We show further that all our group averaging quantum theories can be obtained within Ashtekar's algebraic quantization,[19,20] using the $\mathfrak{o}(p,q)$ observables to determine the physical inner product, and we display explicitly the correspondence between the two schemes. We have not gained sufficient control over the $\mathfrak{o}(p,q)$ algebra to ascertain whether algebraic quantization might for some p and q yield also quantum theories not recovered by the group averaging, but we show that this does not happen for $p+q\equiv 1 \pmod 2$, nor does it happen for $p+q\equiv 0 \pmod 2$ if $p\leqslant 3$ and $q\leqslant 3$.

We also give a detailed description of the classical reduced phase space. The reduced phase space contains a symplectic manifold if and only if $p\geqslant 2$ and $q\geqslant 2$. This manifold is separated by the $\mathfrak{o}(p,q)$ observables, and it is connected if and only if $p\geqslant 3$ and $q\geqslant 3$. This suggests that interesting quantum theories should exist only when $p\geqslant 2$ and $q\geqslant 2$, possibly with some subtleties when $\min(p,q)=2$. As outlined above, this agrees with our findings.

The rest of the article is as follows. Section II introduces and analyzes the classical system. Section III discusses algebraic quantization, laying out the task for general p and q and completing it for $\max(p,q)\leqslant 3$. Refined algebraic quantization with group averaging is carried out in Sec. IV for $\min(p,q)\geqslant 3$ and in Sec. V for other values of p and q.

Section VI presents a summary and concluding remarks. Appendix A collects some basic properties of $\mathrm{SL}(2,\mathbb{R})$, and Appendixes B–E contain the proofs of several technical results stated in the main text.

II. CLASSICAL SYSTEM

In this section we analyze a classical constrained system with the unreduced phase space $T^*\mathbb{R}^{p+q}$, where $p\geqslant 1$ and $q\geqslant 1$. The system was introduced for $p=q=2$ in Ref. 16, and our discussion of the gauge transformations and the distinguished $\mathfrak{o}(p,q)$ observables generalizes the observations of Ref. 16 in a straightforward manner. We shall, however, show that the structure of the reduced phase space depends sensitively on p and q.

A. The system

The system is defined by the action

$$S=\int dt\,(\mathbf{p}\cdot\dot{\mathbf{u}}+\boldsymbol{\pi}\cdot\dot{\mathbf{v}}-NH_1-MH_2-\lambda D), \tag{2.1}$$

where $\mathbf{u}$ and $\mathbf{p}$ are real vectors of dimension $p \geqslant 1$, $\mathbf{v}$ and $\boldsymbol{\pi}$ are real vectors of dimension $q \geqslant 1$, and the overdot denotes differentiation with respect to t. $\mathbf{p}$ and $\boldsymbol{\pi}$ are, respectively, the momenta conjugate to $\mathbf{u}$ and $\mathbf{v}$, the symplectic structure is

$$\Omega = \sum_{i=1}^{p} dp_i \wedge du_i + \sum_{j=1}^{q} d\pi_j \wedge dv_j, \tag{2.2}$$

and the phase space is $\Gamma := T^*\mathbb{R}^{p+q} \simeq \mathbb{R}^{2(p+q)}$. N, M and λ are Lagrange multipliers associated with the constraints

$$\begin{aligned} H_1 &:= \tfrac{1}{2}(\mathbf{p}^2 - \mathbf{v}^2), \\ H_2 &:= \tfrac{1}{2}(\boldsymbol{\pi}^2 - \mathbf{u}^2), \\ D &:= \mathbf{u}\cdot\mathbf{p} - \mathbf{v}\cdot\boldsymbol{\pi}. \end{aligned} \tag{2.3}$$

The Poisson algebra of the constraints is the $\mathfrak{sl}(2,\mathbb{R})$ Lie algebra (see Appendix A),

$$\begin{aligned} \{H_1, H_2\} &= D, \\ \{H_1, D\} &= -2H_1, \\ \{H_2, D\} &= 2H_2, \end{aligned} \tag{2.4}$$

and the system is a first class constrained system.[39,40] The finite gauge transformations on Γ generated by the constraints are

$$\begin{pmatrix} \mathbf{u} \\ \mathbf{p} \end{pmatrix} \mapsto g \begin{pmatrix} \mathbf{u} \\ \mathbf{p} \end{pmatrix}, \quad \begin{pmatrix} \boldsymbol{\pi} \\ \mathbf{v} \end{pmatrix} \mapsto g \begin{pmatrix} \boldsymbol{\pi} \\ \mathbf{v} \end{pmatrix}, \tag{2.5}$$

where g is an $\mathrm{SL}(2,\mathbb{R})$ matrix. The gauge group is thus $\mathrm{SL}(2,\mathbb{R})$. As the Hamiltonian is a sum of the constraints, the constraints entirely determine the dynamics.

B. Classical observables

Recall that an observable is a function on Γ whose Poisson brackets with the first class constraints vanish when the first class constraints hold.[40] Consider on Γ the functions $\mathcal{O}_{kj} := x_k \times x_j$, where $x_k = (u_k, p_k)^T$ for $1 \leqslant k \leqslant p$, $x_{p+k} = (\pi_k, v_k)^T$ for $1 \leqslant k \leqslant q$, and the cross stands for the scalar-valued cross product on $\mathbb{R}^2$. As the $\mathrm{SL}(2,\mathbb{R})$ action on $\mathbb{R}^2$ preserves areas, (2.5) shows that $\mathcal{O}_{kj}$ are invariant under the gauge transformations. Hence $\mathcal{O}_{kj}$ are observables. The Poisson algebra of these observables is the $\mathfrak{o}(p,q)$ Lie algebra,

$$\{\mathcal{O}_{ij}, \mathcal{O}_{kl}\} = g_{ik}\mathcal{O}_{jl} - g_{il}\mathcal{O}_{jk} + g_{jl}\mathcal{O}_{ik} - g_{jk}\mathcal{O}_{il}, \tag{2.6}$$

where

$$g_{ik} = \mathrm{diag}(\underbrace{1,\ldots,1}_{p}, \underbrace{-1,\ldots,-1}_{q})_{ik}.$$

The algebra generated by $\{\mathcal{O}_{ij}\}$ is denoted by $\mathcal{A}_{\mathrm{class}}$. The finite transformations that $\mathcal{A}_{\mathrm{class}}$ generates on Γ are

$$\begin{pmatrix} \mathbf{u} \\ \boldsymbol{\pi} \end{pmatrix} \mapsto R \begin{pmatrix} \mathbf{u} \\ \boldsymbol{\pi} \end{pmatrix}, \quad \begin{pmatrix} \mathbf{p} \\ \mathbf{v} \end{pmatrix} \mapsto R \begin{pmatrix} \mathbf{p} \\ \mathbf{v} \end{pmatrix}, \tag{2.8}$$

where R is an $O(p,q)$ matrix, in the connected component $O_c(p,q)$. Note that as none of the above relies on the constraints being satisfied, the $SL(2,\mathbb{R})$ action (2.5) and the $O_c(p,q)$ action (2.8) commute on all of Γ, not just on the subset where the constraints hold.

It will be useful to decompose the basis $\{\mathcal{O}_{ij}\}$ of $\mathcal{A}_{\text{class}}$ as $\mathfrak{o}(p,q)=\mathfrak{o}(p)\oplus\mathfrak{o}(q)\oplus\mathfrak{p}$, where $\mathfrak{p}$ is spanned by the observables transverse to those in the Lie algebra of the maximal compact subgroup $O_c(p)\times O_c(q)$.[41] Explicitly, we write

$$\begin{aligned} A_{ij} &:= \mathcal{O}_{ij} = u_i p_j - u_j p_i, \quad 1\leqslant i\leqslant p,\ 1\leqslant j\leqslant p, \\ B_{ij} &:= \mathcal{O}_{p+i,p+j} = v_i \pi_j - v_j \pi_i, \quad 1\leqslant i\leqslant q,\ 1\leqslant j\leqslant q, \\ C_{ij} &:= \mathcal{O}_{i,p+j} = u_i v_j - p_i \pi_j, \quad 1\leqslant i\leqslant p,\ 1\leqslant j\leqslant q, \end{aligned} \tag{2.9}$$

where $A_{ij}\in\mathfrak{o}(p)$, $B_{ij}\in\mathfrak{o}(q)$ and $C_{ij}\in\mathfrak{p}$.

Other observables of interest in $\mathcal{A}_{\text{class}}$ are the Casimir elements of the universal enveloping algebra of $\mathfrak{o}(p,q)$.[42] We consider only the quadratic Casimir observable,

$$\mathcal{C} := \frac{1}{2}\sum_{ijkl} g_{ij}g_{kl}\mathcal{O}_{ik}\mathcal{O}_{jl} = \sum_{i<j}(A_{ij})^2 + \sum_{i<j}(B_{ij})^2 - \sum_{i,j}(C_{ij})^2 = -4H_1H_2 - D^2, \tag{2.10}$$

where the last equality follows by direct computation. When the constraints hold, $\mathcal{C}$ thus vanishes.

C. Reduced phase space

Let $\overline{\Gamma}$ be the subset of Γ where the constraints hold. The reduced phase space, denoted by $\mathcal{M}$, is the quotient of $\overline{\Gamma}$ under the gauge action (2.5). As the Hamiltonian is a linear combination of the constraints, there is no dynamics on $\mathcal{M}$, and $\mathcal{M}$ can be identified with the space of classical solutions. As the functions in $\mathcal{A}_{\text{class}}$ are gauge invariant, they project to functions on $\mathcal{M}$: We use for these functions the same symbols.

For $p=q=2$, the generic sectors of $\mathcal{M}$ were found in Refs. 16 and 21 and the global properties of $\mathcal{M}$ were exhibited in Ref. 10. We now analyze $\mathcal{M}$ for general $p\geqslant 1$ and $q\geqslant 1$.

Γ is clearly connected. Hence also $\mathcal{M}$ is connected.

To proceed, we decompose $\overline{\Gamma}$ into three subsets. Let $\overline{\Gamma}_0=\{\mathsf{q}_0\}$, where q_0 is the origin of Γ, $\mathbf{u}=\mathbf{p}=\mathbf{0}=\mathbf{v}=\boldsymbol{\pi}$. Let $\overline{\Gamma}_{\text{ex}}$ contain all other points of $\overline{\Gamma}$ at which at least one of the pairs $(\mathbf{u},\mathbf{p})$ and $(\mathbf{v},\boldsymbol{\pi})$ is linearly dependent. Finally, let $\overline{\Gamma}_{\text{reg}}$ contain the rest of $\overline{\Gamma}$. We refer to $\overline{\Gamma}_{\text{ex}}$ and $\overline{\Gamma}_{\text{reg}}$ as respectively the "exceptional" and "regular" parts of $\overline{\Gamma}$. We show in Appendix B that the gradients of the constraints are all vanishing on $\overline{\Gamma}_0$, linearly dependent but not all vanishing on $\overline{\Gamma}_{\text{ex}}$, and linearly independent on $\overline{\Gamma}_{\text{reg}}$. $\overline{\Gamma}_0$ and $\overline{\Gamma}_{\text{ex}}$ are nonempty for all p and q, while $\overline{\Gamma}_{\text{reg}}$ is nonempty if and only if $p\geqslant 2$ and $q\geqslant 2$.

As $\overline{\Gamma}_0$, $\overline{\Gamma}_{\text{ex}}$ and $\overline{\Gamma}_{\text{reg}}$ are preserved by the gauge transformations, they project onto disjoint subsets of $\mathcal{M}$. We denote these sets respectively by $\mathcal{M}_0$, $\mathcal{M}_{\text{ex}}$ and $\mathcal{M}_{\text{reg}}$ and analyze each in turn.

1. $\mathcal{M}_0$

$\mathcal{M}_0$ contains only one point, the projection of q_0. All observables in $\mathcal{A}_{\text{class}}$ vanish on $\mathcal{M}_0$.

2. $\mathcal{M}_{\text{ex}}$

As $\mathsf{q}_0\notin\overline{\Gamma}_{\text{ex}}$, the constraints $H_1=0=H_2$ show that all points in $\overline{\Gamma}_{\text{ex}}$ have $(\mathbf{u},\mathbf{p})\neq(\mathbf{0},\mathbf{0})$ and $(\mathbf{v},\boldsymbol{\pi})\neq(\mathbf{0},\mathbf{0})$. Given a point at which the pair $(\mathbf{u},\mathbf{p})$ is linearly dependent, there thus exists a gauge-equivalent point with $\mathbf{u}=\mathbf{0}$ and $\mathbf{p}^2=1$, at which the constraints imply $\boldsymbol{\pi}=\mathbf{0}$ and $\mathbf{v}^2=1$. Given a point at which the pair $(\mathbf{v},\boldsymbol{\pi})$ is linearly dependent, a similar argument shows that there exists a gauge-equivalent point at which $\boldsymbol{\pi}=\mathbf{0}$, $\mathbf{v}^2=1$, $\mathbf{u}=\mathbf{0}$ and $\mathbf{p}^2=1$. Thus, each point in $\overline{\Gamma}_{\text{ex}}$ is gauge-equivalent to a point that satisfies

$$\mathbf{v}^2=\mathbf{p}^2=1,\ \mathbf{u}=\mathbf{0}=\boldsymbol{\pi}. \tag{2.11}$$

It follows that both the pair $(\mathbf{u},\ \mathbf{p})$ and the pair $(\mathbf{v},\ \boldsymbol{\pi})$ are linearly dependent on $\overline{\Gamma}$.

The gauge transformations that preserve the set (2.11) act on it either trivially or by

$$(\mathbf{v},\mathbf{p})\mapsto(-\mathbf{v},-\mathbf{p}). \tag{2.12}$$

$\mathcal{M}_{\rm ex}$ can therefore be represented as the quotient of the set (2.11), with topology $S^{p-1}\times S^{q-1}$, under the $\mathbb{Z}_2$ action generated by (2.12). If in particular $p=1$ (respectively $q=1$), $\mathcal{M}_{\rm ex}$ has topology S^{q-1} (S^{p-1}). If $p=q=1$, $\mathcal{M}_{\rm ex}$ contains just two points.

Other representations of $\mathcal{M}_{\rm ex}$ are obtained by replacing in (2.11) the first equations by $\mathbf{v}^2=\mathbf{p}^2=r$, where r is an arbitrary prescribed positive number. This shows that in the topology of $\mathcal{M}$ induced from Γ, every open set that includes $\mathcal{M}_0$ includes also $\mathcal{M}_{\rm ex}$.

Equations (2.9) and (2.11) show that all observables in $\mathcal{A}_{\rm class}$ vanish on $\mathcal{M}_{\rm ex}$. Equations (2.2) and (2.11) show that the projection of the symplectic form Ω vanishes on $\mathcal{M}_{\rm ex}$. We refer to $\mathcal{M}_{\rm ex}$ as the ''exceptional'' part of $\mathcal{M}$.

3. $\mathcal{M}_{\rm reg}$

When $p=1$ or $q=1$ (or both), $\overline{\Gamma}_{\rm reg}$ and hence also $\mathcal{M}_{\rm reg}$ are empty. We now assume $p\geqslant 2$ and $q\geqslant 2$.

We show in Appendix B that the gradients of the constraints are linearly independent on $\overline{\Gamma}_{\rm reg}$. It follows (Ref. 40, Sec. 1.1.2 and Appendix 2A) that $\mathcal{M}_{\rm reg}$ is a manifold of dimension $2p+2q-6$ with a symplectic form induced from Γ. We refer to $\mathcal{M}_{\rm reg}$ as the ''regular'' part of $\mathcal{M}$.

Given a point in $\Gamma_{\rm reg}$, the linear independence of the pair $(\mathbf{u},\ \mathbf{p})$ implies that there exists a gauge-equivalent point at which $\mathbf{u}\cdot\mathbf{p}=0$ and $\mathbf{u}^2=\underline{\mathbf{p}}^2>0$. The constraints imply that at this point $\mathbf{v}\cdot\boldsymbol{\pi}=0$, $\mathbf{v}^2=\mathbf{p}^2$ and $\boldsymbol{\pi}^2=\mathbf{u}^2$. Hence each point in $\Gamma_{\rm reg}$ is gauge-equivalent to a point that satisfies

$$\mathbf{u}^2=\mathbf{p}^2=\mathbf{v}^2=\boldsymbol{\pi}^2>0,\ \mathbf{u}\cdot\mathbf{p}=\mathbf{v}\cdot\boldsymbol{\pi}=0. \tag{2.13}$$

The gauge transformations that preserve the set (2.13) are (2.5) with

$$g=\begin{pmatrix}\cos\theta & \sin\theta\\ -\sin\theta & \cos\theta\end{pmatrix}, \tag{2.14}$$

where $0\leqslant\theta<2\pi$. It follows that $\mathcal{M}_{\rm reg}$ can be represented as the quotient of the set (2.13) under the $U(1)$ action given by (2.5) and (2.14).

We show in Appendix C that $\mathcal{A}_{\rm class}$ separates $\mathcal{M}_{\rm reg}$: Given two distinct points in $\mathcal{M}_{\rm reg}$, there exist functions in $\mathcal{A}_{\rm class}$ that take distinct values at the two points.

For $p=q=2$, $\mathcal{M}_{\rm reg}$ consists of four connected components,[10,16,21] which can be pairwise joined into two connected symplectic manifolds by adding certain points from $\mathcal{M}_{\rm ex}$.[10]

Suppose $p=2$ and $q>2$. Within each gauge equivalence class in (2.13), there is a unique representative at which $p_1=0$ and $u_1>0$. It follows that at this point $p_2\neq 0$ and $u_2=0$. A gauge transformation by $g=\mathrm{diag}(|p_2|,|p_2|^{-1})$ brings this point to

$$\mathbf{v}^2=1,\ \mathbf{v}\cdot\boldsymbol{\pi}=0,\ \boldsymbol{\pi}^2>0,\ \mathbf{p}=(0,\epsilon),\ \mathbf{u}=(|\boldsymbol{\pi}|,0), \tag{2.15}$$

where $\epsilon=\pm 1$. For each ϵ, the set (2.15) is recognized as the cotangent bundle over S^{q-1}, with the zero fibers omitted. Hence $\mathcal{M}_{\rm reg}$ consists of two connected components, given by (2.15) with the respective values of ϵ. Equations (2.2) and (2.15) show that the symplectic structure of this cotangent bundle description is precisely the symplectic structure induced from Γ. For each ϵ, it is possible to include the zero fibers by allowing $\boldsymbol{\pi}^2=0$ in (2.15); this means adding from $\mathcal{M}_{\rm ex}$ the subset represented uniquely by (2.11) with $\mathbf{p}=(0,\epsilon)$ and $\boldsymbol{\pi}=\mathbf{0}$. Note that because of the identification (2.12) in (2.11), this subset of $\mathcal{M}_{\rm ex}$ is the same for both signs of ϵ. The mechanism of

pairwise smoothly joining the disconnected sectors for $q=2$ (Ref. 10) is not available now because the fibers without origin are disconnected for $q=2$ but connected for $q>2$.

The case $q=2$ and $p>2$ is isomorphic to $p=2$ and $q>2$.

When $p>2$ and $q>2$, $\mathcal{M}_{\mathrm{reg}}$ is connected. We have not found a simpler description of the global properties in this case. Convenient local gauge fixings are introduced in Appendix C.

III. ALGEBRAIC QUANTIZATION

In this section we apply the algebraic quantization framework of Ref. 19, adopting $\mathcal{A}_{\mathrm{class}}$ as the classical observable algebra whose complex conjugation relations are promoted into adjointness relations. Seeking solutions to the quantum constraints by separation of variables, we show in Sec. III A that necessary conditions for obtaining a quantum theory with a nontrivially represented observable algebra are $p\geqslant 2$, $q\geqslant 2$ and $p+q\equiv 0 \pmod 2$. The case $p=q=2$ was analyzed in Refs. 10 and 16. In Sec. III B we complete the quantization for $p=q=3$.

Detailed expositions of algebraic quantization can be found in Refs. 19 and 20.

A. Setup for $p\geqslant 1$ and $q\geqslant 1$

We take the elementary "position" and "momentum" operators to act on smooth functions $\Psi(\mathbf{u},\mathbf{v})$ as

$$\begin{aligned} &\hat{\mathbf{u}}\Psi(\mathbf{u},\mathbf{v})=\mathbf{u}\Psi(\mathbf{u},\mathbf{v}), \quad \hat{\mathbf{p}}\,\Psi(\mathbf{u},\mathbf{v})=-i\boldsymbol{\nabla}_u\Psi(\mathbf{u},\mathbf{v}),\\ &\hat{\mathbf{v}}\,\Psi(\mathbf{u},\mathbf{v})=\mathbf{v}\Psi(\mathbf{u},\mathbf{v}), \quad \hat{\boldsymbol{\pi}}\Psi(\mathbf{u},\mathbf{v})=-i\boldsymbol{\nabla}_v\Psi(\mathbf{u},\mathbf{v}), \end{aligned} \tag{3.1}$$

so that $[\hat{u}_k,\hat{p}_j]=i\delta_{kj}$ and $[\hat{v}_k,\hat{\pi}_j]=i\delta_{kj}$. Inserting these operators into the classical constraints (2.3) and making a judicious ordering choice, we obtain the quantum constraints

$$\hat{H}_1 := -\tfrac{1}{2}(\Delta_u+\mathbf{v}^2), \tag{3.2a}$$

$$\hat{H}_2 := -\tfrac{1}{2}(\Delta_v+\mathbf{u}^2), \tag{3.2b}$$

$$\hat{D} := -i\left(\mathbf{u}\cdot\boldsymbol{\nabla}_u-\mathbf{v}\cdot\boldsymbol{\nabla}_v+\frac{p-q}{2}\right), \tag{3.2c}$$

where Δ_u (respectively, Δ_v) stands for the Laplacian in $\mathbf{u}$ ($\mathbf{v}$). The nonderivative term in $\hat{D}$ is needed to make the commutators close as the $\mathfrak{sl}(2,\mathbb{R})$ Lie algebra,

$$\begin{aligned} &[\hat{H}_1,\hat{H}_2]=i\hat{D},\\ &[\hat{H}_1,\hat{D}]=-2i\hat{H}_1,\\ &[\hat{H}_2,\hat{D}]=+2i\hat{H}_2. \end{aligned} \tag{3.3}$$

We define the quantum observables $\hat{\mathcal{O}}_{ij}$ by substituting the elementary quantum operators (3.1) in the expressions of the classical observables $\mathcal{O}_{ij}$. These quantum observables commute with the quantum constraints (3.2), and their commutators form the $\mathfrak{o}(p,q)$ Lie algebra, obtained by hatting (2.6) and multiplying the right-hand side by i. As $\mathcal{O}_{ij}$ are real, we introduce on the algebra generated by $\{\hat{\mathcal{O}}_{ij}\}$ an antilinear involution by $\hat{\mathcal{O}}_{ij}^{\star}=\hat{\mathcal{O}}_{ij}$. We denote the resulting star-algebra of quantum observables by $\mathcal{A}_{\mathrm{phys}}^{(\star)}$.

Following (2.9), we decompose the basis of $\mathcal{A}_{\mathrm{phys}}^{(\star)}$ as

$$\hat{A}_{ij} := \hat{\mathcal{O}}_{ij} = -i(u_i \partial_{u_j} - u_j \partial_{u_i}), \quad 1 \leqslant i \leqslant p,\ 1 \leqslant j \leqslant p;$$

$$\hat{B}_{ij} := \hat{\mathcal{O}}_{p+i,p+j} = -i(v_i \partial_{v_j} - v_j \partial_{v_i}), \quad 1 \leqslant i \leqslant q,\ 1 \leqslant j \leqslant q; \tag{3.4}$$

$$\hat{C}_{ij} := \hat{\mathcal{O}}_{i,p+j} = u_i v_j + \partial_{u_i} \partial_{v_j}, \quad 1 \leqslant i \leqslant p,\ 1 \leqslant j \leqslant q.$$

The quantum quadratic Casimir observable is

$$\hat{\mathcal{C}} := \frac{1}{2} \sum_{ijkl} g_{ij} g_{kl} \hat{\mathcal{O}}_{ik} \hat{\mathcal{O}}_{jl} = \sum_{i<j} (\hat{A}_{ij})^2 + \sum_{i<j} (\hat{B}_{ij})^2 - \sum_{i,j} (\hat{C}_{ij})^2$$

$$= -2(\hat{H}_1 \hat{H}_2 + \hat{H}_2 \hat{H}_1) - \hat{D}^2 - \frac{1}{4}(p+q)(p+q-4), \tag{3.5}$$

where the last equality follows by direct computation. In contrast to the classical Casimir (2.10), $\hat{\mathcal{C}}$ vanishes on states annihilated by the constraints only for $p+q=4$.

We seek states annihilated by the constraints,

$$\hat{H}_1 \Psi(\mathbf{u},\mathbf{v}) = 0,\ \hat{H}_2 \Psi(\mathbf{u},\mathbf{v}) = 0,\ \hat{D} \Psi(\mathbf{u},\mathbf{v}) = 0, \tag{3.6}$$

by separation of variables. If $p \geqslant 2$ and $q \geqslant 2$, we make the ansatz

$$\Psi(\mathbf{u},\mathbf{v}) = \psi(u,v) Y_{lk_u}(\theta^{(u)}) Y_{jk_v}(\theta^{(v)}), \tag{3.7}$$

where $u := |\mathbf{u}|$, $v := |\mathbf{v}|$ and $Y_{lk_u}(\theta^{(u)})$ [respectively $Y_{jk_v}(\theta^{(v)})$] are the spherical harmonics on unit S^{p-1} in $\mathbf{u}$ (S^{q-1} in $\mathbf{v}$).[43,44] Here $\theta^{(u)}$ denotes the coordinates on S^{p-1}, the index l ranges over non-negative integers, the eigenvalue of the scalar Laplacian on S^{p-1} is $-l(l+p-2)$, the index k_u labels the degeneracy for each l, and similarly for the quantities appearing in $Y_{jk_v}(\theta^{(v)})$. We extend the ansatz (3.7) to $p=1$, in which case $\theta^{(u)} := u_1/u \in \{1,-1\}$, $l \in \{0,1\}$, the index k_u takes only a single value and can be dropped, and the spherical harmonics are $Y_l(\theta^{(u)}) := (\theta^{(u)})^l/\sqrt{2}$, and similarly for $q=1$. For all $p \geqslant 1$ and $q \geqslant 1$, Eqs. (3.6) then reduce to

$$\left[\frac{1}{u^{p-3}} \frac{\partial}{\partial u} \left(u^{p-1} \frac{\partial}{\partial u} \right) - l(l+p-2) + u^2 v^2 \right] \psi(u,v) = 0, \tag{3.8a}$$

$$\left[\frac{1}{v^{q-3}} \frac{\partial}{\partial v} \left(v^{q-1} \frac{\partial}{\partial v} \right) - j(j+q-2) + u^2 v^2 \right] \psi(u,v) = 0, \tag{3.8b}$$

$$\left(u \frac{\partial}{\partial u} - v \frac{\partial}{\partial v} + \frac{p-q}{2} \right) \psi(u,v) = 0. \tag{3.8c}$$

The general solution to (3.8c) is $\psi(u,v) = u^{(2-p)/2} v^{(2-q)/2} \chi(\zeta)$, where $\zeta := uv$. Substituting this in (3.8a) and (3.8b), we find that the indices satisfy

$$2l + p = 2j + q \tag{3.9}$$

and $\chi(\zeta)$ satisfies the Bessel equation of order $l + (p-2)/2$.[43]

Equation (3.9) shows that solutions exist only when $p+q \equiv 0 \pmod 2$. If $p=1$ or $q=1$, inspection of (3.9) further shows that solutions exist only when $(p,q) = (1,1)$, (1,3) or (3,1). Let us consider these exceptional cases first.

When $p=q=1$, the linearly independent solutions are $\Psi_{\pm}:=\exp(\pm iu_1v_1)$, $\mathcal{A}^{(\star)}_{\text{phys}}$ is generated by the single observable $\hat{C}_{11}$, and $\hat{C}_{11}\Psi_{\pm}=\pm i\Psi_{\pm}$. The representation of $\mathcal{A}^{(\star)}_{\text{phys}}$ on $\mathcal{V}_{\text{phys}}:=\text{span}\{\Psi_{\pm}\}$ is irreducible, but the only sesquilinear forms in which $\hat{C}_{11}$ is symmetric have indefinite signature.

When $p=1$ and $q=3$, the only (smooth) solution is $\Psi_0:=v^{-1}\sin(u_1v)$, which is annihilated by all operators in $\mathcal{A}^{(\star)}_{\text{phys}}$. Promoting $\text{span}\{\Psi_0\}$ into a one-dimensional Hilbert space gives thus a quantum theory in which $\mathcal{A}^{(\star)}_{\text{phys}}$ is represented trivially. The situation for $p=3$ and $q=1$ is similar.

We therefore see that necessary conditions for obtaining a quantum theory with a nontrivial representation of $\mathcal{A}^{(\star)}_{\text{phys}}$ are $p\geqslant 2$, $q\geqslant 2$ and $p+q\equiv 0 \pmod 2$. When these conditions hold, we have found for the quantum constraints the linearly independent solutions

$$\Psi_{ljk_uk_v}:=\delta_{2l+p,2j+q}\,u^{(2-p)/2}v^{(2-q)/2}J_{l+(p-2)/2}(uv)Y_{lk_u}(\theta^{(u)})Y_{jk_v}(\theta^{(v)}), \tag{3.10}$$

where $J_{l+(p-2)/2}$ is the Bessel function of the first kind.[43] The Bessel function of the second kind has been excluded to make $\Psi_{ljk_uk_v}$ smooth at $uv=0$. The motivation for this exclusion may be debatable within algebraic quantization, but we shall see that it is precisely the smooth solutions (3.10) that will emerge from group averaging in Secs. IV and V.

To proceed, we would need to examine the representation of $\mathcal{A}^{(\star)}_{\text{phys}}$ on $\text{span}\{\Psi_{ljk_uk_v}\}$. The representation of the $\mathfrak{o}(p)\oplus\mathfrak{o}(q)$ subalgebra is given directly by its representation on the spherical harmonics,[43,44] but the observables $\hat{C}_{ij}$ mix the states in a more complicated way. The special case $p=q=2$ was analyzed in Refs. 10 and 16. In Sec. III B we address the special case $p=q=3$.

B. Completion for $p=q=3$

When $p=q=3$, the states (3.10) can be written as

$$\Psi_{lmn}=j_l(uv)Y_{lm}(\theta^{(u)})Y_{ln}(\theta^{(v)}), \tag{3.11}$$

where l ranges over non-negative integers, $j_l(uv)$ is the spherical Bessel function of the first kind of order l,[43] m and n are integers satisfying $|m|\leqslant l$ and $|n|\leqslant l$ and the Y's are the usual spherical harmonics on S^2.[43] We write $\mathcal{V}_{\text{phys}}:=\text{span}\{\Psi_{lmn}\}$.

We introduce for $\mathcal{A}^{(\star)}_{\text{phys}}$ the basis

$$\begin{gathered}
\hat{L}_3:=\hat{A}_{12},\\
\hat{L}_{\pm}:=\hat{A}_{23}\pm i\hat{A}_{31},\\
\hat{J}_3:=\hat{B}_{12},\\
\hat{J}_{\pm}:=\hat{B}_{23}\pm i\hat{B}_{31},\\
\hat{C}_0:=\hat{C}_{33},\\
\hat{C}_1^{\pm}:=\hat{C}_{31}\pm i\hat{C}_{32},\\
\hat{C}_2^{\pm}:=\hat{C}_{13}\pm i\hat{C}_{23},\\
\hat{C}_3^{\pm}:=(\hat{C}_{11}+\hat{C}_{22})\pm i(\hat{C}_{21}-\hat{C}_{12}),\\
\hat{C}_4^{\pm}:=(\hat{C}_{11}-\hat{C}_{22})\pm i(\hat{C}_{21}+\hat{C}_{12}).
\end{gathered} \tag{3.12}$$

TABLE I. The action of $\mathcal{A}_{\text{phys}}^{(\star)}$ on $\mathcal{V}_{\text{phys}}$. Whenever the indices of a Ψ on the right-hand side go outside the allowed range, the numerical coefficient vanishes and the term is understood as zero.

$$
\begin{aligned}
\hat{L}_3\Psi_{lmn} &= m\Psi_{lmn}\\
\hat{J}_3\Psi_{lmn} &= n\Psi_{lmn}\\
\hat{L}_\pm\Psi_{lmn} &= \sqrt{(l\pm m+1)(l\mp m)}\,\Psi_{l,m\pm1,n}\\
\hat{J}_\pm\Psi_{lmn} &= \sqrt{(l\pm n+1)(l\mp n)}\,\Psi_{l,m,n\pm1}\\
\hat{C}_0\Psi_{lmn} &= \frac{\sqrt{(l-m+1)(l+m+1)(l-n+1)(l+n+1)}}{2l+3}\Psi_{l+1,m,n}\\
&\quad+\frac{\sqrt{(l-m)(l+m)(l-n)(l+n)}}{2l-1}\Psi_{l-1,m,n}\\
\hat{C}_1^\pm\Psi_{lmn} &= \mp\frac{\sqrt{(l-m+1)(l+m+1)(l\pm n+1)(l\pm n+2)}}{2l+3}\Psi_{l+1,m,n\pm1}\\
&\quad\pm\frac{\sqrt{(l-m)(l+m)(l\mp n)(l\mp n-1)}}{2l-1}\Psi_{l-1,m,n\pm1}\\
\hat{C}_2^\pm\Psi_{lmn} &= \mp\frac{\sqrt{(l\pm m+1)(l\pm m+2)(l-n+1)(l+n+1)}}{2l+3}\Psi_{l+1,m\pm1,n}\\
&\quad\pm\frac{\sqrt{(l\mp m)(l\mp m-1)(l-n)(l+n)}}{2l-1}\Psi_{l-1,m\pm1,n}\\
\hat{C}_3^\pm\Psi_{lmn} &= -\frac{\sqrt{(l\pm m+1)(l\pm m+2)(l\mp n+1)(l\mp n+2)}}{2l+3}\Psi_{l+1,m\pm1,n\mp1}\\
&\quad-\frac{\sqrt{(l\mp m)(l\mp m-1)(l\pm n)(l\pm n-1)}}{2l-1}\Psi_{l-1,m\pm1,n\mp1}\\
\hat{C}_4^\pm\Psi_{lmn} &= +\frac{\sqrt{(l\pm m+1)(l\pm m+2)(l\pm n+1)(l\pm n+2)}}{2l+3}\Psi_{l+1,m\pm1,n\pm1}\\
&\quad+\frac{\sqrt{(l\mp m)(l\mp m-1)(l\mp n)(l\mp n-1)}}{2l-1}\Psi_{l-1,m\pm1,n\pm1}
\end{aligned}
$$

Note that the $\hat{L}$'s (respectively, $\hat{J}$'s) are a standard raising and lowering operator basis for the $\mathfrak{o}(3)$ algebra in $\mathbf{u}$ ($\mathbf{v}$).[43] The action of the basis (3.12) on $\mathcal{V}_{\text{phys}}$ can be computed from standard properties of the spherical harmonics and spherical Bessel functions[43,45] and is displayed in Table I. It follows that $\mathcal{V}_{\text{phys}}$ is invariant under $\mathcal{A}_{\text{phys}}^{(\star)}$. We show in Appendix D that the representation of $\mathcal{A}_{\text{phys}}^{(\star)}$ on $\mathcal{V}_{\text{phys}}$ is irreducible.

The star-relations of the basis (3.12) read

$$
\begin{gathered}
(\hat{L}_3)^\star=\hat{L}_3,\\
(\hat{L}_\pm)^\star=\hat{L}_\mp,\\
(\hat{J}_3)^\star=\hat{J}_3,\\
(\hat{J}_\pm)^\star=\hat{J}_\mp,\\
(\hat{C}_0)^\star=\hat{C}_0,\\
(\hat{C}_k^\pm)^\star=\hat{C}_k^\mp,\ 1\leqslant k\leqslant 4.
\end{gathered}
\tag{3.13}
$$

From Table I it follows by direct computation that these star-relations coincide with the adjoint relations in the inner product

$$(\Psi_{lmn},\Psi_{l'm'n'})_{\mathrm{AQ}} := (2l+1)\,\delta_{ll'}\delta_{mm'}\delta_{nn'}. \tag{3.14}$$

We show in Appendix D that the only inner products on $\mathcal{V}_{\mathrm{phys}}$ with this property are multiples of (3.14).

The physical Hilbert space is the Cauchy completion of $\mathcal{V}_{\mathrm{phys}}$ in the inner product (3.14). It carries by construction a densely defined representation of $\mathcal{A}^{(\star)}_{\mathrm{phys}}$ in which the quadratic $\mathfrak{o}(3,3)$ Casimir (3.5) has the value -3.

IV. REFINED ALGEBRAIC QUANTIZATION FOR $p\geqslant 3$, $q\geqslant 3$

We now turn to refined algebraic quantization. In this section we take $p\geqslant 3$ and $q\geqslant 3$. The remaining values of p and q will be treated in Sec. V.

We employ refined algebraic quantization with group averaging as formulated in Ref. 8. A review can be found in Ref. 12 and an outline adapted to the present situation in Ref. 10.

A. Auxiliary Hilbert space and representation of the gauge group

We introduce the auxiliary Hilbert space $\mathcal{H}_{\mathrm{aux}}\simeq L^2(\mathbb{R}^{p+q})$ of square integrable functions $\Psi(\mathbf{u},\mathbf{v})$ in the inner product

$$(\Psi_1,\Psi_2)_{\mathrm{aux}} := \int d^p\mathbf{u}\, d^q\mathbf{v}\, \overline{\Psi_1}\Psi_2, \tag{4.1}$$

where the overline denotes complex conjugation. The quantum constraints (3.2) are essentially self-adjoint on $\mathcal{H}_{\mathrm{aux}}$, and exponentiating $-i$ times their algebra yields a unitary representation of the universal covering group of $\mathrm{SL}(2,\mathbb{R})$. Denoting this representation by U, the group elements in the Iwasawa decomposition (A3) are represented by

$$U(\exp(\mu e^-)) = \exp(-i\mu\hat{H}_2), \tag{4.2a}$$

$$U(\exp(\lambda h)) = \exp(-i\lambda\hat{D}), \tag{4.2b}$$

$$U(\exp[\theta(e^+-e^-)]) = \exp(-i\theta(\hat{H}_1-\hat{H}_2)). \tag{4.2c}$$

The operators in (4.2a) and (4.2b) act as

$$[\exp(-i\mu\hat{H}_2)\Psi](\mathbf{u},\mathbf{v}) = \int \frac{d^q\mathbf{v}'}{(2\pi i\mu)^{q/2}} \exp\left[\frac{i}{2}\left(\frac{(\mathbf{v}-\mathbf{v}')^2}{\mu}+\mu\mathbf{u}^2\right)\right]\Psi(\mathbf{u},\mathbf{v}'), \tag{4.3a}$$

$$[\exp(-i\lambda\hat{D})\Psi](\mathbf{u},\mathbf{v}) = \exp\left[\frac{\lambda}{2}(q-p)\right]\Psi(e^{-\lambda}\mathbf{u},e^{\lambda}\mathbf{v}). \tag{4.3b}$$

In (4.2c) we have $\hat{H}_1-\hat{H}_2=\hat{H}^{\mathrm{sho}}_{\mathbf{u}}-\hat{H}^{\mathrm{sho}}_{\mathbf{v}}$, where $\hat{H}^{\mathrm{sho}}_{\mathbf{u}}$ and $\hat{H}^{\mathrm{sho}}_{\mathbf{v}}$ are the harmonic oscillator Hamiltonians of unit mass and angular frequency in respectively $\mathbf{u}$ and $\mathbf{v}$. It follows that $U(\exp[\theta(e^+-e^-)])$ is periodic in θ with period 2π when $p+q\equiv 0 \pmod 2$ and with period 4π when $p+q\equiv 1 \pmod 2$. This means that the gauge group is $\mathrm{SL}(2,\mathbb{R})$ when $p+q\equiv 0 \pmod 2$ and the double cover of $\mathrm{SL}(2,\mathbb{R})$ when $p+q\equiv 1 \pmod 2$. U is isomorphic to the (p,q) oscillator representation of the double cover of $\mathrm{SL}(2,\mathbb{R})$[38] via the Fourier transform in $\mathbf{v}$.

B. Test space

The next step is to introduce a linear space of test states in $\mathcal{H}_{\mathrm{aux}}$. The harmonic oscillator Hamiltonians in $U(\exp[\theta(e^+-e^-)])$ suggest that we make use of the harmonic oscillator eigenstates in $\mathbf{u}$ and $\mathbf{v}$,

$$\Psi_{ljmnk_uk_v}(\mathbf{u},\mathbf{v}) := u^l v^j e^{-(1/2)(u^2+v^2)} L_m^{\tilde{l}}(u^2) L_n^{\tilde{j}}(v^2) Y_{lk_u}(\theta^{(u)}) Y_{jk_v}(\theta^{(v)}), \tag{4.4}$$

where l, j, m and n are non-negative integers, $\tilde{l}$ and $\tilde{j}$ are defined by

$$\tilde{l} := l + (p-2)/2, \quad \tilde{j} := j + (q-2)/2, \tag{4.5}$$

$u := |\mathbf{u}|$, $v := |\mathbf{v}|$, the L's are the generalized Laguerre polynomials[45,46] and the Y's are the spherical harmonics in the notation of Sec. III. These states satisfy

$$\begin{aligned} \hat{H}^{\text{sho}}_{\mathbf{u}} \Psi_{ljmnk_uk_v} &= E_u \Psi_{ljmnk_uk_v}, \quad E_u := 2m + l + (p/2) = 2m + \tilde{l} + 1, \\ \hat{H}^{\text{sho}}_{\mathbf{v}} \Psi_{ljmnk_uk_v} &= E_v \Psi_{ljmnk_uk_v}, \quad E_v := 2n + j + (q/2) = 2n + \tilde{j} + 1, \end{aligned} \tag{4.6}$$

and they are orthogonal in $\mathcal{H}_{\text{aux}}$,

$$(\Psi_{ljmnk_uk_v}, \Psi_{l'j'm'n'k_u'k_v'})_{\text{aux}} = \frac{\Gamma(l+m+(p/2))\Gamma(j+n+(q/2))}{4\Gamma(m+1)\Gamma(n+1)} \delta_{ll'}\delta_{jj'}\delta_{mm'}\delta_{nn'}\delta_{k_uk_u'}\delta_{k_vk_v'}. \tag{4.7}$$

We set $\Phi_0 := \text{span}\{\Psi_{ljmnk_uk_v}\} = \{P(\mathbf{u},\mathbf{v})\exp[-\frac{1}{2}(u^2+v^2)]\}$, where $P(\mathbf{u},\mathbf{v})$ is an arbitrary polynomial in $\{u_i\}$ and $\{v_i\}$. Φ_0 is clearly dense in $\mathcal{H}_{\text{aux}}$ and mapped to itself by the quantum constraints (3.2).

Let G denote the gauge group, and let dg be the (left and right) invariant Haar measure on G. An L^1 function h on G defines on $\mathcal{H}_{\text{aux}}$ the bounded operator $\hat{h} := \int_G dg\, h(g) U(g)$, and the set of all such operators generates an algebra $\hat{\mathcal{A}}_G$. Starting with Φ_0, we first take the closure under the algebra generated by $\{U(g)|g \in G\}$, then take the closure under $\hat{\mathcal{A}}_G$, and adopt the resulting space Φ as our test space. Φ is a dense linear subspace of $\mathcal{H}_{\text{aux}}$, invariant under both $\hat{\mathcal{A}}_G$ and the algebra generated by $\{U(g)|g \in G\}$, and it hence satisfies the test space postulates of Ref. 8.

C. Physical Hilbert space

We now construct a rigging map by averaging states in Φ over G.

We define on Φ the sesquilinear form

$$(\phi_2, \phi_1)_{\text{ga}} := \int_G dg\, (\phi_2, U(g)\phi_1)_{\text{aux}}. \tag{4.8}$$

We show in Appendix E, Theorem E.3, that the integral in (4.8) is absolutely convergent for all $\phi_1, \phi_2 \in \Phi$, and $(\cdot\,,\cdot)_{\text{ga}}$ is hence well defined. We also show that $(\cdot\,,\cdot)_{\text{ga}}$ vanishes for $p+q \equiv 1 \pmod 2$. For the rest of this subsection we take $p+q \equiv 0 \pmod 2$.

Let Φ^* be the algebraic dual of Φ and let $f[\phi]$ denote the dual action of $f \in \Phi^*$ on $\phi \in \Phi$. We define the antilinear map $\eta: \Phi \to \Phi^*$ by

$$\eta(\phi_1)[\phi_2] := (\phi_1, \phi_2)_{\text{ga}}, \tag{4.9}$$

and we define on the image of η the sesquilinear form $(\cdot\,,\cdot)_{\text{RAQ}}$ by

$$(\eta(\phi_1), \eta(\phi_2))_{\text{RAQ}} := \eta(\phi_2)[\phi_1]. \tag{4.10}$$

We need to investigate whether the image of η is nontrivial and whether $(\cdot\,,\cdot)_{\text{RAQ}}$ is positive definite. If yes, η is a rigging map and the physical Hilbert space is the Cauchy completion of the image of η in $(\cdot\,,\cdot)_{\text{RAQ}}$.

Note first that if $\phi_i \in \Phi$ and $h_i \in L^1(G)$, (4.8) and (4.9) imply[8]

$$\eta(\hat{h}_1\phi_1)[\hat{h}_2\phi_2]=\overline{\left(\int_G dg\, h_1(g)\right)}\left(\int_G dg\, h_2(g)\right)\eta(\phi_1)[\phi_2] \tag{4.11}$$

and $\eta(\phi_1)[U(g)\phi_2]=\eta(U(g)\phi_1)[\phi_2]=\eta(\phi_1)[\phi_2]$ for all g. Hence it suffices to evaluate $\eta(\phi_1)[\phi_2]$ for $\phi_1,\phi_2\in\Phi_0$.

By Proposition E.4 in Appendix E, Fubini's theorem implies that we can represent the image of η as functions on $\mathbb{R}^{p+q}=\{(\mathbf{u},\mathbf{v})\}$, acting on $\phi\in\Phi$ by

$$f[\phi]=\int d^p\mathbf{u}\, d^q\mathbf{v}\, f(\mathbf{u},\mathbf{v})\phi(\mathbf{u},\mathbf{v}), \tag{4.12}$$

and evaluate η by

$$\eta(\phi)=\overline{\int_G dg\, U(g)\phi}, \tag{4.13}$$

where the integral is taken in the sense of pointwise convergence on $\mathbb{R}^{p+q}$. The value of (4.13) can be read off from the results in Appendix D.1 of Ref. 10, by matching our (E6) to Eq. (D3) in Ref. 10. The result is

$$\eta(\Psi_{ljmnk_uk_v})=4\pi^2(-1)^m\,\delta_{mn}\frac{\Gamma(l+m+(p/2))}{(2l+p-2)\Gamma(m+1)}\overline{\Psi_{ljk_uk_v}}, \tag{4.14}$$

where $\Psi_{ljk_uk_v}$ is as in (3.10). The action of $\overline{\Psi_{ljk_uk_v}}$ on Φ_0 reads (Ref. 46, p. 244)

$$\overline{\Psi_{l'j'k'_uk'_v}}[\Psi_{ljmnk_uk_v}]=(-1)^m\delta_{2l+p,2j+q}\delta_{ll'}\delta_{jj'}\delta_{mn}\delta_{k_uk'_u}\delta_{k_vk'_v}\frac{\Gamma(l+m+(p/2))}{2\Gamma(m+1)}. \tag{4.15}$$

Hence the image of η is nontrivial and spanned by $\{\overline{\Psi_{ljk_uk_v}}\}$. From (4.10), (4.14) and (4.15) we find

$$(\overline{\Psi_{l'j'k'_uk'_v}},\overline{\Psi_{ljk_uk_v}})_{\mathrm{RAQ}}=\frac{2l+p-2}{8\pi^2}\,\delta_{2l+p,2j+q}\delta_{ll'}\delta_{jj'}\delta_{k_uk'_u}\delta_{k_vk'_v}. \tag{4.16}$$

Hence $(\cdot\,,\cdot)_{\mathrm{RAQ}}$ is positive definite, η is a rigging map, and we have a physical Hilbert space $\mathcal{H}_{\mathrm{RAQ}}$. The group averaging sesquilinear form on Φ_0 reads

$$\begin{aligned}(\Psi_{l'j'm'n'k'_uk'_v},\Psi_{ljmnk_uk_v})_{\mathrm{ga}}=&\,2\pi^2(-1)^{m+m'}\,\delta_{2l+p,2j+q}\delta_{mn}\delta_{m'n'}\delta_{ll'}\delta_{jj'}\delta_{k_uk'_u}\delta_{k_vk'_v}\\&\times\frac{\Gamma(l+m'+(p/2))\Gamma(l+m+(p/2))}{(2l+p-2)\Gamma(m'+1)\Gamma(m+1)}.\end{aligned} \tag{4.17}$$

The uniqueness theorem of Ref. 8 shows that every rigging map for our triple $(\mathcal{H}_{\mathrm{aux}},U,\Phi)$ is a multiple of the group averaging rigging map η.

The algebra $\mathcal{A}^{(\star)}_{\mathrm{phys}}$ is represented on $\mathcal{H}_{\mathrm{aux}}$ by (3.4). This representation leaves Φ invariant and commutes with $U(g)$, and the star-relation in this representation coincides with the adjoint map on $\mathcal{H}_{\mathrm{aux}}$. It follows that $\mathcal{H}_{\mathrm{RAQ}}$ carries an antilinear representation ρ of $\mathcal{A}^{(\star)}_{\mathrm{phys}}$, such that the star-relation coincides with the adjoint map on $\mathcal{H}_{\mathrm{RAQ}}$. In the notation of (3.4),

$$\rho(\hat{O}_{ij}):f\mapsto\overline{\hat{O}_{ij}\bar{f}}. \tag{4.18}$$

This shows that the algebraic quantization set up in Sec. III yields a quantum theory anti-isomorphically embedded in our group averaging quantum theory whenever $p\geqslant 3$, $q\geqslant 3$ and p

$+q\equiv 0 \pmod 2$, even though we were able to complete the algebraic quantization explicitly only for $p=q=3$. Apart from $p=q=3$, we do, however, not know whether this quantum theory is the *only* one arising from the algebraic quantization for $p\geqslant 3$, $q\geqslant 3$ and $p+q\equiv 0 \pmod 2$.

V. REFINED ALGEBRAIC QUANTIZATION FOR $p<3$ OR $q<3$

In Sec. IV we assumed $p\geqslant 3$ and $q\geqslant 3$. We now discuss refined algebraic quantization for lower p or q. By interchange of $\mathbf{u}$ and $\mathbf{v}$, it suffices to consider $p\leqslant q$.

A. $p=1$, $q>3$

When $p=1$ and $q>3$, we define $\mathcal{H}_{\text{aux}}$ and Φ as in Sec. IV. The u_1 dependence of the test states (4.4) can be written in terms of Hermite polynomials as $H_{l+2m}(u_1)\exp(-\frac{1}{2}u_1^2)$ (Ref. 46, p. 240), but the notation in (4.4) covers also $p=1$, the spherical harmonics on S^0 being as described in Sec. III A. We drop the redundant index k_u and write

$$\phi_{ljmnk}(u_1,\mathbf{v}) := \Psi_{ljmn0k} = u^l v^j e^{-(1/2)(u^2+v^2)} L_m^{\tilde{l}}(u^2) L_n^{\tilde{j}}(v^2) Y_l(\theta^{(u)}) Y_{jk}(\theta^{(v)}), \tag{5.1}$$

where $l\in\{0,1\}$ and $\tilde{l}=l-\frac{1}{2}$.

As a preliminary, let $Y_{j0}(\theta^{(v)})$ denote the zonal spherical harmonics, which depend only on v_q/v and are given by Gegenbauer polynomials.[43] The recursion relations for the Gegenbauer polynomials and the generalized Laguerre polynomials[46] allow an explicit computation of the action of $\hat{C}_{1q}$ on ϕ_{ljmn0}. We find

$$\begin{aligned}\hat{C}_{1q}\phi_{0jmn0} = &-W_{qj}[(n+\tilde{j})\phi_{1,j-1,m-1,n,0}+(n+1)\phi_{1,j-1,m,n+1,0}]\\ &+W_{q,j+1}(\phi_{1,j+1,m-1,n-1,0}+\phi_{1,j+1,mn0}),\end{aligned} \tag{5.2a}$$

$$\begin{aligned}\hat{C}_{1q}\phi_{1jmn0} = &\,W_{qj}[(m+\tfrac{1}{2})(n+\tilde{j})\phi_{0,j-1,mn0}+(m+1)(n+1)\phi_{0,j-1,m+1,n+1,0}]\\ &-W_{q,j+1}[(m+\tfrac{1}{2})\phi_{0,j+1,m,n-1,0}+(m+1)\phi_{0,j+1,m+1,n0}],\end{aligned} \tag{5.2b}$$

where

$$\begin{aligned}W_{qj} &:= 2\left[\frac{j(j+q-3)}{(2j+q-2)(2j+q-4)}\right]^{1/2} \text{ for } j>0,\\ W_{q0} &:= 0,\end{aligned} \tag{5.3}$$

and any ϕ_{ljmn0} on the right-hand side with $m<0$ or $n<0$ is understood as zero.

Now, by Theorem E.3, the group averaging converges in absolute value. When q is even, the θ dependence in (E7) shows that the image of η is trivial. In the rest of this subsection we take q odd and show that the image of η is trivial also in this case.

It suffices to show that $(\phi_{l'j'm'n'k'},\phi_{ljmnk})_{\text{ga}}$ vanishes. When $l=l'=1$, we can proceed as in Sec. IV C and the result follows from (4.17). When $l=0$ or $l'=0$, (E7) shows that it suffices to consider $(\phi_{0jm'n'0},\phi_{0jmn0})_{\text{ga}}$. The θ-dependence in (E7) shows that the integral over θ gives zero unless $2m=2n+j+(q-1)/2$, and a similar observation with $U(g)$ conjugated to act on the first argument shows that the integral over θ gives zero unless $2m'=2n'+j+(q-1)/2$. When $q=5+4a$, $a=0,1,\ldots$, it therefore suffices to consider $(\phi_{0,2s,n'+s+a+1,n'},\phi_{0,2s,n+s+a+1,n})_{\text{ga}}$, where s, n and n' are non-negative integers and we have suppressed the last index of the ϕ's, understood to take the value zero. When $q=3+4b$, $b=1,2,\ldots$, it similarly suffices to consider $(\phi_{0,2s+1,n'+s+b+1,n'},\phi_{0,2s+1,n+s+b+1,n})_{\text{ga}}$, where s, n and n' are non-negative integers.

Let $q=3+4b$, $b=1,2,\ldots$. Recall that $\hat{C}_{1q}$ is self-adjoint in $\mathcal{H}_{\text{aux}}$ and commutes with $U(g)$. We compute

$$W_{q,2s+1}[(n+s+b+\tfrac{1}{2})(\phi_{0,2s+1,n'+s+b+1,n'},\phi_{0,2s+1,n+s+b,n-1})_{\mathrm{ga}}+(n+s+b+1)$$
$$\times(\phi_{0,2s+1,n'+s+b+1,n'},\phi_{0,2s+1,n+s+b+1,n})_{\mathrm{ga}}]$$
$$=-(\phi_{0,2s+1,n'+s+b+1,n'},\hat{C}_{1q}\phi_{1,2s,n+s+b,n})_{\mathrm{ga}}$$
$$=-(\hat{C}_{1q}\phi_{0,2s+1,n'+s+b+1,n'},\phi_{1,2s,n+s+b,n})_{\mathrm{ga}}=0, \tag{5.4}$$

where the first equality follows from (5.2b) and the last from (5.2a) and (4.17). By induction in n, (5.4) implies $(\phi_{0,2s+1,n'+s+b+1,n'},\phi_{0,2s+1,n+s+b+1,n})_{\mathrm{ga}}=0$.

Let then $q=5+4a$, $a=0,1,\ldots$. An argument similar to (5.4) shows that $(\phi_{0,2s,n'+s+a+1,n'},\phi_{0,2s,n+s+a+1,n})_{\mathrm{ga}}$ vanishes for $s>0$. When $s=0$, we compute

$$W_{q1}[(n+a+\tfrac{3}{2})(n+2a+\tfrac{5}{2})(\phi_{0,0,n'+a+1,n'},\phi_{0,0,n+a+1,n})_{\mathrm{ga}}+(n+a+2)(n+1)$$
$$\times(\phi_{0,0,n'+a+1,n'},\phi_{0,0,n+a+2,n+1})_{\mathrm{ga}}]$$
$$=(\phi_{0,0,n'+a+1,n'},\hat{C}_{1q}\phi_{1,1,n+a+1,n})_{\mathrm{ga}}=(\hat{C}_{1q}\phi_{0,0,n'+a+1,n'},\phi_{1,1,n+a+1,n})_{\mathrm{ga}}=\ 0, \tag{5.5}$$

where the last equality follows from (5.2a) and (4.17). By induction in n, it therefore suffices to consider $(\phi_{0,0,n'+a+1,n'},\phi_{0,0,a+1,0})_{\mathrm{ga}}$. A similar argument in n' shows that it suffices to consider $(\phi_{0,0,a+1,0},\phi_{0,0,a+1,0})_{\mathrm{ga}}$.

In $(\phi_{0,0,a+1,0},U(g)\phi_{0,0,a+1,0})_{\mathrm{aux}}$, we use (E7) and perform the elementary integration over $\mathbf{v}$. We then integrate over G in the Haar measure $dg=\frac{1}{2}dz\,d\mu\,d\theta$. The integration over θ is elementary. Changing the variables in the inner integral from u to $y:=u^2/z$ and in the outer integral from μ to $t:=\mu z/(z+1)$, we find that $(\phi_{0,0,a+1,0},\phi_{0,0,a+1,0})_{\mathrm{ga}}$ equals a numerical constant times

$$\int_0^\infty dz\,\frac{z^{a+1/2}}{(z+1)^{2a+3/2}}\int_{-\infty}^{\infty}\frac{dt}{(1+it)^{2a+5/2}}\int_0^\infty dy\,y^{-1/2}L_{a+1}^{-1/2}(zy)\,L_{a+1}^{-1/2}(y)$$
$$\times\exp\left[-\frac{1}{2}(z+1)(1-it)y\right]. \tag{5.6}$$

We interchange the order of the dt and dy integrals in (5.6), justified by the absolute convergence of the double integral, and perform the dt integral as a contour integral, finding that (5.6) equals a numerical constant times

$$\int_0^\infty dz\,z^{a+1/2}\int_0^\infty dy\,y^{2a+1}L_{a+1}^{-1/2}(zy)\,L_{a+1}^{-1/2}(y)\exp[-(z+1)y]. \tag{5.7}$$

In (5.7) we interchange the order of the dz and dy integrals, justified by the absolute convergence of the double integral. Changing the variable in the new inner integral from z to $x:=zy$, we obtain

$$\int_0^\infty dy\,y^{a-1/2}L_{a+1}^{-1/2}(y)\,e^{-y}\int_0^\infty dx\,x^{a+1/2}L_{a+1}^{-1/2}(x)\,e^{-x}. \tag{5.8}$$

The integrals in (5.8) have factorized, and the integral over y vanishes by the orthogonality of the generalized Laguerre polynomials.[46]

B. $p=1$, $q=3$

When $p=1$ and $q=3$, we define $\mathcal{H}_{\mathrm{aux}}$ as in Sec. IV. With Φ defined as in Sec. IV, the integral in (4.8) is not absolutely convergent for $l=j=0$, and we have not found a weaker unambiguous

sense of convergence. The θ-dependence in (E7) however suggests that if group averaging can be made well-defined, it should annihilate states with $l=j=0$. We shall achieve this by suitably modifying the test space.

Dropping the redundant index k_u, we introduce the states ϕ_{ljmnk} by (5.1) with $q=3$. We define $\Phi_0^{\mathrm{mod}} := \mathrm{span}(\{\phi_{ljmnk} | l+j>0\} \cup \{\psi_{mn}\})$, where

$$\psi_{mn} := \frac{2}{\sqrt{3}}\left[\left(m+\frac{1}{2}\right)\left(n+\frac{3}{2}\right)\phi_{00mn0} + (m+1)(n+1)\,\phi_{00,m+1,n+1,0}\right]. \tag{5.9}$$

Using the basis (3.4) of $\mathcal{A}_{\mathrm{phys}}^{(\star)}$, properties of the spherical harmonics on S^2 (Refs. 43 and 45) and properties of the generalized Laguerre polynomials,[46] it can be verified that Φ_0^{mod} is invariant under $\mathcal{A}_{\mathrm{phys}}^{(\star)}$. In particular, formulas (5.2) and (5.3) hold with $q=3$, implying

$$\hat{C}_{13}\phi_{11mn0} = \psi_{mn} - \frac{4}{\sqrt{15}}\left[\left(m+\frac{1}{2}\right)\phi_{0,2,m,n-1,0} + (m+1)\,\phi_{0,2,m+1,n,0}\right], \tag{5.10a}$$

$$\begin{aligned}\hat{C}_{13}\psi_{mn} = {} & \tfrac{4}{3}\left(m+\tfrac{1}{2}\right)\left(n+\tfrac{3}{2}\right)\left(\phi_{11,m-1,n-1,0} + \phi_{11mn0}\right) + \tfrac{4}{3}(m+1)(n+1) \\ & \times\left(\phi_{11mn0} + \phi_{11,m+1,n+1,0}\right).\end{aligned} \tag{5.10b}$$

We claim that Φ_0^{mod} is dense in $\mathcal{H}_{\mathrm{aux}}$. If this were not the case, there would exist a nonzero vector $y=\Sigma_{ljmnk} a_{ljmnk}\phi_{ljmnk} \in \mathcal{H}_{\mathrm{aux}}$ that is orthogonal to all vectors in Φ_0^{mod}. By (4.7), orthogonality with each ϕ_{ljmnk} with $l+j>0$ implies $a_{ljmnk}=0$ for $l+j>0$. By (4.7) and (5.9), orthogonality with each ψ_{mn} implies $a_{00mn0}+a_{00,m+1,n+1,0}=0$, from which (4.7) further shows that y has finite norm only if y is the zero vector. Hence Φ_0^{mod} is dense in $\mathcal{H}_{\mathrm{aux}}$.

Following Sec. IV with Φ_0 replaced by Φ_0^{mod}, we first take the closure of Φ_0^{mod} under the algebra generated by $\{U(g)|g\in G\}$, then take the closure under $\hat{\mathcal{A}}_G$, and adopt the resulting space Φ^{mod} as our test space. Φ^{mod} is a dense linear subspace of $\mathcal{H}_{\mathrm{aux}}$, invariant under $\mathcal{A}_{\mathrm{phys}}^{(\star)}$, $\hat{\mathcal{A}}_G$ and the algebra generated by $\{U(g)|g\in G\}$, and satisfies hence the test space postulates of Ref. 8. We show in Appendix E, Theorem E.5, that the integral in (4.8) converges in absolute value for all $\phi_1, \phi_2 \in \Phi^{\mathrm{mod}}$.

To evaluate $(\phi_2,\phi_1)_{\mathrm{ga}}$ on Φ^{mod}, it suffices to consider $\phi_1, \phi_2 \in \Phi_0^{\mathrm{mod}}$. When both ϕ_1 and ϕ_2 have $l=1$, we can proceed as in Sec. IV C, arriving at (4.12)–(4.17). When ϕ_1 and ϕ_2 have differing values of l, j or k, (E7) shows that $(\phi_2,\phi_1)_{\mathrm{ga}}$ vanishes. What remains is $(\phi_{0jm'n'k}, \phi_{0jmnk})_{\mathrm{ga}}$ with $j>0$ and $(\psi_{m'n'}, \psi_{mn})_{\mathrm{ga}}$. The vanishing of the former follows as in Sec. V A, noting that (5.4) holds also for $b=0$. For the latter, we use (5.10a), the self-adjointness of $\hat{C}_{13}$ on $\mathcal{H}_{\mathrm{aux}}$ and the vanishing of $(\psi_{m'n'}, \phi_{0jmn0})_{\mathrm{ga}}$ for $j>0$ and compute

$$(\psi_{m'n'}, \psi_{mn})_{\mathrm{ga}} = (\psi_{m'n'}, \hat{C}_{13}\phi_{11mn0})_{\mathrm{ga}} = (\hat{C}_{13}\psi_{m'n'}, \phi_{11mn0})_{\mathrm{ga}} = 0, \tag{5.11}$$

where the last equality follows from (5.10b) and (4.17).

The evaluation of $(\phi_2,\phi_1)_{\mathrm{ga}}$ is now complete. The only nonzero contribution comes from states with $l=1$, in which case formulas (4.12)–(4.17) hold. The image of η is one-dimensional, spanned by $\{\overline{\Psi_0}\}$, where Ψ_0 is the state (3.10) with $l=1$ and $j=0$ and reads explicitly (Ref. 43, Sec. 7.11) $\Psi_0 = v^{-1}\sin(u_1 v)$. The inner product (4.16) is positive definite, and we obtain a one-dimensional physical Hilbert space $\mathcal{H}_{\mathrm{RAQ}}$.

As Φ_0^{mod} is invariant under $\mathcal{A}_{\mathrm{phys}}^{(\star)}$, $\mathcal{H}_{\mathrm{RAQ}}$ carries an antilinear representation of $\mathcal{A}_{\mathrm{phys}}^{(\star)}$. A direct calculation shows that all operators in this representation annihilate $\overline{\Psi_0}$, and the representation is trivial. The quantum theory found in algebraic quantization in Sec. (III A) is thus anti-isomorphically embedded in the group averaging quantum theory.

C. $p=1$, $q=2$

When $p=1$ and $q=2$, and $\mathcal{H}_{\rm aux}$ and Φ are as in Sec. IV, the integral in (4.8) is not absolutely convergent for $l=j=0$. It may be possible to modify the $l=j=0$ sector of Φ as in Sec. V B above, but as now $p+q\equiv 1 \pmod 2$, any test space built from linear combinations of the harmonic oscillator eigenfunctions will give an η with trivial image.

D. $p=q=1$

When $p=q=1$, and $\mathcal{H}_{\rm aux}$ and Φ are as in Sec. IV, the integral in (4.8) is not absolutely convergent for $l=0$ or $j=0$ and is unambiguously divergent for example for $\phi_1=\phi_2=\Psi_{0000}$.

We attempt to cure the divergence by modifying the zero angular momentum sector. For technical simplicity, we choose at the outset to work with states that are symmetric under $(u_1,v_1)\mapsto(-u_1,-v_1)$.

Let $\mathcal{H}^{\rm s}_{\rm aux}\subset\mathcal{H}_{\rm aux}$ be the Hilbert subspace of vectors symmetric under $(u_1,v_1)\mapsto(-u_1,-v_1)$. Dropping the redundant indices k_u and k_v, we write

$$\phi_{lmn}(u_1,v_1) := \Psi_{llmn00} = u^l v^l e^{-(1/2)(u^2+v^2)} L^{\tilde{l}}_m(u^2) L^{\tilde{l}}_n(v^2) Y_l(\theta^{(u)}) Y_l(\theta^{(v)}), \tag{5.12}$$

where $l\in\{0,1\}$ and $\tilde{l}=l-\frac{1}{2}$. $\{\phi_{lmn}\}$ is clearly an orthogonal basis for $\mathcal{H}^{\rm s}_{\rm aux}$.

Let $\Phi^{\rm s}_0 := {\rm span}\{\psi_{mn},\phi_{1mn}\}$, where

$$\psi_{mn} := 2[(m+\tfrac{1}{2})(n+\tfrac{1}{2})\phi_{0mn} + (m+1)(n+1)\phi_{0,m+1,n+1}]. \tag{5.13}$$

We then find (Ref. 46, p. 241)

$$\hat{C}_{11}\psi_{mn} = 4[(m+\tfrac{1}{2})(n+\tfrac{1}{2})(\phi_{1mn}+\phi_{1,m-1,n-1}) + (m+1)(n+1)(\phi_{1mn}+\phi_{1,m+1,n+1})], \tag{5.14a}$$

$$\hat{C}_{11}\phi_{1mn} = \psi_{mn}, \tag{5.14b}$$

where $\hat{C}_{11}$ (3.4) is the single generator of $\mathcal{A}^{(\star)}_{\rm phys}$. Hence $\Phi^{\rm s}_0$ is invariant under $\mathcal{A}^{(\star)}_{\rm phys}$, and it can be shown as in Sec. V B that $\Phi^{\rm s}_0$ is dense in $\mathcal{H}^{\rm s}_{\rm aux}$. We build from $\Phi^{\rm s}_0$ a test space $\Phi^{\rm s}$ satisfying the postulates of Ref. 8 as in Sec. V B. The integral in (4.8) then converges in absolute value for all $\phi_1,\phi_2\in\Phi^{\rm s}$: The proof is a verbatim adaptation of that of Theorem E.5.

We need to evaluate $(\phi_2,\phi_1)_{\rm ga}$ on $\Phi^{\rm s}$. It suffices to consider $\phi_1,\phi_2\in\Phi^{\rm s}_0$. Clearly $(\psi_{m'n'},\phi_{1mn})_{\rm ga}=0$. For $(\phi_{1m'n'},\phi_{1mn})_{\rm ga}$ we proceed as in Sec. IV C and arrive at (4.12)–(4.17), the last of which reads

$$(\phi_{1m'n'},\phi_{1mn})_{\rm ga} = 2\pi^2(-1)^{m+m'}\delta_{mn}\delta_{m'n'}\frac{\Gamma(m+\frac{3}{2})\Gamma(m'+\frac{3}{2})}{\Gamma(m+1)\Gamma(m'+1)}. \tag{5.15}$$

To find $(\psi_{m'n'},\psi_{mn})_{\rm ga}$, we use the self-adjointness of $\hat{C}_{11}$ on $\mathcal{H}^{\rm s}_{\rm aux}$ and compute

$$\begin{aligned}(\psi_{m'n'},\psi_{mn})_{\rm ga} &= (\psi_{m'n'},\hat{C}_{11}\phi_{1mn})_{\rm ga}\\ &= (\hat{C}_{11}\psi_{m'n'},\phi_{1mn})_{\rm ga}\\ &= -2\pi^2(-1)^{m+m'}\delta_{mn}\delta_{m'n'}\frac{\Gamma(m+\frac{3}{2})\Gamma(m'+\frac{3}{2})}{\Gamma(m+1)\Gamma(m'+1)},\end{aligned} \tag{5.16}$$

where the first equality follows from (5.14b) and the last one from (5.14a) and (5.15).

We see that $(\cdot\,,\cdot)_{\rm ga}$ is an *indefinite* sesquilinear form. Hence the map η defined by (4.9) is not a rigging map and we do not recover a Hilbert space. The indefiniteness of $(\cdot\,,\cdot)_{\rm ga}$ further implies, by the uniqueness theorem of Ref. 8, that the triple $(\mathcal{H}^{\rm s}_{\rm aux}, \underline{U}, \underline{\Phi}^{\rm s})$ admits no rigging maps.

The image of η is two-dimensional, spanned by $\{\overline{\Psi_{00}}, \overline{\Psi_{11}}\}$, where Ψ_{00} and Ψ_{11} are given by (3.10) and read explicitly (Ref. 43, Sec. 7.11)

$$\Psi_{00} = \frac{1}{\sqrt{2\pi}} \cos(u_1 v_1), \tag{5.17a}$$

$$\Psi_{11} = \frac{1}{\sqrt{2\pi}} \sin(u_1 v_1). \tag{5.17b}$$

The manifestly indefinite sesquilinear form (4.10) on the image of η is given by (4.16). The representation of $\mathcal{A}^{(\star)}_{\rm phys}$ induced on the image of η by (4.12) is anti-isomorphic to the representation obtained in Sec. III A on the solution space to the algebraic quantization constraints.

E. $p=2$, $q>2$

When $p=2$ and $q>2$, we define $\mathcal{H}_{\rm aux}$ and Φ as in Sec. IV. Theorem E.3 in Appendix E shows that the group averaging converges in absolute value.

When q is odd, the θ dependence in (E7) shows that the image of η is trivial.

Suppose then that q is even. When $l>0$ and $l'>0$, we arrive at Eqs. (4.12)–(4.17) as in Sec. IV C. When $l=0$ or $l'=0$, it can be shown that $(\Psi_{l'j'm'n'k'_u k'_v}, \Psi_{ljmnk_u k_v})_{\rm ga}$ vanishes: The arguments follow those in Sec. V A so closely that we will not spell them out here. This means that Eqs. (4.12)–(4.17) hold for all values of the indices in the sense that terms involving $\delta_{2l+1,2j+q}$ for $l=0$ are understood to vanish. Hence the situation is similar to that for $p\geqslant 3$, $q\geqslant 3$ and $p+q \equiv 0 \pmod 2$ in Sec. IV. The image of η is nontrivial, $(\cdot\,,\cdot)_{\rm RAQ}$ is positive definite, η is a rigging map, and the representation of $\mathcal{A}^{(\star)}_{\rm phys}$ on the physical Hilbert space is as described at the end of Sec. IV C.

F. $p=q=2$

The case $p=q=2$ was analyzed in Ref. 10. Group averaging does not converge on the test space of Sec. IV, but the $l=j=0$ sector of the test space can be modified so that group averaging converges and the physical observable algebra includes $\mathcal{A}^{(\star)}_{\rm phys}$. The physical Hilbert space decomposes into a direct sum of four Hilbert subspaces, each of them carrying a distinct representation of $\mathcal{A}^{(\star)}_{\rm phys}$.

VI. DISCUSSION

We have discussed the quantization of a constrained system with unreduced phase space $\mathbb{R}^{2(p+q)}$, classical gauge group $\mathrm{SL}(2,\mathbb{R})$ and a distinguished $\mathfrak{o}(p,q)$ algebra of classical observables. We employed refined algebraic quantization, using group averaging on an auxiliary Hilbert space to find the inner product on the physical Hilbert space. We took care to select the quantization input so that when a quantum theory is recovered, the classical $\mathfrak{o}(p,q)$ algebra gets promoted into an operator algebra represented on the physical Hilbert space.

When $p\geqslant 2$, $q\geqslant 2$, $p+q>4$ and $p+q\equiv 0 \pmod 2$, we found a quantum theory with a nontrivial representation of the $\mathfrak{o}(p,q)$ observables. For $p=q=2$, a similar result was obtained in Ref. 10. For $(p,q)=(1,3)$ or $(3,1)$, we found a quantum theory with a one-dimensional Hilbert space and a trivial representation of the $\mathfrak{o}(p,q)$ observables. For other values of p and q we found no quantum theory.

We also discussed Ashtekar's algebraic quantization, solving first the quantum constraints without an inner product and then promoting the classical $\mathfrak{o}(p,q)$ algebra into operators whose star-relations determine the physical inner product. For all values of p and q for which

group averaging gave a quantum theory, algebraic quantization gave a quantum theory that is (anti-)isomorphically embedded in the group averaging theory. For $p=q=3$, we showed that this algebraic quantization theory is unique.

With both algebraic quantization and group averaging, qualitative changes emerged depending on whether p and q are less than, equal to, or greater than 2. This could be expected from the properties of the classical reduced phase space: The reduced phase space contains a symplectic manifold when and only when $\min(p,q)\geqslant 2$, and this symplectic manifold is connected when and only when $\min(p,q)\geqslant 3$. However, a phenomenon not expected on classical grounds was that neither algebraic quantization nor group averaging gave a quantum theory for $p+q\equiv 1 \pmod 2$. The technical reason was that both quantization schemes represented the $\mathfrak{o}(p)\oplus\mathfrak{o}(q)$ subalgebra of $\mathfrak{o}(p,q)$ by integer-valued rather than half-integer-valued angular momenta. Obtaining quantum theories for $p+q\equiv 1 \pmod 2$ by some ''fermionic'' modification might be an interesting challenge.

For $p=q=1$, both algebraic quantization and group averaging failed to give a quantum theory, for closely related reasons. Algebraic quantization led to a two-dimensional vector space of solutions to the constraints, but requiring the $\mathfrak{o}(1,1)$ generator to be symmetric forced the sesquilinear form on this vector space to be indefinite. In group averaging, a judicious choice of the test space ensured convergence of the averaging and the inclusion of the $\mathfrak{o}(1,1)$ generator in the would-be physical observable algebra, but the outcome was the same indefinite sesquilinear form on the same two-dimensional vector space as in algebraic quantization. It is not clear whether the case $p=q=1$ has physical interest, especially as the reduced phase space consists of just three points, non-Hausdorff close to each other, but from the mathematical point of view this provides the first example known to us where group averaging fails to produce a Hilbert space owing to indefiniteness of the would-be inner product. As the uniqueness theorem of Ref. 8 does not assume positive definiteness, the theorem is applicable here and implies that our test space admits no rigging maps.

We assumed throughout $p\geqslant 1$ and $q\geqslant 1$. If either p or q vanishes, the action (2.1) still defines a classical theory, but the reduced phase space then consists of a single point. Algebraic quantization in the representation of Sec. III gives no solutions to the constraints, and when group averaging based on the harmonic oscillator eigenstates converges, it gives an identically vanishing sesquilinear form owing to the θ dependence in $U(g)\Psi$ (E7).

Finally, one would like to characterize the representations of $\mathfrak{o}(p,q)$ on our physical Hilbert spaces in terms of invariants,[42] as done in Refs. 10, 16, and 21 for $p=q=2$. The value of the quadratic Casimir operator can be read off from (3.5). As our representation of the gauge group on the auxiliary Hilbert space is isomorphic to the oscillator representation of $\mathrm{SL}(2,\mathbb{R})$,[38] the joint representation theory of the dual pair $(\mathrm{O}(p,q),\mathrm{SL}(2,\mathbb{R}))$[47,48] may be useful with this question.

ACKNOWLEDGMENTS

We thank John Barrett, Marco Mackaay, Don Marolf and Jacek Wiśniewski for discussions and correspondence, Bianca Dittrich for correspondence and bringing Refs. 29–33 to our attention, and John Baez for bringing Ref. 42 to our attention. APPENDIX A: SL(2,$\mathbb{R}$)

In this appendix we collect some relevant properties of $\mathrm{SL}(2,\mathbb{R})$. The notation follows Ref. 38.

$\mathrm{SL}(2,\mathbb{R})$ consists of real 2×2 matrices with unit determinant. The Lie algebra $\mathfrak{sl}(2,\mathbb{R})$ is spanned by the matrices

$$h:=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix},\quad e^{+}:=\begin{pmatrix}0 & 1\\ 0 & 0\end{pmatrix},\quad e^{-}:=\begin{pmatrix}0 & 0\\ 1 & 0\end{pmatrix}, \tag{A1}$$

whose commutators are

$$[h, e^+] = 2e^+,$$
$$[h, e^-] = -2e^-, \tag{A2}$$
$$[e^+, e^-] = h.$$

Elements of $SL(2,\mathbb{R})$ have the unique Iwasawa decomposition

$$g = \exp(\mu e^-)\exp(\lambda h)\exp[\theta(e^+ - e^-)], \tag{A3}$$

or explictly

$$g = \begin{pmatrix} 1 & 0 \\ \mu & 1 \end{pmatrix}\begin{pmatrix} e^\lambda & 0 \\ 0 & e^{-\lambda} \end{pmatrix}\begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix}, \tag{A4}$$

where $\mu \in \mathbb{R}$, $\lambda \in \mathbb{R}$ and $0 \leqslant \theta < 2\pi$. The unique Iwasawa decomposition of the universal covering group of $SL(2,\mathbb{R})$ is given by (A3) with $-\infty < \theta < \infty$, and that of the double cover by $0 \leqslant \theta < 4\pi$. The left and right invariant Haar measure reads $dg = e^{2\lambda}\, d\lambda\, d\mu\, d\theta$.

APPENDIX B: LINEAR INDEPENDENCE OF THE CONSTRAINTS

In this appendix we show that the gradients of the constraints are all vanishing on $\overline{\Gamma}_0$, linearly dependent but not all vanishing on $\overline{\Gamma}_{\text{ex}}$, and linearly independent on $\overline{\Gamma}_{\text{reg}}$.

From (2.3), the gradients of the constraints read

$$dH_1 = \sum_i (p_i dp_i - v_i dv_i),$$
$$dH_2 = \sum_i (\pi_i d\pi_i - u_i du_i), \tag{B1}$$
$$dD = \sum_i (u_i dp_i + p_i du_i - \pi_i dv_i - v_i d\pi_i).$$

For $\alpha, \beta, \gamma \in \mathbb{R}$, the equation $\alpha dH_1 + \beta dH_2 + \gamma dD = 0$ is equivalent to

$$\gamma\mathbf{u} + \alpha\mathbf{p} = \mathbf{0} = -\beta\mathbf{u} + \gamma\mathbf{p},$$
$$\gamma\boldsymbol{\pi} + \alpha\mathbf{v} = \mathbf{0} = -\beta\boldsymbol{\pi} + \gamma\mathbf{v}. \tag{B2}$$

$\overline{\Gamma}_0$ is clearly the set where the gradients of all the constraints vanish.

On $\overline{\Gamma}_{\text{ex}}$, we saw in Sec. II that each point can be brought to the form (2.11) by a gauge transformation (2.5) with some $g \in SL(2,\mathbb{R})$. Given such a g, (B2) is satisfied by $\alpha = (g_{12})^2$, $\beta = -(g_{11})^2$ and $\gamma = g_{11}g_{12}$, where at least one of α and β must be nonvanishing since $\det(g) \neq 0$. Hence the gradients of the constraints are linearly dependent on $\overline{\Gamma}_{\text{ex}}$.

On $\overline{\Gamma}_{\text{reg}}$, the pair $(\mathbf{u}, \mathbf{p})$ [as well as the pair $(\mathbf{v}, \boldsymbol{\pi})$] is linearly independent, and (B2) implies $\alpha = \beta = \gamma = 0$. Hence the gradients of the constraints are linearly independent on $\overline{\Gamma}_{\text{reg}}$.

APPENDIX C: SEPARATION OF $\mathcal{M}_{\text{reg}}$ BY $\mathcal{A}_{\text{class}}$

In this appendix we show that the classical observable algebra $\mathcal{A}_{\text{class}}$ separates $\mathcal{M}_{\text{reg}}$. We assume $p \geqslant 2$ and $q \geqslant 2$, which is necessary and sufficient for $\mathcal{M}_{\text{reg}}$ to be nonempty. The case $p = q = 2$ was treated in Refs. 10, 16, and 21.

Let $\mathcal{M}_i$, $1\leqslant i\leqslant p$, be the subset of $\mathcal{M}_{\rm reg}$ whose points have a representative in $\overline{\Gamma}_{\rm reg}$ satisfying the gauge conditions (2.13) with $u_i^2+p_i^2>0$. It follows that $\mathcal{M}_i\cap\mathcal{M}_j\neq\varnothing$ for all i and j and

$$\mathcal{M}_{\rm reg}=\bigcup_{i=1}^{p}\mathcal{M}_i. \tag{C1}$$

Lemma C.1: Let $\tilde{a}\in\mathcal{M}_{\rm reg}$ and $\tilde{b}\in\mathcal{M}_{\rm reg}$ such that there is no $\mathcal{M}_i$ containing both $\tilde{a}$ and $\tilde{b}$. Then $\mathcal{A}_{\rm class}$ separates $\tilde{a}$ and $\tilde{b}$.

Proof: Let $a=(\mathbf{u},\mathbf{p},\mathbf{v},\boldsymbol{\pi})\in\overline{\Gamma}_{\rm reg}$ and $b=(\mathbf{u}',\mathbf{p}',\mathbf{v}',\boldsymbol{\pi}')\in\overline{\Gamma}_{\rm reg}$ be representatives of, respectively, $\tilde{a}$ and $\tilde{b}$, each satisfying (2.13). As the pair $(\mathbf{u},\mathbf{p})$ is linearly independent, there exist $i\neq j$ such that $u_ip_j-u_jp_i\neq0$. It follows that $\tilde{a}\in\mathcal{M}_i\cap\mathcal{M}_j$. By assumption then $\tilde{b}\notin\mathcal{M}_i\cup\mathcal{M}_j$, which implies $u_i'=p_i'=u_j'=p_j'=0$. Hence $A_{ij}(\tilde{a})=u_ip_j-u_jp_i\neq0$ but $A_{ij}(\tilde{b})=u_i'p_j'-u_j'p_i'=0$, which shows that the observable A_{ij} in (2.9) separates $\tilde{a}$ and $\tilde{b}$. ■

Remark: Repeating the proof with $\tilde{a}$ and $\tilde{b}$ interchanged shows that points satisfying the conditions of Lemma C.1 exist only for $p\geqslant4$.

Theorem C.1: $\mathcal{A}_{\rm class}$ separates $\mathcal{M}_{\rm reg}$.

Proof: By Lemma C.1, it suffices to consider individually each $\mathcal{M}_k$.

From now on let $\mathcal{M}_k$ be fixed. We saw in Sec. II C 3 that $\mathcal{M}_{\rm reg}$ can be represented as the quotient of the set (2.13) under the $U(1)$ action given by (2.5) with (2.14). Within $\mathcal{M}_k$, each $U(1)$ equivalence class in (2.13) has a unique representative that satisfies $p_k=0$ and $u_k>0$. Performing on this representative a gauge transformation (2.5) with $g=\mathrm{diag}(u_k^{-1},u_k)$, we obtain a point in Γ satisfying

$$\begin{gathered}\mathbf{u}^2=\boldsymbol{\pi}^2>0,\quad \mathbf{p}^2=\mathbf{v}^2>0,\\ \mathbf{u}\cdot\mathbf{p}=\mathbf{v}\cdot\boldsymbol{\pi}=0,\\ p_k=0,\quad u_k=1.\end{gathered} \tag{C2}$$

It follows that $\mathcal{M}_k$ can be represented as the subset of Γ satisfying (C2).

Let now $\tilde{a},\tilde{b}\in\mathcal{M}_k$ such that $A(\tilde{a})=A(\tilde{b})$ for all $A\in\mathcal{A}_{\rm class}$. Let $a=(\mathbf{u},\mathbf{p},\mathbf{v},\boldsymbol{\pi})$ and $b=(\mathbf{u}',\mathbf{p}',\mathbf{v}',\boldsymbol{\pi}')$ be the respective representatives of $\tilde{a}$ and $\tilde{b}$ in the gauge (C2). We shall show that $a=b$. We use the basis (2.9) of $\mathcal{A}_{\rm class}$.

Consider the observables A_{ij}. From $A_{ij}(\tilde{a})=A_{ij}(\tilde{b})$ we obtain

$$u_ip_j-u_jp_i=u_i'p_j'-u_j'p_i', \tag{C3}$$

where $1\leqslant i\leqslant p$ and $1\leqslant j\leqslant p$. With $i=k$ and $j\neq k$, the gauge conditions (C2) show that (C3) reduces to $p_j=p_j'$. The gauge conditions (C2) imply directly that $p_k=p_k'$. Hence $\mathbf{p}=\mathbf{p}'$.

Multiplying (C3) by p_j and summing over j gives

$$\mathbf{p}^2u_i-(\mathbf{u}\cdot\mathbf{p})p_i=(\mathbf{p}\cdot\mathbf{p}')u_i'-(\mathbf{u}'\cdot\mathbf{p})p_i'. \tag{C4}$$

Using $\mathbf{p}=\mathbf{p}'$ and (C2), (C4) reduces to $u_i=u_i'$. Hence $\mathbf{u}=\mathbf{u}'$.

Consider then the observables C_{ij}. From $C_{ij}(\tilde{a})=C_{ij}(\tilde{b})$ we obtain

$$u_iv_j-p_i\pi_j=u_i'v_j'-p_i'\pi_j', \tag{C5}$$

where $1\leqslant i\leqslant p$ and $1\leqslant j\leqslant q$. With $i=k$, (C2) shows that (C5) reduces to $v_j=v_j'$. Hence $\mathbf{v}=\mathbf{v}'$.

Substituting $\mathbf{u}=\mathbf{u}'$, $\mathbf{p}=\mathbf{p}'$ and $\mathbf{v}=\mathbf{v}'$ in (C5) gives $p_i(\pi_j-\pi_j')=0$. As $\mathbf{p}^2>0$, this implies $\pi_j=\pi_j'$. Hence $\boldsymbol{\pi}=\boldsymbol{\pi}'$. ■

APPENDIX D: $\mathcal{A}^{(\star)}_{\text{phys}}$ ON $\mathcal{V}_{\text{phys}}$ FOR $p=q=3$

In this appendix we analyze the representation of $\mathcal{A}^{(\star)}_{\text{phys}}$ on $\mathcal{V}_{\text{phys}}$ for $p=q=3$, displayed in Table I. We show first that this representation is irreducible. We then show that the only inner products in which the star-relations (3.13) become adjoint relations are multiples of (3.14).

Proposition D.1: Let $U\subset\mathcal{V}_{\text{phys}}$ be a linear subspace invariant under $\mathcal{A}^{(\star)}_{\text{phys}}$, $U\neq\{0\}$. Then $U=\mathcal{V}_{\text{phys}}$.

Proof: Recall that the operator $\widehat{L^2}:=\hat{L}_0^2+\frac{1}{2}(\hat{L}_+\hat{L}_-+\hat{L}_-\hat{L}_+)$ satisfies $\widehat{L^2}\Psi_{lmn}=l(l+1)\Psi_{lmn}$. Let $u\in U$, $u\neq 0$. Then $u=\Sigma a_{lmn}\Psi_{lmn}$, where only finitely many a_{lmn} are nonzero. Let l_0 be the largest l for which some a_{lmn} is nonzero. Then $u^{(1)}:=\Pi_{l<l_0}[\widehat{L^2}-l(l+1)]u=k\Sigma_{mn}a_{l_0mn}\Psi_{l_0mn}$, where $k\neq 0$. Acting on $u^{(1)}$ finitely many times with $\hat{L}_+$ and $\hat{J}_+$ gives the vector $u^{(2)}=a^{(2)}\Psi_{l_0l_0l_0}\neq 0$, and $u^{(3)}:=(\hat{L}_-)^{l_0}(\hat{J}_-)^{l_0}u^{(2)}=a^{(3)}\Psi_{l_000}\neq 0$. Hence $\Psi_{l_000}\in U$.

A direct computation from Table I shows that $\hat{J}_-\hat{C}_1^+\Psi_{l00}-(l-1)\hat{C}_0\Psi_{l00}$ is a nonzero multiple of $\Psi_{l+1,00}$ for all l and $\hat{J}_-\hat{C}_1^+\Psi_{l00}+(l+1)\hat{C}_0\Psi_{l00}$ is a nonzero multiple of $\Psi_{l-1,00}$ for $l>0$. It follows by induction that $\Psi_{l00}\in U$ for all l. Acting on Ψ_{l00} with $\hat{L}_\pm$ and $\hat{J}_\pm$ shows that $\Psi_{lmn}\in U$ for all values of the indices. ■

Proposition D.2: Let $(\cdot,\cdot)$ *be an inner product in which the star-relations* (3.13) *become adjoint relations. Then* $(\Psi_{lmn},\Psi_{l'm'n'})=r(2l+1)\delta_{ll'}\delta_{mm'}\delta_{nn'}$, *where* r *is a positive constant.*

Proof: The adjointness relations imply that the operator $\widehat{L^2}$ introduced in the proof of Proposition D.1 is self-adjoint. Hence $l'(l'+1)(\Psi_{lmn},\Psi_{l'm'n'})=(\Psi_{lmn},\widehat{L^2}\Psi_{l'm'n'})=(\widehat{L^2}\Psi_{lmn},\Psi_{l'm'n'})=l(l+1)(\Psi_{lmn},\Psi_{l'm'n'})$, which shows that $(\Psi_{lmn},\Psi_{l'm'n'})$ vanishes for $l\neq l'$. By standard angular momentum techniques in the $\mathfrak{o}(3)$ subalgebras generated, respectively, by the $\hat{L}$'s and the $\hat{J}$'s (see, for example, Ref. 49), we then find

$$(\Psi_{lmn},\Psi_{l'm'n'})=A_l\delta_{ll'}\delta_{mm'}\delta_{nn'}, \tag{D1}$$

where A_l depends only on l.

To determine A_l, we use the self-adjointness of $\hat{C}_0$. Writing $\Psi_l:=\Psi_{l00}$ and using the action of $\hat{C}_0$ from Table I and (D1), we compute

$$\begin{aligned}\frac{(l+1)^2}{2l+1}A_l&=\frac{(l+1)^2}{2l+1}(\Psi_l,\Psi_l)\\&=(\Psi_l,\hat{C}_0\Psi_{l+1})\\&=(\hat{C}_0\Psi_l,\Psi_{l+1})\\&=\frac{(l+1)^2}{2l+3}(\Psi_{l+1},\Psi_{l+1})\\&=\frac{(l+1)^2}{2l+3}A_{l+1},\end{aligned} \tag{D2}$$

from which by induction $A_l=(2l+1)A_0$. ■

APPENDIX E: CONVERGENCE OF THE GROUP AVERAGING

In this appendix we provide the group averaging convergence results needed in the main text. When not mentioned otherwise, p and q are arbitrary positive integers.

To begin, consider $U(g)\Psi_{ljmnk_uk_v}$. Writing g in the Iwasawa decomposition (A3), (4.2) gives

$$U(g)=\exp(-i\mu\hat{H}_2)\exp(-i\lambda\hat{D})\exp(-i\theta(\hat{H}_1-\hat{H}_2)). \tag{E1}$$

As $\Psi_{ljmnk_uk_v}$ is an eigenstate of $\hat{H}_1-\hat{H}_2$ with eigenvalue E_u-E_v, (4.3) yields

$$U(g)\Psi_{ljmnk_uk_v}=\frac{z^{(\tilde{j}-\tilde{l})/2}e^{-i\theta(E_u-E_v)}}{(2\pi i\mu)^{q/2}}Y_{lk_u}(\theta^{(u)})\int_0^\infty dv'\,u^l(v')^{j+q-1}L_m^{\tilde{l}}(u^2/z)L_n^{\tilde{j}}(z(v')^2)$$
$$\times\exp\left[-\frac{1}{2}\left(\frac{u^2}{z}+z(v')^2\right)+\frac{i}{2}\left(\mu u^2+\frac{v^2+(v')^2}{\mu}\right)\right]$$
$$\times\int d\Omega_{v'}\exp\left(-\frac{i}{\mu}(\mathbf{v}\cdot\mathbf{v}')\right)Y_{jk_v}(\theta^{(v')}), \tag{E2}$$

where $z:=e^{2\lambda}$ and we are assuming $\mu\neq 0$, $\mathbf{v}\neq\mathbf{0}$ and $\mathbf{u}\neq\mathbf{0}$.

We need to evaluate the angular integral in (E2). Suppose $q>2$. We write $\mathbf{v}\cdot\mathbf{v}'=vv'\cos\gamma$ and expand the exponential under the angular integral by (Ref. 44, p. 98)

$$e^{it\cos\gamma}=\frac{1}{2}\Gamma\left(\frac{q-2}{2}\right)\sum_{a=0}^{\infty}i^a(2a+q-2)\frac{J_{(q-2+2a)/2}(t)}{(t/2)^{(q-2)/2}}C_a^{(q-2)/2}(\cos\gamma). \tag{E3}$$

We then expand the Gegenbauer polynomial $C_a^{(q-2)/2}(\cos\gamma)$ as

$$C_a^{(q-2)/2}(\cos\gamma)=\frac{4\pi^{q/2}}{\Gamma((q-2)/2)(2a+q-2)}\sum_k Y_{ak}(\theta^{(v)})\overline{Y_{ak}(\theta^{(v')})}, \tag{E4}$$

which follows from formula 11.4(2) in Ref. 43 (correcting a typographical error in the normalization factor, as seen from the final step of the proof on p. 247). Using the orthonormality of the spherical harmonics, we obtain

$$\int d\Omega_{v'}\exp\left(-\frac{i}{\mu}(\mathbf{v}\cdot\mathbf{v}')\right)Y_{jk_v}(\theta^{(v')})=(2\pi)^{q/2}i^{-j}\left(\frac{vv'}{\mu}\right)^{(2-q)/2}J_{(q-2+2j)/2}(vv'/\mu)Y_{jk_v}(\theta^{(v)}). \tag{E5}$$

For $q=2$, (E5) follows by recognizing the angular integral as a representation of J_j, and for $q=1$ it follows from the relation of $J_{\pm 1/2}$ to trigonometric functions (Ref. 43, Secs. 7.3.1 and 7.11). Hence, for all $p\geqslant 1$ and $q\geqslant 1$, we have

$$U(g)\Psi_{ljmnk_uk_v}=\frac{i^{-\tilde{j}-1}z^{(\tilde{j}-\tilde{l})/2}e^{-i\theta(E_u-E_v)}}{\mu}Y_{lk_u}(\theta^{(u)})Y_{jk_v}(\theta^{(v)})\,u^{(2-p)/2}v^{(2-q)/2}$$
$$\times\int_0^\infty dv'\,u^{\tilde{l}}(v')^{\tilde{j}+1}J_{\tilde{j}}(vv'/\mu)L_m^{\tilde{l}}(u^2/z)L_n^{\tilde{j}}(z(v')^2)$$
$$\times\exp\left[-\frac{1}{2}\left(\frac{u^2}{z}+z(v')^2\right)+\frac{i}{2}\left(\mu u^2+\frac{v^2+(v')^2}{\mu}\right)\right]. \tag{E6}$$

Performing the integral in (E6) gives (Ref. 50, formula 7.421.4)

$$U(g)\Psi_{ljmnk_uk_v}=e^{-i\theta(E_u-E_v)}z^{(\tilde{j}-\tilde{l})/2}(1+i\mu z)^{-\tilde{j}-1}\left(\frac{1-i\mu z}{1+i\mu z}\right)^n Y_{lk_u}(\theta^{(u)})Y_{jk_v}(\theta^{(v)})$$
$$\times u^l v^j L_m^{\tilde{l}}(u^2/z)\,L_n^{\tilde{j}}\left(\frac{zv^2}{1+\mu^2z^2}\right)\times\exp\left[-\frac{1}{2}\left(\frac{1}{z}-i\mu\right)u^2-\frac{1}{2}\left(\frac{z}{1+i\mu z}\right)v^2\right]. \tag{E7}$$

We can now use (E7) to prove the convergence results.

Proposition E.1: Let $\tilde{l}+\tilde{j}>0$. *Then* $(\Psi_{l'j'm'n'k_u'k_v'}, U(g)\Psi_{ljmnk_uk_v})_{\text{aux}}$ *is integrable in absolute value over* G.

Proof: It suffices to consider $l'=l$, $j'=j$, $k_u'=k_u$ and $k_v'=k_v$, for otherwise the integrand vanishes.

In $\overline{\Psi_{ljm'n'k_uk_v}}U(g)\Psi_{ljmnk_uk_v}$, we use (4.4) and (E7) and expand the product of the generalized Laguerre polynomials as a sum of numerical constants times terms of the form

$$(u^2)^{r'}(v^2)^{s'}\left(\frac{u^2}{z}\right)^{r}\left(\frac{zv^2}{1+\mu^2z^2}\right)^{s}, \tag{E8}$$

where r, s, r' and s' are non-negative integers. Integrating over **u** and **v** term by term, we find that $(\Psi_{ljm'n'k_uk_v}, U(g)\Psi_{ljmnk_uk_v})_{\text{aux}}$ is a sum of terms whose respective absolute values are numerical constants times

$$\frac{z^{(\tilde{l}+\tilde{j})/2+1+s+r'}(1+\mu^2z^2)^{(s'-s)/2}}{[(z+1)^2+\mu^2z^2]^{1+(\tilde{l}+\tilde{j}+r+r'+s+s')/2}}. \tag{E9}$$

An elementary analysis shows that sufficient conditions for (E9) to be integrable over G in the Haar measure $e^{2\lambda}\,d\lambda\,d\mu\,d\theta=\frac{1}{2}dz\,d\mu\,d\theta$ are

$$\begin{aligned}\tilde{l}+\tilde{j}+2r+2s&>0,\\ \tilde{l}+\tilde{j}+1+r+2s&>0,\end{aligned} \tag{E10}$$

which hold since $\tilde{l}+\tilde{j}>0$ by assumption. ■

Proposition E.2: Let $\tilde{l}+\tilde{j}>0$ *and* $p+q\equiv 1 \pmod 2$. *Then the value of the integral in Proposition E.1 is zero.*

Proof: As $p+q\equiv 1 \pmod 2$, G is the double cover of $\mathrm{SL}(2,\mathbb{R})$ and the range of θ in (E1) is θ is $0\leqslant\theta<4\pi$. By Proposition E.1, we may perform the integral over θ first, and the θ-dependence in (E7) shows that this integral evaluates to zero. ■

Theorem E.3: *Let* $p\geqslant 2$, $q\geqslant 2$ *and* $p+q>4$. *Then the integral in (4.8) converges in absolute value for all* $\phi_1,\phi_2\in\Phi$. *If* $p+q\equiv 1 \pmod 2$, *the value of the integral is zero.*

Proof: It suffices to consider $\phi_1,\phi_2\in\{\Psi_{ljmnk_uk_v}\}$. The inequalities on p and q imply that the conditions of Propositions E.1 and E.2 are satisfied. ■

Proposition E.4: Let $\tilde{l}>0$ *and* $\tilde{j}>0$. *Then* $\overline{\Psi_{ljm'n'k_uk_v}}U(g)\Psi_{ljmnk_uk_v}$ *is integrable in absolute value over* $G\times\mathbb{R}^{p+q}$.

Proof: In $\overline{\Psi_{ljm'n'k_uk_v}}U(g)\Psi_{ljmnk_uk_v}$, we use (4.4) and (E7), expand the product of the generalized Laguerre polynomials as in the proof of Proposition E.1 and consider the individual terms in this expansion. We now *first* take the absolute value and then integrate. The integrals over θ, $\theta^{(u)}$ and $\theta^{(v)}$ are bounded by constants, the integrals over u and v are convergent and easily performed, and an elementary analysis shows that the remaining $\int dz\,d\mu$ integral is convergent provided $\tilde{l}>0$ and $\tilde{j}>0$. ■

Theorem E.5: *Let* $p=1$, $q=3$ *and let* Φ^{mod} *be as in Sec. V B. Then the integral in (4.8) converges in absolute value for all* $\phi_1,\phi_2\in\Phi^{\text{mod}}$.

Proof: The only case not covered by Proposition E.1 is $\phi_1=\psi_{mn}$, $\phi_2=\psi_{m'n'}$.

In $\overline{\psi_{m'n'}}U(g)\psi_{mn}$, we use (5.12), (5.13) and (E7) and expand the generalized Laguerre polynomials of argument u^2/z and $zv^2/(1+\mu^2z^2)$ as polynomials in their respective arguments. Inequalities (E10) in the proof of Proposition E.1 show that it suffices to keep only the constant

terms of these polynomials. Doing this, and integrating over u_1 and $\mathbf{v}$ by 7.414.8 in Ref. 50, we obtain two terms whose absolute values are numerical constants times

$$\frac{z^2}{[(z+1)^2+\mu^2 z^2]^2}\times\left[\frac{(z-1)^2+\mu^2 z^2}{(z+1)^2+\mu^2 z^2}\right]^{(m'+n')/2}, \tag{E11}$$

which is integrable in the measure $dz\,d\mu$. ■

(Received 26 September 2003; accepted 9 February 2004; published 5 April 2004)

New theorems on properties of the generalized functions defined on Gelfand–Shilov's spaces S^0_α are established. These functional classes are universal for the operator realization of quantum field theories whose infrared or/and ultraviolet behavior is more singular than that of the standard Wightman quantum field theories (QFT's). The leading role in these applications is played by the notion of a carrier cone of analytic functional which generalizes and replaces the notion of support of distribution. An explicit representation for the generalized functions with a given carrier cone is obtained. It is proved that the restrictions of functionals defined on S^0_α to the spaces with smaller subscripts have the same carrier cones. The precise characterization of the relation between the carrier cones of multilinear forms with respect to their arguments and the carrier cones of their associated generalized functions is given. Applications of the obtained results to indefinite metric QFT and to nonlocal models are discussed. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1695094]

I. INTRODUCTION

In this paper, we present some results concerning the generalized function classes required for the operator realization and nonperturbative investigation of quantum field theory (QFT) models with singular infrared or/and ultraviolet behavior. These classes are considerably wider than that of tempered distributions used originally for formulating the general principles of QFT,[1,2] and than those of ultradistributions corresponding to the strictly localizable Jaffe fields.[3] Moreover, they provide a means for the efficient treatment of singularities much more severe than those of hyperfunctions proposed for further elaborating the axiomatic approach and, particularly, establishing a more symmetrical relation between QFT in Minkowski space–time and Euclidean field theory.[4] The suitable test function spaces are S^β_α introduced by Gelfand and Shilov,[5] with the superscript satisfying $\beta<1$. The spaces S^0_α are minimal among them, and their dual spaces S'^0_α consisting of continuous linear functionals defined on S^0_α provide us with the most general framework for constructing the mentioned QFT models. The properties of functionals of this class are just the subject of our investigation. The theorems established below have obvious analogues for $0<\beta<1$ and the proofs are even simpler in that case. The space S'^0_α is exactly the Fourier-transformed space of Roumieu's ultradistributions[6] of class $\{k^{\alpha k}\}$ and the study of its properties is also interesting from this viewpoint.

The highly singular generalized functions have long been used in the theory of nonlocal interactions for generalizing the Wightman axiomatic approach (see, e.g., Ref. 7 for a review) as well as for constructing phenomenological models.[8] At present this is perhaps the best developed branch of nonlocal QFT which is interesting in view of a possible interplay with string theory and even proposed as an alternative to string theory.[9] There are also attempts to connect it with noncommutative field theory.[10,11] The main motivation for the study of generalized function classes S'^0_α is the desire to obtain a generalization of the distributional and hyperfunctional cal-

a)Electronic mail: soloviev@lpi.ru

culus required for the consistent quantization of gauge theories in a generic covariant gauge. The relevance of Gelfand–Shilov's spaces to this problem was first pointed out by Moschella and Strocchi.[12,13] In particular, the use of them enables one to obtain the complete operator realization[14,15] of the Wick-ordered entire functions of indefinite metric free fields that enter as building blocks in the exact solutions of some simple gauge models.

In nonlocal field theory, the singularities are ultraviolet by their nature and fields are well defined on averaging with configuration-space test functions belonging to S_α^β with a suitable $\beta<1$. On the contrary, when dealing with gauge theories and indefinite metric infrared singularities, we have to use such test functions in momentum space. In both cases, the main difficulty is that these functions are analytic and cannot vanish in any nontrivial domain. Because of this, the possibility of the proper generalization of the microcausality axiom in the former case and of the spectral condition in the latter is not immediately evident. It has been shown,[16,17] however, that an angular localizability property is preserved even for $\beta=0$ and every functional $v\in S_\alpha'^0$ has a unique minimal carrier cone which can be called the "quasisupport" of v. It is natural to use this notion for the mentioned generalizations. As shown in Ref. 18, there is an interrelation between this notion and the concept of analytic wave front set of ultradistribution. By taking this fact into account, it has been possible to construct a new derivation[18,19] of the CPT and spin-statistics theorems which covers nonlocal quantum fields with arbitrary high energy behavior. This approach was also applied[20] to Euclidean formulation of QFT without positivity[21] and an appropriate generalization of the reconstruction theorem was suggested.

However, there are several questions concerning properties of the generalized functions of the class $S_\alpha'^0$, which have not been given due attention although they are important for further developments. The aim of this paper is to give the complete and clear answers to three of them.

In Sec. II, on doing some preliminaries, we derive a structure theorem for elements of $S_\alpha'^0$ with a given carrier cone. It is well known that the structure of usual Schwartz's distributions supported by a closed set M is described by the representation

$$(v,f)=\sum_{|q|\leqslant N}\int D^q f\,\mathrm{d}\mu_q,$$

where μ_q are measures of tempered growth, whose supports can be chosen contained in M if this set satisfies some regularity conditions. This representation is widely used in applications and was generalized to ultradistributions.[6,22] An analogous representation for elements of $S'^0=S_\infty'^0$ was assumed in some works[23] on nonlocal QFT. However, as explained in Ref. 18, its rigorous derivation from the basic definitions, e.g., from those of Refs. 16 and 17 is a nontrivial task. The main difficulty in deriving such representations, which has been pointed by Komatsu[22] and is often overlooked by other authors, lies in the need of proving the equivalence of two natural but a priori different topologies on a subspace of an inductive limit, see below. To our knowledge, there is no consideration of this issue for $S_\alpha'^0$ in the existing literature. It should be emphasized that the structure theorem of Sec. II is helpful in actual applications, for instance, it is required for extending the theory of Lorentz invariant distributions to the functional classes under study, see Ref. 24.

In Sec. III we consider the relation between the carrier properties of a multilinear form w defined on $S_\alpha^0(\mathbb{R}^{d_1})\times\cdots\times S_\alpha^0(\mathbb{R}^{d_n})$ and those of the generalized function v determined by w on $S_\alpha^0(\mathbb{R}^{d_1+\cdots+d_n})$ by the nuclear theorem. In the QFT context, w is a vacuum expectation value and v is the corresponding Wightman function. If w regarded as a functional of $f_j\in S_\alpha^0(\mathbb{R}^{d_j})$, with other variables held fixed, is carried by K_j, then the product $K_1\times\cdots\times K_n$ is a carrier of v, but these two properties proved to be nonequivalent. So, the situation is distinct from the case of the usual distributions and this raises the question of what really is the relevant property of v. This point is important for the extension[20] of the Osterwalder–Schrader theory to infrared singular fields. Moreover, a similar subtlety should be taken into account in deriving the reconstruction theorem for QFT in terms of Fourier hyperfunctions. Since translating the carrier properties of w

into those of v presents difficulties and this procedure was not described anywhere, we will perform it in a simple manner, by using the uniform boundedness principle.

In Sec. IV, we show that the notion of carrier cone is independent of the index α specifying the test function space. More precisely, we prove that the restriction of $v \in S'^0_\alpha$ to any nontrivial smaller space $S^0_{\alpha'}$, $\alpha' < \alpha$, has the same carrier cones as v. Such a proof is also lacking in the literature, although this question is not only of theoretical significance but raises in concrete applications. For instance, it faces us in proving[19] that the vacuum expectation value $\langle \Phi_0, [\phi(x), \phi(x')]_{\overset{-}{(+)}} \Psi_0 \rangle$, where ϕ is a nonlocal field of the class S'^0_α with an integer (half-integer) spin, is carried by the closed cone $\{(x,x') \in \mathbb{R}^8 : (x-x')^2 \geqslant 0\}$.

We will attempt to elucidate the above questions with a minimal amount of technical work. In particular, where possible, we use the language of Hilbert space theory familiar to theoretical physicists and apply theorem quoting proofs. Some technical details are moved to the Appendix. The final section contains conclusions and outlook.

II. STRUCTURE THEOREM

We start by recalling the original definition[5] of the space $S^0_\alpha(\mathbb{R}^d)$. It consists of all smooth functions on $\mathbb{R}^d$ such that

$$|D^q f(x)| \leqslant C b^{|q|} e^{-|x/a|^{1/\alpha}}, \tag{1}$$

where C, a, b are positive constants depending on f. The choice of norm in $\mathbb{R}^d$ is inessential here because all these norms are equivalent, and it can be adapted to each specific application. The space is nontrivial for $\alpha > 1$ only, and this condition is supposed to be met throughout what follows. The definition of $S^0_\alpha(\mathbb{R}^d)$ can be reformulated in terms of complex variables since every element of this space allows an analytic continuation to the whole of $\mathbb{C}^d$ and the resulting entire functions satisfy the estimate $|f(x+iy)| \leqslant C \exp\{-|x/a|^{1/\alpha} + b|y|\}$. Analogous spaces can be associated[16,17] with cones in $\mathbb{R}^d$. Namely, if $U \subset \mathbb{R}^d$ is an open cone, then $S^0_\alpha(U)$ is defined to be the space of all smooth functions on $\mathbb{R}^d$ satisfying (1) for $x \in U$. It is natural to regard this space as the inductive limit of the Banach spaces $S^{0,b}_{\alpha,a}(U)$ whose norms are defined by

$$\|f\|_{U,a,b} = \sup_{x \in U} \sup_{q \in \mathbb{Z}^d_+} |b^{-|q|} \partial^q f(x)| \, e^{|x/a|^{1/\alpha}}, \tag{2}$$

where $\mathbb{Z}_+$ is the set of non-negative integers. This limit coincides with that of the Banach spaces $E^{0,b}_{\alpha,a}(U)$ of entire functions endowed with the norms

$$\|f\|'_{U,a,b} = \sup_{z \in \mathbb{C}^d} |f(z)| \exp\{|x/a|^{1/\alpha} - b\,\delta_U(x) - b|y|\} \quad (z = x+iy), \tag{3}$$

where $\delta_U(x)$ is the distance of x from U.

A closed cone $K \subset \mathbb{R}^d$ is said to be a carrier of $v \in S'^0_\alpha$ if v can be continuously extended to each of $S^0_\alpha(U)$, where $U \supset K \setminus \{0\}$. (If this inclusion holds, we say that K is compact in U and use also the notation $U \ni K$.[25]) Taking into account that S^0_α is dense in every space $S^0_\alpha(U)$,[17] this means that v belongs to the dual space of the inductive limit $S^0_\alpha(K) = \varinjlim_{U \ni K} S^0_\alpha(U)$, which is identified with a vector subspace of S'^0_α. In order to gain a better insight into the construction of Sec. III, we remark that $\{U : U \ni K\}$ is a directed set and $S^0_\alpha(U)$ is an increasing family of spaces only if the closed cone K is nondegenerate. For the degenerate cone consisting of the origin, its associated space $S^0_\alpha(\{0\})$ is the space of all entire analytic functions of order 1 and finite type, i.e., satisfying the estimate $|f(z)| \leqslant C e^{b|z|}$, $z \in \mathbb{C}^d$. By Theorem 6 of Ref. 16 every element $f \in S^0_\alpha(\{0\})$ allows the decomposition $f = f_+ + f_-$, where $f_\pm \in S^0_\alpha(U_\pm)$ and $U_\pm$ are arbitrary open

cones such that $\overline{U}_+ \cap \overline{U}_- = \{0\}$. Because of this, the inductive topology on $S^0_\alpha(\{0\})$ determined by the canonical injections $S^0_\alpha(U) \to S^0_\alpha(\{0\})$, where U runs through all open cones, coincides with that determined by the two injections $S^0_\alpha(U_\pm) \to S^0_\alpha(\{0\})$.

The space $S^0_\alpha(U)$ can also be represented[16] as the inductive limit of the Hilbert spaces $H^{0,b}_{\alpha,a}(U)$ of entire functions with the scalar products

$$\langle f, g\rangle_{U,a,b} = \int \overline{f(z)}\, g(z)\, e^{2(|x/a|^{1/\alpha} - b\,\delta_U(x) - b|y|)}\, \mathrm{d}x\, \mathrm{d}y. \tag{4}$$

As a consequence, it is a nuclear DFS space, i.e., strong dual of a nuclear Fréchet–Schwartz space. Spaces of this type, for which the abbreviation DFN is also used, have nice topological properties convenient in applications and exploited below. In particular, we will use Pták's version[26] of the open mapping theorem, which shows that every continuous linear mapping of a DFS space onto a barrelled space is open. Clearly, an analogous representation is possible in terms of real variables and that is just what we need now. Let $L^{0,b}_{\alpha,a}(U)$ be the space of all infinitely differentiable functions on $\mathbb{R}^d$ for which the norm corresponding to the scalar product

$$(f, g)_{U,a,b} = \sum_q\ b^{-2|q|} \int_U \overline{\partial^q f(x)}\, \partial^q g(x)\, e^{2|x/a|^{1/\alpha}}\, \mathrm{d}x \tag{5}$$

is finite.

Lemma 1: For any open cone U, the space $S^0_\alpha(U)$ coincides with the inductive limit $\lim_{\to} L^{0,b}_{\alpha,a}(U)$ $(a,b \to \infty)$.

For the proof we refer to Appendix A.

Theorem 1: *Let U be an open cone in $\mathbb{R}^d$. Every $v \in S'^0_\alpha(U)$ can be written as*

$$v(f) = \sum_q\ \int_U v_q(x)\, \partial^q f(x)\, \mathrm{d}x, \tag{6}$$

where v_q are locally integrable functions satisfying the condition

$$\sum_q\ b^{|q|} \int_U |v_q(x)|\, e^{-|x/a|^{1/\alpha}}\, \mathrm{d}x < \infty \quad \textit{for all} \quad a,b>0. \tag{7}$$

In particular, such a representation is valid for any functional of class S'^0_α whose quasisupport is contained in $U \cup \{0\}$.

Proof: Lemma 1 enables us to reduce the derivation of this representation to Riesz's theorem characterizing the dual of a Hilbert space. At first we replace the exponential that occurs in definition (5) by the function $(1+|x|)^{-2d} \Sigma_{k \in \mathbb{Z}^d_+} x^{2k} a^{-2|k|} k^{-2\alpha k}$. This leaves the limit space $\lim_{\to} L^{0,b}_{\alpha,a}(U)$ unaltered because

$$c \exp\left(\frac{2\alpha}{e} \sum_{j=1}^d |x_j|^{1/\alpha}\right) \leqslant \sum_k \frac{x^{2k}}{k^{2\alpha k}} \leqslant C_\epsilon \exp\left(\frac{2\alpha}{e} \sum_{j=1}^d |(1+\epsilon)x_j|^{1/\alpha}\right),$$

where $\epsilon > 0$ can be taken arbitrarily small. For the spaces modified in such a way, we keep the same notation $L^{0,b}_{\alpha,a}(U)$ and introduce another family of Hilbert spaces. Namely, let $\mathcal{L}^{0,b}_{\alpha,a}(U)$ be the space consisting of twice multi-indexed sequences $F = \{f_{kq}\}$ of square-integrable functions on U and endowed with the scalar product

$$(G, F)_{U,a,b} = \sum_{k,q}\ a^{-2|k|} b^{-2|q|} k^{-2\alpha k} \int_U \overline{g_{kq}(x)}\, f_{kq}(x)\, \mathrm{d}x. \tag{8}$$

Then $L^{0,b}_{\alpha,a}(U)$ is identified with a subspace of $\mathcal{L}^{0,b}_{\alpha,a}(U)$ by means of the mapping

$$i: f \to f_{kq} = (1+|x|)^{-d} x^k \partial^q f. \tag{9}$$

This subspace, being complete, is evidently closed. Let us provide the image of $\varinjlim L^{0,b}_{\alpha,a}(U)$ in $\varinjlim \mathcal{L}^{0,b}_{\alpha,a}(U)$ with the topology induced by that of the latter space.

Lemma 2: The space $\varinjlim L^{0,b}_{\alpha,a}(U)$ *has the same continuous dual space as the subspace* $i(\varinjlim L^{0,b}_{\alpha,a}(U))$ *of* $\varinjlim \mathcal{L}^{0,b}_{\alpha,a}(U)$.

Proof: For brevity we introduce the designations,

$$L_\nu = L^{0,\nu}_{\alpha,\nu}(U), \quad \mathcal{L}_\nu = \mathcal{L}^{0,\nu}_{\alpha,\nu}(U) \quad (\nu = 1,2,\dots), \quad L = \varinjlim L_\nu, \quad \mathcal{L} = \varinjlim \mathcal{L}_\nu.$$

Since the unit closed ball in a Hilbert space is weakly compact, the continuous injections $\mathcal{L}_\nu \to \mathcal{L}_{\nu+1}$ are evidently weakly compact. Therefore the statement of interest follows from Theorem 7 of Ref. 27. To apply it, we only need to verify that L is closed in $\mathcal{L}$. Let $F \in \mathcal{L}_\mu \backslash L$. Since L_μ is closed in $\mathcal{L}_\mu$, there exists a ball $\mathcal{B}_\mu = \{G \in \mathcal{L}_\mu : \|G\|_\mu \leqslant \epsilon\}$ such that $(F+\mathcal{B}_\mu) \cap L_\mu = \varnothing$. The mapping $\mathcal{L}_\mu \to \mathcal{L}_{\mu+1}$ is continuous under the weak topologies, therefore $\mathcal{B}_\mu$ is weakly compact not only in $\mathcal{L}_\mu$ but also in $\mathcal{L}_{\mu+1}$. The subspace $L_{\mu+1}$ does not meet $F+\mathcal{B}_\mu$, because $L_{\mu+1} \cap \mathcal{L}_\mu = L_\mu$, and so $0 \notin F+\mathcal{B}_\mu+L_{\mu+1}$. Furthermore $L_{\mu+1}$ is weakly closed in $\mathcal{L}_{\mu+1}$ since subspaces have the same closure under any topology consistent with duality. By Theorem I.1.1 of Ref. 26, the set $F+\mathcal{B}_\mu+L_{\mu+1}$ is also weakly closed. Hence, there is a ball $\mathcal{B}_{\mu+1} = \{G \in \mathcal{L}_{\mu+1} : \|G\|_{\mu+1} \leqslant \epsilon_1\}$ such that $\mathcal{B}_{\mu+1} \cap (F+\mathcal{B}_\mu+L_{\mu+1}) = \varnothing$ or, equivalently, $(F+\mathcal{B}_\mu+\mathcal{B}_{\mu+1}) \cap L_{\mu+1} = \varnothing$. The set $\mathcal{B}_\mu+\mathcal{B}_{\mu+1}$ is absolutely convex and weakly compact in $\mathcal{L}_{\mu+1}$ as well as in $\mathcal{L}_{\mu+2}$. We proceed along the same lines and obtain an increasing sequence of absolutely convex neighborhoods $\mathcal{U}_\nu$ of F in the spaces $\mathcal{L}_\nu$, $\nu \geqslant \mu$, such that $\mathcal{U}_\nu$ are disjoint with L_ν. The subspace L does not meet their union which is a neighborhood of F in $\mathcal{L}$ by the definition of inductive topology. Therefore, L is indeed closed in $\mathcal{L}$ and Lemma 2 is proved.

Thus, every $v \in S'^0_\alpha(U)$ may be regarded as a continuous linear form on a subspace of $\varinjlim \mathcal{L}^{0,b}_{\alpha,a}(U)$ and, by the Hahn–Banach theorem, it has a continuous extension $\hat{v}$ to the whole space. Now the Riesz theorem shows that, for every a and b, there is a unique $G \in \mathcal{L}^{0,b}_{\alpha,a}(U)$ such that $\hat{v}(F) = (G,F)_{U,a,b}$ for all $F \in \mathcal{L}^{0,b}_{\alpha,a}(U)$. Using the designation $h_{kq} = a^{-2|k|} b^{-2|q|} k^{-2\alpha k} g_{kq}$, this may be rewritten as

$$\hat{v}(F) = \sum_{k,q} \int_U \overline{h_{kq}(x)} f_{kq}(x)\, \mathrm{d}x\,. \tag{10}$$

The functions h_{kq} belong to $L^2(U)$ and do not depend on a and b. In fact, each of h_{kq} is entirely determined by the values of $\hat{v}$ on those F all of whose components are zero except f_{kq} which is an arbitrary element of $L^2(U)$, and all such F's are contained in every space $\mathcal{L}^{0,b}_{\alpha,a}(U)$. Substituting the specified F's in (10), setting $f_{kq} = h_{kq}$ and using the continuity of $\hat{v}$ on $\mathcal{L}^{0,b}_{\alpha,a}(U)$, we obtain

$$|\hat{v}(h_{kq})| = \|h_{kq}\|^2_{L^2(U)} \leqslant C\|h_{kq}\|_{U,a,b} = Ca^{-|k|} b^{-|q|} k^{-\alpha k} \|h_{kq}\|_{L^2(U)}\,. \tag{11}$$

Taking into account that (11) holds for any positive a and b (although with different constants C), we can change a for $2a$ and b for $2b$ and obtain

$$\sum_{k,q} a^{|k|} b^{|q|} k^{\alpha k} \|h_{kq}\|_{L^2(U)} < \infty, \tag{12}$$

which again is valid for all a, b. When being applied to elements of the initial space by the embedding rule (9), Eq. (10) takes the form

$$v(f)=\sum_{k,q}\int x^k v_{kq}(x)\,\partial^q f(x)\,\mathrm{d}x, \tag{13}$$

where $v_{kq}(x)\overset{\text{def}}{=}(1+|x|)^{-d}\overline{h_{kq}(x)}$. These functions are integrable on U and, applying Schwarz's inequality, we see that (12) holds true after replacing $\|h_{kq}\|_{L^2(U)}$ by $\|v_{kq}\|_{L^1(U)}$. Then making use of the inequality $k^{\alpha k}/|x^k|\geqslant\exp\{-(\alpha d/e)|x|^{1/\alpha}\}$, we conclude that

$$\sum_{k,q} b^{|q|}\int |x^k v_{kq}(x)|\,e^{-|x/a|^{1/\alpha}}\,\mathrm{d}x<\infty,$$

where a and b are arbitrary positive numbers as before. By Levi's theorem, the convergence of the number series $\Sigma_k\int|x^k v_{kq}|\exp\{-|x/a|^{1/\alpha}\}\,\mathrm{d}x$ implies that the series $\Sigma_k|x^k v_{kq}|$ converges almost everywhere to a function integrable with the weight $\exp\{-|x/a|^{1/\alpha}\}$. Calling this function v_q and performing the k summation in (13), which is possible by the same argument, we arrive at (7) and finish the proof.

The above derivation is vastly simplified in the case of functionals carried by the origin. By means of the mapping $f\to f_q=\partial^q f(0)$, the space $S^0_\alpha(\{0\})$ is identified with the inductive limit of the Hilbert spaces whose elements are sequences of complex numbers satisfying $\Sigma b^{-|q|}|f_q|^2<\infty$. Therefore, every $v\in S'^0_\alpha(\{0\})$ can be written as $\Sigma v_q\partial^q\delta(x)$. Clearly, the analogue of (7) is of the form $\lim_{|q|\to\infty}|v_q|^{1/|q|}=0$. This simple fact is helpful, for instance, in proving[24] that every Lorentz invariant functional $v\in S'^0_\alpha(\mathbb{R}^4)$ carried by the closed light cone $\overline{\mathbb{V}}$ admits a Lorentz invariant splitting into two functionals of the same class with carriers $\overline{\mathbb{V}}_+$ and $\overline{\mathbb{V}}_-$.

Remark 1: Komatsu's theorem[27] is called for the derivation of representation (6) because in general the topology induced on a subspace by an inductive limit topology is different from the inductive limit of induced topologies. That theorem shows that the discrepancy between these topologies is unessential in the case of injective limits of weakly compact sequences of locally convex spaces. The replacement of the Banach spaces with the original norms (2) by an equivalent sequence of Hilbert spaces makes it possible to exploit this property. We could show that $S^0_\alpha(U)$ is topologically isomorphic to its image in $\varinjlim\mathcal{L}^{0,b}_{\alpha,a}(U)$, but there is no need to appeal to this more subtle fact here.

Remark 2: The case $\beta>0$ differs only by the additional factor $q^{\beta q}$ on the right-hand sides of the analogues of (6) and (7). When $\beta>1$, the use of measures instead of integrable functions is preferable, because their supports can be chosen contained in $\operatorname{supp} v$. However, this gives no advantage in the nonlocalizable case $\beta<1$. The results of the next section show that not every $v\in S'^0_\alpha(K)$ admits a representation like (6) with measures supported by K.

When applied to the vacuum expectation values in QFT's with singular infrared or ultraviolet behavior, Theorem 1 exhibits their structure and distinguishing features as opposed to those of the usual Wightman functions.[1,2] In extending the axiomatic approach to fields whose infrared singularities violate positivity, it is natural to assume that the Wightman functions $w_n(x_1,\ldots,x_n)$ are well defined as ultradistributions of class $\{k^{\alpha k}\}$ with a suitable α. Then the most general formulation of spectral condition is the requirement that the Fourier transforms of the functionals W_n related to the translation invariant w_n's by $W_{n-1}(x_1-x_2,\ldots,x_{n-1}-x_n)=w_n(x_1,\ldots,x_n)$ be carried by the closed cone $\overline{\mathbb{V}}_+^{(n-1)}$, where $\overline{\mathbb{V}}_+=\{p\in\mathbb{R}^4: p^2\geqslant 0, p_0\geqslant 0\}$. A Paley–Wiener–Schwartz-type theorem[17] shows that this condition makes possible the analytic continuation of the Wightman functions into the usual domains containing Euclidean points and moreover, it is the weakest one ensuring such an analyticity. On the other hand, dealing with nonlocal ultraviolet singular fields $\{\phi_\iota\}$ defined on $S^0_\alpha(\mathbb{R}^4)$ in configuration representation, we say that ϕ_ι and $\phi_{\iota'}$ commute (anticommute) asymptotically for large spacelike separations of their arguments if the functional $\langle\Phi,[\phi_\iota(x),\phi_{\iota'}(x')]_{-\atop(+)}\Psi\rangle$ is carried by the closed cone

$$\{(x,x') \in \mathbb{R}^8 : (x-x')^2 \geqslant 0\} \tag{14}$$

for any Φ, Ψ belonging to the cyclic space D_0 generated from the vacuum by polynomials in the fields $\{\phi_\iota\}$. Theorem 1 clarifies, in particular, the relation between the asymptotic commutativity and some other generalizations of local commutativity which were proposed for extending the PCT and spin-statistics theorems to nonlocal fields. In particular, a representation similar to (6) was assumed and exploited[23] for functionals defined on $S^0 = S^0_\infty$. However this space is not a DFS space and has more complicated topological structure, which leaves open the question of rigorous derivation of that representation. From a technical point of view, the employment of S^0_α is more convenient and in this respect it is desirable to be sure that the restriction of $v \in S'^0$ to S^0_α has the same carrier cones as v. Below we argue that this is the case.

III. CARRIERS OF FUNCTIONALS DEFINED BY MULTILINEAR FORMS

The theory of multilinear forms on products of test function spaces is important for the applications of interest because the vacuum expectation values of quantum fields are just such forms. As known, in the standard axiomatics[1,2] these are uniquely extendable to tempered distributions by Schwartz's nuclear theorem and the content of theory can be reformulated in terms of these Wightman distributions. We want to show that such a possibility is preserved in the more general framework of spaces S^0_α and then we face the problem of continuous extension of multilinear forms to the completions of their domains in a weaker topology. This matter is much more complicated than continuous extension of linear forms (see, e.g., Ref. 26) but we will show that in our case it suffices to use the barrelledness of S^0_α. This property is practically equivalent to the applicability of the uniform boundedness principle which is well known in the theory of Hilbert spaces. It is inherited by inductive topologies and because of this the spaces S^0_α, being the inductive limits of Hilbert spaces, possess this property. A subtlety is that S^0_α are nonmetrizable and we cannot identify topological properties with their sequential form. When A and B are sets in a nonmetrizable topological space, we say that A is sequentially dense in B if every point of B is the limit of a sequence lying in A and convergent in the topology of this space.

Lemma 3: If L is a sequentially dense subspace of a locally convex space E_1 and E_2 is a barrelled space, then every bilinear separately continuous form w defined on $L \times E_2$ has a unique extension to $E_1 \times E_2$ which is bilinear and separately continuous.

Proof: For each fixed $g \in E_2$, the form $w(f,g)$ can be uniquely extended to E_1 by continuity. Letting $\hat{w}$ denote this extension, we have to show that it is linear and continuous in g for each fixed $f \in E_1$. That is just what is ensured by the barrelledness of E_2, because if $f_\nu \in L$, $f_\nu \to f$, then regarding f_ν as elements of E_2' [whose values on g are $w(f_\nu,g)$] and applying Theorem 4.6 of Ref. 26, we see that their pointwise convergence to $f(g) = w(f,g)$ implies that $f(g)$ is also an element of E_2'.

We now note that every multilinear separately continuous form w on $S^0_\alpha(U_1) \times \cdots \times S^0_\alpha(U_n)$ defines a unique linear functional $v \in S'^0_\alpha(U_1 \times \cdots \times U_n)$ such that

$$w(f_1, \ldots, f_n) = v(f_1 \otimes \cdots \otimes f_n), \quad f_j \in S^0_\alpha(U_j)\,. \tag{15}$$

In the case of bilinear forms, this is an immediate consequence of the relation[17]

$$S^0_\alpha(U_1) \hat{\otimes}_\iota S^0_\alpha(U_2) = S^0_\alpha(U_1 \times U_2), \tag{16}$$

where the index ι indicates that the tensor product space is equipped with the inductive topology and the hat means the corresponding completion. Under this topologization, the dual space of the tensor product is canonically identified with the space of bilinear separately continuous forms.[26] In the general case of multilinear forms, we may use the corresponding generalization of formula (16), derivable analogously. It perhaps should be noted that for DFN spaces the binary operation $\hat{\otimes}_\iota$ is associative and this gives another way for drawing the same conclusion.

Theorem 2: *Let K_j be closed cones in $\mathbb{R}^{d_j}$, $j=1,\dots n$, and let w be a multilinear separately continuous form on $S^0_\alpha(\mathbb{R}^{d_1})\times\cdots\times S^0_\alpha(\mathbb{R}^{d_n})$ with the following property:*

(∗) *For every j, the cone K_j is a carrier of all the linear functionals on $S^0_\alpha(\mathbb{R}^{d_j})$ that are determined by $w(f_1,\dots,f_n)$ with the arguments $f_i, i\neq j$, held fixed.*

Then the functional v defined by w in $S'^0_\alpha(\mathbb{R}^{d_1+\cdots+d_n})$ is carried by the cone $K_1\times\cdots\times K_n$.

Proof: For the sake of simplicity, we set $d_j=d$ for all j. It suffices to show that every cone $\mathbb{R}^{d(j-1)}\times K_j\times\mathbb{R}^{d(n-j)}$ is a carrier of v, because then their intersection is also a carrier by Theorem 2 of Ref. 16. We put $j=1$ without loss of generality. Let $n=2$ and let U_1 be an open cone in $\mathbb{R}^d$ such that $K_1\Subset U_1$. According to Theorem 5 of Ref. 17, every element of $S^0_\alpha(U_1)$ can be approximated by elements of some $H^{0,b}_{\alpha,a}(\mathbb{R}^d)$ in the norm of $H^{0,b}_{\alpha,a}(U_1)$. So, by Lemma 3, w can be extended to a bilinear separately continuous form on $S^0_\alpha(U_1)\times S^0_\alpha(\mathbb{R}^d)$. This form in turn determines a continuous linear functional on $S^0_\alpha(U_1\times\mathbb{R}^d)$, which is an extension of v because $S^0_\alpha(\mathbb{R}^d)\otimes S^0_\alpha(\mathbb{R}^d)$ is dense in in $S^0_\alpha(\mathbb{R}^{2d})$. Thus, v allows a continuous extension even to a space larger than $S^0_\alpha(K_1\times\mathbb{R}^d)$ since, for every open cone U in which $K_1\times\mathbb{R}^d$ is compact, there is a U_1 such that $U_1\times\mathbb{R}^d\subset U$, but the converse is not in general true. Next we use the induction on n. Consider an n-linear form w $(n>2)$ as bilinear on $L\times E_2$, where $L=\overset{n-1}{\otimes} S^0_\alpha(\mathbb{R}^d)$ and $E_2=S^0_\alpha(\mathbb{R}^d)$. By the induction hypothesis, it is separately continuous under the topology induced on L by that of $S^0_\alpha(U_1\times\mathbb{R}^{d(n-2)})$. Every element of the latter space can be approximated by elements of L in the norm of $H^{0,b}_{\alpha,a}(U_1\times\mathbb{R}^{d(n-1)})$ with a and b large enough. This follows from the same approximation theorem combined with Lemma 1 of Ref. 17 which shows that, for any pair of open cones, $H^{0,b}_{\alpha,a}(U_1\times U_2)=H^{0,b}_{\alpha,a}(U_1)\otimes H^{0,b}_{\alpha,a}(U_2)$ with the Hilbert tensor product on the right. Applying Lemma 3 again, we conclude that v has a continuous extension to $S^0_\alpha(U_1\times\mathbb{R}^{d(n-1)})$ and so the cone $K_1\times\mathbb{R}^{d(n-1)}$ is a carrier of v as was to be proved.

In order to characterize precisely those elements of $S'^0_\alpha(\mathbb{R}^{d_1+\cdots+d_n})$ that are generated by the multilinear forms with property (∗), we use the following definition.

Definition: Let K_j be closed cones in $\mathbb{R}^{d_j}$, $j=1,\dots,n$. We denote by $S^0_\alpha(K_1,\dots,K_n)$ the linear span of the images of the canonical mappings $S^0_\alpha(U_1\times\cdots\times U_n)\to S^0_\alpha(\{0\})$, where U_j runs through the open cones in $\mathbb{R}^{d_j}$ such that $K_j\Subset U_j$, and endow it with the inductive topology by these mappings. If $v\in S'^0_\alpha(\mathbb{R}^{d_1+\cdots+d_n})$ has a continuous extension to $S^0_\alpha(K_1,\dots,K_n)$, then we say that v is multiplicatively carried by the cone $K_1\times\cdots\times K_n$.

It can be shown that this definition is equivalent to Definition 2 of Ref. 20, where the term ''strong'' was used instead of ''multiplicative'' and auxiliary spaces associated with arbitrary cones were exploited. Because of the obvious inclusion $S^0_\alpha(K_1\times\cdots\times K_n)\subset S^0_\alpha(K_1,\dots,K_n)$, any multiplicative carrier cone of a functional is its carrier cone.

Lemma 4: For any system of closed cones, $S^0_\alpha(K_1,\dots,K_n)$ is a DFN space.

Proof: It suffices to take well-known inheritance properties of DFN spaces into account. In particular, finite direct sums, quotient spaces (modulo closed subspaces) and injective limits of sequences of DFN spaces are DFN. So, the conclusion of Lemma 4 is evident if all K_j are nondegenerate, because then $S^0_\alpha(U_1\times\cdots\times U_n)$ is an increasing family equivalent to an increasing sequence. Now, let some of K_j be degenerate. We form new systems $(K'_1,\dots,K'_n)$ and $(K''_1,\dots,K''_n)$, replacing the degenerate cones by the positive orthants in the first case and by negative ones in the second case and leaving the other cones unchanged. From the decomposition theorem of Ref. 16, it follows that every element of $S^0_\alpha(K_1,\dots,K_n)$ can be decomposed into a sum of functions belonging to $S^0_\alpha(K'_1,\dots,K'_n)$ and $S^0_\alpha(K''_1,\dots,K''_n)$. When being endowed with the inductive topology with respect to the latter spaces, $S^0_\alpha(K_1,\dots,K_n)$ becomes a DFN space, because then it is identified with a quotient space of direct sum of two DFN spaces, and this topology coincides with the original one by the open mapping theorem.

It is not difficult to show that $S^0_\alpha(K_1\times\cdots\times K_n)=S^0_\alpha(K_1,\dots,K_n)$ only in the two trivial cases when all K_j are degenerate or when $K_j=\mathbb{R}^{d_j}$ for all j, and only then their duals coincide because DFN spaces are reflexive. The proof of this assertion is beyond the scope of the present paper, but we give a simple explaining example. Namely, let $K_1=\mathbb{R}$ and let K_2 be the nonpositive semiaxis $\overline{\mathbb{R}}_-$. Clearly $e^z\in S^0_\alpha(\mathbb{R}_-)$ for any $\alpha>1$ and $f_1(z_1)\,e^{z_2}\in S^0_\alpha(\mathbb{R},\overline{\mathbb{R}}_-)=S^0_\alpha(\mathbb{R}\times\mathbb{R}_-)$ for every f_1

$\in S^0_\alpha(\mathbb{R})$. According to Ref. 5, the space $S^0_\alpha(\mathbb{R})$ contains a non-negative function f_0 such that $f_0(0)>0$ and $|f_0(x+iy)|\leqslant e^{-2|x|^{1/\alpha}+|y|}$. The convolution $f_1(x)=\int e^{-|\xi|^{1/\alpha}} f_0(x-\xi)\,\mathrm{d}\xi$ also belongs to $S^0_\alpha(\mathbb{R})$ and satisfies the lower bound

$$f_1(x)\geqslant \int_{-1}^{+1} e^{-|x-\xi|^{1/\alpha}} g_\alpha(\xi)\,\mathrm{d}\xi \geqslant e^{-(|x|+1)^{1/\alpha}} \int_{-1}^{+1} g_\alpha(\xi)\,\mathrm{d}\xi \geqslant c\, e^{-|x|^{1/\alpha}}. \tag{17}$$

The estimate (17) shows that the function $f_1(z_1)\,e^{z_2}$ increases indefinitely along each of the real rays lying in the half-plane $x_2>0$ and hence does not belong to any space $S^0_\alpha(U)$, where $U\ni\mathbb{R}\times\overline{\mathbb{R}}_-$. It follows that $S'^0_\alpha(\mathbb{R},\overline{\mathbb{R}}_-)\neq S'^0_\alpha(\mathbb{R}\times\overline{\mathbb{R}}_-)$.

Theorem 3: *A functional $v\in S'^0_\alpha(\mathbb{R}^{d_1+\cdots+d_n})$ is generated by a multilinear form on $S^0_\alpha(\mathbb{R}^{d_1})\times\cdots\times S^0_\alpha(\mathbb{R}^{d_n})$ with property $(*)$ if and only if it has a continuous extension to $S^0_\alpha(K_1,\ldots,K_n)$.*

Proof: We may use the l-norm $|x|=\Sigma|x_j|$ in $\mathbb{R}^{d_1+\cdots+d_n}$ and substitute $\Sigma|x_j|^{1/\alpha}$ for $|x|^{1/\alpha}$ in definition (3). Then $\delta_{U_1\times\cdots\times U_n}(x)=\Sigma\,\delta_{U_j}(x)$ and the indicator function defined by the exponential in (3) is multiplicative. It follows that the mapping $f_j\to f_1\otimes\cdots\otimes f_j\otimes\cdots\otimes f_n$ from $S^0_\alpha(U_j)$ to $S^0_\alpha(U_1\times\cdots\times U_n)$ is continuous and hence the multilinear forms that correspond to functionals in $S'^0_\alpha(K_1,\ldots,K_n)$ possess property $(*)$. To derive the converse implication $(*)\Rightarrow v\in S'^0_\alpha(K_1,\ldots,K_n)$, which is the main point of the theorem under discussion, we need two lemmas.

Lemma 5: Let U_1, U_2, and U be open cones in $\mathbb{R}^{d_1}$, $\mathbb{R}^{d_2}$, and $\mathbb{R}^d$, respectively, and let $V_1\Subset U_1$, $V_2\Subset U_2$. Then every function $f\in S^0_\alpha(U_1\times U_2\times U)$ allows a decomposition of the form $f=f_1+f_2$, where $f_1\in S^0_\alpha(V_1\times\mathbb{R}^{d_2}\times U)$ and $f_2\in S^0_\alpha(\mathbb{R}^{d_1}\times V_2\times U)$.

This is a simplified version of Lemma 2 in Ref. 20.

Lemma 6: Let E be a vector space and let L_0, L_1, L_2 be its subspaces endowed with locally convex topologies and such that $L_0\subset L_1\cap L_2$. Assume that L_1+L_2 and $L_1\cap L_2$ are equipped with the inductive and projective topologies, respectively. If L_0 is dense in each of L_1, L_2, $L_1\cap L_2$ and the injections $L_0\to L_1$, $L_0\to L_2$ are continuous, then

$$(L_1+L_2)'=L_1'\cap L_2',$$

where the dual spaces are regarded as vector subspaces of L_0'.

Proof: Note that L_0 is dense in L_1+L_2 if it is dense in L_1 and L_2 and so the natural mapping $(L_1+L_2)'\to L_0'$ is injective along with $L_1'\to L_0'$ and $L_2'\to L_0'$. Clearly, $(L_1+L_2)'\subset L_1'\cap L_2'$ and we only need to show the converse inclusion. Let $v\in L_1'\cap L_2'$ and let v_1, v_2 be its continuous extensions to L_1, L_2. Since the projective topology on $L_1\cap L_2$ is the upper bound of the topologies induced by those of L_1 and L_2, the functionals v_1 and v_2 are continuous on $L_1\cap L_2$ and hence coincide on this subspace by the denseness condition. Therefore, the formula $\hat{v}(f_1+f_2)=v_1(f_1)+v_2(f_2)$ defines a linear extension of v to L_1+L_2 which is continuous by the definition of inductive topology.

End of the proof of Theorem 3: We again set $d_j=d$ for simplicity. Let w be a multilinear form with property $(*)$. In deriving Theorem 2, we have shown that its associated functional v belongs to $S'^0_\alpha(\mathbb{R}^{d(j-1)},K_j,\mathbb{R}^{d(n-j)})$ for every $j=1,\ldots,n$. At first assume that $K_j\neq\{0\}$ for all j. Denote by E the space $S^0_\alpha(K_1,K_2,\mathbb{R}^{d(n-2)})$ and by L_1 and L_2 the images of $S^0_\alpha(K_1,\mathbb{R}^{d(n-1)})$ and $S^0_\alpha(\mathbb{R}^d,K_2,\mathbb{R}^{d(n-2)})$ in this space. By Lemma 5, we have $E=L_1+L_2$. If the sum is endowed with the inductive topology, then this equality holds not only algebraically but also topologically by the open mapping theorem. The intersection $L_1\cap L_2$ is identified, as a set, with the inductive limit of directed family of spaces $S^0_\alpha(U)$, where U is the union of open cones $U_1\times\mathbb{R}^{d(n-1)}$ and $\mathbb{R}^d\times U_2\times\mathbb{R}^{d(n-2)}$, with U_1, U_2 running through the conic neighborhoods of K_1, K_2. By the approximation theorem,[17] S^0_α is dense in each of them and so in $L_1\cap L_2$ endowed with the inductive limit topology which is obviously stronger than the projective topology determined by the injections $L_1\cap L_2\to L_1$, $L_1\cap L_2\to L_2$. Applying Lemma 6, we conclude that $v\in S'^0_\alpha(K_1,K_2,\mathbb{R}^{d(n-2)})$. Repeating the same line of argument, we obtain v

$\in S'^{0}_{\alpha}(K_1,K_2,K_3,\mathbb{R}^{d(n-3)})$ and so on. Now, let some of K_j be degenerate. Then we set $E=S^0_\alpha(K_1,\ldots,K_n)$, $L_1=S^0_\alpha(K'_1,\ldots,K'_n)$, and $L_2=S^0_\alpha(K''_1,\ldots,K''_n)$, where the systems of cones are defined in Lemma 4. From what has been said, it follows that $v\in L'_1\cap L'_2$ and applying Lemma 6 completes the proof.

It should be noted that in the usual case of tempered distributions on $\mathbb{R}^{d_1}\times\cdots\times\mathbb{R}^{d_n}$, the situation is quite different because the projections of their supports onto $\mathbb{R}^{d_j}$ certainly contain supports of those distributions that are obtained by fixing the other arguments. Clearly, this difference has its origin in using the conic neighborhoods (in other words, the radial compactification of $\mathbb{R}^d$) in the definition of carrier cones of the functionals belonging to $S'^{0}_{\alpha}(\mathbb{R}^d)$.

When applied to nonlocal fields defined on the test function space $S^0_\alpha(\mathbb{R}^4)$, Theorems 2 and 3 enable one to express the asymptotic commutativity condition stated in Sec. II in terms of the corresponding generalized Wightman functions on $S^0_\alpha(\mathbb{R}^{4n})$. Namely, the functional defined by

$$\langle\Psi_0,\phi_{\iota_1}(x_1)\cdots\phi_{\iota_{k-1}}(x_{k-1})[\phi_{\iota_k}(x_k),\phi_{\iota_{k+1}}(x_{k+1})]_{\substack{-\\(+)}}\phi_{\iota_{k+2}}(x_{k+2})\cdots\phi_{\iota_n}(x_n)\Psi_0\rangle,$$

where the sign $-$ or $+$ corresponds to the type of commutation relation between ϕ_{ι_k} and $\phi_{\iota_{k+1}}$, is carried and even multiplicatively carried by the cone $\mathbb{R}^{4(k-1)}\times\mathbb{V}^8\times\mathbb{R}^{4(n-k-1)}$, with $\mathbb{V}^8$ defined by (14). As a consequence, that condition is actually fulfilled on a larger domain D_1 spanned by the vacuum Ψ_0 and all vectors of the form

$$\int \phi_{\iota_1}(x_1)\ldots\phi_{\iota_n}(x_n)\,f(x_1,\ldots,x_n)\;\mathrm{d}x_1\cdots\mathrm{d}x_n\,\Psi_0\quad(n=1,2,\ldots),$$

where $f\in S^0_\alpha(\mathbb{R}^{4n})$. The notion of multiplicative carrier cone is particularly essential for formulating the spectral condition for the quantum fields whose infrared singularities violate positivity and, specifically, for generalizing the Osterwalder–Schrader theorem to such QFT's.[20] The employment of this notion results in effective estimates for the Schwinger functions and enables one to develop Euclidean formulation in complete analogy to the usual case of tempered distribution fields. It is significant that the spectral condition stated in such a way is fulfilled for the Wick ordered entire functions of indefinite metric free fields.

IV. INDEPENDENCE OF THE QUASISUPPORT FROM THE INDEX α

Theorem 4: *Let $v\in S'^{0}_{\alpha}$ and let $1<\alpha'<\alpha$. If the restriction $v|S^0_{\alpha'}$ is carried by a closed cone K, then so is v.*

Proof: This statement, combined with the obvious converse implication, can be expressed by the relation

$$S'^{0}_{\alpha}\cap S'^{0}_{\alpha'}(K)=S'^{0}_{\alpha}(K),\tag{18}$$

where all the spaces are regarded as vector subspaces of $S'^{0}_{\alpha'}$, which is permissible by the approximation theorem.[17] For $K=\{0\}$, equality (18) is valid by definition and the cone K will henceforth be assumed nontrivial. We begin by deriving the dual formula

$$S^0_\alpha(K)=S^0_\alpha+S^0_{\alpha'}(K)\tag{19}$$

and then apply Lemma 6. Let $f\in E^{0,b}_{\alpha,1}(U)$, $U\ni K$. [Taking advantage of the dilation invariance of the spaces involved, we set $a=1$ without loss of generality. From now on, we shall also use the Euclidean norm in $\mathbb{R}^d$ and the system of norms (3) dropping the prime.] Choose a non-negative function $\chi_0\in C^\infty_0$ with support in the ball $B_\epsilon=\{x:|x|<\epsilon\}$ and such that $\int\chi_0(x)\,\mathrm{d}x=1$ and set

$$\chi(x)=\int_U\chi_0(x-\xi)\,\mathrm{d}\xi.$$

Let us consider the decomposition

$$f=f_1+f_2,\quad f_1(z)=f(z)\chi(x),\quad f_2(z)=f(z)(1-\chi(x)).$$

The functions f_1 and f_2 are not analytic but behave properly at infinity of $\mathbb{C}^d$. Indeed, we have

$$|f_1(z)|\leqslant\|f\|_{U,1,b}\exp\{-|x|^{1/\alpha}+b|y|+b\epsilon\} \tag{20}$$

since $\delta_U(x)\leqslant\epsilon$ for $x\in\operatorname{supp}\chi$. Further, let V be an open cone such that $K\Subset V\Subset U$. Then there is a constant $\gamma>0$ such that $\delta_V(x)\geqslant\gamma|x|$ for all points of $\operatorname{supp}(1-\chi)$ except for a compact subset. At these points, we have $b\,\delta_U(x)\leqslant b\,\delta_V(x)\leqslant\overline{b}\,\delta_V(x)-\overline{\gamma}|x|$, where $\overline{b}>b$ and $\overline{\gamma}=\overline{b}-b$. Therefore,

$$|f_2(z)|\leqslant C\,\|f\|_{U,1,b}\exp\{-\overline{\gamma}|x|+b|y|+\overline{b}\,\delta_V(x)\}. \tag{21}$$

To obtain an analytic decomposition, we write

$$f=f_1'+f_2',\quad f_1'=f_1-\psi,\quad f_2'=f_2+\psi$$

and subject ψ to the equations

$$\frac{\partial\psi}{\partial\overline{z}_j}=\eta_j,\quad \text{where}\quad \eta_j\overset{\text{def}}{=}f\frac{\partial\chi}{\partial\overline{z}_j}=\frac{1}{2}f\frac{\partial\chi}{\partial x_j}\quad (j=1,\ldots,d). \tag{22}$$

The functions $\eta_j(z)$ are nonzero only for $x\in\partial U+B_\epsilon$, where ∂U is the boundary of U, and satisfy the estimate

$$|\eta_j(z)|\leqslant C_j\|f\|_{U,1,b}\exp\{-|x|^{1/\alpha}+b|y|\}. \tag{23}$$

It remains to verify that there exists a solution of Eqs. (22) with the required behavior at infinity. First we shall show that this behavior can be characterized by a plurisubharmonic function, which enables us to apply an existence theorem due to Hörmander.[28]

Lemma 7: For every pair U', U of open cones in $\mathbb{R}^d$ such that $U'\Subset U$ and for each system of numbers $\alpha,\alpha',b,b',\epsilon$ satisfying $\alpha>\alpha'>1$, $b'>\sqrt{d}\,b>0$, $0<\epsilon<1/b$, there is a plurisubharmonic function $\rho(z)$ with the following properties:

$$\rho(z)\geqslant-|x|^{1/\alpha}+b|y|\quad \textit{for}\ \ x\in\partial U+B_\epsilon, \tag{24}$$

$$\rho(z)\leqslant-|x|^{1/\alpha}+b'|y|+C\quad \textit{everywhere}, \tag{25}$$

$$\rho(z)\leqslant-|x|^{1/\alpha'}+b'|y|+C\quad \textit{for}\ \ x\in U', \tag{26}$$

where C is a sufficiently large constant.

The proof of this lemma is given in Appendix B.

Let us go on with our proof of Theorem 4. We choose a cone U' so that $V\Subset U'\Subset U$, take a function ρ defined by Lemma 7, and denote by ϱ the strictly plurisubharmonic function $2\rho+(d+3)\ln(1+|z|^2)$. Using (23) and (24), we see that $\eta_j\in L^2(\mathbb{C}^d,e^{-\varrho}\varkappa^{-1}\,d\lambda)$, where $d\lambda$ stands for the Lebesgue measure on $\mathbb{C}^d$ and

$$\varkappa\overset{\text{def}}{=}\inf_{\zeta}\sum_{j,k}\frac{\partial^2\varrho(z)}{\partial z_j\partial\overline{z}_k}\frac{\zeta_j\overline{\zeta}_k}{|\zeta|^2}\geqslant(d+3)\inf_{\zeta}\sum_{j,k}\frac{\partial^2\ln(1+|z|^2)}{\partial z_j\partial\overline{z}_k}\frac{\zeta_j\overline{\zeta}_k}{|\zeta|^2}\geqslant\frac{d+3}{(1+|z|^2)^2},$$

with the last lower bound taken from Ref. 28, Sec. 15.1. The functions η_j satisfy the consistency conditions $\partial\eta_j/\partial\overline{z}_k=\partial\eta_k/\partial\overline{z}_j$ by definition, and Theorem 15.1.1 of Ref. 28 shows that the system of Eqs. (22) has a solution ψ such that

$$\int |\psi|^2 e^{-\varrho}\,\mathrm{d}\lambda \leqslant \int |\eta|^2 e^{-\varrho}\varkappa^{-1}\,\mathrm{d}\lambda \leqslant \frac{1}{d+3}\int \frac{|\eta|^2 e^{-2\rho}}{(1+|z|^2)^{d+1}}\,\mathrm{d}\lambda \leqslant C'\|f\|^2_{U,1,b}, \tag{27}$$

where we made use of (23) and (24) in the last step. This implies that

$$\psi \in L^2(\mathbb{C}^d, e^{2(|x/a|^{1/\alpha}-b''|y|)}\,\mathrm{d}\lambda) \quad \text{and} \quad \psi \in L^2(\mathbb{C}^d, e^{2(|x/a|^{1/\alpha'}-b''|y|-b'\,\delta_V(x))}\,\mathrm{d}\lambda)$$

for each $a>1$ and for each $b''>\sqrt{d}\,b$. The former membership relation is ensured by (25) and the latter follows from (26) since for $x \notin U'$, we have $\delta_V(x) \geqslant \gamma'|x|$ with some $\gamma'>0$ and the exponent in question evidently does not exceed $-\varrho+C''$ by (25) again. Referring back to (4), (20), and (21), we conclude that the analytic functions f_1' and f_2' belong, respectively, to the spaces $H^{0,b''}_{\alpha,a}$ and $H^{0,b''}_{\alpha',a}(V)$ and so relation (19) is proved. To complete the proof, it remains to verify that $S^0_{\alpha'}$ is dense in the intersection $S^0_\alpha \cap S^0_{\alpha'}(K)$ endowed by its natural (i.e., projective) topology. This is considerably simpler than proving the denseness of $S^0_{\alpha'}$ in $S^0_{\alpha'}(K)$ since the elements of intersection decrease like $\exp(-|x|^{1/\alpha})$ outside the cone K, in contrast to an arbitrary function in $S^0_{\alpha'}(K)$ which has an exponential growth. Namely, an approximating sequence φ_ν can be constructed by setting $\varphi_\nu=\sigma_\nu\varphi$, where $\sigma_\nu(z)$ is a sequence of Riemann sums for the integral $\int\sigma_0(z-\xi)\,\mathrm{d}\xi$, with σ_0 a function in $S^0_{\alpha'}$ whose integral is unity. The sequence $\varphi_\nu \in S^0_{\alpha'}$ is obviously bounded in both the spaces S^0_α and $S^0_{\alpha'}(K)$ and converges to φ uniformly on compact subsets of $\mathbb{C}^d$ by the Vitali–Montel theorem. Thus, by the standard argument,[5] $\varphi_\nu \to \varphi$ in the topology of either of these spaces. Applying Lemma 6 concludes the proof.

Corollary: Let V be an open connected cone in $\mathbb{R}^d$ and let $\alpha'>1$. Suppose that $g(\zeta)$ is an analytic function on the tubular domain $\mathbb{R}^d+iV$ with the property that, for any $\varepsilon,R>0$ and every cone $V' \Subset V$,

$$|g(\zeta)| \leqslant C_{\varepsilon,R}(V')\exp\{\varepsilon\,|\mathrm{Im}\,\zeta|^{-1/(\alpha'-1)}\} \quad (\mathrm{Im}\,\zeta \in V',\ |\zeta| \leqslant R). \tag{28}$$

If the boundary value of g is an ultradistribution of class $\{k^{\alpha k}\}$, where $\alpha>\alpha'$, then this function satisfies a stronger bound of the same type, with α substituted for α'.

This is a direct consequence of Theorem 4 combined with Theorem 4 of Ref. 17 which shows that the Laplace transformation is an isomorphism of the algebra of analytic functions with growth property (28) onto the space $S'^0_\alpha(V^*)$, where V^* is the dual cone of V.

Remark 3: An analogue of Theorem 4 for S'^β_α, where $0<\beta<1$, can be derived more easily. Namely, it suffices to apply Theorem 5.18 of Ref. 24 which shows that, for v in S'^β_α, the condition of belonging to $S'^\beta_\alpha(K)$ amounts to a falloff property of the convolution $v*f$, $f \in S^\beta_{1-\beta}$, in the complementary cone $\complement K$. Any similar proof is impossible for $\beta=0$ because of the absence of a smallest space among the family S^0_α.

Theorem 4 has been stated in Ref. 19 without a proof and used there in deriving some auxiliary theorems, which generalize the well-known fact that the odd Lorentz invariant distributions have support in the closed light cone and which play a significant part in proving the CPT invariance of nonlocal QFT's satisfying the asymptotic commutativity condition as well as in extending the spin-statistics relation to nonlocal fields. The role of Theorem 4 in these applications can be illustrated, in particular, by the following example.

Theorem 5: *Let ϕ be a field defined on the space S^0_α, $\alpha>2$, and satisfying all the standard axioms except temperedness and locality. Assume it transforms according to an irreducible representation of the group* $\mathrm{SL}(2,\mathbb{C})$ *and let $W(x_1-x_2)$ be the Wightman generalized function determined by the vacuum expectation value $\langle\Psi_0, \phi(x_1)\phi^*(x_2)\Psi_0\rangle$. Then the closed light cone $\overline{\mathbb{V}}=\{\xi:\xi^2\geqslant 0\}$ is a carrier of the functional*

$$W(\xi) \mp W(-\xi), \tag{29}$$

where the upper and lower signs correspond to the cases of integer and half-integer spin, respectively.

In deriving Theorem 5 we are to regularize the ultraviolet behavior of W through the multiplication of the Fourier transform $\tilde{W}$ by the Lorentz invariant function $\omega(p/\mu)$, where $\omega(p)=\omega_0(p^2)$, $\omega_0 \in S_0^{\alpha'}(\mathbb{R})$, $1<\alpha'<\alpha$, $\operatorname{supp}\omega_0 \subset (-1,1)$, and $\omega_0(t)=1$ for $|t|\leqslant 1/2$. Theorem 7 of Ref. 19 shows that the regularized functional $\tilde{W}_\mu$ allows a continuous extension to the space $S^{\alpha'}_{\alpha-\alpha'}$. In particular, if $\alpha>2$ and $\alpha'<\alpha-1$, then $\tilde{W}_\mu$ has no worse than exponential growth of the order $1/(\alpha-\alpha')<1$ and hence its Laplace transform $\mathbf{W}_\mu$ is well defined and holomorphic in the usual tubular domain $\mathbb{R}^4-i\mathbb{V}_+$. This enables us to apply the Bargmann–Hall–Wightman theorem[1,2] and to assert that the support of the functional $F_\mu \overset{\text{def}}{=} W_\mu(\xi) \mp W_\mu(-\xi)$, which is defined on the space $S^{\alpha-\alpha'}_{\alpha'}$ containing functions of compact support providing $\alpha'<\alpha-1$, lies in $\overline{\mathbb{V}}$ and therefore F_μ has a continuous extension to $S^0_{\alpha'}(\mathbb{V})$. The extension $\hat{F}_\mu$ can be defined by $(\hat{F}_\mu, f)=(F_\mu, \chi f)$, where χ is a multiplier for $S^{\alpha-\alpha'}_{\alpha'}$ which is equal to 1 in an ϵ-neighborhood of $\overline{\mathbb{V}}$, vanishes outside the 2ϵ-neighborhood and satisfies the estimate $|\partial^q \chi(x)| \leqslant C h^{|q|} q^{(\alpha-\alpha')q}$. It is readily verified that the multiplication by χ is a continuous map from $S^0_{\alpha'}(\mathbb{V})$ into $S^{\alpha-\alpha'}_{\alpha'}$. Taking into account that the Fourier transforms of functions belonging to $E^{0,b}_{\alpha',a}$ have support in the ball of radius $\sim b$, where $\omega(p/\mu)=1$ for μ large enough, and using the denseness of $S^0_{\alpha'}$ in $S^0_{\alpha'}(\mathbb{V})$, we conclude that the nonregularized functional (29) also has a continuous extension to $S^0_{\alpha'}(\mathbb{V})$. Finally, Theorem 4 makes possible a further extension to $S^0_\alpha(\overline{\mathbb{V}})$, which completes the proof. In the same manner it is used in deriving an analogue[19] of Theorem 5 for the n-point vacuum expectation values.

V. CONCLUDING REMARKS

A number of works (see, e.g., Ref. 23 and references therein) on nonlocal QFT exploit another Gelfand–Shilov's class of test-function spaces S^β, $\beta<1$. The generalized functions belonging to S'^β have the same type of singularity as elements of S'^β_α but grow at infinity no faster than a polynomial. Their carrier cones can be defined[24] in a manner analogous to that used in Sec. II. As pointed in Sec. II, the spaces S^β_α are more convenient in operation because their topological structure is simpler, and in this respect it is worth noting that the restriction of $v \in S'^\beta$ to S^β_α has the same carrier cones as v. The proof of this fact for $\beta=0$ is more complicated than the derivation of Theorem 4, but the above construction can be adapted to this case by using Lemma 5.11 of Ref. 24. Theorem 4 can also be extended to the multiplicative carriers. As already remarked, the notion of multiplicative carrier cone is best suited for generalization of the spectral condition to gain the Euclidean formulation of local QFT's without positivity. Perhaps it is reasonable to impose an analogous condition on the generalized functions that serve as kernels of the positive semidefinite scalar product defining an auxiliary Hilbert structure[29] which is associated with the set of Wightman functions to identify the physical states. It is hardly surprising that highly singular generalized functions should be incorporated into the mathematical tools of quantum field theory with indefinite metric. This simply brings the distributional framework of QFT into coordination with the presence of nonphysical degrees of freedom and appears to be essential for the complete implementation of the gauge symmetry. What is more, the employment of such a formalism might contribute to a better insight into the Higgs effect and the confinement mechanism, as discussed in Refs. 13 and 14. The theorems established in Refs. 16–18 and complemented by the results presented here enable one to work with the analytic functionals in S'^0_α almost as easily as with the usual tempered distributions and may be of use in the further rigorous investigation of the singular QFT models.

APPENDIX A: PROOF OF LEMMA 1

We denote the norm of $L^{0,b}_{\alpha,a}(U)$ by $\|\cdot\|''_{U,a,b}$. Let $\xi\in U$, and suppose that the neighborhood $B(\xi,\epsilon)=\{x:|x-\xi|<\epsilon\}$ of this point is contained in U. Then $\|\partial^q f\|_{L^2(B)} \leqslant C_\epsilon \|f\|''_{U,a,b}\, b^{|q|}\, e^{-|\xi/a|^{1/\alpha}}$. By Sobolev's lemma we have

$$|\partial^q f(\xi)|\leqslant C'_\epsilon \sum_{|k|\leqslant[d/2]+1} \|\partial^{q+k} f\|_{L^2(B)} \leqslant C''_\epsilon \|f\|''_{U,a,b}\, b^{|q|}\, e^{-|\xi/a|^{1/\alpha}}. \tag{A1}$$

Therefore, every element of $L^{0,b}_{\alpha,a}(U)$ allows an analytic continuation to the whole of $\mathbb{C}^d$. If f_ν is a Cauchy sequence in this space, than it converges uniformly on compact sets of $\mathbb{C}^d$ and hence its limit f is an entire function. All derivatives $\partial^q f$ are obviously square integrable on U with the weight $\exp\{2|x/a|^{1/\alpha}\}$ and the positive series determining $\|f\|''^{\,2}_{U,a,b}$ is convergent since its partial sums are bounded by the number $\sup_\nu \|f_\nu\|''^{\,2}_{U,a,b}$. Thus, $L^{0,b}_{\alpha,a}(U)$ is a Hilbert space. For each $a>a'$ and $b>b'$, we have $\|f\|''_{U,a,b}\leqslant C\|f\|_{U,a',b'}$ and hence the Banach space $S^{0,b'}_{\alpha,a'}(U)$ with norm (A1) is continuously embedded into $L^{0,b}_{\alpha,a}(U)$. Conversely, using inequality (A1) at the points of U whose distance to the boundary is greater than ϵ and applying the Taylor expansion to estimate $\partial^q f$ elsewhere, we see that the norm $\|f\|''_{U,a,b}$ is not weaker than $\|f\|_{U,a,b}$. Thus the limit spaces in question are indeed the same.

APPENDIX B: PROOF OF LEMMA 7

Let u be a unit vector in $\mathbb{R}^d$ and $\theta>0$. We denote by R_u the ray $\{\lambda u:\lambda\geqslant 0\}$ and by $K_{u,\theta}$ the circular cone $\{\lambda x:|x-u|\leqslant\theta,\ \lambda\geqslant 0\}$. Assume that θ is less than the angular separation between the cones U, U'. It suffices to prove that, for every $u\in\partial U$, there exists a plurisubharmonic function $\rho_u(z)$ bounded by (25) and satisfying estimates of the form (24) and (26) but for $x\in R_u+B_\epsilon$ and for $x\notin K_{u,\theta}$, respectively. Then the upper envelope

$$\rho(z)=\overline{\lim_{z'\to z}}\ \sup\{\rho_u(z'):u\in\partial U,\ |u|=1\} \tag{B1}$$

satisfies all the required conditions because $U'\subset\subset K_{u,\theta}$ for every $u\in\partial U$. The function (B1) is plurisubharmonic since the family $\{\rho_u\}$ is locally uniformly bounded above. The space $S^{\alpha'}_0(\mathbb{R})$, which is the Fourier transform of $S^0_{\alpha'}(\mathbb{R})$, contains a non-negative even function ω such that $\operatorname{supp}\omega\subset[-\delta,\delta]$, $\int\omega(t)\,dt=1$, and $|\omega^{(k)}(t)|\leqslant A_0 a_0^k k^{\alpha' k}$, where a_0 and δ can be taken arbitrarily small, see Ref. 5, Sec. IV.8.3. Let Ω be the convolution of ω by the characteristic function of the segment $|t|\leqslant b+\delta$ and let $1+2\delta/b<\pi/3$. Then $\cos\xi t>1/2$ for $|\xi|<1/b$ and $t\in\operatorname{supp}\Omega$. Let us estimate the Laplace transform $\tilde\Omega(\zeta)$ of Ω in the strip $|\operatorname{Re}\zeta|<1/b$. Taking into account that $\int\Omega(t)\ dt=2(b+\delta)$, we get

$$|\tilde\Omega(\zeta)|\geqslant\operatorname{Re}\int e^{it\zeta}\Omega(t)\,dt\geqslant\frac{1}{2}\int_{|t|>b} e^{-t\operatorname{Im}\zeta}\,\Omega(t)\,dt\geqslant\frac{1}{2}e^{b|\operatorname{Im}\zeta|}\int_{t>b}\Omega(t)dt=\frac{\delta}{2}e^{b|\operatorname{Im}\zeta|}. \tag{B2}$$

Therefore, the subharmonic function $\rho_0(z)=\ln(2|\tilde\Omega(z)|/\delta)$ is bounded from below by $b|\operatorname{Im}\zeta|$ in that strip. According to Ref. 5, we have $\tilde\Omega\in E^{0,b+2\delta}_{\alpha',1}$ if a_0 is small enough, and so

$$\rho_0(\zeta)\leqslant-|\operatorname{Re}\zeta|^{1/\alpha'}+(b+2\delta)|\operatorname{Im}\zeta|+A. \tag{B3}$$

We may assume without loss of generality that u is the first basis vector and then define ρ_u to be the upper envelope of the family

$$\rho_0(z_1-\xi)+\sum_{j>1}\rho_0(z_j)-|\xi|^{1/\alpha},\quad \xi>-\epsilon.$$

If $x\in R_u+B_\epsilon$, then $x_1>-\epsilon$ and $|x_j|<\epsilon<1/b$ for all $j>1$. Setting $\xi=x_1$, we see that (B2) ensures the required lower bound on ρ_u. Further, using (B3) and the elementary inequalities $\Sigma_{j>1}|x_j|^{1/\alpha'}\geqslant\Sigma_{j>1}|x_j|^{1/\alpha}-C'$, $|x_1-\xi|^{1/\alpha}+|\xi|^{1/\alpha}\geqslant|x_1|^{1/\alpha}$, and $\Sigma|y_j|\leqslant\sqrt{d}|y|$, we conclude that ρ_u satisfies (25) provided δ is small enough. Finally, if $x\notin\pm K_{u,\theta}$, then $\Sigma_{j>1}|x_j|^{1/\alpha'}\geqslant|\theta' x|^{1/\alpha'}$ with some $\theta'>0$, and if $x\in -K_{u,\theta}$, we have $|x_1-\xi|\geqslant|x_1|$ for $\xi\geqslant 0$ and $|x_1-\xi|^{1/\alpha'}\geqslant|x_1|^{1/\alpha'}-\epsilon^{1/\alpha'}$ for the rest of ξ. Therefore, the last desired bound on ρ_u is also satisfied and so Lemma 7 is proved.

(Received 27 November 2003; accepted 9 February 2004; published 5 April 2004)

Integrable quantum mechanical systems with magnetic fields are constructed in two-dimensional Euclidean space. The integral of motion is assumed to be a first or second order Hermitian operator. Contrary to the case of purely scalar potentials, quadratic integrability does not imply the separation of variables in the Schrödinger equation. Moreover, quantum and classical integrable systems do not necessarily coincide: the Hamiltonian can depend on the Planck constant $\hbar$ in a nontrivial manner. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1695447]

I. INTRODUCTION

The purpose of this article is to study the integrability properties of a quantum particle moving in an external magnetic field. More specifically, we will consider the Schrödinger equation in a two-dimensional Euclidean space with the Hamiltonian

$$H=-\frac{\hbar^2}{2}(\partial_x^2+\partial_y^2)-\frac{i\hbar}{2}[A(x,y)\partial_x+\partial_x A(x,y)+B(x,y)\partial_y+\partial_y B(x,y)]+V(x,y). \tag{1.1}$$

The vector and scalar potentials (A,B) and V are to be determined from the requirement that the system should be integrable, i.e., a well-defined quantum mechanical operator X should exist, that commutes with the Hamiltonian, i.e.,

$$[H,X]=0. \tag{1.2}$$

In this particular study, we shall restrict to the case when X is a first or second order polynomial in the momenta. We shall be particularly interested in the case of superintegrable systems, when two independent operators, X_1 and X_2, commuting with the Hamiltonian exist. In general, X_1 and X_2 do not commute with each other, but together generate an algebra of operators, commuting with H.

In classical mechanics, integrable systems are of interest, because they have regular trajectories. Indeed, their motion is restricted to a torus in phase space. Superintegrable systems are even more regular. Trajectories are completely determinded by the values of the $2n-1$ integrals of motion. In particular, all bounded trajectories are periodic, as in the case of the harmonic oscillator, or Kepler problem.

In quantum mechanics, integrability, i.e., the existence of n integrals of motion, provides a complete set of quantum numbers, characterizing the system. Moreover, it simplifies the calcula-

tion of energy levels and wave functions. Superintegrability, in all cases studied so for, entails exact solvability. This means that energy levels in superintegrable systems can be calculated algebraicly, i.e., they satisfy algebraic rather than transcendental equations.

Previous searches for integrable and superintegrable systems in quantum mechanics concentrated on scalar potentials only.[1–10] It was established that for scalar potentials the existence of first and second order integrals of motion implies the separation variables in the Schrödinger equation, and also in the Hamilton–Jacobi equation in classical mechanics. Moreover, for scalar potentials and second order integrals of motion, classical and quantum integrable systems coincide (i.e., classical and quantum potentials are the same).

Surprisingly, when third order integrals are considered, a new phenomenon occurs: integrable and superintegrable quantum systems that have no classical counterpart.[11–14] Indeed, in the classical limit $\hbar \to 0$ the potential vanishes, $V(x,y) \to 0$ and we obtain free motion.

Previous studies of integrability in magnetic fields were conducted in the framework of classical mechanics.[15,16] It was established that the existence of second order integrals of motion in the presence of magnetic fields no longer implies the separation of variables. However, the integrals of motion were still classified into equivalence classes under the action of the Euclidean group and the highest order terms have the same form as in the case of a purely scalar potential.

In this paper we restrict ourselves to the two-dimensional Euclidean space $E(2)$, the Hamiltonian (1.1) and to first, or second order integrals. In Sec. II we formulate the problem of finding the integrals of motion, first in the classical, then in the quantum case. We show that the determining equations in the two cases are the same for first order integrals of motion, not however for second order ones. Section III is devoted to first order integrals of motion. They are shown to exist if and only if the magnetic field and an effective scalar potential are invariant under either translations, or rotations. We also show that superintegrability with two (or more) first order integrals occurs only for a constant magnetic field and effective potential. In Sec. IV we consider a specific class of second order operators which we call ''Cartesian integrals.'' In the absence of a magnetic field they lead to separation of variables in Cartesian coordinates. We also show that superintegrability with one Cartesian integral and a second integral of any (quadratic) type occurs only for a constant magnetic field. In the Cartesian case there is no difference between classical and quantum integrability. Polar integrability and superintegrability are investigated in Sec. V. All cases of integrability with one ''polar'' integral of motion are identified. The quantum case differs from the classical one and the magnetic field can depend on the Planck constant $\hbar$ in a nontrivial manner. In Sec. VI we show that a polar integral can exist simultaneously with any other independent second order integral only if the magnetic field is constant. The final Sec. VII is devoted to conclusions and open problems.

II. FORMULATION OF THE PROBLEM

A. Classical mechanics

Since we will be comparing results in quantum and classical mechanis, let us briefly recapitulate some results obtained earlier.[15,16] The classical counterpart of the Hamiltonian (1.1) is

$$H = \tfrac{1}{2}(p_x^2 + p_y^2) + A(x,y)p_x + B(x,y)p_y + V(x,y), \tag{2.1}$$

where p_x and p_y are the momenta conjugate to x and y, respectively. The classical equations of motion in the Hamiltonian form are

$$\dot{x} = \frac{\partial H}{\partial p_x} = p_x + A, \quad \dot{y} = \frac{\partial H}{\partial p_y} = p_y + B,$$

$$\dot{p}_x = -\frac{\partial H}{\partial x} = -V_x - A_x p_x - B_x p_y, \quad \dot{p}_y = -\frac{\partial H}{\partial y} = -V_y - A_y p_x - B_y p_y. \tag{2.2}$$

The equation of motion (2.2) can be rewritten in the Newton form as

$$\ddot{x} = -W_x + \Omega \dot{y},$$

$$\ddot{y} = -W_y - \Omega \dot{x}, \tag{2.3}$$

$$W = V - \tfrac{1}{2}(A^2 + B^2),$$

$$\Omega = A_y - B_x. \tag{2.4}$$

The equations of motion (2.3) are invariant under a gauge transformation of the potentials

$$V(x,y) \to \tilde{V}(x,y) = V + (\mathbf{A}, \nabla\phi) + \tfrac{1}{2}(\nabla\phi)^2,$$

$$\mathbf{A}(x,y) \to \tilde{\mathbf{A}}(x,y) = \mathbf{A} + \nabla\phi, \tag{2.5}$$

where we have put $\mathbf{A} = (A,B)$ and $\phi = \phi(x,y)$ is an arbitrary smooth function. Thus, the quantities that are of actual physical importance are the magnetic field Ω and the effective potential W.

A classical first integral of motion is postulated to have the form

$$C = f_1(x,y)\dot{x} + f_2(x,y)\dot{y} + m(x,y). \tag{2.6}$$

The determining equations for the funtions f_1, f_2, and m are obtained from the requirement

$$\{H,C\} = \frac{dC}{dt} = 0, \tag{2.7}$$

when Eq. (2.2) are satisfied, i.e., C is a constant on the solutions of the equations of motion and Poisson commutes with the Hamiltonian.

Similarly, a classical second order integral of motion has the form

$$C = g_1(x,y)\dot{x}^2 + g_2(x,y)\dot{y}^2 + g_3(x,y)\dot{x}\dot{y} + k_1(x,y)\dot{x} + k_2(x,y)\dot{y} + m(x,y). \tag{2.8}$$

The determining equations for the functions g_i, k_i, and m are again obtained from the condition (2.7).

The equations for the coefficients of the first and second order classical integrals of motion were derived and partially solved elsewhere.[15,16] We shall give them again below as classical limits of the corresponding equations in the quantum case. To facilitate a comparison, we must rewrite the classical integrals in terms of momenta, rather than velocities, i.e., substitute $\dot{x} = p_x + A$, $\dot{y} = p_y + B$.

B. Quantum mechanics

In quantum mechanics an integral of motion will be a Hermitian operator X that commutes with the Hamiltonian H.

Let us first consider a first order integral in the momenta:

$$X = -\frac{i\hbar}{2}(f_1\partial_x + \partial_x f_1 + f_2\partial_y + \partial_y f_2) + f_1 A + f_2 B + m. \tag{2.9}$$

The classical limit of the operator (2.9) is the integral (2.6); f_1, f_2, and m are functions of x and y.

The commutator $[X,H]$ with H as in Eq. (1.1) will contain second, first, and zero order terms in the derivatives. Setting the coefficients of all of them equal to zero, we obtain the following set of determining equations:

$$f_{1,x}=0,\ \ f_{2,y}=0,\ \ f_{1,y}+f_{2,x}=0, \tag{2.10}$$

$$-f_2\Omega+m_x=0,\ \ f_1\Omega+m_y=0,\ \ f_1W_x+f_2W_y=0. \tag{2.11}$$

We see that the Planck constant $\hbar$ does not figure in Eqs. (2.10) and (2.11). Hence these equations must coincide with their classical limit, and indeed, they do.[15] In particular, Eq. (2.10) implies

$$f_1=\alpha y+\beta,\ \ f_2=-\alpha x+\gamma, \tag{2.12}$$

where α, β, and γ are real constants. Hence the leading terms (independent of A, B, and m) of the operator X of Eq. (2.9) lie in the Lie algebra $e(2)$ of the Euclidean group $E(2)$, generated by

$$P_1=-i\hbar\partial_x,\ P_2=-i\hbar\partial_y,\ L_3=-i\hbar(y\partial_x-x\partial_y). \tag{2.13}$$

Thus, we have

$$X=\alpha L_3+\beta P_1+\gamma P_2+\alpha(yA-xB)+\beta A+\gamma B+m. \tag{2.14}$$

We shall write the second order operator corresponding to the integral (2.8), after symmetrization, as

$$\begin{aligned}X=&-\tfrac{1}{2}\hbar^2\{2g_1\partial_x^2+2g_2\partial_y^2+2g_3\partial_x\partial_y+(2g_{1,x}+g_{3,y})\partial_x+(2g_{2,y}+g_{3,x})\partial_y+g_{1,xx}+g_{2,yy}+g_{3,xy}\}\\&-\frac{i\hbar}{2}\{(4g_1A+2g_3B+2k_1)\partial_x+(4g_2B+2g_3A+2k_2)\partial_y+2g_1A_x+2g_{1,x}A+2g_2B_y+2g_{2,y}B\\&+g_3A_y+g_3B_x+Ag_{3,y}+Bg_{3,x}+k_{1,x}+k_{2,y}\}+g_1A^2+g_2B^2+g_3AB+k_1A+k_2B+m.\end{aligned} \tag{2.15}$$

The commutativity condition $[H,X]=0$ implies the following set of determining relations:

$$g_{1,x}=0,\ \ g_{2,y}=0,\ \ g_{1,y}+g_{3,x}=0,\ \ g_{2,x}+g_{3,y}=0, \tag{2.16}$$

$$\begin{gathered}k_{1x}-g_3\Omega=0,\ \ k_{2y}+g_3\Omega=0,\\2\Omega(g_1-g_2)+k_{1y}+k_{2x}=0,\\2g_1W_x+g_3W_y+k_2\Omega-m_x=0,\\2g_2W_y+g_3W_x-k_1\Omega-m_y=0,\end{gathered} \tag{2.17}$$

$$k_1W_x+k_2W_y+\frac{\hbar^2}{4}(g_{2x}\Omega_y-g_{1y}\Omega_x)=0. \tag{2.18}$$

Equations (2.16) and (2.17) are the same as the classical ones.[15] Equation (2.18) is however different. It involves the Planck constant and reduces to the classical case only in the limit $\hbar\to 0$. Thus, in the presence of a nonconstant magnetic field $\Omega(x,y)$, classical and quantum integrability differ!

Equation (2.16) can be solved as in the classical case[15] and they imply

$$\begin{gathered}g_1=\alpha y^2-\beta y+\delta,\\g_2=\alpha x^2+\gamma x+\zeta,\\g_3=-2\alpha xy+\beta x-\gamma y+\xi,\end{gathered} \tag{2.19}$$

where the greek letters represent real constants. Substituting (2.19) into (2.15) we obtain the operator X in the form

$$X=\alpha[(L_3+yA-xB)^2+\hbar^2]-\tfrac{1}{2}\beta[(L_3+yA-xB)(P_1+A)+(P_1+A)(L_3+yA-xB)]$$
$$-\tfrac{1}{2}\gamma[(L_3+yA-xB)(P_2+B)+(P_2+B)(L_3+yA-xB)]+\delta(P_1+A)^2+\zeta(P_2+B)^2$$
$$+\xi(P_1+A)(P_2+B)-\frac{i\hbar}{2}(2k_1\partial_x+k_{1,x}+2k_2\partial_y+k_{2,y})+k_1A+k_2B+m. \tag{2.20}$$

Thus, the leading part of Eq. (2.20) lies in the enveloping algebra of $e(2)$. For $A=B=0$ this coincides with the case of a scalar potential.[1,2,17] As in the scalar case we can simplify Eq. (2.20) by Euclidean transformations and linear combinations with the Hamiltonian. The operator X is transformed into a similar operator, with new values of the constants $\alpha,\ldots,\xi$. Four classes of such operators exist, represented by

$$X_C=(P_1+A)^2-\frac{i\hbar}{2}(2k_1\partial_x+k_{1,x}+2k_2\partial_y+k_{2,y})+k_1A+k_2B+m, \tag{2.21}$$

$$X_R=(L_3+yA-xB)^2+\hbar^2-\frac{i\hbar}{2}(2k_1\partial_x+k_{1,x}+2k_2\partial_y+k_{2,y})+k_1A+k_2B+m, \tag{2.22}$$

$$X_P=-\frac{1}{2}\{(L_3+yA-xB)(P_1+A)+(P_1+A)(L_3+yA-xB)\}$$
$$-\frac{i\hbar}{2}(2k_1\partial_x+k_{1,x}+2k_2\partial_y+k_{2,y})+k_1A+k_2B+m, \tag{2.23}$$

$$X_E=(L_3+yA-xB)^2+\hbar^2+\sigma[(P_1+A)^2-(P_2+B)^2]$$
$$-\frac{i\hbar}{2}(2k_1\partial_x+k_{1,x}+2k_2\partial_y+k_{2,y})+k_1A+k_2B+m,\quad \sigma>0. \tag{2.24}$$

In the case of a purely scalar potential the existence of a commuting operator of the type X_C, X_R, X_P, or X_E implies that the Schrödinger equation will allow separation of variables in Cartesian, polar, parabolic, or elliptic coordinates, respectively. In the last case σ is related to the interfocal distance for the elliptic coordinates.

Substituting Eq. (2.19) into Eq. (2.18) we obtain

$$k_1W_x+k_2W_y+\frac{\hbar^2}{4}[(2\alpha x+\gamma)\Omega_y-(2\alpha y-\beta)\Omega_x]=0. \tag{2.25}$$

Thus, for the special case $\alpha=\beta=\gamma=0$ classical and quantum integrability will coincide.

III. FIRST ORDER INTEGRABILITY AND SUPERINTEGRABILITY

A first order integral (2.9) in quantum mechanics will exist if the overdetermined system (2.10) and (2.11) has a solution. The general solution of Eq. (2.10) is given by Eq. (2.12). Substituting into (2.11) we obtain

$$(\alpha x-\gamma)\Omega+m_x=0,\ (\alpha y+\beta)\Omega+m_y=0,\ (\alpha y+\beta)W_x+(-\alpha x+\gamma)W_y=0. \tag{3.1}$$

We are only interested in cases with a magnetic field present, i.e., $\Omega \neq 0$. With no loss of generality, we need only distinguish two cases:

1. $\alpha=1$, $\beta=\gamma=0$.

We obtain

$$W=W(\rho),\ \Omega=\Omega(\rho),\ \rho=\sqrt{x^2+y^2}. \tag{3.2}$$

We see that in this case the magnetic field Ω and the effective scalar potential must be spherically symmetric. The potentials in the Hamiltonian (1.1) can by a gauge transformation be taken into

$$A=\int \frac{\Omega(\rho)\rho d\rho}{\sqrt{\rho^2-x^2}},\ B=0,\ V=W(\rho)+\tfrac{1}{2}A^2. \tag{3.3}$$

The integral of motion is

$$X=L_3+y\int \frac{\Omega(\rho)\rho d\rho}{\sqrt{\rho^2-x^2}}-\int \rho\Omega(\rho)d\rho. \tag{3.4}$$

2. $\alpha=\beta=0$, $\gamma=1$.

The magnetic field and effective potential are translationally invariant

$$\Omega=\Omega(x),\ W=W(x), \tag{3.5}$$

and we can take

$$A=\Omega y,\ B=0,\ V=W+\tfrac{1}{2}y^2\Omega^2,$$

$$X=P_2+\int \Omega(x)dx. \tag{3.6}$$

The system (1.1) will be first order superintegrable if at least two first order integrals (2.14) exist. This is only possible if the magnetic field and effective potential are constant:

$$\Omega=\Omega_0,\ W=W_0. \tag{3.7}$$

In this case actually three operators commuting with the Hamiltonian exist and we have

$$H=\frac{1}{2}(i\hbar\partial_x-\Omega y)^2-\frac{\hbar^2}{2}\partial_y^2, \tag{3.8}$$

$$X_1=P_1,\ X_2=P_2+x\Omega_0,\ X_3=L_3-\tfrac{1}{2}(x^2-y^2)\Omega_0, \tag{3.9}$$

where we have chosen the gauge to be such that

$$A=\Omega_0 y,\ B=0,\ V=\tfrac{1}{2}\Omega^2y^2. \tag{3.10}$$

The classical equations of motion (2.2) are easily solved. The trajectories are circles (and are hence all closed). The Schrödinger equation allows the separation of variables in Cartesian coordinates. The solution is

$$\Psi(x,y)=e^{i(\lambda/\hbar)x}f(y), \tag{3.11}$$

where $f(y)$ satisfies the harmonic oscillator equation

$$f''-\left\{\left(\frac{\Omega y+\lambda}{\hbar}\right)^2-\frac{2E}{\hbar^2}\right\}f=0. \tag{3.12}$$

The integrals of motion (3.9), together with the constant Ω, satisfy the commutation relations of a central extension of the Euclidean Lie algebra:

$$[X_1,X_2]=-i\hbar\Omega_0,\ [X_3,X_1]=-i\hbar X_2,\ [X_3,X_2]=i\hbar X_1. \tag{3.13}$$

Only three of the integrals X_1, X_2, X_3, and H can be independent and indeed they satisfy

$$X_1^2+X_2^2+2\Omega_0X_3-2H=0. \tag{3.14}$$

In polar coordinates the Schrödinger equation

$$\left\{\frac{1}{2}\left(i\hbar\cos(\phi)\partial_r-\frac{\sin(\phi)}{r}\partial_\phi-\Omega r\sin(\phi)\right)^2-\frac{1}{2}\left(\sin(\phi)\partial_r+\frac{\cos(\phi)}{r}\partial_\phi\right)^2\right\}\Psi=E\Psi \tag{3.15}$$

R-separates,[16,18] rather than separates, and we have

$$\Psi(r,\phi)=e^{-(i/4)\,\Omega r^2\sin 2\phi}J_m(kr)e^{im\phi},\ \ k^2=2E+m\Omega, \tag{3.16}$$

where $J_m(kr)$ is a Bessel function.

IV. CARTESIAN INTEGRABILITY AND SUPERINTEGRABILITY

A. Integrability

In order to find integrable systems with a second order operator commuting with the Hamiltonian, we must solve the system (2.16)–(2.18). To do this, we first transform X to its canonical form, i.e., one of (2.21)–(2.24). We start with the simplest case, namely X_C of (2.21). We call this the ''Cartesian'' case, because for a purely scalar potential it corresponds to separation of variables in Cartesian coordinates. It corresponds to $\alpha=\beta=\gamma=\zeta=\xi=0$ and $\delta=1$ in Eq. (2.20). Equation (2.25) implies that the determining equations (2.16), (2.17), and (2.18) are the same in the classical and quantum cases [the $\hbar^2$ term in Eq. (2.18) vanishes]. For purely scalar potentials $\Omega=k_1=k_2=0$ we reobtain the known result $W=W_0(y)+m(x)$.[1] From now on we assume $\Omega\neq0$. For completeness, we reproduce the result obtained earlier[15] in the classical case, since it is valid in the quantum case as well:

$$\Omega=f_{xx}+g_{yy},$$

$$W=\frac{a}{3}(g-f)^3-\frac{b+d}{2}(g-f)^2+(c+k-e)(g-f),$$

$$k_1=-g_y,\ k_2=-f_x,$$

$$m=-\frac{a}{3}(g^3+2f^3-3gf^2)+b(fg-f^2)+\frac{d}{2}(g^2-f^2)+c(g-2f)+eg-kf. \tag{4.1}$$

Here a, b, c, d, e, and k are constants and the functions $f=f(x)$ and $g=g(y)$ satisfy

$$f_{xx}=af^2+bf+c,\ \ g_{yy}=-ag^2+dg+e,$$

$$f_x\neq0,\ \ g_y\neq0. \tag{4.2}$$

Two exceptional cases occur when we have $f_x=0$ or $g_y=0$. These however imply $\Omega=\Omega(x)$, $W=W(x)$ or $\Omega=\Omega(y)$, $W=W(y)$, respectively. Then a first order invariant exists and the second order one is simply its square. The general solution of Eq. (4.2) are elliptic functions.

B. Cartesian superintegrability

We shall now assume that Ω and W are such that one Cartesian integral X_1 exists, i.e., they satisfy Eq. (4.1). We require that a second integral X_2 of the type (2.20) should exist, in addition to the considered Cartesian one. We can simplify the integral X_2 by translation and by linear combinations with X_1 and H. Rotations cannot be used, since they would change the form of the operator X_1 and of the Hamiltonian. Two cases must be considered, $\alpha\neq 0$ and $\alpha=0$.

Case 1: $\alpha\neq 0$

We set $\alpha=1$, by a translation we transform $(\beta,\gamma)\rightarrow(0,0)$, by linear combinations we set $(\delta,\zeta)\rightarrow(0,0)$. We are left with an operator X_2 in the form (2.20) with $\alpha=1$, $\beta=\gamma=\delta=\zeta=0$. The constant ξ and functions k_1, k_2 and m must be determined from the system (2.17) and (2.18). Let us consider the case when Ω and W are as in Eq. (4.1). The first two equations imply

$$k_1=-2y(xf_x-f)-x^2yg_{yy}+\xi f_x+\xi xg_{yy}+C_1(y),$$

$$k_2=xy^2f_{xx}+2x(yg_y-g)-\xi yf_{xx}-\xi g_y+C_2(x). \tag{4.3}$$

We substitute k_1, k_2, Ω, and W into the remaining four equations and investigate their compatibility. After somewhat lengthy calculations we obtain a simple result: the equations are compatible for $\Omega\neq 0$ if and only if Ω and W are constant. We arrive at the case (3.7), already investigated in Sec. III.

Case 2: $\alpha=0$

In order to obtain an independent second order integral we must have $\beta^2+\gamma^2\neq 0$ and we can normalize $\beta^2+\gamma^2=1$ and put $\delta=\zeta=\xi=0$ (by linear combinations with H and X_1). The set of Eqs. (2.16)–(2.18) is then again compatible only for Ω and W constant.

The conclusion of this section is that for $\Omega\neq 0$ Cartesian superintegrability with two second order integrals exists only in a trivial sense. Thus $\Omega=\Omega_0$, $W=W_0$ and all second order integrals are reducible: they are polynomials in the three first order ones.

V. POLAR INTEGRABILITY

We now request that one second order integral should exist and that it be of the form (2.22). We shall call this operator X_R a polar type integral. Let us transform the determining equations (2.17) and (2.18) to polar coordinates $x=r\cos(\phi)$, $y=r\sin(\phi)$. The resulting equations are

$$P_r=0,\ P+Q_\phi=0, \tag{5.1}$$

$$2r^3\Omega-P_\phi-rQ_r+Q=0, \tag{5.2}$$

$$m_\phi-2r^2W_\phi+rP\Omega=0,\ \ m_r-Q\Omega=0, \tag{5.3}$$

$$\frac{\hbar^2}{2}\Omega_\phi+PW_r+\frac{1}{r}QW_\phi=0, \tag{5.4}$$

where we have put $P=k_1\cos(\phi)+k_2\sin(\phi)$ and $Q=-k_1\sin(\phi)+k_2\cos(\phi)$.

We see that Eq. (5.4) contains a term proportional to $\hbar^2$. It follows that in this case quantum integrable systems will differ from classical ones, at least if we have $\Omega_\phi\neq 0$. In the classical limit $\hbar\rightarrow 0$ the quantum systems will reduce to classical ones, or to free motion. This is a new phenomenon. In the absence of magnetic fields, classical and quantum systems with second order integrals of motion coincide.

Equations (5.1) imply

$$P=-f'(\phi),\quad Q=f(\phi)+R(r), \tag{5.5}$$

with $f(\phi)$ and $R(r)$ to be determined. We shall use primes and dots to denote derivatives with respect to ϕ and r, respectively. We again assume $\Omega\neq 0$. Indeed, for $\Omega=0$ we obtain the known case of a scalar potential, separable in polar coordinates: $W=W_0(r)+W_1(\phi)/r^2$.

We solve Eq. (5.2) for the magnetic field

$$\Omega=-\frac{1}{2r^3}(f''+f+R-r\dot{R}). \tag{5.6}$$

From Eq. (5.3) we obtain a compatibility condition ($m_{r\phi}=m_{\phi r}$), namely,

$$2r^2W_{r\phi}+4rW_{\phi}+\frac{3f'}{2r^3}(f''+f+R-r\dot{R})+\frac{f'\ddot{R}}{2r}+\frac{1}{2r^3}(f+R)(f'''+f')=0. \tag{5.7}$$

Using Eq. (5.4) to eliminate W_ϕ from Eq. (5.7), we obtain, for

$$f+R\neq 0,\quad f'\neq 0 \tag{5.8}$$

an equation for $W(r,\phi)$ that we can solve

$$W_{rr}+\frac{(3(f+R)-r\dot{R})}{r(f+R)}W_r-\frac{\hbar^2\dot{R}(f'''+f')}{4r^3f'(f+R)}+\frac{3(f+R)}{4r^6}(f''+f+R-r\dot{R})$$
$$+\frac{(f+R)\ddot{R}}{4r^4}+\frac{(f+R)^2}{4r^6f'}(f'''+f')=0. \tag{5.9}$$

We obtain

$$W=\frac{\hbar^2(f'''+f')}{8r^2f'}-\frac{3f(f''+f)}{32r^4}-\frac{f'''}{8f'}r^6\dot{u}^2-\frac{r^2}{8}(r^3\ddot{u}+3r^2\dot{u})^2-\frac{f^2(f'''+f')}{32f'r^4}-\frac{Ff}{2r^2}$$
$$+\left(\frac{3f''}{8}+\frac{ff'''}{8f'}\right)r\dot{u}+\frac{3f''}{4}u-\frac{f}{4r}(r^3\ddot{u}+3r^2\dot{u})+Fr^3\dot{u}+W_0, \tag{5.10}$$

where $F=F(\phi)$ and $W_0(\phi)$ are two new functions, introduced as integration "constants." We have also introduced the functions $u(r)$ and $S(r)$, satisfying

$$\dot{S}(r)=\frac{1}{r^3}R(r),\ \dot{u}(r)=\frac{1}{r^3}S(r). \tag{5.11}$$

Let us first consider the two special cases in Eq. (5.8).

For $f(\phi)+R(r)=0$, Eq. (5.6) implies $\Omega=0$ and we are not interested in this case.

In the case $f'(\phi)=0$ we have

$$P=0,\quad Q=Q(r),\quad W=W(r),\quad m=\frac{Q^2}{4r^2},$$

$$k_1=-Q(r)\sin(\phi),\quad k_2=Q(r)\cos(\phi), \tag{5.12}$$

and the classical and quantum cases coincide. Moreover, a first order integral exists and the second order one is its square.

Let us return to the generic case (5.10) with conditions (5.8) satisfied. We substitute W of Eq. (5.10) into Eqs. (5.3) and (5.4) to obtain

$$m=\frac{ff''}{4r^2}+\frac{f^2}{4r^2}+\frac{fR}{2r^2}-\frac{f''S}{2}+\frac{R^2}{4r^2}+m_0(\phi), \tag{5.13}$$

$$m_0'=2\,f'F, \tag{5.14}$$

$$\dddot{u}+\frac{6}{r}\ddot{u}-\frac{r^3\dot{u}^2}{2}\left(\frac{f'''}{f'}\right)'\frac{1}{f'}+\left(\frac{6}{r^2}+\frac{C}{2r^2f'}+\frac{4F'}{f'}\right)\dot{u}+\frac{3f'''}{r^3f'}u+\frac{4A}{r^7f'}+\frac{4B}{r^5f'}+\frac{4W_0'}{r^3f'}=0, \tag{5.15}$$

where

$$A=-\frac{9ff'''}{32}-\frac{f^2}{32}\left(\frac{f'''}{f'}\right)'-\frac{15f'f''}{32}-\frac{3ff'}{4},$$

$$B=\frac{\hbar^2}{8}\left(\frac{f'''}{f'}\right)'-\frac{fF'}{2}-\frac{3f'F}{2},$$

$$C=6f'''+f\left(\frac{f'''}{f'}\right)'. \tag{5.16}$$

The next task is to solve Eq. (5.15). Notice that this is not a partial differential equation. It involves four unknown functions $u(r)$, $f(\phi)$, $F(\phi)$, and $W_0(\phi)$, each depending on one variable only. Hence, we can consider this equation to be an ordinary differential equation for $u(r)$, and then establish the compatibility conditions on the other unknowns for which the ϕ dependence will cancel. The complete analysis is rather lengthy and involves the consideration of many special cases. We shall only present the main arguments and final results.

Case 1:

$$\left(\left(\frac{f'''}{f'}\right)'\left(\frac{1}{f'}\right)\right)'=0. \tag{5.17}$$

All subcases lead to the following solution (or special cases thereof):

$$f=C_0+C_1\cos(\phi)+C_2\sin(\phi),$$

$$F=K_1,\quad W_0=K_2f+K_3. \tag{5.18}$$

Equation (5.15) then reduces to

$$\dddot{u}+\frac{6}{r}\ddot{u}+\frac{3}{r^2}\dot{u}-\frac{3}{r^3}u-\frac{15C_0}{8r^7}-\frac{6K_1}{r^5}+\frac{4K_2}{r^3}=0. \tag{5.19}$$

The general solution of Eq. (5.19) is

$$u=-\frac{C_0}{8r^4}+\frac{2K_1}{r^2}+\frac{4K_2}{3}+ar+\frac{b}{r}+\frac{c}{r^3}, \tag{5.20}$$

and hence we have

$$S=\frac{C_0}{2r^2}-4K_1+ar^3-br-\frac{3c}{r},$$

$$R=-C_0+3ar^5-br^3+3cr. \tag{5.21}$$

Finally, the magnetic field and effective potential in this case are

$$\Omega = 6ar^2 - b, \tag{5.22}$$

$$W = -2ar(C_1\cos(\phi) + C_2\sin(\phi)) + \frac{ab}{2}r^4 - 3acr^2 - a^2r^6. \tag{5.23}$$

Since Ω does not depend on ϕ the classical and quantum cases are the same. The corresponding classical integral of motion is

$$\begin{aligned} C_R = {} & (x\dot{y} - y\dot{x})^2 + (-C_2 - (3ar^5 - br^3 + 3cr)\sin(\phi))\dot{x} + (C_1 + (3ar^5 - br^3 + 3cr)\cos(\phi))\dot{y} \\ & - \frac{3bcr^2}{2} + \frac{9acr^4}{2} - \frac{3abr^6}{2} + 2C_1ar^3\cos(\phi) - C_1br\cos(\phi) + 2C_2ar^3\sin(\phi) \\ & - C_2br\sin(\phi) + \frac{9a^2r^8}{4} + \frac{b^2r^4}{4} + \frac{9c^2}{4}. \end{aligned} \tag{5.24}$$

Case 2:

$$\left(\left(\frac{f'''}{f'}\right)'\left(\frac{1}{f'}\right)\right)' \neq 0. \tag{5.25}$$

A complete analysis[19] shows that Eq. (5.15) in this case is consistent only if we have

$$u = \frac{a}{8r^4} + \frac{b}{2r^2} + c \tag{5.26}$$

and hence

$$S = -\frac{a}{2r^2} - b, \quad R = a. \tag{5.27}$$

Moreover, the function $f(\phi)$ must satisfy

$$(f+a)^2\left(\frac{f'''}{f'}\right)' + 24f'(f+a) + 9f'''(f+a) + 15f'f'' = 0. \tag{5.28}$$

The functions $F(\phi)$ and $W_0(\phi)$ are given explicitly in terms of $f(\phi)$ as

$$F = -\frac{bf'''}{4f'} + \frac{\hbar^2}{4(f+a)^3}\left((f+a)^2\frac{f'''}{f'} - 2(f+a)f'' + (f')^2\right) + \frac{C_1}{(f+a)^3},$$

$$W_0 = \frac{b^2f'''}{8f'} + bF - \frac{3cf''}{4} + C_2. \tag{5.29}$$

We integrate Eq. (5.28) twice and put $y = f + a$ to obtain the second order equation

$$y'' = -\frac{2}{y}(y')^2 - 3y + \frac{4A}{y} + \frac{B^2 - A^2}{y^3}, \tag{5.30}$$

where A and B are constants.

This equation has a first integral K, in terms of which we have

$$y^4(y')^2 = -y^6 + 2Ay^4 + (B^2 - A^2)y^2 + K. \tag{5.31}$$

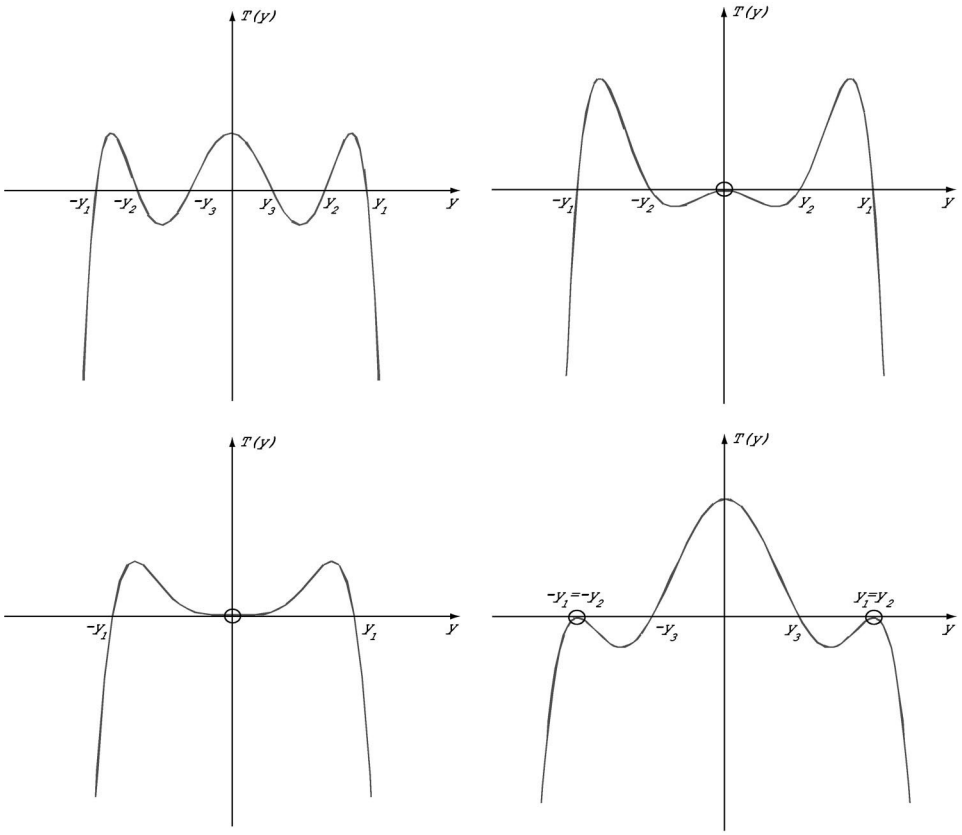

FIG. 1. Roots of the polynomial $T(y)$ in Eq. (5.32). (a) Three pairs of simple roots; (b) one quadruple root, a pair of single ones; (c) one double root, two pairs of single ones; (d) one pair of double roots and one of simple ones.

This equation can be written as a quadrature that will express the independent variable ϕ as a function of y in terms of elliptic integrals. The results are not very illuminating, so instead of presenting them, we restrict ourselves to some special cases. Let us first rewrite Eq. (5.31) as

$$y^4(y')^2 = -(y^2-y_1^2)(y^2-y_2^2)(y^2-y_3^2) \equiv T(y), \tag{5.32}$$

where the roots y_1, y_2, and y_3 are related to the constants A, B, and K by the formulas

$$K = y_1^2 y_2^2 y_3^2, \quad B^2 - A^2 = -(y_1^2 y_2^2 + y_2^2 y_3^2 + y_3^2 y_1^2), \quad 2A = y_1^2 + y_2^2 + y_3^2. \tag{5.33}$$

If all the roots y_i are real and distinct, the behavior of the polynomial $T(y)$ as a function of y is shown in Fig. 1(a).

If all roots are distinct ($0 < y_3 < y_2 < y_1 < \infty$), real periodic solutions are obtained for $-y_3 \leqslant y \leqslant y_3$, $y_2 \leqslant y \leqslant y_1$, and $-y_1 \leqslant y \leqslant y_2$. However, these are expressed in terms of elliptic functions and the period is not a multiple of π. Constant solutions of Eq. (5.32) are obviously $y = \pm y_k$, $k = 1,\ 2$ or 3.

Elementary ϕ dependent real finite periodic solutions are obtained whenever the polynomial $T(y)$ has multiple roots. The corresponding solutions are

(1) $y_3 = y_2 = 0$, $y_1 > 0$ [see Fig. 1(b)]

$$y = y_1 \sin(\phi - \phi_0); \tag{5.34}$$

(2) $0 = y_3 < y_2 < y_1$ [see Fig. 1(c)]

$$y=\pm\frac{1}{\sqrt{2}}\sqrt{y_1^2+y_2^2+(y_1^2-y_2^2)\sin 2(\phi-\phi_0)} \tag{5.35}$$

or in terms of A and B:

$$y=\pm\sqrt{A+B\sin 2(\phi-\phi_0)}; \tag{5.36}$$

(3) $0<y_3<y_2=y_1$ [see Fig. 1(d)].

In this case we give the solution y implicitly as

$$-2\sqrt{y_1^2-y_3^2}\arcsin\left(\frac{y}{y_3}\right)+y_1\left(\arcsin\left(\frac{y_3^2+yy_1}{y_3(y+y_1)}\right)\right)-\arcsin\left(\frac{y_3^2-yy_1}{y_3(y-y_1)}\right)=\pm 2\sqrt{y_1^2-y_3^2}(\phi-\phi_0). \tag{5.37}$$

The solution is real, finite, and periodic for $-y_3\leqslant y\leqslant y_3$.

For any solution $y(\phi)$ of Eq. (5.31) we obtain a magnetic field and effective potential in the form

$$\Omega=-\frac{f''+f+a}{2r^3}, \tag{5.38}$$

$$W=\frac{\hbar^2}{8r^2}\left(1+\frac{2f''}{f+a}-\frac{(f')^2}{(f+a)^2}\right)-\frac{(f+a)^2}{32r^4}\left(\frac{f'''}{f'}+4\right)-\frac{3f''(f+a)}{32r^4}-\frac{C_1}{2r^2(f+a)^2}+C_2. \tag{5.39}$$

The functions P, Q, and m figuring in the polar integral are

$$P=-f'(\phi),\quad Q=f(\phi)+a,$$

$$m=\frac{ff''+(f+a)^2+af''}{4r^2}-\frac{bf''}{2}-\frac{C_1}{(f+a)^2}+\frac{\hbar^2}{4(f+a)^2}(2(f+a)f''-(f')^2). \tag{5.40}$$

Let us sum up the results of this section. Three different cases of polar integrability exist. They are given by Eqs. (5.12), (5.22)–(5.24) and (5.38)–(5.40), respectively. The last case provides an example where the quantum system and the classical one differ. Indeed, the Planck constant figures explicitly in the effective potential W and in the integral of motion.

VI. POLAR SUPERINTEGRABILITY

Let us assume that we have a Hamiltonian (1.1) that is "polar integrable," i.e., allows an integral of motion of the form X_R as in Eq. (2.22). The magnetic field Ω and effective potential W must hence have one of the three forms established in Sec. V. For the system to be superintegrable, it must allow at least one further integral, by assumption of the form (2.20). We can simplify this second integral by linear combinations with X_R and with H and also by rotations, since they will not destroy the form of X_R (nor H). Thus, in Eq. (2.20) we take $\alpha=0$, $\zeta=-\delta$. Furthermore, we can assume $\beta^2+\gamma^2\neq 0$, since otherwise we would be in the case of Cartesian superintegrability, already treated in Sec. IV. By a rotation and normalization, we can set $\beta=1$, $\gamma=0$. It follows that the second integral X_2 is of the parabolic type, conjugate to X_P of Eq. (2.23).

The determining equations for X_2, obtained from (2.17) and (2.18) are

$$k_{1,x}-(x+\xi)\Omega=0,\ k_{2,y}+(x+\xi)\Omega=0, \tag{6.1}$$

$$-2\beta\Omega y+k_{1,y}+k_{2,x}=0, \tag{6.2}$$

$$-2yW_x+(x+\xi)W_y+k_2\Omega-m_x=0,$$

$$(x+\xi)W_x-k_1\Omega-m_y=0, \tag{6.3}$$

$$k_1W_x+k_2W_y+\frac{\hbar^2}{4}\beta\Omega_x=0. \tag{6.4}$$

For each of the three polar integrable systems we obtain the same result, namely, Eqs. (6.1)–(6.4) are compatible only if $\Omega=\Omega_0$ and $W=W_0$ are constant. Then we have three first order integrals and the corresponding second order integrals are polynomial in the first order ones.

VII. CONCLUSIONS

We have constructed all integrable quantum systems with a vector and scalar potential [as in Eq. (1.1)] that possess either a first order integral, or a second order one of the Cartesian, or polar type.

It is interesting to compare such systems with a nonzero magnetic field Ω with systems allowing a scalar potential only.

(1) The first difference is that for $\Omega\neq0$ quantum and classical integrable systems with second order integrals do not necessarily coincide. The Planck constant $\hbar$ can figure in a nontrivial way in the potentials and integrals of motion.
(2) The existence of a first order integral of motion implies a geometrical symmetry, both for $\Omega\neq0$ and $\Omega=0$. Indeed, a first order integral exists if and only if we have either $\Omega=\Omega(r)$, $W=W(r)$, or $\Omega=\Omega(y)$, $W=W(y)$ (up to Euclidean transformations). The functions Ω and W are arbitrary in both cases.
(3) The existence of a second order integral for $\Omega=0$ implies that the Schrödinger equation will allow separation of variables in Cartesian, polar, parabolic, or elliptic coordinates. In each case the potential $V(x,y)$ depends on two arbitrary functions of one variable. For $\Omega\neq0$ the coordinates no longer separate. The requirement that an irreducible second order integral should exist for $\Omega\neq0$ is much more restrictive than for $\Omega=0$. The quanttities $\Omega(x,y)$ and $W(x,y)$ again depend on two functions of one variable, however these functions obey certain ordinary differential equations. They are hence determined completely, up to some arbitrary constants. For instance, in the Cartesian case, they are elliptic functions, or degenerate cases of elliptic functions.
(4) For $\Omega=0$ four families of superintegrable systems in $E(2)$ exist,[1] each depending on three parameters. For $\Omega\neq0$ we have shown that superintegrability with first order integrals of the Cartesian, or polar type, exists only for Ω and W constant.

Several related problems are presently under consideration. To complete the study of quadratic integrability in $E(2)$ for $\Omega\neq0$ we must still consider parabolic and elliptic integrability. For $\Omega=0$ their is a close relation between superintegrability and exact solvability.[20] For $\Omega\neq0$ the requirement of superintegrability seems to be too restrictive. An important question is whether some of the integrable systems found in this article are actually exactly solvable.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 5 MAY 2004

A statistical complexity measure with nonextensive entropy and quasi-multiplicativity

Takuya Yamano[a)]
Max-Planck-Institut für Physik komplexer Systeme, Nöthnitzer Str. 38 D-01187, Dresden, Germany and Department of Physics, Ochanomizu University, 2-1-1 Otsuka, Bunkyo-ku, Tokyo 112-8610, Japan

(Received 7 August 2003; accepted 11 February 2004; published 5 April 2004)

The properties of a statistical complexity measure that are characterized by nonextensivity in entropy have been investigated, which is of so-called disequilibrium type. Considering the composition law for two systems with different nonextensivities (quasi-multiplicativity), a nontrivial relation between the nonextensive parameters and the fluctuating bit number in information theory has been mentioned. To see the time evolution of the nonextensive complexity measure, we examine systems having a lognormal distribution, the underlying dynamics for which is known to obey a random multiplicative process in the presence of a boundary constraint. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1695600]

I. INTRODUCTION

In recent times, quantifying the complexity of a system has been the chief focus of study across various branches of science and has been drawing renewed attention.[1–3] Up to the present date, different definitions of the complexity have been proposed. Among these, a few notable definitions include algorithmic complexities (Kolmogorov–Chaitin complexity[4] and Lempel-Ziv complexity[5]), effective measure of complexity by Grassberger,[6] logical depth by Bennett,[7] and thermodynamical depth by Lloyd and Pagels.[8] These definitions of complexities have been useful in describing the symbolic dynamics of maps; however, they have the disadvantage of complicated calculations. Especially in physics, a measure of statistical complexity is considerably essential. In most of the proposals for complexity measures, utilizing the concept of entropy or relevant information can be regarded as a basic ingredient for quantifying the phenomenon. In the last few years, keen interest in developing new definitions for statistical measure of complexity based on probabilistic descriptions of physical systems has emerged. One of these is the disequilibrium-based complexity, i.e., LMC(López-Ruiz–Mancini–Calbet)[9] complexity measure C (defined as $C=H\cdot D$ where H is the Shannon entropy and D disequilibrium) that has adopted quadratic distances of each state for assessing the equiprobability. The other one is the simple measure for complexity proposed by SDL (Shiner, Davison, and Landsberg).[10] It is defined as the product of a measure of *order* and a measure of *disorder* in a system.

Another current proposal in the applications is to determine the innovative uses of conventional entropy, which are known as the multiscale entropy[11] and the diffusion entropy analysis[12] (these studies use the Shannon entropy without resorting to the introduction of a new complexity measure). In these past studies, considerable attention has been paid to extract the useful information in order to discriminate, for example, health and disease from a physiologic time series and we require a quantification of their complexities. Their leitmotif was to overcome the fact that an increase in conventional entropy does not always accommodate a growth of dynamical complexity.

In the present study, we intend to use nonextensive entropy instead of extensive (additive) Shannon entropy for defining the statistical measure of complexity from its starting point. The

[a)]Present address: Department of Physics, Ochanomizu University, 2-1-1 Otsuka, Bunkyo-ku, Toyko 112-8610, Japan. Electronic mail: yamano@amy.hi-ho.ne.jp

rationale for adopting nonextensive entropy is as follows: It is difficult to imagine that the complexity of a system becomes twice its original when the system size is doubled. However, when two or more systems are merged, it seems rather natural to assume that complexity of a system increases or decreases on the basis of symmetry, hierarchy, and acclimation. Although the nonextensivity property of the LMC measure has already been described in Ref. 13, we shall clamp its nonadditive feature on entropy in order to incorporate this assumption into the measure.

We seek a possibility for defining a statistical measure of complexity based on the Tsallis entropy[14] instead of the Shannon entropy for C (another notation will be used subsequently) and take a stance that the statistical complexity measure should vanish or be negligible for both highly ordered and highly disordered systems. As explained in an earlier paper,[9] these extreme situations with zero complexity correspond with the perfect crystal in the former case and the ideal gas in the latter case. In order to describe the perfect crystals, only a minimal amount of information is needed because the constituent atoms are symmetrically arrayed completely. A sufficient amount of information on the crystals is available from the lattice constant and symmetry (fcc, bcc, etc.) only. On the other hand, the state of a system can be found in the phase space with an equal probability in the case of ideal gases. In such a case, we have to specify a large number of variables for defining the system; therefore, it requires maximum information. These two states are extrema in terms of the order and information, and we assume that the system has a finite complexity at an intermediate state.[3]

In effect, we do not regard nonextensivity as an impediment to the legitimate definition of the statistical measure of complexity, because various kinds of physical systems exist for which the traditional extensive statistical mechanics appears to be inadequate.[15,16] Therefore, a nonextensive thermostatistics can be a possible basis for providing a descriptive framework for dealing with the above mentioned complexity measure. In this sense, the complexity measure as well as entropy need not be extensive. Therefore, examining the consequences of using a nonextensive entropy for the complexity measure might provide a hint posed by some applications. For this purpose, we have presented some properties of the complexity measure and have also shown that it retains some properties of the LMC.

The paper has been organized as follows: In Sec. II, the statistical measure of complexity is introduced with the nonextensive entropy of Tsallis and the basic properties are investigated along the lines of Ref. 17. The nonadditivity in the complexity measure is associated with the fluctuating bit number of systems on the basis of the concept of quasi-additivity in Sec. III. In Sec. IV, the time evolution of the present complexity measure is demonstrated by applying the constrained random multiplicative process. Finally, the results of the present study are summarized in the last section. The exact expressions of the complexity measure are given in the Appendix for a few probability distributions, which are often encountered in natural sciences.

II. A NONEXTENSIVE STATISTICAL MEASURE OF COMPLEXITY AND ITS PROPERTIES

In the present study, a continuous expression instead of the discrete one is considered. In general, translation of any entropy from its discrete form to the continuous form requires mathematical precision. However, in this case, we simply assume that the continuous entropy of Tsallis takes the form[18]

$$H_q(p(x)) = \frac{1}{1-q}\left[\int p^q(x)dx - 1\right]. \tag{1}$$

López-Ruiz *et al.*[9] proposed a quantity called the disequilibrium, whose measure is a distance from the equiprobable state. In the discrete case, it is expressed as

$$D(\{p_i\}) = \sum_{i=1}^{n} (p_i - 1/n)^2, \tag{2}$$

where D attains the maximum value for a fully ordered state and vanishes in the case of completely disordered states or equiprobable states. It is interesting to note that the disequilibrium is the same form as the alternative entropy, proposed by Bruckner and Zeilinger[19] in quantum measure of information. In order to make the present paper self-contained, the properties of D are briefly restated. The equiprobable states can be expressed as the rectangular function,

$$p(x)=\begin{cases}\dfrac{1}{2l} & (-l\leqslant x\leqslant l)\\ 0 & (\text{otherwise}),\end{cases} \tag{3}$$

which results in a well-defined disequilibrium for the continuous case. Then, from the definition, we have

$$\int_{-l}^{l}\left(p(x)-\frac{1}{2l}\right)^2 dx=\int_{-l}^{l}p^2(x)dx-\frac{1}{2l}. \tag{4}$$

Moreover, we may redefine the disequilibrium as $D(p(x))=\int_{-l}^{l}p^2(x)dx$, which ensures positivity in any distribution. Accordingly, distributions are measured from equiprobabilities in the course of our consideration. When a system is in the equiprobable state with large l, the value of D is minimum, and when l become small (peaked shape at zero point), then D tends toward infinity. From the view point of the information theory, D is found to be nonextensive[13] since l consecutive sequences of binary variables, $X_i, X_{i+1}, \ldots, X_{i+l-1}\equiv X^{(l)}$, whose values X_i are generated from a discrete finite alphabet of size 2, have the disequilibrium $D(X^{(l)})=\Sigma p^2(x^l)-1/2^l\leqslant 1-2^{-l}$, where $p(x^l)$ is the joint probability over the length sequence l. If the chain of variables is generated by i.i.d. (independent and identically distributed), we can factorize the joint probability into each probability occurring at X_i. However, the above expression is also valid for all Markov chains. Therefore the disequilibrium does not grow linearly with the length of the word l, thereby concluding that the disequilibrium of this sequence becomes nonextensive in the long sequence limit $l\to\infty$. This property is clearly incompatible with the conventional extensive statistical mechanics. Nevertheless, in the subsequent sections, we have concluded that there is no clear reason for measure of complexity to be extensive. Therefore, the disequilibrium without modifying nonextensivity shall be used and the form of multiplying the two nonextensive quantities to obtain a complexity measure would be adopted for the present consideration. The discussion of Catalán *et al.*[17] also holds for the use of the Tsallis entropy in defining the statistical measure of complexity.

The complexity $C_q(p(x))$ for a continuum number of states x with support on the segment $[-l,l]$ with $\int_{-l}^{l}p(x)dx=1$ is defined as follows:

$$C_q(p(x)):=H_q(p(x))D(p(x))=\left(\frac{\int_{-l}^{l}p^q(x)dx-1}{1-q}\right)\left(\int_{-l}^{l}p^2(x)dx\right). \tag{5}$$

To guarantee the positivity of C_q for each continuous distribution, we take the q-exponential[20] of H_q. The new expression $\hat{C}_q$ is regarded as the statistical measure of complexity for the system,

$$\hat{C}_q(p(x)):=\hat{H}_q(p(x))D(p(x))=e_q^{H_q(p(x))}D(p(x)). \tag{6}$$

As for the probability distributions that maximize this type of complexity measure, using ''the maximum complexity approach'' by the Lagrange multipliers method does not help in obtaining the analytical form of the probability distributions p_i's. Therefore, the complexity measure has been regarded as a function of entropy in previous studies.[9,21,22]

A. Properties of $\hat{C}_q$

We investigate the invariance under the β translation and α rescaling transformation on the normalized density function $p(x)$ defined on $\mathbf{R}$, where $\alpha(>0)$ and β are real numbers. The new probability distribution is $p_{\alpha,\beta}(x)=\alpha p[\alpha(x-\beta)]$, which also satisfies the normalization,

$$\int_{\mathbf{R}} p_{\alpha,\beta}(x)dx=1. \tag{7}$$

The effect of the transformation is that β shifts the peak position of the density function while the α determines its broadness. When $\alpha>1$, $p_{\alpha,\beta}(x)$ has a narrow peak, whereas if $\alpha<1$, it becomes broader. After the transformation, we calculate $H_q(p_{\alpha,\beta})$ with the help of the change of variables $y=\alpha(x-\beta)$,

$$\begin{aligned} H_q(p_{\alpha,\beta}(x)) &= \frac{\int_{\mathbf{R}} p^q_{\alpha,\beta}(x)dx-1}{1-q} \\ &= \frac{1}{1-q}\left[\alpha^{q-1}\left(\int_{\mathbf{R}} p^q(y)dy-1\right)+\alpha^{q-1}-1\right] \\ &= \alpha^{q-1}H_q(p)+\ln_q\alpha. \end{aligned} \tag{8}$$

Therefore we have

$$\hat{H}_q(p_{\alpha,\beta}(x))\equiv e_q^{H_q(p_{\alpha,\beta}(x))}=\{1+(1-q)H_q(p_{\alpha,\beta}(x))\}^{1/(1-q)}=\frac{e_q^{H_q(p(x))}}{\alpha}. \tag{9}$$

Since $D(p_{\alpha,\beta}(x))=\alpha D(p(x))$, the new complexity measure is *invariant* under the present transformation:

$$\hat{C}_q(p_{\alpha,\beta}(x))=\hat{H}_q(p_{\alpha,\beta}(x))D(p_{\alpha,\beta}(x))=\frac{e_q^{H_q(p(x))}}{\alpha}\alpha D(p(x))=\hat{C}_q(p). \tag{10}$$

López-Ruiz *et al.*[9] named $\hat{C}_1$ as "the shape complexity" because the translation and rescaling transformation used in the present study do not alter the original shape of distribution curve. It must be noted that this invariance cannot be established when we use the Rényi entropy because of the expression $H_q^{(R)}(p_{\alpha,\beta}(x))=H_q^{(R)}(p)+(q-1)/(1-\alpha)\ln\alpha$. It might be thought that the probability distributions can be analytically determined, which maximizes $\hat{C}_q$, by adopting the maximum complexity approach with a suitable constraint (normalization of probability); however, this approach is not feasible. Hence, it was unavoidable to regard the complexity measure as a function of entropy in Refs. 21 and 22 for further considerations.

B. Invariance under replication

There have been discussions regarding the properties that the complexity measure should possess. Of all these, Lloyd and Pagels[8] insisted on the invariance under replication of distributions. Catalán *et al.*[17] showed $\hat{C}_1$ to be a definite replica invariant; as a result the $\hat{C}_1$ of m replicas for a given distribution are equal to that of the original one. Below, we show, along the lines of Ref. 17, that the use of the Shannon entropy in the complexity measure $\hat{C}$ is not unique choice for this purpose.

Using n copies of the original distribution $p(x)$, which is a compactly supported density function, with $\int_{-\infty}^{\infty}p(x)dx=1$, the mth replica is denoted as

$$p_m(x)=\frac{1}{\sqrt{n}}p[\sqrt{n}(x-\lambda_m)] \quad (1\leqslant m\leqslant n), \tag{11}$$

where λ_m is the center of the mth distribution, $m=1,\ldots,n$, and the support of each $p_m(x)$ is all disjoint. It can be easily observed that the union of all the replicas $s(x)=\Sigma_{i=1}^{n}p_m(x)$ is normalized because $\int_{-\infty}^{\infty}p_m(x)dx=1/n$. Each replica satisfies

$$H_q(p_m(x))=\left(\frac{1}{\sqrt{n}}\right)^{1+q}H_q(p(x))+\frac{(\sqrt{n})^{-1-q}-1}{1-q}, \quad D(p_m)=\frac{D(p)}{n\sqrt{n}}. \tag{12}$$

Since the supports of m replicas on intervals on $\mathbf{R}$ are disjoint, we have the following equations:

$$\begin{aligned}H_q(s(x))&=\frac{\int_{\mathbf{R}}\left(\sum_{i=1}^{n}p_m(x)\right)^q dx-1}{1-q}\\&=\frac{n\int_{\mathbf{R}}p^q(x)dx-1}{1-q}\\&=nH_q(p_m(x))+\frac{n-1}{1-q}\\&=n(\sqrt{n})^{-1-q}H_q(p(x))+\frac{n(\sqrt{n})^{-1-q}-1}{1-q},\end{aligned} \tag{13}$$

$$D(s(x))=\frac{D(p(x))}{\sqrt{n}}. \tag{14}$$

This leads to $\hat{H}_q(s(x))=e_q^{H_q(s(x))}=\sqrt{n}e_q^{H_q(p(x))}$, which makes the complexity measure invariable, i.e., $\hat{C}_q(s(x))=\hat{H}_q(s(x))D(s(x))=\hat{C}_q(p(x))$. Thus, the complexity measure property shown in the LMC case could also be observed when $q\neq 1$.

Continuity is not an evident property in the present definition. To verify the continuity of the complexity measure, let us use a useful concept which was introduced by Catalán *et al.*,[17] i.e., the concept of near-continuity. If similar density functions are given on a common support in similar systems, the associated complexity measures must have values that are close to each other. We discuss this aspect by considering the two rectangular density functions used in the study by Catalán *et al.*[17] One of the density functions is defined on the interval $[-1,0]$ as follows:

$$\xi_{[-1,0]}(x)=\begin{cases}1 & (-1\leqslant x\leqslant 0)\\ 0 & (\text{otherwise}).\end{cases} \tag{15}$$

The other density function is defined on the interval $[-1,L]$ as

$$g_{\delta,L}(x)=\begin{cases}1-\delta & (-1\leqslant x\leqslant 0)\\ \dfrac{\delta}{L} & (0\leqslant x\leqslant L)\\ 0 & (\text{otherwise}),\end{cases} \tag{16}$$

where $0<\delta<1$ and $L>1$. It must be noted that $\lim_{\delta\to 0}g_{\delta,L}(x)=\xi_{[-1,0]}(x)$, thus resulting in the problem of whether or not the $\hat{C}_q$ for each density function converges to the same value in the limiting case. Straightforward calculations indicate $H_q(\xi_{[-1,0]})=0$ and $D(\xi_{[-1,0]})=1$, leading to $\hat{C}_q(\xi_{[-1,0]})=1$ and we obtain the expression

$$H_q(g_{\delta,L}) = \frac{(1-\delta)^q + \delta^q L^{1-q} - 1}{1-q}, \quad D(g_{\delta,L}) = (1-\delta)^2 + \frac{\delta^2}{L}. \tag{17}$$

Therefore, the corresponding complexity measure is expressed as

$$\hat{C}_q(g_{\delta,L}) = [(1-\delta)^q + \delta^q L^{1-q}]^{1/(1-q)} \left[(1-\delta)^2 + \frac{\delta^2}{L} \right]. \tag{18}$$

From the above equation, we can conclude that the support is maintained and the near-continuity condition is satisfied in this limited process irrespective of the value of the nonadditive parameter q:

$$\lim_{\delta \to 0} \hat{C}_q(g_{\delta,L}) = \hat{C}_q(\xi_{[-1,0]}) = 1. \tag{19}$$

Since $[\lim_{L\to\infty} \hat{C}_q(g_{\delta,L}) \to (1-\delta)^{(2-q)/(1-q)}] \neq 1 = \hat{C}_q(\xi_{[-1,0]})$ for $1 < q$ when the support becomes large, the compactness condition is not satisfied despite the fact that they are the δ-neighboring distributions.[23] In such a case, the near-continuity declines in the limit $L \to \infty$.

C. $\hat{C}_q$ in terms of Rényi entropy

The present statistical complexity measure can be expressed with Rényi entropy,[24]

$$H_q^{(R)}(p_i) = \frac{\ln \sum_i p_i^q}{1-q}, \tag{20}$$

which recovers the Shannon entropy as a special case $\lim_{q\to 1} H_q^{(R)} = -\Sigma_i p_i \ln p_i = H^{(S)}$. Since the probability distribution of a system can convey all information that we possess, we often use the entropy as an indication of the degree of randomness. However, the localized or delocalized nature of the system cannot be quantified only by the standard entropy. Therefore, our area of interest is to identify the extent of complexity for a system. For quantification of the characteristics of complexity for a system, the Rényi entropy appears in quantum systems as a measure of localization and ergodicity in phase space,[25] which informs about the shape of distributions. In Ref. 25, it was shown that the differences of Rényi entropies $H_1^{(R)} - H_2^{(R)}$, which are referred to as the structural entropy, can be a candidate for the spatial characterization of one-particle eigenstates (e.g., spatial localization of the charge distributions).

In the previous section, we redefined the disequilibrium D as a squared sum for each distribution measured from a uniform distribution. Since D can be expressed as $D = e^{\ln \Sigma_i p_i^2} = e^{-H_2^{(R)}(p_i)}$, we find that $\hat{C}_1$ can be expressed as follows:

$$\hat{C}_1 = e^{H^{(S)}} D = e^{H_1^{(R)} - H_2^{(R)}}. \tag{21}$$

Similarly, since the Tsallis entropy can be expressed as $H_q(p_i) = (e^{(1-q)H_q^{(R)}} - 1)/(1-q)$, we obtain

$$\hat{C}_q = e_q^{H_q} \cdot D = e^{H_q^{(R)} - H_2^{(R)}}. \tag{22}$$

Accordingly, the present statistical measure of complexity with Tsallis type nonextensive entropy can be expressed by exponential of the difference between qth order Rényi entropy and the second order one. The exact form of $\hat{C}_q$ for the various distributions calculated have been provided in the Appendix. If $q \leqslant 2$ $(q > 2)$, then $\hat{C}_q \geqslant 1$ $(\hat{C}_q < 1)$ holds due to the fact that if $\alpha \leqslant \beta$, then $H_\alpha^{(R)} \geqslant H_\beta^{(R)}$. It is noteworthy that the uniform distribution, which can be viewed as a dispersed or highly delocalized system, has the same complexity value (unity) as that for an extremely local-

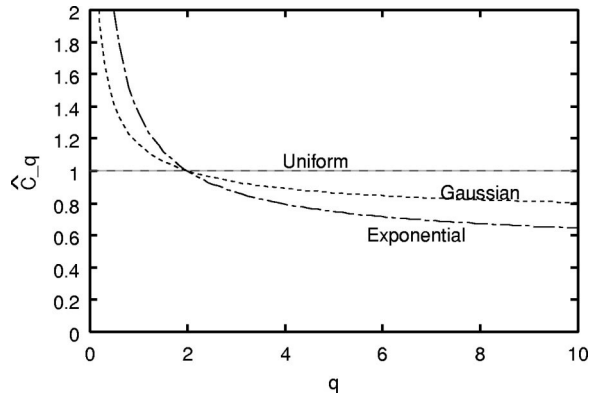

FIG. 1. The behavior of the statistical measure of complexity with respect to q for exponential, Gaussian, and uniform distributions.

ized system. This fact can be easily confirmed by considering a distribution, which assumes the value of $1/\epsilon$ for $-\epsilon/2 \leqslant x \leqslant \epsilon/2$ and 0 for other cases, where ϵ determines the localized region. In this case, therefore, we have $H_q^{(R)} = H_2^{(R)} = \ln \epsilon$. The focus of our attention lies in determining the manner in which a systems's measure of complexity changes when the value of nonextensive parameter is varied. For this purpose, we show the behavior of $\hat{C}_q$ with respect to q in Fig. 1 for three distributions (uniform, Gaussian, and exponential) and in Figs. 2 and 3 for the Weibull distribution and the gamma distribution, respectively.

Although, by definition, $\hat{C}_q$ is made of the two nonextensive quantities, that is, the q-exponentiated Tsallis entropy and the disequilibrium, an assertion regarding its expressivity with an extensive quantity can be made (note that the Rényi entropy is an extensive quantity).

III. THE QUASI-MULTIPLICATIVITY OF $\hat{C}_q$ AND FLUCTUATION OF BIT NUMBER

The quantity $\Sigma_i p_i^q$, which plays a central role in the generalized entropy, can be related to the bit number.[26] The bit number is defined as $B_i = \log p_i$, which has an opposite sign to the information content in Shannon information theory. Assuming that q is close to unity, the Taylor expansion in $q-1$ enables the expression $\Sigma_i p_i^q$ to be written as

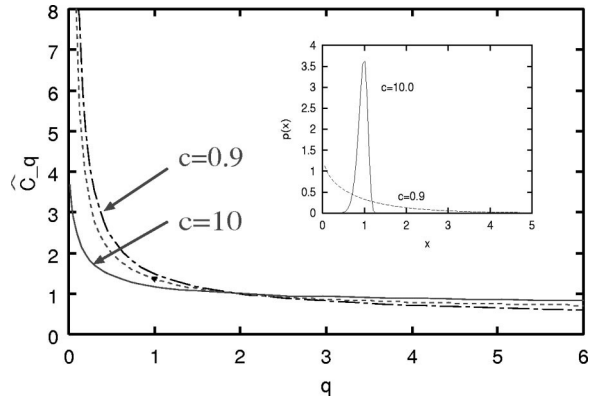

FIG. 2. The behavior of the statistical measure of complexity with respect to q for the Weibull distribution (for $c=0.9$ and $c=10.0$). The dotted curve represents $\hat{C}_q$ for the exponential distribution, which corresponds to the case $c=1$ and the black circle denotes the value $e/2$ when $q=1$. Note that the curves pass through the value 1 when $q=2$ for all the distributions. The inset shows the original distributions when $\alpha=1.0$.

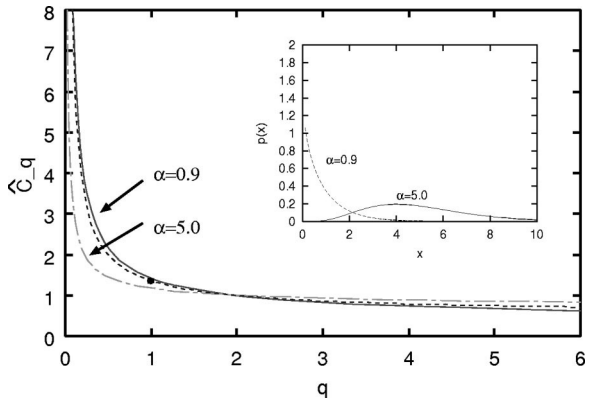

FIG. 3. The behavior of the statistical measure of complexity with respect to q for the gamma distribution (for $\alpha=0.9$ and $\alpha=5.0$). The dotted curve represents $\hat{C}_q$ for the exponential distribution, which corresponds to the case $\alpha=1$ and the black circle denotes the value $e/2$ when $q=1$. Note that the curves pass through the value 1 when $q=2$ for all the distributions. The inset shows the original distributions when $\beta=1.0$.

$$\sum_i p_i^q=\sum_i p_i e^{(q-1)\log p_i}=\sum_{k=0}^{\infty}\frac{\langle B_i^k\rangle(q-1)^k}{k!}, \tag{23}$$

where $\langle B_i^k\rangle=\Sigma_i p_i B_i^k$. Thus, the expectation value of the negative bit number comprises the Shannon entropy. When a joint probability of N systems is factorized into each component and the number of events is the same for all components, Eq. (24) is obtained using the formula shown in Eq. (25):

$$\begin{aligned}\sum_{i_1,\ldots,i_N} p_{i_1,\ldots,i_N}^q&=\left(\sum_i p_i^q\right)^N\\&=\left(\sum_{k=0}^{\infty}\frac{(q-1)^k\langle B_i^k\rangle}{k!}\right)^N\\&=\sum_{\Sigma_s n_s=N}\frac{N!}{n_1!n_2!\cdots}(1)^{n_1}((q-1)\langle B_i\rangle)^{n_2}\cdots\left(\frac{(q-1)^s\langle B_i^s\rangle}{s!}\right)^{n_s}\cdots,\end{aligned} \tag{24}$$

$$(A_1+A_2+\cdots)^N=\sum_{\Sigma_s n_s=N}\frac{N!}{n_1!n_2!\cdots}(A_1)^{n_1}(A_2)^{n_2}\cdots(A_s)^{n_s}\cdots. \tag{25}$$

In what follows, we consider the case $N=2$ and assume that two independent systems X and Y, each of which has a different nonadditive index (q_X and q_Y, respectively) and both these systems are unified to form one system $X+Y$ with a new nonadditive index q_{new} such that the composition of the statistical measure of complexity is as follows:

$$\hat{C}_{q_X}^X(p_i)\times\hat{C}_{q_Y}^Y(p_j)=\hat{C}_{q_{new}}^{X+Y}(p_{ij}). \tag{26}$$

This may be referred to as ''the composition law by multiplication.'' ''The composition law by sum'' inevitably involves the issue of additivity or nonadditivity in entropy, whereas the multiplication conflation does not incur this problem. Subsequently, we assume that the two systems are identical in the level of their probability distributions, which ensures that the fluctuation of the bit number is the same during the composition process as shall be seen in the following sections.

To begin with, the quantity $\ln(\Sigma_i p_i^q)$ can be expanded as $(q-1)\langle B_i\rangle-(q-1)^2(\langle B_i^2\rangle-\langle B_i\rangle^2)/2+O((q-1)^3)$. If the first two terms in Eq. (23) are regarded as infinitesimal quantities compared to unity, then the single Rényi entropy can be expressed as

$$H_q^{(R)}=-\langle B_i\rangle-\tfrac{1}{2}(q-1)(\langle B_i^2\rangle-\langle B_i\rangle^2)+\cdots. \tag{27}$$

When a higher order moment of the bit number in the expression of entropy is required, higher order terms need to be incorporated in $q-1$ for $\ln(1+x)$ type expansion. For our present focus, it is sufficient to expand it up to the second order in $q-1$ because the fluctuation of the bit number appears as the coefficient of $q-1$. Therefore, $\hat{C}_{q_X}^X$ is approximately expressed as

$$\hat{C}_{q_X}^X=e^{H_{q_X}^{(R)}-H_2^{(R)}}\sim e^{(1-q_X/2)(\langle B_i^2\rangle-\langle B_i\rangle^2)} \quad (q_X\sim 1). \tag{28}$$

Accordingly, the product of the statistical measure of complexity for independent systems is reduced to (up to the first order in $q-1$),

$$\hat{C}_{q_X}^X\times\hat{C}_{q_Y}^Y=e^{(1-q_X/2)(\langle B_i^2\rangle-\langle B_i\rangle^2)}e^{(1-q_Y/2)(\langle B_i^2\rangle-\langle B_i\rangle^2)}. \tag{29}$$

On the other hand, by using Eq. (24),

$$\sum_{ij} p_{ij}^{q_{new}}=2\ln\left(\sum_i p_i^{q_{new}}\right)\sim 2(q_{new}-1)\langle B_i\rangle+(q_{new}-1)^2(\langle B_i^2\rangle-\langle B_i\rangle^2)+\cdots, \tag{30}$$

the composed complexity measure $\hat{C}_{q_{new}}^{X+Y}$ satisfies

$$\hat{C}_{q_{new}}^{X+Y}=e^{H_{q_{new}}^{(R)}(p_{ij})-H_2^{(R)}(p_{ij})}\sim e^{-(q_{new}-2)(\langle B_i^2\rangle-\langle B_i\rangle^2)}. \tag{31}$$

Therefore, the present composition law implies a relation among q_X, q_Y, and q_{new}, namely,

$$\left(1-\frac{q_X}{2}\right)+\left(1-\frac{q_Y}{2}\right)=-(q_{new}-2). \tag{32}$$

Based on this, we have $q_{new}=(q_X+q_Y)/2$. If $q_X=q_Y=1$, then q_{new} also becomes unity. For this case, the LMC complexity measure with the exponentiated Shannon entropy was used.

This relation suggests that the composition of two independent systems necessarily involves the average and the variance of bit number when q is close to unity. In other words, the change in the nonadditivity indices relates to the fluctuation of the Shannon entropy. This fact had been indicated when the interpretation of the nonextensive parameter q from the system's fluctuating temperature were analyzed in Ref. 26. If the fluctuation is sufficiently small, i.e., $\langle B_i^2\rangle-\langle B_i\rangle^2 \ll 1$, then Eqs. (28) and (31) are approximately expressed as $(1-q_X/2)b$ and $1-(q_{new}-2)b$, respectively, where we put $b=\langle B_i^2\rangle-\langle B_i\rangle^2$. Therefore, we have the following relation:

$$b=\frac{\frac{1}{2}(q_X+q_Y)-q_{new}}{(1-q_X/2)(1-q_Y/2)}. \tag{33}$$

Note that the above expression is symmetric in q_X and q_Y. When $q_X=q_Y=q_{new}=1$, there is no fluctuation in systems. As special cases, we have two types of *quasi-multiplicativities*.

(i) The case $q_X=q_Y=q$ (type I quasi-multiplicativity): This case corresponds to the situation where two identical systems form a single new system with a new entropic index that is different from its original. This is the case where Beck introduced the concept of quasi-additivity in Ref. 26 in the context of addition of two entropies. In this case, the above relation reduces to

$$b=\frac{q-q_{new}}{(1-q/2)^2}. \tag{34}$$

(ii) The case $q_{new}=q_X$ or $q_{new}=q_Y$ (type II quasi-multiplicativity): This case describes the circumstances where the new entropic index is absorbed either into the index of X or that of Y. Substituting $q_{new}=q_X$ in Eq. (33) and then arranging it, the relation appears as

$$\frac{\langle B_i^2\rangle-\langle B_i\rangle^2}{2}=\frac{1}{q_{new}-2}-\frac{1}{q_Y-2}. \tag{35}$$

In this case, the difference between the reciprocal of the displacements from two in the nonextensive index is equivalent to half of the fluctuation.

IV. TEMPORAL BEHAVIOR OF $\hat{C}_q$ FOR THE RANDOM MULTIPLICATIVE PROCESS

It is noteworthy that both the LMC measure and $\hat{C}_q$ provide time-independent values for the standard diffusion (i.e., Wiener process), indicating that these quantities can measure the shapes of distributions. This time independency comes from the fact that in the standard diffusion process, the dispersion changes with the passage of time; however, the Gaussian forms are maintained during the process (see the Appendix). In this sense, the present disequilibrium based complexity measure captures only the information on shapes of distributions except for the similarity.

It is interesting to observe how the complexity measure evolves with time, or the transient behavior of it. To achieve this end, we examine a lognormal distribution whose form is a result of the Levy and Solomon's random multiplicative processes with a boundary constraint of large time.[27] The random multiplicative process that Levy and Solomon considered is expressed as $x(t+1)=\lambda_t x(t)$ with a stochastic random positive variable λ_t, where $x(t)$ is the position of a particle at time t. The probability distribution for this process at asymptotic time is found to be of the following form:[28]

$$p(x,t)=\frac{1}{\sqrt{2\pi\mathcal{D}t}}\frac{1}{x}\exp\left[-\frac{1}{2\mathcal{D}t}(\ln x-vt)^2\right], \tag{36}$$

where v is the drift velocity, defined as an average of logarithm of λ_t with respect to the probability distribution of λ_t, and $\mathcal{D}$ is its dispersion. Our key interest is in the time regime such that $x\gg e^{(vt+2\mathcal{D}t)}$, whose distributions are clearly distinguished from the power law form $p(x,t)\sim 1/x$. For this distribution, the disequilibrium can be expressed as

$$D(p(x,t))=\int_\epsilon^\infty p^2(x,t)dx=\frac{e^{-(v-\mathcal{D}/4)t}}{2\pi\mathcal{D}t}\int_{\ln\epsilon}^\infty dy e^{-(y-[(2v-\mathcal{D})/2]t)^2/\mathcal{D}t} \tag{37}$$

where $y=\ln x$ is a quantity that arises due to the change of variables. Since the distribution becomes singular at $x=0$, we always set $\epsilon\leqslant x$. This leads the following interpretation: the lower bound ϵ is the boundary that keeps the position of particle away from it at time t (repulsive effect introduced in Ref. 27). The physical description for this process and a derivation based on the random walk analogy are provided in detail in Ref. 28. Furthermore, with the definition of error function $\int_\xi^\infty e^{-z^2}dz=\sqrt{\pi}(1-\mathrm{erf}[\xi])/2$, the following expression is obtained:

$$D(p(x,t))=\frac{e^{-(v-\mathcal{D}/4)}}{4\sqrt{\pi\mathcal{D}t}}(1-\mathrm{erf}[\xi]), \tag{38}$$

where ξ is

$$\xi=\frac{1}{\sqrt{\mathcal{D}t}}\left\{\ln\epsilon-\left(v-\frac{\mathcal{D}}{2}\right)t\right\}. \tag{39}$$

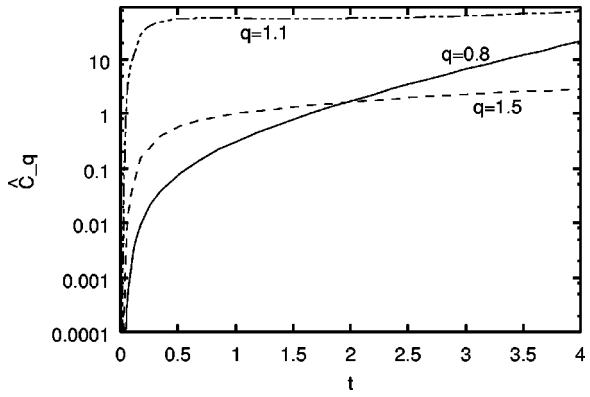

FIG. 4. The change in the complexity measure with time for the random multiplicative process with a boundary constraint for different values of q. The parameters are set as $v=1.5$, $\mathcal{D}=2.5$, and $\epsilon=2.1$.

Since $\xi>0$, the above expression is valid only for $t<\ln\epsilon/(v-\mathcal{D}/2)$. Similarly, the entropy is calculated as

$$H_q(p(x,t))=\frac{\int_\epsilon^\infty p^q(x,t)dx-1}{1-q}. \tag{40}$$

The integral of the numerator for the above equation can be calculated as

$$\int_\epsilon^\infty p^q(x,t)dx=\int_{\ln\epsilon}^\infty dy e^{-(q/2\mathcal{D}t)(y-vt)^2}e^{(1-q)y}=\sqrt{\frac{2\mathcal{D}t}{q}}\frac{\sqrt{\pi}}{2}(1-\mathrm{erf}[\tau])e^{(1-q)(v+[(1-q)/2q]\mathcal{D}t)}, \tag{41}$$

where τ is the lower bound of integration that appears due to the change of variables and attains a positive value,

$$\tau=\sqrt{\frac{q}{2\mathcal{D}t}}\left(\ln\epsilon-\left(v+\frac{1-q}{q}\mathcal{D}\right)t\right)>0. \tag{42}$$

Accordingly, when $q>0(<0)$, the above expression describes the time range $\ln\epsilon/(v+(1-q)\mathcal{D}/q)<t(>t)$. Therefore, the following expression is obtained:

$$\begin{aligned}e_q^{H_q(p(x,t))}&=[1+(1-q)H_q(p(x,t))]^{1/(1-q)}\\&=\sqrt{2\pi\mathcal{D}t}(2\sqrt{q})^{1/(q-1)}(1-\mathrm{erf}[\tau])^{1/(1-q)}e^{(v+[(1-q)/2q]\mathcal{D}t)}.\end{aligned} \tag{43}$$

Combining this with Eqs. (38) and (39), we have the expression

$$\hat{C}_q(p(x,t))=\frac{\sqrt{2}}{4}(2\sqrt{q})^{1/(q-1)}(1-\mathrm{erf}[\xi])(1-\mathrm{erf}[\tau])^{1/(1-q)}e^{[(2-q)/4q]\mathcal{D}t}. \tag{44}$$

In general, $\hat{C}_q$ exhibits varied behavior depending on the value of diffusion constant and that of the boundary constraint. The temporal evolution for some parameter values has been shown in Figs. 4 and 5.

