the solution of the system (13), we obtain

$$\psi(x)=\frac{1}{4\epsilon}\sinh\epsilon(3x-N)+(A+C)\sinh\epsilon x+(B+D)\cosh\epsilon x.$$

This expression for ψ can be parametrized in the following form:

$$\psi(x)=\frac{1}{\epsilon}\sinh\epsilon(x-N_1)\sinh\epsilon(x-N_2)\sinh\epsilon(x-N_3)$$

as one can see representing sinh as the difference of the exponentials with further multiplication term by term.

B. The quantum group case

Now in the realization (7) we consider (m,l_1,l_2) as coordinates and (M,L_1,L_2) as momenta of the three independent (commutative) Heisenberg algebras, and (N_1,N_1,N_2) as "cyclic" variables that commute with all other generators. We choose $f=a\sinh\epsilon x$, since the quantum group should have, as its classical limit, the functional group of Sec. III A.

Commutation relations $[X_1^+,X_2^-]=0$, $[X_2^+,X_1^-]=0$ allow us to reconstruct the dependence of structural functions $f^{1,2}$, $\overline{f^{1,2}}$ upon the momentum M exactly in the form (11).

The only commutation relation

$$[X_2^+,X_2^-]=a\sinh\epsilon(M-2(L_1+L_2)+N_1+N_2+N_3)$$

not used until now, together with (7), has, as its consequence, an additional system of equations determining the structural functions:

$$\begin{aligned}&f^1(L_1,L_2-1)\overline{f^2}(L_1-1,L_2)=f^1(L_1,L_2+1)\overline{f^2}(L_1+1,L_2),\\&\overline{f^1}(L_1,L_2-1)f^2(L_1-1,L_2)=\overline{f^1}(L_1,L_2+1)f^2(L_1+1,L_2).\end{aligned} \tag{15}$$

Finally, we will present the last remaining equation using the following notation: $X^1_{\pm}\equiv-f^1(L_1\pm1,L_2)\overline{f^1}(L_1\pm1,L_2)$, $X^2_{\pm}\equiv f^2(L_1,L_2\pm1)\overline{f^2}(L_1,L_2\pm1)$ for new unknown functions and $x_1\equiv L_1$, $x_2\equiv L_2$ for new coordinates. The equation takes on the form:

$$
\begin{aligned}
&-\sinh\epsilon(x_1-M-1)X^1_- + \sinh\epsilon(x_1-M+1)X^1_+ \\
&\quad -\sinh\epsilon(M-L_2+1)X^2_- + \sinh\epsilon(M-L_2-1)X^2_+ \\
&\quad = 2a\sinh\epsilon(M-2(L_1+L_2)+N_1+N_2+N_3). \qquad (16)
\end{aligned}
$$

After resolution of Eq. (16) (equating terms with $\sinh M$, $\cosh M$ on both sides), we come to the system of two equations for determining the two unknown functions $X^{1,2}$:

$$
\begin{aligned}
&-e^{\epsilon(x_1-1)}X^1_- + e^{\epsilon(x_1+1)}X^1_+ - e^{\epsilon(x_2-1)}X^2_- + e^{\epsilon(x_2+1)}X^2_+ = 2e^{\epsilon(2x_1+2x_2-N)}, \\
&-e^{-\epsilon(x_1-1)}X^1_- + e^{-\epsilon(x_1+1)}X^1_+ - e^{-\epsilon(x_2-1)}X^2_- + e^{-\epsilon(x_2+1)}X^2_+ = 2e^{-\epsilon(2x_1+2x_2+N)}, \qquad (17)
\end{aligned}
$$

where $N=N_1+N_2+N_3$.

To solve this system, we introduce the operation of discrete differentiation as

$$
\Delta_i F(x_1,\ldots,x_n) \equiv \frac{F(x_1,\ldots,x_i+1,\ldots,x_n)-F(x_1,\ldots,x_i-1,\ldots,x_n)}{2}.
$$

These operations commute with each other, $\Delta_i\Delta_j=\Delta_j\Delta_i$, and possess the linearity properties in the following sense:

$$
\Delta_i(F^1+F^2)=\Delta_iF^1+\Delta_iF^2, \quad \Delta_i(CF)=C\Delta_iF
$$

if the function C is independent of the x_i coordinate.

The system (16) and (17) can be rewritten in terms of these operations as

$$
\Delta_1(e^{\epsilon x_1}X^1)+\Delta_2(e^{\epsilon x_2}X^2)=e^{\epsilon(2x_1+2x_2-N)},
$$

$$
\Delta_1(e^{-\epsilon x_1}X^1)+\Delta_2(e^{-\epsilon x_2}X^2)=e^{-\epsilon(2x_1+2x_2-N)}.
$$

As in Sec. III A, we seek for a solution of the last system in the form

$$
X^1=\Delta_2(Y^2), \quad X^2=\Delta_1(Y^1).
$$

Keeping in mind the relation (that can be easily checked)

$$
\Delta_2\Delta_1 e^{\epsilon(2x_1+2x_2)}=(\sinh 2\epsilon)^2 e^{\epsilon(2x_1+2x_2)},
$$

we obtain the linear system of algebraic equations determining Y^1, Y^2. After resolution of this system, the solution of the initial system takes the form

$$
\begin{aligned}
X^1 &= \Delta_2\left(\frac{1}{\sinh^2 2\epsilon}\frac{\sinh\epsilon(2x_1+x_2-N)}{\sinh\epsilon(x_1-x_2)}+\coth\epsilon(x_1-x_2)\Theta(x_1)+\frac{\overline{\Theta}(x_2)}{\sinh\epsilon(x_1-x_2)}\right), \\
X^2 &= -\Delta_1\left(\frac{1}{\sinh^2 2\epsilon}\frac{\sinh\epsilon(x_1+2x_2-N)}{\sinh\epsilon(x_1-x_2)}+\coth\epsilon(x_1-x_2)\overline{\Theta}(x_2)+\frac{\Theta(x_1)}{\sinh\epsilon(x_1-x_2)}\right). \qquad (18)
\end{aligned}
$$

After all necessary calculations, from (18) we obtain the final expression:

$$
\begin{aligned}
X^1 &= \frac{1}{2\sinh 2\epsilon}\frac{\sinh\epsilon(3x_1-N)}{\sinh\epsilon(x_1-x_2-1)\sinh\epsilon(x_1-x_2+1)} \\
&\quad + \frac{\sinh 2\epsilon\Theta(x_1)+\overline{\Theta}(x_2+1)\sinh\epsilon(x_1-x_2+1)-\overline{\Theta}(x_2-1)\sinh\epsilon(x_1-x_2-1)}{\sinh\epsilon(x_1-x_2-1)\sinh\epsilon(x_1-x_2+1)} \qquad (19)
\end{aligned}
$$

and the same kind of expression for X^2. If we want to satisfy the additional condition (15) that can be rewritten in the form

$$X^1(L_1,L_2-1)X^2(L_1-1,L_2)=X^1(L_1,L_2+1)X^2(L_1+1,L_2),$$

then it is necessary to find a solution in the form

$$X^1=\frac{\psi_1(x_1)}{\phi(x_1-x_2)},\quad X^2=\frac{\psi_2(x_2)}{\phi(x_1-x_2)}. \tag{20}$$

It is easy to see that with this form of solution, the additional condition (15) is satisfied automatically. Comparing Eqs. (19) and (20), we come to the only possible choice of the function $(\Theta,\overline{\Theta})$,

$$\Theta(x)=A\sinh x+B\cosh x,\quad \overline{\Theta}(x)=C\sinh x+D\cosh x.$$

And as a consequence, we find that $\psi_1(x)=\psi_2(x)=\sinh\epsilon(3x-N)+p\sinh\epsilon x+q\cosh\epsilon x \equiv\sinh\epsilon(x-N_1)\sinh\epsilon(x-N_2)\sinh\epsilon(x-N_3)$. Finally, the solution of the initial system satisfying all necessary additional conditions can be written in the form:

$$\begin{aligned}X^1&=\frac{\sinh\epsilon(x_1-N_1)\sinh\epsilon(x_1-N_2)\sinh\epsilon(x_1-N_3)}{2\sinh 2\epsilon\sinh\epsilon(x_1-x_2-1)\sinh\epsilon(x_1-x_2+1)},\\ X^2&=\frac{\sinh\epsilon(x_2-N_1)\sinh\epsilon(x_2-N_2)\sinh\epsilon(x_2-N_3)}{2\sinh 2\epsilon\sinh\epsilon(x_1-x_2-1)\sinh\epsilon(x_1-x_2+1)}.\end{aligned} \tag{21}$$

IV. GENERAL CASE OF ARBITRARY *n*

A. The algebra representation level

Let us assume that the generators of simple roots and Cartan elements of $U(n+1)$ algebra can be represented in the form

$$\begin{aligned}X_s^+&=\sum_{k=1}^{s} e^{l_k^s}g_k^s e^{l_k^s},\quad X_s^-=\sum_{k=1}^{s} e^{-l_k^s}\overline{g}_k^s e^{-l_k^s},\\ h_s&=-\frac{1}{2}\sum_{r=1}^{s-1}L_r^{s-1}+\sum_{k=1}^{s}L_k^s-\frac{1}{2}\sum_{l=1}^{s+1}L_l^{s+1},\quad 1\leqslant s\leqslant n,\end{aligned} \tag{22}$$

where nonzero commutators of the operators involved are

$$[L_k^s,L_l^t]=\delta_{st}\delta_{kl}I.$$

We assume that the structural functions are ''factorizable'' and, as functions of their arguments, can be represented in the following form:

$$g_k^s=F_k^s(L^{s+1},L^s)f_k^s(L^{s-1},L^{s-1})\quad \overline{g}_k^s=\overline{F}_k^s(L^{s+1},L^s)\overline{f}_k^s(L^{s-1},L^{s-1}).$$

Without any difficulty, the reader can identify L^1 with M, L^2 with L_1,L_2 and L^3 with N_1,N_2,N_3 from Sec. III.

We assume also that all necessary commutation relations for $1\leqslant s\leqslant(n-1)$ are correctly satisfied and

$$(F_k^{n-1})^2=(\overline{F}_k^{n-1})^2=\frac{\Pi_{r=1}^{n}\sinh\epsilon(L_k^{n-1}-L_r^n)}{\Phi(L^{n-1})},$$

where the function Φ is translation-invariant with respect to the simultaneous shift of all the arguments L_k^{n-1}. We prove by induction that the squares of the structural functions $F_i^n=\overline{F_i^n}$ conserve their form and find the explicit expressions for the denominator.

It is obvious that under the above-mentioned restrictions, the commutation relations between generators of the Cartan subalgebra h_l and generators of simple roots $X_k^{\pm}$ are correctly satisfied. It is also clear that the generators $X_n^{\pm}$ commute with all generators $X_k^{\mp}$ with $1\leqslant k\leqslant(n-2)$, because they act on essentially different arguments. And finally, the commutation relations

$$[X_n^{\pm},X_{n-1}^{\mp}]=0$$

allow us to reconstruct the explicit dependence of structural functions f_k^n, $\overline{f_k^n}$ on their arguments L_k^{n-1}.

As a direct corollary of the last commutation relations, we arrive at the expressions: $f_k^n(L^n;\ldots,L_r^{n-1}-1,\ldots)\overline{F_r^{n-1}}(\ldots,L_k^n-1,\ldots,L^{n-1})=f_k^n(L^n;\ldots,L_r^{n-1}+1,\ldots)\overline{F_r^{n-1}}(\ldots,L_k^n+1,\ldots,L^{n-1})$ $\times\overline{f_k^n}(L^n;\ldots,L_r^{n-1}-1,\ldots)F_r^{n-1}(\ldots,L_k^n-1,\ldots,L^{n-1})=\overline{f_k^n}(L^n,\ldots,L_r^{n-1}+1,\ldots)F_r^{n-1}(\ldots,L_k^n+1,\ldots,L^{n-1})$ that should be satisfied for all the possible choices of k and r indices. Keeping in mind the explicit forms $\overline{F_k^{n-1}}$ as assumed previously, we can resolve the last equations in the form:

$$g_k^n=F_k^n(L^{n+1};L^n)\sqrt{\prod_{r=1}^{n-1}\sinh\epsilon(L_k^n-L_r^{n-1})},\quad \overline{g_k^n}=\overline{F_k^n}(L^{s+1};L^s)\sqrt{\prod_{r=1}^{s-1}\sinh\epsilon(L_k^n-L_r^{n-1})}. \tag{23}$$

The only commutation relation that is not satisfied up to now is

$$[X_n^+,X_n^-]=\sinh\epsilon(h_n). \tag{24}$$

It consists of the ''diagonal'' part (that does not contain the coordinates of Heisenberg subalgebras l_i) and the nondiagonal one (in the above-mentioned sense). The arising equation for the diagonal part can naturally be written by using the notation:

$$\begin{aligned} X_k^{\pm n}&=F_k^n(L^{n+1};\ldots L_k^n\pm1,\ldots)\overline{F_k^n}(L^{n+1};\ldots,L_k^n\pm1,\ldots)\\ \sum_{k=1}^{n}\prod_{r=1}^{n-1}\sinh\epsilon(L_k^n+1-L_r^{n-1})X_k^{+n}&-\sum_{k=1}^{n}\prod_{r=1}^{n-1}\sinh\epsilon(L_k^n-1-L_r^{n-1})X_k^{-n}\\ &=\sinh\epsilon\left(\sum_{r=1}^{n-1}L_r^{n-1}+2\sum_{k=1}^{n}L_k^n-\sum_{j=1}^{n+1}L_j^{n+1}\right). \end{aligned} \tag{25}$$

The unknown functions $X_k^{\pm n}$ depend only on L^{n+1},L^n variables (as it follows from their definition) and thus, with respect to the variables L^{n-1} (25) they are to be satisfied identically. Let us consider the structure of the product on the left-hand side of (25) representing each hyperbolic function as a sum of two exponentials:

$$\prod_{r=1}^{n-1}\sinh\epsilon(x-L_r^{n-1})=\frac{1}{2^{n-1}}\sum_{k=0}^{n-1}A_k e^{\epsilon[(n-1)-2k]x]}.$$

It is clear that $A_0=\exp(-\epsilon\Sigma_{r=1}^{n-1}L_r^{n-1})$, $A_{n-1}=(-1)^{n-1}\exp(\epsilon\Sigma_{r=1}^{n-1}L_r^{n-1})$ and all other A_k are some complicated symmetric functions constructed from the components of the $(n-1)$-dimensional vector L^{n-1}. On the right-hand side of (25) (after the decomposition of the hyperbolic function), the dependence on L^{n-1} is concentrated only in the two exponentials. Thus, equating the coefficients of such terms on both sides of (25), we come to the system of n equations for X_k^n functions (we introduce the notation: $L_k^{n-1}\equiv x_k$ and for the moment put $\epsilon=1$):

$$\sum_{k=1}^{n}\left[e^{(n-1)(x_k+1)}X_k^{+n}-e^{(n-1)(x_k-1)}X_k^{-n}\right]=2^{n-2}\exp\left(2\sum_{k=1}^{n}x_k-\sum_{j=1}^{s+1}L_j^{s+1}\right)$$

$$\sum_{k=1}^{n}\left[e^{s(x_k+1)}X_k^{+s}-e^{s(x_k+1)}X_k^{-s}\right]=0,\quad s\equiv n-1-2r,\quad r=1,2,...(n-2) \tag{26}$$

$$\sum_{k=1}^{n}\left[e^{-(n-1)(x_k+1)}X_k^{+n}-e^{-(n-1)(x_k-1)}X_k^{-n}\right]=(-1)^n2^{n-2}\exp\left(-2\sum_{k=1}^{n}x_k+\sum_{j=1}^{s+1}L_j^{s+1}\right).$$

The zero value of the ''nondiagonal'' part of (24) is equivalent to the additional conditions that should hold for the structural functions $F,\overline{F}$:

$$F_k^n(L^{n+1};\ldots,L_j^n-1,\ldots)\overline{F}_j^n(L^{n+1};\ldots,L_k^n-1,\ldots)=F_k^n(L^{n+1};\ldots,L_j^n+1,\ldots)\overline{F}_j^n(L^{n+1};\ldots,L_k^n+1,\ldots)$$

$$\overline{F}_k^n(L^{n+1};\ldots,L_j^n-1,\ldots)F_j^n(L^{n+1};\ldots,L_k^n-1,\ldots)=\overline{F}_k^n(L^{n+1};\ldots,L_j^n+1,\ldots)F_j^n(L^{n+1};\ldots,L_k^n+1,\ldots). \tag{27}$$

From (27) we see that the solution $F_j^n=\overline{F}_j^n$ is the possible one and, functions $X_k^n\equiv X^k$ [being the solution of (25)] should satisfy additional conditions:

$$X^k(L^{n+1};\ldots,L_j^n-1,\ldots)X^j(L^{n+1};\ldots,L_k^n-1,\ldots)=X^k(L^{n+1};\ldots,L_j^n+1,\ldots)X^j(L^{n+1};\ldots,L_n^s+1,\ldots). \tag{28}$$

The reader can easily obtain, from general equations of the present section, all results of Sec. III for the case $n=2$. At this point we interrupt our consideration for a moment to represent the general solution of a continuous version of equations (26).

B. General solution of linear system in the continuous limit

In this section, we give the general solution of the system (26) in the continuous limit or at the level of the functional group approach. In this limit, the system (26) can be obviously rewritten as

$$\sum_{k=1}^{n}\left(e^{(n-1)x_k}X^k\right)_{x_k}=-2^{n-2}\exp\left(2\sum_{k=1}^{n}x_k-L_{n+1}\right),$$

$$\sum_{k=1}^{n}\left(e^{sx_k}X^k\right)_{x_k}=0,\quad s\equiv n-1-2r,\quad r=1,2,...(n-2), \tag{29}$$

$$\sum_{k=1}^{n}\left(e^{-(n-1)x_k}X^k\right)_{x_k}=(-1)^{n-1}2^{n-2}\exp\left(-2\sum_{k=1}^{n}x_k+L_{n+1}\right)$$

[compare with the corresponding Eq. (12) of Sec. III A]. We have introduced the following abbreviation, $\Sigma_{j=1}^{n+1}L_j^{n+1}\equiv L_{n+1}$.

Keeping in mind the ways of resolution of the systems of that kind known for us,[1] we find the solution in the form:

$$X^i=(Y^i)_{x_1,\ldots,x_{i-1},x_{i+1},\ldots,x_n}.$$

After substitution of these expressions into (29), we arrive at the linear system of algebraic equations with the known right-hand side (we have used the obvious relation $(\exp(2\Sigma_{k=1}^{n}x_k-L_{n+1}))_{x_1,\ldots,x_n}=2^n(\exp(2\Sigma_{k=1}^{n}x_k-L_{n+1}))$ to determine the unknown functions Y^i:

$$\sum_{k=1}^{n} e^{(n-1)x_k} Y^k = 2^{-3} \exp\left(2\sum_{k=1}^{n} x_k - L_{n+1} \right) + \Phi^{n-1},$$

$$\sum_{k=1}^{n} e^{sx_k} Y^k = \Phi^s, \quad s \equiv n-1-2r, \quad r = 1,2,...,(n-2), \tag{30}$$

$$\sum_{k=1}^{n} e^{-(n-1)x_k} Y^k = 2^{-3} \exp\left(-2\sum_{k=1}^{n} x_k + L_{n+1} \right) + \Phi^{-n+1}.$$

All functions Φ^{n-1-2s}, $0 \leqslant s \leqslant (n-1)$ are solutions of the single equation $\Phi_{x_1,\ldots,x_n} = 0$ (differentiation with respect to all arguments of the problem!).

The following notation will be useful for resolution of (30). Let W_r be a coefficient of the polynomial of $(n-1)$ degree expressed in terms of its roots:

$$P_{n-1}(z) = W_0 z^{n-1} + W_1 z^{n-2} + \cdots + W_{n-1} = \prod_{k=1}^{n-1} (z - z_k) \quad (W_0 = 1).$$

We denote the coefficients of the polynomial as $W_r^{(k}$; the $(n-1)$ roots of this polynomial coincide with the $(n-1)$ exponentials e^{2x_i} except for only one e^{2x_k}.

In this notation, the resolution of the algebraic system of equations (30) can be represented as

$$Y^k = \frac{1}{2^2} \frac{(\sinh)\cosh(2x_k + \Sigma'^{k}_{i=1} x_i - L_{n+1})}{\Pi'^{n}_{i=1} \sinh(x_k - x_i)} + \frac{\Sigma_{s=0}^{n-1} \Phi^{(n-1-2s)} W_s^{(k}}{\Pi'^{n}_{i=1} \sinh(x_k - x_i)}.$$

In the numerator of the last expression, the sign of cosh arises in the case of odd $n = 2r+1$, and the sign of sinh, in the case of even $n = 2r$, and $L_{n+1} = \Sigma_{j=1}^{n+1} L_j^{n+1}$. By consequent differentiation of Y^k with respect to all independent arguments, except for x_k, we come to the explicit solution of the initial system (30):

$$X^k = \frac{1}{2^2} \frac{(\sinh)\cosh((n+1)x_k - L_{n+1})}{\Pi'^{n}_{i=1} \sinh^2(x_k - x_i)} + \left(\frac{\Sigma_{s=0}^{n-1} \Phi^{(n-1-2s)} W_s^{(k}}{\Pi'^{n}_{i=1} \sinh^2(x_k - x_i)} \right)_{x_1,\ldots,x_{k-1}x_{k+1},\ldots,x_n}. \tag{31}$$

The first term in (31) is a particular solution of the inhomogeneous system (30), the second one is a general solution of the homogeneous part of it. Of course, after performing all the differentiations, the general solution will contain the only function that satisfies the scalar equation $(\Phi)_{x_1,\ldots,x_n} = 0$.

In the following we demonstrate only a particular solution of the homogeneous system, sufficient for the aim to satisfy all necessary additional conditions of our problem. We will directly show that

$$X^i = \frac{e^{[(n+1)-2s]x_i}}{\Pi'^{n}_{k=1} \sinh^2(x_i - x_k)} = \left(e^{[(n+1)-2s]x_i} \prod_{k=1}^{'n} \frac{e^{2x_i} + e^{2x_k}}{e^{2x_i} - e^{2x_k}} \right)_{x_1,\ldots,x_{i-1}x_{i+1},\ldots,x_n}, \quad 2 \leqslant s \leqslant (n-1). \tag{32}$$

In the above-mentioned transformation, we have used the equality $(\coth(x_i - x_k))_{x_k} = \sinh^{-2}(x_i - x_k)$ and the decomposition of sinh,cosh functions into two exponentials. Replacing X^i in that form on the left-hand side of the system (30), we have:

$$\left(\sum_{k=1}^{n} e^{[(n+1)-2s+(n-1)-2r]x_k} \prod_{i=1}^{'n} \frac{e^{2x_k} + e^{2x_i}}{e^{2x_k} - e^{2x_i}} \right)_{x_1,\ldots,x_n}, \quad 0 \leqslant r \leqslant (n-1). \tag{33}$$

In all cases from restrictions on s,r, we have $-n+2\leqslant n-r-s\leqslant n-2$. In further transformations of the last expression, it is suitable to distinguish between two different cases: $0\leqslant n-r-s\leqslant n-2$ and $-n+2\leqslant n-r-s\leqslant 0$. In the first one we introduce $\lambda_i\equiv e^{2x_i}$ and rewrite (33) in the form

$$2^n(\lambda_1,\ldots,\lambda_n)\left(\sum_{k=1}^{n}\lambda_k^{(n-s-r)}\frac{\Pi'^{n}_{i=1}(\lambda_k+\lambda_i)}{\Pi'^{n}_{i=1}(\lambda_k-\lambda_i)}\right)_{\lambda_1,\ldots,\lambda_n},\quad 0\leqslant n-r-s\leqslant n-2$$

and in the second case we will get the same expression (up to unessential factors) introducing $\lambda_i\equiv e^{-2x_i}$.

In both cases, we have a symmetric function under the sign of differentiation. Reducing to a common denominator, we obtain the ratio of two n-dimensional polynomial functions, one of which (denominator) is exactly the Wandermond determinant (the single function that is antisymmetric with respect to permutation of each pair of coordinates). Thus, the numerator must also be an antisymmetric polynomial (since the ratio is a symmetric one!). This is impossible if $n-r-s$ is less than $n-1$ (the degree of numerator in this case is less than the degree of the Wandermond determinant).

We thus prove that (32) is a particular solution of the homogeneous system (30).

Adding the particular solution (32) to the particular solution of inhomogeneous equations (31), we arrive at the following solution of the inhomogeneous system (30) that satisfies all necessary additional conditions as one can check directly:

$$X^k=\frac{1}{2^2}\frac{(\sinh)\cosh((n+1)x_k-L_{n+1})+\Sigma_{s=1}^{n-2}(A_s e^{((n+1)x_k-2s)})+B_s e^{(-(n+1)x_k+2s)}}{\Pi'^{n}_{i=1}\sinh^2(x_k-x_i)}$$
$$\equiv\frac{1}{2^2}\frac{\Pi_{j=1}^{n+1}\sinh(x_k-L_j^{n+1})}{\Pi'^{n}_{i=1}\sinh^2(x_k-x_i)}. \tag{34}$$

One can verify the validity of the last representation by decomposition of sinh into two exponentials in each factor of the product with further multiplication term by term.

The last representation for X^n accomplishes the proof of the induction procedure in the case of the functional group.

C. Solution of the problem in the discrete case

In this section, we present the solution of the finite difference system (26) together with all additional conditions (28) and thus prove the induction assumption.

As the reader will see, the most surprising feature of this approach is that both the calculations themselves and the final result are not changed essentially in comparison with the continuous functional group case.

Being rewritten in terms of the operation of discrete differentiation (see Sec. III C), the system (26) takes the form

$$\sum_{k=1}^{n}\Delta_k(e^{(n-1)x_k}X^k)=-2^{n-3}\exp\left(2\sum_{i=1}^{n}x_i-L_{n+1}\right),$$
$$\sum_{k=1}^{n}\Delta_k(e^{sx_k}X^k)=0,\quad s=\equiv(n-1-2r),\quad r=1,2,\ldots(n-2), \tag{35}$$
$$\sum_{k=1}^{n}\Delta_k(e^{-(n-1)x_k}X^k)=(-1)^n2^{n-3}\exp\left(-2\sum_{i=1}^{n}x_i+L_{n+1}\right).$$

Let us seek for the solution of this system in the conventional form:

$$X^k=(Y^k)_{x_1,\ldots,x_{k-1}x_{k+1},\ldots,x_n}.$$

Replacing this expression in (35) and using the obvious equality $\Delta_i e^{\pm 2x_i}=\pm\sinh 2e^{\pm 2x_i}$, we come to linear algebraic equations for determining the unknown functions Y^k:

$$\sum_{k=1}^{n} e^{(n-1)x_k}Y^k=2^{n-3}(\sinh 2)^{-n}\exp\left(2\sum_{k=1}^{n}x_k-L_{n+1}\right)+\Phi^{n-1},$$

$$\sum_{k=1}^{n} e^{sx_k}Y^k=\Phi^s,\quad s\equiv n-1-2r,\quad r=1,2,\ldots,(n-2), \tag{36}$$

$$\sum_{k=1}^{n} e^{-(n-1)x_k}Y^k=-2^{n-3}(\sinh 2)^{-n}\exp\left(-2\sum_{k=1}^{n}x_k+L_{n+1}\right)+\Phi^{-n+1},$$

where all Φ^a are solutions of the same equation

$$(\Delta_1,\Delta_2,\ldots,\Delta_n)\Phi^a=0.$$

In the last expression, the discrete differentiation is performed with respect to all coordinates of the problem.

The system (36) coincides with (??) up to unessential factors. Thus, its general solution (up to obvious corrections) is the same as (31) (of course, with discrete differentiation).

To conduct the last operation, the following equality is necessary:

$$\Delta_i\frac{(\cosh)\sinh(x_i+A)}{\sinh(x_i-x_k)}=\frac{\sinh 2}{2}\frac{(\cosh)\sinh(x_k+A)}{\sinh(x_i-x_k-1)\sinh(x_i-x_k+1)}.$$

Finally for the solution of (35), we obtain:

$$X^k=\frac{1}{2\sinh 2}\frac{(\sinh)\cosh((n+1)x_k-L_{n+1})}{\Pi'^{n}_{i=1}\sinh(x_k-x_i-1)\sinh(x_k-x_i+1)}+X_0^k, \tag{37}$$

where X_0^k is the general solution of the homogeneous system.

As the reader can notice, the only difference from the continuous case is the appearance of the product of sinh functions with shifted arguments in the denominator instead of the single square.

As in the continuous case, it is not difficult to verify that the form

$$X^k=\frac{\Psi(x_k)}{\Phi(x_k-x_i)}$$

is self-consistent with all additional restrictions. We want to show now that the corresponding solution of a homogeneous system [the second term in (37)] can be chosen.

By the same methods, we show that the homogeneous system possesses solutions of the form

$$X^i=\frac{e^{[(n+1)-2s]x_i}}{\Pi'^{n}_{k=1}\sinh(x_i-x_k-1)\sinh(x_i-x_k+1)}$$

$$=\Delta_1\ldots\Delta_{i-1}\Delta_{i+1}\ldots\Delta_n\left(e^{[(n+1)-2s]x_i}\prod_{k=1}^{\prime n}\frac{e^{2x_i}+e^{2x_k}}{e^{2x_i}-e^{2x_k}}\right),\quad 2\leqslant s\leqslant(n-1). \tag{38}$$

Taking the sum of this solution and the particular solution of the inhomogeneous system (37) we obtain X^k in the factorized form,

$$X^k=\frac{1}{2\sinh 2}\,\frac{\Pi_{j=1}^{n+1}\sinh(x_k-L_j^{n+1})}{\Pi_{i=1}'^{n}\sinh(x_k-x_i-1)\sinh(x_k-x_i+1)}.$$

The last expression accomplishes the proof of the induction procedure in the quantum algebra case.

V. OUTLOOK

The main result of the present paper consists in the explicit realization of irreducible representations of quantum algebras A_n^q of the semisimple series. The method we have used is essentially different from the commonly used approaches to the solution of this problem in literature.[5,6] Of the fundamental suggestions, we have used only the Gel'fand–Zeitlin selection rules and commutation relations between generators of the simple roots and Cartan elements of the A_n^q algebra with arbitrary functional dependence in the principal commutation relation $[X_i^+,X_j^-]=\delta_{ij}\phi_i(h_i)$.

Already for the case of A_2^q algebra (and for all A_n^q, $n>2$), this construction is self-consistent only for the choice of ϕ_i functions in the standard trigonometrical form. No additional assumption about the existence of a coproduct is made. In fact, the result can be obtained at the level of the functional group (classic limit), and the only thing that is necessary is to check it at the algebra-theoretical level.

From the physical point of view, this means that the quasiclassical approach in fact leads to a correct quantum result. We are in a position to describe this situation but would not like to make final conclusions at this step.

APPENDIX

Choosing the new unknown function as $F^1(X)\equiv X_x^2, F^2(Y)=Y_y^2$ and $x_1=X^2, x_2=Y^2$ as new independent coordinates, we rewrite (9) in the form of linear equation:

$$(x_1F_{x_1}^1+x_2F_{x_2}^2)(x_1-x_2)=(F^1-F^2)(x_1+x_2).$$

It possesses the three obvious solutions $F=x, F=1, F=1/x$. Their linear combination with arbitrary coefficients is also a solution. This solution is the general one. Indeed, twice differentiating the last equation with respect, say, to the x_1 coordinate, we come to a system of self-consistent equations of the form presented above.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Characterizing entanglement

Dagmar Bruß[a)]
Institut für Theoretische Physik, Universität Hannover,
Appelstr. 2, D-30167 Hannover, Germany

(Received 9 May 2002; accepted for publication 16 May 2002)

Quantum entanglement is at the heart of many tasks in quantum information. Apart from simple cases (low dimensions, few particles, pure states), however, the mathematical structure of entanglement is not yet fully understood. This tutorial is an introduction to our present knowledge about how to decide whether a given state is separable or entangled, how to characterize entanglement via witness operators, how to classify entangled states according to their usefulness (i.e., distillability), and how to quantify entanglement with appropriate measures.
[DOI: 10.1063/1.1494474]

I. INTRODUCTION

The role of entanglement in quantum information processing is manifold. Rather than considering entanglement as a mystery, like in the early years of quantum mechanics, it is nowadays viewed as a resource for certain tasks that can be performed faster or in a more secure way than classically. This genuinely new aspect of quantum properties has launched intensive experimental efforts to create entangled states and theoretical efforts to understand the mathematical structure of entanglement. This tutorial presents the status regarding our understanding of entanglement.

As the number of articles about entanglement has ernomously increased during the last 10 years, it is almost impossible to give a complete overview, and this is not the purpose of this article. It will rather introduce the reader to the established knowledge and some important tools in this field, and discuss some of the questions that remain open at present.

Throughout this tutorial, we will mostly consider entanglement of just two parties, unless stated otherwise explicitly. Most concepts can be explained best with bipartite systems; some of them could then be generalized to more parties in an evident way, for others the situation changes completely for more than two parties. Not many results are known for multipartite systems. In Sec. V D some reasons for this will become clear from studying tripartite states.

Various aspects of entanglement have recently been summarized in the following review articles, which were partially used as a source for this tutorial: the ''primer'' [1] aims at introducing the nonexpert reader to the problem of separability and distillability of quantum states. The Horodecki family discusses entanglement in the context of quantum communication,[2] where the distillability properties of a given state are important. B. Terhal summarizes the use of witness operators for detecting entanglement in Ref. 3. Various entanglement measures are presented in the context of the theorem of their uniqueness in Ref. 4. Other reviews on theoretical and experimental aspects of entanglement can be found in the first issues of the newly launched journal QIC.[5]

This article is organized as follows: Section II presents various possible answers to the question ''what is entanglement?,'' thus shedding light upon different facets of quantum correlations. In Sec. III several criteria are introduced that allow us to distinguish separable from entangled states. In Sec. IV we discuss the possibility to distill entanglement, and give a distillability criterion. Finally, Sec. V concerns attempts to quantify entanglement via entanglement measures. Some important measures are defined and their properties are discussed. The classification of

a)Electronic mail: bruss@itp.uni-hannover.de

entangled states according to their Schmidt number is introduced, and a generalization to tripartite states is included.

II. WHAT *IS* ENTANGLEMENT?

It is nearly 70 years ago that Erwin Schrödinger gave the name ''Verschränkung'' to a correlation of quantum nature.[6] In colloquial German for nonphysicists this term is only used in the sense of ''folding the arms.'' It was then rather loosely translated to ''entanglement,'' with more inspiring connotations.

Over the decades the meaning of the word ''entanglement'' has changed its flavor. The following list is an attempt to sketch the attitude towards entanglement of various important persons in the fields of foundations of quantum physics and later in quantum information theory. These statements are not quotations, unless indicated explicitly.

Einstein/Podolsky/Rosen: An entangled wavefunction does not describe the physical reality in a complete way.

E. Schrödinger: For an entangled state ''the best possible knowledge of the whole does *not* include the best possible knowledge of its parts.'' [6]

Entanglement is ...

J. Bell: ...a correlation that is stronger than any classical correlation.

D. Mermin: ...a correlation that contradicts the theory of elements of reality.

A. Peres: ''...a trick that quantum magicians use to produce phenomena that cannot be imitated by classical magicians.'' [7]

C. Bennett: ...a resource that enables quantum teleportation.

P. Shor: ...a global structure of the wavefunction that allows for faster algorithms.

A. Ekert: ...a tool for secure communication.

Horodecki family: ...the need for first applications of positive maps in physics.

Our view of the nature of entanglement may continue to be modified during the coming years.

III. GIVEN A QUANTUM STATE, IS IT *SEPARABLE* OR *ENTANGLED*?

In this section we will summarize *operational* and *nonoperational* criteria that allow us to classify a given state as separable or entangled. Here the word ''operational'' is used in the sense of ''user-friendly:'' an operational criterion is a recipe that can be applied to an explicit density matrix ϱ, giving some immediate answer like ''ϱ is entangled,'' or ''ϱ is separable,'' or ''this criterion is not strong enough to decide whether ϱ is separable or entangled.''

But, first of all, we need a mathematical definition for entanglement versus separability. This is very simple for *pure states:* a pure state $|\psi\rangle$ is called *separable* iff it can be written as $|\psi\rangle = |a\rangle \otimes |b\rangle$, otherwise it is *entangled*. (Remember that throughout most of this article we talk about bipartite entanglement. In some cases the generalization to more particles is straightforward, like here.) An example for a pure separable state is $|\psi\rangle = |00\rangle$; examples for pure entangled states are the *Bell states*

$$|\Phi^{\pm}\rangle = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle), \tag{1}$$

$$|\Psi^{\pm}\rangle = \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle). \tag{2}$$

A *mixed state* is called separable if it can be prepared by the two parties (which are traditionally called Alice and Bob) in a ''classical'' way, that is, by agreeing over the phone on the *local* preparation of states. A density matrix that has been created in this way can only contain classical correlations. Mathematically this means: a mixed state ϱ is called *separable* iff it can be written as[8]

$$\varrho = \sum_i p_i |a_i\rangle\langle a_i| \otimes |b_i\rangle\langle b_i|, \tag{3}$$

otherwise it is *entangled*. Here the coefficients p_i are probabilities, i.e., $0 \leqslant p_i \leqslant 1$ and $\Sigma_i p_i = 1$. Note that in general $\langle a_i|a_j\rangle \neq \delta_{ij}$, and also Bob's states need not be orthogonal. This decomposition is not unique. An example for a mixed separable state that contains classical correlations, but no quantum correlations, is $\varrho = 1/2(|00\rangle\langle 00| + |11\rangle\langle 11|)$. An example for a mixed entangled state is a Werner state, an admixture of a Bell state as in (1) or (2) to the identity: $\varrho_W = (1-p)1/4\,\mathbb{1} + p|\Phi^+\rangle\langle\Phi^+|$ with $\frac{1}{3} < p \leqslant 1$. The lower limit of p for ϱ_W to be entangled can be easily found with the operational criteria discussed below. In fact, any density matrix that is ''close enough'' to the identity is separable.[9]

Finding a decomposition as in (3) for a given ϱ, or proving that it does not exist, is a nontrivial task which has been solved explicitly only for a few cases. Therefore, this simple-looking definition of separability is by no means ''user-friendly,'' and we are in demand of criteria that are easier to test.

A. Operational separability criteria

Here we present some separability criteria that are easy to check in an explicit case. In the following we will assume that $\varrho \in \mathcal{H}_A \otimes \mathcal{H}_B$ with $\dim \mathcal{H}_A = M$ and $\dim \mathcal{H}_B = N \geqslant M$, without loss of generality.

For *pure states* there is a very simple necessary and sufficient criterion for separability, the **Schmidt decomposition**. A pure state has Schmidt rank $r \leqslant M$ if it can be decomposed as the biorthogonal sum

$$|\psi^r\rangle = \sum_{i=1}^{r} a_i |e_i\rangle |f_i\rangle, \tag{4}$$

with $a_i > 0$ and $\Sigma_i^r a_i^2 = 1$, where $\langle e_i|e_j\rangle = \delta_{ij} = \langle f_i|f_j\rangle$. Note that a_i^2 are the eigenvalues of the reduced density matrices, and therefore the Schmidt rank is easy to compute. A given pure state $|\psi\rangle$ is separable iff $r = 1$.

For *mixed states* the situation is less simple. There are several operational separability criteria for this case. Here they are ordered in decreasing strength, i.e., the last criterion fails to detect an entangled state as entangled in more cases than the previous ones:

(1) **Peres-Horodecki criterion (positive partial transpose):**[10,11] The partial transpose of a composite density matrix is given by transposing only one of the subsystems. Thus, the entries of a density matrix that is partially transposed with respect to Alice are given by

$$(\varrho^{T_A})_{m\mu,n\nu} = \varrho_{n\mu,m\nu}, \tag{5}$$

where Latin indices are referring to Alice's subsystem and Greek ones to Bob's subsystem. As any separable state can be decomposed according to (3), its partial transpose is given by

$$\varrho_{\mathrm{sep}}^{T_A}=\sum_i p_i(|a_i\rangle\langle a_i|)^T\otimes|b_i\rangle\langle b_i|. \tag{6}$$

Since the $(|a_i\rangle\langle a_i|)^T$ are again valid density matrices for Alice, one finds immediately that $\varrho_{\mathrm{sep}}^{T_A}\geqslant 0$. The same holds for partial transposition with respect to Bob (or any other party for multipartite systems). In conclusion, the partial transpose of a separable state ϱ with respect to any subsystem is positive.[10] (In our terminology a positive operator has positive or vanishing eigenvalues—more precisely it should be called positive semidefinite. The expectation value of a positive operator with any state is positive or zero.)

It was shown in Ref. 11 for bipartite systems that the converse (i.e., if $\varrho^{T_A}\geqslant 0$, then ϱ is separable) is true only for low-dimensional systems, namely for composite states of dimension 2×2 and 2×3. In this case the positivity of the partial transpose (PPT) is a necessary and sufficient condition for separability. For higher dimensions it is only necessary, and the existence of entangled PPT states has been shown[12]—these states have been called *bound entangled states*, as their entanglement does not seem to be "useful," as explained in Sec. IV.

(2) **Reduction criterion:**[13] According to the reduction criterion, if ϱ is separable, then

$$\varrho_A\otimes\mathbb{1}-\varrho\geqslant 0 \quad \text{and} \quad \mathbb{1}\otimes\varrho_B-\varrho\geqslant 0, \tag{7}$$

where ϱ_A is Alice's reduced density matrix, and ϱ_B is Bob's. In order to understand why the positivity of the left-hand sides in (7) is a separability criterion, one has to note that they correspond to the application of the positive map $\Lambda(\sigma)=(\mathrm{Tr}\sigma)\mathbb{1}-\sigma$ to Bob's subsystem, or to Alice's subsystem. (The important role of positive maps will be discussed in the next subsection, Sec. III B.) A positive map applied to one subsystem of a separable state preserves the properties of a density matrix—therefore the resulting density matrix has to remain positive.

Like the partial transpose criterion, the reduction criterion is a necessary and sufficient separability condition only for dimensions 2×2 and 2×3, and a necessary condition otherwise.

(3) **Majorization criterion:**[14] The majorization criterion says that if a state ϱ is separable, then

$$\lambda_\varrho^\downarrow\prec\lambda_{\varrho_A}^\downarrow \quad \text{and} \quad \lambda_\varrho^\downarrow\prec\lambda_{\varrho_B}^\downarrow \tag{8}$$

has to be fulfilled. Here $\lambda_\varrho^\downarrow$ denotes the vector consisting of the eigenvalues of ϱ, in decreasing order, and a vector $x^\downarrow$ is *majorized* by a vector $y^\downarrow$, denoted as $x^\downarrow\prec y^\downarrow$, when $\Sigma_{j=1}^k x_j^\downarrow\leqslant\Sigma_{j=1}^k y_j^\downarrow$ holds for $k=1,\ldots,d-1$, and the equality holds for $k=d$, with d being the dimension of the vector. Zeros are appended to the vectors $\lambda_{\varrho_{A,B}}^\downarrow$ in (8), in order to make their dimension equal to the one of $\lambda_\varrho^\downarrow$.

Thus, for a separable state the ordered vector of eigenvalues for the whole density matrix is majorized by the ones of the reduced density matrices. This is was summarized by Nielsen and Kempe as "Separable states are more disordered globally than locally."[14] Note that the spectra of a density matrix and its reduced density matrices do not allow us to distinguish separable and entangled states. The majorization criterion is only a necessary, not a sufficient condition for separability.

The logical ordering of the separability criteria introduced in this section is as follows:

(i) *dimension 2×2 and 2×3:* ϱ is separable$\Leftrightarrow$satisfies PPT$\Leftrightarrow$satisfies reduction criterion$\Rightarrow$satisfies majorization criterion, and

(ii) *higher dimensions:* ϱ is separable$\Rightarrow$satisfies PPT$\Rightarrow$satisfies reduction criterion$\overset{?}{\Rightarrow}$satisfies majorization criterion

B. Nonoperational separability criteria

In this subsection we will discuss two nonoperational separability criteria. Both are necessary and sufficient criteria for any bipartite system. They bear the major problem, however, that they do not provide us with a simple procedure to check the separability properties of a given state. This will become clear from their description.

(1) **Positive maps:** It was shown in Ref. 11 that ϱ *is separable iff for any positive map* Λ

$$(\mathbb{1}\otimes\Lambda)(\varrho)\geqslant 0 \tag{9}$$

holds.

A positive map is a map that takes positive operators to positive operators. A positive map Λ is called *completely positive* (CP) if any extension to a larger Hilbert space, i.e., $\mathbb{1}_x\otimes\Lambda$, is a positive map. Here x denotes the dimension of the extension and is arbitrary. It is clear from Eq. (9) that, for the purpose of finding separability criteria, only those maps are interesting which are positive, but *not* CP, as a CP map will fulfill (9) for any given ϱ.

In the previous section we have already studied two examples for positive maps that are not CP and the extensions of which provide separability criteria: the transpose and the map $\Lambda(\sigma)=(\mathrm{Tr}\sigma)\mathbb{1}-\sigma$. There we have already explained the reason why (9) has to hold for separable states: it is the possibility to decompose a separable state into a sum of tensor products according to (3). Applying a positive map to one of the subsystems will keep each term positive, and therefore also their sum.

Note that the problem about the nonoperational criterion of positive maps lies in the little word ''any'' just before (9): we do not have a complete characterization of the set of all positive maps.

(2) **Entanglement witnesses:** The criterion of the so-called entanglement witnesses was given in Ref. 11 and studied in Ref. 15:

A density matrix ϱ *is entangled iff there exists a Hermitian operator* $\mathcal{W}$ *with* $Tr(\mathcal{W}\varrho)<0$ *and* $Tr(\mathcal{W}\varrho_{sep})\geqslant 0$ *for any separable state* ϱ_{sep}.

We say that the witness $\mathcal{W}$ ''detects'' the entanglement of ϱ.

Correspondence between (1) and (2): These two criteria are not independent—there is the Jamiołkowski isomorphism[16] that provides us with a correspondence between an entanglement witness and a positive map,

$$\mathcal{W}=(\mathbb{1}\otimes\Lambda)(P_+), \tag{10}$$

where $P_+=(1/M)\,(\Sigma_{i=1}^{M}|ii\rangle)(\Sigma_{j=1}^{M}\langle jj|)$ is the projector onto the maximally entangled state.

Let us for the rest of this subsection pursue the concept of entanglement witnesses. What seems at first sight to be a rather abstract theorem will prove to be a powerful tool, as it allows us to answer explicit questions about entanglement properties of certain states (see, e.g., Sec. V E).

The existence of entanglement witnesses is a consequence of the Hahn–Banach theorem, which states the following:

Let S *be a convex, compact set, and let* $\varrho\notin S$. *Then there exists a hyper-plane that separates* ϱ *from* S.

This fact is illustrated in Fig. 1: the bigger ''egg''-shaped set symbolizes the convex, compact set of all density matrices. The smaller one stands for the separable density matrices, and is a convex, compact subset of the bigger one. The state ϱ is entangled and therefore $\notin S$. The dotted line sketches the hyper-plane that separates ϱ from S, and is given by those σ that fulfill $\mathrm{Tr}(\mathcal{W}\sigma)=0$.

It is helpful to realize that $\mathrm{Tr}(\mathcal{W}\varrho)$ defines a scalar product. Let us for a moment look at a scalar product which is familiar to everybody, the scalar product of two vectors of unit length with common origin. Let us call them $\vec{w}$ and $\vec{r}$. Their scalar product $\vec{w}\cdot\vec{r}$ is equal to $\cos\alpha$, where α is

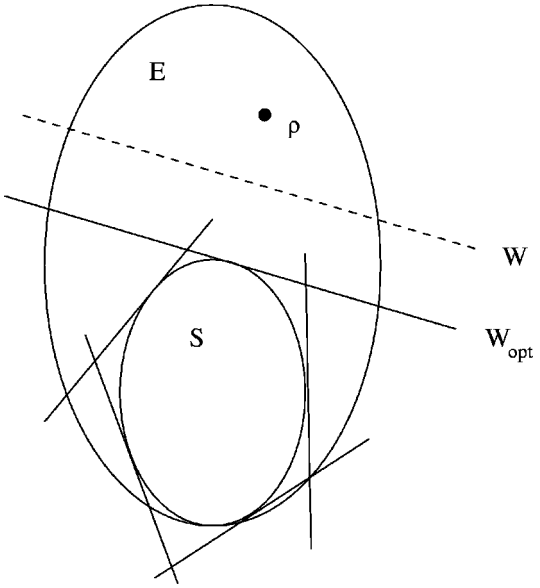

FIG. 1. Intuitive picture of entanglement witnesses and their optimization.

the relative angle between the two vectors. A *fixed* $\vec{w}$ defines a certain plane—the one to which $\vec{w}$ is orthogonal. Vectors $\vec{r}$ from this plane have a vanishing scalar product with $\vec{w}$. All vectors $\vec{r}$ that are ''on one side'' of this plane have a positive scalar product with $\vec{w}$; all vectors $\vec{r}$ ''on the other side'' a negative one—due to the properties of the cosine function. The scalar product $\mathrm{Tr}(\mathcal{W}\varrho)$ has the same property: all density operators on one side of the hyper-plane lead to a positive outcome; the ones on the other side to a negative one.

This intuitive picture of entanglement witnesses also helps to understand how they can be optimized:[17] performing a parallel transport of the hyper-plane such that it becomes tangent to the set of separable states means that the corresponding optimized witness $\mathcal{W}_{\mathrm{opt}}$ detects more entangled states than before. This is also indicated in Fig. 1.

In order to completely characterize the set S one would in principle need infinitely many witnesses, unless the shape of S is a polytope. This is not known nowadays. But several witnesses can already give a good approximation of the set of separable states. Methods to construct entanglement witnesses in a canonical way have been provided in Ref. 17.

IV. GIVEN AN ENTANGLED STATE, IS THE ENTANGLEMENT *USEFUL*?

In an ideal experiment an initially prepared maximally entangled state would remain maximally entangled. In reality, the resource of entanglement is very fragile, due to interaction with the environment. As entanglement is the foundation of many quantum information processing tasks, it would therefore be desirable to concentrate nonmaximal entanglement. A central question is: given several copies of a nonmaximally entangled state, is there a process that allows us to locally ''distill'' its entanglement, i.e., to retrieve a maximally entangled state?

This is a straightforward motivation to study entanglement distillation. In addition, this concept is useful in any other quantum communication task: assume that Alice wants to send a quantum message to Bob. As a simple illustration she will send a polarized photon along an optical fiber. Interaction with the environment disturbs the original quantum state—in general one has to deal with ''noisy channels.'' An initial pure state $|\psi\rangle$ will arrive as some disturbed mixed state ϱ. This situation is sketched in Figs. 2(a) and 2(b).

In the wide field of error correction one deals with this problem by ''repairing the state,'' i.e., via encoding, finding the error and then restoring the original state. The idea of distillation of

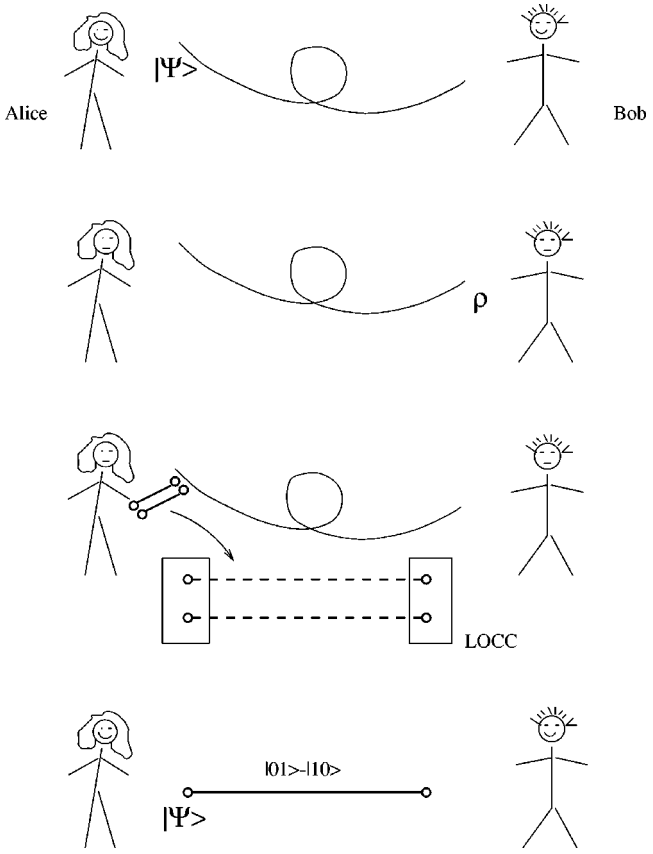

FIG. 2. Providing a noiseless channel via distillation: (a) Alice wants to send the message $|\psi\rangle$ to Bob. (b) Bob receives ϱ instead, as the channel is noisy. (c) Alice sends one subsystem of a maximally entangled state through the noisy channel to Bob, and repeats this with a second pair. They employ a distillation protocol. (d) Alice and Bob have created a maximally entangled singlet which they can use as a noiseless teleportation channel.

nonmaximally entangled states pursues a different path, by ''providing a noiseless channel,'' as explained below.

Figure 2(c) visualizes this concept: Alice sends one subsystem of a maximally entangled state through the noisy channel to Bob. The resulting state will not be maximally entangled and mixed, due to the noise. She repeats this with a second pair or more pairs. Alice and Bob then operate locally on their respective qubits and communicate classically (LOCC=local operations and classical communication), thus employing a distillation protocol. One explicit protocol will be introduced below. Thus they create a maximally entangled state as indicated in Fig. 2(d). This state can now be used as a noiseless channel via teleportation.

In summary, it is an essential question to ask: Given an entangled density matrix ϱ, can its entanglement be *distilled*?

A. A distillation protocol

The following distillation protocol for nonmaximally entangled mixed states was proposed in Ref. 18. It is designed for the case that Alice and Bob share a supply of many identical entangled bipartite systems of qubits. They can always convert them by local operations to the isotropic state $\varrho_{iso}=(1-p)1/4\,\mathbb{1}+p|\Phi^+\rangle\langle\Phi^+|$, with $\frac{1}{3}<p\leqslant 1$.

In the first step Alice and Bob use two ϱ's, as illustrated in Fig. 3. Each of them applies a local CNOT-gate to his/her two qubits. The action of this gate is given by $U_{\mathrm{CNOT}}|a_1\rangle|a_2\rangle=|a_1\rangle|(a_1+a_2)\mathrm{mod}\,2\rangle$.

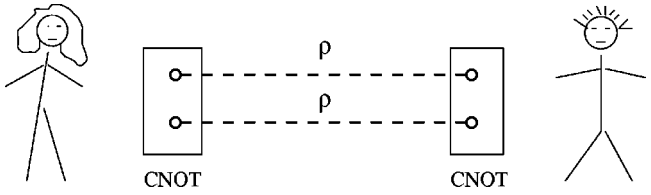

FIG. 3. First step in the distillation protocol: applying local CNOT's.

In the next step, both Alice and Bob do a measurement on their second qubit, as shown in Fig. 4. They only keep the first density matrix, which had changed to some ϱ', if their outcomes are identical. Otherwise the two pairs have to be discarded.

This process has increased the overlap of the new density matrix ϱ' with the maximally entangled state. Thus both entanglement and purity are enhanced. The new fidelity is defined as $F'=\langle\Phi^+|\varrho'|\Phi^+\rangle$ and is plotted in Fig. 5, as a function of the original fidelity $F=\langle\Phi^+|\varrho|\Phi^+\rangle = (1+3p)/4$. This procedure is then repeated with new pairs of the higher fidelity. In this way the entanglement is increased in successive steps, finally being maximal when enough original pairs were available. A distillation protocol is successful, i.e., enhances the entanglement, whenever the curve for the new fidelity lies above the line $F'=F$ (dashed line in Fig. 5).

B. Which states can be *distilled*?

For the general reasons discussed at the beginning of Sec. IV it is a very fundamental question to ask: which entangled states can be distilled? For two-qubit states the answer was given in Ref. 19: *all* entangled two-qubit states are distillable.

In general, this question is unsolved, however. A necessary and sufficient criterion for distillability of a given ϱ was proved in Ref. 20:

The state ϱ *is distillable iff there exists* $|\psi^2\rangle=a_1|e_1\rangle|f_1\rangle+a_2|e_2\rangle|f_2\rangle$ *such that* $\langle\psi^2|(\varrho^{T_A})^{\otimes n}|\psi^2\rangle<0$ *for some* n.

In other words, if for a certain number n of copies the partial transpose of the total state has a negative expectation value with some vector of Schmidt rank 2, then ϱ can be distilled (one says: ϱ is n-distillable), and vice versa. From this theorem it follows immediately that a state with a positive partial transpose cannot be distilled: if $\varrho^{T_A}\geqslant 0$, then $(\varrho^{T_A})^{\otimes n}\geqslant 0$, and thus PPT states are undistillable. As mentioned above, entangled PPT states are therefore called ''bound entangled.''

It is an open question whether the reverse of the statement ''PPT states are undistillable'' is also true, i.e., if a state is undistillable, does it have to be PPT? For the dimension $2\times N$ this is indeed true.[21] For higher dimensions there is a strong conjecture that it is false, i.e., that there are undistillable states with a nonpositive partial transpose (NPT). A family of such states in dimension $N\times N$ was discussed in Refs. 21 and 22. This family consists of a convex combination of projectors onto the symmetric and the antisymmetric subspace, where the relative weight of these two contributions is the only free parameter. Depending on the value of this parameter, the state is PPT or NPT. The undistillability of NPT states with a certain constant finite range of this param-

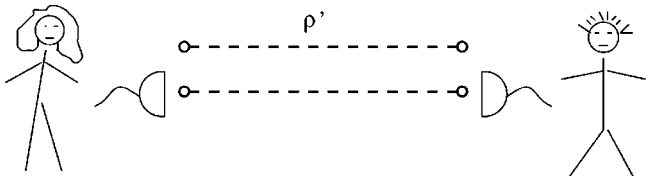

FIG. 4. Second step in the distillation protocol: measurement.

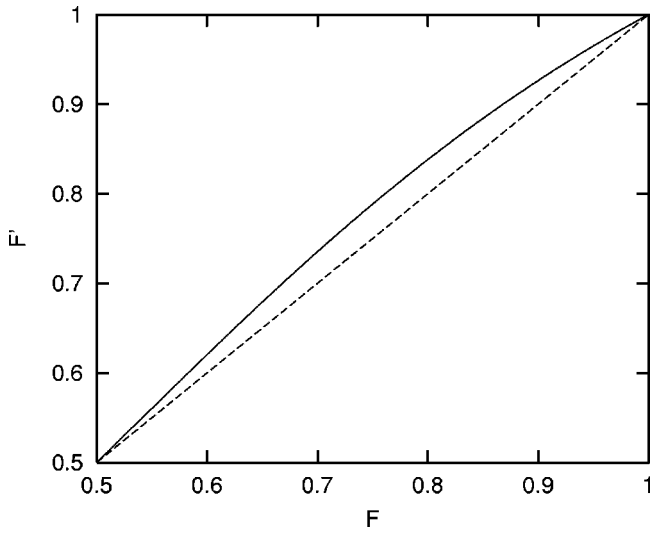

FIG. 5. New fidelity after one distillation step, as a function of the fidelity in the previous step.

eter was shown numerically for up to three copies in the case $N=3$. The problem in finding a rigorous answer to the question of distillability for these NPT states lies in the fact that one has to consider the limit $n\to\infty$.

Our present understanding of how the set of all states is decomposed into separable, entangled undistillable and distillable states is summarized in Fig. 6.

V. GIVEN AN ENTANGLED STATE, *HOW MUCH* IS IT ENTANGLED?

So far we have shown that it is still an open question how to *qualify* a given state as separable versus entangled or undistillable versus distillable. How can we hope to answer the question of *quantifying* the amount of entanglement of a given state? It is not surprising that there is no simple answer to that. We will summarize the requirements for a good entanglement measure, and introduce the reader to some important entanglement measures, without making the attempt to discuss all existing entanglement measures.

In Sec. V C we will explain the concept of Schmidt witnesses, which us allows to classify entangled states in classes according to their Schmidt number. In the final two subsections we will study composite systems of three qubits, showing that the question of quantification of entanglement has to be reformulated in that case.

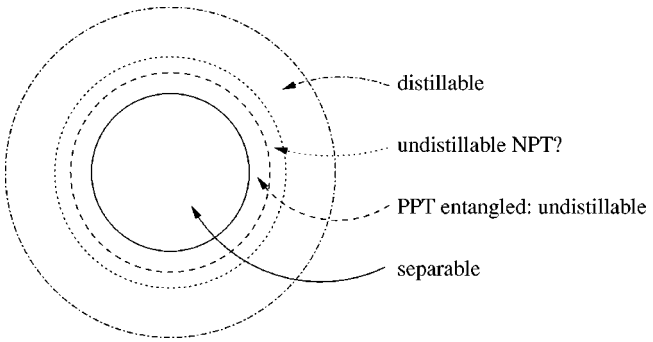

FIG. 6. Decomposition of the set of all states into distillable and undistillable states.

A. Requirements for entanglement measures

A good entanglement measure E has to fulfill several requirements. However, it is still an open question whether all of these conditions are indeed necessary. In fact, some of the entanglement measures that are introduced below do not fulfill the whole list of properties (see Table I).

(1) If ϱ is *separable*, then $E(\varrho)=0$.
(2) *Normalization:* The entanglement of a maximally entangled state of two d-dimensional systems is given by

$$E(P_+^d)=\log d. \tag{11}$$

(3) *No increase under LOCC:* Applying local operations to ϱ and classically communicating cannot increase the entanglement of ϱ, i.e.,

$$E(\Lambda_{\mathrm{LOCC}}(\varrho))\leqslant E(\varrho). \tag{12}$$

(4) *Continuity:* In the limit of vanishing distance between two density matrices the difference between their entanglement should tend to zero, i.e.,

$$E(\varrho)-E(\sigma)\to 0 \quad \text{for } \|\varrho-\sigma\|\to 0. \tag{13}$$

(5) *Additivity:* A certain number n of identical copies of the state ϱ should contain n times the entanglement of one copy,

$$E(\varrho^{\otimes n})=nE(\varrho). \tag{14}$$

(6) *Subadditivity:* The entanglement of the tensor product of two states ϱ and σ should not be larger than the sum of the entanglement of each of the states,

$$E(\varrho\otimes\sigma)\leqslant E(\varrho)+E(\sigma). \tag{15}$$

(7) *Convexity:* The entanglement measure should be a convex function, i.e.,

$$E(\lambda\varrho+(1-\lambda)\sigma)\leqslant\lambda E(\varrho)+(1-\lambda)E(\sigma) \tag{16}$$

for $0<\lambda<1$.

B. Some important entanglement measures

For a pure bipartite state $|\psi\rangle$ a good entanglement measure is the von Neumann entropy of its reduced density matrix, $S(\varrho_{\mathrm{red}})=-\mathrm{Tr}(\varrho_{\mathrm{red}}\log\varrho_{\mathrm{red}})$. For mixed states there is no unique entanglement measure, but all entanglement measures should coincide on pure bipartite states and be equal to the von Neumann entropy of the reduced density matrix (uniqueness theorem).[5] Some important entanglement measures are defined as follows:

Entanglement cost: The entanglement cost tells us how expensive it is to create an entangled state ϱ, i.e., what is the ratio of the number of maximally entangled input states $|\Phi^+\rangle$ over the produced output states ϱ, minimized over all LOCC operations. In the limit of infinitely many outputs this reads

$$E_C(\varrho)=\inf_{\{\Lambda_{\mathrm{LOCC}}\}}\lim_{n_\varrho\to\infty}\frac{n^{in}_{|\Phi^+\rangle}}{n^{\mathrm{out}}_{\varrho}}. \tag{17}$$

Entanglement of formation: Any state ϱ can be decomposed as a convex combination of projectors onto pure states, $\varrho=\Sigma_i p_i|\psi_i\rangle\langle\psi_i|$. The entanglement of formation is the averaged von Neumann entropy of the reduced density matrices of the pure states $|\psi_i\rangle$, minimized over all possible decompositions,

$$E_F(\varrho)=\inf_{\{\mathrm{dec}\}}\sum_i p_i S(\varrho_{i,\mathrm{red}}). \tag{18}$$

Relative entropy of entanglement: The relative entropy can be seen intuitively as the ''distance'' of the entangled ϱ to the closest separable state σ, although it is not a distance in the mathematical sense,

$$E_R(\varrho)=\inf_{\sigma\in S}\mathrm{tr}[\varrho(\log\varrho-\log\sigma)]. \tag{19}$$

Distillable entanglement: The distillable entanglement tells us how much entanglement we can extract from an entangled state ϱ, i.e., what is the ratio of the number of maximally entangled output states $|\Phi^+\rangle$ over the needed input states ϱ, maximized over all LOCC operations. In the limit of infinitely many inputs this reads

$$E_D(\varrho)=\sup_{\{\Lambda_{\mathrm{LOCC}}\}}\lim_{n_\varrho\to\infty}\frac{n^{\mathrm{out}}_{|\Phi^+\rangle}}{n^{\mathrm{in}}_{\varrho}}. \tag{20}$$

There are some known relations between these entanglement measures: the distillable entanglement (entanglement cost) is a lower (upper) bound for *any* entanglement measure, i.e., $E_D(\varrho)\leqslant E(\varrho)\leqslant E_C(\varrho)$. For any bound entangled state $E_D(\varrho)<E_C(\varrho)$ holds, but there is also an example for a free entangled state, i.e., a distillable state, with the same property.[23] It is conjectured that the entanglement of formation and the entanglement cost are identical, i.e., $E_F(\varrho)\overset{?}{=}E_C(\varrho)$.

Some known and unknown properties of the entanglement measures discussed above are given in Table I.[24,25]

C. Schmidt witnesses

A slightly different question from ''how much entangled is a state ϱ?'' can be addressed via the generalization of entanglement witnesses to so-called Schmidt witnesses. They give an answer to the question ''how many degrees of freedom are entangled in ϱ?'' This corresponds to a finer classification of entangled states.

The Schmidt rank for pure bipartite states, as defined in Eq. (4), was generalized to the so-called Schmidt number k for mixed bipartite states in Ref. 26. For a given decomposition of ϱ into a convex combination of projectors onto pure states, let us call the highest occurring Schmidt rank $r_{\max}$. The Schmidt number is the minimization of this highest Schmidt rank over all possible decompositions:

$$\varrho=\sum_i p_i|\Psi_i^{r_i}\rangle\langle\Psi_i^{r_i}|,\quad k=\min_{\{\mathrm{dec}\}}(r_{\max}). \tag{21}$$

The Schmidt number cannot be higher than M, the smaller of the dimensions of the two subsystems.

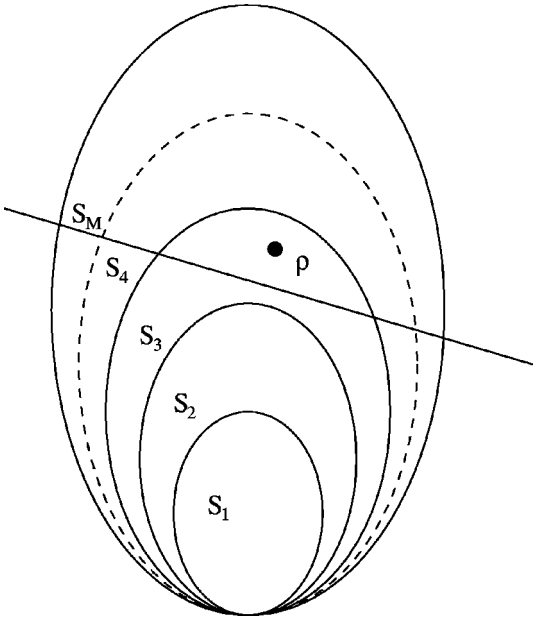

FIG. 7. Schmidt classes and the detection of the Schmidt number by a Schmidt witness.

Entangled states can now be classified according to Schmidt classes:[27] the Schmidt class S_k is a subset of the set of all density matrices and contains all density matrices with Schmidt number $\leqslant k$. The Schmidt classes are successively embedded into each other, as visualized in Fig. 7: $S_1 \subset S_2 \subset \ldots \subset S_M$.

A Schmidt witness $\mathcal{W}_k$ for the Schmidt class S_k is defined as a straightforward generalization of the entanglement witnesses discussed in Sec. III B. A Schmidt witness $\mathcal{W}_k$ is a Hermitian operator for which

$$\exists \varrho \in S_k \quad \text{with} \quad \mathrm{Tr}(\mathcal{W}_k \varrho) < 0, \tag{22}$$

$$\forall \varrho_{k-1} \in S_{k-1}: \quad \mathrm{Tr}(\mathcal{W}_k \varrho_{k-1}) \geqslant 0. \tag{23}$$

Constructive methods for Schmidt witnesses have been shown; they can be optimized in analogy with entanglement witnesses, and they can be used for example as a tool to study properties of bound entangled states.

D. "Many" systems: Pure three-qubit states

So far we have only considered bipartite systems. Unfortunately, according to current knowledge one already has to call three subsystems ''many.'' Can we generalize the concepts that were introduced so far to tripartite states? Again, one can ask whether a given state is separable or entangled. But now one can also specify the kind of entanglement: is it genuine three-particle entanglement or are just two of the three subsystems entangled? Like for bipartite states, one can ask whether a given tripartite state can be distilled. This question will not be addressed here, however. And, finally, does it make sense to ask ''how much is a given tripartite state entangled?''

For *pure* three-qubit states the situation is as follows:

A *separable* state can be written as

$$|\psi_S\rangle = |\phi_A\rangle \otimes |\phi_B\rangle \otimes |\phi_C\rangle. \tag{24}$$

A *biseparable* state is a state where only two out of the three systems are entangled, and the third system is a tensor product with the entangled ones, e.g., A–BC:

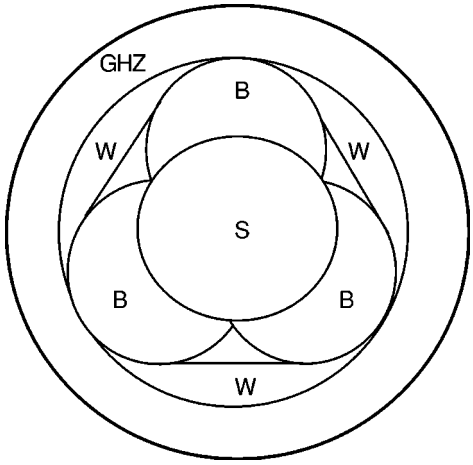

FIG. 8. Schematic structure of the set of all three-qubit states. *S*: separable class; *B*: biseparable class (convex hull of biseparable states with respect to any partition); *W*-class and GHZ-class.

$$|\psi_B\rangle = |\phi_A\rangle \otimes \sum_{i=1}^{2} a_i |e_i\rangle |f_i\rangle. \tag{25}$$

The other two possible partitions for biseparable states are B–AC and C–AB.

A *three-qubit correlated* state is one with genuine entanglement of all three subsystems. It was shown in Ref. 28 that there exist two classes of *inequivalent* states:

$$|\psi_{\mathrm{GHZ}}\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle), \tag{26}$$

$$|\psi_W\rangle = \frac{1}{\sqrt{3}}(|100\rangle + |010\rangle + |001\rangle). \tag{27}$$

Any three-qubit correlated pure state $|\psi\rangle$ can be transformed into either $|\psi_{\mathrm{GHZ}}\rangle$ or $|\psi_W\rangle$ by local reversible operations $\mathcal{A}\otimes\mathcal{B}\otimes\mathcal{C}$.

Therefore, it is not enough to ask whether a given three-qubit state is separable or biseparable or three-party entangled, but also whether a genuinely three-qubit entangled state belongs to the GHZ- or *W*-class. For mixed states, the tool of witness operators is again useful for this purpose, as will be discussed in the following subsection.

E. Classification of mixed three-qubit states

Let us introduce entanglement classes for mixed three-qubit states.[29] A mixed three-qubit state ϱ can be written as convex combination of pure states: if ϱ can be decomposed as a sum of projectors onto pure separable states $|\psi_S\rangle\langle\psi_S|$, then it belongs to the convex compact set S. If one needs at least one biseparable state $|\psi_B\rangle\langle\psi_B|$ in the sum, but no genuine tripartite entanglement, then ϱ belongs to the class B, more precisely to $B\setminus S$. In the same way we define the *W*-class (needs at least one *W*-state in the decomposition) and the GHZ-class (at least one GHZ-state needed).

These sets are embedded into each other: $S\subset B\subset W\subset \mathrm{GHZ}$. This is schematically shown in Fig. 8. It is important to note that $W\subset\mathrm{GHZ}$ and not the other way round: otherwise the class GHZ would not be compact, as can be seen by studying the most general form of a *W*-versus a GHZ-state, as given in Ref. 30.

In analogy to entanglement witnesses and Schmidt witnesses one can construct tripartite witnesses. A GHZ witness $\mathcal{W}_{\mathrm{GHZ}}$ is an Hermitian operator with $\mathrm{Tr}(\mathcal{W}_{\mathrm{GHZ}}\varrho)<0$ for some $\varrho \in \mathrm{GHZ}\setminus W$, and $\mathrm{Tr}(\mathcal{W}_{\mathrm{GHZ}}\varrho_W)\geqslant 0$ for all $\varrho_W \in W$. An example for a GHZ witness is given by

$$\mathcal{W}_{\mathrm{GHZ}}=\tfrac{3}{4}\mathbb{1}-P_{\mathrm{GHZ}}, \tag{28}$$

where P_{GHZ} is the projector onto $|\psi_{\mathrm{GHZ}}\rangle$, given in (26). It is straightforward to show that this operator has the desired properties, when one realizes that the maximal squared overlap between a pure W-state and $|\psi_{\mathrm{GHZ}}\rangle$ is given by $\frac{3}{4}$.

In a similar manner one can define a W-witness. An example for such a witness that detects a W-state, but has a positive or vanishing expectation value for all states in B, is given by

$$\mathcal{W}_W=\tfrac{2}{3}\mathbb{1}-P_W, \tag{29}$$

where P_W is the projector onto $|\psi_W\rangle$, given in (27), and $\frac{2}{3}$ is the maximal squared overlap between $|\psi_W\rangle$ and a pure biseparable state.

Using the witness in (29), one can show that the set of mixed $W\setminus B$-states is not of measure zero. This is contrary to the pure case, where W-states are of measure zero.[28] The idea of the proof is to show that there is a finite ball around a state from the family

$$\varrho=\frac{1-p}{8}\mathbb{1}+pP_W, \tag{30}$$

for a certain given parameter p, such that the ball is contained in the W-class. This is an example where the concept of witnesses helps to answer an explicit question about the structure of the set of entangled states.

Another interesting topic in this context is the properties of bound entangled states. Using again the tool of witness operators, there is some evidence that bound entangled three-qubit states cannot be in $\mathrm{GHZ}\setminus W$, i.e., they are at most in W.[29]

By studying mixed three-qubit states we have realized that in this case it is not enough to ask ''how much a given state is entangled.'' As there are different inequivalent entanglement classes, this question makes sense only within a given class W or GHZ. For more than three qubits the number of inequivalent classes grows fast.[28]

VI. SUMMARY

The section headings in this tutorial were phrased as questions. Let us summarize some answers.

What is entanglement?

There are many possible answers, maybe as many as there are researchers in this field.

Given a state ϱ, is it separable or entangled?

This question is easy to answer for pure states, and for low dimensions (2×2 and 2×3). It is very difficult to answer otherwise. Several separability criteria have been explained.

Given an entangled ϱ, is the entanglement useful?

We have discussed that states with a positive partial transpose are undistillable, most states with a nonpositive partial transpose (NPT) are distillable; but some NPT states are conjectured to be undistillable.

Given an entangled ϱ, how much is it entangled?

There are several different bipartite entanglement measures which quantify the degree of entanglement. For multipartite systems there are inequivalent entanglement classes, and therefore the above question has to be rephrased accordingly.

(Received 12 November 2001; accepted for publication 12 March 2002)

We explore and develop the mathematics of the theory of entanglement measures. After a careful review and analysis of definitions, of preliminary results, and of connections between conditions on entanglement measures, we prove a sharpened version of a uniqueness theorem which gives necessary and sufficient conditions for an entanglement measure to coincide with the reduced von Neumann entropy on pure states. We also prove several versions of a theorem on extreme entanglement measures in the case of mixed states. We analyze properties of the asymptotic regularization of entanglement measures proving, for example, convexity for the entanglement cost and for the regularized relative entropy of entanglement. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1495917]

I. INTRODUCTION

Quantifying entanglement[1–4] is one of the central topics of quantum information theory. Any function that quantifies entanglement is called an entanglement measure. Entanglement is a complex property of a state and, for arbitrary states, there is no unique definitive measure. In general, there are two ''regimes'' under which entanglement can be quantified: they may be called the ''finite'' and the ''asymptotic'' regimes. The first deals with the entanglement of a single copy of a quantum state. In the second, one is interested in how entanglement behaves when one considers tensor products of a large number of identical copies of a given state. It turns out that by studying the asymptotic regime it is possible to obtain a clearer physical understanding of the nature of entanglement. This is seen, for example, in the so-called ''uniqueness theorem'' [3–6] which states that, under appropriate conditions, all entanglement measures coincide on pure bipartite states and are equal to the von Neumann entropy of the corresponding reduced density operator. However, this theorem was never rigorously proved under unified assumptions and definitions. Rather, there are various versions of the argument scattered through the literature.

In Ref. 4, the uniqueness theorem was put into a more general perspective. Namely, there are two basic measures of entanglement[1]—entanglement of distillation (E_D) and entanglement cost (E_C)—having the following dual meanings:

(i) $E_D(\varrho)$ is the maximal number of singlets that can be produced from the state ϱ by means of local quantum operations and classical communication (LQCC operations).
(ii) $E_C(\varrho)$ is the minimal number of singlets needed to produce the state ϱ by LQCC operations.

a)Electronic mail: matthew.donald@phy.cam.ac.uk
b)Electronic mail: fizmh@univ.gda.pl
c)Author to whom correspondence should be addressed. Electronic mail: rudolph@fisicavolta.unipv.it

[More precisely (cf. Definitions 16 and 17): $E_D(\varrho)$ ($E_C(\varrho)$) is the maximal (minimal) number of singlets *per copy* distillable from the state ϱ (needed to form ϱ) by LQCC operations in the asymptotic regime of $n\to\infty$ copies.] It is important here that the conversion is not required to be perfect: the transformed state needs to converge to the required state only in the limit of large n. Now, in Ref. 4 it was shown that the two basic measures of entanglement are, respectively, a lower and an upper bound for any entanglement measure satisfying appropriate postulates in the asymptotic regime.[7] This suggests the following clear picture: entanglement cost and entanglement of distillation are extreme measures, and provided they coincide on pure states, all other entanglement measures coincide with them on pure states as well. However, as mentioned above, the fact that E_D and E_C coincide on pure states was not proven rigorously. Moreover, it turned out that the postulates are too strong. They include convexity, and some additivity and continuity requirements. It is not known whether any measure exists which satisfies all the requirements. E_D and E_C satisfy the additivity requirement, but it is not known whether or not they are continuous in the sense of Ref. 4. There are also indications that the entanglement of distillation is not convex.[8] On the other hand, two other important measures, the *entanglement of formation* (denoted by E_F) and the *relative entropy of entanglement* (denoted by E_R) are continuous[6,9] and convex, but there are problems with additivity. The relative entropy of entanglement is certainly not additive,[10] and we do not know about the entanglement of formation.

In this situation it is desirable to prove the uniqueness theorem from first principles, and to study to what extent we can relax the assumptions and still get uniqueness of entanglement measures on pure states. In the present article we have solved the problem completely by providing *necessary and sufficient* conditions for a measure of entanglement to be equal to the von Neumann entropy of the reduced density operator for pure states. We also show that if we relax the postulate of asymptotic continuity, then any measure of entanglement (not unique any longer) for pure states must lie between the two analogs of E_D and E_C corresponding to *perfect* fidelity of conversion. These are $\tilde{E}_C(\psi)=S_0(\varrho)$ and $\tilde{E}_D(\psi)=S_\infty(\varrho)$, where ϱ is the reduced density matrix of $|\psi\rangle$, and S_0, S_∞ are Rènyi entropies. In Refs. 11 and 12, one of us has studied entanglement measures based on cross norms and proved an alternative uniqueness theorem for entanglement measures stemming from the Khinchin–Faddeev characterization of Shannon entropy.

The present article also contains further developments on the problem of extreme measures. We provide two useful new versions of the theorem of Ref. 4. In one of them, we show that for any (suitably normalized) function E for which the regularization $E^\infty(\varrho)=\lim_{n\to\infty}E(\varrho^{\otimes n})/n$ exists and which is (i) nonincreasing under local quantum operations and classical communication (LQCC operations) and (ii) asymptotically continuous, the regularization E^∞ must lie between E_D and E_C. The theorem and its proof can easily be generalized by replacing the class of LQCC operations by other classes of operations, or by considering conversions between any two states. Moreover, it is valid for multipartite cases. Therefore, the result will be an important tool for analyzing asymptotic conversion rates between different states. In particular, it follows from our result that to establish irreversibility of conversion between two states (see Ref. 13), one needs to compare regularizations of asymptotically continuous entanglement measures for these states.

In the other new version of the extreme measures theorem, we are able to weaken the postulates of Ref. 4, so that they are at least satisfied by E_C. On the other hand, we do not have a proof that E_D is asymptotically continuous for mixed states, although there is strong evidence that this is the case. If it is, then we would finally have a form of the theorem, in which both E_D and E_C could be called extreme measures, not only in the sense provided by the inequalities we prove, but also in the sense that they belong to the set described by the postulates.

To obtain our results we perform a detailed study of possible postulates for entanglement measures in the finite and the asymptotic regime. In particular, we examine which postulates survive the operation of regularization. We show that if a function is convex and subadditive [i.e., $f(\varrho\otimes\sigma)\leqslant f(\varrho)+f(\sigma)$], then its regularization is convex, too. Hence, both the regularization of the relative entropy of entanglement[2] as well as of the entanglement of formation[1] are convex.

It should be emphasized that our results are stated and proved in language accessible for mathematicians or mathematical physicists who have not previously been involved in quantum

information theory. This is in contrast to many papers in this field, where many implicit assumptions are obstacles for understanding the meaning of the theorems and their proofs by nonspecialists. For this reason, we devote Secs. II and III to careful statements of some essential definitions and results. In Sec. IV we present a self-contained and straightforward proof of the difficult implication in Nielsen's theorem. This is a theorem which we shall use several times. Properties of entanglement measures and relations between them are analyzed in Sec. V. The most prominent entanglement measures—entanglement of distillation, entanglement cost, entanglement of formation and relative entropy of entanglement—are defined and studied in Sec. VI. In Sec. VII we present our versions of the theorem on extreme measures. Finally, Sec. VIII contains our version of the uniqueness theorem for entanglement measures, stating necessary and sufficient conditions for a functional to coincide with the reduced von Neumann entropy on pure states.

II. PRELIMINARIES

Throughout this article, all spaces considered are assumed to be finite dimensional. The set of trace class operators on a Hilbert space $\mathcal{H}$ is denoted by $\mathcal{T}(\mathcal{H})$ and the set of bounded operators on $\mathcal{H}$ by $\mathcal{B}(\mathcal{H})$. A density operator (or *state*) is a positive trace class operator with trace one. The set of states on $\mathcal{H}$ is denoted by $\Sigma(\mathcal{H})$ and the set of pure states by $\Sigma_p(\mathcal{H})$. The trace class norm on $\mathcal{T}(\mathcal{H})$ is denoted by $\|\cdot\|_1$. For a wavefunction $|\psi\rangle \in \mathcal{H}$ the corresponding state will be denoted by $P_\psi \equiv |\psi\rangle\langle\psi|$. The *support* of a trace class operator is the subspace spanned by its eigenvectors with nonzero eigenvalues.

In the present article we restrict ourselves mainly to the situation of a composite quantum system consisting of two subsystems with Hilbert space $\mathcal{H}^A \otimes \mathcal{H}^B$ where $\mathcal{H}^A$ and $\mathcal{H}^B$ denote the Hilbert spaces of the subsystems. Often these systems are to be thought of as being spatially separate and accessible to two independent observers, Alice and Bob.

Definition 1: Let $\mathcal{H}^A$ and $\mathcal{H}^B$ be Hilbert spaces. A density operator ϱ on the tensor product $\mathcal{H}^A \otimes \mathcal{H}^B$ is called separable *or* disentangled *if there exist a sequence (r_i) of positive real numbers, a sequence (ρ_i^A) of density operators on $\mathcal{H}^A$ and a sequence (ρ_i^B) of density operators on $\mathcal{H}^B$ such that*

$$\varrho = \sum_i r_i \rho_i^A \otimes \rho_i^B, \tag{1}$$

where the sum converges in trace class norm.

The Schmidt decomposition[14] is of central importance in the characterization and quantification of entanglement associated with pure states.

Lemma 2: Let $\mathcal{H}^A$ and $\mathcal{H}^B$ be Hilbert spaces and let $|\psi\rangle \in \mathcal{H}^A \otimes \mathcal{H}^B$. Then there exist a sequence of non-negative real numbers $(p_i)_i$ summing to one and orthonormal bases $(|a_i\rangle)_i$ and $(|b_i\rangle)_i$ of $\mathcal{H}^A$ and $\mathcal{H}^B$, respectively, such that

$$|\psi\rangle = \sum_i \sqrt{p_i} |a_i \otimes b_i\rangle.$$

■

By $S(\varrho)$ we will denote von Neumann entropy of the state ϱ given by

$$S(\varrho) := -\operatorname{tr}\varrho \log_2 \varrho. \tag{2}$$

The *von Neumann reduced entropy* for a pure state σ on a tensor product Hilbert space $\mathcal{H}^A \otimes \mathcal{H}^B$ is defined as

$$S_{\mathrm{vN}}(\sigma) := -\operatorname{tr}_A((\operatorname{tr}_B \sigma)\log_2(\operatorname{tr}_B \sigma)), \tag{3}$$

where tr_A and tr_B denote the partial traces over $\mathcal{H}^A$ and $\mathcal{H}^B$, respectively. For $\sigma = P_\psi = |\psi\rangle\langle\psi|$, it is a straightforward consequence of Lemma 2 that

$$-\mathrm{tr}_A((\mathrm{tr}_B P_\psi)\log_2(\mathrm{tr}_B P_\psi)) = -\mathrm{tr}_B((\mathrm{tr}_A P_\psi)\log_2(\mathrm{tr}_A P_\psi)) = -\sum_i p_i \log_2 p_i,$$

where $(p_i)_i$ denotes the sequence of Schmidt coefficients of $|\psi\rangle$. However, for a general mixed state σ, $\mathrm{tr}_A((\mathrm{tr}_B\sigma)\log_2(\mathrm{tr}_B\sigma))$ may not equal $\mathrm{tr}_B((\mathrm{tr}_A\sigma)\log_2(\mathrm{tr}_A\sigma))$.

III. CLASSES OF QUANTUM OPERATIONS

In quantum information theory it is important to distinguish between the class of quantum operations on a composite quantum system which can be realized by separate *local* actions on the subsystems (i.e., separate actions by ''Alice'' and by ''Bob'') and those which cannot. The class of local quantum operations assisted by classical communication (LQCC) is of central importance in quantum cryptography and the emerging theory of quantum entanglement.

An *operation* is a positive linear map $\Lambda:\mathcal{T}(\mathcal{H}_1)\to\mathcal{T}(\mathcal{H}_2)$ such that $\mathrm{tr}(\Lambda(\sigma))\leqslant 1$ for all $\sigma\in\Sigma(\mathcal{H}_1)$. *Quantum operations* are operations which are *completely positive*.[15,16] We shall be interested in the trace preserving quantum operations. By the Choi–Kraus representation,[15–18] these are precisely the linear maps $\Lambda:\mathcal{T}(\mathcal{H}_1)\to\mathcal{T}(\mathcal{H}_2)$ which can be written in the form $\Lambda(B)=\Sigma_{i=1}^{n_1 n_2} W_i B W_i^\dagger$ for $B\in\mathcal{T}(\mathcal{H}_1)$ with operators $W_i:\mathcal{H}_1\to\mathcal{H}_2$ satisfying $\Sigma_{i=1}^{n_1 n_2} W_i^\dagger W_i = 1_1$, where $n_1\equiv\dim\mathcal{H}_1$, $n_2\equiv\dim\mathcal{H}_2$, and 1_1 is the identity operator on $\mathcal{H}_1$. These can also be characterized as precisely the linear maps which can be composed out of the following elementary operations.

(O1) Adding an uncorrelated ancilla:
$\Lambda_1:\mathcal{T}(\mathcal{H}_1)\to\mathcal{T}(\mathcal{H}_1\otimes\mathcal{K}_1)$, $\Lambda_1(\rho):=\rho\otimes\sigma$, where $\mathcal{H}_1$ and $\mathcal{K}_1$ denote the Hilbert spaces of the original quantum system and of the ancilla, respectively, and where $\sigma\in\Sigma(\mathcal{K}_1)$.

(O2) Tracing out part of the system:
$\Lambda_2:\mathcal{T}(\mathcal{H}_2\otimes\mathcal{K}_2)\to\mathcal{T}(\mathcal{H}_2)$, $\Lambda_2(\rho):=\mathrm{tr}_{\mathcal{K}_2}(\rho)$, where $\mathcal{H}_2\otimes\mathcal{K}_2$ and $\mathcal{K}_2$ denote the Hilbert spaces of the full original quantum system and of the dismissed part, respectively, and where $\mathrm{tr}_{\mathcal{K}_2}$ denotes the partial trace over $\mathcal{K}_2$.

(O3) Unitary transformations:
$\Lambda_3:\mathcal{T}(\mathcal{H}_3)\to\mathcal{T}(\mathcal{H}_3)$, $\Lambda_3(\rho):=U\rho U^\dagger$, where U is a unitary operator on $\mathcal{H}_3$.

A discussion of this material with complete proofs from first principles may be found in the initial archived draft of this article.[19]

Defining a local operation as quantum operation on a individual subsystem, we now turn to the definition of local operations assisted by classical communication. As always in this article we consider a quantum system consisting of two (possibly separate) subsystems A and B with (initial) Hilbert spaces $\mathcal{H}^A$ and $\mathcal{H}^B$, respectively. There are three cases: the communication between A and B can be unidirectional (in either direction) or bidirectional.

Let us first define the class of local quantum operations (LO) assisted by unidirectional classical communication (operations in this class will be called one-way LQCC operations) with direction from system A (Alice) to system B (Bob). In this case, the operations performed by Bob depend on Alice's operations, but not conversely.

Definition 3: A completely positive map $\Lambda:\mathcal{T}(\mathcal{H}_1^A\otimes\mathcal{H}_1^B)\to\mathcal{T}(\mathcal{H}_2^A\otimes\mathcal{H}_2^B)$ is called a one-way LQCC *operation from A to B if it can be written in the form*

$$\Lambda(\sigma)=\sum_{i,j=1}^{K,L}(1_2^A\otimes W_{ji}^B)(V_i^A\otimes 1_1^B)\sigma(V_i^{A\dagger}\otimes 1_1^B)(1_2^A\otimes W_{ji}^{B\dagger}) \tag{4}$$

for all $\sigma\in\mathcal{T}(\mathcal{H}_1^A\otimes\mathcal{H}_1^B)$ and some sequences of operators $(V_i^A:\mathcal{H}_1^A\to\mathcal{H}_2^A)_i$ and $(W_{ji}^B:\mathcal{H}_1^B\to\mathcal{H}_2^B)_{ji}$ with $\Sigma_{i=1}^K V_i^{A\dagger}V_i^A=1_1^A$ and $\Sigma_{j=1}^L W_{ji}^{B\dagger}W_{ji}^B=1_1^B$ for each i, where 1_1^A, 1_1^B and 1_2^A are the unit operators acting on the Hilbert spaces $\mathcal{H}_1^A$, $\mathcal{H}_1^B$ and $\mathcal{H}_2^A$, respectively.

Of course, by the Choi–Kraus representation any operation Λ of the form

$$\Lambda=\Lambda^A\otimes I_1^B, \tag{5}$$

where $\Lambda^A:\mathcal{T}(\mathcal{H}_1^A)\to\mathcal{T}(\mathcal{H}_2^A)$ is a completely positive trace preserving map and I_1^B is the identity operator on $\mathcal{T}(\mathcal{H}_1^B)$, is a one-way LQCC operation from A to B.

Let us now define local quantum operations assisted by bidirectional classical communication (LQCC operations).

Definition 4: A completely positive map $\Lambda:\mathcal{T}(\mathcal{H}^A\otimes\mathcal{H}^B)\to\mathcal{T}(\mathcal{K}^A\otimes\mathcal{K}^B)$ is called an LQCC *operation if there exist $n>0$ and sequences of Hilbert spaces $(\mathcal{H}_k^A)_{k=1}^{n+1}$ and $(\mathcal{H}_k^B)_{k=1}^{n+1}$ with $\mathcal{H}_1^{A(B)}=\mathcal{H}^{A(B)}$ and $\mathcal{H}_{n+1}^{A(B)}=\mathcal{K}^{A(B)}$, such that Λ can be written in the following form,*

$$\Lambda(\sigma)=\sum_{i_1,\ldots,i_{2n}=1}^{K_1,\ldots,K_{2n}} V_{i_1,\ldots,i_{2n}}^{AB}\sigma V_{i_1,\ldots,i_{2n}}^{AB\,\dagger} \tag{6}$$

for all $\sigma\in\mathcal{T}(\mathcal{H}^A\otimes\mathcal{H}^B)$ where $V_{i_1,\ldots,i_{2n}}^{AB}:\mathcal{H}^A\otimes\mathcal{H}^B\to\mathcal{K}^A\otimes\mathcal{K}^B$ is given by

$$V_{i_1,\ldots,i_{2n}}^{AB}:=(\mathbb{1}_{n+1}^A\otimes W_{2n}^{i_{2n},\ldots,i_1})(V_{2n-1}^{i_{2n-1},\ldots,i_1}\otimes\mathbb{1}_n^B)(\mathbb{1}_n^A\otimes W_{2n-2}^{i_{2n-2},\ldots,i_1})\cdots(\mathbb{1}_2^A\otimes W_2^{i_2,i_1})(V_1^{i_1}\otimes\mathbb{1}_1^B)$$

with families of operators

$$(V_{2k-1}^{i_{2k-1},\ldots,i_1}:\mathcal{H}_k^A\to\mathcal{H}_{k+1}^A)_{k=1}^n, \tag{7a}$$

$$(W_{2k}^{i_{2k},\ldots,i_1}:\mathcal{H}_k^B\to\mathcal{H}_{k+1}^B)_{k=1}^n, \tag{7b}$$

such that for $k=0,\ldots,n-1$ and each sequence of indices $(i_{2k},\ldots,i_1)$,

$$\sum_{i_{2k+1}=1}^{K_{2k+1}}(V_{2k+1}^{i_{2k+1},\ldots,i_1})^\dagger V_{2k+1}^{i_{2k+1},\ldots,i_1}=\mathbb{1}_{k+1}^A, \tag{8a}$$

and for $k=1,\ldots,n$ and each sequence of indices $(i_{2k-1},\ldots,i_1)$,

$$\sum_{i_{2k}=1}^{K_{2k}}(W_{2k}^{i_{2k},\ldots,i_1})^\dagger W_{2k}^{i_{2k},\ldots,i_1}=\mathbb{1}_k^B, \tag{8b}$$

where for all $k>0$, $\mathbb{1}_k^A$ and $\mathbb{1}_k^B$ denote the unit operator on $\mathcal{H}_k^A$ and $\mathcal{H}_k^B$, respectively.

Obviously the class of one-way LQCC operations is a subclass of the class of LQCC operations. There is another important class: separable operations. A separable operation is an operation of the form

$$\Lambda:\mathcal{T}(\mathcal{H}^A\otimes\mathcal{H}^B)\to\mathcal{T}(\mathcal{K}^A\otimes\mathcal{K}^B),\quad \Lambda(\sigma)\equiv\sum_{i=1}^k (V_i\otimes W_i)\sigma(V_i\otimes W_i)^\dagger, \tag{9}$$

with $\Sigma_{i=1}(V_i\otimes W_i)^\dagger V_i\otimes W_i=\mathbb{1}^{AB}$ where $\mathbb{1}^{AB}$ denotes the unit operator acting on $\mathcal{H}^A\otimes\mathcal{H}^B$. The class of separable operations is strictly larger than the LQCC class.[20]

One can also consider a small class obtained by taking the convex hull C of the set of all maps of the form $\Lambda^A\otimes\Lambda^B$. Such operations require in general one-way classical communication, but they do not cover the whole class of one-way LQCC operations.

All the classes above are closed under tensor multiplication, convex combinations, and composition. The results of our article apply in principle to all the classes apart from the last (i.e., apart from the class of all operations in the convex hull C of the set of all maps of the form $\Lambda^A\otimes\Lambda^B$). For definiteness, in the sequel we will use LQCC operations.

Finally, we conclude this section with a useful technical lemma.

Lemma 5: Let $\Lambda:\mathcal{T}(\mathcal{H}_1)\to\mathcal{T}(\mathcal{H}_2)$ be a positive trace-preserving map and suppose that $B\in\mathcal{T}(\mathcal{H}_1)$ with $B=B^\dagger$. Then $\|\Lambda(B)\|_1\leqslant\|B\|_1$.

Proof: Suppose that B has eigenvalue expansion $B=\Sigma_{i=1}^{n_1}\beta_i|\psi_i\rangle\langle\psi_i|$. Then

$$\|\Lambda(B)\|_1 \leqslant \sum_{i=1}^{n_1} |\beta_i| \|\Lambda(|\psi_i\rangle\langle\psi_i|)\|_1 = \|B\|_1$$

as $\|B\|_1 = \Sigma_{i=1}^{n_1} |\beta_i|$ and $\Lambda(|\psi_i\rangle\langle\psi_i|)$ is a positive trace class operator with unit trace. ■

IV. NIELSEN'S THEOREM

A beautiful and powerful result of entanglement theory is Nielsen's theorem.[21] In one direction, the proof is straightforward, and we refer to Ref. 21. The other direction is more difficult. We present here an entirely self-contained, simple, and direct proof. Alternative proofs have previously been given by Hardy[22] and by Jensen and Schack.[23]

Before we state the theorem we need the following definition.

Definition 6: Let $(p_i)_{i=1}^{m_1}$ *and* $(q_i)_{i=1}^{m_2}$ *be two probability distributions with probabilities arranged in decreasing order, i.e.,* $p_1 \geqslant p_2 \geqslant \cdots \geqslant p_{m_1}$ *and similarly for* $(q_i)_i$. *Then we will say that* $(q_i)_i$ majorizes $(p_i)_i$ [*in symbols* $(q_i)_i \succ (p_i)_i$] *if for all* $k \leqslant \min\{m_1, m_2\}$ *we have*

$$\sum_{i=1}^{k} q_i \geqslant \sum_{i=1}^{k} p_i . \tag{10}$$

Theorem 7 (Nielsen): *Let* $\mathcal{H}^A$ *and* $\mathcal{H}^B$ *be Hilbert spaces and let* $(|\chi_m\rangle)_{m=1}^M$ *and* $(|\kappa_m\rangle)_{m=1}^M$ *be orthonormal bases for* $\mathcal{H}^A$ *and* $\mathcal{H}^B$, *respectively. Let* $|\Psi\rangle = \Sigma_{m=1}^M \sqrt{p_m}|\chi_m \kappa_m\rangle$ *and* $|\Phi\rangle = \Sigma_{m=1}^M \sqrt{q_m}|\chi_m \kappa_m\rangle$ *be Schmidt decompositions of normalized vectors* $|\Psi\rangle$ *and* $|\Phi\rangle$ *in* $\mathcal{H}^A \otimes \mathcal{H}^B$ *with* $p_1 \geqslant p_2 \geqslant \cdots \geqslant p_M$ *and* $q_1 \geqslant q_2 \geqslant \cdots \geqslant q_M$. *Then* $|\Psi\rangle\langle\Psi|$ *can be converted into* $|\Phi\rangle\langle\Phi|$ *by* LQCC *operations if and only if* (q_i) *majorizes* (p_i).

Proof: (One direction only.) Suppose that (q_i) majorizes (p_i). Set $\rho \equiv |\Psi\rangle\langle\Psi|$ and $\sigma \equiv |\Phi\rangle\langle\Phi|$. We shall prove that there is a sequence $(\Lambda_n)_{n=1}^N$ with $N < M$ of completely positive maps on $\mathcal{T}(\mathcal{H}^A \otimes \mathcal{H}^B)$ of the form

$$\Lambda_n(\omega) = (C_n \otimes U_n)\omega(C_n \otimes U_n)^\dagger + (D_n \otimes V_n)\omega(D_n \otimes V_n)^\dagger, \tag{11}$$

where U_n, $V_n \in \mathcal{B}(\mathcal{H}^B)$ are unitary and C_n, $D_n \in \mathcal{B}(\mathcal{H}^A)$ satisfy $C_n^\dagger C_n + D_n^\dagger D_n = \mathbb{1}^A$ such that $\Lambda_1 \circ \Lambda_2 \circ \cdots \circ \Lambda_N(\rho) = \sigma$. Note that all the Λ_n are one-way LQCC operations from A to B and hence their composition also is. As the Schmidt decomposition is symmetrical between A and B, we could also use one-way LQCC operations from B to A. Set $\delta_k \equiv \Sigma_{m=1}^k q_m - \Sigma_{m=1}^k p_m$ for $k = 1,2,\ldots,M$. Then $\delta_M = 0$. Let $N = N(|\Psi\rangle, |\Phi\rangle)$ be the number of nonzero δ_k. We shall prove the result by induction on N. $|\Psi\rangle = |\Phi\rangle$ if and only if $\delta_1 = \delta_2 = \cdots = \delta_{M-1} = 0$. In this case $N(|\Psi\rangle, |\Phi\rangle) = 0$, $\rho = \sigma$, and the result is certainly true.

Suppose that the result holds for all pairs $(|\Psi\rangle, |\Phi\rangle)$ satisfying the conditions of the proposition with $N(|\Psi\rangle, |\Phi\rangle) = 0,\ldots,L$ and that $(|\Psi\rangle, |\Phi\rangle)$ is a pair with $N(|\Psi\rangle, |\Phi\rangle) = L+1$. Then there exists $J \geqslant 1$ such that $\delta_1 = \delta_2 = \cdots = \delta_{J-1} = 0$ and $\delta_J > 0$. Setting $\delta_0 := 0$, we have $q_j - p_j = \delta_{j-1} + q_j - p_j = \delta_j$ for $j = 1,\ldots,J$. This implies that $p_j = q_j$ for $j = 1,\ldots,J-1$ and that $q_J > p_J$. Suppose that $\delta_k > 0$ for $k = J, J+1,\ldots,K-1$ and that $\delta_K = 0$. $p_K - q_K = p_K - q_K + \delta_K = \delta_{K-1}$ and $p_K > q_K$. Moreover, if $K < M$, then $q_{K+1} - p_{K+1} = \delta_K + q_{K+1} - p_{K+1} = \delta_{K+1} \geqslant 0$. Summarizing, we have

$$p_{J-1} = q_{J-1} \geqslant q_J > p_J \geqslant p_K > q_K \geqslant q_{K+1} \geqslant p_{K+1}.$$

Define $(r_m)_{m=1}^M$ by $r_m := p_m$ for $m \neq J, K$ and by $r_J := p_J + \delta$, $r_K := p_K - \delta$ where $\delta := \min\{\delta_k : k = J,\ldots,K-1\}$. By construction $\delta > 0$. Now $\delta \leqslant \delta_J$ implies $q_J \geqslant r_J \geqslant p_J$, and $\delta \leqslant \delta_{K-1}$ implies $p_K \geqslant r_K \geqslant q_K$. This in turn implies that $r_1 \geqslant r_2 \geqslant \cdots \geqslant r_M$. Thus for $k = 1,\ldots,J-1$ and for $k = K,\ldots,M$,

$$\sum_{m=1}^{k} r_m = \sum_{m=1}^{k} p_m \leqslant \sum_{m=1}^{k} q_m .$$

For $k=J,\ldots,K-1$, $\Sigma_{m=1}^{k} r_m = \Sigma_{m=1}^{k} p_m + \delta$ and so, as $0<\delta\leqslant\delta_k$,

$$\sum_{m=1}^{k} p_m < \sum_{m=1}^{k} r_m \leqslant \sum_{m=1}^{k} q_m .$$

Define $|\Xi\rangle := \Sigma_{m=1}^{M} \sqrt{r_m}|\chi_m \kappa_m\rangle$. Then $N(|\Xi\rangle,|\Phi\rangle)\leqslant L$ so that, by the inductive hypothesis, there is a sequence $(\Lambda_n)_{n=1}^{N}$ of maps of the required form with $N=N(|\Xi\rangle,|\Phi\rangle)$ such that

$$\Lambda_1 \circ \Lambda_2 \circ \cdots \circ \Lambda_N(|\Xi\rangle\langle\Xi|) = \sigma.$$

Thus to complete the proof, we need only find a completely positive map Λ of the required form such that

$$\Lambda(|\Psi\rangle\langle\Psi|) = |\Xi\rangle\langle\Xi|. \tag{12}$$

To this end set $P := \Sigma_{m\neq J,K}|\chi_m\rangle\langle\chi_m|$. Set

$$C := \sqrt{\frac{r_J p_J - r_K p_K}{r_J^2 - r_K^2}}\left(P + \sqrt{\frac{r_J}{p_J}}|\chi_J\rangle\langle\chi_J| + \sqrt{\frac{r_K}{p_K}}|\chi_K\rangle\langle\chi_K| \right)$$

and $U := 1^B$. Set

$$D := \sqrt{\frac{r_J p_K - r_K p_J}{r_J^2 - r_K^2}}\left(P + \sqrt{\frac{r_K}{p_J}}|\chi_K\rangle\langle\chi_J| + \sqrt{\frac{r_J}{p_K}}|\chi_J\rangle\langle\chi_K| \right)$$

and

$$V := |\kappa_K\rangle\langle\kappa_J| + |\kappa_J\rangle\langle\kappa_K| + \sum_{m\neq J,K} |\kappa_m\rangle\langle\kappa_m|.$$

Note that $p_J \geqslant p_K > q_K \geqslant 0$, that $r_J > r_K$, that $r_J p_J > r_K p_K$, and that $r_J p_K - r_K p_J = (p_J+\delta)p_K - (p_K-\delta)p_J = \delta(p_K+p_J) > 0$. Note also that $r_J^2 - r_K^2 = (r_J - r_K)(r_J + r_K) = (r_J - r_K)(p_J + p_K)$ so that

$$\frac{r_J p_J - r_K p_K}{r_J^2 - r_K^2} + \frac{r_J p_K - r_K p_J}{r_J^2 - r_K^2} = 1.$$

With these definitions and notes, the completion of the proof is straightforward. ■

V. ENTANGLEMENT MEASURES

Definition 8: Consider a bipartite composite quantum system with Hilbert space of the form $\mathcal{H}^A \otimes \mathcal{H}^B$ where $\mathcal{H}^A \equiv \mathcal{H}^B \equiv \mathbb{C}^d$. Assume that isomorphisms between $\mathbb{C}^d$, $\mathcal{H}^A$, and $\mathcal{H}^B$ are chosen. For a chosen orthonormal basis $(|\psi_i\rangle)_{i=1}^{d}$ of $\mathbb{C}^d$, we let

$$|\Psi_+(\mathbb{C}^d)\rangle \equiv \sum_{i=1}^{d} \frac{1}{\sqrt{d}}|\psi_i \otimes \psi_i\rangle \in \mathcal{H}^A \otimes \mathcal{H}^B.$$

$|\Psi_+(\mathbb{C}^d)\rangle$ *is a* maximally entangled *wavefunction. All other maximally entangled wavefunctions in* $\mathcal{H}^A\otimes\mathcal{H}^B$ *can be obtained by applying a unitary operator of the form* $\mathbb{1}^A\otimes U^B$ *to* $|\Psi_+(\mathbb{C}^d)\rangle$ *where* U^B *is a unitary operator on* $\mathcal{H}^B$. *The pure state corresponding to* $|\Psi_+(\mathbb{C}^d)\rangle$ *will be denoted by* $P_+(\mathbb{C}^d)\equiv|\Psi_+(\mathbb{C}^d)\rangle\langle\Psi_+(\mathbb{C}^d)|$.

In an arbitrary bipartite composite system, we shall refer to any wavefunction with the same Schmidt coefficients as $|\Psi_+(\mathbb{C}^d)\rangle$ *as a* representative *of* $|\Psi_+(\mathbb{C}^d)\rangle$ *and to the corresponding state as a* representative *of* $P_+(\mathbb{C}^d)$.

A. Conditions on mixed states

The degree of entanglement of a density operator on the Hilbert space of a bipartite composite quantum system can be expressed by an ''entanglement measure.'' This is a non-negative real-valued functional E defined on $\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ for all finite-dimensional Hilbert spaces $\mathcal{H}^A$ and $\mathcal{H}^B$. Any of the following conditions might be imposed on E.[1–4,24]

(E0) If σ is separable, then $E(\sigma)=0$.

(E1) (Normalization) If P_+^d is any representative of $P_+(\mathbb{C}^d)$, then $E(P_+^d)=\log_2 d$ for $d=1,2,\ldots$.

A weaker condition is the following.

(E1′) $E(P_+(\mathbb{C}^2))=1$.

(E2) (LQCC Monotonicity) Entanglement cannot increase under procedures consisting of local operations on the two quantum systems and classical communication. If Λ is an LQCC operation, then

$$E(\Lambda(\sigma))\leqslant E(\sigma) \tag{13}$$

for all $\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$.

A condition which, as we shall confirm below (Lemma 9), is weaker than (E2), is the following.

(E2′) $E(\Lambda(\sigma))=E(\sigma)$ whenever $\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ and Λ is a strictly local operation which is either unitary or which adds extraneous dimensions. On Alice's side, these local operations take the form of either $\Lambda_1(\varrho)=(U^A\otimes I^B)\varrho(U^A\otimes I^B)^\dagger$ where $U^A:\mathcal{H}^A\to\mathcal{H}^A$ is unitary or $\Lambda_2(\varrho)=(W^A\otimes I^B)\varrho(W^A\otimes I^B)^\dagger$ where $\mathcal{H}^A\subset\mathcal{K}^A$ and $W^A:\mathcal{H}^A\to\mathcal{K}^A$ is the inclusion map. There are equivalent local operations on Bob's side.

(E2″) $E(\Lambda(\sigma))=E(\sigma)$ whenever $\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ and Λ is a strictly local unitary operation. Without further remark, we shall always assume that all our measures satisfy (E2″).

(E3) (Continuity) Let $(\mathcal{H}_n^A)_{n\in\mathbb{N}}$ and $(\mathcal{H}_n^B)_{n\in\mathbb{N}}$ be sequences of Hilbert spaces and let $\mathcal{H}_n\equiv\mathcal{H}_n^A\otimes\mathcal{H}_n^B$ for all n. For all sequences $(\varrho_n)_{n\in\mathbb{N}}$ and $(\sigma_n)_{n\in\mathbb{N}}$ of states with $\varrho_n,\sigma_n\in\Sigma(\mathcal{H}_n^A\otimes\mathcal{H}_n^B)$, such that $\|\varrho_n-\sigma_n\|_1\to 0$, we require that

$$\frac{E(\varrho_n)-E(\sigma_n)}{1+\log_2\dim\mathcal{H}_n}\to 0.$$

A weaker condition deals only with approximations to pure states:

(E3′) Same as (E3) but with $\varrho_n\in\Sigma_p(\mathcal{H}_n^A\otimes\mathcal{H}_n^B)$ for all n.

Sometimes we are interested in entanglement measures which satisfy an additivity property:

(E4) (Additivity) For all $n\geqslant 1$ and all $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$

$$\frac{E(\varrho^{\otimes n})}{n}=E(\varrho).$$

Here $\varrho^{\otimes n}$ denotes the n-fold tensor product of ϱ by itself which acts on the tensor product $(\mathcal{H}^A)^{\otimes n}\otimes(\mathcal{H}^B)^{\otimes n}$.

An apparently weaker property, which as we shall see in Lemma 10 is actually equivalent to (E4), is the following.

(E4′) (Asymptotic Additivity) Given $\epsilon>0$ and $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$, there exists an integer $N>0$ such that $n\geqslant N$ implies

$$\frac{E(\varrho^{\otimes n})}{n}-\epsilon\leqslant E(\varrho)\leqslant\frac{E(\varrho^{\otimes n})}{n}+\epsilon.$$

(E5) (Subadditivity) For all $\varrho,\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$,

$$E(\varrho\otimes\sigma)\leqslant E(\varrho)+E(\sigma).$$

(E5′) For all $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ and $m,n\geqslant 1$,

$$E(\varrho^{\otimes(m+n)})\leqslant E(\varrho^{\otimes m})+E(\varrho^{\otimes n}).$$

(E5″) (Existence of a regularization) For all $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$, the limit

$$E^\infty(\varrho)\equiv\lim_{n\to\infty}\frac{E(\varrho^{\otimes n})}{n}$$

exists.

In Lemma 12 we shall prove the well-known result that (E5′) is a sufficient condition for (E5″). When (E5″) holds, we shall refer to E^∞ as the regularization of E. We shall discuss some general properties of E^∞ in Proposition 13.

(E6) (Convexity) Mixing of states does not increase entanglement:

$$E(\lambda\varrho+(1-\lambda)\sigma)\leqslant\lambda E(\varrho)+(1-\lambda)E(\sigma)$$

for all $0\leqslant\lambda\leqslant 1$ and all $\varrho,\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$.

(E6) might seem to be essential for a measure of entanglement. Nevertheless, there is some evidence that an important entanglement measure (the entanglement of distillation) which describes asymptotic properties of multiple copies of identical states may not be convex.[8] A weaker condition is to require convexity only on decompositions into pure states. We shall prove below that this property is satisfied by the entanglement of distillation.

(E6′) For any state $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ and any decomposition $\varrho=\Sigma_i p_i|\psi_i\rangle\langle\psi_i|$ with $|\psi_i\rangle\in\mathcal{H}^A\otimes\mathcal{H}^B$, $p_i\geqslant 0$ for all i and $\Sigma_i p_i=1$, we require

$$E(\varrho)\leqslant\sum_i p_i E(P_{\psi_i}).$$

B. Conditions on pure states

The conditions imposed on an entanglement measure can be weakened by requiring that they only apply for pure states. Indeed, it might not even be required that the measure is defined except on pure states. Recall that $\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$ denotes the set of pure states on the composite space.

(P0) If $\sigma\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$ is separable, then $E(\sigma)=0$.

(P1)=(E1) (Normalization) If P_+^d is any representative of $P_+(\mathbb{C}^d)$, then $E(P_+^d)=\log_2 d$ for $d=1,2,\ldots$.

(P1′)=(E1′) $E(P_+(\mathbb{C}^2))=1$.

(P2) Let Λ be an operation which can be realized by means of local operations and classical communications. If $\sigma\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$ is such that $\Lambda(\sigma)$ is also pure, then

$$E(\Lambda(\sigma))\leqslant E(\sigma).$$

(P2′) For $\sigma\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$, $E(\sigma)$ depends only on the nonzero coefficients of a Schmidt decomposition of σ.

By Nielsen's theorem and the proof of Lemma 9 below, (P2) is equivalent to assuming (P2′) and that if the Schmidt coefficients of ϱ majorize those of σ, then $E(\varrho)\leqslant E(\sigma)$. Our proof of the theorem shows that, given (P2′), only local operations and operations of the specific form of Eq. (11) need be considered for (P2) (cf. Ref. 25).

Below we will in particular be interested in entanglement measures satisfying the following additional conditions:

(P3) Let $(\mathcal{H}_n^A)_{n\in\mathbb{N}}$ and $(\mathcal{H}_n^B)_{n\in\mathbb{N}}$ be sequences of Hilbert spaces and let $\mathcal{H}_n\equiv\mathcal{H}_n^A\otimes\mathcal{H}_n^B$ for all n. For all sequences $(\varrho_n)_{n\in\mathbb{N}}$ and $(\sigma_n)_{n\in\mathbb{N}}$ of states with $\varrho_n,\sigma_n\in\Sigma_p(\mathcal{H}_n^A\otimes\mathcal{H}_n^B)$, such that $\|\varrho_n-\sigma_n\|_1\to 0$, we require that

$$\frac{E(\varrho_n)-E(\sigma_n)}{1+\log_2\dim\mathcal{H}_n}\to 0.$$

(P4) For all $n\geqslant 1$ and all $\varrho\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$,

$$\frac{E(\varrho^{\otimes n})}{n}=E(\varrho).$$

Of course, when ϱ is pure, so is $\varrho^{\otimes n}$.

(P4′) Given $\epsilon>0$ and $\varrho\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$, there exists an integer $N>0$ such that $n\geqslant N$ implies

$$\frac{E(\varrho^{\otimes n})}{n}-\epsilon\leqslant E(\varrho)\leqslant\frac{E(\varrho^{\otimes n})}{n}+\epsilon.$$

(P5″) (Existence of a regularization on pure states) For all $\varrho\in\Sigma_p(\mathcal{H}^A\otimes\mathcal{H}^B)$, the limit

$$E^\infty(\varrho)\equiv\lim_{n\to\infty}\frac{E(\varrho^{\otimes n})}{n}$$

exists.

C. Some connections between the conditions

Lemma 9: (*E2′*) *is implied by* (*E2*).

Proof: By Eq. (5), the operations considered in (E2′) are LQCC. To see this for Λ_2, note that $W^{A\dagger}W^A=1_{\mathcal{H}^A}$. Thus (E2) implies $E(\Lambda_i(\sigma))\leqslant E(\sigma)$ for $i=1,2$. Unitary maps are invertible and so $E(\Lambda_1(\sigma))\geqslant E(\sigma)$. On the other hand, if $\mathcal{H}^A\subset\mathcal{K}^A$ and P^A is the projection onto $\mathcal{H}^A$, then, for any $\tau^A\in\Sigma_p(\mathcal{H}^A)$, the map $\Lambda_3^A:\Sigma(\mathcal{K}^A)\to\Sigma(\mathcal{H}^A)$ defined by $\Lambda_3^A(\varrho):=P^A\varrho P^{A\dagger}+\mathrm{tr}(\varrho(1-P^A))\tau^A$ is completely positive and trace preserving, so by Eq. (5), the map on $\Sigma(\mathcal{K}^A\otimes\mathcal{H}^A)$ defined by $\Lambda_3=\Lambda_3^A\otimes I^B$ is LQCC.

$\Lambda_3(\Lambda_2(\sigma))=\sigma$ and hence (E2) implies $E(\sigma)\leqslant E(\Lambda_2(\sigma))$. ■

Lemma 10: (*E4′*) *is equivalent to* (*E4*) *and* (*P4′*) *is equivalent to* (*P4*).

Proof: That (E4) implies (E4′) is immediate. Suppose (E4′) and choose m, ϱ, and ϵ.

By (E4′), there exists N such that $n\geqslant N$ implies $|E(\varrho)-E(\varrho^{\otimes n})/n|\leqslant\epsilon$ and $|E(\varrho^{\otimes m})-(E(\varrho^{\otimes m})^{\otimes n})/n|\leqslant\epsilon$. But, by definition, $(\varrho^{\otimes m})^{\otimes n}=\varrho^{\otimes mn}$ where the equality relates equivalent density matrices on products of isomorphic local spaces. Thus $n\geqslant N$ implies

$$\left|E(\varrho)-\frac{E(\varrho^{\otimes m})}{m}\right|\leqslant\left|E(\varrho)-\frac{E(\varrho^{\otimes mn})}{mn}\right|+\left|\frac{E(\varrho^{\otimes mn})}{mn}-\frac{E(\varrho^{\otimes m})}{m}\right|\leqslant 2\epsilon.$$

(E4) follows. The same proof shows the equivalence of (P4′) and (P4). ■

Lemma 11: Let E be an entanglement measure which satisfies $(P1')$, $(P2)$, and $(P4)$. Then E satisfies $(P0)$ and $(P1)$. Moreover, if E is defined on mixed states and satisfies either $(E2)$ or $(E6')$, then $(E0)$ is satisfied.

Proof: First we deal with separable states.

Choose $\epsilon>0$. Any pair of separable pure states is interconvertible by local unitary operators. If σ is such a state, then so is $\sigma^{\otimes n}$, and so, by (P2), $E(\sigma)=E(\sigma^{\otimes n})$. But (P4) implies that $E(\sigma)=E(\sigma^{\otimes n})/n$ and hence $E(\sigma)=0$. This gives (P0) and the $d=1$ case of (P1).

Now let $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ be a mixed separable state. Expanding the states ϱ_i^A and ϱ_i^B of Eq. (1) into pure components shows that σ is a convex combination of pure separable states: $\sigma=\Sigma_i p_i\sigma_i$.

Thus (E6′) is sufficient to go from (P0) to (E0). But (E2) is also sufficient, because if $\Lambda_i:\mathcal{T}(\mathcal{H}^A\otimes\mathcal{H}^B)\to\mathcal{T}(\mathcal{H}^A\otimes\mathcal{H}^B)$ is a local operation such that $\Lambda_i(\sigma_1)=\sigma_i$, then $\Lambda:=\Sigma_i p_i\Lambda_i$ is a LQCC operation such that $\Lambda(\sigma_1)=\sigma$ and so (E2) and (P0) yield $E(\sigma)\leqslant E(\sigma_1)=0$.

Now we turn to showing that, for $d\geqslant 2$, $E(P_+^d)=\log_2 d$ follows from (P1′), (P2), and (P4). By (P2′), $E(P_+^d)$ is independent of the representative of $P_+(\mathbb{C}^d)$ considered.

Choose $\epsilon>0$ and $d\geqslant 2$. Choose $N>1/\epsilon$. Set $w(n)\equiv E(P_+^n)$.

By Nielsen's theorem, (P2) implies that $w(d_1)\leqslant w(d_2)$ whenever $d_1\leqslant d_2$.

Up to local isomorphisms, $(P_+^d)^{\otimes n}=P_+^{d^n}$, so that, by (P4), $w(d)=w(d^n)/n$ for all n and, by (P1′), $w(2)=w(2^n)/n=1$.

Choose $n_1,n_2>N$ such that $2^{n_2+1}\geqslant d^{n_1}\geqslant 2^{n_2}$. Then $\log_2 d\geqslant n_2/n_1$, $|n_2/n_1-\log_2 d|\leqslant 1/n_1<\epsilon$, and, using (P4),

$$|w(d)-\log_2 d|\leqslant|w(d^{n_1})-n_2|/n_1+|n_2/n_1-\log_2 d|\leqslant|w(d^{n_1})-n_2w(2)|/n_1+\epsilon$$

and

$$|w(d^{n_1})-n_2w(2)|/n_1=|w(d^{n_1})-w(2^{n_2})|/n_1\leqslant|w(2^{n_2+1})-w(2^{n_2})|/n_1=1/n_1\leqslant\epsilon.$$

It follows that $w(d)$ is arbitrarily close to $\log_2 d$. ■

Lemma 12: $(E5')$ implies $(E5'')$. Indeed, $(E5')$ implies that

$$E(\varrho^{\otimes m})/m\to\inf\{E(\varrho^{\otimes m})/m:m\geqslant 1\}.$$

Proof: (See Ref. 26, Theorem 4.9.) Fix $k>0$. Every $m\geqslant 1$ can be written $m=nk+r$ with $0\leqslant r<k$. Then for all $m>0$ set $f(m):=E(\varrho^{\otimes m})$. $(E5')$ implies that

$$\frac{f(m)}{m}\leqslant\frac{nf(k)+f(r)}{nk+r}\leqslant\frac{nf(k)}{nk}+\frac{f(r)}{nk}=\frac{f(k)}{k}+\frac{f(r)}{nk}.$$

As $m\to\infty$ then $n\to\infty$ so $\limsup_{m\to\infty}f(m)/m\leqslant f(k)/k$ and thus $\limsup_{m\to\infty}f(m)/m\leqslant\inf_{k\geqslant 1}f(k)/k$. Now $\inf_{k\geqslant 1}f(k)/k\leqslant\liminf_{m\to\infty}f(m)/m$ shows that $\lim_{m\to\infty}f(m)/m$ exists and equals $\inf_{m\geqslant 1}f(m)/m$. ■

Proposition 13: Let E be an entanglement measure which satisfies $(E5'')$. Then we have the following.

(1) *E^∞ satisfies $(E4)$*
(2) *If E satisfies $(E0)$, then so does E^∞.*
(3) *If E satisfies $(E1)$, then so does E^∞.*
(4) *If E satisfies $(E2)$, then so does E^∞.*
(5) *If E satisfies $(E5)$, then so does E^∞.*
(6) *If E satisfies $(E5)$ and $(E6)$, then so does E^∞.*

Proof:

(1) For all m and ϱ,

$$\frac{E^{\infty}(\varrho^{\otimes m})}{m}=\lim_{n\to\infty}\frac{E(\varrho^{\otimes nm})}{nm}=E^{\infty}(\varrho).$$

(2) If σ is separable, then so is $\sigma^{\otimes n}$ for all n.
(3) If P_+^d is a representative of $P_+(\mathbb{C}^d)$, then $(P_+^d)^{\otimes n}$ is a representative of $P_+(\mathbb{C}^{d^n})$.
(4) If Λ is LQCC, then so is $\Lambda^{\otimes n}$ and $\Lambda(\sigma)^{\otimes n}=\Lambda^{\otimes n}(\sigma^{\otimes n})$.
(5) For all ϱ,σ and $k\geqslant 1$, (E5) implies that

$$\frac{E((\varrho\otimes\sigma)^{\otimes k})}{k}\leqslant\frac{E(\varrho^{\otimes k})}{k}+\frac{E(\sigma^{\otimes k})}{k}.$$

(6) Suppose that E satisfies (E5) and (E6). Let $\varrho,\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ and choose $x_1,x_2\in[0,1]$ with $x_1+x_2=1$. Let $\omega=x_1\varrho+x_2\sigma$. Expanding $\omega^{\otimes n}$ as a sum of products, using convexity of E, and then using local isomorphisms to reorder the terms in each product gives

$$E(\omega^{\otimes n})\leqslant\sum_{k=0}^{n}\binom{n}{k}x_1^k x_2^{n-k}E(\varrho^{\otimes k}\otimes\sigma^{\otimes(n-k)})\leqslant\sum_{k=0}^{n}\binom{n}{k}x_1^k x_2^{n-k}(E(\varrho^{\otimes k})+E(\sigma^{\otimes(n-k)})),$$

where the second inequality is a consequence of (E5). To complete the proof, we need the following lemma:

Lemma 14: As $n\to\infty$, $(1/n)\sum_{k=0}^{n}\binom{n}{k}x_1^k x_2^{n-k}E(\varrho^{\otimes k})\to x_1E^{\infty}(\varrho)$ *and* $(1/n)\sum_{k=0}^{n}\binom{n}{k}x_1^k x_2^{n-k}\times E(\sigma^{\otimes(n-k)})\to x_2E^{\infty}(\sigma)$.

Proof: It is sufficient to prove the first limit. Set $g(m)=E(\varrho^{\otimes m})/m$ and $L=E^{\infty}(\varrho)$. Choose $\epsilon>0$. By Lemma 12, there exists K such that $k\geqslant K$ implies $|g(k)-L|<\epsilon/2$ and there is a constant $C>0$ such that $|g(k)-L|<C$ for all k. $N>K$ implies that

$$\frac{1}{N}\sum_{k=0}^{K}\binom{N}{k}kx_1^k x_2^{N-k}\leqslant\frac{K}{N}\sum_{k=0}^{N}\binom{N}{k}x_1^k x_2^{N-k}=\frac{K}{N}.$$

Set $h(x)=(x+y)^n=\sum_{k=0}^{n}\binom{n}{k}x^k y^{n-k}$. $xh'(x)=nx(x+y)^{n-1}=\sum_{k=0}^{n}\binom{n}{k}kx^k y^{n-k}$. Thus $x_1+x_2=1$ implies that $\sum_{k=0}^{n}\binom{n}{k}kx_1^k x_2^{n-k}=nx_1$.

Choose $N_0>K$ such that $KC/N_0<\epsilon/2$. Then $N>N_0$ implies

$$\begin{aligned}\left|\frac{1}{N}\sum_{k=0}^{N}\binom{N}{k}x_1^k x_2^{N-k}E(\varrho^{\otimes k})-x_1E^{\infty}(\varrho)\right|&=\left|\frac{1}{N}\sum_{k=0}^{N}\binom{N}{k}kx_1^k x_2^{N-k}g(k)-x_1L\right|\\&=\left|\frac{1}{N}\sum_{k=0}^{N}\binom{N}{k}kx_1^k x_2^{N-k}(g(k)-L)\right|\\&\leqslant\frac{1}{N}\sum_{k=0}^{K}\binom{N}{k}kx_1^k x_2^{N-k}C\\&\quad+\frac{1}{N}\sum_{k=K+1}^{N}\binom{N}{k}kx_1^k x_2^{N-k}(g(k)-L)\\&\leqslant KC/N+\epsilon/2\sum_{k=K+1}^{N}\binom{N}{k}x_1^k x_2^{N-k}\\&\leqslant\epsilon.\end{aligned}$$

■

Continuity (E3) is not mentioned in Proposition 13, although we could use Lemma 12 to deduce upper-semicontinuity from (E3) and (E5′), as the infimum of a family of real continuous

functions is upper-semicontinuous. For an example which may be relevant, consider the sequence of functions on [0,1] defined by $f_n(x)=nx^n$. Clearly $f_{m+n}(x)\leqslant f_m(x)+f_n(x)$. $g_n(x)=x^n$ converges (pointwise) as $n\to\infty$ to a discontinuous but upper-semicontinuous function.

VI. EXAMPLES OF IMPORTANT ENTANGLEMENT MEASURES

In this section we will present some important entanglement measures and check which of the postulates from Sec. V they satisfy.

A. Operational measures

Here we shall describe two entanglement measures, *entanglement of distillation* and *entanglement cost*[1] (see also Refs. 27 and 28), which are defined in terms of specific state conversions.

Lemma 15: Let $\varrho\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ *with* $\mathcal{H}^A\equiv\mathcal{H}^B\equiv\mathcal{H}$ *and* $\dim\mathcal{H}=d$. *Let* $|\phi\rangle=|\phi^A\rangle\otimes|\phi^B\rangle\in\mathcal{H}^A\otimes\mathcal{H}^B$ *be a separable wavefunction and* P_+^d *be a representative of* $P_+(\mathbb{C}^d)$ *on* $\mathcal{H}^A\otimes\mathcal{H}^B$. *Then there exist* LQCC *operations* Λ_1 *and* Λ_2 *such that* $\Lambda_1(\varrho)=|\phi\rangle\langle\phi|$ *and* $\Lambda_2(P_+^d)=\varrho$.

Proof: Let $(\psi_i^A)_{i=1}^d$ [resp. $(\psi_i^B)_{i=1}^d$] be an orthonormal basis for $\mathcal{H}^A$ [resp. $\mathcal{H}^B$] and define Λ_1 by

$$\Lambda_1(\sigma)\equiv\sum_{j=1}^d (1^A\otimes|\phi^B\rangle\langle\psi_j^B|)\left(\sum_{i=1}^d (|\phi^A\rangle\langle\psi_i^A|\otimes 1^B)\sigma(|\psi_i^A\rangle\langle\phi^A|\otimes 1^B)\right)(1^A\otimes|\psi_j^B\rangle\langle\phi^B|)$$

$$=\sum_{i,j=1}^d |\phi^A\otimes\phi^B\rangle\langle\psi_i^A\otimes\psi_j^B|\sigma|\psi_i^A\otimes\psi_j^B\rangle\langle\phi^A\otimes\phi^B|=|\phi\rangle\mathrm{tr}(\sigma)\langle\phi|=|\phi\rangle\langle\phi|$$

for all $\sigma\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$.

For Λ_2, we note that if $|\Psi\rangle\langle\Psi|\in\Sigma(\mathcal{H}^A\otimes\mathcal{H}^B)$ is any pure state, then, by Nielsen's theorem, there exists an LQCC operation mapping P_+^d to $|\Psi\rangle\langle\Psi|$ because the distribution $(1/d)_{i=1}^d$ is majorized by any probability distribution on $\{1,\ldots,d\}$. Now, as in the proof of Lemma 11, we can construct Λ_2 as a convex combination of operations mapping P_+^d to pure components of ϱ.■

Given a state ϱ on $\mathcal{H}^A\otimes\mathcal{H}^B$, consider a sequence of LQCC operations (Λ_n) with $\Lambda_n:\mathcal{T}((\mathcal{H}^A)^{\otimes n}\otimes(\mathcal{H}^B)^{\otimes n})\to\mathcal{T}((\mathcal{H}^A)^{\otimes n}\otimes(\mathcal{H}^B)^{\otimes n})$. Suppose that $\sigma_n\equiv\Lambda_n(\varrho^{\otimes n})$ satisfies

$$\|P_+^{d_n}-\sigma_n\|_1\to 0$$

for some representative $P_+^{d_n}$ of $P_+(\mathbb{C}^{d_n})$ on $(\mathcal{H}^A)^{\otimes n}\otimes(\mathcal{H}^B)^{\otimes n}$. We call such a sequence (Λ_n) an LQCC *distillation protocol*. The asymptotic ratio attainable via this protocol is then defined by

$$E_D((\Lambda_n),\varrho)\equiv\limsup_{n\to\infty}\frac{\log_2 d_n}{n}. \tag{14}$$

Lemma 15 shows that, for any state, a distillation protocol always exists with $d_n\equiv 1$.

Definition 16: The distillable entanglement *or* entanglement of distillation E_D *is defined as the supremum of Eq. (14) over all possible* LQCC *distillation protocols:*

$$E_D(\varrho)\equiv\sup_{(\Lambda_n)} E_D((\Lambda_n),\varrho). \tag{15}$$

By construction E_D satisfies the properties (E2) and (E4) of entanglement measures. The proof is analogous to the proof of Lemma 1 in Ref. 28. It is not known whether E_D satisfies (E3) or (E6). (Indeed, as already mentioned, there is evidence that (E6) may not be satisfied.[8]) We shall confirm in Lemma 24 that (E0) and (E1) are satisfied.

The so-called *entanglement cost* E_C is defined in a complementary way. Given a state ϱ, consider a sequence of LQCC operations $\Lambda_n:\mathcal{T}(\mathbb{C}^{d_n}\otimes\mathbb{C}^{d_n})\to\mathcal{T}((\mathcal{H}^A)^{\otimes n}\otimes(\mathcal{H}^B)^{\otimes n})$ transforming a representative of $P_+(\mathbb{C}^{d_n})$ into a state σ_n such that

$$\|\sigma_n - \varrho^{\otimes n}\|_1 \to 0.$$

The asymptotic ratio attainable via this *formation*-protocol is then given by

$$E_C((\Lambda_n), \varrho) \equiv \liminf_{n\to\infty} \frac{\log_2 d_n}{n}. \tag{16}$$

Once again Lemma 15 shows that, for any state, a formation protocol always exists with $d_n \equiv d^n$ where $d = \max\{\dim\mathcal{H}^A, \dim\mathcal{H}^B\}$.

Definition 17: The entanglement cost E_C *is defined as the infimum of Eq. (16) over all possible* LQCC *formation protocols:*

$$E_C(\varrho) \equiv \inf_{\{\Lambda_n\}} E_C((\Lambda_n), \varrho). \tag{17}$$

By construction E_C satisfies property (E2). As we shall discuss in the next section, by Ref. 28 and Proposition 13, it also satisfies (E0), (E1), (E2), (E4), (E5), and (E6). It is not known whether it satisfies (E3). We shall also prove below that for pure states both E_D and E_C are equal to the reduced von Neumann entropy given by Eq. (3). (This was first realized in Ref. 29 and a rigorous proof was sketched in Ref. 21.)

B. Abstract measures

The entanglement measures discussed in this subsection quantify entanglement mathematically, but their definitions do not admit a direct operational interpretation in terms of entanglement manipulations. The first one is the so-called *entanglement of formation*[1] which is defined as follows:

Definition 18: Let $\mathcal{H}^A$ *and* $\mathcal{H}^B$ *be finite dimensional Hilbert spaces and let* $|\psi\rangle \in \mathcal{H}^A \otimes \mathcal{H}^B$. *Then the* entanglement of formation *is defined for pure states as*

$$E_F(P_\psi) := S_{\mathrm{vN}}(P_\psi), \tag{18a}$$

where $S_{\mathrm{vN}}(P_\psi)$ [*defined in Eq. (3)*] *is the von Neumann entropy of either of the reduced density matrices of* $|\psi\rangle$. *For mixed states* $\varrho \in \Sigma(\mathcal{H}^A \otimes \mathcal{H}^B)$ *we define*

$$E_F(\varrho) := \inf \sum_i p_i E_F(P_{\psi_i}), \tag{18b}$$

where the infimum is taken over all possible decompositions of ϱ *of the form* $\varrho = \Sigma_i p_i |\psi_i\rangle\langle\psi_i|$ *with* $p_i \geqslant 0$ *for all* i *and* $\Sigma_i p_i = 1$.

The entanglement of formation satisfies (E0)–(E3), (E5), and (E6). In particular, (E2) was shown in Ref. 1, (E3) in Ref. 6, and (E0), (E1), (E5), and (E6) follow directly from the definition of E_F.

The entanglement of formation E_F is believed but not known to be equal to the entanglement cost E_C. However, it is known that the *regularized* entanglement of formation E_F^∞ [which exists by (E5′)] is equal to the entanglement cost.[28] This allows us to apply Proposition 13 to E_C.

Let us now present another important measure, namely, the *relative entropy of entanglement*.[24,2] It is defined as follows:

$$E_R(\varrho) \equiv \inf_\sigma S_{\mathrm{rel}}(\varrho|\sigma), \tag{19}$$

where $S_{\mathrm{rel}}(\varrho|\sigma) \equiv \mathrm{tr}\varrho \log_2 \varrho - \mathrm{tr}\varrho \log_2 \sigma$ is the quantum relative entropy, and where the infimum is taken over all separable states σ. One can consider variations of the above measure, by changing the set of states over which the infimum is taken (this set should be closed under LQCC

operations though). Like the entanglement of formation, E_R satisfies (E0)–(E3), (E5), and (E6). In particular, (E1) and (E2) were shown in Ref. 24, (E3) in Ref. 9, (E0) follows immediately and (E5) almost immediately from the definition of E_R, and (E6) follows from the convexity of the quantum relative entropy S_{rel}.

The properties of E_R and Proposition 13 show that the *regularized* relative entropy of entanglement E_R^∞ exists and satisfies (E0), (E1), (E2), (E4), (E5), and (E6). It is shown in Ref. 10 that E_R does *not* satisfy (E4). This implies, of course, that E_R and E_R^∞ are not always equal (cf. Ref. 30).

Finally, let us note that for pure states both the entanglement of formation (by definition) and the relative entropy of entanglement (as shown in Refs. 2 and 31) are equal to the reduced von Neumann entropy S_{vN} [defined in Eq. (3)]. An immediate consequence of the additivity of S_{vN} is that $E_F^\infty = E_C$ and E_R^∞ are also equal to S_{vN} on pure states (see also Theorem 23).

VII. ENTANGLEMENT OF DISTILLATION AND ENTANGLEMENT COST AS EXTREME MEASURES

In this section we improve the theorem of Ref. 4 by giving precise conditions under which E_D and E_C are lower and upper bounds for entanglement measures. We propose three versions of the theorem.

Proposition 19: Suppose that E is an entanglement measure defined on mixed states which satisfies (E1)–(E4). Then for all states $\varrho \in \Sigma(\mathcal{H}^A \otimes \mathcal{H}^B)$

$$E_D(\varrho) \leqslant E(\varrho) \leqslant E_C(\varrho). \tag{20}$$

Proof: Choose $\epsilon > 0$. We shall prove the result in three steps:

(**I**) First we prove that, having if necessary passed to a subsequence, there exists an integer $N_1 > 0$ such that $n \geqslant N_1$ implies

$$\frac{E(\varrho^{\otimes n})}{n} \geqslant E_D(\varrho) - \epsilon. \tag{21}$$

Consider a near-optimal LQCC protocol $(\Lambda_n)_n$. By the definition of distillable entanglement, there exists a LQCC protocol $(\Lambda_n)_n$ such that, after possibly passing to a subsequence,

$$\| P_+^{d_n} - \Lambda_n(\varrho^{\otimes n}) \|_1 \to 0 \tag{22a}$$

and

$$\left| E_D(\varrho) - \frac{\log_2 d_n}{n} \right| \leqslant \frac{\epsilon}{2} \tag{22b}$$

for all $n \geqslant N_1'$. (E3) implies that

$$\left| \frac{E(\Lambda_n(\varrho^{\otimes n})) - E(P_+^{d_n})}{1 + n \log_2 d} \right| \to 0 \tag{23}$$

as $n \to \infty$ where $d = \dim \mathcal{H}^A \otimes \mathcal{H}^B$. It follows that we can choose $N_1'' > 0$ such that $n \geqslant N_1''$ implies

$$\left| \frac{E(\Lambda_n(\varrho^{\otimes n}))}{n} - \frac{E(P_+^{d_n})}{n} \right| \leqslant \frac{\epsilon}{2}, \tag{24}$$

and, so, using (E2), for $n \geqslant N_1 = \max\{N_1', N_1''\}$,

$$\frac{E(\varrho^{\otimes n})}{n} \geqslant \frac{E(\Lambda_n(\varrho^{\otimes n}))}{n} \geqslant \frac{E(P_+^{d_n})}{n} - \frac{\epsilon}{2} = \frac{\log_2 d_n}{n} - \frac{\epsilon}{2} \geqslant E_D(\varrho) - \epsilon. \tag{25}$$

(**II**) As a second step, we prove that, having if necessary passed to another (perhaps disjoint) subsequence, there exists an integer $N_2 \geqslant N_1$ such that $n \geqslant N_2$ implies

$$\frac{E(\varrho^{\otimes n})}{n} \leqslant E_C(\varrho) + \epsilon. \tag{26}$$

This is similar to the first step. Consider a near-optimal protocol $(\Lambda_n)_n$ for ϱ. We have [after possibly passing to a suitable subsequence of $(\Lambda_n)_n$], for all sufficiently large n,

$$\frac{E(\varrho^{\otimes n})}{n} \leqslant \frac{E(\Lambda_n(P_+^{d_n}))}{n} + \frac{\epsilon}{2} \leqslant \frac{E(P_+^{d_n})}{n} + \frac{\epsilon}{2} = \frac{\log_2 d_n}{n} + \frac{\epsilon}{2} \leqslant E_C(\varrho) + \epsilon. \tag{27}$$

(**III**) The final step is to invoke (E4) to give

$$E_D(\varrho) - \epsilon \leqslant E(\varrho) = \frac{E(\varrho^{\otimes n})}{n} \leqslant E_C(\varrho) + \epsilon. \tag{28}$$

■

Unfortunately, as we do not at present know of any function for which we can prove that postulates (E1)–(E4) hold for all states, it is possible that Proposition 19 may be empty. Nevertheless, by modifying the final step of the proof, we can obtain the following:

Proposition 20: Let E be an entanglement measure defined on mixed states and satisfying (E1), (E2), (E3), and (E5″). Then for all states $\varrho \in \Sigma(\mathcal{H}^A \otimes \mathcal{H}^B)$,

$$E_D(\varrho) \leqslant E^\infty(\varrho) \leqslant E_C(\varrho). \tag{29}$$

Proof: Without using condition (E4) or any properties of E^∞ except its existence, we can maintain the structure of the previous proof, simply by replacing $E(\varrho)$ in (28) by $E^\infty(\varrho)$. ■

Proposition 20 is certainly nonempty. Indeed, as mentioned in the previous section, both the entanglement of formation and the relative entropy of entanglement satisfy all assumptions of the proposition. We obtain the following corollary.

Corollary 21: The entanglement of distillation E_D is less than or equal to the entanglement cost E_C for all states.

Although, in physical terms, Corollary 21 seems almost necessary, a rigorous proof requires some control both over changes in state and over changes in dimension.

Let us now consider yet another version, where we weaken the assumptions in the theorem on extreme measures of Ref. 4. We impose the condition (E3′), which is stronger than (P3) but weaker than (E3).

One mechanism for deriving condition (E3′) for a given function E might be to establish the inequalities

$$f(\varrho) \leqslant E(\varrho) \leqslant g(\varrho), \tag{30}$$

where f, g are functions satisfying (E3′) which coincide on pure states. We will take $f(\varrho) \equiv S(\varrho_A) - S(\varrho)$ and $g(\varrho) \equiv S(\varrho_A)$ (where $\varrho_A := \mathrm{tr}_{\mathcal{H}_B}\varrho$). Both of these functions f and g do satisfy (E3′). This follows immediately from two facts:

(i) Fannes inequality[32,33]

$$|S(\sigma) - S(\varrho)| \leqslant \|\sigma - \varrho\|_1 \log_2 \dim\mathcal{H} + \eta(\|\sigma - \varrho\|_1), \tag{31}$$

which holds for any two states σ and ϱ acting on the Hilbert space $\mathcal{H}$ and satisfying $\|\sigma-\varrho\|_1 \leqslant 1/3$; here $\eta(s)\equiv -s\log s$ and S denotes the standard von Neumann entropy as above.

(ii) $\|\sigma_A-\varrho_A\|_1 \leqslant \|\sigma-\varrho\|_1$, where σ_A and ϱ_A are the reduced density operators of ϱ and σ, respectively.

With the above choices for f and g one can show that E_F and E_R satisfy the inequalities in (30) (see Refs. 1, 2, 31, and 34). Then, E_R^∞ and E_F^∞ also satisfy inequalities (30), because the additivity of the von Neumann entropy implies that both f and g satisfy (E4). E_D also satisfies the inequality $E_D \leqslant g$, but we do not know whether or not it satisfies the second inequality. However, a stronger inequality (the so-called *hashing inequality*), which would have many interesting implications, was conjectured in Ref. 35. Strong evidence for this conjecture was collected there.

We shall also use the weak form of convexity (E6′).

Proposition 22: Let E be an entanglement measure defined on mixed states and satisfying (E1), (E2), (E3′), and (E6′). Then for all states $\varrho \in \Sigma(\mathcal{H}^A \otimes \mathcal{H}^B)$ *we have*

$$E_D(\varrho) \leqslant E(\varrho) \leqslant E_C(\varrho) \tag{32}$$

if (E4) holds and

$$E_D(\varrho) \leqslant E^\infty(\varrho) \leqslant E_C(\varrho) \tag{33}$$

if (E5) holds.

Proof: Step I of the proof of Proposition 19 goes through with (E3′) replacing (E3) in inequality (24).

To replace step II, we use the estimate $E_C \geqslant E_F^\infty$. This follows from Proposition 20 (but also, of course, from Ref. 28, where it was shown that $E_C = E_F^\infty$). For any state ϱ consider its finite decompositions into pure states

$$\varrho = \sum_i p_i |\psi_i\rangle\langle\psi_i|$$

for which

$$E_F(\varrho) = \sum_i p_i S_{\mathrm{vN}}(P_{\psi_i}).$$

In Ref. 36 it was shown that such a decomposition exists.

As (E1)=(P1)⇒(P1′), (E2)⇒(P2), and (E3′)⇒(P3), we can apply Theorem 23 (to follow) to show that $E(P_{\psi_i}) = S_{\mathrm{vN}}(P_{\psi_i})$ if E satisfies (E4) and $E^\infty(P_{\psi_i}) = S_{\mathrm{vN}}(P_{\psi_i})$ if E satisfies (E5).

Now (E6′) implies, in the first case, that $E(\varrho) \leqslant E_F(\varrho)$ (cf. Ref. 36) and hence

$$E(\varrho) = \frac{E(\varrho^{\otimes n})}{n} \leqslant \frac{E_F(\varrho^{\otimes n})}{n},$$

which yields the required upper bound when $n \to \infty$. For the second case, we can use the proof of part (6) of Proposition 13 to show that (E6′) holds for E^∞. This yields $E^\infty(\varrho) \leqslant E_F(\varrho)$ and

$$E^\infty(\varrho) = \frac{E^\infty(\varrho^{\otimes n})}{n} \leqslant \frac{E_F(\varrho^{\otimes n})}{n}.$$

Again the required bound follows on taking $n \to \infty$. ■

VIII. THE UNIQUENESS THEOREM FOR ENTANGLEMENT MEASURES

Theorem 23: *Let E be a functional on pure states. Then the following are equivalent:*

(1) *E satisfies $(P1')$, $(P2)$, $(P3)$, and $(P4')$.*
(2) *E satisfies $(P0)$, $(P1)$, $(P2)$, $(P3)$, and $(P4)$.*
(3) *E coincides with the reduced von Neumann entropy $E=S_{\mathrm{vN}}$.*

On the other hand, if E satisfies $(P0)$, $(P1)$, $(P2)$, and $(P3)$, then E satisfies $(P5'')$ and, on pure states, $E^{\infty}=S_{\mathrm{vN}}$.

Proof: The equivalence of (1) and (2) is proved in Lemmas 10 and 11.

It is clear that the reduced von Neumann entropy satisfies (P0), (P1), and (P4). (P3) follows from the facts (i) and (ii) of the previous section. Finally (P2) is a consequence of Nielsen's theorem and the fact that the von Neumann entropy is a Schur-concave function.[37] Indeed, with the inductive decomposition of LQCC operations introduced in our proof of Nielsen's theorem, we can prove (P2) just by showing, in the notation of Eq. (12), that $S_{\mathrm{vN}}(\Lambda(|\Psi\rangle\langle\Psi|))\leqslant S_{\mathrm{vN}}(|\Psi\rangle\times\langle\Psi|)$. This amounts to proving that, for $p_J\geqslant p_K$ and suitable δ,

$$-(p_J+\delta)\log_2(p_J+\delta)-(p_K-\delta)\log_2(p_K-\delta)\leqslant -p_J\log_2 p_J-p_K\log_2 p_K,$$

and this is easily confirmed by differentiating with respect to δ.

Now suppose that E satisfies (P0), (P1), (P2), and (P3). Using $(P2')$, we may assume that $\mathcal{H}^A\equiv\mathcal{H}^B\equiv\mathcal{H}$. Suppose that $\dim\mathcal{H}=d$ and let $|\psi\rangle\in\mathcal{H}\otimes\mathcal{H}$. Write $\mathsf{S}\equiv S_{\mathrm{vN}}(|\psi\rangle\langle\psi|)$ for the von Neumann entropy of the reduced density matrix of $|\psi\rangle$. Consider n copies of the wavefunction $|\psi\rangle$: $|\psi^{\otimes n}\rangle\in\mathcal{H}_{\mathrm{tot}}\equiv\mathcal{H}^{\otimes n}\otimes\mathcal{H}^{\otimes n}$. Let $\{q_j:j=1,\ldots,d\}$ be the set of eigenvalues of the reduced density matrix of $|\psi\rangle$ and $\{p_i:i=1,\ldots,d^{2n}\}$ be the set of eigenvalues of the reduced density matrix of $|\psi^{\otimes n}\rangle$. Again using $(P2')$, we may adjust d so that $q_j>0$ for $j=1,\ldots,d$. In view of (P0), we may also assume that $\mathsf{S}>0$. Considered as a probability distribution, $\{p_i\}$ is the distribution for n independent trials each with distribution $\{q_j\}$. Choose bases $(e_i)\subset\mathcal{H}^{\otimes n}$ and $(f_i)\subset\mathcal{H}^{\otimes n}$ such that

$$|\psi^{\otimes n}\rangle=\sum_i\sqrt{p_i}|e_i\rangle\otimes|f_i\rangle.$$

Choose $\epsilon>0$. By the asymptotic equipartition theorem (Ref. 38, Theorem 3.1.2), there exists an integer $N\equiv N(\epsilon)$ such that, for all $n\geqslant N$, one can find a subset $\mathsf{TYP}\equiv\mathsf{TYP}(n,\epsilon)$ of the set of indices $\{i\}_{i=1}^{d^{2n}}$ with the following properties:

$$2^{-n(\mathsf{S}+\epsilon)}\leqslant p_i\leqslant 2^{-n(\mathsf{S}-\epsilon)},\quad \text{for } i\in\mathsf{TYP}, \tag{34a}$$

$$p\equiv\sum_{i\in\mathsf{TYP}}p_i\geqslant 1-\epsilon, \tag{34b}$$

$$\#\mathsf{TYP}\leqslant 2^{n(\mathsf{S}+\epsilon)}. \tag{34c}$$

Here #TYP denotes the number of elements in TYP.

Introduce another wavefunction $|\phi_n\rangle\in\mathcal{H}_{\mathrm{tot}}$ given by

$$|\phi_n\rangle\equiv\frac{1}{\sqrt{p}}\sum_{i\in\mathsf{TYP}}\sqrt{p_i}|e_i\rangle\otimes|f_i\rangle.$$

This wavefunction satisfies

$$|\langle\psi^{\otimes n}|\phi_n\rangle|^2=p\geqslant 1-\epsilon \tag{35}$$

and so

$$\| |\psi^{\otimes n}\rangle\langle\psi^{\otimes n}| - |\phi_n\rangle\langle\phi_n| \|_1 = 2\sqrt{(1-|\langle\psi^{\otimes n}|\phi_n\rangle|^2)} \leqslant 2\sqrt{\epsilon}. \tag{36}$$

Now, the crucial observation (cf. Ref. 21) is that for $\epsilon < \min\{1/2\mathsf{S}, 1/2\}$ and n sufficiently large, there exist completely positive maps Λ_n and Λ_n' such that

$$\Lambda_n(|\phi_n\rangle\langle\phi_n|) = P_+^a \tag{37a}$$

for P_+^a a representative of $P_+(\mathbb{C}^a)$ in $\mathcal{H}_{\text{tot}}$ with $|(\log_2 a)/n - \mathsf{S}| < \epsilon + 2/n$ and

$$\Lambda_n'(P_+^b) = |\phi_n\rangle\langle\phi_n| \tag{37b}$$

for P_+^b a representative of $P_+(\mathbb{C}^b)$ in $\mathcal{H}_{\text{tot}}$ with $|(\log_2 b)/n - \mathsf{S}| < \epsilon + 1/n$. Indeed, to see Eq. (37a), set $a \equiv \lfloor p2^{n(\mathsf{S}-\epsilon)} \rfloor$, i.e., a is the largest integer smaller than or equal to $p2^{n(\mathsf{S}-\epsilon)}$. Then $a \leqslant p2^{n(\mathsf{S}-\epsilon)} \leqslant p/p_i$ and we see that the distribution $(p_i/p)_{i \in \mathsf{TYP}}$ is majorized by $(1/a)_{i=1}^a$, hence Eq. (37a) follows from Nielsen's theorem. Equation (37b) follows by a similar argument when we take $b \equiv \lceil p2^{n(\mathsf{S}+\epsilon)} \rceil$, i.e., b is the smallest integer larger than or equal to $p2^{n(\mathsf{S}+\epsilon)}$. The conditions on ϵ and n are sufficient to go from $a \equiv \lfloor p2^{n(\mathsf{S}-\epsilon)} \rfloor$ to $|(\log_2 a)/n - \mathsf{S}| < \epsilon + 2/n$ and from $b \equiv \lceil p2^{n(\mathsf{S}+\epsilon)} \rceil$ to $|(\log_2 b)/n - \mathsf{S}| < \epsilon + 1/n$, ensuring, for example, that $a \neq 0$.

Now choose a sequence $(\epsilon_j)_{j \in \mathbb{N}}$ of positive numbers such that $\epsilon_j \to 0$ for $j \to \infty$. Suppose that $(n_k)_{k \in \mathbb{N}}$ is a sequence of integers such that $n_k \to \infty$ and $E(|\psi^{\otimes n_k}\rangle\langle\psi^{\otimes n_k}|)/n_k \to L$ for some L.

For each j, choose $n_{k_j} \geqslant \max\{N(\epsilon_j), 1/\epsilon_j\}$. We can apply the postulates (P0)–(P3) to obtain the following estimates:

$$\begin{aligned}
\frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|)}{n_{k_j}} &= \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} \\
&\geqslant \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{E(\Lambda_{n_{k_j}}(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|))}{n_{k_j}} \\
&= \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{E(P_+^{a_{n_{k_j}}})}{n_{k_j}} \\
&= \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{\log_2 a_{n_{k_j}}}{n_{k_j}}.
\end{aligned}$$

As $j \to \infty$, the first term vanishes due to (P3) and the second approaches $S_{\text{vN}}(P_\psi)$ (cf. Ref. 6). This implies that $L \geqslant S_{\text{vN}}(|\psi\rangle\langle\psi|)$. The proof of the inequality $L \leqslant S_{\text{vN}}(|\psi\rangle\langle\psi|)$ is similar:

$$\begin{aligned}
\frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|)}{n_{k_j}} &= \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} \\
&\leqslant \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{E(P_+^{b_{n_{k_j}}})}{n_{k_j}} \\
&= \frac{E(|\psi^{\otimes n_{k_j}}\rangle\langle\psi^{\otimes n_{k_j}}|) - E(|\phi_{n_{k_j}}\rangle\langle\phi_{n_{k_j}}|)}{n_{k_j}} + \frac{\log_2 b_{n_{k_j}}}{n_{k_j}}.
\end{aligned}$$

We have now shown that every limit point of the sequence $E(|\psi^{\otimes n}\rangle\langle\psi^{\otimes n}|)/n$ has the value $L = S_{\text{vN}}(|\psi\rangle\langle\psi|)$. But, by (P1), (P2), and Lemma 15, this sequence is bounded, and so (P5″) holds

with $E^{\infty}(|\psi\rangle\langle\psi|)=L=S_{\mathrm{vN}}(|\psi\rangle\langle\psi|)$. This proves the final statement of the theorem. On the other hand, if (P4) holds, then $L=E(|\psi\rangle\langle\psi|)$, and so we have proved that (2) implies (3). This completes the proof of Theorem 23. ■

It is natural to wonder whether the conditions in Theorem 23 can be weakened, and, in particular, whether (P3) is necessary. That it is has been noted by Vidal.[3] Consider the entanglement measures defined on pure states by $S_{\infty}(\sigma)=-\log_2 p_1(\sigma)$ where $p_1(\sigma)$ is the largest coefficient in a Schmidt decomposition of σ and by $S_0(\sigma)=\log d(\sigma)$, where d is the number of nonzero coefficients. S_0 and S_{∞} both satisfy (P0), (P1), (P2) (by Nielsen's theorem), and (P4). S_{∞} is even trace norm continuous on Hilbert spaces of fixed dimension. (P3), however, does not hold for either. This is, of course, a consequence of Theorem 23. An explicit example of the failure of (P3) for S_{∞} is provided by the states $\sigma_n\equiv|\Psi_n\rangle\langle\Psi_n|$, $\varrho_n\equiv|\Phi_n\rangle\langle\Phi_n|$ with Schmidt decompositions $|\Psi_n\rangle\equiv\sqrt{1/2^n}|\psi_1\psi_1\rangle+\Sigma_{i=2}^{4^n-2^{n+1}}(1/2^n)|\psi_i\psi_i\rangle$ and $|\Phi_n\rangle\equiv\Sigma_{i=1}^{4^n}(1/2^n)|\psi_i\psi_i\rangle$ for some orthonormal family $(|\psi_i\rangle)$ of wavefunctions. In fact, any entanglement measure E defined on pure states and satisfying (P0), (P1), (P2), and (P4) will satisfy $S_{\infty}(\sigma)\leqslant E(\sigma)\leqslant S_0(\sigma)$ for all pure σ. The upper bound here is a consequence of Lemma 15 while, for the lower bound, we modify the proof of Theorem 23 using the fact that $|\psi^{\otimes n}\rangle\langle\psi^{\otimes n}|$ can always be converted without approximation into P_+^c where c is the largest integer smaller than or equal to $1/p_1$.

An example of a measure on pure states satisfying (P0), (P1), (P2), and (P3), but not (P4), is given by $E(\sigma)=2(1-p_1(\sigma))S_{\mathrm{vN}}(\sigma)$ for $p_1(\sigma)\geqslant 1/2$, $E(\sigma)=S_{\mathrm{vN}}(\sigma)$ for $p_1(\sigma)\leqslant 1/2$.

Finally, let us consider entanglement of distillation and entanglement cost in the above context. Using the maps constructed in Theorem 23, we show that they are equal to S_{vN}. We have already noted that for E_C this also follows from Ref. 28.

Lemma 24: The entanglement of distillation E_D and the entanglement cost E_C both coincide on pure states with the von Neumann reduced entropy $E_D(P_\psi)=E_C(P_\psi)=S_{\mathrm{vN}}(P_\psi)$ for all $|\psi\rangle\in\mathcal{H}\otimes\mathcal{H}$.

Proof: From Sec. VII we know that $E_D\leqslant E_C$. It suffices to show that on pure states $E_D\geqslant S_{\mathrm{vN}}$ and $E_C\leqslant S_{\mathrm{vN}}$. We will continue to use the notation from the proof of Theorem 23.

That $E_C(P_\psi)\leqslant S_{\mathrm{vN}}(P_\psi)$ follows directly from the definition of E_C, using the operations defined by the Λ'_{n_j} which satisfy Eq. (37b) and estimate (36).

To show that $E_D(P_\psi)\geqslant S_{\mathrm{vN}}(P_\psi)$, let us apply the map Λ_{n_j} from Eq. (37a) to the state $|\psi^{\otimes n_j}\rangle\langle\psi^{\otimes n_j}|$. We only need check that the resulting state $\Lambda_{n_j}(|\psi^{\otimes n_j}\rangle\langle\psi^{\otimes n_j}|)$ approaches P_+^a as $j\to\infty$. But, by Lemma 5,

$$\begin{aligned}\|\Lambda_{n_j}(|\psi^{\otimes n_j}\rangle\langle\psi^{\otimes n_j}|)-P_+^a\|_1&=\|\Lambda_{n_j}(|\psi^{\otimes n_j}\rangle\langle\psi^{\otimes n_j}|)-\Lambda_{n_j}(|\phi_{n_j}\rangle\langle\phi_{n_j}|)\|_1\\&\leqslant\||\psi^{\otimes n_j}\rangle\langle\psi^{\otimes n_j}|-|\phi_{n_j}\rangle\langle\phi_{n_j}|\|_1\end{aligned}$$

and once again estimate (36) is sufficient. ■

With the results obtained in this article, we can now prove that E_D is convex on pure decompositions, i.e., we have the following Lemma.

Lemma 25:

$$E_D\left(\sum_i p_i|\psi_i\rangle\langle\psi_i|\right)\leqslant\sum_i p_i E_D(|\psi_i\rangle\langle\psi_i|),\tag{38}$$

where $p_i\geqslant 0$ for all i and $\Sigma_i p_i=1$.

Proof: We have seen that E_C is convex and satisfies $E_D\leqslant E_C$. Using Lemma 24 gives

$$E_D\left(\sum_i p_i|\psi_i\rangle\langle\psi_i|\right) \leqslant E_C\left(\sum_i p_i|\psi_i\rangle\langle\psi_i|\right)$$
$$\leqslant \sum_i p_i E_C(|\psi_i\rangle\langle\psi_i|)$$
$$= \sum_i p_i S_{\mathrm{vN}}(P_{\psi_i})$$
$$= \sum_i p_i E_D(|\psi_i\rangle\langle\psi_i|). \tag{39}$$

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Global entanglement in multiparticle systems

David A. Meyer[a] and Nolan R. Wallach[b]
Project in Geometry and Physics, Department of Mathematics, University of California/San Diego, La Jolla, California 92093-0112

(Received 23 January 2002; accepted for publication 16 May 2002)

We define a polynomial measure of multiparticle entanglement which is scalable, i.e., which applies to any number of spin-$\frac{1}{2}$ particles. By evaluating it for three particle states, for eigenstates of the one dimensional Heisenberg antiferromagnet and on quantum error correcting code subspaces, we illustrate the extent to which it quantifies global entanglement. We also apply it to track the evolution of entanglement during a quantum computation. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1497700]

Although entanglement has been recognized as a remarkable feature of quantum mechanics since Schrödinger introduced the word[1] in response to Einstein, Podolsky and Rosen's famous paper,[2] it remains only incompletely understood. In fact, for more than two particles—even of only spin-$\frac{1}{2}$—there is no complete classification of entanglement. To be more precise, a *measure of entanglement* is a function on the space of states of a multiparticle system which is invariant under local unitary operators, i.e., unitary transformations on individual particles. Thus a complete classification of entanglement for a multiparticle system is a characterization of all such functions. Under the most general local operations assisted by classical communication (LOCC[3]), entanglement can change. A measure of entanglement which decreases under LOCC is called an *entanglement monotone*.[4]

On two particle pure states, for example, all measures of entanglement are functions of the eigenvalues of the reduced density matrix (obtained by tracing the density matrix for the whole system over the degrees of freedom of one of the particles), and sums of the k smallest eigenvalues are entanglement monotones.[5] The same information—in somewhat less familiar, but more algebraically convenient form—is contained in the coefficients of the characteristic polynomial of the reduced density matrix. These coefficients are polynomials in the components of the state vector and their complex conjugates. They generate the ring of polynomial functions invariant under the action of local unitary transformations; thus they completely classify two particle pure state entanglement.

As the number of particles n increases, however, the number of independent invariants—measures of entanglement—grows exponentially. Complete classification rapidly becomes impractical. Our goal in this article is more modest: we seek a measure of entanglement which is *scalable*, i.e., which is defined for any number of particles; which is easily calculated; and which provides physically relevant information. We concentrate on the case of spin-$\frac{1}{2}$ particles (*qubits*) and begin by defining a family (parametrized by n) of functions on $(\mathbb{C}^2)^{\otimes n}$. We show that each function is a measure of entanglement, vanishing exactly on product states. Next we evaluate this measure for several example states which illustrate its properties, most importantly that it measures *global* entanglement. This is perhaps best exemplified by its values on eigenstates of the antiferromagnetic Hamiltonian, for which we show that it is maximal only on the ground state. In a less traditional context, quantum computation relies heavily on multiparticle entangled states, particularly for error correction. We show that quantum error correcting code states also maximize

[a]Electronic mail: dmeyer@math.ucsd.edu
[b]Electronic mail: nwallach@math.ucsd.edu

our measure of entanglement. Finally, we illustrate its use in a dynamical setting, tracking the evolution of entanglement during a specific quantum computation.

The Hilbert space $(\mathbb{C}^2)^{\otimes n}$ of n qubits has a basis labeled by the 2^n n-bit strings: $|b_1\cdots b_n\rangle$, $b_j\in\{0,1\}$. For $b\in\{0,1\}$, define

$$\imath_j(b)|b_1\cdots b_n\rangle=\delta_{bb_j}|b_1\cdots\hat{b}_j\cdots b_n\rangle,$$

where $\hat{}$ denotes absence. We extend $\imath_j$ by linearity to be a map $\mathbb{C}^2\otimes(\mathbb{C}^2)^{\otimes n}\to(\mathbb{C}^2)^{\otimes n-1}$. For $u,v\in(\mathbb{C}^2)^{\otimes n-1}$ we can write $u=\Sigma u_x|x\rangle$ and $v=\Sigma v_y|y\rangle$, where $0\leqslant x,y<2^{n-1}$ are $(n-1)$-bit strings. Next, let

$$D(u,v)=\sum_{x<y}|u_xv_y-u_yv_x|^2,$$

the norm-squared of the wedge product of u and v. Finally, for $\psi\in(\mathbb{C}^2)^{\otimes n}$, define

$$Q(\psi)=\frac{4}{n}\sum_{j=1}^{n}D(\imath_j(0)\psi,\imath_j(1)\psi).$$

As we will see shortly, the $4/n$ factor provides a convenient normalization for Q.

Proposition 1: For each $n\in\mathbb{Z}_{\geqslant 2}$, $Q:(\mathbb{C}^2)^{\otimes n}\to\mathbb{R}$ is a measure of entanglement.

Proof: For $u,v\in(\mathbb{C}^2)^{\otimes n-1}$, $D(u,v)$ is invariant under $U(2^{n-1})$. A transformation of the jth qubit in $\psi\in(\mathbb{C}^2)^{\otimes n}$ multiplies the jth summand in Q by the norm squared of its determinant. Thus each summand is invariant under $\mathrm{TSL}(2)\times\mathrm{U}(2^{n-1})$, where T denotes the unit scalars. The intersection of these groups for all the summands is $\mathrm{U}(2)^n$, i.e., the local unitary transformations. ■

The most basic property that a measure of entanglement can have is to identify completely unentangled, i.e., product states. Q has this property:

Proposition 2: $Q(\psi)=0$ iff ψ is a product state.

Proof: Two vectors $u,v\in(\mathbb{C}^2)^{\otimes n-1}$, are linearly dependent iff $D(u,v)=0$. Thus $Q(\psi)=0$ implies the existence of $\alpha_j\in\mathbb{C}$ such that $\imath_j(1)\psi=\alpha_j\imath_j(0)\psi$ for all $1\leqslant j\leqslant n$. In particular,

$$\psi=|0\rangle\otimes\imath_1(0)\psi+|1\rangle\otimes\imath_1(1)\psi=(|0\rangle+\alpha_1|1\rangle)\otimes\imath_1(0)\psi=(g\otimes I)\cdot(|0\rangle\otimes\psi')$$

for some $g\in\mathrm{SU}(2)$, $\psi'\in(\mathbb{C}^2)^{\otimes n-1}$. By Proposition 1, Q is invariant under the local unitary transformation $g\otimes I$, so

$$0=Q(\psi)=Q(|0\rangle\otimes\psi')=0+\sum_{j=2}^{n}D(\imath_j(0)[|0\rangle\otimes\psi'],\imath_j(1)[|0\rangle\otimes\psi'])=Q(\psi').$$

Then, by induction, ψ is a product state.

Conversely, if ψ is a product state, then for all $1\leqslant j\leqslant n$, $\imath_j(0)\psi$ is parallel to $\imath_j(1)\psi$. Thus $Q(\psi)=0$. ■

Having demonstrated that Q vanishes on product states, we should now calculate it for some entangled states. First consider the EPR-Bohm[2,6] state $(|01\rangle-|10\rangle)/\sqrt{2}$, or, equivalently, $\gamma_2=(|00\rangle+|11\rangle)/\sqrt{2}$. It is straightforward to calculate:

$$Q(\gamma_2)=2\cdot\frac{4}{2}\left[\det\frac{1}{\sqrt{2}}\begin{pmatrix}1&0\\0&1\end{pmatrix}\right]^2=1.$$

Next, the three qubit GHZ-Mermin[7,8] state is $\gamma_3=(|000\rangle+|111\rangle)/\sqrt{2}$. Calculating the invariant, we again find

$$Q(\gamma_3)=3\cdot\frac{4}{3}\left[\det\frac{1}{\sqrt{2}}\begin{pmatrix}1&0\\0&1\end{pmatrix}\right]^2=1.$$

Finally, it is now clear that for the n qubit state $\gamma_n=(|0\cdots0\rangle+|1\cdots1\rangle)/\sqrt{2}$, $Q(\gamma_n)=1$. These examples demonstrate that the $4/n$ factor provides a natural normalization for Q.

Proposition 3: With this normalization, $0\leqslant Q\leqslant 1$.

Proof: Since $D(u,v)$ is the norm-squared of the wedge product of the two vectors u and v, it is bounded above by $\|u\|^2\|v\|^2$, which takes its maximal value of $\frac{1}{4}$ when $\|u\|^2=\|v\|^2=\frac{1}{2}$ for vectors $\psi=|0\rangle\otimes\imath_1(0)\psi+|1\rangle\otimes\imath_1(1)\psi$ with $\|\psi\|^2=1$. Since there are n summands in Q, it is bounded above by $n\cdot(4/n)\cdot\frac{1}{4}=1$. ■

Proposition 2 and the calculations above show that these bounds are saturated on, respectively, product states and the entangled states γ_n. Of course, Q does take other values: Under the action of $\mathrm{U}(2)\times\mathrm{U}(2)\times\mathrm{U}(2)$, the Hilbert space for three qubits, $\mathbb{C}^2\otimes\mathbb{C}^2\otimes\mathbb{C}^2$, decomposes into multiple orbits.[9–15] Representative states are $|000\rangle$ (product states), $|0\rangle\otimes\gamma_2=|0\rangle(|00\rangle+|11\rangle)/\sqrt{2}$ (and cyclic permutations), $(|100\rangle+|010\rangle+|001\rangle)/\sqrt{3}$, and γ_3. By Proposition 2, $Q(|000\rangle)=0$. By Proposition 2 and the calculation above, $Q(|0\rangle\otimes\gamma_2)=\frac{4}{3}\cdot\frac{1}{2}=\frac{2}{3}$. A straightforward calculation gives $Q((|100\rangle+|010\rangle+|001\rangle)/\sqrt{3})=\frac{8}{9}$. And we have already calculated $Q(\gamma_3)=1$. Thus for three qubits our measure of entanglement behaves in the way we would want, decreasing through states we would consider successively less globally entangled (and taking different values on each of these states, unlike the "tangle,"[16] for example, which vanishes on all but γ_3). In fact, on three qubits Q is an entanglement monotone and numerical evidence indicates that this is true in general.[17]

The traditional context in which globally entangled multiparticle states occur is lattice spin systems. Consider, for example, the one-dimensional spin-$\frac{1}{2}$ Heisenberg antiferromagnet[18,19] on a lattice of size n, with periodic boundary conditions, defined by the Hamiltonian

$$H_n=\sum_{j=1}^{n}X_jX_{j+1}+Y_jY_{j+1}+Z_jZ_{j+1},$$

where the subscripts are to be interpreted mod n, and X, Y, Z denote the Pauli matrices σ_x, σ_y, σ_z, respectively. H_n commutes with $S_z=\Sigma Z_j$, so the eigenstates of H_n can be labeled by their total spin S_z, i.e., each eigenstate of H_n is a superposition of basis vectors $|b_1\cdots b_n\rangle$ with $|\{j|b_j=1\}|=s$ for some fixed $0\leqslant s\leqslant n$. When $s=1$, the translation invariance of H_n implies that the eigenstates are plane waves

$$\psi_n^{(k)}=\frac{1}{\sqrt{n}}\sum_{j=0}^{n-1}e^{ikj}|0\cdots010\cdots0\rangle,$$

where the jth summand has a single 1 at the jth bit and the wave number $k=2\pi m/n$ for some integer $0\leqslant m\leqslant n-1$. For $n=3$ these plane waves are equivalent under local unitary transformations to the state $(|100\rangle+|010\rangle+|001\rangle)/\sqrt{3}$, for which we calculated $Q=\frac{8}{9}$ above. In fact, for arbitrary n the entanglement of these plane waves is simply

$$Q(\psi_n^{(k)})=\frac{4}{n}\cdot n\cdot(n-1)\frac{1}{n^2}=\frac{4(n-1)}{n^2}.$$

For $s>1$ the eigenstates of H_n can be computed using the Bethe *Ansatz*; the ground state has $s=n/2$ (for even n).[20] Using the translation invariance of these eigenstates we can evaluate Q easily. The result is

$$Q(S_z=s\ \text{ eigenstate of }H_n)=\frac{4}{n}\cdot n\cdot\binom{n-1}{s}\binom{n-1}{s-1}\binom{n}{s}^{-2}=\frac{4s(n-s)}{n^2}.$$

Notice that for the ground state this entanglement measure is maximal, $Q=1$. This result contrasts with O'Connor and Wootters' calculations of the ''concurrence'' C in these states:[21] they find that C is not maximal on the ground state, but rather for $s/n\approx 0.3$ as $n\to\infty$. This difference is due to the fact that C is really a measure of two particle entanglement, even when generalized to multiparticle states, while Q is a global measure of multiparticle entanglement.

Highly entangled multiparticle states also occur in the relatively new context of quantum error correcting codes. In fact, the code subspace for an additive code can be described as the space of ground states of the Hamiltonian formed by the sum of the stabilizers.[22] For example, the code subspace for a 5 qubit code [5,1,3] encoding 1 qubit against single bit errors[23,24] is the space of ground states of the translation invariant Hamiltonian on a one-dimensional lattice of five qubits:

$$H_{[5,1,3]}=\sum_{j=1}^{5} X_j Z_{j+1} Z_{j+2} X_{j+3},$$

where the subscripts are to be interpreted mod 5. The space of ground states is two dimensional—which is why it can encode 1 qubit. A basis is

$$|0\rangle\mapsto[|00000\rangle-(|11000\rangle+\text{cyc})+(|10100\rangle+\text{cyc})-(|11110\rangle+\text{cyc})]/4,$$

$$|1\rangle\mapsto[|11111\rangle-(|00111\rangle+\text{cyc})+(|01011\rangle+\text{cyc})-(|00001\rangle+\text{cyc})]/4,$$

where ''cyc'' indicates cyclic permutations. From these equations it is straightforward to calculate that $Q=1$ for all states in this code space. Here the difference from the concurrence is even more dramatic: C vanishes on the code subspace since tracing over all but two qubits leaves a reduced density matrix proportional to the identity.[25]

Shor's original 9 qubit code protecting 1 qubit against single qubit errors[26] can also be described as the ground state subspace of a lattice Hamiltonian—for a lattice triangulating $\mathbb{R}P^2$.[27] In this case a basis for the code space is

$$|0\rangle\mapsto(|000\rangle+|111\rangle)^{\otimes 3}/3,$$

$$|1\rangle\mapsto(|000\rangle-|111\rangle)^{\otimes 3}/3.$$

Calculating Q for the states in this subspace we find that again it is maximal, despite the fact that these states decompose into products of three qubit factors. So Q does not distinguish all subglobal entanglements; this is a consequence of using a single invariant. Finer resolution requires a more complete set of invariants, and, in general, higher degree polynomials.[9,10,12,15,28]

Nevertheless, as we have seen, Q provides useful information about global entanglement in certain contexts. Furthermore, in dynamical problems, Q quantifies the evolution of entanglement. Consider Grover's algorithm,[29] for example: Given $a_j\in\{0,1\}$, $1\leqslant j\leqslant n$, define

$$U_a|b_1\cdots b_n\rangle=(-1)^{\Pi\delta_{a_j b_j}}|b_1\cdots b_n\rangle$$

and then extend U_a by linearity to a map $(\mathbb{C}^2)^{\otimes n}\to(\mathbb{C}^2)^{\otimes n}$. The goal of Grover's algorithm is to convert an initial state of n qubits, say $|0\cdots 0\rangle$, to a state with probability bounded above $\frac{1}{2}$ of being in the state $|a_1\cdots a_n\rangle$, using U_a the fewest times possible. Grover showed that it can be done with $O(\sqrt{2^n})$ uses of U_a by preparing the state

$$\frac{1}{\sqrt{2^n}}\sum_{x=0}^{2^n-1}|x\rangle=H^{\otimes n}|0\cdots 0\rangle,\quad\text{where}\quad H=\frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\ 1 & -1\end{pmatrix},$$

and then iterating the transformation $H^{\otimes n}U_0H^{\otimes n}U_a$ on this state.[29] The initial state is a product state, as is the target state $|a_1\cdots a_n\rangle$, but intermediate states $\psi(k)$ are entangled for $k>0$ iterations. We can evaluate Q on these states to quantify this entanglement:

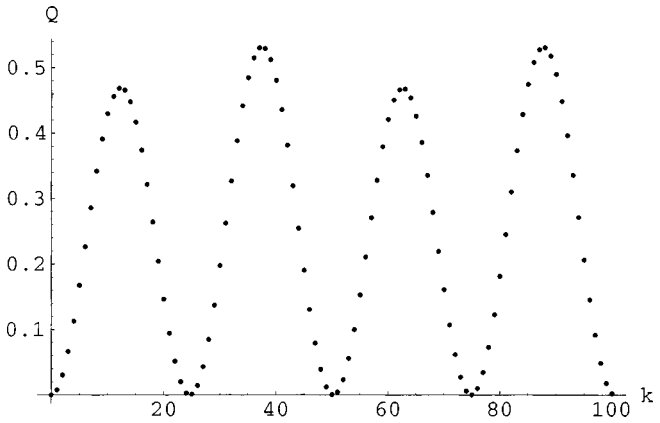

FIG. 1. Entanglement in Grover's algorithm for ten qubits as a function of number of iterations.

$$Q(\psi(k))=4\left(\frac{N}{2}-1\right)\frac{\cos^2\theta_k}{N-1}\left(\sin\theta_k-\frac{\cos\theta_k}{\sqrt{N-1}}\right)^2,$$

where $\theta_k=(2k+1)\csc^{-1}(\sqrt{N})$ and $N=2^n$. The results are plotted in Fig. 1 for $n=10$: the entanglement oscillates, first returning to close to 0 at

$$k=\left\lfloor\frac{1}{2}\left(\frac{\pi}{2\csc^{-1}(\sqrt{N})}-1\right)\right\rceil\sim\left\lfloor\frac{\pi}{4}\sqrt{N}\right\rceil \quad \text{as} \quad N\to\infty,$$

where $\lfloor\cdot\rceil$ denotes "closest integer to"; this is when the probability of measuring $|a_1\cdots a_n\rangle$ is first close to 1.

Three qubit states, eigenstates of lattice Hamiltonians, quantum error correcting code subspaces, and the intermediate states in Grover's algorithm all illustrate how a measure of multiparticle entanglement such as Q provides insight into global properties of quantum multiparticle systems. While Q has the satisfactory properties of Propositions 2 and 3, is an entanglement monotone on three qubits, and is a straightforwardly computable polynomial, it is in no sense a unique measure of multiparticle entanglement. A more complete (but still partial) characterization can be obtained by also using some of the other measures which have been proposed, like the concurrence,[21] the closely related n-tangle,[30] the Schmidt rank,[31] the negativity,[32] etc. Each emphasizes a specific feature of multiparticle entanglement and describes a different physical property. We anticipate that multiparticle entanglement measures—whose current development is largely motivated by quantum computation—will contribute to the understanding of the physics of quantum multiparticle systems more generally.[33–35]

The entanglement of formation gives a necessary and sufficient condition for the existence of a perfect quantum error correction procedure. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1497183]

I. QUANTUM ERROR CORRECTION

Suppose a composite quantum system RQ is initially in a pure joint input state $|\Psi^{RQ}\rangle$. The subsystem Q undergoes a dynamical evolution described by a trace-preserving, completely positive (CP) map $\mathcal{E}$. The joint output state is therefore

$$\rho^{RQ'} = I \otimes \mathcal{E}(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|). \tag{1}$$

This situation describes the transmission of ''quantum information'' (the entanglement between R and Q) via a noisy quantum channel. For example, imagine that RQ is a quantum computing device. The overall state of the device is entangled. Subsystem Q is imperfectly isolated from the environment, and thus experiences noise and distortion given by $\mathcal{E}$. The problem of sending entanglement through a channel in this way is closely related to other tasks of quantum information transfer, such as the transmission of an unknown quantum state of Q.[1]

We are interested in the question of whether the original input state $|\Psi^{RQ}\rangle$ can be restored by some possible operation on Q alone. Such a restoring operation is called a ''quantum error correction'' procedure.[2] We say that *perfect* quantum error correction is possible when there exists a trace preserving CP map $\mathcal{D}$ on Q such that

$$|\Psi^{RQ}\rangle\langle\Psi^{RQ}| = I \otimes \mathcal{D}(\rho^{RQ'}). \tag{2}$$

If no such $\mathcal{D}$ exists, we may still be able to do *approximate* quantum error correction, in which case we restore $\rho^{RQ'}$ to a state close to the original. (''Close'' here is usually defined in terms of the fidelity or some equivalent measure.) In this article, we will mostly be concerned with the question of perfect (unit fidelity) error correction.

We first note that, if the input state of RQ is a product state, then it is always possible to restore the input state by means of an operation on Q. Thus, the problem of error correction is only nontrivial when $|\Psi^{RQ}\rangle$ is entangled. The entanglement of a pure state of RQ is measured by the entropy S^Q of the subsystem Q:

$$S^Q = -\operatorname{Tr}\rho^Q \log \rho^Q. \tag{3}$$

Of course, since RQ is in a pure state, then $S^Q = S^R$.

The output state $\rho^{RQ'}$ is generally not pure. Schumacher and Nielsen[3] defined the ''coherent information'' to be

$$I = S^{Q'} - S^{RQ'}. \tag{4}$$

a)Electronic mail: schumacherb@kenyon.edu

This quantity has a number of significant properties. It is positive only if the output state $\rho^{RQ'}$ is entangled. Furthermore, it cannot be increased by any operation on Q alone. Since the initial coherent information is just S^Q, this means that $I \leqslant S^Q$ after the action of $\mathcal{E}$. Furthermore, any loss of I due to the action of $\mathcal{E}$ is irreversible, i.e., cannot be reversed by any subsequent evolution of Q. It follows that $I = S^Q$ is a necessary condition for the existence of a perfect quantum error correction operation $\mathcal{D}$.

In Ref. 3, it is shown that the condition $I = S^Q$ is also *sufficient* for the existence of such an operation. In outline, we imagine a larger quantum system RQE that includes the environment E with which Q interacts. The initial state of the environment is a pure state $|0^E\rangle$, and the interaction of Q and E is described by the unitary operator U^{QE}. (Since the operation $\mathcal{E}$ is a trace-preserving CP map, it must always be realizable in this way as a unitary evolution on a larger system.) The condition $I = S^Q$ implies that the output state of the subsystem RE is a product state. From this product structure, a perfect error correction procedure can be constructed. In short, the lack of any correlation between R and E after the evolution is sufficient to permit the restoration of the original QE state by an error-correction operation $\mathcal{D}$.

Although the error-correction operation $\mathcal{D}$ is constructed for a particular input entangled state $|\Psi^{RQ}\rangle$, the same procedure will also work for any other state $|\Phi^{RQ}\rangle$ whose support in Q lies within the Q-support for $|\Psi^{RQ}\rangle$. Furthermore, if we have an ensemble of pure input Q states within this subspace, $\mathcal{D}$ will restore these states with unit average fidelity.[3]

II. ENTANGLEMENT OF FORMATION

The coherent information I is a measure of the entanglement of Q with R after it has undergone its noisy evolution. There are, however, many other ways to measure the entanglement of the output state $\rho^{RQ'}$. One of the most fundamental is the "entanglement of formation,"[4] denoted $\mathbf{E}$. The entanglement of formation of a pure state $|\psi^{AB}\rangle$ is just $\mathbf{E} = S^A$, the entropy of one of the subsystems. A mixed state ρ^{AB} has an entanglement of formation

$$\mathbf{E} = \min \sum_k p_k \mathbf{E}_k , \tag{5}$$

where $\mathbf{E}_k$ is the entanglement of the pure state $|\phi_k^{AB}\rangle$ and the minimum is taken over all pure-state ensembles such that $\rho^{AB} = \Sigma_k\, p_k |\phi_k^{AB}\rangle\langle\phi_k^{AB}|$. $\mathbf{E}$ has the property that it cannot be increased by local quantum operations on, or the exchange of classical information between, the two subsystems.