V. SUMMARY

In this work, a statistical complexity measure has been examined with a nonextensive entropy based on the LMC type (disequilibrium-based) measure. The LMC measure can be regarded as

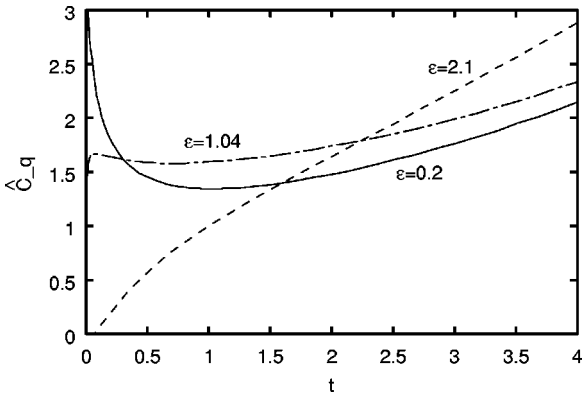

FIG. 5. The change in the complexity measure with time for the random multiplicative process with a boundary constraint for different values of ϵ, with nonextensivity fixed at $q=1.5$. The values of parameters for v and $\mathcal{D}$ are identical to those used in Fig. 4.

one class of measures that satisfies the so-called one-hump criterion—possessing concavity with respect to the order parameter such as entropy.[2,3,29] The more general types of complexity measure are categorized according to their behavior as a function of disorder (or order) using SDL classification[10] with two parameters, and this is referred to as the simple measure for complexity (see also consequent discussions for its validity[13,30–32]). Although it is difficult to choose a specific measure among these, we think that the LMC type complexity measure deserves to be investigated as a prototype. In the LMC measure, the one-hump criterion is realized by using a quantity of disequilibrium. Hence, this criterion has been retained in this study.

In general, analyzing the compositions of two systems that are characterized by different nonextensive parameters is essential because the probability of two complex systems having the same nonextensive value may be rare. In the case of a physical system, a series of analyses has led to the conclusion that the entropy composition with the same nonextensive parameter results in the equibration (the zeroth law of thermodynamics) that occurs when normalized temperature is used over the system's temperature itself.[33] The concept of the quasi-multiplicativity was introduced for the composed system, thereby the idea of defining the statistical complexity measure in terms of a system's bit number leads to the formulation of two kinds of quasi-multiplicativity under the condition where the nonextensivity is small ($q\sim 1$).

Although static distributions yield single values corresponding to their shapes, it is interesting to note how the present measure of complexity changes with time under a specific (often nonlinear) dynamics. In ordinary diffusion process (i.e., Wiener process), the shape of distribution maintains the Gaussian form during its evolution, resulting in that the present measure of complexity yields a constant value. As a specific illustration, a random multiplicative process was considered, in which probability distribution of the position of a particle at asymptotic time obeys a lognormal distribution. Observations revealed that the measure increased with time for different values of q; however, the relation depends on the value of the lower bound (boundary condition).

Vitanov for reading the manuscript as well as acknowledging the support received in part from the Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists and the Grant-in-Aid for the JSPS fellow No. 06632 from the Ministry of Education, Science, Sports, and Culture of Japan.

APPENDIX: $\hat{C}_q$ AND $\hat{C}$ FOR DIFFERENT KINDS OF DISTRIBUTIONS

Given below are the explicit forms of the present complexity measure defined by Eq. (6) [equivalently by Eq. (22)] for some distribution functions, which are often encountered in the various branches of science.

1. Uniform distribution

$$p(x)=\frac{1}{\beta-\alpha} \quad (\alpha\leqslant x\leqslant\beta). \tag{A1}$$

We have $H^{(S)}(p(x))=-\int_{\alpha}^{\beta}p(x)\ln p(x)dx=\ln(\beta-\alpha)$. Furthermore, $H_q^{(R)}(p(x))=\ln(\beta-\alpha)$, $\forall q$ whence $\hat{C}_q=\hat{C}=1$.

2. Gaussian distribution

$$p(x)=\frac{1}{\sqrt{2\pi\sigma^2}}e^{-x^2/2\sigma^2} \quad (0<\sigma). \tag{A2}$$

We have $H^{(S)}(p(x))=-\int_{-\infty}^{\infty}p(x)\ln p(x)dx=\ln(\sqrt{2\pi}\sigma)+\frac{1}{2}$. Furthermore, $H_q^{(R)}(p(x))=(\ln\sqrt{q})/(q-1)+\ln(\sqrt{2\pi}\sigma)$ and $H_2^{(R)}(p(x))=\ln(\sqrt{2\pi}\sigma)+(\ln 2)/2$. Hence $\hat{C}_q=\sqrt{q^{1/(q-1)}/2}$ and $\hat{C}=\sqrt{e/2}$.

3. Exponential distribution

$$p(x)=\frac{1}{\lambda}e^{-x/\lambda} \quad (x,\lambda>0). \tag{A3}$$

We have $H^{(S)}(p(x))=-\int_{0}^{\infty}p(x)\ln p(x)dx=\ln\lambda+1$. Furthermore, $H_q^{(R)}(p(x))=\ln\lambda-(\ln q)/(1-q)$ and $H_2^{(R)}(p(x))=\ln(2\lambda)$. Hence $\hat{C}_q=q^{1/(q-1)}/2$ and $\hat{C}=e/2$. Note that $\lim_{q\to 1}\hat{C}_q=e/2=\hat{C}$.

4. Pareto distribution

$$p(x)=\frac{ak^a}{x^{a+1}} \quad (0<a, \quad 0<k\leqslant x). \tag{A4}$$

We have $H^{(S)}(p(x))=-\int_{k}^{\infty}p(x)\ln p(x)dx=\ln(k/a)+1+1/a$. Furthermore, $H_q^{(R)}(p(x))=\ln[[k/(q(a+1)-1)](a/k)^q]/(1-q)$ and $H_2^{(R)}(p(x))=\ln[k(2a+1)/a^2]$. Hence $\hat{C}_q=(k/a)\,e^{1+1/a}[[k/(q(a+1)-1)](a/k)^q]^{1/(1-q)}$ and $\hat{C}=ae^{(1+1/a)}/(2a+1)$.

5. Weibull distribution

$$p(x)=\frac{c}{\alpha}x^{c-1}e^{-x^2/\alpha} \quad (x,c,\alpha>0). \tag{A5}$$

$H^{(S)}(p(x))=-\int_{0}^{\infty}p(x)\ln p(x)dx=[(c-1)/c]\,\gamma+\ln(\alpha^{1/c}/c)+1$, where $\gamma=0.577\,215\,66\ldots$ is Euler's constant. Furthermore, $H_q^{(R)}(p(x))=[1/(1-q)]\ln[c^{q-1}\alpha^{(1-q)/c}q^{q(1/c-1)-1/c}\Gamma(q(1-1/c)+1/c))]$ and $H_2^{(R)}(p(x))=\ln[c\alpha^{-1/c}2^{1/c-2}\Gamma(2-1/c)]^{-1}$. Hence $\hat{C}_q=2^{1/c-2}q^{q/(q-1)-1/c}\Gamma(2-1/c)[\Gamma(q(1-1/c)+1/c)]^{1/(1-q)}$. The value of $\hat{C}$ is calculated to be $2^{1/c-2}e^{1+(1-1/c)\gamma}\Gamma(2-1/c)$.

Remark: When $c=1$, $\hat{C}$ and $\hat{C}_q$ are reduced to $e/2$ and $q^{1/(q-1)}/2$, respectively, because the Weibull distribution recovers the exponential distribution. The form $\hat{C}_q$ is independent of the scale parameter α; however, it is affected by the value of the shape parameter c.

6. Gamma distribution

$$p(x)=\frac{x^{\alpha-1}e^{-x/\beta}}{\beta^{\alpha}\Gamma(\alpha)} \quad (x,\alpha,\beta>0). \tag{A6}$$

We have $H^{(S)}(p(x))=-\int_0^{\infty}p(x)\ln p(x)dx=\ln(\beta\Gamma(\alpha))+(1-\alpha)\psi(\alpha)+\alpha$, where $\psi(\alpha)=d\Gamma(\alpha)/d\alpha$ is the digamma function. Then $\hat{C}=e^{(1-\alpha)\psi(\alpha)+\alpha}2^{1-2\alpha}\Gamma(2\alpha-1)/\Gamma(\alpha)$. On the other hand, we have $H_q^{(R)}(p(x))=[\,1/(1-q)\,]\ln[\beta^{1-q}q^{-q(\alpha-1)-1}\Gamma(q(\alpha-1)+1)/[\Gamma(\alpha)]^q]$ and $H_2^{(R)}(p(x))=-\ln[2^{1-2\alpha}\Gamma(2\alpha-1)/\beta[\Gamma(\alpha)]^2]$. Hence $\hat{C}_q=2^{1-2\alpha}q^{[q/(q-1)\,]\alpha-1}\Gamma(2\alpha-1)[\Gamma(\alpha)]^{q/(q-1)-2}\times[\Gamma(q(\alpha-1)+1)]^{1/(1-q)}$.

Remark: When $\alpha=1$, $\hat{C}$ and $\hat{C}_q$ are reduced to $e/2$ and $q^{1/(q-1)}/2$, respectively, because the gamma distribution recovers the exponential distribution. The scale parameter β does not get modified to the form $\hat{C}_q$; however, it is influenced by the value of the shape parameter α.

(Received 31 December 2003; accepted 11 February 2004; published 7 April 2004)

A central finite difference approximation for the radial contribution Δ_r to the Laplacian $\nabla^2=\Delta_r+\Delta_{r_\perp}(r)$ is considered in a three-dimensional cylindrical coordinate system (r,θ,z). A free-particle Schrödinger time evolution operator is constructed by exponentiation, $e^{(i/2)\,\xi\nabla^2}=\cdots e^{-(1/2)\xi^2[\Delta_r,\Delta_{r_\perp}(r)]}\ e^{(i/2)\,\xi\Delta_{r_\perp}(r)}\ e^{(i/2)\,\xi\Delta_r}\to\cdots e^{(i/2)\,\xi\Delta_r}$. Denoting the central finite difference approximation of Δ_r by $(1/\Delta r^2)\,\mathbb{T}$, the matrix $\mathbb{S}\equiv e^{(i/2)\,\lambda\mathbb{T}}$, with $\lambda=\xi/\Delta r^2$, is shown to be similar to a particular unitary representation U_{VK} of the group of motions on Euclidean three-space that has been described by Vilenkin and Klimyk. The matrix elements of U_{VK} generalize the Bessel function and provide an approximation of the leading term in the radial contribution to the evolution operator. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1695601]

I. INTRODUCTION

We work in standard cylindrical coordinates (r,θ,z) and denote the Laplacian as $\nabla^2=\partial^2/\partial r^2+(1/r)(\partial/\partial r)+(1/r^2)(\partial^2/\partial\theta^2)+\partial^2/\partial z^2\equiv\Delta_r+\Delta_{\theta z}(r)$, where $\Delta_r=\partial^2/\partial r^2+(1/r)(\partial/\partial r)$. Let $\mathcal{H}=-(\hbar^2/2m)\,\nabla^2$ denote the Hamiltonian of a free spinless particle of mass m, and $\Psi(r,\theta,z,t)$ denote its Schrödinger wavefunction. Integration of the Schrödinger equation gives

$$\Psi(r,\theta,z,t+\delta t)=e^{\delta t\partial_t}\Psi(r,\theta,z,t)=e^{(i\hbar\,\delta t/2m)\ \nabla^2}\Psi(r,\theta,z,t). \tag{1}$$

The evolution operator may be expanded using the Zassenhaus formula as

$$e^{(i\hbar\,\delta t/2m)\,\nabla^2}=\cdots e^{A_3\delta t^3}e^{A_2\delta t^2}e^{(i\hbar\,\delta t/2m)\,\Delta_{\theta z}(r)}\,e^{(i\hbar\,\delta t/2m)\,\Delta_r}, \tag{2}$$

where the $A_2,A_3,\ldots$ are anti-Hermitian operators. To each order in δt the decomposition of the evolution operator is in terms of unitary operators, so that the norm of Ψ is preserved as the "dynamics" unfolds. A numerical algorithm based on this expansion will be unconditionally stable. In this note we develop a unitary approximation for the radial contribution to $e^{(i\hbar\,\delta t/2m)\,\nabla^2}$ in terms of a set of special functions, the *associated Bessel functions*, that have been defined by Vilenkin and Klimyk.

We employ a uniform discrete lattice approximation with lattice spacing Δr for the radial coordinate $r\to r_n=(n+\frac{1}{2})\Delta r, n\in\mathbb{N}\quad(n=0,1,2,\ldots)$. The action of Δ_r on Ψ is approximated by $\{\Delta_r\,\Psi\}_n\approx(1/\Delta r^2)\,(\mathbb{T}\Psi)_n$ where $(\mathbb{T}\Psi)_n=\Psi_{n+1}-2\,\Psi_n+\Psi_{n-1}+[1/2\,(n+\frac{1}{2})]\,(\Psi_{n+1}-\Psi_{n-1})$. The matrix elements of $\mathbb{T}$ are

[a]Electronic mail: pnash@utsa.edu

$$\mathbb{T}_{nn'} = \delta_{n\,n'-1}\left(1+\frac{1}{2\,(n+\frac{1}{2})}\right)) + \delta_{n\,n'}(-2) + \delta_{n\,n'+1}\left(1-\frac{1}{2\,(n+\frac{1}{2})}\right), \tag{3}$$

where $n,n' \in \mathbb{N}$. Let $\lambda = \hbar\ \delta t/m\ \Delta r^2$. We show below that a unitary approximation to $e^{(i\hbar\,\delta t/2m)\,\Delta_r}$ is given by

$$\mathbb{S} = e^{(i/2)\,\lambda \mathbb{T}}, \tag{4}$$

up to a similarity transformation. It will be seen that the matrix elements of $\mathbb{S}$ have a simple, remarkable realization in terms of Vilenkin and Klimyk's associated Bessel functions.

II. ELEMENTARY PROPERTIES OF $\mathbb{S}$

Let us define matrices $\hat{\mathbb{T}}$ and $\hat{\mathbb{S}}$ by

$$\hat{\mathbb{T}}_{nn'} = \delta_{n\,n'-1}\left(1+\frac{1}{2\,n+1}\right) + \delta_{n\,n'+1}\left(1-\frac{1}{2\,n+1}\right), \tag{5}$$

where $n,n' \in \mathbb{N}$, and

$$\hat{\mathbb{S}} = e^{(i/2)\,\lambda \hat{\mathbb{T}}}, \tag{6}$$

so that $\mathbb{S} = e^{-i\lambda}\, e^{(i/2)\,\lambda \hat{\mathbb{T}}} = e^{-i\lambda}\,\hat{\mathbb{S}}$. This is a change of variable that deletes the diagonal matrix elements from $\hat{\mathbb{T}}$ and removes the simple exponential λ-dependence from $\hat{\mathbb{S}}$.

We also define a "weight" matrix $\mathbb{W}$ by

$$\mathbb{W}_{n\,n'} = \delta_{n\,n'}\sqrt{2n+1}, \tag{7}$$

$n,n' \in \mathbb{N}$. $\mathbb{W}$ corresponds to the radial weight function r in this cylindrical coordinate system. It is not too difficult to show that the similarity transform of $\hat{\mathbb{S}}$ by $\mathbb{W}$, $\mathbb{U} = \mathbb{W}\hat{\mathbb{S}}\mathbb{W}^{-1} = \mathbb{W}e^{(i/2)\,\lambda \hat{\mathbb{T}}}\mathbb{W}^{-1} = e^{(i/2)\,\lambda \mathbb{W}\hat{\mathbb{T}}\mathbb{W}^{-1}}$ is a unitary matrix. For brevity we put $\mathbb{Q} \equiv \mathbb{W}\hat{\mathbb{T}}\mathbb{W}^{-1}$ so that $\mathbb{U} = e^{(i/2)\,\lambda \mathbb{Q}}$.

Lemma 1: $\mathbb{Q}$ *is symmetric and* $\mathbb{U} = e^{(i/2)\,\lambda \mathbb{Q}}$ *is unitary.*

Proof: To show that $\mathbb{Q}$ is symmetric consider

$$\begin{aligned}
\mathbb{Q}_{n\,n'} &= (\mathbb{W}\hat{\mathbb{T}}\mathbb{W}^{-1})_{n\,n'} \\
&= \sqrt{\frac{2n+1}{2n'+1}}(\hat{\mathbb{T}})_{n\,n'} \\
&= \sqrt{\frac{2n+1}{2n'+1}}\left[\delta_{n\,n'-1}\left(1+\frac{1}{2\,n+1}\right) + \delta_{n\,n'+1}\left(1-\frac{1}{2\,n+1}\right)\right] \\
&= \sqrt{\frac{2n+1}{2n'+1}}[\delta_{n\,n'-1} + \delta_{n\,n'+1}] + \sqrt{\frac{1}{(2n+1)(2n'+1)}}[\delta_{n\,n'-1} - \delta_{n\,n'+1}] \\
&\equiv \sqrt{\frac{2n+1}{2n'+1}}\,\sigma_{n\,n'} + \sqrt{\frac{1}{(2n+1)(2n'+1)}}\,\Delta_{n\,n'},
\end{aligned}$$

where σ is symmetric and Δ is antisymmetric. We see that $\mathbb{Q}_{n\,n'} - \mathbb{Q}_{n'\,n} = 2\sqrt{1/(2n+1)(2n'+1)}[(n-n')\,\sigma_{n\,n'} + \Delta_{n\,n'}]$. Clearly $(n-n')\,\sigma_{n\,n'} + \Delta_{n\,n'}$ is (possibly) nonvanishing only when $n' = n \pm 1$. However, in both cases $(n-n')\,\sigma_{n\,n'} + \Delta_{n\,n'} = 0$. Hence $\mathbb{Q}$ is symmetric (thus $\mathbb{U}$ is also symmetric). The fact that $\mathbb{Q}$ is a real symmetric matrix implies that $\mathbb{U} = e^{(i/2)\,\lambda \mathbb{Q}}$ is unitary. □

Since $\mathbb{U}$ is unitary and symmetric and $\mathbb{U}_{n\,n'} = \sqrt{(2n+1)/(2n'+1)}\,\hat{\mathbb{S}}_{n\,n'}$ we immediately have

$$\hat{\mathbb{S}}_{n'\,n} = \hat{\mathbb{S}}^T_{n\,n'} = \frac{2n+1}{2n'+1}\ \hat{\mathbb{S}}_{n\,n'}, \tag{8}$$

where ^{T} denotes the transpose. This is equivalent to

$$\hat{\mathbb{S}}^T = \mathbb{W}^2 \ \hat{\mathbb{S}} \ \mathbb{W}^{-2}. \tag{9}$$

III. GENERATING FUNCTION FOR THE $\hat{\mathbb{S}}_{n\,n'}(\lambda)$

We now turn to the problem of expressing the matrix elements $\hat{\mathbb{S}}_{n\,n'}(\lambda)$ in terms of known special functions. We note that, for each $n \in \mathbb{N}$, $\Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda)\hat{\mathbb{S}}^*_{n'\,n}(\lambda) = 1$, so that each row of $\hat{\mathbb{S}}(\lambda)$, $\{\hat{\mathbb{S}}_{n\,n'}(\lambda)\}_{n' \in \mathbb{N}}$ defines a square summable sequence.

We shall construct a vector generating function with components $h_n(\lambda, \xi)$, where $n \in \mathbb{N}$, $-1 \leqslant \xi \leqslant 1$ and $\lambda \in \mathbb{R}$, that will yield the matrix elements $\hat{\mathbb{S}}_{n\,n'}(\lambda)$ upon "projection" onto suitable basis functions. Let $P_n(\xi)$ denote the Legendre polynomial of order n satisfying $[(n+1)/(2n+1)]P_{n+1}(\xi) + [n/(2n+1)]P_{n-1}(\xi) = \xi P_n(\xi)$. For each row of $\hat{\mathbb{S}}(\lambda)$, a generating function is defined as a simple discrete Fourier–Legendre transform of the columns of this row of $\hat{\mathbb{S}}(\lambda)$ with weights $P_{n'}(\xi)$,

$$h_n(\lambda, \xi) \equiv \sum_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) P_{n'}(\xi) = \sum_{n'=0}^{\infty} \frac{2n'+1}{2n+1} \hat{\mathbb{S}}_{n'\,n}(\lambda) P_{n'}(\xi). \tag{10}$$

Since $|P_{n'}(\xi)| \leqslant 1$ and $\{\hat{\mathbb{S}}_{n\,n'}(\lambda)\}_{n' \in \mathbb{N}} \in \ell^2_\lambda$, this series is convergent for $-1 \leqslant \xi \leqslant 1$ and $\lambda \in \mathbb{R}$.

The generating function may be associated with a partial differential equation whose solution depends on initial values provided by the following.

Lemma 2:

$$\sum_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) = \sum_{n'=0}^{\infty} \frac{2n'+1}{2n+1} \hat{\mathbb{S}}_{n'\,n}(\lambda) = e^{i\lambda}. \tag{11}$$

Proof: Note that $\mathbb{T}$ (*not* $\hat{\mathbb{T}}$) annihilates constant vectors. Let Φ denote the constant column vector with a one in each row, $\Phi_n = 1$, $n = 0,1,2,\ldots$. Then $\mathbb{T}\Phi = 0$ and $\mathbb{S}\Phi = \Phi = e^{-i\lambda}\hat{\mathbb{S}}\Phi$. The action of $\hat{\mathbb{S}}$ on Φ is $(\hat{\mathbb{S}}\Phi)_n = \Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda)\Phi_{n'} = \Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda)$, which must yield $(\hat{\mathbb{S}}\Phi)_n = e^{i\lambda}\Phi_n = e^{i\lambda}$. Hence $\Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) = \Sigma_{n'=0}^{\infty} [(2n'+1)/(2n+1)] \ \hat{\mathbb{S}}_{n'\,n}(\lambda) = e^{i\lambda}$.

With this initial value in hand, it is not difficult to calculate the following.

Lemma 3:

$$e^{i\lambda\,\xi} P_n(\xi) = \sum_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) P_{n'}(\xi), \tag{12}$$

where $P_{n'}(\xi)$ is a Legendre polynomial satisfying $[(n'+1)/(2n'+1)]P_{n'+1}(\xi) + [n'/(2n'+1)]P_{n'-1}(\xi) = \xi P_{n'}(\xi)$.

Proof: Let $h_n(\lambda, \xi) \equiv \Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) P_{n'}(\xi) = \Sigma_{n'=0}^{\infty} [(2n'+1)/(2n+1)] \ \hat{\mathbb{S}}_{n'\,n}(\lambda) P_{n'}(\xi)$. $h_n(\lambda, \xi)$ is subject to the "initial" conditions $h_n(0, \xi) = \Sigma_{n'=0}^{\infty} \delta_{n\,n'} P_{n'}(\xi) = P_n(\xi)$ and $h_n(\lambda, 1) = \Sigma_{n'=0}^{\infty} \hat{\mathbb{S}}_{n\,n'}(\lambda) = e^{i\lambda}$ by Lemma 2.

To generate a partial differential equation for $h_n(\lambda, \xi)$, consider the one-parameter subgroup $\hat{\mathbb{S}}_{n\,n'}(\lambda + \lambda') = \Sigma_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,k}(\lambda)\hat{\mathbb{S}}_{k\,n'}(\lambda')$. The Fourier–Legendre transformation yields $h_n(\lambda + \lambda', \xi) = \Sigma_{n'=0}^{\infty} \Sigma_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,k}(\lambda) \hat{\mathbb{S}}_{k\,n'}(\lambda') P_{n'}(\xi)$. Differentiating this result with respect to λ', then putting $\lambda' = 0$ yields $(\partial/\partial\lambda) h_n(\lambda, \xi) = [(\partial/\partial\lambda') h_n(\lambda + \lambda', \xi)]_{\lambda'=0} = \Sigma_{n'=0}^{\infty} \Sigma_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,k}(\lambda)[(\partial/\partial\lambda')\hat{\mathbb{S}}_{k\,n'} \times (\lambda')]_{\lambda'=0} P_{n'}(\xi) = (i/2) \Sigma_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,k}(\lambda) \Sigma_{n'=0}^{\infty} \mathbb{T}_{k\,n'} P_{n'}(\xi) = i \Sigma_{k=0}^{\infty} \hat{\mathbb{S}}_{n\,k}(\lambda) [[(k+1)/(2k+1)] \times P_{k+1}(\xi) + [k/(2k+1)] P_{k-1}(\xi)] = i \Sigma_{k=0}^{\infty} \xi P_k(\xi) \hat{\mathbb{S}}_{n\,k}(\lambda) = i\,\xi\, h_n(\lambda, \xi)$. Integration and application of the initial conditions gives $h_n(\lambda, \xi) = P_n(\xi)\, e^{i\,\lambda\,\xi}$. □

IV. MATRIX ELEMENTS $\mathbb{U}_{n\,n'}$ AS KNOWN SPECIAL FUNCTIONS

An integral representation of $\mathbb{U}_{n\,n'}=\sqrt{(2n+1)/(2n'+1)}\,\hat{\mathbb{S}}_{n\,n'}$ and an expansion in terms of spherical Bessel functions may obtained by multiplying Eq. (12) by $P_h(\xi)\,d\,\xi$ and integrating over $-1\leqslant\xi\leqslant+1$. This gives the following theorem.

Theorem 1 ($\hat{\mathbb{U}}_{n\,n'}(\lambda)$):

$$\begin{aligned}\mathbb{U}_{n\,n'}(\lambda)&=\frac{\sqrt{(2n+1)(2n'+1)}}{2}\int_{-1}^{+1}e^{i\lambda\,\xi}P_n(\xi)P_{n'}(\xi)d\,\xi\\&=\frac{\sqrt{(2n+1)(2n'+1)}}{2\pi}\sum_{k=0}^{\min(n\,n')}i^{n+n'-2k}[2(n+n'-2k)+1]\\&\quad\times\frac{(n+n'-k)!}{(n-k)!(n'-k)!k!}\,\frac{\Gamma(n-k+\frac{1}{2})\Gamma(n'-k+\frac{1}{2})\Gamma(k+\frac{1}{2})}{\Gamma(n+n'-k+\frac{3}{2})!}\,j_{n+n'-2k}(\lambda)\\&=J^{4}_{n\,n'\,0}(-i\lambda).\end{aligned}\tag{13}$$

Here j_n denotes a spherical Bessel function of the first kind. For reference, we recall that the recursion relations for the spherical Bessel functions are $(2n+1)\,j_n'(\lambda)=n\,j_{n-1}(\lambda)-(n+1)\,j_{n+1}(\lambda)$ and $(2n+1)\,j_n(\lambda)=\lambda\,[j_{n-1}(\lambda)+j_{n+1}(\lambda)]$ (Ref. 2), and that $j_n(0)=\delta_{n\,0}$.

In the next to last equation of Eq. (13) we have used Bauer's addition theorem (Ref. 4, p. 368) $e^{i\lambda\xi}=\Sigma_{h=0}^{\infty}(2h+1)i^h j_h(\lambda)\,P_h(\xi)$ and Adams'[1] product decomposition

$$\begin{aligned}P_n(\xi)P_{n'}(\xi)=\frac{1}{2\pi}\sum_{k=0}^{\min(n\,n')}&[2(n+n'-2k)+1]\frac{(n+n'-k)!}{(n-k)!(n'-k)!k!}\\&\times\frac{\Gamma(n-k+\frac{1}{2}\Gamma(n'-k+\frac{1}{2})\Gamma(k+\frac{1}{2})}{\Gamma(n+n'-k+\frac{3}{2})!}P_{n+n'-2k}(\xi)\,.\end{aligned}\tag{14}$$

In the last equation of Eq. (13), $J^{4}_{n\,n'\,0}(-i\lambda)$ denotes the matrix elements of Vilenkin and Klimyk's unitary irreducible representation of the group of motions on Euclidean three-space that generalizes the Bessel function [Ref. 3, p. 101, Eq. (5)]. They have named these functions *associated Bessel functions*. This correspondence is discussed in more detail in the Conclusion.

V. USEFUL RECURRENCE RELATIONS

Recurrence relations can reduce the amount of computation required to calculate a number of the $\hat{\mathbb{S}}_{n\,n'}$ when using a set of these functions in a zeroth-order approximation to the solution of a scattering problem.

A simple recurrence relation may be obtained from

$$-2\,i\,\frac{\partial}{\partial\lambda}\mathbb{S}_{n\,n'}(\lambda)=[\hat{\mathbb{T}}\hat{\mathbb{S}}]_{n\,n'}=[\hat{\mathbb{S}}\hat{\mathbb{T}}]_{n\,n'}\,.\tag{15}$$

The result is consistent with the recurrence relation obtained by differentiating Eq. (13) with respect to λ and using $(2n'+1)\xi\,P_{n'}(\xi)=(n'+1)P_{n'+1}(\xi)+n'\,P_{n'-1}(\xi)$. More generally, a generator of parity recurrence relations for the $\hat{\mathbb{S}}_{n\,n'}(\lambda)$ may be obtained by differentiating Eq.

(12) with respect to ξ, then multiplying by $(1-\xi^2)$ and recalling the Legendre polynomial recurrence relation $(1-\xi^2)(\partial/\partial\xi)\,P_n(\xi)=n\,[P_{n-1}(\xi)-\xi\,P_n(\xi)]$. This yields

$$\begin{aligned}
&(1-\xi^2)(\partial/\partial\xi)\{e^{i\lambda\,\xi}P_n(\xi)\}\\
&\quad=e^{i\lambda\,\xi}\{i\lambda\,(1-\xi^2)P_n(\xi)+n\,[P_{n-1}(\xi)-\xi\,P_n(\xi)]\}\\
&\quad=[i\lambda\,(1-\xi^2)-n\,\xi\,]\{e^{i\lambda\,\xi}P_n(\xi)\}+n\,\{e^{i\lambda\,\xi}P_{n-1}(\xi)\}\\
&\quad=[i\lambda\,(1-\xi^2)-n\,\xi\,]\left\{\sum_{k=0}^{\infty}\hat{\mathbb{S}}_{n\,k}(\lambda)\,P_k(\xi)\right\}+n\left\{\sum_{k=0}^{\infty}\hat{\mathbb{S}}_{n-1\,k}(\lambda)\,P_k(\xi)\right\}\\
&\quad=\sum_{k=0}^{\infty}\hat{\mathbb{S}}_{n\,k}(\lambda)\,(1-\xi^2)\,\frac{\partial}{\partial\xi}P_k(\xi)=\sum_{k=0}^{\infty}\hat{\mathbb{S}}_{n\,k}(\lambda)\;k\,[P_{k-1}(\xi)-\xi\,P_k(\xi)].
\end{aligned}$$

Hence

$$\sum_{k=0}^{\infty}\,[\hat{\mathbb{S}}_{n\,k}(\lambda)\,\{[i\lambda\,(1-\xi^2)+(k-n)\,\xi\,]P_k(\xi)-k\,P_{k-1}(\xi)\}+n\,\hat{\mathbb{S}}_{n-1\,k}(\lambda)\,P_k(\xi)]=0. \quad (16)$$

Multiplying Eq. (16) by $d\,\xi$ and integrating over $-1\leqslant\xi\leqslant+1$ yields, for $n>0$,

$$i\,\lambda\,(\;\hat{\mathbb{S}}_{0\,n}(\lambda)-\;\hat{\mathbb{S}}_{2\,n}(\lambda)\,)-\frac{3}{2}(2+n)\hat{\mathbb{S}}_{1\,n}(\lambda)+n\,\frac{3}{2}\,\frac{(2n+1)}{(2n-1)}\hat{\mathbb{S}}_{0\,n-1}(\lambda)=0. \quad (17)$$

Here we have used $1=P_0(\xi), \xi=P_1(\xi), \xi^2=\frac{1}{3}(P_0(\xi)+2P_2(\xi))$.

The general relation is obtained by multiplying Eq. (16) by $P_h(\xi)\,d\,\xi$ and integrating over $-1\leqslant\xi\leqslant+1$. We may assume that $h>0$ since the case $h=0$ has just been evaluated. We obtain the following.

Proposition 1 (General parity recurrence relation): The parity recursion relations for the $\hat{\mathbb{S}}_{h\,n}(\lambda)$, $h=0,1,2,\ldots$, *are given by Eq. (17) for* $h=0$ *and*

$$\begin{aligned}
&i\lambda\,\frac{2(h^2+h-1)(2h+1)}{(2h+3)(2h-1)}\hat{\mathbb{S}}_{h\,n}(\lambda)\;-i\lambda\,\frac{(h+1)(h+2)}{(2h+3)}\hat{\mathbb{S}}_{h+2\;n}(\lambda)-i\lambda\,\frac{h(h-1)}{(2h-1)}\hat{\mathbb{S}}_{h-2\;n}(\lambda)\\
&\quad-(h+2+n)(h+1)\,\hat{\mathbb{S}}_{h+1\;n}(\lambda)+h(h-1-n)\,\hat{\mathbb{S}}_{h-1\;n}(\lambda)\\
&\quad+\frac{n(2n+1)}{(2n-1)(2h+1)}\hat{\mathbb{S}}_{h\;n-1}(\lambda)\;=0
\end{aligned} \quad (18)$$

for $h>0$.

VI. CONCLUSION

In this section we adopt the notation of Vilenkin and Klimyk.[3] Let $ISO(n-1)$ denote the group of motions of $n-1$-dimensional Euclidean space $\mathbb{E}_{n-1}$. Let $\mathbf{x}\in\mathbb{E}_{n-1}$; every $g\in ISO(n-1)$ has the action $g\mathbf{x}=k\mathbf{x}+\mathbf{a}$, where $k\in SO(n-1)$ is a rotation of $\mathbb{E}_{n-1}$ about the origin and $\mathbf{a}\in\mathbb{R}^{n-1}$. The group $ISO(n-1)$ is isomorphic to the group of $n\times n$ real matrices of the form

$$g(k,\mathbf{a})=\begin{pmatrix} k & \mathbf{a}\\ \mathbf{0}^T & 1\end{pmatrix},$$

where $\mathbf{0}^T=(0,\ldots,0)$ has $n-1$ components.

Let

$$D^{n}_{k\,m\,j}=\frac{2^{2j+n-5}}{\pi}\Gamma^{2}\left(j+\frac{n-3}{2}\right)\left[\frac{(k-j)!(m-j)!(2k+n-3)(2m+n-3)}{(k+j+n-4)!(m+j+n-4)!}\right]^{1/2}, \tag{19}$$

$\mathbf{a}_r^T=(0,\ldots,0,r)$ and $g_r=g(\text{identity},\mathbf{a}_r)$; Vilenkin and Klimyk[3] show that the matrix elements $t^{n\,R}_{k\,m\,j}(g_r)$ of the representation $T^{n\,R}(g_r)$ of $ISO(n-1)$ possess the integral representation

$$t^{n\,R}_{k\,m\,j}(g_r)=D^{n}_{k\,m\,j}\int_0^{\pi} e^{R\,r\,\cos(\phi)}C^{j+(n-3)/2}_{k-j}(\cos(\phi))C^{j+(n-3)/2}_{m-j}(\cos(\phi))\sin^{2j+n-3}(\phi)\,d\phi\,, \tag{20}$$

where C^j_k is the Gegenbauer polynomial. The representation is unitary when $R=i\,\rho,\rho\in\mathbb{R}$. In our case we see that $\mathbb{U}_{n\,n'}(\lambda)=J^{4}_{n\,n'\,0}(-i\lambda)$. Vilenkin and Klimyk show that $J^{n}_{k\,m\,j}(-i\,R\,r)=t^{n\,R}_{k\,m\,j}(g_r)$ defines a generalization of the Bessel function that they call the associated Bessel functions. Hence the associated Bessel functions $J^{4}_{n\,n'\,0}(-i\lambda)$ provide an approximation for the leading term in the radial contribution of the evolution operator.

(Received 11 April 2003; accepted 3 February 2004; published 7 April 2004)

For the nonrotating Bañados, Teitelboim, and Zanelli black hole, the distributional curvature tensor field is found. It is shown to have singular parts proportional to a δ-distribution with support at the origin. This singularity is related, through Einstein field equations, to a point source. Coordinate invariance and independence on the choice of differentiable structure of the results are addressed. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1699482]

I. INTRODUCTION

The $(2+1)$-dimensional black hole of Bañados, Teitelboim, and Zanelli (BTZ)[1,2] provides us with a useful model to study various classical and quantum aspects of black hole physics.[3] The BTZ black hole shares many of the properties of the more complicated $(3+1)$-dimensional Kerr black hole. However, it differs from the Kerr solution in which it is asymptotically anti–de Sitter rather than asymptotically flat. Furthermore, by admitting closed time-like curves, the rotating BTZ black hole has no curvature singularities. Nevertheless, when there is no angular momentum the space–time fails to be Hausdorff at the origin and turns out to be singular.[2]

The purpose of this work is to analyze the distributional BTZ black hole geometry for the nonrotating case. There are several reasons to carry out such analysis. The nonrotating BTZ black hole provides an example of a singular space–time whose singularities cannot be identified with the unboundedness of some scalar constructed from the curvature tensor. In this sense, it resembles the well-known conical singularities[4] whose meaning has attracted wide interest for many years.[5] On the other hand, besides the fact that the distributional analysis has not been considered hitherto, regularization procedures required to multiply distributions need not be invoked in the calculation of the distributional nonrotating BTZ black hole curvature tensor. Most of the distributional treatments of the $(3+1)$-dimensional Schwarzschild[6–8] and Kerr black holes[7] rely on suitable regularization procedures; while general regularization procedures using Colombeau's generalized functions[9] to obtain the distributional curvature associated to the Schwarzschild[10] and Kerr geometries[11] and to a conical singularity[12–14] have been put forward (see also Refs. 6 and 15 for other approaches to conical singularities). We show that the nonrotating BTZ black hole metric belongs to the class of semiregular metrics, as defined in Ref. 16, for which a direct distributional meaning may be assigned to the curvature tensor field. Notice that not many semiregular metrics are known. It has been shown that the $(3+1)$-dimensional Minkowski metric with an angular deficit, and a certain kind of traveling wave metric are semiregular.[16] Recently, the metric associated to the $(2+1)$-dimensional space–time around a point source[4] was demonstrated to be a third example.[8]

In order to consider the coordinate dependence of the results, the distributional description of the BTZ black hole space–time is carried out in Schwarzschild coordinates and in Kerr–Schild coordinates. We find the distributional Ricci and Einstein tensor fields for the nonrotating BTZ

black hole, which turn out to be equivalent in both coordinate systems. This indicates that, although the intermediate calculations depend upon the choice of coordinates, the final result does not. Remarkably, a complete agreement with what is physically expected is found. The distributional curvature tensor becomes, besides the constant curvature part, a δ-distribution supported at the origin. Furthermore, this singularity is related through Einstein field equations to a point source.

The paper is organized as follows. In the next section, following the procedure of Ref. 16, the distributional curvature and Einstein tensor fields are found for the nonrotating BTZ solution in Schwarzschild coordinates. In Sec. III, we carry out the distributional analysis using the Kerr–Schild form of the BTZ solution, and the question of whether one can also obtain these results as the distributional limit of a suitable regularized metric is addressed. The last section is devoted to summarize and discuss the coordinate invariance (and differentiable structure dependence) of our results.

II. BTZ BLACK HOLE IN SCHWARZSCHILD COORDINATES

The nonrotating BTZ black hole solution[1,2] written in Schwarzschild coordinates is given by

$$g_{ab}=-\left(-m+\frac{r^2}{l^2}\right)\mathrm{d}t_a\,\mathrm{d}t_b+\left(-m+\frac{r^2}{l^2}\right)^{-1}\mathrm{d}r_a\,\mathrm{d}r_b+r^2\,\mathrm{d}\varphi_a\,\mathrm{d}\varphi_b\,, \tag{1}$$

where $-\infty<t<\infty$, $0<r<\infty$, and $0\leqslant\varphi<2\pi$, with the surfaces $\varphi=0,2\pi$ identified. The dimensionless quantity m is the mass parameter. In $(2+1)$-dimensions we have

$$R_{abc}{}^{d}=g_{ac}R_b{}^{d}-g_{bc}R_a{}^{d}+\delta_b{}^{d}R_{ac}-\delta_a{}^{d}R_{bc}-\tfrac{1}{2}(g_{ac}\delta_b{}^{d}-g_{bc}\delta_a{}^{d})R \tag{2}$$

and from (1) we obtain

$$R_{ab}=-\frac{2}{l^2}g_{ab}\,. \tag{3}$$

Hence, (1) has constant negative curvature.

The BTZ metric (1) is a solution of the vacuum Einstein field equations with cosmological constant $\Lambda=-1/l^2$,

$$R_{ab}-\tfrac{1}{2}g_{ab}R+\Lambda g_{ab}=0, \tag{4}$$

and may be obtained by identifying certain points of (the covering manifold of) the anti–de Sitter space.[1,2] For $m>0$, (1) describes a black hole of mass m with horizon at $r_+=\sqrt{m}l$. For $m\leqslant 0$ the horizon disappears and there is no black hole. The solution with $-1<m<0$ may be associated to the metric generated by a point source at the origin.[17] The solution with $m=-1$ is anti–de Sitter space. The massless black hole, $m=0$, is commonly considered as the vacuum state. For a review of the properties of BTZ black holes see Ref. 3.

In (1), $\sqrt{g_{\varphi\varphi}}=r$ represents the radius associated with the proper circumference. Therefore with $x=r\cos\varphi$ and $y=r\sin\varphi$ we have

$$g_{ab}=\eta_{ab}+\left(1+m-\frac{r^2}{l^2}\right)\mathrm{d}t_a\,\mathrm{d}t_b-\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right)\frac{1}{r^2}(x\,\mathrm{d}x_a+y\,\mathrm{d}y_a)(x\,\mathrm{d}x_b+y\,\mathrm{d}y_b), \tag{5}$$

where $r=\sqrt{x^2+y^2}$ and η_{ab} is the ordinary Minkowski metric on $\mathcal{R}^3$. The metric (5) is singular when $r=0$, except for $m=-1$. This singularity is not a coordinate singularity. The spinless BTZ black hole is geodesically incomplete[18] and the singularity at $r=0$ corresponds to fixed points of

the identifications from which the BTZ solution is obtained.[19] Assuming that (5) can be extended to $r=0$, we look for the distributional curvature tensor and its relation with a possible distributional source.

Suppose $(\mathcal{M},g_{ab})$ are given such that

(1) g_{ab} and $(g^{-1})^{ab}$ exist almost everywhere and are locally integrable,
(2) the weak first derivative $\nabla_c g_{ab}$ of g_{ab} in a smooth derivative operator ∇_c exists and the tensors

$$C^c_{ab}\equiv \tfrac{1}{2}(g^{-1})^{cd}(\nabla_a g_{bd}+\nabla_b g_{ad}-\nabla_d g_{ab}), \tag{6}$$

and $C^d_{m[b}C^m_{a]c}$ are locally integrable.

Following Ref. 16, these are sufficient conditions for $R_{abc}{}^d$ to be definable as a distribution by the usual coordinate formula,

$$R_{abc}{}^d=\tilde{R}_{abc}{}^d+2\nabla_{[b}C^d_{a]c}+2C^d_{m[b}C^m_{a]c}, \tag{7}$$

where $\tilde{R}_{abc}{}^d$ is the curvature tensor associated to the smooth derivative operator ∇_c and we shall say that g_{ab} is a semiregular metric.

A semiregular metric may have no distributional Einstein tensor due to the fact that contractions of the metric with the curvature tensor may have no sense as distributions. Stronger conditions can be imposed to isolate the class of metrics for which the distributional meaning of the Einstein tensor is ensured, but then the distributional curvature tensor must have its support on a submanifold of codimension of at most one.[20] Metrics for surface layers[21] lie in this class, but neither strings nor point particles can be described by metrics in this class. Alternatively, by considering Colombeau's generalized functions,[9] distributional curvatures can be defined for those cases where a direct calculation would not work, but we will not consider it here.

We shall prove that (5) is a semiregular metric. We take for the differentiable structure that in which $t,x,$ and y form a smooth chart. For a test tensor field U^{ab} on $\mathcal{R}^3$ we have

$$\begin{aligned} g_{ab}[U^{ab}]\equiv\int_{\mathcal{R}^3} g_{ab}U^{ab}\omega_\eta=\int_{\mathcal{R}^3}\eta_{ab}U^{ab}\omega_\eta+\int_{\mathcal{R}^3}\left(1+m-\frac{r^2}{l^2}\right)U^{tt}\omega_\eta \\ -\int_{\mathcal{R}^3}\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right)\mathrm{d}r_a\,\mathrm{d}r_b U^{ab}\omega_\eta, \end{aligned} \tag{8}$$

where ω_η is the volume element associated to η_{ab} and it is understood that all tensor components are Cartesian components as functions of Cartesian coordinates. For $m>0$ we require that U^{ab} be a test tensor with support on $r<\sqrt{m}l$, while for $m<0$ we simply require that U^{ab} be a test tensor of compact support. The black vacuum can not be handled in the Schwarzschild-type coordinates because the last term in the right-hand side of (8) is not locally integrable for $m=0$. Note that, with this choice, the natural volume element ω_g associated to g_{ab} agrees with the volume element ω_η of η_{ab}.

It follows that

$$\begin{aligned} g_{ab}[U^{ab}]=\int_{\mathcal{R}^3}\eta_{ab}U^{ab}\omega_\eta+\int_{\mathcal{R}^3}\left(1+m-\frac{r^2}{l^2}\right)U^{tt}\omega_\eta-\int_{\mathcal{R}^3}\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right) \\ \times(\cos^2\varphi U^{xx}+\cos\varphi\sin\varphi(U^{xy}+U^{yx})+\sin^2\varphi U^{yy})\omega_\eta. \end{aligned} \tag{9}$$

Therefore, g_{ab} is locally integrable for $m\neq 0$.

Next, let U_{ab} be a test tensor field on $\mathcal{R}^3$. For

$$(g^{-1})^{ab}\equiv\eta^{ab}+\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right)\partial_t^a\partial_t^b-\left(1+m-\frac{r^2}{l^2}\right)\partial_r^a\partial_r^b, \tag{10}$$

we have

$$(g^{-1})^{ab}[U_{ab}]=\int_{\mathcal{R}^3}\eta^{ab}U_{ab}\omega_\eta+\int_{\mathcal{R}^3}\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right)\ U_{tt}\omega_\eta-\int_{\mathcal{R}^3}\left(1+m-\frac{r^2}{l^2}\right)$$
$$\times(\cos^2\varphi U_{xx}+\cos\varphi\sin\varphi(U_{xy}+U_{yx})+\sin^2\varphi U_{yy})\omega_\eta. \tag{11}$$

Therefore, $(g^{-1})^{ab}$ is locally integrable for $m\neq 0$.

We now calculate the weak derivative in η_{ab} of g_{ab}. Let U^{abc} be a test tensor field. We find

$$\nabla_c g_{ab}[U^{cab}]\equiv-\int_{\mathcal{R}^3}g_{ab}\nabla_c U^{cab}\omega_\eta=\int_{\mathcal{R}^3}W_{cab}U^{cab}\omega_\eta, \tag{12}$$

where W_{cab} is the locally integrable but not locally square integrable tensor given by

$$W_{cab}=-\frac{2r}{l^2}\mathrm{d}r_c\left(\mathrm{d}t_a\,\mathrm{d}t_b+\left(m-\frac{r^2}{l^2}\right)^{-2}\mathrm{d}r_a\,\mathrm{d}r_b\right)-\frac{1}{r}\left(\frac{l^2+ml^2-r^2}{ml^2-r^2}\right)r\,\mathrm{d}\varphi_c(r\,\mathrm{d}\varphi_a\,\mathrm{d}r_b+r\,\mathrm{d}r_a\,\mathrm{d}\varphi_b). \tag{13}$$

From (6), we find

$$C^c_{ab}=\frac{-r(ml^2-r^2)}{l^4}\mathrm{d}t_a\,\mathrm{d}t_b\,\partial^c_r-\frac{r}{ml^2-r^2}(\mathrm{d}r_a\,\mathrm{d}t_b+\mathrm{d}t_a\,\mathrm{d}r_b)\partial^c_t$$
$$+\frac{r}{ml^2-r^2}\mathrm{d}r_a\,\mathrm{d}r_b\,\partial^c_r+\frac{1}{r}\,\frac{ml^2+l^2-r^2}{l^2}r^2\,\mathrm{d}\varphi_a\,\mathrm{d}\varphi_b\,\partial^c_r, \tag{14}$$

which is locally integrable. On the other hand,

$$2C^d_{m[b}C^m_{a]c}=\frac{4r}{ml^2-r^2}\mathrm{d}t_{[a}\mathrm{d}r_{b]}\left(\frac{r}{ml^2-r^2}\mathrm{d}r_c\,\partial^d_t-\frac{r(ml^2-r^2)}{l^4}\mathrm{d}t_c\,\partial^d_r\right)$$
$$-2\,\frac{ml^2+l^2-r^2}{(ml^2-r^2)l^2}(r^2\,\mathrm{d}\phi_{[a}\mathrm{d}t_{b]}\,\mathrm{d}\phi_c\partial^d_t-r^2\,\mathrm{d}\phi_{[a}\mathrm{d}r_{b]}\,\mathrm{d}\phi_c\,\partial^d_r), \tag{15}$$

which is locally integrable. Hence, g_{ab} is a semiregular metric in the differentiable structure chosen.

Now, contracting (7) and using (14) and (15) we find for the Ricci tensor of g_{ab},

$$R_{ac}[U^{ac}]\equiv-\int_{\mathcal{R}^3-B_\varepsilon}C^b_{ac}\nabla_b U^{ac}\omega_\eta-\int_{\mathcal{R}^3-B_\varepsilon}C^b_{ma}C^m_{bc}U^{ac}\omega_\eta, \tag{16}$$

where

$$-\int_{\mathcal{R}^3-B_\varepsilon}C^b_{ac}\nabla_b U^{ac}\omega_\eta=\int_{r=\varepsilon}\mathrm{d}r_b\,C^b_{ac}U^{ac}\sigma+\int_{r>\varepsilon}\nabla_b C^b_{ac}U^{ac}\omega_\eta, \tag{17}$$

with σ the volume element induced on the surface $r=$constant by the metric η_{ab}, B_ε is the ε-ball around the origin with $\varepsilon\to 0$ and

$$\nabla_b C^b_{ac}=-\frac{2(ml^2-2r^2)}{l^4}\mathrm{d}t_a\,\mathrm{d}t_c+2\,\frac{ml^2}{(ml^2-r^2)^2}\mathrm{d}r_a\,\mathrm{d}r_c-2\,\frac{r^2}{l^2}\mathrm{d}\varphi_a\,\mathrm{d}\varphi_c, \tag{18}$$

which is a locally integrable tensor.

From (16) and (15), (17), and (18) we find

$$R_{ac}[U^{ac}]=\pi(1+m)\int \mathrm{d}t(U^{xx}(t,\vec{0})+U^{yy}(t,\vec{0}))-\frac{2}{l^2}\int_{\mathcal{R}^3} g_{ac}U^{ac}\omega_\eta, \tag{19}$$

where g_{ac} is the locally integrable tensor defined by (9). Thus we obtain

$$R_{ac}=\pi(1+m)\,\delta^{(2)}_{(0)}(\mathrm{d}x_a\,\mathrm{d}x_c+\mathrm{d}y_a\,\mathrm{d}y_c)-\frac{2}{l^2}g_{ac}\,. \tag{20}$$

Note that $\forall m>-1$, the Ricci tensor has a singular part proportional to a δ distribution. As expected, for $m=-1$ the singular part of the curvature is absent, as follows from the fact that in this case we have AdS_3 space–time. Since for $-1<m<0$, there is no horizon, we have a naked singularity at $r=0$. For $m>0$ we have a singularity at $r=0$ hidden by a horizon at $r_+=\sqrt{m}l$. As stated before, for $m=0$ the metric (8) is not a semiregular metric and the massless BTZ black hole cannot be properly discussed from the above derivation.

We now calculate the Einstein tensor of g_{ab}. Following Ref. 8 we will concentrate on the mixed-index Einstein tensor field $G^a{}_b$. Define

$$\begin{aligned}G^a{}_b=R^a{}_b-\tfrac{1}{2}(g^{-1})^{cd}\tilde{R}_{cd}\delta^a{}_b+(g^{-1})^{cd}C^e_{m[c}C^m_{e]d}\delta^a{}_b\\ +\nabla_{[c}(C^e_{e]d}(g^{-1})^{cd})\,\delta^a{}_b+C^e_{d[c}\nabla_{e]}(g^{-1})^{cd}\delta^a{}_b\,,\end{aligned} \tag{21}$$

where

$$R^a{}_b=(g^{-1})^{ac}\tilde{R}_{cb}+2\nabla_{[c}(C^c_{d]b}(g^{-1})^{ad})+2C^c_{b[c}\nabla_{d]}(g^{-1})^{ad}+2(g^{-1})^{ad}C^c_{m[c}C^m_{d]b}\,. \tag{22}$$

We shall say that (21) is the Einstein tensor distribution of (5), whenever each term in the right-hand sides of (21) and (22) may be interpreted as a distribution.

From (14), (15), and (22) we find

$$\begin{aligned}R^d{}_c=\nabla_b((g^{-1})^{ad}C^b{}_{ac})=\nabla_b\Big(-\frac{r}{l^2}\partial^d_t\,\mathrm{d}t_c\,\partial^b_r-\frac{rl^2}{(ml^2-r^2)^2}\partial_t\,\mathrm{d}r_c\,\partial^b_t+\frac{r}{l^2}\partial^d_r\,\mathrm{d}t_c\,\partial^b_t\\ --\frac{r}{l^2}\partial^d_r\,\mathrm{d}r_c\,\partial^b_r+\frac{ml^2+l^2-r^2}{rl^2}\partial^d_\varphi\,\mathrm{d}\varphi_c\,\partial^b_r\Big).\end{aligned} \tag{23}$$

Note that the right-hand side of (23) is the derivative of a locally integrable tensor. Therefore a distributional meaning can be given to (23).

An analogous calculation to that of (20) leads to

$$R^a{}_b=\pi(1+m)\,\delta^{(2)}_{(0)}(\partial^a_x\,\mathrm{d}x_b+\partial^a_y\,\mathrm{d}y_b)-\frac{2}{l^2}(\partial^a_t t_b+\partial^a_x\,\mathrm{d}x_a+\partial^a_y\,\mathrm{d}y_b). \tag{24}$$

Finally, from (14) and (15) and (21) and (24) we obtain

$$G^a{}_b-\frac{1}{l^2}(\partial^a_t t_b+\partial^a_x\,\mathrm{d}x_a+\partial^a_y\,\mathrm{d}y_b)=-\pi(1+m)\,\delta^{(2)}_{(0)}\partial^a_t\,\mathrm{d}t_b\,. \tag{25}$$

Remarkably enough, the right-hand side of (25) resembles the physically expected result for the distributional energy momentum tensor $T^a{}_b=-m\,\delta^{(3)}_{(0)}\partial^a_t\,\mathrm{d}t_b$ of the Schwarzschild four-dimensional black hole.[22,6–8,10] (The Schwarzschild metric is not a semiregular metric and cannot be handled with the methods used here to obtain its distributional curvature.[8])

Now, let us consider the dependence of these results on the coordinate system. Note that whether or not a metric is semiregular depends in general on the differentiable structure imposed on the manifold. In this section, the choice of the manifold differentiable structure was made on

the basis of an interpretation of the coordinate system in which the metric is given: we use Cartesian coordinates associated with the Schwarzschild coordinates. In the next section the distributional curvature and Einstein tensor fields are evaluated using the Kerr–Schild form of the BTZ metric. This amounts to change both the coordinates and the differentiable structure.

III. BTZ BLACK HOLE IN KERR–SCHILD COORDINATES

In previous works the Kerr–Schild form of the Schwarzschild metric has been proved to be useful, from both conceptual and technical points of view, for the analysis of the distributional Schwarzschild geometry from quite different approaches.[22,7,11,10] In the following we shall prove that the nonrotating BTZ solution in Kerr–Schild coordinates is a semiregular metric.

The AdS_3 black hole solution of BTZ is given in the Kerr–Schild form by[23]

$$g_{ab}=\eta_{ab}+f\,k_a k_b\,, \tag{26}$$

where $r=\sqrt{x^2+y^2}$ and

$$f=\left(1+m-\frac{r^2}{l^2}\right),\quad k_a=\mathrm{d}t_a+\frac{1}{r}(x\,\mathrm{d}x_a+y\,\mathrm{d}y_a), \tag{27}$$

with $k^a=\eta^{ab}k_b$ a null vector field with respect to η_{ab} and g_{ab}. It follows that there are two metrical structures, η_{ab} and g_{ab}, associated to the manifold. Furthermore,

$$k^a\nabla_a k^b=k^a\nabla_a^g k^b=0, \tag{28}$$

where ∇_a and ∇_a^g are the derivatives in η_{ab} and g_{ab}, respectively, i.e., k^a is geodetic with respect to η_{ab} and g_{ab}. Hence, the conditions of the Kerr–Schild class are met by the decomposition (26) and (27), a fact that will be used later. We choose as the underlying manifold structure that of $\mathcal{R}^3$ with the smooth metric η_{ab} in Cartesian coordinates $\{t,x,y\}$. Note that in Kerr–Schild coordinates r is a spacelike coordinate $\forall r>0$, which is not the case in Schwarzschild-type coordinates. Note also that the natural volume element ω_g associated to g_{ab} agrees with the volume element ω_η of η_{ab}.

Now,

$$(g^{-1})^{ab}=\eta^{ab}-\left(1+m-\frac{r^2}{l^2}\right)\left(\partial_t^a-\frac{1}{r}(x\partial_x^a+y\partial_y^a)\right)\left(\partial_t^b-\frac{1}{r}(x\partial_x^b+y\partial_y^b)\right). \tag{29}$$

Clearly, g_{ab} and $(g^{-1})^{ab}$ are locally bounded and locally integrable $\forall m$.

The weak derivative in η_{ab} of g_{ab} exists almost everywhere and is given by

$$\nabla_c g_{ab}[U^{cab}]=\int_{\mathcal{R}^3}W_{cab}U^{cab}\omega_\eta, \tag{30}$$

where

$$W_{cab}=-\frac{r}{l^2}\mathrm{d}r_c(\mathrm{d}t_a+\mathrm{d}r_a)(\mathrm{d}t_b+\mathrm{d}r_b)+\frac{1}{r}\left(1+m-\frac{r^2}{l^2}\right)r\,\mathrm{d}\varphi_c(r\,\mathrm{d}\varphi_a(\mathrm{d}t_b+\mathrm{d}r_b)$$
$$+(\mathrm{d}t_a+\mathrm{d}r_a)r\,\mathrm{d}\varphi_b), \tag{31}$$

which is locally integrable $\forall m$.

From (6), it follows

$$C^c{}_{ab}=\frac{2r}{l^2}(\mathrm{d}r_a(\mathrm{d}t_b+\mathrm{d}r_b)+\mathrm{d}r_b(\mathrm{d}t_a+\mathrm{d}r_a))(\partial_t^c-\partial_r^c)+\frac{2r}{l^2}\left(1+m-\frac{r^2}{l^2}\right)(\mathrm{d}t_a+\mathrm{d}r_a)(\mathrm{d}t_b+\mathrm{d}r_b)$$
$$\times(\partial_t^c-\partial_r^c)+\frac{2r}{l^2}(\mathrm{d}t_a+\mathrm{d}r_a)(\mathrm{d}t_b+\mathrm{d}r_b)\partial_r^c-\frac{2}{r}\left(1+m-\frac{r^2}{l^2}\right)r^2\,\mathrm{d}\varphi_a\,\mathrm{d}\varphi_b(\partial_t^c-\partial_r^c), \tag{32}$$

which is locally integrable $\forall m$. Note that $C^b{}_{ab}=0$.

Finally, from (32) we find

$$2C^d_{m[b}C^m_{a]c}=2\frac{r^2}{l^4}(\mathrm{d}t_a\,\mathrm{d}r_b-\mathrm{d}r_a\,\mathrm{d}t_b)(\mathrm{d}t_c+\mathrm{d}r_c)(\partial_t^d-\partial_r^d)-\frac{1}{l^2}\left(1+m-\frac{r^2}{l^2}\right)$$
$$\times((\mathrm{d}t_a+\mathrm{d}r_a)r\,\mathrm{d}\varphi_b-r\,\mathrm{d}\varphi_a(\mathrm{d}t_b+\mathrm{d}r_b))r\,\mathrm{d}\varphi_c(\partial_t^d-\partial_r^d), \tag{33}$$

which is locally integrable $\forall m$. Therefore the metric (26) is semiregular. Furthermore, since (26) is a semiregular metric $\forall m$, we can now consider the distributional geometry of the BTZ black hole including the $m=0$ black vacuum.

We now calculate the Ricci tensor of (26). We have

$$R_{ac}[U^{ac}]=-\int_{\mathcal{R}^3-B_\varepsilon}C^b{}_{ac}\nabla_b U^{ac}\omega_\eta-\int_{\mathcal{R}^3-B_\varepsilon}\frac{2r}{l^2}k_ak_c\,U^{ac}\omega_\eta. \tag{34}$$

An analogous calculation to that of (20) leads to

$$R_{ac}=\pi(1+m)\,\delta^{(2)}_{(0)}(\mathrm{d}x_a\,\mathrm{d}x_c+\mathrm{d}y_a\,\mathrm{d}y_c)-\frac{2}{l^2}g_{ac}, \tag{35}$$

where g_{ac} is the locally integrable tensor (26). Note that (35) is equivalent to (20) which was obtained using Schwarzschild-type coordinates.

Calculations analogous to the ones done previously show that

$$R^a{}_b=\pi(1+m)\,\delta^{(2)}_{(0)}(\partial_x^a\,\mathrm{d}x_b+\partial_y^a\,\mathrm{d}y_b)-\frac{2}{l^2}(\partial_t^a t_b+\partial_x^a\,\mathrm{d}x_b+\partial_y^a\,\mathrm{d}y_b), \tag{36}$$

which is equivalent to (24) and

$$G^a{}_b-\frac{1}{l^2}(\partial_t^a t_b+\partial_x^a\,\mathrm{d}x_a+\partial_y^a\,\mathrm{d}y_b)=-\pi(1+m)\,\delta^{(2)}_{(0)}\partial_t^a\,\mathrm{d}t_b \tag{37}$$

which is equivalent to (25).

Now, it would be interesting to see if the distributional curvatures obtained above can also be obtained employing regularization methods. This is far from being obvious, since for conical singularities the results of the regularization approaches taken so far[6,12–14,8] are in disagreement with the ones obtained following the procedure of Ref. 16 which is the one that we have employed. A property of the Kerr–Schild class of metrics is that the mixed Ricci curvature tensor takes the form

$$R^a{}_b=\tfrac{1}{2}(\nabla^a\nabla_c(fk^ck_b)+\nabla^b\nabla_c(fk_ck^a)+\nabla^c\nabla_c(fk^ak_b)) \tag{38}$$

(recall that ∇_a is the derivative in η_{ab}) which allows a distributional evaluation whenever fk^ak_b is a well-defined distribution.[7] However, it should be kept in mind that due to the nonlinear character of the curvatures, we must first regularize, then carry out the nonlinear operations and finally compute the distributional limits.

For the metric tensor (26) and (27), f is indeed a smooth function and although k_a is a nonsmooth vector field, fk^ak_b is a locally integrable tensor field,

$$fk^a k_b[U^b{}_a]=\int_{\mathcal{R}^3} fk^a k_b\, U^b{}_a \omega_\eta=\int_{\mathcal{R}^3}\left(1+m-\frac{r^2}{l^2}\right)(U^t{}_t+\cos\varphi(U^x{}_t+U^t{}_x)+\sin\varphi(U^y{}_t+U^t{}_y)$$
$$+\cos^2\varphi\, U^x{}_x+\cos\varphi\sin\varphi(U^x{}_y+U^y{}_x)+\sin^2\varphi\, U^y{}_y)\omega_\eta. \quad (39)$$

Hence, due to the fact that (38) turns out to be second derivatives of a distribution it is then possible to carry out the calculation, without specifying the regularization procedure, requiring only that the regularization chosen retains the Kerr–Schild form of the metric (for a discussion on this point see Refs. 7, 11, and 10).

Now, let us exemplify the calculation of the distributional Ricci tensor field by the evaluation of the first term of (38) explicitly. We have

$$\nabla^a\nabla_c(fk^c k_b)[U^b{}_a]\equiv\int_{\mathcal{R}^3-B_\varepsilon} fk^c k_b\nabla^a\nabla_c U^b{}_a\omega_\eta$$
$$=-\int_{r=\varepsilon} \mathrm{d}r_c\, fk^c k_b\nabla^a U^b{}_a\sigma+\int_{r=\varepsilon}\partial_r^a\nabla_c(fk^c k_b)U^b{}_a\sigma$$
$$+\int_{r>\varepsilon}\nabla^a\nabla_c(fk^c k_b)U^b{}_a\omega_\eta. \quad (40)$$

The first term on the right-hand side of (40) is of order ε and vanishes in the limit $\varepsilon\to 0$, the third term contributes to the Ricci curvature in the region $\mathcal{R}^3-B_\varepsilon$. For the second term we have

$$\int_{r=\varepsilon}\partial_r^a\nabla_c(fk^c k_b)U^b{}_a\sigma=\int_{r=\varepsilon}\left(-\frac{2r}{l^2}+\left(1+m-\frac{r^2}{l^2}\right)\frac{1}{r}\right)(\mathrm{d}t_b+\mathrm{d}r_b)\,\partial_r^a U^b{}_a\,\sigma$$
$$=\pi(1+m)\int \mathrm{d}t(U^x{}_x(t,\vec{0})+U^y{}_y(t,\vec{0}))$$
$$=\pi(1+m)\,\delta^{(2)}_{(0)}(\partial_x^a\,\mathrm{d}x_b+\partial_y^a\,\mathrm{d}y_b)[U^b{}_a]. \quad (41)$$

Analogous calculations for the remaining terms of (38) lead to

$$R^a{}_b=\pi(1+m)\,\delta^{(2)}_{(0)}(\partial_x^a\,\mathrm{d}x_b+\partial_y^a\,\mathrm{d}y_b)-\frac{2}{l^2}(\partial_t^a t_b+\partial_x^a\,\mathrm{d}x_b+\partial_y^a\,\mathrm{d}y_b), \quad (42)$$

and we obtain for the Einstein tensor

$$G^a{}_b=-\pi(1+m)\,\delta^{(2)}_{(0)}\partial_t^a\,\mathrm{d}t_b+\frac{1}{l^2}(\partial_t^a t_b+\partial_x^a\,\mathrm{d}x_a+\partial_y^a\,\mathrm{d}y_b), \quad (43)$$

which are the same results obtained in (36) and (37).

IV. DISCUSSIONS

As noted above, the distributional Ricci tensor fields (20) and (35) are equivalent, as is the case with the mixed index versions (24) and (36). We take (35) and (36), which are valid $\forall m$, as the distributional R_{ab} and $R^a{}_b$ Ricci tensor fields. The nonrotating BTZ black hole geometry is singular and this singularity is a curvature singularity proportional to a δ-distribution supported at the origin. As follows from (35) and (36), even for the $m=0$ black vacuum this singularity is present. As expected, for $m=-1$ (anti–de Sitter space–time) a nonsingular space–time is recovered.

On the other hand, (25) and (37) are equivalent. Hence, we take (37) as the distributional Einstein tensor field $G^a{}_b$ of the nonrotating BTZ black hole. As expected on physical grounds, the distributional energy momentum tensor $T^a{}_b$ of the BTZ black hole geometry is then given by

$$T^a{}_b = -(1+m)\,\delta^{(2)}_{(0)}\partial^a_t\,\mathrm{d}t_b\,, \tag{44}$$

where we have set the gravitational constant G equal to $\frac{1}{8}$. Note that (44) is a nonzero distribution for $m=0$. The constant shift in the mass is due to the fact that in (1) the zero point of energy has been set so that the mass vanishes when the horizon size, the length of the minimal geodesic of the horizon, goes to zero.[2] As follows from the fact that the singular parts of the distributional curvature and Einstein tensor fields are equal to zero only for $m=-1$, if the zero of energy is adjusted so that anti–de Sitter space has zero mass then $1+m\to m$.

Finally, let us briefly discuss the coordinate independence of these results. As already mentioned in Sec. II, whether or not a given metric is semiregular depends in general on the differentiable structure imposed on the underlying manifold. In Secs. II and III, the choice of the differentiable structure was made on the basis of an interpretation of the coordinate system in which the metric is given. In this sense, the choice of coordinates determines the differentiable structure of the underlying manifold. Here we find that the distributional curvature and Einstein tensor fields are well defined and that they are equivalent in both descriptions. Furthermore, we have shown that the same distributional mixed index Ricci and Einstein tensor fields can be obtained by standard regularization approaches. Thus, in a restricted sense, the present distributional treatment in Schwarzschild and Kerr–Schild coordinates provides invariant results for the distributional curvature and Einstein tensor fields of the BTZ black hole geometry.

(Received 6 January 2004; accepted 17 February 2004; published 8 April 2004)

Fisher–Hartwig asymptotics refers to the large n form of a class of Toeplitz determinants with singular generating functions. This class of Toeplitz determinants occurs in the study of the spin–spin correlations for the two-dimensional Ising model, and the ground state density matrix of the impenetrable Bose gas, amongst other problems in mathematical physics. We give a new application of the original Fisher–Hartwig formula to the asymptotic decay of the Ising correlations above T_c, while the study of the Bose gas density matrix leads us to generalize the Fisher–Hartwig formula to the asymptotic form of random matrix averages over the classical groups and the Gaussian and Laguerre unitary matrix ensembles. Another viewpoint of our generalizations is that they extend to Hankel determinants the Fisher–Hartwig asymptotic form known for Toeplitz determinants. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1699484]

ENCOMIUM

In celebration of Freeman Dyson on his

$$\left(32\left(\frac{40960001}{25600}\right)^3-6\left(\frac{40960001}{25600}\right)+\sqrt{\left[32\left(\frac{40960001}{25600}\right)^3-6\left(\frac{40960001}{25600}\right)\right]^2-1}\right)^{1/6}\ \text{th}$$

birthday. (This radical appears in the works on Ramanujan,[1] who is very dear to Dyson.)

Dyson's legendary works[2] on random matrices are now standards in physics, mathematics and fields far(ther) afield. These works and, in particular his powerful log-Coulomb gas model, developed to liberate the mathematics where none yet exists, are the very essential tools in our ongoing pursuits.[3]

I. INTRODUCTION

Fisher–Hartwig asymptotics refers to the large n form of a class of Toeplitz determinants $D_n[g]$. By definition, the entries of the latter depend only on the difference of the row and column indices, and thus

$$D_n[g]=\det[g_{j-k}]_{j,k=1,\ldots,n} \tag{1.1}$$

for some $\{g_k\}_{k=0,\pm1,\pm2,\ldots}$. Crucial to the structure of the asymptotic form of (1.1) are analytic properties of the so-called symbol

a)Electronic mail: p.forrester@ms.unimelb.edu.au
b)Electronic mail: n.frankel@physics.unimelb.edu.au

$$g(\theta) := \sum_{n=-\infty}^{\infty} g_n e^{in\theta}, \tag{1.2}$$

or more particularly the decay of the Fourier coefficients of $\log g(\theta)$. Explicitly, let

$$\log g(\theta) = \sum_{p=-\infty}^{\infty} c_p e^{ip\theta}. \tag{1.3}$$

Then if

$$\sum_{p=-\infty}^{\infty} |p| c_p c_{-p} < \infty \tag{1.4}$$

a strong form of the Szegö limit theorem (see, e.g., Refs. 4 and 5) asserts that for $n \to \infty$,

$$D_n[g] = \exp\left(n c_0 + \sum_{k=1}^{\infty} k c_k c_{-k} + o(1) \right). \tag{1.5}$$

Two cases for which (1.4) will not hold are when $g(\theta)$ has a jump discontinuity or a zero for some $-\pi < \theta \leqslant \pi$. It is for such singular symbols (in the case of a zero it is the logarithm of the symbol which is singular) that Fisher and Hartwig[6] sought the asymptotic form of (1.1). Symbols with singularities of this type have the functional form

$$\begin{aligned} \log g(\theta) &= \log a(\theta) - i \sum_{r=1}^{R} b_r \arg e^{i(\theta_r + \pi - \theta)} + \sum_{r=1}^{R} a_r \log |2 - 2\cos(\theta - \theta_r)| \\ &= \log a(\theta) + \sum_{r=1}^{R} ((a_r + b_r)\log(1 + e^{i(\theta - (\theta_r + \pi))}) + (a_r - b_r)\log(1 + e^{i(\theta_r + \pi - \theta)})). \end{aligned} \tag{1.6}$$

Here $-\pi < \arg z \leqslant \pi$ and $a(\theta)$ is assumed to be sufficiently smooth that if we write

$$\log a(\theta) = \sum_{p=-\infty}^{\infty} c_p e^{ip\theta} \tag{1.7}$$

[cf. (1.3)] then the condition (1.4) holds. By using data following from the fact that special cases of (1.6) correspond to Toeplitz determinant expressions for the spin–spin correlation in the two-dimensional Ising model at criticality (see Sec. II below), the asymptotic form of which had previously been calculated,[7] Fisher and Hartwig[6] conjectured that for some range of parameter values $\{a_r\}_{r=1,\ldots,R}$, $\{b_r\}_{r=1,\ldots,R}$,

$$D_n[g] \underset{n \to \infty}{\sim} e^{c_0 n} e^{\sum_{r=1}^{R} (a_r^2 - b_r^2)\log n} E, \tag{1.8}$$

where E is independent of n. Subsequently this was proved for various ranges of parameter values (see e.g., Ref. 8) and furthermore the constant was determined to be given by

$$\begin{aligned} E = e^{\sum_{k=1}^{\infty} k c_k c_{-k}} \prod_{r=1}^{R} e^{-(a_r + b_r)\log a_-(\theta_r)} e^{-(a_r - b_r)\log a_+(\theta_r)} \prod_{1 \leqslant r \neq s \leqslant R} (1 - e^{i(\theta_s - \theta_r)})^{-(a_r + b_r)(a_s - b_s)} \\ \times \prod_{r=1}^{R} \frac{G(1 + a_r + b_r) G(1 + a_r - b_r)}{G(1 + 2a_r)}, \end{aligned} \tag{1.9}$$

where G is the Barnes G-function and

$$\log a_+(\theta) := \sum_{p=1}^{\infty} c_p e^{ip\theta}, \quad \log a_-(\theta) := \sum_{p=-\infty}^{-1} c_p e^{ip\theta}. \tag{1.10}$$

Our interest is in applications and generalizations of the Fisher–Hartwig asymptotic formula (1.8). We begin in Sec. II with an application of (1.8) to the calculation of the asymptotic form of the spin–spin correlation for the two-dimensional Ising model above criticality. In Sec. III the well-known equivalence of the Toeplitz determinant (1.1) to a random matrix average over the unitary group $\mathrm{U}(n)$ is revised. This average is in turn equivalent to the partition function of the one-component log-gas on a circle, subject to a one-body potential with Boltzmann factor $g(\theta)$ at the special coupling $\beta=2$. As such there is a natural generalization for couplings $\beta>0$, and in the case $b_r=0$, $r=1,\ldots,R$ this can be used to predict the corresponding generalization of (1.8). Moreover, in the special case $a(\theta)=1$, $R=1$ the sought asymptotic form can be deduced from an exact formula valid for general a_r, b_r. This can be used to extend the conjectured generalization of (1.8) to nonzero b_r.

In Sec. IV we recall the problem of computing the asymptotic form of the density matrix for impenetrable bosons in Dirichlet and Neumann boundary conditions. This is immediately identifiable as an average over the classical groups $\mathrm{Sp}(N)$ and $\mathrm{O}^+(2N)$, respectively, with the function being averaged over having two zeros, and thus analogous to the random matrix formulation of the Toeplitz determinant (1.1) with symbol (1.6) in the case $R=2$, $b_r=0$. We point out that the same class of averages over the groups $\mathrm{O}^+(2N+1)$ or $\mathrm{O}^-(2N+1)$ result from considering the density matrix for the impenetrable Bose gas in the case of mixed Dirichlet and Neumann boundary conditions. In Ref. 9 the sought asymptotics were calculated on the basis of a combination of analytic and log-gas arguments, and a Fisher–Hartwig-type generalization (with $b_r=0$) conjectured. The conjecture of Ref. 9 can used to predict the asymptotic form in the case of mixed Dirichlet and Neumann boundary conditions. Moreover we show that this asymptotic form can be proved by making use of asymptotic formulas recently obtained[10] for Toeplitz plus Hankel determinants

$$\det[a_{j-k}+a_{j+k+1}]_{j,k=0,\ldots,n-1} \tag{1.11}$$

in the case of singular generating functions (1.6).

In addition to averages over the classical groups, the study of the density matrix for impenetrable bosons naturally leads to the question of obtaining the asymptotic form of averages over the eigenvalue probability density function for the GUE and LUE, in the case that the function being averaged over has zeros. Here the GUE denotes the Gaussian unitary ensemble of random Hermitian matrices, and the LUE denotes the Laguerre unitary ensemble of positive definite matrices with complex entries. These random matrix averages are equivalent to pure Hankel determinants,

$$\det[a_{j+k}]_{j,k=0,\ldots,n-1}, \quad a_n = \int_{-\infty}^{\infty} a(x) x^n \, d\mu(x), \tag{1.12}$$

where $d\mu(x)=e^{-x^2}\,dx$ for the GUE and $d\mu(x)=x^a e^{-x}\,dx$, $x>0$ for the LUE. Conjectures for such asymptotic forms are given in Sec. V. The paper ends with some concluding remarks on the universal form for Hankel asymptotics in Sec. VI, and attention is also drawn to the fluctuation formula perspective of our asymptotic results.

II. SPIN–SPIN CORRELATIONS FOR THE TWO-DIMENSIONAL ISING MODEL

In the two-dimensional Ising model on a square lattice each site (i,j) of the lattice exists in one of two possible states $\sigma_{ij}=\pm 1$ with coupling between nearest neighbors in the horizontal and vertical directions. Explicitly, the joint probability density function for a particular configuration $\{\sigma_{ij}\}$ of the states on a $(2N+1)\times(2N+1)$ lattice is given by

$$P_{2N+1}(\{\sigma_{ij}\})=\frac{1}{Z_{2N+1}}\exp\left(K_1\sum_{j=-N}^{N}\sum_{i=-N}^{N-1}\sigma_{ij}\sigma_{i+1\,j}+K_2\sum_{i=-N}^{N}\sum_{j=-N}^{N-1}\sigma_{ij}\sigma_{i\,j+1}\right), \tag{2.1}$$

where Z_{2N+1} is the normalization. The spin–spin correlation function between the spin σ_{00} at the center of the lattice, and the spin $\sigma_{i^*j^*}$ at site (i^*,j^*) is, in the infinite lattice limit, defined as

$$\langle\sigma_{00}\sigma_{i^*j^*}\rangle=\lim_{N\to\infty}\sum_{\{\sigma_{ij}\}}\sigma_{00}\sigma_{i^*j^*}P_{2N+1}(\{\sigma_{ij}\}). \tag{2.2}$$

Onsager knew of, but never published (see instead, e.g., Ref. 11) a Toeplitz determinant form for the case of (2.2) for which $(i^*,j^*)=(n,n)$ and thus lies on the diagonal. Explicitly

$$\langle\sigma_{00}\sigma_{nn}\rangle=\det[a_{i-j}]_{i,j=1,\ldots,n},\quad a_p=\frac{1}{2\pi}\int_{-\pi}^{\pi}h(\theta)e^{-ip\theta}\,\mathrm{d}\theta, \tag{2.3}$$

where

$$h(\theta):=\left(\frac{1+(1/k)e^{-i\theta}}{1+(1/k)e^{i\theta}}\right)^{1/2},\quad k=\sinh 2K_1\sinh 2K_2. \tag{2.4}$$

Also, in the case of (2.2) with $(i^*,j^*)=(0,n)$ so that the two spins lie in the same row, Onsager and Kaufmann[12] expressed (2.2) as the sum of two Toeplitz determinants. A different approach to this problem was undertaken by Potts and Ward,[13] who obtained instead the single Toeplitz determinant form

$$\langle\sigma_{00}\sigma_{0n}\rangle=\det[\tilde{a}_{i-j}]_{i,j=1,\ldots,n},\quad \tilde{a}_p=\frac{1}{2\pi}\int_{-\pi}^{\pi}\tilde{h}(\theta)e^{-ip\theta}\,\mathrm{d}\theta, \tag{2.5}$$

where

$$\tilde{h}(\theta):=\left(\frac{(1+\alpha_1e^{i\theta})(1+\alpha_2e^{-i\theta})}{(1+\alpha_1e^{-i\theta})(1+\alpha_2e^{i\theta})}\right)^{1/2} \tag{2.6}$$

with

$$\alpha_1:=e^{-2K_2}\tanh K_1,\quad \alpha_2:=\frac{e^{-2K_2}}{\tanh K_1}.$$

The formula obtained in Ref. 12 was shown to be identical to (2.3), (2.4) by Montroll, Potts, and Ward.[14] We remark that if α_1,α_2 in (2.6) and k in (2.4) are regarded as parameters not specified by K_1,K_2, then setting $\alpha_1=0,\alpha_2=1/k$ in the former gives (2.4).

A detailed study of the asymptotic form of (2.6) was undertaken by Wu.[7] Indeed, it was the asymptotic form of (2.5) at the critical coupling

$$\alpha_1<\alpha_2=1 \tag{2.7}$$

obtained in Ref. 7 which, partially at least, inspired the formulation of the Fisher–Hartwig asymptotic formula (1.8).[6] To see how (1.8) relates to (2.5) with parameters (2.7), note

$$\log \tilde{h}(\theta)|_{\alpha_2=1} = \log\left(\frac{1+\alpha_1 e^{i\theta}}{1+\alpha_1 e^{-i\theta}}\right)^{1/2} + i \arg e^{-i\theta/2}. \tag{2.8}$$

For $|\alpha_1|<1$ this has the structure of (1.6) with

$$a(\theta) = \left(\frac{1+\alpha_1 e^{i\theta}}{1+\alpha_1 e^{-i\theta}}\right)^{1/2}, \quad R=1, \quad b_r = -\frac{1}{2}, \quad a_r = 0, \quad \theta_r = -\pi.$$

Recalling the definitions (1.3) [with $g(\theta)$ replaced by $a(\theta)$] and (1.10), application of (1.8) implies

$$\langle \sigma_{00}\sigma_{0n}\rangle|_{\substack{\alpha_2=1 \\ \alpha_1<1}} \underset{n\to\infty}{\sim} \left(\frac{1+\alpha_1}{1-\alpha_1}\right)^{1/4} \frac{\sqrt{\pi}G^2(1/2)}{n^{1/4}}, \tag{2.9}$$

where use has been made of the functional equation

$$G(z+1) = \Gamma(z)G(z),$$

in agreement with the result of Wu.

The high temperature phase corresponds to couplings

$$\alpha_1 < 1 < \alpha_2, \quad \alpha_1\alpha_2 < 1. \tag{2.10}$$

In this case $\log \tilde{h}(\theta)$ is of the form (1.6) with

$$a(\theta) = \left(\frac{(1+\alpha_1 e^{i\theta})(1+e^{i\theta}/\alpha_2)}{(1+\alpha_1 e^{-i\theta})(1+e^{-i\theta}/\alpha_2)}\right)^{1/2}, \quad R=1, \quad b_r=-1, \quad a_r=0, \quad \theta_r=-\pi. \tag{2.11}$$

With $R=1, b_r=-1, a_r=0$ we see that the Fisher–Hartwig asymptotic formula (1.8) breaks down because according to (1.9) the constant E contains the factor $G(0)=0$ and thus vanishes. To obtain the asymptotics in this case the approach taken in Ref. 7 was to relate it back to the original strong Szegö theorem, multiplied by an auxiliary factor. Here we will show that by transforming (2.6), a form of $\log \tilde{h}(\theta)$ can be obtained which has the general structure (1.6) but is distinct from the specification (2.11). We will see that applying the Fisher–Hartwig formula then correctly reproduces the result of Wu for the leading asymptotic decay in the high temperature phase.

For this purpose, let us introduce the notation $f(\theta) \equiv g(\theta)$ to mean that

$$\int_{-\pi}^{\pi} f(\theta) e^{-ip\theta}\, d\theta = c^{-p} \int_{-\pi}^{\pi} g(\theta) e^{-ip\theta}\, d\theta$$

for some c independent of p. According to the definitions (2.6) and (2.11) we have $\tilde{h}(\theta) = e^{-i\theta} a(\theta)$. Now, since with $z=e^{i\theta}$, $\tilde{h}(\theta)$ is an analytic function of z in the annulus $1/\alpha_2 < |z| < \alpha_2$, by Cauchy's theorem

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} \tilde{h}(\theta) e^{-ip\theta}\, d\theta = \int_{\mathcal{C}} \tilde{h}(\theta) z^{-p} \frac{dz}{2\pi i z}$$

for any simple closed contour encircling the origin in this annulus. Choosing $\mathcal{C}$ to be the circle with radius α_2 (the outer boundary of the annulus) shows

$$\tilde{h}(\theta) \equiv \frac{e^{-i\theta}}{\alpha_2}\left(\frac{1+\alpha_1\alpha_2 e^{i\theta}}{1+(\alpha_1/\alpha_2)e^{-i\theta}}\right)^{1/2}\frac{(1+e^{i\theta})^{1/2}}{(1+e^{-i\theta}/\alpha_2^2)^{1/2}}$$
$$= \frac{1}{\alpha_2}\frac{1}{(1+e^{-i\theta}/\alpha_2^2)^{1/2}}\left(\frac{1+\alpha_1\alpha_2 e^{i\theta}}{1+(\alpha_1/\alpha_2)e^{-i\theta}}\right)^{1/2} e^{-3i\theta/4}|1+e^{i\theta}|^{1/2}.$$

This is of the form (1.6) with

$$a(\theta) = \frac{1}{\alpha_2}\frac{1}{(1+e^{-i\theta}/\alpha_2^2)^{1/2}}\left(\frac{1+\alpha_1\alpha_2 e^{i\theta}}{1+(\alpha_1/\alpha_2)e^{-i\theta}}\right)^{1/2}, \quad R=1, \quad b_r=-\frac{3}{4}, \quad a_r=\frac{1}{4}, \quad \theta_r=-\pi. \tag{2.12}$$

Application of (1.8) implies

$$\langle \sigma_{00}\sigma_{0n}\rangle|_{\substack{\alpha_1<1<\alpha_2 \\ \alpha_1\alpha_2<1}} \underset{n\to\infty}{\sim} \frac{\alpha_2^{-n}}{(\pi n)^{1/2}}(1-\alpha_1^2)^{1/4}(1-\alpha_2^{-2})^{-1/4}(1-\alpha_1\alpha_2)^{-1/2} \tag{2.13}$$

in agreement with the result of Wu.[7] Moreover the Fisher–Hartwig formula (1.8) with $R=1$ has been proved[15] for parameter values satisfying all three of the inequalities,

$$\mathrm{Re}\, a_1 \geqslant 0, \quad \mathrm{Re}\, a_1 + \mathrm{Re}\, b_1 > -1, \quad \mathrm{Re}\, a_1 - \mathrm{Re}\, b_1 > -1.$$

These inequalities are satisfied by the parameters in (2.12) and so the Fisher–Hartwig formula provides a proof of (2.13).

III. β-GENERALIZATION OF THE FISHER–HARTWIG FORMULA

It is well known, and easy to verify, that the Toeplitz determinant (1.2) can be written as a random matrix average according to

$$D_n[g] = \left\langle \prod_{l=1}^{n} g(\theta_l) \right\rangle_{\mathrm{U}(n)}. \tag{3.1}$$

Here $\mathrm{U}(n)$ refers to the eigenvalue probability density function for the unitary group

$$\frac{1}{(2\pi)^n n!}\prod_{1\leqslant j<k\leqslant n}|e^{i\theta_k}-e^{i\theta_j}|^2, \quad -\pi<\theta_l\leqslant\pi. \tag{3.2}$$

As first noted by Dyson,[2] (3.2) is proportional to the Boltzmann factor for the one-component log-potential Coulomb gas on a circle, at the special coupling $\beta=2$. From the log-gas viewpoint a natural generalization of (3.2) is the probability density function $C\beta E_n$ proportional to the Boltzmann factor for the same statistical mechanical system but with general coupling $\beta>0$,

$$\frac{1}{(2\pi)^n C_{n,\beta}}\prod_{1\leqslant j<k\leqslant n}|e^{i\theta_k}-e^{i\theta_j}|^\beta, \quad C_{n,\beta}=\frac{\Gamma(n\beta/2+1)}{(\Gamma(\beta/2+1))^n}. \tag{3.3}$$

The identity (3.1) then allows us to formulate a β-generalization of the Toeplitz determinant (1.2) as the average

$$D_n^{(\beta)}[g] := \left\langle \prod_{l=1}^{n} g(\theta_l) \right\rangle_{C\beta E_n}. \tag{3.4}$$

Choosing $g(\theta)$ according to (1.6) in this we obtain a natural β-generalization of the Toeplitz determinant with a Fisher–Hartwig symbol. In the case $b_r=0$, $r=1,\dots,R$, the log-gas viewpoint can be used to conjecture the corresponding analogue of the asymptotic formula (1.8).

Let

$$Z_n^{(\beta)}[g(\theta)] := \frac{1}{(2\pi)^n}\int_{-\pi}^{\pi} d\theta_1 \cdots \int_{-\pi}^{\pi} d\theta_n \prod_{l=1}^{n} g(\theta_l) \prod_{1\leqslant j<k\leqslant n} |e^{i\theta_k}-e^{i\theta_j}|^{\beta}. \tag{3.5}$$

As the first step, guided by both the log-gas viewpoint and the structure of (1.8), we conjecture the factorization

$$\frac{Z_n^{(\beta)}\left[a(\theta)\prod_{j=1}^{R}|e^{i\theta}-e^{i\phi_j}|^{q_j\beta}\right]}{Z^{(\beta)}_{n+\Sigma_{j=1}^{R}q_j}[1]} \sim e^{-\Sigma_{j=1}^{R}q_j \log a(\theta_j)} \frac{Z_n^{(\beta)}[a(\theta)]}{Z^{(\beta)}_{n+\Sigma_{j=1}^{R}q_j}[1]} \frac{Z_n^{(\beta)}\left[\prod_{j=1}^{R}|e^{i\theta}-e^{i\phi_j}|^{q_j\beta}\right]}{Z^{(\beta)}_{n+\Sigma_{j=1}^{R}q_j}[1]}. \tag{3.6}$$

From the work of Johansson,[5,16] with the Fourier expansion of $\log a(\theta)$ specified by (1.7) and assuming the coefficients satisfy (1.4), it has been proved for general $\beta>0$ that

$$\frac{Z^{(\beta)}_{n+Q}[a(\theta)]}{Z^{(\beta)}_{n+Q}[1]} \sim e^{c_0(n+Q)} e^{(2/\beta)\Sigma_{k=1}^{\infty} k c_k c_{-k}}. \tag{3.7}$$

Regarding the second ratio on the right-hand side of (3.6), as first noted in Refs. 17 and 18 and revised in Ref. 20, the log-gas viewpoint suggests that for $n\to\infty$ we have the factorization

$$\prod_{1\leqslant j<k\leqslant R}|e^{i\theta_k}-e^{i\theta_j}|^{\beta q_j q_k} \frac{Z_n^{(\beta)}\left[\prod_{j=1}^{R}|e^{i\theta}-e^{i\phi_j}|^{q_j\beta}\right]}{Z^{(\beta)}_{n+\Sigma_{j=1}^{R}q_j}[1]} \sim \prod_{j=1}^{R} \frac{Z_n^{(\beta)}\left[\prod_{j=1}^{R}|e^{i\theta}-e^{i\phi_j}|^{q_j\beta}\right]}{Z^{(\beta)}_{n+q_j}[1]}. \tag{3.8}$$

The large-n expansion of a ratio closely related to the product on the right-hand side of (3.8) is known for β rational, in particular

$$\beta/2 = s/r, \quad s \text{ and } r \text{ relatively prime}. \tag{3.9}$$

Thus we have[18]

$$\prod_{j=1}^{R} \frac{Z_n^{(\beta)}\left[\prod_{j=1}^{R}|e^{i\theta}-e^{i\phi_j}|^{q_j\beta}\right]}{Z_n^{(\beta)}[1]} \sim n^{q^2\beta/2} A_q, \tag{3.10}$$

where

$$A_q := r^{-q^2\beta/2} \prod_{\nu=0}^{r-1}\prod_{p=0}^{s-1} \frac{G^2(q/r+\nu/r-p/s+1)}{G(2q/r+\nu/r-p/s+1)G(\nu/r-p/s+1)}. \tag{3.11}$$

Finally, the formula for $C_{n,\beta}$ in (3.3) together with Stirling's formula shows

$$\frac{Z_n^{(\beta)}[1]}{Z^{(\beta)}_{n+q}[1]} \sim (\Gamma(\beta/2+1))^q (n\beta/2)^{-q\beta/2}. \tag{3.12}$$

Combining the above results gives the sought β-generalization of the Fisher–Hartwig formula in the case $b_r=0$.

Conjecture 1: Let β be rational and of the form (3.9), and let $a(\theta)$ be as assumed for the validity of (3.7). For $q_j\beta>-1$ we expect

$$\left\langle \prod_{l=1}^{N} \left(a(\theta_l) \prod_{j=1}^{R} |e^{i\theta_l} - e^{i\phi_j}|^{q_j \beta} \right) \right\rangle_{C\beta E_n} \underset{n\to\infty}{\sim} e^{c_0(n+\sum_{j=1}^{R} q_j)} n^{(\beta/2)\sum_{j=1}^{R} q_j^2} E^{(\beta)}, \tag{3.13}$$

where, with A_q specified by (3.11),

$$E^{(\beta)} = e^{-\sum_{j=1}^{R} q_j \log a(\theta_j)} e^{(2/\beta)\sum_{k=1}^{\infty} k c_k c_{-k}} \prod_{1\le j<k\le R} |e^{i\theta_k} - e^{i\theta_j}|^{-\beta q_j q_k} \prod_{j=1}^{R} A_{q_j}. \tag{3.14}$$

It is of interest to extend Conjecture 1 to include a factor

$$\prod_{j=1}^{R} e^{-i(\beta/2) b_r \arg e^{i(\phi_j + \pi - \theta)}} \tag{3.15}$$

in the average, and so obtain a β-generalization of the Fisher–Hartwig formula for general parameters. Although we do not have a log-gas interpretation of the factor (3.15), the case $R=1$ substituted in (3.13) with $a(\theta)=1$ gives an average which can be evaluated in closed form, and the corresponding asymptotics computed for rational β. This together with the structure of the original Fisher–Hartwig formula (1.8), (1.9) allows us to formulate the sought β-generalization.

Now, by rotational invariance, independent of the value of ϕ

$$\begin{aligned} \left\langle \prod_{l=1}^{n} e^{-i(\beta/2) b \arg e^{i(\phi+\pi-\theta_l)}} |e^{i\theta_l} - e^{i\phi}|^{\beta q} \right\rangle_{C\beta E_n} &= \left\langle \prod_{l=1}^{n} e^{i\beta b \theta_l/2} |1 + e^{i\theta_l}|^{\beta q} \right\rangle_{C\beta E_n} \\ &= \frac{Z_n^{(\beta)}[e^{i\beta b\theta/2}|1+e^{i\theta}|^{\beta q}]}{Z_n^{(\beta)}[1]}. \end{aligned} \tag{3.16}$$

But, from the theory of the Selberg integral (see, e.g., Ref. 3), we know the right-hand side of (3.16) has the explicit gamma function evaluation

$$\frac{f_n(2cq,c)}{f_n(c(q+b),c) f_n(c(q-b),c)}, \quad \text{where } f_n(\alpha,c) := \prod_{j=0}^{n-1} \frac{(\alpha+jc)!}{(jc)!}, \quad c := \beta/2. \tag{3.17}$$

For $c \in \mathbb{Z}^+$ it was shown in Ref. 18 that

$$f_n(\alpha,c) \underset{n\to\infty}{\sim} \exp(\alpha n \log n) c^{\alpha n} e^{-\alpha n} n^{-(c-1)\alpha/2 + \alpha^2/2c} \prod_{p=0}^{c-1} \frac{G(-p/c+1)}{G((\alpha-p)/c+1)}, \tag{3.18}$$

while for r and s relatively prime

$$f_{rn}(\alpha, s/r) = \prod_{\nu=0}^{r-1} \frac{f_n(\alpha + s\nu/r, s)}{f_n(s\nu/r, s)}. \tag{3.19}$$

Using (3.19) and (3.18) in (3.17) it follows that for β rational of the form (3.9),

$$\left\langle \prod_{l=1}^{n} e^{i\beta b\theta_l/2} |1 + e^{i\theta_l}|^{\beta q} \right\rangle_{C\beta E_{rn}} \underset{n\to\infty}{\sim} (rn)^{(\beta/2)(q^2-b^2)} A_{q,b}, \tag{3.20}$$

where

$$A_{q,b} := r^{-(q^2-b^2)\beta/2} \prod_{\nu=0}^{r-1} \prod_{p=0}^{s-1} \frac{G((q+b)/r+\nu/r-p/s+1)G^2((q-b)/r+\nu/r-p/s+1)}{G(2q/r+\nu/r-p/s+1)G(\nu/r-p/s+1)}. \tag{3.21}$$

Note that in the case $b=0$ this reduces to (3.11), (3.10) as it must.

Knowing how, from the Fisher–Hartwig formula (1.8), (1.9), to generalize from the case $R=1$, general parameters, and the case general R but $b_r=0$ $(r=1,\dots,R)$, to the case of general parameters and general R lets us use (3.13) and (3.20) to formulate a β-generalization of the Fisher–Hartwig formula for general parameters.

Conjecture 2: Let β be rational and of the form (3.9), and let $a(\theta)$ be as assumed for the validity of (3.7). We expect, for some range of parameters $\{b_j\}$ and $\{q_j\}$,

$$\left\langle \prod_{l=1}^{n} a(\theta_l) \prod_{j=1}^{R} e^{-i(\beta/2)b_j \arg e^{i(\phi_j+\pi-\theta_l)}} |e^{i\theta_l}-e^{i\phi_j}|^{q_j\beta} \right\rangle_{C\beta E_n} \underset{n\to\infty}{\sim} e^{c_0 n} n^{(\beta/2)\Sigma_{j=1}^{R}(q_j^2-b_j^2)} \tilde{E}(\beta), \tag{3.22}$$

where, with $A_{q,b}$ specified by (3.21),

$$\tilde{E}(\beta) = e^{(2/\beta)\Sigma_{k=1}^{\infty} k c_k c_{-k}} \prod_{r=1}^{R} e^{-(q_r+b_r)\log a_-(\theta_r)} e^{-(q_r-b_r)\log a_+(\theta_r)}$$

$$\times \prod_{1\le r\ne s\le R} (1-e^{i(\theta_s-\theta_r)})^{-\beta(q_r+b_r)(q_s-b_s)/2} \prod_{j=1}^{R} A_{q_j,b_j}. \tag{3.23}$$

IV. FISHER–HARTWIG ASYMPTOTICS FOR AVERAGES OVER THE ORTHOGONAL AND SYMPLECTIC GROUPS

A problem in mathematical physics which, along with the Ising correlations, motivated the Fisher–Hartwig formula (1.8) is the impenetrable Bose gas on a circle. If the circle has circumference length L, it was shown by Lenard[19] that the ground state density matrix $\rho_{N+1}^{C}(x)$ has the Toeplitz determinant form

$$\rho_{N+1}^{C}(x;0) = \frac{1}{L} \det[a_{j-k}^{C}(x)]_{j,k=1,\dots,N},$$
$$a_l^{C}(x) := \frac{1}{2\pi} \int_{-\pi}^{\pi} |e^{2\pi i x/L} + e^{i\theta}||1+e^{i\theta}| e^{-il\theta}\, d\theta. \tag{4.1}$$

The symbol in (4.1) is of the form (1.6) with

$$a(\theta)=1, \quad R=2, \quad a_1=a_2=\tfrac{1}{2}, \quad b_1=b_2=0, \quad \theta_1=0, \quad \theta_2=2\pi x/L. \tag{4.2}$$

Now a fundamental issue relating to the Bose gas is the occupation λ_0 of the zero momentum state, which quantifies the phenomenon of Bose–Einstein condensation (see, e.g., Ref. 20). In the present system, which is translationally invariant, λ_0 is related to the density matrix by the simple formula

$$\lambda_0 = \int_0^L \rho_{N+1}^{C}(x;0)\, dx = L \int_0^1 \rho_{N+1}^{C}(LX;0)\, dX. \tag{4.3}$$

For fixed $0<X<1$ one thus seeks the $L\to\infty$ asymptotic form of $\rho_{N+1}^{C}(LX;0)$. In an unpublished work as of 1968, made available to the authors of Ref. 6 and subsequently published in 1972,[21] Lenard obtained for the sought expansion

$$\rho_{N+1}^{C}(LX;0)\sim\rho_0\frac{G^4(3/2)}{\sqrt{2\pi}}\left(\frac{\pi}{N\sin(\pi X)}\right)^{1/2}, \tag{4.4}$$

where ρ_0 denotes the bulk density. Lenard obtained (4.4) as an upper bound, which soon after was shown to be attained by Widom.[22] Applying the Fisher–Hartwig formula (1.8) with variables (4.2) reproduces (4.4).

According to (3.1) the Toeplitz formula (4.1) can equivalently be written as the U(N) average

$$\rho_{N+1}^{C}(x;0)=\frac{1}{L}\left\langle\prod_{l=1}^{N}\left|2\sin\left(\frac{\pi x}{L}-\frac{\theta_l}{2}\right)\right|\left|2\sin\frac{\theta_l}{2}\right|\right\rangle_{\mathrm{U}(N)}. \tag{4.5}$$

The study of the ground state density matrices for the impenetrable Bose gas on a line of length L with Dirichlet or Neumann boundary conditions leads to formulas analogous to (4.5), only now the averages are with respect to the eigenvalue probability density functions for the classical groups Sp(N) and $\mathrm{O}^+(2N)$, respectively (see, e.g., Ref. 3 for the specification of these PDFs). Thus one has[20]

$$\begin{aligned}\rho_{N+1}^{D}(x;y)&=\frac{2}{L}\sin\frac{\pi x}{L}\sin\frac{\pi y}{L}\left\langle\prod_{l=1}^{N}\left|2\left(\cos\frac{\pi x}{L}-\cos\theta_l\right)\right|\left|2\left(\cos\frac{\pi y}{L}-\cos\theta_l\right)\right|\right\rangle_{\mathrm{Sp}(N)},\\ \rho_{N+1}^{N}(x;y)&=\frac{1}{2L}\left\langle\prod_{l=1}^{N}\left|2\left(\cos\frac{\pi x}{L}-\cos\theta_l\right)\right|\left|2\left(\cos\frac{\pi y}{L}-\cos\theta_l\right)\right|\right\rangle_{\mathrm{O}^+(2N)}.\end{aligned} \tag{4.6}$$

Impenetrable bosons on the interval $[0,L]$ with Dirichlet boundary conditions at $x=0$ and Neumann boundary conditions at $x=L$ also relate to a classical group. Thus from the fact that the single particle wave functions are given by

$$\phi_k^M(x)=\sqrt{\frac{2}{L}}\sin\frac{\pi(k-1/2)x}{L}\quad(k=1,2,\dots)$$

(the superscript M stands for "mixed") we see that the ground state wave function

$$\psi_0^M(x_1,\dots,x_N)=\frac{1}{\sqrt{N!}}|\det[\,\phi_k^M(x_j)\,]_{j,k=1,\dots,N}|$$

has the product form

$$\psi_0^M(x_1,\dots,x_N)=\frac{1}{\sqrt{N!}}\left(\frac{1}{2\sqrt{L}}\right)^N\prod_{l=1}^{N}2\sin(\pi x_l/2L)\prod_{1\le j<k\le N}2|\cos\pi x_k/L-\cos\pi x_j/L|.$$

The square of this quantity coincides with the eigenvalue PDF of the classical group $\mathrm{O}^+(2N+1)$ with $\theta=\pi x/L$ (for this we ignore the fixed eigenvalue at $\theta=0$). From this fact, as in the derivation of (4.6) detailed in Ref. 20, it follows that

$$\rho_{N+1}^{M}(x;y)=\frac{2}{L}\sin\frac{\pi x}{2L}\sin\frac{\pi y}{2L}\left\langle\prod_{l=1}^{N}\left|2\left(\cos\frac{\pi x}{L}-\cos\theta_l\right)\right|\left|2\left(\cos\frac{\pi y}{L}-\cos\theta_l\right)\right|\right\rangle_{\mathrm{O}^+(2N+1)}. \tag{4.7}$$

Using a combination of analytic calculations based on the Selberg correlation integral,[23] and physical arguments based on log-gas analogies, the large N, fixed $x/L, y/L, N/L$ limit of the density matrices (4.6) was computed in Ref. 9 to be equal to

$$\rho^D_{N+1}(x;y)\sim\rho^N_{N+1}(x;y)\sim\rho\frac{G^4(3/2)}{\sqrt{2N}}\frac{(X(1-X))^{1/8}(Y(1-Y))^{1/8}}{|X-Y|^{1/2}}\Bigg|_{\substack{X=(1+\cos\,\pi x/L)/2\\ Y=(1+\cos\,\pi y/L)/2}}. \tag{4.8}$$

Here we will show how recent rigorous asymptotic analysis[10] of Toeplitz and Hankel determinants (1.11) with Fisher–Hartwig-type symbols can be used to prove that $\rho^M_{N+1}(x;y)$ exhibits the same asymptotic form (4.8). We will also show how a result of Ref. 10 can be used to confirm the asymptotic form of a more general class of averages over $\mathrm{O}^+(2N+1)$ which can be deduced from a conjecture in Ref. 9, and how this conjecture in turn can be used to predict analogous asymptotics in the case of averages over $\mathrm{Sp}(N)$ and $\mathrm{O}^+(2N)$.

To begin we require a simple to verify identity noted in Ref. 24.

Lemma 1: Suppose $g(\theta)=g(-\theta)$ *and set* $g_j=(1/2\pi)\int_{-\pi}^{\pi}g(\theta)e^{-ij\theta}\,\mathrm{d}\theta$. *We have*

$$\det[g_{j-k}+g_{j+k+1}]_{j,k=0,\dots,N-1}=\left\langle\prod_{j=1}^{N}g(\theta_j)\right\rangle_{\mathrm{O}^-(2N+1)}=\left\langle\prod_{j=1}^{N}g(\pi-\theta_j)\right\rangle_{\mathrm{O}^+(2N+1)}. \tag{4.9}$$

Note that by the assumption on $g(\theta)$ the matrix in (4.9) is symmetric. Also, the average in (4.7) is an even function of θ_l and corresponds to the special case

$$\begin{aligned}g(\theta)&=2\left|\cos\frac{\pi x}{L}-\cos\theta\right|\,2\left|\cos\frac{\pi y}{L}-\cos\theta\right|\\&=\left(\left|2-2\cos\left(\theta-\frac{\pi x}{L}\right)\right|\left|2-2\cos\left(\theta+\frac{\pi x}{L}\right)\right|\left|2-2\cos\left(\theta-\frac{\pi y}{L}\right)\right|\left|2-2\cos\left(\theta+\frac{\pi y}{L}\right)\right|\right)^{1/2}\end{aligned} \tag{4.10}$$

of (4.9). We observe that (4.10) is an example of a symbol of the form (1.6). Fortunately, recent rigorous works[25,10] have determined the asymptotic form of the Hankel plus Toeplitz determinant in (4.9) for all symbols (1.6), with the restriction that for $g(\theta)$ even [the case of interest in relation to (4.9)], $\theta_r\neq 0,\pm\pi$. Let us recall the result of Ref. 10, Theorem 6.1, simplified so that it relates to the even case of (1.6) with each $b_r=0$.

Theorem 1: *Let*

$$\log g(\theta)=\log a(\theta)+\sum_{r=1}^{R}a_r(\log(2|\cos\theta-\cos\theta_r|)), \tag{4.11}$$

where $a(\theta)$ *is an even periodic function with the property that the Fourier expansion of its logarithm (1.7) satisfies (1.4), together with some technical assumptions (for the latter, which may not be necessary, see Ref. 10). We have*

$$\det[g_{j-k}+g_{j+k+1}]_{j,k=0,\dots,N-1}\sim e^{(N+\Sigma_{j=1}^{R}a_j)c_0}(2N)^{\Sigma_{r=1}^{R}a_r^2}E, \tag{4.12}$$

where

$$\begin{aligned}E=&\prod_{r=1}^{R}\frac{G^2(1+a_r)}{G(1+2a_r)}e^{1/2\,\Sigma_{k=1}^{\infty}kc_k^2+\Sigma_{k=1}^{\infty}c_{2k-1}}e^{-\Sigma_{j=1}^{N}a_j\log a(\theta_j)}\\&\times\prod_{r=1}^{R}\frac{|1-e^{i\theta_r}|^{a_r}}{|1+e^{i\theta_r}|^{a_r}|1-e^{2i\theta_r}|^{a_r^2}}\prod_{1\leqslant r<s\leqslant R}(|1-e^{i(\theta_r-\theta_s)}||1-e^{i(\theta_r+\theta_s)}|)^{-2a_ra_s}.\end{aligned} \tag{4.13}$$

Recalling (4.9) it follows from Theorem 1 that

$$\left\langle \prod_{j=1}^{N} \left| 2\left(\cos\frac{\pi x}{L} - \cos\theta_j \right) \right| \left| 2\left(\cos\frac{\pi y}{L} - \cos\theta_j \right) \right| \right\rangle_{\mathrm{O}^-(2N+1)}$$
$$\sim (2N)^{1/2} G^4(3/2) \frac{|1+e^{\pi i x/L}|^{1/4}}{|1-e^{\pi i x/L}|^{3/4}} \frac{|1+e^{\pi i y/L}|^{1/4}}{|1-e^{\pi i y/L}|^{3/4}} \frac{1}{|1-e^{\pi i (x-y)/L}|^{1/2} |1-e^{\pi i (x+y)/L}|^{1/2}}. \tag{4.14}$$

Substituting this in (4.7) shows

$$\rho_{N+1}^{M}(x,y) \sim \frac{(2N)^{1/2}}{2L} G^4(3/2) \frac{|1-e^{2\pi i x/L}|^{1/4} |1-e^{2\pi i y/L}|^{1/4}}{|1-e^{\pi i (x-y)/L}|^{1/2} |1-e^{\pi i (x+y)/L}|^{1/2}}$$
$$= \rho \frac{G^4(3/2)}{\sqrt{2N}} \frac{(X(1-X))^{1/8} (Y(1-Y))^{1/8}}{|X-Y|^{1/2}} \Big|_{\substack{X=(1+\cos \pi x/L)/2 \\ Y=(1+\cos \pi y/L)/2}}, \tag{4.15}$$

thus rigorously establishing the asymptotic form (4.8) derived, but not rigorously proved, in Ref. 9 for the cases of Dirichlet and Neumann boundary conditions.

The eigenvalue distributions for $\mathrm{Sp}(N)$, $\mathrm{O}^+(2N)$, $\mathrm{O}^-(2N+1)$, and $\mathrm{O}^+(2N+1)$ are proportional to

$$\prod_{l=1}^{N} (1+\cos\theta_l)^{\lambda_1} (1-\cos\theta_l)^{\lambda_2} \prod_{1 \leqslant j < k \leqslant N} (\cos\theta_k - \cos\theta_j)^2, \quad 0 \leqslant \theta_l \leqslant \pi \tag{4.16}$$

for $(\lambda_1,\lambda_2)=(1,1)$, $(0,0)$, $(1,0)$, and $(0,1)$, respectively (our convention is not to include the delta function corresponding to a fixed eigenvalue, nor the delta functions corresponding to the conjugate eigenvalues). Thus to obtain the asymptotics of the averages in (4.6) it is sufficient to obtain the asymptotics of

$$\left\langle \prod_{l=1}^{N} \prod_{r=1}^{R} (2|\cos\theta_l - \cos\phi_r|)^{2a_r} \right\rangle_{C_N(\lambda_1,\lambda_2)}, \tag{4.17}$$

where $C_N(\lambda_1,\lambda_2)$ refers to the normalized form of (4.16). In the cases $(\lambda_1,\lambda_2)=(1,0)$ or $(0,1)$, due to the identity (4.9), we can read off the asymptotic form from (4.12). But for general (λ_1,λ_2) the asymptotic form of (4.17) is not included in Theorem 1. Instead, we will use a conjecture from Ref. 9 to formulate the result.

Let us first recall the conjectured asymptotic form from Ref. 9. Define

$$H_{n,\lambda_1,\lambda_2}[f(x)] := \int_0^1 dx_1 \cdots \int_0^1 dx_n \prod_{l=1}^{n} f(x_l) x_l^{\lambda_1} (1-x_l)^{\lambda_2} \prod_{1 \leqslant j < k \leqslant n} |x_k - x_j|^2. \tag{4.18}$$

Then the argument given in Ref. 9 predicts

$$\frac{H_{n,\lambda_1,\lambda_2}\left[e^{h(x)} \prod_{r=1}^{R} |y_r - x|^{2q_r} \right]}{H_{n+\Sigma_{j=1}^{R} q_j,\lambda_1,\lambda_2}[1]} \sim \exp\left[\frac{n + \sum_{r=1}^{R} q_r + (\lambda_1+\lambda_2)/2}{\pi} \int_0^1 \frac{h(x)}{[x(1-x)]^{1/2}} dx \right]$$
$$\times \exp\left[\sum_{r=1}^{R} (-q_r + q_r^2) \log 2n \right] K, \tag{4.19}$$

where

$$K=\prod_{j=1}^{R} y_j^{-\lambda_1 q_j}(1-y_j)^{-\lambda_2 q_j}\prod_{1\leqslant j<k\leqslant R}|y_k-y_j|^{-2q_jq_k}e^{-(\lambda_1 h(0)+\lambda_2 h(1))/2}e^{-\Sigma_{r=1}^{R}q_r h(y_r)}$$
$$\times\exp\left[\frac{1}{4\pi^2}\int_0^1 dx\,\frac{h(x)}{(x(1-x))^{1/2}}\int_0^1 dy\,\frac{h'(y)(y(1-y))^{1/2}}{x-y}\right]$$
$$\times\prod_{r=1}^{R}(y_r(1-y_r))^{-q_r^2/2}\prod_{r=1}^{R}\frac{1}{\pi^{q_r}}\frac{G^2(q_r+1)}{G(2q_r+1)}. \tag{4.20}$$

[Unfortunately there are a number of inaccuracies in the reporting of the conjecture in Ref. 9. The term $H_{n+\Sigma_{j=1}^{R}q_j,\lambda_1,\lambda_2}[1]$ in the denominator on the left-hand side of (4.19) has mistakenly been written as $H_{n,\lambda_1,\lambda_2}[1]$ in Eqs. (90), (94), (96), and (97); the factors $\Pi_{j=1}^{R}y_j^{-\lambda_1 q_j}(1-y_j)^{-\lambda_2 q_j}$ are missing and should be paired with $\Pi_{1\leqslant j<k\leqslant R}|y_k-y_j|^{-2q_jq_k}$ throughout; and the term $e^{-(\lambda_1+\lambda_2)[h(0)+h(1)]/4}$ in (96) and (97) should read $e^{-(\lambda_1 h(0)+\lambda_2 h(1))/2}$.]

In preparation for relating this to the average (4.17) let

$$h\left(\frac{1}{2}(1+\cos\theta)\right)=c_0+2\sum_{n=1}^{\infty}c_n\cos n\theta. \tag{4.21}$$

We then have that

$$\frac{1}{\pi}\int_0^1\frac{h(x)}{(x(1-x))^{1/2}}dx=\frac{1}{\pi}\int_0^{\pi}h\left(\frac{1}{2}(1+\cos\theta)\right)d\theta=c_0, \tag{4.22}$$

$$\frac{1}{2}(\lambda_1 h(0)+\lambda_2 h(1))=\frac{1}{2}(\lambda_1+\lambda_2)c_0+\sum_{n=1}^{\infty}c_n(\lambda_1+(-1)^n\lambda_2), \tag{4.23}$$

while (4.21) together with the cosine expansion

$$\log(2|\cos\theta-\cos\phi|)=-\sum_{n=1}^{\infty}\frac{2}{n}\cos n\theta\cos n\phi$$

shows

$$\frac{1}{4\pi^2}\int_0^1 dx\,\frac{h(x)}{(x(1-x))^{1/2}}\int_0^1 dy\,\frac{h'(y)(y(1-y))^{1/2}}{x-y}=\frac{1}{2}\sum_{n=1}^{\infty}nc_n^2. \tag{4.24}$$

Also, as noted in Ref. 9,

$$H_{n,a,b}[1]=\frac{G(n+1+a)G(n+1+b)G(n+1+a+b)}{G(1+a)G(1+b)G(2n+1+a+b)}G(n+2). \tag{4.25}$$

Since[26]

$$\log\frac{G(n+1+a)}{G(n+1+b)}\underset{n\to\infty}{\sim}(b-a)n+\frac{a-b}{2}\log(2\pi)+\left((a-b)n+\frac{a^2-b^2}{2}\right)\log n+o(1) \tag{4.26}$$

we deduce

$$\frac{H_{n,a,b}[1]}{H_{n+Q,a,b}[1]}\sim\frac{2^{4nQ+2Q^2+2Q(a+b)}}{(2\pi n)^Q}. \tag{4.27}$$

Finally we note that under the change of variables

$$x_l = \tfrac{1}{2}(1+\cos\theta_l)$$

the integrand in (4.18) contains as a factor the (un-normalized) eigenvalue probability density function (4.16). Explicitly, with $\tilde{h}(\theta) := h(1/2\,(1+\cos\theta))$ we have

$$\left.\frac{H_{n,\lambda_1,\lambda_2}\left[e^{h(x)}\prod_{r=1}^{R}|y_r-x|^{2q_r}\right]}{H_{n,\lambda_1,\lambda_2}[1]}\right|_{y_r=1/2(1+\cos\phi_r)} = \left\langle \prod_{l=1}^{n} e^{\tilde{h}(\theta_l)}\prod_{r=1}^{R}\left|\frac{1}{2}(\cos\phi_r-\cos\theta_l)\right|^{2q_r}\right\rangle_{C_N(\lambda_1,\lambda_2)}. \tag{4.28}$$

Making use of (4.22)–(4.28) shows that the asymptotic formula (4.19) for the integral (4.18) is equivalent to an asymptotic formula generalizing Theorem 1.

Conjecture 3: Let $\log a(\theta)$ *have the Fourier expansion (1.7), with coefficients satisfying (1.4). We expect that for* $N\to\infty$,

$$\left\langle \prod_{l=1}^{N} a(\theta_l)\prod_{r=1}^{R}|2(\cos\phi_r-\cos\theta_l)|^{2a_r}\right\rangle_{C_N(\lambda_1+1/2,\lambda_2+1/2)} \sim e^{(N+\sum_{r=1}^{R}a_r)c_0}(2N)^{\sum_{r=1}^{R}a_r^2}\tilde{K}, \tag{4.29}$$

where, with E specified by (4.13),

$$\tilde{K}=\prod_{r=1}^{R}\frac{1}{|1+e^{i\phi_r}|^{2(\lambda_1-1)a_r}|1+e^{i\phi_r}|^{2\lambda_2 a_r}}e^{-\sum_{n=1}^{\infty}c_n(\lambda_1-1+(-1)^n\lambda_2)}E. \tag{4.30}$$

We can apply some checks to (4.19). As already remarked, with $(\lambda_1,\lambda_2)=(1,0)$ the probability density function $C_N(\lambda_1,\lambda_2)$ coincides with the eigenvalue probability density function for $\mathrm{O}^-(2N+1)$, and (4.29) must coincide with (4.12), as indeed it does. Also, changing variables $\theta_l\mapsto\pi-\theta_l$ and interchanging λ_1 and λ_2 leaves (4.16) invariant, and thus the average (4.17) invariant if we also set $\phi_r\mapsto\pi-\phi_r$, $a(\theta)\mapsto a(\pi-\theta)$ [and thus $c_n\mapsto(-1)^n c_n$]. Recalling the definition (4.13) of E we see that (4.30) exhibits this symmetry. Another check follows from a factorization identity, relating an average over the unitary group to a product of averages over the orthogonal and symplectic groups.[27,24,28]

Proposition 1: With $g(\theta)=g(-\theta)$ *we have*

$$\left\langle \prod_{l=1}^{2N+1} g(\theta_l)\right\rangle_{\mathrm{U}(2N+1)} = \left\langle \prod_{l=1}^{N+1} g(\theta_l)\right\rangle_{\mathrm{O}^+(2N+2)}\left\langle \prod_{l=1}^{N} g(\theta_l)\right\rangle_{\mathrm{Sp}(N)}. \tag{4.31}$$

With

$$g(\theta)=a(\theta)\prod_{r=1}^{R}(2|\cos\theta-\cos\phi_r|)^{2a_r}$$

in (4.31) we see that the conjectured asymptotic form (4.29) for the right-hand side is consistent with the Fisher–Hartwig formula (1.8).

The identity (4.31) is also of interest for providing an exact formula for the product of the density matrix in Dirichlet boundary conditions and in Neumann boundary conditions. Thus recalling (4.6) we see from (4.31) that

$$\frac{1}{L^2}\sin\frac{\pi x}{L}\sin\frac{\pi y}{L}\left\langle \prod_{l=1}^{2N+1}\left|2\left(\cos\frac{\pi x}{L}-\cos\theta_l\right)\right|\left|2\left(\cos\frac{\pi x}{L}-\cos\theta_l\right)\right|\right\rangle_{\mathrm{U}(2N+1)}$$
$$=\rho^N_{N+2}(x,y)\rho^D_{N+1}(x,y).$$

V. IMPENETRABLE BOSONS IN A HARMONIC TRAP AND RANDOM MATRIX AVERAGES OVER THE GUE AND LUE

From a physical viewpoint the most relevant setting for the impenetrable Bose gas is confinement by a harmonic potential (see Refs. 20 and 29 and references therein). Then the ground state wave function ψ_0^H is proportional to

$$\prod_{l=1}^{N} e^{-x_l^2/2}\prod_{1\leqslant j<k\leqslant N}|x_k-x_j|,$$

and $|\psi_0^H|^2$ is identical to the eigenvalue probability density function for the Gaussian unitary ensemble of complex Hermitian matrices. The combination of log-gas arguments and analytic calculation based on the Selberg correlation integral used to analyze (4.18) was used in Ref. 29 to analyze the asymptotic form of

$$e^{-\Sigma_{j=1}^R 2Nq_r y_r^2}\frac{G_{N,\sqrt{2N}}\left[\prod_{r=1}^{R}|x-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}, \tag{5.1}$$

where

$$G_{N,a}[f(x)]:=\int_{-\infty}^{\infty}\mathrm{d}x_1\cdots\int_{-\infty}^{\infty}\mathrm{d}x_N\prod_{l=1}^{N}f(x_l)e^{-a^2x_l^2}\prod_{1\leqslant j<k\leqslant N}|x_k-x_j|^2, \tag{5.2}$$

in the special case $R=2$, $q_1=q_2=1/2$ which specifies the ground state density matrix. As our first point of interest we will generalize this calculation to general R and q_r $(q_r>-1/2)$.

The log-gas perspective[18] suggests the factorization

$$\prod_{1\leqslant j<k\leqslant R}|y_j-y_k|^{2q_jq_k}e^{-\Sigma_{r=1}^R 2Nq_ry_r^2}\frac{G_{N,\sqrt{2N}}\left[\prod_{r=1}^{R}|x-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}$$
$$\underset{N\to\infty}{\sim}\prod_{r=1}^{R}e^{-2Nq_ry_r^2}\frac{G_{N,\sqrt{2N}}[|x-y_r|^{2q_r}]}{G_{N+q_r,\sqrt{2N}}[1]}. \tag{5.3}$$

Next, from the theory of Selberg correlation integrals,[23] for $q_r\in\mathbb{Z}_{\geqslant 0}$ we have the duality formula[30]

$$\frac{G_{N,a}[(x-y_r)^{2q_r}]}{G_{N,a}[1]}=\frac{G_{2q_r,a}[(y_r+ix)^N]}{G_{2q_r,a}[1]}. \tag{5.4}$$

It is a fairly straightforward exercise, detailed in Ref. 30, Sec. 5.3 for a related problem, to use the saddle point method to compute the large N expansion of the integral on the right-hand side of (5.4). One finds

$$e^{-2Nq_rx_r^2}G_{2q_r,\sqrt{2N}}[(y_r+ix)^N]\underset{N\to\infty}{\sim}\binom{2q_r}{q_r}(G_{q_r,1}[1])^2e^{-q_rN}2^{-2q_rN}(4N)^{-q_r^2}(1-y_r^2)^{q_r^2/2}. \tag{5.5}$$

Also, we know (see, e.g., Ref. 3) the exact evaluation

$$G_{n,1}[1]=2^{-n(n-1)/2}\pi^{n/2}G(n+2), \tag{5.6}$$

which together with the asymptotic expansion (4.26) implies

$$\frac{G_{N,\sqrt{2N}}[1]}{G_{N+q,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}\frac{2^{2Nq+q^2-q}}{\pi^q}e^{qN}N^{-q}. \tag{5.7}$$

Combining (5.4)–(5.7) gives the asymptotic formula

$$e^{-2Nq_ry_r^2}\frac{G_{N,\sqrt{2N}}[|x-y_r|^{2q_r}]}{G_{N+q_r,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}\frac{G^2(q_r+1)}{G(2q_r+1)}\frac{2^{2q_r^2-q_r}}{\pi^{q_r}}N^{q_r^2-q_r}(1-y_r^2)^{q_r^2/2} \tag{5.8}$$

which we have proved for $q_r\in\mathbb{Z}_{\geqslant 0}$, and conjecture as being valid for all $q_r>-1/2$. This same result can also be deduced from results in Ref. 31. Substituting this in (5.3) gives the sought asymptotic form of (5.1).

Conjecture 4: Let $q_r>-1/2$, and let $G_{N,a}[f]$ be given by (5.2). We expect

$$e^{-\Sigma_{r=1}^R 2Nq_ry_r^2}\frac{G_{N,\sqrt{2N}}\left[\prod_{r=1}^R|x-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}\prod_{1\leqslant j<k\leqslant R}|y_j-y_k|^{-2q_jq_k}\times\prod_{r=1}^R\frac{G^2(q_r+1)}{G(2q_r+1)}\frac{2^{2q_r^2-q_r}}{\pi^{q_r}}N^{q_r^2-q_r}(1-y_r^2)^{q_r^2/2}. \tag{5.9}$$

An extension of (5.9) can also be formulated. Let $a(x)$ be analytic on $[-1,1]$. Then it has rigorously been proved that[16]

$$\frac{G_{N,\sqrt{2N}}[e^{a(x)}]}{G_{N,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}\exp\left(\frac{2N}{\pi}\int_{-1}^1 a(x)\sqrt{1-x^2}\,dx\right)\times\exp\left(\frac{1}{4\pi^2}\int_{-1}^1 dx\,\frac{a(x)}{(1-x^2)^{1/2}}\int_{-1}^1 dy\,\frac{a'(y)(1-y^2)^{1/2}}{x-y}\right). \tag{5.10}$$

The structure of (4.19) in the case $\lambda_1=\lambda_2=0$ suggests how (5.10) can be combined with (5.9) to generalize the latter.

Conjecture 5: Let $a(x)$ be analytic on $[-1,1]$. It is expected that

$$e^{-\Sigma_{r=1}^R 2Nq_ry_r^2}\frac{G_{N,\sqrt{2N}}\left[e^{a(x)}\prod_{r=1}^R|x-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}(\text{RHS}\,(5.10))|_{N\mapsto N+\Sigma_{r=1}^R q_r}(\text{RHS}\,(5.9))e^{-\Sigma_{r=1}^R q_r a(y_r)}. \tag{5.11}$$

We remark that in the special case $a(x)=kx$, Conjecture 5 can be reduced to Conjecture 4. To see this, use completion of squares to note

$$G_{N,\sqrt{2N}}\left[e^{kx}\prod_{r=1}^R|x-y_r|^{2q_r}\right]=e^{k^2/8}G_{N,\sqrt{2N}}\left[\prod_{r=1}^R\left|x+\frac{k}{2N}-y_r\right|^{2q_r}\right].$$

According to Conjecture 4 we have

$$e^{-\Sigma_{r=1}^R 2Nq_r(y_r-k/4N)^2}\frac{G_{N,\sqrt{2N}}\left[e^{kx}\prod_{r=1}^R|x+\frac{k}{2N}-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}\underset{N\to\infty}{\sim}\text{RHS}\,(5.10)$$

and thus

$$e^{-\Sigma_{r=1}^R 2Nq_r y_r^2}\frac{G_{N,\sqrt{2N}}\left[e^{kx}\prod_{r=1}^R|x-y_r|^{2q_r}\right]}{G_{N+\Sigma_{r=1}^R q_r,\sqrt{2N}}[1]}\sim e^{k^2/8}\,\text{RHS}\,(5.10)\,e^{-\Sigma_{r=1}^R q_r y_r}.$$

Since (4.24) gives

$$\frac{1}{4\pi^2}\int_{-1}^1 dx\,\frac{a(x)}{(1-x^2)^{1/2}}\int_{-1}^1 dy\,\frac{a'(y)(1-y^2)^{1/2}}{x-y}\bigg|_{a(x)=kx}=\frac{k^2}{8}$$

this is in agreement with (5.11).

Let us now turn our attention to a variation of the impenetrable Bose gas in a harmonic well, which also has the features of being related to a random matrix ensemble. In reduced units, the Hamiltonian for the system is

$$H=-\sum_{j=1}^N\frac{\partial^2}{\partial x_j^2}+\sum_{j=1}^N\left(a'(a'-1)\frac{1}{x_j^2}+x_j^2\right),\quad x_j>0. \tag{5.12}$$

Thus in addition to the harmonic well, the particles are restricted to the half line by a repulsive potential (requiring $a'>1$) at the origin proportional to $1/r^2$. This is the noninteracting case of the so-called type B Calogero–Sutherland Hamiltonian,[32] for which the interacting case has $1/r^2$ pair repulsion. The ground state wave function for (5.12) is proportional to

$$\prod_{l=1}^N e^{-x_l^2/2}(x_l^2)^{a'/2}\prod_{1\le j<k\le N}|x_k^2-x_j^2|. \tag{5.13}$$

We recognize the square of the ground state wave function as being identical to the probability density function for the singular values of $n\times N$ complex Gaussian matrices with $a'=n-N+1/2$ (see, e.g., Ref. 3, Chap. 2). Changing variables $x_l^2\mapsto x_l$ this is refered to as the Laguerre unitary ensemble. The problem of computing the asymptotic form of the density matrix for this system suggests analyzing the asymptotic form of the more general quantity

$$\prod_{r=1}^R y_r^{2a'q_r}e^{-4Nq_ry_r^2}\frac{L_N\left[\prod_{r=1}^R|x^2-y_r^2|^{2q_r}\right]}{L_{N+\Sigma_{r=1}^R q_r}[1]}, \tag{5.14}$$

where

$$L_N[f]:=\int_0^\infty dx_1\cdots\int_0^\infty dx_N\prod_{l=1}^N f(x_l)x_l^{2a'}e^{-4Nx_l^2}\prod_{1\le j<k\le N}|x_k^2-x_j^2|^2, \tag{5.15}$$

in analogy with (5.1).

From a log-gas perspective, the integrand in (5.15) corresponds to a one-component system interacting on the half-line $x>0$, subject to a one-body confining potential $2Nx^2-(a'-1/2)\log x$. In addition to the electrostatic energy $-\log|x-x'|$ at the point x due to the interaction with a charge at x', there is also a term $-\log|x+x'|$ due to the interaction with an image charge at $-x'$ (outside the system, since $x'>0$). In keeping with the image charge interpretation, for each charge at x one requires a term $-\frac{1}{2}\log|2x|$ to account for the interaction between a charge and its own image (the factor of 1/2 is because this energy is shared between the charge and its image, the latter being outside the system). From this viewpoint we can interpret

$$\prod_{1\leqslant j<k\leqslant R}|y_k^2-y_j^2|^{2q_jq_k}\prod_{r=1}^{R}(2y_r)^{q_r^2}e^{-q_r4Ny_r^2}|y_r|^{(2a'-1)q_r}\frac{L_N\Big[\prod_{r=1}^{R}|x^2-y_r^2|^{2q_r}\Big]}{2^{\sum_{r=1}^{R}q_r}L_{N+\sum_{r=1}^{R}q_r}[1]}$$

as a ratio of partition functions for log-gas systems, and analogous to (5.3) we expect the factorization into

$$\prod_{r=1}^{R}(2y_j)^{q_j^2}e^{-q_r4Ny_r^2}|y_r|^{(2a'-1)q_r}\frac{L_N[|x^2-y_r^2|^{2q_r}]}{2^{q_r}L_{N+q_r}[1]} \tag{5.16}$$

for $N\to\infty$.

To analyze (5.16) in the limit $N\to\infty$ we make the change of variables $x_l^2\mapsto x_l$ and introduce

$$\widetilde{L}_{N,c}[f]:=\int_0^\infty dx_1\cdots\int_0^\infty dx_N\prod_{l=1}^{N}f(x_l)x_l^{a'-1/2}e^{-cx_l}\prod_{1\leqslant j<k\leqslant N}(x_k-x_j)^2 \tag{5.17}$$

so that it reads

$$\prod_{r=1}^{R}(2y_r)^{q_r^2}e^{-q_r4Ny_r^2}y_r^{(2a'-1)q_r}\frac{\widetilde{L}_{N,4N}[|x-y_r^2|^{2q_r}]}{\widetilde{L}_{N+q_r,4N}[1]}. \tag{5.18}$$

To proceed further, we use the fact that for $q\in\mathbb{Z}_{\geqslant 0}$ we have the duality formula[33]

$$\frac{\widetilde{L}_{N,c}[|x-t|^{2q}]}{\widetilde{L}_{N,c}[1]|_{a\mapsto a+2q}}=\frac{1}{M_{2q}(a,N)}\int_{-1/2}^{1/2}dx_1\cdots\int_{-1/2}^{1/2}dx_{2q}\prod_{l=1}^{2q}e^{\pi ix_l(a-N)}$$

$$\times|1+e^{2\pi ix_l}|^{a+N}e^{-cte^{2\pi ix_l}}\prod_{1\leqslant j<k\leqslant 2q}|e^{2\pi ix_k}-e^{2\pi ix_j}|^2, \tag{5.19}$$

where on the right-hand side $a=a'-1/2$ and

$$M_n(a,b):=\int_{-1/2}^{1/2}dx_1\cdots\int_{-1/2}^{1/2}dx_n\prod_{l=1}^{n}e^{\pi ix_l(a-b)}|1+e^{2\pi ix_l}|^{a+b}\prod_{1\leqslant j<k\leqslant n}|e^{2\pi ix_k}-e^{2\pi ix_j}|^2$$

$$=\frac{G(n+1+a+b)}{G(1+a+b)}\frac{G(1+a)}{G(n+1+a)}\frac{G(1+b)}{G(n+1+b)}G(n+2) \tag{5.20}$$

(for the last equality see, e.g., Ref. 3). If we suppose temporarily that $a\in Z_{\geqslant 0}$, the right-hand side of (5.19) with $c=4N$ can be written as the contour integral

$$\frac{1}{M_{2q}(a,-N)}\int_{\mathcal{C}}\frac{dz_1}{2\pi iz_1}\cdots\int_{\mathcal{C}}\frac{dz_{2q}}{2\pi iz_{2q}}\prod_{l=1}^{2q}(1+z_l)^a(1+1/z_l)^Ne^{-4Ntz_l}\prod_{1\leqslant j<k\leqslant 2q}(z_k-z_j)(1/z_k-1/z_j), \tag{5.21}$$

where $\mathcal{C}$ is any simple closed contour which encircles the origin. To analyze this for $N\to\infty$, following Ref. 33 where the case $q=1$ was considered, we note the N-dependent terms in the integrand have a stationary point when

$$z=z_\pm:=-\tfrac{1}{2}\pm i\tfrac{1}{2}(1/t-1)^{1/2}. \tag{5.22}$$

By deforming the contour $\mathcal{C}$ to pass through z_+ for q of the integrations, and to pass through z_- for the remaining q integrations, we readily deduce from the representation (5.21) of (5.19) that

$$
\begin{aligned}
&e^{-q_r 4Ny_r^2} y_r^{(2a'-1)q_r} (2y_r)^{q_r^2} \widetilde{L}_{N,4N}[|x-y_r^2|^{2q_r}] \\
&\quad = \frac{\widetilde{L}_{N,4N}[1]|_{a'\mapsto a'+2q_r}}{M_{2q_r}(a'-1/2,N)} e^{-q_r 4Ny_r^2} y_r^{(2a'-1)q_r} (2y_r)^{q_r^2} \binom{2q_r}{q_r} e^{-4Ny_r^2 q_r(z_+ + z_-) + Nq_r \log|1+1/z_+|^2} \\
&\qquad \times \frac{1}{|z_+|^{4q_r^2}} |z_+ - z_-|^{2q_r^2} |1+z_+|^{q_r(2a'-1)} \left(\frac{1}{2\pi}\right)^{2q_r} \\
&\qquad \times \left| \frac{N}{2} \left(\frac{1}{z_+^2} - \frac{1}{(1+z_+)^2} \right) \right|^{-q_r^2} (G_{q_r}[1])^2.
\end{aligned} \tag{5.23}
$$

Now, with $t = y_r^2$ in (5.22)

$$
\begin{gathered}
z_+ + z_- = -1, \quad \left| 1 + \frac{1}{z_+} \right|^2 = 1, \quad |z_+ - z_-|^2 = \left(\frac{1}{y_r^2} - 1 \right), \\
|1+z_+|^2 = |z_+|^2 = \frac{1}{4y_r^2}, \quad \left| \frac{1}{z_+^2} - \frac{1}{(1+z_+)^2} \right| = 16 y_r^4 \left(\frac{1}{y_r^2} - 1 \right)^{1/2},
\end{gathered} \tag{5.24}
$$

so the right-hand side of (5.23) simplifies to

$$
\frac{\widetilde{L}_{N,4N}[1]|_{a'\mapsto a'+2q_r}}{M_{2q_r}(a'-1/2,N)} N^{-q_r^2} \left(\frac{1}{2\pi} \right)^{2q_r} \binom{2q_r}{q_r} 2^{2q_r^2} 2^{-q_r(2a'-1)} (G_{q_r}[1])^2 (1-y_r^2)^{q_r^2/2}. \tag{5.25}
$$

Furthermore we know (see, e.g., Ref. 3)

$$
\widetilde{L}_{N,c}[1] = c^{-N^2 - N(a'-1/2)} \frac{G(N+2)G(a'+N+1/2)}{G(a'+1/2)}, \tag{5.26}
$$

and making use of (5.22) it follows from the asymptotic expansion (4.26) that

$$
\frac{\widetilde{L}_{N,4N}[1]|_{a'\mapsto a'+2q_r}}{\widetilde{L}_{N+q_r,4N}[1] M_{2q_r}(a'-1/2,N)} N^{-q_r^2} \sim 2^{2(q_r^2 + q_r(a'-1/2))} N^{q_r^2 - q_r}. \tag{5.27}
$$

Substituting (5.27) in (5.25), evaluating $G_{q_r}[1]$ therein according to (5.6) and simplifying we obtain the $N \to \infty$ expansion

$$
e^{-q_r 4Ny_r^2} y_r^{(2a'-1)q_r} (2y_r)^{q_r^2} \frac{L_N[|x^2-y_r^2|^{2q_r}]}{2^{q_r} L_{N+q_r}[1]} \sim \frac{G^2(q_r+1)}{G(2q_r+1)} \frac{2^{3q_r^2 - q_r}}{\pi^{q_r}} N^{q_r^2 - q_r} (1-y_r^2)^{q_r^2/2}, \tag{5.28}
$$

proved for $q_r \in \mathbb{Z}_{\geqslant 0}$ and expected to be true for all $q_r > -1/2$. Substituting this in (5.16) gives, as a conjecture, the sought asymptotic form of (5.14).

Conjecture 6: For $N \to \infty$, and assuming $q_r > -1/2$ for each $r = 1, \ldots, R$,

$$\prod_{r=1}^{R} y_r^{2a'q_r} e^{-4Nq_r y_r^2} \frac{L_N\left[\prod_{r=1}^{R} |x^2-y_r^2|^{2q_r}\right]}{L_{N+\Sigma_{r=1}^{R} q_r}[1]} \sim \prod_{1\leqslant j<k\leqslant R} |y_k^2-y_j^2|^{-2q_jq_k} \times \prod_{r=1}^{R} \frac{G^2(q_r+1)}{G(2q_r+1)} \frac{2^{2q_r^2}}{\pi^{q_r}} N^{q_r^2-q_r} y_r^{-q_r^2+q_r} (1-y_r^2)^{q_r^2/2}. \tag{5.29}$$

It is of interest to extend (5.29) in an analogous way to how (5.11) extends (5.9). First we use (4.19) with $q_r=0$, and (5.10) to conjecture that for $a(x)$ analytic on [0,1],

$$\frac{L_N[e^{a(x)}]}{L_N[1]} \sim \exp\left(\frac{4(N+(2a'-1)/4)}{\pi} \int_0^1 a(x)\sqrt{1-x^2}\,dx\right) \times \exp\left(\frac{1}{\pi^2}\int_0^1 dx \frac{a(x)}{(1-x^2)^{1/2}} \int_0^1 dy \frac{ya'(y)(1-y^2)^{1/2}}{x^2-y^2}\right) e^{-a'a(0)/2}. \tag{5.30}$$

Combining this with (5.29) as in (5.11) gives us the LUE analogue of Conjecture 5.

Conjecture 7: Let $a(x)$ be analytic on [0,1]. *It is expected that*

$$\prod_{r=1}^{R} y_r^{2a'q_r} e^{-4Nq_r y_r^2} \frac{L_N\left[e^{a(x)}\prod_{r=1}^{R} |x^2-y_r^2|^{2q_r}\right]}{L_{N+\Sigma_{r=1}^{R} q_r}[1]} \underset{N\to\infty}{\sim} (\text{RHS}\,(5.30))\big|_{N\to N+\Sigma_{r=1}^{R} q_r} \times (\text{RHS}\,(5.29)) e^{-\Sigma_{r=1}^{R} q_r a(y_r)}. \tag{5.31}$$

We can check the consistency of (5.11) and (5.31). For this we make use of a factorization identity analogous to Proposition 1.[28]

Proposition 2: Let $g(\theta)=g(-\theta)$. We have

$$\frac{G_{2N,a}[g(x)]}{G_{2N,a}[1]} = \frac{L_{N,a}^{(0)}[g(x)]}{L_{N,a}^{(0)}[1]} \frac{L_{N,a}^{(2)}[g(x)]}{L_{N,a}^{(2)}[1]}, \tag{5.32}$$

where

$$L_{N,a}^{(p)}[g(x)] := \int_{-\infty}^{\infty} dx_1 \cdots \int_{-\infty}^{\infty} dx_N \prod_{l=1}^{N} g(x_l)|x_l|^p e^{-a^2x_l^2} \prod_{1\leqslant j<k\leqslant N} (x_k^2-x_j^2)^2.$$

Let $a(x)$ be even and choose

$$a=\sqrt{4N}, \quad g(x)=e^{a(x)}\prod_{r=1}^{R} |x^2-y_r^2|^{2q_r}.$$

According to Conjecture 5,

$$e^{-2a^2\Sigma_{r=1}^{R} q_r y_r^2} \frac{G_{2N,a}[g(x)]}{G_{2(N+\Sigma_{r=1}^{R} q_r),a}[1]} \underset{N\to\infty}{\sim} \exp\left(\frac{4}{\pi}\left(2N+2\sum_{r=1}^{R} q_r\right)\int_0^1 a(x)\sqrt{1-x^2}\,dx\right) \times \exp\left(\frac{1}{\pi^2}\int_0^1 dx \frac{a(x)}{(1-x^2)^{1/2}} \int_0^1 dy \frac{ya'(y)(1-y^2)^{1/2}}{x^2-y^2}\right) \times \prod_{1\leqslant j<k\leqslant R} |y_j^2-y_k^2|^{-4q_jq_k} \prod_{r=1}^{R} (1-y_r^2)^{q_r^2} |2y_r|^{-2q_r^2} \times \left(\prod_{r=1}^{R} \frac{G^2(q_r+1)}{G(2q_r+1)} \frac{2^{2q_r^2-q_r}}{\pi^{q_r}} (2N)^{q_r^2-q_r}\right)^2 e^{-2\Sigma_{r=1}^{R} q_r a(y_r)}. \tag{5.33}$$

For the right-hand side of (5.32) as implied by Conjecture 7 to be consistent with this we require

$$2^{4\Sigma_{r=1}^{R}q_r}\frac{G_{2N,\sqrt{4N}}[1]}{L_N[1]|_{a'=0}L_N[1]|_{a'=1}}\sim\frac{G_{2(N+\Sigma_{r=1}^{R}q_r),\sqrt{4N}}[1]}{L_{N+\Sigma_{r=1}^{R}q_r}[1]|_{a'=0}L_{N+\Sigma_{r=1}^{R}q_r}[1]|_{a'=1}}. \tag{5.34}$$

But the method of derivation of (5.32) given in Ref. 28 shows that for general n,

$$\frac{G_{2n,\sqrt{4n}}[1]}{L_n|_{a'=0}L_n|_{a'=1}}=2^{2n}\frac{(2n)!}{(n!)^2}\sim\frac{2^{4n}}{(\pi n)^{1/2}},$$

verifying (5.34).

Let us now apply Conjecture 7 to the calculation of the density matrix $\rho_{N+1}^{L}(x,y)$ for the state (5.13) with $N+1$ particles,

$$\rho_{N+1}^{L}(x,y):=\frac{N+1}{C_{N+1}}e^{-x^2/2-y^2/2}(xy)^{a'}\int_0^\infty dx_1\cdots\int_0^\infty dx_N\prod_{l=1}^{N}x_l^{2a'}e^{-x_l^2}|x^2-x_l^2||y^2-y_l^2|$$

$$\times\prod_{1\leqslant j<k\leqslant N}(x_k^2-x_j^2)^2, \tag{5.35}$$

where

$$C_{N+1}:=\int_0^\infty dx_1\cdots\int_0^\infty dx_{N+1}\prod_{l=1}^{N+1}x_l^{2a'}e^{-x_l^2}\prod_{1\leqslant j<k\leqslant N+1}(x_k^2-x_j^2)^2.$$

In terms of the average (5.15) we thus have

$$2\sqrt{N}\rho_{N+1}^{L}(2\sqrt{N}X,2\sqrt{N}Y)=(N+1)e^{-2NX^2-2NY^2}(XY)^{a'}\frac{L_N\left[\prod_{l=1}^{N}|x^2-X^2||x^2-Y^2|\right]}{L_{N+1}[1]}.$$

On the right-hand side we can apply Conjecture 7 with $R=2$, $q_1=q_2=1/2$ and so obtain the asymptotic form

$$2\sqrt{N}\rho_{N+1}^{L}(2\sqrt{N}X,2\sqrt{N}Y)\sim 2\sqrt{N}\,\frac{G^4(3/2)}{\pi}\,\frac{(XY)^{1/4}}{|X^2-Y^2|^{1/2}}(1-X^2)^{1/8}(1-Y^2)^{1/8}. \tag{5.36}$$

The asymptotic form (5.36) can in turn be used to specify the occupations λ_j of the low-lying effective single particle states ϕ_j, which by definition satisfy the eigenvalue equation

$$\int\rho_N(x,y)\,\phi_j(y)\,dy=\lambda_j\phi_j(x). \tag{5.37}$$

Thus, with $x=2\sqrt{N}X$, $y=2\sqrt{N}Y$ and j fixed, introducing the scaled effective single particle states[34,20]

$$(4N)^{1/2}\phi_j(x)\mapsto\varphi_j(X),$$

substituting (5.38) and using the fact that $\rho_N^L(x,y)$ is supported on $x,y\in[0,2\sqrt{N}]$ we obtain the explicit integral equation

$$2\int_0^1\frac{X^{1/4}(1-X^2)^{1/8}\varphi_j(X)}{|X^2-Y^2|^{1/2}}\,dX=\overline{\lambda}_j\frac{\varphi_j(Y)}{Y^{1/4}(1-Y^2)^{1/8}}, \tag{5.38}$$

where

$$\lambda_j = \sqrt{N}\frac{G^4(3/2)}{\pi}\overline{\lambda}_j . \tag{5.39}$$

We see immediately that the occupations of the low-lying effective single particle states are proportional to $\sqrt{N}$, as has been found for the impenetrable Bose gas in periodic boundary conditions,[19,20] in a harmonic trap[34,29] and in Dirichlet and Neumann boundary conditions.[9] An appropriate analysis similar to that undertaken in Ref. 29, Appendix B gives the same upper bound on $\overline{\lambda}_0$ as found for the same quantity in the case of the harmonic trap,[29] but a detailed analysis of (5.38) remains.

VI. CONCLUDING REMARKS

A. Universal form for Hankel asymptotics

Analogous to (3.1), Hankel determinants are related to log-gas partition functions according to the formula

$$\begin{aligned}\det[a_{j+k}]_{j,k=0,\dots,n-1} &= \frac{1}{n!}\int_{-\infty}^{\infty} dx_1\, e^{-nV(x_1)}\cdots\int_{-\infty}^{\infty} dx_n\, e^{-nV(x_n)}\prod_{l=1}^{n} a(x_l)\prod_{1\le j<k\le n}(x_k-x_j)^2 \\ &=: A_n(e^{-nV(x)})[a(x)],\end{aligned} \tag{6.1}$$

where

$$a_p = \int_{-\infty}^{\infty} a(x)x^p e^{-nV(x)}\,dx.$$

For $V(x)$ an even degree polynomial independent of n with positive leading coefficient and no real zeros, it was proved by Johansson[16] that

$$\begin{aligned}\frac{A_n(e^{-nV(x)})[e^{a(x)}]}{A_n(e^{-nV(x)})[1]} &\underset{n\to\infty}{\sim} \exp\left(n\int_{c_1}^{c_2} a(x)\rho(x)\,dx\right) \\ &\quad\times\exp\left(\frac{1}{4\pi^2}\int_{c_1}^{c_2} dx\,\frac{a(x)}{\sqrt{(x-c_1)(c_2-x)}}\int_{c_1}^{c_2} dy\,\frac{a'(y)\sqrt{(y-c_1)(c_2-y)}}{x-y}\right).\end{aligned} \tag{6.2}$$

Here $\rho(x)$ is the scaled density in the log-gas system corresponding to $A_n(e^{-nV(x)})[1]$, supported on $[c_1,c_2]$ and normalized so that

$$\int_{c_1}^{c_2}\rho(x)\,dx = 1.$$

The asymptotic formula (5.10) corresponds to the special case $V(x)=\frac{1}{2}x^2$, $\rho(x)=(2/\pi)\sqrt{1-x^2}$ of (6.2). To extend Conjecture 5 to more general V this suggests we simply write the latter in terms of $\rho(x)$.

Conjecture 8: Under the conditions of the validity of (6.2) we expect

$$e^{-n\Sigma_{r=1}^{R} q_r V(y_r)} \frac{A_n(e^{-nV(x)})\left[e^{a(x)} \prod_{j=1}^{r} |x-y_j|^{q_j} \right]}{A_{n+\Sigma_{j=1}^{R} q_j}(e^{-nV(x)})[e^{a(x)}]}$$

$$\underset{n\to\infty}{\sim} e^{-\Sigma_{r=1}^{R} q_r a(y_r)} \prod_{1\leqslant j<k\leqslant R} |y_k-y_j|^{-2q_jq_k} \times \prod_{r=1}^{R} \frac{G^2(q_r+1)}{G(2q_r+1)} (2\pi n)^{q_r^2-q_r} (\rho(y_r))^{q_r^2}. \tag{6.3}$$

We remark that in the case $R=1$, $e^{a(x)}=1$, this conjecture (together with some corroborative analysis) was formulated earlier by Brézin and Hikami[31] (see also Ref. 35).

Conjecture 7 can similarly be extended, although we work with the quantity (5.17) in favor of (5.15) so as to have a Hankel determinant interpretation according to (6.1). In the log-gas system corresponding to (5.17) one has $\rho(x)=(2/\pi x^{1/2})(1-x)^{1/2}$. Recalling the equality between (5.16) and (5.18), and writing $y_r^2 \mapsto y_r$, $a(x^{1/2}) \mapsto a(x)$ we see that Conjecture 7 can be rewritten to imply

$$\prod_{r=1}^{R} y_r^{(a'-1/2)q_r} e^{-4Nq_ry_r} \frac{\widetilde{L}_{N,4N}\left[e^{a(x)} \prod_{r=1}^{R} |x-y_r|^{2q_r} \right]}{\widetilde{L}_{N+\Sigma_{r=1}^{R} q_r,4N}[e^{a(x)}]}$$

$$\underset{N\to\infty}{\sim} e^{-\Sigma_{r=1}^{R} q_r a(y_r)} \prod_{1\leqslant j<k\leqslant R} |y_k-y_j|^{-2q_jq_k} \times \prod_{r=1}^{R} \frac{G^2(q_r+1)}{G(2q_r+1)} (2\pi N)^{q_r^2-q_r} (\rho(y_r))^{q_r^2}, \tag{6.4}$$

thus assuming the universal form (6.3) and suggesting the following analogue of (6.2) and Conjecture 8.

Conjecture 9: Let $V(x)$ be a polynomial independent of n, with positive leading coefficient and no real zeros on $[0,\infty)$. Let

$$\widetilde{A}_n(x^\alpha e^{-nV(x)})[a(x)] := \frac{1}{n!} \int_0^\infty dx_1\, x_1^\alpha e^{-nV(x_1)} \cdots \int_0^\infty dx_n\, x_n^\alpha e^{-nV(x_n)} \prod_{l=1}^{n} a(x_l) \prod_{1\leqslant j<k\leqslant n} (x_k-x_j)^2. \tag{6.5}$$

Analogous to (6.2) we expect that

$$\frac{\widetilde{A}_n(x^\alpha e^{-nV(x)})[e^{a(x)}]}{\widetilde{A}_n(x^\alpha e^{-nV(x)})[1]} \underset{n\to\infty}{\sim} \exp\left(n \int_0^{c_2} a(x)\rho(x)\, dx \right) \times \exp\left(\frac{1}{4\pi^2} \int_0^{c_2} dx \frac{a(x)}{\sqrt{x(c_2-x)}} \int_{c_1}^{c_2} dy \frac{a'(y)\sqrt{y(c_2-y)}}{x-y} \right), \tag{6.6}$$

where $\rho(x)$ is the scaled density in the log-gas corresponding to $\widetilde{A}_n(x^\alpha e^{-nV(x)})[1]$, with support on $[0,c_2]$. Furthermore, with the same meaning of $\rho(x)$, we expect

$$\prod_{r=1}^{R} y_r^\alpha e^{-nq_rV(y_r)} \frac{\widetilde{A}_n(x^\alpha e^{-nV(x)})\left[e^{a(x)} \prod_{j=1}^{r} |x-y_j|^{q_j} \right]}{\widetilde{A}_{n+\Sigma_{j=1}^{R} q_j}(x^\alpha e^{-nV(x)})[e^{a(x)}]} \underset{n\to\infty}{\sim} \text{RHS}\,(6.3). \tag{6.7}$$

As a final comment on this point, we note that the universal form given by the right-hand side of (6.3) is also exhibited by the Fisher–Hartwig formula (1.8). Thus, with $z_r := e^{i\theta_r}$ we see that

$$\frac{D_n\left[e^{a(\theta)}\prod_{r=1}^{R}|e^{i\theta}-z_r|\right]}{D_{n+\Sigma_{j=1}^{R}}[e^{a(\theta)}]} \underset{n\to\infty}{\sim} \mathrm{RHS}\,(6.3)\big|_{\substack{y_r=z_r\\ \rho(y)=N/2\pi}}.$$

B. Further Toeplitz and Hankel structures

The identity (4.9) of Lemma 1 has counterparts for averages over $\mathrm{Sp}(N)$ and $\mathrm{O}^+(2N)$.[24]

Lemma 2: Suppose $g(\theta)=g(-\theta)$, set $g_j=(1/2\pi)\int_{-\pi}^{\pi} g(\theta)e^{-ij\theta}\,d\theta$, and let $C_N(\lambda_1,\lambda_2)$ refer to the normalized form of (4.16). We have

$$\begin{aligned}\det[a_{j-k}+a_{j+k}]_{j,k=0,\dots,N-1} &= \left\langle \prod_{j=1}^{N} g(\theta_j)\right\rangle_{\mathrm{O}^+(2N)} = \left\langle \prod_{j=1}^{N} g(\theta_j)\right\rangle_{C_N(0,0)},\\ \det[a_{j-k}-a_{j+k+2}]_{j,k=0,\dots,N-1} &= \left\langle \prod_{j=1}^{N} g(\theta_j)\right\rangle_{\mathrm{Sp}(N)} = \left\langle \prod_{j=1}^{N} g(\theta_j)\right\rangle_{C_N(1,1)}.\end{aligned} \tag{6.8}$$

Choosing $g(\theta)$ as in (4.11), Conjecture 3 gives the asymptotic behavior of the right-hand sides in (6.8), and thus the conjectured form of these Toeplitz and Hankel structures.

C. Fluctuation formula perspective and future directions

Let $p := p(x_1,\dots,x_N)$ be an N-dimensional probability density function. The stochastic quantity $A=\Sigma_{j=1}^{N} a(x_j)$, with the $\{x_j\}$ sampled from p, is referred to as a linear statistic. Its distribution $P_A(t)$ is defined by

$$P_A(t)=\left\langle \delta\left(t-\sum_{j=1}^{N} a(x_j)\right)\right\rangle_p, \tag{6.9}$$

and taking the Fourier transform of this gives

$$\tilde{P}_A(k)=\left\langle \prod_{j=1}^{N} e^{ika(x_j)}\right\rangle_p. \tag{6.10}$$

The structure of the average (6.10) is common to the averages studied in this paper. As an illustration of the content of the asymptotic formulas from this viewpoint, consider Johansson's result (3.7). Written in terms of the average (3.1) with $g(\theta)=e^{ika(\theta)}$, it reads

$$D_n^{(\beta)}[e^{ika(\theta)}] \underset{n\to\infty}{\sim} e^{ikc_0 n}e^{-(2/\beta)k^2\Sigma_{n=1}^{\infty} nc_n c_{-n}}, \tag{6.11}$$

where $\{c_n\}_{n=0,\pm1,\dots}$ are the Fourier coefficients in the expansion of $a(\theta)$,

$$a(\theta)=\sum_{n=-\infty}^{\infty} c_n e^{in\theta}. \tag{6.12}$$

A key feature of the exponents in the exponentials on the right-hand side of (6.11) is that they form a quadratic polynomial in k. Thus substituting this in (6.9) and taking the inverse transform gives the Gaussian distribution

$$P_A(t) \underset{n\to\infty}{\sim} \frac{1}{(2\pi\sigma^2)^{1/2}} e^{-(t-\mu)^2/2\sigma^2} \tag{6.13}$$

with

$$\mu = nc_0, \quad \sigma^2 = \frac{4}{\beta} \sum_{p=1}^{\infty} p c_p c_{-p}. \tag{6.14}$$

As noted by Johansson,[5] in the case $\beta = 2$ this gives a Gaussian fluctuation formula interpetation of Szegö's theorem. A peculiar feature is that although the mean is proportional to n, the variance is O(1), so fluctuations are strongly suppressed. It is formulas of the type (6.13), (6.14) which led to the successful theoretical explanation of the phenomenon of universal conductance fluctuations in mesoscopic wires (see, e.g., Ref. 36), in which the conductance—an order N quantity—is written as a linear statistic of certain eigenvalues and is shown to have O(1) fluctuations with variance given by an analytic formula of the type (6.14).

All our generalizations of the Fisher–Hartwig formula involve a term of the form $e^{Q^2 \log n}$ as the first correction to the leading order behavior $e^{c_0 n}$. However again when written as an average of the type (6.10) the exponential of a quadratic in k again results. Consider for example (3.13). With $\{c_n\}$ specified by (6.12) we have

$$\langle e^{ika(\theta) + ik\beta \Sigma_{j=1}^R q_j \log|e^{i\theta} - e^{i\phi_j}|} \rangle_{C\beta E_n} \underset{n\to\infty}{\sim} e^{ikc_0 n} e^{-k^2(\beta/2)(\Sigma_{j=1}^R q_j^2)\log n}$$

and thus, as first noted in Ref. 37, with

$$A = \sum_{l=1}^{N} \left(a(\theta_l) + \beta \sum_{j=1}^{R} q_j \log|e^{i\theta_l} - e^{i\phi_j}| \right)$$

the asymptotic form of the corresponding distribution is given by the Gaussian (6.13) with

$$\mu = nc_0, \quad \sigma^2 = \beta \left(\sum_{j=1}^{R} q_j^2 \right) \log n.$$

Thus the variance diverges logarithmically. This class of Gaussian fluctuation theorem has found use in the application of random matrix theory to the study of the statistical properties of the zeros of the Riemann zeta function.[38,39] The study of the statistical properties of the zeros of families of L-functions requires averages over the different classical groups.[40–43] We might anticipate that our new results of Sec. IV will find application in this topic.

Of course it remains to prove the conjectures of this paper. Of these, Conjecture 2 is the most general, as it involves Fisher–Hartwig-type parameters $\{q_j\}$, $\{b_j\}$ as well as the log-gas type parameter β. It is also of interest to extend Conjectures 3, 8, and 9 to this level of generality. Another direction of generality is to extend the domain of integration from a circle or line to a two-dimensional region.[44,45]

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 5 MAY 2004

Adiabatic approximation of the Schrödinger–Poisson system with a partial confinement: The stationary case

Olivier Pinaud[a)]
MIP, Laboratoire CNRS (UMR 5640), Université Paul Sabatier, 31062 Toulouse Cedex 04, France

(Received 16 September 2003; accepted 27 January 2004; published 13 April 2004)

Asymptotic quantum transport models of a two-dimensional gas are presented. The models are the stationary versions of those introduced in a previous paper by Ben Abdallah, Méhats, Pinaud. The starting point is a singular perturbation of the three-dimensional stationary Schrödinger–Poisson system posed on bounded domain. The electron injection in the device is modeled thanks to open boundary conditions. Under a small density assumption, the asymptotics lead to a full two-dimensional first-order approximation of the initial model. An intermediate model, called the ''2.5D adiabatic model'' in Ben Abdallah, Méhats, Pinaud is then introduced. It shares the same structure as the limit but is shown to be a second-order approximation of the three-dimensional model. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1688432]

I. INTRODUCTION

The paper presents the stationary versions of the models previously analyzed in Ref. 11. These models, first introduced in Refs. 32 and 33 in a formal approach, were originally implemented in a stationary framework and with open boundary conditions. The objective of the paper is, as for Ref. 11, to prove rigorously the asymptotics derived in Refs. 32 and 33. Before going into the details, we recall the motivations of the introduction of open boundary conditions and confined systems.

In nanoscale semiconductor, the electronic transport can be described in various ways. Very often, like in resonant tunneling diodes,[15,22,29,31] the electrons are injected, through a wave guide or quantum wire, into an active device where all the important physical effects take place. Consequently, due to the ultrashort scale, a quantum description is needed into the device while in the leads, two situations are possible: the transport can be considered either as classical or as quantum. Then, the different descriptions have to be connected at the interface lead-active region. A quantum–quantum case was first treated in Ref. 26 thanks to the introduction of suitable boundary conditions and was analyzed in Ref. 6 while a classical–quantum one was studied in Ref. 5. Some other examples of such coupling can be found in Refs. 7, 8, 12, and 18.

Besides, the operation of many quantum devices relies on the formation of a bidimensional electron gas. Such a system is obtained by confining the electrons in one direction and allowing for transport in the two other directions, the confining appearing at some junctions between different layers. The reduced extension of the electron gas results, at low temperature, in an increase of the mobility and therefore to a ballistic transport.[2,25,30] Again, at this level, several strategies can be used: the transport along the nonconfined directions can be considered either as classical or as quantum. The classical–quantum description give rises to the theory of sub-bands which is widely used in the semiconductor physics literature.[2,3,17,38] Such a model has been rigourously derived in Ref. 9 and analyzed in Ref. 10.

The situation described in the paper is a fully quantum model: a heterostructure coupled to electrons reservoirs through wave guides is considered. The electrons behavior is assumed to be

a)Electronic mail: pinaud@mip.ups-tlse.fr

quantum both in the device and in the leads and the electrons gas is assumed to be confined in a particular direction. The initial model is a three-dimensional Schrödinger–Poisson system, where the electrons are described by a mixed state,

$$-\Delta \Psi_\lambda^\varepsilon + \frac{1}{\varepsilon^2} V_c\left(\frac{z}{\varepsilon}\right)\Psi_\lambda^\varepsilon + V^\varepsilon \Psi_\lambda^\varepsilon = E^\varepsilon \Psi_\lambda^\varepsilon, \tag{1.1}$$

$$-\Delta V^\varepsilon = n^\varepsilon, \tag{1.2}$$

$$n^\varepsilon = \int_\Lambda |\Psi_\lambda^\varepsilon|^2 \, \mathrm{d}\mu(\lambda) + \text{boundary conditions}, \tag{1.3}$$

where μ represents the statistics of the injected electrons and λ is a set of quantum numbers with values in Λ, and ε can be seen as the ratio between the kinetic and the confining energies of the electrons, see Ref. 11 for more details on the scaling. The external potential $(1/\varepsilon^2)\, V_c(z/\varepsilon)$ is a confining potential and the potential V^ε is the self-consistent potential due to space charge effects and is expected to be slowly varying in the z direction. Due to the strong confinement, the wave functions concentrate around the plane $\{z=0\}$ and the transport effects are almost two dimensional. In Ref. 11, in a time-dependent and whole space picture, the limit $\varepsilon \to 0$ was performed. The electronic density $n^\varepsilon(t,x,z)$ concentrates into a surface density $n_s(t,x)\,\delta(z)$ and the limit model was called *2D surface density model*. This model involves bidimensional Schrödinger equations, coupled to a bidimensional equation for the potential. An intermediate model, called the *2.5D adiabatic model*, first introduced in Refs. 32 and 33, was also derived and was shown to be a second order approximation of the initial model. This model couples 2D Schrödinger equations and a 3D equation for the potential. It has been shown numerically in Refs. 32 and 33, that the 2.5D model gives results in a very good agreement with those of the 3D model with a much lower computational cost. In this paper, we will develop a similar strategy to justify the asymptotics in the stationary framework. The differences in the analysis come from the boundedness of the transport domain and the stationary character of the problem. This requires to derive new estimates for the Poisson equation and to take particular care of the existence and uniqueness theory of the nonlinear stationary problem. More precisely, the results are proven under three main hypothesis: the first one states that the electrons are injected into the device on the ground state and is necessary in order to obtain ε-independent estimates. The two others hypothesis are directly related to uniqueness result concerning the solutions of the open Schrödinger–Poisson system stated in Ref. 6. In order to have uniqueness, one requires a weak coupling between the Schrödinger and the Poisson equations and also requires a statistics of injection avoiding the bound states of the device.

Within the time-dependent picture, quantum confining on very general surfaces have been previously investigated in Refs. 16, 23, and 28 for the linear Schrödinger equation. As pointed out in Ref. 37, the quantum constrained system can be related to the Born–Oppenheimer theory for molecular dynamics.[24,35] Even if these theories are mainly developed in a time-dependent and linear framework, they share similar properties with the problem presented in this paper. In the different cases, the electron dynamics is located on the eigenspaces of the confining (or transverse) Hamiltonian and is governed by an effective potential. In the present work, the main difficulty stems from the nonlinearity due to the Coulombian interaction.

The paper is organized as follows: in Sec. II we introduce the spectral elements of the confining operator, which enable to define the 2.5D adiabatic model; then we present in details the different models where special care is given to boundary conditions; the main results of the paper are presented in Sec. III; in Sec. IV we obtain some ε-independent estimates for (1.1)–(1.3) and we give existence and uniqueness results for the approximate models; in Sec. V, we prove that the 2.5D model is a second order approximation while in Sec. VI, the 2D model is proven to be only

a first order approximation; Sec. VII is devoted to some extensions and comments; finally, an appendix contains some basic results on the Schrödinger equation and some regularity estimates for the Poisson equation which are used all along the paper.

II. NOTATIONS AND PRESENTATION OF THE MODELS

In the paper, Ω_0 denotes a regular domain of dimension 2. First, we define the following functional space.

Definition 2.1: Let $1 \leqslant p,\ q \leqslant +\infty$. *Then*

$$L_x^q L_z^p = \left\{ u \in L^1(\Omega_0 \times \mathbb{R}), \quad \|u\|_{L^{q,p}} = \left(\int_{\Omega_0} \|u(x,\cdot)\|_{L^p(\mathbb{R})}^q \, \mathrm{d}x \right)^{1/q} < +\infty \right\}$$

(*with an obvious generalization of this definition for* $q = +\infty$). In the sequel, $L^p(\Omega_0 \times \mathbb{R})$ will be more simply denoted L^p.

For a function $f = f(z)$ belonging to $L^1(\mathbb{R})$ we denote $\langle f \rangle = \int_{\mathbb{R}} f(z)\mathrm{d}z$. In particular, if $n(x,z)$ is the particle density, the surface density is defined by $n_s(x) = \langle n(x,\cdot) \rangle$.

A. Spectrum of the confinement operator

We introduce the properties of the confining potential V_c. We assume that it satisfies the

Assumption 2.2: The rescaled confining potential $V_c = V_c(z)$ *is a non-negative real-valued function in* $L^2_{loc}(\mathbb{R})$ *such that*

$$\lim_{|z| \to +\infty} V_c(z) = +\infty.$$

Under this assumption, the operator $A = -\frac{1}{2}(d^2/dz^2) + V_c$ defined on $X = L^2(\mathbb{R})$ with the domain

$$\mathcal{D}(A) = \{ u \in H^2(\mathbb{R}) \ \text{ such that } \ V_c\, u \in L^2(\mathbb{R}) \}$$

is self-adjoint, non-negative, and has a compact resolvent (see, e.g., Ref. 34). Hence, its spectrum is purely discrete and consists in a strictly increasing sequence of non-negative real numbers tending to infinity $(E_p)_{p \in \mathbb{N}^*}$. Moreover, the associated eigenfunctions $(\chi_p)_{p \in \mathbb{N}^*}$, chosen real-valued, form an orthonormal basis of $L^2(\mathbb{R})$ and verify

$$\forall a > 0, \quad \forall p \in \mathbb{N}^*, \quad \exists C_{a,p} > 0, \quad \text{such that,} \quad \forall z \in \mathbb{R}, \quad |\chi_p(z)| \leqslant C_{a,p}\, e^{-a|z|}. \tag{2.1}$$

The partial Hamiltonian involved in (1.1) is obtained by rescaling A:

$$A^\varepsilon = -\frac{1}{2}\frac{d^2}{dz^2} + V_c^\varepsilon = -\frac{1}{2}\frac{d^2}{dz^2} + \frac{1}{\varepsilon^2} V_c\left(\frac{z}{\varepsilon}\right).$$

This operator A^ε on $X = L^2(\mathbb{R})$ has the domain

$$\mathcal{D}(A^\varepsilon) = \{ u \in H^2(\mathbb{R}) \ \text{ such that } \ V_c^\varepsilon\, u \in L^2(\mathbb{R}) \}.$$

Its eigenfunctions $(\chi_p^\varepsilon)_{p \in \mathbb{N}^*}$ and eigenvalues $(E_p^\varepsilon)_{p \in \mathbb{N}^*}$ can be deduced by a simple rescaling from those of A:

$$\chi_p^\varepsilon(z) = \frac{1}{\sqrt{\varepsilon}} \chi_p\left(\frac{z}{\varepsilon}\right), \quad E_p^\varepsilon = \frac{E_p}{\varepsilon^2}.$$

We shall denote by Π_p^ε the orthogonal projector on $span(\chi_p^\varepsilon)$. The space $L^2(\mathbb{R}^2, span(\chi_p^\varepsilon))$ will be called the pth subband. With an abuse of notation, we shall also denote by Π_p^ε the orthogonal projector $\mathbb{I} \otimes \Pi_p^\varepsilon$ of $L^2(\mathbb{R}^3)$ on $L^2(\mathbb{R}^2, span(\chi_p^\varepsilon))$.

The following technical lemma, proved in Ref. 11, will be used several times in this paper.

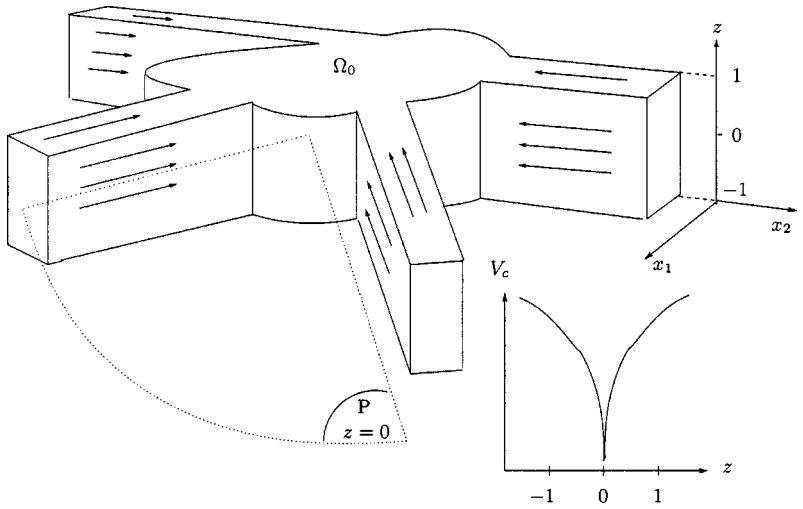

FIG. 1. The device projected in $\{z\in[-1,1]\}$.

Lemma 2.3: Let $V^\varepsilon \in W^{1,\alpha}(\mathbb{R})$ *with* $\alpha\in[1,+\infty]$. *Then for any* $p\in\mathbb{N}^*$ *we have*

$$\|[\Pi_p^\varepsilon, V^\varepsilon]\|_{\mathcal{L}(L^2(\mathbb{R}))} \leqslant C_p\, \varepsilon^{1-1/\alpha}\, \|\partial_z V^\varepsilon\|_{L^\alpha(\mathbb{R})},$$

where $[\cdot,\cdot]$ *denotes the commutator of operators and* C_p *only depends on* p.

Notice that this type of commutator estimates was already used in the semiclassical analysis of electrons motion in periodic crystals. In that case, the projector is the projector on the energy bands related to the Bloch decomposition, see Refs. 27 and 4.

B. Definition of the models

For the sake of completeness, the open boundary conditions introduced in Ref. 26 are derived step by step in Appendix A. We set now the geometry of the device.

The device domain consists in an active region, denoted by $\Omega_0\times\mathbb{R}$ connected to semi-infinite electrons reservoirs by n leads $\Omega_j\times\mathbb{R}$, $j=1,...,n$, see Fig. 1 for a schematic drawing of the device in $\Omega_0\times[-1,1]$ and Fig. 2. The full domain of the device is $\Omega\times\mathbb{R}$, where $\Omega=\cup_{j=0}^n\Omega_j$. The boundary of Ω_0 is split into a part Γ_0 and n parts Γ_j, $j=1,...,n$. We denote by ω_0 the boundary $(\Gamma_0\times\mathbb{R})\cup(\Omega_0\times\{z=\pm\infty\})$. The transport directions are denoted by $x:=(x_1,x_2)$ and the confined direction by z. The local coordinates of the lead j, $j\neq 0$ are denoted by η_j and ξ_j, see Fig. 2. The confining potential insures that the electrons stay around the plane $P=\{x\in\Omega, z=0\}$, see Figs. 1 and 2.

1. The 3D model

The 3D model is obtained by coupling the Poisson equation to a set of Schrödinger equations to be solved on the domain $\Omega_0\times\mathbb{R}$ with open boundary conditions. A single electron injected with an energy E^ε is represented by a wave function Ψ^ε solution of the Schrödinger equation

$$-\Delta\Psi^\varepsilon(x,z)+(V_c^\varepsilon(z)+V^\varepsilon(x,z))\Psi^\varepsilon(x,z)=E^\varepsilon\,\Psi^\varepsilon(x,z) \quad \text{in } \Omega_0\times\mathbb{R}, \tag{2.2}$$

where V_c^ε is a confining potential and V^ε is, up to now, a given potential supported only in $\Omega_0\times\mathbb{R}$. Ψ^ε satisfies the nonhomogeneous open boundary conditions derived in Appendix A:

$$\left.\frac{\partial\Psi^\varepsilon}{\partial\eta_j}\right|_{\Gamma_j}=\mathbb{Z}_j^{3D}[E^\varepsilon](\Psi^\varepsilon)+\mathbb{S}_j^{3D}[E^\varepsilon], \tag{2.3}$$

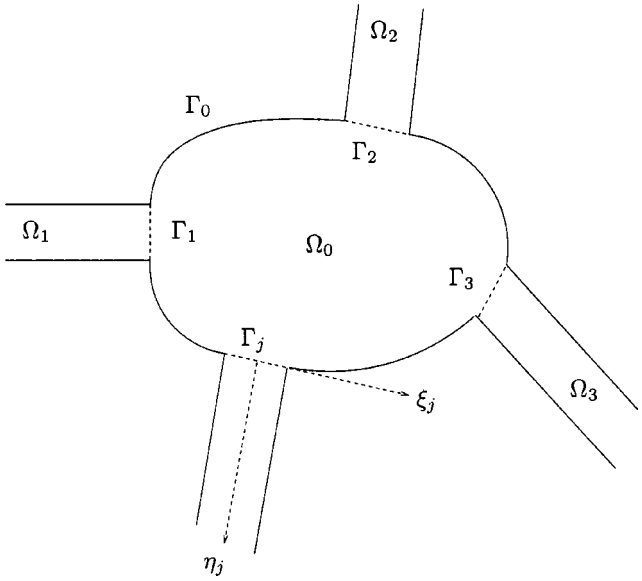

FIG. 2. The plane P.

$$\Psi^\varepsilon = 0 \quad \text{on} \quad \omega_0 . \tag{2.4}$$

The electrons populate the different sub-bands starting from the first sub-band. In Ref. 11, a model close to the one presented is analyzed in the time-dependent picture. Therein, the ε-independent estimates are obtained using crucially the Stricharz estimates introduced by Castella in Ref. 14 in order to solve the Schrödinger–Poisson system in L^2. This theory does not use H^1 energy estimates. Obviously, within the stationary framework, the Stricharz estimates are not available and one needs H^1 theory to obtain energy estimates. In the time-dependent picture, when the initial condition has a nonzero component on a sub-band with index $p \geqslant 2$, ε-independent *a priori* bounds in H^1 are only derived on a small time interval while the time interval can be made arbitrarily large for wave functions supported only on the first sub-band. Therefore, there is a little hope to obtain estimates for the stationary problem if the electrons populate the upper sub-bands. Consequently, we will only focus on the electrons injected on this first sub-band by assuming the following hypothesis.

*Assumption 2.4: Let Θ_m^j and $\mathcal{E}_m^j$ be the eigenfunctions and eigenvalues of the j*th *transversal Schrödinger operator $-\partial_{\xi_j}^2$ with Dirichlet boundary conditions. Then, we suppose that the electrons are injected in the lead j_0, on the first sub-band, on the transversal mode m_0 and with a longitudinal kinetic energy k^2. This implies that $\mathbb{S}_j^{3\mathrm{D}} = -2\,\delta_j^{j_0}\, ik\, \Theta_{m_0}^j\, \chi_1^\varepsilon$ and $E^\varepsilon = E_1^\varepsilon + \mathcal{E}_{m_0}^{j_0} + k^2$.*

The wave functions Ψ^ε are thus parametrized by $\lambda = (m_0, j_0, k)$, $\Psi^\varepsilon := \Psi_\lambda^\varepsilon$ (the dependence on the parameter 1 of first sub-band is omitted). Notice that the assumption is compatible with some physical situations called electrical quantum limit, see for instance the numerical simulations in Refs. 32 and 33, where only the first sub-band is populated. This hypothesis is often verified in structures like T-stubs, quantum couplers, or various types of transistors. Indeed, in two-dimensional electron gases, the electron occupancy in the second sub-band is usually a small fraction (typically less than 10%) of the total electron density, see Refs. 36 and 20. Nervertheless, in parabolic quantum well structures, the electrons population in the sub-bands can be carefully controlled and the densities in two lowest sub-band can be similar to within 30%, see Refs. 19 and 21.

Assumption 2.4 thus implies that the boundary condition (2.3) reads

$$\left.\frac{\partial \Psi_\lambda^\varepsilon}{\partial \eta_j}\right|_{\Gamma_j} = \mathbb{Z}_j^{3D}[E_1^\varepsilon + E_\lambda](\Psi_\lambda^\varepsilon) - 2\,\delta_j^{j_0}\, ik\, \Theta_{m_0}^j\, \chi_1^\varepsilon. \tag{2.5}$$

In order to take into account self-consistent effects, the electrons are supposed to be injected in the state λ by a source in the leads and the electronic density is assumed to be in a mixed state. It reads

$$n^\varepsilon(x,z) = \int_\Lambda |\Psi_\lambda^\varepsilon(x,z)|^2 \, d\mu(\lambda) = \sum_{j_0=1}^{n} \sum_{m_0=1}^{\infty} \int_{\mathbb{R}_+^\star} \Phi(j_0,m_0,k) |\Psi_{j_0,m_0,k}^\varepsilon(x,z)|^2 \, dk, \tag{2.6}$$

where $\Phi(j_0,m_0,k)$ is the statistics of injection and Λ is the set

$$\Lambda = [0,\ldots,n] \times \mathbb{N}^\star \times \mathbb{R}_+^\star .$$

The electrons being charged particles, they generate a self-consistent potential V^ε through the Poisson equation. It is assumed that the nonlinear interaction takes place only in the active region, the domain $\Omega_0 \times \mathbb{R}$. Hence, V^ε solves

$$-\Delta V^\varepsilon = n^\varepsilon \quad \text{on } \Omega_0 \times \mathbb{R}, \tag{2.7}$$

$$V^\varepsilon = 0 \quad \text{on } \partial\Omega_0 \times \mathbb{R}, \tag{2.8}$$

$$V^\varepsilon \to 0 \quad \text{as } |z| \to \infty. \tag{2.9}$$

The fact that the electrons are injected on the first sub-band does not imply that the wave function Ψ_λ^ε has only a contribution on this sub-band. Indeed, the different sub-bands are coupled through the z-dependence of V^ε. Nevertheless, it will be shown that the upper sub-bands are weakly populated since the potential V^ε is slowly varying with respect to the variable z. The 3D model finally read as follows.

The 3D model:

$$\begin{gathered}
-\Delta \Psi_\lambda^\varepsilon(x,z) + (V_c^\varepsilon(z) + V^\varepsilon(x,z))\Psi_\lambda^\varepsilon(x,z) = (E_1^\varepsilon + E_\lambda)\, \Psi_\lambda^\varepsilon(x,z) \quad \text{in } \Omega_0 \times \mathbb{R}, \\
\Psi_\lambda^\varepsilon = 0 \quad \text{on } \omega_0; \ \Psi_\lambda^\varepsilon \text{ satisfies } (2.5) \quad \text{on } \Gamma_j \times \mathbb{R}, \quad j \neq 0, \\
-\Delta V^\varepsilon = n^\varepsilon \quad \text{on } \Omega_0 \times \mathbb{R}, \quad n^\varepsilon(x,z) = \int_\Lambda |\Psi_\lambda^\varepsilon(x,z)|^2 \, d\mu(\lambda), \\
V^\varepsilon = 0 \quad \text{on } \partial\Omega_0 \times \mathbb{R}; \ V^\varepsilon \to 0 \quad \text{as } |z| \to \infty.
\end{gathered} \tag{2.10}$$

Existence and uniqueness: The model presented in Ref. 6 is slighty different from the 3D model but the results can be easily adapted. It is proven in Ref. 6 that, for a general μ satisfying an assumption of boundedness of the support, the 3D model admits a weak solution Ψ_λ^ε in $H^1(\Omega_0 \times \mathbb{R})$. More precisely, the obtained density reads

$$n^\varepsilon = \int_\Lambda |\Psi_\lambda^\varepsilon|^2 \, d\mu(\lambda) + \quad \text{sum of bound states.}$$

This last statement means that the electrons having adequate energies are trapped into the active region. In other words, the bound states of the device can be excited by the injected beam of electrons (see Ref. 6 for more details). This implies, conjugated with the nonlinear character of the problem, the nonuniqueness of the solutions. Morever, the wave function satisfies estimates of the type

$$\|\Psi_\lambda^\varepsilon\|_{L^2} \leqslant \frac{C}{|\mathcal{E}^\varepsilon - E_\lambda|}, \tag{2.11}$$

where $\mathcal{E}^\varepsilon$ denotes an energy of the bound states. This leads to a nonintegrable singularity in the computation of the density. To derive the asymptotic models, the nonuniqueness property is not fundamental but in order to obtain error estimates, we need to recover uniqueness. This can be done thanks to the uniqueness result of Ref. 6: if the bound states are avoided by the statistics μ and if the nonlinearity is supposed to be weak enough the solutions are unique. Moreover, the fact that the bound states are avoided implies also, thanks to (2.11), some uniform bounds with respect to λ. This leads to the following definition.

Definition 2.5: Assume that V^ε is a given regular potential. Consider the operator $-\Delta + V_c^\varepsilon + V^\varepsilon - E_1^\varepsilon$ equipped with Dirichlet boundary conditions on ω_0 and with the homogeneous transparent boundary conditions (2.3) on $\Gamma_j \times \mathbb{R}$, $j=1,..,n$ with $\mathbb{S}_j^{3D}[E_1^\varepsilon + E_\lambda] := 0$. According to Ref. 6, this operator has a purely discrete spectrum and we will call "energies of the bound states" its eigenvalues $(\mathcal{E}_i^\varepsilon(V^\varepsilon))_{i \geqslant 1}$.

In order to simplify the analysis and to avoid additional technicalities, we set in the simplest way to make the electrons avoid the bound states, see Ref. 6. The requirement is given by the following

Assumption 2.6: The measure μ has a bounded support such that, for $\lambda \in supp\ \mu$, there exists $C>0$, ε-independent such that

$$C \leqslant \mathcal{E}_1^\varepsilon(0) - E_\lambda .$$

This implies that the electrons avoid all the bound states. Indeed, by the maximum principle, V^ε is positive and then $\mathcal{E}_1^\varepsilon(0) \leqslant \mathcal{E}_1^\varepsilon(V^\varepsilon)$. Notice that above, this choice of μ is ε-independent since $\mathcal{E}_1^\varepsilon(0)$ is also ε-independent. This assumption is rather stringent in the general case and some ways to waive this restriction are proposed in Sec. VII. Nevertheless, in the case of confined devices at low temperatures, this hypothesis may nearly be verified. Indeed, in these structures, the typical statistics of injection is a Fermi–Dirac statistics. It reads

$$\Phi(E^\varepsilon) = \frac{1}{1 + \exp\left(\dfrac{E_F^\varepsilon - E^\varepsilon}{k_B T}\right)},$$

where k_B is the Boltzmann constant, T the temperature, and E_F^ε the rescaled Fermi level. In practical,

$$E_F^\varepsilon = E_1^\varepsilon + \mathcal{O}(1),$$

and the Fermi–Dirac reads

$$\Phi(E^\varepsilon) = \frac{1}{1 + \exp\left(\dfrac{E_\lambda + \mathcal{O}(1)}{k_B T}\right)},$$

which exhibits an exponential decay at low temperatures and also at high energies.

The theorem of Ref. 6 reads, for given ε, after a slight adaptation.

Theorem 2.7: *(Ref. 6) There exists $\delta(\varepsilon)$ positive, such that for every μ satisfying assumption 2.6 and*

$$\mu(\Lambda) < \delta(\varepsilon)$$

the 3D model admits a unique solution.

We shall see in the sequel that $\delta(\varepsilon)$ can be chosen ε-independent.

2. The 2D surface density model

The 2D surfacic density model is the coupling between many 2D Schrödinger equations and a 2D potential. When ε goes to zero, $|\chi_p^\varepsilon|^2$ concentrates around 0 and becomes then a Dirac measure. This leads to the definition of the limit model by replacing the self-consistent potential by its trace on the plane $\{x\in\Omega_0, z=0\}$ and by replacing the 3D density by a 2D density multiplied by a Delta measure. The boundary condition (2.5) becomes

$$\left.\frac{\partial\psi_\lambda}{\partial\eta_j}\right|_{\Gamma_j} = \mathbb{Z}_j^{2D}[E_\lambda](\psi_\lambda) - 2\,\delta_j^{j_0}\, ik\,\Theta_{m_0}^j, \tag{2.12}$$

where

$$\mathbb{Z}_j^{2D}[E_\lambda](\psi_\lambda) = \sum_{m=1}^{N^j(E_\lambda)} ik_m^j(E_\lambda)\psi_{m,j}(0)\Theta_m^j(\xi_j) - \sum_{m=N^j(E_\lambda)+1}^{\infty} k_m^j(E_\lambda)\,\psi_{m,j}(0)\,\Theta_m^j(\xi_j).$$

The 2D surface density model then reads

$$\begin{gathered}
-\Delta_x\psi_\lambda(x) + V(x,0)\psi_\lambda(x) = E_\lambda\,\psi_\lambda \quad \text{in } \Omega_0,\\
\psi_\lambda = 0 \quad \text{on } \Gamma_0;\ \psi_\lambda \text{ satisfies (2.12) on } \Gamma_j,\quad j\neq 0,\\
-\Delta V(x,z) = n_s(x)\delta(z) \quad \text{on } \Omega_0\times\mathbb{R},\quad n_s = \int_\Lambda |\psi_\lambda|^2\,d\mu(\lambda),\\
V = 0 \quad \text{on } \partial\Omega_0\times\mathbb{R};\ \lim_{|z|\to\infty} V = 0 \quad \text{a.e. on } \Omega_0.
\end{gathered} \tag{2.13}$$

Definition 2.8: Assume that V is a given regular potential. Consider the operator $-\Delta_x + V(\cdot,0)$ equipped with Dirichlet boundary conditions on Γ_0 and with the homogeneous transparent boundary conditions (2.12) on Γ_j, $j=1,..,n$ without source term. According to Ref. 6, this operator has a purely discrete spectrum and we will call "energies of the 2D bound states" its eigenvalues $(\mathcal{E}_i(V(\cdot,0))_{i\geqslant 1}$.

3. The 2.5D model

The 2.5D adiabatic model is an intermediate model between the fully 3D model and the 2D surfacic density one. It takes into account the small thickness of the electron gas and consists in coupling a set of two-dimensional Schrödinger equations and the three-dimensional Poisson equation:

$$\begin{gathered}
-\Delta_x\psi_\lambda^\varepsilon + \langle V^\varepsilon|\chi_1^\varepsilon|^2\rangle\,\psi_\lambda^\varepsilon(x) = E_\lambda\,\psi_\lambda^\varepsilon \quad \text{in } \Omega_0,\\
\psi_\lambda^\varepsilon = 0 \quad \text{on } \Gamma_0;\ \psi_\lambda^\varepsilon \text{ satisfies (2.12)} \quad \text{on } \Gamma_j,\quad j\neq 0,\\
-\Delta V^\varepsilon = n^\varepsilon|\chi_1^\varepsilon|^2 \quad \text{on } \Omega_0\times\mathbb{R},\ n^\varepsilon = \int_\Lambda |\psi_\lambda^\varepsilon|^2\,d\mu(\lambda),\\
V^\varepsilon = 0 \quad \text{on } \partial\Omega_0\times\mathbb{R};\ \lim_{|z|\to\infty} V^\varepsilon = 0 \quad \text{a.e. on } \Omega_0.
\end{gathered} \tag{2.14}$$

Remark 2.9: According to Definition 2.8, the energies of the bound states of the 2.5D model are naturaly denoted by $(\mathcal{E}_i(\langle V^\varepsilon|\chi_1^\varepsilon|^2\rangle))_{i\in\mathbb{N}^\star}$. Morever, if V is a potential independent of the variable z, it comes easily that $\mathcal{E}_i(V) = \mathcal{E}_i^\varepsilon(V)$.

III. MAIN RESULTS

In this paper, we will prove the following theorems.

Theorem 3.1: *Suppose that Assumptions 2.2, 2.4, and 2.6 are satisfied. Then, there exists η positive ε-independent such that, for every μ satisfying Assumption 2.6 and*

$$\mu(\Lambda) < \eta,$$

the 3D model (2.10) and the 2.5D adiabatic model (2.14) admit unique weak solutions, respectively, denoted by $(\Psi_\lambda^{3D}, V^{3D})$ and by $(\psi_\lambda^{2.5D}, V^{2.5D})$. Moreover, η can be chosen such that we have the following error estimates, uniformly in λ, for $\alpha>0$, for $p\in[1,2)$,

$$\|\Psi_\lambda^{3D} - \psi_\lambda^{2.5D}\chi_1^\varepsilon\|_{W^{1,p}(\Omega_0, L^2(\mathbb{R}))} = \mathcal{O}(\varepsilon^{1-\alpha}), \tag{3.1}$$

$$\|V^{3D} - V^{2.5D}\|_{W^{1,p}(\Omega_0, L^\infty(\mathbb{R}))} = \mathcal{O}(\varepsilon^{2-\alpha}). \tag{3.2}$$

Furthermore the surfacic densities defined by $n_s^{3D} = \int_\Lambda \langle |\Psi_\lambda^{3D}|^2\rangle \, d\mu(\lambda)$ and $n_s^{2.5D} = \int_\Lambda |\psi_\lambda^{2.5D}|^2 \, d\mu(\lambda)$ satisfy

$$\|n_s^{3D} - n_s^{2.5D}\|_{W^{1,p}(\Omega_0)} = \mathcal{O}(\varepsilon^{2-\alpha}) \quad \forall \alpha>0, \quad \forall p\in[1,2). \tag{3.3}$$

Theorem 3.2: *Suppose that Assumptions 2.2, 2.4, and 2.6 are satisfied. Then, there exists η positive ε-independent such that, for every μ satisfying Assumption 2.6 and*

$$\mu(\Lambda) < \eta,$$

as $\varepsilon\to 0$, the unique solution $(\psi_\lambda^{2.5D}, n^{2.5D}, V^{2.5D})$ of the 2.5D adiabatic model converges to the unique solution $(\phi^{2D}, n_s^{2D}, V^{2D})$ of the 2D surfacic density model (2.13) in the following sense: for $\alpha>0$, for $p\in[1,2)$,

$$\|\psi_\lambda^{2.5D} - \phi^{2D}\|_{W^{1,p}(\Omega_0)} = \mathcal{O}(\varepsilon^{1-\alpha}), \tag{3.4}$$

$$\|V^{2.5D} - V^{2D}\|_{W^{1,p}(\Omega_0, L^\infty(\mathbb{R}))} = \mathcal{O}(\varepsilon^{1-\alpha}), \tag{3.5}$$

$$\|n_s^{2.5D} - n_s^{2D}\|_{W^{1,p}(\Omega_0)} = \mathcal{O}(\varepsilon^{1-\alpha}), \tag{3.6}$$

where $n_s^{2D} = \int_\Lambda |\phi_\lambda^{2D}|^2 \, d\mu(\lambda)$ and $n_s^{2.5D} = \int_\Lambda |\psi_\lambda^{2.5D}|^2 \, d\mu(\lambda)$. Furthermore, we have the following bound from below:

$$\|V^{2D} - V^{2.5D}\|_{L^2} + \|n_s^{2D} - n_s^{2.5D}\|_{L^2} \geq C\,\varepsilon, \tag{3.7}$$

where C does not depend on ε.

A straightforward consequence of these theorems is the following.

Corollary 3.3: Suppose that Assumptions 2.2, 2.4, and 2.6 are satisfied. Then, under the notations of Theorems 3.1 and 3.2, there exists η positive ε-independent such that, for every μ satisfying Assumption 2.6 and

$$\mu(\Lambda) < \eta,$$

the 3D model converges as $\varepsilon\to 0$ to the 2D model. Furthermore, we have the estimate

$$C_1\,\varepsilon \leq \|V^{2D} - V^{3D}\|_{L^2} + \|n_s^{2D} - n_s^{3D}\|_{L^2} \leq C_2\,\varepsilon^{1-\alpha}.$$

IV. ε-INDEPENDENT ESTIMATES AND WELL-POSEDNESS

In this section, we shall obtain some ε-independent estimates for the 3D and the 2.5D models. To this aim, we will use Proposition A.1 for both models. Besides, the well-posedness of the 2D and 2.5D models will also be studied.

Proposition 4.1: Let V^ε and Ψ^ε_λ be the solutions of the 3D model. Then, under assumption 2.2, 2.4, and 2.6 we have the following estimates, uniformly in λ,

$$\|\Psi^\varepsilon_\lambda\|_{H^1(\Omega_0,L^2(\mathbb{R}))}\leqslant C, \tag{4.1}$$

$$\|(\mathbb{I}-\Pi^\varepsilon_1)\Psi^\varepsilon_\lambda\|_{L^2}\leqslant C\,\varepsilon, \tag{4.2}$$

$$\|V^\varepsilon\|_{W^{1,p}(\Omega_0,H^s(\mathbb{R}))}\leqslant C \quad for \;\; p\in(1,\infty),\;\; s<\tfrac{3}{2},\quad p(1+2s)<8, \tag{4.3}$$

$$\|(\mathbb{I}-\Pi^\varepsilon_1)\Psi^\varepsilon_\lambda\|_{H^1(\Omega_0,L^2(\mathbb{R}))}\leqslant C\,\varepsilon^{1-\alpha},\quad \alpha>0, \tag{4.4}$$

where C is ε-independent.

Proof: The proof of (4.1) and (4.2) is a direct application of Proposition A.1 Indeed, according to the maximum principle V^ε is positive and according to hypothesis 2.4, Ψ^ε_λ satisfies the boundary condition (A10) with $a=1$. It suffices to apply (A12) and (A13) with $f=0$ to conclude.

The estimate (4.3) will be obtained by using the regularity properties of the Poisson equation given in Appendix B. To this aim, we first remark that $\int_\Lambda|\nabla_x\Psi^\varepsilon_\lambda|^2 d\mu(\lambda)\;\in L^1$ and $\int_\Lambda|\Psi^\varepsilon_\lambda|^2 d\mu(\lambda)\in L^p_x L^1_z$, for all $p\in[1,\infty)$, thanks to (4.1) and the embedding $H^1(\Omega_0)\hookrightarrow L^p(\Omega_0)$, $p<\infty$. This implies by interpolation, that for $r<2$,

$$\nabla_x n^\varepsilon = 2\,\mathrm{Re}\int_\Lambda \overline{\Psi^\varepsilon_\lambda}\,\nabla_x\Psi^\varepsilon_\lambda\, d\mu(\lambda)\in L^{r,1}.$$

It suffices then to apply (B3) to conclude.

To prove (4.4), we form the quantity $w^\varepsilon_\lambda:=(\mathbb{I}-\Pi^\varepsilon_1)\Psi^\varepsilon_\lambda$. It can be easily seen that w^ε_λ solves

$$-\Delta w^\varepsilon_\lambda+(V^\varepsilon_c(z)+V^\varepsilon(x,z))w^\varepsilon_\lambda=(E^\varepsilon_1+E_\lambda)\,w^\varepsilon_\lambda+[\Pi^\varepsilon_1,V^\varepsilon]\Psi^\varepsilon_\lambda \tag{4.5}$$

with boundary conditions (A10) with $a=0$ and (A11). Hence, the estimate (A12) of Appendix A with $f=[\Pi^\varepsilon_1,V^\varepsilon]\Psi^\varepsilon_\lambda$ implies

$$\|w^\varepsilon_\lambda\|_{H^1(\Omega_0,L^2(\mathbb{R}))}\leqslant C\|[\Pi^\varepsilon_1,V^\varepsilon]\Psi^\varepsilon_\lambda\|_{L^2}\leqslant C\,\varepsilon^{1-1/p}\|\partial_z V^\varepsilon\|_{L^4_x L^p_z}\|\Psi^\varepsilon_\lambda\|_{L^4_x L^2_z}$$

thanks to Lemma 2.3. We conclude the proof by using (4.1) and by noticing that (4.3) implies that $\partial_z V^\varepsilon$ is bounded in $L^4_x L^p_z$ for any $p<\infty$, thanks to the embedding $H^{1/2-(1/p)}(\mathbb{R})\hookrightarrow L^p(\mathbb{R})$, for $p\in[2,\infty)$, see Ref. 1. □

Proposition 4.2: Let V^ε and ψ^ε_λ be the solutions of the 2.5D model. Then, under Assumptions 2.2, 2.4, and 2.6, we have the following estimates, uniformly in λ,

$$\|\psi^\varepsilon_\lambda\|_{H^1(\Omega_0)}\leqslant C, \tag{4.6}$$

$$\|V^\varepsilon\|_{W^{1,p}(\Omega_0,H^s(\mathbb{R}))}\leqslant C \quad for \;\; p\in(1,\infty),\quad s<\tfrac{3}{2},\quad p(1+2s)<8, \tag{4.7}$$

where C is ε-independent.

Proof: To prove (4.6) and in order to apply Proposition A.1, we form artificially the function $\Phi^\varepsilon_\lambda(x,z):=\psi^\varepsilon_\lambda(x)\,\chi^\varepsilon_1(z)$ which solves

$$-\Delta\Phi^\varepsilon_\lambda+(V^\varepsilon_c+\langle V^\varepsilon\,|\chi^\varepsilon_1|^2\rangle)\Phi^\varepsilon_\lambda=(E^\varepsilon_1+E_\lambda)\,\Phi^\varepsilon_\lambda \quad \text{in}\;\; \Omega_0\times\mathbb{R}$$

equipped with boundary conditions (A10) with $a=1$ and (A11). (A12) concludes then the proof since V^ε is positive by the maximum principle.

The estimate (4.7) is proven analogously to (4.3) by using (4.6). □

The existence and uniqueness of solution for the 2.5D and the 2D models are direct applications of Theorem 7.2 of Ref. 6. The result is the following.

Theorem 4.3: *Let Assumptions 2.2, 2.4, and 2.6 be verified. Let* $\Psi_\lambda^{3D}\in H^1(\Omega_0\times\mathbb{R})$ *be a solution of the 3D model. Then, there exists an* η *positive such that, for every* μ *satisfying Assumption 2.6 and*

$$\mu(\Lambda)<\eta,$$

the 3D, the 2.5D, and the 2D models admit unique weak solutions. The solutions in $H^1(\Omega_0)$ *of the 2.5D and the 2D models are, respectively, denoted by* $\psi_\lambda^{2.5D}$ *and* ϕ_λ^{2D}. *Moreover, we have the estimates, uniformly in* λ,

$$\|\phi_\lambda^{2D}\|_{H^1(\Omega_0)}\leqslant C, \tag{4.8}$$

$$\|V^{2D}\|_{W^{1,p}(\Omega_0,H^s(\mathbb{R}))}\leqslant C \quad for \;\; p\in(1,\infty), \quad s<\tfrac{3}{2}, \quad p(1+2s)<8. \tag{4.9}$$

Sketch of the proof: The basic tools are the Leray–Schauder fixed point theorem and the regularity properties of the Poisson equation. The positivity of the potentials V^{2D} and $V^{2.5D}$ coupled to Assumption 2.6 imply direct bounds on the densities thanks to (A12) with $f=0$ and $a=1$. It follows, thanks to the Poisson equation, Lemmas B.1 and B.2, some compactness properties of the mapping and then to the existence result. The uniqueness is given by the fact that the fixed point procedures become contractions if the densities are small enough in L^1 norm. To this aim, we notice that, thanks to (4.1), (4.6) for n^{3D} and $n^{2.5D}$, and thanks to (A12) for n^{2D},

$$\|n^{3D}\|_{L^1}\leqslant C\mu(\Lambda),\;\; \|n^{2.5D}\|_{L^1}\leqslant C\mu(\Lambda), \quad \|n^{2D}\|_{L^1}\leqslant C\mu(\Lambda),$$

and then it suffices to choose η small enough such that each of the Leray–Schauder mappings are contractions. Equations (4.8) and (4.9) are direct applications of (A12) and Lemma B.2.

V. THE 2.5D MODEL IS A SECOND ORDER APPROXIMATION

In this section, we end the proof of Theorem 3.1 initiated in the preceding section. The used strategies are the same as Ref. 11. We assume that we are under the hypothesis of Theorem 4.3 which insure that the 3D and 2.5D models admit unique solutions. We denote respectively, by $(\Psi_\lambda^{3D},V^{3D})$ and $(\psi_\lambda^{2D},V^{2D})$, these solutions. We start by proving (3.2) by setting $V^{3D}-V^{2.5D}=V+R_1^\varepsilon+R_2^\varepsilon$ with

$$-\Delta V=|\chi_1^\varepsilon|^2(n_s^{3D}-n^{2.5D}), \quad -\Delta R_1^\varepsilon=r_1^\varepsilon, \quad -\Delta R_2^\varepsilon=r_2^\varepsilon$$

equipped with boundary conditions (B2) and where

$$n_s^{3D}=\int_\Lambda\int_{\mathbb{R}}|\Pi_1^\varepsilon\Psi_\lambda^{3D}|^2\,\mathrm{d}z\,\mathrm{d}\mu(\lambda), \quad r_1^\varepsilon=2\,\mathrm{Re}\int_\Lambda\overline{\Pi_1^\varepsilon\Psi_\lambda^{3D}}\;\;(\mathbb{I}-\Pi_1^\varepsilon)\Psi_\lambda^{3D}\,\mathrm{d}\mu(\lambda),$$

$$r_2^\varepsilon=\int_\Lambda|(\mathbb{I}-\Pi_1^\varepsilon)\Psi_\lambda^{3D}|^2\,\mathrm{d}\mu(\lambda).$$

Estimating the remainder terms R_1^ε *and* R_2^ε*:* Thanks to (4.1) and (4.4), we have directly, for $r<2$ and $\delta>0$,

$$\|r_1^\varepsilon\|_{W^{1,r}(\Omega_0,L^1(\mathbb{R}))}\leqslant C\,\varepsilon^{1-\delta},$$

$$\|r_2^\varepsilon\|_{W^{1,r}(\Omega_0,L^1(\mathbb{R}))}\leqslant C\,\varepsilon^{2-\delta},$$

$$\|z\,r_1^\varepsilon\|_{W^{1,r}(\Omega_0,L^1(\mathbb{R}))}\leqslant\|z\chi_1^\varepsilon\|_{L^2(\mathbb{R})}\,\varepsilon^{1-\alpha}\leqslant C\,\varepsilon^{2-\alpha}.$$

This implies that R_2^ε is almost of order two while R_1^ε is, up to now, almost of order one. To get one order more for R_1^ε, we will use (B5) of Appendix B. To this aim, we remark by orthogonality of $\Pi_1^\varepsilon\Psi_\lambda^{3\mathrm{D}}$ and $(\mathbb{I}-\Pi_1^\varepsilon)\Psi_\lambda^{3\mathrm{D}}$ that

$$\int_{\mathbb{R}} r_1^\varepsilon(x,z)\,\mathrm{d}z=0.$$

Thereby, (B5) applies. Choosing $s=\frac{1}{2}+\alpha$, $\beta=1-2\alpha$ with α positive and close to 0, we obtain, for all δ positive and $p<2$,

$$\|R_1^\varepsilon\|_{W^{1,p}(\Omega_0,H^{1/2+\alpha}(\mathbb{R}))}\leqslant C\,\varepsilon^{2-\delta},$$

$$\|R_2^\varepsilon\|_{W^{1,p}(\Omega_0,H^{1/2+\alpha}(\mathbb{R}))}\leqslant C\,\varepsilon^{2-\delta}$$

which leads to bounds in $W^{1,p}(\Omega_0,L^\infty(\mathbb{R}))$ thanks to the embedding $H^{1/2+\alpha}(\mathbb{R})\hookrightarrow L^\infty(\mathbb{R})$ for all α positive.

It remains now to treat V. In order to estimate $|\chi_1^\varepsilon|^2(n_s^{3\mathrm{D}}-n^{2.5\mathrm{D}})$, we use the Schrödinger equation solved by $w_\lambda^\varepsilon:=\Pi_1^\varepsilon\Psi_\lambda^{3\mathrm{D}}-\chi_1^\varepsilon\,\psi_\lambda^{2.5\mathrm{D}}$:

$$-\Delta w_\lambda^\varepsilon+V_c^\varepsilon w_\lambda^\varepsilon+\langle V^{3\mathrm{D}}\,|\chi_1^\varepsilon|^2\rangle\,w_\lambda^\varepsilon=(E_1^\varepsilon+E_\lambda)w_\lambda^\varepsilon+f^\varepsilon+g^\varepsilon$$

equipped with the transparent homogeneous boundary conditions (A10) with $a=0$ and where

$$f^\varepsilon=-\Pi_1^\varepsilon\,V^{3\mathrm{D}}\,(\mathbb{I}-\Pi_1^\varepsilon)\Psi_\lambda^{3\mathrm{D}},\quad g^\varepsilon=\langle(V^{2.5\mathrm{D}}-V^{3\mathrm{D}})\,|\chi_1^\varepsilon|^2\rangle\chi_1^\varepsilon\psi_\lambda^{2.5\mathrm{D}}.$$

Remarking that

$$\Pi_1^\varepsilon\,V^{3\mathrm{D}}\,(\mathbb{I}-\Pi_1^\varepsilon)=\Pi_1^\varepsilon[\Pi_1^\varepsilon,V^{3\mathrm{D}}],$$

we deduce from Lemma 2.3, (4.3) and (4.4) that, for δ strictly positive,

$$\|f^\varepsilon\|_{L^2}\leqslant C\,\varepsilon^{1-1/p}\|\partial_z V^{3\mathrm{D}}\|_{L_x^4L_z^p}\|(\mathbb{I}-\Pi_1^\varepsilon)\Psi_\lambda^\varepsilon\|_{H^1(\Omega_0,L^2(\mathbb{R}))}=\mathcal{O}(\varepsilon^{2-\delta})$$

thanks to the embedding $H^{\frac{1}{2}-(1/p)}(\mathbb{R})\hookrightarrow L^p(\mathbb{R})$, for $p\in[2,\infty)$. Besides, according to (4.6), for $r>2$

$$\|g^\varepsilon\|_{L^2}\leqslant C\|V^{3\mathrm{D}}-V^{2\mathrm{D}}\|_{L_x^rL_z^\infty}$$

and we obtain finally, thanks to (A12), (4.22), and (4.6), that

$$\|w_\lambda^\varepsilon\|_{H^1(\Omega_0,L^2(\mathbb{R}))}\leqslant C\|f^\varepsilon\|_{L^2}+C\|g^\varepsilon\|_{L^2}\leqslant\mathcal{O}(\varepsilon^{2-\delta})+C\|V^{3\mathrm{D}}-V^{2\mathrm{D}}\|_{L_x^rL_z^\infty},$$

$$\|n_s^{3\mathrm{D}}-n^{2.5\mathrm{D}}\|_{W^{1,p}(\Omega_0)}\leqslant C\mu(\Lambda)^{1/2}\left(\int_\Lambda\|w_\lambda^\varepsilon\|^2_{H^1(\Omega_0,L^2(\mathbb{R}))}\,\mathrm{d}\mu(\lambda)\right)^{1/2}$$

$$\leqslant\mathcal{O}(\varepsilon^{2-\delta})+C\,\mu(\Lambda)\,\|V^{3\mathrm{D}}-V^{2\mathrm{D}}\|_{L_x^rL_z^\infty},$$

for $\delta>0$, $r>2$, and $p<2$. Applying (B3) in order to bound V, we find, according to the above estimate,

$$\|V\|_{W^{1,p}(\Omega_0,L^\infty(\mathbb{R}))} \leqslant C\,\varepsilon^{2-\delta} + C\,\mu(\Lambda)\,\|V^{3D}-V^{2D}\|_{L^r_x L^\infty_z}.$$

Gathering now the different estimates on R_1^ε, R_2^ε, and V leads to

$$\|V^{3D}-V^{2D}\|_{W^{1,p}(\Omega_0,L^\infty(\mathbb{R}))} \leqslant C\,\varepsilon^{2-\delta} + C\,\mu(\Lambda)\,\|V^{3D}-V^{2D}\|_{L^r_x L^\infty_z}.$$

Choosing $r \leqslant [2p/(2-p)]$ and $\mu(\Lambda)$ small enough end the proof thanks to the embedding $W^{1,p}(\Omega_0) \hookrightarrow L^r(\Omega_0)$.

VI. THE 2D MODEL IS A FIRST ORDER APPROXIMATION

In this section, we end the proof of Theorem 3.2. We first assume that we are under the hypothesis of Theorem 4.3 which insure that the 2D and 2.5D models admit unique solutions. We denote, respectively, by $(\psi_\lambda^{2.5D}, V^{2.5D})$ and $(\phi_\lambda^{2D}, V^{2D})$, these solutions. We start by proving (3.5) by writing

$$-\Delta(V^{2.5D}-V^{2D}) = |\chi_1^\varepsilon|^2(n_s^{2.5D}-n_s^{2D}) + n_s^{2D}(|\chi_1^\varepsilon|^2-\delta(z)) \tag{6.1}$$

equipped with the boundary conditions (B2). In order to apply (B3) to (6.1), we first estimate the quantity $n_s^{2.5D}-n_s^{2D}$ by using the Schrödinger equation solved by $w_\lambda^\varepsilon := \chi_1^\varepsilon(\psi_\lambda^{2.5D}-\phi_\lambda^{2D})$:

$$-\Delta w_\lambda^\varepsilon + V_c^\varepsilon w_\lambda^\varepsilon + \langle V^{2.5D}\,|\chi_1^\varepsilon|^2\rangle\, w_\lambda^\varepsilon = (E_1^\varepsilon + E_\lambda) w_\lambda^\varepsilon + f^\varepsilon$$

equipped with the transparent homogeneous boundary conditions (A10) with $a=0$ and where

$$f^\varepsilon = (V^{2D}(\cdot,0) - \langle V^{2.5D}\,|\chi_1^\varepsilon|^2\rangle)\chi_1^\varepsilon\phi_\lambda^{2D}.$$

Estimating the source term f^ε: We have

$$\begin{aligned}\|f^\varepsilon\|_{L^2} &\leqslant (\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z} + \|\langle (V^{2D}(\cdot,0)-V^{2D})\,|\chi_1^\varepsilon|^2\rangle\|_{L^p(\Omega_0)})\|\phi_\lambda^{2D}\|_{H^1(\Omega_0)} \\ &\leqslant C\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z} + C\|\partial_z V^{2D}\|_{L^p_x L^\alpha_z}\langle z^{1-1/\alpha}|\chi_1^\varepsilon|^2\rangle, \\ p>2 &\leqslant C\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z} + \mathcal{O}(\varepsilon^{1-\delta}), \quad \delta>0,\end{aligned}$$

where we used the estimates (4.8), (4.9) and the embeddings $H^1(\Omega_0) \hookrightarrow L^q(\Omega_0)$, $q<\infty$ and $H^{1/2-(1/\alpha)}(\mathbb{R}) \hookrightarrow L^\alpha(\mathbb{R})$, $\alpha \in [2,\infty)$. Applying now (A12) in order to estimate w_λ^ε, we obtain uniformly in λ, thanks to the above estimate of the source term f^ε, for $p>2$, $\delta>0$, and $r<2$,

$$\|w_\lambda^\varepsilon\|_{H^1(\Omega_0,L^2(\mathbb{R}))} \leqslant C\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z} + \mathcal{O}(\varepsilon^{1-\delta}), \tag{6.2}$$

$$\|n_s^{2.5D}-n_s^{2D}\|_{W^{1,r}(\Omega_0)} \leqslant C\mu(\Lambda)\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z} + \mathcal{O}(\varepsilon^{1-\delta}). \tag{6.3}$$

It remains now to estimate the second part on the right-hand side of (B2). To this aim, we find, according to (B6), for $r<2$, $p(1+2(s+\beta)) \leqslant 4r$, $s+\beta<\frac{3}{2}$,

$$\|(-\Delta)^{-1}(n_s^{2D}(|\chi_1^\varepsilon|^2-\delta(z)))\|_{W^{1,p}(\Omega_0,H^s(\mathbb{R}))} \leqslant C\langle z|\chi_1^\varepsilon|^2\rangle^\beta \|n_s^{2D}\|_{W^{1,r}(\Omega_0)}.$$

Since $\|n_s^{2D}\|_{W^{1,r}(\Omega_0)}$ is bounded for $r \leqslant 2$ thanks to (4.8) and since $\langle z|\chi_1^\varepsilon|^2\rangle = \mathcal{O}(\varepsilon)$ thanks to 2.1, we have finally, by choosing $\beta = 1-\delta$, $s = \frac{1}{2} + (\delta/2)$,

$$\|(-\Delta)^{-1}(n_s^{2D}(|\chi_1^\varepsilon|^2-\delta(z)))\|_{W^{1,p}(\Omega_0,H^s(\mathbb{R}))} \leqslant \mathcal{O}(\varepsilon^{1-\delta}). \tag{6.4}$$

We are able now to estimate the difference $V^{2D}-V^{2.5D}$ by applying (B3). Gathering the bounds (6.1), (6.3), and (6.4) and thanks to the embedding $H^{1/2+\alpha}(\mathbb{R})\hookrightarrow L^\infty(\mathbb{R})$, $\alpha>0$, we find, for $\delta>0$, $q<2$, and $p>2$,

$$\|V^{2D}-V^{2.5D}\|_{W^{1,q}(\Omega_0,L^\infty(\mathbb{R}))}\leqslant C\mu(\Lambda)\|V^{2D}-V^{2.5D}\|_{L^p_x L^\infty_z}+\mathcal{O}(\varepsilon^{1-\delta}).$$

Choosing $p\leqslant 2q/(2-q)$ and $\mu(\Lambda)$ small enough end the proof of (3.5).

In order to prove (3.4) and (3.6), it suffices to apply (3.5), (6.2), and (6.3).

The estimate from below: For the proof of (3.7), we introduce $(e_i,\lambda_i)_{i\in\mathbb{N}^*}$, the Hilbertian decomposition of the x-Laplacian equipped with Dirichlet boundary condition on $\partial\Omega_0$. Let $g\in L^2(\Omega_0\times\mathbb{R})$ and let u be the solution of $-\Delta u=g$ on the domain $\Omega_0\times\mathbb{R}$ with Dirichlet boundary conditions on $\partial(\Omega_0\times\mathbb{R})$. It can be easily seen that the Fourier transform $\hat{u}$ of u reads

$$\hat{u}(x,\xi)=\sum_{i\geqslant 1}\frac{(\hat{g}(\cdot,\xi),e_i(\cdot))_{L^2_x}}{\lambda_i+\xi^2}e_i(x)$$

and thus, thanks to the Fourier–Plancherel equality

$$\|u\|^2_{L^2}=\|(-\Delta)^{-1}g\|^2_{L^2}=\sum_{i\geqslant 1}\int_{\mathbb{R}}d\xi\left|\frac{(\hat{g},e_i)_{L^2_x}}{\lambda_i+\xi^2}\right|^2.$$

Hence, using the above equality, we find

$$\begin{aligned}\|(-\Delta)^{-1}(n_s^{2D}(|\chi_1^\varepsilon|^2-\delta(z)))\|^2_{L^2}&=\sum_{i\geqslant 1}\int_{\mathbb{R}}d\xi\left|\frac{(n_s^{2D},e_i)_{L^2_x}}{\lambda_i+\xi^2}\right|^2\left|\int_{\mathbb{R}}|\chi_1^\varepsilon|^2(e^{-i\xi z}-1)\,dz\right|^2\\&\geqslant\sum_{i\geqslant 1}\left|\frac{(n_s^{2D},e_i)_{L^2_x}}{\lambda_i+1}\right|^2\int_0^1 d\xi\left|\int_{\mathbb{R}}|\chi_1^\varepsilon|^2(e^{-i\xi z}-1)\,dz\right|^2\\&\geqslant C\,\|n_s^{2D}\|^2_{H^{-1}(\Omega_0)}\int_0^1 d\xi\left|\int_{\mathbb{R}}|\chi_1|^2(e^{-i\varepsilon\xi z}-1)\,dz\right|^2.\end{aligned}\tag{6.5}$$

Moreover, pointwise in ξz, as $\varepsilon\to 0$, we have

$$\frac{e^{-i\,\varepsilon\,\xi\,z}-1}{-i\,\varepsilon\,\xi\,z}\to 1.$$

Consequently, defining h by

$$\frac{h(\varepsilon)}{\varepsilon^2}=\frac{1}{\varepsilon^2}\int_0^1 d\xi\left|\int_{\mathbb{R}}|\chi_1|^2(e^{-i\varepsilon\xi z}-1)\,dz\right|^2,$$

the Lebesgue dominated convergence theorem implies that

$$\frac{h(\varepsilon)}{\varepsilon^2}\to\frac{1}{3}\left|\int_{\mathbb{R}}z\,|\chi_1|^2\,dz\right|^2=C.$$

To conclude, we come back to (6.1) and (6.5). By noticing that $\|n_s^{2D}\|_{H^{-1}(\Omega_0)}=C$, there exists finally C_0 ε-independent such that

$$\|V^{2D}-V^{2.5D}\|^2_{L^2}+\|n_s^{2D}-n_s^{2.5D}\|^2_{L^2}\geqslant\|(-\Delta)^{-1}(n_s^{2D}(|\chi_1^\varepsilon|^2-\delta(z)))\|^2_{L^2}\geqslant C_0\,\varepsilon^2.$$

This ends the proof.

VII. REMARKS

We considered here a model without exterior potential. The analysis still holds if a regular enough potential is added, for instance, a potential in $L^p(\Omega_0, W^{1,\infty}(\mathbb{R}))$, with $p>2$.

We also assumed that the open set Ω_0 is regular. This hypothesis can be weakened if the boundary conditions prescribed for the Poisson equation are modified: for instance, considering a square, we put Dirichlet boundary conditions in two parallel interfaces and Neumann conditions in the orthogonal ones.

All the analysis presented in the paper strongly relies on the Assumption 2.6 which is essential in order to obtain existence and uniqueness results. We conjecture that all the results still hold if this assumption is replaced by the

Assumption 7.1: The measure μ has a bounded support and there exists δ positive, ε-independent, such that, $\forall i \geqslant 1$,

$$\inf_{\lambda \in supp\ \mu} |E_\lambda - \mathcal{E}_i(0)| > \delta,$$

where the $\mathcal{E}_i$ are the energies of the bound states introduced in Definition 2.8.

This assumption means that the statistics avoids the bound states of the linear open Schrödinger equation, see Ref. 6 for more details. To prove the theorems under this framework, one has to show that the statistics still avoids the bound states when considering a nonzero self-consistent potential. This can be done by a careful analysis of the open Schrödinger equation and by setting a statistics whose total mass is weak enough such that there exists $\eta(\delta)$ such that, $\forall i \geqslant 1$,

$$\inf_{\lambda \in \mathrm{supp}\ \mu} |E_\lambda - \mathcal{E}_i(V^\varepsilon)| > \eta(\delta).$$

On the other hand, following again,[6] a limit absorption procedure can be performed as well. One may add to the energy E^ε, a complex term $i\nu$ with $\nu>0$. Then all the results applies without Assumption 2.6. Then, the limit ν goes to zero has to be investigated and the difficulty in this step is to obtain ν-independent estimates. This will require a precise statement of the rate of convergence in ν in order to preserve the different errors estimates. To conclude, the Assumption 2.6 can be actually weakened but this improvment involves more technicalities than in the present analysis and not directly related to the purpose of this work.

APPENDIX A: THE LINEAR SCHRÖDINGER EQUATION ON OPEN DOMAINS

In this section, we derive the open boundary conditions introduced in Ref. 6 and we give some estimates for the solution of the Schrödinger equation equipped with such conditions. More precisely, we seek a generalized eigenfunction Ψ^ε solution of the Schrödinger equation associated with the energy E^ε, this means

$$-\Delta\Psi^\varepsilon(x,z) + (V_c^\varepsilon(z) + V^\varepsilon(x,z))\Psi^\varepsilon(x,z) = E^\varepsilon\,\Psi^\varepsilon(x,z) \quad \text{in } \Omega\times\mathbb{R}, \tag{A1}$$

$$\Psi^\varepsilon \text{ is bounded}, \tag{A2}$$

$$\Psi^\varepsilon = 0 \quad \text{on } \partial(\Omega\times\mathbb{R}), \tag{A3}$$

where V_c^ε is a confining potential and was defined in Introduction and V^ε is a given regular potential, supported only in $\Omega_0\times\mathbb{R}$. The equation (A1) is, in the lead j,

$$(-\partial_z^2-\Delta_{\xi_j,\eta_j})\Psi^\varepsilon(\xi_j,\eta_j,z)+V_c^\varepsilon(z)\Psi^\varepsilon(\xi_j,\eta_j,z)=E^\varepsilon\,\Psi^\varepsilon(\xi_j,\eta_j,z),\quad j\neq 0, \tag{A4}$$

where ξ_j and η_j are the local coordinates of the lead j, see Fig. 2. The boundary conditions are obtained by explictly solving the Schrödinger equation in each lead. For this purpose, let Θ_m^j and $\mathcal{E}_m^j$, be the eigenfunctions and eigenvalues of the jth transversal Schrödinger operator $-\partial_{\xi_j}^2$ with Dirichlet boundary conditions. Ψ^ε can be written under the form, in the lead j,

$$\Psi^\varepsilon(\eta_j,\xi_j,z)=\sum_p\ \Pi_p^\varepsilon\Psi^\varepsilon=\sum_{p,m}\ \Psi_{p,m,j}^\varepsilon(\eta_j)\Theta_m^j(\xi_j)\chi_p^\varepsilon(z),$$

where $\Psi_{p,m,j}^\varepsilon$ is the component of Ψ^ε on the basis $(\Theta_m^j\otimes\chi_p^\varepsilon)_{p,m}$ and solves

$$-\frac{\partial^2\Psi_{m,p,j}^\varepsilon}{\partial\eta_j^2}=(E^\varepsilon-E_p^\varepsilon-\mathcal{E}_m^j)\Psi_{m,p,j}^\varepsilon. \tag{A5}$$

Hence, setting

$$k_m^j(E^\varepsilon-E_p^\varepsilon)=\sqrt{|E^\varepsilon-E_p^\varepsilon-\mathcal{E}_m^j|},$$

$$N^j(E^\varepsilon-E_p^\varepsilon)=\sup\{m\geqslant 1,\ E^\varepsilon-E_p^\varepsilon>\mathcal{E}_m^j\},$$

we obtain

$$\Psi_{m,p,j}^\varepsilon(\eta_j)=a_{m,p}^j e^{-ik_m^j\eta_j}+b_{m,p}^j e^{ik_m^j\eta_j}\quad\text{if } m\leqslant N^j(E^\varepsilon-E_p^\varepsilon), \tag{A6}$$

$$\Psi_{m,p,j}^\varepsilon(\eta_j)=b_{m,p}^j e^{-k_m^j\eta_j}\quad\text{if } m>N^j(E^\varepsilon-E_p^\varepsilon). \tag{A7}$$

The modes associated with $m\leqslant N^j(E^\varepsilon-E_p^\varepsilon)$ are the propagating modes and the modes associated with $m>N^j(E^\varepsilon-E_p^\varepsilon)$ are the evanescent modes. The coefficients $a_{m,p}^j$ are known whereas the $b_{m,p}^j$ are the reflection–transmission coefficients and deduced from the solution. The boundary conditions on Γ_j are obtained by eliminating the $b_{m,p}^j$ coefficients and the result is,[6,26]

$$\left.\frac{\partial\Psi^\varepsilon}{\partial\eta_j}\right|_{\Gamma_j}=\mathbb{Z}_j^{3\mathrm{D}}[E^\varepsilon](\Psi^\varepsilon)+\mathbb{S}_j^{3\mathrm{D}}[E^\varepsilon], \tag{A8}$$

where

$$\mathbb{Z}_j^{3\mathrm{D}}[E^\varepsilon](\Psi^\varepsilon)=\sum_{p=1}^{\infty}\left(\sum_{m=1}^{N^j(E^\varepsilon-E_p^\varepsilon)} ik_m^j(E^\varepsilon-E_p^\varepsilon)\Psi_{p,m,j}^\varepsilon(0)\,\Theta_m^j(\xi_j)\right.$$

$$\left.-\sum_{m=N^j(E^\varepsilon-E_p^\varepsilon)+1}^{\infty} k_m^j(E^\varepsilon-E_p^\varepsilon)\,\Psi_{p,m,j}^\varepsilon(0)\,\Theta_m^j(\xi_j)\right)\chi_p^\varepsilon,$$

$$\mathbb{S}_j^{3\mathrm{D}}[E^\varepsilon]=-2\sum_{p=1}^{\infty}\sum_{m=1}^{N^j(E^\varepsilon-E_p^\varepsilon)} ik_m^j(E^\varepsilon-E_p^\varepsilon)\,a_{m,p}^j\,\Theta_m^j(\xi_j)\,\chi_p^\varepsilon(z).$$

To summarize, the problem is solved only on the bounded domain $\Omega_0\times\mathbb{R}$ with the boundary conditions (A8) and $\Psi=0$ on ω_0.

We rewrite now these boundary conditions in the case of the nonlinear transport model of Sec. II B 1. According to Assumption 2.4, the energy E^ε is equal to $E_1^\varepsilon + E_\lambda$, where $E_\lambda = E_{m_0}^{j_0} + k^2$ and $a_{m,p}^j = \delta_p^1\, \delta_m^{m_0}\, \delta_j^{j_0}$. This implies that $\mathbb{S}_j^{3D}$ takes the simpler form

$$\mathbb{S}_j^{3D}[E_1^\varepsilon + E_\lambda] = -2\, \delta_j^{j_0}\, ik\, \Theta_{m_0}^j(\xi_j)\, \chi_1^\varepsilon(z).$$

Finally, in order to derive estimates for more general problems, we consider the following system:

$$-\Delta \Psi^\varepsilon(x,z) + (V_c^\varepsilon(z) + V^\varepsilon(x,z))\Psi^\varepsilon(x,z) = (E_1^\varepsilon + E_\lambda)\, \Psi^\varepsilon(x,z) + f(x,z) \quad \text{in } \Omega_0 \times \mathbb{R}, \tag{A9}$$

$$\left.\frac{\partial \Psi^\varepsilon}{\partial \eta_j}\right|_{\Gamma_j} = \mathbb{Z}_j^{3D}[E_1^\varepsilon + E_\lambda](\Psi^\varepsilon) - 2a\, \delta_j^{j_0}\, ik\, \Theta_{m_0}^j(\xi_j)\, \chi_1^\varepsilon(z), \tag{A10}$$

$$\Psi^\varepsilon = 0 \quad \text{on } \omega_0, \tag{A11}$$

where a is a positive parameter and f a given source term. The well-poseness of this system has been studied in Ref. 6.

Proposition A.1: Let Ψ^ε be the solution of (A9)–(A11). Let $f \in L^2(\Omega_0 \times \mathbb{R})$, $V^\varepsilon \in L^\infty(\Omega_0 \times \mathbb{R})$ and V^ε non-negative a.e. Then, under Assumption 2.2, 2.4, and 2.6, we have, uniformly in λ,

$$\|\Psi^\varepsilon\|_{H^1(\Omega_0, L^2(\mathbb{R}))} \leqslant C\,(2a + \|f\|_{L^2}), \tag{A12}$$

$$\|(\mathbb{I} - \Pi_1^\varepsilon)\Psi^\varepsilon\|_{L^2} \leqslant C\,\varepsilon\,(2a + \|f\|_{L^2}), \tag{A13}$$

where C is a generic constant ε-independent.

Proof: Consider the kinetic energy along x and the kinetic energy along z defined by

$$\mathcal{E}_{\text{kin},x}^\varepsilon = \int_{\Omega_0 \times \mathbb{R}} |\nabla_x \Psi^\varepsilon|^2\, dx\, dz, \quad \mathcal{E}_{\text{kin},z}^\varepsilon = \int_{\Omega_0 \times \mathbb{R}} |\partial_z \Psi^\varepsilon|^2\, dx\, dz.$$

The potential energy and the external potential energy are, respectively, defined by

$$\mathcal{E}_{\text{pot}}^\varepsilon = \int_{\Omega_0 \times \mathbb{R}} V^\varepsilon |\Psi^\varepsilon|^2\, dx\, dz, \quad \mathcal{E}_{\text{ext}}^\varepsilon = \int_{\Omega_0 \times \mathbb{R}} V_c^\varepsilon\, |\Psi^\varepsilon|^2 dx\, dz.$$

We introduce also the energy coming from the boundary terms

$$\mathcal{E}_{BC}^\varepsilon = -\sum_{j=1}^n \int_{\Gamma_j \times \mathbb{R}} \left.\frac{\partial \Psi^\varepsilon}{\partial \eta_j}\right|_{\Gamma_j} \overline{\Psi^\varepsilon}\, d\xi_j\, dz.$$

A standard energy estimate for the Schrödinger equation, obtained after multiplication of (A9) by $\overline{\Psi_\lambda^\varepsilon}$ and some integration by parts, yields

$$\mathcal{E}_{\text{kin},x}^\varepsilon + \mathcal{E}_{\text{kin},z}^\varepsilon + \mathcal{E}_{\text{pot}}^\varepsilon + \mathcal{E}_{\text{ext}}^\varepsilon + \text{Re}\, \mathcal{E}_{BC}^\varepsilon = (E_1^\varepsilon + E_\lambda)\|\Psi^\varepsilon\|_{L^2}^2 + \int_{\Omega_0 \times \mathbb{R}} f\, \overline{\Psi^\varepsilon} dx\, dz, \tag{A14}$$

$$\text{Im}\, \mathcal{E}_{BC}^\varepsilon = 0. \tag{A15}$$

Besides, the boundary condition (A10) implies that

$$\mathrm{Re}\,\mathcal{E}^{\varepsilon}_{BC}=\sum_{j=1}^{n}\sum_{p=1}^{\infty}\sum_{m=N^j(E_\lambda+E_1^\varepsilon-E_p^\varepsilon)+1}^{\infty}k_m^j(E_\lambda+E_1^\varepsilon-E_p^\varepsilon)|\Psi^{\varepsilon}_{p,m,j}|^2-2a\,k\,\mathrm{Im}\,\Psi^{\varepsilon}_{1,m_0,j_0}, \tag{A16}$$

$$\mathrm{Im}\,\mathcal{E}^{\varepsilon}_{BC}=\sum_{j=1}^{n}\sum_{p=1}^{\infty}\sum_{m=1}^{N^j(E_\lambda+E_1^\varepsilon-E_p^\varepsilon)}k_m^j(E_\lambda+E_1^\varepsilon-E_p^\varepsilon)|\Psi^{\varepsilon}_{p,m,j}|^2+2a\,k\,\mathrm{Re}\,\Psi^{\varepsilon}_{1,m_0,j_0}=0, \tag{A17}$$

and we first deduce from (A16) and (A17) that

$$|\Psi^{\varepsilon}_{1,m_0,j_0}|\leqslant 2a \tag{A18}$$

$$0\leqslant \mathrm{Re}\,\mathcal{E}^{\varepsilon}_{BC}+2a\,k\,\mathrm{Im}\,\Psi^{\varepsilon}_{1,m_0,j_0}. \tag{A19}$$

Moreover, according to Ref. 6, the operator $-\Delta+V_c^\varepsilon+V^\varepsilon-E_1^\varepsilon$ equipped with (A10) and (A11) with $a=0$, has a compact resolvent and denote $(\mathcal{E}_i^\varepsilon(V^\varepsilon))_{i\in\mathbb{N}^*}$ its spectrum and $(\Phi_i^\varepsilon)_{i\in\mathbb{N}^*}$ its associated eigenvectors. Since $V^\varepsilon\geqslant 0$, then $\mathcal{E}_1^\varepsilon(V^\varepsilon)\geqslant\mathcal{E}_1^\varepsilon(0)$ and it can be easily seen that $\mathcal{E}_1^\varepsilon(0)$ is ε-independent. It follows, after a projection of Ψ^ε on the basis $(\Phi_i^\varepsilon)_{i\in\mathbb{N}^*}$ that

$$\mathcal{E}^{\varepsilon}_{\mathrm{kin},x}+\mathcal{E}^{\varepsilon}_{\mathrm{kin},z}+\mathcal{E}^{\varepsilon}_{\mathrm{pot}}+\mathcal{E}^{\varepsilon}_{\mathrm{ext}}+\mathrm{Re}\,\mathcal{E}^{\varepsilon}_{BC}+2a\,k\,\mathrm{Im}\,\Psi^{\varepsilon}_{1,m_0,j_0}-E_1^\varepsilon\|\Psi^\varepsilon\|_{L^2}^2=\sum_{i\geqslant 1}\mathcal{E}_i^\varepsilon(V^\varepsilon)|(\Psi^\varepsilon,\Phi_i^\varepsilon)|^2.$$

Injecting this relation in (A14) leads to

$$(\mathcal{E}_1^\varepsilon(0)-E_\lambda)\|\Psi^\varepsilon\|_{L^2}^2\leqslant\sum_{i\geqslant 1}(\mathcal{E}_i^\varepsilon(V^\varepsilon)-E_\lambda)|(\Psi^\varepsilon,\Phi_i^\varepsilon)|^2\leqslant 4a^2k+\|f\|_{L^2}\|\Psi^\varepsilon\|_{L^2},$$

where we used (A18) for the second inequality while the first inequality follows from the fact that $\mathcal{E}_i^\varepsilon(0)\leqslant\mathcal{E}_i^\varepsilon(V^\varepsilon)$ since V^ε is positive. We use now crucially Assumption 2.6 which implies that $\mathcal{E}_1^\varepsilon(0)-E_\lambda>C$, where C is ε-independent and this gives the L^2 estimate, uniform in λ,

$$\|\Psi^\varepsilon\|_{L^2}\leqslant C(2a\sqrt{k}+\|f\|_{L^2}). \tag{A20}$$

To conclude the proof, we come back to (A14) and by using (A19) and (A20), we obtain

$$\mathcal{E}^{\varepsilon}_{\mathrm{kin},x}+\mathcal{E}^{\varepsilon}_{\mathrm{kin},z}+\mathcal{E}^{\varepsilon}_{\mathrm{pot}}+\mathcal{E}^{\varepsilon}_{\mathrm{ext}}\leqslant E_1^\varepsilon\|\Psi^\varepsilon\|_{L^2}^2+C(4a^2+\|f\|_{L^2}^2),$$

where C depends on $\sup_{\lambda\in\mathrm{supp}\,\mu}E_\lambda$. Since

$$\mathcal{E}^{\varepsilon}_{\mathrm{kin},z}+\mathcal{E}^{\varepsilon}_{\mathrm{ext}}=\sum_{p=1}^{\infty}E_p^\varepsilon\|\Pi_p^\varepsilon\Psi^\varepsilon\|_{L^2}^2$$

and since V^ε is non-negative, we have $\mathcal{E}^{\varepsilon}_{\mathrm{pot}}\geqslant 0$ and finally

$$\mathcal{E}^{\varepsilon}_{\mathrm{kin},x}+\frac{1}{\varepsilon^2}(E_2-E_1)\|(\mathbb{I}-\Pi_1^\varepsilon)\Psi^\varepsilon\|_{L^2}^2\leqslant C(4a^2+\|f\|_{L^2}^2)$$

which ends the proof. □

APPENDIX B: THE POISSON EQUATION WITH $L^r_xL^1_z$ DENSITIES

This section deals with the regularity of the solution of the Poisson equation

$$-\Delta V=n \quad \text{on} \quad \Omega_0\times\mathbb{R}, \tag{B1}$$

$$V(\cdot,z)=0 \quad \text{on } \partial\Omega_0, \qquad \lim_{|z|\to\infty} V(x,z)=0. \tag{B2}$$

In the whole section, $L^p_x L^q_z$ denotes the spaces introduced in Definition 2.1.

Lemma B.1: (i) Let V be the solution of (B1) and (B2), let $n\in L^r_x L^1_z$ *with* $r\in(1,\infty)$. *Then for* $s<\frac{3}{2}$ *and* $p(1+2s)\leqslant 4r$, *we have*

$$\|V\|_{L^p(\Omega_0,H^s(\mathbb{R}))}\leqslant C\|n\|_{L^r_x L^1_z}. \tag{B3}$$

(ii) Besides, for $s<\frac{1}{2}$ *and* $p(3+2s)\leqslant 4r$, *we have also*

$$\|\nabla_x V\|_{L^p(\Omega_0,H^s(\mathbb{R}))}\leqslant C\|n\|_{L^r_x L^1_z}. \tag{B4}$$

(iii) Let $n\in L^r_x L^1_z$ *such that* $z\,n\in L^r_x L^1_z$, *with* $r\in(1,+\infty)$ *and* $\int_{\mathbb{R}} n(\cdot,z)\mathrm{d}z=0$. *Then, for* $0\leqslant\beta\leqslant 1$, $p\in[2,+\infty)$, $s+\beta<\frac{3}{2}$ *and* $p(1+2(s+\beta)\leqslant 4r$, *we have*

$$\|V\|_{L^p(\Omega_0,H^s(\mathbb{R}))}\leqslant C\|z\,n\|^{\beta}_{L^r_x L^1_z}\|n\|^{1-\beta}_{L^r_x L^1_z}. \tag{B5}$$

(iv) Assume that $n(x,z)=n_s(x)\,(\rho(z)-\delta(z))$ *where* $n_s\in L^r(\Omega_0)$ *with* $r\in(1,+\infty)$, *where* $\rho\in L^1(\mathbb{R})$, *non-negative such that* $z\,\rho\in L^1(\mathbb{R})$ *and* $\|\rho\|_{L^1(\mathbb{R})}=1$. *Then, for* $0\leqslant\beta\leqslant 1$, $p\in[2,+\infty)$, $s+\beta<\frac{3}{2}$ *and* $p(1+2(s+\beta)\leqslant 4r$, *we have*

$$\|V\|_{L^p(\Omega_0,H^s(\mathbb{R}))}\leqslant C\|z\,\rho\|^{\beta}_{L^1}\|n_s\|_{L^r(\Omega_0)}. \tag{B6}$$

Proof: Taking the Fourier transform of (B1) with respect to z leads to

$$-\Delta_x\hat{V}(x,\xi)+\xi^2\,\hat{V}(x,\xi)=\hat{n}(x,\xi),$$

where

$$\hat{V}(x,\xi)=\int_{\mathbb{R}} V(x,z)\,e^{-i\,z\,\xi}\,\mathrm{d}z, \quad \hat{n}(x,\xi)=\int_{\mathbb{R}} n(x,z)\,e^{-i\,z\,\xi}\,\mathrm{d}z. \tag{B7}$$

Since $-\Delta_x$, equipped with Dirichlet boundary conditions on Ω_0, is a sectorial operator on $L^p(\Omega_0)$, for $p\in(1,+\infty)$, we have

$$\|\hat{V}(\cdot,\xi)\|_{L^p(\Omega_0)}\leqslant\frac{1}{\xi^2}\|-\Delta_x\hat{V}(\cdot,\xi)+\xi^2\hat{V}(\cdot,\xi)\|_{L^p(\Omega_0)}\leqslant\frac{1}{\xi^2}\|\hat{n}(\cdot,\xi)\|_{L^p(\Omega_0)}. \tag{B8}$$

Moreover, (B8), (B7), and standard elliptic estimates imply

$$\|\hat{V}(\cdot,\xi)\|_{W^{2,p}(\Omega_0)}\leqslant C\|\hat{n}(\cdot,\xi)\|_{L^p(\Omega_0)}, \tag{B9}$$

where C does not depend on ξ. Besides, for $p\geqslant 2$, we have thanks to the Hölder inequality,

$$\begin{aligned}\|V\|^p_{L^p(\Omega_0,H^s(\mathbb{R}))}&=\int_{\Omega_0}\left(\int_{\mathbb{R}}(1+\xi^{2s})\,|\hat{V}(x,\xi)|^2\,\mathrm{d}\xi\right)^{p/2}\mathrm{d}x\\&\leqslant\left\|\frac{1}{1+\xi^{\alpha}}\right\|_{L^{p/(p-2)}(\mathbb{R})}\int_{\Omega_0}\int_{\mathbb{R}}(1+\xi^{(2s+\alpha)p/2})\,|\hat{V}(x,\xi)|^p\,\mathrm{d}\xi\,\mathrm{d}x\\&\leqslant C\int_{\mathbb{R}}(1+\xi^{(2s+\alpha)p/2})\,\|\hat{V}(\cdot,\xi)\|^r_{L^r(\Omega_0)}\|\hat{V}(\cdot,\xi)\|^{p-r}_{L^\infty(\Omega_0)}\,\mathrm{d}\xi,\end{aligned} \tag{B10}$$

as soon as

$$0 \leqslant 1-\frac{2}{p} < \alpha, \quad 1 \leqslant r \leqslant p \leqslant \infty.$$

Coupling now (B8) and (B9) and using the embedding $W^{2,r}(\Omega_0) \hookrightarrow L^\infty(\Omega_0)$, for $r>1$, leads to

$$\begin{aligned}\|V\|^p_{L^p(\Omega_0,H^s(\mathbb{R}))} &\leqslant C\int_{\mathbb{R}} (1+\xi^{(2s+\alpha)p/2})\,\|\hat{V}(\cdot,\xi)\|^r_{L^r(\Omega_0)}\,\|\hat{V}(\cdot,\xi)\|^{p-r}_{W^{2,r}(\Omega_0)}\,\mathrm{d}\xi \\ &\leqslant C\int_{\mathbb{R}} (1+\xi^{2r-(2s+\alpha)p/2})^{-1}\,\|\hat{n}(\cdot,\xi)\|^p_{L^r(\Omega_0)}\,\mathrm{d}\xi \\ &\leqslant C\|n\|^p_{L^r_x L^1_z} \quad \text{if } \frac{1}{\xi^{2r-(2s+\alpha)p/2}} \in L^1([1,+\infty)),\end{aligned} \tag{B11}$$

where we used the fact that $|\hat{n}(x,\xi)| \leqslant \|n(x,\cdot)\|_{L^1(\mathbb{R})}$. After some easy algebra, this gives the final conditions for (B3),

$$2 \leqslant p < \infty, \quad s \leqslant \tfrac{3}{2}, \quad p(1+2s) < 4r.$$

For (B4), we use a classical interpolation equality in Ref. 13 which insures that

$$\|\nabla_x \hat{V}\|_{L^p(\Omega_0)} \leqslant C\|\Delta_x \hat{V}\|^{1/2}_{L^r(\Omega_0)}\ \ \|\hat{V}\|^{1/2}_{L^t(\Omega_0)} \leqslant C\|\Delta_x \hat{V}\|^{1/2}_{L^r(\Omega_0)}\ \ \|\hat{V}\|^{r/2r}_{L^r(\Omega_0)}\ \ \|\hat{V}\|^{1/2[1-(r/t)]}_{L^\infty(\Omega_0)} \tag{B12}$$

with $1/p = \frac{1}{2}[(1/t) + (1/r).]$ This inequality implies, together with (B8), (B9), for $t \geqslant r > 1$,

$$\|\nabla_x \hat{V}\|_{L^p(\Omega_0)} \leqslant \frac{C}{\xi^{r/t}} \|\hat{n}\|_{L^r(\Omega_0)}. \tag{B13}$$

Replacing V by $\nabla_x V$ in (B11), using estimates (B9) and (B13), we obtain by proceeding as for (B11),

$$\begin{aligned}\|\nabla_x V\|^p_{L^p(\Omega_0,H^s(\mathbb{R}))} &\leqslant \left\| \frac{1}{1+\xi^\alpha} \right\|_{L^{p/(p-2)}(\mathbb{R})}\ \int_{\Omega_0}\int_{\mathbb{R}} (1+\xi^{(2s+\alpha)p/2})\,|\nabla_x \hat{V}(x,\xi)|^p\,\mathrm{d}\xi\,\mathrm{d}x \\ &\leqslant C\int_{\mathbb{R}} (1+\xi^{rp/t-(2s+\alpha)p/2})^{-1}\,\|\hat{n}(\cdot,\xi)\|^p_{L^r(\Omega_0)}\,\mathrm{d}\xi \leqslant C\|n\|^p_{L^r_x L^1_z}\end{aligned}$$

as soon as

$$0 \leqslant 1-\frac{2}{p} < \alpha, \quad \frac{1}{p} = \frac{1}{2}\left(\frac{1}{t}+\frac{1}{r}\right), \quad r \leqslant t, \quad \frac{rp}{t} - \frac{1}{2}(2s+\alpha)p > 1.$$

This concludes the proof of (B4) after some easy manipulations.

We end now the proof of Lemma B.1 by proving (B5). If $\int_{\mathbb{R}} n\,\mathrm{d}z = 0$, it can easily remarked that

$$\left|\frac{\hat{n}(x,\xi)}{\xi}\right| = \left|\frac{1}{\xi}\int_{\mathbb{R}} (e^{-i\,z\,\xi}-1)n(x,z)\,\mathrm{d}z\right| \leqslant \|z n(x,.)\|_{L^1(\mathbb{R})},$$

since $|e^{-i\,z\,\xi}-1| \leqslant |z\,\xi|$, $\forall (k,\xi) \in \mathbb{R}^2$. This leads to, thanks to (B11),

$$\|V\|^p_{L^p(\Omega_0,H^s(\mathbb{R}))} \leqslant C\int_{\mathbb{R}} (1+\xi^{2r-(2s+\alpha)p/2-\beta p})^{-1}\left(\frac{\|\hat{n}(\cdot,\xi)\|^p_{L^r(\Omega_0)}}{\xi^p}\right)^{\beta}(\|\hat{n}(\cdot,\xi)\|^p_{L^r(\Omega_0)})^{1-\beta}\,\mathrm{d}\xi$$

$$\leqslant C\|z\,n\|^{\beta p}_{L^r_x L^1_z}\|n\|^{(1-\beta)p}_{L^r_x L^1_z} \quad \text{if} \quad \frac{1}{\xi^{2r-(2(s+\beta)+\alpha)p/2}} \in L^1([1,+\infty)),$$

which gives the result.

For (B6), we just remark that

$$\hat{n}(x,\xi) = n_s(x)\int_{\mathbb{R}} (e^{-i\,z\,\xi}-1)\rho(z)\,\mathrm{d}z$$

which is exactly the same form as above. □

In the same way, if n is given by $n(x,z) := n_s(x)\,\delta(z)$, we have the following.

Lemma B.2: (i) Let V be the solution of (B1) and (B2) with $n(x,z) := n_s(x)\delta(z)$, *where* $n_s \in L^r(\Omega_0)$ *with* $r \in (1,\infty)$. *Then, for* $s < \frac{3}{2}$ *and* $p(1+2s) \leqslant 4r$, *we have*

$$\|V\|_{L^p(\Omega_0,H^s(\mathbb{R}))} \leqslant C\|n\|_{L^r(\Omega_0)}. \tag{B14}$$

Besides, for $s < \frac{1}{2}$ *and* $p(3+2s) \leqslant 4r$, *we have also*

$$\|\nabla_x V\|_{L^p(\Omega_0,H^s(\mathbb{R}))} \leqslant C\|n\|_{L^r(\Omega_0)}. \tag{B15}$$

(Received 22 July 2003; accepted 8 February 2004; published 13 April 2004)

''Pseudo-cohomology,'' as a refinement of Lie group cohomology, is soundly studied aiming at classifying the symplectic manifolds associated with Lie groups. In this study, the framework of symplectic cohomology provides fundamental new insight, which enriches the analysis previously developed in the setting of Cartan–Eilenberg $H^2(G,\mathrm{U}(1))$ cohomology. © *2004 American Institute of Physics.*

I. INTRODUCTION

From the strict mathematical point of view, the orbits of the coadjoint representation of Lie groups provide a source for symplectic manifolds on which a given Lie group acts as a group of symplectomorphisms, i.e., G-symplectic manifolds. Even, for finite-dimensional semisimple groups, this mechanism essentially exhausts all models of they. These G-symplectic manifolds could then be considered as phase spaces of physical systems for which G can be called the ''basic symmetry.'' From the physical point of view, however, the simplest physical systems (the free nonrelativistic particle, for instance) possess a phase space endowed with a symplectic form whose associated Poisson bracket realizes the Lie algebra of a central extension of the basic ''classical'' symmetry. Central extensions of Lie groups by U(1), associated with projective unitary representations, were classified long ago by Bargmann[1] by means of the cohomology group $H^2(G,\mathrm{U}(1))$.[2] Later, the momentum map from the phase space to the coalgebra $\mathcal{G}^*$ of the basic ''classical'' symmetry group, constructed with the set of Noether invariants of the physical system, was used by Souriau[3] to define the symplectic cohomology group $H^1_S(G,\mathcal{G}^*)$ characterizing equivalently the central extensions of a simply connected group G.

In this paper we revisit the notion of Lie group ''pseudo-cohomology'' in an attempt to classify all possible (quantizable) G-symplectic manifolds for an arbitrary Lie group G, in such a way that both coadjoint orbits and phase spaces realizing central extensions can be put together into (''pseudo''-)cohomology classes. By the way, the prefix ''pseudo'' had its origin[4] in the fact that the corresponding central extensions are trivial from the mathematical point of view, the associated cocycle being a coboundary, although they behave as if they were non-trivial in some aspects, as we shall show.

Our study here is made in the language of symplectic cohomology of Lie groups. The insight provided by the natural and explicit role of phase spaces in symplectic cohomology offers a more intuitive understanding of the significance of pseudo-cohomology in classifying dynamics, as well as an easier mathematical handling which allows a generalization of the mathematical results obtained in its original presentation.[5,6]

Roughly speaking, pseudo-cohomology emerges as a refinement of the equivalence classes of 2-cocycles in the cohomology group $H^2(G,\mathrm{U}(1))$. The first clues for the need of such a refinement occurred when studying the problem of the Inönü-Wigner contraction of centrally extended

Lie groups (see Saletan[7]). An example of this need appears in the contraction Poincaré $\rightarrow$Galileo where a special kind of trivial 2-cocycles in the Poincaré group, become true (nontrivial) 2-cocycles for the Galileo group in the $c\rightarrow\infty$ limit. The underlying reason is that, while the 2-cocycle is well-behaved in the limit, its generating function is not, thus occurring a generation of cohomology.[4] The second indication for the need of pseudo-cohomology appeared in the context of generalized Hopf fibrations of semi-simple Lie groups related to Čech (true, i.e., noncoboundary) cocycles of coadjoint orbits. Such pseudo-cocycles play in fact a fundamental role in the explicit construction of the local exponent associated with Lie-algebra cocycles of the corresponding Kac–Moody groups.[8]

In spite of these antecedents, the importance of pseudo-cohomology is more evident in the framework of Group Approach to Quantization (GAQ), a group theoretical quantization scheme designed for obtaining the dynamics of a physical system out of a Lie group.[9] In particular, GAQ starts from a central extension $\tilde{G}$ of a Lie group G by U(1) in such a way that the symplectic form of the classical phase space is derived from the 2-cocycle which defines the central extension. Nevertheless, the correspondence between central extensions and symplectic forms is not one-to-one. The most obvious illustration of this is the case of groups with trivial cohomology group $H^2(G,\mathrm{U}(1))$ (such as the Poincaré group in $3+1$ dimensions or finite-dimensional semisimple groups). In fact, even though these groups do not admit nontrivial central extensions, genuine symplectic structures and dynamics can be derived out of them.[4,8] The rationale for this is the existence of 2-cocycles which are coboundaries, and therefore trivial from the cohomological point of view, but which do define authentic symplectic structures. Coboundaries with this property are called *pseudo-cocycles*, giving rise to trivial central extension referred to as *pseudo-extensions*.

The study of this mechanism and the characterization of the classes of pseudo-extensions associated with nonequivalent symplectic structures, led in an explicit way to the notion of pseudo-cohomology, constituting the more systematic and clarifying approach to the problem.[5,6] This *standard* view of pseudo-cohomology is described in the next section.

II. PSEUDO-COHOMOLOGY IN GAQ

As commented in the introduction, GAQ is a formalism devised for obtaining the (quantum or classical) dynamics of a physical system out of a Lie group (of its symmetries). The starting point is a central extension $\tilde{G}$ of the symmetry group G by U(1) (or $\mathbb{R}$ to recover the classical dynamics), determined by a 2-cocycle (local exponent) $\xi: G\times G\rightarrow\mathbb{R}$. The group law then reads

$$g''=g'*g, \quad \zeta''=\zeta'\zeta e^{i\xi(g',g)}, \tag{1}$$

where $g'',g',g\in G$ and $\zeta'',\zeta',\zeta\in\mathrm{U}(1)$. On the Lie group $\tilde{G}$ we have at our disposal left- and right-invariant vector fields. If we choose a coordinate system $(\{g^i\}_{i=1}^{\dim G},\zeta)$ in $\tilde{G}$, a basis for the vector fields is given by $\tilde{X}_i^L$ and $\tilde{X}_i^R$, respectively, and their dual sets of left- and right-invariant 1-forms are denoted by $\theta^{L(i)}$ and $\theta^{R(i)}$, respectively. One of the left-invariant 1-forms, $\Theta\equiv\theta^{L(\zeta)}$, the U(1)-component of the left-invariant canonical 1-form on the Lie group $\tilde{G}$, is chosen as the connection 1-form of the principal bundle $\mathrm{U}(1)\rightarrow\tilde{G}\rightarrow G$, thus defining a notion of *horizontality*.

This connection 1-form, named the quantization 1-form, depends directly on the 2-cocycle ξ and can be used to define a symplectic structure in a unique manner. In fact, if $\mathcal{G}_\Theta$ is the characteristic distribution of Θ, i.e., the intersection of the kernel of Θ and $\mathrm{d}\Theta$, then $\tilde{G}/\mathcal{G}_\Theta$ is a quantum manifold P.[9,10] This means that $\tilde{G}/\mathcal{G}_\Theta$ is a contact manifold with contact 1-form $\Theta|_P$. The quantum manifold P is in turn a U(1) Principal bundle $\mathrm{U}(1)\rightarrow P\xrightarrow{\pi}S$ with base a symplectic manifold, $S=P/\mathrm{U}(1)$ endowed with a symplectic form ω such that $\pi^*\omega=\mathrm{d}\Theta$.

The symplectic structure (S,ω) is not completely determined by the cohomology class to which the 2-cocycle ξ belongs. In fact, different yet cohomologous 2-cocycles can lead to completely different symplectic structures (S,ω) (think, for instance, of a semisimple Lie group, with trivial cohomology but with many different kinds of symplectic structures determined by its coadjoit orbits). This phenomenon suggests, again, a refinement in the classification of 2-cocycles in such a way that a one-to-one correspondence between the refined classes and the symplectic structures could be established. This refinement will define pseudo-cohomology. Therefore, the latter is intrinsically tied to the classification of possible symplectic structures constructed out of a Lie group.

The main idea for the definition of these subclasses in $H^2(G,\mathrm{U}(1))$ can be intuited from the expression of Θ in terms of the 2-cocycle ξ:

$$\Theta = \frac{\mathrm{d}\zeta}{i\zeta} + \left.\frac{\partial \xi(g',g)}{\partial g^i}\right|_{g'=g^{-1}} \mathrm{d}g^i. \tag{2}$$

If, now, a 2-coboundary $\xi_\lambda(g',g)=\lambda(g'*g)-\lambda(g')-\lambda(g)$ generated by the function $\lambda: G \to \mathbb{R}$, is added to ξ, the expression for the new quantization 1-form Θ' [as the U(1)-component of the canonical 1-form for the centrally extended Lie group defined by $\xi+\xi_\lambda$] is given by

$$\Theta' = \Theta + \Theta_\lambda = \Theta + \lambda_i^0 \theta^{L(i)} - \mathrm{d}\lambda, \tag{3}$$

where $\lambda_i^0 \equiv [\partial\lambda(g)/\partial g^i]|_{g=e}$. Thus, the new term Θ_λ added to the connection 1-form Θ by the inclusion of a 2-coboundary depends only, up to a total differential, on the gradient at the identity λ^0 of the generating function $\lambda(g)$. In fact, if we denote $\Theta_{\lambda^0}=\lambda_i^0\theta^{L(i)}$, then the total differential disappears when the presymplectic 2-form $\mathrm{d}\Theta$ is considered, in such a way that $\mathrm{d}\Theta' = \mathrm{d}\Theta + \mathrm{d}\Theta_{\lambda^0}$.

From these considerations two conclusions can be drawn:

(i) A 2-coboundary contributes nontrivially to the connection 1-form Θ and to the symplectic structure determined by $\mathrm{d}\Theta$, if and only if $\lambda^0 \neq 0$.

(ii) This contribution depends only (up to a total differential, which does not affect the symplectic structure) on the local properties of the generating function $\lambda(g)$ at the identity of the group, through its gradient at the identity λ^0.

A 2-coboundary ξ_λ such that $\lambda^0 \neq 0$ is named a *pseudo-cocycle*. The name reflects the fact that they are trivial 2-cocycles but, from the dynamical point of view, behave as if they were nontrivial. If we consider the group G centrally extended by this pseudo-cocycle ξ_λ, the extended group $\tilde{G}$ is isomorphic to $G\times\mathrm{U}(1)$. However, we will refer to this extension as a *pseudo-extension*, to underline the fact that, although trivial as a central extension, it can lead to a nontrivial symplectic structure and nontrivial dynamics.

The next point to explore is the conditions under which two different 2-coboundaries, ξ_λ and $\xi_{\lambda'}$, generated by functions λ and λ' with different gradients at the identity λ^0 and λ'^0, determine the same symplectic structure (S,ω), up to symplectomorphisms. This condition will define a refined equivalence relation inside each cohomology class. For the sake of simplicity, we shall restrict ourselves to simply connected Lie groups.

The clue in the definition of the new equivalence relation is given by the fact that λ^0 defines an element of $\mathcal{G}^*$, the dual of the Lie algebra $\mathcal{G}$ of G, usually named the *coalgebra*. This can be seen by noting that $\Theta_{\lambda^0}=\lambda_i^0\theta^{L(i)}$ defines, at the identity of G, an element of $\mathcal{G}^*$ given by $\Theta_{\lambda^0}|_{g=e}=\lambda^0$. It is also important to note that $\Theta_\lambda|_{g=e}=0\in\mathcal{G}^*$ (due to the presence of $\mathrm{d}\lambda$), in such a way that the quantization 1-form Θ verifies $\Theta|_{g=e}=(0,\ldots,0,1)\in\tilde{\mathcal{G}}^*$, whatever the 2-cocycle ξ we are considering (here $\tilde{\mathcal{G}}^*$ is the dual of the extended algebra $\tilde{\mathcal{G}}$ associated with the extended group $\tilde{G}$). This fact will be of relevance in the relationship between pseudo-cohomology and symplectic cohomology.

Once we have established that $\lambda^0 \in \mathcal{G}^*$, it is natural to propose their classification in accordance with the coadjoint orbits. This will prove to be the correct ansatz, provided we use the correct coadjoint action.

A bit of notation is in order. Let us denote the equivalence class of the cocycle ξ, defining a certain central extension $\tilde{G}$ of G by U(1), by $[[\xi]] \in H^2(G,\mathrm{U}(1))$. We are going to introduce a further partition in each class $[[\xi]]$ into equivalence subclasses $[\xi]$.

For the sake of clarity, we shall firstly define this partition for the trivial cohomology class $[[\xi]]_0$, made out of trivial cocycles, i.e., 2-coboundaries ξ_λ. This would be enough for groups with trivial cohomology $H^2(G,\mathrm{U}(1))=0$ (that is, with only the trivial class), such as finite-dimensional semisimple groups or the Poincaré group (in $3+1$ dimensions). It is also valid for fully centrally extended groups $\tilde{G}$, for which $H^2(\tilde{G},\mathrm{U}(1))=0$. The case of groups with nontrivial cohomology or nonfully central-extended groups $\tilde{G}$, with $H^2(\tilde{G},\mathrm{U}(1))\neq 0$, will be considered in Sec. II B.

A. The trivial class

Given a Lie group G, a natural action of G on $\mathcal{G}^*$ is provided by the coadjoint action *Coad*, defined as the dual of the adjoint action of G on $\mathcal{G}$. More explicitly, with the adjoint action of G on $\mathcal{G}$ given by $Adg(X)=(R^T_{g^{-1}}L^T_g)(e)\cdot X$, where $g\in G$, $X\in\mathcal{G}$ and L^T_g, R^T_g stand for the tangent application to the left and right translations, respectively, the coadjoint action $Coad{:}G \rightarrow Aut(\mathcal{G}^*)$ has the form $Coad(g)\mu(X)=\mu(Adg^{-1}(X))$, where $\mu\in\mathcal{G}^*$. It is also convenient to make explicit the infinitesimal version of this action. Linearizing on the g variable we obtain the coadjoint action of the Lie algebra on the coalgebra: $(Coad)^T(e)\equiv coad{:}\mathcal{G}\rightarrow End(\mathcal{G}^*)$. Its explicit expression is given by $coadX(\mu)(Y)=\mu(ad\ \ X(Y))=\mu([X,Y])$, with $X,Y\in\mathcal{G}$ and $\mu \in \mathcal{G}^*$.

The orbits of this action are specially relevant in our study. Given a point $\mu\in\mathcal{G}^*$, the orbit through this point by the action of the whole group G is $Orb(\mu)=\{Coad(g)\mu \ / \ g\in G\}$, diffeomorphic to G/G_μ where G_μ is the isotropy group of μ. The coadjoint action determines a foliation of $\mathcal{G}^*$ in orbits, in such a way that any point belongs to one (and just one) orbit [by definition, the point μ belongs to $Orb(\mu)$], and two points in the same orbit are always connected by the coadjoint action.

Coadjoint orbits of Lie groups are interesting from the physical point of view since they possess a natural symplectic structure $[Orb(\mu),\omega]$ with the symplectic form given by

$$\omega_\nu(X_\nu,Y_\nu)=\nu([X,Y]),X_\nu,Y_\nu\in T_\nu(Orb(\mu)), \tag{4}$$

where $\nu\in Orb(\mu)\subset\mathcal{G}^*$, $X_\nu,Y_\nu\in T_\nu(Orb(\mu))$ and $X\in\mathcal{G}$ is related to $X_\nu\in T_\nu(Orb(\mu))$ by $X_\nu = coad(X)\nu$, and analogously for Y_ν and Y (note we are using the fact that $\mathcal{G}^*$ is a linear space in order to identify its points with tangent vectors).

There is a close relationship between pseudo-extensions and coadjoint orbits, that can be stated as follows. A pseudo-extension characterized by the generating function $\lambda(g)$ with gradient at the identity $\lambda^0\neq 0$ defines a presymplectic form $\mathrm{d}\Theta_\lambda=\mathrm{d}\Theta_{\lambda^0}$ depending only on λ^0. In the trivial case we are discussing in this section, the quotient of $\tilde{G}$ by the characteristic subalgebra $\mathcal{G}_{\Theta_{\lambda^0}}\equiv\ker\Theta_\lambda\cap\ker\mathrm{d}\Theta_{\lambda^0}$, defines a quantum manifold P, and the quotient $S=\tilde{G}/(G_{\Theta_{\lambda^0}}\times\mathrm{U}(1)) \sim G/G_{\Theta_{\lambda^0}}$ is a symplectic manifold with symplectic form ω_{λ^0} given by $\pi^*\omega_{\lambda^0}=\mathrm{d}\Theta_{\lambda^0}$, where $\pi{:}\ P\rightarrow S$ is the canonical projection and $G_{\Theta_{\lambda^0}}$ is the (connected) subgroup associated with $\mathcal{G}_{\Theta_{\lambda^0}}$. $G/G_{\Theta_{\lambda^0}}$ is in fact locally diffeomorphic to a coadjoint orbit (the one passing through λ^0). This can be seen by noting the following:

(a) The presymplectic form adopts the expression

$$\mathrm{d}\Theta_{\lambda^0}=\tfrac{1}{2}\lambda^0_k C^k_{ij}\theta^{L(i)}\wedge\theta^{L(j)}, \tag{5}$$

when using the Maurer–Cartan equations, and therefore,

$$d\Theta_{\lambda^0}(X_i^L, X_j^L) = \lambda_k^0 C_{ij}^k = \lambda^0([X_i^L, X_j^L]) \tag{6}$$

where $\{X_i^L\}$ is a basis for $\mathcal{G}$ and $\lambda^0 \in \mathcal{G}^*$, thus reproducing (4) (before falling down to the quotient).

(b) The characteristic group $G_{\Theta_{\lambda^0}}$ coincides with (the connected component of) the isotropy group of λ^0, G_{λ^0} under the coadjoint action, thus defining (locally) the same quotient space. At the infinitesimal level, a vector $Y = Y^i X_i^L$ belongs to $\mathcal{G}_{\Theta_{\lambda^0}}$ if $Y^i \lambda_k^0 C_{ij}^k = 0, \forall j$, which is the same condition for Y to belong to $\mathcal{G}_{\lambda^0}$.

Using the transformation properties of left-invariant 1-forms under translation by the group, it is easy to check that

$$Ad(g)^*(\Theta_{\lambda^0}) = \Theta_{Coad(g)\lambda^0}, \tag{7}$$

where $Ad(g)^*$ denotes the pull-back of the adjoint action of the group on itself (conjugation), acting on $\theta^{L(i)}$, and on the right-hand side $Coad(g)$ acts on λ^0.

Although the connection 1-form is given by Θ_λ rather than Θ_{λ^0}, the symplectic form is determined by just λ^0, and it transforms in a similar way,

$$Ad(g)^*(d\Theta_{\lambda^0}) = d\Theta_{Coad(g)\lambda^0}. \tag{8}$$

These results can be summarized in the following proposition.

Proposition 1: Let G be a Lie group and consider two coboundaries ξ_{λ_1} and ξ_{λ_2} with generating functions $\lambda_1(g)$ and $\lambda_2(g)$, defining the (trivial) central extensions $\tilde{G}_1$ and $\tilde{G}_2$, respectively. If Θ_{λ_1} and Θ_{λ_2} are the quantization one-forms associated with each group, and $G_{\Theta_{\lambda_1^0}}$ and $G_{\Theta_{\lambda_2^0}}$ their respective characteristic subgroups, the two symplectic spaces $\tilde{G}_1/(G_{\Theta_{\lambda_1^0}} \times \mathrm{U}(1))$ and $\tilde{G}_2/(G_{\Theta_{\lambda_2^0}} \times \mathrm{U}(1))$, with symplectic forms given by $\omega_{\lambda_1^0}$ and $\omega_{\lambda_2^0}$ such that $d\Theta_{\lambda_1^0} = \pi^* \omega_{\lambda_1^0}$ and $d\Theta_{\lambda_2^0} = \pi^* \omega_{\lambda_2^0}$, respectively, are symplectomorphic if there exists $h \in G$ such that

$$\lambda_1^0 = Coad(h)\lambda_2^0, \tag{9}$$

the symplectomorphism being given by $Ad(h)$:

$$d\Theta_{\lambda_1^0} = Ad(h)^* \, d\Theta_{\lambda_2^0}. \tag{10}$$

Proof: It simply remains to prove that the two spaces $\tilde{G}_1/(G_{\Theta_{\lambda_1^0}} \times \mathrm{U}(1))$ and $\tilde{G}_2/(G_{\Theta_{\lambda_2^0}} \times \mathrm{U}(1))$ are diffeomorphic. Since the extensions are trivial, $\tilde{G}_i$, $i = 1,2$ are isomorphic to $G \times \mathrm{U}(1)$, therefore $\tilde{G}_i/(G_{\Theta_{\lambda_i^0}} \times \mathrm{U}(1)) \approx G/G_{\Theta_{\lambda_i^0}}$, $i = 1,2$. If $\lambda_1^0 = Coad(h)\lambda_2^0$, then $G_{\Theta_{\lambda_1^0}}$ and $G_{\Theta_{\lambda_2^0}}$ are conjugated subgroups by the adjoint action and this implies that the two spaces $G/G_{\Theta_{\lambda_i^0}}$, $i = 1,2$ are diffeomorphic.

This suggests us to define the equivalence relation in $[[\xi]]_0$ in the following way.

Definition 1: Two coboundaries ξ_λ and $\xi_{\lambda'}$ with generating functions λ and λ', respectively, belong to the same equivalence subclass $[\xi]$ of $[[\xi]]_0$ if and only if the gradients at the identity of the generating functions are related by

$$\lambda^{0\prime} = Coad(g)\lambda^0, \tag{11}$$

for some $g \in G$.

We shall denote by $[\xi]_{\lambda^0}$ the equivalence class of coboundaries "passing through" λ^0. The equivalence relation introduced in this way will be named pseudo-cohomology, even though this

equivalence relation does not define a cohomology in the usual sense, and the subclass of (trivial) central extensions defined by all $\xi_\lambda \in [\xi]_{\lambda^0}$ will be called the central pseudo-extension associated with $[\xi]_{\lambda^0}$.

The condition $\lambda^{0\prime} = Coad(g)\lambda^0$ means that λ^0 and $\lambda^{0\prime}$ are related by the coadjoint action of the group G. Therefore, λ^0 and $\lambda^{0\prime}$ lie in the same coadjoint orbit of G in $\mathcal{G}^*$. A pseudo-cohomology class is therefore directly associated with a coadjoint orbit in $\mathcal{G}^*$.

If $\lambda^{0\prime} = \lambda^0$, then ξ_λ, $\xi_{\lambda'} \in [\xi]_{\lambda^0}$. Thus, we can always choose a representative element in each subclass "linear" in the local coordinate system, $\xi_{\lambda^0}(g) = \lambda^0_i g^i$. If the local coordinates $\{g^i\}$ are canonical, and if we restrict ourselves to canonical 2-cocycles (see Ref. 1), then two cohomologous 2-cocycles differ in a 2-coboundary ξ_λ with $\lambda(g)$ linear in the canonical coordinates. Then pseudo-cohomology is a further partition of "linear" coboundaries into equivalence classes through the coadjoint action of the group G on $\mathcal{G}^*$ (for the trivial class, at the moment).

However, the correspondence between pseudo-cohomology classes and coadjoint orbits for a Lie group G is not onto. The relation is established in the following theorem.

Proposition 2: Pseudo-cohomology classes are associated with coadjoint orbits which satisfy an integrality condition: the symplectic 2-form ω naturally defined on the coadjoint orbit by (4) has to be of integer class.

In fact, this integrality condition is required for ξ_{λ^0} to define a global coboundary on G; nonintegral coadjoint orbits of G cannot be related to central pseudo-extensions of G, since they do not define a proper (global) Lie group.

Proof: A (pseudo-)centrally extended Lie group gives rise to a quantum manifold in the sense of geometric quantization (see Sec. II) when taking quotient by the characteristic subalgebra.[9] Therefore, as a consequence of the necessary and sufficient condition for the existence of a quantization of a given symplectic manifold (see Refs. 10 and 9), the closed 2-form on the coadjoint orbit is of integer class.

Let us see another way of looking at the integrality condition. The vector λ^0 is an element of $\mathcal{G}^*$ and, therefore, it is a linear mapping from $\mathcal{G}$ to $\mathbb{R}$. It is easy to check that when restricted to $\mathcal{G}_{\lambda^0}$ (the Lie algebra of the isotropy group G_{λ^0} of the coadjoint orbit passing through λ^0), λ^0 defines a one-dimensional representation of the latter. Then, the integrality condition on the coadjoint orbit parallels the requirement for λ^0 of being exponentiable (integrable) to a unitary character of the group G_{λ^0} (note however that this remark resorts to the level of representation theory of the group, whereas the above-stated theorem involves only the Lie group structure).

This relationship between integrality condition of the coadjoint orbit and "integrality" of the character defined by λ^0 reveals, in passing, that the coadjoint orbit method of Kostant–Kirillov,[11,12] intended to obtain unitary irreducible representations of Lie groups using (what in Physics is now known as) geometric quantization[10] on coadjoint orbits of Lie groups, is a particular case of the induced representation technique of Mackey.[13]

Let us denote by $\check{G}$ the central pseudo-extension of G, characterized by ξ_{λ^0}. It defines a central pseudo-extension of $\mathcal{G}$:

$$[\check{X}^L_i, \check{X}^L_j] = C^k_{ij}(\check{X}^L_k + \lambda^0_k X_0), \tag{12}$$

where X_0 is the (central) generator associated with U(1) (our convention is to take $X_0 = iI$ in any faithful unirrep of $\check{G}$). The left-invariant vector fields of $\check{G}$ (denoted with check) are related to those of G by

$$\check{X}^L_i = X^L_i + (X^L_i \lambda - \lambda^0_i) X_0, \tag{13}$$

with a similar relation for the right-invariant vector fields.

From this point of view, central pseudo-extensions are on the same footing as true (nontrivial) central extensions, and we can employ with them the same techniques for obtaining (projective) unirreps of G (especially for semisimple Lie groups). Once a projective representation of G

(which is a true representation of $\check{G}$, the pseudo-extended group) has been obtained in this way, in order to obtain the true (nonprojective) representations of G associated with it we simply redefine the generators in the following way:

$$\check{X}_i^L \to \check{X}_i^L + \lambda_i^0 X_0 = X_i^L + (X_i^L \lambda) X_0 , \tag{14}$$

or, equivalently, redefine the functions of the Hilbert space carring the representation by multiplying them by an appropriate factor.

B. Nontrivial classes

Let us consider now nontrivial cohomology classes $[[\xi]] \neq [[\xi]]_0$, in the case of groups G with nontrivial cohomology, or extended groups $\tilde{G}$ which still admit further central extensions, that is, with $H^2(\tilde{G}, \mathrm{U}(1)) \neq 0$.

In order to proceed, a representative element $\xi \in [[\xi]]$ must be chosen. We can add to ξ a coboundary ξ_λ generated by a function λ, with nontrivial gradient at the identity of G. The resulting cocycle $\xi' = \xi + \xi_\lambda$ defines a new central extension $\tilde{G}'$ of G isomorphic, from the group-theoretical point of view, to $\tilde{G}$. The question is whether these pseudo-extensions can be classified into equivalence classes leading to the same symplectic structures, as in the case of the trivial class of Sec. II A. The naive classification in coadjoint orbits of the group G does not work in this case (since there is a mixture of true cohomology and pseudo-cohomology), and there is no clue, at this level, of how the classification should be done.

The direct relation between pseudo-cohomology and coadjoint orbits obtained for the trivial class, allows us to resort to symplectic cohomology, as a tool for classifying symplectic structures (see Sec. III), to come in our help. In this framework, it will be shown that a classification of pseudo-cocyles in the nontrivial classes is possible and entails a slight generalization with respect to that of the trivial class, in the sense that the classification should be done using the deformed coadjoint action (associated with the central extension determined by the nontrivial class we are considering).

III. SYMPLECTIC COHOMOLOGY

In the preceding section we have seen how GAQ can be used to define symplectic structures out of a Lie group, naturally leading to the notion of pseudo-cohomology. In this section we review a different approach to the discussion of the symplectic structures defined in terms of a Lie group G. First, we briefly recall the fundamentals of the so-called symplectic cohomology of G. The rationale for this structure can be found in the context of momentum mapping (Ref. 3 and below). Second, we use this mathematical structure to classify a family of symplectic spaces which generalize the ones obtained by the coadjoint action of a group G.

A. Lie group cohomology. Symplectic cohomology

Given a Lie group G, an Abelian Lie group A and a (left) action L of G on A, we define the n-cochains γ_n as mappings

$$\gamma_n : G \times \overset{n)}{\cdots} \times G \to A, \tag{15}$$

in such a way that the standard sum of mappings

$$(\gamma_n + \gamma_n')(g_1, \ldots, g_n) = \gamma_n(g_1, \ldots, g_n) + \gamma_n'(g_1, \ldots, g_n) \tag{16}$$

endows the space of n-cochains, denoted as $C_L^n(G,A)$, with the structure of an Abelian group. The coboundary operators $\delta: C_L^n(G,A) \to C_L^{n+1}(G,A)$ are defined by

$$(\delta\gamma_n)(g_1,\ldots,g_n,g_{n+1}) \equiv L(g_1)(\gamma_n)(g_2,\ldots,g_n,g_{n+1}) + \sum_{i=1}^{n} (-1)^i \gamma_n(g_1,\ldots,g_i g_{i+1},g_{i+2},\ldots,g_{n+1}) + (-1)^{n+1}\gamma_n(g_1,\ldots,g_n), \tag{17}$$

satisfying the nilpotency condition $\delta\circ\delta=0$. We can define the subspaces of n-cochains $Z^n \equiv Ker(\delta)\subset C_L^n(G,A)$, whose elements are *closed n-cochains* and $B^n\equiv \mathrm{Im}(\delta)\subset C_L^n(G,A)$, whose elements are n-coboundaries. Two exact n-cochains are equivalent if their difference is a coboundary. Cohomology groups are defined by this equivalence

$$H_L^n(G,A)=\frac{Z^n}{B^n} \tag{18}$$

and their elements are called *n-cocycles*. For the first cohomology groups the expression of (17) takes the form

$$(\delta\gamma_0)(g)=L(g)\gamma_0-\gamma_0,$$

$$(\delta\gamma_1)(g_1,g_2)=L(g_1)\gamma_1(g_2)-\gamma_1(g_1g_2)+\gamma_1(g_1),$$

$$(\delta\gamma_2)(g_1,g_2,g_3)=L(g_1)\gamma_2(g_2,g_3)+\gamma_2(g_1,g_2g_3)-\gamma_2(g_1g_2,g_3)-\gamma_2(g_1,g_2). \tag{19}$$

As we will see below, the generalization of the coadjoint action and its associated orbits naturally involves a cohomological structure. In order to address this point, we consider the general elements above and choose $A=\mathcal{G}^*$ and $L=Coad$, i.e., the coadjoint action of G on $\mathcal{G}^*$. This choice leads in particular to the cohomology group $H^1_{Coad}(G,\mathcal{G}^*)$, where a 1-cocycle $\gamma: G\rightarrow\mathcal{G}^*$ is characterized by $(\delta\gamma\equiv 0)$

$$\gamma(g'g)=Coad(g')\gamma(g)+\gamma(g'), \tag{20}$$

meanwhile a 1-coboundary has the form $(\Delta_\mu\equiv\delta\mu)$

$$\Delta_\mu=Coad(g)\mu-\mu, \quad g\in G,\mu\in\mathcal{G}^* \quad . \tag{21}$$

Symplectic cohomology $H_S(G,\mathcal{G}^*)$ is defined out of this cohomology group by restricting the 1-cocycles to functions γ which satisfy the following antisymmetry condition on its differential γ^T:

$$\gamma^T(e)(X,Y)\equiv\gamma^T(e)\cdot X(Y), \qquad \gamma^T(e)(X,Y)=-\gamma^T(e)(Y,X) \quad \forall X,Y\in\mathcal{G}. \tag{22}$$

The reason for this condition will be apparent in the next section.

For the sake of completeness, we mention that the cohomology group $H^2(G,\mathrm{U}(1))$ we found in the preceding section and which classifies the central extensions of the Lie group G, is obtained by setting $A=\mathrm{U}(1)$ and L as the trivial representation in the general construction above of Lie group cohomology. Second and third lines in (19) then define the expression of a coboundary and the cocycle condition.

B. Deformed coadjoint orbits

As we have seen in Sec. II A, orbits of the coadjoint action of a group G on its coalgebra $\mathcal{G}^*$ constitute a class of symplectic manifolds characterized in terms of group-theoretical structures.

Symplectic cohomology provides a way of introducing a notion of *affine-deformations* of coadjoints actions which allow us to generalize the notion of coadjoint orbit. Defining the mapping $g \mapsto Coad_\gamma(g)$

$$Coad_\gamma(g)\mu_0 \equiv Coad(g)\mu_0 + \gamma(g), \quad \mu_0 \in \mathcal{G}^*, \tag{23}$$

the condition for this expression to actually define a (left) action of G on $\mathcal{G}^*$, i.e., $Coad_\gamma(g'g)\mu = Coad_\gamma(g')(Coad_\gamma(g)\mu)$, reduces to expression (20), which is simply the cocycle condition in $H_S(G,\mathcal{G}^*)$.

On the other hand, and denoting the orbit of $Coad_\gamma$ through the point $\mu_0 \in \mathcal{G}^*$ by $Orb_\gamma(\mu_0)$, we note that γ functions which differ by a coboundary, (21), define the same set of orbits. In fact, since

$$Coad_{\gamma+\Delta_\mu}(g)\mu_0 = Coad_\gamma(g)\mu_0 + Coad(g)\mu - \mu = Coad_\gamma(g)(\mu+\mu_0) - \mu, \forall g \in G, \forall \mu_0 \in \mathcal{G}^*, \tag{24}$$

we realize that $Orb_{\gamma+\Delta_\mu}(\mu_0)$ and $Orb_\gamma(\mu_0+\mu)$ coincide modulo a translation by μ. Therefore, if we allow μ to vary on $\mathcal{G}^*$, each element in $H^1_{Coad}(G,\mathcal{G}^*)$ characterizes a family of orbits (modulo translations) obtained from the deformed coadjoint action on $\mathcal{G}^*$.

Finally, the antisymmetry condition on $\gamma^T(e)$ is necessary in order to define a symplectic structure on $Orb_\gamma(\mu)$. If we define

$$\Gamma(X,Y) \equiv \gamma^T(e)\cdot X(Y) \tag{25}$$

the following theorem follows (Ref. 3).

Theorem: The orbit $Orb_\gamma(\mu) \subset \mathcal{G}^*$ admits a symplectic form ω which is pointwise given by

$$\omega_\nu(X_\nu, Y_\nu) = \nu([X,Y]) + \Gamma(X,Y), \quad \nu \in Orb_\gamma(\mu), X_\nu, Y_\nu \in T_\nu(Orb_\gamma(\mu)), \tag{26}$$

where $X \in \mathcal{G}$ is related to $X_\nu \in T_\nu(Orb_\gamma(\mu))$ by $X_\nu = coad_\gamma(X)\nu$ and analogously for Y_ν and Y [where $coad_\gamma \equiv (Coad_\gamma)^T(e)$].

C. Convergence with the problem of central extensions

In Sec. II the techniques of GAQ were used in order to define a specific symplectic structure that could be used as the support for the Hamiltonian description of a classical system. The algorithm started from a U(1)-centrally extended Lie group $\tilde{G}$, where the 2-cocycle which defines the central extension permits the identification of the set of variables building the sought phase space (for concreteness, those coordinates associated with nonvertical vector fields which are absent from the characteristic module of $\Theta \equiv \theta^{L(\zeta)}$). However, the object classifying the nonisomorphic U(1)-central extensions of G, $H^2(G,\mathrm{U}(1))$, is not fine enough in order to classify the specific symplectic spaces, since some ambiguity still remains linked to the choice of the particular coboundary for the 2-cocycle.

In an analogous manner, the approach followed in this section, based on deformed coadjoint actions, permits the classification of the different classes of deformed coadjoint orbits by the elements of $H_S(G,\mathcal{G}^*)$, but not the characterization of individual symplectic spaces.

Therefore, the crucial mathematical structures of both approaches, the groups $H^2(G,\mathrm{U}(1))$ and $H_S(G,\mathcal{G}^*)$, respectively, need to be refined in order to account for such specific symplectic manifolds.

Even at this intermediate step, a nontrivial convergence occurs between the conceptually different problems of classifying the central extensions of a given Lie group G by U(1), on the one hand, and the affine deformations of the coadjoint actions on $\mathcal{G}^*$, on the other hand. In fact, the same object classifies the solutions to both problems, since $H^2(G,\mathrm{U}(1)) \approx H_S(G,\mathcal{G}^*)$.

Although we shall dwell on this point in Sec. III C 2, we can outline this equivalence by noting that, for simply connected groups, the isomorphism $H^2(\mathcal{G},\mathrm{U}(1)) \approx H^2(G,\mathrm{U}(1))$ is satisfied

and therefore it is enough to discuss the equivalence at the infinitesimal level. (On behalf of concision, we avoid a presentation of Lie algebra cohomology and refer the reader to standard references like Ref. 14. We just note that for simply connected groups, Lie algebra cohomology emerges as an infinitesimal version of Lie group cohomology.) In fact, the cocycle condition (20) implies the following condition on its differential $\Gamma(X,Y)$:

$$\Gamma([X,Y],Z)+\Gamma([Y,Z],X)+\Gamma([Z,X],Y)=0, \tag{27}$$

which, together with the antisymmetry condition (22), $\Gamma(X,Y)=-\Gamma(Y,X)$ defines a 2-cocycle in $H^2(\mathcal{G},\mathrm{U}(1))$ [from the point of view of the central extensions of the Lie algebra $\mathcal{G}$ (27) is simply the Jacobi identity for the central generator in the Lie algebra; see Ref. 14]. Likewise the infinitesimal expression of the coboundary condition (21) implies

$$\Gamma_{cob}(X,Y)=\mu([X,Y]) \quad \text{for some} \quad \mu\in\mathcal{G}^*, \tag{28}$$

which is the coboundary condition in $H^2(\mathcal{G},\mathrm{U}(1))$.

In Sec. II, pseudo-extensions have been introduced as the element necessary to account for the specific symplectic manifolds, that we can construct out of a Lie group G via a central extension of it. However the discussion was carried out only for the trivial class of $H^2(G,\mathrm{U}(1))$. For the nontrivial cohomology classes the analysis was not so straightforward. However the convergence with the approach based on symplectic cohomology, and which aims directly at the problem of defining symplectic structures completely in terms of a Lie group, sheds a new light on the problem. From this perspective, the characterization of a specific symplectic structure for a (in general nontrivial) cohomology class γ of $H^2(\mathcal{G},\mathrm{U}(1))\approx H^2(G,\mathrm{U}(1))$, simply parallels the characterization of a particular orbit in the family of orbits defined by $Coad_\gamma$.

1. Singularization of coadjoint orbits in symplectic cohomology

In order to singularize a specific symplectic manifold out of the family defined by a cocycle in $H_S(G,\mathcal{G}^*)$, i.e., in order to characterize a particular deformed coadjoint orbit, we have two options.

(i) We can fix a pair (γ,μ_0), where γ specifies the cocycle which defines the deformation of the action and μ_0 precises a point in the orbit. In this case, varying the second entry we scan all the possible orbits.

(ii) Alternatively, we can fix the point μ_0 in the coalgebra and vary instead the representative of the cocycle γ by modifying the coboundary, Δ_μ. Since the coalgebra is a linear space, there is a canonical choice for the fixed point μ_0: the zero vector. We can see from expression (24) that the set of spaces constructed this way is the same that the one derived with option (i), although translated with respect to them in such a way that all these spaces share the zero vector in $\mathcal{G}^*$.

However both characterizations are redundant since different pairs (γ,μ_0), or alternatively different specific representatives $\gamma+\Delta_\mu$, give rise essentially to the same orbits. Therefore it is necessary to establish an equivalence relationship in order to eliminate this ambiguity. The analysis of Sec. II A. establishing the relationship between specific symplectic structures and pseudo-cohomology understood as a refinement of a true cohomology, suggests us to choose the characterization (ii) for the deformed orbits. In fact, it directly leads to a refinement of symplectic cohomology, intrinsically tied to group cohomology.

In this sense we have to determine under which conditions two coboundaries Δ_μ and $\Delta_{\mu'}$ generate the same orbit. A direct computation shows that if there exists an element $h\in G$ such that $\mu=Coad_\gamma(h)\mu'$ (that is, if μ and $\mu'\in\mathcal{G}^*$ belong to the same γ-orbit) then

$$Coad_{\gamma+\Delta_\mu}(g)\,0=Coad_{\gamma+\Delta_{\mu'}}(gh)\,0+\mu'-\mu \quad \forall g\in G. \tag{29}$$

Since $\mu'-\mu$ is independent of g, spaces spanned by the action of $Coad_{\gamma+\Delta_\mu}$ and $Coad_{\gamma+\Delta'_\mu}$ through the zero in $\mathcal{G}^*$ coincide, modulo a rigid translation. These orbits are trivially symplectomorphic, the symplectomorphism being this translation in $\mathcal{G}^*$.

Summarizing with the language of symplectic cohomology, individual symplectic spaces associated with deformed coadjoints actions are classified by refinement of symplectic cohomology in such a way that two coboundaries Δ_μ and $\Delta_{\mu'}$ are equivalent if μ and μ' belong to the same γ-orbit. In other words, these individual symplectic spaces are classified by elements $\mu\in\mathcal{G}^*$ modulo the corresponding γ-deformed coadjoint action. Note the similarity with Definition 1, to which it directly generalizes in the context of deformed coadjoint orbits.

2. Pseudo-cohomology from symplectic cohomology

In this section we see in a more systematic way the close relation between pseudo-cohomology and symplectic cohomology for the nontrivial classes $(H^2(G,\mathrm{U}(1))\neq 0)$. The idea is to investigate how the coadjoint action *Coad* of G on $\mathcal{G}^*$ is modified by a central extension. The result is that when G is centrally extended by a 2-cocycle ξ, the coadjoint action of the extended group $\tilde{G}$, denoted by $\widetilde{Coad}$, acting on $\tilde{\mathcal{G}}^*=\mathcal{G}^*\times\mathbb{R}$, turns out to be

$$\widetilde{Coad}(\tilde{g})\tilde{\mu}=(Coad(g)\mu+\mu_\zeta F(g),\mu_\zeta), \tag{30}$$

where $\tilde{g}=(g,\zeta)\in\tilde{G}$, $\zeta\in\mathrm{U}(1)$ and $\tilde{\mu}=(\mu,\mu_\zeta)\in\tilde{\mathcal{G}}^*$. Here $F(g)\in\mathcal{G}^*$, and it is related to the 2-cocyle ξ through the quantization 1-form θ, by $F_i(g)=i_{\tilde{X}_i^R}\Theta$. These functions are nothing other than the Noether invariants of the classical theory.[9] Observe that $\widetilde{Coad}(\tilde{g})$ does not depend on ζ, and that μ_ζ does not change by this extended action [these two facts are related to the central character of U(1)]. Since the case $\mu_\zeta=0$ reproduces the original coadjoint action *Coad* of G, let us suppose $\mu_\zeta\neq 0$.

From (30) it can be derived that $\widetilde{Coad}(g)$ can be restricted to the foliations of $\tilde{\mathcal{G}}^*$ of constant μ_ζ, which can be identified with $\mathcal{G}^*$. Since $\widetilde{Coad}$ is an action, so it is its restriction, and this implies that $F(g)$ must verify the condition (this relation can also be checked by direct computation):

$$F(g'g)=Coad(g')F(g)+F(g'). \tag{31}$$

Therefore Noether invariants are nothing other than 1-cocycles for the coadjoint action *Coad* of G. Even more, they are symplectic, since its differential at the identity is precisely the Lie algebra 2-cocycle. Therefore, $\widetilde{Coad}$ can be identified with a deformed coadjoint action $Coad_\gamma$, with $\gamma(g)=\mu_\zeta F(g)$.

Without losing generality, we can take $\mu_\zeta=1$. Let us see what happens to $Coad_\gamma$ when we add to ξ a coboundary ξ_λ generated by $\lambda(g)$. A simple calculation shows that γ changes to $\gamma'=\gamma+\gamma_\lambda$, where γ_λ is given by

$$\gamma_\lambda(g)=Coad(g)\lambda^0-\lambda^0. \tag{32}$$

Surprisingly, γ_λ is a symplectic coboundary, associated with $\lambda^0\in\mathcal{G}^*$, and, what is more important, it depends just on λ^0, not on the particular choice of λ. This simple relation has deep consequences since it provides the close relation between pseudo-cocycles and symplectic cohomology. It also guides us in the correct definition of subclasses of pseudo-cocycles for the nontrivial case, using the characterization of single coadjoint orbits found in the symplectic cohomology setting (see Sec. III C 1).

According to this, and since the quantization 1-form Θ for any central extension $\tilde{G}$ characterized by the 2-cocycle ξ always verifies $\Theta|_e=(0,0,\ldots,1)$ (that is, $\mu=0$ and $\mu_\zeta=1$), we can singularize a deformed orbit in $\mathcal{G}^*$ by considering

$$\widetilde{Coad}(\tilde{g})\,\Theta|_e=(Coad_\gamma(g)\,0,1)=(Coad(g)\,0+F(g),1)=(F(g),1). \tag{33}$$

That is, this orbit is the image of the Noether invariants. This fact simply affirms that Noether invariants parametrize classical phase spaces.

The question now is that if we add to the 2-cocycle ξ a pseudo-cocycle ξ_λ generated by $\lambda(g)$ with gradient at the identity λ^0, does it define a new deformed coadjoint orbit? Can we define an equivalence relation among pseudo-cocycles as for the case of the trivial class?

Again, from the symplectic cohomology framework (see Sec. III C 1), we have the answer. First we define the following.

Definition 2: Two coboundaries ξ_λ and $\xi_{\lambda'}$ with generating functions λ and λ', respectively, define two cocycles $\xi+\xi_\lambda$, $\xi+\xi_{\lambda'}$ belonging to the same equivalence subclass $[\xi]$ of $[[\xi]]$ if and only if the gradients at the identity of the generating functions are related by

$$\lambda^{0\prime} = Coad_\gamma(g)\lambda^0, \tag{34}$$

for some $g \in G$, where $Coad_\gamma$ stands for the deformed coadjoint action, which is equivalent to the coadjoint action $\widetilde{Coad}$ of $\tilde{G}$ on $\tilde{\mathcal{G}}^* = \mathcal{G}^* \times \mathbb{R}$, where $\tilde{G}$ is the central extension associated with the two-cocycle ξ.

According to this definition, equivalent pseudo-extensions (for the nontrivial class $[[\xi]]$) are determined by generating functions whose gradient at the identity lie in the same coadjoint orbit of $\tilde{G}$.

The ultimate justification of this definition is the following proposition.

Proposition 3: Given a Lie group G and a 2-cocycle ξ on G, consider the two coboundaries ξ_{λ_1} and ξ_{λ_2} with generating functions $\lambda_1(g)$ and $\lambda_2(g)$. Define the central extensions $\tilde{G}_1$ and $\tilde{G}_2$ characterized by the two-cocycles $\xi+\xi_{\lambda_1}$ and $\xi+\xi_{\lambda_2}$, respectively, and construct the quantization 1-forms $\Theta_1 = \Theta + \Theta_{\lambda_1}$ and $\Theta_2 = \Theta + \Theta_{\lambda_2}$, following expressions (2) *and* (3). *The two symplectic spaces $\tilde{G}_1/(G_{\Theta_1} \times U(1))$ and $\tilde{G}_2/(G_{\Theta_2} \times U(1))$, with symplectic forms ω_1 and ω_2, such that $d\Theta_1 = \pi^*\omega_1$ and $d\Theta_2 = \pi^*\omega_2$, respectively, are symplectomorphic if there exists $h \in G$ such that*

$$\lambda_1^0 = Coad_\gamma(h)\lambda_2^0, \tag{35}$$

the symplectomorphism being given by $\widetilde{Ad}(\tilde{h})$,

$$d\Theta_1 = (\widetilde{Ad}(\tilde{h}))^*\, d\Theta_2, \tag{36}$$

where $\tilde{h}$ is such that $p(\tilde{h}) = h$, with $p: \tilde{G} \to G$ the canonical projection.

Proof: Even though the result can be shown by direct calculation, the most straightforward derivation comes from splitting the central extension into two steps. First, the central extension by ξ alone is constructed, and this group $\tilde{G}$ is taken as the departing point for a second trivial extension by ξ_{λ_1} and ξ_{λ_2}. The study of the trivial class in $\tilde{G}$ amounts for the study of that nontrivial class in G characterized by the cocycle ξ. At this point we can apply Proposition 1 to the trivial extension of $\tilde{G}$ and then take advantage of the identification between the nontrivial part ($\mathcal{G}^*$-component in $\tilde{\mathcal{G}}^*$) of $\widetilde{Coad}$ in $\tilde{G}$ and $Coad_\gamma$ in G, which follows from expression (30) and its subsequent discussion. This leads directly to the claimed result.

As in the case of the trivial class, the correspondence between pseudo-cohomology classes in $[[\xi]]$ and ''deformed'' coadjoint orbits in $\mathcal{G}^*$ is not onto. Only when we demand these coadjoint orbits to satisfy the integrality condition (that is, to be quantizable), the correspondence with pseudo-cohomology classes is one-to-one. The proof of this statement is the same as in the trivial case, see Ref. 9.

IV. SIMPLE PHYSICAL EXAMPLES

For the sake of completeness we shall include some simple examples of relevant elementary physical phase spaces which can be obtained along the general lines here drawn.

A. The Poincaré group in 1+1 dimensions

The simplest physical example of a phase space associated with a pseudo-cocycle corresponds to the $1+1$ dimensional relativistic particle. The ordinary Poincaré group in $3+1$ dimensions is the semidirect product of the Lorentz group (SO(3,1)) by the four-dimensional space–time translations. In $1+1$ dimensions, any element g can be parametrized by two space–time translations x^0, x, and the boost velocity $v \equiv c\,\mathrm{th}\,\chi$ in SO(1,1), or $u=\gamma v$, where $\gamma = 1/\sqrt{1-v^2/c^2}$.

We should comment that although the standard $3+1$ Poincaré group has trivial cohomology, the $1+1$-Poincaré group admits a nontrivial cocycle associated with the space–time translation subgroup. However, we shall disregard this cocycle, which has no $3+1$ dimensional analogue (that is, we shall restrict ourselves to the trivial cohomology class). We dwell, therefore, on the setting of Sec. II A.

The composition law, in terms of the parametrization $(x^0 \equiv ct, x, u)$, is

$$x^{0\prime\prime} = x^{0\prime} + \gamma' x^0 + \frac{u'}{c} x,$$

$$x'' = x' + \gamma' x + \frac{u'}{c} x^0,$$

$$u'' = \gamma u' + \gamma' u. \tag{37}$$

Right- and left-invariant vector fields are easily obtained by deriving the group law,

$$X^L_{x^0} = \gamma \frac{\partial}{\partial x^0} + \frac{u}{c}\frac{\partial}{\partial x}, \quad X^R_{x^0} = \frac{\partial}{\partial x^0},$$

$$X^L_{x} = \gamma \frac{\partial}{\partial x} + \frac{u}{c}\frac{\partial}{\partial x^0}, \quad X^R_{x} = \frac{\partial}{\partial x},$$

$$X^L_{u} = \gamma \frac{\partial}{\partial u}, \quad X^R_{u} = \gamma \frac{\partial}{\partial u} + \frac{x^0}{c}\frac{\partial}{\partial x} + \frac{x}{c}\frac{\partial}{\partial x^0}\ . \tag{38}$$

The Lie algebra $\mathcal{G}$ of the $1+1$ Poincaré group is the one satisfied by, say, left-invariant vector fields,

$$[X^L_{x^0}, X^L_x] = 0,$$

$$[X^L_{x^0}, X^L_u] = -\frac{1}{c} X^L_x, \tag{39}$$

$$[X^L_x, X^L_u] = -\frac{1}{c} X^L_{x^0},$$

and the Casimir for this algebra is $\hat{C} = (X^L_{x^0})^2 - (X^L_x)^2$.

The left-invariant 1-forms (dual to the set of left-invariant vector fields) are given by

$$\theta^{L(x^0)} = \gamma\, \mathrm{d}x^0 - \frac{u}{c}\mathrm{d}x,$$

$$\theta^{L(x)} = -\frac{u}{c}\mathrm{d}x^0 + \gamma\, \mathrm{d}x,$$

$$\theta^{L(u)} = \frac{1}{\gamma}\mathrm{d}u\ . \tag{40}$$

We can parametrize a vector λ^0 in $\mathcal{G}^*$ by its expansion coefficients in the basis associated with, say, the left-invariant forms on the group, $\theta^{L(i)}$, at the identity e of the group. That is, $\lambda^0 = -P_0\theta^{L(x^0)}|_e + P\theta^{L(x)}|_e - K\theta^{L(u)}|_e$ (the minus signs are chosen for convenience, to reproduce standards results).

We shall construct all possible pseudo-extensions of the $1+1$ Poincaré group by means of an arbitrary pseudo-cocycle generated by a function with nontrivial gradient $\lambda^0 \in \mathcal{G}^*$ at the identity. Let us define the generating function $\lambda(g) = -P_0x^0 + Px - Ku$, whose gradient at the identity is λ^0 (note that we have chosen a linear function in the coordinates).

The question is how many different (nonequivalent) pseudo-extensions can we construct for the $1+1$ Poincaré group. The answer, as we already know, is given by the different coadjoint orbits in $\mathcal{G}^*$.

The generating function $\lambda(g)$ previously introduced defines a pseudo-cocycle $\xi_\lambda = \lambda(g'*g) - \lambda(g') - \lambda(g)$,

$$\xi_\lambda(g',g) = -P_0\left((\gamma'-1)x^0 + \frac{u'}{c}x\right) + P\left((\gamma'-1)x + \frac{u'}{c}x^0\right) - K((\gamma-1)u' + (\gamma'-1)u). \tag{41}$$

This defines a central pseudo-extension $\tilde{G}$ of G by U(1), with group law given by (37) together with

$$\zeta'' = \zeta'\zeta e^{i\xi_\lambda(g',g)}. \tag{42}$$

Left- and right-invariant vector fields for the pseudo-extended group are ($X_0 = \partial/\partial\phi$, $\phi = -i\ln\zeta$)

$$\begin{aligned}
\tilde{X}^L_{x^0} &= \gamma\frac{\partial}{\partial x^0} + \frac{u}{c}\frac{\partial}{\partial x} + \left(-P_0(\gamma-1) + P\frac{u}{c}\right)X_0,\\
\tilde{X}^L_{x} &= \gamma\frac{\partial}{\partial x} + \frac{u}{c}\frac{\partial}{\partial x^0} + \left(-P_0\frac{u}{c} + P(\gamma-1)\right)X_0,\\
\tilde{X}^L_{u} &= \gamma\frac{\partial}{\partial u} + K(\gamma-1)X_0,\\
\tilde{X}^R_{x^0} &= \frac{\partial}{\partial x^0},\\
\tilde{X}^R_{x} &= \frac{\partial}{\partial x},\\
X^R_{u} &= \gamma\frac{\partial}{\partial u} + \frac{x^0}{c}\frac{\partial}{\partial x} + \frac{x}{c}\frac{\partial}{\partial x^0} + \left(-P_0\frac{x}{c} + P\frac{x^0}{c} - K(\gamma-1)\right)X_0.
\end{aligned} \tag{43}$$

The Lie algebra $\tilde{\mathcal{G}}$ of the pseudo-extended group is

$$\begin{aligned}
[\tilde{X}^L_{x^0}, \tilde{X}^L_{x}] &= 0,\\
[\tilde{X}^L_{x^0}, \tilde{X}^L_{u}] &= -\frac{1}{c}(\tilde{X}^L_{x} + PX_0),\\
[\tilde{X}^L_{x}, \tilde{X}^L_{u}] &= -\frac{1}{c}(\tilde{X}^L_{x^0} - P_0X_0).
\end{aligned} \tag{44}$$

The quantization 1-form is given by

$$\Theta = \frac{d\zeta}{i\zeta} - P_0\theta^{L(x^0)} + P\theta^{L(x)} - K\theta^{L(u)} - d\lambda$$

$$= \frac{d\zeta}{i\zeta} - P_0(\theta^{L(x^0)} - dx^0) + P(\theta^{L(x)} - dx) - K(\theta^{L(u)} - du), \tag{45}$$

where $\theta^{L(i)}$ are given by Eq. (40). The characteristic subalgebra is generated by $\mathcal{G}_\Theta = \langle P_0\tilde{X}^L_{x^0} + P\tilde{X}^L_x\rangle$.

The Noether invariants are defined as $F_i = i_{\tilde{X}^R_i}\Theta$, which can be rewritten as $F_i = i_{X^R_i}\theta^{L(j)}\lambda^0_j - \lambda^0_i$, where $i_{X^R_i}\theta^{L(j)}$ turn out to be the matrix elements associated with the coadjoint action. That is, for the case of trivial cohomology (or the trivial cohomology class), Noether invariants coincide with symplectic coboundaries γ_λ [see Eq. (32)]. In this case, the coadjoint action is given by the matrix

$$Coad(x^0,x,u) = \begin{pmatrix} \gamma & -\frac{u}{c} & 0 \\ -\frac{u}{c} & \gamma & 0 \\ \frac{\gamma x}{c} - \frac{ux^0}{c^2} & \frac{\gamma x^0}{c} - \frac{ux}{c^2} & 1 \end{pmatrix}. \tag{46}$$

The Noether invariants prove to be, then

$$F_{x^0} = -(\gamma - 1)P_0 - \frac{u}{c}P,$$

$$F_x = \frac{u}{c}P_0 + (\gamma - 1)P,$$

$$F_u = -\left(\frac{\gamma x}{c} - \frac{ux^0}{c^2}\right)P_0 + \left(\frac{\gamma x^0}{c} - \frac{ux}{c^2}\right)P. \tag{47}$$

The Noether invariants are not independent but, rather, they satisfy the relation

$$(F_{x^0} - P_0)^2 - (F_x + P)^2 = P_0^2 - P^2 \equiv C. \tag{48}$$

The function $C:\mathcal{G}^* \to \mathbb{R}$ is named a Casimir function, and it is invariant under the coadjoint action. Casimir functions are closely related to Casimir operators, in fact they can be considered the classical (commutative) version of the Casimir operators. Since they are invariant under the coadjoint action, coadjoint orbits are included in the level sets of the Casimir functions.

With the help of the Casimir functions we can obtain the coadjoint orbits in $\mathcal{G}^*$ avoiding their direct computation, which can be rather involved. For the case of the $1+1$ Poincaré group there is a single Casimir function, the one already found $C = P_0^2 - P^2$, whose level sets are conics since it is a quadratic function. We should only care about the fact that level sets can be disconnected (coadjoint orbits of connected Lie groups are connected) or, even nondifferentiable manifolds. In these cases, the level set is the disjoint union of two or more (even infinite) coadjoint orbits.

Three cases should be distinguished: $C>0, C<0$, or $C=0$.

(1) In the case $C>0$ we have $P_0 = \pm\sqrt{C+P^2}$ and $K \in \mathbb{R}$. This is the translation in the K axis of the upper and lower hyperbolas, with vertices $(\pm\sqrt{C},0,K)$, respectively.

(2) In the case $C<0$ we have $P=\pm\sqrt{C+P_0^2}$ and $K\in\mathbb{R}$. This is the translation in the K axis of the left and right hyperbolas, with vertices $(0,\pm\sqrt{-C},K)$, respectively.
(3) In the case $C=0$ we have $P_0=\pm P$ and $K\in\mathbb{R}$. This is the union of four half-planes, $(\pm P,P,K)$ with either $P>0$ or $P<0$, and $K\in\mathbb{R}$, and the union of zero-dimensional coadjoint orbits $(0,0,K)$, $K\in\mathbb{R}$.

Physically, the case $C>0$ corresponds to the mass shell condition $P_0^2-P^2=C=m^2c^2$, representing relativistic particles with rest mass $m=\pm\sqrt{C}/c$, or particles with positive and negative energies $P_0=\pm\sqrt{m^2c^2+P^2}$ (they can be also interpreted as particles moving forward and backward in time). The case $C<0$ corresponds to tachyons with "imaginary mass" $m=\sqrt{C}/c$ moving in the right and left directions (with $P>0$ or $P<0$, respectively). And the case $C=0$ corresponds to photons moving forward and backward in time and in the right and left direction.

When passing to $3+1$ dimensions, and discarding the spin, the case $C>0$ remains essentially the same, the two sheets (for each value of C) of the mass shell condition. The case $C<0$, due to rotations, become a single connected orbit for each value of C (a particle moving to the right can be converted to a particle moving to the left by a rotation). In the case $C=0$, the four half-planes become two coadjoint orbits, associated with the future and past light cones. The zero-dimensional orbits $(0,0,K)$ with $K\neq 0$ do not have a counterpart in $3+1$ dimensions [the origin $(0,0,0)$ is always a zero dimensional orbit for any Lie group].

Now we select a particular point λ^0 in each coadjoint orbit, which will be used to define a pseudo-extension of the $1+1$ Poincaré group (different choices of λ^0 in the same coadjoint orbit will lead to equivalent pseudo-extensions). For the case $C=m^2c^2>0$, the easiest choice is $\lambda^0=(\pm mc,0,0)$ [note that, by our sign convention, particles with positive energy are associated with $(-mc,0,0)$]. For the case $C<0$, we can use $\lambda^0=(0,\pm\sqrt{-C},0)$, and for the case $C=0$ we use $\lambda^0=(\pm\nu,\pm\nu,0)$ with $\nu>0$.

Finally, all coadjoint orbits satisfy the integrality condition, therefore there is a one-to-one correspondence between coadjoint orbits and pseudo-cohomology classes for this group.

Group contraction Poincaré→Galileo

Coming back to the original motivation for pseudo-cohomology in terms of Inönü–Wigner contractions, we shall present an example of generation of cohomology from pseudo-cohomology by means of group contraction.

In general, given a pseudo-cohomology class and the corresponding quantization group $\tilde{G}$, with quantization 1-form Θ, an Inönü–Wigner contraction with respect to the characteristic subgroup G_Θ of Θ automatically leads to a contracted group $\tilde{G}_c$ which proves to be a nontrivial extension by U(1) of the contraction G_c of G by the same subgroup G_Θ.

Let us consider the pseudo-cohomology class of the $1+1$ Poincaré group associated with the upper sheet of the mass-shell $P_0^2-P^2=m^2c^2$. We can choose as representative point $\lambda^0=(-mc,0,0)$, and consider the pseudo-extension associated with the pseudo-cocycle ξ_λ with generating function,

$$\lambda(g)=-mcx^0, \tag{49}$$

so that

$$\xi_\lambda(g',g)=-mc(x^{0\prime\prime}-x^{0\prime}-x^0)=-mc\left((\gamma'-1)x^0+\frac{u'}{c}x\right)=-(p^{0\prime}-mc)x^0-p'x, \tag{50}$$

where $p\equiv mu$ and $p^0\equiv\sqrt{m^2c^2+p^2}=mc\,\gamma$.

We should realize that in the nonrelativistic limit, $c\to\infty$, ξ_λ is well-behaved, in fact

$$\xi_\lambda\to\xi_m\equiv-mv'x-\tfrac{1}{2}mv'^2t, \tag{51}$$

which coincides with the true cocycle of the $1+1$ version of the Galilei group (64) (see the next section), whereas λ, itself, proves to be ill-defined.

Particularizing (43) for this case we have the left-invariant vector fields,

$$\tilde{X}^L_{x^0}=\gamma\frac{\partial}{\partial x^0}+\frac{u}{c}\frac{\partial}{\partial x}-mc(\gamma-1)X_0,$$

$$\tilde{X}^L_{x}=\gamma\frac{\partial}{\partial x}+\frac{u}{c}\frac{\partial}{\partial x^0}-muX_0,$$

$$\tilde{X}^L_{u}=\gamma\frac{\partial}{\partial u} \tag{52}$$

with commutation relations

$$[\tilde{X}^L_{x^0},\tilde{X}^L_{x}]=0,$$

$$[\tilde{X}^L_{x^0},\tilde{X}^L_{u}]=-\frac{1}{c}\tilde{X}^L_{x},$$

$$[\tilde{X}^L_{x},\tilde{X}^L_{u}]=-\frac{1}{c}(\tilde{X}^L_{x^0}-mcX_0), \tag{53}$$

and it should be again remarked that, under the nonrelativistic limit, (53) goes to the $1+1$ version of the Galilean algebra (68).

The left-invariant 1-form Θ is

$$\Theta=p\,\mathrm{d}x-(p^0-mc)\mathrm{d}x^0+\frac{\mathrm{d}\zeta}{i\zeta}, \tag{54}$$

and its differential

$$\mathrm{d}\Theta=\mathrm{d}p\wedge\mathrm{d}x-\frac{p}{p^0}\mathrm{d}p\wedge\mathrm{d}x^0 \tag{55}$$

is a presymplectic form that, taking quotient by the characteristic subalgebra, becomes the symplectic form on the upper sheet of the mass-shell $P_0^2-P^2=m^2c^2$, i.e., the co-adjoint orbit of mass m in the co-algebra of the Poincaré group. The symplectic structure also goes, in the limit $c\to\infty$, to the symplectic structure of the $1+1$ version of the Galilei group (69) and (70).

B. Phase space of the nonrelativistic spinning particle

The next example corresponds to a family of phase spaces associated with a refinement of a nontrivial cohomology class in the $3+1$ Galilei group. In order to illustrate the ideas in Sec. III, we first discuss the classification of these spaces as orbits of deformed coadjoint actions [in the spirit of option (ii) in Sec. III C 1], and then we present the results in the framework of central extensions (Sec. III C 2).

1. Deformed coadjoint orbits

Let us explicitly write the composition law of the $3+1$ Galilei group,

$$\begin{aligned}
t''&=t'+t,\\
\vec{x}\,''&=\vec{x}\,'+R(\vec{\epsilon}\,')\vec{x}+\vec{v}\,'t,\\
\vec{v}\,''&=\vec{v}\,'+R(\vec{\epsilon}\,')\vec{v},\\
\vec{\epsilon}\,''&=\sqrt{1-\frac{\epsilon'^2}{4}}\,\vec{\epsilon}+\sqrt{1-\frac{\epsilon^2}{4}}\,\vec{\epsilon}\,'-\frac{1}{2}\vec{\epsilon}\,'\times\vec{\epsilon},
\end{aligned} \tag{56}$$

where the rotation matrix $R(\vec{\epsilon})$ has the explicit form

$$R(\vec{\epsilon})=(1-\epsilon^2/2)I-\sqrt{1-\frac{\epsilon^2}{4}}\,\vec{\epsilon}\times\,\cdot+\frac{1}{2}(\vec{\epsilon}\cdot\ \ )\vec{\epsilon}\,. \tag{57}$$

We can parametrize a vector μ in the coalgebra by its expansion coefficients in the basis associated with the left-invariant forms, $\theta^{L(i)}$, at the identity element e of the group. That is, $\mu=-E\,\theta^{L(t)}|_e+P_i\theta^{L(x^i)}|_e-Q_i\theta^{L(v^i)}|_e+J_i\theta^{L(\epsilon^i)}|_e$. The coadjoint action, $Coad(t,\vec{x},\vec{v},\vec{\epsilon})$, has then the expression

$$\begin{gathered}(-E',\vec{P}',-\vec{Q}',\vec{J}')=Coad(t,\vec{x},\vec{v},\vec{\epsilon})(-E,\vec{P},-\vec{Q},\vec{J})\\ E'=E+\vec{v}\cdot R(\vec{\epsilon})\vec{P},\\ \vec{P}'=R(\vec{\epsilon})\vec{P},\\ \vec{Q}'=R(\vec{\epsilon})\vec{Q}-tR(\vec{\epsilon})\vec{P},\\ \vec{J}'=R(\vec{\epsilon})\vec{J}+\vec{x}\times R(\vec{\epsilon})\vec{P}-\vec{v}\times R(\vec{\epsilon})\vec{Q}.\end{gathered} \tag{58}$$

As discussed previously, the study of the symplectic manifolds obtained by deforming this coadjoint action demands the introduction of a symplectic cocycle γ. In the case of the $3+1$ Galilei group, there exists a one-dimensional family (vector space) of nontrivial cohomology classes. A representative (a basis) for this family can be chosen as[3]

$$\gamma_m(t,\vec{x},\vec{v},\vec{\epsilon})=m(-\tfrac{1}{2}\vec{v}\cdot\vec{v},\vec{v},-\vec{x}+\vec{v}t,\vec{x}\wedge\vec{v}), \tag{59}$$

where the parameter m will be related to the mass of the free particle. In order to classify the symplectic manifolds, we construct different representatives of the symplectic cocycle by first correcting γ_m with a symplectic coboundary Δ_μ and, then, applying $Coad_{\gamma_m+\Delta_\mu}$ to the 0 vector. Choosing as the generator of the coboundary the vector $\mu=(-E_0,0,0,j\vec{n})$, where $\vec{n}$ is an arbitrary unit vector and E_0 is considered the ''internal energy,'' we find

$$\Delta_\mu=Coad(t,\vec{x},\vec{v},\vec{\epsilon})(-E_0,0,0,j\vec{n})-(-E_0,0,0,j\vec{n})=(0,0,0,jR(\vec{\epsilon})\vec{n}-j\vec{n}). \tag{60}$$

The orbits are then generated by the action

$$\begin{gathered}Coad_{\gamma_m+\Delta_\mu}(t,\vec{x},\vec{v},\vec{\epsilon})0=\left(-\frac{m}{2}\vec{v}\cdot\vec{v},m\vec{v},-m(\vec{x}-\vec{v}t),m\vec{x}\wedge\vec{v}+jR(\vec{\epsilon})\vec{n}-j\vec{n}\right),\\ \forall t,\vec{x},\vec{v},\vec{\epsilon}.\end{gathered} \tag{61}$$

From this expression, one can characterize the orbits as subspaces in $\mathbb{R}^{1+3+3+3}$ defined by the constraints

$$E=\frac{1}{2m}\vec{P}^2,\quad (\vec{J}-(m\vec{x}\wedge\vec{v}-j\vec{n}))^2=j^2. \tag{62}$$

In the case $j\neq 0$, this is an eight-dimensional space, which can be seen as the topological product of $\mathbb{R}^{3+3}$ parametrized by the position and momentum of the particle, $(\vec{Q},\vec{P})$, times a sphere of radius j related to a *spinning* angular momentum. These orbits could be regarded as the classical

phase space for the quantization of the free particle with mass m and spin j. In the case $j=0$, the second constraint expands into three, $\vec{J}=\vec{x}\wedge m\vec{v}$, giving rise to the six-dimensional phase space of a particle without spin.

Finally, we note that these spaces in fact exhaust all possible orbits. This can be seen by using the result that orbits are classified by elements $\mu\in\mathcal{G}^*$ modulo γ-orbits: Δ_μ and $\Delta_{\mu'}$ give rise (modulo a rigid translation) to the same orbit if and only if the relation $\mu'=Coad_\gamma(h)\mu$ holds for some h. In our case, $\mu=(-E_0,0,0,j\vec{n})$, and denoting $h=(t,\vec{x},\vec{v},\vec{\epsilon})$, we find

$$\mu'=\left(-E_0-\frac{m}{2}\vec{v}\cdot\vec{v},m\vec{v},-m(\vec{x}-\vec{v}t),jR(\vec{\epsilon})\vec{n}+m\vec{x}\wedge\vec{v}\right). \tag{63}$$

Under free variation of the parameters in this expression, $\mathbb{R}^{10}$ is fully spanned. In addition, noting that the parameter E_0 simply induces a rigid translation of the orbits, we conclude that $\mu=(0,0,0,j\vec{n})$ covers all possible different cases up to symplectomorphism (in fact, it suffices with varying j, the direction of $\vec{n}$ being irrelevant).

2. Quotient spaces in the extended Galilei group

We now study the way in which this family of symplectic spaces parametrized by j, emerges from pseudo-cohomology classes. First, the Galilei group must be extended by introducing a new group variable ζ. The composition law (56) is completed with

$$\zeta''=\zeta'\zeta e^{i\xi_m(g',g)}e^{i\xi_j(g',g)},$$

where $\xi_m(g',g)$ is the "standard" cocycle given by

$$\xi_m(g',g)=-m\vec{v}'\cdot R(\vec{\epsilon}')\vec{x}-\tfrac{1}{2}m\vec{v}'^2t, \tag{64}$$

and $\xi_j(g',g)$ is the pseudo-cocycle generated by the function of the rotation parameters (with nontrivial gradient at the identity)

$$\lambda_j(g)\equiv j\vec{n}\cdot\vec{\epsilon}. \tag{65}$$

Again, $\vec{n}$ is an arbitrary unit vector in the "spin-quantization direction." In this way, the explicit law for the parameter $\phi\equiv -i\,\mathrm{Log}\,\zeta$ is

$$\begin{aligned}\phi''=\phi'+\phi-m\left(\vec{v}'\cdot R(\vec{\epsilon}')\vec{x}+\frac{1}{2}\vec{v}'^2t\right)\\ +j\vec{n}\cdot\left(\sqrt{1-\frac{\epsilon'^2}{4}}\vec{\epsilon}+\sqrt{1-\frac{\epsilon^2}{4}}\vec{\epsilon}\,'-\frac{1}{2}\vec{\epsilon}\,'\times\vec{\epsilon}-\vec{\epsilon}\,'-\vec{\epsilon}\right).\end{aligned} \tag{66}$$

The left-invariant vector fields are straightforwardly computed,

$$\tilde{X}_t^L = \frac{\partial}{\partial t} + \vec{v}\cdot\frac{\partial}{\partial \vec{x}} - \frac{1}{2}mv^2 X_0,$$

$$\tilde{X}_{\vec{x}}^L = \left(\frac{\partial}{\partial \vec{x}} - m\vec{v}X_0\right)\cdot R(\vec{\epsilon}),$$

$$\tilde{X}_{\vec{v}}^L = \frac{\partial}{\partial \vec{v}}\cdot R(\vec{\epsilon}),$$

$$\tilde{X}_{\vec{\epsilon}}^L = \sqrt{1-\frac{\epsilon^2}{4}}\frac{\partial}{\partial \vec{\epsilon}} - \frac{1}{2}\vec{\epsilon}\times\frac{\partial}{\partial \vec{\epsilon}} + j\left(\left(\sqrt{1-\frac{\epsilon^2}{4}}-1\right)\vec{n} - \frac{1}{2}\vec{\epsilon}\times\vec{n}\right)X_0,$$

$$\tilde{X}_\phi^L = \frac{\partial}{\partial \phi} \equiv X_0, \tag{67}$$

providing the following nontrivial commutators:

$$\begin{aligned}
&[\tilde{X}_{\epsilon^i}^L, \tilde{X}_{\epsilon j}^L] = \eta_{ij.}^{\ k}(\tilde{X}_{\epsilon^k}^L + jn_k X_0),\\
&[\tilde{X}_t^L, \tilde{X}_{v^i}^L] = -\tilde{X}_{x^i}^L, \qquad [\tilde{X}_{\epsilon^i}^L, \tilde{X}_{xj}^L] = \eta_{ij.}^{\ k}\tilde{X}_{x^k}^L,\\
&[\tilde{X}_{x^i}^L, \tilde{X}_{vj}^L] = m\delta_{ij}X_0, \qquad [\tilde{X}_{\epsilon^i}^L, \tilde{X}_{vj}^L] = \eta_{ij.}^{\ k}\tilde{X}_{vk}^L.
\end{aligned} \tag{68}$$

Again, from (67), the precontact 1-form Θ and the presymplectic 2-form $d\Theta$ can be derived, with the result

$$\Theta = m\vec{v}\cdot d\vec{x} - \frac{1}{2}mv^2\,dt + \frac{(\vec{n}\times\vec{S})\cdot d\vec{S}}{j+\vec{S}\cdot\vec{n}} + \frac{d\zeta}{i\zeta}, \tag{69}$$

$$d\Theta = m\,d\vec{v}\wedge d\vec{x} - m\vec{v}\cdot d\vec{v}\wedge dt + \frac{\vec{n}\cdot(d\vec{S}\overset{\times}{\wedge}d\vec{S})}{2\vec{n}\cdot\vec{S}}, \tag{70}$$

where we have introduced the "spin" parameter $\vec{S}\equiv jR(\vec{\epsilon})\vec{n}$ (which is related to Noether invariants for the rotations group).

Finally, the quotient of the Galilei group by the kernel of $d\Theta$ leads to the $4+4$ dimensional symplectic manifolds with the topology $\mathbb{R}^3\times\mathbb{R}^3\times S^2$, for $j\neq 0$, and to $\mathbb{R}^3\times\mathbb{R}^3$, for $j=0$. It must be stressed that the half-integral value of the spin, j, is associated with the winding number of the application $e^{i\lambda_j}: \mathrm{SU}(2)\to\mathrm{U}(1)$, which generate the cocycle $e^{i\xi_j}$, where SU(2) is the universal covering of the rotation subgroup, SO(3).

We can make explicit contact with the deformed coadjoint orbit approach, by illustrating the formula (33), where $F(g)=(F_1(g),\ldots,F_{10}(g))=(i_{\tilde{X}_1^R}\Theta,\ldots,i_{\tilde{X}_{10}^R}\Theta)$. Calculating the right-invariant vector fields,

$$\tilde{X}_t^R = \frac{\partial}{\partial t},$$

$$\tilde{X}_{\vec{x}}^R = \frac{\partial}{\partial \vec{x}},$$

$$\tilde{X}^R_{\vec{v}} = t\frac{\partial}{\partial \vec{x}} + \frac{\partial}{\partial \vec{v}} - m\vec{x}X_0,$$

$$\tilde{X}^R_{\vec{\epsilon}} = \vec{x}\times\frac{\partial}{\partial \vec{x}} + \vec{v}\times\frac{\partial}{\partial \vec{v}} + \sqrt{1-\frac{\epsilon^2}{4}}\frac{\partial}{\partial \vec{\epsilon}} + \frac{1}{2}\vec{\epsilon}\times\frac{\partial}{\partial \vec{\epsilon}} + j\left(\left(\sqrt{1-\frac{\epsilon^2}{4}}-1\right)\vec{n} + \frac{1}{2}\vec{\epsilon}\times\vec{n}\right)X_0,$$

$$\tilde{X}^R_{\phi} = \frac{\partial}{\partial \phi} \equiv X_0, \tag{71}$$

we obtain

$$F(t,\vec{x},\vec{v},\vec{\epsilon}) = (i_{\tilde{X}^R_1}\Theta, \ldots, i_{\tilde{X}^R_{10}}\Theta) = (-\tfrac{1}{2}m\vec{v}^2, m\vec{v}, -m(\vec{x}-t\vec{v}), \vec{x}\wedge m\vec{v} + jR(\epsilon)\vec{n} - j\vec{n}),$$

which is exactly the set of representatives for the symplectic cocycle, $\gamma_m(t,\vec{x},\vec{v},\vec{\epsilon}) + \Delta_\mu$, that we have employed in the discussion of the symplectic orbits for the Galilei group.

V. FINAL REMARKS

In this paper we have established a neat characterization of the concept of pseudo-cohomology as the mathematical object classifying the single G-symplectic spaces that can be constructed out of a Lie group G. The role of symplectic cohomology has been crucial in this analysis: (a) on the one hand, it provides a clearer setting for the problem than the one based on central extensions; (b) on the other hand, it offers a straightforward bridge for the translation of the results into the language of central extensions.

This characterization is something more than an academic problem, since these symplectic spaces constitute the classical phase spaces of the quantum theories associated with a fundamental symmetry. The *a priori* knowledge of the available classical structures provides a most valuable information in the study of the quantum theory. In this sense, and although this paper focuses on the discussion of classical structures, a remark on their quantum counterparts is in order. In fact, once the classification of symplectic spaces (deformed coadjoint orbits) associated with a symmetry group has been done by means of pseudo-cohomology, the question on the existence of nonequivalent quantizations corresponding to a given coadjoint orbit S naturally arises. As is well-known from geometric quantization[3] (see also Ref. 10) such a variety of nonisomorphic quantum manifolds is classified by $\pi_1^*(S)$, i.e., the dual group of the first homotopy group of the classical phase space. Although this problem goes beyond the scope of the present work, where we are interested in the classification of symplectic spaces, not in their quantization, let us remark that when considering multiply connected coadjoint orbits there exists the possibility of finding pseudo-cocycles associated with the same coadjoint orbit and which leads to nonequivalent representations (see the end of Sec. II A for the relation between pseudo-extensions and quantization), hence to nonequivalent quantizations. These pseudo-cocycles are generated by nonhomotopic functions having the same gradient at the identity. An example of this situation can be found in the case of the SL(2,$\mathbb{R}$) group which admits two nonequivalent classes of unirreps associated with the multiply connected coadjoint orbits.[15,16] A precise analysis of this example can be seen in Ref. 17. As a consequence, the classification of nonequivalent representations associated with the same coadjoint orbit would require a further refinement in the characterization of pseudo-cohomology classes.

It should be stressed that although pseudo-cohomology with values on U(1) classifies quantizable G-symplectic manifolds through the integrality condition, general classical G-symplectic manifolds can be regained by considering pseudo-cohomology with values on the additive group R, rather than U(1). In fact, the Group Approach to Quantization recovers Classical Mechanics, in the Hamilton–Jacobi version, by just considering the additive group $\mathbb{R}$ instead of the multiplicative one U(1), the former being a local approximation to the latter.

(Received 18 November 2002; accepted 20 February 2004; published 13 April 2004)

Given a family of monodromy matrices $\mathsf{T}_0,\mathsf{T}_1,\ldots,\mathsf{T}_{K-1}$ corresponding to integrable anisotropic vertex models of $A_{n_\mu-1}$ type, $\mu=0,1,\ldots,K-1$, we built up a related mixed vertex model by means of gluing the lattices on which they are defined, in such a way that integrability property is preserved. The gluing process is implemented through one-dimensional representations of rectangular quantum matrix algebras $\mathrm{A}(R_{n_{\mu-1}}:R_{n_\mu})$, namely, the *gluing matrices* ζ_μ. Algebraic Bethe ansatz is applied on a pseudovacuum space with a selected basis and, for each element of this basis, it yields a set of nested Bethe ansatz equations matching up to the ones corresponding to an A_{m-1} quasiperiodic model, with m equal to $\min_{\mu\in\mathbb{Z}_K}\{\mathrm{rank}\,\zeta_\mu\}$. © *2004 American Institute of Physics.*

I. INTRODUCTION

There exists a deep link between solvable two-dimensional vertex models in statistical mechanics and the quantum Yang–Baxter (YB) equation, where it appears as a condition for integrability related to some basic quantities of the model.[1,2] This linking relies on the existence of an underlying symmetry, the quantum group,[3,4] which comes to provide a nice algebraic framework to study these systems. There, solutions of the YB equation are representations of some quadratic relations defining the quantum group structure and, through a process called baxterization,[5] they connect with the monodromy matrices of the model. From an algebraic point of view, baxterization makes an ordinary quantum group into a YB algebra. In this way, different representations of a YB algebra lead to different integrable lattice models.

The main aim of this work is to present a gluing process of models associated to several YB algebras preserving the integrability of the total system. We restrict ourselves to those YB algebras YB_n, $n\in\mathbb{N}$, coming from baxterization of the quantum groups $\mathrm{A}(R_n)$,[4] i.e., the duals of $U_q(\mathrm{su}_n)$.[3] Beside algebras YB_n, the gluing process also involves their rectangular generalizations $\mathrm{YB}_{n,m}$, defined as the spectral parameter dependent versions of the rectangular quantum matrix algebras $\mathrm{A}(R_n:R_m)$.[6] Here $\mathrm{A}(R_n:R_n)=\mathrm{A}(R_n)$ and, accordingly, $\mathrm{YB}_{n,n}=\mathrm{YB}_n$. The process is based on the existence of algebra homomorphisms $\mathrm{YB}_{n,m}\to\mathrm{YB}_{n,p}\otimes\mathrm{YB}_{p,m}$, the cocomposition maps, that generalize the concept of coproduct in a bialgebra. Such maps can be used to build up representations of a given YB algebra YB_n as a product of representations of another algebras YB_m, $m\neq n$, in an analogous way as the standard coproduct is used for building up usual tensor representations. More precisely, given families T_μ and ζ_μ, $\mu=0,1,\ldots,K-1$, of representations of YB_{n_μ} and $\mathrm{YB}_{n_{\mu-1},n_\mu}$, respectively, cocomposition maps ensure operator $\mathsf{T}^{\mathrm{mix}}=\zeta_0\dot{\otimes}\mathsf{T}_0\dot{\otimes}\cdots\dot{\otimes}\zeta_{K-1}\dot{\otimes}\mathsf{T}_{K-1}$ is a representation of $\mathrm{YB}_{n_{K-1}}$ (symbol $\dot{\otimes}$ will be defined in the next section). If each T_μ defines the monodromy matrix of a given vertex model, we say $\mathsf{T}^{\mathrm{mix}}$ is that of the mixed model with gluing matrices ζ_μ.

We shall see that this procedure is compatible with the algebraic Bethe ansatz method for solving these models, in the sense there exists a set of pseudovacuum vectors with respect to which these techniques can be applied. Moreover, we show a set of nested Bethe ansatz equations identical to the ones corresponding to an A_{m-1} quasiperiodic model, with m equal to $\min_{\mu\in\mathbb{Z}_K}\{\mathrm{rank}\,\zeta_\mu\}$, is related to each one of these vectors.

This work is organized as follows: in Sec. II, we review some well known facts on the connection between YB algebras and integrable lattice models; in Sec. III, we describe the gluing process and the gluing matrices as one-dimensional representations of the rectangular YB algebras; finally in Sec. IV, we prove integrability of mixed vertex models, showing that diagonalization of mixed transfer matrices reduces to solve nested Bethe equations of a family of A-type vertex models.

II. YANG–BAXTER ALGEBRAS AND INTEGRABLE VERTEX MODELS

To start with, we describe briefly the connection between two-dimensional vertex models and A_{n-1} type solutions of the YB equation.

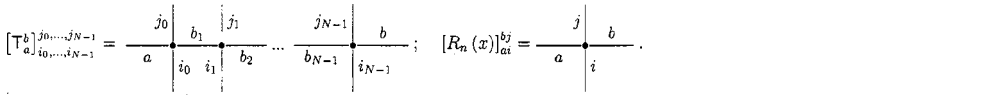
Let us consider the class of YB operators or constant R-matrices,

$$[R_n]^{kl}_{ab}=\begin{cases} q\,\delta^k_a\,\delta^{kl}, & a=b;\\ \delta^k_a\,\delta^l_b+(q-1/q)\,\delta^l_a\;\delta^k_b, & a<b;\\ \delta^k_a\,\delta^l_b, & a>b; \end{cases}\qquad 1\leqslant a,b,k,l\leqslant n; \tag{1}$$

$q\in\mathbb{C}\backslash\{0,1\}$, related to the standard Hopf algebra deformations of the simple Lie algebras A_{n-1}, i.e., the quantum groups $U_q(\mathrm{su}_n)$ and $\mathrm{A}(R_n)$, $n\in\mathbb{N}$. Baxterization process yields the spectral parameter dependent versions $R_n(x)=xR_n-PR_n^{-1}P/x$ of each R_n, with $P^{kl}_{ij}=\delta^l_i\delta^k_j$ the permutation matrix and $x\in\mathbb{C}$. Then, for every $N\in\mathbb{N}$ a related integrable (inhomogeneous) lattice model[7] is defined by a monodromy matrix $\mathsf{T}\doteq\mathsf{T}^{(n,N)}(x;\alpha)$ with entries (sum over repeated indices convention is assumed)

$$\mathsf{T}^b_a=\mathsf{R}^{b_1}_a(x/\alpha_0)\otimes\mathsf{R}^{b_2}_{b_1}(x/\alpha_1)\otimes\cdots\otimes\mathsf{R}^{b}_{b_{N-1}}(x/\alpha_{N-1}),\qquad 1\leqslant a,b\leqslant n, \tag{2}$$

being $\alpha=(\alpha_0,\ldots,\alpha_{N-1})$ a vector of $\mathbb{C}^N$. Operators $\mathsf{R}^b_a(x):\mathbb{C}^n\to\mathbb{C}^n$ are entries of a matrix $\mathsf{R}=\mathsf{R}(x)$ such that $[\mathsf{R}^b_a(x)]^j_i=[R_n(x)]^{bj}_{ai}$ in the canonical basis of $\mathbb{C}^n$. Compact notation $\mathsf{T}=\mathsf{R}\,\dot\otimes\cdots\dot\otimes\,\mathsf{R}$, where $\dot\otimes$ denotes matrix multiplication between consecutive factors, will be used. Note that $\mathsf{T}^{(n,1)}=\mathsf{R}^n=\mathsf{R}$. These models are the anisotropic analogs of the A_{n-1} invariant vertex models with periodic boundary conditions. Quasiperiodic versions[7] are given by elements Υ in the symmetry group of $R_n(x)$, i.e., $\Upsilon\in\mathrm{GL}(n)$ and $[R_n(x),\Upsilon\otimes\Upsilon]=0$. Related monodromy matrices read $\mathsf{T}^\Upsilon=\mathsf{T}\cdot\Upsilon$. Equation (2) defines operators $\mathsf{T}^b_a:(\mathbb{C}^n)^{\otimes N}\to(\mathbb{C}^n)^{\otimes N}$ that describe the statistical weights assigned to each vertex configuration in a given row of the lattice, graphically,



If the lattice has N' rows, the partition function is $\mathsf{Z}=\mathrm{trace}(\mathsf{t}^{N'})$, being $\mathsf{t}=\Sigma_a\mathsf{T}^a_a$ the transfer matrix. On the other hand, the operators $\mathsf{T}^b_a(x;\alpha)$, as it is well known, give a representation of the YB algebra related to $R_n(x)$. This algebra, which we shall indicate YB_n, is generated by indeterminates $\mathsf{T}^j_i(x)$, $1\leqslant i,j\leqslant n$; $x\in\mathbb{C}$, subject to relations

$$[R_n(x/y)]^{kl}_{ij}\,\mathsf{T}^r_k(x)\,\mathsf{T}^s_l(y)=\mathsf{T}^l_j(y)\,\mathsf{T}^k_i(x)\,[R_n(x/y)]^{rs}_{kl};\qquad 1\leqslant i,j,r,s\leqslant n. \tag{3}$$

These relations entail the formal integrability of the system. In fact, by taking the trace, one gets $[\mathsf{t}(x),\mathsf{t}(y)]=0$ for all $x,y\in\mathbb{C}$, i.e., the transfer matrix is a generating function of *conserved quantities*. Beside this, the model is effectively solved by means of algebraic Bethe ansatz,[8,9,10] where the central ingredient is the existence of an eigenstate $\omega\in(\mathbb{C}^n)^{\otimes N}$ of each entry T^a_a (and consequently of the transfer matrix t), such that $\mathsf{T}^b_a\,\omega=0$ for all $a\neq b$ and $a\geqslant 2$, and $\mathsf{T}^b_1\,\omega\neq c\,\omega$, $\forall c\in\mathbb{C}$, for all $b\geqslant 2$. For latter convenience, let us express T in the block form

$$\mathsf{T}=\begin{bmatrix}\mathsf{A} & \mathsf{B}_j\\ \mathsf{C}_i & \mathsf{D}_{ij}\end{bmatrix};\qquad 1\leqslant i,j\leqslant n-1,$$

i.e., define $\mathsf{A}\doteq\mathsf{T}_1^1$, $\mathsf{B}_j\doteq\mathsf{T}_1^{j+1}$, $\mathsf{C}_i\doteq\mathsf{T}_{i+1}^1$ and $\mathsf{D}_{ij}\doteq\mathsf{T}_{i+1}^{j+1}$. Then, ω is an eigenstate of A and of each diagonal entry D_{ii}, fulfilling $\mathsf{C}_i\,\omega=0$ and $\mathsf{D}_{ij}\,\omega=0$ for $i\neq j$. A vector satisfying these conditions is called *pseudovacuum vector*. On the other hand, since $\mathsf{B}_j\,\omega=\mathsf{T}_1^{j+1}\,\omega\neq c\,\omega$ for all j, each $\mathsf{B}_j(x)$ plays the role of a creation operator. Applying them repeatedly on ω (varying j from 1 to $n-1$ and x satisfying the so-called Bethe equations) we generate new eigenstates for the transfer matrix, namely the *Bethe vectors*, giving *a priori* a complete set of eigenstates for t. In such a case we say the system is exactly solvable or completely integrable.[11] Nevertheless, sometimes not only a vector but a *pseudovacuum subspace*[12,13] is needed in order to insure complete integrability. This will be our case.

Since each YB_n is a bialgebra, with coalgebra structure

$$\Delta:\mathsf{T}_i^j(x)\mapsto\mathsf{T}_i^k(x)\otimes\mathsf{T}_k^j(x),\quad \varepsilon:\mathsf{T}_i^j(x)\mapsto\delta_i^j, \tag{4}$$

for every couple of monodromy matrices $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(n,P)}$ as above we have another one,

$$\mathsf{T}^{(n,N+P)}=\mathsf{T}^{(n,N)}\dot{\otimes}\,\mathsf{T}^{(n,P)},\quad \text{with entries}\quad \mathsf{T}_a^{b(n,N+P)}=\mathsf{T}_a^{c(n,N)}\otimes\mathsf{T}_c^{b(n,P)},$$

giving again a representation of YB_n. Furthermore, if ω and ϕ are the pseudovacuums of $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(n,P)}$, then $\omega\otimes\phi$ defines a pseudovacuum for $\mathsf{T}^{(n,N+P)}$. Consequently the enlarged model, or the *gluing* of $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(n,P)}$, is also integrable. In particular, thermodynamic limit $N\to\infty$ preserves integrability. But, can we glue models which give representations of different YB algebras, e.g., YB_n and YB_m with $n\neq m$, and such that a pseudovacuum exists for the resulting model? The aim of this paper is to answer last question. More precisely, we build up from a family $\{\mathsf{T}_\mu:\mu\in\mathbb{Z}_K\}$ of *pure* models, i.e., $\mathsf{T}_\mu=\mathsf{T}^{(n_\mu,N_\mu)}$, $n_\mu,N_\mu\in\mathbb{N}$, a *mixing* of them by means of gluing the lattices on which they are defined, in such a way that resulting mixed model can be solved by means of algebraic Bethe ansatz techniques.

III. THE GLUING PROCESS

For any pair (R_n,R_m) of matrices (1), there exist an associated quadratic algebra $\mathrm{A}(R_n:R_m)$. They are called rectangular quantum matrix algebras.[6] There are also parameter dependent versions, the algebras $\mathrm{YB}_{n,m}$, generated by indeterminates $\mathsf{T}_i^j(x)$, $1\leqslant i\leqslant n$, $1\leqslant j\leqslant m$ and $x\in\mathbb{C}$, and defined by the quadratic relations

$$[R_n(x/y)]_{ij}^{kl}\,\mathsf{T}_k^r(x)\,\mathsf{T}_l^s(y)=\mathsf{T}_j^l(y)\,\mathsf{T}_i^k(x)\,[R_m(x/y)]_{kl}^{rs}, \tag{5}$$

$1\leqslant i,j\leqslant n$, $1\leqslant r,s\leqslant m$. Obviously, $\mathrm{YB}_{n,n}=\mathrm{YB}_n$. In the same way as for the constant case,[6,14] there exist homomorphisms

$$\Delta_p:\mathrm{YB}_{n,m}\to\mathrm{YB}_{n,p}\otimes\mathrm{YB}_{p,m};\quad n,m,p\in\mathbb{N}; \tag{6}$$

inherited from the cocomposition notion of the internal $coHom$ objects, enjoying the coassociativity property $(\Delta_p\otimes id)\Delta_r=(id\otimes\Delta_r)\Delta_p$.[15] In the $n=m=p$ cases, these reduce to the usual comultiplication maps [see Eq. (4)]. In particular, we have morphisms

$$\mathrm{YB}_m\to\mathrm{YB}_{m,n}\otimes\mathrm{YB}_n\otimes\mathrm{YB}_{n,m}\otimes\mathrm{YB}_m$$

for all n,m. Now, consider pure monodromy matrices $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(m,P)}$ related to YB_n and YB_m, and representations λ and β of $\mathrm{YB}_{m,n}$ and $\mathrm{YB}_{n,m}$, respectively, where λ and β denote rectangular matrices whose coefficients are representative of the corresponding generator algebra elements. Mentioned morphism implies $\lambda\dot{\otimes}\mathsf{T}^{(n,N)}\dot{\otimes}\beta\dot{\otimes}\mathsf{T}^{(m,P)}$ gives a representation of YB_m. As we do not want to add new degrees of freedom others than the related to the original models $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(m,P)}$, we ask λ and β to be constant (i.e., spectral parameter independent) one-dimensional representations. In this case $\lambda\dot{\otimes}\mathsf{T}^{(n,N)}\dot{\otimes}\beta\dot{\otimes}\mathsf{T}^{(m,P)}$ gives an operator on $(\mathbb{C}^n)^{\otimes N}\otimes(\mathbb{C}^m)^{\otimes P}$, which

we shall call the *gluing* of $\mathsf{T}^{(n,N)}$ and $\mathsf{T}^{(m,P)}$ through matrices λ and β. It is worth remarking that this is not the gluing operation defined by Majid and Markl.[6] Physically, λ and β define vertices with statistical weights

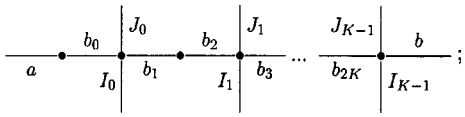
$$\lambda_a^b \quad \text{and} \quad \beta_c^d, \quad 1 \leqslant a,d \leqslant m \quad \text{and} \quad 1 \leqslant b,c \leqslant n.$$

In general, for a family of pure monodromy matrices as described above, we can define a *mixing* of them, namely,

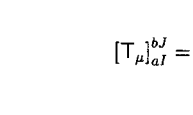
$$\mathsf{T}^{\mathrm{mix}} = \lambda_0 \dot{\otimes} \mathsf{T}_0 \dot{\otimes} \lambda_1 \dot{\otimes} \mathsf{T}_1 \dot{\otimes} \cdots \dot{\otimes} \lambda_{K-1} \dot{\otimes} \mathsf{T}_{K-1}, \tag{7}$$

where each λ_μ is a constant one-dimensional representation of the rectangular YB algebra $\mathrm{YB}_{n_{\mu-1},n_\mu}$ $(\mathrm{mod}\, K)$. Graphically,

$$[\mathsf{T}_a^{b\ mix}]_{I_0,\ldots,I_{K-1}}^{J_0,\ldots,J_{K-1}} =$$



$$[\mathsf{T}_\mu]_{aI}^{bJ} =$$



$$; \quad [\lambda_\mu]_a^b =$$

being I_μ and J_μ multi-indices for spaces $(\mathbb{C}^{n_\mu})^{\otimes N_\mu}$ on which each T_μ acts. Since the quadratic relations (5) and the cocomposition maps (6), one may see that $\mathsf{T}^{\mathrm{mix}}$ provides a representation of $\mathrm{YB}_{n_{K-1}}$. This is a direct consequence of the algebra map

$$\mathrm{YB}_{n_{K-1}} \to \mathrm{YB}_{n_{K-1},n_0} \otimes \mathrm{YB}_{n_0} \otimes \mathrm{YB}_{n_0,n_1} \otimes \cdots \otimes \mathrm{YB}_{n_{K-2},n_{K-1}} \otimes \mathrm{YB}_{n_{K-1}}. \tag{8}$$

Of course, these representations are highly reducible in general, as we shall see later.

A. Constant one-dimensional representations of $\mathrm{YB}_{n,m}$

Representations λ_μ appearing in (7) match exactly with one-dimensional representations of $\mathrm{A}(R_n:R_m)$, i.e., rectangular matrices $\lambda \in \mathrm{Mat}[n \times m]$ in $\mathbb{C}$ such that

$$[R_n]_{ij}^{kl}\, \lambda_k^r \lambda_l^s = \lambda_j^l\, \lambda_i^k [R_m]_{kl}^{rs}; \quad 1 \leqslant i,j \leqslant n, \ \ 1 \leqslant r,s \leqslant m. \tag{9}$$

We are considering the same parameter $q \neq 0,1$ for all involved R-matrices. Otherwise, the only solution to (9) is the trivial one. Using an explicit form of R_n given in (1), the last equation is equivalent to

$$\lambda_i^r \lambda_j^r = 0, \quad 1 \leqslant r \leqslant m, \ \ 1 \leqslant i \leqslant j \leqslant n,$$

$$\lambda_i^r \lambda_i^s = 0, \quad 1 \leqslant r < s \leqslant m, \ \ 1 \leqslant i \leqslant n,$$

$$\lambda_i^r \lambda_j^s = 0, \quad 1 \leqslant r < s \leqslant m, \ \ 1 \leqslant j < i \leqslant n.$$

First and second lines imply coefficients of λ in a given column and row, respectively, are null except for almost one of them. The last line says, if $\lambda_i^j \neq 0$, then all coefficients λ_a^b with $i < a$, $b < j$, and with $a < i$, $j < b$, are null. Thus, each solution λ of (9) is a diagonal matrix to which columns and rows of zeros were added. From that it follows immediately the set of solutions for

all m,n form a semigroupoid, or a category, generated by the Abelian groups $\mathcal{D}_n$ of invertible $n\times n$ diagonal matrices, and also by matrices $\sigma_i^n \in \mathrm{Mat}[n\times(n+1)]$ and $\partial_i^n \in \mathrm{Mat}[(n+1)\times n]$, $i=1,\ldots,n+1$, $n\in\mathbb{N}$, given by

$$\sigma_i^n = \begin{bmatrix} Id_{(i-1)\times(i-1)} & O_{(i-1)\times(n-i+2)} \\ O_{1\times(i-1)} & O_{1\times(n-i+2)} \\ O_{(n-i)\times(i-1)} & Id_{(n-i)\times(n-i+2)} \end{bmatrix},$$

$$\partial_i^n = \begin{bmatrix} Id_{(i-1)\times(i-1)} & O_{(i-1)\times 1} & O_{(i-1)\times(n-i)} \\ O_{(n-i+2)\times(i-1)} & O_{(n-i+2)\times 1} & Id_{(n-i+2)\times(n-i)} \end{bmatrix},$$

being $O_{n,m}$ the $n\times m$ null matrix. In fact, a general solution of Eq. (9) has the form

$$\lambda = \partial_{j_b}^{n-1}\cdots\ \partial_{j_1}^{k}\, D\, \sigma_{i_1}^{k}\cdots\ \sigma_{i_a}^{m-1} \in \mathrm{Mat}[n\times m];$$

$$a,b\geqslant 0, \quad m-a=n-b=k\geqslant 0, \tag{10}$$

with $i_1\leqslant\cdots\leqslant i_a\leqslant m$, $j_1\leqslant\cdots\leqslant j_b\leqslant n$, and $D\in\mathcal{D}_k$. If a (resp. b) is equal to zero, then factors of type σ (resp. ∂) do not appear. Such a solution has k nonnull entries equal to the diagonal elements of D, a number a of null columns in positions $i_1,\ldots,i_a$, and b null rows in positions $j_1,\ldots,j_b$. Note that rank $\lambda=k$.

Matrices σ_i^n and ∂_i^m, which give solutions to (9) for $m=n+1$ and $n=m+1$, respectively, are related each other by matrix transposition, i.e., $\partial_i^n=(\sigma_i^n)^t$, and enjoy relations

$$\sigma_j^{n-1}\,\sigma_i^n=\sigma_i^{n-1}\sigma_{j+1}^n, \qquad i\leqslant j;$$

$$\partial_i^{n+1}\,\partial_j^n=\partial_{j+1}^{n+1}\,\partial_i^n, \qquad i\leqslant j;$$

$$\sigma_j^{n+1}\,\partial_i^{n+1}=\partial_i^n\,\sigma_{j-1}^n, \qquad i<j;$$

$$\sigma_j^n\,\partial_i^n=Id, \qquad i=j;$$

$$\sigma_j^{n+1}\,\partial_i^{n+1}=\partial_{i-1}^n\,\sigma_j^n, \qquad i\geqslant j+1.$$

In spite of these relations, they do **not** define the simplicial category. Note that, for instance, $\sigma_j^n\,\partial_{j+1}^n\neq Id$. Nevertheless we name $\Delta=\vee_{n,m\in\mathbb{N}}\Delta_{n,m}$ the category formed out by them.

On the other hand, as it is well known, the group of diagonal matrices $\mathcal{D}_n$ defines precisely the symmetry group of R_n, given by matrices $D\in\mathrm{GL}(n)$ such that $[R_n,D\otimes D]=0$. Moreover, they are also the symmetry group of $R_n(x)$ or $R_n(x,y)=R_n(x/y)$. Let us mention that, when $R_n(x,y)$ is changed by a similarity transformation $Q(x)\otimes Q(y)$ such that $Q_k^l(x)=\delta_k^l\,x^{2l/n}$, the group enlarges to $\mathcal{D}_n\times\mathbb{Z}_n$.[7] This is why systems related to such R-matrices were called $\mathbb{Z}_n$-symmetric vertex models.[16]

Elements $D\in\mathcal{D}_n$ give rise to multiparametric solutions $(id\otimes D)^{-1}R_n(D\otimes id)$ of the YB equation,[17] and related twist transformations of original quantum groups.[14,18] Associated integrable models differ from the original ones by a twisting of the boundary conditions.[19] We shall see later that also in mixed models the role of matrices D is to make a twist on the boundary conditions.

The commutation relations between elements of $\mathcal{D}=\vee_{n\in\mathbb{N}}\mathcal{D}_n$ and Δ can be written

$$D\,\sigma_i^n=\sigma_i^n\,D_i^+, \qquad \partial_i^n\,D=D_i^+\,\partial_i^n,$$

$$\sigma_i^{n-1}\,D=D_i^-\,\sigma_i^{n-1}, \qquad D\,\partial_i^{n-1}=\partial_i^{n-1}\,D_i^-, \tag{11}$$

being $D_i^+ = \mathrm{diag}(d_1,\ldots,d_{i-1},1,d_i,\ldots,d_n)$ and $D_i^- = \mathrm{diag}(d_1,\ldots,d_{i-1},d_{i+1},\ldots,d_n)$ whenever $D = \mathrm{diag}(d_1,\ldots,d_n) \in \mathcal{D}_n$. It is worth mentioning that λ can also be expressed as a product $\lambda = \zeta D'$, where $\zeta \in \Delta$ is obtained from λ by taking $D = Id$, and $D' \in \mathcal{D}_n$ is the result of passing D to the right, through matrices σ's, using commutation rules (11).

B. Equivalent forms for a mixed monodromy matrix

From results of last section, it is clear that any mixed model has a monodromy matrix

$$\lambda_0 \cdot \mathsf{R}_0 \dot{\otimes} \lambda_1 \cdot \mathsf{R}_1 \dot{\otimes} \cdots \dot{\otimes} \lambda_{N-1} \cdot \mathsf{R}_{N-1}, \tag{12}$$

with $\mathsf{R}_\nu = \mathsf{R}^{n_\nu}$ for some related dimension n_ν, and $\lambda_\nu = \zeta_\nu D_\nu$, where ζ_ν is in $\Delta_{n_{\nu-1},n_\nu}$ and D_ν in $\mathcal{D}_{n_\nu}$. Here $\nu \in \mathbb{Z}_N$. Equation (7) corresponds to the case in which there exist K numbers N_μ, $\mu \in \mathbb{Z}_K$, giving a partition of N and such that

$$\mathsf{R}_{M_\mu} = \cdots = \mathsf{R}_{M_\mu + N_\mu - 1} = \mathsf{R}^{n_{M_\mu}} \quad \text{and} \quad \lambda_\nu = Id_{n_\nu} \ \text{ for } \ \nu \neq M_0,\ldots,M_{K-1}, \tag{13}$$

being $M_0 = 0$ and $M_\mu = \Sigma_{\sigma=0}^{\mu-1} N_\sigma$ for $1 \leqslant \mu \leqslant K-1$. Furthermore, Eq. (12) can be brought to an equivalent form

$$\mathsf{T}^{\mathrm{mix}} = \zeta_0 \cdot \mathsf{R}_0 \dot{\otimes} \zeta_1 \cdot \mathsf{R}_1 \dot{\otimes} \cdots \dot{\otimes} \zeta_{N-1} \cdot \mathsf{R}_{N-1}\, \Upsilon, \tag{14}$$

where Υ is an element of $\mathcal{D}_{n_{N-1}}$. To see that, let us define matrices $D_\nu^{(k)} \in \mathcal{D}_{n_k}$, $k \in \mathbb{Z}_N$, by

$$D_\nu^{(k)} = \begin{cases} Id_{n_k}, & 0 \leqslant k < \nu, \\ D_\nu, & k = \nu, \end{cases}$$

and for each $k > \nu$ by the solution of $D_\nu \zeta_{\nu+1} \zeta_{\nu+2} \cdots \zeta_k = \zeta_{\nu+1} \zeta_{\nu+2} \cdots \zeta_k D_\nu^{(k)}$. We mean by "the solution" of the last equation the inversible diagonal matrix $D_\nu^{(k)}$ that arises when passing, in the first member, the matrix D_ν to the right using (11). Then (12) and (14) are similar through $\Pi_{\nu \in \mathbb{Z}_N} \otimes_{k \in \mathbb{Z}_N} D_\nu^{(k)}$, and $\Upsilon = \Pi_{\nu \in \mathbb{Z}_N} D_\nu^{(N-1)}$.

In other words, every mixed model is physically equivalent to a twisted version of another one whose corresponding matrices λ_ν are in the category Δ. The role of matrices D's is to implement a twisting of the boundary conditions. Accordingly, we can describe each mixing $\mathsf{T}^{\mathrm{mix}}$ in terms of a family of elements $\zeta_\nu \in \Delta_{n_{\nu-1},n_\nu}$, the *gluing matrices*, and a diagonal matrix $\Upsilon = \mathrm{diag}(\tau_1,\ldots,\tau_{n_{N-1}})$ of $\mathcal{D}_{n_{N-1}}$, the *boundary matrix*.

Another useful expression for the monodromy matrices of these models can be given from the following observation. Any matrix $\lambda \in \Delta_{n,m}$ of rank k (note that $k \leqslant m,n$) may be written $\lambda = P\,\hat{\lambda}\,P'$, where $\hat{\lambda} = \partial_n^{n-1} \cdots \partial_{k+1}^k \sigma_{k+1}^k \cdots \sigma_m^{m-1} \in \mathrm{Mat}[n \times m]$, that is,

$$\hat{\lambda} = \begin{pmatrix} Id_k & O_{k\times(m-k)} \\ O_{(n-k)\times k} & O_{(n-k)\times(m-k)} \end{pmatrix}, \tag{15}$$

and P, P' are appropriate permutations. More precisely, if

$$\lambda = \partial_{j_b}^{n-1} \cdots \partial_{j_1}^k \sigma_{i_1}^k \cdots \sigma_{i_a}^{m-1}, \quad i_1 \leqslant \cdots \leqslant i_a \leqslant m, \quad j_1 \leqslant \cdots \leqslant j_b \leqslant n$$

[see Eq. (10)], then we can choose, for instance, $P \in \mathrm{Mat}[n]$ and $P' \in \mathrm{Mat}[m]$ to be

$$P = C_{j_b,n}\, C_{j_{b-1},n} \cdots C_{j_1,n} \qquad \text{and} \qquad P' = C_{i_1,m} \cdots C_{i_{a-1},m}\, C_{i_a,m},$$

respectively, being $C_{r,s}$, $r \leqslant s$, the matrix that acting on the right (resp. left) makes a cyclic permutation sending the sth column (resp. row) to the rth one, and acts as an identity for the rest

of columns (resp. rows). Hence, for a given family of gluing matrices we have $\zeta_\nu = P_\nu \hat{\zeta}_\nu P'_\nu$. Introducing last expression for ζ_ν into Eq. (14), and making a similarity transformation $\otimes_{\nu\in\mathbb{Z}_N} P'_\nu$, an equivalent system

$$\tilde{\mathsf{T}}^{\mathrm{mix}} = P_0\ \hat{\zeta}_0 \cdot \tilde{\mathsf{R}}_0 \cdot Q_0 \dot{\otimes} \hat{\zeta}_1 \cdot \tilde{\mathsf{R}}_1 \cdot Q_1 \dot{\otimes} \cdots \dot{\otimes} \hat{\zeta}_{N-2} \cdot \tilde{\mathsf{R}}_{N-2} \cdot Q_{N-2} \dot{\otimes} \hat{\zeta}_{N-1} \cdot \tilde{\mathsf{R}}_{N-1}\, P'_{N-1}\, \Upsilon, \quad (16)$$

where $Q_\nu = P'_\nu P_{\nu+1}$ and $\tilde{\mathsf{R}}_\nu = (P'_\nu \otimes P'_\nu)\, \mathsf{R}_\nu\, (P'_\nu \otimes P'_\nu)^{-1}$, follows. That is,

$$\tilde{\mathsf{T}}^{\mathrm{mix}} = (\otimes_{\nu\in\mathbb{Z}_N} P'_\nu)\, \mathsf{T}^{\mathrm{mix}}\, (\otimes_{\nu\in\mathbb{Z}_N} P'_\nu)^{-1}. \quad (17)$$

It can be seen for an arbitrary permutation that

$$\tilde{\mathsf{R}}^a_a(x) = \mathsf{R}^a_a(x), \quad \text{and} \quad \tilde{\mathsf{R}}^b_a(x) = x^{2\varepsilon_{ab}}\, \mathsf{R}^b_a(x) \quad \text{for} \quad a \neq b, \quad (18)$$

where coefficients ε_{ab} takes values $-1,0,1$ depending on the considered permutation. We shall show in the next section that mixed models with

$$P_0 = P'_{N-1} = Id_{n_{N-1}}, \quad \text{and} \quad Q_\nu = Id_{n_\nu}, \ \forall \nu \in \mathbb{Z}_{N-1}, \quad (19)$$

are solvable by means of algebraic Bethe ansatz techniques [actually, (19) can be slightly relaxed and ask $Q_\nu = Id_{n_\nu}, \forall \nu \in \mathbb{Z}_N$, instead]. Furthermore, we shall see complete integrability implies transfer matrix obtained from (16) is similar to the trace of

$$\mathsf{T}^{\mathrm{mix}} = \hat{\zeta}_0 \cdot \mathsf{R}_0 \dot{\otimes} \hat{\zeta}_1 \cdot \mathsf{R}_1 \dot{\otimes} \cdots \dot{\otimes} \hat{\zeta}_{N-1} \cdot \mathsf{R}_{N-1}\, \Upsilon. \quad (20)$$

Thus, we can solve all vertex models with gluing matrices $\zeta_\nu = P_\nu \hat{\zeta}_\nu P'_\nu$ satisfying (19) by solving those with $\mathsf{T}^{\mathrm{mix}}$ given in Eq. (20). In addition, all $\hat{\zeta}_\nu$ can be supposed to have the same rank.

IV. INTEGRABILITY OF MIXED VERTEX MODELS

In order to show exact solvability of these models (or unless of a subclass of them), since needed commutation rules follow from map (8), we must prove there exists a suitable set of pseudovacuum vectors for $\mathsf{T}^{\mathrm{mix}}$ from which all its eigenstates and corresponding eigenvalues can be constructed. In other terms, using block form

$$\mathsf{T}^{\mathrm{mix}} = \begin{bmatrix} \mathsf{A}^{\mathrm{mix}} & \mathsf{B}^{\mathrm{mix}}_j \\ \mathsf{C}^{\mathrm{mix}}_i & \mathsf{D}^{\mathrm{mix}}_{ij} \end{bmatrix}; \quad 1 \leqslant i,j \leqslant n_{N-1} - 1,$$

we look for elements $\Phi \in \mathcal{H}^{\mathrm{mix}} = \otimes_{\nu\in\mathbb{Z}_N} \mathbb{C}^{n_\nu}$ which are eigenvectors of $\mathsf{A}^{\mathrm{mix}}$ and of each diagonal entry $\mathsf{D}^{\mathrm{mix}}_{ii}$, such that $\mathsf{C}^{\mathrm{mix}}_i \Phi = 0$, and $\mathsf{D}^{\mathrm{mix}}_{ij} \Phi = 0$ for $i \neq j$. In this way, we build up recursively all eigenvalues and eigenstates by applying repeatedly operators $\mathsf{B}^{\mathrm{mix}}_j$ to the mentioned vectors. Completeness problem will be studied separately. Of course, the smaller the rank of involved gluing matrices, the smaller the set of monomials in $\mathsf{B}^{\mathrm{mix}}_j$ and the bigger the number of pseudovacuum vectors we need to construct the complete set of eigenstates. In the singular case for which $\mathrm{rank}\zeta_\nu = 0$ for some ν, we have $\mathsf{T}^{\mathrm{mix}} = 0$ and accordingly every vector of $\mathcal{H}^{\mathrm{mix}}$ is trivially a pseudovacuum vector, and no creation operator is needed in order to diagonalize the transfer matrix $\mathsf{t}^{\mathrm{mix}}$. Note in this case, operators $\mathsf{B}^{\mathrm{mix}}_j$ are null. Thus we can have pseudovacuum vectors which are annihilated by operators $\mathsf{B}^{\mathrm{mix}}_j$ and still be able to build up an eigenstate basis for $\mathsf{t}^{\mathrm{mix}}$.

We actually show exact solvability for a particular class of mixed models. Concretely, we concentrate ourself in monodromy matrices whose related gluings ζ_ν satisfy Eq. (19).

A. The pseudovacuum subspace

Let us first consider the mixed models with monodromy matrices $\mathsf{T}^{\mathrm{mix}}$ defined by Eq. (20), that is, each $\zeta_\nu = \hat{\zeta}_\nu$ is of the form (15). They are a particular case of those with gluing matrices satisfying (19). At the end of this section the general case will be addressed. In order to simplify our calculations, we shall suppose

$$m \doteq \operatorname{rank} \zeta_0 \leqslant \operatorname{rank} \zeta_\nu \qquad \text{for all} \qquad \nu \in \mathbb{Z}_N . \tag{21}$$

This can be reached by a similarity transformation cyclically permuting tensor factors of the linear space $\mathcal{H}^{\mathrm{mix}}$. Of course, $m \leqslant \operatorname{rank} \zeta_\nu \leqslant \min\{n_{\nu-1}, n_\nu\} \pmod N$. Also, we suppose $m > 0$, since for $m = 0$ diagonalization of $\mathsf{T}^{\mathrm{mix}}$ is immediate. Note that (21) implies

$$\mathsf{T}_a^{b\ \mathrm{mix}} = 0 \qquad \text{for} \qquad a > m, \tag{22}$$

and in particular

$$\mathsf{t}^{\mathrm{mix}} = \sum_{a=1}^{n_{N-1}} \mathsf{T}_a^{a\ \mathrm{mix}} = \sum_{a=1}^{m} \mathsf{T}_a^{a\ \mathrm{mix}} = \mathsf{A}^{\mathrm{mix}} + \sum_{i=1}^{m-1} \mathsf{D}_{ii}^{\mathrm{mix}} . \tag{23}$$

For $a \leqslant m$ we have (nonsum over b)

$$\mathsf{T}_a^{b\ \mathrm{mix}} = \tau_b [\mathsf{R}^{n_0}]_a^{c_1} \otimes [\mathsf{R}^{n_1}]_{c_1}^{c_2} \cdots [\mathsf{R}^{n_{N-2}}]_{c_{N-2}}^{c_{N-1}} \otimes [\mathsf{R}^{n_{N-1}}]_{c_{N-1}}^{b} , \tag{24}$$

where sum over each c_ν is in the interval $1 \leqslant c_\nu \leqslant \operatorname{rank} \zeta_\nu$.

Let us indicate by $e_1, \ldots, e_n$ the elements of the canonical basis of $\mathbb{C}^n$. Then $\mathcal{H}^{\mathrm{mix}}$ is spanned by vectors of the form $e_{f_0} \otimes \cdots \otimes e_{f_{N-1}}$, which can be identified with an obvious subset F of functions $f : \mathbb{Z}_N \to \mathbb{N} : \nu \mapsto f_\nu$. In particular, given $f \in \mathsf{F}$, we denote Ω^f the corresponding vector of $\mathcal{H}^{\mathrm{mix}}$. We shall show there exists a set of pseudovacuum vectors, on which algebraic Bethe ansatz will be applied, labeled by the subset F_0 of functions

$$f \in \mathsf{F} / \operatorname{Image} f \subset \{1\} \cup \{n \in \mathbb{N} : n > m\}. \tag{25}$$

More precisely, there exist vectors $\Phi^f \in \mathcal{H}^{\mathrm{mix}}$, $f \in \mathsf{F}_0$, expanding a space

$$\mathcal{H}_0 \doteq \operatorname{span}\{\Omega^f \in \mathcal{H}^{\mathrm{mix}} : f \in \mathsf{F}_0\} \subset \mathcal{H}^{\mathrm{mix}}, \tag{26}$$

namely, the pseudovacuum subspace, and fulfilling

$$\mathsf{A}^{\mathrm{mix}} \Phi^f = \tau_1 \, d \prod_{\nu \in f^{-1}(1)} G(x/\alpha_\nu) \, \Phi^f ,$$

$$\mathsf{D}_{ii}^{\mathrm{mix}} \Phi^f = \tau_{i+1} \, d \, \Phi^f (i < m), \qquad \mathsf{D}_{i \neq j}^{\mathrm{mix}} \Phi^f = \mathsf{C}_i^{\mathrm{mix}} \Phi^f = 0, \tag{27}$$

being $d = \Pi_{\nu \in \mathbb{Z}_N} 1/G(x/\alpha_\nu)$ and $G(x) = (xq - 1/qx)/(x - 1/x)$. In particular for the *equal rank case*, i.e., if $\operatorname{rank} \zeta_\nu = m$ for all ν, then $\Phi^f = \Omega^f$. Note that $\mathcal{H}_0 \subset \ker \mathsf{C}_i^{\mathrm{mix}}\ \forall i$.

We also show

$$\mathsf{B}_j^{\mathrm{mix}} \Phi^f \neq c \, \Phi^f \qquad \text{if} \quad 1 \in \operatorname{Image} f ; \quad \text{otherwise,} \quad \mathsf{B}_j^{\mathrm{mix}} \Phi^f = 0 ; \tag{28}$$

i.e., each $\mathsf{B}_j^{\mathrm{mix}}$ creates new states when $f^{-1}(1) \neq \varnothing$. Using that we construct a set of Bethe vectors from each Φ^f, with j from 1 to m and $f^{-1}(1) \neq \varnothing$, and generate in this way all eigenstates of the transfer matrix.

To find the vectors Φ^f we need some previous results.

1. The action of $\mathsf{T}^{\mathrm{mix}}$ on vectors Ω^f

Let us evaluate the entries $\mathsf{T}_a^{b\ \mathrm{mix}}$ on each vector Ω^f. From Eq. (22) it follows that $\mathsf{T}_a^{b\ \mathrm{mix}}\Omega^f=0$ for all $a>m$. So we only consider $a\leqslant m$. As usual,[7] we normalize operators $\mathsf{R}_a^b=\mathsf{R}^{n_\nu\, b}_{\ \ a}(x/\alpha_\nu):\mathbb{C}^{n_\nu}\to\mathbb{C}^{n_\nu}$ in such a way that on the canonical basis of $\mathbb{C}^{n_\nu}$,

$$\mathsf{R}_a^b\, e_k=\begin{cases}\delta_a^b/G(x/\alpha_\nu)\, e_k, & k\neq a,\\ (\delta_a^b+(1-\delta_a^b)\, c_{\mathrm{sg}(b-a)}(x/\alpha_\nu))\, e_b, & k=a,\end{cases} \tag{29}$$

being $c_\pm(x)=(q-1/q)\ x^{\pm 1}/(xq-1/qx)$. Then, from (24) and the first part of (29), it follows that

$$\mathsf{T}_a^{b\ \mathrm{mix}}\Omega^f=\tau_b\,\delta_a^b\prod_{\nu\in\mathbb{Z}_N}1/G(x/\alpha_\nu)\,\Omega^f=\tau_a\,\delta_a^b\,d\,\Omega^f \tag{30}$$

if $a\notin\mathrm{Image}\, f$, i.e., if $f(\nu)\neq a$ for all $\nu\in\mathbb{Z}_N$. In particular

$$\mathsf{T}_a^{b\ \mathrm{mix}}\Omega^f=0\qquad\text{if}\qquad a\notin\mathrm{Image}\, f\cup\{b\}. \tag{31}$$

Also, if $f\in\mathsf{F}_0$ and $1<a\leqslant m$, since in this case $a\notin\mathrm{Image}\, f$ [see (25)], we have that

$$\begin{gathered}\mathsf{D}_{ii}^{\mathrm{mix}}\Omega^f=\mathsf{T}_{i+1}^{i+1\ \mathrm{mix}}\Omega^f=\tau_{i+1}\,d\,\Omega^f,\quad\text{for}\quad 1\leqslant i<m,\\ \mathsf{D}_{ij}^{\mathrm{mix}}\Omega^f=\mathsf{T}_{i+1}^{j+1\ \mathrm{mix}}\Omega^f=0,\quad\text{for}\quad 1\leqslant i,j<m,\quad i\neq j,\\ \mathsf{C}_i^{\mathrm{mix}}\Omega^f=\mathsf{T}_{i+1}^{1\ \mathrm{mix}}\Omega^f=0,\quad\text{for}\quad 1\leqslant i<m,\end{gathered} \tag{32}$$

putting $i=a-1$ in (30). Otherwise, let σ_a be the first integer such that $f(\sigma_a)=a$, that is, $f(\nu)\neq a$ for all $\nu<\sigma_a$ and $f(\sigma_a)=a$. Let us write

$$\Omega^f=\Omega^{g^a}\otimes e_a\otimes\Omega^{f^a},\qquad\text{with}\qquad g^a,f^a:\mathbb{Z}_{\sigma_a},\mathbb{Z}_{N-\sigma_a-1}\to\mathbb{N}. \tag{33}$$

If $\sigma_a=N-1$, we take Ω^{f^a} equal to 1. Then, using (24) and (29) again (note that a does not belong to Image g^a) we have

$$\mathsf{T}_a^{b\ \mathrm{mix}}\Omega^f=\sum_{i=1}^{\mathrm{rank}\,\zeta_{\sigma_a}}C_{a,i}\,\Omega^{g^a}\otimes e_i\otimes\hat{\mathsf{T}}_i^{b\ \mathrm{mix}}\Omega^{f^a},$$

$$C_{a,i}=D_{a,i}\prod_{\nu<\sigma_a}1/G(x/\alpha_\nu);\quad D_{a,i}=\delta_a^i+(1-\delta_a^i)\,c_{\mathrm{sg}(i-a)}(x/\alpha_{\sigma_a}). \tag{34}$$

Here, operators $\hat{\mathsf{T}}_i^{b\ \mathrm{mix}}$ are given by the last $N-\sigma_a-1$ factors of $\mathsf{T}^{\mathrm{mix}}$. From Eq. (31) applied to $\hat{\mathsf{T}}_i^{b\ \mathrm{mix}}\Omega^{f^a}$, since $C_{a,i}\neq 0$ for all $1\leqslant i\leqslant\mathrm{rank}\,\zeta_{\sigma_a}$, the nonzero terms of (34) are those with i inside $I_a=\{i\in\mathrm{Image}\, f^a\cup\{b\}:i\leqslant\mathrm{rank}\,\zeta_{\sigma_a}\}$. If b is the unique element of I_a and $b\notin\mathrm{Image}\, f^a$, then

$$\mathsf{T}_a^{b\ \mathrm{mix}}\Omega^f=\tau_b\,C_{a,b}\left(\prod_{\nu\neq\sigma_a}1/G(x/\alpha_\nu)\right)\Omega^{g^a}\otimes e_b\otimes\Omega^{f^a}=\tau_b\,C_{a,b}\,d\,G(x/\alpha_{\sigma_a})\,\Omega^{g^a}\otimes e_b\otimes\Omega^{f^a}. \tag{35}$$

Otherwise, suppose there exists $c_1\in I_a\cap\mathrm{Image}\, f^a$, and let σ_{ac_1} be the first integer such that $f^a(\sigma_{ac_1}-\sigma_a)=c_1$. Then $\hat{\mathsf{T}}_{c_1}^{b\ \mathrm{mix}}\Omega^{f^a}=\Sigma_{i\in I_{ac_1}}C_{ac_1,i}\,\Omega^{g^{ac_1}}\otimes e_i\otimes\hat{\mathsf{T}}_i^{b\ \mathrm{mix}}\Omega^{f^{ac_1}}$ with

$$C_{ac_1,i}=D_{c_1,i}\prod_{\sigma_a<\nu<\sigma_{ac_1}}1/G(x/\alpha_\nu),\qquad \Omega^{f^a}=\Omega^{g^{ac_1}}\otimes e_{c_1}\otimes\Omega^{f^{ac_1}},$$

$$I_{ac_1}=\{i\in\text{Image}\,f^{ac_1}\cup\{b\}:i\leqslant\text{rank}\,\zeta_{\sigma_{ac_1}}\}.$$

A recursive process easily follows and the generic term reads

$$\hat{\mathsf{T}}^{b\ \text{mix}}_{c_k}\Omega^{f^{ac_1\cdots c_{k-1}}}=\sum_{i\in I_{ac_1\cdots c_k}}C_{ac_1\cdots c_k,i}\,\Omega^{g^{ac_1\cdots c_k}}\otimes e_i\otimes\hat{\mathsf{T}}^{b\ \text{mix}}_{i}\Omega^{f^{ac_1\cdots c_k}},$$

with $C_{ac_1\cdots c_k,i}=D_{c_k,i}\,\Pi_{\sigma_{ac_1\cdots c_{k-1}}<\nu<\sigma_{ac_1\cdots c_k}}1/G(x/\alpha_\nu)$. Of course, $c_1\in I_a\cap\text{Image}\,f^a$,

$$I_{ac_1c_2\cdots c_{j-1}}=\{i\in\text{Image}\,f^{ac_1c_2\cdots c_{j-1}}\cup\{b\}:i\leqslant\text{rank}\,\zeta_{\sigma_{ac_1\cdots c_{j-1}}}\}\tag{36}$$

and $c_j\in I_{ac_1c_2\cdots c_{j-1}}\cap\text{Image}\,f^{ac_1c_2\cdots c_{j-1}}$ for $2\leqslant j\leqslant k$. The process ends when $b\in I_{ac_1\cdots c_k}$, $b\notin\text{Image}\,f^{ac_1\cdots c_k}$, and we choose $c_{k+1}=b$. In this case

$$\hat{\mathsf{T}}^{b\ \text{mix}}_{c_k}\Omega^{f^{ac_1\cdots c_{k-1}}}=\tau_b\,C_{ac_1\cdots c_k,b}\prod_{\nu>\sigma_{ac_1\cdots c_k}}1/G(x/\alpha_\nu)\,\Omega^{g^{ac_1\cdots c_k}}\otimes e_b\otimes\Omega^{f^{ac_1\cdots c_k}}.$$

In particular, writing $\mathsf{T}^{b\ \text{mix}}_{a}\Omega^{f}=\Sigma_{g\in\mathsf{F}}\,t^{fg}_{ab}\,\Omega^{g}$ we have the given sequence of numbers $c_1,\ldots,c_k\in\text{Image}\,f$ defined by a function g such that $t^{fg}_{ab}\neq0$, being

$$\Omega^{g}=\Omega^{g^a}\otimes e_{c_1}\otimes\Omega^{g^{ac_1}}\otimes e_{c_2}\otimes\Omega^{g^{ac_1c_2}}\otimes\cdots\otimes\Omega^{g^{ac_1c_2\cdots c_{k-1}}}\otimes e_{c_k}\otimes\Omega^{g^{ac_1\cdots c_k}}\otimes e_b\otimes\Omega^{f^{ac_1c_2\cdots c_k}}.\tag{37}$$

Note that Ω^f can be written

$$\Omega^{f}=\Omega^{g^a}\otimes e_a\otimes\Omega^{g^{ac_1}}\otimes e_{c_1}\otimes\Omega^{g^{ac_1c_2}}\otimes\cdots\otimes\Omega^{g^{ac_1c_2\cdots c_{k-1}}}\otimes e_{c_{k-1}}\otimes\Omega^{g^{ac_1c_2\cdots c_k}}\otimes e_{c_k}\otimes\Omega^{f^{ac_1c_2\cdots c_k}}.\tag{38}$$

Furthermore, defining $J_{fg}=\{\sigma_a,\sigma_{ac_1},\ldots,\sigma_{ac_1\cdots c_k}\}$ and $c_0=a$, and recalling $c_{k+1}=b$, we have [compare with Eq. (35)]

$$t^{fg}_{ab}=\tau_b\,d\prod_{j=1}^{k+1}D_{c_{j-1},c_j}\prod_{\nu\in J_{fg}}G(x/\alpha_\nu).\tag{39}$$

If $\#[f^{-1}(a)]=k+1$ and $a=b$, the sequence of numbers $c_i=a$, $i=1,\ldots,k$, corresponds to the vector $\Omega^g=\Omega^f$. Also, $J_{ff}=f^{-1}(a)$ and accordingly, since $D_{a,a}=1$,

$$t^{ff}_{aa}=\tau_a\,d\prod_{\nu\in f^{-1}(a)}G(x/\alpha_\nu).\tag{40}$$

Comparing (37) and (38), we see that functions g such that $t^{fg}_{ab}\neq0$ necessarily satisfy

$$\text{Image}\,g\cup\{a\}=\text{Image}\,f\cup\{b\}.\tag{41}$$

In addition, for each element $\mu\in\text{Image}\,f$, $\mu\neq a,b$, function g must hold

$$\#[g^{-1}(\mu)]=\#[f^{-1}(\mu)],\tag{42}$$

and

$$\#[g^{-1}(a)]=\#[f^{-1}(a)]-(1-\delta_{ab}),$$
$$\#[g^{-1}(b)]=\#[f^{-1}(b)]+(1-\delta_{ab}). \tag{43}$$

Now, defining the classes of functions $C\subset\mathsf{F}$, in such a way that $f,g\in C$ iff

$$\text{Image}\, f=\text{Image}\, g \qquad \text{and} \qquad \#[f^{-1}(\mu)]=\#[g^{-1}(\mu)]$$

for all μ contained in their respective images, we can write

$$\mathsf{T}_a^{b\ \text{mix}}\,\Omega^f=\sum_{g\in C_{-a}^{+b}} t_{ab}^{fg}\,\Omega^g, \qquad \text{if} \quad f\in C, \tag{44}$$

where C_{-a}^{+b} is the class given by functions g satisfying (41), (42), and (43). Let us note that $C=C_{-a}^{+b}$ iff $a=b$. Then, denoting

$$\mathcal{H}_X\doteq\text{span}\{\Omega^f\in\mathcal{H}^{\text{mix}}: f\in X\} \quad \text{for each} \quad X\subset\mathsf{F}, \tag{45}$$

spaces $\mathcal{H}_C$ are $\mathsf{T}_a^{a\ \text{mix}}$-invariant for all a. On the other hand, when $a\neq b$ (since $C\neq C_{-a}^{+b}$), vector Ω^f cannot be written as a linear combination of vectors Ω^g's appearing in (44) (they form a linearly independent set of vectors). That is, $\mathsf{T}_a^{b\ \text{mix}}\,\Omega^f$ is not proportional to Ω^f. Also, if $a\notin\text{Image}\, f$, then $C_{-a}^{+b}=\varnothing$ and consequently $\mathsf{T}_a^{b\ \text{mix}}\,\Omega^f=0$, such as follows from Eq. (30) for $a\neq b$. Last observations translate for operators $\mathsf{B}_j^{\text{mix}}$ into equations

$$\mathsf{B}_j^{\text{mix}}\,\Omega^f\neq c\,\Omega^f, \quad \text{if} \quad f^{-1}(1)\neq\varnothing; \quad \mathsf{B}_j^{\text{mix}}\,\Omega^f=0 \quad \text{otherwise.} \tag{46}$$

Let us briefly study the reducibility of the action on $\mathcal{H}^{\text{mix}}$ of the algebra generated by operators T^{mix}. It follows from Eq. (36) that, if $M=\max_\nu\{\text{rank}\,\zeta_\nu\}$, numbers $c_1,\ldots,c_k$ and $c_{k+1}=b$ must be smaller than or equal to M. This implies $\mathsf{T}_a^{b\ \text{mix}}=0$ for $b>M$, and we can restrict ourselves to the $a,b\leqslant M$ case. Also, comparing (37) and (38), if $f(\nu)>M$ then $g(\nu)=f(\nu)$. As a consequence, besides (41), (42), and (43), condition

$$g(\nu)=f(\nu) \quad \forall\,\nu\in\mathbb{Z}_N \quad \text{such that} \quad g(\nu),f(\nu)>M \tag{47}$$

is necessary in order to have $t_{ab}^{fg}\neq 0$. Thus, defining the classes $E\subset\mathsf{F}$ as those whose functions satisfy (47), it is clear that spaces $\mathcal{H}_E$ are invariant under the action of T^{mix}. It actually can be found smaller invariant spaces inside $\mathcal{H}_E$, depending *locally* on the ranks of gluing matrices, but we will not discuss it here.

For the equal rank case we have $m=M$, and accordingly the classes E are in bijection with elements of F_0. Thus, we can decompose $\mathcal{H}^{\text{mix}}$ into T^{mix}-invariant subspaces $\mathcal{H}_{E(f)}$ labeled by elements of F_0. In addition, by a simple inspection of coefficients (39), it can be shown the actions on $\mathcal{H}_{E(f)}$ and $\mathcal{H}_{E(g)}$ are equivalent provided $f^{-1}(1)=g^{-1}(1)$. Moreover, in the homogeneous case, namely, $\alpha_\nu=1$ for all ν, above equivalence still holds when $\#[f^{-1}(1)]=\#[g^{-1}(1)]$.

In the following subsection we diagonalize (when possible) the operator A^{mix} restricted to each $\mathcal{H}_C$, and show its eigenvectors, when $C\subset\mathsf{F}_0$, are precisely the pseudovacuum vectors we are looking for.

2. Diagonalization of A^{mix} and vectors Φ^f

Let us consider a class of functions C. Using Eqs. (40) and (44) for $a=b=1$, and defining $a_{fg}\doteq t_{11}^{fg}$ for $f\neq g$, we have that

$$\mathsf{A}^{\text{mix}}\,\Omega^f=a_f\,\Omega^f+\sum_{g\in C, g\neq f} a_{fg}\,\Omega^g, \qquad a_f=\tau_1\,d\prod_{\nu\in f^{-1}(1)} G(x/\alpha_\nu). \tag{48}$$

Now, we are going to show there exists a total order relation between the functions of C, such that w.r.t. this order we can write

$$\mathsf{A}^{\mathrm{mix}}\,\Omega^f = a_f\,\Omega^f + \sum_{g<f} a_{fg}\,\Omega^g. \tag{49}$$

In other words, operator $\mathsf{A}^{\mathrm{mix}}$ restricted $\mathcal{H}_C$ is represented by a triangular matrix w.r.t. the resulting ordered basis [recall Eq. (45) for $X=C$].

To see that, let us consider a function $f\in C$. Assign to f_ν the number 1 if $f_\nu=1$ or 0 if $f_\nu \neq 1$. Denote b^f the binary expression related to the sequence $f_0,\ldots,f_{N-1}$. From Eqs. (37) and (38) for $a=b=1$, we see that $b^f>b^g$ (as real numbers) for $f\neq g$, since unless one $f_\nu=1$ were moved to the right. This implies $a_{fg}=0$ if $b^f\leqslant b^g$, that is,

$$\mathsf{A}^{\mathrm{mix}}\,\Omega^f = a_f\,\Omega^f + \sum_{b^g<b^f} a_{fg}\,\Omega^g. \tag{50}$$

So let us define an order $<$ between the elements of C by saying $g<f$ if $b^g<b^f$, and when $b^g=b^f$ we choose an arbitrary order. Using that and equation above, Eq. (49) follows immediately.

Since eigenvalues of $\mathsf{A}^{\mathrm{mix}}$ are given by the numbers a_f, in order to insure its diagonalizability we can ask the considered model to be completely inhomogeneous, i.e., $\alpha_\nu\neq\alpha_\mu$ for all $\nu,\mu\in\mathbb{Z}_N$. Then $a_f\neq a_g$ provided $f^{-1}(1)\neq g^{-1}(1)$. Thus, eigenvalues are distinct, unless those related to the fth and gth rows for which $f^{-1}(1)=g^{-1}(1)$. But $f^{-1}(1)\neq g^{-1}(1)$ if $b^f>b^g$. Therefore [see Eq. (50)], $\mathsf{A}^{\mathrm{mix}}$ does not mix vectors related to rows with the same diagonal entries, and accordingly $\mathsf{A}^{\mathrm{mix}}$ is diagonalizable. Actually, we just can insure $\mathsf{A}^{\mathrm{mix}}=\mathsf{A}^{\mathrm{mix}}(x)$ is diagonalizable for almost all values x of the spectral parameter. Note that for some isolated points $x_o\in\mathbb{C}$, we can have $a_f(x_o)=a_g(x_o)$, in spite of condition $f^{-1}(1)\neq g^{-1}(1)$ holds.

Using usual recursion formulas for diagonalizing triangular matrices, we can define for each subspace $\mathcal{H}_C$ the basis Φ^f, $f\in C$, given by

$$\Phi^f = \begin{cases} \Omega^{\min_C}, & f=\min_C, \\ \Omega^f + \sum_{g<f} \chi_{fg}\,\Phi^g, & f>\min_C, \end{cases} \tag{51}$$

with

$$\chi_{fg} = \begin{cases} a_{g^+g}/(a_{g^+}-a_g), & f=g^+, \\ \left(a_{fg} - \sum_{g<h<f} a_{fh}\,\chi_{hg}\right)/(a_f-a_g), & f>g^+. \end{cases} \tag{52}$$

Here $\min_C$ is the minimal $f\in C$ w.r.t. the defined order, and g^+ is the first element in C bigger than g. Equation (52) must be understood as a recursive formula on f for each g. Because $[\mathsf{A}^{\mathrm{mix}}(x),\mathsf{A}^{\mathrm{mix}}(x')]=0$ for all $x,x'\in\mathbb{C}$ [that follows from commutation relations given in (3)], operators $\mathsf{A}^{\mathrm{mix}}(x)$ can be diagonalized simultaneously. Thus numbers χ_{fg} and vectors Φ^f do not depend on the spectral parameter.

Let us note diagonal entries $\mathsf{D}^{\mathrm{mix}}_{ii}$ can be diagonalized as above. But this is not enough to diagonalize $\mathsf{t}^{\mathrm{mix}}$, since operators $\mathsf{A}^{\mathrm{mix}}$ and $\mathsf{D}^{\mathrm{mix}}_{ii}$ do not commute among themselves. Nevertheless, last operators restricted to $\mathcal{H}_0$ do commute, and accordingly can be simultaneously diagonalized. This follows from the facts that $\mathcal{H}_0\subset\ker\mathsf{C}^{\mathrm{mix}}_i$ and that Eq. (3) implies

$$[\,\mathsf{D}^{\mathrm{mix}}_{ii}(x),\mathsf{A}^{\mathrm{mix}}(y)] = -\mathsf{B}^{\mathrm{mix}}_i(x)\,\mathsf{C}^{\mathrm{mix}}_i(y)\,c_-(x/y) + \mathsf{B}^{\mathrm{mix}}_i(y)\,\mathsf{C}^{\mathrm{mix}}_i(x)\,c_+(x/y).$$

Now, let us see that vectors Φ^f for $f\in\mathsf{F}_0$, given by (51) and (52), satisfy Eqs. (27) and (28). Since they are eigenvectors of $\mathsf{A}^{\mathrm{mix}}$ with eigenvalues a_f, the first part of (27) follows immediately.

For the second part, note Φ^f is a linear combination of vectors Ω^g with g inside C. Also note, if $f\in \mathsf{F}_0$, then the class defined by f is inside F_0 too. Hence, using Eq. (32) we arrive at the wanted result. The same happens for (28) using Eq. (46).

For the equal rank case, it can be shown that $a_{fg}=0$ for all $f\in \mathsf{F}_0$. In fact, sets $I_{1c_1\cdots c_j}$ defined by (36) (putting $a=b=1$) has 1 as the unique element, and consequently the only possible sequence is $c_i=1$ for $i=1,\ldots,\#[f^{-1}(1)]-1$. Such sequence corresponds to the vector Ω^f. Then, the latter is an eigenvector of $\mathsf{A}^{\mathrm{mix}}$ (without any inhomogeneity condition). In other words, $\mathsf{A}^{\mathrm{mix}}$ restricted to $\mathcal{H}_0$ is represented by a diagonal matrix for the basis Ω^f, $f\in \mathsf{F}_0$, and accordingly $\Phi^f=\Omega^f$.

To end this subsection let us say last results, valid for monodromy matrices $\mathsf{T}^{\mathrm{mix}}$ of the form (20), also holds for those given by Eq. (16) and satisfying condition (19). In fact, on the canonical basis $e_1,\ldots,e_{n_\nu}$ of $\mathbb{C}^{n_\nu}$, using Eqs. (18) and (29), we have that

$$\tilde{\mathsf{R}}_{a}^{b\ \ n_\nu} e_k=\begin{cases} \delta_a^b/G(x/\alpha_\nu)\, e_k, & k\neq a,\\ (\,\delta_a^b+(1-\delta_a^b)\,(x/\alpha_\nu)^{2\varepsilon^\nu_{ab}}\, c_{\mathrm{sg}(b-a)}(x/\alpha_\nu))\, e_b, & k=a. \end{cases}$$

Then, applying $\tilde{\mathsf{T}}_a^{b\ \ \mathrm{mix}}$ to a vector Ω^f we arrive at Eqs. (30) or (34), depending on Image f, where the second term of coefficients C_i [see Eq. (34)] must be just changed by a factor $(x/\alpha_\sigma)^{2\varepsilon^\sigma_{ai}}$. Therefore, all above results follow. In particular, all we have said for $\mathsf{A}^{\mathrm{mix}}$ is also true for $\tilde{\mathsf{A}}^{\mathrm{mix}}$, and the former is diagonalizable iff so is the latter. There is a minor change in coefficients a_{fg}, and consequently in the linear combinations (51) that define eigenvectors of $\tilde{\mathsf{A}}^{\mathrm{mix}}$. Denoting the latter by $\tilde{\Phi}^f$, and recalling Eq. (17), we conclude

Theorem 1: *Given a mixed vertex model* $\mathsf{T}^{\mathrm{mix}}=\zeta_0\cdot\mathsf{R}_0\dot{\otimes}\zeta_1\cdot\mathsf{R}_1\dot{\otimes}\cdots\dot{\otimes}\zeta_{N-1}\cdot\mathsf{R}_{N-1}\,\Upsilon$, *with gluing matrices* $\zeta_\nu=P_\nu\hat{\zeta}_\nu P'_\nu$ *satisfying Eqs. (19) and (21), and assuming* $\mathsf{A}^{\mathrm{mix}}$ *is diagonalizable (e.g.,* $\mathsf{T}^{\mathrm{mix}}$ *is completely inhomogeneous), it follows that vectors*

$$\Phi^f\doteq(\otimes_{\nu\in\mathbb{Z}_N}P'_\nu)^{-1}\,\tilde{\Phi}^f,\qquad f\in \mathsf{F}_0,$$

are pseudovacuum states for $\mathsf{T}^{\mathrm{mix}}$ *satisfying Eqs. (27) and (28). When* $\mathrm{rank}\zeta_\nu=m\ \forall\nu$, $\mathsf{A}^{\mathrm{mix}}$ *is diagonalizable and* $\Phi^f\doteq(\otimes_{\nu\in\mathbb{Z}_N}P'_\nu)^{-1}\,\Omega^f$. □

All that can be rephrased in terms of our original mixed monodromy matrices, i.e., in the form (7). We just must regard them as particular cases of (12) subject to (13).

B. Nested Bethe equations

Let $\mathsf{T}^{\mathrm{mix}}$ be a monodromy matrix as that given in theorem above. Thanks to the algebra embeddings $\mathrm{YB}_{n-1}\hookrightarrow\mathrm{YB}_n$, $n>1$, which are a direct consequence of equations

$$[R_{n-1}]^{kl}_{ab}=[R_n]^{kl}_{ab},\qquad \text{for } 1\leqslant a,b,k,l\leqslant n-1,$$

it follows that $\mathsf{T}_a^{b\ \ \mathrm{mix}}$ for $a,b\leqslant m$ satisfy relations corresponding to the YB algebra YB_m. Then, following standard techniques for each $\Phi^f\in\mathcal{H}_0$,[7,20] that is, proposing as eigenstates for $\mathsf{t}^{\mathrm{mix}}$ [see (23)] the Bethe vectors

$$\Psi^f=\Psi^{j_1\cdots j_{r_1}}\mathsf{B}^{\mathrm{mix}}_{j_1}(x_1;\alpha)\,\cdots\,\mathsf{B}^{\mathrm{mix}}_{j_r}(x_r;\alpha)\,\Phi^f,\qquad j_1,\ldots,j_r<m,$$

and separating in the so-called *wanted* and *unwanted* terms, we arrive at a set of nested Bethe ansatz equations which in its recursive form are given by

$$\frac{\prod_{p=1}^{r_1}G(x_k^{(1)}/x_p^{(1)})}{\prod_{\nu\in f^{-1}(1)}G(x_k^{(1)}/\alpha_\nu)}\Lambda_1(x_k^{(1)})+\tau_1\prod_{p=1}^{r_1}G(x_p^{(1)}/x_k^{(1)})=0,$$

$$\frac{\prod_{p=1}^{r_l} G(x_k^{(l)}/x_p^{(l)})}{\prod_{v=1}^{r_{l-1}} G(x_k^{(l)}/x_v^{(l-1)})}\Lambda_l(x_k^{(l)})+\tau_l\prod_{p=1}^{r_l} G(x_p^{(l)}/x_k^{(l)})=0 \quad (l>1), \tag{53}$$

and

$$\Lambda_{m-1}(x)=\tau_m,$$

$$\Lambda_l(x)=\frac{\prod_{p=1}^{r_{l+1}} G(x/x_p^{(l+1)})}{\prod_{u=1}^{r_l} G(x/x_u^{(l)})}\Lambda_{l+1}(x)+\tau_{l+1}\prod_{p=1}^{r_{l+1}} G(x_p^{(l+1)}/x) \quad (l<m-2), \tag{54}$$

where $l=1,\ldots,m-1$, $k=1,\ldots,r_l$, and $0\leqslant r_l\leqslant r_{l-1}\leqslant\#[f^{-1}(1)]$. Thus, Bethe equations related to a given $\Phi^f\in\mathcal{H}_0$, are the ones corresponding to an A_{m-1} type quasiperiodic vertex model with $n_f\doteq\#[f^{-1}(1)]$ sites per row and inhomogeneity vector $\alpha_f=(\alpha_{\nu_0},\alpha_{\nu_1},\ldots,\alpha_{\nu_{n_f-1}})$, such that $\nu_i\in f^{-1}(1)$ and $\nu_i<\nu_{i+1}$ for all $i\in\mathbb{Z}_{n_f}$.

When $\#[f^{-1}(1)]=0$ we have no Bethe equations. Note in this case $\mathsf{B}_j^{\mathrm{mix}}\Phi^f=0$ for all $j<m$ [see Eq. (28)].

For each solution

$$\mathbf{x}=\{\mathbf{x}^{(l)}=(x_1^{(l)},\ldots,x_{r_l}^{(l)}):l=1,\ldots,m-1\}$$

of Eqs. (53) and (54),

$$\Lambda^f(x;\mathbf{x})=d\prod_{k=1}^{r_1} G(x/x_k^{(1)})\,\Lambda_1(x)+\tau_1\,d\prod_{\nu\in f^{-1}(1)} G(x/\alpha_\nu)\prod_{k=1}^{r_1} G(x_k^{(1)}/x) \tag{55}$$

gives an eigenvalue of $\mathsf{t}^{\mathrm{mix}}$. Note that $\Lambda^f(x;\mathbf{x})=\Lambda^g(x;\mathbf{x})$ if $f^{-1}(1)=g^{-1}(1)$. This is the main source of degeneracy for the transfer matrix. It can be seen each $\Lambda^f(x;\mathbf{x})$ differs by a factor $\Pi_{\nu\notin f^{-1}(1)}1/G(x/\alpha_\nu)$ from the corresponding eigenvalue related to the mentioned A_{m-1} model. Eigenvectors $\Psi^f(\mathbf{x})$, i.e., the Bethe vectors, can also be given recursively, but now through vectors $\Psi_l\in(\mathbb{C}^{m-l})^{\otimes r_l}$ with coordinates $(\Psi_l)^{j_1\cdots j_{r_l}}$ (w.r.t. the canonical basis of $\mathbb{C}^{m-l}$) such that

$$\Psi^f(\mathbf{x})=(\Psi_1)^{j_1\cdots j_{r_1}}\mathsf{B}_{j_1}^{\mathrm{mix}}(x_1^{(1)};\alpha)\cdots\mathsf{B}_{j_{r_1}}^{\mathrm{mix}}(x_{r_1}^{(1)};\alpha)\,\Phi^f, \tag{56}$$

for $1\leqslant l\leqslant m-2$

$$\Psi_l=(\Psi_{l+1})^{j_1\cdots j_{r_{l+1}}}\mathsf{B}_{j_1}^{(m-l,r_l)}(x_1^{(l+1)};\mathbf{x}^{(l)})\cdots\mathsf{B}_{j_{r_{l+1}}}^{(m-l,r_l)}(x_{r_{l+1}}^{(l+1)};\mathbf{x}^{(l)})\,\omega_l,$$

and $\Psi_{m-1}=1$. Here $j_1,\ldots,j_{r_{l+1}}<m$. We are denoting by ω_l the pseudovacuum for the pure monodromy matrix $\mathsf{T}^{(m-l,r_l)}$. Let us mention, in the lth level of the nesting process the involved monodromy matrix actually is the twisting

$$\mathsf{T}^{(m-l,r_l)}\cdot\Upsilon_l, \qquad \text{being} \qquad \Upsilon_l=\mathrm{diag}(\tau_1,\ldots,\tau_{m-l}),$$

which also has ω_l as pseudovacuum vector.

Summing up, we have constructed a set of eigenvectors for $\mathsf{t}^{\mathrm{mix}}$ by applying creation operators $\mathsf{B}_j^{\mathrm{mix}}$'s over all Φ^f, $f\in\mathsf{F}_0$. In the following section we address the combinatorial completeness of that set of states.

By last, let us say that Eqs. (53) and (54) do not depend either on permutations P_ν,P'_ν defining the gluing matrices of $\mathsf{T}^{\mathrm{mix}}$ (recall conditions of theorem above), or on the set of ranks of the latter. They only depend on the minimum $m=\min_\nu\{\mathrm{rank}\,\zeta_\nu\}$ of that set, on the boundary matrix

Υ, and on the inhomogeneity vector α. Hence, assuming complete integrability, the spectrum of the related transfer matrix $\mathrm{t}^{\mathrm{mix}}$, which would be given by the numbers $\Lambda^f(x;\mathbf{x})$ defined in (55), only depends on m, Υ, and α. Accordingly,

Theorem 2: *Assuming complete integrability, every mixed model with gluing matrices satisfying Eq. (19) is physically equivalent to one with monodromy matrix of the form (20) and satisfying the equal rank condition:* $\operatorname{rank}\zeta_\nu = m$ *for all* ν. □

C. Combinatorial completeness

In this section we are going to show that Eq. (56) (varying indices j from 1 to m, functions f in F_0, and $\mathbf{x}$ along solutions of (53) and (54)) defines unless $\dim \mathcal{H}^{\mathrm{mix}} = \Pi_{\nu\in\mathbb{Z}_N} n_\nu$ different vectors. That is to say, we have a set of Bethe vectors from which, *a priori*, a basis of eigenstates for the related transfer matrix can be extracted. To see that, we shall assume combinatorial completeness of Bethe ansatz equations related to the A_{n-1} vertex models, i.e., for a model with N sites in a row we suppose there is unless $(n-1)^r\binom{N}{r}$ different solutions for the Bethe equations corresponding to r creation operators. This has been shown[21] for $n=2$, but we do not know about any similar result for bigger n. In our case, we would be saying for each vector Φ^f with $f \in \mathsf{F}_0$, there exists unless a number $(m-1)^r\binom{n_f}{r}$ of different solutions of (53) and (54) corresponding to $r_1 = r$ creation operators. Recall that $n_f = \#[f^{-1}(1)]$. Let us first see why this assumption is useful for our purposes.

It is enough to analyze the case of monodromy matrices given by (20). The other cases, i.e., those given by (14) and satisfying (19), follow analogously. So let us come back to Sec. IV A 1 and consider the action of operators $\mathsf{B}_j^{\mathrm{mix}}$ with $j<m$, on vectors Ω^f with $f\in\mathsf{F}_0$. Suppose first that $\operatorname{rank}\zeta_\nu = m$ for all ν. For $a=1$ and $b=j+1$, sequences $c_i=1$, $i=1,\ldots,k$, with $1\leqslant k<n_f$ define terms proportional to vectors $\Omega^g=\Omega^{f_{\mu,j}}$, with $\mu\in f^{-1}(1)$, $f_{\mu,j}(\nu)=f(\nu)$ for all $\nu\neq\mu$ and $f_{\mu,j}(\mu)=j+1$. That is, we change a vector e_1 by a vector e_{j+1} in position $\mu\in f^{-1}(1)$. They are the only possible sequences. Thus, the action of each $\mathsf{B}_j^{\mathrm{mix}}$, $j=1,\ldots,m-1$, on a vector Ω^f gives rise to a linear combination of n_f linearly independent vectors. Existence of n_f different solutions to Eqs. (53) and (54) for $r_1=1$ and for each j, is a necessary condition to obtain n_f l.i. eigenstates from the set of Bethe vectors. Then, varying j from 1 to $m-1$, we shall have, *a priori*, $(m-1)\,n_f$ l.i. eigenstates. Applying $\mathsf{B}_i^{\mathrm{mix}}$ and $\mathsf{B}_j^{\mathrm{mix}}$ we have $(m-1)^2$ vectors, each one of them having $n_f(n_f-1)/2$ l.i. terms. In general, if we apply r creation operators to Ω^f, we have $(m-1)^r$ vectors with related $\binom{n_f}{r}$ terms. Now it becomes clear why our assumption is needed. The same argument can be given for the general rank case. There, when an operator $\mathsf{B}_j^{\mathrm{mix}}$ acts on Ω^f we have as above the terms proportional to $\Omega^{f_{\mu,j}}$, $\mu\in f^{-1}(1)$, together with additional terms given by vectors $\Omega^{h_{\sigma,j}}$ with h belonging to the same class of f. Thus, the latter appears as terms when $\mathsf{B}_j^{\mathrm{mix}}$ is applied to Ω^h. Accordingly, in order to avoid overcounting, we do not have to take them into account.

Let us come back to our original problem. If combinatorial completeness holds there exists unless a number $\Sigma_{r=0}^{n_f}(m-1)^r\binom{n_f}{r} = ((m-1)+1)^{n_f} = m^{n_f}$ of Bethe vectors for each function $f\in\mathsf{F}_0$. Thus, since $0\leqslant n_f\leqslant N$ for every $f\in\mathsf{F}$, the total number of Bethe vectors is $\Sigma_{f\in\mathsf{F}_0} m^{n_f} = \Sigma_{k=0}^{N} m^k p_k$, being p_k the number of functions $f\in\mathsf{F}_0$ such that $n_f=k$. Let us calculate p_k. It is clear that the number of functions f in F_0 with the same preimage $f^{-1}(1)$ is

$$\prod_{\nu\in\mathbb{Z}_N}(n_\nu - m)^{\varepsilon_\nu}, \quad \varepsilon_\nu = \begin{cases} 0, & \nu\in f^{-1}(1), \\ 1, & \text{otherwise.} \end{cases} \tag{57}$$

In terms of numbers $\varepsilon_0,\ldots,\varepsilon_{N-1}$, the condition $n_f=\#[f^{-1}(1)]=k$ can be characterized by an equality $\varepsilon_0+\cdots+\varepsilon_{N-1}=N-k$. Then, in order to obtain p_k we must sum over all configurations of $\varepsilon_0,\ldots,\varepsilon_{N-1}$ (ε_ν equal to 0 or 1), such that last condition holds, i.e.,

$$p_k=\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}(n_\nu-m)^{\varepsilon_\nu}\,\delta_{\varepsilon_0+\cdots+\varepsilon_{N-1},N-k}. \tag{58}$$

Accordingly,

$$\begin{aligned}\sum_{k=0}^{N}m^k p_k&=\sum_{k=0}^{N}m^k\left(\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}(n_\nu-m)^{\varepsilon_\nu}\,\delta_{\varepsilon_0+\cdots+\varepsilon_{N-1},N-k}\right)\\&=\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}(n_\nu-m)^{\varepsilon_\nu}\sum_{k=0}^{N}m^k\,\delta_{\varepsilon_0+\cdots+\varepsilon_{N-1},N-k}\\&=\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}(n_\nu-m)^{\varepsilon_\nu}\,m^{N-(\varepsilon_0+\cdots+\varepsilon_{N-1})}\\&=m^N\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}\left(\frac{n_\nu}{m}-1\right)^{\varepsilon_\nu}.\end{aligned}$$

But

$$\begin{aligned}\sum_{\varepsilon_0,\ldots,\varepsilon_{N-1}}\prod_{\nu\in\mathbb{Z}_N}\left(\frac{n_\nu}{m}-1\right)^{\varepsilon_\nu}&=\prod_{\nu\in\mathbb{Z}_N}\left(\sum_{\varepsilon_\nu}\left(\frac{n_\nu}{m}-1\right)^{\varepsilon_\nu}\right)\\&=\prod_{\nu\in\mathbb{Z}_N}\left(\left(\frac{n_\nu}{m}-1\right)^0+\left(\frac{n_\nu}{m}-1\right)\right)\\&=\prod_{\nu\in\mathbb{Z}_N}\frac{n_\nu}{m}\\&=m^{-N}\prod_{\nu\in\mathbb{Z}_N}n_\nu,\end{aligned}$$

and consequently $\Sigma_{f\in\mathsf{F}_0}m^{n_f}=\Pi_{\nu\in\mathbb{Z}_N}n_\nu$, as we wanted to see.

V. CONCLUSIONS

From the last equation we see that, under conditions of Theorem 1 and assuming complete integrability, $\mathcal{H}^{\mathrm{mix}}$ can be decomposed into a direct sum of m^{n_f}-dimensional spaces $\mathcal{H}_f$, each one of them generated by the Bethe vectors related with some f inside F_0. Note this sum, in general, is not orthogonal w.r.t. the usual scalar product in $\otimes_{\nu\in\mathbb{Z}_N}\mathbb{C}^{n_\nu}$. Thinking of the quantum spin ring related to our vertex model, whose Hamiltonian H is constructed from the logarithmic derivative (if there exists) of the transfer matrix, states of $\mathcal{H}_f$ can be interpreted as those of an anisotropic A_{m-1} type spin chain with n_f sites, which are *localized* on the subring $\mathbb{Z}_{n_f}\sim f^{-1}(1)\subset\mathbb{Z}_N$. In other words, we have decomposed a mixed spin model as a direct sum of A_{m-1} type ones with different numbers of sites and generically different inhomogeneities. Multiplicity of these models is given by (57) [recall eigenvalues (55) only depend on f through $f^{-1}(1)$]. In connection with Theorem 2 let us say that for the equal rank case, since we have $\mathcal{H}_f=\mathcal{H}_{E(f)}$ (see at the end of Sec. IV A 1), described decomposition (which results orthogonal) and mentioned multiplicity are direct consequences of the facts that last spaces are $\mathsf{T}^{\mathrm{mix}}$-invariant, and that corresponding actions on spaces $\mathcal{H}_f$ and $\mathcal{H}_g$ are equivalent when $f^{-1}(1)=g^{-1}(1)$.

In the homogeneous case we have in addition actions on $\mathcal{H}_f$ and $\mathcal{H}_g$ are equivalent still when $n_f=n_g$. In other terms, for the homogeneous equal rank case we can write $\mathcal{H}^{\mathrm{mix}}$ as the orthogonal direct sum $\mathcal{H}^{\mathrm{mix}}=\oplus_{k=0}^{N}\mathbb{C}^{p_k}\otimes\mathcal{H}_{f_k}$ [see (58) for numbers p_k], being f_k some function with $n_{f_k}=k$.

Concluding, we have presented a procedure for gluing different integrable vertex models in such a way that the integrability of the whole system is preserved. This procedure relies on some generalization of the coalgebra structure to the case of rectangular quantum matrices and their representations, enhancing the deep linking between these algebraic structures and integrability.

(Received 28 March 2003; accepted 12 December 2003; published 14 April 2004)

Let $\mathcal{T}(\mathcal{L})$ be the space of all tensors over a Lie algebra $\mathcal{L}$ in which the Lie bracket is obtained by taking commutators in an associative algebra. We show that $\mathcal{T}(\mathcal{L})$ becomes a Hopf algebra when equipped with a noncommutative modification of the shuffle product together with the standard coproduct. A definition is given of directed double product integrals as iterated single product integrals driven by formal power series with coefficients in the tensor product of $\mathcal{L}$ with an appropriate associative algebra. For the Hopf algebra $\mathcal{T}(\mathcal{L})[[h]]$ of formal power series we show that elements $R[h]$ of $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$ satisfying $(\Delta\otimes\mathrm{id})R[h]=R[h]^{13}R[h]^{23}$, $(\mathrm{id}\otimes\Delta)R[h]=R[h]^{13}R[h]^{12}$, and which are unitalized by the counit in either copy of $\mathcal{T}(\mathcal{L})$, can be characterized as such directed double product integrals $\Pi\Pi(1+\vec{d}\otimes\vec{d}r[h])$ where $r[h]$ is a formal power series with coefficients in $\mathcal{L}\otimes\mathcal{L}$ and vanishing constant term. © *2004 American Institute of Physics.*

I. INTRODUCTION

Enriquez[1] has introduced a new method of functorial quantization of Lie bialgebras based on deformation of the Hopf algebra got by equipping the vector space of tensors $\mathcal{T}(\mathcal{L})$ over a Lie bialgebra $\mathcal{L}$ with the shuffle multiplication, defined by

$$(L_1\otimes L_2\otimes\cdots\otimes L_m)(L_{m+1}\otimes L_{m+2}\otimes\cdots\otimes L_{m+n})=\sum_{\pi\in S_{m,n}} L_{\pi(1)}\otimes L_{\pi(2)}\otimes\cdots\otimes L_{\pi(m+n)}, \quad (1)$$

where $S_{m,n}$ is the set of permutations of $(1,2,\ldots,m+n)$ which conserve the order of $(1,2,\ldots,m)$ and of $(m+1,m+2,\ldots,m+n)$, and the coproduct defined by

$$\Delta(L_1\otimes L_2\otimes\cdots\otimes L_m)=\sum_{k=0}^{m}(L_1\otimes L_2\otimes\cdots\otimes L_k)\otimes(L_{k+1}\otimes L_{k+2}\otimes\cdots\otimes L_m). \quad (2)$$

Enriquez' method suggests an alternative more algebraic approach to the quantization problem to that of Etingof and Kazhdan.[2]

In Ref. 4 it was shown that in the case of a Lie algebra $\mathcal{L}$ whose Lie bracket is formed by taking commutators in a not necessarily unital associative algebra, $\mathcal{T}(\mathcal{L})$ can be equipped with a noncommutative associative unital multiplication in which the homogeneous components of the product $\gamma=\alpha\beta$ of two tensors are given in terms of those of α and β by

$$\gamma_n=\sum_{A\cup B=\{1,2,\ldots,n\}}\alpha^A_{|A|}\beta^B_{|B|}. \quad (3)$$

[a]Electronic mail: robin.hudson@ntu.ac.uk

Here the sum is over all 3^n ordered pairs (A,B) of not necessarily disjoint subsets whose union is $\{1,2,\ldots,n\}$, and we use the place notation that $\alpha^A_{|A|}$ indicates that the homogeneous component $\alpha_{|A|}$ is placed in the tensor product of the $|A|$ copies of $\mathcal{L}$ within $\otimes^n\mathcal{L}$ labeled by the elements of A, $\beta^B_{|B|}$ is defined analogously, so that since $A\cup B=\{1,2,\ldots,n\}$ all copies of $\mathcal{L}$ within $\otimes^n\mathcal{L}$ are occupied by $\alpha^A_{|A|}\beta^B_{|B|}$, and double occupancies are reduced using the multiplication in $\mathcal{L}$. The shuffle product (1) corresponds to restricting the sum in (3) to disjoint pairs (A,B). Alternatively we may define the multiplication (3) by bilinear extension of its action on homogeneous product tensors, which is:

$$(L_1\otimes L_2\otimes\cdots\otimes L_m)(L_{m+1}\otimes L_{m+2}\otimes\cdots\otimes L_{m+n})=\sum_{j=m\vee n}^{m+n}\sum_{(P_1,P_2,\ldots,P_j)\in\mathcal{P}_j} L_{P_1}\otimes L_{P_2}\otimes\cdots\otimes L_{P_j}, \tag{4}$$

where $\mathcal{P}_j$ is the set of ordered partitions $(P_1,P_2,\ldots,P_j)$ of $\{1,2,\ldots,m+n\}$ into j subsets such that:

(i) Each subset P is either a singleton $\{i\}$, in which case $L_P=L_i$, or a pair $\{k,l\}$ with $k\in\{1,2,\ldots,m\}$ and $l\in\{m+1,m+2,\ldots,m+n\}$, in which case $L_P=L_kL_l$;
(ii) the permutation $(P_1,P_2,\ldots,P_j)$ of $(1,2,\ldots,m+n)$, in which each pair is in increasing order, is an element of $S_{m,n}$.

Remark: We are grateful to the referee for the interesting observation that the multiplication (4) is similar to the general product formula for multizeta functions

$$\zeta(s_1,s_2,\ldots,s_m)=\sum_{1\leqslant j_1<j_2<\cdots<j_m<\infty} j_1^{s_1}j_2^{s_2}\cdots j_m^{s_m},$$

of interest in number theory, namely,

$$\zeta(s_1,s_2,\ldots,s_m)\zeta(s_{m+1},s_{m+2},\ldots,s_{m+n})=\sum_{j=m\vee n}^{m+n}\sum_{(P_1,P_2,\ldots,P_j)\in\mathcal{P}_j}\zeta(s_{P_1},s_{P_2},\ldots,s_{P_k}),$$

where $s_P=s_j$ if P is a singleton $\{j\}$ and $s_P=s_j+s_k$ if P is a pair $\{j,k\}$.

Motivated by quantum stochastic calculus, we refer to (3) or (4) as the *Itô shuffle product* and the corresponding algebra as the *Itô shuffle algebra*. We shall show below that this algebra is also a Hopf algebra under the co-product (2). The subspace $\mathcal{S}(\mathcal{L})$ of $\mathcal{T}(\mathcal{L})$ comprising symmetric tensors is a sub-Hopf algebra isomorphic to the universal enveloping $\mathcal{U}$ algebra of $\mathcal{L}$.

By replacing (3) by

$$\gamma_n=\sum_{A\cup B=\{1,2,\ldots,n\}} h^{|A\cap B|}\alpha^A_{|A|}\beta^B_{|B|},$$

we can make $\mathcal{T}(\mathcal{L})[[h]]$ into a formal deformation of the Enriquez-type.[9]

Enriquez' method depends firstly on finding an element $R[h]$ of the deformed Hopf algebra which satisfies the quasitriangular identities

$$(\Delta\otimes\mathrm{id})R[h]=R[h]^{13}R[h]^{23},\quad(\mathrm{id}\otimes\Delta)R[h]=R[h]^{13}R[h]^{12}. \tag{5}$$

In the present work we shall find a characterization of such elements of the Hopf algebra $\mathcal{T}(\mathcal{L})\times[[h]]$ as directed double product integrals, whose definition will now be explained.

We introduce *right* and *left differential maps* $\vec{d}$ and $\overleftarrow{d}$ from $\mathcal{T}(\mathcal{L})$ to $\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ and to $\mathcal{L}\otimes\mathcal{T}(\mathcal{L})$ by linear extension of their actions on homogeneous product tensors

$$\vec{d}(L_1\otimes L_2\otimes\cdots\otimes L_m)=(L_1\otimes L_2\otimes\cdots\otimes L_{m-1})\otimes L_m,$$

$$\overleftarrow{d}(L_1\otimes L_2\otimes\cdots\otimes L_m)=L_1\otimes(L_2\otimes L_3\cdots\otimes L_m).$$

When $\mathcal{T}(\mathcal{L})$ is equipped with the shuffle product (1) these satisfy the Leibniz formulas

$$\overleftarrow{d}(\alpha\beta)=\overleftarrow{d}(\alpha)\beta+\alpha\overleftarrow{d}(\beta), \tag{6}$$

in which $\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ and $\mathcal{L}\otimes\mathcal{T}(\mathcal{L})$ are regarded as $\mathcal{T}(\mathcal{L})$-bimodules using the natural tensorial actions got by linear extension of

$$\alpha(\beta\otimes L)=(\alpha\otimes L)\beta=(\alpha\beta)\otimes L,\quad \alpha(L\otimes\beta)=(L\otimes\alpha)\beta=L\otimes(\alpha\beta). \tag{7}$$

To see that (6) holds for $\vec{d}$, for example, we may decompose into two parts the sum on the right-hand side of (1) according to whether or not $\pi(m+n)$ belongs to $\{1,2,\ldots,m\}$ or to $\{m+1,m+2,\ldots,m+n\}$, and then apply $\vec{d}$ to both sides. It is evident from actions on homogeneous product tensors that the iterates

$$\overleftrightarrow{d}^{(n)}=(\overleftarrow{d}\otimes\mathrm{id}_{\otimes^{n-1}\mathcal{L}})\circ(\overleftarrow{d}\otimes\mathrm{id}_{\otimes^{n-2}\mathcal{L}})\circ\cdots\circ\overleftarrow{d},\quad n=1,2,\ldots,$$

of both the left and right differential maps satisfy

$$\textcircled{+}_{n=0}^{\infty}\overleftrightarrow{d}^{(n)}=\Delta,$$

where we make the identifications

$$\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})=\bigoplus_{n=0}^{\infty}(\mathcal{T}(\mathcal{L})\otimes(\otimes^n\mathcal{L}))=\bigoplus_{n=0}^{\infty}((\otimes^n\mathcal{L})\otimes\mathcal{T}(\mathcal{L})). \tag{8}$$

If we replace the shuffle product (1) by the Itô shuffle product (4) we find, instead of the Leibniz formula (6), the *Leibniz–Itô formula*

$$\overleftarrow{d}(\alpha\beta)=\overleftarrow{d}(\alpha)\beta+\alpha\overleftarrow{d}(\beta)+\overleftarrow{d}(\alpha)\overleftarrow{d}(\beta), \tag{9}$$

where now the first two terms on the right-hand side refer to the tensorial actions defined by (7), but in which the multiplications are now given by (3), and the third term refers to the tensor product multiplication of the Itô shuffle product in $\mathcal{T}(\mathcal{L})$ with the given multiplication in $\mathcal{L}$. (9) may be seen to hold for $\vec{d}$, for example, by decomposing the inner sum on the right-hand side of (4) into three parts, according to whether the final element L_{S_j} is such that S_j is a singleton $\{i\}\subset\{1,2,\ldots,m\}$, a singleton $\{k\}\subset\{m+1,m+2,\ldots,m+n\}$ or a pair $\{i,k\}$.

The Leibniz formula (6) shows that the right or left differential map defines a differential calculus in the sense of Woronowicz[10] when $\mathcal{T}(\mathcal{L})$ is equipped with the shuffle product and $\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ or $\mathcal{L}\otimes\mathcal{T}(\mathcal{L})$ is equipped with the tensorial biaction defined by (7). In the case of the Itô shuffle product the Leibniz–Ito formula (9) can be reduced to the Leibniz formula (6) by modifying either the right or left actions. For example, if we define $\vec{\bullet}$: $(\mathcal{T}(\mathcal{L})\otimes\mathcal{L})\times\mathcal{T}(\mathcal{L})\to\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ by

$$M\vec{\bullet}\alpha=M\alpha+M\vec{d}\alpha,$$

where the first term is the tensorial action (7) with Itô shuffle product and the second is the tensor product multiplication in $\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ then, using the formula (9), it may be verified that $\vec{\bullet}$ defines a right action, compatible with the corresponding left tensorial action, in terms of which (9) assumes the Leibniz form

$$\vec{d}(\alpha\beta)=\vec{d}(\alpha)\vec{\bullet}\beta+\alpha\vec{d}(\beta).$$

Alternatively a similar modification may be made to the left action to achieve the Leibniz formula. But the asymmetry of the two corresponding Woronowicz calculus (which are not bicovariant in the sense of Ref. 10) make them impractical to use in what follows. Henceforth we always assume that $\mathcal{T}(\mathcal{L})$ is equipped with the Itô shuffle product and that $\mathcal{T}(\mathcal{L})$ acts correspondingly on $\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ or $\mathcal{L}\otimes\mathcal{T}(\mathcal{L})$ according to (7), so that (9) holds. Correspondingly, we regard the space $\mathcal{T}(\mathcal{L})\times[[h]]$ of formal power series as a Hopf algebra under the convolution multiplication formed from the Itô shuffle multiplication and action of Δ on coefficients.

In Ref. 7 we formulated an algebraic theory of product integrals of the form $\Pi(1+dL[h])$ where $L[h]$ is an element of the space $h\mathcal{L}[[h]]$ of formal power series with coefficents in $\mathcal{L}$ and with vanishing zero order coefficient. While this theory is originally formulated in terms of a quantum stochastic calculus of which the associative algebra $\mathcal{L}$ is the algebra of Itô differentials, its algebraic character ensures a reformulation independent of the quantum stochastic context, and that each product integral of the theory has an indefinite version living in $\mathcal{S}(\mathcal{L})[[h]]$, or equivalently in $\mathcal{U}[[h]]$. In this form, in view of Ref. 4, the theory can be set up for an arbitrary commutator Lie algebra $\mathcal{L}$. Product integrals of this type are characterized among all elements $X[h]$ of $\mathcal{S}(\mathcal{L})[[h]]$ by the grouplikeness conditions

$$\varepsilon(X[h])=1,\ \ \Delta(X[h])=X[h]\otimes X[h], \tag{10}$$

where ε denotes the co-unit. Note that the simple product integral $X[h]=\Pi(1+dL[h]$ can be defined as the solution of the differential equation

$$dX[h]=X[h]\otimes dL[h],\ \ \varepsilon(X[h])=1, \tag{11}$$

whose unique solution is well defined algebraically.[3]

In Ref. 8 we developed a corresponding theory of double product integrals of the form $\Pi\Pi(1+dr[h])$ where $r[h]$ is an element of $h(\mathcal{L}\otimes\mathcal{L})[[h]]$, again in the quantum stochastic context. In order to obtain a theory whose indefinite version would live in $(\mathcal{U}\otimes\mathcal{U})[[h]]$ or equivalently in $(\mathcal{S}(\mathcal{L})\otimes\mathcal{S}(\mathcal{L}))[[h]]$ the double products were symmetrized in a way which prevents them from enjoying some cogent mathematical properties.

In the present work we shall develop a theory of double product integrals without the symmetry assumption, which thus live not in $(\mathcal{S}(\mathcal{L})\otimes\mathcal{S}(\mathcal{L}))[[h]]$, but in $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$. We must now distinguish between forward, mixed, and backward double products $\Pi\Pi(1+\vec{d}\otimes\vec{d}r[h])$, $\Pi\Pi(1+\vec{d}\otimes\overleftarrow{d}r[h])$, $\Pi\Pi(1+\overleftarrow{d}\otimes\vec{d}r[h])$ and $\Pi\Pi(1+\overleftarrow{d}\otimes\overleftarrow{d}r[h])$, for which we also use the abbreviated notations $\overrightarrow{\Pi\Pi}(1+dr[h])$, $\overrightarrow{\Pi\Pi}(1+dr[h])$, $\overleftarrow{\Pi\Pi}(1+dr[h])$, and $\overleftarrow{\Pi\Pi}(1+dr[h])$, respectively. We shall show that each such double product integral can be defined, in two different ways, as a simple product integral, which is the solution of an algebraic differential equation, generalizing (11), but in which the driving term which generalizes $L[h]$ has coefficients living in the tensor product of $\mathcal{L}$ with another associative algebra called the system algebra, and is itself also essentially a simple product integral of the same type driven by $r[h]\in h(\mathcal{L}\otimes\mathcal{L})[[h]]$ where one of the two copies of $\mathcal{L}$ plays the role of the system algebra. That the two definitions agree may be regarded as loosely analogous to Fubini's theorem.[5] More precisely the agreement may be regarded as a continuous algebraic version of the identity

$$\prod_j^{\rightarrow}\left(\prod_k^{\rightarrow}(1+x_{j,k})\right)=\prod_k^{\rightarrow}\left(\prod_j^{\rightarrow}(1+x_{j,k})\right), \tag{12}$$

which holds[8] whenever the elements $x_{j,k}$ of a unital associative algebra are weakly commuting in the sense that $x_{j,k}$ commutes with $x_{j',k'}$ whenever $j\neq j'$ and $k\neq k'$ (but not necessarily when $j=j'$ but $k\neq k'$, for example).

We shall show that these double product integrals can then be characterized analogously to (10), for example, an element $R[h]$ of $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$ is of form $\overrightarrow{\prod}(1+dr[h])$ if and only if it satisfies (5) as well as

$$(\varepsilon\otimes\mathrm{id})R[h]=(\mathrm{id}\otimes\varepsilon)R[h]=1.$$

The next stage in Enriquez' quantization procedure is to require that $R[h]$ satisfy, in addition to (5), the quantum Yang–Baxter equation

$$R[h]^{12}R[h]^{13}R[h]^{23}=R[h]^{23}R[h]^{13}R[h]^{12}, \tag{13}$$

in $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$. In a subsequent paper we shall establish a condition on $r[h]$ necessary and sufficient for the mixed double integral $\overrightarrow{\prod}(1+dr[h])$ to satisfy (13).

We use the following notational conventions. If $\mathcal{A}$ is a vector space we denote by $\mathcal{A}[[h]]$ the space of formal power series with coefficients in $\mathcal{A}$ and by $h\mathcal{A}[[h]]$ the subspace of $\mathcal{A}[[h]]$ of elements for which the coefficient of h^0 is zero. When $\mathcal{A}$ is a not necessarily unital associative algebra we equip $\mathcal{A}[[h]]$ with the convolution product

$$\sum_{N=0}^{\infty}h^N A_N\sum_{N=0}^{\infty}h^N B_N=\sum_{N=0}^{\infty}h^N\sum_{j=0}^{N}A_{N-j}B_j\,.$$

Linear maps from $\mathcal{A}$ are extended to $\mathcal{A}[[h]]$ by action on the coefficients. If $\mathcal{V}_1,\mathcal{V}_2,\ldots,\mathcal{V}_n$ are vector spaces and π is a permutation of $(1,2,\ldots,n)$, we denote by τ_π the linear map from $\mathcal{V}_1\otimes\mathcal{V}_2\otimes\cdots\otimes\mathcal{V}_n$ to $\mathcal{V}_{\pi(1)}\otimes\mathcal{V}_{\pi(2)}\otimes\cdots\otimes\mathcal{V}_{\pi(n)}$ which appropriately permutes the components of product tensors.

II. $\mathcal{T}(\mathcal{L})$ AS A HOPF ALGEBRA WITH THE ITÔ SHUFFLE PRODUCT

Let $\mathcal{L}$ be a finite dimensional associative algebra, not necessarily unital, over a field $\mathbb{F}$ of characteristic zero fixed once and for all. We are interested in $\mathcal{L}$ as a Lie algebra under the commutator Lie bracket $[L,K]=LK-KL$ and in the universal enveloping algebra $\mathcal{U}$ of this Lie algebra. Let

$$\mathcal{T}(\mathcal{L})=\bigoplus_{n=0}^{\infty}(\otimes^n\mathcal{L}),$$

denote the vector space of all tensors over $\mathcal{L}$. It is well known that $\mathcal{T}(\mathcal{L})$ becomes a Hopf algebra under the coproduct Δ defined by linear extension of its action on homogeneous product tensors (2) when the multiplication is the shuffle product (1); we call this the *shuffle* Hopf algebra. The antipode is defined by linear extension of the map

$$L_1\otimes L_2\otimes\cdots\otimes L_m\mapsto(-1)^m L_m\otimes L_{m-1}\otimes\cdots\otimes L_1\,. \tag{14}$$

Our first task is to show that $\mathcal{T}(\mathcal{L})$ remains a Hopf algebra under the coproduct Δ when the shuffle multiplication is replaced by (3).

Theorem 1: Δ *is multiplicative for the Itô shuffle product* (3).

Proof: Let $\alpha,\beta\in\mathcal{T}(\mathcal{L})$. To lighten notation we temporarily denote the right differential map $\vec{d}$ by d. We show that, for $n=0,1,2,\ldots$, the nth rank component of $\Delta(\alpha\beta)$ under the identification (8), which is

$$((d\otimes\mathrm{id}_{\otimes^{n-1}\mathcal{L}})\circ(d\otimes\mathrm{id}_{\otimes^{n-2}\mathcal{L}})\circ\cdots\circ d)(\alpha\beta),$$

is equal to the nth rank component of $\Delta(\alpha)\Delta(\beta)$, which by (3) is

$$\sum_{A\cup B=\{1,2,\ldots,n\}} (((d\otimes \mathrm{id}_{\otimes^{|A|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|A|-2}\mathcal{L}})\circ\cdots\circ d)(\alpha))^A,$$

$$(((d\otimes \mathrm{id}_{\otimes^{|B|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|B|-2}\mathcal{L}})\circ\cdots\circ d)(\beta))^B.$$

Here we use the place notation that, for example, the superscript A indicates that the term to which it is attached occupies the tensor product of $\mathcal{T}(\mathcal{L})$ and those copies of $\mathcal{L}$ within $\otimes^n\mathcal{L}$ labeled by elements of A and the two terms are multiplied using the multiplication (3) in $\mathcal{T}(\mathcal{L})$ together with that in $\mathcal{L}$ in case of double occupancy. The proof is by induction on n beginning with the observation that when $n=0$ both expressions are equal to $\alpha\beta$. For general nonzero n we divide the sum in the second expression into three parts depending on whether n belongs to $A\cap B^c$, to $A^c\cap B$, or to $A\cap B$, and write it as

$$\sum_{C\cup D=\{1,2,\ldots,n-1\}} \{(((d\otimes \mathrm{id}_{\otimes^{|C|}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|C|-1}\mathcal{L}})\circ\cdots\circ d)(\alpha))^{C\cup\{n\}}(((d\otimes \mathrm{id}_{\otimes^{|D|-1}\mathcal{L}})$$
$$\circ(d\otimes \mathrm{id}_{\otimes^{|D|-2}\mathcal{L}})\circ\cdots\circ d)(\beta))^D+(((d\otimes \mathrm{id}_{\otimes^{|C|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|C|-2}\mathcal{L}})\circ\cdots\circ d)(\alpha))^C$$
$$\times(((d\otimes \mathrm{id}_{\otimes^{|D|}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|D|-1}\mathcal{L}})\circ\cdots\circ d)(\beta))^{D\cup\{n\}}$$
$$+(((d\otimes \mathrm{id}_{\otimes^{|C|}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|C|-1}\mathcal{L}})\circ\cdots\circ d)(\alpha))^{C\cup\{n\}}$$
$$\times(((d\otimes \mathrm{id}_{\otimes^{|D|}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|D|-1}\mathcal{L}})\circ\cdots\circ d)(\beta))^{D\cup\{n\}}\}.$$

This may be expressed as

$$(d\otimes \mathrm{id}_{\otimes^n\mathcal{L}})\Bigg(\sum_{C\cup D=\{1,2,\ldots,n-1\}} (((d\otimes \mathrm{id}_{\otimes^{|C|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|C|-2}\mathcal{L}})\circ\cdots\circ d)(\alpha))^C$$
$$\times(((d\otimes \mathrm{id}_{\otimes^{|D|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|D|-2}\mathcal{L}})\circ\cdots\circ d)(\beta))^D\Bigg),$$

as is seen by applying the Leibniz–Itô formula (9) to each product occuring in the latter sum. Making the inductive assumption that

$$\sum_{C\cup D=\{1,2,\ldots,n-1\}} (((d\otimes \mathrm{id}_{\otimes^{|C|-1}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{|C|-2}\mathcal{L}})\circ\cdots\circ d)(\alpha))^C(((d\otimes \mathrm{id}_{\otimes^{|D|-1}\mathcal{L}})$$
$$\circ(d\otimes \mathrm{id}_{\otimes^{|D|-2}\mathcal{L}})\circ\cdots\circ d)(\beta))^D$$
$$=((d\otimes \mathrm{id}_{\otimes^{n-2}\mathcal{L}})\circ(d\otimes \mathrm{id}_{\otimes^{n-3}\mathcal{L}})\circ\cdots\circ d)(\alpha\beta)$$

completes the proof. □

Equipped with the Itô product and the co-product Δ, $\mathcal{T}(\mathcal{L})$ becomes a bialgebra equipped with the same unit $1_{\mathcal{T}(\mathcal{L})}=(1_{\mathbb{F}},0,0,\ldots)$ and co-unit

$$\varepsilon:\mathcal{T}(\mathcal{L})=\bigoplus_{n=0}^{\infty}\otimes^n\mathcal{L}\ni(\alpha_0,\alpha_1,\alpha_2,\ldots)\mapsto\alpha_0,$$

as the shuffle Hopf algebra. Since the Itô multiplication acts on homogeneous tensors by adding terms of lower rank to the shuffle product the argument that a deformation bialgebra of a Hopf algebra is itself a Hopf algebra[3] may be adapted to conclude that the new bialgebra is equipped with a antipode whose action on homogeneous tensors is got by adding lower rank terms to (14). We call the resulting Hopf algebra the *Itô–Hopf algebra*.

III. SIMPLE PRODUCT INTEGRALS WITH A SYSTEM ALGEBRA

Let $\mathcal{A}$ be a possibly nonunital associative algebra which we call the *system algebra*. Let $l[h]$ be an element of $h(\mathcal{A}\otimes\mathcal{L})[[h]]$ and write $l[h]=\Sigma_{j=1}^{d} l_j[h]\otimes L^j$ where $l_j[h]\in\mathcal{A}_0[h]$ and $(L^1,L^2,\ldots,L^d)$ is a basis for $\mathcal{L}$. We consider the infinite sum

$$\sum_{n=1}^{\prime\prime\prime} l[h]\boxtimes l[h]\boxtimes\cdots\boxtimes\overset{(n)}{l}[h]=\sum_{n=1}^{\infty}\boxtimes^n l[h]. \tag{15}$$

Here the notation is as follows. The composition $\boxtimes$ denotes multiplication in $h\mathcal{A}[[h]]$ and tensoring in $\mathcal{L}$, thus

$$\boxtimes^n l[h]=\sum_{j_1,\ldots,j_n=1}^{d}\prod_{r=1}^{n} l_{j_r}[h]\otimes(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N}).$$

The sum (15) can be rearranged as a well defined element $\Sigma_{N=1}^{\infty}h^N X_N$ of $h(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$.[7] If $\mathcal{A}$ is unital then the element $X[h]=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+\Sigma_{N=1}^{\infty}h^N X_N$ of $(\mathcal{A}\otimes T(L))[[h]]$ is the unique solution of the algebraic differential equation

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X[h]=X[h]\boxtimes dl[h],\quad (\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}}.$$

We denote it by ${}_{\mathcal{A}}\Pi(1+\vec{d}l[h])$. In the nonunital case we define the original rearranged sum (15) in $h(\mathcal{A}\otimes T(L))[[h]]$ to be the *decapitated* product integral ${}_{\mathcal{A}}\hat{\Pi}(1+\vec{d}l[h])$. In a similar way, starting from an element $m[h]=\Sigma_{j=1}^{d}L^j\otimes m_j[h]$ of $h(\mathcal{L}\otimes A)[[h]]$ we define the product integrals

$$\begin{aligned}\prod{}_{\mathcal{A}}(1+\vec{d}m[h])&=1_{\mathcal{T}(\mathcal{L})\otimes\mathcal{A}}+\sum_{n=1}^{\infty}\boxtimes^n m[h]\\&=1_{\mathcal{T}(\mathcal{L})\otimes\mathcal{A}}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N})\otimes\prod_{r=1}^{N}m_{j_r}[h],\end{aligned}$$

in $(\mathcal{T}(\mathcal{L})\otimes\mathcal{A})[[h]]$ in the unital case, and

$$\widehat{\prod}{}_{\mathcal{A}}(1+\vec{d}m[h])=\sum_{n=1}^{\infty}\boxtimes^n m[h]=\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N})\otimes\prod_{r=1}^{N}m_{j_r}[h],$$

in $h(\mathcal{T}(\mathcal{L})\otimes\mathcal{A})[[h]]$ when $\mathcal{A}$ is nonunital. Thus the position of the subscript $\mathcal{A}$ indicates whether the system algebra is tensored to the right or the left of $\mathcal{T}(\mathcal{L})$. We distinguish these *forward* product integrals from the corresponding *backward* product integrals

$${}_{\mathcal{A}}\prod(1+\overleftarrow{d}l[h]),\quad {}_{\mathcal{A}}\widehat{\prod}(1+\overleftarrow{d}l[h]),\quad \prod{}_{\mathcal{A}}(1+\overleftarrow{d}m[h]),\quad \widehat{\prod}{}_{\mathcal{A}}(1+\overleftarrow{d}m[h]),$$

which are solutions of left differential equations. For example,

$$\begin{aligned}{}_{\mathcal{A}}\prod(1+\overleftarrow{d}l[h])&=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+\tilde{\boxtimes}^n l[h]\\&=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes(L^{j_N}\otimes L^{j_{N-1}}\otimes\cdots\otimes L^{j_1}),\end{aligned}$$

where the symbol $\tilde{\boxtimes}$ denotes multiplication in $\mathcal{A}[[h]]$ combined with tensoring in the opposite direction in $\mathcal{L}$, so that for example $(a\otimes L)\ \tilde{\boxtimes}(b\otimes K)=ab\otimes(K\otimes L)$. ${}_{\mathcal{A}}\Pi(1+\overleftarrow{d}l[h])$ solves the differential equation

$$(\mathrm{id}_{\mathcal{A}}\otimes\tilde{d})X[h]=dl[h]\boxtimes X[h],\quad (\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}}.$$

The theorem which follows generalizes to the case where there is a nontrivial system algebra the characterization[7] of grouplike elements of $\mathcal{S}(\mathcal{L})[[h]]$ as simple product integrals. In preparation for the proof, note that

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\varepsilon\otimes\mathrm{id}_{\mathcal{L}})\circ(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\vec{d})\circ\Delta=\vec{d},$$

as follows from comparison of actions of the two sides on product tensors, and hence

$$(\mathrm{id}_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}\otimes\varepsilon\otimes\mathrm{id}_{\mathcal{L}})\circ(\mathrm{id}_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}\otimes\vec{d})\circ(\mathrm{id}_{\mathcal{A}}\otimes\Delta)=\mathrm{id}_{\mathcal{A}}\otimes\vec{d}. \tag{16}$$

The symbol $\boxtimes$ is used now to denote the operation from $(\mathcal{A}\otimes T(L))[[h]]\times(\mathcal{A}\otimes T(L))[[h]]$ to $(\mathcal{A}\otimes T(L)\otimes T(L))[[h]]$ got by tensoring multiplication from $\mathcal{A}\times\mathcal{A}$ to $\mathcal{A}$ with the tensor product composition from $\mathcal{T}(\mathcal{L})\times\mathcal{T}(\mathcal{L})$ to $\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})$. We regard Δ as a map from $\mathcal{T}(\mathcal{L})[[h]]$ to $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$ by action on coefficients.

Theorem 2: *Let $l[h]\in h(\mathcal{A}\otimes L)[[h]]$ where $\mathcal{A}$ is assumed unital. Then*

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)\prod_{\mathcal{A}}(1+\vec{d}l[h])=\prod_{\mathcal{A}}(1+\vec{d}l[h])\boxtimes\prod_{\mathcal{A}}(1+\vec{d}l[h])$$

and

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)\prod_{\mathcal{A}}(1+\vec{d}l[h])=1_{\mathcal{A}}.$$

Conversely, let $X[h]$ be an element of $(\mathcal{A}\otimes T(L))[[h]]$ satisfying

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)X[h]=X[h]\boxtimes X[h],\quad (\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}}. \tag{17}$$

Then there exists an element $l[h]\in h(\mathcal{A}\otimes L)[[h]]$ such that $X[h]=\prod_{\mathcal{A}}(1+\vec{d}l[h])$.

Proof: Applying the map $\mathrm{id}_{\mathcal{A}}\otimes\Delta$ to

$$\prod_{\mathcal{A}}(1+\vec{d}l[h])=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N}),$$

using (2) we obtain

$$\begin{aligned}
&1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes\sum_{s=0}^{N}(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_s})\otimes(L^{j_{s+1}}\otimes L^{j_{s+2}}\otimes\cdots\\
&\quad\otimes L^{j_N})=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})}+\sum_{N=1}^{\infty}\left(\sum_{j_1,j_2,\ldots j_s=1}^{d}\sum_{s=0}^{N}\prod_{r=1}^{s}l_{j_r}[h]\otimes(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_s})\right)\\
&\quad\boxtimes\left(\sum_{j_{s+1},j_{s+2},\ldots,j_N=1}^{d}\prod_{r=s+1}^{N}l_{j_r}[h]\otimes(L^{j_{s+1}}\otimes L^{j_{s+2}}\otimes\cdots\otimes L^{j_N})\right)\\
&=\Bigg(1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}\\
&\quad+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N})\Bigg)\\
&\quad\boxtimes\left(1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N})\right)\\
&=\left(\prod_{\mathcal{A}}(1+\vec{d}l[h])\right)\boxtimes\left(\prod_{\mathcal{A}}(1+\vec{d}l[h])\right),
\end{aligned}$$

also

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)\,{}_{\mathcal{A}}\prod\,(1+\vec{d}l[h])=1_{\mathcal{A}}+\sum_{N=1}^{\infty}\sum_{j_1,j_2,\ldots,j_N=1}^{d}\prod_{r=1}^{N}l_{j_r}[h]\otimes\varepsilon(L^{j_1}\otimes L^{j_2}\otimes\cdots\otimes L^{j_N})=1_{\mathcal{A}},$$

as required.

To prove the converse we adapt the corresponding proof for the case $\mathcal{A}=\mathbb{F}$.[4] Thus let $X[h]$ satisfy (17) and be of form $1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+Y[h]$, where $Y[h]\in h(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$. Applying $(\mathrm{id}_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}\otimes\varepsilon\otimes\mathrm{id}_{\mathcal{L}})\circ(\mathrm{id}_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}\otimes\vec{d})$ to $(\mathrm{id}_{\mathcal{A}}\otimes\Delta)X[h]=X[h]\boxtimes X[h]$ and using (16) we obtain that $X[h]$ satisfies the differential equation

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X[h]=X[h]\boxtimes dl[h],\quad(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}},$$

where $l[h]=(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon\otimes\mathrm{id}_{\mathcal{L}})X[h]\in\mathcal{A}\otimes\mathcal{T}(\mathcal{L})[[h]]$. Comparing coefficients of h^0 we see that

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X_0=X_0\boxtimes dl_0,\quad(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X_0=1_{\mathcal{A}}.$$

Since $\vec{d}$ is degree reducing on the graded algebra $\mathcal{T}(\mathcal{L})$ this can hold only if $l_0=0$. Hence $l[h]\in h(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$ and the proof is complete. □

Corollary 3: Let $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ where $\mathcal{A}$ is possibly nonunital. Then the element $Y[h]={}_{\mathcal{A}}\hat{\Pi}(1+\vec{d}l[h])$ of $(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$ satisfies

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)Y[h]=Y[h]\otimes1_{\mathcal{T}(\mathcal{L})}+\tau_{(1,3,2)}(Y[h]\otimes1_{\mathcal{T}(\mathcal{L})})+Y[h]\boxtimes Y[h]$$

and

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)Y[h]=0_{\mathcal{A}}.$$

Conversely, let $Y[h]$ be an element of $(\mathcal{A}\otimes T(\mathcal{L}))[[h]]$ satisfying these conditions. Then there exists an element $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ such that $Y[h]={}_{\mathcal{A}}\hat{\Pi}(1+\vec{d}l[h])$.

Proof: We adjoin a unit to $\mathcal{A}$ if it lacks one. Then the Corollary follows from the Theorem by writing ${}_{\mathcal{A}}\Pi(1+\vec{d}l[h])=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\hat{\Pi}(1+\vec{d}l[h])$ and $X[h]=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+Y[h]$. □

Analogous characterisations hold to those of Theorem 2 and its corollary for product integrals of form $\Pi\,{}_{\mathcal{A}}(1+\vec{d}m[h])$ and $\hat{\Pi}\,{}_{\mathcal{A}}(1+\vec{d}m[h])$. To formulate the analogues for backward directed products we need the composition $\tilde{\boxtimes}$ in which elements of $\mathcal{A}$ are multiplied and elements of $\mathcal{T}(\mathcal{L})$ are tensored, but in the reverse direction.

Theorem 4: *Let $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ where $\mathcal{A}$ is assumed unital. Then*

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)\,{}_{\mathcal{A}}\prod\,(1+\tilde{d}l[h])={}_{\mathcal{A}}\prod\,(1+\tilde{d}l[h])\,\tilde{\boxtimes}\,{}_{\mathcal{A}}\prod\,(1+\tilde{d}l[h])$$

and

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)\,{}_{\mathcal{A}}\prod\,(1+\tilde{d}l[h])=1_{\mathcal{A}}.$$

Conversely, let $X[h]$ be an element of $(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$ satisfying

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)X[h]=X[h]\tilde{\boxtimes}X[h],\quad(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}}.\tag{18}$$

Then there exists an element $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ such that $X[h]={}_{\mathcal{A}}\Pi(1+\tilde{d}l[h])$.

This Theorem and its Corollary which follows are proved analogously to Theorem 2 and its Corollary.

Corollary 5: Let $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ *where* $\mathcal{A}$ *is possibly nonunital. Then the element* $Y[h]={}_{\mathcal{A}}\hat{\Pi}(1+\tilde{d}l[h])$ *of* $(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$ *satisfies*

$$(\mathrm{id}_{\mathcal{A}}\otimes\Delta)Y[h]=Y[h]\otimes 1_{\mathcal{T}(\mathcal{L})}+\tau_{(1,3,2)}(Y[h]\otimes 1_{\mathcal{T}(\mathcal{L})})+Y[h]\tilde{\boxtimes}Y[h]$$

and

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)Y[h]=0_{\mathcal{A}}.$$

Conversely, let $Y[h]$ *be an element of* $(\mathcal{A}\otimes\mathcal{T}(\mathcal{L}))[[h]]$ *satisfying these conditions. Then there exists an element* $l[h]\in h(\mathcal{A}\otimes\mathcal{L})[[h]]$ *such that* $Y[h]={}_{\mathcal{A}}\hat{\Pi}(1+\tilde{d}l[h])$.

Now let $l[h]=\Sigma_{j=1}^{d}l_j[h]\otimes L^j$ and $m[h]=\Sigma_{k=1}^{d}m_k[h]\otimes L^k$ be elements of $h(\mathcal{A}\otimes\mathcal{L})[[h]]$. We say that they are $\mathcal{A}$-commuting if each $l_j[h]$ commutes with each $m_k[h]$ as elements of $\mathcal{A}[[h]]$. $\mathcal{A}$-commuting elements $h(\mathcal{L}\otimes\mathcal{A})[[h]]$ are defined analogously.

Theorem 6: *Let* $l[h]$ *and* $m[h]$ *be* $\mathcal{A}$*-commuting elements of* $h(\mathcal{A}\otimes\mathcal{L})[[h]]$ *and let*

$$n[h]=l[h]+m[h]+l[h]m[h],$$

where $l[h]m[h]$ *is formed using the tensor product associative multiplication in* $\mathcal{A}\otimes\mathcal{L}$*. Then if* $\mathcal{A}$ *is unital*

$${}_{\mathcal{A}}\prod(1+\vec{d}l[h])\,{}_{\mathcal{A}}\prod(1+\vec{d}m[h])={}_{\mathcal{A}}\prod(1+\vec{d}n[h]),$$

and in the nonunital case

$${}_{\mathcal{A}}\widehat{\prod}(1+\vec{d}l[h])+{}_{\mathcal{A}}\widehat{\prod}(1+\vec{d}m[h])+{}_{\mathcal{A}}\widehat{\prod}(1+\vec{d}l[h])\,{}_{\mathcal{A}}\widehat{\prod}(1+\vec{d}k[h])={}_{\mathcal{A}}\widehat{\prod}(1+\vec{d}n[h]).$$

Proof: In the unital case $X[h]={}_{\mathcal{A}}\Pi(1+\vec{d}l[h])$ and $Y[h]\,{}_{\mathcal{A}}\Pi(1+\vec{d}m[h])$ are, respectively, the unique solutions of the differential equations

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X[h]=X[h]\boxtimes dl[h],\quad(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h]=1_{\mathcal{A}}$$

and

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})Y[h]=Y[h]\boxtimes dm[h],\quad(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)Y[h]=1_{\mathcal{A}}.$$

By the Leibniz–Itô formula, their product satisfies

$$\begin{aligned}(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})(X[h]Y[h])&=((\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X[h])Y[h]+X[h](\mathrm{id}_{\mathcal{A}}\otimes\vec{d})Y[h]\\&\quad+((\mathrm{id}_{\mathcal{A}}\otimes\vec{d})X[h])(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})Y[h]\\&=(X[h]\boxtimes dl[h])Y[h]+X[h](Y[h]\boxtimes dm[h])\\&\quad+(X[h]\boxtimes dl[h])(Y[h]\boxtimes dm[h])\\&=X[h]Y[h]\boxtimes dl[h]+X[h]Y[h]\boxtimes dm[h]+X[h]Y[h]\boxtimes dl[h]dm[h]\\&=X[h]Y[h]\boxtimes dn[h],\end{aligned}$$

where in the penultimate line we used the $\mathcal{A}$-commutativity of $l[h]$ and $m[h]$. Also, since ε is multiplicative,

$$(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)(X[h]Y[h])=(\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)X[h](\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)Y[h]=1_{\mathcal{A}}.$$

Thus $Z[h]=X[h]Y[h]$ is the unique solution of the differential equation

$$(\mathrm{id}_{\mathcal{A}}\otimes\vec{d})Z[h]=Z[h]\boxtimes dn[h],\quad (\mathrm{id}_{\mathcal{A}}\otimes\varepsilon)Z[h]=1_{\mathcal{A}},$$

which is ${}_{\mathcal{A}}\Pi(1+\vec{d}l[h])$. If $\mathcal{A}$ is nonunital we adjoin a unit. Then, by the unital case,

$$\left(1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}l[h])\right)\left(1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}k[h])\right)=\left(1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}n[h])\right),$$

that is

$$1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}l[h])+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}k[h])+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}l[h])_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}k[h])$$

$$=1_{\mathcal{A}\otimes\mathcal{T}(\mathcal{L})}+{}_{\mathcal{A}}\widehat{\prod}\,(1+\vec{d}n[h])$$

Cancelling the unit on both sides completes the proof. □

Analogous results hold for backward product integrals and for right system algebras.

IV. DEFINITION OF DOUBLE PRODUCT INTEGRALS

Now let $r[h]$ be an element of $h(\mathcal{L}\otimes\mathcal{L})[[h]]$. Regarding the left copy of $\mathcal{L}$ in $\mathcal{L}\otimes\mathcal{L}$ as the system algebra we may form the decapitated product integral ${}_{\mathcal{L}}\hat{\Pi}(1+\vec{d}r[h])$. This is an element of $h(\mathcal{L}\otimes\mathcal{T}(\mathcal{L}))[[h]]$, so, regarding $\mathcal{T}(\mathcal{L})$ as a unital right system algebra, we may form the product integral $\Pi_{\mathcal{T}(\mathcal{L})}(1+\vec{d}({}_{\mathcal{L}}\hat{\Pi}(1+\vec{d}r[h])))$. In the same way, regarding the right copy of $\mathcal{L}$ in $\mathcal{L}\otimes\mathcal{L}$ as the system algebra, we may form, first the decapitated product integral $\hat{\Pi}_{\mathcal{L}}(1+\vec{d}r[h])$ in $(\mathcal{T}(\mathcal{L})\otimes\mathcal{L})[[h]]$, and then the product integral ${}_{\mathcal{T}(\mathcal{L})}\Pi(1+\vec{d}(\hat{\Pi}_{\mathcal{L}}(1+\vec{d}r[h])))$. We shall prove the "Fubini theorem," that ${}_{\mathcal{T}(\mathcal{L})}\Pi(1+\vec{d}(\hat{\Pi}_{\mathcal{L}}(1+\vec{d}r[h])))$ and $\Pi_{\mathcal{T}(\mathcal{L})}(1+\vec{d}({}_{\mathcal{L}}\hat{\Pi}(1+\vec{d}r[h])))$ are equal, so that we may define their common value to be the double product integral $\Pi\Pi(1+\vec{d}\otimes\vec{d}r[h])$ $=\overrightarrow{\Pi}^{\rightarrow}(1+dr[h])$. By changing directions of the single products we define $\overrightarrow{\Pi}^{\leftarrow}(1+dr[h])$, $\overleftarrow{\Pi}^{\rightarrow}(1+dr[h])$, and $\overleftarrow{\Pi}^{\leftarrow}(1+dr[h])$ similarly. For example,

$$\overrightarrow{\prod}^{\leftarrow}(1+dr[h])=\prod_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left({}_{\mathcal{L}}\widehat{\prod}\,(1+\vec{d}r[h])\right)\right)=\prod_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left(\widehat{\prod}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right).$$

We shall prove the Fubini theorem by showing that both definitions are equivalent to a third more explicit but less intuitive form, in fact essentially the unsymmetrized version of the definition used in Ref. 8. To describe this third form we need some combinatorial preliminaries.

For each natural number N let $\mathcal{M}(N)$ denote the set of rectangular matrices M all of whose entries M_{jk} are either 0 or 1 with the properties that each row and each column contains at least one entry 1, that is $\Sigma_k M_{jk}>0$ for each fixed j and $\Sigma_j M_{jk}>0$ for each fixed k, and the total number of entries 1 is N, $\Sigma_{j,k}M_{jk}=N$. For example $\mathcal{M}(1)=\{[1]\}$ and

$$\mathcal{M}(2)=\left\{\begin{bmatrix}1&0\\0&1\end{bmatrix},\begin{bmatrix}0&1\\1&0\end{bmatrix},\begin{bmatrix}1\\1\end{bmatrix},[1\ \ 1]\right\}.$$

Each $\mathcal{M}(N)$ is finite since an element can have at most N rows and columns and each entry must be 0 or 1. Let $M\in\mathcal{M}(N)$ have m rows and n columns. We are going to define a corresponding element $\Pi_M r[h]$ of $((\otimes^m\mathcal{L})\otimes(\otimes^n\mathcal{L}))[[h]]$.

We say that an ordering $\omega=((j_1,k_1),(j_2,k_2),\ldots,(j_{mn},j_{mn}))$ of the elements of the Cartesian product $\{1,2,\ldots,m\}\times\{1,2,\ldots,n\}$ is *allowed* if (j,k) precedes (j',k') whenever both $j<j'$ and $k<k'$. For example, the *row* and *column* orderings

$$\omega_{\rightarrow}=((1,1),(1,2),\ldots,(1,n),(2,1),(2,2),\ldots,(2,n),\ldots,(m,1),(m,2),\ldots,(m,n)),$$

$$\omega_{\downarrow}=((1,1),(2,1),\ldots,(m,1),(1,2),(2,2),\ldots,(m,2),\ldots,(1,n),(2,n),\ldots,(m,n)),$$

are allowed orderings, but there are many others.

Given an allowed ordering $\omega=(P_1,P_2,\ldots,P_{mn})$ we construct the corresponding *reduced ordering* $\omega_M=(Q_1,Q_2,\ldots,Q_N)=((j_1,k_1),(j_2,k_2),\ldots,(j_N,k_N))$ by deleting from ω those $P=(j,k)$ for which the matrix element $M_{j,k}=0$. Finally we define the element $\Pi_M^{(\omega)}r[h]$ of $((\otimes^m\mathcal{L})\otimes(\otimes^n\mathcal{L}))[[h]]$ using place notation as

$$\prod_M^{(\omega)} r[h]=r[h]^{(j_1,k_1)}r[h]^{(j_2,k_2)}\ldots r[h]^{(j_N,k_N)}.$$

Here the coefficients of the formal power series $r[h]^{(j,k)}$ occupies the jth copy of $\mathcal{L}$ in $\otimes^m\mathcal{L}$ and the kth copy of $\mathcal{L}$ in $\otimes^n\mathcal{L}$. The defining properties of $\mathcal{M}(N)$ ensure that every copy of $\mathcal{L}$ in $\otimes^m\mathcal{L}$ and in $\otimes^n\mathcal{L}$ is occupied; multiple occupancies are reduced using the multiplication in $\mathcal{L}$.

Lemma 7: $\Pi_M^{(\omega)}r[h]$ *is independent of the choice of allowed ordering* ω.

Proof: By adjoining a unit and setting all terms with $M_{j,k}=0$ equal to this, we may assume that all $M_{j,k}=1$. The second term of the allowed ordering ω must be either (1,2) or (2,1) since any other choice would make it impossible to subsequently place at least one of these terms. Let us show that if the second term is (1,2) then $\Pi_M^{(\omega)}r[h]=\Pi_M^{(\omega_{\rightarrow})}r[h]$. A similar argument shows that if the second term is (2,1) then $\Pi_M^{(\omega)}r[h]=\Pi_M^{(\omega_{\downarrow})}r[h]$. Since it follows from (12) that $\Pi_M^{(\omega_{\rightarrow})}r[h]=\Pi_M^{(\omega_{\downarrow})}r[h]$, this proves the Lemma. Suppose that the second, third,..., kth terms of ω are $(1,2),(1,3),\ldots,(1,k)$ but the $(k+1)$th is not $(1,k+1)$. [Then it must be (2,1).] If $k=n$ we may detach the first row to the left of the ordering and argue by induction that the ordering of the remaining $(m-1)n$ terms is equivalent to the corresponding row ordering and hence, reattaching the first row, that $\Pi_M^{(\omega)}r[h]=\Pi_M^{(\omega_{\rightarrow})}r[h]$. If $k<n$ then $r[h]^{1,k+1}$ commutes with all preceding terms except $r[h]^{1,1},r[h]^{1,2},\ldots,r[h]^{1,k}$ since these are of the form $r[h]^{j,k'}$ with $j>1$ and $k'<k$. Hence we may move $r[h]^{1,k+1}$ to immediately follow $r[h]^{1,1}r[h]^{1,2}\cdots r[h]^{1,k}$, effectively increasing k by 1. Iterating, we arrive at the case $k=n$ already proved. □

We denote by $\Pi_M r[h]$ the common value of the products $\Pi_M^{(\omega)}r[h]$. It is evidently a formal power series of which the coefficents of $h^0,h^1,h^2,\ldots,h^{N-1}$ vanish. Thus $\Sigma_{N=1}^{\infty}\Sigma_{M\in\mathcal{M}(N)}\,\Pi_M r[h]$ is a well defined element of $h(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$. We can also rearrange it as

$$\sum_{N=1}^{\infty}\sum_{M\in\mathcal{M}(N)}\prod_M r[h]=\sum_{m,n=1}^{\infty}\sum_{M\in\mathcal{M}_{m,n}}\prod_M r[h],$$

where $\mathcal{M}_{m,n}$ denotes the finite subset of $\cup_{N=1}^{\infty}\mathcal{M}(N)$ consisting of $m\times n$ matrices.

For natural numbers m,n, we introduce the sets $\mathcal{A}_{m,n}$ of ordered m-tuples $A=(A_1,A_2,\ldots,A_m)$ of nonempty subsets whose union is $\{1,2,\ldots,n\}$, and $\mathcal{B}_{m,n}$ of ordered n-tuples $(B_1,B_2,\ldots,B_n)$ of nonempty subsets whose union is $\{1,2,\ldots,m\}$. There is a one–one correspondence between elements of $\mathcal{M}_{m,n}$, $\mathcal{A}_{m,n}$, and $\mathcal{B}_{m,n}$ given by

$$M_{j,k}=1\Leftrightarrow k\in A_j\Leftrightarrow j\in B_k,\quad j=1,2,\ldots,m,\ k=1,2,\ldots,n.$$

For each $M\in\mathcal{M}_{m,n}$, evaluating $\Pi_M r[h]$ using the row allowed ordering we get

$$\prod_M r[h] = (r[h]^{1,a_{1,1}} \boxtimes r[h]^{1,a_{1,2}} \boxtimes \cdots \boxtimes r[h]^{1,a_{1,|A_1|}}) \\ \boxtimes \quad (r[h]^{2,a_{2,1}} \boxtimes r[h]^{2,a_{2,2}} \boxtimes \cdots \boxtimes r[h]^{2,a_{2,|A_2|}}) \\ \boxtimes \quad \cdots \\ \boxtimes \quad (r[h]^{m,a_{m,1}} \boxtimes r[h]^{m,a_{m,2}} \boxtimes \cdots \boxtimes r[h]^{m,a_{m,|A_m|}}),$$

where the corresponding elements of $\mathcal{A}_{m,n}$ are given by $A_j = \{a_{j,1} < a_{j,2} < \cdots < a_{j,|A_j|}\}$, $j = 1,2,\ldots,m$. Here the inner compositions $\boxtimes$ denote multiplication in $\mathcal{L}$ on the left and tensoring on the right, while the outer compositions $\boxtimes$ denote tensoring on the left and tensoring disjoint indices and multiplying coincident indices on the right. Thus in particular

$$\sum_{N=1}^{\infty} \sum_{M \in \mathcal{M}(N)} \prod_M r[h] = \sum_{m,n=1}^{\infty} \sum_{A \in \mathcal{A}_{m,n}} (r[h]^{1,a_{1,1}} \boxtimes r[h]^{1,a_{1,2}} \boxtimes \cdots \boxtimes r[h]^{1,a_{1,|A_1|}}) \\ \boxtimes \quad (r[h]^{2,a_{2,1}} \boxtimes r[h]^{2,a_{2,2}} \boxtimes \cdots \boxtimes r[h]^{2,a_{2,|A_2|}}) \\ \boxtimes \quad \cdots \\ \boxtimes \quad (r[h]^{m,a_{m,1}} \boxtimes r[h]^{m,a_{m,2}} \boxtimes \cdots \boxtimes r[h]^{m,a_{m,|A_m|}}). \tag{19}$$

Similarly, using the column allowed ordering, we get

$$\sum_{N=1}^{\infty} \sum_{M \in \mathcal{M}(N)} \prod_M r[h] = \sum_{m,n=1}^{\infty} \sum_{B \in \mathcal{B}_{m,n}} (r[h]^{b_{1,1},1} \boxtimes r[h]^{b_{2,1},2} \boxtimes \cdots \boxtimes r[h]^{b_{|B_1|},1}) \\ \boxtimes \quad (r[h]^{b_{1,2},2} \boxtimes r[h]^{b_{2,2},2} \boxtimes \cdots \boxtimes r[h]^{b_{|B_2|},2}) \\ \boxtimes \quad \cdots \\ \boxtimes \quad (r[h]^{b_{1,n},n} \boxtimes r[h]^{b_{2,n},n} \boxtimes \cdots \boxtimes r[h]^{b_{|B_n|},n}), \tag{20}$$

where the elements of $B \in \mathcal{B}_{m,n}$ are given by $B_k = \{b_{1,k} < b_{2,k} < \cdots < b_{|B_k|,k}\}$, $k = 1,2,\ldots,n$.

We are now ready to prove the multiplicative Fubini theorem.

Theorem 8:

$$\prod_{\mathcal{T}(\mathcal{L})} \left(1 + \vec{d}\left(\widehat{\prod_{\mathcal{L}}} (1 + \vec{d}r[h])\right)\right) = 1_{\mathcal{T}(\mathcal{L}) \otimes \mathcal{T}(\mathcal{L})} + \sum_{N=1}^{\infty} \sum_{M \in \mathcal{M}(N)} \prod_M r[h] \\ = {}_{\mathcal{T}(\mathcal{L})}\prod \left(1 + \vec{d}\left(\widehat{\prod_{\mathcal{L}}} (1 + \vec{d}r[h])\right)\right).$$

Proof: To prove the first equality let us denote the element $\hat{\Pi}_{\mathcal{L}}(1 + \vec{d}r[h]))$ of $\mathcal{L} \otimes \mathcal{T}(\mathcal{L})$ by $R[h]$ and use place notation to write it in the form

$$R[h] = \sum_{N=1}^{\infty} r[h]^{1,N+1} \boxtimes r[h]^{1,N+2} \boxtimes \cdots \boxtimes r[h]^{1,2N},$$

where $\boxtimes$ denotes multiplication in the left hand copy of $\mathcal{L}$ and tensoring in $\mathcal{L}$ on the right. Thus

$$\prod_{\mathcal{T}(\mathcal{L})} \left(1 + \vec{d}\left(\widehat{\prod_{\mathcal{L}}} (1 + \vec{d}r[h])\right)\right) = 1_{\mathcal{T}(\mathcal{L}) \otimes \mathcal{T}(\mathcal{L})} + \sum_{N=1}^{\infty} R[h]^1 \boxtimes R[h]^2 \boxtimes \cdots \boxtimes R[h]^N,$$

where now the superscripts denote places in $\otimes^N \mathcal{L}$ and $\boxtimes$ now denotes tensoring in $\mathcal{L}$ on the left and multiplication in $\mathcal{T}(\mathcal{L})$ on the right. Carrying out these multiplications using (3) we obtain

$$\prod_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left(\widehat{\prod_{\mathcal{L}}}(1+\vec{d}r[h])\right)\right)$$

$$\begin{aligned}
&= 1_{\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})}+\sum_{m,n=1}^{\infty}\sum_{A\in\mathcal{A}_{m,n}}(r[h]^{1,a_{1,1}}\boxtimes r[h]^{1,a_{1,2}}\boxtimes\cdots\boxtimes r[h]^{1,a_{1,|A_1|}})\\
&\quad\boxtimes\ (r[h]^{2,a_{2,1}}\boxtimes r[h]^{2,a_{2,2}}\boxtimes\cdots\boxtimes r[h]^{2,a_{2,|A_{2v}|}})\\
&\quad\boxtimes\ \cdots\\
&\quad\boxtimes\ (r[h]^{m,a_{m,1}}\\
&\quad\boxtimes\ r[h]^{m,a_{m,2}}\boxtimes\cdots\boxtimes r[h]^{m,a_{m,|A_m|}}),
\end{aligned}$$

which is precisely $1_{\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})}+\Sigma_{N=1}^{\infty}\Sigma_{M\in\mathcal{M}(N)}\Pi_M r[h]$ by (19). The second equality is proved similarly using (20). □

V. CHARACTERIZATION THEOREM

Theorem 9: *Double product integrals satisfy the pairs of relations*

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\overrightarrow{\prod}(1+dr[h])=\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,2}\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,3},$$

$$(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overrightarrow{\prod}(1+dr[h])=\left(\overrightarrow{\prod}(1+dr[h])^{1,3}\left(\overrightarrow{\prod}(1+dr[h])\right)^{2,3},\right.$$

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\overrightarrow{\prod}(1+dr[h])=\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,3}\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,2},$$

$$(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overrightarrow{\prod}(1+dr[h])=\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,3}\left(\overrightarrow{\prod}(1+dr[h])\right)^{2,3},$$

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\overleftarrow{\prod}(1+dr[h])=\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,2}\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,3},$$

$$(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overleftarrow{\prod}(1+dr[h])=\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,3}\left(\overleftarrow{\prod}(1+dr[h])\right)^{2,3},$$

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\overleftarrow{\prod}(1+dr[h])=\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,3}\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,2},$$

$$(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overleftarrow{\prod}(1+dr[h])=\left(\overleftarrow{\prod}(1+dr[h])\right)^{2,3}\left(\overleftarrow{\prod}(1+dr[h])\right)^{1,3},$$

in $(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$, *together with*

$$(\varepsilon\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overset{**}{\prod}(1+dr[h])=(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\varepsilon)\overset{**}{\prod}(1+dr[h])=1_{\mathcal{T}(\mathcal{L})},\tag{21}$$

in each case. Conversely if $R[h]\in(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$ *satisfies any one of these pairs of relations together with (21) then there exists an element* $r[h]\in h(\mathcal{L}\otimes L)[[h]]$ *such that* $R[h]=\overset{**}{\Pi}(1+dr[h])$.

Proof: We shall prove the characterziation theorem for forward double product integrals $\overrightarrow{\Pi}\overrightarrow{\Pi}(1+dr[h])$; the others are proved similarly using appropriate variants of Theorems 2 and 4 and their corollaries.

Writing $\overrightarrow{\Pi}\overrightarrow{\Pi}(1+dr[h])=\Pi_{\mathcal{T}(\mathcal{L})}(1+\vec{d}({}_{\mathcal{L}}\hat{\Pi}(1+\vec{d}r[h])))$ and using Theorem 2 we get

$$\begin{aligned}(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\overrightarrow{\prod}(1+dr[h]) &= (\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)\left({}_{\mathcal{T}(\mathcal{L})}\prod\left(1+\vec{d}\left(\widehat{\prod}{}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right)\right)\\ &= \left({}_{\mathcal{T}(\mathcal{L})}\prod\left(1+\vec{d}\left(\widehat{\prod}{}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right)\right)\\ &\boxtimes \left({}_{\mathcal{T}(\mathcal{L})}\prod\left(1+\vec{d}\left(\widehat{\prod}{}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right)\right)\\ &= \left(\overrightarrow{\prod}(1+dr[h])\right)^{1,2}\left(\overrightarrow{\prod}(1+dr[h])\right)^{1,3}.\end{aligned}$$

Also

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\varepsilon)\overrightarrow{\prod}(1+dr[h])=(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\varepsilon)\left({}_{\mathcal{T}(\mathcal{L})}\prod\left(1+\vec{d}\left(\widehat{\prod}{}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right)\right)=1_{\mathcal{T}(\mathcal{L})}.$$

Similarly, writing $\overrightarrow{\Pi}\overrightarrow{\Pi}(1+dr[h])=\Pi_{\mathcal{T}(\mathcal{L})}(1+\vec{d}({}_{\mathcal{L}}\hat{\Pi}(1+\vec{d}r[h])))$ and using the analogue of Theorem 2 for right system algebras we have

$$\begin{aligned}(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overleftarrow{\prod}(1+dr[h]) &= (\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\left(\prod{}_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left({}_{\mathcal{L}}\widehat{\prod}(1+\vec{d}r[h])\right)\right)\right)\\ &= \left(\prod{}_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left({}_{\mathcal{L}}\widehat{\prod}(1+\vec{d}r[h])\right)\right)\right)\\ &\boxtimes \left(\prod{}_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left({}_{\mathcal{L}}\widehat{\prod}(1+\vec{d}r[h])\right)\right)\right)\\ &= \left(\overrightarrow{\prod}(1+dr[h])\right)^{1,3}\left(\overrightarrow{\prod}(1+dr[h])\right)^{2,3}\end{aligned}$$

and

$$(\varepsilon\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\overleftarrow{\prod}(1+dr[h])=(\varepsilon\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})\left(\prod{}_{\mathcal{T}(\mathcal{L})}\left(1+\vec{d}\left({}_{\mathcal{L}}\widehat{\prod}(1+\vec{d}r[h])\right)\right)\right)=1_{\mathcal{T}(\mathcal{L})},$$

as required.

Conversely let $R[h]\in(\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L}))[[h]]$ satisfy

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\Delta)R[h]=(R[h])^{1,2}(R[h])^{1,3}, \tag{22}$$

$$(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})R[h]=(R[h])^{1,3}(R[h])^{2,3}, \tag{23}$$

$$(\mathrm{id}_{\mathcal{T}(\mathcal{L})}\otimes\varepsilon)R[h]=(\varepsilon\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})R[h]=1_{\mathcal{T}(\mathcal{L})}. \tag{24}$$

Using the converse of Theorem 2 we deduce from (22) and the left hand equation of (24) that $R[h]=_{\mathcal{T}(\mathcal{L})}\Pi(1+\vec{d}l[h])$ for some element $l[h]\in h(\mathcal{T}(\mathcal{L})\otimes\mathcal{L})[[h]]$. We express $R[h]=_{\mathcal{T}(\mathcal{L})}\Pi(1+\vec{d}l[h])$ as

$$R[h]=(1_{\mathcal{T}(\mathcal{L})},l[h],l[h]\boxtimes l[h],\ldots,\boxtimes^n l[h],\ldots), \tag{25}$$

as an element of $\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})=\oplus_{n=0}^{\infty}(\mathcal{T}(\mathcal{L})\otimes(\otimes^n\mathcal{L}))$, where $\boxtimes$ denotes multiplication in $\mathcal{T}(\mathcal{L})$ on the left and tensoring in $\mathcal{L}$ on the right. Using the right hand equation of (24) and the multiplicativity of ε, we find that

$$1_{\mathcal{T}(\mathcal{L})}=(\varepsilon\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})R[h]=(1_{\mathbb{F}},(\varepsilon\otimes\mathrm{id}_{\mathcal{L}})l[h],\otimes^2((\varepsilon\otimes\mathrm{id}_{\mathcal{L}})l[h]),\ldots,\otimes^n((\varepsilon\otimes\mathrm{id}_{\mathcal{L}})l[h]),\ldots),$$

from which, since $1_{\mathcal{T}(\mathcal{L})}=(1_{\mathbb{F}},0,0,\ldots)$, it follows that

$$(\varepsilon\otimes\mathrm{id}_{\mathcal{L}})l[h]=0_{\mathcal{L}}. \tag{26}$$

Similarly, applying $\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})}$ to both sides of (25) and using (23) we get

$$\begin{aligned}&(1_{\mathcal{T}(\mathcal{L})},l[h],l[h]\boxtimes l[h],\ldots,\boxtimes^n l[h],\ldots)\boxtimes(1_{\mathcal{T}(\mathcal{L})},l[h],l[h]\boxtimes l[h],\ldots,\boxtimes^n l[h],\ldots)\\&\quad=(R[h])^{1,3}(R[h])^{2,3}\\&\quad=(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})R[h]\\&\quad=(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})(1_{\mathcal{T}(\mathcal{L})},l[h],l[h]\boxtimes l[h],\ldots,\boxtimes^n l[h],\ldots),\end{aligned}$$

where the outer $\boxtimes$ on the left denotes tensoring in $\mathcal{T}(\mathcal{L})$ on the left and multiplication in $\mathcal{T}(\mathcal{L})=\oplus_{n=0}^{\infty}(\otimes^n\mathcal{L})$ on the right. We compare the entries in $\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})\otimes\mathcal{L}$ within $\oplus_{n=0}^{\infty}[\mathcal{T}(\mathcal{L})\otimes\mathcal{T}(\mathcal{L})\otimes(\otimes^n\mathcal{L})]$ in this identity. From (3) contributions to the entry on the left can come only from composing terms of rank not exceeding 1. Thus we find that

$$\tau_{(1,3,2)}(l[h]\otimes 1_{\mathcal{T}(\mathcal{L})})+1_{\mathcal{T}(\mathcal{L})}\otimes l[h]+l[h]\boxtimes l[h]=(\Delta\otimes\mathrm{id}_{\mathcal{T}(\mathcal{L})})l[h]. \tag{27}$$

Using the analogue of Corollary 3 for right system algebras it follows from (26) and (27) that $l[h]=\hat{\Pi}_{\mathcal{L}}(1+\vec{d}r[h])$ for some $r[h]\in h(\mathcal{L}\otimes\mathcal{L})[[h]]$. Hence

$$R[h]=_{\mathcal{T}(\mathcal{L})}\prod\left(1+\vec{d}\left(\widehat{\prod}_{\mathcal{L}}(1+\vec{d}r[h])\right)\right)=\overrightarrow{\prod}^{\rightarrow}(1+dr[h]).$$

(Received 13 February 2004; accepted 13 February 2004; published 14 April 2004)

[DOI: 10.1063/1.1695095]

The purpose of this article is to derive both the ''Fubini theorem'' and the ''quasitriangular relations'' shown by the authors of the preceding paper[1] at the same time, not using the results of their Sec. IV. We first recall these results, using the notation of the paper.

Let $r[h] \in h\mathcal{L} \otimes \mathcal{L}[[h]]$. Set

$$X = \sum_{n>0} r^{0,1} \cdots r^{0,n} \in h\mathcal{L} \otimes \mathcal{T}(\mathcal{L})[[h]]$$

[the product of $\mathcal{L}$ is used in the factor $\mathcal{L}$, concatenation is used in $\mathcal{T}(\mathcal{L})$],

$$Z = \sum_{n \geqslant 0} X^{1,\infty} \cdots X^{n,\infty} \in \mathcal{T}(\mathcal{L}) \otimes \mathcal{T}(\mathcal{L})[[h]]$$

[concatenation in the first $\mathcal{T}(\mathcal{L})$, product in the second $\mathcal{T}(\mathcal{L})$],

$$Y = \sum_{n>0} r^{1,\infty} \cdots r^{n,\infty} \in h\mathcal{T}(\mathcal{L}) \otimes \mathcal{L}[[h]]$$

(concatenation then product),

$$Z' = \sum_{n \geqslant 0} Y^{0,1} \cdots Y^{0,n} \in \mathcal{T}(\mathcal{L}) \otimes \mathcal{T}(\mathcal{L})[[h]]$$

(product then concatenation).

Theorem 1: *(1) ("Fubini theorem") $Z = Z'$. (2) ("Quasitriangular relations")*

$$(\Delta \otimes \mathrm{id})(Z) = Z^{1,3} Z^{2,3}, \quad (\mathrm{id} \otimes \Delta)(Z) = Z^{1,3} Z^{1,2}.$$

Proof: Let $\mathcal{T}(\mathcal{L})_0 = \oplus_{i>0} \mathcal{L}^{\otimes i}$, $\tilde{\mathcal{L}} = \mathcal{L} \oplus \mathbb{F}1$ ($\tilde{\mathcal{L}}$ is $\mathcal{L}$ with a unit adjoined).

Lemma 2: The map $\alpha: \mathcal{T}(\tilde{\mathcal{L}}) \to \mathcal{L}$, $1 \mapsto 1$, and taking $x \in \mathcal{T}(\mathcal{L})_0$ to its homogeneous component x_1 of rank 1 is an algebra homomorphism.

Proof of Lemma: Clear.

Proof of Theorem: We have obviously $(\Delta \otimes \mathrm{id})(Z) = Z^{1,3} Z^{2,3}$. Let us prove $(\mathrm{id} \otimes \Delta)(Z) = Z^{1,3} Z^{1,2}$. Set $u = (\mathrm{id} \otimes \Delta)(Z)$ and $v = Z^{1,3} Z^{1,2}$. Then $u, v \in \mathcal{T}(\mathcal{L})^{\otimes 3}[[h]]$. Moreover both u and v satisfy $(\Delta \otimes \mathrm{id}^{\otimes 2})(x) = x^{1,3,4} x^{2,3,4}$. To apply Theorem 4 of Hudson and Pulmannova it remains to check that

$$(\alpha \otimes \mathrm{id}^{\otimes 2})(u) = (\alpha \otimes \mathrm{id}^{\otimes 2})(v).$$

*Electronic mail: enriquez@math.u-strasbg.fr

Now $(\alpha\otimes \mathrm{id}^{\otimes 2})(u)=(\mathrm{id}\otimes\Delta)(X)$ and $(\alpha\otimes \mathrm{id}^{\otimes 2})(v)=X^{1,3}X^{1,2}$ using the Lemma and the fact that $(\alpha\otimes \mathrm{id})(Z)=X$. Since $(\mathrm{id}\otimes\Delta)(X)=X^{1,3}X^{1,2}$ we are done. Therefore, Z satisfies both quasitriangularity identities.

Z' obviously satisfies $(\mathrm{id}\otimes\Delta)(Z')=(Z')^{1,3}(Z')^{1,2}$. Since Z also satisfies this relation we will apply Theorem 4 of Hudson and Pulmannova to prove $Z'=Z$. For this we need to prove that $(\mathrm{id}\otimes\alpha)(Z)=(\mathrm{id}\otimes\alpha)(Z')$. Now the Lemma implies that

$$(\mathrm{id}\otimes\alpha)(Z)=\sum_{n\geqslant 0}(\mathrm{id}\otimes\alpha)(X)^{1,\infty}\cdots(\mathrm{id}\otimes\alpha)(X)^{n,\infty},$$

and since $(\mathrm{id}\otimes\alpha)(X)=1$ we get $(\mathrm{id}\otimes\alpha)(Z)=Y$. We also have $(\mathrm{id}\otimes\alpha)(Z')=Y$, so by Theorem 4 of Hudson and Pulmannova, $Z=Z'$. This proves "Fubini's theorem." Since $Z=Z'$, Z' also satisfies both quasitriangularity identities. □

The left side of Eqs. (3.15) and (3.24) should contain a projection operator "$\mathcal{P}_S$" with respect to the 2-surface S: i.e.,

$$\mathcal{P}_S(\mathcal{L}_v \epsilon_{ab}) = \kappa(v)\epsilon_{ab}$$

and

$$\mathcal{P}_S(\mathcal{L}_{\theta^\pm} \epsilon_{ab}) = \kappa^\pm \epsilon_{ab}\,.$$

The sentences before and after Eqs. (4.53)–(4.55), (4.62)–(4.65), (4.79)–(4.81), and (4.89)–(4.91) all refer to 2-spheres S that lie outside any horizon.

The sentence after Eq. (4.91) should refer to the *normal part of* P^a.

In Eq. (4.37), the log expressions are missing a term R^2: i.e.,

$$\ln(R^2 + \kappa(u)/\kappa(v)).$$

Likewise, the formula in the sentence after Eq. (4.37) should be changed to

$$(P^{\mathrm{D}}_{\|})_a = \tfrac{1}{2}\nabla^S_a \ln(R^2 + \kappa(u)/\kappa(v)).$$

In this paper we analyze Abelian diagonal orthogonally transitive space–times with spacelike orbits for which the matter content is a stiff perfect fluid. The Einstein equations are cast in a suitable form for determining their geodesic completeness. A sufficient condition on the metric of these space–times is obtained, that is fairly easy to check and to implement in exact solutions. These results confirm that nonsingular space–times are abundant among stiff fluid cosmologies. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1705715]

I. INTRODUCTION

After the discovery of the first nonsingular perfect fluid cosmological model by Senovilla,[1] the possibility of constructing regular cosmologies was renewed. The interest for regular cosmologies had stifled for nearly 30 years due to the powerful singularity theorems (cf., for instance, Refs. 2 and 3), which seemed to preclude such space–times under very general requirements, such as chronology protecting, energy and generic conditions. The open way to regular cosmologies was found in the violation of some technical premises of the theorems. For instance, in Ref. 4 it was shown that the Senovilla space–time did not possess a compact achronal set without edge and could not have closed trapped surfaces.

However, the first results were not encouraging. The extension of the Senovilla solution to a family of space–times left the set of regular models limited to a zero-measure subset surrounded by space–times with Ricci and Weyl curvature singularities.[5] During the following decade only a few new nonsingular cosmologies were added to the list.[6]

Another estrategy to approach singularities arose with the publication of regularity theorems.[7–9] Whereas singularity theorems stated general sufficient conditions for the appearance of singularities, these theorems aimed the contrary, namely particular conditions to achieve regular space–times.

The application of the conclusions of Ref. 8 to a restricted family of stiff fluids provided an unexpected result. The set of known nonsingular perfect fluid cosmologies was enlarged with a huge family depending on two nearly arbitrary functions.[10]

The purpose of this paper is the extension of those results to determine which space–times among Abelian diagonal orthogonally transitive space–times with spacelike orbits and with a stiff fluid as matter content are nonsingular. Instead of restricting to an integrable family of solutions of the Einstein equations, we analyze the whole set of diagonal cylindrical stiff fluid space–times with a spacelike transitivity surface element.

With this aim in mind we write in Sec. II the Einstein equations for such space–times and we cast them in a form suitable for the application of the theorems. The analysis of the restrictions imposed by regularity conditions is done in Sec. III. Finally in Sec. IV we check the possibility of constructing regular space–times with nonvaninishing matter scalar space averages on Cauchy hypersurfaces in order to support the validity of a regularity conjecture by Senovilla.[11]

II. EQUATIONS FOR G_2 STIFF FLUID SPACE–TIMES

As it has been stated in the introduction, we shall focus on space–times endowed with an Abelian orthogonally transitive group of isometries G_2 acting on spacelike surfaces, since this is the framework where most nonsingular space–times have been found so far. We further impose that generators for the group can be found that are mutually orthogonal. We follow Ref. 8 for writing the Einstein equations for such space–times using a formalism based on differential forms.

If the generators of the isometry group are chosen to be $\{\xi,\eta\}$, we may write an orthonormal tetrad, $\{\theta^0,\theta^1,\theta^2,\theta^3\}$, where just θ^2 and θ^3 lie in $\mathrm{lin}\{\xi,\eta\}$. We may impose that these 1-forms be Lie-invariant under the isometry group.[12] The metric is written as

$$ds^2=-\theta^0\otimes\theta^0+\theta^1\otimes\theta^1+\theta^2\otimes\theta^2+\theta^3\otimes\theta^3. \tag{1}$$

Making use of the spacelike congruence for θ^2 and its kinematical quantities, we may define the tetrad basis according to the vanishing torsion equations,

$$d\theta^0=\nu\wedge\theta^1, \tag{2a}$$

$$d\theta^1=\nu\wedge\theta^0, \tag{2b}$$

$$d\theta^2=\alpha\wedge\theta^2, \tag{2c}$$

$$d\theta^3=(\beta-\alpha)\wedge\theta^3, \tag{2d}$$

where ν is just a connection in the $\theta^0-\theta^1$ subspace, α is an ''acceleration'' for θ^2 and β is related to the expansion of the surface element in the $\theta^2-\theta^3$ subspace, since $d(\theta^2\wedge\theta^3)=\beta\wedge\theta^2\wedge\theta^3$.

The integrability conditions for these equations are easily obtained by exterior differentiation of the system,

$$d\beta=0, \tag{3a}$$

$$d\alpha=0. \tag{3b}$$

Finally, Einstein field equations are written in terms of these differential forms as an exterior system,

$$d*\alpha+\beta\wedge*\alpha=(\tfrac{1}{2}T-T_{22})\,\theta^0\wedge\theta^1, \tag{4a}$$

$$d*\beta+\beta\wedge*\beta=(T_{11}-T_{00})\,\theta^0\wedge\theta^1, \tag{4b}$$

$$d\nu+\alpha\wedge*\alpha-\beta\wedge*\alpha=\tfrac{1}{2}(T_{00}-T_{11}+T_{22}+T_{33})\,\theta^0\wedge\theta^1, \tag{4c}$$

$$d*\tilde{\beta}+\beta\wedge*\tilde{\beta}+2(\alpha-\beta)\wedge*\tilde{\alpha}+2\,\nu\wedge\tilde{\beta}=(T_{00}+T_{11})\,\theta^0\wedge\theta^1, \tag{4d}$$

$$d\tilde{\beta}+\beta\wedge\tilde{\beta}+2(\alpha-\beta)\wedge\tilde{\alpha}+2\,\nu\wedge*\tilde{\beta}=2T_{01}\theta^0\wedge\theta^1, \tag{4e}$$

for a matter content defined by the energy-momentum tensor $T=T_{ab}\theta^a\otimes\theta^b$.

The tilde denotes a reflection in the $\theta^0-\theta^1$ subspace, that is, if $\alpha=a\,\theta^0+b\,\theta^1$, then $\tilde{\alpha}=a\,\theta^0-b\,\theta^1$. The $*$ denotes the Hodge duality operator in the same subspace, $*\alpha=-a\,\theta^1-b\,\theta^0$.

Integration of the first Bianchi equations (3a) and (3b),

$$\alpha=-dU, \tag{5a}$$

$$\beta = \frac{d\ln\rho}{\rho}, \tag{5b}$$

allows integration of Cartan equations in terms of two functions, z, ϕ,

$$\theta^2 = e^{-U}\,dz, \quad \theta^3 = \rho e^{U}\,d\phi, \tag{6}$$

that we take as coordinates in order to write the metric in a conventional form,

$$g = e^{2K}(-dt^2 + dr^2) + e^{-2U}\,dz^2 + \rho^2 e^{2U}\,d\phi^2. \tag{7}$$

The coordinates are adapted to the Killing fields, so that $\xi = \partial_z$, $\eta = \partial_\phi$. The nonignorable coordinates t, r are chosen so that the metric is isotropic in the subspace spanned by θ^0 and θ^1,

$$\theta^0 = e^{K}\,dt, \quad \theta^1 = e^{K}\,dr. \tag{8}$$

The range for these coordinates is the usual one,

$$-\infty < t, \quad z < \infty, \quad 0 < r < \infty, \quad 0 < \phi < 2\pi, \tag{9}$$

if we require the space–time to be cylindrically symmetric. The remaining metric functions, K, U, and ρ, depend just on t and r.

The connection in this case is $\nu = *dK$.

This is the general framework for an orthogonally transitive diagonal space–time with spacelike orbits. If the matter content is a perfect fluid with 4-velocity u, pressure p, and density μ, the Bianchi equations for such energy-momentum tensor,

$$T = \mu u \otimes u + p\,(g + u \otimes u), \tag{10}$$

may be written in compact expressions involving the kynematical 1-forms,

$$du + \frac{1}{\mu + p}\,dp \wedge u = 0, \tag{11a}$$

$$d*u + \left(\beta + \frac{d\mu}{\mu + p}\right) \wedge *u = 0, \tag{11b}$$

which state that the fluid is irrotational.

We might choose $\theta^0 = u$ for writing the Einstein equations, as it was done in Ref. 10, but since we aim full generality, we shall not follow that way and explore arbitrary possibilities of alignment for this 1-form. Preserving the unitarity of u, we may parametrize it in terms of a function ξ,

$$u = -\theta^0 \cosh\xi - \theta^1 \sinh\xi, \tag{12}$$

so that the Einstein equations for a perfect fluid take the following form:

$$U_{tt} - U_{rr} + \frac{1}{\rho}(U_t\rho_t - U_r\rho_r) = \frac{p-\mu}{2}e^{2K}, \tag{13a}$$

$$\rho_{tt} - \rho_{rr} = (\mu - p)\rho e^{2K}, \tag{13b}$$

$$K_t\rho_r + K_r\rho_t = \rho_{tr} + U_t\rho_r + U_r\rho_t + 2\rho U_t U_r + e^{2K}\rho\frac{\mu + p}{2}\sinh 2\xi, \tag{13c}$$

$$K_t\rho_t+K_r\rho_r=\frac{\rho_{tt}+\rho_{rr}}{2}+U_t\rho_t+U_r\rho_r+\rho\left(U_t^2+U_r^2+e^{2K}\frac{\mu+p}{2}\cosh 2\xi\right), \tag{13d}$$

$$K_{rr}-K_{tt}+\frac{U_r\rho_r-U_t\rho_t}{\rho}+U_r^2-U_t^2=\frac{\mu+p}{2}e^{2K}, \tag{13e}$$

and the energy-momentum conservation laws yield

$$K_r-\xi_t+\frac{p_r\cosh^2\xi+(\mu_t-p_t)\sinh\xi\cosh\xi-\mu_r\sinh^2\xi}{\mu+p}+\frac{\rho_t\cosh\xi-\rho_r\sinh\xi}{\rho}\sinh\xi=0, \tag{14a}$$

$$K_t-\xi_r+\frac{\mu_t\cosh^2\xi+(p_r-\mu_r)\sinh\xi\cosh\xi-p_t\sinh^2\xi}{\mu+p}+\frac{\rho_t\cosh\xi-\rho_r\sinh\xi}{\rho}\cosh\xi=0. \tag{14b}$$

The system of equations becomes much simpler if we restrict to stiff fluids, $\mu=p$,

$$U_{tt}-U_{rr}+\frac{1}{\rho}(U_t\rho_t-U_r\rho_r)=0, \tag{15a}$$

$$\rho_{tt}-\rho_{rr}=0, \tag{15b}$$

$$\frac{K_t\rho_r+K_r\rho_t}{\rho}=\frac{\rho_{tr}+U_t\rho_r+U_r\rho_t}{\rho}+2U_tU_r+e^{2K}p\sinh 2\xi, \tag{15c}$$

$$\frac{K_t\rho_t+K_r\rho_r}{\rho}=\frac{\rho_{tt}+\rho_{rr}}{2\rho}+\frac{U_t\rho_t+U_r\rho_r}{\rho}+U_t^2+U_r^2+e^{2K}p\cosh 2\xi, \tag{15d}$$

$$K_{rr}-K_{tt}+\frac{U_r\rho_r-U_t\rho_t}{\rho}+U_r^2-U_t^2=p\,e^{2K}, \tag{15e}$$

$$K_r-\xi_t+\frac{p_r}{2p}+\frac{\rho_t\cosh\xi-\rho_r\sinh\xi}{\rho}\sinh\xi=0, \tag{15f}$$

$$K_t-\xi_r+\frac{p_t}{2p}+\frac{\rho_t\cosh\xi-\rho_r\sinh\xi}{\rho}\cosh\xi=0. \tag{15g}$$

The reason why the stiff fluid equations are easy to integrate is that the metric functions U, ρ decouple from the pressure, which only appears in the equations for the conformal factor K. Therefore the stiff fluid case is fairly similar to vaccuum and can be generated from this one.

A further simplification can be obtained if we take ρ as coordinate. This is fully compatible with an isotropic parametrization, since equation (15b),

$$0=d*\beta+\beta\wedge*\beta=d\left(\frac{*d\rho}{\rho}\right)+\frac{d\rho\wedge*d\rho}{\rho^2}=\frac{d*\mathrm{d}\rho}{\rho},$$

states that $*d\rho$ is also an exact differential form.

We take $\rho=r$ as a spatial coordinate, since every known nonsingular solution has a surface element with spacelike gradient. With this choice of coordinates the differential system becomes even simpler,

$$U_{tt}-U_{rr}-\frac{U_r}{r}=0, \tag{16a}$$

$$K_t=U_t+2rU_tU_r+e^{2K}pr\sinh 2\xi, \tag{16b}$$

$$K_r=U_r+r(U_t^2+U_r^2)+e^{2K}pr\cosh 2\xi, \tag{16c}$$

$$K_{rr}-K_{tt}+\frac{U_r}{r}+U_r^2-U_t^2=pe^{2K}, \tag{16d}$$

$$K_r-\xi_t+\frac{p_r}{2p}-\frac{\sinh^2\xi}{r}=0, \tag{16e}$$

$$K_t-\xi_r+\frac{p_t}{2p}-\frac{\sinh\xi\cosh\xi}{r}=0. \tag{16f}$$

The integrability condition, $K_{rt}=K_{tr}$, for (16b) and (16c) requires that a combination of functions be an exact differential form,

$$dH=e^{2K}rp(\sinh 2\xi\,dt+\cosh 2\xi\,dr), \tag{17}$$

from which we can read ξ and the pressure, if K is known,

$$\tanh 2\xi=\frac{H_t}{H_r},\quad |p|=\frac{e^{-2K}}{r}\sqrt{H_r^2-H_t^2}. \tag{18}$$

The integrability of dH is also a consequence of the energy-momentum conservation equations (16e) and (16f).

For consistency these expressions imply that the gradient of H be spacelike and that H_r be positive in order to have positive pressure.

The simple case, $\xi=0$, for which u is parallel to the time direction corresponds to $H=\gamma r^2/2$, where γ is a positive constant.

The remaining system of differential equations,

$$U_{tt}-U_{rr}-\frac{U_r}{r}=0, \tag{19a}$$

$$H_{rr}-H_{tt}=\frac{\sqrt{H_r^2-H_t^2}}{r}, \tag{19b}$$

$$K_t=U_t+2rU_tU_r+H_t, \tag{19c}$$

$$K_r=U_r+r(U_t^2+U_r^2)+H_r, \tag{19d}$$

is formed by a reduced wave equation in polar coordinates for U on the plane and a nonlinear wave equation for H. Once these equations are solved, we are left with a quadrature for K. The integrability of this quadrature is guaranteed by the other equations.

As it has already been stated, these equations are pretty similar to those of vaccuum. The only diference is the additional conformal factor defined by H.

Regularity of the metric at the axis $r=0$ is already implicit in the equations, provided that metric functions are regular. Following Ref. 13, we have a regular axis whenever

$$\lim_{r\to 0}\frac{\langle \mathrm{grad}\,\Delta,\mathrm{grad}\,\Delta\rangle}{4\Delta}=e^{2(U-K)}|_{r=0}=1,\quad \Delta=\langle\partial_\phi,\partial_\phi\rangle=r^2e^{2U}. \tag{20}$$

But according to Eqs. (17), (19c), and (19d), K and U are equal at the axis, except for a constant, since

$$K_r(t,0)=U_r(t,0),\quad K_t(t,0)=U_t(t,0), \tag{21}$$

if pressure and K are regular functions, so that $H_t(t,0)=0=H_r(t,0)$, and therefore condition (20) is fulfilled either by taking the constant equal to zero or conveniently rescaling the angular coordinate.

The problem of obtaining solutions for H is solved by the Wainright–Ince–Marshman formalism.[14] Solutions to (19b) may be generated from solutions of the reduced wave equation on the plane with timelike gradient,

$$\sigma_{tt}-\sigma_{rr}-\frac{\sigma_r}{r}=0,\quad \sigma_t^2-\sigma_r^2>0, \tag{22}$$

by a quadrature identical to the one which defines $K-U$ in the vacuum case,

$$H_t=2r\sigma_t\sigma_r, \tag{23a}$$

$$H_r=r(\sigma_t^2+\sigma_r^2). \tag{23b}$$

The functions H generated by this mechanism have trivially a spacelike gradient and positive radial derivative. The fluid properties may be read directly from the generating function,

$$\tanh 2\xi=\frac{2\sigma_t\sigma_r}{\sigma_t^2+\sigma_r^2},\quad p=e^{-2K}(\sigma_t^2-\sigma_r^2). \tag{24}$$

The function that generates the $\xi=0$ case is $\sigma=\sqrt{\gamma}t$.