The entanglement of formation is related to the "entanglement resources" necessary to create the quantum state. However, to make this connection sharp one must define an *asymptotic* entanglement of formation

$$\mathbf{E}_\infty(\rho^{AB}) = \lim_{n\to\infty} \frac{1}{n} \mathbf{E}((\rho^{AB})^{\otimes n}). \tag{6}$$

$\mathbf{E}_\infty$ is the asymptotic number of maximally entangled qubit pairs needed to create the state ρ^{AB} by local operations and classical communication—that is, for large n, about $n\mathbf{E}_\infty$ pairs are required to make n copies of the state ρ^{AB}. Though the definitions of $\mathbf{E}_\infty$ and $\mathbf{E}$ are distinct, and we can see that $\mathbf{E}_\infty \leqslant \mathbf{E}$, it is not known whether or not these are actually equal in general.[5] We will here use the "single system" definition of the entanglement of formation $\mathbf{E}$, since we are not primarily concerned with asymptotic questions.

The coherent information I and the entanglement of formation $\mathbf{E}$ of the output state $\rho^{RQ'}$ satisfy $I \leqslant \mathbf{E}$. To see this, suppose we have an ensemble of RQ states such that $\rho^{RQ'} = \Sigma_k\, p_k \rho_k^{RQ}$, then

$$S^{Q'} - \sum_k p_k S_k^Q \leqslant S^{RQ'} - \sum_k p_k S_k^{RQ}. \tag{7}$$

(This follows from the strong subadditivity of the entropy functional.[6]) For any ensemble of pure states, $S_k^{RQ}=0$ and so

$$S^{Q'} - S^{RQ'} \leqslant \sum_k p_k S_k^Q. \tag{8}$$

If we choose the pure state ensemble that minimizes the right-hand side, we obtain $I \leqslant \mathbf{E}$.

For the input pure state of RQ, both $\mathbf{E}$ and I are equal to S^Q. For the output state, the condition that $\mathbf{E}=S^Q$ is weaker than the condition that $I=S^Q$, since we can have $I<\mathbf{E}$. Thus, $\mathbf{E}=S^Q$ is a necessary condition for the existence of a perfect quantum error correction operation $\mathcal{D}$. Remarkably, it turns out that this is also a sufficient condition. We now show this. Suppose that $\mathbf{E}=S^Q$ for our output state $\rho^{RQ'}$. Our argument is based on three facts.

Fact 1: Concavity of the entropy. Suppose we write a mixed state as an ensemble of states: $\rho=\Sigma_k p_k \rho_k$. Then

$$S \geqslant \sum_k p_k S_k \tag{9}$$

with equality if and only if $\rho_k=\rho$ for all k with $p_k>0$.[7] In our context, the condition that $\mathbf{E}=S^Q$ means that

$$0 = S^{R'} - \min \sum_k p_k S_k^R, \tag{10}$$

where the minimum is taken over all pure state ensembles for $\rho^{RQ'}$, and where we have recalled that $S^Q=S^R=S^{R'}$. Equation (9) then tells us that

$$0 = S^{R'} - \sum_k p_k S_k^R \tag{11}$$

for *any* pure state ensemble for $\rho^{RQ'}$, and therefore all of the elements of such an ensemble have $\rho_k^R=\rho^{R'}$. Since we can consider any mixed state to be made up of pure states, this is also true for $\rho^{RQ'}$ ensembles that include mixed states.

Fact 2: Choice of ensemble is choice of ancilla measurement. Hughston, Jozsa and Wootters[8] give a useful characterization of all the pure state ensembles that can lead to a particular density operator ρ^A for a system A. We "purify" the state by envisioning a pure state $|\psi^{AB}\rangle$ of a larger composite system AB such that $\rho^A=\mathrm{Tr}_B|\psi^{AB}\rangle\langle\psi^{AB}|$. A measurement on system B will lead to an ensemble of relative states of A. In Ref. 8 it is shown that, given a purification $|\psi^{AB}\rangle$ of ρ^A, we can realize *any* ensemble for ρ^A as an ensemble of relative states for some measurement on B. In other words, the choice of ρ^A ensemble is exactly the same as the choice of measurement on the purifying system B.

In our context, we can include the environment system E as before, with the whole system RQE in the pure state $|\Psi^{RQE'}\rangle$ after the interaction of Q and E. E purifies RQ, so an ensemble of RQ states corresponds to a measurement on E. From fact 1, we know that every element of an ensemble for $\rho^{RQ'}$ yields the same state $\rho^{R'}$ on R alone. Thus, for any possible outcome of any measurement on E, the relative state of R will be $\rho^{R'}$. This means that the probabilities of the outcomes of possible R-measurements are unaffected by the particular outcomes of an E-measurement.

Fact 3: No correlation implies product state. Quantum state tomography[2] allows the reconstruction of a quantum state ρ from the outcome distributions of a finite number of possible measurements on the quantum system. This procedure, when applied to a composite quantum system AB, has two important features. First, it is sufficient to consider only product measurements of A and B to do tomography of the joint state. Second, if no statistical correlations appear between the outcomes of the A and B measurements, the resulting joint state must be a product state $\rho^A \otimes \sigma^B$. Thus, a necessary and sufficient condition for A and B to be in a product state is that no correlations arise in any product measurement of the systems.

Since we have shown that $\mathbf{E}=S^Q$ implies no statistical correlations between E- and R-measurements on the output state, we can conclude that the output state of the subsystem RE is a product state $\rho^{R'} \otimes \sigma^{E'}$. Given such a product state, we can apply the procedure in Ref. 3 to give an explicit error correction operation $\mathcal{D}$ that will restore the input state $|\Psi^{RQ}\rangle$ of RQ with perfect fidelity. Therefore, perfect quantum error correction is possible if and only if $\mathbf{E}=S^Q$.

III. INTRINSIC EXPRESSIONS FOR *I* AND E

Both the coherent information I and the entanglement of formation $\mathbf{E}$ are "intrinsic" quantities to the system Q—that is, they can be expressed entirely in terms of the input state ρ^Q of Q alone and the trace-preserving CP map $\mathcal{E}$ that describes Q's dynamics. First, we note that the map $\mathcal{E}$ can be given an "operator sum" representation:[2]

$$\mathcal{E}(\rho^Q)=\sum_k A_k \rho^Q A_k^\dagger, \tag{12}$$

where the A_k operators satisfy $\Sigma_k A_k^\dagger A_k = 1$. A given $\mathcal{E}$ always has many different operator sum representations. Suppose we have a unitary matrix V_{kl}, and define some operators B_k as linear combinations of the A_k's:

$$B_k=\sum_l V_{kl} A_l. \tag{13}$$

Then the B_k's give an alternate operator sum representation for $\mathcal{E}$.

The operator sum representation is closely related to the unitary representation for $\mathcal{E}$, in which $\mathcal{E}$ is given via unitary evolution on a larger system that includes the environment E. Once again, E is taken to be initially in a pure state $|0^E\rangle$, and the interaction of Q and E is given by the unitary operator U^{QE}. Let $|k^E\rangle$ be a basis of E states, and define the operator A_k on Q by the "partial inner product"

$$A_k|\psi^Q\rangle=\langle k^E|U^{QE}|\psi^Q 0^E\rangle, \tag{14}$$

where $|\psi^Q 0^E\rangle$ is shorthand for $|\psi^Q\rangle\otimes|0^E\rangle$. We can use the $|k^E\rangle$ basis to do a partial trace over the E system, so that

$$\mathcal{E}(\rho^Q)=\mathrm{Tr}_E[U^{QE}(\rho^Q\otimes|0^E\rangle\langle 0^E|)U^{QE\dagger}]=\sum_k \langle k^E|U^{QE}(\rho^Q\otimes|0^E\rangle\langle 0^E|)U^{QE\dagger}|k^E\rangle=\sum_k A_k\rho^Q A_k^\dagger. \tag{15}$$

The unitary freedom in the operator sum representation is the same as the freedom to choose a basis for the environment system E.

The operator sum representation of $\mathcal{E}$ gives the output state $\rho^{Q'}=\mathcal{E}(\rho^Q)$ as an ensemble of Q states. If we let

$$p_k=\mathrm{Tr}A_k\rho^Q A_k^\dagger,$$

$$\rho_k^Q = \frac{1}{p_k}(A_k \rho^Q A_k^\dagger), \tag{16}$$

then $\rho^{Q'} = \Sigma_k p_k \rho_k^Q$. Different operator sum representations yield different ensembles for the same output state.

The entanglement of formation $\mathbf{E}$ of the $\rho^{RQ'}$ state can be written

$$\mathbf{E} = \min \sum_k p_k S_k^Q, \tag{17}$$

where S_k^Q is the entropy of ρ_k^Q (as defined above) and the minimum is taken over all operator sum representations for $\mathcal{E}$. In a similar way, the coherent information I can be written

$$I = S^{Q'} - \min H(\vec{p}), \tag{18}$$

where $H(\vec{p}) = -\Sigma_k p_k \log p_k$ and the minimum is once again taken over all operator sum representations.[1] We can see why this is true by appealing to a unitary representation. The p_k's are the diagonal entries of the output density matrix for the environment E, and $S^{E'} = \min H(\vec{p})$ (where we minimize over basis states). Since the global state of RQE is pure, $S^{E'} = S^{RQ'}$.

IV. GENERALIZATION

We pointed out that both I and $\mathbf{E}$ were measures of entanglement of the state $\rho^{RQ'}$, and that $I = \mathbf{E} = S^Q$ for the input pure state $|\Psi^{RQ}\rangle$. We now consider other possible measures of the entanglement of $\rho^{RQ'}$. Suppose M is such a measure, and that it satisfies the following conditions:

(1) $M = S^Q$ when RQ is in a pure state.

(2) M is additive if we have many copies of $\rho^{RQ'}$; that is,

$$M((\rho^{RQ'})^{\otimes n}) = nM(\rho^{RQ'}). \tag{19}$$

(3) M does not increase on average under local operations on, or classical communication between, R and Q.

The requirement that M be nonincreasing ''on average'' allows us to include nondeterministic operations, such as local measurements. Though M may increase conditionally for some measurement outcomes, we require that, if M is averaged over all outcomes, then it cannot increase.

Coherent information satisfies (1) and (2) but not (3); the asymptotic entanglement of formation $\mathbf{E}_\infty$ satisfies all three; it is not known whether the ''single system'' entanglement of formation $\mathbf{E}$ satisfies (2) (for this is exactly the question of whether $\mathbf{E} = \mathbf{E}_\infty$). Conditions (1)–(3) are similar to those discussed in Ref. 9.

We will now show that perfect quantum error correction is possible if and only if $M = S^Q$ for the output state $\rho^{RQ'}$.

''Only if'' is easy to see. Initially, $M = S^Q$. If M decreases under the action of $\mathcal{E}$ on Q, then this loss cannot be made up by any error correction procedure, which must be a local operation on Q. Thus, the original state can be restored only if $M = S^Q$ after $\mathcal{E}$ acts.

To show that $M = S^Q$ is sufficient to allow perfect error correction, we will show that $M \leqslant \mathbf{E}$. Imagine that we begin with $n\mathbf{E}_\infty$ maximally entangled qubit pairs, for which $M_n = n\mathbf{E}_\infty$. We know that, if n is large, we can use these pairs to make about n copies of our state $\rho^{RQ'}$ by local operations and classical communication. Since M cannot increase in this process, $nM \leqslant M_n$, and so $M \leqslant \mathbf{E}_\infty$. But we have seen that $\mathbf{E}_\infty \leqslant \mathbf{E}$, so $M \leqslant \mathbf{E}$.

We know that $\mathbf{E} \leqslant S^Q$. Thus, if $M = S^Q$, then $\mathbf{E} = S^Q$. As we have seen, this is sufficient to guarantee the existence of a perfect error correction operation $\mathcal{D}$ for Q. $M = S^Q$ is therefore both necessary and sufficient for the existence of $\mathcal{D}$.

Remarkably, inequivalent entanglement measures lead to equivalent conditions for perfect quantum error correction. The coherent information I, the entanglement of formation $\mathbf{E}$ (or its asymptotic form $\mathbf{E}_\infty$), and entanglement measures M satisfying our properties all share the feature that they are conserved by the evolution $\mathcal{E}$ on Q only when that evolution produces no correlations between R and E.

V. REMARKS

We have assumed that Q may interact with environment, while R remains untouched. Suppose instead that both Q and R independently interact with separate parts of the environment, so that

$$\rho^{RQ\prime} = \mathcal{E}^R \otimes \mathcal{E}^Q(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|). \tag{20}$$

We say in this case that perfect quantum error correction is possible if the original state of RQ can be restored by local operations and classical communication. It turns out that this can be done if and only if $\mathbf{E}=S^Q$; furthermore, if error correction is possible at all, then no classical communication between R and Q is necessary.

Once again, $\mathbf{E}=S^Q$ is plainly a necessary condition, and we must show that it is also sufficient. Suppose $\mathbf{E}=S^Q$ after the operation $\mathcal{E}^R\otimes\mathcal{E}^Q$. We can imagine that this operation occurs in two stages:

$$\rho^{RQ\prime} = (\mathcal{E}^R \otimes I^Q)\circ(I^R \otimes \mathcal{E}^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|). \tag{21}$$

After the first stage, in which $I^R\otimes\mathcal{E}^Q$ acts, we must have $\mathbf{E}=S^Q$. Therefore, at this stage there exists an operation $\mathcal{D}^Q$ on Q that can accomplish perfect error correction. That is,

$$|\Psi^{RQ}\rangle\langle\Psi^{RQ}| = (I^R \otimes \mathcal{D}^Q)\circ(I^R \otimes \mathcal{E}^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|). \tag{22}$$

Alternately, we note that

$$\rho^{RQ\prime} = (I^R \otimes \mathcal{E}^Q)\circ(\mathcal{E}^R \otimes I^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|), \tag{23}$$

in which case $\mathbf{E}=S^Q=S^R$ after the first operation, and an error-correction operation $\mathcal{D}^R$ exists at this stage:

$$|\Psi^{RQ}\rangle\langle\Psi^{RQ}| = (\mathcal{D}^R \otimes I^Q)\circ(\mathcal{E}^R \otimes I^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|). \tag{24}$$

Now we can see that $\mathcal{D}^R\otimes\mathcal{D}^Q$ will correct the complete operation:

$$\begin{aligned}
&(\mathcal{D}^R \otimes \mathcal{D}^Q)\circ(\mathcal{E}^R \otimes \mathcal{E}^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|) \\
&\quad = (I^R \otimes \mathcal{D}^Q)\circ(\mathcal{D}^R \otimes I^Q)\circ(I^R \otimes \mathcal{E}^Q)\circ(\mathcal{E}^R \otimes I^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|) \\
&\quad = (I^R \otimes \mathcal{D}^Q)\circ(I^R \otimes \mathcal{E}^Q)\circ(\mathcal{D}^R \otimes I^Q)\circ(\mathcal{E}^R \otimes I^Q)(|\Psi^{RQ}\rangle\langle\Psi^{RQ}|) \\
&\quad = |\Psi^{RQ}\rangle\langle\Psi^{RQ}|.
\end{aligned} \tag{25}$$

Thus, $\mathbf{E}=S^Q$ is a necessary and sufficient condition for local correction of the quantum state, even if both subsystems have experienced independent noisy evolutions.

Throughout this article, we have focused our attention on the issue of *perfect* error correction. What about *approximate* error correction? We have elsewhere[10] shown that, if the loss of coherent information is small, then an operation $\mathcal{D}$ exists that will nearly restore the original state $|\Psi^{RQ}\rangle$. To be precise, if $S^Q - I < \epsilon$, then there exists an operation $\mathcal{D}$ on Q that will restore the input state with fidelity $F > 1-2\sqrt{\epsilon}$. Is there an analogous theorem for the entanglement of formation $\mathbf{E}$? That is, suppose $S^Q - \mathbf{E} < \epsilon$. With what fidelity can error correction be performed? This and many other questions remain unresolved.

(Received 6 February 2002; accepted for publication 16 May 2002)

We introduce a measure of both quantum as well as classical correlations in a quantum state, the entanglement of purification. We show that the (regularized) entanglement of purification is equal to the entanglement cost of creating a state ρ asymptotically from maximally entangled states, with negligible communication. We prove that the classical mutual information and the quantum mutual information divided by two are lower bounds for the regularized entanglement of purification. We present numerical results of the entanglement of purification for Werner states in $\mathcal{H}_2 \otimes \mathcal{H}_2$. © *2002 American Institute of Physics.*

I. INTRODUCTION

The theory of quantum entanglement aims at quantifying and characterizing uniquely quantum correlations. It does so by analyzing how entangled quantum states can be processed and transformed by quantum operations. A crucial role in the theory is played by the class of local operations and classical communication (LOCC), since quantum entanglement is nonincreasing under these operations. Indeed, by considering this class of operations we are able to neatly distinguish between the quantum entanglement and the classical correlations that are present in the quantum state.

Given the success of this theory, we may be daring enough to ask whether we can similarly construct a theory of purely classical correlations in quantum states and their behavior under local or nonlocal processing. At first sight, such an effort seems doomed to fail since merely local actions can convert quantum entanglement into classical correlations. Namely, Alice and Bob who possess an entangled state $|\psi\rangle = \Sigma_i \sqrt{\lambda_i} |a_i\rangle \otimes |b_i\rangle$ with Schmidt coefficients λ_i can, by local measurements, obtain a joint probability distribution with mutual information equal to $H(\lambda)$. Thus it does not seem possible to separate the classical correlations from the entanglement if we try to do this in an operational way. Note that it may be possible to separate quantum and classical correlations in a nonoperational way (see, for example, Ref. 1 or 2. The drawback of such an approach is that no connection is made to the dynamical processing of quantum information, which is precisely what has made the theory of quantum entanglement so elegant and innovative. An

a)Electronic mail: terhal@watson.ibm.com

operational approach to the quantification of quantum and classical correlations was recently formulated in Ref. 3.

In this article we propose to treat quantum entanglement and classical correlation in a unified framework, namely we express both correlations in units of entanglement. Such a theory of ''all'' correlations may have potential applications outside quantum information theory as well. Researchers have started to look at entanglement properties of many-particle systems for example at (quantum) phase transitions (see, for example, Ref. 4 and references therein). Instead of considering the entanglement of formation in these studies, one may choose to look at the behavior of a complete correlation measure. In this article we introduce such a measure, called the entanglement of purification. We would like to emphasize that our correlation measure is *not* an entanglement measure, but a measure of correlations expressed in terms of the entanglement of a pure state.

It has been the experience in (quantum) information theory that questions in the asymptotic approximate regime are easier to answer than exact nonasymptotic queries. Thus we ask how to create a bipartite quantum state ρ in the asymptotic regime, allowing approximation, from an initial supply of EPR-pairs by means of *local operations and asymptotically vanishing communication*. This latter class of operations will be denoted as LOq [local operations with $o(n)$ communication in the asymptotic regime] versus the class LO for strictly local operations. We can properly define this formation cost E_{LOq} as follows:

$$E_{LOq}(\rho)=\lim_{\epsilon\to 0}\inf\left\{\frac{m}{n}\;\middle|\;\exists\,\mathcal{L}_{LOq}, D(\mathcal{L}_{LOq}(|\Psi_-\rangle\langle\Psi_-|^{\otimes m}),\rho^{\otimes n})\leq\epsilon\right\}. \tag{1}$$

Here $|\Psi_-\rangle$ is the singlet state in $\mathcal{H}_2\otimes\mathcal{H}_2$ and $\mathcal{L}_{LOq}$ is a local superoperator using $o(n)$ quantum communication. D is the Bures distance $D(\rho,\rho')=2\sqrt{1-F(\rho,\rho')}$ and the square-root-fidelity is defined as $F(\rho,\rho')=\mathrm{Tr}(\sqrt{\rho^{1/2}\rho'\rho^{1/2}})$.[5] We could have allowed classical instead of quantum communication in our definition (our results will not depend on this choice), so we may as well call all communication quantum communication.

Before we consider this entanglement cost for mixed states, we observe that by allowing asymptotically vanishing communication, we have preserved the interconvertibility result for pure states.[6] This is due to the fact that both the process of entanglement dilution as well as entanglement concentration can be accomplished with no more than asymptotically vanishing amount of communication, see Ref. 7.

We see that the cost $E_{LOq}(\rho)$ of creating the state ρ is defined analogously to the entanglement cost $E_c(\rho)$,[8,9] with the restriction that Alice and Bob can only do a negligible amount of communication. It is immediate that $E_{LOq}(\rho)$ will in general be larger than $E_c(\rho)$. In particular, for a separable density matrix, $E_c(\rho)=0$, whereas we will show that for any correlated (i.e., not of the form $\rho_{AB}=\rho_A\otimes\rho_B$) density matrix $E_{LOq}(\rho)>0$. The entanglement cost E_c was found[9] to be equal to

$$E_c(\rho)=\lim_{n\to\infty}\frac{E_f(\rho^{\otimes n})}{n}, \tag{2}$$

where $E_f(\rho)$ is the entanglement of formation.[8] We will similarly find an expression for E_{LOq},

$$E_{LOq}=\lim_{n\to\infty}\frac{E_p(\rho^{\otimes n})}{n}\equiv E_p^{\infty}(\rho), \tag{3}$$

where $E_p(\rho)$ is a new quantity, the entanglement of purification of ρ.

Our article is organized in the following manner. We start by defining the entanglement of purification and deriving some basic properties of this new function, such as continuity and monotonicity under local operations. We will relate the entanglement of purification to the problem of minimizing the entropy of a state under a local TCP (trace-preserving completely positive) map. With these tools in hand, we can prove our main result, Theorem 2. Then we spend some

time proving the mutual information lower bounds for $E_{LOq}(\rho)$. We also compare our correlation measure with the induced Holevo correlation measures $C_{A/B}$ that were introduced in Ref. 1. We prove that for Bell-diagonal states the correlation measure C_A is equal to the classical capacity of the related one-qubit Pauli channel. At the end of the article we present our numerical results for $E_p(\rho)$ where ρ is a Werner state on $\mathcal{H}_2 \otimes \mathcal{H}_2$. The proofs of the lemmas and theorems in this article are all fairly straightforward and use many basic properties of entropy and mutual information (concavity, subadditivity of entropy, nonincrease of mutual information under local actions, etc.).

II. ENTANGLEMENT OF PURIFICATION

We define the entanglement of purification:

Definition 1: Let ρ be a bipartite density matrix on $\mathcal{H}_A \otimes \mathcal{H}_B$. Let $|\psi\rangle \in \mathcal{H}_{AA'} \otimes \mathcal{H}_{BB'}$. The entanglement of purification $E_p(\rho)$ is defined as

$$E_p(\rho) = \min_{\psi: \mathrm{Tr}_{A'B'}|\psi\rangle\langle\psi| = \rho} E_f(|\psi\rangle\langle\psi|), \tag{4}$$

where $E_f(|\psi\rangle\langle\psi|)$ is the entanglement of $|\psi\rangle$ which is equal to the von Neumann entropy $S(\sigma_{BB'}) = -\mathrm{Tr}\sigma_{BB'} \log \sigma_{BB'}$ where $\sigma_{BB'} = \mathrm{Tr}_{AA'}|\psi\rangle\langle\psi|$. Let $\{\lambda_i, |\psi_i\rangle\}$ be the eigenvalues and eigenvectors of ρ_{AB}. The "standard purification" of ρ is defined as

$$|\psi_s\rangle = \sum_i \sqrt{\lambda_i} |\psi_i\rangle_{AB} \otimes |0\rangle_{A'} |i\rangle_{B'}. \tag{5}$$

Every purification of ρ can be written as $|\psi\rangle = (I_{AB} \otimes U_{A'B'})|\psi_s\rangle$ for some unitary operator $U_{A'B'}$ on A' and B'. Therefore, Eq. (4) can be rephrased as

$$E_p(\rho) = \min_{U_{A'B'}} E((I_{AB} \otimes U_{A'B'})|\psi_s\rangle\langle\psi_s|(I_{AB} \otimes U_{A'B'})^\dagger) \tag{6}$$

$$= \min_{U_{A'B'}} S(\mathrm{Tr}_{AA'}(I_{AB} \otimes U_{A'B'})|\psi_s\rangle\langle\psi_s|(I_{AB} \otimes U_{A'B'})^\dagger))$$

$$= \min_{\Lambda_{B'}} S((I_B \otimes \Lambda_{B'})(\mu_{BB'}(\rho))), \tag{7}$$

where we have taken the trace over A and A' to obtain Eq. (7),

$$\mu_{BB'}(\rho) = \mathrm{Tr}_{AA'}|\psi_s\rangle\langle\psi_s|, \tag{8}$$

and $\Lambda_{B'}(\nu) \equiv \mathrm{Tr}_{A'} U_{A'B'}(\nu_{B'} \otimes |0\rangle\langle 0|_{A'}) U^\dagger_{A'B'}$. The minimization in Eq. (7) is over all possible TCP maps $\Lambda_{B'}$ since every TCP map can be implemented by performing a unitary transformation on the system and some ancilla and tracing over the ancilla. Note that the minimizations over $U_{A'B'}$ and $\Lambda_{B'}$ are equivalent. Equations (6) and (7) provide two different formulations of the same minimization. Conceptually the first formulation is based on purifications of ρ and variation over $U_{A'B'}$. The second formulation is based on extensions of ρ, $\sigma_{ABB'}$, such that $\mathrm{Tr}_{B'}\sigma_{ABB'} = \rho_{AB}$, and variation over $\Lambda_{B'}(\nu)$. Both formulations will be used throughout the article.

The idea of bipartite purifications was considered in Ref. 10 where the authors proved that every correlated state has, in our language, a nonzero entanglement of purification. If we would have included mixed states in the minimization in Eq. (4) and used the entanglement of formation as the entanglement measure, then the defined quantity would be equal to the entanglement of formation of ρ, since the optimal extension of ρ is ρ itself.

We put some simple bounds on $E_p(\rho)$. Intuitively, "the amount of quantum correlation in a state is smaller than or equal to the total amount of correlation," or $E_f(\rho) \leqslant E_p(\rho)$. To prove this lower bound, let $|\psi_\rho\rangle = \Sigma_{i,j}|i\rangle_{A'}|j\rangle_{B'} \otimes |\psi_{ij}\rangle$ be the purification that achieves the minimum in Eq.

(4). Alice and Bob locally measure the labels $i_{A'}$ and $j_{B'}$ of the state $|\psi_\rho\rangle$ such that they obtain $|\psi_{ij}\rangle$ with probability $p_{ij}=\langle\psi_{ij}|\psi_{ij}\rangle$. Since entanglement is nonincreasing under local operations, we have

$$E_f(\rho)\leqslant\sum_{ij} p_{ij}E\left(\frac{|\psi_{ij}\rangle\langle\psi_{ij}|}{p_{ij}}\right)\leqslant E_p(\rho). \tag{9}$$

It is immediate that we have equality between the entanglement of formation and the entanglement of purification for pure states, where the optimal purification of a pure state is the pure state itself.

An easy upper bound is $E_p(\rho)\leqslant E(|\psi_s\rangle\langle\psi_s|)=S(\rho_A)$, where $\rho_A=\mathrm{Tr}_B(\rho)$ is the reduced density matrix in A. This corresponds to $U_{A'B'}=I_{A'B'}$ or equivalently $\Lambda_{B'}=I_{B'}$ on the rhs of Eq. (6) or (7). Applying the same argument with AA' and BB' interchanged, we obtain

$$E_p(\rho)\leqslant\min(S(\rho_A),S(\rho_B)), \tag{10}$$

where the purifications correspond to either completely purifying the state on A' or on B'. In general this is not the optimal purification, as we will see in Sec. V.

The entanglement of purification is neither convex nor concave, unlike the entanglement of formation. For instance, a mixture of product states, each with zero entanglement of purification, need not have zero entanglement of purification (for example, consider an equal mixture of $|00\rangle$ and $|11\rangle$). On the other hand, the completely mixed state has zero entanglement of purification equal to zero yet it is a mixture of four Bell states, each with one ebit of entanglement of purification.

Before we present continuity bounds for the entanglement of purification, we analyze the optimization problem of Eq. (4) in more detail. We can omit doubly stochastic maps $\Lambda_{B'}$ in the optimization in Eq. (7) since they never decrease the entropy. Furthermore, the von Neumann entropy is concave, so that the optimum in Eq. (7) can always be achieved when $\Lambda_{B'}$ is an *extremal* TCP map. An extremal TCP map is a TCP map that cannot be expressed as a convex combination of other TCP maps. Choi[11] has proved that an extremal TCP map with input dimension d has at most d operation elements in its operator-sum representation. This result will allow us to upper bound the dimensions of the optimal purifying Hilbert spaces, as stated in the following lemma.

Lemma 1: Let ρ act on a Hilbert space of dimension $d_{AB}=d_Ad_B$. The minimum of Eq. (4) can always be achieved by a state ψ for which the dimension of A' is $d_{A'}=d_{AB}$ and the dimension of B' is $d_{B'}=d_{AB}^2$ (or vice versa).

Proof: We use the formulation of the entanglement of purification as an optimization of a TCP map in Eq. (7). Since the density matrix $\mu_{BB'}(\rho)$ is on $\mathcal{H}_{d_B}\otimes\mathcal{H}_{d_{AB}}$, the optimal map $\Lambda_{B'}$ maps $\mathcal{H}_{d_{AB}}$ into a space of some unspecified dimension. The optimal map $\Lambda_{B'}$ can be assumed to be extremal. Theorem 5 of Ref. 11 shows that an extremal TCP map $\Lambda:B(\mathcal{H}_{d_1})\to B(\mathcal{H}_{d_2})$ (Refs. 12 and 13) can be written with at most d_1 operations elements, that is, has the form

$$\Lambda(\rho)=\sum_{i=1}^{d_1} V_i\rho V_i^\dagger. \tag{11}$$

In our case $d_1=d_{AB}$. Consider implementing the TCP map by applying a unitary operation U to the input state with an ancilla appended. In our case, this ancilla can be taken as Alice's purifying system A', and U acts on $A'B'$. The dimension of the ancilla A' can always be taken to be the number of operation elements. Thus we have $d_{A'}=d_{AB}$. The B' dimension is equal to the output dimension d_2 of the optimal map Λ, which is unconstrained by the extremality condition. However, we note that the operator $\Lambda(\rho)$ of Eq. (11) has a rank of at most d_{AB}^2. This is obtained by observing that the range of this operator is exactly that of the vectors given by all the columns of the matrices V_i for all i (the V_i matrices have d_1 columns and d_2 rows). Thus, there exists a unitary operator U that permits the construction of a new map $\Lambda'=U\Lambda$ whose output is confined

to the first d_1^2 dimensions of the output space. The operator U may be obtained explicitly via a Gram–Schmidt procedure applied to the column vectors of the V_i matrices. Λ' is also optimal, since the entropy of Eq. (7) is not changed by a unitary operation. Since the output space of Λ' has dimension d_1^2, we conclude that $d_{B'}$ can be taken to be $d_{B'}=d_{AB}^2$. □

It is interesting to note that a similar minimization problem was encountered in Ref. 14. There the goal was to use a set of noisy states for classical information transmission and we wanted to minimize the coherent information divided by the entropy of a quantum state under the action of a local map.

Theorem 1 (continuity of the entanglement of purification): *Let ρ and σ be two density matrices on $\mathcal{H}_{d_A}\otimes\mathcal{H}_{d_B}$ with Bures distance $D(\rho,\sigma)\leqslant\epsilon$. Then*

$$|E_p(\rho)-E_p(\sigma)|\leqslant 20D(\rho,\sigma)\log d_{AB}-D(\rho,\sigma)\log D(\rho,\sigma), \tag{12}$$

for small enough ϵ.

Proof: Let $|\psi'_\sigma\rangle$ and $|\psi'_\rho\rangle$ be the purifications of ρ and σ which achieve the maximum[5] in

$$F(\rho,\sigma)=\max_{\psi_\sigma,\psi_\rho}|\langle\psi_\sigma|\psi_\rho\rangle|. \tag{13}$$

Let $|\phi_\rho\rangle$ and $|\phi_\sigma\rangle$ correspond to the optimal purifications of ρ and σ with respect to E_p. There exists a unitary transformation U relating $|\psi'_\rho\rangle$ to $|\phi_\rho\rangle$, i.e., $(U\otimes\mathbf{1})|\psi'_\rho\rangle=|\phi_\rho\rangle$. We define the (nonoptimal) purification $|\psi_\sigma\rangle$ as $(U\otimes\mathbf{1})|\psi'_\sigma\rangle=|\psi_\sigma\rangle$. Now we have

$$E_p(\sigma)-E_p(\rho)=E(|\phi_\sigma\rangle\langle\phi_\sigma|)-E(|\phi_\rho\rangle\langle\phi_\rho|)\leqslant E(|\psi_\sigma\rangle\langle\psi_\sigma|)-E(|\phi_\rho\rangle\langle\phi_\rho|). \tag{14}$$

We use continuity of entanglement,[15,16] Lemma 1 (which indicates that the pure state has support on a space of dimension at most d_{AB}^4), and the fact that $|\langle\psi_\sigma|\phi_\rho\rangle|=|\langle\psi'_\sigma|\psi'_\rho\rangle|=F(\rho,\sigma)$ to bound

$$E_p(\sigma)-E_p(\rho)\leqslant 5D(\rho,\sigma)\log d_{AB}^4-2D(\rho,\sigma)\log D(\rho,\sigma) \tag{15}$$

for small enough $D(\rho,\sigma)$. We can obtain the full bound in Eq. (12) by alternatively relating $|\psi'_\sigma\rangle$ to the optimal purification $|\phi_\sigma\rangle$ by a unitary transformation U. □

It is fairly straightforward to prove monotonicity of the entanglement of purification from monotonicity of entanglement:

Lemma 2 (monotonicity of the entanglement of purification): The entanglement of purification of a density matrix ρ is nonincreasing under strictly local operations. Let Alice carry out a local TCP map $\mathcal{S}_A$ on the state ρ. We have

$$E_p((\mathcal{S}_A\otimes\mathbf{1})(\rho))\leqslant E_p(\rho). \tag{16}$$

Let Alice carry out a local measurement on ρ through which she obtains the state ρ_i with probability p_i. We have

$$\sum_i p_i E_p(\rho_i)\leqslant E_p(\rho). \tag{17}$$

Let $\mathcal{L}_{LOq}$ be a local operation assisted by m qubits of communication. The entanglement of purification obeys the equation

$$E_p(\mathcal{L}_{LOq}(\rho))\leqslant E_p(\rho)+m. \tag{18}$$

Proof: Let $|\psi_\rho\rangle$ be the optimal purification of ρ. This optimal purification is related to *some* purification of $(\mathcal{S}_A\otimes\mathbf{1})(\rho)$ by a unitary transformation on Alice's system only. Then Eq. (16) follows from the fact that entanglement is nonincreasing under local partial traces. The state

$|\psi_i\rangle = A_i \otimes I_B |\psi\rangle / \sqrt{\langle\psi|A_i^\dagger A_i \otimes I_B|\psi\rangle}$, where A_i corresponds to a measurement outcome of Alice, is some purification of ρ_i. The entanglement is nonincreasing under local operations and thus

$$E_p(\rho) = E(|\psi_\rho\rangle\langle\psi_\rho|) \geqslant \sum_i p_i E(|\psi_i\rangle\langle\psi_i|) \geqslant \sum_i p_i E_p(\rho_i). \tag{19}$$

For the last inequality, let Alice and Bob start with the entangled state $|\psi_\rho\rangle$ and carry out their LOq protocol. By subadditivity of entropy, the entanglement of this state can increase by at most m bits when m qubits of communication are sent (back and forth). Thus the entanglement of the final state which is some purification of $\mathcal{L}_{LOq}(\rho)$ is smaller than or equal to $E_p(\rho)+m$. □

Now we are ready to prove our main theorem:

Theorem 2: *The entanglement cost of ρ on $\mathcal{H}_d \otimes \mathcal{H}_d$ without classical communication equals* $E_{LOq}(\rho) = E_p^\infty(\rho)$.

Proof: The inequality $E_{LOq}(\rho) \leqslant E_p^\infty(\rho)$ uses entanglement dilution. Let k be the number of copies of ρ for which the regularized entanglement of purification E_p^∞ is achieved. One way of making many (p) copies of $\rho^{\otimes k}$ out of EPR pairs and $o(p) \leqslant o(pk)$ classical communication is to first perform entanglement dilution on the EPR pairs so as to create (an approximation to) the purification $|\psi\rangle^{\otimes p}$ and then trace over the additional registers to get $\rho^{\otimes kp}$. The other inequality $E_p^\infty(\rho) \leqslant E_{LOq}(\rho)$ can be proved from monotonicity and continuity of the entanglement of purification. We start with n EPR pairs which have E_p equal to n. The LOq process for creating an approximation $\tilde{\rho}_k$ to $\rho^{\otimes k}$ using $o(k)$ qubits of communication increases the entanglement of purification by at most $o(k)$ bits, see Lemma 2, or $E_p(\tilde{\rho}_k) \leqslant n + o(k)$. Using the continuity of Theorem 1 and dividing the last inequality by k and taking the limit $k \to \infty$ gives $E_p^\infty(\rho) \leqslant E_{LOq}(\rho)$. □

III. MUTUAL INFORMATION LOWER BOUNDS

The entanglement cost E_{LOq} is a measure of the quantum and classical correlations in a quantum state. The quantum and classical mutual information of a quantum state are similar measures that capture correlations in a quantum state. How do these measures relate to the new correlation measure? The quantum mutual information $I_q(\rho_{AB})$ is defined as

$$I_q(\rho_{AB}) = S(\rho_A) + S(\rho_B) - S(\rho_{AB}). \tag{20}$$

We define the classical mutual information of a quantum state $I_c(\rho_{AB})$ as

$$I_c(\rho_{AB}) = \max_{M_A : p_A, M_B : p_B} H(p_A) + H(p_B) - H(p_{AB}). \tag{21}$$

Here local measurements M_A and M_B give rise to local probability distributions p_A and p_B. The classical mutual information of a quantum state is the maximum classical mutual information that can be obtained by local measurements by Alice and Bob. Both quantum as well as classical mutual information share the important property that they are nonincreasing under local operations (LO) by Alice and Bob. For the classical mutual information, this basically follows from the definition Eq. (21). The definition itself as a maximum over local measurements makes sense since the classical mutual information of a probability distribution is nonincreasing under local manipulations of the distribution. The proof of this well known fact is analogous to the proof for the quantum mutual information which we will give here for completeness.

We can write the quantum mutual information as

$$I_q(\rho_{AB}) = S(\rho_{AB} || \rho_A \otimes \rho_B), \tag{22}$$

where $S(.||.)$ is the relative entropy. The relative entropy is nonincreasing under any map Λ (cf. Ref. 17), i.e.,

$$S(\Lambda(\rho_{AB})||\Lambda(\rho_A\otimes\rho_B))\leqslant S(\rho_{AB}||\rho_A\otimes\rho_B). \tag{23}$$

When Λ is of a local form, i.e., $\Lambda_A\otimes\Lambda_B$, the lhs of this equation equals the quantum mutual information of the state $(\Lambda_A\otimes\Lambda_B)(\rho_{AB})$ and thus the inequality $I_q((\Lambda_A\otimes\Lambda_B)(\rho_{AB}))\leqslant I_q(\rho_{AB})$ is proved.

Proof of lower bounds

We show that the quantities $I_q(\rho)/2$ and the regularized classical information $I_c^\infty(\rho)=\lim_{n\to\infty}(I_c(\rho^{\otimes n})/n)$ are both lower bounds for the entanglement cost E_{LOq}. The argument is similar to the proof of the E_p^∞ lower bound on E_{LOq} in Theorem 2. [The reasoning is in fact a special case of Theorem 4 in Ref. 18 (cf. Ref. 19) applied to the class LOq instead of the original LOCC.]

We start with a number, say k, of EPR pairs which have $I_q=2k$ and I_c equal to k.[20] In the limit of large n, the ratio k/n is the entanglement cost $E_{LOq}(\rho)$. We apply the LOq map $\mathcal{L}$ which uses $o(n)$ communication to obtain an approximation $\tilde{\rho}_n$ to $\rho^{\otimes n}$. Since the quantum mutual information and the classical mutual information can only increase by $o(n)$ by the process $\mathcal{L}$ applied to the initial EPR pairs, see Lemma 3, it follows that

$$I_q(\tilde{\rho}_n)\leqslant o(n)+2k, \tag{24}$$

and similarly

$$I_c(\tilde{\rho}_n)\leqslant o(n)+k. \tag{25}$$

The last step is to relate the mutual informations of $\tilde{\rho}_n$ to the mutual information of $\rho^{\otimes n}$. For this, we need a continuity result of the form

$$|I_{q/c}(\sigma)-I_{q/c}(\rho)|\leqslant C\log d\|\rho-\sigma\|_1+O(1) \tag{26}$$

for ρ, σ on $\mathcal{H}_d$, $\|\rho-\sigma\|_1$ sufficiently small and C is some constant.[21] Below we will prove these desired continuity results. We can divide Eqs. (24) and (25) by n and take the limit of large n. We use the continuity relation of Eq. (26) and the fact that in the large n limit $\tilde{\rho}_n$ tends to $\rho^{\otimes n}$. Thus we have

$$\lim_{n\to\infty}\frac{I_q(\rho^{\otimes n})}{n}=I_q(\rho)\leqslant 2E_{LOq}(\rho), \tag{27}$$

where we used that the quantum mutual information is additive, and similarly

$$I_c^\infty(\rho)\leqslant E_{LOq}(\rho). \tag{28}$$

What remains is to prove the continuity relations and the nonincrease modulo $o(n)$ under LOq operations.

Continuity of mutual information

The continuity of the quantum mutual information $I_q(\rho)$ can be proved by invoking Fannes' inequality[22] and Ruskai's proof of nonincrease of the trace-distance under TCP maps.[23] Let ρ and σ be two density matrices which are close, i.e., $\|\rho-\sigma\|_1=\mathrm{Tr}|\rho-\sigma|\leqslant\epsilon$ for sufficiently small ϵ. We have

$$|I_q(\rho_{AB})-I_q(\sigma_{AB})|\leqslant|S(\rho_A)-S(\sigma_A)|+|S(\rho_B)-S(\sigma_B)|+|S(\sigma_{AB})-S(\rho_{AB})|, \tag{29}$$

which can be bounded as

$$|I_q(\rho_{AB})-I_q(\sigma_{AB})|\leqslant 3\log d_{AB}\|\rho_{AB}-\sigma_{AB}\|_1+3\,\eta(\|\rho_{AB}-\sigma_{AB}\|_1), \tag{30}$$

where $\eta(x)=-x\log x$ and $\|\rho-\sigma\|_1\leqslant\frac{1}{3}$.

It is not hard to prove the continuity of the classical information of a quantum state, again using the nonincrease of $\|.\|_1$ under TCP maps. Let M_A^ρ and M_B^ρ be the optimal measurement achieving the classical mutual information $I_c(\rho)$. Under this measurement the states ρ and σ, which is, say, close to ρ, go to probability distributions $p^\rho(i,j)$ and $p^\sigma(i,j)$ which are close again, i.e., $\|p^\rho-p^\sigma\|_1\leqslant\|\rho-\sigma\|_1$. We have that

$$I_c(\sigma)-I_c(\rho)\leqslant I(p^\sigma)-I(p^\rho)\leqslant\log k\|p^\rho-p^\sigma\|_1+O(1), \tag{31}$$

where k is the number of joint outcomes in the optimal measurement (M_A^ρ,M_B^ρ) and I is the classical mutual information of a joint probability distribution. The last inequality in Eq. (31) could in principle be derived from Fannes' inequality, using diagonal matrices, but it is a standard continuity result in information theory[24] as well. To finish the argument, we should argue that k, the number of joint measurement outcomes, is bounded. The classical mutual information I is a concave function of the joint probability $p(i,j)$.[24] Therefore only extremal measurements M_A and M_B need to be considered in the optimization over measurements. An extremal measurement has at most d^2 outcomes when acting on a space of dimension d (Ref. 25) and thus $k\leqslant d_{AB}^2$. The same argument, interchanging σ and ρ, can be used to upperbound $I_c(\rho)-I_c(\sigma)$.

Lemma 3 (monotonicity properties of mutual information): Let $\mathcal{L}$ consist of a series of local operations assisted by m qubits of two-way communication. The quantum mutual information obeys the inequality

$$I_q(\mathcal{L}(\sigma))\leqslant I_q(\sigma)+2m, \tag{32}$$

for all states σ. For the classical mutual information we have

$$I_c(\mathcal{L}(|\psi\rangle\langle\psi|)\leqslant I_c(|\psi\rangle\langle\psi|)+m, \tag{33}$$

for all pure states $|\psi\rangle$.

Proof: Let us first consider the quantum mutual information. We can decompose the two-way scheme $\mathcal{L}$ into a sequence of one-way schemes. It is sufficient to prove for such a one-way scheme using m qubits of communication, say from Alice to Bob, that

$$I_q(\mathcal{L}(\sigma))\leqslant I_q(\sigma)+2m. \tag{34}$$

Alice's local action can consist of adding an ancilla A' in some state and apply a TCP map to the systems AA' thus obtaining the state $\sigma_{AA':B}$. Such an action does not increase the quantum nor classical mutual information as we showed before. Now Alice sends system A' to Bob. We have

$$\begin{aligned} I_q(\sigma_{AB})\geqslant I_q(\sigma_{AA':B}) &= S(AA')+S(B)-S(AA'B)\\ &\geqslant S(AA')-S(A')+S(BA')-S(AA'B)\\ &\geqslant S(A)-2S(A')+S(BA')-S(AA'B)\\ &= I_q(\sigma_{A:BA'})-2S(A'), \end{aligned} \tag{35}$$

where we used $|S(A)-S(B)|\leqslant S(AB)\leqslant S(A)+S(B)$. The quantum mutual information of the final state is $I_q(\sigma_{A:BA'})$. Since $S(A')\leqslant m$, we obtain the needed inequality. Alice could send only a part of ancilla A', but this does not change the bound.

Let us now consider the classical mutual information. We may convert the entire process $\mathcal{L}$ into a coherent process $\mathcal{L}$ where all the measurements are deferred to the end; this does not change the amount of communication that Alice and Bob carry out. Thus, prior to the measurements Alice and Bob have converted the pure state $|\psi\rangle$ into some pure state $|\phi\rangle$ whose local entropy is at most $E+m$ where E is the entanglement of the state $|\psi\rangle$, which is equal to $I_c(|\psi\rangle\langle\psi|)$ (see Ref. 20). Now Alice and Bob locally measure and/or trace out some registers which are operations that do

not increase the classical mutual information. Therefore the final state $\mathcal{L}(|\psi\rangle\langle\psi|)$ has a classical mutual information that is bounded by the initial classical mutual information plus m. □

Remark: Note that Eq. (32) for the quantum mutual information applies to both pure and mixed states while we have found mixed states that violate Eq. (33) for the classical mutual information.

Let us state the final result once more:

Corollary 1: $E_{LOq}(\rho) \geq I_q(\rho)/2$ *and* $E_{LOq} \geq I_c^{\infty}(\rho)$.

With this corollary we can show that the LOq-entanglement cost of any correlated density matrix ρ is nonzero.[26] Indeed, the quantum mutual information $I_q(\rho)$ of a correlated density matrix is strictly larger than zero, since $S(\rho_{AB})$ is strictly less than $S(\rho_A)+S(\rho_B)$ (equality is only obtained when $\rho_{AB}=\rho_A \otimes \rho_B$) and therefore $E_{LOq}(\rho)>0$.

We present a simple example for which $E_{LOq}(\rho)=E_p^{\infty}(\rho)>I_q(\rho)/2$.

Example 1 (All correlation is classical correlation): Consider the separable state $\rho = \Sigma_i p_i |a_i\rangle\langle a_i| \otimes |b_i\rangle\langle b_i|$ *where* $\langle a_i|a_j\rangle = \delta_{ij}$ *and* $\langle b_i|b_j\rangle = \delta_{ij}$. *In this case* $I_q(\rho)/2 = H(p)/2$. *However, we can show that* $E_p(\rho) \geq H(p)$. *We have* [*cf. Eq. (8)*] $\mu(\rho) = \Sigma_i p_i |b_i\rangle\langle b_i| \otimes |i\rangle\langle i|$. *Under some local TCP map* Λ *we obtain a state* $\mu' = \Sigma_i p_i |b_i\rangle\langle b_i| \otimes \rho_i$ *where* ρ_i *are density matrices. The entropy of* μ' *equals* $S(\mu') = \Sigma_i p_i S(\rho_i) + H(p) \geq H(p)$. *The entanglement of purification* $E_p(\rho)$ *may be nonadditive, so we have to consider* $E_p(\rho^{\otimes n})$. *We have* $\mu(\rho^{\otimes n}) = \mu^{\otimes n}$ *and now* $\mu' = \Sigma_{i_1,\ldots,i_n} p_{i_1} \cdots p_{i_n} |i_1,\ldots,i_n\rangle\langle i_1,\ldots,i_n| \otimes \rho_{i_1,\ldots,i_n}$. *Again the von Neumann entropy of* μ' *is larger than or equal to* $nH(p)$. *Note that in this example we do achieve the classical mutual information lower bound.*

Here is an example where the upper and lower bounds fix the (regularized) entanglement of purification:

Example 2: Let ρ *be an equal mixture of the state* $|\Psi_0\rangle = (1/\sqrt{2})(|00\rangle + |11\rangle)$ *and* $|\Psi_1\rangle = (1/\sqrt{2})(|00\rangle - |11\rangle)$. *Alice and Bob can get one bit of classical mutual information by both measuring in the* $\{0,1\}$ *basis. Thus* $E_{LOq}(\rho) \geq I_c(\rho) = 1$, *but* $E_{LOq}(\rho) \leq S(\rho_A) \leq 1$, *Eq. (10). Therefore* $E_{LOq} = 1$.

IV. OTHER CORRELATION MEASURES: THE LOCALLY INDUCED HOLEVO INFORMATION

In Ref. 1 the authors considered the locally induced Holevo information as a measure of classical correlations in the state. It is defined either with respect to Alice's measurement (C_A) or Bob's measurement (C_B)

$$C_{A/B}(\rho) = \max_{M_A/M_B} S\left(\sum_i p_i^{B/A} \rho_i^{B/A}\right) - \sum_i p_i^{B/A} S(\rho_i^{B/A}), \tag{36}$$

where $M_A(M_B)$ on ρ gives reduced density matrices $\rho_i^B(\rho_i^A)$ with probability $p_i^B(p_i^A)$. The classical mutual information $I_c^{\infty}(\rho)$ will in general be less than these quantities, since to achieve the Holevo information one may have to do coding. In Ref. 1 it was shown that $C_{A/B}$ are nonincreasing under local operations. We leave it as an exercise for the reader to prove continuity and nonincrease modulo $o(n)$ under LOq operations (applied to some pure state), thus showing that the regularized versions of these two quantities are also lower bounds for E_{LOq}.

Bell-diagonal states

We show that for Bell-diagonal states ρ_{Bell} the quantity C_A (equal to C_B by symmetry of the Bell-diagonal states) is equal to the classical capacity of the corresponding qubit channels. By the previous arguments this give us some lower bounds on the regularized entanglement of purification of these states. The Bell-diagonal states are of the following form,

$$\rho_{\text{Bell}} = \sum_i p_i |\Psi_i\rangle\langle\Psi_i|, \tag{37}$$

where $\Psi_{0\ldots3}$ are the four Bell states where $|\Psi_0\rangle$ is $(1/\sqrt{2})(|00\rangle+|11\rangle)$. The corresponding channel, the so called generalized depolarizing channel, or Pauli channel, is of the form

$$\Lambda_\rho(\cdot)=\sum_i p_i\sigma_i(\cdot)\sigma_i, \tag{38}$$

where $\sigma_0=\mathbf{1}$, and $\sigma_{1,2,3}$ are the three Pauli matrices. It is known[27] that all two qubit states with maximally mixed subsystems are Bell-diagonal, up to a unitary transformation $U_A\otimes U_B$. From the isomorphism between states and channels,[8,11,28] it follows that all unital channels are of the form (38) (cf. Ref. 29), up to unitary transformations applied before and after the action of the channel. The classical one-shot capacity of the quantum channel Λ is given by[30,31]

$$C_1(\Lambda)=\sup_{\{q_i,\rho_i\}}\chi(\{q_i,\Lambda(\rho_i)\}), \tag{39}$$

where χ is the Holevo function of the ensemble

$$\chi(\{q_i,\rho_i\})=S\left(\sum_i q_i\rho_i\right)-\sum_i q_iS(\rho_i). \tag{40}$$

The optimal states ρ_i that achieve the capacity C_1 are always pure states, moreover it can be shown[29] that the ensemble $\{q_i,|\psi_i\rangle\}$ that achieves C_1 for unital one-qubit channels satisfies

$$\sum_i q_i|\psi_i\rangle\langle\psi_i|=\frac{1}{2}\mathbf{1}. \tag{41}$$

Let us argue that $C_A(\rho)=C_1(\Lambda)$ for a Bell-diagonal state $\rho_{\mathrm{Bell}}=(\mathbf{1}_A\otimes\Lambda_\rho)(|\Psi_0\rangle\langle\Psi_0|)$. Alice's POVM measurement on this state commutes with the channel Λ_ρ. By doing a measurement on $|\Psi_0\rangle$ she can create any pure-state-ensemble on system B, obeying the relation Eq. (41). This ensemble is then sent through the channel Λ_ρ. If the ensemble is optimal for C_1, then its Holevo information χ equals C_1 and thus $C_A=C_1$.

For unital one-qubit channels C_1 is given by[29,32]

$$C_1(\Lambda)=1-\min_\psi S(\Lambda(|\psi\rangle\langle\psi|)). \tag{42}$$

We can perform the minization in the last inequality and we obtain the following formula for the capacity of a Pauli channel or the induced Holevo information of the Bell-diagonal states,

$$C_A(\rho_{Bell})=C_1(\Lambda_\rho)=1-H(1-\lambda), \tag{43}$$

where λ is the sum of the two largest probabilities p_i and $H(.)$ is the binary entropy function $H(x)=-x\log x-(1-x)\log(1-x)$. For two-qubit Werner states of the form

$$\rho_W=e|\Psi_0\rangle\langle\Psi_0|+(1-e)/3\sum_{i=1}^{3}|\Psi_i\rangle\langle\Psi_i|, \tag{44}$$

we obtain

$$\begin{aligned} C_A&=1-H\left(\frac{1+2e}{3}\right)\quad \text{for } e\in\left[\frac{1}{4},1\right],\\ C_A&=1-H\left(\frac{2-2e}{3}\right)\quad \text{for } e\in\left[0,\frac{1}{4}\right]. \end{aligned} \tag{45}$$

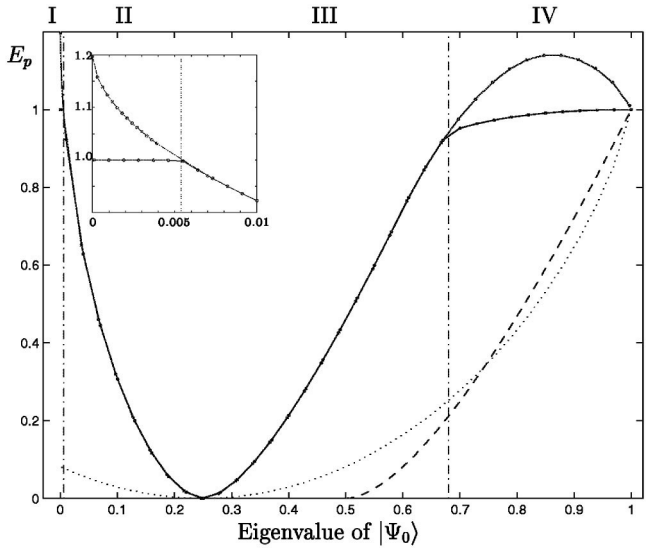

FIG. 1. Numerical bounds on E_p for Werner states. In the upper curve we restrict to $\dim(A')=\dim(B')=2$; for the next curve, we permit $\dim(A')=\dim(B')=4$. The inset shows the curious behavior of E_p around the point where the eigenvalue of $|\Psi_0\rangle$ approaches zero. The dotted curve is the C_A lower bound of Sec. IV A. The dashed curve is the entanglement of formation lower bound which vanishes when the eigenvalue is smaller than or equal to $\frac{1}{2}$.

It was shown by King[32] that the classical capacity of unital one-qubit channels is equal to the one shot capacity, or $C_1=C_1^{\infty}\equiv\lim_{n\to\infty}(1/n)\,C_1(\rho^{\otimes n})$. Therefore $C_A=C_A^{\infty}=C_1$, which is a lower bound on E_{LOq}.

V. WERNER STATES

A numerical minimization based on Eq. (6) was performed for the Werner states Eq. (44) for E_p. We plot the results as a function of the $|\Psi_0\rangle$ eigenvalue e in Fig. 1. We permitted various output dimensions; The two curves shown have $\dim(A')=\dim(B')=2$ and $\dim(A')=\dim(B')=4$. In the first case, the initial variable of the minimization was determined by a random 4×4 unitary $U_{A'B'}$ picked according to the Haar measure. In the second case, the initial point was determined by a random 16×4 isometry picked according to a parameterization derived from Ref. 33. We did not explore the largest dimensions permitted by Lemma 1, which would have required an optimization over a 64×4 isometry.

It is evident from the numerics presented in the figure that the C_A bound of Eq. (45) is not achieved for the Werner states: the C_A lower bound is only tight at the trivial points $e=\frac{1}{4}$ and $e=1$. Our results indicate that E_p is a very complex function, neither concave nor convex, with several distinct regimes. In fact, we find four different regimes in our numerics: (I) In this regime the standard purification of Eq. (5) appears to be optimal, so the U of Eq. (6) is the identity, and the purifying dimensions are $\dim(A')=1$ and $\dim(B')=4$. This regime only extends over a tiny range, approximately $0\leqslant e\leqslant0.005$. (II) In the range $0.005\leqslant e\leqslant0.25$ we find an optimal purification of the form

$$\sqrt{e}|\Psi_0\rangle_{AB}|\Psi_0\rangle_{A'B'}+\sqrt{\frac{1-e}{3}}(|\Psi_1\rangle_{AB}|\Psi_1\rangle_{A'B'}+|\Psi_2\rangle_{AB}|\Psi_2\rangle_{A'B'}+|\Psi_3\rangle_{AB}|\Psi_3\rangle_{A'B'}). \tag{46}$$

In this region the E_p curve is given by $E_p=-x\log x-(1-x)\log((1-x)/3)$, with $x=(1+2e-2\sqrt{3}\sqrt{e(1-e)})/12$. Here the purifying dimensions are $\dim(A')=2$ and $\dim(B')=2$. Of course E_p drops to zero for the completely mixed state at $e=\frac{1}{4}$. (III) In the range $0.25\leqslant e\leqslant0.69$ we also find purifying dimensions $\dim(A')=2$ and $\dim(B')=2$, but we were unable to determine the

analytical form of the purifying state or of E_p. (IV) In the range $0.69 \leqslant e \leqslant 1$ the purifying dimensions were $\dim(A')=2$ and $\dim(B')=3$. Again, we were unable to come to any analytical understanding of the result. Of course, $E_p=1$ for $e=1$, corresponding to the pure maximally entangled state.

VI. CONCLUSION

We have shown that the entanglement cost $E_{LOq}(\rho)$ is equal to the regularized entanglement of purification. It is an open question whether the entanglement of purification is additive:

$$E_p(\rho\otimes\rho) \stackrel{?}{=} E_p(\rho)+E_p(\rho). \tag{47}$$

In the alternative formulation using the state $\mu(\rho)$ the additivity question is the following. Is the minimum in

$$\min_{\Lambda_{CD}} S((I_{AB}\otimes\Lambda_{CD})(\mu_{AC}\otimes\mu_{BD})), \tag{48}$$

achieved by a TCP map $\Lambda_{CD}=\mathcal{S}\otimes\mathcal{S}$? This problem is similar again to the additivity question encountered in Ref. 14 where a local map could possibly lower the ratio of the coherent information and the entropy of many copies of a state together.

It is interesting not only to ask the formation question with respect to this class LOq, but also consider ''the distillation'' question. One can consider different versions. For example, how much entanglement can we distill from ρ using $o(n)$ communication? One would expect that this quantity $D_{LOq}(\rho)$ is always zero for states for which the entanglement cost E_c (using *LOCC*) is lower than the distillable entanglement D. We do not have a proof of this statement, relating irreversibility to a need for classical communication.

Instead of trying to convert the correlations in ρ back to entanglement, we may ask what classical correlations Alice and Bob can establish using ρ. We could allow Alice and Bob to perform an asymptotically vanishing amount of communication in this extraction process. A little bit of communication could potentially increase the classical mutual information in a quantum state by a large amount (when the classical correlation is initially ''hidden''), thus this may not be the best problem to pose. Researchers[34,35] have investigated the possibly more interesting problem of the *secret* key K that Alice and Bob can establish given ρ where one allows arbitrary public classical communication between the parties. There is again more than one version of this problem, one in which Eve possesses the purification of the density matrix[34] and a situation in which Eve is initially uncorrelated with the density matrix. In Ref. 36 a general framework is developed to address these issues also in the multipartite setting.

Quite recently, entanglement properties of bipartite density matrices were studied by looking at mixed extensions of the density matrix.[37] It would be interesting to explore the connection between our results here on the entanglement of purification and this other approach.

[20] One can prove that $I_c \leqslant k$ by observing that any local measurement that is not projecting in the Schmidt basis is a noisy version of the measurement that does project in the Schmidt basis. In other words, the probability distribution of any set of local measurements can be obtained from the probability distribution of the Schmidt basis measurement by local processing, which does not increase the classical mutual information.
[21] We can alternatively write down a continuity relation using the Bures distance. Since the trace distance $\|.\|_1$ and the Bures distance are equivalent distances, one continuity relation follows from the other and vice versa.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Conditional entropies and their relation to entanglement criteria

Karl Gerd H. Vollbrecht[a] and Michael M. Wolf[b]
Institute for Mathematical Physics, TU Braunschweig, Germany

(Received 12 February 2002; accepted for publication 16 May 2002)

We discuss conditional Rényi and Tsallis entropies for bipartite quantum systems of finite dimension. We investigate the relation between the positivity of conditional entropies and entanglement properties. It is in particular shown that any state having a negative conditional entropy with respect to any value of the entropic parameter is distillable since it violates the reduction criterion. Moreover, we show that the entanglement of Werner states in odd dimensions can neither be detected by entropic criteria nor by any other spectral criterion. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1498490]

I. INTRODUCTION

Entanglement has always been a key issue in the ongoing debate about the foundations and interpretation of quantum mechanics since Einstein[1] and Schrödinger[2] expressed their deep dissatisfaction about this astonishing part of quantum theory. Whereas for the long period from 1935 to 1964, until Bell[3] published his famous work, discussions about entanglement were purely meta-theoretical, nowadays quantum information theory has established entanglement as a physical resource and key ingredient for quantum computation and quantum information processing. This led to a dramatic increase of general structural knowledge about entanglement in the last few years, and the resource point of view often led to results that are reminiscent of those known from thermodynamics: *free entanglement* is distinguished from *bound entanglement*,[4] irreversibility can be observed in the process of preparing and distilling entangled states[5] and entanglement itself is defined in a way that it must not increase by means of local operations and classical communication (LOCC). Moreover, there is recent effort in order to quantify quantum correlations through heat engines.[6]

Entropies lay at the heart of both theories, thermodynamics and entanglement theory. Concerning the latter it was shown that a few reasonable assumptions lead to a unique measure of entanglement[7] for pure bipartite quantum states, which is just the *von Neumann entropy* of the reduced state. Hence, it is obvious that the two subsystems of a pure entangled state exhibit more disorder than the system as a whole, so that the respective conditional entropy is negative. This is a remarkable property of entangled states, which is impossible for classical systems (i.e., classical random variables).

The present article is primarily devoted to settling the relationship between the negativity of conditional Rényi and Tsallis entropies and other entanglement properties. We will in particular show how the property of having a positive conditional entropy enters into the known implication chain of entanglement, resp., separability criteria.

In the second part we will then follow the result of Nielsen and Kempe[8] and give examples of entangled states having the property that their entanglement can neither be detected by entropic criteria nor by any other spectral criterion. In Sec. IV we show that this is indeed the case for symmetric *Werner states* (in odd dimensions), which play a crucial role in entanglement theory.

II. PRELIMINARIES ON SEPARABILITY CRITERIA

To fix ideas we will start by recalling some of the basic notions and previous results concerning separability, resp., entanglement criteria.

A bipartite quantum state described by its density matrix ρ acting on a Hilbert space $\mathcal{H}=\mathcal{H}^{(A)}\otimes\mathcal{H}^{(B)}$ is said to be *separable*, unentangled or classically correlated if it can be written as a convex combination of tensor product states[9]

$$\rho=\sum_j p_j\rho_j^{(A)}\otimes\rho_j^{(B)}, \tag{1}$$

where the positive weights p_j sum up to one and $\rho^{(A)}$ ($\rho^{(B)}$) describes a state on $\mathcal{H}^{(A)}$ ($\mathcal{H}^{(B)}$). This means in particular that pure states are separable if and only if they are product states. Moreover, all entanglement properties of pure states, which can always be written in their Schmidt form (cf. Ref. 10) as $|\Psi\rangle=\Sigma_i\sqrt{\lambda_i}|i\rangle\otimes|i\rangle$, are completely determined by the eigenvalues $\{\lambda_i\}$ of the reduced state $\rho_A=\mathrm{tr}_B|\Psi\rangle\langle\Psi|$. The unique measure of entanglement for pure states is then given by the *von Neumann entropy* of the reduced state:

$$S_1(\rho_A)=-\mathrm{tr}(\rho_A\log\rho_A). \tag{2}$$

For mixed quantum states, however, the situation is much more difficult and deciding whether a state is entangled or separable is not yet feasible in general. Currently, the most efficient necessary criterion for separability is the positivity of the partial transpose (PPT), i.e., the condition that ρ^{T_A} has to be a positive semi-definite operator.[11] The partial transpose of the state is thereby defined in terms of its matrix elements with respect to some basis by $\langle kl|\rho^{T_A}|mn\rangle=\langle ml|\rho|kn\rangle$. For the smallest nontrivial systems with 2×2, resp., 2×3, dimensional Hilbert spaces and a few other special cases the PPT criterion also turned out to be sufficient.[12] In higher dimensional systems, however, so-called *bound entangled* states exist, which satisfy the PPT condition without being separable.[4]

Another well known condition is given by the *reduction criterion*[13,14]

$$\rho_A\otimes\mathbf{1}-\rho\geqslant0 \qquad \text{and} \qquad \mathbf{1}\otimes\rho_B-\rho\geqslant0, \tag{3}$$

which is implied by the PPT criterion but is nevertheless an important condition since its violation implies the possibility of recovering entanglement by distillation (which is yet unclear for PPT violating states). For the case of two qubits (and 2×3) the reduction criterion is also known to be sufficient for separability.[13,14] Moreover, it was shown in Ref. 15 that Eq. (3) implies that the rank of the reduced state has to be smaller than or equal to the rank of ρ. The general line of implication is then

$$\begin{array}{c}\rho \text{ separable}\\ \Downarrow\\ \rho^{T_A}\geqslant0\\ \Downarrow\\ \rho \text{ undistillable}\\ \Downarrow\\ \rho_A\otimes\mathbf{1}-\rho\geqslant0\wedge\mathbf{1}\otimes\rho_B-\rho\geqslant0\\ \Downarrow\\ \max[\mathrm{rank}(\rho_A),\mathrm{rank}(\rho_B)]\leqslant\mathrm{rank}(\rho).\end{array} \tag{4}$$

The last condition we want to mention was recently derived by Nielsen and Kempe[8] and is based on majorization. However, it is yet not known how the *majorization criterion* enters into the above implication chain. Since it is closely related to conditional entropies we will discuss it in more detail in the following section.

III. CONDITIONAL ENTROPIES

The idea to use entropic inequalities as separability, resp., entanglement, criteria for mixed states goes back to the mid-1990s when Cerf and Adami[16] and the Horodecki family[17] recognized that certain conditional Rényi entropies are non-negative for separable states, and it was recently resurrected by several groups[18–23] in the form of conditional Tsallis entropies.

The quantum *Rényi entropy* depending on the entropic parameter $\alpha \in \mathbb{R}$ is given by

$$S_\alpha(\rho) = \frac{\log \mathrm{tr}(\rho^\alpha)}{1-\alpha}, \tag{5}$$

where S_0, S_1, S_∞ reduce to the logarithm of the rank, the von Neumann entropy and the negative logarithm of the operator norm, respectively. For the case of separable states it was shown in Refs. 15–17 that the conditional entropy[24]

$$S_\alpha(B|A;\rho) := S_\alpha(\rho) - S_\alpha(\rho_A) \tag{6}$$

is non-negative for $\alpha = 0, \infty$ and $\alpha \in [1,2]$.

In Refs. 18 and 20 essentially the same criterion was expressed in terms of the *Tsallis entropy*

$$T_\alpha(\rho) = \frac{1-\mathrm{tr}(\rho^\alpha)}{\alpha-1}, \tag{7}$$

which is non-negative, concave (convex) for $\alpha > 0$ ($\alpha < 0$) and becomes the von Neumann entropy in the limit $\alpha \to 1$. The *conditional Tsallis entropy* defined in Ref. 18 reads

$$T_\alpha(B|A;\rho) := \frac{\mathrm{tr}(\rho_A^\alpha) - \mathrm{tr}(\rho^\alpha)}{(\alpha-1)\mathrm{tr}(\rho_A^\alpha)}. \tag{8}$$

Concerning positivity, however, the two conditional entropies are equivalent, i.e.,

$$T_\alpha(B|A;\rho) \geqslant 0 \Leftrightarrow S_\alpha(B|A;\rho) \geqslant 0, \tag{9}$$

which is in turn equivalent to $\mathrm{tr}(\rho_A^\alpha) \geqslant \mathrm{tr}(\rho^\alpha)$ for $\alpha > 1$, $\mathrm{tr}(\rho_A^\alpha) \leqslant \mathrm{tr}(\rho^\alpha)$ for $0 \leqslant \alpha < 1$, and the positivity of the conditional von Neumann entropy for $\alpha = 1$.

Obviously, for pure states the conditional entropies are negative if and only if the state is entangled.

A. Monotonicity counterexample

It was conjectured in Ref. 20 that $T_\alpha(B|A;\rho)$ is monotonically decreasing in α, such that it would be sufficient to calculate $T_\infty(B|A;\rho)$ in order to decide positivity. However, monotonicity does not hold in general and can most easily be ruled out by low rank examples like

$$\rho = \frac{1}{2}(|\Phi_+\rangle\langle\Phi_+| + |01\rangle\langle 01|), \quad |\Phi_+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle),$$

for which the reduced state has eigenvalues $\frac{1}{4}, \frac{3}{4}$ and therefore $T_0 = T_\infty = 0 \neq T_2 = \frac{1}{5}$. We note that similar counterexamples can be found for the monotonicity of the conditional Rényi entropy as well. Fortunately, however, monotonicity is not necessary for proving the positivity of the conditional Tsallis/Rényi entropies for separable states for other values than $\alpha = 0, \infty$, $\alpha \in [1,2]$.[25]

B. Majorization and convex functions

Majorization turned out to be a powerful tool in the discussion of quantum state transformations by means of LOCC operations (cf. Ref. 26), and it was recently proven to yield the strongest

separability criterion, which is based on the spectra of a state and one of its reductions. It was proven in Ref. 8 that any separable state ρ acting on $\mathbb{C}^d\otimes\mathbb{C}^d$ is majorized by its reduced state ρ_A:

$$\rho_A \succ \rho, \quad \text{i.e.,} \quad \forall k \leqslant d: \sum_{i=1}^{k} \lambda_i^{(A)} \geqslant \sum_{i=1}^{k} \lambda_i, \tag{10}$$

where $\{\lambda_i\}$ and $\{\lambda_i^{(A)}\}$ are the decreasingly ordered eigenvalues of ρ, resp., ρ_A.

It is a well known result in the theory of majorization that $x \succ y$ iff $\mathrm{tr}(f(x)) \geqslant \mathrm{tr}(f(y))$ for all convex functions $f:\mathbb{R}\to\mathbb{R}$.[27] Since $f(x)=x^\alpha$ is convex for $\alpha \geqslant 1$ and concave on $\mathbb{R}^+$ for $0 \leqslant \alpha \leqslant 1$ and the von Neumann entropy is concave (needed for $\alpha=1$), this immediately implies (cf. Ref. 28) the following.

Theorem 1: *Let ρ be a bipartite quantum state, which is majorized by its reduction $\rho_A \succ \rho$. Then for every $\alpha \geqslant 0$ the conditional Tsallis/Rényi entropies of ρ are non-negative, i.e.,*

$$S_\alpha(B|A;\rho) \geqslant 0 \quad \textit{and} \quad T_\alpha(B|A;\rho) \geqslant 0. \tag{11}$$

The result of Nielsen and Kempe implies that this holds in particular for any separable state.

It is yet not known how the majorization criterion (10) is related to other separability criteria like PPT, undistillability and the reduction criterion. However, we will show in the next subsection how the positivity of conditional entropies is related to these properties.

C. Conditional entropies and the reduction criterion

Positivity of the conditional entropies for $\alpha=0$ reduces to the rank criterion in the implication chain (4). The following theorem will show, however, that all the other properties stated in (4) in turn imply positivity of the conditional entropies for every value of the entropic parameter α.

Theorem 2: *Let ρ be a bipartite quantum state satisfying the reduction criterion $\rho_A\otimes\mathbf{1} \geqslant \rho$. Then for every $\alpha \geqslant 0$ the conditional Tsallis/Rényi entropies are non-negative*:

$$S_\alpha(B|A;\rho) \geqslant 0 \quad \textit{and} \quad T_\alpha(B|A;\rho) \geqslant 0. \tag{12}$$

We note that Theorem 2 implies, in particular, that states with negative conditional entropies are distillable.

Proof: We will divide the proof into three steps depending on the value of the entropic parameter.

For $\alpha > 1$ the proof is essentially based on the Golden–Thompson inequality (cf. Ref. 29) stating that

$$\mathrm{tr}(e^A e^B) \geqslant \mathrm{tr}(e^{A+B}) \tag{13}$$

for Hermitian matrices A,B. Utilizing the definition of the reduced state, i.e.,

$$\forall P \geqslant 0: \mathrm{tr}(\rho(P\otimes\mathbf{1})) \equiv \mathrm{tr}(\rho_A P), \tag{14}$$

this leads to

$$\begin{aligned}\mathrm{tr}(\rho_A^\alpha) &= \mathrm{tr}[\rho(\rho_A^{\alpha-1}\otimes\mathbf{1})] = \mathrm{tr}[\exp(\ln\rho)\exp((\alpha-1)\ln(\rho_A\otimes\mathbf{1}))] \\ &\geqslant \mathrm{tr}[\exp(\ln(\rho)+(\alpha-1)\ln(\rho_A\otimes\mathbf{1}))].\end{aligned} \tag{15}$$

At this point we need two monotonicity properties in order to exploit the validity of the reduction criterion. First of all we use the fact that the logarithm is operator monotone,[30] i.e.,

$$A \geqslant B \Rightarrow \ln A \geqslant \ln B. \tag{16}$$

Thus, for $\alpha > 1$ the reduction criterion $\rho_A\otimes\mathbf{1} \geqslant \rho$ implies

$$\ln(\rho)+(\alpha-1)\ln(\rho_A\otimes\mathbf{1})\geqslant\ln(\rho)+(\alpha-1)\ln(\rho)=\alpha\ln(\rho). \tag{17}$$

In the second step we utilize the fact that the exponential function is monotone under the trace. This can be seen by noting that for any A Hermitian, $P\geqslant 0$ and $B=(A+\epsilon P)$ with $\epsilon\geqslant 0$:

$$\frac{\partial}{\partial\epsilon}\mathrm{tr}(e^B)=\mathrm{tr}(e^B P)\geqslant 0. \tag{18}$$

Hence $\mathrm{tr}(e^B)\geqslant\mathrm{tr}(e^A)$ is implied by $B\geqslant A$. Combining (15) and (17), this leads to

$$\mathrm{tr}(\rho_A^\alpha)\geqslant\mathrm{tr}[\exp(\alpha\ln\rho)]=\mathrm{tr}(\rho^\alpha). \tag{19}$$

For $0\leqslant\alpha<1$ the reduction criterion can immediately be applied since $f(A)=A^r$ is an operator decreasing function for $-1\leqslant r\leqslant 0$, $A\geqslant 0$ (cf. Ref. 31) and thus

$$\mathrm{tr}(\rho_A^\alpha)=\mathrm{tr}[\rho(\rho_A^{\alpha-1}\otimes\mathbf{1})]\leqslant\mathrm{tr}(\rho^\alpha). \tag{20}$$

For the case $\alpha=1$ we have to look at the conditional von Neumann entropy $S_1(\rho)-S_1(\rho_A)$, for which positivity is directly implied by the reduction criterion and the operator monotonicity of the logarithm:

$$S_1(\rho_A)=-\mathrm{tr}\rho_A\log\rho_A \tag{21}$$

$$=-\mathrm{tr}\rho\log\rho_A\otimes\mathbf{1} \tag{22}$$

$$\leqslant-\mathrm{tr}\rho\log\rho \tag{23}$$

$$=S_1(\rho), \tag{24}$$

which completes the proof. □

D. Negative entropic parameters

So far we have only discussed conditional entropies for non-negative values of the entropic parameter α. For these cases we know that they can become negative for entangled states, the simplest examples being pure entangled states. However, for $\alpha<0$ (and states of full rank) the sign of the conditional entropy contains no information

Theorem 3: *Let ρ be a bipartite quantum state of full rank. Then for every $\alpha<0$ the conditional Tsallis/Rényi entropies are non-negative*:

$$\forall\,\alpha<0: S_\alpha(B|A;\rho)\geqslant 0 \quad \textit{and} \quad T_\alpha(B|A;\rho)\geqslant 0. \tag{25}$$

Proof: Let $\{|a\rangle\}$ be an eigenbasis of ρ_A. Then

$$\mathrm{tr}(\rho_A^\alpha)=\sum_a\langle a|\rho_A|a\rangle^\alpha \tag{26}$$

$$=\sum_a\left[\sum_i\langle a\otimes i|\rho|a\otimes i\rangle\right]^\alpha \tag{27}$$

$$\leqslant\sum_{a,i}\langle a\otimes i|\rho|a\otimes i\rangle^\alpha$$

$$\leqslant\mathrm{tr}(\rho^\alpha), \tag{28}$$

where Eqs. (27) and (28) use that $(\Sigma_i b_i)^\alpha \leqslant \Sigma_i b_i^\alpha$ holds for $b_i \geqslant 0$, $\alpha \leqslant 0$, and the last inequality is implied by the convexity of negative powers on $\mathbb{R}^+$.

IV. ISOSPECTRAL STATES

The fact that positivity of conditional entropies is implied by the reduction criterion (Theorem 2) shows already that such an entropic criterion cannot be sufficient for separability. In fact, it was shown in Ref. 8 that no spectral property is capable of distinguishing any entangled state from separable ones.

We will in this section follow the idea of Ref. 8 and construct particular examples of states, such that their entanglement cannot be detected by any spectral criterion, since there exist separable states having the same spectrum and the same reductions.

Werner states[9] have always played an important and paradigmatic role in quantum information theory. Their characteristic property is that they commute with all unitaries of the form $U \otimes U$ and they can be expressed as

$$\rho(p) = (1-p)\frac{P_+}{r_+} + p\frac{P_-}{r_-}, \quad 0 \leqslant p \leqslant 1, \tag{29}$$

where P_+ (P_-) is the projector onto the symmetric (antisymmetric) subspace of $\mathbb{C}^d \otimes \mathbb{C}^d$ and $r_\pm = \mathrm{tr}[P_\pm] = (d^2 \pm d)/2$ are the respective dimensions. Werner showed that these states are entangled iff $p > \frac{1}{2}$ independent of the dimension d. The following shows, however, that none of these entangled states for odd dimension d can be detected by any separability criterion, which is based on the spectrum of the state and its reductions.

Theorem 4: *Any entangled state in $\mathbb{C}^d \otimes \mathbb{C}^d$ with maximal chaotic reductions and eigenvalues having multiplicities, which are multiples of d, has a separable isospectral counterpart, which is locally undistinguishable as it has the same reductions.*

Proof: Let us consider a special basis of maximally entangled states in $\mathbb{C}^d \otimes \mathbb{C}^d$:[32]

$$|\Psi_{jk}\rangle = \frac{1}{\sqrt{d}} \sum_{n=1}^{d} \exp\left(\frac{2\pi i}{d} jn\right) |n, n \oplus k\rangle, \tag{30}$$

where $j,k = 1,\ldots,d$ and $\oplus$ means addition modulo d. Any equal weight combination of all states of the form (30), which belong to the same value of k, is then a projector onto a separable state since

$$\begin{aligned} P_k &= \sum_{j=1}^{d} |\Psi_{jk}\rangle\langle\Psi_{jk}| \\ &= \frac{1}{d} \sum_{j,n,m=1}^{d} \exp\left[\frac{2\pi i}{d} j(n-m)\right] |n, n\oplus k\rangle\langle m, m\oplus k| \\ &= \sum_{n=1}^{d} |n\rangle\langle n| \otimes |n\oplus k\rangle\langle n\oplus k| \end{aligned} \tag{31}$$

is an equal weight combination of product states. Here we have used that $(1/d)\,\Sigma_{j=1}^{d} \exp[(2\pi i/d)\, j(n-m)] = \delta_{n,m}$. Moreover, the reductions of the respective states P_k/d are maximally chaotic, i.e., $\rho_A = \mathbf{1}/d$, just as the reductions of any maximally entangled state.

If we now have a state with multiplicities being multiples of d, we can replace the projectors onto its eigenspaces with sufficiently many projectors of the form P_k. The resulting state will then be again a convex combination of product states, i.e., separable, having the same spectrum and maximal chaotic reductions. □

For the case of Werner states we note that the unitary invariance of the state $\rho(p)$ in Eq. (29) implies that its reductions are $\rho_A = \mathbf{1}/d$. Moreover, $\rho(p)$ has two eigenvalues $(1-p)/r_+$ and p/r_- with multiplicities r_+, r_- which are indeed multiples of d in odd dimensions.

Following Proposition 2 we can now construct a state

$$\rho'(p) = \frac{(1-p)}{r_+} \sum_{k=1}^{r_+/d} P_k + \frac{p}{r_-} \sum_{l=1}^{r_-/d} P_{l+r_+/d}, \tag{32}$$

which has then both, the same spectrum and the same reductions as $\rho(p)$. However, as a convex combination of separable states, it is itself separable for any $0 \leqslant p \leqslant 1$.

V. CONCLUSION

We discussed conditional Rényi and Tsallis entropies and the relation between their positivity and other separability properties. We showed in particular that states having a negative conditional entropy are distillable since they violate the reduction criterion.

Conditional entropies are a special instance of criteria using just the spectra of a state and its reductions. Concerning the detection of entanglement, it was shown in Ref. 8 that majorization is the strongest spectral criterion, which uses the spectra of a state and just one of its reductions. Its relation to other separability criteria is yet not known. The present result and numerical evidence may indicate that majorization is also implied by the reduction criterion. However, the proof presented in Sec. III C does not work for arbitrary convex functions and, in fact, majorization is not implied by the conditional entropy criteria.

Concerning separability, the most efficient criterion is still the PPT criterion, which is also a spectral criterion, however, for the partially transposed state. One interesting question in this context would therefore be: how can other (easy calculable) invariants provide information about the separability of a state, which is not yet encoded in the smallest eigenvalue of its partial transpose?

ACKNOWLEDGMENTS

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Parallel transport in an entangled ring

William K. Wootters
Department of Physics, Williams College, Williamstown, Massachusetts 01267

(Received 7 February 2002; accepted for publication 16 May 2002)

This article defines a notion of parallel transport in a lattice of quantum particles, such that the transformation associated with each link of the lattice is determined by the quantum state of the two particles joined by that link. We focus particularly on a one-dimensional lattice—a ring—of entangled *rebits*, which are binary quantum objects confined to a *real* state space. We consider states of the ring that maximize the correlation between nearest neighbors, and show that some correlation must be sacrificed in order to have nontrivial parallel transport around the ring. An analogy is made with lattice gauge theory, in which nontrivial parallel transport around closed loops is associated with a reduction in the *probability* of the field configuration. We discuss the possibility of extending our result to qubits and to higher dimensional lattices. © *2002 American Institute of Physics.*
[DOI: 10.1063/1.1499207]

I. INTRODUCTION

In lattice gauge theory, the gauge field assigns to every pair of neighboring lattice sites a transformation that tells how to ''transport'' a vector, representing an internal property such as quark color, from one site to the other. That is, with every ordered pair $\langle j,k\rangle$ of neighboring sites, or link, one associates a transformation $U(k,j)$ which is an element of the gauge group. Indeed, this assignment of transformations to links *constitutes* the configuration of the gauge field. If we apply $U(k,j)$ to a vector v associated with site j, we can interpret the image vector, $v' = U(k,j)v$, as the result of moving v from site j to site k. (It helps to read the arguments of U from right to left. This notation makes sense when combined with the usual notation for a sequence of operations, in which the operator on the right acts first.) This process is called parallel transport, and the transformation $U(k,j)$ is sometimes called a parallel transporter.

This article is not about lattice gauge theory but about actual lattices consisting of simple quantum particles, in which each particle is correlated with its nearest neighbors. As we will see later in this work, for typical states of the lattice, one can use the state itself to specify a notion of parallel transport. Our conception is distinct from the more familiar notion of quantum parallel transport (expressible in terms of gauge fields[1,2]), in which a quantum particle is physically moved either in actual space or in a parameter space.[2–4] In our approach there is no physical motion or evolution; rather, the transformation that we associate with a link expresses something about the relationship between the particles joined by that link. The present work is an initial exploration into a possible analogy between the quantum state of a lattice of quantum particles and the configuration of the gauge field in a lattice gauge theory. Roughly, the analogy we are looking for would be along the following lines (it will be spelled out more precisely in later sections of the article).

A lattice gauge theory assigns a probability distribution to the set of possible field configurations, the probability density of a configuration $\mathcal{A}$ being proportional to $\exp[-S(\mathcal{A})]$ where the real function $S(\mathcal{A})$ is the action. The action depends on the effect of parallel transport around each of the elementary plaquettes of the lattice; that is, it depends on the transformations that the field configuration associates with these elementary closed paths. The more these transformations differ from the identity, the higher the action, and therefore the lower the probability of that particular field configuration. Let us call this effect ''the probability cost of twisting.'' I am looking for something similar in a lattice of correlated quantum objects, but instead of a probability cost, I am

looking for a ''correlation cost.'' We will be focusing our attention on states in which nearest neighbors are maximally correlated. The question is whether this maximal correlation must be reduced if there is to be nontrivial parallel transport around closed loops (that is, transport whose net effect is not null), and, if so, whether the reduction in correlation becomes more severe as the effect of such parallel transport differs further from the identity. In other words, in an entangled lattice, is there a correlation cost of twisting?

In fact this article only begins to answer this question. Although we set up the problem for lattices of arbitrary dimension, the one concrete example we work out in detail is the case of a one-dimensional ring. Moreover, for most of the article we will restrict our attention to the simplest possible quantum object, namely, a *rebit*, a fictitious object whose state space is a two-dimensional vector space over the *real* numbers.[5] Thus we will mostly be analyzing a closed ring of rebits. At the end of the article I discuss the generalization to qubits and to higher-dimensional lattices.

This research is related to a recent line of work on ''entanglement sharing,'' concerning the ways in which quantum entanglement can be shared among several objects. A number of authors have found constraints on the sharing of entanglement that follow directly from the structure of quantum mechanics itself and not from any particular Hamiltonian. For example, it has been shown that any entanglement that might exist between a pair of qubits limits the extent to which either of them can be entangled with a third qubit.[6,7] There are similar limits for n qubits all entangled with each other.[8–10] Another example is an entangled ring: in a translationally invariant state of a ring of qubits, there is a certain maximum possible entanglement between nearest neighbors.[11] (The measure of entanglement used in all of these studies is the entanglement of formation.[12,13]) In this article we are putting a different sort of condition on the quantum state of a multipartite system—we are imposing a certain configuration of twists in the nearest-neighbor correlations—and we are asking what constraint this condition places on the strength of the correlations.

I hope that the results of this research will ultimately be useful in analyzing systems of entangled particles on a lattice, such as magnetic systems. If there are simple laws of quantum correlations that transcend any particular Hamiltonian, then these laws might lead to the identification of interesting generic properties of quantum many-body systems. Arguments along these lines, particularly focusing on entanglement, have appeared recently in the literature.[14–17] But at least as much of the actual motivation for the present work comes from pure curiosity: I wonder how close an analogy one can draw between the degree of correlation between particles in a quantum lattice and the probability density of a field configuration in lattice gauge theory. Of course there are many connections between lattice gauge theory and the theory of many-body systems—see, for example, Ref. 18 and references cited therein—but I am looking for an analogy along the particular lines traced out above.

The reader may have noticed that in describing the work to be presented here (as opposed to earlier work), I have been using the word ''correlation'' rather than ''entanglement.'' Though they are related, the two concepts are not the same. In this article I focus on correlation because it seems natural in this context and it is easy to work with. But it would also be interesting to explore the same questions using one of the standard measures of entanglement. I might add that the states we will primarily be concerned with are in fact highly entangled, hence the reference to an ''entangled ring'' in the title.

The article is organized as follows. First we review briefly those aspects of lattice gauge theory that have suggested our main question. We then define a rebit more precisely and develop our notion of parallel transport. We analyze in some detail the case of a ring of rebits and determine whether nontrivial parallel transport does indeed entail a ''correlation cost.'' Finally, we ask how the problem and the results are likely to change when extended to more complex systems.

II. LATTICE GAUGE THEORY AND A SIMPLE ANALOGY

Ideally, lattice gauge theory is done on a four-dimensional lattice representing space–time, except that the fourth dimension represents *imaginary* time, so that it acts in many respects like

another spatial dimension. The results of a calculation can be interpreted in terms of *real* time by means of analytic continuation. One consequence of the use of imaginary time is this: in computing the expectation value of an observable, one does not sum up complex amplitudes associated with different histories; rather, one takes a weighted average of the observable of interest using *real* weights.[19] As mentioned above, the weighting function is proportional to $\exp(-S)$, where the action S is a real function of the field configuration. More precisely, in a pure gauge theory, in which there are no matter fields but only the gauge field itself, the expectation value of an observable B is

$$\langle B\rangle = \frac{1}{Z}\int Be^{-S(\mathcal{A})}\prod_{\langle j,k\rangle} dU(k,j). \tag{1}$$

Here $\mathcal{A}$ is the configuration of the gauge field, which assigns a parallel transporter $U(k,j)$ to each link $\langle j,k\rangle$. Each such transformation U is an element of the gauge group, e.g., U(1) for electrodynamics or SU(3) for chromodynamics. The integral in Eq. (1) is over all field configurations, that is, over all possible parallel transporters for each link, and $dU(k,j)$ indicates the invariant measure over the gauge group. In the integral, the parallel transporters for different links are independent, except that $U(k,j)=U(j,k)^{-1}$, so that only one of these two ordered pairs needs to be represented in the integral. The normalizing constant Z is simply

$$Z = \int e^{-S(\mathcal{A})}\prod_{\langle j,k\rangle} dU(k,j). \tag{2}$$

The action S depends only on the results of parallel transport around plaquettes of the lattice, e.g., elementary squares in a cubic lattice. Let $\mathcal{P}$ be a plaquette, which we can think of as a sequence of lattice sites; for a cubic lattice $\mathcal{P}$ would consist of four sites j,k,l,m. Let $U(\mathcal{P})$ be the net effect of parallel transport around plaquette $\mathcal{P}$; in the square example, $U(\mathcal{P})$ would be $U(j,m)U(m,l)U(l,k)U(k,j)$ (the right-most operator acting first). S is defined so that it increases as the plaquette transformations $U(\mathcal{P})$ get farther from the identity. Various action functions with this property have been used in the literature; the one originally proposed by Wilson for an SU(N) gauge field is[20]

$$S \propto -\sum_{\mathcal{P}} \mathrm{Re}(\mathrm{Tr}(U(\mathcal{P}))), \tag{3}$$

where the sum is over all plaquettes in the lattice. Note that if $\mathcal{P}'$ consists of the same set of points as $\mathcal{P}$, but with a different starting point or with the points taken in the opposite order, then $\mathrm{Re}(\mathrm{Tr}(U(\mathcal{P}')))=\mathrm{Re}(\mathrm{Tr}(U(\mathcal{P})))$. Thus we need include in the above sum only one ordered set $\mathcal{P}$ representing each geometric plaquette.

A gauge transformation associates with each lattice point j a group element $\Lambda(j)$, and under such a transformation each parallel transporter $U(k,j)$ transforms according to

$$U(k,j)\rightarrow \Lambda(k)U(k,j)\Lambda(j)^{-1}. \tag{4}$$

It is easy to see that, though a gauge transformation changes the field configuration, it does not change any of the plaquette transformations $U(\mathcal{P})$. Therefore, it does not affect the action S and so has no physical consequences.

This invariance under gauge transformations provides a simple analogy between the configuration of a gauge field and the state of a lattice of quantum particles. Consider, for example, a lattice of qubits. Rotating each of the individual qubits separately is analogous to a gauge transformation. The state of the lattice changes under such rotations, but certain physical properties do not change. In particular, any reasonable measure of the degree of *entanglement* or *correlation* between two qubits does not change. So at least in this one modest respect, the degree of corre-

lation in a quantum lattice is similar to the action or the probability density of a field configuration in a lattice gauge theory. We want to see whether the similarity goes any further than this.

III. WHAT IS A REBIT?

As we have said, the quantum object we will mostly be concerned with in this article is the *rebit*. We now define this object more precisely.

A pure state $|\psi\rangle$ of a single rebit is simply a normalized vector in a two-dimensional real vector space. A mixed state of a rebit is a mixture of pure states:

$$\rho = \sum_i p_i |\psi_i\rangle\langle\psi_i|, \tag{5}$$

where $p_i > 0$ and $\Sigma_i p_i = 1$. Equivalently, a mixed state can be represented as a real, symmetric 2×2 matrix with unit trace and no negative eigenvalues.

Of course any rebit state is also a qubit state, and for our purposes it will be helpful to think of rebits simply as restricted qubits. On the Bloch sphere, the restriction to real density matrices becomes a restriction to the x-z plane. But it will be more useful to change the representation by rotating the Bloch sphere. Let us rotate all states by 90° in the left-handed sense around the positive x axis, so that our rebit states now lie in the x-y plane. A general mixed state lying in this plane can be written as

$$\rho = \tfrac{1}{2}[I + a\sigma_x + b\sigma_y], \tag{6}$$

where the σ's are Pauli matrices and the real numbers a and b satisfy $a^2 + b^2 \leqslant 1$. Let us call this representation of rebit states the ''horizontal representation,'' as opposed to the original ''real-number representation.'' Given a rebit density matrix ρ expressed in the horizontal representation, we can always reexpress it as a *real* density matrix ρ_{real} simply by reversing the rotation around the x axis:

$$\rho_{\text{real}} = U\rho U^\dagger, \tag{7}$$

where

$$U = e^{-i(\pi/4)\sigma_x} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & -i \\ -i & 1 \end{pmatrix}. \tag{8}$$

Here we have written the matrix in the basis of eigenstates of σ_z, $\{|\uparrow\rangle, |\downarrow\rangle\}$. Note that $U\sigma_y U^\dagger = \sigma_z$ and $U\sigma_x U^\dagger = \sigma_x$.

In the real-number representation, a pure state of n rebits is a real vector in 2^n dimensions, and a mixed state of such a system is a real, symmetric $2^n \times 2^n$ density matrix. But again we will usually work in the horizontal representation, in which each rebit has been rotated by 90° around the x axis. It will be helpful to have a simple way of recognizing whether a given n-qubit state is a legitimate n-rebit state expressed in the horizontal representation. Conceptually, the test is straightforward: apply the above transformation U to each qubit—that is, rotate each qubit by 90° (in the right-handed sense) around the positive x axis—and see whether the resulting state has only real components. Thus for a pure state $|\Psi\rangle$, we insist that $U^{\otimes n}|\Psi\rangle$ be real in the standard up–down basis. But this is the same as saying that $U^{\otimes n}|\Psi\rangle = (U^{-1})^{\otimes n}|\Psi^*\rangle$, where the asterisk indicates complex conjugation in the standard basis. Multiplying both sides of this equation by $U^{\otimes n}$ and noting that $U^2 = -i\sigma_x$, we arrive at the following criterion:

$$(-i\sigma_x)^{\otimes n}|\Psi\rangle = |\Psi^*\rangle. \tag{9}$$

In practice it will be simplest if we also allow ourselves to use state vectors of the form $\exp(i\alpha)|\Psi\rangle$, where α is real and $|\Psi\rangle$ satisfies Eq. (9). Though such state vectors do not become real when they are transformed by $U^{\otimes n}$, their density matrices do become real. Allowing this possibility leads to the following weaker condition on an n-qubit state $|\Psi\rangle$,

$$\sigma_x^{\otimes n}|\Psi\rangle = e^{i\beta}|\Psi^*\rangle, \tag{10}$$

β being any real phase. Note that the matrix σ_x simply interchanges $|\uparrow\rangle$ and $|\downarrow\rangle$. Thus we can recognize a pure n-qubit state $|\Psi\rangle$ as a legitimate horizontal representation of an n-rebit state by checking to see that the coefficient of each basis state, e.g., $|\uparrow\uparrow\downarrow\uparrow\rangle$, is the complex conjugate of the coefficient of the opposite state, in this case $|\downarrow\downarrow\uparrow\downarrow\rangle$, multiplied by a phase factor that is the same for all basis states. Let us call Eq. (10) the ''rebit condition'' for pure states. The corresponding test for mixed states can be obtained by a similar argument; one finds that a density matrix ρ of n qubits is the horizontal representation of a legitimate n-rebit state if and only if

$$\sigma_x^{\otimes n}\rho\sigma_x^{\otimes n} = \rho^*, \tag{11}$$

the complex conjugation again being in the standard basis.

We conclude this section with a word about *rotations* of a rebit. Viewing the states of a rebit as qubit states confined to the equatorial plane of the Bloch sphere, we could take as the allowed rotations all the unitary transformations that represent rotations around the z axis, that is, all transformations of the form

$$R = \begin{pmatrix} e^{i\alpha} & 0 \\ 0 & e^{i\beta} \end{pmatrix}. \tag{12}$$

However, our definition of parallel transport will not be able to distinguish unitary transformations that are different only by an overall phase factor; so we will call such transformations identical. For definiteness we pick a standard representative from each of the resulting equivalence classes: a rotation by an angle ξ around the z axis, with $0 \leqslant \xi < 2\pi$, will be represented by the matrix

$$R = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\xi} \end{pmatrix}. \tag{13}$$

IV. PARALLEL TRANSPORT IN A LATTICE OF REBITS

We now consider a lattice of rebits, on which we want to define a notion of parallel transport. For now the structure of the lattice does not matter, as long as any two rebits are identified as either being neighbors or not. Thus the lattice is simply a graph. The mathematical object that is to be parallel transported is a pure state of a single rebit, which we can picture as a direction in the horizontal plane. The parallel transporter associated with a link in the lattice will be a rebit rotation—represented in the form (13)—which we can identify with an element of U(1). We want the assignment of parallel transporters to links to be determined by the quantum state of the lattice itself.

We begin with the following scenario. Consider a pair of neighboring rebits labeled j and k. They are in some joint state $\rho^{(jk)}$, a 4×4 density matrix obtained from the state of the whole lattice by tracing over all the other particles. Imagine performing an arbitrary orthogonal measurement on particle j. In the standard von Neumann model this measurement brings particle j into a certain pure state—one of the eigenstates of the measurement—and it also brings particle k into some state, typically a mixed state, determined as follows. Let $|\psi^{(j)}\rangle$ be the eigenstate into which particle j is brought by the measurement. Then the postmeasurement state of particle k is the 2×2 density matrix

$$\omega^{(k)}=\frac{1}{P}\langle\psi^{(j)}|\rho^{(jk)}|\psi^{(j)}\rangle, \tag{14}$$

where $P=\langle\psi^{(j)}|\mathrm{Tr}_k\rho^{(jk)}|\psi^{(j)}\rangle$ is the probability with which that particular outcome occurs. In Eq. (14) the matrix operations are done only in the space of particle j. To be more explicit, if $r=0,1$ and $s=0,1$ are indices associated with particles j and k, respectively, we can write the components of $\omega^{(k)}$ in terms of the components of $|\psi^{(j)}\rangle$ and $\rho^{(jk)}$ as

$$\omega^{(k)}_{ss'}=\frac{1}{P}\sum_{r,r'}\psi^{(j)*}_r\rho^{(jk)}_{rs,r's'}\psi^{(j)}_{r'}. \tag{15}$$

We want to use this measurement scenario to associate with the two-particle state $\rho^{(jk)}$ a simple rotation $U(k,j)$. First, let $\mathcal{M}$ (for "measurement") be the mapping defined by Eq. (14), which takes each pure state of particle j for which $P\neq 0$ into a pure or mixed state of particle k; that is, $\mathcal{M}(\psi^{(j)})=\omega^{(k)}$. If $P=0$, let us say for definiteness that $\mathcal{M}(\psi^{(j)})=\mathrm{Tr}_j\rho^{(jk)}$, though it will not actually matter in what follows. For an arbitrary rebit rotation R, we define a function $F(R)$ by

$$F(R)=\frac{\int\langle\psi|R^\dagger\mathcal{M}(\psi)R|\psi\rangle P\,d\psi}{\int P\,d\psi}. \tag{16}$$

Here P is the probability given above, and $d\psi$ indicates the uniform measure over the circle of pure rebit states, normalized so that $\int d\psi=1$. Thus $F(R)$ is an average fidelity of $\mathcal{M}(\psi)$, not with respect to $|\psi\rangle$ itself but with respect to a rotated version of $|\psi\rangle$. As we will see in the next paragraph, depending on the density matrix $\rho^{(jk)}$, one of the following two conditions will hold: (i) $F(R)$ is independent of R or (ii) there is a unique rotation $R=U$ that maximizes $F(R)$. In case (i), we say that there is no correlation between particles j and k. In case (ii), we take the special rotation U that maximizes $F(R)$ to be the parallel transporter associated with the link $\langle j,k\rangle$. In a certain sense, U is the rotation that most closely approximates the action of $\mathcal{M}$.

Combining Eqs. (14) and (16) and the definition of P, we have

$$F(R)=\frac{\int(\langle\psi|\otimes\langle\psi|R^\dagger)\rho^{(jk)}(|\psi\rangle\otimes R|\psi\rangle)\,d\psi}{\int\langle\psi|\mathrm{Tr}_k\rho^{(jk)}|\psi\rangle\,d\psi}. \tag{17}$$

It is not hard to show that the denominator is always $\frac{1}{2}$. Also, in the horizontal representation, the integral in the numerator involves rotating $|\psi\rangle$ around the z axis, so that we can rewrite Eq. (17) as

$$F(R)=2(\langle\psi_0|\otimes\langle\psi_0|R^\dagger)\left[\frac{1}{2\pi}\int_0^{2\pi}e^{i\gamma S_z}\rho^{(jk)}e^{-i\gamma S_z}d\gamma\right](|\psi_0\rangle\otimes R|\psi_0\rangle), \tag{18}$$

where $S_z=(\sigma_z^{(j)}+\sigma_z^{(k)})/2$ and $|\psi_0\rangle$ is some fixed reference state which for definiteness we take to be $|\psi_0\rangle=(|\uparrow\rangle+|\downarrow\rangle)/\sqrt{2}$. Now, a general two-particle density matrix satisfying the rebit condition (11) is of the form

$$\rho^{(jk)}=\begin{pmatrix} a & x_1 & x_2 & x_3\\ x_1^* & b & c & x_2\\ x_2^* & c^* & b & x_1\\ x_3^* & x_2^* & x_1^* & a\end{pmatrix}, \tag{19}$$

the representation being in the standard basis $\{|\uparrow\uparrow\rangle,|\uparrow\downarrow\rangle,|\downarrow\uparrow\rangle,|\downarrow\downarrow\rangle\}$. The average over γ in Eq. (18) has the effect of replacing the x_i's in $\rho^{(jk)}$ with zero and leaving the matrix elements a, b, and c unchanged. To evaluate $F(R)$, we write R explicitly as a rotation around the z axis by some angle ξ:

$$R=\begin{pmatrix} 1 & 0 \\ 0 & e^{i\xi} \end{pmatrix}. \tag{20}$$

Inserting this matrix into Eq. (18) we find that

$$F(R)=\tfrac{1}{2}[1+2|c|\cos(\xi-\phi)], \tag{21}$$

where ϕ is the phase of the matrix element c; that is, $c=|c|e^{i\phi}$. If c is zero, then we find ourselves in case (i) mentioned above: $F(R)$ is independent of R. Otherwise F is maximized when the angle of rotation ξ is equal to the phase ϕ. According to our prescription, then, the parallel transporter $U(k,j)$ is the rotation given in Eq. (20) with $\xi=\phi$.

We will take as our measure of the degree of correlation between particles j and k the quantity $2|c|$, which ranges from 0 to 1. Equation (21) makes it clear that $2|c|$ measures the degree of angular correlation between the two particles. We can also interpret this quantity in terms of the more standard correlation matrix $\tau_{\mu\nu}=\mathrm{Tr}[\rho^{(jk)}(\sigma_\mu\otimes\sigma_\nu)]$, in which both μ and ν take as values the axis labels x and y. One finds that $(2|c|)^2=[(\tau_{xx}+\tau_{yy})^2+(\tau_{xy}-\tau_{yx})^2]/4=[2\det\tau+\mathrm{Tr}(\tau^T\tau)]/4$.

Note that the single complex number c determines both the parallel transporter (through its phase) and the degree of correlation (through its magnitude). Typically we will be trying to maximize the magnitude of c for a given value of its phase. The fact that it is possible for a link $\langle j,k\rangle$ to have an undefined parallel transporter $U(k,j)$ [case (i) above, where $c=0$] will not cause any difficulties for the problem we will be studying. We will be considering the set of all states that are consistent with a given specification of the parallel transporters, i.e., the phases of the c's. If a link has $c=0$, then we simply say that that link is consistent with any specified phase.

Our notion of parallel transport has a particularly simple interpretation if $\rho^{(jk)}$ has the form (19) with all the x_i's equal to zero. This will happen, for example, if the state of the lattice is invariant under identical rotations of all the rebits. If $\rho^{(jk)}$ has this form, then Eq. (14) yields

$$\omega^{(k)}=pU(k,j)|\psi^{(j)}\rangle\langle\psi^{(j)}|U(k,j)^\dagger+(1-p)(I/2), \tag{22}$$

where I is the 2×2 identity and $p=2|c|$. Thus the postmeasurement state of particle k is simply a rotated and partially depolarized version of $|\psi^{(j)}\rangle$, and the weight p of the pure rotated state is our measure of correlation.

Let us now imagine transporting, mathematically, a rebit state around a closed loop in accordance with the above prescription. As we will see, the final state in such a process need not be the same as the initial state but could be rotated by some angle θ. One might ask: How does one interpret physically this process of transport, and what is the meaning of the rotation angle θ? I regard our concept of parallel transport primarily as a mathematical notion; nothing is being physically transported. However, in the special case considered above, in which the state of the lattice is rotationally invariant, one can extract from our definition a simple physical interpretation of the net rotation angle. Consider a closed loop of n lattice sites $j_0,j_1,\ldots,j_{n-1}$. At each of the sites $j_0,\ldots,j_{n-2}$, that is, at all but the last site, perform an orthogonal measurement, with outcomes labeled "0" and "1," choosing the measurement at j_m so that it maximizes the probability of getting the same outcome (0 or 1) as at site j_{m-1}. That is, we are trying to minimize the expected number of flips from 0 to 1 or from 1 to 0 as we go around the loop. Now, at the last site, j_{n-1}, one is faced with a dilemma: there will be a measurement that maximizes the probability of agreement between j_{n-2} and j_{n-1}, and there will be a (possibly different) measurement that maximizes the probability of agreement between j_{n-1} and j_0. The angle between these two

measurements, that is, between their ''0'' eigenstates, is the angle θ associated with parallel transport around the loop. We can think of this angle as measuring the net ''twist'' in the nearest-neighbor correlations.

When the state of the lattice is not rotationally invariant, the angle between the two competing optimal measurements at the last site (the two being reckoned optimal from different directions) may depend on the choice of the initial measurement on the first particle. So the interpretation in this case is not as simple. Still, it is reasonable to think of the net rotation angle as a measure of the net twist in the correlations. In the following section where we analyze the case of a rebit ring, we will find that the optimal states, which are the states most relevant to our problem, are in fact rotationally invariant, so that the above interpretation applies.

V. ANALYSIS OF A REBIT RING

So far we have not made any assumptions about the structure of the lattice. In order to obtain a concrete result, we now specialize to the simplest possible lattice for which our general question can be addressed, namely, a closed one-dimensional ring. Let the ring consist of n rebits with $n \geqslant 2$, labeled by $j=0,1,\ldots,n-1$; the labeling is mod n, so that $j=n$ is the same as $j=0$. Let c_j be the matrix element c of Eq. (19) when the two particles in question are particles j and $j+1$. The quantity $K=(2/n)\,\Sigma_j|c_j|$ will be the measure of average nearest-neighbor correlation that we will be trying to maximize; note that $0\leqslant K\leqslant 1$. The product $\Pi_j(c_j/|c_j|)$, which we will call $e^{i\theta}$, is the net phase factor associated with transport around the whole ring, and θ (defined only mod 2π) is the net rotation angle. Our question is this: what is the maximum possible value of K for a fixed value of θ? Let us call this maximum value $K_{\max}(\theta)$. If $K_{\max}(\theta)$ decreases as $e^{i\theta}$ gets farther from unity, then we can say that there is a correlation cost associated with nontrivial parallel transport.

As we have stated the problem so far, the phases of the different c_j's, that is, the phases that define the individual parallel transporters, need not be the same for all links in the ring. However, for our purpose there is no loss of generality in assuming that these phases are all equal. This is because if they were not equal, we could always apply local rotations to the individual rebits (analogous to a gauge transformation) so as to make them equal. Local rotations can change neither the magnitude of any c_j nor the overall phase factor $e^{i\theta}$. So the restriction to equal phases does not eliminate any states that might change the answer to our question. That is, states with maximal K for any given θ are still represented in the restricted set.

With this restriction, we can simplify our problem by expressing the average correlation K and the overall phase θ in terms of creation and annihilation operators. Let a_j be an operator on particle j defined by $a_j|\uparrow\rangle=|\downarrow\rangle$ and $a_j|\downarrow\rangle=0$. Then for the link between the jth and the $(j+1)$st rebits, we can write c_j as

$$c_j=\mathrm{Tr}(\rho a_{j+1}^{\dagger}a_j), \tag{23}$$

ρ being the density matrix of the ring. Now if we define the operator Γ to be

$$\Gamma=\frac{1}{n}\sum_{j=0}^{n-1} a_{j+1}^{\dagger}a_j \tag{24}$$

and write $\langle\Gamma\rangle=\mathrm{Tr}\rho\Gamma$, it follows (assuming that each c_j has the same phase) that

$$K=2|\langle\Gamma\rangle|, \tag{25}$$

and that the overall phase θ (mod 2π) is simply

$$\theta=n\arg(\langle\Gamma\rangle). \tag{26}$$

Γ is not a Hermitian operator—so its eigenvalues may be complex and indeed must be complex if θ is to take any nontrivial value—but Γ does commute with its adjoint, which implies that eigenvectors corresponding to distinct eigenvalues are orthogonal. Note also that Γ commutes with

the total z component of spin; so the eigenstates of Γ can be taken to be states with a definite number u of up spins. Our immediate goal is to find the eigenvalues of Γ, from which we will be able to determine the set of possible values of $\langle\Gamma\rangle$, which in turn will give us $K_{\max}(\theta)$.

The a operators are not quite fermionic creation and annihilation operators, because the operators associated with different sites commute with each other rather than anticommute. However, we can use a standard trick[21] to define genuinely fermionic operators b_j:

$$b_j = \exp\left[i\pi \sum_{k=0}^{j-1} a_k^\dagger a_k \right] a_j . \tag{27}$$

The operators b_j satisfy the usual fermionic anticommutation relations:

$$\{b_j, b_k\} = \{b_j^\dagger, b_k^\dagger\} = 0; \quad \{b_j, b_k^\dagger\} = \delta_{jk} . \tag{28}$$

We now express Γ in terms of the b's. The expression depends on whether u, the number of up spins in the ring, is even or odd; that is, the expression is different in different subspaces. For odd values of u, Γ looks the same in terms of the b's as it does in terms of the a's:

$$\Gamma = \frac{1}{n} \sum_{j=0}^{n-1} b_{j+1}^\dagger b_j . \tag{29}$$

For even values of u, there is a sign change in the last term:

$$\Gamma = \frac{1}{n} \left[\sum_{j=0}^{n-2} b_{j+1}^\dagger b_j - b_0^\dagger b_{n-1} \right]. \tag{30}$$

In either case, we can diagonalize Γ and find its exact single-fermion eigenvalues. From these we can obtain the eigenvalues of Γ for an arbitrary value of u by summing u of the single-fermion eigenvalues.

For odd u, the single-fermion eigenstates of Γ are $|\omega_m\rangle = d_m^\dagger |0\rangle$, $m = 0, \ldots, n-1$, where $|0\rangle$ is the vacuum state, that is, the state with all spins down, and the creation operator $d_m^\dagger$ is given by

$$d_m^\dagger = \frac{1}{\sqrt{n}} \sum_{j=0}^{n-1} e^{-2m\pi ij/n} b_j^\dagger . \tag{31}$$

The corresponding eigenvalues of Γ are

$$g_m = (1/n) e^{2m\pi i/n}. \tag{32}$$

For even u, the creation operators for the single-fermion eigenstates are

$$d_m^\dagger = \frac{1}{\sqrt{n}} \sum_{j=0}^{n-1} e^{-(2m+1)\pi ij/n} b_j^\dagger , \quad m = 0, \ldots, n-1, \tag{33}$$

and the corresponding eigenvalues are

$$g_m = (1/n) e^{(2m+1)\pi i/n}. \tag{34}$$

Regardless of the value of u, the single-fermion eigenvalues of Γ are complex numbers of length $1/n$, with phases uniformly spaced around the complex plane.

The eigenvalues of Γ corresponding to a system of u fermions (that is, u up spins) are all the possible sums of u of the g_m's. That is, we can write each such eigenvalue as

$$G(M)=\sum_{m\in M} g_m, \tag{35}$$

where M is a set of exactly u integers chosen from the set $\{0,\ldots,n-1\}$. (We cannot use the same value of m twice in this sum because no two identical fermions can be in the same state, and all the single-fermion eigenvalues are nondegenerate.)

As we will see, the most important eigenvalues $G(M)$ for our purpose will be the ones with the greatest magnitude. For even values of n, these are the ones for which $u=n/2$ and the set M consists of a string of consecutive integers (mod n), so that the corresponding values g_m constitute a "fan" of complex numbers spread out over half of the complex plane. Performing the sum in Eq. (35), we find that these extreme eigenvalues are

$$G_r=\frac{e^{2r\pi i/n}}{n\sin(\pi/n)}, \quad r=0,\ldots,n-1 \quad (\text{even } n), \tag{36}$$

an equation that holds for all even values of n (even though $u=n/2$ might be even or odd). For odd values of n, the eigenvalues with largest magnitude are obtained by setting u equal to either $(n+1)/2$ or $(n-1)/2$, and again letting M consist of a string of consecutive integers mod n. For either of these choices of u, the eigenvalues thereby obtained are

$$G_r=\frac{e^{2r\pi i/n}}{n\sin(\pi/n)}\cos(\pi/(2n)), \quad r=0,\ldots,n-1 \quad (\text{odd } n). \tag{37}$$

For either even or odd n, each eigenstate corresponding to one of the eigenvalues G_r can be written as

$$|\Omega_{r,u}\rangle=d^\dagger_{m_0}d^\dagger_{m_0+1}\cdots d^\dagger_{m_0+u-1}|0\rangle, \tag{38}$$

where $m_0=r-\lfloor u/2\rfloor$ mod n. (Here and below, addition in the subscript of d is always mod n.) This value of m_0 places $\exp(2r\pi i/n)$ in the center of the fan of complex eigenvalues $g_{m_0},\ldots,g_{m_0+u-1}$. For later convenience, we define the following density matrices based on these eigenstates. For even n,

$$\rho_r=|\Omega_{r,n/2}\rangle\langle\Omega_{r,n/2}|, \tag{39}$$

and for odd n,

$$\rho_r=\tfrac{1}{2}[|\Omega_{r,(n+1)/2}\rangle\langle\Omega_{r,(n+1)/2}|+|\Omega_{r,(n-1)/2}\rangle\langle\Omega_{r,(n-1)/2}|]. \tag{40}$$

As we will see shortly, both of these density matrices satisfy the rebit condition, even though $|\Omega_{r,(n+1)/2}\rangle$ and $|\Omega_{r,(n-1)/2}\rangle$ do not. Note also that for both even and odd n, $\mathrm{Tr}\,\rho_r\Gamma=G_r$.

One can check that ρ_r is translationally invariant and thus is in accord with the assumption we made earlier, that the matrix element c_j has the same phase for each link of the ring. But we also want to check that ρ_r is a legitimate rebit state, i.e., that it satisfies Eq. (11). Let us do this first for even values of n, in which case we are dealing with a pure state $|\Omega_{r,n/2}\rangle$.

We begin by noting that

$$\sigma_x^{\otimes n}b_j^\dagger=(-1)^j b_j\sigma_x^{\otimes n}, \tag{41}$$

which can be seen directly from the definition of b_j. It follows that

$$\sigma_x^{\otimes n}d^\dagger_{m_1}\cdots d^\dagger_{m_u}|0\rangle=[d_{m_1+n/2}\cdots d_{m_u+n/2}\sigma_x^{\otimes n}|0\rangle]^*, \tag{42}$$

where $m_1,\ldots,m_u$ are any distinct values chosen from the set $\{0,\ldots,n-1\}$. [The addition of $n/2$ in the subscripts on the right-hand side comes from $(-1)^j$ in the preceding equation.] In general, a state of the form $d^\dagger_{m_1}\cdots d^\dagger_{m_u}|0\rangle$ will not satisfy the rebit condition, even if $u=n/2$. However, for the special case in which $m_1,\ldots,m_u$ are $n/2$ *consecutive* integers, as they are in the definition of $|\Omega_{r,n/2}\rangle$, the subscripts on the right-hand side of Eq. (42) are precisely those elements of $\{0,\ldots,n-1\}$ that are not included in $\{m_1,\ldots,m_u\}$. Therefore, when those annihilation operators are applied to the all-up-spin state $\sigma_x^{\otimes n}|0\rangle$, which within a phase factor is the same as $d_0^\dagger d_1^\dagger\cdots d_{n-1}^\dagger|0\rangle$, the resulting state, again up to an overall phase factor, is $d^\dagger_{m_1}\cdots d^\dagger_{m_u}|0\rangle$. We have thus shown that

$$\sigma_x^{\otimes n}|\Omega_{r,n/2}\rangle = e^{i\beta}|\Omega^*_{r,n/2}\rangle \tag{43}$$

for some phase β, so that ρ_r satisfies the rebit condition (10) for even values of n.

Turning now to the case of odd n, one can use an argument like the one in the preceding paragraph to show that

$$\sigma_x^{\otimes n}|\Omega_{r,(n-1)/2}\rangle\langle\Omega_{r,(n-1)/2}|\sigma_x^{\otimes n} = |\Omega^*_{r,(n+1)/2}\rangle\langle\Omega^*_{r,(n+1)/2}|, \tag{44}$$

and vice versa, so that

$$\sigma_x^{\otimes n}\rho_r\sigma_x^{\otimes n} = \rho_r^* . \tag{45}$$

So ρ_r satisfies the rebit condition for odd values of n as well.

We are now in position to find the set—call it $\mathcal{G}$—of possible values of $\langle\Gamma\rangle$, from which we will be able to determine $K_{\max}(\theta)$. The complex numbers G_r given by Eq. (36) or (37), being values of $\langle\Gamma\rangle$ corresponding to the legitimate rebit states ρ_r, are elements of $\mathcal{G}$. By taking mixtures of these states, we can obtain other possible values of $\langle\Gamma\rangle$. Let

$$\rho = \sum_r q_r\rho_r , \tag{46}$$

where the q's are non-negative numbers summing to 1. For this state we have

$$\langle\Gamma\rangle = \mathrm{Tr}\ \rho\Gamma = \sum_r q_r G_r . \tag{47}$$

The complex numbers G_r are the vertices of a regular n-gon in the complex plane, and Eq. (47) shows that this n-gon and its interior are contained in $\mathcal{G}$.

In fact, it is easy to see that $\mathcal{G}$ contains no other points. Any complex number $\langle\Gamma\rangle$ in $\mathcal{G}$ must be a weighted average of eigenvalues of Γ:

$$\langle\Gamma\rangle = \sum_M q_M G(M). \tag{48}$$

But one can show that each eigenvalue $G(M)$, regardless of the value of u, lies on or inside the n-gon defined by the special eigenvalues discussed above. Therefore it is impossible for the average to get outside this region.

For the special case $n=2$, the interior of the "n-gon" is simply a segment of the real axis, running from $-\frac{1}{2}$ to $+\frac{1}{2}$. Thus the only possible phases of $\langle\Gamma\rangle$ are zero and π, so that according to Eq. (26) the only possible value of $\exp(i\theta)$ is 1. (This is because there is no real loop to traverse; to return to the starting place, one has to retrace one's steps.) For all other values of n, all values of θ from 0 to 2π are possible. To see this, it is enough to consider a single side of the n-gon; let us take the side consisting of the line segment joining the point G_0, on the positive real axis, with

the point $G_1 = e^{2\pi i/n} G_0$. As we travel along this segment, the phase of $\langle \Gamma \rangle$ varies from 0 to $2\pi/n$, so that θ varies from 0 to 2π. The range of values of $|\langle \Gamma \rangle|$ as a function of θ is the same for each of the other sides of the n-gon.

It thus becomes a simple geometric problem to find $K_{\max}(\theta)$. For $n > 2$, consider the line segment just described, connecting G_0 to G_1, and note that for any θ in the range $0 \leq \theta \leq 2\pi$, $K_{\max}(\theta)$ is twice the magnitude of the unique point along this segment whose phase is θ/n. Doing the geometry, and using the values of G_r given in Eqs. (36) and (37), one finds that for even n,

$$K_{\max}(\theta) = \frac{2\cos(\pi/n)}{n \sin(\pi/n)\cos[(\pi-\theta)/n]}, \tag{49}$$

and for odd n,

$$K_{\max}(\theta) = \frac{2\cos(\pi/n)\cos(\pi/(2n))}{n \sin(\pi/n)\cos[(\pi-\theta)/n]}. \tag{50}$$

It is clear both from the geometric picture and from Eqs. (49) and (50) that $K_{\max}$ is largest at $\theta = 0$ and $\theta = 2\pi$ and smallest at $\theta = \pi$. Indeed, the value of $K_{\max}$ becomes smaller the more $e^{i\theta}$ differs from unity. In this sense there is a correlation cost of nontrivial parallel transport around the ring.

It is not hard to interpret the states ρ_r physically. The state ρ_0, which entails no twisting as one goes around the ring, is the ground state, or, in the case of odd n an equal mixture of the two degenerate ground states, of the ferromagnetic XY model[21] on a one-dimensional ring, whose Hamiltonian is $H = -\Sigma_j (a_j^\dagger a_{j+1} + a_{j+1}^\dagger a_j) = -n(\Gamma^\dagger + \Gamma)$. The state ρ_r can be obtained from ρ_0 by rotating each rebit, the rotation angle at site j being $2\pi r j/n$. These rotations do not change the strength of the nearest-neighbor correlations, but for each site j they change the phase of the matrix element c_j from zero to $2\pi r/n$. Still, this does not change the *overall* phase factor $e^{i\theta}$ associated with the whole ring. When one creates a mixture of two of these differently rotated states, e.g., ρ_0 and ρ_1, the resulting matrix element c_j is an average of two complex numbers with different phases. It is this averaging process that allows the possibility of a nontrivial net phase change around the ring.

In the case of even n, where ρ_r represents the pure state $|\Omega_{r,n/2}\rangle$, one could achieve the same averaging effect by creating coherent superpositions of eigenstates of Γ rather than incoherent mixtures. I have chosen to use mixtures because superpositions of these eigenstates are not necessarily translationally invariant. However, just to demonstrate that it is possible for a translationally invariant pure state to have a nonzero rotation angle θ associated with parallel transport around the ring, I offer the following example for $n = 6$:

$$|\Psi\rangle = \frac{i}{\sqrt{12}}[e^{i\phi/2}(|\uparrow\uparrow\downarrow\uparrow\downarrow\downarrow\rangle + \cdots) + e^{-i\phi/2}(|\uparrow\uparrow\downarrow\downarrow\uparrow\downarrow\rangle + \cdots)]. \tag{51}$$

Here each ellipsis stands for all possible translations of the given state. [Though we are not paying particular attention to the overall phase factors of pure states, I have chosen the overall phase in Eq. (51) to satisfy Eq. (9).] One finds that the matrix element c_j for each link in this ring is $(\frac{1}{6})\exp(i\phi)$, so that the overall rotation angle is $\theta = 6\phi$ and the average correlation is $K = \frac{1}{3}$. Thus any value of θ can be realized with a translationally invariant pure state. But the value $K = \frac{1}{3}$ is not optimal. To obtain the optimal value $K_{\max}(\theta)$ in a translationally invariant state, one must typically use mixed states rather than pure states.

We finish this section by giving asymptotic expressions for $K_{\max}(\theta)$ as the number of rebits in the ring gets very large. For even n, Eq. (49) to order $1/n^2$ becomes (for $0 \leq \theta \leq 2\pi$)

$$K_{\max}(\theta) = \frac{2}{\pi}\left[1 + \frac{1}{n^2}\left(\frac{\pi^2}{6} - \pi\theta + \frac{\theta^2}{2}\right)\right], \tag{52}$$

while for odd n we have

$$K_{\max}(\theta)=\frac{2}{\pi}\left[1+\frac{1}{n^2}\left(\frac{\pi^2}{24}-\pi\theta+\frac{\theta^2}{2}\right)\right]. \tag{53}$$

Thus the correlation cost of nontrivial parallel transport becomes smaller as the size of the ring increases.

VI. OTHER LATTICES

Let us now think about how the above problem might be generalized to a finite or infinite lattice of higher dimension (still using rebits as our basic objects). We can state the problem as follows. As in Sec. IV, let $\rho^{(jk)}$ be the density matrix of the pair of rebits at the neighboring sites j and k, and let $c_{j,k}$ be the coefficient of $|\uparrow\downarrow\rangle\langle\downarrow\uparrow|$ in this density matrix. (This $c_{j,k}$ is analogous to the c_j of the preceding section.) Now suppose that the phases of all the c's, for all the links $\langle j,k\rangle$, are specified. We will call this complete specification $\mathcal{A}$, since it is analogous to a field configuration in the U(1) gauge theory. Given this specification, we have two questions: (i) Is it possible to find a lattice state for which the numbers $c_{j,k}$ are all nonzero and have the chosen phases? (One can always find a state in which all the $c_{j,k}$'s are zero, making the state consistent with any phases, but such a state is not very interesting.) (ii) What is the maximum possible value of

$$K=\frac{2}{L}\sum_{\langle j,k\rangle}|c_{j,k}|, \tag{54}$$

consistent with the specification $\mathcal{A}$? Here L is the number of links in the lattice. In the case of an infinite lattice, K can be defined as a limit over a sequence of finite lattices. Let us call the maximum value $K_{\max}(\mathcal{A})$.

For definiteness let us consider a specific lattice, namely, an infinite square lattice in two dimensions. Let us consider first the configuration $\mathcal{A}_0$ in which the phases of all the $c_{j,k}$'s are zero. In this case it is again helpful to invoke the Hamiltonian of the ferromagnetic XY model:

$$H=-\sum_{\langle j,k\rangle}(a_k^\dagger a_j+a_j^\dagger a_k). \tag{55}$$

Here the sum is over all links in the square lattice. The optimal value of K is the infinite-lattice limit of $(-E_0/L)$, E_0 being the minimum eigenvalue of this Hamiltonian. In the thermodynamic limit, the ground state of the XY model on a square lattice breaks the SO(2) symmetry of the problem and picks out a preferred direction of magnetization in the x-y plane,[22,23] which can be characterized by a single angle α. But if we choose to do so (in order to simplify the interpretation of parallel transport), we can easily generate a rotationally invariant state with the same energy—or in our context, with the same degree of correlation—simply by averaging the ground state density matrix $\rho(\alpha)$ over all angles: $\rho_0=(1/2\pi)\int\rho(\alpha)d\alpha$. The ground-state energy has been evaluated numerically,[24–26] and one finds that $K_{\max}(\mathcal{A}_0)=0.549$. Notice that this value is smaller than the corresponding value for a rebit ring in the limit $n\to\infty$ [see Eqs. (52) and (53) or Ref. 21], which is $2/\pi=0.637$.

Given a different specification of the phases, it is not immediately obvious whether there exists a state that has all nonzero $c_{j,k}$'s—let us call such a state "fully connected"—and that is also consistent with the given phases. Consider, for example, the configuration $\mathcal{A}$ in which all the phases are zero except at a specific link $\langle j,k\rangle$, where the phase is required to be ϕ. Can one find a fully connected state of the lattice consistent with these phases? The following method will work, though it is not likely to be optimal. Start with the state ρ_0 defined in the preceding paragraph, in which all the phases are zero. Construct the following sum:

$$\rho(j,k,\phi)=\tfrac{1}{3}[V_j\rho_0 V_j^\dagger+V_k^\dagger\rho_0 V_k+(V_j^\dagger\otimes V_k)\rho_0(V_j\otimes V_k^\dagger)], \tag{56}$$

where V_j is the matrix

$$V_j=\begin{pmatrix}1 & 0\\ 0 & e^{i\xi}\end{pmatrix} \tag{57}$$

applied to particle j and V_k is the same matrix applied to particle k. Here ξ will be a function of ϕ to be determined later. Because the rotations in Eq. (56) affect only particles j and k, all links not involving either of these particles will continue to have zero phase. Moreover, any link involving only one of the two special sites will likewise have its phase unchanged. Consider, for example, the link $\langle j,l\rangle$ where $l\neq k$. The value of $c_{j,l}$ is

$$c_{j,l}=\frac{1}{3}(c_0e^{-i\xi}+c_0+c_0e^{i\xi})=\left(\frac{1+2\cos(\xi)}{3}\right)c_0, \tag{58}$$

so that the phase has not been affected. On the other hand, the value of c associated with the link $\langle j,k\rangle$ is

$$c_{j,k}=\left(\frac{2e^{-i\xi}+e^{2i\xi}}{3}\right)c_0, \tag{59}$$

which has a phase that can be made equal to ϕ by a proper choice of the value of ξ.

An even simpler strategy, which is surely not optimal, shows that *any* phase configuration $\mathcal{A}$ can be realized in a fully connected quantum state of the lattice. Let us imagine the two dimensions of the lattice to be horizontal and vertical. Start with a state in which each vertical column of lattice sites is in the ground state of the ferromagnetic XY model for an infinite chain. Call this state $|\phi_V\rangle$. Now rotate each of the rebits in each of these chains so as to achieve the desired phases for the vertical links. This can be done with no loss of correlation, because we are simply performing local rotations. Similarly, consider the state $|\phi_H\rangle$ in which each *horizontal* row is in the XY ground state, and rotate the rebits so as to achieve the desired phases for the horizontal links. Let $|\phi_V'\rangle$ and $|\phi_H'\rangle$ be the states resulting from these rotations. Then the mixed state

$$\rho=\tfrac{1}{2}(|\phi_V'\rangle\langle\phi_V'|+|\phi_H'\rangle\langle\phi_H'|) \tag{60}$$

completely matches the phase configuration $\mathcal{A}$. We can even compute the value of K for the state ρ: it is equal to half of $K_{\max}$ for the infinite chain, independent of the configuration $\mathcal{A}$. That is, $K=1/\pi=0.318$. For the special configuration considered above, in which only one link has nonzero phase, this value is smaller than what one can achieve with the specialized method of Eq. (57). Nevertheless, the method we have just described does answer our first question: all configurations $\mathcal{A}$ can be achieved without making any $c_{j,k}$ vanish. Notice also that this construction gives us a lower bound on $K_{\max}(\mathcal{A})$ for all configurations $\mathcal{A}$: $K_{\max}(\mathcal{A})\geqslant 1/\pi$.

Actually finding $K_{\max}(\mathcal{A})$, even for simple configurations $\mathcal{A}$, is probably a very hard problem. If one uses strategies similar in spirit to the one given in Eq. (57), then it would seem that the value of $K_{\max}(\mathcal{A})$ must decrease in order to achieve nontrivial parallel transport around a loop. [One can see the decrease in the values of $|c_{j,l}|$ and $|c_{j,k}|$ in Eqs. (58) and (59).] But it is conceivable that a completely different strategy could do much better; so we must leave this basic question unanswered.

VII. LATTICES OF QUBITS

In our definition of parallel transport for rebits, developed in Sec. III, we implicitly made use of the fact that for rebits, there exists a two-particle state $\rho^{(+)}$ such that if particles j and k are in this state, and if particle j is measured and found to be in the state $|\psi\rangle$, then particle k will always be brought to the *same* state $|\psi\rangle$. Mathematically,

$$\omega = \frac{1}{P}\langle\psi|\rho^{(+)}|\psi\rangle = |\psi\rangle\langle\psi|. \tag{61}$$

The state $\rho^{(+)}$ is in fact $|\Psi^{(+)}\rangle\langle\Psi^{(+)}|$, with $|\Psi^{(+)}\rangle = (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/\sqrt{2}$. So for this state, the parallel transporter is the identity and the degree of correlation is 1. In effect, our definition of parallel transport compares other two-particle states to this special state; when the parallel transporter U is not the identity, it is because one of the particles has been rotated (and possibly distorted in other ways as well) compared to the standard state $\rho^{(+)}$.

For qubits, there is no two-particle state with this property. The most closely analogous state is the singlet state $|\Psi^{(-)}\rangle = (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)/\sqrt{2}$. It has the property that if a measurement on one of the particles brings it to the state $|\psi\rangle$, the other particle will be brought to the *orthogonal* state $|\tilde{\psi}\rangle = \sigma_y|\psi^*\rangle$, where the complex conjugation is in the standard basis. In defining parallel transport for qubits, we will take the singlet state as our standard state, for which the parallel transporter is defined to be the identity. All other states will then be compared with this one. A general parallel transporter will be a rotation of the Bloch sphere, that is, an element of SO(3); as in the case of rebits, our definition will not allow us to distinguish overall phases. We will usually represent such a rotation as a 2×2 unitary matrix, keeping in mind that the overall phase is irrelevant.

We start again with Eq. (14):

$$\omega^{(k)} = \frac{1}{P}\langle\psi^{(j)}|\rho^{(jk)}|\psi^{(j)}\rangle, \tag{62}$$

and again let $\mathcal{M}$ be the map that takes $|\psi^{(j)}\rangle$ to $\omega^{(k)}$. But now we define our generalized fidelity as

$$F(R) = \frac{\int\langle\tilde{\psi}|R^\dagger\mathcal{M}(\psi)R|\tilde{\psi}\rangle P\,d\psi}{\int P\,d\psi}, \tag{63}$$

where $d\psi$ refers to the uniform measure over the surface of the Bloch sphere. Note that F compares $\mathcal{M}(\psi)$ with a rotated version of $|\tilde{\psi}\rangle$ rather than a rotated version of $|\psi\rangle$. If there is a unique rotation $R=U$ (up to an overall phase) that maximizes $F(R)$, then we will take this U to be the parallel transporter for the link $\langle j,k\rangle$. Thus, if $\rho^{(jk)}$ happens to be the singlet state, we have $U(k,j)=I$.

The fact that we base our notion of parallel transport for qubits on *antiparallel* states has the following consequence when we consider a closed loop. If the loop consists of an odd number of qubits, then the expression "no net twist," by our definition, implies a net reflection of the state. This is not what we intend to convey by this expression; so, I regard our definition as appropriate only for loops consisting of an *even* number of qubits. In a cubic lattice, every loop is of this sort. This restriction to even numbers of qubits is less than perfectly satisfying, but it is hard to see how it can be avoided, since there is no two-qubit state expressing a perfect *positive* correlation along every axis.

Carrying out the integrals in Eq. (63), we find that

$$F(R) = \tfrac{1}{3} + \tfrac{2}{3}\langle\Psi^{(-)}|(I\otimes R^\dagger)\rho^{(jk)}(I\otimes R)|\Psi^{(-)}\rangle. \tag{64}$$

Now, it is a fact that any maximally entangled state of two qubits can be written as $(I\otimes R)|\Psi^{(-)}\rangle$. So maximizing $F(R)$ over all rotations R is the same as finding the maximally entangled state that has the greatest overlap with $\rho^{(jk)}$. The quantity

$$f=\max_R \langle\Psi^{(-)}|(I\otimes R^\dagger)\rho^{(jk)}(I\otimes R)|\Psi^{(-)}\rangle \tag{65}$$

has been called the ''fully entangled fraction'' of $\rho^{(jk)}$.[13] It ranges from $\frac{1}{4}$ (for the completely mixed state) to 1 (for a maximally entangled state).[27] We will take $(4f-1)/3$, which ranges from 0 to 1, as our measure of the degree of correlation between particles j and k, and define K_q (q for ''qubit'') to be the average of this quantity over all the links of the lattice. As has been mentioned, the rotation R that achieves this maximum value, if it is unique, will be our parallel transporter $U(k,j)$.[28] We would like to maximize K_q for a fixed set of parallel transporters.

Our notion of parallel transport for qubits is particularly simple if $\rho^{(jk)}$ happens to be a ''twisted Werner state,'' that is, a state of the form[29]

$$p(I\otimes V)|\Psi^{(-)}\rangle\langle\Psi^{(-)}|(I\otimes V^\dagger)+(1-p)(I/4). \tag{66}$$

Here $0<p\leqslant 1$, $|\Psi^{(-)}\rangle$ is the singlet state, I is the 4×4 identity matrix, and V is a unitary transformation acting on particle k. If $\rho^{(jk)}$ is of this form, then the parallel transporter $U(k,j)$ works out, not surprisingly, to be the transformation V. Moreover, the weight p appearing in Eq. (66) is none other than our measure of correlation $(4f-1)/3$. Thus both the parallel transporter and the degree of correlation are particularly easy to interpret in this case. One can show that the six-rebit state of Eq. (51), reinterpreted as the state of a six-qubit ring, has the property that each pair of nearest neighbors is of the twisted Werner form.

A more interesting example of a qubit ring exhibiting nontrivial parallel transport—but whose pairs are not necessarily of the twisted Werner form—is given by the following state of six qubits,

$$\begin{aligned}|\psi\rangle=\alpha(|\uparrow\uparrow\uparrow\downarrow\downarrow\downarrow\rangle-\cdots)+\beta[e^{-i\xi}(|\uparrow\downarrow\uparrow\downarrow\downarrow\uparrow\rangle-\cdots)+e^{i\xi}(|\uparrow\uparrow\downarrow\downarrow\uparrow\downarrow\rangle-\cdots)]\\ +\gamma(|\downarrow\uparrow\downarrow\uparrow\downarrow\uparrow\rangle-|\uparrow\downarrow\uparrow\downarrow\uparrow\downarrow\rangle).\end{aligned} \tag{67}$$

Here each ellipsis indicates all the translations of the given state, but with *alternating* signs. For example, the coefficient α multiplies

$$|\uparrow\uparrow\uparrow\downarrow\downarrow\downarrow\rangle-|\uparrow\uparrow\downarrow\downarrow\downarrow\uparrow\rangle+|\uparrow\downarrow\downarrow\downarrow\uparrow\uparrow\rangle-|\downarrow\downarrow\downarrow\uparrow\uparrow\uparrow\rangle+|\downarrow\downarrow\uparrow\uparrow\uparrow\downarrow\rangle-|\downarrow\uparrow\uparrow\uparrow\downarrow\downarrow\rangle. \tag{68}$$

The coefficients α, β and γ are real and positive; their values will be specified shortly. Note that each pair of nearest neighbors in this state has the same density matrix, so that each has the same degree of correlation and the same parallel transporter. Because the state $|\psi\rangle$ is an eigenstate of S_z with eigenvalue zero, the density matrix of each pair is of the form (19) with all the x_i's equal to zero. (It is convenient to introduce a negative sign in the off-diagonal elements since our standard state is now the singlet.)

$$\rho^{(jk)}=\begin{pmatrix} a & 0 & 0 & 0\\ 0 & b & -c & 0\\ 0 & -c^* & b & 0\\ 0 & 0 & 0 & a\end{pmatrix}. \tag{69}$$

Carrying out the trace of $|\psi\rangle\langle\psi|$ over the other particles, one finds that $a=2\alpha^2+2\beta^2$, $b=\alpha^2+4\beta^2+\gamma^2$, and $c=2\beta[(\alpha+\gamma)e^{i\xi}+\beta e^{-2i\xi}]$. The correlation K_q is $(4f-1)/3$, where

$$f=b+|c|=\alpha^2+4\beta^2+\gamma^2+2\beta|(\alpha+\gamma)e^{i\xi}+\beta e^{-2i\xi}|, \tag{70}$$

and the parallel transporter is

$$U=\begin{pmatrix} 1 & 0 \\ 0 & e^{i\phi} \end{pmatrix}, \tag{71}$$

where ϕ is the phase of c, that is, the phase of $(\alpha+\gamma)e^{i\xi}+\beta e^{-2i\xi}$. The fact that K_q depends on the matrix element b, while the analogous quantity K for rebits depended only on c, ultimately comes from the fact that in Eq. (63) we average over the entire surface of the Bloch sphere and not just over the equator.

In the spirit of our main problem, we would like to choose α, β and γ so as to maximize K_q. Let us do this extremization for the special case $\xi=0$, for which the parallel transporter given in Eq. (71) is the identity. In this case one finds that the optimal values are $\alpha=(130+34\sqrt{13})^{-1/2}$, $\beta=(1/2)(3+\sqrt{13})\alpha$, and $\gamma=(4+\sqrt{13})\alpha$, which satisfy the normalization condition $6\alpha^2+12\beta^2+2\gamma^2=1$. (By no accident, the state $|\psi\rangle$ with these values of the coefficients is the ground state of the antiferromagnetic Heisenberg model for a ring of six qubits.) In what follows we will assume that α, β and γ have these values. One finds then that for $\xi=0$, each pair of nearest neighbors is in a Werner state, and the correlation K_q is $(2+\sqrt{13})/9=0.623$. Let us call this value $K_q^{(0)}$.

How do K_q and U for the state $|\psi\rangle$ change as ξ departs from zero? Let us first look at U. To lowest order in ξ, the angle ϕ, which is the rotation angle associated with parallel transport across a link, is

$$\phi=\arg[(\alpha+\gamma)(1+i\xi)+\beta(1-2i\xi)]=\left(\frac{\alpha+\gamma-2\beta}{\alpha+\gamma+\beta}\right)\xi. \tag{72}$$

Note that $\alpha+\gamma-2\beta>0$, so that this linear contribution to ϕ does not vanish. Meanwhile, the correlation K_q diminishes by an amount proportional to the square of ξ:

$$K_q=K_q^{(0)}-\left(\frac{12\beta^2(\alpha+\gamma)}{\alpha+\gamma+\beta}\right)\xi^2. \tag{73}$$

Letting $\theta=6\phi$ be the net rotation associated with parallel transport around the whole ring, we can see how K_q depends on θ to lowest order:

$$K_q=K_q^{(0)}-\left(\frac{\beta^2(\alpha+\gamma)(\alpha+\gamma+\beta)}{3(\alpha+\gamma-2\beta)^2}\right)\theta^2=0.623-(0.369)\theta^2. \tag{74}$$

Notice that the reduction in correlation is of second order in θ, whereas in the case of rebits it is of first order as seen in Eqs. (52) and (53). Of course we have not done the thorough optimization for qubits that we have done for rebit rings, but this example indicates that there is a significant difference between the two cases.

VIII. DISCUSSION

We have shown, first of all, that there is a sense in which certain quantum states exhibit nontrivial parallel transport around a closed loop, which is to say that the nearest-neighbor correlations exhibit a net twist as one goes around the loop. One might regard this result as somewhat surprising, since there is, after all, only a single quantum state for the whole loop, and one might think that the local twists would therefore have to cancel each other out. We have also shown that in the case of the rebit ring, there is a loss of nearest-neighbor correlation associated with nontrivial parallel transport around the ring. For other lattices or for lattices of qubits, we do not know whether there is such a correlation cost, though it is certainly plausible that there would be.

As we have seen, there is a close relationship between our rebit problem and the XY model, a model that has been very well studied. Studies of spin stiffness in this model (see, for example, Ref. 26) have a certain similarity with the problem we have been considering in that in both cases one enforces a twist between neighboring spins. What distinguishes the present work is the fact

that we have not actually specified any Hamiltonian. Though it has been helpful for us to use an operator similar to the Hamiltonian of the XY model, we are really working with what might be called the *kinematics* of quantum mechanics. We are asking what correlation properties of quantum states follow from certain other correlation properties—specifically, we are asking what one can say about the *strength* of correlations given some information about the *twist* in the correlations—and this question is independent of any considerations of energy.

I introduced the subject by relating it to lattice gauge theory. To what extent, then, have we found an analogy between the state of a quantum lattice and the configuration of a lattice gauge field? In a qualitative sense, the reduction in correlation that we have observed in a rebit ring can be compared to the reduction in probability that one finds in a lattice gauge theory. But for this rebit case, the analogy must be regarded as quite rough, because there is a significant lack of congruence in the details. In gauge theory, the initial decrease in the probability is of *second order* in the net rotation angle θ associated with transport around a plaquette. In the U(1) theory, for example, the function $\exp(-S)$, with S given by Eq. (3), decreases in proportion to θ^2 for small values of θ. In contrast, in the rebit ring, the average correlation K, as given by Eqs. (49) and (50), decreases in proportion to θ itself. The second-order dependence is in fact important in lattice gauge theory for taking the continuum limit. Moreover, our first-order dependence makes $K_{\max}(\theta)$ a nonanalytic function, since near $\theta=0$ it takes the form $a-b|\theta|$. So this difference is not trivial.

On the other hand, we have just seen that the *qubit* correlation as we have defined it does seem to diminish quadratically in θ, at least for a ring of six qubits. It is interesting to ask whether in the case of a two-dimensional or higher-dimensional lattice, the dependence of $K_{\max}(\mathcal{A})$ is of second order in the rotation angles. In the one relevant example we have considered for a rebit lattice, namely, the strategy given in Eq. (57), the value of K decreases as $\phi^{2/3}$, which is an even sharper dependence than in the rebit ring. But we have not explored at all fully the range of possible states that one might consider for these higher-dimensional lattices.

It is worth commenting on the fact that in the case of qubits, our approach makes the parallel transporters elements of SO(3), whereas one might have expected SU(2). The nature of our definition does not allow us to pick out a relative phase in the relation between neighboring qubits. For example, we cannot distinguish between the identity operation and a rotation by 2π, even though a pure qubit state experiencing the latter rotation picks up a phase factor of -1. It is conceivable that by taking into account the density matrix of an entire loop, in addition to the density matrices of the neighboring pairs, one might be able to make sense of this distinction as it applies to the *net* rotation associated with the loop as a whole.

There are other ways in which one might modify the problem we have been considering. One could use a different measure of correlation or entanglement. Moreover, even if one continues to use the quantity $2|c|$ for rebits and the quantity $(4f-1)/3$ for qubits as the measure of nearest-neighbor correlation, one could combine the correlations from all the links in a different way. For example, in the case of a ring it would make some sense to consider the *product* of the individual correlations rather that the average; this measure has the pleasing feature that it vanishes if any of the links in the ring is broken.

Again, our main conclusion is this: in the one example we have worked out in detail, if there is a nontrivial twist in the nearest-neighbor correlations, that is, a twisting that cannot be undone by local rotations, then there is a corresponding reduction in the maximum possible magnitude of these correlations. That is, in this one example at least, twisted correlations are weaker correlations. This conclusion follows from the structure of the quantum state space and is true irrespective of the system's Hamiltonian.

[28] In the case of qubits, in contrast to that of rebits, it is possible for R not to be unique even when the correlation $(4f-1)/3$ is not zero. For example, if $\rho^{(jk)}=(|\uparrow\downarrow\rangle\langle\uparrow\downarrow|+|\downarrow\uparrow\rangle\langle\downarrow\uparrow|)/2$, then any rotation around the z axis maximizes $F(R)$, and yet the correlation $(4f-1)/3$ has the value $\frac{1}{3}$. However, as in the case of rebits, this sort of ambiguity does not cause any difficulties for the problem we are considering.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

On entanglement-assisted classical capacity

A. S. Holevo[a)]
Steklov Mathematical Institute, Gubkina 8, 117966 Moscow, Russia

(Received 18 October 2001; accepted for publication 16 May 2002)

We give a modified proof of the recent result of C. H. Bennett, P. W. Shor, J. A. Smolin, and A. V. Thapliyal concerning entanglement-assisted classical capacity of a quantum channel and discuss the relation between entanglement-assisted and unassisted classical capacities. © *2002 American Institute of Physics.*
[DOI: 10.1063/1.1495877]

I. INTRODUCTION

The classical capacity of a quantum channel is the capacity of transmission of classical information through the channel. It is well known that the classical capacity can be increased if there is an additional resource in the form of an entangled state shared between the input A and the output B of the channel. While entanglement itself cannot serve for transmission of information from A to B, it may enhance the transmission provided there is a quantum channel connecting the systems. If the channel is ideal (i.e., the identity map Id from A to B), then the entanglement-assisted capacity is twice as great as the unassisted classical capacity, the enhancement being realized by the dense coding protocol.[1]

Recently C. H. Bennett, P. W. Shor, J. A. Smolin, and A. V. Thapliyal (BSST) studied the effect of the shared entanglement on the classical capacity of a quantum nonideal (noisy) channel[2,3] and obtained a remarkably simple formula for the entanglement-assisted capacity in terms of the maximal mutual quantum information between A and B. The proof, which is by no means trivial, involves in particular a rather tricky derivation of an important continuity property of quantum entropy. In this article we give a modified proof of the BSST theorem, including a more transparent proof of this property; moreover, we make further simplifications by using heavily properties of conditional quantum entropy rather than the underlying strong subadditivity.

In Ref. 2 it was shown that the enhancement in the classical capacity can achieve arbitrarily large values. To this end the case of a d-dimensional depolarizing channel in the limit of strong noise ($p\to 1$) was considered; we remark that the enhancement is even greater for the extreme case $p=d^2/(d^2-1)$. Moreover, we derive a general inequality between entanglement-assisted and unassisted capacities which may be relevant to the additivity problem in quantum information theory.

II. THE BSST THEOREM

We refer the reader to Refs. 4 and 5 for some basic definitions and results of quantum information theory used in this article.

Consider the following protocol for the classical information transmission through a quantum channel Φ. Systems A and B of the same dimension share an entangled (pure) state S_{AB}. A does some encoding $i\to\mathcal{E}_A^i$ depending on a classical signal i with probabilities π_i and sends its part of this shared state through the channel Φ to B. Thus B gets the states $(\Phi\otimes \mathrm{Id}_B)[S_{AB}^i]$, where $S_{AB}^i=(\mathcal{E}_A^i\otimes \mathrm{Id}_B)[S_{AB}]$, with probabilities π_i, and B is trying to extract the maximal classical information by doing measurements on these states. This is similar to the dense coding, but instead of the ideal channel, A uses a noisy channel Φ. We now look for the classical capacity of this protocol, which is called the *entanglement-assisted classical capacity* of the channel Φ.

a)Electronic mail: holevo@mi.ras.ru

The maximum over measurements of B can be evaluated using the coding theorem for the classical capacity.[6] First we have the it *one-shot entanglement-assisted classical capacity*

$$C_{ea}^{(1)}(\Phi)=\max_{\pi_i,\mathcal{E}_A^i,S_{AB}}\left[H\left(\sum_i \pi_i(\Phi\otimes \mathrm{Id}_B)[S_{AB}^i]\right)-\sum_i \pi_i H((\Phi\otimes \mathrm{Id}_B)[S_{AB}^i])\right], \tag{1}$$

where $H(S)$ denotes the von Neumann entropy of the density operator S. Using the channel n times and allowing entangled measurements on B's side, one gets

$$C_{ea}^{(n)}(\Phi)=C_{ea}^{(1)}(\Phi^{\otimes n}). \tag{2}$$

The full entanglement-assisted classical capacity is then

$$C_{ea}(\Phi)=\lim_{n\to\infty}\frac{1}{n}C_{ea}^{(1)}(\Phi^{\otimes n}). \tag{3}$$

The following result was announced in Ref. 2, and a proof was given in Ref. 3:

$$C_{ea}(\Phi)=\max_{S_A} I(S_A;\Phi), \tag{4}$$

where

$$I(S_A;\Phi)=H(S_A)+H(\Phi(S_A))-H(S_A;\Phi) \tag{5}$$

is the quantum mutual information, with $H(S_A;\Phi)$ denoting the entropy exchange (see Refs. 4 and 5). Below we give a simplified proof of this remarkable formula.

Proof of the inequality:

$$C_{ea}(\Phi)\geqslant \max_{S_A} I(S_A;\Phi). \tag{6}$$

It is shown in Ref. 3 by generalizing the dense coding protocol that

$$C_{ea}^{(1)}(\Phi^{\otimes n})\geqslant I\left(\frac{P}{\dim P},\Phi^{\otimes n}\right) \tag{7}$$

for arbitrary projection P in $\mathcal{H}_A^{\otimes n}$. We give this proof for completeness here. Indeed, let $P=\Sigma_{k=1}^m |e_k\rangle\langle e_k|$, where $\{e_k;k=1,\ldots,m=\dim P\}$ is an orthonormal system. Define unitary operators in $\mathcal{H}_A$ acting as

$$V|e_k\rangle=\exp\left(\frac{2\pi i k}{m}\right)|e_k\rangle,\quad U|e_k\rangle=|e_{k+1(\mathrm{mod}m)}\rangle,\quad k=1,\ldots,m,$$

$$W_{\alpha\beta}=U^\alpha V^\beta,\quad \alpha,\beta=1,\ldots,m,$$

on the subspace generated by $\{e_k\}$, and as the identity onto its orthogonal complement. The operators $W_{\alpha\beta}$ are a finite-dimensional version of the Weyl–Segal operators for Boson systems (see, e.g., Ref. 5). Let

$$|\psi_{AB}\rangle=\frac{1}{\sqrt{m}}\sum_{k=1}^m |e_k\rangle\otimes|e_k\rangle.$$

Then it is easy to show the following.

(1) $(W_{\alpha\beta}\otimes I_B)|\psi_{AB}\rangle$; $\alpha,\beta=1,\ldots,m$, is an orthonormal system in $\mathcal{H}_A\otimes\mathcal{H}_B$. In particular, if $m=\dim\mathcal{H}_A$, it is a basis.
(2) $\Sigma_{\alpha,\beta=1}^{m}(W_{\alpha\beta}\otimes I_B)|\psi_{AB}\rangle\langle\psi_{AB}|(W_{\alpha\beta}\otimes I_B)^*=P\otimes P$.

Thus operators $\{W_{\alpha\beta};\alpha,\beta=1,\ldots,m\}$ play a role similar to Pauli matrices in the dense coding protocol for qubits.

Take the classical signal to be transmitted as $i=(\alpha,\beta)$ with equal probabilities $1/m^2$, the entangled state $|\psi_{AB}\rangle\langle\psi_{AB}|$, and the unitary encodings $\mathcal{E}_A^i[S]=W_{\alpha\beta}SW_{\alpha\beta}^*$. Then we have

$$C_{ea}^{(1)}(\Phi^{\otimes n})\geqslant H\left(\frac{1}{m^2}\sum_{\alpha\beta}(\Phi\otimes\mathrm{Id}_B)[S_{AB}^{\alpha\beta}]\right)-\frac{1}{m^2}\sum_{\alpha\beta}H((\Phi\otimes\mathrm{Id}_B)[S_{AB}^{\alpha\beta}]),$$

where $S_{AB}^{\alpha\beta}=(W_{\alpha\beta}\otimes I_B)|\psi_{AB}\rangle\langle\psi_{AB}|(W_{\alpha\beta}\otimes I_B)^*$. Then by the property (2) the first term on the right hand side is equal to $H((\Phi\otimes\mathrm{Id}_B)[P/m\otimes P/m])=H(P/m)+H(\Phi[P/m])$. Since $S_{AB}^{\alpha\beta}$ is a purification of P/m in $\mathcal{H}_B$, the entropies in the second term are all equal to $H(P/m,\Phi)$. By the expression for quantum mutual information (5) this proves (7). For future use, note that the last term in the quantum mutual information—the entropy exchange $H(S_A;\Phi)$—is equal to the final environment entropy $H(\Phi_E[S_A])$, where Φ_E is a channel from the system space $\mathcal{H}_A$ to the environment space $\mathcal{H}_E$, the actual form of which we need not know (see Ref. 5).

Now let $S_A=S$ be an arbitrary state in $\mathcal{H}_A$, and let $P^{n,\delta}$ be the typical projection of the state $S^{\otimes n}$ in $\mathcal{H}_A^{\otimes n}$. It was suggested in Ref. 2 that for *arbitrary* channel Ψ from $\mathcal{H}_A$ to possibly other Hilbert space $\tilde{\mathcal{H}}$

$$\lim_{\delta\to 0}\lim_{n\to\infty}\frac{1}{n}H\left(\Psi^{\otimes n}\left(\frac{P^{n,\delta}}{\dim P^{n,\delta}}\right)\right)=H(\Psi(S)),$$

which would imply, by the expressions for the mutual information and the entropy exchange, that

$$\lim_{\delta\to 0}\lim_{n\to\infty}\frac{1}{n}I\left(\frac{P^{n,\delta}}{\dim P^{n,\delta}};\Phi^{\otimes n}\right)=I(S;\Phi),\tag{8}$$

and, hence, by (7), the required inequality (6). We shall prove (8) with $P^{n,\delta}$ being the *strongly typical projection* of the state $S^{\otimes n}$.

Let us fix small positive δ, and let λ_j be the eigenvalues and $|e_j\rangle$ be the eigenvectors of the density operator S. Then the eigenvalues and eigenvectors of $S^{\otimes n}$ are $\lambda_J=\lambda_{j_1}\cdot\cdots\cdot\lambda_{j_n}$, $|e_J\rangle=|e_{j_1}\rangle\otimes\cdots\otimes|e_{j_n}\rangle$ where $J=(j_1,\ldots,j_n)$. The sequence J is called *strongly typical*[7] if the numbers $N(j|J)$ of appearance of the symbol j in J satisfy the condition

$$\left|\frac{N(j|J)}{n}-\lambda_j\right|<\delta,\quad j=1,\ldots,d,$$

and $N(j|J)=0$ if $\lambda_j=0$. Let us denote the collection of all strongly typical sequences as $B^{n,\delta}$, and let P^n be the probability distribution given by the eigenvalues λ_J. Then by the Law of Large Numbers, $\mathsf{P}^n(\mathsf{B}^{n,\delta})\to 1$ as $n\to\infty$. It is shown in Ref. 7 that the size of $B^{n,\delta}$ satisfies

$$2^{n[H(S)-\Delta_n(\delta)]}<|B^{n,\delta}|<2^{n[H(S)+\Delta_n(\delta)]},\tag{9}$$

where $H(S)=-\Sigma_{j=1}^{d}\lambda_j\log\lambda_j$, and $\lim_{\delta\to 0}\lim_{n\to\infty}\Delta_n(\delta)=0$.

For arbitrary function $f(j)$, $j=1,\ldots,d$, and $J=(j_1,\ldots,j_n)\in B^{n,\delta}$, we have

$$\left|\frac{f(j_1)+\cdots+f(j_n)}{n}-\sum_{j=1}^{d}\lambda_j f(j)\right|<\delta\max f. \tag{10}$$

In particular, any strongly typical sequence is (entropy) typical: taking $f(j)=-\log\lambda_j$ gives

$$n[H(S)-\delta_1]<-\log\lambda_J<n[H(S)+\delta_1], \tag{11}$$

where $\delta_1=\delta\max_{\lambda_j>0}(-\log\lambda_j)$. The converse is not true—not every typical sequence is strongly typical.

The strongly typical projector is defined as the following spectral projector of $S^{\otimes n}$:

$$P^{n,\delta}=\sum_{J\in B^{n,\delta}}|e_J\rangle\langle e_J|.$$

We denote $d_{n,\delta}=\dim P^{n,\delta}=|B^{n,\delta}|$ and $\overline{S}^{n,\delta}=P^{n,\delta}/d_{n,\delta}$ and we are going to prove that

$$\lim_{\delta\to 0}\lim_{n\to\infty}\frac{1}{n}H(\Psi^{\otimes n}(\overline{S}^{n,\delta}))=H(\Psi(S)) \tag{12}$$

for arbitrary channel Ψ.

We have

$$\begin{aligned}nH(\Psi(S))-H(\Psi^{\otimes n}(\overline{S}^{n,\delta}))&=H(\Psi(S)^{\otimes n})-H(\Psi^{\otimes n}(\overline{S}^{n,\delta}))\\&=H(\Psi^{\otimes n}(\overline{S}^{n,\delta})|\Psi^{\otimes n}(S^{\otimes n}))\\&\quad+\mathrm{Tr}\log\Psi(S)^{\otimes n}(\Psi^{\otimes n}(\overline{S}^{n,\delta})-\Psi(S)^{\otimes n}),\end{aligned} \tag{13}$$

where $H(\cdot|\cdot)$ is relative entropy. Strictly speaking, this formula is correct if the density operator $\Psi(S)^{\otimes n}$ is nondegenerate, which we assume for a moment. Later we shall show how the argument can be modified to the general case.

For the first term we have the estimate by the fundamental property of monotonicity of the relative entropy

$$H(\Psi^{\otimes n}(\overline{S}^{n,\delta})|\Psi^{\otimes n}(S^{\otimes n}))\leqslant H(\overline{S}^{n,\delta}|S^{\otimes n}),$$

with the right-hand side computed explicitly as

$$H(\overline{S}^{n,\delta}|S^{\otimes n})=\sum_{J\in B^{n,\delta}}\frac{1}{d_{n,\delta}}\log\frac{1}{d_{n,\delta}\lambda_J}=-\log d_{n,\delta}-\sum_{J\in B^{n,\delta}}\frac{1}{d_{n,\delta}}\log\lambda_J,$$

which is less than or equal to $n(\delta_1+\Delta_n(\delta))$ by (11) and (9), giving sufficient estimate.

By using the identity

$$\log\Psi(S)^{\otimes n}=\log\Psi(S)\otimes I\otimes\cdots\otimes I+\cdots+I\otimes\cdots\otimes I\otimes\log\Psi(S),$$

and introducing the operator $F=\Psi^*(\log\Psi(S))$ where Ψ^* is the dual channel, we can rewrite the second term as

$$\begin{aligned}&n\,\mathrm{Tr}\frac{(F\otimes I\otimes\cdots\otimes I+\cdots+I\otimes\cdots\otimes I\otimes F)}{n}(\overline{S}^{n,\delta}-S^{\otimes n})\\&=\frac{n}{d_{n,\delta}}\sum_{J\in B^{n,\delta}}\left[\frac{f(j_1)+\cdots+f(j_n)}{n}-\sum_{j=1}^{d}\lambda_j f(j)\right],\end{aligned}$$

where $f(j)=\langle e_j|F|e_j\rangle$, which is evaluated by $n\delta\max f$ via (10). This establishes (12) in the case of a nondegenerate $\Psi(S)$.

Coming back to the general case, let us denote by P_Ψ the supporting projector of $\Psi(S)$. Then the supporting projector of $\Psi(S)^{\otimes n}$ is $P_\Psi^{\otimes n}$, and the support of $\Psi^{\otimes n}(\overline{S^{n,\delta}})$ is contained in the support of $\Psi(S)^{\otimes n}=\Psi^{\otimes n}(S^{\otimes n})$, because the support of $\overline{S^{n,\delta}}$ is contained in the support of $S^{\otimes n}$. Thus the second term in (13) should be understood as

$$\mathrm{Tr}P_\Psi^{\otimes n}\log[P_\Psi^{\otimes n}\Psi(S)^{\otimes n}P_\Psi^{\otimes n}]P_\Psi^{\otimes n}(\Psi^{\otimes n}(\overline{S^{n,\delta}})-\Psi(S)^{\otimes n}),$$

where now we have log of a nondegenerate operator in $P_\Psi^{\otimes n}\mathcal{H}_A^{\otimes n}$. We can then repeat the argument with F defined as $\Psi^*(P_\Psi[\log P_\Psi\Psi(S)P_\Psi]P_\Psi)$. This fulfills the proof of (8), from which (6) follows.

Proof of the inequality:

$$C_{ea}(\Phi)\leqslant\max_{S_A} I(S_A,\Phi). \tag{14}$$

We first prove that

$$C_{ea}^{(1)}(\Phi)\leqslant\max_{S_A} I(S_A,\Phi). \tag{15}$$

The proof is a modification of that from Ref. 3, using properties of conditional quantum entropy which are known to follow from the strong subadditivity of the entropy (see, e.g., Refs. 8 and 4), rather than the strong subadditivity itself.

Let us denote $\mathcal{E}_A^i$ the encodings used by A. Let S_{AB} be the pure state initially shared by A and B. Then the state of the system AB (resp. A) after the encoding is

$$S_{AB}^i=(\mathcal{E}_A^i\otimes\mathrm{Id}_B)[S_{AB}],\quad \text{resp.}\quad S_A^i=\mathcal{E}_A^i[S_A]. \tag{16}$$

Note that the partial state of B does not change after the encoding, $S_B^i=S_B$. We are going to prove that

$$H\left(\sum_i \pi_i(\Phi\otimes\mathrm{Id}_B)[S_{AB}^i]\right)-\sum_i \pi_i H((\Phi\otimes\mathrm{Id}_B)[S_{AB}^i])\leqslant I\left(\sum_i \pi_i S_A^i;\Phi\right). \tag{17}$$

By the quantum coding theorem, the maximum of the left-hand side with respect to all possible $\pi_i,\mathcal{E}_A^i$ is just $C_{ea}^{(1)}(\Phi)$, whence (15) will follow.

By using subadditivity of quantum entropy, we can evaluate the first term on the left-hand side of (17) as

$$H\left(\sum_i \pi_i\Phi[S_A^i]\right)+H(S_B)=H\left(\Phi\left[\sum_i \pi_i S_A^i\right]\right)+\sum_i \pi_i H(S_B).$$

Here the first term already gives the output entropy from $I(\Sigma_i\pi_i S_A^i;\Phi)$. Let us proceed with evaluation of the remainder

$$\sum_i \pi_i[H(S_B)-H((\Phi\otimes\mathrm{Id}_B)[S_{AB}^i])].$$

We first show that the term in square brackets does not exceed $H(S_A^i)-H((\Phi\otimes\mathrm{Id}_{R^i})[S_{AR^i}^i])$, where R^i is the purifying (reference) system for S_A^i, and $S_{AR^i}^i$ is the purified state. To this end consider the unitary extension of the encoding $\mathcal{E}_A^i$ with the environment E_i, which is initially in

a pure state. From (16) we see that we can take $R^i=BE_i$ (after the unitary interaction which involves only AE_i). Then, again denoting with primes the states after the application of the channel Φ, we have

$$H(S_B)-H((\Phi\otimes \mathrm{Id}_B)[S^i_{AB}])=H(S_B)-H(S^i_{A'B})=-H_i(A'|B), \tag{18}$$

where the lower index i of the conditional entropy points out to the joint state $S^i_{A'B}$. Similarly

$$H(S^i_A)-H((\Phi\otimes \mathrm{Id}_{R^i})[S^i_{AR^i}])=H(S^i_{R^i})-H(S^i_{A'R^i})=-H_i(A'|R^i)=-H_i(A'|BE_i),$$

which is greater than or equal to (18) by monotonicity of the conditional entropy.

Using the concavity of the function $S_A\to H(S_A)-H((\Phi\otimes \mathrm{Id}_R)[S_{AR}])$ to be shown below, we get

$$\sum_i \pi_i[H(S^i_A)-H((\Phi\otimes \mathrm{Id}_{R^i})[S^i_{AR^i}])]\leqslant H\left(\sum_i \pi_i S^i_A\right)-H((\Phi\otimes \mathrm{Id}_R)[\hat{S}_{AR}]),$$

where $\hat{S}_{AR}$ is the state purifying $\Sigma_i\pi_i S^i_A$ with a reference system R.

To complete this proof it remains to show the above concavity. By introducing the environment E for the channel Φ, we have

$$H(S_A)-H((\Phi\otimes \mathrm{Id}_R)[S_{AR}])=H(S_R)-H(S_{A'R})=H(S_{A'E'})-H(S_{E'})=H(A'|E').$$

The conditional entropy $H(A'|E')$ is a concave function of $S_{A'E'}$. The map $S_A\to S_{A'E'}$ is affine and therefore $H(A'|E')$ is a concave function of S_A.

Applying the same argument to the channel $\Phi^{\otimes n}$ gives

$$C^{(n)}_{ea}(\Phi)\leqslant \max_{S^n_A} I(S^n_A;\Phi^{\otimes n}). \tag{19}$$

Then from subadditivity of quantum mutual information,[9] we have

$$\max_{S_{12}} I(S_{12};\Phi_1\otimes\Phi_2)=\max_{S_1} I(S_1;\Phi_1)+\max_{S_2} I(S_2;\Phi_2),$$

implying the remarkable additivity property

$$\max_{S^n_A} I(S^n_A;\Phi^{\otimes n})=n\max_{S_A} I(S_A;\Phi).$$

Therefore, finally we obtain (14).

III. RELATION BETWEEN ENTANGLEMENT-ASSISTED AND UNASSISTED CAPACITIES

The definition of $C^{(1)}_{ea}(\Phi)$ and hence of $C_{ea}(\Phi)$ can be formulated without explicit introduction of the encoding operations $\mathcal{E}^i_A$, namely,

$$C^{(1)}_{ea}(\Phi)=\max_{\pi_i,\{S^i_{AB}\}\in\Sigma_B}\left[H\left(\sum_i \pi_i(\Phi\otimes \mathrm{Id}_B)[S^i_{AB}]\right)-\sum_i \pi_i H((\Phi\otimes \mathrm{Id}_B)[S^i_{AB}])\right], \tag{20}$$

where Σ_B is the collection of families of the states $\{S^i_{AB}\}$ satisfying the condition that their partial states S^i_B do not depend on i, $S^i_B=S_B$. This follows from the next lemma.

Lemma: Let $\{S^i_{AB}\}$ be a family of the states satisfying the condition $S^i_B=S_B$. Then there exist a pure state S_{AB} and encodings $\mathcal{E}^i_A$ such that

$$S_{AB}^i=(\mathcal{E}_A^i\otimes \mathrm{Id}_B)[S_{AB}]. \tag{21}$$

Proof: For simplicity assume that S_B is nondegenerate. Then

$$S_B=\sum_{k=1}^{d}\lambda_k|e_k^B\rangle\langle e_k^B|,$$

where $\lambda_k>0$ and $\{|e_k^B\rangle\}$ is an orthonormal basis in $\mathcal{H}_B$. Let $\{|e_k^A\rangle\}$ be an orthonormal basis in $\mathcal{H}_A$. For a vector $|\psi^A\rangle=\Sigma_{k=1}^d c_k|e_k^A\rangle$ we denote $|\overline{\psi}^B\rangle=\Sigma_{k=1}^d\overline{c_k}|e_k^B\rangle$. The map $|\psi^A\rangle\to|\overline{\psi}^B\rangle$ is an anti-isomorphism of $\mathcal{H}_A$ and $\mathcal{H}_B$. Put

$$|\psi_{AB}\rangle=\sum_{k=1}^{d}\sqrt{\lambda_k}|e_k^A\rangle\otimes|e_k^B\rangle,$$

so that $S_{AB}=|\psi_{AB}\rangle\langle\psi_{AB}|$ and define encodings by the relation

$$\mathcal{E}_A^i[|\psi^A\rangle\langle\phi^A|]=\langle\overline{\psi}^B|S_B^{-1/2}S_{AB}^iS_B^{-1/2}|\overline{\phi}^B\rangle,\quad |\psi^A\rangle,|\phi^A\rangle\in\mathcal{H}_A.$$

Then one can check that $\mathcal{E}_A^i$ are indeed channels fulfilling the formula (21).

In the case S_B is degenerate, the above construction should be modified by replacing $S_B^{-1/2}S_{AB}^iS_B^{-1/2}$ in the formula above with $\sqrt{S_B^-}S_{AB}^i\sqrt{S_B^-}+P_B^0$ where S_B^- is the generalized inverse of S_B and P_B^0 is the projection onto the null subspace of S_B.

We now observe an inequality relating the asymptotic entanglement-assisted and unassisted capacities. Apparently,

$$C_{ea}^{(1)}(\Phi)\leqslant\max_{\pi_i,S_{AB}^i}\left[H\left(\sum_i\pi_i(\Phi\otimes\mathrm{Id}_B)[S_{AB}^i]\right)-\sum_i\pi_iH((\Phi\otimes\mathrm{Id}_B)[S_{AB}^i])\right], \tag{22}$$

where S_{AB}^i are already arbitrary states, not necessarily of the form (21). The quantity on the right hand side is nothing but the one-shot classical capacity $C^{(1)}(\Phi\otimes\mathrm{Id}_B)$ of the channel $\Phi\otimes\mathrm{Id}_B$. It was shown in Ref. 10 that $C^{(1)}(\Phi\otimes\mathrm{Id}_B)=C^{(1)}(\Phi)+C^{(1)}(\mathrm{Id}_B)=C^{(1)}(\Phi)+\log d$. Applying the same argument to $\Phi^{\otimes n}$ instead of Φ, we have

$$C_{ea}^{(1)}(\Phi^{\otimes n})\leqslant C^{(1)}(\Phi^{\otimes n})+n\log d.$$

Dividing by n and taking limit $n\to\infty$, we obtain

$$C_{ea}(\Phi)\leqslant C(\Phi)+\log d.$$

One can expect that a similar inequality,

$$C_{ea}(\Phi)\leqslant C^{(1)}(\Phi)+\log d,$$

holds generally for the one-shot classical capacity; if it breaks for some channel Φ, then for this channel $C^{(1)}(\Phi)<C(\Phi)$, which would imply a negative answer to the long-standing question concerning additivity of the classical capacity.

It is not difficult to check that the inequality indeed holds for all unital qubit channels and for d-depolarizing channel

$$\Phi[\mathcal{S}]=(1-p)S+p\frac{I}{d}\mathrm{Tr}S. \tag{23}$$

Here $\dim\mathcal{H}=d$ and the parameter p should lie in the range $0\leqslant p\leqslant d^2/(d^2-1)$, as can be seen from the Kraus representation

$$\Phi[\mathcal{S}]=\left(1-p\frac{d^2-1}{d^2}\right)S+p\frac{1}{d^2}\sum_{\alpha,\beta\neq d}W_{\alpha\beta}SW_{\alpha\beta}^{*}, \tag{24}$$

with $W_{\alpha\beta};\alpha,\beta=1,\ldots,d$ built upon an arbitrary orthonormal basis in $\mathcal{H}$.

The quantity $C_{ea}(\Phi)$ can be computed by using unitary covariance of the depolarizing channel and concavity of the function $S\rightarrow I(S;\Phi)$. It follows that it achieves the maximum at the chaotic state $\overline{S}=I/d$. We have $H(\overline{S})=H(\Phi[\overline{S}])=\log d$. The entropy exchange $H(\overline{S};\Phi)$ can be computed by as the entropy of the matrix $[\mathrm{Tr}\overline{S}A_{\alpha\beta}^{*}A_{\alpha\beta}]$, where $A_{\alpha\beta}=(\sqrt{p}/d)W_{\alpha\beta};\alpha,\beta\neq d;A_{dd}=\sqrt{1-p\,[(d^2-1)/d^2]}\,I$ are the Kraus operators from the representation (24). We thus obtain

$$C_{ea}(\Phi)=\log d^2+\left(1-p\frac{d^2-1}{d^2}\right)\log\left(1-p\frac{d^2-1}{d^2}\right)+p\frac{d^2-1}{d^2}\log\frac{p}{d^2}. \tag{25}$$

This should be compared with the unassisted classical capacity, which is equal to

$$C^{(1)}(\Phi)=\log d+\left(1-p\frac{d-1}{d}\right)\log\left(1-p\frac{d-1}{d}\right)+p\frac{d-1}{d}\log\frac{p}{d}, \tag{26}$$

and is achieved for an ensemble of equiprobable pure states taken from an orthonormal basis in $\mathcal{H}$. One then sees as in Ref. 2 that $C_{ea}(\Phi)/C^{(1)}(\Phi)\rightarrow d+1$ in the limit of strong noise $p\rightarrow 1$. (Note that both capacities tend to zero!)

Moreover, taking the maximal possible value $p=d^2/(d^2-1,)$ we obtain

$$C_{ea}=\log\frac{d^2}{d^2-1},$$

$$C^{(1)}=\frac{1}{d+1}\log\frac{d}{d+1}+\frac{d}{d+1}\log\frac{d^2}{d^2-1}.$$

Here the ratio $C_{ea}/C^{(1)}$ monotonically increases from the value 5.0798 for $d=2$, approaching tightly the asymptotic line $2(d+1)$ as d grows to infinity.

Additivity of the classical capacity of entanglement-breaking quantum channels

Peter W. Shor[a)]
AT&T Labs, Florham Park, New Jersey 07922

(Received 24 January 2002; accepted for publication 16 May 2002)

We show that for the tensor product of an entanglement-breaking quantum channel with an arbitrary quantum channel, both the minimum entropy of an output of the channel and the Holevo–Schumacher–Westmoreland capacity are additive. In addition, for the tensor product of two arbitrary quantum channels, we give a bound involving entanglement of formation for the amount of subadditivity (for minimum entropy output) or superadditivity (for classical capacity) that can occur. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1498000]

One of the more important open questions of quantum information theory is the determination of the capacity of a quantum channel for carrying classical information. This question has been only partially resolved. If entanglement between multiple inputs to the channel is not allowed, a formula for the classical capacity of a quantum channel has indeed been discovered.[1,2] This capacity formula for a quantum channel Ψ is

$$\chi^*(\Psi)=\max_{p_i,\rho_i} H\left(\sum_i \Psi(p_i\rho_i)\right)-\sum_i p_i H(\Psi(\rho_i)), \tag{1}$$

where H is the von Neumann entropy $H(\rho)=-\mathrm{Tr}\,\rho\log\rho$, and where the maximization is over probability distributions p_i on density matrices ρ_i over the input space of the channel. This maximum can be attained because we need at most d^2 density matrices ρ_i to achieve any attainable value of

$$\chi(\{p_i,\rho_i\})=H\left(\sum_i \Psi(p_i\rho_i)\right)-\sum_i p_i H(\Psi(\rho_i)) \tag{2}$$

and are thus maximizing over a compact space. The general capacity of a quantum channel Ψ, without feedback or prior entanglement between sender and receiver, but possibly using entangled inputs, is

$$C(\Psi)=\lim_{n\to\infty}\frac{1}{n}\chi^*(\Psi^{\otimes n}), \tag{3}$$

i.e., the limit for large n of the capacity when we permit the input to be entangled over blocks of n channel uses. This limit can be shown to exist because χ^* satisfies the superadditivity condition

$$\chi^*(\Psi\otimes\Phi)\geqslant\chi^*(\Psi)+\chi^*(\Phi). \tag{4}$$

It is conjectured that equality holds, i.e., that χ^* is additive, in which case χ^* would give the classical capacity of a quantum channel without feedback. Substantial work has been done on this conjecture,[3,4] and it has been proven for several special cases. In particular, it has been proven

a)Electronic mail: shor@research.att.com

when one of the channels is the identity channel,[4,5] when one of the channels is what A. S. Holevo calls a c-q or q-c channel (these terms will be defined later),[6,7] and when one of the channels is a unital qubit channel.[8]

We will prove additivity for the special case where one of the two channels is entanglement breaking. Entanglement breaking channels are channels which destroy entanglement with other quantum systems. That is, when the input state is entangled between the input space $\mathcal{H}_{\text{in}}$ and another quantum system $\mathcal{H}_{\text{ref}}$, the output of the channel is no longer entangled with the system $\mathcal{H}_{\text{ref}}$. Both c-q and q-c channels are special cases of entanglement breaking channels. A c-q channel is a channel which can be expressed by the composition of a complete von Neumann measurement on the input space followed by an arbitrary completely positive trace-preserving (CPT) map. A q-c channel can be expressed as the composition of a CPT map followed by a complete von Neumann measurement on the output space. Stated more intuitively, for c-q maps, the input can be treated as being classical, and for q-c maps, the output can be taken to be classical. In either case, the von Neumann measurement eliminates any entanglement between the input space and another system, so c-q and q-c maps are both special cases of entanglement breaking channels. In a conversation with the author, Michal Horodecki[9] gave a simple proof that any entanglement breaking channel can be expressed as a q-c-q channel; that is, the composition of a CPT operator followed by a complete von Neumann measurement followed by another CPT operator. (See also Ref. 10 for details of this proof.) As a consequence, the action of an entanglement breaking channel Φ on a state ρ can always be written in the following form introduced by Holevo:[6]

$$\Phi(\rho)=\sum_i \operatorname{Tr}(X_i\rho)\,\theta_i \tag{5}$$

where $\{X_i\}$ form a general POVM and $\{\theta_i\}$ are arbitrary states. For a c-q map, $X_i=|i\rangle\langle i|$ where $|i\rangle$ form an orthonormal basis, and for a q-c map $\theta_i=|i\rangle\langle i|$.

The additivity problem for capacity is closely related to another additivity problem, that of the minimum entropy output of a channel.[11] For the case of entanglement breaking channels, we first found the additivity proof for the minimum entropy output, and then discovered a straightforward way to extend this additivity proof to cover the classical capacity. In this article, we first give the proof for additivity of minimum entropy output, as this proof contains the important ideas for the capacity proof, but has significantly fewer technicalities.

Theorem 1: *For an arbitrary quantum channel Ψ and an entanglement breaking channel Φ*

$$\min_{\rho_{AB}} H((\Psi\otimes\Phi)(\rho_{AB}))=\min_{\rho_A} H(\Psi(\rho_A))+\min_{\rho_B} H(\Phi(\rho_B)). \tag{6}$$

Proof: The left-hand side is clearly at most the right-hand side, as can be seen by choosing $\rho_{AB}=\rho_A\otimes\rho_B$. We would like to show that it is at least the right-hand side. We use the strong subadditivity property of von Neumann entropy.[12] Consider the minimum obtainable value of $H((\Psi\otimes\Phi)(\rho_{AB}))$. Because Φ is entanglement breaking,

$$(I\otimes\Phi)(\rho_{AB})=\sum_j q_j|a_j\rangle\langle a_j|\otimes|b_j\rangle\langle b_j| \tag{7}$$

for some q_j, $|a_j\rangle\in\mathcal{H}_A$ and $|b_j\rangle\in\mathcal{H}_B$. Now, we apply to the state

$$\sigma_{ABC}=\sum_j q_j\Psi(|a_j\rangle\langle a_j|)\otimes|b_j\rangle\langle b_j|\otimes|j\rangle\langle j| \tag{8}$$

the property of strong subadditivity in the form

$$H(\sigma_{AB})\geqslant H(\sigma_{ABC})-H(\sigma_{BC})+H(\sigma_B). \tag{9}$$

We have

$$\sigma_{AB}=\sum_j q_j\Psi(|a_j\rangle\langle a_j|)\otimes|b_j\rangle\langle b_j|=(\Psi\otimes\Phi)(\rho_{AB}), \tag{10}$$

the quantity for the entropy of which we would like a lower bound. Now, note that

$$H(\sigma_{ABC})-H(\sigma_{BC})=H(\sigma_{AC})-H(\sigma_C)=\sum_j q_j H(\Psi(|a_j\rangle\langle a_j|)). \tag{11}$$

The first equality above follows from the facts that the $|j\rangle$ form an orthonormal set and ρ_B is in a pure state, so that $H(\sigma_{ABC})=H(\sigma_{AC})$ and $H(\sigma_{BC})=H(\sigma_C)$. The second equality follows from the chain rule for entropy, namely,

$$H\left(\sum_j q_j\gamma_j\otimes|j\rangle\langle j|\right)-\sum_j H(q_j|j\rangle\langle j|)=\sum_j q_j H(\gamma_j), \tag{12}$$

for a probability distribution q_j, orthonormal states $|j\rangle$, and arbitrary density matrices γ_j. Now, note that

$$\sigma_B=\sum_j q_j|b_j\rangle\langle b_j|=\mathrm{Tr}_A(I\otimes\Phi)(\rho_{AB})=\Phi(\mathrm{Tr}_A\rho_{AB}). \tag{13}$$

Putting the above equalities together, we see that

$$H((\Psi\otimes\Phi)(\rho_{AB}))\geqslant\sum_j q_j H(\Psi(|a_j\rangle\langle a_j|))+H(\Phi(\mathrm{Tr}_A\rho_{AB})). \tag{14}$$

Since $\Sigma_j q_j=1$, the right-hand side is clearly at least the sum of the minimum output entropies of Ψ and of Φ. We have thus shown that the minimum output entropy is additive for the tensor product of two channels if one of the channels is an entanglement breaking channel. □

We now prove the corresponding additivity result for the Holevo–Schumacher–Westmoreland capacity χ^*; recall

$$\chi^*(\Psi)=\max_{p_i,\rho_i} H\left(\Psi\left(\sum_i p_i\rho_i\right)\right)-\sum_i p_i H(\Psi(\rho_i)) \tag{15}$$

over probability distributions p_i and density matrices ρ_i.

Theorem 2: *For an arbitrary quantum channel Ψ and an entanglement breaking channel Φ,*

$$\chi^*(\Psi\otimes\Phi)=\chi^*(\Psi)+\chi^*(\Phi). \tag{16}$$

Proof: The capacity χ^* is composed of two terms. We will be treating these two terms separately. For the second term, additivity is shown in essentially the same way as in the proof of additivity for minimum entropy, and, for the first term, additivity follows from the subadditivity of von Neumann entropy.