Using this formalism, the remaining system of equations is formed by a quadrature and two reduced wave equations,

$$U_{tt}-U_{rr}-\frac{U_r}{r}=0, \tag{25a}$$

$$\sigma_{tt}-\sigma_{rr}-\frac{\sigma_r}{r}=0, \tag{25b}$$

$$K_t=U_t+2rU_tU_r+2r\sigma_t\sigma_r, \tag{25c}$$

$$K_r=U_r+r(U_t^2+U_r^2)+r(\sigma_t^2+\sigma_r^2). \tag{25d}$$

III. NONSINGULAR MODELS

We have obtained a fairly simple system of equations (25a)–(25c) that will be useful for analyzing the regularity of the solutions. Following Ref. 2 we take causal geodesic completeness as our definition for regularity.

Even if we have regular metric components, geodesic completeness of the space–time is not guaranteed and we have to check explicitly that every timelike and lightlike geodesic in the space–time can be extended to all values of the affine parameter, that is, in the parametrization for which the geodesic equations take the form

$$\ddot{x}^i+\Gamma^i_{jk}\dot{x}^j\dot{x}^k=0, \tag{26}$$

in terms of the Christoffel symbols.

Fortunately, results concerning causal geodesic completeness of diagonal Abelian orthogonally transitive space–times have already been obtained in Ref. 8. The conclusions of that paper may be condensed in two theorems. We follow the simplified version of Ref. 10.

Theorem 1: A diagonal Abelian orthogonally transitive space–time with spacelike orbits endowed with a metric in the form (7) with C^2 metric functions K,U,ρ, where ρ has a spacelike gradient, is future causally geodesically complete provided that along causal geodesics.

(1) For large values of t and increasing r,
   (a) $(K-U-\ln\rho)_r+(K-U-\ln\rho)_t\geqslant 0$, and either $(K-U-\ln\rho)_r\geqslant 0$ or $|(K-U-\ln\rho)_r|\leqslant(K-U-\ln\rho)_r+(K-U-\ln\rho)_t$,
   (b) $K_r+K_t\geqslant 0$, and either $K_r\geqslant 0$ or $|K_r|\leqslant K_r+K_t$,
   (c) $(K+U)_r+(K+U)_t\geqslant 0$, and either $(K+U)_r\geqslant 0$ or $|(K+U)_r|\leqslant(K+U)_r+(K+U)_t$.
(2) For large values of t, a constant b exists such that

$$\left.\begin{matrix} K(t,r)-U(t,r) \\ 2K(t,r) \\ K(t,r)+U(t,r)+\ln\rho(t,r)\end{matrix}\right\}\geqslant -\ln|t|+b.$$

Theorem 2: A diagonal Abelian orthogonally transitive space–time with spacelike orbits endowed with a metric in the form (7) with C^2 metric functions K,U,ρ, where ρ has a spacelike gradient, is past causally geodesically complete provided that along causal geodesics.

(1) For small values of t and increasing r,
   (a) $(K-U-\ln\rho)_r-(K-U-\ln\rho)_t\geqslant 0$, and either $(K-U-\ln\rho)_r\geqslant 0$ or $|(K-U-\ln\rho)_r|\leqslant(K-U-\ln\rho)_r-(K-U-\ln\rho)_t$.
   (b) $K_r-K_t\geqslant 0$, and either $K_r\geqslant 0$ or $|K_r|\leqslant K_r-K_t$.
   (c) $(K+U)_r-(K+U)_t\geqslant 0$, and either $(K+U)_r\geqslant 0$ or $|(K+U)_r|\leqslant(K+U)_r-(K+U)_t$.
(2) For small values of t, a constant b exists such that

$$\left.\begin{matrix} K(t,r)-U(t,r) \\ 2K(t,r) \\ K(t,r)+U(t,r)+\ln\rho(t,r)\end{matrix}\right\}\geqslant -\ln|t|+b.$$

Therefore now we just have to verify under which conditions these theorems can be applied to stiff fluid space–times. Since the theorems do not make use of Einstein equations, it is expected that when we take them into account the conditions will not be so restrictive as they seem.

We begin with future-pointing geodesics. The first part of the theorem is a set of conditions on the derivatives of the metric functions.

(1)

(a) From (19c) and (19d) we obtain

$$(K-U-\ln\rho)_t+(K-U-\ln\rho)_r=r(U_t+U_r)^2+H_t+H_r-\frac{1}{r}.$$

The sum of the derivatives of H is always positive, since $H_r>|H_t|$ in order to have positive pressure. In fact, this is the $r(\sigma_t+\sigma_r)^2$ term in the Wainright–Ince–Marshman formalism. This expression is positive if either $|U_t+U_r|$ or H_t+H_r ($|\sigma_t+\sigma_r|$ in the Wainright–Ince–Marshman formalism) does not decrease as $1/r$ or faster for large values of t and r. That is, we need either U or H to overcome the negative term. Under such conditions, the second part of the premise,

$$(K-U-\ln\rho)_r=r(U_t^2+U_r^2)+H_r-\frac{1}{r}\geqslant 0,$$

is also satisfied.

(b) Once (1) (a) is fulfilled, this condition,

$$K_t+K_r=U_t+U_r+r(U_t+U_r)^2+H_t+H_r>0,$$

is trivial, since the only possible negative contribution would be that of U_t+U_r and this is counteracted by H_t+H_r if it decreases as $1/r$ or faster, or by $r(U_t+U_r)^2$ if it does not. Following a similar line of thought we also conclude that

$$K_r=U_r+r(U_t^2+U_r^2)+H_r$$

is positive for large values of t and r.

(c) The last set of conditions on the derivatives,

$$(K+U)_t+(K+U)_r=2(U_t+U_r)+r(U_t+U_r)^2+H_t+H_r\geqslant 0,$$
$$K_r+U_r=2U_r+rU_r^2+H_r\geqslant 0,$$

is also a consequence of (1) (a). Therefore the first part of the theorem is satisfied if

$$\left.\begin{array}{c} r^{1-\varepsilon}|U_r+U_t| \\ \text{or} \\ r^{1-\varepsilon}(H_r+H_t) \end{array}\right\} \not\to 0 \tag{27}$$

for large values of t and r. The conclusion for past-pointing geodesics is quite similar. We just have to change the sign of the time derivatives,

$$\left.\begin{array}{c} r^{1-\varepsilon}|U_r-U_t| \\ \text{or} \\ r^{1-\varepsilon}(H_r-H_t) \end{array}\right\} \not\to 0 \tag{28}$$

for large values of r and small values of t. For instance, these restrictions are trivial for the $\xi=0$ case, since $H=\gamma r^2/2$ does not decrease.

(2) The dependence on the matter content of the space–time may be removed from these conditions, since we may write

$$K(t,r)=U(t,r)+\int_0^r dr'(r'U_r^2(t,r')+r'U_t^2(t,r')+H_r(t,r'))=U(t,0)+\int_0^r dr'\,K_r(t,r'), \tag{29}$$

and according to (19d) or (25d) K_r is a positive term if the first part of the theorem is satisfied.

(a) The first condition is tautological since

$$K(t,r)-U(t,r)=\int_0^r dr'\,(r'U_r^2(t,r')+r'U_t^2(t,r')+H_r(t,r'))>0.$$

(b) For geodesics along the axis, this condition requires for large values of the time coordinate that

$$K(t,0)=U(t,0)\geqslant -\tfrac{1}{2}\ln|t|+b, \tag{30}$$

and for general geodesics the only difference is the positive term in (29). Therefore (30) is the only restriction for all geodesics.

(c) The same restriction is achieved likewise when applied to the expression $K+U+\ln\rho$.

Therefore we are left with just three regularity conditions on the metric of an Abelian diagonal orthogonally transitive space–time with spacelike orbits and with a stiff perfect fluid as matter content. We may summarize these results in two theorems:

Theorem 3: A cylindrical space–time with a stiff perfect fluid as matter content, endowed with a metric in the form (7) with C^2 metric functions K,U,ρ is future geodesically complete if the gradient of the surface element is spacelike and

(1) For large values of t, $U(t,0) \geqslant -\frac{1}{2}\ln|t|+b$.
(2) Either $r^{1-\varepsilon}|U_r+U_t|$ or $r^{1-\varepsilon}(H_r+H_t)$ does not tend to zero for large values of t and r.

Theorem 4: A cylindrical space–time with a stiff perfect fluid as matter content, endowed with a metric in the form (7) with C^2 metric functions K,U,ρ is past geodesically complete if the gradient of the surface element is spacelike and

(1) For small values of t, $U(t,0) \geqslant -\frac{1}{2}\ln|t|+b$.
(2) Either $r^{1-\varepsilon}|U_r-U_t|$ or $r^{1-\varepsilon}(H_r-H_t)$ does not tend to zero for small values of t and large values of r.

For vaccuum space–times both theorems hold just dropping the conditions on the derivatives of H.

The restrictions imposed by both theorems in order to have a nonsingular space–time are rather simple to implement, since U is just a solution of the wave equation and H is related to another one. We may state that regularity conditions are quite weak for stiff fluids, since it is very easy to provide solutions that fulfill such requirements. For instance,

Corollary: A metric with arbitrary H and a function U which grows for large $|t|$ and for large r makes the spacetime geodesically complete.

It is not difficult to derive such functions. The solutions to the reduced wave equation in the plane can be written as solutions of the initial value problem,

$$U_{tt}-U_{rr}-\frac{U_r}{r}=0,$$
$$U(0,r)=f(r), \quad U_t(0,r)=g(r). \tag{31}$$

The solution to this problem can be written in closed form,[15]

$$U(x,y,t)=\frac{1}{2\pi}\int_0^{2\pi}d\phi\int_0^t dR\,R\frac{g(x+R\cos\phi,y+R\sin\phi)}{\sqrt{t^2-R^2}}$$
$$+\frac{1}{2\pi}\frac{\partial}{\partial t}\int_0^{2\pi}d\phi\int_0^t dR\,R\frac{f(x+R\cos\phi,y+R\sin\phi)}{\sqrt{t^2-R^2}}, \tag{32}$$

for initial data $U(x,y,0)=f(x,y)$, $U_t(x,y,0)=g(x,y)$, taking into account that f and g are to have circular symmetry.

If we split U in U_f and U_g, the terms depending, respectively, on the initial data for U and its derivative, we notice that U_f is even in the time coordinate whereas U_g is odd. This implies that if U_f satisfies the first condition in theorem 3 for future-pointing geodesics, it will fulfill it for past-pointing geodesics too. On the contrary, if U_g satisfies it for future-pointing geodesics, it may not fulfill it for past-pointing ones, unless it behaves for large values of $|t|$ slower than a logarithm. Therefore one is to require either that U_f dominates over U_g for large $|t|$ or that both terms behave slower than a logarithm in order to have nonsingular behavior.

IV. DISCUSSION

In this paper we have derived sufficient conditions for an Abelian diagonal orthogonally transitive space–time with spacelike orbits and with a stiff perfect fluid as matter content to be geodesically complete. One of the metric functions appears to be determinant for the regularity of the space–time. These conditions are easy to check and do not mean much restriction on these space–times.

This means that nonsingular space–times are not as scarce as it was thought, considering the reduced list of geodesically complete perfect fluid cosmologies in the literature. Further work is

needed with more generic symmetries and matter contents in order to clarify the issue, since stiff perfect fluids are rather peculiar. They may be interpreted as a massless scalar field and they are the limiting case for which a barotropic perfect fluid with linear equation of state satisfies every energy condition. These space–times also fulfill the generic condition and are causally stable.

The latter assert is true since they possess a cosmic time, which is the coordinate t. This coordinate has a timelike gradient everywhere. Therefore,[2] these space–times satisfy weaker causality conditions. For instance, the chronology condition is true for them and no closed causal curves are possible.

As it was stated in the introduction, the existence of these nonsingular space–times is possible because they do not possess causally trapped sets. They obviously do not contradict then the singularity theorems. They just fall out of their scope.

Another interesting point that is worthwhile mentioning is that the regularity theorems appear to encourage a growing K for large values of $|t|$. This seems to support a conjecture that states that the spatial average value of the pressure in nonsingular space–times is zero,[11] since p decreases with large K according to (24),

$$p=e^{-2K}(\sigma_t^2-\sigma_r^2). \tag{33}$$

In our regular space–times, constant t sheets are Cauchy hypersurfaces and we may write the whole system of equations as an initial value problem for U, K, and H for any constant t. Without breaking the generality of the result, we may focus on $t=0$. The initial value problem can be stated as

$$U_{tt}-U_{rr}-\frac{U_r}{r}=0, \tag{34a}$$

$$\sigma_{tt}-\sigma_{rr}-\frac{\sigma_r}{r}=0, \tag{34b}$$

$$K_t=U_t+2r(U_tU_r+\sigma_t\sigma_r), \tag{34c}$$

$$U(0,r)=f(r), \quad U_t(0,r)=g(r), \tag{34d}$$

$$\sigma(0,r)=f_\sigma(r), \quad \sigma_t(0,r)=g_\sigma(r), \tag{34e}$$

$$K(0,r)=h(r), \tag{34f}$$

and the remaining equation in the system,

$$K_r=U_r+r(U_t^2+U_r^2+\sigma_t^2+\sigma_r^2), \tag{35}$$

is used to complete the initial data,

$$h(r)=U(0,0)+\int_0^r dr'\,K_r(0,r')=f(r)+\int_0^r dr'\,r'\{g(r)^2+f'(r)^2+g_\sigma(r')^2+f'_\sigma(r')^2\}. \tag{36}$$

In order to know the pressure on the hypersurface $t=0$ we just have to prescribe the initial data,

$$p(0,r)=e^{-2h(r)}\{g_\sigma(r)^2-f'_\sigma(r)^2\}. \tag{37}$$

We show that it must necessarily vanish at infinity if the space–time is causally geodesically complete.

If the term $g_\sigma^2 - f_\sigma'^2$ in the pressure does not tend to zero at infinity, the σ terms would contribute to h as r^2 (if $g_\sigma^2 + f_\sigma'^2$ tends to a constant) or greater. Unless a negative f overcomes this quadratic term, we would have a pressure decreasing as a Gaussian exponential and the average on $t=0$ would be zero.

But f cannot beat a quadratic term, because the f' term in the integral would mean a positive r^4 contribution to h, and we would have again a negative exponential. That is, if $g_\sigma^2 - f_\sigma'^2$ does not vanish at infinity, it grows much slower than the exponential term decreases and the pressure tends to zero.

The only possibility we have left then is a positive exponential. This means a negative h. If we want f to overcome just the f' term in h, we require $|f(r)| \leqslant \ln r$ for large values of r, a very narrow strip.

But we also need to keep under control the σ terms in h. They remain bounded for large values of r if $r^2(g_\sigma^2 + f_\sigma'^2)$ tends to zero. This means that the σ term in the pressure decreases faster than r^{-2}. Admitting that $h(r)$ might behave as $-\ln r$ for large r, the exponential in the pressure would be a r^2 term, that cannot compensate the σ term.

Therefore, pressure tends to zero for large r on constant time hypersurfaces, thereby supporting Senovilla's conjecture in Ref. 11.

(Received 23 December 2002; accepted 5 March 2004; published online 29 April 2004)

A classical phase space with a suitable symplectic structure is constructed together with functions which have Poisson brackets algebraically identical to the Lie algebra structure of the Lie group SU(n). In this phase space we show that the orbit of the generators corresponding to the simple roots of the Lie algebra give rise to fibers that are complex lines containing spheres. There are $n-1$ spheres on a fiber and they intersect in exactly the same way as the Cartan matrix of the Lie algebra. This classical phase space bundle, being compact, has a description as a variety. Our construction shows that the variety containing the intersecting spheres is exactly the one obtained by resolving the singularities of the variety $x_0x_1-x_2^n=0$ in $\mathcal{C}^3$. A direct connection between this singular variety and the classical phase space corresponding to the Lie group SU(n) is thus established. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1723700]

I. INTRODUCTION

It has long been known that there is an intriguing algebraic correspondence between the Cartan matrix of simply laced Lie groups and the intersection matrix of spheres that appear when certain simple singularities are resolved.[1] The reason for such a correspondence has also been long known within the framework of algebraic groups.[2] That this correspondence might be more than a mathematical curiosity was established when it was shown that duality in string theory made effective use of such a link.[3] A type 2A string compactified on a $K3$ surface (a four-dimensional surface) was conjectured to be dual to a heterotic string compactified on T^4 (the four torus). A test of this conjecture required the zero mass excitations in the two theories to match. The zero mass excitations at the type 2A end came from certain singular points that appear on the $K3$ surface in a certain limit while those at the heterotic string end came from gauge excitations associated with an SU(n) Lie group. The excitations at the type 2A end were ''classical'' solitonic-type excitations while those at the heterotic end were ''quantum'' gauge excitations. This result suggests that a link between minimally resolved singularities and the ''classical limit'' of simply laced Lie groups might exist.

In this paper we establish such a link. We demonstrate this link explicitly for the Lie groups SU(2), SU(3), and SU(4). Generalization to SU(n) is then straightforward. We find, using a Gauss decomposition Z_+HZ_-, where Z_+ is an upper triangular matrix with unit diagonal elements, H is a diagonal matrix, Z_- is a lower triangular matrix with unit diagonal elements that the classical phase space, in which Poisson brackets mirror the Lie algebra structure, can be constructed using a standard coherent state approach.[4] We use the Gauss decomposition in order to use the Borel–Weil Theorem. This theorem shows how irreducible representations of a compact Lie group G can

a)Electronic mail: smr@bose.res.in
b)Electronic mail: sen@maths.tcd.ie

be constructed as holomorphic sections over G/T, where T is the maximal torus of G. The approach thus describes the group in terms of complex variables and is thus a natural setting for making contact between the group and complex algebraic varieties. We have

Borel–Weil Theorem 1 (Ref. 5): *The space of holomorphic sections of the line bundle L_λ over G/T is nontrivial if λ is the highest weight of an irreducible representation of G. When λ is the highest weight then this space of holomorphic sections is a realization of the representation space V_λ of G.*

The coherent state approach is an explicit way of implementing the Borel–Weil Theorem. Use is made, in this approach, of the fact that $G/T=G_c/B$, where G_c is the complexification of G and B is the Borel subgroup. In terms of the Gauss decomposition B is generated by H and Z_-. It is in this framework that we search for and identify classical phase space. For SU(n) the phase space is CP^{n-1}. This is a Kähler symplectic manifold. It is identified cleanly in G_c/B as follows. We first introduce some definitions. Triangular matrices with unit diagonal elements are called unipotent. Z_+,Z_- are unipotent. We claim that by using unipotent group elements of a special kind we can construct the required Kähler symplectic manifold. To do this the unipotent elements used must have two special features. First they must mutually commute. Second the number of elements that commute with the these unipotent elements must equal the rank r of the group. Such elements are called regular. In this coherent state approach the symplectic structure is derived from a Kähler potential which we construct from a scalar product using the group elements described acting on the highest weight vector for the fundamental representation. It is then shown that the expectation value of the generators of the Lie algebra have Poisson brackets, defined in terms of this symplectic structure, isomorphic to the Lie algebra of the group. On this Kähler phase space a fiber bundle structure can be constructed whose fibers are complex curves, containing intersecting spheres. The fiber bundle considered is constructed from the orbit of group elements arising from the simple roots of the corresponding Lie algebra. In our construction we classify the unipotent elements of Z_+ in the following way:

One class has a centralizer (elements of the group commuting among themselves) of dimension equal to the rank r of the group. These are the regular elements. The other class comes from the generators of the Lie algebra for simple roots. These are unipotent elements that commute with $r+2$ group elements. Such elements are called subregular. These unipotent subregular elements play a crucial role in our construction. The special unipotent regular elements are used to construct classical phase space. This is done by acting on the highest weight vector with the the elements described. Choosing to work with the highest weight vector is the way the quotienting of G_c by B is implemented in this framework. The unipotent subregular elements acting on a point of this phase space give rise to a fiber containing intersecting spheres. The way these spheres intersect can be summarized in the form of an intersection matrix. This intersection matrix is found to be identical to the negative of the Cartan matrix of the Lie algebra. We show this explicitly for SU(3) where there are two intersecting spheres, for SU(4) where there are three spheres and for SU(n) where there are $n-1$ spheres. Precisely such intersecting spheres also appear when certain singular points are resolved on the hypersurface $x_0x_1-x_2^n=0$, where $(x_0,x_1,x_2)\in\mathcal{C}^3$, the space of three complex variables. In Sec. II we summarize the basic facts we need from the theory of resolution of singularities. In Sec. III the classical phase space for the Lie groups SU(2), SU(3), and SU(4) is constructed and the link with the resolved singularities established. Finally in Sec. IV we summarize our conclusions.

II. RESOLVING SINGULARITIES

Consider the hypersurface V_n in $\mathcal{C}^3$ defined by the algebraic equation:

$$V_n(x_0,x_1,x_2)=x_0x_1-x_2^n=0, \tag{1}$$

where n is an integer $\geqslant 2$ and $(x_0,x_1,x_2)\in\mathcal{C}^3$. We have the following definition:[1,6]

Definition: A point $(x_0,x_1,x_2)\in V_n=0$ is a singular point of the hypersurface if $\partial_{x_i}V_n=0$ at that point.

It follows from the definition that the point (0,0,0) i.e., the origin is a singular point of the hypersurface $V_n \equiv x_0 x_1 - x_2^n = 0$, for $n \geqslant 2$. Indeed a simple definition of this hypersurface as an orbifold is possible. To see this set $x_0 = \xi^n$, $x_1 = \eta^n$, $x_2 = \xi\eta$, where $(\xi, \eta) \in \mathcal{C}^2$. We note that in terms of these variables ξ, η the equation $x_0 x_1 - x_2^n = 0$ is identically satisfied, i.e., ξ, η parametrize the hypersurface $V_n = 0$. There is however one restriction on the variables ξ, η when they are on the hypersurface $V_n = 0$ namely the point (ξ, η) must be identified with $(\omega^{1/n}\xi, \omega^{-1/n}\eta)$, where ω is an nth root of identity $(\omega^n = 1)$. Thus the hypersurface $V_n = 0$ can be identified with the orbifold $\mathcal{C}^2/\mathcal{Z}_n$ with $\mathcal{Z}_n$ action defined by $(\xi, \eta) \to (\omega^{1/n}\xi, \omega^{-1/n}\eta)$, $\omega^n = 1$.

There is a standard method of minimally resolving this singularity,[1,6] i.e., of constructing a globally well defined hypersurface which is in 1–1 correspondence with the original hypersurface $V_n = 0$ except at the point (0,0,0). The singular point is "blown up." We describe this procedure first for the case $n = 2$ and $n = 3$ and then for the general case where $n > 3$.

Let us introduce the space $\mathcal{C}^3 \times \mathcal{P}^2$, where $\mathcal{P}^2$ is the complex projective two space (henceforth we denote $\mathcal{CP}^n$ by $\mathcal{P}^n$). Points in $\mathcal{C}^3 \times \mathcal{P}^2$ can be written as the pair $((x_0, x_1, x_2), [s_0, s_1, s_2])$ where $(x_0, x_1, x_2) \in \mathcal{C}^3$ and $[s_0, s_1, s_2]$ is an element of $\mathcal{P}^2$, i.e., it represents the equivalence class of points (s_0, s_1, s_2) under the equivalence relation $(s_0, s_1, s_2) \sim \lambda(s_0, s_1, s_2)$, where λ is a complex number $\neq 0$. Next we introduce the space $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$. This is defined as the set:

$$\mathcal{C}^3(\mathcal{P}^2, \mathcal{R}) = \{(x_0, x_1, x_2), [s_0, s_1, s_2] | x_i s_j = x_j s_i, \forall i, j\}. \tag{2}$$

Geometrically the restriction $x_i s_j = x_j s_i$ means that s_i is proportional to x_i. This gives a space consisting of points (x_0, x_1, x_2) in $\mathcal{C}^3$ and lines through the origin and these points. These lines are elements of $\mathcal{P}^2$. Thus for all points in $\mathcal{C}^3$, other than the origin, the element of $\mathcal{P}^2$ is uniquely fixed by (x_0, x_1, x_2). There is thus a 1–1 correspondence between points in $\mathcal{C}^3$ and the pair of points in $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$ defined by Eq. (2). For the origin however the situation is different. When $x_0 = x_1 = x_2 = 0$, there is no restriction on $[s_0, s_1, s_2]$. Thus the origin of $\mathcal{C}^3$ is replaced by the entire $\mathcal{P}^2$ in $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$; it is "blown up." Let us now study the way the hypersurface $x_0 x_1 - x_2^2 = 0$ behaves in $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$. To see the way the singular point in $V_2 = 0$ in $\mathcal{C}^3$ gets mapped in $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$ we approach the origin in $\mathcal{C}^3$. This is done by scaling the points (x_0, x_1, x_2) in $\mathcal{C}^3$ by t and letting $t \to 0$. Note that the constraints $x_i s_j = x_j s_i \forall i, j$ imply that $x_i = k s_i$ (where k = constant). Thus $(t x_0, t x_1, t x_2) = t k (s_0, s_1, s_2)$, i.e., we get from Eqs. (1) and (2) in the $t \to 0$ limit, points on $V_2 = 0$ satisfy $s_0 s_1 - s_2^2 = 0$ in $\mathcal{P}^2$. We now have the following theorem.

Theorem 2 (Ref. 7): *A polynomial equation of degree n in $\mathcal{P}^2$ describes a compact Riemann surface of genus g with $g = \frac{1}{2}(n-1)(n-2)$.*

In our case the polynomial equation $s_0 s_1 - s_2^2 = 0$ in $\mathcal{P}^2$ is of degree 2. Hence the surface in $\mathcal{P}^2$ is a genus zero surface, i.e., topologically it is a sphere. Thus the singular point of the hypersurface $x_0 x_1 - x_2^2 = 0$ in $\mathcal{C}^3$ is replaced by a sphere in $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$. The singularity has been resolved by a process of "blowing up" tuning the singular point into a sphere. We next consider the case $n = 3$. Repeating the procedure for the $n = 2$ case we find, the points $[s_0, s_1, s_2]$ satisfying Eq. (1) for $n = 3$, i.e., $V_3 = 0$ and Eq. (2) in the vicinity of the origin now have to satisfy the polynomial equation $t^2(s_0 s_1 - k t s_2^3) = 0$, i.e., the equation $s_0 s_1 = 0$ in the $t \to 0$ limit. This gives a pair of spheres $\mathcal{P}^1$'s in $\mathcal{P}^2$ (theorem 2) corresponding to setting $s_0 = 0$, $s_1 = 0$. These two spheres intersect once at the point (0,0,1) in $\mathcal{P}^2$. For $n \geqslant 4$, we again get the equation $s_0 s_1 = 0$ in the limit $t \to 0$ and a pair of spheres. However the intersection of these spheres is still a singular point. To see this we choose to describe $\mathcal{C}^3(\mathcal{P}^2, \mathcal{R})$ by first selecting a point in $\mathcal{P}^2$, say, (s_0, s_1, s_2) with $s_2 \neq 0$. Choosing this point does not uniquely fix a point in $\mathcal{C}^3$ but gives a line through the point (s_0, s_1, s_2) and the origin in $\mathcal{C}^3$. Let us set $s_2 = y_2$ $s_0 = y_0 y_2$, $s_1 = y_1 y_2$, where $(y_0, y_1, y_2) \in \mathcal{C}^3$. Finally set $y_2 = x_2$. Then $x_0 = y_0 y_2$, $x_1 = y_1 y_2$, and $0 = x_0 x_1 - x_2^n = y_2^2(y_0 y_1 - y_2^{n-2}) = 0$. By construction $y_2 \neq 0$. So $y_0 y_1 - y_2^{n-2} = 0$. For $n \geqslant 4$ this hyperplane has a singularity at the origin $y_0 = y_1 = y_2 = 0$, where $s_0 = 0$, $s_1 = 0$. The process of blowing up has to be repeated. The spheres produced by this process of blowing up self-intersect in an invariant way. Following a standard procedure[1] it can be shown that the self-intersection of the spheres can be taken to be -2. We

FIG. 1. Dynkin diagram 1.

summarize the results presented regarding the way the spheres in the ''resolved singularity'' intersect in the form of a matrix. For $n=3$, we have the intersection matrix $\left(\begin{smallmatrix}-2 & 1\\ 1 & -2\end{smallmatrix}\right)$. For $n=4$ we have

$$\begin{pmatrix} -2 & 1 & 0 \\ 1 & -2 & 1 \\ 0 & 1 & -2 \end{pmatrix}.$$

This intersection information can be encoded in the form of a Dynkin diagram shown in Fig. 1 where each dot denotes a sphere with self intersection -2 and a line joining two dots denote intersection between two spheres with intersection number one. The construction described here extends to the case of arbitrary n where the diagram is shown in Fig. 2.

III. THE CLASSICAL PHASE SPACE FOR THE LIE GROUPS SU(2), SU(3), AND SU(4)

We now look at the classical origins of the Lie groups SU(2), SU(3), and SU(4) in the following sense. The groups have a local structure encoded by their Lie algebras. We will call the associated phase space, defined with a suitable symplectic structure, the classical counterpart of the Lie group if functions on the phase space can be constructed which have Poisson brackets algebraically identical to the Lie algebra structure of the Lie group. The construction we will describe involves coherent states associated with the Lie group of interest.[4] We start by quickly summarising the results for SU(2). This simple example contains a crucial ingredient needed for our subsequent analysis. Let us introduce the highest weight representation for SU(2), which we write as the vector $\left(\begin{smallmatrix}0\\1\end{smallmatrix}\right)$. The coherent state $|\lambda\rangle$ is then defined as

$$|\lambda\rangle = e^{\lambda J_+}\begin{pmatrix}0\\1\end{pmatrix},\quad J_+ = \begin{pmatrix}0 & 1\\ 0 & 0\end{pmatrix} \equiv e_{12},\quad \langle\lambda|\lambda\rangle = (1+\lambda\bar{\lambda}), \tag{3}$$

λ being a complex variable. We then construct the Kähler potential $V(\lambda,\bar{\lambda}) = k\cdot\log(1+\lambda\bar{\lambda})$. This gives rise to a symplectic form on the coordinate chart $\lambda_0 \neq 0$ in $\mathcal{P}^1$ as well as the Fubini–Study metric,[6,8] where $\lambda = \lambda_1/\lambda_0$. The symplectic structure is given by

$$\omega_{\lambda\bar{\lambda}} = \partial_\lambda \partial_{\bar{\lambda}} V(\lambda\bar{\lambda}), \omega = \omega_{\lambda\bar{\lambda}} d\lambda \wedge d\bar{\lambda} + \omega_{\bar{\lambda}\lambda} d\bar{\lambda}\wedge d\lambda, \tag{4}$$

where the symplectic matrix is given by

$$[\omega] = k\cdot\begin{pmatrix} 0 & \dfrac{1}{(1+\lambda\bar{\lambda})^2} \\ -\dfrac{1}{(1+\lambda\bar{\lambda})^2} & 0 \end{pmatrix}, \tag{5}$$

k is a constant. We next note that

FIG. 2. Dynkin diagram 2.

$$X_+ = \frac{\langle \lambda | J_+ | \lambda \rangle}{\langle \lambda | \lambda \rangle} = \frac{2\lambda}{1+\lambda\bar{\lambda}},$$

$$X_- = \frac{\langle \lambda | J_- | \lambda \rangle}{\langle \lambda | \lambda \rangle} = \frac{2\bar{\lambda}}{1+\lambda\bar{\lambda}},$$

$$X_0 = \frac{\langle \lambda | J_0 | \lambda \rangle}{\langle \lambda | \lambda \rangle} = \frac{1-\lambda\bar{\lambda}}{1+\lambda\bar{\lambda}}, \tag{6}$$

with $J_- = e_{21}$, $J_+ = e_{12}$, $J_0 = e_{11} - e_{22}$, where e_{ij} stands for the 3×3 matrix with one in the ijth position and zero elsewhere, and X_+, X_-, X_0 are functions on the phase space $\mathcal{P}^1$ described by the complex variable λ and the symplectic form ω given by Eq. (4).

Furthermore $X_+X_- + X_0^2 = 1$, i.e., these functions represent points on S^2. Also

$$\{X_+, X_-\} = (\omega^{-1})_{\lambda\bar{\lambda}}\partial_\lambda X_+ \partial_{\bar{\lambda}} X_- + (\omega^{-1})_{\bar{\lambda}\lambda}\partial_{\bar{\lambda}} X_+ \partial_\lambda X_- = 2iX_0,$$

$$\{X_0, X_\pm\} = \pm X_\pm, \tag{7}$$

for suitable choice of k. Thus the expectation values of the generators $J_\pm$, J_0 in the normalized state vector $|\lambda\rangle$ represent the classical functions whose quantization, achieved by replacing Poisson brackets by commutators leads to the Lie algebra structure. The classical phase space of SU(2) is thus S^2 or $\mathcal{P}^1$. Note that the presence of S^2 could be spotted simply by evaluating $\int \omega d\lambda \wedge d\bar{\lambda} = 4\pi$, where ω is given by Eq. (4) and noting that the curvature of the phase space manifold is constant and positive. Also the metric on the phase space derived from the Kähler potential can be seen to be precisely the metric on S^2. The emergence of S^2 for the Lie group SU(2) is the key observation we want to record. For the groups SU(3), SU(4) we will construct appropriate Kähler forms which describe the classical phase space associated with these groups. It will then be demonstrated that the fiber obtained from the orbit of the generators corresponding to simple roots of the Lie algebra acting on this phase space contain intersecting spheres. The spheres can easily be identified by the presence of nontrivial cycles with $\int \omega = 4\pi$ on the fiber and a sphere metric in an appropriate subspace. The intersection properties of these spheres can be determined by using the methods of differential topology.[6] We demonstrate that the spheres described intersect in a manner precisely mirroring the Dynkin diagram of the group. Such a result was established by Tits and Steinberg in a different setting (see the theorem by Tits and Steinberg in the article by Brieskorn in Ref. 2). We saw in Sec. II that the spheres present when the singular hypersurface considered there was resolved also contain intersecting spheres of exactly the same kind. We now make use of the following theorems:

Chow's Theorem 3 (Refs. 6, 7): *A compact hypersurface can always be represented by an algebraic variety in a higher dimensional projective space.*

Theorem 4 (Ref. 7): *A complex curve in $\mathcal{C}^n$ can always be embedded in $\mathcal{C}^3$.*

The space constructed here is compact and hence the system can be represented as an algebraic variety and the intersecting spheres, present in $\mathcal{C}^{n-1}$, can be embedded in $\mathcal{C}^3$.

With the help of these theorems we see that the fibers containing the intersecting spheres can be embedded in $\mathcal{C}^3$. Thus the two different mathematical objects: the resolved singular curve and the algebraic curve present in the phase space bundle of SU(n) both live in $\mathcal{C}^3$ and both contain the same number of spheres that intersect in the same way.

Now for the details. For SU(3) we again work with the fundamental representation and introduce the coherent state

$$|\nu_1,\nu_2\rangle = e^{\nu_1 e_{13}} e^{\nu_2 e_{23}} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} \nu_1 \\ \nu_2 \\ 1 \end{pmatrix}. \tag{8}$$

Note that

$$g = e^{\nu_1 e_{13} + \nu_2 e_{23}} = \begin{pmatrix} 1 & 0 & \nu_1 \\ 0 & 1 & \nu_2 \\ 0 & 0 & 1 \end{pmatrix}$$

has generators e_{13}, e_{23} that commute. Furthermore g commutes with e_{13} and e_{23} so that dimension of the center of g is 2 = rank of SU(3). It is thus a regular element in SU(3,c). The element is also unipotent as it is an upper triangular matrix with unit diagonal elements.

The Kähler potential is given by

$$V(\nu_1,\nu_2,\overline{\nu_1},\overline{\nu_2}) = k\cdot \log\langle \nu_1,\nu_2|\overline{\nu_1},\overline{\nu_2}\rangle = k\cdot \log(1+\nu_1\overline{\nu_1}+\nu_2\overline{\nu_2}) = k\cdot \log\langle \nu|\nu\rangle \tag{9}$$

and the symplectic structure determined by

$$\omega_{i\bar{j}} = k\cdot \partial_{\nu_i}\partial_{\overline{\nu_j}} V, \omega = \omega_{i\bar{j}} d\nu_i \wedge d\overline{\nu_j} \tag{10}$$

is precisely that on $\mathcal{P}^2$ (Refs. 6 and 8) in the coordinate chart $\nu_0' \neq 0$, (ν_0',ν_1',ν_2') being the homogeneous coordinates and ν_1,ν_2 stand for ν_1'/ν_0' and ν_2'/ν_0'. Also the symplectic structure (10) can be proved to be global.[6] It is then easy to verify that the commutation relations of SU(3) are reflected in the Poisson brackets between the functions $\langle e_{ij}\rangle$ and $\langle e_{kl}\rangle$, where

$$\langle e_{ij}\rangle = \frac{\langle \nu_1\nu_2|e_{ij}|\nu_1\nu_2\rangle}{\langle \nu_1\nu_2|\nu_1\nu_2\rangle}.$$

Note that

$$[\omega] = \begin{pmatrix} 0 & a & 0 & b \\ -a & 0 & -b' & 0 \\ 0 & b' & 0 & c \\ -b & 0 & -c & 0 \end{pmatrix}, \tag{11}$$

$$[\omega^{-1}] = \frac{1}{ac-bb'} \begin{pmatrix} 0 & -c & 0 & b' \\ c & 0 & -b & 0 \\ 0 & b & 0 & -a \\ -b' & 0 & a & 0 \end{pmatrix}, \tag{12}$$

where

$$a = \partial_{\nu_1}\partial_{\overline{\nu_1}} \log\langle \nu|\nu\rangle, b = \partial_{\nu_1}\partial_{\overline{\nu_2}} \log\langle \nu|\nu\rangle, c = \partial_{\nu_2}\partial_{\overline{\nu_2}} \log\langle \nu|\nu\rangle \tag{13}$$

and prime stands for complex conjugate.

We now proceed to construct fibers on this phase space:

The generators corresponding to the simple roots of SU(3) are e_{12}, e_{23} and the group elements $\in Z_+$ are $e^{\mu e_{12}}$, $e^{\lambda e_{23}}$. They are unipotent subregular elements $\in Z_+$. To see this set $x = e^{\mu e_{12}}$. Then $y = e^{\alpha e_{13} + \beta(h_1+2h_2) + \gamma e_{32} + \delta e_{12}} \in \mathrm{SU}(3,c)$, where α, β, γ, δ are complex parameters, commutes with x. So dimension of the center of x in SU(3,c) is $4 = 2+2 =$ rank of SU(3) + 2. Thus x is subregular in SU(3,c). Similarly the element $e^{\lambda e_{23}}$ is subregular. We now consider the orbits

of $e^{\mu e_{12}}$ and $e^{\lambda e_{23}}$ at the base point on the phase space

$$\begin{pmatrix} \nu_1 \\ \nu_2 \\ 1 \end{pmatrix}.$$

We have then μ-orbit and λ-orbit as the fiber elements as

$$\begin{pmatrix} \nu_1 \\ \nu_2 \\ 1 \end{pmatrix}$$

and

$$\begin{pmatrix} \nu_1 \\ \nu_2+\lambda \\ 1 \end{pmatrix}.$$

Relabeling the first orbit as

$$\begin{pmatrix} z_1 \\ \nu_2 \\ 1 \end{pmatrix}$$

we can associate with it a Kähler potential $\log(1+z_1\overline{z_1})$. This is a sphere $\mathcal{P}^1$. Similarly the λ orbit is also a sphere. To demonstrate that these two spheres intersect with intersection number 1 we consider

$$e^{\mu e_{12}} e^{\lambda e_{23}} \begin{pmatrix} \nu_1 \\ \nu_2 \\ 1 \end{pmatrix}.$$

The common z_1-z_2 (the first two coordinates) plane has an associated Kähler potential $\log(1+z_1\overline{z_1}+z_2\overline{z_2})$. The symplectic structure is then given by Eq. (10) with $i,j=1,2$. We now note the following theorems:

Theorem 5 (Ref. 6): *The de Rham cohomology and Dolbeault cohomology groups for $\mathcal{P}^n$ are related*:

$$H_{\partial}^{p,p}(\mathcal{P}^n) \cong H_{DR}^{2p} \cong C.$$

Theorem 6 (Ref. 6): *The intersection of the two surfaces $\mathcal{C}_i$ and $\mathcal{C}_j$ are given by $\mathcal{C}_i \cdot \mathcal{C}_j = 1/(4\pi)^2 \int \omega_i \wedge \omega_j$, where the integration is in the space containing the surface $\mathcal{C}_i$ and $\mathcal{C}_j$ and is a space of dimension four and ω_i, ω_j are (de Rham cohomology) elements of $H_{DR}^2(M,R)$.*

The cohomology groups associated with the symplectic form constructed are Dolbeault cohomology groups while the intersection formula is valid for de Rham cohomology groups. However for $\mathcal{P}^n$ they are equivalent (Theorem 5). We can thus determine intersection of spheres by simply evaluating $(1/(4\pi)^2)\int \omega \wedge \omega$, where the relevant four-dimensional manifold (complex dimension 2) is the common z_1-z_2 plane. This is precisely seen to be one. Thus the two spheres on the fiber intersect once with intersection number one.

The procedure outlined can be repeated for SU(4). This time

$$|\nu\rangle = |\nu_1, \nu_2, \nu_3\rangle = e^{\nu_1 e_{14}} e^{\nu_2 e_{24}} e^{\nu_3 e_{34}} \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} \nu_1 \\ \nu_2 \\ \nu_3 \\ 1 \end{pmatrix} \tag{14}$$

and the Kähler potential is

$$V(\nu_1, \nu_2, \nu_3, \overline{\nu_1}, \overline{\nu_2}, \overline{\nu_3}) = k \cdot \log\langle \nu|\nu\rangle = k \cdot \log(1 + \nu_1\overline{\nu_1} + \nu_2\overline{\nu_2} + \nu_3\overline{\nu_3}). \tag{15}$$

Here again

$$\omega_{i,\bar{j}} = \partial_{\nu_i}\partial_{\overline{\nu_j}} \log\langle \nu|\nu\rangle, \omega = \omega_{i,\bar{j}} d\nu_i \wedge d\overline{\nu_j} \tag{16}$$

is a symplectic structure on $\mathcal{P}^3$. The corresponding $[\omega]$ and $[\omega^{-1}]$ matrices are given by

$$[\omega] = \begin{pmatrix} 0 & a & 0 & b & 0 & c \\ -a & 0 & -b' & 0 & -c' & 0 \\ 0 & b' & 0 & d & 0 & f \\ -b' & 0 & -d & 0 & -f' & 0 \\ 0 & c' & 0 & f' & 0 & g \\ -c & 0 & -f & 0 & -g & 0 \end{pmatrix}, \tag{17}$$

where the primed entries stand for complex conjugates and

$$[\omega^{-1}] = \frac{1}{N} \begin{pmatrix} 0 & dg - ff' & 0 & fc' - gb' & 0 & b'f' - dc' \\ ff' - dg & 0 & bg - cf' & 0 & cd - bf & 0 \\ 0 & cf' - bg & 0 & ag - cc' & 0 & bc' - af' \\ gb' - fc' & 0 & cc' - ag & 0 & af - b'c & 0 \\ 0 & bf - cd & 0 & b'c - af & 0 & ad - bb' \\ dc' - b'f' & 0 & af' - bc' & 0 & bb' - ad & 0 \end{pmatrix}, \tag{18}$$

where

$$N^2 = \det[\omega], \quad a = \partial_{\nu_1}\partial_{\overline{\nu_1}} \log\langle \nu|\nu\rangle, \quad b = \partial_{\nu_1}\partial_{\overline{\nu_2}} \log\langle \nu|\nu\rangle, \quad c = \partial_{\nu_1}\partial_{\overline{\nu_3}} \log\langle \nu|\nu\rangle,$$

$$d = \partial_{\nu_2}\partial_{\overline{\nu_2}} \log\langle \nu|\nu\rangle, \quad f = \partial_{\nu_2}\partial_{\overline{\nu_3}} \log\langle \nu|\nu\rangle, \quad g = \partial_{\nu_3}\partial_{\overline{\nu_3}} \log\langle \nu|\nu\rangle, \tag{19}$$

and the prime denotes complex conjugate. Using $[\omega^{-1}]$ from Eq. (18) it is again straightforward to verify that the commutation relations of SU(4) are reflected in the Poisson bracket between the functions $\langle e_{ij}\rangle$ and $\langle e_{kl}\rangle$ where again $\langle e_{ij}\rangle \equiv \langle \nu|e_{ij}|\nu\rangle / \langle \nu|\nu\rangle$.

Finally we look at the fiber. The unipotent subregular elements corresponding to the simple roots are $e^{\mu e_{12}}$, $e^{\lambda e_{23}}$, and $e^{\rho e_{34}}$. So we have μ, λ, and ρ orbits on the fiber at the base point

$$\begin{pmatrix} \nu_1 \\ \nu_2 \\ \nu_3 \\ 1 \end{pmatrix}.$$

Each element acts on a 2-complex dimensional subspace. It is easy to determine, as we have shown for the SU(3) case that an individual orbit is $\mathcal{P}^1$ on the fiber. Two generators intersect if

they act on a common subspace i.e., group elements corresponding to e_{12} and e_{23} both act on the space labeled by 2, while e_{34} and e_{12} have no common subspace. A differential topology way of spotting this is to construct the vector obtained by acting $e^{\mu e_{12}}\, e^{\lambda e_{23}}$, say, on the base point. The variables μ, λ appear in the 1,2 position. Setting the variables corresponding to 1,2 as z_1, z_2 the symplectic structure can be constructed from the corresponding Kähler potential and

$$\frac{1}{(4\pi)^2}\int \omega\wedge\omega=\frac{1}{(4\pi)^2}\int 2(\omega_{z_1\bar{z}_1}\omega_{z_2\bar{z}_2}-\omega_{z_1\bar{z}_2}\omega_{z_2\bar{z}_1})dz_1\wedge d\bar{z}_1\wedge dz_2\wedge d\bar{z}_2$$

gives the intersection. Similarly e_{23}, e_{34} will give rise to intersection in the subspace z_2-z_3. The intersection corresponding to e_{12}, e_{34} will be zero since they have no subspace in common. Here we have to evaluate $\int\omega\wedge\omega$ in the subspace 1,2 or 3,4 in each of which $\omega\wedge\omega$ vanishes. Hence there is no intersection. The intersection properties of the orbits described easily generalizes to the case of SU(n). For SU(n) the symplectic structure will come from the group elements constructed from the generators e_{12}, $e_{13},\ldots,e_{1n}$ while the simple roots are $e_{12},e_{23},\ldots,e_{n,n-1}$. It is the orbit of the group elements generated by these simple roots acting at any point on phase space that give fibers containing $n-1$ intersecting spheres.

IV. CONCLUSIONS

We have shown in two examples, i.e., for SU(3) and SU(4) how a classical phase space can be associated with these groups. In this phase space the orbit of the generators corresponding to the simple roots of the Lie algebra gives rise to intersecting spheres as fibers. For SU(n) the fiber of the bundle consists of $n-1$ (equal to the rank of SU(n)) intersecting spheres. These spheres intersect precisely as the negative of the Cartan matrix of SU(n). A simple understanding of how this happens is provided in our work. The structure of SU(n), contained in the commutation properties of the simple roots of its Lie algebra, is exactly the structure used to construct the orbit of these generators in phase space. This structure in phase space gives rise to the resolved variety associated with a singular variety. An algebraic group demonstration of the relationship between simple singularities of the ADE type and simply laced Lie groups of ADE type was proved by Brieskorn,[2] where the role of the unipotent subregular elements of the groups was stressed and the earlier result regarding intersecting spheres of Tits and and Steinberg (theorem by Tits and Steinberg discussed in the article by Brieskorn in Ref. 2) stated. Our explicit construction uses unipotent regular elements of a special kind (viz., ones involving mutually commuting generators) to construct classical phase space and confirms the role played by subregular unipotent elements for making contact with resolved singularity. In our physically motivated approach it is geometrically very clear why unipotent subregular elements are crucial: they are the group elements that come from the simple roots of the Lie algebra. The classical phase space for SU(n) is shown explicitly to be contained in G_c/B as CP^{n-1}. The orbit of the generators of the simple roots of the corresponding Lie algebra then provide a local trivialization of a bundle contained in G_c/B with the classical phase space as the base. It is in the fiber of this space that the variety corresponding to the resolved singularity is contained. Our construction extends easily to SU(n). Extention of the construction described here to the D,E groups should be straightforward. It is pleasing that classical phase space is where the resolved singular variety corresponding to $x_0x_1-x_2^n=0$ makes its appearance. Our work thus provides confirmation of the classical/quantum correspondence discovered in string theory between groups and singularities.

ACKNOWLEDGMENT

(Received 27 July 2003; accepted 15 February 2004; published online 3 May 2004)

We consider a general weak bounded finite range perturbation of a general free quantum spin Hamiltonian on a lattice. We prove that if the free Hamiltonian has a nondegenerate ground state and a spectral gap, then the perturbation also has a ground state, and estimate the localization of the spectrum in the corresponding ground state representation. © *2004 American Institute of Physics.*

I. INTRODUCTION AND RESULTS

We consider a weak finite range perturbation of a free quantum lattice Hamiltonian with a nondegenerate ground state and a spectral gap. It is natural to expect that in this situation there must exist some sort of a general perturbation theory for the ground and low-lying excited states, and in this report we establish certain results supporting this point of view.

This problem has been studied earlier for a variety of models. A possible approach here is to obtain the ground state as a zero temperature limit of temperature Gibbs states, which can be analyzed using Trotter-type (in particular, Feynman–Kac) formulas and cluster expansions; low-lying excitations can also be analyzed in this way.[1,3,6,17,18,20] In Refs. 7, 8 Kennedy and Tasaki used this method to develop a general perturbation theory for weak quantum perturbations of classical systems with a finite spin space.

There is, however, a more direct way to the ground states, suggested by Kirkwood and Thomas in Ref. 9. The key idea is to write a special ansatz for it and substitute into the Schrödinger equation. The resulting (Kirkwood–Thomas) equation can then be solved in a sense uniformly in the volume. These authors applied this technique to obtain infinite volume ground states and to establish short- or long-range order in certain spin-1/2 models.

The method was subsequently generalized to higher spins and used to prove the uniqueness of a translationally invariant ground state by Matsui in Refs. 13, 14. In Ref. 4, Datta and Kennedy simplified it and employed to find quasi-particle states. In particular, they showed that the Kirkwood–Thomas equation can be conveniently viewed as a fixed point equation for certain contraction mapping. Also see Ref. 5 for an application to interface states.

In this paper we give a further generalization of the method. While in the previous applications it was assumed that the Hilbert space of the model is realized as a functional space and the ground state as a Gibbs measure, we show that this is not necessary and the method works in the general C^*-algebraic framework (though a significant role in the proofs is played by a commutative subalgebra).

We give now the precise statements.

We consider a quantum spin system on the lattice $\mathbb{Z}^\nu$. Suppose that for each $x \in \mathbb{Z}^\nu$ there is a Hilbert space $\mathcal{H}_x$ (generally infinite-dimensional) assigned to this site. The Hilbert space of the model confined to a finite volume $\Lambda \subset \mathbb{Z}^\nu$ is then

$$\mathcal{H}_\Lambda := \otimes_{x \in \Lambda} \mathcal{H}_x .$$

a)Electronic mail: yarotsky@mail.ru

In $\mathcal{H}_\Lambda$ we consider a Hamiltonian H_Λ, having the form

$$H_\Lambda = H_{\Lambda,0} + \Phi_\Lambda .$$

Here $H_{\Lambda,0}$ is a free Hamiltonian:

$$H_{\Lambda,0} = \sum_{x \in \Lambda} h_x .$$

We assume that each h_x is a non-negative self-adjoint, generally unbounded operator on $\mathcal{H}_x$ with a nondegenerate ground state $\Omega_x \in \mathcal{H}_x$:

$$h_x \Omega_x = 0,$$

and a uniform in an x spectral gap:

$$h_x|_{\mathcal{H}_x \ominus \Omega_x} \geqslant \mathbf{1}. \tag{1}$$

In order to introduce the perturbation Φ_Λ we fix a finite subset $\Lambda_0 \subset \mathbb{Z}^\nu$ and set

$$\Phi_\Lambda = \sum_{x \in \mathbb{Z}^\nu : \Lambda_0 + x \subset \Lambda} \phi_x . \tag{2}$$

Here $\Lambda_0 + x$ is a shift of Λ_0 and ϕ_x a self-adjoint bounded operator on $\mathcal{H}_{\Lambda_0 + x}$. Since Φ_Λ is bounded, H_Λ is self-adjoint and $\mathrm{Dom}\,(H_\Lambda) = \mathrm{Dom}\,(H_{\Lambda,0})$. We will assume that $\sup_{x \in \mathbb{Z}^\nu} \|\phi_x\|$ is finite and small enough.

The first theorem shows the existence of the finite volume ground states and gives a spectral localization estimate.

Theorem 1: *There exists a constant $c_1 = c_1(\Lambda_0) > 0$ such that if $\sup_x \|\phi_x\| < c_1$ then for any finite Λ the Hamiltonian H_Λ has a nondegenerate ground state Ω_Λ:*

$$H_\Lambda \Omega_\Lambda = E_\Lambda \Omega_\Lambda , \quad H_\Lambda|_{\mathcal{H}_\Lambda \ominus \Omega_\Lambda} > E_\Lambda \mathbf{1}.$$

Moreover, denote

$$\tilde{H}_\Lambda := H_\Lambda - E_\Lambda \mathbf{1}.$$

There exists a constant $c_2 = c_2(\Lambda_0)$ such that

$$\mathrm{Sp}(\tilde{H}_\Lambda) \subset \bigcup_{a \in \mathrm{Sp}(H_{\Lambda,0})} \{z : |z - a| \leqslant c_2 \sup_x \|\phi_x\| a\}. \tag{3}$$

In particular, this gives a lower bound on the spectral gap:

$$\tilde{H}_\Lambda|_{\mathcal{H}_\Lambda \ominus \Omega_\Lambda} \geqslant (1 - c_2 \sup_x \|\phi_x\|)\mathbf{1}. \tag{4}$$

The second result concerns the thermodynamic limit of the ground states. Let $\mathcal{B}(\mathcal{H}_\Lambda)$ be the algebra of bounded operators in $\mathcal{H}_\Lambda$ for any finite Λ, and

$$\mathcal{A}_\infty := \bigcup_{\Lambda \subset \mathbb{Z}^\nu, |\Lambda| < \infty} \mathcal{B}(\mathcal{H}_\Lambda)$$

the full local algebra. Define the ground states found above as states on $\mathcal{B}(\mathcal{H}_\Lambda)$ (i.e., normalized positive linear functionals):

$$\omega_\Lambda(A) := (A\Omega_\Lambda, \Omega_\Lambda), \quad A \in \mathcal{B}(\mathcal{H}_\Lambda),$$

where Ω_Λ is assumed normalized. Let $\Lambda \nearrow \mathbb{Z}^\nu$ mean that Λ converges to $\mathbb{Z}^\nu$ in the sense that it eventually contains any finite subset.

Theorem 2: *There exists the thermodynamic limit of the finite volume ground states as a state ω_∞ on the quasi-local algebra $\overline{\mathcal{A}_\infty}$, in the sense that for any $A \in \mathcal{A}_\infty$ one has*

$$\omega_\Lambda(A) \overset{\Lambda \nearrow \mathbb{Z}^\nu}{\to} \omega_\infty(A).$$

Finally we consider the thermodynamic limit of the Hamiltonian. Let $(\mathcal{H}_\infty, \pi_\infty, \Omega_\infty)$ be the cyclic representation of $\overline{\mathcal{A}_\infty}$, associated with the state ω_∞:

$$(\pi_\infty(A)\Omega_\infty, \Omega_\infty)_{\mathcal{H}_\infty} = \omega_\infty(A).$$

Theorem 3: *There exists a self-adjoint operator H_∞ on $\mathcal{H}_\infty$, which is the weak resolvent limit of $\tilde{H}_\Lambda$ in the following sense: for any $A, B \in \mathcal{A}_\infty$ and $z \in \mathbb{C}\backslash\mathbb{R}$,*

$$((\tilde{H}_\Lambda - z)^{-1} A\Omega_\Lambda, B\Omega_\Lambda) \overset{\Lambda \nearrow \mathbb{Z}^\nu}{\to} ((H_\infty - z)^{-1}\pi_\infty(A)\Omega_\infty, \pi_\infty(B)\Omega_\infty).$$

Moreover, $H_\infty\Omega_\infty = 0$ and estimates (3),(4) hold with $\tilde{H}_\Lambda, \mathcal{H}_\Lambda, \Omega_\Lambda$ replaced by $H_\infty, \mathcal{H}_\infty, \Omega_\infty$, and $\mathrm{Sp}(H_{\Lambda,0})$ replaced by

$$\mathrm{Sp}(H_{\infty,0}) := \left\{ \sum_{x \in \mathbb{Z}^\nu} a_x \,\middle|\, a_x \in \mathrm{Sp}(h_x), a_x \neq 0 \ \textit{only for finitely many } x \right\}.$$

We prove our main result, Theorem 1, in two steps: first we find the ground state (in some implicit form), and then prove the spectral estimate (3). In the first step we follow the procedure developed by Datta and Kennedy in Ref. 4. We rewrite the Kirkwood–Thomas equation as a fixed point equation for a certain mapping, which is proved to be a contraction on a properly defined set. We introduce, however, a different, more general ansatz for the ground state, which allows us to treat abstract Hamiltonians without referring to special functional realizations.

Our derivation of the spectral estimate (3) partly relies on ideas from the Malyshev–Minlos method of isolating invariant many-particle subspaces of cluster operators.[12] [We remark that if the model is translationally invariant and $\mathrm{Sp}(h_x)$ discrete, then $\mathrm{Sp}(H_{\infty,0})$ is also discrete and H_∞ is expected to have a particle structure. Some of the one-particle subspaces can then be obtained as the invariant subspaces corresponding to certain isolated components of the spectrum induced by the relation (3).[2,3,10,15,16,19,20]] But technically our treatment is different and more simple than in the original Malyshev–Minlos approach. Namely, we explicitly represent the renormalized Hamiltonian as a sum of an operator similar to the free Hamiltonian and a relatively bounded, in some special sense, perturbation. The conclusion about the spectrum then follows directly from resolvent expansions relevant for relatively bounded perturbations, like in the well-known Kato–Rellich and KLMN theorems.

A natural conjecture for the model considered in our report is the uniqueness of the infinite volume ground state. We plan to give a proof of this in a subsequent publication.

II. PROOF OF THEOREM 1

In this section we fix a finite volume Λ (throughout the paper all the proper subsets of $\mathbb{Z}^\nu$ will be finite); the dependence on Λ will be occasionally suppressed in the notation.

By the standard perturbation theory, H_Λ has a nondegenerate ground state if $\sup_x \|\phi_x\| < c$ with some constant c, depending on Λ. We will show that the constant can in fact be chosen independent of Λ, and the ground state can be found in the form of some multiplicative expression. First we introduce some notation. Let

$$\mathcal{H}'_x := \mathcal{H}_x \ominus \Omega_x$$

and

$$\mathcal{H}'_I := \otimes_{x\in I}\mathcal{H}'_x, \quad \Omega_{I,0} := \otimes_{x\in I}\Omega_x,$$

for any $\varnothing \neq I \subset \Lambda$. Throughout the paper by u_I, v_I, etc. we will always denote vectors from $\mathcal{H}'_I$.

It follows that

$$\mathcal{H}_\Lambda \ominus \Omega_{\Lambda,0} = \bigoplus_{\varnothing\neq I\subset\Lambda} \mathcal{H}'_I \otimes \Omega_{\Lambda\setminus I,0} \tag{5}$$

(with $\mathcal{H}'_\Lambda \otimes \Omega_{\varnothing,0} \equiv \mathcal{H}'_\Lambda$). Now let $\tilde{\Omega}_\Lambda$ be the ground state vector of H_Λ, normalized by the condition

$$(\tilde{\Omega}_\Lambda, \Omega_{\Lambda,0}) = 1.$$

Then there exists a unique collection of vectors $\{u_I \in \mathcal{H}'_I\}_{\varnothing\neq I\subset\Lambda}$ such that

$$\tilde{\Omega}_\Lambda = \Omega_{\Lambda,0} + \sum_{\varnothing\neq I\subset\Lambda} u_I \otimes \Omega_{\Lambda\setminus I,0}, \tag{6}$$

and finding $\tilde{\Omega}_\Lambda$ is reduced to finding this collection. It is more natural, however, to search for the corresponding truncated objects, rather than u_I themselves. Namely, for any collection $\{u_I \in \mathcal{H}'_I\}_{\varnothing\neq I\subset\Lambda}$ we can define another collection $\{v_I \in \mathcal{H}'_I\}_{\varnothing\neq I\subset\Lambda}$ by

$$u_I = \sum_{\{I_1,\ldots,I_k\}\in\mathcal{P}(I)} \otimes_{l=1}^{k} v_{I_l}, \quad \forall I \subset \Lambda, I \neq \varnothing, \tag{7}$$

where $\mathcal{P}(I)$ is the set of all partitions of I into disjoint nonempty subsets. Such a collection exists and is uniquely determined by the inverse relation

$$v_I = \sum_{\{I_1,\ldots,I_k\}\in\mathcal{P}(I)} (-1)^{k-1}(k-1)! \otimes_{l=1}^{k} u_{I_l}. \tag{8}$$

The perturbed ground state $\tilde{\Omega}_\Lambda$ can be obtained from $\Omega_{\Lambda,0}$ by a "dressing transformation," connected with the above decompositions. For any $v_I \in \mathcal{H}'_I$, define the one-dimensional "creation operator" $\hat{v}_I \in \mathcal{B}(\mathcal{H}_I)$ by

$$\hat{v}_I \Omega_{I,0} = v_I, \quad \hat{v}_I|_{\mathcal{H}_I \ominus \Omega_{I,0}} = 0. \tag{9}$$

These operators have some useful properties. First of all, they commute: for any u_I, v_J one has

$$[\hat{u}_I, \hat{v}_J] = 0. \tag{10}$$

Moreover,

$$\hat{u}_I \hat{v}_J = 0, \quad \text{if } I \cap J \neq \varnothing. \tag{11}$$

Finally,

$$\|\hat{v}_I\| = \|v_I\|. \tag{12}$$

Now it easily follows from (10), (11) that for any collection $\{v_I\}_{\varnothing\neq I\subset\Lambda}$,

$$\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}=\Omega_{\Lambda,0}+\sum_{\varnothing\neq I\subset\Lambda}\sum_{\{I_1,\dots,I_k\}\in\mathcal{P}(I)}(\otimes_{l=1}^{k}v_{I_l})\otimes\Omega_{\Lambda\setminus I,0}.$$

So we see that a collection $\{v_I\}_{\varnothing\neq I\subset\Lambda}$ is related to $\tilde{\Omega}_\Lambda$ by Eqs. (6), (7) if and only if

$$\tilde{\Omega}_\Lambda=\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}. \tag{13}$$

Since the decomposition (5) is invariant with respect to $H_{\Lambda,0}$, relations (7), (8) imply that the rhs of (13) lies in $\mathrm{Dom}(H_\Lambda)(=\mathrm{Dom}(H_{\Lambda,0}))$ if and only if $v_I\in\mathrm{Dom}(H_{I,0})$ for all I (where $H_{I,0}=\Sigma_{x\in I}h_x$).

We will find $\tilde{\Omega}_\Lambda$ in the form (13). Precisely, let us fix any $\lambda>1$. We will show that there exists a constant $c_1=c_1(\lambda,\Lambda_0)>0$ such that if $\sup_x\|\phi_x\|<c_1$ then $\tilde{\Omega}_\Lambda$ has the form (13) with

$$\max_{x\in\Lambda}\sum_{I\subset\Lambda:x\in I}\|H_{I,0}v_I\|\lambda^{d_I+1}\leqslant 1, \tag{14}$$

where d_I is the minimal length of a connected graph containing I.

To this end we substitute the ansatz (13) into the Schrödinger equation,

$$H_\Lambda\tilde{\Omega}_\Lambda=E_\Lambda\tilde{\Omega}_\Lambda, \tag{15}$$

and find

$$\exp\left(-\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)H_\Lambda\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}=E_\Lambda\Omega_{\Lambda,0}. \tag{16}$$

Recall that $H_\Lambda=H_{\Lambda,0}+\Phi_\Lambda$. A simple computation shows that for any $x\in\Lambda$,

$$\begin{aligned}h_x\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}&=\sum_{I\subset\Lambda:x\in I}\sum_{J\subset\Lambda\setminus I}\sum_{\{I_1,\dots,I_k\}\in\mathcal{P}(J)}(h_xv_I)\otimes(\otimes_l v_{I_l})\otimes\Omega_{\Lambda\setminus(I\sqcup J)}\\&=\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\sum_{\varnothing\neq I\subset\Lambda}h_x\hat{v}_I\Omega_{\Lambda,0}\end{aligned}$$

(by $\sqcup$ we denote a disjoint union). Therefore

$$\exp\left(-\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)H_{\Lambda,0}\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}=H_{\Lambda,0}\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\Omega_{\Lambda,0}=\sum_{\varnothing\neq I\subset\Lambda}\widehat{H_{I,0}v_I}\Omega_{\Lambda,0},$$

and Eq. (16) becomes

$$\sum_{\varnothing\neq I\subset\Lambda}\widehat{H_{I,0}v_I}\Omega_{\Lambda,0}+\exp\left(-\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Phi_\Lambda\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat{v}_I\right)\Omega_{\Lambda,0}=E_\Lambda\Omega_{\Lambda,0}. \tag{17}$$

Now, let $P_I:\mathcal{H}_\Lambda\to\mathcal{H}'_I$ be the operator, defined for each $I\subset\Lambda$ by

$$u=\sum_{I\subset\Lambda}(P_Iu)\otimes\Omega_{\Lambda\setminus I,0},\quad\forall u\in\mathcal{H}_\Lambda$$

(where $\mathcal{H}'_\varnothing\equiv\mathbb{C}$). Let T be the map on the linear space of collections $\{v_I\}_{\varnothing\neq I\subset\Lambda}$, defined by

$$T(\{v_I\}_{\varnothing\neq I\subset\Lambda}):=\{u_I\}_{\varnothing\neq I\subset\Lambda}, \tag{18}$$

where

$$u_I := -(H_{I,0}|_{\mathcal{H}_I'})^{-1} P_I \exp\Big(-\sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big) \Phi_\Lambda \exp\Big(\sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big) \Omega_{\Lambda,0}. \tag{19}$$

The inverse $(H_{I,0}|_{\mathcal{H}_I'})^{-1}$ is well-defined, since the spectral gap condition (1) implies

$$H_{I,0}|_{\mathcal{H}_I'} \geqslant |I| \mathbf{1}. \tag{20}$$

We see now that Eq. (17) is equivalent to the fixed point (Kirkwood–Thomas) equation,

$$T(\{v_I\}_{\varnothing \neq I \subset \Lambda}) = \{v_I\}_{\varnothing \neq I \subset \Lambda}, \tag{21}$$

on the space of collections [the eigenvalue E_Λ has been eliminated; it can be found by substituting the solution of (21) onto the lhs of (17) and taking the scalar product with $\Omega_{\Lambda,0}$]. Consider the Banach space $\mathcal{K}_\lambda$ of collections $\{v_I \in \mathcal{H}_I' \cap \mathrm{Dom}\,(H_{I,0})\}_{\varnothing \neq I \subset \Lambda}$, equipped with the norm

$$\|\{v_I\}_{\varnothing \neq I \subset \Lambda}\|_\lambda := \max_{x \in \Lambda} \sum_{I \subset \Lambda : x \in I} \|H_{I,0} v_I\| \lambda^{d_I + 1}. \tag{22}$$

We will show that T is a contraction in the unit ball in this space and hence has there a unique fixed point.

Let us first estimate $\|T(\{u_I\}) - T(\{v_I\})\|_\lambda$ for any two collections $\{u_I\}, \{v_I\} \in \mathcal{K}_\lambda$. We begin by expanding (19) using the identity

$$\exp\Big(-\sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big) \Phi_\Lambda \exp\Big(\sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big) = \sum_{k=0}^{\infty} \frac{1}{k!} \underbrace{\Big[\ldots\Big[}_{k} \Phi_\Lambda, \sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big], \ldots, \sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big] \tag{23}$$

(with the $k=0$ term equal to Φ_Λ). Let

$$T = \sum_{k=0}^{\infty} \frac{1}{k!} T^{(k)},$$

where $T^{(k)}$ is the contribution to T coming from the k-th term in (23). It follows that

$$\|T(\{u_I\}) - T(\{v_I\})\|_\lambda \leqslant \sum_{k=1}^{\infty} \frac{1}{k!} \|T^{(k)}(\{u_I\}) - T^{(k)}(\{v_I\})\|_\lambda \tag{24}$$

(because $T^{(0)}$ is a constant map). To estimate the k-th term in this sum we use (2) and write

$$\underbrace{\Big[\ldots\Big[}_{k} \Phi_\Lambda, \sum_{\varnothing \neq I \subset \Lambda} \hat{u}_I\Big], \ldots, \sum_{\varnothing \neq I \subset \Lambda} \hat{u}_I\Big] - \underbrace{\Big[\ldots\Big[}_{k} \Phi_\Lambda, \sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big], \ldots, \sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I\Big]$$

$$= \sum_{l=1}^{k} \sum_{y : \Lambda_0^+ y \in \Lambda} \sum_{\varnothing \neq I_1, \ldots, I_k \subset \Lambda} [\ldots[[[\ldots[\phi_y, \hat{u}_{I_1}], \ldots, \hat{u}_{I_{l-1}}], \hat{u}_{I_l} - \hat{v}_{I_l}], \hat{v}_{I_{l+1}}], \ldots, \hat{v}_{I_k}]. \tag{25}$$

So we see that

$$T^{(k)}(\{u_I\}) - T^{(k)}(\{v_I\}) = \sum_{l=1}^{k} T_l^{(k)}(\{u_I\}, \{v_I\}), \tag{26}$$

where $T_l^{(k)}$ is the contribution to $T^{(k)}(\{u_I\})-T^{(k)}(\{v_I\})$ from the lth term in (25), i.e., for $l=1$,

$$T_1^{(k)}(\{u_I\}_{\varnothing\neq I\subset\Lambda},\{v_I\}_{\varnothing\neq I\subset\Lambda})=\{w_I\}_{\varnothing\neq I\subset\Lambda},$$

where

$$w_I=-(H_{I,0}|_{\mathcal{H}_I'})^{-1}P_I\sum_{y:\Lambda_0+y\in\Lambda}\ \sum_{\varnothing\neq I_1,\ldots,I_k\subset\Lambda}[\ldots[[\phi_y,\hat{u}_{I_1}-\hat{v}_{I_1}],\hat{v}_{I_2}],\ldots,\hat{v}_{I_k}]\Omega_{\Lambda,0},$$

etc. We will consider the $l=1$ term first. By (22),

$$\|T_1^{(k)}(\{u_I\},\{v_I\})\|_\lambda=\max_{x\in\Lambda}\sum_{I\subset\Lambda:x\in I}\left\|\sum_{y:\Lambda_0+y\in\Lambda}\ \sum_{\varnothing\neq I_1,\ldots,I_k\subset\Lambda}P_I[\ldots[[\phi_y,\hat{u}_{I_1}-\hat{v}_{I_1}],\hat{v}_{I_2}],\ldots,\hat{v}_{I_k}]\Omega_{\Lambda,0}\right\|\lambda^{d_I+1}. \tag{27}$$

Now we make some observations concerning

$$P_I[\ldots[[\phi_y,\hat{u}_{I_1}-\hat{v}_{I_1}],\hat{v}_{I_2}],\ldots,\hat{v}_{I_k}]\Omega_{\Lambda,0}. \tag{28}$$

Expanding the commutators, we see that the norm of this expression does not exceed

$$2^k\sup_z\|\phi_z\|\|u_{I_1}-v_{I_1}\|\prod_{s=2}^{k}\|v_{I_s}\|, \tag{29}$$

because of (12). Next, note that (28) can be nonzero only if

$$I_s\cap(\Lambda_0+y)\neq\varnothing,\quad \forall s=1,\ldots,k \tag{30}$$

and

$$I=\bigsqcup_{s=1}^{k}(I_s\backslash(\Lambda_0+y))\sqcup J,\ \text{with some}\ J\subset\Lambda_0+y. \tag{31}$$

Indeed, since $\hat{u}_{I_1}-\hat{v}_{I_1},\hat{v}_{I_2},\ldots,\hat{v}_{I_k}$ commute with each other, (28) can be nonzero only if $[\phi_y,\hat{u}_{I_1}-\hat{v}_{I_1}]\neq 0$ and $[\phi_y,\hat{v}_{I_s}]\neq 0$ for all $s=2,\ldots,k$, which implies (30). To see (31), note that after expanding the commutators in (28) we get 2^k terms of the form

$$P_I\hat{w}_{I_{\sigma(1)}}\cdots\hat{w}_{I_{\sigma(t)}}\phi_y\hat{w}_{I_{\sigma(t+1)}}\ldots\hat{w}_{I_{\sigma(k)}}\Omega_{\Lambda,0}, \tag{32}$$

where

$$w_{I_s}:=\begin{cases}u_{I_1}-v_{I_1}, & \text{for } s=1,\\ v_{I_s}, & \text{else,}\end{cases}$$

and σ is a permutation. If (28) is nonzero, then at least one of the terms (32) is nonzero. For this term, by (11) $I_{\sigma(1)},\ldots,I_{\sigma(t)}$ do not overlap and also $I_{\sigma(t+1)},\ldots,I_{\sigma(k)}$ do not overlap, so that it has the form

$$P_I\hat{w}^{(1)}_{I^{(1)}}\phi_y\hat{w}^{(2)}_{I^{(2)}}\Omega_{\Lambda,0}, \tag{33}$$

where $I^{(1)}=\sqcup_{s=1}^{t} I_{\sigma(s)}, I^{(2)}=\sqcup_{s=t+1}^{k} I_{\sigma(s)}$ and $w^{(1)}_{I^{(1)}}=\otimes_{s=1}^{t} w_{I_{\sigma(s)}}, w^{(2)}_{I^{(2)}}=\otimes_{s=t+1}^{k} w_{I_{\sigma(s)}}$. As $\phi_y \in \mathcal{B}(\mathcal{H}_{\Lambda_0+y})$,

$$\phi_y \hat{w}^{(2)}_{I^{(2)}} \Omega_{\Lambda,0} = \sum_{K \subset \Lambda_0+y} \hat{w}^{(3)}_{K \sqcup (I^{(2)} \setminus (\Lambda_0+y))} \Omega_{\Lambda,0},$$

with some vectors $w^{(3)}_{K\sqcup(I^{(2)}\setminus(\Lambda_0+y))} \in \mathcal{H}'_{K\sqcup(I^{(2)}\setminus(\Lambda_0+y))}$. It follows that (33) can be nonzero only if $I^{(1)} \cap (I^{(2)} \setminus (\Lambda_0+y))=\varnothing$ and $I=I^{(1)} \sqcup (I^{(2)} \setminus (\Lambda_0+y)) \sqcup K$ with some $K \subset \Lambda_0+y, K \cap I^{(1)}=\varnothing$, in which case (33) equals

$$w^{(1)}_{I^{(1)}} \otimes w^{(3)}_{K\sqcup(I^{(2)}\setminus(\Lambda_0+y))}.$$

In particular, this implies (31).

Now, for any given $y, I_1, \ldots, I_k$ there exist at most $2^{|\Lambda_0|}$ sets I obeying (31). Further, (30) implies the inequality

$$d_I \leqslant d_{(\cup_{s=1}^{k} I_s) \cup (\Lambda_0+y)} \leqslant \sum_{s=1}^{k} d_{I_s} + d_{\Lambda_0}, \tag{34}$$

which in turn implies

$$\lambda^{d_I+1} \leqslant \lambda^{d_{\Lambda_0}-k+1} \prod_{s=1}^{k} \lambda^{d_{I_s}+1} \leqslant \lambda^{d_{\Lambda_0}} \prod_{s=1}^{k} \lambda^{d_{I_s}+1}.$$

It follows from these observations and the bound (29) that (27) does not exceed

$$\max_{x \in \Lambda} \sum^{(x)} \|u_{I_1} - v_{I_1}\| \lambda^{d_{I_1}+1} \left(\prod_{s=2}^{k} \|v_{I_s}\| \lambda^{d_{I_s}+1} \right) \lambda^{d_{\Lambda_0}} 2^k 2^{|\Lambda_0|} \sup_z \|\phi_z\|, \tag{35}$$

where $\Sigma^{(x)}$ is the sum over all those $y, I_1, \ldots, I_k$, for which $I_s \cap (\Lambda_0+y) \neq \varnothing, s=1,\ldots,k$, and $x \in (\cup_{s=1}^{k} I_s) \cup (\Lambda_0+y)$. We will estimate (35) by rearranging summation in it. Since $x \in (\cup_{s=1}^{k} I_s) \cup (\Lambda_0+y)$, and because $I_2, \ldots, I_k$ enter into (35) symmetrically, we have

$$\sum^{(x)} \leqslant \sum_1^{(x)} + \sum_2^{(x)} + (k-1) \sum_3^{(x)},$$

where

$$\sum_1^{(x)} := \sum_{y:\Lambda_0+y \ni x} \sum_{z_1,\ldots,z_k \in \Lambda_0+y} \sum_{I_s \ni z_s, s=1,\ldots,k},$$

$$\sum_2^{(x)} := \sum_{I_1 \ni x} \sum_{y:(\Lambda_0+y)\cap I_1 \neq \varnothing} \sum_{z_2,\ldots,z_k \in \Lambda_0+y} \sum_{I_s \ni z_s, s=2,\ldots,k},$$

$$\sum_3^{(x)} := \sum_{I_2 \ni x} \sum_{y:(\Lambda_0+y)\cap I_2 \neq \varnothing} \sum_{z_1,z_3,\ldots,z_k \in \Lambda_0+y} \sum_{I_s \ni z_s, s=1,3,\ldots,k}.$$

First we estimate the $\Sigma_1^{(x)}$ term. Since y and each of z_s can be chosen in at most $|\Lambda_0|$ ways, this term does not exceed

$$|\Lambda_0|^{k+1}\left(\max_{z_1}\sum_{I_1\ni z_1}\|u_{I_1}-v_{I_1}\|\lambda^{d_{I_1}+1}\right)\left(\prod_{s=2}^{k}\max_{z_s}\sum_{I_1\ni z_s}\|v_{I_s}\|\lambda^{d_{I_s}+1}\right)\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_z\|\phi_z\|. \quad (36)$$

Recall that for any I and w_I,

$$\|H_{I,0}w_I\|\geqslant|I|\|w_I\|, \quad (37)$$

by (20). It follows then by the definition of the norm (22) that

$$(36)\leqslant|\Lambda_0|^{k+1}\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_z\|\phi_z\|\|\{u_I-v_I\}\|_\lambda\|\{v_I\}\|_\lambda^{k-1}.$$

The $\Sigma_2^{(x)}$ term does not exceed

$$|I_1||\Lambda_0|^k\left(\max_{x}\sum_{I_1\ni x}\|u_{I_1}-v_{I_1}\|\lambda^{d_{I_1}+1}\right)\left(\prod_{s=2}^{k}\max_{z_s}\sum_{I_1\ni z_s}\|v_{I_s}\|\lambda^{d_{I_s}+1}\right)\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_z\|\phi_z\|, \quad (38)$$

because y can be chosen in at most $|I_1||\Lambda_0|$ ways, while each of z_s can be chosen then in at most $|\Lambda_0|$ ways. Again, by (37) and the definition of the norm, (38) is not greater than

$$|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_z\|\phi_z\|\|\{u_I-v_I\}\|_\lambda\|\{v_I\}\|_\lambda^{k-1}. \quad (39)$$

Similarly, the $\Sigma_3^{(x)}$ term can be bounded by (39) too. We conclude that

$$\|T_1^{(k)}(\{u_I\},\{v_I\})\|_\lambda\leqslant(k+|\Lambda_0|)|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_x\|\phi_x\|\|\{u_I-v_I\}\|_\lambda\|\{v_I\}\|_\lambda^{k-1}. \quad (40)$$

If $l=2,\ldots,k$, we have a similar bound for $T_l^{(k)}$ with $\|\{v_I\}\|_\lambda^{k-1}$ replaced by $\|\{u_I\}\|_\lambda^{l-1}\|\{v_I\}\|_\lambda^{k-l}$ in (40). Finally, if $\|\{v_I\}\|_\lambda\leqslant1$ and $\|\{u_I\}\|_\lambda\leqslant1$, then by (24),(26),

$$\|T(\{u_I\})-T(\{v_I\})\|_\lambda\leqslant\sum_{k=1}^{\infty}\frac{1}{k!}k(k+|\Lambda_0|)|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_x\|\phi_x\|\|\{u_I-v_I\}\|_\lambda. \quad (41)$$

So we see that if $\sup_x\|\phi_x\|\leqslant c_1'$, where

$$c_1'=\frac{1}{2}\left(\sum_{k=1}^{\infty}\frac{1}{(k-1)!}(k+|\Lambda_0|)|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\right)^{-1}, \quad (42)$$

then

$$\|T(\{u_I\})-T(\{v_I\})\|_\lambda\leqslant\tfrac{1}{2}\|\{u_I-v_I\}\|_\lambda,$$

for any two collections $\{u_I\},\{v_I\}$ from the unit ball.

Now we estimate $\|T(\{v_I\})\|_\lambda$. Consider the zero collection $\{0\}$ and note that $T^{(k)}(\{0\})=0$ for $k\geqslant1$; hence

$$\|T(\{0\})\|_\lambda=\|T^{(0)}(\{0\})\|_\lambda=\max_x\sum_{I\ni x}\left\|\sum_{y:\Lambda_0+y\ni x}P_I\phi_y\Omega_{\Lambda,0}\right\|\lambda^{d_I+1}\leqslant|\Lambda_0|2^{|\Lambda_0|}\lambda^{d_{\Lambda_0}+1}\sup_x\|\phi_x\|.$$

In particular, if $\sup_x\|\phi_x\|\leqslant c_1''\coloneqq(|\Lambda_0|2^{|\Lambda_0|}\lambda^{d_{\Lambda_0}+1})^{-1}/2$, then $\|T(\{0\})\|_\lambda\leqslant1/2$. It follows that if $\sup_x\|\phi_x\|\leqslant c_1\coloneqq\min(c_1',c_1'')$; then for any $\{v_I\}$ from the unit ball we have

$$\|T(\{v_I\})\|_\lambda\leqslant\|T(\{v_I\})-T(\{0\})\|_\lambda+\|T(\{0\})\|_\lambda\leqslant1/2+1/2=1.$$

So we see that if $\sup_x \|\phi_x\| \leqslant c_1$, then T is a contraction in the unit ball in $\mathcal{K}_\lambda$, and hence the Kirkwood–Thomas equation (21) there has a unique solution, which we will denote by $\{v_I^{(gs)}\}_{\varnothing \neq I \subset \Lambda}$. It obeys condition (14) and the vector

$$\tilde{\Omega}_\Lambda = \exp\left(\sum_{\varnothing \neq I \subset \Lambda} \hat{v}_I^{(gs)} \right) \Omega_{\Lambda,0}$$

is a solution of the Schrödinger equation (15) with some E_Λ. However, we have not proved yet that this $\tilde{\Omega}_\Lambda$ is the ground state and that it is non-degenerate. This will be seen from the spectral analysis of H_Λ given below.

Note first that any $u \in \mathcal{H}_\Lambda$ can be uniquely expanded as

$$u = \sum_{I \subset \Lambda} \hat{u}_I \tilde{\Omega}_\Lambda ,$$

with some $u_I \in \mathcal{H}_I'$ (where $\hat{u}_\varnothing$ is a multiple of **1**). Indeed, by the commutativity of the creation operators this relation is equivalent to

$$\exp\left(- \sum_{\varnothing \neq K \subset \Lambda} \hat{v}_K^{(gs)} \right) u = \sum_{I \subset \Lambda} \hat{u}_I \Omega_{\Lambda,0} ,$$

i.e.,

$$u_I = P_I \exp\left(- \sum_{\varnothing \neq K \subset \Lambda} \hat{v}_K^{(gs)} \right) u . \tag{43}$$

It is easy to check that $u \in \mathrm{Dom}\,(H_\Lambda)$ iff $u_I \in \mathrm{Dom}\,(H_{I,0})$ for all I.

Now recall that we defined $\tilde{H}_\Lambda = H_\Lambda - E_\Lambda \mathbf{1}$, so that $\tilde{H}_\Lambda \tilde{\Omega}_\Lambda = 0$. Below we will decompose $\tilde{H}_\Lambda$ into the sum

$$\tilde{H}_\Lambda = \tilde{H}_{\Lambda,0} + \tilde{\Phi}_\Lambda ; \tag{44}$$

$\tilde{H}_{\Lambda,0}$ will be a ''simple'' operator and $\tilde{\Phi}_\Lambda$ will be ''small'' with respect to $\tilde{H}_{\Lambda,0}$; both will have $\tilde{\Omega}_\Lambda$ as a zero eigenvector.

To this end take some $I \subset \Lambda$ and $u_I \in \mathcal{H}_I' \cap \mathrm{Dom}\,(H_{I,0})$. First we note that

$$H_{\Lambda,0} \hat{u}_I \tilde{\Omega}_\Lambda = \hat{u}_I H_{\Lambda,0} \tilde{\Omega}_\Lambda + \widehat{H_{I,0} u_I} \tilde{\Omega}_\Lambda .$$

Indeed, if $H_{\Lambda,0}$ is bounded, this formula follows because

$$\widehat{H_{I,0} u_I} = [H_{\Lambda,0}, \hat{u}_I];$$

for an unbounded $H_{\Lambda,0}$ one can justify it by a direct calculation. Then

$$\tilde{H}_\Lambda \hat{u}_I \tilde{\Omega}_\Lambda = \hat{u}_I \tilde{H}_\Lambda \tilde{\Omega}_\Lambda + \widehat{H_{I,0} u_I} \tilde{\Omega}_\Lambda + [\Phi_\Lambda, \hat{u}_I] \tilde{\Omega}_\Lambda = \widehat{H_{I,0} u_I} \tilde{\Omega}_\Lambda + [\Phi_\Lambda, \hat{u}_I] \tilde{\Omega}_\Lambda .$$

So we can define the operators $\tilde{H}_{\Lambda,0}, \tilde{\Phi}_\Lambda$ on $\mathrm{Dom}\,(\tilde{H}_{\Lambda,0}) := \mathrm{Dom}\,(H_{\Lambda,0})$ and $\mathrm{Dom}\,(\tilde{\Phi}_\Lambda) := \mathcal{H}_\Lambda$ by

$$\tilde{H}_{\Lambda,0} \hat{u}_I \tilde{\Omega}_\Lambda := \widehat{H_{I,0} u_I} \tilde{\Omega}_\Lambda , \quad \tilde{\Phi}_\Lambda \hat{u}_I \tilde{\Omega}_\Lambda := [\Phi_\Lambda, \hat{u}_I] \tilde{\Omega}_\Lambda , \tag{45}$$

and by linearity. We will rewrite $\tilde{\Phi}_\Lambda$ in a more convenient form using creation operators. Namely, for all $I, J \subset \Lambda$ and $u_I \in \mathcal{H}_I'$, define $(F_\Lambda u_I)_J \in \mathcal{H}_J'$ by

$$\tilde{\Phi}_\Lambda \hat{u}_I \tilde{\Omega}_\Lambda = \sum_{J\subset\Lambda} \widehat{(F_\Lambda u_I)_J} \tilde{\Omega}_\Lambda . \tag{46}$$

Applying (43), we find

$$\begin{aligned}(F_\Lambda u_I)_J &= P_J \exp\left(-\sum_{\varnothing\neq K\subset\Lambda} \hat{v}_K^{(gs)}\right)[\Phi_\Lambda,\hat{u}_I]\exp\left(\sum_{\varnothing\neq K\subset\Lambda} \hat{v}_K^{(gs)}\right)\Omega_{\Lambda,0}\\ &= P_J \sum_{s=0}^{\infty} \frac{1}{s!}\Bigg[\underbrace{\dots\Bigg[}_{s}[\Phi_\Lambda,\hat{u}_I],\sum_{\varnothing\neq K\subset\Lambda}\hat{v}_K^{(gs)}\Bigg],\dots,\sum_{\varnothing\neq K\subset\Lambda}\hat{v}_K^{(gs)}\Bigg]\Omega_{\Lambda,0}. \end{aligned}\tag{47}$$

Let us estimate $\Sigma_J\|(F_\Lambda u_I)_J\|$. Recall that

$$P_J[\dots[[\phi_y,\hat{u}_I],\hat{v}_{K_1}^{(gs)}],\dots,\hat{v}_{K_s}^{(gs)}]\Omega_{\Lambda,0}, \tag{48}$$

can be nonzero only if $(\Lambda_0+y)\cap I\neq\varnothing$ and $(\Lambda_0+y)\cap K_t\neq\varnothing$ for all $t=1,\dots,s$. Moreover, for $y,K_1,\dots,K_s$ fixed there are at most $2^{|\Lambda_0|}$ different sets J, for which (48) can be nonzero. Using also the fact that the norm of (48) is not greater than $2^{s+1}\|\phi_y\|\|u_I\|\Pi_{t=1}^s\|v_{K_t}^{(gs)}\|$, we find that

$$\begin{aligned}\sum_{J\subset\Lambda}\|(F_\Lambda u_I)_J\| &\leqslant \|u_I\|\sup_x\|\phi_x\|\\ &\times\sum_{s=0}^{\infty}\frac{2^{s+1+|\Lambda_0|}}{s!}\sum_{y:(\Lambda_0+y)\cap I\neq\varnothing}\ \sum_{y_1,\dots,y_s\in\Lambda_0+y}\ \sum_{K_t\ni y_t,t=1,\dots,s}\ \prod_{t=1}^{s}\|v_{K_t}^{(gs)}\|.\end{aligned}$$

Recall that $\|\{v_I^{(gs)}\}\|_\lambda\leqslant 1$ and hence $\max_x\Sigma_{K\ni x}\|v_K^{(gs)}\|\leqslant 1$. It follows that

$$\sum_{J\subset\Lambda}\|(F_\Lambda u_I)_J\|\leqslant\|u_I\|\sup_x\|\phi_x\||I|\sum_{s=0}^{\infty}\frac{2^{s+1+|\Lambda_0|}}{s!}|\Lambda_0|^{s+1}.$$

So if we set

$$c_2=\sum_{s=0}^{\infty}\frac{2^{s+1+|\Lambda_0|}}{s!}|\Lambda_0|^{s+1},$$

then

$$\sum_{J\subset\Lambda}\|(F_\Lambda u_I)_J\|\leqslant c_2\sup_x\|\phi_x\|\|H_{I,0}u_I\|. \tag{49}$$

By assumption and (42), $\sup_x\|\phi_x\|<c_1'<1/c_2$, so the inequality (49) indicates a sort of ''relative boundedness'' of $\tilde{\Phi}_\Lambda$ wrt $\tilde{H}_{\Lambda,0}$. Our spectral estimate (3) will follow from this inequality. Let us introduce a new norm $\|\cdot\|_1$ (equivalent to the usual norm) in $\mathcal{H}_\Lambda$ by

$$\left\|\sum_{I\subset\Lambda}\hat{u}_I\tilde{\Omega}_\Lambda\right\|_1 := \sum_{I\subset\Lambda}\|u_I\|.$$

Then for any $z\notin \mathrm{Sp}\,(H_{\Lambda,0})$,

$$\|\tilde{\Phi}_\Lambda(\tilde{H}_{\Lambda,0}-z)^{-1}\|_1=\max_{I\subset\Lambda}\sup_{\|u_I\|=1}\sum_{J\subset\Lambda}\|(F_\Lambda(H_{I,0}-z)^{-1}u_I)_J\|$$

$$\leqslant\max_{I\subset\Lambda}\sup_{\|u_I\|=1}c_2\sup_x\|\phi_x\|\|H_{I,0}(H_{I,0}-z)^{-1}u_I\|=\sup_{a\in\,\mathrm{Sp}\,(H_{\Lambda,0})}\frac{c_2\sup_x\|\phi_x\|a}{|z-a|}.$$

Let

$$f(a):=\frac{c_2\sup_x\|\phi_x\|a}{|z-a|},$$

and suppose now that

$$z\in\mathcal{O}_\Lambda:=\bigcap_{a\in\,\mathrm{Sp}\,(H_{\Lambda,0})}\{z\in\mathbb{C}:|z-a|>c_2\sup_x\|\phi_x\|a\}. \tag{50}$$

Then $f(a)<1$ for all $a\in\mathrm{Sp}\,(H_{\Lambda,0})$. Clearly f is continuous on the closed set $\mathrm{Sp}\,(H_{\Lambda,0})$, and $\lim_{a\to+\infty}f(a)=c_2\sup_x\|\phi_x\|<1$. It follows that $\sup_{a\in\,\mathrm{Sp}\,(H_{\Lambda,0})}f(a)<1$ and therefore

$$\|\tilde{\Phi}_\Lambda(\tilde{H}_{\Lambda,0}-z)^{-1}\|_1<1. \tag{51}$$

Let

$$S_{\Lambda,N}(z):=(\tilde{H}_{\Lambda,0}-z)^{-1}\sum_{k=0}^{N}(-\tilde{\Phi}_\Lambda(\tilde{H}_{\Lambda,0}-z)^{-1})^k.$$

Then by (51),

$$S_{\Lambda,N}(z)\overset{N\to\infty}{\to}S_\Lambda(z):=(\tilde{H}_{\Lambda,0}-z)^{-1}\sum_{k=0}^{\infty}(-\tilde{\Phi}_\Lambda(\tilde{H}_{\Lambda,0}-z)^{-1})^k,$$

with a bounded $S_\Lambda(z)$. Moreover,

$$(\tilde{H}_\Lambda-z)S_{\Lambda,N}(z)=(\tilde{H}_{\Lambda,0}-z+\tilde{\Phi}_\Lambda)S_{\Lambda,N}(z)=\mathbf{1}+(-1)^N(\tilde{\Phi}_\Lambda(\tilde{H}_{\Lambda,0}-z)^{-1})^{N+1}\overset{N\to\infty}{\to}\mathbf{1}.$$

The closedness of $\tilde{H}_\Lambda$ thus implies $(\tilde{H}_\Lambda-z)S_\Lambda(z)=\mathbf{1}$. Since $\tilde{H}_\Lambda$ is self-adjoint, this means that $\tilde{H}_\Lambda-z$ is invertible for $z\in\mathcal{O}_\Lambda$, which proves the spectral estimate (3).

Now to finish the proof of Theorem 1 it remains to show that $\tilde{\Omega}_\Lambda$ is a nondegenerate ground state of $\tilde{H}_\Lambda$. It follows from (3) that $\tilde{H}_\Lambda\geqslant 0$, so $\tilde{\Omega}_\Lambda$ is a ground state. The nondegeneracy can be deduced by a continuity argument. Consider the family of operators $H_\Lambda^{(\delta)}=H_{\Lambda,0}+\delta\Phi_\Lambda$ parametrized by $\delta\in[0,1]$. If $\tilde{H}_\Lambda^{(\delta)}=H_\Lambda^{(\delta)}-E_\Lambda^{(\delta)}$ are the corresponding renormalized operators, they all obey the common spectral estimate (3) and hence 0 is an isolated eigenvalue for all of them. By the continuity of the resolvents $(H_\Lambda^{(\delta)}-z)^{-1}$ in δ it follows then that the multiplicity of 0 is constant in δ, i.e., identically equals 1.

III. PROOF OF THEOREM 2

In the previous section we showed that if $\sup_x\|\phi_x\|<c_1$, then for any finite Λ the ground state of H_Λ can be found by solving the Kirkwood–Thomas equation $T_\Lambda(\{v_I\}_{\varnothing\neq I\subset\Lambda})=\{v_I\}_{\varnothing\neq I\subset\Lambda}$, where T_Λ is the map (18)–(19) on the Banach space $\mathcal{K}_{\lambda,\Lambda}$ of collections $\{v_I\in\mathcal{H}_I'\cap\mathrm{Dom}\,(H_{I,0})\}_{\varnothing\neq I\subset\Lambda}$, equipped with the norm (22). This map is a contraction in the unit ball in $\mathcal{K}_{\lambda,\Lambda}$ and has a unique fixed point $\{v_I^{(\Lambda,gs)}\}_{\varnothing\neq I\subset\Lambda}$ there.

In fact, one can consider the Kirkwood–Thomas equation for an arbitrary, not necessarily finite, subset of $\mathbb{Z}^\nu$, and in particular for $\mathbb{Z}^\nu$ itself. Namely, let $\mathcal{K}_{\lambda,\infty}$ be the Banach space of collections $\{v_I \in \mathcal{H}_I' \cap \mathrm{Dom}\,(H_{I,0})\}_{\varnothing \neq I \subset \mathbb{Z}^\nu}$ with I running over the finite subsets of $\mathbb{Z}^\nu$. The norm is defined as in (22), but with $\sup_{x\in\mathbb{Z}^\nu}$ instead of $\max_{x\in\Lambda}$ and with summation extended to all finite $I \ni x$. The map T_∞ can be defined by

$$T_\infty(\{v_I\}_{\varnothing\neq I\subset\mathbb{Z}^\nu}) := \left\{ \lim_{\Lambda \nearrow \mathbb{Z}^\nu} u_I^{(\Lambda)} \right\}_{\varnothing\neq I\subset\mathbb{Z}^\nu},$$

where

$$\{u_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda} := T_\Lambda(\{v_I\}_{\varnothing\neq I\subset\Lambda}).$$

Alternatively, one can define T_∞ directly, using the commutator expansion (23) with the summation extended to all finite subsets. Conditions (30), (31) and uniform bounds derived in the previous section ensure that T_∞ is well-defined and is a contraction in the unit ball of $\mathcal{K}_{\lambda,\infty}$. The corresponding Kirkwood–Thomas equation $T_\infty(\{v_I\}_{\varnothing\neq I\subset\mathbb{Z}^\nu}) = \{v_I\}_{\varnothing\neq I\subset\mathbb{Z}^\nu}$ then has there a unique solution, which we will denote by $\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\mathbb{Z}^\nu}$. We begin by proving that the finite volume solutions converge to this infinite volume solution.

Lemma 1: Let $\tilde{d}_{I;\Lambda^c}$ be the minimal length of a connected graph containing I and at least one point of $\Lambda^c := \mathbb{Z}^\nu \setminus \Lambda$. There exists $\tilde{c} = \tilde{c}(\lambda, \Lambda_0) > 0$ such that if $\sup_x \|\phi_x\| < \tilde{c}$ then for any finite Λ,

$$\max_{x\in\Lambda} \sum_{I\subset\Lambda : I\ni x} \|H_{I,0}(v_I^{(\Lambda,gs)} - v_I^{(\infty,gs)})\| \lambda^{\tilde{d}_{I;\Lambda^c}+1} \leqslant 1.$$

In particular, for any I,

$$v_I^{(\Lambda,gs)} \overset{\Lambda\nearrow\mathbb{Z}^\nu}{\longrightarrow} v_I^{(\infty,gs)}.$$

Proof: Let $\Delta v_I^{(\Lambda)} := v_I^{(\Lambda,gs)} - v_I^{(\infty,gs)}$ for $\varnothing \neq I \subset \Lambda$. Then the collection $\{\Delta v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda}$ satisfies the fixed point equation,

$$\{\Delta v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda} = T_{\Lambda;\Lambda^c}(\{\Delta v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda}), \tag{52}$$

where the map $T_{\Lambda;\Lambda^c}$ on $\mathcal{K}_{\lambda,\Lambda}$ is defined by

$$T_{\Lambda;\Lambda^c}(\{v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda}) := T_\Lambda(\{v_I^{(\infty,gs)} + v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda}) - \{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\Lambda}. \tag{53}$$

Let us introduce a new norm $\|\cdot\|_{\lambda,\Lambda;\Lambda^c}$ in $\mathcal{K}_{\lambda,\Lambda}$ by

$$\|\{v_I\}_{\varnothing\neq I\subset\Lambda}\|_{\lambda,\Lambda;\Lambda^c} := \max_{x\in\Lambda} \sum_{I\subset\Lambda : I\ni x} \|H_{I,0} v_I\| \lambda^{\tilde{d}_{I;\Lambda^c}+1}.$$

This new norm is clearly equivalent to the old norm $\|\cdot\|_{\lambda,\Lambda}$, defined by (22). We will prove that $T_{\Lambda;\Lambda^c}$ is a contraction in the unit ball in $\mathcal{K}_{\lambda,\Lambda}$ wrt this new norm, if $\sup_x \|\phi_x\| < \tilde{c}$ with some $\tilde{c} = \tilde{c}(\lambda, \Lambda_0)$ (there is no loss of generality in this assumption, since c_1 in the hypothesis of Theorem 1 can be taken smaller).

Indeed, for any two collections $\{u_I\}, \{v_I\} \in \mathcal{K}_{\lambda,\Lambda}$ by (53) we have

$$\|T_{\Lambda;\Lambda^c}(\{u_I\}) - T_{\Lambda;\Lambda^c}(\{v_I\})\|_{\lambda,\Lambda;\Lambda^c} = \|T_\Lambda(\{v_I^{(\infty,gs)} + u_I\}_{\varnothing\neq I\subset\Lambda}) - T_\Lambda(\{v_I^{(\infty,gs)} + v_I\}_{\varnothing\neq I\subset\Lambda})\|_{\lambda,\Lambda;\Lambda^c}.$$

We can estimate this norm in the same way as we estimated $\|T_\Lambda(\{u_I\})-T_\Lambda(\{v_I\})\|_{\lambda,\Lambda}$ in the previous section; the only difference is the factor $\lambda^{\tilde{d}_{I;\Lambda^c}+1}$ instead of λ^{d_I+1} in the definition of the norm. So instead of (34) we use the inequality

$$\tilde{d}_{I;\Lambda^c}\leqslant\tilde{d}_{(\cup_{s=1}^k I_s)\cup(\Lambda_0+y);\Lambda^c}\leqslant\tilde{d}_{I_l;\Lambda^c}+\sum_{s\neq l} d_{I_s}+d_{\Lambda_0}.$$

As a result we arrive at the following analog of (41):

$$\|T_{\Lambda;\Lambda^c}(\{u_I\})-T_{\Lambda;\Lambda^c}(\{v_I\})\|_{\lambda,\Lambda;\Lambda^c}\leqslant\sum_{k=1}^{\infty}\frac{k+|\Lambda_0|}{(k-1)!}|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_x\|\phi_x\|\|\{u_I-v_I\}\|_{\lambda,\Lambda;\Lambda^c}$$
$$\times(\max(\|\{v_I^{(\infty,gs)}+u_I\}\|_{\lambda,\Lambda},\|\{v_I^{(\infty,gs)}+v_I\}\|_{\lambda,\Lambda}))^{k-1}. \quad (54)$$

Suppose that $\|\{u_I\}\|_{\lambda,\Lambda;\Lambda^c}\leqslant 1$ and $\|\{v_I\}\|_{\lambda,\Lambda;\Lambda^c}\leqslant 1$. From the inequalities $\|\cdot\|_{\lambda,\Lambda}\leqslant\|\cdot\|_{\lambda,\Lambda;\Lambda^c}$ and $\|\{v_I^{(\infty,gs)}\}\|_{\lambda,\Lambda}\leqslant 1$ we see that $\max(\cdots)\leqslant 2$ in (54). It follows that if $\sup_x\|\phi_x\|<\tilde{c}$, where

$$\tilde{c}=\frac{1}{2}\left(\sum_{k=1}^{\infty}\frac{k+|\Lambda_0|}{(k-1)!}|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{2k-1+|\Lambda_0|}\right)^{-1},$$

then

$$\|T_{\Lambda;\Lambda^c}(\{u_I\})-T_{\Lambda;\Lambda^c}(\{v_I\})\|_{\lambda,\Lambda;\Lambda^c}\leqslant\tfrac{1}{2}\|\{u_I-v_I\}\|_{\lambda,\Lambda;\Lambda^c}.$$

Now let us estimate $\|T_{\Lambda;\Lambda^c}(\{0\})\|_{\lambda,\Lambda;\Lambda^c}$, which equals

$$\|T_\Lambda(\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\Lambda})-\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\Lambda}\|_{\lambda,\Lambda;\Lambda^c}. \quad (55)$$

Recall that $\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\mathbb{Z}^\nu}=T_\infty(\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\mathbb{Z}^\nu})$; so the norm (55) can be estimated by expanding $T_\infty(\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\mathbb{Z}^\nu})$ and $T_\Lambda(\{v_I^{(\infty,gs)}\}_{\varnothing\neq I\subset\Lambda})$ into commutator series in $P_I[\cdots[\phi_x,\hat{v}_{I_1}^{(\infty,gs)}],\ldots,\hat{v}_{I_k}^{(\infty,gs)}]\Omega_{\Lambda,0}$ and comparing the resulting terms. Clearly, the expansion for T_∞ contains that for T_Λ; the extra terms are those for which $I_t\not\subset\Lambda$ for some t. For such I_t we have $\tilde{d}_{I_t;\Lambda^c}=d_{I_t}$ and hence we can write

$$\tilde{d}_{I;\Lambda^c}\leqslant\sum_{s=1}^{k} d_{I_s}+d_{\Lambda_0},$$

instead of (34). Repeating again the estimates of the previous section, we find

$$\|T_{\Lambda;\Lambda^c}(\{0\})\|_{\lambda,\Lambda;\Lambda^c}\leqslant\sum_{k=1}^{\infty}\frac{k+|\Lambda_0|}{(k-1)!}|\Lambda_0|^k\lambda^{d_{\Lambda_0}}2^{k+|\Lambda_0|}\sup_x\|\phi_x\|,$$

which is less than 1/2 if $\sup_x\|\phi_x\|<\tilde{c}$.

Hence $T_{\Lambda;\Lambda^c}$ is a contraction in the $\|\cdot\|_{\lambda,\Lambda;\Lambda^c}$-unit ball and Eq. (52) has a unique solution there. It only remains to check that this solution is the same as $\{\Delta v_I^{(\Lambda)}\}_{\varnothing\neq I\subset\Lambda}$. This again follows by a continuity argument. Consider, as before, the family $H_\Lambda^{(\delta)}=H_{\Lambda,0}+\delta\Phi_\Lambda$, $\delta\in[0,1]$. As is easy to see, both $\{\Delta v_I^{(\delta,\Lambda)}\}_{\varnothing\neq I\subset\Lambda}$ and the above-mentioned solution continuously depend on δ; since they are equal for $\delta=0$, they are equal for all δ. □

The remaining part of the proof is quite analogous to the standard cluster expansion for Gibbs fields and our exposition will be sketchy.

Let A act on $\mathcal{H}_\Lambda$; then, by definition,

$$\omega_\Lambda(A)=\frac{(A\tilde\Omega_\Lambda,\tilde\Omega_\Lambda)}{\|\tilde\Omega_\Lambda\|^2}.$$

First consider the "partition function" $Z_\Lambda:=\|\tilde\Omega_\Lambda\|^2$. We have

$$Z_\Lambda=\left\|\exp\left(\sum_{\varnothing\neq I\subset\Lambda}\hat v_I^{(\Lambda,gs)}\right)\Omega_{\Lambda,0}\right\|^2=1+\sum_{\varnothing\neq I\subset\Lambda}\left\|\sum_{\{I_1,\dots,I_k\}\in\mathcal{P}(I)}\otimes_{s=1}^k v_{I_s}^{(\Lambda,gs)}\right\|^2.$$

For any $\Lambda_1\subset\Lambda$, set

$$Z_{\Lambda_1}^{(\Lambda)}:=1+\sum_{\varnothing\neq I\subset\Lambda_1}\left\|\sum_{\{I_1,\dots,I_k\}\in\mathcal{P}(I)}\otimes_{s=1}^k v_{I_s}^{(\Lambda,gs)}\right\|^2.$$

In particular $Z_\Lambda^{(\Lambda)}=Z_\Lambda, Z_\varnothing^{(\Lambda)}=1$. Then for any nonempty $\Lambda_1\subset\Lambda$ and any $x\in\Lambda_1$,

$$Z_{\Lambda_1}^{(\Lambda)}=Z_{\Lambda_1\setminus\{x\}}^{(\Lambda)}+\sum_{\Lambda_2\subset\Lambda_1:\Lambda_2\ni x}K_{\Lambda_2}^{(\Lambda)}Z_{\Lambda_1\setminus\Lambda_2}^{(\Lambda)},\tag{56}$$

where

$$K_{\Lambda_2}^{(\Lambda)}:=\sum_{\substack{\{I_1,\dots,I_k\},\{J_1,\dots,J_l\}\in\mathcal{P}(\Lambda_2):\\ \{I_1,\dots,I_k,J_1,\dots,J_l\}\text{conn.}}}(\otimes_{s=1}^k v_{I_s}^{(\Lambda,gs)},\otimes_{t=1}^l v_{J_t}^{(\Lambda,gs)}),\tag{57}$$

and summation in the last formula is over *connected* double partitions of Λ_2, i.e., such that the collection $\{I_1,\dots,I_k,J_1,\dots,J_l\}$ cannot be decomposed into two non-empty subcollections, whose unions do not overlap. Now suppose that A acts on $\mathcal{H}_{\Lambda_1}$ and $\varnothing\neq\Lambda_1\subset\Lambda$. Then

$$\omega_\Lambda(A)=\sum_{\Lambda_2\subset\Lambda\setminus\Lambda_1}M_{A,\Lambda_1,\Lambda_2}^{(\Lambda)}\frac{Z_{\Lambda\setminus(\Lambda_1\sqcup\Lambda_2)}^{(\Lambda)}}{Z_\Lambda},\tag{58}$$

where

$$M_{A,\Lambda_1,\Lambda_2}^{(\Lambda)}:=\sum_{\Lambda_3,\Lambda_4\subset\Lambda_1}\sum_{\substack{\{I_1,\dots,I_k\}\in\mathcal{P}(\Lambda_2\sqcup\Lambda_3),\\ \{J_1,\dots,J_l\}\in\mathcal{P}(\Lambda_2\sqcup\Lambda_4):\\ \{I_1,\dots,I_k,J_1,\dots,J_l,\Lambda_1\}\text{conn.}}}(A\otimes_{s=1}^k v_{I_s}^{(\Lambda,gs)},\otimes_{t=1}^l v_{J_t}^{(\Lambda,gs)}).$$

Lemma 2 (cluster estimates): If $\lambda\geqslant 2$ *and* $\sup_x\|\phi_x\|<c_1(\lambda,\Lambda_0)$, *then for any* $x\in\Lambda$,

$$\sum_{\Lambda_1\ni x}|K_{\Lambda_1}^{(\Lambda)}|\lambda^{d_{\Lambda_1}+1}\leqslant 1,\tag{59}$$

and for any $\varnothing\neq\Lambda_1\subset\Lambda$ *and* $A\in\mathcal{B}(\mathcal{H}_{\Lambda_1})$,

$$\sum_{\Lambda_2\subset\Lambda\setminus\Lambda_1}|M_{A,\Lambda_1,\Lambda_2}^{(\Lambda)}|\lambda^{d_{\Lambda_1\sqcup\Lambda_2}}\leqslant c_{\Lambda_1}\|A\|,\tag{60}$$

with some constant c_{Λ_1}.

Proof: We will prove (59); (60) is analogous. All the connected double partitions of finite sets containing x can be uniquely generated by a successive choice of I's and J's as follows. For any

nonempty $I\subset\mathbb{Z}^\nu$ fix some $x(I)\in I$. Choose $I_1\ni x$. Then proceed by induction. Suppose we have already chosen a connected family $\{I_1,\ldots,I_k,J_1,\ldots,J_l\}$ such that the I's are mutually disjoint, and the J's are mutually disjoint. Set

$$\Lambda^{(k+l)}:=[(\sqcup_{n=1}^k I_n)\setminus(\sqcup_{n=1}^l J_n)]\sqcup[(\sqcup_{n=1}^l J_n)\setminus(\sqcup_{n=1}^k I_n)]$$

and consider two possibilities.

(1) $\Lambda^{(k+l)}=\varnothing$. Then the family $\{I_1,\ldots,I_k,J_1,\ldots,J_l\}$ forms a connected double partition of some set containing x.

(2) $\Lambda^{(k+l)}\neq\varnothing$. Then consider $x(\Lambda^{(k+l)})$. If $x(\Lambda^{(k+l)})\in(\sqcup_{n=1}^k I_n)\setminus(\sqcup_{n=1}^l J_n)$; then choose J_{l+1} such that $J_{l+1}\ni x(\Lambda^{(k+l)})$ and $J_{l+1}\cap(\sqcup_{n=1}^l J_n)=\varnothing$. Otherwise, if $x(\Lambda^{(k+l)})\in(\sqcup_{n=1}^l J_n)\setminus(\sqcup_{n=1}^k I_n)$, choose I_{k+1} such that $I_{k+1}\ni x(\Lambda^{(k+l)})$ and $I_{k+1}\cap(\sqcup_{n=1}^k I_n)=\varnothing$. Then repeat the inductive step.

Clearly, all the connected double partitions of finite sets containing x can be obtained in this way. Now we bound the scalar product in (57) by $\Pi_{s=1}^k\|v_{I_s}^{(\Lambda,gs)}\|\Pi_{t=1}^l\|v_{J_t}^{(\Lambda,gs)}\|$. If $\{I_1,\ldots,I_k,J_1,\ldots,J_l\}$ is a connected double partition of Λ_1, then $d_{\Lambda_1}\leqslant\Sigma_{s=1}^k d_{I_s}+\Sigma_{t=1}^l d_{J_t}$. It follows that

$$\sum_{\Lambda_1\ni x}|K_{\Lambda_1}^{(\Lambda)}|\lambda^{d_{\Lambda_1}+1}\leqslant\lambda\sum_{n=2}^{\infty}\left(\max_y\sum_{I\ni y}\|v_I^{(\Lambda,gs)}\|\lambda^{d_I}\right)^n$$

(n is the number of elements in a double partition). Using the bound (14) and the inequality $\lambda\geqslant 2$, we find

$$\sum_{\Lambda_1\ni x}|K_{\Lambda_1}^{(\Lambda)}|\lambda^{d_{\Lambda_1}+1}\leqslant\lambda\sum_{n=2}^{\infty}\lambda^{-n}=\frac{1}{\lambda-1}\leqslant 1.$$

□

The desired convergence of $\omega_\Lambda(A)$ follows now for sufficiently large λ from the expansions (56), (58), cluster estimates and Lemma 1 by standard arguments.[11]

IV. PROOF OF THEOREM 3

We introduce the commutative subalgebras $\mathcal{U}_\Lambda,\mathcal{U}_\infty$, generated by the creation operators:

$$\mathcal{U}_\Lambda:=\left\{\sum_{I\subset\Lambda}\hat{u}_I\,\middle|\,u_I\in\mathcal{H}_I'\right\},\quad|\Lambda|<\infty,$$

$$\mathcal{U}_\infty:=\bigcup_{|\Lambda|<\infty}\mathcal{U}_\Lambda.$$

Note that if $A\in\mathcal{U}_\Lambda$, then $\|A\|=\|A\Omega_{\Lambda,0}\|$.

Lemma 3: (a) If $A\in\mathcal{U}_\infty$ and $A\neq 0$, then $\pi_\infty(A)\Omega_\infty\neq 0$.

(b) The set $\pi_\infty(\mathcal{U}_\infty)\Omega_\infty$ is dense in $\mathcal{H}_\infty$.

Proof: (a) Let $A\in\mathcal{U}_\Lambda$; then for any $\Lambda_1\supset\Lambda$ by the commutativity

$$\|A\Omega_{\Lambda_1}\|=\frac{\|A\tilde{\Omega}_{\Lambda_1}\|}{\|\tilde{\Omega}_{\Lambda_1}\|}=\frac{\left\|\exp\left(\sum_{\substack{I\subset\Lambda_1:\\ I\cap\Lambda\neq\varnothing}}\hat{v}_I^{(\Lambda_1,gs)}\right)A\exp\left(\sum_{\substack{I\subset\Lambda_1\setminus\Lambda:\\ I\neq\varnothing}}\hat{v}_I^{(\Lambda_1,gs)}\right)\Omega_{\Lambda_1,0}\right\|}{\left\|\exp\left(\sum_{\substack{I\subset\Lambda_1:\\ I\cap\Lambda\neq\varnothing}}\hat{v}_I^{(\Lambda_1,gs)}\right)\exp\left(\sum_{\substack{I\subset\Lambda_1\setminus\Lambda:\\ I\neq\varnothing}}\hat{v}_I^{(\Lambda_1,gs)}\right)\Omega_{\Lambda_1,0}\right\|}.\tag{61}$$

It follows from the bound (14) that

$$\left\| \exp\left(\pm \sum_{\substack{I\subset\Lambda_1:\\ I\cap\Lambda\neq\varnothing}} \hat{v}_I^{(\Lambda_1,gs)} \right) \right\| \leqslant \exp\left(|\Lambda| \sup_x \sum_{I\ni x} \|v_I^{(\Lambda_1,gs)}\| \right) \leqslant e^{|\Lambda|},$$

and hence

$$(61) \geqslant e^{-2|\Lambda|} \frac{\left\| A \exp\left(\sum_{\substack{I\subset\Lambda_1\setminus\Lambda:\\ I\neq\varnothing}} \hat{v}_I^{(\Lambda_1,gs)} \right) \Omega_{\Lambda_1,0} \right\|}{\left\| \exp\left(\sum_{\substack{I\subset\Lambda_1\setminus\Lambda:\\ I\neq\varnothing}} \hat{v}_I^{(\Lambda_1,gs)} \right) \Omega_{\Lambda_1,0} \right\|} = e^{-2|\Lambda|} \|A\Omega_{\Lambda,0}\| = e^{-2|\Lambda|} \|A\|.$$

Taking the limit $\Lambda_1 \nearrow \mathbb{Z}^\nu$, we find

$$\|\pi_\infty(A)\Omega_\infty\|^2 = \omega_\infty(A^*A) = \lim_{\Lambda_1\nearrow\mathbb{Z}^\nu} \omega_{\Lambda_1}(A^*A) = \lim_{\Lambda_1\nearrow\mathbb{Z}^\nu} \|A\Omega_{\Lambda_1}\|^2 \geqslant e^{-4|\Lambda|}\|A\|^2.$$

(b) Let $A \in \mathcal{A}_\Lambda$, then $A\Omega_\Lambda = \Sigma_{I\subset\Lambda} \hat{u}_I^{(\Lambda)} \Omega_\Lambda$, where

$$u_I^{(\Lambda)} = P_I^{(\Lambda)} \exp\left(- \sum_{\varnothing\neq I\subset\Lambda} \hat{v}_I^{(\Lambda,gs)} \right) A \exp\left(\sum_{\varnothing\neq I\subset\Lambda} \hat{v}_I^{(\Lambda,gs)} \right) \Omega_{\Lambda,0}$$

[see (43)]. Fix A and let $\Lambda \nearrow \mathbb{Z}^\nu$; expanding the rhs and using Lemma 1, one finds that there exist limits,

$$u_I^{(\infty)} := \lim_{\Lambda\nearrow\mathbb{Z}^\nu} u_I^{(\Lambda)},$$

and then, using Theorem 2,

$$A\Omega_\infty = \sum_{I\subset\mathbb{Z}^\nu} \hat{u}_I^{(\infty)} \Omega_\infty,$$

with an absolutely convergent series on the rhs. In particular, it follows that $\pi_\infty(\mathcal{U}_\infty)\Omega_\infty$ is dense in $\mathcal{A}_\infty\Omega_\infty$ and hence in $\mathcal{H}_\infty$. □

Recall that for the renormalized Hamiltonian $\tilde{H}_\Lambda$ in a finite volume Λ we had the decomposition $\tilde{H}_\Lambda = \tilde{H}_{\Lambda,0} + \tilde{\Phi}_\Lambda$, where $\mathrm{Dom}(\tilde{H}_\Lambda) = \{\Sigma_{I\subset\Lambda} \hat{u}_I \Omega_\Lambda | u_I \in \mathcal{H}_I' \cap \mathrm{Dom}(H_{I,0})\}$, and on this domain,

$$\tilde{H}_{\Lambda,0}\left(\sum_{I\subset\Lambda} \hat{u}_I\Omega_\Lambda \right) = \sum_{I\subset\Lambda} \widehat{H_{I,0}u_I}\Omega_\Lambda,$$

$$\tilde{\Phi}_\Lambda\left(\sum_{I\subset\Lambda} \hat{u}_I\Omega_\Lambda \right) = \sum_{I\subset\Lambda} \sum_{J\subset\Lambda} \widehat{(F_\Lambda u_I)_J}\Omega_\Lambda$$

[see (44)–(47)]. Using the expansion (47) and Lemma 1, we find that there exist the limits

$$(F_\infty u_I)_J := \lim_{\Lambda\nearrow\mathbb{Z}^\nu} (F_\Lambda u_I)_J,$$

and, moreover,

$$\sum_{J\subset\mathbb{Z}^\nu} \|(F_\infty u_I)_J\| \leqslant c_2 \sup_x \|\phi_x\| \|H_{I,0}u_I\|, \tag{62}$$

as in (49).

Now we can define the limiting Hamiltonian H_∞. First we define it on the subspace $\mathcal{D}\subset\mathcal{H}_\infty$, consisting of vectors of the form $\pi_\infty(\Sigma_I \hat{u}_I)\Omega_\infty$, where the sum is finite and $u_I \in \mathcal{H}_I' \cap \mathrm{Dom}\,(H_{I,0})$ for all I; then we will take the closure. On the domain $\mathcal{D}$ we set

$$H_\infty|_{\mathcal{D}} := H_{\infty,0} + \Phi_\infty,$$

where

$$H_{\infty,0}\pi_\infty\left(\sum_I \hat{u}_I\right)\Omega_\infty := \pi_\infty\left(\sum_I \widehat{H_{I,0}u_I}\right)\Omega_\infty,$$

$$\Phi_\infty\pi_\infty\left(\sum_I \hat{u}_I\right)\Omega_\infty := \pi_\infty\left(\sum_I \sum_{J\subset\mathbb{Z}^\nu} (\widehat{F_\infty u_I})_J\right)\Omega_\infty.$$

Operator $H_\infty|_{\mathcal{D}}$ is well-defined by Lemma 3(a) and inequality (62). Using Theorem 2 and the symmetricity of the finite-volume Hamiltonians $\tilde{H}_\Lambda$, one deduces that $H_\infty|_{\mathcal{D}}$ is symmetric. Now let H_∞ be the closure of $H_\infty|_{\mathcal{D}}$. First we prove that it is self-adjoint. Let $z\in\mathcal{O}_\infty := \cap_\Lambda \mathcal{O}_\Lambda$, where $\mathcal{O}_\Lambda$ is defined in (50). Then for any $u\in\pi_\infty(\mathcal{U}_\infty)\Omega_\infty$, using inequality (62) and arguing as in the proof of Theorem 1, we see that one can form the series

$$S_{\mathbb{Z}^\nu}(z)u = (H_{\infty,0}-z)^{-1}\sum_{k=0}^{\infty}(-\Phi_\infty(H_{\infty,0}-z)^{-1})^k u, \tag{63}$$

defining an element of $\mathcal{H}_\infty$. The closedness of H_∞ then implies that $S_{\mathbb{Z}^\nu}(z)u\in\mathrm{Dom}\,(H_\infty)$ and $(H_\infty - z)S_{\mathbb{Z}^\nu}(z)u = u$. Since $\pi_\infty(\mathcal{U}_\infty)\Omega_\infty$ is dense in $\mathcal{H}_\infty$ by Lemma 3(b), it follows that $\mathrm{Ran}\,(H_\infty - z) = \mathcal{H}_\infty$ and hence H_∞ is self-adjoint with the series (63) being its resolvent for $u \in \pi_\infty(\mathcal{U}_\infty)\Omega_\infty$ and $z\in\mathcal{O}_\infty\cap(\mathbb{C}\backslash\mathbb{R})$. But the expression (63) is analytic in z in $\mathcal{O}_\infty$ and hence the spectral measure for such u is supported on $\mathbb{R}\backslash\mathcal{O}_\infty$ (this follows, e.g., from Stone's resolvent formula for spectral projectors). By the density of such u's, we conclude that $\mathrm{Sp}\,(H_\infty)\subset\mathbb{R}\backslash\mathcal{O}_\infty$, which is the desired spectral localization estimate.

Now suppose that $A\in\mathcal{U}_\infty$ and $z\in\mathcal{O}_\infty$. Then for any Λ large enough, expressing the resolvent via $S_\Lambda(z)$ and using the expansions for $S_\Lambda, \tilde{\Phi}_\Lambda$, we can find $A_\Lambda\in\mathcal{U}_\Lambda$ such that $(\tilde{H}_\Lambda - z)^{-1}A\Omega_\Lambda = A_\Lambda\Omega_\Lambda$. Since the expansion for $\tilde{\Phi}_\Lambda$ converges to that for Φ_∞, there exists $A_\infty = \lim_{\Lambda\nearrow\mathbb{Z}^\nu} A_\Lambda$, and $(H_\infty - z)^{-1}\pi_\infty(A)\Omega_\infty = \pi_\infty(A_\infty)\Omega_\infty$. It follows then by Theorem 2 that for any $B\in\mathcal{A}_\infty$,

$$((\tilde{H}_\Lambda - z)^{-1}A\Omega_\Lambda, B\Omega_\Lambda) = \omega_\Lambda(B^*A_\Lambda) \overset{\Lambda\nearrow\mathbb{Z}^\nu}{\longrightarrow} \omega_\infty(B^*A_\infty) = ((H_\infty - z)^{-1}\pi_\infty(A)\Omega_\infty, \pi_\infty(B)\Omega_\infty). \tag{64}$$

Since $\pi_\infty(\mathcal{U}_\infty)\Omega_\infty$ is dense in H_∞, this convergence extends to all $A\in\mathcal{A}_\infty$. Finally, the extension to $z\in\mathbb{C}\backslash\mathbb{R}$ follows by Vitali's theorem.

It only remains to show that 0 as an eigenvalue of H_∞ is nondegenerate. Since it is a nondegenerate eigenvalue of $\tilde{H}_\Lambda$ in any finite volume Λ, for any $A\in\mathcal{B}(\mathcal{H}_\Lambda)$ we have

$$(Q_\Lambda A\Omega_\Lambda, A\Omega_\Lambda) = |(A\Omega_\Lambda, \Omega_\Lambda)|^2, \tag{65}$$

where Q_Λ is the projector onto $\mathrm{Ker}\,(\tilde{H}_\Lambda)$ in $\mathcal{H}_\Lambda$. Let γ be a contour in $\mathcal{O}_\infty$, surrounding 0; then by the Cauchy formula $Q_\Lambda = -(2\pi i)^{-1}\int_\gamma(\tilde{H}_\Lambda - z)^{-1}\,dz$ we can use (64) to take the limit $\Lambda\nearrow\mathbb{Z}^\nu$ in (65) and write

$$(Q_\infty\pi_\infty(A)\Omega_\infty, \pi_\infty(A)\Omega_\infty) = |(\pi_\infty(A)\Omega_\infty, \Omega_\infty)|^2,$$

where Q_∞ is the projector onto Ker (H_∞) in $\mathcal{H}_\infty$. Hence, Ker (H_∞) contains only multiples of Ω_∞.

ACKNOWLEDGMENTS

I would like to thank Robert Minlos for his constant support and encouragement and Serguey Pirogov for many helpful discussions. The work was supported by RFBR Grant No. 02-01-00404.

published online 6 May 2004)

Working within the HPO (History Projection Operator) Consistent Histories formalism, we follow the work of Savvidou on (scalar) field theory [J. Math. Phys. **43**, 3053 (2002)] and that of Savvidou and Anastopoulos on (first-class) constrained systems [Class. Quantum Gravt. **17**, 2463 (2000)] to write a histories theory (both classical and quantum) of Electromagnetism. We focus particularly on the foliation-dependence of the histories phase space/Hilbert space and the action thereon of the two Poincaré groups that arise in histories field theory. We quantize in the spirit of the Dirac scheme for constrained systems. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1723702]

I. INTRODUCTION

Our aim in this paper is to demonstrate the application of certain ideas and techniques that have been developed within the HPO (History Projection Operator) histories formalism over recent years to the theory of Electromagnetism. Specifically, we follow up on two pieces of work which are naturally combined therein:

Field theory. In Ref. 1, Savvidou describes the histories theory of the (classical and quantum) scalar field. This has the important feature that there exist two distinct Poincaré groups. The ''internal'' group is simply the histories analog of that of the standard theory, but there also exists an ''external'' group that explicitly performs changes of the foliation. This is important as it provides a way of relating quantities that are defined with respect to different foliations. These groups arise as a consequence of one of the most powerful and interesting features of histories theories, namely that there exist two distinct types of time transformation each of which represents a distinct *quality* of time: (a) the internal time (''time of becoming''), which is related to the dynamics of the particular system in question, and (b) the external time (''time of being''), which is related to the causal ordering of events, i.e., the kinematics. (For a detailed exposition of the HPO continuous time histories program, the reader is referred to Ref. 2.)

Constrained systems. In Ref. 3, Savvidou and Anastopoulos describe an algorithm for working with systems with first-class constraints within the HPO formalism. They focused specifically on parametrized systems, i.e., those systems whose Hamiltonian is itself a first-class constraint, as a natural precursor to understanding ''histories'' general relativity, and demonstrated that the histories on the reduced phase space *retained* their intrinsic temporal ordering. The quantization algorithm is in the spirit of the Dirac scheme for constrained systems. (For progress with this enterprise, see Refs. 4–6.)

The theory of Electromagnetism, as a field theory with first-class constraints, thus perfectly combines the above pieces of work, but also brings something new to each when studied within the histories framework. In the first instance we shall see explicitly how the histories phase space and reduced phase space depend on the foliation and discuss the importance of the external boost in this respect. Second, we will have to deal with the fact (not tackled in detail in Ref. 3) that our constraints have continuous spectra, and thus the physical Hilbert space cannot be a true linear subspace of the full (unconstrained) Hilbert space.

The outline of the paper is as follows: in Sec. II we give a brief account of those aspects of the

a)Electronic mail: aidan.burch@ic.ac.uk

Histories program most relevant to our needs, and then we present the histories theory of Electromagnetism, starting with the classical theory in Sec. III, and then its quantization in Sec. IV. We conclude in Sec. V.

Finally we note that the classical history theory of vector fields has been studied by Noltingk[7] as well as their BRST quantization,[8] though he follows a fundamentally different approach which centers on defining five component vector fields to incorporate the two times.

II. THE HISTORIES PROGRAM

The consistent histories version of quantum mechanics was originally developed in the 1980s by Griffiths[9] and then built on (each with different emphases) by Omnès[10] and then Gell-Mann and Hartle[11] and Hartle.[12] The main aim (particularly of the latter) was to develop a quantum mechanics of closed systems.

As formulated by Gell-Mann and Hartle, a history, α, is represented by a class operator, C_α, that is a product of Heisenberg picture projection operators. Dynamic information is contained in the decoherence functional, defined on a pair of histories as

$$d(\alpha,\beta)=\mathrm{tr}(C_\alpha^\dagger \rho_0 C_\beta), \tag{2.1}$$

where ρ_0 is the density matrix describing the initial state of the system. If a history is part of a ''consistent'' set, then probabilities (in the usual Kolmogorov sense) may be assigned to the individual histories according to $p(\alpha)=d(\alpha,\alpha)$.

The HPO formalism was developed initially by Isham[13] and Isham and Linden[14] who sought a histories version of single-time quantum logic. To this end they re-defined the class operator as a *tensor* product of *Schrödinger* picture operators, so it would be a genuine projection operator on some suitable ''history'' Hilbert space. This formalism was extended to the case of continuous time histories by Isham and co-workers,[15,16] in which the ''history group''—analogous to the usual Heisenberg–Weyl group—was introduced. However, this structure lacked any clear notion of time evolution. It was only with Savvidou's introduction of the action operator—the quantum analog of the classical Hamilton–Jacobi action functional—that the temporal structure of histories theory was established in the form as it is used now (see Ref. 17). It is these two—the history group and action operator—that are the key elements of any history theory.

A. The history group

By introducing the history group, a HPO theory may be seen as seeking a suitable representation of a certain algebra, e.g., for a (nonrelativistic) particle moving on the real line (see Ref. 2) and a continuous time label, $t\in\mathbb{R}$, the (nonzero) commutation relation is ($\hbar=1$)

$$[x_t,p_{t'}]=i\delta(t-t'). \tag{2.2}$$

This algebra is isomorphic to that of a field theory in one spatial dimension, and field-theoretic techniques are usefully employed to find a suitable representation. Following Araki,[18] the proper representation of this algebra is selected by requiring that the Hamiltonian exist as a self-adjoint operator, and it will come as no surprise that a Fock representation provides the necessary ''history'' Hilbert space.

In histories quantum scalar field theory (see Ref. 1), after foliating Minkowski space with a unit timelike vector, n_μ, we have

$$[\phi(X),\pi(X')]=i\delta^4(X-X'), \tag{2.3}$$

where we are using a ''pseudo-covariant'' notation $X=n\cdot t+x_n$ (x_n is a four vector such that $n\cdot x_n=0$). [We use the metric signature $(+,-,-,-)$.] A representation of this algebra is found in terms of creation and annihilation, $b^\dagger(X)$ and $b(X)$, on the (history) Fock space, $\mathcal{V}_{\mathrm{scalar}}=\exp(L^2(\mathbb{R}^4,d^4X))$. Indeed, it is found that all foliation dependent representations exist *on the same* Fock space.

B. The action operator

The other key element of a histories theory is the action operator, $S(\gamma)$ (see Ref. 17). It is this that is the generator of time transformations of a HPO theory, combining the Liouville operator, $V(\gamma)$, which generates time translations in the external (kinematical) time label, and the Hamiltonian, $H(\gamma)$, which generates time translations in the internal (dynamical) time label. For our nonrelativistic particle, the action would be written as

$$S(\gamma)=V(\gamma)-H(\gamma)=\int dt[p_t\dot{x}_t-H_t(p_t,x_t)](\gamma), \tag{2.4}$$

where H_t is a one parameter family of Hamiltonians.

In the field theory case, we have two Poincaré groups, with the Hamiltonian being the time translations generator of the internal group, and the Liouville being the time translations generator of the external group. The generators of the internal group are time-averaged versions of the generators of the standard group, but it is the external group that is the novel object, as the boost of this group generates *changes of the foliation* as well. Its action on the foliation-dependent scalar field is given by

$$^{\text{ext}}U(\Lambda)^n\phi(X)^{\text{ext}}U(\Lambda)^{-1}=^{\Lambda n}\phi(\Lambda^{-1}X) \tag{2.5}$$

[where $U(\Lambda)$ is the unitary operator that generates the Lorentz transformation] and thus we have a way of relating quantities defined with respect to different foliations.

Finally, we note, without going into great detail, that there is an analogous formalism for classical histories which we will use to write the classical history theory of EM below (see Chap. 5 of Ref. 2 for further details). This involves thinking of a history as a map from the real line into the classical phase space, Γ. A natural symplectic structure can be defined on Π (the history phase space), giving rise to the Poisson algebra. The equations of motion can be expressed by saying that, for any function F on Π, their solutions, γ_{cl}, will satisfy

$$\{F,S\}(\gamma_{\text{cl}}) = 0. \tag{2.6}$$

C. The constrained systems algorithm

The theory of constrained systems was extensively studied by Dirac,[19] though we primarily use Refs. 20 and 21. In essence, a first-class constraint, $\phi(x,p)=0$, is to be seen as a generator of gauge transformations which partitions the phase space, Γ (and, thus, the constraint surface) into orbits. The reduced phase space, Γ_{red}, is then isomorphic to the space of orbits. There exists a unique "reduction" of a function F on Γ to a function $\tilde{F}$ on Γ_{red} if F has a weakly vanishing Poisson bracket with the constraint. Dirac quantization proceeds by constructing the unconstrained Hilbert space, $\mathcal{H}$, writing the constraint as an operator, and then defining the physical Hilbert space as that linear subspace (modulo considerations of the constraint spectrum) of $\mathcal{H}$ which is spanned by those eigenvectors of the constraint whose corresponding eigenvalue is zero.

In histories theory[3] we write the (time-averaged) constraint as $\Phi_\lambda(\gamma)=\int dt\,\lambda(t)\phi(x_t,p_t)\times(\gamma)$. As above, the action of the constraint will partition Π (the history phase space) into orbits, and we can define Π_{red} (the reduced phase space) as the space of equivalence classes of histories on the constraint surface, C_h. (Histories will be equivalent if they lie on the same orbit.) Again, there will be a unique "reduction" of any function, F, on Π to a function, $\tilde{F}$, on Π_{red} if $\{F,\Phi_\lambda\}\approx 0$.

The quantization algorithm for a histories theory follows the spirit of the Dirac scheme, briefly described above. It is implemented, once the constraint is suitably defined as an operator, by first observing that we require

$$d(e^{i\Phi_\lambda}\alpha e^{-i\Phi_\lambda},e^{i\Phi_\lambda}\beta e^{-i\Phi_\lambda})=d(\alpha,\beta). \tag{2.7}$$

To meet this requirement (modulo, as above, issues concerning the nature of the constraint spectrum) we define a projector, E, onto the closed linear subspace of the (unconstrained) history space, $\mathcal{V}$, corresponding to the zero eigenvalue of Φ_λ and then substitute α for $E\alpha E$ in the expression for the decoherence functional (evidently $e^{i\Phi_\lambda}E=E$).

We are now in a position to put these ideas into practice, writing the classical histories theory of Electromagnetism in the next section, and its quantization in the subsequent one.

III. ELECTROMAGNETISM—CLASSICAL

We begin with a brief review of the standard theory.

A. Basics

The EM Action is

$$S=-\frac{1}{4}\int d^4x \;\; F_{\mu\nu}F^{\mu\nu}, \tag{3.1}$$

where $F_{\mu\nu}=\partial_\mu A_\nu-\partial_\nu A_\mu$. The equations of motion are computed from setting $\delta S=0$, and we get

$$\partial^\mu F_{\mu\nu}=0. \tag{3.2}$$

To write this in Hamiltonian form we first define the momentum conjugate to the vector potential:

$$\pi^\mu=\frac{\delta L}{\delta \dot{A}_\mu}=F^{\mu 0}. \tag{3.3}$$

So $\pi^i=\partial^i A^0-\partial^0 A^i=-[(\nabla A^0)^i+\dot{A}^i]=(\underline{E})_i$, and we have the following constraints:

$$\pi^0=0 \tag{3.4}$$

(this is a primary, first-class constraint), and the Gauss Law constraint (this is a secondary, first-class constraint),

$$\partial_i\pi^i=0, \tag{3.5}$$

derived from the consistency condition that the primary constraint be conserved in time, i.e., $\{H,\pi^0\}=0$ (where H is the canonical Hamiltonian given below). In terms of the observable fields, $\underline{E}$ and $\underline{B}=\nabla\times\underline{A}$ the canonical Hamiltonian is written as

$$H=\int d^3x \;\; \left(\frac{1}{2}\underline{E}^2+\frac{1}{2}\underline{B}^2-A^0\nabla\cdot\underline{E}\right). \tag{3.6}$$

1. Poincaré invariance in the standard theory

The generators of the Poincaré group of the standard theory are ''taken over'' (in time-averaged form) to the histories theory as the ''internal'' group. Following Ref. 22, these are derived from the energy–momentum tensor (to which a total divergence has to be added):

$$\tilde{\Theta}^{\mu\nu}=-F^{\mu\rho}\partial^\nu A_\rho+\tfrac{1}{4}\eta^{\mu\nu}F^2+\partial_\rho(F^{\mu\rho}A^\nu). \tag{3.7}$$

The ten generators of the Poincaré group are then written as

$$P^\alpha=\int d^3x \;\; \tilde{\Theta}^{0\alpha}, \tag{3.8}$$

$$M^{\alpha\beta}=\int d^3x\ \ (x^{\alpha}\tilde{\Theta}^{0\beta}-x^{\beta}\tilde{\Theta}^{0\alpha}). \tag{3.9}$$

From these, we deduce the explicit, canonical form of the Hamiltonian, linear momentum, angular momentum and boost generators to be, respectively,

$$H=\int d^3x\left(-\frac{1}{2}\pi_i\pi^i+\frac{1}{2}(\nabla\times\underline{A})^2-A^0\partial_i\pi^i\right), \tag{3.10}$$

$$P_i=\int d^3x\,\pi^j\,\partial_iA_j\,, \tag{3.11}$$

$$J^i=\epsilon^{ijk}\int d^3x(\pi^lx_j\,\partial_kA_l+\pi_jA_k), \tag{3.12}$$

$$K_i=\int d^3x-x_i\left(-\frac{1}{2}\pi_j\pi^j+\frac{1}{2}(\nabla\times\underline{A})^2-A^0\,\partial_j\pi^j\right) \tag{3.13}$$

(where we have chosen $x^0=0$ in the expression for the boost). This algebra closes only weakly, i.e., subject to the Gauss Law constraint, a fact that will be of significance when we come to the quantization.

We now turn to the histories formulation of classical electromagnetism.

B. The histories phase space, Π

The phase space of canonical EM is $\Gamma=(A_i(\underline{x}),\pi_j(\underline{x}))$, and a history is defined to be a path:

$$\gamma:\mathbb{R}\rightarrow\Gamma, \tag{3.14}$$

$$t\mapsto(A_i(t,\underline{x}),\pi_j(t,\underline{x})). \tag{3.15}$$

The space of histories, Π, is defined to be the space of all such smooth paths γ. As explained before we can use a ''covariant-like'' notation, writing $X=n\cdot t+x_n$ where n_μ is a unit time-like vector, so $t=n\cdot X$ and x_n is ''n-spatial,'' i.e., $n\cdot x_n=0$.

However, we wish to find a representation of the time-averaged canonical expressions on the phase space coordinated by $(A_\mu(X),\pi^\nu(X))$. This is so we can write a representation of both the internal *and* external groups on the same space. This is achieved using the n-spatial projector, $P_{\mu\nu}$, introduced earlier, along with the foliating timelike vector, n_μ. In this notation, we write the foliation dependent (canonical) fields ${}^nA_\mu:=P^\nu_\mu A_\nu$ (and likewise for the conjugate momenta). The Hamiltonian is written as

$$H_n=\int d^4X\ \ \left(\frac{1}{2}[P^{\mu\nu}\pi_\mu\pi_\nu+(\nabla^\mu_\sigma A^\sigma)(\nabla_{\mu\delta}A^\delta)]+n^\rho A_\rho P^{\mu\nu}\,\partial_\mu\pi_\nu\right)\chi(n\cdot X) \tag{3.16}$$

(where the subscript ''n'' refers to the particular foliation, and we have introduced the notation $\nabla_{\mu\sigma}A^\sigma\equiv\epsilon_{\mu\nu\rho\sigma}n^\nu\,\partial^\rho A^\sigma$). This is the generator of time translations of the internal group. We then define the Liouville operator (the generator of time translations in the external group):

$$V_n=\int d^4X\ \ \pi^\mu n^\rho\,\partial_\rho A_\mu\,, \tag{3.17}$$

and thus can write the action functional:

$$S_n=V_n-H_n\,. \tag{3.18}$$

It is the action functional that is to be understood as the ''true'' generator of time translations of the theory, naturally intertwining the two modes of time represented by the Hamiltonian and Liouville operators. The fundamental Poisson brackets are now

$$\{A_\mu(X),A_\nu(Y)\}=0=\{\pi^\mu(X),\pi^\nu(Y)\} \tag{3.19}$$

and

$$\{A_\mu(X),\pi^\nu(Y)\}=\delta^\nu_\mu\delta^4(X-Y). \tag{3.20}$$

We now turn to the central issue of Poincaré invariance.

C. The Poincaré groups

As was the case for the scalar field, we seek representations for two Poincaré groups on the history space: one associated with the internal time label, and one associated with the external time label. The generators for spatial translations and spatial rotations will be the same for each group, so we focus our attentions on the time translation and boost generators in each case.

1. The internal Poincaré group

The generators of the internal Poincaré group will be time-averaged versions of the generators of the standard theory [Eqs. (3.10)–(3.13)]. The time translation generator is, of course, just the Hamiltonian of Eq. (3.16) and we define the boost at $s=0$ as

$$^{\text{int}}K(m)=-m_\mu\int d^4X\ \ X^\mu\left(\frac{1}{2}[P^{\mu\nu}\pi_\mu\pi_\nu+(\nabla^\mu_\sigma A^\sigma)(\nabla_{\mu\delta}A^\delta)]+n^\rho A_\rho P^{\mu\nu}\partial_\mu\pi_\nu\right), \tag{3.21}$$

where m_μ is a space-like vector, i.e., $n\cdot m=0$, parametrizing the boost. Given a function A on Π, we can denote the one parameter group of transformations it generates as $s\mapsto T_A(s)$ and its action on the algebra of functions, B, as

$$T_A(s)[B]=\sum_n\frac{s^n}{n!}\underbrace{\{A,\{A,\ldots\{A}_{n\text{-times}},B\ldots.\}\} \tag{3.22}$$

So, we first define the classical analog of the Heisenberg picture fields by

$$T_{\text{H}}(s)[^nA_\mu(X)]=^nA_\mu(X,s), \tag{3.23}$$

$$T_{\text{H}}(s)[^n\pi^\mu(X)]=^n\pi^\mu(X,s), \tag{3.24}$$

and can now see explicitly the sense in which the Hamiltonian generates time translations in the internal time label by looking at its action on the ''Heisenberg'' picture fields:

$$T_{\text{H}}(\tau)[^nA_\mu(X,s)]=^nA_\mu(X,s+\tau), \tag{3.25}$$

$$T_{\text{H}}(\tau)[^n\pi^\mu(X,s)]=^n\pi^\mu(X,s+\tau). \tag{3.26}$$

The internal boost generator will mix the internal time parameter, ''s,'' with the spatial coordinates

$$T_{\text{int}_{K(m)}}[^nA_\mu(X,s)]=^nA_\mu(\Lambda^{-1}(X,s)), \tag{3.27}$$

$$T_{\text{int}_{K(m)}}[^n\pi^\mu(X,s)]=^n\pi^\mu(\Lambda^{-1}(X,s)), \tag{3.28}$$

where $\Lambda^{-1}(X,s)$ is related to (X,s) (the time label "t" is, of course, constant) by the Lorentz boost parametrized by m^μ, i.e., the velocity of the moving frame is given by

$$v^i = c\frac{\tanh|m|m^i}{|m|}. \tag{3.29}$$

2. The external Poincaré group

In contrast to the definition of the generators of the internal group, we use the covariant fields, $(A_\mu(X),\pi^\mu(X))$ in the definition of the generators for the external Poincaré group. These are

$$P^\mu = \int d^4X \;\; \pi^\nu \partial^\mu A_\nu \tag{3.30}$$

and

$$M^{\mu\nu} = \int d^4X[\,\pi^\rho(X^\mu\partial^\nu - X^\nu\partial^\mu)A_\rho] + \sigma^{\mu\nu}, \tag{3.31}$$

where $\sigma^{\mu\nu}$ is the spin term, given by

$$\sigma^{\mu\nu} = \int d^4X(\pi^\mu A^\nu - \pi^\nu A^\mu). \tag{3.32}$$

As before, we are particularly interested in the actions of the time translation generator $V = P^0$ and the boosts generator $K(m) = n_\mu m_\nu M^{\mu\nu}$. These are therefore written as

$$V = \int d^4X \;\; \pi^\mu n^\nu \partial_\nu A_\mu \tag{3.33}$$

and

$${}^{\text{ext}}K(m) = m_\mu \int d^4X[(n\cdot X)\pi^\nu \partial^\mu A_\nu - X^\mu \pi^\rho n^\nu \partial_\nu A_\rho] + n_\mu m_\nu \sigma^{\mu\nu}. \tag{3.34}$$

The effect of the Liouville functional is to generate the following algebra automorphisms, in which we can clearly see that it generates time translation in the external time label:

$$T_V(\tau)[A_\mu(X,s)] = e^{-\tau n_\sigma \partial^\sigma} A_\mu(X,s) = A_\mu(X',s), \tag{3.35}$$

$$T_V(\tau)[\,\pi^\mu(X,s)] = e^{-\tau n_\sigma \partial^\sigma} \pi^\mu(X,s) = \pi^\mu(X',s), \tag{3.36}$$

where X' is the point in $\mathcal{M}$ associated with the pair $(\underline{x}, t+\tau)$.

Let us now turn to the transformations generated by the external boosts. These will mix the external time parameter, "t," with the spatial coordinates. The finite transformations can be written as

$$T_{\text{ext}_{K(m)}}[A_\mu(X,s)] = \Lambda_\mu^\nu A_\nu(\Lambda^{-1}(X),s), \tag{3.37}$$

$$T_{\text{ext}_{K(m)}}[\,\pi^\mu(X,s)] = \Lambda_\nu^\mu \pi^\nu(\Lambda^{-1}(X),s). \tag{3.38}$$

As previously stated, the role of the external group is an interesting one, and it is this that is one of the novel features of histories field theory. The effect of the external boosts is to mix the

spatial coordinate with the external time label "t" and, as the phase space has an implicit foliation dependence, it will also boost the foliation vector itself, thus generating transformations between different foliation-dependent representations.

D. The reduced phase space, Π_{red}

Our next task is to follow the algorithm of Ref. 3 to ascertain a suitable description of the reduced phase space, Π_{red}, on which the true degrees of freedom of the theory are defined. To this end, we are interested in the actions of the constraints on the phase space (and in particular the history constraint surface, C_h) because, by examining their action, we can define suitable coordinates (i.e., ones constant along the orbits) for the reduced phase space Π_{red}.

We write the time-averaged analogs of the constraints of the standard theory as follows:

$$\Psi_\lambda = \int d^4X \;\; \lambda(X) n_\mu \pi^\mu \approx 0, \tag{3.39}$$

$$\Phi_\lambda = \int d^4X \;\; \lambda(X) P^{\mu\nu} \partial_\mu \pi_\nu \approx 0, \tag{3.40}$$

and consider their action on the coordinates of Π. Under Ψ_λ we have

$$(A_\mu(X), \pi^\mu(X)) \rightarrow (A_\mu(X) - \lambda(X) n_\mu, \pi^\mu(X)). \tag{3.41}$$

Under Φ_λ we have

$$(A_\mu(X), \pi^\mu(X)) \rightarrow (A_\mu(X) + P^\rho_\mu \partial_\rho \lambda(X), \pi^\mu(X)). \tag{3.42}$$

Evidently $\pi^\mu(X)$ is constant along the orbits, so we just seek a quantity associated with the vector potential that is gauge invariant.

Equations (3.41) and (3.42) tell us that the transverse components of the vector potential remain constant along the orbits of the constraints and are thus good coordinates for Π_{red}, whereas the scalar and longitudinal components correspond to the degenerate directions of Ψ_λ and Φ_λ, respectively. (This state of affairs is more clearly seen if we use a Fourier transform and work in momentum space.) If we combine this knowledge with a look at the constraints themselves, which (if we were to Fourier transform them) readily show us that the constraint surface, C_h, is defined by $\pi^0 = \pi^L = 0$, where these are, respectively, the scalar and longitudinal components of the conjugate momentum, we can deduce that Π_{red} is suitably coordinated by $(A^\perp_\mu(X), \pi^\perp_\mu(X))$, where the superscript "$\perp$" indicates the transverse components, and these are defined by

$$A^\perp_\mu(X) = \left(\frac{{}^n\partial_\mu \, {}^n\partial^\nu}{{}^n\Delta} - P^\nu_\mu \right) A_\nu(X) \tag{3.43}$$

(and likewise for $\pi^\perp$) and where ${}^n\partial_\mu$ is shorthand for $P^\alpha_\mu \partial_\alpha$ and the (invertible) partial differential operator ${}^n\Delta$ is defined as

$$({}^n\Delta f_\rho)(X) = (P^{\mu\nu} \partial_\mu \partial_\nu) f_\rho(X). \tag{3.44}$$

The (nonzero) Poisson bracket relation on the reduced phase space is given by

$$\{A^\perp_\mu(X), \pi^{\perp\,\nu}(X')\} = T^\nu_\mu \delta^4(X - X'), \tag{3.45}$$

where

$$(T^\nu_\mu f_\nu)(X) \equiv \left(\frac{{}^n\partial_\mu \, {}^n\partial^\nu}{{}^n\Delta} - P^\nu_\mu \right) f_\mu(X). \tag{3.46}$$

We are now in a position to examine whether or not we can write a representation of the two Poincaré groups on Π_{red}.

E. The reduced Poincaré algebras

As explained in Sec. II C, for a function on the whole phase space to reduce to a corresponding function on the reduced phase space, it is necessary that its Poisson bracket with the constraints is weakly zero. We expect to find that the generators of the *internal* Poincaré group reduce to Π_{red}. However, we do not expect to find a full representation of the *external* Poincaré group on the reduced phase space. In Ref. 1 the foliation dependence of the phase space was emphasized but not explicit. In the case of EM we shall see this dependence explicitly as the action of the external boost will affect the definition of Π_{red} and so we do not expect to find a reduced version of this generator. We now turn to the explicit results.

As before, we are only interested in the time translation and boost generators of each Poincaré group and thus we need only compute the Poisson brackets of S, ${}^{\text{int}}K(m)$ and ${}^{\text{ext}}K(m)$ with the constraints. We find the following results (recall that Ψ_λ is the "π^0" constraint and Φ_λ the Gauss Law constraint):

$$\{S,\Psi_\lambda\}=\Psi_{\dot{\lambda}}-\Phi_\lambda\approx 0 \tag{3.47}$$

and

$$\{S,\Phi_\lambda\}=\Phi_{\dot{\lambda}}\approx 0. \tag{3.48}$$

So the action functional weakly commutes with both constraints and so can be reduced to a functional $\tilde{S}$ acting on Π_{red}.

The internal boost generator has the following Poisson brackets with the constraints:

$$\{{}^{\text{int}}K(m),\Psi_\lambda\}=\Phi_{-m_\alpha X^\alpha\lambda}\approx 0 \tag{3.49}$$

and

$$\{{}^{\text{int}}K(m),\Phi_\lambda\}=0. \tag{3.50}$$

This in line with what we expected, i.e., that the generators of the internal Poincaré group commute with the constraints and thus we have a representation of the internal group on Π_{red}. (Of course, something would be quite amiss if we did not have this as the internal group is the histories analog of the Poincaré group of standard Maxwell theory.)

The external boost generator forms the following Poisson brackets with the constraints:

$$\{{}^{\text{ext}}K(m),\Psi_\lambda\}=\Psi_{(n_\beta X^\beta m_\alpha\partial^\alpha-m_\beta X^\beta n_\alpha\partial^\alpha)\lambda}-\int d^4X\ \ \lambda(X)m_\alpha\pi^\alpha \tag{3.51}$$

and

$$\{{}^{\text{ext}}K(m),\Phi_\lambda\}=\Psi_{m_\alpha\partial^\alpha\lambda}+\int d^4X(n_\alpha\partial^\alpha\lambda(X))m_\beta\pi^\beta. \tag{3.52}$$

Neither of these are weakly zero, and so the external boost generator cannot be reduced to Π_{red}.

For those functions that *can* be reduced, we use the coordinates for the reduced phase space that we worked out in the previous section. The Hamiltonian and Liouville functionals on the reduced phase space are written as follows:

$$\tilde{H}=\int d^4X\frac{1}{2}(\pi^{\perp\mu}\pi^{\perp}_{\mu}+A^{\perp n}_{\mu}\,\Delta A^{\perp\mu}), \tag{3.53}$$

$$\tilde{V}=\int d^4X \;\; \pi^{\perp\mu} n_\nu \partial^\nu A^\perp_\mu, \tag{3.54}$$

where we have used, in the expression for the Hamiltonian,

$$A_\mu \, {}^n\Gamma^{\mu\nu} A_\nu = A^\perp_\mu \, {}^n\Delta A^{\perp\mu}, \tag{3.55}$$

with ${}^n\Delta$ defined in Eq. (3.44). Thus the action functional on Π_{red} is written as

$$\tilde{S}=\tilde{V}-\tilde{H}, \tag{3.56}$$

and the classical paths which are solutions to the equations of motion are those which satisfy

$$\{\tilde{S},\tilde{F}\}(\gamma_{\text{cl}})=0, \tag{3.57}$$

for all functions $\tilde{F}$ defined on Π_{red}.

IV. ELECTROMAGNETISM—QUANTIZATION

For the quantization of the theory we continue to follow the algorithm laid down by Savvidou and Anastopolous, which, as outlined in Sec. II C, essentially follows the Dirac scheme. We define the history space, $\mathcal{V}$, by consideration of the history group, and define the constraints thereon. However, as we mentioned, the constraints have continuous spectra, and thus the physical Hilbert space, $\mathcal{V}_{\text{phys}}$, will not be a genuine subspace of the history Hilbert space. This will be explicitly demonstrated. And so we are led to a creative implementation of the algorithm (the central idea here is due to Savvidou[25]), in which the physical Hilbert space is defined separately, based on an analysis, in terms of coherent states, of how the constraints act on $\mathcal{V}$. Appropriate mappings are then defined between $\mathcal{V}$ and $\mathcal{V}_{\text{phys}}$ such that objects on one can be related to objects on the other.

A. The History Hilbert space $\mathcal{V}$

So the first stage is to define the History Hilbert space. Following the methods of Refs. 15 and 1, we start by defining the History Algebra:

$$[A_\mu(X),A_\nu(X')]=0, \tag{4.1}$$

$$[\pi_\mu(X),\pi_\nu(X')]=0, \tag{4.2}$$

$$[A_\mu(X),\pi^\nu(X')]=i\,\delta^\nu_\mu\delta^4(X-X'), \tag{4.3}$$

or, in its more rigorous, smeared form:

$$[A_\mu(f^\mu),A_\nu(f'^\nu)]=0, \tag{4.4}$$

$$[\pi_\mu(h^\mu),\pi_\nu(h'^\nu)]=0, \tag{4.5}$$

$$[A_\mu(f^\mu),\pi^\nu(h_\nu)]=i\int \; d^4X\; \delta^\nu_\mu f^\mu(X) h_\nu(X), \tag{4.6}$$

where $f^\mu(X)$, $h_\mu(X)$ are elements of a suitable space of smearing functions which we will leave unspecified beyond saying that it must at least be a subspace of $\oplus_{i=1\cdots4} L^2_{\mathbb{R}}(\mathbb{R}^4,d^4X)_i$. Let us denote this space $\mathcal{T}_{\mathbb{R}}$. It is natural to seek a Fock representation of this algebra, and this is achieved by first taking the complexification of the space of smearing functions, i.e., $\mathcal{T}_{\mathbb{C}}=\mathcal{T}_{\mathbb{R}}\oplus\mathcal{T}_{\mathbb{R}}$ and then exponentiating the resulting space to give $\mathcal{V}=e^{\mathcal{T}_{\mathbb{C}}}$. The Fock space thus defined will carry a natural representation of the above History Algebra, which we seek explicitly below, in terms of creation and annihilation operators:

$$[b_\mu(X), b^{\dagger\nu}(X)] = \delta_\mu^\nu \delta^4(X - X'). \tag{4.7}$$

1. The representation of (A, π) in terms of $(b^\dagger, b)$

We can easily write a representation of the fully covariant fields $(A_\mu(X), \pi^\mu(X))$:

$$A_\mu(X) = \frac{1}{\sqrt{2}}(b_\mu(X) + b_\mu^\dagger(X)), \tag{4.8}$$

$$\pi_\mu(X) = -\frac{i}{\sqrt{2}}(b_\mu(X) - b_\mu^\dagger(X)). \tag{4.9}$$

However, what we require in order to define the Hamiltonian is foliation-dependent fields. So we start from a normal-ordered analog of the classical unconstrained Hamiltonian:

$${}^nH =: \frac{1}{2}\int d^4X (P^{\mu\nu\,n}\pi_\mu\,{}^n\pi_\nu + {}^nA_\mu\,{}^n\Gamma^{\mu\nu\,n}A_\nu): \tag{4.10}$$

and may think, at first, to define

$${}^nA_\mu(X) = \frac{1}{\sqrt{2}}({}^n\Gamma^\nu_\mu)^{-1/4}(b_\nu(X) + b_\nu^\dagger(X)), \tag{4.11}$$

$${}^n\pi_\mu(X) = -\frac{i}{\sqrt{2}}({}^n\Gamma^\nu_\mu)^{1/4}(b_\nu(X) - b_\nu^\dagger(X)). \tag{4.12}$$

However, there is a problem here, as the operator $\Gamma^{\mu\nu}$ has zero eigenvalues, and is, therefore, not invertible. To see this, it is easier to use ''canonical notation,'' i.e., $\Gamma^{ij} = \partial^i\partial^j - \delta^{ij}\partial_k\partial^k$. We then examine the action of this operator on an element, $f_i(x)$, of the smearing function space—which we split into its transverse and longitudinal components, $f_i = f_i^\perp + f_i^\parallel$—and find

$$\Gamma^{ij}f_i(x) = \Gamma ij(f_i^\perp(x) + f_i^\parallel(x)) = \Gamma^{ij}f_i^\perp(x). \tag{4.13}$$

So the longitudinal components of the smearing functions are the zero eigenvectors of Γ^{ij}. If we now split the Hamiltonian into its transverse and longitudinal parts, we find (reverting to the full ''histories'' notation, and dropping the n superscript for ease),

$$H = \frac{1}{2}\int d^4X (\pi_\mu^\perp\pi^{\perp\mu} + A_\mu^\perp\,{}^n\Delta A^{\perp\mu} + \pi_\mu^\parallel\pi^{\parallel\mu}), \tag{4.14}$$

where the operator ${}^n\Delta$ was defined in Eq. (3.44). And now we see that the transverse part of the Hamiltonian is, in essence, that of the usual ''harmonic oscillators,'' whereas the longitudinal part is that of a ''free particle.'' This form now prompts us towards the correct definition of the fields in terms of the creation and annihilation operators:

$${}^nA_\mu(X) = \frac{1}{\sqrt{2}}\,{}^n\Delta^{-1/4}(b_\mu(X) + b_\mu^\dagger(X)), \tag{4.15}$$

$${}^n\pi_\mu(X) = -\frac{i}{\sqrt{2}}\,{}^n\Delta^{1/4}(b_\mu(X) - b_\mu^\dagger(X)). \tag{4.16}$$

Now, on the one hand, we can consider the Fock space in terms of the orthonormal basis obtained by a continual application of the creation operator on a translationally invariant vacuum state (defined by $b_\mu|0\rangle=0$). However, it has also proved very useful to consider the Fock space in terms of coherent states—indeed, in Ref. 15, these were vital to the demonstration that there exists a natural isomorphism between an exponential Hilbert space and the ''continuous tensor product'' of Hilbert spaces so vital to the Histories program. In the next section, we make use of the technology of coherent states (an excellent reference is Ref. 23) as we seek to define the Physical Hilbert space.

B. The Physical Hilbert space $\mathcal{V}_{\text{phys}}$

Recall that the constraints are written as

$$\Psi_\lambda=\int d^4X\ \ \lambda(X)n_\mu\pi^\mu, \tag{4.17}$$

$$\Phi_\lambda=\int d^4X\ \ \lambda(X)P^{\mu\nu}\partial_\mu\pi_\nu. \tag{4.18}$$

Substituting for the fields in terms of the creation and annihilation operators, these become

$$\Psi_\lambda=\frac{-i}{2}\int d^4X\ \ \lambda(X)n_\mu{}^n\Delta^{1/4}(b^\mu-b^{\dagger\mu}), \tag{4.19}$$

$$\Phi_\lambda=\frac{-i}{2}\int d^4X\ \ \lambda(X)P^{\mu\nu}\partial_\mu{}^n\Delta^{1/4}(b_\nu-b^\dagger_\nu). \tag{4.20}$$

It is clear that these constraints are self-adjoint operators on $\mathcal{V}$, and also that they have continuous spectra, so the physical Hilbert space will not be a genuine subspace. However, by consideration of the Fock space, $\mathcal{V}$, in terms of coherent states we are led naturally to the correct definition of $\mathcal{V}_{\text{phys}}$, and explicitly show in what sense the latter is not a true subspace of the former.

The Weyl operator which generates the (overcomplete) set of coherent states is written as

$$U[f,h]=\exp[i({}^nA_\mu(f^\mu)-{}^n\pi_\nu(h^\nu))]|0\rangle, \tag{4.21}$$

$$=\exp[b^\dagger_\mu(z^\mu)-b_\mu(z^{*\mu})]|0\rangle, \tag{4.22}$$

with $z_\mu(X)=(1/\sqrt{2})\,({}^n\Delta^{1/4}h_\mu(X)+i\,{}^n\Delta^{-1/4}f_\mu(X))$. The un-normalized coherent states on $\mathcal{V}$ are defined for each $z^\mu(X)\in\mathcal{T}_{\mathbb{C}}$ as

$$|\exp z\rangle=e^{b^\dagger_\mu(z^\mu)}|0\rangle. \tag{4.23}$$

Their overlap is given by

$$\langle\exp z|\exp z'\rangle=e^{\langle z,z'\rangle} \tag{4.24}$$

[where the inner product is $\langle z,z'\rangle=\int d^4Xz^*_\mu(X)z'^\mu(X)$] and there exists a measure, $d\sigma[z]$, such that

$$1=\int|\exp z\rangle\langle\exp z|d\sigma[z]. \tag{4.25}$$

(That this measure exists was demonstrated in Ref. 15.) With the aid of this resolution of unity, we can thus define an integral representation of $\mathcal{V}$ in terms of wave functionals, $\psi[z]$:

$$|\psi\rangle = \int |\exp z\rangle\langle \exp z|\psi\rangle d\sigma[z] = \int \psi[z]|\exp z\rangle d\sigma[z]. \tag{4.26}$$

Furthermore, we can write a differential representation of a general operator, O on $\mathcal{V}$:

$$\langle \exp z|:O(b_\mu^\dagger, b_\mu):|\psi\rangle = O\left(z_\mu^*, \frac{\delta}{\delta z_\mu^*}\right)\psi[z]. \tag{4.27}$$

Given this last construction, we can now rewrite the constraint operators as follows:

$$\langle \exp z|\Psi_\lambda|\psi\rangle = \int d^4X g_\mu\left(\frac{\delta}{\delta z^{*\mu}} - z^{*\mu}\right)\psi[z] \tag{4.28}$$

[where $g_\mu(X) = (-i/2)\lambda(X)\,{}^n\Delta^{1/4} n_\mu$] and, similarly,

$$\langle \exp z|\Phi_\lambda|\psi\rangle = \int d^4X w_\mu\left(\frac{\delta}{\delta z^{*\mu}} - z^{*\mu}\right)\psi[z] \tag{4.29}$$

[where $w_\mu(X) = (i/2)P_\mu^\nu \partial_\nu \lambda(X)\,{}^n\Delta^{1/4}$].

So now we can consider the action of the constraints on a general wave functional $\psi[z]$, finding

$$e^{i\Psi_\lambda}\psi[z] = e^{-(1/2)\langle g,g\rangle - i\langle z,g\rangle}\psi[z+ig], \tag{4.30}$$

and, similarly,

$$e^{i\Phi_\lambda}\psi[z] = e^{-(1/2)\langle w,w\rangle - i\langle z,w\rangle}\psi[z+iw]. \tag{4.31}$$

We can now explicitly see that $\mathcal{V}_{\text{phys}}$ will not be a subspace of $\mathcal{V}$ as we require the subspace to be invariant under the action of the constraints, and are thus essentially looking for solutions to the pair of equations

$$\psi[z] = \psi[z+ig], \tag{4.32}$$

$$\psi[z] = \psi[z+iw]. \tag{4.33}$$

The solutions to these will be $\psi[z^\perp]$, where $z_\mu^\perp(X)$ are only the transverse components of $z_\mu(x)$ defined as

$$z_\mu^\perp(X) = \left(\frac{{}^n\partial_\mu\,{}^n\partial^\nu}{{}^n\Delta} - P_\mu^\nu\right) z_\nu(X) \tag{4.34}$$

(where ${}^n\partial_\mu$ is just shorthand for $P_\mu^\rho\partial_\rho$). However, it is clear that the corresponding wave-functionals, $\psi[z^\perp]$, will not be square integrable. To see this, we need only consider $\int\int\int |\psi[z^\perp]|^2 d\sigma[z^\perp]d\sigma[z^0]d\sigma[z^\parallel]$ which will be infinite on account of the contributions from the integrations over the scalar and longitudinal parts. This leads us to the conclusion that what we need to do is to construct the physical Hilbert space *separately* so that the wave-functionals, $\psi[z^\perp]$, *are* square-integrable, and then define a suitable mapping from $\mathcal{V}$ to $\mathcal{V}_{\text{phys}}$.

Equipped with what we know from the classical theory, and what we have ascertained from the analysis above, we construct $\mathcal{V}_{\text{phys}}$ in the usual way—first by positing the algebra

$$[A_\mu(f^{\perp\mu}), A_\nu(f'^{\perp\nu})] = 0, \tag{4.35}$$

$$[\pi_\mu(h^{\perp\mu}), \pi_\nu(h'^{\perp\nu})] = 0, \tag{4.36}$$

$$[A_\mu(f^{\perp\mu}),\pi^\nu(h^\perp_\nu)]=i\int d^4X\ \delta^\nu_\mu f^{\perp\mu}(X)h^\perp_\nu(X), \tag{4.37}$$

where the smearing functions belong to $\mathcal{T}^\perp_{\mathbb{R}}=L^2_{\mathbb{R}}(\mathbb{R}^4,d^4X)\oplus L^2_{\mathbb{R}}(\mathbb{R}^4,d^4X)$. We then take the complexification of this space $\mathcal{T}^\perp_{\mathbb{C}}=\mathcal{T}^\perp_{\mathbb{R}}\oplus\mathcal{T}^\perp_{\mathbb{R}}$ and exponentiate the resulting space to give $\mathcal{V}_{\text{phys}}=e^{\mathcal{T}^\perp_{\mathbb{C}}}$. We can then write a representation of the transverse fields in terms of the creation and annihilation operators of this Fock space:

$${}^nA^\perp_\mu(X)=\frac{1}{\sqrt{2}}{}^n\Delta^{-1/4}(b^\perp_\mu(X)+b^{\perp\dagger}_\mu(X)), \tag{4.38}$$

$${}^n\pi^\perp_\mu(X)=-\frac{i}{\sqrt{2}}{}^n\Delta^{1/4}(b^\perp_\mu(X)-b^{\perp\dagger}_\mu(X)), \tag{4.39}$$

where

$$[b_\mu(z^{\perp\mu}),b^{\dagger\nu}(z'^\perp_\nu)]=\langle z^\perp,z'^\perp\rangle, \tag{4.40}$$

and $z^\perp_\mu(X)=(1/\sqrt{2})\,({}^n\Delta^{1/4}h^\perp_\mu(X)+i\,{}^n\Delta^{-1/4}f^\perp_\mu(X))$.

In direct analogy to $\mathcal{V}$, we can consider $\mathcal{V}_{\text{phys}}$ in terms of the un-normalized coherent states defined by

$$|\exp z^\perp\rangle_{\mathcal{V}_{\text{phys}}}=e^{b^\mu(z^\perp_\mu)}|0\rangle, \tag{4.41}$$

and these will admit a resolution of unity:

$$1=\int|\exp z^\perp\rangle\langle\exp z^\perp|d\sigma[z^\perp], \tag{4.42}$$

and thus an integral representation for $|\psi\rangle\in\mathcal{V}_{\text{phys}}$:

$$|\psi\rangle=\int\psi[z^\perp]|\exp z^\perp\rangle_{\mathcal{V}_{\text{phys}}}d\sigma[z^\perp]. \tag{4.43}$$

We now define a mapping between $\mathcal{V}$ and $\mathcal{V}_{\text{phys}}$:

$$L:\mathcal{V}\to\mathcal{V}_{\text{phys}},$$

$$|\exp z\rangle_{\mathcal{V}}\mapsto L(|\exp z\rangle_{\mathcal{V}})\equiv|\exp z^\perp\rangle_{\mathcal{V}_{\text{phys}}}, \tag{4.44}$$

where $|\exp z^\perp\rangle_{\mathcal{V}_{\text{phys}}}$ is defined as in Eq. (4.41). We define the (continuous) dual mapping:

$$L^\dagger:\mathcal{V}^*_{\text{phys}}\to\mathcal{V}^* \tag{4.45}$$

by

$${}_{\mathcal{V}_{\text{phys}}}\langle\exp z^\perp|L^\dagger|\exp w\rangle_{\mathcal{V}}={}_{\mathcal{V}_{\text{phys}}}\langle\exp z^\perp|L|\exp w\rangle_{\mathcal{V}}. \tag{4.46}$$

We can now use these maps (and the fact that, due to the Riesz Lemma (see, e.g., Ref. 24), there is an isomorphism between a Hilbert space, $\mathcal{H}$, and the space of continuous linear functionals, $\mathcal{H}^*$, from $\mathcal{H}$ to $\mathbb{C}$) to relate objects on $\mathcal{V}_{\text{phys}}$ to objects on $\mathcal{V}$:

$$b_{\mathcal{V}_{\text{phys}}}=Lb_{\mathcal{V}}L^\dagger. \tag{4.47}$$

Having now established the relationship between the ''full'' Hilbert space, $\mathcal{V}$, and the ''physical'' Hilbert space, $\mathcal{V}_{\rm phys}$, we can now turn to the issue of Poincaré invariance and use Eq. (4.47) to define the action operator on $\mathcal{V}_{\rm phys}$.

C. The Poincaré groups

In the case of classical histories electromagnetism, we proved the existence of the two Poincaré groups on the histories phase space, Π, and analyzed their ''reduction'' to the reduced phase space, $\Pi_{\rm red}$, by considering their compatibility with the constraints. We demonstrated the existence of the internal group on Π, finding that the algebra closed only weakly, i.e., was only satisfied on the constraint surface. We then proved the existence of a ''reduced'' internal Poincaré group on $\Pi_{\rm red}$, with the generators written in terms of the transverse components of the fields. We also demonstrated the existence of the external Poincaré on Π, but found that the external boost generator did not commute with the constraints, and thus could not be represented on $\Pi_{\rm red}$. This, as we shall see in greater detail in the quantum case below, results from the fact that Π and $\Pi_{\rm red}$ are foliation dependent, and that the external boost boosts the foliation vector as well. So let us now discuss the issue of Poincaré invariance in the quantum theory.

1. The internal Poincaré group

Our starting point for the internal Poincaré group is (a normal ordered version of) the unconstrained Hamiltonian given in Sec. IV A 1 and repeated here:

$$H=\frac{1}{2}:\int d^4X(\pi_\mu^\perp\pi^{\perp\mu}+A_\mu^{\perp\ n}\Delta A^{\perp\mu}+\pi_\mu^\parallel\pi^{L\mu}):. \tag{4.48}$$

In terms of the creation and annihilation operators [Eqs. (4.38)–(4.39)], this reads as

$$H=\int d^4X\left[b_\mu^{\perp\dagger\ n}\Delta^{1/2}b^{\perp\mu}-\frac{1}{4}((b_\mu^\parallel-b_\mu^{\parallel\dagger})^n\Delta^{1/2}(b^{\parallel\mu}-b^{\parallel\dagger\mu}))\right]. \tag{4.49}$$

However, while the transverse part can easily be shown to exist in the usual way, the longitudinal part does not generate automorphisms which are unitarily implementable on account of the presence of terms quadratic in b_μ and $b_\mu^\dagger$. And so the Hamiltonian does not exist on $\mathcal{V}$ as a self-adjoint operator. Of course, this is no tragedy and we half-expected it anyway as we had already seen in the classical case that the algebra of the internal group closed only weakly.

What is important is that a representation of the internal group can be found on $\mathcal{V}_{\rm phys}$. This is straightforward. The generators are taken straight from the classical case, suitably ordered and then written in terms of $b_\mu^\perp$ and $b_\mu^{\perp\dagger}$ using Eqs. (4.38)–(4.39). They are

$$\tilde{H}=\int d^4Xb_\mu^{\perp\dagger\ n}\Delta^{1/2}b^{\perp\mu}, \tag{4.50}$$

$$\tilde{P}(m)=im_\nu\int d^4Xb_\mu^{\perp\dagger}\,\partial^\nu b^{\perp\mu}, \tag{4.51}$$

$$\tilde{J}(m)=i\epsilon_{\mu\nu\rho\sigma}n^\mu m^\nu\int d^4X(b_\alpha^{\perp\dagger}X^\rho\,\partial^\sigma b^{\perp\alpha}+b^{\perp\dagger\rho}b^{\perp\sigma}), \tag{4.52}$$

$$\tilde{K}(m)=m_\nu\int d^4Xb_\mu^{\perp\dagger\ n}\Delta^{1/4}X^{\nu\ n}\Delta^{1/4}b^{\perp\mu}, \tag{4.53}$$

where we have used an obvious shorthand for operators on $\mathcal{V}_{\rm phys}$ [see Eq. (4.47)], i.e.,

$$b^{\perp\mu}\equiv b^\mu_{\mathcal{V}_{\rm phys}}=Lb^\mu_{\mathcal{V}}L^\dagger. \tag{4.54}$$

The analysis of this group is essentially the same as the classical case. We define the Heisenberg picture fields:

$$b_\mu^\perp(X,s)=e^{is\tilde{H}}b_\mu^\perp(X)e^{-is\tilde{H}}, \tag{4.55}$$

$$b_\mu^{\perp\dagger}(X,s)=e^{is\tilde{H}}b_\mu^{\perp\dagger}(X)e^{-is\tilde{H}}. \tag{4.56}$$

The Hamiltonian generates transformations in the internal time label "s," and the internal boost mixes the internal time parameter with the spatial coordinates. These transformations all happen at constant "t" (where "t" is the external time parameter).

2. The external Poincaré group

As in the case of the scalar field, one of the novel features of histories theories is the existence of a second Poincaré group—the external group—that is associated with the external time label, "t." Again we start from the classical expressions, suitably ordered:

$$P^\mu=:\int d^4X \;\; \pi^\nu\,\partial^\mu A_\nu: \tag{4.57}$$

$$M^{\mu\nu}=:\int d^4X[\,\pi^\rho(X^\mu\partial^\nu-X^\nu\partial^\mu)A_\rho+(\,\pi^\mu A^\nu-\pi^\nu A^\mu)]: \tag{4.58}$$

Note that these expressions use the covariant fields defined in Eqs. (4.8)–(4.9), and thus we write

$$P^\mu=i\int d^4X b^{\dagger\nu}\,\partial^\mu b_\nu, \tag{4.59}$$

$$M^{\mu\nu}=i\int d^4X[\,b^{\dagger\rho}(X^\mu\partial^\nu-X^\nu\partial^\mu)b_\rho+(\,b^{\dagger\mu}b^\nu-b^{\dagger\nu}b^\mu)]. \tag{4.60}$$

As in the classical case, the Liouville operator, $V=n_\mu P^\mu$, generates translations in the external time parameter. And it is the external boost generator, ${}^{\text{ext}}K(m)=n_\mu m_\nu M^{\mu\nu}$ that is of the most importance as we can see in its action on foliation dependent objects:

$$U(\Lambda)^n A_\mu(X)U(\Lambda)^{-1}=\Lambda_\mu^{\ \nu}\,{}^{\Lambda n}A_\nu(\Lambda^{-1}X), \tag{4.61}$$

where $U(\Lambda)=e^{iK(m)}$. The crucial point here is that it generates Lorentz transformations on the foliation vector as well. Let us now analyze this issue in a bit more detail.

Though the set of all coherent states is independent of the foliation vector, n_μ (they are eigenstates of the annihilation operator), the definition of them in terms of the Weyl generator, Eqs. (4.21)–(4.22) is clearly not. It is thus that the Fock space, $\mathcal{V}$, depends upon the choice of foliation. Now, as in the case of the scalar field, all the foliation-dependent representations of the history algebra exist on the same Fock space, $\mathcal{V}$, and ${}^{\text{ext}}K(m)$ relates the objects defined with respect to a foliation "n," with those same objects defined with respect to the foliation "Λn." For example, under ${}^{\text{ext}}K(m)$, the constraint operators will transform

$${}^n\Psi_\kappa \overset{{}^{\text{ext}}K(m)}{\rightarrow} {}^{\Lambda n}\Psi_\kappa, \tag{4.62}$$

$${}^n\Phi_\kappa \overset{{}^{\text{ext}}K(m)}{\rightarrow} {}^{\Lambda n}\Phi_\kappa. \tag{4.63}$$

Now the map L from $\mathcal{V}$ to $\mathcal{V}_{\text{phys}}$ is also evidently n-dependent and thus $\mathcal{V}_{\text{phys}}$ also depends on the choice of foliation used to define $\mathcal{V}$. However, whereas all foliation-dependent representations can

exist on $\mathcal{V}$ (and we can thus talk about transformations between them), the physical Hilbert spaces, ${}^{n}\mathcal{V}_{\text{phys}}$ and ${}^{\Lambda n}\mathcal{V}_{\text{phys}}$ (where, we trust, the point of the added superscript is self-evident), are clearly different. This is why there will be no representation of ${}^{\text{ext}}K(m)$ on $\mathcal{V}_{\text{phys}}$. Mathematically (and analogously to the classical case) this situation is represented by the fact that the external boost does not (weakly) commute with either of the constraints.

Of course, we can still relate the important quantities on ${}^{n}\mathcal{V}_{\text{phys}}$ such as the action, ${}^{n}S$, to those same quantities on ${}^{\Lambda n}\mathcal{V}_{\text{phys}}$ via the prescription given at the end of Sec. IV B, i.e., by mapping back to $\mathcal{V}$, boosting there, and then mapping to ${}^{\Lambda n}\mathcal{V}_{\text{phys}}$.

The other generators will be represented on $\mathcal{V}_{\text{phys}}$, we just make use of Eq. (4.47) to define them. The most important of these is the Liouville operator, and this will be defined on the physical Hilbert space as

$$\tilde{V}=i\int d^4X b_{\nu}^{\perp\dagger} n_{\mu}\partial^{\mu}b^{\perp\nu}. \tag{4.64}$$

This will generate time transformations in the external time label, "t," on the physical Hilbert space. We thus arrive, using Eqs. (4.50) and (4.64), at the definition of the action operator on the physical Hilbert space:

$$\tilde{S}=\tilde{V}-\tilde{H}. \tag{4.65}$$

V. CONCLUSION

Our aim in this paper has been to construct a histories theory of Electromagnetism working in the HPO consistent histories framework. As a vector field theory with two first class constraints, we have built on the work of Savvidou[1] on scalar field theory, as well as demonstrating an application of the constrained systems algorithm developed by Savvidou and Anastopoulos.[3]

Classically, we defined the histories phase space and the two Poincaré groups that are a feature of histories field theories. The constraints partition the constraint surface (and indeed the whole phase space) into orbits, and by defining coordinates that are constant on each orbit, we defined the reduced phase space that carries the physical degrees of freedom of the theory. We stressed the importance of the foliation dependence of the phase space (and thus the reduced phase space) focusing particularly on the action of the external boost generator which transforms between different foliations.

Quantizing within the Dirac scheme, we first constructed the Hilbert space of the unconstrained theory ($\mathcal{V}$), motivated by finding a suitable representation of the History algebra. We then defined the constraints as operators, and, making use of the technology of coherent states, sought to define the physical Hilbert space ($\mathcal{V}_{\text{phys}}$). As the constraints have continuous spectra, this was not going to be a true linear subspace of the full Hilbert space. We got around this issue by analyzing $\mathcal{V}$ in terms of coherent states, which led to a definition of $\mathcal{V}_{\text{phys}}$ in terms of just the transverse components of the vector field and their conjugate momenta (or, more strictly, the space of test functions). We then defined a suitable mapping from $\mathcal{V}$ to $\mathcal{V}_{\text{phys}}$ and used this to define the action operator on $\mathcal{V}_{\text{phys}}$.

We consider the existence in arbitrary finite dimensions d of a positive operator valued measure (POVM) comprised of d^2 rank-one operators all of whose operator inner products are equal. Such a set is called a ''symmetric, informationally complete'' POVM (SIC–POVM) and is equivalent to a set of d^2 equiangular lines in $\mathbb{C}^d$. SIC–POVMs are relevant for quantum state tomography, quantum cryptography, and foundational issues in quantum mechanics. We construct SIC–POVMs in dimensions two, three, and four. We further conjecture that a particular kind of group-covariant SIC–POVM exists in arbitrary dimensions, providing numerical results up to dimension 45 to bolster this claim. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1737053]

I. INTRODUCTION

In quantum theory, measurements are represented by *positive operator valued measures* (POVMs). A POVM is termed *informationally complete* if its statistics determine completely the quantum state on which the measurement is carried out.[2,4,20,21] In order to be maximally efficient at determining the state, such a measurement should also be *rank-one*; i.e., the measurement operators or *POVM elements* should be positive multiples of projectors onto pure states, in which case each POVM element corresponds uniquely (up to a phase) to a subnormalized vector in $\mathbb{C}^d$. A particularly appealing and potentially useful measurement is one which is *symmetric*, meaning all pairwise inner products between the POVM elements are equal. Such a POVM is a ''symmetric, informationally complete positive operator-valued measure,'' or SIC–POVM for short. The set of vectors comprising a SIC–POVM has also been studied in a very different context, where it has a different name: it is a set of d^2 equiangular lines in $\mathbb{C}^d$, first studied by Lemmens and Seidel[19] and subsequently by many others.[5–7,11,16–18,22,24] In quantum information theory such measurements are relevant to quantum state tomography,[3] quantum cryptography,[9] and to foundational studies[8] where they would make for a particularly interesting ''standard quantum measurement.'' The outstanding question we address in this paper is whether SIC–POVMs exist in any finite dimension.

We conjecture that SIC–POVMs exist in all finite dimensions and, moreover, that there exists in all finite dimensions a SIC–POVM that is covariant under a standard representation of $\mathbb{Z}_d \times \mathbb{Z}_d$. To state the conjecture, let us formalize the definition of a SIC–POVM. The simplest definition is that a SIC–POVM P is a set of d^2 normalized vectors $|\phi_k\rangle$ in $\mathbb{C}^d$ satisfying

$$|\langle \phi_j|\phi_k\rangle|^2 = \frac{1}{d+1}, \quad j \neq k. \tag{1}$$

More precisely, the POVM elements of P are the subnormalized projectors $|\phi_k\rangle\langle\phi_k|/d=\Pi_k/d$, which have pairwise Hilbert–Schmidt inner product $(\Pi_j,\Pi_k)/d^2=\mathrm{Tr}[\Pi_j^\dagger\Pi_k]/d^2=1/d^2(d+1)$ for $j\neq k$. It turns out that the other properties of a SIC–POVM, i.e., completeness and informational completeness, follow from Eq. (1), as we show in Sec. II.

We can now state our conjecture.

Conjecture 1: For any dimension $d\in\mathbb{N}$, let $\{|k\rangle\}_{k=0}^{d-1}$ be an orthonormal basis for $\mathbb{C}^d$, and define

$$\omega=\exp(2\pi i/d),\quad D_{jk}=\omega^{jk/2}\sum_{m=0}^{d-1}\omega^{jm}|k\oplus m\rangle\langle m|\,, \tag{2}$$

where $\oplus$ denotes addition modulo d. Then there exists a normalized $|\phi\rangle\in\mathbb{C}^d$ such that the set $\{D_{jk}|\phi\rangle\}_{j,k=1}^{d}$ is a SIC–POVM P.

Analytic solutions are known for $d=2,3,8$,[16] and to this list we add $d=4$. Additionally, computer calculations reveal numerical solutions (with an accuracy better than 1 part in 10^8) in dimensions up to 45, some derived using the aforementioned group, but others using other suitable groups. These results are detailed herein according to the following plan. Section II states the problem in the language of frame theory and derives a connection to the problem of finding spherical t-designs. Section III specializes to the group-covariant case and explains why our conjecture might be generally true. Section IV presents our analytic solutions for $d=2,3,4$, and Sec. V the method of obtaining the numerical results. Finally, in Sec. VI we discuss possible approaches to a general proof, as well as related open questions.

II. FRAMES AND SPHERICAL *t*-DESIGNS

The concepts of frame theory provide a simple and elegant means of putting our problem in a general setting, for a SIC–POVM is a particular kind of frame. Frames are a generalization of basis sets, with the requirements of orthogonality and normalization relaxed. For a finite-dimensional vector space $\mathcal{H}$, a collection of vectors $|\psi_k\rangle\in\mathcal{H}$ is a frame if there exist constants $0<a\leqslant b<\infty$ such that

$$a\langle\xi|\xi\rangle\leqslant\sum_k|\langle\xi|\psi_k\rangle|^2\leqslant b\langle\xi|\xi\rangle \tag{3}$$

for all $|\xi\rangle\in\mathcal{H}$. Any collection of vectors is a frame in the subspace spanned by the vectors. The constants a and b are called the *frame bounds*, and if $a=b$, the frame is said to be *tight*. The *frame operator* is the positive operator

$$S=\sum_k|\psi_k\rangle\langle\psi_k|. \tag{4}$$

It should be immediately clear that for a tight frame $S=aI$. This tight-frame condition is equivalent to the completeness condition for the corresponding POVM elements $|\psi_k\rangle\langle\psi_k|/a$, and thus rank-one POVMs and tight frames are the same mathematical object.

Now let $\mathbb{S}^d\subset\mathbb{C}^d$ be the subset consisting of vectors that have unit norm. Any frame can be rewritten in terms of the corresponding normalized vectors, but tightness is not preserved under this transformation. For a frame $\{|\psi_k\rangle\in\mathbb{S}^d\}_{k=1}^n$ made up of normalized vectors, the quantity

$$\mathrm{Tr}[S^2]=\sum_{j,k}|\langle\psi_j|\psi_k\rangle|^2 \tag{5}$$

is called the *frame potential*. We consider only frames made up of normalized vectors throughout the following.

A useful theorem due to Benedetto and Fickus[1] states the following.

Theorem 1 (Benedetto–Fickus): *Given any d and n, let $\{|\psi_k\rangle \in \mathbb{S}^d\}_{k=1}^n$ be a set of normalized vectors with frame operator S. Then*

$$\mathrm{Tr}[S^2] \geqslant \max(n, n^2/d). \tag{6}$$

Furthermore, the bound is achieved if and only if $\{|\psi_k\rangle\}$ consists of orthonormal vectors, when $n \leqslant d$, or is a tight frame, when $n \geqslant d$.

Proof: The proof is so simple that we can include it here for completeness. Denoting the ordered eigenvalues of S by $\lambda_1 \geqslant \lambda_2 \geqslant \cdots \geqslant \lambda_d$, we first note that the number of nonzero eigenvalues is at most $q = \min(n,d)$. Thus we have

$$\mathrm{Tr}[S] = n = \sum_{k=1}^{q} \lambda_k \quad \text{and} \quad \mathrm{Tr}[S^2] = \sum_{k=1}^{q} \lambda_k^2. \tag{7}$$

Minimizing $\mathrm{Tr}[S^2]$ subject to the constraint $\mathrm{Tr}[S] = n$ gives the inequality. Equality holds if and only if $\lambda_k = n/q$, $k = 1,\ldots,q$. Thus for $n \leqslant d$, S is a projector onto an n-dimensional subspace, implying that the vectors $|\psi_k\rangle$ are orthogonal, and if $n \geqslant d$, $S = (n/d)I$, implying that the set $\{|\psi_k\rangle\}$ is a tight frame. □

Since the frame potential of P is $\mathrm{Tr}[S^2] = d^3 = n^2/d$, the theorem establishes immediately that P is a tight frame, hence P is also a POVM.

For P to be informationally complete, the d^2 operators $\Pi_k = |\phi_k\rangle\langle\phi_k|$ must be linearly independent so that they span the space of operators. The linear independence follows from considering the rank of their Gram matrix $(\Pi_j, \Pi_k) = \mathrm{Tr}[\Pi_j^\dagger \Pi_k] = (d\delta_{jk} + 1)/(d+1)$, which being circulant (each row is a cyclic shift of the previous row), has eigenvalues given by the Fourier transform of one of the rows. A simple calculation reveals that due to the combination of constant term and Kronecker delta, the eigenvalues are exactly the same as the values in any row. Since no eigenvalues are zero, the Gram matrix has full rank, the projection operators Π_k are linearly independent, and P is informationally complete.

Since every rank-one POVM is a tight frame, a SIC–POVM P is clearly something more. To fully elucidate the properties and applications of P, we need to introduce *spherical t-designs*. Building on the result of Benedetto and Fickus, we can establish a connection between frames and spherical t-designs applicable to the SIC–POVM problem.

A *spherical t-design* is a set of n normalized vectors $\{|\phi_k\rangle \in \mathbb{S}^d\}$ such that the average value of any tth order polynomial $f_t(\psi)$ over the set $\{|\phi_k\rangle\}$ is equal to the average of $f_t(\psi)$ over *all* normalized vectors $|\psi\rangle$. Note that if a set is a t-design, it is also an s-design for all $s \leqslant t$, since an sth order polynomial is also a tth order polynomial. Spherical t-designs were originally developed as subsets of the real sphere S^d; here we apply the concept to the set $\mathbb{S}^d$.

Let $\mathcal{H} = \mathbb{C}^d$, $\mathcal{H}_t$ be the t-fold tensor product of such spaces, and $\mathcal{S}_t$ be the symmetric subspace of $\mathcal{H}_t$, and consider a function $f_t : \mathcal{H} \to \mathbb{C}$ defined as

$$f_t(\psi) = \langle \Psi^t | F_t | \Psi^t \rangle, \quad |\Psi^t\rangle = |\psi\rangle^{\otimes t}, \quad |\psi\rangle \in \mathcal{H}, \tag{8}$$

where the choice of f_t is equivalent to a choice of a symmetric operator $F_t \in \mathcal{B}(\mathcal{S}_t)$. Such a function is a tth order polynomial function on $\mathcal{H}$. We can decompose F_t into a sum of product operators, i.e., $F_t = \Sigma_k \otimes_{j=1}^t A_{j;k}$; thus any such function can be decomposed into monomial terms like

$$\langle \Psi^t | \bigotimes_{j=1}^{t} A_j | \Psi^t \rangle = \prod_{j=1}^{t} \langle \psi | A_j | \psi \rangle. \tag{9}$$

Without loss of generality, we can restrict our attention to such monomial functions and rewrite them as

$$f_t(\psi)=\prod_{j=1}^{t}\mathrm{Tr}[A_j|\psi\rangle\langle\psi|]=\mathrm{Tr}\left[\left(\bigotimes_{j=1}^{t}A_j\right)\Pi_\psi^{\otimes t}\right],\quad \Pi_\psi=|\psi\rangle\langle\psi|. \tag{10}$$

Since the set $\{|\phi_k\rangle\}$ is a t-design if and only if the average of any f_t over $\{|\phi_k\rangle\}$ is equal to its average over all $|\psi\rangle\in\mathbb{S}^d$, we are led to compute the average of an arbitrary monomial term:

$$\langle f_t\rangle=\int \mathrm{d}\psi\,\mathrm{Tr}\left[\left(\bigotimes_{j=1}^{t}A_j\right)\Pi_\psi^{\otimes t}\right]=\mathrm{Tr}\left[\left(\bigotimes_{j=1}^{t}A_j\right)\int \mathrm{d}\psi\,\Pi_\psi^{\otimes t}\right]=\mathrm{Tr}\left[\left(\bigotimes_{j=1}^{t}A_j\right)K_t\right]. \tag{11}$$

Hence we focus on finding K_t, since it effectively takes the average of f_t. A spherical t-design is then a set of vectors for which

$$S_t=\sum_{k=1}^{n}|\Phi_k^t\rangle\langle\Phi_k^t|=nK_t,\quad |\Phi_k^t\rangle=|\phi_k\rangle^{\otimes t}. \tag{12}$$

Note that S_t is the t-fold tensor-product analog of the frame operator S.

To find the operator K_t, note that K_t has support only on the symmetric subspace $\mathcal{S}_t$. Further, because K_t is invariant under any $U^{\otimes t}$ for $U\in\mathrm{SU}(d)$, we conclude that $K_t\propto\Pi_{\mathrm{sym}}$, the projector onto $\mathcal{S}_t$. (Recall that $\mathcal{S}_t$ is an irreducible invariant subspace of the group consisting of the operators $U^{\otimes t}$.) Finally, to determine the constant of proportionality, we consider the average of the trivial function $f_t(\psi)=1$. Equation (11) then becomes $\mathrm{Tr}[K_t]=1$, and since $\mathcal{S}_t$ has dimension $\binom{t+d-1}{d-1}$, we have

$$K_t=\frac{t!(d-1)!}{(t+d-1)!}\Pi_{\mathrm{sym}}. \tag{13}$$

For $t=1$, we see that a 1-design is a tight frame made up of normalized vectors and, hence, also a POVM made up of equally weighted rank-one projectors.

Equation (12) now says that the set $\{|\phi_k\rangle\}$ is a t-design if and only if the set $\{|\Phi_k^t\rangle\}$ is a tight frame on $\mathcal{S}_t$, whence we can apply Theorem 1 to obtain the following result.

Theorem 2: *A set of normalized vectors* $\{|\phi_k\rangle\in\mathbb{S}^d\}_{k=1}^n$ *with* $n\geqslant\binom{t+d-1}{d-1}$ *forms a spherical* t*-design if and only if*

$$\mathrm{Tr}[S_t^2]=\sum_{j,k}|\langle\phi_j|\phi_k\rangle|^{2t}=\frac{n^2t!\,(d-1)!}{(t+d-1)!}. \tag{14}$$

Furthermore, this value is the global minimum of $\mathrm{Tr}[S_t^2]$.

This theorem links the spherical t-design property with the minimization of the tth frame potential, $\mathrm{Tr}[S_t^2]$. Immediately we can infer that every SIC–POVM is a 2-design since $\mathrm{Tr}[S_2^2]=\Sigma_{j,k}|\langle\phi_j|\phi_k\rangle|^4=2d^3/(d+1)$, the required value for a 2-design. The converse is also true, namely, every 2-design with $n=d^2$ elements is a SIC–POVM. To show this, let $\lambda_{jk}=|\langle\phi_j|\phi_k\rangle|^2$, $j\neq k$, and interpret these λ_{jk} as coordinates in $\mathbb{R}^{d^2(d^2-1)}$. Using the values of the frame potentials for a 2-design with $n=d^2$ elements, we can write

$$\sum_{j\neq k}\lambda_{jk}=\mathrm{Tr}(S^2)-d^2=\frac{d^2(d^2-1)}{d+1}\quad\text{and}\quad\sum_{j\neq k}\lambda_{jk}^2=\mathrm{Tr}(S_2^2)-d^2=\frac{d^2(d^2-1)}{(d+1)^2}. \tag{15}$$

The first equation describes a plane and the second a sphere. They intersect at the single tangent point $\lambda_{jk}=1/(d+1)$, thus showing that all 2-designs with d^2 elements are SIC–POVMs. These considerations make clear that the crucial distinguishing property of a SIC–POVM is that it is also a 2-design. Moreover, this ensures that minimizing the second frame potential, as we do in the numerical work reported in Sec. IV, yields vectors that do indeed form a SIC–POVM.

Furthermore, d^2 is the smallest number of elements a 2-design can have, so a SIC–POVM is a *minimal* 2-design (see also Ref. 16). Theorem 2 does not provide the minimum number of states, $n_{\min}$, for a t-design in d dimensions, but we can establish lower bounds. For the $t=2$ case, consider again the steps leading to the definition of the operator K_t. In carrying out the average of the function f_2, we could have written

$$\langle f_2\rangle = \mathrm{Tr}\left[A_2 \int \mathrm{d}\psi\, |\psi\rangle\langle\psi|A_1|\psi\rangle\langle\psi|\right] = \mathrm{Tr}[A_2\mathcal{G}(A_1)] \tag{16}$$

and thus considered the superoperator $\mathcal{G}:\mathcal{B}(\mathbb{C}^d)\to\mathcal{B}(\mathbb{C}^d)$. Here $\mathcal{G}(UAU^\dagger)=U\mathcal{G}(A)U^\dagger$ for any $U\in \mathrm{SU}(d)$, so by Schur's lemma, $\mathcal{G}$ is some linear combination of projectors onto the invariant subspaces of U acting on $\mathcal{B}(\mathbb{C}^d)$. These invariant subspaces are (i) the (d^2-1)-dimensional subspace of traceless operators and (ii) the one-dimensional subspace spanned by the identity operator I. Thus we can write $\mathcal{G}=a\mathcal{I}+b\mathbf{I}$ where $\mathcal{I}(A)=A$ and $\mathbf{I}(A)=\mathrm{Tr}[A]I$ (i.e., $\mathcal{I}$ is the identity superoperator, and $\mathbf{I}$ projects onto the identity operator). To find a and b, we first let $A_1=A_2=I$, which gives the function $f_2(\psi)=1$, so that Eq. (16) yields $d(a+bd)=1$. Next we consider $A_1=A_2=|\phi\rangle\langle\phi|$, for which $\langle f_2\rangle=\int \mathrm{d}\psi\,|\langle\phi|\psi\rangle|^4=a+b$. We can use Eqs. (11) and (13) to show that $\langle f_2\rangle=2/d(d+1)$; combined with the previous result, this implies $a=b=1/d(d+1)$. Therefore, $\mathcal{G}$ has no null subspace, must be rank-d^2, and cannot be constructed from less than d^2 linearly independent rank-one superoperators. Similar arguments can be applied to all spherical t-designs. By similar rearrangements, we can make several different types of operators K_t', and the rank of each serves as a lower bound on the number of vectors required to comprise a t-design.

III. GROUP COVARIANCE

Our results are obtained by considering group-covariant sets, so it is appropriate to specialize to this case. The SIC–POVM P is group covariant if there exists a group G with a d-dimensional projective unitary representation $\{U_g\}$ such that (i) P is invariant under any U_g, i.e., for any $|\phi_j\rangle\in P$ and any U_g, $U_g|\phi_j\rangle\in P$ (up to a phase), and (ii) $\{U_g\}$ acts transitively on P, i.e., for any $|\phi_j\rangle,|\phi_k\rangle\in P$, there exists U_g such that $U_g|\phi_j\rangle=|\phi_k\rangle$ (also up to a phase). Assuming group covariance simplifies the search for SIC–POVMs. We simply search for a fiducial vector such that $P=\{U_g|\phi\rangle\}$ is a SIC–POVM (note that the transitivity property implies that the order of G must be at least d^2). To do this, we use groups such that $\{U_g|\phi\rangle\}$ is a 1-design, i.e., a POVM, for any normalized vector $|\phi\rangle$, and then we search for a particular vector $|\phi\rangle$ such that $|\langle\phi|U_g|\phi\rangle|^2=1/(d+1)$ for all $g\neq e$. All other inner products are then guaranteed to have this value due to the group action.

We suspect the case of group covariance to be general for the following reason. Consider the map $\alpha:\mathbb{S}^d\to\mathcal{B}(\mathbb{C}^d)$ that takes a normalized vector to the corresponding projector, i.e., $\alpha(|\phi_j\rangle)=|\phi_j\rangle\langle\phi_j|$. Now consider the operators

$$\sigma_j=\sqrt{\frac{d}{d-1}}\left(|\phi_j\rangle\langle\phi_j|-\frac{I}{d}\right) \quad . \tag{17}$$

Being both traceless and Hermitian, these operators lie in a subspace of $\mathcal{B}(\mathbb{C}^d)$ that is isomorphic to $\mathbb{R}^{d^2-1}$; indeed, since $(\sigma_j,\sigma_j)=1$, they all lie on the unit sphere in $\mathbb{R}^{d^2-1}$. This sphere is a generalization of the Bloch sphere for two-dimensional systems, the difference being that for $d>2$, not all operators on the sphere are images of vectors in $\mathbb{S}^d$ under the map α. From the SIC–POVM condition (1), one finds immediately that

$$(\sigma_j,\sigma_k)=-\frac{1}{d^2-1} \quad \forall\, j\neq k. \tag{18}$$

This is the condition for the d^2 operators $\{\sigma_j\}$ to form a regular simplex in $\mathbb{R}^{d^2-1}$, whose automorphism group is the permutation group S_{d^2}. Given this result, some group covariance

seems natural. One is tempted to think that from here it is a simple matter to establish the existence of the set P. This is not the case, however, as working in the operator space obscures the very difficult task of determining when a given operator is the image of some element of $\mathbb{S}^d$ under the map α. In the same vein, most of the elements of the permutation group cannot be represented in this framework as unitary transformations of $\mathbb{C}^d$; thus, while we know that any G satisfying the conditions above must be a subgroup of S_{d^2}, it is not obvious which subgroups are candidates.

The outstanding choice for G is the group $\mathbb{Z}_d \times \mathbb{Z}_d$, as described in the conjecture. We note in passing that using this group to find a SIC–POVM makes P a Gabor or Weyl–Heisenberg frame, this being the definition of such a frame;[10] such a SIC–POVM P is useful in defining finite-dimensional analogs of the familiar P and Q quasidistributions of infinite dimensions. The group's usefulness here stems from the fact that, for any normalized $|\psi\rangle \in \mathbb{S}^d$,

$$S_\psi = \sum_{jk} D_{jk} |\psi\rangle\langle\psi| D_{jk}^\dagger = dI, \tag{19}$$

a fact readily checked by direct calculation.

The property in Eq. (19) of producing a 1-design for any input state is quite general. The following argument is adapted from Proposition 3 of Ref. 23. Any set of d^2 orthogonal unitary operators T_j, thus satisfying $\mathrm{Tr}[T_j^\dagger T_k] = d\delta_{jk}$, is a complete set for expanding operators in $\mathcal{B}(\mathbb{C}^d)$; the unitary operators $\{D_{jk}\}$ are one example of operators that satisfy this orthogonality condition. It is a simple matter to turn the completeness relation into $\Sigma_k T_k C T_k^\dagger = d\,\mathrm{Tr}[C] I$ for any operator C. Simply consider the inner product of two arbitrary operators A and B. The completeness relation means that

$$(A,B) = \frac{1}{d} \sum_k (A,T_k)(T_k,B). \tag{20}$$

Setting $A = |\phi_1\rangle\langle\phi_2|$ and $B = |\psi_1\rangle\langle\psi_2|$ [which we can do without loss of generality because such outer products span $\mathcal{B}(\mathbb{C}^d)$], we find

$$\langle\phi_1|\psi_1\rangle\langle\psi_2|\phi_2\rangle = \frac{1}{d} \sum_k \langle\phi_1|T_k|\phi_2\rangle\langle\psi_2|T_k^\dagger|\psi_1\rangle, \tag{21}$$

from which it follows that $\Sigma_k T_k |\phi_2\rangle\langle\psi_2| T_k^\dagger = d\,\langle\psi_2|\phi_2\rangle$, whence the result follows.

Thus the property of producing a 1-design regardless of the fiducial $|\phi_0\rangle$ is common to all groups of size d^2 whose representation operators are a complete, orthogonal set. Such groups were introduced by Knill in connection with quantum error-correcting codes and are called ''nice error bases'' or unitary error bases.[14,15] Klappenecker and Rötteler have kindly detailed all such nice error bases up to dimension 10, so we can apply them to the problem at hand.[12,13,25] Only the nice error bases associated with the group $\mathbb{Z}_d \times \mathbb{Z}_d$ exist in every dimension, thus accounting for our focus on this group.

IV. ANALYTIC SIC–POVMS

Here we concentrate specifically on using the group $\mathbb{Z}_d \times \mathbb{Z}_d$. Fixing the representation operators D_{jk} of this group we can determine the set of fiducial vectors that under the group action make a SIC–POVM. From this we can determine also the number of distinct SIC–POVMs generated by our fixed representation. In three dimensions there are an uncountably infinite number of such covariant SIC–POVMs, but in two dimensions there are just two, and in four, 16. We write the fiducial state as

$$|\phi\rangle = \sum_k r_k e^{i\theta_k} |k\rangle, \tag{22}$$

where we can, of course, immediately choose $\theta_0 = 0$.

A. $d=2$

The two solutions, represented as column vectors in the standard basis, are

$$\left\{ \frac{1}{\sqrt{6}} \begin{pmatrix} \sqrt{3+\sqrt{3}} \\ e^{i\pi/4}\sqrt{3-\sqrt{3}} \end{pmatrix}, \quad \frac{1}{\sqrt{6}} \begin{pmatrix} -\sqrt{3-\sqrt{3}} \\ e^{i\pi/4}\sqrt{3+\sqrt{3}} \end{pmatrix} \right\}. \tag{23}$$

These have a simple interpretation on the Bloch sphere, where the nontrivial group operators are simply rotations by π about the x, y, and z axes, respectively. Then the Bloch vectors of the two fiducial states are $\pm(1,1,1)/\sqrt{3}$, and the two SIC–POVM states thus formed are regular tetrahedra, each one related to the other by inversion of the Bloch vectors.

B. $d=3$

For r_0 satisfying $1/\sqrt{2} < r_0 < \sqrt{2/3}$, define

$$r_\pm(r_0) = \tfrac{1}{2} r_0 \pm \tfrac{1}{2}\sqrt{2 - 3r_0^2}. \tag{24}$$

Hence $0 < r_- \leqslant 1/\sqrt{6} \leqslant r_+ < 1/\sqrt{2} < r_0 \leqslant \sqrt{2/3}$. The complete set of fiducial states, represented as column vectors in the standard basis, is then

$$\left\{ \begin{pmatrix} r_0 \\ r_+ e^{i\theta_1} \\ r_- e^{i\theta_2} \end{pmatrix}, \begin{pmatrix} \text{plus all vectors formed} \\ \text{by permuting of elements} \end{pmatrix} \middle| \ \theta_1, \theta_2 \in \left\{ \frac{\pi}{3}, \pi, \frac{5\pi}{3} \right\}, \frac{1}{\sqrt{2}} < r_0 \leqslant \sqrt{\frac{2}{3}} \right\}$$
$$\cup \left\{ \begin{pmatrix} 1/\sqrt{2} \\ e^{i\theta_1}/\sqrt{2} \\ 0 \end{pmatrix}, \begin{pmatrix} \text{plus all vectors formed} \\ \text{by permuting of elements} \end{pmatrix} \middle| \ 0 \leqslant \theta_1 < 2\pi \right\}. \tag{25}$$

C. $d=4$

Now let

$$r_0 = \frac{1 - 1/\sqrt{5}}{2\sqrt{2-\sqrt{2}}} \quad , \quad r_1 = (\sqrt{2}-1) r_0 \quad , \quad r_\pm = \tfrac{1}{2}\sqrt{1 + 1/\sqrt{5} \pm \sqrt{1/5 + 1/\sqrt{5}}}, \tag{26}$$

along with

$$a = \arccos \frac{2}{\sqrt{5+\sqrt{5}}}, \quad b = \arcsin \frac{2}{\sqrt{5}}, \tag{27}$$

and define the set

$$\Omega \equiv \{((-1)^m(a/2+b/4) + \pi(m+2n+7j+1)/4,\ \pi(2k+1)/2, \quad (-1)^m(-a/2+b/4)$$
$$+ \pi(m+2n+3j+4k+1)/4) \mid j,k,m = 0,1 \ \text{ and } \ n = 0,\ldots,3\}. \tag{28}$$

The complete set of fiducial states, represented as column vectors in the standard basis, is now

TABLE I. Number of SIC–POVM sets generated by a fixed representation of the group $\mathbb{Z}_d \times \mathbb{Z}_d$ in dimensions 2 through 7. The infinity in dimension 3 is uncountable.

d	#(SIC–POVMs)
2	2
3	∞
4	16
5	80
6	96
7	336

$$\left\{ \begin{pmatrix} r_0 \\ r_+ e^{i\theta_+} \\ r_1 e^{i\theta_1} \\ r_- e^{i\theta_-} \end{pmatrix}, \begin{pmatrix} r_0 \\ r_- e^{i\theta_-} \\ r_1 e^{i\theta_1} \\ r_+ e^{i\theta_+} \end{pmatrix}, \begin{pmatrix} \text{plus all vectors formed} \\ \text{by cycling of elements} \end{pmatrix} \middle| \ (\theta_+, \theta_1, \theta_-) \in \Omega \right\}. \tag{29}$$

V. NUMERICAL SIC–POVMS

Because analytic solutions to the SIC–POVM condition (1) are so few, our conjectures are based almost entirely on numerical evidence (even the $d=4$ solution was originally inspired by close examination of numerical solutions). To find numerical instances of P, we simply minimize the second frame potential $\mathrm{Tr}[S_2^2]$ over sets of d^2 normalized vectors generated by a representation of $\mathbb{Z}_d \times \mathbb{Z}_d$ from a vector $|\phi\rangle$. It is also possible to vary independently the d^2 elements of P, but this is much less efficient; taking advantage of the group-covariance conjecture permits us to search a space of $O(d)$ complex parameters instead of $O(d^3)$ complex parameters.

The quantity that we minimize, $\Sigma_{j,k}|\langle\phi|D_{jk}|\phi\rangle|^4$, is proportional to the frame potential because of the group covariance. Since it is a quartic function of $|\phi\rangle$, we have to use numerical methods to minimize it, using either Mathematica (simpler) or C++ (much faster). The method used is an adaptive conjugate gradient method; this has the advantage of converging with exponential rapidity to a local minimum, but the disadvantage of being insensitive to global conditions. As a result, the most time-intensive portion of the computation by far is identifying one of the global minima among the many local minima.

Once the correct minimum is located, we quickly obtain P such that Eq. (1) is satisfied to an accuracy of 10^{-8}. The sole exception to this rule is $d=3$ (where an exact analytic solution is known): in $d=3$ there exists a continuously infinite family of solutions, and this degeneracy makes numerical solution difficult. For every dimension between $d=5$ and $d=45$, however, we have found $\mathbb{Z}_d \times \mathbb{Z}_d$-covariant solutions to within machine precision.[26]

Additionally, in small dimensions, one can attempt an exhaustive search for *all* possible $\mathbb{Z}_d \times \mathbb{Z}_d$-covariant SIC–POVMs, by simply running the minimization many times with differing presumptive fiducial states, tabulating all the while the distinct SIC–POVM fiducial states found. Table I lists the results for the number of distinct SIC–POVMs.

Finally, we have tested some of the other nice error bases tabulated by Klappenecker and Rötteler. These are also easy handled, and although not all groups were tested, at least four groups were found to generate SIC–POVM sets. In the notation of the library of small groups used by GAP3, GAP4, and MAGMA, these groups are G(36,11), G(36,14), G(64,8), and G(81,9). Each of these solutions has an accuracy of 10^{-15} in the individual vector inner products. Perhaps surprisingly, many of the tabulated groups do not seem to yield group-covariant SIC–POVMs.

VI. ODDS AND ENDS

A rigorous proof of existence of SIC–POVMs in all finite dimensions seems tantalizingly close, yet remains somehow distant. Although the numerical evidence makes very clear the relevance of the group $\mathbb{Z}_d \times \mathbb{Z}_d$, this is not definitively established. Given the apparent importance of

$\mathbb{Z}_d \times \mathbb{Z}_d$, it would seem to be just a short step to some general form for an operator whose eigenvectors could be a fiducial state, but a proof by this method has not been forthcoming. For instance, in three dimensions the Fourier transform operator has an eigenvector that is a fiducial state (the one associated with the eigenvalue i), but this does not hold in general. In five dimensions a fiducial vector can be found among the degenerate eigenvectors of a particular $\mathbb{Z}_3$ subgroup of the normalizer of $\mathbb{Z}_d \times \mathbb{Z}_d$ in $\mathrm{SU}(d)$, but there is no such subgroup at all in the normalizer for dimension seven. The group-theoretic structure of SIC–POVMs is exceedingly rich, however, and ongoing efforts to understand the full automorphism group of a SIC–POVM might yield insights into operators that yield fiducial states. We hope that by establishing the framework and providing motivating numerical results in this paper, a proof might be completed.

Finally, regardless of whether their existence can be proved rigorously, SIC–POVMs appear to exist in many dimensions. They might be of use in many areas of quantum information theory—signal ensembles, quasidistributions on discrete phase space, error-correcting codes, and quantum measurement, just to name a few. In addition, they appear to be connected to a number of interesting mathematical problems, including spherical codes and the putative existence of mutually unbiased bases.

A method to generate traveling wave solutions of the generalized modified Kadomtsev–Petviashvili equation is reported and several physical solutions, including conditions of their existence, are presented. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1737813]

I. INTRODUCTION

As is well known, the Kadomtsev–Petviashvili equations (KPI, KPII) are universal models for the propagation of weakly nonlinear dispersive long waves which are essentially one directional, with weak transverse effects.[1] Both KPI and KPII have been solved by the inverse scattering technique.[2] Certain physical problems[3,4] motivated the investigation of generalizations of the KP equations.[5] Recently, the $(2+1)$-dimensional modified KP equation[6]

$$\psi_t - \tfrac{1}{8}(\psi_{xxx} - 6\psi^2\psi_x + 6\psi_x\partial_x^{-1}\psi_y + 3\partial_x^{-1}\psi_{yy}) = 0 \tag{1}$$

was solved by a decomposition procedure.[7] The generalized KPI equation

$$(\psi_t + (\psi^{q+1})_x + \psi_{xxx})_x - \psi_{yy} = 0, \quad q \in \mathbb{R} \ , \tag{2}$$

used as a model to describe the evolution of sound waves in antiferromagnetics,[3] was treated by a virial method.[8]

In this article we consider the generalized modified Kadomtsev–Petviashvili equation (gmKPE)

$$\psi_{xt} + ((a + b\psi^q)\psi^q\psi_x)_x + c\psi_{xxxx} - \sigma^2\psi_{yy} = 0, \tag{3}$$

where a,b,c,q are real constants and $\sigma^2 = \pm 1$.

II. TRAVELING WAVE SOLUTIONS

We look for real traveling wave solutions

$$\psi(x,y,t) = g(z), \tag{4}$$

with $z = x + ky + vt$. The ansatz (4) implies $\partial_x^{-1} = k\partial_y^{-1}$ and hence Eqs. (1) and (2) are particular cases of Eq. (3), subject to ansatz (4). Our main purpose is to prove the following theorem.

Theorem: Suppose that q is real, $q \neq 0, \pm 1/2, \pm 1, \pm 2$ and the parameters a,b,c,k,σ,v satisfy the condition

$$\frac{a^2}{(q+1)(q+2)^2} \geqslant \frac{b(v - k^2\sigma^2)}{2q+1}. \tag{5}$$

Then there exists a real and bounded solution of Eq. (3) of the form (4). Moreover, for

$$\frac{k^2\sigma^2-v}{c}<0 \tag{6}$$

this solution is periodic and for

$$\frac{k^2\sigma^2-v}{c}\geqslant 0 \tag{7}$$

this solution is solitary wavelike.

Remark 1: The exact solutions from this Theorem can be found in Eqs. (22) and (23).

Proof of Theorem: Substitution of Eq. (4) into Eq. (3) leads to the ODE

$$(v-k^2\sigma^2+ag^q+bg^{2q})g_{zz}+cg_{zzzz}+(ag^{q-1}+2bg^{2q-1})q(g_z)^2=0 \tag{8}$$

that can be integrated once to yield

$$(v-k^2\sigma^2+ag^q+bg^{2q})g_z+cg_{zzz}=C_1, \tag{9}$$

where C_1 is an arbitrary constant. For simplicity we continue with $C_1=0$. Applying the transformation

$$g(z)=f(z)^{1/q}, \quad q\neq 0 \tag{10}$$

and multiplying by $f^{3-(1/q)}$, Eq. (9) reads

$$\frac{1}{q^3}\{c(q-1)(2q-1)(f_z)^3-3c(q-1)qff_zf_{zz} + q^2f^2((v-k^2\sigma^2+(a+bf)f)f_z+cf_{zzz})\}=0. \tag{11}$$

We look for particular real solutions $f(z)$ of Eq. (11) that satisfy

$$R(f)\equiv(f_z)^2=\alpha f^4+4\beta f^3+6\gamma f^2+4\delta f+\epsilon. \tag{12}$$

As is well known[9,10] these solutions $f(z)$ can be expressed in terms of Weierstrass' elliptic function $\wp$. The coefficients α, β, γ, δ, ϵ in Eq. (12) have to be determined by the parameters of the gmKPE.

Equation (12) implies

$$f_{zz}=2\alpha f^3+6\beta f^2+6\gamma f+2\delta,$$
$$f_{zzz}=6(\gamma+2\beta f+\alpha f^2)f_z. \tag{13}$$

Inserting Eqs. (12) and (13) into Eq. (11) and dividing by f_z one obtains

$$\frac{1}{q^3}\{(bq^2+c\alpha(q+1)(2q+1))f^4+(aq^2+2c\beta(q+1)(q+2))f^3 + (6c\gamma+vq^2-k^2\sigma^2q^2)f^2+2c\delta(q-1)(q-2)f+c\epsilon(q-1)(2q-1)\}=0. \tag{14}$$

The sought for coefficients α, β, γ, δ, ϵ and the parameter q can be determined from Eq. (14). Disregarding the case $q=0$ (the gmKPE is linear in this case) and excluding first the cases

$$q=\pm\tfrac{1}{2},\pm 1,\pm 2, \tag{15}$$

and setting equal to zero the coefficients of f^ν in Eq. (14) one obtains

$$\alpha=-\frac{b\cdot q^2}{c(q+1)(2q+1)},\quad \beta=-\frac{aq^2}{2c(q+1)(q+2)},$$

$$\gamma=\frac{q^2(k^2\sigma^2-v)}{6c},\quad \delta=\epsilon=0,\quad c\neq 0. \tag{16a}$$

If q is equal to one of the values in (15), Eq. (14) yields for $q=-\frac{1}{2}$

$$\beta=-\frac{a}{6c},\quad \gamma=\frac{k^2\sigma^2-v}{24c},\quad \delta=\epsilon=0,\quad b=0,\quad c\neq 0, \tag{16b}$$

and arbitrary α;
for $q=-1$

$$\gamma=\frac{k^2\sigma^2-v}{6c},\quad \delta=\epsilon=0,\quad a=b=0,\quad c\neq 0, \tag{16c}$$

and arbitrary α, β;
for $q=-2$

$$\alpha=-\frac{4b}{3c},\quad \gamma=\frac{2(k^2\sigma^2-v)}{3c},\quad \delta=\epsilon=0,\quad a=0,\quad c\neq 0, \tag{16d}$$

and arbitrary β;
for $q=\frac{1}{2}$

$$\alpha=-\frac{b}{12c},\quad \beta=-\frac{a}{30c},\quad \gamma=\frac{k^2\sigma^2-v}{24c},\quad \delta=0,\quad c\neq 0, \tag{16e}$$

and arbitrary ϵ;
for $q=1$

$$\alpha=-\frac{b}{6c},\quad \beta=-\frac{a}{12c},\quad \gamma=\frac{k^2\sigma^2-v}{6c},\quad c\neq 0, \tag{16f}$$

and arbitrary δ, ϵ;
for $q=2$

$$\alpha=-\frac{4b}{15c},\quad \beta=-\frac{a}{6c},\quad \gamma=\frac{2(k^2\sigma^2-v)}{3c},\quad \epsilon=0,\quad c\neq 0, \tag{16g}$$

and arbitrary δ.

Summing up, a subset of traveling wave solutions to Eq. (3) is determined by the ODE (12) where $f(z)=g(z)^q$. The coefficients α, β, γ, δ, ϵ are given by Eqs. (16) relating the coefficients to the parameters of Eq. (3) (a,b,c,q) and of the ansatz (k,v).

It is known since 1865 (Ref. 11) that solutions to Eq. (12) are given by

$$f(z)=f_0+\frac{\sqrt{R(f_0)}\dfrac{d\wp(z;g_2,g_3)}{dz}+\frac{1}{2}R'(f_0)[\wp(z;g_2,g_3)-\frac{1}{24}R''(f_0)]+\frac{1}{24}R(f_0)R'''(f_0)}{2[\wp(z;g_2,g_3)-\frac{1}{24}R''(f_0)]^2-\frac{1}{48}R(f_0)R'''{}'(f_0)}, \tag{17}$$

where the prime denotes differentiation with respect to f and f_0 is any constant, not necessarily a zero of $R(f)$. The invariants g_2, g_3 of Weierstrass' elliptic function $\wp(z;g_2,g_3)$ are related to the coefficients of $R(f)$ according to[12]

$$g_2 = \alpha\epsilon - 4\beta\delta + 3\gamma^2, \tag{18}$$

$$g_3 = \alpha\gamma\epsilon + 2\beta\gamma\delta - \alpha\delta^2 - \gamma^3 - \epsilon\beta^2. \tag{19}$$

The discriminant [of $\wp$ and R (Ref. 13)]

$$\Delta = g_2^3 - 27g_3^2 \tag{20}$$

is suitable to classify the behavior of $f(z)$. In general, $f(z)$ is periodic.[14] If $\Delta = 0$, $g_2 \geqslant 0$, $g_3 \leqslant 0$, $f(z)$ is solitary wavelike and given by[15]

$$f(z) = f_0 + \frac{R'(f_0)}{4\left[e_1 - \frac{R''(f_0)}{24} + 3e_1 \operatorname{csch}^2(\sqrt{3e_1}z)\right]}, \tag{21}$$

where $e_1 = \sqrt[3]{-g_3}$ and f_0 now is a simple root of $R(f)$. In general, $f(z)$ (according to Eqs. (17) and (21)) is not real and bounded. Conditions for real and bounded solutions $f(z)$ can be obtained by considering the phase diagrams of $R(f)$.[16]

Inspection of Eqs. (16) shows that in most cases $\delta = \epsilon = 0$ holds or either δ or ϵ is zero and ϵ or δ is arbitrary. Thus a large set of solutions of Eq. (12) can be found by choosing $\delta = \epsilon = 0$ in Eqs. (16) simplifying the evaluation of the phase diagrams considerably. Following the lines of Ref. 10 real and bounded solutions $f(z)$ are associated to phase diagrams shown in Fig. 1. The periodic bounded solutions to Eq. (12) are associated to diagrams (a), (e). Choosing f_0 in Eq. (17) as the simple root

$$f_0 = -\frac{4\beta + \sqrt{(4\beta)^2 - 24\alpha\gamma}}{2\alpha}$$

evaluation of Eq. (17) yields

$$f(z) = \frac{-(4\beta + \sqrt{(4\beta)^2 - 24\alpha\gamma})(\gamma - 2\wp(z;3\gamma^2, -\gamma^3))}{2(4\beta^2 - 5\alpha\gamma + \beta\sqrt{(4\beta)^2 - 24\alpha\gamma} - 2\alpha\wp(z;3\gamma^2, -\gamma^3))}, \tag{22}$$

subject to $2\beta^2 - 3\alpha\gamma \geqslant 0$, $\gamma < 0$. These two inequalities are equivalent to the conditions (5) and (6). Thus, a subset of periodic solutions $f(z)$ of Eq. (12) compactly is represented by Eq. (22), where the coefficients α, β, γ are related to the parameters a, b, c, σ^2, k, v according to Eqs. (16a)–(16g).

Solitary wavelike solutions are represented by phase diagrams (b), (c), (d), (f), (g), (h) in Fig. 1.

Evaluation of Eq. (21) yields

$$f_{\pm}(z) = \frac{\gamma(\pm 4\beta + \sqrt{(4\beta)^2 - 24\alpha\gamma})\left(\gamma^2 - 1 + 3\gamma^2 \operatorname{csch}^2\left(\sqrt{\frac{3\gamma^3}{2}}z\right)\right)}{2\left(\pm 4\beta^2 + \beta\sqrt{(4\beta)^2 - 24\alpha\gamma} \mp \alpha\gamma(5+\gamma)^2 \mp 3\alpha\gamma^3 \operatorname{csch}^2\left(\sqrt{\frac{3\gamma^3}{2}}z\right)\right)} \tag{23}$$

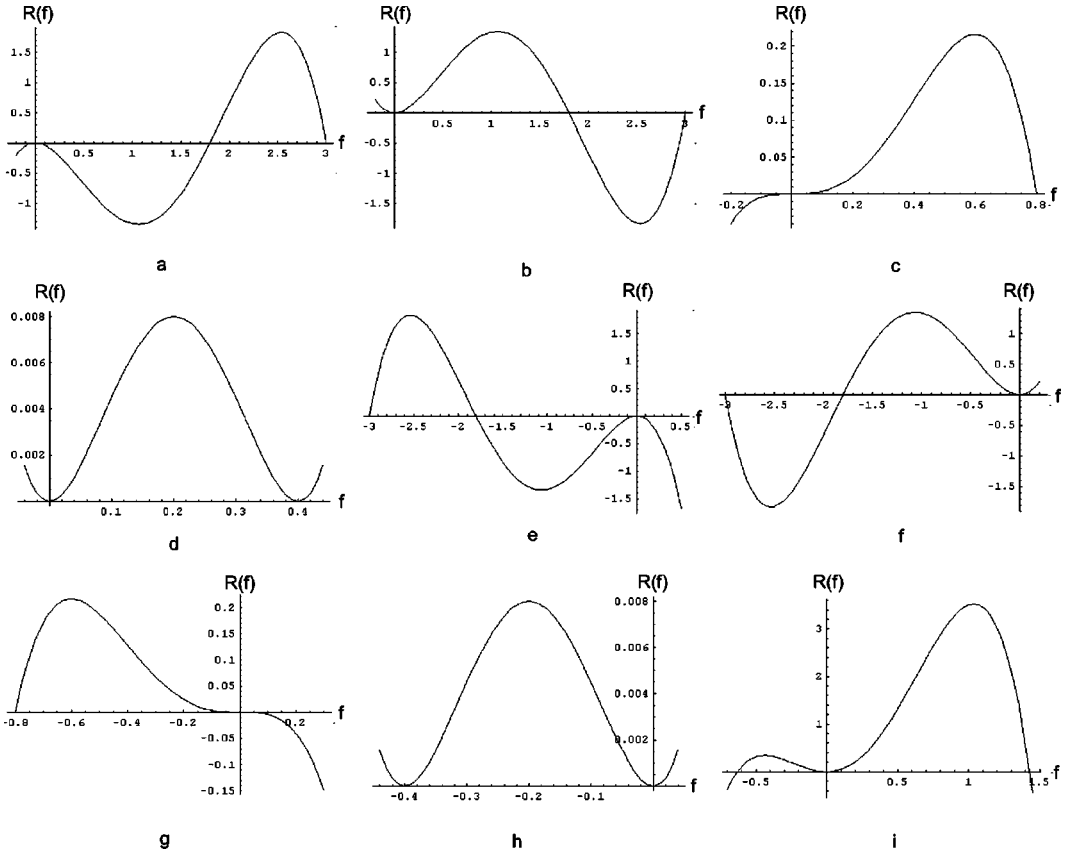

FIG. 1. Phase diagrams associated to real and bounded solutions if $\delta=\epsilon=0$.

for diagrams (b) and (f), where the upper and lower sign corresponds to (b) and (f), respectively, and subject to $\alpha\geqslant 0$, $\gamma>0$ and $2\beta^2-3\alpha\gamma\geqslant 0$. If $\alpha<0$, $\gamma>0$, $2\beta^2-3\alpha\gamma\geqslant 0$ (diagram (i)) two solitary wavelike solutions $f_+(z)$ and $f_-(z)$ exist, represented by Eq. (23). The conditions for these two cases are equivalent to the conditions (5) and (7).

By taking the limiting case ($\gamma\to 0$) of Weierstrass' elliptic function in Eq. (22), diagrams (c), (g) are associated with

$$f(z)=\frac{4\beta}{-\alpha+4\beta^2 z^2}, \tag{24}$$

representing algebraic solitary wavelike solutions.

To find the solutions corresponding to diagrams (d), (h) of Fig. 1 ($\alpha>0,\beta\lesseqgtr 0,\gamma=2\beta^2/3\alpha$) we choose $f_0=-(\beta/\alpha)$ in Eq. (17) and substitute $\wp(z;g_2,g_3)$ for the limiting case $\Delta=0$, $g_3=-(8\beta^6/27\alpha^3)<0$ according to[17]

$$\wp(z;g_2,g_3)=\sqrt[3]{-g_3}\left(1+\frac{3}{\sinh^2(3\sqrt[6]{-g_3}z)}\right)$$

to obtain the kink solitary wavelike solutions

$$f(z)=-\frac{\alpha}{\gamma}\left[1+\tanh\left(\frac{\beta z}{\sqrt{\alpha}}\right)\right],\quad \alpha>0,\quad \beta\lesseqgtr 0. \tag{25}$$

Thus we may conclude that this theorem is proved.

Remark 2: The modified Korteweg–de Vries equation (mKdVE)

$$\psi_t+6\psi^2\psi_x+\psi_{xxx}=0$$

is a particular case of Eq. (3) ($q=1,a=0,b=6,c=1,k=0$). Thus the parameters in (16f) are given by $\alpha=-1,\beta=0,\gamma=-(v/6)$ and δ, ϵ arbitrary. Since we assumed (for simplicity) $\delta=\epsilon=0$ in deriving Eqs. (22)–(25) these solutions belong to the subset of solutions restricted by $\delta=\epsilon=0$ (e.g., if $\gamma=1$ we obtain $f_{\pm}=\pm\sqrt{6}\,\mathrm{sech}(\sqrt{6}z)$ according to Eq. (23)). In this case all solutions (with $\gamma>0$ arbitrary) of the mKdVE exhibit a sech-shape behavior. If $\delta\neq 0,\epsilon\neq 0$ the analysis of the gmKPE and its relation to the mKdVE seems rather involved.

Remark 3: To evaluate the traveling wave (Weierstrass) solutions $\psi=f(x+ky+vt)^{1/q}$ of Eq. (3) we have to discriminate between positive and negative q and between positive and negative f (cf. Fig. 1).[18] If q is positive and f is positive, real and bounded, $\psi(x+ky+vt)$ is real and given by Eqs. (22)–(25) subject to the corresponding constraints (cf. Figs. 1(a)–1(d), partly (i)) for the various triples $\{\alpha,\beta,\gamma\}$ according to Eqs. (16). In this case q is restricted either by (16e)–(16g) or by (16a) with $q>0$, subject to restrictions for α, β, γ so that f is positive (cf. Figs. 1(a)–1(d), partly (i)).

If f is negative, real and bounded, the restrictions for positive q are different. In this case the parameter q must satisfy

$$q=\frac{1}{2m},\quad m\in\mathbb{N}. \tag{26}$$

Thus, the cases (16f), (16g) have to be excluded, the cases (16b), (16e) are consistent with (26) if α, β, γ fullfill the constraints for f to be negative (cf. Figs. 1(e)–1(h), partly (i)). These constraints also must be satisfied in case (16a). Hence one obtains for this case

$$\alpha<0,\ \beta<0,\ \gamma\leqslant 0\quad\text{or}\quad \alpha>0,\ \beta>0,\ \gamma>0\left(\text{or}\ \gamma=\frac{2\beta^2}{3\alpha}\right)\quad\text{or}\quad \alpha<0,\ \gamma>0, \tag{27}$$

with

$$\alpha=\frac{-b}{2c(1+m)(1+2m)},\quad \beta=\frac{-a}{2c(1+2m)(1+4m)},\quad \gamma=\frac{k^2\sigma^2-v}{24cm^2},\quad m\in\mathbb{N} \tag{28}$$

as constraints for $q=1/2m$, if f, represented by Eqs. (22)–(25), is negative, real and bounded. If q is negative, $f(z)$ may be unbounded but $f=0$ must be excluded for $g(z)$ to be real and bounded. The condition $f\neq 0$ is satisfied for a certain interval in (a), (e) of Fig. 1. Phase diagram (a) is associated to $f>0$ so that $g(z)$ is real and bounded for negative q with no further restriction. Diagram (e) is related to $f<0$ leading to $q=-(1/2m),m\in\mathbb{N}$.

It follows from these remarks and the proof of the Theorem that we proved the following corollaries.

Corollary 1: Let $q=-1/2$ or $q=-2$. Assume that in Eq. (3) $b=0$ if $q=-\frac{1}{2}$ and $a=0$ if $q=-2$, respectively. Assume also that the following condition:

$$2\beta^2-3\alpha\gamma\geqslant 0 \tag{29}$$

holds, where α, β, γ satisfy (16b) and (16d), respectively. Then there exists a real and bounded solution of Eq. (3) of the form (4) and this solution is periodic if condition (6) holds and solitary wavelike if condition (7) is valid.

Corollary 2: Let $q=1/2, q=1$ or $q=2$. Assume that inequality (29) is satisfied and the conditions

$$\Delta=0, \quad g_2\geqslant 0, \quad g_3\leqslant 0 \tag{30}$$

hold, where α, β, γ, δ, ϵ are given by (16e), (16f), and (16g), respectively. Then there exists a solitary wavelike solution of Eq. (3) of the form (4) which is real and bounded. If the conditions (30) are not satisfied, then Eq. (3) has a periodic solution of the form (4) which is also real and bounded.

Remark 4: If $q=-1$, we have to assume, in order to use the method, that $a=0$ and $b=0$ (cf. (16c)). In this case Eq. (8) will be linear with constant coefficients (corresponding to $q=0$ in Eq. (3)) and can be solved by standard methods.

III. SUMMARY

We have shown that via an ansatz $\psi(x,y,t)=g(z)=(f(z))^{1/q}$, $z=x+ky+vt$, and subject to the nonlinear ordinary differential equation (12) a rather large set of solutions to the gmKPE can be obtained. Periodic and solitary wave solutions can be presented in compact form in terms of Weierstrass' elliptic functions and its limiting cases ($\Delta=0$, $g_3\leqslant 0$), respectively. A phase diagram analysis (cf. Fig. 1) yields conditions for the existence of real bounded solutions and conditions for the parameters $\{a,b,c,\sigma^2,k,v,q\}$ of the gmKPE.

A grading of a Lie algebra is called fine if it cannot be further refined. Fine gradings provide basic information about the structure of the algebra. There are six fine gradings of the semisimple Lie algebra of type $A_1 \times A_1$ over the complex number field. An explicit description of all the fine gradings of $A_1 \times A_1$ is given in terms of the four-dimensional representation $o(4,\mathbb{C})$ of the algebra. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1737054]

I. INTRODUCTION

This paper is the fourth one in a series,[1–3] containing description of maximal gradings, i.e., gradings not refinable any further, for simple/semisimple Lie algebras of particular types.

The algebra $D_2 = o(4,\mathbb{C})$ is exceptional among the classical Lie algebras by the fact that it is not simple. It is semisimple and consists of two ideals A_1. This widens its group of automorphisms, and thus the number of its fine gradings is bigger than one would expect for an algebra of dimension 6. Compare that, e.g., $B_2 = C_2$ of dimension 10 has three fine gradings, A_2 of dimension 8 has four fine gradings, $A_3 = D_3$ of dimension 15 has eight fine gradings. All the fine gradings of the three cases mentioned—A_2, $B_2 = C_2$, and $A_3 = D_3$—are found in Refs. 1–3. The fine gradings of $sl(3,\mathbb{C})$ (i.e., A_2) and of its real forms are found in Ref. 1, in Ref. 2 there are the fine gradings of $sp(4,\mathbb{C})$, $o(5,\mathbb{C})$, and of their real forms (i.e., $C_2 = B_2$). Finally, in Ref. 3 the fine gradings of $sl(4,\mathbb{C})$ and $o(6,\mathbb{C})$ (i.e., $A_3 = D_3$) are given.

The nonsimplicity of $o(4,\mathbb{C})$ also implies the rich structures of fine gradings of real forms. Existence of an automorphism that permutes the two ideals $sl(2,\mathbb{C})$ determines which of the fine gradings of $o(4,\mathbb{C})$ appear in the real forms of $o(4,\mathbb{C})$. In principle, one could study the fine gradings of real forms independently of the complex algebra. However, the gradings of real forms are naturally related to the gradings of the complex algebra. For simplicity of the presentation we have chosen to describe the fine gradings of the real forms separately in the forthcoming paper. Let us point out that the number of fine gradings of the real forms varies between two on the real form $o(4)$ and six on the real form $o(2,2)$.

The algebra D_2 has two nonequivalent representations of dimension 4. One of them is of the type $o(4,\mathbb{C}) = \{X \in \mathbb{C}^{4\times 4} \mid XK + KX^T = 0\}$, where $K = K^T$, $\det K \neq 0$. Often one puts $K = I_4$, and then the algebra is represented by matrices that are skew symmetric with respect to transposition.

The second representation of dimension 4 is reducible. It decomposes into two irreducible ones of dimension 2 each. In each of them one of the ideals is represented trivially. In terms of the highest weights of the representations one has the representation $(1)(0)+(0)(1)$, while the first case is irreducible with the highest weight $(1)(1)$. The reducible representation can be written as

[a)]Electronic mail: patera@crm.umontreal.ca
[b)]Electronic mail: pelantova@km1.fjfi.cvut.cz
[c)]Electronic mail: svobodov@km1.fjfi.cvut.cz

$$\left\{ \begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix} \middle| A,B \in \mathbb{C}^{2\times 2}, \operatorname{tr} A = \operatorname{tr} B = 0 \right\}.$$

Isomorphic gradings in these different representations look different. Moreover, the reducible representation admits a symplectic invariant form so that it can be viewed as representing the subalgebra of type $sl(2,\mathbb{C})+sl(2,\mathbb{C})$ of $sp(4,\mathbb{C})$.

II. PRELIMINARIES

A. Basic terminology

For motivation and for general comments concerning our undertaking, we refer the reader to Refs. 2 and 3. Here we confine ourselves to our immediate task, namely the fine gradings of $o(4,\mathbb{C})$. A *fine grading* Γ of a Lie algebra L is a decomposition of L into a direct sum of subspaces $0 \neq L_j \subset L$, $j \in \mathcal{J}$,

$$\Gamma: L = \bigoplus_{j \in \mathcal{J}} L_j, \tag{1}$$

such that for each pair j,k of indices from the index set $\mathcal{J}$ the commutator fulfills

$$[L_j, L_k] \subset L_l \tag{2}$$

for some $l \in \mathcal{J}$. With suitable choice of the index set $\mathcal{J}$, we are able to ensure that the index l from (2) turns into $[L_j, L_k] \subset L_{j+k}$ for $[L_j, L_k] \neq 0$. In order to do so we embed the index set $\mathcal{J}$ into an additive commutative group. The indices $j \in \mathcal{J}$ can be multicomponent ones. We use here from one up to four components.

A fine grading cannot be further refined while remaining a grading: it decomposes the Lie algebra into a maximal number of subspaces. Particularly interesting are the gradings which decompose the algebra into the sum of one-dimensional subspaces. Indeed, they provide a basis which is convenient to work with. A graded basis reflects structural properties of the Lie algebra such as the simplicity of commutation relations of the generators.

Fine gradings have a special position among all the gradings. That is because out of the fine gradings one can derive all gradings of the algebra, namely by "coarsening" the fine gradings, i.e., merging some of the grading subspaces. However, it is a rather complicated process and currently the result is only known for Lie algebras of rank 2.

Gradings $\Gamma_1: L = \oplus_{j \in \mathcal{I}} L_j$ and $\Gamma_2: L = \oplus_{m \in \mathcal{J}} K_m$ of the Lie algebra L are equivalent when

(i) $|\mathcal{I}| = |\mathcal{J}|$ and

(ii) there exist an automorphism h on L and a bijection $\pi: \mathcal{I} \to \mathcal{J}$ fulfilling the property $h(L_j) = K_{\pi(j)}$ for all $j \in \mathcal{I}$. Equivalence of the gradings Γ_1 and Γ_2 is denoted by $\Gamma_1 \cong \Gamma_2$.

The Lie algebra $o(4,\mathbb{C})$ is a direct sum of two $sl(2,\mathbb{C})$ algebras. Thus some of the fine gradings of $o(4,\mathbb{C})$ arise from fine gradings of $sl(2,\mathbb{C})$. Therefore it is logical to begin by description of fine gradings of the Lie algebra $sl(2,\mathbb{C})$.

B. Fine gradings of the Lie algebra $sl(2,\mathbb{C})$

The Lie algebra $sl(2,\mathbb{C})$ consists of 2×2 matrices with zero trace, i.e.,

$$sl(2,\mathbb{C}) = \left\{ \begin{pmatrix} a & b \\ c & -a \end{pmatrix} \middle| a,b,c \in \mathbb{C} \right\}. \tag{3}$$

Its two fine gradings are notorious. They are also the two types of fine gradings that occur in all the Lie algebras of the type $sl(n,\mathbb{C})$: one is the Cartan (root) grading, the other one is the Pauli grading (studied in Ref. 4). (See Table I.)

TABLE I. The two nonequivalent fine gradings of the Lie algebra $sl(2,\mathbb{C})$; the index sets $\mathcal{J}$ are embedded into additive groups $\mathbb{Z}_3, \mathbb{Z}_2\times\mathbb{Z}_2$, respectively, so that they reflect the commutation relations between the grading subspaces.

Cartan grading	Pauli grading
$\Upsilon_1: sl(2,\mathbb{C}) = L_0 \oplus L_1 \oplus L_2$	$\Upsilon_2: sl(2,\mathbb{C}) = L_{01} \oplus L_{10} \oplus L_{11}$
$L_0 = \mathbb{C}\cdot\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$	$L_{01} = \mathbb{C}\cdot\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$
$L_1 = \mathbb{C}\cdot\begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$	$L_{10} = \mathbb{C}\cdot\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$
$L_2 = \mathbb{C}\cdot\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$	$L_{11} = \mathbb{C}\cdot\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$
$\mathcal{J}\subset\mathbb{Z}_3$	$\mathcal{J}\subset\mathbb{Z}_2\times\mathbb{Z}_2$
$[L_j, L_k] = L_{j+k \bmod 3}$	$[L_{jk}, L_{lm}] = L_{(j+l)(k+m)\bmod 2,2}$
for all $j,k\in\mathcal{J}, j\neq k$	for all $(j,k),(l,m)\in\mathcal{J}, (j,k)\neq(l,m)$

It is convenient to present here also the graphs depicting the commutation relations within the gradings. The vertices of the graph stand for the grading subspaces, each of them denoted by the label of the subspace. It is convenient to visualize a grading as follows. Two vertices are connected by an edge when the two corresponding subspaces do not commute, i.e., their commutator does not equal zero. In that case, necessarily, their commutator must fall into one of the grading subspaces; its label is given by the grading property (2). Note that the labels are always chosen in such a way that the label of the commutator of two subspaces is the sum of labels of the two commuted subspaces (using a suitable modulo). (See Fig. 1.)

An important use of these graphs is the following: **Two fine gradings are equivalent if and only if their graphs of commutators are equivalent.**

Later on, when a fine grading of the Lie algebra $o(4,\mathbb{C})$ is in the form of a direct sum of two fine gradings of $sl(2,\mathbb{C})$, the graph related to that grading is purely composed of two appropriate graphs.

C. MAD-groups on $o(4,\mathbb{C})$

When describing fine gradings of a complex simple Lie algebra L we can follow the result published in Ref. 5 (using subgroups of the group $\mathrm{Aut}\,L$ of all automorphisms on L).

Theorem 2.1: *A decomposition $\Gamma: L = \oplus_j L_j$ is a fine grading of a simple Lie algebra L over an algebraically closed field of characteristic zero if and only if there exists a maximal Abelian subgroup $\mathcal{G}\subset \mathrm{Aut}\,L$ of diagonalizable automorphisms on L (MAD-group) such that Γ is a decomposition of L into simultaneous eigensubspaces L_j of all elements from $\mathcal{G}$.*

But $o(4,\mathbb{C}) = sl(2,\mathbb{C})\times sl(2,\mathbb{C})$ is not simple, so only one implication in the aforesaid theorem holds, thus that each fine grading of $o(4,\mathbb{C})$ is a decomposition of L into simultaneous eigenspaces

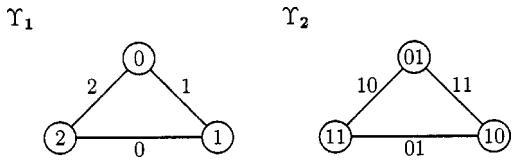

FIG. 1. These graphs depict commutation relations in the two fine gradings of the Lie algebra $sl(2,\mathbb{C})$: Υ_1 represents the Cartan grading and Υ_2 the Pauli grading. When summing the labels in order to obtain the label of the commutator we use mod 3, mod 2,2, respectively, for Υ_1, Υ_2.

of all automorphisms from some MAD-group. But there exists a MAD-group in $\mathrm{Aut}\, o(4,\mathbb{C})$ which generates a grading that is not fine.

However, we use this method with the six nonconjugate MAD-groups on $o(4,\mathbb{C})$. Five of them generate a fine grading of $o(4,\mathbb{C})$, one of them does not; namely the maximal torus. The torus generates a grading with one two-dimensional and four one-dimensional subspaces. Nevertheless, the two-dimensional subspace can be split into two one-dimensional subspaces so that we obtain a decomposition of $o(4,\mathbb{C})$ which remains a grading. All the six (nonequivalent) fine gradings of $o(4,\mathbb{C})$ consist of six one-dimensional subspaces. With each of the fine gradings we provide a graph depicting the commutation relations in the grading. It is obvious from these graphs that the six fine gradings are nonequivalent.

In terms of 4×4 matrices the Lie algebra $o(4,\mathbb{C})$ is expressed as

$$o_K(4,\mathbb{C})=\{X\in\mathbb{C}^{4\times 4}\,|\,XK+KX^T=0\} \tag{4}$$

with $K\in\mathbb{C}^{4\times 4}$ symmetric ($K^T=K$) and nonsingular. All the representations $o_K(4,\mathbb{C})$ are equivalent, and, having a grading on one of them, we can transfer it onto another representation of $o(4,\mathbb{C})$ by $\widetilde{L}_j=\mathrm{Ad}_M L_j$ with a suitable matrix M. We provide our results on the representation $o_K(4,\mathbb{C})$ with

$$K=\begin{pmatrix}0&1\\-1&0\end{pmatrix}\otimes\begin{pmatrix}0&1\\-1&0\end{pmatrix}=\begin{pmatrix}0&0&0&1\\0&0&-1&0\\0&-1&0&0\\1&0&0&0\end{pmatrix},$$

which reflects how $o(4,\mathbb{C})$ arises as a product of two Lie algebras $sl(2,\mathbb{C})$:

$$o(4,\mathbb{C})=\left\{X\in\mathbb{C}^{4\times 4}\,\middle|\,X\begin{pmatrix}0&0&0&1\\0&0&-1&0\\0&-1&0&0\\1&0&0&0\end{pmatrix}+\begin{pmatrix}0&0&0&1\\0&0&-1&0\\0&-1&0&0\\1&0&0&0\end{pmatrix}X^T=0\right\}$$

$$=\left\{\begin{pmatrix}a&b&c&0\\d&e&0&c\\f&0&-e&b\\0&f&d&-a\end{pmatrix}\,\middle|\,a,\ldots,f\in\mathbb{C}\right\}, \tag{5}$$

$$(sl(2,\mathbb{C})\otimes I)+(I\otimes sl(2,\mathbb{C}))=\left\{\begin{pmatrix}A&B\\C&-A\end{pmatrix}\otimes I\right\}+\left\{I\otimes\begin{pmatrix}D&E\\F&-D\end{pmatrix}\right\}$$

$$=\left\{\begin{pmatrix}A+D&E&B&0\\F&A-D&0&B\\C&0&-A+D&E\\0&C&F&-A-D\end{pmatrix}\,\middle|\,A,\ldots,F\in\mathbb{C}\right\}. \tag{6}$$

As well as for each Lie algebra of the type $o(n,\mathbb{C})$ (with the exception of $n=8$), the group $\mathrm{Aut}\, o(4,\mathbb{C})$ contains only inner automorphisms Ad_A with $A\in O(4,\mathbb{C})$,

$$O(4,\mathbb{C})=\{A\in\mathbb{C}^{4\times 4}|AKA^T=K\}.$$

The inner automorphism Ad_A acts on elements $X\in o(4,\mathbb{C})$ by $\mathrm{Ad}_A(X)=A^{-1}XA$.

TABLE II. The full list of nonconjugate maximal Abelian subgroups of diagonalizable automorphisms (MAD-groups) on $o(4,\mathbb{C})$: MAD-group $\mathcal{H}=\{\mathrm{Ad}_A|A\in H_{\mathrm{Ad}}\}$.