Again, we assume that we have an arbitrary quantum channel Ψ and an entanglement breaking channel Φ. We use strong subadditivity. Consider the optimal signal states for $\Psi\otimes\Phi$, i.e., the p_i and ρ_i such that

$$\chi^*(\Psi\otimes\Phi)=H((\Psi\otimes\Phi)(\rho))-\sum p_i H((\Psi\otimes\Phi)(\rho_i)), \tag{17}$$

where $\rho=\Sigma p_i\rho_i$. Let us consider the state $(I\otimes\Phi)(\rho_i)$. Because Φ is an entanglement breaking map, this state is separable, and so

$$(I\otimes\Phi)(\rho_i)=\sum_j q_{ij}|a_{ij}\rangle\langle a_{ij}|\otimes|b_{ij}\rangle\langle b_{ij}| \tag{18}$$

for some q_{ij}, $|a_{ij}\rangle$, $|b_{ij}\rangle$. Now, we apply strong subadditivity to the state

$$\sigma_{ABC}=\sum_j q_{ij}\Psi(|a_{ij}\rangle\langle a_{ij}|)\otimes|b_{ij}\rangle\langle b_{ij}|\otimes|j\rangle\langle j|. \tag{19}$$

To simplify notation, we let the dependence of σ on i be implicit. Again, we apply strong subadditivity in the form

$$H(\sigma_{AB})\geqslant H(\sigma_{ABC})-H(\sigma_{BC})+H(\sigma_B). \tag{20}$$

As before,

$$H(\sigma_{AB})=H((\Psi\otimes\Phi)(\rho_i)). \tag{21}$$

We also have that

$$H(\sigma_B)=H(\Phi(\mathrm{Tr}_A\rho_i)) \tag{22}$$

and

$$H(\sigma_{ABC})-H(\sigma_{BC})=\sum_j q_{ij}H(\Psi(|a_{ij}\rangle\langle a_{ij}|)). \tag{23}$$

We let $|a_{ij}\rangle\langle a_{ij}|=\tau_{ij}$. Then $\mathrm{Tr}_B\rho_i=\Sigma q_{ij}\tau_{ij}$. Combining the terms, we observe

$$H((\Psi\otimes\Phi)(\rho_i))\geqslant\sum_j q_{ij}H(\Psi(\tau_{ij}))+H(\Phi(\mathrm{Tr}_A\rho_i)). \tag{24}$$

Now, let us sum over all the states ρ_i. We obtain

$$\sum_i p_iH((\Psi\otimes\Phi)(\rho_i))\geqslant\sum_{i,j} p_iq_{ij}H(\Psi(\tau_{ij}))+\sum_i p_iH(\Phi(\mathrm{Tr}_A\rho_i)). \tag{25}$$

Using subadditivity of von Neumann entropy and the above inequality (25), we get that

$$\begin{aligned}\chi^*(\Psi\otimes\Phi)&=H((\Psi\otimes\Phi)(\rho))-\sum_i p_iH((\Psi\otimes\Phi)(\rho_i))\\&\leqslant H(\Psi(\mathrm{Tr}_B\rho))+H(\Phi(\mathrm{Tr}_A\rho))-\sum_{i,j} p_iq_{ij}H(\Psi(\tau_{ij}))-\sum_i p_iH(\Phi(\mathrm{Tr}_A\rho_i)).\end{aligned} \tag{26}$$

However, since

$$\sum_{i,j} p_iq_{ij}\tau_{ij}=\sum_i p_i\mathrm{Tr}_B\rho_i=\mathrm{Tr}_B\rho \quad\text{and}\quad \sum_i p_i\mathrm{Tr}_A\rho_i=\mathrm{Tr}_A\rho, \tag{27}$$

we see that

$$\chi^*(\Psi\otimes\Phi)\leqslant\chi^*(\Psi)+\chi^*(\Phi). \tag{28}$$

As the opposite inequality is easy, we have additivity of χ^* for entanglement breaking channels.□

We finally give a bound on the amount of superadditivity for general channels. For this, we need to define the entanglement of formation of a bipartite state. This is another quantity that is conjectured to be additive, but for which additivity has not been proved. Entanglement of formation for a bipartite state ρ_{AB} is defined

$$E_F(\rho_{AB}) = \min_{\substack{p_i,\rho_i \\ \Sigma_i p_i \rho_i = \rho_{AB}}} \sum p_i H(\mathrm{Tr}_A \rho_i), \tag{29}$$

where the minimization is over probability distributions p_i on rank-one density matrices ρ_i such that $\Sigma_i p_i \rho_i = \rho_{AB}$. The theorem is

Theorem 3: *Suppose we have two quantum channels, i.e., completely positive trace preserving maps, Ψ and Φ. Then*

$$\min_{\rho_{AB}} H((\Psi\otimes\Phi)(\rho_{AB})) \geqslant \min_{\rho_A} H(\Psi(\rho_A)) + \min_{\rho_B} H(\Phi(\rho_B)) - \max_{\rho_{AB}} E_F((I\otimes\Phi)(\rho_{AB})) \tag{30}$$

and

$$\chi^*(\Psi\otimes\Phi) \leqslant \chi^*(\Psi) + \chi^*(\Phi) + \max_{\rho_{AB}} E_F((I\otimes\Phi)(\rho_{AB})). \tag{31}$$

Note that the formulation of the theorem is asymmetric with respect to Ψ and Φ. Thus, to bound the amount of sub- or superadditivity, one can use either the entanglement of formation of $(I\otimes\Phi)(\rho_{AB})$ or of $(\Psi\otimes I)(\rho_{AB})$, whichever is smaller.

Proof: We first give the proof of the first part of Theorem 3 Let

$$(I\otimes\Phi)(\rho_{AB}) = \sum_i q_i \nu_i \tag{32}$$

be the decomposition of $(I\otimes\Phi)(\rho_{AB})$ into pure states ν_i that minimizes entanglement of formation, i.e., so that $\Sigma_j q_j H(\mathrm{Tr}_A \nu_j)$ is minimum. Now, we consider

$$\sigma_{ABC} = \sum_j q_j (\Psi\otimes I)(\nu_j)\otimes |j\rangle\langle j| \tag{33}$$

and apply strong subadditivity to this state. We obtain

$$H(\sigma_{AB}) \geqslant (H(\sigma_{ABC}) - H(\sigma_C)) + (H(\sigma_B)) - (H(\sigma_{BC}) - H(\sigma_C)). \tag{34}$$

As in (10), we have

$$H(\sigma_{AB}) = H((\Psi\otimes\Phi)(\rho_{AB})). \tag{35}$$

Similar to (13), we get

$$H(\sigma_B) = H\left(\sum_j q_j \mathrm{Tr}_A \nu_j\right) = H(\Phi(\mathrm{Tr}_A \rho_{AB})). \tag{36}$$

Furthermore, the choice of ν_j and the definition of E_F give

$$H(\sigma_{BC}) - H(\sigma_C) = E_F((I\otimes\Phi)(\rho_{AB})). \tag{37}$$

Finally, application of the entropy chain rule (12) gives

$$H(\sigma_{ABC})-H(\sigma_C)=\sum_j q_j H((\Psi\otimes I)(\nu_j)). \tag{38}$$

The expression (36) is bounded below by $\min_\rho H(\Phi(\rho))$. The second expression (37) is bounded above by $\max_\rho E_F((I\otimes\Phi)(\rho))$. The third expression (38) is bounded below by $\min_\rho H((\Psi\otimes I)(\rho))$, which is known to equal $\min_\rho H(\Psi(\rho))$. Combining these three expressions give the first part of Theorem 3.

To prove the second part of the theorem, (38) must be replaced by

$$H(\sigma_{ABC})-H(\sigma_C)\geqslant\sum_{jk} q_j r_{jk} H(\Psi(|v_{jk}\rangle\langle v_{jk}|)) \tag{39}$$

for states $|v_{jk}\rangle$ and probabilities $q_j r_{jk}$ such that

$$\sum_{j,k} q_j r_{jk}|v_{jk}\rangle\langle v_{jk}|=\mathrm{Tr}_B\nu_j. \tag{40}$$

We then consider the signal states ρ_i and the associated probabilities p_i which give the value of $\chi^*(\Psi\otimes\Phi)$ in Eq. (1), and let $\Sigma_i p_i\rho_i=\rho$. We now use expressions (36), (37), and (39) with ρ_i in the place of ρ_{AB}. Combining these three expressions yields

$$H((\Psi\otimes\Phi)(\rho_i))\geqslant H(\Phi(\mathrm{Tr}_A\rho_i))+\sum_{j,k} q_{ij}r_{ijk}H(\Psi(|v_{ijk}\rangle\langle v_{ijk}|))-E_F((I\otimes\Phi)(\rho_i)). \tag{41}$$

The second part of Theorem 3 then follows in a way entirely analogous to the proof of Theorem 2. We use the equalities

$$\mathrm{Tr}_B\rho=\sum_i p_i\mathrm{Tr}_A\rho_i \tag{42}$$

and

$$\mathrm{Tr}_A\rho=\sum_{i,j,k} p_i q_{ij} r_{ijk}|v_{ijk}\rangle\langle v_{ijk}|, \tag{43}$$

and expand $\chi^*(\Psi\otimes\Phi)$ similarly to Eq. (26) to obtain Eq. (31).

We still must prove the inequality (39). The left-hand side of (39) is

$$\sum_j q_j H((\Psi\otimes I)(\nu_j)). \tag{44}$$

Now, ν_j is a purification of $\mathrm{Tr}_B\nu_j$, and $H((\Psi\otimes I)(\nu_j))=H((\Psi\otimes I)(\tau))$ for any quantum state τ which is a purification of $\sigma_j=\mathrm{Tr}_B\nu_j$. Let $\sigma_j=\Sigma_k q_{jk}|v_{jk}\rangle\langle v_{jk}|$ be the eigenvector decomposition of σ_j. A different purification is

$$\tau_j=\left(\sum_k q_{jk}|v_{jk}\rangle\otimes|k\rangle\otimes|k\rangle\right)\left(\sum_k q_{jk}\langle v_{jk}|\otimes\langle k|\otimes\langle k|\right). \tag{45}$$

It suffices to show that

$$H((\Psi\otimes I)(\tau_j))\geqslant H(\mathrm{Tr}_3(\Psi\otimes I)(\tau_j))-H(\mathrm{Tr}_{12}(\Psi\otimes I)(\tau_j)) \tag{46}$$

as the first term in the above equation is $H((\Psi\otimes I)(\nu_j))$, the second is $H(\{q_{jk}\}_k)+\Sigma_k q_{jk}H(\Psi(|v_{jk}\rangle\langle v_{jk}|))$, and the third is $H(\{q_{jk}\}_k)$. However, the above equation follows from

the inequality $H(\rho_{34}) \geqslant H(\rho_3) - H(\rho_4)$, which is a consquence (after another purification) of the subadditivity property of entropy.[13] □

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Scalable programmable quantum gates and a new aspect of the additivity problem for the classical capacity of quantum channels

Andreas Winter[a)]
Department of Computer Science, University of Bristol, Merchant Venturers Building, Woodland Road, Bristol BS8 1UB, United Kingdom

(Received 24 October 2001; accepted for publication 16 May 2002)

We consider two apparently separated problems: in the first part of the article we study the concept of a *scalable (approximate) programmable quantum gate* (SPQG). These are special (approximate) programmable quantum gates, with nice properties that could have implications on the theory of universal computation. Unfortunately, as we prove, such objects do not exist in the domain of usual quantum theory. In the second part the problem of noisy dense coding (and generalizations) is addressed. We observe that the additivity problem for the classical capacity obtained is of apparently greater generality than for the usual quantum channel (completely positive maps): i.e., the latter occurs as a special case of the former, but, as we shall argue with the help of the nonexistence result of the first part, the former cannot be reduced to an instance of the latter. We conclude by suggesting that the additivity problem for the classical capacity of quantum channels, as posed until now, may conceptually not be in its appropriate generality. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1498489]

I. INTRODUCTION

The present article brings together two subjects in the realm of quantum information theory that might at first glance seem far apart: the theory of universal computation in a quantum computer, and noise resistant coding of classical information in quantum channels.

The former deals with implementing arbitrary transformation of the (quantum) data in the memory of a computer by a sequence of commands (a *program*) that are themselves presented to the machine as data. From the first days of the theory of quantum computation this issue was of central importance, as a tool to show that there is essentially only one quantum Turing machine, and to parallel Turing's insight of the existence of universal classical machines (see Refs. 1 and 2). A great deal of work has been invested into finding small universal sets of ''quantum gates,'' acting on only a few qubits at a time, so that by concatenation any multi-qubit unitary can be approximated arbitrarily.[3–7] This concatenation (represented as a certain directed graph with labeled nodes) can be given to a machine as classical data, which then interprets it as a series of controlled actions on the quantum data.

The universality problem was studied abstractly by Nielsen and Chuang[8] in the notion of *programmable quantum gate* (PQG), where one allows *arbitrary quantum* data for a program, their results being further developed by Vidal, Masanes, and Cirac.[9,10] We review these studies, as far as they are relevant for the present purpose, in Sec. II. Then, in Sec. III, the notion of *scalability* is introduced, which captures the idea that a sufficiently powerful universal programmable quantum gate might give a universal gate if tensored with itself and fed with entangled programs. Unfortunately, it turns out that such objects do not exist, and we point out some implications for the general theory of universal computation.

Then, we switch to the apparently completely distinct problem of quantum channel coding of

a)Electronic mail: winter@cs.bris.ac.uk

classical data: a quantum channel usually is modeled by a completely positive, trace preserving, linear map $\varphi:\mathcal{B}(\mathcal{H}_1)\to\mathcal{B}(\mathcal{H}_2)$. We may use this channel to communicate by choosing states σ_i on $\mathcal{H}_1$ at the sender's side, the receiver getting $\varphi(\sigma_i)$. By the result of Holevo[11] and Schumacher and Westmoreland[12] the maximum rate at which classical information can be transmitted asymptotically reliably (the *capacity*) is given by

$$C(\varphi)=\max_{\{\sigma_i,p_i\}} I(p;\varphi(\sigma)), \tag{1}$$

with the *Holevo mutual information*

$$I(p;\varphi(\sigma))=H\left(\sum_i p_i\varphi(\sigma_i)\right)-\sum_i p_i H(\varphi(\sigma_i)),$$

H being the von Neumann entropy on density operators. This holds when in the block coding (implicit in the statement) for $\varphi^{\otimes n}$ one is restricted to using product states $\sigma_{i_1}\otimes\cdots\otimes\sigma_{i_n}$. Strictly speaking, we should write "sup" over *all* probability distributions p on states, and integrals instead of finite sums. However, we restrict our attention to finite dimensional spaces, and there it is possible to show that the supremum is achieved by a finitely supported measure p (see Ref. 12).

Unfortunately it is unknown whether it is sufficient to restrict coding to product states. It would be if the additivity conjecture

$$C(\varphi\otimes\vartheta)=C(\varphi)+C(\vartheta)$$

is true. To show this one would need to consider input state ensembles with entangled states, and prove that the corresponding Holevo information can be achieved by an ensemble without entangled states, or, more directly, that a code using entangled states can be modified to an equally good code (in terms of error probability and rate) without entangled states. Neither of these has been achieved in generality so far, though there have been advances recently: see Refs. 13–17.

In Sec. IV we present an example of a special classical–quantum channel as a case study: dense coding in the presence of noisy entanglement, and by use of a general quantum channel, in particular a noiseless one. Here, coding is done by selecting not a state of a system, to be sent down the channel, but by selecting an operation on a given state. This is a more general concept of coding, as we demonstrate in Sec. V. It appears that the coding of such a channel can be approximated by programmable quantum gates (in this sense the new model is a special case of the old one), but that the parallel use of these systems cannot: there will always be actions on the combined space that cannot be mimicked by entangled inputs to the PQG-augmented channel.

We conclude with the suggestion that the additivity problem for classical capacities of quantum channels has not been posed until now in its appropriate generality.

II. PROGRAMMABLE QUANTUM GATES

In classical computers there is no fundamental distinction in a univeral machine's memory between data and program. In fact, a program may modify itself during the computation (a feature considered essential by von Neumann when he designed his computer model). To which extent can a quantum computer memory be used to modify other parts of the memory in a programlike fashion? More precisely (following Ref. 8), assume that a unitary process G acts on $\mathcal{H}_D\otimes\mathcal{H}_P$, with the *data register* $\mathcal{H}_D$ and the *program register* $\mathcal{H}_P$:

$$|\zeta\rangle\otimes|\psi\rangle\mapsto G(|\zeta\rangle\otimes|\psi\rangle).$$

We call $|\psi\rangle$ a *program* if it has the property that

$$\forall|\zeta\rangle\quad G(|\zeta\rangle\otimes|\psi\rangle)=U_\psi|\zeta\rangle\otimes|\psi'\rangle. \tag{2}$$

Note that—though *a priori* $|\psi'\rangle$ could also depend on $|\zeta\rangle$—for $|\zeta_1\rangle$, $|\zeta_2\rangle \in \mathcal{H}_D$ the corresponding $|\psi_1'\rangle$, $|\psi_2'\rangle$ are linearly dependent:

$$G((\alpha|\zeta_1\rangle+\beta|\zeta_2\rangle)\otimes|\psi\rangle)=\alpha U_\psi|\zeta_1\rangle\otimes|\psi_1'\rangle+\beta U_\psi|\zeta_2\rangle\otimes|\psi_2'\rangle,$$

which generally is entangled unless $|\psi_1'\rangle \in \mathbb{C}|\psi_2'\rangle$.

(We thus *can* have a global phase—which we shall systematically ignore.) Henceforth, we assume that $|\psi'\rangle$ is independent of $|\zeta\rangle$, just as Eq. (2) suggests. It follows that U_ψ is unitary, which is encoded (via G) in the program $|\psi\rangle$. How many unitaries can be implemented in this way?

Theorem 1 (Nielsen and Chuang[8]): *If* $U_{\psi_1} \neq \gamma U_{\psi_2}$ *for all* $\gamma \in \mathbb{C}$, *then* $|\psi_1\rangle \perp |\psi_2\rangle$.

Proof: Let

$$G(|\zeta\rangle\otimes|\psi_1\rangle)=U_{\psi_1}|\zeta\rangle\otimes|\psi_1'\rangle,$$

$$G(|\zeta\rangle\otimes|\psi_2\rangle)=U_{\psi_2}|\zeta\rangle\otimes|\psi_2'\rangle.$$

Hence

$$\langle\psi_1|\psi_2\rangle=(\langle\zeta|\otimes\langle\psi_1|)G^*G(|\zeta\rangle\otimes|\psi_2\rangle)=\langle\psi_1'|\psi_2'\rangle\langle\zeta|U_{\psi_1}^*U_{\psi_2}|\zeta\rangle.$$

If $\langle\psi_1'|\psi_2'\rangle=0$, also $\langle\psi_1|\psi_2\rangle=0$, and we are done. Else $\langle\zeta|U_{\psi_1}^*U_{\psi_2}|\zeta\rangle$ is a constant, independent of $|\zeta\rangle$, hence $U_{\psi_1}^*U_{\psi_2}=\gamma\mathbb{1}$, contradicting the assumption. □

As a consequence we have only at most $\dim\mathcal{H}_P$ many essentially different programs. There is no way to encode all possible unitaries on $\mathcal{H}_D$ by "quantum code" unless we allow for an infinite-dimensional $\mathcal{H}_P$.

We have already in the Introduction pointed out that it is well possible to implement arbitarily good approximations to all unitaries (at the cost of ever increasing $\dim\mathcal{H}_P$). In Ref. 8, however, there was proposed a more interesting solution: a *probabilistic* programmable quantum gate, i.e., an encoding of unitaries in a state, and a process that performs the encoded unitary with some probability, and otherwise fails (does something else): the process is able to report which of the two events happened. This result was refined in subsequent work of Vidal, Masanes, and Cirac,[9,10] but we will not follow this line of research here.

To fix notions, let us define our concept of approximation: a (unitary) gate G on $\mathcal{H}_D\otimes\mathcal{H}_P$ is said to be *ϵ-approximating* if for every unitary U on $\mathcal{H}_D$ there is a state vector $|\psi\rangle \in \mathcal{H}_P$ (it is easily seen that pure state program register contents suffice) such that

$$\forall|\zeta\rangle \quad \|U|\zeta\rangle\langle\zeta|U^*-\mathrm{Tr}_{\mathcal{H}_P}(G(|\zeta\rangle\langle\zeta|\otimes|\psi\rangle\langle\psi|)G^*)\|_1\leq\epsilon.$$

Of course there are ϵ-approximating gates such that the approximating induced maps

$$\Gamma_\psi(\sigma)=\mathrm{Tr}_{\mathcal{H}_P}(G(\sigma\otimes|\psi\rangle\langle\psi|)G^*)$$

in the above equation all may be chosen unitary, but the present formulation has the appropriate generality for the nonexistence theorem of the following section.

A sequence $(G^{(n)})_{n\in\mathbb{N}}$ of programmable quantum gates $G^{(n)}$ on $\mathcal{H}_{P_n}\otimes\mathcal{H}_D$ is called *approximating for* $\mathcal{H}_D$ if each $G^{(n)}$ is ϵ_n-approximating, with $\epsilon_n\to 0$ for $n\to\infty$.

III. SCALABLE PROGRAMMABLE QUANTUM GATES

Given $\epsilon>0$ we can devise ϵ-approximating quantum gates G_1 and G_2 for given data registers $\mathcal{H}_{D_1}$ and $\mathcal{H}_{D_2}$, respectively, by allowing for sufficiently large program registers.

Programming, however, is about making data act together in a potentially unlimited number of registers. In general, to approximately perform an arbitary unitary on $\mathcal{H}_{D_1}\otimes\mathcal{H}_{D_2}$ it is necessary to define a new quantum gate G.

This motivates us to the following definition: we say that two sequences $(G_1^{(n)})_{n\in\mathbb{N}}$ and $(G_2^{(n)})_{n\in\mathbb{N}}$ of programmable quantum gates that are approximating for $\mathcal{H}_{D_1}$ and $\mathcal{H}_{D_2}$, respectively, are *scalable*, if the sequence $(G_1^{(n)}\otimes G_2^{(n)})_{n\in\mathbb{N}}$ is approximating for $\mathcal{H}_{D_1}\otimes\mathcal{H}_{D_2}$.

Such approximating gate sequences thus spare us the task to find and implement new programmable quantum gates when we scale up our computing system.

Unfortunately, nature does not supply us with such objects:

Theorem 2: *Let $(G_1^{(n)})_{n\in\mathbb{N}}$ and $(G_2^{(n)})_{n\in\mathbb{N}}$ be sequences of programmable quantum gates with fixed data registers $\mathcal{H}_{D_1}$ and $\mathcal{H}_{D_2}$, respectively. Assume that the unitary U on $\mathcal{H}_{D_1}\otimes\mathcal{H}_{D_2}$ is approximated arbitarily close by programs $\psi^{(n)}\in\mathcal{H}_{P_{1n}}\otimes\mathcal{H}_{P_{2n}}$, i.e.,*

$$\mathrm{Tr}_{\mathcal{H}_{P_{1n}}\otimes\mathcal{H}_{P_{2n}}}[G_1^{(n)}\otimes G_2^{(n)}(|\zeta\rangle\langle\zeta|\otimes|\psi^{(n)}\rangle\langle\psi^{(n)}|)G_1^{(n)*}\otimes G_2^{(n)*}]\to U|\zeta\rangle\langle\zeta|U^* \tag{3}$$

as $n\to\infty$. Then U is not entangling, i.e., it is of the form $U=U_1\otimes U_2$.

Proof: Consider the expressions of Eq. (3) for data of the form $|\zeta\rangle=|\zeta_1\rangle\otimes|\zeta_2\rangle$. The first claim is that the reduced state of the left hand side on $\mathcal{H}_{D_1}$ is independent of ζ_2: this becomes clear by first tracing out $\mathcal{H}_{D_2}\otimes\mathcal{H}_{P_{2n}}$ and then $\mathcal{H}_{P_{2n}}$. Then the same applies to the limit at the right hand side.

So, for fixed $|\zeta_1\rangle$ we have

$$\mathrm{Tr}_{\mathcal{H}_{D_2}}U(|\zeta_1\rangle\langle\zeta_1|\otimes|\zeta_2\rangle\langle\zeta_2|)U^*=\rho_0=\sum_i \lambda_i|e_i\rangle\langle e_i|, \tag{4}$$

with a constant state ρ_0 (that we wrote in diagonalized form), regardless of $|\zeta_2\rangle$.

Now assume that U is entangling, and choose $|\zeta_1\rangle$ such that there exists $|\zeta_2\rangle$ so that $U|\zeta_1\rangle\otimes|\zeta_2\rangle$ is entangled. Then ρ_0 is mixed, and its diagonalization contains at least two terms. We shall derive a contradiction from this: first observe that for arbitrary $|\zeta_2\rangle$ the state $U|\zeta_1\rangle\otimes|\zeta_2\rangle$ is a purification of ρ_0, hence, by Eq. (4) there exists an orthonormal basis $\{|f_i\rangle\}$ of $\mathcal{H}_{D_2}$ such that

$$U|\zeta_1\rangle\otimes|\zeta_2\rangle=\sum_i \sqrt{\lambda_i}|e_i\rangle\otimes|f_i\rangle.$$

For $|\zeta_2'\rangle$ orthogonal to $|\zeta_2\rangle$ there is another such basis $\{|f_i'\rangle\}$ with

$$U|\zeta_1\rangle\otimes|\zeta_2'\rangle=\sum_i \sqrt{\lambda_i}|e_i\rangle\otimes|f_i'\rangle.$$

By linearity we get thus

$$U|\zeta_1\rangle\otimes(\alpha|\zeta_2\rangle+\beta|\zeta_2'\rangle)=\sum_i \sqrt{\lambda_i}|e_i\rangle\otimes(\alpha|f_i\rangle+\beta|f_i'\rangle),$$

for $|\alpha|^2+|\beta|^2=1$. This again must be a purification of ρ_0, so the resulting $\{\alpha|f_i\rangle+\beta|f_i'\rangle\}$ must form an orthonormal basis: this leads quickly to the condition (for all i, j)

$$\overline{\alpha}\beta\langle f_i|f_j'\rangle+\alpha\overline{\beta}\langle f_i'|f_j\rangle=0,$$

implying $\langle f_i|f_j'\rangle=\langle f_i'|f_j\rangle=0$, otherwise z and $\overline{z}$ would be linearly dependent over the complex field.

As a consequence, to each orthonormal system of $|\zeta_2\rangle$'s of $\mathcal{H}_{D_2}$ we would get an orthonormal system of $|f_i\rangle$'s of at least double size, contradicting the finite dimension of $\mathcal{H}_{D_2}$. Thus U cannot be entangling, forcing $U=U_1\otimes U_2$. To see this either consult Ref. 18 or follow this simple argument: since

$$\sigma_{12}\mapsto U\sigma_{12}U^*$$

maps product states to product states, the map

$$T_1:\sigma\mapsto \mathrm{Tr}_2 U(\sigma\otimes|\zeta_2\rangle\langle\zeta_2|)U^*$$

maps pure states to pure states and is completely positive and trace preserving, entailing that it has to be of the form $T_1(\sigma)=U_1\sigma U_1^*$, or is constant which cannot occur. Here U_1 is a unitary which cannot—except for a global phase—depend on $|\zeta_2\rangle$, or else there would be entangled states $U(\sigma_1\otimes\sigma_2)U^*$. The same applies to the second factor, yielding a unitary U_2. In total we have that the unitary $U_1\otimes U_2$ coincides with U on the pure states, hence $U=U_1\otimes U_2$ (again except for an unimportant global phase). □

Observe the following peculiarity of the argument: it is not true that the reduced state on the left hand side of Eq. (3) is always a product (if it is, our proof is simplified drastically). For example, G_1 and G_2 may be swapping operations, so their product may be used to swap in any entangled state! What is true, however, is that entangled states cannot occur as a result of a unitary action on the data registers.

This nonexistence should not be mixed up with the existence of the beautiful model of *one-way quantum computer* by Raussendorf and Briegel:[19] there, too, a single state is prepared and acted on locally (even only by measurements), to produce any given effect on the data register. There is no contradiction, however, to our result, as there is implied *classical* communication between the sites of these quantum operations, which we had to exclude.

In a sense, the result had to be expected: it reproduces on a somewhat different level the insight in universal computation that single qubit actions are not sufficient for universality, but one needs interacting gates like the C–NOT gate.

We shall show in the following, however, that this nonexistence result has some bearing on quantum channel coding.

IV. NOISY DENSE CODING CAPACITY

Consider the following communication scenario: a sender A and a receiver B share a state ρ on the $d_A\times d_B$-system $\mathcal{H}_A\otimes\mathcal{H}_B$, i.e., $\dim\mathcal{H}_A=d_A$, $\dim\mathcal{H}_B=d_B$. They have at their disposal a quantum channel from A to B that allows noiseless transmission of an arbitrary quantum state in $\mathcal{H}\simeq\mathbb{C}^d$. They want to use this channel to communicate classical information, taking advantage of the correlation (or even entanglement) of ρ. The most general thing possible for A to do is to subject her share of the state to an operation, and send the result through the channel. It is well known that, if ρ supplies only classical correlation (for instance, if

$$\rho=\sum_{i=0}^{d_A-1}\sum_{j=0}^{d_B-1} p_{ij}|i\rangle\langle i|\otimes|j\rangle\langle j|,$$

for orthogonal bases $\{|i\rangle: i=0,\ldots,d_A-1\}$ and $\{|j\rangle: j=0,\ldots,d_B-1\}$ of $\mathcal{H}_A$ and $\mathcal{H}_B$, respectively), then this is of no help at all, and the capacity is just that of the noiseless channel: $\log d$ (in this article log and exp are to basis 2).

However, for entangled ρ the phenomenon of *dense coding* arises, which was first described in Ref. 20: there $d_A=d_B=d=2$ was considered, with the joint singlet state

$$\rho=|\Psi^-\rangle\langle\Psi^-|=\tfrac{1}{2}(|01\rangle-|10\rangle)(\langle 01|-\langle 10|).$$

It was demonstrated that by applying one of the three Pauli unitaries σ_x, σ_y, σ_z, or the identity $\mathbb{1}$, A can drive the state to any of the four Bell states, hence can encode 2 bits. It is quite clear that by starting with any maximally entangled state, e.g.,

$$\rho=|\Phi\rangle\langle\Phi|, \text{ with } |\Phi\rangle=\frac{1}{\sqrt{d}}\sum_{i=0}^{d-1}|i\rangle\otimes|i\rangle$$

on the system $\mathbb{C}^d\otimes\mathbb{C}^d$, i.e., $d_A=d_B=d$, one can devise a scheme to transmit $2\log d=\log d^2$ bits (see Ref. 21 for a detailed discussion).

It is less clear what happens if the state is not maximally entangled, or even mixed: however, since the protocol A and B have to follow depends even in the maximally mixed case on the actual state, we allow them to use *the protocol optimally adapted to* ρ. Formally, A chooses an operation (i.e., a completely positive, trace preserving linear map)

$$T:\mathfrak{L}(\mathcal{H}_A)\to\mathfrak{L}(\mathcal{H}),$$

and applies it to her part of ρ, after which she sends the resulting state to B. He thus receives the signal state

$$\rho^T:=(T\otimes\mathrm{id})\rho.$$

We here assume that one copy of ρ is available per use of the noiseless channel. Below we will discuss the case of more or unlimited many copies per round.

Then we can compute the mutual information

$$I(\mu;\rho):=H\left(\int \mathrm{d}\mu(T)\rho^T\right)-\int \mathrm{d}\mu(T)H(\rho^T),$$

with respect to a probability measure μ on the space $\mathbf{CP}(\mathcal{H}_A,\mathcal{H})$ of quantum operations (i.e., completely positive, trace preserving, linear maps) from $\mathcal{B}(\mathcal{H}_A)$ to $\mathcal{B}(\mathcal{H})$. By the quantum channel coding theorem, Eq. (1), of Refs. 11 and 12, the *dense coding capacity*

$$DC(d,\rho):=\sup_{\mu} I(\mu;\rho)$$

is the classical capacity of the channel with signal states ρ^T, when block coding using product states

$$\rho^{T_1}\otimes\cdots\otimes\rho^{T_n}=((T_1\otimes\mathrm{id})\rho)\otimes\cdots\otimes((T_n\otimes\mathrm{id})\rho)=((T_1\otimes\cdots\otimes T_n)\otimes\mathrm{id}^{\otimes n})\rho^{\otimes n}$$

is allowed.

If we impose no restriction on the block coding, i.e., all states

$$(\mathbf{T}\otimes\mathrm{id}^{\otimes n})\rho^{\otimes n},$$

with $\mathbf{T}\in\mathbf{CP}(\mathcal{H}_A^{\otimes n},\mathcal{H}^{\otimes n})$ are admissible, we get the *ultimate dense coding capacity*

$$\overline{DC}(d,\rho)=\lim_{n\to\infty}\frac{1}{n}DC(d^n,\rho^{\otimes n}).$$

Note that the limit exists by the trivial superadditivity of DC:

$$DC(d_1d_2,\rho\otimes\sigma)\geqslant DC(d_1,\rho)+DC(d_2,\sigma).$$

Our first task is the evaluation of $DC(d,\rho)$:

Assume any probability distribution μ on $\mathbf{CP}(\mathcal{H}_A,\mathcal{H})$, and denote the Haar measure on the group $\mathcal{U}(d)$ of unitaries on $\mathcal{H}$ as $\mathrm{d}U$. Then for every unitary U we have (by unitary invariance of entropy)

$$H\left(\int \mathrm{d}\mu(T)\rho^T\right)=H\left(\int \mathrm{d}\mu(T)(U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*\right),$$

$$H(\rho^T)=H((U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*),$$

i.e., $I(\mu;\rho)=I(\mu^U;\rho)$, with the translated measure

$$\mu^U(F)=\mu(U^*FU),\ \text{for measureable}\ F\subset\mathbf{CP}(\mathcal{H}_A,\mathcal{H}).$$

With concavity of H we find

$$I(\mu;\rho)=\int_{\mathcal{U}(d)}\mathrm{d}U\left[H\left(\int \mathrm{d}\mu(T)(U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*\right)-\int \mathrm{d}\mu(T)H((U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*)\right]$$

$$\leqslant H\left(\int \mathrm{d}\mu(T)\int \mathrm{d}U(U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*\right)-\int \mathrm{d}\mu(T)H(\rho^T).$$

The latter quantity is exactly $I(\overline{\mu};\rho)$, with $\overline{\mu}=\int \mathrm{d}U\mu^U$.

Now it is straightforward to prove (essentially by Schur's lemma) that

$$\int \mathrm{d}U(U\otimes\mathbb{1})\rho^T(U\otimes\mathbb{1})^*=\frac{1}{d}\mathbb{1}\otimes\rho_B,$$

where we observed that by definition

$$\mathrm{Tr}_A\rho^T=\mathrm{Tr}_A((T\otimes\mathrm{id})\rho)=\mathrm{Tr}_A\rho=\rho_B.$$

Hence maximization yields

$$DC(d,\rho)=\log d+H(\rho_B)-\inf_{\mu}\int \mathrm{d}\mu(T)H(\rho^T).$$

This infimum in turn is achieved at the point mass on a T minimizing $H(\rho^T)$.

Hence we arrive at the following result.

Theorem 3: *The dense coding capacity of the state ρ and a d-level noiseless transmission system, using one copy of ρ per round and product states for coding, is given by*

$$DC(d,\rho)=\log d+H(\rho_B)-\min_{T}H((T\otimes\mathrm{id})\rho),$$

where the minimization is over all quantum operations $T:\mathcal{B}(\mathcal{H}_A)\to\mathcal{B}(\mathcal{H})$. □

As a consequence we obtain the following.

Theorem 4: *Without the restriction on product state encoding, but still using one copy of ρ per round, the capacity is*

$$\overline{DC}(d,\rho)=\log d+H(\rho_B)-\lim_{n\to\infty}\frac{1}{n}\min_{\mathbf{T}}H((\mathbf{T}\otimes\mathrm{id}^{\otimes n})\rho^{\otimes n}),$$

where the minimization is over all quantum operations $\mathbf{T}:\mathcal{B}(\mathcal{H}_A^{\otimes n})\to\mathcal{B}(\mathcal{H}^{\otimes n})$. □

Note that the argument describes at the same time a distribution on $\mathbf{CP}(\mathcal{H}_A,\mathcal{H})$ that achieves the capacity: A should apply a fixed minimizing T, followed by uniformly distributed unitary rota-

tions. The effect of the latter can be achieved equally by a uniform distribution on an orthogonal basis of unitaries [with respect to the Hilbert–Schmidt inner product $(A,B)=\mathrm{Tr}A^*B$ on operators] (see Ref. 21).

As applications of the theorem we can see immediately that for pure states $|\psi\rangle$

$$DC(d,|\psi\rangle\langle\psi|)=\log d+E(\psi)=\log d+H(\mathrm{Tr}_B|\psi\rangle\langle\psi|),$$

a result already reported in Refs. 22 and 23, and that $DC(d,\rho)=\log d$ if ρ is separable (later in this work, Theorem 7, we will see that this holds true even for *nondistillable* ρ): in the first case the optimizing T is any unitary map, in the second case it is the projection onto any pure state [note that $DC(d,\rho)\leqslant\log d$ follows from the inequality $H(\sigma_B)-H(\sigma)\leqslant 0$ for separable σ]. This latter choice shows that always $DC(d,\rho)\geqslant\log d$ (it amounts to ignoring the correlation provided by ρ).

In general, however, the minimization required by the theorem seems not an easy task itself.

Remark 5: The quantity $H(\sigma_B)-H(\sigma)$, $\sigma=(T\otimes 1)\rho$, from Theorem 3 has appeared in another context before: it is the coherent information *of Schumacher*.[24]

Remark 6: Until now we stuck to using one copy of ρ per use of the noiseless channel. In recent work by Horodecki et al.[25] *this restriction was lifted: unlimited many copies of ρ were assumed to be available. Of course, the theorem can be used to obtain a formula for that case, too, which we give, because it interestingly differs from the one in Ref. 25 (though of course the numbers coincide):*

Assume k copies of ρ may be used per round. Obviously the resulting dense coding capacity is

$$DC^{(k)}(d,\rho)=DC(d,\rho^{\otimes k}),$$

and for unlimited use of ρ we get

$$DC^{(\infty)}(d,\rho)=\lim_{k\to\infty}DC(d,\rho^{\otimes k}).$$

Similarly, for the ultimate dense coding capacity with k copies of ρ per round,

$$\overline{DC^{(k)}}(d,\rho)=\overline{DC}(d,\rho^{\otimes k})=\lim_{n\to\infty}\frac{1}{n}DC(d^n,\rho^{\otimes kn}),$$

and with unlimited use of ρ

$$\begin{aligned}\overline{DC^{(\infty)}}(d,\rho)=\lim_{k\to\infty}\overline{DC^{(k)}}(d,\rho)&=\lim_{k\to\infty}\lim_{n\to\infty}\frac{1}{n}DC(d^n,\rho^{\otimes kn})\\&=\lim_{n\to\infty}\lim_{k\to\infty}\frac{1}{n}DC(d^n,\rho^{\otimes kn})\\&=\lim_{n\to\infty}\frac{1}{n}DC^{(\infty)}(d,\rho)=\overline{DC}^{(\infty)}(d,\rho).\end{aligned}$$

(*The limits are exchangeable because the double* lim *is actually a joint* sup *over n and k, because of monotonicity*.)

In Ref. 25 the differently looking expression (*for the case $d=2$*)

$$\overline{DC}(\rho)=\sup_n\sup_{\mathbf{T}}\left\{1+\frac{nH(\rho_B)-H((\mathbf{T}\otimes\mathrm{id}^{\otimes n})(\rho^{\otimes n}))}{H(\mathbf{T}(\rho_A^{\otimes n}))}\right\}$$

was given, the sup *being over all quantum operations* **T** *defined on* $\mathcal{B}(\mathcal{H}_A^{\otimes n})$. *However, the derivation in that work is sufficiently close to ours so as to see the identity of the results*.

Let us comment here a bit on other related work, and the relation of $DC(d,\rho)$ to entanglement:

In Refs. 26 and 27 the relation of the dense coding capacity to entanglement measures was stressed. With our results, it is easy to reproduce the observations of these papers, and go even a little further:

We use the following inequality from Ref. 28: for a (two–way) nondistillable state σ

$$H(\rho_B)-H(\rho)\leqslant D(\rho\|\sigma).$$

Applying $T\otimes\mathrm{id}$ to both ρ and σ, and invoking the monotonicity of relative entropy under completely positive maps,[29,30] we find

$$H(\rho_B)-H((T\otimes\mathrm{id})\rho)\leqslant D((T\otimes\mathrm{id})\rho\|(T\otimes\mathrm{id})\sigma)\leqslant D(\rho\|\sigma).$$

Now minimize over T and nondistillable σ: this proves the following.

Theorem 7: *For all states* ρ *one has*

$$DC(d,\rho)\leqslant\log d+E_{\mathrm{re}}(\rho),$$

where $E_{\mathrm{re}}(\rho)=\inf_{\sigma\in\mathcal{D}}D(\rho\|\sigma)$ *is the relative entropy of entanglement with respect to the set* $\mathcal{D}$ *of nondistillable states*. □

In particular, when ρ is nondistillable, $DC(d,\rho)=\log d$ (see also Ref. 25 for this observation). One may wonder whether the inverse is true, too: when ρ is distillable, does $DC(d,\rho)>\log d$ follow?

To compare this result to the statements in Refs. 26 and 27 and the result of the recently published Ref. 31 we have to note that in these works only *unitary* encodings were considered. Hence our $DC(d,\rho)$ is typically a strict upper bound to the capacity in the cited works. Still, questions raised in Refs. 26 and 27 receive answers: the conjectured capacity formulas and inequalities from these works follow immediately, by the same method of Haar averaging we employed above (see also Ref. 31).

To get a bound in the other direction is not so easy. We might try to go further on the road of entanglement, and find an entanglement measure lower bound. For example, if we could prove that

$$f(\rho)=\overline{DC}^{(\infty)}(d,\rho)-\log d$$

is an entanglement measure itself, we would find the lower bound

$$\overline{DC}^{(\infty)}(d,\rho)\geqslant\log d+E_D(\rho),$$

with the *distillable entanglement* $E_D(\rho)$: this follows from general inequalities in Ref. 32. We leave this question, however, to another occasion.

We would like now to discuss the additivity of D, i.e., whether for states ρ, σ

$$DC(d_1d_2,\rho\otimes\sigma)=DC(d_1,\rho)+DC(d_2,\sigma). \tag{5}$$

Note that if this is true for ρ and all $\sigma=\rho^{\otimes n}$ (e.g., inductively), it immediately follows that $\overline{DC}(d,\rho)=DC(d,\rho)$. In particular, all ultimate capacities in Remark 6 are identical to their ''unbarred'' versions. The capacity with unlimited use of ρ from Ref. 25 would then read

$$\overline{DC}^{(\infty)}(d,\rho)=DC^{(\infty)}(d,\rho)=\log d+H(\rho_B)-\inf_k\min_T H((T\otimes\mathrm{id}^{\otimes k})\rho^{\otimes k}),$$

where the minimization is over all quantum operations $T:\mathcal{B}(\mathcal{H}_A^{\otimes k})\to\mathcal{B}(\mathcal{H})$.

By Theorem 3, the statement of Eq. (5) is equivalent to asking if

$$\min_{T_{12}} H((T_{12}\otimes \mathrm{id}^{\otimes 2})(\rho\otimes\sigma)) = \min_{T_1} H((T_1\otimes \mathrm{id})\rho) + \min_{T_2} H((T_2\otimes \mathrm{id})\sigma).$$

Obviously, and fitting with the superadditivity of D, "$\leqslant$" (subadditivity) is trivial, and the question is if "$<$" can occur. Note that in this generality it is quite easy to come up with states that violate the additivity property (see the discussion below). The problem is rather to find conditions where additivity holds.

Generalizing, one may assume not a noiseless but a noisy channel $\varphi:\mathcal{B}(\mathcal{H})\to\mathcal{B}(\mathcal{H})$ between A and B, and consider the dense coding capacities

$$DC(\varphi,\rho), \quad \overline{DC}(\varphi,\rho),$$

$$DC^{(k)}(\varphi,\rho), \quad \overline{DC}^{(k)}(\varphi,\rho),$$

$$DC^{(\infty)}(\varphi,\rho), \quad \overline{DC}^{(\infty)}(\varphi,\rho).$$

For example, we can define

$$DC(\varphi,\rho) = \sup_{\mu} I(\mu;\varphi\circ\rho)$$

over all probability distributions μ on $\mathbf{CP}(\mathcal{H}_A,\mathcal{H})$, with

$$I(\mu;\varphi\circ\rho) := H\left(\int \mathrm{d}\mu(T)\rho^{\varphi\circ T}\right) - \int \mathrm{d}\mu(T) H(\rho^{\varphi\circ T}).$$

Observe that our previous $DC(d,\rho)$ is reproduced in the new definition as $DC(\mathrm{id}_d,\rho)$. Further, observe that for a pure entangled state ρ the definition relates to the entanglement assisted classical capacity[33] of the quantum channel φ: in fact, $\overline{DC}^{(\infty)}(\varphi,\rho)$ *is* this latter quantity.

Again, the superadditivity

$$DC(\varphi\otimes\vartheta,\rho\otimes\sigma) \geqslant DC(\varphi,\rho) + DC(\vartheta,\sigma) \tag{6}$$

trivially holds, and we may study conditions for equality in Eq. (6), i.e., additivity.

Note that it is fairly easy to come up with situations $(\varphi, \vartheta, \rho, \sigma)$ where strict superadditivity holds. In fact, one can even have either $\varphi=\vartheta$ or $\rho=\sigma$: e.g., consider

$$\varphi=\vartheta=\mathrm{id}_{\mathcal{B}(\mathbb{C}^2)}, \quad \begin{cases} \rho = |00\rangle\langle 00| \text{(un-entangled)}, \\ \sigma = |\Psi^-\rangle\langle\Psi^-|^{\otimes 2}, \end{cases}$$

or alternatively

$$\left.\begin{aligned} &\varphi = \mathrm{id}_{\mathcal{B}(\mathbb{C}^4)}, \\ &\vartheta = \tfrac{1}{2}\mathbb{1} \ \text{(constant map)}, \end{aligned}\right\} \quad \rho=\sigma=|\Psi^-\rangle\langle\Psi^-|.$$

But with both these conditions simultaneously it seems not so easy. It may even be that *weak additivity* holds, i.e.,

$$DC(\varphi^{\otimes n},\rho^{\otimes n}) = nDC(\varphi,\rho),$$

for all channels φ and joint states ρ, but we could not reach a conclusive result on this question.

V. REDUCTIONS AMONG ADDITIVITY QUESTIONS

We have encountered two paradigms of coding in quantum channels, the first in the established discussion (a good overview is in Ref. 34, and some recent developments are reviewed in Ref. 13), the second in the previous section:

(1) State preparation: The encoder may prepare any state on the input system space $\mathcal{H}_1$ for the quantum channel $\varphi:\mathcal{B}(\mathcal{H}_1)\to\mathcal{B}(\mathcal{H}_2)$.

(2) Action on given state: On the input system a state is given in advance (possibly entangled with the receiver), and the encoder may act on it in an arbitary way, and the result is sent down the channel φ.

It is quite obvious that method 1 can be reduced to method 2: the previously given state is just any state not entangled with the receiver (say, a pure state). Then by executing an appropriate operation the encoder can drive the input into any desired state.

Less obvious, but still quite canonical, is the converse reduction: any operation T: $\mathcal{B}(\mathcal{H}_A)\to\mathcal{B}(\mathcal{H}_1)$ can be implemented as a unitary

$$U:\mathcal{H}_A\otimes\mathcal{H}'\to\mathcal{H}_1\otimes\mathcal{H}'',$$

followed by a partial trace over $\mathcal{H}''$, the system $\mathcal{H}'$ being prepared initially in a null state σ_0. This is a formulation of the Stinespring dilation theorem,[35] and it is quite easy to see that $\dim\mathcal{H}'$ can be chosen fixed and finite for all possible T. Now pick an ϵ-approximating quantum gate G_ϵ for $\mathcal{H}_A\otimes\mathcal{H}'$, with program register $\mathcal{H}_{P_\epsilon}$: by choosing ψ in the program register appropriately one obtains (using monotonicity of the trace norm under partial trace), for all states σ on $\mathcal{H}_A$,

$$\|T(\sigma)-\mathrm{Tr}_{\mathcal{H}''\otimes\mathcal{H}_{P_\epsilon}}(G_\epsilon(\sigma\otimes|0\rangle\langle 0|\otimes|\psi\rangle\langle\psi|)G_\epsilon^*)\|_1\leq\epsilon. \tag{7}$$

Thus every coding process by acting on the input system can be arbitrarily well approximated by coding via choice of $|\psi\rangle\in\mathcal{H}_{P_\epsilon}$.

These two reductions, however, are of a very different nature, as we can see by considering their behavior under tensor products of channels: while the reduction $1\to 2$ scales correctly (any entangled input state can be obtained by a suitable entangling operation on the product of the initial states), the reduction $2\to 1$ that we proposed does not. In fact, as we have seen in Theorem 2, on a product $\mathcal{H}_{A1}\otimes\mathcal{H}_{A2}$ of two input systems we can never implement an entangling operation, once we have chosen approximating quantum gates for each of them individually according to Eq. (7), and tensor them.

We have seen that there are channels where classical information is encoded after method 1 (these are just the operations φ), and that there are channels where it is encoded after method 2 (the generalized noisy dense coding channels). The above reductions show that the two approaches are equivalent in the sense that a channel of the one kind can be simulated to arbitary accuracy by one of the other kind.

However, for the additivity question of channel capacity one has to look at higher tensor products of the channel at hand. By the above argument the reduction $1\to 2$ provides a reduction of the additivity question for channels of the first type to those of the second type. It is unknown to us if the additivity question can be reduced in the other direction: the construction above, summarized in Eq. (7), at least does not provide this, as we have seen. On the other hand, it appears to be most natural: it seems the most reasonable thing to do to associate a channel of the first type to the given channel of the second type that has the same properties with respect to classical information transmission, by simply enabling to emulate the effect of any encoding transformation T by a suitable input state.

VI. CONCLUSION

By studying entanglement assisted classical communication via quantum channels, attention was drawn towards channels which require *actions* for signaling rather than *state preparations* like

the usual quantum dynamics, represented by completely positive maps. An attempted reduction of the more general scenario to the usual one was shown to fail, because no *scalable programmable quantum gates* exist. This was taken to indicate that the new concept is strictly more general, which leads us to conjecture that the additivity question for quantum channel capacity really is not about ''whether entangled inputs help,'' but rather ''whether *entangling* inputs help.'' It must be stressed that in the more general vista we presented, additivity is not a mere matter of ''right'' or ''false.'' Rather, it becomes (as we demonstrated by examples) a question of *characterization* of the situations where it holds. Note finally that the very occurrence of the above mentioned distinction in coding concepts is a purely quantum phenomenon.

(Received 4 March 2002; accepted for publication 16 May 2002)

A conjecture arising naturally in the investigation of additivity of classical information capacity of quantum channels states that the maximal purity of outputs from a quantum channel, as measured by the p-norm, should be multiplicative with respect to the tensor product of channels. We disprove this conjecture for $p>4.79$. The same example (with $p=\infty$) also disproves a conjecture for the multiplicativity of the injective norm of Hilbert space tensor products. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1498491]

I. STATEMENT OF THE PROBLEM

A. Multiplicativity of output purity

In many applications of quantum information theory the entanglement of states or the capacity of channels appear as resources, which are needed to perform a task and are used up in the process. Therefore, it is natural to expect that certain entanglement or capacity measures should be *additive* in the sense that preparing two pairs of entangled particles should give us twice the entanglement of one pair and, similarly, using a channel twice doubles its capacity. However, such additivity properties have turned out to be notoriously difficult to prove, and in some cases folk conjectures claiming additivity have turned out to be wrong.

The purpose of this work is to provide a counterexample of this kind, i.e., to show that a family of quantities, which had been conjectured to be additive in an earlier paper by the present authors,[1] actually is not. The quantities considered all characterize the highest purity of the outputs of a channel. That is, if S is a completely positive map, taking density operators on a finite dimensional Hilbert space $\mathcal{H}_1$ to density operators on another finite dimensional Hilbert space $\mathcal{H}_2$, and $1<p<\infty$, we defined

$$\nu_p(S)=\sup\|S(\rho)\|_p, \tag{1}$$

where the supremum is over all input density operators, and $\|\rho\|_p=(\mathrm{tr}|\rho|^p)^{1/p}$ is the standard p-norm. The conjecture in Ref. 1 was that $\log\nu_p$ is additive in the sense that

$$\nu_p(S_1\otimes S_2)=\nu_p(S_1)\,\nu_p(S_2) \tag{2}$$

for arbitrary channels S_1, S_2.

This conjecture was supported by some numerical evidence (the inequality "$\geqslant$" being trivial anyhow), and a proof for very noisy and almost noiseless channels in Ref. 1, as well as some depolarizing channels. Further supporting evidence was given by C. King.[2,3] The main application would probably have been in the limit $p\to 1$, where it would be the additivity of "maximal purity

[a)]Electronic mail: r.werner@tu-bs.de
[b)]Electronic mail: holevo@mi.ras.ru

as measured by entropy." This in turn is closely related[1,3,4] to the question of additivity of classical channel capacity, i.e., whether transmission of classical information over multiple quantum channels can sometimes be improved by using entangled signal states.

B. Injective tensor norm for Hilbert space vectors

The case $p=\infty$, i.e., when $\|\cdot\|_\infty$ is the ordinary operator norm, is implied by another additivity conjecture, namely for the *injective tensor norm* of Hilbert space vectors. For any vector $\Phi \in \mathcal{H}_1\otimes\cdots\otimes\mathcal{H}_N$ we define this norm as

$$\mu_N(\Phi)=\sup|\langle\Phi,\phi_1\otimes\cdots\otimes\phi_N\rangle|, \tag{3}$$

where the supremum is over all tuples of vectors $\phi_\alpha\in\mathcal{H}_\alpha$ with $|\phi_\alpha|=1$. The conjectured property for this quantity was that $\mu_N(\Phi\otimes\Psi)=\mu_N(\Phi)\mu_N(\Psi)$, where $\Phi\in\mathcal{H}_1\otimes\cdots\otimes\mathcal{H}_N$ and $\Psi\in\mathcal{K}_1\otimes\cdots\otimes\mathcal{K}_N$ may be in different N-fold Hilbert space tensor products, and the supremum in $\mu_N(\Phi\otimes\Psi)$ is taken over unit vectors $\phi_\alpha\in\mathcal{H}_\alpha\otimes\mathcal{K}_\alpha$. Again, the inequality "$\geqslant$" and the case $N=2$ are trivial. The connection with the previous problem is seen by writing S in Kraus form $S(\rho)=\Sigma_x A_x\rho A_x^*$. Then

$$\langle\varphi,S(|\phi\rangle\langle\phi|)\varphi\rangle=\sum_x\ |\langle\varphi,A_x\phi\rangle|^2=\sup_\psi\left|\sum_x\ \overline{\psi_x}\langle\varphi,A_x\phi\rangle\right|^2, \tag{4}$$

where at the last equality we consider the $\langle\varphi,A_x\phi\rangle$ as the components of a Hilbert space vector, whose norm can also be written as the largest scalar product with a unit vector. Accordingly, the supremum in the last line is over all unit vectors ψ. Taking the supremum over the unit vectors ϕ and φ, too, we find that

$$\nu_\infty(S)=\mu_3(\tilde{A})^2, \tag{5}$$

where $\tilde{A}$ denotes the vector in a threefold Hilbert space tensor product with components $\langle h_j,A_x e_k\rangle$, where h_j and e_k are orthonormal bases of the appropriate spaces. In particular, since the tensor product of channels S corresponds to the tensor product of vectors $\tilde{A}$, the conjectured multiplicativity of μ_3 would imply the multiplicativity of ν_∞. Conversely, the counterexample given to the latter disproves the multiplicativity of μ_N for all $N\geqslant 3$.

II. THE COUNTEREXAMPLE

We give an explicit example of a channel violating conjecture (2) for large values of p. It is the channel S on the $d\times d$-matrices defined as

$$S(\rho)=\frac{1}{d-1}(\mathrm{tr}(\rho)\mathbb{1}-\rho^T) \tag{6}$$

$$=\frac{1}{2(d-1)}\sum_{ij}\ (|i\rangle\langle j|-|j\rangle\langle i|)^*\rho(|i\rangle\langle j|-|j\rangle\langle i|). \tag{7}$$

Here ρ^T denotes the matrix transpose with respect to some fixed basis. In the first form it is easy to verify that S is linear and trace preserving, in the second it becomes clear that it is also completely positive. The equality of the two forms is a straightforward exercise. Further interesting properties are that S is Hermitian with respect to the Hilbert–Schmidt scalar product $(A,B)\mapsto\mathrm{tr}(A^*B)$ on $d\times d$-matrices, and covariant for arbitrary unitary transformations in the sense that $S\circ\mathrm{ad}_U=\mathrm{ad}_{\overline{U}}\circ S$, $\mathrm{ad}_U(X)=UXU^*$, where $\overline{U}$ denotes the matrix element-wise complex conjugate of a unitary in the fixed basis. We remark that S is the dual of the state which provided the counterexample to the additivity of the relative entropy of entanglement for bipartite states in

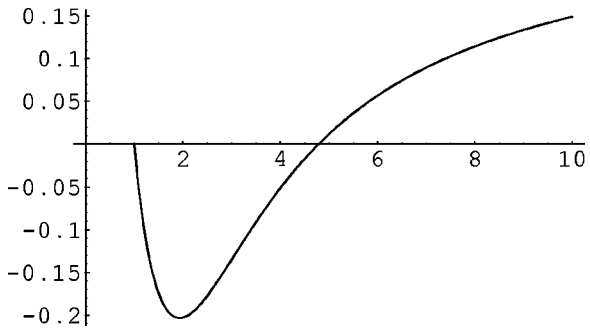

FIG. 1. $\Delta(p,\Phi_m)$ over p, as explained in the text.

Ref. 5, i.e., that state, the normalized projection onto the Fermi subspace of $\mathbb{C}^d\otimes\mathbb{C}^d$ $(d\geqslant 3)$, is obtained by acting with S on one partner of a maximally entangled pair on $\mathbb{C}^d\otimes\mathbb{C}^d$.

Now $\rho\mapsto\|S(\rho)\|_p$ is a convex function, and hence takes its maximum on the extremal states. Therefore it suffices to take pure input states, for which

$$S(|\phi\rangle\langle\phi|)=\frac{1}{d-1}(\mathbb{1}-|\overline{\phi}\rangle\langle\overline{\phi}|). \tag{8}$$

Clearly, the p-norm is the same for all pure inputs, and we get

$$\nu_p(S)=(d-1)^{-(1-1/p)}. \tag{9}$$

On the other hand, let us consider $S\otimes S$ acting on a pure state Φ. Due to covariance we may take Φ in Schmidt diagonal form $\Phi=\Sigma_\alpha c_\alpha|\alpha\alpha\rangle$. Then with the reduced density operator $\rho=\Sigma_\alpha c_\alpha^2|\alpha\rangle\langle\alpha|$ we get

$$S\otimes S(|\Phi\rangle\langle\Phi|)=\frac{1}{(d-1)^2}(\mathbb{1}-\mathbb{1}\otimes\rho-\rho\otimes\mathbb{1}+|\Phi\rangle\langle\Phi|). \tag{10}$$

We now specialize further to *maximally entangled* $\Phi=\Phi_m$, i.e., all $c_\alpha=1/\sqrt{d}$ and $\rho=(1/d)\mathbb{1}$, all terms in this expression commute, and the operator in parenthesis has one eigenvalue $(1-2/d)$ with multiplicity (d^2-1) and a nondegenerate eigenvalue $(1-2/d+1)$. From this we find, for $d=3$,

$$\|S\otimes S(|\Phi_m\rangle\langle\Phi_m|)\|_p=\tfrac{1}{3}(1+2^{3-2p})^{1/p}. \tag{11}$$

If additivity were true, the following quantity should be negative, becoming zero upon maximization with respect to Φ:

$$\Delta(p,\Phi)=\log\|S\otimes S(|\Phi\rangle\langle\Phi|)\|_p-2\log\nu_p(S). \tag{12}$$

However, inserting for Φ the maximally entangled state we get

$$\Delta(p,\Phi_m)=\log\frac{4}{3}+\frac{1}{p}\log\left(\frac{1}{4}+2^{1-2p}\right). \tag{13}$$

This quantity is plotted in Fig. 1. Thus additivity is violated for $p>p_0$, where the zero p_0 is numerically determined as $p_0=4.7823$. In particular, we get $\Delta(\infty,\Phi_m)=\log(\frac{4}{3})>0$, so additivity fails for $p=\infty$. Transcribed to the problem for injective Hilbert space norms, the counterexample

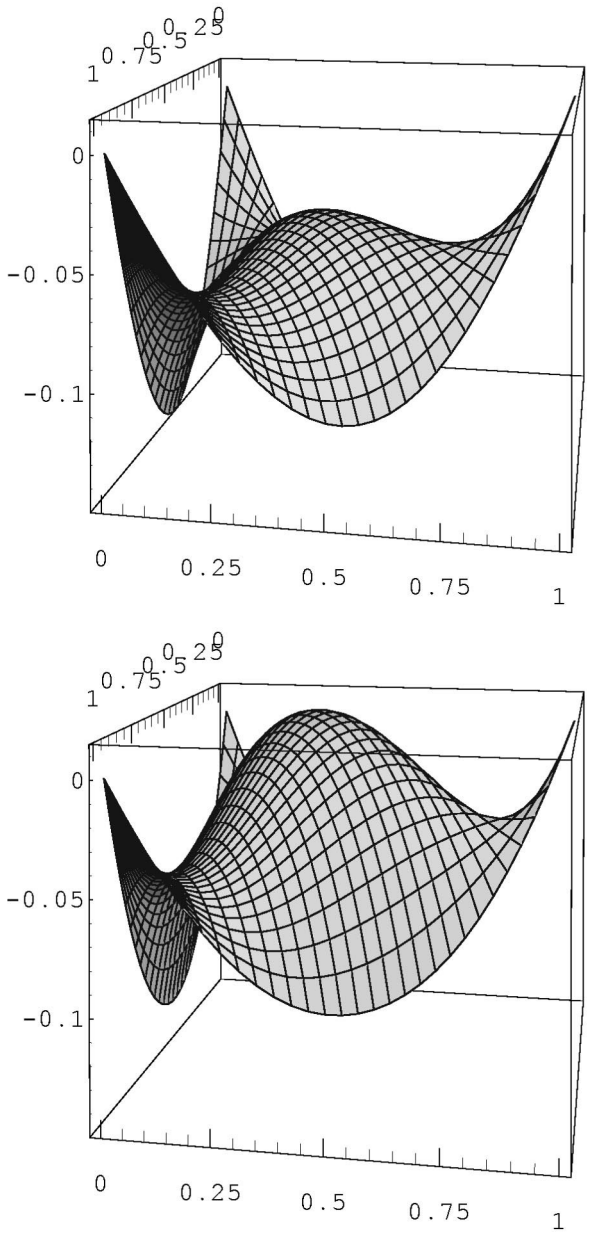

FIG. 2. $\Delta(p,\Phi)$ for $d=3$ over the Schmidt parameters c_1^2 and c_2^2 of Φ, for $p=4$ (top) and for $p=5$ (bottom).

is the unique antisymmetric vector Φ on $\mathbb{C}^3\otimes\mathbb{C}^3\otimes\mathbb{C}^3$, tensored with itself. On the other hand, for $p\to 1$ we have $\Delta(p,\Phi_m)<0$, so in this case, which is of main interest for classical channel capacity, the additivity conjecture survives.

The boundary point p_0 cannot be improved by choosing another vector Φ, i.e., the maximizing Φ in the definition of $\nu_p(S\otimes S)$ jumps discontinuously from a product state to a maximally entangled state, as p increases beyond p_0. This is seen by plotting Δ for fixed p over the Schmidt parameters of Φ. There is little difference between the plots for $p=4$ and $p=5$ (see Fig. 2) except that the global maximum switches from corners (Φ a product vector) to the center ($\Phi=\Phi_m$).

III. CONCLUDING REMARKS

We have seen that multiplicativity of maximal purity depends crucially on how we measure purity: if we use p-norms for large p, it fails. But the conjecture remains open for small p, and in particular for purity as measured by entropy. There seems to be no simple modification of the example given here to improve the critical value of p. On the other hand, it is hardly expected to be optimal.

Inequalities for quantum entropy: A review with conditions for equality

Mary Beth Ruskai[a)]
Department of Mathematics, University of Massachusetts Lowell, Lowell, Massachusetts 01854

(Received 28 April 2002; accepted for publication 16 May 2002)

This article presents self-contained proofs of the strong subadditivity inequality for von Neumann's quantum entropy, $S(\rho)$, and some related inequalities for the quantum relative entropy, most notably its convexity and its monotonicity under stochastic maps. Moreover, the approach presented here, which is based on Klein's inequality and Lieb's theorem that the function $A \to \mathrm{Tr}\, e^{K+\log A}$ is concave, allows one to obtain conditions for equality. In the case of strong subadditivity, which states that $S(\rho_{123})+S(\rho_2) \leqslant S(\rho_{12})+S(\rho_{23})$ where the subscripts denote subsystems of a composite system, equality holds if and only if $\log \rho_{123} = \log \rho_{12} - \log \rho_2 + \log \rho_{23}$. Using the fact that the Holevo bound on the accessible information in a quantum ensemble can be obtained as a consequence of the monotonicity of relative entropy, we show that equality can be attained for that bound only when the states in the ensemble commute. The article concludes with an Appendix giving a short description of Epstein's elegant proof of Lieb's theorem. [DOI: 10.1063/1.1497701]

I. INTRODUCTION

A. Quantum entropy

Quantum information science[32] is the study of the information carrying and processing properties of quantum mechanical systems. Recent work in this area has generated renewed interest in the properties of the quantum mechanical entropy. It is interesting to note that von Neumann[45,46] introduced the notion of mixed state, represented by a density matrix ρ (a positive semi-definite operator with $\mathrm{Tr}\rho=1$), into quantum theory and defined its entropy as $S(\rho)\equiv-\mathrm{Tr}(\rho\log\rho)$ in 1927, well before the corresponding classical quantity was introduced in Shannon's seminal work[41] on "The Mathematical Theory of Communication" in 1948. (Admittedly, von Neumann's motivation was the extension of the classical theory of statistical mechanics, developed by Gibbs *et al.* to the quantum domain rather than the development of a theory of quantum communication.) Many fundamental properties of the quantum entropy were proved in a remarkable, but little-known, 1936 paper of Delbrück and Molèiere.[9] For further discussion of the history of quantum entropy, see Refs. 33, 38 and 47 and the introductory remarks in Ref. 40.

One important class of inequalities relates the entropy of subsystems to that of a composite system, whose Hilbert space is a tensor product $\mathcal{H}_{12}=\mathcal{H}_1\otimes\mathcal{H}_2$ of the Hilbert spaces for the subsystems. When the state of the composite system is described by the density matrix ρ_{12}, the states of the subsystems are given by the reduced density matrices, e.g., $\rho_1=T_2(\rho_{12})$, obtained by taking the partial trace. The subadditivity inequality

$$S(\rho_{12})\leqslant S(\rho_1)+S(\rho_2) \tag{1}$$

was proved in Refs. 9 and 24. [It should not be confused with the concavity

$$S(x\rho'+(1-x)\rho'')\geqslant xS(\rho')+(1-x)S(\rho''), \tag{2}$$

which can actually be obtained *from* subadditivity by considering block matrices.[27,28,47]] In the more complex situation in which the composite system is composed of three subsystems, the following stronger inequality, known as strong subadditivity (SSA), holds:

$$S(\rho_{123})+S(\rho_2)\leqslant S(\rho_{12})+S(\rho_{23}). \tag{3}$$

This inequality was conjectured by Lanford and Robinson in Ref. 24 and proved in Refs. 28 and 29. In this article, we review its proof in a form that easily yields the following condition for equality.

Theorem 1: *Equality holds in strong subadditivity (3) if and only if*

$$\log\rho_{123}-\log\rho_{12}=\log\rho_{23}-\log\rho_2. \tag{4}$$

We have suppressed implicit tensor products with the identity so that, e.g., $\log\rho_{12}$ means $(\log\rho_{12})\otimes I_3$. Rewriting (4) as $\log\rho_{123}+\log\rho_2=\log\rho_{12}+\log\rho_{23}$, multiplying by ρ_{123} and taking the trace immediately establishes the sufficiency of this equality condition. In Sec. IV, we will show that it is also necessary.

B. Relative entropy

The SSA inequality can be restated as a property of the *quantum relative entropy* which is defined as

$$H(\rho,\gamma)\equiv \mathrm{Tr}\rho(\log\rho-\log\gamma). \tag{5}$$

It is usually assumed that ρ, γ are density matrices, although (5) is well-defined for any pair of positive semi-definite matrices for which $\ker(\gamma)\subset\ker(\rho)$. Strong subadditivity can now be restated as

$$H(\rho_{12},\rho_2)\leqslant H(\rho_{123},\rho_{23}), \tag{6}$$

where we again write, e.g., ρ_{23} for $I_1\otimes\rho_{23}$. More generally, the relative entropy is monotone under completely positive, trace-preserving maps (also known as ''quantum operations'' [32] and ''stochastic maps'' [1,20] and discussed in more detail in Sec. III D), i.e.,

$$H[\Phi(\rho),\Phi(\gamma)]\leqslant H(\rho,\gamma). \tag{7}$$

This monotonicity implies (6) when $\Phi=T_3$ is the partial trace operation; perhaps surprisingly, the converse is also true.[31] This, and other connections between strong subadditivity and relative entropy, are discussed in Sec. V C.

The approach to SSA presented here can also be used to obtain conditions for equality in properties of relative entropy, including its joint convexity and monotonicity. The explicit statements are postponed to later sections. Since the monotonicity can be used to give a simple proof of the celebrated Holevo bound[14,32] on accessible information, we show how our results can be used to recover the equality conditions in that bound. As discussed in Sec. II C, Petz[33,36] has also obtained several equality conditions in different, but equivalent, forms. However, Theorem 8, which applies to the most general form of monotonicity, appears to be new.

C. Lieb's convex trace functions

One of the most frequently cited approaches to strong subadditivity is to present it as a consequence of the concavity of a quantity known as the Wigner–Yanase–Dyson entropy.[49] This property, conjectured by Bauman,[6] is equivalent to the joint concavity in A and B of the map

$$(A,B)\to \mathrm{Tr}A^sK^\dagger B^{(1-s)}K \quad \text{for} \quad A,B>0,\ 0<s<1 \tag{8}$$

(where † is used to denote the adjoint). Lieb's proof[26] of the concavity of the WYD function (8) and his realization of a connection between SSA and Bauman's concavity conjecture was a crucial breakthrough. However, concavity of the WYD function was only one of several concave trace functions studied in Ref. 26; the following result was also established by Lieb.

Theorem 2: *For any fixed self-adjoint matrix K, the function* $A\mapsto F(A)=\mathrm{Tr}\ e^{K+\log A}$ *is concave in* $A>0$.

This result played a fundamental role in the original proof[28,29] of SSA and the closely related property of joint concavity of the relative entropy.[28–30] Although SSA is a deep theorem, a complete proof is not as forbidding as is sometimes implied. Therefore, for completeness, we include Epstein's elegant proof[11] of Theorem 2 in the Appendix, and then follow the original strategies of Lieb and Ruskai[29] to show how it implies SSA.

D. Overview

Although this article grew out of questions about the conditions for equality in strong subadditivity and related inequalities, it seems useful to present these conditions within a more comprehensive exposition. For simplicity, we confine our discussion to finite dimensions, and assume that, unless otherwise stated, the density matrices under consideration are strictly positive.

The remainder of the article is structured as follows. In Sec. II we discuss some consequences and interpretations of the SSA equality condition. In Sec. III we summarize some mathematical results needed for the proofs in the sections that follow. Section IV, which might be regarded as the heart of the paper, presents the proof of strong subadditivity in a form which easily yields the equality conditions. (A reader primarily interested in this proof can proceed directly to Sec. IV with a willingness to accept the results of Sec. III.) Section V presents proofs with equality conditions for the monotonicity of the relative entropy under partial traces, the joint convexity of the relative entropy, and the general monotonicity under stochastic maps. This section also contains a discussion of the connection between these properties, SSA and their proofs. Section VI contains the proof of the equality conditions for monotonicity of relative entropy. Section VII considers bounds, most notably the Holevo bound, on the accessible information that can be extracted from an ensemble of quantum states, and the conditions under which they can be attained. The article concludes with some additional historical comments in Sec. VIII.

II. IMPLICATIONS OF THE EQUALITY CONDITIONS FOR SSA

A. Classical conditions

To describe the corresponding classical inequalities, let the subsystems A, B and C correspond to classical random variables. One can recover the classical Shannon entropy $-\Sigma_a p(a)\log p(a)$ from the von Neumann entropy by taking ρ to be a diagonal matrix with elements $p(a)$ on the diagonal. Employing a slight abuse of notation, we write $S[p(a)]$ for this quantity. Then the classical strong subadditivity inequality can be stated as

$$S[p(a,b,c)]+S[p(b)]\leqslant S[p(a,b)]+S[p(b,c)]. \tag{9}$$

The classical relative entropy of the distribution $q(a)$ with respect to $p(a)$ is $H[p(a),q(a)]=\Sigma_a p(a)\log p(a)/q(a)$. It is well-known (see, e.g., Ref. 23) that the convexity of the function $f(x)=x\log x$ implies that $H[p(a),q(a)]\geqslant 0$ and its strict convexity implies that equality holds if and only if $p(a)=q(a)\forall a$. (The generalization of this result to quantum situations is discussed in Sec. III A.)

The classical form (9) of SSA is equivalent to $H[p(a,b,c),q(a,b,c)]\geqslant 0$ when the second distribution is $q(a,b,c)=p(a,b)[p(b)]^{-1}p(b,c)$. Thus, equality holds in (9) if and only if

$$p(a,b,c)=p(a,b)[p(b)]^{-1}p(b,c)\quad \forall a,b,c, \tag{10}$$

which can be rewritten as

$$\log p(a,b,c)-\log p(a,b)=\log p(b,c)-\log p(b)\quad \forall a,b,c, \tag{11}$$

which is identical to what one would obtain from Theorem 1. Using $p(c|b)$ to denote the classical conditional probability distribution, (11) can be rewritten as

$$p(c|a,b)=p(c|b), \tag{12}$$

which is precisely the condition that the sequence $A\rightarrow B\rightarrow C$ forms a Markov chain.

B. Special cases of SSA equality

Some insight into equality condition (4) may be obtained by looking at special cases in which it is satisfied. The most obvious is when ρ_{123} is a tensor product of its three reduced density matrices. However, it is readily verified that (4) also holds when either $\rho_{123}=\rho_1\otimes\rho_{23}$ *or* $\rho_{123}=\rho_{12}\otimes\rho_3$. One can generalize this slightly further. If the subsystem 2 can be partitioned further into two subsystems $2'$ and $2''$, then one can verify equality holds if $\rho_{123}=\rho_{12'}\otimes\rho_{2''3}$, where $\rho_{12'}$ and $\rho_{2''3}$ are states of the composite systems 1, $2'$ and $2''$, 3 respectively.

However, such a decomposition into tensor products is not necessary; indeed, we have already seen that equality also holds for the case of classical Markov processes. Moreover, by comparison to (12) it is natural to regard (4) as a kind of quantum Markov condition. Thus, the conditions in Theorem 1 can also be viewed as a natural noncommutative analog of the conditions for equality in classical SSA. Another way of regarding (4) is as a concise statement of a subtle intertwining condition discussed below. Unfortunately, we have not found explicit examples which satisfy it other than the two classes discussed above, that is, a partial decomposition into tensor products or a classical Markov chain.

C. Petz's conditions

Using a completely different approach, Petz[33,36] gave conditions for equality in (7) when Φ can be identified with a mapping of an algebra onto a subalgebra, a situation which includes (6). In that case Petz's conditions become

$$\rho_{12}^{it}\rho_{2}^{-it}=\rho_{123}^{it}\rho_{23}^{-it}. \tag{13}$$

Taking the derivative of both sides of (13) at $t=0$ yields (4). Although (13) appears stronger than (4), it is not since, as noted above, (4) is sufficient for equality in (6). Moreover, since (4) implies

$$e^{it\log(\rho_{123})}=e^{it[\log\rho_{12}-\log\rho_{12}+\log\rho_{23}]}, \tag{14}$$

our results can be combined with those of Petz to see that equality holds in SSA$\Leftrightarrow$(4)$\Leftrightarrow$(13) and that any of these conditions suffices to imply

$$e^{it[\log\rho_{12}-\log\rho_{2}+\log\rho_{23}]}=e^{it\log(\rho_{12})}e^{-it\log(\rho_{2})}e^{it\log(\rho_{23})}. \tag{15}$$

Note that one can also relate Petz's conditions to those for equality in classical SSA by rewriting (10) as $p(a,b,c)[p(b,c)]^{-1}=p(a,b)[p(b)]^{-1}$ and then raising to the *it* power.

III. FUNDAMENTAL MATHEMATICAL TOOLS

A. Klein's inequality

The fact that the relative entropy is positive, i.e., $H(\rho,\gamma)\geqslant 0$ when $\mathrm{Tr}\rho=\mathrm{Tr}\gamma$, is an immediate consequence of the following fundamental convexity result due to Klein.[22,32,47]

Theorem 3 (Klein's inequality): *For A, B>0*

$$\mathrm{Tr}\ \ A(\log A-\log B)\geqslant \mathrm{Tr}(A-B), \tag{16}$$

with equality if and only if A=B.

The closely related Peierls–Bogoliubov inequality[33,47] is sometimes used instead of Klein's inequality. However, the equality conditions in Theorem 3 play a critical role in the sections that follow.

B. Lieb's golden corollary

The proofs in Sec. IV do not use Theorem 2 directly, but a related result generalizing the following inequality, which we will also need.

Theorem 4 (Golden–Thompson–Symanzik): *For self-adjoint matrices A and B,* $\mathrm{Tr}\ e^{A+B}\leqslant \mathrm{Tr}\ e^{A}e^{B}$ *with equality if and only if A and B commute*.

Although this inequality is extremely well-known, the conditions for equality do not appear explicitly in such standard references as Refs. 16, 42 and 47. However, one method of proof is based on the observation that $\mathrm{Tr}[e^{A/2^k}e^{B/2^k}]^{2^k}$ is monotone decreasing in k, yielding e^{A+B} in the limit as $k\to\infty$. The equality conditions then follow easily from those for the Schwarz inequality for the Hilbert–Schmidt inner product $\mathrm{Tr}C^{\dagger}D$. Indeed, $k=1$ yields

$$\mathrm{Tr}(e^{A/2}e^{B/2})(e^{A/2}e^{B/2})\leqslant[\mathrm{Tr}\ \ e^{B/2}e^{A}e^{B/2}]^{1/2}[\mathrm{Tr}\ \ e^{A/2}e^{B}e^{A/2}]^{1/2}=\mathrm{Tr}\ \ e^{A}e^{B}$$

with $C=e^{B/2}e^{A/2}$ and $D=e^{A/2}e^{B/2}$. The equality condition that C is a multiple of D implies $e^{B/2}e^{A/2}=e^{A/2}e^{B/2}$ which holds if and only if A and B commute. One reference[33] that does discuss equality does so by making the interesting observation that (as shown in Ref. 37) Theorem 4 and its equality conditions can be derived as a consequence of the monotonicity of relative entropy, Theorem 7.

The natural extension to three matrices $\mathrm{Tr}\ e^{A+B+C}\leqslant|\mathrm{Tr}\ e^{A}e^{B}e^{C}|$, fails; see, for example, Problem 20 on pp. 512–513 of Ref. 16. Therefore, the following result of Lieb[26] is particularly noteworthy.

Theorem 5 (Lieb): *For any R,S,T>0*

$$\mathrm{Tr}\ \ e^{\log R-\log S+\log T}\geqslant\mathrm{Tr}\int_0^\infty R\,\frac{1}{S+uI}\,T\,\frac{1}{S+uI}\,du. \tag{17}$$

One might expect that equality holds if and only if R,S,T commute. Although this is sufficient, it is not necessary. One easily checks that both sides of (17) equal $\mathrm{Tr}\rho_1\otimes\rho_{23}$ when $R=\rho_1\otimes\rho_2\otimes I_3$, $S=I_1\otimes\rho_2\otimes I_3$, and $T=I_1\otimes\rho_{23}$, even when T does not commute with R or S.

Proof: Lieb's proof of (17) begins with the easily established fact[39] that if $F(A)$ is concave and homogeneous in the sense $F(xA)=xF(A)$, then

$$\lim_{x\to0}\frac{F(A+xB)-F(A)}{x}\geqslant F(B). \tag{18}$$

Applying this to the functions in Theorem 2 with $A=S$, $B=T$, $K=\log R-\log S$ yields

$$\mathrm{Tr}\ \ e^{\log R-\log S+\log T}\leqslant\lim_{x\to0}\frac{\mathrm{Tr}\ \ e^{\log R-\log S+\log(S+xT)}-\mathrm{Tr}R}{x}. \tag{19}$$

To complete the proof, we need the well-known integral representation

$$\log(S+xT)-\log S=\int_0^\infty\frac{1}{S+uI}\,xT\,\frac{1}{S+xT+uI}\,du. \tag{20}$$

Substituting (20) into (19) and noting that

$$\mathrm{Tr}\ e^{\log R+x\int_0^\infty[1/(S+uI)]T[1/(S+xT+uI)]du}=\mathrm{Tr}R+x\mathrm{Tr}R\int_0^\infty\frac{1}{S+uI}\,T\,\frac{1}{S+uI}\,du+O(x^2)$$

yields the desired result. Q.E.D.

C. Purification

Araki and Lieb[5,27] observed that one could obtain useful new entropy inequalities by applying what is now known as the ''purification process'' to known inequalities. Any density ρ_1 can be extended to a pure state density matrix ρ_{12} on a tensor product space; moreover, $S(\rho_1)=S(\rho_2)$. Applying this to the subadditivity inequality (1), i.e., $S(\rho_{12})\leqslant S(\rho_1)+S(\rho_2)$, yields the equivalent result $S(\rho_3)\leqslant S(\rho_{23})+S(\rho_2)$ which can be combined with (1) to give the triangle inequality[5,27]

$$|S(\rho_1)-S(\rho_2)|\leqslant S(\rho_{12})\leqslant S(\rho_1)+S(\rho_2). \tag{21}$$

By purifying ρ_{123} to ρ_{1234} one can similarly show that SSA (3) is equivalent to

$$S(\rho_4)+S(\rho_2)\leqslant S(\rho_{12})+S(\rho_{14}). \tag{22}$$

D. Lindblad's representation of stochastic maps

Stochastic maps arise naturally in quantum information as a description of the effect on a subsystem A interacting with the environment in the pure state $\gamma_B=|\psi_B\rangle\langle\psi_B|$ via the unitary operation U_{AB},

$$\rho_A \to \mathrm{Tr}_B(U_{AB}\rho_A\otimes\gamma_B U_{AB}^\dagger). \tag{23}$$

Lindblad[31] used Stinespring's representation to show that any completely positive trace-preserving map Φ which maps an algebra into itself can be represented as if it arose in this way. That is, given such a map Φ one can always find an auxiliary system, $\mathcal{H}_B$, a density matrix γ_B on $\mathcal{H}_B$, and a unitary map U_{AB} on the combined system $\mathcal{H}_A\otimes\mathcal{H}_B$ (where A denotes the original system) such that

$$\Phi(\rho)=\mathrm{Tr}_B(U_{AB}\rho\otimes\gamma_B U_{AB}^\dagger) \tag{24}$$

where Tr_B denotes the partial trace over the auxiliary system.

Using the Kraus representation $\Phi(\rho)=\Sigma_k F_k\rho F_k^\dagger$ (and noting that the requirement that Φ be trace-preserving is equivalent to $\Sigma_k F_k^\dagger F_k=I$), one can give a construction equivalent to Lindblad's by initially defining U_{AB} as

$$U_{AB}|\psi\rangle\otimes|\beta\rangle\equiv\sum_k F_k|\psi\rangle\otimes|k\rangle, \tag{25}$$

where $|\beta\rangle$ is a fixed normalized state of the auxiliary system, and $\{|k\rangle\}$ is some orthonormal basis for the auxiliary system. Then U_{AB} is a partial isometry from $\mathcal{H}_A\otimes|\beta\rangle\langle\beta|$ to $\mathcal{H}_A\otimes\mathcal{H}_B$ which can be extended to a unitary operator on all of $\mathcal{H}_A\otimes\mathcal{H}_B$. This yields (24) with $\gamma_B=|\beta\rangle\langle\beta|$ a pure state.

However, U_{AB} can also be extended to $\mathcal{H}_A\otimes\mathcal{H}_B$ in other ways. In particular, it can be extended, instead, to the partial isometry for which $U_{AB}^\dagger U_{AB}$ is the projection onto $\mathcal{H}_A\otimes|\beta\rangle\langle\beta|$ so that $U_{AB}=0$ on the orthogonal complement of $\mathcal{H}_A\otimes|\beta\rangle\langle\beta|$. We describe this in more detail when Φ requires at most m Kraus operators F_k, in which case one can choose the auxiliary system to be $\mathbf{C}^m$. One can also choose $|k\rangle=|e_k\rangle$, and $|\beta\rangle=|e_1\rangle$ with $|e_k\rangle$ the standard basis of column vectors with elements $c_j=\delta_{jk}$. Then (25) depends only on the first column of U_{AB} which we denote V and regard as a map from $\mathcal{H}$ to $\mathcal{H}\otimes\mathbf{C}^m$. In block form

$$V_\rho V^\dagger=U_{AB}\rho\otimes|e_1\rangle\langle e_1|U_{AB}^\dagger=\begin{pmatrix}F_1\\F_2\\\vdots\\F_m\end{pmatrix}\rho(F_1^\dagger\ F_2^\dagger\ \cdots\ F_m^\dagger)=\begin{pmatrix}F_1\rho F_1^\dagger & F_1\rho F_2^\dagger & \cdots & F_1\rho F_m^\dagger\\F_2\rho F_1^\dagger & F_2\rho F_2^\dagger & \cdots & F_2\rho F_m^\dagger\\\vdots & \vdots & & \vdots\\F_m\rho F_1^\dagger & & \cdots & F_m\rho F_m^\dagger\end{pmatrix} \tag{26}$$

from which it easily follows that $\mathrm{Tr}_B(V\rho V^\dagger)=\Sigma_k F_k\rho F_k^\dagger=\Phi(\rho)$. The requirement that Φ be trace-preserving gives $V^\dagger V=\Sigma_k F_k^\dagger F_k=I$ which again implies that V is a partial isometry. Moreover, $V\rho V^\dagger$ has the same nonzero eigenvalues as $(V\sqrt{\rho})^\dagger(V\sqrt{\rho})=\rho$ so that $S[V\rho V^\dagger]=S(\rho)$.

This construction can be readily extended to situations in which Φ maps operators acting on one Hilbert space $\mathcal{H}_A$ to those acting on another space $\mathcal{H}_{A'}$, e.g., $\Phi:\mathcal{B}(\mathcal{H}_A)\mapsto\mathcal{B}(\mathcal{H}_{A'})$. In this case, the Kraus operators $F_k:\mathcal{H}_A\mapsto\mathcal{H}_{A'}$, and U_{AB} is a partial isometry from $\mathcal{H}_A\otimes|\beta\rangle\langle\beta|$ to a subspace of $\mathcal{H}_{A'}\otimes\mathcal{H}_B$. Alternatively, V can be defined as a partial isometry from $\mathcal{H}_A$ to $\mathcal{H}_{A'}\otimes\mathbf{C}^m$.

E. Measurements and their representations

A von Neumann or *projective measurement* is a partition of the identity $I=\Sigma_b E_b$ into mutually orthogonal projections, i.e., $E_b E_c=\delta_{bc}E_b$. A positive operator valued measurement (POVM) is a set of positive semi-definite operators E_b such that $\Sigma_b E_b=I$, i.e., the orthogonality condition is dropped. It is well-known that a general POVM can be represented as a projective measurement on a tensor product space.[32]

In fact, by noting that the map $\rho\mapsto\Sigma_b\sqrt{E_b}\rho\sqrt{E_b}$ is completely positive and trace-preserving with Kraus operators $F_b=\sqrt{E_b}$ one can use the construction above. Write $V=\Sigma_b\sqrt{E_b}\otimes|b\rangle$ where $|b\rangle$ is an orthonormal basis for $\mathbf{C}^M$ and M is the number of measurements in the POVM, i.e., $b=1,...,M$. Then $V\rho V^\dagger=\Sigma_{b,c}\sqrt{E_b}\rho\sqrt{E_c}\otimes|b\rangle\langle c|$. Now, if $F_b=I\otimes|b\rangle\langle b|$, then $\{F_b\}$ is a projective measurement on $\mathcal{H}\otimes\mathbf{C}^M$ and $\mathrm{Tr}F_b(V\rho V^\dagger)=\mathrm{Tr}E_b\rho$.

F. Adjoint maps

It is sometimes useful to consider the adjoint, which we denote $\widehat{\Phi}$, of a stochastic map Φ with respect to the Hilbert–Schmidt inner product $\langle A,B\rangle=\mathrm{Tr}A^\dagger B$. When Φ acts on $n\times n$ matrices, this adjoint (or dual) is fully defined by the requirement

$$\mathrm{Tr}[\Phi(A)]^\dagger B=\mathrm{Tr}A^\dagger\widehat{\Phi}(B) \tag{27}$$

for all $n\times n$ matrices, A,B. Indeed, when $\Phi(\rho)=\Sigma_k F_k\rho F_k^\dagger$, the adjoint is given by $\widehat{\Phi}(\rho)=\Sigma_k F_k^\dagger\rho F_k$. Moreover, Φ is trace-preserving if and only if $\widehat{\Phi}$ is unital, i.e., $\widehat{\Phi}(I)=I$. When Φ is the partial trace, T_2, its adjoint takes $A\mapsto A\otimes I_2$.

IV. SUBADDITIVITY PROOFS

To understand the proof of strong subadditivity, it is instructive to first understand how Klein's inequality can be used to prove two weaker inequalities. First, we consider the subadditivity inequality (1). Substituting $A=\rho_{12}$ and $B=\rho_1\otimes\rho_2$ into Klein's inequality (16) yields

$$-S(\rho_{12})+S(\rho_1)+S(\rho_2)\geqslant\mathrm{Tr}(\rho_{12}-\rho_1\otimes\rho_2)=0, \tag{28}$$

which is equivalent to subadditivity. Furthermore, the well-known conditions for equality in subadditivity follow from the conditions for equality in Klein's inequality, namely that equality holds if and only if ρ_{12} is a tensor product, that is, $\rho_{12}=\rho_1\otimes\rho_2$.

A second, more powerful subadditivity inequality was obtained by Araki and Lieb,[5]

$$S(\rho_{123})\leqslant S(\rho_{12})+S(\rho_{23}) \tag{29}$$

under the constraint $\mathrm{Tr}\rho_{123}=1$. To prove this, choose $A=\rho_{123}$ and $B=e^{\log\rho_{12}+\log\rho_{23}}$ in Klein's inequality to obtain

$$-S(\rho_{123})+S(\rho_{12})+S(\rho_{23})\geqslant 1-\mathrm{Tr}\ e^{\log\rho_{12}+\log\rho_{23}}. \tag{30}$$

Applying Theorem 4 to the right-hand side gives

$$-S(\rho_{123})+S(\rho_{12})+S(\rho_{23})\geqslant 1-\mathrm{Tr}_{123}\rho_{12}\rho_{23}=1-\mathrm{Tr}_2(\rho_2)^2\geqslant 1-\mathrm{Tr}_2\rho_2=0,$$

where the last line follows from $(\rho_2)^2\leqslant\rho_2$ (which is the *only* place the normalization condition $\mathrm{Tr}\rho_{123}=1$ is needed). Q.E.D.

The strategy for proving SSA is similar to that above, but with Theorem 4 replaced by Theorem 5. Let $A=\rho_{123}$ and choose B so that $\log B=\log\rho_{12}-\log\rho_2+\log\rho_{23}$. Then Klein's inequality implies

$$-S(\rho_{123})+S(\rho_{12})-S(\rho_2)+S(\rho_{23})\geqslant\mathrm{Tr}(\rho_{123}-e^{\log\rho_{12}-\log\rho_2+\log\rho_{23}}). \tag{31}$$

Applying Lieb's result (17) to the right-hand side above, we obtain

$$-S(\rho_{123})+S(\rho_{12})-S(\rho_2)+S(\rho_{23}) \geqslant \mathrm{Tr}\left(\rho_{123} - \int_0^\infty \rho_{12}\frac{1}{\rho_2+uI}\rho_{23}\frac{1}{\rho_2+uI}\,du \right)$$

$$= \mathrm{Tr}_{123}\rho_{123} - \mathrm{Tr}_2 \int_0^\infty \rho_2\frac{1}{\rho_2+uI}\rho_2\frac{1}{\rho_2+uI}\,du$$

$$= (\mathrm{Tr}_{123}\rho_{123} - \mathrm{Tr}_2\rho_2) = 0.$$

This proves SSA. Moreover, this approach allows us to easily determine the conditions for equality, and thus complete the proof of Theorem 1. The first inequality in the derivation above is satisfied with equality if and only if $A=B$, which is just the condition (4). Although the conditions for equality in (17) are more difficult to analyze, this is not necessary here. When $A=B$, it immediately follows that $\mathrm{Tr}A=\mathrm{Tr}B$ so that the second inequality in the above derivation automatically becomes an equality when (4) holds.

V. INEQUALITIES FOR RELATIVE ENTROPY

A. Monotonicity under partial trace

We now show how the same strategy can be applied to obtain a proof with equality conditions for the monotonicity of relative entropy under partial trace.

Theorem 6: *When* $\rho_{12},\gamma_{12}>0$ *and* $\mathrm{Tr}\rho_{12}=\mathrm{Tr}\gamma_{12}$,

$$H(\rho_2,\gamma_2) \leqslant H(\rho_{12},\gamma_{12}) \tag{32}$$

with equality if and only if $\log\rho_{12}-\log\gamma_{12}=\log\gamma_2+\log\rho_2$.

This condition should be interpreted as $\log\rho_{12}-\log\gamma_{12}=I_1\otimes[\log\gamma_2-\log\rho_2]$. Since, as noted in Sec. III F, when $\Phi=T_1$, the action $\hat{\Phi}$ is precisely $I_1\otimes$, the equality condition can be written as $\log\rho_{12}-\log\gamma_{12}=\hat{T}_1[\log T_1(\gamma_{12})-\log T_1(\rho_{12})]$ which is a special case of the more general form (40) developed later.

SSA can be regarded as a special case of this monotonicity result via the correspondence $\rho_{12}\to\rho_{123}$, $\gamma_{12}\to\rho_{12}$, and Petz's form of the equality condition becomes $\rho_2^{it}\gamma_2^{-it}=\rho_{12}^{it}\gamma_{12}^{-it}$. It is interesting to note that in Ref. 29, Lieb and Ruskai actually obtained Eq. (32) *from* SSA using the convexity of the conditional entropy $S(\rho_1)-S(\rho_{12})$ and the inequality (18).

Proof: Let $A=\rho_{12}$, $\log B=\log\gamma_{12}-\log\gamma_2+\log\rho_2$. Then Klein's inequality and (17) imply

$$H(\rho_{12},\gamma_{12})-H(\rho_2,\gamma_2) \geqslant \mathrm{Tr}_{12}(\rho_{12}-e^{\log\gamma_{12}-\log\gamma_2+\log\rho_2})$$

$$\geqslant \mathrm{Tr}_{12}\left(\rho_{12} - \int_0^\infty \gamma_{12}\frac{1}{\gamma_2+uI}\rho_2\frac{1}{\gamma_2+uI}\,du \right)$$

$$= \mathrm{Tr}_{12}\rho_{12} - \mathrm{Tr}_2\int_0^\infty \gamma_2\frac{1}{\gamma_2+uI}\rho_2\,\frac{1}{\gamma_2+uI}\,du = \mathrm{Tr}_{12}\rho_{12}-\mathrm{Tr}_2\rho_2 = 0.$$

The equality condition is again precisely the condition $A=B$. Q.E.D.

B. Joint convexity of the relative entropy

The joint convexity of relative entropy can be obtained directly from Theorem 6 by choosing ρ_{12} (and similarly γ_{12}) to be a block diagonal matrix with blocks $\lambda_k\rho^{(k)}$ (and $\lambda_k\gamma^{(k)}$). We can interpret the partial trace as a sum over blocks so that $\rho\equiv\rho_2=\Sigma_k\lambda_k\rho^{(k)}$. However, it is worth giving a direct proof of the joint convexity since it demonstrates the central role of Theorem 2.

Theorem 7: *The relative entropy is jointly convex in its arguments, i.e., if* $\rho=\Sigma_k\lambda_k\rho^{(k)}$ *and* $\gamma=\Sigma_k\lambda_k\gamma^{(k)}$, *then*

$$H(\rho,\gamma)\leqslant\sum_k \lambda_k H(\rho^{(k)},\gamma^{(k)}) \tag{33}$$

with equality if and only if $\log\rho-\log\gamma=\log\rho^{(k)}-\log\gamma^{(k)}$ *for all k.*

Proof: Let $A=\rho^{(k)}$ and $\log B=\log\rho-\log\gamma+\log\gamma^{(k)}$ with $\rho=\Sigma_k\lambda_k\rho^{(k)}$ and $\gamma=\Sigma_k\lambda_k\gamma^{(k)}$. Then Klein's inequality implies

$$H(\rho^{(k)},\gamma^{(k)})-\mathrm{Tr}\rho^{(k)}[\log\rho-\log\gamma]\geqslant\mathrm{Tr}(\rho-e^{\log\rho-\log\gamma+\log\gamma^{(k)}}). \tag{34}$$

Multiplying this by λ_k with $\lambda_k>0$ and $\Sigma_k\lambda_k=1$ yields, after summation,

$$\begin{aligned}\sum_k \lambda_k H(\rho^{(k)},\gamma^{(k)})-H(\rho,\gamma)&\geqslant\mathrm{Tr}\left(\rho-\sum_k \lambda_k e^{\log\rho-\log\gamma+\log\gamma^{(k)}}\right)\\&\geqslant\mathrm{Tr}\left(\rho-e^{\log\rho-\log\gamma+\log\sum_k \lambda_k\gamma^{(k)}}\right)\\&=\mathrm{Tr}(\rho-e^{\log\rho})=0,\end{aligned}$$

where the second inequality is precisely the concavity of $C\to F(C)=\mathrm{Tr}\ e^{K+\log C}$ with $K=\log\rho-\log\gamma$ and $C=\Sigma_k\lambda_k\gamma^{(k)}$. Q.E.D.

C. Relationships among inequalities

We make some additional remarks about connections between SSA and various properties of relative entropy. To facilitate the discussion, we will use MONO to denote the general monotonicity inequality (7), MPT to denote the special case of monotonicity under partial traces, i.e., Theorem 6, and JC to denote the joint convexity, Theorem 7. Using the restatement of SSA in the form (6), it is easy to see that MONO⇒MPT⇒SSA. Before Theorem 7, we showed that MPT⇒JC. Similarly, by choosing ρ_{123} to be block diagonal with blocks ρ^k_{123} one can show that SSA implies that the map $\rho_{12}\mapsto S(\rho_1)-S(\rho_{12})$ is convex. In Ref. 29 it was observed that applying the convexity inequality (18) to this map (with $A+xB=\rho_{12}+x\gamma_{12}$) yields (32). This shows that SSA⇒MPT, so that we have the chain of implications

$$\mathrm{MONO}\Rightarrow\mathrm{MPT}\Leftrightarrow\mathrm{SSA}\Rightarrow\mathrm{JC}. \tag{35}$$

One can show that JC⇒MPT by using Uhlmann's observation[43] that the partial trace can be written as a convex combination of unitary transformations.

One can also show directly that JC⇒SSA by using the purification process described in Sec. III C to show that SSA is equivalent to

$$\rho_4+\rho_2\leqslant\rho_{12}+\rho_{14}. \tag{36}$$

Moreover, if ρ_{124} is pure, then $\rho_4=\rho_{12}$ and $\rho_2=\rho_{14}$ so that equality holds in (36). Since the extreme points of the convex set of density matrices are pure states, the inequality (36) then follows from the joint convexity, Theorem 7. Thus we have

$$\mathrm{MONO}\Rightarrow\mathrm{MPT}\Leftrightarrow\mathrm{SSA}\Leftrightarrow\mathrm{JC}. \tag{37}$$

Lindblad[31] completed this circuit by showing that MPT⇒MONO.

Using the representation described in Sec. III D, with V the partial isometry from $\mathcal{H}$ to $\mathcal{H}\otimes\mathbf{C}^m$ as in (26), one finds

$$H[\Phi(\rho),\Phi(\gamma)] = H[\mathrm{Tr}_B(V\rho V^\dagger),\ \mathrm{Tr}_B(V\gamma V^\dagger)]$$
$$\leqslant H[V\rho V^\dagger, V\gamma V^\dagger] \tag{38}$$
$$= H(\rho,\gamma). \tag{39}$$

since $\mathrm{Tr}V\rho V^\dagger \log(V\gamma V^\dagger) = \mathrm{Tr}\rho \log \gamma$ for a partial isometry V.

VI. EQUALITY IN MONOTONICITY UNDER STOCHASTIC MAPS

Conditions for equality in the general monotonicity inequality (7) may be more subtle since it is not always possible to achieve equality. Indeed, it was noted in Ref. 25 that $\sup_{\rho\neq\gamma} H[\Phi(\rho),\Phi(\gamma)]/H(\rho,\gamma)$ can be strictly less than 1. Using the reformulation (38) above, we prove the following result.

Theorem 8: *Equality holds in (7), $H[\Phi(\rho),\Phi(\gamma)] \leqslant H(\rho,\gamma)$, if and only if*

$$\log\rho - \log\gamma = \widehat{\Phi}\,[\log\Phi(\rho) - \log\Phi(\gamma)] \tag{40}$$

where $\widehat{\Phi}$ denotes the adjoint of Φ with respect to the Hilbert–Schmidt inner product as defined in (27).

To verify sufficiency, multiply (40) by ρ and take the trace to obtain

$$H(\rho,\gamma) = \mathrm{Tr}\rho\,\widehat{\Phi}\,[\log\Phi(\rho) - \log\Phi(\gamma)] = \mathrm{Tr}\Phi(\rho)[\log\Phi(\rho) - \log\Phi(\gamma)] = H[\Phi(\rho),\Phi(\gamma)].$$

It is tempting to follow our previous strategy and choose $A=\rho$, $\log B = \log\gamma + \widehat{\Phi}[\log\Phi(\rho) - \log\Phi(\gamma)]$. However, we have been unable to verify that $\mathrm{Tr}\, e^{\log\gamma + \widehat{\Phi}[\log\Phi(\rho) - \log\Phi(\gamma)]} \leqslant 1$ as required by this approach.

Instead, we use the representation (24) or (26). Rather than applying the equality conditions in Theorem 6 directly to (38), it is useful to repeat the argument for an appropriate choice of A and B.

Proof: Choose $A = V\rho V^\dagger$, $\log B = \log(V\gamma V^\dagger) + \log \mathrm{Tr}_2(V\rho V^\dagger) - \log \mathrm{Tr}_2(V\gamma V^\dagger)$ where V is again the partial isometry as in (26) of Sec. III D. B is defined so that the last two terms in $\log B$ are extended from $\mathcal{H}$ to $\mathcal{H}\otimes\mathbf{C}^m$ so that $\ker(B)\subset\ker(A)$. The condition for equality in (38) is then

$$\log(V\rho V^\dagger) - \log(V\gamma V^\dagger) = \log \mathrm{Tr}_2(V\rho V^\dagger) - \log \mathrm{Tr}_2(V\gamma V^\dagger) = \log\Phi(\rho) - \log\Phi(\gamma). \tag{41}$$

We can put this into a more useful form by noting that for a partial isometry V,

$$\log(V\rho V^\dagger) - \log(V\gamma V^\dagger) = V[\log\rho - \log\gamma]V^\dagger, \tag{42}$$

from which it follows that (41) is equivalent to

$$V[\log\rho - \log\gamma]V^\dagger = \log\Phi(\rho) - \log\Phi(\gamma). \tag{43}$$

Multiplying by $V^\dagger$ on the left and V on the right and using that $V^\dagger V = I$, one sees that (43) implies

$$\log\rho - \log\gamma = V^\dagger[\log\Phi(\rho) - \log\Phi(\gamma)]V. \tag{44}$$

Taking the partial trace Tr_2 over the auxiliary space in (44) yields (40) since $\widehat{\Phi}(P) = \Sigma_k F_k^\dagger P F_k = V^\dagger P V$ for all P in $\mathcal{H}$. Q.E.D.

Another useful necessary condition for equality in (7) can be obtained by multiplying both sides of (43) by the projection $VV^\dagger$. Since $V^\dagger V = I$, one finds

$$VV^\dagger[\log\Phi(\rho) - \log\Phi(\gamma)] = V[\log\rho - \log\gamma]V^\dagger = [\log\Phi(\rho) - \log\Phi(\gamma)]VV^\dagger, \tag{45}$$

i.e., the projection $VV^\dagger$ commutes with $[\log\Phi(\rho)-\log\Phi(\gamma)]$. Taking the partial trace and noting that $\Phi(I)=\mathrm{Tr}_2 VV^\dagger$ we can summarize this discussion in the following.

Corollary 9: If equality holds in (7), then

$$\Phi(\log\rho-\log\gamma)=\Phi(I)[\log\Phi(\rho)-\log\Phi(\gamma)]=[\log\Phi(\rho)-\log\Phi(\gamma)]\Phi(I). \tag{46}$$

Moreover, $\log\Phi(\rho)-\log\Phi(\gamma)$ *commutes with the projection* $VV^\dagger=\Sigma_{k,\ell}|k\rangle\langle\ell|F_k F_\ell^\dagger$ *where* $\{F_k\}$ *is a set of Kraus operators for* Φ*, i.e.,* $\Phi(\rho)=\Sigma_k F_k\rho F_k^\dagger$ *and* $|k\rangle$ *is an orthonormal basis for the auxiliary space* $\mathcal{H}_2$.

The results of this section also hold in the more general situation when $\Phi:\mathcal{B}(\mathcal{H}_A)\mapsto\mathcal{B}(\mathcal{H}'_A)$ maps operators on one Hilbert space to those on another, in which case $F_k:\mathcal{H}_A)\mapsto\mathcal{H}'_A$.

VII. THE HOLEVO BOUND

A. Background

One reason for studying conditions for equality is that other results, such as Holevo's celebrated bound[14] on the accessible information, can be obtained rather easily from SSA or some form of the monotonicity of relative entropy. However, obtaining the corresponding conditions for equality is not as straightforward as one might hope because of the need to introduce an auxiliary system. Although Holevo's bound is quite general, it is often applied in situations where $\tilde\rho_j=\Phi(\rho_j)$ is the output of a noisy quantum channel Φ with input ρ_j. We use the tilde $\tilde{}$ as a reminder of this, as well as to ensure a distinction from other density matrices which arise.

For any fixed POVM and density matrix γ, $p(b)=\mathrm{Tr}(\gamma E_b)$ defines a classical probability distribution whose entropy we denote $S[\mathrm{Tr}\gamma E_b]$. The Holevo bound states that for any ensemble of density matrices $\mathcal{E}=\{\pi_j\tilde\rho_j\}$ with average density matrix $\tilde\rho=\Sigma_j\pi_j\tilde\rho_j$, the accessible information in the ensemble satisfies

$$I(\mathcal{E},\mathcal{M})\equiv S[\mathrm{Tr}\tilde\rho E_b]-\sum_j \pi_j S[\mathrm{Tr}\tilde\rho_j E_b] \tag{47}$$

$$\leqslant S(\tilde\rho)-\sum_j \pi_j S(\tilde\rho_j) \tag{48}$$

for any POVM $\mathcal{M}=\{E_b\}$. If all of the $\tilde\rho_j$ commute, then it is easy to see that equality can be achieved by choosing the E_b to be the spectral projections which simultaneously diagonalize the density matrices $\tilde\rho_j$. We wish to show that this condition is also necessary, i.e., equality can only be achieved in (48) if all the $\tilde\rho_j$ commute.

It is known[21,50] that (48) can be obtained from (7). First, observe that

$$S(\tilde\rho)-\sum_j \pi_j S(\tilde\rho_j)=\sum_j \pi_j H(\tilde\rho_j,\tilde\rho). \tag{49}$$

Now let $\Omega_{\mathcal{M}}$ be the map $\Omega_{\mathcal{M}}(A)=\Sigma_b|b\rangle\langle b|\mathrm{Tr}(AE_b)$ where $\mathcal{M}=\{E_b\}$. Then $\Omega_{\mathcal{M}}$ is a stochastic map of the special type known as a Q-C channel[15] and the Holevo bound (48) follows immediately from (49) and

$$H[\Omega_{\mathcal{M}}(\tilde\rho_j),\Omega_{\mathcal{M}}(\tilde\rho)]\leqslant H(\tilde\rho_j,\tilde\rho). \tag{50}$$

B. Equality conditions

We will henceforth assume that $\{\pi_j,\tilde\rho_j\}$ is a fixed ensemble and seek conditions under which we can find a POVM satisfying the equality requirements. Since $\widehat{\Omega}_{\mathcal{M}}(D)=\Sigma_b E_b\langle b,Db\rangle$, applying Theorem 8 yields conditions for equality in (50). For equality in (48) these conditions must hold for every j and reduce to

$$\log\tilde{\rho}_j - \log\tilde{\rho} = \sum_b E_b \log\frac{\mathrm{Tr}E_b\tilde{\rho}_j}{\mathrm{Tr}E_b\tilde{\rho}}\,\forall j, \tag{51}$$

where this should be interpreted as a condition on $\ker(\tilde{\rho}_j)^\perp$ in which case all terms are well-defined. (Indeed, since the condition arises from the use of Klein's inequality and the requirement $A=B$, the operators in B must be defined to be zero on $\ker(A)$, which reduces to $\ker(\tilde{\rho}_j)$ in the situation considered here.) If the POVM $\{E_b\}$ consists of a set of mutually orthogonal projections, then it is immediate that the operators $Z_j \equiv \log\tilde{\rho}_j - \log\tilde{\rho}$ commute, since (51) can be regarded as the spectral decomposition of Z_j. To show that the $\tilde{\rho}_j$ themselves commute, observe that

$$\begin{aligned}
1 = \mathrm{Tr}\tilde{\rho}_j &= \mathrm{Tr}\ \ e^{\log\tilde{\rho}+[\log\tilde{\rho}_j-\log\tilde{\rho}]} \\
&\leqslant \mathrm{Tr}\tilde{\rho}e^{\log\tilde{\rho}_j-\log\tilde{\rho}} \\
&= \mathrm{Tr}\tilde{\rho}e^{\Sigma_b E_b \log(\mathrm{Tr}E_b\tilde{\rho}_j/\mathrm{Tr}E_b\rho)} \\
&= \mathrm{Tr}\tilde{\rho}\ \sum_b E_b\frac{\mathrm{Tr}E_b\tilde{\rho}_j}{\mathrm{Tr}E_b\tilde{\rho}} = \sum_b \mathrm{Tr}E_b\tilde{\rho}_j = 1,
\end{aligned}$$

where we have used Theorem 4 with $A=\log\tilde{\rho}$, $B=\log\tilde{\rho}_j-\log\tilde{\rho}$, and the fact that for orthogonal projections $e^{\Sigma_b a_b E_b}=\Sigma_b e^{a_b}E_b$. The conditions for equality in Theorem 4 then imply that $\log\tilde{\rho}_j$ and $\log\tilde{\rho}$ commute for all j. Hence $\tilde{\rho}_j$ and $\tilde{\rho}_k$ also commute for all j,k when the POVM consists of mutually orthogonal projections.

Using King's observation in the next section, one can reduce the general case to that of projective measurements. However, we prefer to use the equality conditions to show directly that the elements of the POVM must be orthogonal. Moreover, the commutativity condition involving $VV^\dagger$ is reminiscent of the more sophisticated Connes cocyle approach used by Petz, and thus of some interest.

Since the Kraus operators for the Q-C map $\Omega_{\mathcal{M}}$ can be chosen as $F_{kb}=|b\rangle\langle k|\sqrt{E_b}$ where $|b\rangle$ and $|k\rangle$ are orthonormal bases, one finds

$$VV^\dagger = \sum_{b,c}\ \sum_{k,\ell}\ |b\rangle\langle c|\langle k\sqrt{E_b}\sqrt{E_c}\ell\rangle = \sum_{b,c}\ |b\rangle\langle c|\langle\phi\sqrt{E_b}\sqrt{E_c}\phi\rangle, \tag{52}$$

where $|\phi\rangle=\Sigma_k|k\rangle$. By (45), this must commute for all j with $\log\Omega_{\mathcal{M}}(\tilde{\rho}_j)-\log\Omega_{\mathcal{M}}(\tilde{\rho}_j)$ which can be written in the form $\Sigma_b z_{bj}|b\rangle\langle b|$ with $z_{bj}=\log(\mathrm{Tr}E_b\tilde{\rho}_j/\mathrm{Tr}E_b\rho)$. A diagonal operator of the form $\Sigma_b z_b|b\rangle\langle b|$ with all $z_b\neq 0$ will commute with the projection in (52) if and only if all off-diagonal terms are zero. This will hold if the POVM is a projective measurement, since then $\sqrt{E_b}\sqrt{E_c}=E_bE_c=E_b\delta_{bc}$. To see that this is necessary, note that the possibility that the vector ϕ is orthogonal to all E_b is precluded by the condition that $\Sigma_b E_b=I$. Moreover, since the orthonormal basis $|k\rangle$ is arbitrary, ϕ can be chosen to be arbitrary. The restriction that (51) hold only on $\ker(\tilde{\rho}_j)^\perp$ may permit some $z_{bj}=0$; however, for each b there will always be at least one j for which $z_{bj}\neq 0$, and this suffices. Q.E.D.

One can obtain an alternate form of the equality conditions from Corollary 9. Since $\Phi(I)=\Sigma_b|b\rangle\langle b|\mathrm{Tr}E_b$, another necessary condition for equality in (48) is

$$\mathrm{Tr}E_b[\log\tilde{\rho}_j-\log\tilde{\rho}] = \mathrm{Tr}E_b(\log\mathrm{Tr}E_b\tilde{\rho}_j-\log\mathrm{Tr}E_b\tilde{\rho})\ \ \forall j,b. \tag{53}$$

Inserting this in (51) yields the requirement

$$\log\tilde{\rho}_j-\log\tilde{\rho} = \sum_b \frac{1}{\mathrm{Tr}E_b}E_b\mathrm{Tr}E_b[\log\tilde{\rho}_j-\log\tilde{\rho}], \tag{54}$$

which can be rewritten as

$$Z_j = \sum_b \frac{|E_b\rangle}{\mathrm{Tr}E_b}\langle E_b, Z_j\rangle \quad \forall j, \tag{55}$$

where $Z_j = \log\tilde{\rho}_j - \log\tilde{\rho}$ and the bra-ket now refer to the Hilbert–Schmidt inner product. This implies that $\Sigma_b|E_b\rangle\langle E_b|/\mathrm{Tr}E_b$ projects onto the span($\{Z_j\}$). However, this alone is not sufficient to imply that the E_b form a projective measurement.

C. Other approaches

Chris King has observed[19] that when the POVM is a projective measurement of the form $E_b = |b\rangle\langle b|$, one can obtain the Holevo bound from the joint convexity of relative entropy. Let $\beta(\tilde{\rho}) = \Sigma_b|b\rangle\langle b|\mathrm{Tr}E_b\tilde{\rho}$. Then applying Theorem 7 to $H[\tilde{\rho}, \beta(\tilde{\rho})]$ yields

$$-S(\tilde{\rho}) + S(\mathrm{Tr}E_b\tilde{\rho}) \leqslant \sum_j \pi_j[-S(\tilde{\rho}_j) + S(\mathrm{Tr}E_b\tilde{\rho}_j)] \tag{56}$$

or

$$S(\mathrm{Tr}E_b\tilde{\rho}) - \sum_j \pi_j S(\mathrm{Tr}E_b\tilde{\rho}_j) \leqslant S(\tilde{\rho}) - \sum_j \pi_j S(\tilde{\rho}_j)$$

with equality if and only if

$$\log\tilde{\rho} - \sum_b |b\rangle\langle b|\log \mathrm{Tr}E_b\tilde{\rho} = \log\tilde{\rho}_j - \sum_b |b\rangle\langle b|\log \mathrm{Tr}E_b\tilde{\rho}_j \quad \forall j. \tag{57}$$

This is equivalent to (51) when $E_b = |b\rangle\langle b|$, and the argument can be extended to more general projective measurements.

King also pointed out that if $\{E_b\}$ is an arbitrary POVM, the construction in Sec. III E can be used to show that (48) and (51) are equivalent to the equalities obtained when $\tilde{\rho}_j$ is replaced by $V\tilde{\rho}_j V^\dagger$ and E_b by F_b. Since the $\{F_b\}$ form a projective measurement, we can conclude from the argument above that equality implies that all $V\tilde{\rho}_j V^\dagger$ commute, which implies that all $\tilde{\rho}_j$ also commute since $V^\dagger V = I$.

It should be noted that Petz was able to use his equality conditions to find the conditions for equality in the Holevo bound and this is sketched in Ref. 34. Indeed, Petz's analog of (57) is $\tilde{\rho}^{it}D^{-it} = \tilde{\rho}_j^{it}D_j^{-it} \forall j$ where D, D_j denotes the diagonal parts of $\tilde{\rho}$, $\tilde{\rho}_j$, respectively. Then

$$\tilde{\rho}_j^{it} = \tilde{\rho}^{it}D^{-it}D_j^{it}. \tag{58}$$

Since (58) holds for all real t, as well as all j, it also implies $\tilde{\rho}_j^{-it} = \tilde{\rho}^{-it}D^{it}D_j^{-it}$. However, taking the adjoint of (58) yields $\tilde{\rho}_j^{-it} = D_j^{-it}D^{it}\tilde{\rho}^{-it}$. Therefore, $\tilde{\rho}^{-it}$ commutes with the diagonal matrix $D^{it}D_j^{-it} = D_j^{-it}D^{it}$ and must also be diagonal. This gives a simultaneous diagonalization of all $\tilde{\rho}_j^{it}$ which means that all $\tilde{\rho}_j$ commute.

Holevo's original longer derivation[14] of the bound (48) also concluded that commutativity was necessary and sufficient for equality. Some simplifications of this argument were given by Fuchs[12] in his thesis.

D. Another bound on accessible information

When ρ is a density matrix, the mapping $A \mapsto \rho^{-1/2}A\rho^{-1/2}$ and its inverse gives a duality between ensembles and POVMs. Hall[13] observed that this duality can be used to give another upper bound on the accessible information (47) in terms of the POVM and average density ρ, i.e.,

$$I(\mathcal{E},\mathcal{M}) \leqslant S(\rho) - \sum_b \tau_b S\left(\frac{1}{\tau_b}\sqrt{\rho}E_b\sqrt{\rho}\right) \tag{59}$$

$$= \sum_b \tau_b H\left(\frac{1}{\tau_b}\sqrt{\rho}E_b\sqrt{\rho},\rho\right), \tag{60}$$

where $\tau_b = \mathrm{Tr}\, E_b\rho$. This inequality can be obtained from the monoticity of relative entropy under the Q-C map $\Omega_{\mathcal{E}}(A) = \Sigma_j |j\rangle\langle j| \pi_j \rho^{-1/2}\rho_j\rho^{-1/2}$ applied to $H((1/\tau_b)\sqrt{\rho}E_b\sqrt{\rho},\rho)$ as in (50); or as in Ref. 21 where an equivalent bound was given. The argument in Sec. VII B can then be used to show that equality can be achieved in (59) if and only if all $\sqrt{\rho}E_b\sqrt{\rho}$ commute. Hall[13] also found this condition and noted that it implies that ρ commutes with every E_b in the POVM.

One is often interested in (48) and (59) when one wants to optimize the accessible information after using a noisy quantum channel, Φ. It was observed in Ref. 21 that, since $\mathrm{Tr}\Phi(\rho_j)E_b = \mathrm{Tr}\rho_j\,\widehat{\Phi}(E_b)$, one can regard the noise as either acting to transform pure inputs ρ_j to mixed state outputs $\Phi(\rho_j)$ or as acting through the adjoint $\widehat{\Phi}$ on the POVM with uncorrupted outputs. In the first case, one can bound the right side of (59) by choosing the E_b to be the spectral projections of the average output state $\Phi(\rho)$ to yield $I[\Phi(\mathcal{E}),\mathcal{M}] \leqslant S[\Phi(\rho)]$ which is weaker than the corresponding Holevo bound. Moreover, since the optimal choice for $\Phi(\rho_j)$ need not be in the image of Φ, it is not necessarily achievable even though the commutativity condition holds. Hall[13] discussed other situations in which the bound can not be achieved despite the fact that all $\sqrt{\rho}E_b\sqrt{\rho}$ commute.

Viewing the noise as acting on the POVM, King and Ruskai[21] defined

$$U_{EP}(\Phi) = \sup_{\rho,\mathcal{M}}\left[S(\rho) - \sum_b \tau_b S\left(\frac{1}{\tau_b}\sqrt{\rho}\,\widehat{\Phi}(E_b)\sqrt{\rho}\right)\right] \tag{61}$$

with $\tau_b = \mathrm{Tr}\rho\,\widehat{\Phi}(E_b) = \mathrm{Tr}\Phi(\rho)E_b$. If the supremum in (61) is achieved with an average density and POVM for which $\sqrt{\rho}\,\widehat{\Phi}(E_b)\sqrt{\rho}$ do not commute, then $U_{EP}(\Phi)$ is strictly greater than the accessible information. The questions of whether or not (61) can actually exceed the optimal accessible information, and how it might then be interpreted, are under investigation.

VIII. CONCLUDING REMARKS

The proof presented here for each inequality, SSA, Theorem 6, Theorem 7 and the general monotonicity (7), is quite short—only half a page using results from Sec. III which require less than one additional page *and* Theorem 2. However, as shown in the Appendix, even this result does *not* require a long argument if one is permitted to use some powerful tools of complex analysis.

It is certainly not unusual to find that complex analysis can be extremely useful, even when the functions of interest are real-valued. Indeed, Lieb's original proof of the concavity of WYD entropy used a complex interpolation argument. In his influential book[42] on trace ideals, Simon (extracting ideas from Uhlmann[44]) gave a longer ''elementary'' proof using the Schwarz inequality, perhaps inadvertently reinforcing the notion that any complete proof of SSA is long and forbidding. Similar ideas are implicit in Ando,[3] who restates the result in terms of tensor product spaces and block matrices. Uhlmann[44] again demonstrated the power of complex interpolation by using it to prove the monotonicity of relative entropy under trace-preserving maps which satisfy the slightly weaker condition of two-positivity (rather than complete positivity). SSA then follows immediately as a special case. However, Uhlmann's approach, which has been extended by Petz,[35,33] was developed within the framework of the relative modular operator formalism introduced by Araki[4,7,33] for much more general situations. Recently, Lesniewski and Ruskai[25] observed that within this relative modular operator framework, monotonicity can be established directly using an argument based on the Schwarz inequality.

The approach of this review is similar to that of Wehrl[47] in that we view Theorem 2 as the ''essential ingredient.'' Indeed, Uhlmann,[43,47] using a completely different approach, had independently recognized that Theorem 2 would imply SSA. However, Wehrl's otherwise excellent review stated (at the end of Sec. III B) that ''Unfortunately, the proof of [this] is not easy at all.'' Later (in Sec. III C) Wehrl again states that ''...the proof is surprisingly complicated. I want to indicate only that the concavity of Tr $e^{K+\log A}$ can be obtained from Lieb's theorem [on concavity of the WYD entropy] through a sequence of lemmas.'' Although aware that Epstein's approach,[11] which was developed shortly after Lieb announced his results, permitted a ''direct'' proof of Theorem 2, Wehrl does not seem to have fully appreciated it. The utility of Epstein's technique may have been underestimated, in part, because he presented his results in a form which applied to the full collection of convex trace functions studied in Ref. 26. Checking Epstein's hypotheses for the WYD function requires some nontrivial mapping theorems. This may have obscured the elegance of the argument in Appendix A.

It is worth noting that if the concavity of WYD entropy is regarded as the key result, it is not necessary to use the long sequence of lemmas Wehrl refers to in order prove SSA. Lindblad[30] gave a direct proof of the joint convexity, Theorem 7, directly by differentiating the WYD function. Once this is done, SSA follows via the purification argument sketched after Eq. (36) or, alternatively, the variant of Uhlmann's argument described in Refs. 42 and 47. Combining this with Lieb's original complex interpolation proof of the concavity of the WYD function yields another ''short'' proof of SSA, albeit one which does not appear to be well-suited to establishing conditions for equality.

Finally, we mention that Carlen and Lieb[8] obtained another proof of SSA by using Epstein's technique to prove some Minkowski type inequalities for L_p trace norms. Using a different approach, King[17,18] recently proved several additivity results for the minimal entropy and Holevo capacity of a noisy channel by using L_p inequalities in which Epstein's technique provided a critical estimate. This suggests that connections with L_p inequalities, as advocated by Amosov, Holevo and Werner,[2] may be a promising avenue for studying entropy and capacity in quantum information. Despite the results mentioned above, many open conjectures remain; see Refs. 2, 8, 17, 18, and 48 for further details.

ACKNOWLEDGMENTS

This work was partially supported by the National Security Agency (NSA) and Advanced Research and Development Activity (ARDA) under Army Research Office (ARO) Contract No. DAAG55-98-1-0374 and by the National Science Foundation under Grant Nos. DMS-9706981 and DMS-0074566. This article is the result of questions first posed to the author by M. Nielsen and it is a pleasure to acknowledge the value of extensive discussions with him. Some of these discussions took place, and parts of this article were written, when MBR and M. Nielsen were visiting the Institute for Theoretical Physics at the University of California, Santa Barbara, and thereby also partly supported by the National Science Foundation under Grant No. PHY-9907949. The author is extremely grateful to C. King for careful readings of earlier versions of the manuscript leading to many useful comments, and for communicating (and allowing to be included) several critical observations needed to obtain the equality conditions for the Holevo bound in Sec. VII. It is also a pleasure to thank C. Fuchs for explaining the history of the equality conditions in the Holevo bound, E. Lieb for clarifying remarks about Bauman's responsibility for the actual conjecture of the concavity of the WYD function, D. Petz for discussions about his approach, P. Shor for asking a question which stimulated the analysis in Sec. VII D, and M. J. W. Hall for bringing Ref. 13 to the author's attention.

APPENDIX: EPSTEIN'S PROOF OF CONCAVITY OF $A \to \mathrm{Tr}\, e^{K+\log A}$

Let $f(x) = \mathrm{Tr}\, e^{K+\log(A+xB)}$ with $A > 0$ strictly positive and K, B self-adjoint. For sufficiently small x, the function $f(x)$ is well-defined and the concavity of $F(A)$ in Theorem 2 follows immediately if $f''(0) < 0$ for all choices of $B = B^*$.

Instead of dealing with f directly, Epstein considered the function $g(x)=xf(x^{-1})$ which is well-defined for $|x|>\mu^{-1}\equiv\|A^{-1}\|\|B\|$ and can be analytically continued to the upper half plane so that

$$g(z)=\mathrm{Tr}\ \ e^{K+\log(zA+B)}. \tag{A1}$$

There are a number of equivalent (when meaningful) ways of defining functions of matrices. For the purposes needed here it is natural to assume that the spectrum $\sigma(A)$ of the operator A is contained in the domain of an analytic function $F(z)$ and that

$$F(A)=\frac{1}{2\pi i}\oint\frac{F(z)}{zI-A}dz. \tag{A2}$$

One can then use the spectral mapping theorem $\sigma[F(A)]\subset F[\sigma(A)]$ for an appropriate sequence of functions to verify that

$$\begin{aligned}
&\Im z>0 \Rightarrow \Im\ \omega(zA+B) > 0\\
&\Rightarrow\ \pi > \Im\ \omega[\log(zA+B)] > 0\\
&\Rightarrow\ \pi > \Im\ \omega[K+\log(zA+B)] > 0\\
&\Rightarrow \Im\ \omega[e^{K+\log(zA+B)}] > 0\\
&\Rightarrow \Im\ \mathrm{Tr}\ \ e^{K+\log(zA+B)} > 0,
\end{aligned}$$

where $\Im$ denotes the imaginary part of a complex number and ω is used to denote an arbitrary element of the spectrum of the indicated operator. Thus, $g(z)$ maps the upper half plane into the upper half plane. Functions with this property have been studied extensively under various names, including, ''operator monotone,'' ''Herglotz'' or ''Pick.'' (See, for example, Refs. 3, 10 and 33.) It then follows that g has an integral representation of the form

$$g(z)=a+bz+\int_{-\mu}^{\mu}\frac{1}{t-z}dm(t) \tag{A3}$$

for some positive measure $\mu(t)$. This yields (via the change of variables $s=t^{-1}$)

$$f(x)=ax+b+\int_{-\mu}^{\mu}\frac{x^2}{tx-1}dm(t). \tag{A4}$$

Differentiation under the integral sign can then be used to establish that $f''(0)<0$ as desired by observing $x^2/(tx-1)=t^{-2}[(xt+1)+(xt-1)^{-1}]$. Q.E.D.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Quantum operations that cannot be implemented using a small mixed environment

Christof Zalka[a)]

(Received 18 October 2001; accepted for publication 16 May 2002)

To implement any quantum operation (a.k.a. ''superoperator'' or ''CP map'') on a d-dimensional quantum system, it is enough to apply a suitable overall unitary transformation to the system and a d^2-dimensional environment which is initialized in a fixed pure state. It has been suggested that a d-dimensional environment might be enough if we could initialize the environment in a mixed state of our choosing. In this note we show with elementary means that certain explicit quantum operations cannot be realized in this way. Our counterexamples map some pure states to pure states, giving strong and easily manageable conditions on the overall unitary transformation. Everything works in the more general setting of quantum operations from d-dimensional to d'-dimensional spaces, so we place our counterexamples within this more general framework. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1499763]

I. QUANTUM OPERATIONS

Quantum operations (see, e.g., Schumacher, 1996) are also known as ''superoperators,'' ''superscattering operators'' or ''completely positive maps'' (''CP maps''). They can be viewed as a generalization of unitary transformations and are the most general transformations that can be applied to a quantum system in an unknown (possibly mixed) state. More precisely, quantum operations are the most general transformations that can be implemented deterministically, thus excluding operations which only succeed with a certain probability, like those depending on a measurement outcome. Under a quantum operation pure states are frequently mapped to mixed states.

All quantum operations on a d-dimensional system can be implemented as the partial trace of a unitary operator acting on the system together with an auxiliary system (the ''environment''). The question is how small an environment suffices to implement all possible quantum operations on a d-dimensional system. The answer is easy, and has long been known, for the case in which the environment is initialized in a pure state. The answer is more interesting when the environment can be initialized in a mixed state.

II. INITIALIZING THE ENVIRONMENT IN A PURE STATE

The environment is initialized in a standard pure state (let's call it $|0\rangle$). We apply an overall unitary transformation to the system plus environment (which typically involves interaction between the two). Finally, we are only interested in the (now generally mixed) state of the system alone, thus we ''trace over'' the environment. Decoherence is a typical example of such a process. It is easy to see that quantum operations act linearly on density matrices.

a)Electronic mail: zalka@cacr.math.uwaterloo.ca
b)Electronic mail: rieffel@pal.xerox.com

We will think of quantum operations as given in the above way, as overall unitary transformations on a system together with an environment. For example, a quantum operation on a single-qubit system can be given by the action of an overall unitary transformation on basis vectors for the space consisting of the system together with the environment. As the environment starts out in the state $|0\rangle$, we need only to give the images of the vectors $|i\rangle|0\rangle$ (where the first vector corresponds to the system and the second to the environment):

$$|0\rangle|0\rangle \rightarrow |0\rangle|\psi_{00}\rangle + |1\rangle|\psi_{01}\rangle,$$

$$|1\rangle|0\rangle \rightarrow |0\rangle|\psi_{10}\rangle + |1\rangle|\psi_{11}\rangle,$$

where the environment vectors $|\psi_{ij}\rangle$ have to be such that the two right-hand sides are orthonormal.

The action of the quantum operation on (density) operators is obtained by first lifting the above overall unitary transformation to the level of density operators and then tracing over the environment (using $tr|\varphi\rangle\langle\psi| = \langle\psi|\varphi\rangle$). Thus

$$|i\rangle|0\rangle\langle 0|\langle i'| \overset{U}{\rightarrow} \sum_{jj'} |j\rangle|\psi_{ij}\rangle\langle\psi_{i'j'}|\langle j'| \overset{tr_{env}}{\rightarrow} \sum_{jj'} |j\rangle\langle j'|\langle\psi_{i'j'}|\psi_{ij}\rangle.$$

Since only the inner product of the $|\psi_{ij}\rangle$ matter, we may assume that $|0\rangle = |\psi_{00}\rangle$. Thus we see that any quantum operation on a single-qubit system can be implemented with a four-dimensional environment, as the $|\psi_{ij}\rangle$ span at most a four-dimensional space. For a d-dimensional system we have d^2 environment vectors $|\psi_{ij}\rangle$, so an environment of that dimension will always do. It is also not hard to show that in this setting some quantum operations really need an environment of this size.

A. Initializing the environment in a mixed state

While it does not matter in which pure state we initialize the environment, initializing in a mixed state rather than a pure state does matter. A mixed state is not unitarily equivalent to a pure state, rather the unitary equivalence is characterized by the eigenvalues p_i of the density matrix of the state. The question at hand is whether we could implement any quantum operation with an environment smaller than d^2 if, for each map we want to implement, we are allowed to initialize the environment in a mixed state of our choosing.

Without loss of generality we can assume the initial state of the environment to be of the form $\rho_{\text{env,initial}} = \Sigma_i p_i |i\rangle\langle i|$. Because the environment now is smaller, the overall unitary transformation has fewer parameters, but more of them matter; it is no longer sufficient to know only the action on the subspace in which the environment is in state $|0\rangle$.

A parameter count (including the choice of the p_i) suggests that an environment of the same dimension as the system might just be enough to implement any quantum operation were we allowed to choose the initial mixed state of the environment, thus the conjecture in Lloyd (1996 [see Eq. (2)]). We give a more general version of the parameter count in Sec. II B 1.

It has been shown (Terhal, 1999) for the qubit case ($d=2$) that this conjecture is not true; there are quantum operations which cannot be implemented with a mixed single-qubit environment. The proof in Terhal (1999) was rather "brute force," as it used computer algebra to show that a system of equations does not have a solution. Here we give a simple proof using only elementary means that also generalizes to arbitrary dimensions.

Thus we show the following: There are quantum operations on a d-dimensional system which cannot be implemented using an environment which is only of the same dimension. In particular, this statement remains true even if we can initialize the environment in a mixed state of our choosing.

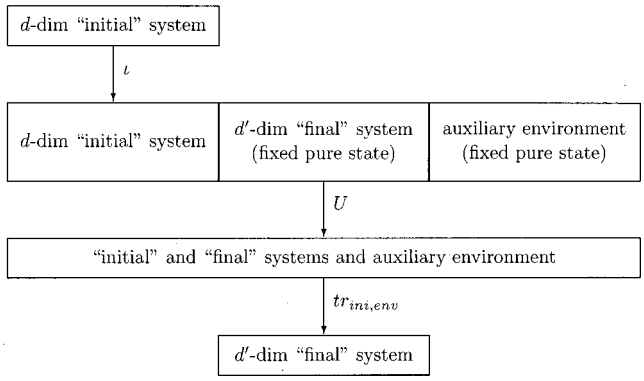

FIG. 1. Map from d-dimensional "initial" system to d'-dimensional "final" system induced by unitary transformation U acting on the two systems and an auxiliary environment. The "final" system and the auxiliary environment are initialized in fixed pure states.

B. General framework

In general we consider maps between systems of (possibly) different dimensions d and d'. We embed the "initial" d-dimensional system in a larger system, apply a unitary operator, and then take the partial trace over everything except the d'-dimensional "final" system. Thus physically we start with a system in some (generally mixed) state and end with a different system in some state. Note that the dimension can increase or decrease.

When the larger system contains a d'-dimensional system and an auxiliary environment initialized in pure states (see Fig. 1), the same argument as in Sec. II shows that besides the d-dimensional initial system and the d'-dimensional final system, a d-dimensional environment is enough (and in general necessary) to realize general quantum operations between the two systems.

Were we to initialize the "final" system in a mixed state, a parameter count (misleadingly) suggests that the d-dimensional auxiliary environment could simply be left away. We place our counterexamples in this general framework of maps from a d-dimensional "initial" system to a d'-dimensional final (or "target") system initialized in a mixed state of our choosing. An overall unitary transformation is applied to the initial plus final system, and, then, as we are only interested in the state of the final system, we "trace over" the initial one. (See Fig. 2.)

Note that the question we were initially interested in, of whether a d-dimensional environment that can be initialized in a mixed state is sufficient to implement any quantum operation on a d-dimensional system, can be answered in this general framework by looking at initial and final systems of the same dimension d and then swapping them at the end.

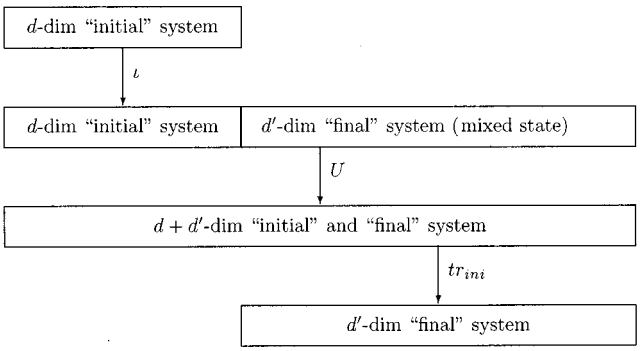

FIG. 2. General framework: map from d-dimensional "initial" system to d'-dimensional "final" system induced by unitary transformation U. The "final" system is initialized in a mixed state.

1. A sketch of the parameter count

Here is a sketch of the parameter count that leads to the wrong conjecture. The d'-dimensional mixed state in the standard form is given by $d'-1$ (real) parameters. Note that it is invariant under diagonal (special) unitary transformations (''rephasings''). The overall (special) unitary transformation has $d^2d'^2-1$ parameters. Finally, we have to take into account that after this overall transformation, a (special) unitary transformation just on the initial system alone does not matter. In the end we get $(d'-1)-(d'-1)+(d^2d'^2-1)-(d^2-1)=d^2(d'^2-1)$ real parameters, which is the correct number for a quantum operation $d\to d'$.

III. THE COUNTEREXAMPLE

A. The basic idea

We explain the basic idea behind the counterexamples in the simple setting of a map from a d-dimensional system to itself induced by a unitary map on the system together with a d'-dimensional environment. Imagine we initialize the d'-dimensional environment in a mixed state, say $\rho_{\text{ini}}=p|0\rangle\langle 0|+(1-p)|1\rangle\langle 1|$. The resulting map (quantum operation) will be a probabilistic mixture (convex linear combination) of the two ''pure-environment'' maps we would get by initializing the environment either in state $|0\rangle$ or $|1\rangle$. A convex linear combination of quantum operations is defined through the convex linear combination of the density matrices to which they map. Also note that given one of these maps, the other has to fulfill certain conditions because they come from the same overall unitary transformation.

The main idea of our counterexample is as follows: A pure state cannot be written as a nontrivial mixture of two pure states. This gives us strong restrictions on maps that take certain pure system states to pure states. For example, consider a quantum operation that maps $|0\rangle \to|0\rangle$. Then any ''pure-environment'' maps that make up part of a convex linear combination that gives this map must also map $|0\rangle$ to $|0\rangle$.

B. The counterexample

As announced, we use the general framework of a quantum operation from an ''initial'' d-dimensional system to a ''final'' d'-dimensional system (Fig. 2). We will mark vectors in the final system with a prime: $|\ldots\rangle'$.

In our counterexample, we require that all but one of the initial system basis states go to one pure state, say $|0\rangle'$,

$$|i\rangle\langle i|\to|0\rangle'\langle 0|', \quad i=0,\ldots,d-2.$$

Before further specifying the counterexample, let us look at the consequences of this condition. If the target system has been initialized in a (truly, thus nonpure) mixed state, say $\rho'_{\text{ini}}=p|0\rangle'\langle 0|' +(1-p)|1\rangle'\langle 1|'$ with $0<p<1$, we get for the overall unitary transformation

$$|i\rangle|0\rangle'\to|\psi_i\rangle|0\rangle' \quad \text{and} \quad |i\rangle|1\rangle'\to|\xi_i\rangle|0\rangle', \quad i=0,\ldots,d-2.$$

All $2(d-1)$ states on the right-hand side have to be orthonormal, thus the $|\psi_i\rangle$ and $|\xi_i\rangle$ have to be orthonormal. But for $d>2$ their number exceeds the dimension of the system. It is clear that were we to initialize the final system in a mixed state of rank >2, things would only be worse. It follows that the final system cannot start out in a mixed state, thus we assume it is initialized in the pure state $|0\rangle'$. (We treat the special case $d=2$ below.)

Without loss of generality we set $|\psi_i\rangle=|i\rangle$. We have $|i\rangle|0\rangle'\to|i\rangle|0\rangle'$ for $i=0,\ldots,d-2$. The image of the remaining basis state $|d-1\rangle$ can be written

$$|d-1\rangle|0\rangle'\to\sum_{i=0}^{d-1}|i\rangle|\varphi_i\rangle'.$$

Now we require that the image of $|d-1\rangle$ be a truly mixed state ρ'_{d-1}. Furthermore, we require that under the quantum operation, $|d-1\rangle$ should "totally decohere" from the other basis states $|i\rangle$, meaning that a superposition should go to a mixture of the individual images of the states, so $(\alpha|i\rangle+\beta|d-1\rangle)(\overline{\alpha}\langle i|+\overline{\beta}\langle d-1|)\rightarrow|\alpha|^2|0\rangle'\langle 0|'+|\beta|^2\rho'_{d-1}$ $(i=0,\ldots,d-2)$. But the "totally decohere" condition means that $|\varphi_i\rangle'=0$ for all $i\neq d-1$, from which it follows that the image of $|d-1\rangle$ would have to be pure after all.

C. The special case $d\rightarrow d'$ with $d=2$

For $d=2$ we still have to consider the case in which the final system is initialized in a mixed state, although from above it is clear that it would have to be a mixed state of rank 2, thus a mixture of just two different pure states. Thus $\rho'_{\mathrm{ini}}=p|0\rangle'\langle 0|'+(1-p)|1\rangle'\langle 1|'$ with $0<p<1$. Then we have for the overall unitary transformation

$$|0\rangle|0\rangle'\rightarrow|0\rangle|0\rangle' \quad \text{and} \quad |0\rangle|1\rangle'\rightarrow|1\rangle|0\rangle'.$$

It follows that $|1\rangle|0\rangle'\rightarrow\alpha|0\rangle|0^{\perp}\rangle'+\beta|1\rangle|0'^{\perp}\rangle'$ where both $|0^{\perp}\rangle'$ and $|0'^{\perp}\rangle'$ are vectors orthogonal to $|0\rangle'$ and similarly for the image of $|1\rangle|1\rangle'$. We can now make our counterexample above work also for $d=2$ by additionally requiring that the (truly mixed) image of $|d-1\rangle$ have some overlap with $|0\rangle'$, thus we require that

$$\langle 0|'\rho'_{d-1}|0\rangle'\neq 0.$$

D. Summary of the counterexample

In summary we give the counterexample map by its action on pure states:

$$\left(\sum_{i=0}^{d-2}\alpha_i|i\rangle+\beta|d-1\rangle\right)\left(\sum_{i=0}^{d-2}\overline{\alpha_i}\langle i|+\overline{\beta}\langle d-1|\right)\rightarrow\left(\sum_{i=0}^{d-2}|\alpha_i|^2\right)|0\rangle'\langle 0|'+|\beta|^2\rho'_{d-1},$$

where ρ'_{d-1} is not a pure state. For $d=2$ we must additionally require that $\langle 0|'\rho'_{d-1}|0\rangle'\neq 0$. (Actually for $d'=2$ this is always true.)

E. The counterexample is a quantum operation

Finally we show that the counterexample is a possible quantum operation, thus that with a large enough environment it can be implemented. So besides the initial and final systems we also have an environment. The map is simple, but for completeness we show it. The following overall unitary transformation implements the counterexample map (including the additional property required for the case $d=2$), with $\alpha,\beta\neq 0$:

$$|i\rangle|0\rangle'|0\rangle_{\mathrm{env}}\rightarrow|i\rangle|0\rangle'|0\rangle_{\mathrm{env}}, \quad i=0,\ldots,d-2,$$

$$|d-1\rangle|0\rangle'|0\rangle_{\mathrm{env}}\rightarrow\alpha|d-1\rangle|0\rangle'|0\rangle_{\mathrm{env}}+\beta|d-1\rangle|1\rangle'|1\rangle_{\mathrm{env}}.$$

IV. FURTHER REMARKS

A. How many counterexamples are there?

Once a single counterexample has been found, basic topological properties of the (convex) set of all quantum operations and the (also convex) subset of those that can be realized with a d-dimensional (possibly) mixed environment imply that the set of counterexamples contains balls and thus is a set of nonzero measure. All that is needed is that the subset of maps that can be realized with a d-dimensional mixed environment is closed, and that the "outer" set is a regular

set, thus it is a closure of its inner points. The latter is simply because the set of all quantum operations is a ''closed voluminous'' convex set, thus one which does not happen to lie in some hyperplane.

Note that our counterexample lies on the boundary of the set of quantum operations, so we must take the intersection of a ball around it with the set of quantum operations to find inner points of the set of counterexamples. Around these points there will then be balls of counterexamples.

Also note that the counterexample given in Terhal (1999), for the single-qubit case ($d=2$), is unital and thus very different from ours.

A complete characterization of exactly which maps can be realized with a d-dimensional mixed environment and which cannot has yet to be found even in the single-qubit case. Ruskai (2001) gives a parameterization of the space of all quantum operations for the single-qubit space that might be useful here.

B. How big an environment is necessary?

From the counterexamples for $d>2$ we can see that more could be said about how large a mixed environment has to be, but we have not investigated further.

C. Implications for simulating quantum operations (?)

It looks like our subject is mostly a mathematical challenge. In Terhal (1999) it was said that one may want to simulate quantum operations (e.g., on a quantum computer) with as few resources as possible (see also Bacon, 2001). But Choi (1975) shows that every extremal map of the convex set of quantum operations can be realized with a d-dimensional environment initialized in a pure state. To achieve any mixture of such extremal maps (and thus any map) one can simply carry out each of them with a certain probability, using a probabilistic protocol. On the other hand, certain extremal maps do need an environment of dimension d, thus this probably is a necessary resource.

D. What about ''Markovian'' quantum operations?

By ''Markovian'' quantum operations we mean those quantum operations that can be ''generated'' from ones that are infinitesimally close to the identity. Of course this notion makes sense only for dimension preserving quantum operations. It is known that not all quantum operations can be generated in this way, so we may wonder whether all those maps could be implemented with a ''small'' mixed environment.

A lower bound on the quantum capacity of channels with correlated errors

Mitsuru Hamada[a)]

(Received 15 January 2002; accepted for publication 16 May 2002)

The highest fidelity of quantum error-correcting codes of length n and rate R is proven to be lower bounded by $1-\exp[-nE(R)+o(n)]$ for some function $E(R)$ on noisy quantum channels that are subject to not necessarily independent errors. The $E(R)$ is positive below some threshold R_0, which implies R_0 is a lower bound on the quantum capacity. This work is an extension of the author's previous works [M. Hamada, Phys. Rev. A, **65**, 052305 (2002); quant-ph/0109114, LANL (2001); M. Hamada, quant-ph/0112103, LANL (2001)], which presented the bound for channels subject to independent errors, or channels modeled as tensor products of copies of a completely positive linear map. The relation of the channel class treated in this article to those in the previous works is similar to that of Markov chains to sequences of independent identically distributed random variables. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1495537]

I. INTRODUCTION

Quantum error-correcting codes (simply called quantum codes or *codes* in this work) were discovered by Shor[1] and Steane[2] as schemes that protect quantum states from decoherence during quantum computation. Shor[1] not only gave the first quantum code but also posed a problem of determining the quantum analog of Shannon's channel capacity. In classical information theory, channels with independent errors are called memoryless channels and channels with correlated errors are called channels with memory,[3] which will be applied to quantum channels as well in the present work. On quantum memoryless channels, several bounds on the quantum capacity have been known,[1,4–7] and also exponential convergence of fidelity of codes was recently proved by the present author.[8,9] It is natural to ask whether such bounds and exponential convergence hold true or not on channels with memory, which will be answered affirmatively in this work.

While one of the greatest incentives to investigate quantum codes is need in quantum computing, we are not sure which devices to use for this purpose currently. Hence, we do not know which channel models are appropriate, so that treating general channels may be among what we can proceed to now. Thus, this article analyzes the code performance on a class of quantum channels that is much wider than was treated in the literature.

In the proof of the main result below, the method of types, which is a powerful tool from classical information theory, plays an important role.[10,11] This method was exploited by the Hungarian mathematician (information theorist) Csiszár and co-workers around 1980 to present the strongest coding theorems such as the one showing the existence of universal channel codes asymptotically as good as any codes.[10,11] It has often produced results in elementary enumerative manners, which is also the case in this article.

II. MAIN RESULT FOR SIMPLE CASE

As usual, all quantum channels and decoding (state-recovery) operations in coding systems are described in terms of *trace-preserving completely positive* (TPCP) linear maps.[4,7,12–14] Given

a)Electronic mail: mitsuru@ieee.org

a Hilbert space H of finite dimension, let $\mathsf{L}(\mathsf{H})$ denote the set of linear operators on H. In general, every CP linear map $\mathcal{M}:\mathsf{L}(\mathsf{H})\to\mathsf{L}(\mathsf{H})$ has an operator-sum representation $\mathcal{M}(\rho)=\Sigma_{i\in\mathcal{I}}M_i\rho M_i^\dagger$ for some $M_i\in\mathsf{L}(\mathsf{H})$, $i\in\mathcal{I}$.[4,12–14] When $\mathcal{M}$ is specified by a set of operators $\{M_i\}_{i\in\mathcal{I}}$ in this way, we write $\mathcal{M}\sim\{M_i\}_{i\in\mathcal{I}}$.

Hereafter, H denotes an arbitrarily fixed Hilbert space of dimension d, which is a prime number. A quantum channel is a sequence of TPCP linear maps $\{\mathcal{A}_n:\mathsf{L}(\mathsf{H}^{\otimes n})\to\mathsf{L}(\mathsf{H}^{\otimes n})\}$. We want a large subspace $\mathcal{C}_n\subseteq\mathsf{H}^{\otimes n}$, every state vector in which remains almost unchanged after the effect of a channel followed by some suitable recovery operation $\mathcal{R}_n:\mathsf{L}(\mathsf{H}^{\otimes n})\to\mathsf{L}(\mathsf{H}^{\otimes n})$. A pair $(\mathcal{C}_n,\mathcal{R}_n)$ consisting of such a subspace $\mathcal{C}_n$ and a TPCP map $\mathcal{R}_n$ is called a *code* and its performance is evaluated in terms of minimum fidelity[6,7,15]

$$F(\mathcal{C}_n,\mathcal{R}_n\mathcal{A}_n)=\min_{|\psi\rangle\in\mathcal{C}_n}\langle\psi|\mathcal{R}_n\mathcal{A}_n(|\psi\rangle\langle\psi|)|\psi\rangle,$$

where $\mathcal{R}_n\mathcal{A}_n$ denotes the composition of $\mathcal{A}_n$ and $\mathcal{R}_n$. Throughout, bras $\langle\cdot|$ and kets $|\cdot\rangle$ are assumed normalized. A subspace $\mathcal{C}_n$ alone is also called a code assuming implicitly some recovery operator.

Let $F^\star_{n,k}(\mathcal{A}_n)$ denote the supremum of $F(\mathcal{C}_n,\mathcal{R}_n\mathcal{A}_n)$ such that there exists a code $(\mathcal{C}_n,\mathcal{R}_n)$ with $\log_d\dim\mathcal{C}_n\geqslant k$, where n is a positive integer and k is a non-negative real number. Our goal is to estimate $F^\star_{n,k}(\mathcal{A}_n)$ as precisely as possible.

First, we state the main result for an easy case, and give a more general statement later. Fix an orthonormal basis $\{|0\rangle,\ldots,|d-1\rangle\}$ of H. Put $\mathcal{X}=\{0,\ldots,d-1\}^2$ and $N_{(i,j)}=X^iZ^j$ for $(i,j)\in\mathcal{X}$. Here, $X,Z\in\mathsf{L}(\mathsf{H})$ are Weyl's unitaries, which could be viewed as generalized Pauli operators, and are defined by

$$X|j\rangle=|(j-1)\mod d\rangle,\quad Z|j\rangle=\omega^j|j\rangle,\tag{1}$$

where ω is a primitive dth root of unity.[16–20] From the $\mathsf{L}(\mathsf{H})$ basis $\{N_{(i,j)}\}$, we obtain a basis $\mathsf{N}_n=\{N_x|x\in\mathcal{X}^n\}$ of $\mathsf{L}(\mathsf{H}^{\otimes n})$, where $N_x=N_{x_1}\otimes\cdots\otimes N_{x_n}$ for $x=(x_1,\ldots,x_n)\in\mathcal{X}^n$. The first channel class to be considered here consists of those $\{\mathcal{A}_n\}$ such that $\mathcal{A}_n\sim\{\sqrt{P_n(x)}N_x\}_{x\in\mathcal{X}^n}$, where we assume that P_n are the probability distributions of a (first-order) homogeneous Markov chain, i.e., that P_n has the form

$$P_n(x_1,\ldots,x_n)=p(x_1)\prod_{j=1}^{n-1}P(x_{j+1}|x_j)\tag{2}$$

with some transition probabilities $P(v|u)$, $u,v\in\mathcal{X}$, and some initial distribution p. These are generalizations of the so-called depolarizing channel;[5,6] see Ref. 21 for a thorough analysis of memoryless channels with $d=2$.

Given a probability distribution Q on $\mathcal{X}^2$, we let $\overline{Q}$ and $\bar{\bar{Q}}$ denote the two marginal distributions:

$$\overline{Q}(u)=\sum_{v\in\mathcal{X}}Q(u,v),\quad \bar{\bar{Q}}(u)=\sum_{v\in\mathcal{X}}Q(v,u),\quad u\in\mathcal{X}.$$

The classical (conditional) Kullback–Leibler information (informational divergence or relative entropy) is denoted by D and entropy by H.[10,11,22] Specifically, for a probability distribution Q on $\mathcal{X}^2$, transition (or conditional) probabilities $P(v|u)$, $u,v\in\mathcal{X}$, and a probability distribution p on $\mathcal{X}$, we define $\tilde{Q}(\cdot|\cdot)$ by $\tilde{Q}(v|u)=Q(u,v)/\overline{Q}(u)$ for $\overline{Q}(u)>0$, $D(Q\|P)$ by

$$D(Q\|P)=\sum_{u\in\mathcal{X}:Q(u)>0}\sum_{v\in\mathcal{X}}Q(u,v)\log_d\frac{\tilde{Q}(v|u)}{P(v|u)},$$

and $H(P|p)$ by

$$H(P|p)=-\sum_{u\in\mathcal{X}:\ p(u)>0}\ \sum_{v\in\mathcal{X}} p(u)P(v|u)\log_d P(v|u),$$

which is called the entropy of $P(\cdot|\cdot)$ conditional on p. We remark that $D(Q\|P)$ is a conditional Kullback–Leibler information, so that in a more consistent notation,[10] it would be denoted by $D(\tilde{Q}\|P|\overline{Q})$.

By convention, we assume $\log(a/0)=\infty$ for $a>0$, $0\log 0=0\log(0/0)=0$. The first form of this work's main result is the next one.

Theorem 1: *Let a channel* $\mathcal{A}_n\sim\{\sqrt{P_n(x)}N_x\}_{x\in\mathcal{X}^n}$, $n=1,2,\ldots$, *be specified by (2) with some* $P(\cdot|\cdot)$ *and* p. *Then, for* $0\leqslant R\leqslant 1$, *we have*

$$\liminf_{n\to\infty}-\frac{1}{n}\log_d[1-F^{\star}_{n,Rn}(\mathcal{A}_n)]\geqslant E(R,P), \tag{3}$$

where

$$E(R,P)=\min_{Q:\overline{Q}=\bar{\bar{Q}}}[D(Q\|P)+|1-H(\tilde{Q}|\overline{Q})-R|^{+}],$$

$|x|^{+}=\max\{x,0\}$, *and the minimization with respect to* Q *is taken over all probability distributions on* $\mathcal{X}^2$ *with* $\overline{Q}=\bar{\tilde{Q}}$.

Remarks: Roughly speaking, the theorem says $F^{\star}_{n,Rn}(\mathcal{A}_n)\overset{>}{\approx}1-\exp_d[-nE(R,P)]$. An immediate consequence of the theorem is that when the Markov chain is irreducible, the quantum capacity[1,4–7] of $\{\mathcal{A}_n\}$ is lower bounded by $1-H(P|q)$, where q is the unique stationary (steady state, or equilibrium) distribution of the Markov chain.[23] To see this, observe that $E(R,P)$ is positive for $R<1-H(P|q)$ due to an easily established inequality $D(Q\|P)\geqslant 0$ where equality occurs if and only if $Q(u,v)=q(u)P(v|u)$ for all $u,v\in\mathcal{X}$ under the constraint $\overline{Q}=\bar{\tilde{Q}}$.

Example: Let us assume $d=2$, rename the elements (0,0),(1,0),(0,1),(1,1) in $\mathcal{X}$ as $\underline{0}$, $\underline{1}$, $\underline{2}$, $\underline{3}$, and define $P(v|u)$, $u,v\in\mathcal{X}$, by

$$P(v|u)=\begin{cases}1-\varepsilon & \text{if } u=\underline{0} \text{ and } v=\underline{0},\\ \varepsilon/3 & \text{if } u=\underline{0} \text{ and } v\neq\underline{0},\\ 1-\gamma & \text{if } u\neq\underline{0} \text{ and } v=\underline{0},\\ \gamma/3 & \text{if } u\neq\underline{0} \text{ and } v\neq\underline{0}.\end{cases}$$

In this case, $\{A_n\}$ is analogous to the channel with memory discussed by Gilbert[24] in the context of classical channel coding (see also Ref. 3, Sec. 4.6). If we brought Gilbert's idea into our quantum case innocently, we might assume $0<\varepsilon\leqslant\gamma<1$ and interpret $\underline{0}$ as "good state," $\underline{1}$, $\underline{2}$, $\underline{3}$ as "bad ones," where a state means that of the Markov chain, not a quantum state, and ε (resp., γ) as the probability of going into a "bad state" provided the current state be "good (resp., bad)." For the above quantum channel, the lower bound $1-H(P|q)$ becomes

$$1-\frac{(1-\gamma)[h(\varepsilon)+\varepsilon\log_2 3]+\varepsilon[h(\gamma)+\gamma\log_2 3]}{1-\gamma+\varepsilon},$$

where h is the binary entropy function $h(z)=-z\log_2 z-(1-z)\log_2(1-z)$. Note that when $\varepsilon=\gamma$, the channel becomes the depolarizing channel and the lower bound on the capacity becomes the known one.[5,8]

III. PROOF OF THEOREM 1

A. Codes based on symplectic geometry

The codes to be proven to have the desired performance are *symplectic (stabilizer, or additive) codes*.[25–27] Let us recall first the basics of symplectic codes. We can regard the index of $N_{(i,j)} = X^i Z^j$, $(i,j) \in \mathcal{X}$, as a pair of elements from the field $\mathsf{F} = \mathbb{F}_d = \mathbb{Z}/d\mathbb{Z}$, the finite field consisting of d elements. Recall we put $N_x = N_{x_1} \otimes \cdots \otimes N_{x_n}$ for $x = (x_1, \ldots, x_n) \in (\mathsf{F}^2)^n$. We write N_J for $\{N_x \in \mathsf{N}_n | x \in J\}$ where $J \subseteq (\mathsf{F}^2)^n$. The index $((u_1, v_1), \ldots, (u_n, v_n)) \in (\mathsf{F}^2)^n$ of a basis element can be regarded as the plain $2n$-dimensional vector

$$x = (u_1, v_1, \ldots, u_n, v_n) \in \mathsf{F}^{2n}.$$

We can equip the vector space F^{2n} over F with a *symplectic bilinear form* (symplectic paring), which is defined by

$$(x,y)_{\mathrm{sp}} = \sum_{i=1}^{n} u_i v_i' - v_i u_i'$$

for the above x and $y = (u_1', v_1', \ldots, u_n', v_n') \in \mathsf{F}^{2n}$.[28–30] Given a subspace $L \subseteq \mathsf{F}^{2n}$, let

$$L^{\perp} = \{x \in \mathsf{F}^{2n} | \forall y \in L, \quad (x,y)_{\mathrm{sp}} = 0\}.$$

Lemma 1:[25,27] *Let a subspace $L \subseteq \mathsf{F}^{2n}$ satisfy*

$$L \subseteq L^{\perp} \quad \textit{and} \quad \dim\ L = n - k.$$

In addition, let $J_0 \subseteq \mathsf{F}^{2n}$ be a set satisfying

$$\forall x, y \in J_0, \quad [y - x \in L^{\perp} \Rightarrow x = y]. \tag{4}$$

Then, there exist d^k-dimensional N_{J_0}-correcting codes.

In fact, given a subspace L as above, there are d^k subspaces of the form

$$\{\psi \in \mathsf{H}^{\otimes n} | \forall M \in N_L, M\psi = \tau(M)\psi\},$$

with some scalars $\tau(M)$ (eigenvalues of $M \in N_L$), and each of them, together with a suitable recovery operator, serves as an N_{J_0}-correcting quantum code of dimension d^k. Note that the direct sum of these subspaces is the whole space $\mathsf{H}^{\otimes n}$. The precise meaning of N_{J_0}-correcting can be found, e.g., in Ref. 15. Originally, Lemma 1 was claimed for the case where $d = 2$, and has been generalized to the case where d is a general prime.[18–20,31]

By definition, for an N_{J_0}-correcting code $(\mathcal{C}_n, \mathcal{R}_n)$ and the channel $\{\mathcal{A}_n\}$ in the theorem, it holds

$$1 - F(\mathcal{C}) \leqslant \sum_{x \notin J_0} P_n(x), \tag{5}$$

where $F(\mathcal{C}) = F(\mathcal{C}, \mathcal{R}_n \mathcal{A}_n)$. We remark that, as is usually done in the literature, it is assumed in this article that when we speak of an N_{J_0}-correcting code $(\mathcal{C}_n, \mathcal{R}_n)$, the $\mathcal{R}_n$ indicates the one constructed by Knill and Laflamme.[15] Note that $\mathcal{R}_n$ is determined from J_0 and $\mathcal{C}$. The premise (4) of Lemma 1 is restated as that J_0 is a set of representatives of cosets of $L^{\perp}$ in F^{2n}. A natural choice for J_0 would be a set consisting of representatives each of which maximizes the probability $P_n(x)$ in its coset[27] since it is analogous to maximum likelihood decoding, which is an optimum strategy for classical coding (see Ref. 32 or any textbook of information theory). In the proof below, we

choose another set of representatives, the classical counterpart of which (minimum entropy decoding) asymptotically yields the same performance as maximum likelihood decoding.[10,33]

B. The method of types

The theorem can be proved along the lines of Ref. 8, which employed the method of types.[10,11,22,33] In the present case, second-order (Markov) types rather than the usual types are used. Needed technical tools from the method of types in the Markov case can be found in Ref. 22 and papers cited therein. We collect here a few basic facts on this method to be used below.

For $x=(x_1,\ldots,x_n)\in\mathcal{X}^n$, $n>1$, define a probability distribution M_x on $\mathcal{X}^2$ by

$$\mathsf{M}_x(u,v)=\frac{|\{i|1\leqslant i\leqslant n-1,(x_i,x_{i+1})=(u,v)\}|}{n-1},\quad u\in\mathcal{X},$$

which is called the second-order *type* or Markov type of x. With $\mathcal{X}$ and an element $u\in\mathcal{X}$ fixed, the set of all possible Markov types of sequences $(x_1,\ldots,x_n)$ from $\mathcal{X}^n$ satisfying $x_1=u$ is denoted by $\mathcal{Q}_n(\mathcal{X},u)$ or simply by $\mathcal{Q}_n(u)$, and $\mathcal{Q}_n$ stands for $\cup_{u\in\mathcal{X}}\mathcal{Q}_n(u)$. For a type $Q\in\mathcal{Q}_n(u)$, $\mathcal{T}_Q^n(u)$ is defined as $\{(x_1,\ldots,x_n)\in\mathcal{X}^n|x_1=u \text{ and } \mathsf{M}_x=Q\}$, and $\mathcal{T}_Q^n$ denotes $\cup_{u\in\mathcal{X}}\mathcal{T}_Q^n(u)$.

In what follows, we use

$$|\mathcal{T}_Q^n(u)|\leqslant\exp_d[(n-1)H(\tilde{Q}|\overline{Q})],\quad u\in\mathcal{X}. \tag{6}$$

Note that if $x=(x_1,\ldots,x_n)\in\mathcal{X}^n$ with $x_1=u$ has type Q, then $P_n(x)=p(u)\Pi_{(a,b)\in\mathcal{X}^2}P(b|a)^{(n-1)Q(a,b)}=p(u)\exp_d\{-(n-1)[H(\tilde{Q}|\overline{Q})+D(Q\|P)]\}$ and, hence, (6) is equivalent to the latter inequality in (39) of Ref. 22, i.e.,

$$\Pr\{\mathsf{M}_{\mathbf{X}}=Q|\mathbf{X}_1=u\}\leqslant\exp_d\{-(n-1)D(Q\|P)\}, \tag{7}$$

where the sequence of random variables $\mathbf{X}=(\mathbf{X}_1,\ldots,\mathbf{X}_n)$ represents the Markov chain in the theorem, i.e., $\Pr\{\mathbf{X}_1=x_1,\ldots,\mathbf{X}_n=x_n\}=P_n(x_1,\ldots,x_n)$ with P_n defined in (2). Equation (6) or (7) is a consequence of Whittle's formula for $|\mathcal{T}_Q^n(u)|$, a simple proof of which was given by Billingsley.[34] The upper bound in (6) can be proved more easily with a simple way of enumeration (Ref. 35 or the paragraph containing (9) of Ref. 36).

C. Proof of theorem I

The case where $R=1$ is trivial, so we assume $R<1$ from now on. Putting $k=\lceil Rn\rceil$, we apply Lemma 1, where we choose J_0 as follows. Assume dim $L=n-k$. Then, dim $L^{\perp}=n+k$.[28,30] For notational simplicity, we write $H_c(Q)$ in place of $H(\tilde{Q}|\overline{Q})$ for a probability distribution Q on $\mathcal{X}^2$. From each of the d^{n-k} cosets of $L^{\perp}$ in F^{2n}, select a vector that minimizes $H_c(\mathsf{M}_x)$, i.e., a vector x satisfying $H_c(\mathsf{M}_x)\leqslant H_c(\mathsf{M}_y)$ for any y in the coset. This selection uses the idea of the minimum entropy decoder known in the classical information theory literature.[33]

Let $J_0(L)$ denote the set of the d^{n-k} selected vectors, let

$$\mathsf{A}=\{L\subseteq\mathsf{F}^{2n}|L \text{ linear},\quad L\subseteq L^{\perp},\quad \dim L=n-k\},$$

and, for each $L\in\mathsf{A}$, let $\mathcal{C}(L)$ be an $N_{J_0(L)}$-correcting code, the existence of which is ensured by Lemma 1. Putting

$$\overline{F}=\frac{1}{|\mathsf{A}|}\sum_{L\in\mathsf{A}}F(\mathcal{C}(L)),$$

we will show $\liminf_n -n^{-1}\log_d(1-\overline{F})\geqslant E(R,P)$, which implies that, at least, one sequence of codes has fidelity as high as promised in the theorem. Such a method for a proof is referred to as random coding.[10,37]

As in the proof of Theorem 1 of Ref. 8, we have

$$1-\overline{F}\leqslant \sum_{x\in \mathsf{F}^{2n}} P_n(x)\frac{|\mathsf{B}(x)|}{|\mathsf{A}|}, \tag{8}$$

where

$$\mathsf{B}(x)=\{L\in \mathsf{A}|x\notin J_0(L)\},\quad x\in \mathsf{F}^{2n}.$$

The fraction $|\mathsf{B}(x)|/|\mathsf{A}|$ is trivially bounded as

$$\frac{|\mathsf{B}(x)|}{|\mathsf{A}|}\leqslant 1,\quad x\in \mathsf{F}^{2n}. \tag{9}$$

We use the next inequality.[9] Let

$$\mathsf{A}(x)=\{L\in \mathsf{A}|x\in L^{\perp}\backslash\{0\}\}.$$

Then, $|\mathsf{A}(0)|=0$ and

$$\frac{|\mathsf{A}(x)|}{|\mathsf{A}|}=\frac{d^{n+k}-1}{d^{2n}-1}\leqslant \frac{1}{d^{n-k}},\quad x\in \mathsf{F}^{2n},\quad x\neq 0. \tag{10}$$

This is a variant of the relation established by Calderbank *et al.*,[25] or its analog proved by Matsumoto and Uyematsu[38] with an explicit use of the Witt lemma[28,29] from the theory of bilinear forms.

Since $\mathsf{B}(x)\subseteq\{L\in \mathsf{A}|\exists y\in \mathsf{F}^{2n}, H_{\mathrm{c}}(\mathsf{M}_y)\leqslant H_{\mathrm{c}}(\mathsf{M}_x), y-x\in L^{\perp}\backslash\{0\}\}$ from the design of $J_0(L)$ specified above (cf. Ref. 37), it follows that

$$|\mathsf{B}(x)|\leqslant \sum_{y\in \mathsf{F}^{2n}:H_{\mathrm{c}}(\mathsf{M}_y)\leqslant H_{\mathrm{c}}(\mathsf{M}_x),\ y\neq x}|\mathsf{A}(y-x)|\leqslant \sum_{y\in \mathsf{F}^{2n}:H_{\mathrm{c}}(\mathsf{M}_y)\leqslant H_{\mathrm{c}}(\mathsf{M}_x),\ y\neq x}|\mathsf{A}|d^{-n+k}, \tag{11}$$

where we have used (10) for the latter inequality. Combining (8), (9), and (11), we obtain the following chain of inequalities with the aid of the basic inequalities in (6) and (7) as well as the inequality $\min\{a+b,1\}\leqslant\min\{a,1\}+\min\{b,1\}$ for $a,b\geqslant 0$:

$$\begin{aligned}
1-\overline{F}&\leqslant \sum_{x\in \mathsf{F}^{2n}} P_n(x)\ \min\left\{\sum_{y\in \mathsf{F}^{2n}:H_{\mathrm{c}}(\mathsf{M}_y)\leqslant H_{\mathrm{c}}(\mathsf{M}_x),\ y\neq x} d^{-(n-k)},\ 1\right\}\\
&\leqslant \sum_{u\in \mathcal{X}} p(u)\sum_{Q\in \mathcal{Q}_n(u)}\Pr\{\mathsf{M}_{\mathbf{X}}=Q|\mathbf{X}_1=u\}\min\left\{\sum_{Q'\in \mathcal{Q}_n:H_{\mathrm{c}}(Q')\leqslant H_{\mathrm{c}}(Q)}\frac{|\mathcal{T}^n_{Q'}|}{d^{n(1-R)-1}},\ 1\right\}\\
&\leqslant d^3\sum_{u\in \mathcal{X}} p(u)\sum_{Q\in \mathcal{Q}_n}\exp_d[-(n-1)D(Q\|P)]\\
&\quad\times\sum_{Q'\in \mathcal{Q}_n:H_{\mathrm{c}}(Q')\leqslant H_{\mathrm{c}}(Q)}\exp_d[-(n-1)|1-R-H_{\mathrm{c}}(Q')|^{+}]\\
&\leqslant d^3\sum_{Q\in \mathcal{Q}_n}\exp_d[-(n-1)D(Q\|P)]|\mathcal{Q}_n|\max_{Q'\in \mathcal{Q}_n:H(Q')\leqslant H(Q)}\\
&\quad\exp_d[-(n-1)|1-R-H_{\mathrm{c}}(Q')|^{+}]
\end{aligned}$$

$$\leqslant d^3 \sum_{Q \in \mathcal{Q}_n} \exp_d[-(n-1)D(Q\|P)]\,|\mathcal{Q}_n| \exp_d[-(n-1)|1-R-H_c(Q)|^+]$$

$$\leqslant d^3 |\mathcal{Q}_n|^2 \exp_d\{-(n-1) \min_{Q \in \mathcal{Q}_n} [D(Q\|P)+|1-R-H_c(Q)|^+]\}.$$

Since $|\mathcal{Q}_n|$ is polynomial in n, the remaining task is to show that

$$\liminf_{n\to\infty} \min_{Q \in \mathcal{Q}_n} [D(Q\|P)+|1-R-H_c(Q)|^+]$$

is not less than

$$\min_{Q:\|\overline{Q}-\bar{\bar{Q}}\|=0} [D(Q\|P)+|1-R-H_c(Q)|^+],$$

which is $E(R,P)$. One sees this holds immediately, noticing that any $Q \in \mathcal{Q}_n$ satisfies $\|\overline{Q}-\bar{\bar{Q}}\| \leqslant 1/(n-1)$ for the norm $\|(z_1,\ldots,z_{|\mathcal{X}|})\| = \max_i |z_i|$,[22] the set of all probability distributions is compact, and $D(Q)=D(Q\|P)$ is continuous in its effective domain $\{Q|D(Q)<\infty\}$ (cf. the proof of Lemma 2 in Ref. 22). This completes the proof.

IV. MAIN RESULT FOR GENERAL CASE

Theorem 1 actually holds for a wider class of channels. To evaluate the fidelity of codes on a more general channel $\{\mathcal{A}_n\}$, we first associate a sequence of probability distributions $\{P_{\mathcal{A}_n}\}$ with the channel $\{\mathcal{A}_n\}$ as in Ref. 9.

Definition 1: For each n, let $\mathcal{A}_n \sim \{A_x^{(n)}\}_{x \in \mathcal{X}^n}$, *expand* $A_x^{(n)}$ *as* $A_x^{(n)} = \Sigma_{y \in \mathcal{X}^n} a_{xy} N_y$, $x \in \mathcal{X}^n$, *and define a probability distribution* $P_{\mathcal{A}_n}$ *on* $\mathcal{X}^n$ *by*

$$P_{\mathcal{A}_n}(y) = \sum_x |a_{xy}|^2, \quad y \in \mathcal{X}^n.$$

Example: Let $\{\mathcal{A}_n\}$ be a memoryless channel $\mathcal{A}_n = \mathcal{A}^{\otimes n}$, $n=1,2,\ldots$. It is easy to see that $P_{\mathcal{A}_n}(y_1,\ldots,y_n) = \Pi_{i=1}^n P_{\mathcal{A}}(y_i)$.

The case of memoryless channels as above was discussed in this author's previous work.[9] This work claims the next.

Theorem 2: *Consider a channel* $\{\mathcal{A}_n\}$ *whose* $\{P_n = P_{\mathcal{A}_n}\}$ *satisfies (2) with some* $P(\cdot|\cdot)$ *and* p. *Then, again, for* $0 \leqslant R \leqslant 1$, *(3) in Theorem 1 holds*.

The above theorem can be proved along the lines of this author's previous work,[9] which treated general memoryless quantum channels. Namely, Theorem 1 can be generalized to Theorem 2 in the same way as the result in Ref. 8 was strengthened in Ref. 9. Here it is briefly described how to prove Theorem 2. First, we evaluate the minimum average fidelity $F_a(\mathcal{C})$, which is another performance measure for a code $\mathcal{C}$ introduced in Ref. 9, instead of the minimum fidelity $F(\mathcal{C})$. Actually, we evaluate the average of $F_a(\mathcal{C})$ over the whole ensemble of quantum codes $\{\mathcal{C}(L,i)|L \in \mathsf{A}, 0 \leqslant i < d^{n-k}\}$, where $\mathcal{C}(L,i)$, $i=0,\ldots,d^{n-k}-1$, are the d^{n-k} quantum codes associated with L as in Lemma 1; compare the proof of Theorem 1 above, where using an arbitrarily chosen code $\mathcal{C}(L,i)$ for each L was enough. The average of $F_a(C(L,i))$ turns out to be lower bounded by $1-\exp_d[-nE(R,P)+o(n)]$. Then, at least, one code $\mathcal{C}(L,i)$ has this performance or higher. As proved in Ref. 9, if we have a code with $1-F_a(\mathcal{C}) \leqslant G$, we can choose a subcode $\mathcal{C}'$ of half the dimension with $1-F(\mathcal{C}') \leqslant 2G$, which implies Theorem 2.

The major difficulty in the analysis on general channels lies in the fact that (5) is no longer true in the general case; this was resolved in Ref. 9 by proving that (5) holds true if we replace $F(\mathcal{C})=F(\mathcal{C}(L))$ by $F_a(\mathcal{C}(L,i))$ averaged over $0 \leqslant i < d^{n-k}$.

We remark that the result of this article readily extends to the case where P_n is the probability distribution of a higher-order Markov chain. For this extension, we have only to use higher-order types instead of second-order types.[11,22]

V. CONCLUDING REMARKS

It should be remarked that the lower bound $1-H(P|q)$ on the quantum capacity is not tight in general since there is an example of a code which slightly goes beyond the bound for some very noisy memoryless channels.[6] This work, however, seems the first to demonstrate that standard error correction schemes work reliably even in the presence of correlated errors with positive information rate for all large enough code lengths. Moreover, the established convergence of the fidelity is exponential. Research in this direction is yet to be developed in quantum information theory, while exponent problems have already been central issues in other fields including large-deviation theory[39] and classical information theory.[40,41]

Lower bound for the quantum capacity of a discrete memoryless quantum channel

Ryutaroh Matsumoto[a] and Tomohiko Uyematsu[b]
Department of Communications and Integrated Systems, Tokyo Institute of Technology, 152-8552 Japan

(Received 24 October 2001; accepted for publication 16 May 2002)

We generalize the random coding argument of stabilizer codes and derive a lower bound on the quantum capacity of an arbitrary discrete memoryless quantum channel. For the depolarizing channel, our lower bound coincides with that obtained by Bennett *et al.* We also slightly improve the quantum Gilbert–Varshamov bound for general stabilizer codes, and establish an analog of the quantum Gilbert–Varshamov bound for linear stabilizer codes. Our proof is restricted to the binary quantum channels, but its extension of to l-adic channels is straight forward. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1497999]

I. INTRODUCTION

The quantum capacity of a quantum channel is the amount of quantum states that can be reliably transmitted through the channel. It is one of the fundamental unsolved problems in the quantum information theory. Except for the quantum erasure channel, we know only lower and upper bounds for the quantum capacity of a quantum channel, and, in addition, a tight lower bound is not known for a general memoryless quantum channel. In this article we shall demonstrate a lower bound on the capacity of a general memoryless quantum channel. A quantum channel is said to be memoryless if the state change of one transmitted quantum system (of the fixed degree of freedom) is statistically independent of the state change of another.

The problem of quantum capacity has attracted great attention, and rapid progress has been made. To be precise, the quantum capacity of a binary memoryless channel Γ is the maximum number $Q(\Gamma)$ such that for any rate $R<Q(\Gamma)$ and any $\epsilon>0$ there exists an $[[n,k]]$ quantum code Q with $k/n \geqslant R$ such that the fidelity between the recovered state and the original state $|\varphi\rangle \in Q$ is at least $1-\epsilon$ for any $|\varphi\rangle$.[1,2] In Refs. 1 and 2, the authors obtained the exact capacity of the quantum erasure channel, and showed lower and upper bounds for that of the quantum depolarizing channel. The same lower bounds for those channels were also obtained in Ref. 3 by using random coding of the stabilizer codes introduced in Refs. 4–6. After that, DiVincenzo *et al.*[7] improved the lower bound for a depolarizing channel by using nonrandom stabilizer codes. The upper bound of the depolarizing channel was improved in Refs. 8–10, and generalized to asymmetric depolarizing channels in Ref. 11. An apparently different definition of the quantum capacity was formalized in Ref. 12, in which an upper bound of a general memoryless quantum channel was established by using the notion of coherent information introduced in Ref. 13. It is informally argued in Ref. 14 that the upper bound in Ref. 12 is achieved by random coding over a general memoryless channel. Barnum *et al.*[15] showed that the definitions of quantum capacity in Refs. 1, 2, and 12 were equivalent.

It is the random coding that is the most commonly used technique in classical information theory to show that a specific rate is achieved by a code in a specific class of codes. For example, Elias showed that the capacity of the binary symmetric channel is achieved by binary linear codes

[a]Electronic address: ryutaroh@rmatsumoto.org; URL: http: //www.rmatsumoto.org
[b]Electronic address: uyematsu@ieee.org; URL: http: //www.it.ss.titech.ac.jp

using random coding[16] (a readable proof of this fact can be found in Sec. 6.2 of Ref. 17). A proof by random coding usually proceeds as follows: one first calculates the average of error probability of all codes in a specific class of codes of the same rate and the same code length, then shows that the average converges to 0 as the code length increases, and finally concludes that there exists at least one sequence of codes of the fixed rate with which the error probability converges to 0.

The technique of random coding is also used in the quantum information theory. Gottesman[3] showed using random coding that the lower bound on the quantum capacity of the depolarizing channel[2] can be achieved by stabilizer codes. However, his proof does not seem to extend easily to the case of general memoryless channel. The aim of the present article is to derive a lower bound on the quantum capacity of a general memoryless channel by using random coding of stabilizer codes. In our argument of random coding, we shall use the fidelity[18,19] as a replacement of error probability in the classical random coding, and use the idea behind the proof of the quantum Gilbert–Varshamov bound for the stabilizer codes.[4] As a byproduct, we also improve the quantum Gilbert–Varshamov bound for stabilizer codes. Our improved bound (Remark 10) is slightly better than the quantum Gilbert–Varshamov bound for general codes.[20]

As a natural consequence of the quantum Gilbert–Varshamov bound[4,20] and the fidelity bound of t-error correcting quantum codes,[21–23] we can also derive lower bounds for the quantum capacity of a general memoryless quantum channel. However, for the depolarizing channel, the derived lower bounds are much smaller than that obtained in Ref. 2. In contrast to this, our lower bound coincides with the bound in Ref. 2 for the depolarizing channel.

It is interesting whether the proposed lower bound is achieved by a subclass of general stabilizer codes. We also show that the random coding of linear stabilizer codes yields the same lower bound on the quantum capacity. As a byproduct we obtain an analog of the quantum Gilbert–Varshamov bound for linear stabilizer codes (Remark 13), which is asymptotically the same as that for general quantum codes.[20]

The quantum channel considered in this article is discrete in the sense that the channel carries finite-dimensional quantum systems, and we do not touch the quantum capacity of a continuous quantum channel recently studied in Refs. 24 and 25. Our proof is restricted to the binary quantum channels for the simplicity of presentation, but its extension to l-adic channels is straightforward for prime l.

This article is organized as follows: In Sec. II we introduce notations and review relevant research results. In Sec. III we derive a lower bound [Eq. (16)] for the quantum capacity of an arbitrary discrete memoryless quantum channel by random coding of stabilizer codes.

II. NOTATIONS AND PRELIMINARIES

In this section we fix notations used in this article, and review known research results that are necessary to establish our results.

A. Quantum channel and its quantum capacity

For a finite-dimensional complex Hilbert space $\mathcal{H}$, let $\mathcal{S}(\mathcal{H})$ be the set of density operators on $\mathcal{H}$ and $\mathcal{L}(\mathcal{H})$ be the set of linear operators on $\mathcal{H}$. The standard description of a quantum channel is the completely positive trace-preserving map (CP map).[26–28] Suppose that we send a state $\rho \in \mathcal{S}(\mathcal{H})$. The statistical ensemble of the received states is described as $\Gamma(\rho)$ by a CP map Γ.

Suppose that we send a state $\rho \in \mathcal{S}(\mathcal{H}^{\otimes n})$ through a quantum channel. The quantum channel is said to be *memoryless* if the received state is described as $\Gamma^{\otimes n}(\rho)$ for all $\rho \in \mathcal{S}(\mathcal{H}^{\otimes n})$ and for some CP map Γ on $\mathcal{L}(\mathcal{H})$.

Fidelity is a measure of closeness between two quantum states. The fidelity F between a pure state $|\varphi\rangle \in \mathcal{H}$ and a state $\rho \in \mathcal{S}(\mathcal{H})$ is defined by $\langle\varphi|\rho|\varphi\rangle$.[18,19] We have $0 \leqslant F \leqslant 1$ and two states are closer if the fidelity between them is larger.

Let H_2 be the two-dimensional complex Hilbert space. Unless otherwise stated we consider the binary memoryless quantum channel, that is, when we send $\rho \in \mathcal{S}(H_2^{\otimes n})$ we receive $\Gamma^{\otimes n}(\rho)$, where Γ is a CP map on $\mathcal{L}(H_2)$. We shall identify a binary memoryless channel with a CP map on $\mathcal{L}(H_2)$.

A binary $[[n,k]]$ quantum code Q is a 2^k-dimensional subspace of $H_2^{\otimes n}$. The rate of an $[[n,k]]$ quantum code is k/n. The quantum capacity of a binary memoryless channel Γ is the maximum number $Q(\Gamma)$ such that for any rate $R<Q(\Gamma)$ and any $\epsilon>0$ there exists an $[[n,k]]$ quantum code Q with $k/n \geqslant R$ such that the fidelity between the recovered state and the original state $|\varphi\rangle \in Q$ is at least $1-\epsilon$ for any $|\varphi\rangle$.[1,2]

B. Fidelity bound of the quantum error correction

In this subsection we review Preskill's lower bound on the fidelity of quantum error correction in terms of the set of uncorrectable errors of a quantum code. Let

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

and $\mathcal{E}=\{w_1 \otimes \cdots \otimes w_n\}$, where w_i is either I, σ_x, σ_z or $\sigma_x\sigma_z$. For a quantum code Q and a fixed error correction process for Q, an operator $M \in \mathcal{E}$ is said to be correctable if the error correction process of Q recovers $M|\varphi\rangle$ to $|\varphi\rangle$ for all $|\varphi\rangle \in Q$. An operator M is uncorrectable if it is not correctable. Let $\mathcal{E}_{\mathrm{unc}} \subset \mathcal{E}$ be the set of uncorrectable errors of a quantum code $Q \subset H_2^{\otimes n}$. Suppose that we send a pure state $|\varphi\rangle \in Q$ through a binary memoryless channel described by a CP map Γ on $\mathcal{L}(H_2)$. By a unitary representation of a CP map,[29] there exists a finite-dimensional Hilbert space H_{env}, a pure state $|0_{\mathrm{env}}\rangle \in H_{\mathrm{env}}$ and a unitary operator U on $H_2^{\otimes n} \otimes H_{\mathrm{env}}$ such that

$$\Gamma(\rho) = \mathrm{Tr}_{H_{\mathrm{env}}}(U(\rho \otimes |0_{\mathrm{env}}\rangle\langle 0_{\mathrm{env}}|)U^*) \tag{1}$$

for all $\rho \in \mathcal{S}(H_2^{\otimes n})$, where $\mathrm{Tr}_{H_{\mathrm{env}}}$ is the partial trace over H_{env}. Since $\mathcal{E}$ is a basis of $\mathcal{L}(H_2^{\otimes n})$ we can write U in Eq. (1) as

$$U = \sum_{M \in \mathcal{E}} M \otimes L_M,$$

where L_M is a linear operator on H_{env}. Preskill proved the following theorem in Sec. 7.4 of Ref. 23.

Theorem 1: *Let Q and $\mathcal{E}_{\mathrm{unc}}$ be as above. When we send a pure state $|\varphi\rangle \in Q$, the fidelity between $|\varphi\rangle$ and the recovered state is not less than*

$$1 - \left\| \sum_{M \in \mathcal{E}_{\mathrm{unc}}} M|\varphi\rangle \otimes L_M|0_{\mathrm{env}}\rangle \right\|^2,$$

where $\|\cdot\|$ denotes the norm of a vector.

C. Stabilizer codes and their error correction process

In this subsection we review stabilizer quantum codes introduced in Refs. 4–6. Let $E = \{\pm w_1 \otimes \cdots \otimes w_n\}$, where w_i is either I, σ_x, σ_z or $\sigma_x\sigma_z$, S is a commutative subgroup of E, and

$$S' = \{M \in E : \forall N \in S, \quad MN = NM\}.$$

A stabilizer code Q is defined as a simultaneous eigenspace of all matrices in S. If S' has 2^{n+k+1} elements, then $\dim Q = 2^k$. The set of simultaneous eigenspaces of S is equal to $\{MQ: \ M \in \mathcal{E}\}$, where $MQ = \{M|\varphi\rangle : |\varphi\rangle \in Q\}$.

We shall describe the error correction process of a stabilizer code. Suppose that we send a pure state $|\varphi\rangle \in Q$ and received $\rho \in \mathcal{S}(H_2^{\otimes n})$. We measure an observable of $H_2^{\otimes n}$ whose eigenspaces are the same as those of S. Then the received state ρ is projected to a state ρ' that is an ensemble of pure states in some eigenspace Q' of S. For $M = \pm w_1 \otimes \cdots \otimes w_n \in E$ we define the weight $w(M)$ of M by $\sharp\{i : w_i \neq I\}$, where $\sharp$ denotes the number of elements in a set. Let

$M \in \mathcal{E}$ such that $MQ = Q'$ and that, if $MQ = M'Q$ for $M' \in \mathcal{E}$, then $w(M) \leqslant w(M')$. We recover ρ' to $M^{-1}\rho'(M^{-1})^*$. With this error correction process the set of uncorrectable errors is contained in

$$\{M \in \mathcal{E}: \text{ there exists } M' \in \mathcal{E} \text{ such that } w(M') \leqslant w(M),$$
$$M'Q = MQ, \text{ and } MS \neq \pm M'S\} = \{M \in \mathcal{E}: \text{ there exists } M' \in \mathcal{E} \text{ such that } w(M') \leqslant w(M), \tag{2}$$
$$M'S' = MS', \text{ and } MS \neq \pm M'S\}.$$

Hamada[30] showed the following theorem based on Theorem 1.

Theorem 2: *Notations as in Theorem 1. Let Q be a stabilizer code with the decoding process described above. Then there exists a subspace $Q' \subset Q$ such that* $\dim Q' = \dim Q/2$ *and that for all pure state $|\varphi\rangle \in Q'$, the fidelity between $|\varphi\rangle$ and the recovered state is not less than*

$$1 - 2 \sum_{M \in \mathcal{E}_{\text{unc}}} \| L_M |0_{\text{env}}\rangle \|^2. \tag{3}$$

Observe that the information rates of Q and Q' in Theorem 2 differ by $\log 2/n$, which becomes negligible as $n \to \infty$. We call a subspace Q' as a subcode of Q as in the classical coding theory. We shall consider the subcode Q' of a stabilizer code Q in the discussion of Sec. III.

D. Symplectic geometry

In this subsection we review the symplectic geometric interpretation of stabilizer codes introduced in Refs. 4 and 5. A symplectic geometry is a linear space with a nondegenerate symplectic form.[31] Let $\mathbf{F}_2$ be the finite field with two elements. For $\vec{a} = (a_1, \ldots, a_n) \in \mathbf{F}_2^n$ and $\vec{b} = (b_1, \ldots, b_n) \in \mathbf{F}_2^n$, we define $(\vec{a}|\vec{b})$ by $(a_1, \ldots, a_n, b_1, \ldots, b_n) \in \mathbf{F}_2^{2n}$ and

$$f(\pm \sigma_x^{a_1}\sigma_z^{b_1} \otimes \cdots \otimes \sigma_x^{a_n}\sigma_z^{b_n}) = (\vec{a}|\vec{b}).$$

We also define the standard symplectic form of $(\vec{a}|\vec{b})$ and $(\vec{a}'|\vec{b}') \in \mathbf{F}_2^{2n}$ by

$$\langle \vec{a}, \vec{b}' \rangle - \langle \vec{a}', \vec{b} \rangle, \tag{4}$$

where $\langle \cdot, \cdot \rangle$ denotes the standard inner product in $\mathbf{F}_2^n$. For a subspace $C \subseteq \mathbf{F}_2^{2n}$ we denote by $C^\perp$ the orthogonal space of C with respect to (4). For a subgroup $S \subseteq E$, S is commutative if and only if $f(S) \subseteq (f(S))^\perp$, and $S' = f^{-1}((f(S))^\perp)$.

E. Linear stabilizer codes and unitary geometry

Calderbank *et al.*[5] related stabilizer codes to classical error-correcting codes and unitary geometry, which is a linear space with a nondegenerate hermitian form.[31] Let ω be a primitive element in $\mathbf{F}_4$, and define

$$g(\pm \sigma_x^{a_1}\sigma_z^{b_1} \otimes \cdots \otimes \sigma_x^{a_n}\sigma_z^{b_n}) = \omega\vec{a} + \omega^2\vec{b} \in \mathbf{F}_4^n.$$

For vectors $\vec{x}, \vec{y} \in \mathbf{F}_4^n$ we define an $\mathbf{F}_2$-bilinear map

$$\langle \vec{x}^2, \vec{y} \rangle - \langle \vec{x}, \vec{y}^2 \rangle, \tag{5}$$

where $\langle , \rangle$ denotes the standard inner product in $\mathbf{F}_4^n$ and $\vec{x}^2 = (x_1^2, \ldots, x_n^2)$. For an $\mathbf{F}_2$-linear subspace C of $\mathbf{F}_4^n$, let $C^\perp$ denotes the orthogonal space of C with respect to (5). For a subgroup $S \subseteq E$, S is commutative if and only if $g(S) \subseteq (g(S))^\perp$, and $S' = g^{-1}((g(S))^\perp)$.

For $\vec{x}$, $\vec{y} \in \mathbf{F}_4^n$, we define the standard Hermitian form of $\vec{x}$, $\vec{y}$ by

$$\tau(\vec{x},\vec{y}) = \langle \vec{x}^2, \vec{y} \rangle, \tag{6}$$

which is used only in Sec. III D. If C is an $\mathbf{F}_4$-linear subspace of $\mathbf{F}_4^n$, $C^\perp$ is equal to the orthogonal space of C with respect to (6). A stabilizer code constructed from an $\mathbf{F}_2$-linear self-orthogonal space $C \subset \mathbf{F}_4^n$ is said to be linear if C is $\mathbf{F}_4$-linear. This connection between binary stabilizer codes and classical codes over $\mathbf{F}_4$ is generalized to nonbinary case in Refs. 32–34.

III. LOWER BOUND ON THE QUANTUM CAPACITY

As described in the Introduction, we have to calculate the average of fidelity over all the stabilizer codes, and show that the average converges to 1. Strictly speaking, we shall use the subcode of a stabilizer code introduced in Theorem 2. This section is organized as follows: In Sec. III A we introduce a definition of the distance of a quantum channel from the identity channel. In Sec. III B we calculate the average of fidelity over subcodes of general stabilizer codes of the fixed rate. In Sec. III C we deduce a sufficient condition for the rate to let the average of fidelity converge to 1. In Sec. III D we indicate that a small modification of the argument in Secs. III B and III C shows that the same lower bound on the capacity is obtained from the random coding of linear stabilizer codes.

A. A definition of distance of a quantum channel from the identity channel

We give a lower bound on the quantum capacity in terms of the distance of a quantum channel from the identity channel. Let us first review a definition of the distance of a quantum channel from the identity channel introduced in Ref. 22, then show some properties of the definition. Let Γ be a CP map on $\mathcal{L}(H_2)$.

Definition 3: Suppose that there exist a four-dimensional space H_E, $|e_0\rangle \in H_E$, and a unitary operator U on $H_2 \otimes H_E$ such that

$$\Gamma(\rho) = \mathrm{Tr}_E[U(\rho \otimes |e_0\rangle\langle e_0|)U^*] \tag{7}$$

for all $\rho \in \mathcal{S}(H_2)$. Write U as

$$U = I \otimes L_I + \sigma_x \otimes L_x + \sigma_z \otimes L_z + \sigma_x\sigma_z \otimes L_{xz},$$

where L_I, L_x, L_z, and L_{xz} are linear operators on H_E. Then the distance $p(\Gamma)$ and $q(\Gamma)$ of the channel Γ from the identity channel are defined by

$$q(\Gamma) = \| L_I |e_0\rangle \|^2,$$

$$p(\Gamma) = \| L_x |e_0\rangle \|^2 + \| L_z |e_0\rangle \|^2 + \| L_{xz} |e_0\rangle \|^2.$$

It is not clear whether the values of $p(\Gamma)$ and $q(\Gamma)$ are uniquely determined by Γ alone, that is, whether they are independent of choice of U and $|e_0\rangle$ in Eq. (7). In order to answer this question in Corollary 5, we shall represent $p(\Gamma)$ and $q(\Gamma)$ using the operator-sum representation of Γ induced by U and $|e_0\rangle$.

Proposition 4: Let $|e_0\rangle, \ldots, |e_3\rangle$ be an orthonormal basis of H_E, and

$$A_i = \langle e_i | U | e_0 \rangle.$$

By Eq. (8.10) of Ref. 35,

$$\Gamma(\rho) = \sum_{i=0}^{3} A_i \rho A_i^*$$

for all $\rho \in \mathcal{S}(H_2)$. Write A_i as

$$A_i = a_{i,I} I + a_{i,x}\sigma_x + a_{i,z}\sigma_z + a_{i,xz}\sigma_x\sigma_z .$$

Then we have another representations of $p(\Gamma)$ *and* $q(\Gamma)$ *as*

$$p(\Gamma) = \sum_{i=0}^{3} |a_{i,x}|^2 + |a_{i,z}|^2 + |a_{i,xz}|^2,$$

$$q(\Gamma) = \sum_{i=0}^{3} |a_{i,I}|^2.$$

Proof: By definition of A_i,

$$A_i = \langle e_i|L_I|e_0\rangle I + \langle e_i|L_x|e_0\rangle\sigma_x + \langle e_i|L_z|e_0\rangle\sigma_z + \langle e_i|L_{xz}|e_0\rangle\sigma_x\sigma_z .$$

Therefore,

$$a_{i,I} = \langle e_i|L_I|e_0\rangle, \quad a_{i,x} = \langle e_i|L_x|e_0\rangle, \quad a_{i,z} = \langle e_i|L_z|e_0\rangle, \quad a_{i,xz} = \langle e_i|L_{xz}|e_0\rangle.$$

Since $|e_0\rangle,\ldots,|e_3\rangle$ are an orthonormal basis, we have

$$q(\Gamma) = \| L_I|e_0\rangle \|^2 = \sum_{i=0}^{3} |a_{i,I}|^2.$$

The equality of $p(\Gamma)$ can be shown in a similar way. ■

Corollary 5: The values of $p(\Gamma)$ *and* $q(\Gamma)$ *do not depend on choice of* U *and* $|e_0\rangle$ *in Eq. (7).*

Proof: Let

$$\Gamma(\rho) = \sum_{i=0}^{3} B_i \rho B_i^*$$

be another operator-sum representation of Γ. By Theorem 8.2 of Ref. 35, there exists a 4×4 unitary matrix V such that

$$\begin{pmatrix} B_0 \\ \vdots \\ B_3 \end{pmatrix} = V \begin{pmatrix} A_0 \\ \vdots \\ A_3 \end{pmatrix}.$$

Write B_i as

$$B_i = b_{i,I} I + b_{i,x}\sigma_x + b_{i,z}\sigma_z + b_{i,xz}\sigma_x\sigma_z ,$$

and define $\vec{a}_I = (a_{0,I},\ldots,a_{3,I})^T$, $\vec{b}_I = (b_{0,I},\ldots,b_{3,I})^T$. Since I, σ_x, σ_z, and $\sigma_x\sigma_z$ are linearly independent, we have $\vec{b}_I = V\vec{a}_I$. Since V is unitary, $\|\vec{b}_I\| = \|\vec{a}_I\|$, which shows that $q(\Gamma)$ does not depend on choice of representation. The independence of $p(\Gamma)$ can be shown in a similar way. ■

The following corollary drastically simplifies the formula for the lower bound in Eq. (16).

Corollary 6: $p(\Gamma) + q(\Gamma) = 1$.

Proof: Notations as in Proposition 4. We have

$$I = \sum_{i=0}^{3} A_i^* A_i .$$

Taking trace on the both side, we have

$$\begin{aligned}\mathrm{Tr}[I] &= \sum_{i=0}^{3} \mathrm{Tr}[A_i^* A_i] \\ &= \sum_{i=0}^{3} \mathrm{Tr}[(a_{i,I} I + a_{i,x}\sigma_x + a_{i,z}\sigma_z + a_{i,xz}\sigma_x\sigma_z)^* \times (a_{i,I} I + a_{i,x}\sigma_x + a_{i,z}\sigma_z + a_{i,xz}\sigma_x\sigma_z)] \\ &= \mathrm{Tr}[I] \sum_{i=0}^{3} |a_{i,I}|^2 + |a_{i,x}|^2 + |a_{i,z}|^2 + |a_{i,xz}|^2 = \mathrm{Tr}[I](p(\Gamma) + q(\Gamma)).\end{aligned}$$

■

B. Average of the fidelity over all the stabilizer codes

In this subsection we shall prove that the average fidelity of the subcodes of all $[[n,\lfloor Rn \rfloor]]$ stabilizer codes converges to 1 as $n \to \infty$ under the conditions (8) and (9). The proof is proceeded as follows:

(1) For every stabilizer code, there exists its subcode whose fidelity of error correction is lower bounded by Eq. (3). The lower bound (3) is expressed as a sum indexed by error operators. The average of the sum will be divided according to the weight of error operators in Eq. (10).
(2) It is easy to see the part indexed by operators of larger weights converges to 0 as $n \to \infty$.
(3) We shall show that the other part indexed by operators of smaller weights converges to 0 by the fact that most of stabilizer codes can correct an error of small weight, which will be rigorously proved in Eq. (13) from Lemma 9.

Let δ and R be real numbers such that

$$\lim_{n\to\infty} \sum_{i=\lfloor \delta n \rfloor + 1}^{n} \binom{n}{i} p(\Gamma)^i q(\Gamma)^{n-i} = 0, \tag{8}$$

$$1 - \lim_{n\to\infty} \frac{\log_2 [\sum_{i=1}^{\lfloor \delta n \rfloor} \binom{n}{i} p(\Gamma)^i q(\Gamma)^{n-i} \Sigma_{j=0}^{i} \binom{n}{j} 3^j]}{n} > R, \tag{9}$$

where $\lfloor x \rfloor$ denotes the largest integer $\leqslant x$.

Let

$$A_n = \{C \subset \mathbf{F}_2^{2n} : \ C \text{ is linear}, \quad \dim C = n - \lfloor Rn \rfloor, C \subseteq C^{\perp}\}.$$

Recall that we can construct an $[[n,\lfloor Rn \rfloor]]$ stabilizer code from every $C \in A_n$. Note that A_n is not empty because there exists a self-orthogonal subspace of dimension n in $\mathbf{F}_2^{2n}$.[31] This subsection is devoted to show the following.

Proposition 7: If R satisfies Eq. (9), then there exists a sequence of subcodes of stabilizer codes whose rates are greater than or equal to R and whose fidelity converges to 1 as $n \to \infty$.

Since the information rates of the subcode Q' and Q in Theorem 2 are asymptotically the same as $n \to \infty$, it is sufficient to show that the average of the fidelity bound (3) of Q' over all the stabilizer codes in A_n converges to 1 as $n \to \infty$.

Let $|0_{\mathrm{env}}\rangle = |e_0\rangle^{\otimes n}$, and for $M = \sigma_{i_1} \otimes \cdots \otimes \sigma_{i_n} \in \mathcal{E}$ let

$$L_M = L_{i_1} \otimes \cdots \otimes L_{i_n},$$

where $\sigma_I = I$ and $|e_0\rangle$, L_I, L_x, L_z, and L_{xz} are as defined in Definition 3. For $C \in A_n$ we denote the set of uncorrectable errors of C in $\mathcal{E}$ by $\mathcal{E}_{\mathrm{unc}}(C)$. The average of the fidelity bound (3) of Q' over all the stabilizer codes in A_n is not less than

$$\frac{1}{\sharp A_n}\sum_{C\in A_n}\left(1-2\sum_{M\in\mathcal{E}_{\mathrm{unc}}(C)}\|L_M|0_{\mathrm{env}}\rangle\|^2\right)$$
$$=1-\frac{2}{\sharp A_n}\sum_{C\in A_n}\left(\sum_{\substack{M\in\mathcal{E}_{\mathrm{unc}}(C)\\1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|^2+\sum_{\substack{M\in\mathcal{E}_{\mathrm{unc}}(C)\\w(M)>\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|^2\right)$$
$$\geqslant 1-\left(\frac{2}{\sharp A_n}\sum_{C\in A_n}\sum_{\substack{M\in\mathcal{E}_{\mathrm{unc}}(C)\\1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|^2\right)-2\sum_{\substack{M\in\mathcal{E}\\w(M)>\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|^2. \tag{10}$$

By the same argument as Ref. 22, one can show that

$$\sum_{\substack{M\in\mathcal{E}\\w(M)>\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|\leqslant\sum_{i=\lfloor\delta n\rfloor+1}^{n}\binom{n}{i}p(\Gamma)^i q(\Gamma)^{n-i},$$

which converges to 0 as $n\to\infty$ by the condition (8).

We shall calculate an upper bound for the second term in Eq. (10). For $M\in\mathcal{E}$ we define

$$B_n(M)=\{C\in A_n : M\in\mathcal{E}_{\mathrm{unc}}(C)\}.$$

It follows that

$$\frac{1}{\sharp A_n}\sum_{C\in A_n}\sum_{\substack{M\in\mathcal{E}_{\mathrm{unc}}(C)\\1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\|L_M|0_{\mathrm{env}}\rangle\|^2\leqslant\frac{1}{\sharp A_n}\sum_{\substack{M\in\mathcal{E}\\1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\sharp B_n(M)\|L_M|0_{\mathrm{env}}\rangle\|^2. \tag{11}$$

Note that we omitted the factor 2 from Eq. (10) for simplicity, because we shall show that the right-hand side of Eq. (11) converges to 0 and factor 2 is negligible.

We shall give an upper bound for $\sharp B_n(M)$. To estimate $\sharp B_n(M)$ we shall introduce Lemma 9. In the proof of Lemma 9 we use the Witt theorem, so we review it.

Theorem 8 (Witt): *Let K be a field, V_1, V_2 finite-dimensional K-linear spaces, and τ_1, τ_2 symplectic forms on V_1, V_2, respectively. An injective linear map $T:V_1\to V_2$ is said to be an* isometry *if*

$$\tau_1(x,y)=\tau_2(Tx,Ty).$$

Let W_1 be a subspace of V_1. If there exists a bijective isometry from V_1 to V_2 and an isometry $T_{W_1}:W_1\to V_2$, then there exists an isometry $T_{V_1}:V_1\to V_2$ such that the restriction of T_{V_1} to W_1 is equal to T_{W_1}. The same result also holds when τ_1,τ_2 are Hermitian forms.

Proof: See Sec. 20 of Ref. 31. ■

Lemma 9: For $M\in E-\{\pm I\}$, let $A_n(M)=\{C\in A_n : f(M)\in C^{\perp}\backslash C\}$. We have

$$\sharp A_n(M)\leqslant(1/2^{n-\lfloor Rn\rfloor})\frac{1-2^{-2\lfloor Rn\rfloor}}{1-2^{-2n}}\sharp A_n<\sharp A_n/2^{n-\lfloor Rn\rfloor}.$$

Proof: Let $\mathrm{Sp}_n(\mathbf{F}_2)$ be the group of bijective linear maps on $\mathbf{F}_2^{2n}$ preserving the symplectic form (4). For every pair of spaces C_1, $C_2\in A_n$, every bijective linear map from C_1 to C_2 is an isometry. Consequently, there exists $\sigma\in\mathrm{Sp}_n(\mathbf{F}_2)$ such that $\sigma C_1=C_2$ by the Witt theorem. A similar argument shows that there exists $\sigma'\in\mathrm{Sp}_n(\mathbf{F}_2)$ such that $\sigma'(\vec{a}|\vec{b})=(\vec{a}'|\vec{b}')$ for every pair of nonzero vectors $(\vec{a}|\vec{b})$, $(\vec{a}'|\vec{b}')\in\mathbf{F}_2^{2n}$.

It follows that

$$\begin{aligned}\sharp A_n(M) &= \sharp\{C \in A_n : f(M) \in C^{\perp}\backslash C\} \\ &= \sharp\{\alpha C_1 : f(M) \in (\alpha C_1)^{\perp}\backslash \alpha C_1, \alpha \in \mathrm{Sp}_n(\mathbf{F}_2)\} \\ &= \sharp\{\alpha C_1 : \beta(f(M)) \in (\alpha C_1)^{\perp}\backslash \alpha C_1, \alpha \in \mathrm{Sp}_n(\mathbf{F}_2)\},\end{aligned}$$

where C_1 (resp. β) is an arbitrary fixed element in A_n [resp. $\mathrm{Sp}_n(\mathbf{F}_2)$]. Therefore $\sharp A_n(M)$ is the same among every nonzero $f(M)$.

Since $\sharp(C^{\perp}\backslash C) = 2^{n+\lfloor Rn\rfloor} - 2^{n-\lfloor Rn\rfloor}$, there are $(2^{n+\lfloor Rn\rfloor} - 2^{n-\lfloor Rn\rfloor})\sharp A_n$ pairs of $((\vec{a}|\vec{b}), C)$ such that $(\vec{a}|\vec{b}) \in C^{\perp}\backslash C$ and $C \in A_n$. Thus if $M \neq \pm I$, then

$$\sharp A_n(M) \leqslant \frac{2^{n+\lfloor Rn\rfloor} - 2^{n-\lfloor Rn\rfloor}}{2^{2n}-1}\sharp A_n = (1/2^{n-\lfloor Rn\rfloor})\frac{1-2^{-2\lfloor Rn\rfloor}}{1-2^{-2n}}\sharp A_n < \sharp A_n/2^{n-\lfloor Rn\rfloor}.$$

■

Remark 10: From Lemma 9 we can improve the quantum Gilbert–Varshamov bound slightly. There exists an $[[n,k,d]]$ *stabilizer code if*

$$\frac{1-2^{-2k}}{1-2^{-2n}} \cdot \frac{1}{2^{n-k}} \sum_{i=1}^{d-1} 3^i \binom{n}{i} < 1. \tag{12}$$

The proof is as follows: For each error $M \in \mathcal{E}$, $A_n(M)$ *is equal to the set of stabilizer codes unable to detect* M *as an error. Therefore, by replacing* $\lfloor Rn\rfloor$ *with* k *in Lemma 9, we see that if Eq. (12) holds, then there is at least one stabilizer code* C *is able to detect all the errors* M *with* $w(M) < d$, *which means that the minimum distance of* C *is at least* d. *The idea behind this proof already appeared in the original proof of the quantum Gilbert–Varshamov bound for stabilizer codes.*[4] *Observe that our bound is slightly better than the quantum Gilbert–Varshamov bound for general codes,*[20] *which implies that an* $[[n,k,d]]$ *quantum code exists if*

$$\frac{1}{2^{n-k}} \sum_{i=0}^{d-1} 3^i \binom{n}{i} < 1.$$

By Eq. (2), $M \in \mathcal{E}$ belongs to $\mathcal{E}_{\mathrm{unc}}(C)$ only if there exists $M' \in \mathcal{E}$ such that $w(M') \leqslant w(M)$, $Mf^{-1}(C^{\perp}) = M'f^{-1}(C^{\perp})$, and $Mf^{-1}(C) \neq M'f^{-1}(C)$. A space $C \in A_n$ belongs to $B_n(M)$ only if there exists $M' \in \mathcal{E}$ such that $w(M') \leqslant w(M)$ and $M^{-1}M' \in f^{-1}(C^{\perp}\backslash C)$. The last condition is equivalent to $C \in A_n(M^{-1}M')$. Since there are

$$\sum_{j=0}^{w(M)} \binom{n}{j} 3^j$$

operators $M' \in \mathcal{E}$ such that $w(M') \leqslant w(M)$, it follows that

$$\begin{aligned}\sharp B_n(M) &\leqslant \sum_{\substack{M' \in \mathcal{E} \\ w(M') \leqslant w(M)}} \sharp A_n(M^{-1}M') \\ &\leqslant \sum_{\substack{M' \in \mathcal{E} \\ w(M') \leqslant w(M)}} \frac{\sharp A_n}{2^{n-[Rn]}} \leqslant \frac{\sharp A_n}{2^{n-[Rn]}} \sum_{j=0}^{w(M)} \binom{n}{j} 3^j.\end{aligned} \tag{13}$$

An upper bound for Eq. (11) is derived as follows:

$$\frac{1}{\sharp A_n}\sum_{\substack{M\in\mathcal{E}\\ 1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\sharp B_n(M)\|L_M|0_{\mathrm{env}}\rangle\|^2$$
$$\leqslant\frac{1}{\sharp A_n}\sum_{\substack{M\in\mathcal{E}\\ 1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\frac{\sharp A_n}{2^{n-[Rn]}}\sum_{j=0}^{w(M)}\binom{n}{j}3^j\|L_M|0_{\mathrm{env}}\rangle\|^2$$
$$=\frac{1}{2^{n-[Rn]}}\sum_{\substack{M\in\mathcal{E}\\ 1\leqslant w(M)\leqslant\lfloor\delta n\rfloor}}\sum_{j=0}^{w(M)}\binom{n}{j}3^j\|L_M|0_{\mathrm{env}}\rangle\|^2. \tag{14}$$

For an integer $0\leqslant i\leqslant n$, by the same argument as Ref. 22, one can show that

$$\sum_{\substack{M\in\mathcal{E}\\ w(M)=i}}\|L_M|0_{\mathrm{env}}\rangle\|^2=\binom{n}{i}p(\Gamma)^i q(\Gamma)^{n-i}.$$

Therefore Eq. (14) is equal to

$$\frac{1}{2^{n-[Rn]}}\sum_{i=1}^{\lfloor\delta n\rfloor}\binom{n}{i}p(\Gamma)^i q(\Gamma)^{n-i}\sum_{j=0}^{i}\binom{n}{j}3^j,$$

which converges to 0 as $n\to\infty$ by the condition (9).

C. Achievable rate by general stabilizer codes

In the previous subsection, we have shown that if the rate R satisfies Eq. (9), then there exists at least one sequence of subcodes of stabilizer codes of the rate R such that the average of fidelity converges to 1. In this subsection we shall simplify Eqs. (8) and (9) with which we can easily compute a lower bound on the capacity of the channel Γ.

We shall deduce a sufficient condition for δ to satisfy Eq. (8). By Appendix A of Ref. 36, for $0\leqslant\epsilon<\lambda\leqslant 1$ we have

$$\sum_{i=\lambda n}^{n}\binom{n}{i}\epsilon^i(1-\epsilon)^{n-i}\leqslant 2^{-nD(\lambda\|\epsilon)},$$

where $D(\lambda\|\epsilon)$ is the classical relative entropy defined by

$$\lambda\log_2\frac{\lambda}{\epsilon}+(1-\lambda)\log_2\frac{1-\lambda}{1-\epsilon}.$$

Since $p(\Gamma)+q(\Gamma)=1$ by Corollary 6, the condition (8) holds if

$$\delta>p(\Gamma). \tag{15}$$

The term inside of $\log_2$ in Eq. (9) can be bounded as follows:

$$\sum_{i=1}^{\lfloor \delta n \rfloor} \binom{n}{i} p(\Gamma)^i q(\Gamma)^{n-i} \sum_{j=0}^{i} \binom{n}{j} 3^j \leq \sum_{i=0}^{n} \binom{n}{i} p(\Gamma)^i q(\Gamma)^{n-i} \sum_{j=0}^{\lfloor \delta n \rfloor} \binom{n}{j} 3^j$$

$$= [p(\Gamma)+q(\Gamma)]^n \sum_{j=0}^{\lfloor \delta n \rfloor} \binom{n}{j} 3^j = \sum_{j=0}^{\lfloor \delta n \rfloor} \binom{n}{j} 3^j \quad \text{(by Corollary 6)}$$

$$\leq (\delta n+1) \binom{n}{\lfloor \delta n \rfloor} 3^{\delta n}$$

$$\leq (\delta n+1) \exp_2[nH_e(\delta)] 3^{\delta n} \quad \text{(by Appendix B of Ref. 36)}$$

$$= (\delta n+1) \exp_2\{n[H_e(\delta)+\delta \log_2 3]\},$$

where H_e is the binary entropy function.

From Proposition 7, Eq. (15), and the observations above, we see that the capacity of the channel Γ is at least

$$1-\{H_e[p(\Gamma)]+p(\Gamma)\log_2 3\}. \tag{16}$$

Note that the same lower bound on the capacity can also be obtained by the method of Bennett *et al.*,[2] though they stated their result only for the depolarizing channel. However, Bennett *et al.*[2] did not address the achievability of the bound (16) with stabilizer codes, which is the main focus of this article.

We shall compare our bound on the capacity [Eq. (16)] with the conventional bound for a general memoryless channel derived from the quantum Gilbert–Varshamov bound[4,20] and the fidelity bounds for t-error-correcting codes.[21,22] Suppose that we have a sequence of $\lfloor \delta n_i \rfloor$-error-correcting quantum codes of length n_i with $\lim_{i\to\infty} n_i = \infty$. The condition (15) is sufficient in order that the fidelity of error correction by $\lfloor \delta n_i \rfloor$-error-correcting codes converges to 1 as $i \to \infty$. By the quantum Gilbert–Varshamov bound the derived lower bound on the capacity is

$$1-\{H_e[2p(\Gamma)]+2p(\Gamma)\log_2 3\},$$

which is always smaller than Eq. (16).

When the channel Γ is the depolarizing channel of the fidelity parameter f, $p(\Gamma)=1-f$ and $q(\Gamma)=f$. The proposed lower bound [Eq. (16)] for the capacity is

$$1-[H_e(1-f)+(1-f)\log_2 3],$$

which coincides with the lower bound given in Ref. 2. It is not clear to the authors whether our lower bound can be improved by the method in Ref. 7.

Our analysis for the quantum capacity can be generalized to the capacity of an l-adic channel using the l-adic stabilizer codes[37,38] in a straightforward manner when l is prime. The quantum Gilbert–Varshamov bound for l-adic stabilizer codes can also be proved by Lemma 9.

D. Achievable rate by linear stabilizer codes

In this subsection we shall show that the achievable rate (16) by subcodes of general stabilizer codes can also be achieved by those of linear stabilizer codes, which shows the asymptotic optimality of linear stabilizer codes among general ones. As a byproduct we establish an analog of Gilbert–Varshamov bound for linear stabilizer codes.

Let

$$A_n' = \{C \subset \mathbf{F}_4^n : C \text{ is } \mathbf{F}_4\text{-linear}, \ \dim_{\mathbf{F}_4} C = \lfloor (n-Rn)/2 \rfloor, \quad C \subseteq C^{\perp}\}.$$

Recall that we can construct an $[[n,n-2\lfloor(n-Rn)/2\rfloor]]$ linear stabilizer code from every $C \in A'_n$. Note that A'_n is not empty because there exists a self-orthogonal subspace of dimension $\lfloor n/2 \rfloor$ in $\mathbf{F}_4^n$ (see Proposition 2.3.2 in Ref. 39). For $M \in \mathcal{E}$, define

$$A'_n(M)=\{C \in A'_n : g(M) \in C^{\perp} \backslash C\},$$

$$B'_n(M)=\{C \in A'_n : M \text{ is uncorrectable by } C\}.$$

By these definitions of $A'_n(M)$ and $B'_n(M)$, all the arguments except Lemma 9 in the previous subsections can be used for showing that the rate (16) is achieved by subcodes of linear stabilizer codes. In this subsection we prove an upper bound (Lemma 11) for $\sharp A'_n(M)$ that can be used as a substitute for Lemma 9.

Lemma 11: Define τ by Eq. (6). The number of nonzero vectors $\vec{x} \in \mathbf{F}_4^n$ such that $\tau(\vec{x},\vec{x})=0$ is $2^{2n-1}+(-1)^n 2^{n-1}-1$.

Proof: See the proof of Proposition 2.3.3 in Ref. 39. ■

Lemma 12: Let $u=\lfloor(n-Rn)/2\rfloor$. For $M \in E\backslash\{\pm I\}$

$$\sharp A'_n(M) \leqslant \frac{4^{n-u}-4^u}{\min\{2^{2n-1}+(-1)^n 2^{n-1}-1, 2^{2n-1}-(-1)^n 2^{n-1}\}} \sharp A'_n \leqslant \frac{4^{n-u}-4^u}{2^{2n-1}-2^{n-1}-1} \sharp A'_n .$$

Proof: Let $\mathrm{GU}_n(\mathbf{F}_4)$ be the group of bijective linear maps on $\mathbf{F}_4^n$ that preserve the value of the Hermitian form τ. For every pair of spaces $C_1, C_2 \in A'_n$, every bijective linear map from C_1 to C_2 is an isometry. Thus there exists $\sigma \in \mathrm{GU}_n(\mathbf{F}_4)$ such that $\sigma C_1 = C_2$ by the Witt theorem. For a pair of nonzero vectors $\vec{x},\vec{y} \in \mathbf{F}_4^n$ with $\tau(\vec{x},\vec{x})=\tau(\vec{y},\vec{y})=0$, a similar argument shows that there exists $\sigma \in \mathrm{GU}_n(\mathbf{F}_4)$ such that $\sigma\vec{x}=\vec{y}$.

We want to show that for a pair of vectors $\vec{x},\vec{y} \in \mathbf{F}_4^n$ with $\tau(\vec{x},\vec{x}) \neq 0$ and $\tau(\vec{y},\vec{y}) \neq 0$, there exists $\sigma \in \mathrm{GU}_n(\mathbf{F}_4)$ such that $\sigma\vec{x}=\vec{y}$. Since τ is a Hermitian form, $\tau(\vec{x},\vec{x}) \in \mathbf{F}_2$. Therefore $\tau(\vec{x},\vec{x})=\tau(\vec{y},\vec{y})=1$, and there exists $\sigma \in \mathrm{GU}_n(\mathbf{F}_4)$ such that $\sigma\vec{x}=\vec{y}$ by the Witt theorem.

A similar argument to the proof of Lemma 9 shows that for $M \in E\backslash\{\pm I\}$ we have

$$\sharp A'_n(M) \leqslant \frac{4^{n-u}-4^u}{2^{2n-1}+(-1)^n 2^{n-1}-1} \sharp A'_n \quad \text{if} \quad \tau(g(M),g(M))=0,$$

$$\sharp A'_n(M) \leqslant \frac{4^{n-u}-4^u}{2^{2n-1}-(-1)^n 2^{n-1}} \sharp A'_n \quad \text{if} \quad \tau(g(M),g(M)) \neq 0.$$

■

Remark 13: From Lemma 11 we can show that there exists an $[[n,k,d]]$ linear stabilizer code if k is even and

$$\frac{2(1-2^{-2k})}{1-2^{-n}-2^{-2n+1}} \cdot \frac{1}{2^{n-k}} \sum_{i=1}^{d-1} 3^i \binom{n}{i} < 1,$$

which is asymptotically the same as the quantum Gilbert–Varshamov bound for general quantum codes.[20]

Remark 14: The connection between stabilizer codes and classical codes over $\mathbf{F}_4$ was generalized to nonbinary case in Refs. 32–34. The argument in this subsection can be extended to linear l-adic stabilizer codes for a prime l with the following exception: In the proof of Lemma 11, there does not always exist $\sigma \in \mathrm{GU}_n(\mathbf{F}_{l^2})$ such that $\sigma\vec{x}=\vec{y}$ for a pair of vectors $\vec{x},\vec{y} \in \mathbf{F}_{l^2}^n$ with $\tau(\vec{x},\vec{x}) \neq 0$ and $\tau(\vec{y},\vec{y}) \neq 0$. However, there always exists $\sigma \in \mathcal{U}$ such that $\sigma\vec{x}=\vec{y}$, where $\mathcal{U}$ is the group generated by $\mathrm{GU}_n(\mathbf{F}_{l^2})$ and nonzero scalar multiples of the identity map on $\mathbf{F}_{l^2}^n$.

ACKNOWLEDGMENTS

We would like to thank Dr. Mitsuru Hamada for drawing our attention to the random coding of stabilizer codes and for providing detailed comments on this article, and Dr. Masahito Hayashi, Dr. Keiji Matsumoto, and Dr. Tomohiro Ogawa for helpful discussions.

(Received 12 April 2002; accepted for publication 21 May 2002)

We study the visible compression of a source $\mathcal{E}=\{|\varphi_i\rangle,p_i\}$ of pure quantum signal states or, more formally, the minimal resources per signal required to represent arbitrarily long strings of signals with arbitrarily high fidelity, when the compressor is given the identity of the input state sequence as classical information. According to the quantum source coding theorem, the optimal quantum rate is the von Neumann entropy $S(\mathcal{E})$ qubits per signal. We develop a refinement of this theorem in order to analyze the situation in which the states are coded into classical and quantum bits that are quantified separately. This leads to a trade-off curve $Q^*(R)$, where $Q^*(R)$ qubits per signal is the optimal quantum rate for a given classical rate of R bits per signal. Our main result is an explicit characterization of this trade-off function by a simple formula in terms of only single-signal, perfect fidelity encodings of the source. We give a thorough discussion of many further mathematical properties of our formula, including an analysis of its behavior for group covariant sources and a generalization to sources with continuously parametrized states. We also show that our result leads to a number of corollaries characterizing the trade-off between information gain and state disturbance for quantum sources. In addition, we indicate how our techniques also provide a solution to the so-called remote state preparation problem. Finally, we develop a probability-free version of our main result which may be interpreted as an answer to the question: ''How many classical bits does a qubit cost?'' This theorem provides a type of dual to Holevo's theorem, insofar as the latter characterizes the cost of coding classical bits into qubits. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1497184]

I. INTRODUCTION

When the term ''quantum information'' was first coined, it would have been hard to predict how thorough and fruitful the analogy between quantum mechanics and classical information theory would ultimately prove to be. The general approach, characterized by the treatment of quantum states as resources to be manipulated, has yielded a promising collection of applications, ranging from unconditionally secure cryptographic protocols[1–3] to quantum algorithms.[4–6] Moreover, the analogy, which was initially unavoidably vague, has gradually been filled in by a diverse variety of rigorous theorems describing achievable limits to the manipulation of quantum states, such as the characterization of the classical information capacity of quantum sources,[7,8] the identification of optimal strategies for entanglement concentration and dilution[9] and many more. One of the pivotal results of the emerging theory is the quantum source coding theorem,[10–12] demonstrating that for the task of compressing quantum states, the von Neumann entropy plays a role directly analogous to the Shannon entropy of classical information theory. Indeed, the quantum theorem subsumes the classical one as the special case in which all the quantum states to be compressed are mutually orthogonal.

A quantum source (or ensemble) $\mathcal{E}=\{|\varphi_i\rangle,p_i\}$ is defined by a set of pure quantum signal (or ''letter'') states $|\varphi_i\rangle$ with given prior probabilities p_i (cf. below for precise definitions of these and other terms used in the Introduction). In this article we will study the so-called *visible* compression of $\mathcal{E}$. More specifically, we wish to characterize the minimal resources per signal that are necessary and sufficient to represent arbitrarily long strings of signals with arbitrarily high fidelity, when the compressor is given the identity of the input state sequence as *classical* information (as the sequence of labels $i_1,\ldots,i_n$ rather than the quantum states $|\varphi_{i_1}\rangle,\ldots,|\varphi_{i_n}\rangle$ themselves, for example). According to the quantum source coding theorem the optimal *quantum* rate in this scenario is the von Neumann entropy $S(\mathcal{E})$ qubits per signal. We will develop a refinement of this theorem in which the states are coded into classical and quantum bits which are quantified *separately*. This leads to a trade-off curve $Q^*(R)$ where $Q^*(R)$ qubits per signal is the optimal quantum rate that suffices for a given classical rate R bits per signal. The quantum source coding theorem implies that $Q^*(0)=S(\mathcal{E})$ and evidently we also have $Q^*(H(p))=0$ where $H(p)$ is the Shannon entropy of the prior distribution of the source. [By standard classical compression, the compressor can represent the full information of the input sequence in $H(p)$ classical bits per signal.] Thus the trade-off curve extends between the limits $0\leqslant R\leqslant H(p)$.

There are various reasons why we might wish to maintain a separation between classical and quantum resources in an encoding.[13] On a purely practical level it seems to be far easier to manufacture classical storage and communication devices than it is to make quantum ones. But

perhaps the primary reason is conceptual: classical and quantum information have quite different fundamental characters, with classical information exhibiting special properties not shared by quantum information in general. For example, classical information is robust compared to quantum information—it may be readily stabilized and corrected by repeated measurement that would destroy quantum information. Also, unlike quantum information, it may be cloned or copied. These and other singular properties indicate that for many purposes it may be useful to regard classical information as a separate resource, distinct from quantum information. Classical information is sometimes formally regarded as a special case of quantum information *viz.* the quantum information of a fixed set of orthogonal states. While this characterization is useful for formal analyses, it is unsatisfactory conceptually because it relies on the essentially nonphysical infinite precision of orthogonality. It is, therefore, desirable to view classical information as a separate resource.

Exploring the trade-off possibilities between the two resources will lead to a better understanding of the interrelation of these concepts and the nature of quantum information itself. If bits can always be represented as qubits (and indeed, by Holevo's information bound,[14] one qubit per bit is necessary and sufficient), what are the limitations on representing qubits as bits? Under what conditions is it possible at all? If there is a penalty to be paid, how large is it? In this article we will give answers to these questions.

Our main result is a simple characterization of the trade-off function $Q^*(R)$ which may be paraphrased as follows. Given the ensemble $\mathcal{E}=\{|\varphi_i\rangle,p_i\}$ comprising m states $|\varphi_i\rangle$ we consider decompositions of $\mathcal{E}$ into at most $(m+1)$ ensembles $\mathcal{E}_j$ with associated probabilities q_j, i.e., the ensembles $\mathcal{E}_j=\{|\varphi_i\rangle,q(i|j)\}$ have the same states as $\mathcal{E}$ and their union $\cup_j q_j\mathcal{E}_j$ reproduces $\mathcal{E}$. This is equivalent to the condition

$$p_i=\sum_j q(i|j)q_j \tag{1}$$

on the chosen probabilities q_j and $q(i|j)$ defining the decomposition. Let $\overline{S}=\Sigma_j q_j S(\mathcal{E}_j)$ be the average von Neumann entropy of any such decomposition and let $H(i:j)$ be the classical mutual information of the joint distribution $q(i,j)$. For any R let $\overline{S}_{\min}(R)$ be the least average von Neumann entropy over all decompositions that have $H(i:j)=R$. Then we will prove that the trade-off function is given by $Q^*(R)=\overline{S}_{\min}(R)$.

The prescription of a decomposition $\mathcal{E}=\cup_j q_j\mathcal{E}_j$ may be equivalently given in terms of a visible encoding map E of the states of $\mathcal{E}$:

$$E(i)=|\varphi_i\rangle\langle\varphi_i|\otimes\sum_j p(j|i)|j\rangle\langle j|. \tag{2}$$

Here $p(j|i)$ are chosen freely subject only to the condition that $H(i:j)=R$ and the previous probability distributions are constructed as $q_j=\Sigma_i p(j|i)p_i$ and $q(i|j)=p(j|i)p_i/q_j$. Under this map, i is encoded into a quantum register, simply containing the state $|\varphi_i\rangle$ itself, and a classical register, containing a classical mixture of j values. Note that this is a *single* signal encoding with *perfect* fidelity since the state $|\varphi_i\rangle$ may be regained perfectly from the encoded version by simply discarding the classical register. Hence our result characterizes optimal classical and quantum resources in compression, in terms of very simple single-signal perfect-fidelity encodings, despite the fact that compression is defined asymptotically in terms of arbitrarily long signal strings and fidelities merely *tending* to 1. This is a remarkable and unexpected simplification—even in classical information theory it is by no means the rule that coding problems have solutions that do *not* involve asymptotics (despite a few well-known examples such as Shannon's source and channel coding theorems[15]). The situation is even more tenuous in quantum information theory, which seems to be plagued by further nonadditivity (or unresolved additivity questions) for some of its basic quantities so that, at the present stage, many basic constructions require a limit over optimization problems of exponentially growing size.

Using our formula we will give a thorough discussion of further properties of the trade-off curve including a generalization to group covariant sources and to sources with infinitely many (continuously parametrized) states. We show that our result also leads to a number of corollaries characterizing the trade-off between information gain and state disturbance for quantum sources (yielding the results of Ref. 13 on blind compression as a corollary), and we indicate how our techniques for characterizing $Q^*(R)$ provide a solution to the so-called remote state preparation problem as well. Finally, we develop a probability-free version of our main result which may be interpreted as an answer to the intuitive question: ''How many classical bits does a qubit cost?'' This may also be interpreted as a kind of dual to Holevo's theorem, insofar as the latter characterizes the qubit cost of coding classical information into qubits.

The presentation of these results is organized as follows. At the top level, the article is divided broadly into two parts. The first part, Secs. II–VIII, sets up a precise formulation of the basic definitions and the trade-off problem and gives the proof of the main theorem characterizing $Q^*(R)$, as well as a discussion of some of its important basic properties. The second part, Secs. IX and X, then goes on to provide some further generalizations of the main result. In more detail, the contents of the various sections are as follows.

In Sec. II, we will define the notions of blind and visible compression, the essential difference being that in the blind setting the encoder is given the actual quantum states, while in the visible setting the encoder is given the names of the quantum states as classical data. We then extend these definitions to quantum-classical trade-off coding and introduce the trade-off function $Q^*(R)$.

In Sec. III we will prove a lower bound to the trade-off curve in terms of the simple single-letter formula of the ensemble decomposition construction paraphrased above. In Sec. IV we will, in turn, show that the lower bound is achievable so that the trade-off curve is identical to the single-letter formula. This is our main result, Theorem 4.4.

In Sec. V we use our characterization of the trade-off curve to evaluate $Q^*(R)$ numerically for a selection of particular ensembles, chosen to illustrate various important properties of the trade-off function. In Sec. VI we extend our results to a different asymptotic setting, known as the arbitrarily varying source (AVS), in which there is no (or only limited) knowledge of the prior probability distribution of the states to be compressed. This provides a probability-free generalization of our main result. In Sec. VII we show that our main result can be reinterpreted to provide statements about the trade-off between information gain and state disturbance for blind sources of quantum states (in particular entailing a new proof of the main result of Ref. 13). Finally, in Sec. VIII we indicate how our techniques—developed to study $Q^*(R)$–can also be used to characterize the trade-off curve for the coding problem of remote state preparation posed in Refs. 16 and 17.

Sections IX and X treats two significant further issues. In Sec. IX we show how to apply our results in the setting of group covariant ensembles, which leads to considerable further elegant simplifications. Section X is devoted to the technicalities of generalizing our main result to sources with infinitely many (continuously parametrized) states. Finally, in the Appendix, we collect proofs of various auxiliary propositions that have been quoted in the body of the article.

II. BLIND AND VISIBLE COMPRESSION

We begin by introducing a number of definitions that are required to give a precise statement of the variations of quantum source coding that we will be considering in this article. We will denote an ensemble of quantum states φ_i with prior probabilities p_i as $\mathcal{E}=\{\varphi_i,p_i\}$. In turn, we will write $S(\mathcal{E})=S(\Sigma_i p_i\varphi_i)$ for the von Neumann entropy of the average state of the ensemble: $S(\rho)=-\mathrm{Tr}\rho\log\rho$. (Throughout this article log and exp will denote the logarithm and exponential functions *to base* 2.) Starting from an ensemble $\mathcal{E}$, we can consider the quantum source producing quantum states that are sequentially drawn independently from $\mathcal{E}$. Such a source corresponds to a sequence of ensembles $\mathcal{E}^{\otimes n}=\{\varphi_I,p_I\}$, where

$$I:=i_1\cdots i_n, \tag{3}$$

$$\varphi_I := \varphi_{i_1} \otimes \cdots \otimes \varphi_{i_n}, \tag{4}$$

$$p_I := p_{i_1} \cdots p_{i_n}. \tag{5}$$

This sequence will be referred to as an independent identically distributed (i.i.d.) source and the states of $\mathcal{E}^{\otimes n}$ are called blocks of length n from $\mathcal{E}$. In this article we will focus on sources of pure quantum states $|\varphi_i\rangle$, often making use of the notation $\varphi_i = |\varphi_i\rangle\langle\varphi_i|$. The measure that we will use to determine whether two quantum states are close is the fidelity F. For two mixed states ρ and ω, F is given by the formula

$$F(\rho,\omega) := (\mathrm{Tr}\sqrt{\omega^{1/2}\rho\omega^{1/2}})^2. \tag{6}$$

(Note that some authors use the name ''fidelity'' to refer to the square-root of this quantity.) If $\omega = |\omega\rangle\langle\omega|$ is a pure state, then the fidelity has a particularly simple form:

$$F(\rho,\omega) = \langle\omega|\rho|\omega\rangle = \mathrm{Tr}(\rho\omega). \tag{7}$$

Finally, we will use the notation $\mathcal{H}_d$ to denote the Hilbert space of dimension d and $\mathcal{B}_d$ to denote the set of all mixed states on $\mathcal{H}_d$. Likewise, $\mathcal{H}_d^{\otimes n}$ will refer to the n-fold tensor product of $\mathcal{H}_d$ and, in a slight abuse of notation, $\mathcal{B}_d^{\otimes n}$ will refer to the set of density operators on $\mathcal{H}_d^{\otimes n}$. We are now ready to introduce the definition of *blind* quantum compression.

Definition 2.1: A blind coding scheme *for blocks of length n, to R qubits per signal and fidelity $1-\epsilon$, comprises the following ingredients:*

(1) a completely positive, trace-preserving (CPTP) encoding map $E_n : \mathcal{B}_d^{\otimes n} \to \mathcal{B}_2^{\otimes nR}$, and

(2) a CPTP decoding map $D_n : \mathcal{B}_2^{\otimes nR} \to \mathcal{B}_d^{\otimes n}$,

such that average fidelity

$$\sum_I p_I \langle\varphi_I|D_n(E_n(\varphi_I))|\varphi_I\rangle \geqslant 1-\epsilon. \tag{8}$$

We say that an i.i.d. source $\mathcal{E}$ can be blindly compressed to R qubits per signal if for all $\delta,\epsilon > 0$ and sufficiently large n there exists a blind coding scheme to $R+\delta$ qubits per signal with fidelity at least $1-\epsilon$.

The definition of visible compression is the same except that the (CPTP) restrictions on the encoding map E_n are relaxed; for visible compression E_n can be an arbitrary association of input states to output states. Equivalently, E_n is a mapping from the *names* of the input states to output states. Thus, we write $E_n(I) \in \mathcal{B}_2^{\otimes nR}$. Note that blind and visible compression schemes differ only in the set of encoding maps that are permitted. For blind (respectively visible) compression, the input states are given as quantum (respectively classical) information. In both cases the decoding must be CPTP. In this language, the central result on the compression of quantum information can be expressed as follows.

Theorem 2.2 (Quantum source coding theorem[10–12]): *A source $\mathcal{E}$ of pure quantum states can be compressed to α qubits per signal if and only if $\alpha \geqslant S(\mathcal{E})$. The result holds for both blind and visible compression.*

It is interesting to study a refinement of quantum source coding in which the states are coded into classical and quantum resources which are quantified separately. Because of restrictions on the manipulation of quantum states such as the no-cloning theorem,[18] blind compression is typically weaker than visible. In Refs. 13 and 19, for example, it was shown that in blind compression it is typically impossible to make use of classical storage. The same is not true in the visible setting, where it is possible to trade classical storage for quantum. In this article we study this trade-off for *visible* compression but, before we begin, we need to recall some basic definitions introduced in Ref. 13.

Consider an encoding operation E_n which maps a signal state $|\varphi_I\rangle$ into a joint state on a quantum register B and a classical register C. If $\{|j\rangle\}$ is the classical orthonormal basis of C, then the most general classical state on C is a probability distribution over j values, implying that the most general form of the encoded state can be written as

$$E_n(I)=\sum_j p(j|I)\omega_{I,j}^B\otimes|j\rangle\langle j|^C. \tag{9}$$

The quantum and classical storage requirements (i.e., resources) of the encoding map are simply the sizes of the registers B and C, respectively.

Definition 2.3: The quantum rate *of the encoding map E_n is defined to be*

$$\mathrm{qsupp}(E_n,\mathcal{E}^{\otimes n})=\frac{1}{n}\log\dim\mathcal{H}_B,$$

while the classical rate *of the encoding is defined to be*

$$\mathrm{csupp}(E_n,\mathcal{E}^{\otimes n})=\frac{1}{n}\log\dim\mathcal{H}_C.$$

With these definitions in place, we can make precise the notion of compression with a quantum and a classical part.

Definition 2.4: A source $\mathcal{E}$ can be compressed to R classical bits per signal plus Q qubits per signal if for all $\epsilon,\delta>0$ there exists an $N>0$ such that for all $n>N$ there exists an encoding-decoding scheme (E_n,D_n) with fidelity $1-\epsilon$ satisfying the inequalities

$$\mathrm{csupp}(E_n,\mathcal{E}^{\otimes n})\leqslant R+\delta, \tag{10}$$

$$\mathrm{qsupp}(E_n,\mathcal{E}^{\otimes n})\leqslant Q+\delta. \tag{11}$$

The main result of this article will be a complete characterization of the curve describing the trade-off between R and Q. As mentioned above, for blind encodings there is usually no trade-off to be made: generically, $Q\geqslant S(\mathcal{E})$, regardless of the size of R. The reason is essentially that making effective use of the classical register amounts to extracting classical information from a quantum system in a reversible fashion, which is impossible unless the quantum states of interest obey some orthogonality condition. The more interesting case, therefore, is to study the structure of the trade-off curve for visible encodings. As it turns out, our technique will yield the older results for blind compression as a corollary.

Definition 2.5: For a given source $\mathcal{E}=\{|\varphi_i\rangle,p_i\}$, define the function $Q^*(R)$ to be the infimum over all values of Q for which the source can be visibly compressed to R classical bits per signal and Q quantum bits per signal.

Some properties of the curve $Q^*(R)$ are immediate. For example, the endpoints of the curve are easily found. If $R=0$, then the compression must be fully quantum mechanical and the quantum source coding Theorem 2.2 applies: $Q^*(0)=S(\mathcal{E})$. More generally, the theorem implies that $Q^*(R)+R\geqslant S(\mathcal{E})$ for all R. Similarly, for $R=H(p)$ we have $Q^*(R)=0$, by Shannon's classical source coding theorem. Moreover, for intermediate values of R, the curve is necessarily convex because one method of compressing with classical rate $\lambda_1R_1+\lambda_2R_2$ is simply to timeshare between the optimal protocols for R_1 and R_2 individually, resulting in quantum rate of $\lambda_1Q^*(R_1)+\lambda_2Q^*(R_2)$.

Example (Parametrized BB84 ensemble): Let us consider in more detail the example of a parametrized version of the BB84 ensemble in order to see what sorts of protocols are possible beyond simple timesharing. For $0<\theta\leqslant\pi/4$, let $\mathcal{E}_{BB}(\theta)$ be the ensemble consisting of the states

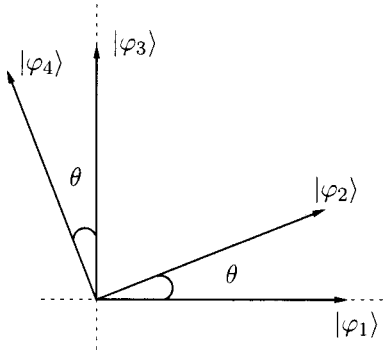

FIG. 1. Parametrized BB84 ensemble $\mathcal{E}_{BB}(\theta)$.

$$|\varphi_1\rangle = |0\rangle, \tag{12}$$

$$|\varphi_2\rangle = \cos\theta|0\rangle + \sin\theta|1\rangle, \tag{13}$$

$$|\varphi_3\rangle = |1\rangle, \tag{14}$$

$$|\varphi_4\rangle = -\sin\theta|0\rangle + \cos\theta|1\rangle, \tag{15}$$

as illustrated in Fig. 1, each occurring with probability $p_i = 1/4$. We then have $S(\mathcal{E}) = 1$ and $H(p) = 2$. From the argument above, we therefore already know two points on the $(R, Q^*(R))$ curve, namely (0,1) and (2,0). To get a better upper bound than the straight line joining these two points, suppose we were to partition the four states into two subsets, $\mathcal{X}_1 = \{|\varphi_1\rangle, |\varphi_2\rangle\}$ and $\mathcal{X}_2 = \{|\varphi_3\rangle, |\varphi_4\rangle\}$. For a given input string $I = i_1 i_2 \cdots i_n$, the classical register could be used to encode, for each k, whether $|\varphi_{i_k}\rangle \in \mathcal{X}_1$ or $|\varphi_{i_k}\rangle \in \mathcal{X}_2$. The classical rate required to do so would be 1 classical bit per signal. Independent of the value of the classical register, the quantum resource required to compress the subensembles is then just the quantum resource required to compress a pair of equiprobable quantum states subtended by the angle θ. Therefore,

$$Q^*(1) \leqslant S(\tfrac{1}{2}|\varphi_1\rangle\langle\varphi_1| + \tfrac{1}{2}|\varphi_2\rangle\langle\varphi_2|) = H_2(\tfrac{1}{2}(1+\cos\theta)). \tag{16}$$

By timesharing between the point corresponding to this protocol and the two endpoints of the curve that we already calculated, we get a piecewise linear upper bound on Q^*. As we will see later, however, the true curve is strictly below this upper bound. (The impatient reader is allowed to peek at Fig. 5 in Sec. V.)

With this example in mind, let us move on to our analysis of the general case.

III. SINGLE-LETTER LOWER BOUND ON $Q^*(R)$

In this section we will prove a lower bound on the quantum-classical trade-off curve by reducing the asymptotic problem to a single-copy problem. Because compression is only possible asymptotically, however, we need to shift the emphasis away from the quantum and classical resources towards quantum and classical mutual information quantities. In the next section we will then prove that nothing was lost by making this shift—we will show that the resulting lower bound to $Q^*(R)$ is actually achievable.

A. Mutual information and additivity

The information quantities in question will be the mutual information between the name of the state being compressed and the quantum and classical registers containing the output of the encoding map E_n. Thus, we define the state

$$\rho^{ABC} := \sum_{I,j} p_I |I\rangle\langle I|^A \otimes p(j|I)\omega_{I,j}^B \otimes |j\rangle\langle j|^C. \tag{17}$$

The names I are stored in orthogonal states on system A while the quantum and classical encoding registers are labeled B and C, respectively. We can then make the following definitions:

$$S(A:C) := S(A) + S(C) - S(AC), \tag{18}$$

$$S(A:B|C) := S(AC) + S(BC) - S(ABC) - S(C), \tag{19}$$

where, for any subsystem X, $S(X)$ denotes the von Neumann entropy of the reduced state of X. Note that $S(A:C)$ is just the classical mutual information $H(I:j)$ between I and j. To interpret $S(A:B|C)$, observe that for a given classical output j, we can write down a conditional ensemble

$$\mathcal{E}_j = \{\omega_{I,j}, q(I|j)\}, \tag{20}$$

where $q(I|j)$ is calculated using Bayes' rule to be $q(I|j) = p(j|I)p_I/q_j$, with $q_j = \Sigma_I p(j|I)p_I$. The conditional quantum mutual information $S(A:B|C)$ is just the average Holevo information χ of the conditional ensembles $\mathcal{E}_j$:

$$S(A:B|C) = \sum_j q_j \chi(\mathcal{E}_j), \tag{21}$$

where χ is defined, for an ensemble $\mathcal{E} = \{\rho_k, p_k\}$, as[14]

$$\chi(\mathcal{E}) := S\left(\sum_k p_k \rho_k\right) - \sum_k p_k S(\rho_k). \tag{22}$$

Because $\mathcal{E}_j$ is an ensemble supported on system B, $\chi(\mathcal{E}_j) \leqslant n\text{qsupp}$, which implies that

$$n\text{qsupp} \geqslant S(A:B|C). \tag{23}$$

Therefore, roughly speaking, we will derive a lower bound on $Q^*(R)$ by minimizing $S(A:B|C)$ subject to the constraint $S(A:C) \leqslant nR$ and developing further properties of that minimum. To that end, define $T_\epsilon(\mathcal{E}^{\otimes n}, nR)$ to be the set of all encoding maps E for which $S(A:C) \leqslant nR$ and there exists a decoding map D satisfying

$$\sum_I p(I) F(\varphi_I, (D \circ E)\varphi_I) \geqslant 1 - \epsilon. \tag{24}$$

Next define $M_\epsilon(\mathcal{E}^{\otimes n}, nR)$ to be the infimum of $S(A:B|C)$ over all $E \in T_\epsilon(\mathcal{E}^{\otimes n}, nR)$. We begin by noting the following basic properties of $M_\epsilon(\mathcal{E}, R)$.

Lemma 3.1: $M_\epsilon(\mathcal{E}, R)$ is a monotonically decreasing function of R. Moreoever, it is jointly convex in ϵ and R, in the sense that, for any set of $\epsilon_k > 0$ and $R_k \geqslant 0$ as well as probabilities $\Sigma_k \lambda_k = 1$,

$$M_\epsilon(\mathcal{E}, R) \leqslant \sum_k \lambda_k M_{\epsilon_k}(\mathcal{E}, R_k), \tag{25}$$

where $\epsilon = \Sigma_k \lambda_k \epsilon_k$ and $R = \Sigma_k \lambda_k R_k$.

Proof: Monotonicity follows immediately from the definitions. If $R_1 \leqslant R_2$ and $S(A:C) \leqslant R_1$, then $S(A:C) \leqslant R_2$. Thus the set $T_\epsilon(\mathcal{E}, R_1)$ is contained in $T_\epsilon(\mathcal{E}, R_2)$ and $M_\epsilon(\mathcal{E}, R_1) \geqslant M_\epsilon(\mathcal{E}, R_2)$.

To prove joint convexity, let ϵ_k, R_k and λ_k be as in the statement of the lemma and assume that $E_k \in T_{\epsilon_k}(\mathcal{E}, R_k)$. Furthermore, suppose that the encoding maps E_k map into orthogonal sectors

C_k of the classical register C. We construct an encoding map with information rate $R \leqslant \Sigma_k \lambda_k R_k$ and fidelity $\epsilon \leqslant \Sigma_k \lambda_k \epsilon_k$ by applying the map E_k with probability λ_k. The first inequality follows from the fact that the sectors C_k are orthogonal:

$$S(A:C) = \sum_k \lambda_k S(A:C_k) \leqslant R. \tag{26}$$

The decoding map for the new encoding consists of first determining which sector C_k was used and then applying the decoding map corresponding to E_k. The output of the encoding-decoding scheme will, therefore, be the average of the outputs of the individual schemes, yielding $1-\epsilon \geqslant \Sigma_k \lambda_k (1-\epsilon_k)$ by the concavity of the fidelity. Finally, if we define $S_k(A:B|C)$ to be the conditional quantum mutual information for the encoding map E_k, then we can calculate the value for the new scheme,

$$S(A:B|C) = \sum_k \lambda_k S_k(A:B|C). \tag{27}$$

Since $M_\epsilon(\mathcal{E},R) \leqslant S(A:B|C)$ by definition and this inequality must hold for all encoding maps E_k, we can conclude that $M_\epsilon(\mathcal{E},R) \leqslant \Sigma_k \lambda_k M_\epsilon(\mathcal{E},R_k)$. □

The particular usefulness of the M_ϵ function derives from an additivity property with respect to the input ensemble given in the next lemma, a property that can be converted into a single-letter lower bound on $Q^*(R)$.

Lemma 3.2: For any ensemble $\mathcal{E}$, numbers $R, \epsilon \geqslant 0$ and non-negative integer n,

$$M_\epsilon(\mathcal{E}^{\otimes n}, nR) \geqslant n M_\epsilon(\mathcal{E},R). \tag{28}$$

Proof: To begin, recall that $I = i_1 i_2 \cdots i_n$ and decompose A into $A_1 A_2 \cdots A_n$, with $|i_k\rangle$ stored on A_k. We will frequently make use of the notation $A_{<k} = A_1 A_2 \cdots A_{k-1}$ and the analogous $I_{<k} = i_1 i_2 \cdots i_{k-1}$, as well the similar $A_{>k}$ and $I_{>k}$. For a fixed $E \in T_\epsilon(\mathcal{E}^{\otimes n}, nR)$, the chain rule for mutual information (cf. Appendix C of Ref. 13) implies that

$$S(A:B|C) = \sum_{k=1}^{n} S(A_k:B|C,A_{<k}). \tag{29}$$

The bulk of the proof will consist of definitions for the purpose of interpreting the individual summands in the chain rule in terms of single-copy encoding maps. Consider one such term, $S(A_k:B|C,A_{<k})$, which we can express as

$$S(A_k:B|C,A_{<k}) = \sum_{I_{<k},j} p(I_{<k},j) \chi(\mathcal{E}_{I_{<k},j}), \tag{30}$$

where $\mathcal{E}_{I_{<k},j}$ is the ensemble of states

$$\mathcal{E}_{I_{<k},j} = \left\{ \sum_{I_{>k}} p(I_{>k}) \omega_{I,j}, q_{I_{<k}}(i_k|j) \right\}, \tag{31}$$

with

$$q_{I_{<k}}(i_k|j) = \frac{\Sigma_{I_{>k}} p(i_k) p(I_{>k}) p(j|I)}{\Sigma_{I_{\geqslant k}} p(I_{\geqslant k}) p(j|I)}. \tag{32}$$

Now define the encoding map $E_{I_{<k}}$ on the ensemble $\mathcal{E}$ to be

$$E_{I_{<k}}(i_k) := \sum_{I_{>k}} p(I_{>k}) E(I) = \sum_{I_{>k}} \sum_j p(I_{>k}) p(j|I) \omega_{I,j} \otimes |j\rangle\langle j|. \tag{33}$$

The output of $E_{I_{<k}}$ on the quantum register is described by the set of ensembles $\mathcal{E}_{I_{<k},j}$. Next, define the decoding map $D_k = \mathrm{Tr}_{\neq k} \circ D$ and the fidelity

$$F_{I_{<k}} := 1 - \epsilon_{I_{<k}} := \sum_{i_k} p(i_k) F(\rho_{i_k}, (D_k \circ E_{I_{<k}})(i_k)). \tag{34}$$

We can then calculate that

$$\begin{aligned}
\sum_{I_{<k}} p(I_{<k}) F_{I_{<k}} &= \sum_{I_{<k}} p(I_{<k}) \sum_{i_k} p(i_k) F(\rho_{i_k}, (D_k \circ E_{I_{<k}})(i_k)) \\
&= \sum_{I_{\leqslant k}} p(I_{\leqslant k}) F\left(\rho_{i_k}, \mathrm{Tr}_{\neq k} D\left(\sum_{I_{>k}} p(I_{>k}) E(I) \right) \right) \\
&= \sum_{I_{\leqslant k}} p(I_{\leqslant k}) F\left(\sum_{I_{>k}} p(I_{>k}) \rho_{i_k}, \sum_{I_{>k}} p(I_{>k}) (\mathrm{Tr}_{\neq k} \circ D \circ E)(I) \right) \\
&\geqslant \sum_I p(I) F(\mathrm{Tr}_{\neq k} \rho_I, (\mathrm{Tr}_{\neq k} \circ D \circ E)(I)) \\
&\geqslant \sum_I p(I) F(\rho_I, (D \circ E)(I)) \geqslant 1 - \epsilon.
\end{aligned} \tag{35}$$

The first three lines are by definition and using linearity to shuffle the terms. The first inequality comes from the joint concavity of the fidelity, the second from its monotonicity under partial trace, and the last from the fidelity condition on $D \circ E$.

Therefore, if we write $j(E_{I_{<k}})$ for the random variable representing the classical output of the encoding map $E_{I_{<k}}$ and $R_{I_{<k}}$ for the corresponding mutual information, then $E_{I_{<k}} \in T_{\epsilon_{I_{<k}}}(\mathcal{E}, R_{I_{<k}})$. Defining $R_k := \Sigma_{I_{<k}} p(I_{<k}) R_{I_{<k}}$ for the average classical information and applying the joint convexity of M then finally yields

$$S(A_k : B|C, A_{<k}) \geqslant M_\epsilon(\mathcal{E}, R_k). \tag{36}$$

A simple calculation allows us to bound the R_k from above; however,

$$\sum_k R_k = \sum_k \sum_{I_{<k}} p(I_{<k}) H(i_k : j(E_{I_{<k}})) \tag{37}$$

$$= \sum_k S(A_k : C|A_{<k}) \tag{38}$$

$$= S(A : C) \leqslant nR. \tag{39}$$

Combining Eqs. (36) and (39) with the chain rule, and applying the convexity of M one more time gives the simple inequality

$$S(A : B|C) \geqslant \sum_k M_\epsilon(\mathcal{E}, R_k) \geqslant n M_\epsilon(\mathcal{E}, R). \tag{40}$$

Since this lower bound must hold for all encoding maps in $T_\epsilon(\mathcal{E}^{\otimes n},R)$, that concludes the proof of the lemma. □

B. Perfect encodings and their properties

Within the set $T_0(\mathcal{E},R)$ of encoding maps with *perfect* fidelity decodings there is a particularly simple subset, in terms of which we will phrase our final bound on $Q^*(R)$. Let $T(\mathcal{E},R)\subset T_0(\mathcal{E},R)$ be the set of all encoding maps E of the form

$$E(i)=|\varphi_i\rangle\langle\varphi_i|^B\otimes\sum_j p(j|i)|j\rangle\langle j|^C. \tag{41}$$

In other words, $T(\mathcal{E},R)$ consists of the encoding maps in which a perfect copy of the state to be compressed is placed in register B. The decoding map is simply to trace over the register C. While such encodings, which simply reproduce the input, are obviously useless for compression, they turn out to be quite sufficient for minimizing $S(A:B|C)$. Indeed, let us define

$$M(\mathcal{E},R)=\inf\{S(A:B|C):E\in T(\mathcal{E},R)\} \tag{42}$$

$$=\inf_{p(\cdot|\cdot)}\{S(A:B|C):S(A:C)\leqslant R\}. \tag{43}$$

By construction, this optimization is no longer over general CPTP maps but only over different possible conditional probability distributions on register C.

Let us collect a few properties of M for later use: First of all, M inherits the convexity of M_ϵ in the variable R. Also, it is clearly nonincreasing, and $M(\mathcal{E},0)=S(\mathcal{E})$ is immediate from the definition. Furthermore, for any choice of $p(\cdot|\cdot)$, we have

$$S(A:C)+S(A:B|C)=S(A:BC)\geqslant S(A:B)=S(\mathcal{E}), \tag{44}$$

from which we conclude that $R+M(\mathcal{E},R)\geqslant S(\mathcal{E})$. This, together with the convexity, implies continuity in R, and the estimates

$$M(\mathcal{E},R)\geqslant M(\mathcal{E},R+\delta)\geqslant M(\mathcal{E},R)-\delta. \tag{45}$$

In what follows, it will also frequently be helpful to use the following fact:

Proposition 3.3:

$$M(\mathcal{E},R)=\inf_{p(\cdot|\cdot)}\{S(A:B|C):S(A:C)=R\}, \tag{46}$$

with an equality condition in the infimum [rather than the inequality of Eq. (43)].

The proof is given in the Appendix, Sec. 1.

In principle one might envisage a limit with larger and larger classical register C. This would constitute a serious obstacle to calculating $M(\mathcal{E},R)$ and carrying through our larger program of evaluating $Q^*(R)$. Fortunately, the next proposition ensures that the range of j's we need to consider in the definition of $M(\mathcal{E},R)$ is bounded universally. Since the mutual informations involved are continuous, the infimum in the definition of $M(\mathcal{E},R)$ can be replaced by a minimum.

Proposition 3.4: In the definition of $M(\mathcal{E},R)$ given in Eq. (43), it suffices to consider encodings of the form Eq. (41) with at most $(m+1)$ j values, where m is the number of states in $\mathcal{E}$.

The proof is given in the Appendix, Sec. 2.

C. Completing the lower bound

Returning to the main argument, we are now prepared to relate $M(\mathcal{E},R)$ to the trade-off curve:

Theorem 3.5: *If a source $\mathcal{E}$ can be visibly compressed to Q qubits per signal and R classical bits per signal, then $Q \geq M(\mathcal{E},R)$. Equivalently, $Q^*(R) \geq M(\mathcal{E},R)$.*

Proof: By the definition of compression and the previous lemma, we note that, for all $\epsilon, \delta > 0$, the inequality $Q^*(R) \geq M_\epsilon(\mathcal{E}, R+\delta)$ must hold. We will give a proof that M_ϵ is continuous at $\epsilon = 0$, from which the stronger lower bound in terms of $M(\mathcal{E},R)$ will follow.

So, fix ϵ, δ for now and suppose that $E \in T_\epsilon(\mathcal{E}, R+\delta)$. Let D be the decoding map associated to E. As usual,

$$E(i) = \sum_j \omega_{i,j}^B \otimes p(j|i)|j\rangle\langle j|^C. \tag{47}$$

For a given j value, the decoding map will produce the ensemble of states $\{\sigma_{i,j}, p(i|j)\}$ where $\sigma_{i,j} = D(\omega_{i,j}^B \otimes |j\rangle\langle j|^B)$. Therefore, applying Markov's inequality (cf. Lemma 6.3 of Ref. 13) and the fidelity condition in the definition of $T_\epsilon(\mathcal{E},R)$, the probability weight of the j's with

$$\sum_i q(i|j) F(\varphi_i, \sigma_{i,j}) \geq 1 - \sqrt{\epsilon} \tag{48}$$

is at least $1-\sqrt{\epsilon}$. In other words, for these good j values, the output of the decoding map is close to $\mathcal{E}_j$. Therefore, for these same good j values, by the monotonicity and continuity of χ, we must have

$$\chi(\mathcal{E}_j) \geq S\left(\sum_i q(i|j) |\varphi_i\rangle\langle\varphi_i| \right) - f(\epsilon), \tag{49}$$

where we may choose $f(\epsilon) = 4(\sqrt[4]{\epsilon} \log d - \sqrt[4]{\epsilon} \log(2\sqrt[4]{\epsilon}))$ (as shown in Appendix A of Ref. 13). Consequently,

$$S(A:B|C) = \sum_j q_j \chi(\mathcal{E}_j) \geq \sum_j q_j S\left(\sum_i q(i|j) |\varphi_i\rangle\langle\varphi_i| \right) - f(\epsilon). \tag{50}$$

Since $f(\epsilon) \to 0$ as $\epsilon \to 0$ we conclude that $\lim_{\epsilon \downarrow 0} M_\epsilon(\mathcal{E}, R+\delta) = M_0(\mathcal{E}, R+\delta)$ and, moreover, in the limit $\epsilon \to 0$ it suffices to consider encoding maps of the type

$$E(i) = |\varphi_i\rangle\langle\varphi_i|^B \otimes \sum_j p(j|i) |j\rangle\langle j|^C. \tag{51}$$

Thus we obtain $Q^*(R) \geq M(\mathcal{E}, R+\delta)$, for all $\delta > 0$, which, by Eq. (45) above yields our claim.□

Remark: The estimate $f(\epsilon)$ above may also be derived using Fannes' inequality,[20] which states that for density operators ρ and σ on a d-dimensional space,

$$\|\rho - \sigma\|_1 \leq \epsilon \Rightarrow |S(\rho) - S(\sigma)| \leq d\, \eta(\epsilon/d). \tag{52}$$

where

$$\eta(x) = \begin{cases} -x \log x & \text{for } x \leq \frac{1}{4}, \\ \frac{1}{2} & \text{for } x > \frac{1}{4}. \end{cases} \tag{53}$$

We will use this inequality again later. □

D. On alternative definitions

Inspecting the proofs of Lemma 3.2 and Theorem 3.5 reveals that we do not actually need the block-based fidelity condition

$$\langle F\rangle := \sum_I p_I F(\varphi_I, (D\circ E)(I)) \geqslant 1-\epsilon \tag{54}$$

of Eq. (8), but only the weaker mean letterwise fidelity

$$\langle \overline{F}\rangle := \sum_I p_I \overline{F}_I \geqslant 1-\epsilon, \tag{55}$$

where

$$\overline{F}_I := \frac{1}{n}\left[\sum_{k=1}^{n} F(\varphi_{i_k}, (\mathrm{Tr}_{\neq k}\circ D\circ E)(I))\right]. \tag{56}$$

By the monotonicity of the fidelity under partial traces, the latter is directly implied by the former.

The lower bound Eq. (35) is then replaced by $1-\epsilon_k$, with $(1/n)\,\Sigma_k \epsilon_k = \epsilon$, and we conclude, instead of Eq. (36), that

$$S(A_k:B|C,A_{<k}) \geqslant M_{\epsilon_k}(\mathcal{E},R_k). \tag{57}$$

The remaining argument is only altered at Eq. (40):

$$S(A:B|C) \geqslant \sum_{k=1}^{n} M_{\epsilon_k}(\mathcal{E},R_k) \geqslant n M_{\epsilon}(\mathcal{E},R), \tag{58}$$

using joint convexity once more.

Hence, we could define the function $\overline{M}_{\epsilon}(\mathcal{E},R)$ in a fashion analogous to $M_{\epsilon}(\mathcal{E},R)$ but using the fidelity function $\overline{F}$ instead of F and Lemma 3.2 would continue to hold for the new function. In fact, $\overline{M}_{\epsilon}(\mathcal{E},R)$ will be strictly additive, in the sense that

$$\overline{M}_{\epsilon}(\mathcal{E}^{\otimes n}, nR) = n\overline{M}_{\epsilon}(\mathcal{E},R), \tag{59}$$

because any single-letter encoding with fidelity $1-\epsilon$ repeated n times gives rise to an n-block coding with mean letterwise fidelity $1-\epsilon$.

We also note at this stage that we could have opted for a slightly more sophisticated definition of the quantum resource of the encoding. In particular, if we introduce $\mathrm{qsupp}_j = (1/n)\log \mathrm{Rank}\,\mathcal{E}_j$ as the minimal number of qubits per signal required to support the conditional ensemble $\mathcal{E}_j$, then we could have defined the quantum rate of the encoding map as

$$\overline{\mathrm{qsupp}} = \sum_j q_j \mathrm{qsupp}_j\,. \tag{60}$$

In this picture, the quantum resource would be the average over classical j values of the minimal number of qubits per signal required to support the quantum portion of the encoded state $E_n(I)$. Such a definition, by treating the classical and quantum storage requirements differently, allows the possibility of variable-length quantum encodings, where the length is a function of the classical message j. Such encodings could potentially be more powerful than the encodings with fixed-sized quantum supports used to define the original qsupp. However, because $\mathrm{qsupp}_j \geqslant \chi(\mathcal{E}_j)$, the analog of Eq. (23) continues to hold. (For a more detailed investigation of the properties of such variable-length quantum memories, see Ref. 21.) More precisely,

$$n\overline{\mathrm{qsupp}} \geqslant S(A:B|C). \tag{61}$$

Therefore, the lower bound of Theorem 3.5 on the trade-off curve $Q^*(R)$ would apply equally well if we had defined $Q^*(R)$ using $\overline{\text{qsupp}}$ instead of qsupp.

Thus, while replacing either F by $\overline{F}$ or qsupp by $\overline{\text{qsupp}}$ in the definition of compression could potentially have reduced the resource requirements, we find that our lower bounds would apply to the modified definitions. Since we will see later in the article that the lower bounds are achievable using the original, restrictive formulation of compression, we can conclude that no advantage can be gained by relaxing the definitions to use $\overline{F}$ and $\overline{\text{qsupp}}$.

IV. ACHIEVING THE LOWER BOUND $M(\mathcal{E},R)$

Recall that the trade-off function $Q^*(R)$ gives the minimal quantum resource Q^* qubits per letter that is sufficient to encode arbitrarily long strings with arbitrarily high fidelity $1-\epsilon$ for any $\epsilon>0$, given a classical resource of R bits per letter. On the other hand, the lower bound $M(\mathcal{E},R)$ is defined as the minimal quantum resource for a particular kind of *single*-letter *perfect* fidelity (i.e., $\epsilon=0$) encoding given in Eq. (51), subject to the constraint that the classical *mutual information* $S(A:C)$ between i and j is R. Hence in the latter case, the classical resource will generally exceed R bits per letter. Thus by implementing the simple encodings of Eq. (51) we can attain $M(\mathcal{E},R)$ as the quantum resource but not generally with a classical resource bounded by R. We now argue that, nevertheless, the classical resource can be reduced to R while retaining the quantum resource at $M(\mathcal{E},R)$ i.e., that the lower bound $M(\mathcal{E},R)$, to $Q^*(R)$ is attainable, so we must then have $Q^*(R)=M(\mathcal{E},R)$.

Our strategy intuitively is the following. We think of the conditional distribution $p(j|i)$ with mutual information $S(A:C)$ in Eq. (51) as a noisy channel from i to j. Then the reverse Shannon theorem[22] states that this noisy channel can be simulated with a noiseless channel of capacity $S(A:C)$ if the receiver and sender have shared randomness, i.e., in the presence of shared randomness, the classical resource can be reduced to $R=S(A:C)$ bits per letter. Finally, we show that only $O(\log n)$ bits of shared randomness suffice to provide a high fidelity encoding-decoding scheme for blocks of length n. Hence this amount of shared randomness can be included in the classical resource of the encoding with asymptotically vanishing cost per letter.

To make the above intuitions mathematically rigorous, we begin by recalling some basic facts from the theory of typical sequences[23,24] and typical subspaces[12,25] in the following two subsections.

A. Typical sequences

For a sequence $I=i_1\cdots i_n\in\mathcal{I}^n$ define the *type* P_I of I as its empirical distribution of letters, i.e.,

$$P_I(i):=\frac{1}{n}N(i|I):=\frac{1}{n}\left|\{k|i_k=i\}\right|. \tag{62}$$

The number of types of sequences is polynomial in n: it is $\binom{n+|\mathcal{I}|-1}{|\mathcal{I}|-1}\leqslant(n+1)^{|\mathcal{I}|}$.

The *type class* $\mathcal{T}_P$ of P is the set of all sequences with type P:

$$\mathcal{T}_P:=\{I\in\mathcal{I}^n|P_I=P\}. \tag{63}$$

Consider now any probability distribution P on $\mathcal{I}$, and let $\delta>0$. Then the set of *typical sequences* (with respect to the distribution P and δ) is

$$\mathcal{T}_{P,\delta}:=\{I\in\mathcal{I}:\forall i\left|P_I(i)-P(i)\right|\leqslant\delta/\sqrt{n}\}. \tag{64}$$

Note that this set is a union of certain type classes.

The following are standard facts:[23,24]

$$P^{\otimes n}(\mathcal{T}_{P,\delta}) \geqslant 1 - \frac{1}{\delta^2}, \tag{65}$$

$$(n+1)^{-|\mathcal{I}|} \exp(n(H(P))) \leqslant |\mathcal{T}_P|, \tag{66}$$

$$\exp(n(H(P))) \geqslant |\mathcal{T}_P|, \tag{67}$$

$$(n+1)^{-|\mathcal{I}|} \exp(n(H(P) - |\mathcal{I}|\,\eta(\delta/\sqrt{n}))) \leqslant |\mathcal{T}_{P,\delta}|, \tag{68}$$

$$(n+1)^{|\mathcal{I}|} \exp(n(H(P) + |\mathcal{I}|\,\eta(\delta/\sqrt{n}))) \geqslant |\mathcal{T}_{P,\delta}|. \tag{69}$$

Note that the latter two follow from the former two by the following well–known explicit estimate on the difference of two entropies[23] [this being a classical case of the Fannes inequality, Eq. (52)]: if P and Q are probability distributions on a set of k elements, then

$$\|P - Q\|_1 \leqslant \epsilon \Rightarrow |H(P) - H(Q)| \leqslant k\,\eta\left(\frac{\epsilon}{k}\right), \tag{70}$$

where the function η is given in Eq. (53).

For sequences $I \in \mathcal{I}^n$, $J \in \mathcal{J}^n$, the *conditional type* $W_{J|I}$ of J (conditional on I) is defined as the stochastic matrix given by

$$\forall ij \quad P_I(i) W_{J|I}(j|i) = P_{IJ}(ij), \tag{71}$$

where P_{IJ} is the joint type of $IJ = (i_1 j_1, \ldots, i_n j_n)$. It is undetermined if $P_I(i) = 0$.

The *conditional type class* of W given I is defined as

$$\mathcal{T}_W(I) := \{J : W_{J|I} = W\} = \{J : \forall ij \quad P_{IJ}(ij) = P_I(i) W(j|i)\}. \tag{72}$$

Let W be now an arbitrary stochastic matrix and $\delta > 0$. The *set of conditionally typical sequences* of W given I is defined as

$$\mathcal{T}_{W,\delta}(I) := \{J : \forall ij \,|\, W_{J|I}(j|i) - W(j|i)| \leqslant \delta/\sqrt{N(i|I)}\}. \tag{73}$$

Again, there are a couple of standard facts:

$$W_I(\mathcal{T}_{W,\delta}(I)) \geqslant 1 - \frac{|\mathcal{I}|}{\delta^2}, \tag{74}$$

for the product distribution $W_I = W_{i_1} \otimes \cdots \otimes W_{i_n}$, and

$$(n+1)^{-|\mathcal{I}||\mathcal{J}|} \exp(nH(W|P_I)) \leqslant |\mathcal{T}_W(I)|, \tag{75}$$

$$\exp(nH(W|P_I)) \geqslant |\mathcal{T}_W(I)|, \tag{76}$$

$$(n+1)^{-|\mathcal{I}||\mathcal{J}|} \exp(n(H(W|P_I) - |\mathcal{I}||\mathcal{J}|\,\eta(\delta|\mathcal{I}|/\sqrt{n}))) \leqslant |\mathcal{T}_{W,\delta}(I)|, \tag{77}$$

$$(n+1)^{|\mathcal{I}||\mathcal{J}|} \exp(n(H(W|P_I) + |\mathcal{I}||\mathcal{J}|\,\eta(\delta|\mathcal{I}|/\sqrt{n}))) \geqslant |\mathcal{T}_{W,\delta}(I)|, \tag{78}$$

where $H(W|P_I)$ is just the conditional Shannon entropy $\Sigma_i P_I(i) H(W(\cdot|i))$.

B. Typical subspaces

The concepts in the previous subsection translate straightforwardly to their Hilbert space versions via the following recipe:

For a state ρ choose a diagonalization $\rho=\Sigma_{i\in\mathcal{I}}r_i|e_i\rangle\langle e_i|$, with eigenvectors $|e_i\rangle$ and eigenvalues r_i, which define a probability distribution on $\mathcal{I}$. Then we have a diagonalization of $\rho^{\otimes n}$:

$$\rho^{\otimes n}=\sum_{I\in\mathcal{I}} r_I|e_I\rangle\langle e_I|, \tag{79}$$

with

$$|e_I\rangle=|e_{i_1}\rangle\otimes\cdots\otimes|e_{i_n}\rangle, \tag{80}$$

$$r_I=r_{i_1}\cdots r_{i_n}. \tag{81}$$

Now for any subset $\mathcal{A}\subset\mathcal{I}^n$ we can define the subspace spanned by the vectors $\{|e_I\rangle: I\in\mathcal{A}\}$, which is most conveniently described by the subspace projector

$$\Pi_{\mathcal{A}}:=\sum_{I\in\mathcal{A}}|e_I\rangle\langle e_I|. \tag{82}$$

In this way we can define, for any distribution P on $\mathcal{I}$,

$$\Pi_P:=\sum_{i\in\mathcal{T}_P}|e_I\rangle\langle e_I|, \tag{83}$$

(note that this is not uniquely specified by the distribution P alone, but also requires specification of the basis $|e_i\rangle$), and

$$\Pi_{\rho,\delta}:=\sum_{i\in\mathcal{T}_{r,\delta}}|e_I\rangle\langle e_I|. \tag{84}$$

Statements on the cardinality of sets translate into statements on the dimension of the corresponding subspaces (i.e., rank, or equivalently, trace, of the projectors).

Similarly, if we have states W_i with diagonalizations $W_i=\Sigma_j W(j|i)|e_{j|i}\rangle\langle e_{j|i}|$, we can define, for any subset $\mathcal{A}\subset\mathcal{J}^n$ and $I\in\mathcal{I}^n$,

$$\Pi_{\mathcal{A}}(I):=\sum_{J\in\mathcal{A}}|e_{J|I}\rangle\langle e_{J|I}|. \tag{85}$$

This leads to the concept of *conditional typical subspace projector*, for $\delta\geqslant 0$,

$$\Pi_{W,\delta}(I):=\sum_{J\in\mathcal{T}_{W,\delta}}|e_{J|I}\rangle\langle e_{J|I}|, \tag{86}$$

and again probability and cardinality statements about the typical sequences translate into equivalent statements about certain traces.

In particular we shall use the following estimate of the rank of the conditional typical subspace projector:

$$\mathrm{Tr}\Pi_{\rho,\delta}(I)\leqslant(n+1)^{|\mathcal{I}|d}\exp(n(S(\rho|P_I)+|\mathcal{I}|d\,\eta(\delta|\mathcal{I}|/\sqrt{n}))). \tag{87}$$

[Here we make use of the notation $S(\rho|P_I):=\Sigma_i S(W_i)$ in an attempt to match the statements about typical sequences as closely as possible.] We'll also use the important probability estimate

$$\mathrm{Tr}(W_I\mathcal{T}_{W,\delta}(I))\geqslant 1-\frac{|\mathcal{I}|}{\delta^2}. \tag{88}$$

C. Trade-off coding

We will use the coding technique that is summarized in the following proposition. The statement is slightly more technical and the estimates more explicit than we would need to prove our main Theorem 4.4. This is because we will reuse it in Secs. VI and X.

Proposition 4.1: For a probability distribution p on $\mathcal{I}$ and a classical noisy channel $p(\cdot|\cdot):\mathcal{I}\to\mathcal{J}$ consider the tripartite state

$$\rho=\sum_i p_i|i\rangle\langle i|^A\otimes|\varphi_i\rangle\langle\varphi_i|^B\otimes\sum_j p(j|i)|j\rangle\langle j|^C.$$

Then there exists a visible code (E,D) such that

$$\forall I\in\mathcal{T}_{p,\delta}\quad F(|\varphi_I\rangle\langle\varphi_I|,(D\circ E)(I))\geqslant 1-\frac{4|\mathcal{I}||\mathcal{J}|}{\delta^2},$$

and having classical and quantum resources

$$nS(A:C)+nK|\mathcal{I}||\mathcal{J}|\eta(\delta/\sqrt{n})+K'|\mathcal{I}||\mathcal{J}|\log(n+1)\quad classical\ \ bits,$$

$$nS(A:B|C)+n\cdot 3d|\mathcal{I}||\mathcal{J}|\eta(2\delta|\mathcal{I}||\mathcal{J}|/\sqrt{n})+d|\mathcal{J}|\log(n+1)\quad quantum\ \ bits,$$

where K and K' are absolute constants.

Proof: We design an n-block code as follows (typicality conditions throughout are with respect to a previously fixed δ):

(a) Encoding:

(1) Given I generate J according to $p(J|I)$.

(2) Compress (i.e., project) the quantum state $|\varphi_I\rangle\langle\varphi_I|$ to the conditional typical subspace $\Pi_{\tilde{\rho}^{IJ},\delta}(J)$, where $\tilde{\rho}_j^{IJ}=\Sigma_i W_{I|J}(i|j)|\varphi_i\rangle\langle\varphi_i|$.

If I is typical and J is conditionally typical, send J and the joint type of I and J as classical data, and send the projected state on $\Pi_{\tilde{\rho}^{IJ},\delta}(J)$ as quantum data.

(b) Decoding:

Given J, one can isometrically embed the quantum state transmitted back into the ambient Hilbert space.

The fidelity of this scheme is analyzed as follows. (We assume that if, at any point of the above protocol, an "if" is not satisfied, then some fixed failure action is taken. Such would be the case when the POVM involving the above subspace projection yields an orthogonal result, for example.) With probability at least $1-|\mathcal{I}|/\delta^2$, J is conditionally typical, and in this case the projection is successful with probability at least $1-|\mathcal{J}|/\delta^2$ [by virtue of Eq. (88)], leaving a state which (cf. Ref. 12) has fidelity $\geqslant 1-2|\mathcal{J}|/\delta^2$ to $|\varphi_I\rangle\langle\varphi_I|$.

Looking at the classical cost of this procedure, we see that it is dominated by sending J, which requires too many, namely $nS(C)$, classical bits. Here the reverse Shannon theorem[22] is invoked. (For a precise statement, see Theorem 4.2 below.) Using this theorem we can simulate the channel p on the typical sequences I sending $nS(A:C)+o(n)$ classical bits, but at the same time needing an amount of shared randomness. The simulation, in fact, has the property that it endows sender and receiver with a common J, the distribution of which is $|\mathcal{I}||\mathcal{J}|/\delta^2$-close to $p(J|I)$. Taking all these points into account, we see that the fidelity of this protocol is at least $1-3|\mathcal{I}||\mathcal{J}|/\delta^2$ for every individual $|\varphi_I\rangle\langle\varphi_I|$ for which I is typical.

The analysis of the quantum resources needed is equally straightforward. By Eq. (87) the number of qubits needed to transmit the projected state is

$$nS(\tilde{\rho}^{IJ}|P_J)+dn|\mathcal{J}|\eta(\delta/\sqrt{n})+d|\mathcal{J}|\log(n+1). \tag{89}$$

Note that the leading term is a conditional von Neumann entropy of the bipartite state

$$\rho=\sum_j \tilde{\rho}_j^{IJ}\otimes P_J(j)|j\rangle\langle j|, \tag{90}$$

which has trace norm distance at most $2\delta|\mathcal{I}||\mathcal{J}|/\sqrt{n}$ from

$$\omega=\sum_{ij} p(i)|\varphi_i\rangle\langle\varphi_i|\otimes p(j|i)|j\rangle\langle j|. \tag{91}$$

(This follows from the typicality of I and conditional typicality of J.) Next, using the Fannes inequality (52), we can upper bound Eq. (89) by

$$nS(\tilde{\rho}|q)+2dn|\mathcal{J}|\eta(2\delta|\mathcal{I}||\mathcal{J}|/\sqrt{n})+dn|\mathcal{J}|\eta(\delta/\sqrt{n})+d|\mathcal{J}|\log(n+1), \tag{92}$$

with $q_j=\Sigma_i P(i)p(j|i)$ and $\tilde{\rho}_j=q_j^{-1}\Sigma_i P(i)p(j|i)|\varphi_i\rangle\langle\varphi_i|$.

We are left with one remaining feature to address: the protocol uses shared randomness (and to a considerable extent, according to Theorem 4.2). We shall now show that we can reduce this requirement to $O(\log n)$ shared random bits using a technique very much like the derandomization argument in Ref. 26. The proof will then be complete because setting up these bits can be absorbed into the classical communication with asymptotically vanishing cost per letter. (Actually, in order to achieve high average fidelity, no random bits are needed at all, but our goal is to prove that high fidelity can be achieved for every state in the typical subspace, a more stringent requirement that is used later in our study of arbitrarily varying sources.)

Observe that a protocol using shared randomness can be viewed as a probabilistic mixture of ordinary, deterministic protocols. Index these by a variable ν, accompanied by a probability x_ν. For each ν we have a corresponding fidelity $F_I(\nu)$ for each individual I. Our construction shows that for typical I,

$$\sum_\nu x_\nu F_I(\nu)\geqslant 1-\frac{3|\mathcal{I}||\mathcal{J}|}{\delta^2}=:\mu. \tag{93}$$

Note that the left hand side is exactly the expectation of the random variable F_I. We now choose $\nu_1,\ldots,\nu_L$ independently and identically distributed (i.i.d.), according to the probabilities x_ν. For fixed I the $F_I(\nu_l)$, $l=1,\ldots,L$ are i.i.d. as well, and in the interval [0, 1]. Thus we can apply the Chernoff–Hoeffding bound for their arithmetic mean (Lemma 4.3 below):

$$\Pr\left\{\frac{1}{L}\sum_{l=1}^{L} F_I(\nu_l)<(1-\epsilon)\mu\right\}\leqslant\exp\left(-L\frac{\epsilon^2\mu}{2\ln 2}\right). \tag{94}$$

By the union bound we can estimate the probability that the above event occurs for a single typical I to be less than or equal to

$$\exp\left(-L\frac{\epsilon^2\mu}{2\ln 2}\right)|\mathcal{I}|^n. \tag{95}$$

Choosing $\epsilon=|\mathcal{I}||\mathcal{J}|/\delta^2$, this bound is itself less than 1 if

$$L>\frac{2\delta^4\ln 2}{|\mathcal{I}|^2|\mathcal{J}|^2\mu}n\log|\mathcal{I}|, \tag{96}$$

in which case we can conclude that there exist values $\nu_1,\ldots,\nu_L$ such that, for all typical I, we have

$$\frac{1}{L}\sum_{l=1}^{L} F_I(\nu_l)\geqslant 1-\frac{4|\mathcal{I}||\mathcal{J}|}{\delta^2}.$$

Therefore, a shared uniform distribution over the numbers $1,\ldots,L$ is sufficient, where L need only satisfy Eq. (96). This can be accomplished with $O(\log n)$ shared random bits, which is what we wanted. □

Here are the auxiliary results we needed in the proof:

Theorem 4.2 (Reverse Shannon Theorem; see Refs. 22 and 27): *For any channel* $W:\mathcal{I}\to\mathcal{J}$, *distribution* P *on* $\mathcal{I}$, *and* $0<\lambda<1$ *there exist maps*

$$E_\nu:\mathcal{I}^n\to\{1,\ldots,M\},$$

$$D_\nu:\{1,\ldots,M\}\to\mathcal{J}^n,$$

$\nu=1,\ldots,N$, *such that*

$$\forall I\in\mathcal{T}_{P,\delta}\quad \frac{1}{2}\left\| W(I)-\frac{1}{N}\sum_{\nu=1}^{N} D_\nu(E_\nu(I))\right\|_1 \leqslant \frac{|\mathcal{I}||\mathcal{J}|}{\delta^2}.$$

Moreover, with an absolute constant K,

$$\log M\leqslant nH(P:W)+nK|\mathcal{I}||\mathcal{J}|\,\eta(\delta/\sqrt{n})+K|\mathcal{I}||\mathcal{J}|\log(n+1),$$

$$\log N\leqslant nH(W|P)+nK|\mathcal{I}||\mathcal{J}|\,\eta(\delta/\sqrt{n})+K|\mathcal{I}||\mathcal{J}|\log(n+1).$$

□

Lemma 4.3 (Chernoff-Hoeffding bound.[28,29]*) Let* $X_1,\ldots,X_L$ *be independent, identically distributed random variables, taking real values in the interval* $[0,1]$, *and with expectation* $\mathbb{E}X_l\geqslant\mu$. *Then, for* $\epsilon>0$,

$$\Pr\left\{\frac{1}{L}\sum_{l=1}^{L} X_l<(1-\epsilon)\mu\right\}\leqslant\exp\left(-L\,\frac{\epsilon^2\mu}{2\ln 2}\right).$$

□

With this we are ready to state our main result:

Theorem 4.4: $Q^*(R)=M(\mathcal{E},R)$.

Proof: The inequality "$\geqslant$" is theorem 3.5. For the opposite inequality choose a $p(\cdot|\cdot)$ such that $S(A:C)\leqslant R$ and $S(A:B|C)\leqslant M(\mathcal{E},R)+\epsilon$. Then, according to Proposition 4.1, there exist n-block codes (E,D) with classical and quantum rates bounded by $R+o(1)$ and $M(\mathcal{E},R)+\epsilon+o(1)$, respectively, which have fidelity $1-\epsilon$ for all *typical* I. But since these carry almost all the probability weight (say, larger than $1-\epsilon$) of all sequences, the fidelity of the scheme is at least $1-2\epsilon$, regardless of what is done on nontypical sequences. As ϵ was arbitrary, we get $Q^*(R)=M(\mathcal{E},R)$. □

Remark: The proof of Proposition 4.1, as the eventual "derandomization" shows, does not use the full power of the reverse Shannon theorem, but only a consequence that is actually also used in rate-distortion coding: that one can map the typical sequences I onto $\exp(nH(P:W)+o(n))$ many J's such that all the pairs $(I,f(I))$ are jointly typical. □

V. EXPLORING THE TRADE-OFF CURVE

In this section we use our formula for the trade-off curve to evaluate $Q^*(R)$ numerically for a selection of particular ensembles chosen to illustrate further important properties of the trade-off function.

To begin, let us consider the simplest possibility, a pair of nonorthogonal states. Figure 2 plots the trade-off curve for the pair $\{|0\rangle,(1/\sqrt{2})(|0\rangle+|1\rangle)\}$, each occurring with probability $\frac{1}{2}$. At first glance, $Q^*(R)$ appears to coincide with the linear upper bound given by interpolating between $(0,S(\mathcal{E}))$ and $(H_2(\frac{1}{2}),0)$. A more detailed examination, however, reveals that the curve is actually

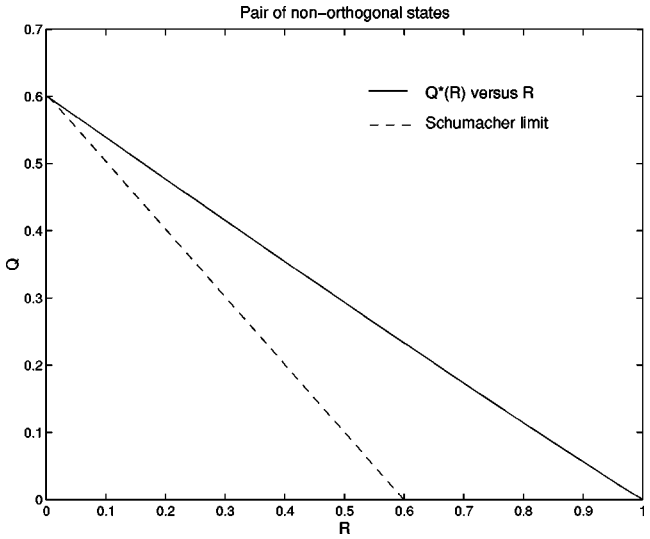

FIG. 2. The trade-off curve for a pair of equiprobable, nonorthogonal states. The dashed line represents the lower bound $Q^*(R)+R \geqslant S(\mathcal{E})$ imposed by the Schumacher limit.

very slightly nonlinear. Therefore, somewhat surprisingly, the simple quantum-classical coding scheme given by timesharing between fully quantum and fully classical coding is nearly optimal but not completely so. As we will see below, this need not always be true.

In general, more complicated ensembles with internal structure will have trade-off curves reflecting that structure. Consider, for example, the three-state ensemble $\mathcal{E}_3$ illustrated in Fig. 3, consisting of the states $|\varphi_1\rangle = |0\rangle$, $|\varphi_2\rangle = (1/\sqrt{2})(|0\rangle + |1\rangle)$ and $|\varphi_3\rangle = |2\rangle$ with equal probabilities. Since the set of states decomposes into two subsets $\mathcal{X}_1 = \{|\varphi_1\rangle, |\varphi_2\rangle\}$ and $\mathcal{X}_2 = \{|\varphi_3\rangle\}$ with mutually orthogonal supports, it is possible to encode whether a given $|\varphi_i\rangle \in \mathcal{X}_1$ or $|\varphi_i\rangle \in \mathcal{X}_2$ efficiently using $H_2(\frac{1}{3})$ classical bits. Indeed, Fig. 4 plots $Q^*(R)$ for this ensemble and we see that the Schumacher limit is achieved for values of $R \leqslant H_2(1/3)$. For values of $R > H_2(\frac{1}{3})$, or once the classical information in the ensemble has been exhausted, the trade-off curve departs from the Schumacher lower bound to meet the point $(H(\frac{1}{3},\frac{1}{3},\frac{1}{3}),0)$.

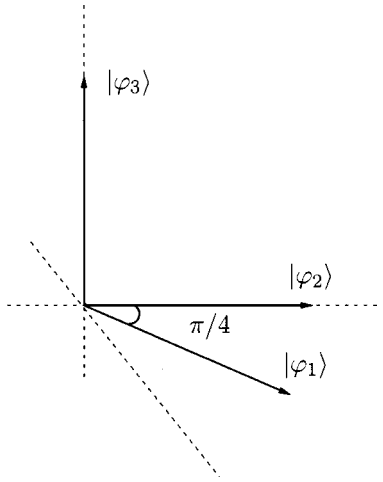

FIG. 3. The three-state ensemble $\mathcal{E}_3$ consists of the states $|\varphi_1\rangle$, $|\varphi_2\rangle$, $|\varphi_3\rangle$ occurring with equal probabilities.

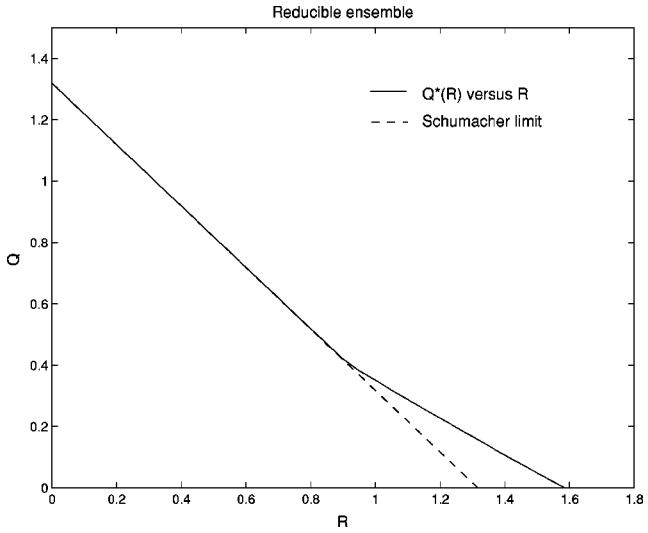

FIG. 4. The trade-off curve for three-state ensemble $\mathcal{E}_3$. The dashed line again represents the Schumacher lower bound, which in this case is achievable for $R \leqslant H(\frac{1}{3})$.

Our third example, the parametrized BB84 ensemble $\mathcal{E}_{BB}(\theta)$ introduced in Sec. II, is an ensemble that, like $\mathcal{E}_3$ above, decomposes naturally into subensembles. On the other hand, unlike for $\mathcal{E}_3$, the subensembles are generally not orthogonal. The trade-off curve for $\theta = \pi/8$ is plotted in Fig. 5. As usual, the dashed lower bound is the Schumacher limit. The dashed-dot line is the piecewise linear upper bound constructed in Sec. II. Squeezed into the intermediate region, we see that $Q^*(R)$ is typically strictly less than the upper bound and, especially in the region $0 < R < 1$, quite strongly curved. The point $(1, H_2(\frac{1}{2}(1+\cos \pi/8))$ provides another surprise: $Q^*(R)$ and the upper bound coincide there. Therefore, the partitioning scheme is optimal if exactly one bit of classical storage is to be consumed per copy but not otherwise.

We now turn to another interesting property of the trade-off curve. Contrary to what one might expect, the function $M(\mathcal{E},R)$ is *not concave in the ensemble*, violating the intuition that it should

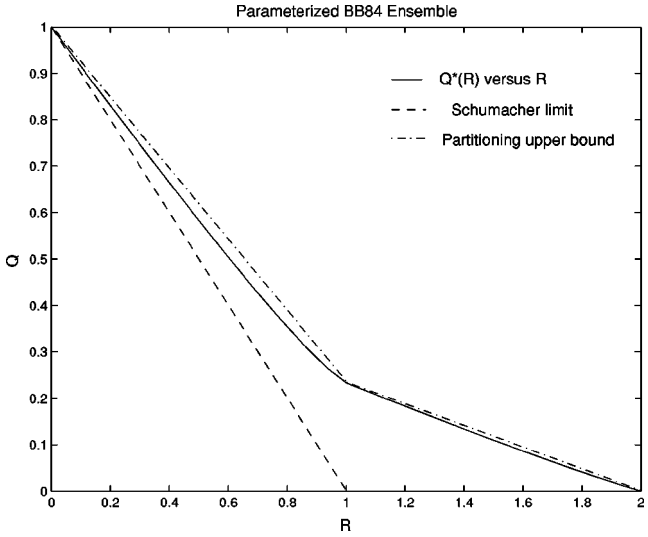

FIG. 5. Trade-off curve for the BB84 ensemble $\mathcal{E}_{BB}(\pi/8)$. The dashed line represents the Schumacher lower bound and the dashed-dot line represents the upper bound from partitioning into the sets $\mathcal{X}_1$ and $\mathcal{X}_2$.

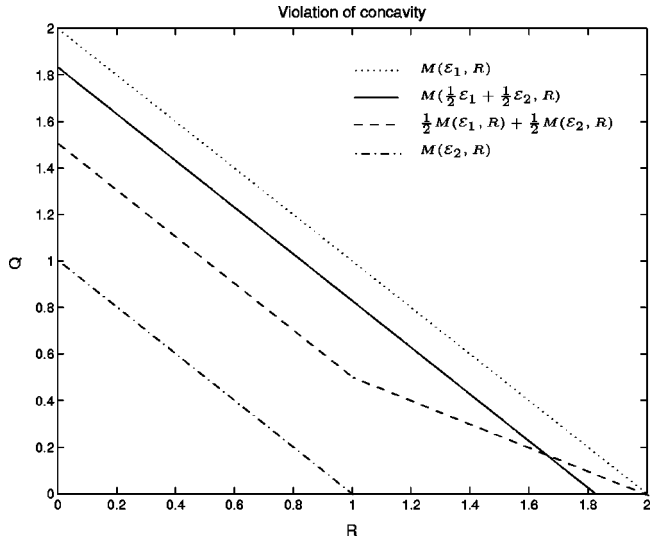

FIG. 6. Violation of concavity in the ensemble. If Q^* were concave in the ensemble, the solid line representing $M(\frac{1}{2}\mathcal{E}_1 + \frac{1}{2}\mathcal{E}_2, R)$ would always exceed the dashed line of $\frac{1}{2}M(\mathcal{E}_1, R) + \frac{1}{2}M(\mathcal{E}_2, R)$. For large values of R we see that is not the case in this example.

be harder to send the mixture of two ensembles than it is to probabilistically send either one. [Note that $M(\mathcal{E},0)$, however, is just the von Neumann entropy $S(\mathcal{E})$ and is, therefore, concave in $\mathcal{E}$.] In fact, counterexamples to concavity can be constructed without even making use of nonorthogonal states. Let $\mathcal{E}_1 = \{|i\rangle, \frac{1}{4}\}_{i=0}^{3}$ be an ensemble consisting of four equiprobable orthonormal states and let $\mathcal{E}_2 = \{|i\rangle, \frac{1}{2}\}_{i=0}^{1}$. We can also consider the mixture of ensembles

$$\mathcal{E} := \tfrac{1}{2}\mathcal{E}_1 + \tfrac{1}{2}\mathcal{E}_2 = \{(|0\rangle, \tfrac{3}{8}), (|1\rangle, \tfrac{3}{8}), (|2\rangle, \tfrac{1}{8}), (|3\rangle, \tfrac{1}{8})\}. \tag{97}$$

Since each of these ensembles is effectively classical, the Schumacher lower bound is attainable and their trade-off curves are just straight lines with slope -1. From there, we can also evaluate $\frac{1}{2}(M(\mathcal{E}_1,R) + M(\mathcal{E}_1,R))$ and compare it to $M(\mathcal{E},R)$. This is done in Fig. 6, revealing a violation of concavity when R comes close to 2.

In the same spirit, note that an analogous construction shows that, while

$$M(\mathcal{E}_1 \otimes \mathcal{E}_2, 2R) \leqslant M(\mathcal{E}_1,R) + M(\mathcal{E}_2,R) \tag{98}$$

always holds, equality (i.e., the natural ''additivity'' property of M under tensor products) may be violated if the ensembles are sufficiently different from each other. More generally we have the following.

Proposition 5.1:

$$M(\mathcal{E}_1 \otimes \mathcal{E}_2, R) = \min\{M(\mathcal{E}_1,R_1) + M(\mathcal{E}_2,R_2) : R_1 + R_2 = R\}.$$

Also, while $M(\mathcal{E},R)$ may not be concave in the ensemble $\mathcal{E}$, it does obey a weaker condition analogous to Schur concavity.

Proposition 5.2: Let $\mathcal{E} = \{|\varphi_i\rangle, p_i\}$ be an ensemble. Let $\{a_k\}$ be a set of probabilities with corresponding unitary operators U_k and $\mathcal{F}$ be the ensemble $\mathcal{F} = \{U_k|\varphi_i\rangle, p_i a_k\}$. Then $M(\mathcal{E},R) \leqslant M(\mathcal{F},R)$.

The proofs of these propositions can be found in Appendix Secs. 3 and 4, respectively.

As our last example, we include the trade-off curve for the uniform (unitarily invariant) ensemble on a single qubit as Fig. 7. Devetak and Berger[30] actually calculated an explicit parametrization of the optimal trade-off curve for a restricted class of encodings. Our lower bound of

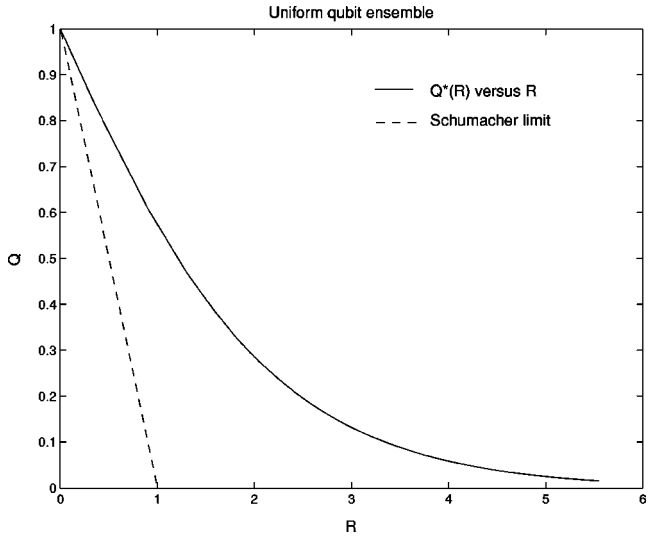

FIG. 7. Trade-off curve for the uniform qubit ensemble. Note that the curve never reaches the $Q=0$ axis, encoding the fact that no finite amount of classical information is sufficient to perfectly transmit an arbitrary qubit state.

Theorem 3.5, or, rather, its infinite source ensemble variant, Theorem 10.1, proves that their construction is optimal within all possible quantum-classical coding strategies. Thus, we can quote their result that, for $\lambda \in (0,\infty)$,

$$R = \frac{\lambda}{\epsilon^{\lambda}-1} - 1 + \log\left(\frac{\lambda e^{\lambda}}{\epsilon^{\lambda}-1}\right), \tag{99}$$

$$Q^*(R) = H_2\left(\frac{1}{\lambda} - \frac{1}{e^{\lambda}-1}\right), \tag{100}$$

gives a parametrization of $Q^*(R)$. This curve will also play an important role when we construct a probability-free version of our main result in Sec. VI. We will find that, in an extremely strong sense, it describes the cost of a qubit in classical bits.

VI. ARBITRARILY VARYING SOURCES

Our main result does not yet say, however, what a qubit costs in bits because it only supplies the trade-off curve $Q^*(R)$ for a given set of quantum states once a set of prior probabilities have been prescribed. Without the probabilities, the curve is undefined and the rate of exchange between bits and qubits cannot be uniquely identified. However, using the theory of *arbitrarily varying sources (AVS)* (see Ref. 31 for an exposition of this concept in classical information theory), we can develop a probability-independent version of our trade-off curve that will eliminate the ambiguity.

Throughout this section, let $\mathcal{E}$ denote not an ensemble, but just a set of states, and let $\mathbf{P} \subset \mathcal{P}_{\mathcal{E}}$ be a subset of probability distributions on $\mathcal{E}$. For each string $I \in \mathcal{I}^n$ of length n we will consider product distributions

$$p^n(I) := p_1(i_1)\cdots p_n(i_n), \tag{101}$$

where each $p_k \in \mathbf{P}$. An *AVS-code of fidelity* $1-\epsilon$ is defined as a visible code, as before (see Definition II), only that now the fidelity condition is required to hold for all probability distributions in $\mathbf{P}$:

$$\forall p^n \in \mathbf{P}^n \quad \sum_I p^n(I) F(\varphi_I, (D \circ E)(I)) \geqslant 1 - \epsilon. \tag{102}$$

The classical and quantum rates are exactly as in Definition 2.3 and, likewise, Definition 2.4 can be used unchanged to characterize attainable rate pairs (R,Q). This leads to the definition of the trade-off function $Q^*(R,\mathbf{P})$ as the minimum Q such that (R,Q) is attainable.

Intuitively, the encoder-decoder pair plays a game against a clairvoyant adversary whose aim is to minimize their average fidelity and who can control the source mechanism so as to create any of the distributions $p^n \in \mathbf{P}^n$. Their goal is to win by keeping the average fidelity above $1-\epsilon$ against arbitrary strategies of the adversary.

A special case is that of $\mathbf{P} = \mathcal{P}_{\mathcal{E}}$, in which case we have no restriction on the source, so that all possible state strings are to maintain high fidelity.

We shall use the notation $M(\mathcal{E},p,R)$ to designate our earlier function M for the ensemble consisting of the states $\mathcal{E}$ and the probabilities p, and define now

$$M(\mathcal{E},\mathbf{P},R) := \sup_{p \in \mathbf{Q}} M(\mathcal{E},p,R), \tag{103}$$

where $\mathbf{Q} := \mathrm{conv}(\mathbf{P})$ is the convex hull of $\mathbf{P}$.

Theorem 6.1: $Q^*(R,\mathbf{P}) = M(\mathcal{E},\mathbf{P},R)$.

Proof: The inequality "$\geqslant$" follows almost directly from Theorem 3.5: only observe that the adversary can simulate any source ensemble $p \in \mathbf{Q}$, and then Theorem 3.5 applies. [More formally, choose a probability distribution s on $\mathbf{P}$ such that $p = \Sigma_k s_k p_k$, and note that averaging Eq. (102) over the measure $s^{\otimes n}$ gives (102) for $p^{\otimes n}$.]

In the other direction, we only need to exhibit a covering of the union of the "probable sets" of the distributions $p^n \in \mathbf{P}^n$ by appropriate sets of typical sequences, and apply Proposition 4.1. This is done as follows:

For $p^n = p_1 \otimes \cdots \otimes p_n \in \mathbf{P}^n$ observe that the set

$$\mathcal{T}_{p^n} := \left\{ I : \forall i \left| N(i|I) - \sum_{k=1}^{n} p_k(i) \right| \leqslant \delta \sqrt{n} \right\} \tag{104}$$

carries (by Chebyshev's inequality) almost all the weight of the distribution:

$$p^n(\mathcal{T}_{p^n}) \geqslant 1 - \delta^{-2}. \tag{105}$$

Since $\mathcal{T}_{p^n}$ is in fact the same as the set of typical sequences $\mathcal{T}_{\overline{p},\delta}$, for $\overline{p} = (1/n)\Sigma_k p_k \in \mathbf{Q}$, the union $\cup_{p^n} \mathcal{T}_{p^n}$ is actually a union of certain type classes, and hence we may choose $\overline{p_1}, \ldots, \overline{p_T}$, $T \leqslant (n+1)^{|\mathcal{I}|}$, such that

$$\mathcal{T} := \bigcup_{p^n \in \mathbf{P}^n} \mathcal{T}_{p^n} = \bigcup_{t=1}^{T} \mathcal{T}_{\overline{p_t},\delta}. \tag{106}$$

The coding is very simple: when $I \in \mathcal{T}$ the encoder chooses t such that $I \in \mathcal{T}_{\overline{p_t},\delta}$. He then communicates t to the decoder, and uses the protocol of Proposition 4.1. (In fact, communication of t is not even necessary, as in the latter protocol the type of I is communicated anyway.) When $I \notin \mathcal{T}$ some fixed default choice is sent.

By construction and by Proposition 4.1, for sufficiently large δ this scheme uses $R+\epsilon$ classical bits and $M(\mathcal{E},\mathbf{P},R)+\epsilon$ qubits per source symbol. For each $p^n \in \mathbf{P}^n$ we obtain high fidelity for all states outside a set of arbitrarily small probability. □

In particular, for the above-mentioned case of no restrictions at all on the probabilities, we get the trade-off function

$$\mathbf{Q}^*(R,\mathcal{P}_{\mathcal{E}}) = \sup_{p\in\mathcal{P}_{\mathcal{E}}} M(\mathcal{E},p,R). \tag{107}$$

which depends only on the states of $\mathcal{E}$. For a finite ensemble it is quite easy to show that $M(\mathcal{E},p,R)$ is continuous in the distribution p. This implies that the suprema in Eqs. (103) and (107) are, in fact, *maxima* (in the former case over the closure of $\mathbf{Q}$).

VII. INFORMATION AND DISTURBANCE

The function $M(\mathcal{E},R)$, in addition to providing the quantum-classical trade-off curve, has a number of other useful interpretations. Recall from Proposition 3.3 that

$$M(\mathcal{E},R) = \inf_{p(\cdot|\cdot)} \{S(A:B|C) : S(A:C) = R\}, \tag{108}$$

with an equality for $S(A:C)$ rather than the inequality we usually use. By the chain rule,

$$S(A:C) + S(A:B|C) = S(A:BC) \tag{109}$$

and $S(A:BC)$ is just the Holevo χ quantity of the ensemble

$$\mathcal{F}^{BC} := \left\{ \varphi_i^B \otimes \sum_j p(j|i)|j\rangle\langle j|^C, p_i \right\}. \tag{110}$$

Therefore, if we define the function $X(\mathcal{E},R) := R + M(\mathcal{E},R)$, then we can rewrite Eq. (108) as

$$X(\mathcal{E},R) = \inf_{p(\cdot|\cdot)} \{\chi(\mathcal{F}^{BC}) : S(A:C) = R\}. \tag{111}$$

The quantity on the right is now perhaps more familiar than the conditional mutual information $S(A:B|C)$: it is a standard measure of the distinguishability present in the ensemble $\mathcal{F}^{BC}$, minimized over all possible ways of including a fixed amount of classical information about the index i in register C. Now suppose that Alice is initially given a state $|\varphi_i\rangle$ from $\mathcal{E}$ (without the name i this time) and, via a CPTP map, manages to extract an amount R of classical information about i without damaging any of the states $|\varphi_i\rangle$. Then her final Holevo χ would necessarily be at least as large as $X(\mathcal{E},R)$, by definition. Typically, however, $X(\mathcal{E},R) > S(\mathcal{E})$ [by the Schumacher lower bound to $Q^*(R) = M(\mathcal{E},R)$], so such an operation will be forbidden by the monotonicity of χ. Therefore, it is impossible for Alice to extract information without disturbing the states.

The simple argument above combined with the additivity of $M_\epsilon(\mathcal{E},R)$ from Sec. III A can be used to prove interesting statements about the trade-off between information gain and state disturbance in an asymptotic and approximate setting. In contrast to the compression problem, however, we can make stronger statements if we use the mean letterwise fidelity measure $\overline{F}$ from Sec. III D instead of the global fidelity measure F. Therefore, we will express our results in terms of the corresponding function $\overline{M}_\epsilon(\mathcal{E}^{\otimes n},nR)$ instead of $M_\epsilon(\mathcal{E}^{\otimes n},nR)$. Recall that these functions are defined identically except that the first uses the mean fidelity function $\overline{F}$ and the second uses the global fidelity F. Likewise, define $\overline{X}_\epsilon(\mathcal{E},R) = R + \overline{M}_\epsilon(\mathcal{E},R)$. Since F and $\overline{F}$ are identical for a single copy, we have $\overline{M}_\epsilon(\mathcal{E},R) = M_\epsilon(\mathcal{E},R)$ and similarly for X and $\overline{X}$. By the discussion in Sec. III D, we know that $\overline{M}_\epsilon(\mathcal{E}^{\otimes n},nR) = n\overline{M}_\epsilon(\mathcal{E},R)$, which in turn implies

$$\overline{X}_\epsilon(\mathcal{E}^{\otimes n},nR) = nX_\epsilon(\mathcal{E},R). \tag{112}$$

Now, generalizing the above single copy argument, suppose that Alice is given a state $|\varphi_I\rangle$ drawn from $\mathcal{E}^{\otimes n}$, which, by a CPTP map Γ, she manages to convert into the state

$$\rho_I = \sum_j \tilde{\varphi}^B_{I,j} \otimes p(j|I)|j\rangle\langle j|^C, \tag{113}$$

with a quantum and classical part such that the mutual information $H(I:j) \geqslant nR$ and the mean letterwise fidelity between Alice's initial states and her final states of system B satisfies

$$\overline{F}(\mathcal{E}^{\otimes n}, \mathrm{Tr}_C \circ \Gamma(\mathcal{E}^{\otimes n})) := \sum_I p_I \frac{1}{n} \sum_{k=1}^{n} F(\varphi_{i_k}, \mathrm{Tr}_{\neq k} \circ \mathrm{Tr}_C(\rho_I)) \geqslant 1 - \epsilon. \tag{114}$$

Writing $\mathcal{F}^{BC} = \{\Gamma(\varphi_I), p_I\}$, the monotonicity of χ guarantees that $nS(\mathcal{E}) \geqslant \chi^{BC}$ and it is easy to see that $\chi^{BC} \geqslant \overline{X}_\epsilon(\mathcal{E}^{\otimes n}, nR)$. By applying Eq. (112), we then find

$$S(\mathcal{E}) \geqslant X_\epsilon(\mathcal{E}, R), \tag{115}$$

in which, conspicuously, all dependence on n has vanished. In other words, in order to maximize her information at a given mean letterwise fidelity, Alice should just repeat the optimal single letter strategy for each position; she need not ever apply any collective operations. Summarizing these observations, we have the following.

Theorem 7.1: *Suppose we have a set of states $|\varphi_I\rangle$ drawn from the ensemble $\mathcal{E}^{\otimes n}$ represented on system B and let Γ be a CPTP map from B to the joint system BC, where C is classical, satisfying the following conditions:*

(1) *$H(I:j) \geqslant nR$, where j is the classical output on system C.*
(2) *The mean letterwise fidelity $\overline{F}(\mathcal{E}^{\otimes n}, \mathrm{Tr}_C \circ \Gamma(\mathcal{E}^{\otimes n})) \geqslant 1 - \epsilon$.*

Then, for each $\epsilon > 0$, the inequality $S(\mathcal{E}) \geqslant X_\epsilon(\mathcal{E}, R)$ holds. Moreover, the Holevo quantity of the ensemble $\mathcal{F}^{BC} = \{\Gamma(\varphi_I), p_I\}$ satisfies the inequality $\chi(\mathcal{F}^{BC}) \geqslant nX_\epsilon(\mathcal{E}, R)$.

□

One application of the theorem is that it provides an alternative method for analyzing the quantum resources required for blind compression, which was the subject of Ref. 13. The idea is simply to think of the map Γ as the composition $D_n \circ E_n$ of the encoding and decoding maps for blocks of size n. (Because classical information can be copied, we can assume without loss of generality that the decoder keeps his classical information around after the decoding stage has been completed.) Now suppose that the scheme has classical mutual information $H(I:j) \geqslant nR$. If it also has mean letterwise fidelity $1 - \epsilon_n$, then, as for the visible case,

$$\mathrm{qsupp} \geqslant \frac{1}{n} \overline{M}_{\epsilon_n}(\mathcal{E}^{\otimes n}, nR) = M_{\epsilon_n}(\mathcal{E}, R). \tag{116}$$

By the previous theorem, however, we must also have the inequality $S(\mathcal{E}) \geqslant X_{\epsilon_n}(\mathcal{E}, R)$. Moreover, if perfect compression is possible asymptotically (using either the block or letterwise fidelity conditions), we get the stronger inequality

$$S(\mathcal{E}) \geqslant \lim_{\epsilon \downarrow 0} X_\epsilon(\mathcal{E}, R) = X_0(\mathcal{E}, R). \tag{117}$$

(The continuity at $\epsilon = 0$ follows from the continuity of M_0, demonstrated earlier.) Because the ensemble $\mathcal{E}$ can always be recovered by tracing over the C register, the monotonicity of χ guarantees that the right hand side is always at least as large as the left, implying $S(\mathcal{E}) = X_0(\mathcal{E}, R)$. We are, therefore, interested in the equality conditions for monotonicity.

Recalling some terminology from Ref. 13, we say an ensemble $\mathcal{E}$ is *reducible* if its states can be partitioned into two nonempty sets with orthogonal supports. An ensemble is said to be irreducible if it is not reducible. Every ensemble, therefore, can be decomposed into orthogonal, irreducible subensembles as

$$\mathcal{E}=\bigcup_{l=1}^{L} a_l\mathcal{E}_l, \tag{118}$$

where a_l is the total probability weight of states in subensemble $\mathcal{E}_l$.

Proposition 7.2: Let $\mathcal{E}=\cup_{l=1}^{L}a_l\mathcal{E}_l$ be a decomposition of the pure-state ensemble $\mathcal{E}$ into irreducible subensembles $\mathcal{E}_l=\{|\varphi_{il}\rangle,p_{i|l}\}$ and let $\mathcal{F}^{BC}=\{\varphi_{il}^B\otimes\omega_{il}^C,a_lp_{i|l}\}$ be a bipartite extension of the ensemble $\mathcal{E}$. Then $S(\mathcal{E})=\chi(\mathcal{F}^{BC})$ if and only if $\omega_{il}=\omega_{jl}$ for all i, j, and l.

A proof is given in the Appendix, Sec. 5. The meaning of the proposition is essentially that the only information that can be stored on register C without increasing χ is the classical information already present on register B, so that ω_{il} must be a function of l alone. Therefore, in order to satisfy Eq. (117) it is necessary that $R\leqslant H(a_1,\ldots,a_L)$. Conversely, provided the inequality holds, it is possible to extract R bits per signal without disturbance at the encoding stage, at which point the encoding scheme we used for visible compression can be used to achieve the quantum rate $S(\mathcal{E})-R$. Putting these observations together, we obtain an alternative demonstration of the main theorem of Ref. 13:

Theorem 7.3: *Let $\mathcal{E}=\cup_{l=1}^{L}a_l\mathcal{E}_l$ be a decomposition of the ensemble $\mathcal{E}$ into orthogonal, irreducible subensembles. Then blind compression of $\mathcal{E}$ to Q qubits per signal plus auxiliary classical storage is possible if and only if*

$$Q\geqslant\sum_l a_lS(\mathcal{E}_l)=S(\mathcal{E})-H(a_1,\ldots,a_L). \tag{119}$$

□

Thus, the techniques we have introduced to analyze the visible compression problem provide a unified framework for analyzing blind compression as well. In fact, we will see in the next section that the trade-off curve for yet another related problem—remote state preparation—can also be calculated using similar methods.

VIII. APPLICATION TO REMOTE STATE PREPARATION

Remote state preparation, introduced in Ref. 17 following a conjecture of Lo's,[16] is very similar to what we have considered here: it is a visible coding problem for quantum states involving classical resources, in the form of communication, and quantum resources, this time in the form of entanglement. Furthermore, these two types of resources can be traded against each other so it is natural to study the optimal trade-off curve.

Without giving formal definitions, let $E^*(R)$ be the minimum rate of entanglement sufficient for a remote state preparation protocol with classical rate R, such that the average fidelity tends to 1 with growing blocklength.

Given that entanglement can be set up using quantum communication at a cost of one qubit per ebit, and that, on the other hand, quantum communication can be accomplished using teleportation[32] at a cost of two cbits and one ebit per qubit, it is clear that coding methods for the one problem immediately yield (possibly suboptimal) procedures for the other. (In fact, by making use of quantum-classical trade-off coding, this resulted in the ''cap-method'' of Ref. 17, which was further refined in Ref. 30.)

In Ref. 33 a method of remote state preparation is developed that works for visible coding of product states and is more efficient than teleportation: we really need only to use *one* cbit and one ebit per qubit, asymptotically.

Theorem 8.1 (See Ref. 33): *Given a finite set $\mathcal{X}$ of states (density operators) on $\mathcal{K}$, there is a probabilistic exact (one-shot) remote state preparation protocol working for all states in $\mathcal{X}$ and with failure probability uniformly ϵ, using a maximally entangled state $|\Phi\rangle$ on $\mathcal{K}\otimes\mathcal{K}$ and classical communication of a message out of*

$$M \leqslant 1 + \frac{2\ln 2}{\epsilon^2} \log(2|\mathcal{X}|\dim\mathcal{K})\dim\mathcal{K}.$$

□

This leads immediately to the following.

Theorem 8.2: *For the source* $\mathcal{E}=\{|\varphi_i\rangle,p_i\}$ *of quantum states, if* $R\geqslant 0$ *and* $Q=Q^*(R)$, *then* $E^*(R+Q)\leqslant Q$.

As a consequence, we obtain

$$E^*(R) \leqslant N(\mathcal{E},R) := \min_{p(\cdot|\cdot)} \{S(A:B|C) : S(A:BC) \leqslant R\},$$

minimization over the same set of tripartite states as in the definition of M.

Proof: We apply Theorem 8.1 to the space $\mathcal{K}$ of *encoded states* of an optimal trade-off coding using R cbits and Q qubits per source symbol, and to the set of all possible encoded states: note that $|\mathcal{X}| \leqslant (|\mathcal{I}||\mathcal{J}|)^n$.

By that result, we need Q ebits to do this, and an additional $Q+o(1)$ cbits to the R cbits from the trade-off coding. □

In fact, in Ref. 33 it is shown, by methods very similar to those in Sec. III, that the above estimate for E^* is in fact an equality, and that our AVS considerations also carry over.

Theorem 8.3: *For the state set* $\mathcal{E}$ *and AVS* $\mathbf{P}$,

$$E^*(R,\mathbf{P}) = \sup_{p\in\mathbf{Q}} N(\mathcal{E},p,R),$$

with $\mathbf{Q}=\mathrm{conv}(\mathbf{P})$. □

For $\mathbf{P}$ the set of all distributions on the pure states (as indeed for any symmetric family of distributions) we can prove symmetry results like those in the upcoming Sec. IX, and arrive at the conclusion that the *absolute trade-off* between cbits and ebits in remote state preparation is given by the curve $N(\mathcal{P}(\mathcal{H}),u)$, where u is the uniform (i.e., unitarily invariant) measure on the set $\mathcal{P}(\mathcal{H})$ of all pure states on $\mathcal{H}$. Devetak and Berger[30] arrived at a slightly different curve as an upper bound to the true trade-off, starting from $M(\mathcal{P}(\mathcal{H}),u)$ as we did, but employing teleporation instead of the newer technique in Theorem 8.1. For this reason their conjecture that their bound is tight is not correct.

IX. SYMMETRY IN THE ENSEMBLE

Our formulas for the trade-off curve, both in the known and arbitrarily varying source case, can be considerably simplified if there is symmetry in the set of states.

Assume that there is a group G acting on the labels i of the states by a projective unitary representation U_g,

$$\forall g\in G, i\in\mathcal{I} \quad |\varphi_{gi}\rangle\langle\varphi_{gi}| = U_g|\varphi_i\rangle\langle\varphi_i|U_g^\dagger. \tag{120}$$

(We will present the following arguments for a finite group, but they also apply to compact groups: in fact, we only need the existence of an invariant measure, see Ref. 34.) The action of G on $\mathcal{I}$ induces an action on the probability distributions on $\mathcal{I}$ in a natural way: if $p\in\mathcal{P}(\mathcal{I})$ is a distribution, then $p^g(i)=p(g^{-1}i)$ defines the translated distribution. Assume now further that the arbitarily varying source $\mathbf{P}$ is stable under this induced action:

$$\forall p\in\mathbf{P} \quad p^g\in\mathbf{P}. \tag{121}$$

[In the "known source" case, $\mathbf{P}=\{p\}$, this simply means that $p(gi)=p(i)$ for all $i\in\mathcal{I}$ and $g\in G$.]

By the formula for the trade-off curve, Eq. (103), we may assume that $\mathbf{P}$ is convex. Letting

$$\mathbf{P}^G := \{p \in \mathbf{P} : \forall g \in G\, p^g = p\}, \tag{122}$$

we can then prove the following.

Theorem 9.1: *For any G-invariant state set and AVS* $\mathbf{P}$,

$$M(\mathcal{E},\mathbf{P},R) = M(\mathcal{E},\mathbf{P}^G,R). \tag{123}$$

Proof: The lhs is by definition greater than or equal than the rhs.

For the opposite inequality we make use of the ''restricted concavity'' given in proposition 5.2. For the rotations U_g applied with equal probabilities to the ensemble $(\mathcal{E},p)$, we get

$$M\left(\bigcup_g U_g \mathcal{E} U_g^\dagger, \frac{1}{|G|}\sum_g p^g, R\right) \geqslant \frac{1}{|G|} M(U_g \mathcal{E} U_g^\dagger, p^g, R) = M(\mathcal{E},p,R). \tag{124}$$

Note that $(1/|G|)\,\Sigma_g p^g \in \mathbf{P}^G$ and, since the state set is G invariant, we have $\cup_g U_g \mathcal{E} U_g^\dagger = \mathcal{E}$, which proves our claim. □

If G acts *transitively*, this leads to a dramatic simplification of the formula for the AVS trade-off curve (Theorem 6.1): in this case the only G-invariant distribution is the uniform distribution, so from Theorem 6.1 we obtain the following.

Corollary 9.2: For an AVS $(\mathcal{E},\mathbf{P})$ *with transitive group action under which* $\mathbf{P}$ *is stable, (e.g., for* $\mathbf{P}=\mathcal{P}_\mathcal{E}$*), we have*

$$Q^*(R,\mathbf{P}) = M(\mathcal{E},u,R),$$

where u is the uniform distribution on $\mathcal{E}$. □

The particular example of $\mathcal{E}$ being the set of all pure states on $\mathcal{H}$ and $\mathbf{P}$ being the set of all distributions on $\mathcal{E}$ is arguably the setting for *the* trade-off between classical and quantum bits: the trade-off coding becomes a statement solely about states, with no mention of prior probabilities. Of course we have not yet justified the application of our results to infinite state sets. The corresponding but more involved treatment of the coding bounds will be given in Sec. X.

Given this generalization to infinite state sets, we conclude that the *absolute trade-off* for pure states on $\mathcal{H}$ is given by $M(\mathcal{P}(\mathcal{H}),u)$, with the uniform (i.e., unitarily invariant) measure u on the set $\mathcal{P}(\mathcal{H})$ of all pure states. The Devetak-Berger curve introduced earlier corresponds to the case $\mathcal{H}=\mathbb{C}^2$.

Remark: From the proof of Theorem 9.1, we see that we may always restrict the classical encodings $p(\cdot|\cdot)$ to be group covariant as well, in the sense that, for each $j \in \mathcal{J}$, the distribution $q(\cdot|j)$ has the property that for each $g \in G$ there exists a j' satisfying $q_{j'} = q_j$ and $q(gi|j) = q(i|j')$ for all $i \in \mathcal{I}$:

Define a new encoding p' by letting

$$p'(j,g|gi) := \frac{1}{|G|} p(j|i). \tag{125}$$

For a G-invariant distribution p on the ensemble states this does not change the values of $S(A:C)$ and $S(A:B|C)$. However, the resulting probabilities $q'_{j,g} = q_j$ and $q'(gi|j,g) = p_i p(j|i)/q'_{j,g}$ have a useful property: there is a group action of G on the indices (j,g) under which the distribution q' is invariant, and the set of conditional distributions $q'(\cdot|j,g)$ is stable. More precisely, h acts on (j,g) by $h\cdot(j,g) = (j,hg)$. Obviously, q' is invariant under this, and

$$q'(gi|h\cdot(j,g)) = q'(gi|j,hg) = q'(h^{-1}hgi|j,gh), \tag{126}$$

saying that $q'(\cdot|h\cdot(j,g)) = (q'(\cdot|j,hg))^h$.

Hence, when discussing optimal codings given by q_j and $q(\cdot|j)$ such that $\Sigma_j q_j q(\cdot|j) = p$, we may always assume that G also acts on the set of j's, and that

$$\forall j \forall g \quad q_{gj} = q_j \text{ and } q(\cdot|gj) = (q(\cdot|j))^g. \tag{127}$$

□

We close this section by giving a bound on the size of the classical register for a finite ensemble with symmetry, which sometimes improves our earlier result in Proposition 3.4:

Proposition 9.3: Let the group G act on the ensemble $\mathcal{E}=\{\varphi_i, p_i\}_{i\in\mathcal{I}}$ in the way described at the beginning of this section, and assume that p is G-invariant. If the group action partitions $\mathcal{I}$ into t G-orbits, then for every R there exists a classical encoding $p(\cdot|\cdot):\mathcal{I}\to\mathcal{J}$ which is covariant in the above sense, and satisfies

$$|\mathcal{J}| \leq |G|(t+1), \quad S(A:C) \leq R, \quad S(A:B|C) = M(\mathcal{E},R).$$

In fact, $\mathcal{J}$ partitions into $t+1$ G-orbits, in the sense described above.

The proof is given in the Appendix, Sec. 6

Example: Let $\mathcal{E}$ consist of any two states: $\mathcal{E}=\{|\varphi_i\rangle\}_{i=1}^2$. By choosing a reflection that swaps $|\varphi_1\rangle$ and $|\varphi_2\rangle$, we get a transitive $\mathbb{Z}_2$ action on the indices i. Therefore, for the AVS $(\mathcal{E},\mathcal{P}_\mathcal{E})$, we have $Q^*(R,\mathbf{P})=M(\mathcal{E},u,R)$, where u is the uniform distribution $p_i=\frac{1}{2}$. This distribution is clearly G-invariant, so Proposition 9.3 ensures that there is an optimal encoding for which $\mathcal{J}$ partitions into at most $t+1=2$ orbits, each of size either 1 or 2. □

Example: For states in the BB84 ensemble $\mathcal{E}_{BB}(\theta)$, the group $\mathbb{Z}_2\times\mathbb{Z}_2$ acts transitively via reflection along the $\theta/2$ axis and rotation by $\pi/2$. Therefore, once again, the unrestricted AVS can be reduced to the uniform ensemble, for which the optimal encoding can be assumed G-covariant, with $\mathcal{J}$ partitioning into at most two orbits of length 1, 2 or 4. □

X. INFINITE SOURCE ENSEMBLES

It should be noted that, even in the technical parts of our proofs, and, indeed, in the very statements of the *coding theorems*, we assumed that the sets of states under consideration were *finite*.

As there are interesting examples of ensembles with infinite state sets, including perhaps most notably the whole manifold of pure states in a Hilbert space, we show here how a certain approximation technique (used in Ref. 25 to deal with coding for nonstationary quantum channels) can be used to transfer our main results quite directly. The procedure, unfortunately, is not entirely painless; we have to go through the proof of Proposition 4.1 again with a modified and more technical version of the typical subspace. That is why we have chosen to treat the infinite source case separately, confining the details to this section.

A. Formulation of information quantities and the lower bound

To be able to consider infinite ensembles and encodings, we have to reformulate our notions from Secs. II and III in terms of general measure spaces (for the background and terminology see any textbooks on probability, such as Ref. 35, and measure theory[34]):

The source ensemble $\mathcal{E}$ is described by a measure space Ω (with probability measure P), and a measurable map $\varphi:\Omega\to\mathcal{P}(\mathcal{H})\subset\mathcal{S}(\mathcal{H})$ from Ω into the set of pure states on the Hilbert space $\mathcal{H}$ (which is still of finite dimension d), mapping $\omega\in\Omega$ to $|\varphi_\omega\rangle\langle\varphi_\omega|$. We can then easily define encoding and decoding (E,D) for blocks of length n:

$$E:\Omega^n\to\mathcal{S}(\mathcal{H}_B)\times\Omega_C, \tag{128}$$

$$D:\mathcal{B}(\mathcal{H}_B)\otimes\mathcal{B}(\ell^2(\Omega_C))\to\mathcal{B}_d^{\otimes n}, \tag{129}$$

where E is a Markov kernel, Ω_C is a *finite set*, and D is CPTP. The quantification of classical and quantum resources we adopt unchanged, and the fidelity condition reads as follows: the combined encoding and decoding gives rise to a Markov kernel

$$D\circ E:\Omega^n\to\mathcal{B}_d^{\otimes n}, \tag{130}$$

and, using the abbreviation

$$(D\circ E)(\omega_1\cdots\omega_n)=\int_{\mathcal{B}(\mathcal{H}_B)}(D\circ E)(\mathrm{d}\sigma|\omega_1\cdots\omega_n)\sigma, \tag{131}$$

we require that

$$F=\int_{\Omega^n}P^{\otimes n}(\mathrm{d}\omega_1\cdots\omega_n)F(\varphi_{\omega_1\cdots\omega_n},(D\circ E)(\omega_1\cdots\omega_n))\geqslant 1-\epsilon. \tag{132}$$

Let us denote by μ the measure induced by P and this Markov kernel on $\Omega\times\mathcal{S}(\mathcal{H}_B)\times\Omega_C$:

$$\mu(F_A\times G_{BC}):=\int_{F_A}P(\mathrm{d}\omega)E(G_{BC}|\omega). \tag{133}$$

We denote its restrictions (marginals) to factors $\Omega_A=\Omega$, $\mathcal{S}(\mathcal{H}_B)$, Ω_C by $P=\mu_A$, μ_B, $q:=\mu_C$, respectively, and analogously μ_{AC}, etc.

With the help of Radon–Nikodym derivatives we can always construct the Bayesian ''inverse'' Markov kernel

$$q:\Omega_C\to\Omega_A\times\mathcal{S}(\mathcal{H}_B) \tag{134}$$

that gives rise to the same joint distribution:

$$\int_{G_C}\mu_C(\mathrm{d}j)q(F_{AB}|j)=\mu(F_{AB}\times G_C). \tag{135}$$

In fact, μ_C-almost everywhere,

$$q(F_{AB}|j)=\frac{\mathrm{d}\mu(F_{AB}\times\{j\})}{\mathrm{d}\mu_C(j)}. \tag{136}$$

To follow the procedure of Sec. III we have to define the relevant information quantities (for their properties, see Refs. 36 and 37):

First, $S(A:C)$ can be expressed as $D(\mu_{AC}\|\mu_A\otimes\mu_C)$, in terms of the relative entropy (or Kullback–Leibler divergence) of two measures

$$D(\mu\|\lambda):=\int\mu(\mathrm{d}x)\log\left(\frac{\mathrm{d}\mu(x)}{\mathrm{d}\lambda(x)}\right), \tag{137}$$

where $\mathrm{d}\mu(x)/\mathrm{d}\lambda(x)$ denotes the Radon–Nikodym derivative. If this does not exist μ-almost everywhere, we define $D(\mu\|\lambda)=\infty$. It is a fact that in Eq. (137) the Radon–Nikodym derivative always exists, and it can be checked that in the finite case the new definition coincides with the old.

Second, $S(A:B|C)=\int_{\Omega_C}q(\mathrm{d}j)S(A:B|C=j)$, with $S(A:B|C=j)$ denoting the quantum mutual information associated to the conditional probability measure $q(\cdot\,|j)$ on $\Omega_A\times\mathcal{S}(\mathcal{H}_B)$: for any such distribution λ, with first marginal λ_A and Markov kernel $L:\Omega_A\to\mathcal{S}(\mathcal{H})$,

$$S_\lambda(A:B)=S\left(\int_{\mathcal{S}(\mathcal{H})}\lambda_B(\mathrm{d}\sigma)\sigma\right)-\int_{\Omega_A}\lambda_A(\mathrm{d}\omega)S\left(\int_{\mathcal{S}(\mathcal{H})}L(\mathrm{d}\sigma|\omega)\sigma\right). \tag{138}$$

Again, it is possible to check that for discrete probability spaces we obtain the same expressions as before.

The proofs of Lemmas 3.1 and 3.2 and of Theorem 3.5 are directly adapted to this language, essentially replacing all sums representing probability averages by integrals. (Note that even the "continuity in ϵ" part in the latter applies as the functions f and g depend only on ϵ and d.) This is possible since the monotonicity and convexity properties we used are still true in the infinite setting.

At the end of the proof we arrive at encodings mapping $\omega\in\Omega$ to $|\varphi_\omega\rangle\langle\varphi_\omega|\otimes\Sigma_j p(j|\omega)|j\rangle\times\langle j|$ (i.e., the corresponding Markov kernel maps i to the point mass at $|\varphi_\omega\rangle\langle\varphi_\omega|$ times a discrete measure on Ω_C). Such encodings we denote "$p:\Omega_A\to\Omega_C$," and we get

$$Q^*(R)\geqslant \inf_{p:\Omega_A\to\Omega_C,|\Omega_C|<\infty}\{S(A:B|C):S(A:C)\leqslant R\}. \tag{139}$$

Dropping the finiteness of Ω_C can only decrease the lower bound, and we arrive at the following general version of Theorem 3.5:

Theorem 10.1: *For the ensemble* $\mathcal{E}=(\Omega,P,\varphi)$,

$$Q^*(R)\geqslant M(\mathcal{E},R):=\inf_{p:\Omega_A\to\Omega_C}\{S(A:B|C):S(A:C)\leqslant R\},$$

with

$$S(A:C)=D(\mu\|P\otimes q),$$

$$S(A:B|C)=\int_{\Omega_C}q(\mathrm{d}j)S\left(\int_{\Omega_A}q(\mathrm{d}\omega|j)|\varphi_\omega\rangle\langle\varphi_\omega|\right),$$

where μ *is the measure on* $\Omega_A\times\Omega_C$ *induced by* P *and the Markov kernel* $p(\cdot|\cdot)$, q *is its marginal on* Ω_C *and* $q(\cdot|\cdot)$ *is the Bayesian Markov kernel* $\Omega_C\to\Omega_A$. □

B. Adaptation of the coding theorem

The obstacles to an application of our coding scheme, Proposition 4.1, are the potentially infinite range of the source register (Ω) and the classical encoding (Ω_C). Of course, when in the previous subsection we allowed the latter to be infinite, we only made M smaller, and at that point it was not clear that this was a good move.

The purpose of the present subsection is to show that it is possible to approximate the effect of an infinite encoding by a strictly finite one: finitely many possible states on $\mathcal{H}$ and finitely many classical symbols. This will inevitably introduce some error, which we will have to counter by a suitably adapted notion of typical subspace.

Lemma 10.2: For $\epsilon>0$ *there exists a partition of* $\mathcal{S}(\mathcal{H})$ *into* $m\leqslant C(d)\epsilon^{-d^2}$ *Borel sets each of which has radius at most* ϵ*: in each part* $\mathcal{S}_i$ *there exists a state* σ_i *such that for all* $\rho\in\mathcal{S}_i$, $\|\rho-\sigma_i\|_1\leqslant\epsilon$. *The constant* $C(d)$ *depends only on* d.

Proof: The set of states on $\mathcal{H}$ is affinely isomorphic to the set of positive complex $d\times d$-matrices with trace 1, which is contained in the set of self-adjoint complex matrices with all d^2 real and imaginary parts of entries in the interval $[-1,1]$: this is a d^2-dimensional hypercube. This can be partitioned into $(2\sqrt{2}d^3)^{d^2}\epsilon^{-d^2}$ many small hypercubes of edge length $\epsilon/(d^3\sqrt{2})$. It is easy to check that for any ρ,σ in the same small cube, $\|\rho-\sigma\|_1\leqslant\epsilon$. □

For a source (Ω,P,φ) such a partition entails a partition $\mathcal{Z}$ of Ω into at most m measurable pieces Z_i, with $\omega_i\in Z_i$ such that $|\varphi_{\omega_i}\rangle\langle\varphi_{\omega_i}|=\sigma_i$. (We need only consider pieces that intersect the image of φ.) A central role will be played by the "contraction" of the infinite ensemble $\mathcal{E}$ to the finite ensemble $\mathcal{E}'=\{\varphi_{\omega_i},\hat{P}(i)=P(Z_i)\}$ which is obtained by identifying all of Z_t to the single state φ_{ω_i}.

We have already defined the set of $\hat{P}$-typical sequences $\mathcal{T}_{\hat{P},\delta}$, and now can define the following typical set for P:

$$\mathcal{T}^{\mathcal{Z}}_{P,\delta} := \bigcup_{I \in \mathcal{T}_{P,\delta}} Z_{i_1} \times \cdots \times Z_{i_n}. \tag{140}$$

It obviously inherits the large probability property of $\mathcal{T}_{p',\delta}$:

$$P^{\otimes n}(\mathcal{T}^{\mathcal{Z}}_{P,\delta}) \geq 1 - \frac{1}{\delta^2}. \tag{141}$$

Before we can describe the coding scheme we have to introduce a variant of the conditional typical sequences and subspaces: for a channel $W:\mathcal{I} \to \mathcal{J}$ and $\delta, \epsilon > 0$ define

$$\mathcal{T}^{(\epsilon)}_{W,\delta}(I) := \{J : \forall ij \, |N(ij|IJ) - N(i|I)W(j|i)| \leq \delta\sqrt{N(i|I)} + \epsilon N(i|I)\}. \tag{142}$$

(Our previous notion is recovered with $\epsilon = 0$, and in the sequel ϵ will be small, compared to δ which we shall choose large.) Observe that this is a union of conditional type classes. Using Eq. (78) it is quite easy to show that

$$\begin{aligned} |\mathcal{T}^{(\epsilon)}_{W,\delta}(I)| &\leq (n+1)^{|\mathcal{I}||\mathcal{J}|} \exp\left(nH(W|P_I) + \sum_i N(i|I)|\mathcal{J}|\, \eta(\epsilon + \delta N(i|I)^{-1/2}) \right) \\ &\leq (n+1)^{|\mathcal{I}||\mathcal{J}|} \exp(nH(W|P_I) + n|\mathcal{J}|\, \eta(\epsilon) + n\, \eta(\delta|\mathcal{I}|/\sqrt{n})), \end{aligned} \tag{143}$$

where we have used the inequality $\eta(x+y) \leq \eta(x) + \eta(y)$ and concavity of η.

Similarly, for a collection of states W_i, which we endow with fixed diagonalizations $W_i = \sum_{j=1}^{d} W(j|i)|e_{j|i}\rangle\langle e_{j|i}|$, we can define the projector

$$\Pi^{(\epsilon)}_{W,\delta}(I) := \sum_{J \in \mathcal{T}^{(\epsilon)}_{W,\delta}(I)} |e_{J|I}\rangle\langle e_{J|I}|, \tag{144}$$

and get from Eq. (143) the estimate

$$\mathrm{Tr}\Pi^{(\epsilon)}_{W,\delta}(I) \leq (n+1)^{d|\mathcal{I}|} \exp(nH(W|P_I) + nd\, \eta(\epsilon) + n\, \eta(\delta|\mathcal{I}|/\sqrt{n})). \tag{145}$$

Its other most important property that we shall use is the following: consider a product state $\sigma = \sigma_1 \otimes \cdots \otimes \sigma_n$ such that, with some $I = i_1 \cdots i_n$,

$$\forall i \quad \left\| \frac{1}{N(i|I)} \sum_{k: i_k = i} \sigma_k - W_i \right\|_1 \leq \epsilon. \tag{146}$$

Then we claim that

$$\mathrm{Tr}(\sigma \Pi^{(\epsilon)}_{W,\delta}(I)) \geq 1 - \frac{|\mathcal{I}|}{\delta^2}. \tag{147}$$

The proof goes as follows: the left hand side above does not change if we replace σ_k by $\sigma'_k := \sum_j |e_{j|i_k}\rangle\langle e_{j|i_k}|\sigma_k|e_{j|i_k}\rangle\langle e_{j|i_k}|$, because the projector is a sum of one-dimensional projectors $|e_{J|I}\rangle\langle e_{J|I}|$. Thus we may assume that σ_k has diagonal form in the chosen eigenbasis of W_{i_k}: $\sigma_k = \sum_j S_k(j)|e_{j|i_k}\rangle\langle e_{j|i_k}|$.

Note that the left hand side of Eq. (147) can be rewritten as $(S_1 \otimes \cdots \otimes S_n)(\mathcal{T}^{(\epsilon)}_{W,\delta}(I))$, a classical probability. Now it is immediate from the definition of the latter set [Eq. (142)] and from the condition (146) on σ that

$$\mathcal{T}^{(\epsilon)}_{W,\delta}(I) \supset \mathcal{T}_{S,\delta}(I), \tag{148}$$

with the channel $\overline{S}(j|i)=[1/N(i|I)]\,\Sigma_{k:i_k=i}S_k(j)$. Hence

$$(S_1\otimes\cdots\otimes S_n)(\mathcal{T}^{(\epsilon)}_{W,\delta}(I))\geqslant(S_1\otimes\cdots\otimes S_n)(\mathcal{T}^{-}_{S,\delta}(I))\geqslant\left(1-\frac{1}{\delta^2}\right)^{|\mathcal{I}|}\geqslant 1-\frac{|\mathcal{I}|}{\delta^2}, \tag{149}$$

the second line by Chebyshev's inequality.

After these preparations we are ready to prove the infinite source version of Proposition 4.1:

Proposition 10.3: Let $\mathcal{E}=(\Omega_a,P,\varphi)$ be a source. For a probability distribution P on Ω and a Markov kernel $p(\cdot|\cdot):\Omega_A\to\Omega_C$, $\epsilon>0$, there exists a partition $\mathcal{Z}$ of Ω_A into $m-1<C(d)\epsilon^{-d^2}$ measurable sets, corresponding to an ϵ-fine partition of the state space, and for $\delta>0$ a visible code (E,D) such that

$$\forall\,\omega=(\omega_1\cdots\omega_n)\in\mathcal{T}^{\mathcal{Z}}_{P,\delta}\quad F(|\varphi_\omega\rangle\langle\varphi_\omega|,(D\circ E)(\omega))\geqslant 1-\frac{4m^2}{\delta^2}.$$

and sending

$$nS(A:C)+nKm^2\eta(\delta/\sqrt{n})+K'm^2\log(n+1)\quad \textit{classical bits},$$

$$nS(A:B|C)+n(3dm^2\eta(2\delta m^2/\sqrt{n})+3d\eta(\epsilon))+dm\log(n+1)\quad \textit{quantum bits}.$$

Proof: We can find the partition by Lemma 10.2 and the discussion thereafter.

Consider now the (measurable) coarse-graining map

$$T:\omega\mapsto i\in\{1,\ldots,m-1\}\text{for}\ \ \omega\in Z_i\,. \tag{150}$$

Applying T to Ω_A [and the identity map to $\mathcal{B}(\mathcal{H}_B)$ and Ω_C] leads to a new distribution μ' on $\Omega_{A'}\times\mathcal{B}(\mathcal{H}_B)\times\Omega_C$, with $\Omega_{A'}=\{1,\ldots,m-1\}$. By the data-processing inequality[23,37] we have

$$S(A':C)\leqslant S(A:C)\ \text{ and }\ S(A':B|C)\leqslant S(A:B|C). \tag{151}$$

Next we change the quantum part of the encoding by collecting all the weight of a piece Z_i into $\varphi_i:=\varphi_{\omega_i}$: we can do this by a similar coarse-graining map

$$\tilde{T}:\sigma\mapsto|\varphi_i\rangle\langle\varphi_i|\ \text{ for }\ \sigma\in Z_i\,. \tag{152}$$

The resulting distribution will be denoted by μ'': it is supported on a finite set $\Omega_{A'}$ and a finite set of states φ_i (in fact, the "contracted" ensemble $\mathcal{E}'$ of the discussion after Lemma 10.2). It is generated by a Markov kernel $\hat{p}:\Omega_{A'}\to\Omega_C$, which in this case is simply a finite collection of (conditional) distributions $\hat{p}(\cdot|i)$ on Ω_C. Note that this is a valid encoding in the sense of the definition of $M(\mathcal{E}',R)$, in the main section. Let us denote the corresponding conditional quantum mutual information by $S(A':B'|C)$.

By definition of $S(A':B|C)$ and the partition $\mathcal{Z}$, we have

$$S(A':B'|C)\leqslant S(A':B|C)+2d\eta(\epsilon/d), \tag{153}$$

using Fannes' inequality (52) twice.

To end this step-by-step discretization, we may change the encoding to a stochastic matrix $p':\Omega_{A'}\to\{1,\ldots,m\}=:\Omega_{C'}$, by the considerations of Sec. III (see also Proposition 9.3), such that

$$S(A':B'|C')\leqslant S(A':B'|C)\ \text{ and }\ S(A':C')=S(A':C). \tag{154}$$

So, finally, we are in a position to apply the coding method of Proposition 4.1, with the sole difference that we use for the quantum encoding the projector $\Pi^{(\epsilon)}_{p',\delta}(I)$ instead of our previous conditional typical projector, and I is such that $\omega_1\cdots\omega_n\in Z_I$.

The fidelity estimate is obtained just like there, only using Eq. (147). The classical rate estimate we copy from Proposition 4.1, and for the quantum rate estimate, we follow its derivation in the proof, using Eq. (145) to estimate the range of the projectors $\Pi^{(\epsilon)}_{p',\delta}(I)$: we have to send

$$nS(A':B'|C')+n(3dm^2\eta(2\delta m^2/\sqrt{n})+d\eta(\epsilon))+dm\log(n+1) \tag{155}$$

quantum bits, which, by Eqs. (151)–(154), yields our desired estimate. □

This immediately leads to the result that we wanted:

Theorem 10.4: *For any ensemble* $\mathcal{E}=(\Omega,P,\varphi)$,

$$Q^*(R)=M(\mathcal{E},R).$$

Proof: That $M(\mathcal{E},R)$ is a lower bound to Q^* is proved by Theorem 10.1. For its achievability choose $\epsilon>0$ and a Markov kernel p such that both $S(A:C)\leqslant R$ and $S(A:B|C)\leqslant M(\mathcal{E},R)+\epsilon$.

Choose now a partition $\mathcal{Z}$ according to Proposition 10.3, fixing m. Now choose δ large enough, so that according to that proposition a code exists which has fidelity $1-\epsilon$ on a state set of probability $1-\epsilon$, i.e., it has average fidelity $1-2\epsilon$ on the ensemble. By the proposition it has cbit rate $S(A:C)+o(1)$ and qubit rate

$$S(A:B|C)+2\eta(\epsilon)+o(1)\leqslant M(\mathcal{E},R)+2\eta(\epsilon)+\epsilon+o(1), \tag{156}$$

as $n\to\infty$. As ϵ was arbitrary, our claim is proved. □

C. On the AVS in the infinite setting

With the help of the above Proposition 10.3 the case of an arbitarily varying source of an *infinite* ensemble is dealt with easily, in much the same way as we did in the finite case (see Sec. VI):

Formally, of course, an arbitrarily varying source is a triple $(\Omega,\mathbf{P},\varphi)$, where Ω and φ are a measurable space and a measurable map into states, as before, and $\mathbf{P}$ is a set of probability distributions on Ω.

With the definitions of encoding and decoding from Sec. X A we require

$$\forall P^n\in\mathbf{P}^n\int_{\Omega^n}P^{\otimes n}(\mathrm{d}\omega_1\cdots\omega_n)F(|\varphi_\omega\rangle\langle\varphi_\omega|,(D\circ E)(\omega))\geqslant 1-\epsilon. \tag{157}$$

Denoting the trade-off function as $Q^*(R,\mathbf{P})$, we obtain the expected result:

Theorem 10.5: $Q^*(R,\mathbf{P})=M(\mathbf{P},R)$, *with*

$$M(\mathbf{P},R)=\sup_{P\in\mathbf{Q}}M(P,R),$$

where $\mathbf{Q}=\mathrm{conv}(\mathbf{P})$ *is the convex hull of* $\mathbf{P}$.

Proof: The inequality "$\geqslant$" is obvious, like in the finite case: the adversary can certainly always mock up an i.i.d. source $P\in\mathbf{Q}$, hence Theorem 10.1 applies.

For the opposite inequality, we start by choosing an $\epsilon>0$ and a partition $\mathcal{Z}$ according to Proposition 10.3. Every distribution P in $\mathbf{P}$ gives rise to a distribution $\hat{P}\in\mathcal{P}_{m-1}$, and we denote

$$\hat{\mathbf{P}}:=\{\hat{P}:P\in\mathbf{P}\}. \tag{158}$$

Note that, because the map $P\mapsto\hat{P}$ is affine linear, we get $\hat{\mathbf{Q}}=\mathrm{conv}(\hat{\mathbf{P}})$.

Now for $\delta>0$ we introduce again the set

$$\mathcal{T}:=\bigcup_{\hat{P}\in\hat{\mathbf{Q}}}\mathcal{T}_{\hat{P},\delta}, \tag{159}$$

and it is easy to see [compare Eq. (141)] that

$$\mathcal{T}^{\mathcal{Z}} := \bigcup_{I \in \mathcal{T}} Z_{i_1} \times \cdots \times Z_{i_n} \tag{160}$$

carries $1-\delta^{-2}$ of the probability of every $P^n \in \mathbf{P}^n$. On the other hand, because $\mathcal{T}$ is a union of type classes, we can find "few" $\hat{P}_1, \ldots, \hat{P}_T$, $T \leqslant (n+1)^m$ such that the corresponding $\mathcal{T}_{\hat{P}_t,\delta}$ cover $\mathcal{T}$. The coding is very simple: on seeing a state $\varphi_{\omega_1 \ldots \omega_n}$ the encoder finds the index I of the piece Z_I in the partition $\mathcal{Z}^n$ such that $\omega_1 \cdots \omega_n \in Z_I$, and the type of I. If $I \in \mathcal{T}$, he looks up t such that $I \in \mathcal{T}_{\hat{P}_t,\delta}$ and uses the coding scheme of Proposition 10.3 for $\hat{P}_t$. (Note that he needs not even send the type of I as that is part of the protocol of Proposition 10.3.) Choosing δ large enough this recipe gives a code with high fidelity for every $P^n \in \mathbf{P}^n$; by construction and Proposition 10.3, it has rates of $R+o(1)$ cbits and $M(\mathbf{P},R)+f(\epsilon)+o(1)$ qubits, with a function $f(\epsilon)$ that tends to 0 as $\epsilon \to 0$. □

To end this discussion, we would like to point out that a similar treatment of remote state preparation can be done: in fact, as we discussed in Sec. VIII, we always use the "1 ebit $+1$ cbit per qubit" technique (Theorem 8.1) on top of an efficient trade-off coding. To do this for an infinite ensemble one only has to understand that the bound of Theorem 8.1 is strong enough to allow approximation of the set of projected (compressed) product states $\varphi_{\omega_1} \otimes \cdots \otimes \varphi_{\omega_n}$, at negligible additional classical cost.

XI. DISCUSSION AND CONCLUSIONS

Our main result is a simple formula for the trade-off between quantum and classical resources in visible compression. The formula expresses the trade-off curve $Q^*(R)$ in terms of a single-letter optimization over conditional probability distributions of bounded size. This unexpectedly simple resolution places optimal trade-off coding into a small but growing class of problems in quantum information theory whose answers are not only known in principle but can be calculated in practice. (Another notable recent addition is the entanglement-assisted capacity of a quantum channel.[22])

At a conceptual level, for any given ensemble $\mathcal{E}$ of quantum states, $Q^*(R)$ can be thought of as a quantitative description of how "classical" the ensemble is. Any deviation from classicality is captured in the trade-off curve in the form of inefficiency of the classical storage. The amount of information that can be extracted from many copies of $\mathcal{E}$ while causing negligible disturbance, for example, can be read directly off the curve by identifying the point at which classical resources begin to become inefficient as compared to quantum. Much more subtle indicators of classicality are also available in $Q^*(R)$, however. We saw, for instance, that for the parametrized BB84 ensemble, $Q^*(R)$ had a kink at the point corresponding to partitioning the ensemble into nearly orthogonal subensembles.

Going beyond the compression of ensembles, we saw that it is possible to formulate a version of our main result in the setting of arbitrarily varying sources, corresponding to the situation in which the encoder and decoder have only partial or even no knowledge of the distribution of input states. Despite this handicap, compression is frequently still possible and we once again find that the trade-off curve can be calculated via a tractable optimization problem. For ensembles with symmetry, the problem can even often be reduced to calculating $Q^*(R)$ for one particular ensemble. Thus, for any given set of pure states, including the whole manifold of states on a given Hilbert space, these tools allow us to calculate the rate of exchange from qubit storage to classical storage. The answer is given, of course, not in terms of a single number but as the trade-off curve. (Like in any market, the going rate depends on supply.)

Our view that $Q^*(R)$ encodes the balance of quantum and classical information in a given ensemble or set of states is further bolstered by the role it was found to play in optimal remote state preparation. In this context, the minimal amount of classical communication required for any given rate of entanglement consumption can, once again, be read directly off the quantum-

classical trade-off curve. That the comparatively exotic process of remote state preparation should reduce, via Theorem 8.1, to visible compression is a tremendous simplification.

Of course, while we have seen that the results of this article resolve some basic questions about trading different types of resources in quantum information, most related questions remain open. To begin, it is possible to trade entanglement, quantum communication and classical communication all together in a generalized type of remote state preparation. Since our results here describe the two extremes when first entanglement and then quantum communication are not permitted, it seems likely that similar techniques could resolve the full trade-off surface. More ambitiously, one could define channel capacities for noisy quantum channels that interpolate between the fully quantum and classical capacities by studying the usefulness of a channel for simultaneously sending quantum and classical information. The problem analogous to the trade-off question studied here would be to determine the achievable *region* of quantum-classical rate pairs. Unfortunately, given that neither the fully classical nor fully quantum extremes are fully understood, it may be a long time before we develop tools capable of analyzing that problem.

Therefore, to end, we offer two related open problems that are perhaps closer to the realm of the tractable. First, it would be useful to have a set of rules for extracting qualitative features of the trade-off curve, such as the location of any kinks and perhaps more detailed differentiability properties, from the structure of the input states (or ensemble). Second, it would be an interesting challenge to apply the observations of Sec. IX on symmetry to the explicit calculation of the trade-off curve for particular examples and, more generally, to find other approaches to simplifying these calculations.

APPENDIX: PROOFS OF AUXILIARY PROPOSITIONS

1. Proof of Proposition 3.3

Proof: Suppose the classical register C decomposes into parts C_1 and C_2 with corresponding joint density operator

$$\rho^{ABC_1C_2}=\sum_i p_i|i\rangle\langle i|^A\otimes|\varphi_i\rangle\langle\varphi_i|^B\otimes\sum_{j,k} p(i|j,k)|j\rangle\langle j|^{C_1}\otimes|k\rangle\langle k|^{C_2}. \tag{A1}$$

If we define the conditional ensembles $\mathcal{E}_{jk}$ and $\mathcal{E}_j$, then

$$S(A:B|C_1C_2)=\sum_{jk} q_{jk}S(\mathcal{E}_{jk})\leqslant S(A:B|C_1)=\sum_j q_jS(\mathcal{E}_j) \tag{A2}$$

by the concavity of the von Neumann entropy.

Therefore, for any map with $S(A:C_1)<R\leqslant H(p)$, we can always adjoin a second classical register C_2 such that $S(A:C_1C_2)=R$ without increasing the conditional mutual information. □

2. Proof of Proposition 3.4

Proof: W.l.o.g. let $i\in\{1,\ldots,m\}$. The information quantities in the definition of M can be reexpressed as follows:

$$S(A:B|C)=\sum_j q_jS\left(\sum_i q(i|j)|\varphi_i\rangle\langle\varphi_i|\right), \tag{A3}$$

$$S(A:C)=H(p)-\sum_j q_j H(q(\cdot|j)), \tag{A4}$$

with $q_j=\Sigma_i p_i p(j|i)$ and $q_j q(i|j)=p_i p(j|i)$. We read q as a probability distribution on the set $\mathcal{P}_m$ of all probability distributions on $\{1,\ldots,m\}$. Thus the minimization problem in the definition of M can be expressed as finding the infimum of $\Sigma_j q_j S(f(q(\cdot|j)))$ over the set

$$\mathcal{P}(p,R)=\left\{q\text{p.d. on } \mathcal{P}_m : \sum_j q_j q(\cdot|j)=p, \sum_j q_j H(q(\cdot|j))\geqslant H(p)-R\right\},$$

where f is an affine linear function on probability distributions, mapping the distribution p to the quantum state $\Sigma_i p_i|\varphi_i\rangle\langle\varphi_i|$.

Now we argue structurally: the set $\mathcal{P}(p,R)$ is convex (as a subset of an infinite dimensional probability simplex with additional linear inequality constraints), and the aim function is linear. Hence the infimum is an infimum over the extreme points of $\mathcal{P}(p,R)$, which are, by Caratheodory's theorem, distributions q with support at most $m+1$, the number of inequalities that define $\mathcal{P}(p,R)\subset\mathcal{P}(\mathcal{P}_m)$ (see, e.g., Ref. 38). In Sec. IX, Proposition 9.3 and Appendix, Sec. 6, we provide a detailed exposition of a more general form of this result. □

3. Proof of Proposition 5.1

Proof: The "$\leqslant$" inequality follows directly by forming the tensor product of two encodings for $\mathcal{E}_1$ and $\mathcal{E}_2$ with classical rates R_1 and R_2 respectively.

The "$\geqslant$" inequality is shown by choosing an encoding for the tensor product with classical rate R and then using the chain rule several times for subdivisions $A=A_1A_2$ and $B=B_1B_2$ as follows. First observe that

$$R\geqslant S(A_1A_2:C)=S(A_1:C)+S(A_2:C|A_1)=:R_1+R_2 \tag{A5}$$

and then

$$\begin{aligned}
S(A_1A_2:B_1B_2|C)&=S(A_1:B_1B_2|C)+S(A_2:B_1B_2|C,A_1)\\
&\geqslant S(A_1:B_1|C)+S(A_2:B_2|C,A_1)\\
&\geqslant M(\mathcal{E}_1,R_1)+\inf\{S(A_2:B_2|C,A_1):S(A_2:C|A_1)\leqslant R_2\}\\
&\geqslant M(\mathcal{E}_1,R_1)+M(\mathcal{E}_2,R_2)\\
&\geqslant \min\{M(\mathcal{E}_1,R_1)+M(\mathcal{E}_2,R_2):R_1+R_2=R\}.
\end{aligned} \tag{A6}$$

The second last line is seen as follows: in the line above it, the two mutual informations are conditional on A_1, so they both can be written as averages over the values of A_1. Hence the inequality follows by the convexity of M in R. □

4. Proof of Proposition 5.2

Proof: It is sufficient to verify that any encoding operator

$$\rho^{ABC}=\sum_{ik} p_i a_k |i\rangle\langle i|^A\otimes|k\rangle\langle k|^A\otimes U_k|\varphi_i\rangle\langle\varphi_i|U_k^{\dagger B}\otimes\sum_j p(j|i,k)|j\rangle\langle j|^C \tag{A7}$$

for $\mathcal{F}$ gives rise to a valid encoding operator

$$\sigma^{ABC}=\sum_i p_i|i\rangle\langle i|^A\otimes|\varphi_i\rangle\langle\varphi_i|^B\otimes\sum_{jk} p(j|i,k)a_k|j\rangle\langle j|^C\otimes|k\rangle\langle k|^C \tag{A8}$$

for $\mathcal{E}$ satisfying $S_\sigma(A:B|C) \leqslant S_\rho(A:B|C)$ and $S_\sigma(A:C) \leqslant S_\rho(A:C)$. □

5. Proof of Proposition 7.2

Proof: We will first prove the proposition for irreducible $\mathcal{E}$. Using a trick introduced by Holevo,[14] we can reduce the problem further to the case of a two-state ensemble: for an ensemble $\{\rho_i^B \otimes \sigma_i^C, p_i\}$ of states (we assume that all $p_i > 0$) and two specific indices k and l, define a new index

$$j(i) := \begin{cases} i & i \neq k,l, \\ * & i \in \{k,l\}. \end{cases} \tag{A9}$$

(Of course, in the case we have in mind, the ρ_i are the pure states from the ensemble $\mathcal{E}$, and the σ_i are commuting mixed states representing the classical information.) Then consider the multipartite state

$$\Omega = \sum_i p_i |i\rangle\langle i|^{A_1} \otimes |j(i)\rangle\langle j(i)|^{A_2} \otimes \rho_i^B \otimes \sigma_i^C.$$

The definition of $j(i)$ and the familiar chain rule imply

$$S(A_1:BC) = S(A_1A_2:BC) = S(A_2:BC) + S(A_1:BC|A_2). \tag{A10}$$

Note that the second term is an average over the values of $j(i)$ of Holevo quantities for the corresponding reduced ensembles. Therefore, it has only one nonzero contribution, which is

$$S(A_1:BC|A_2) = (p_k + p_l)\chi(\{\rho_i \otimes \sigma_i, p_i/(p_k+p_l)\}_{i=k,l}). \tag{A11}$$

Then, using Eq. (A10) and monotonicity of χ under partial trace repeatedly,

$$\begin{aligned} \chi(\{p_i, \rho_i \otimes \sigma_i\}) = S(A_1:BC) &= S(A_2:BC) + S(A_1:BC|A_2) \\ &\geqslant S(A_2:B) + (p_k+p_l)\chi(\{\rho_i \otimes \sigma_i, p_i/(p_k+p_l)\}_{i=k,l}) \\ &\geqslant S(A_2:B) + (p_k+p_l)\chi(\{\rho_i, p_i/(p_k+p_l)\}_{i=k,l}) \\ &= S(A_2:B) + S(A_1:B|A_2) = S(A_1:B) = \chi(\{\rho_i, p_i\}). \end{aligned}$$

Assuming that the first and the last Holevo quantities have the same value, we must have equality in the third line, implying

$$\chi(\{\rho_i \otimes \sigma_i, q_i\}_{i=k,l}) = \chi(\{\rho_i, q_i\}_{i=k,l}), \tag{A12}$$

with $q_i = p_i/(p_k+p_l)$. Then, applying the general formula

$$\chi(\{\omega_i, p_i\}) = \sum_i p_i D(\omega_i \| \omega) \tag{A13}$$

to Eq. (A12), with $\omega = \Sigma_i p_i \omega_i$ and D the relative entropy function, and using the Lindblad monotonicity once more yields

$$D(\rho_k \otimes \sigma_k \| q_k \rho_k \otimes \sigma_k + q_l \rho_l \otimes \sigma_l) = D(\rho_k \| q_k \rho_k + q_l \rho_l). \tag{A14}$$

(And likewise for l.)

With this we are almost done: invoking a result of Ohya and Petz (see Ref. 37, Theorem 9.12) we conclude that there exists a CPTP map R such that

$$R(\rho_k)=\rho_k\otimes\sigma_k, \tag{A15}$$

$$R(q_k\rho_k+q_l\rho_l)=q_k\rho_k\otimes\sigma_k+q_l\rho_l\otimes\sigma_l, \tag{A16}$$

from which it follows by linearity that

$$R(\rho_l)=\rho_l\otimes\sigma_l. \tag{A17}$$

Since CPTP maps (R and Tr_C) cannot decrease fidelity we thus must have $\rho_k\perp\rho_l$ or $\sigma_k=\sigma_l$.

In the particular case that the initial ensemble is irreducible we conclude that all σ_i must be equal, or else the partial trace over C strictly decreases the Holevo quantity. If the ensemble $\mathcal{E}$ is not irreducible, a simple variation on the previous argument shows that, for each of the irreducible subensembles $\mathcal{E}_l$, $\chi(\mathcal{E}_l)$ must be equal to χ of the corresponding subensemble $\{\varphi_{il}\otimes\sigma_{il},p_{i|l}\}$ of $\mathcal{F}^{BC}$. Applying our conclusions to these subensembles finishes the proof of the proposition. □

6. Proof of Proposition 9.3

Proof: As explained earlier in the proof of Proposition 3.4, any classical encoding map can be viewed as a probability distribution q on the set $\mathcal{P}_\mathcal{I}$ of probability distributions on $\mathcal{I}$ with barycenter p: $p=\Sigma_j q_j q(\cdot|j)$.

Covariance of the encoding means invariance of q under the natural action of G on $\mathcal{P}_\mathcal{I}$, i.e., $g:p\mapsto p^g$. Hence for each distribution p in the support of q we must have all the p^g in the support as well. On the other hand, we need far fewer conditions to obey, as it will turn out:

Assume that the covariant encoding is given by the distributions

$$(q(\cdot|j))^g \text{ with probability } \frac{1}{|G|}q_j,\quad g\in G, j=1,\ldots.$$

Now choose representatives $i_1,\ldots,i_t$ of the orbits, and observe that (by G-invariance)

$$\sum_{j,g}\frac{1}{|G|}q_j(q(\cdot|j))^g=p \tag{A18}$$

if and only if

$$\forall\,\tau=1,\ldots,t\quad \sum_{j,g}\frac{1}{|G|}q_j q(g^{-1}i_\tau|j)=p(i_\tau). \tag{A19}$$

Similarly, $S(A:C)\leqslant R$ if and only if

$$\sum_j q_j H(q(\cdot|j))\geqslant H(p)-R, \tag{A20}$$

and, finally, our aim function reads

$$S(A:B|C)=\sum_{j,g}\frac{1}{|G|}q_j S\left(\sum_i q(i|j)|\varphi_{gi}\rangle\langle\varphi_{gi}|\right). \tag{A21}$$

Now consider the affine linear map from $\mathcal{P}_\mathcal{I}$ to $\mathbb{R}^{t+1}$ defined by

$$A:p\mapsto\left(H(p);\frac{1}{|G|}\sum_g p(g^{-1}i_\tau):\tau=1,\ldots,t\right). \tag{A22}$$

Note that the image of this map is in a certain t-dimensional subspace because, if $t-1$ of the conditions (A19) are satisfied, then the tth is also, automatically. Equations (A19) and (A20) are

really conditions on the q_j-weighted average of the images $A_j = A(q(\cdot|j))$, $A = \Sigma_j q_j A_j$. By Caratheodory's theorem[38] the same average can be obtained by convex combination of $t+1$ of these, i.e., by a distribution q' on the j's with support containing at most $t+1$ points. In fact, q is easily seen to be expressible as a convex combination of such small support distributions, say $q'^{(a)}$ with weights λ_a.

To conclude, we observe that our aim function in Eq. (A21) is *linear* in the distribution q: hence, it is the λ_a–weighted sum of similar such expressions with $q'^{(a)}$ in place of q. For one value of a at least this is smaller than $S(A:B|C)$, the corresponding $q'^{(a)}$ satisfies $\Sigma_j q'^{(a)} A_j = A$, and hence Eqs. (A19) and (A20). As explained in the remark preceding the statement of Proposition 9.3, to obtain a G–covariant encoding we can split up each $q(\cdot|j)$ (with j in the support of $q'^{(a)}$) into the G translated distributions $(q(\cdot|j))^g$, proving the claim. □

Efficient discrete approximations of quantum gates

Aram W. Harrow,[a] Benjamin Recht,[b] and Isaac L. Chuang[c]

(Received 8 February 2002; accepted for publication 16 May 2002)

Quantum compiling addresses the problem of approximating an arbitrary quantum gate with a string of gates drawn from a particular finite set. It has been shown that this is possible for almost all choices of base sets and, furthermore, that the number of gates required for precision ϵ is only polynomial in $\log 1/\epsilon$. Here we prove that using certain sets of base gates quantum compiling requires a string length that is linear in $\log 1/\epsilon$, a result which matches the lower bound from counting volume up to constant factor. © *2002 American Institute of Physics.*

I. INTRODUCTION

Quantum computation generalizes computer science to utilize novel quantum physical resources as elementary building blocks for information processing.[1–4] Quantum algorithms, like their classical analogs, can be written in a number of nearly equivalent ways. While a classical program is typically composed of a series of simple boolean functions, such as NAND and FANOUT, a quantum algorithm is typically written as a product of unitary gates, such as the Hadamard transform H, the controlled-NOT (CNOT), and the $\pi/8$-gate T.[5] For classical computers, a common problem is that of compiling a program, in which one typically wishes to express the program in as few elementary operations as possible. By analogy, we can raise the principal questions of *quantum compiling*: Which sets of gates can be composed to form what sorts of quantum algorithm, how many of them are necessary, and what efficient algorithms can be devised to express quantum programs in terms of a particular set of base gates?

Mathematically, a gate on n quantum bits (qubits) is represented by a unitary transformation on a 2^n-dimensional vector space. We will denote the set of all determinant-one unitary transformations of a d-dimensional vector space by $\mathrm{SU}(d)$. This space is a manifold and is hence parametrized by a *continuum* of real parameters; for example, the 2×2 unitary transforms

$$\begin{pmatrix} e^{i\alpha}\cos\theta & e^{i\beta}\sin\theta \\ -e^{-i\beta}\sin\theta & e^{-i\alpha}\cos\theta \end{pmatrix} \tag{1}$$

parametrized by α, β, θ represent the group SU(2) of valid single qubit gates.

In contrast, digital quantum algorithms compute with only a *finite set* of base gates (such as those mentioned previously: H, T, and CNOT). This is a reasonable restriction in real circuit implementations, since the presence of noise reduces the number of reliably distinguishable gates to a finite subset of the continuous set. Finite gate sets are also intrinsic to fault-tolerant quantum computation, the art of constructing arbitrarily reliable circuits from unreliable parts.[6–9] Thus, in general we do not desire perfect computational universality, but only the ability to approximate any quantum algorithm, preferably without using too many more gates than originally required.

A set of base gates $\mathcal{A}\subset\mathrm{SU}(d)$ is *computationally universal* if given any gate U, we can find a string consisting of gates from $\mathcal{A}$ and their inverses, such that the product of the gates in the

[a]Electronic mail: aram@mit.edu
[b]Electronic mail: brecht@media.mit.edu
[c]Electronic mail: ichuang@media.mit.edu

string approximates U to arbitrary precision. Equivalently, $\mathcal{A}$ must generate a dense subgroup of $\mathrm{SU}(d)$.

Which sets of base gates are computationally universal? It turns out that probabilistically speaking, almost all of them are.[10,11] If base gates are chosen at random, then all but a set of measure zero are computationally universal. The idea is that if the eigenvalues of the base gates have phases that are irrationally related to π (which occurs with probability one), then taking powers of them allows each base gate to approximate a one-parameter subgroup to arbitrary precision, just as integer multiples of a random vector modulo a lattice will almost always fill space. Furthermore, the base gates will almost always lie on different one-parameter subgroups, which will generate all of $\mathrm{SU}(d)$ with probability one.