	H_{Ad}
$\mathcal{H}_1$	$\{A=\mathrm{diag}(\alpha,\alpha^{-1})\otimes\mathrm{diag}(\beta,\beta^{-1}),\alpha,\beta\in\mathbb{C}\setminus\{0\}\}$
$\mathcal{H}_2$	$\{A=\sigma_j\otimes\sigma_k,\ j,k=0,1,2,3\}$
$\mathcal{H}_3$	$\{A=\sigma_j\otimes\mathrm{diag}(\alpha,\alpha^{-1}),\alpha\in\mathbb{C}\setminus\{0\}\}$
$\mathcal{H}_4$	$\left\{A\in\left\{\pm\begin{pmatrix}\alpha&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&\alpha^{-1}\end{pmatrix},\pm\begin{pmatrix}\alpha&0&0&0\\0&0&1&0\\0&1&0&0\\0&0&0&\alpha^{-1}\end{pmatrix}\right\},\alpha\in\mathbb{C}\setminus\{0\}\right\}$
$\mathcal{H}_5$	$\left\{A\in\left\{\begin{pmatrix}\varepsilon_1&0&0&0\\0&\varepsilon_2&0&0\\0&0&\varepsilon_2&0\\0&0&0&\varepsilon_1\end{pmatrix},\begin{pmatrix}\varepsilon_1&0&0&0\\0&0&\varepsilon_2&0\\0&\varepsilon_2&0&0\\0&0&0&\varepsilon_1\end{pmatrix},\begin{pmatrix}0&0&0&\varepsilon_1\\0&\varepsilon_2&0&0\\0&0&\varepsilon_2&0\\\varepsilon_1&0&0&0\end{pmatrix},\begin{pmatrix}0&0&0&\varepsilon_1\\0&0&\varepsilon_2&0\\0&\varepsilon_2&0&0\\\varepsilon_1&0&0&0\end{pmatrix}\right\},\varepsilon_j=\pm1\right\}$
$\mathcal{H}_6$	$\left\{A\in\left\{\pm\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix},\pm\begin{pmatrix}1&0&0&0\\0&-1&0&0\\0&0&-1&0\\0&0&0&1\end{pmatrix},\pm\begin{pmatrix}1&0&0&0\\0&0&1&0\\0&-1&0&0\\0&0&0&-1\end{pmatrix},\pm\begin{pmatrix}1&0&0&0\\0&0&-1&0\\0&1&0&0\\0&0&0&-1\end{pmatrix},\right.\right.$ $\left.\left.\pm\begin{pmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{pmatrix},\pm\begin{pmatrix}0&0&0&1\\0&0&-1&0\\0&-1&0&0\\1&0&0&0\end{pmatrix},\pm\begin{pmatrix}0&0&0&-1\\0&-1&0&0\\0&0&1&0\\1&0&0&0\end{pmatrix},\pm\begin{pmatrix}0&0&0&-1\\0&1&0&0\\0&0&-1&0\\1&0&0&0\end{pmatrix}\right\}\right\}$

As already mentioned, there are six (nonequivalent) fine gradings of $o(4,\mathbb{C})$ corresponding to six (nonconjugate) MAD-groups $\mathcal{H}_1,\ldots,\mathcal{H}_6$ listed in Table II (derived from Ref. 6). The symbols σ_k, $k=0,1,2,3$, stand for 2×2 Pauli matrices,

$$\sigma_0=\begin{pmatrix}1&0\\0&1\end{pmatrix},\quad \sigma_1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0&1\\-1&0\end{pmatrix},\quad \sigma_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix}. \tag{7}$$

We describe each MAD-group $\mathcal{H}$ by listing out a group of matrices H_{Ad} such that $\mathcal{H}=\{\mathrm{Ad}_A|A\in H_{\mathrm{Ad}}\}$.

The three MAD-groups $\mathcal{H}_1,\mathcal{H}_2$, and $\mathcal{H}_3$ contain only such automorphisms Ad_A, where A is a direct sum of two parts, $A_1\otimes I$ and $I\otimes A_2$ (with $I,A_1,A_2\in\mathbb{C}^{2\times2}$). It follows that the three fine gradings Γ_1,Γ_2, and Γ_3 generated by $\mathcal{H}_1,\mathcal{H}_2$, and $\mathcal{H}_3$, respectively, have basis elements either in the form $X=Y\otimes I$ or $X=I\otimes Y$, $Y\in sl(2,\mathbb{C})$. They arise as $\Gamma=(\Upsilon_j\otimes I)\oplus(I\otimes\Upsilon_k)$, Υ_j,Υ_k being one of the two fine gradings of $sl(2,\mathbb{C})$ described in Table I.

The remaining three fine gradings $\mathcal{H}_4,\mathcal{H}_5$, and $\mathcal{H}_6$ do not conserve such a nice structure.

III. THE SIX FINE GRADINGS OF THE LIE ALGEBRA $O(4,\mathbb{C})$

As explained in Sec. II C, we find the fine gradings as simultaneous eigensubspaces of all elements (automorphisms) of a MAD-group $\mathcal{H}_k$. But we never need to use all elements from $\mathcal{H}_k$ when searching for the fine grading, but just a few of them, sometimes even one is enough. In this section we provide a list of all the six nonequivalent fine gradings of $o(4,\mathbb{C})$; not only in terms of basis elements of the grading subspaces L_j, but also in terms of so-called grading labels, i.e., indices $j\in\mathcal{J}$ such that $[L_j,L_k]\subset L_{j+k}$ for all $j,k\in\mathcal{J}$, $[L_j,L_k]\neq0$ [as described in (2)]; the index set $\mathcal{J}$ being a subset of a finite additive group. This embedding of $\mathcal{J}$ into an additive group is very

TABLE III. The three fine gradings of $o(4,\mathbb{C})$ which are purely a composition of fine gradings Υ_j of $sl(2,\mathbb{C})$. Υ_1 is the Cartan (root) grading of $sl(2,\mathbb{C})$ with indices from the additive group $\mathbb{Z}_3$, Υ_2 is the Pauli grading of $sl(2,\mathbb{C})$ with indices from the additive group $\mathbb{Z}_2\times\mathbb{Z}_2$.

$\Gamma_1=(\Upsilon_1\otimes I)\oplus(I\otimes\Upsilon_1)$	Cartan/root grading
$\Gamma_2=(\Upsilon_2\otimes I)\oplus(I\otimes\Upsilon_2)$	
$\Gamma_3=(\Upsilon_2\otimes I)\oplus(I\otimes\Upsilon_1)$	

useful because the indices $j\in\mathcal{J}$ provide the vital information on the structure of the fine grading, namely the commutation relations. (It can of course occur that $j+k\notin\mathcal{J}$ for some $j,k\in\mathcal{J}$. In this case, necessarily, $[L_j,L_k]=0$.)

The additive group into which $\mathcal{J}$ is embedded is not uniquely defined. However, we use the smallest possible (regarding its order).

A. Fine gradings of $o(4,\mathbb{C})$ corresponding to the MAD-groups $\mathcal{H}_1$, $\mathcal{H}_2$, and $\mathcal{H}_3$

These fine gradings are composed of gradings Υ_1 and Υ_2 of the algebra $sl(2,\mathbb{C})$ as depicted in Table III. The graded subspaces of Υ_1 are labeled by the group $\mathbb{Z}_3$ and the graded subspaces of Υ_2 are labeled by the group $\mathbb{Z}_2\times\mathbb{Z}_2$. Therefore, the fine grading Γ_1 is labeled by $\mathbb{Z}_3\times\mathbb{Z}_3$, the fine grading Γ_2 is labeled by $\mathbb{Z}_2\times\mathbb{Z}_2\times\mathbb{Z}_2\times\mathbb{Z}_2$, and the fine grading Γ_3 is labeled by $\mathbb{Z}_2\times\mathbb{Z}_2\times\mathbb{Z}_3$.

The graphs corresponding to the gradings Γ_1, Γ_2, and Γ_3 are formed by two independent components, each of them representing one of the grading Υ_i of $sl(2,\mathbb{C})$.

B. Γ_4, fine grading of $o(4,\mathbb{C})$ corresponding to the MAD-group $\mathcal{H}_4$

Now we are coming to the three fine gradings that cannot be expressed as $(\Upsilon_j\otimes I)\oplus(I\otimes\Upsilon_k)$, Υ_j,Υ_k being fine gradings of $sl(2,\mathbb{C})$. Instead there are only three pairs of commuting grading subspaces (i.e., only three zeroes in all the commutations). (See Fig. 2.)

The fine grading Γ_4 is obtained with the use of just one element

$$\mathrm{Ad}_A\in\mathcal{H}_4,\quad A=\begin{pmatrix}\alpha & 0 & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 0 & \dfrac{1}{\alpha}\end{pmatrix};$$

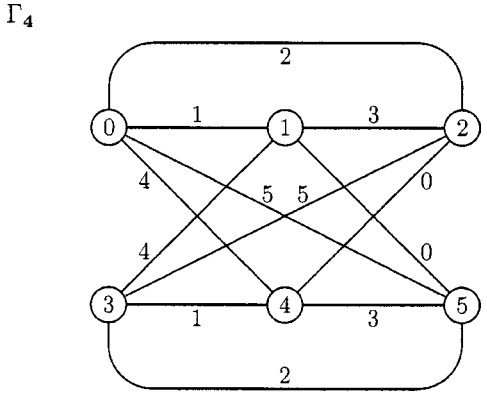

FIG. 2. This graph depicts the commutation relations in the fine grading Γ_4 of $o(4,\mathbb{C})$. The graph is connected and thus the grading is not a direct sum of gradings of $sl(2,\mathbb{C})$ as were the cases of Γ_1, Γ_2, and Γ_3. Commuting two subspaces shows in the graph as summing the respective labels mod 6.

TABLE IV. Eigenvalues of Ad_A corresponding to eigensubspaces L_j, grading subspaces of $o(4,\mathbb{C})$ in the fine grading Γ_4.

Eigensubspace	L_0	L_1	L_2	L_3	L_4	L_5
Eigenvalue	1	α	$-\alpha^{-1}$	-1	$-\alpha$	α^{-1}

the eigenvalues corresponding to the eigensubspaces of Ad_A are listed in Table IV.

The index set $\mathcal{J}$ of indices denoting subspaces L_j equals the additive group $\mathbb{Z}_6$,

$$[L_j,L_k]\subset L_{j+k \bmod 6},$$

$$L_0:X_1=\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&-1\end{pmatrix},\quad L_3:X_4=\begin{pmatrix}0&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&0\end{pmatrix},$$

$$L_1:X_2=\begin{pmatrix}0&0&0&0\\1&0&0&0\\1&0&0&0\\0&1&1&0\end{pmatrix},\quad L_4:X_5=\begin{pmatrix}0&0&0&0\\1&0&0&0\\-1&0&0&0\\0&-1&1&0\end{pmatrix}, \tag{8}$$

$$L_2:X_3=\begin{pmatrix}0&1&-1&0\\0&0&0&-1\\0&0&0&1\\0&0&0&0\end{pmatrix},\quad L_5:X_6=\begin{pmatrix}0&1&1&0\\0&0&0&1\\0&0&0&1\\0&0&0&0\end{pmatrix}.$$

C. Γ_5, fine grading of $o(4,\mathbb{C})$ corresponding to the MAD-group $\mathcal{H}_5$

All automorphisms from the MAD-group $\mathcal{H}_5$ have just two possible eigenvalues, namely ± 1. Thus at least three automorphisms $\mathrm{Ad}_A\in\mathcal{H}_5$ are needed to split $o(4,\mathbb{C})$ into six one-dimensional eigensubspaces. We use the following triplet $\mathrm{Ad}_{A_1},\mathrm{Ad}_{A_2},\mathrm{Ad}_{A_3}$:

$$A_1=\begin{pmatrix}0&0&0&1\\0&-1&0&0\\0&0&-1&0\\1&0&0&0\end{pmatrix},\quad A_2=\begin{pmatrix}0&0&0&1\\0&0&-1&0\\0&-1&0&0\\1&0&0&0\end{pmatrix},\quad A_3=\begin{pmatrix}0&0&0&1\\0&1&0&0\\0&0&1&0\\1&0&0&0\end{pmatrix}.$$

The relationship between the grading subspaces L_j of $o(4,\mathbb{C})$ and these automorphisms can be described as follows:

$$L_{jkl}=\{X\in o(4,\mathbb{C})\mid \mathrm{Ad}_{A_1}X=(-1)^jX,\ \ \mathrm{Ad}_{A_2}X=(-1)^kX,\ \ \mathrm{Ad}_{A_3}X=(-1)^lX\},$$

and, clearly, the index set $\mathcal{J}$ is embedded into the additive group $\mathbb{Z}_2\times\mathbb{Z}_2\times\mathbb{Z}_2$. (See Fig. 3.)

Let us continue by providing the list of basis elements of the grading subspaces:

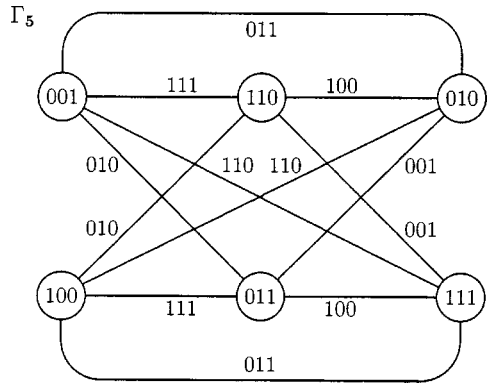

FIG. 3. This graph depicts the commutation relations in the fine grading Γ_5 of $o(4,\mathbb{C})$. Commuting two subspaces shows in the graph as summing the respective labels mod 2,2,2.

$$L_{001}:X_1=\begin{pmatrix} 0 & 1 & 1 & 0 \\ -1 & 0 & 0 & 1 \\ -1 & 0 & 0 & 1 \\ 0 & -1 & -1 & 0 \end{pmatrix}, \quad L_{010}:X_4=\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$L_{100}:X_2=\begin{pmatrix} 0 & 1 & -1 & 0 \\ -1 & 0 & 0 & -1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & -1 & 0 \end{pmatrix}, \quad L_{110}:X_5=\begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix}, \tag{9}$$

$$L_{111}:X_3=\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \quad L_{011}:X_6=\begin{pmatrix} 0 & 1 & -1 & 0 \\ 1 & 0 & 0 & -1 \\ -1 & 0 & 0 & 1 \\ 0 & -1 & 1 & 0 \end{pmatrix}.$$

The commutation relations are expressed with help of the indices $j \in \mathcal{J}$ by

$$[L_{jkl},L_{mno}] \subset L_{(j+m)(k+n)(l+o)\,\mathrm{mod}\,2,2,2} \quad \text{for } [L_{jkl},L_{mno}] \neq 0.$$

D. Γ_6, fine grading of $o(4,\mathbb{C})$ corresponding to the MAD-group $\mathcal{H}_6$

Finally we have come to the last case, the fine grading generated by the MAD-group $\mathcal{H}_6$. (See Fig. 4.) This MAD-group contains not only automorphisms with eigenvalues ± 1, but also with complex eigenvalues $\pm i$, so we are able to reach a splitting into six one-dimensional subspaces/eigenspaces with the use of two elements $\mathrm{Ad}_{A_1},\mathrm{Ad}_{A_2} \in \mathcal{H}_6$ only,

$$A_1=\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}, \quad A_2=\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ & 0 & 0 & -1 \end{pmatrix},$$

the latter one with complex eigenvalues. The indices $j \in \mathcal{J} \subset \mathbb{Z}_2 \times \mathbb{Z}_4$ of subspaces L_j are set down in accordance with the eigenvalues by

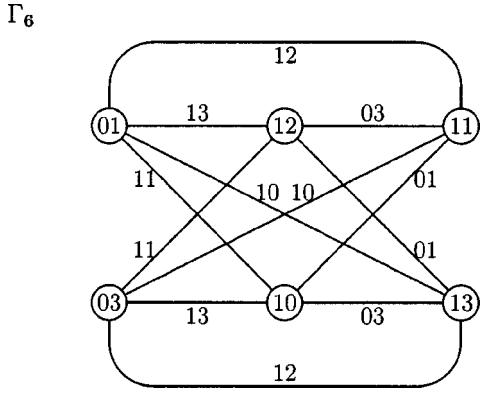

FIG. 4. This graph depicts the commutation relations in the fine grading Γ_6 of $o(4,\mathbb{C})$. Commuting two subspaces shows in the graph as summing the respective labels mod 2,4.

$$L_{jk}=\{X\in o(4,\mathbb{C})\,|\,\mathrm{Ad}_{A_1}X=(-1)^jX,\mathrm{Ad}_{A_2}X=i^kX\}.$$

The list of basis elements of L_j follows:

$$L_{10}:X_1=\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&-1\end{pmatrix},\quad L_{03}:X_4=\begin{pmatrix}0&1&i&0\\1&0&0&i\\i&0&0&1\\0&i&1&0\end{pmatrix},$$

$$L_{12}:X_2=\begin{pmatrix}0&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&0\end{pmatrix},\quad L_{11}:X_5=\begin{pmatrix}0&1&-i&0\\-1&0&0&-i\\i&0&0&1\\0&i&-1&0\end{pmatrix},\tag{10}$$

$$L_{01}:X_3=\begin{pmatrix}0&1&-i&0\\1&0&0&-i\\-i&0&0&1\\0&-i&1&0\end{pmatrix},\quad L_{13}:X_6=\begin{pmatrix}0&1&i&0\\-1&0&0&i\\-i&0&0&1\\0&-i&-1&0\end{pmatrix}.$$

Commutation relations within this grading are summoned by

$$[L_{jk},L_{lm}]\subset L_{(j+l)(k+m)\bmod 2,4}\quad\text{for }[L_{jk},L_{lm}]\neq 0.$$

E. Nonequivalence of the six fine gradings $\Gamma_1,\ldots,\Gamma_6$

Having two fine gradings $\Gamma_1:L=\oplus_{j\in\mathcal{I}}L_j$ and $\Gamma_2:L=\oplus_{m\in\mathcal{J}}K_m$ of a Lie algebra L, we call Γ_1 and Γ_2 equivalent when both $|\mathcal{I}|=|\mathcal{J}|$ and there exist an automorphism h on L and a bijection $\pi:\mathcal{I}\to\mathcal{J}$ fulfilling the property $h(L_j)=K_{\pi(j)}$ for all $j\in\mathcal{I}$. From the structural point of view equivalent gradings are the same because the commutation relations are the same. Thus we are only interested in nonequivalent fine gradings of $o(4,\mathbb{C})$.

It is a general rule that if $\mathcal{H}_1,\mathcal{H}_2\subset\mathrm{Aut}\,L$ are Abelian subgroups of diagonalizable automorphisms on the Lie algebra L and Γ_1,Γ_2 gradings of L generated by subgroups $\mathcal{H}_1,\mathcal{H}_2$, respectively, then the gradings Γ_1 and Γ_2 are equivalent if and only if the subgroups $\mathcal{H}_1$ and $\mathcal{H}_2$ are

conjugate, i.e., $\mathcal{H}_2 = h^{-1}\mathcal{H}_1 h$ for some $h \in \mathrm{Aut}\, L$. We have six nonconjugate MAD-groups $\mathcal{H}_1,\ldots,\mathcal{H}_6$ in $\mathrm{Aut}\, o(4,\mathbb{C})$ (according to Ref. 6), and thus our six fine gradings $\Gamma_1,\ldots,\Gamma_6$ are nonequivalent, since they are generated by $\mathcal{H}_1,\ldots,\mathcal{H}_6$.

But their nonequivalence can also be easily seen from the graphs provided with each of the fine gradings, since these graphs reflect directly the commutation relations among the grading subspaces.

Clearly none of the gradings $\Gamma_1,\Gamma_2,\Gamma_3$ is equivalent to any of the gradings $\Gamma_4,\Gamma_5,\Gamma_6$, just because of the number of commuting subspaces (one pair of noncommuting subspaces corresponds to one edge in the graph). Nonequivalence of the gradings $\Gamma_1,\Gamma_2,\Gamma_3$ follows from the fact that they arise as compositions of the fine gradings Υ_1,Υ_2 of $sl(2,\mathbb{C})$ as described in Table III, and Υ_1 is not equivalent to Υ_2.

Now it remains to show the nonequivalence of gradings $\Gamma_4,\Gamma_5,\Gamma_6$:

(i) Γ_4 contains a subspace $M = L_0$ such that $[M,L_j] \subset L_j$ for all the grading subspaces L_j; Γ_5,Γ_6 do not contain such a subspace M.

(ii) In Γ_5 there exists a triplet of grading subspaces such that they make up a three-dimensional subalgebra of $o(4,\mathbb{C})$. In the graph they are represented by vertices 1,3,5. Again, this is not the case of Γ_6.

So we have two independent proofs of nonequivalence of our six fine gradings $\Gamma_1,\ldots,\Gamma_6$.

IV. CONCLUSION

There is indeed a number of applications of the fine gradings described above as well as further questions one may ask related to the gradings of both $o(4,\mathbb{C})$ and its real forms:

(i) One of the motivations for studying the gradings in general is given by the graded contractions of a concrete algebra, in particular the contraction of $o(4,\mathbb{C})$ which preserves the chosen grading. Due to the large number of possible gradings such contraction will yield many Lie algebras.

(ii) The inhomogeneous $o(4,\mathbb{C})$, which is a semidirect product of $o(4,\mathbb{C}) \ltimes T_4$, where T_4 is Abelian subalgebra of four translations in $\mathbb{C}^4$, is complex form of the Poincare Lie algebra. This is one of the most exploited algebras of physics. Knowledge of the fine gradings of $o(4,\mathbb{C})$ enables one to describe all fine gradings of complex Poincare Lie algebra and of its representations. Even more interesting would be the contractions of infinite dimensional representations of the Poincare Lie algebra.[7,8]

(iii) Let us notice that $o(4,\mathbb{C})$ is a maximal semisimple subalgebra of the exceptional simple algebra G_2 and thus the six fine gradings found for $o(4,\mathbb{C})$ can be extended to fine gradings of G_2.

(iv) It would be interesting to describe also the gradings in terms of representations and find the eigenspaces of MAD-groups for all the representation spaces.

(v) This work is a basis for study of gradings of the real forms.

(vi) As among the real forms of $o(4,\mathbb{C})$ is the Lorenz algebra $o(3,1)$, one feels motivated to study the gradings of the infinite dimensional representation of $o(3,1)$. Indeed, those are the representations of $o(3,1)$ of particular interest in physics applications.

(vii) It would be useful to know all the gradings of $o(4,\mathbb{C})$ (not only the fine ones) and their hierarchy. There are tens of these gradings because we are dealing with a semisimple algebra.

(viii) Another interesting point to study would be the normalizer of each grading in the group of automorphisms $\mathrm{Aut}\, o(4,\mathbb{C})$. They describe, in particular, the symmetries of the contraction equations, hence they simplify the process of solving the contraction equations.[9]

(ix) Unexplored application of the normalizers is their action on the universal enveloping algebra of $o(4,\mathbb{C})$.

(x) It is useful to notice that, because of the embedding $o(4,\mathbb{C}) \subset sl(4,\mathbb{C})$, we obtain from the eight fine gradings of $sl(4,\mathbb{C})$ the six fine gradings of $o(4,\mathbb{C})$.

(xi) The graphical presentation of the gradings introduced in this paper offers the possibility to study gradings of more complicated Lie algebras in terms of the corresponding graphs.

Relativistic quantum field theory with a fundamental length

E. Brüning[a)]
School of Mathematical Sciences, University of KwaZulu-Natal, Durban 4000, South Africa

S. Nagamachi[b)]

(Received 19 November 2003; accepted 17 February 2004; published online 10 May 2004)

Since there are indications (from string theory and concrete models) that one must consider relativistic quantum field theories with a fundamental length the question of a suitable framework for such theories arises. It is immediately evident that quantum field theory in terms of tempered distributions and even in terms of Fourier hyperfunctions cannot meet the (physical) requirements. We argue that quantum field theory in terms of *ultra-hyperfunctions* is a suitable framework. For this we propose a set of axioms for the fields and for the sequence of vacuum expectation values of the fields, prove their equivalence, and we give a class of models (analytic, but not entire functions of free fields). © *2004 American Institute of Physics.* [DOI: 10.1063/1.1737055]

I. INTRODUCTION

Relativistic quantum field theory is defined in terms of a set of conditions for which there is strong physical motivation. These conditions are (1) relativistic covariance, (2) energy momentum spectrum compatible with the principles of special relativity, (3) existence of a vacuum state, and (4) completeness of the field. Then there two conditions in which several technical assumptions enter: (5) fields as operator-valued generalized functions (what class of generalized functions?), (6) uniqueness of the vacuum state. Last, but not least, there is the condition of (7) local commutativity of field operators at spacelike separations.

The first mathematically rigorous realization of all these conditions in one theory is that of Wightman and Gårding[1] where fields are defined as operator valued tempered distributions, and a powerful characterization of such a theory in terms of the sequence of vacuum expectation values of the fields has been derived. Soon a number of physically important general results (existence of a PCT operator, connection between spin and statistics, scattering theory, dispersion relations, etc.) were derived. Furthermore one soon learned that theories with nonunique vacuum state can be decomposed into theories with a unique vacuum and one learned that the apparently weaker condition of local commutativity of field operators at sufficiently large spacelike separations implies local commutativity at all spacelike separations. (More details are given in the textbook.[2])

According to string theory there is a length $\ell > 0$ such that one cannot distinguish events which occur in a distance smaller than ℓ. For example, the T-duality of string theory implies the equivalence of two string theories with toroidal compactification whose radii are R and α'/R. Therefore, in string theory, the existence of a fundamental length is suggested. In a distance smaller than the fundamental length, the space–time is melted down (see Refs. 3, 4). Moreover in string theory there is some discussion about space–time uncertainty $\Delta T \Delta X \geqslant \ell_s^2$, which also suggests the existence of a fundamental length (see Refs. 5, 6).

a)Electronic mail: bruning@ukzn.ac.za
b)Electronic mail: shigeaki@pm.tokushima-u.ac.jp

How can we take the existence of a fundamental length into account in a relativistic quantum field theory?

In Wightman's framework, in terms of the field operators $A(x)$, locality is expressed as the condition that the commutator of the field operators vanishes for spacelike separated points, i.e., by $A(x)A(y)-A(y)A(x)=0$ for all $x,y\in\mathbb{R}^4$ with $(x-y)^2<0$. Even if one replaces this condition by the apparently weaker condition that this commutator vanishes for all points $x,y\in\mathbb{R}^4$ which are spacelike separated and are in a certain distance of at least $\ell>0$ from each other, i.e., $(x-y)^2<-\ell^2<0$, one can prove that this commutator vanishes for all spacelike separated points by using the other axioms of the theory (see, for instance, Theorem 19.3 of Ref. 7).

The situation is the same in hyperfunction quantum field theory (see Ref. 8). The reason is that the n-point functionals in both theories are boundary values of holomorphic functions in $\mathrm{Im}(z_{i+1}-z_i)\in V_+$ and as such, distributions and hyperfunctions have the same type of localization property, expressed by the fact that both form a sheaf over space–time (see, for instance, Ref. 9). Thus, in order to formulate a quantum field theory with a fundamental length, a space of generalized functions different from both Schwartz distributions and Fourier hyperfunctions has to be used.

By a variety of reasons, the problem to formulate relativistic quantum field theory in terms of generalized functions which are different from Schwartz distributions and/or Fourier hyperfunctions, has been addressed in the past. One of the main physical motivations was to be able to describe relativistic quantum field theories not only with polynomial but with exponential high energy behavior. Some prominent articles about this and related problems are Refs. 10–19. In these articles, roughly, it is argued that the resulting theory is nonlocalizable if it is formulated in terms of generalized functions for which the underlying test-function space does not contain test functions of compact support.

In Refs. 19, 20, QFT is formulated in terms of generalized functions over the Gelfand–Shilov space S^0. Such a theory is so singular that the condition of locality cannot be defined in any generalized sense. But instead of it, a condition which is called asymptotic commutativity can be defined. By replacing local commutativity by asymptotic commutativity, PTC theorem, spin-statistics relation and the existence of S-matrix are shown. We do not consider these highly singular cases, but we consider the quasilocal case, i.e., the theory with a fundamental length ℓ indicated from string theory. For this theory, PTC theorem, spin-statistics relation and the existence of S-matrix are valid because the axioms of QFT with a fundamental length is stronger than those of QFT with test-function space S^0.

In Ref. 21 a different position is proposed by arguing that generalized functions are localizable in a natural way as soon as they form a sheaf over space–time (this then allows localizable relativistic quantum fields which do not admit any test function of compact support, Ref. 21).

Clearly, in order to formulate a relativistic quantum field theory with a fundamental length, a different type of generalized functions has to be used. The following simple example will provide some insight into the properties of the class of generalized functions which could be used in theories with fundamental length.

Let $\{a_n\}$ be a sequence of real numbers. The support of the distribution $\Sigma_{i=0}^{N}a_n\delta^{(n)}(x)$ is $\{0\}$, but $\Sigma_{n=0}^{\infty}a_n\delta^{(n)}(x)$ does not define a distribution unless all except finitely many of the coefficients a_n vanish. If $\lim_{n\to\infty}[n!a_n]^{1/n}=0$, then $\Sigma_{n=0}^{\infty}a_n\delta^{(n)}(x)$ converges to a hyperfunction. The support of this limit is the same as the supports of the approximating sums, i.e., the hyperfunction has the support $\{0\}$.

Now consider the case $a_n=a^n/n!$ and take the underlying space of test functions into account. If $f(z)$ is a holomorphic function in $|\mathrm{Im}\,z|<\ell$, then, for $|a|<\ell$, we have

$$\left\langle \sum_{n=0}^{\infty}\frac{a^n}{n!}\delta^{(n)}(x),f(x)\right\rangle=\sum_{n=0}^{\infty}\frac{(-a)^n}{n!}f^{(n)}(0)=f(0-a)=\langle\delta(x+a),f(x)\rangle,$$

that is, as an equation for functionals defined on the function space $\mathcal{T}(T(-\ell,\ell))$ whose elements are holomorphic functions in $T(-\ell,\ell)=\mathbb{R}+i(-\ell,\ell)\subset\mathbb{C}$, the identity

$$\sum_{n=0}^{\infty} \frac{a^n}{n!} \delta^{(n)}(x) = \delta(x+a)$$

holds, i.e., the sequence of generalized functions $S_N = \Sigma_{n=0}^{N} (a^n/n!)\, \delta^{(n)}(x)$ with support $\{0\}$ converges [weakly, in the dual space of $\mathcal{T}(T(-\ell,\ell))$] to the generalized function $\delta(x+a)$ with support $\{-a\}$, as $N \to \infty$. However, if $|a| > \ell$, then this sequence does not converge in $\mathcal{T}(T(-\ell,\ell))'$.

This phenomenon can be understood as follows. If $|a| < \ell$, then elements in $\mathcal{T}(T(-\ell,\ell))'$ do not distinguish between the points $\{0\}$ and $\{-a\}$, but if $|a| > \ell$ then elements in $\mathcal{T}(T(-\ell,\ell))'$ can distinguish between the points $\{0\}$ and $\{-a\}$. Since $|a| < \ell$ is arbitrary, one can say that elements in $\mathcal{T}(T(-\ell,\ell))'$ do not distinguish between points which are separated by less than ℓ. Spaces of functionals with this property have been studied under the name of ultra-hyperfunctions in Refs. 22, 23.

In this paper we propose to formulate relativistic quantum field theory with a fundamental length ℓ in terms of tempered ultra-hyperfunctions, i.e., those ultra-hyperfunctions which admit the Fourier transform as an isomorphism of topological vector spaces. To this end we introduce, in analogy to the test function space $\mathcal{T}(T(-\ell,\ell))$ of the above example, the test-function space $\mathcal{T}(T(\mathbb{R}^4))$ of tempered ultra-hyperfunctions according to Refs. 22, 23. Section II studies the basic properties of this space. Furthermore, the range of the Fourier transform on $\mathcal{T}(T(\mathbb{R}^4))$ is determined. It is a space which we call $H(\mathbb{R}^n;\mathbb{R}^n)$ and which is characterized explicitly as a projective limit of Fréchet spaces. This space too is studied in Sec. II.

The following sections contain our proposal of a relativistic quantum field theory with fundamental length $\ell > 0$ in terms of tempered ultra-hyperfunctions. At first it seems impossible to reconcile the requirements of relativistic covariance with the existence of a fundamental length. Note however that the Poincaré group acts (smoothly) on the test-function space $\mathcal{T}(T(\mathbb{R}^4))$ and thus by duality on the fields. The fundamental length is introduced into the theory by the distinguished localization property of ultra-hyperfunctions.

Naturally, the condition of locality (local commutativity) differs considerably from that of standard quantum field theory. We explain our proposal of *extended local commutativity* which is considered to be the counterpart of local commutativity in standard quantum field theory in two steps.

In a first step we have to ensure that, in a quantum field theory with fundamental length ℓ, field operators $A(x_1)$ and $A(x_2)$ at two distinct points x_1 and x_2 can only be distinguished if the distance between the two points x_1 and x_2 is greater than ℓ. In the light of our discussion of the elementary example given above, we propose to express this condition as follows: The functional

$$\mathcal{T}(T(\mathbb{R}^4)) \otimes \mathcal{T}(T(\mathbb{R}^4)) \ni f_1 \otimes f_2 \to (\Phi, A(f_1)A(f_2)\Psi) \tag{1.1}$$

can be extended continuously to $\mathcal{T}(T(L^\ell))$ in some Lorentz frame, for arbitrary elements Φ, Ψ in the domain of the field operators $A(f)$, where

$$T(L^\ell) = \{(z_1, z_2) \in \mathbb{C}^{4\cdot 2}; |\operatorname{Im} z_1 - \operatorname{Im} z_2|_1 < \ell\}$$

and

$$|x|_1 = |x^0| + |\mathbf{x}|, \quad |\mathbf{x}| = \sqrt{\sum_{i=1}^{3} (x^i)^2}. \tag{1.2}$$

In a second step we introduce our concept of *extended local commutativity* which is defined by the condition that the carrier of the functional on $\mathcal{T}(T(\mathbb{R}^4)) \otimes \mathcal{T}(T(\mathbb{R}^4))$

$$f_1 \otimes f_2 \to (\Phi, A(f_1)A(f_2)\Psi) - (\Phi, A(f_2)A(f_1)\Psi) \tag{1.3}$$

is contained in the set

$$W^{\ell}=\{(z_1,z_2)\in\mathbb{C}^{4\cdot 2};z_1-z_2\in V^{\ell}\},$$

that is, the functional can be extended continuously to $\mathcal{T}(W^{\ell})$, where V^{ℓ} is a complex neighborhood of the light cone V as defined in Sec. III.

The localization properties of tempered ultra-hyperfunction are very different from those of Fourier hyperfunctions and Schwartz distributions, but the spectral condition is not so much different from that of Schwartz distributions because the Fourier transformation of tempered ultra-hyperfunctions are distributions (see Proposition 2.5). From this condition it follows that $W_{n-1}(\zeta)$ is holomorphic in a domain

$$\mathcal{V}_{R,\epsilon}=\bigcup_{i=1}^{n-1}\mathcal{V}_{R,\epsilon,i}, \tag{1.4}$$

where for some $\epsilon,R>0$,

$$\begin{aligned}\mathcal{V}_{R,\epsilon,i}=\{\zeta\in\mathbb{C}^{4(n-1)};&\operatorname{Im}\zeta_i\in V_+ +(\ell-\epsilon,\mathbf{0}),\\ &\operatorname{Im}\zeta_j\in V_+ +(R,\mathbf{0}),\quad j\neq i\}.\end{aligned} \tag{1.5}$$

In Sec. IV we study the basic properties of the sequence of n-point functionals $\mathcal{W}_n$ in a relativistic quantum field theory with fundamental length. As a consequence of the defining conditions we get that the function $W_n(\zeta)$ is analytically continued to (1.4) (Proposition 4.7). $W_n(\zeta)$ is analytically continued to the extended domain which contains real points. This enables us to prove, using extended local commutativity, that $\mathcal{W}_n(z)$ is a symmetric function on its domain of holomorphy (Theorem 4.11).

Having collected all basic properties of the sequence of n-point functionals we can prove in Sec. V, that the fields can be reconstructed from the sequence of its n-point functionals (reconstruction theorem).

Obviously one would like to have examples of ultra-hyperfunction quantum fields. In Sec. VI, we use the reconstruction theorem to show that the field $A(x)=:e^{\phi(x)^2}:$, defined by the free neutral scalar field $\phi(x)$, satisfies all our axioms of a relativistic quantum field theory with a fundamental length.

Finally, in an Appendix, we prove Theorem 2.13 which guarantees the uniqueness of the extensions (1.1) and (1.3).

In order to put our results in a proper perspective we conclude the Introduction with a couple of remarks on related research.

Remark 1.1: The type of generalized functions to be used in a relativistic quantum field theory is not given *a priori*, one must make a choice, in accordance with the physical constraints one would like to incorporate.

In Ref. 14, the test-function space $S^{1,\lambda}(\mathbb{R}^4)$ is used. By this choice, $W_{n-1}(\zeta)$ is analytic in

$$\{\zeta\in\mathbb{C}^{4(n-1)};\operatorname{Im}\zeta_i\in V_+ +\sqrt{2}(\ell,\mathbf{0})\}, \tag{1.6}$$

where $\ell=1/e\lambda$ and the theory of $A(x)=:e^{\phi(x)^2}:$ defined by the free field $\phi(x)$ is excluded because the Wightman function $W_{n-1}(\zeta)$ of $A(x)$ is analytic only in (1.4). However with the choice of the projective limit of these spaces, i.e.,

$$\mathcal{T}(T(\mathbb{R}^4))=\lim_{0\leftarrow\lambda}S^{1,\lambda}(\mathbb{R}^4),$$

a theory of $A(x)=:e^{\phi(x)^2}:$ can be formulated as we are going to show. The absence of the factor $\sqrt{2}$ in (1.5) is due to the choice of the norm (1.2) instead of Euclidean norm.

Remark 1.2: In 1969 Iofa and Fainberg[11] formulated a nonlocalizable quantum field theory. They used the test-function space $\mathcal{M}(\mathbb{R}^{4n})$ with the seminorms

$$\|\tilde{\phi}\|_k = \sup_{p;m\leqslant k} g(k\|p\|^2)|D^m\tilde{\phi}(p)|,$$

where $g(t^2)$ is an entire function of first order growth and type ρ with respect to t, i.e.,

$$\lim_{\|p\|\to\infty} \frac{\ln g(\|p\|^2)}{\|p\|} = \rho.$$

One can show that $\mathcal{M}(\mathbb{R}^{4n})$ is just the space $H(\mathbb{R}^{4n};\mathbb{R}^{4n})$, the space of Fourier transforms of the test-function space $\mathcal{T}(T(\mathbb{R}^{4n}))$ of tempered ultra-hyperfunctions (see Remark 2.3).

The Fourier transform $\tilde{W}_{n-1}(q_1,\ldots,q_{n-1})$ of the n-point functionals $W_{n-1}(\xi_1,\ldots,\xi_{n-1})$ of their theory in the relative coordinates belongs to $\mathcal{M}(\mathbb{R}^{4(n-1)})$, and the growth of $\tilde{W}_{n-1}(q)$ is $\rho_n\sqrt{k_n}$ which depends on n. In Ref. 11, Iofa and Fainberg assume that

$$\overline{\lim_n}\,\rho_n\sqrt{k_n} = \tilde{\ell} > 0. \tag{1.7}$$

Then $W_{n-1}(\zeta)$ is again analytic in (1.6) and excludes the theory of $A(x)=:e^{\phi(x)^2}:$. We do not require condition (1.7) or something equivalent. We think it is too restrictive.

Remark 1.3: As we discussed above, a relativistic quantum field theory with a fundamental length cannot be formulated in terms of generalized functions with standard localization properties. Accordingly one faces the problem of how to include the physical condition of quasilocality or ℓ-locality of the fields. Above we had indicated that we propose to use a condition of extended local commutativity.

In Ref. 11, a condition of quasilocality is defined by symmetry of the (analytically continued) Wightman functions in their domain of holomorphy. In Ref. 14, quasilocality is defined essentially in the same way as our condition of extended local commutativity, i.e., it is defined as a continuity condition of the expectation values of the field commutators in a topology associated to a ℓ-neighborhood of the light cone.

Though the formulation of quasilocality seems to be the same, the properties of Wightman functionals in both theories are different because different types of generalized functions are used.

Remark 1.4: The important result Theorem 4.11, i.e., the result that extended local commutativity implies the symmetry of the analytically continued Wightman functions on their domain of holomorphy or, in the above terminology, quasilocality follows from the standard strategy (see Refs. 2, 14, 24, 25) by using extended tubes $\mathcal{T}^{n-1}_{\text{ext}}(\ell)$ and by proving this symmetry first in real points in these extended tubes $\mathcal{T}^{n-1}_{\text{ext}}(\ell)$.

As in Ref. 14 the symmetry of the Wightman functions at these real points of analyticity (Jost points) is shown first by suitable approximations for sufficiently distant Jost points. For our case of a different type of generalized functions these approximations are done in suitable open neighborhoods of explicitly chosen distant Jost points and all necessary estimates are done explicitly.

II. TEMPERED ULTRA-HYPERFUNCTIONS

For any subset A of $\mathbb{R}^n$, denote by $T(A)=\mathbb{R}^n+iA\subset\mathbb{C}^n$ the tubular set with base A. For a convex compact set K of $\mathbb{R}^n$, $\mathcal{T}_b(T(K))$ is, by definition, the space of all continuous functions f on $T(K)$ which are holomorphic in the interior of $T(K)$ and which satisfy

$$\|f\|^{T(K),j} = \sup\{|z^p f(z)|; z\in T(K), |p|\leqslant j\} < \infty, \quad j=0,1,\ldots, \tag{2.1}$$

where $p=(p_1,\ldots,p_n)$ and $z^p=z_1^{p_1}\cdots z_n^{p_n}$. $\mathcal{T}_b(T(K))$ is a Fréchet space with the seminorms $\|f\|^{T(K),j}$. If $K_1\subset K_2$ are two compact convex sets, we have the canonical injection,

$$\mathcal{T}_b(T(K_2))\to\mathcal{T}_b(T(K_1)). \tag{2.2}$$

For a convex open set O in $\mathbb{R}^n$ we define

$$\mathcal{T}(T(O)) = \lim_{\leftarrow} \mathcal{T}_b(T(K)), \tag{2.3}$$

where K runs through the convex compact sets contained in O and the projective limit is taken following the restriction mappings (2.2).

Definition 2.1: A tempered ultra-hyperfunction *is by definition a continuous linear functional on* $\mathcal{T}(T(\mathbb{R}^n))$.

The Fourier transformation $\mathcal{F}$ is well defined on $\mathcal{T}(T(\mathbb{R}^n))$ by the standard formula (2.8). In order to determine the range of $\mathcal{F}$ on $\mathcal{T}(T(\mathbb{R}^n))$ we introduce another function space.

The gauge functional h_K of a compact convex set $K \subset \mathbb{R}^n$ is defined by

$$h_K(x) = \sup\{\langle x, \xi\rangle; \xi \in K\}. \tag{2.4}$$

For a convex compact set K of $\mathbb{R}^n$, denote by $H_b(\mathbb{R}^n;K)$ the space of all C^∞ functions f on $\mathbb{R}^n$ which satisfy, for $j = 0,1,\ldots,$

$$\|f\|_{K,j} = \sup\{\exp(h_K(x))|D^p f(x)|; x \in \mathbb{R}^n, \ |p| \leqslant j\} < \infty. \tag{2.5}$$

Equipped with the system of seminorms $\|f\|_{K,j}$, $H_b(\mathbb{R}^n;K)$ is a Fréchet space. If $K_1 \subset K_2$ are two compact convex sets, then $h_{K_1} \leqslant h_{K_2}$ and thus one has the canonical injections:

$$H_b(\mathbb{R}^n;K_2) \to H_b(\mathbb{R}^n;K_1). \tag{2.6}$$

For a convex open set $O \subset \mathbb{R}^n$ the space $H(\mathbb{R}^n;O)$ is the projective limit of the spaces $H_b(\mathbb{R}^n;K)$ along the restriction mappings (2.6), i.e.,

$$H(\mathbb{R}^n;O) = \lim_{\leftarrow} H_b(\mathbb{R}^n;K), \tag{2.7}$$

where K runs through the convex compact sets contained in O.

In order to relate the space $H(\mathbb{R}^n;\mathbb{R}^n)$ to the Schwartz space $\mathcal{S}(\mathbb{R}^n)$ we derive a more direct characterization of $H(\mathbb{R}^n;\mathbb{R}^n)$. Observe that for any convex compact set $K \subset \mathbb{R}^n$ there is a number $k > 0$ such that $K \subseteq [-k,k]^n$. For the sets $K = [-k,k]^n$ the gauge function h_K is easily determined:

$$h_K(x) = \sup\{\langle x, \xi\rangle; \xi \in K\} = k\sum_{i=1}^{n} |x_i|,$$

and the system of continuous norms takes the form, using the notation $|x| = \Sigma_{i=1}^n |x_i|$,

$$\|f\|_{K,j} = \sup\{\exp(h_K(x))|D^p f(x)|; \ |p| \leqslant j, x \in \mathbb{R}^n\} = \sup\{e^{k|x|}|D^p f(x)|; \ |p| \leqslant j, x \in \mathbb{R}^n\}.$$

Thus, the space $H(\mathbb{R}^n;\mathbb{R}^n)$ can be defined as the projective limit of the spaces $H_b(\mathbb{R}^n;K)$ along the restriction mappings (2.6), where $K = [-k,k]^n$, $0 < k < \infty$. Accordingly, the space $H(\mathbb{R}^n;\mathbb{R}^n)$ is the space of all $\mathcal{C}^\infty$ functions on $\mathbb{R}^n$ which, together with all derivatives, decrease faster than any (linear) exponential. An easy consequence is the following.

Corollary 2.2:

(1) The space $H(\mathbb{R}^n;\mathbb{R}^n)$ is continuously embedded into the Schwartz space $\mathcal{S}(\mathbb{R}^n)$.
(2) The elements of $\mathcal{S}(\mathbb{R}^n)$ are multipliers for the space $H(\mathbb{R}^n;\mathbb{R}^n)$, and for each $g \in \mathcal{S}(\mathbb{R}^n)$ the map $f \mapsto gf$ is a continuous linear map of $H(\mathbb{R}^n;\mathbb{R}^n)$ into itself.

Proof: See Refs. 22, 23. □

Remark 2.3: Since

$$\lim_{\|p\| \to \infty} \frac{\ln g(\|p\|^2)}{\|p\|} = \rho,$$

it follows that $g(t^2)\sim e^{\rho t}$ as $|t|\to\infty$. Therefore the system of norms

$$\|\tilde{\phi}\|_k=\sup\{g(k\|x\|^2)|D^p\tilde{\phi}(x)|;\quad x\in\mathbb{R}^n,\ |p|\leqslant k\}$$

and

$$\|\tilde{\phi}\|_{K,j}=\sup\{\exp(h_K(x))|D^p\tilde{\phi}(x)|;\quad x\in\mathbb{R}^n,\ |p|\leqslant j\}$$

are equivalent. It follows that the space $\mathcal{M}(\mathbb{R}^n)$ of Iofa and Fainberg[11] and the space $H(\mathbb{R}^n;\mathbb{R}^n)$ are the same.

The following theorem collects the basic facts about the spaces introduced above.

Theorem 2.4: *For the spaces introduced above the following statements hold, for any convex open set O.*

(1) The space $\mathcal{D}(\mathbb{R}^n)$ of all C^∞ functions with compact support is dense in $H(\mathbb{R}^n;O)$.
(2) The space $H(\mathbb{R}^n;\mathbb{R}^n)$ is dense in $H(\mathbb{R}^n;O)$.
(3) $H(\mathbb{R}^m;\mathbb{R}^m)\otimes H(\mathbb{R}^n;\mathbb{R}^n)$ is dense in $H(\mathbb{R}^{m+n};\mathbb{R}^{m+n})$.

Proof: For the proof of the first two items we refer to Refs. 22, 23. To prove the last item let $\alpha(x)\in H(\mathbb{R}^m;\mathbb{R}^m)$ [respectively, $\beta(x)\in H(\mathbb{R}^n;\mathbb{R}^n)$] such that $\alpha(x)=1$ [respectively, $\beta(x)=1$] for $|x|<1$ and $\alpha(x)=0$ [respectively, $\beta(x)=0$] for $|x|\geqslant 2$. If $f\in H(\mathbb{R}^{m+n};\mathbb{R}^{m+n})$ then $f_m(x,y)=\alpha(x/m)\beta(y/m)f(x,y)$ converges to f in $H(\mathbb{R}^{m+n};\mathbb{R}^{m+n})$ and f_m is the limit of a sequence $\{\alpha(x/m)\beta(y/m)P_k(x,y)\}\subset H(\mathbb{R}^m;\mathbb{R}^m)\otimes H(\mathbb{R}^n;\mathbb{R}^n)$ in $H(\mathbb{R}^{m+n};\mathbb{R}^{m+n})$. □

Proposition 2.5: The Fourier transformation $f\mapsto\tilde{f}\equiv\mathcal{F}f$,

$$\tilde{f}(p)=(2\pi)^{-n/2}\int_{\mathbb{R}^n}f(z)e^{i\langle p,z\rangle}\,dz, \tag{2.8}$$

is a topological isomorphism between the spaces $\mathcal{T}(T(O))$ and $H(\mathbb{R}^n;O)$, for any open convex nonempty set $O\subset\mathbb{R}^n$. The inverse transformation is

$$f(z)=\overline{\mathcal{F}}\tilde{f}=(2\pi)^{-n/2}\int_{\mathbb{R}^n}\tilde{f}(p)e^{-i\langle p,z\rangle}\,dp. \tag{2.9}$$

Proof: See Refs. 22, 23. □

Proposition 2.6: Let $O\subset\mathbb{R}^n$ be a nonempty convex open subset. Then the spaces $H(\mathbb{R}^n;O)$ and $\mathcal{T}(T(O))$ are nuclear Fréchet spaces and thus, in particular, reflexive.

Proof: In the case of $O=\mathbb{R}^n$, Hasumi[22] proved this result, and his proof is valid in the general case. We sketch it for $H(\mathbb{R}^n;O)$. Let K be a convex compact subset of O. Then the mapping Φ_K defined by $\phi(f)=\exp(h_K(x))f(x)$ is a continuous linear mapping of $H(\mathbb{R}^n;O)$ into the Schwartz space $\mathcal{S}(\mathbb{R}^n)$. Moreover, if f is C^∞ and $\phi_K(f)\in\mathcal{S}(\mathbb{R}^n)$ for any convex compact subset K of O then $f\in H(\mathbb{R}^n;O)$. Hence $H(\mathbb{R}^n;O)$ is the projective limit of $\mathcal{S}(\mathbb{R}^n)$ with respect to the mappings ϕ_K. Since $\mathcal{S}(\mathbb{R}^n)$ is nuclear, $H(\mathbb{R}^n;O)$ is also nuclear by Proposition 50.1 of Ref. 26. □

Theorem 2.7 (Corollary of Theorem 34.1 of Ref. 26): *Let E be a Fréchet space, E_1 a metrizable space, G a locally convex space. Then a separately continuous bilinear map of $E\times E_1$ into G is continuous.*

Theorem 2.8 (Kernel theorem for ultra-hyperfunctions): *Let M be a separately continuous multilinear map of $[\mathcal{T}(T(\mathbb{R}^4))]^n$ into a Banach space G. Then there is a unique continuous linear map F of $\mathcal{T}(T(\mathbb{R}^{4n}))$ into G such that, for all $f_i\in\mathcal{T}(T(\mathbb{R}^4))$, $i=1,\ldots,n$,*

$$M(f_1,\ldots,f_n)=F(f_1\otimes\cdots\otimes f_n).$$

Proof: It follows from Theorem 2.7 that M is continuous, that is, there exist a constant C and seminorms $\|f\|^{T(K_i),j_i}$ of the form (2.1) such that

$$\|M(f_1,\ldots,f_n)\| \leqslant C\prod_{i=1}^{n} \|f_i\|^{T(K_i),j_i}. \tag{2.10}$$

This shows that M is continuously extended to $\Pi_{i=1}^{n}\mathcal{T}_b(T(K_i))$. For any finite family $K_1,\ldots,K_n$ of compact sets K_i there is $k>0$ such that $K_i\subseteq K=[-k,k]^4$ for $i=1,\ldots,n$. Since $\|f_i\|^{T(K_i),j_i} \leqslant \|f_i\|^{T(K),j_i}$ for all i, we can assume in (2.10): $K_i=K$ for $i=1,\ldots,n$.

Introduce modified Cauchy kernels as follows. Denote

$$h(t)=\prod_{\alpha=0}^{3} \frac{e^{-(t^\alpha)^2}}{2\pi i t^\alpha} \quad \text{and} \quad h_z(t)=h(t-z). \tag{2.11}$$

If $|\mathrm{Im}\, z^\alpha| \geqslant l>k$, then $h_z(t)$ is a continuous function of t in $T(K)$ which is holomorphic in the interior of $T(K)$ and $h_z\in\mathcal{T}_b(T(K))$. Moreover, h_z is a $\mathcal{T}_b(T(K))$-valued continuous function for $|\mathrm{Im}\, z^\alpha| \geqslant l>k$ as follows. Choose $\delta>0$ such that $|\mathrm{Im}\,(z-\zeta)^\alpha| \geqslant l>k$ for $|\zeta|\leqslant\delta$ and fixed z. For any $\epsilon>0$ there exists $R>0$ such that

$$\sup\{|t^p h_{z+\zeta}(t)|; t\in T(K), |t|\geqslant R, |\zeta|\leqslant\delta, |p|\leqslant j\}<\epsilon.$$

Since $h_z(t)$ is uniformly continuous on a compact set $T(K)_R=\{t\in T(K); |t|\leqslant R\}$, for any $\epsilon'>0$ there exists $0<\delta'\leqslant\delta$ such that

$$|h_{z+\zeta}(t)-h_z(t)|=|h_z(t-\zeta))-h_z(t)|<\epsilon',$$

for any $t\in T(K)_R$ and $|\zeta|\leqslant\delta'$. Hence

$$F(z)=M(h_{z_1},\ldots,h_{z_n}) \tag{2.12}$$

is a well-defined vector-valued continuous function for $|\mathrm{Im}\, z_i^\alpha|>l$, $\alpha=0,\ldots,3$, $i=1,\ldots,n$. For any $r>l>0$ and $l<|\mathrm{Im}\, z^\alpha|\leqslant r$, a straightforward estimate shows

$$\begin{aligned}\|h_z\|^{T(K),j} &= \sup\{|t^p h(t-z)|; t\in T(K), |p|\leqslant j\} \\ &= \sup\{|(t+z)^p h(t)|; t+z\in T(K), |p|\leqslant j\} \leqslant C(1+|z|)^j.\end{aligned} \tag{2.13}$$

The inequality

$$\|F(z)\| \leqslant C\prod_{i=1}^{n} (1+|z_i|)^j \tag{2.14}$$

follows from the estimate (2.10) for $l<|\mathrm{Im}\, z_i^\alpha|\leqslant r$.

Next we consider the integration of the vector valued function $F(z)$. For the reader's convenience we recall some useful propositions about Pettis integration of functions whose values are in a Suslin space E. For our purpose, we only have to know that a separable Fréchet space is a Suslin space. In the following propositions, T denotes a set, $\mathcal{A}$ a σ-algebra of subsets of T, and m a σ-finite positive measure defined on $\mathcal{A}$.

Definition 2.9 (Definition 1 of Ref. 27): Let E be a quasicomplete locally convex Hausdorff space. A function $f:T\to E$ is weakly m-summable if $\langle f(\cdot),x'\rangle$ is m-integrable for each $x'\in E'$. The function f is said to be m-summable (or Pettis integrable) if f is weakly m-summable and if for each set $A\in\mathcal{A}$ there exists an element $\int_A f\,dm\in E$ such that $\langle\int_A f\,dm,x'\rangle=\int_A\langle f,x'\rangle dm$ for all $x'\in E'$.

Proposition 2.10 (Theorem 1 of Ref. 27): Given a function $f:T\to E$ with values in a locally convex Suslin space, the following conditions are equivalent:

(a) $f^{-1}(B)\in\mathcal{A}$ for every Borel subsets $B\subset E$,
(b) for every $x'\in E'$ the scalar function $\langle f(\cdot),x'\rangle$ is measurable.

Proposition 2.11 (Theorem 3 of Ref. 27): Let $f:T\to E$ be a measurable function such that $\int|f|_p\,dm<\infty$ for every continuous seminorm p of a quasicomplete locally convex Suslin space E. Then f is m-summable.

Proposition 2.12 (Secs. I, IX of Ref. 27): (a) If $u:E_1\to E_2$ is a continuous linear map, and if $f:T\to E_1$ is summable, then $u\circ f$ is summable and $\int u\circ f\,dm=u\int f\,dm$.

(b) Let $x\to|x|_\beta$ be a lower semicontinuous generalized seminorm on E and $f:T\to E$ measurable. Then $|f(\cdot)|_\beta$ is measurable and $|\int f\,dm|_\beta\leqq\int|f|_\beta\,dm$.

After these preparations, let $\Gamma=\Gamma^+-\Gamma^-$ be the path in $\mathbb{C}$ defined by

$$\Gamma^\pm=\{z\in\mathbb{C};z=\pm x\pm ir,\ \ -\infty<x<\infty\},$$

and $f_j\in\mathcal{T}(T(\mathbb{R}^4))$.

Since $z\to h_z f_j(z)\in\mathcal{T}_b(T(K))$ is continuous and therefore measurable by Proposition 2.10. It follows from the inequality 2.13 and Proposition 2.11 that $h_z f_j(z)$ is summable.

Applying Proposition 2.12 and the Cauchy integral formula

$$\int_{\Gamma^4}h_z f(z)\mathrm{d}z=f(t),$$

we have

$$M(h_{z_1},\ldots,h_{z_{j-1}},f_j,f_{j+1},\ldots,f_n)=M\left(h_{z_1},\ldots,h_{z_{j-1}},\int_{\Gamma^4}h_{z_j}f_j(z_j)\mathrm{d}z_j,f_{j+1},\ldots,f_n\right)$$
$$=\int_{\Gamma^4}M(h_{z_1},\ldots,h_{z_{j-1}},h_{z_j},f_{j+1},\ldots,f_n)f_j(z_j)\mathrm{d}z_j.$$

This gives

$$M(f_1,\ldots,f_n)=\int_{\Gamma^4}\int_{\Gamma^4}\cdots\int_{\Gamma^4}F(z_1,z_2,\ldots,z_n)f_1(z_1)f_2(z_2)\cdots f_n(z_n)\mathrm{d}z_n\cdots\mathrm{d}z_2\,\mathrm{d}z_1$$
$$=F(f_1\otimes\cdots\otimes f_n).$$

Moreover, the integral

$$F(f)=\int_{\Gamma^4}\int_{\Gamma^4}\cdots\int_{\Gamma^4}F(z_1,z_2,\ldots,z_n)f(z_1,z_2,\ldots,z_n)\mathrm{d}z_n\cdots\mathrm{d}z_2\,\mathrm{d}z_1$$

for $f\in\mathcal{T}(T(\mathbb{R}^{4n}))$ defines a continuous mapping,

$$F:\mathcal{T}(T(\mathbb{R}^{4n}))\ni f\to F(f)\in G.$$

In fact, $F(z)f(z)$ is continuous and therefore measurable by Proposition 2.10, and it follows from (2.14) that

$$\|F(z)\|\ \ |f(z)|\leqq C\|f\|^{T(K),j+2}\prod_{i=1}^{n}\ (1+|z_i|)^{-2}$$

for $z\in\Gamma^4$, where $K=[-r,r]^{4n}$. Thus, using Proposition 2.12, we have

$$\|F(f)\|\leqq C'\|f\|^{T(K),j+2}.$$

This completes the proof. □

For an open set V in $\mathbb{R}^n$ and a positive number ϵ introduce the set V^ϵ defined by

$$V^{\epsilon}=\{z\in\mathbb{C}^n;\exists\, x\in V,|\mathrm{Re}\, z-x|+|\mathrm{Im}\, z|_{\beta}<\epsilon\},$$

where $|y|_{\beta}$ is a norm of $\mathbb{R}^n$ satisfying $|y|_{\beta}\geqslant|y|$ for the Euclidean norm $|y|$. Let K_p be the closure of $V^{\epsilon/(1+1/p)}$ in $\mathbb{C}^n$ and $L_p=\{w\in\mathbb{C}^m;|\mathrm{Im}\, w|\leqslant p\}$. Let $U=V^{\epsilon}\times\mathbb{C}^m$ and $M_p=K_p\times L_p$. $\mathcal{T}_b(M_p)$ is, by definition, the space of all continuous functions f on M_p which are holomorphic in the interior of M_p and satisfy, for $k=1,2,\ldots$,

$$\|f\|^{M_p,k}=\sup\{|z^s w^t f(z,w)|;(z,w)\in M_p,|s|+|t|\leqslant k\}<\infty;$$

$\mathcal{T}_b(M_p)$ is a Fréchet space with the seminorms $\|f\|^{M_p,k}$.

If $k<m$, then we have the canonical injections

$$\mathcal{T}_b(M_m)\to\mathcal{T}_b(M_k). \tag{2.15}$$

We define

$$\mathcal{T}(U)=\lim_{\leftarrow}\mathcal{T}_b(M_m), \tag{2.16}$$

where the projective limit is taken following the restriction mappings (2.15).

Theorem 2.13: *$\mathcal{T}(T(\mathbb{R}^{n+m}))$ is dense in $\mathcal{T}(U)$.*

Proof: The proof is similar to the proofs of Proposition 2.4 of Ref. 28 and Proposition 9.1.2 of Ref. 29. For more details we refer to the Appendix. □

Let V be a closed convex cone in $\mathbb{R}^n$ and define the ϵ-neighborhood of V by

$$V_{\epsilon}=\{y;\exists\, x\in V,\ \ |x-y|\leqslant\epsilon\}.$$

Lemma 2.14: There exists a C^{∞}-function ϕ_{ϵ} with support contained in $V_{3\epsilon}$ such that $\phi_{\epsilon}=1$ in V_{ϵ} and

$$|\partial^{\alpha}\phi_{\epsilon}|\leqslant C_{\alpha}\epsilon^{-|\alpha|},$$

where C_{α} depends only on α and n.

Proof: Let χ be a positive C^{∞} function which has support in the unit ball $\{x;|x|<1\}$, such that $\int\chi\,\mathrm{d}x=1$. Then $\chi_{\epsilon}(x)=\epsilon^{-n}\chi(x/\epsilon)$ has the support in the ball $\{x;|x|<\epsilon\}$ and $\int\chi_{\epsilon}\,\mathrm{d}x=1$. Let v be the characteristic function of $V_{2\epsilon}$ and $\phi_{\epsilon}=v*\chi_{\epsilon}$. Then $\phi\in C^{\infty}(\mathbb{R}^n)$ has support in $V_{3\epsilon}$, and $1-\phi_{\epsilon}=(1-v)*\chi_{\epsilon}$ vanishes in V_{ϵ}. Moreover, we have

$$|\partial^{\alpha}\phi_{\epsilon}|\leqslant\int|\partial^{\alpha}\chi_{\epsilon}|\mathrm{d}x=\epsilon^{-|\alpha|}\int|\partial^{\alpha}\chi|\mathrm{d}x,$$

and

$$|\partial^{\alpha}\phi_{\epsilon}|\leqslant C_{\alpha}\epsilon^{-|\alpha|}$$

for $C_{\alpha}>0$. It is clear that C_{α} depends only on α and n. □

Remark 2.15: Note that Lemma 2.14 is just a concise summary of Sec. 1.4 of Ref. 29.

Theorem 2.15: *Let V be a closed convex cone and K a convex compact set in $\mathbb{R}^n$. Define a function $h_{K,V}(\xi)$, $\xi\in\mathbb{R}^n$, and a set V_K^0 as follows [see Eq. (2.4) for the definition of h_K]:*

$$h_{K,V}(\xi)=\sup_{x\in V}h_K(x)-\langle x,\xi\rangle,\quad\text{and}\quad V_K^0=\{\xi\in\mathbb{R}^n;h_{K,V}(\xi)<\infty\}.$$

Then for every $\mu\in H(\mathbb{R}^n;O)'$ with support in the cone V there is a function

$$\hat{\mu}(\zeta)=\langle\mu,e^{i\langle\cdot,\zeta\rangle}\rangle \tag{2.17}$$

with the following properties: $\hat{\mu}$ *is well defined and holomorphic in the interior of* $\mathbb{R}^n \times iV_K^0$ *and satisfies there the following estimate, for a suitable* $K \subset O$,

$$|\hat{\mu}(\zeta)| \leq C(1+|\zeta|)^j \exp(h_{K,V}(\operatorname{Im}\zeta)). \tag{2.18}$$

$\hat{\mu}$ *is called the Fourier–Laplace transform of* μ.

Proof: We choose a C^∞ function ϕ_ϵ with support contained in $V_{3\epsilon}$ such that $\phi_\epsilon = 1$ in V_ϵ and

$$|\partial^\alpha \phi_\epsilon| \leq C_\alpha \epsilon^{-|\alpha|}.$$

Then we have for $\zeta \in \mathbb{R}^n \times iV_K^0$

$$\begin{aligned}|\langle \mu, e^{i\langle \cdot, \zeta\rangle}\rangle| = |\langle \mu, \phi_\epsilon e^{i\langle \cdot, \zeta\rangle}\rangle| &\leq C\|\phi_\epsilon e^{i\langle \cdot, \zeta\rangle}\|_{K,j} \\ &\leq C \sup\{\exp(h_K(x))|D^\alpha(\phi_\epsilon(x)e^{i\langle x,\zeta\rangle})|; |\alpha| \leq j, x \in \mathbb{R}^n\} \\ &\leq C' \exp(h_{K,V}(\operatorname{Im}\zeta) + 3\epsilon|\operatorname{Im}\zeta|) \sum_{|\alpha|\leq j} \epsilon^{-|\alpha|}(1+|\zeta|)^{j-|\alpha|}.\end{aligned}$$

The estimate (2.18) follows if we take $\epsilon = 1/(1+|\zeta|)$. The standard argument shows that $\zeta \to \phi_\epsilon e^{i\langle \cdot, \zeta\rangle} \in H(\mathbb{R}^n; O)$ is complex differentiable in the interior of $\mathbb{R}^n \times iV_K^0$. □

Remark 2.17: Theorem 7.4.2 of Ref. 29 proves this theorem for Schwartz distributions together with its converse.

Remark 2.18: Let $|x|_\infty = \max\{|x^0|, |\mathbf{x}|\}$ be a norm in $\mathbb{R}^4$ and $\overline{V}_+$ the closed forward light cone in $\mathbb{R}^4$. Abbreviate $V = \overline{V}_+^n$ and for $\ell_i > 0$ introduce $h_K(x) = \Sigma_{i=1}^n \ell_i |x_i|_\infty$. Then we estimate

$$h_{K,V}(\xi) = \sup_{x_i \in \overline{V}_+} \sum_{i=1}^n (\ell_i |x_i|_\infty - \langle x_i, \xi_i\rangle) \leq \sum_{i=1}^n \sup_{x_i \in \overline{V}_+} (\ell_i |x_i|_\infty - \langle x_i, \xi_i\rangle).$$

Let V_+ be the open forward light cone. It follows

$$\sup_{x \in \overline{V}_+} -\langle x, \eta\rangle < \infty$$

for $\eta \in V_+$. Let $\xi_i = \eta_i + (\ell_i, \mathbf{0}) \in V_+ + (\ell_i, \mathbf{0})$. Since $|x|_\infty = x^0$ in $\overline{V}_+$, we find

$$\sup_{x_i \in \overline{V}_+} (\ell_i |x_i|_\infty - \langle x_i, \xi_i\rangle) = \sup_{x_i \in \overline{V}_+} (\ell_i x_i^0 - \langle x_i, \eta_i\rangle - x_i^0 \ell_i) = \sup_{x_i \in \overline{V}_+} -\langle x_i, \eta_i\rangle < \infty.$$

Thus the set

$$V_+(\ell_1, \ldots, \ell_n) = \{(\xi_1, \ldots, \xi_n) \in \mathbb{R}^{4n}; \xi_i \in V_+ + (\ell_i, \mathbf{0})\} \tag{2.19}$$

is contained in V_K^0.

III. AXIOMS FOR QUANTUM FIELD THEORIES WITH FUNDAMENTAL LENGTH

The discussion in the Introduction had shown that the framework of standard quantum fields and the framework of hyperfunction quantum fields do not allow a fundamental length in the formulation of the condition of local commutativity. Thus, for such a theory, a new framework has to be used. We argue that quantum fields in terms of ultra-hyperfunctions is a suitable framework. Accordingly we start by listing the defining conditions of an ultra-hyperfunction quantum field theory (UHFQFT) (here we restrict ourselves to the case of a neutral scalar field). We begin in the spirit of our paper[8] by defining such a field as a relativistic quantum field over the test-function

space $E=\mathcal{T}(T(\mathbb{R}^4))$ for ultra-hyperfunctions. While most conditions only need minor modifications, the condition of local commutativity has to be formulated in such a way as to take the existence of a fundamental length into account.

As usual, the defining conditions of an UHFQFT allow one to deduce a set of properties for the sequences of vacuum expectation values or Wightman functions. In the following section a list of conditions for the sequence of all vacuum expectation values is isolated which allow one to reconstruct the ultra-hyperfunction quantum field.

We begin by collecting some properties of the test-function space, in the sense of Ref. 8.

Lemma 3.1: The test-function space $E=\mathcal{T}(T(\mathbb{R}^4))$ has the following properties:

(1) E admits the Fourier transform $\mathcal{F}$ as an isomorphism of topological vector spaces.
(2) On E and $\tilde{E}=\mathcal{F}E$ there are continuous involutions $f\mapsto f^*$ which satisfy $(\mathcal{F}f)^*=\overline{\mathcal{F}f^*}$ for all $f\in E$.
(3) The restricted Poincaré group G acts on E by continuous linear mappings $\alpha_g: E\to E$, $g\in G$ such that for all $f\in E$ and all $g\in G$ one has $\alpha_g(f)^*=\alpha_g(f^*)$, and $g\mapsto\alpha_g(f)$ is a continuous map $G\to E$. G acts on the test-function space $E=\mathcal{T}(T(\mathbb{R}^4))$ as follows:

$$G\ni g=(a,\Lambda)\to\alpha_g(f)(z)=f(\Lambda^{-1}(z-a)).$$

Proof: For the first item see Proposition 2.5. The proof of the second point is a straightforward calculation. For the proof of (3) see the Appendix. □

Definition 3.2: A quadruple $(\mathcal{H},U,\Phi_0,A)$ satisfying conditions (H_i), $i=1,2,3,4,5$ is called a relativistic quantum field theory with fundamental length ℓ *or an* ultra-hyperfunction quantum field theory.

(H_1) *Fields over $E=\mathcal{T}(T(\mathbb{R}^4))$*: A field A over E with state space $\mathcal{H}$, domain $\mathcal{D}$ and cyclic unit vector Φ_0 is specified in the following way.

(a) The state space $\mathcal{H}$ is a separable complex Hilbert space.
(b) The domain $\mathcal{D}$ is a dense subspace of $\mathcal{H}$ containing the cyclic unit vector Φ_0.
(c) The field A is a linear map from E into the algebra $L(\mathcal{D},\mathcal{D})$ of linear operators $\mathcal{D}\to\mathcal{D}$ such that the following conditions hold.

(i) For all $\Phi,\Psi\in\mathcal{D}$, $f\to(\Phi,A(f)\Psi)$ is a continuous linear map $E\to\mathbb{C}$.
(ii) For each $f\in E$, the adjoint operator $A(f)^*$ of the densely defined operator $A(f)$ in $\mathcal{H}$ is an extension of $A(f^*)$.

(H_2) *Poincaré covariance:* A field $(A,\mathcal{H},\mathcal{D},\Phi_0)$ over E is said to be Poincaré covariant if, and only if, there is a unitary continuous representation U of the restricted Poincaré group G on the Hilbert space $\mathcal{H}$ such that, for all $g\in G$ and all $f\in E$,

$$U(g)\mathcal{D}=\mathcal{D},\ U(g)A(f)U(g)^*=A(\alpha_g(f)).$$

(H_3) *Energy-momentum spectrum Σ:* The energy-momentum spectrum Σ of the theory equals the spectrum $\sigma(P)$ of the infinitesimal generator $P=(P^0,P^1,P^2,P^3)$ of the time–space translations in the representation U, i.e.,

$$U(a)=U(a,\mathbf{1})=e^{ia\cdot P},\quad a\in\mathbb{R}^4.$$

$\{p=0\}$ is an isolated eigenvalue of P. The rest of the spectrum of P is contained in the ''forward light cone''

$$V_+=\{(q^0,\mathbf{q})\in\mathbb{R}^4;q^0>|\mathbf{q}|,\mathbf{q}\in\mathbb{R}^3\}.$$

(H_4) *Uniqueness of the vacuum state:* The subspace $\mathcal{H}_0$ of translation invariant vectors in $\mathcal{H}$ is one-dimensional and is generated by the cyclic vector $\Phi_0\in\mathcal{D}$. Accordingly, this cyclic vector Φ_0 is called the vacuum vector of the theory and it follows that

$$\mathcal{D}_0 = \mathrm{lin}\{\Phi_0, A(f_1)\cdots A(f_n)\Phi_0 : f_k \in E, \quad n = 1,2,\ldots\}$$

is dense in $\mathcal{H}$.

Before we can formulate the last condition of local commutativity, respectively, causality in a theory with finite fundamental length ℓ, we need to introduce some notation and formulate some related results. We define the norm $|x|_1$ for $x = (x^0, \mathbf{x}) \in \mathbb{R}^4$ by

$$|x|_1 = |x^0| + |\mathbf{x}|, \quad |\mathbf{x}| = \sqrt{\sum_{i=1}^{3} (x^i)^2},$$

and denote

$$L^\ell = \{x = (x_1, x_2) \in \mathbb{R}^{4\cdot 2}; |x_1 - x_2|_1 < \ell\}.$$

Next define the open set V of all strictly timelike points in $\mathbb{R}^4$ by

$$V = \{\xi \in \mathbb{R}^4; (\xi^0)^2 - \boldsymbol{\xi}^2 > 0\},$$

and the ℓ-neighborhood V^ℓ of V in $\mathbb{C}^4$,

$$V^\ell = \{z \in \mathbb{C}^4; \exists\, x \in V, |\mathrm{Re}\, z - x| + |\mathrm{Im}\, z|_1 < \ell\}.$$

Finally we introduce the set of all pairs of points in $\mathbb{C}^4$ whose difference belongs to this ℓ-neighborhood,

$$W^\ell = \{(z_1, z_2) \in \mathbb{C}^{4\cdot 2}; z_1 - z_2 \in V^\ell\}.$$

Then we can formulate the last defining condition (H_5).

(H_5) *Extended causality or extended local commutativity:* In some Lorentz frame, for any given $\Psi, \Phi \in \mathcal{D}$ and any $\ell' > \ell$, the functional

$$E \otimes E \ni f_1 \otimes f_2 \to (\Phi, A(f_1)A(f_2)\Psi) \in \mathbb{C}$$

can be extended to a continuous linear functional on $\mathcal{T}(T(L^{\ell'}))$ and moreover,

$$E \otimes E \ni f_1 \otimes f_2 \to (\Phi, A(f_1)A(f_2)\Psi) - (\Phi, A(f_2)A(f_1)\Psi) \in \mathbb{C}$$

can be extended to a continuous linear functional on $\mathcal{T}(W^{\ell'})$.

IV. PROPERTIES OF VACUUM EXPECTATION VALUES FOR UHF QUANTUM FIELDS

A. Preliminaries

Given a UHFQFT $(\mathcal{H}, U, \Phi_0, A)$, we want to analyze the properties of its *vacuum expectation values* defined by

$$\mathcal{W}_n(f_1 \otimes \cdots \otimes f_n) = (\Phi_0, A(f_1)\cdots A(f_n)\Phi_0) \quad \forall\, f_i \in E(1), \quad i = 1,\ldots,n, \tag{4.1}$$

for all $n \in \mathbb{N}$.

Proposition 4.1: For any given $\Psi \in \mathcal{D}$ and every $n = 1,2,\ldots$ there is a continuous linear mapping

$$\Psi_n : E(n) \equiv \mathcal{T}(T(\mathbb{R}^{4n})) \to \mathcal{H}$$

satisfying, for all $f_j \in E = E(1)$, $j = 1,\ldots,n$,

$$\Psi_n(f_1 \otimes f_2 \otimes \cdots \otimes f_n) = A(f_1)A(f_2)\cdots A(f_n)\Psi. \tag{4.2}$$

Proof: Let $\Phi,\Psi\in\mathcal{D}$ and $n\in\mathbb{N}$ be given. Then, by the first axiom,

$$\mathcal{T}(T(\mathbb{R}^4))^n\ni(f_1,\ldots,f_n)\to(\Phi,A(f_1)\cdots A(f_n)\Psi)$$

is a separately continuous n-linear form. Therefore Theorem 2.8 implies that there exists $F\in\mathcal{T}(T(\mathbb{R}^{4n}))'$ such that

$$F(f_1\otimes\cdots\otimes f_n)=(\Phi,A(f_1)\cdots A(f_n)\Psi).$$

Next for $g=f_1\otimes\cdots\otimes f_n\in\otimes^n\mathcal{T}(T(\mathbb{R}^4))$, we define $\Psi_n(g)=A(f_1)\cdots A(f_n)\Psi$ and extend it to $\otimes^n\mathcal{T}(T(\mathbb{R}^4))$ by linearity. By Theorem 2.4, for any $f\in\mathcal{T}(T(\mathbb{R}^{4n}))$ there exists a sequence $\{g_\nu\in\otimes^n\mathcal{T}(T(\mathbb{R}^4))\}$ such that $g_\nu\to f$ as $\nu\to\infty$. Therefore $\|\Psi_n(g_\nu)-\Psi_n(g_\mu)\|^2\to0$ as $\nu,\mu\to\infty$. Thus $\Psi_n(g_\nu)$ converges to a vector $\Psi_n(f)$ and evidently $\Psi_n(f)$ is continuous linear mapping from $\mathcal{T}(T(\mathbb{R}^{4n}))$ to $\mathcal{H}$. □

Apply Proposition 4.1 to the special case where $\Psi\in\mathcal{D}$ is the vacuum vector Φ_0 of the theory. Then we have continuous linear mappings

$$\Phi_n:E(n)=\mathcal{T}(T(\mathbb{R}^{4n}))\to\mathcal{H},\quad n=1,2,\ldots$$

which extend the mappings

$$\otimes^nE(1)\ni f_1\otimes\ \cdots\otimes f_n\mapsto A(f_1)A(f_2)\cdots A(f_n)\Phi_0.$$

As an immediate consequence we get the following proposition.

Proposition 4.2: For every $n=1,2,3,\ldots$, the vacuum expectation value (4.1) has a continuous linear extension to an element $\mathcal{W}_n\in\mathcal{T}(T(\mathbb{R}^{4n}))'$.

B. Implications of extended local commutativity I

Proposition 4.3: For any given $n\geqslant2$ and $i\in\{1,\ldots,n-1\}$ introduce the set

$$L_i^\ell=\{x=(x_1,\ldots,x_n)\in\mathbb{R}^{4n};|x_i-x_{i+1}|_1<\ell\}.$$

Then, for any $\ell'>\ell$ and any $1\leqslant i\leqslant n-1$, $\mathcal{W}_n\in\mathcal{T}(T(\mathbb{R}^{4n}))'$ actually belongs to $\mathcal{T}(T(L_i^{\ell'}))'\subset\mathcal{T}(T(\mathbb{R}^{4n}))'$.

Proof: Let $h\in\mathcal{T}(T(\mathbb{R}^{4j}))$ and $g\in\mathcal{T}(T(\mathbb{R}^{4k}))$. It follows from axiom (H_5) that

$$E\otimes E\ni f_1\otimes f_2\to(\Phi_j(h^*),A(f_1)A(f_2)\Phi_k(g))=\mathcal{W}_n(h\otimes f_1\otimes f_2\otimes g)$$

is extended continuously to $\mathcal{T}(T(L^{\ell'}))$, and we have the following separately continuous multilinear form:

$$\mathcal{T}(T(\mathbb{R}^{4j}))\times\mathcal{T}(T(L^{\ell'}))\times\mathcal{T}(T(\mathbb{R}^{4k}))\ni(h,f,g)\to\mathcal{W}_n(h\otimes f\otimes g).$$

According to Theorem 2.7, a separately continuous multilinear form on Fréchet spaces is jointly continuous. Therefore we have

$$|\mathcal{W}_n(h\otimes f\otimes g)|\leqslant C\|h\|^{T(K_1),j_1}\|f\|^{T(K_2),j_2}\|h\|^{T(K_3),j_3},$$

where $\|h\|^{T(K_1),j_1}$, $\|f\|^{T(K_2),j_2}$, $\|h\|^{T(K_3),j_3}$ are some of the defining seminorms of $\mathcal{T}(T(\mathbb{R}^{4j}))$, $\mathcal{T}(T(L^{\ell'}))$, $\mathcal{T}(T(\mathbb{R}^{4k}))$, respectively. The estimate

$$\begin{aligned}&\|h\|^{T(K_1),j_1}\|f\|^{T(K_2),j_2}\|h\|^{T(K_3),j_3}\\&\quad=\sup\{|z_1^{p_1}h(z_1)z_2^{p_2}f(z_2)z_3^{p_3}g(z_3)|;(z_1,z_2,z_3)\in T(K_1\times K_2\times K_3),|p_i|\leqslant j_i\}\\&\quad\leqslant\|h\otimes f\otimes g\|^{T(K_1\times K_2\times K_3),j_1+j_2+j_3}\end{aligned}$$

shows that $\mathcal{W}_n(h\otimes f\otimes g)$ can be extended continuously to $\mathcal{T}(T(L_i^{\ell'}))$ because $\|h\otimes f\otimes g\|^{T(K_1\times K_2\times K_3),j_1+j_2+j_3}$ is one of the defining seminorms. □

In the same way one proves the following proposition.

Proposition 4.4: For $n\geqslant 2$ and $i\in\{1,\ldots,n-1\}$ denote

$$W_i^{\ell}=\{(z_1,\ldots,z_n)\in\mathbb{C}^{4n};z_i-z_{i+1}\in V^{\ell}\}$$

and define

$$c_i^n(f)(z_1,\ldots,z_n)=f(z_1,\ldots,z_i,z_{i+1},\ldots,z_n)-f(z_1,\ldots,z_{i+1},z_i,\ldots,z_n).$$

Then $\mathcal{W}_n\circ c_i^n$ belongs to $\mathcal{T}(W_i^{\ell'})'$ for any $\ell'>\ell$.

C. Analysis of the spectral condition

Let $\tilde{\Phi}_n$ be the Fourier transform of Φ_n defined by

$$\tilde{\Phi}_n(\tilde{f})=\Phi_n(f).$$

For the vector-valued tempered ultra-hyperfunction Φ_n, $\tilde{\Phi}_n$ is a continuous linear mapping,

$$\tilde{\Phi}_n:H(\mathbb{R}^{4n};\mathbb{R}^{4n})\to\mathcal{H},$$

according to Proposition 2.5. In order to analyze the support properties of $\tilde{\Phi}_n$ we proceed as in Refs. 25, 30 and introduce the following change of variables:

$$(q_0,\ldots,q_{n-1})=\chi_n^{-1}(p_1,\ldots,p_n),\quad q_k=\sum_{j=k+1}^{n}p_j,\quad \zeta_0=z_1,\quad \zeta_j=z_{j+1}-z_j,\quad j=1,\ldots,n-1.$$

Then we have

$$p_n=q_{n-1},\quad p_k=q_{k-1}-q_k,\quad k=1,...,n-1,\quad z_k=\sum_{j=0}^{k-1}\zeta_j,\quad k=1,2,\ldots,n,$$

and thus

$$\sum_{j=1}^{n}z_j\cdot p_j=\langle z,p\rangle=\langle z,\chi_n(q)\rangle=\langle\zeta,q\rangle=\sum_{j=0}^{n-1}\zeta_j\cdot q_j.$$

The translation of a function $f\in E(n)$ by $a\in\mathbb{R}^4$ is defined in the natural way as $f_a(x_1,\ldots,x_n)=f(x_1-a,\ldots,x_n-a)$ and thus the Fourier transform of the translated function is $\tilde{f}_a(p_1,\ldots,p_n)=e^{ia\cdot\Sigma_{k=1}^{n}p_k}\tilde{f}(p_1,\ldots,p_n)$. As a function of the variables $(q_0,\ldots,q_{n-1})$ the Fourier transform $\tilde{\Phi}_n$ is denoted by $\tilde{Z}_n$, i.e.,

$$\tilde{Z}_n(\tilde{f}\circ\chi_n)=\tilde{\Phi}_n(\tilde{f}).$$

The unitary group of translations has a spectral representation $U(a)=\int_{\Sigma}e^{ip\cdot a}E(\mathrm{d}p)$ where the spectral measure $E(\mathrm{d}p)$ has its support in Σ. Thus, by spectral calculus, for any integrable continuous function h on $\mathbb{R}^4$,

$$(2\pi)^{-2}\int_{\mathbb{R}^4}h(a)U(a)\mathrm{d}a=\tilde{h}(P)$$

is a bounded function of the generator $P=(P_0,P_1,P_2,P_3)$ of the translation group. For $h \in \mathcal{S}(\mathbb{R}^4)$ we have

$$\begin{aligned}\tilde{h}(P)\Phi_n(f) &= (2\pi)^{-2}\int_{\mathbb{R}^4} h(a)U(a)\Phi_n(f)\mathrm{d}a = (2\pi)^{-2}\int_{\mathbb{R}^4} h(a)\Phi_n(f_a)\mathrm{d}a \\ &= (2\pi)^{-2}\int_{\mathbb{R}^4} h(a)\tilde{\Phi}_n(\tilde{f}_a)\mathrm{d}a = (2\pi)^{-2}\int_{\mathbb{R}^4} \tilde{Z}_n(h(a)\tilde{f}_a\circ\chi_n)\mathrm{d}a \\ &= \tilde{Z}_n\left((2\pi)^{-2}\int_{\mathbb{R}^4} h(a)\tilde{f}_a\circ\chi_n\,\mathrm{d}a\right) = \tilde{Z}_n(\tilde{h}(q_0)\cdot\tilde{f}\circ\chi_n),\end{aligned}$$

where we used Propositions 2.10, 2.11, 2.12 and the relation

$$\int_{\mathbb{R}^4} h(a)\tilde{f}_a(p)\mathrm{d}a = \tilde{h}(q_0)\cdot\tilde{f}(p).$$

The assumptions of Propositions 2.10 and 2.11 are satisfied because of the continuity of $a \to \tilde{f}_a$ which follows from Lemma 3.1 and the fact that $\|\tilde{f}_a\|_{K,j}$ is a polynomially increasing function of a.

If $\tilde{f}\circ\chi_n = \tilde{g}_1\otimes\tilde{g}_2$ with $\tilde{g}_1 \in H(\mathbb{R}^4;\mathbb{R}^4)$ and $\tilde{g}_2 \in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})$ then, for any $h \in \mathcal{S}(\mathbb{R}^4)$, the relation

$$\tilde{h}(P)\tilde{Z}_n(\tilde{g}_1\otimes\tilde{g}_2) = \tilde{Z}_n((\tilde{h}\cdot\tilde{g}_1)\otimes\tilde{g}_2) \tag{4.3}$$

results.

Proposition 4.5: For any $\tilde{g}_2 \in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})$, the vector-valued generalized function

$$H(\mathbb{R}^4;\mathbb{R}^4) \ni \tilde{g}_1 \to \tilde{Z}_n(\tilde{g}_1\otimes\tilde{g}_2)$$

has its support in Σ.

Proof: Take any $\tilde{g}_1 \in \mathcal{D}(\mathbb{R}^4)$ with support in $R^4\backslash\Sigma$. Then there is $\tilde{h} \in \mathcal{D}(\mathbb{R}^4\backslash\Sigma)$ which is equal to 1 on $\operatorname{supp}\tilde{g}_1$. It follows $\tilde{h}\tilde{g}_1 = \tilde{g}_1$ and $\tilde{h}(P) = 0$. We conclude

$$\tilde{Z}_n(\tilde{g}_1\otimes\tilde{g}_2) = \tilde{Z}_n((\tilde{h}\cdot\tilde{g}_1)\otimes\tilde{g}_2) = \tilde{h}(P)\tilde{Z}_n(\tilde{g}_1\otimes\tilde{g}_2) = 0.$$

Hence the support property follows. □

Recall that the vacuum expectation values $\mathcal{W}_n$ have the following representation

$$\mathcal{W}_n(f_n) = \langle\Phi_0,\Phi_n(f_n)\rangle = \langle\Phi_0,\tilde{\Phi}_n(\tilde{f}_n)\rangle = \langle\Phi_0,\tilde{Z}_n(\tilde{f}_n\circ\chi_n)\rangle \tag{4.4}$$

for all $f_n \in \mathcal{T}(T(\mathbb{R}^{4n}))$ and thus $\tilde{f}_n \in H(\mathbb{R}^{4n};\mathbb{R}^{4n})$. Pick a test function $\tilde{h} \in H(\mathbb{R}^4;\mathbb{R}^4)$. Then, because of the spectral properties of the operator P, we know

$$\tilde{h}^*(0)\Phi_0 = \tilde{h}(P)^*\Phi_0, \tag{4.5}$$

and thus if $\tilde{h}(0) = 1$, because of Eq. (4.3),

$$\mathcal{W}_n(f_n) = \langle\Phi_0,\tilde{Z}_n(\tilde{h}(q_0)\cdot\tilde{f}_n\circ\chi_n)\rangle,$$

or, if $\tilde{f}_n = (\tilde{g}_1\otimes\tilde{g}_{n-1})\circ\chi_n^{-1}$ with $\tilde{g}_k \in H(\mathbb{R}^{4k};\mathbb{R}^{4k})$, then

$$\tilde{\mathcal{W}}_n((\tilde{g}_1\otimes\tilde{g}_{n-1})\circ\chi_n^{-1}) = \tilde{\mathcal{W}}_n(((\tilde{h}\cdot\tilde{g}_1)\otimes\tilde{g}_{n-1})\circ\chi_n^{-1}). \tag{4.6}$$

This prepares for the following proposition.

Proposition 4.6: For $n=2,3,\ldots$ *there is* $\tilde{W}_{n-1}\in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})'$ *such that*

(a)

$$\tilde{\mathcal{W}}_n((\tilde{g}_1\otimes\tilde{g}_{n-1})\circ\chi_n^{-1})=\tilde{g}_1(0)\tilde{W}_{n-1}(\tilde{g}_{n-1}) \tag{4.7}$$

for all $\tilde{g}_{n-1}\in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})$ *and all* $\tilde{g}_1\in H(\mathbb{R}^4;\mathbb{R}^4)$, *i.e.*,

$$\tilde{\mathcal{W}}_n\circ\chi_n(q_0,\ldots,q_{n-1})=(2\pi)^2\delta(q_0)\tilde{W}_{n-1}(q_1,\ldots,q_{n-1});$$

(b) $\operatorname{supp}\tilde{W}_{n-1}\subseteq\Sigma^{n-1}$.

Proof: Take any test function $\tilde{h}\in H(\mathbb{R}^4;\mathbb{R}^4)$ with $\tilde{h}(0)=1$. Then, by Eqs. (4.3), (4.1), and (4.5),

$$\begin{aligned}\tilde{\mathcal{W}}_n((\tilde{g}_1\otimes\tilde{g}_{n-1})\circ\chi_n^{-1})&=\langle\Phi_0,\tilde{Z}_n((\tilde{h}\cdot\tilde{g}_1)\otimes\tilde{g}_{n-1})\rangle\\&=\langle\Phi_0,\tilde{g}_1(P)\tilde{Z}_n(\tilde{h}\otimes\tilde{g}_{n-1})\rangle\\&=\langle\tilde{g}_1(P)^*\Phi_0,\tilde{Z}_n(\tilde{h}\otimes\tilde{g}_{n-1})\rangle=\tilde{g}_1(0)\langle\Phi_0,\tilde{Z}_n(\tilde{h}\otimes\tilde{g}_{n-1})\rangle.\end{aligned}$$

Now define a functional $\tilde{W}_{n-1}$ by

$$\tilde{W}_{n-1}(\tilde{g}_{n-1})=\langle\Phi_0,\tilde{Z}_n(\tilde{h}\otimes\tilde{g}_{n-1})\rangle\quad\forall\,\tilde{g}_{n-1}\in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)}). \tag{4.8}$$

The properties of $\tilde{Z}_n$ imply that this functional belongs to $H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})'$. If $\tilde{h}_j\in H(\mathbb{R}^4;\mathbb{R}^4)$ are two test functions with $\tilde{h}_j(0)=1$ for $j=1,2$, then $\tilde{h}=\tilde{h}_1-\tilde{h}_2$ is a test function with $\tilde{h}(0)=0$. Now pick any test function $\tilde{g}$ with $\tilde{g}(0)=1$. Then, as above, we get

$$\langle\Phi_0,\tilde{Z}_n(\tilde{h}\otimes\tilde{g}_{n-1})\rangle=\langle\Phi_0,\tilde{Z}_n((\tilde{g}\cdot\tilde{h})\otimes\tilde{g}_{n-1})\rangle=\tilde{h}(0)\langle\Phi_0,\tilde{Z}_n(\tilde{g}\otimes\tilde{g}_{n-1})\rangle=0.$$

It follows $\langle\Phi_0,\tilde{Z}_n(\tilde{h}_1\otimes\tilde{g}_{n-1})\rangle=\langle\Phi_0,\tilde{Z}_n(\tilde{h}_2\otimes\tilde{g}_{n-1})\rangle$, and this shows that $\tilde{W}_{n-1}$ is well defined by Eq. (4.8) and part (a) follows.

In order to prove the support property (b) take any $\tilde{g}_1\in H(\mathbb{R}^{4j};\mathbb{R}^{4j})$ and $\tilde{g}_2\in H(\mathbb{R}^{4(n-j)};\mathbb{R}^{4(n-j)})$ and denote $\tilde{f}_1=\tilde{g}_1\circ\chi_j^{-1}$, respectively, $\tilde{f}_2=\tilde{g}_2\circ\chi_{n-j}^{-1}$. Explicitly this means

$$\widetilde{(f_1^*)}(p_1,\ldots,p_j)=\bar{\tilde{g}}_1(-p_1-\cdots-p_j,-p_1-\cdots-p_{j-1},\ldots,-p_1),$$

respectively,

$$\tilde{f}_2(p_{j+1},\ldots,p_n)=\tilde{g}_2(p_{j+1}+\cdots+p_n,p_{j+2}+\cdots+p_n,\ldots,p_n).$$

Note that

$$\begin{aligned}\delta(p_1+\cdots+p_n)\widetilde{(f_1^*)}(p_1,\ldots,p_j)&=\delta(p_1+\cdots+p_n)\bar{\tilde{g}}_1(-p_1-\cdots-p_j,-p_1-\cdots-p_{j-1},\ldots,-p_1)\\&=\delta(q_0)\bar{\tilde{g}}_1(q_j,q_{j-1},\ldots,q_1)=\delta(q_0)(\tilde{g}_1)^*(q_1,\ldots,q_j).\end{aligned}$$

Now use part (a) to evaluate

$$\begin{aligned}(\tilde{Z}_j(\tilde{g}_1),\tilde{Z}_{n-j}(\tilde{g}_2))&=(\tilde{\Phi}_j(\tilde{f}_1),\tilde{\Phi}_{n-j}(\tilde{f}_2))=(\Phi_j(f_1),\Phi_{n-j}(f_2))=\mathcal{W}_n(f_1^*\otimes f_2)=\tilde{\mathcal{W}}_n(\widetilde{(f_1^*)}\otimes\tilde{f}_2)\\&=(2\pi)^2\langle\tilde{W}_{n-1}(q_1,\ldots,q_{n-1}),(\tilde{g}_1)^*(q_1,\ldots,q_j)\tilde{g}_2(q_j,\ldots,q_{n-1})\rangle.\end{aligned}$$

Finally choose $\tilde{g}_1=\tilde{g}_{11}\otimes\tilde{g}_{12}$ with $\tilde{g}_{11}\in H(\mathbb{R}^4;\mathbb{R}^4),\tilde{g}_{12}\in H(\mathbb{R}^{4(j-1)};\mathbb{R}^{4(j-1)})$ and $\tilde{g}_2=\tilde{g}_{21}\otimes\tilde{g}_{22}$ with $\tilde{g}_{21}\in H(\mathbb{R}^4;\mathbb{R}^4),\tilde{g}_{22}\in H(\mathbb{R}^{4(n-j-1)};\mathbb{R}^{4(n-j-1)})$. Then the above identity shows that

$$(\tilde{Z}_j(\tilde{g}_1),\tilde{Z}_{n-j}(\tilde{g}_2))=(2\pi)^2\tilde{W}_{n-1}((\tilde{g}_{12})^*\otimes(\bar{\tilde{g}}_{11}\cdot\tilde{g}_{21})\otimes\tilde{g}_{22}),$$

and by Proposition 4.5 and choosing $j=1,\ldots,n-1$, we conclude that the support of $\tilde{W}_{n-1}$ is contained in Σ^{n-1}. □

D. Basic analyticity

According to Proposition 4.6 the distributions $\tilde{W}_{n-1}$ have their supports in $\Sigma^{n-1}\subseteq\overline{V}_+$. Hence we can apply Theorem 2.16 to them and conclude that their Fourier–Laplace transforms $\hat{W}_{n-1}(\zeta_1,\ldots,\zeta_{n-1})$ are analytic in a set which contains $\mathbb{R}^{4(n-1)}+V_+(\ell_1,\ldots,\ell_{n-1})$ for suitable $\ell_i>0$ [see Eq. (2.19)]. Next we take extended local commutativity into account and show that these Fourier–Laplace transforms can be analytically continued to a much larger domain of analyticity described in the following proposition. These analytic continuations of the $\hat{W}_{n-1}$ are denoted by W_{n-1}.

Proposition 4.7: There exist decreasing functions $R_{ij}(r)$ defined for $\ell<r$ such that $W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})$ is holomorphic in

$$\bigcup_{i=1}^{n-1}\{\zeta\in\mathbb{C}^{4(n-1)};\mathrm{Im}\,\zeta_i\in V_+ +(\ell',\mathbf{0}),\quad \mathrm{Im}\,\zeta_j\in V_+ +(R_{ij}(\ell'),\mathbf{0}),\ \ \ell<\ell',j\neq i\},\tag{4.9}$$

and polynomially increasing there.

Proof: Observe the fact that an element in $H(\mathbb{R}^{4(n-1)};O)'$ is an element in $H_b(\mathbb{R}^{4(n-1)};K)'$ for some compact set $K\subset O$. For any compact set K in

$$L_i^{\ell'}=\{y\in\mathbb{R}^{4n};|y_{i+1}-y_i|_1<\ell'\},$$

we can choose $\epsilon,R_{ij}>0$ so that the set

$$K_i^{\epsilon,R}=\{(\eta_0,\ldots,\eta_{n-1})\in\mathbb{R}^{4n};|\eta_i|_1\leqslant\ell'-\epsilon_i,\ \ |\eta_j|_1\leqslant R_{ij},\ \ j\neq i\}$$

contains K, where $\eta_0=y_1$, $\eta_j=y_{j+1}-y_j$ $(j=1,\ldots,n-1)$. It follows from Proposition 4.3 that $\tilde{\mathcal{W}}_n$ is extended to $H(\mathbb{R}^{4n};L_i^{\ell'})$ for any $\ell'>\ell$. This implies that there exist k, $\epsilon_i=\epsilon_i(\ell')$ and $R_{ij}=R_{ij}(\ell')$ such that

$$|\tilde{\mathcal{W}}_n(\tilde{f})|\leqslant C\|\tilde{f}\|_{K_i^{\epsilon,R},k}$$

for $\tilde{f}\in H(\mathbb{R}^{4n};L_i^{\ell'})$. The function $R_{ij}(r)$ can be chosen such that $R_{ij}(\ell')\geqslant R_{ij}(\ell'')$ when $\ell'<\ell''$. Let $|q|_\infty=\max\{|q^0|,|\mathbf{q}|\}$. Then we have

$$h_{K_i^{\epsilon,R}}(q)=(\ell'-\epsilon_i)|q_i|_\infty+\sum_{j\neq i}R_{ij}|q_j|_\infty.$$

Since the support of $\tilde{W}_{n-1}$ is contained in $\overline{V}_+^{n-1}$, it follows from Theorem 2.16 and Remark 2.18 that $W_{n-1}(\zeta)$ is holomorphic in

$$\{\zeta\in\mathbb{C}^{4(n-1)};\mathrm{Im}\,\zeta_i\in V_+ +(\ell',\mathbf{0}),\mathrm{Im}\,\zeta_j\in V_+ +(R_{ij}(\ell'),\mathbf{0}),\ \ \ell<\ell',j\neq i\}$$

and polynomially increasing there for $i=1,\ldots,n-1$. This completes the proof. □

Now choose $R\in\mathbb{R}$ such that $W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})$ is holomorphic on Γ_R^{n-1}, where $\Gamma_R=\mathbb{R}^4\times(iR,0,0,0)\subset\mathbb{C}^4$. This holomorphic function defines a functional on $\mathcal{T}(T(\mathbb{R}^{4(n-1)}))$ (denoted in the same way) according to the following formula:

$$W_{n-1}(g)=\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})g(\zeta_1,\ldots,\zeta_{n-1})\mathrm{d}\zeta_1\cdots\mathrm{d}\zeta_{n-1} \tag{4.10}$$

for all $g\in\mathcal{T}(T(\mathbb{R}^{4(n-1)}))$. One expects that $W_{n-1}(g)=\tilde{W}_{n-1}(\tilde{g})$ holds. We prepare the proof of this basic relation by the following proposition.

Proposition 4.8: Let $k'>k>0$, $K'=\{q\in\mathbb{R}^4;|q|_1\leqslant k'\}$, $K=\{q\in\mathbb{R}^4;|q|_1\leqslant k\}$, $g\in H_b(\mathbb{R}^4;K')$ *and* $g_x(p)=e^{ixp}g(p)$. *Then the mapping*

$$\mathbb{R}^4\ni x\to g_x\in H_b(\mathbb{R}^4;K) \tag{4.11}$$

is continuous at $x=0$.

Proof: The fundamental theorem of calculus gives $e^{izp}-1=izp\int_0^1 e^{itzp}\,\mathrm{d}t$ and thus, using the well-known estimate $(a>0)$ $xe^{-ax}\leqslant 1/ae$, $\forall\, x\geqslant 0$, for $z\neq 0$, $|z|<\delta/2$,

$$\sup_{p\in\mathbb{R}}|e^{izp}-1|e^{-\delta|p|}\leqslant\frac{2}{e\delta}|z|.$$

Observe the decomposition

$$(e^{ixp}-1)=\sum_{k=0}^{3}(e^{ix^kp^k}-1)\prod_{j=k+1}^{3}e^{ix^jp^j}$$

and the obvious bound $|p^j|\leqslant|p|_\infty$. Then the above estimate implies

$$e^{-\delta|p|_\infty}|e^{ix^kp^k}-1|\prod_{j=k+1}^{3}|e^{ix^jp^j}|\to 0$$

as $x\to 0$ uniformly in p. This estimate can easily be extended to include derivatives,

$$|D^\alpha(e^{ixp}-1)|e^{-\delta|p|}=|(ix)^\alpha e^{ixp}|e^{-\delta|p|_\infty}\to 0,$$

as $x\to 0$ uniformly in p. Since $g\in H_b(\mathbb{R}^4;K')$ satisfies

$$|D^qg(p)|e^{k'|p|_\infty}\leqslant M_{q,k'}<\infty,$$

we conclude

$$|D^q(e^{ixp}-1)D^rg(p)|e^{k|p|_\infty}\leqslant M_{r,k'}|D^q(e^{ixp}-1)|e^{-\delta|p|_\infty}\to 0,$$

as $x\to 0$ uniformly in p, where $\delta=k'-k$. By using Leibniz' formula, we finally get

$$|D^q\{(e^{ixp}-1)g(p)\}|e^{k|p|_\infty}\to 0$$

as $x\to 0$, uniformly in p. This shows that the mapping (4.11) is continuous at $x=0$. □

Now consider a C^∞ function f on $\mathbb{R}^4$ with all derivatives bounded such that $f(q)=1$ in the neighborhood Σ_ϵ and $f(q)=0$ outside of $V_{+2\epsilon}\supset\Sigma_{2\epsilon}$. Then for $R>k$, $e^{i\zeta q}f(q)\in H_b(\mathbb{R}^4;K)$ for $\zeta\in\Gamma_R$, and it follows from Proposition 4.8 that the mapping

$$\Gamma_R\ni\zeta\to e^{i\zeta q}f(q)\in H_b(\mathbb{R}^4;K)$$

is continuous, and

$$\|e^{i\zeta q}f(q)\|_{K,j}\leqslant C\prod_{j=1}^{4}(1+|\zeta_j|)^j$$

for some $C>0$. Let $f_{n-1}(q_1,\ldots,q_{n-1})=\Pi_{j=1}^{n-1}f(q_j)$. Then Propositions 2.10 and 2.11 imply that

$$\begin{aligned}\tilde{W}_{n-1}(\tilde{g})=\tilde{W}_{n-1}(f_{n-1}\cdot\tilde{g})&=\tilde{W}_{n-1}\left((2\pi)^{-2(n-1)}\int_{\Gamma_R^{n-1}}f_{n-1}(q)e^{i\langle\zeta,q\rangle}g(\zeta)\mathrm{d}\zeta\right)\\&=(2\pi)^{-2(n-1)}\int_{\Gamma_R^{n-1}}\tilde{W}_{n-1}(f_{n-1}(q)e^{i\langle\zeta,q\rangle})g(\zeta)\mathrm{d}\zeta\\&=(2\pi)^{-2(n-1)}\int_{\Gamma_R^{n-1}}\tilde{W}_{n-1}(e^{i\langle\zeta,q\rangle})g(\zeta)\mathrm{d}\zeta\\&=\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})g(\zeta_1,\ldots,\zeta_{n-1})\mathrm{d}\zeta_1\ldots\mathrm{d}\zeta_{n-1}=W_{n-1}(g).\end{aligned}$$

E. Implications of Poincaré covariance and quasilocality

For $\ell>0$ introduce

$$\mathcal{I}_i^{n-1}(\ell)=\bigcup_{u\in V_+,u^2=1,\ell<\ell'}\mathcal{I}_i^{n-1}(\ell',u),$$

where

$$\mathcal{I}_i^{n-1}(\ell',u)=\{\zeta\in\mathbb{C}^{4(n-1)};\mathrm{Im}\,\zeta_i\in V_+ +\ell' u,\ \ \mathrm{Im}\,\zeta_j\in V_+ +R_{ij}(\ell')u,\ \ j\neq i\}$$

and then

$$\mathcal{I}_{\mathrm{ext},i}^{n-1}(\ell)=\{\zeta\in\mathbb{C}^{4(n-1)};\exists\Lambda\in L_+(\mathbb{C}),\ \ \Lambda\zeta=(\Lambda\zeta_1,\ldots,\Lambda\zeta_{n-1})\in\mathcal{I}_i^{n-1}(\ell)\}.$$

Let $\mathcal{I}^{n-1}=\mathcal{I}^{n-1}(\ell)$ be the convex envelope of $\cup_{i=1}^{n-1}\mathcal{I}_i^{n-1}(\ell)$. Then it follows from Bochner's theorem on tubular domains (see Sec. 17.5 of Ref. 31) that $W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})$ is analytic in $\mathcal{I}^{n-1}$. Moreover, it can be analytically continued to

$$\mathcal{I}_{\mathrm{ext}}^{n-1}=\{\zeta\in\mathbb{C}^{4(n-1)};\exists\Lambda\in L_+(\mathbb{C}),\ \Lambda\zeta=(\Lambda\zeta_1,\ldots,\Lambda\zeta_{n-1})\in\mathcal{I}^{n-1}\},$$

which is equal to the convex envelope of $\cup_{i=1}^{n-1}\mathcal{I}_{\mathrm{ext},i}^{n-1}(\ell)$, since the Bargman–Hall–Wightman theorem holds also in this case. The proof of the ordinary local case (see Ref. 7) is also applicable to our case. $\mathcal{W}_n(z_1,\ldots,z_n)$ is holomorphic in the domain

$$G_n=\{(z_1,\ldots,z_n);(z_2-z_1,\ldots,z_n-z_{n-1})\in\mathcal{I}_{\mathrm{ext}}^{n-1}\}.$$

Denote

$$L_+(\mathbb{C})\ni\Lambda(t)=\begin{pmatrix}\cos t & i\sin t & & & \\ i\sin t & \cos t & & & \\ & & 1 & 0 & \\ & 0 & & & \\ & & 0 & 1 & \end{pmatrix},$$

$$L_+^{\uparrow} \ni R(\theta)=\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta & 0 \\ & \sin\theta & \cos\theta & \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Let $j>0$ and introduce the functions

$$E_j(\zeta)=(j/\pi)^{2(n-1)}\exp\left\{-j\sum_{k=1}^{n-1}\sum_{\alpha=0}^{3}(\zeta_k^{\alpha})^2\right\}.$$

Lemma 4.9: Let $R>0$ be a sufficiently large number as specified for (4.10) and $\rho=(\rho_1,\ldots,\rho_{n-1})$ be a real element of $\mathcal{T}_{\text{ext}}^{n-1}$ satisfying $\xi+ia\in G_n$ for $|\xi-\rho|\leqslant\delta$ for some $\delta\geqslant\sqrt{n}R$ and for any real a such that $a_k=(a_k^0,0,0,0)$. Then we have

$$\int_{\Gamma_R^{n-1}} W_{n-1}(\zeta)E_j(\zeta-\rho)\mathrm{d}\zeta\to W_{n-1}(\rho)$$

as $j\to\infty$.

Proof: Since

$$|\exp\{-j(\zeta-\rho)^2\}|\leqslant\exp\{-j[(\xi-\rho)^2-(n-1)R^2]\}$$

and $W_{n-1}(\zeta)$ is polynomially bounded, we have

$$\left|\int_{\Gamma_R^{n-1},|\xi-\rho|\geqslant\delta} W_{n-1}(\zeta)E_j(\zeta-\rho)\mathrm{d}\zeta\right|\leqslant C_{\delta,R}j^{2(n-1)}\exp\{-j(\delta^2-(n-1)R^2)\}$$

for some constant $C_{\delta,R}>0$. Thus, if $\delta^2\geqslant nR^2$ this contribution tends to zero as $j\to\infty$. Changing the path (surface) of integration, we have

$$\int_{\Gamma_R^{n-1},|\xi-\rho|\leqslant\delta} W_{n-1}(\zeta)E_j(\zeta-\rho)\mathrm{d}\zeta=\int_S W_{n-1}(\zeta)E_j(\zeta-\rho)\mathrm{d}\zeta+\int_{|\xi-\rho|\leqslant\delta} W_{n-1}(\xi)E_j(\xi-\rho)\mathrm{d}\xi \tag{4.12}$$

by Cauchy–Poincaré theorem, where

$$S=\{\zeta\in\mathbb{C}^{n-1};|\xi-\rho|=\delta,y_j^0=tR,\leqslant t\leqslant 1,j=1,\ldots,n-1\}.$$

Since $E_j(\zeta-\rho)\to 0$ for $\zeta\in S$ as $j\to\infty$ and S is compact, the first term of (4.12) vanishes while the second term tends to $W_{n-1}(\rho)$ because $E_j(\xi-\rho)$ tends to $\delta(\xi-\rho)$. □

There exist real points ρ satisfying the condition of Lemma 4.9. In fact, it follows from Proposition 4.7 that for any $\ell'>\ell$ there exists $S>0$ such that $\zeta=(\zeta_1,\ldots,\zeta_{n-1})\in\mathcal{I}_k^{n-1}$ for $\zeta_k\in\Gamma_{R'},\zeta_j\in\Gamma_R$ $(j\neq k)$ for all $R\geqslant S$ and $R'\geqslant\ell'$. We suppose $\ell'\leqslant S$.

Let $\rho_j=(ia_j+\alpha_j,3U+\beta_j,b_j,c_j)$ where $U\geqslant S,|\alpha_j|,|\beta_j|\leqslant U$, and a_j,b_j,c_j are arbitrary real numbers. Then $\Lambda(\pi/2)\rho_j=(i(3U+\beta_j),-a_j+i\alpha_j,b_j,c_j)$ and $\rho=(\rho_1,\ldots,\rho_{n-1})\in\mathcal{I}_{\text{ext}}^{n-1}$.

Let $\rho_j=(ia_j+\alpha_j,b_j,3U+\beta_j,c_j)$. Then $R(-\pi/2)\rho_j=(ia_j+\alpha_j,3U+\beta_j,-b_j,c_j)$ and $\rho\in\mathcal{I}_{\text{ext}}^{n-1}$.

Let σ be the permutation of k and $k+1$, that is, $\sigma(k)=k+1,\sigma(k+1)=k$ and $\sigma(j)=j$ for $j\neq k,k+1$, and $r_j=(0,3\sqrt{n}jR,3\sqrt{n}\sigma(j)R,0)$. Then $\rho_j=r_{j+1}-r_j=(0,3\sqrt{n}R,3\sqrt{n}(\sigma(j+1)-\sigma(j))R,0)$ and therefore $\rho\in\mathcal{I}_{\text{ext}}^{n-1}$. Moreover if $|\xi_j-\rho_j|\leqslant\sqrt{n}R$, $\xi+ia\in\mathcal{I}_{\text{ext}}^{n-1}$. Thus ρ satisfies the condition of Lemma 4.9.

Let $\sigma\rho=\rho'=(\rho_1',\ldots,\rho_{n-1}')$, where $\rho_j'=r_{\sigma(j+1)}-r_{\sigma(j)}$. Then $\sigma\rho$ also satisfies the condition of Lemma 4.9 since $\rho_j'=(0,3\sqrt{n}(\sigma(j+1)-\sigma(j))R,3\sqrt{n}jR,0)$.

The transposition σ of z_k and z_{k+1}, $1\leqslant k\leqslant n-1$, is expressed in terms of the difference variables ζ_j in the following way (compare Sec. IV C):

$$\zeta_k\rightarrow\zeta_k'=-\zeta_k,$$

$$\zeta_{k-1}\rightarrow\zeta_{k-1}'=\zeta_{k-1}+\zeta_k,$$

$$\zeta_{k+1}\rightarrow\zeta_{k+1}'=\zeta_{k+1}+\zeta_k,$$

$$\zeta_j'=\zeta_j \text{ for the remaining indices } j.$$

The following proposition follows from Lemma 4.9.

Proposition 4.10: For the points ρ, $\rho'\in\mathcal{I}_{\mathrm{ext}}^{n-1}$ as above one has, as $j\rightarrow\infty$,

$$\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta)(E_j(\zeta-\rho)-E_j(\zeta'-\rho))\mathrm{d}\zeta\rightarrow W_{n-1}(\rho)-W_{n-1}(\rho').$$

The transformation $(z_1,\ldots,z_n)\rightarrow(\zeta_0,\ldots,\zeta_{n-1})=\lambda_n(z_1,\ldots,z_n)$ introduced in Sec. IV C, maps the set $W_k^{\ell'}$ to the set

$$V_k^{\ell'}=\{(\zeta_0,\ldots,\zeta_{n-1})\in\mathbb{C}^{4n};\zeta_k\in V^{\ell'}\}.$$

For $g_1\in\mathcal{T}(T(\mathbb{R}^4))$ and $g_2\in\mathcal{T}(T(\mathbb{R}^{4(n-1)}))$ define

$$f(z_1,\ldots,z_n)=(g_1g_2)(\lambda_n(z_1,\ldots,z_n))\in\mathcal{T}(T(\mathbb{R}^{4n})).$$

As earlier one gets

$$\mathcal{W}_n(f)=\int_{\mathbb{R}^4}g_1(x)\mathrm{d}x\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta_1,\ldots,\zeta_{n-1})g_2(\zeta_1,\ldots,\zeta_{n-1})\mathrm{d}\zeta_1\cdots\mathrm{d}\zeta_{n-1},$$

which corresponds to Eq. (4.7). Therefore we deduce

$$(\mathcal{W}_n\circ c_k^n)(f)=\int_{\mathbb{R}^4}g_1(x)\mathrm{d}x\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta)(g_2(\zeta)-g_2(\zeta'))\mathrm{d}\zeta$$

and the functional

$$\mathcal{T}(T(\mathbb{R}^{4(n-1)}))\ni f\rightarrow\int_{\Gamma_R^{n-1}}W_{n-1}(\zeta)(f(\zeta)-f(\zeta'))\mathrm{d}\zeta$$

belongs to $\mathcal{T}(V_k^{\ell'})'$.

Since $\rho_k=(0,3\sqrt{n}R,-3\sqrt{n}R,0)$,

$$\mathrm{Re}(\zeta_k-\rho_k)^2=(\mathrm{Re}\,\zeta_k-\rho_k)^2-(\mathrm{Im}\,\zeta_k)^2\geqslant(3/\sqrt{n}R-\ell')^2-\ell'^2$$

if $\zeta_k\in V^{\ell'}$, and

$$\sum_{j=1}^{n-1}\mathrm{Re}(\zeta_j-\rho_j)^2\geqslant(3/\sqrt{n}R-\ell')^2-\ell'^2-(n-2)R^2$$

if $\zeta_k\in V_k^{\ell'}$. If we take $R\geqslant\ell'$, this estimate implies

$$\sup_{\zeta \in V_k^{\ell'}, |\mathrm{Im}\,\zeta_j| \leqslant R} |E_j(\zeta-\rho)| \leqslant (j/\pi)^{(n-1)/2} \exp\{-j5nR^2\} \to 0$$

as $j \to \infty$. Similarly we get that for any multi-index p, as $j \to \infty$,

$$\sup_{\zeta \in V_k^{\ell'}, |\mathrm{Im}\,\zeta_j| \leqslant R} |\zeta^p E_j(\zeta-\rho)| \to 0$$

and this in turn gives

$$\int_{\Gamma_R^{n-1}} (W_{n-1}(\zeta) - W_{n-1}(\zeta')) E_j(\zeta-\rho) \mathrm{d}\zeta \to 0$$

for $j \to \infty$. This and Proposition 4.10 show that $W_{n-1}(\rho) = W_{n-1}(\rho')$ and thus

$$\mathcal{W}_n(r_1,\ldots,r_k,r_{k+1},\ldots,r_n) = \mathcal{W}_n(r_1,\ldots,r_{k+1},r_k,\ldots,r_n).$$

Therefore we can formulate the main result of this section as follows:

Theorem 4.11: *On their respective domains of holomorphy the n-point or Wightman functions $\mathcal{W}_n$ are symmetric.*

V. FUNCTIONAL CHARACTERIZATION OF UHQFT

The analysis of the preceding sections has shown that the sequence of vacuum expectation values of an ultra-hyperfunction quantum field theory has a number of specific properties. In analogy to standard quantum field theory we single out a set of properties of these vacuum expectation values which actually characterizes an ultra-hyperfunction quantum field theory up to isomorphisms.

Properties of UHQFT functionals:

(R0) $\mathcal{W}_0 = 1$, $\mathcal{W}_n \in \mathcal{T}(T(\mathbb{R}^{4n}))'$ for $n \geqslant 1$, and $\mathcal{W}_n(f^*) = \overline{\mathcal{W}_n(f)}$, for all $f \in \mathcal{T}(T(\mathbb{R}^{4n})) \equiv E(n)$, where $f^*(z_1,\ldots,z_n) = \overline{f(\overline{z_n},\ldots,\overline{z_1})}$.

(R1) $\mathcal{W}_n(f) = \mathcal{W}_n(f_{(a,\Lambda)})$ for all $(a,\Lambda) \in \mathcal{P}_+^{\uparrow}$, all $f \in \mathcal{T}(T(\mathbb{R}^{4n}))$, and all $n = 1,2,\ldots$.

(R2) For any finite set f_0, $f_1,\ldots,f_N$ of test functions such that $f_0 \in \mathbb{C}$, $f_n \in \mathcal{T}(T(\mathbb{R}^{4n}))$ for $1 \leqslant n \leqslant N$, one has

$$\sum_{m,n=0}^{N} \mathcal{W}_{m+n}(f_m^* \otimes f_n) \geqslant 0.$$

(R3) For all $n = 2,3,\ldots$ and all $i = 1,\ldots,n-1$ denote

$$L_i^{\ell} = \{x = (x_1,\ldots,x_n) \in \mathbb{R}^{4n}; |x_i - x_{i+1}|_1 < \ell\},$$
$$W_i^{\ell} = \{(z_1,\ldots,z_n) \in \mathbb{C}^{4n}; z_i - z_{i+1} \in V^{\ell}\}.$$

Then, for any $\ell' > \ell$,

(i) $\mathcal{W}_n \in \mathcal{T}(T(\mathbb{R}^{4n}))'$ belongs to $\mathcal{T}(T(L_i^{\ell'}))'$ and

(ii) $\mathcal{W}_n \circ c_i^n$ belongs to $\mathcal{T}(W_i^{\ell'})'$,

where

$$(\mathcal{W}_n \circ c_i^n)(f) = \mathcal{W}_n(c_i^n(f)),$$
$$c_i^n(f)(x_1,\ldots,x_n) = f(x_1,\ldots,x_i,x_{i+1},\ldots,x_n) - f(x_1,\ldots,x_{i+1},x_i,\ldots,x_n).$$

(R4) For the Fourier transform $\tilde{\mathcal{W}}_n \in H(\mathbb{R}^{4n};\mathbb{R}^{4n})'$ of $\mathcal{W}_n$, there exists $\tilde{W}_{n-1} \in H(\mathbb{R}^{4(n-1)};\mathbb{R}^{4(n-1)})'$ such that

$$\tilde{\mathcal{W}}_n \circ \chi_n(q_0,\ldots,q_{n-1}) = (2\pi)^2 \delta(q_0) \tilde{W}_{n-1}(q_1,\ldots,q_{n-1})$$

and supp $\widetilde{W}_{n-1} \subset \Sigma^{n-1}$.

(R5) For a spacelike vector $\mathbf{a} \in \mathbb{R}^4$ and $g_n \in E(n)$ introduce, for all $\lambda > 0$,

$$g_{n,\lambda}(x_1,\ldots,x_n) = g_n(x_1 - \lambda \mathbf{a},\ldots,x_n - \lambda \mathbf{a}).$$

Then, for every $f_m \in E(m)$ and $g_n \in E(n)$ as $\lambda \to \infty$,

$$\mathcal{W}_{m+n}(f_m \otimes g_{n,\lambda}) \to \mathcal{W}_m(f_m)\mathcal{W}_n(g_n).$$

The properties (R0)–(R2) are obvious from the definitions. (R3) and (R4) are shown in the preceding section. (R5) is shown without using locality condition as in the book of Jost.[25]

Theorem 5.1 (Reconstruction theorem): *To a given sequence* $(\mathcal{W}_n)_{n \in \mathbb{N}}$ *of tempered ultra-hyperfunctions satisfying the conditions (R0)–(R5), there corresponds a neutral scalar field* $A(f)$ *which obeys all the axioms* (H_1)–(H_5) *and has the given tempered ultra-hyperfunctions as vacuum expectation values. The field A is unique up to isomorphisms.*

Sketch of the proof: The proof of the theorem differs from the standard one (see for instance Refs. 1, 25) only with regard to those points related to local commutativity. Accordingly we comment only on these aspects.

(R3) implies that, for arbitrary $\Phi = \Phi_m(f_m)$ and $\Psi = \Phi_n(g_n)$, the functional

$$E \otimes E \ni h \otimes k \to (\Phi, A(h)A(k)\Psi) = \mathcal{W}_{m+n+2}(f_m^* \otimes h \otimes k \otimes g_n)$$

can be extended continuously to a functional on $\mathcal{T}(T(L^\ell))$ and moreover

$$E \otimes E \ni h \otimes k \to (\Phi, A(h)A(k)\Psi) - (\Phi, A(k)A(h)\Psi)$$

can be extended continuously to a functional on $\mathcal{T}(W^\ell)$. It follows from the Theorems 2.4 and 2.13 that the above extension is unique. This implies H_5. □

VI. MODELS

We are going to construct models of relativistic quantum fields with a fundamental length by constructing a sequence of n-point functionals which satisfies conditions (R0)–(R5) and then applying the reconstruction theorem 5.1. Our starting points are the well-known results of Jaffe[32] on formal Wick power series of free fields. If we consider the power series of a free field ϕ,

$$\rho^{(i)}(x) = \sum_{n=0}^{\infty} a_n^{(i)} \frac{:\phi(x)^n:}{n!}, \tag{6.1}$$

then we have the following theorem.

Theorem 6.1 (Theorem A.1 of Ref. 32): *As a formal power series*

$$(\Omega, \rho^{(1)}(x_1)\cdots\rho^{(n)}(x_n)\Omega) = \sum_{r_{ij}=0;\ 1 \le i<j \le n}^{\infty} \frac{A(R)T^R}{R!}, \tag{6.2}$$

$$r_{ij} = r_{ji}, \quad r_{ii} = 0, \quad R_i = \sum_{j=1}^{n} r_{ij}, \quad A(R) = \prod_{j=1}^{n} a_{R_j}^{(j)},$$

$$R! = \prod_{1 \le i<j \le n} (r_{ij})!, \quad T^R = \prod_{1 \le i<j \le n} (t_{ij})^{r_{ij}}, \tag{6.3}$$

$$t_{ij} = (\Omega, \phi(x_i)\phi(x_j)\Omega) = D_m^{(-)}(x_i - x_j).$$

Therefore

$$(\Omega,\rho^{(i)}(x)\rho^{(i)}(y)\Omega)=\sum_{n=0}^{\infty}\frac{a_n^{(i)2}}{n!}D_m^{(-)}(x-y)^n,$$

$$D_m^{(-)}(x)=(2\pi)^{-3}\int_{\mathbf{R}^3}[2\omega(\mathbf{k})]^{-1}e^{-i\omega(\mathbf{k})x^0}e^{i\mathbf{k}\cdot\mathbf{x}}\,d\mathbf{k}$$

$$[k\cdot x=k^0x^0-\mathbf{k}\cdot\mathbf{x},\quad \omega(\mathbf{k})=\sqrt{\mathbf{k}^2+m^2}].$$

If the coefficients $\{a_n^{(i)}\}$ satisfy $\lim_{n\to\infty}[|a_n^{(i)}|^2/n!]^{1/n}=0$ then the series (6.1) defines a hyperfunction quantum field (see Ref. 33).

Now we assume that for some $\sigma>0$

$$\limsup_{n\to\infty}[|a_n^{(i)}|^2/n!]^{1/n}=\sigma. \tag{6.4}$$

For example, consider

$$\rho(x)=:e^{g\phi(x)^2}:=\sum_{n=0}^{\infty}g^n\frac{:\phi(x)^{2n}:}{n!}=\sum_{n=0}^{\infty}g^n\frac{(2n)!}{n!}\frac{:\phi(x)^{2n}:}{(2n)!}. \tag{6.5}$$

Then

$$\sigma=\lim_{n\to\infty}\left[g^{2n}\frac{(2n)!}{(n!)^2}\right]^{1/2n}=2g$$

and

$$(\Omega,\rho(x)\rho(y)\Omega)=\sum_{n=0}^{\infty}\left(g^n\frac{(2n)!}{n!}\right)^2\frac{1}{(2n)!}D_m^{(-)}(x-y)^{2n}.$$

Since

$$(1-x)^{-\alpha}=1+\alpha x+\frac{\alpha(\alpha+1)}{2!}x^2+\cdots+\frac{\alpha(\alpha+1)\cdots(\alpha+n-1)}{n!}x^n+\cdots,$$

and for $\alpha=1/2$

$$\frac{\alpha(\alpha+1)\cdots(\alpha+n-1)}{n!}=\frac{(2n)!}{4^n n!}\frac{1}{n!},$$

we get, in the sense of formal power series,

$$(\Omega,\rho(x)\rho(y)\Omega)=[1-4g^2D_m^{(-)}(x-y)^2]^{-1/2}. \tag{6.6}$$

Now we investigate the convergence of this power series, in the sense of tempered ultrahyperfunctions. To this end consider the power series

$$\sum_{r_{ij}=0;\ 1\leqslant i<j\leqslant n}^{\infty}\frac{A(R)Z^R}{R!} \tag{6.7}$$

in the variables z_{ij} $(1\leqslant i<j\leqslant n)$, where $Z^R=\Pi_{1\leqslant i<j\leqslant n}(z_{ij})^{r_{ij}}$. Let

$$\|R\| = \sum_{1 \leqslant i < j \leqslant n} r_{ij} \tag{6.8}$$

and $t_{ij} (1 \leqslant i < j \leqslant n)$ be positive constants. Suppose

$$\limsup_{\|R\| \to \infty} \left[\frac{|A(R)| T^R}{R!} \right]^{1/\|R\|} \leqslant 1.$$

Then the fact that the series (6.7) converges if $|z_{ij}| < t_{ij} (1 \leqslant i < j \leqslant n)$ follows from the following theorem of Lemire.

Theorem 6.2: *The associated convergence radii* $(r_1, \ldots, r_n)$ *of a series* $\Sigma a_{\nu_1, \ldots, \nu_n} z_1^{\nu_1} \cdots z_n^{\nu_n}$ *satisfy*

$$\limsup_{\nu_1 + \cdots + \nu_n \to \infty} [|a_{\nu_1, \ldots, \nu_n}| r_1^{\nu_1} \cdots r_n^{\nu_n}]^{1/(\nu_1 + \cdots + \nu_n)} = 1.$$

The multinomial theorem implies

$$R_i! \prod_{j=1, j \neq i}^{n} \frac{t_{ij}^{r_{ij}}}{(r_{ij})!} \leqslant \left(\sum_{j=1, j \neq i}^{n} t_{ij} \right)^{R_i}$$

and according to Eqs. (6.3) and (6.8) we know

$$\sum_{i=1}^{n} R_i = 2\|R\|, \quad \prod_{i=1}^{n} \prod_{j=1, j \neq i}^{n} (r_{ij})! = (R!)^2, \quad \prod_{i=1}^{n} \prod_{j=1, j \neq i}^{n} t_{ij}^{r_{ij}} = (T^R)^2;$$

hence

$$\left[\frac{|A(R)| T^R}{R!} \right]^2 = \frac{\prod_{i=1}^{n} |a_{R_i}^{(i)}|^2 (T^R)^2}{(R!)^2} = \prod_{i=1}^{n} \left(|a_{R_i}^{(i)}|^2 \prod_{j=1, j \neq i}^{n} \frac{t_{ij}^{r_{ij}}}{(r_{ij})!} \right)$$

and

$$\left[\frac{|A(R)| T^R}{R!} \right]^{1/\|R\|} = \prod_{i=1}^{n} \left[|a_{R_i}^{(i)}|^2 \prod_{j=1, j \neq i}^{n} \frac{t_{ij}^{r_{ij}}}{(r_{ij})!} \right]^{1/2\|R\|} = \prod_{i=1}^{n} \left[\frac{|a_{R_i}^{(i)}|^2}{R_i!} R_i! \prod_{j=1, j \neq i}^{n} \frac{t_{ij}^{r_{ij}}}{(r_{ij})!} \right]^{1/2\|R\|}$$

$$\leqslant \prod_{i=1}^{n} \left[\frac{|a_{R_i}^{(i)}|^2}{R_i!} \left(\sum_{j=1, j \neq i}^{n} t_{ij} \right)^{R_i} \right]^{1/2\|R\|} = \prod_{i=1}^{n} \left[\left(\frac{|a_{R_i}^{(i)}|^2}{R_i!} \right)^{1/R_i} \left(\sum_{j=1, j \neq i}^{n} t_{ij} \right) \right]^{R_i/2\|R\|}.$$

Suppose that $t_{kk+1} < 1/\sigma$, and the other t_{ij}'s are so small that

$$\sum_{1 \leqslant i < j \leqslant n} t_{ij} < \frac{1}{\sigma}.$$

This then implies

$$\limsup_{\|R\| \to \infty} \prod_{i=1}^{n} \left[\left(\frac{|a_{R_i}^{(i)}|^2}{R_i!} \right)^{1/R_i} \left(\sum_{j=1, j \neq i}^{n} t_{ij} \right) \right]^{R_i/2\|R\|} \leqslant 1$$

and the power series (6.7) is convergent for $|z_{ij}| < t_{ij} (1 \leqslant i < j \leqslant n)$. Now we consider the case of $m = 0$ for simplicity. In this case the growth of the two-point function of the free field is easier to estimate. Recall

$$D_0^{(-)}(x)=\lim_{\epsilon\to+0}(2\pi)^{-2}[(x^0-i\epsilon)^2-\mathbf{x}^2]^{-1},$$

$$|(x^0-i\epsilon)^2-\mathbf{x}^2|=|x^2-\epsilon^2-2i\epsilon x^0|.$$

We claim that we can find $\epsilon\geqslant 0$ such that

$$|(2\pi)^{-2}[(x^0-i\epsilon)^2-\mathbf{x}^2]^{-1}|<1/\sigma.$$

For $x^2\leqslant 0$, $|x^2-\epsilon^2-2i\epsilon x^0|\geqslant|x^2-\epsilon^2|\geqslant|x^2|+\epsilon^2$, and for $x^2\geqslant 0$, $|x^2-\epsilon^2-2ix^0|\geqslant|x^2-\epsilon^2-2i\epsilon\sqrt{x^2}|=x^2+\epsilon^2$, and $(|x^2|+\epsilon^2)^{-1}<(2\pi)^2/\sigma$ is equivalent to $\epsilon^2>\sigma/(2\pi)^2-|x^2|$. Choose a number $r'>\sqrt{\sigma}/(2\pi)$ and define

$$\epsilon(x)=\sqrt{\max\{r'^2-|x^2|,0\}}. \tag{6.9}$$

For such a choice one has

$$|(2\pi)^{-2}[(x^0-i\epsilon(x))^2-\mathbf{x}^2]^{-1}|<1/\sigma.$$

Finally we fix the fundamental length for these models,

$$\ell=\sqrt{\sigma}/(2\pi). \tag{6.10}$$

It is easily seen that for any $\ell'>\ell$ there exist $\epsilon(x)$ such that

$$\{(x^0+i\epsilon(x),x^1,x^2,x^3);x\in\mathbb{R}^4\}\subset V^{\ell'}.$$

Therefore, for any $\ell'>\ell$ there exists $R>0$ such that (in formal but suggestive notation)

$$W_{n-1}(\zeta)=\mathcal{W}_n(z)=(\Phi_0,\rho(z_1)\cdots\rho(z_k)\rho(z_{k+1})\cdots\rho(z_n)\Phi_0)$$

is a well-defined holomorphic function for

$$\mathrm{Im}\,\zeta_k=\mathrm{Im}(z_{k+1}-z_j)\in V_+ +(\ell',0,0,0)$$

and

$$\mathrm{Im}\,\zeta_j=\mathrm{Im}(z_{j+1}-z_j)\in V_+ +(R,0,0,0)\quad (j\neq k). \tag{6.11}$$

This implies that $\mathcal{W}_n$ satisfies the condition (i) of the axiom (R3). That is, the mapping

$$\mathcal{T}(T(\mathbb{R}^{4n}))\ni f\to\mathcal{W}(f)=\int_{\Pi_{i=0}^{n-1}\Gamma_i}W_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1}$$

is continuous and can be extended continuously to

$$\mathcal{T}(T(L_k^{\ell'}))\ni f\to\mathcal{W}(f)=\int_{\Pi_{i=0}^{n-1}\Gamma_i}W_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1},$$

where, with $\epsilon(x)$ according to (6.9) and R sufficiently large,

$$\Gamma_k=\{(x^0+i\epsilon(x),x^1,x^2,x^3);x\in\mathbb{R}^4\},\quad \Gamma_j=\{(x^0+iR,x^1,x^2,x^3);x\in\mathbb{R}^4\}$$

and $g(\zeta)=f(\zeta_0,\zeta_0+\zeta_1,\ldots,\zeta_0+\cdots+\zeta_{n-1})$. Now consider the formula

$$\prod_{1\leqslant i<j\leqslant n}(t_{i,j})^{r_{i,j}}=(t_{k,k+1})^{r_{k,k+1}}\prod_{1\leqslant i<j\leqslant n,\ i\neq k,\ j\neq k+1}(t_{i,j})^{r_{i,j}}$$
$$\times\prod_{1\leqslant i<k}(t_{i,k})^{r_{i,k}}\prod_{k+1<j\leqslant n}(t_{k,j})^{r_{k,j}}$$
$$\times\prod_{1\leqslant i<k}(t_{i,k+1})^{r_{i,k+1}}\prod_{k+1<j\leqslant n}(t_{k+1,j})^{r_{k+1,j}}.$$

The transposition of x_k and x_{k+1} causes the transposition of $(t_{k,k+1})^{r_{k,k+1}}$ and $(t_{k+1,k})^{r_{k+1,k}}$ in the first line, and the transposition of the second line and the third line. If x_k and x_{k+1} are spacelike separated, then $t_{k,k+1}=t_{k+1,k}$. The function

$$W^k_{n-1}(\zeta)=(\Phi_0,\rho(z_1)\cdots\rho(z_{k+1})\rho(z_k)\cdots\rho(z_n)\Phi_0)$$

is also holomorphic in a domain defined by (6.11) and

$$-\operatorname{Im}\zeta_k\in V_+ +(\ell',0,0,0).$$

Moreover, if ζ_k lies in $\mathbb{R}^4\backslash V^{\ell'}$, the functions $W_{n-1}(\zeta)$ and $W^k_{n-1}(\zeta)$ are well defined and coincide. Thus we have

$$(\mathcal{W}_n\circ c^n_k)(f)=\int_{\Pi_{i=0}^{n-1}\Gamma_i}W_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1}-\int_{-\Gamma_k\Pi_{i\neq k}\Gamma_i}W^k_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1}$$
$$=\int_{\Gamma^{\ell'}_k\Pi_{i\neq k}\Gamma_i}W_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1}-\int_{-\Gamma^{\ell'}_k\Pi_{i\neq k}\Gamma_i}W^k_{n-1}(\zeta)g(\zeta)\mathrm{d}\zeta_0\cdots\mathrm{d}\zeta_{n-1},$$

where

$$\Gamma^\ell_k=\{(x^0+i\epsilon(x),x^1,x^2,x^3);x\in\mathbb{R}^4\cap V^\ell\}$$

and we used the fact that $W_{n-1}(\zeta)$ and $W^k_{n-1}(\zeta)$ coincides for $\zeta_k\in\mathbb{R}^4\backslash V^{\ell'}$. The above formula shows that the functional $\mathcal{W}_n\circ c^n_k$ belongs to $\mathcal{T}(T(W^{\ell'}_k))'$ for any $\ell'>\ell$ which shows condition (ii) of axiom (R3). We can show that $\mathcal{W}_n$'s satisfy the axioms (R0), (R1), (R2), and (R5) in a similar way as Ref. 34 where it is shown that if the coefficients $\{a^{(i)}_n\}$ satisfy $\lim_{n\to\infty}[|a^{(i)}_n|^2/n!]^{1/n}=0$ then the series (6.1) define hyperfunction quantum fields. There, a Wick polynomial $\rho_N(x)$ is introduced as a truncation of $\rho(x)$,

$$\rho_N(x)=\sum_{n=0}^{N}g^n\frac{:\phi(x)^{2n}:}{n!}.$$

Then the Wightman functions $\mathcal{W}^N_n(x)=(\Phi_0,\rho_N(x_1)\cdots\rho_N(x_n)\Phi_0)$ for $\rho_N(x)$ satisfy all the standard Wightman axioms, and they converge weakly to $\mathcal{W}_n(x)=(\Phi_0,\rho(x_1)\cdots\rho(x_n)\Phi_0)$ as $N\to\infty$ in the sense of tempered ultra-hyperfunctions. Thus they satisfy the above axioms. The proof of spectral condition (R4) is easier than the case of hyperfunction quantum field theory because $\widetilde{W}^N_{n-1}(q)$ and $\widetilde{W}_{n-1}(q)$ are distributions, and $\widetilde{W}^N_{n-1}(q)$ converge weakly to $\widetilde{W}_{n-1}(q)$ as $N\to\infty$ in the sense of distributions. Since the limit in the sense of distributions preserves the support, (R4) is valid for $\rho(x)$. Accordingly we formulate the main result of the section.

Theorem 6.3 (Existence of fields with fundamental length): *For a free field ϕ of mass $m=0$ the Wick power series (6.1) (or more specifically (6.5) define ultra-hyperfunction quantum fields with a fundamental length ℓ given by Eqs. (6.4) and (6.10).*

ACKNOWLEDGMENTS

This project started in 2001 when E.B. was visiting the University of Tokushima. E.B. expresses deep gratitude to the Department of Mathematics, Faculty of Science, University of Tokushima for their kind hospitality and the financial support and to the University of Durban-Westville for generous sabbatical leave conditions.

APPENDIX A: PROOF OF LEMMA 3.1 (3)

Here we show $g\mapsto\alpha_g(f)$ is a continuous map $G\to E=\mathcal{T}(T(\mathbb{R}^4))$. Since Fourier transformation is a homeomorphism between E and $\tilde{E}=\mathcal{F}E=H(\mathbb{R}^4,\mathbb{R}^4)$, it suffices to show the action $G\to\tilde{E}$ is continuous. The following two propositions show this.

Proposition A.1: Let $f\in H(\mathbb{R}^4,\mathbb{R}^4)$. Then, as $h\to 0$,

$$\|(e^{i\langle h,x\rangle}-1)f(x)\|_{K,j}\to 0.$$

Proof: Note that for any $\epsilon>0$, there exists $R>0$ such that

$$\sup_{|x|\geqslant R,|p|\leqslant j}\exp(h_K(x))|D^p(e^{i\langle h,x\rangle}-1)f(x)|<\epsilon$$

uniformly for $|h|\leqslant\delta>0$. The proposition follows from the following identity:

$$\lim_{h\to 0}\sup_{|x|\leqslant R,|p|\leqslant j}\exp(h_K(x))|D^p(e^{i\langle h,x\rangle}-1)f(x)|\to 0.$$

□

Proposition A.2: Let $\Lambda(t)$ be a one-parameter subgroup of the Lorentz group such that $\Lambda(0)=I$, and $f\in H(\mathbb{R}^4,\mathbb{R}^4)$. Then, as $t\to 0$,

$$\|f(\Lambda(t)x)-f(x)\|_{K,j}\to 0.$$

Proof: The proof goes parallel to the preceding proposition. For any $\epsilon>0$, there exists $R>0$ such that uniformly in t, $|t|\leqslant\delta>0$,

$$\sup_{|x|\geqslant R,|p|\leqslant j}\exp(h_K(x))|D^p(f(\Lambda(t)x)-f(x))|<\epsilon.$$

Again the proposition follows from the following identity:

$$\lim_{t\to 0}\sup_{|x|\leqslant R,|p|\leqslant j}\exp(h_K(x))|D^p(f(\Lambda(t)x)-f(x))|\to 0.$$

□

APPENDIX B: PROOF OF THEOREM 2.13

First we recall that V^ϵ is an open set defined by

$$V^\epsilon=\{z\in\mathbb{C}^n;\exists\, x\in V,|\mathrm{Re}\, z-x|+|\mathrm{Im}\, z|_\beta<\epsilon\}$$

for $\epsilon>0$ and an open set V in $\mathbb{R}^n$. K_p is the closure of $V^{\epsilon/(1+1/p)}$ in $\mathbb{C}^n$, $L_p=\{w\in\mathbb{C}^m;|\mathrm{Im}\, w|\leqslant p\}$, and $U=V^\epsilon\times\mathbb{C}^m$, $M_p=K_p\times L_p$.

Lemma B.1: Let f_j be a sequence in $\mathcal{T}(U)$ and $f\in\mathcal{T}(U)$. If the sequence $\|f_j\|^{M_p,k}$ $(j=1,2,\ldots)$ is bounded, and if f_j converges to f uniformly on $M_{p'}\cap\mathbb{C}^{n+m}$ then f_j converges to f in the norms $\|f_j\|^{M_{p'},k'}$ with $p'\leqslant p$ and $k'<k$.

Proof: We may assume $f=0$. Let $C_{p,k}=\sup\{\|f_j\|^{M_p,k},j=1,2,\ldots\}$. For arbitrary $\epsilon>0$ we can choose $R>0$ such that $C_{p,k}R^{k'-k}<\epsilon$. Then

$$|z^s f_j(z)| < C_{p,k} R^{k'-k} < \epsilon \tag{B1}$$

for $z \in M_{p'}$ with $|z| \geqslant R$ and $|s| \leqslant k'$. On the other hand, there exists $N \in \mathbb{N}$ such that $|f_j(z)| < \epsilon R^{-k'}$ for $j > N$ and $z \in M_{p'}$ with $|z| \leqslant R$. This together with (B1) means $\|f_j\|^{M_{p'},k'} < \epsilon$ for $j > N$. □

Lemma B.2: Let $\epsilon > 0$ *and* $C_\epsilon = \exp \sup_{j \in \mathbb{N}} [(n/2)\log(j/\pi) - j\epsilon^2/(1+\delta)]$. *Then* $0 < C_\epsilon < \infty$ *and the function*

$$E_j(z) = (j/\pi)^{n/2} \exp\left\{ -j \sum_{k=1}^{n} z_k^2 \right\}$$

satisfies

$$|E_j(z)| \leqslant C_\epsilon \exp\{-j\Delta |x|^2\}$$

on the set $\{z = x + iy \in \mathbb{C}^n; |x| \geqslant \epsilon$ and $|y| \leqslant \epsilon/(1+\delta)\}$, *where* $\Delta = (\delta^2 + 2\delta)/(1+\delta)^2$.

Proof: See Lemma 2.3 of Ref. 28. □

Now we define for $\epsilon, \delta > 0$,

$$V_\delta^\epsilon = \{z \in \mathbb{C}^n; \exists x \in V, |\mathrm{Re}\, z - x|/(1+\delta) + |\mathrm{Im}\, z|_\beta < \epsilon\}$$

and let $K_{p,\delta}$ denote the closure of

$$V_\delta^{\epsilon/(1+1/p)} = \{z \in \mathbb{C}^n; \exists x \in V, |\mathrm{Re}\, z - x| + (1+\delta)|\mathrm{Im}\, z|_\beta < \epsilon(1+\delta)/(1+1/p)\}$$

in $\mathbb{C}^n$. Observe that $K_{p,\delta} \subset V^\epsilon$ if $\delta < 1/p$.

Proposition B.3: Let $f(z,w) \in \mathcal{T}(U)$ *and define* $f_j^p(z,w)$ *for* $j = 1,2,\ldots,$ *and* $\delta < 1/p$ *by*

$$f_j^p(z,w) = \int_{K_{p,\delta} \cap \mathbb{R}^n} E_j(z-\xi) f(\xi,w) \mathrm{d}\xi,$$

then $f_j^p \in \mathcal{T}(T(\mathbb{R}^{n+m}))$ *and for any* $k > 0$ *and* $0 < p' < p$, *as* $j \to \infty$,

$$\|f_j^p - f\|^{M_{p'},k} \to 0.$$

Proof: Since $E_j(z)$ is entire analytic, $f_j^p(z,w)$ is also entire analytic. $f \in \mathcal{T}(U)$ implies that for any $p > 0, M > 0, N > 0$, there exists a constant C such that

$$|f(z,w)| \leqslant C \frac{1}{(1+|z|^2)^M (1+|w|)^N} \tag{B2}$$

holds for $(z,w) \in M_p$. Let $r > 0$ and estimate the integral accordingly,

$$\begin{aligned}
\sup_{|\mathrm{Im}\, z| \leqslant r, |\mathrm{Im}\, w| \leqslant r} |z^s w^t f_j^p(z,w)| &\leqslant \sup_{|\mathrm{Im}\, z| \leqslant r, |\mathrm{Im}\, w| \leqslant r} \int_{K_{p,\delta} \cap \mathbb{R}^n} |z^s w^t E_j(z-\xi) f(\xi,w)| \mathrm{d}\xi \\
&\leqslant C \sup_{|\mathrm{Im}\, z| \leqslant r} \int_{K_{p,\delta} \cap \mathbb{R}^n} |z^s E_j(z-\xi)| \frac{1}{(1+|\xi|^2)^M} \mathrm{d}\xi \\
&\leqslant C (j/\pi)^{n/2} e^{jr^2} \sup_{x \in \mathbb{R}^n} \int_{K_{p,\delta} \cap \mathbb{R}^n} (r+|x|)^{|s|} e^{-j(x-\xi)^2} \frac{1}{(1+|\xi|^2)^M} \mathrm{d}\xi.
\end{aligned}$$

Since

$$(r+|x|)^{|s|}e^{-j(x-\xi)^2/2}\frac{1}{(1+|\xi|^2)^M}$$

is a bounded function of x and ξ for $M>|s|$, this estimate can be continued by

$$\sup_{|\mathrm{Im}\, z|\leqslant r,|\mathrm{Im}\, w|\leqslant r}|z^s w^t f_j^p(z,w)|\leqslant C'(j/\pi)^{n/2}e^{jr^2}\int_{\mathbb{R}^n}e^{-j(x-\xi)^2/2}\mathrm{d}\xi<\infty.$$

This shows $f_j^p\in\mathcal{T}(T(\mathbb{R}^{n+m}))$. Next we show that the bounds $\|f_j^p\|^{M_p,k}\leqslant C$ for some $C>0$ hold uniformly with respect to j. To show this, we define a surface $\Gamma(z)$ for $z=x+iy\in K_{p,\delta}$ as follows:

$$\Gamma(z):\{\xi\in\mathbb{R}^n;|\xi-x|<(1+\delta)|y|_\beta<\epsilon(1+\delta)/(1+1/p)\}\to K_{p,\delta}\subset V^\epsilon\subset\mathbb{C}^n,$$

$$\xi\to\zeta=\xi+iy\left(1-\frac{|\xi-x|}{(1+\delta)|y|_\beta}\right).$$

Then $f_j^p(z,w)$ is written as

$$f_j^p(z,w)=\int_{K_{p,\delta}\cap\mathbb{R}^n,|\xi-x|\geqslant(1+\delta)|y|_\beta}E_j(z-\xi)f(\xi,w)\mathrm{d}\xi+\int_{\Gamma(z)}E_j(z-\zeta)f(\zeta,w)\mathrm{d}\zeta_1\wedge\cdots\wedge\mathrm{d}\zeta_n. \tag{B3}$$

Let $\epsilon'=\epsilon(1+\delta)/(1+1/p)$ and

$$g_j^p(z,w)=\int_{K_{p,\delta}\cap\mathbb{R}^n,\epsilon'\geqslant|\xi-x|\geqslant(1+\delta)|y|_\beta}E_j(z-\xi)f(\xi,w)\mathrm{d}\xi+\int_{\Gamma(z)}E_j(z-\zeta)f(\zeta,w)\mathrm{d}\zeta_1\wedge\cdots\wedge\mathrm{d}\zeta_n,$$

and

$$h_j^p(z,w)=\int_{K_{p,\delta}\cap\mathbb{R}^n,|\xi-x|\geqslant\epsilon'}E_j(z-\xi)f(\xi,w)\mathrm{d}\xi.$$

The relevant bound for the function h_j is

$$\sup_{(z,w)\in M_p}|z^s w^t h_j^p(z,w)|=\sup_{(z,w)\in M_p}\int_{K_{p,\delta}\cap\mathbb{R}^n,|\xi-x|\geqslant\epsilon'}|z^s w^t E_j(z-\xi)f(\xi,w)|\mathrm{d}\xi$$

$$\leqslant C\sup_{z\in K_{p,\delta}}\int_{K_{p,\delta}\cap\mathbb{R}^n,|\xi-x|\geqslant\epsilon'}|z^s E_j(z-\xi)|\frac{1}{(1+|\xi|^2)^M}\mathrm{d}\xi.$$

For $z=x+iy\in K_{p,\delta}\subset V_\epsilon$ we have $|y|\leqslant|y|_\beta\leqslant\epsilon'/(1+\delta)$ and so, for ξ with $|\xi-x|\geqslant\epsilon'$, by Lemma B.2, we have $|E_j(z-\xi)|\leqslant C_\epsilon\exp(-j\Delta|\xi-x|^2)$ $(j=1,2,\ldots)$. Accordingly we continue this estimate by

$$\leqslant CC_\epsilon\sup_{z\in K_{p,\delta}\cap\mathbb{R}^n}\int_{K_{p,\delta}\cap\mathbb{R}^n,|\xi-x|\geqslant\epsilon'}(|x|+\epsilon/2)^{|s|}\exp(-j\Delta|x-\xi|^2)|\frac{1}{(1+|\xi|^2)^M}\mathrm{d}\xi$$

$$\leqslant C'\int_{\mathbb{R}^n}|\exp(-j\Delta|x-\xi|^2/2)|\mathrm{d}\xi<C'',$$

where C'' does not depend on j.

In order to estimate $g_j^p(z,w)$, take into account that

$$-\mathrm{Re}\langle z-\xi,z-\xi\rangle=-|x-\xi|^2+|y|\leqslant-|x-\xi|^2+|y|_\beta^2\leqslant-|x-\xi|^2(\delta^2+2\delta)/(1+\delta)^2$$
$$=-\Delta|x-\xi|^2$$

if $|x-\xi|>(1+\delta)|y|_\beta$, and

$$-\mathrm{Re}\langle z-\zeta,z-\zeta\rangle=-|x-\xi|^2+|x-\xi|^2/(1+\delta)^2\leqslant-\Delta|x-\xi|^2$$

if $\zeta\in\Gamma(z)$ and $\mathrm{Re}\,\zeta=\xi$. This gives

$$|g_j^p(z,w)|\leqslant C\int_{|\xi-x|\leqslant\epsilon'}(j/\pi)^{n/2}\exp(-j\Delta|x-\xi|^2)\frac{1}{(1+|\xi|^2)^M}\frac{1}{(1+|w|^2)^N}\mathrm{d}\xi$$
$$\leqslant C'\frac{1}{(1+|x|^2)^M}\frac{1}{(1+|w|^2)^N}\int_{|\xi-x|\leqslant\epsilon}(j/\pi)^{n/2}\exp(-j\Delta|x-\xi|^2)\mathrm{d}\xi$$
$$\leqslant C''\frac{1}{(1+|x|^2)^M}\frac{1}{(1+|w|^2)^N}\int_{\mathbb{R}^n}\exp(-j\Delta|\xi|^2)|\mathrm{d}\xi\leqslant C'''\frac{1}{(1+|z|^2)^M}\frac{1}{(1+|w|^2)^N}.$$

Thus we conclude that $\|f_j^p\|^{M_p,k}\leqslant C$ for some positive constant C uniformly in j, i.e., the sequence $\|f_j^p\|^{M_p,k}$ $(j=1,2,\ldots)$ is bounded.

Next we show that the sequence f_j^p converges to f uniformly on $M_{p'}\cap\mathbb{C}^{n+m}$ with $0<p'<p$. Let $(z,w)\in M_{p'}$. It follows from (B2) that $|f(\zeta,w)-f(z,w)|\leqslant C|\mathrm{Re}\,\zeta-\mathrm{Re}\,z|$ for ζ and z in the integral (B3), and therefore we have

$$\left|f_j^p(z,w)-f(z,w)\int_{K_{p,\delta}\cap\mathbb{R}^n}E_j(z-\xi)\mathrm{d}\xi\right|\leqslant C\int(j/\pi)^{n/2}e^{-j\Delta|x-\xi|}|x-\xi|\mathrm{d}\xi\leqslant C'j^{-1/2}.$$

Since $\mathrm{Re}\,\langle z-\xi,z-\xi\rangle$ has a positive lower bound when $z\in K_{p'}$ and $\xi\in\mathbb{R}^n\backslash K_{p,\delta}$,

$$1-\int_{K_{p,\delta}\cap\mathbb{R}^n}E_j(z-\xi)\mathrm{d}\xi=\int_{\mathbb{R}^n\backslash K_{p,\delta}}E_j(z-\xi)\mathrm{d}\xi$$

is exponentially decreasing as $j\to\infty$. It follows from Lemma 1 that $\|f_j^p-f\|^{K_{p'},k}\to0$ as $j\to\infty$. □

Phase-space Green's functions for modeling time-harmonic scattering from smooth inhomogeneous objects

T. Melamed
Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer Sheva 84105, Israel

(Received 7 January 2004; accepted 3 March 2004;
published online 10 May 2004)

The paper deals with inhomogeneous medium Green's functions in the phase-space domain by which the phase-space (local) spectral distributions of the field, scattered by a high contrast object due a genetic time-harmonic incidence, are evaluated. Two forms of phase-space Green's functions are considered: one that links induced sources in the configuration-space to phase-space distributions of the scattered field, while the other one directly links the phase-space distribution of the incident field to phase-space distributions of the scattered field. The scattering mechanism is described in terms of local samplings of the object function which are localized in the object domain according to the scattered- and incidence-processing parameters. Applications in the field of inverse scattering may be expected to yield fast and efficient algorithms, due to the capability of analytically evaluating (forward) scattering Green's functions. © *2004 American Institute of Physics.*

I. INTRODUCTION

The conventional spectral elements for wave synthesis are Green's functions or plane waves.[1] However, tracking these *global* basis functions in inhomogeneous environments or through interactions with objects is complicated, and the resulting representation integrals are spectrally distributed. Invoking constructive interference yields local observables in the form of ray fields, but in many situations a wider spectral range of basis functions is required.[2] Instead of using global basis functions that lead to distributed integrals, the representation may be localized *a priori* by using phase-space (PS) spectral representations in which the *local* basis wave-functions are beams. Each beam basis function then accounts for the radiation from a finite region in the source domain, thereby leading to compact spectral representations.

Several PS expansion schemes for wave propagation have been introduced. For *point source* configurations the source field can be expanded into an angular spectrum of beams that emanate from the source in all directions[3] (see also extension to the time-domain in Ref. 4). A different class of expansions applies for *extended source* configurations, utilizing a spectrum of shifted and tilted beams which emanate in all directions from all points in the source domain. Several alternative formulations for time-harmonic fields have been introduced:[5–11] In Refs. 8, 10, and 11, they have been placed within a unified PS format in which a PS distribution of beam propagators is *locally* matched to the source distribution. Recently, discrete PS spectral representations have been introduced, based on the discrete Wilson basis[12] and on frame theory.[13]

Inhomogeneous medium Green's functions are of fundamental significance for modeling wave propagation, inverse scattering, numerical methods, etc. Green's functions are wave objects that link sources in the configuration space, $\mathbf{r}'$, to the configuration observation domain, $\mathbf{r}$, by a convolution integral. These wave objects are global in nature in the sense that each point in the $\mathbf{r}'$ source domain contributes to *all* points in the $\mathbf{r}$-observation domain, hence, the difficulty in evaluating of these wave objects, both analytically and numerically. Since modeling wave propagation directly in the configuration-space implies global Green's functions, transferring the fields via phase-space (windowed-) Fourier transform facilitates the search after *localized Green's function*, which can be easily evaluated both asymptotically and numerically (see Ref. 3 and also

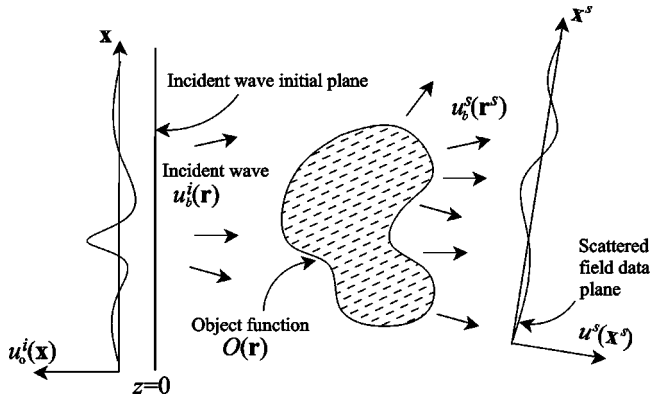

FIG. 1. Physical configuration; the object function $O(\mathbf{r})$ is illuminated by an incident wave $u_b^i(\mathbf{r})$ defined by its initial field distribution over the $z=0$ plane, whereas, the scattered field $u_b^s(\mathbf{r})$ is measured on a data plane $z^s=0$ between which the object is situated.

extension to the time-domain in Ref. 14). Furthermore, since wave interactions with scattering medium have been found to be local in nature, it is suggested that the evaluation of Green's functions should not be carried out in the configuration-space but rather in a *phase-space* (PS) transform domain, which extracts local radiation properties of the data and by that synthesizes local wave-medium interactions.[15,16] The above considerations have been applied in previous publications to the simple case of scattered field due to plane-wave incidence within the Born approximation.[15,16] The present contribution constitutes a general framework for the synthesis and analysis of *inhomogeneous* background scattering due to a *generic* incident wave with applications to inverse scattering, integral equation representation for propagation and scattering, and more.

Following this strategy, we are concerned with the field scattered by an object which is characterized by a wave velocity of $v(\mathbf{r})$, where $\mathbf{r}=(x_1,x_2,z)$ is the conventional Cartesian coordinate system, embedded in a homogeneous medium of save speed v_o (see Fig. 1). The total field $u(\mathbf{r})$, with a $e^{-i\omega t}$ time-dependence assumed and suppressed, satisfies the scalar Helmholtz equation

$$[\nabla^2+k^2(\mathbf{r})]\ \ u(\mathbf{r})=0,\ \ k(\mathbf{r})=\omega/v(\mathbf{r}), \tag{1}$$

subject to Sommerfeld radiation condition $\hat{\mathbf{r}}\cdot\nabla u(\mathbf{r})-iku(\mathbf{r})=o(r^{-1})$, for $r\to\infty$.

In the present investigation, the propagation of the field $u(\mathbf{r})$ in the inhomogeneous medium is formulated by the use of an inhomogeneous background $v_b(\mathbf{r})$ wave speed profile, and the deviation of the scattering medium $v(\mathbf{r})$ from the background $v_b(\mathbf{r})$ is described by the so-called *object function*

$$O(\mathbf{r})=v_o^2[v^{-2}(\mathbf{r})-v_b^{-2}(\mathbf{r})]. \tag{2}$$

The scattering object is illuminated by an incident field, $u_b^i(\mathbf{r})$, defined by the initial field distribution on $z=0$ plane $u_o^i(\mathbf{x})$. Note that $u_o^i(\mathbf{x})$ consists of incident (i.e., having sources in $z<0$ half space) field constituents only, and is therefore, independent of the background medium.

We are concerned with applying PS (local) spectrum techniques to the scattered field, therefore, the scattered field constituents shall be evaluated over planar apertures (observation planes), characterized by $z^s=0$, where $\mathbf{r}^s=(\mathbf{x}^s,z^s)$ with $\mathbf{x}^s=(x_1^s,x_2^s)$ are the Cartesian coordinate system associated with the observation plane (see Fig. 1). The scattered field over the observation plane, $u_b^s(\mathbf{x}^s)\equiv[u(\mathbf{r})-u_b^i(\mathbf{r})]|_{z^s=0}$, satisfies the Lipman–Schwinger integral equation

$$u_b^s(\mathbf{x}^s)=k_o^2\int d^3r'O(\mathbf{r}')u(\mathbf{r}')G_b(\mathbf{r}^s,\mathbf{r}')|_{z^s=0},\ k_o=\omega/v_o, \tag{3}$$

where $u=u_b^i+u_b^s$ is the total field propagating in v_b background medium, and G_b is the inhomogeneous *background* medium Green's function

$$[\nabla^2+k_b^2(\mathbf{r})]\,G_b(\mathbf{r},\mathbf{r}')=-\delta(\mathbf{r}-\mathbf{r}'),\quad k_b(\mathbf{r})=\omega/v_b(\mathbf{r}). \tag{4}$$

Here and henceforth, subscript b denotes background dependent constituents. Equation (3) describes the scattered field in terms of induced sources, $O(\mathbf{r}')u(\mathbf{r}')$, which are radiating in the perturbed medium $v_b(\mathbf{r})$. The background v_b-medium Green's function, $G_b(\mathbf{r},\mathbf{r}')$, propagates these induced sources to the aperture $z^s=0$ via the spatial convolution integral in (3). Relation (3) has been used for the so-called ''Distorted Wave Born Approximation,'' in which the total field $u(\mathbf{r}')$ on the right-hand side of (3), is replaced by the incident field $u_b^i(\mathbf{r}')$ propagating in the background medium (see also discussion following (15)). This approximation is used for iteratively solving (forward) propagation and scattering problems, and for inverse scattering. In the following sections we will aim at obtaining *PS Green's functions* that link sources to scattered fields in a PS transform domain, rather than in the configuration-space.

II. CONFIGURATION-SPACE TO PHASE-SPACE GREEN'S FUNCTIONS

In order to obtain *PS Green's functions* that link sources to scattered PS field distributions, we shall project the scattered field distribution onto the PS (local) domain. In the next subsections, we shall define the (global) plane-wave spectrum and PS transform of the scattered field which are required for the formulation of the PS Green's function representation.

A. Space-wave-number (global) transforms

The wave number (plane-wave) spectrum, $\tilde{u}_o(\boldsymbol{\xi})$, of an initial field distribution, $u_o(\mathbf{x})$, on a planar surface is defined by the spatial Fourier transform

$$\tilde{u}_o(\boldsymbol{\xi})=\int_{-\infty}^{\infty} d^2x\;\; u_o(\mathbf{x})\exp(-ik_o\,\boldsymbol{\xi}\cdot\mathbf{x}), \tag{5a}$$

where, here and henceforth, plane-wave spectral distribution is denoted by superscript . In (5a), $\boldsymbol{\xi}=(\xi_1,\xi_2)$ is the normalized spatial wave number vector (with respect to $k_o=\omega/v_o$), and $\mathbf{x}=(x_1,x_2)$. Accordingly, the reconstruction of the initial field distribution is

$$u_o(\mathbf{x})=\left(\frac{k_o}{2\pi}\right)^2\int d^2\xi\;\; \tilde{u}_o(\boldsymbol{\xi})\;\; \exp(ik_o\,\boldsymbol{\xi}\cdot\mathbf{x}). \tag{5b}$$

The normalization with respect to the wave number k_o anticipates extension to the time-domain, rendering $\boldsymbol{\xi}$ frequency-independent, with direct geometrical interpretation in terms of the spectral plane-wave propagation angles. For the sake of simplicity, integration limits are omitted on all integrals extending from $-\infty$ to $+\infty$.

B. Phase-space processing of the scattered field

In this section, we summarize the PS analysis and synthesis formalisms that parameterize the scattered field on the initial plane $z^s=0$ (for further details refer to Ref. 11). For the desired *local* spectral analysis of the field distribution, we generate the *PS spectral distribution*, $U_b^s(\overline{\mathbf{X}}^s)$, via a windowed Fourier transform of the distribution in the configuration-space,

$$U_b^s(\overline{\mathbf{X}}^s)=\int d^2x^s\;\; u_b^s(\mathbf{x}^s)\;\; W^{s*}(\mathbf{x}^s;\overline{\mathbf{X}}^s),\quad W^s(\mathbf{x}^s;\overline{\mathbf{X}}^s)=w^s(\mathbf{x}^s-\overline{\mathbf{x}}^s)\exp[ik_o\overline{\boldsymbol{\xi}}^s\cdot(\mathbf{x}^s-\overline{\mathbf{x}}^s)], \tag{6}$$

where, here and henceforth, superscript s denotes scattered field constituents, the asterisk denotes the complex conjugate and $\overline{\mathbf{X}}^s=(\overline{\mathbf{x}}^s,\overline{\boldsymbol{\xi}}^s)$. Here, $w^s(\mathbf{x}^s)$ is a spatial window function, centered at $\mathbf{x}^s=(0,0)$. The vector $\overline{\mathbf{X}}^s$ incorporates the configuration-spectrum *PS coordinates* $(\overline{\mathbf{x}}^s,\overline{\boldsymbol{\xi}}^s)$, whence

$U_b^s(\overline{\mathbf{X}}^s)$ is referred to as a *PS distribution* of the initial field distribution $u_b^s(\mathbf{x}^s)$ over the $z^s=0$ plane. The transform in (6) extracts from $u_b^s(\mathbf{x}^s)$ the local spectrum around the $\overline{\boldsymbol{\xi}}^s$-directed propagation at the window center $\overline{\mathbf{x}}^s$. In typical propagation/scattering problems, the spectrum at a given $\overline{\mathbf{x}}^s$ is localized about a preferred spectral direction $\overline{\boldsymbol{\xi}}^s(\overline{\mathbf{x}}^s)$ that describes the (stationary) direction of propagation of the field at $\overline{\mathbf{x}}^s$ point (the so-called Lagrange manifold). Consequently, the PS spectrum $U^s(\overline{\mathbf{X}}^s)$ is localized *a priori* about the subdomain $(\overline{\mathbf{x}}^s,\overline{\boldsymbol{\xi}}^s)=(\overline{\mathbf{x}}^s,\overline{\boldsymbol{\xi}}^s(\overline{\mathbf{x}}^s))$ in the $\overline{\mathbf{X}}^s$-domain (see synthetic examples in Refs. 8, 11). Note that the PS spectrum of the scattered field depends on the specific background medium profile, $v_b(\mathbf{r})$, since according to (3), both the inhomogeneous medium Green's function, the medium object function, and the incident field propagating in the $v_b(\mathbf{r})$ medium, affect the scattered field.

The degree of spatial and spectral localization achieved by the PS transform can be quantified in terms of the spatial and spectral RMS widths of the window, defined, respectively, by

$$\Delta_{x^s}=\frac{1}{N^s}\left[\int d^2x^s|\mathbf{x}^s|^2\ \ |w^s(\mathbf{x}^s)|^2\right]^{1/2}, \tag{7a}$$

$$\Delta_{\xi^s}=\frac{k_o}{2\pi N^s}\left[\int d^2\xi^s|\boldsymbol{\xi}^s|^2\ \ |\tilde{w}^s(\boldsymbol{\xi}^s)|^2\right]^{1/2}, \tag{7b}$$

where $\tilde{w}^s(\boldsymbol{\xi}^s)$ is the plane-wave distribution (5a) of the window $w^s(\mathbf{x}^s)$, and

$$N^s=\left[\int d^2x^s|w^s(\mathbf{x}^s)|^2\right]^{1/2}=\frac{k_o}{2\pi}\left[\int d^2\xi^s|\tilde{w}^s(\boldsymbol{\xi}^s)|^2\right]^{1/2} \tag{8}$$

is the $\mathcal{L}^2_{\mathbf{x}^s}$ norm of w^s. Note that $\Delta_{x^s}\Delta_{\xi^s}\geqslant 1/k_o$ according to the uncertainty principle. The inverse PS transform is given by[11]

$$u_b^s(\mathbf{x}^s)=\left(\frac{k_o}{2\pi N^s}\right)^2\int d^4\overline{X}^s\ \ U_b^s(\overline{\mathbf{X}}^s)\ \ W^s(\mathbf{x}^s;\overline{\mathbf{X}}^s), \tag{9}$$

where W^s is given in (6). This representation has been used to obtain a PS field representation for homogeneous medium in the 2D (Refs. 8, 17) and 3D (Ref. 11) frequency- and time-domains.

C. PS Green's functions

In order to establish the locally-transformed Data–Object relation, we insert (3) into (6), obtaining

$$U_b^s(\overline{\mathbf{X}}^s)=k_o^2\int d^3r'O(\mathbf{r}')u(\mathbf{r}')B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s), \tag{10}$$

with the scattering propagators

$$B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)=\int d^2x^s\ \ W^{s*}(\mathbf{x}^s;\overline{\mathbf{X}}^s)G_b(\mathbf{r}^s;\mathbf{r}')\big|_{z^s=0}, \tag{11}$$

where $G_b(\mathbf{r},\mathbf{r}')$ is the background medium Green's function in (4) and $W^s(\mathbf{x}^s;\overline{\mathbf{X}}^s)$ is given in (6). Equation (10) describes the local spectrum of the data in terms of a spatial convolution integral of the induced sources $O(\mathbf{r}')u(\mathbf{r}')$ in the configuration-space, with $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$. Comparing relation (10) with the Lipman–Schwinger equation in (3), one finds that the two have essentially the same form. Therefore, $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$ may be regarded as *configuration-space to phase-space* (CS2PS) *Green's function* (see Appendix A for operator representation of the CS2PS Green's function). The CS2PS Green's function propagates the contribution of the configuration-space induced sources to

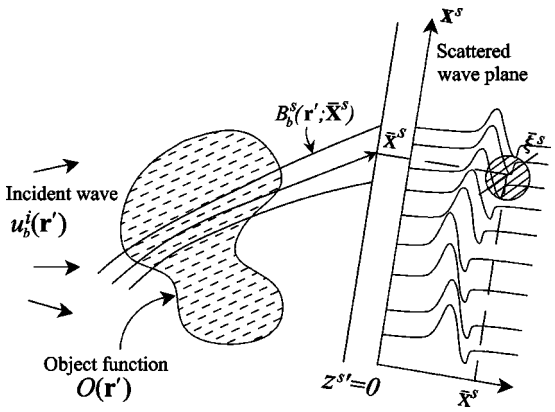

FIG. 2. Configuration-space to phase-space Green's function; the CS2PS Green's function is obtained by a spatial integration of the induced sources $u(\mathbf{r}')O(\mathbf{r}')$ multiplied by the scattering propagator, $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$. This results in a link between the total field propagating in the background medium, and a single phase-space constituent of the scattered field, $U_b^s(\overline{\mathbf{X}}^s)$. The integration domain is limited to points near the B_b^s beam-axis; thus, unlike the Lipman–Schwinger integral (3), the PS spectral distribution of the scattered field synthesizes wave interaction only near the beam-axis.

the PS transform of the data over the observation plane. Also, from (11), we note that the scattering propagators satisfy the wave equation in the v_b background medium, and therefore, for a proper choice of window function w^s, may be evaluated asymptotically using the method described in Sec. IV C (see also Fig. 2). Finally, using $u(\mathbf{r})=u_b^i(\mathbf{r})+u_b^s(\mathbf{r})$, we rewrite (10) in the form

$$U_b^s(\overline{\mathbf{X}}^s)=U_i^s(\overline{\mathbf{X}}^s)+U_s^s(\overline{\mathbf{X}}^s), \tag{12}$$

where

$$U_i^s(\overline{\mathbf{X}}^s)=k_o^2\int d^3r'\,O(\mathbf{r}')u_b^i(\mathbf{r}')B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s), \tag{13}$$

and

$$U_s^s(\overline{\mathbf{X}}^s)=k_o^2\int d^3r'\,O(\mathbf{r}')u_b^s(\mathbf{r}')B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s), \tag{14}$$

in which U_s^i and U_s^s are the contributions of the sources induced by either the incident or scattered fiels, respectively. The above exact formalism may be used for the Distorted Wave Born Approximation (DWBA) in which the total field $u(\mathbf{r}')$ in the exact formulation (3) is replaced by the incident field $u_b^i(\mathbf{r}')$ propagating in the background medium. The DWBA is often used for solving high contrast scattering iteratively, especially in inverse scattering scenarios. In the framework of the DWBA, we may use

$$U_b^s(\overline{\mathbf{X}}^s)\approx U_i^s(\overline{\mathbf{X}}^s). \tag{15}$$

The scattering propagators, $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$, result in a beam wave objects which, for the case of the Gaussian window in (23), are Gaussian beams localized about ray trajectories (i.e., beam-axes). Therefore, the CS2PS mapping in (10) (or (13)), is obtained by integrating over induced sources *locally about beam-axes*. The ray trajectories that describe the beam-axes depend on the background medium v_b and on the processing parameters: $\overline{\mathbf{x}}^s$ determines the emanating point of the ray from the data plane while $\overline{\boldsymbol{\xi}}^s$ sets its direction in the $\mathbf{r}'$ (source) domain (see Fig. 2).

The CS2PS representation in (10) or (12), has several advantages over the Lipman–Schwinger representation: (a) the inhomogeneous Green's function, $G_b(\mathbf{r},\mathbf{r}')$ is difficult to evaluate both analytically and numerically, while the scattering propagators may be evaluated asymptotically (see Sec. IV C); (b) the integration domain in (3) includes the entire object domain, since the induced sources, $O(\mathbf{r}')u(\mathbf{r}')$ exist in the entire object domain and contribute to each point $\mathbf{x}^s$ on the observation plane. Using the CS2PS relation, the integration domain is limited to points near the local Green's function (beam-) axis, since the beam exhibits Gaussian decay away from its axis (see (49) and Fig. 2). Though the induced sources exist in the entire object domain, the PS transform for a given set of PS variables, $\overline{\mathbf{X}}^s$, extracts from the scattered field only those constituents that are scattered in the direction $\overline{\boldsymbol{\xi}}^s$ and are aimed at the point $\overline{\mathbf{x}}^s$; and finally, (c) there exist applications in which the PS spectrum, rather than the scattered field, needs to be evaluated.[15,16] In such cases, direct evaluation using PS Green's function in (10) is more efficient than the conventional route of possibly solving (3), followed by PS processing via (6).

The CS2PS mapping in (10) exhibits *a priori* localization in the source domain only about the coordinates *transverse* to the beam-axis. Furthermore, the incident field $u_b^i(\mathbf{r})$, propagating in the inhomogeneous background medium, $v_b(\mathbf{r})$, has no closed form analytic expression. In the next section, we shall apply local processing to both *scattered* and *incident* fields, resulting in *a priori* localization in all three coordinates, as well as analytical (asymptotic) expressions for the local incident propagators and Green's functions.

III. PHASE-SPACE TO PHASE-SPACE GREEN'S FUNCTIONS

Following the strategy outlined in the previous section, we shall now consider applying PS processing to both *scattered* and *incident* fields. The PS transform operations over the scattered field have been introduced in Sec. II B. Next we define, in a similar way, the operations related to local processing of the incident field.

A. Local processing of the incident field

We generate the *incident field* PS spectral distribution in a way similar to (6), i.e.,

$$U^i(\overline{\mathbf{X}}^i)=\int d^2x \quad u_o^i(\mathbf{x}) \quad W^{i*}(\mathbf{x};\overline{\mathbf{X}}^i), \qquad W^i(\mathbf{x};\overline{\mathbf{X}}^i)=w^i(\mathbf{x}-\overline{\mathbf{x}}^i)\exp[ik_o\overline{\boldsymbol{\xi}}^i\cdot(\mathbf{x}-\overline{\mathbf{x}}^i)], \tag{16}$$

where, as in (6), $w^i(\mathbf{x})$ is a spatial window function. Here and henceforth, superscript i denotes *incident* field constituents and $\overline{\mathbf{X}}^i=(\overline{\mathbf{x}}^i,\overline{\boldsymbol{\xi}}^i)$ are the incidence *PS coordinates*. A key feature in (16) is that, unlike the scattered local spectrum, the incident one is *independent* of the propagation medium, $v_b(\mathbf{r})$. The window's properties (RMS widths, etc.) have been presented in Sec. II B (relations (7), (8)).

Using the inverse transform (as in (9) with $s\rightarrow i$), the PS superposition (16) of the initial field can be propagated into the region $z>0$, giving

$$u_b^i(\mathbf{r})=\left(\frac{k_o}{2\pi N^i}\right)^2\int d^4\overline{X}^i \quad U^i(\overline{\mathbf{X}}^i)B_b^i(\mathbf{r};\overline{\mathbf{X}}^i), \tag{17}$$

where N^i is the $\mathcal{L}_{\mathbf{x}}^2$ norm of w^i (similar to (8)), and the *PS incident propagator* B_b^i is the field radiated by each PS window element $W^i(\mathbf{x};\overline{\mathbf{X}}^i)$ in (9), and can therefore be expressed by Kirchhoff-type integration of the form

$$B_b^i(\mathbf{r};\overline{\mathbf{X}}^i)=\int 2W^i(\mathbf{x};\overline{\mathbf{X}}^i)\partial_{z'}G_b(\mathbf{r};\mathbf{r}')|_{z'=0}, \tag{18}$$

where $G_b(\mathbf{r};\mathbf{r}')$ is the v_b medium Green's function, and W^i is given in (16).

The representation in (17) describes the radiated field as a continuous superposition of shifted and tilted beams, centered at and directed along $\overline{\mathbf{x}}$ and $\overline{\boldsymbol{\xi}}$, respectively. The PS distribution $U^i(\overline{\mathbf{X}}^i)$ defines the excitation strengths of these beams via local matching to the aperture field $u_o^i(\mathbf{x})$.

B. PS Green's functions

By inserting the incident field PS representation in (17) into (13), and inverting the order of integration, one obtains

$$U_i^s(\overline{\mathbf{X}}^s)=\left(\frac{k_o^2}{2\pi N^i}\right)^2\int d^4\overline{X}^i \quad U^i(\overline{\mathbf{X}}^i)\int d^3r' O(\mathbf{r}')B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s). \tag{19}$$

Equation (19) links contributions of PS initial field distribution to the PS scattered field distribution over the $z^s=0$ observation plane in the following manner: the windowed incident (initial-) field distribution is propagated into the $\mathbf{r}'$ configuration-space via the local domain PS incident propagators $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$, which are beam-type wave objects. For a given $\overline{\mathbf{X}}^i$, the beam emanates from the processing-dependent point, $\overline{\mathbf{x}}^i$, in a processing-dependent direction, $\overline{\boldsymbol{\xi}}^i$, into $\mathbf{r}'$ space. The PS scattering propagators, $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$, accumulate, via d^3r' integration, contributions of the incident beams to the local scattered field PS distribution at point $\overline{\mathbf{x}}^s$ on the observation plane, arriving from direction $\overline{\boldsymbol{\xi}}^s$. The PS spectral distribution of the scattered field is obtained by collecting these contributions from all beams emanating from the incidence plane points, in all directions via the $d^4\overline{X}^i$ integration. The contribution of each incident-window element to the scattered PS spectrum is weighted by the PS distribution of the initial incident field.

In order to gain insight into the scattering mechanism, we rewrite (19) in the form

$$U_i^s(\overline{\mathbf{X}}^s)=k_o^2\int d^4\overline{X}^i \quad U^i(\overline{\mathbf{X}}^i)\Psi_b(\overline{\mathbf{X}}^s,\overline{\mathbf{X}}^i), \tag{20}$$

where

$$\Psi_b(\overline{\mathbf{X}}^s,\overline{\mathbf{X}}^i)=\int d^3r' O(\mathbf{r}')\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s), \tag{21}$$

is hereby termed the *phase-space to phase-space* (PS2PS) *Green's function*, and $\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s)$ is a sampling window in the $\mathbf{r}'$-object domain

$$\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s)=\left(\frac{k_o}{2\pi N^i}\right)^2 B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s). \tag{22}$$

Relation (20) presents the PS spectrum of the time-harmonic scattered field distribution in terms of local spatial samples of $O(\mathbf{r})$ (Fig. 3). Since both $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$ and $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$ are beam-like wave objects, the multiplication in (22) results in a *local scattering cell* which exhibits a spatial Gaussian decay away from its center over the intersection of the incident and scattered beam-axes. Here, Λ_b provides windowing along the beam-axis as determined by the PS parameters $\overline{\mathbf{X}}^i$ and $\overline{\mathbf{X}}^s$. The above results imply that the interaction of the incident spectral beam with the object domain, when parameterized in terms of scattered Gaussian beam propagators (i.e., the scattered PS spectrum), occurs as if each scattered beam were *specularly reflected* from the local medium inhomogeneities (see Fig. 3 and further discussion following (56)).

IV. GAUSSIAN WINDOWS

In this section, we examine the special case of Gaussian windows, which have been used extensively for modeling beam propagation since they maximize the PS localization as implied by the uncertainty principle, and yield analytically trackable beam-type propagators.[3,8,14,11]

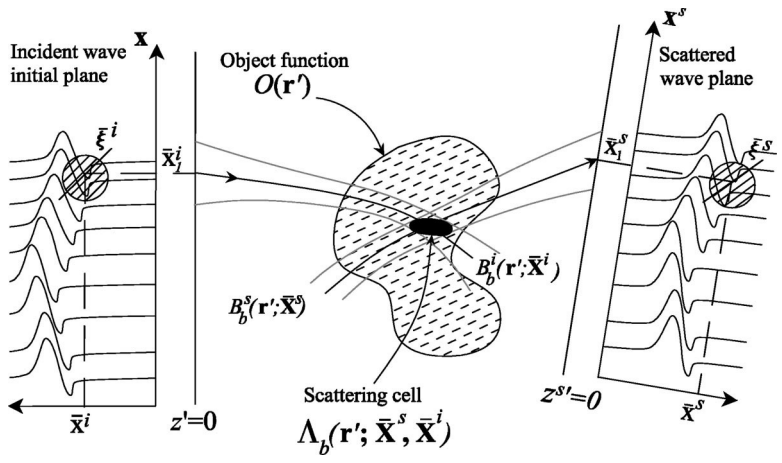

FIG. 3. Phase-space to phase-space mapping phenomenology; the phase-space transform, applied to both incident and scattered field distributions, synthesizes local reflections between isolated local cells, Λ_n, dynamically oriented and located according to the phase-space processing parameters $\bar{\mathbf{X}}^i$ and $\bar{\mathbf{X}}^s$. The PS2PS Green's function in (21) is obtained by a spatial windowing of the object function with the scattering cells.

A. Definitions

For locally (PS-)processing the scattered field distribution, we use a Gaussian window whose spatial and spectral distributions are

$$w^s(\mathbf{x}^s)=\exp\left[\frac{i}{2}k_o\mathbf{x}^s\ \ \mathbf{\Gamma}^s\cdot\mathbf{x}^s\right],\quad \tilde{w}^s(\boldsymbol{\xi}^s)=\frac{2\pi i}{k_o\Gamma^s}\exp\left[-\frac{i}{2}k_o\boldsymbol{\xi}^s\ \ (\mathbf{\Gamma}^s)^{-1}\cdot\boldsymbol{\xi}^s\right], \tag{23}$$

where $\mathbf{\Gamma}^s=\Gamma^s\mathbf{I}$, with $\mathbf{I}$ being the unity matrix and $\Gamma^s=\Gamma^s_r+i\Gamma^s_i$ is the window complex parameter with $\Gamma^s_i>0$. Anticipating extension to the time-domain, definition (23) has been constructed so that the frequency $k_o=\omega/v_o$ appears explicitly in the exponent, while Γ^s is *frequency-independent*. These features may be used to construct collimated time-domain wave objects. $\mathbf{\Gamma}^s$ is a complex symmetric matrix with $\mathrm{Im}\,\mathbf{\Gamma}^s$ positive definite, so that the quadratic phase in the exponent in (23), $\mathbf{x}^s\ \ \mathbf{\Gamma}^s\cdot\mathbf{x}^s=[(x_1^{s2}+x_2^{s2})]\Gamma^s$, has a positive imaginary part that is generating a smooth Gaussian window which is strongest for $|\mathbf{x}^s|=0$ and weakens as $|\mathbf{x}^s|$ increases. The spatial and spectral localization can be quantified in terms of the spatial and spectral RMS widths of the windows given in (7), (8)

$$(N^s)^2=\pi/(k_o\Gamma^s_i),\quad \Delta_{x^s}=1/\sqrt{\Gamma^s_i k_o}=\Delta_{\xi^s}/|\Gamma^s|. \tag{24}$$

Note the uncertainty principle $\Delta_{x^s}\Delta_{\xi^s}=|\Gamma^s|/\Gamma^s_i k_o\geqslant 1/k_o$ with an equality for $\Gamma^s_r=0$.

Following the definition in (23), we shall define the *incident* field distribution processing window, $w^i(\mathbf{x})$, having the same structure as in (23), with the processing parameter Γ^i, i.e.,

$$w^i(\mathbf{x})=\exp\left[\frac{i}{2}k_o\mathbf{x}\ \ \mathbf{\Gamma}^i\cdot\mathbf{x}\right],\quad \mathbf{\Gamma}^i=\Gamma^i\mathbf{I}, \tag{25}$$

etc. All the parametrization and analysis following (23) apply to w^i by replacing $\Gamma^s\to\Gamma^i$ and $\mathbf{x}^s\to\mathbf{x}$ in (23)–(24).

B. Special case: The Born approximation

In order to gain insight into the PS2PS mapping process, we first consider the Born approximation in which the background medium is the *homogeneous* medium v_o. In this case, the background Green's function is free-space Green's function, $G(\mathbf{r},\mathbf{r}')=\exp(ik_o|\mathbf{r}-\mathbf{r}'|)/(4\pi|\mathbf{r}$

$-\mathbf{r}'|$) and the PS propagators and scattering cells yield clear and simple asymptotic expressions. The general scattering over an inhomogeneous background is discussed in Sec. IV C.

1. Asymptotic evaluation of the scattering propagators

The formal integral representation of the scattering propagators using Gaussian windows may be obtained by inserting (23) into (11), with $G_b = G$ being free-space Green's function. Alternatively, a plane-wave spectral representation may be more useful for asymptotic evaluation. In order to obtain such a representation, we insert free-space Green's function plane-wave spectral representation[1]

$$G(\mathbf{r},\mathbf{r}') = \left(\frac{k_o}{2\pi}\right)^2 \int d^2\xi \frac{1}{-2ik_o\zeta} \exp[ik_o(\boldsymbol{\xi}\cdot(\mathbf{x}-\mathbf{x}') + \zeta|z-z'|)] \tag{26}$$

into (11) and invert the order of integration, yielding

$$B_b^s(\mathbf{r}^s;\overline{\mathbf{X}}^s) = \left(\frac{k_o}{2\pi}\right)^2 \int d^2\xi \frac{i}{2k_o\zeta} \tilde{w}^{s*}(\boldsymbol{\xi}-\overline{\boldsymbol{\xi}}^s) \exp[ik_o(-\boldsymbol{\xi}\cdot(\mathbf{x}^s-\overline{\mathbf{x}}^s) - \zeta z^s)], \tag{27}$$

where $\tilde{w}^s(\boldsymbol{\xi})$ is given in (23). For the Gaussian (scattering) window in (23), the scattering propagator has been evaluated asymptotically in Ref. 15 with connection to the PS processing of pulsed plane-wave excited scattering. It was found there that if the window is "large" on a wavelength scale, $B_b^s(\mathbf{r}^s;\overline{\mathbf{X}}^s)$ in (27) yields collimated beam fields in the $\mathbf{r}'$-domain. Via asymptotic evaluation and paraxial approximation, one obtains

$$B_b^s(\mathbf{r};\overline{\mathbf{X}}^s) = \frac{i}{2k_o\overline{\zeta}^s} \sqrt{\frac{\det\boldsymbol{\Gamma}^i(z_b^s)}{\det\boldsymbol{\Gamma}^s(0)}} \exp\left[ik_o\left(-z_b^s + \frac{1}{2}\mathbf{x}_b^s\boldsymbol{\Gamma}^s(z_b^s)\cdot\mathbf{x}_b^s\right)\right], \tag{28}$$

where

$$\boldsymbol{\Gamma}^s(z_b^s) = \begin{bmatrix} (-z_b^s - \overline{\zeta}^{s2}/\Gamma^{s*})^{-1} & 0 \\ 0 & (-z_b^s - 1/\Gamma^{s*})^{-1} \end{bmatrix}, \tag{29}$$

with $\overline{\zeta}^s = \sqrt{1-\overline{\boldsymbol{\xi}}^s\cdot\overline{\boldsymbol{\xi}}^s}$. In (28), we utilize the *beam-coordinates* $(x_{b_1}^s, x_{b_2}^s, z_b^s)$, defined, for a given PS point $\overline{\mathbf{X}}^s$, by the rotation transformation

$$\begin{bmatrix} x_{b_1}^s \\ x_{b_2}^s \\ z_b^s \end{bmatrix} = \begin{bmatrix} \cos\overline{\vartheta}^s\cos\overline{\varphi}^s & \cos\overline{\vartheta}^s\sin\overline{\varphi}^s & -\sin\overline{\vartheta}^s \\ -\sin\overline{\varphi}^s & \cos\overline{\varphi}^s & 0 \\ \sin\overline{\vartheta}^s\cos\overline{\varphi}^s, & \sin\overline{\vartheta}^s\sin\overline{\varphi}^s & \cos\overline{\vartheta}^s \end{bmatrix} \begin{bmatrix} x_1^s - \overline{x}_1^s \\ x_2^s - \overline{x}_2^s \\ z^s \end{bmatrix}, \tag{30}$$

where $(\overline{\vartheta}^s, \overline{\varphi}^s)$ are the spherical angles associated with the unit-vector (see Fig. 4)

$$\hat{\overline{\boldsymbol{\kappa}}}^s = (\overline{\boldsymbol{\xi}}^s, \overline{\zeta}^s) = (\sin\overline{\vartheta}^s\cos\overline{\varphi}^s, \sin\overline{\vartheta}^s\sin\overline{\varphi}^s, \cos\overline{\vartheta}^s). \tag{31}$$

Thus, the z_b^s axis coincides with the beam-axis in the positive (outward) $\hat{\overline{\boldsymbol{\kappa}}}^s$ direction; the transverse coordinates $\mathbf{x}_b^s = (x_{b_1}^s, x_{b_2}^s)$ are rotated such that $x_{b_2}^s$ is parallel to the z^s plane while $x_{b_1}^s$ lies in the plane $(\overline{\boldsymbol{\xi}}^s, \hat{\overline{\boldsymbol{\kappa}}}^s)$ with its positive direction defined so that $\overline{\boldsymbol{\xi}}^s\cdot\hat{\mathbf{x}}_{b_1}^s > 0$ (see Fig. 4). Furthermore, the system $(\mathbf{x}_b^s, z_b^s)$ is defined to be right-handed. Accordingly, the linear phase $\overline{\boldsymbol{\xi}}^s\cdot(\mathbf{x}^s-\overline{\mathbf{x}}^s)$ implied by the window function in the $z^s=0$ plane is operative in the $x_{b_1}^s$ direction *but not* in the $x_{b_2}^s$ direction. Consequently, $\overline{\boldsymbol{\xi}}^s$ affects only the $\boldsymbol{\Gamma}_{11}^s$ term in (29) but not the $\boldsymbol{\Gamma}_{22}^s$ term, thereby describing *astigmatic* beams.

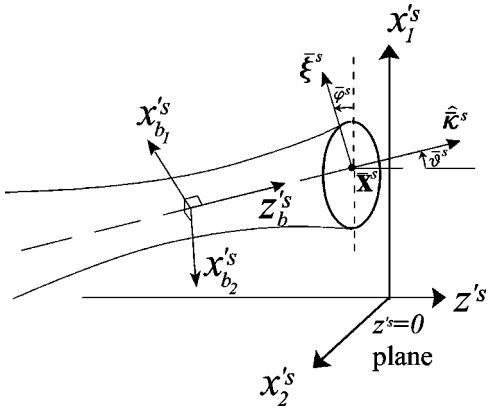

FIG. 4. Scattering propagators' local beam-coordinates; for a given PS spectral parameter $\bar{\mathbf{X}}^s$, the corresponding phase-space scattering propagator $B^s_b(\mathbf{r}';\bar{\mathbf{X}}^s)$ behaves like a collimated beam generated in the $\mathbf{r}'$-domain, whose axis reaches point $\bar{\mathbf{x}}^s$ on the $z'^s=0$ plane along the direction of the beam-axis unit-vector $\hat{\boldsymbol{\kappa}}^s$. The figure depicts the global fixed (x'^s_1,x'^s_2,z'^s) coordinate frame as well as the beam-centered coordinates $(x'^s_{b_1},x'^s_{b_2},z'^s_b)$ (referenced to the $z'^s=0$ plane), which extend along the beam-axis and along the two orthogonal directions perpendicular to the beam-axis.

The parameters of this astigmatic beam field, may be obtained by rewriting the diagonal elements in (29) in the form $\mathbf{\Gamma}=\mathrm{diag}(\Gamma_1,\Gamma_2)$ where $\Gamma^s_{1,2}(z^s_b)=(-z^s_b+Z^s_{1,2}-iF^s_{1,2})^{-1}$ with

$$Z^s_1=-\overline{\zeta}^{s^2}\Gamma^s_r/|\Gamma^s|^2,\quad Z^s_2=-\Gamma^s_r/|\Gamma^s|^2, \tag{32}$$

are identified as the beam *waist* location in the $(z^s_b,x^s_{b_{1,2}})$ plane, and

$$F^s_1=\overline{\zeta}^{s^2}\Gamma^s_i/|\Gamma^s|^2,\quad F^s_2=\Gamma^s_i/|\Gamma^s|^2, \tag{33}$$

are the corresponding *collimation lengths*. Furthermore, the *beam widths* in the $(z^s_b,x^s_{b_{1,2}})$ plane, $D^s_{1,2}$ are found from $\mathrm{Re}\,\Gamma^s(z^s_b)$, giving

$$D^s_{1,2}=\sqrt{F^s_{1,2}/k_o}\sqrt{1+(z^s_b-Z^s_{1,2})^2/F^{s2}_{1,2}}, \tag{34}$$

and the *phase front radius of curvature*, $R^s_{1,2}$ may be obtained from $\mathrm{Im}\,\Gamma^s(z^s_b)$, giving

$$R^s_{1,2}=(Z^s_{1,2}-z^s_b)+F^2_{1,2}/(Z^s_{1,2}-z^s_b). \tag{35}$$

The beam propagator astigmatism is caused by the beam tilt which reduces the effective initial beam width in the x_{b_1} direction. Note that the waist location Z, the collimation length F as well as the phase as a whole, are frequency-independent. However, beam width D is frequency dependent, being proportional to $k_o^{-1/2}$. These properties identify the scattering propagators as ''iso-diffracting'' wave packets.[18]

2. Asymptotic evaluation of the incident propagators

Using Gaussian windows, the PS incident propagators, $B^i_b(\mathbf{r};\bar{\mathbf{X}}^i)$ may be evaluated by inserting free-space Green's function into (18). In the present context it is convenient to express the free-space propagators by the plane-wave representation

$$B^i_b(\mathbf{r};\bar{\mathbf{X}}^i)=\left(\frac{k_o}{2\pi}\right)^2\int d^2\xi\ \ \tilde{w}(\boldsymbol{\xi}-\bar{\boldsymbol{\xi}}^i)\ \ \exp[ik_o(\boldsymbol{\xi}\cdot(\mathbf{x}-\bar{\mathbf{x}}^i)+\zeta z)]. \tag{36}$$

If w is wide on a wavelength scale then the spatial and spectral distributions of $\tilde{w}$ are localized around $\mathbf{x}=\overline{\mathbf{x}}^i$ and $\boldsymbol{\xi}=\overline{\boldsymbol{\xi}}^i$, respectively. Consequently, $B_b^i(\mathbf{r};\overline{\mathbf{X}}^i)$ behaves like a collimated beam whose axis emerges from the $z=0$ plane at $\mathbf{x}=\overline{\mathbf{x}}^i$ with a direction

$$\overline{\boldsymbol{\kappa}}^i=(\overline{\boldsymbol{\xi}}^i,\overline{\zeta}^i),\quad \overline{\zeta}^i=\sqrt{1-|\overline{\boldsymbol{\xi}}^i|^2}, \tag{37}$$

where $|\overline{\boldsymbol{\xi}}^i|^2=\overline{\boldsymbol{\xi}}^i\cdot\overline{\boldsymbol{\xi}}^i$. Next, the general formulation for the scattering process is evaluated for the special case of the Gaussian windows in (25). These windows enable closed form asymptotic evaluation of the PS2PS Green's function, $\Psi_b(\overline{\mathbf{X}}^s,\overline{\mathbf{X}}^i)$, and the scattering cell Λ_b. Via asymptotic evaluation and paraxial approximation, one obtains[11]

$$B_b^i(\mathbf{r};\overline{\mathbf{X}}^i)=\sqrt{\frac{\det\boldsymbol{\Gamma}^i(z_b^i)}{\det\boldsymbol{\Gamma}^i(0)}}\exp\left[ik_o\left(z_b^i+\frac{1}{2}\mathbf{x}_b^i\boldsymbol{\Gamma}^i(z_b^i)\cdot\mathbf{x}_b^i\right)\right], \tag{38}$$

where

$$\boldsymbol{\Gamma}^i(z_b^i)=\begin{bmatrix}(z_b^i+\overline{\zeta}^{i2}/\Gamma^i)^{-1} & 0\\ 0 & (z_b^i+1/\Gamma^i)^{-1}\end{bmatrix}, \tag{39}$$

with $\overline{\zeta}^i=\sqrt{1-\overline{\boldsymbol{\xi}}^i\cdot\overline{\boldsymbol{\xi}}^i}$. In (38), we utilize the beam-coordinates $(x_{b_1}^i,x_{b_2}^i,z_b^i)$ defined, for a given PS point $\overline{\mathbf{X}}^i$, by the transformation in (30) with $(\overline{\vartheta}^s,\overline{\varphi}^s)\to(\overline{\vartheta}^i,\overline{\varphi}^i)$ where $(\overline{\vartheta}^i,\overline{\varphi}^i)$ are the spherical angles associated with the unit-vector

$$\hat{\overline{\boldsymbol{\kappa}}}^i=(\overline{\boldsymbol{\xi}}^i,\overline{\zeta}^i)=(\sin\overline{\vartheta}^i\cos\overline{\varphi}^i,\sin\overline{\vartheta}^i\sin\overline{\varphi}^i,\cos\overline{\vartheta}^i). \tag{40}$$

The parametrization of the beam field in (38) may be obtained in a similar manner to (32)–(35).

The asymptotic beams in (38) facilitate insight into the role of the paraxial approximation: these beams do not satisfy the boundary condition $B^i(\mathbf{r};\overline{\mathbf{X}}^i)|_{z=0}=W^i(\mathbf{x};\overline{\mathbf{X}}^i)$, since near the $z=0$ plane, the paraxial approximation $z_b^i\gg\sqrt{x_{b_1}^{i\,2}+x_{b_2}^{i\,2}}$ is invalid. The paraxially approximated (astigmatic) beam is obtained by projecting the initial window onto the transverse plane $z_b^i=0$ over which the initial effective beam width in the $x_{b_1}^i$ direction is reduced by a factor of $\overline{\zeta}^i$ whereas the width in the $x_{b_2}^i$ direction remains unchanged. Therefore, the paraxial beam boundary conditions on a plane transverse to the beam propagation direction $(z_b^i=0)$ are

$$B^i(\mathbf{r}_b^i;\overline{\mathbf{X}}^i)|_{z_b^i=0}=\exp\left[\frac{i}{2}k_o\mathbf{x}_b^i\quad\boldsymbol{\Gamma}_{\text{parax}}^i\cdot\mathbf{x}_b^i\right], \tag{41}$$

with

$$\boldsymbol{\Gamma}_{\text{parax}}^i=\begin{bmatrix}\Gamma^i/\overline{\zeta}^{i2} & 0\\ 0 & \Gamma^i\end{bmatrix}. \tag{42}$$

Comparing the scattering propagator in (28) to the incident propagator in (38), one finds that they have a similar Gaussian beam type form. They differ mainly in the beam-axis directions: in (40) the beam-axis is directed along the *outgoing* direction (i.e., towards the scattering object) whereas in (31), the scattering propagators are directed *away from the object*. Furthermore, the incident beam is forward propagating (i.e., accumulates positive phase along the beam-axis), whereas the $-z_b^s$ term in (29) implies that the scattering propagators are *back-propagated* into the scattering object domain.

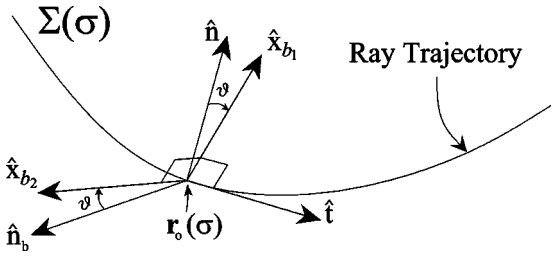

FIG. 5. Local beam-coordinates and ray trajectories; the beam propagator is propagating along ray trajectory Σ. The local orthogonal coordinate system $\mathbf{r}=\mathbf{r}_o(\sigma)+x_1\hat{\mathbf{x}}_1+x_2\hat{\mathbf{x}}_2$, where σ is the arc length along the ray trajectory, is obtained by the rotation transformation in (45).

3. PS2PS mapping

Next, we examine the local scattering cell in the $\mathbf{r}'$ object domain, $\Lambda_b(\mathbf{r}';\overline{\mathbf{X}})$, under the Born approximation. By inserting (38) with (28) into (22), one obtains

$$\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s)=\frac{ik_o^3}{8\overline{\zeta}^s(\pi N^i)^2}\sqrt{\frac{\det\boldsymbol{\Gamma}^i(z_b^i)}{\det\boldsymbol{\Gamma}^i(0)}}\sqrt{\frac{\det\boldsymbol{\Gamma}^s(z_b^s)}{\det\boldsymbol{\Gamma}^s(0)}}$$
$$\times\exp\left[ik_o\left(z_b^i-z_b^s+\frac{1}{2}\mathbf{x}_b^i\boldsymbol{\Gamma}^i(z_b^i)\cdot\mathbf{x}_b^i+\frac{1}{2}\mathbf{x}_b^s\boldsymbol{\Gamma}^s(z_b^s)\cdot\mathbf{x}_b^s\right)\right]. \tag{43}$$

Relation (43) describes a local 3D spatial window; it is centered at the intersection of the incident and scattering propagators axes, where both $\mathbf{x}_b^i$ and $\mathbf{x}_b^s$ are zero, and exhibits a Gaussian decay as the transverse coordinates $\mathbf{x}_b^i$ and $\mathbf{x}_b^s$ increase. The orientation of the cell is determined by the rotation transformation in (30) for incident and scattering propagators, and by the processing parameters Γ^i and Γ^s. For the special case $\Gamma^i=\Gamma^s$, the exponent in (43) contains the sum of $\mathbf{x}_b^i$ and $\mathbf{x}_b^s$. Since both are determined by a rotation transformation of the (30) kind, the result is a new rotation transformation that bisects the incident direction $\hat{\boldsymbol{\kappa}}^i$ in (37) with the scattering direction $\hat{\boldsymbol{\kappa}}^s$ in (31). Therefore, the interaction of the incident spectral beam with the object domain, when parameterized in terms of scattered Gaussian beam propagators, occurs as if each scattered beam were *specularly reflected* from the local medium inhomogeneities (see Fig. 3 and further discussion following (56)).

C. Propagation in the perturbed medium

Next, we consider the propagation of beam propagators (such as B_b^i and B_b^s) in an *inhomogeneous medium* with a wave velocity $v_b(\mathbf{r})$.

1. Local beam-coordinates

An asymptotic solution for general beam-type propagation in an inhomogeneous medium is given in Ref. 3 (see also extension to the time-domain in Refs. 14 and 19). It has been shown there that the field is propagating along a ray trajectory, Σ (see Fig. 5). Denoting σ as the arc length along the ray trajectory, the ray local coordinates are defines by the unit-vectors $\hat{\mathbf{t}}$, $\hat{\mathbf{n}}$, $\hat{\mathbf{n}}_b=\hat{\mathbf{t}}\times\hat{\mathbf{n}}$, denoting the tangent, normal, and bi-normal of Σ at a point $\mathbf{r}_o(\sigma)$ on Σ, respectively. They are related by the Fernet equations[20]

$$\mathbf{r}_o'=\hat{\mathbf{t}},\quad \hat{\mathbf{t}}'=K\hat{\mathbf{n}},\quad \hat{\mathbf{n}}'=-K\hat{\mathbf{t}}+\kappa\hat{\mathbf{n}}_b,\quad \hat{\mathbf{n}}_b'=-\kappa\hat{\mathbf{n}}, \tag{44}$$

where the prime denotes a derivative with respect to σ, K is the curvature of Σ, and κ is its torsion. The ray coordinates are nonorthogonal for $\kappa\neq 0$. A locally orthogonal coordinate system along the ray may be obtain by transverse rotation of the unit-vectors[20] (see Fig. 5)

$$\begin{pmatrix} \hat{\mathbf{x}}_{b_1} \\ \hat{\mathbf{x}}_{b_2} \end{pmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} \hat{\mathbf{n}} \\ \hat{\mathbf{n}}_b \end{pmatrix}, \tag{45}$$

where $\theta(\sigma)$ satisfies

$$\theta'(\sigma) = \kappa(\sigma). \tag{46}$$

Points near the ray may now be expressed as

$$\mathbf{r} = \mathbf{r}_o(\sigma) + n\hat{\mathbf{n}}(\sigma) + n_b\hat{\mathbf{n}}_b(\sigma) = \mathbf{r}_o(\sigma) + x_{b_1}\hat{\mathbf{x}}_{b_1} + x_{b_2}\hat{\mathbf{x}}_{b_2}, \tag{47}$$

where the coordinate frame $(\sigma, x_{b_1}, x_{b_2})$ is locally orthogonal with $dr = \hat{\mathbf{t}}h_\sigma d\sigma + \hat{\mathbf{x}}_{b_1}dx_{b_1} + \hat{\mathbf{x}}_{b_2}dx_{b_2}$, with the Lamé coefficient

$$h_\sigma = 1 - K(\sigma)[x_1\cos\theta + x_2\sin\theta] = 1 - K(\sigma)n. \tag{48}$$

2. Asymptotic evaluation of the scattering propagator

The ray coordinate system may now be applied to the scattering propagators, $B_b^s(\mathbf{r}'; \overline{\mathbf{X}}^s)$. Each propagator arrives at the observation plane to point $\overline{\mathbf{x}}^s$ from a direction $\overline{\boldsymbol{\xi}}^s$; thus, we associate a ray coordinate system to each beam, so that ray parameters σ, x_{b_1} and x_{b_2} are all processing parameters $(\overline{\mathbf{X}}^s)$-dependent, and are denoted as $\sigma^s = \sigma(\overline{\mathbf{X}}^s)$, $\mathbf{x}_b^s = (x_{b_1}(\overline{\mathbf{X}}^s), x_{b_2}(\overline{\mathbf{X}}^s))$, etc. The inhomogeneous medium in the high frequency-localized beam excitation regime may be modelled by the wave speed along the excited ray and its second order transverse derivative matrix $\mathbf{V}_b^{(2)}(\sigma^s)$, whose (ij) elements are $\partial_{x_{b_i}}\partial_{x_{b_i}} v_b|_{\Sigma^s}$. Using the ray coordinate frame, the paraxially approximated scattering propagators may be evaluated in the high frequency regime, giving (see details in Appendix B)

$$B_b^s(\mathbf{r}^s; \overline{\mathbf{X}}^s) = \frac{i}{2k_o\overline{\zeta}^s}\sqrt{\frac{v_b(\sigma^s)}{v_o}\frac{\det\mathbf{Q}_b^s(0)}{\det\mathbf{Q}_b^s(\sigma^s)}}\exp[i\Phi_b^s(\mathbf{r}^s; \overline{\mathbf{X}}^s)], \tag{49}$$

with

$$\Phi_b^s(\mathbf{r}^s; \overline{\mathbf{X}}^s) = -\left[\int_0^{\sigma^s} d\sigma' k_b(\sigma')\right] + \frac{1}{2}k_b(\sigma^s)\mathbf{x}_b^s \quad \boldsymbol{\Gamma}_b^s(\sigma^s)\cdot\mathbf{x}_b^s, \tag{50}$$

where $k_b(\sigma^s) = \omega/v_b(\mathbf{r})|_{\mathbf{r}\in\Sigma^s}$ is the wave number along the excited ray Σ^s. The transverse matrix $\boldsymbol{\Gamma}^s(\sigma^s)$ is a complex symmetric 2×2 matrix with $\mathrm{Im}\,\boldsymbol{\Gamma}^s$ positive definite. One may calculate $\boldsymbol{\Gamma}^s$ by the standard procedure of solving the matrix Riccati equation, setting

$$\boldsymbol{\Gamma}_b^s(\sigma^s) = v_b(\sigma^s)\mathbf{P}_b(\sigma^s)\mathbf{Q}_b^{-1}(\sigma^s), \tag{51}$$

and solving, along Σ^s, the first order system of coupled differential equations

$$\mathbf{Q}_b'(\sigma^s) = v_b(\sigma^s)\mathbf{P}_b(\sigma^s), \quad \mathbf{P}_b'(\sigma^s) = -v_b(\sigma^s)^{-2}\mathbf{V}_b^{(2)}(\sigma^s)\mathbf{Q}_b(\sigma^s), \tag{52}$$

where the prime denotes a derivative with respect to the argument. Relation (52) is subject to the initial conditions

$$\mathbf{Q}_b(0) = \mathbf{I}, \quad \mathbf{P}_b(0) = v_o\boldsymbol{\Gamma}^s. \tag{53}$$

As in the special case of homogeneous background medium (i.e., the Born approximation) in (28), one can show that if $\boldsymbol{\Gamma}^s(0)$ is symmetric with $\mathrm{Im}\,\boldsymbol{\Gamma}^s(0)$ positive definite, then $\boldsymbol{\Gamma}^s(\sigma^s)$ has these

properties for all σ^s, and that $\mathbf{Q}(\sigma^s)\neq 0$ for all σ^s. Following the procedure in (32)–(35), one identifies $\mathrm{Re}\,\mathbf{\Gamma}^s(\sigma^s)$ and $\mathrm{Im}\,\mathbf{\Gamma}^s(\sigma^s)$ as the beam curvature and beam-amplitude matrices, respectively. Note that the special case of the Born approximation in (28), in which the background medium is homogeneous, may be obtained by substituting $v_b(\mathbf{r})=v_o$ into (49)–(53).

The scattering propagators, $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$, are backpropagating along the ray trajectory initiating from the scattered data plane in $z^s=0$, from a processing $\overline{\mathbf{x}}^s$-dependent point, in a processing $\overline{\boldsymbol{\xi}}^s$-dependent direction. The propagator exhibits a Gaussian decay normal to the ray trajectory, i.e., in $\mathbf{x}_b^s$.

3. Asymptotic evaluation of the incident propagators

For the case of the incident propagators, $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$, in (18), each propagator emanates from point $\overline{\mathbf{x}}'$ on the initial distribution plane, in a direction $\overline{\boldsymbol{\xi}}^i$ (see Fig. 3); thus, the ray coordinates associated with each processed beam are denoted accordingly as $\sigma^i=\sigma(\overline{\mathbf{X}}^i)$, etc. As in (49), the inhomogeneous medium may be modeled by the wave number along the excited ray, $k_b(\sigma^i)$, and its second order transverse derivative matrix $\mathbf{V}_b^{(2)}(\sigma^i)$ along the beam-axis. Using the ray coordinate frame, the paraxially approximated scattering propagators may be evaluated in the high frequency regime in a manner similar to (49), giving

$$B_b^i(\mathbf{r};\overline{\mathbf{X}}^i)=\sqrt{\frac{v_b(\sigma^i)}{v_o}\frac{\det\mathbf{Q}_b^i(0)}{\det\mathbf{Q}_b^i(\sigma^i)}}\exp[i\Phi_b^i(\mathbf{r};\overline{\mathbf{X}}^i)] \tag{54}$$

with

$$\Phi_b^i(\mathbf{r};\overline{\mathbf{X}}^i)=\left[\int_0^{\sigma^i}d\sigma' k_b(\sigma')\right]+\frac{1}{2}k_b(\sigma^i)\mathbf{x}_b^i\quad\mathbf{\Gamma}_b^i(\sigma^i)\cdot\mathbf{x}_b^i, \tag{55}$$

where the matrix $\mathbf{\Gamma}_b^i(\sigma^i)$ is found by solving (52) along the incident beam-axis $\sigma^i\in\Sigma^i$ with the initial conditions $\mathbf{Q}_b(0)=\mathbf{I}$ and $\mathbf{P}_b(0)=v_o\mathbf{\Gamma}^i$.

4. PS2PS mapping

Next, we consider the scattering cell under Gaussian windows processing. By inserting $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$ in (49) with $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$ in (54) into (22), we obtain the asymptotic expression for the scattering cell

$$\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s)=\frac{ik_o}{8\pi^2\overline{\zeta}^sN^i}\sqrt{\frac{v_b(\sigma^s)v_b(\sigma^i)/v_o^2}{\det\mathbf{Q}_b^s(\sigma^s)\det\mathbf{Q}_b^i(\sigma^i)}}\exp\{i[\Phi_b^s(\mathbf{r}^s;\overline{\mathbf{X}}^s)+\Phi_b^i(\mathbf{r};\overline{\mathbf{X}}^i)]\}, \tag{56}$$

where Φ_b^s and Φ_b^i are given in (50) and (55), respectively. Relation (56) implies the following: The local scattering cell exhibits Gaussian decay normal to both the incident and scattering ray trajectories (i.e., in $\mathbf{x}_b^i$ and $\mathbf{x}_b^s$). Thus, the window center is located at the intersection of the incident spectral beam $B_b^i(\mathbf{r}';\overline{\mathbf{X}}^i)$ and the scattered beam propagator $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$ axes. Therefore, the location of the scattering cell is resolved by the PS processing parameters $\overline{\mathbf{X}}^s$ and $\overline{\mathbf{X}}^i$, which determine, via (30), the PS propagators ray trajectories (see Fig. 3).

The localization in the object domain as determined by $\Lambda_b(\mathbf{r}';\overline{\mathbf{X}}^i,\overline{\mathbf{X}}^s)$ may be interpreted by using fundamental wave physics. Consider an incident propagator emanating from $z=0$ plane from point $\overline{\mathbf{x}}'$ at angle $\overline{\theta}^i$ along ray Σ^i, arriving at the $z^s=0$ scattering plane at point $\overline{\mathbf{x}}^s$ at angle $\overline{\theta}^s$. In this case, the scattering propagator, $B_b^s(\mathbf{r};\overline{\mathbf{X}}^s)$, corresponding to $\overline{\mathbf{x}}^s$ and $\overline{\theta}^s$, backpropagates along the same ray trajectory $\Sigma^s=\Sigma^i$, and the corresponding scattering cell exhibits Gaussian decay *only* in the transverse coordinates $(\mathbf{x}_{b_1},\mathbf{x}_{b_2})$ and not along the (shared) beam-axis. Therefore, the integration domain in (21) is local *only normal to* Σ^i, which indicates the stationary

contribution to PS spectral distribution at that particular $\overline{\mathbf{X}}^s$ in accord with the Fermat principle. Furthermore, the phase accumulation along Σ^i, $2\int_0^{\sigma^i} d\sigma' k_b(\sigma')$, when introduced into (21), acts as a ''scaled Fourier transform'' operating along the ray trajectory; thus, large contributions to Ψ_b in (21) arise from medium variations *along* Σ in accord with fundamental 1D wave physics.

V. CONCLUDING REMARKS

Inhomogeneous medium Green's function in the phase-space domain were presented, linking the phase-space spectral distributions of the field scattered by a high contrast object to a genetic time-harmonic incident field. Two forms of phase-space Green's function were presented: (a) A *configuration-space to phase-space* Green's function that links induced sources in the object domain to phase-space distributions of the scattered field is obtained by applying PS transform to the scattered field over planar surfaces; and (b) a *phase-space to phase-space* Green's function, which directly links incident- to scattered-phase-space distribution, obtained by applying the PS transform to *both* incident and scattered field distributions, s. The scattering mechanism has been described in terms of local samplings of the object function which are localized in the object domain according to the scattered- and incidence-processing parameters. The special case of Gaussian windows has been considered and asymptotic expressions for the PS Green's functions and scattering cells have been derived for both the Born approximated- and the generic-inhomogeneous medium profiles. The wave phenomenology associated with the PS Green's functions and the scattering mechanism have also been explored.

Equations (20)–(22) establish the building blocks for an *inverse scattering* procedure in which the strong scatterer is found via iterative algorithm where at the nth iteration, the background $v_b(\mathbf{r})=v_n(\mathbf{r})$ is known, and the sampling operation in (20) is inverted to evaluate $O(\mathbf{r})$, from which the next v_{n+1} is found. This operation may be carried out for large scatterers since it can be shown that under appropriate illuminating conditions, the operation in (20) may be reduced to 1D samplings along the (synthesized) scattered ray trajectories.

APPENDIX A: OPERATOR REPRESENTATION OF CS2PS GREEN'S FUNCTION

In order to establish the scattering propagators in (11) as Green's functions, an operator equation associated with the CS2PS is derived hereby. We define the Helmholtz operator $(L_1u)(\mathbf{r})$

$$(L_1u)(\mathbf{r})\equiv[\nabla^2+k_b^2(\mathbf{r})]u(\mathbf{r}), \tag{A1}$$

and the inverse-PS operator $(L_2U)(\overline{\mathbf{X}})$

$$(L_2U)(\overline{\mathbf{X}})\equiv\left(\frac{k_o}{2\pi N^s}\right)^2\int d^4\overline{X}^s \;\; U(\overline{\mathbf{X}},z^s) \;\; W^s(\mathbf{x}^s;\mathbf{X}^s), \tag{A2}$$

where $U(\overline{\mathbf{X}},z^s)$ are PS distributions over planar surfaces of constant z^s. Next, we define the cascade operator $(LU)(\overline{\mathbf{X}})=[L_1(L_2U)(\overline{\mathbf{X}})][\mathbf{r}]$. Using (9), in (1), we identify the operator equation

$$(LU^s)(\overline{\mathbf{X}}^s)=-f(\mathbf{r}), \quad f(\mathbf{r})=k_o^2O(\mathbf{r})u(\mathbf{r}). \tag{A3}$$

The Green's function, B_b^s, associated with the operator Eq. (A3) is obtained by solving

$$(LB_b^s)(\overline{\mathbf{X}}^s) = -\delta(\mathbf{r}-\mathbf{r}') \tag{A4}$$

and the resolvent operator of L, $U^s=(L^{-1}f)(\mathbf{r})$ takes the form in (10), thereby identifying B_b^s in (11) as a Green's function. Furthermore, by substituting (11) into (A3) and inverting the order of integration, one finds that the PS scattering propagators satisfy definition (A4).

APPENDIX B: EVALUATION OF EQ. (49)

In order to establish Eq. (49), we note that generic solution for beam-type wave objects propagating in the background medium $v_b(\mathbf{r})$, along the ray Σ^s, is given by[3,14,19]

$$B_b^s(\mathbf{r}) = A\sqrt{\frac{v_b(\sigma^s)}{v_o}\frac{\det\mathbf{Q}_b(0)}{\det\mathbf{Q}_b(\sigma^s)}}\exp[i\Phi_b(\mathbf{r})], \tag{B1}$$

where A is a constant, and the phase

$$\Phi_b(\mathbf{r}) = \pm\left[\int_0^{\sigma^s} d\sigma' k_b(\sigma')\right] + \frac{1}{2}k_b(\sigma^s)\mathbf{x}_b \quad \mathbf{\Gamma}_b(\sigma^s)\cdot\mathbf{x}_b\,. \tag{B2}$$

Since, according to (11), the scattering propagator $B_b^s(\mathbf{r}';\overline{\mathbf{X}}^s)$ satisfies wave equation (1) with $v(\mathbf{r})=v_b(\mathbf{r})$, we seek for solutions in the form of (B1). Under the paraxial approximation, the initial distribution of the scattering propagator over the $z^s=0$ plane may be replaced by the initial parameter matrix (see discussion following (42))

$$\mathbf{\Gamma}^s_{\text{parax}} = \begin{bmatrix} \Gamma^{s*}/\overline{\zeta^s}^2 & 0 \\ 0 & \Gamma^{s*} \end{bmatrix}, \tag{B3}$$

over the $z_b^s=0$ plane. Note that the projected initial paraxial distribution, which was originally obtained for homogeneous medium, may serve for inhomogeneous propagation as well, as long as the initial plane is embedded in an homogeneous medium, since in the high-frequency limit Bremmer-type reflections are negligible, and the beam-type field is forward propagating along the ray trajectories.[3,14] Therefore, we may use the homogeneous background asymptotic field in (28) with the above-mentioned initial distribution in the general solution (B1) yielding (49). Note that solution (49) satisfies the radiation condition of sources in the $z^s<0$ as exhibited by the propagation phase accumulation of $-\int_0^{\sigma^s} d\sigma' k_b(\sigma')$ for $\sigma^s<0$ (see also Fig. 4).

A metric with signature $(-+++)$ can be constructed from a metric with signature $(++++)$ and a double-sided vector field called the line element field. Some of the classical and quantum properties of this vector field are studied. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738190]

I. INTRODUCTION

The difference between a Lorentzian and a positive definite metric can be expressed as a double-sided vector field U called the line element field. This is done in Ref. 4, p.38, but there only the ratio of vectors in the two spaces is considered; this appears to be the only reference on the line element field and it is from it that the nomenclature is taken. Thus the study of fields or extented objects in Lorentzian space–time is reduced to the study of the same object in a positive definite space and the study of the corresponding line element field. In particlular this can be done for gravity, where the positive defininte action is sometimes called the Euclidean action.[3]

In Sec. II some examples of positive definite metrics are presented and how to change their signature via a vector field is shown; this is successively generalized to vanishing shift metrics and then the general theory, next the first derivatives are studied, and expressed in terms of a contorsion tensor. The second derivatives of the metric are governed by the Riemann tensor which can be expressed by independent terms in the contorsion and Christoffel connection. In Sec. III the Einstein–Hilbert action is decomposed into a positive definite part and a line element field part, the line element field part is varied with repect to both U and $\dot{U}$. The variation with respect to $\dot{U}$ gives the momentum. Quantization is implemented by replacing this momentum by a differential operator to give a modified Klein–Gordon equation. Then the lowest order approximation to the modified Klein–Gordon equation is calculated, and the wave function is calculated for some specific space–times.

Notation used includes the bracket notation of Ref. 4, p. 20,

$$2V_{(a,c)}=V_{a,c}+V_{c,a}=2V_{(a;c)}+2\{^{e}_{ca}\}V_{e}\,,\quad 2V_{[a,c]}=2V_{[a;c]}=V_{a,c}-V_{c,a}\,, \tag{1}$$

the scalars constructed from the expansion and vorticity Ref. 4, p. 82,

$$\omega_{ab}\equiv h^{c}_{a}h^{d}_{b}V_{[c;d]}\,,\quad \theta_{ab}\equiv h^{c}_{a}h^{d}_{b}V_{(c;d)}\,,\quad \sigma_{ab}\equiv\theta_{ab}-\tfrac{1}{3}h_{ab}\theta,$$

$$\theta\equiv\theta_{ab}h^{ab}=V_{a;b}h^{ab}=V^{a}{}_{a}\,,\quad \omega^{2}\equiv\omega^{ab}\omega_{ab}\,,\quad \sigma^{2}\equiv\sigma^{ab}\sigma_{ab}\,, \tag{2}$$

and vector fields

$$\begin{aligned} U_{a}&\quad\text{for a general vector,}\\ V_{a}&\quad\text{for a normalization of this to }\pm1,\\ W_{a}&\quad\text{for a specific vector.}\end{aligned} \tag{3}$$

II. CURVATURE

A. Relationship between a positive definite metric and a Lorentzian metric

For a given positive definite metric $\overset{-+}{p}_{ab}$ and vector field U_{++a}, one can construct a Lorentzian space–time with covariant metric

$$\overset{-+}{g}_{ab}=-2\frac{\overset{++}{U}_a\overset{++}{U}_b}{\overset{++}{U}^2}+\overset{++}{p}_{ab}, \tag{4}$$

This can be illustrated using the positive definite Schwarzschild metric

$$\overset{++}{ds}^2=+\left(1-\frac{2m}{r}\right)dx_0^2+\left(1-\frac{2m}{r}\right)^{-1}+r^2d\Sigma_2^2,\quad d\Sigma_2^2=d\theta^2+\sin^2\theta d\phi^2,$$

$$\overset{++}{W}_a=\left(\sqrt{1-\frac{2m}{r}},0\right),\quad \overset{++}{W}^a\overset{++}{W}_a=+1, \tag{5}$$

or the positive definite Robertson–Walker metric

$$\overset{++}{ds}^2=+dx_0^2+R^2d\Sigma_3^2,\qquad d\Sigma_3^2=d\chi^2+f^2(\chi)(d\theta^2+\sin^2\theta d\phi^2),\qquad \overset{++}{W}_a=(1,0), \tag{6}$$

then using (4) the space–time metric is recovered. Instead of U it is often convenient to work with the unit vector

$$V_a=\frac{U_a}{\sqrt{\pm U^2}},\qquad U^2=U_aU_b\overset{++}{p}^{ab}, \tag{7}$$

There is a problem of what the contravariant form of $\overset{-+}{g}$, p and U should be. One can generalize (5) and (6) to a positive definite space with shift-free metric ($N_i=0$); being shift-free implies that the metric has no cross $g_{\tau i}$ terms and can be represented thus

$$\overset{++}{p}_{ab}=(q^2,p_{ij}),\qquad \overset{++}{p}^{ab}=\left(\frac{1}{q^2},p^{ij}\right),\qquad \det(\overset{++}{p}_{ab})=q\det(p_{ij}),$$

$$\overset{++}{W}_a=(q,0),\qquad \overset{++}{W}^a=(1/q,0). \tag{8}$$

No cross metric terms $g_{\tau i}=0$, allows W_a to have only one component, if there is a cross term $g_{\tau i}\neq 0$, then either W_a or W^a or both, will have more than one component. Now one can construct a Lorentzian space–time with covariant metric

$$\overset{-+}{g}_{ab}=(-p^2,p_{ij}),\qquad \det(\overset{-+}{g}_{ab})=-\det(\overset{++}{p}_{ab}). \tag{9}$$

Consistency seems to require

$$\overset{-+}{g}^{ab}=-2\overset{++}{V}^a\overset{++}{V}^b+\overset{++}{p}^{ab}=\left(-\frac{1}{p^2},p^{ij}\right). \tag{10}$$

Note that only cross terms in V occur so perhaps $\overset{-+}{V}$ could have been used; (17) shows that this is not the case. Taking $\overset{-+}{V}_a=\overset{++}{V}_a$ and raising using this metric

$$\overset{-+}{W}^a=\left(-\frac{1}{p},0\right),\quad \overset{-+}{W}^2=-1, \tag{11}$$

so that $\overset{-+}{V}$ is a timelike vector. Similarly taking $\overset{-+}{p}_{ab}=\overset{++}{p}_{ab}$ and raising indices using (10) gives

$$\overset{-+}{p}^{ab}=\overset{++}{p}^{ab}. \tag{12}$$

Some products using the above tensors are

$$\overset{-+}{g}{}^{c}{}_{c} \equiv \overset{-+}{g}{}^{ab}\overset{-+}{g}{}_{bc} = \overset{++}{p}{}^{a}{}_{c} - 2\overset{++}{V}{}^{a}\overset{++}{V}{}_{c},$$

$$\overset{++}{p}{}^{ab}\overset{-+}{g}{}_{bc} = 2\overset{-+}{V}{}^{a}\overset{-+}{V}{}_{c} + \overset{-+}{g}{}^{a}{}_{c},$$

$$-\overset{-+}{V}{}_{a} = \overset{-+}{V}{}^{b}\overset{-+}{g}{}_{bc}, \qquad \overset{-+}{V}{}^{a} = \overset{-+}{V}{}^{c}\overset{-+}{g}{}^{a}{}_{c} = -\overset{-+}{V}{}_{c}\overset{++}{p}{}^{ab}, \quad \overset{++}{p}{}^{ac}\overset{-+}{V}{}_{c} = -\overset{-+}{V}{}^{a}. \tag{13}$$

Collecting this together consistency requires

$$\overset{-+}{g}{}^{ab} = -2\frac{\overset{++}{U}{}^{a}\overset{++}{U}{}^{b}}{\overset{++}{U}{}^{2}} + \overset{++}{p}{}^{ab}, \tag{14}$$

and

$$\overset{-+}{V}{}_{a} = \overset{++}{V}{}_{a}, \quad \overset{-+}{V}{}^{a} = -\overset{++}{V}{}^{a}, \quad \overset{-+}{p}{}_{ab} = \overset{++}{p}{}_{ab}, \quad \overset{-+}{p}{}^{ab} = +\overset{++}{p}{}_{ab}. \tag{15}$$

B. Common pitfalls

The above system is new and slips can be made by relying on ones intuition from studying spacetimes using the projection tensor, defined here at (18) below, or confusing the $(-+)$ and $(++)$ spaces. For any metric there is the equation $g_{ab}g^{bc} = \delta^{c}_{a}$, which can be contracted to $g_{ab}g^{ab} =$ dimension of the space $= 4$. The most common pitfall is to use this equation thus

$$4 = g^{a}_{a} \overset{?}{=} -2V_{a}V^{a} + p^{a}_{a} = -2V_{a}V^{a} + 4, \tag{16}$$

suggesting that V is null, contrary to assumption. The correct calculation is

$$4 = \overset{-+}{g}{}^{ab}\overset{-+}{g}{}_{ab} = \left(-2\frac{\overset{++}{U}{}^{a}\overset{++}{U}{}^{b}}{\overset{++}{U}{}^{2}} + p^{ab}\right)\left(-2\frac{\overset{++}{U}{}_{a}\overset{++}{U}{}_{b}}{\overset{++}{U}{}^{2}} + p_{ab}\right) = \left(4\frac{\overset{++}{U}{}^{2}}{\overset{++}{U}{}^{2}} - 2 - 2\right)\frac{\overset{++}{U}{}^{2}}{\overset{++}{U}{}^{2}} + 4, \tag{17}$$

which also serves as showing that $\overset{++}{U}$ rather than $\overset{-+}{U}$ should be used for $\overset{-+}{g}$ in (14). The projection tensor is defined as

$$\overset{-+}{h}{}_{ab} \equiv \overset{-+}{g}{}_{ab} + \frac{\overset{-+}{U}{}_{a}\overset{-+}{U}{}_{b}}{-\overset{-+}{U}{}^{2}} = \overset{++}{p}{}_{ab} - 2\frac{\overset{++}{U}{}_{a}\overset{++}{U}{}_{b}}{\overset{++}{U}{}^{2}} - \frac{\overset{-+}{U}{}_{a}\overset{-+}{U}{}_{b}}{\overset{-+}{U}{}^{2}} = \overset{-+}{p}{}_{ab} + \frac{\overset{-+}{U}{}_{a}\overset{-+}{U}{}_{b}}{\overset{-+}{U}{}^{2}} = \overset{++}{p}{}_{ab} - \frac{\overset{++}{U}{}_{a}\overset{++}{U}{}_{b}}{\overset{++}{U}{}^{2}}, \tag{18}$$

where in this case the indices can be raised and lowered without change of form.

C. First derivatives of the metric

Having formed the metric the next problem is the properties of its first derivatives. To form the connection Γ with g in terms of the connection $\{\}$ with p one has

$$\begin{aligned} 2\overset{g}{\Gamma}_{abc} &\equiv g_{ba,c} + g_{ca,b} - g_{bc,a} \\ &= 2\{_{abc}\} + 4U^{-2}(-U_{a}\{^{e}_{bc}\}U_{e} - U_{a}U_{(b;c)} + U_{b}U_{[c;a]} + U_{c}U_{[b;a]}) \\ &\quad + 4U^{-4}U_{e}(2U_{a}U_{(b}U^{e}_{\ ;c)} - U_{b}U_{c}U^{e}_{\ ;a}), \end{aligned} \tag{19}$$

where in the last two terms the bracket notation 1 for $U_{[a;b]}$ and $U_{(a;b)}$ is used; the covariant derivatives on the rhs of (20) are formed with p. Raising with the metric (10)

$$\overset{g}{\Gamma}{}^{a}_{bc} \equiv \overset{-+}{g}{}^{ad} \overset{g}{\Gamma}_{dbc}, \tag{20}$$

so that

$$\overset{g}{\Gamma}{}^{a}_{bc} = \left\{ \begin{matrix} p \\ a \\ bc \end{matrix} \right\} + \overset{p}{L}{}^{a}{}_{e} \left\{ \begin{matrix} p \\ e \\ bc \end{matrix} \right\} + \overset{p}{K}{}^{a}_{bc}, \tag{21}$$

it is found that $L=0$ implying that the system is covariant. From (21) there is the relation between the covariant derivatives.

$$\overset{++}{V}{}^{-+}_{a;b} = \overset{++}{V}{}^{++}_{a;b} - K^{c}_{ab} \overset{++}{V}{}_{c}, \tag{22}$$

The contorsion tensor K, define by (21), can be expressed in terms of the auxiliary tensors $J\&M$

$$2K^{a}_{bc} = +8U^{-2}U_{(b}J_{c)}{}^{a} + 4U^{-2}U^{a}U_{(bc)} - 2U^{-4}M^{a}_{bc},$$

$$J_{ab} \equiv U_{[a;b]} - 2U^{-2}U_{b}U^{c}U_{[a;c]}, \tag{23}$$

$$M^{a}_{bc} \equiv (U^{2})^{a}U_{b}U_{c} + (U^{2})_{b}U^{a}U_{c} + (U^{2})_{c}U^{a}U_{b} - 2U^{-2}U^{a}U_{b}U_{c}U^{e}(U^{2})_{e},$$

where $(U^{2})_{c} = (U_{a}U^{a})_{c} = 2U^{a}U_{a;c}$. There is no term in the accelerations $\dot{U}^{a}$, $\dot{U}^{b}$, or $\dot{U}^{c}$, M vanishes if U is a constant vector. Some properties of the contorsion K are

$$K^{a}_{ac} = 0, \qquad K^{a}_{ba} = 0, \qquad K^{a}_{bc} = K^{a}_{cb}, \qquad U^{b}U^{c}K^{a}_{bc} = 0,$$

$$U_{a}K^{a}_{bc} = 2U_{bc} - 2U^{-2}(U_{(b}\dot{U}_{c)} + U_{e}U_{(b}U^{e}_{.c)}) + 2U^{-4}U_{b}U_{c}U_{e}\dot{U}^{e}, \tag{24}$$

the dot being formed with the p covariant derivatives; such systems involving a connection and a contorsion occur repeatedly in the study of curvature; for instance, in geometries involving torsion and/or metricity such as the geometries of Weyl and Schouten,[11] the study of a conformal factor, and the study of weak metric perturbations.[9] Alternatively the contorsion can be expressed in terms of the decomposed vector field for a $(-+)$ Lorentzian space–time define θ as in (2) and

$$\omega_{ab} \equiv h_{a}{}^{c}h_{b}{}^{d}V_{[c;d]}, \qquad \theta_{ab} \equiv h_{a}{}^{c}h_{b}{}^{d}V_{(c;d)}, \qquad \sigma_{ab} \equiv \theta_{ab} - \tfrac{1}{3}\theta h_{ab}, \qquad \dot{X}_{abc\ldots} \equiv V^{e}X_{abc\ldots;e}, \tag{25}$$

which allow the covariant derivative of a $(-+)$ space–time to be decomposed

$$U_{a;b} = \theta_{ab} + \omega_{ab} + U^{-2}U_{b}\dot{U}_{a} + U^{-2}U_{a}U^{e}U_{eb} - U^{-4}U_{a}U_{b}U^{e}\dot{U}_{e}, \tag{26}$$

choosing a constant vector field this reduces to Ref. 4, Eq. (4.17). Now Eqs. (24) are in the $(++)$ space and (25) are in a $(-+)$ space–time; they can be related using the projection tensor (18). The projection tensor (18) can be applied to (26) to give the projections of the covariant derivative

$$h^{c}_{a}h^{d}_{b}U_{(c;d)} = U_{(a;b)} - U^{-2}U_{(a}\dot{U}_{b)} - \tfrac{1}{2}U^{-2}U_{(a}(U^{2})_{b)} + \tfrac{1}{2}U^{-4}U_{a}U_{b}(\dot{U}^{2}),$$

$$h^{c}_{a}h^{d}_{b}U_{[c;d]} = U_{[a;b]} - U^{-2}\dot{U}_{[a}U_{b]} - \tfrac{1}{2}U^{-2}U_{[a}(U^{2})_{b]}. \tag{27}$$

To transfer these quantities to the $(++)$ space, the projection tensor (18) shows that it is only necessary to note that the negative quantity $U^2=\overset{-+}{U}_a\overset{-+}{U}{}^a<0$ is changed to the positive quantity $U^2=\overset{++}{U}_a\overset{++}{U}{}^a>0$, and also that the covariant derivative in the expansion is changed using (22). $U_eK^e_{ab}$ is -2 times θ_{ab} so that the sign of θ_{ab} in the $(++)$ space is the negative of the form in (27) and from (25). In particular the expansion (2) becomes

$$-\theta=U^a_{.;a}-\frac{(\dot{U}^2)}{U^2}. \tag{28}$$

Using (24) and (27) the contorsion tensor is found to be

$$J_{ab}=\omega_{ab}-\frac{\dot{U}_{(a}U_{b)}}{U^2}+\frac{U_{(a}(U^2)_{b)}}{2U^2},\qquad K^a_{bc}=\frac{4}{U^2}U_{(b}\omega_{c)}{}^a-\frac{2}{U^2}U^a\theta_{bc}-2\sqrt{U^2}\left(\frac{\dot{U}^a}{\sqrt{U^2}}\right)\frac{U_bU_c}{U^4}. \tag{29}$$

D. Second derivatives of the metric

The second derivatives are governed by the Riemann tensor, the Riemann tensor constructed with a Lorentzian metric can be decomposed into the Riemann tensor constructed with a positive definite metric and the contorsion

$$\overset{g}{R}{}^a{}_{bcd}=\overset{p}{R}{}^a{}_{bcd}+2K^a_{.[d|b|;c]}+2K^a_{.[c|e|}K^e_{.d]b}, \tag{30}$$

such decompositions of the Riemann tensor also happen for several other systems: (1) Weak field gravity requires that the metric be of the form $g_{ab}=\eta_{ab}+w_{ab}$, where η is a flat metric and w is a small adjustment to it, in this case the connection constructed from w is a contorsion tensor, and the analog of (30) is of the form $Rie=\partial K+K\times K$, (2) weakly perturbed gravity requires that the metric be of the form $g=\overline{g}+w$, where $\overline{g}$ is a given background metric and w is a small adjustment to it, again the connection constructed from w is a contorsion tensor, and the analog of (30) is of the form $Rie=R\overline{ie}+\partial K+K\times K$, cf Eq. (111),[4] (3) a metric conformal to another Eq. (2.28)[4] $\hat{g}=\Omega^2g$, gives a contorsion given by the last term of Eq. (2.29),[1] and the analog of (30) is of the form $R\hat{ie}=\Omega^{-2}Rie+\partial K$, (4) different geometries such as those of Weyl and Schouten[11] also have connections which split up into a Christoffel part and a contorsion part and then give equations of the same form as (30). The important thing is that these examples and (30) all have no cross L term in (21), $L=0$ showing that the connection can be split into a Christoffel part and a contorsion part and nothing else.

III. QUANTIZATION

A. The Lagrangian

Contracting the expression for the Riemann tensor (30) and using (9) the Einstein–Hilbert Lagrangian becomes

$$\mathcal{L}_H=\sqrt{-g}\overset{g}{R}=\sqrt{\det(p_{ab})}[\overset{p}{R}+2K^{ab}_{.[b|.|;a]}+2K^a_{.[a|e|}K^{eb]}_{..}{}_b]=\mathcal{L}_1+\mathcal{L}_2+\mathcal{L}_3, \tag{31}$$

$\mathcal{L}_1$ is given by the first term in the square brackets [], and is the positive definite action, sometimes called the Euclidean action and this has previously been studied; $\mathcal{L}_2$ & $\mathcal{L}_3$ are given by the second and third terms in the square bracket [], and are new and they are easiest to describe in terms of the decomposed vector quantities (25) thus

$$\mathcal{L}_2 = -\frac{2}{U^2}(\dot{\theta}-\theta^2) - 2\left(\frac{1}{\sqrt{U^2}}\left(\frac{U^a}{\sqrt{U^2}}\right)^{\circ}\right)_a \equiv l_1 + l_2 + l_3,$$
$$\mathcal{L}_3 = \frac{4\omega^2}{U^2} - \frac{4}{U^4}\left[\left(\frac{U^a}{\sqrt{U^2}}\right)^{\circ} U_a\right]^2 \equiv l_4 + l_5, \qquad \omega^2 \equiv \omega^{ab}\omega_{ab}, \tag{32}$$

where $(U^2)^\circ$ is the absolute derivative of U^2, explicitly $(U^2)^\circ = (U^2)_{;a}U^a$. Expanding (32) $l_5 = 0$. Varying with respect to U,

$$\frac{\delta l_1}{\delta U^c} = -2U^{-2}\theta_c + 2((U^{-2}U^eU^2)_e)_c - 2U^{-2}(U^{-2}U^e)_e(U^2)_c - 4U_c(U^{-2}(^{-2}U^f)_fU^e)_e$$
$$-4U^{-4}(U^{-2}U^e)_e(U^2)^\circ U_c,$$
$$\frac{\delta l_2}{\delta U^c} = 4(U^{-2}\theta)_c + 4U^{-4}\theta(U^2)_c - 8U_c(U^{-4}\theta U^e)_e - 8U^{-6}(U^2)^\circ U_c, \tag{33}$$
$$\frac{\delta l_4}{\delta U^c} = -8(U^{-2}\omega^{ce})_e + 4U^{-2}\omega^{ce}(2\dot{U}_e - U^2(U^2)_e),$$
$$\frac{\delta l_3}{\delta U^c} = \frac{\delta l_5}{\delta U^c} = 0.$$

B. The momentum

In order to produce momenta it is necessary to vary with respect to $\dot{U}^c$

$$\frac{\delta l_1}{\delta \dot{U}^c} = -\frac{4\theta U_c}{U^4}, \qquad \frac{\delta l_2}{\delta \dot{U}^c} = +8\frac{\theta U_c}{U^4}, \qquad \frac{\delta l_3}{\delta \dot{U}^c} = \frac{\delta l_3}{\delta \dot{U}^c} = \frac{\delta l_3}{\delta \dot{U}^c} = 0. \tag{34}$$

Therefore

$$\Pi_a = \frac{\delta}{\delta \dot{U}^a}(l_1 + l_2) = \frac{4\theta U_a}{U^4}. \tag{35}$$

This equation is not fully invertible in terms of the momenta Π thus $U_a = f(\Pi)\Pi_a$, but is partially invertible in terms of both the momenta Π and the vector field U thus $U_a = f(\Pi, U)\Pi_a$,

$$\frac{U_a}{\sqrt{U^2}} = \frac{\Pi_a}{\sqrt{\Pi^2}}, \tag{36}$$

and partially invertible in terms of the expansion θ and momenta Π thus $U_a = f(\Pi, \theta)\Pi_a$,

$$U_a = (4\theta)^{1/3}\Pi^{-4/3}\Pi_a. \tag{37}$$

(35) gives the constraint

$$\lambda = \Pi_c\Pi^c - \frac{16\theta^2}{U^6}. \tag{38}$$

This is the only constraint so that quantization can be achieved via

$$\Pi_a \rightarrow -i\hbar\nabla_a, \tag{39}$$

with U and hence θ remaining unchanged. Plancks constant $\hbar$ is of the same dimensions as action, explicitly $Mass\times Length^2\times Time^{-1}$, so that (39) has introduced a ''mass'' into the system.

C. The modified Klein–Gordon equation

Applying (39) to the constraint gives a modified Klein–Gordon equation

$$\lambda\psi = -\hbar^2\left(\Box + \frac{16\theta^2}{\hbar^2 U^6}\right)\psi = 0. \tag{40}$$

D. Approximation

Defining

$$S \equiv -i\hbar \ln\psi \tag{41}$$

and then substituting S from (41) for ψ everywhere in (40), the modified Klein–Gordon equation (40) becomes

$$-i\hbar S^s_{.a} + S^a S_a - \frac{16\theta^2}{U^6} = 0, \tag{42}$$

expanding in terms of $\hbar$ using

$$S_a = \Pi_a + \hbar\epsilon_a + \mathcal{O}(\hbar^2), \tag{43}$$

the $\hbar^0$ term of (43) is just the constraint (38), the $\hbar^1$ term of (43) is

$$-\imath\Pi^a_{.a} + 2\epsilon_a\Pi^a = 0, \tag{44}$$

For $\theta = 0$, the Lagrangians l_1 and l_2 vanish as does Π, so that to lowest order $\hbar^0$, $S_a = 0$, implying that the wave function ψ is a constant to lowest order, thus for $\theta = 0$ the wave function has no dynamical information corresponding to the classical theory.

U remains unchanged during quantization, but once a solution ϵ to (43) is known, one would hope to be able to calculates the $\hbar^1$ order correction to U and hence g. There is a problem with trying this, as Π is only partially invertible (36) and (37) this cannot be done without an additional assumption. Here this assumption is that θ remains negligible to order $\hbar^1$ in the quantum theory, then it is possible to find the correction to U from (37), denoting the quantum quantities with a ''*'' U becomes

$$U^*_a = (4\theta)^{1/3} S^{4/3} S_a. \tag{45}$$

Substituting for S using (43) and expanding

$$U^*_a = U_a + \frac{\hbar}{4}\frac{U^4}{\theta}\left(\epsilon_a - \frac{8}{3}\frac{U_c\epsilon^c}{U^2}U_a\right) + \mathcal{O}(\hbar^2), \tag{46}$$

with this value of U^* it is now possible to investigate whether the assumption that θ is negligible by noting

$$-\theta^* \equiv U^{*a}_{\ ;a} - U^{*-2}(U^{*2})^\circ = -\theta + \frac{\hbar}{4}\left[\frac{U^4}{\theta}\left(\epsilon^a - \frac{8}{3}U^{-2}U^c\epsilon_c U^a\right)\right]_a + \frac{5\hbar}{6}\left[U^{-2}\left(\frac{U^4\epsilon_a U^a}{\theta}\right)^\circ - \frac{(U^2)^\circ \epsilon_a U^a}{\theta}\right] + \mathcal{O}(\hbar^2). \tag{47}$$

Substituting for U^* the change in the metric is

$$g^*_{ab} = g_{ab} + \frac{\hbar}{\theta}(U_c\epsilon^c U_a U_b - U^2 U_{(a}\epsilon_{b)}) + \mathcal{O}(\hbar^2). \tag{48}$$

The change in the metric can also be directly calculated from the wave function

$$g^*_{ab} - g_{ab} - 2U^{-2}U_aU_b = -2U^{-2}U^*_aU^*_b = -2S^{-4/3}S_aS_b = 2\hbar^2(-i\hbar\ln\psi)^{-4/3}\psi^{-2}\psi_a\psi_b. \tag{49}$$

E. Examples of exact spaces

The modified Klein–Gordon equation (40) can be studied for particular examples, for example, in Robertson–Walker space–time (6) it is

$$\psi_{00} + 3\frac{R_0}{R}\psi_0 + \frac{144}{\hbar^2}\frac{R_0^2}{R^2}\psi - \frac{l(l+2)}{R^2}\psi = 0, \tag{50}$$

where the last term comes from decomposing the ''spatial'' part into spherical harmonics Ref. 9, Sec. IV A. For the Milne universe, which is flat when $k=-1$,[8] $R=t$ and (50) has solution

$$\psi = At^{-1\pm\sqrt{1-\alpha}}, \qquad \alpha = \frac{144}{\hbar^2} - l(l+2), \tag{51}$$

so that g^* is of the form $f\hbar^2/t^2$. For deSitter space Ref. 4, p.125, $R=\exp(\sqrt{\Lambda/3}t)$ and when $l=0$ 50 has solution

$$\psi = A\exp\left(\tfrac{1}{2}\sqrt{3\Lambda}(-1\pm\sqrt{1-16/\hbar^2})t\right), \tag{52}$$

so that g^* is of the form $f\hbar^2$.

IV. CONCLUSION

A. Things not looked at

Things not looked at here include:

(1) Any relationship to analytic continuation, whether for quantum field theory on curved space time or for the energy condition Ref. 4, p. 89;
(2) any classical or quantum detailed mechanism or perturbation whereby a positive definite space could change to a Lorentzian space–time, for example, in the early universe;
(3) the connection with the Kubo–Martin–Schwinger[2] condition where the transformation $\tau \to it$ has thermal properties;
(4) a quantized line element field might fluctuate, this fluctuation could be thought of in terms of the tetrad rather than the metric, leading to fluctuating null cones, compare Penrose,[6]
(5) any comparison with the Toll[12]–Scharnhorst[10] effect, where fluctuations in the quantum electrodynamical vacuum cause fluctuations in the speed of light;
(6) any comparison with the average size of these fluctuations, compare Ellis *et al.*[1] and Yu and Ford;[13]

(7) not only can the difference between the two signatures be thought of as a vector field, also the difference between tensors constructed from the resulting metrics is tensorial, the Bianchi identities will also differ by a tensorial object constructed from the line element field and this gives another way of investigating conservation laws for the two signatures, compare Ref. 5.

B. The classical theory

The transformation between some specific positive definite spaces and Lorentzian spacetime can be achieved via a line element fields 5 and 6. This can be generalized to shift-free and then arbitrary metrics; there is a problem of what the contravariant form of the metric should be, consistency requires (14). Once the Lorenztian metric has been expressed in terms of a positive definite metric and a vector field it is possible to study first derivatives. In (21) $L=0$ so that the Lorentzian connection splits up into the positive definite connection and a contorsion term constructed from the line element field U; this is similar to many other systems, such as those involving Schouten[11] geometries and weak perturbations;[9] that $L=0$ perhaps is not surprising as the decomposition of the Lorentzian metric is covariant. The form of the contorsion tensor (24) involves a lot of terms when expressed solely in terms of U, however, using rotation and shear it takes a simpler form (29). Covariant derivatives in Lorentzian spacetime and the positive definite space are equated via (22), so that the difference is expressible as $V_c K^c_{ab}$ and this is proportional to the expansion of U, changing spaces has the effect of changing the sign of the expansion. Second derivatives of the line element field U can be calculated once the contorsion K is known via (30).