Given that compiling is generically possible, it is vital to determine *how short a string of base gates is typically required to approximate a given gate to a specified precision*; this is the question we consider in this article. The construction described by Lloyd[10] requires using a number of base gates exponential in $\log 1/\epsilon$ to achieve a precision of ϵ. This is an unreasonable cost for many applications. However, Solovay[12] and Kitaev[13] have independently described an efficient (meaning its running time is polynomial in $\log 1/\epsilon$) algorithm for quantum compiling that produces strings of length only $O(\log^c(1/\epsilon))$, where c is a constant between 3 and 4.[14] The algorithm works by constructing successively finer ϵ-nets; finite sets of gates that can approximate any element of $\mathrm{SU}(d)$ to an accuracy of ϵ.

On the other hand, as we will later discuss, since a ball of radius ϵ in $\mathrm{SU}(d)$ has volume proportional to ϵ^{d^2-1}, it takes $O((1/\epsilon)^{d^2-1})$ different strings of gates to approximate every element of $\mathrm{SU}(d)$ to a precision of ϵ. Therefore, no algorithm will ever be able to reduce c below 1. Furthermore, it is unlikely that the successive approximation method used by the Solovay–Kitaev theorem will be able to do better than $c=2$.[14] This still leaves open the question of whether some other technique could establish an upper bound asymptotically smaller than the one achieved by the Solovay–Kitaev theorem.

Here, our main result is that for at least some universal sets of base gates only $O(\log 1/\epsilon)$ gates are sufficient to approximate any gate to a precision ϵ (i.e., $c=1$). This is within a constant factor of the lower bound obtained from counting arguments. We say that these base gates are not only computationally universal, but also *efficiently universal*, since using them for quantum compiling requires a string length that is optimal up to a constant multiplicative factor.

We present this result as follows. The set of strings from a fixed computationally universal set of base gates covers $\mathrm{SU}(d)$ increasingly densely and uniformly, as the string length grows.[15] First, in Sec. II, we quantify how quickly this occurs by introducing a framework for comparing the distribution of strings with the uniform distribution. We use this formalism in Sec. III to identify a condition on base sets that implies their efficient universality. In Sec. IV we then combine this condition with results from the literature to show that efficiently universal gate sets exist for Hilbert spaces of any finite dimension. In Sec. V we discuss lower bounds for compilation and demonstrates the optimality of the result; we conclude with open questions and further directions.

II. PRELIMINARIES

We begin by developing a metric of how well strings drawn from a finite set of gates approximate arbitrary elements of $\mathrm{SU}(d)$.

Let dg be the Haar measure on $\mathrm{SU}(d)$ normalized so that $\int dg = 1$. Consider the Hilbert space $L^2(\mathrm{SU}(d))$ with norm defined by the usual inner product $\langle \psi, \varphi \rangle \equiv \int \psi(g)^* \varphi(g) dg$. The norm of a linear transformation on $L^2(\mathrm{SU}(d))$ is given by

$$|M| \equiv \sup\{\|Mf\| \,|\, f \in L^2(\mathrm{SU}(d)), \|f\| = 1\}. \tag{2}$$

When M is bounded and Hermitian, the norm is simply the supremum of its spectrum and, as a result, $|M^n| = |M|^n$.

Define a representation $U \mapsto \tilde{U}$ of $\mathrm{SU}(d)$ on $L^2(\mathrm{SU}(d))$ by

$$\tilde{U}f(x)=f(U^{-1}x). \tag{3}$$

Using the right invariance of the Haar measure, we see that $\tilde{U}$ is unitary. For any finite set $\mathcal{A}\subset \mathrm{SU}(d)$, define the mixing operator $T(\mathcal{A})$ by

$$T(\mathcal{A})=\frac{1}{2|\mathcal{A}|}\sum_{A\in\mathcal{A}}\tilde{A}+\tilde{A}^{-1}. \tag{4}$$

All such T's are Hermitian and have norm one. We will often simply write T instead of $T(\mathcal{A})$. These represent averaging the action of the elements of $\mathcal{A}$ and their inverses on a function; when the function is a probability distribution on $\mathrm{SU}(d)$ we can think of T as multiplying by a random element of $\mathcal{A}$.

Applying T^n represents averaging over the action of words of length n. Denote the set of words of length n made up of elements of $\mathcal{A}$ and their inverses by $W_n(\mathcal{A})$, or when the set $\mathcal{A}$ is understood, simply W_n. This set comprises $(2|\mathcal{A}|)^n$ words, though as matrices there are generally some duplicates since substrings such as $AA^{-1}=1$ for all $A\in\mathcal{A}$. For any positive integer n, expanding T^n gives

$$T^n=\sum_{w\in W_n}\frac{\tilde{w}}{(2|\mathcal{A}|)^n}. \tag{5}$$

We want to compare T^n to the integral operator P:

$$Pf(h)=\int f(gh)dg=\int f(g)dg. \tag{6}$$

Note that P is the projection operator onto the set of constant functions on $\mathrm{SU}(d)$, and hence $P=P^\dagger$ and $P^2=P$. It is not hard to show that $TP=P=PT$ and, consequently,

$$(T-P)^n=T^n-P. \tag{7}$$

The metric for comparing $T(\mathcal{A})$ to P is given by

$$\Lambda(\mathcal{A})\equiv|T(\mathcal{A})-P|. \tag{8}$$

From Eq. (7) and the Hermiticity of T and P, it follows that

$$\Lambda(\mathcal{A})^n=|T^n(\mathcal{A})-P|. \tag{9}$$

If one thinks of T^n as a Riemann sum then Λ serves to quantify how quickly T^n converges to the integral. It has been shown[15] that if $\mathcal{A}$ is a computationally universal set, then all the eigenvalues of $T-P$ have absolute value strictly less than one. However, this only implies that $\Lambda(\mathcal{A})\leqslant 1$, since $T-P$ has an infinite number of eigenvalues.

The proof of the main result of our article—that efficiently universal sets of gates exist—is divided in the next two sections. In Sec. III we show that $\Lambda(\mathcal{A})<1$ implies that $\mathcal{A}$ is efficiently universal and in Sec. IV we demonstrate that for any d an efficiently universal set of gates can be found in $\mathrm{SU}(d)$.

III. A CONDITION FOR EFFICIENT UNIVERSALITY

Theorem 1: *For any $\mathcal{A}\subset\mathrm{SU}(d)$ such that $\Lambda(\mathcal{A})<1$, $\mathcal{A}$ is efficiently universal. Specifically, there exists a constant C such that for all $U\in\mathrm{SU}(d)$, $\epsilon>0$, and $n>C\log 1/\epsilon$, there is a $w\in W_n(\mathcal{A})$ such that $|w-U|<\epsilon$.*

Before proving the theorem, we will need to note a fact about the geometry of SU(d). For any d and r_0, if $V(r)$ is the Haar measure of a ball of radius r in SU(d), then there exist constants k_1 and k_2 such that

$$k_1 r^{d^2-1} < V(r) < k_2 r^{d^2-1} \tag{10}$$

for all $r \in (0, r_0)$. This is true because SU(d) is a d^2-1-dimensional manifold and because $V(r)$ does not depend on the center of the ball under the Haar measure.

Now we can proceed with the proof of Theorem 1:

Proof: Define $\chi \in L^2(\mathrm{SU}(d))$ by

$$\chi(g) = \begin{cases} 1 & \text{for } |g-I| < \epsilon/2 \\ 0 & \text{otherwise.} \end{cases} \tag{11}$$

Let $V = \|P\chi\| = \|\chi\|^2$ be the measure of the ball around the identity of radius $\epsilon/2$. We will not perform this integration, but recall from Eq. (10) that $V > k_1(\epsilon/2)^{d^2-1}$.

Let $T = T(\mathcal{A})$ and $\Lambda = \Lambda(\mathcal{A})$.

First we use the Cauchy–Schwartz inequality to give

$$|\langle \chi, (T^n - P)\tilde{U}\chi\rangle| \leq \|\chi\| \|(T^n - P)\tilde{U}\chi\| \leq \|\chi\|^2 |(T^n - P)\tilde{U}| < \Lambda^n V. \tag{12}$$

Another way to compute the same inner product is

$$\langle \chi, (T^n - P)\tilde{U}\chi\rangle = \langle \chi, T^n \tilde{U}\chi\rangle - V^2. \tag{13}$$

Combining Eq. (12) and Eq. (13) gives that $|\langle \chi, T^n\tilde{U}\chi\rangle - V^2| < \Lambda^n V$. This means that there exists C which depends only on $\mathcal{A}$ such that if $n > C \log 1/\epsilon$ then $\Lambda^n < V$ and $\langle \chi, T^n\tilde{U}\chi\rangle > 0$. Specifically, it suffices to choose

$$n > \frac{d^2-1}{\log(1/\Lambda)} \log(1/\epsilon) + \frac{\log(2^{d^2-1}/k_1)}{\log(1/\Lambda)}. \tag{14}$$

When this occurs it means that

$$\int \chi(g) \sum_{w \in W_n} \frac{\chi(wU^{-1}g)}{(2|\mathcal{A}|)^n} dg > 0, \tag{15}$$

which implies that $\exists g \in \mathrm{SU}(d)$ and $w \in W_n$ such that $\chi(g) \neq 0$ and $\chi(wU^{-1}g) \neq 0$. Thus $|g-I| < \epsilon/2$ and $|wU^{-1}g - I| < \epsilon/2$, implying that $|w - g^{-1}U| < \epsilon/2$. Combining these and using the triangle inequality gives $|w-U| < \epsilon$. ■

IV. A CLASS OF EFFICIENTLY UNIVERSAL GATE SETS

In this section we show that for each d there exists a set of gates $\mathcal{G}_d$ in SU(d) such that $\Lambda(\mathcal{G}_d) < 1$ (and thus $\mathcal{G}_d$ is efficiently universal). We begin with a result demonstrating this for SU(2) and then extend it to SU(d).

Lemma 2 (Lubotsky, Phillips and Sarnak): Let

$$V_1 = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & 2i \\ 2i & 1 \end{pmatrix}, \quad V_2 = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & 2 \\ -2 & 1 \end{pmatrix},$$
$$V_3 = \frac{1}{\sqrt{5}} \begin{pmatrix} 1+2i & 0 \\ 0 & 1-2i \end{pmatrix}. \tag{16}$$

Then $\lambda=\Lambda(\{V_1,V_2,V_3\})=\sqrt{5}/3<1$. *Furthermore, for any* U_1, U_2, $U_3\in \mathrm{SU}(2)$, $\Lambda(\{U_1,U_2,U_3\})\geqslant\lambda$.

The proof of this Lemma is presented in Refs. 16 and 17. Let $\mathcal{G}_2=\{V_1,V_2,V_3\}$, as it is a family of quantum gates from SU(2) for which Λ is strictly less than one. The optimality of Λ for this set is an interesting aside, but has little bearing on what follows.

Extending the result to SU(d) will require slightly more effort. To this end, if I_k denotes the $k\times k$ identity matrix, then, for any $U\in\mathrm{SU}(2)$ and $2\leqslant j\leqslant d$, define $\beta_j^{(d)}(U)$ to be

$$\beta_j^{(d)}(U)=\begin{pmatrix} I_{j-2} & 0 & 0 \\ 0 & U & 0 \\ 0 & 0 & I_{d-j} \end{pmatrix}\in \mathrm{SU}(d). \tag{17}$$

We will typically omit the $^{(d)}$ where it is understood.

Lemma 3 (Diaconis and Shahshahani): Let $\{G_j^i\}$, $1\leqslant i<j\leqslant d$ *be a series of* $\binom{d}{2}$ *independent random matrices in* SU(2) *that are chosen uniformly according to a Haar measure. Then*

$$\prod_{i=1}^{d-1}\prod_{j=i+1}^{d}\beta_j(G_j^i) \tag{18}$$

is uniformly distributed in SU(d).

This Lemma is proved in Ref. 18. It means that if we had access to random elements of SU(2) that were completely uniformly distributed, then we could generate uniformly distributed elements of SU(d). When the elements of SU(2) are only approximately uniform, we can bound the distance to uniformity of the words they form by using what is known as a hybrid argument:[19]

Lemma 4 (Bernstein and Vazirani): If $U_1,\ldots,U_m$, $V_1,\ldots,V_m$ *are linear operators such that* $|U_i|\leqslant 1$, $|V_i|\leqslant 1$ *and* $|U_i-V_i|<\delta$, *then* $|U_m\cdots U_2U_1-V_m\cdots V_2V_1|<m\delta$.

Proof: If we replace a single U_i in the product $U_m\ldots U_1$ with the corresponding V_i, then the entire product will still change by less than δ since $|AB|\leqslant|A|\cdot|B|$ for any operators A, B. Thus we can construct a series of $m+1$ "hybrid" operators, which start with $U_1\cdots U_m$, end with $V_1\cdots V_m$, and are each separated by less than δ. The proof follows from the triangle inequality.■

We now combine all of the other results in this section to demonstrate a set of gates in SU(d) for which Λ is strictly less than one.

Proposition 5: For any $d>2$, *define* $\mathcal{G}_d$ *by*

$$\mathcal{G}_d=\{\beta_j(V)\,|\,1\leqslant j\leqslant(d-1),V\in\mathcal{G}_2\}. \tag{19}$$

Then $\Lambda(\mathcal{G}_d)<1$.

Proof: The approach of our proof will be to approximate the uniform distribution in Lemma 3, and then we show that this forces Λ to be less than one. To this end, let $R_m\subset W_{m\binom{d}{2}}(\mathcal{G}_d)$ be the set of all products of the form

$$\prod_{i=1}^{d-1}\prod_{j=i+1}^{d}\beta_j(G_j^i) \tag{20}$$

such that the G_j^i are selected from $W_m(\mathcal{G}_2)$.

From Lemma 2 we have that $\forall m$, $|T(V_1,V_2,V_3)-P|^m=\lambda^m$ for some $\lambda<1$. There are $\binom{d}{2}$ terms in Eq. (18), each of which is approximated to within an accuracy of λ^m by the appropriate length m substring of R_m. Thus, using the hybrid argument and Lemma 3 gives that

$$\Lambda(R_m)=\left|\sum_{w\in R_m}\frac{\tilde{w}-P}{|R_m|}\right|\leqslant\binom{d}{2}\lambda^m. \tag{21}$$

Now, if we let R_m' denote $W_{m\binom{d}{2}}-R_m$ then

$$\Lambda(W_{m(\binom{d}{2})}) \leqslant \frac{|R'_m|}{|W|}\Lambda(R'_m) + \frac{|R_m|}{|W|}\Lambda(R_m) \leqslant \left(1 - \frac{|R_m|}{|W|}\right) + \frac{|R_m|}{|W|}\Lambda(R_m) = 1 - \frac{|R_m|}{|W|}(1 - \Lambda(R_m)). \tag{22}$$

If we choose m large enough so that $\binom{d}{2}\lambda^m < 1$, then this last expression will be less than one, and $\Lambda(\mathcal{G}_d) < 1$. ■

Thus, efficient quantum compiling is possible for d-dimensional systems, given the appropriate choice of base gate set.

V. LOWER BOUNDS

This proves that sets of base gates exist which can achieve a precision of ϵ in $O(\log 1/\epsilon)$ gates, but can we do any better? An ϵ-ball in SU(d) has measure of order ϵ^{d^2-1}, so if we expect to cover all of SU(d) with strings of length n, then we will require $(2|\mathcal{A}|)^n k_2 \epsilon^{d^2-1} > 1$, or equivalently,

$$n \geqslant \frac{d^2-1}{\log 2|\mathcal{A}|}\log 1/\epsilon - \frac{\log k_2}{\log 2|\mathcal{A}|}. \tag{23}$$

Thus the result is optimal up to a constant factor. This fact is quite general, since it follows from simple counting arguments. However, if the assumptions of the problem are relaxed to allow many gates to act in parallel, then using ancilla qubits it is possible to approximate single-qubit gates with a circuit of *size* poly($\log 1/\epsilon$) but *depth* of only poly($\log\log 1/\epsilon$).[20] This construction, like the one in this article, relies on having access to a specific set of base gates; to date, only the Solovay–Kitaev theorem applies to any computationally universal set.

In our original problem, though, eliminating the constant linear factor turns out to be impossible. Consider any set $\mathcal{A}$ of l base gates that is *not* computationally universal. Let $B(\mathcal{A}, \delta)$ be the set of gates obtained by perturbing each gate in $\mathcal{A}$ by no more than δ. Then $B(\mathcal{A}, \delta)$ has nonzero measure (in SU$(d)^l$), almost all of its elements are computationally universal and from the hybrid argument, any string of length n drawn from gates in $B(\mathcal{A}, \delta)$ will be within $n\delta$ of something in the (nondense) group generated by $\mathcal{A}$. Since we can make δ arbitrarily small, any fixed prefactor in front of $\log 1/\epsilon$ will fail on a computationally universal set of nonzero measure for some values of ϵ.

Note that unlike most results about quantum compiling, this argument also holds if the base gates are parametrized; say, $A_1, \ldots, A_l$ are elements of the algebra $su(d)$ and a single operation now has the form $e^{\pm A_i t}$, for any $t > 0$. The above proof demonstrates that there exist sets with nonzero measure which require arbitrarily many steps, even if the steps are continuous. If we measure cost not in terms of number of steps, but by the total time taken, then we have to modify the argument slightly. For small values of t, $|e^{A_i t} - I|$ is on the order of $t\delta$, but for large t the difference never gets any higher than δ. This means that no matter how many steps we take, in time t, we will stay within $t\delta$ of some nondense subgroup and the same result holds.

These results can be obtained more simply by considering the (nonzero measure) set of gates which are very close to the identity. If every gate does very little, then we will need a large number them in order to accomplish anything. The reason why universal sets that are very close to nonuniversal sets are interesting is because of their frequent appearance in actual physical systems, such as NMR under the weak coupling approximation.[21]

VI. CONCLUSIONS

We have found a condition that implies the efficient universality of a set of gates and demonstrated a family of gate sets in SU(d) that satisfy this condition. This means that given access to such a gate set, arbitrary quantum gates can be approximated to accuracy ϵ using only $O(\log 1/\epsilon)$ gates. Such knowledge will likely be invaluable in crafting future physical implementations of quantum information processing systems.

Many open questions remain, however. For example, determining or bounding Λ (even numerically) for a given set of base gates seems to be very difficult, though it is likely an important step in determining the prefactor C, which measures how effective a set of gates would be for compiling. The method used by Refs. 16 and 17 involves specialized arguments from number theory that do not generalize easily to other sets of gates or to SU(d) for $d>2$. Our proof (like the Solovay–Kitaev algorithm) also requires the ability to perform the inverse of each gate in the base set. This restriction feels unnecessary, yet very little is known in the case where inverses are unavailable.

More broadly, it is also generally unknown which gate sets are efficiently universal and when $\Lambda<1$. Note that $\Lambda(\mathcal{A})<1$ implies that $\mathcal{A}$ is efficiently universal, but the converse is not known to be true. Thus it is possible that the questions of efficient universality and Λ being less than one will be settled separately.

However, if $\Lambda(\mathcal{A})$ were to be a continuous function of $\mathcal{A}$ (for fixed $|\mathcal{A}|$), then the situation would simplify considerably. In this case, it is not hard to show that $\Lambda(\mathcal{A})<1$ if and only if $\mathcal{A}$ is computationally universal, so that computational universality, efficient universality and $\Lambda<1$ would all become equivalent conditions. We suspect that this is the case, but have been unable to prove it.

Finally, the techniques used in our results do not suggest any efficient (i.e., running time polynomial in $\log 1/\epsilon$) algorithms for quantum compiling. The most important, and possibly most difficult, open problem remaining is to find a polynomial time algorithm to approximate any unitary gate by a fixed efficiently universal set of base gates with a string whose length saturates the $O(\log 1/\epsilon)$ bound.

We analyze *surface codes*, the topological quantum error-correcting codes introduced by Kitaev. In these codes, qubits are arranged in a two-dimensional array on a surface of nontrivial topology, and encoded quantum operations are associated with nontrivial homology cycles of the surface. We formulate protocols for error recovery, and study the efficacy of these protocols. An order-disorder phase transition occurs in this system at a nonzero critical value of the error rate; if the error rate is below the critical value (the *accuracy threshold*), encoded information can be protected arbitrarily well in the limit of a large code block. This phase transition can be accurately modeled by a three-dimensional Z_2 lattice gauge theory with quenched disorder. We estimate the accuracy threshold, assuming that all quantum gates are *local*, that qubits can be measured rapidly, and that polynomial-size classical computations can be executed instantaneously. We also devise a robust recovery procedure that does not require measurement or fast classical processing; however, for this procedure the quantum gates are local only if the qubits are arranged in *four* or more spatial dimensions. We discuss procedures for encoding, measurement, and performing fault-tolerant universal quantum computation with surface codes, and argue that these codes provide a promising framework for quantum computing architectures.

I. INTRODUCTION

The microscopic world is quantum mechanical, but the macroscopic world is classical. This fundamental dichotomy arises because a coherent quantum superposition of two readily distinguishable macroscopic states is highly unstable. The quantum state of a macroscopic system rapidly *decoheres* due to unavoidable interactions between the system and its surroundings.

Decoherence is so pervasive that it might seem to preclude subtle quantum interference phenomena in systems with many degrees of freedom. However, recent advances in the theory of quantum error correction suggest otherwise.[1,2] We have learned that quantum states can be cleverly encoded so that the debilitating effects of decoherence, if not too severe, can be resisted. Furthermore, fault-tolerant protocols have been devised that allow an encoded quantum state to be reliably processed by a quantum computer with imperfect components.[3] In principle, then, very intricate quantum systems can be stabilized and accurately controlled.

The theory of quantum fault tolerance has shown that, even for delicate coherent quantum states, information *processing* can prevent information *loss*. In this article, we will study a particular approach to quantum fault tolerance that has notable advantages: in this approach, based on the *surface codes* introduced in Refs. 4 and 5, the quantum processing needed to control errors has

especially nice locality properties. For this reason, we think that surface codes suggest a particularly promising approach to quantum computing architecture.

One glittering achievement of the theory of quantum fault tolerance is the *threshold theorem*, which asserts that an arbitrarily long quantum computation can be executed with arbitrarily high reliability, provided that the error rates of the computer's fundamental quantum gates are below a certain critical value, the *accuracy threshold*.[6–10] The numerical value of this accuracy threshold is of great interest for future quantum technologies, as it defines a standard that should be met by designers of quantum hardware. The critical error probability per gate p_c has been estimated as $p_c \gtrsim 10^{-4}$; very roughly speaking, this means that robust quantum computation is possible if the decoherence time of stored qubits is at least 10^4 times longer than the time needed to execute one fundamental quantum gate,[11] assuming that decoherence is the only source of error.

This estimate of the accuracy threshold is obtained by analyzing the efficacy of a *concatenated code*, a hierarchy of codes within codes, and it is based on many assumptions, which we will elaborate in Sec. II. For now, we just emphasize one of these assumptions: that a quantum gate can act on any pair of qubits, with a fidelity that is independent of the spatial separation of the qubits. This assumption is clearly unrealistic; it is made because it greatly simplifies the analysis. Thus this estimate will be reasonable for a practical device only to the extent that the hardware designer is successful in arranging that qubits that must interact are kept close to one another. It is known that the threshold theorem still applies if quantum gates are required to be local,[7,12] but for this realistic case careful estimates of the threshold have not been carried out.

We will perform a quite different estimate of the accuracy threshold, based on surface codes rather than concatenated codes. This estimate applies to a device with strictly local quantum gates, if the device is controlled by a classical computer that is perfectly reliable, and whose clock speed is much faster than the clock speed of the quantum computer. In this approach, some spatial nonlocality in effect is still allowed, but we demand that all the nonlocal processing be classical. Specifically, an error syndrome is extracted by performing local quantum gates and measurements; then a classical computation is executed to infer what quantum gates are needed to recover from error. We will assume that this classical computation, which actually requires a time bounded above by a polynomial in the number of qubits in the quantum computer, can be executed in a constant number of time steps. Under this assumption, the existence of an accuracy threshold can be established and its value can be estimated. If we assume that the classical computation can be completed in a single time step, we estimate that the critical error probability p_c per qubit and per time step satisfies $p_c \geq 1.7 \times 10^{-4}$. This estimate applies to the accuracy threshold for reliable *storage* of quantum information, rather than for reliable processing. The threshold for quantum computation is not as easy to analyze definitively, but we will argue that its numerical value is not likely to be substantially different.

We believe that principles of fault tolerance will dictate the shape of future quantum computing architectures. In Sec. II we compile a list of hardware features that are conducive to fault-tolerant processing, and outline the design of a fault-tolerant quantum computer that incorporates surface coding. We review the properties of surface codes in Sec. III, emphasizing in particular that the qubits in the code block can be arranged in a *planar* sheet,[13,14] and that errors in the syndrome measurement complicate the recovery procedure. The core of the article is Sec. IV, where we relate recovery from errors using surface codes to a statistical-mechanical model with local interactions. In the (unrealistic) case where syndrome measurements are perfect, this model becomes the two-dimensional Ising model with quenched disorder, whose phase diagram has been studied by Monte Carlo simulations. These simulations indicate that if the syndrome information is put to optimal use, error recovery succeeds with a probability that approaches one in the limit of a large code block, if and only if both phase errors and bit-flip errors occur with a probability per qubit less than about 11%. In the more realistic case where syndrome measurements are imperfect, error recovery is modeled by a three-dimensional Z_2 gauge theory with quenched disorder, whose phase diagram (to the best of our knowledge) has not been studied previously. The third dimension that arises can be interpreted as time—since the syndrome information cannot be trusted, we must repeat the measurement many times before we can be confident about the correct

way to recover from the errors. We argue that an order-disorder phase transition of this model corresponds to the accuracy threshold for quantum storage, and, furthermore, that the optimal recovery procedure can be computed efficiently on a classical computer. We proceed in Sec. V to prove a rather crude lower bound on the accuracy threshold, concluding that the error recovery procedure is sure to succeed in the limit of a large code block under suitable conditions: for example, if in each round of syndrome measurement, qubit phase errors, qubit bit-flip errors, and syndrome bit errors all occur with probability below 1.14%. Tighter estimates of the accuracy threshold could be obtained through numerical studies of the quenched gauge theory.

In deriving this accuracy threshold for quantum storage, we assumed that an unlimited amount of syndrome data could be deposited in a classical memory, if necessary. But in Sec. VI we show that this threshold, and a corresponding accuracy threshold for quantum computation, remain intact even if the classical memory is limited to polynomial size. Then in Sec. VII we analyze quantum circuits for syndrome measurement, so that our estimate of the accuracy threshold can be reexpressed as a fidelity requirement for elementary quantum gates. We conclude that our quantum memory can resist decoherence if gates can be executed in parallel, and if the qubit decoherence time is at least 6000 times longer than the time needed to execute a gate. In Sec. VIII we show that encoded qubits can be accurately prepared and reliably measured. We also describe how a surface code with a small block size can be built up gradually to a large block size; this procedure allows us to enter a qubit in an unknown quantum state into our quantum memory with reasonable fidelity, and then to maintain that fidelity for an indefinitely long time. We explain in Sec. IX how a universal set of quantum gates acting on protected quantum information can be executed fault-tolerantly.

Most of the analysis of the accuracy threshold in this article is premised on the assumption that qubits can be measured quickly and that classical computations can be done instantaneously and perfectly. In Sec. X we drop these assumptions. We devise a recovery procedure that does not require measurement or classical computation, and infer a lower bound on the accuracy threshold. Unfortunately, though, the quantum processing in our procedure is not spatially local unless the dimensionality of space is at least four. Section XI contains some concluding remarks.

This article analyzes applications of surface coding to quantum memory and quantum computation that could in principle be realized in any quantum computer that meets the criteria of our computational model, whatever the details of how the local quantum gates are physically implemented. It has also been emphasized[4,5] that surface codes may point the way toward realizations of intrinsically stable quantum memories (*physical* fault tolerance). In that case, protection against decoherence would be achieved without the need for active information processing, and how accurately the protected quantum states can be processed might depend heavily on the details of the implementation.

II. FAULT TOLERANCE AND QUANTUM ARCHITECTURE

To prove that a quantum computer with noisy gates can perform a robust quantum computation, we must make some assumptions about the nature of the noise and about how the computer operates. In fact, similar assumptions are needed to prove that a classical computer with noisy gates is robust.[15] Still, it is useful to list these requirements—they should always be kept in mind when we contemplate proposed schemes for building quantum computing hardware:

(i) *Constant error rate*. We assume that the strength of the noise is independent of the number of qubits in the computer. If the noise increases as we add qubits, then we cannot reduce the error rate to an arbitrarily low value by increasing the size of the code block.

(ii) *Weakly correlated errors*. Errors must not be too strongly correlated, either in space or in time. In particular, fault-tolerant procedures fail if errors act simultaneously on many qubits in the same code block. If possible, the hardware designer should strive to keep qubits in the same block isolated from one another.

(iii) *Parallel operation*. We need to be able to perform many quantum gates in a single time step. Errors occur at a constant rate per unit time, and we are to control these errors through

information processing. We could never keep up with the accumulating errors except by doing processing in different parts of the computer at the same time.

(iv) *Reusable memory*. Errors introduce entropy into the computer, which must be flushed out by the error recovery procedure. Quantum processing transfers the entropy from the qubits that encode the protected data to ''ancilla'' qubits that can be discarded. Thus fresh ancilla qubits must be continually available. The ability to erase (or replace) the ancilla quickly is an essential hardware requirement.[16]

In some estimates of the threshold, additional assumptions are made. While not strictly necessary to ensure the existence of a threshold, these assumptions may be useful, either because they simplify the analysis of the threshold or because they allow us to increase its numerical value. Hence these assumptions, too, should command the attention of the prospective hardware designer:

(i) *Fast measurements*. It is helpful to assume that a qubit can be measured as quickly as a quantum gate can be executed. For some implementations, this may not be a realistic assumption—measurement requires the amplification of a microscopic quantum effect to a macroscopic signal, which may take a while. But by measuring a classical error syndrome for each code block, we can improve the efficiency of error recovery. Furthermore, if we can measure qubits and perform quantum gates conditioned on classical measurement outcomes, then we can erase ancilla qubits by projecting onto the $\{|0\rangle,|1\rangle\}$ basis and flipping the qubit if the outcome is $|1\rangle$.

(ii) *Fast and accurate classical processing*. If classical processing is faster and more accurate than quantum processing, then it is beneficial to substitute classical processing for quantum processing when possible. In particular, if the syndrome is measured, then a classical computation can be executed to determine how recovery should proceed. Ideally, the classical processors that coordinate the control of the quantum computer should be integrated into the quantum hardware.

(iii) *No leakage*. It is typically assumed that, though errors may damage the state of the computer, the qubits themselves remain accessible—they do not ''leak'' out of the device. In fact, at least some types of leakage can be readily detected. If leaked qubits, once detected, can be replaced easily by fresh qubits, then leakage need not badly compromise performance. Hence, a desirable feature of hardware is that leaks are easy to detect and correct.

(iv) *Nonlocal quantum gates*. Higher error rates can be tolerated, and the estimate of the threshold is simplified, if we assume that two-qubit quantum gates can act on any pair of qubits with a fidelity independent of the distance between the qubits. However useful, this assumption is not physically realistic. What the hardware designer can and should do, though, is try to arrange that qubits that will need to interact with one another are kept close to one another. In particular, the ancilla qubits that absorb entropy should be carefully integrated into the design.[12]

If we do insist that all quantum gates are local, then another desirable feature is the following.

(v) *High coordination number*. A threshold theorem applies even if qubits form a one-dimensional array.[7,12] But local gates are more effective if the qubits are arranged in three dimensions, so that each qubit has more neighbors.

Suppose, then, that we are blessed with an implementation of quantum computation that meets all of our desiderata. Qubits are arranged in a three-dimensional lattice, and can be projectively measured quickly. Reasonably accurate quantum gates can be applied in parallel to single qubits or to neighboring pairs of qubits. Fast classical processing is integrated into the qubit array. Under these conditions planar surface codes provide an especially attractive way to operate the quantum computer fault-tolerantly.

We may envision our quantum computer as a stack of planar sheets, with a protected logical qubit encoded in each sheet. Adjacent to each logical sheet is an associated sheet of ancilla qubits that are used to measure the error syndrome of that code block; after each measurement, these ancilla qubits are erased and then immediately reused. Encoded two-qubit gates can be performed between neighboring logical sheets, and any two logical sheets in the stack can be brought into contact by performing swap gates that move the sheets through the intervening layers of logical and ancilla qubits. As a quantum circuit is executed in the stack, error correction is continually applied to each logical sheet to protect against decoherence and other errors. Portions of the stack are designated as ''software factories,'' where special ancilla states are prepared and purified—this software is then consumed during the execution of certain quantum gates that cannot be implemented directly.

A notable feature of this design (or other fault-tolerant designs) is that most of the information processing in the device is devoted to controlling errors, rather than moving the computation forward. How accurately must the fundamental quantum gates be executed for this error control to be effective, so that our machine is computationally powerful? Our goal in this article is to address this question.

III. SURFACE CODES

We will study the family of quantum error-correcting codes introduced in Refs. 4 and 5. These codes are especially well suited for fault-tolerant implementation, because the procedure for measuring the error syndrome is highly local.

A. Toric codes

For the code originally described in Refs. 4 and 5, it is convenient to imagine that the qubits are in one-to-one correspondence with the links of a square lattice drawn on a torus, or, equivalently, drawn on a square with opposite edges identified. Hence we will refer to them as ''toric codes.'' Toric codes can be generalized to a broader class of quantum codes, with each code in the class associated with a tessellation of a two-dimensional surface. Codes in this broader class will be called ''surface codes.''

A surface code is a special type of ''stabilizer code.'' [17,18] A (binary) stabilizer code can be characterized as the simultaneous eigenspace with eigenvalue one of a set of mutually commuting check operators (or ''stabilizer generators''), where each generator is a ''Pauli operator.'' We use the notation

$$I=\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}, \quad X=\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}, \tag{1}$$

$$Y=\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}, \quad Z=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix} \tag{2}$$

for the 2×2 identity and Pauli matrices; a Pauli operator acting on n qubits is one of the 2^{2n} tensor product operators

$$\{I,X,Y,Z\}^{\otimes n}. \tag{3}$$

For the toric code defined by the $L\times L$ square lattice on the torus, there are $2L^2$ links of the lattice, and hence $2L^2$ qubits in the code block. Check operators are associated with each site and with each elementary cell (or ''plaquette'') of the lattice, as shown in Fig. 1. The check operator at site s acts nontrivially on the four links that meet at the site; it is the tensor product

$$X_s=\otimes_{\ell\ni s}X_\ell \tag{4}$$

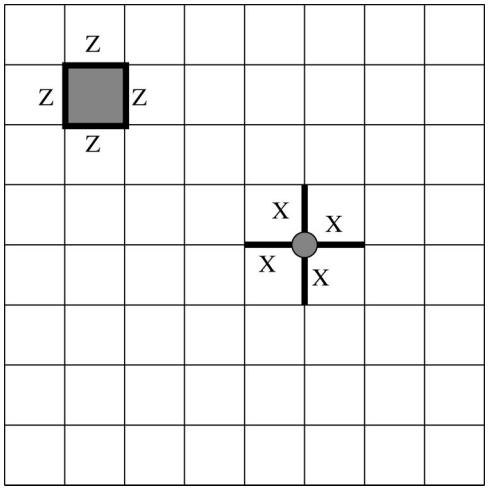

FIG. 1. Check operators of the toric code. Each plaquette operator is a tensor product of Z's acting on the four links contained in the plaquette. Each site operator is a tensor product of X's acting on the four links that meet at the site.

acting on those four qubits, times the identity acting on the remaining qubits. The check operator at plaquette P acts nontrivially on the four links contained in the plaquette, as the tensor product

$$Z_P = \otimes_{\ell \in P} Z_\ell , \tag{5}$$

times the identity on the remaining links.

Although X and Z anticommute, the check operators are mutually commuting. Obviously, site operators commute with site operators, and plaquette operators with plaquette operators. Site operators commute with plaquette operators because a site operator and a plaquette operator act either on disjoint sets of links, or on sets whose intersection contains two links. In the former case, the operators obviously commute, and in the latter case, two canceling minus signs arise when the site operator commutes through the plaquette operator. The check operators generate an Abelian group, the code's stabilizer.

The check operators can be simultaneously diagonalized, and the toric code is the space in which each check operator acts trivially. Because of the periodic boundary conditions, each site or plaquette operator can be expressed as the product of the other L^2-1 such operators; the product of all L^2 site operators or all L^2 plaquette operators is the identity, since each link operator occurs twice in the product, and $X^2=Z^2=I$. There are no further relations among these operators; therefore, there are $2\cdot(L^2-1)$ independent check operators, and hence two encoded qubits (the code subspace is four-dimensional).

A Pauli operator that commutes with all the check operators will preserve the code subspace. What operators have this property? To formulate the answer, it is convenient to recall some standard mathematical terminology. A mapping that assigns an element of $Z_2=\{0,1\}$ to each link of the lattice is called a (Z_2-valued) *one-chain*. In a harmless abuse of language, we will also use the term one-chain (or simply chain) to refer to the set of all links that are assigned the value 1 by such a mapping. The one-chains form a vector space over Z_2—intuitively, the sum $u+v$ of two chains u and v is a disjoint union of the links contained in the two one-chains. Similarly, zero-chains assign elements of Z_2 to lattice sites and two-chains assign elements of Z_2 to lattice plaquettes; these also form vector spaces. A linear boundary operator ∂ can be defined that takes two-chains to one-chains and one-chains to zero-chains: the boundary of a plaquette is the sum of the four links comprising the plaquette, and the boundary of a link is the sum of the two sites at the ends of the link. A chain whose boundary is trivial is called a *cycle*.

Now, any Pauli operator can be expressed as a tensor product of X's (and I's) times a tensor product of Z's (and I's). The tensor product of Z's and I's defines a Z_2-valued one-chain, where

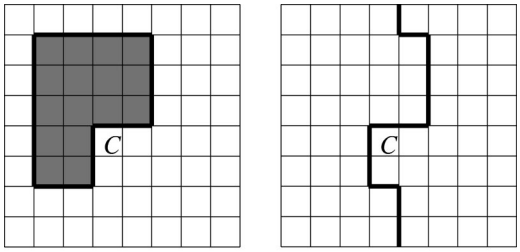

FIG. 2. Cycles on the lattice. (a) A homologically trivial cycle bounds a region that can be tiled by plaquettes. The corresponding tensor product of Z's lies in the stabilizer of the toric code. (b) A homologically nontrivial cycle is not a boundary. The corresponding tensor product of Z's commutes with the stabilizer but is not contained in it. It is a logical operation that acts nontrivially in the code subspace.

links acted on by Z are mapped to 1 and links acted on by I are mapped to 0. This operator trivially commutes with all of the plaquette check operators, but commutes with a site operator if and only if an even number of Z's act on the links adjacent to the site. Thus, the corresponding one-chain must be a cycle. Similarly, the tensor product of X's trivially commutes with the site operators, but commutes with a plaquette operator only if an even number of X's act on the links contained in the plaquette. This condition can be more conveniently expressed if we consider the dual lattice, in which sites and plaquettes are interchanged; the links dual to those on which X acts form a cycle of the dual lattice. In general, then, a Pauli operator that commutes with the stabilizer of the code can be represented as a tensor product of Z's acting on a cycle of the lattice, times a tensor product of X's acting on a cycle of the dual lattice.

Cycles are of two distinct types. A one-cycle is *homologically trivial* if it can be expressed as the boundary of a two-chain [Fig. 2(a)]. Thus, a homologically trivial cycle on our square lattice has an interior that can be "tiled" by plaquettes, and a product of Z's acting on the links of the cycle can be expressed as a product of the enclosed plaquette operators. This operator is therefore a product of the check operators—it is contained in the code stabilizer and acts trivially on the code subspace. Similarly, a product of X's acting on links that comprise a homologically trivial cycle of the dual lattice is also a product of check operators. Furthermore, *any* element of the stabilizer group of the toric code (any product of the generators) can be expressed as a product of Z's acting on a homologically trivial cycle of the lattice times X's acting on a homologically trivial cycle of the dual lattice.

But a cycle could be homologically nontrivial, that is, not the boundary of anything [Fig. 2(b)]. A product of Z's corresponding to a nontrivial cycle commutes with the code stabilizer (because it is a cycle), but is not contained in the stabilizer (because the cycle is nontrivial). Therefore, while this operator preserves the code subspace, it acts nontrivially on encoded quantum information. Associated with the two fundamental nontrivial cycles of the torus, then, are the encoded operations $\overline{Z}_1$ and $\overline{Z}_2$ acting on the two encoded qubits. Associated with the two dual cycles of the dual lattice are the corresponding encoded operations $\overline{X}_1$ and $\overline{X}_2$, as shown in Fig. 3.

A Pauli operator acting on n qubits is said to have *weight* w if the identity I acts on $n-w$ qubits and nontrivial Pauli matrices act on w qubits. The *distance* d of a stabilizer code is the weight of the minimal-weight Pauli operator that preserves the code subspace and acts nontrivially within the code subspace. If an encoded state is damaged by the action of a Pauli operator whose weight is less than half the code distance, then we can recover from the error successfully by applying the minimal weight Pauli operator that returns the damaged state to the code subspace (which can be determined by measuring the check operators). For a toric code, the distance is the number of lattice links contained in the shortest homologically nontrivial cycle on the lattice or dual lattice. Thus in the case of an $L\times L$ square lattice drawn on the torus, the code distance is $d=L$.

The great virtue of the toric code is that the check operators are so simple. Measuring a check

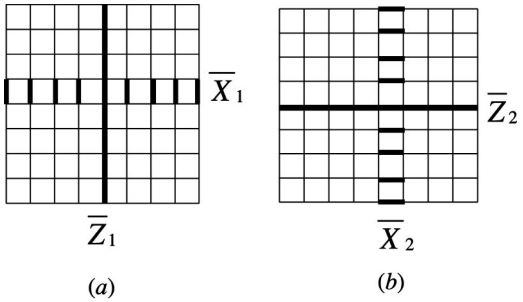

FIG. 3. Basis for the operators that act on the two encoded qubits of the toric code. The logical operators $\overline{Z}_1$ and $\overline{Z}_2$ are tensor products of Z's associated with the fundamental nontrivial cycles of the torus constructed from links of the lattice. The complementary operators $\overline{X}_1$ and $\overline{X}_2$ are tensor products of X's associated with nontrivial cycles constructed from links of the dual lattice.

operator requires a quantum computation, but because each check operator involves just four qubits in the code block, and these qubits are situated near one another, the measurement can be executed by performing just a few quantum gates. Furthermore, the ancilla qubits used in the measurement can be situated where they are needed, so that the gates act on pairs of qubits that are in close proximity.

The observed values of the check operators provide a ''syndrome'' that we may use to diagnose errors. If there are no errors in the code block, then every check operator takes the value 1. Since each check operator is associated with a definite position on the surface, a site of the lattice or the dual lattice, we may describe the syndrome by listing all positions where the check operators take the value -1. It is convenient to regard each such position as the location of a particle, a ''defect'' in the code block.

If errors occur on a particular chain (a set of links of the lattice or dual lattice), then defects occur at the sites on the *boundary* of the chain. Evidently, then, the syndrome is highly ambiguous, as many error chains can share the same boundary, and all generate the same syndrome. For example, the two chains shown in Fig. 4 end on the same two sites. If errors occur on one of these

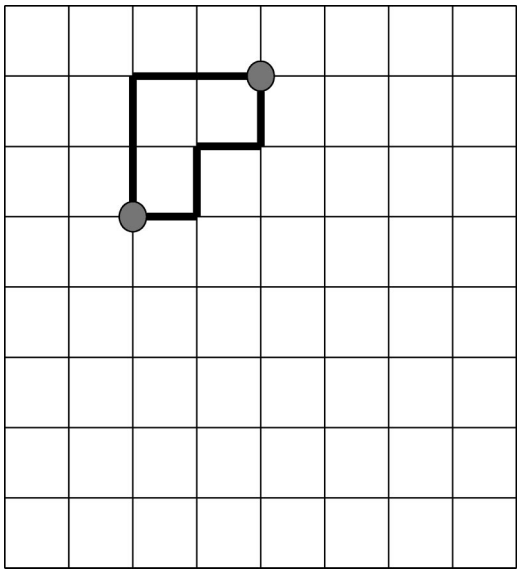

FIG. 4. The highly ambiguous syndrome of the toric code. The two site defects shown could arise from errors on either one of the two chains shown. In general, error chains with the same boundary generate the same syndrome, and error chains that are homologically equivalent act on the code space in the same way.

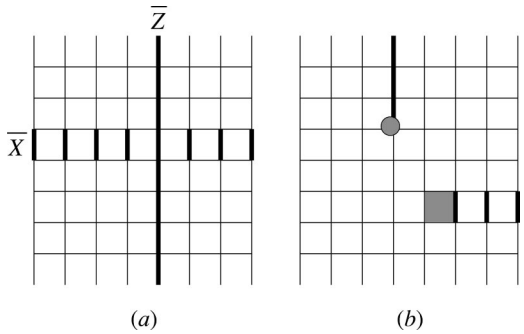

FIG. 5. A planar quantum code. (a) At the top and bottom are the ''plaquette edges'' (or ''rough edges'') where there are three-qubit plaquette operators, and at the left and right are the ''site edges'' (or ''smooth edges'') where there are three-qubit site operators. The logical operation $\overline{Z}$ for the one encoded qubit is a tensor product of Z's acting on a chain running from one rough edge to the other, and the logical operation $\overline{X}$ is a tensor product of X's acting on a chain of the dual lattice running from one smooth edge to the other. For the lattice shown, the code's distance is $L=8$. (b) Site and plaquette defects can appear singly, rather than in pairs. An isolated site defect arises from an error chain that ends at a rough edge, and an isolated plaquette defect arises from a dual error chain that ends at a smooth edge.

chains, we might incorrectly infer that the errors actually occured on the other chain. Fortunately, though, this ambiguity need not cause harm. If Z errors occur on a particular chain, then by applying Z to each link of *any* chain with the same boundary as the actual error chain, we will successfully remove all defects. Furthermore, as long as the chosen chain is *homologically* correct (differs from the actual error chain by the one-dimensional boundary of a two-dimensional region), then the encoded state will be undamaged by the errors. In that event, the product of the actual Z errors and the Z's that we apply is contained in the code stabilizer and therefore acts trivially on the code block.

Heuristically, an error chain can be interpreted as a physical process in which a defect pair nucleates, and the two members of the pair drift apart. To recover from the errors, we lay down a ''recovery chain'' bounded by the two defect positions, which we can think of as a physical process in which the defects are brought together to reannihilate. If the defect world line consisting of both the error chain and the recovery chain is homologically trivial, then the encoded quantum state is undamaged. But if the world line is homologically nontrivial (if the two members of the pair wind around a cycle of the torus before reannihilating), then an error afflicts the encoded quantum state.

B. Planar codes

If all check operators are to be readily measured with local gates, then the qubits of the toric code need to be arranged on a topologically nontrivial surface, the torus, with the ancilla qubits needed for syndrome measurement arranged on an adjacent layer. In practice, the toroidal topology is likely to be inconvenient, especially if we want qubits residing in different tori to interact with one another in the course of a quantum computation. Fortunately, surface codes can be constructed in which all check operators are local and the qubits are arranged on planar sheets.[13,14] The planar topology will be more conducive to realistic quantum computing architectures.

In the planar version of the surface code, there is a distinction between the check operators at the boundary of the surface and the check operators in the interior. Check operators in the interior are four-qubit site or plaquette operators, and those at the boundary are three-qubit operators. Furthermore, the boundary has two different types of edges as shown in Fig. 5. Along a ''plaquette edge'' or ''rough edge,'' each check operator is a three-qubit plaquette operator $Z^{\otimes 3}$. Along a ''site edge'' or ''smooth edge,'' each check operator is a three-qubit site operator $X^{\otimes 3}$.

As before, in order to commute with the code stabilizer, a product of Z's must act on an even number of links adjacent to each site of the lattice. Now, though, the links acted upon by Z's may comprise an *open* path that begins and ends on a rough edge. We may then say that the one-chain

comprised of all links acted upon by Z is a cycle *relative to the rough edges*. Similarly, a product of X's that commutes with the stabilizer acts on a set of links of the dual lattice that comprise a cycle relative to the smooth edges.

Cycles relative to the rough edges come in two varieties. If the chain contains an even number of the free links strung along the rough edge, then it can be tiled by plaquettes (including the boundary plaquettes), and so the corresponding product of Z's is contained in the stabilizer. We say that the relative one-cycle is a relative boundary of a two-chain. However, a chain that stretches from one rough edge to another is not a relative boundary—it is a representative of a nontrivial relative homology class. The corresponding product of Z's commutes with the stabilizer but does not lie in it, and we may take it to be the logical operation $\overline{Z}$ acting on an encoded logical qubit. Similarly, cycles relative to the smooth edges also come in two varieties, and a product of X's associated with the nontrivial relative homology cycle of the dual lattice may be taken to be the logical operation $\overline{X}$ [see Fig. 5(a)].

A code with distance L is obtained from a square lattice, if the shortest paths from rough edge to rough edge, and from smooth edge to smooth edge, both contain L links. The lattice has $L^2+(L-1)^2$ links, $L(L-1)$ plaquettes, and $L(L-1)$ sites. Now all plaquette and site operators are independent, which is another way to see that the number of encoded qubits is $L^2+(L-1)^2-2L(L-1)=1$.

The distinction between a rough edge and a smooth edge can also be characterized by the behavior of the defects at the boundary, as shown in Fig. 5(b). In the toric codes, defects always appear in pairs, because every one-chain has an even number of boundary points. But for planar codes, individual defects can appear, since a one-chain can terminate on a rough edge. Thus a propagating site defect can reach the rough edge and disappear. But if the site defect reaches the smooth edge, it persists at the boundary. Similarly, a plaquette defect can disappear at the smooth edge, but not at the rough edge.

Let us briefly note some generalizations of the toric codes and planar codes that we have described. First, there is no need to restrict attention to lattices that have coordination number 4 at each site and plaquette. Any tessellation of a surface (and its dual tessellation) can be associated with a quantum code. Second, we may consider surfaces of higher genus. For a closed orientable Riemann surface of genus g, $2g$ qubits can be encoded—each time a handle is added to the surface, there are two new homology cycles and hence two new logical $\overline{Z}$'s. The distance of the code is the length of the shortest nontrivial cycle on lattice or dual lattice. For planar codes, we may consider a surface with e distinct rough edges separated by e distinct smooth edges. Then $e-1$ qubits can be encoded, associated with the relative one-cycles that connect one rough edge with any of the others. The distance is the length of the shortest path reaching from one rough edge to another, or from one smooth edge to another on the dual lattice. Alternatively, we can increase the number of encoded qubits stored in a planar sheet by punching holes in the lattice. For example, if the outer boundary of the surface is a smooth edge, and there are h holes, each bounded by a smooth edge, then h qubits are encoded. For each hole, a cycle on the lattice that encloses the hole is associated with the corresponding logical $\overline{Z}$, and a path on the dual lattice from the boundary of the hole to the outer boundary is associated with the logical $\overline{X}$.

If (say) phase errors are more common than bit-flip errors, quantum information can be stored more efficiently with an *asymmetric* planar code, such that the distance from rough edge to rough edge is longer than the distance from smooth edge to smooth edge. However, these asymmetric codes are less convenient for processing of the encoded information.

The surface codes can also be generalized to higher dimensional manifolds, with logical operations again associated with homologically nontrivial cycles. In Sec. X, we will discuss a four-dimensional example.

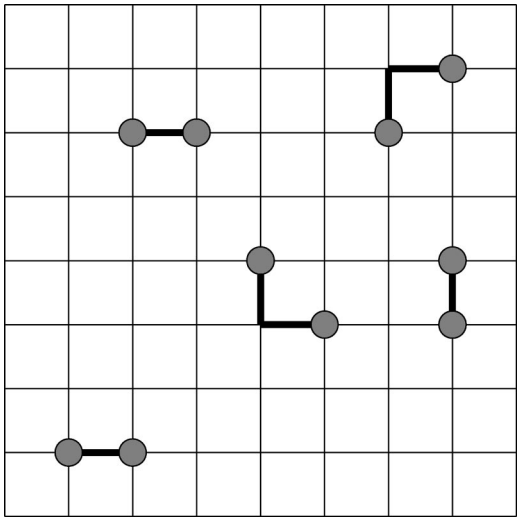

FIG. 6. Pairs of defects. If the error rate is small and errors on distinct links are uncorrelated, then connected error chains are typically short and the positions of defects are highly correlated. It is relatively easy to guess how the defects should be paired up so that each pair is the boundary of a connected chain.

C. Fault-tolerant recovery

A toric code defined on a lattice of linear size L has block size $2L^2$ and distance L. Therefore, if the probability of error per qubit is p, the number of errors expected in a large code block is of order pL^2, and therefore much larger than the code distance.

However, the performance of a toric code is much better than would be guessed naively based on its distance. In principle, $L/2$ errors could suffice to cause damage to the encoded information. But in fact this small number of errors can cause irrevocable damage only if the distribution of the errors is highly atypical.

If the error probability p is small, then links where errors occur (''error links'') are dilute on the lattice. Long connected chains of error links are quite rare, as indicated in Fig. 6. It is relatively easy to guess a way to pair up the observed defects that is homologically equivalent to the actual error chain. Hence we expect that a number of errors that scales *linearly* with the block size can be tolerated. That is, if the error probability p per link is small enough, we expect to be able to recover correctly with a probability that approaches one as the block size increases. We therefore anticipate that there is an accuracy threshold for storage of quantum information using a toric code.

Unfortunately, life is not quite so simple, because the measurement of the syndrome will not be perfect. Occasionally, a faulty measurement will indicate that a defect is present at a site even though no defect is actually there, and sometimes an actual defect will go unobserved. Hence the population of real defects (which have strongly correlated positions) will be obscured by a population of phony ''ghost defects'' and ''missing defects'' (which have randomly distributed positions), as in Fig. 7.

Therefore, we should execute recovery cautiously. It would be dangerous to blithely proceed by flipping qubits on a chain of links bounded by the observed defect positions. Since a ghost defect is typically far from the nearest genuine defect, this procedure would introduce many additional errors—what was formerly a ghost defect would become a real defect connected to another defect by a long error chain. Instead we must repeat the syndrome measurement an adequate number of times to verify its authenticity. It is subtle to formulate a robust recovery procedure that incorporates repeated measurements, since further errors accumulate as the measurements are repeated and the gas of defects continues to evolve.

We know of three general strategies that can be invoked to achieve robust macroscopic control

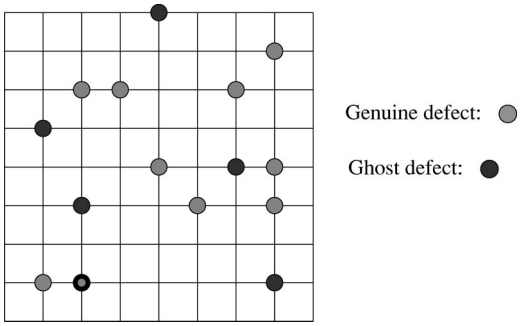

FIG. 7. Ghost defects. Since faults can occur in the measurement of the error syndrome, the measured syndrome includes both genuine defects (lightly shaded) associated with actual errors and phony ''ghost defects'' (darkly shaded) that arise at randomly distributed locations. To perform recovery successfully, we need to be able to distinguish reliably between the genuine defects and the ghost defects. The position that is shaded both lightly and darkly represents a genuine defect that goes unseen due to a measurement error.

of a system that is subjected to microscopic disorder. One method is to introduce a hierarchical organization in such a way that effects of noise get weaker and weaker at higher and higher levels of the hierarchy. This approach is used by Gács[15] in his analysis of robust one-dimensional classical cellular automata, and also in concatenated quantum coding.[6–10] A second method is to introduce more spatial dimensions. A fundamental principle of statistical physics is that local systems with higher spatial dimensionality and hence higher coordination number are more resistant to the disordering effects of fluctuations. In Sec. X we will follow this strategy in devising and analyzing a topological code that has nice locality properties in four dimensions. From the perspective of block coding, the advantage of extra dimensions is that local check operators can be constructed with a higher degree of redundancy, which makes it easier to reject faulty syndrome information.

In the bulk of this article we will address the issue of achieving robustness through a third strategy, namely by introducing a modest amount of nonlocality into our recovery procedure. But we will insist that all quantum processing is strictly local; the nonlocality will be isolated in *classical* processing. Specifically, to decide on the appropriate recovery step, a classical computation will be performed whose input is an error syndrome measured at all the sites of the lattice. We will require that this classical computation can be executed in a time bounded by a polynomial in the number of lattice sites. For the purpose of estimating the accuracy threshold, we will imagine that the classical calculation is instantaneous and perfectly accurate.

Our approach is guided by the expectation that quantum computers will be slow and unreliable while classical computers are fast and accurate. It is advantageous to replace quantum processing by classical processing if the classical processing can accomplish the same task.

D. Surface codes and physical fault tolerance

In this article, we regard the surface codes as block quantum error-correcting codes with properties that make them especially amenable to fault-tolerant quantum storage and computation. But we also remark here that because of the locality of the check operators, these codes admit another tempting interpretation that was emphasized in Refs. 4 and 5.

Consider a model physical system, with qubits arranged in a square lattice, and with a (local) Hamiltonian that can be expressed as minus the sum of the check operators of a surface code. Since the check operators are mutually commuting, we can diagonalize the Hamiltonian by diagonalizing each check operator separately, and its degenerate ground state is the code subspace. Thus, a real system that is described well enough by this model could serve as a robust quantum memory.

The model system has several crucial properties. First of all, it has a mass gap, so that its qualitative properties are stable with respect to generic weak local perturbations. Second, it has

two types of localized quasiparticle excitations, the site defects and plaquette defects. And third, there is an exotic long-range interaction between a site defect and a plaquette defect.

The interaction between the two defects is exactly analogous to the Aharonov–Bohm interaction between a localized magnetic flux Φ and a localized electric charge Q in two-spatial dimensions. When a charge is adiabatically carried around a flux, the wave function of the system is modified by a phase $\exp(iQ\Phi/\hbar c)$ that is independent of the separation between charge and flux. Similarly, if a site defect is transported around a plaquette defect, the wave function of the system is modified by the phase -1 independent of the separation between the defects. Formally, this phase arises because of the anticommutation relation satisfied by X and Z. Physically, it arises because the ground state of the system is very highly entangled and thus is able to support very-long-range quantum correlations. The protected qubits are encoded in the Aharonov–Bohm phases acquired by quasiparticles that travel around the fundamental nontrivial cycles of the surface; these could be measured in principle in a suitable quantum interference experiment.

It is useful to observe that the degeneracy of the ground state of the system is a necessary consequence of the unusual interactions among the quasiparticles.[19,20] A unitary operator $U_{S,1}$ can be constructed that describes a process in which a pair of site defects is created, one member of the pair propagates around a nontrivial cycle C_1 of the surface, and then the pair reannihilates. Similarly a unitary operator $U_{P,2}$ can be constructed associated with a plaquette defect that propagates around a complementary nontrivial cycle C_2 that intersects C_1 once. These operators commute with the Hamiltonian H of the system and can be simultaneously diagonalized with H, but $U_{S,1}$ and $U_{P,2}$ do not commute with one another. Rather, they satisfy (in an infinite system)

$$U_{P,2}{}^{-1}\ U_{S,1}{}^{-1}\ U_{P,2}\ U_{S,1} = -1. \tag{6}$$

The nontrivial commutator arises because the process in which (1) a site defect winds around C_1, (2) a plaquette defect winds around C_2, (3) the site defect winds around C_1 in the reverse direction, and (4) the plaquette defect winds around C_2 in the reverse direction is topologically equivalent to a process in which the site defect winds once around the plaquette defect.

Because $U_{S,1}$ and $U_{P,2}$ do not commute, they cannot be simultaneously diagonalized—indeed applying $U_{P,2}$ to an eigenstate of $U_{S,1}$ flips the sign of the $U_{S,1}$ eigenvalue. Physically, there are two distinct ground states that can be distinguished by the Aharonov–Bohm phase that is acquired when a site defect is carried around C_1; we can change this phase by carrying a plaquette defect around C_2. Similarly, the operator $U_{S,2}$ commutes with $U_{S,1}$ and $U_{P,2}$ but anticommutes with $U_{P,1}$. Therefore there are four distinct ground states, labeled by their $U_{S,1}$ and $U_{S,2}$ eigenvalues.

This reasoning shows that the topological interaction between site defects and plaquette defects implies that the system on an (infinite) torus has a generic four-fold ground-state degeneracy. The argument is easily extended to show that the generic degeneracy on a genus g Riemann surface is 2^{2g}. By a further extension, we see that the generic degeneracy is q^{2g} if the Aharonov–Bohm phase associated with winding one defect around another is

$$\exp(2\pi i p/q), \tag{7}$$

where p and q are integers with no common factor.

The same sort of argument can be applied to planar systems with a mass gap in which single defects can disappear at an edge. For example, consider an annulus in which site defects can disappear at the inner and outer edges. Then states can be classified by the Aharonov–Bohm phase acquired by a plaquette defect that propagates around the annulus, a phase that flips in sign if a site defect propagates from inner edge to outer edge. Hence there is a two-fold degeneracy on the annulus. For a disc with h holes, the degeneracy is 2^h if site defects can disappear at any boundary, or q^h if the Aharonov–Bohm phase of site defect winding about plaquette defect is $\exp(2\pi i p/q)$.

These degeneracies are exact for the unperturbed model system, but will be lifted slightly in a weakly perturbed system of finite size. Loosely speaking, the effect of perturbations will be to

give the defects a finite effective mass, and the lifting of the degeneracy is associated with quantum tunneling processes in which a virtual defect winds around a cycle of the surface. The amplitude A for this process has the form

$$A \sim C \exp(-\sqrt{2}(m^*\Delta)^{1/2}L/\hbar), \tag{8}$$

where L is the physical size of the shortest nontrivial (relative) cycle of the surface, m^* is the defect effective mass, and Δ is the minimal energy cost of creating a defect. The energy splitting is proportional to A, and like A becomes negligible when the system is large compared to the characteristic length $l \equiv \hbar(m^*\Delta)^{-1/2}$.

In this limit, and at sufficiently low temperature, the degenerate ground state provides a reliable quantum memory. If a pair of defects is produced by a thermal fluctuation, and one of the defects wanders around a nontrivial cycle before the pair reannihilates, then the encoded quantum information will be damaged. These fluctuations are suppressed by the Boltzman factor $\exp(-\Delta/kT)$ at low temperature. Even if defect nucleation occurs at a non-negligible rate, we could enhance the performance of the quantum memory by continually monitoring the state of the defect gas. If the winding of defects around nontrivial cycles is detected and carefully recorded, damage to the encoded quantum information can be controlled.

IV. THE STATISTICAL PHYSICS OF ERROR RECOVERY

One of our main objectives in this article is to invoke surface coding to establish an accuracy threshold for quantum computation—how well must quantum hardware perform for quantum storage, or universal quantum computation, to be achievable with arbitrarily small probability of error? In this section, rather than study the efficacy of a particular fault-tolerant protocol for error recovery, we will address whether the syndrome of a surface code is adequate in principle for protecting quantum information from error. Specifically, we will formulate an order parameter that distinguishes two phases of a quantum memory: an ''ordered'' phase in which reliable storage is possible, and a ''disordered phase'' in which errors unavoidably afflict the encoded quantum information. Of course, this phase boundary also provides an upper bound on the accuracy threshold that can be reached by any particular protocol. The toric code and the planar surface code have the same accuracy threshold, so we may study either to learn about the other.

A. The error model

Let us imagine that in a single time step, we will execute a measurement of each stabilizer operator at each site and each plaquette of the lattice. During each time step, new qubit errors might occur. To be concrete and to simplify the discussion, we assume that all qubit errors are stochastic, and so can be assigned probabilities. (For example, errors that arise from decoherence have this property.) We will also assume that the errors acting on different qubits are independent, that bit-flip (X) errors and phase (Z) errors are uncorrelated with one another, and that X and Z errors are equally likely. Thus the error in each time step acting on a qubit with state ρ can be represented by the quantum channel

$$\rho \to (1-p)^2 I\rho I + p(1-p)X\rho X + p(1-p)Z\rho Z + p^2 Y\rho Y, \tag{9}$$

where p denotes the probability of either an X error or a Z error. It is easy to modify our analysis if some of these assumptions are relaxed; in particular, correlations between X and Z errors would not cause much trouble, since we have separate procedures for recovery from the X errors and the Z errors.

Faults can also occur in the syndrome measurement. We assume that these measurement errors are uncorrelated. We will denote by q the probability that the measured syndrome bit is faulty at a given site or plaquette.

Aside from being uncorrelated in space, the qubit and measurement errors are also assumed to be uncorrelated in time. Furthermore, the qubit and measurement errors are not correlated with one another. We assume that p and q are known quantities—our choice of recovery algorithm depends

on their values. In Sec. VII, we will discuss how p and q can be related to more fundamental quantities, namely the fidelities of elementary quantum gates. There we will see that the execution of the syndrome measurement circuit can introduce correlations between errors. Fortunately, these correlations (which we ignore for now) do not have a big impact on the accuracy threshold.

B. Defects in space–time

Because syndrome measurement may be faulty, it is necessary to repeat the measurement to improve our confidence in the outcome. But since new errors may arise during the repeated measurements, it is a subtle matter to formulate an effective procedure for rejecting measurement errors.

Let us suppose, for a toric block of arbitrarily large size, that we measure the error syndrome once per time step, that we monitor the block for an arbitrarily long time, and that we store all of the syndrome information that is collected. We want to address whether this syndrome information enables us to recover from errors with a probability of failure that becomes exponentially small as the size of the toric block increases. The plaquette check operators identify bit flips and the site check operators identify phase errors; therefore we consider bit-flip and phase error recovery separately.

For analyzing how the syndrome information can be used most effectively, it is quite convenient to envision a *three-dimensional* simple cubic lattice, with the third dimension representing an integer-valued *time*. We imagine that the error operation acts at each integer-valued time t, with a syndrome measurement taking place in between each t and $t+1$. Qubits in the code block can now be associated with timelike plaquettes, those lying in the tx and ty planes. A qubit error that occurs at time t is associated with a horizontal (spacelike) link that lies in the time slice labeled by t. The outcome of the measurement of the stabilizer operator $X_s = X^{\otimes 4} = \pm 1$ at site s, performed between time t and time $t+1$, is marked on the vertical (timelike) link connecting site s at time t and site s at time $t+1$. A similar picture applies to the history of the Z_P stabilizer operators at each plaquette, but with the lattice replaced by its dual.

On some of these vertical links, the measured syndrome is erroneous. We will repeat the syndrome measurement T times in succession, and the ''error history'' can be described as a set of marked links on a lattice with altogether T time slices. The error history encompasses both error events that damage the qubits in the code block, and faults in the syndrome measurements. On the initial $(t=0)$ slice are marked all uncorrected qubit errors that are left over from previous rounds of error correction; new qubit errors that arise at a later time t $(t=1,2,\ldots,T-1)$ are marked on horizontal links on slice t. Errors in the syndrome measurement that takes place between time t and $t+1$ are marked on the corresponding vertical links. Errors on horizontal links occur with probability p, and errors on vertical links occur with probability q.

For purposes of visualization, it is helpful to consider the simpler case of a quantum repetition code, which can be used to protect coherent quantum information from bit-flip errors if there are no phase errors (or phase errors if there are no bit-flip errors). In this case we may imagine that qubits reside on sites of a periodically identified one-dimensional lattice (i.e., a circle); at each link the stabilizer generator ZZ acts on the two neighboring sites. Then there is one encoded qubit—the two-dimensional code space is spanned by the state $|000\ldots0\rangle$ with all spins ''up,'' and the state $|111\ldots\rangle$ with all spins ''down.'' In the case where the syndrome measurement is repeated to improve reliability, we may represent the syndrome's history by associating qubits with plaquettes of a two-dimensional lattice, and syndrome bits with the timelike links, as shown in Figs. 8 and 9. Again, bit-flip errors occur on horizontal links with probability p and syndrome measurement errors occur on vertical links with probability q.

Of course, as already noted in Sec. III C, we may also use a two-dimensional lattice to represent the error configuration of the toric code, in the case where the syndrome measurements are perfect. In that case, we can collect reliable information by measuring the syndrome in one shot, and errors occur on links of the two-dimensional lattice with probability p.

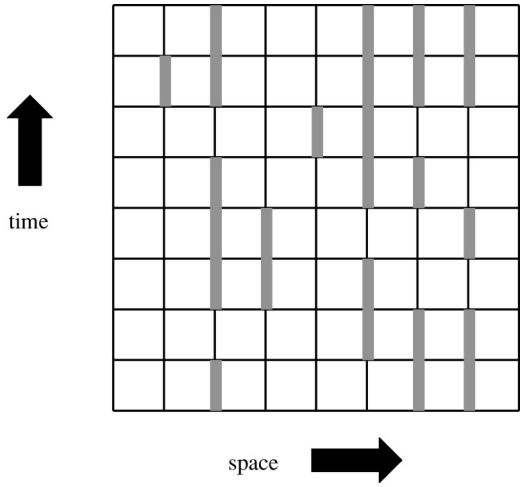

FIG. 8. The two-dimensional lattice depicting a history of the error syndrome for the quantum repetition code, with time running upward. Each row represents the syndrome at a particular time. Qubits reside on plaquettes, and two-qubit check operators are measured at each vertical link. Links where the syndrome is nontrivial are shaded.

C. Error chains, world lines, and magnetic flux tubes

In practice, we will always want to protect quantum information for some finite time. But for the purpose of investigating whether error correction will work effectively in principle, it is convenient to imagine that our repeated rounds of syndrome measurement extend indefinitely into the past and into the future. Qubit errors are continually occurring; as defects are created in pairs, propagate about on the lattice, and annihilate in pairs, the world lines of the defects form closed loops in space–time. Some loops are homologically trivial and some are homologically nontrivial. Error recovery succeeds if we are able to correctly identify the homology class of each closed loop. But if a homologically nontrivial loop arises that we fail to detect, or if we mistakenly believe that a homologically nontrivial loop has been generated when none has been, then error

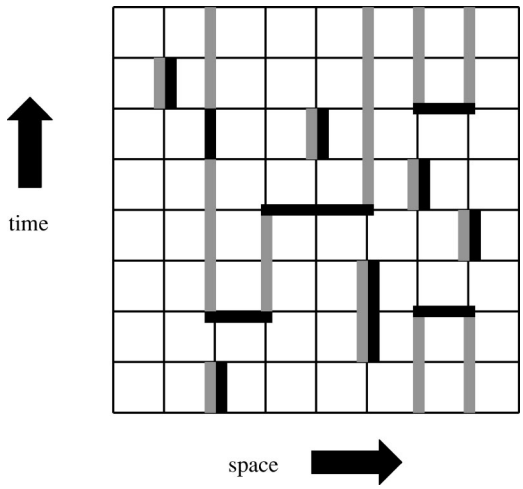

FIG. 9. An error history shown together with the syndrome history that it generates, for the quantum repetition code. Links where errors occurred are darkly shaded, and links where the syndrome is nontrivial are lightly shaded. Errors on horizontal links indicate where a qubit flipped between successive syndrome measurements, and errors on vertical links indicate where the syndrome measurement was wrong. Vertical links that are shaded both lightly and darkly are locations where a nontrivial syndrome was found erroneously. The chain of lightly shaded links (the syndrome) and the chain of darkly shaded links (the errors) both have the same boundary.

recovery will fail. For now, let us consider this scenario in which we continue to measure the syndrome forever—in Sec. VI, we will consider some issues that arise when we perform error correction for a finite time.

So let us imagine a particular history extending over an indefinite number of time slices, with the observed syndrome marked on each vertical link, measurement errors marking selected vertical links, and qubit errors marking selected horizontal links. For this history we may identify several distinct one-chains (sets of links). We denote by S the *syndrome chain* containing all (vertical) links at which the measured syndrome is nontrivial ($X_s=-1$). We denote by E the *error chain* containing all links where errors have occurred, including both qubit errors on horizonal links and measurement errors on vertical links. Consider $S+E$, the disjoint union of S and E ($S+E$ contains the links that are in either S or E, but not both). The chain $S+E$ represents the ''actual'' world lines of the defects generated by qubit errors, as illustrated in Fig. 9. Its vertical links are those on which the syndrome would be nontrivial were it measured without error. Its horizontal links are events where a defect pair is created, a pair annihilates, or an existing defect propagates from one site to a neighboring site. Since the world lines never end, the chain $S+E$ has no boundary, $\partial(S+E)=0$. Equivalently S and E have the same boundary, $\partial S=\partial E$.

Hence, the measured syndrome S reveals the boundary of the error chain E; we may write $E=S+C$, where C is a *cycle* (a chain with no boundary). But any other error chain $E'=S+C'$, where C' is a cycle, has the same boundary as E and therefore could have caused the same syndrome. To recover from error, we will use the syndrome information to make a hypothesis, guessing that the actual error chain was $E'=S+C'$. Now, E' may not be the same chain as E, but, as long as the cycle $E+E'=C+C'$ is homologically trivial (the boundary of a surface), then recovery will be successful. If $C+C'$ is homologically nontrivial, then recovery will fail. We say that C and C' are in the same *homology class* if $C+C'$ is homologically trivial. Therefore, whether we can protect against error hinges on our ability to identify not the cycle C, but rather the homology class of C.

Considering the set of all possible histories, let prob(E') denote the probability of the error chain E' (strictly speaking, we should consider the total elapsed time to be finite for this probability to be defined). Then the probability that the syndrome S was caused by any error chain $E'=S+C'$, such that C' belongs to the homology class h, is

$$\mathrm{prob}(h|S)=\frac{\Sigma_{C'\in h}\mathrm{prob}(S+C')}{\Sigma_{C'}\mathrm{prob}(S+C')}. \tag{10}$$

Clearly, then, given a measured syndrome S, the optimal way to recover is to guess that the homology class h of C is the class with the highest probability according to Eq. (10). Recovery succeeds if C belongs to this class, and fails otherwise.

We say that the probability of error per qubit lies below the accuracy threshold if and only if the recovery procedure fails with a probability that vanishes as the linear size L of the lattice increases to infinity. Therefore, below threshold, the cycle C actually belongs to the class h that maximizes Eq. (10) with a probability that approaches one as $L\to\infty$. It is convenient to restate this criterion in a different way that makes no explicit reference to the syndrome chain S. We may write the relation between the actual error chain E and the hypothetical error chain E' as $E'=E+D$, where D is the cycle that we called $C+C'$ above. Let prob$[(E+D)|E]$ denote the normalized conditional probability for error chains $E'=E+D$ that have the same boundary as E. Then, the probability of error per qubit lies below threshold if and only if, in the limit $L\to\infty$,

$$\sum_E \mathrm{prob}(E)\cdot\sum_{D\ \mathrm{nontrivial}}\mathrm{prob}[(E+D)|E]=0. \tag{11}$$

Equation (11) says that error chains that differ from the actual error chain by a homologically nontrivial cycle have probability zero. Therefore, the observed syndrome S is sure to point to the correct homology class, in the limit of an arbitrarily large code block.

This accuracy threshold achievable with toric codes can be identified with a phase transition in a particular statistical physics model defined on a lattice. In a sense that we will make precise, the error chains are analogous to magnetic flux tubes in a superconductor, and the boundary points of the error chains are magnetic monopoles where these flux tubes terminate. Fixing the syndrome pins down the monopoles, and the ensemble of chains with a specified boundary can be regarded as a thermal ensemble. As the error probability increases, the thermal fluctuations of the flux tubes increase, and at the critical temperature corresponding to the accuracy threshold, the flux tubes condense and the superconductivity is destroyed.

A similar analogy applies to the case where the syndrome is measured perfectly, and a two-dimensional system describes the syndrome on a single time slice. Then the error chains are analogous to domain walls in an Ising ferromagnet, and the boundary points of the error chains are ''Ising vortices'' where domain walls terminate. Fixing the syndrome pins down the vortices, and the ensemble of chains with a specified boundary can be interpreted as a thermal ensemble. As the error probability increases, the domain walls heat up and fluctuate more vigorously. At a critical temperature corresponding to the accuracy threshold, the domain walls condense and the system becomes magnetically disordered. This two-dimensional model also characterizes the accuracy threshold achievable with a quantum repetition code, if the syndrome is imperfect and the qubits are subjected only to bit-flip errors (or only to phase errors).

D. Derivation of the model

Let us establish the precise connection between our error model and the corresponding statistical physics model. In the two-dimensional case, we consider a square lattice with links representing qubits, and assume that errors arise independently on each link with probability p. In the three-dimensional case, we consider a simple cubic lattice. Qubits reside on the timelike plaquettes, and qubit errors arise independently with probability p on spacelike links. Measurement errors occur independently with probability q on timelike links. For now, we will make the simplifying assumption that $q=p$ so that the model is isotropic; the generalization to $q\neq p$ is straightforward.

An error chain E, in either two or three dimensions, can be characterized by a function $n_E(l)$ that takes a link ℓ to $n_E(\ell)\in\{0,1\}$, where $n_E(\ell)=1$ for each link ℓ that is occupied by the chain. Hence the probability that error chain E occurs is

$$\mathrm{prob}(E)=\prod_\ell\,(1-p)^{1-n_E(\ell)}p^{n_E(\ell)}=\left[\prod_\ell\,(1-p)\right]\cdot\prod_\ell\,\left(\frac{p}{1-p}\right)^{n_E(\ell)}, \tag{12}$$

where the product is over all links of the lattice.

Now suppose that the error chain E is fixed, and we are interested in the probability distribution for all chains E' that have the same boundary as E. Note that we may express $E'=E+C$, where C is a cycle (a chain with no boundary) and consider the probability distribution for C. Then if $n_C(\ell)=1$ and $n_E(\ell)=0$, the link ℓ is occupied by E' but not by E, an event whose probability (aside from an overall normalization) is

$$\left(\frac{p}{1-p}\right)^{n_C(\ell)}. \tag{13}$$

But if $n_C(\ell)=1$ and $n_E(\ell)=1$, then the link ℓ is not occupied by E', an event whose probability (aside from an overall normalization) is

$$\left(\frac{1-p}{p}\right)^{n_C(\ell)}. \tag{14}$$

Thus a chain $E'=E+C$ with the same boundary as E occurs with probability

$$\mathrm{prob}(E'|E) \propto \prod_{\ell} \exp(J_\ell u_\ell); \tag{15}$$

here we have defined

$$u_\ell = 1 - 2n_C(\ell) \in \{1,-1\}, \tag{16}$$

and the coupling J_ℓ assigned to link ℓ has the form

$$e^{-2J_\ell} = \begin{cases} p/(1-p), & \text{for } \ell \notin E, \\ (1-p)/p, & \text{for } \ell \in E. \end{cases} \tag{17}$$

Recall that the one-chain $\{\ell | u_l = -1\}$ is required to be a *cycle*—it has no boundary.

It is obvious from this construction that $\mathrm{prob}(E'|E)$ does not depend on how the chain E is chosen—it depends only on the boundary of E. We will verify this explicitly below.

The cycle condition satisfied by the u_l's can be expressed as

$$\prod_{\ell \ni s} u_\ell = 1; \tag{18}$$

at each site s, an even number of links incident on that site have $u_\ell = -1$. It is convenient to *solve* this condition, expressing the u_ℓ's in terms of unconstrained variables. To achieve this in two dimensions, we associate with each link ℓ a link ℓ^* *of the dual lattice*. Under this duality, sites are mapped to plaquettes, and the cycle condition becomes

$$\prod_{\ell^* \in P^*} u_{\ell^*} = 1. \tag{19}$$

To solve the constraint, we introduce variables $\sigma_i \in \{1,-1\}$ associated with each site i of the dual lattice, and write

$$u_{ij} = \sigma_i \sigma_j \tag{20}$$

where i and j are nearest-neighbor sites.

Our solution to the constraint is not quite the most general possible. In the language of differential forms, we have solved the condition $du = 0$ (where u is a discrete version of a one-form, and d denotes the exterior derivative) by writing $u = d\sigma$, where σ is a zero-form. Thus our solution misses the cohomologically nontrivial closed forms, those that are not exact. In the language of homology, our solution includes all and only those cycles that are homologically trivial—that is, cycles that bound a surface.

In three dimensions, links are dual to plaquettes, and sites to cubes. The cycle condition becomes, on the dual lattice,

$$\prod_{P^* \in C^*} u_{P^*} = 1; \tag{21}$$

each dual cube C^* contains an even number of dual plaquettes that are occupied by the cycle. We solve this constraint by introducing variables $\sigma_{\ell^*} \in \{1,-1\}$ on the dual links, and defining

$$u_{P^*} = \prod_{\ell^* \in P^*} \sigma_{\ell^*}. \tag{22}$$

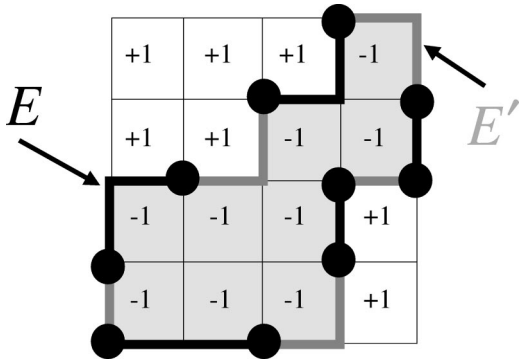

FIG. 10. The "quenched" error chain E and the "fluctuating" error chain E', as represented in the two-dimensional random-bond Ising model. Ising spins taking values in $\{\pm 1\}$ reside on plaquettes, Ising vortices are located on the sites marked by filled circles, and the coupling between neighboring spins is antiferromagnetic along the path E that connects the Ising vortices. The links of E' comprise a domain wall connecting the vortices. The closed path $C=E+E'$ encloses a domain of spins with the value -1.

In this case, we have solved a discrete version of $du=0$, where u is a two-form, by writing $u=d\sigma$, where σ is a one-form. Once again, our solution generates only the cycles that are homologically trivial.

We have now found that, in two dimensions, the "fluctuations" of the error chains E' that share a boundary with the chain E are described by a statistical-mechanical model with partition function

$$Z[J,\eta]=\sum_{\{\sigma_i\}} \exp\left(J\sum_{\langle ij\rangle} \right) \eta_{ij}\sigma_i\sigma_j, \tag{23}$$

where $e^{-2J}=p/(1-p)$. The sum in the exponential is over pairs of nearest neighbors on a square lattice, and $\eta_l \in \{1,-1\}$ is defined by

$$\eta_\ell=\begin{cases} 1, & \text{if } \ell \notin E^*, \\ -1, & \text{if } \ell \in E^*. \end{cases} \tag{24}$$

Furthermore, if the error chains E and E' are generated by sampling the same probability distribution, then the η_ℓ's are chosen at random subject to

$$\eta_\ell=\begin{cases} 1, & \text{with probability } 1-p, \\ -1, & \text{with probability } p. \end{cases} \tag{25}$$

This model is the well-known "random-bond Ising model." Furthermore, the relation $e^{-2J}=p/(1-p)$ between the coupling and the bond probability defines the "Nishimori line" [21] in the phase diagram of the model, which has attracted substantial attention because the model is known to have enhanced symmetry properties on this line. (For a recent discussion, see Ref. 22.)

Perhaps the interpretation of this random-bond Ising model can be grasped better if we picture the original lattice rather than the dual lattice, so that the Ising spins reside on plaquettes as in Fig. 10. The coupling between spins on neighboring plaquettes is antiferromagnetic on the links belonging to the chain E (where $\eta_\ell=-1$), meaning that it is energetically preferred for the spins to antialign at these links. At links not in E (where $\eta=1$), it is energetically preferred for the spins to align. Thus a link ij is excited if $\eta_{ij}\sigma_i\sigma_j=-1$. We say that the excited links constitute "domain walls." In the case where $\eta_\ell=1$ on every link, a wall marks the boundary between two regions in which the spins point in opposite directions. Walls can never end, because the boundary of a boundary is zero.

But if the η configuration is nontrivial, then the ''walls'' can end. Indeed each boundary point of the chain E of links with $\eta_l=-1$ is an endpoint of a wall, what we will call an ''Ising vortex.'' For example, for the configuration shown in Fig. 10, a domain wall occupies the chain E' that terminates on Ising vortices at the marked sites. The figure also illustrates that the model depends only on the boundary of the chain E, and not on other properties of the chain. To see this, imagine performing the change of variables

$$\sigma_i \rightarrow -\sigma_i \tag{26}$$

on the shaded plaquettes of Fig. 10. A mere change of variable cannot alter the locations of the excited links—rather, the effect is to shift the antiferromagnetic couplings from the chain E to a different chain E' with the same boundary.

In three dimensions, the fluctuations of the error chains that share a boundary with the specified chain E are described by a model with partition function

$$Z[J,\eta]=\sum_{\{\sigma_\ell\}} \exp\left(J\sum_P \eta_P u_P \right), \tag{27}$$

where $u_P=\Pi_{\ell\in P}\sigma_\ell$ and

$$\eta_P=\begin{cases} 1, & \text{if } P\notin E^*, \\ -1, & \text{if } P\in E^*. \end{cases} \tag{28}$$

This model is a ''random-plaquette'' Z_2 gauge theory in three dimensions, which, as far as we know, has not been much studied previously. Again, we are interested in the ''Nishimori line'' of this model where $e^{-2J}=p/(1-p)$, and p is the probability that a plaquette has $\eta_P=-1$.

In this three-dimensional model, we say that a plaquette P is excited if $\eta_P u_P=-1$. The excited plaquettes constitute ''magnetic flux tubes''—these form closed loops on the original lattice if $\eta_P=1$ on every plaquette. But at each boundary point of the chain E on the original lattice (each cube on the dual lattice that contains an odd number of plaquettes with $\eta_P=-1$), the flux tubes can end. The sites of the original lattice (or cubes of the dual lattice) that contain endpoints of magnetic flux tubes are said to be ''magnetic monopoles.''

E. Order parameters

As noted, our statistical-mechanical model includes a sum over those and only those chains E' that are *homologically equivalent* to the chain E. To determine whether errors can be corrected reliably, we want to know whether chains E' in a *different* homology class than E have negligible probability in the limit of a large lattice (or code block). The relative likelihood of different homology classes is determined by the free energy difference of the classes; in the ordered phase, we anticipate that the free energy of nontrivial classes exceeds that of the trivial classes by an amount that increases linearly with L, the linear size of the lattice.

But for the purpose of finding the value of the error probability at the accuracy threshold, it suffices to consider the model in an infinite volume (where there is no nontrivial homology). In the ordered phase where errors are correctable, large fluctuations of domain walls or flux tubes are suppressed, while in the disordered phase the walls or tubes ''dissolve'' and cease to be well defined.

Thus, the phase transition corresponding to the accuracy threshold is a singularity, in the infinite-volume limit, in the ''quenched'' free energy, defined as

$$[\beta F(J,\eta)]_p \equiv -\sum_{\{\eta\}} \text{Prob}(\eta)\cdot \ln Z[J,\eta], \tag{29}$$

where

$$\mathrm{Prob}(\eta)=\prod_{\ell}(1-p)^{1-\eta_\ell}p^{\eta_\ell} \tag{30}$$

in two dimensions, or

$$\mathrm{Prob}(\eta)=\prod_{P}(1-p)^{1-\eta_P}p^{\eta_P} \tag{31}$$

in three dimensions. The term ''quenched'' signifies that, although the η chains are generated at random, we consider thermal fluctuations with the positions of the vortices or monopoles pinned down. The inverse temperature β is identical to the coupling J. We use the notation $[\cdot]_p$ to indicate an average with respect to the quenched randomness, and we will denote by $\langle\cdot\rangle_\beta$ an average over thermal fluctuations.

There are various ways to describe the phase transition in this system, and to specify an order parameter. For example, in the two-dimensional Ising system, we may consider a ''disorder parameter'' $\Phi(x)$ that inserts a single Ising vortex at a specified position x. To define this operator, we must consider either an infinite system or a finite system with a boundary; on the torus, Ising vortices can only be inserted in pairs. But for a system with a boundary, we can consider a domain wall with one end at the boundary and one end in the bulk. In the *ferromagnetic* phase, the cost in free energy of introducing an additional vortex at x is proportional to L, the distance from x to the boundary. Correspondingly we find

$$[\langle\Phi(x)\rangle_\beta]_p=0 \tag{32}$$

in the limit $L\to\infty$. The disorder parameter vanishes because we cannot introduce an isolated vortex without creating an infinitely long domain wall. In the disordered phase, an additional vortex can be introduced at finite free energy cost, and hence

$$[\langle\Phi(x)\rangle_\beta]_p\neq 0. \tag{33}$$

On the torus, we may consider an operator that inserts not a semi-infinite domain wall terminating on a vortex, but instead a domain wall that winds about a cycle of the torus. Again, in the ferromagnetically ordered phase, the cost in free energy of inserting the domain wall will be proportional to L, the minimal length of a cycle. Specifically, in our two-dimensional Ising spin model, consider choosing an η-chain and evaluating the corresponding partition function

$$Z[J,\eta]=\exp[-\beta F(J,\eta)]. \tag{34}$$

Now choose a set of links C of the original lattice that constitute a nontrivial cycle wound around the torus, and replace $\eta_l\to-\eta_l$ for the corresponding links of the dual lattice, $l\in C^*$. Evaluate, again, the partition function, obtaining

$$Z_C[J,\eta]=\exp[-\beta F_C(J,\eta)]. \tag{35}$$

Then the free energy cost of the domain wall is given by

$$\beta F_C(J,\eta)-\beta F(J,\eta)=-\ln\left(\frac{Z_C[J,\eta]}{Z[J,\eta]}\right). \tag{36}$$

After averaging over $\{\eta\}$, this free energy cost diverges as $L\to\infty$ in the ordered phase, and converges to a constant in the disordered phase.

There is also a dual order parameter that vanishes in the disordered phase—the spontaneous magnetization of the Ising spin system. Strictly speaking, the defining property of the nonferromagnetic disordered phase is that spin correlations decay with distance, so that

$$\lim_{r\to\infty}[\langle\sigma_0\sigma_r\rangle_\beta]_p=0 \tag{37}$$

in the disordered phase. Correspondingly, the mean squared magnetization per site,

$$m^2\equiv N^{-2}\sum_{i,j}\ [\langle\sigma_i\sigma_j\rangle_\beta]_p\,, \tag{38}$$

where i,j are summed over all spins and N is the total number of spins, approaches a nonzero constant as $N\to\infty$ in the ordered phase, and approaches zero as a positive power of $1/N$ in the disordered phase.

Similarly in our three-dimensional gauge theory, there is a disorder parameter that inserts a single magnetic monopole, which we may think of as the end of a semi-infinite flux tube. Alternatively, we may consider the free energy cost of inserting a flux tube that wraps around the torus, which is proportional to L in the magnetically ordered phase. In the three-dimensional model, the partition function $Z_C[J,\eta]$ in the presence of a flux tube wrapped around the nontrivial cycle C of the original lattice is obtained by replacing $\eta_P\to-\eta_P$ on the plaquettes dual to the links of C. The magnetically ordered phase is called a ''Higgs phase'' or a ''superconducting phase.'' The magnetically disordered phase is called a ''confinement phase'' because in this phase introducing an isolated electric charge has a infinite cost in free energy, and electric charges are confined in pairs by electric flux tubes.

An order parameter for the Higgs-confinement transition is the Wilson loop operator

$$W(C)=\prod_{\ell\in C}\ \sigma_\ell \tag{39}$$

associated with a closed loop C of links on the lattice. This operator can be interpreted as the insertion of a charged particle source whose world line follows the path C. In the confinement phase, this world line becomes the boundary of the world sheet of an electric flux tube, so that the free energy cost of inserting the source is proportional to the minimal area of a surface bounded by C; that is,

$$-\ln[\langle W(C)\rangle_\beta]_p \tag{40}$$

increases like the area enclosed by the loop C in the confinement phase, while in the Higgs phase it increases like the perimeter of C. [A subtle point is that the relevant Wilson loop operator differs from that considered in Sec. 10 of Ref. 23. In that reference, the Wilson loop was modified so that the ''Dirac strings'' connecting the monopoles would be invisible. But in our case, the Dirac strings have a physical meaning (they comprise the chain E) and we are genuinely interested in how far the physical flux tubes (comprising the chain E') fluctuate away from the Dirac strings!]

In the case $q\neq p$, our gauge theory becomes anisotropic—p controls the coupling and the quenched disorder on the timelike plaquettes, while q controls the coupling and the quenched disorder on the spacelike plaquettes. The tubes of flux in $E+E'$ will be stretched in the time direction for $q>p$ and compressed in the time direction for $q<p$. Correspondingly, spacelike and timelike Wilson loops will decay at different rates. Still, one expects that (for $0<q<\frac{1}{2}$) a single phase boundary in the $p-q$ plane separates the region in which both timelike and spacelike Wilson loops decay exponentially with area (confinement phase) from the region in which both timelike and spacelike Wilson loops decay exponentially with perimeter. In the limit $q\to0$, flux on the spacelike plaquettes becomes completely suppressed, and the timelike plaquettes on distinct time slices decouple, each described by the two-dimensional spin model described earlier. Similarly, in the limit $p\to0$, the gauge theory reduces to decoupled one-dimensional spin models extending in the vertical direction, with a critical point at $q=\frac{1}{2}$.

F. Accuracy threshold

What accuracy threshold can be achieved by surface codes? We have found that in the case where the syndrome is measured perfectly ($q=0$), the answer is determined by the value of critical point of the two-dimensional random-bond Ising model on the Nishimori line. This value has been determined by numerically evaluating the domain wall free energy; recent studies by Honecker *et al.*[24] and Merz and Chalker[25] find

$$p_c = 0.1094 \pm 0.0002. \tag{41}$$

A surface code is a Calderbank–Shor–Steane (CSS) code, meaning that each stabilizer generator is either a tensor product of X's or a tensor product of Z's.[26,27] If X errors and Z errors each occur with probability p, then it is known that CSS codes exist with asymptotic rate $R \equiv k/n$ (where n is the block size and k is the number of encoded qubits) such that error recovery will succeed with probability arbitrarily close to one, where

$$R = 1 - 2H_2(p); \tag{42}$$

here $H_2(p) = -p \log_2 p - (1-p)\log_2(1-p)$ is the binary Shannon entropy. This rate hits zero when p has the value

$$p_c = 0.1100, \tag{43}$$

which marginally agrees with Eq. (41) within statistical errors. Thus the critical error probability is (at least approximately) the same regardless of whether we allow arbitrary CSS codes or restrict to those with a locally measurable syndrome. This result is analogous to the property that the classical repetition code achieves reliable recovery from bit-flip errors for any error probability $p < \frac{1}{2}$, the value for which the Shannon capacity hits zero. Note that Eq. (41) can also be interpreted as a threshold for the quantum repetition code, in the case where the bit-flip error rate and the measurement error rate are equal ($p=q$).

If measurement errors are incorporated, then the accuracy threshold achievable with surface codes is determined by the critical point along the Nishimori line of the three-dimensional Z_2 gauge theory with quenched randomness. In that model the measurement error probability q (the error weight for vertical links) and the bit-flip probability p (the error weight for horizontal links) are independent parameters. It seems that numerical studies of this quenched gauge theory have not been done previously, even in the isotropic case; work on this problem is in progress.

Since recovery is more difficult with imperfect syndrome information than with perfect syndrome information, the numerical data on the random-bond Ising model indicate that $p_c < 0.11$ for any $q > 0$. For the case $p=q$, we will derive the lower bound $p_c \geqslant 0.0114$ in Sec. V.

G. Free energy versus energy

In either the two-dimensional model (if $q=0$) or the three-dimensional model (if $q>0$), the critical error probability along the Nishimori line provides a criterion for whether it is possible in principle to perform flawless recovery from errors. In practice, we would have to execute a classical computation, with the measured syndrome as input, to determine how error recovery should proceed. The defects revealed by the syndrome measurement can be brought together to annihilate in several homologically distinct ways; the classical computation determines which of these ''recovery chains'' should be chosen.

We can determine the right homology class by computing the free energy for each homology class, and choosing the one with minimal free energy. In the ordered phase (error probability below threshold) the correct sector will be separated in free energy from other sectors by an amount linear in L, the linear size of the lattice.

The computation of the free energy could be performed by, for example, the Monte Carlo method. It should be possible to identify the homology class that minimizes the free energy in a

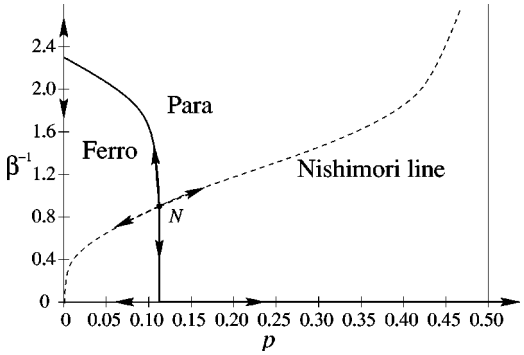

FIG. 11. The phase diagram of the random-bond Ising model, with the temperature β^{-1} on the vertical axis and the probability p of an antiferromagnetic bond on the horizontal axis. The solid line is the boundary between the ferromagnetic (ordered) phase and the paramagnetic (disordered) phase. The dotted line is the Nishimori line $e^{-2\beta}=p/(1-p)$, which crosses the phase boundary at the Nishimori point N. It has been suggested that the phase boundary is *vertical* from the point N to the horizontal axis.

time polynomial in L, unless the equilibration time of the system is exponentially long. Such a long equilibration time would be associated with spin-glass behavior—the existence of a large number of metastable configurations. In the random-bond Ising model, spin glass behavior is not expected in the ferromagnetically ordered phase corresponding to error probability below threshold. Thus, we expect that in the two-dimensional model the correct recovery procedure can be computed efficiently for any $p<p_c$. Similarly, it is also reasonable to expect that, for error probability below threshold, the correct recovery chain can be found efficiently in the three-dimensional model that incorporates measurement errors.

In fact, some folklore concerning the random-bond Ising model suggests that we can recover successfully by finding a recovery chain that minimizes *energy* rather than free energy. Nishimori[28] notes that along the Nishimori line, the free energy $[\beta F(J)]_p$ coincides with the *entropy of frustration*; that is, the *Shannon entropy* of the distribution of Ising vortices. (He considered the isotropic two-dimensional model, but his argument applies just as well to our three-dimensional gauge theory, or to the anisotropic model with $q\neq p$.) Thus, the singularity of the free energy on the Nishimori line can be regarded as a singularity of this Shannon entropy, which is a purely geometrical effect having nothing to do with thermal fluctuations.

On this basis, Nishimori proposed that there is a vertical phase boundary in our model, occurring at a fixed value of p for all temperatures below the critical temperature at the Nishimori point, as indicated in Fig. 11; further support for this conclusion was later offered by Kitatani.[29] If this proposal is correct, then the critical error probability can be computed by analyzing the phase transition at zero temperature, where the thermal entropy of the fluctuating chains can be neglected. In other words, in the ordered phase, the chain of minimal energy with the same boundary as the actual error chain will with probability one be in the same homology class as the error chain, in the infinite-volume limit. Ordinarily, minimizing free energy and energy are quite different procedures that give qualitatively distinct results. What might make this case different is that the quenched disorder (the error chain E) and the thermal fluctuations (the error chain E') are drawn from the same probability distribution.

Minimizing the energy has advantages. For one, the minimum energy configuration is the minimum weight chain with a specified boundary, which we know can be computed in a time polynomial in L using the perfect matching algorithm of Edmonds.[30,31] Kawashima and Rieger[32] computed the energetic cost of introducing a domain wall at zero temperature, and found $p_c \simeq 0.104 \pm 0.001$. It is debatable whether this result is compatible with the value $p_c \simeq 0.1094 \pm 0.0002$ found by Honecker *et al.*[24] and Merz and Chalker[25] at the Nishimori point, but in any case p_c at zero temperature is reasonably close to p_c on the Nishimori line.

Minimizing the energy is easier to analyze than minimizing the free energy, and at the very

least the critical value of p at zero temperature provides a *lower bound* on p_c along the Nishimori line. In Sec. V we will derive a rigorous bound on the accuracy threshold in our error model, by considering the efficacy of the energy minimization procedure in the three-dimensional model.

V. CHAINS OF MINIMAL WEIGHT

A. The most probable world line

As argued in Sec. IV G, an effective way use the error syndrome in our three-dimensional model is to construct an error chain that has the minimal ''energy''—that is, we select from among all error chains that have the same boundary as the syndrome chain S, the single chain $E_{\min}$ that has the highest probability. In this section, we will study the efficacy of this procedure, and so obtain a lower bound on the accuracy threshold for quantum storage.

An error chain E with H horizontal links and V vertical links occurs with probability (aside from an overall normalization)

$$\left(\frac{p}{1-p}\right)^H\left(\frac{q}{1-q}\right)^V, \tag{44}$$

where p is the qubit error probability and q is the measurement error probability. Thus we choose $E_{\min}$ to be the chain with

$$\partial E_{\min}=\partial S \tag{45}$$

that has the *minimal* value of

$$H\cdot\log\left(\frac{1-p}{p}\right)+V\cdot\log\left(\frac{1-q}{q}\right); \tag{46}$$

we minimize the effective length (number of links) of the chain, but with horizontal and vertical links given different linear weights for $p\neq q$. If the minimal chain is not unique, one of the minimal chains is selected randomly.

Given the measured syndrome, and hence its boundary ∂S, the minimal chain $E_{\min}$ can be determined on a classical computer, using standard algorithms, in a time bounded by a polynomial of the number of lattice sites.[30,31] If p and q are small, so that the lattice is sparsely populated by the sites contained in ∂S, this algorithm typically runs quite quickly. We assume this classical computation can be performed instantaneously and flawlessly.

B. A bound on chain probabilities

Recovery succeeds if our hypothesis $E_{\min}$ is homologically equivalent to the actual error chain E that generated the syndrome chain S, and fails otherwise. Hence, we wish to bound the likelihood of homologically nontrivial paths appearing in $E+E_{\min}$.

Consider a particular cycle on our space–time lattice (or in fact any connected path, whether or not the path is closed). Suppose that this path contains H horizontal links and V vertical links. How likely is it that $E+E_{\min}$ contains this particular set of links?

For our particular path with H horizontal links and V vertical links, let H_m, V_m be the number of those links contained in $E_{\min}$, and let H_e, V_e be the number of those links contained in E (cf. Fig. 12). These quantities obey the relations

$$H_m+H_e\geqslant H,\quad V_m+V_e\geqslant V, \tag{47}$$

and so it follows that

$$\left(\frac{p}{1-p}\right)^{H_m}\left(\frac{q}{1-q}\right)^{V_m}\cdot\left(\frac{p}{1-p}\right)^{H_e}\left(\frac{q}{1-q}\right)^{V_e}\leqslant\left(\frac{p}{1-p}\right)^{H}\left(\frac{q}{1-q}\right)^{V}. \tag{48}$$

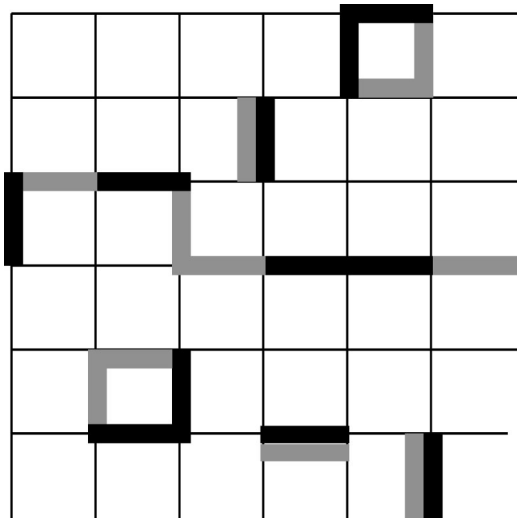

FIG. 12. The error chain E (darkly shaded) and one possible choice for the chain $E_{\min}$ (lightly shaded), illustrated for a 6×6 torus in two dimensions. In this case $E+E_{\min}$ contains a homologically nontrivial cycle of length 8, which contains $H_e=4$ links of E and $H_m=4$ links of $E_{\min}$.

Furthermore, our procedure for constructing $E_{\min}$ ensures that

$$\left(\frac{p}{1-p}\right)^{H_e}\left(\frac{q}{1-q}\right)^{V_e}\leqslant\left(\frac{p}{1-p}\right)^{H_m}\left(\frac{q}{1-q}\right)^{V_m}. \tag{49}$$

This must be so because the e links and the m links share the same boundary; were Eq. (49) not satisfied, we could replace the m links in $E_{\min}$ by the e links and thereby increase the value of $[p/(1-p)]^{H_m}[q/(1-q)]^{V_m}$. Combining the inequalities (48) and (49) we obtain

$$\left(\frac{p}{1-p}\right)^{H_e}\left(\frac{q}{1-q}\right)^{V_e}\leqslant\left[\left(\frac{p}{1-p}\right)^{H}\left(\frac{q}{1-q}\right)^{V}\right]^{1/2}. \tag{50}$$

What can we say about the probability $\mathrm{Prob}(H,V)$ that a particular connected path with (H,V) horizontal and vertical links is contained in $E+E_{\min}$? There are altogether 2^{H+V} ways to distribute errors (links contained in E) at locations on the specified chain—each link either has an error or not. And once the error locations are specified, the probability for errors to occur at those particular locations is

$$p^{H_e}(1-p)^{H-H_e}q^{V_e}(1-q)^{V-V_e}=(1-p)^{H}(1-q)^{V}\left(\frac{p}{1-p}\right)^{H_e}\left(\frac{q}{1-q}\right)^{V_e}. \tag{51}$$

But with those chosen error locations, the cycle can be in $E+E_{\min}$ only if Eq. (50) is satisfied. Combining these observations, we conclude that

$$\mathrm{Prob}(H,V)\leqslant 2^{H+V}(\tilde{p}^{H}\tilde{q}^{V})^{1/2}, \tag{52}$$

where

$$\tilde{p}=p(1-p),\quad \tilde{q}=q(1-q). \tag{53}$$

We can now bound the probability that $E+E_{\min}$ contains any connected path with (H,V) links (whether an open path or a cycle) by counting such paths. We may think of the path as a walk on the lattice (in the case of a cycle we randomly choose a point on the cycle where the walk begins

and ends). Actually, our primary interest is not in how long the walk is (how many links it contains), but rather in how far it wanders—in particular we are interested in whether a closed walk is homologically nontrivial. The walks associated with connected chains of errors visit any given *link* at most once, but it will suffice to restrict the walks further, to be *self-avoiding walks* (SAWs)—those that visit any given *site* at most once (or in the case of a cycle, revisit only the point where the walk starts and ends). This restriction proves adequate for our purposes, because given any open error walk that connects two sites, we can always obtain a SAW by eliminating some closed loops of links from that walk. Similarly, given any homologically nontrivial closed walk, we can obtain a closed SAW (a *self-avoiding polygon*, or SAP) by eliminating some links.

If we wish to consider the probability of an error per unit time in the encoded state, we may confine our attention to SAWs that lie between two time slices separated by the finite time T. [In fact, we will explain in Sec. VI why we can safely assume that $T=O(L)$.] Such a SAW can begin at any one of $L^2\cdot T$ lattice sites of our three-dimensional lattice (and in the case of a SAP, we may arbitrarily select one site that it visits as its "starting point.") If $n_{\mathrm{SAP}}(H,V)$ denotes the number of SAPs with (H,V) links and a specified starting site, then the probability $\mathrm{Prob}_{\mathrm{SAP}}(H,V)$ that $E+E_{\min}$ contains any SAP with (H,V) links satisfies

$$\mathrm{Prob}_{\mathrm{SAP}}(H,V)\leqslant L^2T\cdot n_{\mathrm{SAP}}(H,V)\cdot 2^{H+V}(\tilde{p}^H\tilde{q}^V)^{1/2}. \tag{54}$$

The upper bound Eq. (54) will be the foundation of the results that follow.

The encoded quantum information is damaged if $E+E_{\min}$ contains homologically nontrivial paths. At a minimum, the homologically nontrivial (self-avoiding) path must contain at least L horizontal links. Hence we can bound the failure probability as

$$\mathrm{Prob}_{\mathrm{fail}}\leqslant\sum_V\sum_{H\geqslant L}\mathrm{Prob}_{\mathrm{SAP}}(H,V)\leqslant L^2T\sum_V\sum_{H\geqslant L}n_{\mathrm{SAP}}(H,V)\cdot(4\tilde{p})^{H/2}(4\tilde{q})^{V/2}. \tag{55}$$

C. Counting anisotropic self-avoiding walks

We will obtain bounds on the accuracy threshold for reliable quantum storage with toric codes by establishing conditions under which the upper bound Eq. (55) rapidly approaches zero as L gets large. For this analysis, we will need bounds on the number of self-avoiding polygons with a specified number of horizontal and vertical links.

One such bound is obtained if we ignore the distinction between horizontal and vertical links. The first step of a SAP on a simple (hyper)cubic lattice in d dimensions can be chosen in any of $2d$ directions, and each subsequent step in at most $2d-1$ directions, so for walks containing a total of ℓ links we obtain

$$n^{(d)}_{\mathrm{SAP}}(\ell)\leqslant 2d(2d-1)^{\ell-1},\quad d\ \text{dimensions}. \tag{56}$$

Some tighter bounds are known[33,34] in the cases $d=2,3$:

$$n^{(2)}_{\mathrm{SAP}}(\ell)\leqslant P_2(\ell)(\mu_2)^{\ell},\quad \mu_2\approx 2.638, \tag{57}$$

and

$$n^{(3)}_{\mathrm{SAP}}(\ell)\leqslant P_3(\ell)(\mu_3)^{\ell},\quad \mu_3\approx 4.684, \tag{58}$$

where $P_{2,3}(\ell)$ are polynomials.

Since a SAP with H horizontal and V vertical links has $\ell=H+V$ total links, we may invoke Eq. (58) together with Eq. (55) to obtain

$$\mathrm{Prob}_{\mathrm{fail}}\leqslant L^2T\sum_V\sum_{H\geqslant L}P_3(H+V)\cdot(4\mu_3^2\ \tilde{p})^{H/2}(4\mu_3^2\ \tilde{q})^{V/2}. \tag{59}$$

Provided that

$$\tilde{p}<(4\mu_3^2)^{-1}, \quad \tilde{q}<(4\mu_3^2)^{-1}, \tag{60}$$

we have

$$(4\mu_3^2\ \tilde{p})^{H/2}\cdot(4\mu_3^2\ \tilde{q})^{V/2}\leqslant(4\mu_3^2\ \tilde{p})^{L/2} \tag{61}$$

for every term appearing in the sum. Since there are altogether $2L^2T$ horizontal links and L^2T vertical links on the lattice, the sum over H,V surely can have at most $2L^4T^2$ terms, so that

$$\mathrm{Prob}_{\mathrm{fail}}<Q_3(L,T)\cdot(4\mu_3^2\ \tilde{p})^{L/2}, \tag{62}$$

where $Q_3(L,T)$ is a polynomial. To ensure that quantum information can be stored with arbitrarily good reliability, it will suffice that $\mathrm{Prob}_{\mathrm{fail}}$ becomes arbitrarily small as L gets large (with T increasing no faster than a polynomial of L). Thus Eq. (60) is sufficient for reliable quantum storage. Numerically, the accuracy threshold is surely attained provided that

$$\tilde{p},\tilde{q}<(87.8)^{-1}=0.0113, \tag{63}$$

or

$$p,q<0.0114. \tag{64}$$

Not only does Eq. (62) establish a lower bound on the accuracy threshold, it also shows that, below threshold, the failure probability decreases exponentially with L, the square root of the block size of the surface code.

Equation (64) bounds the accuracy threshold in the case $p=q$, where the sum in Eq. (55) is dominated by isotropic walks with $V\sim H/2$. But for $q<0.0114$, higher values of p can be tolerated, and for $q>0.0114$, there is still a threshold, but the condition on p is more stringent. To obtain stronger results than Eq. (64) from Eq. (55), we need better ways to count anisotropic walks, with a specified ratio of V to H.

One other easy case is the $q\to 0$ limit (perfect syndrome measurement), where the only walks that contribute are two-dimensional SAPs confined to a single time slice. Then we have

$$\mathrm{Prob}_{\mathrm{fail}}<Q_2(L,T)\cdot(4\mu_2^2\ \tilde{p})^{L/2} \tag{65}$$

[where $Q_2(L,T)$ is a polynomial] provided that

$$\tilde{p}=p(1-p)<(4\mu_2^2)^{-1}\approx(27.8)^{-1}=0.0359, \tag{66}$$

or

$$p<0.0373; \tag{67}$$

the threshold value of p can be relaxed to at least 0.0373 in the case where syndrome measurements are always accurate.

This estimate of p_c is considerably smaller than the value $p_c\simeq 0.1094\pm 0.0002$ quoted in Sec. IV F, obtained from the critical behavior of the random-bond Ising model. That discrepancy is not a surprise, considering the crudeness of our arguments in this section. If one accepts the results of the numerical studies of the random-bond Ising model, and Nishimori's argument that the phase boundary of the model is vertical, then apparently constructing the minimum weight chain is a more effective procedure than our bound indicates.

One possible way to treat the case $q\neq p$ would be to exploit an observation due to de Gennes,[35] which relates the counting of SAPs to the partition function of a classical $O(N)$ spin

model in the limit $N \to 0$. This spin model is anisotropic, with nearest-neighbor couplings J_H on horizontal links and J_V on vertical links, and its (suitably rescaled) free energy density has the high-temperature expansion

$$f(J_H, J_V) = \sum_{H,V} n_{\mathrm{SAP}}(H,V)(J_H)^H (J_V)^V. \tag{68}$$

This expansion converges in the disordered phase of the spin system, but diverges in the magnetically ordered phase. Thus, the phase boundary of the spin system in the $J_H - J_V$ plane can be translated into an upper bound on the storage accuracy threshold in the $p-q$ plane, through the relations

$$\tilde{p} = J_H^2/4, \quad \tilde{q} = J_V^2/4, \tag{69}$$

obtained by comparing Eqs. (68) and (55).

To bound the failure probability for a planar code rather than the toric code, we should count the ''relative polygons'' that stretch from one edge of the lattice to the opposite edge. This change has no effect on the estimate of the threshold.

VI. ERROR CORRECTION FOR A FINITE TIME INTERVAL

In estimating the threshold for reliable *storage* of encoded quantum information, we have found it convenient to imagine that we perform error syndrome measurement forever, without any beginning or end. Thus $S+E$ is a cycle (where S is the syndrome chain and E is the error chain) containing the closed world lines of the defects. Though some of these world lines may be homologically nontrivial, resulting in damage to the encoded qubits, we can recover from the damage successfully if the chain $S+E'$ (where E' is our estimated error chain) is homologically equivalent to $S+E$. The analysis is simplified because we need to consider only the errors that have arisen during preceding rounds of syndrome measurement, and need not consider any preexisting errors that were present when the round of error correction began.

However, if we wish to perform a *computation* acting on encoded toric blocks, life will not be so simple. In our analysis of the storage threshold, we have assumed that the complete syndrome history of an encoded block is known. But when two blocks interact with one another in the execution of a quantum gate, the defects in each block may propagate to the other block. Then to assemble a complete history of the defects in any given block, we would need to take into account the measured syndrome of all the blocks in the ''causal past'' of the block in question. In principle this is possible. But in practice, the required classical computation would be far too complex to perform efficiently—in T parallelized time steps, with two-qubit gates acting in each step, it is conceivable that defects from as many as 2^T different blocks could propagate to a given block. Hence, if we wish to compute fault-tolerantly using toric codes, we will need to intervene and perform recovery repeatedly. Since the syndrome measurement is imperfect and the defect positions cannot be precisely determined, errors left over from one round of error correction may cause problems in subsequent rounds.

Intuitively, it should not be necessary to store syndrome information for a very long period to recover successfully, because correlations decay exponentially with time in our statistical-mechanical model. To take advantage of this property, we must modify our recovery procedure.

A. Minimal-weight chains

Consider performing syndrome measurement T times in succession (starting at time $t=0$), generating syndrome chain S and error chain E. Let the error chain E contain any qubit errors that were already present when the syndrome measurements began. Then the chain $S+E$ consisting of all defect world lines contains both closed loops and open paths that end on the final time slice—we say that $S+E$ is closed relative to the final time slice, or $\partial_{\mathrm{rel}}(S+E)=0$. The open connected paths contained in $S+E$ are of two types: pairs of defects created prior to $t=0$ that

have persisted until $t=T$ (if the world line contains links on the initial time slice), and pairs of defects created after $t=0$ that have persisted until $t=T$ (if the world line contains no links on the initial slice).

The syndrome S could have been caused by any error chain E' with the same *relative* boundary as E. To reconstruct the world lines, we should choose an E' that is likely given the observed S. A reasonable procedure is to choose the chain E' with $\partial_{\mathrm{rel}}E'=\partial_{\mathrm{rel}}S$ that minimizes the weight Eq. (46).

The chain $S+E'$ can be projected onto the final time slice—the projected chain $\Pi(S+E')$ contains those and only those horizonal links that are contained in $S+E'$ on an odd number of time slices. Of course, E' has the same projection as $S+E'$; the syndrome chain S contains only vertical links so that its projection is trivial. The projection $\Pi(E')$ is our hypothesis about which links have errors on the final time slice. After $\Pi(E')$ is constructed, we may perform X's or Z's on these links to compensate for the presumed damage. Note that, to construct E', we do not need to store all of S in our (classical) memory—only the relative boundary of S is needed.

Actually, any homologically trivial closed loops in $\Pi(E')$ are harmless and can be safely ignored. Each homologically nontrivial world line modifies the encoded information by the logical operation $\overline{X}$ or $\overline{Z}$. Thus, after the hypothetical closed world lines are reconstructed, we may compensate for the homologically nontrivial closed loops by applying $\overline{X}$ and/or $\overline{Z}$ as needed. Projecting the open world lines in E' onto the final time slice produces a pairing of the presumed positions of surviving defects on the final slice. These defects are removed by performing Z's or X's along a path connecting the pair that is homologically equivalent to the projected chain that connects them. Thus, this recovery step in effect brings the paired defects together to annihilate harmlessly.

Of course, our hypothesis E' will not necessarily agree exactly with the actual error chain E. Thus $E+E'$ contains open chains bounded by the final time slice. Where these open chains meet the final time slice, defects remain that our recovery procedure has failed to remove.

B. Overlapping recovery method

The procedure of constructing the minimal-weight chain E' with the same *relative* boundary as S is not as effective as the procedure in which we continue to measure the syndrome forever. In the latter case, we are in effect blessed with additional information about where monopoles will appear in the future, at times later than T, and that additional information allows us to make a more accurate hypothesis about the defect world lines. However, we can do nearly as well if we use a procedure that stores the syndrome history for only a finite time, if we recognize that the older syndrome is more trustworthy than the more recent syndrome. In our statistical physics model, the fluctuating closed loops in $E+E'$ do not grow indefinitely large in either space or in time. Therefore, we can reconstruct an E' that is homologically equivalent to E *quasilocally in time*—to pair up the monopoles in the vicinity of a given time slice, we do not need to know the error syndrome at times that are much earlier or much later.

So, for example, imagine measuring the syndrome $2T$ times in succession (starting at time $t=0$), and then constructing E' with the same relative boundary as S. The chain E' can be split into two disjoint subchains, as indicated in Fig. 13. The first part consists of all connected chains that terminate on two monopoles, where both monopoles lie in the time interval $0\leqslant t<T$; call this part E'_{old}. The rest of E' we call E'_{keep}. To recover, we flip the links in the projection $\Pi(E'_{\mathrm{old}})$, after which we may erase from memory our record of the monopoles connected by E'_{old}; only E'_{keep} (indeed only the relative boundary of E'_{keep}) will be needed to perform the next recovery step.

In the next step we measure the syndrome another T times in succession, from $t=2T$ to $t=3T-1$. Then we choose our new E' to be the minimal-weight chain whose boundary relative to the new final time slice is the union of the relative boundary of S in the interval $2T\leqslant t<3T$ and the relative boundary of E'_{keep} left over from previous rounds of error correction. We call this procedure the ''overlapping recovery method'' because the minimal-weight chains that are constructed in successive steps occupy overlapping regions of space–time.

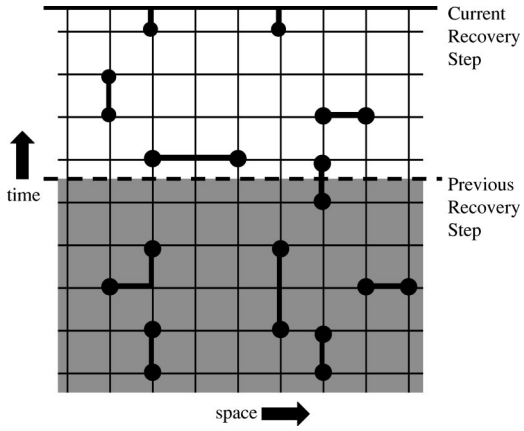

FIG. 13. The "overlapping recovery" method, shown schematically. All monopoles (boundary points of the error syndrome chain) are indicated as filled circles, including both monopoles left over from earlier rounds of error recovery (those in the shaded region below the dotted line) and monopoles generated after the previous round (those in the unshaded region above the dotted line). Also shown is the minimum weight chain E' that connects each monopole to either another monopole or to the current time slice. The chain E' contains E'_{old}, whose boundary lies entirely in the shaded region, and the remainder E'_{keep}. In the current recovery step, errors are corrected on the horizontal links of E'_{old}, and its boundary is then erased from the recorded syndrome history. The boundary of E'_{keep} is retained in the record, to be dealt with in a future recovery step.

If we choose T to be large compared to the characteristic correlation time of our statistical physics model, then only rarely will a monopole survive for more than one round, and the amount of syndrome information we need to store will surely be bounded. Furthermore, for such T, this overlapping recovery method will perform very nearly as well as if an indefinite amount of information were stored.

The time T should be chosen large enough so that connected chains in $E+E'$ are not likely to extend more than a distance T in the time direction. Arguing as in Sec. V C [and recalling that the number $n_{\text{SAW}}(\ell)$ of self-avoiding walks of length ℓ differs from the number $n_{\text{SAP}}(\ell)$ of self-avoiding polygons of length ℓ by a factor polynomial in ℓ], we see that a connected chain containing H horizontal links and V vertical links occurs with a probability

$$\text{Prob}(H,V) \leqslant Q'_3(H,V)(4\mu_3^2\tilde{p})^{H/2}(4\mu_3^2\tilde{q})^{V/2}, \tag{70}$$

where $Q'_3(H,V)$ is a polynomial. Furthermore, a connected chain with temporal extent T must have at least $V=2T$ vertical links if both ends of the chain lie on the final time slice. Therefore the probability $\text{Prob}(H,V)$ is small compared to the failure probability Eq. (62), so that our procedure with finite memory differs in efficacy from the optimal procedure with infinite memory by a negligible amount, provided that

$$T \gg \frac{L}{2} \cdot \frac{\log(4\mu_3^2\tilde{p})^{-1}}{\log(4\mu_3^2\tilde{q})^{-1}}. \tag{71}$$

In particular, if the measurement error and qubit error probabilities are comparable ($q \simeq p$), it suffices to choose $T \gg L$, where L is the linear size of the lattice.

Thus we see that the syndrome history need not be stored indefinitely for our recovery procedure to be robust. The key to fault tolerance is that we should not overreact to syndrome information that is potentially faulty. In particular, if we reconstruct the world lines of the defects and find open world lines that do not extend very far into the past, it might be dangerous to accept the accuracy of these world lines and respond by bringing the defects together to annihilate. But

world lines that persist for a time comparable to L are likely to be trustworthy. In our overlapping recovery scheme, we take action to remove only these long-lived defects, leaving those of more recent vintage to be dealt with in the next recovery step.

C. Computation threshold

Our three-dimensional model describes the history of a single code block; hence its phase transition identifies a threshold for reliable storage of quantum information. Analyzing the threshold for reliable quantum *computation* is more complex, because we need to consider interactions between code blocks.

When two encoded blocks interact through the execution of a gate, errors can propagate from one block to another, or potentially from one qubit in a block to another qubit in the same block. It is important to keep this error propagation under control. We will discuss in Sec. IX how a universal set of fault-tolerant quantum gates can be executed on encoded states. For now let us consider the problem of performing a circuit consisting of CNOT gates acting on pairs of encoded qubits. The encoded CNOT gate with block 1 as its control and block 2 as its target can be implemented *transversally*—that is, by performing CNOT gates in parallel, each acting on a qubit in block 1 and the corresponding qubit in block 2. A CNOT gate propagates bit-flip errors from control to target and phase errors from target to control. Let us first consider the case in which storage errors occur at a constant rate, but errors in the gates themselves can be neglected.

Suppose that a transversal CNOT gate is executed at time $t=0$, propagating bit-flip errors from block 1 to block 2, and imagine that we wish to correct the bit-flip errors in block 2. We suppose that many rounds of syndrome measurement are performed in both blocks before and after $t=0$. Denote by S_1 and S_2 the syndrome chains in the two blocks, and by E_1 and E_2 the error chains. Due to the error propagation, the chain S_2+E_2 in block 2 has a nontrivial boundary at the $t=0$ time slice. Therefore, to diagnose the errors in block 2 we need to modify our procedure.

We may divide each syndrome chain and error chain into two parts, a portion lying in the past of the $t=0$ time slice, and a portion lying in its future. Then the chain

$$S_{1,\text{before}}+S_{2,\text{before}}+S_{2,\text{after}}+E_{1,\text{before}}+E_{2,\text{before}}+E_{2,\text{after}} \tag{72}$$

has a trivial boundary. Therefore, we can estimate $E_{1,\text{before}}+E_{2,\text{before}}+E_{2,\text{after}}$ by constructing the minimal chain with the same boundary as $S_{1,\text{before}}+S_{2,\text{before}}+S_{2,\text{after}}$. Furthermore, because of the error propagation, it is $E_{1,\text{before}}+E_{2,\text{before}}+E_{2,\text{after}}$ whose horizontal projection identifies the damaged links in block 2 after $t=0$.

If in each block the probability of error per qubit and per time step is p, while the probability of a syndrome measurement error is q, then the error chain $E_{1,\text{before}}+E_{2,\text{before}}+E_{2,\text{after}}$ has in effect been selected from a distribution in which the error probabilities are $(2p(1-p),2q(1-q))$ before the gate and (p,q) after the gate. Obviously, these errors are no more damaging than if the error probabilities had been $(2p(1-p),2q(1-q))$ at all times, both before and after $t=0$. Therefore, if (p,q) lies below the accuracy threshold for accurate storage, then error rates $(2p(1-p),2q(1-q))$ will be below the accuracy threshold for a circuit of CNOT gates.

Of course, the transversal CNOT might itself be prone to error, damaging each qubit with probability p_{CNOT}, so that the probability of error is larger on the $t=0$ slice than on earlier or later slices. However, increasing the error probability from p to $p+p_{\text{CNOT}}$ on a single slice is surely no worse than increasing the probability of error to $p+p_{\text{CNOT}}$ on all slices. For a given q, there is a threshold value $p_c(q)$, such that for $p<p_c(q)$ a circuit of CNOTs is robust if the gates are flawless; then the circuit with imperfect gates is robust provided that $p+p_{\text{CNOT}}<p_c(q)$.

By such reasoning, we can infer that the accuracy threshold for quantum computation is comparable to the threshold for reliable storage, differing by factors of order one. Furthermore, below threshold, the probability of error in an encoded gate decreases exponentially with L, the linear size of the lattice. Therefore, to execute a quantum circuit that contains T gates with reasonable fidelity, we should choose $L=O(\log T)$, so that the block size $2L^2$ of the code is $O(\log^2 T)$.

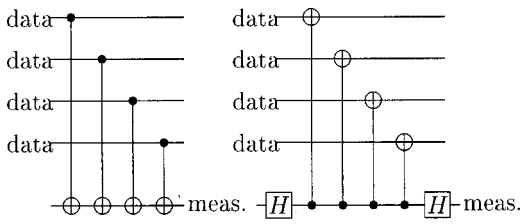

FIG. 14. Circuits for measurement of the plaquette ($Z^{\otimes 4}$) and site ($X^{\otimes 4}$) stabilizer operators.

VII. QUANTUM CIRCUITS FOR SYNDROME MEASUREMENT

In our model with uncorrelated errors, in which qubit errors occur with probability p per time step and measurement errors occur with probability q, we have seen in Sec. IV that it is possible to identify a sharp phase boundary between values of the parameters such that error correction is sure to succeed in the limit of a large code block, and values for which error correction need not succeed. How can we translate this accuracy threshold, expressed as a phase boundary in the $p-q$ plane, into a statement about how well the hardware in our quantum memory must perform in order to protect quantum states effectively? The answer really depends on many details about the kinds of hardware that are potentially at our disposal. For purposes of illustration, we will relate p and q to the error probabilities for the fundamental gates in a particular computational model.

A. Syndrome measurement

Whenever a check operator X_s or Z_P is measured, a quantum circuit is executed in which each of the qubits occurring in the check operator interacts with an ancilla, and then the ancilla is measured to determine the result. Our task is to study this quantum circuit to determine how the faults in the circuit contribute to p and to q. To start we must decide what circuit to study.

For many quantum codes, the design of the syndrome measurement circuit involves subtleties. If the circuit is badly designed, a single error in the ancilla can propagate to many qubits in the code block, compromising the effectiveness of the error correction procedure. To evade this problem, Shor[3] and Steane[36] proposed two different methods for limiting the propagation of error from ancilla to data in the measurement of the check operators of a stabilizer code. In Shor's method, to extract each bit of the error syndrome, an ancilla ''cat state'' is prepared that contains as many qubits as the weight of the check operator. The ancilla interacts with the data code block, and then each qubit of the ancilla is measured; the value of the check operator is the parity of the measurement outcomes. In Steane's method, the ancilla is prepared as an encoded block (containing as many qubits as the length of the code). The ancilla interacts with the data, each qubit in the ancilla is measured, and a classical parity check matrix is applied to the measurement outcomes to extract the syndrome. In either scheme, each ancilla qubit interacts with only a single qubit in the data, so that errors in the ancilla cannot seriously damage the data. The price we pay is the overhead involved in preparing the ancilla states and verifying that the preparation is correct.

We could use the Shor method or the Steane method to measure the stabilizer of a surface code, but it is best not to. We can protect against errors more effectively by using just a single ancilla qubit for the measurement of each check operator, avoiding all the trouble of preparing and verifying ancilla states. The price we pay is modest—a single error in the ancilla might propagate to become two errors in the data, but we will see that these correlated errors in the data are not so damaging.

So, we imagine placing a sheet of ancilla qubits above the qubits of a planar code block. Directly above the site s is the ancilla qubit that will be used to measure X_s, and directly above the center of the plaquette P is the ancilla qubit that will be used to measure Z_P. We suppose that CNOT gates can be executed acting on a data qubit and its neighboring ancilla qubits. The circuits for measuring the plaquette operator $Z^{\otimes 4}$ and the site operator $X^{\otimes 4}$ are shown in Fig. 14.

We have included the Hadamard gates in the circuit for measuring the site operator to signify that the ancilla qubit is initially prepared in the $X=1$ state, and the final measurement is a

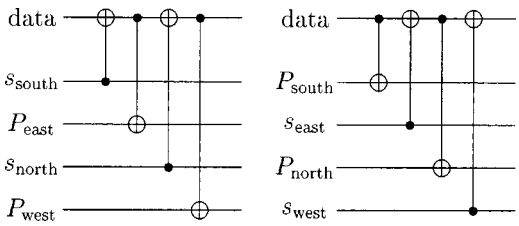

FIG. 15. Gates acting on a given qubit in a complete round of syndrome measurement. Data qubits on links with a north–south orientation participate successively in measurements of check operators at the site to the south, the plaquette to the east, the site to the north, and the plaquette to the west. Qubits on links with an east–west orientation participate successively in measurements of check operators at the plaquette to the south, the site to the east, the plaquette to the north, and the site to the west.

measurement of X, while in the case of the plaquette operator measurement the ancilla is prepared in the $Z=1$ state and Z is measured at the end. But we will suppose that our computer can measure X as easily as it can measure Z; hence in both cases the circuit is executed in six time steps (including preparation and measurement), and there is really no Hadamard gate.

B. Syndrome errors and data errors

We will assume that all errors in the circuit are stochastic (for example, they could be errors caused by decoherence). We will consider both ''storage errors'' and ''gate errors.'' In each time step, the probability that a ''resting'' qubit is damaged will be denoted p_s. For simplicity, we will assume that an error, when it occurs, is one of the Pauli operators X, Y, or Z. (The analysis of the circuit is easily generalized to more general models of stochastic errors.) In our analysis, we will always make a maximally pessimistic assumption about which error occurred at a particular position in the circuit. If a gate acts on a qubit in a particular time step, we will assume that there is still a probability p_s of a storage error in that step, plus an additional probability of error due to the execution of the gate. We denote the probability of an error in the two-qubit CNOT gate by p_{CNOT}; the error is a tensor product of Pauli operators, and again we will always make maximally pessimistic assumptions about which error occurs at a particular position in the circuit. If a storage error and gate error occur in the same time step, we assume that the gate error acts first, followed by the storage error. When a single qubit is measured in the $\{|0\rangle,|1\rangle\}$ basis, p_m is the probability of obtaining the incorrect outcome. (If a storage error occurs during a measurement step, we assume that the error precedes the measurement.) And when a fresh qubit is acquired in the state $|0\rangle$, p_p denotes the probability that its preparation is faulty (it is $|1\rangle$ instead).

In a single cycle of syndrome measurement, each data qubit participates in the measurement of four stabilizer operators: two site operators and two plaquette operators. Each of these measurements requires four time steps (excluding the preparation and measurement steps), as a single ancilla qubit is acted upon by four sequential CNOTs. But to cut down the likelihood of storage errors, we can execute the four measurement circuits in parallel, so that every data qubit participates in a CNOT gate in every step. For example, for each plaquette and each site, we may execute CNOT gates that act on the four edges of the plaquette or the four links meeting at the site in the counterclockwise order north–west–south–east. The CNOT gates that act on a given data qubit, then, alternate between CNOTs with the data qubit as control and CNOTs with the data qubit as target, as indicated in Fig. 15.

For either a site check operator or a plaquette check operator, the probability that the measurement is faulty is

$$q_{\text{single}}=p_p+4p_{\text{CNOT}}+6p_s+p_m+\text{h. o.}, \tag{73}$$

where ''+h. o.'' denotes terms of higher than linear order in the fundamental error probabilities. The measurement can fail if any one of the CNOT gates has an error, if a storage error occurs during any of the six time steps needed to execute the circuit (including the preparation and

measurement step), or because of a fault in the initial preparation or final measurement of the ancilla qubit. By omitting the higher order terms we are actually *overestimating* q. For example, p_s is the probability that a storage error occurs in the first time step, disregarding whether or not additional errors occur in the circuit.

We have used the notation q_{single} in Eq. (73) to emphasize that this is an estimate of the probability of an isolated error on a vertical (timelike) link. More troublesome are syndrome measurement errors that are correlated with qubit errors. These arise if, say, a qubit suffers a Z error that is duly recorded in the syndrome measurement of one of the two adjoining sites but not the other. In our space–time picture, then, there is a timelike plaquette with an error on one of its horizontal links and one of its vertical links. We will refer to this type of correlated error as a ''vertical hook''—hook because the two links with errors meet at a 90° angle, and vertical because one of the links is vertical (and to contrast with the case of a horizontal hook which we will discuss later).

We can estimate the probability of a vertical hook on a specified timelike plaquette by considering the circuits in Fig. 15. The qubit in question participates in the measurement of two site check operators, through the two CNOT gates in the circuit in which the data qubit is the target of the CNOT. A vertical hook can arise due to a fault that occurs in either of these CNOT gates or at a time in between the execution of these gates. Hence the probability of a vertical hook is

$$q_{\text{hook}} = 3p_{\text{CNOT}} + 2p_s + \text{h. o.}; \tag{74}$$

faults in any of three different CNOT gates, or storage errors in either of two time steps, can generate the hook. Note that the hook on the specified plaquette has a unique orientation; the first of the two site operator measurements that the data qubit participated in is the one that fails to detect the error. Of course, the same formula for q_{hook} applies if we are considering the measurement of the plaquette operators rather than the site operators.

A CNOT gate propagates X errors from control qubit to target qubit, and Z errors from target to control. Thus we do not have to worry about a vertical hook that arises from an error in an ancilla bit that propagates to the data. For example, if we are measuring a plaquette operator, then X errors in the ancilla damage the syndrome bit while Z errors in the ancilla propagate to the data; the result is a vertical error in the X-error syndrome that is correlated with a horizontal Z-error in the data. This correlation is not problematic because we deal with X errors and Z errors separately. However, propagation of error from ancilla to data also generates correlated horizontal errors that we need to worry about. In the measurement of, say, the plaquette operator $Z_P = Z^{\otimes 4}$, Z errors (but not X errors) can feed back from the ancilla to the data. Feeding back four Z's means no error at all, because $Z^{\otimes 4}$ is in the code stabilizer, and feeding back three Z's generates the error $IZZZ$, which is equivalent to the single Z error $ZIII$. Therefore, the only way to get a double qubit error from a single fault in the circuit is through an error in the second or third CNOT, or through an ancilla storage error in between the second and third CNOT. (The second CNOT might apply Z to the ancilla but not to the data, and that Z error in the ancilla can then feed back to two data qubits, or the third CNOT could apply Z to both ancilla and data, and the Z error in the ancilla can then feed back to one other data qubit.) Because of the order we have chosen for the execution of the CNOTs, this double error, when it occurs, afflicts the southeast corner of the plaquette (or equivalently the northwest corner, which has the same boundary). We will refer to this two-qubit error as a ''horizontal hook,'' because the two horizontal errors meet at a 90° angle. Similarly, error propagation during the measurement of the site operator X_s can produce X errors on the north and west links meeting at that site. One should emphasize that the only correlated XX or ZZ errors that occur with a probability linear in the fundamental error probabilities are these hooks. This is a blessing—correlated errors affecting two collinear links would be more damaging.

Feedback from the measurement of a plaquette operator can produce ZZ hooks but not XX hooks, and feedback from the measurement of a site operator can produce XX hooks but not ZZ hooks. Thus, in each round of syndrome measurement, the probability of a ZZ hook at a plaquette or an XX hook at a site is

$$p_{\text{hook}} = 2p_{\text{CNOT}} + p_s + \text{h. o.} \tag{75}$$

(Remember that a ''hook'' means two Z's or two X's; in addition, an error in a single CNOT gate could induce, say, an X error in the data and a Z error in the ancilla that subsequently feeds back, but correlated X and Z errors will not cause us any trouble.)

Now we need to count the ways in which a single error can occur in the data during a round of syndrome measurement. First suppose that we measure a single plaquette operator Z_P, and consider the scenarios that lead to a single Z error in the data. The Z error can arise either because a gate or storage error damages the data qubit directly, or because an error in the ancilla feeds back to the data. Actually, single errors occur with slightly different probabilities for different data qubits acted on by the circuit. The worst case occurs for the first and last qubit acted on by the circuit; the probability that the circuit produces a single error that acts on the first (or last) qubit is

$$p_{\text{single,Z}}^{Z_P,1} = p_{\text{single,Z}}^{Z_P,4} = p_{\text{CNOT}} + 6p_s + p_{\text{CNOT}} + p_s + \text{h. o.} \tag{76}$$

The first two terms arise from gate errors and storage errors that damage the data qubit directly. For the first qubit, the last two terms arise from the case in which a Z error in the ancilla is fed back to the data by each of the last three CNOTs—the resulting $IZZZ$ error is equivalent to a $ZIII$ error because $ZZZZ$ is in the code stabilizer. For the fourth qubit, the last two terms arise from an error fed back by the last CNOT gate in the circuit. On the other hand, for the second and third qubit acted on by the circuit, it is not possible for just a single error to feed back; e.g., if the error feeds back to the third qubit, it will feed back to the fourth as well, and the result will be a hook instead of a single error. Hence, the probability of a single error acting on the second or third qubit is

$$p_{\text{single,Z}}^{Z_P,2} = p_{\text{single,Z}}^{Z_P,3} = p_{\text{CNOT}} + 6p_s + \text{h. o.}; \tag{77}$$

there is no feedback term. If we are measuring a site operator X_s, then X errors might feed back from the ancilla to the data, but Z errors will not. Therefore, for each of the four qubits acted on by the circuit, the probability that a single Z error results from the execution of the circuit, acting on that particular qubit, is

$$p_{\text{single,Z}}^{X_s} = p_{\text{CNOT}} + 6p_s + \text{h. o.}; \tag{78}$$

again there is no feedback term.

In a single round of syndrome measurement, each qubit participates in the measurement of four check operators, two site operators and two plaquette operators. For the plaquette operator measurements, depending on the orientation of the link where the qubit resides, the qubit will be either the first qubit in one measurement and the third in the other, or the second in one and the fourth in the other. Either way, the total probability of a single Z error arising that afflicts that qubit is

$$p_{\text{single}} = 4p_{\text{CNOT}} + 6p_s + p_{\text{CNOT}} + p_s + \text{h. o.} = 5p_{\text{CNOT}} + 7p_s + \text{h. o.}, \tag{79}$$

with the $4p_{\text{CNOT}} + 6p_s$ arising from direct damage to the qubit and the $p_{\text{CNOT}} + p_s$ from feedback due to one of the four check operator measurements. The same equation applies to the probability of a single X error arising at a given qubit in a single round of syndrome measurement.

C. Error-chain combinatorics

With both single errors and hooks to contend with, it is more complicated to estimate the failure probability, but we can still obtain useful upper bounds. In fact, the hooks do not modify the estimate of the accuracy threshold as much as might have been naively expected. Encoded information is damaged if $E + E_{\min}$ contains a homologically nontrivial (relative) cycle, which can

wrap around the code block with either a north–south or east–west orientation. Either way, the cycle contains at least L links all with the *same* orientation, where L is the linear size of the lattice. A horizontal hook introduces two errors with *different* orientations, which is not as bad as two errors with the same orientation. Similarly, a vertical hook contains only one horizontal error.

There are two other reasons why the hooks do not badly compromise the effectiveness of error correction. While single errors can occur with any orientation, horizontal hooks can appear only on the northwest corner of a plaquette (hooks on southeast corners are equivalent to hooks on northwest corners and should not be counted separately), and vertical hooks on timelike plaquettes have a unique orientation, too. Therefore, hooks have lower ''orientational entropy'' than the single errors, which means that placing hooks on self-avoiding walks reduces the number of walks of a specified length. And, finally, p_{hook} is smaller than p_{single}, and q_{hook} is smaller than q_{single}, which further reduces the incentive to include hooks in $E+E_{\min}$.

We will suppose that $E_{\min}$ is constructed by the same procedure as before, by minimizing the weight

$$H \log p_{\text{single}}^{-1} + V \log q_{\text{single}}^{-1}. \tag{80}$$

To simplify later expressions, we have replaced $p/(1-p)$ by p here, which will weaken our upper bound on the failure probability by an insignificant amount. Note that our procedure finds the most probable chain under the assumption that only single errors occur (no hooks). If p_{hook} and q_{hook} are assumed to be known, then in principle we could retool our recovery procedure by taking these correlated errors into account in the construction of $E_{\min}$. To keep things simple we will not attempt to do that. Then, as before, for any connected subchain of $E+E_{\min}$ with H horizontal links and V vertical links, the numbers H_e and V_e of horizontal and vertical links of the subchain that are contained in E must satisfy

$$p_{\text{single}}^{H_e} q_{\text{single}}^{V_e} \leqslant p_{\text{single}}^{H/2} q_{\text{single}}^{V/2}. \tag{81}$$

To bound the failure probability, we wish to count the number of ways in which a connected chain with a specified number of horizontal links can occur in $E+E_{\min}$, keeping in mind that the error chain E could contain hooks as well as single errors. Notice that a hook might contribute only a single link to $E+E_{\min}$, if one of the links contained in the hook is also in $E_{\min}$. But since $p_{\text{hook}} < p_{\text{single}}$ and $q_{\text{hook}} < q_{\text{single}}$, we will obtain an upper bound on the failure probability if we pessimistically assume that all of the errors in $E+E_{\min}$ are either two-link hooks occurring with probabilities $p_{\text{hook}}, q_{\text{hook}}$ or single errors occuring with probabilities $p_{\text{single}}, q_{\text{single}}$. If the H_e horizontal errors on a connected chain include H_{hook} horizontal hooks and V_{hook} vertical hooks, then there are $H_e - 2H_{\text{hook}} - V_{\text{hook}}$ single horizontal errors and $V_e - V_{\text{hook}}$ single vertical errors; once the locations of the hooks and the single errors are specified, the probability that errors occur at those locations is no larger than

$$\begin{aligned} &(p_{\text{single}})^{H_e - 2H_{\text{hook}} - V_{\text{hook}}} (p_{\text{hook}})^{H_{\text{hook}}} \cdot (q_{\text{single}})^{V_e - V_{\text{hook}}} (q_{\text{hook}})^{V_{\text{hook}}} \\ &< p_{\text{single}}^{H/2} \left(\frac{p_{\text{hook}}}{p_{\text{single}}^2} \right)^{H_{\text{hook}}} q_{\text{single}}^{V/2} \left(\frac{q_{\text{hook}}}{p_{\text{single}} q_{\text{single}}} \right)^{V_{\text{hook}}}. \end{aligned} \tag{82}$$

Because a horizontal hook contains two errors with different orientations, it will be convenient to distinguish between links oriented east–west and links oriented north–south. We denote by H_1 the number of horizontal links in the connected chain with east–west orientation and by H_2 the number of horizontal links with north–south orientation; then clearly

$$H_{\text{hook}} \leqslant H_1, \quad H_{\text{hook}} \leqslant H_2. \tag{83}$$

To estimate the threshold, we will bound the probability that our connected chain has $H_1 \geqslant L$; of course, the same expression bounds the probability that $H_2 \geqslant L$.

For a specified connected chain, suppose that altogether H_e of the horizontal links and V_e of the vertical links have errors, and that there are H_{hook} horizontal hooks and V_{hook} vertical hooks, so that there are $H_e - 2H_{\text{hook}} - V_{\text{hook}}$ single horizontal errors and $V_e - V_{\text{hook}}$ single vertical errors. In how many ways can we distribute the hooks and single errors along the path? Since each horizontal hook contains a link with north-south orientation, there are no more than $\binom{H_2}{H_{\text{hook}}}$ ways to choose the locations of the horizontal hooks; similarly there are no more than $\binom{V}{V_{\text{hook}}}$ ways to choose the locations of the vertical hooks. (Actually, we have given short shrift here to a slight subtlety. Once we have decided that a vertical hook will cover a particular vertical link, there may be two ways to place the hook—it might cover either one of two adjacent horizontal links. However, for the hook to be free to occupy either position, the orientation of the second horizontal link must be chosen in one of only two possible ways. Thus the freedom to place the hook in two ways is more than compensated by the reduction in the orientational freedom of the other horizontal link by a factor of $\frac{2}{5}$, and can be ignored. A similar remark applies to horizontal hooks.) Then there are no more than $2^{H_1+H_2-2H_{\text{hook}}-V_{\text{hook}}}$ ways to place the single horizontal errors among the remaining horizontal links, and no more than $2^{V-V_{\text{hook}}}$ ways to place the single vertical errors among remaining $V - V_{\text{hook}}$ vertical links on the chain. Now consider counting the self-avoiding paths starting at a specified site, where the path is constructed from hooks, single errors, and the links of $E_{\min}$. Whenever we add a horizontal hook to the path there are at most two choices for the orientation of the hook, and whenever we add a vertical hook there are at most four choices; hence there are no more than $2^{H_{\text{hook}}} 4^{V_{\text{hook}}}$ ways to choose the orientations of the hooks. For the remaining $H_1 + H_2 - 2H_{\text{hook}} + V - 2V_{\text{hook}}$ links of the path, the orientation can be chosen in no more than five ways. Hence, the total number of paths with a specified number of horizontal links, horizontal hooks, vertical links, and vertical hooks is no more than

$$\binom{H_2}{H_{\text{hook}}}\binom{V}{V_{\text{hook}}} \cdot 2^{H_1+H_2-2H_{\text{hook}}-V_{\text{hook}}} 2^{V-V_{\text{hook}}} \cdot 2^{H_{\text{hook}}} 4^{V_{\text{hook}}} \cdot 5^{H_1+H_2-2H_{\text{hook}}+V-2V_{\text{hook}}}. \quad (84)$$

Combining this counting of paths with the bound Eq. (82) on the probability of each path, we conclude that the probability that $E + E_{\min}$ contains a connected path with specified starting site, containing H_1 links with east–west orientation, H_2 links with north–south orientation, V vertical links, H_{hook} horizontal hooks, and V_{hook} vertical hooks, is bounded above by

$$\binom{H_2}{H_{\text{hook}}}\left(\frac{p_{\text{hook}}}{50p_{\text{single}}^2}\right)^{H_{\text{hook}}} (100p_{\text{single}})^{(H_1+H_2)/2} \cdot \binom{V}{V_{\text{hook}}}\left(\frac{q_{\text{hook}}}{25p_{\text{single}}q_{\text{single}}}\right)^{V_{\text{hook}}} \cdot (100q_{\text{single}})^{V/2}. \quad (85)$$

Here H_{hook} can take any value from zero to H_2, and V_{hook} can take any value from zero to V. We can sum over H_{hook} and V_{hook}, to obtain an upper bound on the probability of a chain with an unspecified number of hooks:

$$(100p_{\text{single}})^{(H_1+H_2)/2}\left(1+\frac{p_{\text{hook}}}{50p_{\text{single}}^2}\right)^{H_2} \cdot (100q_{\text{single}})^{V/2}\left(1+\frac{q_{\text{hook}}}{25p_{\text{single}}q_{\text{single}}}\right)^{V}. \quad (86)$$

Finally, since a path can begin at any of L^2T sites, and since there are two types of homologically nontrivial cycles, the probability of failure $\text{Prob}_{\text{fail}}$ satisfies the bound

$$\text{Prob}_{\text{fail}} < 2L^2T \sum_{H_1 \geq L} (100p_{\text{single}})^{H_1/2} \cdot \sum_{H_2 \geq 0}\left[100p_{\text{single}}\left(1+\frac{p_{\text{hook}}}{50p_{\text{single}}^2}\right)^2\right]^{H_2/2} \cdot \sum_{V \geq 0}\left[100q_{\text{single}}\left(1+\frac{q_{\text{hook}}}{25p_{\text{single}}q_{\text{single}}}\right)^2\right]^{V/2}. \quad (87)$$

This sum will be exponentially small for large L provided that

$$p_{\text{single}} < \frac{1}{100}, \quad q < \frac{1}{100},$$

$$p_{\text{hook}} < 5 \; p_{\text{single}}^2 \left(\frac{1}{\sqrt{p_{\text{single}}}} - 10 \right), \tag{88}$$

$$q_{\text{hook}} < \frac{5}{2} p_{\text{single}} q_{\text{single}} \left(\frac{1}{\sqrt{q_{\text{single}}}} - 10 \right).$$

Of course, making p_{single} and q_{single} smaller can only make things better. Our conditions on p_{hook} and q_{hook} in Eq. (88) are not smart enough to know this—for p_{single} sufficiently small, we find that making it still smaller gives us a *more* stringent condition on p_{hook}, and similarly for q_{hook}. Clearly, this behavior is an artifact of our approximations. Thus, for a given p_{single} and q_{single}, we are free to choose any smaller values of p_{single} and q_{single} in order to obtain more liberal conditions on p_{hook} and q_{hook} from Eq. (88). Our expression that bounds p_{hook} achieves its maximum for $p_{\text{single}} = (\frac{3}{40})^2$, and for fixed p_{single}, our expression that bounds q_{hook} achieves its maximum for $q_{\text{single}} = (\frac{1}{20})^2$. We therefore conclude that for recovery to succeed with a probability that approaches one as the block size increases, it suffices that

$$p_{\text{single}} < \tfrac{9}{1600}, \quad q_{\text{single}} < \tfrac{1}{400},$$

$$p_{\text{hook}} < \tfrac{3}{32} \cdot \tfrac{9}{1600}, \quad q_{\text{hook}} < \tfrac{1}{16} \cdot \tfrac{9}{1600}. \tag{89}$$

Comparing to our expressions for q_{single}, p_{single}, and p_{hook}, we see that, unless q_{single} is dominated by preparation or measurement errors, these conditions are all satisfied provided that

$$q_{\text{hook}} = 3p_{\text{CNOT}} + 2p_s < 3.5 \times 10^{-4}. \tag{90}$$

If the probability of a CNOT error is negligible, then we obtain a lower bound on the critical error probability for storage errors,

$$(p_s)_c > 1.7 \times 10^{-4}. \tag{91}$$

In view of the crudeness of our combinatorics, we believe that this estimate is rather conservative, if one accepts the assumptions of our computational model.

VIII. MEASUREMENT AND ENCODING

A. Measurement

At the conclusion of a quantum computation, we need to measure some qubits. If the computation is being executed fault tolerantly, this means measuring an encoded block. How can we perform this measurement fault tolerantly?

Suppose we want to measure the logical operator $\overline{Z}$, that is, measure the encoded block in the basis $\{|\overline{0}\rangle, |\overline{1}\rangle\}$. If we are willing to destroy the encoded block, we first measure Z for each qubit in the block, projecting each onto the basis $\{|0\rangle, |1\rangle\}$. Were there no errors in the code block at the time of the measurement, and were all measurements of the individual qubits performed flawlessly, then we could choose any homologically nontrivial path on the lattice and evaluate the parity of the outcomes for the links along that path. Even parity indicates that the encoded block is in the state $|\overline{0}\rangle$, odd parity the state $|\overline{1}\rangle$.

But the code block *will* contain some errors (not too many, we hope), and some of the measurements of the individual qubits *will* be faulty. Since a single bit flip along the path could

alter the parity of the measurement outcomes, we need to devise a fault-tolerant procedure for translating the observed values of the individual qubits into a value of the encoded qubit.

One such procedure is to evaluate the parity $Z^{\otimes 4}$ of the measurement outcomes at each plaquette of the lattice, determining the locations of all plaquette defects. These defects can arise either because defects were already present in the code block before the measurement, or they could be introduced by the measurement itself. It is useful and important to recognize that the defects introduced by the measurement do not pose any grave difficulties. An isolated measurement error at a single link will produce two neighboring defects on the plaquettes that contain that link. Widely separated defects can arise from the measurement only if there are many correlated measurement errors.

Therefore we can apply a suitable classical algorithm to remove the defects—for example, by choosing a chain of minimal total length that is bounded by the defect locations, which can be found in a polynomial-time classical computation. Flipping the bits on this chain corrects the errors in the measurement outcomes, so that we can then proceed to evaluate the parity along a nontrivial cycle. Assuming sufficiently small rates for the qubit and measurement errors, the encoded qubit will be evaluated correctly, with a probability of error that is exponentially small for large block size.

We can measure $\overline{X}$ by the same procedure, by measuring X for each qubit, and evaluating all site operators $X^{\otimes 4}$ from the outcomes. After removal of the site defects by flipping bits appropriately, $\overline{X}$ is the parity along a nontrivial cycle of the dual lattice.

To measure $\overline{Z}$ of a code block without destroying the encoded state, we can prepare an ancilla block in the encoded state $|\overline{0}\rangle$, and perform a bitwise CNOT from the block to be measured into the ancilla. Then we can measure the ancilla by the destructive procedure just described. A nondestructive measurement of $\overline{X}$ is executed similarly.

B. Encoding of known states

At the beginning of a quantum computation, we need to prepare encoded qubits in eigenstates of the encoded operations, for example the state $|\overline{0}\rangle$ of the planar code, a $\overline{Z}=1$ eigenstate. If syndrome measurement were perfectly reliable, the state $|\overline{0}\rangle$ could be prepared quickly by the following method: Start with the state $|0\rangle^{\otimes n}$ where n is the block size of the code. This is the simultaneous eigenstate with eigenvalue 1 of all plaquette stabilizer operators $Z_P=Z^{\otimes 4}$ and of the logical operator $\overline{Z}$, but not of the site stabilizer operators $X_s=X^{\otimes 4}$. Then measure all the site operators. Since the site operators commute with the plaquette operators and the logical operators, this measurement does not disturb their values. About half of the site measurements have outcome $X_s=1$ and about half have outcome $X_s=-1$; to obtain the state $|\overline{0}\rangle$, we must remove all of the site defects (sites where $X_s=-1$). Thus we select an arbitrary one-chain whose boundary consists of the positions of all site defects, and we apply Z to each link of this chain, thereby imposing $X_s=1$ at each site. In carrying out this procedure, we might apply $\overline{Z}$ to the code block by applying Z to a homologically nontrivial path, but this has no effect since the state is a $\overline{Z}=1$ eigenstate.

Unfortunately, syndrome measurement is not perfectly reliable; therefore this procedure could generate long *open* chains of Z errors in the code block. To keep the open chains under control, we need to repeat the measurement of both the X and Z syndromes of order L times (where L is the linear size of the lattice), and use our global recovery method. Then the initial configuration of the defects will be ''forgotten'' and the error chains in the code block will relax to the equilibrium configuration in which long open chains are highly unlikely. The probability of an $\overline{X}$ error that causes a flip of the encoded state will be exponentially small in L. We can prepare the encoded state with $\overline{X}=1$ by the dual procedure, starting with the state $[(1/\sqrt{2})(|0\rangle+|1\rangle)]^{\otimes n}$.

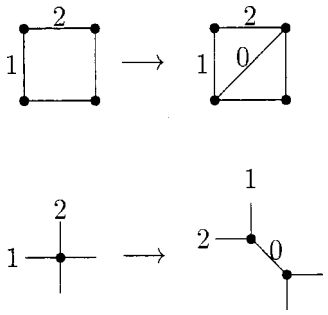

FIG. 16. Two basic moves that modify the triangulation of a surface by adding a link: splitting a plaquette, and splitting a vertex.

C. Encoding of unknown states

Quantum error-correcting codes can protect *unknown* coherent quantum states. This feature is crucial in applications to quantum computation—the operator of a quantum computer need not ''monitor'' the encoded quantum state to keep the computation on track. But to operate a quantum computer, we do not typically need to *encode* unknown quantum states. It is sufficient to initialize the computer by encoding known states, and then execute a known quantum circuit.

Still, a truly robust ''quantum memory'' should be able to receive an unknown quantum state and store it indefinitely. But given any nonzero rate of decoherence, to store an unknown state for an indefinitely long time we need to encode it using a code of indefinitely long block size. How, then, can we expect to encode the state before it decoheres?

The key is to encode the state quickly, providing some measure of protection, while continuing to build up toward larger code blocks. Concatenated codes provide one means of achieving this. We can encode, perform error correction, then encode again at the next level of concatenation. If the error rates are small enough, encoding can outpace the errors so that we can store the unknown state in a large code block with reasonable fidelity.

The surface codes, too, allow us to build larger codes from smaller codes and so to protect unknown states effectively. The key to enlarging the code block is that a code corresponding to one triangulation of a surface can be transformed into a code corresponding to another triangulation.

For example, we can transform one surface code to another using local moves shown in Fig. 16.

Links can be added to (or removed from) the triangulation in either of two ways—one way adds a new plaquette, the other adds a new site. Either way, the new triangulation corresponds to a new code with an additional qubit in the code block and an additional stabilizer generator.

When a new plaquette is added, the new code stabilizer is obtained from the old one by adding the new plaquette operator

$$Z_1 Z_2 Z_0 \tag{92}$$

and by modifying the site operators with the replacements

$$X_1 \to X_1 X_0, \quad X_2 \to X_2 X_0. \tag{93}$$

When a new site is added, the stabilizer is modified similarly, but with X's and Z's interchanged:

$$X_1 X_2 X_0 \tag{94}$$

is a new stabilizer generator, and the existing plaquette operators are modified as

$$Z_1 \to Z_1 Z_0, \quad Z_2 \to Z_2 Z_0. \tag{95}$$

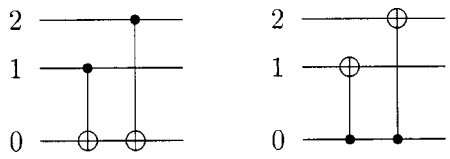

FIG. 17. Circuits that implement the two basic moves of Fig. 16. The circuit with qubit 0 as the target of the CNOTs adds a plaquette; the circuit with qubit 0 as the control of the CNOTs adds a site.

To add a plaquette or a site to a stabilizer code, we prepare the additional qubit in a $Z_0=1$ or $X_0=1$ eigenstate, and then execute the circuit shown in Fig. 17. We recall that, acting by conjugation, a CNOT gate changes a tensor product of Pauli operators acting on its control and target according to

$$IZ\leftrightarrow ZZ, \quad XI\leftrightarrow XX; \tag{96}$$

that is, the CNOT transforms an IZ eigenstate to a ZZ eigenstate and an XI eigenstate to an XX eigenstate, while leaving ZI and IX eigenstates invariant. The circuit in Fig. 17 with qubit 0 as target, then, transforms the site operators as in Eq. (93) while also implementing

$$Z_0\rightarrow Z_1Z_2Z_0\,. \tag{97}$$

The initial $Z_0=1$ eigenstate is transformed into a state that satisfies the plaquette parity checks of the new triangulation. Similarly, the circuit in Fig. 17 with qubit 0 as control implements Eq. (95) as well as

$$X_0\rightarrow X_1X_2X_0\,; \tag{98}$$

the circuit transforms the $X_0=1$ eigenstate into a state that satisfies the new site parity checks.

Of course, these circuits are reversible; they can be used to extricate qubits from a stabilizer code instead of adding them.

If planar codes are used, we can lay out the qubits in a planar array. Starting with a small encoded planar block in the center, we can gradually add new qubits to the boundary using the moves shown in Fig. 18.

These moves add a new three-qubit plaquette or site operator, and can also be implemented by the circuits of Fig. (17).

A procedure that transforms a distance-L planar code to a distance-$(L+1)$ code is shown in Fig. 19. By adding a new row of plaquette operators, we transform what was formerly a smooth edge into a rough edge, and by adding a new row of site operators we transform a rough edge to a smooth edge. We start the row of plaquettes by adding a two-qubit plaquette operator to the corner via the transformations

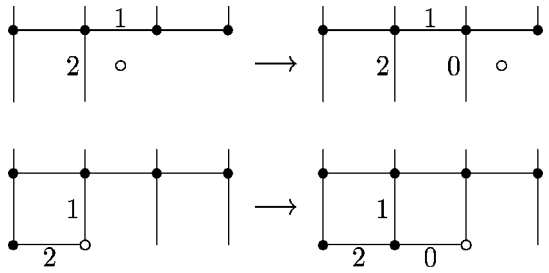

FIG. 18. The same circuits as in Fig. 17 can also be used to build up a planar code by adding a link at the boundary. Sites or plaquettes marked by open circles do not correspond to stabilizer operators.

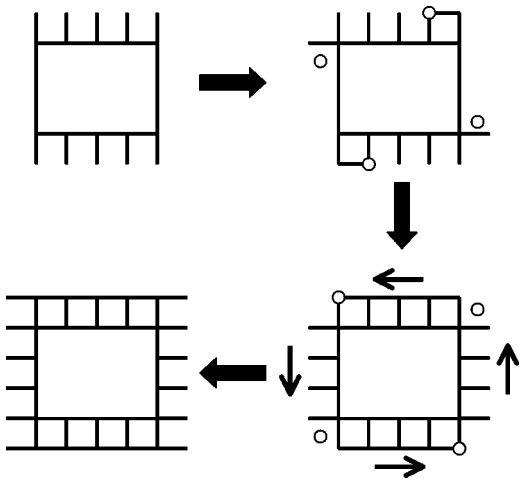

FIG. 19. Building a distance-$(L+1)$ planar code by adding qubits to a distance-L planar code. (Here, $L=5$.) In the first step, new two-qubit stabilizer operators are added in the corners with single CNOTs; in subsequent steps, three-qubit stabilizer operators are added with double CNOTs. The last step promotes the corner operators to three-qubit operators.

$$Z_0 \to Z_1 Z_0, \quad X_1 \to X_1 X_0, \tag{99}$$

which can be implemented by a single CNOT; similarly, we start a row of sites by adding a two-qubit site operator with

$$X_0 \to X_1 X_0, \quad Z_1 \to Z_1 Z_0. \tag{100}$$

Then a new row of boundary stabilizer operators can be ''zipped'' into place.

As is typical of encoding circuits, this procedure can propagate errors badly; a single faulty CNOT can produce a long row of qubit errors (a widely separated pair of defects) along the edge of the block. To ensure fault tolerance, we must measure the boundary stabilizer operators frequently during the procedure. Examining the syndrome record, we can periodically identify the persistent errors and remove them before proceeding to add further qubits.

IX. FAULT-TOLERANT QUANTUM COMPUTATION

We will now consider how information protected by planar surface codes can be processed fault-tolerantly. Our objective is to show that a universal set of fault-tolerant encoded quantum gates can be realized using only local quantum gates among the fundamental qubits and with only polynomial overhead. We will describe one gate set with this property.[4,8] This construction suffices to show that there is an accuracy threshold for quantum computation using surface codes: each gate in our set can be implemented acting on encoded states with arbitrarily good fidelity, in the limit of a large code block. We have not analyzed the numerical value of this computation threshold in detail. Better implementations of fault-tolerant quantum computation can probably be found, requiring less overhead and yielding a better threshold.

We choose the basis introduced by Shor,[3] consisting of four gates. Three of these generate the ''symplectic'' or ''normalizer'' group, the finite subgroup of the unitary group that, acting by conjugation, takes tensor products of Pauli operators to tensor products of Pauli operators. Of these three, two are single-qubit gates: the Hadamard gate

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \tag{101}$$

which acts by conjugation on Pauli operators according to

$$H{:}X\leftrightarrow Z, \tag{102}$$

and the phase gate

$$P\equiv\Lambda(i)=\begin{pmatrix}1 & 0\\ 0 & i\end{pmatrix}, \tag{103}$$

which acts by conjugation on Pauli operators according to

$$P{:}X\rightarrow Y, \quad Z\rightarrow Z. \tag{104}$$

The third generator of the normalizer group is the two-qubit CNOT$=\Lambda(X)$ gates, which acts by conjugation on Pauli operators according to

$$\begin{gathered}\text{CNOT:}\ \ XI\rightarrow XX, \quad IX\rightarrow IX,\\ ZI\rightarrow ZI, \quad IZ\rightarrow ZZ.\end{gathered} \tag{105}$$

Quantum computation in the normalizer group is no more powerful than classical computation.[37] To realize the full power of quantum computing we need to complete the basis with a gate outside the normalizer group. This gate can be chosen to be the three-qubit Toffoli gate $T\equiv\Lambda^2(X)$, which acts on the standard three-qubit orthonormal basis $\{|a,b,c\rangle\}$ as

$$T{:}|a,b,c\rangle\rightarrow|a,b,c\oplus ab\rangle. \tag{106}$$

A. Normalizer gates for surface codes

1. CNOT gate

Implementing normalizer computation on planar codes is relatively simple. First of all, a planar surface code is a Calderbank–Shor–Steane[26,27] (CSS) code, and as for any CSS code with a single encoded qubit, an encoded CNOT can be performed *transversally*—in other words, if simultaneous CNOTs are executed from each qubit in one block to the corresponding qubit in the other block, the effect is to execute the encoded CNOT.[38] To see this, we first need to verify that the transversal CNOT preserves the code space, i.e., that its action by conjugation preserves the code's stabilizer. This follows immediately from Eq. (105), since each stabilizer generator is either a tensor product of X's or a tensor product of Z's. Next we need to check that CNOT$^{\otimes n}$ acts on the encoded operations $\overline{X}$ and $\overline{Z}$ as in Eq. (105), which also follows immediately since $\overline{Z}$ is a tensor product of Z's and $\overline{X}$ is a tensor product of X's.

2. Hadamard gate

What about the Hadamard gate? In fact, applying the bitwise operation $H^{\otimes n}$ does not preserve the code space; rather it maps the code space of one planar code to that of another, different, planar code. If the stabilizer generators of the initial code are site operators X_s and plaquette operators Z_P, then the action of the bitwise Hadamard is

$$H^{\otimes n}{:}X_s\rightarrow Z_s, \quad Z_P\rightarrow X_P. \tag{107}$$

Compared to the initial code, the stabilizer of the new code has sites and plaquettes interchanged. We may reinterpret the new code as a code with X_s and Z_P check operators, but defined on a lattice dual to the lattice of the original code. If the original lattice has its ''rough'' edges at the north and south, then the new lattice has its rough edges at the east and west. We will refer to the two codes as the ''north–south'' (NS) code and the ''east–west'' (EW) code. As indicated in Fig. 20, the action of $H^{\otimes n}$ on the encoded operations $\overline{X}$ and $\overline{Z}$ of the NS code is

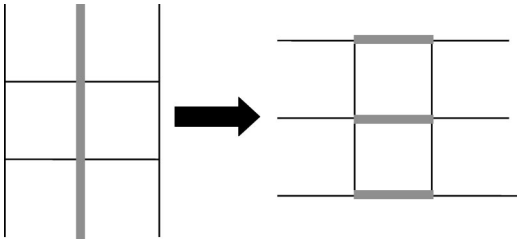

FIG. 20. Action of the bitwise Hadamard gate on the planar code. If Hadamard gates are applied simultaneously to all the qubits in the block, an "NS code" with rough edges at the north and south is transformed to an "EW code" with rough edges at the east and west; the encoded operation $\overline{Z}_{\mathrm{NS}}$ of the NS code is transformed to $\overline{X}_{\mathrm{EW}}$ of the EW code, and $\overline{X}_{\mathrm{NS}}$ is transformed to $\overline{Z}_{\mathrm{EW}}$.

$$H^{\otimes n}\colon \overline{X}_{\mathrm{NS}} \to \overline{Z}_{\mathrm{EW}}, \quad \overline{Z}_{\mathrm{NS}} \to \overline{X}_{\mathrm{EW}}. \tag{108}$$

If we rigidly rotate the lattice by 90°, the EW code is transformed back to the NS code. Hence, the overall effect of a bitwise Hadamard and a 90° rotation is an encoded Hadamard $\overline{H}$.

Of course, a physical rotation of the lattice might be inconvenient in practice! Instead, we will suppose that "peripheral" qubits are available at the edge of the code block, and that we have the option of incorporating these qubits into the block or ejecting them from the block using the method described in Sec. VIII C. After applying the bitwise Hadamard, transforming the $L \times L$ NS code to the EW code, we add $L-1$ plaquettes to the northern edge and $L-1$ sites to the western edge, while removing $L-1$ plaquettes on the east and $L-1$ sites on the south. This procedure transforms the block back to the NS code, but with the qubits shifted by half a lattice spacing to the north and west—we will call this shifted code the NS′ code. Furthermore, this modification of the boundary transforms the logical operations $\overline{Z}_{\mathrm{EW}}$ and $\overline{X}_{\mathrm{EW}}$ of the EW code to the operations $\overline{Z}_{\mathrm{NS}'}$ and $\overline{X}_{\mathrm{NS}'}$ of the NS′ code. The overall effect, then, of the bitwise Hadamard followed by the boundary modification is the operation

$$\overline{X}_{\mathrm{NS}} \to \overline{Z}_{\mathrm{NS}'}, \quad \overline{Z}_{\mathrm{NS}} \to \overline{X}_{\mathrm{NS}'}. \tag{109}$$

In principle, we could complete the encoded Hadamard gate by physically shifting the qubits half a lattice spacing to the south and east, transforming the NS′ code back to the NS code. One way to execute this shift might be to swap the qubits of the NS′ with qubits located at the corresponding sites of the NS lattice. If we prefer to avoid the additional quantum processing required by the swaps, then what we can do instead is associate a classical flag bit with each code block, recording whether the number of Hadamard gates that have been applied in our circuit to that logical qubit is even or odd, and hence whether the logical qubit is encoded in the NS code or the NS′ code. This classical bit is consulted whenever the circuit calls for a Hadamard or CNOT acting on the block. If we perform a Hadamard on a qubit that is initially encoded with the NS′ code, we add qubits on the south and east while removing them from the north and west, returning to the NS code. The CNOT gates are performed transversally between blocks that are both in the NS code or both in the NS′ code; that is, each qubit in one layer interacts with the corresponding qubit directly below it in the next layer. But if one block is in the NS code and the other is in the NS′ code, then each qubit in one layer interacts with the qubit in the next layer that is half a lattice spacing to north and west. Note that the modification of the boundary requires a number of computation steps that is linear in L.

3. Phase gate

For implementation of the phase gate P, note that if we can execute CNOT and H then we can also construct the "controlled-(iY)" gate

$$\Lambda(iY)=\Lambda(ZX)=(IH)\cdot\Lambda(X)\cdot(IH)\cdot\Lambda(X). \tag{110}$$

Hence it suffices to be able to prepare an eigenstate $|+\rangle$ or $|-\rangle$ of Y,

$$Y|\pm\rangle=\pm|\pm\rangle; \tag{111}$$

if we prepare an ancilla in the state $|+\rangle$, and apply a CNOT with the data as its control and the ancilla as its target, the effect on the data is the same as $\Lambda(i)=P$. If the ancilla is the state $|-\rangle$, then we apply $\Lambda(-i)=P^{-1}$ to the data instead.

Now, it is not obvious how to prepare a large toric block in an eigenstate of the encoded Y with good fidelity. Fortunately, we can nevertheless use a CNOT and an ancilla to implement P, thanks to a trick that works because P is the only gate in our set that is not real. Consider a circuit that applies the unitary transformation U to the data if the ancilla has actually been prepared in the state $|+\rangle$. Then if $|+\rangle$ were replaced by $|-\rangle$, this same circuit would apply the complex conjugate unitary U^*, since each P in the circuit would be replaced by P^*.

Instead of a Y eigenstate, suppose we prepare the ancilla in any encoded state we please, for example, $|\overline{0}\rangle$. And then we use this same ancilla block, and a CNOT, every time a P is to be executed. The state of the ancilla can be expressed as a linear combination $a|+\rangle+b|-\rangle$ of the Y eigenstates, and our circuit, acting on the initial state $|\psi\rangle$ of the data, yields

$$a|+\rangle\otimes U|\psi\rangle+b|-\rangle\otimes U^*|\psi\rangle. \tag{112}$$

Now, at the very end of a quantum computation, we will need to make a measurement to read out the final result. Let A denote the observable that we measure. The expectation value of A will be

$$\langle A\rangle=|a|^2\langle\psi|U^\dagger AU|\psi\rangle+|b|^2\langle\psi|U^\dagger A^T U|\psi\rangle, \tag{113}$$

where A^T denotes the transpose of A. Without losing any computational power, we may assume that the observable A is real ($A=A^T$)—for example, it could be $1/2\,(I-Z)$ acting on one of our encoded blocks. Then we get the same answer for the expectation value of A as if the ancilla had been prepared as $|+\rangle$ (or $|-\rangle$); hence our fault-tolerant procedure successfully simulates the desired quantum circuit.

Since there is just one ancilla block that must be used each time the P gate is executed, this block has to be swapped into the position where it is needed, a slowdown that is linear in the width of the quantum circuit that is being simulated.

Thus we have described a way to perform fault-tolerant normalizer computation for planar surface codes. We envision, then, a quantum computer consisting of a stack of planar sheets, with a logical qubit residing in each sheet. Each logical sheet has associated with it an adjacent sheet of ancilla qubits that are used to measure the check operators of the surface code; after each measurement, these ancilla qubits are refreshed in place and then reused. The quantum information in one sheet can be swapped with that in the neighboring sheet through the action of local gates. To perform a logical CNOT between two different logical qubits in the stack, we first use swap gates to pass the qubits through the intervening sheets of logical and ancilla qubits and bring them into contact, then execute the transversal CNOT between the two layers, and then use swap gates to return the logical qubits to their original positions. By inserting a round of error correction after each swap or logical operation, we can execute a normalizer circuit reliably.

B. State purification and universal quantum computation

Now we need to consider how to complete our universal gate set by adding the Toffoli gate. As Shor observed,[3] implementation of the gate can be reduced to the problem of preparing a particular three-qubit state, which may be chosen to be

$$|\psi\rangle_{\text{anc}}=2^{-3/2}\sum_{a,b,c\in\{0,1\}}(-1)^{abc}|a\rangle_1|b\rangle_2|c\rangle_3; \tag{114}$$

this state is the simultaneous eigenstate of three commuting symplectic operators: $\Lambda(Z)_{1,2}X_3$ and its two cyclic permutations, where $\Lambda(Z)$ is the two-qubit conditional phase gate

$$\Lambda(Z):|a,b\rangle\rightarrow(-1)^{ab}|a,b\rangle. \tag{115}$$

Shor's method for constructing this state involved the preparation and measurement of an unprotected n-qubit cat state, where n is the block size of the code. But this method cannot be used for a toric code on a large lattice, because the cat state is too highly vulnerable to error.

Fortunately, there is an alternative procedure for constructing the needed encoded state with high fidelity—*state purification*. Suppose that we have a supply of noisy copies of the state $|\psi\rangle_{\rm anc}$. We can carry out a purification protocol to distill from our initial supply of noisy states a smaller number of states with much better fidelity.[39,40] In this protocol, normalizer gates are applied to a pair of noisy copies, and then one member of the pair is measured. Based on the outcome of the measurement, the other state is either kept or discarded. If the initial ensemble of states approximates the $|\psi\rangle_{\rm anc}$ with adequate fidelity, then, as purification proceeds, the fidelity of the remaining ensemble converges rapidly toward one.

For this procedure to work, it is important that our initial states are not *too* noisy—there is a purification threshold. Therefore, to apply the purification method to toric codes, we will need to build up the size of the toric block gradually, as in the procedure for encoding unknown states described in Sec. VIII C. We start out by encoding $|\psi\rangle_{\rm anc}$ on a small planar sheet of qubits, with a fidelity below the purification threshold. Then we purify for a while to improve the fidelity, and build on the lattice to increase the size of the code block. By building and purifying as many times as necessary, we can construct a copy of the ancilla state that can be used to execute the Toffoli gate with high fidelity.

The time needed to build up the encoded blocks is quadratic in L, and the number of rounds of purification needed is linear in L, if we wish to reach a fidelity that is exponentially small in L. Thus the overhead incurred in our implementation of the Toffoli gate is polynomial in the block size.

We have now assembled all the elements of a fault-tolerant universal quantum computer based on planar surface codes. The computer is a stack of logical qubits, and it contains ''software factories'' where the ancilla states needed for execution of the Toffoli gate are prepared. Once prepared, these states can be transported through swapping to the position in the stack where the Toffoli gate is to be performed.

X. A LOCAL ALGORITHM IN FOUR DIMENSIONS

In our recovery procedure, we have distinguished between quantum and classical computation. Measurements are performed to collect syndrome information about errors that have accumulated in the code block, and then a fast and reliable classical computer processes the measured data to infer what recovery step is likely to remove most of the errors. Our procedures are fault tolerant because the quantum computation needed to measure the syndrome is highly local. But the classical computation is not so local—our algorithm for constructing the chain of minimal weight requires as input the syndrome history of the entire code block.

It would be preferable to replace this procedure by one in which measurements and classical processing are eliminated, and all of the processing is local quantum processing. Can we devise a stable quantum memory based on topological coding such that rapid measurements of the syndrome are not necessary?

Heuristically, errors create pairs of defects in the code block, and trouble may arise if these defects diffuse apart and annihilate other defects, eventually generating homologically nontrivial defect world lines. In principle, we could protect the encoded quantum information effectively if there is a strong attractive interaction between defects that prevents them from wandering apart. A recovery procedure that simulates such interactions was discussed in Ref. 40. For that procedure, an accuracy threshold can be established, but only if the interactions have arbitrarily long range, in

which case the order-disorder transition in the code block is analogous to the Kosterlitz–Thouless transition in a two-dimensional Coulomb gas. But to simulate these infinite-range interactions, nonlocal processing is still required.

A similar problem confronts the proposal[5,41,42] to encode quantum information in a configuration of widely separated nonabelian anyons. Errors create anyons in pairs, and the encoded information is endangered if these ''thermal anyons'' diffuse among the anyons that encode the protected quantum state. In principle, a long-range attractive interaction among anyons might control the diffusion, but this interaction might also interfere with the exchanges of anyons needed to process the encoded state. In any case, a simulation of the long-range dynamics involves nonlocal processing.

We will now describe a procedure for recovery that, at least mathematically, requires no such nonlocal processing of quantum or classical information. With this procedure, based on ''locally available'' quantum information, we can infer a recovery step that is more likely to remove errors than add new ones. Because the procedure is local we can dispense with measurement without degrading its performance very much—measurements followed by quantum gates conditioned on measurement outcomes can be replaced by unitary transformations acting on the data qubits and on nearby ancilla qubits. But since we will still need a reservoir where we can dispose the entropy introduced by random errors, we will continue to assume as usual that the ancilla qubits can be regularly refreshed as needed.

Unfortunately, while our procedure is local in the mathematical sense that recovery operations are conditioned on the state of a small number of ''nearby'' qubits, we do not know how to make it *physically* local in a space of fewer than four dimensions.

A. Repetition code in two dimensions

The principle underlying our local recovery procedure can be understood if we first consider the simpler case of a repetition code. We can imagine that the code block is a periodically identified one-dimensional lattice of binary spins, with two codewords corresponding to the configurations with all spins up or all spins down. To diagnose errors, we can perform a local syndrome measurement by detecting whether each pair of neighboring spins is aligned or anti-aligned, thus finding the locations of defects where the spin orientation flips.

To recover we need to bring these defects together in pairs to annihilate. One way to do this is to track the history of the defects for a while, assembling a record S of the measured syndrome, and then find a minimum-weight chain E' with the same boundary, in order to reconstruct hypothetical world lines of the defects. But in that case the processing required to construct E' is nonlocal.

The way to attain a local recovery procedure is to increase the dimensionality of the lattice. In two dimensions, errors will generate droplets of flipped spins (as in Fig. 21), and the local syndrome measurement will detect the boundary of the droplet. Thus the defects now form one-dimensional closed loops, and our recovery step should be designed to reduce the total length of such defects. Local dynamical rules can easily be devised that are more likely to shrink a loop than stretch it, just as it is possible to endow strings with local dynamics (tension and dissipation) that allow the strings to relax. Thus, in equilibrium, very long loops will be quite rare. If the error rate is small enough, then the droplets of flipped spins will typically remain small, and the encoded information will be well protected.

That the two-dimensional version of the repetition code is more robust than the one-dimensional version illustrates a central principle of statistical mechanics—that order is more resistant to fluctuations in higher dimensions. The code block is described by an Ising spin model, and while the one-dimensional Ising model is disordered at any nonzero temperature, the two-dimensional Ising model remains ordered up to a nonvanishing critical temperature. From the perspective of coding theory, the advantage of the two-dimensional version is that the syndrome is highly redundant. If we check each pair of nearest-neighbor spins to see if they are aligned or anti-aligned, we are collecting more information than is really needed to diagnose all the errors in the block. Hence there is a constraint that must be satisfied by a valid syndrome, namely that the

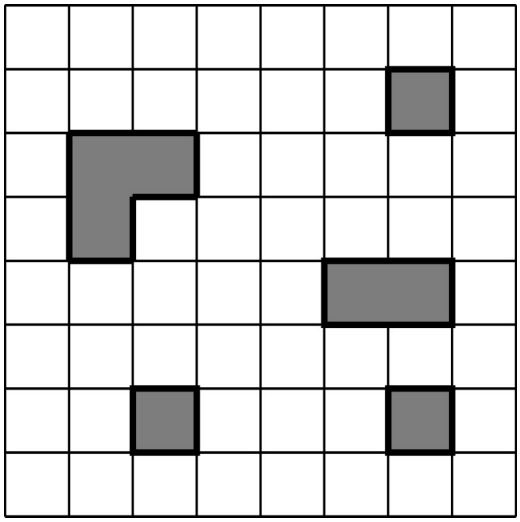

FIG. 21. Droplets of flipped qubits in the two-dimensional quantum repetition code. Qubits reside on plaquettes, and the qubits that have been flipped are shaded. Thick links are locations of ''defects'' where the error syndrome is nontrivial because neighboring qubits are anti-aligned. The defects form closed loops that enclose the droplets.

boundary of a droplet can never end; therefore errors in the syndrome can be detected. Of course, physically, the stability of the ordered state of the Ising model in more than one dimension is the reason that magnetic memories are robust in Nature.

B. Toric code in four dimensions

The defects detected by the measurement of the stabilizer operators of a two-dimensional toric code are also pointlike objects, and error recovery is achieved by bringing the defects together to annihilate. We can promote the annihilation by introducing an effective long-range interaction between defects, but a more local alternative procedure is to increase the dimensionality of the lattice.

So consider a *four-dimensional* toric code. Qubits are associated with each plaquette. With each link is associated the six-qubit stabilizer operator $X_l = X^{\otimes 6}$ acting on the six plaquettes that contain the link, and with each cube is associated the six-qubit stabilizer operator $Z_C = Z^{\otimes 6}$ acting on the six plaquettes contained in the cube. Thus the four-dimensional code maintains the duality between phase and flip errors that we saw in two dimensions. The encoded $\overline{Z}$ or $\overline{X}$ operation is constructed from Z's or X's acting on a homologically nontrivial surface of the lattice or dual lattice, respectively. Z errors on a connected open surface generate a closed loop of defects on the boundary of the surface, and X errors on a connected open surface of the dual lattice generate defects on a set of cubes that form a closed loop on the dual lattice. As in the two-dimensional case, there is a ''hyperplanar'' version of the code that can be defined on a four-dimensional region with a boundary.

Now we want to devise a recovery procedure that will encourage the defect loops to shrink and disappear. Assuming that syndrome measurements are employed, a possible procedure for controlling phase errors can be described as follows: First, the stabilizer operator X_l is measured at each link, and a record is stored of the outcome. We say that each link with $X_l = -1$ is occupied by a string, and each link with $X_l = 1$ is unoccupied. We choose a set of nonoverlapping plaquettes (with no link shared by two plaquettes in the set), and based on the syndrome for the links of that plaquette, decide whether or not to flip the plaquette (by applying a Z). If three or four of the plaquette's links are occupied by string, we always flip the plaquette. If zero or one link is occupied, we never flip it. And if two links are occupied, we flip the plaquette with probability

$\frac{1}{2}$. Then in the next time step, we again measure the syndrome, and decide whether to flip another nonoverlapping set of plaquettes. And so on.

Naturally, we also measure the bit-flip syndrome—Z_C on every cube—in each time step. The procedure for correcting the bit-flip errors is identical, with the lattice replaced by the dual lattice, and X replaced by Z.

Of course the measurement is not essential. A simple reversible computation can imprint the number of string bits bounding a plaquette on ancilla qubits, and subsequent unitary gates controlled by the ancilla can ''decide'' whether to flip the plaquette. Note that a CNOT that is applied with probability $\frac{1}{2}$, needed in the event that the plaquette has two string bits on its boundary, can be realized by a Toffoli gate, where one of the control qubits is a member of a Bell pair so that the control takes the value 1 with probability $\frac{1}{2}$.

This recovery procedure has the property that, if it is perfectly executed and no further errors occur during its execution, it will never increase the total length of string on the lattice, but it will sometimes reduce the length. Indeed, if it is applied repeatedly while no further errors occur, it will eventually eliminate every string. We have chosen to make the procedure nondeterministic in the case where there are two string bits on a plaquette, because otherwise the procedure would have closed orbits—some string configurations would oscillate indefinitely rather than continuing to shrink and annihilate. With the nondeterministic procedure, a steady state can be attained only when all the strings have disappeared.

Actually, following the ideas of Toom,[43] it is possible to devise *anisotropic deterministic* procedures that also are guaranteed to remove all strings. These procedures, in fact, remove the strings more efficiently than our nondeterministic one, but are a little more difficult to analyze.

Of course, the recovery procedure will not really be executed flawlessly, and further errors will continue to accumulate. Still, as error recovery is performed many times, an equilibrium will eventually be attained in which string length is being removed by recovery as often as it is being created by new errors. If the error rates are small enough, the equilibrium population of long string loops will be highly suppressed, so that the encoded quantum information will be well protected.

Eventually, say at the conclusion of a computation, we will want to measure encoded qubits. This measurement procedure does have a nonlocal component (as the encoded information is topological), and for this purpose only we will assume that a reliable classical computer is available to help with the interpretation of the measured data. To measure the logical operator $\overline{Z}$, say, we first measure every qubit in the code block. Then we apply a classical parity check, evaluating Z_C for each cube of the lattice, thereby generating a configuration of closed defect loops on the dual lattice. To complete the measurement, we first eliminate the defects by applying flips to a set of plaquettes bounded by each loop. Then we can evaluate the product of Z's associated with a homologically nontrivial surface to find the value of $\overline{Z}$.

Of course, when we eliminate the defects, we need to make sure that we choose correctly among the homologically inequivalent surfaces bounded by the observed strings. One way to do so, which is unlikely to fail when qubit and measurement error probabilities are small, is to invoke the relaxation algorithm formulated above to the classical measurement outcome. Since our classical computer is reliable, the algorithm eventually removes all strings, and then the value of $\overline{Z}$ can be determined.

C. Accuracy threshold

To evaluate the efficacy of the local recovery method, we need to find the equilibrium distribution of defects. This equilibrium configuration is not so easily characterized, but it will suffice to analyze a less effective algorithm that does attain a simple steady state—the heat bath algorithm. To formulate the heat bath algorithm, suppose that strings carry an energy per lattice unit length that we may normalize to one, and suppose that each plaquette is in contact with a thermal reservoir at inverse temperature β. In each time step, plaquettes are updated, with the change in the string length bounding a plaquette governed by the Boltzmann probability distribution. Thus survival or creation of a length-4 loop is suppressed by the factor

$$\frac{\text{Prob}(0\to 4)}{\text{Prob}(0\to 0)}=\frac{\text{Prob}(4\to 4)}{\text{Prob}(4\to 0)}=e^{-4\beta}. \tag{116}$$

Similarly, the probability of a plaquette flip when the length of bounding string is 3 or 1 satisfies

$$\frac{\text{Prob}(1\to 3)}{\text{Prob}(1\to 1)}=\frac{\text{Prob}(3\to 3)}{\text{Prob}(3\to 1)}=e^{-2\beta}. \tag{117}$$

In the case of a plaquette with two occupied links, we again perform the flip with probability $\frac{1}{2}$. As before, this ensures ergodicity—any initial configuration has some nonvanishing probability of reaching any final configuration.

Damage to encoded information arises from string ''world sheets'' that are homologically nontrivial. At low temperature, string loops are dilute and failure is unlikely, but at a critical temperature the strings ''condense,'' and the encoded data are no longer well protected. The critical temperature is determined by a balance between Boltzmann factor $e^{-\beta l}$ suppressing a string of length l and the string entropy. The abundance of self-avoiding closed loops of length l behaves like,[34]

$$n_{\text{SAW}}^{(4)}(l)\sim P_4(l)(\mu_4)^l, \quad \mu_4\approx 6.77, \tag{118}$$

in $d=4$ dimensions, where $P_4(l)$ is a polynomial. Thus, large loops are rare when the sum

$$\sum_l n_{\text{SAW}}^{(4)}(l)e^{-\beta l}\sim\sum_l P_4(l)(\mu_4 e^{-\beta})^l \tag{119}$$

converges, and the system is surely ordered for $e^{-\beta}<\mu_4^{-1}$. Thus the critical inverse temperature β_c satisfies

$$e^{-\beta_c}\geqslant(\mu_4)^{-1}. \tag{120}$$

Now, our local recovery procedure will not be precisely a heat bath algorithm. But like the heat bath algorithm it is more likely to destroy string than create it, and we can bound its performance by assigning to it an effective temperature. For example, if no new errors arise and the algorithm is perfectly executed, it will with probability one remove a length-4 string loop bounding a plaquette. In practice, though, the plaquette may not flip when the recovery computation is performed, either because of a fault during its execution, or because other neighboring plaquettes have flipped in the meantime. Let us denote by q_4 the probability that a plaquette, occupied by four string bits at the end of the last recovery step, does not in fact flip during the current step. Similarly, let q_3 denote the probability that a plaquette with three string bits fails to flip, and let q_1, q_0 denote the probabilities that plaquettes containing one or zero string bits *do* flip. These quantities can all be calculated, given the quantum circuit for recovery and a stochastic error model.

Now we can find a positive quantity q such that

$$q_0,q_4\leqslant q/(1+q),$$

$$q_1,q_3\leqslant\sqrt{q}/(1+\sqrt{q}). \tag{121}$$

Comparing to Eqs. (116) and (117), we see that our recovery algorithm is at least as effective as a heat bath algorithm with the equivalent temperature

$$e^{-4\beta}=q; \tag{122}$$

in equilibrium strings of length l are therefore suppressed by a factor no larger than $e^{-\beta l}=q^{l/4}$. From our estimate of the critical temperature Eq. (120), we then obtain a lower bound on the critical value of q:

$$q_c \geqslant (\mu_4)^{-4} \approx 4.8\times 10^{-4}. \tag{123}$$

This quantum system with local interactions has an accuracy threshold.

A local procedure that controls the errors in a quantum memory is welcome, but it is disheartening that four spatial dimensions are required. Of course, the four-dimensional code block can be projected to $d<4$ dimensions, but then interactions among four-dimensional neighbors become interactions between qubits that are distance $L^{(4-d)/d}$ apart, where L is the linear size of the lattice. In a three-dimensional version of the toric code, we can place qubits on plaquettes, and associate check operators with links and cubes. Thus, phase error defects are strings and bit-flip error defects are point particles, or vice versa. Then we can recover locally (without measurement or classical computation) from either the phase errors or the bit-flip errors, but not both.

In fewer than four spatial dimensions, how might we devise an intrinsically stable quantum memory, analogous to a magnetic domain with long-range order that encodes a robust classical bit? Perhaps we can build a two-dimensional material with a topologically degenerate ground state, such that errors create point defects that have infinite-range attractive interactions. That system's quasi-long-range order at nonzero temperature could stabilize an arbitrary coherent superposition of ground states.

XI. CONCLUSIONS

In foreseeable quantum computers, the quantum gates that can be executed with good fidelity are likely to be *local* gates—only interactions between qubits that are close to one another will be accurately controllable. Therefore, it is important to contemplate the capabilities of large-scale quantum computers in which all gates are local in three-dimensional space. It is also reasonable to imagine that future quantum computers will include some kind of integrated classical processors, and that the classical processors will be much more accurate and much faster than the quantum processors.

Such considerations have led us to investigate the efficacy of quantum error correction in a computational model in which all quantum gates are local, and in which classical computations of polynomial size can be done instantaneously and with perfect accuracy. We have also assumed that the measurement of a qubit can be done as quickly as the execution of a quantum gate.

These conditions are ideally suited for the use of topological quantum error-correcting codes, such that all quantum computations needed to extract an error syndrome have excellent locality properties. Indeed, we have shown that if the two-dimensional surface codes introduced in Refs. 4 and 5 are used, then an accuracy threshold for quantum storage can be established, and we have estimated its numerical value. This accuracy threshold can be interpreted as a critical point of a three-dimensional lattice gauge theory with quenched randomness, where the third dimension represents time. There is also an accuracy threshold for universal quantum computation, but we have not calculated it carefully.

Topological codes provide a compelling framework for controlling errors in a quantum system via local quantum processing; for this reason, we expect these codes to figure prominently in the future evolution of quantum technologies. In any case, our analysis amply illustrates that principles from statistical physics and topology can be fruitfully applied to the daunting task of accurately manipulating intricate quantum states.

Qubits as parafermions

L.-A. Wu and D. A. Lidar[a)]

(Received 21 November 2001; accepted for publication 16 May 2002)

Qubits are neither fermions nor bosons. A Fock space description of qubits leads to a mapping from qubits to parafermions: particles with a hybrid boson-fermion quantum statistics. We study this mapping in detail, and use it to provide a classification of the algebras of operators acting on qubits. These algebras in turn classify the universality of different classes of physically relevant qubit-qubit interaction Hamiltonians. The mapping is further used to elucidate the connections between qubits, bosons, and fermions. These connections allow us to share universality results between the different particle types. Finally, we use the mapping to study the quantum computational power of certain anisotropic exchange Hamiltonians. In particular, we prove that the XY model with nearest-neighbor interactions only is *not* computationally universal. We also generalize previous results about universal quantum computation with encoded qubits to codes with higher rates. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1499208]

I. INTRODUCTION

It is an experimental fact that there are only two types of *fundamental* particles in nature: bosons and fermions. Bosons are particles whose wavefunction is unchanged under permutation of two identical particles. The wavefunction of fermions is multiplied by -1 under the same operation. An equivalent statement is that bosons transform according to the one-dimensional, symmetric, irreducible representation (irrep) of the permutation group, while fermions belong to the one-dimensional antisymmetric irrep. The permutation group has only these two one-dimensional irreps. What about particles transforming according to higher-dimensional irreps of the symmetric group? Much research went into studying this possibility, in the early days of the quark model, before the concept of ''colored'' quarks gained widespread acceptance.[1,2] However, there are now good reasons to believe that particles obeying such ''parastatistics'' do not exist (Ref. 3, p. 137). Nevertheless, as we will show below, the traditional definition of a Hilbert space of qubits is inconsistent with the properties of either bosons or fermions.

The description of bosons and fermions in terms of their properties under particle permutations uses the language of first quantization. A useful alternative description is the second-quantized formalism of Fock space.[3,4] A basis state in the boson or fermion Hilbert–Fock space can be written as $|n_1^\alpha, n_2^\alpha, \ldots\rangle$, where n_i^α counts how many bosons ($\alpha = b$) or fermions ($\alpha = f$) occupy a given mode, or site i. Note that the total number of modes does not need to be specified in the Fock-basis. Ignoring normalization, raising, $\alpha_i^\dagger$ (lowering, α_i) operators increase (decrease) n_i^α by 1. A consequence of the permutation properties of bosons and fermions is that their corresponding raising and lowering operators satisfy commutation and anticommutation relations:

$$[b_i^\dagger, b_j^\dagger] = 0, \quad [b_i, b_j^\dagger] = \delta_{ij} \quad \text{bosons},$$

$$\{f_i^\dagger, f_j^\dagger\} = 0, \quad \{f_i, f_j^\dagger\} = \delta_{ij} \quad \text{fermions}.$$

a)Electronic mail: dlidar@chem.utoronto.ca

From this follow a number of well-known facts.[3,4] Let $\hat{n}_i^\alpha = \alpha_i^\dagger \alpha_i$; this is the number operator, which is diagonal in the Fock-basis $|n_1^\alpha, n_2^\alpha, \dots\rangle$, and has eigenvalues n_i^α. Then we have the following.

(i) $[b_i^\dagger, b_j^\dagger] = 0 \Rightarrow$ an arbitrary number of bosons n_i^α can occupy a given mode i. On the other hand, $\{f_i^\dagger, f_j^\dagger\} = 0 \Rightarrow$ only $n_i^f = 0,1$ is possible for fermions.

(ii) $[b_i, b_j^\dagger] = \delta_{ij} \Rightarrow$ the Hilbert space of bosons has a natural tensor product structure, i.e., $|n_1^b, n_2^b, \dots\rangle = |n_1^b\rangle \otimes |n_2^b\rangle \otimes \cdots$. More specifically, it is possible to *independently* operate on each factor of the Hilbert space. However,

$$\{f_i, f_j^\dagger\} = \delta_{ij} \Rightarrow f_j |n_1^f, \dots, n_{j-1}^f, 1, n_{j+1}^f, \dots\rangle = (-1)^{\sum_{k=1}^{j-1} n_k^f} |n_1^f, \dots, n_{j-1}^f, 0, n_{j+1}^f, \dots\rangle,$$

which means that the outcome of operating on a mode of a multi-fermion state depends on all previous modes (the order of modes is actually arbitrary). This nonlocal property means that the fermionic Fock space does not have a natural tensor product structure, although it can be mapped onto one that does using the Jordan–Wigner transformation[5] (see Ref. 6 for a more detailed discussion).

What about qubits? The standard notion of what a qubit is, is the following:[7]

Qubit:

(i) A qubit is a vector in a two-dimensional Hilbert space $\mathcal{H}_i = \mathrm{span}\{|0\rangle_i, |1\rangle_i\}$ (like a fermion).

(ii) An N-qubit Hilbert space has a tensor product structure: $\mathcal{H} = \otimes_{i=1}^N \mathcal{H}_i$ (like bosons).

It appears that a qubit is a hybrid fermion-boson particle! We conclude that *qubits do not exist as fundamental particles*. This motivates us to consider an intermediate statistics of ''parafermions'' in order to have a Fock space description of a qubit. We define the parafermionic commutation relations by[8,9]

$$\begin{aligned} \{a_i, a_i^\dagger\} &= 1, \\ [a_i, a_j^\dagger] &= 0 \quad \text{if} \quad i \neq j. \end{aligned} \tag{1}$$

Here i,j are different modes, or different qubits. The relation $[a_i, a_j^\dagger] = 0$ for $i \neq j$ immediately implies a tensor product structure, while $\{a_i, a_i^\dagger\} = 1$, which together with $a_i|0\rangle = 0$ ($|0\rangle$ is the vacuum state) implies

$$a_i a_i = a_i^\dagger a_i^\dagger = 0 \tag{2}$$

in the standard (irreducible) two-dimensional representation. Therefore a double-occupation state cannot be realized, i.e., the single-particle Hilbert space is two-dimensional. These are exactly the requirements for a qubit.

In fact, the notion of particles with ''intermediate'' statistics such as parafermions is well known and established in condensed matter physics, e.g., hard-core bosons, excitons, or the Cooper pairs of superconductivity[10] (see also Sec. VI). Such particles are always *composite*, i.e., they are not fundamental. Another way of obtaining a particle that is neither a boson nor a fermion is to simply ignore one or more degrees of freedom. This is by and large the approach taken in current proposals for the physical implementation of quantum computers. For example, a single spin-$\frac{1}{2}$, without the orbital component of its wavefunction, behaves exactly like a qubit. This is the case of the electron-spin qubit in quantum dots.[11] Related to this, a truncated multi-level atom can also approximate a qubit, as in the ion-trap proposal.[12] What are the implications of this for quantum computing (QC)? In a nutshell, ''ideal'' qubits are hard to come by. If a qubit is to exist as an approximate two-level system, or as a composite particle, or as a partial description of an object with additional degrees of freedom, this means that some robustness is lost and the door is

opened to decoherence. For example, the additional levels in a multi-level Hilbert space can cause ''leakage,'' the orbital degrees of freedom act as a bath coupled to the spin-qubit, and a composite particle may decay (e.g., the exciton-qubit[13]).

The advantages of the parafermionic formalism for qubits, however, are not necessarily in understanding these sources of decoherence, because this formalism ''accepts'' qubits as particles. Instead, the parafermionic formalism allows us to naturally establish mappings between qubits, fermions, and bosons. This mapping serves to transport well-known results about one type of particle to another, which, as we show below, clarifies questions regarding the ability of sets of one type of particle to act as universal simulators[14] of sets of another type of particle. It also helps in connecting the Hamiltonians of condensed matter physics to standard tools of quantum computation.

The structure of the article is as follows. In the next section we formally introduce the second quantization of qubits. We then classify the algebraic structure of parafemionic operators in Sec. III. This classification, into subalgebras with different conservation properties, is very useful for establishing which subsets of qubit operators are universal, either on the full Hilbert space, or only on a subspace. This is taken up in the next two sections, where we establish the connection between parafermions and fermions (Sec. IV) and bosons (Sec. V). The connection to fermions and bosons also works in the opposite direction: we are able to classify which fermionic and bosonic operator sets are universal. This has implications, e.g., for the linear optics quantum computing proposals.[15,16] Section VI shows how to construct parafermions out of paired fermions and bosons, emphasizing the compound-particle aspect of qubits. With the connections between fermions, bosons, and parafermions clarified, we explain in Sec. VII a remarkable difference between parafermions and the other particle types: bilinear parafermionic Hamiltonians are sufficient for universal quantum computation, whereas fermionic and bosonic Hamiltonians are not. In Sec. VIII we briefly use the mapping to fermions to derive the thermal fluctuations of noninteracting parafermions at finite temperature. In Sec. IX we apply the classification of the various parafermionic operator subalgebras to the problem of establishing universality of typical Hamiltonians encountered in solid state physics. We generalize a number of our previous results.[17,18] In particular, we establish that the XY model is not universal with nearest-neighbor interactions only; and, we prove universality of the XXZ model for codes with arbitrarily high rates. We conclude in Sec. X.

II. SECOND QUANTIZATION OF QUBITS

As in the cases of bosons and fermions, a parafermion number operator in mode i can be defined as

$$\hat{n}_i = a_i^\dagger a_i ,$$

with eigenvalues $n_i = 0,1$. The total number operator is $\hat{n} = \Sigma_i \hat{n}_i$. A normalized basis state in the parafermionic Fock space is

$$|\cdots n_i \cdots\rangle = \prod_i \, (a_i^\dagger)^{n_i} |0\rangle,$$

which we think of as representing a state with the ith qubit in the ''up'' (''down'') state if the ith parafermion is present (absent), i.e., $n_i = 1$ (0). *Qubit computational basis states are thus mapped to parafermionic Fock states*. Equivalently, consider the following mapping from qubits to parafermions:

$$|0_1 \cdots 0_{i-1} 0_i 0_{i+1} \cdots\rangle \to |0\rangle,$$

$$|0_1 \cdots 0_{i-1} 1_i 0_{i+1} \cdots\rangle \to a_i^\dagger |0\rangle,$$

where on the left 0 and 1 represent the standard (first-quantized) logical states of a qubit. *Qubits can thus be identified with parafermionic operators*.

The mapping of qubits to parafermions is completed by mapping the Pauli matrices σ_i^α to parafermionic operators:

$$\sigma_i^+ \to a_i^\dagger, \quad \sigma_i^- \to a_i, \quad \sigma_i^z \to 2n_i - 1. \tag{3}$$

It is then straightforward to check that the standard sl(2) commutation relations of the Pauli matrices,

$$[\sigma_i^+, \sigma_j^-] = \delta_{ij}\sigma_i^z,$$

$$[\sigma_i^z, \sigma_j^\pm] = \pm \delta_{ij}\sigma_i^\pm,$$

are preserved, so that we have a faithful second-quantized representation of the qubit system Hilbert space and algebra. [Of course we could also have mapped su(2)$=\{\sigma^x, \sigma^y, \sigma^z\}$ to the parafermionic operators, by appropriate linear combinations.] To illustrate the multi-qubit Hilbert–Fock space representation, consider the case of two modes, i.e., $i,j=1,2$. The space splits into a vacuum state $|00\rangle = |0\rangle$, single-particle states $|01\rangle = a_1^\dagger|0\rangle$ and $|10\rangle = a_2^\dagger|0\rangle$, and a two-particle state $|11\rangle = a_1^\dagger a_2^\dagger|0\rangle$. It is important to emphasize that the parafermionic formalism is mathematically equivalent to the standard Pauli matrix formalism. We will be using both in the sections that follow, starting with the parafermionic, as it makes particularly transparent the translation of known results about fermions to qubits.

III. GENERAL PROPERTIES OF PARAFERMIONIC OPERATORS

N-qubit operators in QC are elements of the group U(2^N). We will begin our discussion by identifying a set of infinitesimal parafermionic generators for U(2^N). Recall that with any r-parameter Lie group there are associated r infinitesimal generators,[19] e.g., in the case of su(2) these are, in the two-dimensional irreducible representation, the Pauli matrices $\{\sigma_x, \sigma_y, \sigma_z\}$. Now, let $\alpha=\{\alpha_i\}, \beta=\{\beta_j\}$, where α_i, β_j can be 0 or 1. In terms of parafermionic operations, any element of U(2^N) can be written as $\mathrm{U}(b) = \exp(-i\Sigma_{\alpha,\beta} b^{\alpha\beta} Q_{\alpha,\beta}(N))$, where $b^{\alpha\beta}$ are continuous parameters (generalized Euler angles) and the $2^N \times 2^N$ *infinitesimal group generators* $Q_{\alpha,\beta}(N)$ are defined as follows: Let $N_\alpha = \Sigma_{i=1}^N \alpha_i$, and

$$q_\alpha^\dagger(N_\alpha) = (a_N^\dagger)^{\alpha_N} \cdots (a_1^\dagger)^{\alpha_1}, \quad q_\beta(N - N_\alpha) = a_N^{\beta_N} \cdots a_1^{\beta_1}. \tag{4}$$

Then,

$$Q_{\alpha,\beta}(N) = q_\alpha^\dagger(N_\alpha) q_\beta(N - N_\alpha). \tag{5}$$

The $Q_{\alpha,\beta}(N)$ will be recognized as all possible transformations between N-qubit computational basis states, e.g., for $N=2$ the set of 16 operators is

$$\{I, a_1^\dagger, a_2^\dagger, a_1, a_2, a_2^\dagger a_1^\dagger, a_1 a_2, a_1^\dagger a_1, a_1^\dagger a_2, a_2^\dagger a_1, a_2^\dagger a_2, a_2^\dagger a_1^\dagger a_1, a_2^\dagger a_1^\dagger a_2, a_1^\dagger a_1 a_2, a_2^\dagger a_2 a_1, a_2^\dagger a_1^\dagger a_2 a_1\},$$

where I is the identity operator. The set $Q_{\alpha,0}(N)$ generates all possible basis states from the vacuum state. Hermitian forms are $Q + Q^\dagger$ and $i(Q - Q^\dagger)$. We will turn to the Hermitian set of generators in the discussion of applications, in Sec. IX.

Note that infinitesimal generators are not the generators one usually considers in QC. Rather, in QC, a gate operation is obtained by the unitary evolution generated through the turning on/off of a set of physically available *Hamiltonians* $\{H_\mu\}$, which are generally a small subset of the $2^N \times 2^N$ infinitesimal generators $Q_{\alpha,\beta}(N)$. "Generated" here has the usual meaning of allowing linear combinations and commutation of Hamiltonians. We will say that *a set of Hamiltonians* $\{H_\mu\}$ *is universal with respect to a Lie group* $\mathcal{G}$ if it generates the Lie algebra of that group. The

question of the dimension of the universal set of Hamiltonians with respect to $\mathrm{U}(2^N)$ is somewhat subtle, since it is context dependent. Lloyd showed that given two noncommuting operators A, B, represented by $n\times n$ matrices, one can almost always generate $\mathrm{U}(n)$.[20] However, it is not necessarily clear how this result is related to *physically available* Hamiltonians, since in practice one may have only limited control over terms in a Hamiltonian, e.g., the standard Hamiltonian generators for SU(4) (two qubits) is the five-element set $\{\sigma_1^z,\sigma_2^z,\sigma_1^x,\sigma_2^x,\sigma_1^z\sigma_2^z\}$. However, the four-element set $\{\sigma_1^z,\sigma_2^z,\sigma_1^z\sigma_2^x-\sigma_1^x\sigma_2^z,\vec{\sigma}_1\cdot\vec{\sigma}_2\}$ also generates SU(4), and may be physically available.[17] Another example are the following sets of, respectively, five, four, and three generators: $\{\sigma_1^x,\sigma_2^x,\sigma_1^z,\sigma_2^z,\sigma_1^z\sigma_2^z\}$, $\{\sigma_1^x,\sigma_2^x,c_1\sigma_1^z+c_2\sigma_2^z,\sigma_1^z\sigma_2^z\}$, and $\{\sigma_1^x,\sigma_2^x,c_1\sigma_1^z+c_2\sigma_2^z+c_3\sigma_1^z\sigma_2^z\}$ (where c_i are constants). Which set of generators is physically available (i.e., directly controllable) depends on the specific system used to implement the quantum computer. As we will show later in this work, it is sometimes the case that a given, physically available, set of Hamiltonians is universal with respect to a *subgroup* of $\mathrm{U}(2^N)$, which may be quite useful, provided the subgroup is sufficiently large (typically, still exponential in N). This notion of universality with respect to a subgroup is what gives rise to the idea of *encoded universality*:[17,18,21–24,52] one encodes a logical qubit into two or more physical qubits, and studies the universality of the subgroup-generating Hamiltonians with respect to these encoded/logical qubits.

The infinitesimal parafermionic generators $Q_{\alpha,\beta}(N)$ can be rearranged into certain subsets of operators with clear physical meaning, which we now detail.

(1) Local subalgebras: The tensor product structure of qubits is naturally enforced by $[a_i,a_j^\dagger]=0$ for $i\neq j$. This induces a tensor product structure $\otimes_{i=1}^N \mathrm{sl}_i(2)$ on the subalgebras formed by the grouping $\mathrm{sl}_i(2)=\{a_i,a_i^\dagger,1-2n_i\}$. Each $\mathrm{sl}_i(2)$ can only change states within the same mode.

(2) SAp—Subalgebra with *conserved parity*: Define a *parity* operator as

$$\hat{p}=(-1)^{\hat{n}}.$$

It has eigenvalues 1 (-1) for even (odd) total particle number. The operators that commute with the parity operator form a subalgebra, which we denote by SAp. Let k (l) be the number of $a_i^\dagger$ (a_i) factors in $Q_{\alpha,\beta}(N)$, i.e.,

$$k=\sum\ \alpha_i,\quad l=\sum\ \beta_i.$$

SAp consists of those operators having $k-l$ even, so its dimension (i.e., number of generators) is $2^{2N}/2$. To see this, let Q_I be in SAp, and consider its action on a state with an even number of particles $|n\rangle$. Since $k-l$ is even, $Q_I|n\rangle=|n'\rangle$ where n' is also even. Now, $\hat{p}Q_I|n\rangle=\hat{p}|n'\rangle=+|n'\rangle$, but also $Q_I\hat{p}|n\rangle=Q_I(+|n\rangle)=|n'\rangle$ so $[\hat{p},Q]=0$. For example, for $N=2$ SAp consists of $\{I,a_2^\dagger a_1^\dagger,a_1a_2,a_1^\dagger a_1,a_1^\dagger a_2,a_2^\dagger a_1,a_2^\dagger a_2,a_2^\dagger a_1^\dagger a_2a_1\}$.

(3) SAn—subalgebra with *conserved particle number*. This subalgebra, which we denote SAn, is formed by all operators commuting with the number operator $\hat{n}$. These are the operators for which $k=l$, so its dimension is $\Sigma_{k=0}^N\ (\binom{N}{k})^2=(2N)!/N!N!$. To see this, let Q_{II} be in SAn, and consider its action on a state $|n\rangle$ with n particles. Q_{II} cannot change this number since $k=l$, but it can transform $|n\rangle$: $\hat{n}Q_{II}|n\rangle=\hat{n}|n\rangle'=n|n\rangle'$. However, $Q_{II}\hat{n}|n\rangle=nQ_{II}|n\rangle=n|n\rangle'$, so $[Q_{II},\hat{n}]=0$. For example, for $N=2$ SAn consists of $\{I,a_1^\dagger a_1,a_1^\dagger a_2,a_2^\dagger a_1,a_2^\dagger a_2,a_2^\dagger a_1^\dagger a_2a_1\}$. Clearly, SA$n\subset$SA$p$.

(4) Subsets of bilinear operators: There are two types of bilinear operators for $i\neq j$: $a_i^\dagger a_j$ (which conserve the particle number) and $a_ia_j,a_i^\dagger a_j^\dagger$ (which conserve parity). Let $\mu=(ij)$. Then first

$$\begin{aligned} T_\mu^x&=a_j^\dagger a_i+a_i^\dagger a_j,\\ T_\mu^z&=n_i-n_j, \end{aligned}\tag{6}$$

and $T_\mu^y=i[T_\mu^x,T_\mu^z]$ form an su(2) subalgebra, that we denote $\mathrm{su}_\mu^t(2)$. Clearly, $\mathrm{su}_\mu^t(2)\in\mathrm{SA}n$. Second,

$$R^x_\mu = a_i a_j + a_i^\dagger a_j^\dagger ,$$
$$R^z_\mu = n_i + n_j - 1, \tag{7}$$

and R^y_μ form another su(2) subalgebra, that we denote $\mathrm{su}^r_\mu(2) \in \mathrm{SA}p$. Note that $[\mathrm{su}^t_\mu(2), \mathrm{su}^r_\mu(2)] = 0$ since any product of raising/lowering operators from these algebras contains a factor of $a_i a_i$ or $a_i^\dagger a_i^\dagger$. Consider as an example the case of $N=2$ modes. Whereas the direct product group $\mathrm{SU}_1(2) \otimes \mathrm{SU}_2(2)$ yields all product states, the group $\mathrm{SU}^t(2) \oplus \mathrm{SU}^r(2)$ can transform between states with equal particle number and states differing by two particle numbers.

(5) Generators of SA$n(N)$: The set of Hamiltonians $\{a_i^\dagger a_j\}_{i,j=1}^{N+1}$ generates SA$n(N)$, i.e., the subalgebra of conserved particle number on N modes (qubits). Proof: this set maps to the XY model (see Sec. IX B). The rest follows using the method of Ref. 18. Note that $\{a_i^\dagger a_j\}_{i,j=1}^{N+1}$ does *not* generate SA$n(N+1)$, since this set cannot generate $\hat{n}_1 \hat{n}_2 \cdots \hat{n}_N$.

(6) Generators of SA$p(N)$: The set of Hamiltonians $\{a_i^\dagger a_j, a_i a_j + a_i^\dagger a_j^\dagger, i(a_i a_j - a_i^\dagger a_j^\dagger)\}_{i,j=1}^{N}$ yields all states with even particle number on N modes from the vacuum state. (Proof is trivial.)

(7) Generators of SU(2^N): In order to transform between states differing by an odd number of particles it is necessary to include the operators $\{a_i, a_i^\dagger\}$ as well. The corresponding set $\{a_i^\dagger a_j, a_i a_j, a_i^\dagger a_j^\dagger, a_i, a_i^\dagger\}_{i,j=1}^{N}$ generates a set of universal gates (proof is trivial), and then by standard universality results[25,26] the entire SU(2^N).

Additional structure emerges from a mapping between fermions and parafermions. This structure helps both in simulating fermionic system using qubits, and in understanding the universality of qubit systems.

IV. FERMIONS AND PARAFERMIONS

A general fermionic Fock state is

$$|n_1, n_2, \cdots\rangle_F , \tag{8}$$

where $n_i = 0,1$ is the occupation number of mode i. As is well known,[27] the fermionic ("supergroup" [19]) U(2^N) has infinitesimal generators

$$\tilde{Q}^f_{\alpha,\beta}(N) = (f_N^\dagger)^{\alpha_N} \cdots (f_1^\dagger)^{\alpha_1} A f_N^{\beta_N} \cdots f_1^{\beta_1},$$

where

$$A = \bigotimes_{i=1}^{N} (1 - n_i).$$

This basis is equivalent by a linear transformation to the more familiar set

$$Q^f_{\alpha,\beta}(N) = (f_N^\dagger)^{\alpha_N} \cdots (f_1^\dagger)^{\alpha_1} f_N^{\beta_N} \cdots f_1^{\beta_1},$$

which transforms between all possible fermionic Fock states ("fermionic computational basis state"). There is a group chain of this group,

$$\mathrm{U}(2^N) \supset \mathrm{SO}(2N+1) \supset \mathrm{SO}(2N) \supset \mathrm{U}(N) \tag{9}$$

and the generators of the subgroups are known.[19]

The Jordan–Wigner (JW) transformation,[5] recently generalized in Ref. 28, allows one to establish an isomorphism between fermions and parafermions. Defining

$$S_i^f \equiv \bigotimes_{k=1}^{i-1} (1 - 2n_k^f), \quad S_i \equiv \bigotimes_{k=1}^{i-1} (1 - 2n_k), \tag{10}$$

TABLE I. Infinitesimal generators (h.c.=Hermitian conjugate).

Group	Fermions	Parafermions
$U(2^N)$	$Q^f_{\alpha,\beta}(N)$	$Q_{\alpha,\beta}(N)$
$SO(2N+1)$	$f_i^\dagger f_j, f_i f_j, f_i$, h.c.	$a_i^\dagger S_i S_j a_j, a_i S_i S_j a_j, a_i S_i$, h.c.
$SO(2N)$	$f_i^\dagger f_j, f_i f_j$, h.c.	$a_i^\dagger S_i S_j a_j, a_i S_i S_j a_j$, h.c.
$U(N)$	$f_i^\dagger f_j$	$a_i^\dagger S_i S_j a_j$

the mapping is

$$n_i^f \to n_i,$$
$$f_i \to a_i S_i, \tag{11}$$
$$f_i^\dagger \to a_i^\dagger S_i.$$

The action of the fermionic operators on the state (8) is equivalent to that of the corresponding parafermionic operators on the state $|n_1,n_2,\ldots\rangle$. To see this, note that $[a_i,S_i]=0$. Therefore the effect of the JW transformation is quite simple: by commuting all S_i to the left when mapping a fermionic infinitesimal generator to a parafermionic one, we see that (i) the parafermionic $a_i, a_i^\dagger$ operators will yield a state with the same parafermionic occupation numbers as the corresponding fermionic state and (ii) the action of the product of S_i's is to produce a phase ± 1. (This may become a relative phase when acting on a state that is a superposition of computational basis states.) This allows us to study algebraic properties of one set of particles in terms of the other.

Using the JW transformation we find that the same subgroup chain (9) holds for parafermions, and we can immediately write down also the infinitesimal generators for the corresponding parafermionic subgroups. The result is given in Table I.

The significance of these subgroups for QC is in the classification of the universality properties of fermionic and parafermionic Hamiltonians. For example, a Hamiltonian of noninteracting fermions, i.e., one including only bilinear terms $\{f_i^\dagger f_j, f_i f_j, f_j^\dagger f_i^\dagger\}$, is not by itself universal since it merely generates $SO(2N)$. Recent work has clarified what needs to be added to such a Hamiltonian in order to establish universality.[6,29,30] Regarding $SO(2N+1)$, note that one must carefully discuss the Hermitian terms $f_i+f_i^\dagger$ and $i(f_i-f_i^\dagger)$ if one wants to consider them as Hamiltonians, since it is unclear which physical process can be described by such Hamiltonians (a single fermion creation/annihilation operator can turn an isolated fermion into a boson, a process that does not seem to occur in nature).

A more powerful classification, from the QC viewpoint, is in terms of physically available Hamiltonian generators of the subgroups. An interesting restriction of the set of infinitesimal generators to a physically reasonable set of Hamiltonians is to consider only nearest-neighbor interactions, where possible. The results known to us in this case are presented in Table II.

A couple of comments are in order regarding Table II: First, note the group $SO(2N+1)$ may be unphysical not just for fermions since its generators must contain terms like $f_i+f_i^\dagger$ in its Hamiltonian, but also for parafermions: it requires a nonlocal Hamiltonian due to the S_i term. Second, the corresponding fermionic generators for $U(2^N)$ given here is unphysical because it

TABLE II. Hamiltonian generators.

Group	Fermions	Parafermions
$U(2^N)$	$f_i S_i^f, f_i^\dagger f_{i+1}$, h.c.	$a_i, a_i^\dagger a_{i+1}$, h.c.
$SO(2N+1)$	f_i, h.c.	$a_i S_i$, h.c.
$SO(2N)$	$f_i^\dagger f_{i+1}, f_i f_{i+1}$, h.c.	$a_i^\dagger a_{i+1}, a_i a_{i+1}$, h.c.
$SU(N)$	$f_i^\dagger f_{i+1}$, h.c.	$a_i^\dagger a_{i+1}$, h.c.

includes terms that are linear in f_i and furthermore nonlocal. A physically acceptable set is $\{f_i^\dagger f_{i+1}, f_i f_{i+1}, f_i^\dagger f_{i+1}^\dagger f_i f_{i+1}$, h.c.$\}$, but this set is not universal over the full 2^N-dimensional Hilbert space (since it conserves parity). This means that a qubit needs to be encoded into two fermions in this case, a situation we explore further in Sec. VI. Now let us verify the claims of Table II. Our strategy is to show that in each case, we can use the Hamiltonians for generating all infinitesimal generators of the corresponding subgroup in Table I.

Consider first the subgroup SU(N): In the fermionic case, we claim that this subgroup has nearest-neighbor Hamiltonian generators $f_i^\dagger f_{i+1}$ and their Hermitian conjugates. For example, for $N=3$, if we have the four operators $f_1^\dagger f_2$, $f_2^\dagger f_3$ and h.c., then we can generate $f_1^\dagger f_3 = [f_1^\dagger f_2, f_2^\dagger f_3]$ and h.c., as well as $\hat{n}_i^f - \hat{n}_j^f = [f_i^\dagger f_j, f_j^\dagger f_i]$. This yields a total of nine operators, eight of which are linearly independent, that generate SU(3). As for parafermions, we can use the JW transformation to get $f_{i+1}^\dagger f_i \to a_{i+1}^\dagger S_{i+1} a_i S_i = a_{i+1}^\dagger (1-2\hat{n}_i) a_i = a_{i+1}^\dagger a_i$ (where we have used $[a_i, S_i]=0$ and $\hat{n}_i a_i = a_i^\dagger a_i a_i = 0$). This establishes an isomorphism between the fermionic and parafermionic generators for SU(N). Hence the parafermionic subgroup SU(N) is generated by $a_i^\dagger a_{i+1}$ and h.c.

Now consider SO($2N$): In the fermionic case we have $f_1^\dagger f_2^\dagger$, and using the result for U(N) we also have $f_4^\dagger f_1$; therefore we have $[f_4^\dagger f_1, f_1^\dagger f_2^\dagger] = f_4^\dagger f_2^\dagger$. Clearly, the interaction range can be extended to cover all generators. For the parafermionic case, using the JW transformation we find $f_{i+1}^\dagger f_i^\dagger \to a_{i+1}^\dagger S_{i+1} a_i^\dagger S_i = a_{i+1}^\dagger (1-2\hat{n}_i) a_i^\dagger = a_{i+1}^\dagger a_i^\dagger$, so that we again have an isomorphism with the fermionic case.

Next consider the (unphysical) subgroup SO($2N+1$): In the fermionic case it suffices to note that $\frac{1}{2}[f_i, f_j] = f_i f_j$ and $\frac{1}{2}[f_i^\dagger, f_j] = f_i^\dagger f_j$, $i \leqslant j$ so that we can generate all infinitesimal generators by the linear terms f_i and $f_i^\dagger$. The parafermionic case follows by the JW transformation.

Finally, in the U(2^N) case the universality of the parafermionic set $\{a_i, a_i^\dagger a_{i+1}$, h.c.$\}$ follows from that of the set of all single qubit operations together with the Hamiltonian of the nearest-neighbor XY model [Eq. (17) below], proved in Ref. 31. The fermionic case follows by the JW transformation.

Let us recapitulate the meaning of the results presented in this section: we have shown how to classify subalgebras of fermionic/parafermionic operators in terms of the groups they generate. This therefore classifies their universality properties with respect to these groups. This is particularly important in the context of a given set of physically available Hamiltonians. Our method employed a mapping between fermions and parafermions, which allowed us to easily transport known results about one type of particle to the other.

V. BOSONS FROM PARAFERMIONS

A linear combination of different-mode parafermions can approximately form a boson. Define

$$B = \frac{1}{\sqrt{N}} \sum_{i=1}^{N} a_i .$$

Then using Eq. (1) we have

$$[B, B^\dagger] = \frac{1}{N} \sum_{i=1}^{N} 1 - 2\hat{n}_i = 1 - \frac{2\hat{n}}{N}.$$

If the parafermion number is much smaller than the available number of sites/modes, i.e., when $n \ll N$, then $[B, B^\dagger] \approx 1$, which is an approximate single-mode boson commutation relation.

To get K boson modes, we can divide N into K approximately equal parts. Each part has $N_\alpha = N/K$ qubits and approximately represents a boson. The kth boson is $B_\alpha = (1/\sqrt{N_\alpha}) \sum_{i=1}^{N_\alpha} a_i$. Then

$$[B_\alpha, B_\beta^\dagger] = \delta_{\alpha\beta} \left(1 - \frac{2\hat{n}_\alpha}{N_\alpha}\right)^{n_\alpha \ll N_\alpha} \approx \delta_{\alpha\beta} .$$

Physically, this means that a low-energy qubit system (with most qubits in their ground state) can macroscopically behave like a boson, or a collection of bosons. If the Hamiltonian is of the bilinear form $H=-B^\dagger B=-(1/N)(\hat{n}+\Sigma_{i\neq j}^N a_i^\dagger a_j)$, the ground state with $n\ll N$ parafermions is $(B^\dagger)^n|0\rangle$, i.e., $\hat{n}[(B^\dagger)^n|0\rangle]\approx n[(B^\dagger)^n|0\rangle]$.

A separate conclusion that follows from this result is that a low-energy noninteracting qubit system can *naturally simulate the dynamics of bosons*.

VI. PARAFERMIONS FROM FERMIONS AND BOSONS

As stated in the Introduction, qubits do not exist as fundamental particles. This means that they are either approximate descriptions (e.g., a spin in the absence of its spatial degrees of freedom) or have to be prepared by appropriately combining bosons or fermions, i.e., a qubit can be *encoded* in terms of bosons or fermions under certain conditions (see also Ref. 32). We consider bosonic or fermionic systems with $2N$ single-particle states. Let $k=1,2,\ldots,N$ denote all relevant quantum numbers (including spin, if necessary). The following three cases yield parafermions.

Case 1: Fermionic particle-particle pairs—Under the condition $n_{2k-1}^f=n_{2k}^f$ it can be shown that $\{f_{2k}f_{2k-1},f_{2k-1}^\dagger f_{2k}^\dagger\}=1$ and $[f_{2k-1}f_{2k},f_{2l-1}^\dagger f_{2l}^\dagger]=0$ for $k\neq l$. Furthermore, the set $\{f_{2k-1},f_{2k-1}^\dagger f_{2k}^\dagger,n_{2k-1}^f+n_{2k}^f-1\}$ satisfies the commutation relations of sl(2). Therefore the mapping $a_k\Leftrightarrow f_{2k}f_{2k-1}$, $a_k^\dagger\Leftrightarrow f_{2k-1}^\dagger f_{2k}^\dagger$ and $2n_k\Leftrightarrow n_{2k-1}^f+n_{2k}^f$ is a mapping to parafermions. The vacuum state of parafermions in this case corresponds to the vacuum state $|0\rangle_f$ of fermions. An example is Cooper pairs.

Case 2: Fermionic particle-hole pairs—Under the condition $n_{2k-1}^f+n_{2k}^f=1$ it can be shown as in case 1 that $a_k\Leftrightarrow f_{2k}^\dagger f_{2k-1}$, $a_k^\dagger\Leftrightarrow f_{2k-1}^\dagger f_{2k}$ and $2n_k-1\Leftrightarrow n_{2k-1}^f-n_{2k}^f$ is a mapping to parafermions. However, in this case the vacuum state of parafermions is $|0\rangle=f_{2N}^\dagger\cdots f_4^\dagger f_2^\dagger|0\rangle_f$, because then $a_k|0\rangle=0$ for all k. This vacuum state plays the role of a Fermi level. An example is excitons. In fact, all quantum computer proposals that use electrons, e.g., quantum dots,[11] and electrons on Helium,[33,34] are equivalent to this case. For example, $f_2^\dagger f_1$ and $f_1^\dagger f_2$ can represent the transition operators between two spin states in the quantum dot proposal.

Case 3: Bosonic "particle-hole" pairs—Under the condition $n_{2k-1}^b+n_{2k}^b=1$ it can be shown as in case 1 that $a_k\Leftrightarrow b_{2k}^\dagger b_{2k-1}$, $a_k^\dagger\Leftrightarrow b_{2k-1}^\dagger b_{2k}$ and $2n_k-1\Leftrightarrow n_{2k-1}^b-n_{2k}^b$ is a mapping to parafermions. However, in this case the vacuum state of parafermions is $|0\rangle=b_{2N}^\dagger\cdots b_{2k}^\dagger\cdots b_4^\dagger b_2^\dagger|0\rangle_b$, again because then $a_k|0\rangle=0$ for all k. An example is dual-rail photons in the optical quantum computer proposal.[15]

This classification illustrates the by-necessity compound nature of a qubit, and puts into a unified context the many different proposals for constructing qubits in physical systems. Note that it is possible to use more than two fermions or bosons to construct a parafermion. Further implications, especially as related to the simulation of models of superconductivity (Case 1) on a quantum computer, have been explored in Ref. 35.

VII. PARAFERMIONIC BILINEAR HAMILTONIANS ARE UNIVERSAL BUT FERMIONIC AND BOSONIC ARE NOT

In this section we discuss a rather striking difference between the universality of bilinear Hamiltonians acting on fermions and bosons, as compared to parafermions. Let us consider the set of particle-number-conserving bilinear operators of bosons, fermions and parafermions:

$$b_i^\dagger b_j,\quad f_i^\dagger f_j,\quad a_i^\dagger a_j.$$

As noted in Table I, in the fermionic case these operators generate the group U(N) where N is the number of particles. The same is true for bosons.[19] Clearly, therefore, fermionic and bosonic Hamiltonians containing only these operators are not universal with respect to an interesting (i.e., exponentially large) SU(2^N) subgroup. On the other hand, as discussed in the previous section, these fermionic and bosonic operators can be used to define parafermionic operators $a_i^\dagger a_j$ in

two-to-one correspondence. As mentioned in Sec. III, the set $\{a_i^\dagger a_j\}_{i,j=1}^{N+1}$ generates the subalgebra SA$n(N)$, with dimension $(2N)!/N!N!$ $(>2^N)$ [recall that the total number of $Q_{\alpha,\beta}(N)$ operators is 2^{2N}]. The corresponding Lie group appears to be large enough to be interesting for universal quantum computation. This expectation is borne out, since one can construct an XY model, Eq. (17), using the set $\{a_i^\dagger a_j\}$. As shown in Ref. 23, the XY model is by itself universal provided one uses three physical qubits per *encoded qutrit*, together with nearest-neighbor and next-nearest-neighbor interactions (see also Sec. IX D 1). We discuss the XY model in detail in Sec. IX B. First, however, let us argue qualitatively where the difference between parafermions (qubits) and fermions and bosons originates from. An example will illuminate this. For the case of bosons and fermions, $[b_1^\dagger b_2, b_2^\dagger b_3]=b_1^\dagger b_3$ and $[f_1^\dagger f_2, f_2^\dagger f_3]=f_1^\dagger f_3$. But for parafermions, $[a_1^\dagger a_2, a_2^\dagger a_3]=a_1^\dagger a_3(1-2\hat{n}_2)$. (An easy way to check this, without explicitly calculating the commutator, is to use the mapping to fermions: $f_i^\dagger f_{i+1} \leftrightarrow a_i^\dagger a_{i+1}$ and the Jordan–Wigner transformation $f_i \rightarrow a_i S_i$.) Thus the difference is that *bosons and fermions preserve locality, but parafermions do not*.

Similarly, we can consider additional bilinear operators. For fermions, if we also have $f_i f_j$ and $f_j^\dagger f_i^\dagger$, the group is SO$(2N)$, which is too small to be interesting for QC. In fact this is a model of noninteracting fermions: there exists a canonical transformation to a sum of quadratic terms each of which acts only on a single mode (see also Refs. 6, 29, 30, 32, and 36). For bosons, if we include $b_i b_j$ and $b_j^\dagger b_i^\dagger$, the group generated is the $N(2N+1)$-parameter symplectic group Sp$(2N,R)$ which is noncompact, implying that it has no finite dimensional irreps.[19] If we further include the set of annihilation and creation operators $b_i, b_i^\dagger$ together with the identity operator I, the set $\{I, b_i, b_i^\dagger, b_i b_j, b_j^\dagger b_i^\dagger, b_j^\dagger b_i\}$ generates the semidirect-product group $N(N) \otimes \mathrm{Sp}(2N,R)$, where $N(N)$ is the Heisenberg group, with $(N+1)(2N+1)$ generators (Ref. 19, Chap. 20). This is therefore still too small to be interesting for universal QC. In fact, *this is exactly the reason why linear optics by itself is insufficient for universal QC*. The situation does not change even after introduction of the displacement operators $D_i(\alpha)=\exp(\alpha b_i^\dagger - \alpha^* b_i)$,[16] since $D_i(\alpha) \in N(N) \otimes \mathrm{Sp}(2N,R)$.

The way to universality [with respect to SU(2^N)] is to introduce nonlinear operations such as a Kerr nonlinearity,[37] self-interaction,[38] or conditional measurements.[15,16] A Kerr nonlinearity is a two-qubit interaction of the form $n_i^b n_j^b$ (where i and j are different modes), which directly provides a CPHASE gate. To see this, consider a dual-rail encoding:[37] Suppose that one qubit is encoded into $|0\rangle = b_1^\dagger|0\rangle$, $|1\rangle = b_2^\dagger|0\rangle$, while a second qubit is encoded into $|0\rangle = b_3^\dagger|0\rangle$, $|1\rangle = b_4^\dagger|0\rangle$ ($|0\rangle$ is the vacuum state). The two-qubit states are

$$|00\rangle = b_3^\dagger b_1^\dagger|0\rangle, \quad |01\rangle = b_3^\dagger b_2^\dagger|0\rangle,$$

$$|10\rangle = b_4^\dagger b_1^\dagger|0\rangle, \quad |11\rangle = b_4^\dagger b_2^\dagger|0\rangle.$$

(This is related to case 3 of Sec. VI, where we showed how to make qubits from bosons.) It is then simple to verify that $\exp(-i\pi n_2^b n_4^b)$ acts exactly as a CPHASE gate, i.e., it is represented by the matrix diag(1,1,1,−1) in this two-qubit basis. Here we wish to point out that a recently introduced alternative to a Kerr nonlinearity,[38] namely the self-interaction $(n_i^b)^2$, is in fact closely related to the Kerr nonlinearity. Thus methods developed to use one of these nonlinear interactions can be transported to the other. Let us demonstrate this point by giving a simple circuit to show how one interaction simulates the other. We start with the operator identity

$$\exp(\phi(a^\dagger b - b^\dagger a)) b^\dagger \exp(-\phi(a^\dagger b - b^\dagger a)) = \cos\phi b^\dagger + \sin\phi a^\dagger,$$

which can be proved directly from the Baker–Hausdorff formula

$$e^{-\alpha A} B e^{\alpha A} = B - \alpha[A,B] + \frac{\alpha^2}{2!}[A,[A,B]] - \frac{\alpha^3}{3!}[A,[A,[A,B]]] + \cdots. \tag{12}$$

Using the latter identity it is then simple to verify the following identity, *which holds on the two-qubit subspace above*,

$$\exp(-i\pi n_2^b n_4^b)=\exp\left(-\frac{\pi}{4}(b_2^\dagger b_4-b_4^\dagger b_2)\right)\exp\left(-i\pi\frac{(n_2^b)^2+(n_4^b)^2-n_2^b-n_4^b}{2}\right)$$
$$\times\exp\left(\frac{\pi}{4}(b_2^\dagger b_4-b_4^\dagger b_2)\right).$$

This is an exact three-gate simulation of the Kerr CPHASE gate in terms of the self-interaction. The simulation uses the linear bosonic operators $b_i^\dagger b_j$ and the local energies n_i^b in order to unitarily rotate the self-interaction terms $(n_2^b)^2+(n_4^b)^2$ to a Kerr interaction.

VIII. FLUCTUATIONS IN PARAFERMION NUMBER AT FINITE TEMPERATURE

So far we have not really made use of the full power of the Fock space representation, which allows to consider the case of fluctuating particle number. The quantum statistics of parafermions is determined by their commutation relations, like fermions (Fermi–Dirac statistics) and bosons (Bose–Einstein statistics). A simple case to consider is that of noninteracting parafermions. The Fermi–Dirac distribution for an ideal Fermi gas is derived using only the restriction that no more than a single fermion can occupy a given mode.[39] Hence the statistics of noninteracting parafermions is clearly the same as that of noninteracting fermions.

Fluctuations in particle number will be a result of interaction of the system with an external bath, which imposes a chemical potential μ (essentially the gradient of the particle flow). As a simple example, consider the following system-bath interaction Hamiltonian:

$$H_I=\sum_{i=1}^{N}\sigma_i^z\otimes B_i^z\rightarrow\sum_{i=1}^{N}(2\hat{n}_i-1)\otimes B_i^z, \tag{13}$$

where B_i^z are bath operators. To further simplify things assume the bath is treated classically, i.e., B_i^z are positive c-numbers. With this Hamiltonian, one can study the fluctuations of parafermions under finite temperature T. Mapping from the well-know result for a noninteracting Fermi gas,[39] it then follows that the average occupation for the ith qubit site is

$$\langle n_i\rangle=\frac{1}{e^{(2B_i^z-\mu)/kT}+1},$$

where k is Boltzman's constant. This is the average value of the qubit-''spin'' (whether it is $|0\rangle$ or $|1\rangle$). Keeping the chemical potential μ fixed, in the limit of $T\rightarrow 0$ we find that $\langle n_i\rangle\rightarrow 1$ if $B_i^z<\mu$, but $\langle n_i\rangle\rightarrow 0$ if $B_i^z>\mu$. Thus, as expected, it is essential to keep the interaction with the bath weak (compared to μ) to prevent fluctuations in qubit ''orientation'' at low temperatures. At finite T we find $\langle n_i\rangle<1$, meaning that some fluctuation is unpreventable. Of course, our model is very naive, and the picture is modified when qubit interactions are taken into account. However, it should be clear that a Fock space description of qubits, i.e., in terms of parafermions, could be valuable in studying qubit statistics at finite temperatures.

IX. UNIVERSALITY OF EXCHANGE-TYPE HAMILTONIANS

In this final section we conclude with an application of the formalism we developed earlier to the study of the universality power of Hamiltonians. We have considered this question in detail before for general exchange-type Hamiltonians (isotropic and anisotropic).[17,18] We first briefly review the universality classification of various physically relevant bilinear Hamiltonians. It will be seen that while in certain cases the Hamiltonian is not sufficiently powerful to be universal with respect to $\mathrm{U}(2^N)$, it is universal with respect to a subgroup. As mentioned in Sec. III, this result requires the use of *encoding of physical qubits into logical qubits*.[21–24,52] We then consider in detail the representative example of the XY model, where we give a new proof about universality (in fact, the lack thereof) in the case of nearest-neighbor-only interactions. We then present new

results about codes with higher rates than considered in Refs. 17 and 18. For simplicity we revert when convenient to the Pauli matrix notation in this section, which is more familiar to practitioners of QC.

A. Classification of bilinear Hamiltonians

The most general bilinear Hamiltonian for a qubit system is

$$H(t)\equiv H_0+V+F=\sum_i \frac{1}{2}\varepsilon_i\sigma_i^z+\sum_{i<j} V_{ij}+F, \tag{14}$$

where H_0 is the qubit energy term, the interaction between qubits i and j is

$$V_{ij}=\sum_{\alpha,\beta=x,y,z} J_{ij}^{\alpha\beta}(t)\sigma_i^\alpha\sigma_j^\beta,$$

and the external single-qubit operations are

$$F=\sum_i f_i^x(t)\sigma_i^x+f_i^y(t)\sigma_i^y.$$

Recall the ''standard'' result about universal quantum computation: The group $\mathrm{U}(2^N)$ on N qubits can be generated using arbitrary single qubit gates and a nontrivial two-qubit entangling gate such as CNOT.[25] The general Hamiltonian $H(t)$ can generate such a universal gate set, e.g., as follows: Suppose there are controllable σ_i^z and σ_i^x terms. Then σ_i^y can be generated using Euler angles:

$$\sigma_i^y=\exp(-i\pi\sigma_i^z/4)\sigma_i^x\exp(i\pi\sigma_i^z/4).$$

This is an instance of a simple but extremely useful result: let A and B be anticommuting Hermitian operators where $A^2=I$ (I is the identity matrix). Then, using $Ue^VU^\dagger=e^{UVU^\dagger}$ (U is unitary, V is arbitrary),

$$C_A^\varphi\circ\exp(i\theta B)\equiv\exp(-iA\varphi)\exp(i\theta B)\exp(iA\varphi)=\begin{cases}\exp(-i\theta B) & \text{if } \varphi=\pi/2,\\ \exp[i\theta(iAB)] & \text{if } \varphi=\pi/4.\end{cases} \tag{15}$$

One can also derive these relations for su(2) angular momentum operators, without assuming that $\{A,B\}=0$ and $A^2=I$. Let J_x and J_z be generators of su(2). Then, using the Baker–Hausdorff relation Eq. (12), and $[J_z,J_x]=iJ_y$,

$$\exp(-i\varphi J_z)J_x\exp(i\varphi J_z)=J_x\cos\varphi+J_y\sin\varphi.$$

From here follows, using $Ue^VU^\dagger=e^{UVU^\dagger}$ again,

$$C_{J_z}^\varphi\circ\exp(i\theta J_x)=\exp(i\theta(J_x\cos\varphi+J_y\sin\varphi)),$$

and Eq. (15) can be verified, with $\varphi\to 2\varphi$, and $AB\to[A,B]$.

Different QC proposals usually have different two-qubit interactions. Typical types include $\sigma_i^z\sigma_{i+1}^z,\sigma_i^y\sigma_{i+1}^y$ (or $\sigma_i^x\sigma_{i+1}^x$), $\sigma_i^x\sigma_{i+1}^x+\sigma_i^y\sigma_{i+1}^y$ (XY model), and $\vec{\sigma}_i\cdot\vec{\sigma}_j$ (Heisenberg model). It is simple to show that they can all be transformed into a common canonical form $\sigma_i^z\sigma_{i+1}^z$, using a few unitary transformation. The term $\sigma_i^z\sigma_{i+1}^z$ can be used to generate CPHASE and, from there, CNOT.[7] For example, the XY term can first be transformed into $\sigma_i^x\sigma_{i+1}^x$ using Euler angle rotations about σ_i^x, which flips the sign of the $\sigma_i^y\sigma_{i+1}^y$ term:

$$\exp\left[\frac{i\theta}{2}(\sigma_i^x\sigma_{i+1}^x+\sigma_i^y\sigma_{i+1}^y)\right]\left(C_{\sigma_i^x}^{\pi/2}\circ\exp\left[\frac{i\theta}{2}(\sigma_i^x\sigma_{i+1}^x+\sigma_i^y\sigma_{i+1}^y)\right]\right)=\exp(i\theta\sigma_i^x\sigma_{i+1}^x),$$

which can subsequently be transformed into the canonical form using another Euler angle rotation,

$$C_{\sigma_i^y+\sigma_{i+1}^y}^{\pi/4}\circ\sigma_i^x\sigma_{i+1}^x=\sigma_i^z\sigma_{i+1}^z,$$

where using $[\sigma_i^y,\sigma_{i+1}^y]=0$ we have abbreviated $C_{\sigma_{i+1}^y}^{\pi/4}\circ C_{\sigma_i^y}^{\pi/4}$ as $C_{\sigma_i^y+\sigma_{i+1}^y}^{\pi/4}$. The method of Euler angle rotations as applied here is also known as "selective recoupling" in the NMR literature.[40]

Not all QC proposals have an interaction Hamiltonian that appears to be of the form V_{ij}, e.g., the ion-trap proposal[12] looks quite different since it involves interactions between ions mediated by a phonon. The interaction between the ith ion and the phonon has the form $\sigma_i^- b^\dagger+\sigma_i^+ b$. This is nevertheless equivalent to an XY model, since

$$\sigma_i^x\sigma_{i+1}^x+\sigma_i^y\sigma_{i+1}^y=C_{\sigma_i^z-\sigma_{i+1}^z}^{\pi/4}\circ 2i[\sigma_i^- b^\dagger+\sigma_i^+ b,\sigma_{i+1}^- b^\dagger+\sigma_{i+1}^+ b].$$

Therefore, in many cases it suffices to study the interaction $\sigma_i^z\sigma_{i+1}^z$.

Let us now consider a number of more restricted models.

1. No external single-qubit operations

If $F=0$, then the *nearest-neighbor* set $\{\sigma_i^z,\sigma_i^z\sigma_{i+1}^z,\sigma_i^x\sigma_{i+1}^z,\sigma_{i+1}^x\sigma_i^z\}$ is still universal, since

$$\sigma_i^y=C_{\sigma_{i+1}^z\sigma_i^z}^{\pi/4}\circ\sigma_{i+1}^z\sigma_i^x.$$

This is the case when H_0 is controllable. More physically, the set $\{\sigma_i^z,\vec{\sigma}_i\cdot\vec{\sigma}_{i+1},(\vec{\sigma}_i\times\vec{\sigma}_{i+1})_y=\sigma_i^z\sigma_{i+1}^x-\sigma_{i+1}^z\sigma_i^x\}$ is also universal, where $\vec{\sigma}=(\sigma^x,\sigma^y,\sigma^z)$. The term $\vec{\sigma}_i\times\vec{\sigma}_{i+1}$ is an anisotropic (Dzyaloshinskii–Moriya) interaction which arises, e.g., in quantum dots in the presence of spin-orbit coupling.[17,41–44]

2. No external single-qubit operations and H_0 uncontrollable

If $F=0$ and H_0 is not controllable, then the nearest-neighbor set $\{\sigma_i^z\sigma_{i+1}^z,\sigma_i^x\sigma_{i+1}^z,\sigma_i^z\sigma_{i+1}^x,\sigma_i^y\sigma_{i+1}^z,\sigma_i^z\sigma_{i+1}^y\}$ is universal, meaning that the interaction term V by itself is universal. One way to see this is to map the set to parafermionic operators and note that it overlaps with the set that generates the parafermionic U(2^N) (Table II).

3. Scalar anisotropic exchange-type interactions

Consider the case $J_{ij}^{\alpha\beta}=J_{ij}^{\alpha}\delta_{\alpha\beta}$ (denoting V by V'), which amounts to limiting the Hamiltonian to scalar anisotropic exchange-type interactions. Using Eq. (3) we then arrive at the second-quantized form

$$H_0=\sum_i\ \eta_i n_i,$$

$$F=\sum_i\ (f_i^* a_i+f_i a_i^\dagger), \tag{16}$$

$$V'=\sum_{i<j}\Delta_{ij}(a_i a_j+a_i^\dagger a_j^\dagger)+J_{ij}(a_i^\dagger a_j+a_j^\dagger a_i)+4J_{ij}^z n_i n_j,$$

where

$$\eta_i=\varepsilon_i+\left(\sum_j J^z_{ij}+J^z_{ji}\right), \quad f_i=(f^x_i-if^y_i),$$

$$\Delta_{ij}=J^x_{ij}-J^y_{ij}, \quad J_{ij}=J^x_{ij}+J^y_{ij},$$

and we dropped a constant energy term.

V' is the so-called XYZ model of solid state physics. Considering the structure of V' and the classification of operator algebras we carried out in Secs. III and IV, it should be clear that some immediate conclusions can be drawn about the universality power of this Hamiltonian. The full Hamiltonian $H_0+V'+F$ contains the generators of the parafermionic $U(2^N)$ (Table II), so it is universal. On the other hand, without external single qubit operations ($F=0$), we have $[H_0+V',\hat{p}]=0$, so $H_0+V'\in \mathrm{SA}p$, i.e., preserves parity. This immediately implies that the XYZ model (even with H_0) is by itself not universal. However, it can be made universal by *encoding* logical qubits into several (two are in fact sufficient) physical qubits.[17] The elimination of single-qubit operations ($F=0$) can be quite useful, since typically single- and two-qubit operations involve very different constraints. In some cases single-qubit operations can be very difficult to implement (see Refs. 17, 18, and 22 and references therein for extensive discussions of this point).

B. XY model

Consider now the XY model, which is defined by

$$V_{XY}=\sum_{i<j} J_{ij}(a^\dagger_i a_j+a^\dagger_j a_i). \tag{17}$$

It is relevant to a number of proposals for quantum computing, including quantum Hall systems,[45,46] quantum dots in microcavities,[32] quantum dots coupled by exciton exchange,[47] and atoms in microcavities.[48] Let us summarize what is currently known about quantum computational universality of this model.

(i) In Ref. 31 it was shown that the XY model with nearest-neighbor interactions only, together with single-qubit operations, is universal.

(ii) In Ref. 23 it was argued that the XY model is universal without single-qubit operations, provided these gates can be applied between nearest-neighbor and next-nearest-neighbor pairs of qubits. This involved encoding a logical qutrit into three physical qubits: $|0_L\rangle=|001\rangle$, $|1_L\rangle=|010\rangle$, $|2_L\rangle=|100\rangle$. We reconsider this in Sec. IX D in the context of the XXZ model (but using the methods of Ref. 18, the results are valid also for the XY model).

(iii) In Ref. 18 we showed that the XY model is universal using only nearest- and next-nearest-neighbor ($J_{i,i+2}$) interactions, together with single-qubit σ_z terms. This too involved an encoding of a logical qubit into two physical qubits: $|0_L\rangle=|01\rangle$, $|1_L\rangle=|10\rangle$. Two comments are in order about this result: first, next-nearest-neighbor interactions can be nearest neighbor in 2D (e.g., in an hexagonal array); second, unlike Ref. 31, we did not assume the σ_z terms to be controllable, i.e., there is no individual control over ε_i [Eq. (14)]. A similar model is treated in Sec. IX C.

The question now arises: *Is the XY model universal with nearest-neighbor interactions only?* We prove that it is not.

The nearest-neighbor XY model in its parafermionic form is

$$H=\sum_i^N \epsilon_i n_i+\sum_i^N J_{i,i+1}(a^\dagger_i a_{i+1}+a^\dagger_{i+1}a_i).$$

Consulting Table II, we see that H can only generate SU(N), which is clearly too small even for encoded quantum computation.

C. Antisymmetric XY model

To illustrate the idea of encoding for universality, let us briefly consider the ''antisymmetric XY model:''

$$V_{aXY}=\sum_{i<j} J_{ij}^{xy}\sigma_i^x\sigma_j^y+J_{ij}^{yx}\sigma_i^y\sigma_j^x. \tag{18}$$

Here J_{ij}^{xy} and J_{ij}^{yx} are real. We encode a logical qubit into pairs of nearest-neighbor physical qubits. Letting

$$\tilde{\Delta}_{ij}=J_{ij}^{xy}-J_{ij}^{yx},\quad \tilde{J}_{ij}\equiv J_{ij}^{xy}+J_{ij}^{yx},\quad \epsilon_m^{\pm}\equiv\varepsilon_{2m-1}-\varepsilon_{2m}, \tag{19}$$

using the compact notation $\cdot_m\equiv\cdot_{2m-1,2m}$, and assuming that interactions are on only inside pairs of qubits encoding one qubit, we find for the Hamiltonian $H=H_0+V_{aXY}$

$$H_{aXY}=\sum_{m=1}^{N/2}(\tilde{J}_m R_m^y+\epsilon_m^+ R_m^z)+(\tilde{\Delta}_m T_m^y+\epsilon_m^- T_m^z), \tag{20}$$

where the T and R operators were defined in Eqs. (6) and (7). Since the T and R operators form commuting sl(2) algebras, the Hilbert space splits into two independent computational subspaces. The R operators conserve parity, so that an appropriate encoding in the axially symmetric case ($\tilde{\Delta}_m=0$), using standard qubit notation, is $|0_L\rangle=|00\rangle$ and $|1_L\rangle=|11\rangle$. On the other hand, the T operators preserve particle number, so that if $\tilde{J}_m=0$ (axially antisymmetric case), the encoding is $|0_L\rangle=|01\rangle$, $|1_L\rangle=|10\rangle$. In both cases control over the pair of parameters $\{\tilde{J}_m,\epsilon_m^+\}$ (or $\{\tilde{\Delta}_m,\epsilon_m^-\}$) is sufficient for the implementation of the single-encoded-qubit $\mathrm{SU}_m(2)$ group (the subscript m refers to the mth logical/encoded qubit).

Logic operations between encoded qubits require the ''encoded selective recoupling'' method introduced in Ref. 18. Consider the ''axially antisymmetric qubit'' $|0_L\rangle=|01\rangle$, $|1_L\rangle=|10\rangle$. First, note that, using Eq. (15),

$$C_{T_{12}^x}^{\pi/2}\circ T_{23}^x=i\sigma_1^z\sigma_2^z T_{13}^x. \tag{21}$$

Now assume we can control $\tilde{\Delta}_{13}$. Then,

$$C_{T_{13}^x}^{\pi/4}\circ(C_{T_{12}^x}\circ T_{23}^x)=\sigma_2^z(\sigma_3^z-\sigma_1^z)/2. \tag{22}$$

Since $\sigma_1^z\sigma_2^z$ is constant on the code subspace it can be ignored. On the other hand, $\sigma_2^z\sigma_3^z$ acts as $-T_1^zT_2^z$:

$$|0_L\rangle_1|0_L\rangle_2=|01\rangle_{12}|01\rangle_{34}\overset{\sigma_2^z\sigma_3^z}{\rightarrow}-|01\rangle_{12}|01\rangle_{34}=-|0_L\rangle_1|0_L\rangle_2, \tag{23}$$

and similarly for the other three combinations: $|0_L\rangle|1_L\rangle\rightarrow|0_L\rangle|1_L\rangle$, $|1_L\rangle|0_L\rangle\rightarrow|1_L\rangle|0_L\rangle$, $|1_L\rangle|1_L\rangle\rightarrow-|1_L\rangle|1_L\rangle$, i.e., $\sigma_2^z\sigma_3^z$ acts as an encoded $\sigma^z\otimes\sigma^z$. This establishes universal encoded computation in the antisymmetric XY model.

D. Codes with higher rates

The encoding of one logical qubit into two physical qubits is not very efficient. Can we do better? That is, can we perform encoded universal QC on codes with a rate (no. of logical qubit to no. of physical qubits) that is greater than $\frac{1}{2}$? We will show how in the case of the XXZ model, defined as $H=H_0+H_{XXZ}$, where

$$H_{XXZ}=\sum_{i<j} J_{ij}^{x}(\sigma_i^x\sigma_j^x+\sigma_i^y\sigma_j^y)+J_{ij}^{z}\sigma_i^z\sigma_j^z.$$

When surface and interface effects are taken into account, the XY examples of QC proposals,[31,45–48] as well as the Heisenberg examples,[11,49,50] are better described by the axially symmetric XXZ model. Additional sources of nonzero J_{ij}^{z} in the XY examples can be second-order effects (e.g., virtual cavity-photon generation without spin-flips[31]). A natural XXZ example is that of electrons on helium.[33,34]

First, note that the code used in the XY model, $|0_L\rangle=|01\rangle$, $|1_L\rangle=|10\rangle$, is applicable here as well: $T_{ij}^{x}=\frac{1}{2}(\sigma_i^x\sigma_j^x+\sigma_i^y\sigma_j^y)$ preserves particle number, and serves as an encoded σ^x; σ_i^z terms from H_0 serve as encoded σ^z, and $\sigma_i^z\sigma_{i+1}^z$ applied to physical qubits belonging to different encoded qubits acts as encoded $\sigma^z\otimes\sigma^z$.

In the general encoding case we consider a block of N qubits where codewords are computational basis states (bitstrings of 0's and 1's): $\{q_\alpha^\dagger(N_\alpha)|0\rangle\}_\alpha$, where $\alpha=\{\alpha_i\}$ and α_i can be 0 or 1, while $N_\alpha=0,\ldots,N$. A code-subspace $\mathcal{C}(N,n)$ will be defined by having a fixed number n of 1's (i.e., of parafermions). Thus there are

$$d_{N,n}\equiv\dim[\mathcal{C}(N,n)]=\binom{N}{n}$$

codewords in a subspace. Examples are considered below. Note that these subspaces are decoherence-free under the process of collective dephasing,[51] and have been analyzed extensively in this context in Ref. 52. Figure 1 in Ref. 52 provides a nice graphical illustration of the $\mathcal{C}(N,n)$ subspaces. Since the decoherence-avoidance properties of the codes we consider here have been extensively discussed before,[51,52] and even implemented experimentally,[53,54] we do not address this issue here. We further note that Ref. 52 provided an in-principle proof that universal encoded QC is possible on all subspaces $\mathcal{C}(N,n)$ independently. However, this proof had several shortcomings: (i) it used a short-time approximation, (ii) it did not make explicit contact with physically realizable Hamiltonians, and (iii) it proceeded by induction, and thus did not explicitly provide an *efficient* algorithm for universal QC. We remedy all these shortcomings here, i.e., we (i) use only finite-time operations, (ii) use only the XXZ Hamiltonian, and (iii) provide an efficient algorithm that scales polynomially in N.

We need a measure that captures how efficient a $\mathcal{C}(N,n)$ code is. If there are d codewords, supported over N p-dimensional objects ($p=2$ is the case of bits), and information is measured in units of q, then we define the rate of the code as

$$r(d,p,q)=\frac{\log_q d}{\log_q p^N}.$$

The traditional definition for qubits is recovered by setting $p=q=2$, i.e., the rate of a code is the ratio of the number of logical qubits $\log_2 d$ to the number of physical qubits N, which in our case becomes

$$r=\frac{\log_2 d_{N,n}}{N}\overset{N\gg 1}{\longrightarrow}S(\epsilon),\tag{24}$$

where $\epsilon\equiv k/N$,

$$S(\epsilon)=-\epsilon\log_2\epsilon-(1-\epsilon)\log_2(1-\epsilon)$$

is the Shannon entropy, and we have used the Stirling formula $\log x!\approx x\log x-x$. Since $S(\frac{1}{2})=1$ the code has a rate that is asymptotically unity for the ''symmetric subspace'' $\mathcal{C}(N,N/2)$, where the number of 1's equals the number of 0's in each computational basis state. However, we will not in

fact attempt to encode $\log_2 d_{N,n}$ logical qubits in the subspace $\mathcal{C}(N,n)$, since the subspace does not have a natural tensor product structure. Instead we will consider $\mathcal{C}(N,n)$ as a subspace encoding a qu$d$it, where $d=d_{N,n}$. Using the generalized definition of a rate above, and measuring information in units of d so that each subspace encodes one unit of information, the rate of such a code is $r=(\log_d d)/(\log_d 2^N)$. This, however, exactly coincides with r of Eq. (24). Therefore we see that the advantage of working with the symmetric subspace $\mathcal{C}(N,N/2)$ in the limit of large N is that its rate approaches unity.

Before embarking on the general analysis, let us note that for an encoding of one logical qubit into N physical qubits, there is a simple construction in terms of parafermionic operators: $Q_{\alpha,\beta}(N)$, $Q^\dagger_{\alpha,\beta}(N)$, and $[Q^\dagger_{\alpha,\beta}(N), Q_{\alpha,\beta}(N)]$ (which is a function of parafermion number) form an su(2) algebra in the basis $|0_L\rangle=q^\dagger_\alpha(N_\alpha)|\mathtt{0}\rangle$ and $|1_L\rangle=q^\dagger_\beta(N-N_\alpha)|\mathtt{0}\rangle$, e.g., for $N=2$ there are two cases: the sets $\{a_1a_2, a_2^\dagger a_1^\dagger, \hat{n}_1+\hat{n}_2-1\}$ and $\{a_1^\dagger a_2, a_2^\dagger a_1, \hat{n}_1-\hat{n}_2\}$, with corresponding bases $|0_L\rangle=|\mathtt{0}\rangle$, $|1_L\rangle=a_1^\dagger a_2^\dagger|\mathtt{0}\rangle$ and $|0_L\rangle=a_1^\dagger|\mathtt{0}\rangle$, $|1_L\rangle=a_2^\dagger|\mathtt{0}\rangle$. These two encodings are universal (in the sense of blocks of N physical qubits) when only H_0 and V' are controllable [Eq. (16)].

Let us now move on to the general subspace case, starting with an example.

1. Encoded operations: Example

Consider $\mathcal{C}(3,1)=\mathrm{Span}\{|0\rangle\equiv|001\rangle, |1\rangle\equiv|010\rangle, |2\rangle\equiv|100\rangle\}$, i.e., an encoding of a logical qutrit into three physical qubits, as in Ref. 23. Let us count qubits as $i=0,\ldots,N-1$. Our first task is to show how to generate su(3) on this subspace. It is simple to check that $T^x_{01}|001\rangle=0$, $T^x_{01}|010\rangle=|100\rangle$, $T^x_{01}|100\rangle=|010\rangle$, and in total

$$T^x_{01}=\begin{pmatrix}0&0&0\\0&0&1\\0&1&0\end{pmatrix}=|1\rangle\langle 2|+|2\rangle\langle 1|\equiv X_{12},$$

where the notation X_{12} denotes a σ^x operation between states $|1\rangle\equiv|010\rangle$ and $|2\rangle\equiv|100\rangle$. Similarly, it is simple to check that $T^x_{12}=X_{01}$ and $T^x_{02}=X_{02}$. Further, using $T^z_{ij}\equiv\frac{1}{2}(\sigma^z_i-\sigma^z_j)$, we have $T^z_{01}=Z_{12}$, $T^z_{12}=Z_{01}$, and $T^z_{02}=Z_{02}$, where Z_{12} denotes a σ^z operation between states $|1\rangle$ and $|2\rangle$, etc. Therefore each pair $\{T^x_{ij}, T^z_{ij}\}$ generates an encoded su(2). But in the sense of generating, su(N) is a sum of overlapping su(2)'s,[55] so using just the nearest-neighbor interactions $\{T^x_{01}, T^z_{01}, T^x_{12}, T^x_{12}\}$ we can generate all of su(3) on $\mathcal{C}(3,1)$. Note that $[X_{01}, X_{12}]=iY_{02}$, so that su(2) between states $|0\rangle, |2\rangle$ can in fact be generated using T^x_{ij}'s alone, without T^z_{ij}'s. This conclusion clearly holds for the generation of all of su(3) on $\mathcal{C}(3,1)$, as first pointed out in Ref. 23.

Next, we need to show how to implement encoded logical operations between two $\mathcal{C}(3,1)$ code subspaces. Let us number the qubits as $i=0,1,2$ for the first block and $i=3,4,5$ for the second block. Consider the effect of turning on J^z_{23}, i.e., consider the action of $\sigma^z_2\sigma^z_3$ on the tensor product space $\mathcal{C}(3,1)\otimes\mathcal{C}(3,1)$. The operator $\sigma^z_2\sigma^z_3$ is represented by a nine-dimensional diagonal matrix on this space, which is easily found to have the following form in the ordered basis $\{|0\rangle\otimes|0\rangle, |0\rangle\otimes|1\rangle, \ldots, |2\rangle\otimes|2\rangle\}$:

$$\sigma^z_2\sigma^z_3=\mathrm{diag}(-1,1,1,-1,1,1,1,-1,-1)=\mathrm{diag}(-1,1,1)\otimes\mathrm{diag}(1,1,-1),$$

e.g., $\sigma^z_2\sigma^z_3|2\rangle\otimes|2\rangle=\sigma^z_2\sigma^z_3|100\rangle\otimes|100\rangle=(+|100\rangle)\otimes(-|100\rangle)=-|2\rangle\otimes|2\rangle$, which explains the -1 in the ninth position in the diagonal matrix above. The important point is that $\sigma^z_2\sigma^z_3$ acts as a tensor product operator on $\mathcal{C}(3,1)\otimes\mathcal{C}(3,1)$, which *puts a relative phase* between the basis states of each $\mathcal{C}(3,1)$ factor. This means that $\sigma^z_2\sigma^z_3$ acts as an "su(3)-like" $\sigma^z\otimes\sigma^z$ on $\mathcal{C}(3,1)\otimes\mathcal{C}(3,1)$. [It is an "su(3)-like" $\sigma^z\otimes\sigma^z$ since for su(2) $\sigma^z=\mathrm{diag}(1,-1)$ and here we have instead diag($-1,1,1$) and diag($1,1,-1$).] It is well known[7] that the CPHASE gate can be generated from the Hamiltonian $\sigma^z\otimes\sigma^z$. The same holds here, so that we can generate a CPHASE gate between two $\mathcal{C}(3,1)$ subspaces by simply turning on a nearest-neighbor interaction between the last qubit in the first block and the first qubit in the second block.

With this example in mind we can move on to the general case.

2. Encoded operations: General subspace case

Let us now consider the case of a general subspace $\mathcal{C}(N,n)$. We can enumerate the codewords as $\{|0\rangle,\ldots,|d_{N,n}\rangle\}$ where $|0\rangle=|0,\ldots,01,\ldots,1\rangle$, etc., to $|d_{N,n}\rangle=|1,\ldots,10,\ldots,0\rangle$, where there are N qubits in total and n 1's in each codeword. Consider a fixed nearest-neighbor pair of qubits at positions $i,i+1$, and the action of $T^x_{i,i+1},T^z_{i,i+1}$. The four possibilities for qubit values at these positions are {00,01,10,11}. Now consider a pair of codewords $|t\rangle$, $|t'\rangle$ such that $|t\rangle$ has 01 in the $i,i+1$ positions while $|t'\rangle$ has 10 in the $i,i+1$ positions, and they are identical everywhere else. We can always find such a pair by definition of $\mathcal{C}(N,n)$. The action of $T^x_{i,i+1},T^z_{i,i+1}$ on $|t\rangle$, $|t'\rangle$ is to generate su(2) between them, just as shown in the case of $\mathcal{C}(3,1)$ above. On the other hand, the action of $T^x_{i,i+1},T^z_{i,i+1}$ in the case of 00 or 11 in the $i,i+1$ positions is to annihilate all corresponding codewords [which are anyhow outside of the given $\mathcal{C}(N,n)$ subspace]. This null action means that, when exponentiated, $T^x_{i,i+1},T^z_{i,i+1}$ act as identity on these codewords. Therefore the action of $T^x_{i,i+1},T^z_{i,i+1}$ is precisely to generate su(2) between $|t\rangle$, $|t'\rangle$, and nothing more. Denote this by $\mathrm{su}(2)^{(1)}_{i,i+1}$. Let us now keep the 01 and 10 at positions $i,i+1$ fixed, and vary all other $N-2$ positions in $|t\rangle$, $|t'\rangle$, subject to the constraint of n 1's, and in the same manner in both $|t\rangle$, $|t'\rangle$. We then run over $K=\binom{N-2}{n-1}$ codewords, and $T^x_{i,i+1},T^z_{i,i+1}$ generate su(2) between each pair of new $|t\rangle$, $|t'\rangle$. Denote these by $\mathrm{su}(2)^{(k)}_{i,i+1}$, $k=1,...,K$. By further letting $i=0,...,N-2$ we generate $N-1$ *overlapping* su(2)'s. These su(2)'s can be connected by swaps so that we can generate all $\mathrm{su}(2)^{(k)}_{i,j}$, $k=1,...,K$, $i<j$. We thus have a total of $\binom{N-2}{n-1}$ $\binom{N}{2}$ su(2)'s. To generate the entire $\mathrm{su}(d_{N,n})$ we need no more than $d_{N,n}=\binom{N}{n}$ overlapping su(2)'s. Since $\binom{N-2}{n-1}$ $\binom{N}{2}/\binom{N}{n}=\frac{1}{2}n(N-n)>1$, we have more than enough overlapping su(2)'s, and $\mathrm{su}(d_{N,n})$ can be generated.

What is left is to show that we can perform a controlled operation between two $\mathcal{C}(N,n)$ subspaces. To do so we again use the nearest-neighbor interaction $\sigma^z_{N-1}\sigma^z_N$, where the first factor (σ^z_{N-1}) acts on the last qubit $(N-1)$ of the first $\mathcal{C}(N,n)$ subspace, and the second factor (σ^z_N) acts on the first qubit (N) of the second $\mathcal{C}(N,n)$ subspace. Now let us sort the codewords in the two subspaces in an identical manner, e.g., by increasing binary value. Then consider the action of $\sigma^z_{N-1}\sigma^z_N$ on the resulting ordered basis $\{|0\rangle\otimes|0\rangle,|0\rangle\otimes|1\rangle,\ldots,|d_{N,n}\rangle\otimes|d_{N,n}\rangle\}$. This action generates a representation of $\sigma^z_{N-1}\sigma^z_N$ by a $d_{N,n}\times d_{N,n}$ diagonal matrix. As in the $\mathcal{C}(3,1)$ case considered earlier, this matrix is actually a tensor product of an "$\mathrm{su}(d_{N,n})$-like" $\sigma^z\otimes\sigma^z$ on $\mathcal{C}(N,n)\otimes\mathcal{C}(N,n)$. It is simple to determine the form of these two (different) σ^z's. For the codewords belonging to the left $\mathcal{C}(N,n)$ factor, write down a $+1$ (-1) for each 0 (1) in the Nth position. These numbers are the diagonal entries of the left "$\mathrm{su}(d_{N,n})$-like" σ^z factor. Similarly, for the codewords belonging to the right $\mathcal{C}(N,n)$ factor, write down a $+1$ (-1) for each 0 (1) in the $(N+1)$th position. These numbers are the diagonal entries of the right "$\mathrm{su}(d_{N,n})$-like" σ^z factor. Since each such "$\mathrm{su}(d_{N,n})$-like" σ^z puts relative phases between the basis states of $\mathcal{C}(N,n)$, the action of $\sigma^z_{N-1}\sigma^z_N$ is that of a generalized CPHASE between the two code subspaces. This is sufficient together with $\mathrm{su}(d_{N,n})$ on each block to perform universal quantum computation.[56]

X. CONCLUSIONS

The standard quantum information-theoretic approach to qubits and operations on qubits emphasizes qubits as *vectors* in a Hilbert space and operations as *transformations* of these vectors.[7] This is the point of view of the first-quantized formulation of quantum mechanics. An alternative, mathematically equivalent, point of view is the Fock space, second-quantized formulation of quantum mechanics, which emphasizes the particlelike nature of quantum states. Qubit up/down states are replaced by qubit presence/absence, while rotations are replaced by operators that count or change particle occupation numbers. The mapping of qubits to parafermions discussed in this article is a mapping between these first- and second-quantized formulations. It proved to be a useful tool in studying the connection between qubits, bosons, and fermions, in analyzing the algebraic structure of qubit Hamiltonians, and in studying related quantum computational universality questions. In particular, it allowed us to classify subalgebras of fermion, boson, and qubit operators and decide their power for quantum computational universality. These results are relevant for physical implementation of quantum computers: a physical N-qubit system

comes equipped with a given Hamiltonian, which generates a subalgebra of su(2^N). It is important to know whether this Hamiltonian is by itself universal or needs to be supplemented with additional operations, or whether one needs to encode physical qubits into logical qubits in order to attain universality. Our classification settles this question for many subalgebras of physical interest.

Another potential advantage of the parafermionic approach, as a second-quantized formalism for qubits, lies in its ability to naturally deal with a ''qubit-field,'' i.e., situations where the qubit number is not a conserved quantity. This is certainly a concern for optical and various solid-state quantum computer implementations. We leave the study of a qubit field theory as an open area for future explorations.

[8] The mapping from qubits to parafermions was first pointed out in L.-A. Wu and D. A. Lidar, quant-ph/0103039v1. Our definition of a parafermion is inspired by Green[1] and Greenberg,[9] but differs somewhat. Like these authors we start from $\{a_i, a_i^\dagger\}=1$ and $[a_i, a_j^\dagger]=0$ for $i\neq j$. Green was the first to introduce these commutation relations, but did not name the corresponding particles. Greenberg did not name them either, but called ''parafermion'' a particle defined by $a^\dagger = \sum_{j=1}^N a_j^\dagger$. The commutation relation we use to define parafermions is therefore different from Greenberg's. Nevertheless we prefer to call a particle satisfying these relations a ''parafermion,'' since they emphasize the two-dimensional Hilbert–Fock space of an individual particle (like fermions). The opposite choice of commutation relations, $[a_i, a_i^\dagger]=1$ and $\{a_i, a_j^\dagger\}=0$ for $i\neq j$, can be used to define ''parabosons:'' particles with unlimited occupation number per mode, but without a natural tensor product structure. Finally, we note that the particle we are referring to as a parafermion is also known sometimes as a ''hardcore boson,'' e.g., K. Bernardet *et al.*, Phys. Rev. B **65**, 104519 (2002).

Secrecy capacity in the four-state protocol of quantum key distribution

Howard E. Brandt[a)]
U.S. Army Research Laboratory, 2800 Powder Mill Road, Adelphi, Maryland 20783

(Received 15 February 2002; accepted for publication 16 May 2002)

The process of key distillation from the quantum transmission in quantum key distribution is reviewed, with the objective of calculating the secrecy capacity of the four-state protocol in the presence of an individual attack in which the eavesdropping probe is entangled with the signal states, and states of the probe become correlated with the states measured by the legitimate receiver. Emphasis is placed on information leakage to the eavesdropping probe. The calculation generalizes earlier work to include an arbitrary angle between the signal bases.
[DOI: 10.1063/1.1495072]

I. INTRODUCTION

One effective implementation of the four-state quantum-key-distribution protocol (BB84)[1] uses single photons linearly polarized along one of the four basis vectors of two sets of coplanar orthogonal bases oriented at an angle of $\pi/4$ relative to each other. The polarization measurement operators in one basis do not commute with those in the other, since they correspond to nonorthogonal polarization states. At a fundamental level, the potential security of the key rests on the fact that nonorthogonal photon polarization measurement operators do not commute, and this gives rise to quantum uncertainty in the measurement of those states by an eavesdropper. Before transmission of each photon, the transmitter and receiver each independently and randomly select one of the two bases. The transmitter sends a single photon with polarization chosen at random along one of the orthogonal basis vectors in the chosen basis. The receiver makes a polarization measurement in its chosen basis. Next, the transmitter and the receiver openly compare their choices of basis, without disclosing the polarization states transmitted or received. Events in which the transmitter and the receiver choose different bases are ignored, while the remaining events ideally have completely correlated polarization states. The two orthogonal states in each of the two bases encode binary numbers 0 and 1, and thus a sequence of photons transmitted in this way establishes a random binary sequence shared by both the transmitter and the receiver and can serve as the secret key, following error correction and privacy amplification. The key can then be used to encode a message, using the Vernam cipher, and the message can then be securely transmitted over an open communication line and then decoded, using the shared secret key at the receiver end.

Privacy amplification is, of course necessary, because of the possibility of an eavesdropping attack.[2–4] It is important to note at this point that the present article is not a comprehensive review, but primarily discusses the work of the author and that of Slutsky *et al.*[5–11] In the individual attack,[5–9,12] the most general possible eavesdropping probe consistent with unitarity is assumed, in which each individual transmitted bit is made to interact with the probe so that the carrier and the probe are left in an entangled state, and measurement by the probe, made subsequent to measurement by the legitimate receiver, yields information about the carrier state.

To proceed first with a review of key distillation, let m bits of raw data be received by the legitimate receiver in the four-state quantum-key-distribution protocol, and suppose n bits of sifted data remain following removal of $(m-n)$ inconclusive bits, and suppose there are e_T bits of

a)Electronic mail: hbrandt@arl.army.mil

erroneous data, leaving $(n-e_T)$ bits of corrected data. Corrected data includes data remaining after discarding inconclusive results and also erroneous data as determined by block checksums and bisective search. Privacy amplification is the procedure for obtaining a more secure, but shorter, key. This is achieved by removing from the $(n-e_T)$ bits of corrected data a number s of bits (the privacy amplification compression level) that is the sum of the possible contributions to information leakage. There then remain $(n-e_T-s)$ bits, and this is the size of the final key. The privacy amplification compression level s is given by[10,11]

$$s=t(n,e_T)+q+\nu+g, \tag{1}$$

where q is the estimated information leakage during error correction, ν is the estimated leakage from any multi-photon bits, g is an extra safety margin, and $t(n,e_T)$ is the defense function. The defense function, in general, depends on the size n of the sifted data, and on the number e_T of errors, and is chosen appropriately by the legitimate users, in order to effectively defend against an eavesdropping attack. The defense function $t(n,e_T)$ is the estimated upper bound on possible information leakage through eavesdropping on the quantum channel. Quantitatively it is determined by the maximum total Renyi information gain I_T^R by the eavesdropping probe. (It is proved in Ref. 5 that the optimum individual attack maximizes both the Renyi and Shannon information gain by the eavesdropping probe.) The maximum Renyi information gain by the eavesdropper is based on minimizing the overlap of the measured probe states correlated with the disturbed signal states of the legitimate receiver, conditional on fixed induced error rate. The compression level s must be chosen so that the probability is small that $I_T^R>t(n,e_T)$. An attack is successful if it introduces e_T errors on the n bits of sifted data, and yields a Renyi information $I_T^R>t(n,e_T)$ on the $(n-e_T)$ bits of corrected data. The probability of a successful attack must be negligible. In the presence of noise and channel losses, it is not sufficient, for the security of a quantum key distribution system, to detect eavesdropping. It must be insured that the shared data is sufficiently secure.

It is well to recall the privacy amplification theorem.[4] First, however, recall the definition of the Renyi information $I^R(l)$ on an l bit string X having probability distribution $P_X(X)$, namely,

$$I^R(l)=l+\log_2\langle P_X(X)\rangle=l+\log_2\sum_X P_X^2(X), \tag{2}$$

where the bracket denotes the expectation value. [$P_X^2(X)$ is often referred to as the collision probability.] The privacy amplification theorem states that if the eavesdropper's Renyi information gain $I^R(l)$ on an l bit data string is less than some quantity r, namely,

$$I^R(l)\leqslant r, \tag{3}$$

then the eavesdropper's Shannon information $I^H(l-s)$ on the reduced $(l-s)$ bit string, averaged over the choice of privacy amplification hash function, is bounded above, namely,

$$\langle I^H(l-s)\rangle\leqslant\frac{1}{\ln 2}2^{r-s}, \tag{4}$$

where here the brackets denote the average. By choosing the compression level s sufficiently large, the exponent on the right-hand side of Eq. (4) becomes sufficiently negative that the average Shannon information can be made arbitrarily small. Thus, given an upper bound on the eavesdropper's Renyi information gain, the corrected data can be subjected to the reduction procedure of privacy amplification to yield an even shorter string on which the eavesdropper's Shannon information is arbitrarily low. The secrecy of the final key is recovered (but reduced in size) if an upper bound can be determined on the maximum Renyi information gain by the eavesdropper on corrected data.

The average secrecy capacity C_s' of a quantum cryptosystem is the number of secret bits produced per bit from the transmitter, and is given by

$$C_s' = \operatorname*{Lim}_{m\to\infty}\left\langle \frac{n-e_T-s}{m}\right\rangle. \tag{5}$$

Here the limit of a very long transmission is understood in which m, the number of bits of raw data, is very large.

II. CALCULATING SECRECY CAPACITY

The numerator of Eq. (5), $(n-e_T-s)$, is the size of the final key, where n is the number of bits of sifted data with the inconclusive bits removed, e_T is the number of bits of erroneous discarded data due to error correction, and s is the privacy amplification compression level. The average secrecy capacity, Eq. (5), converges in distribution to[10]

$$C_s' = \left\langle \frac{n}{m}\right\rangle\left(1-\left\langle \frac{e_T}{n}\right\rangle - \frac{t_F}{n}\bigg|_{e_T/n=\langle e_T/n\rangle} - \operatorname*{Lim}_{m\to\infty}\left\langle \frac{q}{n}\right\rangle\right). \tag{6}$$

The factor $\langle n/m\rangle$ in Eq. (6) is the conclusive rate. Since the inconclusive rate $R_?$ is $\frac{1}{2}$ for the BB84 protocol,[5,10,11] and remains unchanged in the presence of the individual attack, the conclusive rate must also be $\frac{1}{2}$, namely,

$$\left\langle \frac{n}{m}\right\rangle = (1-R_?) = \left(1-\frac{1}{2}\right) = \frac{1}{2}. \tag{7}$$

Also in Eq. (6), $\langle e_T/n\rangle$ is the average intrinsic error rate, and $\langle q/n\rangle$ is the average information leakage during error correction. Since the present work focuses on the information leakage through eavesdropping [represented by the third term in Eq. (6)], possible additional terms, $(-\langle \nu/n\rangle)$ and $(-\langle g/n\rangle)$, are dropped in Eq. (6). [See Eq. (1)]. In the third term of Eq. (6), $(t_F/n)\,|_{e_T/n=\langle e_T/n\rangle}$ is the average defense frontier t_F evaluated at the average intrinsic error rate. In the individual attack, each signal is attacked individually and in the same way, and it is assumed that the signal states, errors, and measurement outcomes of the probe and the legitimate receiver are all independently and identically distributed.[10] Multiple eavesdropping strategies are considered with different induced error rates, but the attack is restricted to the set of strategies yielding the greatest attainable expected Renyi information gain for a given expected error rate. The defense frontier t_F is, for all possible eavesdropping strategies, the upper bound on the information leakage through eavesdropping, based on an optimal eavesdropper in the limit of a long transmission. The defense frontier t_F is chosen to minimize the chance of any successful eavesdropping strategy, and, for the individual attack, it is given by[10]

$$t_F(n,e_T) = \max_{e\leqslant e_T}\left\{ n\left(1-\frac{e}{n}\right) I^R_{\rm opt}\left(\frac{e}{n}+\xi\right) + \xi\left[n^2\left(1-\frac{e}{n}\right)\right]^{1/2}\right\}, \tag{8}$$

where $I^R_{\rm opt}(E)$ is the maximum Renyi information gain on corrected data by the eavesdropping probe, and conditional on fixed error rate $E=(e/n)$; and ξ is defined by

$$\xi = \frac{1}{(2n)^{1/2}}\,{\rm erf}^{-1}(1-p), \tag{9}$$

where ${\rm erf}^{-1}$ denotes the inverse standard error function. The standard error function ${\rm erf}(z)$ is defined by

$$\mathrm{erf}(z)=\frac{2}{\sqrt{\pi}}\int_0^z e^{-y^2}dy. \tag{10}$$

Also in Eq. (9), p is the probability for successful eavesdropping $[I_R^T>t(n,e_T)]$ on $(n-e_T)$ bits of corrected data and producing e_T errors; and p can be made arbitrarily small. The defense frontier, Eq. (8), was determined by Slutsky, Rao, Sun, Tancevski, and Fainman[10] by clever use of the central limit theorem of probability theory, and is constructed to minimize the chance of successful eavesdropping. Using Eqs. (6)–(8), the asymptotic secrecy capacity, in the limit of long transmission with $m\to\infty$, $n\to\infty$, and $\xi\to 0$, and for $q=0$, becomes[10]

$$C_s'|_{q=0,n\to\infty,\xi\to 0}=\tfrac{1}{2}(1-E-\max_{E'\leqslant E}(1-E')I_{\mathrm{opt}}^R(E')), \tag{11}$$

where E is the error rate, and $(\max_{x'\leqslant x}f(x'))$ denotes the maximum value of a function $f(x')$ for $x'\leqslant x$. Also in Eq. (11), $I_{\mathrm{opt}}^R(E')$ is the maximum Renyi information gain on corrected data by the eavesdropping probe, conditional on fixed error rate E'. The asymptotic secrecy capacity, Eq. (11), is based on the definition of average secrecy capacity, Eq. (5), as given in the literature,[10] however it is important to emphasize that the condition of maximum Renyi information gain by the eavesdropper may be overly conservative. (See Sec. VI of Ref. 4.)

For the four-state protocol, the maximum Renyi information gain I_{opt}^R on corrected data by the probe, conditional on fixed error rate E, for the individual attack is given by[5–9]

$$I_{\mathrm{opt}}^R=\log_2(2-Q^2). \tag{12}$$

Here Q is the minimum overlap of the probe states correlated with the signal states, and, for an arbitrary angle between the signal bases, it is given by[9]

$$Q=\begin{cases}\dfrac{1+(1-2\csc^2 2\alpha)E}{1-E}, & \alpha\leqslant\pi/8,\\[2ex] \dfrac{1+(1-2\sec^2 2\alpha)E}{1-E}, & \alpha\geqslant\pi/8,\end{cases} \tag{13}$$

with

$$\alpha=\frac{1}{2}\left(\frac{\pi}{2}-\hat{\theta}\right), \tag{14}$$

where $\hat{\theta}$ is the angle between the nonorthogonal linear polarization states of the signal. The optimization given by Eqs. (12)–(14) is over the set of probe parameters which define the general eavesdropping probe used in the individual attack.[5–9,12] For $\alpha=\pi/8$, corresponding to the standard BB84 protocol with $\hat{\theta}=\pi/4$, Eqs. (12) and (13) agree with Ref. 5. Substituting Eqs. (12) and (13) in Eq. (11), one obtains for the asymptotic secrecy capacity:

$$C_s'|_{q=0,n\to\infty,\xi\to 0}=\begin{cases}\dfrac{1}{2}\left(1-E-\max\limits_{E'\leqslant E}(1-E')\log_2\left[2-\left(\dfrac{1+(1-2\csc^2 2\alpha)E'}{1-E'}\right)^2\right]\right), & \alpha\leqslant\dfrac{\pi}{8}\\[2ex] \dfrac{1}{2}\left(1-E-\max\limits_{E'\leqslant E}(1-E')\log_2\left[2-\left(\dfrac{1+(1-2\sec^2 2\alpha)E'}{1-E'}\right)^2\right]\right), & \alpha\geqslant\dfrac{\pi}{8}.\end{cases} \tag{15}$$

For $\alpha=\pi/8$, Eq. (15) also agrees with Ref. 10. It is evident from Eqs. (12)–(15) that as a function of α, for fixed error rate, the overlap of correlated probe states is greatest, the Renyi information gain by the probe is least, and the secrecy capacity is greatest for $\alpha=\pi/8$, which corresponds to the standard BB84 protocol[1] with $\hat{\theta}=\pi/4$.

III. SUMMARY

Following a review of the process of key distillation from the quantum transmission in quantum key distribution, the asymptotic secrecy capacity, Eq. (15), of the four-state protocol has been calculated for the case of an individual attack in which the eavesdropping probe is entangled with the signal states, and states of the probe become correlated with the states measured by the legitimate receiver. The calculation generalizes earlier work to include an arbitrary angle between the signal bases.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 43, NUMBER 9 SEPTEMBER 2002

Hiding messages in quantum data

Julio Gea-Banacloche[a)]
Department of Physics, University of Arkansas, Fayetteville, Arkansas 72701

(Received 15 January 2002; accepted for publication 16 May 2002)

A method is proposed to hide messages in arbitrary quantum data files. The messages may act as ''watermarks,'' to secure the authenticity and/or integrity of the data. With the help of classical secret keys, they can be made unreadable by other parties and to reveal whether thay have been tampered with. The basic idea is to encode the data using a quantum error-correcting code and hide the message as (correctible) errors, deliberately inserted, which can be read out from the error syndrome. Also discussed briefly is a ''reverse encoding,'' which would involve putting the actual data in the error syndrome, and letting the encoded qubit itself carry the message. © *2002 American Institute of Physics.*

I. INTRODUCTION

Steganography is a branch of cryptography concerned with embedding ''invisible'' messages in data files. The message, which is revealed by some appropriate decoding operation, may contain information regarding the owner of the file or its date of creation, for instance. Such techniques have become of particular interest in recent years because of the proliferation of means available to copy, legally or illegally, all sorts of data, such as images, audio, or video files.[1]

Although quantum information processing is still, in practice, a long way from the day where sizable files of ''quantum data'' will be moved from one location to another, it may already be of interest to begin to explore the possibilities inherent in a quantum sort of steganography, and the ways in which this would differ from its classical counterpart. This article is intended to serve as a (small) first step in this direction.

It should be clear from the outset, of course, that copyright protection in its most literal sense could never be an issue for quantum information, since, by the celebrated no-cloning theorem, it is inherently impossible to copy. Nonetheless, there are other useful purposes that could be served by a hidden message embedded in a quantum data file. It could function as a ''watermark,'' for instance, allowing one to identify the file's owner or creator, either as protection against theft or reassurance to the party receiving the data that they come, in fact, from the right source. Also, as will be shown below, the watermark could be embedded in such a way as to provide the receiving party with information that the file has been corrupted, either by errors upon transmission or by tampering by a third party. Another potential use might be in a distributed quantum computing environment, where packets of information are processed at some location and then sent to other processors: a message could be embedded in the data to tell the receiving processor what it is supposed to do with it. Again, corruption of the data could be detected at the receiving end by these means.

A large component of all of the above is, clearly, the question of data authentication, in the broadest sense of making sure both that the data have come from the right source and that they have not been tampered with or otherwise corrupted. A number of ideas have recently been put forth regarding this general issue. Buhrman *et al.*[2] have studied ways to associate a quantum fingerprint with a classical data string; a variation on this idea, due to Gottesman and Chuang,[3] would allow one to attach a quantum signature to a classical message, which would serve to

[a)]Electronic mail: jgeabana@uark.edu

certify its authenticity. The general question of authenticating a single classical bit using a single qubit has been studied by Curty and Santos.[4] Moving on to the problem of authenticating *quantum* data, Curty *et al.*[5] have shown that it is impossible to authenticate a qubit with a one-bit (or one-qubit) key (in all authentication schemes, the sender and receiver must share a key in advance, in order to read out the authentication information). Nonetheless, if longer keys are allowed, schemes to authenticate arbitrary quantum data exist; for instance, in Ref. 6, Leung has proposed a scheme to authenticate n qubits given an authenticated two-way classical channel, $2r$ bits of classical key, and an extra $2r$ qubits of quantum communication. In this scheme, forging succeeds with probability no better than 2^{-r} and the fidelity of an accepted message with respect to the original is of the order of $1-O(2^{-r})$. Finally, Barnum *et al.*[7] have also recently reported on a powerful general method of quantum data authentication, whose details should soon be made widely available.

In Leung's scheme, the $2r$ extra qubits are simply appended to the message, as a sort of authentication tag. The tag is uniquely related to the message, so that a would-be forger cannot simply remove it and attach it to a false message to make it pass for an authentic one. Nonetheless, the tag could still be simply removed, leaving the adversary in possession of the data, with no indication as to its provenance. In this respect this scheme differs from a classical steganography situation, where (part of) the idea is that the identification tag could not be deleted without damaging the data.

In what follows I wish to present a simple authentication scheme which accomplishes this last purpose, and has other potential advantages (such as the fact that it is based on a conventional quantum error correction code, and so, under some circumstances, it may function as such, thus helping to protect the integrity of the data). Perhaps it should be acknowledged from the outset that, even though the starting point draws some inspiration from classical steganography, the final result may not look much like it. The main guiding principle has been to arrange for the data and the message (or ''tag'') to be inextricably linked, in such a way that somebody who does not have the key could not alter the one without altering the other.

The approach is heuristic throughout; no attempt has been made to provide formal proofs of security or optimize the resources needed. Nonetheless, it is interesting that this simple-minded approach leads in a natural way to a construction which ends up having some similarities to the much more formal approach of Ref. 7. Hence, it is hoped that the present work may provide some insight into some of the issues involved in quantum data authentication.

II. EMBEDDING A MESSAGE IN A QUANTUM DATA FILE ENCODED WITH AN ERROR-CORRECTING CODE

A. Basic concept

One conventional approach in clasical steganography is to write the hidden message in the data file by replacing some of the original data's bits, according to a certain pattern or key. Such an approach, however, could not work, in general, with quantum data, which are often in coherent superpositions for which the actual state of an individual qubit may simply not be defined, due to entanglement with other qubits. Arbitrarily setting the state of a random qubit to a specific value would not only destroy that qubit's entanglement, it would also collapse the state of any other qubits entangled with it.

This means that one needs to add qubits to the original file, perhaps interspersing them among the original data qubits, and write the message in them. Then one may observe that a systematic method to add qubits to a quantum data file, in such a way that one could, at the same time, introduce ''errors'' in it harmlessly, is provided by QECCs.[8] Hence the simplest approach to ''quantum steganography'' might be as follows: encode the original data file using a suitable QECC; hide the message as ''errors'' in the encoded qubits; and read it out in the *error syndrome*.

As an example of this approach, consider the following simple three-qubit code, which protects one logical qubit against a single bit flip error (of any of the three physical qubits):

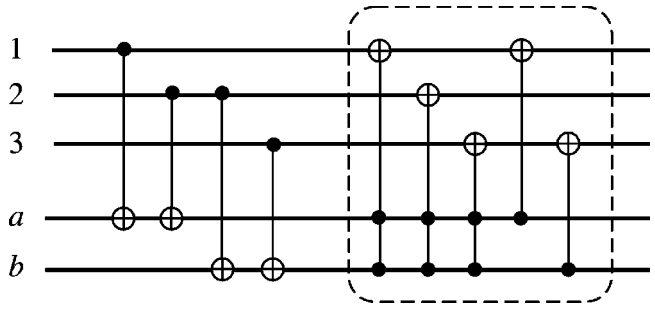

FIG. 1. A circuit to read out the error syndrome for the 3-qubit repetition code. The dashed box shows how the error can be corrected without actually having to measure the state of the ancilla qubits.

$$|0_L\rangle = |000\rangle,$$
$$|1_L\rangle = |111\rangle. \tag{1}$$

The state $|\psi\rangle$ of any of the original data qubits could be encoded as $|\psi\rangle = \alpha|0_L\rangle + \beta|1_L\rangle$. Then, for each such logical qubit, a message of up to four classical bits could be encoded "in parallel," so to speak, on the same three physical qubits, by acting on $|\psi\rangle$ with either the identity or one of the three Pauli operators σ_{ix} (with $i=1, 2, 3$). This message could be read off, for instance, by the error-diagnosing circuit shown on the left half of Fig. 1, which employs two ancillary qubits, a and b. If the state of these ancillary qubits is read out after the four CNOT operations have been carried out, it is easily checked that each of the four possible operations on $|\psi\rangle$ maps to a different joint state of a and b, as follows:

$$1 \rightarrow |00\rangle_{ab},$$
$$\sigma_{1x} \rightarrow |10\rangle_{ab},$$
$$\sigma_{2x} \rightarrow |11\rangle_{ab},$$
$$\sigma_{3x} \rightarrow |01\rangle_{ab}. \tag{2}$$

Thus, all four possible bit values of the two-bit classical mesage can be read and identified, without actually changing the logical qubit's state in any way.

Of course, one problem that arises immediately is that an adversary who knew that the underlying code is the three-qubit, repetition code (1), and wanted to erase the message, could easily do so simply by applying error correction to the encoded qubit! There is, however, a simple way to prevent this from happening, namely, to change the code randomly, from one logical qubit to the next, according to a secret key (shared by the sender and the receiver). For practical purposes, it would be sufficient, for example, to stay with a three-qubit code but encode the message alternatively in bit-flip errors and phase errors. Protection against phase errors is provided by a code like

$$|\overline{0}_L\rangle = H^{\otimes 3}|0_L\rangle = \frac{1}{2^{3/2}}(|0\rangle+|1\rangle)(|0\rangle+|1\rangle)(|0\rangle+|1\rangle),$$
$$|\overline{1}_L\rangle = H^{\otimes 3}|1_L\rangle = \frac{1}{2^{3/2}}(|0\rangle-|1\rangle)(|0\rangle-|1\rangle)(|0\rangle-|1\rangle). \tag{3}$$

(Here, H denotes a Hadamard transform.) Now, a "0" in the classical key could mean that the original qubit is to be encoded as $|\psi\rangle = \alpha|0_L\rangle + \beta|1_L\rangle$, with $|0_L\rangle$ and $|1_L\rangle$ given by (1), and the

message hidden in the error syndrome as any of the four operators identity+one of the σ_{ix}; whereas a "1" in the classical key would mean that the encoding for the original qubit uses the basis $|\overline{0_L}\rangle$ and $|\overline{1_L}\rangle$ given by (3) above, and the error syndrome is encoded using the σ_{iz} operators.

If the eavesdropper does not realize that the message is now encoded as a phase error, he not only cannot read it, but, moreover, he also cannot erase it properly. Suppose that bit-flip error correction is applied to a qubit $\alpha|\overline{0_L}\rangle+\beta|\overline{1_L}\rangle$ originally encoded in the basis (3). The result will be a superposition of the basis states (1); specifically, $\frac{1}{4}$ of the time it will be $\alpha|0_L\rangle+\beta|1_L\rangle$, and $\frac{3}{4}$ of the time it will be $\alpha|1_L\rangle+\beta|0_L\rangle$.[9] Thus, attempts to erase (or, in general, alter) the message result in changes to the data. Needless to say, the message (in the $|\overline{0_L}\rangle,|\overline{1_L}\rangle$ basis) also is changed as a result of this intervention, so if the file is eventually inspected by somebody who knows both the key and the message, he should be able to tell that it has been tampered with.

It is interesting to note that for such a user, who knows both the key and the message, the "errors" deliberately introduced in the encoded qubits do not affect the ability of the code to function as a QECC and protect the data against accidental (additional) errors of the type naturally corrected by the code [e.g., bit errors for the code (1), phase flips for the code (3)]. This can be formally seen as follows: suppose the original (encoded) state is $|\psi\rangle$, and we put an error $\sigma_{i\alpha}$ on it (where i is the qubit index and $\alpha=x,y$ or z). Then suppose another (unknown) error $\sigma_{j\beta}$ occurs; the resulting state is therefore $\sigma_{j\beta}\sigma_{i\alpha}|\psi\rangle$. Then, in order to diagnose properly the error $\sigma_{j\beta}$, all we need to do is apply $\sigma_{i\alpha}$ again to the state, followed by ordinary error correction, since $\sigma_{i\alpha}\sigma_{j\beta}\sigma_{i\alpha}|\psi\rangle=\pm\sigma_{j\beta}|\psi\rangle$. The minus sign only occurs if $i=j$, $\alpha\neq\beta$, and, as an overall sign, it is irrelevant. Therefore, any error that the code could initially diagnose can still be diagnosed correctly. This property alone may make this scheme attractive: if the data are going to be encoded for protection against errors anyway, one might as well take advantage of this to hide a signature in the error syndrome, essentially at no extra cost.

If larger codes are used (to correct for more errors), one can still use essentially the same strategy to protect the message, namely, encode the logical qubits in either the original $|0_L\rangle,|1_L\rangle$, or the conjugate, $|\overline{0_L}\rangle,|\overline{1_L}\rangle$, basis (connected by a Hadamard transform) according to the value of a secret key. Atempts to do error correction on the encoded qubit by somebody who does not know the key will result in the state being projected onto the wrong basis half of the time.

From an authentication perspective, however, one may have to wonder about the reverse possibility: could somebody who does not know the key change the data without changing the message? It turns out that this is, indeed, possible if the message is classical, as will be shown in the next subsection.

B. Inserting a quantum message

Consider again the example (1), as illustrated in Fig. 1. Since the encoding and decoding are linear operations, a coherent superposition of errors acting on the encoded data qubit $|\psi\rangle$ will, in fact, yield a coherent superposition of the ancilla qubits; so the "message" does not have to be classical information, it could be quantum information as well. In other words, the operation

$$(\gamma+\delta\sigma_{1x}+\eta\sigma_{2x}+\epsilon\sigma_{3x})(\alpha|0_L\rangle+\beta|1_L\rangle) \tag{4}$$

actually encodes three qubits worth of information in three physical qubits. The one-qubit state $\alpha|0\rangle+\beta|1\rangle$ is in the "data" that one recovers after error correction, whereas the two-qubit state

$$\gamma|00\rangle+\delta|10\rangle+\eta|11\rangle+\epsilon|01\rangle \tag{5}$$

is the state of the ancilla qubits when the error syndrome is extracted as in Fig. 1. Note that the ancilla qubits will only be in a coherent superposition after error correction has been applied to qubits 1, 2, and 3 (otherwise they are still entangled with them), and only if this is done coherently, i.e., without measurements; this can always be achieved, as indicated, e.g., by the circuit in the

dashed box in Fig. 1. Incidentally, since CNOT gates are their own inverses, the dashed box in Fig. 1 also shows how the encoding (4) could be applied to the qubits 1, 2, 3, if one starts with the qubits a and b in the state (5).

Now consider the possibility mentioned at the end of the previous subsection, that an adversary might attempt to change the data while leaving the message intact. For instance, suppose that he attempts to flip an encoded qubit, by applying the operator $\sigma_{1x}\sigma_{2x}\sigma_{3x}$ to it. If the qubit is encoded in the basis (1), as in Eq. (4), this will indeed change it to $\alpha|1_L\rangle+\beta|0_L\rangle$, while leaving the error syndrome intact, since all the σ_{ix} commute with each other. On the other hand, if the qubit is initially encoded in the conjugate basis $|\overline{0_L}\rangle,|\overline{1_L}\rangle$ as $|\psi\rangle=(\gamma+\delta\sigma_{1z}+\eta\sigma_{2z}+\epsilon\sigma_{3z})\times(\alpha|\overline{0_L}\rangle+\beta|\overline{1_L}\rangle)$, one finds

$$\sigma_{1x}\sigma_{2x}\sigma_{3x}|\psi\rangle=(\gamma-\delta\sigma_{1z}-\eta\sigma_{2z}-\epsilon\sigma_{3z})(\alpha|\overline{0_L}\rangle-\beta|\overline{1_L}\rangle). \tag{6}$$

So, in this basis, the data qubit is also changed (it acquires a ''phase flip''), but now also the syndrome is changed, provided γ and at least one of δ, γ or ϵ are nonzero. That is, in order to provide protection against this type of attack, the ''message'' encoded in the error syndrome must be a quantum superposition state: it must be quantum, not classical, information.

C. Reversing the "data" and "message" roles

The construction in the previous subsection suggests the possibility of reversing the roles of ''data'' and ''message:'' with the scheme in Fig. 1, one could encode two qubits' worth of actual quantum data in the ''error syndrome,'' and a one-bit (or one-qubit) message in the ''logical qubit'' part of Eq. (4) (that is, the part involving α and β). What one gains with this scheme is efficiency, in the sense of a greater data-to-message information ratio. This can be made even greater by going to larger codes: for instance, any $[n,1]$ stabilizer code (encoding 1 logical qubit into n physical qubits) has $n-1$ generators, and measuring them determines the error syndrome; so the error syndrome can be extracted in $n-1$ qubits. With this ''reverse encoding'' approach, therefore, one could ''pack'' $n-1$ qubits worth of data in the error syndrome of every encoded logical qubit, and one qubit worth of ''message'' in the actual logical qubit.

As before, security would be provided by a secret key specifying on what basis each block is to be encoded. Since each block carries only one qubit of message, the key only has to be as long as the message itself; the ratio of length of key to length of data file (in bits, or qubits) is $1/(n-1)$, which could be made very small by using sufficiently large codes. If the total number of packages sent is t, the total number of possible different keys is 2^t, which suggests that the probability of successful tampering with or reading of the message is of the order of $1/2^t$. Clearly, though, this suggestion does not amount to a formal proof of security, and the scheme is only mentioned to give an indication of possibilities—in particular, for greater efficiency—beyond the ''straightforward'' scheme of the previous two subsections.

III. DISCUSSION AND CONCLUSIONS

The ideas proposed here provide some potentially useful ways to hide messages in quantum data for a variety of applications. In all cases, the data and the message are combined so that any change in one is likely to result in a change in the other. The method of Sec. II A is most useful when one is already considering using a QECC to protect the data against accidental errors, and the message to be sent (a sort of ''watermark'') is previously known to all the authorized parties; then the message can ''ride along'' in the error syndrome without compromising the efficacy of the code to correct errors. Note that, for data authentication purposes, the ''watermark'' should be quantum data, in order to provide protection against certain types of attacks.

As emphasized in the Introduction, the presentation here has been heuristic; I have not attempted to study the security features of the proposed schemes, for any specific application, in detail, nor to improve their efficiency beyond the suggestion, in Sec. II C, that smaller ratios of key to data file length might be possible. Nonetheless, as also mentioned in the Introduction, it is

interesting that the result exhibits a number of similarities to the more formal methodology for data authentication studied by Barnum *et al.*;[7] in particular, the use of QECCs (which under some circumstances could be used to provide additional protection for the data, as also remarked in Ref. 7) and the idea of hiding some secret ''key'' information in the error syndrome. It appears as if a careful study of the similarities and differences between the two schemes could be an enlightening and worthwhile task, but at present this must remain beyond the scope of the present manuscript.

In closing, to return, for a moment, to what constituted the original motivation for the present work namely, the idea of exploring the feasiblity of a sort of ''quantum steganography,'' these results do indicate how it may be possible, in principle, to combine a given set of quantum data and a quantum message in an inextricable way. It could be argued, however, that the final result does not look much like classical steganography, since we have ended up encrypting both the message and the data, whereas in classical steganography, instead, the ''data'' are, for the most part, openly visible (although subtly altered), and only the message is hidden. Yet, as I have mentioned above, it is not obvious to me how one could only ''slightly'' alter quantum information in order to accomplish this goal. In fact, it is one of the most interesting results proved in Ref. 7 that (unlike for classical data, where authentication and encryption are two different tasks) in order to authenticate quantum data one must, as it turns out, encrypt them ''almost perfectly.''

ACKNOWLEDGMENTS

I am grateful to Howard Barnum for very useful comments, and to the authors of Ref. 7 for sharing with me a preprint of their work. This research has been supported by the Army Research Office and the National Science Foundation.

(Received 20 November 2001; accepted for publication 16 May 2002)

We present an elementary proof of the *quantum de Finetti representation theorem*, a quantum analog of de Finetti's classical theorem on exchangeable probability assignments. This contrasts with the original proof of Hudson and Moody [Z. Wahrschein. verw. Geb. **33**, 343 (1976)], which relies on advanced mathematics and does not share the same potential for generalization. The classical de Finetti theorem provides an operational definition of the concept of an unknown probability in Bayesian probability theory, where probabilities are taken to be degrees of belief instead of objective states of nature. The quantum de Finetti theorem, in a closely analogous fashion, deals with exchangeable density-operator assignments and provides an operational definition of the concept of an ''unknown quantum state'' in quantum-state tomography. This result is especially important for information-based interpretations of quantum mechanics, where quantum states, like probabilities, are taken to be states of knowledge rather than states of nature. We further demonstrate that the theorem fails for real Hilbert spaces and discuss the significance of this point. © *2002 American Institute of Physics.*

I. INTRODUCTION

What is a quantum state? Since the earliest days of quantum theory, the predominant answer has been that the quantum state is a representation of the observer's knowledge of a system.[1] In and of itself, the quantum state has no objective reality.[2] The authors hold this information-based view quite firmly.[3,4] Despite its association with the founders of quantum theory, however, holding this view does not require a concomitant belief that there is nothing left to learn in quantum foundations. It is quite the opposite in fact: Only by pursuing a promising but incomplete program can one hope to learn something of lasting value. Challenges to the information-based view arise regularly, and dealing with these challenges builds an understanding and a problem-solving agility that reading and rereading the founders can never engender.[5] With each challenge successfully resolved, one walks away with a deeper sense of the physical content of quantum theory and a growing confidence for tackling questions of its interpretation and applicability. Questions as fundamental and distinct as ''Will a nonlinear extension of quantum mechanics be needed to quantize gravity?'' [6,7] and ''Which physical resources actually make quantum computation efficient?'' [8,9] start to feel tractable (and even connected) from this perspective.

In this article, we tackle an understanding-building exercise very much in the spirit of these

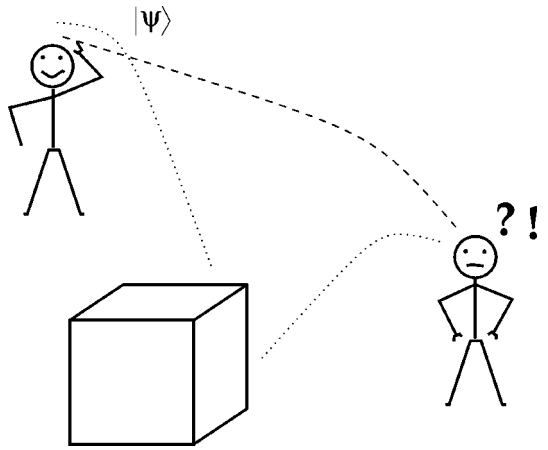

FIG. 1. What can the term ''unknown state'' mean if quantum states are taken exclusively to be states of knowledge rather than states of nature? When we say that a system has an unknown state, must we always imagine a further observer whose state of knowledge is symbolized by some $|\psi\rangle$, and it is the identity of the symbol that we are ignorant of?

remarks. It is motivated by an apparent conundrum arising from quantum information theory. The issue is that of the *unknown* quantum state.

There is hardly a paper in the field of quantum information that does not make use of the idea of an ''unknown quantum state.'' Unknown quantum states are teleported,[10,11] protected with quantum error correcting codes,[12,13] and used to check for quantum eavesdropping.[14,15] The list of uses, already long, grows longer each day. Yet what can the term ''unknown quantum state'' mean? In an information-based interpretation of quantum mechanics, the term is an oxymoron: If quantum states, by their very definition, are states of knowledge and not states of nature,[16] then the state is *known* by someone—at the very least, by the describer himself.

This message is the main point of our article. Faced with a procedure that uses the idea of an unknown quantum state in its description, a consistent information-based interpretation of quantum mechanics offers only two alternatives (see also Fig. 1):

(i) The owner of the unknown state—a further decision-making agent or observer—must be explicitly identified. In this case, the unknown state is merely a stand-in for the unknown *state of knowledge* of an essential player who went unrecognized in the original formulation.

(ii) If there is clearly no further decision-making agent or observer on the scene, then a way must be found to reexpress the procedure with the term ''unknown state'' banished from the formulation. In this case, the end-product of the effort is a single quantum state used for describing the entire procedure—namely, the state that captures the describer's state of knowledge.

Of course, those inclined to an objectivist interpretation of quantum mechanics[17]—that is, an interpretation where quantum states are more like states of nature than states of knowledge—might be tempted to believe that the scarcity of existing analyses of this kind is a hint that quantum states do indeed have some sort of objective status. Why would such currency be made of the unknown-state concept were it not absolutely necessary? As a rejoinder, we advise caution to the objectivist: Tempting though it is to grant objective status to all the mathematical objects in a physical theory, there is much to be gained by a careful delineation of the subjective and objective parts. A case in point is provided by E. T. Jaynes'[18–20] insistence that entropy is a subjective quantity, a measure of ignorance about a physical system. One of the many fruits of this point of view can be found in the definitive solution[21] to the long-standing Maxwell demon problem,[22] where it was realized that the information collected by a demon and used by it to extract work from heat has a thermodynamic cost at least as large as the work extracted.[23]

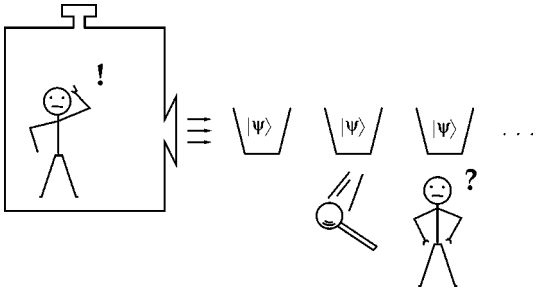

FIG. 2. To make sense of quantum tomography, must we go to the extreme of imagining a ''man in the box'' who has a better description of the systems than we do? How contrived our usage would be if that were so!

The example analyzed in detail in this article provides another case. Along the way, it brings to light a new and distinct point about why quantum mechanics makes use of complex Hilbert spaces rather than real or quaternionic ones.[24–27] Furthermore, the method we use to prove our main theorem employs a novel measurement technique that might be of use in the laboratory.

We analyze in depth a particular use of unknown states, which comes from the measurement technique known as *quantum-state tomography*.[28–30] The usual description of tomography is this. A device of some sort, say a nonlinear optical medium driven by a laser, repeatedly prepares many instances of a quantum system, say many temporally distinct modes of the electromagnetic field, in a fixed quantum state ρ, pure or mixed. An experimentalist who wishes to characterize the operation of the device or to calibrate it for future use might be able to perform measurements on the systems it prepares even if he cannot get at the device itself. This can be useful if the experimenter has some prior knowledge of the device's operation that can be translated into a probability distribution over states. Then learning about the state will also be learning about the device. Most importantly, though, this description of tomography assumes that the precise state ρ is unknown. The goal of the experimenter is to perform enough measurements, and enough kinds of measurements (on a large enough sample), to estimate the identity of ρ.

This is clearly an example where there is no further player on whom to pin the unknown state as a state of knowledge. Any attempt to find a player for the pin is entirely artificial: Where would the player be placed? On the inside of the device the tomographer is trying to characterize?[31] The only available course for an information-based interpretation of quantum-state tomography is the second strategy listed above—to banish completely the idea of the unknown state from the formulation of tomography (see Fig. 2).

To do this, we take a cue from the field of Bayesian probability theory,[32–34] prompted by the realization that Bayesian probability is to probability theory in general what an information-based interpretation is to quantum mechanics.[3,35] In Bayesian theory, probabilities are not objective states of nature, but rather are taken explicitly to be measures of credible belief, reflecting one's state of knowledge. The overarching Bayesian theme is to identify the conditions under which a set of decision-making agents can come to a common belief or probability assignment for a random variable even though their initial beliefs differ.[34] Following that theme is the key to understanding tomography from the informational point of view.

The offending classical concept is an ''unknown probability,'' an oxymoron for the same reason as an unknown quantum state. The procedure analogous to quantum-state tomography is the estimation of an unknown probability from the results of repeated trials on ''identically prepared systems,'' all of which are said to be described by the same, but unknown probability. The way to eliminate unknown probabilities from the discussion, introduced by Bruno de Finetti in the early 1930s,[36,37] is to focus on the equivalence of repeated trials, which means that the systems are indistinguishable as far as probabilistic predictions are concerned and thus that a probability assignment for multiple trials should be symmetric under permutation of the systems. With his *classical representation theorem*, de Finetti[36] showed that a multi-trial probability assignment that is permutation-symmetric for an arbitrarily large number of trials—de Finetti called such multi-

trial probabilities *exchangeable*—is equivalent to a probability for the ''unknown probabilities.'' Thus the unsatisfactory concept of an unknown probability vanishes from the description in favor of the fundamental idea of assigning an exchangeable probability distribution to multiple trials.

This cue in hand, it is easy to see how to reword the description of quantum-state tomography to meet our goals. What is relevant is simply a judgment on the part of the experimenter—notice the essential subjective character of this ''judgment''—that there is no distinction between the systems the device is preparing. In operational terms, this is the judgment that *all the systems are and will be the same as far as observational predictions are concerned*. At first glance this statement might seem to be contentless, but the important point is this: To make this statement, one need never use the notion of an unknown state—a completely operational description is good enough. Putting it into technical terms, the statement is that if the experimenter judges a collection of N of the device's outputs to have an overall quantum state $\rho^{(N)}$, he will also judge any permutation of those outputs to have the same quantum state $\rho^{(N)}$. Moreover, he will do this no matter how large the number N is. This, complemented only by the consistency condition that for any N the state $\rho^{(N)}$ be derivable from $\rho^{(N+1)}$, makes for the complete story.

The words ''quantum state'' appear in this formulation, just as in the original formulation of tomography, but there is no longer any mention of *unknown* quantum states. The state $\rho^{(N)}$ is known by the experimenter (if no one else), for it represents his state of knowledge. More importantly, the experimenter is in a position to make an unambiguous statement about the structure of the whole sequence of states $\rho^{(N)}$: Each of the states $\rho^{(N)}$ has a kind of permutation invariance over its factors. The content of the *quantum de Finetti representation theorem*[38,39]—a new proof of which is the main technical result of this article—is that a sequence of states $\rho^{(N)}$ can have these properties, which are said to make it an *exchangeable* sequence, if and only if each term in it can also be written in the form

$$\rho^{(N)}=\int P(\rho)\,\rho^{\otimes N}\,d\rho, \tag{1.1}$$

where

$$\rho^{\otimes N}=\underbrace{\rho\otimes\rho\otimes\cdots\otimes\rho}_{\substack{N\text{-fold tensor}\\ \text{product}}} \tag{1.2}$$

and $P(\rho)$ is a fixed probability distribution over the density operators.

The interpretive import of this theorem is paramount. It alone gives a mandate to the term unknown state in the usual description of tomography. It says that the experimenter can act *as if* his state of knowledge $\rho^{(N)}$ comes about because he knows there is a ''man in the box,'' hidden from view, repeatedly preparing the same state ρ. He does not know which such state, and the best he can say about the unknown state is captured in the probability distribution $P(\rho)$.

The quantum de Finetti theorem furthermore makes a connection to the overarching theme of Bayesianism stressed above. It guarantees for two independent observers—as long as they have a rather minimal agreement in their initial beliefs—that the outcomes of a sufficiently informative set of measurements will force a convergence in their state assignments for the remaining systems.[40] This ''minimal'' agreement is characterized by a judgment on the part of both parties that the sequence of systems is exchangeable, as described above, and a promise that the observers are not absolutely inflexible in their opinions. Quantitatively, the latter means that though $P(\rho)$ might be arbitrarily close to zero, it can never vanish.

This coming to agreement works because an exchangeable density operator sequence can be updated to reflect information gathered from measurements by a quantum version of Bayes's rule for updating probabilities. Specifically, if measurements on K systems yield results D_K, then the state of additional systems is constructed as in Eq. (1.1), but using an updated probability on density operators given by

$$P(\rho|D_K)=\frac{P(D_K|\rho)P(\rho)}{P(D_K)}. \tag{1.3}$$

Here $P(D_K|\rho)$ is the probability to obtain the measurement results D_K, given the state $\rho^{\otimes K}$ for the K measured systems, and

$$P(D_K)=\int P(D_K|\rho)\,P(\rho)\,d\rho \tag{1.4}$$

is the unconditional probability for the measurement results. Equation (1.3) is a kind of *quantum Bayes rule*.[40] For a sufficiently informative set of measurements, as K becomes large, the updated probability $P(\rho|D_K)$ becomes highly peaked on a particular state ρ_{D_K} dictated by the measurement results, regardless of the prior probability $P(\rho)$, as long as $P(\rho)$ is nonzero in a neighborhood of ρ_{D_K}. Suppose the two observers have different initial beliefs, encapsulated in different priors $P_i(\rho)$, $i=1,2$. The measurement results force them to a common state of knowledge in which any number N of additional systems are assigned the product state $\rho_{D_K}^{\otimes N}$, i.e.,

$$\int P_i(\rho|D_K)\rho^{\otimes N}\,d\rho\rightarrow\rho_{D_K}^{\otimes N}, \tag{1.5}$$

independent of i, for K sufficiently large.

This shifts the perspective on the purpose of quantum-state tomography: It is not about uncovering some ''unknown state of nature,'' but rather about the various observers' coming to agreement over future probabilistic predictions.[41] In this connection, it is interesting to note that the quantum de Finetti theorem and the conclusions just drawn from it work only within the framework of complex vector-space quantum mechanics. For quantum mechanics based on real and quaternionic Hilbert spaces,[24,25] the connection between exchangeable density operators and unknown quantum states does not hold.

The plan of the remainder of the article is as follows. In Sec. II we discuss the classical de Finetti representation theorem[36,42] in the context of Bayesian probability theory. It was our familiarity with the classical theorem[43,44] that motivated our reconsideration of quantum-state tomography. In Sec. III we introduce the information-based formulation of tomography in terms of exchangeable multi-system density operators, accompanied by a critical discussion of the objectivist formulation of tomography, and we state the quantum de Finetti representation theorem. Section IV presents an elementary proof of the quantum de Finetti theorem. There, also, we introduce a novel measurement technique for tomography based upon generalized quantum measurements. Finally, in Sec. V we return to the issue of number fields in quantum mechanics and mention possible extensions of the main theorem.

II. THE CLASSICAL DE FINETTI THEOREM

As a preliminary to the quantum problem, we turn our attention to classical probability theory. In doing so we follow a maxim of the late E. T. Jaynes:[45]

> We think it unlikely that the role of probability in quantum theory will be understood until it is generally understood in classical theory ... . Indeed, our [seventy-five-year-old] bemusement over the notion of state reduction in [quantum theory] need not surprise us when we note that today, in all applications of probability theory, basically the same controversy rages over whether our probabilities represent real situations, or only incomplete human knowledge.

As Jaynes makes clear, the tension between the objectivist and informational points of view is not new with quantum mechanics. It arises already in classical probability theory in the form of the war between ''objective'' and ''subjective'' interpretations.[46] According to the subjective or Bayesian interpretation, probabilities are measures of credible belief, reflecting an agent's poten-

tial states of knowledge. On the other hand, the objective interpretations—in all their varied forms, from frequency interpretations to propensity interpretations—attempt to view probabilities as real states of affairs or "states of nature." Following our discussion in Sec. I, it will come as no surprise to the reader that the authors wholeheartedly adopt the Bayesian approach. For us, the ultimate reason is simply our own experience with this question, part of which is an appreciation that objective interpretations inevitably run into insurmountable difficulties. We will not dwell upon these difficulties here; instead, the reader can find a sampling of criticisms in Refs. 20, 32–34, and 47.

We will note briefly, however, that the game of roulette provides an illuminating example. In the European version of the game, the possible outcomes are the numbers 0,1,...,36. For a player without any privileged information, all 37 outcomes have the same probability $p=\frac{1}{37}$. But suppose that shortly after the ball is launched by the croupier, another player obtains information about the ball's position and velocity relative to the wheel. Using the information obtained, this other player can make more accurate predictions than the first.[48] His probability is peaked around some group of numbers. The probabilities are thus different for two players with different states of knowledge.

Whose probability is the true probability? From the Bayesian viewpoint, this question is meaningless: There is no such thing as a true probability. All probability assignments are subjective assignments based specifically upon one's prior information.

For sufficiently precise data—including precise initial data on positions and velocities and probably also including other details such as surface properties of the wheel—Newtonian mechanics assures us that the outcome can be predicted with certainty. This is an important point: The determinism of classical physics provides a strong reason for adopting the subjectivist view of probabilities.[49] If the conditions of a trial are exactly specified, the outcomes are predictable with certainty, and all probabilities are 0 or 1. In a deterministic theory, all probabilities strictly greater than 0 and less than 1 arise as a consequence of incomplete information and depend upon their assigner's state of knowledge.

Of course, we should keep in mind that our ultimate goal is to consider the status of quantum states and, by way of them, quantum probabilities. One can ask, "Does this not change the flavor of these considerations?" Since quantum mechanics is avowedly *not* a theory of one's ignorance of a set of hidden variables,[50,51] how can the probabilities be subjective? In Sec. III we argue that despite the intrinsic indeterminism of quantum mechanics, the essence of the point above carries over to the quantum setting intact. Furthermore, there are specifically quantum-motivated arguments for a Bayesian interpretation of quantum probabilities.

For the present, though, let us consider in some detail the general problem of a repeated experiment—spinning a roulette wheel N times is an example. As discussed briefly in Sec. I, this allows us to make a conceptual connection to quantum-state tomography. Here the individual trials are described by discrete random variables $x_n \in \{1,2,\ldots,k\}$, $n=1,\ldots,N$; that is to say, there are N random variables, each of which can assume k discrete values. In an objectivist theory, such an experiment has a standard formulation in which the probability in the multi-trial hypothesis space is given by an independent, identically distributed (i.i.d.) distribution

$$p(x_1,x_2,\ldots,x_N)=p_{x_1}p_{x_2}\cdots p_{x_N}=p_1^{n_1}p_2^{n_2}\cdots p_k^{n_k}. \tag{2.1}$$

The number p_j $(j=1,\ldots,k)$ describes the objective, "true" probability that the result of a single experiment will be j $(j=1,\ldots,k)$. The variable n_j, on the other hand, is the number of times outcome j is listed in the outcome vector $(x_1,x_2,\ldots,x_N)$. This simple description—for the objectivist—only describes the situation from a kind of "God's eye" point of view. To the experimentalist, the "true" probabilities $p_1,\ldots,p_k$ will very often be *unknown* at the outset. Thus, his burden is to estimate the unknown probabilities by a statistical analysis of the experiment's outcomes.

In the Bayesian approach, it does not make sense to talk about estimating a true probability. Instead, a Bayesian assigns a prior probability distribution $p(x_1,x_2,\ldots,x_N)$ on the multi-trial hypothesis space, which is generally not an i.i.d., and then uses Bayes's theorem to update the

distribution in the light of measurement results. A common criticism from the objectivist camp is that the choice of distribution $p(x_1,x_2,\ldots,x_N)$ with which to start the process seems overly arbitrary to them. On what can it be grounded, they would ask? From the Bayesian viewpoint, the subjectivity of the prior is a strength rather than a weakness, because assigning a prior amounts to laying bare the necessarily subjective assumptions behind *any* probabilistic argument, be it Bayesian or objectivist. Choosing a prior among all possible distributions on the multi-trial hypothesis space is, however, a daunting task. As we will now see, the de Finetti representation theorem makes this task tractable.

It is very often the case that one or more features of a problem stand out so clearly that there is no question about how to incorporate them into an initial assignment. In the present case, the key feature is contained in the assumption that an arbitrary number of repeated trials are equivalent. This means that one has no reason to believe there will be a difference between one trial and the next. In this case, the prior distribution is judged to have the sort of permutation symmetry discussed briefly in Sec. I, which de Finetti[37] called *exchangeability*. The rigorous definition of exchangeability proceeds in two stages.

A probability distribution $p(x_1,x_2,\ldots,x_N)$ is said to be *symmetric* (or finitely exchangeable) if it is invariant under permutations of its arguments, i.e., if

$$p(x_{\pi(1)},x_{\pi(2)},\ldots,x_{\pi(N)})=p(x_1,x_2,\ldots,x_N) \tag{2.2}$$

for any permutation π of the set $\{1,\ldots,N\}$. The distribution $p(x_1,x_2,\ldots,x_N)$ is called *exchangeable* (or infinitely exchangeable) if it is symmetric and if for any integer $M>0$, there is a symmetric distribution $p_{N+M}(x_1,x_2,\ldots,x_{N+M})$ such that

$$p(x_1,x_2,\ldots,x_N)=\sum_{x_{N+1},\ldots,x_{N+M}} p_{N+M}(x_1,\ldots,x_N,x_{N+1},\ldots,x_{N+M}). \tag{2.3}$$

This last statement means the distribution p can be extended to a symmetric distribution of arbitrarily many random variables. Expressed informally, an exchangeable distribution can be thought of as arising from an infinite sequence of random variables whose order is irrelevant.

We now come to the main statement of this section: If a probability distribution $p(x_1,x_2,\ldots,x_N)$ is exchangeable, then it can be written uniquely in the form

$$p(x_1,x_2,\ldots,x_N)=\int_{\mathcal{S}_k} P(\mathbf{p})p_{x_1}p_{x_2}\cdots p_{x_N}\,d\mathbf{p}=\int_{\mathcal{S}_k} P(\mathbf{p})p_1^{n_1}p_2^{n_2}\cdots p_k^{n_k}\,d\mathbf{p}, \tag{2.4}$$

where $\mathbf{p}=(p_1,p_2,\ldots,p_k)$, and the integral is taken over the probability simplex

$$\mathcal{S}_k=\left\{\mathbf{p}\colon p_j\geqslant 0 \ \text{ for all } \ j \ \text{ and } \ \sum_{j=1}^{k} p_j=1\right\}. \tag{2.5}$$

Furthermore, the function $P(\mathbf{p})\geqslant 0$ is required to be a probability density function on the simplex:

$$\int_{\mathcal{S}_k} P(\mathbf{p})d\mathbf{p}=1. \tag{2.6}$$

Equation (2.4) comprises the classical de Finetti representation theorem for discrete random variables. For completeness and because it deserves to be more widely familiar in the physics and mathematical physics communities, we give a simple proof (due to Heath and Sudderth[42]) of the representation theorem for the binary random-variable case in the Appendix.

Let us reiterate the importance of this result for the present considerations. It says that an agent, making solely the judgment of exchangeability for a sequence of random variables x_j, can proceed *as if* his state of knowledge had instead come about through ignorance of an *unknown*, but

objectively existent set of probabilities **p**. His precise ignorance of **p** is captured by the ''probability on probabilities'' $P(\mathbf{p})$. This is in direct analogy to what we desire of a solution to the problem of the unknown quantum state in quantum-state tomography.

As a final note before finally addressing the quantum problem in Sec. III, we point out that both conditions in the definition of exchangeability are crucial for the proof of the de Finetti theorem. In particular, there are probability distributions $p(x_1,x_2,\ldots,x_N)$ that are symmetric, but not exchangeable. A simple example is the distribution $p(x_1,x_2)$ of two binary random variables $x_1,x_2\in\{0,1\}$,

$$p(0,0)=p(1,1)=0, \tag{2.7}$$

$$p(0,1)=p(1,0)=\tfrac{1}{2}. \tag{2.8}$$

One can easily check that $p(x_1,x_2)$ cannot be written as the marginal of a symmetric distribution of three variables, as in Eq. (2.3). Therefore it can have no representation along the lines of Eq. (2.4). (For an extended discussion of this, see Ref. 52.) Indeed, Eqs. (2.7) and (2.8) characterize a perfect ''anticorrelation'' of the two variables, in contrast to the positive correlation implied by distributions of de Finetti form. The content of this point is that both conditions in the definition of exchangeability (symmetry under interchange and infinite extendibility) are required to ensure, in colloquial terms, ''that the future will appear much as the past,'' [53] rather than, say, the opposite of the past.

III. THE QUANTUM DE FINETTI REPRESENTATION

Let us now return to the problem of quantum-state tomography described in Sec. I. We consider the general situation, where there may be no further agent (or ''man in the box'') whose (unknown) state of knowledge we are trying to determine.

In the objectivist formulation of the problem, a device repeatedly prepares copies of a system in the same quantum state ρ. This is generally a mixed-state density operator on a Hilbert space $\mathcal{H}_d$ of d dimensions; we denote the space of all such density operators by $\mathcal{D}_d$. The joint quantum state of the N systems prepared by the device is then given by

$$\rho^{\otimes N}=\rho\otimes\rho\otimes\cdots\rho, \tag{3.1}$$

the N-fold tensor product of ρ with itself. This, of course, is a very restricted example of a density operator on the tensor-product Hilbert space $\mathcal{H}_d^{\otimes N}\equiv\mathcal{H}_d\otimes\cdots\otimes\mathcal{H}_d$. The experimenter who performs quantum-state tomography tries to determine ρ as precisely as possible; ρ is interpreted as the ''true'' state of each of the systems.

We have already articulated our dissatisfaction with this way of stating the problem, but we give here a further sense of why the interpretation above is untenable. In this discussion it is useful to consider separately the cases of mixed and pure states ρ. The arguments against regarding mixed states as objective properties of a quantum system are essentially the same as those against regarding probabilities as objective. In analogy to the roulette example given in the previous section, we can say that, whenever an observer assigns a mixed state to a physical system, one can think of another observer who assigns a different state based on privileged information.

The quantum argument becomes yet more compelling if the apparently nonlocal nature of quantum states is taken into consideration. Consider two parties, A and B, who are far apart in space, say several light years apart. Each party possesses a spin-$\frac{1}{2}$ particle. Initially the joint state of the two particles is the maximally entangled pure state $(|0\rangle|0\rangle+|1\rangle|1\rangle)/\sqrt{2}$. Consequently, A assigns the totally mixed state $(|0\rangle\langle 0|+|1\rangle\langle 1|)/2$ to her own particle. Now B makes a measurement on his particle, finds the result 0, and assigns to A's particle the pure state $|0\rangle$. Is this now the ''true,'' objective state of A's particle? At what precise time does the objective state of A's particle change from totally mixed to pure? If the answer is ''simultaneously with B's measurement,'' then what frame of reference should be used to determine simultaneity? These questions

and potential paradoxes are avoided if states are interpreted as states of knowledge. In our example, A and B have different states of knowledge and therefore assign different states. For a detailed analysis of this example, see Ref. 54; for an experimental investigation see Ref. 55.

If one admits that mixed states cannot be objective properties, because another observer, possessing privileged information, can know which pure state underlies the mixed state, then it becomes very tempting to regard the pure states as giving the ''true'' state of a system. Probabilities that come from pure states would then be regarded as objective, and the probabilities for pure states within an ensemble decomposition of a mixed state would be regarded as subjective, expressing our ignorance of which pure state is the ''true'' state of the system. An immediate and, in our view, irremediable problem with this idea is that a mixed state has infinitely many ensemble decompositions into pure states,[19,56,57] so the distinction between subjective and objective becomes hopelessly blurred.

This problem can be made concrete by the example of a spin-$\frac{1}{2}$ particle. Any pure state of the particle can be written in terms of the Pauli matrices,

$$\sigma_1=\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0 & -i\\ i & 0\end{pmatrix},\quad \sigma_3=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}, \tag{3.2}$$

as

$$|\mathbf{n}\rangle\langle\mathbf{n}|=\tfrac{1}{2}(I+\mathbf{n}\cdot\boldsymbol{\sigma})=\tfrac{1}{2}(I+n_1\sigma_1+n_2\sigma_2+n_3\sigma_3), \tag{3.3}$$

where the unit vector $\mathbf{n}=n_1\mathbf{e}_1+n_2\mathbf{e}_2+n_3\mathbf{e}_3$ labels the pure state, and I denotes the unit operator. An arbitrary state ρ, mixed or pure, of the particle can be expressed as

$$\rho=\tfrac{1}{2}(I+\mathbf{S}\cdot\boldsymbol{\sigma}), \tag{3.4}$$

where $0\leqslant|\mathbf{S}|\leqslant 1$. This representation of the states of a spin-$\frac{1}{2}$ particle is called the *Bloch-sphere representation*. If $|\mathbf{S}|<1$, there is an infinite number of ways in which $\mathbf{S}$ can be written in the form $\mathbf{S}=\Sigma_j p_j\mathbf{n}_j$, $|\mathbf{n}_j|=1$, with the numbers p_j comprising a probability distribution, and hence an infinite number of ensemble decompositions of ρ:

$$\rho=\sum_j\, p_j\frac{1}{2}(I+\mathbf{n}_j\cdot\boldsymbol{\sigma})=\sum_j\, p_j|\mathbf{n}_j\rangle\langle\mathbf{n}_j|. \tag{3.5}$$

Suppose for specificity that the particle's state is a mixed state with $\mathbf{S}=\frac{1}{2}\mathbf{e}_3$. Writing $\mathbf{S}=\frac{3}{4}\mathbf{e}_3+\frac{1}{4}(-\mathbf{e}_3)$ gives the eigendecomposition,

$$\rho=\tfrac{3}{4}|\mathbf{e}_3\rangle\langle\mathbf{e}_3|+\tfrac{1}{4}|-\mathbf{e}_3\rangle\langle-\mathbf{e}_3|, \tag{3.6}$$

where we are to regard the probabilities $\frac{3}{4}$ and $\frac{1}{4}$ as subjective expressions of ignorance about which eigenstate is the ''true'' state of the particle. Writing $\mathbf{S}=\frac{1}{2}\mathbf{n}_+ +\frac{1}{2}\mathbf{n}_-$, where $\mathbf{n}_\pm=\frac{1}{2}\mathbf{e}_3\pm\sqrt{3/4}\mathbf{e}_1$, gives another ensemble decomposition,

$$\rho=\tfrac{1}{2}|\mathbf{n}_+\rangle\langle\mathbf{n}_+|+\tfrac{1}{2}|\mathbf{n}_-\rangle\langle\mathbf{n}_-|, \tag{3.7}$$

where we are now to regard the two probabilities of $\frac{1}{2}$ as expressing ignorance of whether the ''true'' state is $|\mathbf{n}_+\rangle$ or $|\mathbf{n}_-\rangle$.

The problem becomes acute when we ask for the probability that a measurement of the z component of spin yields spin up; this probability is given by $\langle\mathbf{e}_3|\rho|\mathbf{e}_3\rangle=\frac{1}{2}(1+\frac{1}{2}\langle\mathbf{e}_3|\sigma_3|\mathbf{e}_3\rangle)=\frac{3}{4}$. The eigendecomposition gets this probability by the route

$$\langle \mathbf{e}_3|\rho|\mathbf{e}_3\rangle = \frac{3}{4}\underbrace{|\langle \mathbf{e}_3|\mathbf{e}_3\rangle|^2}_{1} + \frac{1}{4}\underbrace{|\langle \mathbf{e}_3|-\mathbf{e}_3\rangle|^2}_{0}. \tag{3.8}$$

Here the "objective" quantum probabilities, calculated from the eigenstates, report that the particle definitely has spin up or definitely has spin down; the overall probability of $\frac{3}{4}$ comes from mixing these objective probabilities with the subjective probabilities for the eigenstates. The decomposition (3.7) gets the same overall probability by a different route,

$$\langle \mathbf{e}_3|\rho|\mathbf{e}_3\rangle = \frac{1}{2}\underbrace{|\langle \mathbf{e}_3|\mathbf{n}_+\rangle|^2}_{3/4} + \frac{1}{2}\underbrace{|\langle \mathbf{e}_3|\mathbf{n}_-\rangle|^2}_{3/4}. \tag{3.9}$$

Now the quantum probabilities tell us that the "objective" probability for the particle to have spin up is $\frac{3}{4}$. This simple example illustrates the folly of trying to have two kinds of probabilities in quantum mechanics. The lesson is that if a density operator is even partially a reflection of one's state of knowledge, the multiplicity of ensemble decomposition means that a pure state must also be a state of knowledge.

These problems do not arise in an information-based interpretation, according to which all quantum states, pure or mixed, are states of knowledge. In analogy to the classical case, the quantum de Finetti representation provides an operational definition for the idea of an unknown quantum state in this case.

Let us therefore turn to the information-based formulation of the quantum-state tomography problem. Before the tomographic measurements, the Bayesian experimenter assigns a prior quantum state to the joint system composed of the N systems, reflecting his prior state of knowledge. Just as in the classical case, this is a daunting task unless the assumption of exchangeability is justified.

The definition of the quantum version of exchangeability is closely analogous to the classical definition. Again, the definition proceeds in two stages. First, a joint state $\rho^{(N)}$ of N systems is said to be *symmetric* (or finitely exchangeable) if it is invariant under any permutation of the systems. To see what this means formally, first write out $\rho^{(N)}$ with respect to any orthonormal tensor-product basis on $\mathcal{H}_d^{\otimes N}$, say $|i_1\rangle|i_2\rangle\cdots|i_N\rangle$, where $i_k \in \{1,2,\ldots,d\}$ for all k. The joint state takes the form

$$\rho^{(N)} = \sum_{i_1,\ldots,i_N;j_1,\ldots,j_N} R^{(N)}_{i_1,\ldots,i_N;j_1,\ldots,j_N} |i_1\rangle\cdots|i_N\rangle\langle j_1|\cdots\langle j_N|, \tag{3.10}$$

where $R^{(N)}_{i_1,\ldots,i_N;j_1,\ldots,j_N}$ is the density matrix in this representation. What we demand is that for any permutation π of the set $\{1,\ldots,N\}$,

$$\begin{aligned}\rho^{(N)} &= \sum_{i_1,\ldots,i_N;j_1,\ldots,j_N} R^{(N)}_{i_1,\ldots,i_N;j_1,\ldots,j_N} |i_{\pi^{-1}(1)}\rangle\cdots|i_{\pi^{-1}(N)}\rangle\langle j_{\pi^{-1}(1)}|\cdots\langle j_{\pi^{-1}(N)}| \\ &= \sum_{i_1,\ldots,i_N;j_1,\ldots,j_N} R^{(N)}_{i_{\pi(1)},\ldots,i_{\pi(N)};j_{\pi(1)},\ldots,j_{\pi(N)}} |i_1\rangle\cdots|i_N\rangle\langle j_1|\cdots\langle j_N|,\end{aligned} \tag{3.11}$$

which is equivalent to

$$R^{(N)}_{i_{\pi(1)},\ldots,i_{\pi(N)};j_{\pi(1)},\ldots,j_{\pi(N)}} = R^{(N)}_{i_1,\ldots,i_N;j_1,\ldots,j_N}. \tag{3.12}$$

The state $\rho^{(N)}$ is said to be *exchangeable* (or infinitely exchangeable) if it is symmetric and if, for any $M>0$, there is a symmetric state $\rho^{(N+M)}$ of $N+M$ systems such that the marginal density operator for N systems is $\rho^{(N)}$, i.e.,

$$\rho^{(N)} = \mathrm{tr}_M \rho^{(N+M)}, \tag{3.13}$$

where the trace is taken over the additional M systems. In explicit basis-dependent notation, this requirement is

$$\rho^{(N)} = \sum_{i_1,\ldots,i_N;j_1,\ldots,j_N} \left(\sum_{i_{N+1},\ldots,i_{N+M}} R^{(N+M)}_{i_1,\ldots,i_N,i_{N+1},\ldots,i_{N+M};j_1,\ldots,j_N,i_{N+1},\ldots,i_{N+M}} \right) \times |i_1\rangle\cdots|i_N\rangle\langle j_1|\cdots\langle j_N|. \tag{3.14}$$

In analogy to the classical case, an exchangeable density operator can be thought of informally as the description of a subsystem of an infinite sequence of systems whose order is irrelevant.

The precise statement of the quantum de Finetti representation theorem[38,58] is that any exchangeable state of N systems can be written uniquely in the form

$$\rho^{(N)} = \int_{\mathcal{D}_d} P(\rho)\, \rho^{\otimes N}\, d\rho. \tag{3.15}$$

Here $P(\rho) \geqslant 0$ is normalized by

$$\int_{\mathcal{D}_d} P(\rho)\, d\rho = 1, \tag{3.16}$$

with $d\rho$ being a suitable measure on density operator space $\mathcal{D}_d$ [e.g., for a spin-$\frac{1}{2}$ particle, one could choose the standard flat measure $d\rho = S^2 dS\, d\Omega$ in the parametrization (3.4)]. The upshot of the theorem, as already advertised, is that it makes it possible to think of an exchangeable quantum-state assignment *as if* it were a probabilistic mixture characterized by a probability density $P(\rho)$ for the product states $\rho^{\otimes N}$.

Just as in the classical case, both components of the definition of exchangeability are crucial for arriving at the representation theorem of Eq. (3.15). The reason now, however, is much more interesting than it was previously. In the classical case, extendibility served to exclude symmetric, but anticorrelated probability distributions. Here extendibility has the additional role of excluding the possibility of Bell inequality violations for measurements on the separate systems. This is because the assumption of symmetry alone for an N-party quantum system does not exclude the possibility of quantum entanglement, yet all states that can be written as a mixture of product states—Eq. (3.15) being an example—have no entanglement.[59]

A very simple example of this is the Greenberger–Horne–Zeilinger state of three spin-$\frac{1}{2}$ particles,[60]

$$|\mathrm{GHZ}\rangle = \frac{1}{\sqrt{2}}(|0\rangle|0\rangle|0\rangle + |1\rangle|1\rangle|1\rangle), \tag{3.17}$$

which is symmetric, but is not extendible to a symmetric state on four systems. This follows because the only states of four particles that marginalize to a three-particle pure state, like the GHZ state, are product states of the form $|\mathrm{GHZ}\rangle\langle\mathrm{GHZ}| \otimes \rho$, where ρ is the state of the fourth particle; such states clearly cannot be symmetric. These considerations show that in order for the proposed theorem to be valid, it must be the case that as M increases in Eq. (3.13), the possibilities for entanglement in the separate systems compensatingly decrease.[61]

The exclusion of entangled states from the set of exchangeable states is essential if we are to substitute exchangeable state assignments for the offending notion of an unknown quantum state. For if an exchangeable density operator could be entangled, it would be impossible even to talk about the separate systems as having states of their own, unknown or otherwise. We stress, however, that this exclusion does not mean that the information-based view of quantum states as states of knowledge is incapable of dealing with entangled states, since the systems in the de

Finetti representation could each be made up of parts that are entangled. In this case the de Finetti representation integral (3.15) would include entangled density operators from the space of single-system, but many-part, density operators, and the unknown quantum state could be entangled. What is excluded by exchangeability is entanglement among the systems that are deemed to be exchangeable.

IV. PROOF OF THE QUANTUM DE FINETTI THEOREM

To prove the quantum version of the de Finetti theorem, we rely on the classical theorem as much as possible. We start from an exchangeable density operator $\rho^{(N)}$ defined on N copies of a system. We bring the classical theorem to our aid by imagining a sequence of identical quantum measurements on the separate systems and considering the outcome probabilities they would produce. Because $\rho^{(N)}$ is assumed exchangeable, such identical measurements give rise to an exchangeable probability distribution for the outcomes. The trick is to recover enough information from the exchangeable statistics of these measurements to characterize the exchangeable density operators.

With this in mind, the proof is expedited by making use of the theory of generalized quantum measurements or positive operator-valued measures (POVMs).[62,63] We give a brief introduction to that theory. The common textbook notion of a measurement—that is, a von Neumann measurement—is that any laboratory procedure counting as an observation can be identified with a Hermitian operator O on the Hilbert space $\mathcal{H}_d$ of the system. Depending upon the presentation, the measurement outcomes are identified either with the eigenvalues μ_i or with a complete set of normalized eigenvectors $|i\rangle$ for O. When the quantum state is ρ, the probabilities for the various outcomes are computed from the eigenprojectors $\Pi_i=|i\rangle\langle i|$ via the standard Born rule,

$$p_i=\mathrm{tr}(\rho\Pi_i)=\langle i|\rho|i\rangle. \tag{4.1}$$

This rule gives a consistent probability assignment because the eigenprojectors Π_i are positive-semidefinite operators, which makes the p_i non-negative, and because the projectors form a resolution of the identity operator I,

$$\sum_{i=1}^{d}\Pi_i=I, \tag{4.2}$$

which guarantees that $\Sigma_i p_i=1$.

POVMs generalize the textbook notion of measurement by distilling the essential properties that make the Born rule work. The generalized notion of measurement is this: *Any* set $\mathcal{E}=\{E_\alpha\}$ of positive-semidefinite operators on $\mathcal{H}_d$ that forms a resolution of the identity, i.e., that satisfies

$$\langle\psi|E_\alpha|\psi\rangle\geqslant 0 \quad \text{for all } |\psi\rangle\in\mathcal{H}_d \tag{4.3}$$

and

$$\sum_\alpha E_\alpha=I, \tag{4.4}$$

corresponds to at least one laboratory procedure counting as a measurement. The condition (4.3) for positive-semidefiniteness is equivalent to requiring that E_α be Hermitian with nonnegative eigenvalues. The outcomes of the measurement are identified with the indices α, and the probabilities of those outcomes are computed according to the generalized Born rule,

$$p_\alpha=\mathrm{tr}(\rho E_\alpha). \tag{4.5}$$

The set $\mathcal{E}$ is called a POVM, and the operators E_α are called POVM elements. Unlike von Neumann measurements, there is no limitation on the number of values α can take, the operators

E_α need not be rank-1, and there is no requirement that the E_α be mutually orthogonal. This definition has important content because the older notion of measurement is simply too restrictive: There are laboratory procedures that clearly should be called ''measurements,'' but that cannot be expressed in terms of the von Neumann measurement process alone.

One might wonder whether the existence of POVMs contradicts everything taught about standard measurements in the traditional graduate textbooks[64] and the well-known classics.[65] Fortunately it does not. The reason is that any POVM can be represented formally as a standard measurement on an ancillary system that has interacted in the past with the system of main interest. Thus, in a certain sense, von Neumann measurements capture everything that can be said about quantum measurements.[63] A way to think about this is that by learning something about the ancillary system through a standard measurement, one in turn learns something about the system of real interest. Indirect though this might seem, it can be a very powerful technique, sometimes revealing information that could not have been revealed otherwise.[66]

For instance, by considering POVMs, one can consider measurements with an outcome cardinality that exceeds the dimensionality of the Hilbert space. What this means is that whereas the statistics of a von Neumann measurement can only reveal information about the d diagonal elements of a density operator ρ, through the probabilities $\mathrm{tr}(\rho\Pi_i)$, the statistics of a POVM generally can reveal things about the off-diagonal elements, too. It is precisely this property that we take advantage of in our proof of the quantum de Finetti theorem.

Our problem hinges on finding a special kind of POVM, one for which any set of outcome probabilities specifies a unique operator. This boils down to a problem in pure linear algebra. The space of operators on $\mathcal{H}_d$ is itself a linear vector space of dimension d^2. The quantity $\mathrm{tr}(A^\dagger B)$ serves as an inner product on that space. If the POVM elements E_α span the space of operators—there must be at least d^2 POVM elements in the set—the measurement probabilities $p_\alpha = \mathrm{tr}(\rho E_\alpha)$—now thought of as *projections* in the directions E_α—are sufficient to specify a unique operator ρ. Two distinct density operators ρ and σ must give rise to different measurement statistics. Such measurements, which might be called *informationally complete*, have been studied for some time.[67]

For our proof we need a slightly refined notion—that of a *minimal* informationally complete measurement. If an informationally complete POVM has more than d^2 operators E_α, these operators form an overcomplete set. This means that given a set of outcome probabilities p_α, there is generally *no* operator A that generates them according to $p_\alpha = \mathrm{tr}(AE_\alpha)$. Our proof requires the existence of such an operator, so we need a POVM that has precisely d^2 linearly independent POVM elements E_α. Such a POVM has the minimal number of POVM elements to be informationally complete. Given a set of outcome probabilities p_α, there is a unique operator A such that $p_\alpha = \mathrm{tr}(AE_\alpha)$, even though, as we discuss below, A is not guaranteed to be a density operator.

Do minimal informationally complete POVMs exist? The answer is yes. We give here a simple way to produce one, though there are surely more elegant ways with greater symmetry. Start with a complete orthonormal basis $|e_j\rangle$ on $\mathcal{H}_d$, and let $\Gamma_{jk} = |e_j\rangle\langle e_k|$. It is easy to check that the following d^2 rank-1 projectors Π_α form a linearly independent set.

(1) For $\alpha = 1,\ldots,d$, let

$$\Pi_\alpha \equiv \Gamma_{jj}, \tag{4.6}$$

where j, too, runs over the values $1,\ldots,d$.

(2) For $\alpha = d+1,\ldots,\frac{1}{2}d(d+1)$, let

$$\Pi_\alpha \equiv \Gamma^{(1)}_{jk} = \tfrac{1}{2}(|e_j\rangle + |e_k\rangle)(\langle e_j| + \langle e_k|) = \tfrac{1}{2}(\Gamma_{jj} + \Gamma_{kk} + \Gamma_{jk} + \Gamma_{kj}), \tag{4.7}$$

where $j < k$.

(3) Finally, for $\alpha = \frac{1}{2}d(d+1)+1,\ldots,d^2$, let

$$\Pi_\alpha \equiv \Gamma^{(2)}_{jk} = \tfrac{1}{2}(|e_j\rangle + i|e_k\rangle)(\langle e_j| - i\langle e_k|) = \tfrac{1}{2}(\Gamma_{jj} + \Gamma_{kk} - i\Gamma_{jk} + i\Gamma_{kj}), \tag{4.8}$$

where again $j<k$.

All that remains is to transform these (positive-semidefinite) linearly independent operators Π_α into a proper POVM. This can be done by considering the positive semidefinite operator G defined by

$$G = \sum_{\alpha=1}^{d^2} \Pi_\alpha . \tag{4.9}$$

It is straightforward to show that $\langle\psi|G|\psi\rangle > 0$ for all $|\psi\rangle \neq 0$, thus establishing that G is positive definite (i.e., Hermitian with positive eigenvalues) and hence invertible. Applying the (invertible) linear transformation $X \to G^{-1/2} X G^{-1/2}$ to Eq. (4.9), we find a valid decomposition of the identity,

$$I = \sum_{\alpha=1}^{d^2} G^{-1/2} \Pi_\alpha G^{-1/2}. \tag{4.10}$$

The operators

$$E_\alpha = G^{-1/2} \Pi_\alpha G^{-1/2} \tag{4.11}$$

satisfy the conditions of a POVM, Eqs. (4.3) and (4.4), and, moreover, they retain the rank and linear independence of the original Π_α.

With this generalized measurement (or any other one like it), we can return to the main line of proof. Recall we assumed that we captured our state of knowledge by an exchangeable density operator $\rho^{(N)}$. Consequently, repeated application of the (imagined) measurement $\mathcal{E}$ must give rise to an exchangeable probability distribution over the N random variables $\alpha_n \in \{1,2,\ldots,d^2\}$, $n = 1,\ldots,N$. We now analyze these probabilities.

Quantum mechanically, it is valid to think of the N repeated measurements of $\mathcal{E}$ as a single measurement on the Hilbert space $\mathcal{H}_d^{\otimes N} \equiv \mathcal{H}_d \otimes \cdots \otimes \mathcal{H}_d$. This measurement, which we denote $\mathcal{E}^{\otimes N}$, consists of d^{2N} POVM elements of the form $E_{\alpha_1} \otimes \cdots \otimes E_{\alpha_N}$. The probability of any particular outcome sequence of length N, namely $\boldsymbol{\alpha} \equiv (\alpha_1,\ldots,\alpha_N)$, is given by the standard quantum rule,

$$p^{(N)}(\boldsymbol{\alpha}) = \mathrm{tr}(\rho^{(N)} E_{\alpha_1} \otimes \cdots \otimes E_{\alpha_N}). \tag{4.12}$$

Because the distribution $p^{(N)}(\boldsymbol{\alpha})$ is exchangeable, we have by the classical de Finetti theorem [see Eq. (2.4)] that there exists a unique probability density $P(\mathbf{p})$ on $\mathcal{S}_{d^2}$ such that

$$p^{(N)}(\boldsymbol{\alpha}) = \int_{\mathcal{S}_{d^2}} P(\mathbf{p}) p_{\alpha_1} p_{\alpha_2} \cdots p_{\alpha_N} \, d\mathbf{p}, \tag{4.13}$$

where the integral runs over the probability simplex for d^2 outcomes.

It should now begin to be apparent why we chose to imagine a measurement $\mathcal{E}$ consisting of precisely d^2 linearly independent elements. This allows us to assert the existence of a *unique* operator $A_{\mathbf{p}}$ on $\mathcal{H}_d$ corresponding to each point $\mathbf{p}$ in the domain of the integral. The ultimate goal here is to turn Eqs. (4.12) and (4.13) into a single operator equation.

With that in mind, let us define $A_{\mathbf{p}}$ as the unique operator satisfying the following d^2 linear equations:

$$\mathrm{tr}(A_{\mathbf{p}} E_\alpha) = p_\alpha , \quad \alpha = 1,\ldots,d^2. \tag{4.14}$$

Inserting this definition into Eq. (4.13) and manipulating it according to the algebraic rules of tensor products—namely $(A\otimes B)(C\otimes D)=AC\otimes BD$ and $\mathrm{tr}(A\otimes B)=(\mathrm{tr}A)(\mathrm{tr}B)$—we see that

$$p^{(N)}(\boldsymbol{\alpha})=\int_{\mathcal{S}_{d^2}} P(\mathbf{p})\mathrm{tr}(A_{\mathbf{p}}E_{\alpha_1})\cdots\mathrm{tr}(A_{\mathbf{p}}E_{\alpha_N})d\mathbf{p}$$
$$=\int_{\mathcal{S}_{d^2}} P(\mathbf{p})\mathrm{tr}(A_{\mathbf{p}}E_{\alpha_1}\otimes\cdots\otimes A_{\mathbf{p}}E_{\alpha_N})d\mathbf{p}=\int_{\mathcal{S}_{d^2}} P(\mathbf{p})\mathrm{tr}[A_{\mathbf{p}}^{\otimes N}(E_{\alpha_1}\otimes\cdots\otimes E_{\alpha_N})]\,d\mathbf{p}. \tag{4.15}$$

If we further use the linearity of the trace, we can write the same expression as

$$p^{(N)}(\boldsymbol{\alpha})=\mathrm{tr}\left[\left(\int_{\mathcal{S}_{d^2}} P(\mathbf{p})A_{\mathbf{p}}^{\otimes n}\,d\mathbf{p}\right)E_{\alpha_1}\otimes\cdots\otimes E_{\alpha_N}\right]. \tag{4.16}$$

The identity between Eqs. (4.12) and (4.16) must hold for all sequences $\boldsymbol{\alpha}$. It follows that

$$\rho^{(N)}=\int_{\mathcal{S}_{d^2}} P(\mathbf{p})A_{\mathbf{p}}^{\otimes N}\,d\mathbf{p}. \tag{4.17}$$

This is because the operators $E_{\alpha_1}\otimes\cdots\otimes E_{\alpha_N}$ form a complete basis for the vector space of operators on $\mathcal{H}_d^{\otimes N}$.

Equation (4.17) already looks very much like our sought after goal, but we are not there quite yet. At this stage one has no right to assert that the $A_{\mathbf{p}}$ are density operators, i.e., Hermitian operators with non-negative eigenvalues that sum to one. Indeed they generally are not: The integral (4.13) ranges over some points $\mathbf{p}$ in $\mathcal{S}_{d^2}$ that cannot be generated by applying the measurement $\mathcal{E}$ to *any* quantum state. Hence some of the $A_{\mathbf{p}}$ in the integral representation are ostensibly nonphysical. An example might be helpful. Consider any four spin-$\frac{1}{2}$ pure states $|\mathbf{n}_\alpha\rangle$ on $\mathcal{H}_2$ for which the vectors $\mathbf{n}_\alpha$ in the Bloch-sphere representation (3.3) are the vertices of a regular tetrahedron. One can check that the elements $E_\alpha=\frac{1}{2}|\mathbf{n}_\alpha\rangle\langle\mathbf{n}_\alpha|$ comprise a minimal informationally complete POVM. For this POVM, because of the factor $\frac{1}{2}$ in front of each projector, it is always the case that $p_\alpha=\mathrm{tr}(\rho E_\alpha)\leqslant\frac{1}{2}$. Therefore, this measurement simply cannot generate a probability distribution like $\mathbf{p}=(\frac{3}{4},\frac{1}{8},\frac{1}{16},\frac{1}{16})$ from a valid density operator. Nevertheless, such probability distributions are in the domain of the integral in Eq. (4.13), and the corresponding $A_{\mathbf{p}}$ are not valid density operators.

The solution to this conundrum is provided by the overall requirement that $\rho^{(N)}$ be a valid density operator. This requirement places a significantly more stringent constraint on the distribution $P(\mathbf{p})$ than was the case in the classical representation theorem. In particular, it must be the case that $P(\mathbf{p})$ vanishes whenever the corresponding $A_{\mathbf{p}}$ is not a proper density operator. Let us move toward showing that.

We first need to delineate two properties of the operators $A_{\mathbf{p}}$. One is that they are Hermitian and thus have real eigenvalues. The argument is simply

$$\mathrm{tr}(E_\alpha A_{\mathbf{p}}^\dagger)=\mathrm{tr}[(A_{\mathbf{p}}E_\alpha)^\dagger]=[\mathrm{tr}(A_{\mathbf{p}}E_\alpha)]^*=\mathrm{tr}(A_{\mathbf{p}}E_\alpha), \tag{4.18}$$

where the last step follows from Eq. (4.14). Because the E_α are a complete set of linearly independent operators, it follows that $A_{\mathbf{p}}^\dagger=A_{\mathbf{p}}$. The second property tells us something further about the eigenvalues of $A_{\mathbf{p}}$:

$$1=\sum_\alpha p_\alpha=\mathrm{tr}\left(A_{\mathbf{p}}\sum_\alpha E_\alpha\right)=\mathrm{tr}A_{\mathbf{p}}. \tag{4.19}$$

In other words the (real) eigenvalues of $A_{\mathbf{p}}$ must sum to unity. These two properties tell us that if $A_{\mathbf{p}}$ is not a valid density operator, then it must have at least one negative eigenvalue.

We now show that these two facts go together to imply that if there are any nonphysical $A_{\mathbf{p}}$ with positive weight $P(\mathbf{p})$ in Eq. (4.17), then one can find a measurement for which $\rho^{(N)}$ produces illegal "probabilities" for sufficiently large N. For instance, take a particular $A_{\mathbf{q}}$ in Eq. (4.17) that has at least one negative eigenvalue $-\lambda<0$. Let $|\psi\rangle$ be a normalized eigenvector corresponding to that eigenvalue and consider the binary-valued POVM consisting of the elements $\widetilde{\Pi}=|\psi\rangle\langle\psi|$ and $\Pi=I-\widetilde{\Pi}$. Since $\mathrm{tr}(A_{\mathbf{q}}\widetilde{\Pi})=-\lambda<0$, it is true by Eq. (4.19) that $\mathrm{tr}(A_{\mathbf{q}}\Pi)=1+\lambda>1$. Consider repeating this measurement over and over. In particular, let us tabulate the probability of getting outcome Π for every single trial to the exclusion of all other outcomes.

The gist of the contradiction is most easily seen by *imagining* that Eq. (4.17) is really a discrete sum:

$$\rho^{(N)}=P(\mathbf{q})A_{\mathbf{q}}^{\otimes N}+\sum_{\mathbf{p}\neq\mathbf{q}}P(\mathbf{p})A_{\mathbf{p}}^{\otimes N}. \tag{4.20}$$

The probability of N occurrences of the outcome Π is thus

$$\begin{aligned}\mathrm{tr}(\rho^{(N)}\Pi^{\otimes N})&=P(\mathbf{q})\mathrm{tr}(A_{\mathbf{q}}^{\otimes N}\Pi^{\otimes N})+\sum_{\mathbf{p}\neq\mathbf{q}}P(\mathbf{p})\mathrm{tr}(A_{\mathbf{p}}^{\otimes N}\Pi^{\otimes N})\\&=P(\mathbf{q})[\mathrm{tr}(A_{\mathbf{q}}\Pi)]^N+\sum_{\mathbf{p}\neq\mathbf{q}}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N\\&=P(\mathbf{q})(1+\lambda)^N+\sum_{\mathbf{p}\neq\mathbf{q}}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N.\end{aligned} \tag{4.21}$$

There are no assurances in general that the rightmost term in Eq. (4.21) is positive, but if N is an even number, it must be. It follows that if $P(\mathbf{q})\geqslant 0$, for sufficiently large *even* N,

$$\mathrm{tr}(\rho^{(N)}\Pi^{\otimes N})>1, \tag{4.22}$$

contradicting the assumption that it should always be a probability.

All we need to do now is transcribe the argument leading to Eq. (4.22) to the general integral case of Eq. (4.17). Note that by Eq. (4.14), the quantity $\mathrm{tr}(A_{\mathbf{p}}\Pi)$ is a (linear) continuous function of the parameter $\mathbf{p}$. Therefore, for any $\epsilon>0$, there exists a $\delta>0$ such that $|\mathrm{tr}(A_{\mathbf{p}}\Pi)-\mathrm{tr}(A_{\mathbf{q}}\Pi)|\leqslant\epsilon$ whenever $|\mathbf{p}-\mathbf{q}|\leqslant\delta$, i.e., whenever $\mathbf{p}$ is contained within an open ball $B_\delta(\mathbf{q})$ centered at $\mathbf{q}$. Choose $\epsilon<\lambda$, and define $\overline{B}_\delta$ to be the intersection of $B_\delta(\mathbf{q})$ with the probability simplex. For $\mathbf{p}\in\overline{B}_\delta$, it follows that

$$\mathrm{tr}(A_{\mathbf{p}}\Pi)\geqslant 1+\lambda-\epsilon>1. \tag{4.23}$$

If we consider an N that is even, $[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N$ is nonnegative in all of $\mathcal{S}_{d^2}$, and we have that the probability of the outcome $\Pi^{\otimes N}$ satisfies

$$\begin{aligned}\mathrm{tr}(\rho^{(N)}\Pi^{\otimes N})&=\int_{\mathcal{S}_{d^2}}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N\,d\mathbf{p}=\int_{\mathcal{S}_{d^2}-\overline{B}_\delta}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N\,d\mathbf{p}+\int_{\overline{B}_\delta}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N\,d\mathbf{p}\\&\geqslant\int_{\overline{B}_\delta}P(\mathbf{p})[\mathrm{tr}(A_{\mathbf{p}}\Pi)]^N\,d\mathbf{p}\geqslant(1+\lambda-\epsilon)^N\int_{\overline{B}_\delta}P(\mathbf{p})\,d\mathbf{p}.\end{aligned} \tag{4.24}$$

Unless

$$\int_{\overline{B}_\delta} P(\mathbf{p})d\mathbf{p}=0, \tag{4.25}$$

the lower bound (4.24) for the probability of the outcome $\Pi^{\otimes N}$ becomes arbitrarily large as $N \rightarrow \infty$. Thus we conclude that the requirement that $\rho^{(N)}$ be a proper density operator constrains $P(\mathbf{p})$ to vanish almost everywhere in $\overline{B}_\delta$ and, consequently, to vanish almost everywhere that $A_\mathbf{p}$ is not a physical state.

Using Eq. (4.14), we can trivially transform the integral representation (4.17) to one directly over the convex set of density operators $\mathcal{D}_d$ and be left with the following statement. Under the sole assumption that the density operator $\rho^{(N)}$ is exchangeable, there exists a unique probability density $P(\rho)$ such that

$$\rho^{(N)}=\int_{\mathcal{D}_d} P(\rho)\rho^{\otimes N}d\rho. \tag{4.26}$$

This concludes the proof of the quantum de Finetti representation theorem.

V. OUTLOOK

Since the analysis in the previous sections concerned *only* the case of quantum-state tomography, we certainly have not written the last word on unknown quantum states in the sense advocated in Sec. I. There are clearly other examples that need separate analyses. For instance, the use of unknown states in quantum teleportation[10]—where a *single* realization of an unknown state is ''teleported'' with the aid of previously distributed quantum entanglement and a classical side channel—has not been touched upon. The quantum de Finetti theorem, therefore, is not the end of the road for detailing implications of an information-based interpretation of quantum mechanics. What is important, we believe, is that taking the time to think carefully about the referents of various states in a problem can lead to insights into the structure of quantum mechanics that cannot be found by other means.

For instance, one might ask, ''Was this theorem not inevitable?'' After all, is it not already well established that quantum theory is, in some sense, just a noncommutative generalization of probability theory? Should not all the main theorems in classical probability theory carry over to the quantum case?[68,69] One can be skeptical in this way, of course, but then one will miss a large part of the point. There are any number of noncommutative generalizations to probability theory that one can concoct.[70] The deeper issue is, what is it in the natural world that forces quantum theory to the particular noncommutative structure it actually has?[71] It is not a foregone conclusion, for instance, that every theory has a de Finetti representation theorem within it.

Some insight in this regard can be gained by considering very simple modifications of quantum theory. To give a concrete example, let us take the case of real-Hilbert-space quantum mechanics. This theory is the same as ordinary quantum mechanics in all aspects *except* that the Hilbert spaces are defined over the field of real numbers rather than the complex numbers. It turns out that this is a case where the quantum de Finetti theorem fails. Let us start to explain why by first describing how the particular proof technique used above loses validity in the new context.

In order to specify uniquely a Hermitian operator $\rho^{(N)}$ in going from Eq. (4.16) to (4.17), the proof made central use of the fact that a complete basis $\{E_1,\ldots,E_{d^2}\}$ for the vector space of operators on $\mathcal{H}_d$ can be used to generate a complete basis for the operators on $\mathcal{H}_d^{\otimes N}$—one just need take the d^{2N} operators of the form $E_{\alpha_1}\otimes\cdots\otimes E_{\alpha_N}$, $1\leqslant\alpha_j\leqslant d^2$. (All we actually needed was that a basis for the real vector space of Hermitian operators on $\mathcal{H}_d$ can be used to generate a basis for the real vector space of Hermitian operators on $\mathcal{H}_d^{\otimes N}$, but since the vector space of all operators is the complexification of the real vector space of Hermitian operators, this seemingly weaker requirement is, in fact, no different.) This technique works because the dimension of the space of $d^N\times d^N$ matrices is $(d^2)^N$, the Nth power of the dimension of the space of $d\times d$ matrices.

This technique does not carry over to real Hilbert spaces. In a real Hilbert space, states and POVM elements are represented by real symmetric matrices. The dimension of the vector space of real symmetric matrices acting on a d-dimensional real Hilbert space is $\frac{1}{2}d(d+1)$, this then being the number of elements in a minimal informationally complete POVM. The task in going from Eq. (4.16) to (4.17) would be to specify the real matrix $\rho^{(N)}$. When $N\geqslant 2$, however, the dimension of the space of $d^N\times d^N$ real symmetric matrices is strictly greater than the Nth power of the dimension of the space of $d\times d$ real symmetric matrices, i.e.,

$$\tfrac{1}{2}d^N(d^N+1)>(\tfrac{1}{2}d(d+1))^N. \tag{5.1}$$

Hence, specifying Eq. (4.16) for all outcome sequences $\boldsymbol{\alpha}=(\alpha_1,\ldots,\alpha_N)$ is not sufficient to specify a single operator $\rho^{(N)}$. This line of reasoning indicates that the particular *proof* of the quantum de Finetti theorem presented in Sec. IV fails for real Hilbert spaces, but it does not establish that the theorem itself fails. The main point of this discussion is that it draws attention to the crucial difference between real-Hilbert-space and complex-Hilbert-space quantum mechanics—a fact emphasized previously by Araki[26] and Wootters.[27]

To show that the theorem fails, we need a counterexample. One such example is provided by the N-system state

$$\rho^{(N)}=\tfrac{1}{2}\rho_+^{\otimes N}+\tfrac{1}{2}\rho_-^{\otimes N}, \tag{5.2}$$

where

$$\rho_+=\tfrac{1}{2}(I+\sigma_2) \quad \text{and} \quad \rho_-=\tfrac{1}{2}(I-\sigma_2), \tag{5.3}$$

and where σ_2 was defined in Eq. (3.2). In complex-Hilbert-space quantum mechanics, this is clearly a valid density operator: It corresponds to an equally weighted mixture of N spin-up particles and N spin-down particles in the y direction. The state $\rho^{(N)}$ is clearly exchangeable, and the decomposition in Eq. (5.2) is unique according to the quantum de Finetti theorem.

Now consider $\rho^{(N)}$ as an operator in real-Hilbert-space quantum mechanics. Despite the apparent use of the imaginary number i in the σ_2 operator, $\rho^{(N)}$ remains a valid quantum state. This is because, upon expanding the right-hand side of Eq. (5.2), all the terms with an odd number of σ_2 operators cancel away. Yet, even though it is an exchangeable density operator, it cannot be written in de Finetti form of Eq. (3.15) using only real symmetric operators. This follows because Eq. (5.2), the unique de Finetti form, contains σ_2, which is an antisymmetric operator and cannot be written in terms of symmetric operators. Hence the de Finetti representation theorem does not hold in real-Hilbert-space quantum mechanics.

Similar considerations show that in quaternionic quantum mechanics (a theory again precisely the same as ordinary quantum mechanics except that it uses Hilbert spaces over the quaternionic field[25]), the connection between exchangeable density operators and decompositions of the de Finetti form (3.15) breaks down. The failure mode is, however, even more disturbing than for real Hilbert spaces. In quaternionic quantum mechanics, most operators of the de Finetti form (3.15) do not correspond to valid quaternionic quantum states, even though the states ρ in the integral are valid quaternionic states. The reason is that tensor products of quaternionic Hermitian operators are not necessarily Hermitian.