C. The quantum theory

To quantize the system it is necessary to have more information, such as what the Lagrangian and momentum are. Here the vacuum-Einstein–Hilbert Lagrangian is assumed (31), and further that it can be decomposed into a positive definite part and a line element field part which have well-defined and useful variations. Variations with respect to the metric and the line element field (33) can be done, however, of more use is variation with respect to $\dot{U}$ which is taken to give a momentum (35); variations with respect to dotted quantities also occur in the quantization of perfect fluids.[7] The momentum obeys the constraint (38). The two-sided nature of U, the Lorentzian metric is invariant under $U \to -U$; and the ability to use U of different sizes to construct the Lorentzian metric do not seem to lead to further constraints. Quantization can be achieved via (39). The problem with this is that it introduces a mass into the system. The classical theory is just a theory involving length and time, however, Planck's constant has dimensions $Mass \times Length^2 \times Time^{-1}$, so that using it in quantization introduces new quantities of dimension *Mass*. Theories, such as the vacuum-Einstein equations, involving just length and time are usually reversible, in the sense that the sign on the time coordinate can be changed and the field equations still obeyed; however, this is no longer necessarily the case once quantities of dimensions of mass have been introduced, as illustrated by the fact that things fall down not up. This is not only a problem for the theory under study here, similarly using $\hbar$ in quantization of the vacuum-Einstein equations will introduce a mass. The specific wave functions (51) and (52) illustrate the above, of the two terms in the square root one is dimensionless ''1'' and the other is dimensionfull and proportional to $\hbar^{-2}$. A way of avoiding the above is to divide $\hbar$ by the Planck mass or perhaps an arbitrary mass so that objects of dimensions of mass no longer occur in the quantum system; also by analogy with the point particle one could perhaps pre-multiply the line element field Lagrangian by an arbitrary m, but on the analysis so far such an m does not occur naturally, perhaps it might do so in an extended theory which in some way incorporates that U is not necessarily of unit size. Any given Lorentzian metric can be constructed from many different sets of a positive definite metric and a line element field. For example flat space–time can be expressed by the Minkowski metric and this can be constructed from a diagonal metric and unit expansion free line element field; also flat space–time can be expressed by the Milne universe (51) for which U has expansion. In the first case there is no expansion and hence no momentum or quantum theory, in

the second there is with wave function (51). Thus it might be that ''Euclidean'' quantum gravity expresses the full quantum nature of a Lorentzian space–time if the relating line element field is expansion free; however, the main application of such theories is to the early universe where expansion is the most salient feature.

Using a recently developed approach for solving the three-dimensional Dirac equation with spherical symmetry, we obtain the two-point Green's function of the relativistic Dirac–Morse problem. This is accomplished by setting up the relativistic problem in such a way that makes comparison with the nonrelativistic problem highly transparent and results in a mapping of the latter into the former. The relativistic bound states energy spectrum is easily obtained by locating the energy poles of the Green's function components in a simple and straightforward manner. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738950]

INTRODUCTION

Despite all the work that has been done over the years on the Dirac equation, its exact solutions for local interaction has been limited to a very small set of potentials. Since the original work of Dirac in the early part of last century up until 1989 only the relativistic Coulomb problem was solved exactly. In 1989, the relativistic extension of the oscillator problem (Dirac–Oscillator) was finally formulated and solved by Moshinsky and Szczepaniak.[1] Recently, and in a series of articles,[2–6] we presented an effective approach for solving the three-dimensional Dirac equation for spherically symmetric potential interaction. The first step in the program started with the realization that the nonrelativistic Coulomb, oscillator, and *S*-wave Morse problems belong to the same class of shape invariant potentials which carries a representation of so(2,1) Lie algebra. Therefore, the fact that the relativistic version of the first two problems (Dirac–Coulomb and Dirac–Oscillator) were solved exactly makes the solution of the third, in principle, feasible. Indeed, the relativistic Dirac–Morse problem was formulated and solved in Ref. 2. The bound state energy spectrum and spinor wave functions were obtained. Taking the nonrelativistic limit reproduces the familiar Schrödinger–Morse problem. Motivated by these findings, the same approach was applied successfully in obtaining solutions for the relativistic extension of yet another class of shape invariant potentials.[3] These included the Dirac–Scarf, Dirac–Rosen–Morse I and II, Dirac–Pöschl–Teller, and Dirac–Eckart potentials. Furthermore, using the same formalism quasiexactly solvable systems at rest mass energies were obtained for a large class of power-law relativistic potentials.[4] Quite recently, Guo *et al.* succeeded in constructing solutions for the relativistic Dirac–Woods–Saxon and Dirac–Hulthén problems using the same approach.[7] In the fourth and last article of the series in our program of searching for exact solutions to the Dirac equation,[5] we found a special graded extension of so(2,1) Lie algebra. Realization of this superalgebra by 2×2 matrices of differential operators acting in the two component spinor space was constructed. The linear span of this graded algebra gives the canonical form of the radial Dirac Hamiltonian. It turned out that the Dirac–Oscillator class, which also includes the Dirac–Coulomb and Dirac–Morse, carries a representation of this supersymmetry.

The central idea in the approach is to separate the variables such that the two coupled first order differential equations resulting from the radial Dirac equation generate Schrödinger-type equations for the two spinor components. This makes the solution of the relativistic problem easily attainable by simple and direct correspondence with well-known exactly solvable nonrelativistic problems. There are two main ingredients in the formulation of the approach that makes it work.

a)Electronic mail: haidari@mailaps.org

The first is a unitary transformation of the Dirac equation which, of course, reduces to the identity in the nonrelativistic limit. The second is the introduction, in a natural way, of an auxiliary potential component which is constrained to depend, in a particular way, on the independent potential function of the problem.

The main objective in all previous applications of the approach was in obtaining the discrete energy spectrum and spinor wave functions.[2–7] In this article, however, we demonstrate how to utilize the same approach in generating the two-point Green's function which is an important object of prime significance in the calculation of physical processes where relativistic effects become relevant. The main contribution here is in obtaining the relativistic Green's function for the Dirac–Morse problem, which is then used to give the relativistic bound states energy spectrum in a simple and direct manner. For completeness and clarity of presentation, we start by giving a brief account of how to construct the Green's function of the nonrelativistic problem by transforming that of another (reference) problem which belongs to the same class. We take the three-dimensional isotropic oscillator as the reference problem and use ''point canonical transformation'' (PCT)[8,9] to map it into the Green's function of the nonrelativistic S-wave Morse problem. This is possible because, as stated above, the two problems belong to the same class which carries a representation of the dynamical symmetry group SO(2,1).

MAPPING OF GREEN'S FUNCTION UNDER PCT

The nonrelativistic radial Green's function $\mathcal{G}_\ell(\rho,\rho',\mathcal{E})$ of the three-dimensional isotropic oscillator satisfies the following time-independent Schrödinger equation:

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}\rho^2}+\frac{\ell(\ell+1)}{\rho^2}+\omega^4\rho^2-2\mathcal{E}\right]\mathcal{G}_\ell(\rho,\rho',\mathcal{E})=-2\,\delta(\rho-\rho'), \tag{1}$$

where ℓ is the angular momentum quantum number, ω is the oscillator frequency, and $\mathcal{E}$ is the nonrelativistic energy. The nonrelativistic Green's function of the S-wave Morse problem, on the other hand, satisfies the following equation:[2,9]

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2}+A^2e^{-2\mu r}-A(2B+\mu)e^{-\mu r}-2E\right]g_\mu(r,r',E)=-2\,\delta(r-r'), \tag{2}$$

where μ is the potential range parameter. A and μ are real and positive. It is to be noted that our definition of the radial Green's function differs by a factor of $(rr')^{-1}$ from other typical definitions. Now, we apply to Eq. (1) the following transformation:

$$\rho=q(r),\quad \mathcal{G}_\ell(\rho,\rho',\mathcal{E})=p(r)g_\mu(r,r',E)p^*(r'). \tag{3}$$

If the result is a mapping into Eq. (2) then this transformation will be referred to as point canonical transformation (PCT). The action of (3), for real functions, on Eq. (1) maps it into the following equation:

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2}+\left(\frac{q''}{q'}-2\frac{p'}{p}\right)\frac{\mathrm{d}}{\mathrm{d}r}+\left(\frac{q''}{q'}\frac{p'}{p}-\frac{p''}{p}\right)+\ell(\ell+1)\left(\frac{q'}{q}\right)^2+(q')^2(\omega^4q^2-2\mathcal{E})\right]g_\mu(r,r',E)$$
$$=-\frac{2(q')^2}{p(r)p(r')}\,\delta(q(r)-q(r')), \tag{4}$$

where the primes on the transformation functions p and q denote derivatives with respect to r. Identifying this with Eq. (2) and using the relation $q'\,\delta(q(r)-q(r'))=\delta(r-r')$ gives $p(r)=\sqrt{\mathrm{d}q/\mathrm{d}r}$ and results in the following constraint on the transformation (3) to be a PCT:

$$A^2e^{-2\mu r}-A(2B+\mu)e^{-\mu r}-2E=(q')^2(\omega^4q^2-2\mathcal{E})+\ell(\ell+1)\left(\frac{q'}{q}\right)^2+\frac{3}{4}\left(\frac{q''}{q'}\right)^2-\frac{1}{2}\frac{q'''}{q'}. \tag{5}$$

This constraint is solved by taking the PCT function $q(r)=e^{-\mu r/2}$, which will result in the following PCT parameter map:

$$\omega^2 \to \frac{2A}{\mu},$$

$$\mathcal{E} \to \frac{4A}{\mu}\left(\frac{B}{\mu}+\frac{1}{2}\right), \tag{6}$$

$$\ell \to \frac{2}{\mu}\sqrt{-2E}-\frac{1}{2}.$$

It should be noted that since PCT is a map of one equation into another, then the above resulting parameter relation is a ''correspondence'' between the parameters of the two problems and not an equality of the parameters. That is we obtain, for example, the correspondence $\ell \to (2/\mu)\sqrt{-2E}-\frac{1}{2}$ but not the equality $\ell=(2/\mu)\sqrt{-2E}-\frac{1}{2}$. In fact, the right-hand-side term is continuous while the left is, of course, not.

Now, the nonrelativistic radial Green's function for the three-dimensional oscillator is well known.[10] It could be written as

$$\mathcal{G}_\ell(\rho,\rho',\mathcal{E})=\frac{\Gamma\left(\frac{2\ell+3}{4}-\mathcal{E}/2\omega^2\right)}{\omega^2\Gamma(\ell+\frac{3}{2})}\frac{1}{\sqrt{\rho\rho'}}\mathcal{M}_{\mathcal{E}/2\omega^2,[(2\ell+1)/4]}(\omega^2\rho_<^2)\mathcal{W}_{\mathcal{E}/2\omega^2,[(2\ell+1)/4]}(\omega^2\rho_>^2), \tag{7}$$

where Γ is the gamma function and $\rho_<$ ($\rho_>$) is the smaller (larger) of ρ and ρ'. $\mathcal{M}_{a,b}$ and $\mathcal{W}_{a,b}$ are the Whittaker functions of the first and second kind, respectively.[11] The two mappings (3) and (6) transform this Green's function into the following one for the nonrelativistic Morse problem:[12]

$$g_\mu(r,r',E)=\frac{\Gamma\left(\frac{1}{\mu}\sqrt{-2E}-B/\mu\right)}{A\Gamma\left(1+\frac{2}{\mu}\sqrt{-2E}\right)}e^{\mu(r+r')/2}\mathcal{M}_{(B/\mu)+(1/2),(1/\mu)\sqrt{-2E}}\left(\frac{2A}{\mu}e^{-\mu r_>}\right)$$

$$\times\mathcal{W}_{(B/\mu)+(1/2),(1/\mu)\sqrt{-2E}}\left(\frac{2A}{\mu}e^{-\mu r_<}\right). \tag{8}$$

The switching of arguments of the Whittaker functions is because $\rho_<$ ($\rho_>$) corresponds to $r_>$ ($r_<$), respectively. Next, we set up the relativistic problem using the approach mentioned above to obtain the relativistic extension of this Green's function for the Dirac–Morse problem.

SOLVING THE DIRAC EQUATION

In atomic units ($m=\hbar=1$) and taking the speed of light $c=\lambda^{-1}$, we write the Hamiltonian for a Dirac spinor coupled to a four-component potential $(A_0,\vec{A})$ as follows:

$$H=\begin{pmatrix} 1+\lambda A_0 & -i\lambda\vec{\sigma}\cdot\vec{\nabla}+i\lambda\vec{\sigma}\cdot\vec{A} \\ -i\lambda\vec{\sigma}\cdot\vec{\nabla}-i\lambda\vec{\sigma}\cdot\vec{A} & -1+\lambda A_0 \end{pmatrix}, \tag{9}$$

where λ is the Compton wavelength scale parameter $\hbar/mc$ and $\vec{\sigma}$ are the three 2×2 Pauli matrices. It is to be noted that this type of coupling does not support an interpretation of $(A_0,\vec{A})$ as the electromagnetic potential unless, of course, $\vec{A}=0$ (e.g., the Coulomb potential). That is, the

wave equation with this Hamiltonian is not invariant under the usual electromagnetic gauge transformation. Imposing spherical symmetry and writing $(A_0,\vec{A})=[\hbar V(r),\hat{r}W(r)]$, where $\hat{r}$ is the radial unit vector, gives the following two component radial Dirac equation:

$$\begin{pmatrix} 1+\hbar^2V(r)-\varepsilon & \hbar\left[\frac{\kappa}{r}+W(r)-\frac{\mathrm{d}}{\mathrm{d}r}\right] \\ \hbar\left[\frac{\kappa}{r}+W(r)+\frac{\mathrm{d}}{\mathrm{d}r}\right] & -1+\hbar^2V(r)-\varepsilon \end{pmatrix}\begin{pmatrix} f^+(r) \\ f^-(r) \end{pmatrix}=0, \tag{10}$$

where ε is the relativistic energy and κ is the spin–orbit quantum number defined as $\kappa=\pm(j+\frac{1}{2})$ for $\ell=j\pm\frac{1}{2}$. $V(r)$ and $W(r)$ are real radial functions referred to as the even and odd components of the relativistic potential, respectively. Equation (10) results in two coupled first order differential equations for the two radial spinor components. Eliminating one component in favor of the other gives a second order differential equation. This will not be Schrödinger-type (i.e., it contains first order derivatives) unless $V=0$. To obtain Schrödinger-type equation in the general case we proceed as follows. A global unitary transformation $\mathcal{U}(\eta)=\exp[(i/2)\hbar\eta\sigma_2]$ is applied to the Dirac equation (10), where η is a real constant parameter and σ_2 is the 2×2 matrix $\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$. The Schrödinger-type requirement relates the two potential components by the linear constraint $V(r)=\zeta[W(r)+\kappa/r]$, where ζ is a real parameter which is related to the transformation parameter η by $\sin(\hbar\eta)=\pm\hbar\zeta$. This results in a Hamiltonian that will be written in terms of only one arbitrary potential function; either the even potential component $V(r)$ or the odd one $W(r)$. Moreover, the solution of the problem is obtained for a given value of κ. The unitary transformation together with the potential constraint map Eq. (10) into the following one, which we choose to write in terms of the even potential component:[2,3]

$$\begin{pmatrix} C-\varepsilon+(1\pm1)\hbar^2V & \hbar\left(\mp\zeta+\frac{C}{\zeta}V-\frac{\mathrm{d}}{\mathrm{d}r}\right) \\ \hbar\left(\mp\zeta+\frac{C}{\zeta}V+\frac{\mathrm{d}}{\mathrm{d}r}\right) & -C-\varepsilon+(1\mp1)\hbar^2V \end{pmatrix}\begin{pmatrix} \phi^+(r) \\ \phi^-(r) \end{pmatrix}=0, \tag{11}$$

where $C=\cos(\hbar\eta)$ and $\left(\begin{smallmatrix} \phi^+ \\ \phi^- \end{smallmatrix}\right)=\mathcal{U}\left(\begin{smallmatrix} f^+ \\ f^- \end{smallmatrix}\right)$. This gives the following equation for one spinor component in terms of the other

$$\phi^{\mp}(r)=\frac{\hbar}{C\pm\varepsilon}\left[-\zeta\pm\frac{C}{\zeta}V(r)+\frac{\mathrm{d}}{\mathrm{d}r}\right]\phi^{\pm}(r). \tag{12}$$

On the other hand, the resulting Schrödinger-type wave equation for the two spinor components reads

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2}+\left(\frac{C}{\zeta}\right)^2V^2\mp\frac{C}{\zeta}\frac{\mathrm{d}V}{\mathrm{d}r}+2\varepsilon V-\frac{\varepsilon^2-1}{\hbar^2}\right]\phi^{\pm}(r)=0. \tag{13}$$

In all relativistic problems that have been successfully tackled so far, Eq. (13) is solved by correspondence with well-known exactly solvable nonrelativistic problems.[2–7] This correspondence results in two parameter maps (one for each spinor component) relating the relativistic to the nonrelativistic problem. Using these maps and the known solutions (energy spectrum and wave functions) of the nonrelativistic problem one can easily and directly obtain the relativistic energy spectrum and spinor wave functions. An alternative, but equivalent, approach to the one given above is to postulate the one-parameter two-component equation (11) as the relativistic wave equation and show that in the nonrelativistic limit ($\hbar\to0$) the nonrelativistic problem is recovered. However, in this case, one cannot claim that the relativistic problem is a unique extension of the nonrelativistic one.

RELATIVISTIC GREEN'S FUNCTION

Now to the issue at hand—the Green's function. The relativistic 4×4 two-point Green's function $G(\vec{r},\vec{r}',\varepsilon)$ satisfies the inhomogeneous matrix wave equation $(H-\varepsilon)G=-\hbar^2\delta(\vec{r}-\vec{r}')$, where the energy ε does not belong to the spectrum of H. For problems with spherical symmetry, the 2×2 radial component $\mathcal{G}_\kappa(r,r',\varepsilon)$ of G satisfies $(H_\kappa-\varepsilon)\mathcal{G}_\kappa=-\hbar^2\delta(r-r')$, where H_κ is the radial Hamiltonian operator in Eq. (11). Once again, our definition of the radial component of the Green's function differs by a factor of $(rr')^{-1}$ from other typical definitions. We write $\mathcal{G}_\kappa$ as

$$\mathcal{G}_\kappa(r,r',\varepsilon)=\begin{pmatrix}\mathcal{G}_\kappa^{++} & \mathcal{G}_\kappa^{+-}\\ \mathcal{G}_\kappa^{-+} & \mathcal{G}_\kappa^{--}\end{pmatrix}, \tag{14}$$

where $\mathcal{G}_\kappa(r,r',\varepsilon)^\dagger=\mathcal{G}_\kappa(r',r,\varepsilon)$. Let $\Phi=\begin{pmatrix}\phi^+\\ \phi^-\end{pmatrix}$ and $\overline{\Phi}=\begin{pmatrix}\overline{\phi}^+\\ \overline{\phi}^-\end{pmatrix}$ be the regular and irregular solutions of Eq. (13), respectively. Using these two solutions, $\mathcal{G}_\kappa$ could be constructed as

$$\mathcal{G}_\kappa(r,r',\varepsilon)=\frac{1}{\Omega_\kappa(\varepsilon)}[\theta(r'-r)\Phi(r,\varepsilon)\overline{\Phi}^{\mathsf{T}}(r',\varepsilon)+\theta(r-r')\overline{\Phi}(r,\varepsilon)\Phi^{\mathsf{T}}(r',\varepsilon)], \tag{15}$$

where $\theta(r'-r)$ is the Heaviside unit step function and $\Omega_\kappa(\varepsilon)$ is the Wronskian of the regular and irregular solutions,

$$\Omega_\kappa(\varepsilon)=\hbar^{-1}\Phi^{\mathsf{T}}(r,\varepsilon)\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}\overline{\Phi}(r,\varepsilon)=\hbar^{-1}[\phi^+(r,\varepsilon)\overline{\phi}^-(r,\varepsilon)-\phi^-(r,\varepsilon)\overline{\phi}^+(r,\varepsilon)] \tag{16}$$

which is independent of r as can be verified by differentiating with respect to r and using Eq. (12). Equation (15) results in the following expressions for the elements of $\mathcal{G}_\kappa$:

$$\mathcal{G}_\kappa^{\pm\pm}(r,r',\varepsilon)=\frac{1}{\Omega_\kappa(\varepsilon)}\phi^\pm(r_<,\varepsilon)\overline{\phi}^\pm(r_>,\varepsilon), \tag{17}$$

$$\mathcal{G}_\kappa^{\pm\mp}(r,r',\varepsilon)=\frac{1}{\Omega_\kappa(\varepsilon)}[\theta(r'-r)\phi^\pm(r,\varepsilon)\overline{\phi}^\mp(r',\varepsilon)+\theta(r-r')\phi^\mp(r',\varepsilon)\overline{\phi}^\pm(r,\varepsilon)]. \tag{18}$$

The equations satisfied by these elements are obtained from $(H_\kappa-\varepsilon)\mathcal{G}_\kappa=-\hbar^2\delta(r-r')$. They parallel Eqs. (12) and (13) for $\phi^\pm$ and read as follows:

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2}+\left(\frac{C}{\zeta}\right)^2V^2\mp\frac{C}{\zeta}\frac{\mathrm{d}V}{\mathrm{d}r}+2\varepsilon V-\frac{\varepsilon^2-1}{\hbar^2}\right]\mathcal{G}_\kappa^{\pm\pm}(r,r',\varepsilon)=-(C\pm\varepsilon)\delta(r-r'), \tag{19}$$

$$\mathcal{G}_\kappa^{\mp\pm}(r,r',\varepsilon)=\frac{\hbar}{C\pm\varepsilon}\left[-\zeta\pm\frac{C}{\zeta}V(r)+\frac{\mathrm{d}}{\mathrm{d}r}\right]\mathcal{G}_\kappa^{\pm\pm}(r,r',\varepsilon). \tag{20}$$

Using the exchange symmetry $r\leftrightarrow r'$ of $\mathcal{G}_\kappa$, then it is sufficient to solve Eq. (20) only for either $\mathcal{G}_\kappa^{-+}$ or $\mathcal{G}_\kappa^{+-}$ depending on the sign in the transformation constraint $\sin(\hbar\eta)=\pm\hbar\zeta$. That is, we write

$$\begin{aligned}\mathcal{G}_\kappa^{-+}(r,r',\varepsilon)=\mathcal{G}_\kappa^{+-}(r',r,\varepsilon)=&\frac{1\pm1}{2}\frac{\hbar}{C+\varepsilon}\left[-\zeta+\frac{C}{\zeta}V(r)+\frac{\mathrm{d}}{\mathrm{d}r}\right]\mathcal{G}_\kappa^{++}(r,r',\varepsilon)\\ &+\frac{1\mp1}{2}\frac{\hbar}{C-\varepsilon}\left[-\zeta-\frac{C}{\zeta}V(r')+\frac{\mathrm{d}}{\mathrm{d}r'}\right]\mathcal{G}_\kappa^{--}(r,r',\varepsilon)\end{aligned} \tag{21}$$

corresponding to $\sin(\hbar\eta)=\pm\hbar\zeta$, respectively. These developments will now be applied to our problem.

DIRAC–MORSE GREEN'S FUNCTION

In this setting, the Dirac–Morse problem is the system described by Eq. (11) with $V(r)=-\mathcal{B}e^{-\mu r}$ and $C=\mathcal{A}/\tau$, where $\tau\mathcal{A}>0$.[2,5,6] The parameters are related by $\tau^2=\mathcal{A}^2+\chi^2\mathcal{B}^2$ with $\zeta=\mathcal{B}/\tau$. Consequently, Eq. (19) for the diagonal elements of the radial Green's function reads as follows:

$$\left[-\frac{\mathrm{d}^2}{\mathrm{d}r^2}+\mathcal{A}^2e^{-2\mu r}-\mathcal{A}(2\varepsilon\mathcal{B}/\mathcal{A}\pm\mu)e^{-\mu r}-\frac{\varepsilon^2-1}{\chi^2}\right]\mathcal{G}_\mu^{\pm\pm}(r,r',\varepsilon)=-(\mathcal{A}/\tau\pm\varepsilon)\,\delta(r-r'). \tag{22}$$

Comparing this with Eq. (2) gives the following two maps between the relativistic and nonrelativistic problems. The map concerning $\mathcal{G}_\mu^{++}$ is

$$\begin{gathered} g_\mu=2\mathcal{G}_\mu^{++}/(\mathcal{A}/\tau+\varepsilon), \\ A=\mathcal{A} \quad \text{or} \quad A=-\mathcal{A}, \\ B=\varepsilon\mathcal{B}/\mathcal{A} \quad \text{or} \quad B=-\varepsilon\mathcal{B}/\mathcal{A}-\mu, \\ E=(\varepsilon^2-1)/2\chi^2. \end{gathered} \tag{23}$$

The choice $B=\varepsilon\mathcal{B}/\mathcal{A}$ or $B=-\varepsilon\mathcal{B}/\mathcal{A}-\mu$ depends on whether $\mathcal{A}>0$ or $\mathcal{A}<0$, respectively. On the other hand, the map for $\mathcal{G}_\mu^{--}$ is as follows:

$$\begin{gathered} g_\mu=2\mathcal{G}_\mu^{--}/(\mathcal{A}/\tau-\varepsilon), \\ A=\mathcal{A} \quad \text{or} \quad A=-\mathcal{A}, \\ B=\varepsilon\mathcal{B}/\mathcal{A}-\mu \quad \text{or} \quad B=-\varepsilon\mathcal{B}/\mathcal{A}, \\ E=(\varepsilon^2-1)/2\chi^2. \end{gathered} \tag{24}$$

Similarly, the choice $B=\varepsilon\mathcal{B}/\mathcal{A}-\mu$ or $B=-\varepsilon\mathcal{B}/\mathcal{A}$ depends on whether $\mathcal{A}$ is positive or negative, respectively. The two mappings (23) and (24) transform the nonrelativistic Green's function (8) into the following solutions of Eq. (22):

$$\begin{aligned} \mathcal{G}_\mu^{++}=&\frac{\frac{\mathcal{A}}{\tau}+\varepsilon}{2|\mathcal{A}|}\,\frac{e^{\mu(r+r')/2}}{\Gamma(1+2\beta)} \\ &\times\begin{cases}\Gamma(\beta-\alpha)\mathcal{M}_{\alpha+1/2,\beta}\left(\dfrac{2\mathcal{A}}{\mu}e^{-\mu r_>}\right)\mathcal{W}_{\alpha+1/2,\beta}\left(\dfrac{2\mathcal{A}}{\mu}e^{-\mu r_<}\right), & \mathcal{A}>0, \\ \Gamma(1+\beta+\alpha)\mathcal{M}_{-\alpha-1/2,\beta}\left(\dfrac{-2\mathcal{A}}{\mu}e^{-\mu r_>}\right)\mathcal{W}_{-\alpha-1/2,\beta}\left(\dfrac{-2\mathcal{A}}{\mu}e^{-\mu r_<}\right), & \mathcal{A}<0, \end{cases} \end{aligned} \tag{25}$$

$$\mathcal{G}_{\mu}^{--}=\frac{\frac{\mathcal{A}}{\tau}-\varepsilon}{2|\mathcal{A}|}\frac{e^{\mu(r+r')/2}}{\Gamma(1+2\beta)} \times\begin{cases}\Gamma(1+\beta-\alpha)\mathcal{M}_{\alpha-1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r_>}\right)\mathcal{W}_{\alpha-1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r_<}\right), & \mathcal{A}>0,\\ \Gamma(\beta+\alpha)\mathcal{M}_{-\alpha+1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r_>}\right)\mathcal{W}_{-\alpha+1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r_<}\right), & \mathcal{A}<0,\end{cases} \tag{26}$$

where $\alpha=\varepsilon\mathcal{B}/\mu\mathcal{A}$ and $\beta=(1/\mu\lambda)\sqrt{1-\varepsilon^2}$. The off-diagonal elements of $\mathcal{G}_{\mu}$ are obtained by substituting these in Eq. (21), which could be rewritten in terms of the variable $x=(2\mathcal{A}/\mu)e^{-\mu r}$ as

$$\mathcal{G}_{\mu}^{-+}(x,x',\varepsilon)=\mathcal{G}_{\mu}^{+-}(x',x,\varepsilon)=-\frac{\lambda\mu}{\frac{\mathcal{A}}{\tau}+\varepsilon}\frac{1\pm1}{2\sqrt{xx'}}\left(x\frac{\mathrm{d}}{\mathrm{d}x}+\frac{x}{2}+\frac{\mathcal{B}}{\mu\tau}-\frac{1}{2}\right)\sqrt{xx'}\mathcal{G}_{\mu}^{++} -\frac{\lambda\mu}{\frac{\mathcal{A}}{\tau}-\varepsilon}\frac{1\mp1}{2\sqrt{xx'}}\left(x'\frac{\mathrm{d}}{\mathrm{d}x'}-\frac{x'}{2}+\frac{\mathcal{B}}{\mu\tau}-\frac{1}{2}\right)\sqrt{xx'}\mathcal{G}_{\mu}^{--}. \tag{27}$$

Using the differential formulas of the Whittaker functions[11] we obtain the following expressions for the off-diagonal elements of the Dirac–Morse Green's function, depending on the choice of sign in $\sin(\lambda\eta)=\pm\lambda\zeta$, as

$$\begin{aligned}\mathcal{G}_{\mu}^{-+}(r,r',\varepsilon)&=\mathcal{G}_{\mu}^{+-}(r',r,\varepsilon)\\ &=-\frac{\lambda\mathcal{B}}{\mathcal{A}}\left[\left(\frac{1\mp1}{2}\right)\mathcal{G}_{\mu}^{--}+\left(\frac{1\pm1}{2}\right)\mathcal{G}_{\mu}^{++}\right]\pm e^{\mu(r+r')/2}\\ &\quad\times\frac{\lambda\mu}{2\mathcal{A}}\frac{\Gamma(1+\beta-\alpha)}{\Gamma(1+2\beta)}\left[-\theta(r-r')\mathcal{M}_{\alpha-1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r}\right)\mathcal{W}_{\alpha+1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r'}\right)\right.\\ &\quad\left.+(\beta+\alpha)\theta(r'-r)\mathcal{M}_{\alpha+1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r'}\right)\mathcal{W}_{\alpha-1/2,\beta}\left(\frac{2\mathcal{A}}{\mu}e^{-\mu r}\right)\right],\quad \mathcal{A}>0,\end{aligned} \tag{28}$$

$$\begin{aligned}\mathcal{G}_{\mu}^{-+}(r,r',\varepsilon)&=\mathcal{G}_{\mu}^{+-}(r',r,\varepsilon)\\ &=-\frac{\lambda\mathcal{B}}{\mathcal{A}}\left[\left(\frac{1\mp1}{2}\right)\mathcal{G}_{\mu}^{--}+\left(\frac{1\pm1}{2}\right)\mathcal{G}_{\mu}^{++}\right]\pm e^{\mu(r+r')/2}\\ &\quad\times\frac{\lambda\mu}{2\mathcal{A}}\frac{\Gamma(1+\beta+\alpha)}{\Gamma(1+2\beta)}\left[(\beta-\alpha)\theta(r-r')\mathcal{M}_{-\alpha+1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r}\right)\right.\\ &\quad\times\mathcal{W}_{-\alpha-1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r'}\right)-\theta(r'-r)\mathcal{M}_{-\alpha-1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r'}\right)\\ &\quad\left.\times\mathcal{W}_{-\alpha+1/2,\beta}\left(\frac{-2\mathcal{A}}{\mu}e^{-\mu r}\right)\right],\quad \mathcal{A}<0.\end{aligned} \tag{29}$$

One can easily verify that the relativistic bound states energy spectrum of the Dirac–Morse problem[2,5,6] is located at the energy poles of these components of the Green's function. This is simply and directly obtained by taking the argument of the gamma function in the numerator to be equal to $-n$, where $n=0,1,2,\ldots$. That is by taking $\beta-\alpha=-n$ for $\mathcal{A}>0$ and $\beta+\alpha=-n$ for $\mathcal{A}<0$ giving the following spectrum:

$$\varepsilon_n = \frac{\mathcal{A}}{\tau^2}[\mu\lambda^2\mathcal{B}n \pm \sqrt{\tau^2 - (\mu\lambda\mathcal{A}n)^2}], \quad n = 0,1,2,...,n_{\max}, \tag{30}$$

where $n_{\max} \leqslant (1/\mu\lambda)\sqrt{1+(\lambda\mathcal{B}/\mathcal{A})^2}$.

Finally, it might be worthwhile looking at the nonrelativistic limit ($\lambda \to 0$) of the Green's function. One can easily show that in this limit,

$$\varepsilon \approx 1+\lambda^2 E, \quad \alpha \approx \frac{\mathcal{B}}{\mu\mathcal{A}}(1+\lambda^2 E), \quad \beta \approx \frac{1}{\mu}\sqrt{-2E}, \quad \tau \approx \mathcal{A}+\lambda^2\mathcal{B}^2/2\mathcal{A}. \tag{31}$$

Substituting these in formulas (25) and (26) for the diagonal elements of the Green's function shows that their behavior in the limit is $\mathcal{G}_\mu^{++} \approx g_\mu$ and $\mathcal{G}_\mu^{--} \approx \lambda^2 g_\mu$. On the other hand, the off-diagonal elements $\mathcal{G}_\mu^{\pm\mp}$ go to the limit like λ, except for the first term in formulas (28) and (29) which is proportional to $\lambda\mathcal{G}_\mu^{--}$. This term goes to the limit like λ^3. Therefore, the relativistic behavior of the 2×2 radial Green's function could be written symbolically as

$$\mathcal{G}_\mu \sim \begin{pmatrix} 1 & \lambda+\lambda^3 \\ \lambda+\lambda^3 & \lambda^2 \end{pmatrix}. \tag{32}$$

ACKNOWLEDGMENT

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 6 JUNE 2004

A technique to identify solvable dynamical systems, and a solvable generalization of the goldfish many-body problem

Francesco Calogero[a)]

(Received 18 February 2004; accepted 12 March 2004;
published online 10 May 2004)

A simple approach is discussed which associates to (solvable) matrix equations (solvable) dynamical systems, generally interpretable as (interesting) many-body problems, possibly involving auxiliary dependent variables in addition to those identifying the positions of the moving particles. We then focus on cases in which the auxiliary variables can be altogether eliminated, reobtaining thereby (via this unified approach) well-known solvable many-body problems, and moreover a (solvable) extension of the "goldfish" model. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1739297]

I. INTRODUCTION AND MAIN RESULTS

Several decades ago certain many-body problems were introduced and shown to be solvable, first in the quantal context and then as classical dynamical systems (for a review of these results in the classical context, including a capsule account, with appropriate references, of the early history of these developments, see Ref. 15). The seed model[9,23,10] of this development (that over the last few decades featured in many hundreds, perhaps thousands, of papers) is characterized—in the classical context to which our treatment is confined—by the Newtonian equations of motion

$$\ddot{z}_n = 2\,g^2 \sum_{m=1, m\neq n}^{N} (z_n - z_m)^{-3} \tag{1}$$

(the factor 2 in the right-hand side is of course conventional in view of the arbitrariness of the constant g^2, and throughout this paper superimposed dots denote differentiations with respect to the independent variable t, which we always assume to be *real* and we interpret as "time"; the remaining notation is, we trust, self-explanatory).

The Newtonian equations of motion of a related model, usually associated (at least for imaginary values of the constant γ) with the name of Sutherland,[31] reads

$$\ddot{z}_n = 2\,g^2 \sum_{m=1, m\neq n}^{N} \cosh[\,\gamma\,(z_n - z_m)\,]\,\{\gamma^{-1}\sinh[\,\gamma\,(z_n - z_m)\,]\}^{-3} \tag{2}$$

(this model reduces of course to the previous one for $\gamma = 0$).

Another solvable model, to which the honorary name of "goldfish" has been attributed in view of the neatness of its equations of motion[16] (a name also extended to its nonintegrable variants characterized by the presence of arbitrary coupling constants,[20] as well as to its integrable variants characterized by only "nearest-neighbor" interactions[17]), features the Newtonian equations of motion (with velocity-dependent two-body forces)

a)Electronic mail: francesco.calogero@roma1.infn.it

$$\ddot{z}_n = 2 \sum_{m=1, m\neq n}^{N} \frac{\dot{z}_n \dot{z}_m}{z_n - z_m}, \tag{3}$$

while the Newtonian equations of motion of an, also solvable, variant of it reads

$$\ddot{z}_n = 2 \sum_{m=1, m\neq n}^{N} \dot{z}_n \dot{z}_m \, \gamma \coth[\gamma(z_n - z_m)] \tag{4}$$

(note that the factor 2 in the right-hand side of the last two equations is now essential to guarantee the integrable, indeed solvable, character of these many-body models; of course the second one reduces to the first for $\gamma = 0$). The names of Ruijsenaars and Schneider are appropriately associated with these two latter models, which belong to a hierarchy of integrable dynamical systems introduced by them;[30,15] although actually the two specific models quoted above, (3) and (4), had been shown to be solvable earlier.[11,15]

Solvable variants of the first and third of these models, (1) and (3), characterized by the remarkable property that their *generic* solution is *isochronous* (i.e., completely periodic with a fixed period independent of the initial data), are also well known.[9,1,18,15] The Newtonian equations of motions of these *isochronous* models read, respectively,

$$\ddot{z}_n + \omega^2 z_n = 2 g^2 \sum_{m=1, m\neq n}^{N} (z_n - z_m)^{-3}, \tag{5}$$

$$\ddot{z}_n - i \omega \dot{z}_n = 2 \sum_{m=1, m\neq n}^{N} \frac{\dot{z}_n \dot{z}_m}{z_n - z_m}, \tag{6}$$

where the *positive* constant ω characterizes the relevant period T via the standard relation

$$T = \frac{2\pi}{\omega}. \tag{7}$$

The simplest way to obtain these generalized equations, (5) respectively (6)—which of course reduce to (1) respectively (3) for $\omega = 0$—and to thereby demonstrate the origin of their remarkable property of *isochronicity* (as well as showing that their solution is trivially related to the solution of (1) respectively, (3)), is via the following simple change of variables (sometimes called ''the trick'': see, for instance, Refs. 12, 14, 18, 15). First, merely rewrite the original equations (1) respectively (3) with the following, merely notational, change: replace $z_n(t)$ with, say, $\zeta_n(\tau)$, and correspondingly, say, $\dot{z}_n$ with ζ' and $\ddot{z}_n$ with ζ_n'', where the appended primes denote of course differentiations with respect to the new independent variable τ, so that (1) reads

$$\zeta_n'' = 2 g^2 \sum_{m=1, m\neq n}^{N} (\zeta_n - \zeta_m)^{-3}, \tag{8}$$

and likewise (3) read

$$\zeta_n'' = 2 \sum_{m=1, m\neq n}^{N} \frac{\zeta_n' \zeta_m'}{\zeta_n - \zeta_m}. \tag{9}$$

Then, to transform (8) into (5), set

$$z_n(t) = \exp(-i \omega t) \, \zeta_n(\tau), \qquad \tau = \frac{\exp(2 i \omega t) - 1}{2 i \omega}, \tag{10}$$

and likewise to transform (9) into (6) set (even more simply)

$$z_n(t) = \zeta_n(\tau), \quad \tau = \frac{\exp(i\,\omega\,t) - 1}{i\,\omega}. \tag{11}$$

The second of these equations of motion, (6), requires of course that the motion be considered in the *complex* plane, so that (in self-explanatory notation)

$$z_n = x_n + i\,y_n; \tag{12a}$$

but this condition, far from detracting from the ''physical'' significance of this many-body model, allows to interpret it[13,15] as describing the motion of N particles in the horizontal plane (immersed in ordinary, three-dimensional, space), via the introduction of the *real* vectors

$$\mathbf{r}_n = (x_n\,, y_n\,, 0), \tag{12b}$$

since it is easily seen that the *complex* equations of motion (6) become then the following Newtonian (*rotation- and translation-invariant*) equations of motion in the (*real*, horizontal) plane:

$$\ddot{\mathbf{r}}_n - \omega\,\hat{k} \wedge \dot{\mathbf{r}}_n = 2 \sum_{m=1, m\neq n}^{N} r_{nm}^{-2} \cdot [\dot{\mathbf{r}}_n(\dot{\mathbf{r}}_m \cdot \mathbf{r}_{nm}) + \dot{\mathbf{r}}_m(\dot{\mathbf{r}}_n \cdot \mathbf{r}_{nm}) - \mathbf{r}_{nm}(\dot{\mathbf{r}}_n \cdot \dot{\mathbf{r}}_m)]. \tag{13}$$

Here $\hat{k}$ is the unit vector orthogonal to the horizontal plane,

$$\hat{k} = (0, 0, 1), \tag{14a}$$

so that (consistently with the standard definition of vector product in three-dimensional space, see (12b) and (14a))

$$\hat{k} \wedge \mathbf{r}_n = (-y_n\,, x_n\,, 0); \tag{14b}$$

and we use (here and below, see (37)) the short-hand notation

$$\mathbf{r}_{nm} \equiv \mathbf{r}_n - \mathbf{r}_m \tag{15a}$$

so that

$$r_{nm}^2 = (\mathbf{r}_n - \mathbf{r}_m)^2 = r_n^2 + r_m^2 - 2\,(\mathbf{r}_n \cdot \mathbf{r}_m). \tag{15b}$$

After this terse review of results which might by now be considered classical,[15] let us introduce our main findings. First of all—as detailed in the following section—we provide a simple approach that yields directly, in a unified manner, the solution of all the models reported above, and that moreover opens the way to the identification and study of more general solvable models, characterized by equations of motion somewhat analogous to those reported above, although generally also requiring the introduction of additional ''auxiliary variables.'' The study of such models is however postponed to subsequent papers. In this paper we mainly focus on the identification of models which generalize the models described above, with particular attention to those that allow the complete elimination of the auxiliary variables.

The first class of solvable models is characterized by the following Newtonian equations of motion:

$$\ddot{z}_n - a\,\frac{\dot{z}_n^2}{z_n} = -\sum_{m=1, m\neq n}^{N} g_{nm}\,g_{mn}\,(z_n\,z_m)^{2a}\left[\frac{2}{(z_n - z_m)^3} + \frac{a}{z_m\,(z_n - z_m)^2}\right]. \tag{16}$$

Here and throughout a is a constant, and we shall whenever convenient also use (provided $a \neq 1$) the constant α related to it as follows:

$$\alpha = \frac{1}{1-a}, \quad a = \frac{\alpha - 1}{\alpha}. \tag{17}$$

For instance via the change of dependent variables

$$z_n = w_n^{\alpha} \tag{18}$$

the Newtonian equations of motion (16) become

$$\ddot{w}_n = \alpha^{-2} \sum_{m=1, m\neq n}^{N} g_{nm}\, g_{mn}\, w_n^{\alpha-1}\, w_m^{2(\alpha-1)}\, (w_n^{\alpha} - w_n^{\alpha})^{-3} \cdot \left[1 + \alpha - (1-\alpha) \left(\frac{w_n}{w_m} \right)^{\alpha} \right], \tag{19a}$$

$$\ddot{w}_n = \alpha^{-2} \sum_{m=1, m\neq n}^{N} g_{nm}\, g_{mn}\, w_n^{-(\alpha+1)}\, w_m^{-2(\alpha+1)}\, (w_n^{-\alpha} - w_n^{-\alpha})^{-3} \cdot \left[1 - \alpha - (1+\alpha) \left(\frac{w_n}{w_m} \right)^{-\alpha} \right]. \tag{19b}$$

Note the remarkable identity of the right-hand sides of (19a) and (19b), which are obtained from each other via $\alpha \Rightarrow -\alpha$.

In the special case $a = 1$ (corresponding via (17) to $\alpha = \infty$) the formula (18) is replaced by

$$z_n = \exp(2\, \gamma\, w_n), \tag{20}$$

and it is easily seen that (16) then becomes

$$\ddot{w}_n = -2\, (4\, \gamma^2)^{-2} \sum_{m=1, m\neq n}^{N} g_{nm}\, g_{mn} \cosh[\, \gamma\, (w_n - w_m)\,] \{ \gamma^{-1} \sinh[\, \gamma\, (w_n - w_m)\,] \}^{-3}. \tag{21}$$

In these equations of motion, (16), we interpret the quantities $z_n \equiv z_n(t)$ as "particle coordinates" (or alternatively we reserve such an interpretation for the quantities $w_n(t)$, see (18) and (20)), while the "auxiliary variables" $g_{nm} \equiv g_{nm}(t)$ evolve in time according to the following (first-order) equations:

$$\dot{g}_{nm} + g_{nm}\, [F_n - F_m] = -\sum_{\ell=1; \ell\neq n,m}^{N} g_{n\ell}\, g_{\ell m}\, z_{\ell}^{2a} \cdot \{ (z_n - z_{\ell})^{-2} + a\, (z_n - z_{\ell})^{-1}\, z_{\ell}^{-1} - [\, (z_m - z_{\ell})^{-2} + a\, (z_m - z_{\ell})^{-1}\, z_{\ell}^{-1}\,] \}, \quad n \neq m. \tag{22}$$

The quantities F_n in the left-hand side of these evolution equations can be assigned *arbitrarily*, as explicit functions of time or as functions of the dependent variables z_m and $g_{m\ell}$, without spoiling the solvability of the model (16) with (22) nor indeed affecting the time-evolution of the particle coordinates $z_m(t)$ (a proof of this, apparently remarkable but eventually obvious, fact is given in the following section). To (better) exploit this freedom we now set

$$F_n = f_n - \sum_{\ell=1, \ell\neq n}^{N} g_{n\ell}\, z_{\ell}^{2a} [\, (z_n - z_{\ell})^{-2} + a\, (z_n - z_{\ell})^{-1}\, z_{\ell}^{-1}\,], \tag{23}$$

and we thereby rewrite (22) as follows:

$$\dot g_{nm}+g_{nm}[f_n-f_m]-g_{nm}\{g_{nm}z_m^{2a}[(z_n-z_m)^{-2}+a(z_n-z_m)^{-1}z_m^{-1}]-g_{mn}z_n^{2a}[(z_n-z_m)^{-2}$$
$$-a(z_n-z_m)^{-1}z_n^{-1}]\}$$
$$=\sum_{\ell=1;\ell\neq n,m}^{N} z_\ell^{2a}\{(g_{nm}g_{n\ell}-g_{n\ell}g_{\ell m})[(z_n-z_\ell)^{-2}+a(z_n-z_\ell)^{-1}z_\ell^{-1}]$$
$$-(g_{nm}g_{m\ell}-g_{n\ell}g_{\ell m})[(z_m-z_\ell)^{-2}+a(z_m-z_\ell)^{-1}z_\ell^{-1}]\},\quad n\neq m. \tag{24}$$

We now observe that, in the special case $a=0$, these evolution equations simplify to read

$$\dot g_{nm}+g_{nm}[f_n-f_m]-g_{nm}(g_{nm}-g_{mn})(z_n-z_m)^{-2}$$
$$=\sum_{\ell=1;\ell\neq n,m}^{N}\{(g_{nm}g_{n\ell}-g_{n\ell}g_{\ell m})(z_n-z_\ell)^{-2}-(g_{nm}g_{m\ell}-g_{n\ell}g_{\ell m})(z_m-z_\ell)^{-2}\},\quad n\neq m. \tag{25}$$

They therefore admit, for $f_n=0$ (or equivalently for $f_n=f$), the simple solution

$$g_{nm}=i\,g,\quad \dot g=0, \tag{26}$$

whereby the equations of motion (16) (with $a=0$) reproduce the classical model (1) (and of course the same outcome also obtains, up to a merely notational change, from the equations of motion (19) with $\alpha=1$, which corresponds to $a=0$, see (17)).

Likewise, for $a=1$, the equations of motion (24) simplify to read

$$\dot g_{nm}+g_{nm}[f_n-f_m]-g_{nm}(g_{nm}-g_{mn})z_n z_m(z_n-z_m)^{-2}$$
$$=\sum_{\ell=1;\ell\neq n,m}^{N} z_\ell\{(g_{nm}g_{n\ell}-g_{n\ell}g_{\ell m})z_n(z_n-z_\ell)^{-2}$$
$$-(g_{nm}g_{m\ell}-g_{n\ell}g_{\ell m})z_m(z_m-z_\ell)^{-2}\},\qquad n\neq m. \tag{27}$$

They therefore admit, for $f_n=0$ (or equivalently for $f_n=f$), the simple solution

$$g_{nm}=4\,i\,\gamma^2 g,\quad \dot g=0, \tag{28}$$

whereby the equations of motion (21) reproduce (up to a merely notational change) the classical model (2).

And the third case in which the complete elimination of the auxiliary variables g_{nm} can be achieved is for $a=2$, when the evolution equations (24) read

$$\dot g_{nm}+g_{nm}[f_n-f_m]-g_{nm}(z_n-z_m)^{-2}\{g_{nm}z_m^3(2z_n-z_m)-g_{mn}z_n^3(2z_m-z_n)\} \tag{29}$$
$$=\sum_{\ell=1;\ell\neq n,m}^{N} z_\ell^3\{(g_{nm}g_{n\ell}-g_{n\ell}g_{\ell m})(z_n-z_\ell)^{-2}(2z_n-z_\ell)$$
$$-(g_{nm}g_{m\ell}-g_{n\ell}g_{\ell m})(z_m-z_\ell)^{-2}(2z_m-z_\ell)\},\quad n\neq m, \tag{30}$$

hence they admit, for $f_n=i\,g\,z_n^2$, again the solution (26), which yields again, when inserted in (19) with $\alpha=-1$ (which corresponds to $a=2$, see (17)), again the original model (1) (up to the notational replacement of z_n with w_n).

The solvable character of the equations of motion (16) (or, equivalently, (19)) with (22) is exhibited by the following neat result (applicable for any value of the constant a, except $a=1$): the N coordinates $z_n\equiv z_n(t)$ are the N eigenvalues of the $N\otimes N$ matrix

$$U(t)=A\left(1+\frac{B}{\alpha}t\right)^{\alpha}, \tag{31a}$$

where the two constant $N\otimes N$ matrices A, B are given in terms of the initial data by the following formulas:

$$A=\mathrm{diag}[z_n(0)], \tag{31b}$$

$$B_{nm}=\delta_{nm}\frac{\dot{z}_n(0)}{z_n(0)}-(1-\delta_{nm})\frac{g_{nm}(0)\,[z_n(0)\,z_m(0)]^a}{z_n(0)\,[z_n(0)-z_m(0)]}. \tag{31c}$$

In the special case $a=1$ the same prescription applies, except for the replacement of (31a) with

$$U(t)=A\exp(B\,t). \tag{32}$$

These results are demonstrated in the following section, where the formulas suitable to obtain the time evolution of the auxiliary variables $g_{nm}(t)$ are also given. In the special cases identified above in which these variables reduce to a constant independent of the indices n, m and can therefore be essentially eliminated, reproducing thereby, as described above, the classical models (1) and (2), the solutions described here reproduce of course the well-known results originally obtained by Olshanetsky and Perelomov.[26,27,15]

The second class of solvable models is characterized by the Newtonian equations of motion

$$\ddot{z}_n-a\frac{\dot{z}_n^2}{z_n}=\sum_{m=1,m\neq n}^{N}\eta_{nm}\,\eta_{mn}\,\dot{z}_n\,\dot{z}_m\left[\frac{2}{z_n-z_m}+\frac{a}{z_m}\right]. \tag{33a}$$

Here the notation is, we trust, self-explanatory, see above. The auxiliary variables $\eta_{nm}\equiv\eta_{nm}(t)$ evolve now according to the (first-order) equations

$$\begin{aligned}&\dot{\eta}_{nm}+\eta_{nm}\,(1-\eta_{nm}\,\eta_{mn})\left[\frac{\dot{z}_n-\dot{z}_m}{z_n-z_m}-\frac{a}{2}\left(\frac{\dot{z}_n}{z_n}+\frac{\dot{z}_m}{z_m}\right)\right]\\&\quad=-\sum_{\ell=1;\ell\neq n,m}^{N}\dot{z}_\ell\left\{\eta_{n\ell}\,(\eta_{\ell n}\,\eta_{nm}+\eta_{\ell m})\left[(z_n-z_\ell)^{-1}+\frac{a}{2}z_\ell^{-1}\right]\right.\\&\qquad\left.+\eta_{\ell m}\,(\eta_{m\ell}\,\eta_{nm}+\eta_{n\ell})\left[(z_n-z_\ell)^{-1}+\frac{a}{2}z_\ell^{-1}\right]\right\}-\eta_{nm}\,(F_n-F_m),\quad n\neq m.\end{aligned} \tag{33b}$$

We now note that, remarkably, for the assignment $F_n=0$ (or, essentially equivalently, $F_n=F$), the latter equations of motion admit the trivial solution

$$\eta_{nm}=-1, \tag{34}$$

entailing that the equations of motion (33a) become

$$\ddot{z}_n-a\frac{\dot{z}_n^2}{z_n}=\sum_{m=1,m\neq n}^{N}\dot{z}_n\,\dot{z}_m\left[\frac{2}{z_n-z_m}+\frac{a}{z_m}\right]. \tag{35a}$$

The solution of the more general model (33) is described in the following section; in this section we restrict attention to these Newtonian equations of motion, (35a), that obviously can be rewritten in the following form:

$$\ddot{z}_n = 2 \sum_{m=1, m\neq n}^{N} \frac{\dot{z}_n \dot{z}_m}{z_n - z_m} + a \sum_{m=1}^{N} \frac{\dot{z}_n \dot{z}_m}{z_m}. \tag{35b}$$

But before reporting the solution of the corresponding initial-value problem, let us interject two remarks.

First we note that clearly, for $a=0$, these equations of motion reproduce the Newtonian equations of motion (3) of the standard goldfish model, while for $a=1$, via (20), they become (4) and for $a=2$, via (18) with $\alpha=-1$, they reproduce again the equations of motion (3) of the standard goldfish model (up to the notational replacement of z_n with w_n).

Next, we apply to them the trick described above, see (11), obtaining thereby the following modified version of these equations of motion:

$$\ddot{z}_n - i\,\omega\,\dot{z}_n = 2 \sum_{m=1, m\neq n}^{N} \frac{\dot{z}_n \dot{z}_m}{z_n - z_m} + a \sum_{m=1}^{N} \frac{\dot{z}_n \dot{z}_m}{z_m}, \tag{36}$$

which of course reduce to the previous ones, (35b), when the costant ω vanishes. Let us as well exhibit their reformulation (achieved as above, see the paragraph following (11)) in the guise of the following Newtonian equations of motion of a (*real, rotation-invariant*) N-body problem in the (horizontal) plane:

$$\begin{aligned} \ddot{\mathbf{r}}_n - \omega\,\hat{k}\wedge\dot{\mathbf{r}}_n = {} & 2 \sum_{m=1, m\neq n}^{N} r_{nm}^{-2} \cdot [\dot{\mathbf{r}}_n(\dot{\mathbf{r}}_m \cdot \mathbf{r}_{nm}) + \dot{\mathbf{r}}_m(\dot{\mathbf{r}}_n \cdot \mathbf{r}_{nm}) - \mathbf{r}_{nm}(\dot{\mathbf{r}}_n \cdot \dot{\mathbf{r}}_m)] \\ & + \sum_{m=1}^{N} r_m^{-2}\,(a_1 + a_2\,\hat{k}\wedge) \cdot [\dot{\mathbf{r}}_n(\dot{\mathbf{r}}_m \cdot \mathbf{r}_m) + \dot{\mathbf{r}}_m(\dot{\mathbf{r}}_n \cdot \mathbf{r}_m) - \mathbf{r}_m(\dot{\mathbf{r}}_n \cdot \dot{\mathbf{r}}_m)], \end{aligned} \tag{37}$$

where of course the two *real* "coupling constants" a_1 and a_2 are the real and imaginary parts of a, $a = a_1 + i\,a_2$.

As implied by the treatment detailed in the following section, the solution of the initial-value problem for the Newtonian equations of motion (35) is provided by the following prescription: the particle coordinates $z_n(t)$ are the N eigenvalues of the $N\otimes N$ matrix (31a) (for $a\neq 1$) respectively (32) (for $a=1$), with the constant $N\otimes N$ matrix A given by (31b) and the constant $N\otimes N$ matrix B given by

$$B_{nm} = [z_n(0)]^{-1}\,[\dot{z}_n(0)\,\dot{z}_m(0)]^{1/2}. \tag{38a}$$

But the dyadic character of this matrix entails

$$B^p = b^{p-1}\,B, \quad p = 1, 2, 3, \ldots \tag{38b}$$

with

$$b = \sum_{n=1}^{N} \frac{\dot{z}_n(0)}{z_n(0)}, \tag{39}$$

implying that a more explicit expression of the matrix $U(t)$, the eigenvalues of which yield the particle coordinates $z_n(t)$, can be given in this case than (31a) (for $a\neq 1$) respectively (32) (for $a=1$), namely,

$$U_{nm}(t) = \delta_{nm}\,z_n(0) + b^{-1}\left[\left(1 + \frac{b\,t}{\alpha}\right)^{\alpha} - 1\right][\dot{z}_n(0)\,\dot{z}_m(0)]^{1/2}, \qquad \text{if } a\neq 1, \tag{40a}$$

$$U_{nm}(t) = \delta_{nm}\,z_n(0) + b^{-1}\,[\exp(b\,t) - 1]\,[\dot{z}_n(0)\,\dot{z}_m(0)]^{1/2}, \qquad \text{if } a = 1. \tag{40b}$$

Note that this matrix is written as the sum of two $N\otimes N$ matrices, one diagonal and the other dyadic, both depending remarkably neatly on the data of the initial-value problem (see (39)).

The diligent reader will verify that this prescription reproduces the previously known results[11,15] in the cases ($a=0$, $a=1$, $a=2$, corresponding respectively to $\alpha=1$, $\alpha=\infty$, $\alpha=-1$) when, as discussed above, the model (35) reduces, possibly up to simple changes of dependent variables, to the classical models (3) or (4); while a discussion of the behavior of the solutions of the model (35) for arbitrary values of the constant a, and of the (richer) model (36), is tersely outlined in Sec. III, where we also show how the solution of these models can be reduced after all to the solution of the standard goldfish model. The corresponding, remarkably neat, prescription detailing the solution of the initial-value problem for the (*isochronous* version of the) generalized goldfish model (36) or (37) asserts that *the coordinates* $z_n(t)$ *are the* N *roots of the following algebraic equation in* z:

$$\sum_{n=1}^{N}\frac{\dot z_n(0)}{z-z_n(0)}=b\left\{\left[1+\frac{b\,[\exp(i\,\omega\,t)-1]}{i\,\alpha\,\omega}\right]^{\alpha}-1\right\}^{-1},\qquad \text{if } a\neq 1, \tag{41a}$$

$$\sum_{n=1}^{N}\frac{\dot z_n(0)}{z-z_n(0)}=b\left\{\exp\left[\frac{b\,[\exp(i\,\omega\,t)-1]}{i\,\omega}\right]-1\right\}^{-1},\qquad \text{if } a=1, \tag{41b}$$

with the constant b *defined in terms of the initial data by (39) and of course* α *related to* a *by (17).* Obviously key to the behavior of these solutions $z_n(t)$ is the time evolution of the right-hand sides of these formulas, which, for *positive* ω, is clearly periodic with period T, see (7), in the (not new) $a=1$ case, it is as well periodic with the same period T for *arbitrary* a provided the initial data entail via (39) the inequality

$$\left|1+\frac{i\,b}{\omega}\right|>\left|\frac{b}{\omega}\right|, \tag{42a}$$

namely,

$$\mathrm{Im}(b)<\frac{\omega}{2} \tag{42b}$$

(we assume here for definiteness that ω is *positive*, $\omega>0$), and it is instead periodic for *arbitrary* (but *real*) a with the, generally different, period

$$\tilde T=\frac{T}{\alpha}=(1-a)\,T=\frac{2\,(1-a)\,\pi}{\omega} \tag{43}$$

if the inequality (42) is reversed, $\mathrm{Im}(b)>\omega/2$.

II. THE TECHNIQUE

The point of departure of our treatment is the $N\otimes N$ matrix equation

$$\ddot U=a\,\dot U\,U^{-1}\,\dot U, \tag{44}$$

where a is an arbitrary (scalar) constant. As can be easily verified, for $a\neq 1$ this matrix evolution equation has the *general* solution (31a) with (17) where, in terms of the initial-value problem,

$$A=U(0), \tag{45a}$$

$$B=[U(0)]^{-1}\,\dot U(0), \tag{45b}$$

while in the special case $a=1$ (entailing, via (17), $\alpha=\infty$), $U(t)$ is given by (32).

We now introduce the parametrization of the $N\otimes N$ matrix $U(t)$ in terms of its N eigenvalues $z_n(t)$ and of its diagonalizing $N\otimes N$ matrix $R(t)$:

$$U=R\,Z\,R^{-1}, \tag{46a}$$

$$Z=\mathrm{diag}[z_n]. \tag{46b}$$

Before proceeding to obtain the evolution equations implied by (44) for the diagonal matrix $Z(t)$ and for the diagonalizing matrix $R(t)$, or rather (see below) for the matrix $M(t)$ defined in terms of $R(t)$ by the formula

$$M=R^{-1}\dot{R}, \tag{47}$$

let us note that the formulas (46) define the matrix R only up to multiplication from the right by an *arbitrary* diagonal matrix, say

$$D=\mathrm{diag}[d_n], \tag{48}$$

since replacing in (46a) R with

$$\tilde{R}=R\,D \tag{49}$$

is clearly of no consequence. The corresponding change of the matrix M,

$$\tilde{M}=\tilde{R}^{-1}\dot{\tilde{R}}=D^{-1}\,M\,D+D^{-1}\,\dot{D}, \tag{50a}$$

namely,

$$\tilde{M}_{nn}=M_{nn}+\frac{\dot{d}_n}{d_n}, \tag{50b}$$

$$\tilde{M}_{nm}=d_n^{-1}\,M_{nm}\,d_m\,, \quad n\neq m, \tag{50c}$$

entails essentially that in our parametrization of the $N\otimes N$ matrix $U(t)$ (via (46) with (47)) the N^2 matrix elements of this matrix get replaced by the N elements $z_n(t)$ of the diagonal matrix $Z(t)$ (namely, by the N eigenvalues of the matrix $U(t)$: see (46)) and by the $N(N-1)$ off-diagonal elements $M_{nm}(t)$ (with $n\neq m$) of the $N\otimes N$ matrix $M(t)$, while the N diagonal elements $M_{nn}(t)$ can be arbitrarily adjusted by choosing appropriately the elements $d_n(t)$ of the diagonal matrix $D(t)$, see (50b) (of course, up to a corresponding adjustment of the corresponding off-diagonal elements, see (50c)).

Differentiation with respect to the independent variable t of (46a) yields, using (47),

$$\dot{U}=R\,\{\dot{Z}+[M,Z]\}\,R^{-1}, \tag{51a}$$

$$\ddot{U}=R\,\{\ddot{Z}+[\dot{M},Z]+2\,[M,\dot{Z}]+[M,[M,Z]]\}\,R^{-1}. \tag{51b}$$

Here and throughout we use of course the standard notation $[X,Y]\equiv X\,Y-Y\,X$ for the commutator of two matrices.

Hence insertion of these formulas in the matrix evolution equation (44) yields

$$\ddot{Z}+[\dot{M},Z]+2\,[M,\dot{Z}]+[M,[M,Z]\,]=a\,\{\dot{Z}+[M,Z]\}\,Z^{-1}\,\{\dot{Z}+[M,Z]\}, \tag{52a}$$

namely, by separating the diagonal and off-diagonal terms,

$$\ddot{z}_n - a\frac{\dot{z}_n^2}{z_n} = -\sum_{m=1,m\neq n}^{N} M_{nm}\,M_{mn}\,(z_n - z_m)\left[2 + \frac{a\,(z_n - z_m)}{z_m}\right], \tag{52b}$$

$$\dot{M}_{nm}\,(z_n - z_m) + M_{nm}\left[2\,(\dot{z}_n - \dot{z}_m) - a\,(z_n - z_m)\left(\frac{\dot{z}_n}{z_n} + \frac{\dot{z}_m}{z_m}\right)\right]$$
$$= \sum_{\ell=1;\ell\neq n,m}^{N} M_{n\ell}\,M_{\ell m}\left[(z_n - z_\ell) + (z_m - z_\ell) + \frac{a\,(z_n - z_\ell)\,(z_m - z_\ell)}{z_\ell}\right]$$
$$- M_{nm}\,(z_n - z_m)\,(F_n - F_m), \quad n\neq m, \tag{52c}$$

where we did set

$$M_{nn} \equiv F_n \tag{53}$$

and, consistently with the observation made above, we retain the freedom to assign arbitrarily these N quantities F_n (as given functions of time, or possibly of the dependent variables $z_n(t)$ and $M_{nm}(t)$ with $n\neq m$; see below). Note that the ''source terms'' F_n could be altogether eliminated from the evolution equations (52c) via the transformation

$$M_{nm}(t) = \tilde{M}_{nm}(t)\,\exp\left\{\int_0^t dt'\,[F_m(t') - F_n(t')]\right\}, \tag{54}$$

which entails the replacement of (52b) and (52c) with

$$\ddot{z}_n - a\frac{\dot{z}_n^2}{z_n} = -\sum_{m=1,m\neq n}^{N} \tilde{M}_{nm}\,\tilde{M}_{mn}\,(z_n - z_m)\left[2 + \frac{a\,(z_n - z_m)}{z_m}\right], \tag{55a}$$

$$\dot{\tilde{M}}_{nm}\,(z_n - z_m) + \tilde{M}_{nm}\left[2\,(\dot{z}_n - \dot{z}_m) - a\,(z_n - z_m)\left(\frac{\dot{z}_n}{z_n} + \frac{\dot{z}_m}{z_m}\right)\right]$$
$$= \sum_{\ell=1;\ell\neq n,m}^{N} \tilde{M}_{n\ell}\,\tilde{M}_{\ell m}\left[(z_n - z_\ell) + (z_m - z_\ell) + \frac{a\,(z_n - z_\ell)\,(z_m - z_\ell)}{z_\ell}\right], \quad n\neq m \tag{55b}$$

(namely, just the elimination of the terms involving the quantities F_n and F_m, and a merely notational change). This of course explains why the quantities $F_n(t)$ can be assigned essentially arbitrarily, without affecting the time-evolution of the ''particle coordinates'' $z_n(t)$ (but such an assignment will of course affect the off-diagonal elements of the matrix $M(t)$, as implied by the relation (54)).

Before proceeding further we like to point out that the approach presented here is by no means quite new. Indeed, for the case $a=0$, equations analogous to those reported above, (52), have appeared in the literature quite often, both in analogous, and in somewhat different, contexts, see for instance, Refs. 21, 32, 4, 28, 34, 33, 35, 24, 5, 6, 22, 25, 3, 2.

We now set

$$M_{nm} = (z_n - z_m)^{-2}\,(z_n\,z_m)^a\,g_{nm}, \quad n\neq m, \tag{56}$$

and we thereby obtain, from (52b), the Newtonian equations of motion (16), and from (52c) the evolution equations (22). The results reported in the previous section, regarding the solution of these equations, are thereby justified in the light of the developments reported above (in this section), and they are complemented by the formulas detailing the time evolution of the quantities $g_{nm}(t)$ that are rather obviously implied by (31) and (32) via the relations (46), (47), and (56). Note that the easiest way to get these results is to make the (permissible and convenient) assump-

tion $R(0)=1$, entailing $U(0)=A=\mathrm{diag}[z_n(0)]$ (see (31a), (31b) and (46)), $\dot{U}(0)=A\,B=\dot{Z}(0)+[M(0),Z(0)]$ (see (31a), (51a) and (46b)) and $M_{nm}(0)=[z_n(0)-z_m(0)]^{-2}[z_n(0)\,z_m(0)]^a g_{nm}(0)$ (see (56)).

Likewise, the different assignment (suggested by the structure of the Lax matrix introduced in Ref. 7)

$$M_{nm}=(z_n-z_m)^{-1}(\dot{z}_n\,\dot{z}_m)^{1/2}\,\eta_{nm}\,,\quad n\neq m, \tag{57}$$

yields, from (52b), the Newtonian equations of motion (33a), and from (52c) the evolution equations (33b) (note that, to get them, we must also use (33a)).

These latter developments imply that the solution of the initial-value problem for the model (33) is given by the following simple rule: *the "particle coordinates" $z_n(t)$ are the N eigenvalues of the $N\otimes N$ matrix (31a) (for $a\neq 1$) respectively (32) (for $a=1$), with the constant $N\otimes N$ matrix A given by (31b) and the elements of the constant $N\otimes N$ matrix B reading now*

$$B_{nm}=[z_n(0)]^{-1}\{\delta_{nm}\,\dot{z}_n(0)-(1-\delta_{nm})\,\eta_{nm}(0)\,[\dot{z}_n(0)\,\dot{z}_m(0)]^{1/2}\}. \tag{58}$$

These formulas provide the solution of the initial-value problem of the model (33), as regards the time evolution of the particle coordinates $z_n(t)$; and they clearly imply the corresponding results reported in the previous section for the model (35) (which obtains from (33) via (34)). As for the time-evolution of the auxiliary variable $\eta_{nm}(t)$ in the more general case ((33) without (34)), as above we leave its derivation as an easy task for the diligent reader: again, the easiest way to get these results—as well as those mentioned in the first part of this paragraph—from (46), (47) and (57), is to make the assumption $R(0)=1$, entailing $U(0)=A=\mathrm{diag}[z_n(0)]$ (see (31a), (31b) and (46)), $\dot{U}(0)=A\,B=\dot{Z}(0)+[M(0),Z(0)]$ (see (31a), (51a) and (46b)) and $M_{nm}(0)=[z_n(0)-z_m(0)]^{-1}[\dot{z}_n(0)\,\dot{z}_m(0)]^{1/2}\,\eta_{nm}(0)$ (see (57)).

III. GENERALIZED GOLDFISH MODEL

In this section we discuss tersely the solution, obtained in Sec. II and detailed at the end of Sec. I, of the generalized goldfish model (35), as well as of its *isochronous* version (36); and at the end we show how the generalized goldfish model (35) can be reduced back to the standard goldfish model (3).

Clearly the key function determining the behavior of the solutions of the generalized goldfish model (35) is

$$\beta(\alpha;t)=b^{-1}\left[\left(1+\frac{b\,t}{\alpha}\right)^{\alpha}-1\right]\quad \text{if}\ \ a\neq 1, \tag{59a}$$

$$\beta(\infty;t)=b^{-1}[\exp(b\,t)-1]\quad \text{if}\ \ a=1 \tag{59b}$$

(see (40) with (39)), and likewise the function characterizing the behavior of the solutions of the *isochronous* version (36) (as reported at the end of Sec. I) is $\beta(\alpha;\tau)$ with τ defined by (11) (of course τ reduces to t when ω vanishes, namely when the model (36) reduces to (35)). We leave to the alert reader the amusing task to analyze the various behaviors that may emerge, depending on the values of the constants a (hence α, see (17)) and ω and on the initial data. The more interesting case to consider is of course that characterized by all the variables, and the constants (with the possible exception of ω) being *complex*—also in view of the interpretation of the corresponding motions as taking place in the real horizontal plane. The remarks reported at the end of Sec. I provide a useful hint; the following, completely explicit, solution of the model (35) (immediately extendable to the *isochronous* model (36) via the replacement of t with τ, see (11)) in the $N=2$ case,

$$z_{1,2}(t)=\tfrac{1}{2}\{z_1(0)+z_2(0)-\beta(\alpha;t)\,[\dot z_1(0)+\dot z_2(0)]$$
$$\pm[\{z_1(0)-z_2(0)-\beta(\alpha;t)\,[\dot z_1(0)-\dot z_2(0)]\}^2+4\,[\beta(\alpha;t)]^2\,\dot z_1(0)\,\dot z_2(0)]^{1/2}\} \quad (60)$$

may be useful to explore what tipically happens. But such an analysis is likely to be enlightening (perhaps even amusing) only if it is actually done rather than just read, so we provide no further elaboration here.

Finally let us show how the generalized goldfish model (35) can be reduced back to the standard goldfish model (3). To this end we rewrite (35) as follows:

$$\ddot z_n=2\sum_{m=1,m\neq n}^{N}\frac{\dot z_n\,\dot z_m}{z_n-z_m}+a\,\dot z_n\,r, \quad (61a)$$

with

$$r\equiv r(t)=\sum_{n=1}^{N}\frac{\dot z_n(t)}{z_n(t)}. \quad (61b)$$

Time-differentiation of this formula yields

$$\dot r\equiv\sum_{n=1}^{N}\left[\frac{\ddot z_n}{z_n}-\left(\frac{\dot z_n}{z_n}\right)^2\right], \quad (62a)$$

$$\dot r\equiv a\,r^2-\sum_{n=1}^{N}\left(\frac{\dot z_n}{z_n}\right)^2+2\sum_{n,m=1;m\neq n}^{N}\frac{\dot z_n\,\dot z_m}{(z_n-z_m)\,z_n}, \quad (62b)$$

$$\dot r\equiv a\,r^2-\sum_{n=1}^{N}\left(\frac{\dot z_n}{z_n}\right)^2+\sum_{n,m=1;m\neq n}^{N}\frac{\dot z_n\,\dot z_m}{(z_n-z_m)}\left(\frac{1}{z_n}-\frac{1}{z_m}\right), \quad (62c)$$

$$\dot r\equiv a\,r^2-\sum_{n=1}^{N}\left(\frac{\dot z_n}{z_n}\right)^2-\sum_{n,m=1;m\neq n}^{N}\frac{\dot z_n\,\dot z_m}{z_n\,z_m}, \quad (62d)$$

$$\dot r\equiv(a-1)\,r^2 \quad (62e)$$

(to go from (62a) to (62b) we used (61); from (62b) to (62c), the possibility to exchange the indices m and n; and the next two steps are, we trust, pretty obvious, see (61b)). From the last equation, (62e), we immediately infer (see (61b) and (39), entailing $r(0)=b$)

$$r(t)=\frac{b}{1+(1-a)\,b\,t}. \quad (63)$$

Hence the equations of motion of the generalized goldfish model, see (35) or equivalently (61), can be recast in the following form:

$$\ddot z_n-\frac{a\,b\,\dot z_n}{1+(1-a)\,b\,t}=2\sum_{m=1,m\neq n}^{N}\frac{\dot z_n\,\dot z_m}{z_n-z_m}. \quad (64)$$

And it is now easy to check that via the change of dependent variables

$$z_n(t)=\zeta_n(\tau),\quad \tau=\beta(\alpha;t) \quad (65)$$

with $\beta(\alpha;t)$ defined precisely as above, see (59), one gets for $\zeta_n(\tau)$ just the equations of motion of the standard goldfish model, see (9). (Note moreover that this change of variables, (65) with (59), implies $z_n(0)=\zeta_n(0)$, $\dot{z}_n(0)=\zeta_n'(0)$.) This result provides of course another route to obtain the findings reported above for the generalized goldfish model (35) (see the last paragraph of Sec. II); or one can use the equivalent, but perhaps neater, version[11,15] of the solution of the goldfish model (9) according to which the coordinates $\zeta_n(\tau)$ coincide with the N roots of the following algebraic equation in ζ:

$$\sum_{n=1}^{N} \frac{\zeta_n'(0)}{\zeta-\zeta_n(0)} = \frac{1}{\tau}, \tag{66}$$

which implies via (65), for the generalized goldfish model (35), that the coordinates $z_n(t)$ coincide with the N roots of the following algebraic equation in z:

$$\sum_{n=1}^{N} \frac{\dot{z}_n(0)}{z-z_n(0)} = \frac{1}{\beta(\alpha;t)}, \tag{67}$$

with $\beta(\alpha;t)$ given by (59) with (39); as well as the corresponding result for the *isochronous* generalized goldfish model (36) reported at the end of Sec. I.

IV. OUTLOOK

Clearly the approach described in this paper can be applied more generally, by taking other matrix evolution equations than (44) as point of departure; this will be done in separate papers (for instance, the findings obtained by replacing (44) with the solvable matrix equation

$$\ddot{U}+a\,\dot{U}+bU=0 \tag{68}$$

are reviewed in a joint paper with Jean–Pierre Françoise;[19] and several other solvable matrix evolution equations are under consideration jointly with Mario Bruschi[8]).

Finally let us note that in this paper we focussed on many-body problems defined by *Newtonian* equations of motions (possibly with additional auxiliary variables); we did not discuss the possibility that these equations be embeddable in a *Hamiltonian* (or perhaps in a *quasi-Hamiltonian*[29]) formalism, nor the (possibly related) possibility to ascribe a ''physical'' meaning (possibly as ''spin'' degrees of fredom associated with Euler angles[32]) to the auxiliary variables. Such reformulations open the way to the investigation of these models in a quantal context. These remain as tasks for the future.

published online 11 May 2004)

Group classification of a class of third-order nonlinear evolution equations generalizing KdV and mKdV equations is performed. It is shown that there are two equations admitting simple Lie algebras of dimension three. Next, we prove that there exist only four equations invariant with respect to Lie algebras having nontrivial Levi factors of dimension four and six. Our analysis shows that there are no equations invariant under algebras which are semi-direct sums of Levi factor and radical. Making use of these results we prove that there are three, nine, thirty-eight, fifty-two inequivalent KdV-type nonlinear evolution equations admitting one-, two-, three-, and four-dimensional solvable Lie algebras, respectively. Finally, we perform a complete group classification of the most general linear third-order evolution equation. © *2004 American Institute of Physics.*

I. INTRODUCTION

The purpose of this article is classifying equations of the form

$$u_t = u_{xxx} + F(x,t,u,u_x,u_{xx}), \tag{1.1}$$

which admit nontrivial Lie (point) symmetries. The standard Korteweg–de Vries (KdV) equation,

$$u_t = u_{xxx} + uu_x,$$

belongs to the family of evolution equations (1.1). Classification of the KdV equation with variable coefficients (vcKdV),

$$u_t = f(x,t)uu_x + g(x,t)u_{xxx}, \quad f \cdot g \neq 0, \tag{1.2}$$

by their symmetries is done in Ref. 1, where it is shown that the vcKdV can admit at most four-dimensional Lie point symmetry group and those having four-dimensional symmetry group can be transformed into the ordinary KdV equation by local point transformations. In Ref. 2, Eq. (1.2) is investigated from the point of view of its integrability. It is shown, in particular, that equations of the form (1.2) with a three-dimensional Lie point symmetry group have a property of ''partially integrability.''

Our motivation is the same as for classifying vcKdV equations. We start with a rather general class of nonlinear equations generalizing (1.2) for $g_x=0$. Note that any t dependent coefficient of u_{xxx} in (1.1) can be normalized by a reparametrization of time. The main advantage of this classification is that, if we know that the equation under study admits a nontrivial symmetry group, then it is usually possible to apply the whole spectrum of the methods and algorithms of Lie group analysis. This enables us to derive exact analytical solutions of equations that, under study, reveal their integrability properties, find linearizing transformations, etc. Note that the connection between Lie point symmetries and integrability was discussed in Refs. 2, 3.

Recently, a novel generic approach to group classification of low-dimensional partial differential equations (PDEs) has been developed in Ref. 4. The full account of ideas and algorithms applied can be found in the review paper[5] where the approach in question has been applied to classify the most general second-order quasi-linear heat-conductivity equations admitting nontrivial Lie point symmetries. Here we adopt the same approach which basically consists of three steps. We first construct the equivalence group, namely, the most general group of point transformations that transform any equation of the form (1.1) to a (possibly different) equation belonging to the same class. Also, we find the most general element of the symmetry group together with a determining equation for F. As a second step, we realize low-dimensional Lie algebras by vector fields of the above form up to equivalence transformations. To this end, we use various results on the structure of abstract Lie algebras.[6–9] A review of the classification results of nonisomorphic finite-dimensional Lie algebras can be found in Ref. 5. In the last step, after transforming symmetry generators to canonical forms, we proceed to classifying equations that admit nontrivial symmetries. We do this by inserting these generators into the symmetry condition and solving for F.

Let us mention that similar ideas have been used by Winternitz and co-workers for the group classification of several nonlinear partial differential equations[1,10,11] and of discrete dynamical systems.[12–14] Note also that group classification of the nonlinear wave and Schrödinger equations in the same spirit has been done in Refs. 15, 16.

The paper is organized as follows. In Sec. II we present the determining equations for the symmetries and the equivalence group. Section III is devoted to the classification of the equations invariant under low-dimensional symmetry groups. In Sec. IV we perform a classification of linear equations in the class (1.1). A discussion of results and some conclusions are presented in the final section.

II. DETERMINING EQUATIONS AND EQUIVALENCE TRANSFORMATIONS

The Lie algebra of the symmetry group of Eq. (1.1) is realized by vector fields of the form

$$X=\tau(x,t,u)\partial_t+\xi(x,t,u)\partial_x+\phi(x,t,u)\partial_u\,. \tag{2.1}$$

In order to implement the symmetry algorithm we need to calculate the third order prolongation of the field vector field (2.1),[17–19]

$$\mathrm{pr}^{(3)}X=X+\phi^t\partial_{u_t}+\phi^x\partial_{u_x}+\phi^{xx}\partial_{u_{xx}}+\phi^{xxx}\partial_{u_{xxx}}, \tag{2.2}$$

where

$$\phi^t=D_t\phi-u_tD_t\tau-u_xD_t\xi,$$

$$\phi^x=D_x\phi-u_tD_x\tau-u_xD_x\xi,$$

$$\phi^{xx}=D_x\phi^x-u_{xt}D_x\tau-u_{xx}D_x\xi,$$

$$\phi^{xxx}=D_x\phi^{xx}-u_{xxt}D_x\tau-u_{xxx}D_x\xi.$$

Here D_x and D_t denote the total space and time derivatives. In order to find the coefficients of the vector field we require that the prolonged vector field (2.2) annihilate Eq. (1.1) on its solution manifold,

$$\mathrm{pr}^{(3)}X(\Delta)|_{\Delta=0}=0, \quad \Delta=u_t-u_{xxx}-F. \tag{2.3}$$

Equating coefficients of linearly independent terms of invariance criterion (2.3) to zero yields an overdetermined system of linear PDEs (called determining equations). Solving this system we obtain the following assertion.

Proposition 2.1: The symmetry group of the nonlinear equation (1.1) for an arbitrary (fixed) function F is generated by the vector field

$$X=\tau(t)\partial_t+\left(\frac{\dot\tau}{3}x+\rho(t)\right)\partial_x+\phi(x,t,u)\partial_u, \tag{2.4}$$

where the functions $\tau(t)$, $\rho(t)$ and $\phi(x,t,u)$ satisfy the determining equation

$$\begin{aligned}&-3\,u_x\dot\rho-x\,u_x\ddot\tau-9\,u_x\,u_{xx}\,\phi_{uu}-3\,u_x^3\,\phi_{uuu}+3\,\phi_t-9\,u_{xx}\,\phi_{xu}-9\,u_x^2\,\phi_{xuu}-9\,u_x\,\phi_{xxu}-3\,\phi_{xxx}\\&\quad+3(\phi_u-\dot\tau)\,F+(2\,u_{xx}\,\dot\tau-3\,u_{xx}\,\phi_u-3\,u_x^2\,\phi_{uu}-6\,u_x\,\phi_{xu}-3\,\phi_{xx})\,F_{u_{xx}}\\&\quad+(u_x\,\dot\tau-3\,u_x\,\phi_u-3\,\phi_x)\,F_{u_x}-3\,\phi\,F_u-3\,\tau F_t-(3\,\rho+x\,\dot\tau)\,F_x=0.\end{aligned} \tag{2.5}$$

Here the dot over a symbol stands for the time derivative.

If there are no restrictions on F, then (2.5) should be satisfied identically, which is possible only when the symmetry group is a trivial group of identity transformations. Here we shall be concerned with the identification of all specific forms of F for which nontrivial symmetry groups occur. The basic idea is to utilize the fact that for an arbitrarily fixed function F all admissible vector fields form a Lie algebra. This immediately implies the idea of using the classical results on the classification of low-dimensional Lie algebras obtained mostly in the late 1960s.[6–8] Saying it another way, we need to construct a kind of representation theory on low-dimensional Lie algebras generated by Lie vector fields preserving the manifold (2.5).

Our classification is up to equivalence under a group of locally invertible point transformations,

$$\tilde t=T(x,t,u), \quad \tilde x=Y(x,t,u), \quad \tilde u=U(x,t,u), \tag{2.6}$$

that preserve the form of the equation (1.1), but (possibly) change function F into a new one, namely, we have

$$\tilde u_{\tilde t}=\tilde u_{\tilde x\tilde x\tilde x}+\tilde F(\tilde x,\tilde t,\tilde u,\tilde u_{\tilde x},\tilde u_{\tilde x\tilde x}). \tag{2.7}$$

Inserting (2.6) into (1.1) and requiring that the form of the equation be preserved, we arrive at the following assertion.

Proposition 2.2: The maximal equivalence group $\mathcal{E}$ has the form

$$\tilde t=T(t), \quad \tilde x=\dot T^{1/3}x+Y(t), \quad \tilde u=U(x,t,u), \tag{2.8}$$

where $\dot T\neq 0$, $U_u\neq 0$.

We note that the Lie infinitesimal technique can also be used to obtain the equivalence group (2.8). It is straightforward to prove that both approaches produce the same results.

We make use of equivalence transformations (2.8) to transform vector field X into a convenient (canonical) form.

Proposition 2.3: Vector field (2.4) *is equivalent within a point transformation of the form* (2.6) *to one of the following vector fields:*

$$X=\partial_t, \quad X=\partial_x, \quad X=\partial_u. \tag{2.9}$$

Proof: Transformation (2.8) transforms vector field (2.4) into

$$X\to\tilde{X}=\tau(t)\dot{T}(t)\partial_{\tilde{t}}+[\tfrac{1}{3}(\tau\dot{T}^{-1}\ddot{T}+\dot{\tau})(\tilde{x}-Y)+\tau\dot{Y}+\rho\dot{T}^{1/3}]\partial_{\tilde{x}}$$
$$+[\tau U_t+(\tfrac{1}{3}\dot{\tau}x+\rho)U_x+\phi U_u]\partial_{\tilde{u}}. \tag{2.10}$$

There are two cases to consider.

(I) $\phi=0$. Choose $U=U(u)$ so that we have

$$\tilde{X}=\tau(t)\dot{T}(t)\partial_{\tilde{t}}+[\tfrac{1}{3}(\tau\dot{T}^{-1}\ddot{T}+\dot{\tau})(\tilde{x}-Y)+\tau\dot{Y}+\rho\dot{T}^{1/3}]\partial_{\tilde{x}}+\phi U_u\partial_{\tilde{u}}. \tag{2.11}$$

Now if $\tau=0$, then $\rho\neq 0$ (otherwise X would be zero), and we choose $T(t)$ to satisfy

$$\dot{T}=\rho^{-3}.$$

In this case $\tilde{X}$ is transformed into $\partial_{\tilde{x}}$.

If $\tau\neq 0$, then we choose T and Y to satisfy

$$\dot{T}=\tau^{-1}, \quad \tau\dot{Y}+\rho\dot{T}^{1/3}=0.$$

With this choice of T and Y vector field $\tilde{X}$ is transformed into $\partial_{\tilde{t}}$.

(II) $\phi\neq 0$. If $\tau=\rho=0$ then we can choose U to satisfy $\phi U_u=1$ so that we have $\tilde{X}=\partial_{\tilde{u}}$. Otherwise, U can be chosen to satisfy

$$\tau U_t+(\tfrac{1}{3}\dot{\tau}x+\rho)U_x+\phi U_u=0.$$

Hence we recover Case I.

Summing up, the vector field (2.4) is equivalent, up to equivalence under $\mathcal{E}$, to one of the three standard vector fields $\partial_x,\partial_t,\partial_u$. This completes the proof.

III. GROUP CLASSIFICATION OF LINEAR EQUATIONS

To the best of our knowledge no group classification of the most general linear third-order PDE appears in the literature. So we devote this section to the group classification of third-order PDEs:

$$u_t=f_1(x,t)u_{xxx}+f_2(x,t)u_{xx}+f_3(x,t)u_x+f_4(x,t)u+f_5(x,t). \tag{3.1}$$

If we perform the local change of variables $(x,t,u)\to(\tilde{x},\tilde{t},\tilde{u})$ preserving the form of (3.1),

$$\tilde{t}=t, \quad \tilde{x}=F(x,t), \quad u=V(x,t)v(\tilde{x},\tilde{t})+G(x,t), \quad V\neq 0,\ F_x\neq 0, \tag{3.2}$$

we obtain

$$v_{\tilde{t}}=f_1F_x^3v_{\tilde{x}\tilde{x}\tilde{x}}+\{3f_1V^{-1}[V_xF_x^2+VF_xF_{xx}]+f_2F_x^2\}v_{\tilde{x}\tilde{x}}+\{f_1V^{-1}[3V_{xx}F_x+3V_xF_{xx}+VF_{xxx}]$$
$$+f_2V^{-1}[2V_xF_x+Vf_{xx}]+f_3F_x-F_t\}v_{\tilde{x}}+\{f_1V^{-1}V_{xxx}+f_2V^{-1}V_{xx}+f_3V^{-1}V_x+f_4-V^{-1}V_t\}v$$
$$+V^{-1}[f_1G_{xxx}+f_2G_{xx}+f_3G_x+f_4G+f_5-G_t].$$

Now we choose the functions F,V, and G in (3.2) to satisfy constraints,

$$f_1F_x^3=1,$$

$$G_t=f_1G_{xxx}+f_2G_{xx}+f_3G_x+f_4G+f_5,$$

$$3f_1F_x^2V_x+[3f_1F_xF_{xx}+f_2F_x^2]V=0,$$

and thus normalize $f_1(x,t)\to 1$, and set $f_2(x,t)\to 0$, $f_5(x,t)\to 0$.

Thus (3.1) reduces to the following particular form:

$$u_t=u_{xxx}+A(x,t)u_x+B(x,t)u. \tag{3.3}$$

Here A,B are arbitrary smooth functions of x and t.

The most general equivalence transformation preserving the class of equations (3.3), which is a subset of (2.8), reads as

$$\tilde{t}=T(t),\quad \tilde{x}=\dot{T}^{1/3}x+Y(t),\quad \tilde{u}=V(t)u, \tag{3.4}$$

with $\dot{T}\neq 0$, $V\neq 0$.

Performing change of variables (3.4) transforms Eq. (3.3) to become

$$\tilde{u}_{\tilde{t}}=\tilde{u}_{\tilde{x}\tilde{x}\tilde{x}}+\tilde{A}\tilde{u}_{\tilde{x}}+\tilde{B}\tilde{u}, \tag{3.5}$$

where the coefficients $\tilde{A},\tilde{B}$ are expressed in terms of the functions A,B and their derivatives as follows:

$$\begin{aligned}\tilde{A}&=\dot{T}^{-1}(A\dot{T}^{1/3}-\tfrac{1}{3}\ddot{T}\dot{T}^{-2/3}x-\dot{Y}),\\ \tilde{B}&=\dot{T}^{-1}(B+V^{-1}\dot{V}).\end{aligned} \tag{3.6}$$

As Eq. (3.3) is linear, it admits trivial infinite-parameter group having the generator

$$X(\beta)=\beta(x,t)\partial_u,\quad \beta_t=\beta_{xxx}+A\beta_x+B\beta,$$

and the one-parameter group generated by the operator $u\partial_u$. These symmetries give no nontrivial information about the solution structure of the equation under study and therefore are neglected in the sequel.

The nontrivial invariance group of Eq. (3.3) is generated by operators of the form

$$X=\tau(t)\partial_t+(\tfrac{1}{3}\dot{\tau}x+\rho(t))\partial_x+\alpha(t)u\partial_u, \tag{3.7}$$

functions τ,ρ,α,A and B satisfying equations

$$\begin{aligned}&3\dot{\alpha}-3B\dot{\tau}-3\tau B_t-B_x(3\rho+x\dot{\tau})=0,\\ &-3\dot{\rho}-x\ddot{\tau}-2A\dot{\tau}-3\tau A_t-A_x(3\rho+x\dot{\tau})=0.\end{aligned} \tag{3.8}$$

Provided $A=A(x,t)$, $B=B(x,t)$ are arbitrary functions, $\tau=\rho=0$, $\dot{\alpha}=0$. So in this case Eq. (3.3) admits trivial symmetries only.

Transformation (3.4) leaves operator $X_1=u\partial_u$ invariant while transforming operator (3.5) to become

$$X\overset{(3.4)}{\to}\tilde{X}=\tau\dot{T}\partial_{\tilde{t}}+[\tau(\tfrac{1}{3}\ddot{T}\dot{T}^{-2/3}x+\dot{Y})+\dot{T}^{1/3}(\tfrac{1}{3}\dot{\tau}x+\rho)]\partial_{\tilde{x}}+(\tau\dot{V}+\alpha V)u\partial_{\tilde{u}}. \tag{3.9}$$

That is why, if $\tau\neq 0$ in (3.7), then putting

$$\dot{T}=\tau^{-1},\quad Y=-\int^{t}\rho(\xi)\tau^{-4/3}(\xi)d\xi,$$

and taking V as a nonzero solution of the equation

$$\tau\dot{V}+\alpha V=0,$$

in (3.4) transforms (3.9) to the canonical form of the generator of time displacements

$$\widetilde{X}=\partial_{\tilde{t}}.$$

Next, if $\tau=0$, $\rho\neq 0$ in (3.7), then putting $\dot{T}=\rho^{-3}$ in (3.4) yields the operator

$$\widetilde{X}=\partial_{\tilde{x}}+\alpha\tilde{u}\partial_{\tilde{u}}.$$

Finally, if $\tau=\rho=0$, $\dot{\alpha}\neq 0$ in (3.7), we put $T=\alpha$ in (3.4) thus getting the operator

$$\widetilde{X}=\tilde{t}\tilde{u}\partial_{\tilde{u}}.$$

Taking into account the above considerations, we see that there are transformations (3.4), that transform operator (3.7) to one of the following inequivalent forms:

$$\partial_t,\quad \partial_x,\quad \partial_x+f(t)u\partial_u\ \ (\dot{f}\neq 0),\quad tu\partial_u.$$

In what follows, we analyze each of the above operators separately.

Operator $X_1=\partial_t$. The system of determining Eqs. (3.8) for this operator reads as

$$B_t=A_t=0,$$

whence it follows that $A=A(x)$, $B=B(x)$. Inserting these functions into (3.8) yields

$$3\dot{\alpha}-3B\dot{\tau}-B_x(3\rho+x\dot{\tau})=0,$$

$$-3\dot{\rho}-x\ddot{\tau}-2A\dot{\tau}-A_x(3\rho+x\dot{\tau})=0.$$

Analyzing the above system of ordinary differential equations shows that for the case under consideration Eq. (3.3) admits an invariance group whose dimension is higher than one if and only if the following occurs.

(1) $A=mx^{-2}$, $B=nx^{-3}$, $|m|+|n|\neq 0$ with the additional symmetry operator $t\partial_t+\frac{1}{3}x\partial_x$;
(2) $A=0$, $B=\varepsilon x$ $(\varepsilon=\pm 1)$ with the additional symmetry operator $\partial_t+\varepsilon tu\partial_u$;
(3) $A=B\equiv 0$ with the additional symmetry operators $\partial_x, t\partial_t+\frac{1}{3}x\partial_x$.

Operator $X_2=\partial_x$. If Eq. (3.3) is invariant under X_2, then $A=A(t)$, $B=B(t)$. What is more, it follows from (3.6) that there are transformations (3.4), which reduce equation (3.3) to the form (3.5) with $\tilde{A}=\tilde{B}\equiv 0$. So we arrive at the already known case.

Operator $X_3=\partial_x+f(t)u\partial_u$ $(\dot{f}\neq 0)$. If Eq. (3.3) admits operator X_3, then we have $A=0$, $B=\dot{f}x$. Inserting these expressions into (3.8) yields

$$\dot{\rho}=0,\quad \ddot{\tau}=0,\quad \dot{\alpha}=\rho\dot{f},$$
$$3\tau\ddot{f}+4\dot{\tau}\dot{f}=0. \tag{3.10}$$

From the first three equations it follows that $\rho=C_1$, $\tau=C_2t+C_3$, $\alpha=C_1f+C_4$, $C_1,C_2,C_3,C_4\in\mathbb{R}$. Hence we conclude that the last equation of system (3.10) takes the form

TABLE I. Symmetry classification of 3.3.

N	A	B	Symmetry operators
1	$A(x)$	$B(x)$	∂_t
2	0	$\dot{f}(t)x$	$\partial_x+f(t)u\partial_u$, $\dot{f}\neq 0$
3	mx^{-2}, $m\in\mathbb{R}$	nx^{-3}, $n\in\mathbb{R}$, $\lvert m\rvert+\lvert n\rvert\neq 0$	$\partial_t, t\partial_t+\frac{1}{3}x\partial_x$
4	0	εx, $\varepsilon=\pm 1$	$\partial_t, \partial_x+\varepsilon tu\partial_u$
5	0	$-mt^{-4/3}x$, $m\in\mathbb{R}$, $m\neq 0$	$\partial_x+3mt^{-1/3}u\partial_u$, $t\partial_t+\frac{1}{3}x\partial_x$
6	$a\in\mathbb{R}$	0	$\partial_t, \partial_x, t\partial_t+\frac{1}{3}(x-2at)\partial_x$

$$3(C_2t+C_3)\ddot{f}+4C_2\dot{f}=0.$$

Analyzing this equation we see that extension of the symmetry algebra of Eq. (3.3) with $A=0$, $B=\dot{f}x$ is only possible when

$$f=3mt^{-1/3},\quad m\neq 0;$$

$$f=\varepsilon t,\quad \varepsilon=\pm 1.$$

The second case has already been considered. In the first case the basis of nontrivial invariance algebra is formed by the operators $\partial_x+3mt^{-1/3}u\partial_u$, $t\partial_t+\frac{1}{3}x\partial_x$.

Operator $X_4=tu\partial_u$. Inserting the coefficients of this operator into (3.8) leads to the contradiction $3=0$, whence it follows that the operator X_4 cannot be a symmetry operator of Eq. (3.3).

We summarize the above classification results of in Table I, where we give the forms of the functions A and B and basis operators of the nontrivial symmetry algebras of the corresponding equations (3.3).

So the equation $u_t=u_{xxx}$ has the highest symmetry within the class of equations (3.3). Its maximal finite-dimensional symmetry algebra is four-dimensional.

Note that according to Ref. 5 the class of nonlinear equations of the form

$$u_t=F(t,x,u,u_x)u_{xx}+G(t,x,u,u_x),\quad F\neq 0, \tag{3.11}$$

contains five nonlinear equations admitting five-dimensional symmetry algebras. Furthermore, an equation admitting six-dimensional symmetry algebra is equivalent to the heat equation. It is the linear heat conductivity equation $u_t=u_{xx}$ that possess the largest symmetry group within the class of second-order equations (3.11).

This is not the case for the class of third-order PDEs under consideration in the present paper. We shall see that there are examples of nonlinear equations that admits higher symmetry algebras than does the linear equation. For instance, the nonlinear Schwarzian KdV equation (4.14) admits a six-dimensional symmetry algebra.

IV. CLASSIFICATION OF EQUATIONS INVARIANT UNDER SEMI-SIMPLE ALGEBRAS AND ALGEBRAS HAVING NONTRIVIAL LEVI DECOMPOSITIONS

In order to describe equations (1.1) that admit Lie algebras isomorphic to the Lie algebras having nontrivial Levi decomposition, we need, first of all, to describe equations whose invariance algebras are semi-simple.

The lowest order semi-simple Lie algebras are isomorphic to one of the following three-dimensional algebras:

$$\mathrm{sl}(2,\mathbb{R}):[X_1,X_3]=-2X_2,\quad [X_1,X_2]=X_1,\quad [X_2,X_3]=X_3;$$

$$\mathrm{so}(3):[X_1,X_2]=X_3,\quad [X_2,X_3]=X_1,\quad [X_3,X_1]=X_2.$$

Taking into account our preliminary classification we conclude that one of the basis operators reduces to one of the canonical forms $\partial_t,\partial_x,\partial_u$.

First, we study realizations of the algebra so(3) within the class of operators (2.4).

Let $X_1=\partial_t$ and let the operators X_2,X_3 be of the form (2.4). Checking commutation relations $[X_1,X_2]=X_3,[X_3,X_1]=X_2$ we see that

$$X_2=3\alpha\cos t\partial_t+[-\alpha x\sin t+\beta\cos(t+\gamma)]\partial_x+\varphi(x,u)\cos(t+\psi(x,u))\partial_u,$$

$$X_3=-3\alpha\sin t\partial_t-[\alpha x\cos t+\beta\sin(t+\gamma)]\partial_x-\varphi(x,u)\sin(t+\psi(x,u))\partial_u.$$

Here α, β, γ are arbitrary real constants and φ, ψ are arbitrary real-valued smooth functions.

The third commutation relation $[X_2,X_3]=X_1$ implies that $9\alpha^2=-1$. As this equation has no real solutions, there are no realizations of so(3) with $X_1=\partial_t$.

The same assertion holds for the cases when $X_1=\partial_x$ and $X_1=\partial_u$. So the class of operators (2.4) contains no realizations of the algebra so(3). This means that there are no so(3)-invariant equations of the form (1.1).

Theorem 4.1: *There exist no realizations of the algebra* so(3) *in terms of vector fields* (2.4). *Hence no equation of the form* (1.1) *is invariant under* so(3) *algebra.*

Similar reasoning yields that there are three inequivalent realizations of the algebra $\mathrm{sl}(2,\mathbb{R})$ by operators of the form (2.4),

$$\{\partial_t,t\partial_t+\tfrac{1}{3}x\partial_x,-t^2\partial_t-\tfrac{2}{3}tx\partial_x\},$$

$$\{\partial_t,t\partial_t+\tfrac{1}{3}x\partial_x,-t^2\partial_t-\tfrac{2}{3}tx\partial_x-x^3\partial_u\},$$

$$\{\partial_u,u\partial_u,-u^2\partial_u\}.$$

Inserting the coefficients of basis operators of the first realization of the algebra $\mathrm{sl}(2,\mathbb{R})$ into invariance criterion yields the following classifying equations:

$$2u_{xx}F_{u_{xx}}+u_xF_{u_x}-xF_x-3F=0,$$

$$t(2u_{xx}F_{u_{xx}}+u_xF_{u_x}-xF_x-3F)-xu_x=0,$$

from which we get the equation $xu_x=0$. Consequently, the realization in question cannot be invariance algebra of the equation under study.

The two remaining realizations of $\mathrm{sl}(2,\mathbb{R})$ do yield invariance algebras of equation (1.1). The forms of the function F in the corresponding invariant equations read as

$$\{\partial_t,t\partial_t+\tfrac{1}{3}x\partial_x,-t^2\partial_t-\tfrac{2}{3}tx\partial_x-x^3\partial_u\}\quad:\quad F=-x^{-3}[2xu_x+\tfrac{1}{9}x^2u_x^2-G(\omega_1,\omega_2)],$$

$$\omega_1=3u-xu_x,\quad \omega_2=6u-x^2u_{xx};$$

$$\{\partial_u,u\partial_u,-u^2\partial_u\}\quad:\quad F=-\tfrac{3}{2}u_x^{-1}u_{xx}^2+u_xG(x,t).$$

As any semi-simple or simple algebra contains either so(3) or $\mathrm{sl}(2,\mathbb{R})$ (or both) as subalgebra(s),[20] the above result can be utilized to perform the classification of equations (1.1) admitting invariance algebras isomorphic to one having a nontrivial Levi decomposition.

First we turn to the equation

$$u_t = u_{xxx} - \tfrac{3}{2}u_x^{-1}u_{xx}^2 + u_x G(x,t). \tag{4.1}$$

Applying the Lie infinitesimal algorithm we see that the maximal invariance algebra of Eq. (4.1) is spanned by the operators $X_1=\partial_u$, $X_2=u\partial_u$, $X_3=-u^2\partial_u$, and

$$X_4=\tau(t)\partial_t+(\tfrac{1}{3}\dot{\tau}x+\rho(t))\partial_x, \tag{4.2}$$

functions τ, ρ and G satisfying the equation

$$(x\dot{\tau}+3\rho)G_x+3\tau G_t+2\dot{\tau}G+x\ddot{\tau}+3\dot{\rho}=0. \tag{4.3}$$

By direct verification we ensure that the form of basis operators of the realization of $\mathrm{sl}(2,\mathbb{R})$ under study is not altered by the transformations

$$\tilde{t}=T(t),\ \ \tilde{x}=\dot{T}^{1/3}x+Y(t),\ \ \tilde{u}=\gamma u,\ \ \dot{T}\neq 0,\ \ \gamma\neq 0. \tag{4.4}$$

As transformation (4.4) reduces (4.2) to the form

$$X_4 \overset{(4.4)}{\to} \tilde{X}_4=\tau(t)\dot{T}(t)\partial_{\tilde{t}}+[\tfrac{1}{3}(\tau\dot{T}^{-1}\ddot{T}+\tau)(\tilde{x}-Y)+\tau\dot{Y}+\rho\dot{T}^{1/3}]\partial_{\tilde{x}},$$

we can put $X_4=\partial_t$ or $X_4=\partial_x$ within the equivalence relation.

Provided $X_4=\partial_t$, it follows from (4.3) that $G=\tilde{G}(x)$ in (4.1). Next, if $X_4=\partial_x$, then necessarily $G=\tilde{G}(t)$. Consequently, the class of Eqs. (4.1) contains two inequivalent equations:

$$u_t=u_{xxx}-\tfrac{3}{2}u_x^{-1}u_{xx}^2+u_x\tilde{G}(x) \tag{4.5}$$

and

$$u_t=u_{xxx}-\tfrac{3}{2}u_x^{-1}u_{xx}^2+u_x\tilde{G}(t), \tag{4.6}$$

which are invariant under extensions of the algebra $\mathrm{sl}(2,\mathbb{R})$. Namely, they admit algebras $\mathrm{sl}(2,\mathbb{R})\oplus\{\partial_t\}$ and $\mathrm{sl}(2,\mathbb{R})\oplus\{\partial_x\}$, correspondingly. What is more, if the function $\tilde{G}=\tilde{G}(x)$ in (4.5) is arbitrary, the given algebra is maximal (in Lie sense) invariance algebra of Eq. (4.5).

Equation (4.6) is reduced to PDE (4.5) with $\tilde{G}(x)=0$ with the help of the change of variables,

$$\tilde{t}=t,\ \ \tilde{x}=x+\int^t \tilde{G}(\xi)\ \ d\xi,\ \ u=v(\tilde{x},\tilde{t}).$$

Therefore, we can restrict our further considerations to Eq. (4.5), where we need to differentiate between the cases $\tilde{G}=0$ and $\tilde{G}\neq 0$.

Classifying Eq. (4.3) with $G=\tilde{G}(x)$ reads as

$$(x\dot{\tau}+3\rho)\tilde{G}_x+2\dot{\tau}\tilde{G}+x\ddot{\tau}+3\dot{\rho}=0.$$

Hence it follows that there are two cases providing for extension of the symmetry algebra. Namely, the case when $\tilde{G}=0$, which gives rise to two additional symmetry operators $X_5=t\partial_t+\frac{1}{3}x\partial_x$ and $X_6=\partial_x$. Another case of the extension of symmetry of Eq. (4.5) is when $\tilde{G}=\lambda x^{-2}$ $(\lambda\neq 0)$. If this is the case, (4.5) admits the additional operator $X_5=t\partial_t+\frac{1}{3}x\partial_x$.

Now we turn to the equation

$$u_t = u_{xxx} - 2x^{-2}u_x - \tfrac{1}{9}x^{-1}u_x^2 + x^{-3}G(\omega_1,\omega_2),$$
$$\omega_1 = 3u - xu_x, \quad \omega_2 = 6u - x^2u_{xx}. \tag{4.7}$$

First of all, we ensure that the class of PDEs (4.7) does not contain equations whose invariance algebras possess semi-simple subalgebras of the dimension $n>3$.

It is common knowledge[20] that there are four types of abstract simple Lie algebras over the field of real numbers:

- The type A_{n-1} $(n>1)$ contains four real forms of the algebras $\mathrm{sl}(n,\mathbb{C})$: $\mathrm{su}(n)$, $\mathrm{sl}(n,\mathbb{R})$, $\mathrm{su}(p,q)$ $(p+q=n, p\geqslant q)$, $\mathrm{su}^*(2n)$.
- The type B_n $(n>1)$ contains two real forms of the algebra $\mathrm{so}(2n+1,\mathbb{C})$: $\mathrm{so}(2n+1)$, $\mathrm{so}(p,q)$ $(p+q=2n+1, p>q)$.
- The type C_n $(n\geqslant 1)$ contains three real forms of the algebra $\mathrm{sp}(n,\mathbb{C})$: $\mathrm{sp}(n)$, $\mathrm{sp}(n,\mathbb{R})$, $\mathrm{sp}(p,q)$ $(p+q=n, p\geqslant q)$.
- The type D_n $(n>1)$ contains three real forms of the algebra $\mathrm{so}(2n,\mathbb{C})$: $\mathrm{so}(2n)$, $\mathrm{so}(p,q)$ $(p+q=2n,\ p\geqslant q)$, $\mathrm{so}^*(2n)$.

The lowest order classical semi-simple Lie algebras are three-dimensional. The next admissible dimension for classical semi-simple Lie algebras is six. There are four nonisomorphic semi-simple Lie algebras: so(4), so(3,1), so(2,2) and so*(4). As $\mathrm{so}(4)=\mathrm{so}(3)\oplus\mathrm{so}(3)$, $\mathrm{so}^*(4)\sim\mathrm{so}(3)\oplus\mathrm{sl}(2,\mathbb{R})$, and the algebra so(3,1) contains so(3) as a subalgebra, the algebra so(2,2) is the only possible six-dimensional semi-simple algebra that might be invariance algebra of Eq. (4.7). Taking into account that $\mathrm{so}(2,2)\sim\mathrm{sl}(2,\mathbb{R})\oplus\mathrm{sl}(2,\mathbb{R})$ and choosing $\mathrm{so}(2,2)=\{X_1,X_2,X_3\}\oplus\{\tilde{X}_1,\tilde{X}_2,\tilde{X}_3\}$, where X_1,X_2,X_3 form a basis of $\mathrm{sl}(2,\mathbb{R})$, which is invariance algebra of (4.7) and $\tilde{X}_1,\tilde{X}_2,\tilde{X}_3$ are of the form (2.4), we require the commutation relations

$$[X_i,\tilde{X}_j]=0 \quad (i,j=1,2,3)$$

to hold, whence

$$\tilde{X}_j=\lambda_j\partial_u \quad (j=1,2,3),$$

where λ_j are arbitrary real constants. Hence we conclude that the class of operators (2.4) does not contain a realization of so(2,2).

The same result holds for eight-dimensional semi-simple Lie algebras $\mathrm{sl}(3,\mathbb{R})$, su(3), su(2,1).

As $\mathrm{su}^*(4)\sim\mathrm{so}(5,1)$ and the algebra so(5,1) contains so(4) as a subalgebra, the class of operators (2.4) contains no realizations of A_n and D_n $(n>1)$ type algebras that are inequivalent to the algebra $\mathrm{sl}(2,\mathbb{R})$.

The same assertion holds true for B_n $(n>1)$ and C_n $(n\geqslant 1)$ type Lie algebras. Indeed, B_2 type algebras contain so(4) and so(3,1) and what is more,

$$\mathrm{sp}(2,\mathbb{R})\sim\mathrm{so}(3,2)\supset\mathrm{so}(3,1), \quad \mathrm{sp}(1,1)\sim\mathrm{so}(4,1)\supset\mathrm{so}(4), \quad \mathrm{sp}(2)\sim\mathrm{so}(5)\supset\mathrm{so}(4).$$

What remains to be done is to consider the exceptional semi-simple Lie algebras that belong to one of the following five types:[20] G_1,F_4,E_6,E_7,E_8. We consider in some detail G_1 type Lie algebras.

The type G_1 contains one compact real form g_2 and one noncompact real form g_2'. As $g_2\cap g_2'\sim\mathrm{su}(2)\oplus\mathrm{su}(2)\sim\mathrm{so}(4)$ and the algebra so(4) has no realization within the class of operators (2.4), the latter contains no realizations of type G_1.

Summing up, we conclude that class of PDEs (4.7) contains no equations, whose invariance algebras are isomorphic to n-dimensional semi-simple Lie algebras (or contains the latter as subalgebras) under $n>3$.

Consider now Eqs. (4.7), whose invariance algebras has nontrivial Levi factor. First, we turn to equations which are invariant with respect to the Lie algebras that can be decomposed into a direct sum of semi-simple Levi factor and radical, $\mathrm{sl}(2,\mathbb{R})\oplus L$, L being a radical. To this end, we will study possible extensions of the algebra $\mathrm{sl}(2,\mathbb{R})$ by operators (2.4).

Let $\mathrm{sl}(2,\mathbb{R})=\{X_1,X_2,X_3\}$, where X_1,X_2,X_3, form a basis of the invariance algebra of Eq. (4.7). Then it follows from

$$[X_i,Y]=0 \quad (i=1,2,3),$$

Y being an operator of the form (2.4), that $Y=\lambda\partial_u$, $\lambda=\text{const}$. Hence L is the one-dimensional Lie algebra spanned by the operator ∂_u. For Eq. (4.7) to admit the algebra $\mathrm{sl}(2,\mathbb{R})\oplus\{\partial_u\}$, the equation

$$G_{\omega_1}+2G_{\omega_2}=0,$$

has to be satisfied, whence

$$G=\tilde{G}(\sigma), \quad \sigma=x^2u_{xx}-2xu_x.$$

Consequently, an equation of the form (4.7) admits invariance algebra which is the direct sum of semi-simple Levi factor and radical iff it reads as

$$u_t=u_{xxx}-2x^{-2}u_x-\tfrac{1}{9}x^{-1}u_x^2+x^{-3}\tilde{G}(\sigma), \quad \sigma=x^2u_{xx}-2xu_x. \tag{4.8}$$

As Eq. (4.8) contains an arbitrary function of one variable, we can perform direct group classification by a straightforward application of the Lie infinitesimal algorithm. The determining equation for coefficients of the infinitesimal symmetry operator are of the form

(a) $\phi_{uuu}=0$;

(b) $3\phi_{uu}\tilde{G}_\sigma+18\phi_{uu}+9x\phi_{xuu}+\tfrac{1}{3}(x^{-1}\rho-\phi_u)=0$;

(c) $6x^{-1}(\phi_{xu}+x^{-2}\rho)\tilde{G}_\sigma+9x^{-2}\sigma\phi_{uu}+3\rho_t+x\tau_{tt}+6x^{-1}(3\phi_{xu}+2x^{-2}\rho)$
$+9\phi_{xxu}-\tfrac{2}{3}x^{-1}\phi_x=0$;

(d) $[-3x^{-3}(\phi_u+2x^{-1}\rho)\sigma+6x^{-2}\phi_x-3x^{-1}\phi_{xx}]\tilde{G}_\sigma+3x^{-3}(\phi_u+3x^{-1}\rho)\tilde{G}-9x^{-2}\phi_{xu}\sigma$
$+3[\phi_t-\phi_{xxx}+2x^{-2}\phi_x]=0.$

It follows from (a) that

$$\phi=f(x,t)u^2+g(x,t)u+h(x,t), \tag{4.9}$$

where f,g,h are arbitrary smooth functions. Inserting (4.9) into (b) yields

$$6f\tilde{G}_\sigma+36f+18xf_x+\tfrac{1}{3}(x^{-1}\rho-g)-\tfrac{2}{3}fu=0.$$

Taking into account that functions $f,\rho,g,\tilde{G}$ do not depend on u, we get

$$f=0, \ g=x^{-1}\rho.$$

So that equation (c) reduces to

$$3\rho_t+x\tau_{tt}+12x^{-3}\rho+\tfrac{2}{3}x^{-3}\rho u-\tfrac{2}{3}x^{-1}h_x=0.$$

Hence it follows that

$$\rho=0,\ \ h=\tfrac{1}{2}x^3\tau_{tt}+\tilde{h}(t).$$

Finally, inserting the obtained expression for φ into equation (d) gives

$$\tau_{ttt}=0,\ \ \tilde{h}_t=0,$$

whence

$$\tau=C_1t^2+C_2t+C_3,$$

$$\tilde{h}=C_4.$$

Here C_1,C_2,C_3,C_4 are arbitrary (integration) constants.

Summing up, we conclude that the algebra $\mathrm{sl}(2,\mathbb{R})\oplus\{\partial_u\}$ is the maximal invariance algebra admitted by Eq. (4.8). It cannot be extended by specifying the form of an arbitrary function $\tilde{G}(\sigma),\sigma=x^2u_{xx}-2xu_x$.

What remains to be done is classifying Eqs. (4.7), whose invariance algebras are isomorphic to *semi-direct* sums of a semi-simple Levi factor and radical, i.e., whose invariance algebras have the following structure: $\mathrm{sl}(2,\mathbb{R})\in L$. To perform this classification we utilize the classification of these type of Lie algebras obtained by Turkowski.[21]

We choose $\mathrm{sl}(2,\mathbb{R})=\{v_1,v_2,v_3\}$ with

$$v_1=-2t\partial_t-\tfrac{2}{3}x\partial_x,\ \ v_2=\partial_t,\ \ v_3=-t^2\partial_t-\tfrac{2}{3}tx\partial_x-x^3\partial_u.$$

According to Ref. 21, there is only one five-dimensional Lie algebra of the desired form $\mathrm{sl}(2,\mathbb{R})\in L$ with $L=\{e_1,e_2\}$, operators e_1,e_2 satisfying the commutation relations:

$$[e_1,e_2]=0,\ [v_1,e_1]=e_1,\ [v_1,e_2]=-e_2,$$

$$[v_2,e_1]=0,\ [v_2,e_2]=e_1,$$

$$[v_3,e_1]=e_2,\quad [v_3,e_2]=0.$$

As operators e_1,e_2 are necessarily of the form (2.4), we easily get that

$$e_1=|x|^{-3/2}\partial_u,\quad e_2=t|x|^{-3/2}\partial_u.$$

However, checking the invariance criterion for the above realization we find that the algebra in question cannot be invariance algebra of an equation of the form (4.7).

According to Ref. 21, there exist three six-dimensional Lie algebras that are semi-direct sums of semi-simple Levi factor and radical, algebra L being of the form $L=\{e_1,e_2,e_3\}$. Nonzero commutation relations for e_1,e_2,e_3 read as

$$(1)\quad [v_1,e_1]=2e_1,\ [v_2,e_2]=2e_1,\ [v_3,e_1]=e_2,$$

$$[v_1,e_3]=-2e_3,\ [v_2,e_3]=e_2,\ [v_3,e_2]=2e_3;$$

$$(2)\quad [v_1,e_1]=e_1,\ [v_2,e_2]=e_1,\ [v_3,e_1]=e_2,$$

$$[v_1,e_2]=-e_2,\ [e_1,e_2]=e_3;$$

$$(3)\quad [v_1,e_1]=e_1,\ [v_2,e_2]=e_1,\quad [v_3,e_1]=e_2,$$

$$[v_1,e_2]=-e_2,\ [e_1,e_3]=e_1,\ [e_2,e_3]=e_2.$$

Solving the above relations we see that the corresponding realizations cannot be invariance algebras of Eq. (4.7).

Next, we consider seven-dimensional algebras from the Turkowski's classification. According to Ref. 21 there are five inequivalent algebras of the targeted dimension. Four of them contain the above five- and six-dimensional algebras as subalgebras. So we need to consider only the fifth algebra $\mathrm{sl}(2,\mathbb{R})\subset L$, where $L=\{e_1,e_2,e_3,e_4\}$ and the following commutation relations hold:

$$[v_1,e_1]=3e_1,\quad [v_2,e_2]=3e_1,$$

$$[v_3,e_1]=e_2,\quad [v_1,e_2]=e_2,$$

$$[v_2,e_3]=2e_2,\quad [v_3,e_2]=2e_3,$$

$$[v_1,e_3]=-e_3,\quad [v_2,e_4]=e_3,$$

$$[v_3,e_3]=3e_4,\quad [v_1,e_4]=-3e_4.$$

The most general form of operators e_1,e_2,e_3,e_4 satisfying the above relations is as follows:

$$e_1=|x|^{-9/2}\partial_u,\quad e_2=3t|x|^{-9/2}\partial_u,$$

$$e_3=3t^2|x|^{-9/2}\partial_u,\quad e_4=t^3|x|^{-9/2}\partial_u.$$

However, verifying the invariance criterion yields that this algebra cannot be the symmetry algebra of Eq. (4.7).

Thus we proved that the class of PDEs (4.7) contains no equations admitting symmetry algebras of the dimension $n\leqslant 7$, which are semi-direct sums of the Levi factor and radical. It is natural to conjecture that the same assertion holds for an arbitrary n. To prove this fact we need to consider in full details classification of nonlinear equations (1.1), whose invariance algebras are solvable.

Let us sum up the above results as theorems.

Theorem 4.2: *The class of PDEs (1.1) contains two inequivalent equations whose invariance algebra are semi-simple* $(\mathrm{sl}(2,\mathbb{R}))$,

$$u_t=u_{xxx}-\tfrac{3}{2}u_x^{-1}u_{xx}^2+u_xG(x,t);$$

$$u_t=u_{xxx}-x^{-3}[2xu_x+\tfrac{1}{9}x^2u_x^2-G(\omega_1,\omega_2)],$$

$$\omega_1=3u-xu_x,\quad \omega_2=6u-x^2u_{xx}.$$

The maximal invariance algebras of the above equations under arbitrary G read as

$$\mathrm{sl}^1(2,\mathbb{R})=\{\partial_u,u\partial_u,-u^2\partial_u\};$$

$$\mathrm{sl}^2(2,\mathbb{R})=\{\partial_t,t\partial_t+\tfrac{1}{3}x\partial_x,-t^2\partial_t-\tfrac{2}{3}tx\partial_x-x^3\partial_u\}.$$

Theorem 4.3: *Nonlinear equation (1.1) whose invariance algebra is isomorphic to a Lie algebra having nontrivial Levi decomposition is represented by one of the following equations:*

$$u_t=u_{xxx}-\tfrac{3}{2}u_x^{-1}u_{xx}^2+u_x\tilde{G}(x),\quad \mathrm{sl}^1(2,R)\oplus\{\partial_t\};\tag{4.10}$$

$$u_t=u_{xxx}-\tfrac{3}{2}u_x^{-1}u_{xx}^2+\lambda x^{-2}u_x,\quad \lambda\neq 0,\quad \mathrm{sl}^1(2,\mathbb{R})\oplus\{\partial_t,t\partial_t+\tfrac{1}{3}x\partial_x\};\tag{4.11}$$

$$u_t = u_{xxx} - \tfrac{3}{2}u_x^{-1}u_{xx}^2, \quad \mathrm{sl}^1(2,\mathbb{R}) \oplus \{\partial_t, \partial_x, t\partial_t + \tfrac{1}{3}x\partial_x\}; \tag{4.12}$$

$$u_t = u_{xxx} - 2x^{-2}u_x - \tfrac{1}{9}x^{-1}u_x^2 + x^{-3}\tilde{G}(\sigma), \quad \sigma = x^2u_{xx} - 2xu_x, \quad \mathrm{sl}^2(2,\mathbb{R}) \oplus \{\partial_u\}, \tag{4.13}$$

where $\tilde{G}$ is an arbitrary function of x or σ. Moreover, the associated symmetry algebras are maximal.

Note that Eq. (4.12) can be expressed in the form

$$\frac{u_t}{u_x} = \{u;x\}, \tag{4.14}$$

where $\{u;x\}$ denotes the Schwarzian derivative of u with respect to x. It is known that a nonpoint transformation taking this equation into the usual KdV exists.

V. CLASSIFICATION OF EQUATIONS INVARIANT UNDER LOW-DIMENSIONAL SOLVABLE SYMMETRY ALGEBRAS

In this section we apply the strategy summarized in the Introduction to identify representative classes of equations of the form (1.1) invariant under one-, two-, and three-dimensional solvable symmetry algebras. In order to approach this task in a systematic manner we realize all possible inequivalent algebras in terms of vector fields (2.4) under the action of the equivalence group $\mathcal{E}$.

A. Equations with one-dimensional symmetry algebras

We assume that for a given F, Eq. (1.1) is invariant under a one-parameter symmetry group, generated by the vector field (2.4) with coefficients subject to the constraint (2.5). We make use of Proposition 2.3 which characterizes the canonical forms of the vector field X of (2.4). We then substitute the coefficients of the canonical vector field into the determining equation (2.5), which is a first order linear homogeneous PDE for F, and solve the latter in order to construct invariant equations.

According to Proposition 2.3 we have three types of one-dimensional symmetry algebras:

$$A_{1,1}: \quad X_1 = \partial_t, \quad A_{1,2}: X_1 = \partial_x, \quad A_{1,3}: X_1 = \partial_u. \tag{5.1}$$

The corresponding invariant equations will have the form

$$A_{1,1}: \quad u_t = u_{xxx} + F(x,u,u_x,u_{xx}), \tag{5.2a}$$

$$A_{1,2}: \quad u_t = u_{xxx} + F(t,u,u_x,u_{xx}), \tag{5.2b}$$

$$A_{1,3}: \quad u_t = u_{xxx} + F(x,t,u_x,u_{xx}). \tag{5.2c}$$

Theorem 5.1: *There are three inequivalent classes of Eqs. (1.1) invariant under one-parameter symmetry group. Their representatives are given by (5.2).*

B. Equations with two-dimensional symmetry algebras

There are two isomorphy classes of two-dimensional Lie algebras, Abelian and non-Abelian, satisfying the commutation relations $[X_1,X_2] = \kappa X_2$, $\kappa = 0,1$. We denote them by $A_{2,1}$ and $A_{2,2}$.

1. Abelian

We start from each of the one-dimensional cases obtained in (5.1) and add to it vector fields X_2 of the form (2.4) commuting with X_1. We then simplify X_2 by equivalence transformations leaving the vector field X_1 invariant. For further details we refer the reader to Ref. 4. The standardized X_2 and the restricted form of F in (5.2) are then substituted into (2.5). Solving this equation will further restrict the form of the function F. The number of variables of F reduces by

one, three variables in this case. Thus, we find that there exist precisely four classes of two-dimensional Abelian symmetry algebras represented by the following ones:

$$A^1_{2,1}: \quad X_1=\partial_t, \quad X_2=\partial_x, \quad F=F(u,u_x,u_{xx}); \tag{5.3}$$

$$A^2_{2,1}: \quad X_1=\partial_t, \quad X_2=\partial_u, \quad F=F(x,u_x,u_{xx}); \tag{5.4}$$

$$A^3_{2,1}: \quad X_1=\partial_x, \quad X_2=\alpha(t)\partial_x+\partial_u, \quad F=-\dot{\alpha}uu_x+\tilde{F}(t,u_x,u_{xx}); \tag{5.5}$$

$$A^4_{2,1}: \quad X_1=\partial_u, \quad X_2=g(x,t)\partial_u, \quad g_x\neq \text{const}; \tag{5.6}$$

$$F=(g_t-g_{xxx})g_x^{-1}u_x+\tilde{F}(x,t,\omega), \quad \omega=g_{xx}u_x-g_xu_{xx}.$$

2. Non-Abelian

Imposing that X_1 reads as (5.1) and X_2 is in generic form and that they satisfy $[X_1,X_2]=X_2$, we find that five classes of symmetry algebras exist. Those algebras and nonlinear functions F are represented by

$$A^1_{2,2}: \quad X_1=\partial_t, \quad X_2=-t\partial_t-\frac{x}{3}\partial_x,$$

$$F=x^{-3}\tilde{F}(u,\omega_1,\omega_2), \quad \omega_1=xu_x, \quad \omega_2=x^2u_{xx};$$

$$A^2_{2,2}: \quad X_1=-3t\partial_t-x\partial_x, \quad X_2=\partial_x,$$

$$F=t^{-1}\tilde{F}(u,\omega_1,\omega_2), \quad \omega_1=t^{1/3}u_x, \quad \omega_2=t^{2/3}u_{xx};$$

$$A^3_{2,2}: \quad X_1=-u\partial_u, \quad X_2=\partial_u, \quad F=u_x\tilde{F}(x,t,\omega), \quad \omega=u_x^{-1}u_{xx};$$

$$A^4_{2,2}: \quad X_1=\partial_x-u\partial_u, \quad X_2=\partial_u;$$

$$F=e^{-x}\tilde{F}(t,\omega_1,\omega_2), \quad \omega_1=e^xu_x, \quad \omega_2=e^xu_{xx};$$

$$A^5_{2,2}: \quad X_1=\partial_t-u\partial_u, \quad X_2=\partial_u,$$

$$F=u_x\tilde{F}(x,\omega_1,\omega_2), \quad \omega_1=e^tu_x, \quad \omega_2=e^tu_{xx}.$$

Theorem 5.2: *There exist nine classes of two-dimensional symmetry algebras admitted by Eq. (1.1). They are represented by the algebras* $A^1_{2,1},\ldots,A^4_{2,1}$ *and* $A^1_{2,2},\ldots,A^5_{2,2}$.

C. Equations with three-dimensional symmetry algebras

1. Decomposable algebras

A Lie algebra is decomposable if it can be written as a direct sum of two or more Lie algebras $L=L_1\oplus L_2$ with $[L_1,L_2]=0$. There are two types of 3-dimensional decomposable Lie algebras: $A_{3,1}=3A_1=A_1\oplus A_2\oplus A_3$ with $[X_i,X_j]=0$ for $i,j=1,2,3$ and $A_{3,2}=A_{2,2}\oplus A_1$ with $[X_1,X_2]=X_2$, $[X_1,X_3]=0$, $[X_2,X_3]=0$.

We start from the two-dimensional algebras in (5.3) and add a further linearly independent vector field X_3 in the form (2.4) and impose the above commutation relations. We simplify X_3 using equivalence transformations leaving the space $\{X_1,X_2\}$ invariant. We present the following result without proof. We emphasize that there exist several realizations that do not produce invariant equations of the form (1.1):

$$A^1_{3,1}: \quad X_1=\partial_t, \quad X_2=\partial_x, \quad X_3=\partial_u, \quad F=F(u_x,u_{xx});$$

$$A^2_{3,1}: \quad X_1=\partial_t, \quad X_2=\partial_u, \quad X_3=f(x)\partial_u,$$

$$F=-\frac{f'''}{f'}u_x+\tilde{F}(x,\omega), \quad \omega=f''u_x-f'u_{xx};$$

$$A^1_{3,2}: \quad X_1=-t\partial_t-\frac{x}{3}\partial_x, \quad X_2=\partial_t, \quad X_3=\partial_u,$$

$$F=x^{-3}\tilde{F}(\omega_1,\omega_2), \quad \omega_1=xu_x, \quad \omega_2=x^2u_{xx};$$

$$A^2_{3,2}: \quad X_1=-3t\partial_t-x\partial_x, \quad X_2=\partial_x, \quad X_3=\partial_u,$$

$$F=t^{-1}\tilde{F}(\omega_1,\omega_2), \quad \omega_1=tu_x^3, \quad \omega_2=t^2u_{xx}^3;$$

$$A^3_{3,2}: \quad X_1=-3t\partial_t-x\partial_x, \quad X_2=\partial_x, \quad X_3=t^{1/3}\partial_x+\partial_u,$$

$$F=-\tfrac{1}{3}t^{-2/3}uu_x+t^{-1}\tilde{F}(\omega_1,\omega_2), \quad \omega_1=tu_x^3, \quad \omega_2=t^2u_{xx}^3;$$

$$A^4_{3,2}: \quad X_1=\partial_x-u\partial_u, \quad X_2=\partial_u, \quad X_3=e^{-x}f(t)\partial_u, \quad f\neq 0,$$

$$F=-\left(1+\frac{\dot{f}}{f}\right)u_x+e^{-x}\tilde{F}(t,\omega), \quad \omega=e^x(u_x+u_{xx});$$

$$A^5_{3,2}: \quad X_1=\partial_x-u\partial_u, \quad X_2=\partial_u, \quad X_3=\alpha(t)\partial_x, \quad \alpha\neq 0,$$

$$F=-\frac{\dot{\alpha}}{\alpha}u_x\ln(e^xu_x)+u_x\tilde{F}(t,\omega), \quad \omega=u_x^{-1}u_{xx};$$

$$A^6_{3,2}: \quad X_1=\partial_x-u\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_t,$$

$$F=e^{-x}\tilde{F}(\omega_1,\omega_2), \quad \omega_1=e^xu_x, \quad \omega_2=e^xu_{xx};$$

$$A^7_{3,2}: \quad X_1=\partial_t-u\partial_u, \quad X_2=\partial_u, \quad X_3=e^{-t}f(x)\partial_u, \quad f'\neq 0,$$

$$F=-\frac{f'''+f}{f'}u_x+e^{-t}\tilde{F}(x,\omega), \quad \omega=e^t(f''u_x-f'u_{xx});$$

$$A^8_{3,2}: \quad X_1=\partial_t-u\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_x,$$

$$F=e^{-t}\tilde{F}(\omega_1,\omega_2), \quad \omega_1=e^tu_x, \quad \omega_2=e^tu_{xx};$$

$$A^9_{3,2}: \quad X_1=\partial_t-u\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_t+\lambda\partial_x, \quad \lambda\neq 0,$$

$$F=\exp(x/t-\lambda)\tilde{F}(\omega_1,\omega_2),$$

$$\omega_1=\exp(t-x/\lambda)u_x, \quad \omega_2=\exp(t-x/\lambda)u_{xx};$$

$$A^{10}_{3,2}: \quad X_1=\partial_t-u\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_t,$$

$$F=u_x\tilde{F}(x,\omega),\quad \omega=u_x^{-1}u_{xx}.$$

2. Nondecomposable algebras

The isomorphy classes of these algebras are represented by the following list:

$$A_{3,3}:\quad [X_2,X_3]=X_1,\quad [X_1,X_2]=[X_1,X_3]=0;$$

$$A_{3,4}:\quad [X_1,X_3]=X_1,\quad [X_2,X_3]=X_1+X_2;$$

$$A_{3,5}:\quad [X_1,X_3]=X_1,\quad [X_2,X_3]=X_2;$$

$$A_{3,6}:\quad [X_1,X_3]=X_1,\quad [X_2,X_3]=-X_2;$$

$$A_{3,7}:\quad [X_1,X_3]=X_1,\quad [X_2,X_3]=qX_2\quad (0<|q|<1);$$

$$A_{3,8}:\quad [X_1,X_3]=-X_2,\quad [X_2,X_3]=X_1;$$

$$A_{3,9}:\quad [X_1,X_3]=qX_1-X_2,\quad [X_2,X_3]=X_1+qX_2,\quad q>0.$$

Remark: Solvable nondecomposable algebras can be written as semidirect sums of a one-dimensional subalgebra $\{X_3\}$ and an Abelian ideal $\{X_1,X_2\}$. Note that the algebras $A_{3,6}$ and $A_{3,8}$ are isomorphic to $\mathfrak{e}(1,1)$, and $\mathfrak{e}(2)$, respectively. The algebra $A_{3,3}$ is a non-Abelian nilpotent algebra (Heisenberg algebra).

The commutation relations of the algebras in question can be represented in the matrix notation

$$\begin{pmatrix}[X_1,X_3]\\ [X_2,X_3]\end{pmatrix}=J\begin{pmatrix}X_1\\ X_2\end{pmatrix},\quad [X_1,X_2]=0,$$

where J is a 2×2 real matrix that can be taken in Jordan canonical form.

A solvable three-dimensional Lie algebra always possesses a two-dimensional Abelian ideal. We assume that the ideal $\{X_1,X_2\}$ is already of the form (5.3) and add a third element X_3 in the form (2.4) acting on the ideal. Imposing commutation relations and simplifying with equivalence transformations (2.6) (we consider each canonical form of the matrix individually) yield the realizations of solvable Lie algebras together with the corresponding invariant equations.

There exist nine classes of realizations of nilpotent algebras which give rise to invariant equations:

$$A_{3,3}:\quad J=\begin{pmatrix}0 & 0\\ 1 & 0\end{pmatrix}. \tag{5.7}$$

$$A_{3,3}^1:\quad X_1=\partial_t,\quad X_2=\partial_u,\quad X_3=t\partial_u+\lambda\partial_x,\quad \lambda>0,$$

$$F=\frac{x}{\lambda}+\tilde{F}(u_x,u_{xx});$$

$$A_{3,3}^2:\quad X_1=\partial_u,\quad X_2=\partial_x,\quad X_3=x\partial_u+b(t)\partial_x,\quad \dot{b}\neq 0,$$

$$F=-\frac{\dot{b}}{2}u_x^2+\tilde{F}(t,u_{xx});$$

$$A_{3,3}^3:\quad X_1=\partial_u,\quad X_2=\partial_x,\quad X_3=x\partial_u+\lambda\partial_t,\quad \lambda\neq 0,$$

$$F=\tilde{F}(t-3\lambda u_x,u_{xx});$$

$$A^4_{3,3}:\quad X_1=\partial_u+3\lambda t^{1/2}\partial_x,\quad X_2=\partial_x,$$

$$X_3=6\lambda t^{3/2}\partial_t+3\lambda t^{1/2}x\partial_x+(x-3\lambda t^{1/2}u)\partial_u,\quad \lambda\neq 0,$$

$$F=-\tfrac{3}{2}\lambda t^{-1/2}uu_x+t^{-2}\tilde{F}(\omega_1,\omega_2),\quad \omega_1=tu_x-\frac{1}{3\lambda}t^{1/2},\quad \omega_2=t^{3/2}u_{xx};$$

$$A^5_{3,3}:\quad X_1=\partial_x,\quad X_2=\partial_t,\quad X_3=t\partial_x+\partial_u,$$

$$F=-uu_x+\tilde{F}(u_x,u_{xx});$$

$$A^6_{3,3}:\quad X_1=\partial_u,\quad X_2=(f(x)-t)\partial_u,\quad X_3=\partial_t,\quad (f'\neq 0),$$

$$F=-(1+f''')(f')^{-1}u_x+\tilde{F}(x,\omega),\quad \omega=f''u_x-f'u_{xx};$$

$$A^7_{3,3}:\quad X_1=\partial_u,\quad X_2=(t-x)\partial_u,\quad X_3=\partial_x,$$

$$F=u_x+\tilde{F}(t,u_{xx});$$

$$A^8_{3,3}:\quad X_1=\partial_u,\quad X_2=-x\partial_u,\quad X_3=\partial_x,$$

$$F=-\tilde{F}(t,u_{xx});$$

$$A^9_{3,3}:\quad X_1=-x^{-1}\partial_u,\quad X_2=\partial_u,\quad X_3=\partial_x-x^{-1}u\partial_u,$$

$$F=3x^{-1}u_{xx}+x^{-1}\tilde{F}(t,\omega),\quad \omega=2u_x+xu_{xx};$$

$$A_{3,4}:\quad J=\begin{pmatrix}1 & 0\\ 1 & 1\end{pmatrix};\tag{5.8}$$

$$A^1_{3,4}:\quad X_1=\partial_u,\quad X_2=\partial_t,\quad X_3=t\partial_t+\frac{x}{3}\partial_x+(u+t)\partial_u,$$

$$F=3\ln x+\tilde{F}(\omega_1,\omega_2),\quad \omega_1=x^{-2}u_x,\quad \omega_2=x^{-1}u_{xx};$$

$$A^2_{3,4}:\quad X_1=\partial_x,\quad X_2=\partial_u-\tfrac{1}{3}\ln t\partial_x,\quad X_3=3t\partial_t+x\partial_x+u\partial_u,$$

$$F=\frac{1}{3t}uu_x+t^{-2/3}\tilde{F}(u_x,\omega),\quad \omega=t^{1/3}u_{xx};$$

$$A^3_{3,4}:\quad X_1=\partial_u,\quad X_2=\partial_x,\quad X_3=3t\partial_t+x\partial_x+(u+x)\partial_u,$$

$$F=t^{-2/3}\tilde{F}(\omega_1,\omega_2),\quad \omega_1=u_x-\tfrac{1}{3}\ln t,\quad \omega_2=t^{1/3}u_{xx};$$

$$A^4_{3,4}:\quad X_1=\alpha(t)\partial_x+\partial_u,\quad X_2=\partial_x,$$

$$X_3=(\alpha')^{-1}\alpha^2\partial_t+(1+\alpha)x\partial_x+[x+(1-\alpha)u]\partial_u,\quad \alpha'\neq 0,$$

$$\alpha^2\alpha''+(3+\alpha)(\alpha')^2=0,$$

$$F=-\alpha' u u_x+\alpha^{-4}\exp(2\alpha^{-1})\tilde{F}(\omega_1,\omega_2),$$

$$\omega_1=\alpha^3\exp(-\alpha^{-1})u_{xx},\quad \omega_2=\alpha^2 u_x-\alpha;$$

$$A^5_{3,4}:\quad X_1=\partial_u,\quad X_2=(-t+f(x))\partial_u,\quad X_3=\partial_t+u\partial_u,\quad f'\neq 0,$$

$$F=-(1+f''')(f')^{-1}u_x+e^t\tilde{F}(x,\omega),\quad \omega=e^{-t}(f''u_x-f'u_{xx});$$

$$A^6_{3,4}:\quad X_1=\partial_u,\quad X_2=-x\partial_u,\quad X_3=\partial_x+u\partial_u,$$

$$F=e^x\tilde{F}(t,\omega),\quad \omega=e^{-x}u_{xx};$$

$$A_{3,5}:\quad J=\begin{pmatrix}1&0\\0&1\end{pmatrix};\tag{5.9}$$

$$A^1_{3,5}:\quad X_1=\partial_t,\quad X_2=\partial_u,\quad X_3=t\partial_t+\frac{x}{3}\partial_x+u\partial_u,$$

$$F=\tilde{F}(\omega_1,\omega_2),\quad \omega_1=x^{-2}u_x,\quad \omega_2=x^{-1}u_{xx};$$

$$A^2_{3,5}:\quad X_1=\partial_x,\quad X_2=\partial_u,\quad X_3=3t\partial_t+x\partial_x+u\partial_u,$$

$$F=t^{-2/3}\tilde{F}(u_x,t^{1/3}u_{xx});$$

$$A^3_{3,5}:\quad X_1=\partial_u,\ X_2=f(x)\partial_u,\quad X_3=\partial_t+u\partial_u,\ f'\neq 0,$$

$$F=-f'''(f')^{-1}u_x+e^t\tilde{F}(x,\omega),$$

$$\omega=e^{-t}[f''u_x-f'u_{xx}];$$

$$A_{3,6}:\quad J=\begin{pmatrix}1&0\\0&-1\end{pmatrix};\tag{5.10}$$

$$A^1_{3,6}:\quad X_1=\partial_t,\quad X_2=\partial_u,\quad X_3=t\partial_t+\frac{x}{3}\partial_x-u\partial_u,$$

$$F=x^{-6}\tilde{F}(x^4u_x,x^5u_{xx});$$

$$A^2_{3,6}:\quad X_1=\partial_x,\quad X_2=\partial_u+\lambda t^{2/3}\partial_x,\quad X_3=3t\partial_t+x\partial_x-u\partial_u,$$

$$F=-\frac{2\lambda}{3}t^{-1/3}uu_x+t^{-4/3}\tilde{F}(t^{2/3}u_x,tu_{xx});$$

$$A^3_{3,6}:\quad X_1=\partial_u,\quad X_2=e^{2t}f(x)\partial_u,\quad X_3=\partial_t+u\partial_u,\quad f'\neq 0,$$

$$F=(2f-f''')(f')^{-1}u_x+e^t\tilde{F}(x,\omega),\quad \omega=e^{-t}(f''u_x-f'u_{xx});$$

$$A^4_{3,6}:\quad X_1=\partial_u,\quad X_2=e^{2\int f^{-1}x}h(t)\partial_u,\quad X_3=f(t)\partial_x+u\partial_u,\quad fh\neq 0,$$

$$F=-[4f^{-2}-\tfrac{1}{2}hh^{-1}f+f^{-1}f'x]u_x+e^{\int f^{-1}x}\tilde{F}(t,\omega),$$

$$\omega = e^{-f^{-1}x}(2u_x - f u_{xx});$$

$$A_{3,7}: \quad J = \begin{pmatrix} 1 & 0 \\ 0 & q \end{pmatrix}, \quad 0 < |q| < 1; \tag{5.11}$$

$$A^1_{3,7}: \quad X_1 = \partial_t, \quad X_2 = \partial_x, \quad X_3 = t\partial_t + \frac{x}{3}\partial_x, \quad q = 1/3,$$

$$F = u_x^3 \tilde{F}(u, u_x^{-2} u_{xx});$$

$$A^2_{3,7}: \quad X_1 = \partial_t, \quad X_2 = \partial_x, \quad X_3 = t\partial_t + \frac{x}{3}\partial_x + u\partial_u, \quad q = 1/3,$$

$$F = \tilde{F}(\omega_1, \omega_2), \quad \omega_1 = u^{-2/3} u_x, \quad \omega_2 = u^{-1/3} u_{xx};$$

$$A^3_{3,7}: \quad X_1 = \partial_t, \quad X_2 = \partial_u, \quad X_3 = t\partial_t + \frac{x}{3}\partial_x + qu\partial_u, \quad q \neq 0, \pm 1,$$

$$F = x^{3(q-1)} \tilde{F}(\omega_1, \omega_2), \quad \omega_1 = x^{1-3q} u_x, \quad \omega_2 = x^{2-3q} u_{xx};$$

$$A^4_{3,7}: \quad X_1 = \partial_x, \quad X_2 = \partial_u + \lambda t^{(1-q)/3}\partial_x, \quad X_3 = 3t\partial_t + x\partial_x + qu\partial_u,$$

$$q \neq 0, \pm 1, \ \lambda \in \mathbb{R},$$

$$F = \frac{\lambda}{3}(q-1) t^{-(q+2)/3} u u_x + \tilde{F}(\omega_1, \omega_2),$$

$$\omega_1 = t^{-(q-1)/3} u_x, \quad \omega_2 = t^{-(q-2)/3} u_{xx};$$

$$A^5_{3,7}: \quad X_1 = \partial_u, \quad X_2 = e^{(1-q)t} f(x)\partial_u, \quad X_3 = \partial_t + u\partial_u, \quad f' \neq 0, \quad q \neq 0, \pm 1,$$

$$F = [(1-q)f - f'''](f')^{-1} u_x + e^t \tilde{F}(x, \omega),$$

$$\omega = e^{-t}[f'' u_x - f' u_{xx}];$$

$$A^6_{3,7}: \quad X_1 = \partial_u, \quad X_2 = e^{(1-q)f^{-1}(t)x} h(t)\partial_u,$$

$$X_3 = f(t)\partial_x + u\partial_u, \quad f \cdot h \neq 0, \quad q \neq 0, \ \pm 1,$$

$$F = -[(1-q)^2 f^2 + f^{-1} f' x - (1-q)^{-1} f h^{-1} h'] u_x + e^{f^{-1}x} \tilde{F}(t, \omega),$$

$$\omega = e^{-f^{-1}x}[(1-q)u_x - f u_{xx}].$$

Remark: The algebra $A_{3,7}$ has another realization,

$$\{X_1 = \partial_t, X_2 = \partial_x, X_3 = t\partial_t + \tfrac{1}{3}(x + b_0 t)\partial_x + u\partial_u\},$$

that is isomorphic to $A^2_{3,7}$ under the change of basis

$$X_1 \to X_1 + \frac{b_0}{2} X_2, \quad X_2 \to X_2, \quad X_3 \to X_3.$$

Note that its equivalence to the latter is established by the change of variables,

$$\tilde{t}=t, \quad \tilde{x}=x-\tfrac{1}{2}b_0 t, \quad \tilde{u}=u.$$

That is why we have excluded it from the above list:

$$A_{3,8}: \quad J=\begin{pmatrix} 1 & -1 \\ 1 & 0 \end{pmatrix}; \tag{5.12}$$

$$A^1_{3,8}: \quad X_1=\partial_x, \quad X_2=\alpha(t)\partial_x+\partial_u,$$

$$X_3=-\frac{1}{\dot{\alpha}}(1+\alpha^2)\partial_t-\alpha x\partial_x+(\alpha u-x)\partial_u,$$

$$F=-\dot{\alpha}uu_x+(1+\alpha^2)^{-2}\tilde{F}(\omega_1,\omega_2),$$

$$\omega_1=(1+\alpha^2)u_x-\alpha, \quad \omega_2=(1+\alpha^2)^{3/2}u_{xx},$$

where $\alpha(t)$, $\dot{\alpha}\neq 0$ satisfies

$$(1+\alpha^2)\ddot{\alpha}+\alpha\dot{\alpha}^2=0; \tag{5.13}$$

$$A_{3,9}: \quad J=\begin{pmatrix} q & -1 \\ 1 & q \end{pmatrix}, \quad q>0; \tag{5.14}$$

$$A^1_{3,9}: \quad X_1=\partial_x, \quad X_2=\alpha(t)\partial_x+\partial_u,$$

$$X_3=-\frac{1}{\dot{\alpha}}(1+\alpha^2)\partial_t+(q-\alpha)x\partial_x+[(q+\alpha)u-x]\partial_u,$$

$$F=-\dot{\alpha}uu_x+\exp\{2q\arctan\alpha\}(1+\alpha^2)^{-2}\tilde{F}(\omega_1,\omega_2),$$

$$\omega_1=(1+\alpha^2)u_x-\alpha, \quad \omega_2=(1+\alpha^2)^{3/2}\exp\{-q\arctan\alpha\}u_{xx},$$

where $\alpha(t)$, $\dot{\alpha}\neq 0$ satisfies

$$(1+\alpha^2)\ddot{\alpha}+(\alpha-3q)\dot{\alpha}^2=0. \tag{5.15}$$

Remark: $\alpha(t)$ can be obtained implicitly by quadratures as

$$\int^{\alpha}\exp(-3q\arctan\xi)(1+\xi^2)^{1/2}d\xi=c_1t+c_0.$$

Theorem 5.3: *There are thirty-eight inequivalent three-dimensional solvable symmetry algebras admitted by Eq. (1.1).*

VI. EQUATIONS WITH FOUR-DIMENSIONAL SOLVABLE ALGEBRAS

For $\dim L=4$, we proceed exactly in the same manner as above. We start from the already standardized three-dimensional algebras, and add a further linearly independent element X_4, and require that they form a Lie algebra.

A. Decomposable algebras

The list of decomposable four-dimensional Lie algebras consists of the twelve algebras: $4A_1=A_{3,1}\oplus A_1$, $A_{2,2}\oplus 2A_1=A_{3,2}\oplus A_1$, $2A_{2,2}=A_{2,2}\oplus A_{2,2}$, $A_{3,i}\oplus A_1$ $(i=3,4,\ldots,9)$. We preserve the notations of the previous section.

There are four inequivalent realizations of the algebra $2A_{2,2}$ which are invariance algebras of PDEs of the form (1.1). We give these realizations together with the corresponding invariant equations:

$$2A^1_{2,2}:\quad X_1=-t\partial_t-\frac{x}{3}\partial_x,\quad X_2=\partial_t,\quad X_3=\partial_u,\quad X_4=e^u\partial_u,$$

$$F=u_x^3-3u_xu_{xx}+x^{-2}u_x\tilde F(\omega),\quad \omega=x(u_x^{-1}u_{xx}-u_x);$$

$$2A^2_{2,2}:\quad X_1=-3t\partial_t-x\partial_x,\quad X_2=\partial_x,\quad X_3=-u\partial_u+\lambda t^{1/3}\partial_x,\quad X_4=\partial_u,$$

$$F=\frac{\lambda}{3t}\omega_1\ln|\omega_1|+\frac{\omega_1}{t}\tilde F(\omega),\quad \omega_1=t^{1/3}u_x,\quad \omega=t^{1/3}u_x^{-1}u_{xx};$$

$$2A^3_{2,2}:\quad X_1=\partial_x-u\partial_u,\quad X_2=\partial_u,\quad X_3=\frac{1}{\lambda}\partial_t,\quad X_4=\exp(\lambda t)\partial_x,$$

$$F=-\lambda xu_x-\lambda u_x\ln|u_x|+u_x\tilde F(\omega),\quad \omega=u_x^{-1}u_{xx};$$

$$2A^4_{2,2}:\quad X_1=\partial_x-u\partial_u,\quad X_2=\partial_u,\quad X_3=\lambda\partial_t,\quad X_4=e^{\lambda^{-1}t-x}\partial_u,\quad \lambda\neq 0,$$

$$F=(1+\lambda^{-1})u_x+e^{-x}\tilde F(\omega),\quad \omega=e^x(u_x+u_{xx});$$

$$2A^5_{2,2}:\quad X_1=\partial_t-u\partial_u,\quad X_2=\partial_u,\quad X_3=\beta(\partial_x+\gamma\partial_t)-\partial_t,$$

$$X_4=e^{\gamma x-t}\partial_u,\quad \beta\gamma\neq 0,$$

$$F=e^{(\gamma-\beta^{-1})x-t}\tilde F(\omega)-\gamma^{-1}(1+\gamma^3)u_x,$$

$$\omega=e^{t+(\beta^{-1}-\gamma)x}(\gamma u_x-u_{xx}).$$

Equations invariant under the algebra $A_{2,2}\oplus 2A_1=A_{3.2}\oplus A_1$:

$$A^6_{3,2}\oplus\{X_4\}:\quad X_1=\partial_x-u\partial_u,\quad X_2=\partial_u,\quad X_3=\partial_t,\quad X_4=e^{-x}\partial_u,$$

$$F=-u_x+e^{-x}\tilde F(\omega),\quad \omega=e^x(u_x+u_{xx});$$

$$A^6_{3,2}\oplus\{X_4\}:\quad X_1=\partial_x-u\partial_u,\quad X_2=\partial_u,\quad X_3=\partial_t,\quad X_4=\partial_x,$$

$$F=u_x\tilde F(\omega),\quad \omega=u_{xx}u_x^{-1};$$

$$A^7_{3,2}(f=e^{\lambda x},\ \lambda\neq 0)\oplus\{X_4\}:\quad X_1=\partial_t-u\partial_u,\quad X_2=\partial_u,$$

$$X_3=e^{\lambda x-t}\partial_u,\quad X_4=\partial_x+\lambda\partial_t,\quad \lambda\neq 0,$$

$$F=-(\lambda^3+1)\lambda^{-1}u_x+e^{-t+\lambda x}\tilde F(\omega),$$

$$\omega=e^{t-\lambda x}(\lambda u_x-u_{xx});$$

$$A^1_{3.3}\oplus\{X_4\}:\quad X_1=\partial_t,\quad X_2=\partial_u,\quad X_3=t\partial_u+\lambda\partial_x,$$

$$X_4=\partial_t+\lambda^{-1}x\partial_u+\beta\partial_x,\quad \lambda>0,\quad \beta\in\mathbb{R},$$

$$F=\lambda^{-1}x-\beta u_x+\tilde{F}(u_{xx});$$

$$A^3_{3,5}\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=\partial_x,\quad X_3=x\partial_u+\lambda\partial_t,\quad X_4=\partial_t+\beta(\partial_x+\lambda^{-1}t\partial_u),$$

$$\lambda\neq 0,\quad \beta\in\mathbb{R},\quad F=\beta(\lambda^{-1}t-3u_x)+\tilde{F}(u_{xx});$$

$$A^6_{3,5}(f=\lambda^{-1}x,\ \lambda\neq 0)\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=(\lambda^{-1}x-t)\partial_u,$$

$$X_3=\partial_t,\quad X_4=\partial_t+\lambda\partial_x,\quad \lambda\neq 0,$$

$$F=-u_x+\tilde{F}(u_{xx});$$

$$A^9_{3,5}\oplus\{X_4\}:\quad X_1=-x^{-1}\partial_u,\quad X_2=\partial_u,\quad X_3=\partial_x-x^{-1}u\partial_u,\quad X_4=\partial_t,$$

$$F=3x^{-1}u_{xx}+x^{-1}\tilde{F}(\omega),\quad \omega=2u_x+xu_{xx};$$

$$A^1_{3,4}\oplus\{X_4\}:\quad X_1=\partial_u,\ X_2=\partial_t,$$

$$X_3=t\partial_t+\tfrac{1}{3}x\partial_x+(u+t)\partial_u,\quad X_4=x^3\partial_u,$$

$$F=3\ln x-2x^{-2}u_x+\tilde{F}(\omega),\ \omega=x^{-1}u_{xx}-2x^{-2}u_x;$$

$$A^5_{3,4}\ (f=\lambda x,\ \lambda\neq 0)\oplus\{X_4\}:\quad X_1=\partial_u,$$

$$X_2=(-t+\lambda x)\partial_u,\quad X_3=\partial_t+u\partial_u,$$

$$X_4=\partial_x+\lambda\partial_t,\quad \lambda\neq 0,$$

$$F=-\lambda^{-1}u_x+e^{t-\lambda x}\tilde{F}(\omega),\ \omega=e^{-t+\lambda x}u_{xx};$$

$$A^6_{3,4}\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=-x\partial_u,$$

$$X_3=\partial_x+u\partial_u,\quad X_4=\partial_t,$$

$$F=e^x\tilde{F}(\omega),\quad \omega=e^{-x}u_{xx};$$

$$A^1_{3,5}\oplus\{X_4\}:\quad X_1=\partial_t,\quad X_2=\partial_u,$$

$$X_3=t\partial_t+\frac{x}{3}\partial_x+u\partial_u,\quad X_4=x^3\partial_u,$$

$$F=-2x^{-2}u_x+\tilde{F}(\omega),\quad \omega=x^{-1}u_{xx}-2x^{-2}u_x;$$

$$A^1_{3,6}\oplus\{X_4\}:\quad X_1=\partial_t,\quad X_2=\partial_u,$$

$$X_3=t\partial_t+\frac{x}{3}\partial_x-u\partial_u,\quad X_4=x^{-3}\partial_u,$$

$$F=-20x^{-2}u_x+x^{-6}\tilde{F}(\omega),\quad \omega=4x^4u_x-x^5u_{xx},$$

$$A^3_{3,6}(f=e^{-2\beta^{-1}x},\ \beta\neq 0)\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=e^{2(t-\beta^{-1}x)}\partial_u,$$

$$X_3=\partial_t+u\partial_u,\quad X_4=\partial_t+\beta\partial_x,\quad \beta\neq 0,$$

$$F=-(\beta+4\beta^{-2})u_x+e^{t-\beta^{-1}x}\tilde{F}(\omega),$$

$$\omega=e^{-t+\beta^{-1}x}(2u_x+\beta u_{xx});$$

$$A^4_{3,6}(f=h=1)\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=e^{2x}\partial_u,$$

$$X_3=\partial_x+u\partial_u,\quad X_4=\partial_t,$$

$$F=-4u_x+e^{x}\tilde{F}(\omega),\quad \omega=e^{-x}(2u_x-u_{xx});$$

$$A^1_{3,7}\oplus\{X_4\}:\quad X_1=\partial_t,\quad X_2=\partial_x,$$

$$X_3=t\partial_t+\tfrac{1}{3}x\partial_x,\quad X_4=u\partial_u,$$

$$F=u^{-2}u_x^3\tilde{F}(\omega),\quad \omega=u_x^{-2}uu_{xx};$$

$$A^3_{3,7}\oplus\{X_4\}:\quad X_1=\partial_t,\quad X_2=\partial_u,$$

$$X_3=t\partial_t+\frac{x}{3}\partial_x+qu\partial_u,\quad X_4=x^{3q}\partial_u,$$

$$q\neq 0,\ \pm 1,$$

$$F=-(3q-1)(3q-2)x^{-2}u_x+x^{3(q-1)}\tilde{F}(\omega),$$

$$\omega=x^{1-3q}[(3q-1)u_x-xu_{xx}];$$

$$A^5_{3,7}(f=e^{-1(1-q)\beta^{-1}x},\beta\neq 0)\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=e^{(1-q)(t-\beta^{-1}x)}\partial_u,\quad X_3=\partial_t+u\partial_u,$$

$$X_4=\partial_t+\beta\partial_x,\quad \beta\neq 0,\ q\neq 0,\ \pm 1,$$

$$F=-[\beta+(1-q)^2\beta^{-2}]u_x+e^{t-\beta^{-1}x}\tilde{F}(\omega),$$

$$\omega=e^{-t+\beta^{-1}x}[(1-q)u_x+\beta u_{xx}];$$

$$A^6_{3,7}(f=h=1)\oplus\{X_4\}:\quad X_1=\partial_u,\quad X_2=e^{(1-q)x}\partial_u,$$

$$X_3=\partial_x+u\partial_u,\quad X_4=\partial_t,\quad q\neq 0,\ \pm 1,$$

$$F=-(1-q)^2u_x+e^{x}\tilde{F}(\omega),$$

$$\omega=e^{-x}[(1-q)u_x-u_{xx}].$$

Remark: The $A^1_{3,7}\oplus A_1$ invariant equation is

$$u_t = u_{xxx} + \frac{u_x^3}{u^2}\tilde{F}(\omega), \quad \omega = \frac{uu_{xx}}{u_x^2}. \tag{6.1}$$

If, in particular, $\tilde{F} = c\omega^2$, $c = \text{const}$, namely,

$$F = cu_x^{-1}u_{xx}^2, \tag{6.2}$$

the symmetry algebra is further extended by $X_5 = \partial_u$ to a five-dimensional one.

B. Nondecomposable algebras

The set of inequivalent abstract four-dimensional Lie algebras contains ten real nondecomposable Lie algebras $A_{4,i} = \{X_1, X_2, X_3, X_4\}$ $(i = 1,\ldots,10)$.[4,5] They are all solvable and therefore can be written as semidirect sums of a one-dimensional Lie algebra $\{X_4\}$ and a three-dimensional ideal $N = \{X_1, X_2, X_3\}$. For $A_{4,i}$ $(i = 1,\ldots,6)$, N is Abelian, for $A_{4,7}, A_{4,8}, A_{4,9}$ it is of type $A_{3,3}$ (nilpotent), and for $A_{4,10}$ it is of the type $A_{3,5}$. The nonzero commutation relations read as

$$A_{4,1}: \quad [X_2, X_4] = X_1, \quad [X_3, X_4] = X_2;$$

$$A_{4,2}: \quad [X_1, X_4] = qX_1, \quad [X_2, X_4] = X_2,$$

$$[X_3, X_4] = X_2 + X_3, \quad q \neq 0;$$

$$A_{4,3}: \quad [X_1, X_4] = X_1, \quad [X_3, X_4] = X_2;$$

$$A_{4,4}: \quad [X_1, X_4] = X_1, \quad [X_2, X_4] = X_1 + X_2,$$

$$[X_3, X_4] = X_2 + X_3;$$

$$A_{4,5}: \quad [X_1, X_4] = X_1, \quad [X_2, X_4] = qX_2,$$

$$[X_3, X_4] = pX_3, \quad -1 \leqslant p \leqslant q \leqslant 1, \quad pq \neq 0;$$

$$A_{4,6}: \quad [X_1, X_4] = qX_1, \quad [X_2, X_4] = pX_2 - X_3,$$

$$[X_3, X_4] = X_2 + pX_3, \quad q \neq 0, \quad p \geqslant 0;$$

$$A_{4,7}: \quad [X_2, X_3] = X_1, \quad [X_1, X_4] = 2X_1,$$

$$[X_2, X_4] = X_2, \quad [X_3, X_4] = X_2 + X_3;$$

$$A_{4,8}: \quad [X_2, X_3] = X_1, \quad [X_1, X_4] = (1+q)X_1,$$

$$[X_2, X_4] = X_2, \quad [X_3, X_4] = qX_3, \quad |q| \leqslant 1;$$

$$A_{4,9}: \quad [X_2, X_3] = X_1, \quad [X_1, X_4] = 2qX_1,$$

$$[X_2, X_4] = qX_2 - X_3, \quad [X_3, X_4] = X_2 + qX_3, \quad q \geqslant 0;$$

$$A_{4,10}: \quad [X_1, X_3] = X_1, \quad [X_2, X_3] = X_2,$$

$$[X_1, X_4] = -X_2, \quad [X_2, X_4] = X_1.$$

In order to obtain realizations of solvable four-dimensional symmetry algebras of PDEs that belong to the class (1.1), we add X_4 in the generic form (2.4) to the already constructed three-

dimensional symmetry algebras and impose the above commutation relations. Once the algebra is found we insert X_4 into Eq. (2.5) and solve it for the function F. The form of F which is invariant under a three-dimensional algebra is further restricted:

$$A^1_{4,1}: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=\partial_t, \quad X_4=t\partial_x+x\partial_u,$$

$$F=-\tfrac{1}{2}u_x^2+\tilde{F}(u_{xx});$$

$$A^2_{4,1}: \quad X_1=\partial_u, \quad X_2=x\partial_u, \quad X_3=\partial_t, \quad X_4=\partial_x+tx\partial_u,$$

$$F=\tfrac{1}{2}x^2+\tilde{F}(u_{xx});$$

$$A^1_{4,2}: \quad X_1=\partial_t, \quad X_2=\partial_u, \quad X_3=\partial_x, \quad X_4=3t\partial_t+x\partial_x+(x+u)\partial_u,$$

$$F=u_{xx}^2\tilde{F}(e^{u_x}u_{xx});$$

$$A^2_{4,2}: \quad X_1=\partial_x, \quad X_2=\partial_u, \quad X_3=\partial_t, \quad X_4=t\partial_t+\frac{x}{3}\partial_x+(t+u)\partial_u,$$

$$F=\frac{3}{2}\ln|u_x|+\tilde{F}(\omega), \quad \omega=\frac{u_{xx}^2}{u_x};$$

$$A^3_{4,2}: \quad X_1=\partial_t, \quad X_2=\partial_u, \quad X_3=-3q^{-1}\ln x\partial_u,$$

$$X_4=qt\partial_t+\tfrac{1}{3}qx\partial_x+u\partial_u, \quad q\neq 0,$$

$$F=-2x^{-2}u_x+x^{3(q^{-1}-1)}\tilde{F}(\omega), \quad \omega=x^{1-3q^{-1}}u_x+x^{2-3q^{-1}}u_{xx};$$

$$A^4_{4,2}: \quad X_1=x^{3(1-q)}\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_t,$$

$$X_4=t\partial_t+\tfrac{1}{3}x\partial_x+(u+t)\partial_u, \quad q\neq 0,1,$$

$$F=-(2-3q)(1-3q)x^{-2}u_x+3\ln x+\tilde{F}(\omega), \quad \omega=(2-3q)x^{-2}u_x-x^{-1}u_{xx};$$

$$A^1_{4,3}: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=\partial_t, \quad X_4=t\partial_x+u\partial_u,$$

$$F=-u_x\ln|u_x|+u_x\tilde{F}\left(\frac{u_{xx}}{u_x}\right);$$

$$A^2_{4,3}: \quad X_1=\partial_t, \quad X_2=\partial_u, \quad X_3=-3\ln x\partial_u,$$

$$X_4=t\partial_t+\tfrac{1}{3}x\partial_x,$$

$$F=-2x^{-2}u_x+x^{-3}\tilde{F}(\omega), \quad \omega=xu_x+x^2u_{xx};$$

$$A^3_{4,3}: \quad X_1=\partial_u, \quad X_2=e^x\partial_u, \quad X_3=\partial_t,$$

$$X_4=\partial_x+(u+te^x)\partial_u;$$

$$F=-u_x+xe^x+e^x\tilde{F}(\omega), \quad \omega=e^{-x}(u_x-u_{xx});$$

$$A^1_{4,4}: \quad X_1=\partial_u,\ X_2=-3\ln x\,\partial_u,\ X_3=\partial_t,$$

$$X_4=t\partial_t+\tfrac{1}{3}x\partial_x+(u-3t\ln x)\partial_u;$$

$$A^1_{4,5}: \quad X_1=\partial_t, \quad X_2=\partial_x, \quad X_3=\partial_u, \quad X_4=t\partial_t+\frac{x}{3}\partial_x+ku\partial_u, \quad k\neq 0,\ \frac{1}{3},$$

$$F=u_x^{3(1-k)/(1-3k)}\tilde{F}(\omega), \quad \omega=u_x^{(3k-2)/(1-3k)}u_{xx};$$

$$A^2_{4,5}: \quad X_1=\partial_t, \quad X_2=\partial_x, \quad X_3=\partial_u,$$

$$X_4=t\partial_t+\frac{x}{3}\partial_x+\frac{u}{3}\partial_u,$$

$$F=u_{xx}^2\tilde{F}(u_{xx});$$

$$A^3_{4,5}: \quad X_1=\partial_t, \quad X_2=u, \quad X_3=x^{3(q-p)}\partial_u,$$

$$X_4=t\partial_t+\tfrac{1}{3}x\partial_x+qu\partial_u, \quad q\neq p, \quad q\cdot p\neq 0,$$

$$F=-[3(q-p)-1][3(q-p)-2]x^{-2}u_x+x^{3(q-1)}\tilde{F}(\omega),$$

$$\omega=[3(q-p)-1]x^{1-3q}u_x-x^{2-3q}u_{xx};$$

$$A^1_{4,7}: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=x\partial_u-\tfrac{1}{3}\ln t\partial_x, \quad X_4=3t\partial_t+x\partial_x+2u\partial_u,$$

$$F=\frac{1}{6t}u_x^2+t^{-1/3}\tilde{F}(u_{xx});$$

$$A^2_{4,7}: \quad X_1=\partial_u, \quad X_2=x\partial_u+b\partial_x, \quad X_3=-\partial_x,$$

$$X_4=-b^2(b')^{-1}\partial_t+(1-b)x\partial_x+(2u-\tfrac{1}{2}x^2)\partial_u, \quad b=b(t),\ b'\neq 0,$$

$$b^2b''+(b-3)(b')^2=0,$$

$$F=-\tfrac{1}{2}b'u_x^2+b^{-3}e^{-b^{-1}}\tilde{F}(\omega), \quad \omega=b^2u_{xx}-b;$$

$$A^3_{4,7}: \quad X_1=\partial_u, \quad X_2=(\lambda x^3-t)\partial_u, \quad X_3=\partial_t,$$

$$X_4=t\partial_t+\tfrac{1}{3}x\partial_x+(2u-\tfrac{1}{2}t^2+\lambda tx^3)\partial_u, \quad \lambda\neq 0,$$

$$F=-\tfrac{1}{3}\lambda^{-1}(1+6\lambda)x^{-2}u_x+3\lambda x^3\ln x+x^3\tilde{F}(\omega), \quad \omega=2x^{-5}u_x-x^{-4}u_{xx};$$

$$A^4_{4,7}: \quad X_1=\partial_u, \quad X_2=(t-x)\partial_u, \quad X_3=\partial_x,$$

$$X_4=3t\partial_t+(x+2t)\partial_x+\left(xt-\frac{x^2}{2}+2u\right)\partial_u,$$

$$F=-u_x+t^{-1/3}\tilde{F}(\omega)+\frac{t}{4}, \quad \omega=u_{xx}+\frac{1}{3}\ln t;$$

$$A_{4,7}^5: \quad X_1=\partial_u, \quad X_2=-x\partial_u, \quad X_3=\partial_x,$$

$$X_4=3t\partial_t+x\partial_x+\left(2u-\frac{x^2}{2}\right)\partial_u,$$

$$F=t^{-1/3}\tilde{F}(\omega), \quad \omega=u_{xx}+\tfrac{1}{3}\ln t;$$

$$A_{4,7}^6: \quad X_1=-x^{-1}\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_x-x^{-1}u\partial_u,$$

$$X_4=3t\partial_t+x\partial_x+(u+\tfrac{1}{2}x)\partial_u,$$

$$F=3x^{-1}u_{xx}+x^{-1}t^{-1/3}\tilde{F}(\omega), \quad \omega=2u_x+xu_{xx}-\tfrac{1}{3}\ln t;$$

$$A_{4,8}^1: \quad X_1=\partial_x, \quad X_2=\partial_t, \quad X_3=t\partial_x+\partial_u, \quad X_4=t\partial_t+\frac{x}{3}\partial_x-\frac{2}{3}u\partial_u,$$

$$F=-uu_x+u_x^{5/3}\tilde{F}(u_x^{-4/3}u_{xx});$$

$$A_{4,8}^2: \quad X_1=\partial_u, \quad X_2=\partial_t, \quad X_3=t\partial_u+\lambda\partial_x, \quad X_4=t\partial_t+\frac{x}{3}\partial_x+\frac{4}{3}u\partial_u,$$

$$F=\frac{x}{\lambda}+u_x^{1/3}\tilde{F}(\omega), \quad \omega=u_x^{-2/3}u_{xx}, \quad \lambda>0;$$

$$A_{4,8}^3: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=x\partial_u+\lambda t^{(1-q)/3}\partial_x,$$

$$X_4=3t\partial_t+x\partial_x+(1+q)u\partial_u, \quad q\in\mathbb{R},$$

$$F=\frac{\lambda(q-1)}{6}t^{-(2+q)/3}u_x^2+t^{(q-2)/3}\tilde{F}(\omega), \quad \omega=t^{(1-q)/3}u_{xx}, \quad \lambda\neq 0, \quad |q|\neq 1;$$

$$A_{4,8}^4: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=x\partial_u+\lambda\partial_t,$$

$$X_4=3t\partial_t+x\partial_x+4u\partial_u, \quad \lambda\neq 0,$$

$$F=(t-3\lambda u_x)^{1/3}\tilde{F}(\omega), \quad \omega=u_{xx}^3(t-3\lambda u_x)^2;$$

$$A_{4,8}^5: \quad X_1=\partial_u, \quad X_2=(\lambda x^3-t)\partial_u, \quad X_3=\partial_t,$$

$$X_4=qt\partial_t+\tfrac{1}{3}qx\partial_x+(1+q)u\partial_u, \quad \lambda\cdot q\neq 0,$$

$$F=-\tfrac{1}{3}\lambda^{-1}(1+6\lambda)x^{-2}u_x+x^{3q^{-1}}\tilde{F}(\omega), \quad \omega=2x^{-(2+3q^{-1})}u_x-x^{-(1+3q^{-1})}u_{xx};$$

$$A_{4,8}^6: \quad X_1=\partial_u, \quad X_2=(t-x)\partial_u, \quad X_3=\partial_x,$$

$$X_4=3qt\partial_t+q(x+2t)\partial_x+(1+q)u\partial_u,$$

$$F=-u_x+t^{(1/3)(1-2q)q^{-1}}\tilde{F}(\omega), \quad \omega=t^{(1/3)(q-1)q^{-1}}u_{xx};$$

$$A_{4,8}^7: \quad X_1=-x^{-1}\partial_u, \quad X_2=\partial_u, \quad X_3=\partial_x-x^{-1}u\partial_u,$$

$$X_4=3qt+qx\partial_x+u\partial_u, \quad q\neq 0,$$

$$F=3x^{-1}u_{xx}+x^{-1}t^{(1/3)(q-1)q^{-1}}\tilde{F}(\omega), \quad \omega=t^{(1/3)(q-1)q^{-1}}(2u_x+xu_{xx});$$

$$A^8_{4,8}: \quad X_1=\partial_u, \quad X_2=-x\partial_u, \quad X_3=x\partial_x, \quad X_4=3qt\partial_t+qx\partial_x+(1+q)u\partial_u,$$

$$F=t^{(1/3)(1-2q)q^{-1}}\tilde{F}(\omega), \quad \omega=t^{(1/3)(q-1)q^{-1}}u_{xx}.$$

Remarks:

- There exists a realization of $A_{4,6}$:

$$A^1_{4,6}: \quad X_1=\partial_t, \quad X_2=\tan\psi\partial_u, \quad X_3=\partial_u,$$

$$X_4=2t\partial_t+\tfrac{2}{3}x\partial_x+[p+\tan\psi]u\partial_u,$$

$$\psi=\tfrac{3}{2}\ln x, \quad p\in\mathbb{R}.$$

However there are no equations that can be invariant under this algebra.

- The algebra $A^1_{4,8}$ is isomorphic to the KdV algebra which is the semidirect sum of the nilradical (maximal nilpotent ideal) $\mathfrak{h}(2)=\{X_1,X_2,X_3\}$ and the dilation $D=\{X_4\}$:

$$A^1_{4,9}: \quad X_1=\partial_u, \quad X_2=\partial_x, \quad X_3=\alpha(t)\partial_x+x\partial_u,$$

$$X_4=-\frac{(1+\alpha^2)}{\dot{\alpha}}\partial_t+(q-\alpha)x\partial_x+\left(2qu-\frac{x^2}{2}\right)\partial_u, \quad q\in\mathbb{R},$$

$$F=-\tfrac{1}{2}\dot{\alpha}u_x^2+(1+\alpha^2)^{-3/2}\exp(q\arctan\alpha)\tilde{F}(\omega), \quad \omega=(1+\alpha^2)u_{xx}-\alpha,$$

$$(1+\alpha^2)\ddot{\alpha}+(\alpha-3q)\dot{\alpha}^2=0.$$

The function $\alpha(t)$, $\dot{\alpha}\neq 0$ is a solution of the ordinary differential equation (5.15):

$$A^1_{4,10}: \quad X_1=\partial_u, \quad X_2=-\tan x\partial_u, \quad X_3=\partial_t+u\partial_u,$$

$$X_4=\beta\partial_t+\partial_x+u\tan x\partial_u, \quad \beta\in\mathbb{R},$$

$$F=-2u_x-3\tan xu_{xx}+e^{t-\beta x}\sec x\tilde{F}(\omega),$$

$$\omega=e^{\beta x-t}(\cos xu_{xx}-2\sin xu_x).$$

We sum up the above results as a theorem.

Theorem 6.1: *There exist fifty-two inequivalent four-dimensional symmetry algebras admitted by Eq. (1.1). The explicit forms of those algebras as well as the associated invariant equations are given above.*

VII. DISCUSSION AND CONCLUSIONS

In this paper we provide a symmetry classification of the KdV type equations involving an arbitrary function of five arguments. We find that the equivalence classes of invariant equations involve an arbitrary function of four, three, two variables and one variable as soon as the symmetry algebra is one-, two-, three- and four-dimensional, respectively. In particular, we studied symmetries of the most general third order linear evolution equation. What came out from this, to our surprise, is that the symmetry group allowed is four-dimensional at most, while there are

nonlinear equations with symmetry algebras greater than four. This result is in contrast to the second-order evolution equations. It is exactly the linear heat equation that allows for the maximal symmetry algebra.

To complete the classification list, it only remains to obtain the inequivalent equations invariant under solvable algebras of the dimension $\dim L \geqslant 5$. But this would require to going through a large number of isomorphism classes. To give an idea of the complexity of this task let us recall that there are sixty-six classes of nonisomorphic real, solvable Lie algebras of dimension five. For dimension six, there exist ninety-nine classes of them with a nilpotent element. We plan to devote a separate article to study equations admitting higher-dimensional symmetry algebras.

Whenever F is an arbitrary function of its arguments, the symmetry algebras given in the paper are maximal. In particular, if we impose the requirement that function F is be independent of u_{xx} then we find that $\phi = R(t)u + S(x,t)$ in (2.4). In this case, invariance under four-dimensional algebras will force F to depend on an arbitrary constant rather than on an arbitrary function. Then, they may admit symmetry groups of the dimension higher than four. We have analyzed this restricted class of equations and obtained that the only equation whose symmetry algebra is higher than four is the one corresponding to the realization $A^1_{4,1}$ for $\tilde{F} = \text{const}$. On the other hand, for the specific choices of $\tilde{F}$ involving one variable, the equations with four-dimensional symmetry algebras may be invariant under larger symmetry groups. For instance, the particular case of the equation invariant under $A^1_{4,1}$ obtained by setting $\tilde{F} = c u_{xx}^{4/3}$, $c = \text{const}$ admits an additional symmetry group generated by the dilation operator $X_5 = 3t\partial_t + x\partial_x - u\partial_u$.

We only presented representative lists of equivalence classes of invariant equations. All other invariant equations can be recovered from these lists by applying the point transformations (2.6). In other words, an equation in the class (1.1) will have a symmetry group with dimension satisfying $\dim L \leqslant 6$ if and only if it can be transformed to one in the (canonical) equations from the list.

As we mentioned, our classification is performed within point transformations of coordinates. Two equations are equivalent if one can be obtained from the other by a change of variables. On the other hand, consider a special case of (6.2) for $c = -3/4$,[24]

$$u_t = u_{xxx} - \frac{3}{4}\frac{u_{xx}^2}{u_x},$$

which additionally allows a symmetry group generated by $\{\partial_u\}$. Though this equation is equivalent to the third-order linear equation $v_t = v_{xxx}$ under the (no-point) transformation $v = \sqrt{u_x}$, we treat them as inequivalent.

To give a reader an insight into possible applications of the results of this article, we consider a subclass of Eqs. (1.1),

$$u_t = u_{xxx} + uu_x + f(t)u, \tag{7.1}$$

which arises in several physical applications such as the propagation of waves in shallow water of variable depth.

When $f(t)$ is arbitrary, (7.1) admits a two-dimensional Abelian symmetry algebra generated by

$$X_1 = \partial_x, \quad X_2 = \xi(t)\partial_x - \dot{\xi}(t)\partial_u, \quad \xi = \int \exp\left\{\int f(t)\ dt\right\}\ dt. \tag{7.2}$$

By the change of dependent variable $\tilde{u} = u/\dot{\xi}$, the generators are transformed to the realization $A^3_{2,1}$ with $\alpha = -\xi$. The corresponding invariant equation takes the form

$$\tilde{u}_t = \tilde{u}_{xxx} + \dot{\xi}\tilde{u}\tilde{u}_x,$$

which is a particular case of (1.2).

For the special case $f(t)=at^k$ $(a\neq 0)$, the algebra is larger and we have the following possibilities for the algebra to be either three- or four-dimensional.

(1) $(a,k)=(a,-1)$, $a\neq -1$: The equation admits the three-dimensional indecomposable solvable symmetry algebra spanned by

$$X_1=\partial_x,\quad X_2=t^{1+a}\partial_x-(1+a)t^a\partial_u,\quad X_3=t\partial_t+\frac{x}{3}\partial_x-\frac{2}{3}u\partial_u, \tag{7.3}$$

with nonzero commutation relations

$$[X_1,X_3]=-\frac{1}{3}X_1,\quad [X_2,X_3]=-\frac{3a+2}{3}X_2.$$

For $a=-1/3$, the algebra is isomorphic, up to the scaling of basis elements, to $A_{3,5}$, for $-1<a<-\frac{1}{3}$, to $A_{3,7}$.

For $a=-2/3$ it is isomorphic to the decomposable solvable algebra $A_{3,2}$ and a suitable basis is

$$X_1=\partial_x,\quad X_2=t^{1/3}\partial_x-\frac{1}{3}t^{-2/3}\partial_u,\quad X_3=t\partial_t+\frac{x}{3}\partial_x-\frac{2}{3}u\partial_u.$$

With the equivalence transformation

$$\tilde{t}=t,\quad \tilde{x}=x,\quad \tilde{u}=-3t^{2/3}u,$$

the basis elements are transformed, up to scaling, to the realization $A^3_{3,2}$. The transformed equation is

$$\tilde{u}_t=\tilde{u}_{xxx}-\tfrac{1}{3}t^{-2/3}\tilde{u}\tilde{u}_x.$$

This equation belongs to the class corresponding to the realization $A^3_{3,2}$.

We note that a member of (1.2) for $f=1$, $g=t^2$ (see Ref. 1) is equivalent, under appropriate point transformation, to the above equation. Similarly, the particular case $a=-\alpha/(1+\alpha)$, $\alpha\neq 0,1,2$ is equivalent to $f=1$, $g=t^\alpha$ of (1.2). In this case, the symmetry algebra is indecomposable and solvable.

(2) $(a,k)=(-1,-1)$: the spherical KdV (sKdV) equation.

In this case the equation is invariant with respect to a three-dimensional symmetry algebra. We choose its basis to be

$$X_1=\partial_x,\quad X_2=\ln t\partial_x-\frac{1}{t}\partial_u,\quad X_3=t\partial_t+\frac{x}{3}\partial_x-\frac{2}{3}u\partial_u, \tag{7.4}$$

with nonzero commutation relations

$$[X_3,X_1]=-\tfrac{1}{3}X_1,\quad [X_3,X_2]=X_1-\tfrac{1}{3}X_2.$$

It is easy to see that this algebra is isomorphic to $A_{3,4}$. Under the transformation $\tilde{u}=3tu$, the generators are transformed to the realization $A^2_{3,4}$. The sKdV equation takes the form

$$\tilde{u}_t=\tilde{u}_{xxx}+\frac{1}{3t}\tilde{u}\tilde{u}_x,$$

which is a particular case of the equation invariant under the algebra $A^2_{3,4}$.

We note that a member of (1.2) for $f=1$, $g=e^{3t1}$ is equivalent to the case (2), i.e. the sKdV equation.

(3) $(a,k)=(a,0)$: The basis of the symmetry algebra reads as

$$X_1=\partial_x, \qquad X_2=e^{at}(\partial_x-a\partial_u), \quad X_3=\partial_t, \tag{7.5}$$

with nonzero commutation relation $[X_3,X_2]=aX_2$. The algebra is isomorphic to $A_{3,2}$. With the transformation $\tilde{u}=e^{-at}u$ the equation is transformed to a special case of (1.2) for $f=1,g=e^{at}$.

(4) $(a,k)=(-1/2,-1)$: the cylindrical KdV (cKdV) equation.

In this case the symmetry algebra is four-dimensional. In a convenient basis we have

$$X_1=2\sqrt{t}\partial_x-\frac{1}{\sqrt{t}}\partial_u,$$

$$X_2=4t^{3/2}\partial_t+2x\sqrt{t}\partial_x-\left(\frac{x}{\sqrt{t}}+4\sqrt{t}u\right)\partial_u, \tag{7.6}$$

$$X_3=\partial_x, \quad X_4=3t\partial_t+x\partial_x-2u\partial_u,$$

with nonzero commutation relations

$$[X_2,X_3]=-X_1, \quad [X_1,X_4]=-\tfrac{1}{2}X_1, \quad [X_2,X_4]=-\tfrac{3}{2}X_2, \quad [X_3,X_4]=X_3.$$

We see that the symmetry algebra of the cKdV equation is isomorphic to the algebra $A_{4,8}$ with $q=1$. The existence of such an isomorphism is a necessary, but not sufficient condition for a local point transformation to exist, transforming the two equations into each other. Comparing these generators with (2.10) and choosing (2.8) suitably, for example, first transforming the commuting elements $\{X_1,X_3\}$ into $\{\partial_{\tilde{x}},\tilde{t}\partial_{\tilde{x}}+\partial_{\tilde{u}}\}$ and then transforming the remaining ones with the aid of the freedom left in equivalence transformations we arrive at

$$\tilde{t}=2t^{-1/2}, \quad \tilde{x}=t^{-1/2}x, \quad \tilde{u}=tu+\frac{x}{2},$$

which establishes the equivalence of the Lie algebra with basis (7.6) and the cKdV equation to the KdV algebra ($A^1_{4,8}$) and KdV equation. This connection between the KdV and cKdV equations is well-known in the literature.[19]

As a further comparison of the results obtained in the article we consider

$$u_t+u_{xxx}+f(u)u_x^k=0, \quad k>0, \tag{7.7}$$

which is clearly a special case of (1.1). Group classification of this equation is given in a table (see Table II).[22] These results can immediately be derived from those obtained in this paper either directly or performing a change of independent or dependent variables.

Note that the equations that do not appear in the classification list can be recovered from those by suitable point transformations.

A number of integrable KdV type equations can be reproduced by restricting the arbitrary functions contained in invariant equations of this article. For example, the realization $A^2_{3,7}$ is equivalent to $\{\partial_t,\partial_x,t\partial_t+x/3\partial_x-u/3\partial_u\}$ under the transformation $u\to u^{-1/3}$. We have the invariant function

$$F=u^4\tilde{F}(\omega_1,\omega_2), \quad \omega_1=u^{-2}u_x, \quad \omega_2=u^{-3}u_{xx}.$$

Setting $\tilde{F}=\omega_1$ produces the modified KdV (mKdV) equation

TABLE II. Symmetry classification of (7.7).

10	1	e^u+c	$\partial_t,\partial_x,t\partial_t+\frac{1}{3}(\partial_x+2ct)\partial_x-\frac{2}{3}\partial_u$	$A_{3,7}^2$
11	1	1	$\partial_t,\partial_x,t\partial_t+\frac{1}{3}(x+2t)\partial_x,u\partial_u,g(x,t)\partial_u$ $g_t+g_{xxx}+g_x=0$	Linear equation ($N=6$ in Table I)

$$u_t=u_{xxx}+u^2u_x. \tag{7.8}$$

Since the maximal symmetry algebra of the mKdV equation is three-dimensional, it is not isomorphic to the KdV algebra. This implies that there is no point transformation, transforming the mKdV equation into KdV equation. In this respect let us mention that there is the well-known nonlocal transformation (Miura transformation),

$$\tilde{u}=u^2\pm\sqrt{6}iu_x,$$

taking the mKdV (7.8) into the KdV equation $\tilde{u}_t=\tilde{u}_{xxx}+\tilde{u}\tilde{u}_x$. Another integrable equation which can be obtained from our classification is[23]

$$u_t=u_{xxx}+3(u_{xx}u^2+3uu_x^2)+3u^4u_x.$$

Its symmetry algebra is isomorphic to $A_{3,7}^2$. Note that this equation can be linearized by a change of dependent variable.

Let us mention that a classification based on higher order symmetries of third order integrable nonlinear equations of the form

$$u_t=u_{xxx}+F(u,u_x,u_{xx}) \tag{7.9}$$

is given in Ref. 24. We should also note that the question of finding PDEs admitting Lie point symmetries is different than finding integrable PDEs. In the latter case one requires the existence of a generalized one as opposed to Lie point symmetries. For the classification of integrable PDEs we refer the reader to Refs. 25–27.

Finally, let us point out that in a very recent work[28] a class of integrable (in the sense of existence of an infinite number of generalized symmetries) third order evolution equations of the

form (7.9) for specific F admitting recursion operators have been analyzed. Among others, the special cases corresponding to $\tilde{F}=3\omega$ and $\tilde{F}=3/2-3\omega$ of (6.1) produce the following equations with 4-dimensional symmetry algebra $A_{3,7}^1\oplus A_1$:

$$u_t=u_{xxx}+3u^{-1}u_xu_{xx},$$

$$u_t=u_{xxx}-3u^{-1}u_xu_{xx}+\tfrac{3}{2}u^{-2}u_x^3,$$

both of which were shown to admit recursion operators. This fact indicates that many equations with relatively large symmetry groups in our classification are among the most probable candidates for being integrable.

We note that the maximal symmetry algebra of the first equation of the above list is infinite-dimensional with basis elements:

$$X_1=\partial_t,\quad X_2=\partial_x,\quad X_3=t\partial_t+\frac{x}{3}\partial_x+\frac{u}{2}\partial_u,$$

$$X(\rho)=\rho(x,t)u^{-1}\partial_u,\quad \rho_t=\rho_{xxx}.$$

The existence of an infinite-dimensional symmetry algebra suggests linearizability of the equation by point transformations and, indeed, it is linearized by the change of dependent variable $v(x,t)=u^2(x,t)/2$.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 6 JUNE 2004

$d^3=0$, $d^2=0$ differential calculi on certain noncommutative (super) spaces

M. El Baz,[a] A. El Hassouni,[b] Y. Hassouni,[c] and E. H. Zakkari[d]
Laboratory of Theoretical Physics, University Mohammed V, Rabat, Morocco

(Received 17 July 2003; accepted 15 March 2004;
published online 12 May 2004)

In this paper, we construct a covariant differential calculus on a quantum plane with two-parametric quantum group as a symmetry group. The two cases $d^2=0$ and $d^3=0$ are completely established. We also construct differential calculi $n=2$ and $n=3$ nilpotent on super quantum spaces with one and two-parametric symmetry quantum supergroup. © *2004 American Institute of Physics.*
[DOI: 10.1063/1.1738949]

I. INTRODUCTION

A noncommutative quantum (super) space[1,2] is an unital, associative algebra with a quantum (super) group as a symmetry group. These objects[3,4] have enriched the arena of mathematics and mathematical physics: they appear in the context of theory of knots and braids,[5] as well as in the study of Yang–Baxter equations.[6] Quantum (super) groups are deformations of the enveloping (super) algebra of classical Lie groups in the sense that one recovers the classical (super) commutator when the deformation parameters go to some particular values. Usually the generators of a quantum (super) group are assumed to commute with the noncommuting coordinates of the corresponding (super) plane. As a consequence, the quantum (super) plane admits a quantum group as a symmetry group with only one parameter: $(GL_q(1/1))GL_q(2)$.[7] More generally, one can obtain a multiparametric quantum (super) group, if one relaxes this property (commutation between space coordinates and group generators), namely, $GL_{p,q}(1/1)$[8] and $GL_{p,q}(2)$,[9] respectively, in the two-dimensional quantum superplane and quantum plane cases.

Many authors[8,10–16] have also studied differential calculus with nilpotency $n=2$ on (super) spaces with one or two-parameter (super) group as symmetry groups. An adequate way leading to generalization of this ordinary differential calculus arises from the graded differential algebra.[17–22] The latter involves a complex parameter that satisfies some conditions allowing to obtain a consistent generalized differential calculus. The most important property of this calculus is that the operator "d" satisfies $\{d^n=0/d^l\neq 0,\ 1\leqslant l\leqslant n-1\}$ and it contains as a consequence, not only first differentials dx^i, $i=1,\ldots,m$, but involves also higher order differentials $d^j x^i$, $j=1,\ldots,n-1$.

In this paper, we construct covariant differential calculus $d^3=0$ on certain quantum (super) spaces with one or two-parametric quantum group as a symmetry groups. We will show that our differential calculus is covariant under the algebra with a quantum group structure. The complex j, which appears in the Leibniz rule, is a third root of unity and will be an interesting and nontrivial aspect of the differential calculus that we will introduce.

This paper is organized as follows:

In Sec. II we start by recalling the two-parameter quantum group acting on a two-dimensional quantum plane. We also establish $n=2$ and $n=3$ covariant differential calculi on this space following the Coquereaux *et al.* approach.[14,15] It will be noticed that some modifications have been brought up to this approach in order to adapt it to the two-parameter quantum group sym-

[d]Electronic mail: hzakkari@hotmail.com

metry and the $n=3$ differential calculus. In Sec. III, the same method will be applied to construct the $n=2$, $n=3$ covariant differential calculus on $1+1$-dimensional superspace with one parameter quantum supergroup as a supersymmetry group. In Sec. IV we generalize the results of Sec. III by taking the two-parameter quantum group acting covariantly on the superspace.

II. DIFFERENTIAL CALCULUS ON A TWO-PARAMETRIC QUANTUM PLANE

A. Preliminaries

The two-dimensional quantum plane is an associative algebra generated by two noncommuting coordinates x and y[1,2,14] satisfying the relation

$$xy=q\,yx \quad , \quad q\neq 0,1 \quad (q\in C). \tag{1}$$

In order to have a two-parameter quantum group $\mathrm{GL}_{p,q'}(2)$ as a symmetry group of such a space,[9] one must assume that the coordinates do not commute in general with elements defining this group. Indeed, for a generic element $T=\left(\begin{smallmatrix} a & b \\ c & \mathrm{d}\end{smallmatrix}\right)$ of $\mathrm{GL}_{p,q'}(2)$, the relations between the matrix entries and the coordinates are assumed to be[9]

$$\begin{aligned} x\,a&=q_{11}\,a\,x, \quad y\,a=q_{21}\,a\,y,\\ x\,b&=q_{12}\,b\,x, \quad y\,b=q_{22}\,b\,y,\\ x\,c&=q_{13}\,c\,x, \quad y\,c=q_{23}\,c\,y,\\ x\,\mathrm{d}&=q_{14}\,\mathrm{d}\,x, \quad y\,\mathrm{d}=q_{24}\,\mathrm{d}\,y. \end{aligned} \tag{2}$$

The coordinates x and y transform under T and ${}^tT$ (transposed matrix) as

$$\begin{pmatrix} x\\ y\end{pmatrix}\overset{T}{\to}\begin{pmatrix} x'\\ y'\end{pmatrix}=\begin{pmatrix} a & b\\ c & \mathrm{d}\end{pmatrix}\begin{pmatrix} x\\ y\end{pmatrix},$$

$$\begin{pmatrix} x\\ y\end{pmatrix}\overset{{}^tT}{\to}\begin{pmatrix} x''\\ y''\end{pmatrix}=\begin{pmatrix} a & c\\ b & \mathrm{d}\end{pmatrix}\begin{pmatrix} x\\ y\end{pmatrix}.$$

The requirement that the transformed coordinates obey a similar relation as Eq. (1) (not necessarily with the same deformation parameter q), i.e.,

$$x'y'=\overline{q}\,y'x', \quad \overline{q}\in C, \tag{3}$$

$$x''y''=\bar{\bar{q}}y''x'', \quad \bar{\bar{q}}\in C, \tag{4}$$

and taking account of the defining relations of $\mathrm{GL}_{p,q'}(2)$,[13]

$$\begin{aligned} ab&=p\,ba, \quad c\mathrm{d}=p\,\mathrm{d}c,\\ ac&=q'\,ca, \quad b\mathrm{d}=q'\,\mathrm{d}b,\\ p\,bc&=q'\,cb, \quad a\mathrm{d}-\mathrm{d}a=\left(p-\frac{1}{q'}\right)bc, \end{aligned} \tag{5}$$

for some nonzero p, q' with $pq'\neq -1$, implicates further constraints on the involved parameters:

$$\overline{q}=\bar{\bar{q}}$$

and

$$
\begin{aligned}
&q_{11}=1, \quad q_{21}=qq'^{-1}k,\\
&q_{12}=\bar{q}p^{-1}, \quad q_{22}=q\bar{q}p^{-1}[\bar{q}-(p-q'^{-1})k],\\
&q_{13}=\bar{q}q'^{-1}, \quad q_{23}=q\bar{q}q'^{-1}[\bar{q}-(p-q'^{-1})k],\\
&q_{14}=\bar{q}q'^{-1}k, \quad q_{24}=q\bar{q}^2q'^{-1}p^{-1}[\bar{q}-(p-q'^{-1})k].
\end{aligned}
\tag{6}
$$

One can check that the matrix $T=\left(\begin{smallmatrix} a & b \\ c & \mathrm{d} \end{smallmatrix}\right)$ is indeed an element of the quantum group $\mathrm{GL}_{p,q'}(2)$ and is consistent with Hopf algebra structures.[9] For supplementary properties and results concerning the quantum group $\mathrm{GL}_{p,q'}(2)$ see, for example, Ref. 13.

It is clear that many quantum planes could be associated to this two-parameter quantum group, depending on choices of the q_{ij}'s. In the following, we shall confine our selves to the case $\bar{q}=q$, which corresponds to the standard definition of the quantum plane.

B. Differential calculus with nilpotency $n=2$ ($\mathrm{d}^2=0$)

Our aim in this section, is to construct a differential calculus on the previously defined quantum plane. We proceed using the same approach as the one adopted in Refs. 14, 15, and 20.

We start by defining the exterior differential "d" which satisfies the usual properties, namely,

(i) linearity;

(ii) nilpotency,

$$\mathrm{d}^2=0;$$

(iii) Leibniz rule,

$$\mathrm{d}(uv)=\mathrm{d}(u)v+(-1)^n u\,\mathrm{d}(v),$$

where $u\in\Omega^n$. Ω^n is the space of forms with degree n,

$$\mathrm{d}:\Omega^n\to\Omega^{n+1}.$$

Ω^0 is the algebra of functions defined on the quantum plane. We have also

$$\mathrm{d}(x)=\mathrm{d}x, \quad \mathrm{d}(y)=\mathrm{d}y, \quad \text{and } \mathrm{d}(1)=0. \tag{7}$$

From (2), we deduce

$$
\begin{aligned}
&(\mathrm{d}x)a=q_{11}\,a(\mathrm{d}x), \quad (\mathrm{d}y)a=q_{21}\,a(\mathrm{d}y),\\
&(\mathrm{d}x)b=q_{12}\,b(\mathrm{d}x), \quad (\mathrm{d}y)b=q_{22}\,b(\mathrm{d}y),\\
&(\mathrm{d}x)c=q_{13}\,c(\mathrm{d}x), \quad (\mathrm{d}y)c=q_{23}\,c(\mathrm{d}y),\\
&(\mathrm{d}x)\mathrm{d}=q_{14}\,\mathrm{d}(\mathrm{d}x), \quad (\mathrm{d}y)\mathrm{d}=q_{24}\,\mathrm{d}(\mathrm{d}y).
\end{aligned}
\tag{8}
$$

One can write *a priori* $x\,\mathrm{d}x, x\,\mathrm{d}y, y\,\mathrm{d}x$, and $y\,\mathrm{d}y$ in terms of $(\mathrm{d}x)x, (\mathrm{d}y)x, (\mathrm{d}x)y$, and $(\mathrm{d}y)y$, by means of 16 unknown coefficients.[14] Imposing the covariance of the obtained relations under $\mathrm{GL}_{p,q'}(2)$, and differentiating Eq. (1), permit to fix 15 of the 16 unknown coefficients. The associativity of the expression $(x\,\mathrm{d}x)\mathrm{d}y=x(\mathrm{d}x\,\mathrm{d}y)$ enables us to fix the last unknown parameter.

We notice that in the usual case $\mathrm{Gl}_q(2)$ this approach yields directly the desired differential calculus. However, when $\mathrm{GL}_{p,q'}(2)$ is a symmetry group, we obtain additional conditions on the parameters k and q',

$$q'=q \quad , \quad k=\frac{q'}{p}. \tag{9}$$

Then Eq. (6) becomes

$$q_{11}=q_{13}=1\ ,\quad q_{12}=q_{14}=q_{21}=q_{23}=qp^{-1}\ ,\quad q_{22}=q_{24}=q^2p^{-2}. \tag{10}$$

So, the covariant differential calculus is given by

$$x\,\mathrm{d}x=\frac{1}{pq}\ \mathrm{d}x\,x,\quad x\,\mathrm{d}y=\frac{1}{p}\ \mathrm{d}y\,x,$$

$$y\,\mathrm{d}y=\frac{1}{pq}\ \mathrm{d}y\,y,\quad y\,\mathrm{d}x=\left(\frac{1}{pq}-1\right)\ \mathrm{d}y\,x+\frac{1}{q}\ \mathrm{d}x\,y, \tag{11}$$

$$\mathrm{d}x\,\mathrm{d}y=-\frac{1}{p}\ \mathrm{d}y\,\mathrm{d}x,\quad (\mathrm{d}x)^2=(\mathrm{d}y)^2=0,$$

and the differential algebra is $\Omega_{x,y}^{q,p}=\{x,y,\mathrm{d}x,\mathrm{d}y\}$.

It is remarkable that the differential calculus on the quantum plane with $\mathrm{GL}_q(2)$, as a symmetry group,[11,12,14] can be obtained from the two-parameter one Eq. (11) in the $p\to q$ limit.

As in the ordinary case, the differential operator d can be realized by

$$\mathrm{d}:=\mathrm{d}x\,\partial x+\mathrm{d}y\,\partial y\ .$$

Based on this realization one can construct a gauge field theory on the two-parameter quantum plane. This should be achieved formally as in Ref. 20.

The nilpotent differential calculus can be extended to higher orders, as there is no reason to constrain this one to $n=2$ nilpotency.[17–20,23–27]

In the following section, we generalize the differential calculus on the quantum plane with one-parameter symmetry group[20] to the two-parameter one, this is done by extending the $n=2$ differential calculus obtained here to $n=3$ case.

C. Differential calculus with nilpotency $n=3$ ($\mathrm{d}^3=0$)

Let us introduce the differential operator "d" that satisfies the following conditions:

(i) linearity;

(ii) nilpotency,

$$\mathrm{d}^3=0\ ,\quad \mathrm{d}^2\neq 0;$$

(iii) Leibniz rule,

$$\mathrm{d}(uv)=(\mathrm{d}u)v+(j)^n u\,\mathrm{d}(v).$$

where j is the cubic root of unity: $j=e^{2i\pi/3}$, $1+j+j^2=0$. u is an element of Ω^n, the space of forms with degree n. It is a subspace of the differential algebra $\tilde{\Omega}_{x,y}^{q,p}=\{x,y,\mathrm{d}x,\mathrm{d}y,\mathrm{d}^2x,\mathrm{d}^2y\}$. The new objects d^2x and d^2y which appear are defined by

$$\mathrm{d}(\mathrm{d}x)=\mathrm{d}^2(x)=\mathrm{d}^2x\quad ,\quad \mathrm{d}(\mathrm{d}y)=\mathrm{d}^2(y)=\mathrm{d}^2y,$$

these are "forms" with degree two.

In order to ensure the covariance of the differential calculus under the two-parameter symmetry group $\mathrm{GL}_{p,q'}(2)$, we proceed as in the preceding section. However, instead of the last step where we have used the associativity property, we shall use the independence between the two different 2-forms $z\,\mathrm{d}^2z'$ and $\mathrm{d}z\,\mathrm{d}z'$, where $z,\ z'=x,y$. Below, we will discuss how to recover this property.

The same constraints on q' and k, Eq. (9), are recovered, thus the q_{ij}'s are the same as in Eq. (10). The covariant differential calculus is then given by

$$x\,\mathrm{d}x = j^2\,\mathrm{d}x\,x, \quad x\,\mathrm{d}y = -\frac{jq}{1+qp}\,\mathrm{d}y\,x + \frac{j^2qp-1}{1+qp}\,\mathrm{d}x\,y,$$

$$y\,\mathrm{d}y = j^2\,\mathrm{d}y\,y, \quad y\,\mathrm{d}x = \frac{j^2-qp}{1+qp}\,\mathrm{d}y\,x - \frac{jp}{1+qp}\,\mathrm{d}x\,y,$$

$$x\,\mathrm{d}^2x = j^2\,\mathrm{d}^2x\,x, \quad x\,\mathrm{d}^2y = -\frac{jq}{1+qp}\,\mathrm{d}^2y\,x + \frac{j^2qp-1}{1+qp}\,\mathrm{d}^2x\,y,$$

$$y\,\mathrm{d}^2y = j^2\,\mathrm{d}^2y\,y, \quad y\,\mathrm{d}^2x = \frac{j^2-qp}{1+qp}\,\mathrm{d}^2y\,x - \frac{jp}{1+qp}\,\mathrm{d}^2x\,y, \tag{12}$$

$$\mathrm{d}x\,\mathrm{d}^2x = j\,\mathrm{d}^2x\,\mathrm{d}x, \quad \mathrm{d}x\,\mathrm{d}^2y = -\frac{q}{1+qp}\,\mathrm{d}^2y\,\mathrm{d}x + \frac{jqp-j^2}{1+qp}\,\mathrm{d}^2x\,\mathrm{d}y,$$

$$\mathrm{d}y\,\mathrm{d}^2y = j\,\mathrm{d}^2y\,\mathrm{d}y, \quad \mathrm{d}y\,\mathrm{d}^2x = \frac{j-j^2qp}{1+qp}\,\mathrm{d}^2y\,\mathrm{d}x - \frac{p}{1+qp}\,\mathrm{d}^2x\,\mathrm{d}y,$$

$$\mathrm{d}x\,\mathrm{d}y = q\,\mathrm{d}y\,\mathrm{d}x, \quad \mathrm{d}^2x\,\mathrm{d}^2y = q\,\mathrm{d}^2y\,\mathrm{d}^2x.$$

Moreover, a realization of "d" in terms of partial derivatives,

$$\mathrm{d} = \mathrm{d}x\,\partial_x + \mathrm{d}y\,\partial_y \tag{13}$$

permits us to have $(\mathrm{d}x)^3 = (\mathrm{d}y)^3 = 0$.[20]

We note that the differential algebra $\tilde{\Omega}^{q,p}_{x,y}$, defined above, is not associative. One can check this statement by first assuming that this property (associativity) is preserved, then deriving some inconsistent relations. Especially, one expects, due to this assumption, the two expressions $(x\,\mathrm{d}x)\mathrm{d}y$ and $x(\mathrm{d}x\,\mathrm{d}y)$ to be equal. However, using (12) and successively moving the parentheses, one obtains two expressions which are manifestly not equal, unless $pq = j^2$.

Thus, the differential algebra $\tilde{\Omega}^{q,p}_{x,y}$ is associative only when $pq = j^2$, otherwise it is not.

Another associative 3-nilpotent differential algebra, for $pq = j$, can be constructed basing on the method already mentioned in Sec. II B, with a proper substitution of the differential operator $\mathrm{d}^2 = 0$ with the one $\mathrm{d}^3 = 0$, $(\mathrm{d}^2 \neq 0)$. It follows from this method that the commutation relations between the coordinates and their first order differentials are given (by the first ones) in (11). The first, second, and third differentiations of these relations give rise to the remaining commutation relations between x, y, $\mathrm{d}x$, $\mathrm{d}y$, d^2x, and d^2y.

The results of Ref. 20 (i.e., differential calculus on a reduced quantum plane, respectively, with $q^3 = 1$ and $q^N = 1$) can be recovered as limiting cases of the one obtained here (12); this is done by taking the adequate limit $p \to q$ (respectively, with $q^3 = 1$ and $q^N = 1$).

It is also remarkable that the case $n = 3$ differential calculus was applied to introduce interesting "Higher order gauge theories."[18–20] Indeed, an interesting manner to do this (in the present case) is to pursue the same steps of Ref. 20.

Another important question arises at this step is how to adapt the techniques applied in Secs. II B and II C to the quantum superplane. This will be developed in the next section.

III. DIFFERENTIAL CALCULUS ON A ONE-PARAMETER QUANTUM SUPERPLANE

A. $n = 2$ differential calculus

The $1+1$ dimensional quantum superspace, in Manin's approach,[2,7] is an algebra generated by a bosonic and a fermionic coordinate satisfying the relations

$$x\theta = q\,\theta x, \quad q \neq 0,1, \tag{14}$$

$$\theta^2=0. \tag{15}$$

In analogy with the quantum plane, a symmetry supergroup of this space is $GL_q(1/1)$, and a generic element of this supergroup is a supermatrix: $T=\left(\begin{smallmatrix} a & \beta \\ \gamma & \mathrm{d} \end{smallmatrix}\right)$, where a, d are bosonic elements commuting with x and θ while β, γ are fermionic elements commuting with x, anticommuting with θ and obeying the following relations:

$$\begin{gathered} a\beta=q\,\beta a, \quad \mathrm{d}\beta=q\,\beta\mathrm{d}, \\ a\gamma=q\,\gamma a, \quad \mathrm{d}\gamma=q\,\gamma\mathrm{d} \\ \beta\gamma+\gamma\beta=0, \quad \beta^2=\gamma^2=0, \\ a\mathrm{d}-\mathrm{d}a=(q^{-1}-q)\,\beta\gamma. \end{gathered} \tag{16}$$

These relations can also be obtained by imposing the invariance of Eqs. (14) and (15) under T and ${}^{st}T=\left(\begin{smallmatrix} a & -\gamma \\ \beta & \mathrm{d} \end{smallmatrix}\right)$ (supertranspose).

Many authors studied the differential calculus on this superspace.[8,10,27,28] Here we construct the differential calculus based on the same technique adopted by Couquereaux *et al.*[14] which is used in the preceding section, with however, some modifications to adapt it to this superspace. We introduce an exterior differential operator "d" satisfying the properties:

(i) linearity,

$$\mathrm{d}(\lambda u)=(-1)^{\hat{\lambda}}\,\lambda\,\mathrm{d}(u), \tag{17}$$

where the parity $\hat{\lambda}=0,1$ respectively, if λ is a bosonic or a fermionic element.

(ii) Nilpotency,

$$\mathrm{d}^2=0.$$

(iii) Leibniz rule,

$$\mathrm{d}(uv)=(\mathrm{d}u)v+(-1)^{\hat{u}}(-1)^{\deg u}u(\mathrm{d}v), \tag{18}$$

where $\hat{u}$ is the parity of u and $\deg u$ is the degree of the differential form u.

Note that consistency requires that $\mathrm{d}\theta$ commutes with a, d, β, γ and $\mathrm{d}x$ commutes with a, d and anticommutes with β, γ.

The same method applied in Sec. II B yields

$$\begin{gathered} x\,\mathrm{d}x=q^{-2}\,\mathrm{d}x\,x, \quad x\,\mathrm{d}\theta = q^{-1}\,\mathrm{d}\theta\,x, \\ \theta\,\mathrm{d}\theta=\mathrm{d}\theta\,\theta, \quad \theta\,\mathrm{d}x = (1-q^{-2})\,\mathrm{d}\theta\,x-q^{-1}\,\mathrm{d}x\,\theta, \\ \mathrm{d}x\,\mathrm{d}\theta=q^{-1}\,\mathrm{d}\theta\,\mathrm{d}x, \quad (\mathrm{d}x)^2 = 0, \end{gathered} \tag{19}$$

and the associative differential algebra is denoted $\Omega^q_{x,\theta}=\{x,\theta,\mathrm{d}x,\mathrm{d}\theta\}$.

As in Sec. II C, one can apply the same method to generalize the differential calculus on the superspace to higher orders ($\mathrm{d}^3=0$). This is the aim of the next section.

B. Differential calculus on superspace with nilpotency $n=3$ ($\mathrm{d}^3=0$)

We proceed as in Sec. II C, in order to construct the $n=3$ covariant differential calculus on superspace. We introduce a differential operator "d" satisfying the usual requirements, namely, linearity is the same as in Eq. (17), the nilpotency will be changed to $n=3$ ($\mathrm{d}^3=0$) and the Leibniz rule, Eq. (18) becomes

$$\mathrm{d}(uv)=(\mathrm{d}u)v+(-1)^{\hat{u}}(j)^{\deg u}u(\mathrm{d}v). \tag{20}$$

The resulting differential algebra $\tilde{\Omega}^{q}_{x,\theta}$ is generated by, x, θ, $\mathrm{d}x$, $\mathrm{d}\theta$, d^2x, and $\mathrm{d}^2\theta$ satisfying

$$
\begin{gathered}
x\,\mathrm{d}x = j^2\,\mathrm{d}x\,x, \quad x\,\mathrm{d}\theta = -\frac{jq}{1+q^2}\ \mathrm{d}\theta\,x + \frac{j^2q^2-1}{1+q^2}\ \mathrm{d}x\ \theta, \\
\theta\,\mathrm{d}\theta = \mathrm{d}\theta\ \theta, \quad \theta\,\mathrm{d}x = \frac{q^2-j^2}{1+q^2}\ \mathrm{d}\theta\,x + \frac{jq}{1+q^2}\ \mathrm{d}x\ \theta, \\
\mathrm{d}x\,\mathrm{d}\theta = -q\,\mathrm{d}\theta\,\mathrm{d}x, \quad (\mathrm{d}\theta)^2 = 0, \\
x\,\mathrm{d}^2x = j^2\,\mathrm{d}^2x\,x, \quad x\,\mathrm{d}^2\theta = -\frac{jq}{1+q^2}\ \mathrm{d}^2\theta\,x + \frac{j^2q^2-1}{1+q^2}\ \mathrm{d}^2x\ \theta, \\
\theta\,\mathrm{d}^2\theta = -\mathrm{d}^2\theta\ \theta, \quad \theta\,\mathrm{d}^2x = \frac{j^2-q^2}{1+q^2}\ \mathrm{d}^2\theta\,x - \frac{jq}{1+q^2}\ \mathrm{d}^2x\ \theta, \\
\mathrm{d}x\,\mathrm{d}^2x = j\,\mathrm{d}^2x\,\mathrm{d}x, \quad \mathrm{d}x\,\mathrm{d}^2\theta = \frac{q}{1+q^2}\ \mathrm{d}^2\theta\,\mathrm{d}x + \frac{jq^2-j^2}{1+q^2}\ \mathrm{d}^2x\,\mathrm{d}\theta, \\
\mathrm{d}\theta\,\mathrm{d}^2\theta = j^2\,\mathrm{d}^2\theta\,\mathrm{d}\theta, \quad \mathrm{d}\theta\,\mathrm{d}^2x = \frac{j^2q^2-j}{1+q^2}\ \mathrm{d}^2\theta\,\mathrm{d}x - \frac{q}{1+q^2}\ \mathrm{d}^2x\,\mathrm{d}\theta, \\
\mathrm{d}^2x\,\mathrm{d}^2\theta = q\,\mathrm{d}^2\theta\,\mathrm{d}^2x, \quad (\mathrm{d}^2\theta)^2 = 0.
\end{gathered}
\tag{21}
$$

Let us point out that the differential algebra $\tilde{\Omega}^{q}_{x,\theta}$ is not associative, unless $q=j$. In the case $q\neq j$, one can recover this property by following the same steps mentioned at the end of Sec. II C with the adequate modifications.

IV. DIFFERENTIAL CALCULUS ON A TWO-PARAMETER QUANTUM SUPERPLANE

A. Differential calculus with nilpotency $n=2$ ($\mathrm{d}^2=0$)

In this section, we generalize the results of Sec. III, in the sense that we choose a two-parametric quantum supergroup $\mathrm{GL}_{p,q'}(1/1)$ as a symmetry group for the superplane Eqs. (14) and (15). This group will be introduced using the same method as in Sec. II.[8,9]

The entries of a matrix element $T=\left(\begin{smallmatrix} a & \beta \\ \gamma & \mathrm{d} \end{smallmatrix}\right)$ of $\mathrm{GL}_{p,q'}(1/1)$ satisfy the following nontrivial relations:

$$
\begin{gathered}
a\beta = p\ \ \beta a, \quad \mathrm{d}\beta = p\ \beta\mathrm{d}, \\
a\gamma = q'\ \ \gamma a, \quad \mathrm{d}\gamma = q'\ \gamma\mathrm{d}, \\
p\ \ \beta\gamma + q'\ \ \gamma\beta = 0, \quad \beta^2 = \gamma^2 = 0, \\
a\mathrm{d} - \mathrm{d}a = (q'^{-1} - p)\ \ \beta\gamma.
\end{gathered}
\tag{22}
$$

As it is done in Sec. II this superspace is covariant under T and ${}^{st}T$ (supertranspose), and the analogous of Eq. (2) are

$$
\begin{aligned}
x\,a &= k\,a\,x, \quad \theta\,a = q\bar{q}q'^{-1}p^{-1}k\,a\,\theta,\\
x\,b &= \bar{q}p^{-1}k\,b\,x, \quad \theta\,b = -q\bar{q}^2q'^{-1}p^{-2}k\,b\,\theta,\\
x\,c &= \bar{q}q'^{-1}k\,c\,x, \quad \theta\,c = -q\bar{q}^2q'^{-2}p^{-1}k\,c\,\theta,\\
x\,\mathrm{d} &= \bar{q}^2q'^{-1}p^{-1}k\,\mathrm{d}\,x, \quad \theta\,\mathrm{d} = q\bar{q}^3q'^{-2}p^{-2}k\,\mathrm{d}\,\theta.
\end{aligned}
\tag{23}
$$

We are interested in establishing a covariant differential calculus on this superspace in the case $\bar{q}=\bar{\bar{q}}=q$. To achieve this construction, for $n=2$, we introduce a differential operator "d" satisfying the same properties as in Sec. III B [linearity Eq. (17), nilpotency, and Leibniz rule Eq. (18)]. The associative differential algebra $\Omega^{p,q}_{x,\theta}=\{x,\theta,\mathrm{d}x,\mathrm{d}\theta\}$ is generated by the following relations:

$$
\begin{aligned}
x\,\mathrm{d}x &= (qp)^{-1}\,\mathrm{d}x\,x, \quad x\,\mathrm{d}\theta = p^{-1}\,\mathrm{d}\theta\,x,\\
\theta\,\mathrm{d}\theta &= \mathrm{d}\theta\,\theta, \quad \theta\,\mathrm{d}x = (1-(qp)^{-1})\ \mathrm{d}\theta\,x - q^{-1}\,\mathrm{d}x\,\theta,\\
\mathrm{d}x\,\mathrm{d}\theta &= p^{-1}\,\mathrm{d}\theta\,\mathrm{d}x, \quad (\mathrm{d}x)^2 = 0.
\end{aligned}
\tag{24}
$$

We have used $q'=q$ and $k=q/p$, which, as in Eq. (9), are consequences of the requirement of the covariance of $\Omega^{p,q}_{x,\theta}$ under $\mathrm{GL}_{p,q'}(1/1)$.

As expected, in the limit $p\to q$, we recover $\Omega^{q}_{x,\theta}$ and relations (19).

B. Differential calculus with nilpotency $n=3$ ($\mathrm{d}^3=0$)

The technique used in Secs. II C and III C, allows us to construct the $n=3$ differential algebra $\tilde{\Omega}^{p,q}_{x,\theta}=\{x,\theta,\mathrm{d}x,\mathrm{d}\theta,\mathrm{d}^2x,\mathrm{d}^2\theta\}$,

$$
\begin{aligned}
x\,\mathrm{d}x &= j^2\,\mathrm{d}x\,x, \quad x\,\mathrm{d}\theta = -\frac{jq}{1+qp}\ \mathrm{d}\theta\,x + \frac{j^2qp-1}{1+qp}\ \mathrm{d}x\,\theta,\\
\theta\,\mathrm{d}\theta &= \mathrm{d}\theta\,\theta, \quad \theta\,\mathrm{d}x = \frac{qp-j^2}{1+qp}\ \mathrm{d}\theta\,x + \frac{jp}{1+qp}\ \mathrm{d}x\,\theta,\\
\mathrm{d}x\,\mathrm{d}\theta &= -q\,\mathrm{d}\theta\,\mathrm{d}x, \quad (\mathrm{d}\theta)^2 = 0,\\
x\,\mathrm{d}^2x &= j^2\,\mathrm{d}^2x\,x, \quad x\,\mathrm{d}^2\theta = -\frac{jq}{1+qp}\ \mathrm{d}^2\theta\,x + \frac{j^2qp-1}{1+qp}\ \mathrm{d}^2x\,\theta,\\
\theta\,\mathrm{d}^2\theta &= -\mathrm{d}^2\theta\,\theta, \quad \theta\,\mathrm{d}^2x = \frac{j^2-qp}{1+qp}\ \mathrm{d}^2\theta\,x - \frac{jp}{1+qp}\ \mathrm{d}^2x\,\theta,\\
\mathrm{d}x\,\mathrm{d}^2x &= j\,\mathrm{d}^2x\,\mathrm{d}x, \quad \mathrm{d}x\,\mathrm{d}^2\theta = \frac{q}{1+qp}\ \mathrm{d}^2\theta\,\mathrm{d}x + \frac{jqp-j^2}{1+qp}\ \mathrm{d}^2x\,\mathrm{d}\theta,\\
\mathrm{d}\theta\,\mathrm{d}^2\theta &= j^2\,\mathrm{d}^2\theta\,\mathrm{d}\theta, \quad \mathrm{d}\theta\,\mathrm{d}^2x = \frac{j^2qp-j}{1+qp}\ \mathrm{d}^2\theta\,\mathrm{d}x - \frac{p}{1+qp}\ \mathrm{d}^2x\,\mathrm{d}\theta,\\
\mathrm{d}^2x\,\mathrm{d}^2\theta &= q\,\mathrm{d}^2\theta\,\mathrm{d}^2x, \quad (\mathrm{d}^2\theta)^2 = 0.
\end{aligned}
\tag{25}
$$

The same limit as in Sec. II C, namely, $p\to q$, yields $\tilde{\Omega}^{q}_{x,\theta}$. The differential algebra $\tilde{\Omega}^{p,q}_{x,\theta}$ is not associative. In order to restore this property we proceed as mentioned at the end of Secs. II C and III B.

One physical application of the differential calculi (Secs. III and IV) is to construct a supersymmetric gauge field theory on the quantum superplane (with one or two parameter quantum supergroup as symmetry groups; the latter will be a generalization of the former). However, this is not straightforward, since one should first start by defining a supersymmetric covariant derivative.

V. CONCLUSION

In this paper, we have constructed differential calculi on certain quantum (super) spaces. Namely, the $n=2$ and $n=3$ nilpotent differential calculi on the quantum plane with two parametric quantum group ($\mathrm{GL}_{p,q}(2)$) as a symmetry group was obtained. We have also considered two cases of quantum superplanes related to the one and two-parametric quantum supergroups $\mathrm{GL}_q(1|1)$ and $\mathrm{GL}_{p,q}(1|1)$, as symmetry groups, respectively. The related $n=2$ and $n=3$ differential calculi were also established.

In general, the differential calculus can be applied to formulate gauge field theories.[29–31] As a consequence, the results obtained here permit us to construct gauge theories on the corresponding noncommutative spaces.[32] Indeed, for the quantum space (Sec. II), this can be done using the same techniques of Ref. 20, where the symmetry group is a one parameter.

The noncommutative supersymmetric case (Secs. III and IV) will be treated in the same fashion, with however, more care since it is essential first, to define a covariant supersymmetric derivative.[33,34]

We note that the differential calculus was also applied to derive a corresponding quantum oscillator, where the latter is seen as a representation of the former.[35] It will be interesting to achieve this with the differential calculus in Sec. II, as the resulting quantum oscillator will be two-parameter dependent.

published online 12 May 2004)

We obtain the exact nontopological soliton lattice solutions of the associated Lamé equation in different parameter regimes and compute the corresponding energy for each of these solutions. We show that in specific limits these solutions give rise to nontopological (pulse-like) single solitons, as well as to different types of topological (kink-like) single soliton solutions of the associated Lamé equation. Following Manton, we also compute, as an illustration, the asymptotic interaction energy between these soliton solutions in one particular case. Finally, in specific limits, we deduce the soliton lattices, as well as the topological single soliton solutions of the Lamé equation, and also the sine-Gordon soliton solution. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738952]

I. INTRODUCTION

Over the years, extensive research has been carried out seeking the exact soliton solutions of both periodic (e.g., sine-Gordon, double sine-Gordon) and nonperiodic (e.g., ϕ^4, ϕ^6) field theory models. For example, the exactly solvable sine-Gordon (SG) equation[1] and its quasi-exactly solvable (QES) partner, i.e., the double sine-Gordon equation (DSG), have exact single soliton[2,3] as well as soliton lattice[4] solutions.

There have been some advances in the study of the hyperbolic analogues of these problems; the exactly solvable hyperbolic analogue of the SG equation is the sine-hyperbolic Gordon (ShG) equation.[5] This potential has only one minimum and thus does not support (topological) soliton solutions. The hyperbolic analogue of the DSG equation is the double sine-hyperbolic Gordon (DShG) equation, which is a QES double-well potential with exact single soliton and soliton lattice solutions.[6]

However, not much is known regarding the elliptic analogues of these problems. The elliptic generalization of the SG is the Lamé equation[7] but, as far as we are aware of, its single soliton and soliton lattice solutions have not been worked out yet. One would surmise that the elliptic analogue of the DSG equation is the Associated Lamé (AL) equation.[8–10] Nevertheless, we find below that this is not the case. There are many physical contexts in which the Lamé equation arises, such as bond-order and charge density wave systems,[11] nonlinear elasticity,[12] and other contexts, e.g., phase slips in superconductors, magnetoelastic interaction on curved surfaces and symmetric monopoles.[13] The Lamé equation appears in systems with a single periodicity such as a one-dimensional array of identical atoms with a certain strength of the potential. The AL equation would arise from two alternating types of atoms with different strengths of the potential. Moreover, one expects an AL equation in many of the above physical systems in the presence of external—electric, magnetic or stress—fields.

Our goal in the present paper is to obtain the exact single soliton and soliton lattice solutions for both the AL and Lamé elliptic potentials. In particular, we obtain here the soliton lattice

solutions of the AL equation in different parameter regimes corresponding to different shapes of the AL potential. The advantage of this approach is that the corresponding single pulse and topological soliton solutions of the AL equation can be immediately obtained from the lattice solution in suitable limits. Furthermore, the soliton lattices and topological single soliton solutions of the Lamé equation are easily obtained by taking a different appropriate limit. Besides, the asymptotic interaction between the solitons can also be readily obtained by using Manton's formalism.[14]

Our results can be summarized as follows: We show that there are six different soliton lattice solutions of the AL equation for different values of the parameters. From these six solutions we obtain the corresponding AL single soliton solutions. It turns out that while in five cases these are topological (kink-like) single solitons, in one case we have a nontopological (pulse-like) single soliton solution. From the AL soliton lattice solutions, by taking appropriate limits, we also obtain the corresponding Lamé soliton lattices and single soliton solutions (which are also new).

These results will serve as a background for future statistical mechanics studies of the AL and Lamé elliptic potentials. The problem of finding the partition function of the system can be mapped onto the spectral problem of a Schrödinger equation with the potential.[15] Generally speaking, the Schrödinger equations with periodic potentials belong to a class known as Hill's equations,[8] and they lead to a band structure of the energy spectrum of the system. For both the SG and DSG potentials one could calculate (either exact or approximate) statistical and thermodynamical properties[16,17] through a knowledge of the spectral band structure (or, at least, of the band edges) and of their soliton and phonon solutions, respectively. Both AL and Lamé are also periodic potentials with a band structure.[7,9,10] Although we do not pursue this any further here, our results will provide the basis for the thermodynamics of these systems, in particular the contribution of the nonlinear soliton excitations to the specific heat, etc.[15]

The plan of the paper is as follows. In Sec. II we discuss some salient features of the AL potential and consider the limits that lead to the Lamé potential. The readers who are interested only in the single soliton and soliton lattice solutions of the Lamé equation can then directly go to Sec. V. In Sec. III we obtain the nontopological soliton lattice solutions of the AL equation in different regimes in the parameter space and also compute the corresponding energies. In Sec. IV we obtain the topological and pulse single soliton solutions of the AL equation by taking the appropriate limits of the various nontopological solutions obtained in the preceding section. It is worth emphasizing here that in one special case, we obtain two different kinds of topological solutions of the AL equation. As an illustration, in one particular case, we also estimate the asymptotic interaction between these single solitons.[14] (In all the other cases one can follow exactly the same procedure, and thus we will not consider these here.) As a crosscheck on our results, we recover in appropriate limit, the sine-Gordon soliton solution. In Sec. V we show that by taking an appropriate limit in the above results, we can also obtain the (previously not known) kink lattice and the topological single soliton solutions of the Lamé equation. Finally, in Sec. VI we summarize the results obtained in this paper and indicate some open problems.

II. THE ASSOCIATED LAMÉ POTENTIAL

Consider the following family of periodic potentials labeled by a pair of real parameters (p, q):

$$V_{\mathrm{AL}}(\phi,k)=pk^2\,\mathrm{sn}^2(\phi,k)+qk^2\frac{\mathrm{cn}^2(\phi,k)}{\mathrm{dn}^2(\phi,k)}+C=pk^2\,\mathrm{sn}^2(\phi,k)+qk^2\,\mathrm{sn}^2(\phi+K(k),k)+C, \quad (1)$$

that are called *Associated Lamé potentials* (since the corresponding Schrödinger equation is called the Associated Lamé equation).[8–10] Here $\mathrm{sn}(\phi,k)$ and $\mathrm{cn}(\phi,k)$ are, respectively, the sine and cosine amplitude Jacobi elliptic functions of real modulus $k(0\leqslant k\leqslant 1)$ and period $4K(k)$; $\mathrm{dn}(\phi,k)$ is the δ-amplitude Jacobi elliptic function of modulus k and period $2K(k)$; and $K(k)$ denotes the complete elliptic integral of the first kind, see Refs. 18 and 19. We will choose the

constant C in the potential so that the absolute minimum of the potential—with respect to ϕ—equals zero, $V_{\min}=0$. The potential is periodic with period $2K(k)$, except in the limit $p=q$ when the period reduces to $K(k)$, as it is clear from Eq. (1).

The case $q=0$ corresponds to the standard Lamé potential $V_{\mathrm{L}}(\phi,k)$. There are two more cases in which the potential (1) reduces to the Lamé potential. Namely, when $p=0$ and also when $p=q$, as shown below. Therefore in all the calculations below we will admit that $p\neq 0$ and $p\neq q$; the results for the standard Lamé potential will be recovered in the limit $q\to 0$, and we refer to these results whenever the potential reduces to the standard Lamé one. From a physical point of view, if one thinks of a Lamé potential $(p, 0)$ as due to a one-dimensional array of atoms with spacing $2K(k)$ and "strength" p, then the Associated Lamé potential (p,q) results from two alternating types of atoms spaced by $K(k)$ with strengths p and q, respectively. If the two types of atoms are identical (which makes $p=q$), one expects a potential of period $K(k)$.

In addition, when $k\to 0$, and $|p|$, $|q|\to\infty$, so that $|p|k^2\to P=$ finite and $|q|k^2\to Q=$ finite, the potential (1) reduces to the sine-Gordon potential,

$$V_{\mathrm{SG}}=(P\ \mathrm{sign}\,p-Q\ \mathrm{sign}\,q)\sin^2\phi, \tag{2}$$

and the results we present below reduce to the well-known ones for the sine-Gordon potential.

Note that we cannot recover the DSG equation under any limiting condition in the parameter space of the AL equation. Indeed, the only limit where one can get sinusoidal functions from Jacobi elliptic functions of modulus k is the above-mentioned limit $k\to 0$ (of course, with $|p|$, $|q|\to\infty$, so that $|p|k^2\to P=$ finite and $|q|k^2\to Q=$ finite, otherwise the potential trivially becomes a flat one), when one obtains the SG, and *not* the DSG equation.

It is also worth noting that under the transformation $\phi\to\phi+K(k)$ the AL potential (1) $V_{\mathrm{AL}}(p,q)$ goes over into $V_{\mathrm{AL}}(q,p)$ and hence for $p>0$, $q\geqslant 0$, as well as for $p<0$, $q\leqslant 0$, without loss of generality, we shall always consider the case of $p^2>q^2$. Further, instead of considering both the possibilities of $p>0$, $q\leqslant 0$ and $p<0$, $q\geqslant 0$, it suffices to consider just the case of $p>0$, $q\leqslant 0$, but now p^2 can be bigger as well as smaller than q^2.

Finally, consider the case of $p=q$, when, by using the Landen transform[18] and choosing the constant $C=-pk^2$, the AL potential (1) can be written as

$$V_{\mathrm{AL}}(\phi,k)=(1-k')^2V_{\mathrm{L}}\left[(1+k')\phi,\frac{1-k'}{1+k'}\right], \tag{3}$$

where $k'=\sqrt{1-k^2}$ is the complementary elliptic modulus. For the rescaled field $\bar{\phi}=(1+k')\phi$ and in the rescaled space coordinate $\bar{x}=(1+k')x$ the field equations [see next section, Eq. (5)] will remain the same as that for the simple Lamé potential. Note that the $p=q$ case cannot be obtained as a limit of $q\to p$ $(q\neq p)$, since—as already mentioned—when $p=q$ the periodicity of the potential (1) is $K(k)$, while for $p\neq q$ it is $2K(k)$, see also Ref. 9.

III. SOLITON LATTICE SOLUTIONS OF THE AL POTENTIAL

For the scalar field $\phi=\phi(x,t)$ the dynamics is described by the second-order hyperbolic differential equation

$$\frac{\partial^2\phi}{\partial t^2}-\frac{\partial^2\phi}{\partial x^2}=-\frac{\partial V_{\mathrm{AL}}}{\partial\phi}. \tag{4}$$

In the stationary case $\phi=\phi(x)$, this reduces simply to

$$\frac{\mathrm{d}^2\phi}{\mathrm{d}x^2}=\frac{\partial V_{\mathrm{AL}}}{\partial\phi}, \tag{5}$$

that can be easily integrated, at least formally, by quadratures. The time-dependent solutions are

immediately obtained from here by Lorentz boosting to velocity v, i.e., $x \to (1-v^2)^{-1/2}(x-vt)$. The physically meaningful solutions (bounded at $x \to \pm\infty$) are given by

$$\pm\sqrt{2}(x-x_0) = \int_{\phi(x_0)}^{\phi(x)} \frac{d\tilde{\phi}}{\sqrt{V_{AL}(\tilde{\phi},k)-A^2}}, \tag{6}$$

where x_0 and $A^2 \equiv |p|k^2a^2$ are the two (suitably chosen) integration constants. Of course, $V_{min} = 0 \leqslant A^2 < V_{max}$, where $V_{min/max}$ is the absolute minimum/maximum of the potential energy with respect to ϕ. In fact, in view of the condition $V_{AL}(\tilde{\phi},k) - A^2 \geqslant 0$, the actual value of A^2 determines the appropriate integration domain in Eq. (6).

Depending on the values of the parameters p and q, the potential $V_{AL}(\phi,k)$ has different behaviors in one period $0 \leqslant \phi < 2K(k)$, and hence the nature of the solutions in Eq. (6) is also different. There are three cases to be considered separately, namely (I) when $p>0$ and $q \geqslant 0$, (II) when $p<0$ and $q \leqslant 0$, and, finally, (III) when $p>0$ and $q \leqslant 0$. Note that in what follows we shall use the shorthand notation $\Gamma \equiv \sqrt{|q|/|p|}$.

A. Case I: $p>0$ and $q \geqslant 0$

As explained above, in this case it is sufficient to consider $0 \geqslant \Gamma < 1$. Note that the case $\Gamma = 0$ corresponds to the standard Lamé potential. Depending on the value of Γ, the potential $V_{AL}(\phi,k)$ can have different behaviors in one period $0 \leqslant \phi < 2K(k)$.

Case I.1: $0 \leqslant \Gamma \leqslant k'$.

Here $0 \leqslant k' = \sqrt{1-k^2} \leqslant 1$ is the complementary elliptic modulus. The potential $V_{AL}(\phi)$ has only one minimum, $V_{min} = 0$ (at $\phi = 0$), and one maximum, $V_{max} = pk^2(1-\Gamma^2)$ [at $\phi = K(k)$], in one period [note that we have chosen $C = -pk^2\Gamma^2$ in Eq. (1) in order to have $V_{min} = 0$]. The plot of the potential V_{AL} as a function of ϕ is given in Fig. 1(a), where the solid and the dashed horizontal lines correspond to two choices of the parameter A^2. Under the change of variable $\tilde{z} = \mathrm{sn}^2(\tilde{\phi},k)$, Eq. (6) can be rewritten as

$$2\sqrt{2pk^4}x = \pm \int_z^1 \frac{d\tilde{z}}{\sqrt{(z_1-\tilde{z})(1-\tilde{z})(\tilde{z}-z_2)(\tilde{z}-0)}}, \tag{7}$$

where $z = \mathrm{sn}^2(\phi,k)$, $x_0 = 0$ for $\phi_0 = K(k)$ (by choice), and $A^2 = pk^2a^2$ with $0 \leqslant a^2 < (1-\Gamma^2)$. The value of a^2 determines the limits of the integration interval in the above equation, through the condition $V(\phi_{1,2}) - pk^2a^2 = 0$; one finds that $z_{1,2} = \mathrm{sn}^2(\phi_{1,2})$ are given by

$$z_{1,2} = \frac{1-\Gamma^2k'^2+a^2k^2}{2k^2}\left[1 \pm \sqrt{1-\frac{4k^2a^2}{(1-\Gamma^2k'^2+a^2k^2)^2}}\right], \tag{8}$$

and $z_1 > 1 > z \geqslant z_2 > 0$. Then the integral in (7) can be evaluated using the formula 3.147(5) of Ref. 18 and one is finally led to the nontopological soliton lattice solution

$$\mathrm{sn}^2(\phi,k) = \frac{[(z_1-z_2)-z_1(1-z_2)\mathrm{sn}^2(y,t)]}{[(x_1-z_2)-(1-z_2)\mathrm{sn}^2(y,t)]}. \tag{9}$$

Here $y = \sqrt{2pk^4(z_1-z_2)}x$ and the period of the lattice $2L = 2K(t)/\sqrt{2pk^4(z_1-z_2)}$ is controlled by the modulus

$$0 < t = \left[\frac{z_1(1-z_2)}{z_1-z_2}\right]^{1/2} \leqslant 1. \tag{10}$$

Note that ϕ oscillates between $K(k)$ and $\mathrm{sn}^{-1}(\sqrt{z_2})$ [respectively, $-K(k)$ and $-\mathrm{sn}^{-1}(\sqrt{z_2})$], i.e., it is indeed a nontopological solution [it does not connect two adjacent degenerate minima of

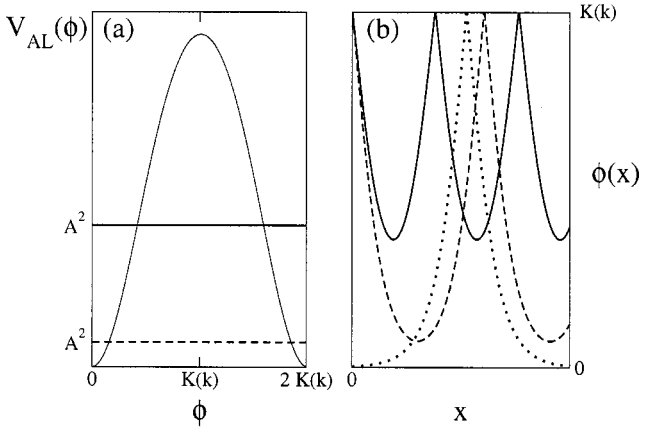

FIG. 1. Case I.1: $0 \leqslant \Gamma \leqslant k'$. (a) The shape of the potential $V_{\mathrm{AL}}(\phi)$. The solid and the dashed horizontal lines correspond to two choices of the integration parameter A^2. (b) The soliton lattice solution [i.e., the field $\phi(x)$] with solid and dashed curves corresponding to the two values of A^2 in (a). The x axis is not labeled because the two lattices have different spatial periods. The dotted curve represents the topological single soliton solution corresponding to $A^2=0$ (for the sake of clarity we have displaced the origin of the x axis for this curve). Note that in (b) and all subsequent figures we have plotted $|\phi(x)|$ modulo $2K(k)$. There are no "cusps" in the actual field $\phi(x)$.

the potential, that are separated by a distance—in the ϕ space—of $2K(k)$]. In Fig. 1(b) we give a plot of the solution (i.e., the field ϕ as a function of x) with solid and dashed curves corresponding to the two choices of A^2 as in Fig. 1(a), while the dotted curve represents the topological single soliton solution (corresponding to $A^2=0$)—see Sec. IV.

We emphasize that there are no "cusps" or slope discontinuities in the actual solutions $\phi(x)$. In order to represent the field in the same range $0<\phi(x)<K(k)$ in Fig. 1(b) and in the subsequent figures we have plotted modulo $2K(k)$ the absolute value of the actual field $\phi(x)$. This is possible because if $\phi(x)$ is a solution then $-\phi(x)$ and $2K(k)-\phi(x)$ are also solutions. Specifically, for solutions that attain the value $K(k)$ such as in Fig. 1(b), the actual field is $\phi(x)$ in $[0,2L]$, $2K(k)-\phi(x)$ in $[2L,4L]$, $\phi(x)$ in $[4L,6L]$, and so on. Similarly, for solutions that attain zero field value such as in Fig. 3(b), the actual field is $\phi(x)$ in $[0,2L]$, $-\phi(x)$ in $[2L,4L]$, $\phi(x)$ in $[4L,6L]$, and so on.

One can compute the energy corresponding to a period $2L$ of this soliton lattice:

$$
\begin{aligned}
E_{\mathrm{SL}} &= \int_{-L}^{L}\left[\frac{1}{2}\left(\frac{\mathrm{d}^2\phi}{\mathrm{d}x^2}\right)+V_{\mathrm{AL}}(\phi)\right]\mathrm{d}x \\
&= \int_{-L}^{L}[2V_{\mathrm{AL}}(\phi)-A^2]\mathrm{d}x \\
&= 4\int_{0}^{L}V_{\mathrm{AL}}(\phi)\mathrm{d}x-2LA^2 \\
&= 4pk^2\int_{0}^{L}\mathrm{sn}^2[\phi(x),k]\mathrm{d}x+4p^2k^2\Gamma^2\int_{0}^{L}\left\{\frac{\mathrm{cn}^2[\phi(x),k]}{\mathrm{dn}^2[\phi(x),k]}-1\right\}\mathrm{d}x-2Lp^2k^2a^2. \qquad (11)
\end{aligned}
$$

After some algebraic manipulations, using the solution (9) one obtains

$$
\begin{aligned}
E_{\mathrm{SL}} = 2\sqrt{\frac{2p}{z_1-z_2}}\Bigg\{&\left[z_1K(t)-(z_1-1)\Pi\left(\frac{1-z_2}{z_1-z_2},t\right)\right]-\frac{a^2K(t)}{2}\Bigg\} \\
&-\Gamma^2\left[\frac{z_1k'^2}{1-z_1k^2}K(t)-\frac{z_1-1}{1-z_1k^2}\Pi\left(\frac{(1-z_2)(1-z_1k^2)}{(z_1-z_2)k'^2},t\right)\right], \qquad (12)
\end{aligned}
$$

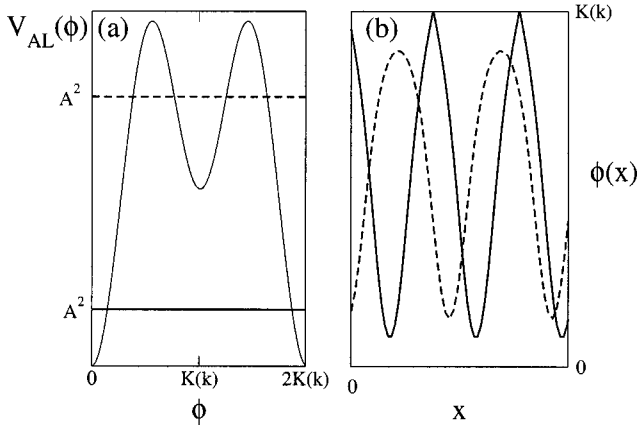

FIG. 2. Case I.2: $k'<\Gamma<1$. (a) The shape of the potential $V_{\mathrm{AL}}(\phi)$. The solid and the dashed horizontal lines correspond to two choices of the integration parameter A^2, namely, Case I.2(i): $V_{\min}\leqslant A^2=pk^2a^2<V^l_{\min}$, i.e., $0\leqslant a^2<1-\Gamma^2$ (solid line); and Case I.2(ii): $V^l_{\min}\leqslant A^2=pk^2a^2<V_{\max}$, i.e., $1-\Gamma^2\leqslant a^2<[(1-\Gamma k')/k]^2$ (dashed line). (b) The soliton lattice solution [i.e., the field $\phi(x)$] with solid and dashed curves corresponding to the two values of A^2 in (a), i.e., respectively, to Case I.2(i) and Case I.2(ii). The x axis is not labeled because the two lattices have different periodicities. We have plotted $|\phi(x)|$ modulo $2K(k)$.

where $\Pi(z_0,t)$ denotes the complete elliptic integral of the third kind.[18,19]

Case I.2: $k'<\Gamma<1$.

The potential $V_{\mathrm{AL}}(\phi)$ has now two minima: $V_{\min}(\phi=0)=0$ and a local minimum $V^l_{\min}[\phi=K(k)]=pk^2(1-\Gamma^2)$, and two symmetric maxima around $\phi=K(k)$, namely, $V_{\max}=pk^2[(1-\Gamma k')/k]^2$ for $\phi=\mathrm{sn}^{-1}[\sqrt{(1-\Gamma k')/k^2}]$, $2K(k)-\mathrm{sn}^{-1}[\sqrt{(1-\Gamma k')/k^2}]$. The plot of the potential $V_{\mathrm{AL}}(\phi)$ as a function of ϕ is given in Fig. 2(a), where the solid and the dashed horizontal lines correspond to the two choices of the integration constant A^2 as explained below. Note that in this case it makes no sense to consider either the limit of the Lamé potential (i.e., $\Gamma\to 0$), or that of the sine-Gordon potential (i.e., $k\to 0$, $pk^2\to P$, $qk^2\to Q$). There are two possible situations, depending on the value of $A^2=pk^2a^2$.

Case I.2(i): $V_{\min}\leqslant A^2=pk^2a^2<V^l_{\min}$, i.e., $0\leqslant a^2<1-\Gamma^2$.

One recovers the same soliton lattice solution as above, Eq. (9), with the same modulus t, Eq. (10), and the same energy per period of the lattice, Eq. (12).

Case I.2(ii): $V^l_{\min}\leqslant A^2=pk^2a^2<V_{\max}$, i.e., $1-\Gamma^2\leqslant a^2<[(1-\Gamma k')/k]^2$. Then the integral (6) becomes

$$2\sqrt{2pk^4}x=\pm\int_{z_2}^{z}\frac{d\tilde{z}}{\sqrt{(1-\tilde{z})(z_1-\tilde{z})(\tilde{z}-z_2)(\tilde{z}-0)}},\tag{13}$$

with $z=\mathrm{sn}^2(\phi,k)$ and $1>z_1\geqslant z>z_2$ [$z_{1,2}$ have the same expressions as above, Eq. (8)]. One can evaluate this integral using the formula 3.147(4) of Ref. 18 and obtain the following nontopological soliton lattice solution

$$\mathrm{sn}^2(\phi,k)=\frac{z_1z_2}{z_1-(z_1-z_2)\mathrm{sn}^2(w,n)},\tag{14}$$

with $w=\sqrt{2pk^4z_1(1-z_2)}x$, and the modulus n given by

$$0<n=\sqrt{\frac{z_1-z_2}{z_1(1-z_2)}}\leqslant 1;\tag{15}$$

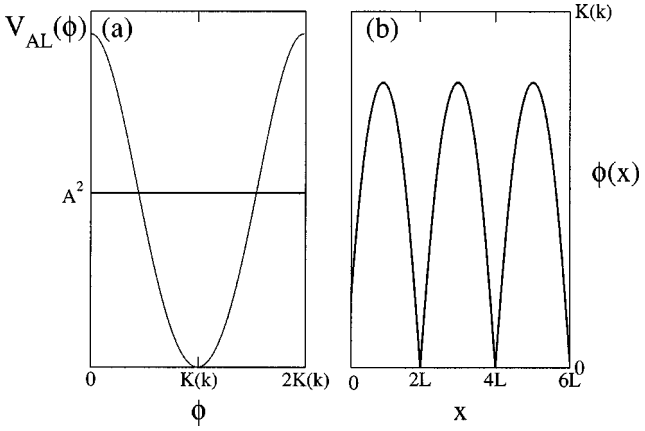

FIG. 3. Case II.1: $0\leqslant\Gamma\leqslant k'$. (a) The shape of the potential $V_{\mathrm{AL}}(\phi)$. The solid horizontal line corresponds to the integration parameter A^2. (b) The soliton lattice solution [i.e., the field $\phi(x)$] corresponding to the value of A^2 in (a). We have plotted $|\phi(x)|$ modulo $2K(k)$.

therefore, the soliton lattice has a spatial period $2L=2K(n)/\sqrt{2pk^4z_1(1-z_2)}$. Note that ϕ varies between $\mathrm{sn}^{-1}(\sqrt{z_1})$ and $\mathrm{sn}^{-1}(\sqrt{z_2})$ [respectively, $-\mathrm{sn}^{-1}(\sqrt{z_1})$ and $-\mathrm{sn}^{-1}(\sqrt{z_2})$] when x varies over one spatial period: indeed, this solution is nontopological.

In Case I.2(ii) in order to compute the energy for one spatial period $2L$, it is useful to shift the potential by $-V^l_{\mathrm{min}}=-pk^2(1-\Gamma^2)$, so that the minimum of the potential explored by the soliton lattice is equal to zero. One finds

$$E_{\mathrm{SL}}=4\int_0^L V_{\mathrm{AL}}(\phi)\mathrm{d}x-2LV^l_{\mathrm{min}}-2Lp^2k^2a^2$$
$$=2\sqrt{\frac{2p^2}{z_1(1-z_2)}}\left[z_2\Pi\left(\frac{z_1-z_2}{z_1},n\right)-\Gamma^2\frac{k'^2z_2}{1-k^2z_2}\Pi\left(\frac{z_1-z_2}{z_1(1-k^2z_2)},n\right)-\frac{a^2+(1-\Gamma^2)}{2}\right]. \tag{16}$$

The plot of the solutions in Case I.2 is given in Fig. 2(b), where the solid line corresponds to the nontopological soliton lattice solution of Case I.2(i), while the dashed line corresponds to the nontopological soliton lattice solution of Case I.2(ii). Note that in the appropriate limits (see Sec. IV) these two types of solutions give birth to a topological [Case I.2(i)] and a nontopological single soliton [Case I.2(ii)] solution, respectively.

B. Case II: $p<0$ and $q\leqslant 0$

As explained above, here again it suffices to focus only on the domain $0\leqslant\Gamma<1$, and we must distinguish between two different behaviors of the potential, depending on the value of Γ.

Case II.1: $0\leqslant\Gamma\leqslant k'$.

The potential $V_{\mathrm{AL}}(\phi,k)$ has only two extrema in $[0,2K(k))$, namely, an absolute maximum $V_{\mathrm{max}}=|p|k^2(1-\Gamma^2)$ for $\phi=0$, and an absolute minimum $V_{\mathrm{min}}=0$ for $\phi=K(k)$ [with the choice of the shift $C=|p|k^2$ in Eq. (1)]. A plot of the potential is given in Fig. 3(a).

One can repeat the integration scheme described in the preceding case. In particular, considering $z=\mathrm{sn}^2(\phi,k)$, Eq. (6) becomes

$$2\sqrt{2|p|k^2}x=\pm\int_0^z\frac{\mathrm{d}\tilde{z}}{\sqrt{(z_1-\tilde{z})(1-\tilde{z})(z_2-\tilde{z})(\tilde{z}-0)}}, \tag{17}$$

where this time

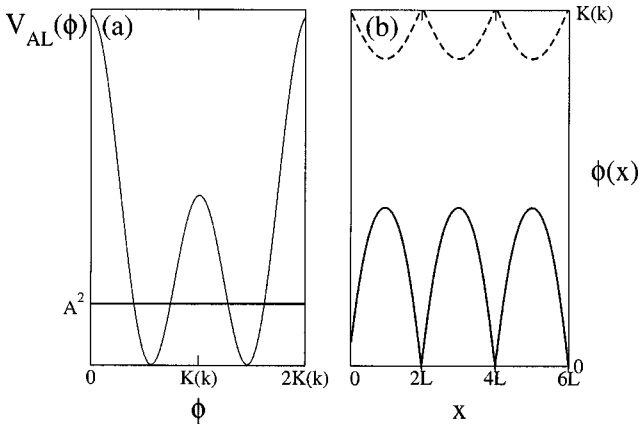

FIG. 4. Case II.2: $k'<\Gamma<1$. (a) The shape of the potential $V_{\mathrm{AL}}(\phi)$. The solid horizontal line corresponds to the integration parameter A^2. (b) The two nontopological soliton lattice solutions [i.e., the field $\phi(x)$] corresponding to the value of A^2 in (a); the solid line represents Solution 1 (see the main text), while the dashed line represents Solution 2. We have plotted $|\phi(x)|$ modulo $2K(k)$.

$$z_{1,2}=\frac{1+k^2-\Gamma^2-a^2k^2}{2k^2}\left[1\pm\sqrt{1-\frac{4k^2(1-\Gamma^2-a^2)}{(1+k^2-\Gamma^2-a^2k^2)^2}}\right], \tag{18}$$

$z_1>1\geqslant z_2>z>0$, and $0\leqslant a^2<(1-\Gamma^2)$. This integral can be evaluated using formula 3.147(2) of Ref. 18 and one obtains the following nontopological soliton lattice:

$$\mathrm{sn}^2(\phi,k)=\frac{z_1z_2\,\mathrm{sn}^2(y,r)}{(z_1-z_2)+z_2\,\mathrm{sn}^2(y,r)}. \tag{19}$$

Here $y=\sqrt{2|p|k^4(z_1-z_2)}x$ and the modulus r that controls the density of solitons in the lattice is given by

$$0<r=\sqrt{\frac{z_2(z_1-1)}{z_1-z_2}}\leqslant 1. \tag{20}$$

The period of the lattice is $2L=2K(r)/\sqrt{2|p|k^4(z_1-z_2)}$ and one notices that ϕ varies between 0 and $\mathrm{sn}^{-1}(\sqrt{z_2})$ [respectively, 0 and $-\mathrm{sn}^{-1}(\sqrt{z_2})$] in one period. A plot of the solution is given in Fig. 3(b).

One can compute the energy for one period $2L$ of this lattice,

$$E_{\mathrm{SL}}=2\sqrt{\frac{2|p|}{z_1-z_2}}\left\{\left[-(z_1-1)K(r)+z_1\Pi\left(-\frac{z_2}{z_1-z_2},r\right)\right]\right.$$
$$\left.-\Gamma^2\left[-\frac{z_1-1}{1-z_1k^2}K(r)+\frac{z_1k'^2}{1-z_1k^2}\Pi\left(-\frac{z_2(1-z_1k^2)}{z_1-z_2},r\right)\right]-\frac{a^2K(r)}{2}\right\}. \tag{21}$$

Case II.2: $k'<\Gamma<1$.

In this case, the potential $V_{\mathrm{AL}}(\phi,k)$ has two maxima and two degenerate minima in one period $0\leqslant\phi<2K(k)$. Namely, an absolute maximum, $V_{\max}=|p|(1-\Gamma k')^2$ (for $\phi=0$); a relative maximum $V^l_{\max}=|p|(\Gamma-k')^2$ [for $\phi=K(k)$]: and two absolute minima $V_{\min}=0$ situated symmetrically around $K(k)$ [for $\phi=\mathrm{sn}^{-1}\sqrt{(1-\Gamma k')/k^2}$, $2K(k)-\mathrm{sn}^{-1}\sqrt{(1-\Gamma k')/k^2}$]. Note that we used a shift $C=|p|(1-2\Gamma k'+\Gamma^2)$ in the expression (1) of the potential. A plot of the potential as a function of ϕ is given in Fig. 4(a).

The very existence of adjacent degenerate minima of the potential separated by different barriers to the right and to the left (on the ϕ axis) implies that in this case one will have two different soliton lattices (and, correspondingly, two different topological single soliton solutions). This is similar to the DSG case.[2–4]

We follow the same type of integration procedure as that described above.

Case II.2(i): When $V_{\min} \leqslant A^2 = |p| k^2 a^2 < V^l_{\max}$, i.e., $0 \leqslant a^2 < (\Gamma - k')^2/k^2$, Eq. (6), under the change of variable $z = \mathrm{sn}^2(\phi, k)$, leads to two different types of solutions.

Solution 1: for $0 < z \leqslant z_2 < z_1 < 1$, one has

$$2\sqrt{2|p|k^4}\,x = \pm \int_0^z \frac{d\tilde{z}}{\sqrt{(1-\tilde{z})(z_1-\tilde{z})(z_2-\tilde{z})(\tilde{z}-0)}}, \tag{22}$$

where now

$$z_{1,2} = \frac{2(1-\Gamma k') - a^2k^2}{2k^2}\left\{1 \pm \sqrt{1 - \frac{4[(1-\Gamma k')^2 - a^2k^2]}{[2(1-\Gamma k') - a^2k^2]^2}}\right\}. \tag{23}$$

Equation (22) can be integrated using formula 3.147(2) of Ref. 18, thus obtaining

$$\mathrm{sn}^2(\phi, k) = \frac{z_2\,\mathrm{sn}^2(w,s)}{(1-z_2) + z_2\,\mathrm{sn}^2(w,s)}, \tag{24}$$

with $w = \sqrt{2|p|k^4 z_1(1-z_2)}\,x$ and the modulus

$$0 < s = \sqrt{\frac{(1-z_1)z_2}{(1-z_2)z_1}} \leqslant 1. \tag{25}$$

It is a nontopological soliton lattice, with ϕ oscillating between 0 and $\mathrm{sn}^{-1}(\sqrt{z_2})$ [respectively, 0 and $-\mathrm{sn}^{-1}(\sqrt{z_2})$]. Its energy for one period $2L = 2K(s)/\sqrt{2|p|k^4 z_1(1-z_2)}$ is given by

$$E_{\mathrm{SL}} = 2\sqrt{\frac{2|p|}{z_1(1-z_2)}}\left\{\left[\frac{(\Gamma-k')^2}{k^2} - \frac{a^2}{2}\right]K(s) + \Pi\left(-\frac{z_2}{1-z_2}, s\right) - \Gamma^2\Pi\left(-\frac{z_2 k'^2}{1-z_2}, s\right)\right\}. \tag{26}$$

Solution 2: for $0 < z_2 < z_1 \leqslant z < 1$ one obtains from Eq. (6),

$$2\sqrt{2|p|k^4} = \pm \int_z^1 \frac{d\tilde{z}}{\sqrt{(1-\tilde{z})(\tilde{z}-z_1)(\tilde{z}-z_2)(\tilde{z}-0)}}, \tag{27}$$

with $z = \mathrm{sn}^2(\phi, k)$ and $z_{1,2}$ given by Eq. (23). This integral can be solved using formula 3.147(7) of Ref. 18, thus leading to the following nontopological pulse-like lattice:

$$\mathrm{sn}^2(\phi, k) = \frac{z_1}{z_1 + (1-z_1)\mathrm{sn}^2(w,s)}, \tag{28}$$

with $w = \sqrt{2|p|k^4 z_1(1-z_2)}\,x$ and the modulus s given by the same expression as above, Eq. (25). Of course, one notices immediately that this soliton lattice is different from the previous one, Eq. (24). In one period $2L = 2K(s)/\sqrt{2|p|k^4 z_1(1-z_2)}$, ϕ oscillates between $\mathrm{sn}^{-1}\sqrt{z_1}$ and $K(k)$ [respectively, $-\mathrm{sn}^{-1}\sqrt{z_1}$ and $-K(k)$].

The energy corresponding to one period $2L$ of this pulse lattice is given by

$$E_{\mathrm{SL}} = s\sqrt{\frac{2|p|}{z_1(1-z_2)}}\left\{\left[\frac{(1-\Gamma k')^2}{k^2} - \frac{a^2}{2}\right]K(s) + \Pi\left(-\frac{1-z_1}{z_1}, s\right) + \Gamma^2\Pi\left(-\frac{1-z_1}{z_1 k'^2}, s\right)\right\}. \tag{29}$$

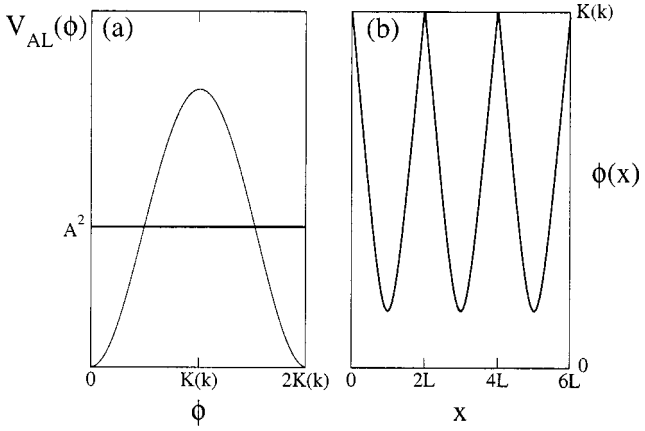

FIG. 5. Case III: $p>0$ and $q\leqslant 0$. (a) The shape of the potential $V_{\mathrm{AL}}(\phi)$. The solid horizontal line corresponds to the integration parameter A^2. (b) The soliton lattice solution [i.e., the field $\phi(x)$] corresponding to the value of A^2 in (a). We have plotted $|\phi(x)|$ modulo $2K(k)$.

A plot of the solutions is given in Fig. 4(b) where the solid and dashed lines correspond, respectively, to the Solution 1 and Solution 2. Therefore, as expected, we obtained two different soliton lattices (with two different limiting cases of topological single solitons). Note that the terms ''large'' and ''small'' applied to the topological solitons do not refer, as usual, to the length of the interval they cover in ϕ space, but to the height of the barrier they ''encounter.''[3]

Case II.2(ii): When $V^{l}_{\max}\leqslant A^2=|p|k^2a^2<V_{\max}$, i.e., $(\Gamma-k')^2/k^2\leqslant a^2<(1-\Gamma k')^2/k^2$ there is no soliton lattice solution.

C. Case III: $p>0$ and $q\leqslant 0$

Unlike the last two cases, here p^2 can be $>$ or $<q^2$. However, it turns out that in this case, whatever the value of $\Gamma=\sqrt{|q|/p}$, the potential $V_{\mathrm{AL}}(\phi)$ has only two extrema in one period $0\leqslant\phi<2K(k)$, namely, an absolute minimum $V_{\min}=0$ for $\phi=0$ and a maximum $V_{\max}=pk^2(1+\Gamma^2)$ for $\phi=K(k)$. Note that we choose $C=pk^2\Gamma^2$ in Eq. (1). A plot of the potential $V_{\mathrm{AL}}(\phi)$ is given in Fig. 5(a). With $z=\mathrm{sn}^2(\phi,k)$, Eq. (6) now becomes

$$2\sqrt{2pk^4}x=\pm\int_z^1\frac{d\tilde{z}}{\sqrt{(z_1-\tilde{z})(1-\tilde{z})(\tilde{z}-z_2)(\tilde{z}-0)}},\tag{30}$$

with

$$z_{1,2}=\frac{(1+\Gamma^2k'^2+a^2k^2)}{2k^2}\left[1\pm\sqrt{1-\frac{4k^2a^2}{(1+\Gamma^2k'^2+a^2k^2)^2}}\right],\tag{31}$$

$z_1>1\geqslant z>z_2>0$. Using the formula 3.147(5) of Ref. 18, one can evaluate the integral in Eq. (30), thus obtaining a nontopological soliton lattice,

$$\mathrm{sn}^2(\phi,k)=\frac{[(z_1-z_2)-z_1(1-z_2)\mathrm{sn}^2(y,t)]}{[(z_1-z_2)-(1-z_2)\mathrm{sn}^2(y,t)]}.\tag{32}$$

Here $y=\sqrt{2pk^4(z_1-z_2)}x$ and the elliptic modulus

$$0<t=\sqrt{\frac{z_1(1-z_2)}{z_1-z_2}}\leqslant 1.\tag{33}$$

In one period $2L=2K(t)/\sqrt{2pk^4(z_1-z_2)}$, ϕ oscillates between $\mathrm{sn}^{-1}\sqrt{z_2}$ and $K(k)$ [respectively, $-K(k)$ and $-\mathrm{sn}^{-1}\sqrt{z_2}$]. A plot of the solution is given in Fig. 5(b).

The energy corresponding to one period $2L$ of this lattice is

$$E_{\mathrm{SL}}=2\sqrt{\frac{2p}{z_1-z_2}}\left\{\left[z_1K(t)-(z_1-1)\Pi\left(\frac{1-z_2}{z_1-z_2},t\right)\right]\right.$$
$$\left.-\Gamma^2k'^2\left[\frac{z_1}{z_1k^2-1}K(t)-\frac{z_1-1}{k'^2(z_1k^2-1)}\Pi\left(-\frac{(1-z_2)(z_1k^2-1)}{k'^2(z_1-z_2)},t\right)\right]-\frac{a^2K(t)}{2}\right\}. \quad (34)$$

IV. SINGLE SOLITON SOLUTIONS OF THE AL POTENTIAL

Having obtained the soliton lattice solutions of the AL problem, it is now straightforward to consider the specific limits of the integration constant A^2 and to obtain the corresponding single soliton solutions of the Associated Lamé potential and compute their energy.

Cases I.1 and I.2(i): The limit of a single soliton (that corresponds to the period of the lattice $L\to\infty$) is obtained for $t\nearrow 1$ [$a^2\searrow 0$; $z_1\to(1-\Gamma^2k'^2)/k^2$ and $z_2\searrow 0$]. One notices that now ϕ can vary continuously between $-K(k)$ and $K(k)$ while x explores the whole real axis; therefore, one obtains a topological single-soliton (kink-like) solution,

$$\mathrm{sn}(\phi,k)=\pm\sqrt{\frac{1-\Gamma^2k'^2}{1-\Gamma^2k'^2+k'^2(1-\Gamma^2)\sinh^2(y^*)}}, \quad (35)$$

where $y^*=\sqrt{2pk^2(1-\Gamma^2k'^2)}x$. The corresponding energy of this single kink-like soliton is obtained from Eq. (12), using the relations

$$\lim_{r\nearrow 1}\Pi(n^2,r)=\lim_{r\nearrow 1}\frac{K(r)}{1-n^2}-\frac{n}{2(1-n^2)}\ln\left(\frac{1+n}{1-n}\right). \quad (36)$$

It may be noted that all the divergences cancel mutually, thus leading to a finite energy of the single soliton:

$$E_{\mathrm{K}}=\sqrt{2p}\left[\ln\left(\frac{\sqrt{1-\Gamma^2k'^2}+k}{\sqrt{1-\Gamma^2k'^2}-k}\right)-\Gamma\ln\left(\frac{\sqrt{1-\Gamma^2k'^2}+(\Gamma k)}{\sqrt{1-\Gamma^2k'^2}-(\Gamma k)}\right)\right]. \quad (37)$$

Following Manton[14] one can compute the asymptotic interaction energy between two solitons in the array, or between a soliton and an antisoliton. As an illustration we will consider this particular soliton solution; for all the other cases one can follow exactly the same procedure.

From Eq. (35) one obtains the asymptotic shape of the soliton, e.g., for $x\to+\infty$:

$$\phi_{\mathrm{as}}\approx\left[\frac{4(1-\Gamma^2k'^2)}{k'^2(1-\Gamma^2)}\right]^{1/2}\exp(-\sqrt{2pk^2(1-\Gamma^2k'^2)}x). \quad (38)$$

Then, if $2L\gg 1$ is the distance between two solitons in the array, according to Ref. 14 the asymptotic interaction energy is

$$U(2L)\approx-\frac{8(2pk^2)^{1/2}(1-\Gamma^2k'^2)^{3/2}}{k'^2(1-\Gamma^2)}\exp(-2L\sqrt{2pk^2(1-\Gamma^2k'^2)}). \quad (39)$$

If one considers now the small parameter $a^2\ll 1$ that measures the distance from the single soliton limit, according to the results in Sec. III we can obtain the asymptotic expression for $2L$ as

$$2L\approx\frac{1}{\sqrt{2pk^2(1-\Gamma^2k'^2)}}\ln\left(\frac{16(1-\Gamma^2k'^2)^2}{a^2k'^2(1-\Gamma^2)}\right), \quad (40)$$

and thus

$$U(a^2) \approx \sqrt{\frac{pk^2}{2(1-\Gamma^2 k'^2)}}\, a^2, \tag{41}$$

that corresponds to a repulsive asymptotic interaction between two solitons in the array. One can consider also the asymptotic interaction energy between a soliton and an antisoliton and obtains simply $U(a^2) \approx -\sqrt{pk^2/[2(1-\Gamma^2 k'^2)]}a^2$, i.e., an attractive interaction.

Sine-Gordon limit: Taking now the limit $k \to 0$, with $|p|, |q| \to \infty$, so that $|p|k^2 \to P =$ finite and $|q|k^2 \to Q =$ finite, in the expressions of the AL single soliton solution, Eq. (35), one obtains the correct kink-like solution of the sine-Gordon potential in Eq. (2), namely,

$$\sin \phi_{\mathrm{SG}} = \pm \operatorname{sech}(y^*), \tag{42}$$

with $y^* = \sqrt{2P(1-\Gamma^2)}x$, and the energy

$$E_{\mathrm{SG}} = 2\sqrt{2P(1-\Gamma^2)}. \tag{43}$$

Case I.2(ii): The single soliton limit $L \to \infty$ [i.e., $n \nearrow 1$; $a^2 \searrow (1-\Gamma^2)$, $z_1 \to 1$, and $z_2 \to (1-\Gamma^2)/k^2$] reads

$$\mathrm{sn}(\phi, k) = \pm \sqrt{\frac{1-\Gamma^2}{1-\Gamma^2+(\Gamma^2-k'^2)\operatorname{sech}^2(\omega^*)}}, \tag{44}$$

with $\omega^* = \sqrt{2pk^2(\Gamma^2-k'^2)}x$. It represents a nonlopological (pulse-like) soliton, with ϕ varying between $K(k)$ and $\mathrm{sn}^{-1}(\sqrt{(1-\Gamma^2)/k^2})$ [respectively, $-K(k)$ and $-\mathrm{sn}^{-1}(\sqrt{(1-\Gamma^2)/k^2})$] when x runs over the real axis, i.e., it does not connect two adjacent degenerate minima of the potential.

Its energy is obtained from Eq. (16) and reads

$$E_{\mathrm{S}} = \sqrt{2p}\left[\Gamma \ln\left(\frac{(\Gamma k)+\sqrt{\Gamma^2-k'^2}}{(\Gamma k)-\sqrt{\Gamma^2-k'^2}}\right) - \ln\left(\frac{k+\sqrt{\Gamma^2-k'^2}}{k-\sqrt{\Gamma^2-k'^2}}\right)\right]. \tag{45}$$

Case II.1: Consider now the single soliton limit $r \nearrow 1$ [$a^2 \searrow 0, z_1 \to (1-\Gamma^2)/k^2$, and $z_2 \to 1$]. One obtains the following topological (i.e., kink-like) soliton:

$$\mathrm{sn}(\phi, k) = \pm \sqrt{\frac{1-\Gamma^2}{k'^2-\Gamma^2+(1-\Gamma^2)\sinh^2(y^*)}}\sinh(y^*), \tag{46}$$

with $y^* = \sqrt{2|p|k^2(k'^2-\Gamma^2)}x$, of energy

$$E_{\mathrm{K}} = 2\sqrt{2|p|}\left[\arctan\left(\frac{k}{k'^2-\Gamma^2}\right) - \Gamma \arctan\left(\frac{(\Gamma k)}{\sqrt{k'^2-\Gamma^2}}\right)\right], \tag{47}$$

where we took the limit $r \nearrow 1$ in Eq. (21) using the relation

$$\lim_{r \nearrow 1} \Pi(-n^2, r) = \lim_{r \nearrow 1} \frac{K(r)}{1+n^2} + \frac{n}{1+n^2}\arctan(n). \tag{48}$$

Note that one can also consider the limit of the sine-Gordon potential in this case and obtain the correct sine-Gordon soliton.

Case II.2(i): Solution 1: large topological kink: Considering the single soliton limit, $s \nearrow 1$ [$a^2 \searrow 0, z_{1,2} \to (1-\Gamma k')/k^2$], one obtains a "large" topological kink, that interpolates between two adjacent minima "across" the large barrier $V_{\max}$ of the potential

$$\mathrm{sn}(\phi,k)=\pm\sqrt{\frac{1-\Gamma k'}{k'(\Gamma-k')+(1-\Gamma k')\tanh^2(\omega^*)}}\tanh(\omega^*), \tag{49}$$

with $\omega^*=\sqrt{2|p|k'(1-\Gamma k')(\Gamma-k')}x$. Its energy is found from Eqs. (26) and (48) as

$$E_{\mathrm{K}}=2\sqrt{2|p|}\left[\arctan\sqrt{\frac{1-\Gamma k'}{k'(\Gamma-k')}}-\Gamma\arctan\sqrt{\frac{k'(1-\Gamma k')}{\Gamma-k'}}\right]. \tag{50}$$

Case II.2(i): Solution 2: small topological kink: Considering now the single soliton limit $s\nearrow 1[a^2\to 0, z_{1,2}\to(1-\Gamma k')/k^2]$, one obtains a "small" topological kink, that interpolates between two adjacent minima "across" the small barrier $V'_{\max}$ of the potential

$$\mathrm{sn}(\phi,k)=\pm\sqrt{\frac{1-\Gamma k'}{1-\Gamma k'+k'(\Gamma-k')\tanh^2(\omega^*)}}, \tag{51}$$

with $\omega^*=\sqrt{2|p|k'(1-\Gamma k')(\Gamma-k')}x$. Its energy is found from Eqs. (29) and (48),

$$E_{\mathrm{K}}=2\sqrt{2|p|}\left[\Gamma\arctan\sqrt{\frac{\Gamma-k'}{k'(1-\Gamma k')}}-\arctan\sqrt{\frac{k'(\Gamma-k')}{1-\Gamma k'}}\right]. \tag{52}$$

Case III: The single soliton limit $t\nearrow 1[a^2\searrow 0, z_1\to(1+\Gamma^2k'^2)/k^2$, and $z_2\to 0]$ represents a topological soliton,

$$\mathrm{sn}(\phi,k)=\pm\sqrt{\frac{(1+k'^2\Gamma^2)}{1+\Gamma^2k'^2+k'^2(1+\Gamma^2)\sinh^2(y^*)}}, \tag{53}$$

with $y^*=\sqrt{2pk^2(1+\Gamma^2k'^2)}x$. Its energy is given by

$$E_{\mathrm{K}}=\sqrt{2p}\left[\ln\left(\frac{\sqrt{1+\Gamma^2k'^2}+k}{\sqrt{1+\Gamma^2k'^2}-k}\right)+2\Gamma\arctan\left(\frac{(\Gamma k)}{\sqrt{1+\Gamma^2k'^2}}\right)\right]. \tag{54}$$

Here again one can consider the limit of the sine-Gordon potential and obtain the correct sine-Gordon soliton of energy $E_{\mathrm{SG}}=2\sqrt{2P(1+\Gamma^2)}$.

V. SOLITON LATTICE AND SINGLE SOLITON SOLUTIONS OF THE LAMÉ POTENTIAL

Let us now consider the standard Lamé potential

$$V_{\mathrm{L}}(\phi,k)=pk^2\,\mathrm{sn}^2(\phi,k). \tag{55}$$

Recall that p is a real parameter and $\mathrm{sn}(\phi,k)$ is the sine amplitude Jacobi elliptic function of real modulus k $(0\leqslant k\leqslant 1)$ and period $4K(k)$, where $K(k)$ denotes the complete elliptic integral of the first kind, see Refs. 18 and 19. As emphasized in Sec. II, the Lamé potential can be obtained from the Associated Lamé potential for special limiting values of the two parameters (p,q) of the latter, Eq. (1).

We shall next demonstrate explicitly that having obtained the AL soliton lattice and single soliton solutions, one can immediately obtain the (previously not known) corresponding solutions of the Lamé problem by taking suitable limits of the appropriate AL solutions.

A. Lamé soliton lattice solutions

Starting from the AL soliton lattice solutions and considering the limit $\Gamma\to 0$, we obtain the two following types of Lamé soliton lattice solutions.

Cases I.1 and III $(p>0)$: These lead to type I Lamé soliton lattice solution. The solution is given by Eq. (9) with simpler forms for z_1, z_2, namely, $z_1=1/k^2$, $z_2=a^2$ $[=A^2/|p|k^2$, see Eq. (6)]:

$$\mathrm{sn}^2(\phi,k)=\frac{(1-k^2a^2)-(1-a^2)\mathrm{sn}^2(y,t)}{(1-k^2a^2)-k^2(1-a^2)\mathrm{sn}^2(y,t)}, \tag{56}$$

where $t=[(1-a^2)/(1-k^2a^2)]^{1/2}$ and $y=\sqrt{2pk^2(1-k^2a^2)}x$. As a result the Lamé soliton lattice energy per period $2L=2K(t)/\sqrt{2pk^2(1-k^2a^2)}$ of the lattice has the simpler form

$$E_{\mathrm{SL}}=2\sqrt{\frac{2pk^2}{1-k^2a^2}}\left[\left(\frac{1}{k^2}-\frac{a^2}{2}\right)K(t)-\frac{k'^2}{k^2}\Pi\left(\frac{k^2(1-a^2)}{1-k^2a^2},t\right)\right], \tag{57}$$

where recall that $\Pi(z_0,t)$ denotes the complete elliptic integral of the third kind.[18,19]

Case II.1 ($p<0$): This produces type II Lamé soliton lattice solution. In this case the solution is in fact the same as that given by Eq. (19), except that now z_1,z_2 take the simpler values $z_1=1/k^2$, $z_2=1-a^2$:

$$\mathrm{sn}^2(\phi,k)=\frac{(1-a^2)\mathrm{sn}^2(y,r)}{1-k^2(1-a^2)+k^2(1-a^2)\mathrm{sn}^2(y,r)}, \tag{58}$$

with $r=[k'^2(1-a^2)/[1-k^2(1-a^2)]^{1/2}$ and $y=\sqrt{2|p|k^2[1-k^2(1-a^2)]}x$. As a result the Lamé soliton lattice energy per period $2L=2K(r)/\sqrt{2|p|k^2[1-k^2(1-a^2)]}$ of the lattice now reads

$$E_{\mathrm{SL}}=2\sqrt{\frac{2|p|k^2}{1-k^2(1-a^2)}}\left[-\left(\frac{k'^2}{k^2}+\frac{a^2}{2}\right)K(r)+\frac{1}{k^2}\Pi\left(-\frac{k^2(1-a^2)}{1-k^2(1-a^2)},r\right)\right]. \tag{59}$$

B. Lamé single soliton solutions

We can now easily obtain the corresponding Lamé topological (kink-like) single soliton solutions, either by taking the appropriate limits of the Lamé soliton lattice solutions, or of the AL single soliton solutions.

Type I ($p>0$)*:* For example, considering $\Gamma=0$ in the expressions for the AL soliton solution as given by Eq. (35), the corresponding Lamé one soliton solution turns out to be

$$\mathrm{sn}(\phi,k)=\frac{1}{\sqrt{1+k'^2\sinh^2(y^*)}}, \tag{60}$$

where $y^*=\sqrt{2pk^2}x$. The corresponding energy is then given by

$$E_{\mathrm{K}}=\sqrt{2p}\ln\left(\frac{1+k}{1-k}\right), \tag{61}$$

where we have used Eq. (37). The asymptotic (repulsive) interaction between two solitons, using Manton's method[14] from Eq. (41), is given by $U(a^2)\simeq\sqrt{p/2}ka^2$.

Type II ($p<0$)*:* Considering $\Gamma=0$ in the expressions for the AL soliton solution as given by Eq. (46) the corresponding Lamé soliton solution turns out to be

$$\mathrm{sn}(\phi,k)=\frac{\sinh(y^*)}{\sqrt{k'^2+\sinh^2(y^*)}}, \tag{62}$$

where $y^*=\sqrt{2|p|k^2k'^2}x$. The corresponding energy is given by

$$E_{\mathrm{K}}=2\sqrt{2|p|}\arctan\left(\frac{k}{k'}\right), \tag{63}$$

where we have used Eq. (47).

VI. CONCLUSION

We have obtained and presented a taxonomy of the exact soliton lattice and single soliton solutions, as well as their corresponding energies, for the Associated Lamé equation[8–10] in various parameter regimes. The class of solutions turns out to be very rich depending on the parameters (p,q) of the AL potential, Eq. (1). In appropriate limits we also obtained the single soliton and soliton lattice solutions of the Lamé equation. The topological and nontopological nature of the different solutions was discussed. As an illustration of Manton's method[14] we also computed, in a particular case, the asymptotic interaction energy between these solitons. In addition to their relevance in the study of nonlinear phenomena, these solutions provide valuable information about domain walls in field theory, materials and many physical systems. It would be worthwhile to study the stability of these solutions, and also the exact thermodynamical properties of these systems.

On bosonic limits of two recent supersymmetric extensions of the Harry Dym hierarchy

S. Yu. Sakovich[a)]
Mathematical Institute, Silesian University, 74601 Opava, Czech Republic

(Received 29 October 2003; accepted 17 March 2004;
published online 12 May 2004)

Two generalized Harry Dym equations, recently found by Brunelli, Das, and Popowicz in the bosonic limit of new supersymmetric extensions of the Harry Dym hierarchy [J. Math. Phys. **44**, 4756 (2003)], are transformed into previously known integrable systems: one, into a pair of decoupled KdV equations, the other one, into a pair of coupled mKdV equations from a bi-Hamiltonian hierarchy of Kupershmidt. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1745128]

I. INTRODUCTION

Integrable supersymmetric differential equations have been attracting much attention in modern mathematical physics and soliton theory (see, e.g., Ref. 1, and references therein). Supersymmetric extensions of known integrable bosonic (or classical) systems are of particular interest, because, if the number N of Grassmann variables is greater than one, those extensions can generate, in their bosonic limits, some new integrable classical systems which generalize the initial ones.

Recently, Brunelli, Das, and Popowicz[2] studied supersymmetric extensions of the Harry Dym hierarchy, and found, as bosonic limits of $N=2$ supersymmetric extensions, the following two new classical generalizations of the Harry Dym equation:

$$w_{0,t}=\tfrac{1}{2}(w_0^{-1/2})_{xxx},$$

$$\begin{aligned} w_{1,t}=\tfrac{1}{64}(&-16w_{1,xxx}w_0^{-3/2}+96w_{1,xx}w_{0,x}w_0^{-5/2}+72w_{1,x}w_{0,xx}w_0^{-5/2}-258w_{1,x}w_{0,x}^2w_0^{-7/2}\\ &-6w_{1,x}w_1^2w_0^{-7/2}+9w_1^3w_{0,x}w_0^{-9/2}-108w_1w_{0,xx}w_{0,x}w_0^{-7/2}+219w_1w_{0,x}^3w_0^{-9/2}), \end{aligned} \tag{1}$$

and

$$w_{0,t}=\tfrac{1}{16}(8(w_0^{-1/2})_{xxx}-6w_{1,x}w_1w_0^{-5/2}+9w_1^2w_{0,x}w_0^{-7/2}),$$

$$\begin{aligned} w_{1,t}=\tfrac{1}{32}(&-8w_{1,xxx}w_0^{-3/2}+48(w_{1,x}w_{0,x})_xw_0^{-5/2}-144w_{1,x}w_{0,x}^2w_0^{-7/2}-6w_{1,x}w_1^2w_0^{-7/2}+9w_1^3w_{0,x}w_0^{-9/2}\\ &+12w_1w_{0,xxx}w_0^{-5/2}-126w_1w_{0,xx}w_{0,x}w_0^{-7/2}+177w_{0,x}^3w_1w_0^{-9/2}), \end{aligned} \tag{2}$$

where w_0 and w_1 are functions of x and t. Note that in system (1), in the seventh term of the right-hand side of its second equation, we have corrected a misprint made in Ref. 2: the degree of w_0 should be $-7/2$ there.

In the present paper, we find chains of transformations which relate these new generalized Harry Dym (GHD) equations (1) and (2) with previously known integrable classical systems. In Sec. II, the GHD equation (1) is transformed into a pair of decoupled KdV equations. In Sec. III, the GHD equation (2) is transformed into a pair of coupled mKdV equations which belongs to the bi-Hamiltonian hierarchy of the modified dispersive water waves equation of Kupershmidt[3] (see also Ref. 4, p. 84). Section IV contains concluding remarks.

II. TRANSFORMING THE FIRST GHD EQUATION

Unfortunately, there are no generally applicable methods of transforming a given nonlinear system into another one, less complicated or better studied. In order to find necessary transformations, one usually follows the trial and error way in combination with some heuristic considerations. In the present case, we also used this way.

First, the transformation

$$w_0 = u(x,t)^{-2}, \quad w_1 = v(x,t), \quad t \mapsto -4t \tag{3}$$

brings the GHD equation (1) into the following simpler form:

$$u_t = u^3 u_{xxx},$$
$$v_t = u^3 v_{xxx} + 9u^2 v_x u_{xx} + 12u^2 u_x v_{xx} + 27uv u_x u_{xx} + \tfrac{57}{2} v u_x^3 + \tfrac{75}{2} u u_x^2 v_x + \tfrac{9}{8} u^6 v^3 u_x + \tfrac{3}{8} u^7 v^2 v_x. \tag{4}$$

Second, we try to transform x, u, and v in (4) as follows:

$$x = p(y,t), \quad u(x,t) = p_y(y,t), \quad v(x,t) = q(y,t). \tag{5}$$

This is an extension of the transformation used by Ibragimov[5] to relate the original Harry Dym equation with the Schwarzian-modified KdV equation. In the case of scalar evolution equations, the Ibragimov transformation (i.e. (5) with $v = q = 0$) is an essential link in chains of transformations between constant separant equations and nonconstant separant ones.[6,7] Also the transformation (5) appeared recently in Ref. 8, as an essential link in a chain of transformations between a system of symmetrically coupled Harry Dym equations and the Hirota–Satsuma system of coupled KdV equations.

The transformation (5) really works in the present case and relates the system (4) with the system

$$p_t = p_{yyy} - \tfrac{3}{2} p_y^{-1} p_{yy}^2,$$
$$q_t = q_{yyy} + 9p_y^{-1} p_{yyy} q_y + 27 p_y^{-2} p_{yy} p_{yyy} q + 18 p_y^{-2} p_{yy}^2 q_y + 9 p_y^{-1} p_{yy} q_{yy} + \tfrac{3}{2} p_y^{-3} p_{yy}^3 q + \tfrac{3}{8} p_y^6 q^2 q_y + \tfrac{9}{8} p_y^5 p_{yy} q^3. \tag{6}$$

To verify this, one may use the following identities:

$$u\partial_x = \partial_y, \quad u_t = p_{yt} - p_y^{-1} p_{yy} p_t, \quad v_t = q_t - p_y^{-1} q_y p_t. \tag{7}$$

Note that (5) is not an invertible transformation: it maps the system (6) into the system (4), whereas its application in the opposite direction, from (4) to (6), requires one integration by y. We have omitted the terms $\alpha(t)p_y$ and $\alpha(t)q_y$ in the right-hand sides of the first and second equations of (6), respectively, where this arbitrary function $\alpha(t)$ appeared as a ''constant'' of that integration.

Third, we make the transformation

$$f(y,t) = p_y^{-1} p_{yy}, \quad g(y,t) = p_y^3 q, \tag{8}$$

admitted by the system (6) owing to the form of its equations, and obtain the pair of decoupled mKdV equations

$$f_t = (f_{yy} - \tfrac{1}{2} f^3)_y, \quad g_t = (g_{yy} + \tfrac{1}{8} g^3)_y. \tag{9}$$

Needless to say that the pair of Miura transformations

$$a(y,t)=\pm f_y-\tfrac{1}{2}f^2, \quad b(y,t)=\pm\tfrac{1}{2}\mathrm{i}g_y+\tfrac{1}{8}g^2, \tag{10}$$

with independent choice of the $\pm$ signs, relates (9) with the two copies of the KdV equation

$$a_t=a_{yyy}+3aa_y, \quad b_t=b_{yyy}+3bb_y. \tag{11}$$

III. TRANSFORMING THE SECOND GHD EQUATION

We follow the same three-step transformation as used in Sec. II.

First, the transformation (3) brings the GHD equation (2) into the form

$$\begin{aligned} u_t&=u^3u_{xxx}-\tfrac{9}{4}u^7v^2u_x-\tfrac{3}{4}u^8vv_x,\\ v_t&=3u^2vu_{xxx}+u^3v_{xxx}+36uvu_xu_{xx}+12u^2v_xu_{xx}\\ &\quad+12u^2u_xv_{xx}+24vu_x^3+36uu_x^2v_x+\tfrac{9}{4}u^6v^3u_x+\tfrac{3}{4}u^7v^2v_x. \end{aligned} \tag{12}$$

Second, we apply the transformation (5) to the system (12) and obtain

$$\begin{aligned} p_t&=p_{yyy}-\tfrac{3}{2}p_y^{-1}p_{yy}^2-\tfrac{3}{8}p_y^7q^2,\\ q_t&=3p_y^{-1}p_{yyyy}q+24p_y^{-2}p_{yy}p_{yyy}q+12p_y^{-1}p_{yyy}q_y+q_{yyy}-3p_y^{-3}p_{yy}^3q\\ &\quad+\tfrac{27}{2}p_y^{-2}p_{yy}^2q_y+9p_y^{-1}p_{yy}q_{yy}+\tfrac{9}{4}p_y^5p_{yy}q^3+\tfrac{3}{8}p_y^6q^2q_y, \end{aligned} \tag{13}$$

where the terms $\alpha(t)p_y$ and $\alpha(t)q_y$, with arbitrary $\alpha(t)$, have been omitted in the right-hand sides of the first and second equations, respectively.

Third, the transformation (8) relates the system (13) with the following system of coupled mKdV equations:

$$\begin{aligned} f_t&=(f_{yy}-\tfrac{3}{4}gg_y-\tfrac{1}{2}f^3-\tfrac{3}{8}fg^2)_y,\\ g_t&=(g_{yy}+3gf_y-\tfrac{3}{2}f^2g-\tfrac{5}{8}g^3)_y. \end{aligned} \tag{14}$$

The system (14) does not admit any further transformation into a system of coupled KdV equations. It is possible to transform (14) into a system of a KdV–mKdV type, but we will not follow this way. Instead, we notice that the system (14) is invariant under the change of variables $f\mapsto f$, $g\mapsto -g$. Therefore the transformation

$$f=c_1(a+b), \quad g=c_2(a-b), \tag{15}$$

with any nonzero constants c_1 and c_2, relates the system (14) with a system of symmetrically coupled mKdV equations for $a(y,t)$ and $b(y,t)$, which is invariant under $a\mapsto b$, $b\mapsto a$. Systems of symmetrically coupled mKdV equations possessing higher-order generalized symmetries were classified by Foursov.[9] The choice of

$$c_1=1, \quad c_2=\pm\mathrm{i} \tag{16}$$

in the transformation (15) brings the system (14) into the form

$$\begin{aligned} a_t&=(a_{yy}+3aa_y-3ba_y+a^3-6a^2b+3ab^2)_y,\\ b_t&=(b_{yy}+3bb_y-3ab_y+b^3-6b^2a+3ba^2)_y, \end{aligned} \tag{17}$$

which is exactly the case (K) in the Foursov classification.[9]

Foursov[9] proved that the system (17) represents the third-order generalized symmetry of the system of coupled Burgers equations

$$a_t=(a_y+a^2-2ab)_y, \quad b_t=(-b_y+2ab-b^2)_y, \tag{18}$$

and found the bi-Hamiltonian structure of this hierarchy with the Hamiltonian operators

$$P=\begin{pmatrix} 0 & \partial_y \\ \partial_y & 0 \end{pmatrix},$$
$$Q=\begin{pmatrix} -2a\partial_y-a_y & \partial_y^2+(a-b)\partial_y+a_y \\ -\partial_y^2+(a-b)\partial_y-b_y & 2b\partial_y+b_y \end{pmatrix}. \tag{19}$$

In its turn, the system of coupled Burgers equations (18) has a long history. As a system of coupled second-order evolution equations possessing higher-order symmetries, it appeared in the classifications of Mikhailov, Shabat, and Yamilov[10] and Olver and Sokolov.[11] Moreover, the bi-Hamiltonian structure (19) turns out to be not new. Indeed, the transformation

$$a=-r, \quad b=s-r, \quad t\mapsto -\tfrac{1}{2}t \tag{20}$$

relates the system (18) with the modified dispersive water waves equation

$$r_t=\tfrac{1}{2}(-r_y+2rs-r^2)_y,$$
$$s_t=\tfrac{1}{2}(s_y-2r_y-2r^2+2rs+s^2)_y, \tag{21}$$

which was introduced, together with its bi-Hamiltonian structure, by Kupershmidt[3] (see also Ref. 4, p. 84). The bi-Hamiltonian structures of (18) and (21) are related by the transformation (20) as well. For this reason, the system (17) is equivalent to a third-order member of the bi-Hamiltonian hierarchy of the modified dispersive water waves equation (21).

IV. CONCLUSION

In this paper, we found chains of transformations which relate the new GHD equations (1) and (2) of Brunelli, Das, and Popowicz with previously known integrable systems. The transformations (3), (5), (8), and (10) relate the GHD equation (1) with the pair of decoupled KdV equations (11). The transformations (3), (5), (8), (15) with the choice of (16), and (20) relate the GHD equation (2) with a third-order member of the bi-Hamiltonian hierarchy of the modified dispersive water waves equation (21).

It can be observed in the literature (see, e.g., Refs. 5, 6, 7, 10, and references therein) that quite often a newly-found remarkable equation turns out to be related to a well-studied old equation through an explicit chain of transformations. In such a situation, one gets a possibility not to study the new equation directly but to derive its properties from the well-known properties of the corresponding old equation, using the transformations obtained. Now this applies to the new generalized Harry Dym equations of Brunelli, Das, and Popowicz as well.

The pseudosymmetry condition on a manifold is a generalization of the notion of spaces of constant curvature. A complete algebraic classification of the pseudosymmetric space–times based on the Petrov type of the Weyl tensor and the Segré type of the Ricci tensor is presented. © *2004 American Institute of Physics.*
[DOI: 10.1063/1.1745129]

I. INTRODUCTION

The most simple generalizations of the flat pseudo-Euclidean space–time, i.e., Minkowski space, are the spaces of constant curvature. For these spaces the sectional curvature K does not depend on the point nor on the tangent plane at any point. Their Riemann tensor is given by

$$R_{\alpha\beta\gamma\mu}=K(g_{\alpha\gamma}g_{\beta\mu}-g_{\alpha\mu}g_{\beta\gamma}),$$

and the space–times of constant curvature are the de Sitter and anti–de Sitter space–times.[1]

Cartan introduced a further generalization by considering the Riemannian spaces for which every local geodesic reflection is an isometry. These are called the locally symmetric spaces and are characterized by the curvature condition

$$\nabla R=0,$$

or equivalently by the property that their sectional curvature is invariant under parallel translation along any curve. The symmetric Riemannian spaces were classified by Cartan[2] and the locally symmetric space–times were classified by Petrov.[3,4]

Of course, the curvature tensor of every locally symmetric space also satisfies the relation $R\cdot R=0$, or in local coordinates:

$$(R\cdot R)_{\alpha\beta\gamma\sigma\mu\nu}=(\nabla_\mu\nabla_\nu-\nabla_\nu\nabla_\mu)R_{\alpha\beta\gamma\sigma}=2R_{\mu\nu\rho[\alpha}R^{\rho}_{\beta]\gamma\sigma}+2R_{\mu\nu\rho[\gamma}R^{\rho}_{\sigma]\alpha\beta}=0.$$

The study of these so-called semisymmetric spaces was initiated by Cartan *et al.* and revitalised by Nomizu,[5] Takagi,[7] and Sekigawa,[6] leading to their classification by Szabó.[8] The semisymmetric spaces are characterized geometrically by the property that the sectional curvature of any plane remains invariant after a parallel translation of the plane along an infinitesimal parallellogram. The semisymmetric space–times were classified by Petrov.[3]

From this notion of semisymmetry we can define a scalar that in general depends on the point in the manifold and two planes, π spanned by $\mathbf{u}$ and $\mathbf{v}$, and $\pi^\star$ spanned by $\mathbf{X}$ and $\mathbf{Y}$, as follows:

$$L(p,\pi,\pi^\star)=\frac{(R\cdot R)(\mathbf{u},\mathbf{v},\mathbf{v},\mathbf{u};\mathbf{X},\mathbf{Y})}{Q(g,R)(\mathbf{u},\mathbf{v},\mathbf{v},\mathbf{u};\mathbf{X},\mathbf{Y})},$$

a)Electronic mail: Stefan.Haesen@kubrussel.ac.be

whereby $Q(g,R)$ is the (0,6)-Tachibana tensor given in component form as

$$Q(g,R)_{\alpha\beta\gamma\sigma\mu\nu}=2g_{\mu[\alpha}R_{\beta]\nu\gamma\sigma}-2g_{\nu[\alpha}R_{\beta]\mu\gamma\sigma}+2g_{\mu[\gamma}R_{\sigma]\nu\alpha\beta}-2g_{\nu[\gamma}R_{\sigma]\mu\alpha\beta}.$$

The vanishing of this tensor is a necessary and sufficient condition for a space to be of constant curvature;[9] the scalar L is therefore only defined on $U_R=\{x\in\mathcal{M}|Q(g,R)\neq 0 \text{ at } x\}$.

A manifold for which $L(p,\pi,\pi^\star)$ is isotropic, i.e., only depends on the point p, but not on the planes π and $\pi^\star$, is called pseudosymmetric in the sense of Deszcz.[10–12] These spaces are a further generalization of the spaces of constant curvature. We remark that there is no theorem here corresponding to that of Schur, i.e., $L(p)$ is not necessarily constant; there exist ample examples of pseudosymmetric manifolds which are not of constant type.

The pseudosymmetric Einstein space–times were classified in Ref. 13. Here we present the full classification of the pseudosymmetric space–times, showing in particular that they are of the Petrov types D or N or conformally flat.

II. PSEUDOSYMMETRIC SPACE–TIMES

We classify the general pseudosymmetric space–times by using the Newman–Penrose formalism (see, e.g., Ref. 14 for an introduction). Consider a general null tetrad $\{l^\alpha,n^\alpha,m^\alpha,\overline{m}^\alpha\}$, with the relations $l_\alpha n^\alpha=1=-m_\alpha\overline{m}^\alpha$. The space–time metric can then be written as

$$g_{\alpha\beta}=2l_{(\alpha}n_{\beta)}-2m_{(\alpha}\overline{m}_{\beta)}.$$

After projection of the pseudosymmetry condition,

$$R_{\mu\nu\rho[\alpha}R^{\rho}_{\beta]\gamma\sigma}+R_{\mu\nu\rho[\gamma}R^{\rho}_{\sigma]\alpha\beta}-L\{g_{\mu[\alpha}R_{\beta]\nu\gamma\sigma}-g_{\nu[\alpha}R_{\beta]\mu\gamma\sigma}+g_{\mu[\gamma}R_{\sigma]\nu\alpha\beta}-g_{\nu[\gamma}R_{\sigma]\mu\alpha\beta}\}=0,$$

on a general null tetrad, we find 34 algebraic relations between the Ricci and Weyl scalars. The 16 given below will suffice to present the classification, the other 18 relations are automatically satisfied in each of the cases we will consider:

$$2\Psi_0(\Psi_2-\Lambda)-2(\Psi_1)^2=L\Psi_0, \tag{1}$$

$$2\Psi_4(\Psi_2-\Lambda)-2(\Psi_3)^2=L\Psi_4, \tag{2}$$

$$\Phi_{02}(\overline{\Psi}_1-\Phi_{10})-\Phi_{01}(\overline{\Psi}_2+2\Lambda)+\Phi_{00}\Phi_{12}=L\Phi_{01}, \tag{3}$$

$$\Psi_3\Phi_{20}-\Psi_4\Phi_{10}=0, \tag{4}$$

$$\Phi_{01}\Phi_{22}+\Phi_{02}(\Psi_3-\Phi_{21})-\Phi_{12}(\Psi_2+2\Lambda)=L\Phi_{12}, \tag{5}$$

$$\Psi_3\Phi_{22}-\Psi_4\Phi_{12}=0, \tag{6}$$

$$2\Psi_1\Psi_3+\Psi_0\Psi_4-3\Psi_2(\Psi_2+2\Lambda)=3L\Psi_2, \tag{7}$$

$$2\Psi_3\Phi_{01}-2\Phi_{11}(\Psi_{22}+2\Lambda)-\Phi_{02}\Phi_{20}+\Phi_{00}\Phi_{22}=2L\Phi_{11}, \tag{8}$$

$$\Psi_3\Phi_{21}-\Psi_4\Phi_{11}=0, \tag{9}$$

$$\Psi_0\Phi_{20}+2\Psi_1\Phi_{10}-3\Psi_2\Phi_{00}=0, \tag{10}$$

$$\overline{\Psi}_0\Phi_{02}-2\Phi_{01}\Phi_{10}-\Phi_{00}(\overline{\Psi}_2-2\Phi_{11}+2\Lambda)=L\Phi_{00}, \tag{11}$$

$$\Psi_0\Phi_{22}+2\Psi_1\Phi_{12}-3\Psi_2\Phi_{02}=0, \tag{12}$$

$$\Psi_0\Phi_{22}-\Psi_1\Phi_{12}+\overline{\Psi}_3\Phi_{01}-\overline{\Psi}_4\Phi_{00}=0, \tag{13}$$

$$\overline{\Psi}_4\Phi_{00}+2\Phi_{01}\Phi_{12}-\Phi_{02}(\overline{\Psi}_2+2\Phi_{11}+2\Lambda)=L\Phi_{02}, \tag{14}$$

$$\Psi_4\Phi_{02}+2\Psi_3\Phi_{12}-3\Psi_2\Phi_{22}=0, \tag{15}$$

and

$$\Psi_4\Phi_{02}-2\Phi_{12}\Phi_{21}-\Phi_{22}(\Psi_2-2\Phi_{11}+2\Lambda)=L\Phi_{22}. \tag{16}$$

The above relations hold for a general null tetrad. For each Petrov type there exists a preferred tetrad, adapted to the principal null directions of the Weyl tensor, which makes a number of Weyl scalars zero.

If the space–time is of Petrov type I, we can find a null tetrad such that $\Psi_0=\Psi_4=0$ and $\Psi_1\neq 0$, $\Psi_2\neq 0$, and $\Psi_3\neq 0$. But from (1) and (2) we then find the contradiction $\Psi_1=\Psi_3=0$.

In a Petrov type II space–time we can construct a null tetrad such that $\Psi_0=\Psi_1=\Psi_4=0$, $\Psi_2\neq 0$, and $\Psi_3\neq 0$. But then again we find a contradiction with (2).

If the space–time is of Petrov type D we can choose l^α and n^α along the two double degenerate null directions such that $\Psi_0=\Psi_1=\Psi_3=\Psi_4=0$ and $\Psi_2\neq 0$. Equations (1)–(16) are then satisfied if and only if $\Phi_{0i}=\Phi_{2i}=0$ and $L=-(\Psi_2+2\Lambda)$. This is only possible when Ψ_2 is real.

In a Petrov type III space–time we can always construct a null tetrad such that $\Psi_0=\Psi_1=\Psi_2=\Psi_4=0$ and $\Psi_3\neq 0$. But then Eq. (2) gives again a contradiction.

If the space–time is of Petrov type N we can find a null tetrad such that $\Psi_0=\Psi_1=\Psi_2=\Psi_3=0$ and $\Psi_4\neq 0$. The pseudosymmetry relations (1)–(16) are satisfied if and only if $\Phi_{0i}=\Phi_{1i}=0$ and $L=-2\Lambda$.

A space–time is conformally flat, i.e., Petrov type O, if $\Psi_i=0$, $\forall i=0,\ldots,4$. Equations (1)–(16) then reduce to

$$2\Phi_{00}(\Phi_{11}-\Lambda)-2\Phi_{01}\Phi_{10}=L\Phi_{00}, \tag{17}$$

$$\Phi_{00}\Phi_{12}-\Phi_{02}\Phi_{10}-2\Phi_{01}\Lambda=L\Phi_{01}, \tag{18}$$

$$2\Phi_{01}\Phi_{12}-2\Phi_{02}(\Phi_{11}+\Lambda)=L\Phi_{02}, \tag{19}$$

$$\Phi_{00}\Phi_{22}-\Phi_{02}\Phi_{20}-4\Phi_{11}\Lambda=2L\Phi_{11}, \tag{20}$$

$$\Phi_{01}\Phi_{22}-\Phi_{02}\Phi_{21}-2\Phi_{12}\Lambda=L\Phi_{12}, \tag{21}$$

$$2\Phi_{22}(\Phi_{11}-\Lambda)-2\Phi_{12}\Phi_{21}=L\Phi_{22}. \tag{22}$$

In summary we have the following:

Theorem II.1: (i) Petrov type I, II, and III space–times are not pseudosymmetric.

(ii) A Petrov type D space–time is pseudosymmetric iff w.r.t. the principal null tetrad the Ricci tensor has the form $R_{\alpha\beta}=2R_{12}l_{(\alpha}n_{\beta)}+2R_{34}m_{(\alpha}\overline{m}_{\beta)}$ (i.e., the Segré type is [(1,1)(11)]) and $L=-(\Psi_2+2\Lambda)$ with real Ψ_2.

(iii) A Petrov type N space–time is pseudosymmetric iff w.r.t. the principal null tetrad the Ricci tensor has the form $R_{\alpha\beta}=R_{22}l_\alpha l_\beta+R_{12}g_{\alpha\beta}$ (i.e., the Segré type is [2,(11)]) and $L=-2\Lambda$.

(iv) A Petrov type O space–time is pseudosymmetric iff the Ricci tensor satisfies the relations (17)–(22).

For $L=0$ the above theorem yields the classification of the semisymmetric space–times (see e.g., Ref. 3, p. 350 for an alternative way of classifying the semisymmetric space–times).

Theorem II.2: (i) Petrov type I, II, III space–times are not semisymmetric.

(ii) A Petrov D space–time is semisymmetric iff w.r.t. the principal null tetrad the Ricci tensor has the form $R_{\alpha\beta}=2R_{12}l_{(\alpha}n_{\beta)}+2R_{34}m_{(\alpha}\overline{m}_{\beta)}$ (i.e., the Segré type is $[(1,1)(11)]$) and real $\Psi_2=-2\Lambda$.

(iii) A Petrov type N space–time is semisymmetric iff w.r.t. the principal null tetrad the Ricci tensor has the form $R_{\alpha\beta}=R_{22}l_\alpha l_\beta$ (i.e., the Segré type is $[(1,111)]$).

(iv) A Petrov type O space–time is semisymmetric iff the Ricci tensor satisfies the relations (17)–(22) with $L=0$.

Using the Segré type of the Ricci tensor we obtain information about the possible matter content of the pseudosymmetric space–times. We hereafter consider only the physically most relevant cases of vacuum, Einstein, perfect fluid, and electromagnetic (non-)null Maxwell fields.

Corollary II.1: (i) Every vacuum Petrov type D space–time with real Ψ_2 w.r.t. the principal null tetrad is pseudosymmetric (e.g., the Schwarzschild and Kantowski–Sachs metrics). Every Petrov type D non-null Maxwell field ($R_{12}=R_{34}$) is pseudosymmetric and also every Petrov type D Einstein space ($R_{12}=-R_{34}$) is pseudosymmetric. Petrov type D perfect fluids and electromagnetic null fields are not pseudosymmetric.

(ii) A Petrov type N Einstein space–time ($R_{22}=0$) is pseudosymmetric. Space–times of Petrov type N vacuum, perfect fluid or electromagnetic (non)-null field, are not pseudosymmetric ($\Lambda\neq 0$).

(iii) Einstein and perfect fluid (e.g., Robertson–Walker) conformally flat space–times are pseudosymmetric. In the latter case the proportionality factor equals $L=-\frac{1}{3}\rho$, ρ being the energy density. Electromagnetic (non-)null Petrov type O space–times are not pseudosymmetric.

Because a Petrov type D vacuum space–time is only pseudosymmetric if Ψ_2 is real this excludes the Kinnersley class[15] II.E. The metrics in the Kinnersley classes I (i.e. the NUT space–times), II.F, III.A, and IV.A are all pseudosymmetric. In the other classes only those with real nonvanishing Weyl scalar are pseudosymmetric. As such, for example, the Kerr metric, which belongs to Kinnersley class II.A, is readily seen to be not pseudosymmetric (as mentioned already in Ref. 13, although we would like to point out here that the calculations done there for this latter fact were not correct).

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 6 JUNE 2004

Calculation of the self force using the extended-object approach

Amos Ori and Eran Rosenthal[a)]
Department of Physics, Technion-Israel Institute of Technology, Haifa 32000, Israel

(Received 24 September 2003; accepted 24 February 2004;
published online 13 May 2004)

We present the extended-object approach for the explanation and calculation of the self-force phenomenon (often called ''radiation-reaction force''). In this approach, one considers a charged extended object of a finite size ϵ that accelerates in a nontrivial manner, and calculates the total force exerted on it by the electromagnetic field (whose source is the charged object itself). We show that at the limit $\epsilon \to 0$ this overall electromagnetic field yields a universal result, independent of the object's shape, which agrees with the standard expression for the self force acting on a point-like charge. Previous implementation of this approach ended up with expressions for the total electromagnetic force that include $O(1/\epsilon)$ terms which do not have the form required by mass-renormalization. (In the special case of a spherical charge distribution, this $\propto 1/\epsilon$ term was found to be 4/3 times larger than the desired quantity.) We show here that this problem was originated from a too naive definition of the notion of ''total electromagnetic force'' used in previous analyses. We then derive the correct notion of total electromagnetic force. This completely cures the problematic $O(1/\epsilon)$ term, for any object's shape, and yields the correct self force at the limit $\epsilon \to 0$. In particular, for a spherical charge distribution, the above ''4/3 problem'' is resolved. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1737052]

I. INTRODUCTION AND SUMMARY

When an electrically charged particle accelerates (nonuniformly) in flat space–time, it exerts a force on itself. This force, known as the *self force* (or ''radiation-reaction force''), results from the particle's interaction with its own electromagnetic field. Early investigations by Abraham[1] and Lorentz,[2] in the case of nonrelativistic motion, showed that the self force is proportional to the time derivative of the acceleration. Later, Dirac[3] obtained the covariant relativistic expression for the self force:

$$f^{\mu}_{\rm self} = \tfrac{2}{3} q^2 (\dot{a}^{\mu} - a^2 u^{\mu}) \ , \tag{1}$$

where q is the electrical charge, u^{μ} and a^{μ} denote the four-velocity and four-acceleration, respectively, an overdot denotes a proper-time derivative, and $a^2 \equiv a^{\mu} a_{\mu}$.[4] Dirac derived this expression by considering the momentum flux through a ''world-tube'' surrounding the particle's worldline, and demanding energy–momentum conservation.

The fact that a particle can exert a force on itself is obviously intriguing. One of the ways to make sense of this phenomenon is by considering a charged, rigid, extended object of finite size ϵ. A model of a continuously charged, finite-size object has the obvious advantage that the electromagnetic field is everywhere regular, allowing (in principle) an almost straightforward calculation of all electromagnetic forces involved (this is of course not the case when a point-like charge is considered, as the field is singular at the particle's location). On physical grounds, one would expect that an extended object of a sufficiently small size will behave like a point-like particle.

a)Electronic mail: pheran@techunix.technion.ac.il

(One should expect finite-size correction terms, which may depend on the object's shape, but one would hope these corrections would become negligible for a sufficiently small object.)

For a finite-size extended object, each charge element exerts an electromagnetic force on each other charge element. Then, roughly speaking, the overall electromagnetic force that the charged object exerts on itself is the sum of the contributions of all mutual forces between all pairs of the object's charge elements. In the case of a static object this sum always vanishes. However for an accelerating object this sum generically does not vanish due to the energy–momentum exchange between the charged object and the electromagnetic field. In particular, the electromagnetic radiation field carries energy and momentum away from the object to infinity (hence the name "radiation-reaction force").

Recognizing that the overall mutual electromagnetic force does not vanish, one is tempted to identify this overall force with the notion of the self force acting on a charged particle. Thus, one would hope that at the limit where the object's size is taken to zero, a universal result (independent of the object's size and shape) will be obtained, which will coincide with Eq. (1). Many attempts have been made to derive this extended-object total force. Two types of models have been considered: objects that are continuously charged,[2,5–7] and objects with a finite number of discrete charges.[7] The simplest model of a discretely charged rigid object is the "dumbbell," i.e., a fixed-length rod with two point charges located at its two edges. The previous analyses of both the continuous and discrete models revealed that indeed the overall electromagnetic force does not generally vanish. But these analyses also indicated a fundamental difficulty (which we shortly explain), which made it impossible to derive the universal small-size limit of this force. The goal of this paper is to provide a simple resolution to this difficulty.

Let $f^{\mu}_{\rm sum}$ denote the sum of (or, in the continuous model, the double-integral over) all mutual electromagnetic forces, acting on all charge elements at a particular moment. (By "particular moment" we refer here to a hypersurface of simultaneity in the particle's rest frame; see the following.) We would like to explore how $f^{\mu}_{\rm sum}$ depends on ϵ. For all types of electrically charged objects, the small-ϵ dependence of $f^{\mu}_{\rm sum}$ is found to be of the form

$$f^{\mu}_{\rm sum}=c^{\mu}_{-1}/\epsilon+c^{\mu}_{0}+O(\epsilon)\,. \tag{2}$$

The $O(\epsilon)$ term will not concern us here, as it vanishes at the limit $\epsilon\to 0$. The coefficients c^{μ}_{0} and c^{μ}_{-1} depend on the object's worldline, but are (by definition) independent of ϵ.

The $O(\epsilon^{-1})$ term is the problematic term, as it diverges at the limit of interest, i.e., $\epsilon\to 0$. Obviously, the small-object limit does not make sense if we do not know how to handle the problematic term c_{-1}/ϵ.

Now, there is a standard procedure of *mass-renormalization*, often used for eliminating such $O(\epsilon^{-1})$ terms. However, the very nature of this procedure requires that the undesired $O(\epsilon^{-1})$ term will be of the form $-ca^{\mu}$, where c is a parameter that is independent of the time and the state of motion (though it may depend on the object's size and shape): A force term of the form $a^{\mu}\cdot$const can be dropped, because it is experimentally indistinguishable from an inertial term in the equation of motion (see Sec. II). In order for the whole theory to make sense (assuming that interaction energy equally contributes to the inertial mass), the constant c must be equal to the object's electrostatic energy, which we denote $E_{\rm es}$. (Recall that the latter scales like ϵ^{-1}.)

The problem is that the term c^{μ}_{-1}/ϵ is actually *not* equal to $-E_{\rm es}a^{\mu}$—and, furthermore, generally it is not in the form $-ca^{\mu}$, nor is it even in the direction of a^{μ}. In the special case of a spherical charge distribution, several authors found[2,5–7] that the term c^{μ}_{-1}/ϵ indeed takes the form $-ca^{\mu}$, but with $c=(4/3)E_{\rm es}$. This is the well-known "4/3 problem." In this special case the mass-renormalization procedure still makes sense from the operational point of view (because any force term of the form $-ca^{\mu}$ is experimentally indistinguishable from an inertial term), though the logical consistency of the theory may be questioned. The situation is worse, however, when the charge distribution is asymmetric. In such a situation one generally finds that the problematic term c^{μ}_{-1}/ϵ is not even in the direction of a^{μ}. Clearly, this type of divergent term cannot be removed by mass renormalization. A simple demonstration of this situation was given by Griffiths and Owen,[7]

who considered a one-directional motion of a dumbbell. They found that when the dumbbell is oriented perpendicular to the direction of motion, then $c^{\mu}_{-1}/\epsilon = -E_{\rm es}a^{\mu}$ as desired. However, if the dumbbell is co-directed with the motion, then $c^{\mu}_{-1}/\epsilon = -ca^{\mu}$ with $c = 2E_{\rm es}$. Furthermore, if the dumbbell is oriented in any other direction, the term c_{-1}/ϵ will not be co-directed with a^{μ}. Clearly, in such a generic situation the problematic term c^{μ}_{-1}/ϵ cannot be removed by mass renormalization. As a consequence, the limit $\epsilon \to 0$ of $f^{\mu}_{\rm sum}$ does not make a physical sense. We note that this problem arises even if the object's motion is treated in a fully relativistic manner[8]—as long as the quantity $f^{\mu}_{\rm sum}$ is considered.

It should be noted that in the case of a spherical charge distribution there is another ''4/3 problem'': When the object is in slow motion, the electromagnetic-field momentum turns out to be 4/3 times the electromagnetic-field energy times the velocity.[2] We may refer to this problem as the ''inertial 4/3 problem'' (as opposed to the ''mass-renormalization 4/3 problem''). We shall not address this problem here. The relation between these two ''4/3 problems'' is not completely clear. Poincaré[10] introduced the nonelectromagnetic internal stresses in order to resolve the inertial 4/3 problem. On the other hand, the analysis presented in the following clearly indicates that no consideration of the nonelectromagnetic internal forces is required for solving the mass-renormalization 4/3 problem.[11]

In this paper we shall provide a simple and natural solution to the above-mentioned mass-renormalization problem. We shall show that the overall mutual electromagnetic force is *not* the quantity $f^{\mu}_{\rm sum}$ (i.e., the naive sum or integration over all mutual forces); By employing simple energy–momentum considerations we show that the overall mutual electromagnetic force, which we denote $f^{\mu}_{\rm mutual}$, is the sum (or integral) over all mutual forces, each multiplied by a certain kinematic factor representing the proper-time lapse of each charge element between two ''moments'' (i.e., between two neighboring hypersurfaces of simultaneity; see Sec. II). This kinematic factor is of the form $1+O(\epsilon)$; and the $O(\epsilon)$ correction (when multiplying the mutual forces $\propto \epsilon^{-2}$) leads to a difference between $f^{\mu}_{\rm sum}$ and $f^{\mu}_{\rm mutual}$, proportional to ϵ^{-1}, which is exactly the amount required to correct the problematic term c^{μ}_{-1}/ϵ. Namely, when $f^{\mu}_{\rm mutual}$ is expanded in powers of ϵ, it takes a form similar to Eq. (2), but with an $O(1/\epsilon)$ term which is precisely of the form $-E_{\rm es}a^{\mu}$. This $O(1/\epsilon)$ term is naturally removed by mass renormalization.

After we have eliminated the problematic $O(\epsilon^{-1})$ term in Eq. (2), we are left with the regular term c^{μ}_{0}. It is this term which should yield the desired expression for the self force. With the anticipation that the self force should be universal, one would expect c^{μ}_{0} to depend only on the object's total charge q, and not on the way it is distributed. In fact, the very nature of the self-force phenomenon—the force that a charge exerts on itself—suggests that the self force must be proportional to q^2. For continuous charge distributions, the term c^{μ}_{0} is indeed found to be $\propto q^2$ and it can be brought to the form (1). However, for discrete charge distributions c^{μ}_{0} is found to depend on the charge distribution. This is best demonstrated in the simplest discrete model, the dumbbell. In this case, c^{μ}_{0} (like the mutual forces) is proportional to the product q_+q_-, rather than to $q^2 = (q_+ + q_-)^2$, where q_+ and q_- denote the two edge charges. This apparent inconsistency has an obvious origin: The overall force exerted on the dumbbell by the electromagnetic field includes not only the mutual forces between different charges, but also the forces that each of the individual charges exerts *on itself* (which we shall refer to as the ''partial self force,'' to distinguish it from the ''overall self force'' acting on the dumbbell). Obviously, it would be inconsistent to neglect these partial self forces: By universality considerations, one may view each of the point charges as a very small extended charged object; And, the result of our analysis, namely, $c^{\mu}_{0} \neq 0$, should apply to each of these individual charged objects as well, therefore, these forces cannot be ignored. Note that the partial self forces do not depend on the other charges in the extended object, so they are by definition independent of ϵ. Therefore they do not affect the divergent term $O(\epsilon^{-1})$, but merely add to the term c^{μ}_{0}. The need to include these partial self forces might appear disturbing, as these quantities are initially unknown. However, basic considerations imply that the self force acting on each charged object must be proportional to the square of its charge. This observation provides us with the required expression for the partial self forces (more precisely, the relation of the latter to the overall self forces). The inclusion of the partial self forces leads to a universal expression for

the overall electromagnetic force acting on the dumbbell (or on any other discrete charge distribution), which is indeed proportional to the square of the total charge as desired, and which coincides with Eq. (1). We further show in Sec. IV that for a continuous charge distribution the contribution of the partial self forces vanishes. Therefore, in the continuous case the quantity c_0^μ (i.e., the properly weighted integral of the mutual electromagnetic forces) directly yields the desired universal expression for the self force, Eq. (1).

The overall mutual force $f^\mu_{\rm mutual}$ may naturally be viewed as the sum (or double-integral) of the contributions of all *pairs* of charge element. The contribution of each such pair is the sum of the two mutual forces, each weighted by the above-mentioned kinematic factor. In summing these two forces, the dominant $O(\epsilon^{-2})$ term always cancels out (leaving a weaker divergence $\propto\epsilon^{-1}$ that is in turn handled by mass-renormalization). This leading-order cancellation occurs for each pair separately, suggesting that the fundamental element in any extended-object model is the single pair of charges. Once the single-pair system is well understood, the analysis of any charge distribution will follow quite immediately—essentially by summing (or double-integrating) over all pairs of charge elements. We shall therefore start by analyzing the *dumbbell model*, i.e., a pair of point-like charges separated by a fixed-length rod. Then we shall consider a discrete system with an arbitrary number N of charges. Then, taking the infinitesimal limit (in which $N\to\infty$), we shall analyze the case of continuous charge distribution. In all cases the object (and the charge distribution) is regarded as rigid, and we allow it to move (nonrotationally) along an arbitrary worldline. For both the discrete and continuous cases, we obtain the same universal result: After calculating the overall mutual electromagnetic force $f^\mu_{\rm mutual}$, mass-renormalizing it, and then taking the limit $\epsilon\to0$, we recover the desired expression (1) for the self force.

We should mention here previous analyses which seemingly overcame the mass-renormalization 4/3 problem in the spherical case. First, Fermi[16] carried out an extended-object analysis of a different type: Instead of summing the contributions of all mutual forces, he constructed an effective relativistic Hamiltonian of a charged rigid body, and derived the equation of motion from this Hamiltonian. It seems that no ''4/3 problem'' is encountered in this method. Later, Nodvick used a similar method[17] and obtained the correct expression for the self force (note, however, that these analyses[16,17] only considered spherically symmetric distributions, whereas we are treating here an arbitrary charge distribution). Also, after this work was completed, we became aware of a previous work by Pearle,[12] in which he analyzed the case of a spherically symmetric charged object. In this analysis he took into account the above-mentioned kinematic weighting factor which expresses the proper-time lapse of each charge element. Then, in a fairly complicated calculation he obtained the correct $O(1/\epsilon)$ term, namely, $-E_{\rm es}a^\mu$, thereby overcoming the 4/3 problem in the case of spherical charge distribution. We believe that our analysis is simpler, more transparent, and it is also much more general; In particular, the analysis presented here resolves the mass-renormalization problem for *any* type of charge distribution.

An outline of the analysis given here was published recently, focusing on the case of dumbbell-like charge distribution.[18] Here we present the full calculations, and also analyze in detail extended objects with an arbitrary number of point charges, as well as continuously charged extended objects (these cases were only briefly mentioned in Ref. 18).

In Sec. II we analyze the dumbbell model, i.e., the case of two point-like charges. We first formulate the dumbbell's relativistic kinematics. Then we calculate the mutual forces, obtain their sum $f^\mu_{\rm sum}$, and (following Griffiths and Owen[7]) demonstrate the severe mass-renormalization directionality problem discussed earlier. Then we use energy–momentum considerations to construct the correct expression for the overall mutual electromagnetic force $f^\mu_{\rm mutual}$. We show that the latter is free of the mass-renormalization problem. In Sec. III we extend the analysis to a system with an arbitrary number of point-like charges. Finally, in Sec. IV we consider the case of a continuous charge distribution. In all three cases we obtain, at the limit $\epsilon\to0$, the universal result (1).

II. A CHARGED DUMBBELL

A. The general approach

We consider a dumbbell made of a rigid rod with two point charges located at its two edges. The forces acting on the dumbbell (or on its parts) may be schematically divided into several types:

(1) Electromagnetic forces: the forces exerted on the two charges by the electromagnetic field they produce.
(2) The ''other internal forces:'' the inter-atomic (or ''elastic'') forces that are responsible for the dumbbell's rigidity.
(3) External forces: forces exerted on the dumbbell by external fields.[19]

The electromagnetic forces acting on the two charges are divided into two types: (i) mutual electromagnetic forces, i.e., forces that one charge exerts on the other one [more precisely, it is the force that the electromagnetic field produced by one charge (in the sense of the retarded Lienard–Wiechert solution) exerts on the other charge]; and (ii) the self forces that each of the two charges exerts on itself, which we shall refer to as the ''partial self forces'' (to be distinguished from the overall self force acting on the dumbbell). The justification and necessity of including the partial self forces in our analysis is discussed in the following, but two remarks should be made already at this stage: First, the partial self forces are not relevant to the mass-renormalization problem, as they only affect the term c_0^μ (above), not the problematic term c_1^μ/ϵ. Second, these partial self forces are very significant for a system of two charges (they contribute at least as much as the mutual forces do), but they become less important in a system including a large number N of point charges (assuming that the magnitude of the individual charges scales line $1/N$). This is because the number of mutual forces scales like N^2, whereas the number of partial self forces scales like N. Most important, the contribution of partial self forces vanishes at the continuum limit, as we discuss in Sec. IV.

In Newtonian theory it is usually presumed that the sum of any pair of mutual forces will always vanish; however, when electromagnetic interactions are concerned, this presumption does not hold. Its failure may be attributed to the long range of the electrodynamical interaction between two charges. It is this long range which is responsible for the electromagnetic radiative phenomena (which transport energy and momentum away from the interacting charges). On the other hand, the nonelectromagnetic internal forces are assumed here to be of ''short range.'' [20] Hence, it will be assumed that upon summation these forces will always cancel out (except for a ''mass-renormalization like'' term, which is the interaction energy associated with these forces, multiplied by the four-acceleration). For this reason, the nonexternal forces that are relevant to the calculations to follow are only the electromagnetic ones, namely, (i) the two mutual forces between the two charges, and (ii) the two ''partial self forces.''

B. Dumbbell's structure and kinematics

The dumbbell consists of two point charges situated at the edges of a rigid rod of a proper length 2ϵ. We shall assume that ϵ is small compared to $1/a$, where a denotes the norm of the acceleration vector. Throughout this section we shall use the subscripts ''$+$'' or ''$-$'' to denote the quantities associated with the two dumbbell's edges. The two electric charges are therefore denoted q_+ and q_-, respectively, and the total charge is $q \equiv q_+ + q_-$. We do *not* require the two charges to be equal. We assume that ϵ is time-independent and that the dumbbell moves in a nonrotational manner (see the following).

We take the dumbbell's central point (i.e., half way between the two edges) to represent the dumbbell's motion. The worldline of this representative point is denoted $z^\mu(\tau)$, where τ is the proper time along the central worldline. The four-velocity and four-acceleration of the central worldline are defined in the usual manner, $u^\mu \equiv \dot{z}^\mu$ and $a^\mu \equiv \dot{u}^\mu$, where an overdot denotes differ-

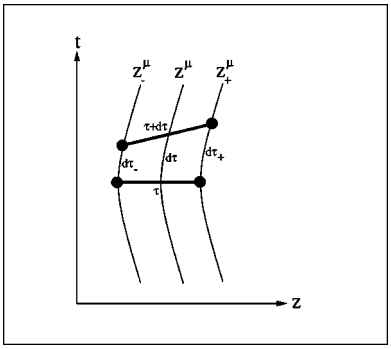

FIG. 1. A space–time diagram describing the dumbbell's kinematics. t is the time coordinate (in some inertial reference frame), and z schematically represents a spatial coordinate. The dumbbell is represented by a straight bold line, with the black points representing the two edge points $z^\mu_\pm$. Two such bold lines are shown, representing the dumbbell's location in space–time at two moments separated by an infinitesimal time interval $d\tau$. The three thin solid lines are the worldlines of the central point z^μ and the two edge points $z^\mu_\pm$.

entiation with respect to τ. We denote the two rod's edges by $z^\mu_+(\tau)$ and $z^\mu_-(\tau)$. At any given moment (by "moment" we mean here a hypersurface of simultaneity in the momentary rest frame of the central point) the two rod's edges are located at (see Fig. 1)

$$z^\mu_\pm(\tau) \equiv z^\mu(\tau) \pm \epsilon w^\mu(\tau) \ , \tag{3}$$

where $w^\mu(\tau)$ is a unit spatial vector, satisfying

$$w_\mu w^\mu = 1, \quad w^\mu u_\mu = 0. \tag{4}$$

The time evolution of w^μ is completely determined by its role here as a vector representing a nonrotating rod: (i) As a unit vector, its norm should be time-independent (corresponding to a rod of fixed length), which implies $\dot{w}^\mu w_\mu = 0$; (ii) as a spatial vector w^μ should be normal to the worldline at all times. Differentiating the second equation in (4) we obtain

$$\dot{w}^\mu u_\mu = -w_\mu a^\mu \ . \tag{5}$$

(iii) Since we assume that w^μ is nonrotating in the momentary rest frame of $z^\mu(\tau)$, $\dot{w}^\mu$ should be free of any spatial component, i.e.,

$$\dot{w}^\mu = c(\tau) u^\mu \ , \tag{6}$$

where $c(\tau)$ is some (yet unspecified) scalar. The last demand, combined with the second equation in (4), guarantees that restriction (i) is satisfied. Substituting Eq. (6) in (5) we find

$$c(\tau) = w_\mu a^\mu \ .$$

We thus arrive at the evolution law

$$\dot{w}^\mu = u^\mu a^\nu w_\nu = u^\mu a_w \ , \tag{7}$$

where we have introduced the scalar $a_w \equiv w_\lambda a^\lambda$. This is in fact an implementation of the more general Fermi–Walker transport law (see, e.g., Ref. 21), $\dot{e}^\mu = (u^\mu a^\nu - u^\nu a^\mu) e_\nu$, to a spatial vector w^μ.

Next, we calculate the four-velocities and accelerations of the dumbbell's edges. We denote the proper times along the worldlines of the two rods' edges $z^\mu_\pm$ by $\tau_\pm$, respectively. Note that

generally τ_+ and τ_- differ from τ (and from each other). The four-velocities of the two charges are defined in the usual manner, $u_\pm^\mu \equiv dz_\pm^\mu/d\tau_\pm$. Differentiating Eq. (3), with respect to $\tau_\pm$, we obtain

$$u_\pm^\mu = (u^\mu \pm \epsilon \dot{w}^\mu)\frac{d\tau}{d\tau_\pm} = \left[(1 \pm \epsilon a_w)\frac{d\tau}{d\tau_\pm}\right]u^\mu \quad . \tag{8}$$

Taking the norm of the two sides of this equation, recalling that both u^μ and $u_\pm^\mu$ are of unit norm, we find that the term in square brackets is just unity, namely,

$$\frac{d\tau_\pm}{d\tau} = 1 \pm \epsilon a_w \quad . \tag{9}$$

It now immediately follows that

$$u_\pm^\mu = u^\mu \quad . \tag{10}$$

These are the two key features of the rod's kinematics.

Equation (10) indicates that in the rest frame of the dumbbell's central point, the two edges (and similarly any other point on the dumbbell) are at rest as well. We can therefore identify this reference frame as the rest frame of the entire dumbbell. Since at any moment there exists a reference frame in which the entire dumbbell is momentarily at rest, it is justified to view this type of motion as a rigid motion.

We denote by $a_\pm^\mu$ the four-accelerations of the two edge points, namely, $a_\pm^\mu = du_\pm^\mu/d\tau_\pm$. From Eqs. (9) and (10) it immediately follows that

$$a_\pm^\mu = \frac{a^\mu}{1 \pm \epsilon a_w} \quad . \tag{11}$$

C. Mutual forces

At the heart of the dumbbell's model are the mutual forces acting between the two charges. To determine these forces, we need an expression for the retarded electromagnetic field tensor $F_{\mu\nu}$ that a single point charge q moving on an arbitrary worldline $z^\mu(\tau)$ produces at a nearby point $z^\mu + \hat{\epsilon}\hat{w}^\mu$, where $\hat{\epsilon}$ is a small positive number ($\hat{\epsilon} = 2\epsilon$), and $\hat{w}^\mu$ is a unit spatial vector satisfying $\hat{w}^\mu \hat{w}_\mu = 1, \hat{w}^\mu u_\mu = 0$. Later we shall apply the limit $\epsilon \to 0$, and therefore we shall only need an expression for $F_{\mu\nu}$ valid up to zero order in $\hat{\epsilon}$. Such an expression was derived by Dirac:[3]

$$\begin{aligned} F_{\mu\nu} &\cong \frac{q}{\sqrt{(1+\hat{\epsilon}a_{\hat{w}})}}\left[\left(\frac{u_\mu \hat{w}_\nu}{\hat{\epsilon}^2} + \frac{a_\mu u_\nu}{2\hat{\epsilon}} + \frac{a^2 u_\mu \hat{w}_\nu}{8} - \frac{\dot{a}_\mu \hat{w}_\nu}{2} - \frac{a_{\hat{w}} a_\mu u_\nu}{2} - \frac{2}{3}\dot{a}_\mu u_\nu\right) - (\mu \leftrightarrow \nu)\right] \\ &\cong q\left[\left(\frac{u_\mu \hat{w}_\nu}{\hat{\epsilon}^2} + \frac{a_\mu u_\nu - a_{\hat{w}} u_\mu \hat{w}_\nu}{2\hat{\epsilon}} - \frac{2}{3}\dot{a}_\mu u_\nu + \hat{Z}_{\mu\nu}\right) - (\mu \leftrightarrow \nu)\right], \end{aligned} \tag{12}$$

where $a_{\hat{w}} \equiv a_\lambda \hat{w}^\lambda$,

$$\hat{Z}_{\mu\nu} \equiv \frac{a^2 u_\mu \hat{w}_\nu}{8} - \frac{\dot{a}_\mu \hat{w}_\nu}{2} + \frac{3a_{\hat{w}}^2 u_\mu \hat{w}_\nu}{8} - \frac{3a_{\hat{w}} a_\mu u_\nu}{4}, \tag{13}$$

$a^2 \equiv a_\mu a^\mu$, and throughout this paper the "$\cong$" symbol denotes an equality up to $O(\epsilon)$ correction terms. $\hat{Z}_{\mu\nu}$ is the collection of all terms that are proportional to $\hat{\epsilon}^0$ and to an odd power of $\hat{w}$. Such terms will cancel out when summing the contributions of the two charges (see the following). The electromagnetic field $F_+^{\mu\nu}$ that the charge q_- produces at the location of charge q_+ is obtained by substituting in Eqs. (12) and (13) $q \to q_-$, $a \to a_-$, $\dot{a} \to da_-/d\tau_-$, $\hat{w}^\mu \to w^\mu$, $a_{\hat{w}} \to a_-^\lambda w_\lambda$, and

$\hat{\epsilon}\to 2\epsilon$ (the four-velocity is unchanged, as $u^\mu_\pm = u^\mu$). The electromagnetic field $F^{\mu\nu}_-$ that the charge q_+ produces at the location of the charge q_- is obtained in a similar manner, by substituting in these equations $q\to q_+$, $a\to a_+$, $\dot{a}\to \mathrm{d}a_+/\mathrm{d}\tau_+$, $\hat{w}^\mu\to -w^\mu$, $a_{\hat{w}}\to -a^\lambda_+ w_\lambda$, and $\hat{\epsilon}\to 2\epsilon$. Let us denote by f^μ_+ (f^μ_-) the Lorentz force that the charge "−" ("+") exerts on the other charge "+" ("−"):

$$f^\mu_\pm = q_\pm F^{\mu\nu}_\pm u_\nu .$$

By virtue of Eq. (12) this becomes

$$f^\mu_\pm \cong q_+ q_- u_\nu \left[\left(\pm\frac{u^\mu w^\nu}{4\epsilon^2} + \frac{a^\mu_\mp u^\nu - (a^\lambda_\mp w_\lambda) u^\mu w^\nu}{4\epsilon} - \frac{2}{3}\dot{a}^\mu_\mp u^\nu \pm Z^{\mu\nu}_\pm \right) - (\mu\leftrightarrow\nu) \right], \tag{14}$$

where

$$Z^{\mu\nu}_\pm \equiv \frac{a^2_\mp u^\mu w^\nu}{8} - \frac{\dot{a}^\mu_\mp w^\nu}{2} + \frac{3(a^\lambda_\mp w_\lambda)^2 u^\mu w^\nu}{8} - \frac{3(a^\lambda_\mp w_\lambda) a^\mu_\mp u^\nu}{4},$$

and $\dot{a}^\mu_\mp \equiv \mathrm{d}a^\mu_\mp/\mathrm{d}\tau_\mp$. Next we re-express $f^\mu_\pm$ in terms of the acceleration a^μ and proper time τ of the central point (rather than those of the source charges). To this end we use Eq. (11), and expand $a^\mu_\mp$ in ϵ. Since the acceleration does not appear in the $O(\epsilon^{-2})$ term, it is sufficient to carry out this expansion up to first order in ϵ:

$$a^\mu_\mp = a^\mu(1 \pm \epsilon a_w) + O(\epsilon^2) .$$

Note that $\dot{a}^\mu_\mp$ only appears in the $O(\epsilon^0)$ term, hence it can be replaced by $\dot{a}^\mu$. [The same holds for all factors $a^\mu_\mp$ and $a^2_\mp$ that appear in the $O(\epsilon^0)$ term.] We find

$$f^\mu_\pm \cong q_+ q_- u_\nu \left[\left(\pm\frac{u^\mu w^\nu}{4\epsilon^2} + \frac{a^\mu u^\nu - a_w u^\mu w^\nu}{4\epsilon} - \frac{2}{3}\dot{a}^\mu u^\nu \pm Z^{\mu\nu} \right) - (\mu\leftrightarrow\nu) \right], \tag{15}$$

where

$$Z^{\mu\nu} \equiv Z^{\mu\nu}_\pm(a^\mu_\mp \to a^\mu) + \frac{a_w a^\mu u^\nu - a^2_w u^\mu w^\nu}{4}.$$

Note that $Z^{\mu\nu}$ is $O(\epsilon^0)$, and is the same for the two charges. Recalling that $u^\nu u_\nu = -1$, $w^\nu u_\nu = a^\nu u_\nu = 0$, and $\dot{a}^\nu u_\nu = -a^2$ (the latter identity is obtained by differentiating $a^\nu u_\nu = 0$), we find

$$f^\mu_\pm \cong q_+ q_- \left[\pm\frac{w^\mu}{4\epsilon^2} - \frac{a^\mu + w^\mu a_w}{4\epsilon} + \frac{2}{3}(\dot{a}^\mu - a^2 u^\mu) \pm Z^\mu \right], \tag{16}$$

where $Z^\mu \equiv u_\nu(Z^{\mu\nu} - Z^{\nu\mu})$.

D. Naive sum of the mutual forces

Next we calculate the sum of the two mutual forces, i.e., the quantity f^μ_{sum}:

$$f^\mu_{\mathrm{sum}} \equiv f^\mu_+ + f^\mu_- \cong -\frac{q_+ q_-}{2\epsilon}(a^\mu + w^\mu a_w) + \frac{4}{3} q_+ q_- (\dot{a}^\mu - a^2 u^\mu) . \tag{17}$$

This quantity would be the simplest candidate for the dumbbell's self force; However, as already discussed in the previous section, it suffers from a serious problem: The first term on the right-hand side is proportional to $1/\epsilon$, and hence diverges at the limit of interest, $\epsilon\to 0$. The usual way to eliminate such an undesired $O(\epsilon^{-1})$ term is by the procedure of *mass renormalization* (see the

following); However, from the very nature of this procedure, it will only be applicable if the term to be removed is of the form $a^\mu \cdot \text{const}$ (a constant that scales like $1/\epsilon$). Instead, in Eq. (17) the term $a^\mu + w^\mu a_w$ is orientation-dependent. Furthermore, this term is *not* co-directed with a^μ. This difficulty was observed by Griffiths and Owen.[7,22] [Note that adding the two "partial self forces" would not change this situation, as it does not affect the $O(\epsilon^{-1})$ term—see the following.]

E. Energy–momentum balance

The above-mentioned pathology of the $O(1/\epsilon)$ term clearly indicates that f^μ_{sum} is not a valid candidate for the dumbbell's self force. The reason is that f^μ_{sum} does not correctly represent the overall mutual force. To understand the reason for this, we shall now employ simple considerations of energy–momentum conservation. These considerations will indicate the appropriate way to sum the two mutual forces, in order to obtain the correct expression for the overall mutual force.

Let us denote the total dumbbell's four-momentum, at a given moment τ, by $p^\mu(\tau)$. This quantity is to be obtained by integrating the appropriate components of the dumbbell's stress–energy tensor over the hypersurface of simultaneity, which we denote σ. Recalling that u^ν is normal to σ, we may write this integral as

$$p^\mu \equiv -\int_\sigma T^{\mu\nu}_{(\text{dumb})} u_\nu d^3\sigma . \tag{18}$$

Here $d^3\sigma$ is a volume element, and $T^{\mu\nu}_{(\text{dumb})}$ denotes the dumbbell's stress–energy tensor, *not including* the electromagnetic field. The integration is performed over the entire volume of the dumbbell (the integrand vanishes off the dumbbell).

It is worth emphasizing two points here: First, the integration is carried out over a *hypersurface of simultaneity*, i.e., a constant-time hypersurface in a Lorentz frame where the dumbbell is instantaneously at rest, and *not* over a hypersurface $t = \text{const}$ of some fixed Lorentz frame. This is the natural covariant way to define the time-dependent four-momentum of a rigid body.[23] Second, we choose not to include the electromagnetic stress–energy tensor in p^μ, because the electromagnetic contribution is not well localized: It is partly scattered throughout the space in the form of electromagnetic waves. The nonelectromagnetic part, however, is by assumption well-localized, and hence monitoring $p^\mu(\tau)$ will provide us with the desired information concerning the dumbbell's motion. Note that the external field (i.e., the above-mentioned "external force") is also not included in $T^{\mu\nu}_{(\text{dumb})}$.

From energy–momentum conservation it follows that $p^\mu(\tau)$ will only change due to external forces acting on the dumbbell (if such exist), and due to energy–momentum exchange between the dumbbell and the electromagnetic field. The electromagnetic energy–momentum exchange is manifested by the electromagnetic forces acting on the two charges. In an infinitesimal time interval $\mathrm{d}\tau$, the change in $p^\mu(\tau)$ will be given by

$$\mathrm{d}p^\mu = \mathrm{d}p^\mu_+ + \mathrm{d}p^\mu_- + \mathrm{d}p^\mu_{\text{ext}} , \tag{19}$$

where $\mathrm{d}p^\mu_{\text{ext}}$ is the contribution of the external force, and $\mathrm{d}p^\mu_\pm$ denote the contributions from the electromagnetic forces acting on the two charges.[24] Let us denote these electromagnetic forces by $f^\mu_{(\text{em})\pm}$. As discussed earlier, $f^\mu_{(\text{em})\pm}$ includes both the mutual electromagnetic force $f^\mu_\pm$, and the partial self force acting on the $\pm$ charge, which we denote $\hat{f}^\mu_\pm$:

$$f^\mu_{(\text{em})\pm} = f^\mu_\pm + \hat{f}^\mu_\pm . \tag{20}$$

Note that simple consistency considerations require us to include the partial self forces in the analysis: Our calculation shows (as many previous analyses did) that there is a nonvanishing self force acting on a charged object (the dumbbell, in our specific model); this force is found to be universal (at the limit of small ϵ), namely it is independent of the object's size and orientation. It must therefore apply to *any* sufficiently small charged object—and, in particular, to the two point

charges q_+ and q_-. Later we shall employ a simple argument to quantitatively relate the two partial self forces $\hat{f}^\mu_\pm$ to the overall self force acting on the dumbbell. (It should be emphasized that the calculation below yields a nonvanishing overall self force even if one does not take into account the partial self forces; Nevertheless the resultant expression for the self force would be incorrect in such a case, due to the inconsistency.) Note that the need for adding the partial self forces is also made obvious from the following observation: Without the partial self forces, the overall mutual electromagnetic force is proportional to the product q_+q_-, whereas the overall self force of the dumbbell (like that of any charged particle) must be proportional to $q^2=(q_+ + q_-)^2$. Adding the partial self forces compensates for this difference exactly, as we show in the following.

Let us now calculate dp^μ_+, the energy–momentum exchange of the "+" charge with the electromagnetic field, between the two hypersurfaces of simultaneity τ and $\tau+d\tau$. An observer located at the "+" charge will measure a proper-time interval $d\tau_+$ between these two hypersurfaces. Therefore, the amount of electromagnetic energy–momentum transfer is $dp^\mu_+ = f^\mu_{(\mathrm{em})+}d\tau_+$. Similar considerations will apply of course to the other charge "−"; therefore,

$$dp^\mu_\pm = f^\mu_{(\mathrm{em})\pm}d\tau_\pm . \tag{21}$$

Combining Eqs. (19), (21), and (20), we obtain

$$dp^\mu = (f^\mu_+ + \hat{f}^\mu_+)d\tau_+ + (f^\mu_- + \hat{f}^\mu_-)d\tau_- + dp^\mu_{\mathrm{ext}} . \tag{22}$$

Defining the overall force acting on the system to be $f^\mu \equiv dp^\mu/d\tau$, we find

$$f^\mu \cong \left[\left\{ f^\mu_+ \frac{d\tau_+}{d\tau} + f^\mu_- \frac{d\tau_-}{d\tau} \right\} + (\hat{f}^\mu_+ + \hat{f}^\mu_-)\right] + f^\mu_{\mathrm{ext}} . \tag{23}$$

Note that since the external force is presumably regular (i.e., it is well-behaved at the limit of small ϵ), and $d\tau_\pm/d\tau \to 1$ at the limit $\epsilon \to 0$, we can simply take $dp^\mu_{\mathrm{ext}} \cong f^\mu_{\mathrm{ext}}d\tau$. For the same reason, since the partial self forces are presumably regular, too, we can ignore the factors $d\tau_\pm/d\tau$ multiplying $\hat{f}^\mu_\pm$. It is only the mutual force $f^\mu_\pm$, which includes negative powers of ϵ, that requires one to make the distinction between $d\tau$ and $d\tau_\pm$.

The overall mutual electromagnetic force f^μ_{mutual} is the term in curly braces in Eq. (23):

$$f^\mu_{\mathrm{mutual}} = f^\mu_+ \frac{d\tau_+}{d\tau} + f^\mu_- \frac{d\tau_-}{d\tau} . \tag{24}$$

Using Eqs. (9) and (16), and again neglecting terms that vanish as $\epsilon \to 0$, we find

$$f^\mu_\pm \frac{d\tau_\pm}{d\tau} = (1 \pm \epsilon a_w) f^\mu_\pm \cong q_+q_- \left[\pm \frac{w^\mu}{4\epsilon^2} - \frac{a^\mu}{4\epsilon} + \frac{2}{3}(\dot{a}^\mu - a^2u^\mu) \pm \tilde{Z}^\mu \right],$$

where

$$\tilde{Z}^\mu = Z^\mu - \frac{a_w(a^\mu + w^\mu a_w)}{4} .$$

It now follows that

$$f^\mu_{\mathrm{mutual}} \cong -\frac{q_+q_-}{2\epsilon}a^\mu + \frac{4}{3}q_+q_-(\dot{a}^\mu - a^2u^\mu) . \tag{25}$$

The overall electromagnetic contribution to the total force f^μ acting on the dumbbell (not including the external force) is the term in square brackets in Eq. (23), i.e., the sum of f^μ_{mutual} and

the two partial self forces. We shall refer to it as the "bare self force" (because subsequently we shall apply to it the mass-renormalization procedure, to obtain the "renormalized self force"), and denote it f^{μ}_{bare}. It is given by

$$f^{\mu}_{\text{bare}} = f^{\mu}_{\text{mutual}} + (\hat{f}^{\mu}_{+} + \hat{f}^{\mu}_{-}) = -\frac{q_+ q_-}{2\epsilon} a^{\mu} + \frac{4}{3} q_+ q_- (\dot{a}^{\mu} - a^2 u^{\mu}) + (\hat{f}^{\mu}_{+} + \hat{f}^{\mu}_{-}) + O(\epsilon) . \tag{26}$$

F. Mass renormalization and the renormalized self force

In Eq. (26) [like in Eq. (25)] the $O(1/\epsilon)$ term has the desired form $-E_{\text{es}} a^{\mu}$, where E_{es} is the dumbbell's electrostatic energy (at rest):

$$E_{\text{es}} \equiv q_+ q_- / 2\epsilon .$$

This is exactly the type of $O(1/\epsilon)$ term that is cured by mass renormalization, as we now briefly discuss.

The expression for the self force is to be used for predicting the dumbbell's motion, through an equation of motion of the form $m_{\text{bare}} a^{\mu} = f^{\mu}$, where f^{μ} refers to the total force acting on the dumbbell, i.e., $f^{\mu} = f^{\mu}_{\text{bare}} + f^{\mu}_{\text{ext}}$. (In the following we shall further discuss the justification to this equation of motion.) Similarly, m_{bare} refers to the so-called "bare mass," i.e., the total dumbbell's energy (in the momentary rest frame) *not including the electromagnetic/electrostatic interaction energy*. We now add the term $E_{\text{es}} a^{\mu}$ to both sides of the equation of motion. Defining the "renormalized mass" m_{ren} and "renormalized self force" f^{μ}_{ren} by

$$m_{\text{ren}} \equiv m_{\text{bare}} + E_{\text{es}} , \quad f^{\mu}_{\text{ren}} \equiv f^{\mu}_{\text{bare}} + E_{\text{es}} a^{\mu} , \tag{27}$$

the equation of motion now takes the form

$$m_{\text{ren}} a^{\mu} = f^{\mu}_{\text{ren}} + f^{\mu}_{\text{ext}} .$$

This is the "renormalized equation of motion." Note that m_{ren} is nothing but the total dumbbell's energy (including the electrostatic interaction) while at rest. This is in fact the measured physical mass of the dumbbell. To simplify the notation, we shall hereafter omit the suffix "ren," denoting the renormalized mass by m and the "renormalized self force" by f^{μ}_{self}. The equation of motion now reads

$$m a^{\mu} = f^{\mu}_{\text{self}} + f^{\mu}_{\text{ext}} ,$$

where

$$f^{\mu}_{\text{self}} \equiv f^{\mu}_{\text{bare}} + E_{\text{es}} a^{\mu} = \tfrac{4}{3} q_+ q_- (\dot{a}^{\mu} - a^2 u^{\mu}) + (\hat{f}^{\mu}_{+} + \hat{f}^{\mu}_{-}) + O(\epsilon) . \tag{28}$$

Now that we eliminated the problematic $O(1/\epsilon)$ term, we can safely take the limit $\epsilon \to 0$. It is at this limit where we expect to obtain the universal expression for the self force. In this limit all the $O(\epsilon)$ correction terms vanish, and we find

$$f^{\mu}_{\text{self}} = \tfrac{4}{3} q_+ q_- (\dot{a}^{\mu} - a^2 u^{\mu}) + (\hat{f}^{\mu}_{+} + \hat{f}^{\mu}_{-}) . \tag{29}$$

As it stands, Eq. (29) provides a single relation for three unknowns, $\hat{f}^{\mu}_{\pm}$ and f^{μ}_{self}. In order to extract from it the expression for f^{μ}_{self}, we need to relate the latter to the two partial self forces $\hat{f}^{\mu}_{\pm}$. Since the self force is the force that a charge experiences due to its own field, it must be proportional (for a prescribed worldline) to q^2, where q is the particle's charge. In the limit of interest, $\epsilon \to 0$, the trajectories of the two charges $\pm$, and also that of the dumbbell itself (i.e., the repre-

sentative point), all converge to the same worldline. Therefore, the two partial self forces $\hat{f}^{\mu}_{\pm}$ will be given by $\hat{f}^{\mu}_{\pm}=(q^2_{\pm}/q^2)f^{\mu}_{\rm self}$, where $q=q_+ + q_-$ is the dumbbell's total charge. Substituting this in Eq. (29), rewriting it as

$$\frac{4}{3}q_+q_-(\dot{a}^{\mu}-a^2u^{\mu})=f^{\mu}_{\rm self}-(\hat{f}^{\mu}_{+}+\hat{f}^{\mu}_{-})=\left[1-\frac{q^2_+}{q^2}-\frac{q^2_-}{q^2}\right]f^{\mu}_{\rm self}\,, \tag{30}$$

and noting that the term in square brackets is nothing but $2q_+q_-/q^2$, we finally obtain the desired expression for the self force:

$$f^{\mu}_{\rm self}=\tfrac{2}{3}q^2(\dot{a}^{\mu}-a^2u^{\mu}). \tag{31}$$

This agrees with Dirac's[3] expression (1).

To summarize, let us formulate all elements of the above-mentioned construction of $f^{\mu}_{\rm self}$ by a single mathematical expression. This expression takes the form

$$f^{\mu}_{\rm self}=\frac{q^2}{2q_+q_-}\lim_{\epsilon\to 0}\left[(1+\epsilon a_w)f^{\mu}_{+}+(1-\epsilon a_w)f^{\mu}_{-}+\frac{q_+q_-}{2\epsilon}a^{\mu}\right]. \tag{32}$$

This involves the following manipulations, which are all justified (and necessitated) by simple physical considerations: (i) the proper-time weighting of the two mutual force (the factors $(1\pm\epsilon a_w)$); (ii) mass renormalization (the last term in the square brackets); (iii) the inclusion of the partial self forces (the factor $q^2/2q_+q_-$); and (iv) taking the limit $\epsilon\to 0$. This expression yields a universal, orientation-independent, result, which conforms with the well-known expression (1) for the self force.

Finally, we briefly discuss the justification of the (''bare'') equation of motion $m_{\rm bare}a^{\mu}=f^{\mu}$ in our case. We have *defined* the total force f^{μ} as the proper-time derivative of the dumbbell's nonelectromagnetic energy–momentum p^{μ}. Let us transform to a Lorentz frame in which the dumbbell is momentarily at rest. In this frame Eq. (18) reads

$$p^{\mu}\equiv\int_{t=\rm const}T^{\mu 0}_{\rm (dumb)}d^3x^i\,, \tag{33}$$

where x^i denotes the three spatial Cartesian coordinates. For simplicity let us approximate the dumbbell's stress–energy by that of a continuous matter (plus, possibly, arbitrary number of point masses situated at fixed locations on the dumbbell). Since the matter that composes each element of the dumbbell is momentarily at rest, $T^{i0}_{\rm (dumb)}$ vanishes, and hence $p^i=0$. The dumbbell's energy in the rest frame is

$$p^0\equiv\int_{t=\rm const}T^{00}_{\rm (dumb)}d^3x^i\quad\text{(rest frame)}. \tag{34}$$

This is by definition the dumbbell's bare mass. Thus, in the momentary rest frame we have $p^{\mu}=(m_{\rm bare},0,0,0)$. Rewriting this in a covariant form (valid in any Lorentz frame), we obtain

$$p^{\mu}=m_{\rm bare}u^{\mu}\,.$$

Since the dumbbell is approximated as rigid, its composition does not change in time, hence $m_{\rm bare}$ is time-independent. Differentiating now p^{μ} with respect to proper time, we obtain the desired equation of motion

$$f^{\mu}=m_{\rm bare}a^{\mu}\,.$$

Recall that this is the ''bare'' equation of motion. After mass renormalization, we obtain the equation of motion in its final, renormalized form:[25]

$$ma^{\mu}=f^{\mu}_{\text{self}}+f^{\mu}_{\text{ext}}=\tfrac{2}{3}q^{2}(\dot{a}^{\mu}-a^{2}u^{\mu})+f^{\mu}_{\text{ext}}\ . \tag{35}$$

III. EXTENDED OBJECT WITH *N* POINT CHARGES

In this section we shall consider a rigid extended object with an arbitrary number N of point charges located on it. The charges are denoted q_i, where hereafter Roman indices like $i,j,\ldots$ run from 1 to N. The total charge is $q=\Sigma_i q_i$. We shall calculate the overall self force acting on the object by a natural extension of the method used earlier in the dumbbell case.

A. Extended object kinematics

We start by describing the extended object kinematics. We choose (quite arbitrarily) a representative point inside this object and denote its worldline by $z^{\mu}(\tau)$, and its four-velocity and four-acceleration by $u^{\mu}\equiv \mathrm{d}z^{\mu}/\mathrm{d}\tau$ and $a^{\mu}\equiv \mathrm{d}u^{\mu}/\mathrm{d}\tau$, respectively, where τ is the proper time along this worldline.

The location of a charge i at each moment τ is given by[27]

$$z^{\mu}_{i}(\tau)\equiv z^{\mu}(\tau)+\epsilon_i w^{\mu}_{i}(\tau), \tag{36}$$

where $\epsilon_i\geqslant 0$ is the distance of the charge i from the representative point, and $w^{\mu}_{i}(\tau)$ is a unit spatial vector normal to $u^{\mu}(\tau)$. We denote the proper time of this worldline by τ_i and its four-velocity and four-acceleration by $u^{\mu}_{i}\equiv \mathrm{d}z^{\mu}_{i}/\mathrm{d}\tau_i$ and $a^{\mu}_{i}\equiv \mathrm{d}u^{\mu}_{i}/\mathrm{d}\tau_i$, respectively.

Since the object is rigid, and it moves in a nonrotational manner, the time evolution of the spatial vectors w^{μ}_{i} is given by the Fermi–Walker transport,

$$\dot{w}^{\mu}_{i}=(u^{\mu}a_{\nu}-u_{\nu}a^{\mu})w^{\nu}_{i}=u^{\mu}a_{\nu}w^{\nu}_{i}. \tag{37}$$

Repeating the above-presented dumbbell kinematic calculations, we again find that

$$\frac{\mathrm{d}\tau_i}{\mathrm{d}\tau}=1+\epsilon_i a_{\mu}w^{\mu}_{i} \tag{38}$$

and

$$u^{\mu}_{i}=u^{\mu}\ . \tag{39}$$

Again, the last equality implies that in the momentary rest frame of the representative point, all charges are (momentarily) at rest too. One also finds that

$$a^{\mu}_{i}=\frac{a^{\mu}}{1+\epsilon_i a_{\nu}w^{\nu}_{i}}. \tag{40}$$

We shall be interested in the limit in which the object's size is taken to be arbitrarily small, but its shape (including the location of the charges) is unchanged in this limiting process. To describe this limit mathematically, let $\epsilon>0$ denote the object's size, e.g., its ''radius'' (i.e., half the maximal distance between pairs of object's points). We now define

$$\epsilon_i\equiv\epsilon\alpha_i\ .$$

The parameters α_i are thus dimensionless numbers of order unity or smaller. The above-noted limiting process is thus described by $\epsilon\to 0$ with all parameters α_i kept fixed.

In the calculations to follow we shall make use of the results that were obtained in Sec. II in the dumbbell case. Recall, however, that in the latter case the representative point was chosen at

half the distance between the two charges. This cannot be done in the present case (as long as $N>2$). In order to allow the implementation of the dumbbell results to our case, we shall also need to consider, for each pair of charges i,j, the worldline of the central point between these two charges, which we denote z^μ_{ij}:

$$z^\mu_{ij}(\tau)\equiv\tfrac{1}{2}[z^\mu_i(\tau)+z^\mu_j(\tau)]=z^\mu(\tau)+\tfrac{1}{2}[\epsilon_i w^\mu_i+\epsilon_j w^\mu_j]\,.$$

Obviously there exists a number $\epsilon_{ij}\geqslant 0$ and a unit vector w^μ_{ij} such that $\epsilon_{ij}w^\mu_{ij}=(1/2)(\epsilon_i w^\mu_i+\epsilon_j w^\mu_j)$. Then ϵ_{ij} is the distance of this central point from the representative point, and (for $\epsilon_{ij}>0$) w^μ_{ij} is a vector normal to u^α which satisfies the Fermi–Walker transport law, as one can easily verify. We denote the proper time along the worldline $z^\mu_{ij}(\tau)$ by τ_{ij}, and the four-velocity and four-acceleration by $u^\mu_{ij}\equiv \mathrm{d}z^\mu_{ij}/\mathrm{d}\tau_{ij}$ and $a^\mu_{ij}\equiv \mathrm{d}u^\mu_{ij}/\mathrm{d}\tau_{ij}$, respectively. Obviously all the above-mentioned kinematic relations satisfied by the point charge $z^\mu_i(\tau)$, e.g., Eqs. (38)–(40), are also satisfied by a central point $z^\mu_{ij}(\tau)$. Of particular importance for the analysis to follow is the relation

$$a^\mu_{ij}\frac{\mathrm{d}\tau_{ij}}{\mathrm{d}\tau}=a^\mu\,, \tag{41}$$

which follows from Eqs. (38) and (40) (with "i" replaced by "ij").

Let us finally emphasize that, for a particular pair i,j, the three points z^μ_i, z^μ_j, and z^μ_{ij} satisfy all the dumbbell's kinematic relations satisfied by the three dumbbell's points z^μ_+, z^μ_-, and z^μ, correspondingly. This will allow us to apply all the above-mentioned dumbbell results to any pair i,j, though with the dumbbell's central point z^μ replaced by z^μ_{ij} (and τ by τ_{ij}, etc.). The dumbbell's length $\hat{\epsilon}=2\epsilon$ is of course replaced by the distance between the charges i and j, which we denote $\hat{\epsilon}_{ij}$.

B. Calculation of the self force

To derive the self force acting on the extended object we shall use energy–momentum considerations similar to those of Sec. II. The four-momentum of the extended object $p^\mu(\tau)$ is defined just as in the dumbbell case, by the integral (18) over a hypersurface of simultaneity. In analogy with Eq. (19), we now have

$$\mathrm{d}p^\mu=\sum_{i=1}^{N}\mathrm{d}p^\mu_i+\mathrm{d}p^\mu_{\mathrm{ext}}\,, \tag{42}$$

where $\mathrm{d}p^\mu_i$ denotes the contribution from all the electromagnetic forces (sourced by all object's charges) acting on the ith charge, and $\mathrm{d}p^\mu_{\mathrm{ext}}$ denotes the contribution from the overall external force. The electromagnetic energy–momentum exchange with the charge i is

$$\mathrm{d}p^\mu_i=f^\mu_{(\mathrm{em})i}\mathrm{d}\tau_i\,,$$

where $f^\mu_{(\mathrm{em})i}$ is the overall electromagnetic forces acting on the charge i, given by

$$f^\mu_{(\mathrm{em})i}=\hat{f}^\mu_i+\sum_{\substack{j=1\\ j\neq i}}^{N}f^\mu_{j\to i}\,.$$

Here $f^\mu_{j\to i}$ denotes the electromagnetic force that the charge j exerts on the charge i, and $\hat{f}^\mu_i$ denotes the partial self force acting on this charge. Therefore,

$$\mathrm{d}p^\mu=\mathrm{d}p^\mu_{\mathrm{ext}}+\sum_{i=1}^{N}\hat{f}^\mu_i\mathrm{d}\tau_i+\sum_{i=1}^{N}\sum_{\substack{j=1\\ j\neq i}}^{N}f^\mu_{j\to i}\mathrm{d}\tau_i\,.$$

Since the external force is presumably well behaved as $\epsilon \to 0$ (it is essentially independent of ϵ), we can use $\mathrm{d}p^{\mu}_{\mathrm{ext}} \cong f^{\mu}_{\mathrm{ext}} \mathrm{d}\tau$, without bothering which proper time exactly one should use. For the same reason we may replace $\mathrm{d}\tau_i$ multiplying the partial self force by $\mathrm{d}\tau$. Defining the overall force acting on the object to be

$$f^{\mu} = \frac{\mathrm{d}p^{\mu}}{\mathrm{d}\tau},$$

we obtain

$$f^{\mu} \cong \left[\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} \frac{\mathrm{d}\tau_i}{\mathrm{d}\tau} f^{\mu}_{j \to i} + \sum_{i=1}^{N} \hat{f}^{\mu}_{i} \right] + f^{\mu}_{\mathrm{ext}}. \tag{43}$$

The overall mutual force is the term including the double-sum over i and j:

$$f^{\mu}_{\mathrm{mutual}} = \sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} \frac{\mathrm{d}\tau_i}{\mathrm{d}\tau} f^{\mu}_{j \to i} = \frac{1}{2} \sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} \frac{\mathrm{d}\tau_{ij}}{\mathrm{d}\tau} \left[\frac{\mathrm{d}\tau_i}{\mathrm{d}\tau_{ij}} f^{\mu}_{j \to i} + \frac{\mathrm{d}\tau_j}{\mathrm{d}\tau_{ij}} f^{\mu}_{i \to j} \right]. \tag{44}$$

Consider the last term in square brackets, for a particular pair of charges i,j. This pair satisfies a ''dumbbell kinematics''; namely, the kinematic relations between the worldlines of the three points z^{μ}_i, z^{μ}_j, and z^{μ}_{ij} are exactly the same as those satisfied by the three dumbbell's points z^{μ}_{+}, z^{μ}_{-}, and z^{μ}, correspondingly. This allows us to apply the dumbbell's results to this new two-charge system. In particular, Eqs. (24) and (25) now yield

$$\frac{\mathrm{d}\tau_i}{\mathrm{d}\tau_{ij}} f^{\mu}_{j \to i} + \frac{\mathrm{d}\tau_j}{\mathrm{d}\tau_{ij}} f^{\mu}_{i \to j} \cong - \frac{q_i q_j}{\hat{\epsilon}_{ij}} a^{\mu}_{ij} + \frac{4}{3} q_i q_j (\dot{a}^{\mu}_{ij} - a^2_{ij} u^{\mu}),$$

where $\hat{\epsilon}_{ij}$ is the distance between the two charges, and $\dot{a}^{\mu}_{ij} \equiv \mathrm{d}a^{\mu}_{ij}/\mathrm{d}\tau_{ij}$. Note that $\hat{\epsilon}_{ij}$, like all other object's distances, scales like ϵ (the object's size). Since the last term at the right-hand side is of order ϵ^0, we are allowed to replace τ_{ij} and a^{μ}_{ij} by the corresponding representative-point quantities, τ and a^{μ} (which we cannot do when treating the other term, the one proportional to $1/\hat{\epsilon}_{ij}$). With the aid of Eq. (41) we obtain

$$\frac{\mathrm{d}\tau_{ij}}{\mathrm{d}\tau} \left[\frac{\mathrm{d}\tau_i}{\mathrm{d}\tau_{ij}} f^{\mu}_{j \to i} + \frac{\mathrm{d}\tau_j}{\mathrm{d}\tau_{ij}} f^{\mu}_{i \to j} \right] \cong - \frac{q_i q_j}{\hat{\epsilon}_{ij}} a^{\mu} + \frac{4}{3} q_i q_j (\dot{a}^{\mu} - a^2 u^{\mu}).$$

Notice that in the last expression all kinematic quantities are those associated with the representative point, and the only reference to the two charges is through q_i, q_j, and $\hat{\epsilon}_{ij}$. Substituting this result back in Eq. (44) we obtain

$$f^{\mu}_{\mathrm{mutual}} \cong - E_{\mathrm{es}} a^{\mu} + \frac{2}{3} \left(\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} q_i q_j \right) (\dot{a}^{\mu} - a^2 u^{\mu}), \tag{45}$$

where

$$E_{\mathrm{es}} \equiv \frac{1}{2} \sum_{i=1}^{N} \sum_{\substack{j=1 \\ j \neq i}}^{N} \frac{q_i q_j}{\hat{\epsilon}_{ij}}. \tag{46}$$

This last expression is exactly the electrostatic energy of the system of N charges (the factor 1/2 corresponds to the fact that every pair i,j appears twice in this sum).

The overall (bare) self force f^{μ}_{bare} is the term in square brackets in Eq. (43), which we write as

$$f^{\mu}_{\text{bare}} = f^{\mu}_{\text{mutual}} + \sum_{i=1}^{N} \hat{f}^{\mu}_{i} = -E_{\text{es}} a^{\mu} + \frac{2}{3}\left(\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j\neq i}}^{N} q_i q_j \right)(\dot{a}^{\mu} - a^2 u^{\mu}) + \sum_{i=1}^{N} \hat{f}^{\mu}_{i} + O(\epsilon) . \qquad (47)$$

Implementing now the mass-renormalization procedure, given by Eq. (27), and then taking the limit $\epsilon \to 0$, we obtain the renormalized self force:

$$f^{\mu}_{\text{self}} = \frac{2}{3}\left(\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j\neq i}}^{N} q_i q_j \right)(\dot{a}^{\mu} - a^2 u^{\mu}) + \sum_{i=1}^{N} \hat{f}^{\mu}_{i} . \qquad (48)$$

To factor out the partial self forces, we again use the fact that the self force is quadratic in the charge, namely,

$$\hat{f}^{\mu}_{i} = (q_i^2/q^2) f^{\mu}_{\text{self}} ,$$

where $q \equiv \Sigma_i q_i$ is the total charge. Transferring all partial self forces to the left-hand side and then multiplying by q^2, we obtain

$$\left[q^2 - \sum_{i=1}^{N} q_i^2 \right] f^{\mu}_{\text{self}} = \frac{2}{3} q^2 \left[\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j\neq i}}^{N} q_i q_j \right](\dot{a}^{\mu} - a^2 u^{\mu}) .$$

Noting that the two terms in square brackets are equal, we obtain the self force in its final form:

$$f^{\mu}_{\text{self}} = \frac{2}{3} q^2 (\dot{a}^{\mu} - a^2 u^{\mu}) . \qquad (49)$$

The equation of motion is given by Eq. (35), just as in the dumbbell case.

IV. CONTINUOUSLY CHARGED EXTENDED OBJECT

In this section we shall consider a rigid extended object which is continuously charged. Again, we denote the object's size (e.g., its "radius") by ϵ. Let (X,Y,Z) be a system of comoving Cartesian coordinates that parametrize the three-dimensional hypersurface of simultaneity, and let $\overline{R} \equiv (X,Y,Z)$. The representative point (an arbitrary point of the object) is taken to be, e.g., at $\overline{R} = 0$. Note that the worldline of any point of fixed $\overline{R}$ satisfies all the kinematic relations described in Sec. III. The charge distribution is denoted $\rho(X,Y,Z)$. We assume that the charge distribution is fixed (in the object's frame), i.e., $\rho(X,Y,Z)$ is independent of the proper time τ.

The calculation of the self force proceeds in full analogy with the discrete case discussed in Sec. III, with the discrete charge q_i replaced by the infinitesimal charge element $\mathrm{d}q \equiv \rho \mathrm{d}X\, \mathrm{d}Y\, \mathrm{d}Z$, and with the summations replaced by integrals. There is a remarkable difference between the two cases, though: In the discrete case, the demand for consistency required us to take into account the partial self forces. No such partial self forces appear in the continuous case (see the following). This makes the continuous case simpler and more elegant.

One can follow all the considerations and calculations of Sec. III, up to Eq. (47). In the continuous variant of this equation, the double-sum becomes a double-integral:

$$\sum_{i=1}^{N} \sum_{\substack{j=1 \\ j\neq i}}^{N} q_i q_j \to \int \int \rho(\overline{R}_1)\rho(\overline{R}_2) d^3\overline{R}_1 d^3\overline{R}_2 = q^2 , \qquad (50)$$

where $q \equiv \int \rho(\overline{R}) d^3\overline{R}$ is the total charge. On the other hand, the term including the partial self forces has only one summation. This term disappears in the continuous case: At the limit $N \to \infty$ (in which the individual charges scale like $1/N$) the magnitude of the individual partial self forces

scales like $q_i^2 \propto 1/N^2$, whereas their number only scales like N. Therefore, the overall contribution of the partial self forces scales like $1/N \to 0$.[28] (This is to be contrasted with the situation of the mutual electromagnetic forces: The magnitude of the mutual forces scales like $1/N^2$ too, but their number scales like N^2, so the overall mutual force attains a nonvanishing value at the limit $N \to \infty$.) The integral analog of Eq. (47) is thus

$$f^{\mu}_{\text{bare}} = -E_{\text{es}} a^{\mu} + \tfrac{2}{3} q^2 (\dot{a}^{\mu} - a^2 u^{\mu}) + O(\epsilon) , \tag{51}$$

where E_{es} is the integral analog of Eq. (46):

$$E_{\text{es}} \equiv \frac{1}{2} \int \int \frac{\rho(\bar{R}_1)\rho(\bar{R}_2)}{|\bar{R}_1 - \bar{R}_2|} d^3\bar{R}_1 d^3\bar{R}_2 . \tag{52}$$

Note that E_{es} is the electrostatic energy of the continuous charge distribution.

The mass-renormalization (27) now removes the irregular term $E_{\text{es}} a^{\mu}$ in Eq. (51), and (after taking the limit $\epsilon \to 0$) one arrives at the final expression for the self force:

$$f^{\mu}_{\text{self}} = \tfrac{2}{3} (\dot{a}^{\mu} - a^2 u^{\mu}) . \tag{53}$$

[8] In Ref. 7 the treatment is fully relativistic, except that the accelerations of the dumbbell's two point charges are taken to be the same as that of the central point, which is inconsistent with relativistic kinematics. Despite this, Griffiths and Owen's analysis yields the correct expression for the term c^{μ}_{-1}/ϵ. [This may be understood by comparing Eqs. (14) and (15)]. In Ref. 9, it was argued that it is the nonrelativistic treatment of the four-acceleration that led to the mass-renormalization problem in Griffiths and Owen's analysis. We disagree with this argument, because Griffiths and Owen obtained the correct relativistic expression for the term c^{μ}_{-1}/ϵ.

[19] Throughout this paper, by "electromagnetic forces" we shall always refer to the forces associated with the interaction of the two charges with the electromagnetic field they themselves produce, and *not* to external forces (or the "other internal forces") even if the latter are of electromagnetic origin. Namely, our terminology is based on the simplified picture according to which the external forces and the "other internal forces" are nonelectromagnetic. However, this presumption is only made for simplifying the terminology, and the analysis below is valid even if these forces are of electromagnetic character.
[20] For our discussion it is sufficient to assume that the range of the "other internal forces" is small compared to the dumbbell's length. This assumption perfectly holds for, e.g., the inter-atomic forces that are responsible for the rod's rigidity. It is also sufficient to assume that this range is small compared to the time scales charactering the world line $z^{\mu}(\tau)$, e.g., $1/a$, $a/\dot{a}$, etc.
[21] C. W. Misner, K. S. Thorne, and J. A. Wheeler, *Gravitation* (Freeman, San Francisco, 1973).
[22] When a spherical charge distribution is considered, after integrating f^{μ}_{sum} over the charge distribution, one obtains an overall force which is co-directed with a^{μ}, due to the symmetry. In this case the only imprint of the problem in the

$O(1/\epsilon)$ term of $f^{\mu}_{\rm sum}$ is the "4/3 problem." However, for generic nonsymmetric distributions, the integrated force will not be co-directed with a^{μ}.

[23] Note that an integration over a hypersurfaces $t=$const of the Lorentz frame in use would produce a quantity $p^{\mu}(\tau)$ that transforms in a complicated, noncovariant manner in a Lorentz transformation. On the other hand, our $p^{\mu}(\tau)$ (defined by integration over the hypersurface of simultaneity) transforms like a four-vector, as desired.

[24] By "electromagnetic forces" we refer here to the forces exerted on the $\pm$ charges by the electromagnetic fields produced by these two charges, as explained above.

[25] This equation is known to have unphysical, run-away solutions. A reduction-of-order procedure is required in order to obtain physically valid solutions from this equation of motion. See Ref. 26, and also E. E. Flanagan and R. M. Wald, Phys. Rev. D **54**, 6233 (1996). We comment that the dumbbell model provides a very useful framework for explaining the origin of the unphysical run-away solutions, but this is beyond the scope of the present paper.

Hydrodynamic reductions of multidimensional dispersionless PDEs: The test for integrability

E. V. Ferapontov[a] and K. R. Khusnutdinova[b]
Department of Mathematical Sciences, Loughborough University, Loughborough, Leicestershire LE11 3TU, United Kingdom

(Received 7 December 2003; accepted 9 March 2004; published online 13 May 2004)

A $(d+1)$-dimensional dispersionless PDE is said to be integrable if its n-component hydrodynamic reductions are locally parametrized by $(d-1)n$ arbitrary functions of one variable. The most important examples include the four-dimensional heavenly equation descriptive of self-dual Ricci-flat metrics and its six-dimensional generalization arising in the context of sdiff(Σ^2) self-dual Yang–Mills equations. Given a multidimensional PDE which does *not* pass the integrability test, the method of hydrodynamic reductions allows one to effectively reconstruct additional differential constraints which, when added to the equation, make it an integrable system in fewer dimensions. As an example of this phenomenon we discuss the second commuting flow of the dispersionless KP hierarchy. Considered separately, this is a four-dimensional PDE which does *not* pass the integrability test. However, the method of hydrodynamic reductions generates additional differential constraints which reconstruct the full $(2+1)$-dimensional dispersionless KP hierarchy. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738951]

I. INTRODUCTION

We address the problem of integrability of multidimensional dispersionless PDEs of the form

$$F(u,u_i,u_{ij})=0, \tag{1}$$

where u is a (vector-) function of $d+1$ independent variables. For definiteness, let us consider $(3+1)$-dimesional PDEs in four independent variables t,x,y,z. Equations of this type naturally arise in mechanics, mathematical physics, general relativity, and differential geometry. Let us look for exact solutions of (1) of the form $u=u(R^1,\ldots,R^n)$ where the Riemann invariants $R^1,\ldots,R^n$ solve a triple of commuting diagonal systems

$$R^i_t=\lambda^i(R)\ R^i_x, \quad R^i_y=\mu^i(R)\ R^i_x, \quad R^i_z=\eta^i(R)\ R^i_x. \tag{2}$$

Notice that the number of Riemann invariants is allowed to be arbitrary. Thus, the original multidimensional equation (1) is decoupled into a collection of commuting $(1+1)$-dimensional systems in Riemann invariants. In some cases one first needs to rewrite the original PDE (1) in a quasilinear form to make the method work: see examples in Sec. II. Solutions of this type, known as nonlinear interactions of n planar simple waves, were investigated in gas dynamics and magnetohydrodynamics.[32,4,29] Later, they appeared in the context of the dispersionless KP hierarchy.[14–16,18,24,25,3] We will call a multidimensional equation integrable if it possesses sufficiently many n-component reductions of the form (2) for arbitrary n (the precise definition follows). Exact solutions arising within this approach can be viewed as dispersionless analogues of n-gap solutions.

Partial classification results of $(2+1)$-dimensional integrable systems of hydrodynamic type (the integrability is understood in the above sense) were obtained in our recent publications.[12,13] Integrable second order PDEs of the form $u_{tt}=f(u_{xx},u_{xt},u_{xy})$ were classified in Ref. 28. Particularly interesting examples arise in the theory of self-dual and Einstein–Weyl spaces,[30,8–11] in the context of the Dirichlet boundary problem in multiconnected domains,[22] and the Whitham averaging procedure (in particular, the dispersionless limit) applied to $(2+1)$-dimensional solitonic PDEs.[20,21,34]

We recall, see Ref. 33, that the requirement of commutativity of the flows (2) is equivalent to the following restrictions on their characteristic speeds:

$$\frac{\partial_j\lambda^i}{\lambda^j-\lambda^i}=\frac{\partial_j\mu^i}{\mu^j-\mu^i}=\frac{\partial_j\eta^i}{\eta^j-\eta^i}, \tag{3}$$

$i\neq j$, $\partial_j=\partial/\partial_{R^j}$; no summation. Once these conditions are met, the general solution of (2) is given by the implicit generalized hodograph formula[33]

$$v^i(R)=x+\lambda^i(R)t+\mu^i(R)\ y+\eta^i(R)z, \quad i=1,\ldots,n, \tag{4}$$

where $v^i(R)$ are characteristic speeds of the general flow commuting with (2), that is, the general solution of the linear system

$$\frac{\partial_j v^i}{v^j-v^i}=\frac{\partial_j\lambda^i}{\lambda^j-\lambda^i}=\frac{\partial_j\mu^i}{\mu^j-\mu^i}=\frac{\partial_j\eta^i}{\eta^j-\eta^i}. \tag{5}$$

Substituting $u(R^1,\ldots,R^n)$ into (1) and using (2) one arrives at an over-determined system for $\lambda^i(R),\mu^i(R),\eta^i(R)$, and $u(R)$ as functions of the Riemann invariants R^i. This system implies, in particular, that the characteristic speeds λ^i,μ^i, and η^i satisfy an algebraic relation which can be interpreted as the dispersion relation for the system (1).

One can show that the requirement of existence of nontrivial three-component reductions is already sufficiently restrictive implying, in particular, the existence of n-component reductions for arbitrary n.[12] This phenomenon is similar to the well-known three-soliton condition in the Hirota bilinear approach[19] (recall that two-soliton solutions exist for arbitrary PDEs transformable to Hirota's bilinear form and, therefore, cannot detect the integrability), and the condition of three-dimensional consistency in the classification of discrete integrable systems on quad-graphs.[1] One can show that the maximum number of n-component reductions a $(d+1)$-dimensional PDE may possess is parametrized, modulo changes of variables $R^i\to f^i(R^i)$, by $(d-1)n$ arbitrary functions of one variable. Therefore, we propose the following.

Definition: A $(d+1)$-dimensional PDE is said to be integrable if its n-component reductions are locally parametrized by $(d-1)n$ arbitrary functions of one variable.

One of the most important examples of PDEs in four dimensions which are integrable in this sense is the second heavenly equation,

$$\theta_{tx}+\theta_{zy}+\theta_{xx}\theta_{yy}-\theta_{xy}^2=0,$$

descriptive of self-dual Einstein spaces[30] (see Example 2 of Sec. II). Its equivalent first heavenly form was discussed in the recent publication[11] where it was shown that n-component reductions are parametrized by $2n$ arbitrary functions of a single variable. It would be interesting to compare these reductions with the solitonic reductions of Ref. 7. The requirement of existence of n-component reductions parametrized by $2n$ arbitrary functions of one variable appears to be very strong, indeed, the heavenly equation is the only nonlinear PDE of the form

$$\theta_{tx}+\theta_{zy}=f(\theta_{xx},\theta_{xy},\theta_{yy}),$$

which passes the integrability test (see the Appendix).

An interesting six-dimensional integrable generalization of the heavenly equation,

$$\theta_{t\tilde{t}}+\theta_{z\tilde{z}}+\theta_{tx}\theta_{zy}-\theta_{ty}\theta_{zx}=0,$$

arises in the context of sdiff(Σ^2) self-dual Yang–Mills equations.[31] Its n-component reductions are parametrized by $4n$ arbitrary functions of a single variable (Example 5 of Sec. III). We would like to thank M. Dunajski for drawing our attention to this equation.

Another integrable example is the six-dimensional system

$$m_t=n_x+nm_r-mn_r, \quad n_z=m_y+mn_s-nm_s,$$

see Sec. III. Its n-component reductions depend on $4n$ arbitrary functions of one variable. Under the additional constraints $m_r=n_r=0$, $s=x$, $z=t$, this system is descriptive of hyperCR Einstein–Weyl structures;[6] it was investigated in a series of recent publications.[27,9,26]

In the Example 3 of Sec. II we apply our method to the four-dimensional PDE

$$F_{xz}=F_{xx}F_{xy}+F_{yt},$$

which is the second flow of the dispersionless KP (dKP) hierarchy

$$F_{xt}=\tfrac{1}{2}F_{xx}^2+F_{yy},$$

$$F_{xz}=F_{xx}F_{xy}+F_{yt},$$

see, e.g., Ref. 5. It is demonstrated that, considered separately, this equation is *not* integrable (as a four-dimensional PDE), the fact which is not at all surprising. What is more important, the method of hydrodynamic reductions allows one to effectively reconstruct the differential constraint $F_{xt}=\frac{1}{2}F_{xx}^2+F_{yy}$ which, when added to the equation, generates the $(2+1)$-dimensional dKP hierarchy.

Although the method of hydrodynamic reductions provides an infinity of (implicit) solutions parametrized by arbitrarily many functions of one variable, the question of solving the initial value problem for integrable multidimensional dispersionless PDEs remains open. A detailed investigation of the behavior and singularity structure of solutions describing nonlinear interactions of planar simple waves is beyond the scope of this paper.

II. EXAMPLES

In this section we list some examples of multidimensional PDEs which are integrable in the sense of hydrodynamic reductions.

Example 1: Let us consider the first two flows of the dispersionless KP hierarchy,

$$F_{xt}=\tfrac{1}{2}F_{xx}^2+F_{yy},$$

$$F_{xz}=F_{xx}F_{xy}+F_{yt}, \tag{6}$$

which, in the new variables

$$F_{xx}=u, \quad F_{xy}=v, \quad F_{yy}=w, \quad F_{yt}=s, \quad F_{xt}=\tfrac{1}{2}u^2+w, \quad F_{xz}=uv+s,$$

assume the quasilinear form

$$\begin{aligned} &u_y=v_x, \quad v_y=w_x, \quad v_t=s_x, \quad w_t=s_y, \quad u_t=(\tfrac{1}{2}u^2+w)_x, \quad u_z=(uv+s)_x,\\ &v_t=(\tfrac{1}{2}u^2+w)_y, \quad v_z=(uv+s)_y, \quad s_x=(\tfrac{1}{2}u^2+w)_y, \quad (\tfrac{1}{2}u^2+w)_z=(uv+s)_t. \end{aligned} \tag{7}$$

Notice that u satisfies the dispersionless KP equation,

$$(u_t - uu_x)_x = u_{yy}.$$

Looking for reductions in the form $u=u(R^1,\ldots,R^n)$, $v=v(R^1,\ldots,R^n)$, $w=w(R^1,\ldots,R^n)$, $s=s(R^1,\ldots,R^n)$ where the Riemann invariants R^i satisfy (2), and substituting into (7), one readily obtains

$$\partial_i v = \mu^i \partial_i u, \quad \partial_i s = \lambda^i \mu^i \partial_i u, \quad \partial_i w = (\mu^i)^2 \partial_i u, \tag{8}$$

along with the dispersion relations

$$\lambda^i = u + (\mu^i)^2, \quad \eta^i = v + 2u\mu^i + (\mu^i)^3. \tag{9}$$

The compatibility condition $\partial_i \partial_j v = \partial_j \partial_i v$ implies

$$\partial_i \partial_j u = \frac{\partial_j \mu^i}{\mu^j - \mu^i} \partial_i u + \frac{\partial_i \mu^j}{\mu^i - \mu^j} \partial_j u, \tag{10}$$

while the commutativity condition (3) results in

$$\partial_j \mu^i = \frac{\partial_j u}{\mu^j - \mu^i}. \tag{11}$$

The substitution of (11) into (10) implies the Gibbons–Tsarev system for $u(R)$ and $\mu^i(R)$,

$$\partial_j \mu^i = \frac{\partial_j u}{\mu^j - \mu^i}, \quad \partial_i \partial_j u = 2 \frac{\partial_i u \partial_j u}{(\mu^j - \mu^i)^2}, \tag{12}$$

$i \neq j$, which was first derived in Refs. 15 and 16 in the context of hydrodynamic reductions of Benney's moment equations. For any solution μ^i, u of the system (12) one can reconstruct λ^i, η^i and v, s, w by virtue of the relations (9) and (10), which are automatically consistent. The general solution of the system (12) depends, modulo reparametrizations $R^i \to f^i(R^i)$, on n arbitrary functions of one variable, thus manifesting the fact that PDEs (6) constitute a $(2+1)$-dimensional integrable system.

Example 2: The so-called second heavenly equation,

$$\theta_{tx} + \theta_{zy} + \theta_{xx}\theta_{yy} - \theta_{xy}^2 = 0, \tag{13}$$

is descriptive of self-dual Ricci-flat metrics.[30] Introducing the variables $\theta_{xx}=u$, $\theta_{xy}=v$, $\theta_{yy}=w$, $\theta_{tx}=p$, $\theta_{zy}=v^2-uw-p$, one can rewrite (13) in a quasilinear form,

$$\begin{gathered} u_y = v_x, \quad u_t = p_x, \quad v_y = w_x, \quad v_t = p_y, \\ v_z = (v^2 - uw - p)_x, \quad w_z = (v^2 - uw - p)_y. \end{gathered} \tag{14}$$

Hydrodynamic reductions are sought in the form $u=u(R^1,\ldots,R^n)$, $v=v(R^1,\ldots,R^n)$, $w=w(R^1,\ldots,R^n)$, $p=p(R^1,\ldots,R^n)$ where the Riemann invariants $R^1,\ldots,R^n$ solve a triple of commuting hydrodynamic type systems (2). The substitution into (14) implies

$$\partial_i p = \lambda^i \partial_i u, \quad \partial_i v = \mu^i \partial_i u, \quad \partial_i w = (\mu^i)^2 \partial_i u, \tag{15}$$

along with the dispersion relation

$$\lambda^i = 2v\mu^i - w - u(\mu^i)^2 - \mu^i \eta^i. \tag{16}$$

Substituting λ^i into the commutativity conditions (3), and taking into account that the compatibility conditions for the relations $\partial_i p = \lambda^i \partial_i u$, $\partial_i v = \mu^i \partial_i u$ imply

$$\partial_i\partial_j u=\frac{\partial_j\mu^i}{\mu^j-\mu^i}\partial_i u+\frac{\partial_i\mu^j}{\mu^i-\mu^j}\partial_j u,$$

one arrives at the following system:

$$\partial_j\mu^i=\frac{(\mu^j-\mu^i)^2}{\eta^j-\eta^i+u(\mu^j-\mu^i)}\partial_j u,\quad \partial_j\eta^i=\frac{(\mu^j-\mu^i)(\eta^j-\eta^i)}{\eta^j-\eta^i+u(\mu^j-\mu^i)}\partial_j u,$$

$$\partial_i\partial_j u=2\frac{\mu^j-\mu^i}{\eta^j-\eta^i+u(\mu^j-\mu^i)}\partial_i u\partial_j u. \tag{17}$$

Solving equations (17) for μ^i,η^i and u, determining λ^i from (16) and calculating p,v,w from Eqs. (15) [which are automatically compatible by virtue of (17)], one obtains the general n-component hydrodynamic reduction of the heavenly equation. Moreover, the commutativity conditions will also be satisfied identically.

We emphasize that the system (17) is in involution and its general solution depends on $3n$ arbitrary functions of one variable. Indeed, one can arbitrarily prescribe the restrictions of μ^i and η^i to the R^i-coordinate line. This gives $2n$ arbitrary functions. Moreover, one can arbitrarily prescribe the restriction of u to each of the coordinate lines, which provides extra n arbitrary functions. However, since reparametrizations $R^i\to f^i(R^i)$ leave the system (17) invariant, one concludes that general n-component reductions are locally parametrized by $2n$ arbitrary functions of one variable. This supports the evidence that the heavenly equation (13) is a true four-dimensional integrable PDE.

Obviously, the same method applies to other equivalent forms of the heavenly equation (13). For instance, hydrodynamic reductions of the first heavenly equation

$$\Omega_{xy}\Omega_{zt}-\Omega_{xt}\Omega_{zy}=1$$

were investigated in detail in Ref. 11. Another possibility is to work with the evolutionary form[17] of the heavenly equation,

$$\psi_{tt}=\psi_{xy}\psi_{zt}-\psi_{xt}\psi_{zy}.$$

In both cases one can derive analogues of equations (17) which, although involutive, look somewhat more complicated.

The requirement of existence of n-component reductions (parametrized by $2n$ arbitrary functions of one variable) is very strong indeed: as demonstrated in the Appendix, the heavenly equation (13) is the only nonlinear PDE of the form

$$\theta_{tx}+\theta_{zy}+f(\theta_{xx},\theta_{xy},\theta_{yy})=0,$$

which passes the integrability test.

Remark: The heavenly equation (and equivalent forms thereof) belongs to the class of special Monge–Ampére equations which can be defined as follows. Consider a function $u(x^1,\dots x^k)$ and introduce a $k\times k$ symmetric matrix $U=|u_{ij}|$ of its second partial derivatives. A special Monge–Ampere equation with constant coefficients is a PDE of the form

$$M_0+M_1+\cdots+M_k=0,$$

where M_l is a constant-coefficient linear combination of all distinct $l\times l$ minors of U, $0\leqslant l\leqslant k$. Here, for instance, M_0 is a constant, $M_k=\det U=\mathrm{Hess}\,u$, etc. Equivalently, this PDE can be obtained by equating to zero a constant-coefficient k-form in $2k$ variables x^i,u_i. It is an interesting problem to classify integrable PDEs within this class, in particular, for $k=4$. We emphasize that the case $k=3$ is understood completely: one can show that, for $k=3$, any special Monge–

Ampére equation is either linearizable by a contact transformation (in this case it is automatically integrable by the method of hydrodynamic reductions), or contact equivalent to either of the three nondegenerate forms,[23,2]

$$\mathrm{Hess}\, u = 1, \quad \mathrm{Hess}\, u = u_{11} + u_{22} + u_{33}, \quad \mathrm{Hess}\, u = u_{11} + u_{22} - u_{33}.$$

We have verified directly that these three PDEs are *not* integrable by the method of hydrodynamic reductions.

Example 3: Let us consider the second flow of the dispersionless KP hierarchy,

$$F_{xz} = F_{xx}F_{xy} + F_{yt}, \tag{18}$$

see Example 1. The question is: should it be regarded as a four-dimensional integrable PDE? We will see that the answer to this question is negative, moreover, the method of hydrodynamic reductions applied to this equation reconstructs additional differential constraints which, when added to (18), generate the $(2+1)$-dimensional dKP hierarchy. In the new variables

$$F_{xx} = u, \quad F_{xy} = v, \quad F_{yy} = w, \quad F_{yt} = s, \quad F_{xt} = p, \quad F_{xz} = uv + s,$$

Eq. (18) assumes the quasilinear form

$$\begin{gathered} u_y = v_x, \quad v_y = w_x, \quad v_t = s_x, \quad w_t = s_y, \quad u_t = p_x, \quad u_z = (uv+s)_x, \\ v_t = p_y, \quad v_z = (uv+s)_y, \quad s_x = p_y, \quad p_z = (uv+s)_t. \end{gathered} \tag{19}$$

Looking for reductions in the form $u = u(R^1, \ldots, R^n)$, $v = v(R^1, \ldots, R^n)$, $w = w(R^1, \ldots, R^n)$, $s = s(R^1, \ldots, R^n)$, $p = p(R^1, \ldots, R^n)$, where the Riemann invariants R^i satisfy (2), and substituting into (19), one readily obtains

$$\partial_i v = \mu^i \partial_i u, \quad \partial_i s = \lambda^i \mu^i \partial_i u, \quad \partial_i w = (\mu^i)^2 \partial_i u, \quad \partial_i p = \lambda^i \partial_i u, \tag{20}$$

along with the dispersion relation

$$\eta^i = v + u\mu^i + \mu^i \lambda^i. \tag{21}$$

The compatibility condition $\partial_i \partial_j v = \partial_j \partial_i v$ implies

$$\partial_i \partial_j u = \frac{\partial_j \mu^i}{\mu^j - \mu^i} \partial_i u + \frac{\partial_i \mu^j}{\mu^i - \mu^j} \partial_j u, \tag{22}$$

while the commutativity condition (3) results in

$$\partial_j \mu^i = \frac{\mu^j + \mu^i}{\lambda^j - \lambda^i} \partial_j u, \quad \partial_j \lambda^i = \frac{\mu^j + \mu^i}{\mu^j - \mu^i} \partial_j u. \tag{23}$$

The substitution of (23) into (22) implies the over-determined system for $\mu^i(R)$, $\lambda^i(R)$, and $u(R)$,

$$\begin{gathered} \partial_j \mu^i = \frac{\mu^j + \mu^i}{\lambda^j - \lambda^i} \partial_j u, \quad \partial_j \lambda^i = \frac{\mu^j + \mu^i}{\mu^j - \mu^i} \partial_j u, \\ \partial_i \partial_j u = 2 \frac{\mu^j + \mu^i}{(\mu^j - \mu^i)(\lambda^j - \lambda^i)} \partial_i u \partial_j u, \end{gathered} \tag{24}$$

$i \neq j$, which is analogous to the system (17). There is one crucial difference: the system (24) is *not* in involution. Calculating compatibility conditions $\partial_k(\partial_j \mu^i) - \partial_j(\partial_k \mu^i) = 0$, $\partial_k(\partial_j \lambda^i) - \partial_j(\partial_k \lambda^i) = 0$, and $\partial_k(\partial_j \partial_i u) - \partial_j(\partial_k \partial_i u) = 0$, one arrives at extra relations

$$[(\mu^i)^2(\lambda^k-\lambda^j)+(\mu^k)^2(\lambda^j-\lambda^i)+(\mu^j)^2(\lambda^i-\lambda^k)]$$
$$\times[\mu^k\mu^j(\lambda^k-\lambda^j)+\mu^i\mu^j(\lambda^j-\lambda^i)+\mu^i\mu^k(\lambda^i-\lambda^k)]=0. \tag{25}$$

Thus, there are two cases to consider.

Case 1: Equating to zero the first set of square brackets in (25),

$$(\mu^i)^2(\lambda^k-\lambda^j)+(\mu^k)^2(\lambda^j-\lambda^i)+(\mu^j)^2(\lambda^i-\lambda^k)=0,$$

one obtains $\lambda^i=a(\mu^i)^2+b$. The substitution of this ansatz into (24) implies $(\mu^i)^2\partial_j a+\partial_j b=\partial_j u$, so that $a=\alpha$, $b=u+\beta$ where α,β are arbitrary constants. Thus, $\lambda^i=\alpha(\mu^i)^2+u+\beta$. Substituting λ^i into the equation $\partial_i p=\lambda^i\partial_i u$ and using (20) one obtains, upon elementary integration, $p=\frac{1}{2}u^2+\beta u+\alpha w+\gamma$. Expressed in terms of second derivatives of F, this constraint reads

$$F_{xt}=\tfrac{1}{2}F_{xx}^2+\beta F_{xx}+\alpha F_{yy}+\gamma.$$

One can show that the constants α,β,γ are not essentials and can be reduced to $\alpha=1,\beta=\gamma=0$. Thus, the method of hydrodynamic reductions applied to the PDE (18) reconstructs the first flow of the dKP hierarchy, $F_{xt}=\frac{1}{2}F_{xx}^2+F_{yy}$.

Case 2: Equating to zero the second set of square brackets in (25),

$$\mu^k\mu^j(\lambda^k-\lambda^j)+\mu^i\mu^j(\lambda^j-\lambda^i)+\mu^i\mu^k(\lambda^i-\lambda^k)=0,$$

one obtains $\lambda^i=(a/\mu^i)+b$. The substitution of this ansatz into (24) implies $\partial_j a+\mu^j\partial_j u+\mu^i(\partial_j b+\partial_j u)=0$, so that $a=-v+\alpha$, $b=-u+\beta$ where α,β are arbitrary constants. Thus, $\lambda^i=[(\alpha-v)/\mu^i]+\beta-u$. Substituting λ^i into the equation $\partial_i s=\lambda^i\mu^i\partial_i u$ and using (20) one has, upon elementary integration, $s=-uv+\alpha u+\beta v+\gamma$. Expressed in terms of second derivatives of F, this constraint reads

$$F_{xx}F_{xy}+F_{yt}=\alpha F_{xx}+\beta F_{xy}+\gamma.$$

Again, the constants α,β,γ are not essentials and can be reduced to zero. The resulting constraint $F_{yt}+F_{xx}F_{xy}=0$ characterizes stationary points of the flow (18). We have checked that this constraint is integrable in the sense of hydrodynamic reductions [as a $(2+1)$-dimensional PDE].

In any case, we conclude that Eq. (18) is *not* integrable as a four-dimensional PDE. This is manifested by the fact that the system (24), which governs hydrodynamic reductions, is not in involution.

Example 4: Let us consider the system

$$m_t=n_x, \quad n_z=m_y+mn_x-nm_x, \tag{26}$$

which, in the limit $z=t$, has been extensively investigated in Refs. 27, 9, and 26. Looking for reductions in the form $m=m(R^1,\ldots,R^n)$, $n=n(R^1,\ldots,R^n)$ where the Riemann invariants R^i satisfy (2), one obtains

$$\partial_i n=\lambda^i\partial_i m, \quad \mu^i=\lambda^i\eta^i-m\lambda^i+n.$$

The commutativity conditions (3) imply

$$\partial_j\eta^i=\partial_j m, \quad \partial_i\partial_j m=0,$$

hence, up to reparametrizations $R^i\to\varphi^i(R^i)$, one has

$$m=\sum_k R^k, \quad \eta^i=f^i(R^i)+\sum_k R^k,$$

where $f^i(R^i)$ are arbitrary functions of a single variable. The characteristic speeds λ^i solve the linear system

$$\frac{\partial_j \lambda^i}{\lambda^j - \lambda^i} = \frac{1}{f^j(R^j) - f^i(R^i)}.$$

We refer to Ref. 27 for the general formula for λ^i and further discussion of this example in the $(2+1)$-dimensional limit $z=t$. Thus, n-component hydrodynamic reductions of the system (26) are parametrized by $2n$ arbitrary functions of one variable [n functions $f^i(R^i)$ plus n functions in the general solution of the linear system for λ^i]. Therefore, the four-dimensional system (26) is integrable. Notice that it can be obtained as the condition of commutativity of two vector fields,

$$[\partial_z - m\partial_x - \lambda\partial_x, \quad \partial_y - n\partial_x - \lambda\partial_t] = 0,$$

$\lambda = \text{const}$, compare with Ref. 9. Some further multidimensional generalizations of this example are discussed in Sec. III.

Example 5: The six-dimensional generalization of the heavenly equation,

$$\theta_{t\tilde{t}} + \theta_{z\tilde{z}} + \theta_{tx}\theta_{zy} - \theta_{ty}\theta_{zx} = 0, \tag{27}$$

has been proposed in Ref. 31. Introducing the variables $\theta_{tx}=a$, $\theta_{zy}=b$, $\theta_{ty}=p$, $\theta_{zx}=q$, $\theta_{z\tilde{z}}=r$, $\theta_{t\tilde{t}}=pq-ab-r$, one can rewrite (27) in a quasilinear form,

$$\begin{gathered} a_y = p_x, \quad a_z = q_t, \quad b_t = p_z, \quad b_x = q_y, \quad b_{\tilde{z}} = r_y, \quad q_{\tilde{z}} = r_x, \\ p_{\tilde{z}} = (pq - ab - r)_y. \end{gathered} \tag{28}$$

Hydrodynamic reductions are sought in the form $a=a(R^1,\ldots,R^n)$, $b=b(R^1,\ldots,R^n)$, $p=p(R^1,\ldots,R^n)$, $q=q(R^1,\ldots,R^n)$, $r=r(R^1,\ldots,R^n)$, where the Riemann invariants $R^1,\ldots,R^n$ solve the commuting equations

$$R^i_x = \lambda^i(R)\ R^i_z, \quad R^i_y = \mu^i(R)\ R^i_z, \quad R^i_{\tilde{z}} = \eta^i(R)\ R^i_z, \quad R^i_t = \beta^i(R)\ R^i_z, \quad R^i_{\tilde{t}} = \gamma^i(R)\ R^i_z.$$

The substitution into (28) implies

$$\partial_i p = \beta^i \partial_i b, \quad \partial_i r = \frac{\eta^i}{\mu^i}\partial_i b, \quad \partial_i q = \frac{\lambda^i}{\mu^i}\partial_i b, \quad \partial_i a = \frac{\lambda^i \beta^i}{\mu^i}\partial_i b, \tag{29}$$

along with the dispersion relation

$$\eta^i = \beta^i \mu^i q + \lambda^i p - \beta^i \lambda^i b - \mu^i a - \beta^i \gamma^i. \tag{30}$$

Substituting η^i into the commutativity conditions

$$\frac{\partial_j \lambda^i}{\lambda^j - \lambda^i} = \frac{\partial_j \mu^i}{\mu^j - \mu^i} = \frac{\partial_j \eta^i}{\eta^j - \eta^i} = \frac{\partial_j \beta^i}{\beta^j - \beta^i} = \frac{\partial_j \gamma^i}{\gamma^j - \gamma^i},$$

and taking into account that the compatibility conditions for the relations $\partial_i p = \beta^i \partial_i b$ imply

$$\partial_i \partial_j b = \frac{\partial_j \beta^i}{\beta^j - \beta^i}\partial_i b + \frac{\partial_i \beta^j}{\beta^i - \beta^j}\partial_j b,$$

one arrives at the following system:

$$\frac{\partial_j\beta^i}{\beta^j-\beta^i}=\frac{\partial_j\lambda^i}{\lambda^j-\lambda^i}=\frac{\partial_j\mu^i}{\mu^j-\mu^i}=\frac{\partial_j\gamma^i}{\gamma^j-\gamma^i}=\frac{\lambda^i-\lambda^j\mu^i/\mu^j}{q(\mu^j-\mu^i)+b(\lambda^i-\lambda^j)+\gamma^i-\gamma^j}\,\partial_j b,$$
$$\partial_i\partial_j b=\frac{\lambda^i(1+\mu^j/\mu^i)-\lambda^j(1+\mu^i/\mu^j)}{q(\mu^j-\mu^i)+b(\lambda^i-\lambda^j)+\gamma^i-\gamma^j}\,\partial_i b\,\partial_j b. \tag{31}$$

Solving equations (31) for β^i, λ^i, μ^i, γ^i, and b, determining η^i from the dispersion relation (30) and calculating p,r,q,a from Eqs. (29) [which are automatically compatible by virtue of (31)], one obtains the general n-component reduction of Eq. (27). The commutativity conditions will be satisfied identically. We have checked that the system (31) is in involution and its general solution depends, up to reparametrizations $R^i\to\varphi^i(R^i)$, on $4n$ arbitrary functions of one variable.

III. MULTIDIMENSIONAL LINEARLY DEGENERATE SYSTEMS OF HYDRODYNAMIC TYPE

In the recent publication,[13] we gave a complete characterization of two-component $(2+1)$-dimensional integrable systems of hydrodynamic type,

$$\begin{pmatrix} v\\ w\end{pmatrix}_t+A(v,w)\begin{pmatrix} v\\ w\end{pmatrix}_x+B(v,w)\begin{pmatrix} v\\ w\end{pmatrix}_y=0,$$

which possess infinitely many hydrodynamic reductions. The integrability conditions constitute a complicated overdetermined system of second order PDEs for 2×2 matrices A and B. In the particular case when the matrix A is assumed to be linearly degenerate,

$$A=\begin{pmatrix} w & 0\\ 0 & v\end{pmatrix}, \tag{32}$$

these conditions imply

$$B=\begin{pmatrix} \dfrac{f(w)}{w-v}-\alpha w^2 & \dfrac{f(v)}{w-v}\\[2ex] \dfrac{f(w)}{v-w} & \dfrac{f(v)}{v-w}-\alpha v^2\end{pmatrix},$$

where f is a cubic polynomial, $f(v)=\alpha v^3+\beta v^2+\gamma v+\delta$, and $\alpha,\beta,\gamma,\delta$ are arbitrary constants. A remarkable property of this example is that *any* matrix in the linear pencil $B+\mu A$ is also linearly degenerate [that is, reduces to the diagonal form (32) after an appropriate change of dependent variables]. Explicitly, one has

$$B=\delta B_1+\gamma B_2+\beta B_3+\alpha B_4=\delta\begin{pmatrix} \dfrac{1}{w-v} & \dfrac{1}{w-v}\\[2ex] \dfrac{1}{v-w} & \dfrac{1}{v-w}\end{pmatrix}+\gamma\begin{pmatrix} \dfrac{w}{w-v} & \dfrac{v}{w-v}\\[2ex] \dfrac{w}{v-w} & \dfrac{v}{v-w}\end{pmatrix}+\beta\begin{pmatrix} \dfrac{w^2}{w-v} & \dfrac{v^2}{w-v}\\[2ex] \dfrac{w^2}{v-w} & \dfrac{v^2}{v-w}\end{pmatrix}$$
$$+\alpha\begin{pmatrix} \dfrac{vw^2}{w-v} & \dfrac{v^3}{w-v}\\[2ex] \dfrac{w^3}{v-w} & \dfrac{wv^2}{v-w}\end{pmatrix}.$$

Let us introduce the $(5+1)$-dimensional system,

$$\begin{pmatrix} v \\ w \end{pmatrix}_t + A\begin{pmatrix} v \\ w \end{pmatrix}_x + B_1\begin{pmatrix} v \\ w \end{pmatrix}_y + B_2\begin{pmatrix} v \\ w \end{pmatrix}_z + B_3\begin{pmatrix} v \\ w \end{pmatrix}_s + B_4\begin{pmatrix} v \\ w \end{pmatrix}_r = 0.$$

Notice that an arbitrary linear combination of matrices A and B_1, B_2, B_3, B_4 is linearly degenerate. In the new variables $m=v+w$, $n=vw$, this system reduces to

$$m_t + n_x + nm_r - mn_r = 0, \quad n_t + mn_x - nm_x + m_y + n_z + mn_s - nm_s = 0,$$

taking a fully symmetric form

$$m_{\tilde{t}} = n_{\tilde{x}} + nm_{\tilde{r}} - mn_{\tilde{r}}, \quad n_{\tilde{z}} = m_{\tilde{y}} + mn_{\tilde{s}} - nm_{\tilde{s}}, \tag{33}$$

after the obvious linear change of independent variables. In the limit $\tilde{s}=\tilde{x}$, $m_{\tilde{r}}=n_{\tilde{r}}=0$ it reduces to the system (26) from Example 4. Notice that the system (33) arises as the condition of commutativity of two vector fields,

$$[\partial_{\tilde{z}} - m\partial_{\tilde{s}} - \lambda\partial_{\tilde{x}} + \lambda m\partial_{\tilde{r}}, \quad \partial_{\tilde{y}} - n\partial_{\tilde{s}} - \lambda\partial_{\tilde{t}} + \lambda n\partial_{\tilde{r}}] = 0.$$

Let us demonstrate that the system (33) possesses enough hydrodynamic reductions and, therefore, should be regarded as an integrable system in $5+1$ dimensions. Looking for reductions in the form $m=m(R^1,\ldots,R^n)$, $n=n(R^1,\ldots,R^n)$ where the Riemann invariants R^i solve five commuting systems,

$$R^i_{\tilde{t}} = \lambda^i(R)\ R^i_{\tilde{x}}, \quad R^i_{\tilde{y}} = \mu^i(R)\ R^i_{\tilde{x}}, \quad R^i_{\tilde{z}} = \eta^i(R)\ R^i_{\tilde{x}}, \quad R^i_{\tilde{r}} = \beta^i(R)\ R^i_{\tilde{x}}, \quad R^i_{\tilde{s}} = \gamma^i(R)\ R^i_{\tilde{x}},$$

and substituting into (33), we obtain

$$(\lambda^i - n\beta^i)\partial_i m = (1-m\beta^i)\partial_i n, \quad (\eta^i - m\gamma^i)\partial_i n = (\mu^i - n\gamma^i)\partial_i m.$$

Setting $\partial_i n = \varphi^i \partial_i m$, one obtains expressions for λ^i and μ^i in the form

$$\lambda^i = n\beta^i + (1-m\beta^i)\varphi^i, \quad \mu^i = n\gamma^i + (\eta^i - m\gamma^i)\varphi^i,$$

as well as the consistency condition

$$\partial_i\partial_j m = \frac{\partial_j \varphi^i}{\varphi^j - \varphi^i}\partial_i m + \frac{\partial_i \varphi^j}{\varphi^i - \varphi^j}\partial_j m.$$

Inserting the expressions for λ^i and μ^i into the commutativity conditions

$$\frac{\partial_j \lambda^i}{\lambda^j - \lambda^i} = \frac{\partial_j \mu^i}{\mu^j - \mu^i} = \frac{\partial_j \eta^i}{\eta^j - \eta^i} = \frac{\partial_j \beta^i}{\beta^j - \beta^i} = \frac{\partial_j \gamma^i}{\gamma^j - \gamma^i},$$

one ends up with the following equations for η^i, β^i, γ^i, φ^i, and m:

$$\frac{\partial_j \eta^i}{\eta^j - \eta^i} = \frac{\partial_j \beta^i}{\beta^j - \beta^i} = \frac{\partial_j \gamma^i}{\gamma^j - \gamma^i} = \frac{\beta^i \eta^i - \gamma^i}{(1-m\beta^j)(\eta^i - m\gamma^i) - (1-m\beta^i)(\eta^j - m\gamma^j)}\partial_j m,$$

$$\frac{\partial_j \varphi^i}{\varphi^j - \varphi^i} = \frac{\beta^i \eta^j - \gamma^i + m(\gamma^i\beta^j - \gamma^j\beta^i)}{(1-m\beta^j)(\eta^i - m\gamma^i) - (1-m\beta^i)(\eta^j - m\gamma^j)}\partial_j m, \tag{34}$$

$$\partial_i\partial_j m = \frac{\gamma^j - \gamma^i + \beta^i\eta^j - \beta^j\eta^i + 2m(\gamma^i\beta^j - \gamma^j\beta^i)}{(1-m\beta^j)(\eta^i - m\gamma^i) - (1-m\beta^i)(\eta^j - m\gamma^j)}\partial_i m \partial_j m.$$

It has been verified directly that this system is in involution and its general solution depends, modulo reparametrizations $R^i \to f^i(R^i)$, on $4n$ arbitrary functions of one variable, thus manifesting the integrability of the $(5+1)$-dimensional system (33).

ACKNOWLEDGMENTS

We would like to thank M. Dunajski and M. Pavlov for stimulating discussions and references.

APPENDIX A: HYDRODYNAMIC REDUCTIONS

Here we apply the method of hydrodynamic reductions to the classification of integrable PDEs of the form

$$\theta_{tx}+\theta_{zy}=f(\theta_{xx},\theta_{xy},\theta_{yy}). \tag{A1}$$

Introducing new variables $\theta_{xx}=u$, $\theta_{xy}=v$, $\theta_{yy}=w$, $\theta_{tx}=p$, $\theta_{zy}=f(u,v,w)-p$, one rewrites (A1) in the quasilinear form

$$\begin{gathered} u_y=v_x, \quad u_t=p_x, \quad v_y=w_x, \quad v_t=p_y, \\ v_z=(f(u,v,w)-p)_x, \quad w_z=(f(u,v,w)-p)_y. \end{gathered} \tag{A2}$$

Hydrodynamic reductions are sought in the form $u=u(R^1,\ldots,R^n)$, $v=v(R^1,\ldots,R^n)$, $w=w(R^1,\ldots,R^n)$, $p=p(R^1,\ldots,R^n)$ where the Riemann invariants $R^1,\ldots,R^n$ solve a triple of commuting hydrodynamic type systems (2). The substitution into (A2) implies

$$\partial_i p=\lambda^i \partial_i u, \quad \partial_i v=\mu^i \partial_i u, \quad \partial_i w=(\mu^i)^2 \partial_i u, \tag{A3}$$

along with the dispersion relation

$$\lambda^i=f_u+f_v\mu^i+f_w(\mu^i)^2-\mu^i\eta^i. \tag{A4}$$

Substituting λ^i into the commutativity conditions (3), and taking into account that the compatibility conditions for the relations (A3) imply

$$\partial_i\partial_j u=\frac{\partial_j\mu^i}{\mu^j-\mu^i}\partial_i u+\frac{\partial_i\mu^j}{\mu^i-\mu^j}\partial_j u,$$

one arrives at the following system:

$$\begin{gathered} \partial_j\mu^i=\frac{S_{ij}}{f_w(\mu^j-\mu^i)+\eta^i-\eta^j}\partial_j u, \quad \partial_j\eta^i=\frac{\eta^j-\eta^i}{\mu^j-\mu^i}\frac{S_{ij}}{f_w(\mu^j-\mu^i)+\eta^i-\eta^j}\partial_j u, \\ \partial_i\partial_j u=\frac{2}{\mu^j-\mu^i}\frac{S_{ij}}{f_w(\mu^j-\mu^i)+\eta^i-\eta^j}\partial_i u\partial_j u; \end{gathered} \tag{A5}$$

here

$$S_{ij}=f_{uu}+(\mu^i+\mu^j)f_{uv}+((\mu^i)^2+(\mu^j)^2)f_{uw}+\mu^i\mu^j f_{vv}+\mu^i\mu^j(\mu^i+\mu^j)f_{vw}+(\mu^i)^2(\mu^j)^2 f_{ww}.$$

Compatibility conditions for the system (A5) are of the form

$$\partial_k(\partial_j\mu^i)-\partial_j(\partial_k\mu^i)=(\cdots)\ \partial_j u\partial_k u, \quad \partial_k(\partial_j\eta^i)-\partial_j(\partial_k\eta^i)=(\cdots)\ \partial_j u\partial_k u,$$

$$\partial_k(\partial_j\partial_i u)-\partial_j(\partial_k\partial_i u)=(\cdots)\ \partial_j u\partial_k u,$$

where dots $(\cdots)$ denote complicated rational expressions in μ^i, μ^j, μ^k and η^i, η^j, η^k whose coefficients are functions of the derivatives of f up to third order. Equating these rational expressions to zero one arrives at the following system for f:

$$f_{uu}=f_{ww}=f_{uv}=f_{wv}=f_{vv}-2\,f_{uw}=f_{vvv}=0.$$

Up to elementary changes of variables, the general nonlinear solution of this system corresponds to the second heavenly equation (13).

APPENDIX B: CONCLUDING REMARKS

We have demonstrated that the requirement of existence of sufficiently many n-component reductions can be used as the effective criterion providing the test for integrability of multidimensional dispersionless PDEs. We believe that using the approach outlined in this paper along with the available computer algebra packages (we have used Mathematica 5.0), one can obtain complete lists of multidimensional integrable systems within various particularly interesting classes, hyperbolic systems of hydrodynamic type being one of them. Partial classification results can be found in Refs. 12, 13, and 28. The main problems arising here are the complexity of integrability conditions (making difficult their geometric analysis), and the volume of symbolic calculations required.

published online 13 May 2004)

It is known that the chiral part of any 2D conformal field theory defines a 3D topological quantum field theory: quantum states of this TQFT are the CFT conformal blocks. The main aim of this paper is to show that a similar CFT/TQFT relation exists also for the full CFT. The 3D topological theory that arises is a certain ''square'' of the chiral TQFT. Such topological theories were studied by Turaev and Viro; they are related to 3D gravity. We establish an operator/state correspondence in which operators in the chiral TQFT correspond to states in the Turaev–Viro theory. We use this correspondence to interpret CFT correlation functions as particular quantum states of the Turaev–Viro theory. We compute the components of these states in the basis in the Turaev–Viro Hilbert space given by colored 3-valent graphs. The formula we obtain is a generalization of the Verlinde formula. The later is obtained from our expression for a zero colored graph. Our results give an interesting ''holographic'' perspective on conformal field theories in two dimensions. © *2004 American Institute of Physics.*

I. INTRODUCTION

To put results of this paper in a somewhat general context we recall that any conformal field theory (CFT) defines a topological quantum field theory (TQFT), see Refs. 1–4. The TQFT arises by extracting a modular tensor category from the CFT chiral vertex operator algebra. Then, as explained in Ref. 5, any modular category gives rise to a 3D TQFT. The TQFT can be (partially) described by saying that its Hilbert space is the space of (holomorphic) conformal blocks of the CFT. The canonical example of such CFT/TQFT correspondence is the well-known relation between Wess–Zumino–Witten (WZW) and Chern–Simons (CS) theories. Let us emphasize that this is always a relation between the holomorphic sector of the CFT (or its chiral part) and a TQFT. As such it is not an example of a holographic correspondence, in which correlation functions (comprising both the holomorphic and antiholomorphic sectors) of CFT on the boundary would be reproduced by some theory in bulk.

It is then natural to ask whether there is some 3D theory that corresponds to the *full* CFT. A proposal along these lines was put forward some time ago by Verlinde,[6] who argued that a relation must exist between the quantum Liouville theory (full, not just the chiral part) and 3D gravity. Recently one of us presented[7] some additional arguments in favor of this relation, hopefully somewhat clarifying the picture. The main goal of the present paper is to demonstrate that such a relation between the full CFT and a certain 3D theory exists for a large class of CFT's. Namely, we show that given a CFT there is a certain 3D field theory, which is a TQFT, and which is a rather natural spin-off of the corresponding ''chiral'' TQFT. The TQFT in question is not new, it is

[a)]Electronic mail: freidel@ens-lyon.fr

the one defined by Turaev–Viro,[8] and described in great detail in Ref. 5. This paper is thus aimed at a clarification of the relation between the Turaev–Viro (TV) 3D TQFT's and CFT's in two dimensions.

The point that given a CFT there exists a relation between the full CFT and some 3D TQFT is to some extent contained in recent works on boundary conformal field theory, see Refs. 2, 3, 4, 9, and references therein, and also a more recent paper.[10] As is emphasized, e.g., in Ref. 4, the full CFT partition function on some Riemann surface X (possibly with a boundary) is equal to the chiral CFT partition function on the double $\tilde{X}$. There is then a certain ''connecting'' 3D manifold $\tilde{M}$ whose boundary $\partial\tilde{M}$ is the double $\tilde{X}$. Using the chiral CFT/TQFT relation one obtains a 3D TQFT in $\tilde{M}$ that reproduces the chiral partition function on $\tilde{X}$, and thus the full partition function on X. This formalism turns out to be very useful for analyzing the case when X has a boundary.

Our analysis was motivated by the above picture, but the logic is somewhat different. Instead of working with the chiral TQFT in the connecting 3-manifold $\tilde{M}$ we work directly with a 3-manifold M whose boundary is X, and the Turaev–Viro TQFT on M. The two approaches are clearly related as the TV theory is a ''square'' of the chiral TQFT. However, bringing the Turaev–Viro TQFT into the game suggests some new interpretations and provides new relations. Thus, most notably, we establish an operator/state correspondence in which the chiral TQFT operators correspond to states in the TV theory, and the trace of an operator product corresponds to the TV inner product. We use this to interpret the CFT correlators as quantum states of TV theory. Then, using the fact that a basis in the Hilbert space of TV theory on X is given by colored trivalent graph states, we will characterize the CFT correlation functions by finding their components in this basis. Thus, the relation that we demonstrate is about a 3D TQFT on a 3-manifold M and a CFT on the boundary X of M. It is therefore an example of a holographic correspondence, while this is not obviously so for the correspondence based on a chiral TQFT in the connecting manifold $\tilde{M}$.

The holography discussed may be viewed by some as trivial, because the three-dimensional theory is topological. What makes it interesting is that it provides a very large class of examples. Indeed, there is a relation of this type for any CFT. Importantly, this holography is not limited to any AdS type background, although a very interesting subclass of examples (not considered in this paper, but see Ref. 7) is exactly of this type.

As the relation chiral CFT/TQFT is best understood for the case of a rational CFT, we shall restrict our analysis to this case. Our constructions can also be expected to generalize to nonrational and even noncompact CFT's with a continuous spectrum, but such a generalization is non-trivial, and is not attempted in this paper. Even with noncompact CFT's excluded, the class of CFT's that is covered by our considerations, namely, rational CFT, is still very large. To describe the arising structure in its full generality we would need to introduce the apparatus of category theory, as it was done, e.g., in Ref. 5. In order to make the exposition as accessible as possible we shall not maintain the full generality. We demonstrate the CFT/TQFT holographic relation using a compact group WZW CFT (and CS theory as the corresponding chiral TQFT) as an example.

We shall often refer to the TV TQFT as ''gravity.'' For the case of chiral TQFT being the Chern–Simons theory for a group $G=\mathrm{SU}(2)$ this ''gravity'' theory is just the usual 3D Euclidean gravity with positive cosmological constant. However, the theory can be associated to any CFT. The reader should keep in mind its rather general character.

In order to describe the holographic correspondence in detail we will need to review (and clarify) the relation between CS theory and gravity (or between the Reshetikhin–Turaev–Witten and Turaev–Viro invariants) for a 3-manifold with boundary. We found that the expositions of this relation available in the literature (see Refs. 5, 11) are rather brief and sketchy. This paper provides a more detailed account and obtains new results. In particular, the operator/state correspondence established in this paper is new.

Finally, we would like to emphasize that the approach presented in this paper is not equivalent to that of Refs. 2, 3, 4, 9, even though it was motivated by these papers. Thus, most of our discussion only concerns the diagonal-type partition functions, while Ref. 4 is applicable to the

more general case. It would be of interest to study the relation to Refs. 2, 3, 4, 9 in more detail, and also extend the approach presented here to modular invaraint partition functions of other types. We shall not attempt this in the present paper.

The paper is organized as follows: In Sec. II we review the quantization of Chern–Simons theory. Section III is devoted to the Turaev–Viro theory. We then review the definition of 3-manifold invariants in Sec. IV, and some facts on the Verlinde formula in Sec. V. The new material starts in Sec. VI, where we discuss the CS/TV operator/state correspondence and the arising relation between the CS and TV Hilbert spaces. In Sec. VII we interpret the CFT partition function as a TV quantum state, and compute components of this state in a natural basis in the TV Hilbert space given by graphs. We conclude with a discussion.

II. CHERN–SIMONS THEORY

This section is a rather standard review of CS theory. We discuss the CS phase space, the Hilbert space that arises as its quantization, review the Verlinde formula, and a particular basis in the CS Hilbert space that arises from a pant decomposition. The reader may consult, e.g., Refs. 12 and 5 for more details.

A. Action

The Chern–Simons (CS) theory is a three-dimensional TQFT of Witten-type. The CS theory for a group G is defined by the following action functional:

$$S^{-}_{\mathrm{CS}}[A]=\frac{k}{4\pi}\int_M \mathrm{Tr}\left(A\wedge dA+\frac{2}{3}A\wedge A\wedge A\right)-\frac{k}{4\pi}\int_{\partial M} dz\wedge d\bar{z}\,\mathrm{Tr}(A_z A_{\bar{z}}). \tag{2.1}$$

Here M is a three-dimensional manifold and A is a connection on the principal G-bundle over M. For the case of a compact G that we consider in this paper the action is gauge invariant (modulo 2π) when k is an integer. The second term in (2.1) is necessary to make the action principle well-defined on a manifold with boundary. To write it one needs to choose a complex structure on ∂M. As ∂M is a 2D Riemann surface, complex structures on it are same as conformal structures. Thus, one has to make a choice of the conformal structure. Then the term in (2.1) is the one relevant for fixing $A_{\bar{z}}$ on the boundary. Another possible choice of boundary condition is to fix A_z. The corresponding action is:

$$S^{+}_{\mathrm{CS}}[A]=\frac{k}{4\pi}\int_M \mathrm{Tr}\left(A\wedge dA+\frac{2}{3}A\wedge A\wedge A\right)+\frac{k}{4\pi}\int_{\partial M} dz\wedge d\bar{z}\,\mathrm{Tr}(A_z A_{\bar{z}}). \tag{2.2}$$

B. Partition function

The partition function arises (formally) by considering the path integral for (2.1). For a closed M it can be given a precise meaning through the surgery representation of M and the Reshetikhin–Turaev–Witten (RTW) invariant of links. Before we review this construction, let us discuss the formal path integral for the case when M has a boundary. For example, let the manifold M be a handlebody H. Its boundary $X=\partial H$ is a (connected) Riemann surface. Recall that TQFT assigns a Hilbert space to each connected component of ∂M, and a map between these Hilbert spaces to M. The map can be heuristically thought of as given by the path integral. For a manifold with a single boundary component, which is the case for a handlebody H, TQFT on H gives a map $\mathcal{F}:\mathcal{H}^{\mathrm{CS}}_X\to\mathbb{C}$ mapping the CS Hilbert space of X into $\mathbb{C}$. This map can be obtained from the following Hartle–Hawking (HH) type state:

$$\mathcal{F}(\underline{A})=\int_{A_{\bar{z}}=\underline{A}}\mathcal{D}A\; e^{iS^{-}_{\mathrm{CS}}[A]}. \tag{2.3}$$

The path integral is taken over connections in H with the restriction of A on X fixed. More precisely, with the choice of boundary term in the action as in (2.1), one fixes only the antiholomorphic part $\underline{A}=A_{\bar{z}}$ of the connection on X, as defined by an auxiliary complex structure. The result of the path integral (2.3) is the partition function of CS theory on H. It can be thought of as a particular quantum state $\mathcal{F}(\underline{A})$ in the CS Hilbert space $\mathcal{H}_X^{\mathrm{CS}}$. The inner product in $\mathcal{H}_X^{\mathrm{CS}}$ is (formally) defined as

$$\langle \Psi_1|\Psi_2\rangle=\int_{\mathcal{A}}\mathcal{D}\underline{A}\overline{\mathcal{D}\underline{A}}\; e^{-(k/\pi)\int_{\partial\mathcal{M}}d^2z\,\mathrm{Tr}(\underline{A}_z\underline{A}_{\bar{z}})}\overline{\Psi_1(\underline{A})}\Psi_2(\underline{A}). \tag{2.4}$$

Here $d^2z=dz\wedge d\bar{z}/2i$ is the real measure on the boundary. The above mentioned map $\mathcal{F}:\mathcal{H}_X^{\mathrm{CS}}\to\mathbb{C}$ is given by

$$\mathcal{F}(\Psi)=\langle\mathcal{F}|\Psi\rangle=\int_{\mathcal{A}}\mathcal{D}\underline{A}\overline{\mathcal{D}\underline{A}}\; e^{-(k/\pi)\int_{\partial\mathcal{M}}dz^2\,\mathrm{Tr}(\underline{A}_z\underline{A}_{\bar{z}})}\overline{\mathcal{F}(\underline{A})}\Psi(\underline{A}). \tag{2.5}$$

The state $\mathcal{F}(\underline{A})\in\mathcal{H}_X^{\mathrm{CS}}$ depends only on the topological nature of the 3-manifold and a framing of M.

C. Phase space

To understand the structure of the CS Hilbert space $\mathcal{H}^{\mathrm{CS}}$ it is natural to use the Hamiltonian description. Namely, near the boundary the manifold has the topology $X\times\mathbb{R}$. Then the phase space $\mathcal{P}^{\mathrm{CS}}$ of CS theory based on a group G is the moduli space of flat G-connections on X modulo gauge transformations:

$$\mathcal{P}_X^{\mathrm{CS}}\sim\mathcal{A}/\mathcal{G}. \tag{2.6}$$

It is finite dimensional.

Let X be a (connected) Riemann surface of type (g,n) with $g\geqslant 0$, $n>0$, $2g+n-2>0$. Denote the fundamental group of X by $\pi(X)$. The moduli space $\mathcal{A}$ can then be parametrized by homomorphisms $\phi:\pi(X)\to G$. The phase space is, therefore, isomorphic to

$$\mathcal{P}_X^{\mathrm{CS}}\sim\mathrm{Hom}(\pi(X),G)/G, \tag{2.7}$$

where one mods out by the action of the group at the base point. The fundamental group is generated by $m_i, i=1,\ldots,n$ and $a_i,b_i, i=1,\ldots,g$ satisfying the following relation:

$$m_1\cdots m_n[a_1,b_1]\cdots[a_g,b_g]=1. \tag{2.8}$$

Here $[a,b]=aba^{-1}b^{-1}$. The dimension of the phase space can now be seen to be

$$\dim\mathcal{P}_X^{\mathrm{CS}}=(2g+n-2)\dim G. \tag{2.9}$$

The fact that (2.7) is naturally a Poisson manifold was emphasized in Ref. 13. The Poisson structure described in Ref. 13 is the same as the one that comes from CS theory. For the case of a compact X the space (2.7) is actually a symplectic manifold. For the case when punctures are present the symplectic leaves are obtained by restricting the holonomy of $\underline{A}$ around punctures to lie in some conjugacy classes in the group. An appropriate power of the symplectic structure can be used as a volume form on the symplectic leaves. Their volume turns out to be finite. One thus expects to get finite dimensional Hilbert spaces upon quantization.

D. Hilbert space

The Hilbert space $\mathcal{H}_X^{\mathrm{CS}}$ was understood[12,14] to be the same as the space of conformal blocks of the chiral Wess–Zumino–Witten (WZW) theory on a genus g-surface with n vertex operators

inserted. Let us fix irreducible representations $\mathbf{R}=\{\rho_1,\ldots,\rho_n\}$ of G labeling the punctures. The dimension of each of $\mathcal{H}_X^{\mathrm{CS}}$ can be computed using the Verlinde formula:[15,16]

$$\dim \mathcal{H}_X^{\mathrm{CS}}=\sum_\rho \frac{S_{\rho_1\rho}\cdots S_{\rho_n\rho}}{S_{0\rho}\cdots S_{0\rho}}(S_{0\rho})^{2-2g}. \tag{2.10}$$

The sum is taken over irreducible representations ρ, $S_{\rho\rho'}$ is the modular S-matrix, see (4.3) below for the case of SU(2), and $S_{0\rho}=\eta\dim_\rho$, where η is given by (4.2).

E. Pant decomposition

The states from $\mathcal{H}_X^{\mathrm{CS}}$ can be understood as the HH type states given by the path integral over a handlebody H with Wilson lines in representations $\mathbf{R}$ intersecting the boundary X transversally at n points. A convenient basis in $\mathcal{H}_X^{\mathrm{CS}}$ can be obtained by choosing a pant decomposition of X. A pair of pants is a sphere with 3 holes (some of them can be punctures). A Riemann surface X of type (g,n) can be represented by $2g+n-2$ pants glued together. For example, the surface of type (0,4) with 4 punctures can be obtained by gluing together 2 spheres each with 2 punctures and one hole. Note that a pant decomposition is not unique. Different pant decompositions are related by simple ''moves.'' A pant decomposition can be conveniently encoded in a tri-valent graph Δ with $2g+n-2$ vertices and $3g+2n-3$ edges. Each vertex of Δ corresponds to a pair of pants, and each internal edge corresponds to two holes glued together. Open-ended edges of Δ end at punctures. We shall call such edges ''loose.'' There are exactly n of them. The graph Δ can be thought of as a 1-skeleton of the Riemann surface X, or as a Feynman diagram that corresponds to the string world-sheet X. The handlebody H can be obtained from Δ as its regular neighborhood $U(\Delta)$, so that Δ is inside H and the loose edges of Δ end at the punctures. Let us label the loose edges by representations $\mathbf{R}$ and internal edges by some other (non-null) irreducible representations. It is convenient to formalize the labeling of Δ in a notion of *coloring* ϕ. A coloring ϕ is the map

$$\phi: E_\Delta \to \mathcal{I}, \quad \phi(e)=\rho_e\in\mathcal{I} \tag{2.11}$$

from the set E_Δ of edges of Δ to the set $\mathcal{I}$ of (non-null) irreducible representations of the quantum group G. The loose edges are colored by representations from $\mathbf{R}$. The CS path integral on H with the spin network Δ^ϕ inserted is a state in $\mathcal{H}_X^{\mathrm{CS}}$. See below for a definition of spin networks. Changing the labels on the internal edges one gets states that span the whole $\mathcal{H}_X^{\mathrm{CS}}$. Different choices of pant decomposition of H (and thus of Δ) lead to different bases in $\mathcal{H}_X^{\mathrm{CS}}$.

F. Inner product

The inner product (2.4) of two states of the type described can be obtained by the following operation. Let one state be given by the path integral over H with Δ^ϕ inserted and the other by H with $\Delta^{\phi'}$ inserted, where both the graph and/or the coloring may be different in the two states. Let us invert orientation of the first copy of H and glue $-H$ to H across the boundary (using the identity homomorphism) to obtain some 3D space $\tilde{H}$ without boundary. We will refer to $\tilde{H}$ as the *double* of H. For H being a handlebody with g handles the double $\tilde{H}$ has the topology of a connected sum:

$$\tilde{H}\sim \#_{g-1} S^2\times S^1. \tag{2.12}$$

The loose ends of Δ are connected at the punctures to the loose ends of Δ' to obtain a colored closed graph $\Delta^\phi\cup\Delta^{\phi'}$ inside $\tilde{H}$. The inner product (2.4) is given by the CS path integral over $\tilde{H}$ with the spin network $\Delta^\phi\cup\Delta^{\phi'}$ inserted. This path integral is given by the RTW evaluation of $\Delta^\phi\cup\Delta^{\phi'}$ in $\tilde{H}$, see below for a definition of the RTW evaluation.

III. GRAVITY

The material reviewed in this section is less familiar, although is contained in the literature. We give the action for Turaev–Viro theory, discuss the phase space, then introduce certain important graph coordinatization of it, define spin networks, and describe the TV Hilbert space. A useful reference for this section is the book of Turaev (Ref. 5 and Ref. 17).

A. Action

What we refer to as ''gravity'' arises as a certain ''square'' of CS theory. We will also refer to this gravity theory as Turaev–Viro (TV) theory, to have uniform notations (CS-TV).

To see how the TV theory (gravity) arises from CS theory, let us introduce two connection fields A and B. Consider the corresponding CS actions $S_{\mathrm{CS}}[A], S_{\mathrm{CS}}[B]$. Introduce the following parametrization of the fields:

$$A=\mathbf{w}+\left(\frac{\pi}{k}\right)\mathbf{e}, \quad B=\mathbf{w}-\left(\frac{\pi}{k}\right)\mathbf{e}. \tag{3.1}$$

Here $\mathbf{w}$ is a G-connection, and $\mathbf{e}$ is a one-form valued in the Lie algebra of G. The TV theory action is essentially given by the difference $S^{-}_{\mathrm{CS}}[A]-S^{+}_{\mathrm{CS}}[B]$, plus a boundary term such that the full action is

$$S_{\mathrm{TV}}[\mathbf{w},\mathbf{e}]=\int_M \mathrm{Tr}\left(\mathbf{e}\wedge\mathbf{f}(\mathbf{w})+\frac{\Lambda}{12}\mathbf{e}\wedge\mathbf{e}\wedge\mathbf{e}\right). \tag{3.2}$$

The boundary condition for this action is that the restriction $\underline{\mathbf{w}}$ of $\mathbf{w}$ on $X=\partial M$ is kept fixed. Here Λ is the ''cosmological constant'' related to k as $k=2\pi/\sqrt{\Lambda}$. For $G=\mathrm{SU}(2)$ the TV theory is nothing else but the Euclidean gravity with positive cosmological constant Λ. We emphasize, however, that the theory is defined for other groups as well. Moreover, it also exists as a square of a chiral TQFT for any TQFT, that is even in cases when the chiral TQFT is not a CS theory.

B. Path integral

Similarly to CS theory, one can consider HH type states given by the path integral on a manifold with a single boundary component. Thus, for a manifold being a handlebody H we get the TV partition function:

$$\mathcal{T}(\underline{\mathbf{w}})=\int_{\mathbf{w}|_X=\underline{\mathbf{w}}}\mathcal{D}\mathbf{w}\mathcal{D}\mathbf{e}\ e^{iS_{\mathrm{TV}}[\mathbf{w},\mathbf{e}]}. \tag{3.3}$$

The integral is taken over both $\mathbf{w}$,$\mathbf{e}$ fields in the bulk with the restriction $\underline{\mathbf{w}}$ of the connection fixed on the boundary. The TV partition function $\mathcal{T}(\underline{\mathbf{w}})$ is thus a functional of the boundary connection. It can also be interpreted as a particular state in the TV Hilbert space $\mathcal{H}^{\mathrm{TV}}_X$.

States from $\mathcal{H}^{\mathrm{TV}}_X$ are functionals of the boundary connection. The inner product on this space can be formally defined by the formula

$$\langle\Psi_1|\Psi_2\rangle=\frac{1}{\mathrm{Vol}\,\mathcal{G}}\int_{\mathcal{A}}\mathcal{D}\underline{\mathbf{w}}\ \overline{\Psi_1(\underline{\mathbf{w}})}\Psi_2(\underline{\mathbf{w}}) \tag{3.4}$$

similar to (2.4). Note, however, that the measure in (3.4) is different from that in (2.4). We shall see this below when we describe how to compute TV inner products in practice.

C. Relation between TV and CS states

Formally, the following relation between TV and CS states exists. As one can easily check, the difference of two CS actions in the parametrization (3.1) is given by

$$S^-_{\rm CS}[A]-S^+_{\rm CS}[B]=S_{\rm TV}[\mathbf{w},\mathbf{e}]+\frac{1}{2}\int_{\partial\mathcal{M}}{\rm Tr}(\mathbf{e}\wedge\mathbf{w})-\frac{k}{2\pi}\int_{\partial\mathcal{M}}dz\wedge d\bar{z}\,{\rm Tr}\left(\mathbf{w}_z\mathbf{w}_{\bar{z}}+\left(\frac{\pi}{k}\right)^2\mathbf{e}_z\mathbf{e}_{\bar{z}}\right). \tag{3.5}$$

Therefore,

$$e^{iS^-_{\rm CS}[A]-iS^+_{\rm CS}[B]-(k/\pi)\int_{\partial\mathcal{M}}d^2z\,{\rm Tr}(A_{\bar{z}}B_z)}=e^{iS_{\rm TV}[\mathbf{w},\mathbf{e}]+(2\pi/k)\int_{\partial\mathcal{M}}dz^2\,{\rm Tr}(\mathbf{e}_z\mathbf{e}_{\bar{z}})}. \tag{3.6}$$

Here $d^2z=dz\wedge d\bar{z}/2i$ is the real measure on $\partial\mathcal{M}$. Note that the last term in the exponential on the left hand side is the same as in the CS inner product (2.4). From this expression one can read off a prescription for obtaining the TV state $\mathcal{T}(\underline{\mathbf{w}})$. Indeed, let us integrate the left-hand side over bulk A,B, keeping A^-_z,B_z fixed on the boundary. Let us denote the result by $\Phi(A^-_z,B_z)$. We have

$$\Phi(A^-_z,B_z)=\Psi(A^-_z)\overline{\Psi}(B_z)\;e^{-(k/\pi)\int_{\partial\mathcal{M}}d^2z\,{\rm Tr}(A_{\bar{z}}B_z)}. \tag{3.7}$$

To get $\mathcal{T}(\mathbf{w})$ one must take $\Phi(A^-_z,B_z)$ in the parametrization (3.1), multiply the result by an exponential factor and integrate over the restriction $\underline{\mathbf{e}}$ of $\mathbf{e}$ on the boundary:

$$\mathcal{T}(\underline{\mathbf{w}})=\int\mathcal{D}\underline{\mathbf{e}}\;e^{-(2\pi/k)\int_{\partial\mathcal{M}}dz^2\,{\rm Tr}(\underline{\mathbf{e}_z\mathbf{e}_{\bar{z}}})}\;\Phi\left(\underline{\mathbf{w}}_{\bar{z}}+\left(\frac{\pi}{k}\right)\underline{\mathbf{e}}_{\bar{z}},\underline{\mathbf{w}}_z-\left(\frac{\pi}{k}\right)\underline{\mathbf{e}}_z\right). \tag{3.8}$$

The functional $\Phi(A^-_z,B_z)$ is a vector in the Hilbert space $\mathcal{H}^{\rm CS}\otimes\overline{\mathcal{H}^{\rm CS}}$. We should view (3.8) as a transform between this Hilbert space and $\mathcal{H}^{\rm TV}$. This transform will play an important role in what follows. Below we shall see how the result of the transform (3.8) can be found in practice.

D. Phase space

The TV phase space is basically two copies of $\mathcal{P}^{\rm CS}$, but with an unusual polarization. The polarization on $\mathcal{P}^{\rm TV}$ is given by $\mathbf{e}$, $\mathbf{w}$, which are canonically conjugate variables. Note that there is no need to choose a complex structure in order to define this polarization.

It turns out to be very convenient to think of $\mathcal{P}^{\rm TV}$ as some deformation of the cotangent bundle $T^*(\mathcal{A}/\mathcal{G})$ over the moduli space $\mathcal{A}/\mathcal{G}$ of flat connections on X. Note, however, that the TV connection $\underline{\mathbf{w}}$ on the boundary is not flat, so the configuration space for TV theory is not really the moduli space of flat connections. One does get $\mathcal{A}/\mathcal{G}$ as the configurational space in an important limit $k\to\infty$, in which the $\mathbf{e}^{\wedge 3}$ term drops from the action (3.2). Thus, it is only in this limit that the TV phase space is the cotangent bundle $T^*(\mathcal{A}/\mathcal{G})$. For a finite k the TV phase space is compact (as consisting of two copies of $\mathcal{P}^{\rm CS}$), while $T^*(\mathcal{A}/\mathcal{G})$ is not. We will see, however, that it is essentially correct to think of $\mathcal{P}^{\rm TV}$ as a deformation of $T^*(\mathcal{A}/\mathcal{G})$ even in the finite k case. The compactness of $\mathcal{P}^{\rm TV}$ will manifest itself in the fact that after the quantization the range of eigenvalues of $\mathbf{e}$ is bounded from above.

These remarks being made we write

$$\mathcal{P}^{\rm TV}\sim T^*_k(\mathcal{A}/\mathcal{G}), \tag{3.9}$$

where T^*_k is certain compact version of the cotangent bundle. The phase space becomes the usual cotangent bundle in the $k\to\infty$ limit. We will not need any further details on spaces T^*_k. As we shall see the quantization of $\mathcal{P}^{\rm TV}$ is rather straightforward once the quantization of the cotangent bundle is understood.

We note that the dimension

$$\dim\mathcal{P}^{\rm TV}=2(2g+n-2)\dim G \tag{3.10}$$

is twice the dimension of the phase space of the corresponding CS theory, as required. A convenient parametrization of the cotangent bundle phase space can be obtained by using graphs.

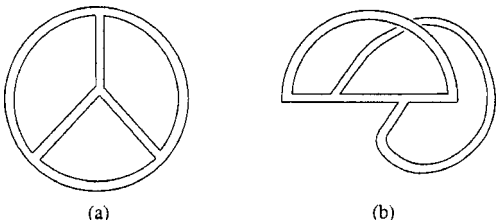

FIG. 1. A fat graph Γ for the (a) sphere with 4 punctures; (b) torus with one puncture.

E. Graphs

The graphs one considers are similar to those that arise in the Penner coordinatization[18] of the moduli space of punctured Riemann surfaces. Namely, given X, introduce a trivalent closed fat graph Γ with the number F of faces equal to the number n of punctures. Such a graph can be obtained by triangulating the surface X using punctures as vertices, and then constructing a dual graph. What arises is exactly a graph Γ. See Fig. 1 for examples of Γ. Note that different triangulations lead to different graphs, so Γ is by no means unique.

Because the graph is trivalent $3V=2E$, where V is the number of vertices and E is the number of edges. We also have the Euler characteristics relation:

$$F-E+V=2-2g. \tag{3.11}$$

We thus get that the number E of edges of Γ is $E=3(2g+n-2)$.

Note that the graph Γ does not coincide with the graph Δ introduced in the previous section. There is, however, a simple relation between them that is worth noting. Let us, as in the previous section, form the double $\tilde{H}=H\cup -H$. It is a closed 3-manifold obtained by gluing two copies of the handlebody H across the boundary X. Let us take a graph Δ in H, and another copy of Δ in $-H$. These graphs touch the boundary $\partial H=X$ at the punctures. Gluing these two copies of Δ at the punctures one obtains a closed graph $\Delta\cup\Delta$ in $\tilde{H}$. It is a trivalent graph with $2(2g+n-2)$ vertices and $3(2g+n-2)$ edges. Now consider the regular neighborhood $U(\Delta\cup\Delta)$ of $\Delta\cup\Delta$ in $H\cup -H$. This is a handlebody, whose boundary is of genus

$$G=2g+n-1. \tag{3.12}$$

The surface $\partial U(\Delta\cup\Delta)$ can be obtained by taking two copies of X, removing some small disks around the punctures, and identifying the resulting circular boundaries to get a closed surface without punctures. We have the following:

Lemma: The surface $\partial U(\Delta\cup\Delta)$ *is a Heegard surface for* $H\cup -H$. *The complement of* $U(\Delta\cup\Delta)$ *in* $H\cup -H$ *is a handlebody that is the regular neighborhood* $U(\Gamma)$ *of the graph* Γ *on* X.

Proof: The complement of $U(\Delta\cup\Delta)$ in $H\cup -H$ can be seen to be the cylinder $X\times[0,1]$ with n holes cut in it. So, it is indeed a handlebody of genus (3.12). Its 1-skeleton that can be obtained by choosing a pant decomposition is the trivalent graph Γ.

F. Graph connections

Given Γ equipped with an arbitrary orientation of all the edges, one can introduce what can be called graph connections. Denote the set of edges e of Γ by E. We use the same letter both for the set E of edges and for its dimension. A graph connection $\mathbf{A}$ is an assignment of a group element to every edge of the graph:

$$\mathbf{A}:E\to G, \quad \mathbf{A}(e)=\mathbf{g}_e\in G. \tag{3.13}$$

One can also introduce a notion of graph gauge transformations. These act at vertices of Γ. A gauge transformation is parametrized by V group elements. Let us introduce:

$$\mathbf{H}: V \to G, \quad \mathbf{H}(v) = \mathbf{h}_v \in G. \tag{3.14}$$

Here V is the set of vertices of Γ. For an edge $e \in E$ denote by $s(e)$ (source) the vertex from which e originates, and by $t(e)$ (target) the vertex where e ends. The action of a gauge transformation $\mathbf{H}$ on a graph connection $\mathbf{A}$ is now as follows:

$$\mathbf{A}^{\mathbf{H}}(e) = \mathbf{h}_{s(t)}^{-1}\, \mathbf{g}_e\, \mathbf{h}_{s(e)}. \tag{3.15}$$

The space of graph connections modulo graph gauge transformations can now be seen to be isomorphic to $G^{\otimes E}/G^{\otimes V}$. Its dimension is given by (2.9). We thus get a parametrization of the CS phase space $\mathcal{P}^{\mathrm{CS}}$ based on a graph Γ:

$$\mathcal{P}^{\mathrm{CS}} \sim G^{\otimes E}/G^{\otimes V}. \tag{3.16}$$

The TV phase space is the cotangent bundle

$$\mathcal{P}^{\mathrm{TV}} \sim T_k^*(G^{\otimes E}/G^{\otimes V}). \tag{3.17}$$

As we shall see, it is rather straightforward to quantize the noncompact, $k \to \infty$ version of $\mathcal{P}^{\mathrm{TV}}$, that is the cotangent bundle. The quantum states are given by spin networks.

G. Spin networks

To quantize the cotangent bundle $T^*(\mathcal{A}/\mathcal{G})$ one introduces a Hilbert space of functionals on the moduli space of flat connections. A complete set of such functionals is given by spin networks. These functions will thus form (an over-complete) basis in the Hilbert space of TV theory. They also serve as observables for CS quantum theory, see below.

Before we define these objects, let us introduce some convenient notations. Denote the set of irreducible representations ρ of the quantum group G by $\mathcal{I}$. Introduce a coloring $\psi: E \to \mathcal{I}, \psi(e) = \rho_e$ of the edges of Γ with irreducible representations of G. A spin network Γ^{ψ} is a functional on the space of graph connections:

$$\Gamma^{\psi}: G^{\otimes E} \to \mathbb{C}. \tag{3.18}$$

Given a connection $\mathbf{A}$ the value of $\Gamma^{\psi}(\mathbf{A})$ is computed as follows. For every edge e take the group element $\mathbf{g}_e$ given by the graph connection in the irreducible representation ρ_e. One can think of this as a matrix with two indices: one for the source $s(e)$ and the other for the target $t(e)$. Multiply the matrices for all the edges of Γ. Then contract the indices at every tri-valent vertex using an intertwining operator. The normalization of intertwiners that we use is specified in the Appendix. The definition we gave is applicable to $G = \mathrm{SU}(2)$. In this case the trivalent intertwiner is unique up to normalization. For other gauge groups one in addition has to label the vertices of Γ with intertwiners, so that a spin network explicitly depends on this labeling. The functional (3.18) so constructed is invariant under the graph gauge transformations (3.14) and is thus a functional on the moduli space of flat connections modulo gauge transformations. As such it is an element of the Hilbert space of TV theory. It is also an observable on the CS phase space (3.16).

H. Quantization

We can define the Hilbert space $\mathcal{H}^{\mathrm{TV}}$ of Turaev–Viro theory to be the space of gauge-invariant functionals $\Psi(\underline{\mathbf{w}})$ on the configurational space $G^{\otimes E}/G^{\otimes V}$. This gives a quantization of the $k \to \infty$ limit, but a modification for the case of finite k is straightforward. As we discussed above, a complete set of functionals on $G^{\otimes E}/G^{\otimes V}$ is given by spin networks. We denote the state corresponding to a spin network Γ^{ψ} by $|\Gamma^{\psi}\rangle$. They form a basis of states in $\mathcal{H}^{\mathrm{TV}}$:

$$\mathcal{H}^{\mathrm{TV}} = \mathrm{Span}\{|\Gamma^{\psi}\rangle\}. \tag{3.19}$$

One can construct certain momenta operators, analogs of $\mathbf{e} \sim \partial/\partial \underline{\mathbf{w}}$ in the continuum theory. Spin networks are eigenfunctions of these momenta operators. To specialize to the case of finite k one has to replace all spin networks by quantum ones. That is, the coloring of edges of Γ must use irreducible representations of the quantum group, which there is only a finite set.

The spin network states $|\Gamma^{\psi}\rangle$ form an overcomplete basis in $\mathcal{H}^{\mathrm{TV}}$, in that the TV inner product between differently colored states is nonzero. However, these states do give a partition of unity in that

$$\sum_{\psi} \left(\prod_{e \in E_{\Gamma}} \dim_{\rho_e} \right) |\Gamma^{\psi}\rangle\langle\Gamma^{\psi}| \tag{3.20}$$

is the identity operator in $\mathcal{H}^{\mathrm{TV}}$. This will become clear from our definition of the TV inner product, and the definition of the TV invariant in the next section.

It seems from the way we have constructed the Hilbert space $\mathcal{H}^{\mathrm{TV}}$ that it depends on the graph Γ. This is not so. Choosing Γ differently one gets a different basis in the same Hilbert space. To describe an effect of a change of Γ it is enough to give a rule for determining the inner products between states from two different bases.

I. Inner product

The inner product on $\mathcal{H}^{\mathrm{TV}}$ is given (formally) by the integral (3.4) over boundary connections. To specify the measure in this integral, one has to consider the path integral for the theory. Namely, consider a 3-manifold $X \times [-1,1]$ over X, which is a 3-manifold with two boundary components, each of which is a copy of X. The TV path integral over $X \times [-1,1]$ gives a kernel that should be sandwiched between the two states whose inner product is to be computed. Thus, the measure in (3.4) is defined by the TV path integral. The measure, in particular, depends on the level k.

In practice the inner product of two states Γ^{ψ} $\Gamma^{\psi'}$, where both the graphs and the coloring may be different, is computed as the TV invariant for the manifold $X \times [-1,1]$ with Γ^{ψ} on $X \times \{-1\}$ and $\Gamma^{\psi'}$ on $X \times \{1\}$. Further details on the TV inner product are given in the next section.

IV. 3-MANIFOLD INVARIANTS

In this section we review the definition of RTW and TV invariants. The main references for this section are Refs. 19 and 20.

A. Reshetikhin–Turaev–Witten invariant

The RTW invariant of a closed 3-manifold (with, possibly, Wilson loops or spin networks inserted) gives a precise meaning to the CS path integral for this manifold. The definition we give is for M without insertions, and is different from, but equivalent to the original definition in Ref. 21. We follow Roberts.[19]

Any closed oriented 3-manifold M can be obtained from S^3 by a surgery on a link in S^3. Two framed links represent the same manifold M if and only if they are related by isotopy or a sequence of Kirby moves, that is either handle-slides or blow-ups, see Refs. 19 or 22 for more detail. Let L be a link giving the surgery representation of M. Define $\Omega L \in \mathbb{C}$ to be the evaluation of L in S^3 with a certain element Ω inserted along all the components of L, paying attention to the framing. The element Ω is defined as follows, see Ref. 19. It is an element of $\mathcal{H}_T^{\mathrm{CS}}$, where T is the torus, and is given by

$$\Omega = \eta \sum_{\rho} \dim_{\rho} R_{\rho}. \tag{4.1}$$

The sum is taken over all irreducible representations $\rho \in \mathcal{I}$, the quantity $\dim_\rho$ is the quantum dimension, and R_ρ is the state in $\mathcal{H}_T^{\mathrm{CS}}$ obtained by inserting the 0-framed unknot in the ρ's representation along the cycle that is noncontractible inside the solid torus having T as its boundary. The quantity η is given by

$$\eta^{-2} = \sum_\rho \dim_\rho^2. \tag{4.2}$$

For example, for $G = \mathrm{SU}(2)$ $\eta = \sqrt{2/k}\sin(\pi/k) = S_{00}$, where

$$S_{ij} = \sqrt{\frac{2}{k}}\sin\left(\frac{(i+1)(j+1)\pi}{k}\right), \quad k \geqslant 3. \tag{4.3}$$

With the normalization chosen, the S^3 value of a 0-framed unknot with Ω attached is η^{-1}, while ± 1 framed unknots with Ω attached give certain unit modulus complex numbers $r^{\pm 1}$. For $G = \mathrm{SU}(2)$ $r = \exp(-i\pi/4 - 2\pi i(3+k^2)/4k)$.

Let us now continue with the definition of the RTW invariant. Define by $\sigma(L)$ the signature of the 4-manifold obtained by attaching 2-handles to the 4-ball B^4 along $L \subset S^3 = \partial B^4$. Define

$$I(M) = \eta r^{-\sigma(L)}\, \Omega L. \tag{4.4}$$

This is the RTW invariant of the manifold M presented by L. We use the normalization of Roberts,[19] in which the RTW invariant satisfies $I(S^3) = \eta, I(S^2 \times S^1) = 1$, as well as the connected sum rule $I(M_1 \# M_2) = \eta^{-1} I(M_1) I(M_2)$.

B. Turaev–Viro invariant

The original Turaev–Viro invariant is defined[8] for triangulated manifolds. A more convenient presentation[20] uses standard 2-polyhedra. Another definition is that of Roberts.[19] It uses a handle decomposition of M. We first give the original definition of Turaev and Viro.

Let T be a triangulation of 3D manifold M. We are mostly interested in case that M has a boundary. Denote by V_T the number of vertices of T, and by $\{e\},\{f\},\{t\}$ collections of edges, faces and tetrahedra of T. Choose a coloring μ of all the edges, so that $\mu(e) = \rho_e$ is the color assigned to an edge e. The Turaev–Viro invariant is defined as

$$\mathrm{TV}(M, T|_{\partial M}, \mu|_{\partial M}) = \eta^{2V_T} \sum_\mu \prod_{e \notin \partial M} \dim_{\rho_e} \prod_t (6j)_t. \tag{4.5}$$

Here $(6j)_t$ is the $6j$-symbol constructed out of 6 colors labeling the edges of a tetrahedron t, and the product is taken over all tetrahedra t of T. The product of dimensions of representations labelling the edges is taken over all edges that do not lie on the boundary. The sum is taken over all colorings μ keeping the coloring on the boundary fixed. The invariant depends on the restriction $T|_{\partial M}$ of the triangulation to the boundary ∂M, and on the coloring $\mu|_{\partial M}$ of this restriction. The invariant is independent of an extension of $T|_{\partial M}$ inside M.

Note that the TV invariant is constructed in such a way that for a closed 3-manifold $M = M_1 \cup M_2$ obtained by gluing two manifolds M_1, M_2 with a boundary across the boundary the invariant $\mathrm{TV}(M)$ is easily obtained once $\mathrm{TV}(M_{1,2}, T_{1,2}|_{\partial M_{1,2}}, \mu_{1,2}|_{\partial M_{1,2}})$ are known. One has to triangulate the boundary of $M_{1,2}$ in the same way $T_1|_{\partial M_1} = T_2|_{\partial M_2}$, multiply the invariants for $M_{1,2}$, multiply the result by the dimensions of the representations labelling the edges of $T_{1,2}|_{\partial M_{1,2}} = T|_{\partial M}$, and sum over these representations. The result is $\mathrm{TV}(M)$:

$$\mathrm{TV}(M) = \sum_{\mu|_{\partial M}} \left(\prod_{e \in \partial M} \dim_{\rho_e} \right) \mathrm{TV}(M_1, T|_{\partial M}, \mu|_{\partial M}) \mathrm{TV}(M_2, T|_{\partial M}, \mu|_{\partial M}). \tag{4.6}$$

This, together with the definition of the TV inner product as the TV invariant for $X\times I$ establishes that (3.20) is indeed the identity operator in $\mathcal{H}^{\mathrm{TV}}$.

C. Roberts invariant

We shall now introduce the more general invariant of Roberts. We consider the case without boundary.

Consider a handle decomposition D of M. The canonical example to have in mind is the handle decomposition coming from a triangulation T of M. A thickening of the corresponding dual complex T^* then gives a handle decomposition. The vertices of the dual complex (baricenters of tetrahedra of the triangulation) correspond to 0-handles, edges of T^* (faces of T) correspond to 1-handles, faces of T^* (edges of T) give 2-handles, and 3-cells of T^* (vertices of T) give 3-handles. The union of 0- and 1-handles is a handlebody. Choose a system of meridian disks for it, one meridian disk for every 1-handle. Now specify the system of attaching curves for 2-handles. If the handle decomposition came from a triangulation there are exactly 3 attaching curves along each 1-handle. Frame all meridian and attaching curves using the orientation of the boundary of the handlebody. Denote the corresponding link by $C(M,D)$. Insert the element Ω on all the components of $C(M,D)$, paying attention to the framing, and evaluate $C(M,D)$ in S^3. This gives the Roberts invariant for M:

$$\mathrm{R}(M)=\eta^{d_3+d_0}\Omega C(M,D). \tag{4.7}$$

Here d_3,d_0 are the numbers of 3- and 0-handles correspondingly. Note that to evaluate $\Omega C(M,D)$ in S^3 one needs to first specify an embedding. The result of the evaluation does not depend on the embedding, see Ref. 19. Moreover, the invariant does not depends on a handle decomposition D and is thus a true invariant of M.

When the handle decomposition D comes from a triangulation T the Roberts invariant (4.7) coincides with the Turaev–Viro invariant (4.5). An illustration of this fact is quite simple and uses the 3-fusion (A2), see Ref. 19 for more detail.

Lemma (Roberts): The described above system $C(M,D)$ of meridian and attaching curves for a handle decomposition D of M gives a surgery representation of $M\#-M$.

This immediately implies the theorem of Turaev and Walker:

$$\mathrm{TV}(M)=\eta\, I(M\#-M)=|I(M)|^2. \tag{4.8}$$

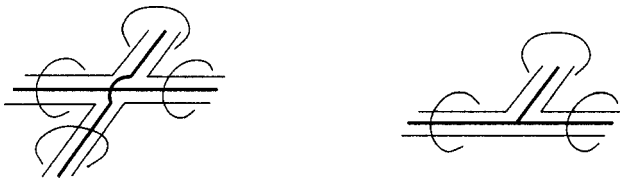
Below we shall see an analog of this relation for a manifold with boundary. All the facts mentioned make it clear that the TV invariant is a natural spin-off of the CS (RTW) invariant.

D. TV inner product

Recall that the Turaev–Viro inner product between the graph states $|\Gamma^{\psi}\rangle$ was defined in the previous section as the TV path integral on $X\times I$. The TV path integral is rigorously defined by the TV invariant (4.5). Here we describe how to compute the inner product in practice. The prescription we give is from Ref. 20, Sec. 4.d. We combine it with the chain-mail idea of Roberts[19] and give this chain-mail prescription.

The product $\langle\Gamma^{\psi}|\Gamma^{\psi'}\rangle$ is obtained by a certain face model on X. Namely, consider the 3-manifold $X\times I$, where I is the interval $[-1,1]$. Put Γ^{ψ} on $X\times\{-1\}$ and $\Gamma^{\psi'}$ on $X\times\{1\}$. Both graphs can be projected onto $X=X\times\{0\}$, keeping track of under- and upper-crossings. By using an isotopy of X the crossings can be brought into a generic position of double transversal crossing of edges. We thus get a graph on X, with both 3 and 4-valent vertices. The 3-valent vertices come from those of $\Gamma^{\psi},\Gamma^{\psi'}$, and 4-valent vertices come from edge intersections between the two graphs. The inner product is given by evaluation in S^3 of a certain chain-mail that can be constructed from $\Gamma^{\psi},\Gamma^{\psi'}$. Namely, let us take one 0-framed link for every face, and one 0-framed link around every edge of the graph $\Gamma^{\psi}\cup\Gamma^{\psi'}$ on X. We get the structure of links at vertices as is shown

in the following drawings:



(4.9)

Denote by $C(\Gamma,\Gamma')$ the obtained collection of links. The inner product is given by

$$\langle \Gamma^{\psi}|\Gamma^{\psi'}\rangle = \eta^{V_\Gamma + V_{\Gamma'} + V_{\rm int}}(\Gamma^{\psi}\cup\Gamma^{\psi'}.\,\Omega C(\Gamma\cup\Gamma')). \tag{4.10}$$

Here $V_\Gamma, V_{\Gamma'}$ are the numbers of 3-valent vertices of graphs Γ,Γ' correspondingly, and $V_{\rm int}$ is the number of 4-valent vertices coming from intersections. The expression in brackets must be evaluated in S^3. Using the 3-fusion (A2) one can easily convince oneself that (4.10) coincides with the prescription given in Ref. 20.

We would also like to note an important relation for the TV inner product that expresses it as the RTW evaluation:

$$\langle \Gamma^{\psi}|\Gamma^{\psi'}\rangle = I(X\times S^1,\Gamma^{\psi},\Gamma^{\psi'}). \tag{4.11}$$

The evaluation is to be carried out in the 3-manifold $X\times S^1$. This relation that does not seem to have appeared in the literature. A justification for it comes from our operator/state correspondence, see below. Let us also note that a direct proof of a particular subcase of (4.11) corresponding to one of the graphs being zero colored is essentially given by our proof in the Appendix of the main theorem of Sec. VII. We decided not to attempt a direct proof of (4.11) in its full generality.

Turaev theorem: Let us note the theorem 7.2.1 from Ref. 5. It states that the TV invariant for H with the spin network Γ^{ψ} on $X=\partial H$ equals the RTW evaluation of Γ^{ψ} in $H\cup -H$:

$$\mathrm{TV}\,(H,\Gamma^{\psi}) = I(H\cup -H,\Gamma^{\psi}). \tag{4.12}$$

This is an analog of (4.8) for a manifold with a single boundary, and is somewhat analogous to our relation (4.11) for the TV inner product.

V. VERLINDE FORMULA

The purpose of this somewhat technical section is to review some facts about the Verlinde formula for the dimension of the CS Hilbert space. Considerations of this section will motivate a more general formula given in Sec. VII for the CFT partition function projected onto a spin network state. This section can be skipped on the first reading.

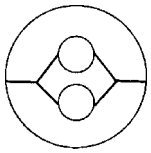
A. Dimension of the CS Hilbert space

Let us first obtain a formula for the dimension of the CS Hilbert space that explicitly sums over all different possible states. This can be obtained by computing the CS inner product. Indeed, as we have described in Sec. II, a basis in $\mathcal{H}_X^{\rm CS}$ is given by spin networks Δ^{ϕ}. With our choice of the normalization of the 3-valent vertices the spin network states $|\Delta^{\phi}\rangle$ are orthogonal but not orthonormal. Below we will show that the dimension can be computed as

$$\dim \mathcal{H}_X^{\rm CS} = \sum_{\phi}\left(\prod_{\text{int } e}\dim_{\rho_e}\right)\langle\Delta^{\phi}|\Delta^{\phi}\rangle = \sum_{\phi}\left(\prod_{\text{int } e}\dim_{\rho_e}\right) I(H\cup -H,\Delta^{\phi}\cup\Delta^{\phi}), \tag{5.1}$$

where the sum is taken over the colorings of the internal edges. The coloring of the edges of Δ that end at punctures are fixed.

To evaluate $\Delta^{\phi}\cup\Delta^{\phi}$ we proceed as follows. Let us project the graph $\Delta\cup\Delta$ to X. We note that there is a canonical way to do this projection so that there are exactly two 3-valent vertices of $\Delta\cup\Delta$ on each pair of pants, and there are exactly two edges of $\Delta\cup\Delta$ going through each boundary circle of a pair of pants. For example, the part of $\Delta\cup\Delta$ projected on a pair of pants with no punctures looks like



(5.2)

One gets a similar structure when projecting on a pair of pants with punctures. In that case the two holes in the center are replaced by punctures and loose edges of Δ are connected at the punctures to the loose edges of the other copy of Δ.

Let us now form a link L_{Δ} whose components are circles along which one glues the pant boundaries together. There are $3g+n-3$ such circles, in one-to-one correspondence with internal edges of Δ. We push all components of L_{Δ} slightly out of X. Using the prescription of the Appendix of Ref. 20 for computing the RTW evaluation of M with a graph inserted, one obtains

$$I(H\cup -H,\Delta^{\phi}\cup\Delta^{\phi})=\eta^{3g+n-3}(\Delta^{\phi}\cup\Delta^{\phi}.\Omega L_{\Delta}). \tag{5.3}$$

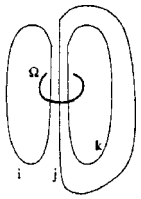
The evaluation on the right-hand side is to be taken in S^3. This relation establishes (5.1). Indeed, there are exactly two edges of $\Delta\cup\Delta$ linked by every component of L_{Δ}. Using the 2-fusion we get them connected at each pair of pants, times the factor of $\eta^{-1}/\dim_{\rho_e}$. The factors of η are canceled by the prefactor in (5.3), and the factors of $1/\dim_{\rho_e}$ are canceled by the product of dimensions in (5.1). What remains is the sum over the colorings of the internal edges of the product of N_{ijk} for every pair of pants. This gives the dimension. This argument also shows that the states $|\Delta^{\phi}\rangle$ with different coloring ϕ are orthogonal.

B. Computing the dimension: Verlinde formula

The sum over colorings of the internal edges in (5.3) can be computed. This gives the Verlinde formula. Let us sketch a simple proof of it, for further reference.

We first observe that, using the 3-fusion, the Verlinde formula for the 3-punctured sphere can be obtained as a chain-mail. Namely,

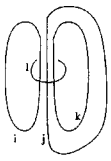
$$\eta^{-1}N_{ijk}=$$



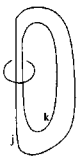
(5.4)

The Verlinde formula for N_{ijk} can be obtained by using the definition (4.1) of Ω and the recoupling identity (A4) of the Appendix. The computation is as follows:

$$\eta^{-1}N_{ijk}=\eta\sum_{l}\dim_l$$



$$=\sum_{l}S_{il}$$



$$=\sum_{l}\frac{S_{il}S_{jl}}{\eta\dim_l}$$

$$=\eta^{-1}\sum_{l}\frac{S_{il}S_{jl}S_{kl}}{S_{0l}}. \tag{5.5}$$

This is the Verlinde formula (2.10) for the case of a 3-punctured sphere. We have used the fact that $\eta\dim_l=S_{0l}$. The above proof of the Verlinde formula for N_{ijk} is essentially that from Ref. 12.

The general Verlinde formula (2.10) can be obtained using a pant decomposition of X and taking a sum over labelings of the internal edges of Δ of the product of N_{ijk} one for every pair of pants. To get (2.10) one just has to use the unitarity $\Sigma_l S_{il} S_{jl} = \delta_{ij}$ of the S-matrix.

C. Verlinde formula using graph Γ: No punctures

Here we find a different representation of the Verlinde dimension. It was noticed in Ref. 23 that the Verlinde formula can be obtained using a certain gauge theory on a graph on X. Here we reinterpret this result using a chain-mail. We first derive a formula for a Riemann surface without punctures. It is obtained by starting from a graph Γ corresponding to a surface with some number n of punctures. Then a sum is carried over the labels at the punctures, so the end result depends only on the genus g, but not on n.

Consider a fat trivalent graph Γ that represents $X_{g,n}$. Let us form a chain-mail $C(\Gamma)$ as follows. Let us introduce a curve for every face of the fat graph Γ, and a linking curve around every $3(2g+n-2)$ edges of Γ, so that the obtained structure of curves at each 3-valent vertex is as in (4.9). Insert the element Ω along each component of $C(\Gamma)$, and evaluate the result in S^3. What is evaluated is just the chain-mail for Γ, no spin network corresponding to Γ is inserted. We get the following result:

Theorem (Boulatov): *The dimension of the Hilbert space of CS states on X_g is equal:*

$$\dim \mathcal{H}_{X_g}^{\mathrm{CS}} = \eta^{V_\Gamma} \Omega C(\Gamma). \tag{5.6}$$

The expression on the right-hand side is independent of the graph Γ that is used to evaluate it.

To prove this formula we use the 2-strand fusion. We get that all of the n different colorings on the links of Γ become the same. Denote by ρ the corresponding representation. The result is then obtained by a simple counting. Each $3(2g+n-2)$ of links around edges introduces the factor of $\eta^{-1}/\dim_\rho$. Every $2(2g+n-2)$ vertices of Γ gives a factor of $\dim_\rho$. Each of n faces of Γ gives another factor of $\eta \dim_\rho$. All this combines, together with the prefactor to give

$$\dim \mathcal{H}_{X_g}^{\mathrm{CS}} = \sum_\rho (\eta \dim_\rho)^{2-2g}, \tag{5.7}$$

which is the Verlinde formula (2.10) for the case with no punctures.

VI. OPERATOR/STATE CORRESPONDENCE

This section is central to the paper. Here we discuss a one-to-one correspondence between observables of CS theory and quantum states of TV theory. The fact that the algebra of observables in CS theory is given by graphs is due to Refs. 24 and 25, see also references below. The notion of the connecting 3-manifold $\tilde{M}$ is from Refs. 4 and 9. The operator/state correspondence of this section, as well as the arising relation between the CS and TV Hilbert spaces, although to some extent obvious, seems new.

A. CS observables and relation between the Hilbert spaces

We have seen that a convenient parametrization of the moduli space $\mathcal{A}/\mathcal{G}$ is given by the graph Γ connections. An expression for the CS Poisson structure in terms of graph connections was found in Ref. 24. A quantization of the corresponding algebra of observables was developed in Refs. 25–29 (see also Ref. 30 for a review). As we have seen in Sec. III a complete set of functionals on $\mathcal{A}/\mathcal{G}$ is given by spin networks. Spin networks thus become operators $\hat{\Gamma}^\psi$ in the CS Hilbert space $\mathcal{H}_X^{\mathrm{CS}}$. We therefore get a version of an operator/state correspondence, in which TV states correspond to observables of CS theory.

The fact that a CS/TV operator/state correspondence must hold follows from the relation between the phase spaces of the two theories. Namely, as we have seen in Sec. III, the TV phase

space is given by two copies of the phase space of Chern–Simons theory: $\mathcal{P}^{\mathrm{TV}}=\mathcal{P}^{\mathrm{CS}}\otimes\overline{\mathcal{P}}^{\mathrm{CS}}$, where the two copies have opposite Poisson structures. This means that in the quantum theory the following relation must hold:

$$\mathcal{H}_X^{\mathrm{TV}}\sim\mathcal{H}_X^{\mathrm{CS}}\otimes\mathcal{H}_{-X}^{\mathrm{CS}}\sim\mathrm{End}\,(\mathcal{H}_X^{\mathrm{CS}}). \tag{6.1}$$

Thus, the TV Hilbert space is isomorphic to the direct product of two copies of $\mathcal{H}^{\mathrm{CS}}$. The above isomorphism is given formally by the formula (3.8). We shall denote it by **I**. It identifies the TV spin network states $|\Gamma^{\psi}\rangle$ with the CS spin network observables $\hat{\Gamma}^{\psi}$. This statement deserves some explanation. The TV spin network states are wave functionals of the connection $\underline{\mathbf{w}}$: $\mathcal{T}(\underline{\mathbf{w}})=\mathcal{T}(A_z+B_z, A_{\bar{z}}+B_{\bar{z}})$, whereas Chern–Simons states are functionals $\Psi(A_z, B_{\bar{z}})$. Thus, the isomorphism (6.1) can be understood as a change of polarization. Being a change of polarization it intertwines the operator algebras acting on the two sides of (6.1). The polarization we have chosen for the TV Viro model is the one for which $\hat{\mathbf{e}}\sim(\hat{A}-\hat{B})$ acts trivially on the TV vacuum state. Using the intertwinning property of **I** this means that $\mathbf{I}(|0\rangle_{\mathrm{TV}})$ is commuting with all CS operators $\hat{\Gamma}^{\psi}$. It is therefore proportional to the identity in $\mathrm{End}\,(\mathcal{H}_X^{\mathrm{CS}})$. It follows from here that the operator that corresponds to the TV state $|\Gamma^{\psi}\rangle$ is the CS spin network operator:

$$\mathbf{I}(|\Gamma^{\psi}\rangle_{\mathrm{TV}})=\hat{\Gamma}^{\psi}\mathbf{I}(|0\rangle_{\mathrm{TV}})\propto\hat{\Gamma}^{\psi}. \tag{6.2}$$

Thus, the described isomorphism (6.1) given by the change of polarization indeed identifies TV graph states with the CS spin network operators.

Another important fact is as follows. Being a change of polarization, the isomorphism (6.1) preserves the inner product. Since the inner product on the right-hand side of (6.1) is just the CS trace, we get an important relation:

$$\mathrm{Tr}_{\mathrm{CS}}(\hat{\Gamma}\hat{\Gamma}')=\langle\Gamma|\Gamma'\rangle_{\mathrm{TV}}. \tag{6.3}$$

In other words, the trace of the product of operators in the CS Hilbert space is the same as the inner product in the TV theory. This relation is central to the operator/state correspondence under consideration. Let us now describe the isomorphism (6.1) more explicitly.

B. Connecting manifold $\tilde{M}$

A very effective description of the above operator/state correspondence uses the ''connecting manifold'' $\tilde{M}$. It is a 3-manifold whose boundary is the Schottky double $\tilde{X}$ of the Riemann surface X. Recall that the Schottky double of a Riemann surface X is another Riemann surface $\tilde{X}$. For the case of a closed X, the surface $\tilde{X}$ consists of two disconnected copies of X, with all moduli replaced by their complex conjugates in the second copy. For X with a boundary (the case not considered in this paper, but of relevance to the subject of boundary CFT, see, e.g., Refs. 4, 9) the double $\tilde{X}$ is obtained by taking two copies of X and gluing them along the boundary. Consider a 3-manifold

$$\tilde{M}=\tilde{X}\times[0,1]/\sigma, \tag{6.4}$$

where σ is an antiholomorphic map such that $\tilde{X}/\sigma=X$, and σ reverses the ''time'' direction. See, e.g., Ref. 4 for more detail on the construction of $\tilde{M}$. The manifold $\tilde{M}$ has a boundary $\partial\tilde{M}=\tilde{X}$, and the original surface X is embedded into $\tilde{M}$. For the case of a closed X, relevant for this paper, the manifold $\tilde{M}$ has the topology $X\times I$, where I is the interval $I=[0,1]$, see Fig. 2.

Consider the RTW evaluation of a spin network Γ^{ψ} in $\tilde{M}$. It gives a particular state in $\mathcal{H}_{\tilde{X}}^{\mathrm{CS}}$:

$$I(\tilde{M},\Gamma^{\psi})\in\mathcal{H}_{\tilde{X}}^{\mathrm{CS}}. \tag{6.5}$$

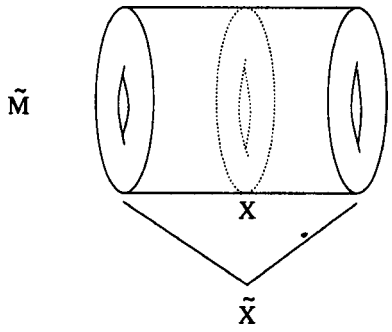


FIG. 2. The manifold $\tilde{M}$.

However, we have

$$\mathcal{H}^{\mathrm{CS}}_{\tilde{X}} \sim \mathcal{H}^{\mathrm{CS}}_{X} \otimes \mathcal{H}^{\mathrm{CS}}_{-X} \sim \mathrm{End}(\mathcal{H}^{\mathrm{CS}}_{X}). \tag{6.6}$$

Thus (6.5) gives an operator in $\mathcal{H}^{\mathrm{CS}}_{X}$ for every graph state $|\Gamma^{\psi}\rangle \in \mathcal{H}^{\mathrm{TV}}_{X}$.

C. Operator product

In the realization described the product of two operators $\hat{\Gamma}^{\psi}, \hat{\Gamma}^{\psi'}$ is an element of $\mathcal{H}^{\mathrm{CS}}_{\tilde{X}}$ obtained by evaluating in $\tilde{M}$ both Γ^{ψ} and $\Gamma^{\psi'}$:

$$I(\tilde{M}, \Gamma^{\psi}, \Gamma^{\psi'}) \in \mathcal{H}^{\mathrm{CS}}_{\tilde{X}}. \tag{6.7}$$

D. Trace

The trace of an operator $\hat{\Gamma}^{\psi}$ is obtained by gluing the two boundaries of $\tilde{M}$ to form a closed manifold of the topology $X \times S^1$:

$$\mathrm{Tr}_{\mathrm{CS}}(\hat{\Gamma}^{\psi}) = I(X \times S^1, \Gamma^{\psi}). \tag{6.8}$$

One can similarly obtain the trace of an operator product:

$$\mathrm{Tr}_{\mathrm{CS}}(\hat{\Gamma}^{\psi} \hat{\Gamma}^{\psi'}) = I(X \times S^1, \Gamma^{\psi}, \Gamma^{\psi\prime}). \tag{6.9}$$

In view of (6.3), the above relation establishes (4.11).

E. Identity operator

It is easy to see that the operator/state correspondence defined by (6.5) is such that the zero colored graph Γ^0 corresponds to the identity operator in the CS Hilbert space:

$$\hat{\Gamma}^0 = \hat{I}. \tag{6.10}$$

Indeed, insertion of Γ^0 into $\tilde{M}$ is the same as $\tilde{M}$ with no insertion, whose RTW evaluation gives the identity operator in $\mathcal{H}^{\mathrm{CS}}$.

F. Matrix elements

We recall that a basis in $\mathcal{H}^{\mathrm{CS}}_{X}$ is obtained by choosing a pant decomposition of X, or, equivalently, choosing a trivalent graph Δ, with a coloring ϕ. The matrix elements $\langle \Delta^{\phi} | \hat{\Gamma}^{\psi} | \Delta^{\phi'} \rangle$ are obtained by the following procedure. Take a handlebody H with a graph Δ^{ϕ} in it, its loose ends

ending at the punctures. The boundary of H is X, so that we can glue H from the left to $\tilde{M}$. One similarly takes $-H$ with $\Delta^{\phi'}$ in it, and glues it to $\tilde{M}$ from the right. One connects the punctures on the boundary of H to those on the boundary of $-H$ by strands inside $\tilde{M}$. What one gets is a closed manifold of the topology $H\cup -H$, with closed graphs $\Delta^{\phi}\cup\Delta^{\phi'}$ and Γ^{ψ} sitting inside it. The matrix elements are obtained as the evaluation:

$$\langle\Delta^{\phi}|\hat{\Gamma}^{\psi}|\Delta^{\phi'}\rangle = I(H\cup -H, \Delta^{\phi}\cup\Delta^{\phi'}, \Gamma^{\psi}). \tag{6.11}$$

VII. CFT PARTITION FUNCTION AS A STATE

Here we interpret the CFT partition function (correlator) as a particular state in the Hilbert space of TV theory. We also compute components of this state in the basis of states given by spin networks.

A. CFT partition function

The partition function of any CFT holomorphically factorizes. To understand this holomorphic factorization, and the relation to the chiral TQFT, it is most instructive to consider the partition function as a function of an external connection. Namely, let CFT be the WZW model coupled to an external connection (gauged model), and consider its partition function $Z_X^{\mathrm{CFT}}[\mathbf{m},\overline{\mathbf{m}},\mathbf{z},\overline{\mathbf{z}},\underline{A}_z,\underline{A}_{\bar{z}}]$ on X. Note that no integration is carried over $\underline{A}$ yet. Thus, the above quantity is not what is usually called the gauged WZW partition function. The later is obtained by integrating over $\underline{A}$. The introduced partition function depends on the moduli (both holomorphic and antiholomorphic) $\mathbf{m},\overline{\mathbf{m}}$, on positions of insertions of vertex operators coordinatized by $\mathbf{z},\overline{\mathbf{z}}$, and on both the holomorphic and anti-holomorphic components of the connection $\underline{A}$ on X. The partition function holomorphically factorizes according to

$$Z_X^{\mathrm{CFT}}[\mathbf{m},\overline{\mathbf{m}},\mathbf{z},\underline{\mathbf{z}},\underline{A}_z,\underline{A}_{\bar{z}}] = \sum_i \Psi_i[\mathbf{m},\mathbf{z},\underline{A}_z]\overline{\Psi}_i[\overline{\mathbf{m}},\overline{\mathbf{z}},\underline{A}_{\bar{z}}]. \tag{7.1}$$

Here $\Psi_i[\mathbf{m},\mathbf{z},\underline{A}_z]$ are the (holomorphic) conformal blocks with respect to the affine Lie algebra (in the case of WZW theories that we consider). The conformal blocks can be thought of as forming a basis in the Hilbert space $\mathcal{H}_X^{\mathrm{CS}}$ of CS theory on X. More precisely, there is a fiber bundle over the moduli space $\mathcal{M}_{g,n}$ of Riemann surfaces of type (g,n) with fibers isomorphic to $\mathcal{H}_{X_{g,n}}^{\mathrm{CS}}$. The conformal blocks are (particular) sections of this bundle, see Ref. 31 for more detail. Note that the sum in (7.1) is finite as we consider a rational CFT. As was explained in Ref. 14, the usual CFT partition function is obtained by evaluating (7.1) on the "zero" connection. The formula (7.1) then gives the factorization of the usual partition function, with $\Psi_i[\mathbf{m},\mathbf{z},0]$ being what is usually called the Virasoro conformal blocks.

Instead of evaluating (7.1) on the zero connection one can integrate over $\underline{A}$. The result is the partition function of the gauged model, which gives the dimension of the CS Hilbert space:

$$\dim \mathcal{H}_X^{\mathrm{CS}} = \frac{1}{\mathrm{Vol}\,\mathcal{G}}\int_{\mathcal{A}} \mathcal{D}\underline{A}\; Z_X^{\mathrm{CFT}}[\mathbf{m},\overline{\mathbf{m}},\mathbf{z},\overline{\mathbf{z}},\underline{A}_z,\underline{A}_{\bar{z}}]. \tag{7.2}$$

The value of the integral on the right-hand side is independent of moduli (or positions of insertion points).

A particular basis of states in $\mathcal{H}_X^{\mathrm{CS}}$ was described in Sec. II and is given by states $|\Delta^{\phi}\rangle$. Let us use these states in the holomorphic factorization formula (7.1). We can therefore think of the partition function (correlator) as an operator in the CS Hilbert space:

$$\hat{Z}_X^{\mathrm{CFT}} = \sum_{\phi}\left(\prod_{\mathrm{int}\,e}\dim_{\rho_e}\right)|\Delta^{\phi}\rangle\otimes\langle\Delta^{\phi}|. \tag{7.3}$$

The dimension of the CS Hilbert space is obtained by taking the CS trace of the above operator, which gives (5.1).

The CFT partition function (7.3) is the simplest possible modular invariant (the diagonal) that can be constructed out of the chiral CFT data. There are other possible modular invariants, and it is an ongoing effort to try to understand and classify different possibilities, see, e.g., the recent paper.[10] In this paper we only consider and give a TV interpretation of the simplest invariant (7.3). Our TV interpretation might prove useful also for the classification program, but we do not pursue this.

B. CFT partition function as a state

The formula (7.3) for the partition function, together with the operator/state correspondence of the previous section imply that Z_X^{CFT} can be interpreted as a particular state in the TV Hilbert space. We introduce a special notation for this state:

$$|Z_X^{\mathrm{CFT}}\rangle \in \mathcal{H}_X^{\mathrm{TV}}. \tag{7.4}$$

In order to characterize this state we first of all note that $\hat{Z}_X^{\mathrm{CFT}}$ is just the identity operator in $\mathcal{H}_X^{\mathrm{CS}}$:

$$\hat{Z}_X^{\mathrm{CFT}} = \hat{I}. \tag{7.5}$$

The representation (7.3) gives the decomposition of the identity over a complete basis of states in $\mathcal{H}_X^{\mathrm{CS}}$. Using (6.10) we see that the state $|Z_X^{\mathrm{CFT}}\rangle$ is nothing else but the spin network state with zero coloring, together with a set of strands labeled with representations $\mathbf{R}$ and taking into account the punctures:

$$|Z_X^{\mathrm{CFT}}\rangle = |\Gamma^0, \mathbf{R}\rangle. \tag{7.6}$$

Another thing that we are interested in is the components of $|Z_X^{\mathrm{CFT}}\rangle$ in the basis of spin networks $|\Gamma^\psi\rangle$. In view of (4.11) we have

$$\langle \Gamma^\psi | Z_X^{\mathrm{CFT}}\rangle = I(X\times S^1, \mathbf{R}, \Gamma^\psi). \tag{7.7}$$

The evaluation in $X\times S^1$ is taken in the presence of n links labeled by representations $\mathbf{R}$. Note that all the dependence on the moduli of X is lost in (7.7). However, the coloring ψ of Γ can be thought of as specifying the ''geometry'' of X, see more on this below.

C. Zero colored punctures

Here, to motivate the general formula to be obtained below, we deduce an expression for (7.7) for the case where the colors at all punctures are zero. In this case there is no extra links to be inserted in $X\times S^1$, and (7.7) reduces to $\langle \Gamma^\psi | \Gamma^0\rangle$. This can be evaluated using the prescription (4.10). One immediately obtains

$$\langle \Gamma^\psi | \Gamma^0\rangle = \eta^{V_\Gamma}(\Gamma^\psi . \Omega C(\Gamma)) = \eta^{2-2g} \sum_{\{\rho_f\}} \prod_{f\in F_\Gamma} \dim_{\rho_f} \prod_{v\in V_\Gamma} (6j)_v . \tag{7.8}$$

Here $C(\Gamma)$ is the chain-mail for Γ, as defined in the formulation of the theorem (5.6). In the last formula the sum is taken over irreducible representations labeling the faces of the fat graph Γ, the product of $6j$-symbols is taken over all vertices of Γ, and the $6j$-symbols $(6j)_v$ are constructed out of three representations labeling the edges incident at v, and three representations labeling the faces adjacent at v. The last formula is obtained using the 3-fusion recoupling identity (A2).

D. Verlinde formula

The dimension of the CS Hilbert space can be obtained as the inner product of $|Z_X^{\mathrm{CFT}}\rangle$ with the "vacuum" state $|\Gamma^0\rangle \in \mathcal{H}_X^{\mathrm{TV}}$, which corresponds to the spin network with zero (trivial representation) coloring on all edges:

$$\dim \mathcal{H}_X^{\mathrm{CS}} = \langle \Gamma^0 | Z_X^{\mathrm{CFT}} \rangle. \tag{7.9}$$

Expression (7.9) gives an unusual perspective on the Verlinde formula: it appears as a particular case of a more general object (7.7).

E. General formula

Here we find the result of the evaluation (7.7). As we have just explained, (7.7) must reduce to the Verlinde formula (2.10) when the graph Γ has zero colors. We have seen in Sec. V that, at least for the case with no punctures, the Verlinde formula can be obtained from the chain-mail $C(\Gamma)$ with no graph Γ inserted. We have also seen in (7.8) that for the case with no punctures the quantity (7.7) is given by the evaluation of $C(\Gamma)$ together with the graph. Thus, a natural proposal for (7.7) is that it is given by the evaluation (5.6), with the graph Γ added, and with an additional set of curves taking into account the punctures. This results in:

Main Theorem: *The CFT partition function (correlator), interpreted as a state of TV theory, projected onto a spin network state is given by*

$$\langle \Gamma^{\psi} | Z_X^{\mathrm{CFT}} \rangle = \eta^{2-2g-n} \sum_{\{\rho_f\}} \prod_{f \in F_\Gamma} S_{\rho_i \rho_{f_i}} \prod_{v \in V_\Gamma} (6j)_v \,. \tag{7.10}$$

A proof is given in the Appendix.

VIII. DISCUSSION

Thus, the CFT partition function (correlator) receives the interpretation of a state of TV theory. This state is the TV "vacuum" given in (7.6) by the graph with zero coloring. Thus, quite a nontrivial object from the point of view of the CFT, the partition function receives a rather simple interpretation in the TV theory.

We note that, apart from the partition function state $|Z_{\mathrm{CFT}}\rangle$, there is another state in $\mathcal{H}^{\mathrm{TV}}$ with a simple CS interpretation. This is the state that can be denoted as

$$|H\rangle \in \mathcal{H}^{\mathrm{TV}}. \tag{8.1}$$

It arises as the TV partition function for a handlebody H. The TV invariant (4.5) for a manifold with boundary has the interpretation of the TV inner product of $|H\rangle$ with a spin network state:

$$\mathrm{TV}(H, \Gamma^{\psi}) = \langle H | \Gamma^{\psi} \rangle. \tag{8.2}$$

In view of the Turaev theorem (4.12),

$$\langle H | \Gamma^{\psi} \rangle = I(H \cup -H, \Gamma^{\psi}). \tag{8.3}$$

From this, and the relation (6.11) for the matrix elements it can be seen that the state $|H\rangle$ corresponds in CS theory to the operator

$$\hat{H} = |\Delta^0\rangle \otimes \langle \Delta^0|, \tag{8.4}$$

which is just the projector on the CS "vacuum" state Δ^0, given by the zero colored pant decomposition graph Δ. We note that the TV state $|H\rangle$ has a rather nontrivial expression when decomposed into the spin network basis. Thus, the described relation between CS and TV theories (the operator/state correspondence) is a nontrivial duality in that simple objects on one side correspond

to nontrivial objects on the other: CFT correlators, nontrivial from the point of view of CS, are the TV ''vacuum'' states; the nontrivial TV handlebody state $|H\rangle$ is a rather trivial ''vacuum'' projector on the CS side.

We would like to emphasize that the CFT partition function state $|Z_X^{\rm CFT}\rangle$ does not coincide with the TV partition function state $|H\rangle$ on a handlebody H. However, the state $|Z_X^{\rm CFT}\rangle$ can be interpreted as a certain sum of TV handlebody states, provided a certain generalization of the Turaev theorem (4.12) holds. An attempt to prove this generalized Turaev theorem would lead us too far, so we shall formulate it as a conjecture:

Conjecture 1: Let $\mathrm{TV}((H,\Delta^\phi),\Gamma^\psi)$ *denote the Turaev–Viro invariant for a manifold H with a spin network* Δ^ϕ *inserted in it, and a spin network* Γ^ψ *on the boundary. This invariant can be evaluated as the RTW invariant for the double* $H\cup -H$*:*

$$\mathrm{TV}((H,\Delta^\phi),\Gamma^\psi)=\mathrm{I}((H,\Delta^\phi)\cup -(H,\Delta^\phi),\Gamma^\psi). \tag{8.5}$$

The justification for this conjecture is the theorem (4.12), which is nothing but (8.5) with no graph Δ insertion. Let us now introduce a set of states $|H,\phi\rangle$ obtained as the TV partition function inside a handlebody H with a spin network Δ^ϕ inserted inside. From the point of view of CS theory these states are just the projection operators:

$$\hat{H}^\phi=|\Delta^\phi\rangle\langle\Delta^\phi|. \tag{8.6}$$

Indeed, let us compute the TV inner product between the state $|H,\Delta^\phi\rangle$ and a spin network state $|\Gamma^\psi\rangle$:

$$\langle H,\phi|\Gamma^\psi\rangle=\mathrm{TV}((H,\Delta^\phi),\Gamma^\psi). \tag{8.7}$$

If the above conjecture holds this equals to the right hand side of (8.5). The later, on the other hand, is equal to

$$\langle\Delta^\phi|\hat{\Gamma}^\psi|\Delta^\phi\rangle. \tag{8.8}$$

This implies (8.6). Using relation (8.6) the CFT partition function as a state in TV Hilbert space can be represented as a sum of HH-type TV states obtained as the TV partition function over a handlebody with spin network insertion:

$$|Z_{\rm CFT}\rangle=\sum_\phi\left(\prod_{\mathrm{int}\,e}\dim_{\rho_e}\right)|H,\phi\rangle. \tag{8.9}$$

This formula should be contrasted with the usual AdS/CFT prescription, which states that the CFT partition function on the boundary is obtained as a sum of gravity partition functions on all manifolds H that have X as a boundary. In other words, one must sum over all ways to fill in the surface X so that the resulting 3-manifold H is non-singular inside. As we see, the ''holography'' arising in our context is different. Instead of taking a sum over all nonsingular manifolds H that have X as the boundary, in (8.9) one takes some fixed H, but sums over all labelings of the graph Δ sitting inside H. The graph Δ is a 1-skeleton of H; it can be thought of as a singularity inside the handlebody. Thus, to obtain the CFT partition function (modular invariant) one sums over labelings of the singularity inside H. This is a finite sum. The sum over different ways to fill in X is, on the other hand, infinite. It would be of interest to find if there is any relation between these two sums. If no such relation exists then the holographic prescription (8.9) predicted by our analysis is different from the AdS/CFT one.

Thus, we have seen that there are two TV states that correspond to CFT modular invariants: one is the TV vacuum (7.6) that gives the diagonal modular invariant, the other is the handlebody state $|H\rangle$ that gives the trivial modular invariant (8.4). An interesting question is what other states

in TV give CFT modular invariants. An answer to this question may be instrumental in understanding the structure of rational CFT's, see the recent paper[10] for a discussion along these lines.

Let us now discuss a physical interpretation of the formula (7.10). We note that the object (7.7) can be interpreted as the CFT partition function on a surface X whose ''geometry'' is specified by the state $|\Gamma^{\psi}\rangle$. This ''geometry'' should not be confused with the conformal geometry of X, on which the usual CFT partition function depends. Once the state $|Z_X^{\mathrm{CFT}}\rangle$ is projected onto $|\Gamma^{\psi}\rangle$ the dependence on the moduli of X is traded for the dependence on the coloring ψ of Γ. All the dependence on the moduli is encoded in the spin network states. Let us first discuss the dependence on the ''geometry'' as specified by the colored graph Γ^{ψ}, and then make comments as to the dependence of $|\Gamma^{\psi}\rangle$ on the moduli.

To understand the spin network Γ^{ψ} as specifying the ''geometry'' of X we recall, see Sec. III, that $|\Gamma^{\psi}\rangle$ are eigenstates of the ''momentum'' operators $\mathbf{e}\sim\partial/\partial\underline{\mathbf{w}}$. In this sense they are states of particular configuration of the **e** field on the boundary. To understand this in more detail let us consider the TV partition function $\mathrm{TV}(H,\Gamma^{\psi})$. Let us take the simple example of the 4-punctured sphere. Thus, we take $H=B^3$, a 3-ball. We will put all representations at the punctures to be trivial. In view of the Turaev theorem (4.12), $\mathrm{TV}(B^3,\Gamma^{\psi})=I(S^3,\Gamma^{\psi})$. Thus, for $X=S^2$, the TV invariant is given simply by the evaluation of the spin network Γ^{ψ} in S^3. In our simple example of the 4-punctures sphere this evaluation is a single $6j$-symbol. Let us now restrict ourselves to the case $G=\mathrm{SU}(2)$. As we have mentioned above, the TV theory in this case is nothing else but 3D gravity with positive cosmological constant. On the other hand, it is known that the quantum $(6j)$-symbol has, for large k and large spins, an asymptotic of the exponential of the classical Einstein–Hilbert action evaluated inside the tetrahedron:

$$(6j)\sim e^{iS_{\mathrm{TV}}[\mathrm{tet}]}+\mathrm{c.c.} \tag{8.10}$$

This fact was first observed[32] by Ponzano and Regge for the classical $(6j)$-symbol. In that case one evaluates the classical gravity action inside a flat tetrahedron. The action reduces to a boundary term (the usual integral of the trace of the extrinsic curvature term), which for a tetrahedron is given by the so-called Regge action:

$$S_{\mathrm{TV}}[\mathrm{tet},\Lambda=0]\sim\sum_e l_e\theta_e, \tag{8.11}$$

where the sum is taken over the edges of the tetrahedron, and l_e,θ_e are the edge length and the dihedral angle at the edge correspondingly. Dihedral angles are fixed once all the edge length are specified. Ponzano and Regge observed that the $(6j)$-symbol has the asymptotic of (8.10) with the action given by (8.11) if spins labeling the edges are interpreted as the length of edges. A similar (8.10) interpretation is true for the $\mathrm{SU}_q(2)$ $(6j)$-symbol, as was shown in Ref. 33. The gravity action in this case is that with a positive cosmological constant $\Lambda=(k/2\pi)^2$, and is evaluated in the interior of tetrahedron in S^3 whose edge length are given by spins. To summarize, in these examples the $(6j)$-symbol gets the interpretation of the exponential of the classical gravity action evaluated inside a tetrahedron embedded in either $\mathbb{R}^3$ or S^3, depending on whether one takes the classical limit $k\to\infty$ or considers a quantum group with finite k. The tetrahedron itself is fixed once all edge length are specified. The edge length are essentially given by the spins. We also note that the graph Γ in this example is the dual graph to the triangulated boundary of the tetrahedron in question.

Thus, the TV partition function (given by a single $(6j)$-symbol) inside a 4-punctured sphere (tetrahedron) has the interpretation of the gravity partition function inside the tetrahedron with its boundary geometry (edge length) fixed by the spins. This interpretation of Γ^{ψ} is valid also for other surfaces. One should think of Γ^{ψ} as specifying the geometry **e** on X. The TV invariant is, in the semi-classical limit of large representations, dominated by the exponential of the classical action evaluated inside the handlebody. The geometry inside is completely determined by the

geometry of the surface, in other words, the spins. The interpretation is valid not only for SU(2), but also for other groups. In such a general case the notion of ''geometry'' is more complicated, as described by the field **e** and the TV action (3.2).

The bottom line is that the TV spin network states $|\Gamma^{\psi}\rangle$ should be thought of as specifying the ''geometry'' of X. The quantity (7.10) then receives the interpretation of the CFT partition function on a surface X whose ''geometry'' is specified by Γ^{ψ}.

The other question is how the states $|\Gamma^{\psi}\rangle$ depend on the moduli of the surface. The fact that the graph Γ is the same as the one used in the Penner[18] coordinatization of the moduli space suggests that this dependence may be not very complicated. In fact, we believe that for the groups $SL(2,\mathbb{R})$ or $SL(2,\mathbb{C})$ that are relevant in the description of the moduli spaces, the dependence is rather simple: the described above ''geometry'' in this case must coincide with the usual conformal geometry of the surface. An argument for this is as follows. In the Penner coordinatization of the moduli space, or in any of its versions[34,35] the moduli are given by prescribing a set of real numbers: one for each edge of the graph Γ. The numbers specify how two ideal triangles are glued together across the edge, see Refs. 34, 35 for more detail. For the case when $G=\mathrm{SL}_q(2,\mathbb{R})$, as is relevant for, e.g., Liouville theory, see Ref. 36, the representations are also labeled by a single real number. We believe that the Penner coordinates and the representations that label the edges are simply dual to each other, in the sense of duality between the conjugacy classes of elements in the group and its irreducible representations. A similar proposal for the relation between the SL(2) spin and length was made in Ref. 6. Thus, there is some hope that the dependence $|\Gamma^{\psi}\rangle$ on the moduli can be understood rather explicitly, at least for some groups. Having this said we note that considerations of the present paper do not immediately generalize to the case of noncompact groups, relevant for the description of the moduli spaces. It is an outstanding problem to develop a noncompact analog of the Verlinde formula, not speaking of the formula (7.10). Thus, at this stage of the development of the subject considerations of this paragraph remain mere guesses. However, progress along these lines may be instrumental in developing a better technique for integrating over the moduli spaces, and thus, eventually, for a better understanding of the structure of string theory.