In classical probability theory, exchangeability characterizes those situations where the only data relevant for updating a probability distribution are frequency data, i.e., the numbers n_j in Eq. (2.4) which tell how often the result j occurred. The quantum de Finetti representation shows that the same is true in quantum mechanics: Frequency data (with respect to a sufficiently robust measurement) are sufficient for updating an exchangeable state to the point where nothing more can be learned from sequential measurements; that is, one obtains a convergence of the form (1.5), so that ultimately any further measurements on the individual systems are statistically independent. That there is no quantum de Finetti theorem in real Hilbert space means that there are fundamental differences between real and complex Hilbert spaces with respect to learning from

measurement results. The ultimate reason for this is that in ordinary, complex-Hilbert-space quantum mechanics, exchangeability implies separability, i.e., the absence of entanglement among the component systems. This follows directly from the quantum de Finetti theorem, because states of the form Eq. (3.15) are not entangled. This implication does not carry over to real Hilbert spaces. By the same reasoning used to show that the de Finetti theorem itself fails, the state in Eq. (5.2) cannot be written as *any* mixture of real product states. Interpreted as a state in real Hilbert space, the state in Eq. (5.2) is thus not separable, but rather has entanglement among the component systems.[72] In a real Hilbert space, exchangeable states can be entangled, and local measurements cannot reveal that.

Beyond these conceptual points, we also believe that the technical methods exhibited here might be of interest in the practical arena. Recently there has been a large literature on which classes of measurements have various advantages for tomographic purposes.[73,74] To our knowledge, the present work is the only one to consider tomographic reconstruction based upon minimal informationally complete POVMs. One can imagine several advantages to this approach via the fact that such POVMs with rank-one elements are automatically extreme points in the convex set of all measurements.[75]

Furthermore, the classical de Finetti theorem is only the tip of an iceberg with respect to general questions in statistics to do with exchangeability and various generalizations of the concept.[76] One should expect no less of quantum exchangeability studies. In particular here, we are thinking of things like the question of representation theorems for finitely exchangeable distributions.[52,77] Just as our method for proving the quantum de Finetti theorem was able to rely heavily on the classical theorem, so one might expect similar benefits from the classical results in the case of quantum finite exchangeability—although there will certainly be new aspects to the quantum case due to the possibility of entanglement in finite exchangeable states. A practical application of such representation theorems could be their potential to contribute to the solution of some outstanding problems in constructing security proofs for various quantum key distribution schemes.[78]

In general, our effort in the present article forms part of a larger program to promote a consistent information-based interpretation of quantum mechanics and to delineate its consequences. We find it encouraging that the fruits of this effort might not be restricted solely to an improved understanding of quantum mechanics, but might also possess the potential to contribute to practical applications.

APPENDIX: PROOF OF THE CLASSICAL DE FINETTI THEOREM

In this Appendix we reprise the admirably simple proof of the classical de Finetti representation theorem given by Heath and Sudderth[42] for the case of binary variables.

Suppose we have an exchangeable probability assignment for M binary random variables, $x_1,x_2,\ldots,x_M$, taking on the values 0 and 1. Let $p(n,N)$, $N\leqslant M$, be the probability for n 1s in N trials. Exchangeability guarantees that

$$p(n,N)=\binom{N}{n}p(x_1=1,\ldots,x_n=1,x_{n+1}=0,\ldots,x_N=0). \tag{A1}$$

We can condition the probability on the right on the occurrence of m 1's in all M trials:

$$p(n,N)=\binom{N}{n}\sum_{m=0}^{M} p(x_1=1,\ldots,x_n=1,x_{n+1}=0,\ldots,x_N=0|m,M)p(m,M). \tag{A2}$$

Given m 1's in M trials, exchangeability guarantees that the $\binom{M}{m}$ sequences are equally likely. Thus the situation is identical to drawing from an urn with m 1's on M balls, and we have that

$$p(x_1=1,\ldots,x_n=1,x_{n+1}=0,\ldots,x_N=0|m,M) = \frac{m}{M}\,\frac{m-1}{M-1}\cdots\frac{m-(n-1)}{M-(n-1)}\,\frac{M-m}{M-n}\,\frac{M-m-1}{M-n-1}\cdots\frac{M-m-(N-n-1)}{M-(N-1)}=\frac{(m)_n(M-m)_{N-n}}{(M)_N}, \tag{A3}$$

where

$$(r)_q\equiv\prod_{j=0}^{q-1}(r-j)=r(r-1)\cdots(r-q+1)=\frac{r!}{(r-q)!}. \tag{A4}$$

The result is that

$$p(n,N)=\binom{N}{n}\sum_{m=0}^{M}\frac{(m)_n(M-m)_{N-n}}{(M)_N}p(m,M). \tag{A5}$$

What remains is to take the limit $M\to\infty$, which we can do because of the extendibility property of exchangeable probabilities. We can write $p(n,N)$ as an integral,

$$p(n,N)=\binom{N}{n}\int_0^1\frac{(zM)_n((1-z)M)_{N-n}}{(M)_N}P_M(z)\,dz, \tag{A6}$$

where

$$P_M(z)=\sum_{m=0}^{M}p(zM,M)\,\delta(z-m/M) \tag{A7}$$

is a distribution concentrated at the M-trial frequencies m/M. In the limit $M\to\infty$, $P_M(z)$ converges to a continuous distribution $P_\infty(z)$, and the other terms in the integrand go to $z^n(1-z)^{N-n}$, giving

$$p(n,N)=\binom{N}{n}\int_0^1 z^n(1-z)^{N-n}P_\infty(z)\,dz. \tag{A8}$$

Thus, if $p(n,N)$ is part of an infinite exchangeable sequence, it has a de Finetti representation in terms of a ''probability on probabilities'' $P_\infty(z)$.

To demonstrate the uniqueness of $P_\infty(z)$, recall that the binomial factor in Eq. (A8),

$$\binom{N}{Ny}z^{Ny}(1-z)^{N(1-y)}, \tag{A9}$$

becomes a multiple of $\delta(z-y)$ as N goes to infinity. The constant is determined by a beta function integral,

$$\int_0^1 z^n(1-z)^{N-n}\,dz=\frac{n!(N-n)!}{(N+1)!}, \tag{A10}$$

thus implying that

$$(N+1)\binom{N}{Ny}z^{Ny}(1-z)^{N(1-y)}\to\delta(y-z) \tag{A11}$$

as N goes to infinity. The result is that as N goes to infinity,

$$\frac{p(yN,N)}{1/N}\to P_\infty(y). \tag{A12}$$

What this means is that, in accordance with the first part of the proof, $P_\infty(z)\,dz$ is uniquely determined to be the probability that the frequency of 1's will lie between z and $z+dz$ in an infinite number of trials.

We have demonstrated the classical de Finetti representation theorem for binary variables: If $p(n,N)$ is part of an infinite exchangeable sequence, then it has a unique de Finetti representation in terms of a "probability on probabilities" $P_\infty(z)$. The proof can readily be extended to nonbinary variables.

[16] Few have said this more elegantly than J. B. Hartle, in Am. J. Phys. **36**, 704 (1968). Here we quote the most important passage in that regard. Self-servingly, we have inserted the word "experimental" and substituted the phrase "probabilities of occurrence" for "truth values" to push it into a mildly better agreement with our own point of view:

> The state of a classical system is an objective property of the system and therefore changes only by dynamical laws. A quantum-mechanical state, being a summary of the observers' information about an individual physical system, changes both by dynamical laws and whenever the observer acquires new information about the system through the process of measurement. The existence of two laws for the evolution of the state vector by the Schrödinger equation on the one hand and by the process of measurement (sometimes described as the "reduction of the wave packet") on the other, is a classic subject for discussion in the quantum theory of measurement. The situation becomes problematical only if it is believed that the state vector is an objective property

of the system. Then, the state vector must be required to change only by dynamical law, and the problem must be faced of justifying the second mode of evolution from the first. If, however, the state of a system is defined as a list of [*experimental*] propositions together with their [*probabilities of occurrence*], it is not surprising that after a measurement the state must be changed to be in accord with the new information ... . The ''reduction of the wave packet'' does take place in the consciousness of the observer, not because of any unique physical process which takes place there, but only because the state is a construct of the observer and not an objective property of the physical system.

Compatibility of state assignments

N. David Mermin[a)]
Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca, New York 14853-2501

(Received 16 January 2002; accepted for publication 16 May 2002)

Rudolf Peierls raised the question of when different density matrices can characterize the knowledge available to different people about one and the same physical system. I describe counterexamples to the condition he imposed on such state assignments, and suggest what the correct condition ought to be. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1495897]

According to Rudolph Peierls[1] the answer to the question of what the quantum mechanical formalism represents is ''that the wavefunction or, more generally, the density matrix represents our *knowledge* of the system we are trying to describe.'' Heisenberg took the same position and one can argue that Bohr did, too, though I am unaware of an explicit statement to this effect in his writings. But only Peierls raised and offered an answer to the next question: ''*Whose* knowledge?''

Peierls noted that density matrices describing a system ''may differ, as the nature and amount of knowledge may differ. People may have observed the system by different methods, with more or less accuracy; they may have seen part of the results of another physicist. However, there are limitations to the extent to which their knowledge may differ.... This limitation can be compactly and conveniently expressed by the condition that the density matrices used by the two observers must commute with each other.'' To this he added a second requirement that ''the two observers should not contradict each other. This means the product of the two density matrices should not be zero.'' [2]

So, according to Peierls, if Alice and Bob use density matrices ρ_a and ρ_b to encapsulate what each of them knows about one and the same physical system, then their density matrices must satisfy

$$[\rho_a, \rho_b] = 0 \tag{1}$$

and

$$\rho_a \rho_b \neq 0. \tag{2}$$

While requirement (2) seems fairly straightforward, given (1), I worried about (1) for several years. It had a nice feel to it, but I couldn't see why it had to hold, except in very special cases. There was a time when I went around asking people why the density matrices different people might use to describe the same system had to commute. Nobody could tell me why or even seemed particularly interested in the question, until I put it to Christopher Fuchs. He said he'd think about it. After I kept pestering him by e-mail, he finally wrote that the reason I couldn't understand the condition was that it wasn't true,[3] and he gave me a simple counterexample: Bob knows the system is in one of two nonorthogonal states, but doesn't know which; Alice does know which. For a while I kept inventing objections that Peierls might have raised to this counterexample, but in the end I was able to cast it in a form I feel fairly sure Peierls would have acknowledged to be valid.

a)Electronic mail: ndm4@cornell.edu

Before examining my Peierls-proof version of Fuchs's counterexample, first consider a case where Peierls' criterion (1) does hold. Suppose Alice and Bob start off both knowing that two qubits are in the entangled but not maximally entangled pure state

$$|\Psi\rangle = \cos\theta|0\rangle|0\rangle + \sin\theta|1\rangle|1\rangle, \quad 0 < \theta < \pi/4. \tag{3}$$

Both will use the same reduced density matrix for the qubit on the left:

$$\rho_a = \rho_b = \mathrm{Tr}_r|\Psi\rangle\langle\Psi| = \cos^2\theta\,|0\rangle\langle 0| + \sin^2\theta|1\rangle\langle 1|. \tag{4}$$

If Alice now measures the qubit on the right in the computational basis $\{|0\rangle,|1\rangle\}$, then, depending on the outcome, she can update her knowledge of the qubit on the left to

$$\rho_a' = |0\rangle\langle 0| \quad \text{or} \quad \rho_a' = |1\rangle\langle 1|. \tag{5}$$

If she tells Bob nothing about the result of her measurement, or even whether she made a measurement at all, then his density matrix for the qubit on the left must remain ρ_b. In either of the cases (5) we have $[\rho_a', \rho_b] = 0$. Peierls' condition (1) holds.

But now suppose that before she measures the qubit on the right Alice applies to it a unitary (Hadamard) transformation changing the state (3) of the two-qubit system into

$$\begin{aligned} |\Psi\rangle' &= \cos\theta|0\rangle\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) + \sin\theta|1\rangle\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \\ &= \frac{1}{\sqrt{2}}(\cos\theta\,|0\rangle + \sin\theta|1\rangle)|0\rangle + \frac{1}{\sqrt{2}}(\cos\theta\,|0\rangle - \sin\theta|1\rangle)|1\rangle. \end{aligned} \tag{6}$$

This by itself leaves both their reduced density matrices ρ_b and ρ_a for the qubit on the left unchanged. But if Alice now measures the qubit on the right in the computational basis, depending on the outcome, she can update her knowledge of the qubit on the left to

$$\rho_a' = (\cos\theta|0\rangle \pm \sin\theta|1\rangle)(\cos\theta\langle 0| \pm \sin\theta\langle 1|) = \rho_b \pm \cos\theta\sin\theta(|0\rangle\langle 1| + |1\rangle\langle 0|). \tag{7}$$

Either outcome violates Peierls' condition (1):

$$[\rho_b, \rho_a'] = \pm\tfrac{1}{4}\sin 4\theta(|0\rangle\langle 1| - |1\rangle\langle 0|) \neq 0. \tag{8}$$

I believe Peierls would have accepted this as a valid counterexample because all of Alice's actions are applied only to the qubit on the right and Bob knows nothing about those actions and their outcomes, or even whether there were any actions at all. So unless one takes a very literal view of ''quantum nonlocality'' (as Peierls did not), insisting that Alice's actions on the right have disrupted the qubit on the left, thereby rendering Bob's knowledge of it obsolete, one must acknowledge that Alice did nothing to affect the validity of Bob's knowledge of the qubit on the left. She merely took advantage of an opportunity to refine her own knowledge of that qubit in an entirely noninvasive way, by acting only on the qubit on the right. Since Bob is ignorant of what Alice did to the qubit on the right or even whether she did anything at all to it, he has acquired no new information to refine his knowledge of the qubit on the left. Since nothing has been done to that qubit, he must therefore continue to describe it with the same density matrix, ρ_b.

But although Peierls' first requirement (1) is overly restrictive, his second requirement (2) remains valid even in the absence of his first, in that it is equivalent to requiring that there should be no measurement that Alice knows *must* have a certain outcome while Bob knows that it *cannot* have that same outcome.

To see this, note first that if (2) fails to hold, so that $\rho_a\rho_b = 0$, then since density matrices are Hermitian we also have $\rho_b\rho_a = 0$, so ρ_a and ρ_b do indeed commute, and there is a basis of joint

eigenstates. The vanishing of $\rho_a\rho_b$ requires at least one of ρ_a and ρ_b to have zero eigenvalue for each eigenstate, so we can resolve the identity (not necessarily uniquely) into the sum of two projections, $1=P_a+P_b$ where P_a and P_b project onto subspaces of eigenstates of ρ_a and ρ_b with eigenvalue zero. The outcomes of any measurement that discriminates between these two orthogonal subspaces will be assigned probabilities 1 or 0 by Alice, and 0 or 1 by Bob. Whatever outcome Alice knows must happen Bob knows cannot happen, and vice versa.

Conversely, and somewhat less trivially, suppose there is some measurement with some outcome that Alice gives probability 0 and Bob gives probability 1. This means there is some Hermitian operator M with eigenvalues m in the range[4]

$$0\leqslant m\leqslant 1 \tag{9}$$

with

$$\mathrm{Tr}\rho_a M=0, \quad \mathrm{Tr}\rho_b M=1. \tag{10}$$

If the eigenstates of M are $|\phi_j\rangle$ with eigenvalues m_j, then expanding (10) in the basis of those eigenstates gives

$$\sum_j \langle\phi_j|\rho_a|\phi_j\rangle m_j=0, \tag{11}$$

and

$$\sum_j \langle\phi_j|\rho_b|\phi_j\rangle m_j=1, \tag{12}$$

or, since $\mathrm{Tr}\rho_b=1$,

$$\sum_j \langle\phi_j|\rho_b|\phi_j\rangle(1-m_j)=0. \tag{13}$$

Since the diagonal matrix elements of ρ_a and ρ_b are non-negative and since the m_j satisfy (9), we conclude from (11) and (13) that

$$\langle\phi_j|\rho_a|\phi_j\rangle=0, \quad m_j\neq 0, \tag{14}$$

$$\langle\phi_j|\rho_b|\phi_j\rangle=0, \quad m_j\neq 1. \tag{15}$$

But if $\langle\phi|\rho|\phi\rangle=0$ for a positive operator ρ, then $\rho|\phi\rangle=0$, so (14) and (15) require every eigenstate $|\phi_k\rangle$ of M to be an eigenstate with zero eigenvalue of either ρ_a or ρ_b. It follows that

$$\langle\phi_i|\rho_a\rho_b|\phi_j\rangle=\sum_k \langle\phi_i|\rho_a|\phi_k\rangle\langle\phi_j|\rho_b|\phi_k\rangle^* \tag{16}$$

must be zero for arbitrary i and j. Since the $|\phi_i\rangle$ are a complete set, we then have $\rho_a\rho_b=0$.

So the existence of at least one measurement with at least one outcome that Alice's density matrix forbids and Bob's requires (or vice versa) means that the product of their density matrices must vanish. Peierls's second requirement (2) is valid even in the absence of his first requirement (1), as a direct expression of the condition that Alice and Bob should not uncover a logical contradiction when they compare what their knowledge implies about the outcomes of measurements made on one and the same system $\mathcal{S}$.

Is (2) the only constraint implied by the requirement that their knowledge not be contradictory?[5] This might appear plausible, since outright contradictions only involve probabilities 0 or 1: if Alice assigns probability 0 to an outcome that Bob assigns any probability less than

1, the failure of the outcome to occur contradicts neither assignment. But the logical structure of quantum mechanics leads to a broader set of restrictions than (2), provided we impose the following compatiblity condition on what different people know about the same system $\mathcal{S}$.[6]

Let us say that the knowledge Alice, Bob, Carol, Dick,... have about one and the same system $\mathcal{S}$ is *compatible* if there is some density matrix ρ that combines all their judgments about impossible outcomes, assigning zero probability to any outcome of any measurement that any one of them assigns zero probability. In particular, under this definition the knowledge of Alice and Bob is incompatible if Alice knows that an outcome of a measurement has probability 0 while Bob knows that the same outcome of that same measurement has probability 1. For Bob then also knows that all the other possible outcomes have probability 0. So any density matrix ρ assigning zero probability to all the outcomes that either one of them assigns zero probability would have to assign zero probability to all possible outcomes, which violates the requirement that $\mathrm{Tr}\rho=1$.

But these are not the only conditions under which there is no density matrix that incorporates all their judgments of impossible outcomes. To formulate the broader condition, let us say that a given pure state is the outcome of a measurement if the projection operator on that state is measured and the result is 1.[7] A state $|\phi\rangle$ is forbidden by a density matrix ρ to be the outcome of a measurement if $\langle\phi|\rho|\phi\rangle=0$. Because ρ is a positive operator any such forbidden state is an eigenstate of ρ with zero eigenvalue, so the set $N(\rho)$ of all forbidden states is a subspace of the state space, called the *null space* of ρ. The orthogonal complement of $N(\rho)$, the subspace $S(\rho)$ spanned by all the eigenvectors of ρ with nonzero eigenvalues, is called the *support* of ρ.

If a group of density matrices ρ_a, ρ_b, ρ_c,... describe compatible knowledge of a system $\mathcal{S}$, then there must be some density matrix ρ whose null space $N(\rho)$ contains all the null spaces $N(\rho_a),N(\rho_b),N(\rho_c),\ldots$. Since $\mathrm{Tr}\rho\neq 0$, its support $S(\rho)$ cannot be empty. Any vector $|\phi\rangle$ in $S(\rho)$ must be orthogonal to any vector in $N(\rho)$ and therefore orthogonal to any vector in $N(\rho_a),N(\rho_b),N(\rho_c),\ldots$. It must therefore be in all the supports $S(\rho_a),S(\rho_b),S(\rho_c),\ldots$. We conclude that *for a set of density matrices to be compatible, their supports must all have at least one state in common.*

What about a converse proposition? If a set of density matrices is compatible in this sense, can there be circumstances under which they actually do represent the knowledge available to Alice, Bob, Carol,... about one and the same physical system? If the state space is finite dimensional, then, if all their supports do have a state in common, such circumstances can indeed arise. To see this we first note the following.[8]

Consider an expansion of a density matrix ρ in orthonormal projections onto its eigenvectors with nonzero eigenvalue:

$$\rho=\sum_i r_i|\psi_i\rangle\langle\psi_i|. \tag{17}$$

If the dimension of the support $S(\rho)$ is finite, then the positive r_i appearing in (17) are all bounded away from 0 by some $r_0>0$, and we can define a positive s_i by

$$s_i=r_i-r_0, \tag{18}$$

in terms of which

$$\rho=\sum_i s_i|\psi_i\rangle\langle\psi_i|+r_0P, \tag{19}$$

where P is the projection operator onto $S(\rho)$. If $|\phi\rangle$ is any unit vector in $S(\rho)$, then one can find an orthonormal basis $|\eta_i\rangle$ for $S(\rho)$ with $|\eta_0\rangle=|\phi\rangle$. Since

$$P=\sum_i |\eta_i\rangle\langle\eta_i|, \tag{20}$$

it follows that ρ has an expansion (not necessarily unique, in not necessarily orthogonal states) in which $|\phi\rangle$ appears with nonzero weight:

$$\rho = p|\phi\rangle\langle\phi| + \sum p_i|\phi_i\rangle\langle\phi_i|, \quad p>0, \ p_i \geqslant 0. \tag{21}$$

So if the supports of ρ_a and ρ_b share a common state $|\phi\rangle$, then Alice and Bob's density matrices have expansions of the form (21),

$$\rho_a = p_a|\phi\rangle\langle\phi| + \sum_{i\geqslant 1} p_{ai}|\phi_{ai}\rangle\langle\phi_{ai}|,$$

$$\rho_b = p_b|\phi\rangle\langle\phi| + \sum_{i\geqslant 1} p_{bi}|\phi_{bi}\rangle\langle\phi_{bi}|, \tag{22}$$

$$p_a, p_b, p_{ai}, p_{bi} > 0,$$

which share a common state $|\phi\rangle$. These density matrices can indeed represent the knowledge Alice and Bob have of one and the same system $\mathcal{S}$ under the following circumstances.[9]

Let there be two more systems, $\mathcal{S}_a$ and $\mathcal{S}_b$, with both Alice and Bob's knowledge of $\mathcal{S}_a + \mathcal{S}_b + \mathcal{S}$ initially described by the pure state

$$|\Psi\rangle \propto |a_0\rangle|b_0\rangle|\phi\rangle + \sum_{i\geqslant 1} \sqrt{p_{ai}/p_a}|a_0\rangle|b_i\rangle|\phi_{ai}\rangle + \sum_{i\geqslant 1} \sqrt{p_{bi}/p_b}|a_i\rangle|b_0\rangle|\phi_{bi}\rangle, \tag{23}$$

where $\{|a_n\rangle\}$ and $\{|b_n\rangle\}$ are orthonormal bases for $\mathcal{S}_a$ and $\mathcal{S}_b$. Alice has access only to $\mathcal{S}_a$ and Bob only to $\mathcal{S}_b$. Each of them knows that nobody has access to $\mathcal{S}$.

Suppose Alice measures on $\mathcal{S}_a$ the nondegenerate observable A with eigenstates $|a_0\rangle, |a_1\rangle, |a_2\rangle, \ldots$, and finds the result associated with $|a_0\rangle$, while Bob measures an analogous observable, B, on $\mathcal{S}_b$ and finds the result associated with $|b_0\rangle$, neither knowing what, if anything, the other did.

Alice will then assign to $\mathcal{S}_b + \mathcal{S}$ the state

$$|\Psi_a\rangle \propto |b_0\rangle|\phi\rangle + \sum \sqrt{\frac{p_{ai}}{p_a}}|b_i\rangle|\phi_{ai}\rangle, \tag{24}$$

leading to the reduced density matrix for $\mathcal{S}$,

$$p_a|\phi\rangle\langle\phi| + \sum p_{ai}|\phi_{ai}\rangle\langle\phi_{ai}| = \rho_a, \tag{25}$$

while Bob will assign to $\mathcal{S}_a + \mathcal{S}$ the state

$$|\Psi_b\rangle \propto |a_0\rangle|\phi\rangle + \sum \sqrt{\frac{p_{bi}}{p_b}}|a_i\rangle|\phi_{bi}\rangle, \tag{26}$$

leading to the reduced density matrix for $\mathcal{S}$,

$$p_b|\phi\rangle\langle\phi| + \sum p_{bi}|\phi_{bi}\rangle\langle\phi_{bi}| = \rho_b. \tag{27}$$

In order for their reduced density matrices for $\mathcal{S}$ to have these desired forms, Alice and Bob must find the appropriate outcomes for their measurements of $\mathcal{S}_a$ and $\mathcal{S}_b$. This is not under anybody's control, but the probability of it happening is nonzero, if p_a and p_b in (21) are both

nonzero. So there can be circumstances under which Alice and Bob will end up assigning the density matrices ρ_a and ρ_b to $\mathcal{S}$. The probability of such circumstances arising under this protocol will, of course, be very small if one or the other member of all possible pairs of common states in all possible expansions (21) of ρ_a and ρ_b has a very small weight.

This construction generalizes to any number of observers. For Alice, Bob, and Carol, for example, we can take $\mathcal{S}_a+\mathcal{S}_b+\mathcal{S}_c+\mathcal{S}$ to be initially in the state

$$|\Psi\rangle\propto|a_0\rangle|b_0\rangle|c_0\rangle|\phi\rangle+\sum_{i\geqslant 1}\sqrt{p_{ai}/p_a}|a_0\rangle|b_i\rangle|c_i\rangle|\phi_{ai}\rangle+\sum_{i\geqslant 1}\sqrt{p_{bi}/p_b}|a_i\rangle|b_0\rangle|c_i\rangle|\phi_{bi}\rangle$$

$$+\sum_{i\geqslant 1}\sqrt{p_{ci}/p_c}|a_i\rangle|b_i\rangle|c_0\rangle|\phi_{ci}\rangle, \tag{28}$$

and then follow the obvious generalization of the Alice–Bob protocol.

We conclude that if the supports of a group of density matrices share a common state, then there can be circumstances under which each density matrix describes the knowledge available to a particular observer of one and the same physical system. But if there is no pure state common to all the supports, then there can be no density matrix that assigns zero probability to every measurement outcome that any one of the observers assigns zero probability; the combined knowledge of the individual observers cannot be reconciled with any quantum-mechanically consistent description of the system.

As a special case of this conclusion, note that since the support of a pure-state density matrix is the one-dimensional subspace spanned by that state, two pure-state density matrices are compatible in this sense only if they are identical: pure state assignments (and only pure state assignments) are unique. If one takes the view that pure states are objective physical properties of the system they describe, this conclusion has very little content. But if, following Peierls, Heisenberg, and perhaps Bohr, one takes the view that a quantum state characterizes the knowledge of the system available to a particular observer, then whether pure-state assignments must be unique becomes a nontrivial question. From the perspective described above their uniqueness follows from the fact that if some body of knowledge about a system leads to the pure state $|\psi\rangle$, then no state orthogonal to $|\psi\rangle$ can be the outcome of a measurement on the system. If a different subset of all the available knowledge of the system leads to the assignment of a different pure state $|\psi'\rangle$, then no state orthogonal to $|\psi'\rangle$ can occur as the outcome of a measurement. But the laws of quantum mechanics require that any superposition of zero-probability outcomes must also have zero probability. Since the states orthogonal to two distinct states span the entire state space, if different subsets of the available knowledge justified two different pure-state assignments, no state whatever could occur as the outcome of a measurement.

One might argue that nobody can ever know with certainty that any outcome of any measurement is strictly impossible. The support of any realistic density matrix would then be the entire Hilbert space, and all these conditions would be vacuous—any set of density matrices would be mutually compatible, though the probability of measurement outcomes leading to such state assignments could be minuscule. But although the quantum theory is inherently probabilistic, the theory is also capable of deterministic assertions, which strictly prohibit certain measurement outcomes under ideal conditions. It is surely a significant feature of that theory that consideration of impossible outcomes leads, without any invocation of ''the uncertainty principle'' or ''maximal information,'' to the uniqueness of pure-state assignments, as well as the more general constraint on mixed-state assignments.

ACKNOWLEDGMENTS

My understanding of these questions has benefited from communications with Todd Brun, Carlton Caves, Jerry Finkelstein, Christopher Fuchs, Rüdiger Schack, and Benjamin Schumacher. This work was supported by the National Science Foundation Grant No. PHY0098429.

[4] For an ordinary von Neumann measurement M is just a projection operator. By allowing the eigenvalues of M to be in the interior as well as the end points of the interval $[0,1]$ we can cover the case where the problematic measurement is of a more general kind (a POVM).
[5] I raised this question in N. David Mermin, "Whose Knowledge?" in *Quantum (Un)speakables: Essays in Commemoration of John S. Bell*, edited by R. Bertlmann and A. Zeilinger (Springer Verlag, New York, 2002); quant-ph/0107051.
[6] Almost immediately after Ref. 5 appeared on the ePrint Archive, I received apparently different answers to the question from Todd Brun and Jerry Finkelstein. Those answers and a proof of their equivalence were given in T. A. Brun, J. Finkelstein, and N. D. Mermin, Phys. Rev. A **65**, 032315 (2002); quant-ph/0109041. The derivation that follows is essentially that of Ref. 6, though I have modified the formulation of that derivation in response to criticisms raised by C. Caves, C. Fuchs, and R. Schack (private communication).
[7] This does not, of course, imply anything about the state of the system prior to the measurement.
[8] This was first schown by E. Schrödinger, Proc. Cambridge Philos. Soc. **32**, 446 (1936). Schrödinger does not explicitly require the state space to be finite dimensional, but some such condition is required to validate his assumption that any density matrix has an inverse when restricted to its support.
[9] In general, such a pair of density matrices will not commute, so this construction provides a large class of counterexamples to Peierls-first condition (1).

Behavior of the survival probability in some one-dimensional problems

(Received 5 February 2002; accepted for publication 3 April 2002)

We study the behavior of the survival probability $P_\varphi(t)$ in potential barrier problems on the half-line. We consider two cases: when the initial state φ is a truncated outgoing solution corresponding to a scattering frequency and when it is an approximate bound state. Using techniques and methods from Spectral Theory, Fourier Analysis, and from Ordinary Differential Equations, we obtain approximate exponential decay in both cases. © *2002 American Institute of Physics.*

I. INTRODUCTION

In the usual mathematical formalism in Quantum Mechanics, the *Survival Probability*,

$$P_\varphi(t)=|\langle \varphi, e^{-iHt}\varphi\rangle|^2, \tag{1.1}$$

represents the probability that, at time t, the system is in its initial state φ. Here, H is a self-adjoint operator on a Hilbert space $\mathcal{H}$ and φ is a state, that is, a unit vector in $\mathcal{H}$.

If the operator H is absolutely continuous then, by the Riemann–Lebesgue Lemma, $P_\varphi(t)$ tends to 0 when $|t|$ approaches ∞. The rate of decay of this quantity is relevant from a physical point of view.

Here, we study the behavior of $P_\varphi(t)$ in potential barrier problems in the half-line. First we consider an outgoing solution corresponding to a scattering frequency near the real axis. We show that if φ is a truncated resonant solution, then $P_\varphi(t)$ has an approximate exponential behavior. This result, in this sense of the L^∞-norm appears in Ref. 6. In Sec. III we establish estimates in terms of the L^2-norm, while in Sec. II we prove a formula for computing the spectral measure, for a general potential with compact support.

In the last section, we study the following related problem. Suppose that H is Hamiltonian in the half-line, for a nonnegative potential with compact support. When the potential has a barrier with a long width, H will be close, in a large interval, to a Hamiltonian H^∞ having a bound state φ. We prove that in this case $P_\varphi(t)$ also behaves almost exponentially.

For the sake of completeness we recall some results for general self-adjoint operators. If H is an absolutely continuous self-adjoint operator on a Hilbert space $\mathcal{H}$, then its spectral measure E_λ can be represented as

$$p_\varphi(\lambda)\equiv\frac{d\langle \varphi, E_\lambda\varphi\rangle}{d\lambda}=\frac{1}{\pi}\lim_{\delta\to 0+}\ \mathrm{Im}\langle \varphi,(H-\lambda-i\delta)^{-1}\varphi\rangle, \tag{1.2}$$

for any unit vector φ in a dense subspace of $\mathcal{H}$. The Fourier transform of this expression is precisely,

[a]Electronic mail: angelica@mat.puc.cl

$$\langle \varphi, e^{-iHt}\varphi\rangle = \frac{1}{\pi}\int_{-\infty}^{\infty} e^{-i\lambda t}\,\mathrm{Im}\langle \varphi,(H-\lambda-i0)^{-1}\varphi\rangle d\lambda, \tag{1.3}$$

where we have used the notation,

$$\mathrm{Im}\langle \varphi,(H-\lambda-i0)^{-1}\varphi\rangle = \lim_{\delta\to 0+}\ \mathrm{Im}\langle \varphi,(H-\lambda-i\delta)^{-1}\varphi\rangle.$$

Our goal is to prove that in the resonant case, the probability $P(t)=|\langle \varphi, e^{-iHt}\varphi\rangle|^2$ has an almost exponential behavior. More explicitly, we shall estimate,

$$\int_{-\infty}^{\infty} \left|\langle \varphi, e^{-iHt}\varphi\rangle - e^{-i\lambda_0 t}e^{-\epsilon|t|}\right|^2 dt,$$

for adequate φ, λ_0, and ϵ.

Our approach follows the ideas of Lavine,[6] who proved that when φ is a normalized truncated resonant state (see Sec. III), then, for all time t,

$$\left|\langle \varphi, e^{-iHt}\varphi\rangle - e^{-i\lambda_0 t}e^{-\epsilon|t|}\right| \leqslant c\,\epsilon\left|\ln \epsilon\right|,$$

where $\lambda_0 - i\epsilon$ is the corresponding resonance.

The almost exponential behavior, in the sense of the L^2-norm, turns out to give also an explicit estimate on the size of the sojourn time $\tau(\varphi)$, in terms of the imaginary part of the resonance.

Lavine's approach is time-independent and it is based on (1.3), which establishes the fact that the unitary group e^{-iHt} is the Fourier transform of limiting values of the resolvent $R(z)$, as z approaches the real axis.

On the other hand,

$$\begin{aligned} e^{-i\lambda_0 t}e^{-\epsilon|t|} &= \frac{1}{\pi}\int_{-\infty}^{\infty} e^{-i\lambda t}\,\mathrm{Im}(\lambda-\lambda_0-i\epsilon)d\lambda \\ &= \frac{1}{\pi}\int_{-\infty}^{\infty} e^{-i\lambda t}\frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}d\lambda. \end{aligned}$$

By Plancherel's Theorem, we then have that

$$\begin{aligned} &\int_{-\infty}^{\infty} \left|\langle \varphi, e^{-iHt}\varphi\rangle - e^{-i\lambda_0 t}e^{-\epsilon|t|}\right|^2 dt \\ &\quad = \left(\frac{1}{\pi}\right)^2 \int_{-\infty}^{\infty} \left|\mathrm{Im}\langle \varphi,(H-\lambda-i0)^{-1}\varphi\rangle - \frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}\right|^2 d\lambda. \end{aligned}$$

It is sufficient then to estimate the L^2-norm of the difference between the imaginary part of the resolvent in the real axis and the Lorentzian $\epsilon/[(\lambda-\lambda_0)^2+\epsilon^2]$, for adequate values of ϵ.

As indicated by Lavine in Ref. 10, the integrand is singular in $\lambda=0$. In Ref. 9 he estimates the L^1-norm of this difference and in Ref. 10 he proposes to truncate the state in energy away from the origin in order to handle the L^2-norm. Here we manage to estimate it for all energy λ.

We mention Refs. 3, 7, 8, and 11–13 for results on decay in presence of a resonant state. Also, Refs. 4–6 for a different characterization of the resonance phenomena.

II. THE SPECTRAL MEASURE

Let H_0 be the (negative) Laplace operator on the half-line $[0, \infty)$, with the Dirichlet boundary condition at the origin. Then, H_0 is a self-adjoint operator on $L^2[0,\infty)$, with domain $\mathcal{H}^2\cap\mathcal{H}_0^1$. We consider a perturbation $H=H_0+V(x)$, where $V(x)$ is a non-negative bounded potential with compact support. This operator is the total Hamiltonian for a quantum mechanical particle in the half-line, moving under the influence of the potential $V(x)$.

If we prescribe the Dirichlet boundary condition at the origin, then H is also a self-adjoint operator on L^2. Moreover, H is positive and absolutely continuous, with spectrum $[0, \infty]$.

We first study the resolvent of the operator H. To this end, given a complex number $z=\lambda+i\delta$ with $\delta\geqslant 0$ and $\lambda>0$, we consider two solutions $\psi_1(x,z)$ and $\psi_2(x,z)$ of the homogeneus equation,

$$-\psi''+V(x)\psi-z\psi=0, \quad x\geqslant 0 \tag{2.1}$$

satisfying the initial conditions,

$$\psi_1(0,z)=0, \psi_1'(0,z)=1,$$

and

$$\psi_2(x,z)=ce^{i\sqrt{z}x} \quad \text{for } x\geqslant R,$$

where c is chosen such that $\psi_2(0,z)=1$.

Here, R is such that the support of V is contained in the interval $[0,R)$. Also, we are choosing the square root in such a way that $\operatorname{Im}\sqrt{z}>0$, for $\delta>0$.

Lemma 2.1: Suppose that $\delta>0$. Given $\varphi\in L^2$, the function,

$$\psi(x,z)=-\left\{\psi_1(x,z)\int_x^\infty \psi_2(y,z)\varphi(y)dy+\psi_2(x,z)\int_0^x \psi_1(y,z)\varphi(y)dy\right\} \tag{2.2}$$

is the solution of the problem,

$$-\psi''+V(x)\psi-z\psi=\varphi, \quad x\geqslant 0, \tag{2.3}$$

$$\psi(0)=0, \tag{2.4}$$

$$\psi\in L^2. \tag{2.5}$$

In other words, ψ is precisely the resolvent $(H-z)^{-1}\varphi$.

Proof: It follows immediately from variation of parameters. □

Lemma 2.2: Suppose that $z=\lambda>0$. Given $\varphi\in L^1\cap L^2$, the function,

$$\psi(x,\lambda)=-\left\{\psi_1(x,\lambda)\int_x^\infty \psi_2(y,\lambda)\varphi(y)dy+\psi_2(x,\lambda)\int_0^x \psi_1(y,\lambda)\varphi(y)dy\right\} \tag{2.6}$$

is a solution of the problem,

$$-\psi''+V(x)\psi-\lambda\psi=\varphi, \quad x\geqslant 0, \tag{2.7}$$

$$\psi(0)=0, \tag{2.8}$$

$$\psi\in L^\infty. \tag{2.9}$$

Moreover, $\langle\varphi,\psi(\cdot,\lambda+i\delta)\rangle$ converges to $\langle\varphi,\psi(\cdot,\lambda)\rangle$, when δ approaches 0.

Proof: The function $\psi(x,\lambda)$ clearly satisfies the differential equation and the initial condition. Moreover, for real λ all the solutions are bounded. The last assertion follows from the Dominated Convergence Theorem. □

The following result is straightforward:

Lemma 2.3: Suppose that $0\leqslant a<b$ and let $V_1(x)$ be a function in $L^\infty(a,b)$. Assume that φ is a solution of

$$-\varphi''+V_1(x)\varphi=z_1\varphi, \quad \text{for } x\in(a,b).$$

Then

$$W(\psi_i(\cdot,\lambda),\varphi)\Big|_a^b=\int_a^b (V(x)-V_1(x)+z_1-\lambda)\psi_i(x,\lambda)\varphi(x))dx. \tag{2.10}$$

Lemma 2.4: Given $\varphi\in L^1[0,\infty]\cap Ł^2[0,\infty]$, *the spectral measure of the operator H satisfies*

$$\frac{d\langle\varphi,E_\lambda\varphi\rangle}{d\lambda}=\frac{1}{\pi}\mathrm{Im}\langle\varphi,\psi(\cdot,\lambda)\rangle, \tag{2.11}$$

where $\psi(\cdot,\lambda)$ *is given by Lemma 2.2.*

Proof: It follows from (1.3) and Lemma 2.2. □

The above result is an explicit formula for the Radon Nikodym derivative of the spectral measure that works on a dense subset of the Hilbert space. For an explicit potential $V(x)$, the integral that appears in this formula will be computed with the aid of Lemma 2.3.

III. ESTIMATES FOR RESONANT SOLUTIONS

Let k be a *scattering frequency* for $-(d^2/dx^2)+V(x)$ and let $z=k^2=\lambda_0-i\epsilon$.
This means that ψ is a nontrivial outgoing [i.e. $\psi(x)=ce^{ikx}$, for $x\geqslant R$] solution of

$$-\frac{d^2}{dx^2}\psi+V(x)\psi=z\psi,\quad 0<x, \tag{3.1}$$

$$\psi(0)=0. \tag{3.2}$$

We choose the constant c in such a way that $\varphi=\chi_{[0,R]}\psi$ satisfies

$$\int_0^R|\varphi(x)|^2dx=1.$$

Lemma 3.1: The spectral measure of the operator $H=(-d^2/dx^2)+V(x)$ *at the state* φ *satisfies*

$$\pi\frac{d\langle\varphi,E_\lambda\varphi\rangle}{d\lambda}-\frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}=\frac{1}{|z-\lambda|^2}\mathrm{Im}\,W(\psi_2,\varphi)W(\psi_1,\overline{\varphi})(R). \tag{3.3}$$

Proof: By Lemma 2.4, we have that

$$\pi\frac{d}{d\lambda}\langle\varphi,E_\lambda\varphi\rangle=-\mathrm{Im}\Bigg[\int_0^\infty\overline{\varphi}(x)\psi_1(x)\int_x^\infty\psi_2(y)\varphi(y)dydx + \int_0^\infty\overline{\varphi}(x)\psi_2(x)\int_0^x\psi_1(y)\varphi(y)dydx\Bigg].$$

We call I_1 and I_2 the two expressions inside the square brackets. Since $\varphi\equiv 0$ for $x>R$, it follows that

$$I_1=\int_0^R\overline{\varphi}(x)\psi_1(x)\int_x^R\psi_2(y)\varphi(y)dydx,$$

$$I_2=\int_0^R\overline{\varphi}(x)\psi_2(x)\int_0^x\psi_1(y)\varphi(y)dydx.$$

By Lemma 2.3, we obtain

$$\int_x^R \psi_2(y)\varphi(y)dy = \frac{1}{\lambda - z} W(\psi_2, \varphi)|_x^R,$$

$$\int_0^x \psi_1(y)\varphi(y)dy = \frac{1}{\lambda - z} W(\psi_1, \varphi)|_R^x,$$

and substituting these expressions we obtain

$$I_1 + I_2 = \frac{1}{\lambda - z} \int_0^R \overline{\varphi}(x)\{\psi_1(x) W(\psi_2, \varphi)|_x^R + \psi_2(x) W(\psi_1, \varphi)|_0^x\} dx.$$

If we call $B(x)$ the expression in brackets, then

$$B(x) = \psi_1(x) W(\psi_2, \varphi)(R) - \psi_1(x)(\psi_2(x)\varphi'(x) - \psi_2'(x)\varphi(x)) + \psi_2(x)(\psi_1(x)\varphi'(x) - \psi_1'(x)\varphi(x)),$$

since $W(\psi_1, \varphi)(0) = 0$. After some cancellations we get,

$$B(x) = \psi_1(x) W(\psi_2, \varphi)(R) + W(\psi_1, \psi_2)(x)\varphi(x).$$

But the Wronskian of ψ_1, ψ_2 is constant,

$$W(\psi_1, \psi_2)(x) = W(\psi_1, \psi_2)(0) = -1.$$

Hence,

$$B(x) = \psi_1(x) W(\psi_2, \varphi)(R) - \varphi(x)$$

and

$$I_1 + I_2 = \frac{W(\psi_2, \varphi)(R)}{\lambda - z} \int_0^R \overline{\varphi}(x)\psi_1(x)dx - \frac{1}{\lambda - z},$$

since $\int_0^R |\varphi(x)|^2 dx = 1$;

We use Lemma 2.3 again to obtain that

$$\int_0^R \overline{\varphi(x)}\psi_1(x)dx = \frac{1}{\overline{z} - \lambda} W(\psi_1, \overline{\varphi})(R). \tag{3.4}$$

Hence,

$$I_1 + I_2 = -\frac{1}{|z - \lambda|^2} W(\psi_2, \varphi) W(\psi_1, \overline{\varphi})(R) - \frac{1}{\lambda - z}. \tag{3.5}$$

Finally, we compute the imaginary part and obtain the desired result.

□

We again use the fact that the Wronskian $W(\psi_1, \psi_2)$ is constant to obtain that

$$W(\psi_2,\varphi)W(\psi,\overline{\varphi})(R)=\frac{(\psi_2\varphi'-\psi_2'\varphi)(\psi_1\overline{\varphi}'-\psi_1'\overline{\varphi})}{\psi_1\psi_2'-\psi_1'\psi_2}(R)$$

$$=|\varphi(R)|^2\frac{\left(\frac{\varphi'}{\varphi}-\frac{\psi_2'}{\psi_2}\right)\left(\frac{\overline{\varphi}'}{\overline{\varphi}}-\frac{\psi_1'}{\psi_1}\right)}{\frac{\psi_2'}{\psi_2}-\frac{\psi_1'}{\psi_1}}(R). \tag{3.6}$$

Let us introduce the notation,

$$\beta=\frac{\varphi'(R)}{\varphi(R)}$$

and

$$\beta_1=\beta_1(\lambda)=\frac{\psi_1'(R)}{\psi_1(R)}.$$

Also, ψ_2 is known explicitly, for $R\leqslant x$, therefore,

$$W(\psi_2,\varphi)W(\psi_1\overline{\varphi})(R)=|\varphi(R)|^2\frac{(\beta-i\sqrt{\lambda})(\overline{\beta}-\beta_1)}{i\sqrt{\lambda}-\beta_1}$$

$$=|\varphi(R)|^2\frac{(\beta-i\sqrt{\lambda})(\overline{\beta}-i\sqrt{\lambda}+i\sqrt{\lambda}-\beta_1)}{i\sqrt{\lambda}-\beta_1}$$

$$=|\varphi(R)|^2\frac{(\beta-i\sqrt{\lambda})(-\beta_1-i\sqrt{\lambda})}{i\sqrt{\lambda}-\beta_1}+\frac{|\beta-i\sqrt{\lambda}|^2}{i\sqrt{\lambda}-\beta_1}. \tag{3.7}$$

Theorem 3.1: *Suppose that k is a scattering frequency for* $-(d^2/dx^2)+V(x)$. *Then,*

$$\int_{-\infty}^{\infty}\left|\langle\varphi,e^{-iHt}\varphi\rangle-e^{-i\lambda_0 t}e^{-\epsilon|t|}\right|^2dt\leqslant c\,\epsilon.$$

Proof: Consider the function,

$$f(\lambda)=\mathrm{Im}\langle\varphi,(H-\lambda-i0)^{-1}\varphi\rangle-\frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}.$$

We note that for λ negative,

$$f(\lambda)=\frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}.$$

Our starting point is the following pointwise estimate, which is a direct consequence of Lemma 3.1 and the identity (3.7)

$$|f(\lambda)| \leqslant \left\{ |i\sqrt{\lambda} - \beta(R)| + \frac{|i\sqrt{\lambda} - \beta(R)|^2}{(\beta_1(R)^2 + \lambda)^{1/2}} \right\} \frac{|\varphi(R)|^2}{(\lambda - \lambda_0)^2 + \epsilon^2},$$

for positive λ.

Also, given $\lambda \geqslant 0$, $\psi_1 = \psi_1(x,\lambda)$ is a nontrivial real-valued solution of the eigenvalue equation,

$$-\frac{d^2}{dx^2}\psi + V(x)\psi = \lambda\psi, \quad 0 < x,$$

with $\psi(0) = 0$.

In this particular case the potential is supported on the interval $[0,R]$, hence $\beta = i\sqrt{\lambda_0 - i\epsilon}$.

Moreover, since,

$$(\operatorname{Im} \overline{\varphi}\varphi')' = \operatorname{Im} \overline{\varphi}(V - k^2)\varphi = \epsilon|\varphi|^2,$$

we obtain, by integrating over $[0, R]$,

$$|\varphi(R)|^2 = \frac{\epsilon}{\operatorname{Im} \beta(R)} = \frac{\epsilon}{\operatorname{Re} \sqrt{\lambda_0 - i\epsilon}}.$$

Using this, we can estimate the L^2-norm of $f(\lambda)$, by separating the integral with respect to λ in four pieces: $(-\infty, 0)$, $(0,\lambda_0/2)$, $(\lambda_0/2,3\lambda_0/2)$, $(3\lambda_0/2,\infty)$.

For $\lambda < 0$,

$$\int_{-\infty}^{0} |f(\lambda)|^2 d\lambda \leqslant \frac{\epsilon^2}{3\lambda_0^3}.$$

On the interval $(3\lambda_0/2,\infty)$, we use $\operatorname{Re} \sqrt{\lambda_0 - i\epsilon} > \sqrt{\lambda_0/2}$ and $|\sqrt{\lambda} - \sqrt{\lambda_0 - i\epsilon}| < \sqrt{[(\lambda - \lambda_0)^2 + \epsilon^2]/\lambda}$. Also neglect the term β_1^2, and get

$$|f(\lambda)| \leqslant \frac{\epsilon\sqrt{2}}{\sqrt{\lambda\lambda_0}} \left(\frac{1}{\sqrt{(\lambda - \lambda_0)^2 + \epsilon^2}} + \frac{1}{\lambda} \right).$$

Thus,

$$\int_{3\lambda_0/2}^{\infty} |f(\lambda)|^2 d\lambda \leqslant C(\lambda_0)\epsilon^2.$$

For $\lambda \in (\lambda_0/2,3\lambda_0/2)$,

$$|f(\lambda)| \leqslant \frac{2\epsilon}{\lambda_0} \left(\frac{1}{\sqrt{(\lambda - \lambda_0)^2 + \epsilon^2}} + \frac{2}{\lambda_0} \right).$$

This gives,

$$\int_{\lambda_0/2}^{3\lambda_0/2} |f(\lambda)|^2 d\lambda \leqslant C_1(\lambda_0)\epsilon + C_2(\lambda_0)\epsilon^2.$$

When working on the interval $[0,\lambda_0/2]$, we cannot neglect the term involving β_1, because the integrand does not belong to L^2 (it does converge in L^1). We then need a lower bound for it. This is given by Lemma 3.2, which after some manipulations, gives

$$|f(\lambda)| \leqslant C \frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2}.$$

Then,

$$\int_0^{\lambda_0/2} |f(\lambda)|^2 d\lambda \leqslant C \int_0^{\lambda_0/2} \left(\frac{\epsilon}{(\lambda-\lambda_0)^2+\epsilon^2} \right)^2 d\lambda \leqslant c\epsilon^2.$$

By combining these four estimates, we obtain the desired result. □

Lemma 3.2: If $0<\lambda<\pi^2/16R^2$, *then,* $\beta_1(R) \geqslant C/R$, *where* $C=M^{-1}$ *and* $M=\max_{[0,\pi/4]}(\tan x/x)=4/\pi$.

Proof: The variable $u=\psi_1/\psi_1'$ is a solution of

$$u' = 1+(\lambda-V)u^2 \leqslant 1+\lambda u^2. \tag{3.8}$$

Moreover, u is real and satisfies $u(0)=0$ and $u'(0)=1$.
The result follows by integration. □

IV. POTENTIAL BARRIERS

We now consider a sequence of barriers of finite height and whose supports are increasing to ∞. Here, we shall establish some explicit estimates concerning the approximate exponential behavior in the resonant case, and, for simplicity, we only consider barriers which are step functions. Explicitly, let us consider $V_n(x)=h\chi_{[a,a+n]}(x)$, $V_\infty(x)=h\chi_{[a,\infty)}(x)$, $H_n=H_0+V_n$, and $H_\infty=H_0+V_\infty$.

The spectrum of H_∞ consists of a finite number of eigenvalues $\lambda_1<\lambda_2\cdots<h$ and an absolutely continuous part $[h, \infty)$. On the other hand, each H_n is absolutely continuous with spectrum $[0, \infty)$.

We consider the first eigenvalue λ_1 of H_∞ with corresponding eigenvector φ. For large n, φ is "almost" an eigenvector of H_n, indeed, one can explicitly estimate $\|(H_n-\lambda_1)\varphi)\|$ and prove that this quantity is small since φ is exponentially decreasing at infinity. By the energy-time uncertainty principle (see Ref. 9), we have that the sojourn time $\tau(\varphi)=\int|\langle\varphi,e^{-iH_nt}\varphi\rangle|^2dt$ satisfies $\tau(H)\|(H_n-\lambda_1)\varphi\| \geqslant 1$, hence, $\tau(\varphi)$ is large. Physically, this means that φ is a resonant state.

According to this fact, one expects that $\langle\varphi,e^{-iH_nt}\varphi\rangle$ has an approximate exponential behavior. Here we prove that there exists a translation in energy by $b\in\mathbb{R}$ and a time rescaling function Γ_n, with $\lim_{n\to\infty}\Gamma_n=0$, such that

$$\lim_{n\to\infty} |\langle\varphi,e^{-i(H_n-\lambda_1-b)(\tau/\Gamma_n)}\varphi\rangle|^2 = e^{-\tau}, \quad \tau>0.$$

We mention Refs. 1 and 2 for similar results.

Since the function φ is exponentially decaying at infinity we can use the formulas of Sec. II to compute the Radon Nikodym derivative $P_n(\lambda)=d/d\lambda\langle\varphi,E_\lambda^n\varphi\rangle$.

To this end, we again consider $\psi_i=\psi_{i,n}(x;\lambda)$, $i=1, 2$, the solutions of

$$-\psi''+V_n\psi=\lambda\psi, \quad x>0,$$

satisfying the boundary conditions,

$$\psi_1(0)=0, \psi_1'(0)=1,$$

and

$$\psi_2(0)=1, \psi_2(x)=c_2(\lambda)e^{i\sqrt{\lambda}x}, \text{ for } x\geqslant a+n.$$

Clearly, the Wronskian $W(\psi_1,\psi_2)=-1$ and ψ_1 is real.

Lemma 4.1: The boundary values of the resolvent satisfy

$$\langle\varphi,(H_n-\lambda-i0)^{-1}\varphi\rangle=\int_0^\infty\overline{\varphi}(x)\psi(x)dx,$$

where

$$\psi(x)=\psi_1(x,\lambda)\int_x^\infty\psi_2\varphi+\psi_2(x,\lambda)\int_0^x\psi_1\varphi.$$

As in the previous section, we can also prove

Lemma 4.2:

$$W(\psi_i,\varphi)|_a^b=\int_a^b(V_\infty-V_n+\lambda-\lambda_1)\varphi\psi_i\,.$$

This can be used to compute $\int_a^b\psi_i\varphi$, for different intervals (a, b), which allows us to obtain the following formula for $\langle\varphi,(H_n-\lambda-i0)^{-1}\varphi\rangle$:

Lemma 4.3: Let $s=\lambda-\lambda_1$. Then,

$$\langle\varphi,(H-\lambda-i0)^{-1}\varphi\rangle=-\frac{1}{s}\int_0^{a+n}|\varphi|^2-\frac{1}{s+h}\int_{a+n}^\infty|\varphi|^2+\frac{h^2}{s^2(s+h)^2}W(\psi_1,\varphi)W(\psi_2,\varphi)(a+n).$$

Proof: This is a straightforward application of Lemmas 4.1 and 4.2. □

We now introduce the logarithmic derivative of ψ_1,

$$\beta(\lambda)\equiv\beta_n(\lambda)=\frac{\psi_1'(a+n,\lambda)}{\psi_1(a+n,\lambda)}.\tag{4.1}$$

Lemma 4.4: The spectral measure,

$$P_n(\lambda)=\frac{1}{\pi}\mathrm{Im}\langle\varphi,(H-\lambda-i0)^{-1}\varphi\rangle\tag{4.2}$$

satisfies

$$\pi P_n(\lambda)=\frac{2\sqrt{\lambda}\lambda_1 h}{(\lambda-\lambda_1)^2(\lambda-\lambda_1+h)^2}\cdot\frac{\sqrt{h-\lambda_1}}{a\sqrt{h-\lambda_1}+1}e^{-2\sqrt{h-\lambda_1}n}\cdot\frac{(\beta(\lambda)+\sqrt{h-\lambda_1})^2}{(\beta^2(\lambda)+\lambda)}.$$

Proof: We know explicitly ψ_1. Also, $W(\psi_1,\psi_2)=-1$. From these facts, it follows that

$$W(\psi_1,\varphi)W(\psi_2,\varphi)(a+n)=\frac{(\varphi'-\beta(\lambda)\varphi)(\varphi'-\beta(\lambda)\varphi)}{\beta(\lambda)-i\sqrt{\lambda}}+(\varphi'-\beta(\lambda)\varphi).$$

Hence,

$$\mathrm{Im}\langle\varphi,(H_n-\lambda-i0)^{-1}\varphi\rangle=\frac{h^2}{(\lambda-\lambda_1)^2(\lambda-\lambda_1+h)^2}\cdot\frac{\sqrt{\lambda}(\varphi'-\beta(\lambda)\varphi)^2(a+n)}{\beta^2(\lambda)+\lambda}.$$

The proof follows by substituting the values of the eigenfunction φ, which are explicitly known for large x. □

One can easily obtain the following formula for the function $\beta=\beta_n$:

$$\beta_n(\lambda)=2\sqrt{h-\lambda}\frac{t(\lambda)}{t(\lambda)+t_1(\lambda)e^{-2\sqrt{h-\lambda}_n}}-\sqrt{h-\lambda},$$

where $t(\lambda)=\tan(a\sqrt{\lambda})+\sqrt{\lambda/(h-\lambda)}$ and $t_1(\lambda)=\tan(a\sqrt{\lambda})-\sqrt{\lambda/(h-\lambda)}$.

By substituting in the expression for the resolvent, we obtain,

$$\Gamma_n\,\mathrm{Im}\langle\varphi,(H_n-\lambda_1-\Gamma_n\lambda-i0)^{-1}\varphi\rangle=F_n(\lambda)G_n(\lambda)(H_n(\lambda))^2,$$

where

$$F_n(\lambda)=\frac{2\lambda_1 h\sqrt{\lambda_1+\Gamma_n\lambda}\sqrt{h-\lambda_1}}{(\Gamma_n\lambda+h)^2(a\sqrt{h-\lambda_1}+1)},$$

$$G_n(\lambda)=(\beta_n^2(\lambda_1+\Gamma_n\lambda)+\lambda_1+\Gamma_n\lambda)^{-1},$$

$$H_n(\lambda)=2\sqrt{h-\lambda_1-\Gamma_n\lambda}\frac{t(\lambda_1+\Gamma_n\lambda)}{\Gamma_n\lambda}R_n(\lambda)+\frac{\sqrt{\Gamma_n}e^{-\sqrt{h-\lambda_1}n}}{\sqrt{h-\lambda_1-\Gamma_n\lambda}+\sqrt{h-\lambda_1}},$$

and

$$R_n(\lambda)=\frac{\sqrt{\Gamma_n}e^{-\sqrt{h-\lambda_1}n}}{t(\lambda_1+\Gamma_n\lambda)+t_1(\lambda_1+\Gamma_n\lambda)e^{-2\sqrt{h-\lambda_1-\Gamma_n\lambda_n}n}}.$$

Assuming that $\Gamma_n\to 0$, we can compute the limit of some of these terms. In order to handle all of them, we choose $\Gamma_n=re^{-2\sqrt{h-\lambda_1}n}$.

With this choice, we have that

(i) $F_n(\lambda)\to 2\lambda_1^{3/2}\sqrt{h-\lambda_1}/h(a\sqrt{h-\lambda_1}+1)$;
(ii) $\beta_n(\lambda)\to\sqrt{h-\lambda_1}\lambda rt'(\lambda_1)-t_1(\lambda_1)/\lambda rt'(\lambda_1)+t_1(\lambda_1)$;
(iii) $G_n(\lambda)\to((h-\lambda_1)(\lambda rt'(\lambda_1)-t_1(\lambda_1)/\lambda rt'(\lambda_1)+t_1(\lambda_1))^2+\lambda_1)^{-1}$;
(iv) $H_n(\lambda)\to 2\sqrt{h-\lambda_1}t'(\lambda_1)\cdot\sqrt{r}/t'(\lambda_1)r\lambda+t_1(\lambda_1)$.

But, $t'(\lambda_1)$ and $t_1(\lambda_1)$ can be explicitly computed. Finally, with the proper choice of r we obtain

Theorem 4.1: *For* $\Gamma_n=re^{-2\sqrt{h-\lambda_1}n}$, *where*

$$r=\frac{8(\lambda_1(h-\lambda_1))^{3/2}}{h^2(a\sqrt{h-\lambda_1}+1)},$$

we have

$$\lim_{n\to\infty} \Gamma_n \operatorname{Im}\langle \varphi, (H_n - \lambda_1 - \lambda\Gamma_n - i0)^{-1}\varphi\rangle = \frac{1}{(\lambda - b)^2 + 1},$$

where

$$b = \frac{h - 2\lambda_1}{2\sqrt{\lambda_1(h - \lambda_1)}}.$$

The convergence is uniform for λ *in compact sets.*

Remark 4.1: Uniform convergence on compact sets implies convergence in L', since the function in question are probability distributions (up to a factor) and this implies uniform convergence of the Fourier transform. Hence,

Corollary 4.1: For all positive τ,

$$\lim_{n\to\infty} \langle \varphi, e^{-i(H_n - \lambda_1 - b)\tau/\Gamma_n}\varphi\rangle = e^{-\tau}.$$

Clearly, upon reintroducing the unscaled time $t = \tau/\Gamma_n$, one obtains that the survival probability $|\langle \varphi, e^{-iH_n t}\varphi\rangle|^2$ behaves asymptotically as $e^{-2\Gamma_n t}$, for all t.

Defining commutation relations between symmetry operators and fundamental operators, we set up the symmetry group for a many-particle Hamiltonian. Using the irreducible representations of the symmetry group, we decompose the Hilbert space. We discuss the advantage of this approach to find the dimensions of reduced Hilbert spaces in numerical exact diagonalization. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1506956]

I. INTRODUCTION

Strongly correlated systems such as the Hubbard model and the Heisenberg model have attracted renewed interest. One method to study strongly correlated systems would be exact diagonalization with the Lanczös algorithm. In relation with high T_c superconductor, an exact diagonalization approach to the $t-J$ model has been used intensively by many authors.[1,2] As a strongly correlated system, the Hall effect has also been studied by the numerical method of exact diagonalization.[3,4]

Nowadays, exact diagonalization has become more popular due to the case of access to a tremendous amount of memory in computers. However, the size of Hilbert space still grows exponentially. The remedy for the exponentially growing problem is to use symmetries that the system has. The symmetries help in reducing the numerical factor in front of the exponential of the Hilbert space dimension. In fact, representation theory[5] makes it possible to find the exact dimension of the reduced Hilbert space. It will be an advantage if one can compare the dimensions of reduced Hilbert spaces obtained analytically with the results found numerically.

In this paper, in order to find the dimension of the reduced Hilbert space, we first define commutation relations between fundamental operators and symmetry operators, and then use representation theory. To the authors' knowledge, no symmetry group representation can be found for any many-particle interacting system.

We can describe general processes of analytical works to find the dimensions of reduced Hilbert spaces. In order to reduce the Hilbert space by using group representation theory, we carry out the following program.

(1) Set up a Hamiltonian, commutation relations between fundamental operators, and an orthonormal basis of the corresponding Hilbert space.
(2) Define relationships between the symmetry operators and the fundamental operators. Then, prove that the symmetry operators commute with the Hamiltonian, and also preserve the commutation relations of fundamental operators.
(3) Find how the symmetry operators commute with themselves in the Hilbert space, and construct the corresponding symmetry group.
(4) Find irreducible representations of the group.

[a)]Author to whom all correspondence should be addressed; electronic mail: mhchung@hongik.ac.kr

(5) Calculate the reducible representation of the group with the basis of the Hilbert space.
(6) Decompose the Hilbert space into the irreducible components. The multiplicities in this decomposition are the dimensions of reduced Hilbert spaces.

The purpose of this paper is to emphasize this general procedure as analytical works in exact diagonalization. In doing so, we treat a toy Hamiltonian, which is originated from the second quantized Hamiltonian introduced by Yoshioka, Halperin, and Lee (YHL)[6] to explain the fractional quantum Hall effect.[7,8] The above-mentioned procedure with the YHL Hamiltonian has been done in Ref. 9. Here we take the same procedure with the toy Hamiltonian. Before presenting the toy model, we briefly review the YHL Hamiltonian according to the above-mentioned six steps.

(1) The YHL Hamiltonian is written as

$$H=\sum_{a,b=0}^{N-1} W(a,b)\sum_{k=0}^{N-1} c_{k+a}^{\dagger}c_{k+b}^{\dagger}c_{k+a+b}c_{k}, \tag{1}$$

where the degeneracy of the Landau level is denoted by N, and $c_k^{\dagger}c_l+c_lc_k^{\dagger}=\delta_{kl}$, and $c_{k+N}^{\dagger}=c_k^{\dagger}$. The couplings satisfy $W(a,b)=W(\pm a\pm N,b)=W(a,\pm b\pm N)$. For a system of M electrons, a typical basis of the Hilbert space $\mathcal{H}(N,M)$ is expressed by creation operators:

$$\{c_{i_1}^{\dagger}\cdots c_{i_M}^{\dagger}|0\rangle|0\leqslant i_1<\cdots<i_M\leqslant N-1\}. \tag{2}$$

The dimension of $\mathcal{H}(N,M)$ is given by ${}_NC_M$. Using the symmetries of Hamiltonian H, we study the structure of the Hilbert space $\mathcal{H}(N,M)$.

(2) We define two operators S and T, which act on the Hilbert space in such a way:

$$Sc_k^{\dagger}=\exp\left(i\frac{2\pi}{N}k\right)c_k^{\dagger}S,\quad Sc_k=\exp\left(-i\frac{2\pi}{N}k\right)c_kS,\quad S|0\rangle=|0\rangle, \tag{3}$$

$$Tc_k^{\dagger}=c_{k+1}^{\dagger}T,\quad Tc_k=c_{k+1}T,\quad T|0\rangle=|0\rangle. \tag{4}$$

We find that $SH=HS$, and $TH=HT$, and that S and T are consistent with $c_k^{\dagger}c_l+c_lc_k^{\dagger}=\delta_{kl}$.

(3) When p and q are coprime and $M/N=pG/qG=p/q$ with a greatest common divisor G, the commutation relation between S and T in the Hilbert space $\mathcal{H}(qG,pG)$ is given by

$$ST=\exp\left(i2\pi\frac{p}{q}\right)TS\ \text{ with }\ \xi\equiv\exp\left(i2\pi\frac{p}{q}\right). \tag{5}$$

Note that $S^N=T^N=S^{\dagger}S=T^{\dagger}T=1$. We now consider the symmetry group:

$$G_{\text{core}}=\{\xi^lT^aS^b|l=0,\ldots,q-1;\ a,b=0,\ldots,qG-1\}, \tag{6}$$

where $ST=\xi TS$, and $\xi T=T\xi$, $\xi S=S\xi$.

(4) The irreducible representations, $\Psi_{xts}(\xi^lT^aS^b)$, of the group, G_{core}, are found in Ref. 5.

(5) It is straightforward to calculate the reducible representation:

$$\chi(\xi^lT^aS^b)=\sum_{i_1,\ldots,i_M}\langle 0|c_{i_M}\cdots c_{i_1}\xi^lT^aS^bc_{i_1}^{\dagger}\cdots c_{i_M}^{\dagger}|0\rangle. \tag{7}$$

(6) Using the irreducible representations and the reducible representation, we decompose the Hilbert space $\mathcal{H}(qG,pG)$ as

$$\mathcal{H}(qG,pG)=\bigoplus_{t,s=0}^{G-1}(\mathcal{H}_{pts})^{\oplus d_{ts}}, \tag{8}$$

where $\mathcal{H}_{pts}$ is q-dimensional, and the multiplicity, d_{ts}, is the dimension of the reduced Hilbert space. It is remarkable that the symmetries S and T always exist for any $W(a,b)$. Thus, this structure of the Hilbert space does not depend upon detailed forms of interactions.

A detailed review on $\mathcal{H}_{pts}$ is as follows. A basis of a typical q-dimensional Hilbert space $\mathcal{H}_{pts}$ is given by

$$\{|t,s;n\rangle, T|t,s;n\rangle, \ldots, T^{q-1}|t,s;n\rangle\}, \tag{9}$$

where the quantum number n, which runs from 0 to $d_{ts}-1$, is related with energy spectrum as $H|t,s;n\rangle = E_n|t,s;n\rangle$. The reference state $|t,s;n\rangle$ is actually a linear combination of M creation operators acting on the vacuum state $|0\rangle$. The operators T^a and S^b act on $|t,s;n\rangle$ such that

$$T^{mq+x}|t,s;n\rangle = \exp\left(i\frac{2\pi}{G}mt\right)T^x|t,s;n\rangle, \tag{10}$$

$$S^{lq+y}|t,s;n\rangle = \exp\left(i\frac{2\pi}{G}ls\right)|t,s;n\rangle, \tag{11}$$

where m and l are integers, and $0 \leqslant x,\ y \leqslant q-1$.

It is well known that the ground state of the YHL Hamiltonian always belongs to the $t=s=0$ sector of $\mathcal{H}_{p00}$. Hence, we denote the q-fold ground state as

$$\{|0,0;0\rangle, T|0,0;0\rangle, \ldots, T^{q-1}|0,0;0\rangle\}. \tag{12}$$

The operators, S and T, are actually magnetic translational symmetries, which have been studied for a long time.[10–15] Using magnetic translational symmetries, Haldane[16] showed that many-particle states should have the q-fold degeneracy at rational Landau-level filling p/q in the fractional quantum Hall system. Our work to find the multiplicities in Ref. 9 was beyond Haldane's analysis.

In this paper, we apply this procedure to a toy system, in order to find multiplicities in its energy spectrum. The toy system is described by the unperturbed Hamiltonian, $H_0 = \Sigma_{m=0}^{D-1} H^{(m)}$, and the perturbing Hamiltonian, H_1, where the mth subsystem of $H^{(m)}$ is exactly the quantum Hall system. In the case where some symmetries are broken by H_1, we study the spectrum of low energy states.

Contents are summarized as follows. In Sec. II, we present the unperturbed Hamiltonian in relation with the YHL Hamiltonian. Then, we discuss the symmetries of the unperturbed Hamiltonian. In Sec. III, we construct the symmetry group in the case of lowering symmetries with the perturbing Hamiltonian. Using representations of the group, we find the structure of energy spectrum. We propose future works, and conclude in Sec. IV.

II. DEFORMED YHL HAMILTONIAN AND SYMMETRIES

We now attempt to introduce our unperturbed Hamiltonian H_0 from the YHL Hamiltonian. The first manipulation is to deform the couplings $W(a,b)$. In fact, we write the deformed YHL Hamiltonian from Eq. (1) as

$$\tilde{H} = \sum_{a,b=0}^{qG-1} \sum_{\alpha,\beta=0}^{D-1} W(Da,Db) \sum_{k=0}^{qG-1} \sum_{\kappa=0}^{D-1} c^{\dagger}_{D(k+a)+\kappa+\alpha} c^{\dagger}_{D(k+b)+\kappa+\beta} c_{D(k+a+b)+\kappa+\alpha+\beta} c_{Dk+\kappa}, \tag{13}$$

where we trivially rewrite the indices in a D-times bigger system, $\tilde{N} = qGD$, and deform $W(Da+\alpha, Db+\beta)$ to $W(Da,Db)$. We notice that $\tilde{H}$ still has the symmetries S and T. The next deformation is to transform the operators in $\tilde{H}$. Finally, we present the Hamiltonian H_0, which is rewritten in terms of the new operators as

$$H_0=\sum_{m=0}^{D-1} D \sum_{a,b=0}^{qG-1} W(Da,Db) \sum_{k=0}^{qG-1} a^{\dagger}_{D(k+a)+m} a^{\dagger}_{D(k+b)+m} a_{D(k+a+b)+m} a_{Dk+m}. \tag{14}$$

It should be emphasized that replacing $a^{\dagger}_{Da+m}$ in H_0 by $(1/\sqrt{D})\,\Sigma_{\alpha=0}^{D-1}\exp(-i(2\pi/D)\alpha m)c^{\dagger}_{Da+\alpha}$ does not show $H_0=\tilde{H}$. Furthermore, after this replacement, it turns out that H_0 does not commute with S and T. At this point, H_0 has lost connection to $\tilde{H}$. From now on, we should treat H_0 as a starting point in the following discussion.

We adopt the periodic boundary condition for the operators: $a^{\dagger}_{N+k}=a^{\dagger}_k$, and $a^{\dagger}_k a_l + a_l a^{\dagger}_k = \delta_{kl}$. Denoting $H_0=\Sigma_{m=0}^{D-1} H^{(m)}$, we find that the Hamiltonian $H^{(m)}$ for the mth subsystem has the same structure as that of the original YHL Hamiltonian of Eq. (1). This similarity is reminiscent of scaling. Note that the Hilbert space of H_0 is simply a direct product of the Hilbert space of $H^{(m)}$.

We define the following operators acting on the Hilbert space of the Hamiltonian H_0:

$$S_m a^{\dagger}_{Dk+m}=\exp\left(i\frac{2\pi}{qG}k\right)a^{\dagger}_{Dk+m}S_m, \tag{15}$$

$$S_m a_{Dk+m}=\exp\left(-i\frac{2\pi}{qG}k\right)a_{Dk+m}S_m, \tag{16}$$

$$S_m a^{\dagger}_{Dk+l}=a^{\dagger}_{Dk+l}S_m \quad \text{for } m\neq l, \tag{17}$$

$$S_m a_{Dk+l}=a_{Dk+l}S_m \quad \text{for } m\neq l, \tag{18}$$

$$T_m a^{\dagger}_{Dk+m}=a^{\dagger}_{D(k+1)+m}T_m, \tag{19}$$

$$T_m a_{Dk+m}=a_{D(k+1)+m}T_m, \tag{20}$$

$$T_m a^{\dagger}_{Dk+l}=a^{\dagger}_{Dk+l}T_m \quad \text{for } m\neq l, \tag{21}$$

$$T_m a_{Dk+l}=a_{Dk+l}T_m \quad \text{for } m\neq l, \tag{22}$$

$$Q a^{\dagger}_{Dj+m}=a^{\dagger}_{Dj+m+1}Q, \tag{23}$$

$$Q a_{Dj+m}=a_{Dj+m+1}Q, \tag{24}$$

$$P a^{\dagger}_{Dj+m}=a^{\dagger}_{D(qG-1-j)+D-m}P, \tag{25}$$

$$P a_{Dj+m}=a_{D(qG-1-j)+D-m}P, \tag{26}$$

$$|0\rangle=S_m|0\rangle=T_m|0\rangle=Q|0\rangle=P|0\rangle. \tag{27}$$

We find that $S_m H_0=H_0 S_m$, $T_m H_0=H_0 T_m$, $QH_0=H_0 Q$, and $PH_0=H_0 P$.

We now focus on low energy states of H_0 with $\tilde{M}=pGD$ particles. Note that the ground state of the Hamiltonian H_0 is in the special Hilbert space characterized by equal partition, that is,

$$\bigotimes_{m=0}^{D-1}\mathcal{H}^{(m)}(qG,pG), \tag{28}$$

where the Hilbert space $\mathcal{H}^{(m)}(qG,pG)$ corresponds to the mth subsystem of qG states with pG particles. Since there is no difference between $H^{(m)}$'s except for the dummy index m, the ground state of each Hamiltonian $H^{(m)}$ lives in the subspace characterized by the values $t=s=0$, regardless of m. As a result, the ground state of H_0 lives in

$$\bigotimes_{m=0}^{D-1} \mathcal{H}_{p00}^{(m)} \equiv \mathcal{H}_{\mathrm{g}}. \tag{29}$$

We observe that the degeneracy of ground state for H_0 is given by q^D. The operators S_m and T_m acting on the Hilbert space of $\mathcal{H}_{p00}^{(m)}$ satisfy $S_m^q = T_m^q = 1$ as seen in Eqs. (10) and (11). Like Eq. (12), a basis of the corresponding q^D-dimensional Hilbert space of $\mathcal{H}_{\mathrm{g}}$ is given by

$$\{|\psi_A\rangle = T_0^{i_0} T_1^{i_1} \cdots T_{D-1}^{i_{D-1}} |\psi_0\rangle | 0 \leqslant i_0, \ldots, i_{D-1} \leqslant q-1\}, \tag{30}$$

$$|\psi_0\rangle \equiv |0,0;0\rangle^{(0)} \otimes \cdots \otimes |0,0;0\rangle^{(D-1)}, \tag{31}$$

where the index A runs from 0 to q^D-1, and the reference state $|0,0;0\rangle^{(m)}$ for the mth subsystem is a linear combination of Slater determinants written in terms of the fundamental operators $a_{Dk+m}^{\dagger}$:

$$|0,0;0\rangle^{(m)} = \sum_{k_1,\ldots,k_{pG}=0}^{qG-1} C(k_1,\ldots,k_{pG}) a_{Dk_1+m}^{\dagger} \cdots a_{Dk_{pG}+m}^{\dagger} |0\rangle. \tag{32}$$

III. PERTURBATION WITH LOWERED SYMMETRIES

Symmetries play an important role in studying an energy spectrum of a Hamiltonian. The power of symmetry becomes apparent, when we attempt to analyze a perturbation. Here, the perturbing Hamiltonian, H_1, breaks some symmetries. As a result, degenerated states split in the presence of H_1. Our aim here is to decompose $\mathcal{H}_{\mathrm{g}}$ in the presence of H_1.

The unperturbed Hamiltonian in Sec. II, H_0, certainly has more symmetries than the above-given description. However, when a perturbing Hamiltonian, H_1, is involved, we need to consider only symmetries of the total Hamiltonian, H_0+H_1. We assume that the perturbing Hamiltonian, H_1, has the symmetries Q, P, and $\tilde{S}$, $\tilde{T}$, which are defined as

$$\tilde{S} \equiv \prod_{m=0}^{D-1} S_m, \qquad \tilde{T} \equiv \prod_{m=0}^{D-1} T_m. \tag{33}$$

Although we do not need to present the explicit form of H_1 in the following discussion, a possible form of H_1 would be

$$H_1 = \sum_{n,m=0}^{D-1} \sum_{a,b=0}^{q-1} J(n-m;a,b) T_n^{-b} S_n^{-a} S_m^a T_m^b, \tag{34}$$

which can commute with $\tilde{S}$, $\tilde{T}$, Q, and P with properly chosen couplings $J(n-m;a,b)$. Note that H_1 does not commute with S_m and T_m anymore. For this form of H_1, the operators S_m and T_m effectively play the role of fundamental operators. Their commutation relations in $\mathcal{H}_{\mathrm{g}}$ are given by

$$S_m T_m = \xi T_m S_m \quad \text{with} \quad \xi \equiv \exp\left(i 2\pi \frac{p}{q}\right), \tag{35}$$

$$S_m T_l = T_l S_m \quad \text{for} \quad m \neq l. \tag{36}$$

We calculate commutation relations between the symmetry operators and the fundamental operators. In the space of $\mathcal{H}_{\mathrm{g}}$, the operators satisfy

$$\tilde{S}S_m = S_m\tilde{S}, \tag{37}$$

$$\tilde{S}T_m = \xi T_m\tilde{S}, \tag{38}$$

$$\tilde{T}S_m = \xi^{-1}S_m\tilde{T}, \tag{39}$$

$$\tilde{T}T_m = T_m\tilde{T}, \tag{40}$$

$$QS_m = S_{m+1}Q, \qquad S_D \equiv \xi^{-1}S_0, \tag{41}$$

$$QT_m = T_{m+1}Q, \qquad T_D \equiv T_0, \tag{42}$$

$$PS_m = \xi^{-1}S_{D-m}^{-1}P, \tag{43}$$

$$PT_m = T_{D-m}^{-1}P, \tag{44}$$

$$\tilde{S}|\psi_0\rangle = |\psi_0\rangle, \tag{45}$$

$$\tilde{T}|\psi_0\rangle = \prod_{m=0}^{D-1} T_m|\psi_0\rangle, \tag{46}$$

$$Q|\psi_0\rangle = T_0|\psi_0\rangle, \tag{47}$$

$$P|\psi_0\rangle = \prod_{m=1}^{D-1} T_m^{-1}|\psi_0\rangle. \tag{48}$$

These commutation relations are verified when the operators act on a typical state of Eq. (30). For Eqs. (47) and (48), we have used the definition of Eqs. (23), (25), and (31), and the fact that the coefficients $C(k_1,\cdots,k_{pG})$ in Eq. (32) are independent of m.

We calculate commutation relations between the four symmetry operators in $\mathcal{H}_{\mathrm{g}}$. In order to simplify the commutation relation of $\tilde{S}Q = \xi Q\tilde{S}$, we introduce

$$\tilde{Q} \equiv T^{\alpha}Q, \tag{49}$$

where α is determined for $\tilde{Q}$ to commute with $\tilde{S}$, in fact, as a solution of $\alpha D + 1 \equiv 0 \mod q$. The commutation relations in $\mathcal{H}_{\mathrm{g}}$ between the four operators are given by

$$\tilde{S}\tilde{T} = \xi^D\tilde{T}\tilde{S}, \quad \tilde{S}\tilde{Q} = \tilde{Q}\tilde{S}, \quad \tilde{S}P = \xi^{1-D}P\tilde{S}^{-1}, \tag{50}$$

$$\tilde{T}\tilde{Q} = \tilde{Q}\tilde{T}, \quad \tilde{T}P = P\tilde{T}^{-1}, \quad \tilde{Q}P = P\tilde{Q}^{-1}. \tag{51}$$

The orders of the symmetry operators in $\mathcal{H}_{\mathrm{g}}$ are given by

$$\xi^q = \tilde{S}^q = \tilde{T}^q = \tilde{Q}^{qD} = P^2 = 1, \tag{52}$$

where Eqs. (37)–(48) have been used.

For simplicity, we impose that q and D are coprime. We now consider the symmetry group:

$$G_D^q = \{\xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^b | l,a,b = 0,\ldots,q-1;\ \ n = 0,1;\ \ d = 0,\ldots,qD-1\}. \tag{53}$$

Representations of G_D^q are essential to decompose the Hilbert space of $\mathcal{H}_g$.

Taking the same approach given in Ref. 9, we find that every irreducible character of G_D^q is a component of Ψ_{xkts}:

$$\Psi_{xkts}(\xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^b) = \begin{cases} q_x \zeta_q^{xl} (\zeta_{qD}^{kd} \zeta_q^{ta+sb} + \zeta_{qD}^{-kd} \zeta_q^{-ta-sb}) & \text{if } n=0, q_x | a,b, \\ 0 \quad \text{otherwise,} \end{cases} \tag{54}$$

where $0 \leqslant x \leqslant q-1$, $0 \leqslant k \leqslant qD-1$, $0 \leqslant t$, $s \leqslant \gcd(q,x)-1$, $q_x = q/\gcd(q,x)$, and $\zeta_y \equiv \exp(i2\pi/y)$. In order to avoid double counting, we should note that $\Psi_{xkts} = \Psi_{x(qD-k)(q/q_x-t)(q/q_x-s)}$.

It is found that all Ψ_{xkts} are irreducible characters except for $\Psi_{x(\alpha qD/2)(\beta q/2q_x)(\gamma q/2q_x)}$, where $\alpha,\beta,\gamma = 0,1$. Of course, the cases containing $qD/2$ or $q/2q_x$ are meaningful only when they are integers. We decompose the characters, and find the irreducible components,

$$\Psi_{x(\alpha qD/2)(\beta q/2q_x)(\gamma q/2q_x)} = \chi^+_{x\alpha\beta\gamma} + \chi^-_{x\alpha\beta\gamma}. \tag{55}$$

For mathematical completeness, we show the components for $x=0$,

$$\chi^{\pm}_{0\alpha\beta\gamma}(\xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^b) = (\pm 1)^n (-1)^{\alpha d + \beta a + \gamma b}. \tag{56}$$

For $x \neq 0$, we obtain that

$$\begin{aligned} &\chi^{\pm}_{x\alpha 0\gamma}(\xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^{q_x m+b}) \\ &\quad = \zeta_q^{xl} (-1)^{\alpha d + \gamma m} \\ &\qquad \times \begin{cases} q_{x,} \quad n=0, \quad q_x | a,b \\ \pm \zeta_q^{xb[(q_x-1)/2][(a+1)D-1]}, \quad n=1, \quad q_x \equiv 1 \mod 2, \ \left(\dfrac{q_x-1}{2}\right) b \in I^+ \\ \pm (-1)^{\gamma} \zeta_q^{xb[(q_x-1)/2][(a+1)D-1]}, \quad n=1, \quad q_x \equiv 1 \mod 2, \ \left(\dfrac{q_x-1}{2}\right) b \in I^- \\ \pm \zeta_q^{-(xb/2)[(a+1)D-1]} (1+(-1)^{x_q[1+(a-1)D]+\gamma}), \quad n=1, \quad q_x \equiv b \equiv 0 \mod 2, \\ 0 \quad \text{otherwise,} \end{cases} \end{aligned} \tag{57}$$

where

$$x_q = x/\gcd(q,x), \quad I^+ = \left\{ \frac{q_x+1}{2}, \ldots, q_x-1, 0 \right\}, \quad \text{and} \quad I^- = \left\{ 1,2,\ldots, \frac{q_x-1}{2} \right\}.$$

We omit presenting $\chi^{\pm}_{x\alpha 1\gamma}$, which is not necessary in the decomposition process.

In summary, the irreducible characters of G_D^q are given by

$$\Psi_{xkts} \quad \text{with } 0 \leqslant x \leqslant q-1, \quad 0 < k < \frac{qD}{2}, \quad 0 < t,s < \frac{q}{2q_x}, \tag{58}$$

$$\chi^+_{x\alpha\beta\gamma}, \ \chi^-_{x\alpha\beta\gamma} \quad \text{with } \alpha,\beta,\gamma = 0,1. \tag{59}$$

The reducible character of the symmetry group for the Hilbert space of $\mathcal{H}_g$ is calculated by using Eqs. (30) and (37)–(48). We find the reducible character of $\mathcal{H}_g$:

$$\chi(\xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^b) = \sum_{i=0}^{q^D-1} \langle \psi_i | \xi^l P^n \tilde{Q}^d \tilde{T}^a \tilde{S}^b | \psi_i \rangle = \zeta_q^{pl} \times \begin{cases} q^{\gcd(D,d)}, & n=0, \quad q|a,b \\ \zeta^{(pb/2)(q-1)[(a+1)D-1]} q^{(D-1)/2}, & n=1, \quad q\equiv 1, D\equiv 1 \mod 2 \\ \zeta^{(pb/2)(q-1)[(a+1)D-1]} q^{(D/2)-1} & \\ \quad [1+\frac{1}{2}(q-1)(1-(-1)^d)], & n=1, \quad q\equiv 1, D\equiv 0 \mod 2 \\ \zeta^{-(pb/2)[(a+1)D-1]} q^{(D-1)/2} 2, & n=1, \quad q\equiv a\equiv b\equiv 0 \mod 2 \\ 0, \quad \text{otherwise.} & \end{cases} \tag{60}$$

Using the irreducible characters Ψ_{xkts}, $\chi^{\pm}_{x\alpha\beta\gamma}$, and the reducible character χ, we decompose the Hilbert space $\mathcal{H}_g$. Note that (Ψ_{xkts},χ) becomes nonzero only for $x=p$. Furthermore, since $0\leqslant t,\ s\leqslant \gcd(q,p)-1=0$, the case of $t=s=0$ is only possible. Fixing the indices as $x=p$ and $t=s=0$, we calculate the inner product, which is a multiplicity:

$$(\Psi_{pk00},\chi) = \begin{cases} \dfrac{1}{qD} \displaystyle\sum_{d=0}^{D-1} q^{\gcd(D,d)} \cos\left(\frac{2\pi}{qD} kd\right) & k\equiv 0 \mod q \\ 0 \quad \text{otherwise.} \end{cases} \tag{61}$$

Since the multiplicity is nonzero only for $k\equiv 0 \bmod q$, we let $k=ql$ with integer l.

The Hilbert space $\mathcal{H}_g$ is decomposed as

$$\mathcal{H}_g = \bigoplus_{0\leqslant l\leqslant D/2} (\mathcal{H}_l)^{\oplus m_l}, \tag{62}$$

where $m_l=(\Psi_{pql00},\chi)$.

The sectors $(\mathcal{H}_0)^{\oplus m_0}$ and $(\mathcal{H}_{D/2})^{\oplus m_{D/2}}$ are decomposed more as

$$(\mathcal{H}_0)^{\oplus m_0} = (\mathcal{H}_0^+)^{\oplus m_0^+} \bigoplus (\mathcal{H}_0^-)^{\oplus m_0^-}, \tag{63}$$

$$(\mathcal{H}_{D/2})^{\oplus m_{D/2}} = (\mathcal{H}_{D/2}^+)^{\oplus m_{D/2}^+} \bigoplus (\mathcal{H}_{D/2}^-)^{\oplus m_{D/2}^-}, \tag{64}$$

where the multiplicities are given by

$$m_0^{\pm} = (\chi^{\pm}_{p000},\chi) = \frac{1}{2qD} \sum_{d=0}^{D-1} q^{\gcd(D,d)} \pm \begin{cases} \frac{1}{2} q^{(D-1)/2} & D\equiv 1 \mod 2 \\ \dfrac{q+1}{4} q^{(D/2)-1} & D\equiv 0 \mod 2 \end{cases}, \tag{65}$$

and

$$m_{D/2}^{\pm} = (\chi^{\pm}_{p100},\chi) = \frac{1}{2qD} \sum_{d=0}^{D-1} (-1)^d q^{\gcd(D,d)} \pm \frac{1-q}{4} q^{(D/2)-1} \quad \text{for } D\equiv 0 \mod 2. \tag{66}$$

One comment for $m_{D/2}^{\pm}$ is that an integer $D/2$ requires $D\equiv 0 \bmod 2$, and $q\equiv 1 \bmod 2$ because of coprime q and D.

In consequence, with coprime q and D, the Hilbert space $\mathcal{H}_g$ is decomposed as

$$\mathcal{H}_g=(\mathcal{H}_0^+)^{\oplus m_0^+}\bigoplus(\mathcal{H}_0^-)^{\oplus m_0^-}\bigoplus_{1\leqslant l\leqslant(D-1)/2}(\mathcal{H}_l)^{\oplus m_l}\quad\text{for } D\equiv 1 \mod 2, \tag{67}$$

$$\mathcal{H}_g=(\mathcal{H}_0^+)^{\oplus m_0^+}\bigoplus(\mathcal{H}_0^-)^{\oplus m_0^-}\bigoplus_{1\leqslant l\leqslant(D-2)/2}(\mathcal{H}_l)^{\oplus m_l}\bigoplus(\mathcal{H}_{D/2}^+)^{\oplus m_{D/2}^+}\bigoplus(\mathcal{H}_{D/2}^-)^{\oplus m_{D/2}^-}$$

$$\text{for } D\equiv 0 \mod 2. \tag{68}$$

This decomposition is useful in numerical calculations, especially in the Lanczös method. While $q^D=4\,782\,969$ with $q=3$ and $D=14$, we note that $m_0^+=57\,696$.

IV. CONCLUSION

In summary, emphasizing the usefulness of group representation theory, we have considered a model Hamiltonian originated from the YHL Hamiltonian. We consider the symmetries, and construct the symmetry group. Using the representations of the group, we decompose the q^D-fold states into the irreducible components. The main point of this paper is not the model, but the method to find the dimension of the reduced Hilbert space. This method will be useful for exact diagonalization in finite strongly correlated systems.

Future works are proposed as follows. We can consider the reduction of the Hilbert space for a general system that has the symmetry group, $G_t^{(n)}\otimes G_p$, where $G_t^{(n)}$ is an n-dimensional translational group and G_p is a point group. The symmetries of $G_t^{(n)}\otimes G_p$ is not new, but the corresponding representations are not known.

For instance, the Hubbard model in the two-dimensional $N\times N$ square lattice may have the symmetry group $G_t^{(2)}\otimes C_{4v}$, where $G_t^{(2)}$ has two generators, T_x and T_y, and where C_{4v} is one of the Schoenflies symbols. The fundamental operators with two indices satisfy $c_{ij}^\dagger=c_{i+Nj}^\dagger=c_{ij+N}^\dagger$. It is crucial to define commutation relations between symmetry operators and fundamental operators. The generators of the symmetry group are defined as

$$T_x c_{ij}^\dagger=c_{i+1\,j}^\dagger T_x, \tag{69}$$

$$T_y c_{ij}^\dagger=c_{ij+1}^\dagger T_y, \tag{70}$$

$$C_4 c_{ij}^\dagger=c_{-ji}^\dagger C_4, \tag{71}$$

$$\sigma_x c_{ij}^\dagger=c_{i-j}^\dagger \sigma_x, \tag{72}$$

$$\sigma_y c_{ij}^\dagger=c_{-ij}^\dagger \sigma_y, \tag{73}$$

$$\sigma_d c_{ij}^\dagger=c_{ji}^\dagger \sigma_d, \tag{74}$$

$$\sigma_d' c_{ij}^\dagger=c_{-j-i}^\dagger \sigma_d', \tag{75}$$

$$|0\rangle=T_x|0\rangle=T_y|0\rangle=C_4|0\rangle=\sigma_x|0\rangle=\sigma_y|0\rangle=\sigma_d|0\rangle=\sigma_d'|0\rangle. \tag{76}$$

This will be the starting point for the discussion on the reduction of the Hilbert space. Progress in the discussion with all crystallographic point symmetry groups is anticipated.

(Received 19 March 2002; accepted for publication 30 May 2002)

We consider electrons in uniform external magnetic and electric fields which move on a plane whose coordinates are noncommuting. Spectrum and eigenfunctions of the related Hamiltonian are obtained. We derive the electric current whose expectation value gives the Hall effect in terms of an effective magnetic field. We present a receipt to find the action which can be utilized in path integrals for noncommuting coordinates. In terms of this action we calculate the related Aharonov–Bohm phase and show that it also yields the same effective magnetic field. When magnetic field is strong enough this phase becomes independent of magnetic field. Measurement of it may give some hints on spatial noncommutativity. The noncommutativity parameter θ can be tuned such that electrons moving in noncommutative coordinates are interpreted as either leading to the fractional quantum Hall effect or composite fermions in the usual coordinates. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1504484]

I. INTRODUCTION

To clarify the role which noncommutative coordinates may play in physics a better understanding of quantum mechanics in noncommutative spaces would be useful. Obviously, the simplest case is to consider particles moving in two-dimensional noncommutative spaces. Actually, there exist some realistic physical systems like electrons in a uniform external magnetic field which are effectively moving in a two-dimensional space which is perpendicular to magnetic field. These electrons are investigated in noncommuting coordinates[1] and interesting phenomena like nonextensive statistics[2] and orbital magnetism[3] are resulted. We would like to consider electrons moving in two-dimensional noncommutative space when both uniform external magnetic and electric fields are present. In the usual case this system leads to Hall effect. Indeed, we will show that in noncommuting coordinates one obtains Hall effect in terms of an effective magnetic field.

Once noncommutativity is imposed coordinates behave as operators. However, we can bring in noncommutativity by keeping coordinates as commuting but requiring that composition of their functions is given by star product. After canonical quantization is performed we deal with ordinary coordinates but replace ordinary product with star product. This procedure leads to an ordinary quantum mechanics problem in terms of an effective Hamiltonian depending on the noncommutativity parameter θ. As far as operator description of quantum mechanics is concerned this procedure suits well. However, if one deals with path integrals the suitable action should be given in terms of c-number phase space variables. One of the possibilities is to find an effective action which leads to the Green functions which are calculated in terms of operators.[4] We will adopt another method: The effective action which we use in path integrals is found by replacing deriva-

[a)]Electronic mail: dayi@itu.edu.tr-dayi@gursey.gov.tr
[b)]Electronic mail: jellal@gursey.gov.tr-jellal@na.infn.it

tives appearing in Hamiltonian with c-number momentum variables. A similar approach is given in Ref. 5 and a different one in Ref. 6. We will use the action obtained in this manner in path integrals to calculate the related Aharonov–Bohm phase after generalizing the action obtained in symmetric gauge to embrace the other vector potentials at the first order in θ.

In Sec. II we recall how one can find energy eigenvalues and eigenfunctions of an electron moving on plane in uniform external magnetic and electric fields. This serves as a guide in Sec. III when we deal with the same system in noncommuting coordinates. In Sec. IV we present an approach to derive the electric current in noncommutative coordinates. Then, we calculate its expectation value utilizing eigenfunctions derived in Sec. III, yielding the Hall effect in noncommuting coordinates. This can be envisaged as the usual Hall effect in terms of an effective magnetic field. Section V is devoted to calculate Aharonov–Bohm phase in noncommuting coordinates after presenting our receipt to obtain the action suitable to be used in path integrals. This phase is used to define an effective magnetic field in terms of commuting coordinates. We observe that effective magnetic fields obtained in Sec. IV and in Sec. V are the same. In the last section by tuning the parameter θ and utilizing the effective magnetic field we offer two different interpretations of electrons moving in noncommutative space as either leading to the fractional quantum Hall effect[7] or composite fermions[8] in the usual space. Moreover, we propose to measure the Aharonov–Bohm phase for large magnetic fields which may give some hints on the existence of spatial noncommutativity.

II. ELECTRON MOVING ON PLANE

An electron moving on the plane (x,y) in the uniform external electric field $\vec{E}=-\vec{\nabla}\phi$ and the uniform external magnetic field B which is perpendicular to the plane is described by the Hamiltonian

$$H=\frac{1}{2m}\left(\vec{p}+\frac{e}{c}\vec{A}\right)^2-e\phi. \tag{1}$$

We neglect the spin, because taking it into account does not affect our results.

Let us adopt the symmetric gauge

$$\vec{A}=\left(-\frac{B}{2}y,\frac{B}{2}x\right). \tag{2}$$

During the related experiments the electric field $\vec{E}$ is taken in one of the two possible directions. Thus let the scalar potential be

$$\phi=-Ex. \tag{3}$$

Making use of (2) and (3) in (1) leads to the Hamiltonian function

$$H(\vec{p},\vec{r})=\frac{1}{2m}\left[\left(p_x-\frac{eB}{2c}y\right)^2+\left(p_y+\frac{eB}{2c}x\right)^2\right]+eEx. \tag{4}$$

As usual canonical quantization of this system is achieved by introducing the coordinate and momentum operators $\hat{r}_i$, $\hat{p}_i$ satisfying

$$[\hat{r}_i,\hat{p}_j]=i\hbar\delta_{ij} \tag{5}$$

and dealing with the Hamiltonian operator $\hat{H}$ obtained from (4) as $\hat{H}=H(\hat{\vec{p}},\hat{\vec{r}})$.

To discuss the eigenvalue problem

$$\hat{H}\Psi=E\Psi, \tag{6}$$

it is convenient to perform the change of variables

$$\hat{z}=\hat{x}+i\hat{y}, \quad \hat{p}_z=\tfrac{1}{2}(\hat{p}_x-i\hat{p}_y)$$

and introduce two sets of creation and annihilation operators:

$$b^\dagger=-2i\hat{p}_{\bar{z}}+\frac{eB}{2c}\hat{z}+\lambda, \quad b=2i\hat{p}_z+\frac{eB}{2c}\hat{\bar{z}}+\lambda, \tag{7}$$

and

$$d=2i\hat{p}_z-\frac{eB}{2c}\hat{\bar{z}}, \quad d^\dagger=-2i\hat{p}_{\bar{z}}-\frac{eB}{2c}\hat{z}, \tag{8}$$

where $\lambda=mcE/B$. These two sets commute with each other and satisfy the commutation relations

$$[b,b^\dagger]=2m\hbar\omega, \quad [d^\dagger,d]=2m\hbar\omega, \tag{9}$$

where $\omega=eB/mc$ is the cyclotron frequency. Now, the Hamiltonian $\hat{H}$ can be written as

$$\hat{H}=\frac{1}{4m}(b^\dagger b+bb^\dagger)-\frac{\lambda}{2m}(d^\dagger+d)-\frac{\lambda^2}{2m}. \tag{10}$$

To calculate the eigenvalues E and the eigenfunctions Ψ we separate (10) into two mutually commuting parts:

$$\hat{H}=\hat{H}_{\text{osc}}-\hat{T},$$

where $\hat{H}_{\text{osc}}$ denotes the harmonic oscillator part

$$\hat{H}_{\text{osc}}=\frac{1}{4m}(b^\dagger b+bb^\dagger) \tag{11}$$

and the part linear in d and $d^\dagger$ is given by

$$\hat{T}=\frac{\lambda}{2m}(d^\dagger+d)+\frac{\lambda^2}{2m}. \tag{12}$$

The harmonic oscillator eigenvalue equation $\hat{H}_{\text{osc}}\Phi_n=E_n^{\text{osc}}\Phi_n$ is easily solved:

$$\begin{aligned}\Phi_n&=\frac{1}{\sqrt{(2m\hbar\omega)^n n!}}(b^\dagger)^n|0\rangle,\\ E_n^{\text{osc}}&=\frac{\hbar\omega}{2}(2n+1), \quad n=0,1,2,\ldots\end{aligned} \tag{13}$$

leading to a discrete spectrum. However, the eigenvalue equation $\hat{T}\phi=E\phi$ can be analyzed in terms of the eigenvalues of the operators $\hat{r}_i$ denoted by r_i as

$$\begin{aligned}\phi_\alpha&=\exp\left(i(\alpha y+i\frac{m\omega}{2\hbar}xy)\right),\\ E_\alpha&=\frac{\hbar\lambda}{m}\alpha+\frac{\lambda^2}{2m}, \quad \alpha\in\mathbb{R},\end{aligned} \tag{14}$$

yielding a continuous spectrum labeled by α.

Therefore, the eigenfunctions and the energy spectrum of the Hamiltonian $\hat{H}$ are

$$\Psi_{(n,\alpha)}=\Phi_n\otimes\phi_\alpha\equiv|n,\alpha\rangle,$$
$$E_{(n,\alpha)}=\frac{\hbar\omega}{2}(2n+1)-\frac{\hbar\lambda}{m}\alpha-\frac{\lambda^2}{2m},\quad n=0,1,2,\ldots,\quad \alpha\in\mathbb{R}, \tag{15}$$

where $\otimes$ denotes the direct product.

III. ELECTRON MOVING ON NONCOMMUTATIVE PLANE

Let the coordinates of the plane be noncommuting:

$$[\mathbf{x},\mathbf{y}]=i\theta. \tag{16}$$

The parameter θ is a real constant. Noncommutativity can be imposed by treating the coordinates as commuting but requiring that composition of their functions is given in terms of the star product

$$\star\equiv\exp\frac{i\theta}{2}(\overleftarrow{\partial}_x\overrightarrow{\partial}_y-\overleftarrow{\partial}_y\overrightarrow{\partial}_x). \tag{17}$$

Now, we deal with the commutative coordinates x and y but replace the ordinary products with the star product (17). For example, instead of the commutator (16) one defines

$$x\star y-y\star x=i\theta. \tag{18}$$

We would like to study the Hamiltonian (4) in terms of the noncommutative coordinates (16). First we quantize this system by establishing the commutation relations (5). Then, the noncommutativity of the coordinates is taken into account by defining a new operator as

$$\hat{H}\star\Psi(\vec{r})\equiv\hat{H}_{\mathrm{nc}}\Psi(\vec{r}). \tag{19}$$

This definition yields the Hamiltonian operator $\hat{H}_{\mathrm{nc}}$,

$$\hat{H}_{\mathrm{nc}}=\frac{1}{2m}\left[\left((1-\kappa)\hat{p}_x-\frac{eB}{2c}\hat{y}\right)^2+\left((1-\kappa)\hat{p}_y+\frac{eB}{2c}\hat{x}\right)^2\right]+eE\left(\hat{x}-\frac{\theta}{2\hbar}\hat{p}_y\right), \tag{20}$$

when the coordinate representation of momentum $\hat{p}_i=-i\hbar\partial_i$ is used and $\kappa=e\theta B/4\hbar c$.

The eigenvalue problem

$$\hat{H}_{\mathrm{nc}}\Psi^{\mathrm{nc}}=E^{\mathrm{nc}}\Psi^{\mathrm{nc}} \tag{21}$$

is as in ordinary quantum mechanics in spite of the fact that electron moves on noncommutative plane. The solutions of this problem can be worked out in a manner similar to the one used in Sec. II although here there exists a term linear in momentum which was not present in $\hat{H}$. Then, let us introduce two sets of operators

$$\tilde{b}^\dagger=-2i\hat{\bar{p}}_z+\frac{eB}{2c}\hat{z}+\lambda_-,\quad \tilde{b}=2i\hat{\bar{p}}_z+\frac{eB}{2c}\hat{\bar{z}}+\lambda_-, \tag{22}$$

and

$$\tilde{d}=2i\hat{\bar{p}}_z-\frac{eB}{2c}\hat{\bar{z}},\quad \tilde{d}^\dagger=-2i\hat{\bar{p}}_{\bar{z}}-\frac{eB}{2c}\hat{z}, \tag{23}$$

where $\hat{\tilde{p}}_z=\gamma\hat{p}_z$; $\gamma=1-\kappa$. The real parameter λ_- will be fixed later. The sets of operators $(\tilde{b},\tilde{b}^\dagger)$ and $(\tilde{d},\tilde{d}^\dagger)$ commute with each other. Moreover, they satisfy the commutation relations

$$[\tilde{b},\tilde{b}^\dagger]=2m\hbar\tilde{\omega},\quad [\tilde{d}^\dagger,\tilde{d}]=2m\hbar\tilde{\omega}, \tag{24}$$

where $\tilde{\omega}=\gamma\omega$. The Hamiltonian $\hat{H}_{\rm nc}$ can be written as

$$\hat{H}_{\rm nc}=\frac{1}{4m}(\tilde{b}^\dagger\tilde{b}+\tilde{b}\tilde{b}^\dagger)-\frac{\lambda_+}{2m}(\tilde{d}^\dagger+\tilde{d})-\frac{\lambda_-^2}{2m}, \tag{25}$$

where the parameters $\lambda_\pm$ are fixed to be

$$\lambda_\pm=\lambda\pm\frac{emE\theta}{4\gamma\hbar}. \tag{26}$$

We take into account only the values of the noncommutativity parameter $\theta\neq 4\hbar c/eB$. Otherwise, $\lambda_\pm$ diverge. We will give a brief discussion of this fact in the last section.

Observing the similarity between the Hamiltonians (10) and (25) the solutions of the eigenvalue problem (21) can be read from (15) as

$$\begin{aligned}\Psi^{\rm nc}_{(n,\alpha,\theta)}\equiv|n,\alpha,\theta\rangle&=\frac{1}{\sqrt{(2m\hbar\tilde{\omega})^n n!}}\exp\left(i(\alpha y+\frac{m\tilde{\omega}}{2\hbar}xy)\right)(\tilde{b}^\dagger)^n|0\rangle,\\ E^{\rm nc}_{(n,\alpha,\theta)}&=\frac{\hbar\tilde{\omega}}{2}(2n+1)-\frac{\hbar\gamma\lambda_+}{m}\alpha-\frac{m}{2}\lambda_-^2,\quad n=0,1,2,\ldots,\quad \alpha\in\mathbb{R}.\end{aligned} \tag{27}$$

We would like to emphasize that the results of Sec. II are recovered if the noncommutativity parameter θ is switched off.

IV. HALL CONDUCTIVITY ON NONCOMMUTATIVE PLANE

We would like to find conductivity resulting from the Hamiltonian $\hat{H}_{\rm nc}$. The first step in this direction is to define the related current. Although the identification of derivatives with momentum operators $\partial_i=(i/\hbar)\hat{p}_i$ is only valid in coordinate representation, we will use this definition in defining the current operator $\hat{\vec{J}}$ on noncommutative plane as

$$\hat{\vec{J}}=\frac{ie\rho}{\hbar}[\hat{H}_{\rm nc},\hat{\vec{r}}]=\frac{e\gamma\rho}{m}\left(\gamma\hat{\vec{p}}+\frac{e}{c}\vec{A}+\vec{a}\right), \tag{28}$$

where $\vec{a}=(0,-meE\theta/2\hbar\gamma)$ and ρ denotes electron density.

Now, the expectation value of the current operator $\langle\hat{\vec{J}}\rangle$ can be calculated with respect to the eigenstates $|n,\alpha,\theta\rangle$ (27) leading to

$$\begin{aligned}\langle\hat{J}_x\rangle&=0,\\ \langle\hat{J}_y\rangle&=-\gamma\left(\frac{\rho ec}{B}\right)E.\end{aligned} \tag{29}$$

Therefore, the Hall conductivity on noncommutative plane, denoted by $\sigma_H^{\rm nc}$, is

$$\sigma_H^{\rm nc}=-\gamma\left(\frac{\rho ec}{B}\right). \tag{30}$$

Recall that in the ordinary case the Hall conductivity σ_H and the filling factor ν are given as

$$\sigma_H=\frac{e^2}{h}\nu, \quad \nu=\frac{\Phi_0\rho}{B}, \tag{31}$$

where $\Phi_0=hc/e$. Comparison of (30) with (10) suggests that one can interpret the noncommutative case as a theory of Hall effect on commuting plane with an effective magnetic field

$$B_{\text{eff}}=\frac{B}{1-\dfrac{e\theta B}{4\hbar c}}. \tag{32}$$

Moreover, the effective filling factor

$$\nu_{\text{eff}}=\frac{\Phi_0\rho}{B}\left(1-\frac{e\theta B}{4\hbar c}\right), \tag{33}$$

can also be defined.

V. THE AHARONOV–BOHM EFFECT

We would like to calculate the Aharonov–Bohm effect on noncommutative plane by examining the action appearing in the related path integral. When we deal with quantum mechanics in the usual spaces it is the related classical action. However, it is not clear what should be the definition of action appropriate for path integrals when noncommutativity is taken into account. Because, we define Hamiltonian operators in terms of the receipt used in (19) where we identify $\partial_i\equiv(i/\hbar)\hat{p}_i$. We propose to define the path integral in noncommutative space as

$$Z=\int d^2p\,d^2r\,\exp\left(\frac{i}{\hbar}\int \mathrm{d}t[\vec{p}\cdot\dot{\vec{r}}-H_{\text{eff}}(\vec{r},\vec{p})]\right), \tag{34}$$

where $(\vec{r},\vec{p})$ define the commuting phase space and $H_{\text{eff}}(\vec{r},\vec{p})$ will be obtained from the related Hamiltonian operator in noncommutative space by replacing the operators $\hat{\vec{p}}$, $\hat{\vec{r}}$ with c-number variables $\vec{p}$, $\vec{r}$.

Let us deal with the Hamiltonian operator on noncommutive plane in the constant external electric field $\vec{E}=(E_x,E_y)$ and the constant magnetic field B in the symmetric gauge (2):

$$\hat{H}'_{\text{nc}}=\frac{1}{2m}\left[\left(\gamma\hat{p}_x-\frac{eB}{2c}\hat{y}\right)^2+\left(\gamma\hat{p}_y+\frac{eB}{2c}\hat{x}\right)^2\right]+eE_x\left(\hat{x}-\frac{\theta}{2\hbar}\hat{p}_y\right)+eE_y\left(\hat{y}+\frac{\theta}{2\hbar}\hat{p}_x\right). \tag{35}$$

Although the Hamiltonian operator

$$\hat{H}_\theta\equiv\frac{\gamma^2}{2m}\hat{\vec{p}}^2+\frac{e^2}{2mc^2}\vec{A}^2+\frac{e\gamma}{2mc}(\hat{\vec{p}}\cdot\vec{A}+\vec{A}\cdot\hat{\vec{p}})+\hat{\vec{p}}\cdot\vec{K}+e\vec{E}\cdot\hat{\vec{r}}, \tag{36}$$

where $\vec{K}=(e\theta/2\hbar)(-E_y,E_x)$, is equivalent to (35) only when the vector potential $\vec{A}$ is as given in (2), we assume that at least at the first order in θ it is valid for any gauge potential.

The c-number effective Hamiltonian corresponding to (36) is

$$H_{\text{eff}}=\frac{\gamma^2}{2m}\vec{p}^2+\frac{e^2}{2mc^2}\vec{A}^2+\vec{p}\cdot\left(\frac{e\gamma}{mc}\vec{A}+\vec{K}\right)+e\vec{E}\cdot\vec{r}. \tag{37}$$

Thus, the partition function can be written as

$$Z_{\rm nc}=N\int d^2pd^2r\,\exp\left(\frac{i}{\hbar}\int_{t_1}^{t_2}{\rm d}t\left[\vec{p}\cdot\left(\dot{\vec{r}}-\frac{e\gamma}{mc}\vec{A}-\vec{K}\right)-\frac{\gamma^2}{2m}\vec{p}^{\,2}-\frac{e^2}{2mc^2}\vec{A}^2-e\vec{E}\cdot\vec{r}\right]\right), \tag{38}$$

where N is a normalization constant. Now, we can integrate over the momenta $\vec{p}$ to obtain

$$Z_{\rm nc}=\frac{2m}{\gamma^2}N\int d^2r\,\exp\left(\frac{i}{\hbar}\int_{t_1}^{t_2}{\rm d}t\left[\frac{m}{2\gamma^2}\dot{\vec{r}}^{\,2}-\frac{m}{\gamma^2}\dot{\vec{r}}\cdot\left(\frac{e\gamma}{mc}\vec{A}+\vec{K}\right)+\frac{e}{c\gamma}\vec{A}\cdot\vec{K}+\frac{m}{2\gamma^2}\vec{K}^2-e\vec{E}\cdot\vec{r}\right]\right). \tag{39}$$

The constant K^2 term is irrelevant. In terms of a new normalization constant N' we can write

$$Z_{\rm nc}=N'\int d^2r\,\exp\left(\frac{i}{\hbar}S_0-\frac{im}{\hbar\gamma^2}\int_{t_1}^{t_2}{\rm d}t\,\dot{\vec{r}}\cdot\left(\frac{e\gamma}{mc}\vec{A}+\vec{K}\right)\right), \tag{40}$$

where we defined

$$S_0=\int_{t_1}^{t_2}{\rm d}t\left[\frac{m}{2\gamma^2}\dot{\vec{r}}^{\,2}-e\vec{E}\cdot\vec{r}+\frac{e}{c\gamma}\vec{A}\cdot\vec{K}\right]. \tag{41}$$

The last term in the exponent of (40) can be written as

$$i\delta=-\frac{im}{\gamma^2\hbar}\int_{\vec{r}(t_1)}^{\vec{r}(t_2)}{\rm d}\vec{r}\cdot\left(\frac{e\gamma}{mc}\vec{A}+\vec{K}\right). \tag{42}$$

To investigate the Aharonov–Bohm effect for noncommuting coordinates, let $\vec{A}=\vec{\nabla}f(\vec{r})$. Then

$$\delta=-\frac{m}{\gamma^2\hbar}\int_{\vec{r}(t_1)}^{\vec{r}(t_2)}{\rm d}\vec{r}\cdot\left(\frac{e\gamma}{mc}\vec{\nabla}f(\vec{r})+\vec{K}\right) \tag{43}$$

depends only on the points $\vec{r}(t_1)$, $\vec{r}(t_2)$ which are kept fixed in path integrals. Therefore, it is a phase factor. i.e., propagation with the action S_0 is changed up to the phase factor (43).

The Aharonov–Bohm effect can now be calculated as the integral of the phase factor (43) along a loop enclosing a magnetic flux. $\vec{K}$ is a constant vector so that, it does not contribute to the Aharonov–Bohm phase:

$$\oint{\rm d}\vec{r}\cdot\vec{K}=0. \tag{44}$$

As in the ordinary case the unique contribution is due to the gauge potential

$$\Phi_{\rm AB}^{\rm nc}=-2\pi\frac{BS}{\gamma\Phi_0}, \tag{45}$$

where S denotes the surface enclosed. Obviously, when $\theta=0$ the usual Aharonov–Bohm phase results

$$\Phi_{\rm AB}=-2\pi\frac{BS}{\Phi_0}. \tag{46}$$

Thus we can envisage the noncommutative case as a theory in commuting coordinates with an effective magnetic field

$$B_{\text{eff}}=\frac{B}{1-\dfrac{e\theta B}{4\hbar c}}, \tag{47}$$

which is the one obtained previously (32).

VI. DISCUSSIONS

Electrons moving on a noncommutative plane when uniform external magnetic and electric fields are present can be envisaged as the usual motion of electrons experiencing an effective magnetic field (32). This is one of our main results. It followed by considering either Hall effect or Aharonov–Bohm phase in noncommuting coordinates. By tuning the value of the noncommutativity parameter θ we can offer two different interpretations of this fact.

The fractional quantum Hall effect is one of the most interesting features of low dimensional systems.[7] For electrons moving on a plane in a magnetic field which is perpendicular to the plane and a uniform external electric field which is in the plane, the observed Hall conductivity is

$$\sigma_H=f\frac{e^2}{h},$$

where $f=1/3,2/3,1/5,\ldots$, denoting the fractional quantized values of the filling factor ν. We would like to interpret this phenomena, which is known as the fractional quantum Hall effect, in terms of the Hall effect on noncommutative plane. More precisely we identify the effective filling factor (33) with the observed value f by fixing the value of θ to be θ_H:

$$\nu_{\text{eff}}\big|_{\theta=\theta_H}=f. \tag{48}$$

In fact, this can be solved as

$$\theta_H=\frac{2\Phi_0}{\pi B}\left(1-f\frac{B}{\Phi_0\rho}\right). \tag{49}$$

Therefore, when θ is fixed to be θ_H one can envisage the Hall effect on noncommutative plane as the usual fractional quantum Hall effect.

Composite fermions are a new kind of particles appearing in condensed matter physics to provide an explanation of the behavior of electrons moving on plane when a strong magnetic field B is present.[8] Electrons possessing $2p$; $p=1,2,\ldots$, flux quanta (vortices) can be thought of as being composite fermions. One of the most important features of them is they feel effectively the magnetic field

$$B^*=B-2p\Phi_0\rho, \tag{50}$$

where ρ is the electron density. To interpret electrons moving on noncommutative space in the magnetic field B as the usual composite fermions we should tune θ such that

$$B_{\text{eff}}\big|_{\theta=\theta_c}=B^*, \tag{51}$$

where B_{eff} is given in (32). We solve this to obtain

$$\theta_c=\frac{2\Phi_0}{\pi B}\left[1-\left(1-2p\frac{\rho\Phi_0}{B}\right)^{-1}\right], \tag{52}$$

which in the limit of strong magnetic field leads to

$$\theta_c \approx 4p\frac{\rho}{\pi}\left(\frac{\Phi_0}{B}\right)^2. \tag{53}$$

Thus, composite fermions can be envisaged as electrons moving in noncommutative plane in the magnetic field B and the electric field E when we fix $\theta=\theta_c$.

The Aharonov–Bohm phase $\Phi_{\mathrm{AB}}^{\mathrm{nc}}$ possesses a very interesting limit. Let us deal with $\theta\neq 0$ and the magnetic field satisfying the condition

$$B \gg \frac{4c\hbar}{e\theta}. \tag{54}$$

For these values of magnetic field the Aharonov–Bohm phase $\Phi_{\mathrm{AB}}^{\mathrm{nc}}$ (45) becomes

$$\Phi_{\mathrm{AB}}^{\mathrm{nc}} \approx \frac{4c\hbar S}{e\theta\Phi_0}, \tag{55}$$

which is independent of B. For $\vec{E}=0$ the action S_0 reads

$$\tilde{S}_0 \equiv S_0|_{\vec{E}=0} = \frac{m}{2\gamma^2}\int \mathrm{d}t\, \dot{\vec{r}}^2,$$

which depends on the magnetic field as B^{-2} when (54) is satisfied. If the phase $\Phi_{\mathrm{AB}}^{\mathrm{nc}}$ can be measured for the particle propagating with the action $\tilde{S}_0$ when B satisfies (54) and observed that it is independent of B after a certain value of B, it may be evidence for spatial noncommutativity. Obviously, this conclusion is valid only for small values of θ. Because we assume it when we write the action (36). In Ref. 9 the Aharonov–Bohm effect in noncommutative coordinates was studied in terms of a field theoretical approach where an experiment to detect spatial noncomutativity was proposed.

Critical value of θ defined as

$$\theta^* = \frac{4\hbar c}{eB} \tag{56}$$

is avoided through this work. At this value of θ all of our analysis fails, because $\gamma=1-eB\theta/4\hbar c$ cannot be inverted, thus $\lambda_{\pm}$ (26) are not well defined. Indeed, when $\theta=\theta^*$ the Hamiltonian in noncommutative coordinates (20) becomes

$$\hat{H}_{\mathrm{nc}}(\theta=\theta^*) = \frac{m\omega^2}{8}(\hat{x}^2+\hat{y}^2) + eE\left(\hat{x}-\frac{\theta^*}{2\hbar}\hat{p}_y\right). \tag{57}$$

i.e., the terms quadratic in momenta disappear, however a term linear in momenta survives. Obviously, this system should be studied separately.

ACKNOWLEDGMENT

We would like to thank I. H. Duru for fruitful discussions on the Aharonov–Bohm effect.

Wigner functions with boundaries

Nuno Costa Dias[a] and João Nuno Prata[b]
Departamento de Matemática, Universidade Lusófona de Humanidades e Tecnologias, Av. Campo Grande, 376, 1749-024 Lisboa, Portugal

(Received 13 September 2001; accepted for publication 22 April 2002)

We consider the general Wigner function for a particle confined to a finite interval and subject to Dirichlet boundary conditions. We derive the boundary corrections to the ''stargenvalue'' equation and to the time evolution equation. These corrections can be cast in the form of a boundary potential contributing to the total Hamiltonian which together with a subsidiary boundary condition is responsible for the discretization of the energy levels. We show that a completely analogous formulation (in terms of boundary potentials) is also possible in standard operator quantum mechanics and that the Wigner and the operator formulations are also in one-to-one correspondence in the confined case. In particular, we extend Baker's converse construction to bounded systems. Finally, we elaborate on the applications of the formalism to the subject of Wigner trajectories, namely in the context of collision processes and quantum systems displaying chaotic behavior in the classical limit. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1504885]

I. INTRODUCTION

The Moyal–Wigner–Weyl quantization constitutes a phase space quantization method alternative to canonical or path integral quantizations.[1–13] Instead of wave functions and operators one deals with quasidistribution (Wigner) functions and ordinary c-functions in phase space. The Weyl symbol associated with a general operator $\hat{A}(\hat{x},\hat{p})$ is given by[1,4,12]

$$A^W(x,p)\equiv\frac{\hbar}{2\pi}\int_{-\infty}^{+\infty}\mathrm{d}\xi\int_{-\infty}^{+\infty}\mathrm{d}\eta\,\mathrm{Tr}\{\hat{A}(\hat{x},\hat{p})e^{i\xi\hat{x}+i\eta\hat{p}}\}e^{-i\xi x-i\eta p}. \tag{1}$$

In this framework the average of $\hat{A}(\hat{x},\hat{p};t)$ is evaluated according to the formula: $\langle\psi|\hat{A}(\hat{x},\hat{p};t)|\psi\rangle=\int_{-\infty}^{+\infty}\mathrm{d}x\int_{-\infty}^{+\infty}\mathrm{d}p\,A^W(x,p;0)F^W(x,p;t)$, where $F^W(x,p;t)$ is proportional to the Weyl symbol of the quantum density matrix, $\hat{\rho}$, and is known as the Wigner function of the system.[2] For a pure state, $\hat{\rho}=|\psi\rangle\langle\psi|$, the Wigner function can be shown to be of the form:

$$F^W(x,p;t)\equiv\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\mathrm{d}y e^{-2ipy/\hbar}\psi^*(x-y;t)\psi(x+y;t), \tag{2}$$

where $\psi(x;t)$ is the solution of Schrödinger's equation: $i\hbar\,(\partial\psi/\partial t)\,(x;t)=\hat{H}\psi(x;t)$. The Weyl ''transform'' establishes a biunivocal correspondence between the quantum algebra $\hat{\mathcal{A}}$ of observables with standard operator product $\cdot$ and quantum commutator $[,]$, on the one hand, and the ''classical'' algebra $\mathcal{A}$ defined over the classical phase space T^*M with a ''star-product'' $*$ and a Moyal sine-bracket $[,]_M$, on the other hand. The two latter operations are given by[3,14]

$$A^W(x,p)*B^W(x,p)=A^W(x,p)e^{(i\hbar/2)\overleftrightarrow{\mathcal{J}}}B^W(x,p)=A^W\left(x,p-\frac{i\hbar}{2}\overrightarrow{\partial}_x\right)B^W\left(x,p+\frac{i\hbar}{2}\overleftarrow{\partial}_x\right), \tag{3}$$

[a]Electronic mail: nuno.dias@ulusofona.pt
[b]Electronic mail: joao.prata@ulusofona.pt

$$[A^W(x,p),B^W(x,p)]_M=\frac{1}{i\hbar}(A^W*B^W-B^W*A^W)=\frac{2}{\hbar}A^W(x,p)\sin\left(\frac{\hbar}{2}\overleftrightarrow{\mathcal{J}}\right)B^W(x,p), \tag{4}$$

where

$$\overleftrightarrow{\mathcal{J}}\equiv\left(\frac{\overleftarrow{\partial}}{\partial x}\frac{\vec{\partial}}{\partial p}-\frac{\overleftarrow{\partial}}{\partial p}\frac{\vec{\partial}}{\partial x}\right).$$

One realizes immediately that in the limit $\hbar\to 0$, the star product and the Moyal bracket become the ordinary product of c-numbers and the Poisson bracket, respectively. It is also easy to check that the dynamics of the Wigner function is governed by the Moyal bracket (4):

$$\frac{\partial F^W}{\partial t}(x,p;t)=[H^W(x,p),F^W(x,p;t)]_M, \tag{5}$$

where $H^W(x,p)$ is the Weyl symbol of the quantum Hamiltonian, $\hat{H}(\hat{x},\hat{p})$.

If the time-independent wave function happens to be an energy eigenstate with eigenvalue E, i.e., $\hat{H}\psi(x)=E\psi(x)$, then[15–18] the Wigner function $F_E^W(x,p)$ satisfies an equivalent $*$-genvalue equation with identical $*$-genvalue:

$$H^W(x,p)*F_E^W(x,p)=F_E^W(x,p)*H^W(x,p)=EF_E^W(x,p). \tag{6}$$

More generally, to every eigenstate $|a\rangle$ with eigenvalue a of some operator $\hat{A}$, there is one and only one associated stargenfunction $F_a^W(x,p)$, which is a solution of the stargenvalue equation: $A^W(x,p)*F_a^W(x,p)=aF_a^W(x,p)$.[6,15,18] This stargenfunction allows for the evaluation of the probability of measuring the eigenvalue a:

$$\mathcal{P}(A=a)=\int \mathrm{d}x\int \mathrm{d}p\, F^W(x,p)F_a^W(x,p). \tag{7}$$

It is important to emphasize that, in most cases, the advantage in the Wigner approach does not reside in solving specific problems. Rather, it should be regarded as a means to grasp certain conceptual aspects of quantum mechanics and its connection with classical mechanics. Nevertheless, in some situations it could be a better starting point for finding solutions to specific problems. The Wigner formulation is a useful tool to derive kinetic equations in particular regimes (dilute gas, weakly interacting particles). In nonequilibrium statistical mechanics this is a familiar approach.[19] In collision processes the Wigner methods are also a useful tool.[4,9] Contrary to the standard operator approach they display the important advantage of making possible the use of approximation methods similar to the ones used in the full classical treatment. Furthermore the related subject of Wigner trajectories[4,5,20,21] provides a pictorial and practical tool to study collision process and it is of similar importance in the context of quantum chaotic systems.[4,13,22–24]

Boundary value problems, on the other hand, are one of the cornerstones of quantum mechanics. These are much more realistic models and moreover they entail a discretization of observables' spectra, which is one of the main features of quantum mechanics. They appear in virtually all branches of physics, ranging from quantum mechanics to general relativity, open strings and D-branes, where the noncommutative *-product and the Moyal bracket also find several applications.[16,25,26] In standard operator quantum mechanics some famous examples of boundary value problems include the Kondo problem,[27] quantum Hall liquids with constriction,[28] and the Callan–Rubakov model.[29] Furthermore one of the simplest collision processes is the collision against an impenetrable boundary and some standard examples of quantum chaotic systems are bounded.[4,24]

In spite of the importance of boundary value problems in general and of these models in particular, Wigner quantum mechanics does not provide a self-contained and consistent formula-

tion of confined systems. The aim of this paper is thus to provide such formulation. More precisely our aim is to generalize the two key equations of Wigner quantum mechanics [Eqs. (5) and (6)] to the case when the original wave function is confined to an interval and satisfies Dirichlet boundary conditions.

Let us then consider a general confined system. In standard operator quantum mechanics, we first solve the Schrödinger equation in the bulk (with Hamiltonian $\hat{H}$), subsequently impose the boundary conditions that pin down the physical solutions, and finally impose the wave function to be zero beyond the bulk. Alternatively, we may be able to provide a boundary potential $\hat{V}_D$ that confines the wave function and then solve the unconstrained system, with extended Hamiltonian $\hat{H}_D=\hat{H}+\hat{V}_D$ and the original conditions at the boundaries.

To obtain the solution of the problem in terms of Wigner functions, we just have to insert the solution obtained in the Schrödinger formulation into the definition of the Wigner function. This was the method followed in Ref. 5. But the question that remains is: how do we solve the problem within the Wigner–Weyl formulation?

The first approach cannot be easily translated into the Wigner framework because the highly nonlocal character of the Wigner function produces nontrivial effects of the boundary on the bulk part of the Wigner function, so that the stargenvalue equation has to be altered, as we shall see [Secs. II–IV].

The second procedure seems to be the natural starting point to derive, through the Weyl map, the Wigner formulation for the bounded system. However this is not an easy task, mainly because the formulation of confined systems in terms of boundary potentials is already problematic at the standard operator level. In Sec. VI we will consider this approach and (a) consistently solve the problem at the standard operator level and (b) use the Weyl map to recover the bounded stargenvalue equation derived in Sec. III.

This paper is organized as follows. In Sec. II, we discuss some aspects of the boundary conditions satisfied by the Wigner function. In Secs. III–V we evaluate the boundary corrections to the $*$-genvalue equation (6) and the time evolution equation (5) directly from the general formula of the confined wave function. Furthermore, we (a) extend Baker's converse construction to bounded systems and (b) argue that the results obtained are compatible with the preservation of the Wigner function's normalization under time evolution. In Sec. VI we develop the boundary potential approach for standard operator quantum mechanics and show that through the Weyl map this formulation yields the proper Wigner formulation of confined systems. In Sec. VII we discuss some practical applications of the formalism: the computation of Wigner trajectories for confined chaotic systems and for collision processes. Finally, in Sec. VIII we present our conclusions.

II. WIGNER FUNCTION IN A FINITE INTERVAL

Let us assume that the domain of the wave function is the finite interval $a<x<b$ with $a<b$, so that the wave function vanishes outside this interval. As we now argue, quantum confined systems cannot be treated, in the Wigner formalism, through the standard procedure of solving a differential equation and imposing the boundary conditions thereafter. In particular, the energy stargenfunctions for these systems do not satisfy the stargenvalue equation (6) with the Hamiltonian of the bulk.

As an example, consider the free particle in the infinite well, with $a=-b=-L/2$. The stargenvalue equation would be of the form:

$$\frac{p^2}{2m}*F^W(x,p)=EF^W(x,p).$$

If we solve the corresponding Schrödinger equation with Dirichlet boundary conditions we get for the fundamental state:

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi(x)=E\psi(x)\Rightarrow\psi_1(x)=\sqrt{\frac{2}{L}}\cos\left(\frac{\pi}{L}x\right).$$

If we now determine the associated Wigner function using (2) we get[5] that $F^W(x,p)$ is given by Eqs. (39) and (40). We can easily check that $F^W(x,p)$ does not satisfy the previous stargenvalue equation and thus the only possible conclusion is that this equation has to be altered. Similarly, we can check that the time evolution of the system does not satisfy the Moyal equation with bulk Hamiltonian.

Let us start by studying the general properties of the Wigner function for a confined system. Since the wave function vanishes outside the interval $]a,b[$, it satisfies the condition:

$$\psi^*(x-y)\psi(x+y)=0 \quad \text{unless} \quad a<x-y<b \quad \text{and} \quad a<x+y<b.$$

This means that: (1) for $a<x\leqslant x_0=(a+b)/2$, we have

$$\psi^*(x-y)\psi(x+y)=0 \quad \text{unless} \quad a-x<y<x-a,$$

similary, (2) for $x_0<x<b$:

$$\psi^*(x-y)\psi(x+y)=0 \quad \text{unless} \quad x-b<y<b-x,$$

and finally, (3) for $x\leqslant a$ or $x\geqslant b$:

$$\psi^*(x-y)\psi(x+y)=0, \quad \forall y.$$

We conclude that the Wigner function (2) for the bounded system can be written as

$$F^W(x,p)=\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\mathrm{d}y\, e^{-2ipy/\hbar}\psi^*(x-y)\psi(x+y)=\Theta_1(x)F_1^W(x,p)+\Theta_2(x)F_2^W(x,p), \quad (8)$$

where

$$\begin{aligned}\Theta_1(x)&=\theta(x-a)-\theta(x-x_0)=\begin{cases}1, & \text{if } a<x\leqslant x_0\\ 0, & \text{otherwise,}\end{cases}\\ \Theta_2(x)&=\theta(x-x_0)+\theta(b-x)-1=\begin{cases}1, & \text{if } x_0<x<b\\ 0, & \text{otherwise.}\end{cases}\end{aligned} \quad (9)$$

$\theta(x)$ is the Heaviside's step function: $\theta(x)=1$ iff $x>0$ and $\theta(x)=0$ otherwise, and finally:

$$\begin{cases}F_1^W(x,p)=\dfrac{1}{\pi\hbar}\displaystyle\int_{a-x}^{x-a}\mathrm{d}y\, e^{-2ipy/\hbar}\psi^*(x-y)\psi(x+y),\\ F_2^W(x,p)=\dfrac{1}{\pi\hbar}\displaystyle\int_{x-b}^{b-x}\mathrm{d}y\, e^{-2ipy/\hbar}\psi^*(x-y)\psi(x+y).\end{cases} \quad (10)$$

Since the wave function or its derivatives are possibly discontinuous at $x=a$ and $x=b$, and to avoid possible misinterpretations in our future calculations, the previous integrals are defined as improper: $\int_{a-x}^{x-a}$ stands for $\lim_{c\to a^+}\int_{c-x}^{x-c}$ and likewise $\int_{x-b}^{b-x}$ stands for $\lim_{c\to b^-}\int_{x-c}^{c-x}$. Notice that this is fully compatible with our previous results identifying the domain where $\psi^*(x-y)\psi(x+y)$ is not identically zero.

As a second remark let us point out that the boundary conditions on $\psi(x)$ are imposed on the bulk side of the boundary. For instance, the Dirichlet boundary conditions would be of the form: $\lim_{\epsilon\to 0^+}\psi(a+\epsilon)=\lim_{\epsilon\to 0^+}\psi(b-\epsilon)=0$, which is not the same as requiring $\psi(a)=\psi(b)=0$, since these are valid independently of the boundary conditions satisfied by $\psi(x)$. This is so

because $\psi(x)$ is confined to the open interval $]a,b[$. It is important to realize that we could equally choose to defined "confined" as "confined to the close interval $[a,b]$" and in fact for Dirichlet boundary conditions the two prescriptions yield exactly the same wave function. However, the confinement to an open interval makes some of the future steps more natural (though occasionally more involved) and this is why we choose to work with this prescription.

Finally, and to make our future expressions more compact, we introduce the notation: $f(c^{\pm})=\lim_{\epsilon\to 0^+} f(c\pm\epsilon)$, which will be used whenever there is no risk of misunderstanding.

Let us then study the boundary conditions that are satisfied by the Wigner function of a confined system. From (8)–(10), one realizes immediately that:

$$\begin{cases} F^W(a^+,p)=F_1^W(a^+,p)=F_2^W(b^-,p)=F^W(b^-,p)=0, \\ F^W(x_0^-,p)=F_1^W(x_0,p)=F_2^W(x_0,p)=F^W(x_0^+,p), \end{cases} \tag{11}$$

where, accordingly to the previous notation, $F^W(a^+,p)$ stands for the limit $\lim_{\epsilon\to 0^+} F^W(a+\epsilon,p)$ and likewise for the other expressions. Since $F^W(x,p)$ is defined as an improper integral it already requires the evaluation of a limit. This limit will always be calculated before the limit $\lim_{x\to a^+} F^W(x,p)$, i.e., first we evaluate the Wigner function for all x and only then do we compute whatever limits of the Wigner function. Let us proceed: Eq. (11) means that $F^W(x,p)$ is continuous at x_0 and obeys Dirichlet boundary conditions irrespective of the particular boundary conditions satisfied by the associated wave function ψ. The boundary conditions obeyed by the confined wave function act only on the derivatives of the Wigner function. For $a<x\leqslant x_0$ a straightforward computation leads to:

$$\frac{\partial F_1^W}{\partial x}(x,p)=\frac{1}{\pi\hbar}\Bigg\{ e^{-(2ip/\hbar)(x-a)}\psi^*(a^+)\psi(2x-a^+)+e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^+)\psi(a^+) + \int_{a-x}^{x-a} dy\, e^{-2ipy/\hbar}[\psi'^*(x-y)\psi(x+y)+\psi^*(x-y)\psi'(x+y)]\Bigg\}, \tag{12}$$

where the prime denotes the derivative with respect to the argument. Consequently,

$$\frac{\partial F^W}{\partial x}(a^+,p)=\lim_{x\to a^+}\frac{\partial F_1^W}{\partial x}(x,p)=\frac{2}{\pi\hbar}|\psi(a^+)|^2,$$

$$\frac{\partial F^W}{\partial x}(x_0^-,p)=\frac{\partial F_1^W}{\partial x}(x_0,p)=\frac{1}{\pi\hbar}[e^{-(ip/\hbar)(b-a)}\psi^*(a^+)\psi(b^-)+e^{-(ip/\hbar)(a-b)}\psi^*(b^-)\psi(a^+)] + \frac{1}{\pi\hbar}\lim_{\epsilon\to 0^+}\int_{((a-b)/2)+\epsilon}^{((b-a)/2)-\epsilon} dy\, e^{-2ipy/\hbar}[\psi'^*(x_0-y)\psi(x_0+y) + \psi^*(x_0-y)\psi'(x_0+y)]. \tag{13}$$

Similarly, from F_2^W we get

$$\frac{\partial F^W}{\partial x}(b^-,p)=\lim_{x\to b^-}\frac{\partial F_2^W}{\partial x}(x,p)=-\frac{2}{\pi\hbar}|\psi(b^-)|^2,$$

$$\frac{\partial F^W}{\partial x}(x_0^+,p)=\frac{\partial F_2^W}{\partial x}(x_0,p)$$

$$=-\frac{1}{\pi\hbar}[e^{-(ip/\hbar)(b-a)}\psi^*(a^+)\psi(b^-)+e^{-(ip/\hbar)(a-b)}\psi^*(b^-)\psi(a^+)]$$

$$+\frac{1}{\pi\hbar}\lim_{\epsilon\to 0^+}\int_{((a-b)/2)+\epsilon}^{((b-a)/2)-\epsilon}dy\, e^{-2ipy/\hbar}[\psi'^*(x_0-y)\psi(x_0+y)$$

$$+\psi^*(x_0-y)\psi'(x_0+y)]. \tag{14}$$

We conclude that in general $(\partial F^W/\partial x)(x_0^-,p)\neq(\partial F^W/\partial x)(x_0^+,p)$, except for Dirichlet boundary conditions [i.e., $\psi(a^+)=\psi^*(a^+)=\psi(b^-)=\psi^*(b^-)=0$], in which case the Wigner function also obeys Neumann boundary conditions: $(\partial F^W/\partial x)(a^+,p)=(\partial F^W/\partial x)(b^-,p)=0$. We can carry on with this process and compute the second and third derivatives. The results concerning the boundary conditions can then be summarized as follows. All Wigner functions for bounded systems satisfy Eq. (11). These are consistency conditions and, given their general character, cannot give countenance to the discretization of the energy spectrum. The boundary conditions satisfied by the confined wave function yield subsidiary conditions on the Wigner function:

Dirichlet: $\psi(a^+)=\psi^*(a^+)=\psi(b^-)=\psi^*(b^-)=0$,

$$\frac{\partial F^W}{\partial x}(a^+,p)=\frac{\partial F^W}{\partial x}(b^-,p)=0. \tag{15}$$

If a Wigner function satisfies these Neumann conditions, then it *automatically* verifies:

$$\begin{cases}\dfrac{\partial F^W}{\partial x}(x_0^-,p)=\dfrac{\partial F^W}{\partial x}(x_0^+,p),\\[2ex] \dfrac{\partial^2 F^W}{\partial x^2}(a^+,p)=\dfrac{\partial^2 F^W}{\partial x^2}(b^-,p)=0,\\[2ex] \dfrac{\partial^2 F^W}{\partial x^2}(x_0^-,p)=\dfrac{\partial^2 F^W}{\partial x^2}(x_0^+,p)\,.\end{cases} \tag{16}$$

Obviously, this pattern does not continue indefinitely. For instance, $(\partial^3 F^W/\partial x^3)(a^+,p)=(8/\pi\hbar)\,|\psi'(a^+)|^2\neq 0$. It is also important to emphasize that contrary to Eq. (15), the additional set of equations (16), being just a consequence of Eq. (15), do not constrain F^W any further.

Neumann: $\psi'(a^+)=\psi'^*(a^+)=\psi'(b^-)=\psi'^*(b^-)=0$,

$$\begin{cases}\dfrac{\partial F^W}{\partial x}(a^+,p)\neq 0, & \dfrac{\partial F^W}{\partial x}(b^-,p)\neq 0,\\[2ex] \dfrac{\partial F^W}{\partial x}(x_0^-,p)\neq\dfrac{\partial F^W}{\partial x}(x_0^+,p),\\[2ex] \dfrac{\partial^2 F^W}{\partial x^2}(a^+,p)=\dfrac{\partial^2 F^W}{\partial x^2}(b^-,p)=0,\\[2ex] \dfrac{\partial^2 F^W}{\partial x^2}(x_0^-,p)=\dfrac{\partial^2 F^W}{\partial x^2}(x_0^+,p).\end{cases} \tag{17}$$

We also have: $(\partial^3 F^W/\partial x^3)(a^+,p)\neq 0$.

The former results show that the confinement of the system and the boundary conditions satisfied by the wave function influence the Wigner function in a very nontrivial way. Furthermore, conditions (11), (15), and (16) will play an important part in the derivation of the new $*$-genvalue equation for bounded systems.

However, one should realize that the previous results also display some less interesting features: let us focus on the case in which the wave function satisfies Dirichlet boundary conditions. If the system is also confined then the Wigner function will satisfy the set of conditions (11), (15), (16). The problem is that the converse result is not valid, i.e., conditions (11), (15), (16) do not imply the confinement of the system and it is also not clear if, in general, they imply that the original wave function satisfy Dirichlet boundary conditions. Hence, (11), (15), (16) will not completely pin down the Wigner transform of the confined wave function satisfying Dirichlet boundary conditions and thus Eqs. (11), (15), (16) fail to provide the proper translation (into the Wigner language) of the Dirichlet boundary conditions on the wave function.

We now introduce a new set of boundary conditions for the Wigner function, which are fully equivalent to Dirichlet boundary conditions on the original wave function, both for the confined as well as for the unconfined case. We call these conditions *integral Dirichlet boundary conditions* and they can be derived as follows: if the wave function satisfies Dirichlet boundary conditions then $\lim_{\epsilon\to 0^+}\mathcal{P}(a+\epsilon)=\lim_{\epsilon\to 0^+}|\psi(a+\epsilon)|^2=0$ and similarly $\lim_{\epsilon\to 0^+}\mathcal{P}(b-\epsilon)=\lim_{\epsilon\to 0^+}|\psi(b-\epsilon)|^2=0$ where $\mathcal{P}(x)$ stands for the probability distribution. These equations can be written in the Wigner context quite straightforwardly:

$$\begin{cases} \lim\limits_{\epsilon\to 0^+}\displaystyle\int_{-\infty}^{+\infty} dp F^W(a+\epsilon,p)=0, \\ \lim\limits_{\epsilon\to 0^+}\displaystyle\int_{-\infty}^{+\infty} dp F^W(b-\epsilon,p)=0. \end{cases} \tag{18}$$

Notice that the use of the limits is valid (though unnecessary) in the unconfined case (where the wave function and its derivatives are continuous) but it is necessary if the system is confined.

From the two sets of boundary conditions satisfied by the Wigner function [Eqs. (11), (15), (16) and Eq. (18)], the Dirichlet integral ones are the most appealing both from the physical and the mathematical points of view: first, because they represent a physically meaningful imposition that the probability of finding the particle at the boundary is zero. Second, because they are fully equivalent to the Dirichlet boundary conditions on the wave function. From Eqs. (7) and (18), we get

$$\lim_{\epsilon\to 0^+}\int_{-\infty}^{+\infty} dp\, F^W(a+\epsilon,p)=0 \Rightarrow \lim_{\epsilon\to 0^+}|\psi(a+\epsilon)|^2=0 \Rightarrow \lim_{\epsilon\to 0^+}\psi(a+\epsilon)=0, \tag{19}$$

and similarly for the b-boundary. Finally, and to avoid a possible misinterpretation let us point out that Eq. (11) does not imply the satisfaction of conditions (18) given the fact that, in general, it is not possible to interchange the order in which one evaluates the limit and the integral in (18). For instance, if a confined wave function satisfies Neumann conditions then the Wigner function will satisfy (11) but not (18).

III. BOUNDARY STARGENVALUE EQUATION

Let us henceforth assume that the wave function satisfies Dirichlet boundary conditions, so that Eqs. (11), (15), (16), and (18) are valid. Furthermore, we assume that $\psi(x)$ is an energy-eigenstate for a Hamiltonian of the form: $\hat{H}(\hat{x},\hat{p})=(\hat{p}^2/2m)+V(\hat{x})$. If we substitute F^W (8) on the left-hand side of Eq. (6), we get

$$H^W * F^W = H^W * \{\Theta_1 F_1^W + \Theta_2 F_2^W\} = \left\{\frac{p^2}{2m} + V(x)\right\} * (\Theta_1 F_1^W) + \left\{\frac{p^2}{2m} + V(x)\right\} * (\Theta_2 F_2^W). \quad (20)$$

A straightforward calculation leads to

$$H^W * (\Theta_1 F_1^W) = \Theta_1 (H^W * F_1^W) - \frac{i\hbar p}{2m}[\delta(x-a) - \delta(x-x_0)] F_1^W + \frac{\hbar^2}{8m}[\delta'(x-x_0) - \delta'(x-a)] F_1^W + \frac{\hbar^2}{4m}[\delta(x-x_0) - \delta(x-a)] \frac{\partial F_1^W}{\partial x}. \quad (21)$$

Taking into account the boundary conditions at $x=a$, we get

$$H^W * (\Theta_1 F_1^W) = \Theta_1 (H^W * F_1^W) + \frac{i\hbar p}{2m}\delta(x-x_0) F_1^W(x_0,p) + \frac{\hbar^2}{4m}\delta(x-x_0)\frac{\partial F_1^W}{\partial x}(x_0,p) + \frac{\hbar^2}{8m}\delta'(x-x_0) F_1^W(x,p). \quad (22)$$

Similarly, we also have

$$H^W * (\Theta_2 F_2^W) = \Theta_2 (H^W * F_2^W) - \frac{i\hbar p}{2m}\delta(x-x_0) F_2^W(x_0,p) - \frac{\hbar^2}{4m}\delta(x-x_0)\frac{\partial F_2^W}{\partial x}(x_0,p) - \frac{\hbar^2}{8m}\delta'(x-x_0)\, F_2^W(x,p). \quad (23)$$

Adding up all contributions and taking into account the fusing conditions (11) and (16), we obtain

$$H^W * F^W = \Theta_1 (H^W * F_1^W) + \Theta_2 (H^W * F_2^W). \quad (24)$$

Let us then calculate the term $H^W * F_1^W$ for $a < x \leqslant x_0$ and the term $H^W * F_2^W$ for $x_0 < x < b$. The following theorem will do this.

Theorem: Let F_1^W and F_2^W be given by Eq. (10) where $\psi(x)$ is an energy eigenstate satisfying Dirichlet boundary conditions at a and b. Let $H^W = (p^2/2m) + V(x)$. We then have

$$\begin{cases} H^W * F_1^W(x,p) = E F_1^W(x,p) + \dfrac{\hbar^2}{2m}\delta'(x-a) * F_1^W(x^+,p) \quad \text{for } a < x \leqslant x_0, \\ H^W * F_2^W(x,p) = E F_2^W(x,p) - \dfrac{\hbar^2}{2m}\delta'(x-b) * F_2^W(x^-,p) \quad \text{for } x_0 < x < b. \end{cases} \quad (25)$$

Proof: Let us consider the product $H^W * F_1^W$. Following the method described in Ref. 15, we get

$$H^W * F_1^W = \frac{1}{\pi\hbar}\left[\frac{1}{2m}\left(p - \frac{i\hbar}{2}\vec{\partial}_x\right)^2 + V(x)\right]\int_{a-x}^{x-a} dy\, e^{-(2iy/\hbar)(p + (i\hbar/2)\vec{\partial}_x)}\psi^*(x-y)\psi(x+y)$$
$$= \frac{1}{\pi\hbar}\int_{a-x}^{x-a} dy\, e^{-2iyp/\hbar} V(x+y)\psi^*(x-y)\psi(x+y) + \frac{1}{2m\pi\hbar}\left[p^2 - i\hbar p\vec{\partial}_x - \frac{\hbar^2}{4}\vec{\partial}_x^2\right]\int_{a-x}^{x-a} dy\, e^{-(2iyp/\hbar)}\psi^*(x-y)\psi(x+y), \quad (26)$$

where $\vec{\partial}_x$ acts on F_1^W and $\overleftarrow{\partial}_x$ acts on H^W. Taking into account that $pe^{-2iyp/\hbar}=(i\hbar/2)\times(\partial/\partial y)\,e^{-2iyp/\hbar}$ and that $\psi(x)$ is an energy eigenstate, we get after a few integrations by parts:

$$H^W(x,p)*F_1^W(x,p)=EF_1^W(x,p)+\mathcal{B}_1(x,p). \tag{27}$$

The extra term $\mathcal{B}_1(x,p)$ is a boundary correction given by

$$\mathcal{B}_1(x,p)=-\frac{\hbar}{2\pi m}e^{-(2ip/\hbar)(a-x)}\left\{\frac{2ip}{\hbar}\psi^*(2x-a^-)\psi(a^+)+\psi'^*(2x-a^-)\psi(a^+)\right.$$
$$\left.+\psi^*(2x-a^-)\psi'(a^+)\right\}. \tag{28}$$

For Dirichlet boundary conditions, we get

$$\mathcal{B}_1^D(x,p)=-\frac{\hbar}{2\pi m}e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^-)\psi'(a^+). \tag{29}$$

Let us now attempt to express $\mathcal{B}_1^D(x,p)$ in terms of the Wigner function $F_1^W(x,p)$. Consider the following integral (where $\epsilon>0$):

$$\Lambda_\epsilon\equiv\int_{-\infty}^{+\infty}\mathrm{d}k\,e^{ik(x-a)}kF_1^W\left(x+\epsilon,p-\frac{\hbar}{2}k\right)$$
$$=\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\mathrm{d}k\int_{a-x-\epsilon}^{x-a+\epsilon}\mathrm{d}y\,e^{ik(x-a+y)}ke^{-2ipy/\hbar}\psi^*(x+\epsilon-y)\psi(x+\epsilon+y)$$
$$=\frac{2}{i\hbar}\int_{a-x-\epsilon}^{x-a+\epsilon}\mathrm{d}y\left[\frac{\partial}{\partial y}\delta(x-a+y)\right]e^{-2ipy/\hbar}\psi^*(x+\epsilon-y)\psi(x+\epsilon+y)$$
$$=-\frac{2}{i\hbar}\int_{a-x-\epsilon}^{x-a+\epsilon}\mathrm{d}y\,\delta(x-a+y)e^{-2ipy/\hbar}\left\{-\frac{2ip}{\hbar}\psi^*(x+\epsilon-y)\psi(x+\epsilon+y)\right.$$
$$\left.-\psi'^*(x+\epsilon-y)\psi(x+\epsilon+y)+\psi^*(x+\epsilon-y)\psi'(x+\epsilon+y)\right\}$$
$$=\frac{2i}{\hbar}\exp^{-(2ip/\hbar)(a-x)}\left\{-\frac{2ip}{\hbar}\psi^*(2x-a+\epsilon)\psi(a+\epsilon)-\psi'^*(2x-a+\epsilon)\psi(a+\epsilon)\right.$$
$$\left.+\psi^*(2x-a+\epsilon)\psi'(a+\epsilon)\right\}. \tag{30}$$

In particular for a wave function satisfying a Dirichlet boundary condition, we conclude that $\lim_{\epsilon\to0^+}\Lambda_\epsilon^D(x,p;a)=(2i/\hbar)\,e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^-)\psi'(a^+)$. It is straightforward to obtain from Eq. (29): $\mathcal{B}_1^D(x,p)=\lim_{\epsilon\to0^+}(i\hbar^2/4\pi m)\,\Lambda_\epsilon^D(x,p;a)$. Let us now try to cast this expression in terms of *-products:

$$\Lambda_\epsilon(x,p)=\sum_{n=0}^{\infty}\frac{1}{n!}\left(-\frac{\hbar}{2}\right)^n\frac{\partial^nF_1^W(x+\epsilon,p)}{\partial p^n}\int_{-\infty}^{+\infty}\mathrm{d}k\,e^{ik(x-a)}k^{n+1}$$
$$=-2i\pi\sum_{n=0}^{\infty}\frac{1}{n!}\left(\frac{i\hbar}{2}\right)^n\delta^{(n+1)}(x-a)\frac{\partial^nF_1^W}{\partial p^n}(x+\epsilon,p)$$
$$=-2i\pi[\,\delta'(x-a)*F_1^W(x+\epsilon,p)]. \tag{31}$$

Taking the limit $\epsilon\to 0^+$ of the previous expression and substituting it in (29) and (27) yields the first equation of (25) directly. As a final remark we notice that $\delta'(x-a)*F_1^W(x^+,p)=\lim_{\epsilon\to 0}\{\delta'(x-a)*F_1^W(x+\epsilon,p)\}$ is not identical to $\delta'(x-a)*\{\lim_{\epsilon\to 0}F_1^W(x+\epsilon,p)\}=\delta'(x-a)*F_1^W(x,p)$. This last expression is not even well defined [cf. (30)] since the Dirac delta function is evaluated at a point where $\psi'(x)$ is not continuous. Hence, we should keep in mind that in general, we cannot interchange the order in which the star product and the limit $\epsilon\to 0$ are evaluated.

Finally, we perform the analogous procedure for F_2^W and get the second equation of (25), which concludes the proof.

Let us then return to Eq. (24). Using Eq. (25) we get

$$H^W(x,p)*F^W(x,p)=\Theta_1(x)\left\{EF_1^W(x,p)+\frac{\hbar^2}{2m}\delta'(x-a)*F_1^W(x^+,p)\right\}$$
$$+\Theta_2(x)\left\{EF_2^W(x,p)-\frac{\hbar^2}{2m}\delta'(x-b)*F_2^W(x^-,p)\right\}. \tag{32}$$

Let us try to find the corresponding compact version for $F^W(x,p)$ [Eq. (8)]. We notice the following.

(1) $\Theta_1 EF_1^W+\Theta_2 EF_2^W=E\{\Theta_1 F_1^W+\Theta_2 F_2^W\}=EF^W$.

$$(2)\Theta_1(x)\{\delta'(x-a)*F_1^W(x^+,p)\}=\Theta_1(x)\left\{-\frac{1}{\pi\hbar}e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^-)\psi'(a^+)\right\}$$
$$=\Theta_1(x^+)\left\{-\frac{1}{\pi\hbar}e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^-)\psi'(a^+)\right\}$$
$$=\delta'(x-a)*\{\Theta_1(x^+)F_1^W(x^+,p)\}, \tag{33}$$

where in the first step we used Eqs. (29) and (31); in the second step the fact that $\Theta_1(x)=\lim_{\epsilon\to 0^+}\Theta_1(x+\epsilon),\forall x\neq a,x_0$ and that $\psi^*(2x-a^-)$ vanishes for $x=a$ and $x=x_0$; and finally in the last step that $\Theta_1(x^+)$ is p-independent.

(3) Similarly, we have $\Theta_2(x)\{\delta'(x-b)*F_2^W(x^-,p)\}=\delta'(x-b)*\{\Theta_2(x^-)F_2^W(x^-,p)\}$.

(4) Finally, we also have

$$\delta'(x-b)*\{\Theta_1(x^+)F_1^W(x^+,p)\}$$
$$=\Theta_1(x^+)\{\delta'(x-b)*F_1^W(x^+,p)\}$$
$$=\frac{i}{2\pi}\Theta_1(x^+)\int_{-\infty}^{+\infty}\mathrm{d}k\,e^{ik(x-b)}kF_1^W\left(x^+,p-\frac{\hbar}{2}k\right)$$
$$=-\frac{1}{\pi\hbar}\Theta_1(x^+)\theta(x^+-x_0)e^{-(2ip/\hbar)(b-x)}$$
$$\times\left\{-\frac{2ip}{\hbar}\psi^*(2x-b^-)\psi(b^+)-\psi'^*(2x-b^-)\psi(b^+)+\psi^*(2x-b^-)\psi'(b^+)\right\}$$
$$=0, \tag{34}$$

where in the third step we made the same calculation as in Eq. (30) and in the last step we used the fact that $\psi(b^+)=\psi'(b^+)=0$, or else that $\Theta_1(x^+)=0,\forall x\geqslant x_0$ and $\theta(x^+-x_0)=0,\forall x<x_0$.

(5) Similarly,

$$\delta'(x-a)*(\Theta_2(x^-)F_2^W(x^-,p))=0. \tag{35}$$

Using these results we can rewrite Eq. (32) as

$$H^W * F^W = EF^W + \frac{\hbar^2}{2m}\delta'(x-a) * \{\Theta_1(x^+)F_1^W(x^+,p) + \Theta_2(x^-)F_2^W(x^-,p)\}$$
$$- \frac{\hbar^2}{2m}\delta'(x-b) * \{\Theta_1(x^+)F_1^W(x^+,p) + \Theta_2(x^-)F_2^W(x^-,p)\}, \tag{36}$$

from where it immediately follows:

$$\left(\frac{p^2}{2m} + V(x)\right) * F^W(x,p) - \frac{\hbar^2}{2m}\delta'(x-a) * F^W(x^+,p) + \frac{\hbar^2}{2m}\delta'(x-b) * F^W(x^-,p) = EF^W(x,p). \tag{37}$$

Following the same procedure, one would also obtain

$$F^W(x,p) * \left(\frac{p^2}{2m} + V(x)\right) - \frac{\hbar^2}{2m}F^W(x^+,p) * \delta'(x-a) + \frac{\hbar^2}{2m}F^W(x^-,p) * \delta'(x-b) = EF^W(x,p). \tag{38}$$

We conclude that, if the eigenfunction satisfies Dirichlet boundary conditions, then the corresponding Wigner function does not satisfy the standard $*$-genvalue equation (6), but rather a modified equation given by (37) and (38). Furthermore, the source of discretization of the energy spectrum are not the Dirichlet conditions on the Wigner function but instead the subsidiary boundary conditions (15) or (18).

As a simple example let us consider the free particle in the infinite potential well. We choose as ansatz:

$$F^W(x,p) = -\frac{\alpha^2}{2\pi p}\cos[2(\beta - k|x|)] \cdot \sin\left[\frac{2p}{\hbar}\left(\frac{L}{2} - |x|\right)\right] + \frac{\alpha^2}{4\pi(p+\hbar k)}\sin\left[\frac{2}{\hbar}(p+\hbar k)\left(\frac{L}{2} - |x|\right)\right]$$
$$+ \frac{\alpha^2}{4\pi(p-\hbar k)}\sin\left[\frac{2}{\hbar}(p-\hbar k)\left(\frac{L}{2} - |x|\right)\right], \tag{39}$$

corresponding to the wave function $\psi(x) = \alpha \sin(kx+\beta)$. This function is continuous at $x_0 = 0$ and satisfies Dirichlet's condition at $x = \pm L/2$, in accordance with (11). If we impose the constraints (15) and substitute this expression in the $*$-genvalue equation (37) and (38), using the integral form Λ [Eq. (30)], we obtain

$$k_n = \frac{n\pi}{L}, \quad \beta_n = \frac{n\pi}{2}, \quad E_n = \frac{\hbar^2 k_n^2}{2m} = \frac{\hbar^2\pi^2}{2mL^2}n^2 \quad (n = 1,2,\ldots). \tag{40}$$

Finally, if we impose the normalization $\int_a^b dx \int_{-\infty}^{+\infty} dp\, F^W(x,p) = 1$, we obtain $\alpha = \sqrt{2/L}$. This result is in perfect agreement with Ref. 5.

IV. BAKER'S CONVERSE CONSTRUCTION

In Sec. III we proved that if the wave function is confined to the interval $]a,b[$, satisfies the operator eigenvalue equation and Dirichlet boundary conditions at a^+ and b^- then the corresponding Wigner function satisfies a modified $*$-genvalue equation together with integral Dirichlet boundary conditions at a^+ and b^-. In this section we want to prove the converse result. In the unconfined case this result is known as Baker's converse construction.[6,15] Hence, in this section we want to extend Baker's converse construction to the confined case, thus proving the full equivalence of the Wigner and operator formulations of quantum mechanics when boundaries are present.

Let us then consider some real function $F^W(x,p)$ satisfying the following conditions:
(i) it is a continuous function of x and p;

(ii) it has an infinite number of derivatives with respect to p and is twice differentiable with respect to x;
(iii) F^W obeys integral Dirichlet boundary conditions at $x=a^+$ and $x=b^-$, Eq. (18);
(iv) it obeys the left- and right-boundary stargenvalue equations (37) and (38) when $\epsilon\to 0^+$:

$$\left(\frac{p^2}{2m}+V(x)\right)*F^W(x,p)-\frac{\hbar^2}{2m}\delta'(x-a)*F^W(x+\epsilon,p)+\frac{\hbar^2}{2m}\delta'(x-b)*F^W(x-\epsilon,p)$$
$$=F^W(x,p)*\left(\frac{p^2}{2m}+V(x)\right)-\frac{\hbar^2}{2m}F^W(x+\epsilon,p)*\delta'(x-a)+\frac{\hbar^2}{2m}F^W(x-\epsilon,p)*\delta'(x-b)$$
$$=EF^W(x,p). \tag{41}$$

We will now prove that under these assumptions, there is a unique (up to a global phase factor) normalized complex and continuous function ψ, related to F^W according to (2), which obeys Dirichlet boundary conditions at $x=a^+$ and $x=b^-$ and is a solution of Schrödinger's equation.

It will prove useful to consider the Fourier transform of F^W:

$$F^W(x,p)=\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\mathrm{d}y\, e^{-2ipy/\hbar}\tilde{F}(x,y). \tag{42}$$

Substituting this expression in the left- and right-stargenvalue equations (41), and following the same steps as in Eq. (26), we obtain

$$\frac{1}{\pi\hbar}\int_{-\infty}^{+\infty}\mathrm{d}y\, e^{-2ipy/\hbar}\left\{\left[-\frac{\hbar^2}{2m}\left(\frac{\partial_x\pm\partial_y}{2}\right)^2+V(x\pm y)-E\right]\tilde{F}(x,y)-\frac{\hbar^2}{2m}\delta'(x\pm y-a)\tilde{F}(x+\epsilon,y)\right.$$
$$\left.+\frac{\hbar^2}{2m}\delta'(x\pm y-b)\tilde{F}(x-\epsilon,y)\right\}=0. \tag{43}$$

This means that $\tilde{F}(x,y)$ satisfies the equations:

$$\left[-\frac{\hbar^2}{2m}\left(\frac{\partial_x\pm\partial_y}{2}\right)^2+V(x\pm y)\right]\tilde{F}(x,y)-\frac{\hbar^2}{2m}\delta'(x\pm y-a)\tilde{F}(x+\epsilon,y)+\frac{\hbar^2}{2m}\delta'(x\pm y-b)\tilde{F}(x-\epsilon,y)$$
$$=E\tilde{F}(x,y). \tag{44}$$

From now on we will follow the steps of the standard Baker converse construction for unconfined systems.[6] Introducing the function F such that $F(x-y,x+y)=\tilde{F}(x,y)$ and performing the change of variables $u=x-y$ and $v=x+y$, we get

$$\begin{cases}\left[-\dfrac{\hbar^2}{2m}\dfrac{\partial^2}{\partial v^2}+V(v)\right]F(u,v)-\dfrac{\hbar^2}{2m}\delta'(v-a)F(u+\epsilon,v+\epsilon)+\dfrac{\hbar^2}{2m}\delta'(v-b)F(u-\epsilon,v-\epsilon)\\ \quad=EF(u,v),\\ \left[-\dfrac{\hbar^2}{2m}\dfrac{\partial^2}{\partial u^2}+V(u)\right]F(u,v)-\dfrac{\hbar^2}{2m}\delta'(u-a)F(u+\epsilon,v+\epsilon)+\dfrac{\hbar^2}{2m}\delta'(u-b)F(u-\epsilon,v-\epsilon)\\ \quad=EF(u,v),\end{cases} \tag{45}$$

from where it follows that $F(u,v)=\xi(u)\psi(v)$ and so $\tilde{F}(x,y)=\xi(x-y)\psi(x+y)$. Furthermore, since $F^W(x,p)$ is real, Eq. (42) implies that $\xi=\psi^*$ and so $\tilde{F}(x,y)=\psi^*(x-y)\psi(x+y)$, where the complex function ψ obeys

$$-\frac{\hbar^2}{2m}\psi''(x)+V(x)\psi(x)-\frac{\hbar^2}{2m}\delta'(x-a)\psi(x^+)+\frac{\hbar^2}{2m}\delta'(x-b)\psi(x^-)=E\psi(x), \tag{46}$$

where we performed the limit $\epsilon\to 0^+$. Finally, if $F^W(x,p)$ satisfies integral Dirichlet conditions at $x=a^+$ and $x=b^-$ then the corresponding wave function satisfies $\psi(a^+)=\psi(b^-)=0$, Eq. (19).

In summary, we have shown that if F^W satisfies the above-mentioned conditions (i)–(iv) then F^W is the Wigner transform (2) of a complex function ψ which (1) is a solution of the Schrödinger equation (46) and (2) obeys Dirichlet boundary condition at $x=a^+$ and $x=b^-$. In Sec. VI we will show how to solve this equation and prove that its unique (up to a global phase factor) solution is the standard solution of the corresponding eigenvalue problem in operator quantum mechanics.

V. BOUNDARY DYNAMICS

Let us now consider the time evolution:

$$\frac{\partial F^W}{\partial t}=\Theta_1\frac{\partial F_1^W}{\partial t}+\Theta_2\frac{\partial F_2^W}{\partial t}, \tag{47}$$

and focus on the time derivative $\partial F_1^W/\partial t$:

$$\begin{aligned}\frac{\partial F_1^W}{\partial t}&=\frac{1}{\pi\hbar}\int_{a-x}^{x-a}\mathrm{d}y\, e^{-2ipy/\hbar}\left[\frac{\partial\psi^*}{\partial t}(x-y)\psi(x+y)+\psi^*(x-y)\frac{\partial\psi}{\partial t}(x+y)\right]\\&=\frac{1}{i\pi\hbar^2}\int_{a-x}^{x-a}\mathrm{d}y\, e^{-2ipy/\hbar}\left\{\frac{\hbar^2}{2m}[\psi''^*(x-y)\psi(x+y)-\psi^*(x-y)\psi''(x+y)]+[V(x+y)\right.\\&\quad\left.-V(x-y)]\psi^*(x-y)\psi(x+y)\right\},\end{aligned} \tag{48}$$

where we used the Schrödinger equation. Consider the first term. After a few integrations by parts and by keeping track of the boundary contributions and Dirichlet's condition, we obtain

$$\begin{aligned}&\frac{1}{2im\pi}\int_{a-x}^{x-a}\mathrm{d}y\, e^{-2ipy/\hbar}\psi''^*(x-y)\psi(x+y)\\&\quad=\frac{i}{2m\pi}\{e^{-(2ip/\hbar)(x-a)}\psi'^*(a^+)\psi(2x-a^-)-e^{-(2ip/\hbar)(a-x)}\psi^*(2x-a^-)\psi'(a^+)\}\\&\qquad+\frac{1}{2im\pi}\int_{a-x}^{x-a}\mathrm{d}y\, e^{-2ipy/\hbar}\psi^*(x-y)\psi''(x+y)-\frac{p}{m}\frac{\partial F_1^W}{\partial x}.\end{aligned} \tag{49}$$

The penultimate term exactly cancels the second term on the right-hand side of Eq. (48). The first two terms in Eq. (49) can be written as

$$\begin{aligned}&-\frac{\hbar}{4m\pi}\int_{-\infty}^{+\infty}\mathrm{d}k[e^{ik(a-x)}+e^{ik(x-a)}]kF_1^W\left(x^+,p-\frac{\hbar}{2}k\right)\\&\quad=-\frac{i\hbar}{2m}[F_1^W(x^+,p)*\delta'(x-a)-\delta'(x-a)*F_1^W(x^+,p)]\\&\quad=-\frac{\hbar^2}{2m}[\delta'(x-a),F_1^W(x^+,p)]_M.\end{aligned} \tag{50}$$

The terms involving the potential $V(x)$ are familiar in Wigner quantum mechanics. They yield the contribution $[V(x),F_1^W(x,p)]_M$. After assembling all the results, we get

$$\frac{\partial F_1^W}{\partial t}(x,p;t)=\left[\frac{p^2}{2m}+V(x),F_1^W(x,p;t)\right]_M-\frac{\hbar^2}{2m}[\delta'(x-a),F_1^W(x^+,p;t)]_M. \tag{51}$$

A similar calculation leads to

$$\frac{\partial F_2^W}{\partial t}(x,p;t)=\left[\frac{p^2}{2m}+V(x),F_2^W(x,p;t)\right]_M+\frac{\hbar^2}{2m}[\delta'(x-b),F_2^W(x^-,p;t)]_M. \tag{52}$$

From these results we get for $F^W(x,p;t)=\Theta_1(x)F_1^W(x,p;t)+\Theta_2(x)F_2^W(x,p;t)$:

$$\frac{\partial F^W}{\partial t}(x,p;t)=\left[\frac{p^2}{2m}+V(x),F^W(x,p;t)\right]_M-\frac{\hbar^2}{2m}[\delta'(x-a),F^W(x^+,p;t)]_M+\frac{\hbar^2}{2m}[\delta'(x-b),F^W(x^-,p;t)]_M, \tag{53}$$

where we used the set of relations given by Eqs. (33)–(36).

A straightforward consequence is that probability is conserved (as expected):

$$\frac{\partial}{\partial t}\int_a^b dx\int_{-\infty}^{+\infty}dp\,F^W(x,p;t)=\frac{\partial}{\partial t}\int_{-\infty}^{+\infty}dx\int_{-\infty}^{+\infty}dp[\Theta_1(x)F_1^W(x,p;t)+\Theta_2(x)F_2^W(x,p;t)]=0. \tag{54}$$

VI. WEYL TRANSFORM OF THE STANDARD QUANTUM DESCRIPTION

The standard approach to derive the Wigner formulation of the eigenvalue problem for confined systems would amount to applying the Weyl transform, W, Eq. (1), to both the eigenvalue equation and to the boundary conditions. However, we saw in Sec. II, that this procedure does not yield the correct results. As we shall see, this is linked to the way operator quantum mechanics handles confined dynamical systems. The standard procedure is to (1) solve the eigenvalue equation for the unconfined wave function $\phi(x)$ and (2) impose the wave function to be zero outside the bulk and produce the confined state $\psi(x)=\phi(x)\,\theta(x-a)\,\theta(b-x)$. The problem in the Wigner formulation is that $W(|\psi\rangle\langle\psi|)\neq W(|\phi\rangle\langle\phi|)\,\theta(x-a)\,\theta(b-x)$ and thus we cannot solve the unconfined stargenvalue equation and manipulate its solution to obtain the confined Wigner function.

The reason for this apparent contradiction between the standard operator and Wigner formulations of quantum mechanics resides in the fact that ψ is not a globally valid solution of the operator eigenvalue equation. Globally, ψ satisfies a different eigenvalue equation which includes boundary potentials. Given the intrinsically nonlocal character of the Wigner function this fact is crucial to derive the correct Wigner description of the bounded system.

In Secs. VI A, VI B, and VI C we will (a) derive a globally valid eigenvalue equation for confined systems satisfying Dirichlet boundary conditions, (b) show that the only solution of this equation is the confined wave function, and (c) briefly discuss the numerical implementation of the new eigenvalue equation. It will then be trivial to realize that the Weyl transform of the new eigenvalue equation is the bounded stargenvalue equation (37) and (38), thus recovering the usual correspondence between standard operator and Wigner quantum mechanics.

A. Bounded eigenvalue equation

Let ϕ be the unconfined solution of the eigenvalue equation satisfying Dirichlet boundary conditions at $x=a$ and $x=b$:

$$\hat{H}\phi = E\phi, \quad \hat{H} = \frac{\hat{p}^2}{2m} + V(\hat{x}), \quad \phi(a) = \phi(b) = 0. \tag{55}$$

Notice that $\phi(x)$ is the solution of Eq. (55) everywhere, i.e., for all $x \in \mathcal{R}$. To obtain the confined wave function (for instance, for a particle in a box) the standard procedure is to cut off ϕ outside the box and produce the new wave function: $\psi(x) = \phi(x)\,\theta(x-a)\,\theta(b-x)$. Notice that ψ satisfies Eq. (55) inside the box, it also satisfies it outside the box, but it does not satisfy it at the boundaries. Hence, ψ is not a global solution of (55). Due to nonlocal effects the Weyl transform of ψ does not satisfy the stargenvalue equation (6), even in the bulk.

It seems quite natural to expect that if we are able to provide the global eigenvalue equation for ψ then the correct stargenvalue equation would just be its Weyl transform. The aim of this section is to derive this global equation. The first step is to introduce a twice differentiable version of the Heaviside step function and of the confined wave function ψ:

$$\theta_\epsilon(x): \begin{cases} \in C^2(\mathcal{R}) \quad \text{and is nondecreasing} \\ = 0, \ x < -\epsilon, \\ = 1, \ x > \epsilon, \quad 0 < \epsilon \ll 1. \end{cases} \qquad \psi_\epsilon(x) = \phi(x)\,\theta_\epsilon(x-a)\,\theta_\epsilon(b-x) \tag{56}$$

The definition of $\theta_\epsilon(x)$ is fully compatible with the distribution $\theta(x)$ we used previously: $\lim_{\epsilon\to 0^+} \theta_\epsilon(x) = 0$ if $x<0$, $\lim_{\epsilon\to 0^+} \theta_\epsilon(x) = 1$ if $x>0$ and $\lim_{\epsilon\to 0^+} \theta_\epsilon(0)$ remains unspecified (it might be any number between 0 and 1 or it may not be defined at all). The results of this section are not dependent on the particular function $\theta_\epsilon(x)$ but only of the general properties given in (56). From (56) the smooth versions of $\delta(x)$ and $\delta'(x)$ follow immediately: $\delta_\epsilon(x) = \theta'_\epsilon(x)$ and $\delta'_\epsilon(x) = \theta''_\epsilon(x)$. It is also clear that $\lim_{\epsilon\to 0^+}(\delta_\epsilon(x), \delta'_\epsilon(x), \psi_\epsilon(x)) = (\delta(x), \delta'(x), \psi(x))$. Let us then apply $\hat{H}$ to $\psi_\epsilon(x)$:

$$\begin{aligned} \hat{H}\psi_\epsilon(x) &= \left\{ -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + V(x) \right\} \psi_\epsilon(x) \\ &= \left\{ -\frac{\hbar^2}{2m}\phi''(x) + V(x)\phi(x) \right\} \theta_\epsilon(x-a)\,\theta_\epsilon(b-x) \\ &\quad - \frac{\hbar^2}{2m}\{2\phi'(x)\,\delta_\epsilon(x-a) - 2\phi'(x)\,\delta_\epsilon(b-x) + \phi(x)\,\delta'_\epsilon(x-a) + \phi(x)\,\delta'_\epsilon(b-x)\} \\ &= E\psi_\epsilon(x) + \frac{\hbar^2}{2m}\{\phi(x)\,\delta'_\epsilon(x-a) - \phi(x)\,\delta'_\epsilon(x-b)\}, \end{aligned} \tag{57}$$

where in the last step we use the fact that $\phi(x)$ satisfies the eigenvalue equation (55) and that the Dirichlet boundary conditions on $\phi(x)$ imply for sufficiently small ϵ: $\phi'(x)\,\delta_\epsilon(x-a) = -\phi(x)\,\delta'_\epsilon(x-a)$ and likewise $\phi'(x)\,\delta_\epsilon(b-x) = -\phi(x)\,\delta'_\epsilon(x-b)$. The former equation is not yet a closed eigenvalue equation for $\psi_\epsilon(x)$ since it also evolves the wave function $\phi(x)$.

In what follows and to simplify the discussion we will consider the case of just one boundary placed at $a=0$. The derivation of the two-boundary eigenvalue equation follows exactly the same steps and will be written explicitly at the end. In the one boundary case Eq. (57) reduces to

$$\hat{H}\psi_\epsilon(x) = E\psi_\epsilon(x) + \frac{\hbar^2}{2m}\delta'_\epsilon(x)\phi(x), \tag{58}$$

where $\phi(x)$ satisfies Eq. (55) with Dirichlet boundary conditions at $x=0$. The former equation follows from applying $\hat{H}$ to the state $\psi_\epsilon(x) = \phi(x)\,\theta_\epsilon(x)$.

To proceed we notice that for $x > \epsilon$ the two equations (55) and (58)—for $\phi(x)$ and for $\psi_\epsilon(x)$, respectively, are identical. If we supply identical boundary conditions, for instance, at $x = 2\epsilon$ we

will get identical solutions for $x>\epsilon$, i.e., if $\phi(2\epsilon)=\psi_\epsilon(2\epsilon)$ and $\phi'(2\epsilon)=\psi'_\epsilon(2\epsilon)$ then $\phi(x)=\psi_\epsilon(x)$ for all $x>\epsilon$. Furthermore, and since $\phi(x)$ is analytical, we also have

$$\phi(x)=\phi(x+2\epsilon)+\sum_{n=1}^{\infty}\frac{(-2\epsilon)^n}{n!}\frac{\partial^n\phi}{\partial x^n}(x+2\epsilon), \tag{59}$$

and for $x>-\epsilon$ we have $\phi(x+2\epsilon)=\psi_\epsilon(x+2\epsilon)$ and equally $(\partial^n\phi/\partial x^n)(x+2\epsilon)=(\partial^n\psi_\epsilon/\partial x^n)(x+2\epsilon)$, $\forall n\in\mathcal{N}$. Hence,

$$\phi(x)=\psi_\epsilon(x+2\epsilon)+\sum_{n=1}^{\infty}\frac{(-2\epsilon)^n}{n!}\frac{\partial^n\psi_\epsilon}{\partial x^n}(x+2\epsilon),\quad \forall x>-\epsilon. \tag{60}$$

The trick here is that while $\phi(x)$ is analytical $\psi_\epsilon(x)$ is not [cf. (56)] and thus the Taylor expansion (60) yields $\phi(x)$ instead of $\psi_\epsilon(x)$. Substituting the former expansion in Eq. (58) we get

$$\hat{H}\psi_\epsilon(x)=E\psi_\epsilon(x)+\frac{\hbar^2}{2m}\delta'_\epsilon(x)\left\{\psi_\epsilon(x+2\epsilon)+\sum_{n=1}^{\infty}\frac{(-2\epsilon)^n}{n!}\frac{\partial^n\psi_\epsilon}{\partial x^n}(x+2\epsilon)\right\}. \tag{61}$$

Notice that Eq. (61) is valid for all $x\in\mathcal{R}$ because $\delta'_\epsilon(x)=0$ if $x<-\epsilon$. Finally by taking the limit $\epsilon\to 0^+$ we obtain

$$\hat{H}\psi(x)=E\psi(x)+\frac{\hbar^2}{2m}\delta'(x)\psi(x^+), \tag{62}$$

where we used the notation x^+ to make it explicit that in the product of δ' by ψ the two factors are evaluated at different points. This is crucial because Eq. (61) is valid for all $x\in\mathcal{R}$ only in this case, i.e., in the limit $\epsilon\to 0^+$ but not for $\epsilon=0$. Equation (62) is the new eigenvalue equation for $\psi(x)$. Following exactly the same procedure we can easily generalize it to the case of a double boundary placed at $x=a$ and $x=b$, $(a<b)$. We get

$$\hat{H}\psi(x)=E\psi(x)+\frac{\hbar^2}{2m}\{\delta'(x-a)\psi(x^+)-\delta'(x-b)\psi(x^-)\}, \tag{63}$$

which together with the boundary conditions $\psi(a^+)=\psi(b^-)=0$ provide the operator formulation of the confined eigenvalue problem for Dirichlet boundary conditions. To finish let us point out that: (1) Eq. (63) was obtained in Sec. IV from the stargenvalue equations (37) and (38), and (2) conversely, the Weyl transform of Eq. (63) immediately yields the stargenvalue equations (37) and (38).

B. Solving the new eigenvalue equation

Our next step is to solve the modified eigenvalue equation (63) and show that the confined wave function $\psi(x)$ is its only solution. To make it simple let us consider again the one boundary example Eq. (62).

For $x>0$, $\delta(x)=0$ and Eq. (62) reduces to the unconfined equation (55). The boundary conditions $\psi(0^+)=0$ and $\psi'(0^+)=\phi'(0^+)$ impose $\psi(x)=\phi(x)$ for all $x>0$.

For $-\sigma\leqslant x\leqslant\sigma$ and $\sigma\ll 1$ we have

$$\int_{-\sigma}^{x}\hat{H}\psi(x')\mathrm{d}x'=\int_{-\sigma}^{x}E\psi(x')\mathrm{d}x'+\frac{\hbar^2}{2m}\int_{-\sigma}^{x}\delta'(x')\psi(x'+0^+)\mathrm{d}x'$$

$$\Rightarrow-\frac{\hbar^2}{2m}\{\psi'(x)-\psi'(-\sigma)\}+\mathcal{O}(x+\sigma)=E\mathcal{O}(x+\sigma)$$

$$+\frac{\hbar^2}{2m}\left\{[\delta(x')\psi(x'+0^+)]_{-\sigma}^{x}-\int_{-\sigma}^{x}\delta(x')\psi'(x'+0^+)\mathrm{d}x'\right\}$$

$$\Rightarrow\psi'(x)-\psi'(-\sigma)=\psi'(0^+)\theta(x)+\mathcal{O}(x+\sigma),\tag{64}$$

where in the first step we introduced the notation $\mathcal{O}(y)$ to designate an arbitrary continuous function such that $\lim_{y\to0}\mathcal{O}(y)=0$, and in the third step we used the fact that $\psi(0^+)=0$. Taking the limits $\sigma\to0^+$ and $x\to0^+$ we get

$$\psi'(0^+)-\psi'(0^-)=\psi'(0^+)\Rightarrow\psi'(0^-)=0.\tag{65}$$

The second integration of the eigenvalue equation yields

$$\int_{-\sigma}^{\sigma}\psi'(x)\mathrm{d}x-\int_{-\sigma}^{\sigma}\psi'(-\sigma)\mathrm{d}x=\int_{-\sigma}^{\sigma}\psi'(0^+)\theta(x)\mathrm{d}x+\int_{-\sigma}^{\sigma}\mathcal{O}(x+\sigma)\mathrm{d}x$$

$$\Rightarrow\psi(\sigma)-\psi(-\sigma)$$

$$=\sigma\{2\psi'(-\sigma)+\psi'(0^+)\}+\mathcal{O}(\sigma^2),\tag{66}$$

and in the limit $\sigma\to0^+$ we have $\psi(0^+)-\psi(0^-)=0$, which together with the original Dirichlet boundary conditions at $x=0^+$ imply $\psi(0^-)=0$.

We conclude that for $x<0$, $\psi(x)$ satisfies Eq. (55) with boundary conditions $\psi(0^-)=\psi'(0^-)=0$ and thus $\psi(x)=0$, $\forall x<0$. Hence, we are left with the original bounded wave function: $\psi(x)=\phi(x)\theta(x)$. The generalization for a system with two boundaries is straightforward. Following exactly the same procedure we solve Eq. (63) and get $\psi(x)=\phi(x)\theta(x-a)\theta(b-x)$, as we should. This result concludes the proof of Baker's converse construction initiated in Sec. IV.

C. The free particle bounded eigenvalue equation: Numerical solution of a simple example

As a simple example let us consider the case of a free particle confined to the interval $]-1,1[$ and subject to Dirichlet boundary conditions.

The unconfined Hamiltonian in the position representation is given by $\hat{H}=-(\hbar^2/2m)\times(\partial^2/\partial x^2)$ and the unconfined fundamental state [solution of Eq. (55)] is: $\phi_1(x)=\cos((\pi/2)x)$ with $E=E_1=\hbar^2\pi^2/8m$. Figure 1 displays the unconfined wave function for $\hbar=m=1$.

We now consider a first possible approximation to the confined eigenvalue equation (63). We make $\epsilon=0.25$ and use a Gaussian approximation to the Dirac delta function: $\tilde{\delta}_\epsilon(x)=1/(\pi^{1/2}\epsilon')\exp\{-(x/\epsilon')^2\}$ where ϵ' substitutes ϵ for the following reason: the function $\tilde{\delta}_\epsilon(x)$ is not identically zero for $x>\epsilon$ or for $x<-\epsilon$ and thus there is no function $\theta_\epsilon(x)$ satisfying conditions (56) and such that $\tilde{\delta}_\epsilon(x)=\theta_\epsilon'(x)$. However, if we define $\tilde{\delta}_\epsilon(x)$ using a sufficiently small spread ϵ' (when compared with ϵ) then, for our numerical purposes $\tilde{\delta}_\epsilon(x)$ will provide a good enough approximation to $\theta_\epsilon'(x)$. In all future applications we will make: $\epsilon'=0.8\epsilon$. Furthermore, and to simplify the notation we will refer to $\tilde{\delta}_\epsilon(x)$ as just $\delta_\epsilon(x)$. Finally, taking into account the considerable large value of ϵ we have to consider the contribution of higher order terms in the

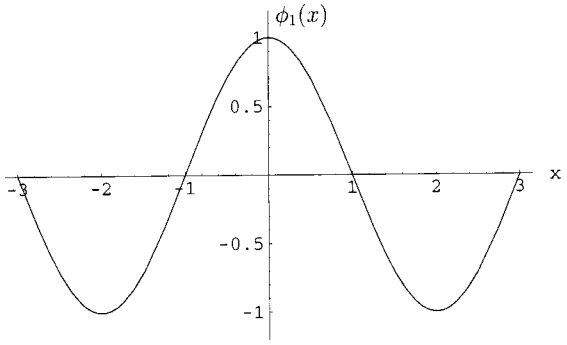

FIG. 1. Unconfined fundamental solution of the free particle eigenvalue equation satisfying Dirichlet boundary conditions at $x=\pm 1$ and for $\hbar=m=1$.

expansion (60), and thus we will use the two boundaries generalization of Eq. (61) as our starting point and truncate the series at the third term. Hence, the equation we want to solve is

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi_\epsilon(x)=E\psi_\epsilon(x)+\frac{\hbar^2}{2m}\delta'_\epsilon(x+1)\{\psi_\epsilon(x+2\epsilon)-2\epsilon\psi'_\epsilon(x+2\epsilon)+2\epsilon^2\psi''_\epsilon(x+2\epsilon)\}$$
$$-\frac{\hbar^2}{2m}\delta'_\epsilon(x-1)\{\psi_\epsilon(x-2\epsilon)+2\epsilon\psi'_\epsilon(x-2\epsilon)+2\epsilon^2\psi''_\epsilon(x-2\epsilon)\}. \tag{67}$$

Figure 2 displays the numerical solution of the former equation for the boundary conditions $\psi_\epsilon(a+2\epsilon=-0.5)=\psi_\epsilon(b-2\epsilon=0.5)=\phi(0.5)=0.707$ and for $E=E_1=\pi^2/8$, $\hbar=m=1$. Notice that the wave function is not completely confined, which follows from the fact that we are not using the true Dirac delta but a (poor) Gaussian approximation of it. If we decrease the value of ϵ the confinement will increase greatly.

Let us then consider a second approximation to the confined eigenvalue equation by making $\epsilon=0.0025$. Given the considerably small value of ϵ we can now truncate the series in the two boundaries generalization of Eq. (61) to zero order and numerically solve the finite version of Eq. (63):

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi_\epsilon(x)=E\psi_\epsilon(x)+\frac{\hbar^2}{2m}\{\delta'_\epsilon(x+1)\psi_\epsilon(x+2\epsilon)-\delta'_\epsilon(x-1)\psi_\epsilon(x-2\epsilon)\}. \tag{68}$$

Figure 3 displays the numerical solution of Eq. (68) for the boundary conditions $\psi_\epsilon(a+2\epsilon=-0.995)=\psi_\epsilon(b-2\epsilon=0.995)=\phi(0.995)=0.008$ and $\hbar=m=1$, $E=E_1=\pi^2/8$.

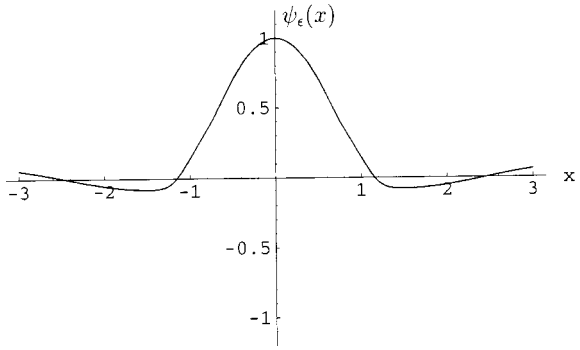

FIG. 2. Numerical solution of the first approximation [Eq. (67)] to the confined eigenvalue equation: $\epsilon=0.25$, $\hbar=m=1$, and $E=\pi^2/8$.

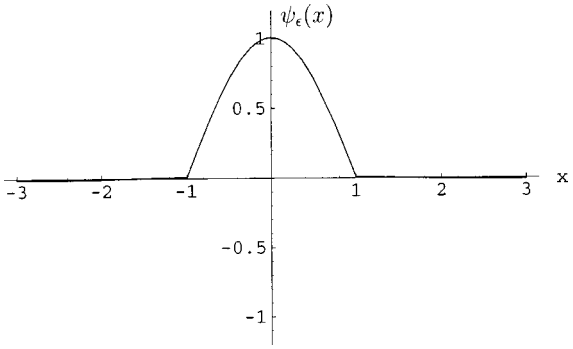

FIG. 3. Numerical solution of the second approximation [Eq. (68)] to the confined eigenvalue equation: $\epsilon=0.0025$, $\hbar=m=1$, and $E=\pi^2/8$.

We will see in Sec. VII that the part of the wave function that escapes from the box corresponds to quantum trajectories with energies much higher than the fundamental state. By making $\epsilon\rightarrow 0^+$ we completely confine the wave function.

VII. WIGNER TRAJECTORIES IN CONFINED SYSTEMS

In the following we briefly review the topic of Wigner trajectories,[4,5,20,21] where the previous work may find some interesting applications. There are two well-known instances where this concept plays an important role: collision processes[4,9] and the study of quantum systems that exhibit chaotic behavior in the classical limit.[4,13,22–24]

The Schrödinger and Wigner formulations of a collision process are obviously equivalent. This notwithstanding, there are important practical differences between the two approaches. In most cases, where an exact solution to the problem is unknown, one has to devise some approximative scheme. If certain conditions hold (concerning the interaction potential), the Moyal equation (5) can be truncated to a good degree of accuracy. Since it does not contain any operator, it is often easier to develop approximations on it than on the Schrödinger equation. Having computed the Wigner function that solves this truncated version of the Moyal equation, one can subsequently evaluate quantum corrections to the classical phase space trajectories. In addition to the benefit of this pictorial and intuitive description in terms of trajectories there is another advantage in this approach: collision cross sections can be computed by applying the same numerical techniques used in classical collision processes.

Another situation where the Wigner trajectories play an important role is that of nonlinear systems exhibiting classical chaotic behavior. In these systems the classical phase space trajectories are of random nature while the Wigner trajectories are smooth paths thus showing that the chaotic behavior disappears upon quantization. A topic of current interest is that of understanding the transition from classical to quantum dynamics. Since the Wigner trajectories might be computed as an $\hbar$ order by order correction to the classical trajectories they provide a powerful, pictorial tool to study this transition.

In following we will (a) briefly review the subject of Wigner trajectories for unconfined systems, (b) discuss the main difficulties in extending the formalism to bounded systems and show that our previous results provide a new approach in this context, and (c) illustrate these results using the simple example of a free particle confined to an infinite square well. The reader should be advised that our aim is not to provide a fully developed and precise formulation of these topics but only to outline (and hopefully motivate) some possible lines of research.

A. Wigner trajectories

Let us then consider the Moyal equation of motion (5) associated with $H=(p^2/2m)+V(x)$:

$$\frac{\partial F^W}{\partial t}(x,p,t) = -\frac{p}{m}\frac{\partial F^W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial F^W}{\partial p} + \frac{(\hbar/2i)^2}{3!}\frac{\partial^3 V}{\partial x^3}\frac{\partial^3 F^W}{\partial p^3} + \cdots . \tag{69}$$

Alternatively, we can write this equation as

$$\frac{\partial F^W}{\partial t}(x,p,t) = -\frac{p}{m}\frac{\partial F^W}{\partial x} + \int_{-\infty}^{+\infty} \mathrm{d}p'\, J(x,p') F^W(x,p+p',t), \tag{70}$$

where

$$J(x,p) = \frac{i}{\pi\hbar^2}\int_{-\infty}^{+\infty} \mathrm{d}y [V(x+y) - V(x-y)] e^{-2ipy/\hbar}. \tag{71}$$

In the absence of a boundary and if the potential V is at most quadratic in x, then the Moyal equation (69) reduces to the Liouville equation:

$$\frac{\partial F^W}{\partial t}(x,p,t) = -\frac{p}{m}\frac{\partial F^W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial F^W}{\partial p}. \tag{72}$$

Equation (72) means that the solution $F^W(x,p,t)$ evolves along the classical trajectories, i.e.,

$$\begin{cases} F^W(x,p,t) = F^W(x(-t),p(-t),0), \\ \dot{x} = \dfrac{p}{m}, \quad \dot{p} = -\dfrac{\partial V}{\partial x}. \end{cases} \tag{73}$$

This motivates the concept of Wigner trajectories. If we define an effective quantum potential $V_{\mathrm{eff}}(x,p,t)$ according to

$$\frac{\partial V_{\mathrm{eff}}}{\partial x}\frac{\partial F^W}{\partial p} = \int_{-\infty}^{+\infty} \mathrm{d}p'\, F^W(x,p+p',t) J(x,p'), \tag{74}$$

then we can express the Moyal equation in the form

$$\frac{\partial F^W}{\partial t} = -\frac{p}{m}\frac{F^W}{\partial x} + \frac{\partial V_{\mathrm{eff}}}{\partial x}\frac{\partial F^W}{\partial p}, \tag{75}$$

which can be interpreted in analogy with (72), by stating that the Wigner function evolves along the Wigner trajectories given by

$$\dot{x} = \frac{p}{m}, \quad \dot{p} = -\frac{\partial V_{\mathrm{eff}}}{\partial x}. \tag{76}$$

If an exact solution for F^W is known, then we can, in principle, calculate the effective potential from (74) and subsequently solve (76) to obtain the Wigner trajectories. However, in general, such is not the case. If the potential $V(x)$ does not deviate appreciably from a quadratic potential then we can address the problem by iteratively evaluating order by order the quantum corrections to the classical trajectories.[4,20,21] The zero-order approximation (i.e., the classical solution), satisfies the Liouville equation:

$$\frac{\partial F_0^W}{\partial t} = -\frac{p}{m}\frac{\partial F_0^W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial F_0^W}{\partial p}. \tag{77}$$

The order zero trajectories correspond to the classical Hamilton equations. The order one equation is given by

$$\frac{\partial F_1^W}{\partial t} = -\frac{p}{m}\frac{\partial F_1^W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial F_1^W}{\partial p} + \frac{(\hbar/2i)^2}{3!}\frac{\partial^3 V}{\partial x^3}\frac{\partial^3 F_0^W}{\partial p^3}. \tag{78}$$

If we solve this equation for F_1^W and substitute in (75) and (76), we obtain the first-order trajectories:

$$\begin{cases} \dot{x} = \dfrac{p}{m}, \\ \dot{p} = -\dfrac{\partial V}{\partial x} + \dfrac{1}{3!}\left(\dfrac{\hbar}{2i}\right)^2 \dfrac{\partial^3 V}{\partial x^3}\dfrac{\partial^3 F_0^W}{\partial p^3} \Big/ \dfrac{\partial F_1^W}{\partial p}. \end{cases} \tag{79}$$

The second-order approximation is

$$\frac{\partial F_2^W}{\partial t} = -\frac{p}{m}\frac{\partial F_2^W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial F_2^W}{\partial p} + \frac{(\hbar/2i)^2}{3!}\frac{\partial^3 V}{\partial x^3}\frac{\partial^3 F_1^W}{\partial p^3} + \frac{(\hbar/2i)^4}{5!}\frac{\partial^5 V}{\partial x^5}\frac{\partial^5 F_0^W}{\partial p^5}, \tag{80}$$

and yields the second-order correction to the classical trajectories:

$$\begin{cases} \dot{x} = \dfrac{p}{m}, \\ \dot{p} = -\dfrac{\partial V}{\partial x} + \dfrac{1}{3!}\left(\dfrac{\hbar}{2i}\right)^2 \dfrac{\partial^3 V}{\partial x^3}\dfrac{\partial^3 F_1^W}{\partial p^3} \Big/ \dfrac{\partial F_2^W}{\partial p} + \dfrac{1}{5!}\left(\dfrac{\hbar}{2i}\right)^4 \dfrac{\partial^5 V}{\partial x^5}\dfrac{\partial^5 F_0^W}{\partial p^5} \Big/ \dfrac{\partial F_2^W}{\partial p}. \end{cases} \tag{81}$$

This procedure can be carried on to any order in $\hbar$. Its main advantage is that it transforms the problem of solving an infinite order partial differential equation (the Moyal equation) into the problem of solving a sequence of first-order partial differential equations. It also displays the advantage of casting the transition from classical to quantum dynamics as an order-by-order correction (in $\hbar$) to classical mechanics. There are, however, some weak points in the procedure, the most significant being perhaps that it is not always clear what is the degree of precision of an approximation to a given order or if the entire scheme will converge.

B. Wigner trajectories in bounded systems

If a system has a boundary, then the former approximative scheme will obviously break down, because the boundary contribution was thus far unknown. As we have seen in the previous sections the boundary interaction has a nonlocal nature and will thus affect the Wigner trajectories well inside the bulk part of the system. It therefore must equally contribute to the quantum corrections of the trajectories.

In this case one was left with a single possible approach: to solve the Schrödinger equation for the confined wave function and compute the Wigner function from it. In some cases where an exact solution of the Schrödinger equation is known this method can be taken to completion. Take for instance the simple example of a free particle confined to the interval $]-1,1[$ and subject to Dirichlet boundary conditions.[5] The fundamental state is $\phi_1(x) = \cos((\pi/2)\,x)$ from which we can compute the Wigner function equations (2), (39), and (40). Since the particle is in an energy eigenstate we have

$$\frac{\partial F^W}{\partial t} = [H, F^W]_M = 0 \Rightarrow F^W(q(-t), p(-t), 0) = F^W(q,p,t) = F^W(q,p,0), \tag{82}$$

and thus the Wigner function evolves along the paths where it displays a constant value, i.e., the Wigner trajectories $(q(-t), p(-t))$ are the equi-Wigner curves. Figure 4 displays the Wigner trajectories for this simple system.

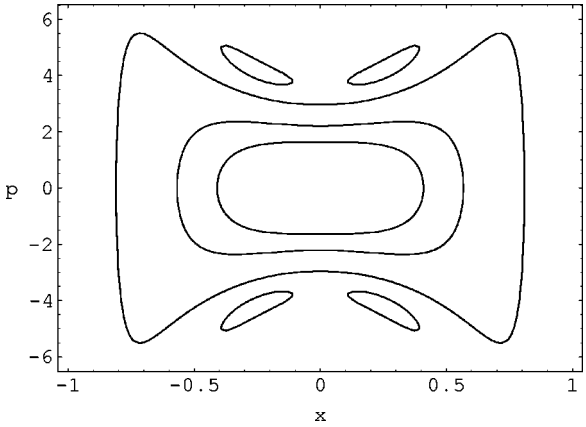

FIG. 4. Exact Wigner trajectories for a particle in the fundamental state and confined to the interval]-1,1[.

For more elaborate examples we are forced to use Eq. (74) or Eq. (75) to calculate the effective potential from the Wigner function and then Eq. (76) to calculate the Wigner trajectories. For instance in Refs. 4 and 24 a system in a symmetric box with Dirichlet boundary conditions and an external driving force was considered. The force, which is of the form $F(t)=F_0\cos(\omega t)$, induces classically the appearance of resonance. Since the system has a boundary, quantum mechanically, the authors were compelled to work in the context of the Schrödinger equation but since an exact, analytic solution is not known the Wigner function and subsequently the Wigner trajectories could not be obtained exactly.

In general, the wave-function-based approach suffers from two major drawbacks: first, in some situations (as in the previous example) it is impossible to obtain an exact solution of the Schrödinger equation, which makes it difficult to infer the degree of precision of the resulting Wigner function. Second, even if an exact solution of the Schrödinger equation is known, this method only provides the exact Wigner trajectories and in some situations it is desirable that the quantum corrections to the classical trajectories might be computed order by order in $\hbar$.

The results of this paper provide a new approach to determine the Wigner trajectories for bounded systems (satisfying Dirichlet boundary conditions) from an exclusive phase space (or c-number) point of view. In fact most of the formalism for the unconfined case can now be applied to the bounded case as well. This is certainly true for Eqs. (69)–(71) and (74)–(76) where one just has to take into account that: (1) $V(x)$ is no longer the bulk potential but it also encompasses a boundary contribution $V_D(x)$ which is associated with the Dirichlet boundary conditions and given in Eq. (53): $V_D(x)=(\hbar^2/2m)\{\delta'(x-b)-\delta'(x-a)\}$, (2) in the boundary corrections to Eqs. (69), (70), and (74) the Wigner function should be evaluated at x^+ and x^- (in the left and right boundary correction, respectively).

It is not so clear if the approximative scheme [Eqs. (77)–(81)] can be also extended to the bounded case. This is because the boundary potential deviates strongly from the harmonic oscillator potential and yields contributions to the Moyal equation to all orders in $\hbar$. We thus have to worry about the magnitude of these contributions and find a suitable criterion to determine the validity of the approximation. These issues are also a problem in the general unconfined case and are certainly not the subject of this paper. Our point here is just that the boundary potential approach is, thus far, the unique exact formulation of confined systems that only appeals to phase space objects and it thus seems to be the proper framework from which the former or other, more suitable, approximative scheme may be devised.

C. Wigner trajectories of a particle in an infinite potential well

In the following we ignore the issues of validity and convergence of the approximative scheme given by Eqs. (77)–(81) and use it to compute the order by order quantum corrections to

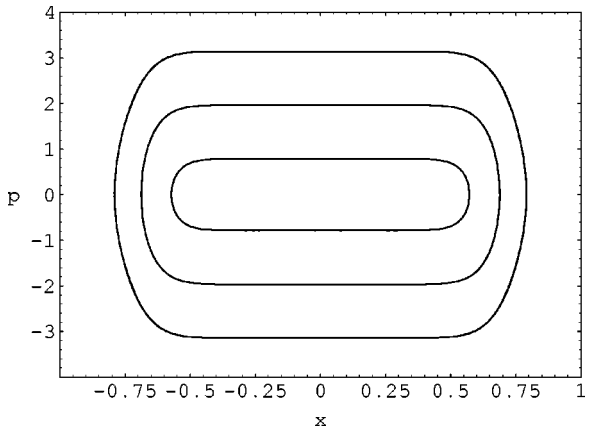

FIG. 5. Zero-order or classical approximation to the Wigner quantum trajectories: $\epsilon=0.25$ and $\hbar=m=1$.

the classical trajectories of a free particle confined to the interval $]-1,1[$. Quite remarkably, we will see that this (in this context, very poor) approximation procedure is already able to reproduce most of the qualitative behavior of the exact quantum trajectories.

The exact Wigner trajectories for a particle in the fundamental state are solutions of Eq. (76) with the effective potential satisfying (74) and (75) and were displayed in Fig. 4. The zero-order approximation to the Moyal equation (53) is given by

$$\frac{\partial F_0^W}{\partial t}(x,p,t)=-\frac{p}{m}\frac{\partial F_0^W}{\partial x}+\frac{\hbar^2}{2m}\left\{\frac{\partial V_R}{\partial x}\frac{\partial F_0^W}{\partial p}(x-\epsilon,p,t)-\frac{\partial V_L}{\partial x}\frac{\partial F_0^W}{\partial p}(x+\epsilon,p,t)\right\}, \tag{83}$$

where $V_R(x)=\delta'_\epsilon(x-1)$ and $V_L(x)=\delta'_\epsilon(x+1)$. To simplify the discussion we assume that for sufficient small ϵ we have

$$\frac{\partial F_0^W/\partial p(x-\epsilon,p,t)}{\partial F_0^W/\partial p(x,p,t)}=\frac{\partial F_0^W/\partial p(x+\epsilon,p,t)}{\partial F_0^W/\partial p(x,p,t)}=1,$$

and use these identities to transform Eq. (83) into the Liouville equation (77) with $V=(\hbar^2/2m)(V_R-V_L)$. The zero-order approximation to the exact quantum trajectories are thus the solutions of Eq. (73). They are displayed in Fig. 5, where we used the Gaussian approximation to the Dirac delta function: $\delta_\epsilon(x)=e^{x^2/\epsilon'^2}/\epsilon'\sqrt{\pi}$, $\epsilon'=0.8\epsilon$ and made $\epsilon=0.25$ (notice that this approximation was used in Sec. VI to compute the numerical solution of the bounded eigenvalue equation, Fig. 2) and $m=\hbar=1$. For sufficiently small ϵ these would be just the classical trajectories.

We now compute the first-order corrections [Eq. (79)]. These are the solutions of

$$\begin{cases}\dot{x}=\dfrac{p}{m},\\ \dot{p}=\dfrac{\hbar^2}{2m}\{\delta''_\epsilon(x+1)-\delta''_\epsilon(x-1)\}+\dfrac{\hbar^2}{48m}\{\delta^{(4)}_\epsilon(x+1)-\delta^{(4)}_\epsilon(x-1)\},\end{cases} \tag{84}$$

where we again ignored the contribution of the factors that involve the (approximate) Wigner function. We get the trajectories displayed in Fig. 6.

Finally, we compute the second-order corrections [Eq. (81)]:

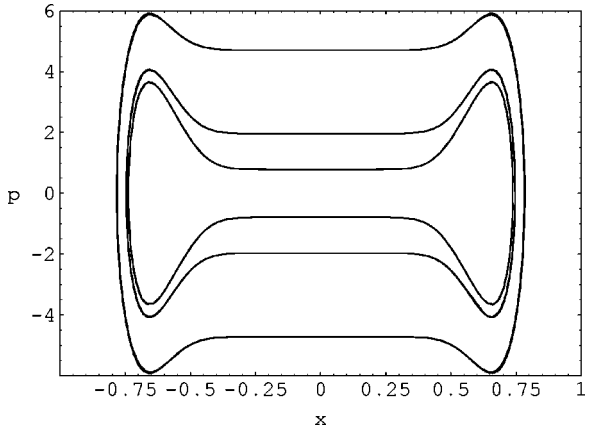

FIG. 6. First-order approximation to the Wigner quantum trajectories: numerical solution of Eq. (84) with $\epsilon=0.25$ and $\hbar=m=1$.

$$\begin{cases} \dot{x}=\dfrac{p}{m}, \\ \dot{p}=\dfrac{\hbar^2}{2m}\{\delta_\epsilon''(x+1)-\delta_\epsilon''(x-1)\}+\dfrac{\hbar^2}{48m}\{\delta_\epsilon^{(4)}(x+1)-\delta_\epsilon^{(4)}(x-1)\} \\ \qquad -\dfrac{\hbar^4}{3840m}\{\delta_\epsilon^{(6)}(x+1)-\delta_\epsilon^{(6)}(x-1)\}, \end{cases} \tag{85}$$

and get the trajectories displayed in Fig. 7.

Several remarks are now in order.

(a) We see that the first-order approximation already displays the deflection of the quantum trajectories toward regions of higher momentum as the particle approaches the boundaries.

(b) In the second approximation the ''islands'' appear. They are not confined, as in the exact case, to regions of positive or negative momentum, but they are already confined to positive or negative positions. Furthermore, the deflection to regions of high momentum is now an exclusive feature (as in the exact case) of the higher momentum trajectories. The slower ones are essentially classical.

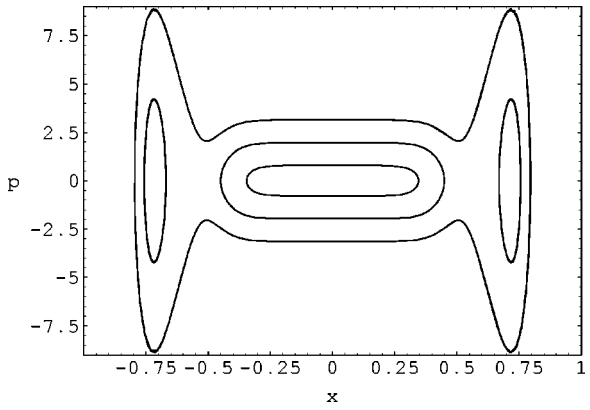

FIG. 7. Second-order approximation to the Wigner quantum trajectories: numerical solution of Eq. (85) with $\epsilon=0.25$ and $\hbar=m=1$.

(c) Not all Wigner trajectories will be confined. For sufficiently high momentum they will escape from the box. This is because we are not using the true Dirac delta but a Gaussian approximation to it. The free Wigner trajectories correspond to the part of the wave function that is outside of the box in Fig. 2.

(d) The former approximative scheme can be refined at least in three different directions: first by taking into account the contributions of the factors that are proportional to the Wigner function. Our rather simple approximative scheme is, in fact, state independent and so could not possibly reproduce the exact Wigner trajectories. This step will be more demanding from the numerical point of view since one will be asked to solve the partial differential equation for the approximate Wigner function before computing each order correction to the classical trajectories. Second, by increasing the degree of approximation to the Dirac delta function, i.e., by decreasing the spread ϵ. This is mandatory if one is interested in the behavior of the quantum trajectories of higher momentum. Finally, and quite obviously, by computing higher order corrections in $\hbar$.

VIII. CONCLUSIONS

In this paper we studied the Wigner–Weyl formulation of a particle confined to a finite interval and subject to Dirichlet boundary conditions. We found that: (1) the standard procedure of solving the unconstrained system and then imposing the boundary conditions does not work out in the Wigner–Weyl formulation; (2) the boundary conditions and the confinement of the wave function determine a boundary correction to the $*$-genvalue equation and to the Moyal equation; (3) Dirichlet boundary conditions on the confined wave function imply both Dirichlet and Neumann boundary conditions on the corresponding confined Wigner function.

Our main task was then the evaluation of the contributions of the boundaries to the $*$-genvalue equation (6) and to the time evolution equation (5) for a wave function satisfying Dirichlet boundary conditions. These contributions were shown to have the form of boundary potentials added to the Hamiltonian, and the same potentials were obtained in the operator formulation of quantum mechanics, when we derived the Schrödinger eigenvalue equation for the confined wave function $\psi(x)=\phi(x)\,\theta(x-a)\,\theta(b-x)$. Together with the boundary conditions they are responsible, both in the Wigner and in the Schrödinger formulations, for the confinement of the system and the consequent discretization of the energy levels. Finally, we extended Baker's converse construction to the bounded case, proving the full equivalence between the operator-Schrödinger and the Wigner formulation of the confined eigenvalue problem.

Finally, we used our previous results to approach the problem of evaluating the Wigner trajectories of bounded systems and ventured the possibility of applying these methods to nonlinear systems displaying classical chaotic behavior.

The procedure described in this work can be generalized to higher-dimensional multiparticle systems and also to any $*$-genvalue equation of the form $A^W(x,p)*F_a^W(x,p)=aF_a^W(x,p)$, associated with the eigenvalue equation: $\hat{A}(\hat{x},\hat{p})\,\psi_a(x)=a\,\psi_a(x)$. From a more general point of view the results of this paper provide a first approach to the problem of solving star-equations with boundaries. This is a difficult but important problem as such equations are known to play a key part in several fields of research ranging from standard topics in quantum mechanics to some important developments in M-theory.[26]

(Received 24 April 2002; accepted for publication 8 July 2002)

In this paper, we construct the Hamiltonians of both periodic and open elliptic quantum Gaudin models and show their relations with the elliptic quantum group, and the boundary elliptic quantum group, respectively. We define the eigenstates of these two models to be the Bethe vectors with $\eta=0$ of the elliptic quantum group and the boundary elliptic quantum group, respectively. Then, the Hamiltonians are exactly diagonalized by using the algebraic Bethe ansatz method. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1505665]

I. INTRODUCTION

The Gaudin model associated with the su(2) Lie algebra was first proposed by Gaudin in 1973.[1–3] It is a new kind of integrable quantum models with the long range interaction. Babujian and Flume generalized it into the general Lie algebra g case, and constructed the corresponding Hamiltonian.[4] They also set up the off-shell Bethe ansatz equation (OSBAE) and gave an explicit proof for su(3). However, they did not give the Bethe ansatz equations. In Ref. 5, Feigin, Frenkel, and Reshetikhin suggested a new method based on the Wakimoto realization of some affine algebra at critical lever, and solved exactly the Gaudin models related to the Lie algebra g. They also obtained the eigenvalues and the corresponding Bethe ansatz equations.

On the other hand, we can simply consider the Gaudin model as the limit of some integrable quantum chains. Sklyanin proposed that the spectrum and eigenfunctions of the spin-1/2 Gaudin models with rational and trigonometric interaction could be derived from those of the XXX and XXZ chains.[6] Then in the Refs. 7–9, Sklyanin and Takebe obtained the arbitrary spin XYZ Gaudin model as a quasiclassical limit of the inhomogeneous higher spin generalization of the XYZ model. Hikami has applied Sklyanin's method into the open Gaudin model by taking quasiclassical limit of the transfer matrix for the inhomogeneous open spin-1/2 XXZ chain.[10] Under the same limit, he has also obtained the eigenvalue and the Bethe ansatz equations.

Recently, the Gaudin models are studied in many integrable systems, such as the supersymmetric Gaudin models[11,12] and the elliptic Gaudin models.[13] In the present paper, we propose the dynamical elliptic quantum Gaudin (DEQG) model with both periodic and open boundary conditions. We obtain the eigenvalues of the Hamiltonians and the Bethe ansatz equations.

The framework of this paper is arranged as follows: In Sec. II we review some basic facts of the elliptic quantum group $E_{\tau,\eta}(\mathrm{sl}_2)$ needed in our paper. In Sec. III we construct the DEQG model under periodic boundary condition, and obtain the eigenvalues of Hamiltonians and the corresponding Bethe ansatz equation in Sec. IV. In Sec. V we construct the open DEQG model and give solutions. In the last section, we give some brief conclusions.

II. THE ELLIPTIC QUANTUM GROUP

The first part of this paper will contribute in the DEQG model with periodic boundary condition. This model is closely associated with the elliptic quantum group $E_{\tau,\eta}(\mathrm{sl}_2)$ (Refs. 14 and 15) which is an algebraic structure underlying the elliptic solutions of the Yang–Baxter relation in the statistical mechanics, and connected with the Knizhnik–Zamolodchikov–Bernard equation on torus. So, we first recall some basic concepts of the elliptic quantum group $E_{\tau,\eta}(\mathrm{sl}_2)$.

Let h be the generator of a one-dimensional commutative Lie algebra h, and $a(\lambda,w)$, $b(\lambda,w)$, $c(\lambda,w)$, $d(\lambda,w)$ be the elements of a matrix $L(\lambda,w)$. The elliptic quantum group $E_{\tau,\eta}(\mathrm{sl}_2)$ is generated by meromorphic functions of the variable h and the elements of $L(\lambda,w)$ with noncommutative entries, subjects to the dynamical Yang–Baxter relations (DYBR)

$$\begin{aligned} &R^{(12)}(\lambda-2\eta h,w_{12})L^{(1)}(\lambda,w_1)L^{(2)}(\lambda-2\eta h^{(1)},w_2)\\ &\quad=L^{(2)}(\lambda,w_2)L^{(1)}(\lambda-2\eta h^{(2)},w_1)R^{(12)}(\lambda,w_{12}), \end{aligned} \tag{1}$$

with $L^{(1)}(\lambda,w_1)=L(\lambda,w_1)\otimes 1$ and $L^{(2)}(\lambda,w_2)=1\otimes L(\lambda,w_2)$. The $L(\lambda,w)$ is a 2×2 matrix whose elements are quamtum operator and $h^{(j)}$ stands for diagonal matrix $\mathrm{Diag}(1,-1)$ in jth matrix space. For the sake of simplicity, we call the matrix space auxillary space and quantum Hilbert space the quantum space. Here $R^{(12)}(\lambda-2\eta h,w_{12})$ is a 4×4 matrix and $w_{ij}=w_i-w_j$. Note that the h in R is a quantum operator acting on the same quantum Hilbert space as L operator acts on. It is the reason that Eq. (1) is called the dynamical Yang–Baxter relation. The explicit expression of R matrix is given by

$$\begin{aligned} R(\lambda,z)=&E_{1,1}\otimes E_{1,1}+E_{-1,-1}\otimes E_{-1,-1}\\ &+\alpha(\lambda,z)E_{1,1}\otimes E_{-1,-1}+\alpha(-\lambda,z)E_{-1,-1}\otimes E_{1,1}\\ &+\beta(\lambda,z)E_{1,-1}\otimes E_{-1,1}+\beta(-\lambda,z)E_{-1,1}\otimes E_{1,-1} \end{aligned} \tag{2}$$

with

$$\alpha(\lambda,z)=\frac{\theta(z)\,\theta(\lambda+2\eta)}{\theta(z-2\eta)\,\theta(\lambda)},$$

$$\beta(\lambda,z)=-\frac{\theta(\lambda+z)\,\theta(2\eta)}{\theta(z-2\eta)\,\theta(\lambda)},$$

$$\theta(\lambda,\tau)=-\sum_{j=-\infty}^{\infty} e^{\pi i(j+\frac{1}{2})^2\tau+2\pi i(j+\frac{1}{2})(\lambda+\frac{1}{2})}.$$

All commutation relations of the elements of L can be found in Ref. 14. Here we only list some of them to be used frequently later,

$$\begin{aligned} &f(\lambda,h)g(\lambda,h)=g(\lambda,h)f(\lambda,h),\\ &f(\lambda-2\eta,h)\tilde{a}(w)=\tilde{a}(w)f(\lambda,h),\\ &f(\lambda+2\eta,h)\tilde{d}(w)=\tilde{d}(w)f(\lambda,h),\\ &f(\lambda+2\eta,h+2)\tilde{b}(w)=\tilde{b}(w)f(\lambda,h),\\ &f(\lambda-2\eta,h-2)\tilde{c}(w)=\tilde{c}(w)f(\lambda,h), \end{aligned} \tag{3}$$

where we have used the notation $\tilde{a}(w)\equiv a(\lambda,w)$ for convenience. And the others are similar.

For complex numbers Λ and z, one can define an infinite dimensional complex vector space $V_\Lambda(z)$ of $E_{\tau,\eta}(\mathrm{sl}_2)$ (evaluation Verma module).[14] Let e_k, $k\in Z_{\geqslant 0}$ be the basis of $V_\Lambda(z)$, the action of generators of $E_{\tau,\eta}(\mathrm{sl}_2)$ are defined by

$$\begin{aligned} f(h)e_k &= f(\Lambda-2k)e_k, \\ a(\lambda,w)e_k &= g(a,\lambda,w,k)e_k, \\ b(\lambda,w)e_k &= g(b,\lambda,w,k)e_{k+1}, \\ c(\lambda,w)e_k &= g(c,\lambda,w,k)e_{k-1}, \\ d(\lambda,w)e_k &= g(d,\lambda,w,k)e_k, \end{aligned} \tag{4}$$

with

$$\begin{aligned} g(a,\lambda,w,k) &= \frac{\theta(z-w+(\Lambda+1-2k)\eta)\,\theta(\lambda+2k\eta)}{\theta(z-w+(\Lambda+1)\eta)\,\theta(\lambda)}, \\ g(b,\lambda,w,k) &= \frac{\theta(-\lambda+z-w+(\Lambda-1-2k)\eta)\,\theta(2\eta)}{\theta(z-w+(\Lambda+1)\eta)\,\theta(\lambda)}, \\ g(c,\lambda,w,k) &= \frac{\theta(-\lambda-z+w+(\Lambda+1-2k)\eta)\,\theta(2(\Lambda+1-k)\eta)\,\theta(2k\eta)}{\theta(z-w+(\Lambda+1)\eta)\,\theta(\lambda)\,\theta(2\eta)}, \\ g(d,\lambda,w,k) &= \frac{\theta(z-w+(-\Lambda+1+2k)\eta)\,\theta(\lambda-2(\Lambda-k)\eta)}{\theta(z-w+(\Lambda+1)\eta)\,\theta(\lambda)}. \end{aligned} \tag{5}$$

The theorem (3) in Ref. 14 ensures the above definition to be an evaluation representation of elliptic quantum $E_{\tau,\eta}(\mathrm{sl}_2)$. If $\Lambda=n+(m+l)/(2\eta)$, where n,m,l are integer, $n\geqslant 0$, then one can obtain a $n+1$-dimensional vector space from $V_\Lambda(z)$. The e_k can be identified with the eigenvectors of the h. This is similar with the $n+1$-dimensional representation of sl(2).

For any space $W=V_\Lambda$ over $E_{\tau,\eta}(\mathrm{sl}_2)$, the transfer matrix can be defined by

$$t(w)=\tilde{a}(w)+\tilde{d}(w), \tag{6}$$

which preserves the space $H=\mathrm{Fun}(W)[0]$ of functions with the value in the zero weight, and commute pairwise on H, $t(w)t(u)=t(u)t(w)$ on H.

Let $W=V_{\Lambda_1}(z_1)\otimes\cdots\otimes V_{\Lambda_n}(z_n)$ be a tensor product of evaluation spaces, and let $\Lambda=\Lambda_1+\cdots+\Lambda_n$. Then, we can obtain a T operator as the tensor product of L operators. The precise form of the T operator can be defined by

$$\begin{aligned} T(\lambda,w) = L_1\Big(\lambda-\sum_{j=2}^{n}2\eta h_j,w\Big)L_2\Big(\lambda-\sum_{j=3}^{n}2\eta h_j,w\Big)\cdots \\ \times L_{n-1}(\lambda-2\eta h_n,w)L_n(\lambda,w). \end{aligned} \tag{7}$$

By using the relation[14]

$$[h^{(1)}+h,T(\lambda,w)]=0 \tag{8}$$

with $h=\sum_{j=1}^{n}h_j$, we can easily prove that the T operator also satisfies the DYBR Eq. (1). Writing the elements of the T operator $\hat{\mathcal{A}},\hat{\mathcal{B}},\hat{\mathcal{C}}$, and $\hat{\mathcal{D}}$, we can rewrite the transfer matrix as

$$t(w)=\hat{\mathcal{A}}(w)+\hat{\mathcal{D}}(w). \tag{9}$$

Then, the highest weight state of the space H, $W[\Lambda]=Cv_0$, obeys the following highest weight condition: for every w,

$$\begin{aligned}&\hat{\mathcal{C}}(w)v_0=0,\quad \hat{\mathcal{A}}(w)v_0=v_0,\\ &\hat{\mathcal{D}}(w)v_0=\frac{\theta(\lambda-2\eta\Lambda)}{\theta(\lambda)}\prod_{j=1}^{n}\frac{\theta(w-z_j-(-\Lambda_j+1)\eta)}{\theta(w-z_j-(\Lambda_j+1)\eta)}v_0.\end{aligned} \tag{10}$$

The quantum determinant of the elliptic quantum algebra is given by[14]

$$\begin{aligned}\tilde{\Delta}(w)&=\frac{\theta(\lambda)}{\theta(\lambda-2\eta h)}(\hat{\mathcal{D}}(w+2\eta)\hat{\mathcal{A}}(w)-\hat{\mathcal{B}}(w+2\eta)\hat{\mathcal{C}}(w))\\ &=\frac{\theta(\lambda)}{\theta(\lambda-2\eta h)}(\hat{\mathcal{A}}(w+2\eta)\hat{\mathcal{D}}(w)-\hat{\mathcal{C}}(w+2\eta)\hat{\mathcal{B}}(w)).\end{aligned} \tag{11}$$

III. THE DEQG MODEL WITH PERIODIC BOUNDARY CONDITION

The Gaudin model was proposed as a new class of integrable quantum systems by Gaudin. In this section, we propose a periodic DEQG model. For the space $H=\mathrm{Fun}(W)[0]$ with $W=V_{\Lambda_1}\otimes\cdots\otimes V_{\Lambda_n}$, the Hamiltonian of the model is

$$\begin{aligned}\hat{\tau}(\lambda,w)&=2(\mathcal{A}^2+\mathcal{H}^2)-4n\Lambda(\partial_\lambda\varphi(\lambda))-8n\Lambda\varphi(\lambda)\partial_\lambda-8n\mathcal{A}'\partial_\lambda+2[(\mathcal{A}')^2+(\mathcal{H}')^2]\\ &\quad-4(\mathcal{A}\mathcal{A}'+\mathcal{H}\mathcal{H}')+8n^2\partial_\lambda^2+\sum_{j,k=1}^{n}W_1(\lambda,w,z_j)W_2(\lambda,w,z_k)[E_j^+E_k^-+E_j^-E_k^+],\end{aligned} \tag{12}$$

where $\mathcal{A}=\Lambda\varphi(\lambda),\mathcal{A}'=\Sigma_j\Lambda_j\varphi(z_j-w),\mathcal{H}=\Sigma_j h_j\varphi(\lambda)$, and $\mathcal{H}'=\Sigma_j h_j\varphi(z_j-w)$ with

$$\varphi(\lambda)=\frac{\theta'(\lambda)}{\theta(\lambda)},$$

$$W_1\equiv 2\frac{\theta'(0)}{\theta(\lambda)}\frac{\theta(-\lambda+z-w)}{\theta(z-w)}$$

and

$$W_2\equiv 2\frac{\theta'(0)}{\theta(\lambda)}\frac{\theta(-\lambda-z+w)}{\theta(z-w)}.$$

Here the operators h_j and $E_j^{\pm}$, which act on the jth infinite-dimensional complex vector space V_{Λ_j}, satisfy

$$[h_i,E_j^{\pm}]=\pm\delta_{i,j}2E_j^{\pm},\quad [E_i^+,E_j^-]=\delta_{i,j}h_j, \tag{13}$$

$$h_je_k=(\Lambda_j-2k)e_k, \tag{14}$$

$$E_j^-e_k=e_{k+1},\quad E_j^+e_k=k(\Lambda_j+1-k)e_{k-1}. \tag{15}$$

In order to find the eigenvalue of $\hat{\tau}(\lambda,w)$, we have to guess the form of the eigenstates. In principle, one may follow Gaudin's method. But it is very difficult. Thanks to Sklyanin's approach,[6,7] this Hamiltonian can be related to the transfer matrix and the quantum determinant of the periodic elliptic quantum group. We will try to find such relations.

Now, let us examine the asymptotic behavior of the operators in the preceding section when η approaches 0. The results are as follows:

$$R(\lambda,w)=1+2\,\eta r(\lambda,w)+O(\eta^2), \tag{16}$$

$$L(\lambda,w)=1+2\,\eta L'(\lambda,w)+O(\eta^2), \tag{17}$$

where $r(\lambda,w)$ is the so-called classical r matrix,

$$\begin{aligned} r(\lambda,w)=&\{\varphi(\lambda)+\varphi(w)\}E_{1,1}\otimes E_{-1,-1}-\{\varphi(\lambda)-\varphi(w)\}E_{-1,-1}\otimes E_{1,1}\\ &-\frac{\theta(\lambda+z)\theta'(0)}{\theta(\lambda)\theta(z)}E_{1,-1}\otimes E_{-1,1}-\frac{\theta(\lambda-z)\theta'(0)}{\theta(\lambda)\theta(z)}E_{-1,1}\otimes E_{1,-1}, \end{aligned} \tag{18}$$

and the elements of L operator are tended as

$$a(\lambda,w)=1+\eta a'(\lambda,w)+O(\eta^2), \tag{19}$$

$$d(\lambda,w)=1+\eta d'(\lambda,w)+O(\eta^2), \tag{20}$$

$$b(\lambda,w)=\eta b'(\lambda,w)+O(\eta^2), \tag{21}$$

$$c(\lambda,w)=\eta c'(\lambda,w)+O(\eta^2), \tag{22}$$

$$\tag{23}$$

and we call the operators $a'(\lambda,w)$, $b'(\lambda,w)$, $c'(\lambda,w)$, and $d'(\lambda,w)$ generating operators of the DEQG model, which are defined by

$$a'(\lambda,w)=(\Lambda-h)[\varphi(\lambda)-\varphi(z-w)]-2\partial_\lambda, \tag{24}$$

$$d'(\lambda,w)=-(\Lambda+h)[\varphi(\lambda)+\varphi(z-w)]+2\partial_\lambda, \tag{25}$$

$$b'(\lambda,w)=W_1(\lambda,w,z)E^+, \tag{26}$$

$$c'(\lambda,w)=W_2(\lambda,w,z)E^-. \tag{27}$$

For the space $H=\mathrm{Fun}(W)[0]$ with $W=V_{\Lambda_1}\otimes\cdots\otimes V_{\Lambda_n}$, the generating operators of the Gaudin model can be defined by $\hat{a}(\lambda,w)$, $\hat{b}(\lambda,w)$, $\hat{c}(\lambda,w)$, $\hat{d}(\lambda,w)$. The concrete forms of them are as follows:

$$\begin{aligned} \hat{a}(\lambda,w)\equiv&\,\eta^{-1}(\hat{\mathcal{A}}(\lambda,w)-1)\\ =&\sum_{j=1}^{n}(\Lambda_j-h_j)[\varphi(\lambda)-\varphi(z_j-w)]-2n\partial_\lambda+O(\eta), \end{aligned} \tag{28}$$

$$\begin{aligned} \hat{d}(\lambda,w)\equiv&\,\eta^{-1}(\hat{\mathcal{D}}(\lambda,w)-1)\\ =&-\sum_{j=1}^{n}(\Lambda_j+h_j)[\varphi(\lambda)+\varphi(z_j-w)]+2n\partial_\lambda+O(\eta), \end{aligned} \tag{29}$$

$$\hat{b}(\lambda,w)\equiv\eta^{-1}\hat{\mathcal{B}}(\lambda,w)$$
$$=\sum_{j=1}^{n} W_1(\lambda,w,z_j)E_j^{+}+O(\eta), \tag{30}$$

$$\hat{c}(\lambda,w)\equiv\eta^{-1}\hat{\mathcal{C}}(\lambda,w)$$
$$=\sum_{j=1}^{n} W_2(\lambda,w,z_j)E_j^{-}+O(\eta). \tag{31}$$

Taking $\eta\to 0$ for Eq. (7), we have

$$T(\lambda,w)=1+\eta\mathcal{T}(\lambda,w)+O(\eta^2). \tag{32}$$

Substituting Eqs. (28)–(31) into the transfer matrix $t(\lambda,w)$ and the quantum determinant element $\tilde{\Delta}(\lambda,w)$, we can obtain

$$t(\lambda,w)=2+\eta\mathrm{tr}\mathcal{T}(\lambda,w)+O(\eta^2), \tag{33}$$

$$\begin{aligned}\tilde{\Delta}(\lambda,w)=&1+2\eta[\mathrm{tr}\mathcal{T}(\lambda,w)+2h\varphi(\lambda)]\\&+\eta^2[-2h^2\varphi^{(2)}(\lambda)+4\mathrm{tr}\mathcal{T}^2(\lambda,w)\\&+\mathrm{tr}(\partial_w\mathcal{T}(\lambda,w)-\partial_\lambda\mathcal{T}(\lambda,w))\\&+2h\varphi(\lambda)\mathrm{tr}\mathcal{T}(\lambda,w)]+O(\eta^2).\end{aligned} \tag{34}$$

One can easily check that $\mathrm{tr}\,\mathcal{T}^2(\lambda,w)$ in the quantum determinant element $\tilde{\Delta}(\lambda,w)$ is equal to the Hamiltonian $\hat{\tau}(\lambda,w)$. Since the quantum determinant is the center of the elliptic quantum group, and $t(\lambda,w)$'s are a commutative family under zero weight condition, $\hat{\tau}(\lambda,w)$'s for different parameters w are also commutative family. Therefore, the DEQG model is integrable. Taking into account the zero weight condition, we can define the Hamiltonian of the periodic DEQG model by the linear combination of $t(\lambda,w)$, and $\tilde{\Delta}(\lambda,w)$,

$$\hat{\tau}(\lambda,w)\equiv\mathrm{tr}\,\mathcal{T}^2(\lambda,w)$$
$$=\frac{1}{4\eta^2}\{\tilde{\Delta}(\lambda,w)-t(\lambda,w)+1-\eta^2(\partial_w-\partial_\lambda)\mathrm{tr}\,\mathcal{T}(\lambda,w)\}. \tag{35}$$

Substituting Eqs. (7) and (11) into Eq. (35), one can check that the Hamiltonian of the model is proven to be Eq. (12).

Expanding the commutation relations of the operators of the elliptic quantum group by $\eta\to 0$, we can obtain

$$\begin{gathered}[h,\hat{a}(\lambda,w)]=0,\quad[\hat{b}(\lambda,w),h]=2\hat{b}(\lambda,w),\\ \hat{a}(\lambda,w)f(\lambda)=F_1(\lambda)\hat{a}(\lambda,w)+F_2(\lambda),\\ \hat{d}(\lambda,w)f(\lambda)=\mathcal{F}_1(\lambda)\hat{d}(\lambda,w)+\mathcal{F}_2(\lambda),\\ \hat{b}(\lambda,w)f(\lambda)=f(\lambda)\hat{b}(\lambda,w)+2\eta f'(\lambda)\hat{b}(\lambda,w),\end{gathered} \tag{36}$$

where

$$F_1(\lambda)=f(\lambda)-2\eta f'(\lambda),\quad F_2(\lambda)=-2f'(\lambda)+2\eta f''(\lambda),$$
$$\mathcal{F}_1(\lambda)=f(\lambda)+2\eta f'(\lambda),\quad \mathcal{F}_2(\lambda)=2f'(\lambda)+2\eta f''(\lambda). \tag{37}$$

Applying the generating operators of the Gaudin model on the highest weight state v_0, we have

$$\hat{a}(\lambda,w)v_0=0,\quad \hat{c}(\lambda,w)v_0=0,$$
$$\hat{d}(\lambda,w)v_0=\left[-2\eta\varphi(\lambda)+2\Lambda\sum_{j=1}^{n}\varphi(w-z_j)\right]v_0. \tag{38}$$

IV. THE ALGEBRAIC BETHE ANSATZ FOR THE PERIODIC DEQG MODEL

In this section, we try our best to find the eigenvalues of the Hamiltonian $\hat{\tau}(\lambda,w)$ of the periodic DEQG model and the Bethe ansatz equations. To construct the algebraic Bethe ansatz for the present model, as usual, we define first the vacuum state as the highest weight state v_0. And we define the Bethe state Ω_s as

$$\Omega_s=\hat{b}(\lambda,t_1)\hat{b}(\lambda,t_2)\cdots\hat{b}(\lambda,t_s)g(\lambda)v_0,\quad g(\lambda)\neq 0. \tag{39}$$

Here we assume Λ to be an integer $2s\geqslant 0$ in this section to ensure the zero-weight space $W[0]$ is nontrivial.

From Ref. 14, we can find the following commutation relations between $\hat{a}(w)$, $\hat{d}(w)$, and $\hat{b}(w)$ [here we abbreviate $\hat{a}(\lambda,w)$ as $\hat{a}(w)$ for convenience, and the other operators are the same]:

$$\hat{b}(w)\hat{b}(t)=\hat{b}(t)\hat{b}(w), \tag{40}$$

$$\begin{aligned}\hat{a}(w)\hat{b}(t)=&\hat{r}(t-w,\lambda)\hat{b}(t)+\hat{b}(t)\hat{a}(w)+\eta\hat{r}(t-w,\lambda)\hat{b}(t)\hat{a}(w)+\hat{s}(t-w,\lambda)\hat{b}(w)\\&+\eta\hat{s}(t-w,\lambda)\hat{b}(w)\hat{a}(t),\\ \hat{d}(w)\hat{b}(t)=&\hat{r}(w-t,\lambda-2\eta)\hat{b}(t)+\hat{b}(t)\hat{d}(w)+\eta\hat{r}(w-t,\lambda-2\eta)\hat{b}(t)\hat{d}(w)\\&-\hat{s}(t-w,\lambda)\hat{b}(w)-\eta\hat{s}(t-w,\lambda)\hat{b}(w)\hat{d}(t)\end{aligned} \tag{41}$$

with

$$\hat{s}(t,\lambda)=\frac{\theta(t+\lambda)\theta'(0)}{\theta(\lambda)\theta(t)}+O(\eta),$$
$$\hat{r}(t,\lambda)=\varphi(\lambda)-\varphi(t)+2\eta\left\{\frac{\theta''(t)}{\theta(t)}-\frac{\theta''(\lambda)}{\theta(\lambda)}+2(\varphi(\lambda))^2-\varphi(\lambda)\varphi(t)\right\}+O(\eta^2).$$

Moving $\hat{a}$ and $\hat{d}$ from the left-hand side to the right-hand side of $\hat{b}$ by using the commutation relations, we obtain

$$\begin{aligned}\hat{a}(w)\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)=&A_0(w,\{t_i\})\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)\\&+A_1(w,\{t_i\})\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)\hat{a}(w)+A_u,\end{aligned} \tag{42}$$

$$\begin{aligned}\hat{d}(w)\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)=&D_0(w,\{t_i\})\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)\\&+D_1(w,\{t_i\})\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_s)\hat{d}(w)+D_u,\end{aligned} \tag{43}$$

where A_0, A_1, A_0, and D_1 are the wanted terms and A_u and D_u are the unwanted terms with

$$A_0=\sum_{j=1}^{s}\hat{r}(t_j-w,\lambda)+2\eta\sum_{j=2}^{s}(j-1)\partial_\lambda\hat{r}(t_j-w,\lambda)+\eta\sum_{j=2}^{s}(j-1)\sum_{k=1}^{j-1}\hat{r}(t_k-w,\lambda)\hat{r}(t_j-w,\lambda)+O(\eta^2), \tag{44}$$

$$A_1=1+\eta\sum_{j=1}^{s}\hat{r}(t_j-w,\lambda)+O(\eta^2), \tag{45}$$

$$A_u=\sum_{k=1}^{s}\left\{\hat{s}(t_k-w,\lambda)+\eta\hat{s}(t_k-w,\lambda)\sum_{j\neq k}^{s}\hat{r}(t_j-w,\lambda)\right\}\times\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_{k-1})\hat{b}(w)\hat{b}(t_{k+1})\cdots\hat{b}(t_s)+\sum_{k=1}^{s}\eta\hat{s}(t_k-w,\lambda)\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_{k-1})\hat{b}(w)\hat{b}(t_{k+1})\cdots\hat{b}(t_s)\hat{a}(t_k)+O(\eta^2),$$

$$j=1,2,3,\ldots,s, \tag{46}$$

$$D_0=\sum_{j=1}^{s}\hat{r}(w-t_j,\lambda-2\eta)-2\eta\sum_{j=1}^{s}(j-1)\partial_\lambda\hat{r}(w-t_j,\lambda-2\eta)+\eta\sum_{j=2}^{s}(j-1)\sum_{k=1}^{j-1}\hat{r}(w-t_k,\lambda)\hat{r}(w-t_j,\lambda-2\eta)+O(\eta^2), \tag{47}$$

$$D_1=1+\eta\sum_{j=1}^{s}\hat{r}(w-t_j,\lambda)+O(\eta^2), \tag{48}$$

$$D_u=\sum_{k=1}^{s}\left\{-\hat{s}(t_k-w,\lambda)-\eta\hat{s}(t_k-w,\lambda)\sum_{j\neq k}^{s}\hat{r}(t_j+w,\lambda)\right\}\times\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_{k-1})\hat{b}(w)\hat{b}(t_{k+1})\cdots\hat{b}(t_s)-\sum_{k=1}^{s}\eta\hat{s}(t_k-w,\lambda)\hat{b}(t_1)\hat{b}(t_2)\cdots\hat{b}(t_{k-1})\hat{b}(w)\hat{b}(t_{k+1})\cdots\hat{b}(t_s)\hat{d}(t_1)+O(\eta^2),$$

$$j=1,2,\ldots,s. \tag{49}$$

In the framework of algebraic Bethe ansatz, when the transfer matrix Eq. (33) acts on the Bethe state Ω_s Eq. (39), the unwanted terms should cancel each other. Thus we can obtain the Bethe ansatz equations

$$\sum_{j\neq k}^{s}\varphi(t_j-t_k)+\sum_{i=1}^{n}\varphi(t_k-z_i)=c, \tag{50}$$

with $g(\lambda)=\theta^s(\lambda)e^{-\lambda c}$, and c is a constant.

With the above restrictions of the Bethe ansatz equations, we can obtain the eigenvalues $\Lambda(\lambda,w)$ of the transfer matrix

$$\Lambda(\lambda,w)=2+\eta\Lambda^{(1)}(\lambda,w)+\eta^2\Lambda^{(2)}(\lambda,w)+O(\eta^3), \tag{51}$$

where

$$\Lambda^{(1)}(\lambda,w)=2\sum_{k=1}^{n}\Lambda\varphi(w-z_k),$$

$$\begin{aligned}\Lambda^{(2)}(\lambda,w)=&4c^2+4\sum_{j\neq k=1}^{s}\varphi(t_j-w)\varphi(t_k-w)+\sum_{j=1}^{s}\left\{\frac{\theta''(t_j-w)}{\theta(t_j-w)}+8c\varphi(t_j-w)\right\}\\&+4c\sum_{k=1}^{n}\Lambda\varphi(w-z_k)+4\sum_{j=1}^{s}\sum_{k=1}^{n}\Lambda_k\varphi(t_j-w)\varphi(w-z_k)\\&+2\sum_{k\neq j=1}^{n}\Lambda_k\Lambda_j\varphi(t_j-w)\varphi(w-z_k)\\&+\sum_{k=1}^{n}\left\{2\Lambda_k(\Lambda_k+1)(\varphi\theta(w-z_k))^2-(\Lambda_k^2+1)\frac{\theta''(w-z_k)}{\theta(w-z_k)}\right\}.\end{aligned}$$

For the quantum determinant commutations with all elements of the generating operators of the DEQG model, the quantum determinant takes the same eigenvalues on both highest weight states v_0 and the Bethe state Ω_s,

$$\begin{aligned}\tilde{\Delta}(w,\lambda)=&1+2\eta\sum_{k=1}^{n}\Lambda_k\varphi(w-z_k)+\eta^2\left\{\sum_{k=1}^{n}4\Lambda_k\frac{\theta''(w-z_k)\theta(w-z_k)-(\theta'(w-z_k))^2}{\theta^2(w-z_k)}\right.\\&+2\Lambda^2\frac{\theta''(\lambda)}{\theta(\lambda)}+2\sum_{j=1}^{s}\sum_{k\neq j=1}^{n}\Lambda_k\Lambda_j\varphi(w-z_j)\varphi(w-z_k)\\&+\sum_{k=1}^{n}\left(2\Lambda_k(\Lambda_k+1)(\varphi(w-z_k))^2-(\Lambda_k^2+1)\frac{\theta''(w-z_k)}{\theta(w-z_k)}\right)\\&\left.-4\Lambda\varphi(\lambda)\sum_{k=1}^{n}\Lambda_k\varphi(w-z_k)+2\Lambda^2\frac{2(\theta'(\lambda))^2-\theta''(\lambda)}{\theta^2(\lambda)}\right\}+O(\eta^3).\end{aligned} \tag{52}$$

From Eq. (51), we know that

$$\mathrm{tr}\,\mathcal{T}(\lambda,w)=\Lambda^{(1)}(\lambda,w)=2\sum_{k=1}^{n}\Lambda_k\frac{\theta'(w-z_k)}{\theta(w-z_k)}.$$

So we have

$$(\partial_w-\partial_\lambda)\mathrm{tr}\,\mathcal{T}(\lambda,w)=2\sum_{k=1}^{n}\Lambda_k\frac{\theta''(w-z_k)\theta(w-z_k)-(\theta'(w-z_k))^2}{\theta^2(w-z_k)}. \tag{53}$$

Thus, applying the $\hat{\tau}(\lambda,w)$ on the Ω_s and taking into account Eqs. (51)–(53), we can obtain the final eigenvalue

$$\hat{\tau}(\lambda,w)\Omega_s=\left\{\partial_w\left[\frac{1}{2}\sum_{k=1}^{n}\Lambda_k\varphi(w-z_k)-\sum_{j=1}^{s}\varphi(w-t_j)\right]-\left[c-\sum_{j=1}^{s}\varphi(w-t_j)\right]^2\right.$$
$$\left.+\left[\sum_{j=1}^{s}\varphi(w-t_j)-c\right]\sum_{k=1}^{n}\Lambda_k\varphi(w-z_k)-\Lambda\varphi(\lambda)\sum_{k=1}^{n}\Lambda_k\varphi(w-z_k)\right\}\Omega_s. \quad (54)$$

In this section, we have derived the eigenvalue and the Bethe ansatz equations of the DEQG model by using generating operators of the model. Calculating the residues of the Hamiltonian Eq. (12) and its eigenvalue Eq. (54) at $w=z_j$, one can get the jth Hamiltonian and the corresponding energy spectrum on Ω_s. In Ref. 14, Felder *et al.* have given the eigenvalue and the Bethe ansatz equations of the elliptic quantum group. The Bethe state in their paper is defined by $\tilde{b}(t_1)\tilde{b}(t_2)\cdots\tilde{b}(t_s)g(\lambda)v_0$. If we apply $t(\lambda,w)$ and $\tilde{\Delta}(\lambda,w)$ on that state, then we take the $\eta\to 0$, we can also obtain the same results as Eq. (54) and the Bethe ansatz equation (50).

V. OPEN DEQG MODEL AND ITS SOLUTION

For the space $W=V_{\Lambda_1}\otimes\cdots\otimes V_{\Lambda_n}$ and the parameter $\Lambda=\Lambda_1+\cdots+\Lambda_n$, we define the Hamiltonian of the open DEQG model as

$$H_j(\lambda,w)=\delta(\lambda,z_j,\xi)(1-h_j)+\sum_{k=1}^{N}\left\{\frac{1}{\Lambda_j+1}\left[\frac{\theta(z_i+\xi)\,\theta(z_j+\lambda-\xi)}{\theta(z_i-\xi)\,\theta(z_j-\lambda+\xi)}W_1^+E_k^-E_j^+\right.\right.$$
$$+\frac{\theta(z_i-\xi)\,\theta(z_j-\lambda+\xi)}{\theta(z_i+\xi)\,\theta(z_j+\lambda-\xi)}W_2^+E_k^+E_j^--\varphi(z_k+z_j)(h_kh_j-\Lambda_k)+\varphi(\lambda)(2\Lambda_k-h_k$$
$$\left.\left.-\Lambda_kh_j)\right]\right\}+\sum_{k=1,\neq j}^{N}\left\{\frac{1}{\Lambda_j+1}[W_1^-E_k^-E_j^++W_2^-E_k^+E_j^-+\varphi(z_k-z_j)(h_kh_j-\Lambda_k)\right.$$
$$\left.-\varphi(\lambda)(h_k-\Lambda_kh_j)]\right\}, \quad (55)$$

where

$$\delta(\lambda,z_j,\xi)=-\frac{1}{\Lambda_j+1}\{[2+\varphi(z_j-\xi)+\varphi(z_j+\xi)]+[\varphi(z_j+\lambda-\xi)+\varphi(z_j-\lambda+\xi)](h+1)\},$$

$$W_1^{\pm}=\mp\frac{\theta(-\lambda+z_k\pm z_j)\,\theta'(0)}{\theta(z_k\pm z_j)\,\theta(\lambda)}.$$

To obtain the eigenvalues of this Hamiltonian, we have to find a proper ansatz for eigenvectors. But it is so hard that we cannot solve the present Hamiltonian directly. Fortunately, according to Hikami,[10] the Hamiltonian of the open DEQG model can also be derived from the transfer matrix $t(w)$ of the boundary elliptic quantum group.

The boundary elliptic quantum group is constructed by[16]

$$R_{21}(\lambda,w_1-w_2)\mathcal{L}_1(\lambda-2\,\eta h^{(2)},w_1)R_{12}(\lambda,w_1+w_2)\mathcal{L}_2(\lambda-2\,\eta h^{(1)},w_2)$$
$$=\mathcal{L}_2(\lambda-2\,\eta h^{(1)},w_2)R_{21}(\lambda,w_1+w_2)\mathcal{L}_1(\lambda-2\,\eta h^{(2)},w_1)R_{12}(\lambda,w_1-w_2), \quad (56)$$

where $\mathcal{L}(\lambda,w)=T^{-1}(\lambda,-w)K(\lambda-2\,\eta h,w)T(\lambda,w)$, and $K(\lambda,w)$ is defined by a diagonal matrix

$$K(\lambda,w)_{1,1}=1,\quad K(\lambda,w)_{2,2}=\frac{\theta(w+\xi)\,\theta(w+\lambda-\xi)}{\theta(w-\xi)\,\theta(w-\lambda+\xi)}, \quad (57)$$

where ξ is an arbitrary parameter. Then, the transfer matrix of the open elliptic quantum group takes the form

$$t(w)=\mathrm{tr}(\widetilde{K}(\lambda,w)\mathcal{L}(\lambda,w)). \tag{58}$$

The diagonal matrix $\widetilde{K}$ reads

$$\widetilde{K}_{11}=1, \quad \widetilde{K}_{22}=\frac{\theta(\lambda-2\eta)}{\theta(\lambda+2\eta)}\frac{\theta(w-2\eta-\tilde{\xi})\theta(w-2\eta-\lambda+\tilde{\xi})}{\theta(w-2\eta+\tilde{\xi})\theta(w-2\eta+\lambda-\tilde{\xi})}. \tag{59}$$

Let $\xi=\tilde{\xi}$ and take the quasiclassical limit $\eta\to 0$ in the transfer matrix of the boundary elliptic quantum group, we have obtained

$$t(\lambda,w=z_j)=2\left(\frac{1}{\Lambda_j+1}+H_j+O(\eta^2)\right). \tag{60}$$

Here the H_j is exactly equal to the Hamiltonian of the open DEQG model defined by Eq. (55). It is also easy to prove $[H_j,H_k]=0$ since the first term of Eq. (55) is only an integer. Therefore, this open DEQG model is a well-defined integrable model.

Since the Hamiltonian of the open DEQG model can be obtained from the transfer matrix of the boundary elliptic quantum group by taking the quasiclassical limit, we can also get the eigenvalue of the Hamiltonian by same procedure. In Ref. 16, the eigenstates of $t(w)$ are defined by applying $B(t_1)\cdots B(t_m)v_0$ on the highest weight state v_0 and the eigenvalue is

$$\begin{aligned}\epsilon(w)=&\prod_{i=1}^{m}\frac{\theta(w+t_i)\theta(w-t_i+2\eta)}{\theta(w-t_i)\theta(w+t_i-2\eta)}+\left\{\prod_{i=1}^{m}\frac{\theta(w+t_i-4\eta)\theta(w-t_i-2\eta)}{\theta(w-t_i)\theta(w+t_i-2\eta)}\right\}\\ &\times\frac{\theta(w-2\eta-\tilde{\xi})\theta(w-2\eta-\lambda+\tilde{\xi})}{\theta(w+\tilde{\xi})\theta(w+\lambda-\tilde{\xi})}\frac{\theta(2w)\theta(w-\xi+\lambda-2(\Lambda+1)\eta)\theta(w+\xi-2\eta)}{\theta(2w-4\eta)\theta(w+\xi-\lambda+2\Lambda\eta)\theta(w-\xi)}\\ &\times\left\{\prod_{j=1}^{n}\frac{\theta(z_j+w+(\Lambda_j-1)\eta)\theta(z_j-w-(\Lambda_j-1)\eta)}{\theta(z_j+w-(\Lambda_j+1)\eta)\theta(z_j-w+(\Lambda_j+1)\eta)}\right\}.\end{aligned} \tag{61}$$

The parameters t_j are governed by the Bethe ansatz equations

$$\begin{aligned}1=&\prod_{i=1}^{m}\frac{\theta(t_k-t_i-2\eta)\theta(t_k+t_i-4\eta)}{\theta(t_k+t_i)\theta(t_k-t_i+2\eta)}\frac{\theta(t_k-2\eta-\tilde{\xi})\theta(t_k-2\eta-\lambda+\tilde{\xi})}{\theta(t_k-\lambda-\tilde{\xi})\theta(t_k+\tilde{\xi})}\\ &\times\frac{\theta(t_k-\xi+\lambda-2(\Lambda+1)\eta)\theta(t_k+\xi-2\eta)}{\theta(t_k-\xi)\theta(t_k+\xi-\lambda+2\Lambda\eta)}\\ &\times\prod_{j=1}^{n}\left\{\frac{\theta(z_j+t_k+(\Lambda_j-1)\eta)\theta(z_j-t_k-(\Lambda_j-1)\eta)}{\theta(z_j+t_k-(\Lambda_j+1)\eta)\theta(z_j-t_k+(\Lambda_j+1)\eta)}\right\}, \quad k=1,2,\ldots,m.\end{aligned} \tag{62}$$

Taking the quasiclassical limit of Eqs. (61) and (62), we can obtain the eigenvalues of the open DEQG model

$$\epsilon(\lambda,w=z_j)=2\left(\frac{1}{\Lambda_j+1}+\hat{\epsilon}(z_j)+O(\eta^2)\right), \tag{63}$$

where

$$\hat{\epsilon}(z_j)=\frac{2\Lambda_j}{1+\Lambda_j}\sum_{i=1}^{m}[\varphi(z_j+t_i)+\varphi(z_j-t_i)]+\frac{1-\Lambda_j}{1+\Lambda_j}\Bigg\{\sum_{l=1}^{n}\Lambda_l\varphi(z_l+z_j)-\sum_{l\pm 1}^{n}\Lambda_l\varphi(z_l-z_j)$$
$$-(\Lambda+1)\varphi(z_j+\lambda-\xi)-(\Lambda+1)\varphi(z_j-\lambda+\xi)+2\varphi(2z_j)-\varphi(z_j-\xi)-\varphi(z_j+\xi)\Bigg\} \tag{64}$$

and the Bethe ansatz equations change into

$$-2\sum_{i=1,\neq k}^{m}[\varphi(t_k-t_i)+\varphi(t_k+t_i)]+\sum_{j=1}^{n}\Lambda_j[\varphi(z_j+t_k)-\varphi(z_j-t_k)]$$
$$=\varphi(t_k-\xi)+\varphi(t_k+\xi)+(\Lambda+1)[\varphi(t_k-\xi+\lambda)+\varphi(t_k+\xi-\lambda)]. \tag{65}$$

We have also investigated carefully the eigenstates of the open DEQG model. They can be written as the rescaled Bethe vectors through the quasiclassical limit

$$\phi\equiv\prod_{\alpha=1}^{m}\left.\frac{dB(t_\alpha)}{d\eta}\right|_{\eta=0}v_0. \tag{66}$$

In fact, when deriving the eigenvalue Eq. (64) and the Bethe ansatz equations (65), we have applied the $t(w)$ on ϕ and found

$$t(w)\phi=\epsilon(w)\phi+\hat{u}\phi, \tag{67}$$

where $\hat{u}$ is the unwanted terms. The vanishing condition of the unwanted terms gives out the Bethe ansatz equations (65) which can be considered as the quasiclassical limit of Eq. (62)

VI. SUMMARY

In this paper, we have defined integrable periodic and open DEQG models. We proved that for the periodic case, the Hamiltonian can also be obtained from the transfer matrix and the quantum determinant of the elliptic quantum group. Expanding the transfer matrix of the boundary elliptic quantum group around $\eta=0$, we can also obtain the Hamiltonian of open DEQG model. For periodic DEQG model, we defined the Bethe vector by setting the generating operator of the DEQG model on the highest weight vector. Then, we obtain eigenvalues of the Hamiltonian and the Bethe ansatz equations. For the open DEQG model, we obtained the eigenvalues of Hamiltonian by taking quasiclassical limit $\eta\to 0$ in the eigenvalues of the boundary elliptic quantum group. We can also define the Bethe vectors of open DEQG model by rescaling the Bethe vectors of the boundary quantum group around $\eta=0$. With the rescaled Bethe vectors we obtained the eigenvalues of the Hamiltonian of open DEQG model and the Bethe ansatz equations.

The DEQG models defined in present paper is related to su(2). One interesting problem is how to generalize it to the su(n) case and how to find the solution of the generalized models. One may apply the same approach in this paper. But, it is not the unique method for solving the Gaudin model. With the Wakimoto construction,[5] the rational Gaudin model based on Lie algebra g was solved. In this method, one can avoid using quasiclassical limit. We expect that the DEQG models given in present paper can be treated in terms of the Wakimoto construction. In fact, we have succeeded in constructing general DEQG models related to the Lie algebra g and finding their solutions,[17] which will appear in another paper. Furthermore, it is well known that the Knizhnik–Zamolodchikov–Bernard equation also play an important role in the integrable system.[18–20] It has been shown that the solutions of integrable Knizhnik–Zamolodchikov–Bernard equations can be constructed by using the results of Gaudin models.[10,21] So, in our forthcoming paper,[22] we will study them for our present models.

Additivity for unital qubit channels

Christopher King[a)]
Department of Mathematics, Northeastern University Boston, Massachusetts 02115

(Received 5 July 2001; accepted for publication 1 May 2002)

Additivity of the Holevo capacity is proved for product channels, under the condition that one of the channels is a unital qubit channel, with the other completely arbitrary. As a byproduct this proves that the Holevo bound is the classical information capacity of such qubit channels, and provides an explicit formula for this classical capacity. Additivity of minimal entropy and multiplicativity of p-norms are also proved under the same assumptions. The proof relies on a new bound for the p-norm of an output state from the half-noisy phase-damping channel. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1500791]

I. INTRODUCTION AND STATEMENT OF RESULTS

There are several outstanding conjectures concerning product channels. These all involve the question of finding the ''best'' state or set of states to transmit through a product channel, using some measure of performance at the output to determine ''best.'' In this article we will consider three well-known measures of performance: the Holevo quantity χ^*, which measures the channel's capacity to transmit classical information; the minimal entropy of an output state; and the maximal p-norm of an output state (this was introduced by Amosov, Holevo, and Werner,[2] who called it the ''maximal output purity'' of the channel). An obvious candidate for the ''best'' set of states in each case is constructed by taking the product of the corresponding best states for the individual channels. For the first two performance measures described above, the outstanding conjecture is that this procedure indeed produces the optimal state. That is, the ''best'' states to send through the channel are always product states—there is no advantage in using entangled states. As a consequence, it would follow that the minimal entropy and the Holevo quantity are additive for product channels. Until recently it was conjectured that the maximal p-norm is also multiplicative for product channels; however, Werner recently discovered counterexamples for $p \geqslant 5$, in dimension three and higher.[17] The multiplicative conjecture for the maximal p-norms is still open for small values of p, in particular for values between 1 and 2. At this time, it seems fair to say that there is no good understanding of why these conjectures should be true.

The conjectures have been verified numerically for products of low dimensional channels. However, numerical testing becomes difficult when the dimensions of the state spaces are large. In part, this is because the allowed input states for the product channel include all entangled states in addition to the product states. So it seems to be necessary to develop an analytical method to investigate the conjectures, and that is the overall goal of the work reported in this article.

Recall that a channel Φ on a Hilbert space $\mathcal{H}$ is a completely positive, trace-preserving map on the algebra of observables on $\mathcal{H}$. When $\mathcal{H}=\mathbf{C}^2$ we will call Φ a *qubit channel*. Qubit channels play an important role in quantum information theory, because many applications involve the manipulation and entanglement of qubit states. If the channel satisfies $\Phi(I)=I$, so that it maps the identity to itself, then Φ is a *unital* channel. Examples of unital qubit channels are the depolarizing channel, the phase-damping channel, and the two-Pauli channel of Bennett, Fuchs, and Smolin.[3] The unital qubit channels provide a very useful laboratory for testing analytical approaches to the conjectures. This is because they are parametrized by three real numbers (up to unitary equivalence), and the geometry of this set of parameters is well understood. In this article we will use

a)Electronic mail: king@neu.edu

detailed properties of this class of channels to derive some new bounds which lead to proofs of the conjectures for unital qubit channels. Hopefully these results will provide clues about how to proceed in the general case.

The results in this article concern product channels $\Omega\otimes\Phi$ where Φ is a *unital qubit channel*, and Ω is *completely arbitrary*. For such channels we are able to establish the conjectures described above, namely that the three performance measures are optimized on product states of the channel. The main ingredient in the proof is a new inequality for the p-norm of an output state from the half-noisy channel $I\otimes\Phi$. The proof of this bound uses details of the classification of unital qubit channels,[11] and does not obviously extend to other classes of channels. In essence, it uses convexity and symmetry arguments to reduce the bound to the case of the *phase-damping channel*. The phase-damping channel [defined later in (20)] is a one-parameter family of unital channels which has been used as a model for decoherence in a two-state system. The inequality for the phase-damping channel can be proved using the method of Lieb and Ruskai which appears in Ref. 10, although in this article we prove it using a result of Epstein[5] concerning concavity of a certain trace function.

Before stating precisely our results we review the three performance measures for a channel that are used here. First, for any $p\geqslant 1$ the maximal p-norm of the channel Φ is defined to be

$$\nu_p(\Phi)=\sup_{\rho}\|\Phi(\rho)\|_p, \tag{1}$$

where the sup runs over states and where the p-norm of a positive matrix A is defined by

$$\|A\|_p=(\mathrm{Tr}A^p)^{1/p}. \tag{2}$$

Second, the minimal entropy of the channel Φ is defined by

$$S_{\min}(\Phi)=\inf_{\rho} S(\Phi(\rho)), \tag{3}$$

where $S(\rho)=-\mathrm{Tr}\rho\log\rho$ is the von Neumann entropy of the state ρ.

Third, the Holevo capacity of Φ is defined by

$$\chi^*(\Phi)=\sup_{\pi_i,\rho_i}\left[S\left(\sum\ \pi_i\Phi(\rho_i)\right)-\sum\ \pi_i S(\Phi(\rho_i))\right], \tag{4}$$

where the sup runs over all probability distributions $\{\pi_i\}$ and collections of states $\{\rho_i\}$ on $\mathcal{H}$.

Theorem 1: *Let Φ be a unital qubit channel. Then for any channel Ω,*

$$\nu_p(\Omega\otimes\Phi)=\nu_p(\Omega)\ \nu_p(\Phi),\quad \textit{for any}\ \ p\geqslant 1, \tag{5}$$

$$S_{\min}(\Omega\otimes\Phi)=S_{\min}(\Omega)+S_{\min}(\Phi), \tag{6}$$

$$\chi^*(\Omega\otimes\Phi)=\chi^*(\Omega)+\chi^*(\Phi). \tag{7}$$

Results related to Theorem 1 have been proven before. Several authors have proven the results for the half-noisy channel $\Omega\otimes I$.[2,6,15] Holevo proved (7) when both Ω and Φ are QC or CQ channels.[9] In Ref. 10, (5)–(7) were proven for any channel Ω, when Φ is either a QC or CQ channel. Bruss *et al.* proved (7) when both Ω and Φ are depolarizing qubit channels.[4] Amosov and Holevo proved (5) for integer values of p when both Ω and Φ are products of depolarizing channels.[1] King and Ruskai presented strong evidence for (7) when both Ω and Φ are unital qubit channels.[11] In Ref. 10 it was shown that (5) holds for any Ω when p is integer and Φ is a unital qubit map, or when $p=2$ and Φ is any qubit map. Recently Shor has proven (6) and (7) for any channel Ω when Φ is an entanglement breaking channel.[16]

It turns out that for a unital qubit channel all of the performance measures are determined by one number, the maximal output norm, which we define now.

Definition 2: Let Φ *be a unital qubit channel. The maximal output norm of* Φ *is defined to be*

$$M_\Phi = \sup_\rho \|\Phi(\rho)\| = \sup_{\rho,\tau} \mathrm{Tr}(\Phi(\rho)\tau). \tag{8}$$

A qubit channel Φ can be viewed as a map on the Bloch sphere, and the image is an ellipsoid which lies inside the Bloch sphere. For a unital map, this image ellipsoid is centered at the origin, and the number M_Φ is its semi-major axis. Define the functions

$$m_p(x) = [x^p + (1-x)^p]^{1/p} \tag{9}$$

and

$$h(x) = -x \log x - (1-x)\log(1-x). \tag{10}$$

Then it is easy to see that for a unital qubit channel Φ,

$$\begin{aligned} \nu_p(\Phi) &= m_p(M_\Phi), \\ S_{\min}(\Phi) &= h(M_\Phi), \\ \chi^*(\Phi) &= \log 2 - h(M_\Phi). \end{aligned} \tag{11}$$

The third line in (11) follows because the sup in (4) is attained with $\pi_1 = \pi_2 = \frac{1}{2}$, and with both ρ_1 and ρ_2 states of minimal entropy which map to opposite ends of the major axis of the ellipsoid, so that $\rho = \Sigma \pi_i \rho_i = I/2$.

The well-known Holevo–Schumacher–Westmoreland theorem[8,14] shows that $\chi^*(\Phi)$ is the best rate for transmission of classical information through the channel Φ when product states are used at the input (and possibly entangled measurements are used at the output). As a consequence, the ultimate capacity of a quantum channel Φ for faithful transmission of classical information (without prior entanglement between sender and receiver, and without a back-channel from receiver to sender) is given by

$$C_{\mathrm{ult}}(\Phi) = \lim_{n\to\infty} \frac{1}{n} \chi^*(\Phi^{\otimes n}). \tag{12}$$

By taking $\Omega = \Phi^{\otimes(n-1)}$ in (7) and using induction on n we deduce that

$$\chi^*(\Phi^{\otimes n}) = n\chi^*(\Phi). \tag{13}$$

This allows us to compute the limit in (12) and we now state this result as a separate theorem.

Theorem 3: *Let* Φ *be a unital qubit channel. Then the classical capacity of the channel is*

$$C_{\mathrm{ult}}(\Phi) = \chi^*(\Phi) = \log\ 2 - h(M_\Phi). \tag{14}$$

The article is organized as follows. Sections II and III contain the proof of Theorem 1 for two special channels. Section II covers the case of the depolarizing channel. All the main estimates are introduced in this section, and the reader should be able to grasp the essential ideas without the additional complications that arise for a general unital qubit channel. Section III does the same for the two-Pauli channel introduced by Bennett, Fuchs and Smolin. Section IV completes the proof for the general case, by reducing it to the two special cases covered in Secs. II and III. Section V contains the proof of the main estimate used, which bounds the p-norm of an output state from the half-noisy phase-damping channel.

II. PROOF FOR THE DEPOLARIZING CHANNEL

The depolarizing channel Δ_λ is defined by

$$\Delta_\lambda(\rho)=\lambda\rho+\frac{(1-\lambda)}{2}\mathrm{Tr}(\rho)I, \tag{15}$$

where $-\frac{1}{3}\leqslant\lambda\leqslant 1$ and I is the 2×2 identity matrix (the asymmetric bounds on the range of λ are required for the map to be completely positive[11]). The image of the Bloch sphere under this map is the sphere with radius $|\lambda|$ centered at the origin. It follows that the maximal output norm [defined in (2)] is given by

$$M_{\Delta_\lambda}=\frac{1+|\lambda|}{2}, \tag{16}$$

and hence the maximal output purity and the minimal entropy are respectively

$$\nu_p(\Delta_\lambda)=m_p\left(\frac{1+\lambda}{2}\right),\quad S_{\min}(\Delta_\lambda)=h\left(\frac{1+\lambda}{2}\right), \tag{17}$$

and the Holevo quantity is

$$\chi^*(\Delta_\lambda)=\log 2-h\left(\frac{1+\lambda}{2}\right). \tag{18}$$

One special feature of the depolarizing channel is its invariance under unitary conjugation, that is,

$$\Delta_\lambda(U\rho U^*)=U\Delta_\lambda(\rho)U^* \tag{19}$$

for all 2×2 unitary matrices U, and all states ρ. This symmetry property will play a crucial role in the argument.

The proof of additivity for the depolarizing channel proceeds by writing it as a convex combination of a special class of unital channels called the phase-damping channels. These channels are defined by

$$\Psi_\lambda^{(i)}(\rho)=\frac{(1+\lambda)}{2}\rho+\frac{(1-\lambda)}{2}\sigma_i\rho\sigma_i, \tag{20}$$

where $i=1,2,3$, where σ_i are the Pauli matrices, and where $-1\leqslant\lambda\leqslant 1$. The term ''phase-damping channel'' usually refers only to the case $i=3$, but we use it here for $i=1,2$ also.

The depolarizing channel can be rewritten in Kraus form as

$$\Delta_\lambda(\rho)=\frac{1+3\lambda}{4}\rho+\frac{1-\lambda}{4}\sum_{i=1}^{3}\sigma_i\rho\sigma_i. \tag{21}$$

It follows by straightforward calculation that

$$\Delta_\lambda=\frac{1+3\lambda}{4+4\lambda}[\Psi_\lambda^{(1)}+\Psi_\lambda^{(2)}]+\frac{1-\lambda}{4+4\lambda}[\sigma_3\Psi_\lambda^{(1)}\sigma_3+\sigma_3\Psi_\lambda^{(2)}\sigma_3]. \tag{22}$$

The convex decomposition (22) can be checked directly by substitution from (21) and (20). However, it can be derived much more easily using the geometric representation of unital qubit channels which will be explained in Sec. IV.

The main technical result behind the proof of Theorem 1 is the next estimate for the p-norm of an output state from the half-noisy phase-damping channel. In order to state this bound, let ρ be a state on $\mathbf{C}^K\otimes\mathbf{C}^2$ for some K. Then ρ can be written in the form

$$\rho = X\otimes I + \sum_{i=1}^{3} Y_i\otimes\sigma_i = \begin{pmatrix} X+Y_3 & Y_1-iY_2 \\ Y_1+iY_2 & X-Y_3 \end{pmatrix}, \tag{23}$$

where X, Y_i are $K\times K$ Hermitian matrices, with $\mathrm{Tr}X=\frac{1}{2}$. Also the positivity of ρ implies that

$$X\pm Y_i \geqslant 0, \quad i=1,2,3. \tag{24}$$

Theorem 4: *Let ρ be a state on $\mathbf{C}^K\otimes\mathbf{C}^2$ for some $K\geqslant 1$, written in the form* (23). *Then for all $p\geqslant 1$, and for $i=1,2,3$,*

$$\|(I\otimes\Psi_\lambda^{(i)})(\rho)\|_p \leqslant 2\, m_p\left(\frac{1+\lambda}{2}\right)\left[\frac{1}{2}\mathrm{Tr}(X+Y_i)^p+\frac{1}{2}\mathrm{Tr}(X-Y_i)^p\right]^{1/p}. \tag{25}$$

The estimate (25) will be derived in Sec. V, using a result from convex analysis due to Epstein.[5] By taking its derivative at $p=1$, we can obtain a lower bound for the entropy of any output state from the half-noisy channel $(I\otimes\Psi_\lambda^{(i)})$, namely,

$$S((I\otimes\Psi_\lambda^{(i)})(\rho)) \geqslant h\left(\frac{1+\lambda}{2}\right)+h(a_i)-\log 2+a_i S(\alpha_i)+(1-a_i)S(\beta_i), \tag{26}$$

where $a_i=\mathrm{Tr}(X+Y_i)$, $1-a_i=\mathrm{Tr}(X-Y_i)$ and $\alpha_i=(X+Y_i)/a_i$, $\beta_i=(X-Y_i)/(1-a_i)$. The author does not know any way to derive this useful entropy bound directly, without first deriving the p-norm bound (25).

The proof of (5) for the depolarizing channel follows by combining the symmetry property (19) with the convex decomposition (22), and using the bound (25). Indeed, by (17) it is sufficient to prove that for any bipartite state ρ_{12}

$$\|(\Omega\otimes\Delta_\lambda)(\rho_{12})\|_p \leqslant \nu_p(\Omega)\, m_p\left(\frac{1+\lambda}{2}\right), \tag{27}$$

since equality can be achieved with product states. Furthermore, using the symmetry property (19) we may assume that the reduced density matrix $\rho_2=\mathrm{Tr}_1\rho_{12}$ is diagonal. This is because we may replace ρ_{12} by $(I\otimes U)\rho_{12}(I\otimes U^*)$, where U is any 2×2 unitary matrix, without changing the left side of (27), and U may be chosen so that ρ_2 is diagonal. When the state ρ_{12} is written in the form (23), this means that

$$\mathrm{Tr}Y_1=\mathrm{Tr}Y_2=0. \tag{28}$$

Furthermore, applying $\Omega\otimes I$ to ρ_{12} and using (23) gives

$$(\Omega\otimes I)(\rho_{12})=\begin{pmatrix} \Omega(X+Y_3) & \Omega(Y_1-iY_2) \\ \Omega(Y_1+iY_2) & \Omega(X-Y_3) \end{pmatrix}. \tag{29}$$

Now we return to the convex decomposition (22). This implies a corresponding decomposition for $(\Omega\otimes\Delta_\lambda)(\rho_{12})$, in terms of $(\Omega\otimes\Psi_\lambda^{(1)})(\rho_{12})$, $(\Omega\otimes\Psi_\lambda^{(2)})(\rho_{12})$, etc. Therefore, it is sufficient to prove the bound for each term in this decomposition, namely,

$$\|(\Omega\otimes\Psi_\lambda^{(i)})(\rho_{12})\|_p \leqslant \nu_p(\Omega)\, m_p\left(\frac{1+\lambda}{2}\right), \tag{30}$$

where $i=1,2$ and where ρ_2 is assumed to be diagonal.

Now we apply (25) and (29) to deduce

$$\|(\Omega\otimes\Psi_\lambda^{(i)})(\rho_{12})\|_p \leq 2\, m_p\left(\frac{1+\lambda}{2}\right)\left[\frac{1}{2}\mathrm{Tr}(\Omega(X+Y_i))^p+\frac{1}{2}\mathrm{Tr}(\Omega(X-Y_i))^p\right]^{1/p}. \tag{31}$$

Using (28) and the definition of $\nu_p(\Omega)$ it follows that

$$\mathrm{Tr}(\Omega(X\pm Y_i))^p \leq \nu_p(\Omega)^p\,(\mathrm{Tr}(X\pm Y_i))^p=\nu_p(\Omega)^p\,(\mathrm{Tr}X)^p \tag{32}$$

for $i=1,2$. Since ρ_{12} is a state it follows that $\mathrm{Tr}\,X=\frac{1}{2}$ and hence the bound (32) becomes

$$\mathrm{Tr}(\Omega(X\pm Y_i))^p \leq 2^{-p}\nu_p(\Omega)^p. \tag{33}$$

Substituting (33) into (31) gives

$$\|(\Omega\otimes\Psi_\lambda^{(i)})(\rho_{12})\|_p \leq 2\, m_p\left(\frac{1+\lambda}{2}\right)\left(\frac{1}{2}\,\nu_p(\Omega)\right)=\nu_p(\Omega)\, m_p\left(\frac{1+\lambda}{2}\right), \tag{34}$$

which is exactly the desired bound (30). So this proves the result (5) for the depolarizing channel.

Turning now to the minimal entropy equality (6), this follows immediately from (5) by taking the derivative at $p=1$, since from the easily established relation

$$\frac{d}{dp}(\|\rho\|_p)_{p=1}=-S(\rho) \tag{35}$$

it follows that for any channel Ω

$$\frac{d}{dp}(\nu_p(\Omega))_{p=1}=-S_{\min}(\Omega). \tag{36}$$

Next we turn to the additivity of the Holevo capacity (7). To establish this we use the representation of Ohya, Petz and Watanabe[13] and Schumacher–Westmoreland (OPWSW),[15] and follow the method described in Ref. 10. Denote the relative entropy of states ω and ρ by

$$H(\omega,\rho)=\mathrm{Tr}\omega(\log\omega-\log\rho). \tag{37}$$

Then the OPWSW representation is

$$\chi^*(\Omega)=\inf_\rho \sup_\omega H(\Omega(\omega),\Omega(\rho)). \tag{38}$$

The state that achieves the infimum in (38) is the optimal average output state from the channel Ω, and we denote this by ρ_Ω. For any unital qubit channel, and in particular for the depolarizing channel Δ_λ, the optimal average output state is the noisiest state $I/2$. Evaluating (38) for the depolarizing channel Δ_λ with optimal output state $I/2$ gives (18).

Our goal is to show that

$$\chi^*(\Omega\otimes\Delta_\lambda)\leq\chi^*(\Omega)+\chi^*(\Delta_\lambda)=\chi^*(\Omega)+\log 2-h\left(\frac{1+\lambda}{2}\right), \tag{39}$$

since the inequality in the other direction is easy. Since $\rho_\Omega\otimes I/2$ is a valid output state from the channel $\Omega\otimes\Delta_\lambda$, it follows from (38) that

$$\chi^*(\Omega\otimes\Delta_\lambda)\leq\sup_{\tau_{12}} H((\Omega\otimes\Delta_\lambda)(\tau_{12}),\rho_\Omega\otimes I/2), \tag{40}$$

and hence to prove (39) it is sufficient to prove that for any entangled state τ_{12},

$$H((\Omega\otimes\Delta_\lambda)(\tau_{12}),\rho_\Omega\otimes I/2)\leqslant\chi^*(\Omega)+\chi^*(\Delta_\lambda). \tag{41}$$

Denote the reduced density matrix of τ_{12} by

$$\tau_1=\mathrm{Tr}_2(\tau_{12}), \tag{42}$$

where Tr_2 is the trace over the second factor. From (37) it follows that

$$H((\Omega\otimes\Delta_\lambda)(\tau_{12}),\rho_\Omega\otimes I/2)=-S((\Omega\otimes\Delta_\lambda)(\tau_{12}))-\mathrm{Tr}\Omega(\tau_1)\log\rho_\Omega+\log 2. \tag{43}$$

Using (18) and (43) reduces (41) to the inequality

$$S((\Omega\otimes\Delta_\lambda)(\tau_{12}))\geqslant h\left(\frac{1+\lambda}{2}\right)-\mathrm{Tr}\,\Omega(\tau_1)\log(\rho_\Omega)-\chi^*(\Omega). \tag{44}$$

Using again the convex decomposition (22) and the symmetry property (19), it follows that it is sufficient to prove the bound

$$S((\Omega\otimes\Psi_\lambda^{(i)})(\tau_{12}))\geqslant h\left(\frac{1+\lambda}{2}\right)-\mathrm{Tr}\,\Omega(\tau_1)\log(\rho_\Omega)-\chi^*(\Omega) \tag{45}$$

for $i=1,2$ under the assumption that τ_1 is diagonal. Referring to (26) the condition that τ_1 is diagonal means that $a_i=\frac{1}{2}$ for $i=1,2$, and hence the bound (26) becomes

$$S((\Omega\otimes\Psi_\lambda^{(i)})(\tau_{12}))\geqslant h\left(\frac{1+\lambda}{2}\right)+\frac{1}{2}S(2\Omega(X+Y_i))+\frac{1}{2}S(2\Omega(X-Y_i)). \tag{46}$$

Furthermore, we can write $\tau_1=2X$ in the form

$$\tau_1=\tfrac{1}{2}[(2X+2Y_i)+(2X-2Y_i)], \tag{47}$$

and so it follows that

$$\begin{aligned}&-\tfrac{1}{2}S(2\Omega(X+Y_i))-\tfrac{1}{2}S(2\Omega(X-Y_i))-\mathrm{Tr}\Omega(\tau_1)\log(\rho_\Omega)\\&\quad=\tfrac{1}{2}H(\Omega(2X+2Y_i),\rho_\Omega)+\tfrac{1}{2}H(\Omega(2X-2Y_i),\rho_\Omega).\end{aligned} \tag{48}$$

Now since ρ_Ω is the optimal average output state for the channel Ω, it is also the state which achieves the infimum in the OPWSW representation (38). Hence (38) implies

$$H(\Omega(2X\pm 2Y_i),\rho_\Omega)\leqslant\chi^*(\Omega), \tag{49}$$

and therefore from (48)

$$\tfrac{1}{2}S(2\Omega(X+Y_i))+\tfrac{1}{2}S(2\Omega(X-Y_i))+\mathrm{Tr}\Omega(\tau_1)\log(\rho_\Omega) \tag{50}$$

$$\geqslant-\chi^*(\Omega). \tag{51}$$

Combining (46) and (50) yields the required bound (45), and this proves additivity for the depolarizing channel.

III. PROOF FOR THE TWO-PAULI CHANNEL

The two-Pauli channel was introduced by Bennett, Fuchs, and Smolin[3] who presented it as an example of a channel which benefits from the use of entangled inputs, in the sense of minimizing

measurement errors over two uses of the channel. For this reason it is particularly interesting to prove the additivity result for this channel, as it implies a significant difference between the role of entanglement in the channel capacity and the error–minimization problems.

The two-Pauli channel is a one-parameter unital qubit channel Θ_λ, defined by

$$\Theta_\lambda(\rho)=\lambda\rho+\frac{1-\lambda}{2}\sigma_1\rho\sigma_1+\frac{1-\lambda}{2}\sigma_2\rho\sigma_2, \tag{52}$$

where $0\leqslant\lambda\leqslant 1$. The maximal output purity $\nu_p(\Theta_\lambda)$ is attained on the input state $(I+\sigma_1)/2$ for $\lambda\geqslant\frac{1}{3}$, and on the state $(I+\sigma_3)/2$ for $0\leqslant\lambda\leqslant\frac{1}{3}$, and so is given by

$$\nu_p(\Theta_\lambda)=\begin{cases} m_p((1+\lambda)/2) & \text{for } \frac{1}{3}\leqslant\lambda\leqslant 1, \\ m_p(1-\lambda) & \text{for } 0\leqslant\lambda\leqslant\frac{1}{3}. \end{cases} \tag{53}$$

When $\lambda=\frac{1}{3}$ the channel is unitarily equivalent to the depolarizing channel $\Delta_{1/3}$. We will prove additivity here only for the range of parameters $\frac{1}{3}\leqslant\lambda\leqslant 1$. The rest of the parameter range will be covered in the following section on the general unital qubit channel.

It will be necessary to consider two related two-Pauli channels, which are defined using the other choices of Pauli matrices in (52). So, for convenience, we will rename the channel defined in (52) as $\Theta_\lambda^{(3)}$, and define the three channels together by

$$\begin{aligned} \Theta_\lambda^{(1)}(\rho)&=\lambda\rho+\frac{1-\lambda}{2}\sigma_2\rho\sigma_2+\frac{1-\lambda}{2}\sigma_3\rho\sigma_3, \\ \Theta_\lambda^{(2)}(\rho)&=\lambda\rho+\frac{1-\lambda}{2}\sigma_3\rho\sigma_3+\frac{1-\lambda}{2}\sigma_1\rho\sigma_1, \\ \Theta_\lambda^{(3)}(\rho)&=\lambda\rho+\frac{1-\lambda}{2}\sigma_1\rho\sigma_1+\frac{1-\lambda}{2}\sigma_2\rho\sigma_2. \end{aligned} \tag{54}$$

The key result in the proof for the depolarizing channel was the fact that for any channel Ω and for any entangled state ρ_{12}, there was a convex decomposition of the form

$$(\Omega\otimes\Delta_\lambda)(\rho_{12})=\sum_k c_k(\Omega\otimes U_k\Psi_\lambda^{(i_k)}U_k^*)(\rho'_{12}), \tag{55}$$

where $\Sigma c_k=1$, and $i_k=1,2$. The 2×2 matrices U_k are unitary, and we write $U\Psi U^*$ to denote the channel that acts on a state ρ by

$$U\,\Psi\,U^*(\rho)=U\,\Psi(\rho)\,U^*, \tag{56}$$

that is, the matrix U conjugates the state *after* Ψ acts. The state ρ'_{12} is unitarily equivalent to ρ_{12}, and has the property that $\rho'_2=\mathrm{Tr}_1(\rho'_{12})$ is diagonal. The decomposition (55) allowed the bound (25) to be used and this in turn led to the additivity result. In order for this to work, it was crucial that the phase-damping channel on the right side of (55) produced the factor $m_p((1+\lambda)/2)$, which was the correct bound for the channel Δ_λ.

The strategy of proof for the two-Pauli channel is similar, that is, we will produce a convex decomposition of the same form as (55), involving phase-damping channels with the same parameter λ. This decomposition is stated next as Theorem 5. This allows us to use the bound (25), and so produce the factor $m_p((1+\lambda)/2)\nu_p(\Omega)$ again. By (53) this equals $\nu_p(\Theta_\lambda^{(i)})\,\nu_p(\Omega)$ for $\frac{1}{3}\leqslant\lambda\leqslant 1$, and hence the result will be proved for this range of values. Again the crucial part is that the matrices $X\pm Y_i$ appearing on the right side of the bound (25), must satisfy $\mathrm{Tr}(X\pm Y_i)=\frac{1}{2}$, and this

must be arranged before applying the convex decomposition, by using symmetry properties of the channel to rotate the state ρ_{12}. Once this has been done, the rest of the additivity proof proceeds verbatim, and does not need to be repeated.

Theorem 5: *Let ρ_{12} be a state on $\mathbf{C}^K \otimes \mathbf{C}^2$ for some $K \geqslant 1$, written in the form (23), and let Ω be any channel acting on $\mathbf{C}^K$. Then for $i=1,2,3$*

$$(\Omega \otimes \Theta_\lambda^{(i)})(\rho_{12}) = \sum_k c_k \, (\Omega \otimes U_k \Psi_\lambda^{(i_k)} U_k^*)(\rho_{12}^{(k)}), \tag{57}$$

where $\Sigma c_k = 1$, the matrices U_k are unitary, and $i_k = 1,2,3$. Furthermore, if $\rho_{12}^{(k)}$ is written in the block form (23), then $TrY_{i_k} = 0$.

Notice that the same index i_k appears in $\Psi_\lambda^{(i_k)}$ and in the condition $\mathrm{Tr} Y_{i_k} = 0$ on the state $\rho_{12}^{(k)}$. This means that all the arguments of Sec. II can be repeated using the decomposition (57) in place of (55), and the additivity results follow. So the proof for the two-Pauli channel reduces to establishing (57).

The crucial ingredient in getting this decomposition is the following symmetry property of the channel: for any *diagonal* unitary matrix U and any state ρ we have

$$\Theta_\lambda^{(3)}(U\rho U^*) = U\Theta_\lambda^{(3)}(\rho)U^*. \tag{58}$$

The identity (58) follows easily from the Kraus representation (52) using the Pauli matrix relations $\sigma_i \sigma_3 = -\sigma_3 \sigma_i$ for $i=1,2$. This is because any diagonal unitary matrix can be written in the form $U = \alpha I + \beta \sigma_3$ with $|\alpha \pm \beta|^2 = 1$, and such matrices clearly commute with the action of $\Theta_\lambda^{(3)}$. Similar identities hold for $\Theta_\lambda^{(1)}$ and $\Theta_\lambda^{(2)}$, which commute respectively with matrices of the form $\alpha I + \beta \sigma_1$ and $\alpha I + \beta \sigma_2$.

We now prove Theorem 5 for $i=3$, that is for the case $(\Omega \otimes \Theta_\lambda^{(3)})(\rho_{12})$. The proofs for the cases $i=1,2$ are identical. We use a two-step construction to reach the result. First, we have the following convex decomposition:

$$\Theta_\lambda^{(3)} = \frac{3\lambda - 1}{2\lambda} \Psi_\lambda^{(2)} + \frac{1-\lambda}{2\lambda} \sigma_1 \Theta_\lambda^{(2)} \sigma_1 . \tag{59}$$

It is elementary to check that this relation holds, and the geometrical picture of Sec. IV will make it easy to derive. However, before applying the decomposition (59) to an entangled state $(\Omega \otimes \Theta_\lambda^{(3)})(\rho_{12})$, we will use the symmetry property (58) to rotate the reduced density matrix $\rho_2 = 1/2(I + w_1\sigma_1 + w_2\sigma_2 + w_3\sigma_3)$ into the form $\rho_2' = 1/2(I + w_1'\sigma_1 + w_3'\sigma_3)$. That is, we conjugate by a diagonal unitary matrix which removes the component in the direction of σ_2—equivalently, the density matrix is made real by conjugation with a diagonal unitary matrix. When the rotated state ρ_{12}' is written in the 2×2 block form (23), this means that

$$\mathrm{Tr}\ Y_2' = 0. \tag{60}$$

So the first step is to write

$$(\Omega \otimes \Theta_\lambda^{(3)})(\rho_{12}) = (\Omega \otimes U\Theta_\lambda^{(3)} U^*)(\rho_{12}'), \tag{61}$$

where U is the diagonal unitary matrix that produces the rotation. Now (59) is used. The first term on the right side of (59) produces $(\Omega \otimes U\Psi_\lambda^{(2)}U^*)(\rho_{12}')$ where the reduced density matrix ρ_2' is real, and this has exactly the form required in Theorem 5.

We now continue to the second step, and use another convex decomposition for the second term on the right side of (59), namely

$$\Theta_\lambda^{(2)} = \frac{2\lambda}{1+\lambda} \Psi_\lambda^{(3)} + \frac{1-\lambda}{1+\lambda} \sigma_1 \Psi_\lambda^{(2)} \sigma_1 . \tag{62}$$

Before applying (62), we use the symmetry of the channel $\Theta_\lambda^{(2)}$ to rotate the state ρ'_{12} by a unitary matrix of the form $I\otimes V$ where $V=\alpha I+\beta\sigma_2$, and obtain the rotated state ρ''_{12}. Since the reduced density matrix $\rho'_2=1/2(I+w'_1\sigma_1+w'_3\sigma_3)$ has no component in the σ_2 direction, the matrix V may be chosen so that after the second rotation the reduced matrix $\rho''_2=1/2(I+w''_1\sigma_1)$ has no components in either the σ_2 or the σ_3 directions. As a result, the second term on the right side of (59) is transformed as follows:

$$(\Omega\otimes U\sigma_1\Theta_\lambda^{(2)}\sigma_1 U^*)(\rho'_{12})=(\Omega\otimes W\Theta_\lambda^{(2)}W^*)(\rho''_{12}) \tag{63}$$

where $W=U\sigma_1 V$. Having done this rotation, the decomposition (62) can be applied, yielding a convex combination of $(\Omega\otimes W\Psi_\lambda^{(2)}W^*)(\rho''_{12})$ and $(\Omega\otimes W\Psi_\lambda^{(3)}W^*)(\rho''_{12})$, and both of these have the form required on the right side of (57). So this completes the proof for the two-Pauli channels.

IV. THE GENERAL CASE

The basic idea is that any unital qubit channel Φ is unitarily equivalent to a convex combination of depolarizing channels and two-Pauli channels, which all share the same values of ν_p and $S_{\min}$. Additivity in the general case then follows from additivity for the depolarizing and two-Pauli channels, combined with the convexity of the p-norm, and the concavity of the entropy.

We first review the classification of unital qubit maps which was developed in Ref. 11. Any unital qubit map Φ can be represented by a real 3×3 matrix with respect to the basis $\sigma_1,\sigma_2,\sigma_3$. In Ref. 11 it was explained that by using independent unitary transformations in its domain and range, this matrix can be put into the following diagonal form:

$$\Phi=\begin{pmatrix}\lambda_1 & 0 & 0\\ 0 & \lambda_2 & 0\\ 0 & 0 & \lambda_3\end{pmatrix}. \tag{64}$$

The diagonal entries satisfy $|\lambda_i|\leqslant 1$, as well as other conditions implied by complete positivity. These conditions were analyzed in Ref. 11 (and also in Ref. 7), and it was shown that the allowed diagonal entries of Φ in (64) comprise the tetrahedron with corners at the points

$$(1,1,1),\ (1,-1,-1),\ (-1,-1,1),\ (-1,1,-1). \tag{65}$$

The corner (1,1,1) corresponds to the identity channel. The corner $(1,-1,-1)$ corresponds to conjugation by σ_1, and so is unitarily equivalent to the identity channel, and similarly for the corners $(-1,-1,1)$ and $(-1,1,-1)$. The top edge of the tetrahedron $(\lambda,\lambda,1)$ is the phase-damping channel $\Psi_\lambda^{(3)}$. The bottom edge $(\lambda,-\lambda,-1)$ is the channel $\sigma_1\Psi_\lambda^{(3)}\sigma_1$. The other edges are obtained by permutation of the coordinates and conjugation with the Pauli matrices, and correspond to the channels $\Psi_\lambda^{(1)}$ and $\Psi_\lambda^{(2)}$.

The depolarizing channels $(\lambda,\lambda,\lambda)$ correspond to an interior line of the tetrahedron, drawn from a corner to the middle of the opposite side. The point $(-\frac{1}{3},-\frac{1}{3},-\frac{1}{3})$ lies on the face of the tetrahedron, so $\lambda=-\frac{1}{3}$ is the smallest allowed value in (15).

Finally, the two-Pauli channels $\Theta_\lambda^{(3)}$ correspond to the points $(\lambda,\lambda,2\lambda-1)$. These points lie on a face of the tetrahedron, on a line connecting a corner to the middle of the opposite side.

The maximal output norm of the channel (64) [as defined in (8)] is

$$M_\Phi=\tfrac{1}{2}(\max\{|\lambda_1|,|\lambda_2|,|\lambda_3|\}+1). \tag{66}$$

Furthermore, the signs of any two of the parameters $\lambda_1,\lambda_2,\lambda_3$ can be simultaneously flipped with a unitary transformation in the domain of Φ (for example, conjugation by σ_1 in the domain of Φ switches the signs of λ_2 and λ_3 without any other changes). Also, the coordinates can be cyclically permuted using unitary transformations. So without loss of generality, we will assume henceforth that the parameters satisfy

$$1 \geqslant \lambda_3 \geqslant \max(|\lambda_1|,|\lambda_2|), \quad M_\Phi = \frac{1+\lambda_3}{2}. \tag{67}$$

We will say that Φ is in *standard form* if it is diagonal in the basis $\sigma_1,\sigma_2,\sigma_3$ and its diagonal entries satisfy (67).

Now assume that Φ is in standard form, and let

$$\lambda = \lambda_3 = \max(|\lambda_i|). \tag{68}$$

Then the quantities ν_p, $S_{\min}$ and χ^* are determined by M_Φ according to (11), and their values are unchanged by unitary transformations in the domain and the range. Hence, using (68) we get

$$\nu_p(\Phi) = m_p\left(\frac{1+\lambda}{2}\right),$$

$$S_{\min}(\Phi) = h\left(\frac{1+\lambda}{2}\right),$$

$$\chi^*(\Phi) = \log 2 - h\left(\frac{1+\lambda}{2}\right).$$

Armed with the geometric picture of the unital qubit channels, it is quite easy to derive relations like (22), (59), and (62). For example, we get (22) by taking a horizontal slice through the tetrahedron at height λ. This cross-section of the tetrahedron is a rectangle with corners at the four points

$$(1,\lambda,\lambda),\ (\lambda,1,\lambda),\ (-1,-\lambda,\lambda),\ (-\lambda,-1,\lambda). \tag{69}$$

Furthermore, each of the maps corresponding to these corners is a phase-damping channel, either $\Psi_\lambda^{(i)}$ or $\sigma_3\Psi_\lambda^{(i)}\sigma_3$, with $i=1,2$. The depolarizing channel sits at $(\lambda,\lambda,\lambda)$, and clearly there are many ways to write it as a convex combination of the four corners. The relation (22) is one such choice.

Now suppose that Φ is a general unital qubit channel in standard form, so that $\lambda_3=\lambda>0$. Then Φ corresponds to a point in the cross-section of the tetrahedron with corners at (69). Furthermore, the condition (67), namely $\lambda=\lambda_3=\max(|\lambda_i|)$, selects a convex subset of this cross-section. For $\frac{1}{3}\leqslant\lambda\leqslant 1$ this subset is the convex hull of the six points

$$\begin{gathered}(\lambda,\lambda,\lambda), \quad (2\lambda-1,\lambda,\lambda), \quad (\lambda,2\lambda-1,\lambda),\\ (-\lambda,-\lambda,\lambda), \quad (1-2\lambda,-\lambda,\lambda), \quad (-\lambda,1-2\lambda,\lambda),\end{gathered} \tag{70}$$

and for $0\leqslant\lambda\leqslant\frac{1}{3}$ this subset is the convex hull of the four points

$$(\lambda,\lambda,\lambda), \quad (-\lambda,\lambda,\lambda), \quad (\lambda,-\lambda,\lambda), \quad (-\lambda,-\lambda,\lambda). \tag{71}$$

It is important to note that every map in the convex hull of (70) has the *same* values for ν_p and $S_{\min}$, since these are determined only by the maximal output norm, and this has the same value $(1+\lambda)/2$ for each of these channels and similarly for all the channels in the convex hull of (71). Therefore, by convexity, it is sufficient to prove the additivity and multiplicativity results (5)–(7) for these corner maps, since this will imply the same bounds for all the maps in the convex hull. However, we recognize that the corner maps in (70) are unitarily equivalent to either depolarizing channels or two-Pauli channels with the same parameter λ. Hence the results of Secs. II and III imply the bounds for these corner maps, and hence for all maps in the convex hull. Notice that the

results of Sec. III for the two-Pauli channel in the range $\frac{1}{3} \leqslant \lambda \leqslant 1$ are sufficient to get the result for the channels (70). Similarly the maps arising in (71) are unitarily equivalent to depolarizing channels, and so Sec. II can be again applied to deduce the result.

V. PROOF OF THEOREM 4

This theorem is a variant of the bound obtained by Lieb and Ruskai, which appeared as an Appendix in Ref. 10, and it can be proved by the same method. That method uses the Lieb–Thirring bound,[12] which in turn was proved using one of Epstein's concavity results.[5] Since Theorem 3 can be obtained directly from Epstein's result, we present that argument here.

Let ρ be a matrix of the form (23). The condition that ρ be positive means that $Y_1 - iY_2 = \sqrt{X+Y_3} R \sqrt{X-Y_3}$ where R is a contraction. Every contraction is a convex combination of unitaries, so it is sufficient to assume that

$$Y_1 - iY_2 = \sqrt{X+Y_3}\, V \sqrt{X-Y_3}, \quad VV^* = I. \tag{72}$$

We have the factorization

$$(I \otimes \Psi_\lambda)(\rho) = F^{1/2} G F^{1/2}, \tag{73}$$

where

$$F = \begin{pmatrix} X+Y_3 & 0 \\ 0 & X-Y_3 \end{pmatrix}, \quad G = \begin{pmatrix} I & \lambda V \\ \lambda V^* & I \end{pmatrix}. \tag{74}$$

From the identity

$$\begin{pmatrix} I & \lambda V \\ \lambda V^* & I \end{pmatrix} = U \begin{pmatrix} (1+\lambda)I & 0 \\ 0 & (1-\lambda)I \end{pmatrix} U^*, \tag{75}$$

where

$$U = \frac{1}{\sqrt{2}} \begin{pmatrix} I & V \\ V^* & -I \end{pmatrix}, \quad UU^* = I, \tag{76}$$

it follows that for all $p \geqslant 1$

$$G^p = \begin{pmatrix} \alpha I & \beta V \\ \beta V^* & \alpha I \end{pmatrix} \tag{77}$$

with

$$\alpha = \tfrac{1}{2}[(1+\lambda)^p + (1-\lambda)^p], \quad \beta = \tfrac{1}{2}[(1+\lambda)^p - (1-\lambda)^p]. \tag{78}$$

We can write

$$\mathrm{Tr}((I \otimes \Psi_\lambda)(\rho))^p = \mathrm{Tr}(F^{1/2} (G^p)^{1/p} F^{1/2})^p. \tag{79}$$

Now we use Epstein's concavity result,[5] which states that for any positive matrix B and any $p \geqslant 1$, the map

$$A \to \mathrm{Tr}(B\,(A)^{1/p}\,B)^p \tag{80}$$

is concave on the set of positive matrices. (In fact Epstein states the result only for integer values of p, but his proof applies to all real values $p \geqslant 1$.) The left side of (79) is an even function of λ, and therefore the right side is unchanged if β is replaced by $-\beta$ in (77). Also note that

$$\tfrac{1}{2}\begin{pmatrix} \alpha I & \beta V \\ \beta V^* & \alpha I \end{pmatrix} + \tfrac{1}{2}\begin{pmatrix} \alpha I & -\beta V \\ -\beta V^* & \alpha I \end{pmatrix} = \begin{pmatrix} \alpha I & 0 \\ 0 & \alpha I \end{pmatrix}. \tag{81}$$

Therefore the concavity result (80) implies that the right side of (79) is bounded above by its value when β is set equal to zero in (77). Furthermore, when $\beta = 0$, the right side of (79) becomes

$$\mathrm{Tr}(F^{1/2}(\alpha I)^{1/p}F^{1/2})^p = \alpha \mathrm{Tr}F^p = 2\alpha[\tfrac{1}{2}\mathrm{Tr}(X+Y_3)^p + \tfrac{1}{2}\mathrm{Tr}(X-Y_3)^p]. \tag{82}$$

Comparing with (9) we see that $2\alpha = 2^p m_p((1+\lambda)/2)^p$, and this proves the theorem.

A method of solving the Bloch equation with infinite relaxation times is given. Applying this method we have found unknown analytic solutions as well as the well-known solutions. © *2002 American Institute of Physics.*
[DOI: 10.1063/1.1504887]

I. INTRODUCTION

Since the Bloch equation[1] was proposed in 1946, various workers have tried to solve it analytically and only a few analytic solutions are well known. Among the various attempts, the spinor approaches by spinorizing the Bloch equation in nuclear magnetic resonance[2] were paid attention to. The reason is due to the fact that there exists a 2×2 unitary evolution matrix. By this unitary transformation the length of the spinor is conserved. The equivalence between vectors and spinors is also well known.[3] Keeping this point in mind, we develop our approach to solving the vector Bloch equation in this paper.

We give a method of solving the homogeneous Bloch equation in Sec. II. Then in Sec. III we apply this method to finding analytic solutions. In Sec. IV we state conclusions.

II. SCENARIO

The homogeneous Bloch equation for magnetization with infinite relaxation times is given by

$$\dot{\vec{M}}+\gamma\vec{B}\times\vec{M}=0, \tag{1}$$

where a dot means differentiation with respect to time. Here γ is the gyromagnetic ratio and $\vec{B}$ is the applied magnetic field.

Taking the scalar product of $\vec{M}$ with Eq. (1) yields

$$\frac{\mathrm{d}}{\mathrm{d}t}(\vec{M}\cdot\vec{M})=0. \tag{2}$$

This turns out to be the magnitude of the magnetic vector being independent of time. This suggests that rotations play a fundamental role. We introduce a time-dependent linear transformation of the magnetic vector as

$$\vec{M}'=A\vec{M}. \tag{3}$$

By using components of Eq. (3), we have

$$M_i'=a_{ij}M_j, \quad (i=1,2,3), \tag{4}$$

with

$$(A)_{ij}=a_{ij}, \quad (i,j=1,2,3). \tag{5}$$

a)Electronic mail: masanori@cc.gifu-u.ac.jp

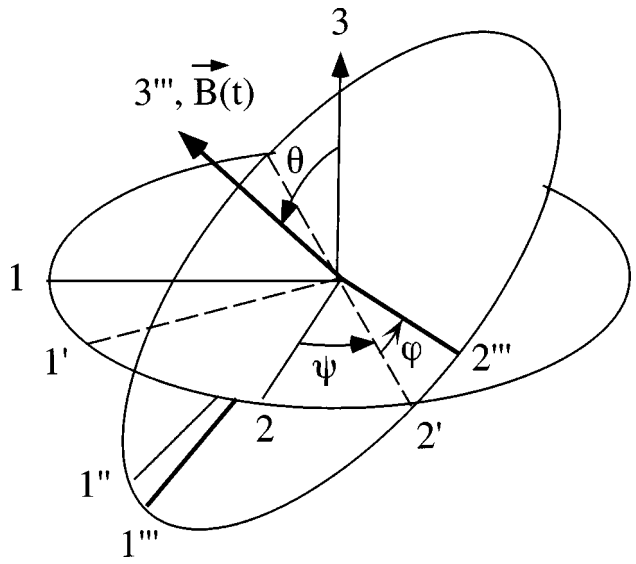

FIG. 1. Definition of the Eulerian angles.

Here the repeated indices mean summation over the index running from 1 to 3. Under the transformation (3), we require

$$\vec{M}'\cdot\vec{M}'=\vec{M}\cdot\vec{M}. \tag{6}$$

Thus the transformation is restricted such that

$$a_{ik}a_{jk}=\delta_{ij}. \tag{7}$$

In the matrix form we have

$$AA^T=A^TA=1, \tag{8}$$

with

$$\det A=\pm 1. \tag{9}$$

This transformation is called the orthogonal transformation. Here we choose proper orthogonal transformations, i.e., rotations in the three-dimensional Euclidean space,

$$\det A=+1. \tag{10}$$

In general a rotation can be expressed in terms of the Eulerian angles (φ,θ,ψ) displayed in Fig. 1 as

$$A=e^{i\varphi T_3}e^{i\theta T_2}e^{i\psi T_3}, \tag{11}$$

where $T_i(i=1,2,3)$ is the generator of rotation around the i axis and given by

$$(T_i)_{kl}=-i\epsilon_{kli}. \tag{12}$$

A straightforward calculation using Eq. (12) shows that an orthogonal evolution matrix becomes

$$A=\begin{pmatrix} \cos\varphi\cos\theta\cos\psi-\sin\varphi\sin\psi & \cos\varphi\cos\theta\sin\psi+\sin\varphi\cos\psi & -\cos\varphi\sin\theta \\ -\sin\varphi\cos\theta\cos\psi-\cos\varphi\sin\psi & -\sin\varphi\cos\theta\sin\psi+\cos\varphi\cos\psi & \sin\varphi\sin\theta \\ \sin\theta\cos\psi & \sin\theta\sin\psi & \cos\theta \end{pmatrix}. \tag{13}$$

By differentiating Eq. (8) with respect to time we have

$$(\dot{A}A^T)_{ij}=-(\dot{A}A^T)_{ji}. \tag{14}$$

Thus we can write $\vec{\omega}$ by

$$(\dot{A}A^T)_{ij}=\epsilon_{ijk}\omega_k. \tag{15}$$

A tedious but straightforward calculation yields

$$\omega_1=\dot{\theta}\sin\varphi-\dot{\psi}\sin\theta\cos\varphi, \tag{16}$$

$$\omega_2=\dot{\theta}\cos\varphi+\dot{\psi}\sin\theta\sin\varphi, \tag{17}$$

and

$$\omega_3=\dot{\varphi}+\dot{\psi}\cos\theta, \tag{18}$$

where ω_i is the angular velocity around the i-axis.

The Bloch equation in the rotated system turns out to be

$$\dot{\vec{M}}'+\gamma\vec{B}'\times\vec{M}'=0, \tag{19}$$

where

$$\vec{B}'=A\vec{B}+\frac{1}{\gamma}\vec{\omega}. \tag{20}$$

Here use has been made of the relationship;

$$a_{ij}\epsilon_{jkl}B_kM_l=\epsilon_{ijn}a_{jk}a_{nl}B_kM_l, \tag{21}$$

which is derived from the definition of $\det A$, i.e.,

$$a_{li}a_{mj}a_{nk}\epsilon_{lmn}=\epsilon_{ijk}\det A. \tag{22}$$

A method of solving the Bloch equation (1) is given as follows.

First we solve the rotated Bloch equation (19) for $\vec{M}'$ by rotating the coordinate system into one with the 3-axis being the direction of the applied magnetic field. Thus we find

$$A\vec{B}=(0,\ 0,\ |\vec{B}|), \tag{23}$$

where

$$\vec{B}=(|\vec{B}|\sin\theta\cos\psi,|\vec{B}|\sin\theta\sin\psi,\ \ |\vec{B}|\cos\theta). \tag{24}$$

Second we try to solve Eq. (19) by choosing

$$\dot{\varphi}=-\gamma|\vec{B}|. \tag{25}$$

This choice has limitations from the beginning. The case of $\dot{\varphi}=0$ is excluded. This case will be discussed later. This allows us a case of having the magnitude of the magnetic vector being time dependent. From this choice $\vec{B}'$ reduces to

$$\vec{B}'=\frac{1}{\gamma}(\omega_1,\ \omega_2,\ \omega_3'), \tag{26}$$

where

$$\omega_3'=\dot{\psi}\cos\theta. \tag{27}$$

By solving Eqs. (16) and (17) for $\dot{\theta}$ and $\dot{\psi}\sin\theta$, we have

$$\dot{\theta}=\omega_1\sin\varphi+\omega_2\cos\varphi=\sqrt{\omega_1^2+\omega_2^2}\sin(\varphi+\delta), \tag{28}$$

and

$$\dot{\psi}\sin\theta=-\omega_1\cos\varphi+\omega_2\sin\varphi=-\sqrt{\omega_1^2+\omega_2^2}\cos(\varphi+\delta), \tag{29}$$

where

$$\delta=\cos^{-1}\frac{\omega_1}{\sqrt{\omega_1^2+\omega_2^2}}=\sin^{-1}\frac{\omega_2}{\sqrt{\omega_1^2+\omega_2^2}}=\tan^{-1}\frac{\omega_2}{\omega_1}. \tag{30}$$

Winding up Eqs. (27), (28), and (29), we find

$$(\dot{\theta})^2+(\dot{\psi})^2=(\omega')^2, \tag{31}$$

$$(\dot{\psi})^2=(\omega')^2-\omega_0^2\sin^2(\varphi+\delta), \tag{32}$$

and

$$\tan\theta=-\frac{\omega_0}{\omega_3'}\cos(\varphi+\delta), \tag{33}$$

where

$$\omega'=\sqrt{\omega_1^2+\omega_2^2+(\omega_3')^2}, \tag{34}$$

and

$$\omega_o=\sqrt{\omega_1^2+\omega_2^2}. \tag{35}$$

Third we look for analytic solutions by combining Eq. (26) with Eqs. (27)–(29). We find a solution such that

$$\vec{M}'=Q\vec{M}_0', \tag{36}$$

where $\vec{M}_0'$ is an initial value of $\vec{M}'$. Moreover we have

$$\vec{M}_0'=A_0\vec{M}_0, \tag{37}$$

where A_0 and $\vec{M}_0$ are initial values of A and $\vec{M}$, respectively. Thus we find a solution:

$$\vec{M}=(A^TA_0)(A_0^TQA_0)\vec{M}_0. \tag{38}$$

Notice that Q is a solution of the rotated Bloch equation (19) with Eq. (26) in the matrix form.

III. EXAMPLES OF ANALYTIC SOLUTIONS

Using the senario developed in Sec. II, we study two cases in the following.

A. $\omega_1=\omega_2=0$

Equations (28) and (29) yield

$$\dot{\theta}=\dot{\psi}\sin\theta=0. \tag{39}$$

1. $\theta=0$

From Eq. (27) we have

$$\omega_3'=\dot{\psi}. \tag{40}$$

The exact solution is obtained by choosing the constant of integration as

$$\int_0^t\omega_3'\,\mathrm{d}t=\psi-\psi(0)+\delta_\psi, \tag{41}$$

with

$$\delta_\psi=\psi(0)=0. \tag{42}$$

Thus we find

$$Q=\begin{pmatrix}\cos\psi & \sin\psi & 0\\ -\sin\psi & \cos\psi & 0\\ 0 & 0 & 1\end{pmatrix}, \tag{43}$$

and

$$A_0=\mathbb{1}. \tag{44}$$

Here we have chosen

$$\varphi(0)=0. \tag{45}$$

The solution is

$$A^TQ=\begin{pmatrix}\cos\varphi & -\sin\varphi & 0\\ \sin\varphi & \cos\varphi & 0\\ 0 & 0 & 1\end{pmatrix}, \tag{46}$$

with

$$\varphi=-\gamma\int_0^t|\vec{B}|\mathrm{d}t. \tag{47}$$

This is the well-known solution.

2. $\dot{\theta}=\dot{\psi}=0$

In this case we have from Eq. (27)

$$\omega_3'=0. \tag{48}$$

Thus we find

$$Q=\mathbb{1}. \tag{49}$$

This case corresponds to the applied magnetic field having a fixed direction.

To get a compact expression of solution we use $\hat{e}$ defined by

$$\hat{e}=\left(\frac{B_1}{|\vec{B}|},\ \frac{B_2}{|\vec{B}|},\ \frac{B_3}{|\vec{B}|}\right)=(\sin\theta\cos\psi,\ \sin\theta\sin\psi,\ \cos\theta), \tag{50}$$

with

$$\hat{e}_3=\cos\theta,\quad \sin\theta=\hat{e}_0=\sqrt{\hat{e}_1^2+\hat{e}_2^2}, \tag{51}$$

and

$$\frac{\hat{e}_1}{\hat{e}_0}=\cos\psi,\quad \sin\psi=\frac{\hat{e}_2}{\hat{e}_0}. \tag{52}$$

The rotation matrix (13) is given by

$$A=\begin{pmatrix} \dfrac{\hat{e}_3\hat{e}_1}{\hat{e}_0}\cos\varphi-\dfrac{\hat{e}_2}{\hat{e}_0}\sin\varphi & \dfrac{\hat{e}_2\hat{e}_3}{\hat{e}_0}\cos\varphi+\dfrac{\hat{e}_1}{\hat{e}_0}\sin\varphi & -\hat{e}_0\cos\varphi \\ -\dfrac{\hat{e}_3\hat{e}_1}{\hat{e}_0}\sin\varphi-\dfrac{\hat{e}_2}{\hat{e}_0}\cos\varphi & -\dfrac{\hat{e}_2\hat{e}_3}{\hat{e}_0}\sin\varphi+\dfrac{\hat{e}_1}{\hat{e}_0}\cos\varphi & \hat{e}_0\sin\varphi \\ \hat{e}_1 & \hat{e}_2 & \hat{e}_3 \end{pmatrix}. \tag{53}$$

Thus we find

$$A_0=\begin{pmatrix} \dfrac{\hat{e}_3\hat{e}_1}{\hat{e}_0} & \dfrac{\hat{e}_2\hat{e}_3}{\hat{e}_0} & -\hat{e}_0 \\ -\dfrac{\hat{e}_2}{\hat{e}_0} & \dfrac{\hat{e}_1}{\hat{e}_0} & 0 \\ \hat{e}_1 & \hat{e}_2 & \hat{e}_3 \end{pmatrix}, \tag{54}$$

and

$$(A^TA_0)_{ij}=\cos\varphi\,\delta_{ij}+(1-\cos\varphi)\hat{e}_i\hat{e}_j+\sin\varphi\,\epsilon_{ikj}\hat{e}_k, \tag{55}$$

where

$$\varphi=-\gamma\int_0^t|\vec{B}|\,\mathrm{d}t. \tag{56}$$

B. $\dot{\omega}_1=\dot{\omega}_2=\dot{\omega}'_3=0$

By differentiating Eq. (33) with respect to time we find the key relationship:

$$\dot{\theta}\left[\dot{\varphi}-\frac{1}{\omega'_3}(\dot{\psi})^2\right]=0. \tag{57}$$

Here we have used Eqs. (27) and (28).

1. $\dot{\theta}=0$

Winding up Eqs. (27), (28), and (29), we find

$$\omega_1=\omega_2=0, \tag{58}$$

$$\theta=0, \tag{59}$$

and

$$\psi=\omega'_3 t. \tag{60}$$

Thus this case is included in Sec. III A 1.

2. $\dot{\varphi}=\frac{1}{\omega'_3}(\dot{\psi})^2$

Using Eq. (32), we have

$$\dot{\varphi}=-\gamma|\vec{B}|=\frac{\omega'}{e_3}[1-e_0^2\sin^2(\varphi+\delta)], \tag{61}$$

where we have defined $\vec{e}$ by

$$\vec{e}=\left(\frac{\omega_1}{\omega'},\frac{\omega_2}{\omega'},\frac{\omega'_3}{\omega'}\right), \tag{62}$$

and

$$e_0=\sqrt{e_1^2+e_2^2}=\frac{\omega_0}{\omega'}. \tag{63}$$

a. $\ddot{\varphi}=0$. Before going into details we comment on the case of $|\vec{B}|$ being independent of time. In this case Eq. (61) yields

$$\omega_1=\omega_2=0, \tag{64}$$

$$\omega'_3=-\gamma|\vec{B}|=\dot{\psi}, \tag{65}$$

and

$$\theta=0. \tag{66}$$

Here we have made the combined use of Eqs. (27) and (32). Thus this case is also included in Sec. III A 1.

b. $\ddot{\varphi}\neq 0$. Solving the differential equation of first order (61) for φ, we find

$$\varphi=-\delta+\tan^{-1}\left[\frac{1}{e_3}\tan(\omega' t+\delta_C)\right], \tag{67}$$

where δ_C is the constant of integration. The magnitude of the applied magnetic field is obtained by differentiating Eq. (67) with respect to time,

$$-\gamma|\vec{B}|=\frac{\omega' e_3}{1-e_0^2\cos^2(\omega' t+\delta_C)} \quad (e_3<0). \tag{68}$$

Again using Eq. (61) we find

$$\dot{\psi}=\frac{\omega' e_3}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}. \tag{69}$$

By substituting Eq. (69) back into Eq. (31), we have

$$\dot{\theta}=-\frac{\omega' e_0\sin(\omega' t+\delta_C)}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}. \tag{70}$$

Equation (69) yields

$$\psi=e_3F(\tau,\ e_0)+\delta_\psi, \tag{71}$$

with

$$\tau=\sin^{-1}\left[\frac{\sin(\omega' t+\delta_C)}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}\right], \tag{72}$$

where $F(x,p)$ is the elliptic integral of the first kind and given by

$$F(x,p)=\int_{x_0}^{x}\frac{\mathrm{d}x}{\sqrt{1-p^2\sin^2 x}} \quad (p^2<1). \tag{73}$$

Also Eq. (70) yields

$$\theta=\sin^{-1}[e_0\cos(\omega' t+\delta_C)]+\delta_\theta. \tag{74}$$

Here δ_ψ and δ_θ are the constants of integration.

Having chosen the constants of integration as

$$\delta_C=\tan^{-1}(e_3\tan\delta), \tag{75}$$

$$\delta_\psi=-e_3F(\tau_0,\ e_0)=0, \tag{76}$$

with

$$\tau_0=\sin^{-1}\left(\frac{\sin\delta_C}{\sqrt{1-e_0^2\cos^2\delta_C}}\right)=-\delta, \tag{77}$$

and

$$\delta_\theta=0, \tag{78}$$

we find

$$\varphi(0)=\psi(0)=0, \tag{79}$$

and

$$\theta_0=\theta(0)=\sin^{-1}(e_0\cos\delta_C)=\sin^{-1}\left(\frac{e_0\cos\delta}{\sqrt{1-e_0^2\sin^2\delta}}\right). \tag{80}$$

In this case the solution of the rotated Bloch equation is well known and given by

$$(Q)_{ij}=\cos(\omega' t)\,\delta_{ij}+[1-\cos(\omega' t)]e_i e_j-\sin(\omega' t)\,\epsilon_{ikj}\,e_k, \tag{81}$$

and

$$A_0=\begin{pmatrix}\cos\theta_0 & 0 & -\sin\theta_0\\ 0 & 1 & 0\\ \sin\theta_0 & 0 & \cos\theta_0\end{pmatrix}=\frac{1}{\sqrt{1-e_2^2}}\begin{pmatrix}-e_3 & 0 & -e_1\\ 0 & \sqrt{1-e_2^2} & 0\\ e_1 & 0 & -e_3\end{pmatrix}. \tag{82}$$

Here we have used Eqs. (79) and (80).

Let us introduce the matrices E_i, $(i=1,2)$ given by

$$(E_1)_{ij}=e_i e_j, \tag{83}$$

and

$$(E_2)_{ij}=-\epsilon_{ikj}e_k, \tag{84}$$

we find

$$A_0^T Q A_0=\cos(\omega' t)\mathbb{1}+[1-\cos(\omega' t)]Q_1+\sin(\omega' t)Q_2, \tag{85}$$

where

$$Q_1=A_0^T E_1 A_0=\begin{pmatrix}0 & 0 & 0\\ 0 & e_2^2 & -e_2\sqrt{1-e_2^2}\\ 0 & -e_2\sqrt{1-e_2^2} & 1-e_2^2\end{pmatrix}, \tag{86}$$

and

$$Q_2=A_0^T E_2 A_0=\begin{pmatrix}0 & -\sqrt{1-e_2^2} & -e_2\\ \sqrt{1-e_2^2} & 0 & 0\\ e_2 & 0 & 0\end{pmatrix}. \tag{87}$$

Thus we find

$$(A^T A_0)(A_0^T Q A_0)=\cos(\omega' t)A^T A_0+[1-\cos(\omega' t)]A^T A_0 Q_1+\sin(\omega' t)A^T A_0 Q_2. \tag{88}$$

Having written Eq. (88) out, we list here in components of $A^T A_0$, $A^T A_0 Q_1$, and $A^T A_0 Q_2$:

$$(A^T A_0)_{ij}=(A^T)_{ik}(A_0)_{kj}=(A)_{ki}(A_0)_{kj}, \tag{89}$$

where

$$(A^TA_0)_{11}=\frac{1}{\sqrt{1-e_2^2}}[-e_3(\cos\varphi\cos\theta\cos\psi-\sin\varphi\sin\psi)+e_1\sin\theta\cos\psi],$$

$$(A^TA_0)_{12}=-\sin\varphi\cos\theta\cos\psi-\cos\varphi\sin\psi,$$

$$(A^TA_0)_{13}=\frac{1}{\sqrt{1-e_2^2}}[-e_1(\cos\varphi\cos\theta\cos\psi-\sin\varphi\sin\psi)-e_3\sin\theta\cos\psi],$$

$$(A^TA_0)_{21}=\frac{1}{\sqrt{1-e_2^2}}[-e_3(\cos\varphi\cos\theta\sin\psi+\sin\varphi\cos\psi)+e_1\sin\theta\sin\psi],$$

$$(A^TA_0)_{22}=-\sin\varphi\cos\theta\sin\psi+\cos\varphi\cos\psi,$$

$$(A^TA_0)_{23}=\frac{1}{\sqrt{1-e_2^2}}[-e_1(\cos\varphi\cos\theta\sin\psi+\sin\varphi\cos\psi)-e_3\sin\theta\sin\psi],$$

$$(A^TA_0)_{31}=\frac{1}{\sqrt{1-e_2^2}}(e_3\cos\varphi\sin\theta+e_1\cos\theta),$$

$$(A^TA_0)_{32}=\sin\varphi\sin\theta,$$

and

$$(A^TA_0)_{33}=\frac{1}{\sqrt{1-e_2^2}}(e_1\cos\varphi\sin\theta-e_3\cos\theta),$$

$$(A^TA_0Q_1)_{ij}=(A^TA_0)_{ik}(Q_1)_{kj}, \tag{90}$$

where

$$(A^TA_0Q_1)_{12}=e_2[(e_1\cos\varphi-e_2\sin\varphi)\cos\theta\cos\psi-(e_2\cos\varphi+e_1\sin\varphi)\sin\psi+e_3\sin\theta\cos\psi],$$

$$(A^TA_0Q_1)_{13}=-\sqrt{1-e_2^2}[(e_1\cos\varphi-e_2\sin\varphi)\cos\theta\cos\psi-(e_2\cos\varphi+e_1\sin\varphi)\sin\psi+e_3\sin\theta\cos\psi],$$

$$(A^TA_0Q_1)_{22}=e_2[(e_1\cos\varphi-e_2\sin\varphi)\cos\theta\sin\psi+(e_2\cos\varphi+e_1\sin\varphi)\cos\psi+e_3\sin\theta\sin\psi],$$

$$(A^TA_0Q_1)_{23}=-\sqrt{1-e_2^2}[(e_1\cos\varphi-e_2\cos\varphi)\cos\theta\sin\psi+(e_2\cos\varphi+e_1\sin\varphi)\cos\psi+e_3\sin\theta\sin\psi],$$

$$(A^TA_0Q_1)_{32}=-e_2[(e_1\cos\varphi-e_2\sin\varphi)\sin\theta-e_3\cos\theta],$$

$$(A^TA_0Q_1)_{33}=\sqrt{1-e_2^2}[(e_1\cos\varphi-e_2\sin\varphi)\sin\theta-e_3\cos\theta],$$

and

$$(A^T A_0 Q_1)_{i1}=0, \quad (i=1,2,3),$$
$$(A^T A_0 Q_2)_{ij}=(A^T A_0)_{ik}(Q_2)_{kj}, \tag{91}$$

where

$$(A^T A_0 Q_2)_{11}=-\frac{1}{\sqrt{1-e_2^2}}\{[e_1e_2\cos\varphi+(1-e_2^2)\sin\varphi]\cos\theta\cos\psi$$
$$+[(1-e_2^2)\cos\varphi-e_1e_2\sin\varphi]\sin\psi+e_2e_3\sin\theta\cos\psi\},$$
$$(A^T A_0 Q_2)_{12}=e_3(\cos\varphi\cos\theta\cos\psi-\sin\varphi\sin\psi)-e_1\sin\theta\cos\psi,$$
$$(A^T A_0 Q_2)_{13}=\frac{e_2}{\sqrt{1-e_2^2}}[e_3(\cos\varphi\cos\theta\cos\psi-\sin\varphi\sin\psi)-e_1\sin\theta\cos\psi],$$
$$(A^T A_0 Q_2)_{21}=-\frac{1}{\sqrt{1-e_2^2}}\{[e_1e_2\cos\varphi+(1-e_2^2)\sin\varphi]\cos\theta\sin\psi$$
$$-[(1-e_2^2)\cos\varphi-e_1e_2\sin\varphi]\cos\psi+e_2e_3\sin\theta\sin\psi\},$$
$$(A^T A_0 Q_2)_{22}=e_3(\cos\varphi\cos\theta\sin\psi+\sin\varphi\cos\psi)-e_1\sin\theta\sin\psi,$$
$$(A^T A_0 Q_2)_{23}=\frac{e_2}{\sqrt{1-e_2^2}}[e_3(\cos\varphi\cos\theta\sin\psi+\sin\varphi\cos\psi)-e_1\sin\theta\sin\psi],$$
$$(A^T A_0 Q_2)_{31}=\frac{1}{\sqrt{1-e_2^2}}\{[e_1e_2\cos\varphi+(1-e_2^2)\sin\varphi]\sin\theta-e_2e_3\cos\theta\},$$
$$(A^T A_0 Q_2)_{32}=-(e_3\cos\varphi\sin\theta+e_1\cos\theta),$$

and

$$(A^T A_0 Q_2)_{33}=-\frac{e_2}{\sqrt{1-e_2^2}}(e_3\cos\varphi\sin\theta+e_1\cos\theta).$$

The Eulerian angles (φ,θ,ψ) are given by

$$\varphi+\delta=\tan^{-1}\left[\frac{1}{e_3}\tan(\omega' t+\delta_C)\right]=\cos^{-1}\left[-\frac{e_3\cos(\omega' t+\delta_C)}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}\right]$$
$$=\sin^{-1}\left[-\frac{\sin(\omega' t+\delta_C)}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}\right], \tag{92}$$
$$\theta=\sin^{-1}[e_0\cos(\omega' t+\delta_C)]=\cos^{-1}[\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}], \tag{93}$$

and

$$\psi=e_3F(\tau,e_0), \quad \tau=\sin^{-1}\left[\frac{\sin(\omega' t+\delta_C)}{\sqrt{1-e_0^2\cos^2(\omega' t+\delta_C)}}\right], \tag{94}$$

with

$$\delta=\cos^{-1}\frac{e_1}{e_0}=\sin^{-1}\frac{e_2}{e_0}=\tan^{-1}\frac{e_2}{e_1}, \tag{95}$$

and

$$\delta_C=\tan^{-1}(e_3\tan\delta)=\cos^{-1}\left(\frac{\cos\delta}{\sqrt{1-e_0^2\sin^2\delta}}\right)=\sin^{-1}\left(\frac{e_3\sin\delta}{\sqrt{1-e_0^2\sin^2\delta}}\right). \tag{96}$$

This solution is a general solution under the condition that the modified angular velocities $(\omega_1,\omega_2,\omega_3')$ are independent of time. The rotated coordinate system moves according to Eqs. (92)–(94) together with Eq. (68).

3. $\dot{\varphi}=0$

As was mentioned before, the choice of Eq. (25) does not make sense for the case of $\dot{\varphi}=0$. Instead of the choice (25) we can impose on φ being independent of time such that

$$\varphi=-\delta, \tag{97}$$

where δ is given by Eq. (30). From this choice Eqs. (27)–(29) together with Eqs. (32) and (33) yield

$$\psi=\omega' t, \tag{98}$$

and

$$\theta=\tan^{-1}\left(-\frac{\omega_0}{\omega_3'}\right)=\cos^{-1}\left(\frac{\omega_3'}{\omega'}\right)=\sin^{-1}\left(-\frac{\omega_0}{\omega'}\right). \tag{99}$$

We can solve the rotated Bloch equation (19) under the condition

$$\dot{|\vec{B}|}=0. \tag{100}$$

Then we have to redefine $\vec{e}$ by

$$\vec{e}=\frac{1}{\omega}(\omega_1,\omega_2,\gamma|\vec{B}|+\omega_3'), \tag{101}$$

with

$$\omega=\sqrt{\omega_0^2+(\gamma|\vec{B}|+\omega_3')^2}, \tag{102}$$

$$\omega_0=\sqrt{\omega_1^2+\omega_2^2}=\omega e_0. \tag{103}$$

Note that

$$\vec{B}=[|\vec{B}|\sin\theta\cos(\omega' t),|\vec{B}|\sin\theta\sin(\omega' t),|\vec{B}|\cos\theta]. \tag{104}$$

The solution is given by

$$(Q)_{ij}=\cos(\omega t)\delta_{ij}+[1-\cos(\omega t)]e_ie_j-\sin(\omega t)\epsilon_{ikj}e_k, \tag{105}$$

where we have used Eq. (101), and

$$A_0=\begin{pmatrix} \cos\delta\cos\theta & -\sin\delta & -\cos\delta\sin\theta \\ \sin\delta\cos\theta & \cos\delta & -\sin\delta\sin\theta \\ \sin\theta & 0 & \cos\theta \end{pmatrix}. \tag{106}$$

Here we have used A as

$$A=\begin{pmatrix} \cos\delta\cos\theta\cos(\omega' t)+\sin\delta\sin(\omega' t) & \cos\delta\cos\theta\sin(\omega' t)-\sin\delta\cos(\omega' t) & -\cos\delta\sin\theta \\ \sin\delta\cos\theta\cos(\omega' t)-\cos\delta\sin(\omega' t) & \sin\delta\cos\theta\sin(\omega' t)+\cos\delta\cos(\omega' t) & -\sin\delta\sin\theta \\ \sin\theta\cos(\omega' t) & \sin\theta\sin(\omega' t) & \cos\theta \end{pmatrix}. \tag{107}$$

Thus we find

$$A^T A_0=\begin{pmatrix} \cos(\omega' t) & -\sin(\omega' t) & 0 \\ \sin(\omega' t) & \cos(\omega' t) & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{108}$$

and

$$A_0^T Q A_0=\cos(\omega t)\mathbb{1}+[1-\cos(\omega t)]Q_1+\sin(\omega t)Q_2, \tag{109}$$

where

$$\begin{aligned} Q_1&=A_0^T E_1 A_0 \\ &=\begin{pmatrix} (e_0\cos\theta+e_3\sin\theta)^2 & 0 & (e_0\cos\theta+e_3\sin\theta)(e_3\cos\theta-e_0\sin\theta) \\ 0 & 0 & 0 \\ (e_0\cos\theta+e_3\sin\theta)(e_3\cos\theta-e_0\sin\theta) & 0 & (e_3\cos\theta-e_0\sin\theta)^2 \end{pmatrix}, \end{aligned} \tag{110}$$

and

$$Q_2=A_0^T E_2 A_0=\begin{pmatrix} 0 & e_3\cos\theta-e_0\sin\theta & 0 \\ -(e_3\cos\theta-e_0\sin\theta) & 0 & e_0\cos\theta+e_3\sin\theta \\ 0 & -(e_0\cos\theta+e_3\sin\theta) & 0 \end{pmatrix}, \tag{111}$$

with

$$e_0\cos\theta+e_3\sin\theta=-\frac{1}{\omega}\gamma|\vec{B}|\frac{\omega_0}{\omega'}, \tag{112}$$

and

$$e_3\cos\theta-e_0\sin\theta=\frac{1}{\omega}\left(\omega'+\gamma|\vec{B}|\frac{\omega_3'}{\omega'}\right). \tag{113}$$

Here E_1 and E_2 are given by Eqs. (83) and (84), respectively. Thus we find

$$(A^T A_0)(A_0^T Q A_0)=\cos(\omega t)(A^T A_0)+[1-\cos(\omega t)](A^T A_0)Q_1+\sin(\omega t)(A^T A_0)Q_2, \tag{114}$$

where Eq. (108) yields $A^T A_0$ being the rotation matrix around the 3-axis.

This example is well known as a circularly polarized rf field. Resonance occurrs when $\omega_3' = -\gamma|\vec{B}|$.

IV. CONCLUSIONS

We have found an unknown solution for the case in Sec. III B 2 b in which the applied magnetic vector behaves as the bounded oscillation in time. All the well-known solutions have been contained in our approach. And even in the well-known case of Sec. III A 2, we allow the case of having the magnitude of the magnetic vector being time dependent.

Semiclassical generalization of the Darboux–Christoffel formula

Robert G. Littlejohn[a] and Paul Wright
Department of Physics, University of California at Berkeley, Berkeley, California 94720

(Received 10 April 2002; accepted for publication 25 April 2002)

The Darboux–Christoffel formula is a closed-form expression for the kernel of the operator that projects onto the first N of a system of one-dimensional polynomials, orthonormal with respect to some weighting function. It is a key element in the theory of Gaussian integration and in the theory of discrete variable representation or Lagrangian mesh methods for diagonalizing quantum Hamiltonians of a few degrees of freedom. The one-dimensional Darboux–Christoffel formula turns out to have a generalization that is valid in a semiclassical or asymptotic sense for a wider class of orthonormal functions than orthonormal polynomials. This class consists of the bound eigenfunctions of one-dimensional Hamiltonians with time-reversal invariance, such as kinetic-plus-potential Hamiltonians. It also has certain generalizations involving the unbound eigenfunctions of such Hamiltonians. © *2002 American Institute of Physics.* [DOI: 10.1063/1.1489071]

I. INTRODUCTION

This paper concerns the Darboux–Christoffel formula, a standard result in the theory of one-dimensional orthonormal polynomials.[1,2] The formula is the following. Let $\{q_n(x),n=0,1,\ldots\}$ be a set of real polynomials, where $q_n(x)$ is of degree n. Let the polynomials be orthonormal on an interval $[a,b]$ with respect to weighting function $\rho(x)>0$, so that $\int_a^b \mathrm{d}x\,\rho(x)q_n(x)q_m(x)=\delta_{nm}$. Let $\phi_n(x)=\sqrt{\rho(x)}q_n(x)$, so that the functions $\{\phi_n(x)\}$ are orthonormal with respect to the measure $\mathrm{d}x$. Then the Darboux–Christoffel formula is

$$\sum_{n=0}^{N-1}\phi_n(x)\phi_n(y)=\langle x|P_N|y\rangle=a_N\frac{\phi_N(x)\phi_{N-1}(y)-\phi_{N-1}(x)\phi_N(y)}{x-y}, \tag{1.1}$$

where P_N is the projection operator onto the first N eigenfunctions,

$$P_N=\sum_{n=0}^{N-1}|\phi_n\rangle\langle\phi_n|, \tag{1.2}$$

and where

$$a_N=\langle\phi_N|x|\phi_{N-1}\rangle=\int_a^b \mathrm{d}x\;\phi_N(x)x\phi_{N-1}(x). \tag{1.3}$$

Here and in the following we use Dirac notation, with $|\phi_n\rangle$ representing $\phi_n(x)$. The Darboux–Christoffel formula has a generalization to systems of orthogonal polynomials in more than one variable,[3] which we shall discuss in the following, but most of this paper is concerned with the one-dimensional case.

This paper presents a semiclassical generalization of the Darboux–Christoffel formula, that is, a generalization that applies to systems of orthogonal functions that are not necessarily orthogonal

[a]Electronic mail: robert@wigner.berkeley.edu

polynomials, but one that is valid only in a semiclassical or asymptotic sense. Our interest in the Darboux–Christoffel formula is an outgrowth of our recent attempts[4–8] to construct multidimensional generalizations of ''Lagrangian mesh'' or ''discrete variable representation'' (LM/DVR) basis functions, which are localized functions useful for diagonalizing Hamiltonians of few degrees of freedom. In the remainder of this section we shall explain what LM/DVR functions are, what their relation to the Darboux–Christoffel formula is, and the reasoning that led us to consider a semiclassical generalization of that formula. In subsequent sections we shall present our derivation of that generalization and a discussion of the result.

The following is a bare outline of one approach to LM/DVR functions. Standard references include Harris *et al.*,[9] Dickinson and Certain,[10] and Baye and Heenan.[11] A review of the application of these functions in chemical physics has recently been given by Light and Carrington,[12] and we have presented our own approach in Ref. 4. A sampling of articles showing the development and the history of the applications of these functions includes Refs. 13–34. These references may be consulted for more details.

Let M be a manifold (possibly multidimensonal) with a metric, let $\mathcal{S}$ be a subspace of $L^2(M)$ of dimension N (possibly infinite), and let P be the orthogonal projector onto $\mathcal{S}$. Let $\{x_\alpha, \alpha = 0,\ldots,N-1\}$ be a collection of N distinct ''grid points'' in M. Let $\Delta_\alpha(x) = P[\,\delta(x-x_\alpha)]$ be the δ function at grid point x_α, projected onto $\mathcal{S}$. This will be written in Dirac notation as $|\Delta_\alpha\rangle = P|x_\alpha\rangle$. Then a simple theorem states that $\langle\Delta_\alpha|\Delta_\beta\rangle = \Delta_\beta(x_\alpha) = \Delta_\alpha(x_\beta)^*$. Finally, we define a *LM/DVR set* as the combination of P plus $\{x_\alpha\}$ such that

$$\Delta_\alpha(x_\beta) = K_\alpha \delta_{\alpha\beta} \tag{1.4}$$

with $K_\alpha > 0$. In view of the theorem just quoted, this implies that the projected δ-functions are orthogonal. In this case, we shall write $F_\alpha(x) = (1/\sqrt{K_\alpha})\Delta_\alpha(x)$ for the orthonormalized versions of these functions. In the case of finite N, the LM/DVR functions $\{F_\alpha(x)\}$ are linearly independent and form an orthonormal basis in $\mathcal{S}$; the same is normally true in the infinite-dimensional case as well.

The LM/DVR functions $\Delta_\alpha(x)$ or $F_\alpha(x)$ are typically localized about their associated grid point x_α, with diffraction-like oscillations that decay slowly as one moves away from the grid point. See Ref. 4 for some plots of these functions. Their virtues in applications to quantum mechanics follow from their orthonormality and the fact that they diagonalize the problem of interpolating on the space $\mathcal{S}$ relative to the grid points $\{x_\alpha\}$ [that is, the matrix $\Delta_\alpha(x_\beta)$ diagonal]. The theory of LM/DVR functions is closely related to that of Gaussian quadratures. The practical advantages of LM/DVR basis functions are the following. First, a simple diagonal approximation is available for the matrix elements of the potential energy in a LM/DVR basis, namely,

$$\langle F_\alpha|V|F_\beta\rangle = V(x_\alpha)\,\delta_{\alpha\beta}\,. \tag{1.5}$$

As it stands, this approximation is not very accurate, but (somewhat paradoxically) its use leads to errors in the computed, low-lying eigenvalues and eigenfunctions of a Hamiltonian that are exponentially small in the size of the matrix, that is, much smaller than the errors in the matrix elements themselves.[4] Second, in applications of LM/DVR functions the basis functions associated with grid points where the wave function is known to be small (for example, deep in a classically forbidden region) can be thrown away, thereby effecting a reduction (or contraction) in the size of the basis. Third, in multidimensional problems with bases that are tensor products of one-dimensional LM/DVR bases, the matrix for the Hamiltonian is sparse, and suitable for iterative algorithms that require the repetitive multiplication of the Hamiltonian matrix times a vector. Fourth, the method of ''sequential diagonalization and truncation,'' in which one diagonalizes a Hamiltonian on sections of increasing dimensionality before finally diagonalizing the full Hamiltonian in the full configuration space, is particularly simple when the basis functions in the last coordinate is a LM/DVR basis.[12]

An important class of LM/DVR functions is associated with real orthonormal polynomials in one dimension. A LM/DVR set requires a projection operator and a set of grid points. Let the

projection operator be P_N of Eq. (1.2), and let the grid points $\{x_\alpha\}$ be the (necessarily simple) zeroes of $\phi_N(x)$, the first polynomial omitted from the sum (1.2). Then by the Darboux–Christoffel formula (1.1), the projected δ-functions are

$$\Delta_\alpha(x) = a_N \phi_{N-1}(x_\alpha) \frac{\phi_N(x)}{x - x_\alpha}. \tag{1.6}$$

These clearly vanish at each other's grid points but not at their own, that is, they satisfy Eq. (1.4) with

$$K_\alpha = a_N \phi_{N-1}(x_\alpha) \phi_N'(x_\alpha), \tag{1.7}$$

and therefore form a LM/DVR set. Note that there is actually a different LM/DVR set for each value of N; in practice, one increases the value of N (the size of the basis) to obtain convergence in a quantum calculation.

On the other hand, a LM/DVR set does not exist on most subspaces $\mathcal{S}$ of functions, that is, given $\mathcal{S}$ (or equivalently, the projection operator P that projects onto $\mathcal{S}$) there does not exist, in general, any set of grid points such that the LM/DVR conditions (1.4) are satisfied. This point is discussed more fully in Refs. 5 and 8, but the basic idea is that given $\mathcal{S}$, Eq. (1.4) can be regarded as a set of $N(N-1)/2$ equations in Nd unknowns, where the unknowns are the coordinates of the N grid points and d is the dimensionality of M. Thus, except possibly for small N the number of equations exceeds the number of unknowns, and, unless the equations are dependent, it is not likely that a solution exists. In fact, in the case of subspaces spanned by orthogonal polynomials, the equations are dependent, since the product of two polynomials is another polynomial. In one dimension, this reduces the number of independent equations below the number of unknowns, and a solution in fact exists, as shown explicitly in the previous paragraph with the aid of the Darboux–Christoffel formula. The same logic does not work, however, for orthogonal polynomials in more than one dimension (see Ref. 8 and the following comments).

Thus there arises the question of what is the most general subspace $\mathcal{S}$ of functions such that grid points exist such that Eq. (1.4) is satisfied. We do not know the answer, but certainly the easiest case is that of one-dimensional, orthogonal polynomials. There also exist certain infinite dimensional subspaces of functions in one dimension that are limiting cases of orthogonal polynomials, with their associated LM/DVR basis functions. These include one-dimensional sinc functions[4] and related functions of the Bessel[6] and Airy[7] types. There are also systematic classes of LM/DVR functions in $\mathbb{R}^n$ that are not obviously limiting cases of orthogonal polynomials;[5] these are generalizations of sinc functions in one dimension. There are also other examples of LM/DVR sets on manifolds such as S^2,[8] but these seem to be isolated cases, not members of systematic families.

The case of multidimensional orthogonal polynomials is one about which much can be said. To be specific, consider two-dimensional polynomials in (x,y), defined over some region of the plane and orthogonal with respect to some weighting function, and let P_N be the projector onto the subspace spanned by all the orthogonal polynomials of degree less than N. This subspace has dimension $N(N+1)/2$. Unlike the case of one-dimensional orthogonal polynomials, the existence of a LM/DVR set on this subspace is not automatic; it only follows when there exists a ''Gaussian cubature formula,'' in the terminolgy of Dunkl and Xu[3] (that is, it only holds for special regions and weighting functions). Those authors give several equivalent conditions for the existence of a Gaussian cubature formula; one is that the $N+1$ polynomials of degree N have $N(N+1)/2$ common roots, and another is that the projected coordinate operators, $P_N x P_N$ and $P_N y P_N$, commute. These facts follow from the multidimensional version of the Darboux–Christoffel formula. There are not many examples known in which these conditions are satisfied, and those examples do not seem useful for quantum mechanical applications.

Thus, while LM/DVR sets could be useful in applications, especially on multidimensional spaces, it does not seem to be easy to find them (the case of one-dimensional orthogonal polyno-

mials being an exception). This is the reason for our interest in the Darboux–Christoffel formula, since generalizations could be useful in finding larger classes of LM/DVR sets. The following considerations led us to consider semiclassical generalizations.

In the case of one-dimensional orthogonal polynomials, the orthogonal polynomials themselves (times the square root of the weighting function) $\{\phi_n(x)\}$ form an orthonormal basis on $\mathcal{S}$, while another orthonormal basis is afforded by the LM/DVR functions $\{F_\alpha(x)\}$. The projection operator P_N corresponds semiclassically to a region of phase space,[35] and the two orthonormal bases correspond to a division of this region into Planck cells of area $2\pi\hbar$ in two different ways (these are two different "polarizations," in the language of geometric quantization[36]). In particular, as argued in Ref. 4, the LM/DVR basis corresponds semiclassically to dividing the region of phase space corresponding to P_N into vertical strips of constant area (see Fig. 5 of Ref. 4 for the case of Hermite polynomials). These strips are centered on the grid points, which are otherwise the roots of $\phi_N(x)$. The grid points are not uniformly spaced, in general, since the height of the strips (the momentum cutoff determined by the region of phase space) depends on x. Indeed, to leading order in $1/N$, the spacing of the roots of $\phi_N(x)$ is precisely that needed to obtain vertical strips in phase space of constant area. This in a sense "explains" the spacing rule for the grid points of the LM/DVR set.

On the other hand, there is nothing in this constant area rule that requires that the projection operator and the region of phase space associated with it should be spanned by orthogonal polynomial functions. Thus, the suggestion arises that something like the Darboux–Christoffel formula might be valid, at least in a semiclassical sense, for more general classes of functions than the orthogonal polynomial functions $\phi_n(x)$ introduced previously. This turns out to be true, as we shall now show.

II. DERIVATION OF THE SEMICLASSICAL DARBOUX–CHRISTOFFEL FORMULA

Consider a one-dimensional Hamiltonian, $H=p^2/2m+V(x)$, with eigenfunctions $\psi_n(x)$ and eigenvalues E_n, $H\psi_n=E_n\psi_n$. The Hamiltonian is invariant under time reversal, so we may choose the eigenfunctions to be real. It is possible to treat more general Hamiltonians (for example, those with fourth powers of the momentum), but time-reversal invariance seems to be necessary for the following derivation. We do not assume that the eigenfunctions $\psi_n(x)$ have any necessary relationship to orthogonal polynomials, although in some special cases (for example, the harmonic oscillator) they may. We shall assume that the classical energy level sets $H(x,p)=E$ are topological circles in phase space, at least in some energy range of interest, or, if the level sets consist of more than one disconnected topological circle, that tunneling between the disconnected pieces can be neglected. For example, a single potential well such as $V(x)=x^4$ satisifes these assumptions.

The projector onto the first N eigenstates is $P_N=\Sigma_{n=0}^{N-1}|\psi_n\rangle\langle\psi_n|$, with kernel

$$\langle x|P_N|y\rangle=\sum_{n=0}^{N-1}\psi_n(x)\psi_n(y). \tag{2.1}$$

We would like to find a semiclassical expression for this sum, analogous to the Darboux–Christoffel formula (1.1). Rather than using the semiclassical expressions for the eigenfunctions ψ_n directly, it will be advantageous to work with the Green's function $G(x,y,E)$, since this is defined for all energies E (not just energy eigenvalues), and at a certain point we shall want to replace the sum in Eq. (2.1) with an integral. Our treatment of the Green's function and its asymptotics follows techniques used by Gutzwiller in his periodic orbit theory,[37–40] but is simpler because we are only dealing with the one-dimensional case. We have also called on techniques demonstrated by Berry and Tabor[41–43] in their classic studies of integrable systems.

The Green's operator $G(z)=1/(z-H)$ is a function of the complexified energy variable $z=E+i\epsilon$. The corresponding kernel is the Green's function, $G(x,y,z)=\langle x|G(z)|y\rangle$. The Green's operator satisfies

$$\delta(E-H)=\frac{i}{2\pi}\lim_{\epsilon\to 0}[G(E+i\epsilon)-G(E-i\epsilon)], \tag{2.2}$$

or, in terms of kernels,

$$\begin{aligned}\langle x|\,\delta(E-H)|y\rangle &= \sum_{n=0}^{\infty}\psi_n(x)\psi_n(y)\,\delta(E-E_n)\\ &= \frac{i}{2\pi}\lim_{\epsilon\to 0}[G(x,y,E+i\epsilon)-G(x,y,E-i\epsilon)]\\ &= -\frac{1}{\pi}\lim_{\epsilon\to 0}\operatorname{Im}G(x,y,E+i\epsilon),\end{aligned} \tag{2.3}$$

where we have used the time-reversal invariance of H in the last step to replace $G(x,y,E-i\epsilon)$ by $G(x,y,E+i\epsilon)^*$. Now let E be some energy such that $E_{N-1}<E<E_N$, so that

$$\int_{-\infty}^{E}\mathrm{d}E'\langle x|\,\delta(E'-H)|y\rangle=\sum_{n=0}^{N-1}\psi_n(x)\psi_n(y). \tag{2.4}$$

Our stategy will be to use the semiclassical expression for the Green's function in Eq. (2.3) to obtain the kernel of $\delta(E-H)$, which we shall then substitute into Eq. (2.4) to obtain the kernel of the projection operator.

The Green's function satisfies an inhomogeneous Schrödinger equation in the variable x,

$$\left[E+\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}-V(x)\right]G(x,y,E)=\delta(x-y). \tag{2.5}$$

This equation is valid as it stands for real E when E does not belong to the spectrum (continuous or discrete) of H, and otherwise E should be given a small imaginary part. Since G satisfies a homogeneous Schrödinger equation both for $x<y$ and $x>y$, we can use ordinary semiclassical theory[44] in these regions. To be specific, suppose E lies between two discrete eigenvalues of H, so that E is an an energy at which a classical orbit (a topological circle in phase space, symmetric about the x-axis) exists. Then there are two classical turning points x_0 (left) and x_1 (right). Suppose also that $x_0<x,y<x_1$ (x and y are in the classically allowed region). Then the semiclassical solutions to Eq. (2.5) in the two regions are

$$G(x,y,E)=\frac{1}{\sqrt{p(x)}}\times\begin{cases}A\cos[S(x_0,x,I)/\hbar-\pi/4], & x<y\\ B\cos[S(x_1,x,I)/\hbar+\pi/4], & x>y,\end{cases} \tag{2.6}$$

where $I=(1/2\pi)\oint p\,\mathrm{d}x$ is the classical action of an orbit of energy E, $S(a,b,I)=\int_a^b p\,\mathrm{d}x$ is the action integral along orbit of action I, $p=p(x)=\sqrt{2m[E-V(x)]}$ is the positive branch of the local momentum, and A and B are constants. The connection between the two branches of the semiclassical solution at the left or right turning points has been made in such a way that the wave function is decaying exponentially in the classically forbidden region. Equation (2.6) is valid only to leading order in $\hbar$.

The constants A and B are determined by matching the two solutions at $x=y$. At this point the Green's function is continuous, but its first derivative is discontinuous, as we find by integrating Eq. (2.5) between $y-\eta$ and $y+\eta$. This gives

$$\lim_{\eta\to 0}\frac{\hbar^2}{2m}\left[\left(\frac{\partial G}{\partial x}\right)_{x=y+\eta}-\left(\frac{\partial G}{\partial x}\right)_{x=y-\eta}\right]=1. \tag{2.7}$$

The conditions on G and $\partial G/\partial x$ at $x=y$ give two equations that can be solved for A and B. In computing $\partial G/\partial x$ from Eq. (2.6), we only retain terms of leading order in $\hbar$. Solving for A and B and substituting into Eq. (2.6), we find finally

$$G(x,y,E)=-\frac{2m}{\hbar\sqrt{p(x)p(y)}}\frac{1}{\cos(\pi I/\hbar)} \times\begin{cases}\cos[S(x_0,x,I)/\hbar-\pi/4]\cos[S(x_1,y,I)/\hbar+\pi/4], & x<y\\ \cos[S(x_0,y,I)/\hbar-\pi/4]\cos[S(x_1,x,I)/\hbar+\pi/4], & x>y.\end{cases} \tag{2.8}$$

This is the semiclassical solution for the Green's function, valid under the stated conditions on E, x, and y. If either x or y or both lie in a classically forbidden region, or if E is less than the classical energy at the bottom of the well (in which case there is no classically allowed region), then other semiclassical expressions apply, involving exponentially decaying solutions. We shall not write these down. If E coincides with a semiclassical eigenvalue E_n, that is, when $I=I_n=(n+1/2)\hbar$, then the denominator $\cos(\pi I/\hbar)$ vanishes, giving the expected pole in the Green's function. In this case we may replace E by $E+i\epsilon$ to obtain a finite result, in which case the action $I=I_n$ is replaced by $I_n+i\epsilon/\omega$, where $\omega=\partial E/\partial I$ is the frequency of the classical motion at action I_n.

In the case of kinetic-plus-potential Hamiltonians, $\partial^2 S(x_i,x,I)/\partial x\partial I=\partial p(x)/\partial I=m\omega/p(x)$, where $x_i=x_0$ or x_1, so the prefactor in Eq. (2.8) can be replaced by

$$-\frac{2m}{\hbar\sqrt{p(x)p(y)}}=-\frac{2}{\hbar\omega}\left[\frac{\partial^2 S(x_0,x,I)}{\partial x\partial I}\frac{\partial^2 S(x_1,y,I)}{\partial y\partial I}\right]^{1/2}=-\frac{\pi}{\hbar\omega}A(x,I)A(y,I), \tag{2.9}$$

where the final expression serves to define the amplitude factors $A(x,I)$, $A(y,I)$. With this substitution (that is, with the ampltitudes expressed in terms of the actions), Eq. (2.8) is actually valid for any one-dimensional, time-reversal invariant Hamiltonian satisfying the stated assumptions on the topology of the orbits in phase space. Moreover, when we extract the residue of (2.8) at the pole $E=E_n$, we find the expected semiclassical eigenfunctions,

$$\psi_n(x)=A(x,I_n)\cos[S(x_0,x,I_n)-\pi/4]. \tag{2.10}$$

This expression for the eigenfunctions may be analytically continued to values of I or E other than the quantized values, but the result does not decay exponentially in the classically forbidden region. It is for this reason that we do not simply use these semiclassical eigenfunctions in Eq. (2.1). In contrast, the Green's function decays exponentially outside the classically allowed regions for all values of E.

Now we replace E by $E+i\epsilon$ in Eq. (2.8) and take the imaginary part, as in Eq. (2.3). Only the factor $1/\cos(\pi I/\hbar)$ gives a nonzero contribution, according to the formula, $\lim_{y\to 0}\mathrm{Im}[1/(x+iy)]=-\pi\delta(x)$. Summing the contributions from the poles, we have

$$-\frac{1}{\pi}\lim_{\epsilon\to 0}\mathrm{Im}\frac{1}{\cos[\pi I(E+i\epsilon)/\hbar]}=-\sum_{n=0}^{\infty}(-1)^n\frac{\hbar\omega}{\pi}\delta(E-E_n)=-\frac{\hbar}{\pi}\sum_{n=0}^{\infty}(-1)^n\delta(I-I_n), \tag{2.11}$$

and

$$\langle x|\,\delta(E-H)\,|y\rangle=\frac{1}{\omega}A(x,I)A(y,I)\sum_{n=0}^{\infty}(-1)^n\delta(I-I_n)F_0(y,I)F_1(x,I), \tag{2.12}$$

where for now we consider only the case $x>y$ and where

$$F_0(y,I)=\cos[S(x_0,y,I)/\hbar-\pi/4]=\cos[S(y,I)/\hbar-\pi/4],$$
$$F_1(x,I)=\cos[S(x_1,x,I)/\hbar+\pi/4]=\cos[S(x,I)/\hbar-\pi I/\hbar+\pi/4]. \tag{2.13}$$

Here and henceforth we write simply $S(x,I)$ for $S(x_0,x,I)$, that is, the left turning point is taken as the origin of the action unless otherwise specified. We have also used $S(x_0,x_1,I)=\pi I$. We recall that we have assumed that x and y are in the classically allowed region for the classical orbit of action I. The δ-functions in Eq. (2.12) suggest that we replace I in F_0 and F_1 in that equation by I_n, but we must worry that the given x and y will not be in the classically allowed regions for all values of I_n. In particular, since the orbits shrink as I decreases, we may in general expect x and y to lie outside the classically allowed region for some values of I_n less than I. We fix this worry by regarding Eq. (2.13) as the definitions of F_0, F_1 only when x and y are in the classically allowed regions for the given I; otherwise they are to be replaced by the corresponding exponentially decaying semiclassical formulas (which we do not write down). With this understanding, I can be freely exchanged with I_n in F_0 and F_1 in Eq. (2.12).

Next we argue that the sum in Eq. (2.12) can be extended downward to $n=-\infty$, since the corresponding actions represent complex classical orbits of energy less that the energy at the bottom of the well. These are all in the classically forbidden region (in energy), and the corresponding semiclassical wave functions are exponentially small. With this change we may use a version of the Poisson sum formula to write

$$\sum_{n\in\mathbb{Z}}(-1)^n\delta(I-I_n)=\frac{1}{\hbar}\sum_{n\in\mathbb{Z}}(-1)^n\delta(\nu-n)=\frac{1}{\hbar}\sum_{k\in\mathbb{Z}}e^{i\pi\nu(2k+1)}, \tag{2.14}$$

where we have written

$$I=(\nu+1/2)\hbar, \tag{2.15}$$

effectively making ν a continuous version of the quantum number n.

The use of the Poisson sum formula converts expression (2.12) into an orbit sum, much as in Gutzwiller's work,[37–40] that is, the sum can be reorganized into a sum over classical orbits of energy E that connect initial point y and final point x in positive time. The orbits are not periodic orbits, as in Gutzwiller's work, because we are not taking the trace, but they are composed of four distinct finite orbits connecting y to x, to which an arbitrary number of periodic orbits are glued. Indeed, we could have derived the resulting expression from Gutzwiller's theory rather than working through the semiclassical expressions for the Green's function directly. We preferred the latter procedure, however, because in parallel studies we are interested in tunneling processes, for which the periodic orbit approach is more difficult.

We now carry out the integral on Eq. (2.12) as in Eq. (2.4), where the upper limit E satisfies $E_{N-1}<E<E_N$, that is, $I_{N-1}<I<I_N$ or $N-1<\nu<N$. We also change the variable of integration to ν, using

$$\int_{-\infty}^{E}\frac{dE'}{\hbar\omega}=\int_{-\infty}^{\nu}d\nu'. \tag{2.16}$$

The product of the two cosine factors gives four terms when written in terms of complex exponentials, which we express in terms of ν. For example, one of these four terms is

$$T_1=\frac{1}{4}\sum_{k\in\mathbb{Z}}\int_{-\infty}^{\nu}d\nu'\,A(x,I')A(y,I')e^{i[2\pi k\nu'+S(y,I')/\hbar+S(x,I')/\hbar-\pi/2]}. \tag{2.17}$$

By integrating the exponential by parts, an asymptotic series in $\hbar$ is generated, of which we keep just the first term. The integrand is considered to vanish at the lower limit of integration, which is deep in the classically forbidden region. For example, for the first term this gives

$$T_1 = -\frac{1}{4} A(x,I)A(y,I) e^{i[S(x,I)+S(y,I)]/\hbar} \sum_{k\in\mathbb{Z}} \frac{e^{2\pi i k\nu}}{\theta(x,I)+\theta(y,I)+2\pi k}, \tag{2.18}$$

where $\theta = \partial S/\partial I$ is the classical angle variable, here measured with respect to the left turning point. Next, the Fourier series in this expression can be summed,

$$\sum_{k\in\mathbb{Z}} \frac{e^{2\pi i k\nu}}{\theta(x,I)+\theta(y,I)+2\pi k} = i \frac{e^{-i(\theta_x+\theta_y)\,\mathrm{frac}\,\nu}}{1-e^{-i(\theta_x+\theta_y)}}, \tag{2.19}$$

where $\theta_x = \theta(x,I)$, $\theta_y = \theta(y,I)$, and then exponents may be combined according to

$$\frac{S(x,I)}{\hbar} - \theta(x,I)\,\mathrm{frac}\,\nu = \frac{S(x,I_{N-1})}{\hbar} + O(\hbar), \tag{2.20}$$

where we use Eq. (2.15) and $\nu = N-1+\mathrm{frac}\,\nu$. Thus we obtain

$$T_1 = -\frac{i}{4} A(x,I)A(y,I) \frac{e^{i[S_{N-1}(x)+S_{N-1}(y)]/\hbar}}{1-e^{-i(\theta_x+\theta_y)}}, \tag{2.21}$$

where $S_{N-1}(x) = S(x,I_{N-1})$, etc. The actions I in the amplitude factors or in the denominator can be replaced by either I_{N-1} or I_N with only $O(\hbar)$ errors (which we are neglecting).

Treating the other three terms similarly, we obtain

$$\sum_{n=0}^{N-1} \psi_n(x)\psi_n(y) = \frac{1}{4} A(x,I)A(y,I) \times \left\{ \frac{e^{i[S_{N-1}(x)+S_{N-1}(y)]/\hbar - i\pi/2}}{1-e^{-i(\theta_x+\theta_y)}} + \frac{e^{i[S_{N-1}(y)-S_{N-1}(x)]/\hbar}}{1-e^{-i(\theta_y-\theta_x)}} + \text{c.c.} \right\}. \tag{2.22}$$

By combining denominators this can be transformed into

$$\frac{A(x,I)A(y,I)}{8[\cos\theta(y,I)-\cos\theta(x,I)]} \{ e^{i[S_{N-1}(x)+S_N(y)]/\hbar - i\pi/2} - e^{i[S_N(x)+S_{N-1}(y)]/\hbar - i\pi/2} + e^{i[S_N(y)-S_{N-1}(x)]/\hbar} - e^{i[S_{N-1}(y)-S_N(x)]/\hbar} + \text{c.c} \}, \tag{2.23}$$

where we have used $S_{N-1}(x)/\hbar + \theta(x,I) = S_N(x)/\hbar + O(\hbar)$, etc. This in turn can be written as

$$\frac{A(x)A(y)}{2[\cos\theta(x,I)-\cos\theta(y,I)]} \{ \cos[S_N(x)/\hbar - \pi/4]\cos[S_{N-1}(y)/\hbar - \pi/4] - \cos[S_{N-1}(x)/\hbar - \pi/4]\cos[S_N(y)/\hbar - \pi/4] \}. \tag{2.24}$$

Finally, using Eq. (2.10), we find

$$\sum_{n=0}^{N-1} \psi_n(x)\psi_n(y) = \frac{1}{2} \frac{\psi_N(x)\psi_{N-1}(y) - \psi_{N-1}(x)\psi_N(y)}{\cos\theta(x,I)-\cos\theta(y,I)}. \tag{2.25}$$

This is the semiclassical Darboux–Christoffel formula, and it is one of the main results of this paper. The derivation was carried out for the case $x>y$, but the case $x<y$ gives the same result. The formula has corrections of order $\hbar$, or, equivalently, $1/N$. Within corrections of this order, the action I in the denominator can be replaced by I_{N-1} or I_N or anything in between. This semiclassical approximation may be compared to its (exact) counterpart, Eq. (1.1), for the case of orthogonal polynomials.

III. DISCUSSION AND LIMITING CASES

A simple limit of Eq. (2.25) is $y \to x$, which produces the total particle density of a system of N fermions at zero temeprature. To leading order in $\hbar$, this turns out to be

$$\sum_{n=0}^{N-1} |\psi_n(x)|^2 = \frac{p(x,I_N)}{\pi\hbar}. \tag{3.1}$$

To leading order in $\hbar$, this is the classical result, since a uniform distrubition of N particles in phase space out to orbit I_N produces a particle density in configuration space that is $N_p(x,I_N)/(\pi I_N)$, and since $I_N = (N+1/2)\hbar$. The 1/2 is not accounted for in this calculation, since it is lost in the higher order terms in Eq. (2.25) that we have not computed.

Equation (2.25) can also be used to construct approximate LM/DVR functions in the same way as the exact Darboux–Christoffel formula. That is, let the subspace $\mathcal{S}$ be defined by the first N eigenfunctions $\{\psi_n(x), n=0,\ldots,N-1\}$ of H, let P_N be the projector onto $\mathcal{S}$, and let the grid points $\{x_\alpha\}$ be the zeroes of $\psi_N(x)$. Then, to within errors of order $\hbar$, the projected δ-functions are

$$\Delta_\alpha(x) = \frac{1}{2}\,\frac{\psi_N(x)\psi_{N-1}(x_\alpha)}{\cos\theta(x,I) - \cos\theta_\alpha}, \tag{3.2}$$

where $\theta_\alpha = \theta(x_\alpha, I)$. These functions vanish at each others' grid points but not at their own, that is, they satisfy Eq. (1.4), to within errors of order $\hbar$. In the semiclassical approximation, the roots of $\psi_N(x)$ occur at

$$S(x_\alpha, I_N) = (\alpha + 3/4)\,\pi\hbar. \tag{3.3}$$

By taking the limit $x \to x_\alpha$ in Eq. (3.2) and using Eq. (2.10) we obtain the normalization,

$$K_\alpha = \frac{p(x_\alpha, I_N)}{\pi\hbar}, \tag{3.4}$$

where $p = \partial S/\partial x$. Notice that $1/K_\alpha$ is approximately the spacing between zeros of $\psi_N(x)$ at $x = x_\alpha$. Finally, we obtain the normalized (and approximately orthonormal) LM/DVR functions,

$$F_\alpha(x) = (-1)^\alpha \sin\theta_\alpha \sqrt{\frac{\hbar}{2p_\alpha}\,\frac{\partial^2 S(x_\alpha, I_N)}{\partial x\,\partial I}}\,\frac{\psi_N(x)}{\cos\theta(x,I_N) - \cos\theta_\alpha}. \tag{3.5}$$

The function $F_\alpha(x)$ has a main lobe centered on the grid point x_α, with a height of order $\hbar^{-1/2}$. Near this grid point, the function behaves like a sinc function, as we see if we write $x = x_\alpha + \xi$ in Eq. (3.5) and expand to first order in ξ. This gives

$$F_\alpha(x_\alpha + \xi) = \frac{\sqrt{a}}{\pi}\,\frac{\sin(\pi\xi/a)}{\xi}, \tag{3.6}$$

where $a = \pi\hbar/p_\alpha$ is the local distance between the roots of $\psi_N(x)$. Sinc functions are a standard example of one-dimensional LM/DVR functions.[4,5]

The semiclassical Darboux–Christoffel formula, Eq. (2.25), may be tested in some cases for which the answer is exactly known. For example, in the case of the harmonic oscillator $H = p^2/2 + x^2/2$ we have $x = -\sqrt{2I}\cos\theta$ and $a_N = (N/2)^{1/2}$ (in units where $m = \hbar = \omega = 1$), so if the denominator in Eq. (2.25) is evaluated at $I = I_N = N + 1/2$, then the semiclassical and exact Darboux–Christoffel formulas do agree to order $1/N$. In fact, if the denominator is evaluated at $I = N$ instead of $I = N + 1/2$, the correct value of a_N comes out exactly. This amounts to using an

orbit half-way between the $(N-1)$st and Nth quantizing orbits for evaluating the denominator (the average of the two numbers which appear in the numerator). This may be the best choice for evaluating the denominator in all cases.

The semiclassical Darboux–Christoffel formula, Eq. (2.25), can be generalized to the case of the continuous spectrum. Let us hold the energy E and the left turning point x_0 fixed, but otherwise deform the potential well so that the right turning point recedes to infinity. The bottom of the potential well may flatten out at some finite value of energy below E, or it may drop down to $-\infty$. In any case, the spectrum becomes continuous in this limit, and the eigenstates become scattering states that come in from the right and bounce off the left wall of the potential. Then it is easy to take the corresponding limit in Eq. (2.25). If we denote the continuum eigenstates by $\psi(x,E) = \langle x|E\rangle$ and normalize them according to $\langle E|E'\rangle = \delta(E-E')$, then the semiclassical Darboux–Christoffel formula turns out to be

$$\langle x|P|y\rangle = \hbar^2 \frac{\psi(x,E)[\partial\psi(y,E)/\partial E] - [\partial\psi(x,E)/\partial E]\psi(y,E)}{T(x,E)^2 - T(y,E)^2}, \tag{3.7}$$

where $T(x,E)$ is the time required for a classical particle with energy E to go from the (left) turning point to position x, and where the projection operator is defined by

$$P = \int_{E_0}^{E} \mathrm{d}E' |E'\rangle\langle E'|. \tag{3.8}$$

Here E_0 is the energy at the bottom of the well.

Equation (3.7) is exact in the case of Bessel and Airy functions, if the wave functions in the numerator are interpreted as the exact wave functions and not their semiclassical approximations. Bessel functions of integer order are free particle solutions in the plane of a definite angular momentum, projected onto the radial half-line. The LM/DVR functions associated with Bessel functions have been explored in Ref. 6. The radial Hamiltonian has the form,

$$H = \frac{p_r^2}{2M} + \frac{m^2\hbar^2 - 1/4}{2Mr^2}, \tag{3.9}$$

where M is the mass and m the angular momentum quantum number, and where (r,p_r) play the role of (x,p) in the above-presented discussion. For $E>0$, the potential (actually only the centrifugal potential) has one (left) turning point, exactly as described in the limit leading to Eq. (3.7). The quantity $T(r,E)$ is the time required for a classical particle of energy E to travel from the turning point r_0 to point r. Computing this is a problem in classical mechanics that is most easily solved by viewing the (free) particle motion in the plane. The radial turning point r_0 is the minimum radius for the straight line orbit, and the distance r from the origin at later time t is $\sqrt{r_0^2 + v^2t^2}$, where v is the velocity. Thus $T(r,E) = \sqrt{r^2 - r_0^2}/v$, and the denominator in Eq. (3.7) is

$$T(r,E)^2 - T(r',E)^2 = (r^2 - r'^2)/v^2. \tag{3.10}$$

In fact, Bessel functions satisfy the identity

$$\int_0^K k\,\mathrm{d}k\, J_\nu(kr)J_\nu(kr') = \frac{K}{r^2 - r'^2}[r'J_\nu(Kr)J'_\nu(Kr') - rJ_\nu(Kr')J'_\nu(Kr)], \tag{3.11}$$

where K is the wave number corresponding to energy $E = \hbar^2K^2/2M$. When details such as the continuum normalization are worked out, Eq. (3.11) is seen to agree precisely with Eq. (3.7). In this case the potential well flattens out at $E=0$, hence the lower limit on the integral.

Similarly, in the case of the Airy functions the Hamiltonian (in dimensionless units) is $H = p^2 + x$, so that the potential has only one turning point and all energy eigenfunctions are in the continuum. The LM/DVR functions associated with Airy functions were studied in Ref. 6. Here it

suffices to take $E=0$ due to the translational invariance of the problem, and the energy at the bottom of the well is $E=-\infty$. The turning point (in this case, the right one) is at $x=0$, and the time required to reach position $-x$ under the classical motion is proportional to $\sqrt{-x}$ (this is motion in a uniform gravitational field). Thus we expect the denominator in the Darboux–Christoffel formula to be proportional to $x-y$. In fact, Airy functions satisfy the identity

$$\int_{-\infty}^{0} \mathrm{d}E\ \mathrm{Ai}(x-E)\mathrm{Ai}(y-E)=\frac{\mathrm{Ai}(x)\mathrm{Ai}'(y)-\mathrm{Ai}'(x)\mathrm{Ai}(y)}{x-y}, \tag{3.12}$$

which is proved in Ref. 6. Once again, when details such as the normalization and the fact that we are working with a right turning point are taken into account, this identity is seen to be an exact version of Eq. (3.7).

Finally, we report on a numerical test of the semiclassical Darboux–Christoffel formula (2.25). We used the potential $V(x)=x^4$, for which the eigenfunctions cannot be expressed in terms of orthogonal polynomials. We computed numerically the eigenfunctions $\psi_n(x)$ in this potential for different values of $\hbar$, carrying the calculation out to the first eigenfunction $n=N$ whose energy E_N exceeds 10. We then computed the projected δ-functions, $\Delta_\alpha(x)=\langle x|P_N|x_\alpha\rangle$, using the numerically computed roots x_α of the $\psi_N(x)$ and the exact expression (2.1) for the projection operator (not the semiclassical approximation). Then we computed the exact norms of these functions using $K_\alpha=\Delta_\alpha(x_\alpha)$ [not the semiclassical approximation (3.4)], and from these the functions $F_\alpha(x)=\Delta_\alpha(x)/\sqrt{K_\alpha}$. Thus, the overlap matrix of the functions $\{F_\alpha(x)\}$ is given by

$$\langle F_\alpha|F_\beta\rangle=\frac{\Delta_\beta(x_\alpha)}{\sqrt{K_\alpha K_\beta}}, \tag{3.13}$$