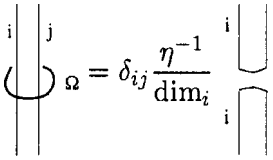
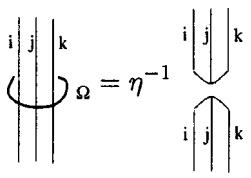
APPENDIX A: SOME RECOUPLING IDENTITIES

The 2-fusion identity:



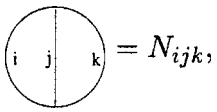
$$= \delta_{ij}\frac{\eta^{-1}}{\dim_i} \tag{A1}$$

The 3-fusion identity:



$$= \eta^{-1} \tag{A2}$$

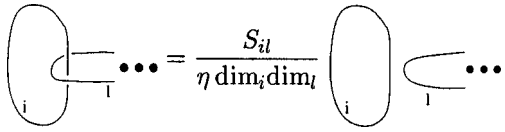
The 3-vertex is normalized so that



$$= N_{ijk}, \tag{A3}$$

where N_{ijk} is the multiplicity with which the trivial representation appears in the tensor product of i,j,k. For SU(2) this is either zero or one. In order to obtain (A1) from (A2) it is necessary to take into account the normalization (A3).

Another recoupling identity uses the modular S-matrix:



(A4)

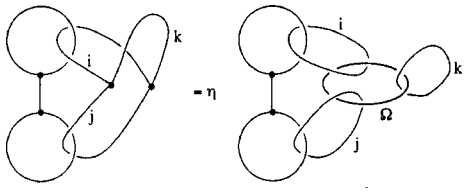
The dots on the right-hand side mean that the open ends can be connected (in an arbitrary way) to a larger graph.

APPENDIX B: PROOF

Here we give a proof of the main theorem.

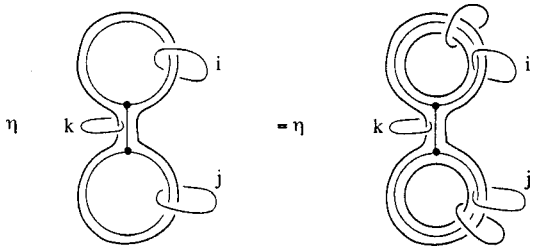
1. Genus zero case

We start by working out the simplest case of the 3-punctured sphere. We choose Γ to be given by a dumbbell. We thus need to compute the following evaluation:



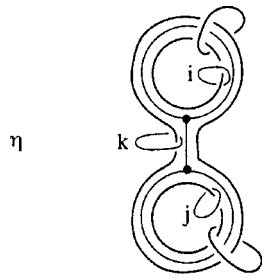
(B1)

Here we have used the observation (5.4) to replace two trivalent vertices of $\Delta \cup \Delta$ by a link with Ω inserted. Let us now slide the curve along which Ω is inserted to go all around the graph Γ, thus making one of the curves of the chain-mail $C(\Gamma)$. In the next step we add two more curves from $C(\Gamma)$ that go around punctures, and at the same time add two meridian curves with Ω inserted. This addition of two pairs of Ω linked does not change the evaluation in view of the killing property of Ω. The steps of sliding the Ω and adding two new pairs of curves is shown here:



(B2)

The last step is to use the sliding property of Ω to slide the links labeled i,j inside Γ:

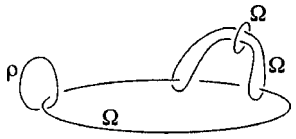


(B3)

One can now use the recoupling identity (A4) to remove the curves i,j,k at the expense of introducing a factor of $\eta^{-1}S_{ii'}/\dim_{i'}$ and similarly for other loops. Here i' is the representation on the loop from $C(\Gamma)$ going around the puncture i. The element Ω on that loop must be expanded to (4.1). The factor $\eta\dim_{i'}$ from that expansion is canceling the factor we got when removing the loop i. What is left is the S-matrix element $S_{ii'}$, with no extra factors. One can now use the 3-fusion identity (A2) to get the formula (7.10). One uses the 3-fusion 2 times, which produces η^{-2}. This combines with the factor of η in (B1)–(B3) to give η^{-1}, as prescribed by (7.10) for the case $g=0,n=3$. One can easily extend this proof to the case $g=0$ arbitrary number of punctures. To understand the general case, we first find a surgery representation for $X\times S^1$.

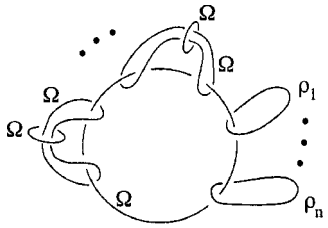
2. Surgery representation for $X\times S^1$

Let us first understand the genus one case. A surgery representation for $X_{1,1}\times S^1$ is given by the following link:



(B4)

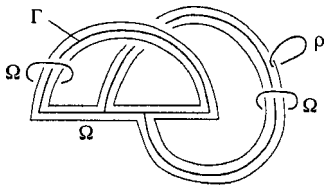
One must insert the element Ω into all components, and evaluate in S^3. Representing all the Ω's as the sum (4.1) and using the recoupling identity (A4) it is easy to show that (B4) gives the correct expression $\eta I(L)=\Sigma_{\rho'}S_{\rho\rho'}/S_{0\rho'}$ for the dimension. The same surgery representation was noticed in Ref. 37. The generalization to higher genus and to a larger number of punctures is straightforward. It is given by the following link:



(B5)

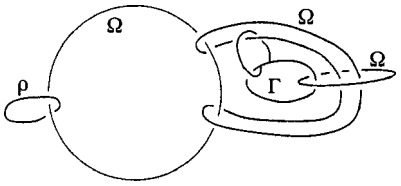
3. General case

We will work out only the (1,1) case. General case is treated similarly. We first note that the formula (7.10) for the (1,1) case can be obtained as the result of the following evaluation:



(B6)

This link is to be evaluated in S^3 and, as usual, the result multiplied by the factor of η. This gives (7.10) specialized to the case (1,1). It is now a matter of patience to verify that by the isotropy moves in S^3 the above link can be brought to the form:



(B7)

This is the correct surgery representation for $X_{1,1}\times S^1$ with the graph Γ inside. Thus, (7.10) indeed gives the evaluation $I(X\times S^1,\Gamma^{\psi})$, which, in view of (7.7), proves the theorem.

The Leibniz bracket of an operator on a (graded) algebra is defined and some of its properties are studied. A basic theorem relating the Leibniz bracket of the commutator of two operators to the Leibniz bracket of them is obtained. Under some natural conditions, the Leibniz bracket gives rise to a (graded) Lie algebra structure. In particular, those algebras generated by the Leibniz bracket of the divergence and the Laplacian operators on the exterior algebra are considered, and the expression of the Laplacian for the product of two functions is generalized for arbitrary exterior forms. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738188]

I. INTRODUCTION

In mathematical physics, some operators of interest are not derivations of the underlying algebraic structures. Their complement to the Leibniz rule of derivation defines then a product, called the Leibniz bracket. The Leibniz bracket of a linear operator on an algebra is thus a bilinear form that gives rise to a new algebra, called the Leibniz algebra. Leibniz algebras present interesting properties, and this work concerns them.

In particular, if the Leibniz bracket of an operator (its adjoint action) is a derivation, the operator is of degree odd and its square vanishes or is also a derivation, then the Leibniz bracket is a Lie bracket.

This is the case, for example, in the antibracket formalism context,[1] for the exterior derivative considered as a second order differential operator on the differential forms of finite codimension: the antibracket can then be defined as the corresponding Leibniz bracket, and some of its known properties are simple consequences of the general results obtained here.

A similar situation occurs for the divergence operator over the exterior algebra, for which the Leibniz bracket is nothing but the Schouten[2,3] bracket (in another different context, an equivalent result has been obtained by Koszul[4]). The expression obtained here relating the Schouten bracket to the divergence operator is of interest in mathematical physics. It allows, for example, to express Maxwell equations in terms of Schouten bracket and to study *proper variations* of Maxwell fields.[5,6] It has been also used to express the electromagnetic field equations in a non linear theory which solves, in part, an old problem concerning the existence and physical multiplicity of null electromagnetic fields in general relativity.[6,7]

The Leibniz bracket of the commutator of two operators admits a simple expression: It is the commutator of the Leibniz bracket of every one of them with respect to the operation defined by the Leibniz bracket of the other one. For the Laplacian operator, which *appears* as the (graded) commutator of the divergence and the exterior derivative, the above expression may be applied directly to it, giving the following interesting result: The Leibniz bracket of the Laplace operator

[a)]Electronic mail: bartolome.coll@obspm.fr
[b)]Electronic mail: joan.ferrando@uv.es

acting over the exterior algebra equals the Leibniz bracket of the exterior derivative acting over the Schouten algebra. This gives an interesting generalization to the exterior algebra of the well known expression for the Laplacian of a product of functions, and it has been applied in the analysis of harmonic coordinates in General Relativity.[8]

II. LEIBNIZ ALGEBRA OF A GRADED OPERATOR

(a) Let $\mathcal{E}=\oplus\mathcal{E}_a$ be a commutative graded group and $\circ:\mathcal{E}\times\mathcal{E}\to\mathcal{E}$ an operation verifying $\mathcal{E}_a\circ\mathcal{E}_b\subseteq\mathcal{E}_{a+b+k}$. Although it is always possible to regraduate $\mathcal{E}$ so that k vanishes, we shall retain the above graduation to avoid confusion when using different operations, as we shall do; such a k will be called the *degree* of the operation $\circ$ (with respect to this graduation).

The known properties (and concepts) on a graded group $\mathcal{E}$ concerning an operation $\circ$ of degree zero admit an equivalent form, depending generically on the degree k, when an arbitrary graduation is considered. Thus, the k-graded operation $\circ$ is *commutative* (resp. *anticommutative*) if it verifies $A\circ B=\epsilon(-1)^{(a+k)(b+k)}B\circ A$ with $\epsilon=1$ (resp. $\epsilon=-1$), and it is *associative* if $A\circ(B\circ C)=(A\circ B)\circ C$.

If $\mathcal{E}$ is a module and $\circ$ is bilinear, $(\mathcal{E},\circ)$ is said a k-*graded algebra*. A *derivation of degree* r is a r-graded endomorphism **D** on $\mathcal{E}$, $\mathbf{D}(\mathcal{E}_a)\subseteq\mathcal{E}_{a+r}$, verifying the Leibniz rule $\mathbf{D}(A\circ B)=\mathbf{D}A\circ B+(-1)^{(a+k)r}A\circ\mathbf{D}B$. An anticommutative k-graded algebra $(\mathcal{E},[,])$ verifying the Jacobi identity $\oint(-1)^{(a+k)(c+k)}[[A,B],C]=0$ is said a k-*graded Lie algebra*. Jacobi identity states, equivalently, that the (a+k)-graded endomorphism ad$A$, ad$A(B)=[A,B]$, is a derivation on $(\mathcal{E},[,])$. If $(\mathcal{E},\circ)$ is a k-graded associative algebra, the commutator defines a k-graded Lie algebra.

Let $\mathcal{E}$ be a graded group, $\circ$ a k-graded operation and **P** a p-graded operator. When **P** does not satisfy the Leibniz rule, its ''deviation'' interests us. So we give the following definition: the *Leibniz bracket* $\mathrm{L}_{\mathbf{P}}\langle\circ\rangle$ of **P** with respect to $\circ$ is the (p+k)-graded operation given by

$$\mathcal{L}_{\mathbf{P}}\langle\circ\rangle(A,B)=A\circ\mathbf{P}(B)+(-1)^{p(a+k)}[\mathbf{P}(A)\circ B-\mathbf{P}(A\circ B)]. \tag{1}$$

Of course, **P** verifies the Leibniz rule iff the Leibniz bracket $\mathcal{L}_{\mathbf{P}}\langle\circ\rangle$ vanishes identically.

The Leibniz bracket of a linear operator with respect to a bilinear operation is a bilinear operation, so that: *when* $(\mathcal{E},\circ)$ *is a k-graded algebra and* **P** *is a p-graded endomorphism*, $(\mathcal{E},\mathcal{L}_{\mathbf{P}}\langle\circ\rangle)$ *is a* $(k+p)$*-graded algebra*. We call it the *Leibniz algebra* of **P** on $(\mathcal{E},\circ)$. If **P** and **Q** are, respectively, p- and q-graded endomorphisms, their commutator $[\mathbf{P},\mathbf{Q}]=\mathbf{PQ}-(-1)^{pq}\mathbf{QP}$ is a (p+q)-graded endomorphism. Then, taking into account that $\mathcal{L}_{\mathbf{P}}\langle\circ\rangle$ and $\mathcal{L}_{\mathbf{Q}}\langle\circ\rangle$ are, respectively, (p+k)- and (q+k)-graded bilinear operations, and applying successively relation (1), one obtains the fundamental result:

Theorem 1: *In a k-graded algebra* $(\mathcal{E},\circ)$*, the Leibniz bracket of the commutator of two endomorphisms is related to the Leibniz bracket of every one of them by*

$$\mathcal{L}_{[\mathbf{P},\mathbf{Q}]}\langle\circ\rangle=\mathcal{L}_{\mathbf{Q}}\langle\mathcal{L}_{\mathbf{P}}\langle\circ\rangle\rangle-(-1)^{pq}\mathcal{L}_{\mathbf{P}}\langle\mathcal{L}_{\mathbf{Q}}\langle\circ\rangle\rangle. \tag{2}$$

In Marx's style:[9] The Leibniz bracket of the commutator [**P**, **Q**] of two endomorphisms **P** and **Q** on the algebra $(\mathcal{E},\circ)$ equals the graded difference between the Leibniz bracket of **Q** on the Leibniz algebra $(\mathcal{E},\mathcal{L}_{\mathbf{P}}\langle\circ\rangle)$ of **P** and the Leibniz bracket of **P** on the Leibniz algebra $(\mathcal{E},\mathcal{L}_{\mathbf{Q}}\langle\circ\rangle)$ of **Q**.

In particular, as $\mathbf{P}^2=\mathbf{P}\cdot\mathbf{P}$ is a 2p-graded operator, it follows that *for any odd-graded operator* **P**, *one has*

$$\mathcal{L}_{\mathbf{P}^2}\langle\circ\rangle=\mathcal{L}_{\mathbf{P}}\langle\mathcal{L}_{\mathbf{P}}\langle\circ\rangle\rangle\ , \tag{3}$$

Let us note that $\mathcal{L}_{\mathbf{P}}\langle x\rangle$ may be thought as *an operator* $\mathcal{L}_{\mathbf{P}}$ *over any operation x on* $\mathcal{E}$. In this sense, theorem 1 says that $\mathcal{L}_{[\mathbf{P},\mathbf{Q}]}\langle x\rangle=[\mathcal{L}_{\mathbf{Q}},\mathcal{L}_{\mathbf{P}}]\langle x\rangle$, and relation (3) says that $\mathcal{L}_{\mathbf{P}^2}\langle x\rangle=(\mathcal{L}_{\mathbf{P}})^2\langle x\rangle$.

Theorem 1 shows directly the well known result that if **P** and **Q** are derivations on $(\mathcal{E},\circ)$, so is [**P**, **Q**]. Also, from (3), it follows:

Lemma 1: The square $\mathbf{P}^2$ *of an endomorphism* **P** *of odd degree is a derivation on* $(\mathcal{E},\circ)$ *iff* **P** *is a derivation on* $(\mathcal{E},\mathcal{L}_{\mathbf{P}}\langle\circ\rangle)$.

On the other hand, if the operation $\circ$ is commutative or anticommutative, i.e., $A\circ B=\epsilon(-1)^{(a+k)(b+k)}B\circ A$, one can find the following result:

$$\mathcal{L}_{\mathbf{P}}\langle\circ\rangle(A,B)=\epsilon(-1)^{(a+k+p)(b+k+q)+p}\mathcal{L}_{\mathbf{P}}\langle\circ\rangle(B,A), \tag{4}$$

that is to say, *for a k-graded commutative (resp. anticommutative) algebra* $(\mathcal{E},\circ)$, *the* $(k+p)$*-graded Leibniz algebra* $(\mathcal{E},\mathcal{L}_{\mathbf{P}}\langle\circ\rangle)$ *is commutative (resp. anticommutative) if* $\mathbf{P}$ *is even-graded, and it is anticommutative (resp. commutative) if* $\mathbf{P}$ *is odd-graded.*

Let us denote, for simplicity, $\{A,B\}_{\mathbf{P}}=\mathcal{L}_{\mathbf{P}}\langle\circ\rangle(A,B)$. Then, when $(\mathcal{E},\circ)$ is a k-graded associative algebra and $\mathbf{P}$ an endomorphism, one has

$$\{A,B\circ C\}_{\mathbf{P}}-\{A,B\}_{\mathbf{P}}\circ C=(-1)^{p(b+k)}[\{A\circ B,C\}_{\mathbf{P}}-A\circ\{B,C\}_{\mathbf{P}}]. \tag{5}$$

(b) Let $(\mathcal{F},\circ)$ be a 0-graded associative and commutative algebra generated by its submodule $\mathcal{F}_1$, $\{,\}_{\mathbf{P}}$ be the Leibniz bracket of the p-graded endomorphism $\mathbf{P}$ on $(\mathcal{F},\circ)$, $\{A,B\}_{\mathbf{P}}\equiv\mathcal{L}_{\mathbf{P}}\langle\circ\rangle(A,B)$, and $\mathrm{ad}\{A\}_{\mathbf{P}}$ be the adjoint of A in the Leibniz algebra $(\mathcal{F},\{,\}_{\mathbf{P}})$, i.e., $\mathrm{ad}\{A\}_{\mathbf{P}}(B)\equiv\{A,B\}_{\mathbf{P}}$.

From the commutativity of $(\mathcal{F},\circ)$ and relation (4), Eq. (5) may be written $\{C,B\}_{\mathrm{ad}\{A\}_{\mathbf{P}}}=(-1)^{ca}\{A,B\}_{\mathrm{ad}\{C\}_{\mathbf{P}}}$. Then, it follows: *for any p-graded endomorphism* $\mathbf{P}$ *in* $(\mathcal{F},\circ)$, *one has*

$$\mathrm{ad}\{C\}_{\mathrm{ad}\{A\}_{\mathbf{P}}}=(-1)^{ca+a+p}\mathrm{ad}\{A\}_{\mathrm{ad}\{C\}_{\mathbf{P}}}. \tag{6}$$

In particular, $\mathrm{ad}\{A\}_{\mathbf{P}}$ obeys the Leibniz rule on the set $\{C\}\times\mathcal{F}$ iff $\mathrm{ad}\{C\}_{\mathbf{P}}$ does it on the set $\{A\}\times\mathcal{F}$. Thus, iff $\mathrm{ad}\{X\}_{\mathbf{P}}$ is a derivation for every $X\in\mathcal{F}_1$, $\mathrm{ad}\{A\}_{\mathbf{P}}$ verifies the Leibniz rule on $\mathcal{F}_1\times\mathcal{F}$. But an endomorphism that verifies the Leibniz rule on $\mathcal{F}_1\circ\mathcal{F}$ is a derivation on $(\mathcal{F},\circ)$, so that one has:

Lemma 2: If $\mathrm{ad}\{X\}_{\mathbf{P}}$ *is a derivation on* $(\mathcal{F},\circ)$ *for any X of* $\mathcal{F}_1$, *then* $\mathrm{ad}\{A\}_{\mathbf{P}}$ *is a derivation on* $(\mathcal{F},\circ)$ *for every A of* $\mathcal{F}$.

If $\mathbf{P}$ is a derivation on its induced Leibniz algebra $(\mathcal{F},\{,\}_{\mathbf{P}})$, the Leibniz rule may be written $[\mathbf{P},\mathrm{ad}\{A\}_{\mathbf{P}}]=\mathrm{ad}\{\mathbf{P}(A)\}_{\mathbf{P}}$. Then, applying theorem 1 it follows that $\mathrm{ad}\{A\}_{\mathbf{P}}$ is a derivation on $(\mathcal{F},\{,\}_{\mathbf{P}})$ when $\mathrm{ad}\{A\}_{\mathbf{P}}$ and $\mathrm{ad}\{\mathbf{P}(A)\}_{\mathbf{P}}$ are derivations on $(\mathcal{F},\circ)$. From this result and lemma 2 one has:

Lemma 3: If $\mathrm{ad}\{X\}_{\mathbf{P}}$ *is a derivation on* $(\mathcal{F},\circ)$ *for any* $X\in\mathcal{F}_1$ *and if* $\mathbf{P}$ *is a derivation on* $(\mathcal{F},\{,\}_{\mathbf{P}})$, *then* $\mathrm{ad}\{A\}_{\mathbf{P}}$ *is a derivation on* $(\mathcal{F},\{,\}_{\mathbf{P}})$ *for any* $A\in\mathcal{F}$.

For p odd, lemma 1 states that $\mathbf{P}$ is a derivation on $(\mathcal{F},\{,\}_{\mathbf{P}})$ iff $\mathbf{P}^2$ do it on $(\mathcal{F},\circ)$. On the other hand, it follows from relation (4) that $(\mathcal{F},\{,\}_{\mathbf{P}})$ is a p-graded anticommutative algebra. But under this condition Jacobi identity says equivalently that $\mathrm{ad}\{A\}_{\mathbf{P}}$ is a derivation on $(\mathcal{F},\{,\}_{\mathbf{P}})$. All that and lemma 3 lead to the following result:

Theorem 2: *For p odd, if* $\mathbf{P}^2$ *and* $\mathrm{ad}\{X\}_{\mathbf{P}}$, *for any X in* $\mathcal{F}_1$, *are derivations on* $(\mathcal{F},\circ)$ *then the Leibniz algebra* $(\mathcal{F},\{,\}_{\mathbf{P}})$ *is a p-graded Lie algebra.*

III. SCHOUTEN BRACKET, DIVERGENCE OPERATOR, AND LAPLACIAN

(a) Let Λ^p (resp. $\Lambda^{\star p}$) be the set of p-forms (*resp.* p-tensors) over the differential manifold M, that is to say, the set of completely antisymmetric covariant (resp. contravariant) tensor fields. Then, $\Lambda=\oplus\Lambda^p$ (resp. $\Lambda^\star=\oplus\Lambda^{\star p}$) with the exterior product $\wedge$ is a 0-graded associative and commutative algebra over the function ring $\chi=\chi(M)$: the *exterior covariant algebra* (*resp. exterior contravariant algebra*). We shall denote by α,β,γ the elements of Λ, and by A,B,C those of $\Lambda^\star$, with corresponding degrees a,b,c.

Denote the interior product $i(A)\beta$, $[i(A)\beta]_{\underline{b-a}}=(1/a!)A^q\beta_{a,\underline{b-a}}$ if $a\leqslant b$, by (A,β) and put $(\beta,A)=(-1)^{a(b-a)}(A,\beta)$. When $X\in\Lambda^1$, one has the usual interior product $i(X)$ which is a derivation of degree -1 on $(\Lambda,\wedge)$. Moreover, one has

$$(\gamma,A\wedge B)=((A,\gamma),B)+(-1)^{ab}((B,\gamma),A)\quad\text{if } c=a+b-1, \tag{7}$$

$$(A\wedge B,\gamma)=(B,(A,\gamma)),\quad (\gamma,A\wedge B)=((\gamma,B),A)\quad \text{if } c\geqslant a+b. \tag{8}$$

Suppose now that M is a n-dimensional and oriented manifold, and let η be a (covariant) volume element, $\eta^\star$ being its (contravariant) dual: $\eta_{p,n-p}\eta^{\star p',n-p}=\epsilon(n-p)^{-1}\delta_p^{p'}$, $\epsilon=\pm 1$. Then, the Hodge operators are given by $*A=(\eta,A)$, $*\alpha=(\eta^\star,\alpha)$ and verify $**A=\epsilon(-1)^{a(n-a)}A$. Therefore, if $a+b\leqslant n$,

$$*(A\wedge B)=(*B,A),\qquad *A\wedge\beta=*(\beta,A)\ . \tag{9}$$

The set of real numbers $\mathcal{R}$ being a sub-ring of the set of functions χ, $(\Lambda,\wedge)$ and $(\Lambda^\star,\wedge)$ are χ-algebras and $\mathcal{R}$-algebras. The exterior differentiation d is a 1-graded $\mathcal{R}$-derivation on $(\Lambda,\wedge)$, and the codifferentiation (divergence up to sign) is a (-1)-graded $\mathcal{R}$-endomorphism given by $\delta=\epsilon(-1)^{na}*d*$. Then, from (9) it follows,

$$\delta(A,\beta)=(\delta A,\beta)+(-1)^r(A,d\beta),\quad r=a-b>0. \tag{10}$$

(b) It is known that for $X,Y\in\Lambda^{\star 1}$, $\delta(X\wedge Y)=(\delta X)Y-(\delta Y)X-L_XY$, where L_X denotes the Lie derivative operator with respect to the vector field X. So that the operator δ is not a derivation on $(\Lambda^\star,\wedge)$. Thus, it is possible to consider the Leibniz bracket $\{\ ,\ \}_\delta$ of the codifferential operator on the exterior contravariant algebra $(\Lambda^\star,\wedge)$,

$$(-1)^a\{A,B\}_\delta=\delta A\wedge B+(-1)^aA\wedge\delta B-\delta(A\wedge B)\ . \tag{11}$$

Taking into account relations (7), (8), and (10), it is not difficult to show that, for any (a+b−1)-form γ, one has

$$(-1)^a i(\{A,B\}_\delta)\gamma=(d(\gamma,B),A)+(-1)^{ab}(d(\gamma,A),B)-(d\gamma,A\wedge B)\ . \tag{12}$$

The Schouten bracket $\{\ ,\}$ of two contravariant tensors[2] is a first order differential concomitant that generalize the Lie derivative.[3] For p-tensors (antisymmetric contravariant tensors) this bracket is defined by its action over the closed forms,[10] $i(\{A,B\})\gamma=(d(\gamma,B),A)+(-1)^{ab}(d(\gamma,A),B)$. Comparing this relation and (12), it follows $\{A,B\}=(-1)^a\{A,B\}_\delta$, and one has the following form of the Koszul[4] result:

Theorem 3: *The Schouten bracket is, up to a graded factor, the Leibniz bracket of the operator* δ *on the exterior contravariant algebra* $(\Lambda^\star,\wedge)$: $\{,\}=(-1)^a\{,\}_\delta$. *Explicitly*:

$$\{A,B\}=\delta A\wedge B+(-1)^aA\wedge\delta B-\delta(A\wedge B), \tag{13}$$

This result justifies that we name *Leibniz–Schouten bracket* the Leibniz bracket $\{,\}_\delta$ of the operator δ on the exterior contravariant algebra. Is is worth pointing out that both, the Schouten bracket and the Leibniz–Schouten bracket, define on the exterior contravariant algebra two *equivalent* structures of (-1)-graded algebra, which we name, respectively, *Schouten algebra* and *Leibniz–Schouten algebra*. Althought equivalent, it is to be noted that the Schouten algebra does *not* satisfies the standard writing of a Lie algebra properties, meanwhile the Leibniz-Schouten algebra does. Let us see that.

It is not difficult to see that $\forall X\in\Lambda^{\star 1}$, $\forall A\in\Lambda^{\star p}$, one has $\{X,A\}=L_XA$; that shows how the Schouten bracket generalizes the Lie derivative. Let us write $\{A,B\}\equiv L_AB$, $\forall A,B\in\Lambda^\star$; as it is known, $L_X, X\in\Lambda^{\star 1}$, is a derivation and δ is a (-1)-graded endomorphism on the 0-graded associative and commutative algebra $(\Lambda^{\star p},\wedge)$ such that $\delta^2=0$. As a consequence, the Leibniz–Schouten bracket $\{,\}_\delta$ satisfies the hypothesis of theorem 2 and so *the Leibniz–Schouten algebra* $(\Lambda^\star,\{,\}_\delta)$ *is a* (-1)*-graded Lie algebra*, that is, $\{\Lambda^{\star a},\Lambda^{\star b}\}_\delta\subseteq\Lambda^{\star a+b-1}$ and

$$\{A,B\}_\delta=-(-1)^{(a-1)(b-1)}\{B,A\}_\delta,\qquad \oint(-1)^{(a-1)(c-1)}\{\{A,B\}_\delta,C\}_\delta=0. \tag{14}$$

The Schouten bracket {,} also satisfies $\{\Lambda^{\star a},\Lambda^{\star b}\}\subseteq\Lambda^{\star a+b-1}$, and the properties of the Leibniz–Schouten Lie algebra (14) can equivalently be written in terms of the Schouten bracket as

$$\{A,B\}=(-1)^{ab}\{B,A\},\qquad \oint(-1)^{ac}\{\{A,B\},C\}=0\,. \tag{15}$$

Let us note that these last relations (15) satisfied by the Schouten algebra do not reduce, by any regraduation, to the standard ones of a Lie algebra.

Jacobi identity equivalently states, the following generalization for the Lie derivative with respect to the Lie bracket:

$$L_{\{A,B\}}=-(-1)^{a}[L_A,L_B].$$

Also, from lemmas 1 and 2 and taking into account the properties of the codifferential operator, it follows that: *(i) The codifferential operator δ is a $\mathcal{R}$-derivation on the Leibniz–Schouten algebra*:

$$-\delta\{A,B\}=\{\delta A,B\}+(-1)^{a}\{A,\delta B\}.$$

(ii) The operator L_A is a $\mathcal{R}$-derivation on the exterior contravariant algebra:

$$L_A(B\wedge C)=L_AB\wedge C+(-1)^{b(a-1)}B\wedge L_AC.$$

The property (i) gives the generalization of the commutator of the codifferential and Lie derivative operators:

$$[\delta,L_A]\equiv\delta L_A+(-1)^{a}L_A\delta=-L_{\delta A}\,.$$

On the other hand, Eq. (10) may be written $[i(\beta),\delta]=i(d\beta)$. But $i(\omega)$ is a derivation on $(\Lambda^{\star},\wedge)$ for any 1-form ω. Then, taking into account theorem 1, we have $\mathcal{L}_{i(\omega)}\langle\{\,\}_{\delta}\rangle=\mathcal{L}_{i(d\omega)}\langle\wedge\rangle$. In particular, when ω is a closed 1-form, then $i(\omega)$ is a derivation on the Leibniz–Schouten algebra.

(c) Suppose now M endowed with a (pseudo-)Riemannian metric g, allowing to identify $(\Lambda,\wedge)$ and $(\Lambda^{\star},\wedge)$. The Laplacian operator is then the *graded* commutator of the differential and codifferential operators:

$$\Delta=[d,\delta]\equiv d\delta+\delta d\ .$$

It is known that Δ is not a derivation on the exterior algebra. From theorem 1 its Leibniz bracket is given by:

Theorem 4: *The Leibniz bracket of the Laplacian operator on the exterior algebra equals the Leibniz bracket of the exterior derivative on the Leibniz–Schouten algebra*: $\mathcal{L}_{\Delta}\langle\wedge\rangle=\mathcal{L}_{d}\langle\{\,\}_{\delta}\rangle$. *Explicitly*:

$$\Delta\alpha\wedge\beta+\alpha\wedge\Delta\beta-\Delta(\alpha\wedge\beta)=\{d\alpha,\beta\}+(-1)^{a}\{\alpha,d\beta\}+d\{\alpha,\beta\}, \tag{16}$$

where α and β are arbitrary a- and b-forms, respectively.

This theorem gives the generalization to the exterior algebra of the expression for the Laplacian of a product of functions: $\Delta f.h+f.\Delta h-\Delta(f.h)=2(df,dh)$.

(Received 1 November 2002; accepted 18 March 2004; published online 14 May 2004)

In earlier work on the one-dimensional sech^2 potential energy [I. A. Howard and N.H. March, Int. J. Quantum Chem. **91**, 119 (2003)] it has been shown that both electron density $\rho(x)$ and kinetic energy $t(x)$ are low-order polynomials in the potential $V(x)$, for a small number of bound states. Here all attention is focused on the continuum states for the sech^2 potential with a single bound state. The tool employed is the Slater sum, which satisfies a partial differential equation. This is first solved explicitly for the bound state, and then the solution is generalized to apply to the continuum. Again, considerable simplification is exhibited for this specific choice of potential. A brief discussion is included of a central sech$^2(r)$ potential. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1745126]

I. BACKGROUND AND OUTLINE

March and Murray,[1,2] in early work on the properties of Fermions moving independently in a one-body potential $V(r)$, calculated the canonical density matrix $C(\mathbf{r},\mathbf{r}_0,\beta)$ by perturbation theory to all orders in V, with the unperturbed state described by plane waves. $C(\mathbf{r},\mathbf{r}_0,\beta)$ can be written exactly in terms of the eigenfunctions $\psi_i(\mathbf{r})$ and the corresponding eigenvalues ϵ_i of the Hamiltonian

$$H_{\mathbf{r}} = -\frac{\hbar^2}{2m}\nabla_{\mathbf{r}}^2 + V(\mathbf{r}) \tag{1.1}$$

as

$$C(\mathbf{r},\mathbf{r}_0,\beta) = \sum_{all\ i} \psi_i(\mathbf{r})\psi_i^*(\mathbf{r}_0)\exp(-\beta\epsilon_i): \quad \beta = (k_B T)^{-1}. \tag{1.2}$$

Here, we shall mainly be concerned with the one-dimensional counterpart, i.e., a potential energy $V(x)$, but of the very specific form

$$\frac{2m}{\hbar^2}V(x) = -2\gamma^2\,\mathrm{sech}^2(\gamma x). \tag{1.3}$$

In a quite different context, Montroll[3] has utilized this potential (1.3) in discussing electronic band structure via a quantum network model.

In Montroll's study,[3] as well as in the book of Landau and Lifshitz,[4] it was recognized that this potential energy (1.3) generates a single bound state, with wave function

$$\psi(x) = \sqrt{\frac{\gamma}{2}}\,\mathrm{sech}(\gamma x) \tag{1.4}$$

corresponding to electron density $\rho(x)$ given by

$$\rho(x) = \frac{\gamma}{2}\,\mathrm{sech}^2(\gamma x) = -\frac{m}{2\gamma\hbar^2}V(x), \tag{1.5}$$

where in the last step Eq. (1.3) has been utilized. This result has been generalized to include a few bound states by two of us,[5] the kinetic energy density $t(x)$ being shown, as with $\rho(x)$, to be a low-order polynomial in this sech^2 potential $V(x)$. In density-functional parlance, this therefore constitutes a specific example of the Legendre transform of the single-particle kinetic energy. As Nagy and March[6] pointed out recently, the perturbation theory of March and Murray[2] and the subsequent derivation by Stoddart and March[7] of the kinetic energy density $t(\mathbf{r})$ in particular, already constitute an example of the Legendre transform of the single-particle kinetic energy.

However, to date these results[2,7] have only been summed to all orders in $V(\mathbf{r})$ for the harmonic oscillator potential, as in the investigation of Sondheimer and Wilson.[8] So it remains of interest to investigate whether one can solve explicitly for the sech^2 potential. In particular, one wishes to handle the entire continuous spectrum, as well as the bound states, generated by this potential.

Before outlining the present study, a referee has asked us to emphasize the importance of the Slater sum, which is the focus of this work. The Slater sum is the diagonal element of the canonical density matrix defined in Eq. (1.2). In turn, the canonical density matrix is determined by the Laplace transform of the one-particle (or Dirac) density matrix. Thus the Slater sum is directly given by the Laplace transform of the (diagonal) density. The role and importance of the Fermion density is well-known. Simple model systems have significance in that exact relations derived for them can often be applied to more complicated systems, at least in an approximate fashion.

The outline of the present article is then as follows: In Sec. II, the partial differential equation satisfied by the one-dimensional Slater sum $S(x,\beta)$ is set out, as follows from the early study of March and Murray,[1] and particular solutions are generated for the potential (1.3). Section III then utilizes these results to obtain the kinetic energy density $t(x)$, which is indeed conveniently presented in Legendre transform manner. Section IV constitutes a summary, with some proposals for future work. In an Appendix, but more formally now, a brief discussion is given of the central potential sech$^2(\gamma r)$.

II. PARTIAL DIFFERENTIAL EQUATION SATISFIED BY THE SLATER SUM

As mentioned above, defining the Slater sum $S(x,\beta)$ in one dimension as $C(x,x_0,\beta)|_{x_0=x}$, the Bloch equation

$$H_x C = -\frac{\partial C}{\partial \beta} \tag{2.1}$$

was shown by March and Murray[1] to be expandable around its diagonal $x=x_0$ to yield a partial differential equation for $S(x,\beta)$ for a general one-dimensional potential $V(x)$ as

$$\frac{1}{8}\frac{\partial^3 S(x,\beta)}{\partial x^3} - \frac{\partial^2 S(x,\beta)}{\partial x \partial \beta} - V(x)\frac{\partial S(x,\beta)}{\partial x} - \frac{1}{2}\frac{\partial V}{\partial x}S(x,\beta) = 0. \tag{2.2}$$

Below, for initial orientation which will lead into the solution of Eq. (2.2) for the sech^2 potential (1.3), we shall make use of the explicit continuum wave functions given in convenient form by Montroll[3] in the very different problem of the quantum theory of periodic networks. He classifies the wave functions of the potential $V(x)$ in Eq. (1.3) into symmetrical forms $\psi_s(x)$ and antisymmetrical forms $\psi_a(x)$. One can now use his results to form explicitly $\psi_s^2(x)+\psi_a^2(x)$, which evidently appears in the Slater sum from the definition (1.2) of $C(\mathbf{r},\mathbf{r}_0,\beta)$ with $\mathbf{r}_0$ put equal to $\mathbf{r}$ and motion restricted to the x-axis only. To obtain $\psi_s^2(x)+\psi_a^2(x)$, we first note with Montroll[3] that the general solution of the Schrödinger equation in the continuum is given by

$$\psi(x)=\mathcal{N}[\cos(kx+\delta)-(\gamma/k)\sin(kx+\delta)\tanh(\gamma x)], \tag{2.3}$$

where $E=k^2/2$ is the energy of the state.

Choosing $\delta=0$ in Eq. (2.3) yields the symmetric wave functions $\psi_s(x)$ while $\delta=\pi/2$ generates the antisymmetric forms. One then finds after a short calculation that $\psi_s^2+\psi_a^2$ takes the form

$$\psi_s^2+\psi_a^2=a^2(\gamma,k)[1+(\gamma/k)^2\tanh^2(\gamma x)]. \tag{2.4}$$

Inserting Eq. (2.4) into the definition of the Slater sum $S(x,\beta)$ set out above, one finds

$$S_c(x,\beta)=\sum_{all\ k>0} a^2(\gamma,k)[1+(\gamma/k)^2\tanh^2(\gamma x)]\exp\left(-\frac{\beta k^2}{2}\right), \tag{2.5}$$

where the subscript c on $S(x,\beta)$ indicates that in the form (2.5) one is summing only over continuum (c) states. This form (2.5) is important, in that it tells us that $S_c(x,\beta)$ has the general "shape"

$$\begin{aligned} S_c(x,\beta)&=F(\gamma,\beta)+\tanh^2(\gamma x)\sum_{all\ k>0} a^2(\gamma,k)(\gamma/k)^2\exp\left(-\frac{\beta k^2}{2}\right)\\ &\equiv F(\gamma,\beta)+G(\gamma,\beta)\tanh^2(\gamma x). \end{aligned} \tag{2.6}$$

Our task below must therefore be to find the explicit forms of the two functions $F(\gamma,\beta)$ and $G(\gamma,\beta)$ in Eq. (2.6). But already, one sees here the appearance of the sech^2 potential (1.3), since

$$\tanh^2(\gamma x)=1-\mathrm{sech}^2(\gamma x) \tag{2.7}$$

and hence Eq. (2.6) can be rewritten as

$$S_c(x,\beta)=[F(\gamma,\beta)+G(\gamma,\beta)]+\frac{G(\gamma,\beta)}{\gamma^2}V(x). \tag{2.8}$$

Equation (2.8) shows similarity of shape with the bound-state result (1.5) for the particle density, which corresponds to a bound-state contribution $S_b(x,\beta)$ to the Slater sum of

$$S_b(x,\beta)=\psi^2(x)\exp(-\beta\epsilon_0) \tag{2.9}$$

with ϵ_0 the bound-state energy $-\gamma^2/2$. Indeed, using Eq. (1.5) one finds

$$S_b(x,\beta)\propto\exp(\gamma^2\beta/2)V(x). \tag{2.10}$$

However one has to be wary, as in Eq. (2.8), that the potential again enters, via γ, in the "proportionality constant" in Eq. (2.10). Returning to Eq. (2.8), since $V(x)\to 0$ as $x\to\pm\infty$, we can see on physical grounds in Eq. (2.8) that $S_c(x,\beta)$ must tend to the well-known result for the partition function per unit length (in one dimension) for free electrons. This, in the units employed in Eq. (2.2) ($\hbar=m=1$), is

$$\lim_{x\to\pm\infty} S_c(x,\beta)=(2\pi\beta)^{-1/2}, \tag{2.11}$$

which shows from Eq. (2.8) that the γ dependence appearing in F and G separately must cancel in the sum $F+G=(2\pi\beta)^{-1/2}$. This is an important simplification to be utilized below.

Before turning to the main task of the present study, namely, the solution of the partial differential equation (2.2) subject to the appropriate physical boundary conditions, one should stress that while $S_b(x,\beta)$ in Eq. (2.10) and $S_c(x,\beta)$ in Eq. (2.8) must separately be solutions, $S_b(x,\beta)$ in Eq. (2.10) is much the simpler to handle, as the solution is a product of a function solely of x and one dependent only on β. Let us therefore take that as the starting point for discussing the solutions of Eq. (2.2).

A. Solutions of Eq. (2.2) for $S(x,\beta)$ obtained by the method of separation of variables

In such a separable solution for $S(x,\beta)$, let us write

$$S(x,\beta)=X(x)B(\beta). \tag{2.12}$$

Inserting this form into Eq. (2.2), but for the present retaining a general one-dimensional potential energy $V(x)$, we can write, after dividing the result obtained by $X'(x)B(\beta)$ where $X'=\partial X/\partial x$, etc.:

$$\frac{1}{8}\frac{X'''}{X'}-\frac{\partial}{\partial\beta}\ln B-V(x)-\frac{1}{2}\frac{V'X}{X'}=0. \tag{2.13}$$

This Eq. (2.13) shows, as yet for general $V(x)$, that separable solutions can be obtained, with separation constant κ such that $X(x)$ and $B(\beta)$ separately satisfy the ordinary differential equations

$$\frac{1}{8}\frac{X'''}{X'}-V(x)-\frac{1}{2}\frac{V'X}{X'}=\text{const}=\kappa \tag{2.14}$$

and

$$\frac{\partial}{\partial\beta}\ln B=\kappa, \tag{2.15}$$

the difference of these two equations (2.14) and (2.15) plainly satisfying Eq. (2.13). Without specifying $V(x)$, the general solution of the differential equation (2.15) is clearly

$$B(\beta)=A\exp(\kappa\beta), \tag{2.16}$$

where A is an arbitrary ''constant.'' To obtain the particular ''bound state'' Slater sum in Eq. (2.10) one must choose, now for the sech^2 potential (1.3), the separation constant $\kappa=\gamma^2/2$. Inserting this value into Eq. (2.14) one must plainly have, from Eq. (2.10), a particular solution $X=\text{const}\times V(x)\propto\text{sech}^2(\gamma x)$.

B. Particular solution for continuum Slater sum having the ''shape'' of Eq. (2.8)

Having established the ''shape'' of the continuum Slater sum $S_c(x,\beta)$, but now for the potential (1.3) alone as

$$S_c(x,\beta)=(2\pi\beta)^{-1/2}+\frac{G(\gamma,\beta)}{\gamma^2}V(x) \tag{2.17}$$

the question that remains is to find $G(\gamma,\beta)$, if that is possible, by direct substitution of Eq. (2.17) into the general partial differential equation (2.2). One then finds straightforwardly that

$$\frac{1}{8}\frac{G}{\gamma^2}V'''(x)-\frac{1}{\gamma^2}\frac{\partial G}{\partial\beta}V'(x)-\frac{3}{2}\frac{G}{\gamma^2}V(x)V'(x)-\frac{1}{2}(2\pi\beta)^{-1/2}V'(x)=0. \tag{2.18}$$

This, on rearrangement, reads

$$\frac{1}{\gamma^2}\frac{\partial G}{\partial\beta}-\frac{G}{\gamma^2}\left[\frac{V'''/V'}{8}-\frac{3}{2}V\right]+\frac{1}{2}(2\pi\beta)^{-1/2}=0. \tag{2.19}$$

Thus, the question posed above resolves into whether the square bracket in Eq. (2.19) is independent of x. This does indeed prove to be the case when $V(x)$ is inserted from Eq. (1.3). The resulting first-order ordinary differential equation may be integrated to yield

$$\begin{aligned}G(\gamma,\beta)&=-\frac{\gamma^2}{2}\exp\left(\frac{\gamma^2\beta}{2}\right)\left[\int_0^\beta\frac{1}{(2\pi\beta)^{1/2}}\exp\left(-\frac{\gamma^2\beta}{2}\right)d\beta+f(\gamma)\right]\\&=\left[-\frac{\gamma}{2}\operatorname{erf}\left(\frac{\gamma}{2}\sqrt{2\beta}\right)-\frac{\gamma^2 f(\gamma)}{2}\right]\exp\left(\frac{\gamma^2\beta}{2}\right),\end{aligned} \tag{2.20}$$

where $f(\gamma)$ is a constant of integration, and thus from (2.17),

$$S_c(x,\beta)=(2\pi\beta)^{-1/2}-\left[\frac{f(\gamma)}{2}+\frac{1}{2\gamma}\operatorname{erf}\left(\frac{\gamma}{2}\sqrt{2\beta}\right)\right]\exp\left(\frac{\gamma^2\beta}{2}\right)V(x). \tag{2.21}$$

In Appendix B, contact is made with a direct calculation of the local density of states in the continuum at $x=0$, namely, $\partial\rho_c(0,E)/\partial E$. Using the Laplace transform relation

$$S_c(x,\beta)=\int_0^\infty\frac{\partial\rho_c(x,E)}{\partial E}\exp(-\beta E)\,dE \tag{2.22}$$

and inserting Eq. (B9) into the right-hand side yields the result (2.17) with $G(\gamma,\beta)$ given in Eq. (2.20) and $f(\gamma)=-1/\gamma$, so that we can write

$$S_c(x,\beta)=(2\pi\beta)^{-1/2}-\frac{1}{2\gamma}\operatorname{erfc}\left(\frac{\gamma}{2}\sqrt{2\beta}\right)\exp\left(\frac{\gamma^2\beta}{2}\right)V(x). \tag{2.23}$$

The Slater sum is plotted in Fig. 1 for representative values of β and γ. We turn finally to discuss how the kinetic energy density $t(x)$ may be obtained from the Slater sum $S_c(x,\beta)$.

III. DERIVATION OF KINETIC ENERGY DENSITY FROM UNIFORM FERMI GAS RESULT IN ONE DIMENSION FOR THE sech^2 POTENTIAL

Returning to the Bloch equation (2.1), and inserting the one-body Hamiltonian

$$H_x=-\frac{1}{2}\frac{\partial^2}{\partial x^2}+V(x), \tag{3.1}$$

use of Eq. (1.2) in one dimension enables one to write almost immediately

$$-\frac{\partial S_c}{\partial\beta}=-\frac{1}{2}\sum_{k>0}\psi_k(x)\frac{\partial^2\psi_k^*(x)}{\partial x^2}\exp\left(\frac{\beta k^2}{2}\right)+V(x)S_c \tag{3.2}$$

or

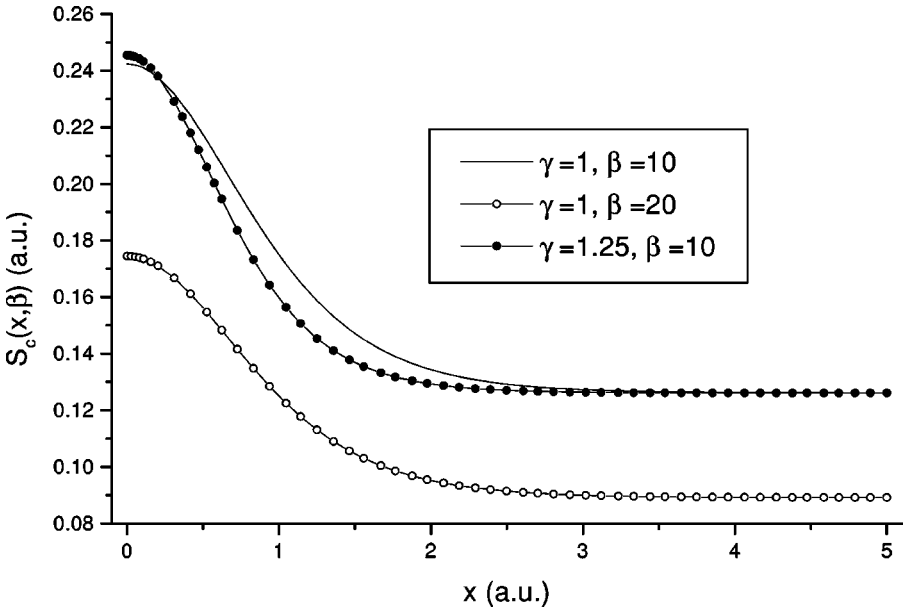

FIG. 1. Continuum Slater sum of Eq. (2.23) as a function of x for selected values of β and potential parameter γ in Eq. (1.3).

$$-\frac{\partial S_c}{\partial \beta} = t_c(x,\beta) + V(x) S_c\,, \tag{3.3}$$

which serves to define a ''kinetic energy density'' $t_c(x,\beta)$ which is related to the desired $t(x,E)$ by a Laplace inversion paralleling Eq. (2.22). But from Eqs. (3.3) and (2.23) one has

$$t_c(x,\beta) = \frac{1}{2\beta}\frac{1}{(2\pi\beta)^{1/2}} - V(x)\left[\frac{1}{2}\frac{3}{(2\pi\beta)^{1/2}} - \frac{\gamma}{4}\mathrm{erfc}\left(\frac{\gamma}{2}\sqrt{2\beta}\right)\exp\left(\frac{\gamma^2\beta}{2}\right)\right]$$
$$+\frac{1}{2\gamma}\mathrm{erfc}\left(\frac{\gamma}{2}\sqrt{2\beta}\right)\exp\left(\frac{\gamma^2\beta}{2}\right)V^2(x). \tag{3.4}$$

In Fig. 2 we plot this kinetic energy density for the β and γ of Fig. 1. Writing explicitly the analogous equation to (2.22), but now for the kinetic energy densities, one has

$$t_c(x,\beta) = \int_0^\infty \frac{\partial t_c(x,E)}{\partial E}\exp(-\beta E)\,dE \tag{3.5}$$

and one then obtains from Eq. (3.4) the kinetic energy change Δt from the one-dimensional Fermi gas, the result being given in Eq. (B3) of Appendix B.

IV. SUMMARY AND PROPOSALS FOR FUTURE STUDY

The main achievements of the present investigation are as follows: (i) the explicit solution of the partial differential equation (2.2) for the (continuum c) Slater sum $S_c(x,\beta)$ given in Eqs. (2.17) and (2.23); (ii) the analogous result (B9) for the continuum density of states and the consequent result (B8) for the total density $\rho(0,E)$ in the continuum, both now at the origin $x=0$; (iii) the kinetic energy density $t_c(x,\beta)$ in the continuum, defined by Eqs. (3.3) and (3.2), and given in Eq. (3.4); and (iv) the corresponding result for $t_c(x,E)$ exhibited in Eq. (B3).

In the future we believe it would be interesting to extend the calculations presented here explicitly to the three-dimensional $\mathrm{sech}^2(\gamma r)$ potential, the route to follow being indicated in

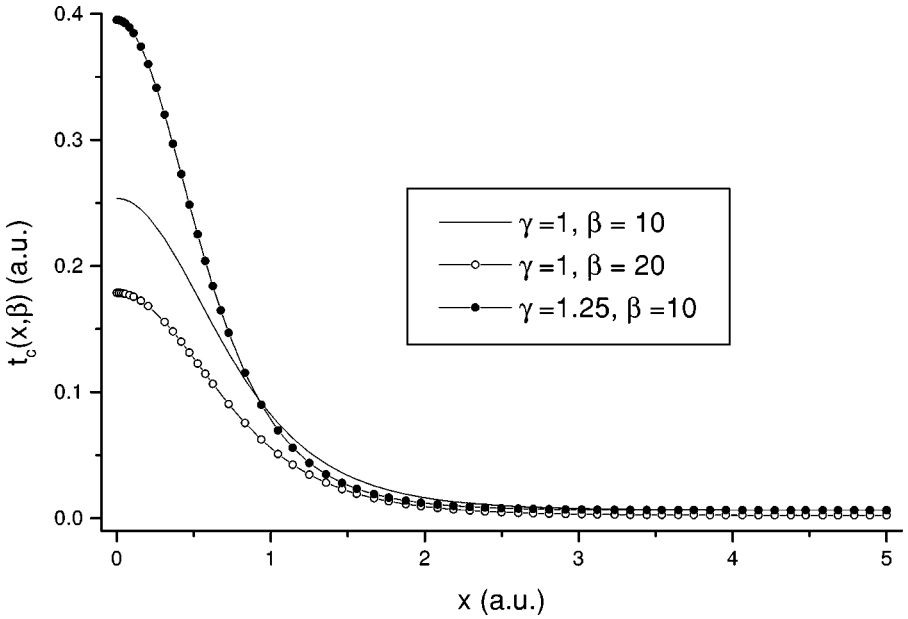

FIG. 2. Statistical mechanical kinetic energy density $t_c(x,\beta)$ of Eq. (3.4), for the same values of β and γ as in Fig. 1.

Appendix A. Furthermore, since separable solutions of Eq. (2.2) can be found for arbitrary $V(x)$, study of the ordinary differential equation (2.14) would seem worthwhile for a wider class of potentials. The progress here on the kinetic energy density $t[V(\mathbf{r})]$ may lead to partial summations to infinite order of the Stoddart–March perturbation series for $t[V(\mathbf{r})]$ measured relative to the Fermi gas value $t_0 = c_k \rho_\infty^{5/3}$, where ρ_∞ is the density of the unperturbed system, and c_k is known from the homogeneous Fermi assembly.

Nagy for a number of valuable discussions on the general area embraced by the present work. The contribution of N.H.M. to this study was brought to fruition during a visit to SNS, Pisa in 2002. He wishes to thank SNS for providing generous hospitality.

APPENDIX A: THE THREE-DIMENSIONAL sech^2 POTENTIAL

For the three-dimensional analog of the potential $V(x)$ above, we can also study the density of states in the continuum for the case of zero angular momentum, $l=0$. The three-dimensional March–Murray equation ((4.12) in Ref. 1) for the density of states $N_s = \partial \rho_s / \partial E$ is

$$\frac{1}{8}\frac{\partial^3 (r^2 N_s)}{\partial r^3} - \frac{r^2 N_s}{2}\frac{\partial V}{\partial r} + (E-V)\frac{\partial (r^2 N_s)}{\partial r} = 0. \tag{A1}$$

Taking the potential to be $V(r) = -\gamma^2 \operatorname{sech}^2(\gamma r)$, we find the solution for energies $E = k^2/2$ to be of the form

$$\begin{aligned} N_s(r) = &[C_1 \cos^2(I_{k,\gamma}(r)) + C_2 \sin(I_{k,\gamma}(r))\cos(I_{k,\gamma}(r)) + C_3 \sin^2(I_{k,\gamma}(r))] \\ &\times ((\gamma^2 + k^2)\cosh(2\gamma r) - \gamma^2 + k^2)/r^2, \end{aligned} \tag{A2}$$

where

$$I_{k,\gamma}(r)=\frac{k}{\gamma}\ln[\cosh(\gamma r)+\sqrt{\cosh^2(\gamma r)-1}]+\frac{1}{2}\arctan\left[2\gamma k\frac{\cosh(\gamma r)\sqrt{\cosh^2(\gamma r)-1}}{(k^2-\gamma^2)\cosh^2(\gamma r)+\gamma^2}\right] \quad \text{(A3)}$$

and C_1, C_2, and C_3 are constants.

APPENDIX B: KINETIC ENERGY DENSITY DEVIATION FROM UNIFORM ELECTRON GAS RESULT

From Eq. (2.4) it can be seen that the total density $\rho(x)$ in the continuum will have the form $\rho(x)\equiv B(\gamma)+C(\gamma)\tanh^2(\gamma x)$. Note that $\rho(x\to 0)\equiv\rho(0)=B$ and $\rho(x\to\infty)\equiv\rho_\infty=B+C$, so that we may also write $\rho(x)=\rho(0)+(\rho_\infty-\rho(0))\tanh^2(\gamma x)$.

If we consider $\overline{t}=(t+t_G)/2$, the average of the gradient (t_G) and Laplacian (t) forms of the kinetic energy density, then the one-dimensional form of the differential virial theorem is, with $\Delta t=t-t_0$: $t_0=c_k\rho_\infty^3$,

$$\Delta\overline{t}'=-\frac{\rho}{2}\frac{\partial V}{\partial x}, \quad \text{(B1)}$$

so that for our potential,

$$\Delta\overline{t}=-\int^x\frac{\rho}{2}\frac{\partial V}{\partial x}dx=\frac{\gamma^2}{2}\left[\rho_\infty+\frac{(\rho(0)-\rho_\infty)}{2}\operatorname{sech}^2(\gamma x)\right]\operatorname{sech}^2(\gamma x),$$

$$=-\frac{1}{2}V(x)\left[\rho_\infty-\frac{(\rho(0)-\rho_\infty)}{2\gamma^2}V(x)\right] \quad \text{(B2)}$$

the constant of integration being chosen so that $\Delta\overline{t}(x\to\pm\infty)\to 0$. Expressing this in terms of the Laplacian $\psi\nabla^2\psi$ form of the kinetic energy density Δt, we have

$$\Delta t=\Delta\overline{t}-\frac{\rho''}{8}=\frac{\gamma^2}{2}[(2\rho_\infty-\rho(0))+2(\rho(0)-\rho_\infty)\operatorname{sech}^2(\gamma x)]\operatorname{sech}^2(\gamma x)$$

$$=\frac{\gamma^2}{2(\rho(0)-\rho_\infty)}(\rho-\rho_\infty)(2\rho-\rho(0)), \quad \text{(B3)}$$

so that the excess total kinetic energy due to the inhomogeneity, $T=\int_{-\infty}^{\infty}\Delta t(x)dx$, is

$$T=\frac{\gamma}{3}(\rho(0)+2\rho_\infty). \quad \text{(B4)}$$

Because Δt is local in ρ, we can write the functional derivative $\delta T/\delta\rho$ as simply $\partial t/\partial\rho$, so that

$$\frac{\delta T}{\delta\rho}=\frac{\partial t}{\partial\rho}=\frac{\gamma^2}{2(\rho_\infty-\rho(0))}(-4\rho(x)+\rho(0)+2\rho_\infty). \quad \text{(B5)}$$

The one-dimensional counterpart of March and Murray's[1] Eq. (4.12) for s-states gives

$$\frac{\rho'''}{8}-\frac{\rho}{2}\frac{\partial V}{\partial x}-V\rho'+\int_0^E E\frac{\partial^2\rho}{\partial x\partial E}dE=0. \quad \text{(B6)}$$

Inserting $\rho(x)$ and differentiating with respect to E, we find

$$(\gamma^2+2E)\frac{\partial\rho(0)}{\partial E}-2E\frac{\partial\rho_\infty}{\partial E}=0. \quad \text{(B7)}$$

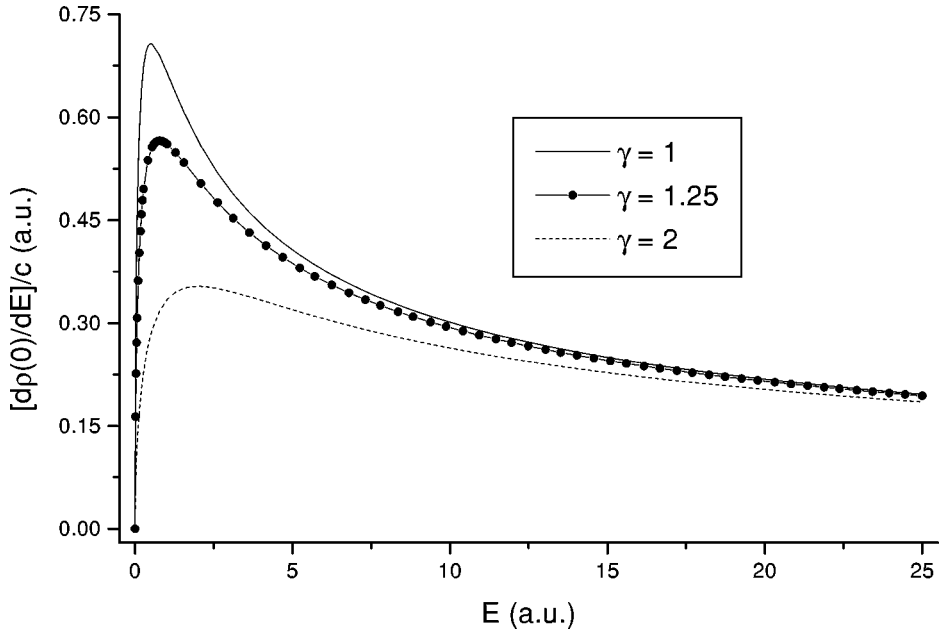

FIG. 3. Local density of states $[\partial\rho(0)/\partial E]/c$ at the origin $x=0$, as given in Eq. (B9), for selected values of γ.

Here $\partial\rho(0)/\partial E$ and $\partial\rho_\infty/\partial E$ are the density of states at the origin and at infinity (i.e., in the region of the uniform electron gas), respectively. But we know that for a uniform electron gas in one dimension, $\partial\rho_\infty/\partial E = c/\sqrt{E}$, where c is a constant; therefore

$$\rho(0,E) = 2c\left[\sqrt{E} - \frac{\gamma}{\sqrt{2}}\arctan\left(\frac{\sqrt{2E}}{\gamma}\right)\right] \tag{B8}$$

and

$$\frac{\partial\rho(0,E)}{\partial E} = \frac{2c\sqrt{E}}{\gamma^2 + 2E}. \tag{B9}$$

If $\gamma\to 0$, $V(x)\to 0$, and so $\rho(x)\to\rho(0)$ everywhere; then $\partial\rho(0,E)/\partial E \to c/\sqrt{E}$ as expected. The behavior of $\partial\rho(0)/\partial E$ is depicted in Fig. 3. Note also that if we subtract from $\rho(x)$ the spatially uniform density ρ_∞, we can integrate over all space to find the total number Δn of electrons in the nonuniform contribution to $\rho(x)$ as $\Delta n(E) = 2[\rho(0,E) - \rho_\infty(E)]/\gamma$. It is known that the potential $V(x)$ has a single bound state,[4] with associated density $\rho_b(x) = (\gamma/2)[1 - \tanh^2(\gamma x)]$ and energy level $E_b = -\gamma/2$. Thus by considering the density $\rho(x)\to(\rho(0) + \gamma/2) + (\rho_\infty - (\rho(0) + \gamma/2))\tanh^2(\gamma x)$ we include both bound and continuum states; all of our arguments above hold, down through Eq. (B5), with replacement of $\rho(0)$ by $(\rho(0) + \gamma/2)$. Equation (B6), however, holds only for the continuum states.

(Received 3 June 2003; accepted 20 February 2004; published online 17 May 2004)

The spatial correlation functions of the thermal fluctuations in systems with smoothly varying structure are calculated by means of the WKB method. As a particular physical problem we consider the behavior of director fluctuations in cholesteric liquid crystals possessing one-dimensional spatial periodicity. The problem leads to the solution of set of two second order differential equations with periodic coefficients. It is shown that in this physical system there exist regions where the WKB approximation is not valid. The analysis of these regions is similar to that of the turning points in quantum mechanics. Contrary to standard approach in our problem the turning point has fourth-order singularity and only decaying solutions have physical sense. We find WKB solutions for normal modes of director fluctuations in cholesteric liquid crystals far from the turning point as well as in its vicinity. We obtain that two fluctuating modes interact in the vicinity of the turning point, but any of these modes does not produce another. The amplitudes of modes change in such a way the product of amplitudes is constant. As a result we obtain explicit expressions for spatial correlation function in cholesteric liquid crystals with the large pitch which are valid in the entire domain. Finally we discuss the use of the correlation function in light scattering experiments. [DOI: 10.1063/1.1705717]

I. INTRODUCTION

In many physical situations such as those occurring in the vicinity of the second order phase transitions, the threshold effects, the turbulence flow, etc. the influence of fluctuations is crucial. In these systems fluctuations are not small and their interaction is essential. Various approaches were developed for describing the behavior of such systems.[1–3]

However there are some obstacles in calculations of fluctuations even in the simplest Gaussian approximation. Formally calculation of the fluctuation spatial correlation function in homogeneous systems requires the matrix conversion. There exists no standard approach for this problem in the case of inhomogeneous systems. Particularly this problem appears in physics of liquid crystals—liquids in which ordering of orientation can be established.[4] This ordering exists due to interaction with surfaces of a cell or due to external electric or magnetic fields. Depending on types of molecules and geometry of the cells the structure of liquid crystals can be both simple (spatially homogeneous) and rather complex [spiral and cubic structures in cholesteric liquid crystals (CLC) in the ordered and blue phases; twist-cells in nematic liquid crystals (NLC); various structures in spherical droplets of liquid crystals, etc]. As far as the energy of the orientation melting in liquid crystals is small the thermal fluctuations in these systems are large, and the correlation length of

[a]Electronic mail: aksev@mail.ru
[b]Electronic mail: v.romanov@pobox.spbu.ru
[c]Electronic mail: alexvalk@mail.ru

the spatial correlation function is not small either. These fluctuations noticeably influence physical properties of liquid crystals and first of all their optical properties. Since liquid crystals with complex spatial structure are intensively used in recent developments of various technical devices of information mapping, the problem of accurate account of thermal fluctuations and, first of all spatial correlation functions become important.

The methods of calculation of correlation functions in infinite uniform systems is well developed.[1–5] For restricted uniform systems with finite or infinite anchoring energy this problem was investigated in detail with the aid of various approaches for obtaining of the correlation functions: an expansion over eigenfunctions,[6,7] a method of the path integrals,[6,8] a method of the self-conjugate operators.[9,10] Meanwhile for systems with regular spatial structure such detailed investigations so far have not been carried out. Typical object is the cholesteric liquid crystal in the ordered phase, in this system the direction of primary orientation of molecules periodically varies along some axis and the correlation length of orientation fluctuations is comparable with the period of the structure. The problem of calculation of fluctuations in cholesterics was first analyzed by Lubensky[11] and later discussed in Refs. 12–14. The problem was solved with an assumption, that the correlation length is greater than the pitch, which allowed to reduce the problem to calculation of fluctuations in spatially homogeneous anisotropic media. In the medium with smoothly varying properties the problem of calculation of fluctuations was not yet considered. As long as the regular structure of the fluctuating system varies smoothly we use here the Wentzel–Kramers–Brillouin (WKB) approximation.[15,16] We generalize this approximation to the vector case. It is found that in our problem only damping solutions have the physical meaning. In terms of the WKB method using the damping solutions only is the specific character of the considered problem. Calculation of the fluctuating modes provided us to obtain the correlation matrix. The analysis of the obtained solution showed that there exist the regions where the WKB approximation is inapplicable. There are turning points in these regions. The method of analysis in the vicinity of these points is similar to that for the turning points in quantum mechanics.[15,16] Similar problems are known for the wave propagation theory, e.g., caustic[17] or the modes transformation,[18] and in the theory of elasticity, e.g., in the case of the Timoshenko beams.[19]

In particular, we find that two fluctuating modes interact in the vicinity of the turning point, but any of these modes does not produce another. The amplitudes of modes change in such a way the product of amplitudes is constant. It is shown that such unusual character of amplitudes behavior results from the exponential decreasing of the WKB solutions and it is consistent with general conservation law which takes place for solutions of second-order differential equations.

The paper is organized as follows. In Sec. II the basic equations describing CLC fluctuations are presented. In Sec. III the description of the WKB approach for the problem to be considered is given. In Sec. IV we calculate the correlation function of the director fluctuations far from the turning point. In Secs. V and VI the correlation function in the vicinity of the turning point is considered. In Conclusions (Sec. VII) we discuss physical consequences of the obtained results, in particular, in the light scattering problems. We consider conservation laws for WKB solutions in relaxation systems in Appendix.

II. BASIC EQUATIONS

Let us consider the cholesteric liquid crystal with the pitch directed along the z axis. Equilibrium vector of the director $\mathbf{n}^0$ in such system rotates in the (x,y) plane

$$\mathbf{n}^0(\mathbf{r})=\mathbf{n}^0(z)=(\cos\phi,\sin\phi,0), \tag{2.1}$$

where $\phi=p_0z+\phi_0$, ϕ_0 is the initial phase. The free energy of CLC has the form

$$F=F_0+\frac{1}{2}\int \mathrm{d}\mathbf{r}\{K_{11}(\nabla\cdot\mathbf{n})^2+K_{22}[\mathbf{n}\cdot(\nabla\times\mathbf{n})+p_0]^2+K_{33}(\mathbf{n}\times(\nabla\times\mathbf{n}))^2\}, \tag{2.2}$$

where F_0 is the energy of a homogeneous system, K_{ll}, $l=1,2,3$ are Frank modules, $d=2\pi/p_0$ is the pitch, $\mathbf{n}$ is the vector of the director. The distribution Eq. (2.1) minimizes the free energy Eq. (2.2).

We are interested in fluctuations of the director in CLC. Let us present the vector director as

$$\mathbf{n}(\mathbf{r})=\mathbf{n}^0(\mathbf{r})+\delta\mathbf{n}(\mathbf{r}), \tag{2.3}$$

where $\delta\mathbf{n}$ is the fluctuation of the director. In the quadratic in $\delta\mathbf{n}$ approximation the contribution of the director fluctuations to the free energy has the form

$$\delta F=\frac{1}{2}\int d\mathbf{r}\{K_{11}(\nabla\cdot\delta\mathbf{n})^2+K_{22}(\mathbf{n}^0\cdot(\nabla\times\delta\mathbf{n}))^2+K_{33}[(\delta\mathbf{n}\cdot\nabla)\mathbf{n}^0+(\mathbf{n}^0\cdot\nabla)\delta\mathbf{n}]^2\}. \tag{2.4}$$

Here we take into account the relations: $\nabla\cdot\mathbf{n}^0=0$; $\nabla\times\mathbf{n}^0=-p_0\mathbf{n}^0$, which follow from Eq. (2.1). Since $|\mathbf{n}|=|\mathbf{n}^0|=1$, in the quadratic approximation the relation $\mathbf{n}^0\cdot\delta\mathbf{n}=0$ is valid. Vector $\delta\mathbf{n}=(\delta n_x,\delta n_y,\delta n_z)$ can be parametrized in the form

$$\delta n_x=-u_1\sin\phi,\quad \delta n_y=u_1\cos\phi,\quad \delta n_z=u_2. \tag{2.5}$$

The functions u_1 and u_2 determine the director fluctuations in the plane (x,y) and along the z axis, respectively. Substituting Eq. (2.5) to Eq. (2.4) we get

$$\begin{aligned}\delta F=\frac{1}{2}\int d\mathbf{r}\{&K_{11}(-\sin\phi\partial_x u_1+\cos\phi\partial_y u_1+\partial_z u_2)^2+K_{22}[\cos\phi(\partial_y u_2-\partial_z(u_1\cos\phi))\\&+\sin\phi(\partial_z(-u_1\sin\phi)-\partial_x u_2)]^2+K_{33}[(-u_2p_0\sin\phi+\cos\phi\partial_x(-u_1\sin\phi)\\&+\sin\phi\partial_y(-u_1\sin\phi))^2+(u_2p_0\cos\phi+\cos\phi\partial_x(u_1\cos\phi)+\sin\phi\partial_y(u_1\cos\phi))^2\\&+(\cos\phi\partial_x u_2+\sin\phi\partial_y u_2)^2]\},\end{aligned} \tag{2.6}$$

where $\partial_l\equiv\partial/\partial l$, $l=x,y,z$.

We investigate the behavior of the correlation function

$$G_{kl}(\mathbf{r},\mathbf{r}_1)=\langle u_k(\mathbf{r})u_l(\mathbf{r}_1)\rangle, \tag{2.7}$$

where $k,l=1,2$, the brackets $\langle\cdots\rangle$ mean the statistical average. Due to CLC symmetry with respect to shifts in the (x,y) plane we have

$$G_{kl}(\mathbf{r},\mathbf{r}_1)=G_{kl}(\mathbf{r}_\perp-\mathbf{r}_{1\perp};z,z_1), \tag{2.8}$$

where $\mathbf{r}_\perp=(x,y)$. The correlation function of the director fluctuations

$$g_{\alpha\beta}(\mathbf{r}_{1\perp}-\mathbf{r}_{2\perp};z_1,z_2)=\langle\delta n_\alpha(\mathbf{r}_{1\perp},z_1)\delta n_\beta(\mathbf{r}_{2\perp},z_2)\rangle \tag{2.9}$$

is connected with the correlation matrix of scalar values $u_{1,2}$ by relationship

$$g_{\alpha\beta}(\mathbf{r}_\perp;z_1,z_2)=\sum_{k,l=1}^{2}G_{kl}(\mathbf{r}_\perp;z_1,z_2)h_\alpha^{(k)}(z_1)h_\beta^{(l)}(z_2), \tag{2.10}$$

where

$$\mathbf{h}^{(1)}(z)=(-\sin\phi(z),\cos\phi(z),0),\quad \mathbf{h}^{(2)}=(0,0,1). \tag{2.11}$$

Since CLC in the plane orthogonal to the z axis is spatially homogeneous it is convenient to use the two-dimensional Fourier transformation

$$u_\beta(\mathbf{r}) = \frac{1}{4\pi^2}\int \mathrm{d}^2\mathbf{q}\exp(i\mathbf{q}\cdot\mathbf{r}_\perp)u_\beta(\mathbf{q},z),$$

$$u_\beta(\mathbf{q},z) = \int \mathrm{d}^2\mathbf{r}_\perp \exp(-i\mathbf{q}\cdot\mathbf{r}_\perp)u_\beta(\mathbf{r}). \tag{2.12}$$

Then the distortion energy (2.6) has the form

$$\delta F = \frac{1}{4\pi^2}\int \mathrm{d}^2\mathbf{q}\,\delta F_q, \tag{2.13}$$

where

$$\delta F_q = \frac{1}{2}\int \mathrm{dz}\{K_{11}|\partial_z u_2 + i(-\sin\phi q_x + \cos\phi q_y)u_1|^2 + K_{22}|-\partial_z u_1 + iu_2(\cos\phi q_y - \sin\phi q_x)|^2$$
$$+ K_{33}[|u_2 p_0 + i(\cos\phi q_x + \sin\phi q_y)u_1|^2 + |u_2|^2(\cos\phi q_x + \sin\phi q_y)^2]\}. \tag{2.14}$$

We present the function δF_q as a quadratic form

$$\delta F_q = \frac{1}{2}\int \mathbf{u}^*(\mathbf{q},z)\hat{A}(\mathbf{q},z)\mathbf{u}(\mathbf{q},z)\mathrm{dz}, \tag{2.15}$$

where

$$\mathbf{u} = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$$

is the two-dimensional vector and superscript "*" denotes the complex conjugation. The $\hat{A}$ matrix represents the differential operator of the second order.

For convenience we direct the x axis along the $\mathbf{q}$ vector, so that $q_x = q$ and $q_y = 0$. In this case the $\hat{A}$ matrix has the form

$$\hat{A} = K_{11}\begin{pmatrix} q^2\sin^2\phi & iq\sin\phi\partial_z \\ iq\partial_z\sin\phi & -\partial_z^2 \end{pmatrix} + K_{22}\begin{pmatrix} -\partial_z^2 & -iq\partial_z\sin\phi \\ -iq\sin\phi\partial_z & q^2\sin^2\phi \end{pmatrix}$$
$$+ K_{33}\begin{pmatrix} q^2\cos^2\phi & -ip_0 q\cos\phi \\ ip_0 q\cos\phi & q^2\cos^2\phi + p_0^2 \end{pmatrix}, \tag{2.16}$$

where $\partial_z \equiv \partial/\partial z$. As the probability of fluctuations $w_q \sim \exp[-\delta F_q/k_B T]$, where k_B is the Boltzmann constant, T is the temperature, the calculation of the correlation function is reduced to an inversion of the matrix $\hat{A}$. This procedure is equivalent to the solution of the equation

$$\hat{A}(\mathbf{q},z)\hat{G}(\mathbf{q},z,z_1) = k_B T\delta(z-z_1)\hat{I}, \tag{2.17}$$

where $\delta(z-z_1)$ is the delta function, $\hat{I}$ is the unit matrix of the second rank.

Equation (2.17) should be supplemented by the boundary conditions. In boundless CLC the principle of correlation decay in the infinity limit, $\hat{G}(\mathbf{q},z,z_1)\to 0$ at $z\to\pm\infty$, may be used as such a condition.

Since $u_{1,2}(\mathbf{r})$ are real the correlation function in $(\mathbf{q},z)$ representation satisfies the symmetry relationship

$$G_{kl}(\mathbf{q},z,z_1) = G_{lk}^*(\mathbf{q},z_1,z). \tag{2.18}$$

Taking into account Eq. (2.16) the problem is reduced to the solution of a set of two inhomogeneous differential equations of the second order, Eq. (2.17), with periodic coefficients. General solution of this equation set satisfies the Floquet theorem. According to this theorem the solution has the form of a product of two matrix functions depending on z and z_1. One of them is periodical with a period of $2\pi/p_0$ and another one is exponential. The procedure of determining the exponents and the Fourier harmonics of the periodical function is presented for instance in Ref. 20. Director fluctuations in CLC were calculated by this method in Ref. 11. In this work large-scale fluctuations, $q/p_0 \ll 1$, were considered when the Fourier-harmonic contribution decreases rapidly with the increasing of the harmonic number. Several lowest harmonics of the correlation function were calculated. From the physical point of view the limit $q/p_0 \ll 1$ corresponds to the smecticlike liquid crystal. This conclusion was supported by the result of Ref. 11 where three-dimensional Fourier component of the correlation function similarly to smectics has the form $\hat{G}(\mathbf{q},k_\parallel) \sim (k_\parallel^2 + c_0 q^4)^{-1}$, where c_0 is a constant.

In this work we are concerned of the opposite case, $p_0/q \to 0$, when CLC is close to nematic liquid crystal. Such situation corresponds to CLC with a large pitch. Complication of the problem from the point of view of the usual approach[11] is related to the fact that the wide spectrum of harmonics contributes to the correlation function. In this case the method based on the Floquet theorem[21] is not effective and the WKB approximation with the large parameter $\Omega = q/p_0 \gg 1$ seems to be more promising.

III. APPLICATION OF THE WKB METHOD TO SOLUTION OF THE PROBLEM

Equation (2.17) and the condition of correlation decay at $z \to \pm\infty$ determine the Green's function. Since for $z \neq z_1$ Eq. (2.17) becomes homogeneous we start with solution of homogeneous equations at $z > z_1$ and $z < z_1$. Then, using the conditions of function continuity and a jump of the derivative we construct the Green's function.

In what follows it is convenient to introduce the dimensionless variable $\xi = p_0 z$. Then the system of homogeneous equations is presented as

$$\left[-\begin{pmatrix} K_{22} & 0 \\ 0 & K_{11} \end{pmatrix} \frac{d^2}{d\xi^2} + i\Omega (K_{11} - K_{22}) \sin\phi \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \frac{d}{d\xi} + \begin{pmatrix} \Omega^2 (K_{11} \sin^2\phi + K_{33} \cos^2\phi) & -i\Omega \cos\phi (K_{22} + K_{33}) \\ i\Omega \cos\phi (K_{11} + K_{33}) & \Omega^2 (K_{22} \sin^2\phi + K_{33} \cos^2\phi) + K_{33} \end{pmatrix} \right] \mathbf{u}(\xi) = 0. \quad (3.1)$$

This system has four linearly independent solutions. Due to boundary conditions for $\hat{G}$, we use linearly independent solutions of Eq. (3.1) for construction of two matrices, $\hat{u}_1(\xi)$ and $\hat{u}_2(\xi)$, so that $\hat{u}_1(\xi) \to \hat{0}$ at $\xi \to +\infty$ and $\hat{u}_2(\xi) \to \hat{0}$ at $\xi \to -\infty$.

The Green's function is sought in the form

$$\hat{G}(\xi,\xi_1) = \begin{cases} \hat{u}_1(\xi)\hat{v}_1(\xi_1) & \text{at } \xi > \xi_1, \\ \hat{u}_2(\xi)\hat{v}_2(\xi_1) & \text{at } \xi < \xi_1, \end{cases} \quad (3.2)$$

where $\hat{v}_1$ and $\hat{v}_2$ are 2×2 matrices depending on ξ_1 only. For determination of eight elements of these matrices we use the conditions of the Green's function continuity and of the first derivative jump at the point $\xi = \xi_1$,

$$\hat{G}(\xi_1 + 0, \xi_1) = \hat{G}(\xi_1 - 0, \xi_1),$$
$$\hat{K}\left[\left.\frac{d\hat{G}}{d\xi}\right|_{\xi=\xi_1-0} - \left.\frac{d\hat{G}}{d\xi}\right|_{\xi=\xi_1+0} \right] = \frac{k_B T}{p_0} \hat{I}, \quad (3.3)$$

where

$$\hat{K}=\begin{pmatrix} K_{22} & 0 \\ 0 & K_{11} \end{pmatrix}.$$

Substituting Eq. (3.2) into Eq. (3.3) we obtain the system of eight equations for the elements of the $\hat{v}_{1,2}$ matrices

$$\begin{aligned} \hat{u}_1(\xi_1)\hat{v}_1(\xi_1)-\hat{u}_2(\xi_1)\hat{v}_2(\xi_1)=0, \\ \hat{u}_1'(\xi_1)\hat{v}_1(\xi_1)-\hat{u}_2'(\xi_1)\hat{v}_2(\xi_1)=-k_BTp_0^{-1}\hat{K}^{-1}. \end{aligned} \tag{3.4}$$

Solution of this system is

$$\hat{v}_j=k_BTp_0^{-1}\hat{u}_j^{-1}(\hat{u}_2'\hat{u}_2^{-1}-\hat{u}_1'\hat{u}_1^{-1})^{-1}\hat{K}^{-1}, \quad j=1,2. \tag{3.5}$$

Substituting Eq. (3.5) into Eq. (3.2) we get the Green's function in the form

$$\hat{G}(\xi,\xi_1)=\frac{k_BT}{p_0}\times\begin{cases} \hat{u}_1(\xi)\hat{u}_1^{-1}(\xi_1)(\hat{u}_2'\hat{u}_2^{-1}-\hat{u}_1'\hat{u}_1^{-1})^{-1}(\xi_1)\hat{K}^{-1} & \text{at } \xi\geqslant\xi_1, \\ \hat{u}_2(\xi)\hat{u}_2^{-1}(\xi_1)(\hat{u}_2'\hat{u}_2^{-1}-\hat{u}_1'\hat{u}_1^{-1})^{-1}(\xi_1)\hat{K}^{-1} & \text{at } \xi<\xi_1. \end{cases} \tag{3.6}$$

Note that the choice of the $\hat{u}_1$ and $\hat{u}_2$ matrices is ambiguous due to arbitrariness in the normalization of the $\hat{u}_1$ and $\hat{u}_2$ columns. But this ambiguity is not essential in Eq. (3.6). Note also that the calculation of the Green's function using the solutions of the homogeneous equations does not require the large parameter Ω.

We construct the solutions of the homogeneous equation set (3.1) by the WKB method. For this purpose it is convenient to reduce Eq. (3.1) to a system of four equations of the first order. Introducing the **v** vector

$$\mathbf{v}=\frac{1}{i\Omega}\frac{\mathrm{d}}{\mathrm{d}\xi}\mathbf{u}, \tag{3.7}$$

we may present Eq. (3.1) in the form

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\boldsymbol{\Psi}=(i\Omega\hat{B}+\hat{C})\boldsymbol{\Psi}. \tag{3.8}$$

Here we use the following notations:

$$\boldsymbol{\Psi}=\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix}, \quad \hat{B}=\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ b_1 & 0 & 0 & b_3 \\ 0 & b_2 & b_4 & 0 \end{pmatrix}, \quad \hat{C}=\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & c_1 & 0 & 0 \\ c_2 & c_3 & 0 & 0 \end{pmatrix}, \tag{3.9}$$

where

$$b_1=-(K_{11}\sin^2\phi+K_{33}\cos^2\phi)K_{22}^{-1}, \quad b_3=(K_{11}-K_{22})\sin\phi K_{22}^{-1},$$

$$b_2=-(K_{22}\sin^2\phi+K_{33}\cos^2\phi)K_{11}^{-1}, \quad b_4=(K_{11}-K_{22})\sin\phi K_{11}^{-1},$$

$$c_1=-(K_{22}+K_{33})\cos\phi K_{22}^{-1}, \quad c_2=(K_{11}+K_{33})\cos\phi K_{11}^{-1}, \quad c_3=-iK_{33}(K_{11}\Omega)^{-1}.$$

We accept as an initial condition the value of $\boldsymbol{\Psi}$ in $\xi=\xi_0$. Then the solution of Eq. (3.8) can be presented in the form

$$\mathbf{\Psi}(\xi)=\hat{M}(\xi,\xi_0)\mathbf{\Psi}(\xi_0), \tag{3.10}$$

where $\hat{M}(\xi,\xi_0)$ is the matrix of evolution satisfying the initial condition $\hat{M}(\xi_0,\xi_0)=\hat{I}$. We calculate this matrix taking into account terms of the first and the second order with respect to the Ω parameter. Substituting Eq. (3.10) into equation set (3.8), we get the equation for the matrix of evolution $\hat{M}(\xi,\xi_0)$,

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\hat{M}(\xi,\xi_0)=(i\Omega\hat{B}+\hat{C})\hat{M}(\xi,\xi_0). \tag{3.11}$$

For solution of this set of equations it is convenient to introduce a new variable chosen in such a way that in principal order over the Ω parameter the equation set becomes diagonal. To do so we present $\hat{M}(\xi,\xi_0)$ as

$$\hat{M}(\xi,\xi_0)=\hat{U}(\xi)\hat{H}(\xi,\xi_0), \tag{3.12}$$

where $\hat{H}(\xi,\xi_0)$ is a new variable, $\hat{H}(\xi_0,\xi_0)=\hat{U}^{-1}(\xi_0)$. The choice of the $\hat{U}$ matrix will be discussed later. Substituting Eq. (3.12) into Eq. (3.11) we get

$$\frac{\mathrm{d}\hat{H}}{\mathrm{d}\xi}=\left(i\Omega\hat{U}^{-1}\hat{B}\hat{U}+\hat{U}^{-1}\hat{C}\hat{U}-\hat{U}^{-1}\frac{\mathrm{d}\hat{U}}{\mathrm{d}\xi}\right)\hat{H}. \tag{3.13}$$

Let us select $\hat{U}(\xi)$ so that the matrix $\hat{U}^{-1}\hat{B}\hat{U}$ becomes diagonal

$$\hat{U}^{-1}\hat{B}\hat{U}=\hat{\Lambda}, \tag{3.14}$$

where the diagonal matrix $\hat{\Lambda}$ is composed of eigenvalues of the $\hat{B}$ matrix. The columns of the $\hat{U}$ matrix are eigenvectors of the $\hat{B}$ matrix. Then the equation (3.13) for the $\hat{H}$ matrix can be written in the form

$$\frac{\mathrm{d}\hat{H}}{\mathrm{d}\xi}=i\Omega\left[\hat{\Lambda}+\frac{i}{\Omega}\left(\hat{U}^{-1}\frac{\mathrm{d}\hat{U}}{\mathrm{d}\xi}-\hat{U}^{-1}\hat{C}\hat{U}\right)\right]\hat{H}. \tag{3.15}$$

In zero approximation we omit the term of the $1/\Omega$ order in the right-hand side of Eq. (3.15). Then Eq. (3.15) is transformed to a set of independent equations

$$\frac{\mathrm{d}\hat{H}_{(0)}}{\mathrm{d}\xi}=i\Omega\hat{\Lambda}\hat{H}_{(0)}. \tag{3.16}$$

Its solution is

$$\hat{H}_{(0)}(\xi,\xi_0)=\exp\left[i\Omega\int_{\xi_0}^{\xi}\hat{\Lambda}(\xi')\mathrm{d}\xi'\right]\hat{U}^{-1}(\xi_0). \tag{3.17}$$

In order to solve Eq. (3.15) in the first approximation we present $\hat{H}(\xi,\xi_0)$ in the form

$$\hat{H}(\xi,\xi_0)=\hat{U}_{(1)}(\xi)\hat{H}_{(1)}(\xi,\xi_0), \tag{3.18}$$

where $\hat{H}_{(1)}(\xi_0,\xi_0)=\hat{U}_{(1)}^{-1}(\xi_0)\hat{U}^{-1}(\xi_0)$, and obtain the equation for $\hat{H}_{(1)}(\xi,\xi_0)$,

$$\frac{\mathrm{d}\hat{H}_{(1)}}{\mathrm{d}\xi}=i\Omega\left\{\hat{U}_{(1)}^{-1}\left[\hat{\Lambda}+\frac{i}{\Omega}\left(\hat{U}^{-1}\frac{\mathrm{d}\hat{U}}{\mathrm{d}\xi}-\hat{U}^{-1}\hat{C}\hat{U}\right)\right]\hat{U}_{(1)}+\frac{i}{\Omega}\hat{U}_{(1)}^{-1}\frac{\mathrm{d}\hat{U}_{(1)}}{\mathrm{d}\xi}\right\}\hat{H}_{(1)}. \tag{3.19}$$

Let us choose the $\hat{U}_{(1)}(\xi)$ matrix so that

$$\hat{U}_{(1)}^{-1}\left[\hat{\Lambda}+\frac{i}{\Omega}\left(\hat{U}^{-1}\frac{d\hat{U}}{d\xi}-\hat{U}^{-1}\hat{C}\hat{U}\right)\right]\hat{U}_{(1)}=\hat{\Lambda}_{(1)}, \tag{3.20}$$

where $\hat{\Lambda}_{(1)}$ is a diagonal matrix composed of eigenvalues of the matrix in square brackets of Eq. (3.20). Then Eq. (3.19) can be written as

$$\frac{d\hat{H}_{(1)}}{d\xi}=\left(i\Omega\hat{\Lambda}_{(1)}-\hat{U}_{(1)}^{-1}\frac{d\hat{U}_{(1)}}{d\xi}\right)\hat{H}_{(1)}. \tag{3.21}$$

For $\Omega\gg 1$ the matrix $\hat{\Lambda}+i\Omega^{-1}(\hat{U}^{-1}\hat{U}'-\hat{U}^{-1}\hat{C}\hat{U})$ is close to $\hat{\Lambda}$, so that matrices $\hat{\Lambda}$ and $\hat{\Lambda}_{(1)}$ are close to each other and $\hat{U}_{(1)}$ matrix is close to the unit one, i.e.,

$$\hat{U}_{(1)}(\xi)\approx\hat{I}+i\Omega^{-1}\hat{V}(\xi),\quad \hat{U}_{(1)}^{-1}(\xi)\approx\hat{I}-i\Omega^{-1}\hat{V}(\xi). \tag{3.22}$$

These expressions allow to get the condition of the WKB method applicability,

$$|V_{lm}|\ll\Omega.$$

Substituting (3.22) into Eq. (3.20), for $\hat{\Lambda}_{(1)}$ and $\hat{V}$ we get

$$(\hat{\Lambda}_{(1)})_{ll}\approx i\mu_l+\frac{i}{\Omega}\left(\hat{U}^{-1}\frac{d\hat{U}}{d\xi}-\hat{U}^{-1}\hat{C}\hat{U}\right)_{ll}, \tag{3.23}$$

$$V_{lm}\approx\frac{1}{i(\mu_m-\mu_l)}\left(\hat{U}^{-1}\frac{d\hat{U}}{d\xi}-\hat{U}^{-1}\hat{C}\hat{U}\right)_{lm},\quad l\neq m, \tag{3.24}$$

where $\mu_l=\Lambda_{ll}/i$. It follows from Eqs. (3.23) and (3.24) that the second term in brackets (3.21) is of the $1/\Omega^2$ order, so that it may be omitted in the first approximation. So we get

$$\hat{H}_{(1)}(\xi,\xi_0)\approx\exp\left[i\Omega\int_{\xi_0}^{\xi}\hat{\Lambda}_{(1)}(\xi')d\xi'\right]\hat{U}_{(1)}^{-1}(\xi_0)\hat{U}^{-1}(\xi_0). \tag{3.25}$$

If we omit terms of the $1/\Omega$ order in the $\hat{U}_{(1)}$ and $\hat{U}_{(1)}^{-1}$ matrices the evolution matrix $\hat{M}(\xi,\xi_0)$ in the first approximation has the form

$$\hat{M}(\xi,\xi_0)\approx\hat{U}(\xi)\widehat{\mathrm{diag}}\left\{\exp\left[-\int_{\xi_0}^{\xi}(\Omega\mu_l(x)+(\hat{U}^{-1}(x)\hat{U}'(x)-\hat{U}^{-1}(x)\hat{C}(x)\hat{U}(x))_{ll})dx\right]\right\}\hat{U}^{-1}(\xi_0). \tag{3.26}$$

This formula is a vector analogue of the classical WKB approximation.

According to Eq. (3.26) vector $\boldsymbol{\Psi}$ has the form

$$\boldsymbol{\Psi}(\xi)\approx\hat{U}(\xi)\widehat{\mathrm{diag}}\left\{\exp\left[-\int_{\xi_0}^{\xi}(\Omega\mu_l(x)+(\hat{U}^{-1}(x)\hat{U}'(x)-\hat{U}^{-1}(x)\hat{C}(x)\hat{U}(x))_{ll})dx\right]\right\}$$
$$\times\hat{U}^{-1}(\xi_0)\boldsymbol{\Psi}(\xi_0), \tag{3.27}$$

where $i\mu_l$ are eigenvalues of the $\hat{B}$ matrix and the columns of the $\hat{U}$ matrix are eigenvectors of the $\hat{B}$ matrix. Note that this expression for the $\mathbf{\Psi}$ vector is not valid, if the eigenvalues of the $\hat{B}$ matrix are becoming close to each other. Indeed, as it is seen from Eq. (3.24) in this case V_{lm} becomes large and condition of the WKB method validity, $|V_{lm}| \ll \Omega$, is violated.

Equation (3.27) allows to get the solution of Eq. (3.8) for any boundary conditions. The solution of Eq. (3.8) in the form (3.27) can be considered as a linear combination of four linearly independent vectors representing the columns of the evolution matrix $\hat{M}(\xi,\xi_0)$, with four factors representing the elements of the $\mathbf{\Psi}(\xi_0)$ vector. In what follows it is convenient to use $\hat{M}(\xi,\xi_0)\hat{U}(\xi_0)$ instead of the $\hat{M}(\xi,\xi_0)$ matrix and $\hat{U}^{-1}(\xi_0)\mathbf{\Psi}(\xi_0)$ instead of the $\mathbf{\Psi}(\xi_0)$ vector.

The solutions $\mathbf{u}$ which represent the first and the second components of the $\mathbf{\Psi}(\xi)$ vector are necessary for construction of the Green's function. The columns of the $\hat{u}_{1,2}(\xi)$ matrices are vectors constructed of first two elements of columns of the $\hat{M}(\xi,\xi_0)\hat{U}(\xi_0)$ matrix or linear combinations of these vectors.

IV. CALCULATION OF THE CORRELATION FUNCTION

In order to get the Green's function, i.e., the correlation function, in an explicit form we calculate the matrix of evolution. For this purpose it is necessary to calculate the eigenvalues and eigenvectors of the $\hat{B}$ matrix. The eigenvalues are determined from the relation

$$\det(\hat{B} - i\mu\hat{I}) = 0, \tag{4.1}$$

which represents the biquadratic equation. The solutions of this equation are

$$\begin{gathered} \mu_l = \sqrt{\sin^2\phi + K_{33}K_{ll}^{-1}\cos^2\phi}, \quad l = 1,2, \\ \mu_3 = -\mu_1, \quad \mu_4 = -\mu_2. \end{gathered} \tag{4.2}$$

Eigenvectors $\boldsymbol{\psi}_l$ satisfy the relation $\hat{B}\boldsymbol{\psi}_l = i\mu_l\boldsymbol{\psi}_l$. The matrix $\hat{U} = (\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \boldsymbol{\psi}_3, \boldsymbol{\psi}_4)$ composed of these vectors has the form

$$\hat{U} = \begin{pmatrix} -i\sin\phi\mu_1^{-1} & 1 & i\sin\phi\mu_1^{-1} & -1 \\ -1 & -i\sin\phi\mu_2^{-1} & -1 & -i\sin\phi\mu_2^{-1} \\ \sin\phi & i\mu_2 & \sin\phi & i\mu_2 \\ -i\mu_1 & \sin\phi & i\mu_1 & -\sin\phi \end{pmatrix}. \tag{4.3}$$

There is an arbitrariness in the choice of the $\boldsymbol{\psi}_l$ vectors due to normalizing factors. But it is possible to show, that solution (3.27) does not depend on normalizing conditions of the eigenvectors. Further we calculate the inverse matrix $\hat{U}^{-1}$,

$$\hat{U}^{-1} = \frac{-1}{2K_{33}\cos^2\phi} \begin{pmatrix} iK_{11}\mu_1\sin\phi & K_{22}\mu_2^2 & K_{22}\sin\phi & -iK_{11}\mu_1 \\ -K_{11}\mu_1^2 & iK_{22}\mu_2\sin\phi & iK_{22}\mu_2 & K_{11}\sin\phi \\ -iK_{11}\mu_1\sin\phi & K_{22}\mu_2^2 & K_{22}\sin\phi & iK_{11}\mu_1 \\ K_{11}\mu_1^2 & iK_{22}\mu_2\sin\phi & iK_{22}\mu_2 & -K_{11}\sin\phi \end{pmatrix}. \tag{4.4}$$

In the $\hat{C}$ matrix we neglect the term of the $1/\Omega$ order since it has order of smallness higher than the approximation (3.27) for the matrix of evolution. Then we have

$$(\hat{U}^{-1}\hat{C}\hat{U})_{ll} = (-1)^{l+1}(K_{11} - K_{22})(2K_{33})^{-1}\tan\phi, \quad l = 1,...,4. \tag{4.5}$$

It is convenient to present the diagonal elements of $\hat{U}^{-1}(d\hat{U}/\mathrm{d}\xi)$ matrix in the form

$$\left(\hat{U}^{-1}\frac{d\hat{U}}{d\xi}\right)_{ll}=\frac{1}{2}\frac{(\cos\phi/\mu_l)'}{\cos\phi/\mu_l}+\frac{1}{2}\frac{(\cos\phi)'}{\cos\phi}-\frac{K_{11}-K_{22}}{2K_{33}}\frac{(\cos\phi)'}{\cos\phi}(-1)^{l+1},\quad l=1,...,4. \tag{4.6}$$

From Eqs. (4.5) and (4.6) we get

$$\int_{\xi_0}^{\xi}\left(\hat{U}^{-1}\hat{C}\hat{U}-\hat{U}^{-1}\frac{d\hat{U}}{d\xi'}\right)_{ll}d\xi'=-\frac{1}{2}\ln\frac{\mu_l(\xi_0)|\cos\phi|}{\mu_l(\xi)|\cos(\xi_0+\phi_0)|}-\frac{1}{2}\ln\frac{|\cos\phi|}{|\cos(\xi_0+\phi_0)|}. \tag{4.7}$$

Thus we found all expressions entering Eq. (3.27). Using expression (4.7) it is possible to write the evolution matrix in the form

$$\hat{M}(\xi,\xi_0)=\hat{U}(\xi)\frac{|\cos(\xi_0+\phi_0)|}{|\cos\phi|}\widehat{\mathrm{diag}}\left\{\sqrt{\frac{\mu_l(\xi)}{\mu_l(\xi_0)}}\exp\left(-\int_{\xi_0}^{\xi}\Omega\mu_l\,d\xi'\right)\right\}\hat{U}^{-1}(\xi_0). \tag{4.8}$$

For determination of the correlation function it is necessary to construct the matrices $\hat{u}_1(\xi)$ and $\hat{u}_2(\xi)$. Selecting the solutions for the $\mathbf{\Psi}(\xi)$ vector, Eq. (3.10), which displays the required behavior at the infinity we obtain

$$\hat{u}_1(\xi)=\begin{pmatrix}-i\sin\phi\mu_1^{-1} & 1\\ -1 & -i\sin\phi\mu_2^{-1}\end{pmatrix}\exp(\hat{\Phi}_-),$$

$$\hat{u}_2(\xi)=\begin{pmatrix}i\sin\phi\mu_1^{-1} & -1\\ -1 & -i\sin\phi\mu_2^{-1}\end{pmatrix}\exp(\hat{\Phi}_+), \tag{4.9}$$

where

$$\exp(\hat{\Phi}_\pm)=\frac{|\cos(\xi_0+\phi_0)|}{|\cos\phi|}\widehat{\mathrm{diag}}\left\{\sqrt{\frac{\mu_l(\xi)}{\mu_l(\xi_0)}}\exp\left(\pm\int_{\xi_0}^{\xi}\Omega\mu_l\,d\xi'\right)\right\},\quad l=1,2. \tag{4.10}$$

It is easy to check that under this choice of the $\hat{u}_{1,2}(\xi)$ matrices the conditions $\hat{u}_1(\xi)\to\hat{0}$ at $\xi\to+\infty$ and $\hat{u}_2(\xi)\to\hat{0}$ at $\xi\to-\infty$ are valid. Substituting the $\hat{u}_{1,2}(\xi)$ matrices, Eq. (4.9), into expression for the correlation function, Eq. (3.6), and neglecting terms of the $1/\Omega$ order in non-exponential factors we get the correlation function in the form

$$\begin{aligned}\hat{G}(\xi,\xi_1)=&\frac{k_BT}{2qK_{33}\cos\phi(\xi_1)\cos\phi(\xi)}\begin{pmatrix}\mathrm{sign}(\xi-\xi_1)\sin\phi(\xi) & \mathrm{sign}(\xi-\xi_1)i\mu_2(\xi)\\ -i\mu_1(\xi) & \sin\phi(\xi)\end{pmatrix}\\ &\times\begin{pmatrix}\dfrac{\exp\left(-\Omega\left|\int_{\xi}^{\xi_1}\mu_1\,d\xi'\right|\right)}{\sqrt{\mu_1(\xi)\mu_1(\xi_1)}} & 0\\ 0 & \dfrac{\exp\left(-\Omega\left|\int_{\xi}^{\xi_1}\mu_2\,d\xi'\right|\right)}{\sqrt{\mu_2(\xi)\mu_2(\xi_1)}}\end{pmatrix}\\ &\times\begin{pmatrix}\mathrm{sign}(\xi_1-\xi)\sin\phi(\xi_1) & i\mu_1(\xi_1)\\ \mathrm{sign}(\xi_1-\xi)i\mu_2(\xi_1) & -\sin\phi(\xi_1)\end{pmatrix}.\end{aligned} \tag{4.11}$$

This expression has a simple structure. It is composed of a diagonal matrix and two matrices which turn the coordinate frame in ξ and ξ_1 points.

It is convenient to split the $\hat{G}$ matrix into two parts, associated with two modes μ_1 and μ_2. We have

$$\hat{G}(\mathbf{q};z_1,z_2)=\hat{G}^{(1)}(\mathbf{q};z_1,z_2)+\hat{G}^{(2)}(\mathbf{q};z_1,z_2), \tag{4.12}$$

where

$$\hat{G}^{(j)}(\mathbf{q};z_1,z_2)=\frac{k_BT}{2qK_{33}\cos\phi(z_1)\cos\phi(z_2)}\exp\left(-q\left|\int_{z_1}^{z_2}\mu_j(z)\mathrm{d}z\right|\right)\hat{W}^{(j)}(\mathbf{q};z_1,z_2), \tag{4.13}$$

$$\hat{W}^{(1)}(\mathbf{q},z_1,z_2)=\begin{pmatrix} -\dfrac{\sin\phi(z_1)\sin\phi(z_2)}{\sqrt{\mu_1(z_1)\mu_1(z_2)}} & i\,\mathrm{sign}(z_1-z_2)\sin\phi(z_1)\dfrac{\sqrt{\mu_1(z_2)}}{\sqrt{\mu_1(z_1)}} \\ i\,\mathrm{sign}(z_1-z_2)\sin\phi(z_2)\dfrac{\sqrt{\mu_1(z_1)}}{\sqrt{\mu_1(z_2)}} & \sqrt{\mu_1(z_1)\mu_1(z_2)} \end{pmatrix}, \tag{4.14}$$

$$\hat{W}^{(2)}(\mathbf{q},z_1,z_2)=-\begin{pmatrix} -\sqrt{\mu_2(z_1)\mu_2(z_2)} & i\,\mathrm{sign}(z_1-z_2)\sin\phi(z_2)\dfrac{\sqrt{\mu_2(z_1)}}{\sqrt{\mu_2(z_2)}} \\ i\,\mathrm{sign}(z_1-z_2)\sin\phi(z_1)\dfrac{\sqrt{\mu_2(z_2)}}{\sqrt{\mu_2(z_1)}} & \dfrac{\sin\phi(z_1)\sin\phi(z_2)}{\sqrt{\mu_2(z_1)\mu_2(z_2)}} \end{pmatrix}. \tag{4.15}$$

Here $\cos\phi=\mathbf{q}\cdot\mathbf{n}^0/q$, $\sin\phi=\sqrt{q^2-(\mathbf{q}\cdot\mathbf{n}^0)^2}/q$ are presented in the form independent on the coordinate frame choice.

Figure 1 shows the correlation matrix components, G_{11} and G_{12}, in arbitrary units. These functions are obtained from Eqs. (4.12)–(4.15). Here G_{12} is imaginary. Both components decrease exponentially with the distance $\xi-\xi_1$. For $\xi=\xi_1$ the component G_{11} has a peak and the value of this peak increases with the growth of ξ. When we approach the point $\phi=\xi+\phi_0=\pi/2$ the functions G_{11} and G_{12} tend to infinity.

We analyze the behavior of the expression (4.12) for $p_0\to 0$. In this limit Eq. (4.12) describes the nematic liquid crystal. If we set $p_0=0$, then $\phi(z)\equiv\phi_0$ and Eq. (4.12) takes the form

$$\begin{aligned}\hat{G}(\mathbf{q};z-z_1)=&\frac{k_BT\exp(-q\mu_1|z-z_1|)}{2qK_{33}\cos^2\phi_0}\begin{pmatrix} -\mu_1^{-1}\sin^2\phi_0 & i\,\mathrm{sign}(z-z_1)\sin\phi_0 \\ i\,\mathrm{sign}(z-z_1)\sin^2\phi_0 & \mu_1 \end{pmatrix}\\ &+\frac{k_BT\exp(-q\mu_2|z-z_1|)}{2qK_{33}\cos^2\phi_0}\begin{pmatrix} \mu_2 & -i\,\mathrm{sign}(z-z_1)\sin\phi_0 \\ -i\,\mathrm{sign}(z-z_1)\sin\phi_0 & -\mu_2^{-1}\sin^2\phi_0 \end{pmatrix}.\end{aligned} \tag{4.16}$$

Note, that there is an indeterminacy in Eq. (4.16) at $\phi_0\to\pi/2$, which can be easily removed. It results in the finite expression for $\phi_0=\pi/2$. Therefore the correlation function has no singularities in the vicinity of this point.

Performing Fourier transform over the $z-z_1$ variable in Eq. (4.16) and using Eq. (2.10) we obtain well-known De Gennes expression[4] for the correlation function of the director fluctuations in NLC,

$$g_{\alpha\beta}(\mathbf{k})=k_BT\sum_{l=1,2}\frac{e_{l\alpha}(\mathbf{k})e_{l\beta}(\mathbf{k})}{K_{33}(\mathbf{n}^0\cdot\mathbf{k})^2+K_{ll}(k^2-(\mathbf{n}^0\cdot\mathbf{k})^2)}, \tag{4.17}$$

where $\mathbf{k}=(\mathbf{q},q_z)$, $\mathbf{e}_l\perp\mathbf{n}^0$, $|\mathbf{e}_l|=1$, $\mathbf{e}_1\perp\mathbf{e}_2$, $\mathbf{e}_1\parallel\mathbf{k}-\mathbf{n}^0(\mathbf{n}^0\cdot\mathbf{k})$.

It is interesting to compare our result, Eq. (4.12) for the correlation function $\hat{G}(\mathbf{q};z_1,z_2)$, which is valid for $q\gg p_0$ (“nematiclike” CLC), to the results for the opposite case $q\ll p_0$ (“smec-

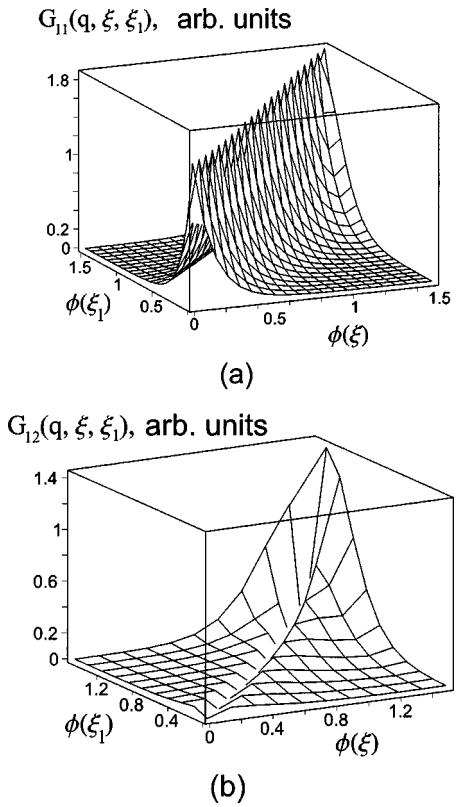

FIG. 1. The $G_{11}(\mathbf{q},\xi,\xi_1)$ (a) and $G_{12}(\mathbf{q},\xi,\xi_1)$ (b) components of the correlation function as a function of ξ and ξ_1 expressed in the same arbitrary units. Here $K_{11}=5.0\times10^{-6}$ dyne, $K_{22}=3.0\times10^{-6}$ dyne, $K_{33}=7.0\times10^{-6}$ dyne.

ticlike'' CLC).[11] For simplicity we consider the case, where all three elastic constants (the Frank modules) are equal $K_{11}=K_{22}=K_{33}=K$. We are interested in behavior of $\hat{G}(\mathbf{q};z_1,z_2)$ as a function of the wave vector module q and the z_1-z_2 variable.

According to Eq. (4.12) all components of the correlation function $\hat{G}$ for the case $q\gg p_0$ behave as

$$G_{kl}(\mathbf{q};z_1,z_2)\sim q^{-1}\exp(-q|z_1-z_2|). \tag{4.18}$$

On the other hand, three-dimensional Fourier-components of the correlation function in the case $q\ll p_0$ have the form[12]

$$\tilde{G}_{11}(\mathbf{q},q_z)=\frac{2p_0^2k_BT}{K(2p_0^2q_z^2+q^2q_z^2+q^4)},$$
$$\tilde{G}_{22}(\mathbf{q},q_z)=\frac{k_BT}{K(p_0^2+q^2+q_z^2)},\quad \tilde{G}_{12}=\tilde{G}_{21}=0. \tag{4.19}$$

Expressions (4.19) have been obtained by averaging over many pitches. Therefore the modes u_1 and u_2 here do not correlate (nondiagonal elements of the correlation function are equal to zero). It differs from our approach which takes into account almost local fluctuations. However if we average Eq. (4.12) over many pitches, the matrices $\hat{W}^{(1)}$ and $\hat{W}^{(2)}$ become diagonal and we obtain $G_{12}=G_{21}=0$ as well.

Note, in this limit the director fluctuations in the plane normal to the pitch axis ($\tilde{G}_{11}$) behaves as the layer-displacement fluctuations in smectic-A liquid crystals.[4] Fluctuations along the pitch axis ($\tilde{G}_{22}$) have the form similar to the director fluctuation in nematic, Eq. (4.17), but they are bounded by the cholesteric pitch [the term p_0^2 in the denominator of $\tilde{G}_{22}$ in Eq. (4.19)].

In $(\mathbf{q},z)$-representation Eq. (4.19) has the form

$$\tilde{G}_{11}(\mathbf{q};z_1-z_2)\propto\frac{2p_0^2}{q^2\sqrt{2p_0^2+q^2}}\exp\left(-\frac{q^2|z_1-z_2|}{\sqrt{2p_0^2+q^2}}\right),$$

$$\tilde{G}_{22}(\mathbf{q};z_1-z_2)\propto\frac{1}{\sqrt{p_0^2+q^2}}\exp(-\sqrt{p_0^2+q^2}|z_1-z_0|). \tag{4.20}$$

Let analyze the behavior of expressions (4.18) and (4.20) in the intermediate range $q\simeq p_0$. Although both formulas are not valid in this range we consider extrapolation,

$$G_{kk}(p_0;z_1,z_2)\sim\frac{1}{p_0}\exp(-p_0|z_1-z_2|),$$

$$\tilde{G}_{11}(p_0;z_1,z_2)\sim\frac{2}{\sqrt{3}p_0}\exp\left(-\frac{p_0}{\sqrt{3}}|z_1-z_2|\right), \tag{4.21}$$

$$\tilde{G}_{22}(p_0;z_1,z_2)\sim\frac{1}{\sqrt{2}p_0}\exp(-\sqrt{2}p_0|z_1-z_2|).$$

It can be seen the mode amplitudes are of the similar order, but the exponents are different. Thus, their asymptotic behaviors for the cases $q\gg p_0$ and $q\ll p_0$ do not match in the range $q\simeq p_0$.

An extrapolation of the expressions (4.20) into the range $q\gg p_0$ gives

$$\begin{aligned}\tilde{G}_{11}(\mathbf{q};z_1-z_2)&\sim p_0^2q^{-3}\exp(-q|z_1-z_2|),\\ \tilde{G}_{22}(\mathbf{q};z_1-z_2)&\sim q^{-1}\exp(-q|z_1-z_2|).\end{aligned} \tag{4.22}$$

It is curious that exponential factors in Eqs. (4.22) and (4.18) coincide. But the nonexponential factors for the u_1 mode corresponding to the fluctuations in the plane perpendicular to the pitch axis (G_{11} and $\tilde{G}_{11}$) are different. The first mode is more sensitive to the pitch and its behavior significantly differs for the cases $q\ll p_0$ and $q\gg p_0$. The factors for the u_2 mode corresponding to the fluctuations along the pitch axis (G_{22} and $\tilde{G}_{22}$) coincide. It is conceivable that expression for $\tilde{G}_{22}$ is applicable in a wider domain over the q variable (just as for $q\ll p_0$, so $q\simeq p_0$, $q\gg p_0$).

Equation (4.11) loses its sense if $\cos\phi=0$ in the point ξ or ξ_1 or if the point ξ_* with $\cos\phi(\xi_*)=0$ lies between ξ and ξ_1. It follows from the fact that eigenvalues of the $\hat{B}$ matrix at these conditions coincide. As it follows from Eq. (3.24) if the values μ_l and μ_m approach each other the function V_{lm} increases and the condition of the WKB applicability, $|V_{lm}|\ll\Omega$, could be violated.

According to Eq. (4.2) $\mu_1=\mu_2=1$, $\mu_3=\mu_4=-1$ at the point $\phi=\pi/2$, and so in the vicinity of $\phi=\pi/2$ the WKB method becomes invalid.

Let us now estimate the applicability region of the WKB method. For this purpose we introduce a new variable $\zeta=p_0z+\phi_0-\pi/2=\phi-\pi/2$ and expand μ_l in a series near the $\zeta=0$ point

$$\mu_l\approx1-C_l\zeta^2/2,\quad l=1,2,$$

$$\mu_3=-\mu_1,\quad \mu_4=-\mu_2,\quad C_l=1-K_{33}/K_{ll}. \tag{4.23}$$

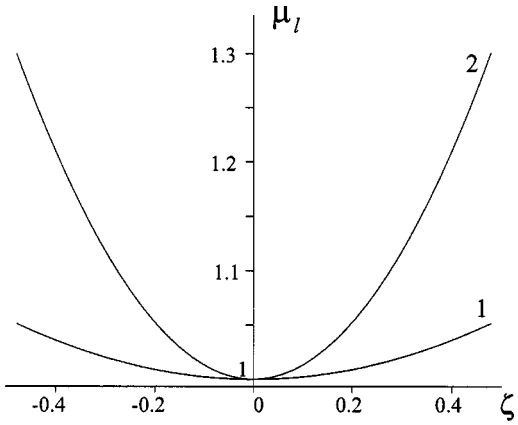

FIG. 2. The behavior of μ_1 (curve 1) and μ_2 (curve 2) in the vicinity of the $\zeta=0$ point. Here $K_{11}=2.0\times10^{-6}$ dyne, $K_{22}=0.8\times10^{-6}$ dyne, $K_{33}=2.9\times10^{-6}$ dyne.

Figure 2 shows schematically the behavior of the μ_1 and μ_2 values in the neighborhood of the turning point. Note that values $\mu_1(\xi)$ and $\mu_2(\xi)$ do not intersect but can only touch each other.

Matrix element V_{12} near the turning point, $\zeta=0$, can be estimated as

$$V_{12}\sim\zeta^{-3}(1+O(\zeta^2)).$$

Then the condition of the WKB method applicability has the form

$$\Omega|\zeta|^3\gg1. \tag{4.24}$$

It means that Eq. (4.11) is valid when $\Omega|\zeta|^3\gg1$, $\Omega|\zeta_1|^3\gg1$ and there are no points between points ζ and ζ_1 where μ_1 and μ_2 coincide.

The analysis of the correlation function behavior in the vicinity of the turning point represents a rather complicated mathematics problem. In what follows two cases will be considered:

(i) one or both variables ξ, ξ_1 are near the point $\cos\phi=0$;
(ii) ξ and ξ_1 are in the region where the WKB method is valid but between them there is the point with $\cos\phi=0$.

In both cases it is necessary to obtain the solution of Eq. (3.8) in a neighborhood of the degeneration point, $\cos\phi=0$.

V. VICINITY OF THE TURNING POINT AND CONNECTION FORMULAS FOR WKB SOLUTIONS

The problem of turning points and of matching WKB solutions has been investigated thoroughly. For scalar problems which have the form $Y''-\Gamma(X)Y=0$ one of the two following methods is usually applied. The first one is the complex plane method. The method solves the problem by contour integration in complex plane around a turning point. The method permits to match WKB solutions, but the contour of integration intersects the so-called Stokes lines where analytical extension of the WKB solutions is broken. The second and most common method is the method of model equations. In the vicinity of the turning point X_0, where $\Gamma(X_0)=0$, the function $\Gamma(X)$ is expanded over $X-X_0$. The resulting model equation depends on the $\Gamma(X)$ behavior in the vicinity of the turning point X_0. If the behavior is linear (simple turning point) we have the Airy equation and the solution is a linear combination of the Airy functions.[22] In the case $\Gamma(X)\sim(X-X_0)^m$, $m\geqslant2$ (multiple turning point of the mth order) the solution of the model equation can be expressed in terms of modified Bessel function of the second kind $K_{1/(m+2)}$. Then the solution of the model equation is used for matching WKB solutions to the left and to the right of the turning point.

Our problem has some distinctions from usual situation. First, the WKB solutions are exponentially increasing and exponentially decreasing. It involves additional difficulties for matching as it requires to consider exponentially small variable in the presence of exponentially large variable. Second, the difference of eigenvalues μ_1 and μ_2 is quadratic over $X-X_0$ in the vicinity of the turning point, which means that the turning point is of the fourth order. Third, our problem is a set of two differential equations of the second order. This multimode character is the main difficulty. For contour integration method there are six Stokes lines and we have problems with analytical extension of WKB solutions. For the second method the problem is that the model equation method gives equation of the fourth order in the vicinity of the turning point. Model equations of the fourth order and their solutions are investigated much less than the model equations of the second order.

In such a situation it is more convenient to analyze the set of four equations of the first order instead of the set of two equations of the second order. We have previously used this approach to construct the WKB solutions far from the turning point in Sec. IV [see Eq. (3.8)]. In this case peculiar character of the turning point is manifested in the nondiagonal normal form of the arising 4×4 matrix in this point, as in Eqs. (3.13) and (3.20). Instead it contains Jordan blocks. Next we expand the equations in the vicinity of the singular point and match the solutions of corresponding model equations to the WKB solutions. The 4×4 problem splits into several independent sets of the lower order separately for each Jordan block. Each of these sets produces a more simpler model equation. This approach for asymptotic solution of systems of linear differential equations was developed and applied in Refs. 23–25. As we shall see later in our problem we have two 2×2 Jordan blocks. Therefore we come to two model equations of the second order instead of the model equation of the fourth order.

It is more convenient to seek the solution for the $\mathbf{\Psi}$ vector, rather than for the matrix of evolution, $\hat{M}$. For this purpose we expand Eq. (3.8) in a series near the point $\zeta=0$,

$$\left[i\hat{B}(0)+\frac{i}{2}\hat{B}''(0)\zeta^2+\frac{i}{24}\hat{B}^{IV}(0)\zeta^4+\frac{1}{\Omega}\hat{C}'(0)\zeta+\cdots\right]\mathbf{\Psi}(\zeta)=\frac{1}{\Omega}\frac{\mathrm{d}\mathbf{\Psi}}{\mathrm{d}\zeta}. \tag{5.1}$$

The direct iterative solution of Eq. (5.1) is difficult due to existence of two small parameters, $1/\Omega$ and ζ. Therefore it is convenient to introduce a new ''stretched'' variable $\tau=\Omega^{1/3}\zeta$. We have

$$\left[i\hat{B}(0)+\frac{i}{2}\Omega^{-2/3}\tau^2\hat{B}''(0)+\Omega^{-4/3}\left(\frac{i}{24}\tau^4\hat{B}^{IV}(0)+\tau\hat{C}'(0)\right)+\cdots\right]\mathbf{\Psi}(\tau)=\Omega^{-2/3}\frac{\mathrm{d}\mathbf{\Psi}}{\mathrm{d}\tau}. \tag{5.2}$$

The terms of this equation represent series over the small parameter $\Omega^{-2/3}$, though τ is not a small parameter in contrast to ζ. Solution of this equation corresponding to μ_1 and μ_2 is sought in the form

$$\mathbf{\Psi}_1(\tau)=\exp(-\Omega^{2/3}\mu_1(0)\tau)(\mathbf{\Psi}_1^{(0)}(\tau)+\Omega^{-2/3}\mathbf{\Psi}_1^{(1)}(\tau)+\Omega^{-4/3}\mathbf{\Psi}_1^{(2)}(\tau)+\cdots), \tag{5.3}$$

where $\mu_1(0)=\mu_2(0)=1$. Substitution of $\mathbf{\Psi}_1(\tau)$ (5.3) into Eq. (5.2) reduces the latter in zero approximation to the equation for the eigenvector

$$\hat{B}(0)\mathbf{\Psi}_1^{(0)}=i\mu_1(0)\mathbf{\Psi}_1^{(0)}. \tag{5.4}$$

Solution of this equation has the form

$$\mathbf{\Psi}_1^{(0)}=\boldsymbol{\chi}_1\beta(\tau), \tag{5.5}$$

where $\boldsymbol{\chi}_1$ is the eigenvector,

$$\boldsymbol{\chi}_1=(1,-i,i,1)^T, \tag{5.6}$$

and $\beta(\tau)$ is an arbitrary function of τ. Here the superscript "T" denotes transposition.

In the first approximation we have

$$(\hat{B}(0)-i\mu_1(0)\hat{I})\mathbf{\Psi}_1^{(1)}=(-i\beta'(\tau)\hat{I}-\tfrac{1}{2}\tau^2\beta(\tau)\hat{B}''(0))\boldsymbol{\chi}_1\equiv\mathbf{R}^{(1)}, \tag{5.7}$$

where $\mathbf{R}^{(1)}$ is the four-component vector. The determinant of the equation set (5.7) is equal to zero, since $i\mu_1$ is the eigenvalue of the $\hat{B}$ matrix. The solvability condition for such systems implies that the right-hand side of Eq. (5.7) should be orthogonal to the adjoint vector $\boldsymbol{\chi}_2$, which determines by the condition

$$(\hat{B}(0)-i\mu_1(0)\hat{I})\boldsymbol{\chi}_2=\boldsymbol{\chi}_1. \tag{5.8}$$

As a solution of this equation it is possible to take

$$\boldsymbol{\chi}_2=\left(0,\frac{K_{11}+K_{22}}{K_{11}-K_{22}},1,\frac{2iK_{22}}{K_{11}-K_{22}}\right)^T. \tag{5.9}$$

Note, that at such choice of $\boldsymbol{\chi}_2$ the orthogonality condition, $\boldsymbol{\chi}_1\cdot\boldsymbol{\chi}_2=0$, is valid. It is easy to check that the solvability condition of the equation $\mathbf{R}^{(1)}\cdot\boldsymbol{\chi}_2=0$ is fulfilled automatically and is not reduce to any conditions for the $\beta(\tau)$ function. Therefore for determination of the $\beta(\tau)$ function it is necessary to take into account the solvability condition for the second approximation.

As a first step it is necessary to find the $\mathbf{\Psi}_1^{(1)}$ vector. We shall seek it as a linear combination of two eigenvectors, $\boldsymbol{\chi}_1$ and $\boldsymbol{\chi}_3$, and corresponding adjoint vectors, $\boldsymbol{\chi}_2$ and $\boldsymbol{\chi}_4$. Here $\boldsymbol{\chi}_3$ is the eigenvector corresponding to the eigenvalue $i\mu_3(0)$

$$\boldsymbol{\chi}_3=(-1,-i,i,-1)^T,\quad \boldsymbol{\chi}_4=\left(0,-\frac{K_{11}+K_{22}}{K_{11}-K_{22}},-1,\frac{2iK_{22}}{K_{11}-K_{22}}\right)^T. \tag{5.10}$$

Vectors $\boldsymbol{\chi}_l$, $l=1,...,4$ can be considered as a basis. If we expand $\mathbf{R}^{(1)}$ over this basis, $\mathbf{R}^{(1)}=\Sigma_{k=1}^{4}\mathrm{d}_k(\tau)\boldsymbol{\chi}_k$, the condition of solvability has the form $(\hat{P}^{-1}\mathbf{R}^{(1)})_2=\mathrm{d}_2(\tau)=0$, where

$$\hat{P}=(\boldsymbol{\chi}_1,\boldsymbol{\chi}_2,\boldsymbol{\chi}_3,\boldsymbol{\chi}_4). \tag{5.11}$$

We seek $\mathbf{\Psi}_1^{(1)}$ as a linear combination of vectors $\boldsymbol{\chi}_l$, $l=1,...,4$

$$\mathbf{\Psi}_1^{(1)}=\sum_{k=1}^{4}a_k(\tau)\boldsymbol{\chi}_k. \tag{5.12}$$

It is possible to assume that $a_1=0$ since $\mathbf{\Psi}_1^{(0)}$ already contains the $\boldsymbol{\chi}_1$ vector and the coefficient a_1 is related to the normalization condition of the $\mathbf{\Psi}_1$ vector, which can be selected arbitrarily.

If we substitute $\mathbf{\Psi}_1^{(1)}$ in the form (5.12) to the first approximation (5.7) and multiply the right- and left-hand sides of the obtained equation by $\hat{P}^{-1}$ we obtain a system of four equations connecting three factors a_2, a_3, and a_4. The second of the obtained equations is the solvability condition of the first approximation. Since this equation represents an identity, we consider

$$a_2=-i\beta'+i\beta\tau^2A_2,\quad -2ia_3+a_4=i\beta\tau^2A_2,\quad -ia_4=\beta\tau^2A_3, \tag{5.13}$$

where

$$A_2=A_1\frac{K_{11}+K_{22}}{K_{22}},\quad A_3=A_1\frac{K_{11}-K_{22}}{K_{22}},\quad A_1=\frac{K_{11}+K_{22}-2K_{33}}{8K_{11}}. \tag{5.14}$$

Solutions of these equations are

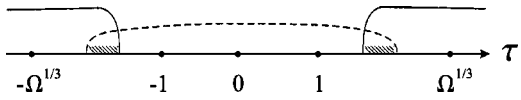

FIG. 3. Regions where the WKB solution and the solution near the turning point are applicable for the τ variable. The solid line shows the regions where the WKB solution is valid. The dotted line shows the vicinity of the turning point. As it can be seen at $1 \ll |\tau| \ll \Omega^{1/3}$ both solutions are applicable (shaded regions).

$$a_2 = -i\beta' + i\beta\tau^2 A_2, \quad a_3 = -\beta\tau^2 A_1, \quad a_4 = i\beta\tau^2 A_3. \tag{5.15}$$

The equation for the second approximation has the form

$$(\hat{B}(0) - i\mu_1(0)\hat{I})\boldsymbol{\Psi}_1^{(2)} = -i\boldsymbol{\Psi}_1^{(1)\prime} - \tfrac{1}{2}\tau^2\hat{B}''(0)\boldsymbol{\Psi}_1^{(1)} + (i\tau\hat{C}'(0) - \tfrac{1}{24}\tau^4\hat{B}^{IV}(0))\boldsymbol{\Psi}_1^{(0)} = \mathbf{R}^{(2)}. \tag{5.16}$$

The solvability condition for the second approximation has the same form as that for the first approximation, $(\hat{P}^{-1}\mathbf{R}^{(2)})_2 = 0$. Substituting to this condition the expressions for $\boldsymbol{\Psi}_1^{(0)}$ and $\boldsymbol{\Psi}_1^{(1)}$, we obtain

$$-ia_2' - \frac{1}{2}\tau^2\left(\hat{P}^{-1}\hat{B}''(0)\sum_{k=2}^{4} a_k\boldsymbol{\chi}_k\right)_2 + \beta(\tau)\left[\hat{P}^{-1}\left(i\tau\hat{C}'(0) - \frac{1}{24}\tau^4\hat{B}^{IV}(0)\right)\boldsymbol{\chi}_1\right]_2 = 0. \tag{5.17}$$

Let us calculate the coefficients of this equation and substitute the expressions (5.15) for the a_k coefficients into (5.17). Then we have

$$\beta''(\tau) - \beta'(\tau)\tau^2\tfrac{1}{2}(C_1 + C_2) - \beta(\tau)\tau\tfrac{1}{2}(C_1 + C_2 - \tfrac{1}{2}C_1C_2\tau^3) = 0. \tag{5.18}$$

In usual cases inequalities $K_{22} < K_{11} < K_{33}$ take place, hence it follows according to Eq. (4.23) $C_1 < 0$, $C_2 < 0$, and $C_1 > C_2$. These conditions do not impose any restrictions on the generality of the obtained results. Then solution of Eq. (5.18) can be written in the form

$$\beta(\tau) = \sqrt{\tau}\exp(C_3\tau^3)[F_1K_{1/6}(C_4\tau^3 e^{-3\pi i}) + F_2K_{1/6}(C_4\tau^3)], \tag{5.19}$$

where $F_{1,2}$ are constants, $K_{1/6}(a)$ is the modified Bessel function of the second kind,

$$C_3 = (C_1 + C_2)/12, \quad C_4 = (C_1 - C_2)/12. \tag{5.20}$$

It is possible to present the solution of Eq. (5.18) as a linear combination of other Bessel functions. The choice $K_{1/6}(a)$ hereinafter will be convenient for matching the solutions inside and outside the turning point vicinity.

Note, that in the vicinity of the zero the solution (5.19) has no singularities such as a pole. Thus, in the zero approximation the solution $\boldsymbol{\Psi}_1(\tau)$ has the form

$$\boldsymbol{\Psi}_1(\tau) = \sqrt{\tau}\exp(-\Omega^{2/3}\tau + C_3\tau^3)[F_1K_{1/6}(C_4\tau^3 e^{-3\pi i}) + F_2K_{1/6}(C_4\tau^3)]\boldsymbol{\chi}_1. \tag{5.21}$$

Since the WKB approximation is valid for $|\zeta|\Omega^{1/3} \gg 1$, in the region $\Omega^{-1/3} \ll |\zeta| \ll 1$ (or $1 \ll |\tau| \ll \Omega^{1/3}$) both the WKB approximation and the solution near the turning point are valid (Fig. 3). Equating these solutions we can get the relation between constants entering these solutions.

Primarily we consider the WKB solution in the regions $1 \ll |\tau| \ll \Omega^{1/3}$. From the solution (3.10), where $\hat{M}(\xi, \xi_0)$ is described by Eq. (4.8), we select two solutions corresponding to μ_1 and μ_2. For this purpose we put third and fourth components of the $\hat{U}^{-1}(\xi_0)\boldsymbol{\Psi}(\xi_0)$ vector equal to zero and expand all functions depending on ξ in series in the vicinity of the point $\phi = \pi/2$ ($\tau = 0$). As a result the solution in the considered region has the form

$$\mathbf{\Psi}(\tau)=B_1\mathbf{\Phi}_1(\tau)+B_2\mathbf{\Phi}_2(\tau), \tag{5.22}$$

where

$$\mathbf{\Phi}_1(\tau)=\Phi_{01}(\tau)\left(-i\left(1+\frac{C_1-1}{2\Omega^{2/3}}\tau^2\right),-1,1-\frac{\tau^2}{2\Omega^{2/3}},-i\left(1-\frac{C_1\tau^2}{2\Omega^{2/3}}\right)\right)^T,$$

$$\mathbf{\Phi}_2(\tau)=\Phi_{02}(\tau)\left(1,-i\left(1+\frac{C_2-1}{2\Omega^{2/3}}\tau^2\right),i\left(1-\frac{C_2\tau^2}{2\Omega^{2/3}}\right),1-\frac{\tau^2}{2\Omega^{2/3}}\right)^T, \tag{5.23}$$

$$\Phi_{0j}(\tau)=\frac{\sqrt{i}\Omega^{1/3}}{|\tau|}\left(1-\frac{C_j\tau^2}{4\Omega^{2/3}}\right)\exp\left(-\Omega^{2/3}\tau+\frac{1}{6}C_j\tau^3\right),\quad j=1,2.$$

Note, that constant factors B_1 and B_2 can differ in regions $\tau>0$ and $\tau<0$ since the regions of the WKB method applicability, $|\tau|\gg 1$, do not intersect. In what follows we shall denote the coefficients B_1 and B_2 at $\tau>0$ and $\tau<0$ as $B_l^{(+)}$ and $B_l^{(-)}$, respectively, $l=1, 2$.

Now we consider the solution (5.21), which is valid near the turning point, at $|\tau|\gg 1$. For this purpose we get its asymptotic behavior at $\tau\to\pm\infty$ in the zero approximation. Actually the problem consists in searching of the Bessel function $K_{1/6}(a)$ asymptotics. At $a\to\infty$ its asymptotics has the form[20]

$$K_{1/6}(a)\sim\sqrt{\pi/(2a)}\exp(-a). \tag{5.24}$$

This formula is valid for $|\arg a|<3\pi/2$. This condition is fulfilled for the second term in (5.21) at $\tau\to+\infty$. The same asymptotics can be used for the first term, but for $\tau\to-\infty$, as in this case $\tau=|\tau|e^{i\pi}$, and argument of the total expression appears to be equal to zero. Thus we have

$$K_{1/6}(C_4\tau^3e^{-3\pi i})\underset{\tau\to-\infty}{\sim}C_5|\tau|^{-3/2}\exp(-C_4|\tau|^3),$$

$$K_{1/6}(C_4\tau^3)\underset{\tau\to+\infty}{\sim}C_5\tau^{-3/2}\exp(-C_4\tau^3), \tag{5.25}$$

where

$$C_5=\sqrt{\pi/(2C_4)}. \tag{5.26}$$

For deriving the rest two asymptotic behaviors, $K_{1/6}(C_4\tau^3e^{-3\pi i})$ at $\tau\to+\infty$ and $K_{1/6}(C_4\tau^3)$ at $\tau\to-\infty$, we use the relation[20]

$$K_\nu(ae^{im\pi})=e^{-im\pi\nu}K_\nu(a)-i\pi\frac{\sin(m\pi\nu)}{\sin(\pi\nu)}I_\nu(a), \tag{5.27}$$

where m is integer, $I_\nu(a)$ is the modified Bessel function of the first kind, which has an asymptotics $I_\nu(a)\underset{a\to+\infty}{\sim}\exp(a)/\sqrt{2\pi a}$. Supposing $m=-3$ and $m=3$, we get the asymptotic behavior of the first and the second term, respectively. Thus we have

$$K_{1/6}(C_4\tau^3e^{-3\pi i})\underset{\tau\to+\infty}{\sim}2iC_5\tau^{-3/2}\exp(C_4\tau^3),$$

$$K_{1/6}(C_4\tau^3)\underset{\tau\to-\infty}{\sim}-2iC_5|\tau|^{-3/2}\exp(C_4|\tau|^3). \tag{5.28}$$

Substituting asymptotics (5.25) and (5.28) in the expression (5.21) for $\mathbf{\Psi}_1(\tau)$ we get

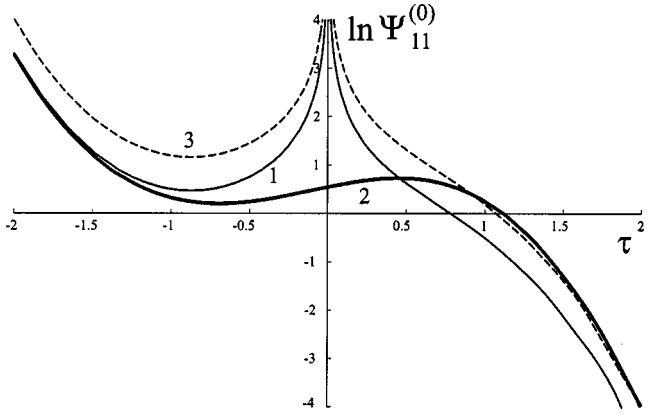

FIG. 4. The first component of the vector $\Psi_1^{(0)}(\tau)$ (curve 2) in the vicinity of the turning point. This curve is obtained by the numerical solution of Eq. (5.2) for $K_{11}=10^{-6}$ dyne, $K_{22}=0.5\times10^{-6}$ dyne, $K_{33}=4.0\times10^{-6}$ dyne. Curves 1 and 3 are the WKB solution and doubled WKB solution, respectively.

$$\mathbf{\Psi}_1(\tau)=C_5|\tau|^{-1}\exp(-\Omega^{2/3}\tau)(1,-i,i,1)^T\times\begin{cases}2iF_1\exp(C_1\tau^3/6)+F_2\exp(C_2\tau^3/6) & \text{at } \tau\to+\infty,\\ iF_1\exp(C_1\tau^3/6)+2F_2\exp(C_2\tau^3/6) & \text{at } \tau\to-\infty.\end{cases} \tag{5.29}$$

Matching solutions (5.29) with the WKB solutions (5.22), (5.23), we obtain two systems of two equations, connecting the factors $B_l^{(\pm)}$, $l=1,2$ with the factors F_1 and F_2

$$-\Omega^{1/3}i^{1/2}B_1^{(+)}=2F_1C_5,\quad -\Omega^{1/3}i^{1/2}B_1^{(-)}=F_1C_5,$$

$$\Omega^{1/3}i^{1/2}B_2^{(+)}=F_2C_5,\quad \Omega^{1/3}i^{1/2}B_2^{(-)}=2F_2C_5. \tag{5.30}$$

Equation (5.30) gives the relation between factors $B_l^{(\pm)}$, $l=1,2$ (connection formulas),

$$B_1^{(+)}=2B_1^{(-)},\quad B_2^{(+)}=B_2^{(-)}/2. \tag{5.31}$$

So, passing by the turning point the mode amplitudes vary. Thus the modes interact, but any of these modes does not produced another.

Figure 4 illustrates the solution of Eq. (5.2). The dependence of the first component $\Psi_{11}^{(0)}$ of the vector $\Psi_1^{(0)}(\tau)$ is presented in the vicinity of the turning point. This dependence corresponds to behavior of the correlation function $G_{11}(\tau,\tau_1)$ for fixed $\tau_1<\tau$. The curve 1 presents the WKB solution diverging at the turning point $\tau=0$. Curve 2 was obtained by numerical solution of Eq. (5.2). Curve 3 illustrates formula (5.31) connecting solution amplitudes before and after the turning point. This curve was obtained by doubling the WKB solution. One can see that to the left of the turning point the numerical solution coincides with the WKB solution and to the right of this point—with the doubled WKB solution.

Note, that the modes do not interact in the zero approximation over the $\Omega^{-2/3}$ parameter. If we take into account the terms of the next order we can get the contributions determined by the mode interaction.

Similarly it is possible to obtain the solution $\mathbf{\Psi}_3(\tau)$ corresponding to μ_3 and μ_4 near the turning point

$$\mathbf{\Psi}_3(\tau)=\sqrt{\tau}\exp(\Omega^{2/3}\tau-C_3\tau^3)[F_3K_{1/6}(C_4\tau^3e^{-3\pi i})+F_4K_{1/6}(C_4\tau^3)](-1,-i,i,-1)^T. \tag{5.32}$$

We select two WKB solutions, corresponding to μ_3 and μ_4 for deriving the connection formulas similar to Eq. (5.31). For this purpose it is enough to set $\hat{U}^{-1}(\xi_0)\Psi(\xi_0)=(0,0,B_3,B_4)^T$. Acting similarly in the case of values μ_1 and μ_2 we obtain the connection formulas

$$B_3^{(+)}=B_3^{(-)}/2, \quad B_4^{(+)}=2B_4^{(-)}. \tag{5.33}$$

In the Appendix we demonstrate that the multiplicative conditions $B_3^{(+)}B_4^{(+)}=B_3^{(-)}B_4^{(-)}$, $B_1^{(+)}B_2^{(+)}=B_1^{(-)}B_2^{(-)}$ are corollaries from conservation law for relaxation system.

Note, that we considered the case $\phi=\pi/2$ only. Actually the developed approach allows to describe all turning points $\phi=\pi/2+2\pi m$, where m is integer. The turning points $\phi=-\pi/2+2\pi m$ should be considered separately. The reason is that the expansion of the $\hat{B}$ matrix in the vicinity of these turning points has another form. But it may be shown that the relation between amplitudes conserves. It is natural since the points $\phi(z)=\pi/2$ and $\phi(z)=-\pi/2$ refer to opposite directions of the director, $\mathbf{n}^0$ and $-\mathbf{n}^0$, which are equivalent for CLC.

VI. CORRELATION FUNCTION NEAR THE TURNING POINTS

First we consider the case, when both points ξ and ξ_1 lie in the regions, where the WKB method is valid, but between them there is one turning point $\xi_*=\pi/2-\phi_0$. Let us consider for definiteness $\xi>\xi_*$, and $\xi_1<\xi_*$, i.e., $\xi>\xi_1$. In this case expression for the Green's function (3.6) still holds. Since Eq. (3.6) contains the $\hat{u}_1$ matrix in both points ξ and ξ_1, it is necessary to take the expression for this matrix which is valid on each side of the turning point, i.e., it is necessary to take into account connection formulas, Eqs. (5.31).

These formulas mean, that on passing through the turning point the amplitudes of the solutions corresponding to μ_1 and μ_2 increase and decrease twice, respectively. Therefore the $\hat{u}_1$ matrix for $|\xi-\xi_*|\gg\Omega^{-1/3}$ can be written in the form

$$\hat{u}_1(\xi)=\begin{cases}\hat{\tilde{u}}_1(\xi) & \text{at } \xi<\xi_*,\\ \hat{\tilde{u}}_1(\xi)\hat{s} & \text{at } \xi>\xi_*,\end{cases} \tag{6.1}$$

where $\hat{\tilde{u}}_1(\xi)$ is described by Eq. (4.9) and the matrix

$$\hat{s}=\begin{pmatrix}2 & 0\\ 0 & 1/2\end{pmatrix}$$

describes the transformation of amplitudes on passing through the turning point. Then Eq. (3.6) is written as

$$\hat{G}(\xi,\xi_1)=k_BTp_0^{-1}\hat{\tilde{u}}_1(\xi)\hat{s}\hat{\tilde{u}}^{-1}(\xi_1)(\hat{u}_2'\hat{u}_2^{-1}-\hat{\tilde{u}}_1'\hat{\tilde{u}}_1^{-1})^{-1}(\xi_1)\hat{K}^{-1}. \tag{6.2}$$

This expression differs from Eq. (4.11) by an insertion of the diagonal matrix $\hat{s}$

$$\hat{G}(\xi,\xi_1)=\frac{k_BT}{2qK_{33}\cos\phi(\xi_1)\cos\phi(\xi)}\begin{pmatrix}\sin\phi(\xi) & i\mu_2(\xi)\\ -i\mu_1(\xi) & \sin\phi(\xi)\end{pmatrix}$$
$$\times\begin{pmatrix}\dfrac{2\exp\left(-\Omega\int_{\xi_1}^{\xi}\mu_1\,d\xi'\right)}{\sqrt{\mu_1(\xi)\mu_1(\xi_1)}} & 0\\ 0 & \dfrac{\exp\left(-\Omega\int_{\xi_1}^{\xi}\mu_2\,d\xi'\right)}{2\sqrt{\mu_2(\xi)\mu_2(\xi_1)}}\end{pmatrix}\begin{pmatrix}-\sin\phi(\xi_1) & i\mu_1(\xi_1)\\ -i\mu_2(\xi_1) & -\sin\phi(\xi_1)\end{pmatrix}. \tag{6.3}$$

The case $\xi<\xi_1$ can be considered in a similar way. The new matrix $\hat{u}_2(\xi)$ is constructed with the aid of connection formulas (5.33). However there is a simpler way to obtain $\hat{G}(\xi,\xi_1)$ for $\xi<\xi_1$. It is enough to apply the symmetry property Eq. (2.18),

$$\hat{G}(\xi,\xi_1)=\hat{G}^{*T}(\xi_1,\xi).$$

If there are several turning points between ξ and ξ_1 the Green's function will contain a set of $\hat{s}$ matrices with the number in this set being equal to the number of the turning points.

Now we consider the case, when the point ξ lies in the vicinity of the turning point ξ_* and the point ξ_1 is situated far from this turning point, i.e., in the region, where the WKB method is valid. For definiteness we consider again $\xi>\xi_1$. In order to find the Green's function, it is necessary to expand the expression (4.9) for the $\hat{u}_1(\xi)$ matrix in the vicinity of the turning point. It can be made, using solution (5.21) for the $\mathbf{\Psi}_1$ function and the second set of equations in (5.30). This set describes the relation between constants which enter to the WKB solution and to the solution near the turning point. From Eq. (5.21) for the $\hat{u}_1$ matrix in the vicinity of the turning point we get

$$\hat{u}_1(\tau)=\sqrt{\tau}\exp(-\Omega^{2/3}\tau+C_3\tau^3)\begin{pmatrix} K_{1/6}(C_4\tau^3e^{-3\pi i}) & K_{1/6}(C_4\tau^3) \\ -iK_{1/6}(C_4\tau^3e^{-3\pi i}) & -iK_{1/6}(C_4\tau^3)\end{pmatrix}\begin{pmatrix} F_1 & 0 \\ 0 & F_2\end{pmatrix}. \quad (6.4)$$

It is necessary to choose F_1 and F_2, so that Eq. (6.4) is consistent with the expression (4.9) for the $\hat{u}_1$ matrix. For this purpose we choose $B_1^{(-)}$ and $B_2^{(-)}$ as

$$B_l^{(-)}=\frac{|\cos(\xi_0+\phi_0)|}{\sqrt{i\mu_l(\xi_0)}}\exp\left(-\Omega\int_{\xi_0}^{\xi_*}\mu_l\,d\xi'\right), \quad l=1,2. \quad (6.5)$$

This choice on the one hand reduces to Eq. (4.9) for the $\hat{u}_1(\xi)$ matrix and on the other hand it is consistent with the solution (5.23) in the regions $1\ll|\tau|\ll\Omega^{1/3}$. From Eqs. (6.5) and (5.30) we obtain F_1 and F_2 in the form

$$F_l=\frac{(-1)^l}{l}\Omega^{1/3}\frac{|\cos(\xi_0+\phi_0)|}{C_5\sqrt{\mu_l(\xi_0)}}\exp\left(-\Omega\int_{\xi_0}^{\xi_*}\mu_l\,d\xi'\right), \quad l=1,2. \quad (6.6)$$

Substituting expression (6.4) for $\hat{u}_1(\xi)$ and expressions (4.9) for $\hat{u}_1(\xi_1)$, $\hat{u}_2(\xi_1)$ into Eq. (3.6) we obtain the correlation function in the form

$$\begin{aligned}\hat{G}(\xi,\xi_1)=&\frac{ik_BT\Omega^{1/6}}{2C_5qK_{33}\cos\phi(\xi_1)\sqrt{\xi-\xi_*}}\exp\{-\Omega[\xi-\xi_*-C_3(\xi-\xi_*)^3]\}\\ &\times\begin{pmatrix} -K_{1/6}(C_4\Omega(\xi-\xi_*)^3e^{-3\pi i}) & 0 \\ 0 & \frac{1}{2}K_{1/6}(C_4\Omega(\xi-\xi_*)^3)\end{pmatrix}\\ &\times\begin{pmatrix} \dfrac{\exp\left(-\Omega\int_{\xi_1}^{\xi_*}\mu_1\,d\xi'\right)}{\sqrt{\mu_1(\xi_1)}} & 0 \\ 0 & \dfrac{\exp\left(-\Omega\int_{\xi_1}^{\xi_*}\mu_2\,d\xi'\right)}{\sqrt{\mu_2(\xi_1)}}\end{pmatrix}\begin{pmatrix} -\sin\phi(\xi_1) & i\mu_1(\xi_1) \\ -i\mu_2(\xi_1) & -\sin\phi(\xi_1)\end{pmatrix}.\end{aligned} \quad (6.7)$$

Finally we consider the case when both points ξ and ξ_1 are in the vicinity of the turning point. On the one hand, this case is more complicate since for calculation of $\hat{u}_1$ and $\hat{u}_2$ matrices it is necessary to take into account the terms of the higher orders, otherwise these matrices are degenerate. On the other hand, this case is more simple as soon as there is no need to match the WKB solutions and solutions in the vicinity of the turning point.

Let us construct the $\hat{u}_1$ matrix in the vicinity of the turning point taking into account the correction $\mathbf{\Psi}_1^{(1)}$ (the $\hat{u}_2$ matrix can be constructed similarly). Note, that two first components of the $\mathbf{\Psi}_1$ vector are used for the $\hat{u}_1$ construction. We denote $\mathbf{w}_1=((\Psi_1)_1,(\Psi_1)_2)$. Using expressions (5.15) and (5.19), we get

$$\mathbf{w}_1(\tau)=\beta(\tau)\begin{pmatrix}1\\-i\end{pmatrix}+\Omega^{-2/3}\begin{pmatrix}A_1\beta(\tau)\tau^2\\ i[A_5\beta(\tau)\tau^2-A_4\beta'(\tau)]\end{pmatrix}, \tag{6.8}$$

where A_1 was defined in Eq. (5.14) and

$$A_4=(K_{11}+K_{22})/(K_{11}-K_{22}),\quad A_5=A_1(3K_{11}+K_{22})/(K_{11}-K_{22}). \tag{6.9}$$

The function $\beta(\tau)$ in Eq. (5.19) contains two arbitrary constants F_1 and F_2. Let

$$\hat{u}_1(\tau)=(\mathbf{w}_1(\tau;F_1=1,F_2=0),\mathbf{w}_1(\tau;F_1=0,F_2=1)). \tag{6.10}$$

Such choice of the constants F_1 and F_2 gives the linear independence of the columns of the $\hat{u}_1(\tau)$ matrix. The components of the $\hat{u}_1(\tau)$ matrix have the form

$$\begin{aligned}
(\hat{u}_1)_{11}(\tau)&=\Theta^{(+)}(\tau)K_{1/6}(C_4\tau^3e^{-3\pi i})(1+\Omega^{-2/3}\tau^2A_1),\\
(\hat{u}_1)_{12}(\tau)&=-i\Theta^{(+)}(\tau)K_{1/6}(C_4\tau^3e^{-3\pi i})\\
&\quad\times\{1+\Omega^{-2/3}A_4\ln[\sqrt{\tau}\exp(C_3\tau^3)K_{1/6}(C_4\tau^3e^{-3\pi i})]'_\tau-\Omega^{-2/3}\tau^2A_5\},\\
(\hat{u}_1)_{21}(\tau)&=\Theta^{(+)}(\tau)K_{1/6}(\tau)K_{1/6}(C_4\tau^3)(1+\Omega^{-2/3}\tau^2A_1),\\
(\hat{u}_1)_{22}(\tau)&=-i\Theta^{(+)}(\tau)K_{1/6}(C_4\tau^3)\\
&\quad\times\{1+\Omega^{-2/3}A_4\ln[\sqrt{\tau}\exp(C_3\tau^3)K_{1/6}(C_4\tau^3)]'_\tau-\Omega^{-2/3}\tau^2A_5\},
\end{aligned} \tag{6.11}$$

where

$$\Theta^{(+)}(\tau)=\exp(-\Omega^{2/3}\tau)\sqrt{\tau}\exp(C_3\tau^3). \tag{6.12}$$

For calculation of the $\hat{u}_2(\tau)$ matrix it is necessary to construct the corrections of the next order for obtaining $\mathbf{\Psi}_3(\tau)$, Eq. (5.32). This procedure is similar to procedure fulfilled for $\mathbf{\Psi}_1(\tau)$. Therefore we present the result for $\hat{u}_2(\tau)$ only

$$\begin{aligned}
(\hat{u}_2)_{11}(\tau)&=-\Theta^{(-)}(\tau)K_{1/6}(C_4\tau^3e^{-3\pi i})(1+\Omega^{-2/3}\tau^2A_1),\\
(\hat{u}_2)_{12}(\tau)&=-i\Theta^{(-)}(\tau)K_{1/6}(C_4\tau^3e^{-3\pi i})\\
&\quad\times\{1-\Omega^{-2/3}A_4\ln[\sqrt{\tau}\exp(-C_3\tau^3)K_{1/6}(C_4\tau^3e^{-3\pi i})]'_\tau-\Omega^{-2/3}\tau^2A_5\},\\
(\hat{u}_2)_{21}(\tau)&=-\Theta^{(-)}(\tau)K_{1/6}(C_4\tau^3)(1+\Omega^{-2/3}\tau^2A_1),\\
(\hat{u}_2)_{22}(\tau)&=-i\Theta^{(-)}(\tau)K_{1/6}(C_4\tau^3)\\
&\quad\times\{1-\Omega^{-2/3}A_4\ln[\sqrt{\tau}\exp(-C_3\tau^3)K_{1/6}(C_4\tau^3)]'_\tau-\Omega^{-2/3}\tau^2A_5\},
\end{aligned} \tag{6.13}$$

where

$$\Theta^{(-)}(\tau)=\exp(\Omega^{2/3}\tau)\sqrt{\tau}\exp(-C_3\tau^3). \tag{6.14}$$

For calculation of the correlation function $\hat{G}(\xi,\xi_1)$ we can now use the expression (3.6) for $\xi > \xi_1$.

VII. CONCLUSIONS

In the present paper we developed the scheme for calculation of the thermal fluctuations in the system with smooth inhomogeneities. We take into account the nonlocal fluctuations in the explicit form. The WKB approximation was applied for the first time to calculate the spatial correlation functions in systems with smooth inhomogeneities. We consider the system with one-dimensional periodicity. As an illustration the director fluctuations in cholesteric liquid crystal were considered.

We construct the correlation function of the director fluctuations in $(\mathbf{q},z)$-representation. Now we will illustrate the application of this function for solving the problem of light scattering in CLC. The light is scattered by the fluctuations of the permittivity tensor $\delta\hat{\varepsilon}(\mathbf{r})$. These fluctuations are connected with the director fluctuations $\delta\mathbf{n}$ by the formula[4]

$$\delta\varepsilon_{\alpha\beta}(\mathbf{r})=\varepsilon_a[n^0_\beta(z)\,\delta n_\alpha(\mathbf{r})+n^0_\alpha(z)\,\delta n_\beta(\mathbf{r})], \tag{7.1}$$

where ε_a is the difference between permittivities along and across equilibrium director. From Eq. (7.1) we obtain the connection for the correlation function of the permittivity fluctuations $\hat{\mathcal{G}}(\mathbf{r}_{1\perp}-\mathbf{r}_{2\perp};z_1,z_2)=\langle\delta\hat{\varepsilon}(\mathbf{r}_1)\delta\hat{\varepsilon}^*(\mathbf{r}_2)\rangle$ and the correlation function of the director fluctuations $\hat{g}(\mathbf{r}_{1\perp}-\mathbf{r}_{2\perp};z_1,z_2)$, Eq. (2.9),

$$\begin{aligned}\mathcal{G}_{\alpha\beta\gamma\delta}(\mathbf{r}_\perp;z,z_1)=\varepsilon_a^2[&n^0_\alpha(z)n^0_\gamma(z_1)g_{\beta\delta}(\mathbf{r}_\perp;z,z_1)+n^0_\alpha(z)n^0_\delta(z_1)g_{\beta\gamma}(\mathbf{r}_1;z,z_1)\\&+n^0_\beta(z)n^0_\gamma(z_1)g_{\alpha\delta}(\mathbf{r}_\perp;z,z_1)+n^0_\beta(z)n^0_\delta(z_1)g_{\alpha\gamma}(\mathbf{r}_\perp;z,z_1)].\end{aligned} \tag{7.2}$$

Using Eq. (7.2) and Eq. (2.10) it is not difficult to express $\hat{\mathcal{G}}$ via obtained correlation matrix $\hat{G}(\mathbf{r}_{1\perp}-\mathbf{r}_{2\perp};z_1,z_2)$, Eq. (2.7).

For solving the problem of light scattering in addition to the correlation function of the permittivity fluctuations normal light waves in the medium $\mathbf{E}(\mathbf{r})$ and the field of a point source (the Green's function of the wave equation) $\hat{T}(\mathbf{r},\mathbf{r}_1)$ are required. These problems are considered in Refs. 26–29. In these studies the vector WKB method corresponding to approximation of geometrical optics in anisotropic inhomogeneous medium is applied for electromagnetic field. According to Refs. 26–29 the presence of large-scale inhomogeneities results in the amplitude and the phase of the field adiabatically following to the local medium characteristics. Moreover the Green's function as well as the fluctuation correlation function depends not only on the difference of spatial coordinates but on their absolute values.

Below we shall describe the general procedure for calculation of the single light scattering intensity in the medium with one-dimensional inhomogeneities which characteristic scale d is much larger than the wavelength of light λ, $d \gg \lambda$. In such medium the single light scattering intensity in the $\mathbf{r}$ point is given by

$$I^{(s)}_{(i)}\propto\int_{V_{sc}}\hat{T}(\mathbf{r},\mathbf{r}_1)\hat{T}^*(\mathbf{r},\mathbf{r}_2)\langle\delta\hat{\varepsilon}(\mathbf{r}_1)\,\delta\hat{\varepsilon}^*(\mathbf{r}_2)\rangle\mathbf{E}^{(i)}(\mathbf{r}_1)\mathbf{E}^{(i)*}(\mathbf{r}_2)\mathrm{d}\mathbf{r}_1\,\mathrm{d}\mathbf{r}_2, \tag{7.3}$$

where V_{sc} is a scattering volume.

We use the approximation of geometrical optics for incident and scattered fields. Let introduce local (depending on z) wave vectors of incident $\mathbf{k}^{(i)}(z)=(\mathbf{k}^{(i)}_\perp,k^{(i)}_z(z))$ and scattered $\mathbf{k}^{(s)}(z)=(\mathbf{k}^{(s)}_\perp,k^{(s)}_z(z))$ light. The corresponding polarization vectors are $\mathbf{e}^{(i)}(\mathbf{k}^{(i)}_\perp,z)$ and $\mathbf{e}^{(s)}(\mathbf{k}^{(s)}_\perp,z)$. Here the components of the wave vectors transversal to the z axis $\mathbf{k}^{(i,s)}_\perp$ are constants since our system is uniform in planes normal to the z axis. Then for the incident field we obtain

$$\mathbf{E}^{(i)}(\mathbf{r})=E^{(i)}(\mathbf{k}_\perp^{(i)},z)\mathbf{e}^{(i)}(\mathbf{k}_\perp^{(i)},z)\exp\left[i\left(\mathbf{k}_\perp^{(i)}\cdot\mathbf{r}_\perp+\int_{z_0}^{z}k_z^{(i)}(z')\mathrm{d}z'\right)\right], \tag{7.4}$$

where $E^{(i)}$ is the amplitude of the incident wave. For the propagator of the scattered field in the far zone $r\gg r_1$ we get

$$T_{\alpha\beta}(\mathbf{r},\mathbf{r}_1)=\sum_{s=1,2}t^{(s)}(\mathbf{r};z_1,\mathbf{k}_\perp^{(s)})e_\alpha^{(s)}(\mathbf{k}_\perp^{(s)},z)e_\beta^{(s)}(\mathbf{k}_\perp^{(s)},z_1)\exp\left[-i\left(\mathbf{k}_\perp^{(s)}\cdot\mathbf{r}_{1\perp}+i\int_0^{z_1}k_z^{(s)}(z')\mathrm{d}z'\right)\right]. \tag{7.5}$$

Here $t^{(s)}(\mathbf{r};z_1,\mathbf{k}_\perp^{(s)})\propto 1/r$ as function of variable $\mathbf{r}$, whereas $E^{(i)}(\mathbf{k}_\perp^{(i)},z)$ and $t^{(s)}(\mathbf{r};z,\mathbf{k}_\perp^{(s)})$ have the characteristic scale d over variable z. Equations (7.4) and (7.5) are valid for $k_z^{(i,s)}\mathrm{d}\gg 1$.

Then by substituting Eqs. (7.4) and (7.5) in Eq. (7.3) and performing integration over $\mathbf{r}_{1,2\perp}$ we obtain for the light scattering intensity

$$I_{(i)}^{(s)}\propto\frac{I^{(i)}S_\perp}{r^2}\int_0^L\mathrm{d}z_1\int_0^L\mathrm{d}z_2\,H(z_1;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})H^*(z_2;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})e_\alpha^{(s)}(z_1)e_\gamma^{(s)}(z_2)$$
$$\times\mathcal{G}_{\alpha\beta\gamma\delta}(\mathbf{Q}_{sc\perp};z_1,z_2)e_\beta^{(i)}(z_1)e_\delta^{(i)}(z_2)\exp\left(i\int_{z_1}^{z_2}Q_{scz}(z')\mathrm{d}z'\right), \tag{7.6}$$

where $\mathbf{Q}_{sc\perp}=\mathbf{k}_\perp^{(s)}-\mathbf{k}_\perp^{(i)}$, $Q_{scz}(z)=k_z^{(s)}(z)-k_z^{(i)}(z)$, $I^{(i)}$ is the intensity of the incident wave, $S_\perp$ is the square of the sample cross section, $H(z_j;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})=E^{(i)}(\mathbf{k}_\perp^{(i)},z_j)t^{(s)}(\mathbf{r};z_j,\mathbf{k}_\perp^{(s)})$. Here we have assumed that the sample with the width L occupies the layer $0\leqslant z\leqslant L$ and the transversal sizes of the sample are sufficiently large in comparison to the wavelength λ, $\sqrt{S_\perp}\gg\lambda$.

The exponential factor in expression (7.6) is a rapidly oscillating function. The $\hat{\mathcal{G}}(\mathbf{Q}_{sc\perp};z_1,z_2)$ function is associated with the function $\hat{G}(\mathbf{Q}_{sc\perp};z_1,z_2)$. As we can see from Eqs. (4.12) and (4.13) the function $\hat{G}(\mathbf{q};z_1,z_2)$ contains rapidly damping exponential factors $\exp(-q|\int_{z_1}^{z_2}\mu_j(z)dz|)$. The factors $H(z_1;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})$ and $H^*(z_2;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})$ are slowly varying as compared to the exponential factors. Let us use the differed $z_-=z_1-z_2$ and summary $z_+=(z_1+z_2)/2$ variables instead of z_1,z_2 $(0\leqslant z_+\leqslant L,|z_-|\leqslant|L-2|z_+-L/2\|)$, and the saddle-point technique for the variable z_-. The vicinity of the point $z_-=0$ gives the main contribution into the integral. Then in all smooth factors (the factors H, H^* and all nonexponential factors in $\hat{\mathcal{G}}$) we can set $z_1=z_2=z_+$ and expand exponents in the vicinity of the line $z_-=0$ up to the first nonzero terms (the first order terms over z_-). We have

$$I_{(i)}^{(s)}\propto\frac{I_0^{(i)}S_\perp}{r^2}\int\mathrm{d}z_+\int\mathrm{d}z_-|H(z_+;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})|^2e_\alpha^{(s)}(z_+)e_\gamma^{(s)}(z_+)\mathcal{G}_{\alpha\beta\gamma\delta}(\mathbf{Q}_{sc\perp};z_-,z_+)e_\beta^{(i)}(z_+)$$
$$\times e_\delta^{(i)}(z_+)\exp[iQ_{scz}(z_+)z_-]$$
$$=\frac{I_0^{(i)}S_\perp}{r^2}\int_0^L|H(z;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})|^2e_\alpha^{(s)}(z)e_\gamma^{(s)}(z)\mathcal{G}_{\alpha\beta\gamma\delta}(\mathbf{Q}_{sc\perp};Q_{scz}(z),z)e_\beta^{(i)}(z)e_\delta^{(i)}(z)\mathrm{d}z. \tag{7.7}$$

We are investigating the problem of light scattering in CLC with the pitch exceeding the wavelength of light λ significantly in detail in Ref. 30 with taking into account anisotropy of CLC and wave refraction effects. Here we restrict our consideration by general consequences of Eq. (7.7). Substituting Eqs. (2.10) and (2.11) into Eq. (2.9) we obtain from Eq. (7.2) the single light scattering intensity in the form

$$I_{(i)}^{(s)}\propto\frac{I_0^{(i)}S_\perp}{r^2}\sum_{k,l=1,2}\int_0^L G_{kl}(\mathbf{Q}_{sc\perp},Q_{scz}(z),z)\mathcal{H}_{kl}(z;\mathbf{k}_\perp^{(i)},\mathbf{k}_\perp^{(s)})\mathrm{d}z, \tag{7.8}$$

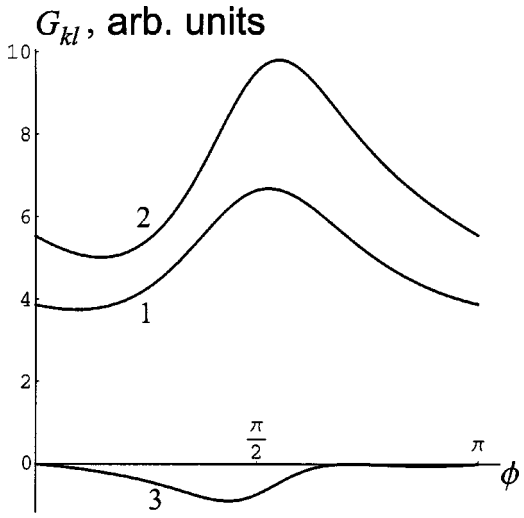

FIG. 5. The $G_{kl}(\mathbf{Q}_{sc\perp}, Q_{scz}(z), z)$ components of the correlation function as functions of $\phi = 2\pi z/d + \phi_0$ (G_{11}, curve 1; G_{22}, curve 2; and G_{12}, curve 3). The components are calculated for the ordinary incident and extraordinary scattered waves. Angles between the z axis and the wave vectors $\mathbf{k}^{(i)}$ and $\mathbf{k}^{(s)}$ outside of the CLC are equal to $\pi/4$ and $\pi/8$, respectively. Angle between $\mathbf{k}_\perp^{(i)}$ and $\mathbf{k}_\perp^{(s)}$ is equal to $\pi/16$. Permittivities are $\varepsilon_\perp = 2.0$, $\varepsilon_a = 0.5$. The Frank modules are $K_{11} = 3.0 \times 10^{-6}$ dyne, $K_{22} = 2.0 \times 10^{-6}$ dyne, $K_{33} = 5.0 \times 10^{-6}$ dyne.

where $\mathcal{H}_{kl}(z; \mathbf{k}_\perp^{(i)}, \mathbf{k}_\perp^{(s)})$ are the functions arising from angular and polarization factors. These functions have the characteristic scale over z of the order of the pitch d.

Figure 5 presents the dependencies $G_{kl}(\mathbf{Q}_{sc\perp}, Q_{scz}(z), z)$ on the $\phi = 2\pi z/d + \phi_0$ variable, $0 \leqslant \phi \leqslant \pi$. In terms of the z variable it corresponds to one period of the helix. One can see that all components contribute to the light scattering intensity. The figure shows that vicinity of $\phi = \pi/2$ brings larger contribution than the other regions to the light scattering intensity. Evidently, this effect is connected with the turning point $\phi = \pi/2$. The components of the correlation function in Fig. 5 were calculated by Eq. (4.13). As we have seen in Secs. V and IV there is a narrow region near the turning point $\phi = \pi/2$ where we should use Eq. (6.7) instead of Eq. (4.13).

Let us discuss the influence of this narrow region near the turning points on the light scattering. In integral Eq. (7.7) over z_- variable the main input to the scattering intensity comes from the range $|z_-| \sim \lambda \ll d$. Note, that for $|z_1 - z_2| \ll d$ the equilibrium director $\mathbf{n}^0$ variation in the space is negligible, $\mathbf{n}^0(z_1) = \mathbf{n}^0(z_2)$. It means that for this scale over variable $z_- = z_1 - z_2$ correlation function of CLC locally coincides with one of NLC. But the characteristic scale over variable $z_+ = (z_1 + z_2)/2$ is equal to d and distinction between CLC and NLC correlation functions still retains. As we have seen in Sec. IV the divergences in $\hat{G}^{(1)}$ and $\hat{G}^{(2)}$ [Eq. (4.12)] for $\phi \to \pi/2$ related by the presence of the turning point cancel each other for the case of NLC [Eq. (4.16)]. Therefore in all geometries of light scattering when at least one of the conditions $|Q_{sc\perp}|d \gg 1$ and $|Q_{scz}|d \gg 1$ is correct Eq. (4.13) is valid. The first of these conditions $Q_{sc\perp} = q \gg p_0$ is the condition of validity for WKB method. Hence for entire region where our results for correlation function are valid we can use Eq. (4.13) for calculation of the light scattering intensity in Eq. (7.8).

Our approach provides to consider nonlocal fluctuations in the inhomogeneous media. This approach is universal for any physical systems with smoothly varying structure and properties. For example, this problem exists in calculations of the order parameter fluctuations in the vicinity of the second order phase transition in inhomogeneous electric and magnetic fields and near liquid-vapor critical point in presence of the gravitational effects. The occurrence of the turning points is not obligatory in such problems. If turning points exist, the considered scheme allows to take them into account in the framework of developed approach.

In the present work we investigate the correlation functions for boundless system. In this case as a boundary condition we use the principle of correlation decay. For this reason exponentially

decreasing solutions contribute to the correlation function only. We suppose the calculation of correlation function of fluctuations in restricted CLC will be the next step in investigation of fluctuations in CLC and twist cells of NLC. In restricted systems an additional input appears in the free energy associated with anchoring effects. In this case we should consider both decreasing and increasing solutions in the correlation function. In restricted CLC our WKB method is perspective for use with method of path integrals[6,8] and method of self-conjugation operators.[9,10]

APPENDIX: CONSERVATION LAW IN RELAXATION SYSTEMS

Now it is essential to clarify the sense of Eqs. (5.31) and (5.33) using the simplest relaxation model described by equation

$$Y''-\Gamma(X)Y=0, \tag{A1}$$

where $\Gamma(X)$ is a positive function. Multiplying Eq. (A1) by Y^* and the conjugate equation by Y we obtain

$$Y''Y^*-\Gamma(X)YY^*=0, \quad Y^{*\prime\prime}Y-\Gamma(X)YY^*=0.$$

Subtracting term by term we have

$$Y''Y^*-Y^{*\prime\prime}Y=(Y'Y^*-Y^{*\prime}Y)'=0.$$

So we arrive at a conservation law for Eq. (A1),

$$\mathrm{Im}(Y'Y^*)=\mathrm{const}. \tag{A2}$$

The exact solution of Eq. (A1) can be written in the form

$$Y(X)=A_1(X)W_1(X)+A_2(X)W_2(X), \tag{A3}$$

where

$$W_{1,2}(X)=\Gamma(X)^{-1/4}\exp\left(\pm\int_{X_0}^{X}\sqrt{\Gamma(X')}\mathrm{d}X'\right) \tag{A4}$$

are WKB solutions, and $A_{1,2}(X)$ are amplitude functions. For eliminating the arbitrariness in the choice of the $A_{1,2}(X)$ functions we use the subsidiary condition

$$A_1'(X)W_1(X)+A_2'(X)W_2(X)=0. \tag{A5}$$

We substitute solution (A3) into Eq. (A2) and take into account identity $W_1'W_2-W_1W_2'=2$. As long as the $W_{1,2}(X)$ functions are real we obtain from Eq. (A5) the resulting conservation law,

$$\mathrm{Im}[A_1^*(X)A_2(X)]=\mathrm{const}. \tag{A6}$$

Let us denote the limit amplitudes of the WKB solutions for $X\to-\infty$ as $A_{1,2}^{(-)}$ and for $X\to+\infty$ as $A_{1,2}^{(+)}$. Equation (A6) is fulfilled for $A_1^{(-)}=A_1^{(+)}$ and $A_2^{(-)}=A_2^{(+)}$. This situation takes place in the

absence of turning points. Note, that this equation is also fulfilled for the case when $\mathrm{Re}\,A_j\,\mathrm{Im}\,A_j=0$ for both $j=1,2$. The very situation takes place due to passing by the turning point. If we draw the analogy to our multimode problem and apply Eq. (5.30) we obtain

$$A_1^{(+)}=2iF_1C_5,\quad A_2^{(+)}=F_2C_5,\quad A_1^{(-)}=iF_1C_5,\quad A_2^{(-)}=2F_2C_5.$$

This yields the relation

$$A_1^{(-)}A_2^{(-)}=A_1^{(+)}A_2^{(+)}.$$

Thus, in an equation of this type the amplitudes may vary with their product remains conserved.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 6 JUNE 2004

Canonical decompositions of *n*-qubit quantum computations and concurrence

Stephen S. Bullock[a)]
Mathematical and Computer Sciences Division, National Institute of Standards and Technology, Gaithersburg, Maryland 20089

Gavin K. Brennen[b)]
Quantum Processes Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20089

(Received 17 September 2003; accepted 20 February 2004; published online 17 May 2004)

The two-qubit canonical decomposition $SU(4)=[SU(2)\otimes SU(2)]\Delta[SU(2)\otimes SU(2)]$ writes any two-qubit unitary operator as a composition of a local unitary, a relative phasing of Bell states, and a second local unitary. Using Lie theory, we generalize this to an n-qubit decomposition, the concurrence canonical decomposition (CCD) $SU(2^n)=KAK$. The group K fixes a bilinear form related to the concurrence, and in particular any unitary in K preserves the tangle $|\overline{\langle\phi|}\times(-i\sigma_1^y)\cdots(-i\sigma_n^y)|\phi\rangle|^2$ for n even. Thus, the CCD shows that any n-qubit unitary is a composition of a unitary operator preserving this n-tangle, a unitary operator in A which applies relative phases to a set of GHZ states, and a second unitary operator which preserves the tangle. As an application, we study the extent to which a large, random unitary may change concurrence. The result states that for a randomly chosen $a\in A\subset SU(2^{2p})$, the probability that a carries a state of tangle 0 to a state of maximum tangle approaches 1 as the even number of qubits approaches infinity. Any $v=k_1ak_2$ for such an $a\in A$ has the same property. Finally, although $|\overline{\langle\phi|}(-i\sigma_1^y)\cdots(-i\sigma_n^y)|\phi\rangle|^2$ vanishes identically when the number of qubits is odd, we show that a more complicated CCD still exists in which K is a symplectic group. © *2004 American Institute of Physics.*

I. INTRODUCTION

Entanglement is a unique feature of quantum systems that plays a key role in quantum information proccessing. Much effort has gone into describing the entanglement present in the state of a quantum system composed of two or more measurably distinct subsystems. Because different amounts of entanglement may be shared among the various partitions of the tensor factors of the Hilbert state space, there is no single measure of entanglement that captures all nonlocal correlations for many-particle systems. Rather, the number of partitions of the tensor factors grows exponentially with the number of factors themselves. Thus, it is reasonable to guess that same is true for the number of useful entanglement measures. In fact, the situation is yet more complicated. Certain definitions create uncountably many entanglement types, which thus may not be associated to countable collections of partitions or monotones.

Nevertheless, it is interesting to consider how much entanglement is created by a given unitary evolution U of an n-qubit state space. To achieve this in a limited context, we focus on a single multi-qubit entanglement measure, the n-concurrence.[25] Using Lie theory, we may decompose a unitary operator acting on n qubits into a form such that the entangling power of the unitary with respect to this measure is manifest.

[a)]Electronic mail: stephen.bullock@nist.gov
[b)]Electronic mail: gavin.brennen@nist.gov

The n-tangle and its square root, the n-concurrence, are two of several proposed multiqubit entanglement measures. Others include polynomial invariants which involve moments of the reduced state eigenvalues,[1] the Schmidt measure[6] which is related to the minimum number of terms in the product state expansion of a state, the Q measure,[16] which is related to the average purity each qubit's reduced state, and distances between a state and its multipartite twirled image.[5] A further measure makes use of hyperdeterminants;[17] this powerful technique makes computation difficult in more than six qubits. The *concurrence* C_n is originally introduced in the two-qubit case.[9] It is generalized to a measure on two systems of arbitrarily many dimensions in Ref. 19 and extends to n-qubits.[25]

We now consider the quantitative expression for the concurrence. Suppose a quantum state space of data for a quantum computer. Specifically, fix n as the number of qubits, $N=2^n$. Throughout, we use $|j\rangle$ not to denote the state of a qubit but rather as an abbreviated multiqubit state via binary form. For example, in three qubits $|5\rangle=|101\rangle=|1\rangle\otimes|0\rangle\otimes|1\rangle$. We write $\mathcal{H}_n=\mathrm{span}_{\mathbb{C}}\{|j\rangle;\ 0\leqslant j\leqslant N-1\}$ for the n-qubit Hilbert state space. Then the concurrence is a map $C_n:\mathcal{H}_n\rightarrow[0,\infty)$ given by $C_n(|\psi\rangle)=|\overline{\langle\psi|}(-i\sigma_1^y)\cdots(-i\sigma_n^y)|\psi\rangle|$. Note that the expression inside the complex norm is in general not real. A related entanglement measure $\tau_n=C_n^2$ is known as the *n-tangle* when n is even.[27] For $\langle\psi|\psi\rangle=1$, the n-tangle of a state $|\psi\rangle$ assumes real values in the range $0\leqslant\tau_n\leqslant 1$. It is moreover an entanglement monotone,[23] as any good measure should be. This means in particular that $\tau_n:\mathcal{H}_n\rightarrow[0,\infty)$ vanishes on full tensor products of local states, and moreover that $\tau_n(v_1\otimes v_2\otimes\cdots\otimes v_n|\psi\rangle)=\tau_n(|\psi\rangle)$ for any $v_1\otimes v_2\otimes\cdots\otimes v_n\in\otimes_1^n SU(2)$. We show in Appendix C that the n-concurrence is also an entanglement monotone.

The n-concurrence only detects certain kinds of entanglement. Specifically, while it returns zero on all separable states, it may also return zero on certain nonseparable states. We illustrate the monotone's behavior by example. First, the n-partite Greenberger–Horne–Zeilinger (GHZ) state $|\mathrm{GHZ}_n\rangle=(1/\sqrt{2})(|0_1\cdots 0_n\rangle+|1_1\cdots 1_n\rangle)$ has maximal n-concurrence while $C_n(|\mathrm{GHZ}_{n-1}\rangle\otimes|0\rangle_n)=0$. As a second example, the generalized $|W\rangle$ state given by $|W\rangle=(1/\sqrt{n})(|10\cdots 0\rangle+|010\cdots 0\rangle+\cdots+|0\cdots 01\rangle)$ has zero n-concurrence despite being entangled. States with subglobal entanglement can also assume maximal n-concurrence; $C_n(|\mathrm{GHZ}_n\rangle)=C_n(|\mathrm{GHZ}_{n/2}\rangle\otimes|\mathrm{GHZ}_{n/2}\rangle)=1$. Generally, the n-concurrence seeks out superpositions between a state and its binary bit flip.

We extend these definitions by introducing a complex bilinear form, the *concurrence form* $\mathcal{C}_n:\mathcal{H}_n\times\mathcal{H}_n\rightarrow\mathbb{C}$. Here, complex bilinear means the function is linear when restricted to each variable. The antisymmetric concurrence form $\mathcal{C}_n(-,-)$ is nonzero even in the case n is odd, although of course $C_{2p-1}\equiv 0$ since $\mathcal{C}_{2p-1}(|\psi\rangle,|\psi\rangle)=-\mathcal{C}_{2p-1}(|\psi\rangle,|\psi\rangle)=0$.

Definition I.1: The concurrence form $\mathcal{C}_n:\mathcal{H}_n\times\mathcal{H}_n\rightarrow\mathbb{C}$ is given by $\mathcal{C}_n(|\psi\rangle,|\phi\rangle)=\overline{\langle\psi|}(-i\sigma_1^y)\times(-i\sigma_2^y)\cdots(-i\sigma_n^y)|\phi\rangle$. Note the complex conjugation of the lead bra is required for complex linearity (rather than antilinearity) in the first variable. The concurrence quadratic form is $Q_n^C(|\psi\rangle)=\mathcal{C}_n(|\psi\rangle,|\psi\rangle)$, so that $C_n(|\psi\rangle)=|Q_n^C(|\psi\rangle)|=\sqrt{\tau_n(|\psi\rangle)}$. Note that Q_n^C is a complex quadratic polynomial on the vector space $\mathcal{H}_n$.

The main technique of this paper is to build a new matrix decomposition of the Lie group of global phase normed quantum computations $SU(N)$. It is optimized for the study of the concurrence and n-tangle and generalizes the two-qubit canonical decomposition,[4,10,13–15,26]

$$SU(4)=[SU(2)\otimes SU(2)]\Delta[SU(2)\otimes SU(2)]. \tag{1}$$

Here, the commutative group Δ applies relative phases to a "magic basis"[2,4,9,10,14] of phase-shifted Bell states. This two-qubit canonical decomposition is used to the study of the entanglement capacity of two-qubit operations,[26] to build efficient (small) circuits in two qubits,[4,20,24] and to classify which two-qubit unitary operators require fewer than average multiqubit interactions.[20,24]

The canonical decomposition is itself an example of the $G=KAK$ metadecomposition theorem of Lie theory (Ref. 8, Theorem 8.6, Sec. VII.8). This theorem produces a decomposition of an input semisimple Lie group G given two further inputs:

(1) a Cartan involution (Ref. 8, Sec. X.6.3, p. 518) $\theta:\mathfrak{g}\to\mathfrak{g}$ for $\mathfrak{g}=\mathrm{Lie}(G)$. By definition, θ satisfies (i) $\theta^2=\mathbf{1}$ and (ii) $\theta[X,Y]=[\theta X,\theta Y]$ for all $X,Y\in\mathfrak{g}$. We write $\mathfrak{g}=\mathfrak{p}\oplus\mathfrak{k}$ for the decomposition of $\mathfrak{g}$ into the $+1$ and -1 eigenspace of θ;
(2) a commutative subalgebra $\mathfrak{a}\subset\mathfrak{p}$ which is maximal commutative in $\mathfrak{p}$.

Then write $K=\exp\mathfrak{k}$, $A=\exp\mathfrak{a}$, where for linear $G\subset GL(n,\mathbb{C})$ the exponential coincides with the matrix power series on each of the Lie subalgebras $\mathfrak{k}$, $\mathfrak{a}$. The theorem asserts then that $G=KAK=\{k_1ak_2;k_1,k_2\in K,a\in A\}$.

For example, the canonical decomposition of $SU(4)$ arises as follows. Take $\theta:\mathfrak{su}(4)\to\mathfrak{su}(4)$ by $\theta(X)=(-i\sigma_1^y)(-i\sigma_2^y)\overline{X}(-i\sigma_1^y)(-i\sigma_2^y)$ and

$$\mathfrak{a}=\mathrm{span}_{\mathbb{R}}\{i|0\rangle\langle 0|-i|1\rangle\langle 1|-i|2\rangle\langle 2|+i|3\rangle\langle 3|,\ i|0\rangle\langle 3|+i|3\rangle\langle 0|,\ i|1\rangle\langle 2|+i|2\rangle\langle 1|\}. \quad (2)$$

We extend this particular construction to n-qubits.

Definition I.2: Let $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)$. Define $\theta:\mathfrak{su}(2^n)\to\mathfrak{su}(2^n)$ by $\theta(X)=S^{-1}\overline{X}S=(-1)^nS\overline{X}S$. Then $\mathfrak{k}$ denotes the $+1$-eigenspace of θ while $\mathfrak{p}$ denotes the -1-eigenspace. Finally, in case n is even, we define

$$\begin{aligned}\mathfrak{a}=\mathrm{span}_{\mathbb{R}}(\{\ & i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|-i|j+1\rangle\langle j+1|-i|N-j-2\rangle\langle N-j-2|;\\ & 0\leqslant j\leqslant 2^{n-1}-2\}\sqcup\{i|j\rangle\langle N-j-1|+i|N-j-1\rangle\langle j|;0\leqslant j\leqslant 2^{n-1}-1\},),\\ & \text{in case } n \text{ even,}\end{aligned} \quad (3)$$

with $A=\exp\ \mathfrak{a}$. In case n odd, we drop the second set:

$$\begin{aligned}\mathfrak{a}=\mathrm{span}_{\mathbb{R}}(\{\ & i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|-i|j+1\rangle\langle j+1|-i|N-j-2\rangle\langle N-j-2|;\\ & 0\leqslant j\leqslant 2^{n-1}-2\}), \quad \text{in case } n \text{ odd.}\end{aligned} \quad (4)$$

Modulo checks reserved for the body, the *concurrence canonical decomposition* (CCD) in n-qubits is the resulting matrix decomposition $SU(2^n)=KAK$. Note that n may be even or odd.

In n-qubits, it is certainly *not* the case that K is the Lie group of local unitaries. Nonetheless, we prove momentarily by direct computation that the local unitary group $SU(2)\otimes SU(2)\otimes\cdots\otimes SU(2)\subset K$, with strict containment in $n\geqslant 3$ qubits by a dimension count. Moreover, for $n=2p$ an even number of qubits the concurrence canonical decomposition is computable via an algorithm familiar from the two-qubit case[4] (see Appendix A). The following theorem provides the key to interpreting this extended canonical decomposition.

Theorem I.3: *Let $K=\exp\mathfrak{k}$ for $\mathfrak{k}$ the $+1$-eigenspace of the Cartan involution $\theta(X)=S^{-1}\overline{X}S$. Then K is the symmetry group of the concurrence form $\mathcal{C}_n$. Specifically, for $u\in SU(N)$,*

$$(u\in K)\Leftrightarrow[\mathcal{C}_n(u|\phi\rangle,u|\psi\rangle)=\mathcal{C}_n(|\phi\rangle,|\psi\rangle),\quad \text{for every } |\phi\rangle,|\psi\rangle\in\mathcal{H}_n]. \quad (5)$$

Moreover, for n even the concurrence form is symmetric. In the even case, it restricts to the usual dot product on the $\mathbb{R}$-span of a collection of n concurrence one states, and this $\mathbb{R}$ subspace of $\mathcal{H}_n$ is preserved by K. On the other hand, for n odd $\mathcal{C}_n$ is antisymmetric, i.e. a two-form. Thus,

$$K\cong Sp(N/2),\quad \textit{if } n \textit{ is an odd number of qubits;}$$

$$K\cong SO(N),\quad \textit{if } n \textit{ is an even number of qubits.}$$

Remark I.4: Bremner *et al.* (Ref. 3, Theorem 5) observe symplectic Lie algebras independently in a context related to the above. We explore this in more detail in a future manuscript. ◇

This interpretation allows for an extension of prior work on the entangling capacity of two-qubit unitaries.[26] Here is the precise result.

Definition I.5: The *concurrence capacity* of a given n-qubit unitary operator $v \in SU(N)$ is defined by $\kappa(v) = \max\{C_n(v|\psi\rangle);\ C_n(|\psi\rangle) = 0, \langle\psi|\psi\rangle = 1\}$.

Corollary I.6 (of I.3): Let $u = k_1 a k_2$ be the n-qubit canonical decomposition of $u \in SU(N)$. Then $\kappa(u) = \kappa(a)$.

Given the CCD, the function κ is properly viewed as a function on the A factor rather than on the entire group of phase-normalized unitaries $SU(N)$. Finally, a careful analysis of $\kappa(a)$ for randomly chosen a in A produces the following, perhaps surprising, result.

Theorem I.7: *Suppose the number of qubits is even, i.e., $n = 2p$. Then for large p almost all $a \in A$ have maximal concurrence capacity. Specifically, suppose we choose $a \in A$ at random per the probability density function given by the unit normalized Haar measure da. Then*

$$\lim_{p\to\infty} \text{Probability}[\kappa(a) = 1] = \lim_{p\to\infty} da(\{a \in A; \kappa(a) = 1\}) = 1. \tag{6}$$

We rephrase this result colloquially. Suppose we think of those states $|\psi\rangle$ in even qubits with $\tau_n(|\psi\rangle) = 1$ as GHZ-like. Then as the even number of qubits grows large, almost every unitary evolution will be able to produce such a maximally concurrent GHZ-like state from some input state of 0 concurrence.

Notation and contents: We provide some samples of our notation for the reader's convenience. Throughout, n is a number of qubits and $N = 2^n$. For $v = \Sigma_{j,k=0}^{N-1} v_{j,k}|k\rangle\langle j|$, we have the adjoint $v^\dagger = \Sigma_{j,k=0}^{N-1} \overline{v}_{k,j}|k\rangle\langle j|$. We also require the transpose operation, most easily visualized in matrix form as $(v_{j,k})^T = (v_{k,j})$. Equivalently, $v^T = \Sigma_{j,k=0}^{N-1} v_{j,k}|j\rangle\langle k|$. Thus $v^\dagger = \overline{v^T}$. Recall also the convention of collapsing the binary for an integer inside the ket of a computational basis state. We use lower rather than upper case letters for most operators to avoid confusing them with Lie groups denoted by capital letters. The older term *scholium* is used to refer to a corollary of the proof of a theorem or proposition rather than its formal statement. Besides these conventions, we follow the notations of either Refs. 18 or 8.

The paper is structured as follows. In Sec. II, we verify that the conventions of Definition I.2 are appropriate for invoking the $G = KAK$ theorem. Having verified that the matrix decomposition exists, Sec. II further describes *entanglers* and *finaglers*, loosely similarity matrices which rotate the CCD onto more standard KAK decompositions of $SU(N)$. In Sec. III, we discuss the concurrence capacity and prove the properties of this capacity asserted above. The three appendixes consecutively (i) provide an algorithm for computing the CCD given a matrix $v \in SU(N)$, exclusively in the case n is even, (ii) argue that any two normalized states $|\phi\rangle$, $|\psi\rangle$ with identical concurrence must have $k|\phi\rangle = |\psi\rangle$ for some k in the symmetry group K, and (iii) prove that the concurrence $C_n(-)$ is an entanglement monotone.

II. ENTANGLERS, FINAGLERS, AND CARTAN INVOLUTIONS OF $\mathfrak{su}(N)$

This section has two goals. First, we show our KAK decomposition is well-defined, by noting that θ is a Cartan involution, checking by direct computation that $\mathfrak{a}$ is Abelian, and arguing that $\mathfrak{a}$ is maximal commutative. Second, we prove Theorem I.3. There are generally two approaches to the theorem. We could recall standard Cartan involutions and KAK decompositions from the literature. We will shortly construct similarity matrices E_0 and F_0 which rotate the standard $G = KAK$ decompositions of $SU(N)$ onto the CCD, and we could simply appeal to these matrices and the standard structures. Alternately, (many) intrinsic computations would suffice to check the required properties for $G = KAK$. The present approach is a compromise. The argument that the CCD $SU(N) = KAK$ is well-defined is intrinsic, except for a single appeal to classification. On the other hand, the classification of the K groups uses similarity matrices. As such, it is ultimately a change of basis in the n-qubit state space $\mathcal{H}_n$.

A. Properties of the CCD $SU(N)=KAK$

The following proposition is not used in the sequel. However, we include a direct proof due to its importance in guiding the choice of θ. It simplifies an older argument and arose from correspondence with Zanardi.

Proposition II.1: Let K be as in Definition I.2. Then there is an inclusion $SU(2)\otimes SU(2)\otimes\cdots\otimes SU(2)\subset K$.

Proof: Recall $i\sigma^x=i|0\rangle\langle 1|+i|1\rangle\langle 0|$, $i\sigma^y=|0\rangle\langle 1|-|1\rangle\langle 0|$, and $i\sigma^z=i|0\rangle\langle 0|-i|1\rangle\langle 1|$ forms a basis of $\mathfrak{su}(2^1)$. For the statement of the proposition, it suffices to check $\mathrm{Lie}[\otimes_1^n SU(2)]=\mathrm{span}\{i\sigma_j^x,i\sigma_j^y,i\sigma_j^z;\ 1\leqslant j\leqslant n\}\subset\mathfrak{k}$. We further recall the last item of Lemma II.2, as well as the fact that the complex conjugates of the Pauli matrices are $\overline{i\sigma^x}=-i\sigma^x$, $\overline{i\sigma^y}=i\sigma^y$, and $\overline{i\sigma^z}=-i\sigma^z$. Then we wish to show that θ fixes every σ_j^x, σ_j^y, and σ_j^z. For this,

$$(-1)^n S\ \overline{(i\sigma_j^x)}S=(-1)^n S(-i\sigma_j^x)S=(-1)^n S^2(i\sigma_j^x)=(i\sigma_j^x),$$

$$(-1)^n S\overline{(i\sigma_j^y)}S=(-1)^n S(i\sigma_j^y)S=(-1)^n S^2(i\sigma_j^y)=(i\sigma_j^y),$$

$$(-1)^n S\overline{(i\sigma_j^z)}S=(-1)^n S(-i\sigma_j^z)S=(-1)^n S^2(i\sigma_j^z)=(i\sigma_j^z).$$

Hence each such infinitesimal unitary is in the $+1$ eigenspace of θ. This concludes the proof. □

We next note that θ is a Cartan involution. Indeed, direct computation shows that $\theta^2=\mathbf{1}$. Moreover,

$$[\theta X,\theta Y]=(S^{-1}\overline{X}S)(S^{-1}\overline{Y}S)-(S^{-1}\overline{Y}S)(S^{-1}\overline{X}S)=S^{-1}\overline{(XY-YX)}S=\theta[X,Y]. \tag{7}$$

Thus we need the following to complete the argument that $SU(N)=KAK$ of Definition I.2 is well-defined: (i) $\mathfrak{a}\subset\mathfrak{p}$, (ii) $\mathfrak{a}$ is commutative, and (iii) no larger subalgebra of $\mathfrak{p}$ containing $\mathfrak{a}$ is commutative.

Lemma II.2: Let #j denote the number of 1's in the binary expansion of j. Let $S=(-i\sigma_1^y)\times(-i\sigma_2^y)\cdots(-i\sigma_n^y)$ be as in Definition I.2. Then (i) $S|j\rangle=(-1)^{\#j}|N-j-1\rangle$, (ii) $\langle j|S=(-1)^{n-\#j}\langle N-j-1|$, and (iii) $S\sigma_j^x=-\sigma_j^x S$, $S\sigma_j^y=\sigma_j^y S$, and $S\sigma_j^z=-\sigma_j^z S$. Note that (ii) refers to a composition of linear maps.

Sketch: For (i), compute. For (ii), consider $\langle j|S|k\rangle$ for $|k\rangle$ varying over all computational basis states. Then apply (i) for (ii). For (iii), distinct Pauli matrices anticommute, while S itself is a tensor. □

Lemma II.3: Let $\mathfrak{a}$ be as in Definition I.2. Then $\mathfrak{a}\subset\mathfrak{p}$.

Proof: There are two coordinate computations to complete in this case. For the first, momentarily extend the definition of θ to $\tilde{\theta}$ acting on $\mathfrak{u}(N)$ by the same formula. Then

$$\begin{aligned}\tilde{\theta}&[i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|]\\&=(-1)^n S(-i|j\rangle\langle j|-i|N-j-1\rangle\langle N-j-1|)S\\&=(-1)^{n+1}i[(-1)^n|N-j-1\rangle\langle N-j-1|+(-1)^n|j\rangle\langle j|]\\&=-i|j\rangle\langle j|-i|N-j-1\rangle\langle N-j-1|.\end{aligned}$$

Thus $i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|$ is in the -1-eigenspace of $\tilde{\theta}$, so that the elements of the first set of the definition of $\mathfrak{a}$ are contained in $\mathfrak{p}$. For the second basis set in case n even,

$$\begin{aligned}
&\theta[i|j\rangle\langle N-j-1|+i|N-j-1\rangle\langle j|]\\
&\quad=S[(-i)|j\rangle\langle N-j-1|+(-i)|N-j-1\rangle\langle j|]S\\
&\quad=[(-1)^{\#j+[n-(n-\#j)]}(-i)|N-j-1\rangle\langle j|+(-1)^{n-\#j+(n-\#j)}(-i)|j\rangle\langle N-j-1|]\\
&\quad=(-i)|N-j-1\rangle\langle j|+(-i)|j\rangle\langle N-j-1|.
\end{aligned}$$

Thus $i|j\rangle\langle N-j-1|+i|N-j-1\rangle\langle j|\in\mathfrak{p}$, in case n even. □

Proposition II.4: Recall $\mathfrak{a}$ *from Definition I.2. Then* $\mathfrak{a}$ *is commutative.*

Proof: Throughout, $0\leqslant j,k\leqslant N/2-1$, $N=2^n$. The following three computations of Lie brackets suffice:

$$\begin{aligned}
&[i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|,i|k\rangle\langle k|+i|N-k-1\rangle\langle N-k-1|]\\
&\quad=-|j\rangle\langle j|k\rangle\langle k|-|N-j-1\rangle\langle N-j-1|N-k-1\rangle\langle N-k-1|\\
&\qquad+|k\rangle\langle k|j\rangle\langle j|+|N-k-1\rangle\langle N-k-1|N-j-1\rangle\langle N-j-1|;
\end{aligned}$$

$$\begin{aligned}
&[(-i)^{n+1}|j\rangle\langle N-j-1|+i^{n-1}|N-j-1\rangle\langle j|,(-i)^{n+1}|k\rangle\langle N-k-1|+i^{n-1}|N-k-1\rangle\langle k|]\\
&\quad=-|j\rangle\langle N-j-1|N-k-1\rangle\langle k|-|N-j-1\rangle\langle j|k\rangle\langle k|\\
&\qquad+|k\rangle\langle N-k-1|N-j-1\rangle\langle j|+|N-k-1\rangle\langle k|j\rangle\langle N-j-1|;
\end{aligned}$$

$$\begin{aligned}
&[i|j\rangle\langle j|+i|N-j-1\rangle\langle N-j-1|,(-i)^{n+1}|k\rangle\langle N-k-1|+i^{n-1}|N-k-1\rangle\langle k|]\\
&\quad=(-i)^n|j\rangle\langle j|k\rangle\langle N-k-1|+i^n|N-j-1\rangle\langle N-j-1|N-k-1\rangle\langle k|\\
&\qquad-(-i)^n|k\rangle\langle N-k-1|N-j-1\rangle\langle N-j-1|-i^n|N-k-1\rangle\langle k|j\rangle\langle j|.
\end{aligned}$$

Each of the final expressions is zero in case $j\neq k$ and also zero in case $j=k$. Thus, $\mathfrak{a}$ is commutative. □

The arguments above almost complete the proof that the CCD $SU(N)=KAK$ is well-defined. In the abstract, one also needs a fairly large coordinate computation which verifies $\mathfrak{a}$ is maximal commutative. This would verify that for any $X\in\mathfrak{p}$ with $[X,H]=0$ for all $H\in\mathfrak{a}$, one must in fact have $X\in\mathfrak{a}$.

Rather than complete that task, we instead appeal to the Cartan classification (Ref. 8, p. 518, Table V). Ostensibly a classification of globally symmetric spaces, this classification also describes all possible Cartan involutions of any real semisimple group G up to Lie isomorphism. For $G=SU(N)$, there are three overall possibilities grouped as type **AI**, **AII**, and **AIII**. For each, the *rank* refers to the dimension of any maximal commutative subalgebra $\mathfrak{a}$ of $\mathfrak{p}$. This dimension may not vary by subalgebra, since any two such $\mathfrak{a}_1$, $\mathfrak{a}_2$ must have $k\mathfrak{a}_1k^{-1}=\mathfrak{a}_2$ for some $k\in K$. We now excerpt from the table the possibilities for $G=SU(N)$:

Type	Domain $\mathfrak{g}$ of $\theta:\mathfrak{g}\to\mathfrak{g}$	Isomorphism representative of K	Rank
AI	$\mathfrak{su}(N)$	$SO(N)$	$N-1$
AII	$\mathfrak{su}(N)$	$Sp(N/2)$	$N/2-1$
AIII	$\mathfrak{su}(N)$	$S[U(p)\oplus U(q)],p+q=N$	$\min(p,q)$

Suppose then for the moment that the number of qubits n is even. No type **AIII** Cartan involution admits an $\mathfrak{a}$ of dimension $N-1$. Indeed, if $p+q=N$, then $\min(p,q)\leqslant N/2<N-1$. The same is true of type **AII** involutions, i.e., $N-1>N/2-1$. Hence we see that A must be maximal, and for n even the Cartan involution θ must have type **AI**.

What remains is to prove that $\mathfrak{a}$ is maximal in $\mathfrak{p}$ in case n odd. This follows by a dimension count *if* the Cartan involution is type **AII**. We thus postpone noting this point until after the proof of Theorem I.3. See Remark II.19.

As an aside, type **AIII** involutions do not appear in this work but have been used in quantum circuit design. Indeed, the CS-decomposition[7,21] is an example of a *KAK* decomposition arising from a type **AIII** involution. Elements within the appropriate K group may be interpreted as products of computations on the last $n-1$ lines with computations on these lines controlled on the first qubit.

B. Entanglers

In the two-qubit case, the following computation E has the following property:

$$E=(1/\sqrt{2})\begin{pmatrix}1 & i & 0 & 0\\ 0 & 0 & 1 & i\\ 0 & 0 & -1 & i\\ 1 & -i & 0 & 0\end{pmatrix} \text{ satisfies } E^{\dagger}[SU(2)\otimes SU(2)]E=SO(4). \tag{8}$$

Using more Lie theory terminology, recall the adjoint representation of G on $\mathfrak{g}$ given by $\mathrm{Ad}(g)\times[X]=gXg^{-1}$. Then we may restate $\{\mathrm{Ad}(E^{\dagger})\}[SU(2)\otimes SU(2)]=SO(4)$. This provides a physical interpretation for the low dimensional isomorphism $\mathfrak{su}(2)\oplus\mathfrak{su}(2)\cong\mathfrak{so}(4)$. We would like entanglers for the concurrence canonical decomposition.

Definition II.5: Let $\theta_{\mathbf{AI}}:\mathfrak{su}(2^n)\to\mathfrak{su}(2^n)$ denote the usual type **AI** Cartan involution $\theta_{\mathbf{AI}}(X)=\overline{X}$ associated to $SO(N)\subset SU(N)$. We say $E\in SU(2^n)$ is an entangler iff the following diagram commutes:

$$\begin{array}{ccc}\mathfrak{su}(N) & \xrightarrow{\theta_{\mathrm{AI}}} & \mathfrak{su}(N)\\ {\scriptstyle \mathrm{Ad}(E)}\downarrow & & \downarrow{\scriptstyle \mathrm{Ad}(E)}\\ \mathfrak{su}(N) & \xrightarrow{\theta} & \mathfrak{su}(N)\end{array}. \tag{9}$$

In particular as both groups are connected, we must have $\mathrm{Ad}(E)[SO(N)]=K$.

We next prove the surprising fact that there are no entanglers when n is odd. For this, we need to recall the central subgroup $\mathcal{Z}[SU(N)]=\{v\in SU(N); vuv^{\dagger}=u \text{ for all } u\in SU(N)\}$. The center is in fact the set of all phase computations corresponding to the Nth roots of unity:

$$\mathcal{Z}[SU(N)]=\{\xi\mathbf{1};\xi^N=1\} \quad (\text{Ref. 8, pp. 310, 516}). \tag{10}$$

With this fact recalled from the literature, we have the following lemma.

Lemma II.6: Suppose that for $v\in SU(N)$, $[\mathrm{Ad}(v)](X)=vXv^{\dagger}=X$ for every $X\in\mathfrak{su}(N)$. Then $v=\xi\mathbf{1}$ for some $\xi\in\mathbb{C}$ with $\xi^N=1$. (Hence $\xi=e^{2\pi ik/N}$,$0\leqslant k\leqslant N-1$.)

Proof: Recall that $\exp:\mathfrak{su}(N)\to SU(N)$ is onto. Thus each $u\in SU(N)$ may be written as $\exp X$ for some X. Thus, consider the one-parameter-subgroup (Ref. 8 p. 104) $\gamma:\mathbb{R}\to SU(N)$ given by $t\mapsto v[\exp(tX)]v^{\dagger}$. This has derivative $(d\gamma/dt)\big|_{t=0}=vXv^{\dagger}=X$, and by uniqueness of one-parameter-subgroups (Ref. 8, p. 103, Corollary 1.5) $v\exp(tX)v^{\dagger}=\exp(tX)$ for all t. Taking $t=1$, we see $vuv^{\dagger}=u$ for a generic $u\in SU(N)$. □

Proposition II.7: If the number of qubits n is odd, then there does not exist an entangler $E\in U(N)$.

Proof: Assume by way of contradiction that there does exist an entangler E for n odd. Then for all $X\in\mathfrak{su}(N)$, we have the following equation:

$$(EE^T)\overline{X}(EE^T)^{\dagger} = E\theta_{\mathbf{AI}}[E^{\dagger}XE]E^{\dagger}=\theta(X)=S\overline{X}S^{-1}. \tag{11}$$

Since we may vary $Y=\overline{X}$ over $\mathfrak{su}(N)$ as well, this implies that $S^{-1}EE^T$ satisfies the hypothesis of Lemma II.6. Thus $S^{-1}EE^T=\xi\mathbf{1}$ for $\xi^N=1$ or $EE^T=(\xi\mathbf{1})S$. The contradiction for EE^T is always a complex symmetric matrix while $(\xi\mathbf{1})S$ is not a complex symmetric matrix when n is odd. □

Scholium II.8: For an even number of qubits n, the matrix $E\in U(N)$ is an entangler iff $EE^T=(\xi\mathbf{1})S$, where $\xi^N=1$.

There are many possible entanglers. Indeed, even in two-qubits other choices have been used.[15,26] One possibility given n even is to take the $n/2$ fold tensor product $E\otimes E\otimes\cdots\otimes E$. However, we prefer the following choice as a standard instead, since it highlights the mapping of the computational basis to Greenberger–Horne–Zeilinger states.

Definition II.9: Suppose n is even, and write $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)=\Sigma_{j=0}^{N/2-1}\varepsilon_j(|j\rangle\times\langle N-j-1|+|N-j-1\rangle\langle j|)$, with $\varepsilon_j=(-1)^{\#j}$, where $\#j$ is the number of 1's in the binary expression for j. The standard entangler E_0 in n-qubits is then given by

$$E_0=\frac{1}{\sqrt{2}}\sum_{j=0}^{N/2-1}|j\rangle\langle 2j|+i|j\rangle\langle 2j+1|+\varepsilon_j(|N-j-1\rangle\langle 2j|-i|N-j-1\rangle\langle 2j+1|). \tag{12}$$

Proposition II.10: The standard entangler E_0 is an entangler.

Proof: First, we omit due to reasons of space a set of row operations which verifies that $\det(E_0)=1$. Then we may write out an expression for E_0^T by reversing the indices in each bra-ket pair:

$$E_0^T=\frac{1}{\sqrt{2}}\sum_{k=0}^{N/2-1}|2k\rangle\langle k|+i|2k+1\rangle\langle k|+\varepsilon_k(|2k\rangle\langle N-k-1|-i|2k+1\rangle\langle N-k-1|). \tag{13}$$

Then Scholium II.8 shows that the following computation suffices to prove that E is an entangler:

$$\begin{aligned}E_0E_0^T=&\frac{1}{2}\sum_{j=0}^{N/2-1}|j\rangle\langle j|+\varepsilon_j|j\rangle\langle N-j-1|+i^2|j\rangle\langle j|+\varepsilon_j|j\rangle\langle N-j-1|+\varepsilon_j|N-j-1\rangle\langle j|\\&+\varepsilon_j^2|N-j-1\rangle\langle N-j-1|+\varepsilon_j(|N-j-1\rangle\langle j|+i^2\varepsilon_j^2|N-j-1\rangle\langle N-j-1|)\\=&\sum_{j=0}^{N/2-1}\varepsilon_j(|j\rangle\langle N-j-1|+|N-j-1\rangle\langle j|)\\=&(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y).\end{aligned} \tag{14}$$

This concludes the coordinate computation. □

In the next section, we will also make use of the following lemma. The computation is similar.

Lemma II.11: $E_0^TE_0$ is diagonal and real. In fact, $E_0^TE_0=|0\rangle\langle 0|-|1\rangle\langle 1|+|2\rangle\langle 2|-|3\rangle\langle 3|+\cdots$.

Proof: Computing the reversed product:

$$\begin{aligned}E_0^TE_0=&\frac{1}{2}\sum_{j=0}^{N/2-1}|2j\rangle\langle 2j|+i|2j+1\rangle\langle 2j|+i|2j\rangle\langle 2j+1|-|2j+1\rangle\langle 2j+1|\\&+\varepsilon_j^2|2j\rangle\langle 2j|-i\varepsilon_j^2|2j\rangle\langle 2j+1|-i\varepsilon_j^2|2j+1\rangle\langle 2j|+i^2\varepsilon_j^2|2j+1\rangle\langle 2j+1|\\=&\sum_{j=0}^{N/2-1}|2j\rangle\langle 2j|-|2j+1\rangle\langle 2j+1|.\end{aligned} \tag{15}$$

This concludes the proof. □

Example II.12: Although this example is large, we explicitly describe the standard four-qubit entangler:

$$E_0=(1/\sqrt{2})\begin{pmatrix}
1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & i & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & i & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & i & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & i\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & i\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & -i & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & -i & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & i & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 1 & -i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & -1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & -1 & i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
1 & -i & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{pmatrix}. \tag{16}$$

Note that the antidiagonal pattern mirrors $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)$ and that each computational basis state maps to a relative phase of a GHZ state. ◇

C. Finaglers

There do not exist entanglers when the number of qubits n is odd, because $\mathfrak{k}\cong\mathfrak{sp}(N/2)$ rather than $\mathfrak{so}(N)$. See the as yet unproven Theorem I.3. Yet the fairly abstract embedding K of $Sp(N/2)$ into $SU(N)$ might be made more standard. This is indeed possible, and we call the any matrix which rotates K to the standard $Sp(N/2)$ a finagler.

Definition II.13: Let $\theta_{\mathbf{AII}}:\mathfrak{su}(N)\to\mathfrak{su}(N)$ be the standard Cartan involution (Ref. 8, p. 445) fixing $\mathfrak{sp}(N/2)$, i.e., $\theta_{\mathbf{AII}}(X)=(-i\sigma^y\otimes\mathbf{1}_{N/2})X^T(-i\sigma^y\otimes\mathbf{1}_{N/2})=(-i\sigma^y\otimes\mathbf{1}_{N/2})^{-1}\overline{X}(-i\sigma^y\otimes\mathbf{1}_{N/2})$. Then a finagler F is any $F\in SU(2^n)$ which causes the following diagram to commute:

$$\begin{array}{ccc}
\mathfrak{su}(N) & \xrightarrow{\theta_{\mathrm{AII}}} & \mathfrak{su}(N)\\
{\scriptstyle \mathrm{Ad}(F)}\downarrow & & \downarrow{\scriptstyle \mathrm{Ad}(F)}\\
\mathfrak{su}(N) & \xrightarrow{\theta} & \mathfrak{su}(N)
\end{array}. \tag{17}$$

If $F\in SU(N)$, then we say F finagles iff F is a finagler.

Proposition II.14: F is a finagler iff $F(-i\sigma^y\otimes\mathbf{1}_{N/2})^TF^T=(\xi\mathbf{1})(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)=(\xi\mathbf{1})S$, $\xi^N=1$.

Proof: For convenience, label $\Sigma=-i\sigma^y\otimes\mathbf{1}_{N/2}$. ($F$ finagles)$\Leftrightarrow[F\Sigma^{-1}(\overline{F^\dagger XF})\Sigma F^\dagger=S^{-1}\overline{X}S\ \forall X\in\mathfrak{su}(N)]\Leftrightarrow[F\Sigma^TF^T=(\xi\mathbf{1})S,\xi^N=1]$. Note that the second equivalence uses Lemma II.6. □

Example II.15: In three qubits, we see the following computation is a finagler by direct computation:

$$F=(1/\sqrt{2})\begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \end{pmatrix}. \tag{18}$$

Unlike entanglers, it is possible for $F=\overline{F}$. The finagler maps computational basis states to GHZ states. ◇

Definition II.16: Fix n an odd number of qubits. Let $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)=\Sigma_{j=0}^{N/2-1}\iota_j(|N-j-1\rangle\langle j|-|j\rangle\langle N-j-1|)$ with $\iota_j=\pm 1$. The standard finagler F_0 is defined to be the following linear operator:

$$F_0=\sum_{j=0}^{N/2-1}|j\rangle\langle j|+|N-j-1\rangle\langle j|+\iota_j(|j\rangle\langle N/2+j|-|N-j-1\rangle\langle N/2+j|). \tag{19}$$

Note that the standard finagler is real.

Proposition II.17: The standard finagler F_0 finagles.

Proof: We again omit the column operations verifying $\det(F_0)=1$, as this would take several pages. Thus, let $\Sigma=-i\sigma^y\otimes\mathbf{1}_{N/2}$ be expanded as $\Sigma=\Sigma_{j=0}^{N/2-1}|j\rangle\langle N/2+j|-|N/2+j\rangle\langle j|$. We have the following equation:

$$F_0\Sigma=\frac{1}{\sqrt{2}}\sum_{j=0}^{N/2-1}|j\rangle\langle N/2+j|+|N-j-1\rangle\langle N/2+j|-\iota_j(|j\rangle\langle j|-|N-j-1\rangle\langle j|). \tag{20}$$

Moreover, $F_0^T=(1/\sqrt{2})\,\Sigma_{j=0}^{N/2-1}|j\rangle\langle j|+|j\rangle\langle N-j-1|+\iota_j(|N/2+j\rangle\langle j|-|N/2+j\rangle\langle N-j-1|)$. Thus we see that

$$\begin{aligned}(F_0\Sigma)F_0^T=&\frac{1}{2}\sum_{j=0}^{N/2-1}\iota_j(|j\rangle\langle j|-|j\rangle\langle N-j-1|+|N-j-1\rangle\langle j|-|N-j-1\rangle\langle N-j-1|)\\&-\iota_j(|j\rangle\langle j|+|j\rangle\langle N-j-1|-|N-j-1\rangle\langle j|-|N-j-1\rangle\langle N-j-1|)\\=&\sum_{j=0}^{N/2-1}\iota_j(|N-j-1\rangle\langle j|-|j\rangle\langle N-j-1|).\end{aligned} \tag{21}$$

This concludes the proof. □

We also briefly review how $Sp(N/2)$ embeds into $SU(N)$. By one standard definition of the group (Ref. 8, p. 446),

$$\mathfrak{sp}(N/2)=\left\{\begin{pmatrix} X_1 & X_2 \\ X_3 & -X_1^T \end{pmatrix};X_j=\overline{X_j},X_{2,3}\ \text{symmetric}\right\}. \tag{22}$$

Another standard definition (Ref. 11, pp. 34–36) uses a symmetry in matrices of quaternions. Note that the matrices of Eq. (22) are not elements of $\mathfrak{su}(N)$. Rather, the $+1$ eigenspace of $\theta_{\mathbf{AII}}(X)=\Sigma^{-1}\overline{X}\Sigma$ is

$$\mathfrak{sp}(N/2)=\left\{\begin{pmatrix} V & W \\ -W^\dagger & \overline{V}\end{pmatrix}; V\in\mathfrak{u}(N/2), W=W^T \text{ is complex symmetric}\right\}. \tag{23}$$

[For example, $Sp(4)\subset SU(8)$; this is 36 dimensional. For W includes two real symmetric matrices with 10 dimensions each, while $\mathfrak{u}(4)$ is 16 dimensional.] One may verify that this is also a copy of $\mathfrak{sp}(N/2)$, so that $\mathfrak{k}$ is a copy of $\mathfrak{sp}(N/2)$ as well. Also, note that for $k\in K$, in particular $k\in\otimes_1^n SU(2)$, we expect $FkF^\dagger$ to be in the *copy of* $Sp(N/2)$ *above* rather than to be a real matrix in an orthogonal subgroup of $SU(N)$. Finally, note that exponentiating the Lie algebra above is not the best way to write out a closed form for elements of the global group $Sp(N/2)$. Rather, we have a block form:

$$\begin{aligned} Sp(N/2)&=\{V\in SU(N); V^T\Sigma V=\Sigma\}\\ &=\left\{\begin{pmatrix} A & B\\ C & D\end{pmatrix}\in SU(N);\ \begin{matrix} A^TC \text{ is symmetric}, B^TD \text{ is symmetric}\\ A^TD-C^TB=\mathbf{1}\end{matrix}\right\}. \end{aligned} \tag{24}$$

D. *K* is the symmetry group of the concurrence form

We are now in a position to provide the physical interpretation of K. Namely, K is the symmetry group of the concurrence bilinear form, as stated in Theorem I.3.

Proof of Theorem I.3: We first prove that $v\in K$ iff $\mathcal{C}_n(v|\phi\rangle, v|\psi\rangle)=\mathcal{C}_n(|\phi\rangle,|\psi\rangle)$ for all $|\phi\rangle$, $|\psi\rangle\in\mathcal{H}_n$. Let $X=\log v$. Since $X\in\mathfrak{su}(N)$, X is anti-Hermitian, i.e., $X=-X^\dagger=-\overline{X^T}$. Finally, recall $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)$. Thus in mathematical notation, we have for $w,x\in\mathcal{H}_n$ the concurrence form given by $\mathcal{C}_n(w,x)=w^TSv$. Hence

$$(X=S^{-1}\overline{X}S)\Leftrightarrow(SX=\overline{X}S)\Leftrightarrow(SX=-X^TS)\Leftrightarrow(X^TS+SX=0)\Leftrightarrow(v^TSv=S). \tag{25}$$

Now the first item is equivalent to $v\in K$ while the last is equivalent to $\mathcal{C}(vw,vx)=(w^Tv^T)S(vx)=w^T(v^TSv)x=w^TSx=\mathcal{C}(w,x)$ for all $w,x\in\mathcal{H}_n$.

We next prove that for n odd, $K\cong Sp(N/2)$. To do so, it suffices to show n odd implies $\mathcal{C}_n$ is a nondegenerate two-form on $\mathcal{H}_n$. We first show $\mathcal{C}_n(x,w)=-\mathcal{C}_n(w,x)$ for any $w,x\in\mathcal{H}_n$. Noting that the transpose of a 1×1 matrix is again the same matrix, we realize that $\mathcal{C}_n$ is a two-form as follows:

$$\mathcal{C}_n(w,x)=w^TSx=[w^TSx]^T=x^TS^Tw=-x^TSw=-\mathcal{C}_n(x,w). \tag{26}$$

Moreover, consider the tensor expression for S. We see that no eigenvalues of S are zero, and hence the form is nondegenerate. Thus, we must have $K\cong Sp(N/2)$.

Suppose now that n is even. We finally prove $K\cong SO(N)$. It suffices to construct a real vector space $V_{\mathbb{R}}\subset\mathcal{H}_n$ so that the following properties hold:

- $K\cdot V_{\mathbb{R}}\subseteq V_{\mathbb{R}}$;
- The restriction of $\mathcal{C}_n$ to $V_{\mathbb{R}}\times V_{\mathbb{R}}$ is the usual dot product in the coordinates of a given basis.

Consider then $V_{\mathbb{R}}=\mathrm{span}_{\mathbb{R}}\{E_0|j\rangle;\ 0\leqslant j\leqslant N-1\}$, for E_0 the standard entangler of Definition II.9. Since E_0 is an entangler, certainly $K\cdot V_{\mathbb{R}}\subset V_{\mathbb{R}}$ since K acts on this real vector space by (real) orthogonal maps. Moreover, consider the concurrence on $V_{\mathbb{R}}$. For w,x in the $\mathbb{R}$ span of the computational basis, we have E_0w, E_0x generic vectors in $V_{\mathbb{R}}$. Then

$$\mathcal{C}_n(E_0w,E_0x)=(E_0w)^TS(E_0x)=w^TE_0^TSE_0x=w^TE_0^TE_0E_0^TE_0x=w^T\mathbf{1}x=w\cdot x, \tag{27}$$

with the fourth equality by Lemma II.11. Hence in an even number of qubits, K fixes a real inner product on a real vector subspace of $\mathcal{H}_n$. Thus $K \cong SO(N)$. □

Scholium II.18: For n even, for E_0 the standard entangler of Definition II.9, for any $|\phi\rangle$, $|\psi\rangle \in \mathcal{H}_n$, we have $\mathcal{C}_n(E_0|\phi\rangle, E_0|\psi\rangle) = \overline{\langle\phi|\psi\rangle}$.

Remark II.19: Note that independent of any discussion of the algebra $\mathfrak{a}$ in n an odd number of qubits, we have shown that the Cartan involution θ has type **AII**. Hence any commutative $N/2-1$ dimensional subalgebra of $\mathfrak{p}$ must be maximal, and the concurrence canonical decomposition $SU(N)=KAK$ is well-defined for n odd. ◇

Remark II.20: Similar to Scholium II.18, note that the standard (real) finagler F_0 of Definition II.16 translates between the concurrence and the more standard two-form $(w,x) \mapsto w^T[(-i\sigma^y) \otimes \mathbf{1}_{N/2}]x$. Indeed, $F_0^{-1} = F_0^T$ since F_0 is orthogonal. Moreover, let w,x be in the real span of the computational basis states $\{|j\rangle;\ 0 \leqslant j \leqslant N-1\}$. Then we may view $\{F_0|j\rangle;\ 0 \leqslant j \leqslant N-1\}$ as a finagled basis, and the pullback of the concurrence from the finagled to the computational basis is the model two-form. Indeed, labeling $\Sigma = (-i\sigma^y) \otimes \mathbf{1}_{N/2}$, $F_0 \Sigma F_0^T = S$ and F_0 real imply $\Sigma = F_0^T S F_0$. Hence $\mathcal{C}_n(F_0 w, F_0 x) = (F_0 w)^T S (F_0 x) = w^T \Sigma x$. ◇

E. Cartan involution in coordinates

We finally present the Cartan involution in coordinates and provide some sample calculations. Let $X \in \mathfrak{su}(N)$, say with $X = \Sigma_{j,k=0}^{N-1} x_{j,k}|k\rangle\langle j|$. We now compute explicitly $\theta(X)$ so as to arrive at coefficient expressions for $\mathfrak{p}$, $\mathfrak{k}$.

$$\theta(X) = (-1)^n \sum_{j,k=0}^{N-1} \overline{x_{j,k}} S|k\rangle\langle j|S = (-1)^{n+n-\#k+\#j} \sum_{j,k=0}^{N-1} \overline{x_{j,k}}|N-k-1\rangle\langle N-j-1|.$$

Consequently, we have the following characterizations:

- $X = \Sigma_{j,k=0}^{N-1} x_{j,k}|k\rangle\langle j| \in \mathfrak{p}$ iff $[(X \in \mathfrak{su}(N))$ and $(x_{N-1-k,N-1-j} = (-1)^{\#j+\#k+1}\overline{x_{k,j}})]$;
- $X = \Sigma_{j,k=0}^{N-1} x_{j,k}|k\rangle\langle j| \in \mathfrak{k}$ iff $[(X \in \mathfrak{su}(N))$ and $(x_{N-1-k,N-1-j} = (-1)^{\#j+\#k}\overline{x_{k,j}})]$.

This moreover produces the following description of $\mathfrak{k}$.

$$\begin{aligned}\mathfrak{k} = \mathrm{span}_{\mathbb{R}}\{&|k\rangle\langle j| - |j\rangle\langle k| + (-1)^{\#j+\#k}|N-k-1\rangle\langle N-j-1| - (-1)^{\#j+\#k}|N-j-1\rangle\langle N-k-1|\} \\ &\sqcup \{i|k\rangle\langle j| + i|j\rangle\langle k| + (-1)^{\#k+\#j+1} i|N-j-1\rangle\langle N-k-1| + (-1)^{\#j+\#k+1} i|N-k-1\rangle \\ &\times \langle N-j-1|\} \sqcup \{i|j\rangle\langle j| - i|N-j-1\rangle\langle N-j-1|\}. \end{aligned} \tag{28}$$

Remark II.21: We *warn* the reader that the above expression does not allow one to count dimensions. Several repetitions occur from set to set, and moreover the expressions may vanish in case $j = N-k-1$. ◇

F. Example in the two-qubit case

Recall the subalgebra $[\mathbf{1} \otimes \mathfrak{su}(2)] \oplus [\mathfrak{su}(2) \otimes \mathbf{1}]$ of infinitesimal transformations by $SU(2) \otimes SU(2) \subseteq SU(4)$. We show how the above equation (28) recovers this subalgebra in the case of $n=2$ qubits.

We begin by plugging $k=0$, $j=1$. Expanding into binary (or writing out the matrix) makes clear this is a tensor, and moreover a tensor by an identity matrix. Recall again that both are required to be in the Lie algebra of $SU(2) \otimes SU(2)$:

$$\begin{aligned}|0\rangle\langle 1| - |1\rangle\langle 0| - |3\rangle\langle 2| + |2\rangle\langle 3| &= |00\rangle\langle 01| - |01\rangle\langle 00| - |11\rangle\langle 10| + |10\rangle\langle 11| \\ &= (|0\rangle\langle 0| + |1\rangle\langle 1|) \otimes (|0\rangle\langle 1| - |1\rangle\langle 0|). \end{aligned} \tag{29}$$

One may similarly analyze the following matrices:

$$
\begin{aligned}
&i|0\rangle\langle 1|+i|1\rangle\langle 0|+i|3\rangle\langle 2|+i|2\rangle\langle 3|,\\
&|0\rangle\langle 2|-|2\rangle\langle 0|-|3\rangle\langle 1|+|1\rangle\langle 3|,\\
&i|0\rangle\langle 2|+i|2\rangle\langle 0|+i|3\rangle\langle 1|+i|1\rangle\langle 3|.
\end{aligned}
\tag{30}
$$

Note that for the next four expressions, substitution returns a 0 matrix:

$$
\begin{aligned}
&|0\rangle\langle 3|-|3\rangle\langle 0|+|3\rangle\langle 0|-|0\rangle\langle 3|,\\
&i|0\rangle\langle 3|+i|3\rangle\langle 0|-i|3\rangle\langle 0|-i|0\rangle\langle 3|,\\
&|1\rangle\langle 2|-|2\rangle\langle 1|+|2\rangle\langle 1|-|1\rangle\langle 2|,\\
&i|1\rangle\langle 2|+i|2\rangle\langle 1|-i|2\rangle\langle 1|-i|1\rangle\langle 2|.
\end{aligned}
\tag{31}
$$

Further substitution yields the following:

$$
\begin{aligned}
&|1\rangle\langle 3|-|3\rangle\langle 1|+|2\rangle\langle 0|-|0\rangle\langle 2|,\\
&i|1\rangle\langle 3|+i|3\rangle\langle 1|+i|2\rangle\langle 0|+i|0\rangle\langle 2|,\\
&|2\rangle\langle 3|-|3\rangle\langle 2|-|1\rangle\langle 0|+|0\rangle\langle 1|,\\
&i|2\rangle\langle 3|+i|3\rangle\langle 2|+i|1\rangle\langle 0|+i|0\rangle\langle 1|.
\end{aligned}
\tag{32}
$$

Finally, we consider the diagonal matrices in $\mathfrak{k}$:

$$
\begin{aligned}
&i|0\rangle\langle 0|-i|3\rangle\langle 3|,\\
&i|1\rangle\langle 1|-i|2\rangle\langle 2|.
\end{aligned}
\tag{33}
$$

Note that the $\mathbb{R}$ span of these two matrices coincides with $\mathbb{R}(i\sigma_z^1)\oplus\mathbb{R}(i\sigma_z^2)$.

The Cartan involution formalism thus works, although in a cumbersome way. We next explore the answer it returns in the three-qubit case.

G. Example in the three-qubit case, $K=Sp(4)$

We now describe explicitly the output of Eq. (28) in three qubits. The corresponding real Lie algebra is thirty-six dimensional, which implies by the Cartan classification that K is an abstract copy of $Sp(4)$. A copy of $SO(8)$ would rather be 28 dimensional.

The simplest way to organize the three qubit computation is to appeal to separation. We say a term $|k\rangle\langle j|$ has separation $|k-j|$ and extend linearly. In Eq. (28), each matrix described has a well-defined separation:

$$
\begin{aligned}
&\text{Separation } 0 && i|0\rangle\langle 0|-i|7\rangle\langle 7|\\
&\text{Total } 4 && i|1\rangle\langle 1|-i|6\rangle\langle 6|,\\
&&& i|2\rangle\langle 2|-i|5\rangle\langle 5|,\\
&&& i|3\rangle\langle 3|-i|4\rangle\langle 4|,
\end{aligned}
\tag{34}
$$

$$
\begin{aligned}
&\text{Separation } 1 && |0\rangle\langle 1|-|1\rangle\langle 0|-|7\rangle\langle 6|+|6\rangle\langle 7|\\
&\text{Total } 8 && i|0\rangle\langle 1|+i|1\rangle\langle 0|+i|7\rangle\langle 6|+i|6\rangle\langle 7|,\\
&&& |1\rangle\langle 2|-|2\rangle\langle 1|+|6\rangle\langle 5|-|5\rangle\langle 6|,\\
&&& i|1\rangle\langle 2|+i|2\rangle\langle 1|-i|6\rangle\langle 5|-i|5\rangle\langle 6|,\\
&&& |2\rangle\langle 3|-|3\rangle\langle 2|-|5\rangle\langle 4|+|4\rangle\langle 5|,\\
&&& i|2\rangle\langle 3|+i|3\rangle\langle 2|+i|5\rangle\langle 4|+i|4\rangle\langle 5|,\\
&&& |3\rangle\langle 4|-|4\rangle\langle 3|,\quad i|3\rangle\langle 4|+i|4\rangle\langle 3|,
\end{aligned}
\tag{35}
$$

$$
\begin{aligned}
&\text{Separation } 2 && |0\rangle\langle 2|-|2\rangle\langle 0|-|7\rangle\langle 5|+|5\rangle\langle 7|\\
&\text{Total } 6 && |0\rangle\langle 2|+i|2\rangle\langle 0|+i|7\rangle\langle 5|+i|5\rangle\langle 7|,\\
&&& |1\rangle\langle 3|-|3\rangle\langle 1|-|6\rangle\langle 4|+|4\rangle\langle 6|,\\
&&& i|1\rangle\langle 3|+i|3\rangle\langle 1|+i|6\rangle\langle 4|+i|4\rangle\langle 6|,\\
&&& |2\rangle\langle 4|-|4\rangle\langle 2|+|5\rangle\langle 3|-|3\rangle\langle 5|,\\
&&& i|2\rangle\langle 4|+i|4\rangle\langle 2|-i|5\rangle\langle 3|-i|3\rangle\langle 5|
\end{aligned}
\tag{36}
$$

$$\begin{aligned}
&\text{Separation 3} \quad |0\rangle\langle 3|-|3\rangle\langle 0|+|7\rangle\langle 4|-|4\rangle\langle 7| \\
&\text{Total 6} \quad i|0\rangle\langle 3|+i|3\rangle\langle 0|-i|7\rangle\langle 4|-i|4\rangle\langle 7|, \\
&\qquad |1\rangle\langle 4|-|4\rangle\langle 1|+|6\rangle\langle 3|-|3\rangle\langle 6|, \\
&\qquad i|1\rangle\langle 4|+i|4\rangle\langle 1|-i|6\rangle\langle 3|-i|3\rangle\langle 6|, \\
&\qquad |2\rangle\langle 5|-|5\rangle\langle 2|, \quad i|2\rangle\langle 5|+i|5\rangle\langle 2|, \qquad (37)
\end{aligned}$$

$$\begin{aligned}
&\text{Separation 4} \quad |0\rangle\langle 4|-|4\rangle\langle 0|-|7\rangle\langle 3|+|3\rangle\langle 7| \\
&\text{Total 4} \quad i|0\rangle\langle 4|+i|4\rangle\langle 0|+i|7\rangle\langle 3|+i|3\rangle\langle 7|, \\
&\qquad |1\rangle\langle 5|-|5\rangle\langle 1|-|6\rangle\langle 2|+|2\rangle\langle 6|, \\
&\qquad i|1\rangle\langle 5|+i|5\rangle\langle 1|+i|6\rangle\langle 2|+i|2\rangle\langle 6|, \qquad (38)
\end{aligned}$$

$$\begin{aligned}
&\text{Separation 5} \quad |0\rangle\langle 5|-|5\rangle\langle 0|+|7\rangle\langle 2|-|2\rangle\langle 7| \\
&\text{Total 4} \quad i|0\rangle\langle 5|+i|5\rangle\langle 0|-i|7\rangle\langle 2|-i|2\rangle\langle 7|, \\
&\qquad |1\rangle\langle 6|-|6\rangle\langle 1|, \\
&\qquad i|1\rangle\langle 6|+i|6\rangle\langle 1|, \qquad (39)
\end{aligned}$$

$$\begin{aligned}
&\text{Separation 6} \quad |0\rangle\langle 6|-|6\rangle\langle 0|+|7\rangle\langle 1|-|1\rangle\langle 7| \\
&\text{Total 2} \quad i|0\rangle\langle 6|+i|6\rangle\langle 0|-i|7\rangle\langle 1|-i|1\rangle\langle 7|, \qquad (40)
\end{aligned}$$

$$\begin{aligned}
&\text{Separation 7} \quad |0\rangle\langle 7|-|7\rangle\langle 0| \\
&\text{Total 2} \quad i|0\rangle\langle 7|+i|7\rangle\langle 0|. \qquad (41)
\end{aligned}$$

Thus we see a total of $4+8+6+6+4+4+2+2=36$ real dimensions in $\mathfrak{k}$. Now by the Cartan classification (Ref. 8, p. 518), the Cartan involution θ must be either type **AI** fixing an abstract copy of $SO(28)$, type **AIII** fixing some $S[U(p)\oplus U(q)]$ for $p+q=2^n$, or else type **AII** fixing an abstract copy of $Sp(4)$. Since only $Sp(4)$ is thirty-six dimensional, we see $\mathfrak{k}\cong\mathfrak{sp}(4)$ and $K\cong Sp(4)$.

III. APPLICATIONS TO CONCURRENCE CAPACITY

In this section we focus on an application of the concurrence canonical decomposition $SU(N)=KAK$ of Definition I.2 when the number of qubits n is even. Namely, we study how a given computation $v\in SU(N)$ may change the concurrence of the quantum data state. Since we have the concurrence $C_n(|\psi\rangle)=|\overline{\langle\psi|}(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)|\psi\rangle|$ with the n-tangle $\tau_n=C_n^2$ for n even, there are immediate applications to the n-tangle as well.

Let $v\in SU(N)$. Recall from Definition I.5 that the concurrence capacity is defined as

$$\kappa(v)=\max\{C_n(v|\psi\rangle);C_n(|\psi\rangle)=0,\langle\psi|\psi\rangle=1\}. \qquad (42)$$

Since we vary over all $C_n(|\psi\rangle)=0$, we see that for $k\in K$ we have $\kappa(vk)=\kappa(v)$ by symmetry. Immediately $\kappa(kv)=\kappa(v)$. Thus, for $v=k_1ak_2$ the C.C. decomposition of any $v\in SU(N)$, we have $\kappa(v)=\kappa(k_1ak_2)=\kappa(a)$.

We next describe the concurrence capacity of any $a\in A$. The formalism makes strong use of entanglers to translate between $\mathcal{C}_n$ and $(w,x)\mapsto w^Tx$.

Definition III.1: The *concurrence spectrum* $\lambda_c(v)$ of $v\in SU(N)$ is the spectrum of $E_0^\dagger vE_0(E_0^\dagger vE_0)^T$, for E_0 the standard entangler of Definition II.9. Note that the spectrum is the set of eigenvalues since $\mathcal{H}_n$ is finite dimensional. The *convex hull* $\mathrm{CH}[\lambda_c(v)]$ of $\lambda_c(v)$ is the set of all line segments joining all points of $\lambda_c(v)$, i.e.,

$$\mathrm{CH}[\lambda_c(v)]=\left\{\sum_{z_j\in\lambda_c(v)} t_jz_j;0\leqslant t_j\leqslant 1,\sum_{j=0}^{\#\lambda_c(v)} t_j=1\right\}. \qquad (43)$$

These definitions allow us then to prove the following general results regarding concurrence capacity. The techniques closely follow those in prior work.[26]

Lemma III.2: Let $v \in SU(N)$, *with* CCD $v = k_1 a k_2$ *for* $a = E_0 d E_0^\dagger$ *for* d *diagonal in* $SU(N)$*:*

- $\lambda_c(v) = \lambda_c(a) = \{d_j^2; d = \Sigma_{j=0}^{N-1} d_j |j\rangle\langle j|\}$.
- $\kappa(v) = \kappa(a) = \max\{|\Sigma_{j=0}^{N-1} a_j^2 d_j^2|; |\psi\rangle = \Sigma_{j=0}^{N-1} a_j |j\rangle, \langle\psi|\psi\rangle = 1, \overline{\langle\psi|}\,|\psi\rangle = 0\}$.
- $(\kappa(v) = \kappa(a) = 1) \Leftrightarrow (0 \in \mathrm{CH}[\lambda_c(v)] = \mathrm{CH}[\lambda_c(a)])$.

Proof: For the first item, recall $v = k_1 a k_2$. Thus the following expression results from expanding Definition III.1:

$$E_0^\dagger v E_0 (E_0^\dagger v E_0)^T = [(E_0^\dagger k_1 E_0)(E_0^\dagger a E_0)(E_0^\dagger k_2 E_0)][(E_0^\dagger k_2 E_0)^T (E_0^\dagger a E_0)^T (E_0^\dagger k_1 E_0)^T]. \quad (44)$$

Label the elements of $SO(N)$ by $o_1 = (E_0^\dagger k_1 E_0)$, $o_2 = (E_0^\dagger k_2 E_0)$, and put $d = E_0^\dagger a E_0$ diagonal. Then the above reduces to $o_1 d o_2 o_2^T d^T o_1^T = o_1 d^2 o_1^{-1}$, with spectrum identical to d.

For the next item, compare the two-qubit case [Ref. 26, Eq. (41)] and recall Scholium II.18. Suppose $C_n(|\varphi\rangle) = 0$. Then per Scholium II.18, for $|\psi\rangle = E_0^\dagger |\varphi\rangle$ we have $0 = \mathcal{C}_n(E_0 E_0^\dagger |\varphi\rangle, E_0 E_0^\dagger |\varphi\rangle) = \overline{\langle\psi|}\,|\psi\rangle$. Now for $\kappa(a)$, take $|\psi\rangle = E_0^\dagger |\varphi\rangle$. We then maximize over expressions $\mathcal{C}_n(a|\varphi\rangle, a|\varphi\rangle) = \mathcal{C}_n(E_0 E_0^\dagger a E_0 |\psi\rangle, E_0 E_0^\dagger a E_0 |\psi\rangle) = \mathcal{C}_n(E_0 d |\psi\rangle, E_0 d |\psi\rangle) = \overline{\langle\psi|} d^2 |\psi\rangle$.

The final item makes use of the Schwarz inequality. For the concurrence capacity to be maximal, there is by compactness of the set of normalized kets some normalized $|\psi\rangle$ with $C_n(|\Phi\rangle) = 1$. For $|\psi\rangle = \Sigma_{j=0}^{N-1} a_j |j\rangle$,

$$1 = \left| \sum_{j=0}^{N-1} a_j^2 d_j^2 \right| \leqslant \sum_{j=0}^{N-1} |a_j^2 d_j^2| = \sum_{j=0}^{N-1} |a_j|^2 = 1. \quad (45)$$

The Schwarz *equality* further requires some $z \in \mathbb{C}$, $z^- z = 1$, so that $a_j^2 d_j^2 = |a_j|^2 z, \forall j$. Now since $\overline{\langle\psi|}\,|\psi\rangle = 0$,

$$0 = \sum_{j=0}^{N-1} a_j^2 = \sum_{j=0}^{N-1} |a_j|^2 \overline{d_j^2} z. \quad (46)$$

Multiplying through by $\overline{z}$ and taking the complex conjugate, we see $0 \in \mathrm{CH}[\lambda_c(v)]$. □

As already noted in the Introduction, the concurrence capacity κ is properly thought of as a function of A rather than a function of $SU(N)$. This is advantageous from a computational standpoint, because in order to calculate $\kappa(v)$ one need minimize over a function involving $N-1$ real parameters in A versus N^2-1 parameters describing a general $v \in SU(N)$. We next consider typical values for a large number of qubits. To do so, we need to be able to randomly choose an element of A.

Definition III.3: Consider the following coordinate map on the commutative group A:

$$[0,2\pi]^{N-1} \to A \text{ by } (t_0, t_2, \ldots, t_{N-2}) \mapsto \exp E_0 \left(\sum_{j=0}^{N-2} i t_j |j\rangle\langle j| - i t_j |j+1\rangle\langle j+1| \right) E_0^\dagger. \quad (47)$$

The Haar measure on da is the group multiplication invariant measure $da = (2\pi)^{-N+1} dt_0\ dt_2\ \cdots\ dt_{N-2}$. This is the pushforward of the independent product of uniform measures $dt_j/(2\pi)$ on each $[0,2\pi]$.

Recall that for $p = 2n$, Theorem I.7 asserts that according to da, almost all $a \in A$ have $\kappa(a) = 1$ for p large. Specifically, we assert

$$\lim_{p \to \infty} da(\{a \in A; \kappa(a) = 1\}) = 1. \quad (48)$$

We prove this assertion shortly, but we first need a lemma.

Lemma III.4: Label as uniform distribution on the circle a distribution whose pullback to $[0,2\pi]$ *under* $t\mapsto e^{2\pi i t}$ *is uniform, and similarly say two random variables* Z_1, Z_2 *on* $\{z\bar{}z=1\}$ *are independent iff their pullbacks to* $[0,2\pi]\times[0,2\pi]$ *are. Then suppose* Z_1 *is any random variable on the circle, and let* Z_2 *be independent to* Z_1 *and uniform. Then* Z_1Z_2 *is uniform.*

Proof: Consider the random variable $T=-i\log Z_1-i\log Z_2 \bmod 2\pi$ on $[0,2\pi]$. Let $f_1(t)$ be the pullback probability density function of the nonuniform random variable Z_1 to $[0,2\pi]$. We let $F_T(t)=\mathrm{Prob}(T\leqslant t)$ be the cumulative density function. Then

$$F_T(t)=\frac{1}{2\pi}\int_0^{2\pi}\mathrm{Prob}(-i\log Z_2\in[s,s+t])f_1(s)ds=\frac{1}{2\pi}\int_0^{2\pi}tf_1(s)ds=t/(2\pi). \tag{49}$$

Since $F_T(t)=t/(2\pi)$, we see that T is uniform. Hence Z_1Z_2 is uniform. □

Proof of Theorem I.7: First, let us check that $\{\kappa(a)=1\}$ is da-measurable. To see this, note that the concurrence spectrum $\lambda_c(a)$ may be expressed in terms of the coordinates t_j as follows:

$$d_0^2=\mathrm{e}^{2it_0},d_1=\mathrm{e}^{2it_1-2it_0},d_2^2=\mathrm{e}^{2it_2-2it_1},\cdots d_j^2=\mathrm{e}^{2it_j-2it_{j-1}},\ldots,d_{N-1}^2=\mathrm{e}^{-2it_{N-2}}. \tag{50}$$

Thus Lemma III.2 induces a measurable condition on the t_j.

Continuing the proof, by direct calculation Z^2 is a uniform random variable on the circle $\{z\bar{}z=1\}$ given that Z is such. Thus note that d_0^2, d_2^2, $d_4^2,\ldots,d_{N-1}^2$ are $p=N/2$ independent, uniform random variables by Lemma III.4. It suffices to show that $\ell+1=p$ independent, random variables on the circle have 0 in their convex hull as $\ell\mapsto\infty$. Relabel $d_0^2=Z_0$, $d_2^2=Z_1,\ldots,d_{N-1}^2=Z_\ell$.

Without loss of generality, say $Z_0=1$. Let C_2 be the event that no $Z_1,Z_2,\ldots,Z_\ell$ is in the second quadrant $\{z=x+iy;x<0,y>0\}$, with C_3 similar for the third quadrant $\{x<0,y<0\}$. Let D be the event that 0 is in the convex hull of Z_0, $Z_1,\ldots,Z_\ell$. Then $(\mathrm{NOT}\ C_2\cap\mathrm{NOT}\ C_3)\subset D$. Then $\mathrm{Prob}(\mathrm{NOT}\ C_2\cap\mathrm{NOT}\ C_3)\leqslant\mathrm{Prob}(D)$, and

$$1-\mathrm{Prob}(D)\leqslant 1-\mathrm{Prob}(\mathrm{NOT}\ \ C_2\ \ \mathrm{and}\ \ \mathrm{NOT}\ \ C_3)=\mathrm{Prob}(C_2\ \ \mathrm{or}\ \ C_3)=(1/2)^\ell. \tag{51}$$

Hence as $\ell\to\infty$, $\mathrm{Prob}(D)$ goes to 1. Hence the probability $\mathrm{CH}[\lambda_c(v)]$ contains 0 limits to 1. □

IV. CONCLUSIONS AND ONGOING WORK

We have shown that there exists a generalized canonical decomposition of unitary operators on n qubits which may be used to study changes in the concurrence entanglement monotone. This decomposition closely resembles the older two-qubit decomposition when n is even, and it may be used to study the concurrence-entanglement capacity of generic unitary operators. The main result is that such a generic unitary operator is almost always perfectly entangling with respect to the concurrence monotone when the number of qubits is large and even.

Ongoing work would attempt to extend the dynamical viewpoint taken in this paper. Specifically, the unitary operator describes the dynamics of a quantum data state, and the present techniques allow us to quantitatively study the dynamics of the concurrence entanglement measure. Similarly, we would wish to study the dynamics of this concurrence capacity of quantum computations in naturally defined families or sequences of such computations. As a separate topic, we might also study the failure of the concurrence function itself by quantifying how entangled with respect to other measures a quantum state with zero concurrence may be.

APPENDIX A: COMPUTING THE CCD WHEN THE NUMBER OF QUBITS IS EVEN

This appendix recalls how to compute the canonical decomposition in an even number $n=2p$ of qubits. Note that other arguments in the case $n=2$[10,14] may be found in the literature, and that the present treatment is a straightforward genearlization of a matrix-oriented treament in the two-qubit case (Ref. 4, Appendix A). It is included for completeness.

The overall structure of the algorithm contains two steps.

(1) Produce an algorithm for computing the decomposition $SU(N)=SO(N)\ D\ SO(N)$ for D the diagonal subgroup of $SU(N)$. We will refer to this decomposition as the *unitary* SVD *decomposition* henceforth.
(2) Recall E_0, the standard entangler of Definition II.9. Given a $v\in SU(N)$ for which we wish to compute the CCD, compute first the unitary SVD $E_0^\dagger v E_0 = o_1 d o_2$. Then we have a CCD given by

$$v=(E_0 o_1 E_0^\dagger)(E_0 d E_0^\dagger)(E_0 o_2 E_0^\dagger)=k_1 a k_2, \tag{A1}$$

since $k_1=E_0 o_1 E_0^\dagger\in K$, $k_2=E_0 o_2 E_0^\dagger\in K$, and $a=E_0 d E_0^\dagger\in A$.

Note that the unitary SVD decomposition exists due to *KAK* metadecomposition theorem, taking as inputs $G=SU(N)$, $\theta_{\mathbf{AI}}(X)=\overline{X}$, and $\mathfrak{a}$ the diagonal subalgebra of $\mathfrak{su}(N)$.

Before continuing to Step 1, we first prove a lemma. It is useful in computing particular instances of the unitary SVD.

Lemma A.1: For any $p\in SU(N)$ with $p=p^T$, there is some $o\in SO(N)$ such that $p=odo^T$ with d a diagonal, determinant one matrix.

Proof: We first show the following:

$\forall\ a,b$, symmetric real $N\times N$ matrices with $ab=ba$; there is some $o\in SO(N)$ such that oao^T and obo^T are diagonal.

It suffices to construct a basis which is simultaneously a basis of eigenvectors for both a and b. Thus, say V_λ is the λ eigenspace of b. For $x\in V_\lambda$, $b(ax)=a(bx)=\lambda ax$, i.e., $x\mapsto ax$ preserves the eigenspace. Now find eigenvectors for a restricted to V_λ, which remains symmetric. Thus we may find the desired $o\in SO(N)$, making choices of orderings and signs on an eigenbasis as appropriate for a determinant one.

Given the above, write $p=a+ib$. Now $\mathbf{1}=pp^\dagger=p\overline{p}=(a+ib)(a-ib)=(a^2+b^2)+i(ba-ab)$. Since the imaginary part of $\mathbf{1}$ is $\mathbf{0}$, we conclude that $ab=ba$. Hence a single o exists per the last paragraph which diagonalizes the real and imaginary parts. □

Suppose then that $v=o_1 d o_2$ is the unitary SVD of some $v\in SU(N)$. For convenience, we also label $v=po_3$ the type **AI** Cartan decomposition (Ref. 8, Theorem 1.1.iii, p. 252) (Ref. 11, Theorem 6.31.c). This is a generalized polar decomposition in which $p=p^T$, $k\in SO(N)$. Note that it is equivalent via Lemma A.1 to compute $v=pk$, as the unitary SVD follows by $v=(o_1 d o_1^T)k=o_1 d o_2$. Continuing to the algorithm for Step 1:

- Compute p^2 as follows: $p^2=pp^T=po_3o_3^Tp^T=vv^T$.
- Apply Lemma A.1 to p^2. Thus $p^2=o_1 d^2 o_1^T$ for $o_1\in SO(N)$.
- Choose square roots entrywise in d^2 to form d. Be careful to ensure $\det d=1$.
- Compute $p=o_1 d o_1^T$.
- Thus $o_3=p^\dagger v$, and $v=p(o_3)=o_1 d o_1^T o_3=o_1 d o_2$.

This concludes the algorithm for computing the unitary SVD of Step 1.

Step 2 is almost follows given the inline description. The reader may produce algorithms outputting E_0.

Another question is computational efficiency. This is ongoing work, but we note immediately that an implementation of the spectral theorem of Lemma A.1 is required. This will be difficult with current technologies in 16+ qubits. Moreover, in the range of 50 to 60 qubits an even spread of the concurrence spectrum $\lambda_c(v)$ of Definition III.1 would make certain elements indistinguishable at 16-digit precision.

APPENDIX B: CONCURRENCE LEVEL SETS AND *K* ORBITS

Mathematically, related measures are often easier to use than C_n. For example, the concurrence quadratic form $Q_n^C(|\psi\rangle)=\mathcal{C}_n(|\psi\rangle,|\psi\rangle)$ with $C_n(|\psi\rangle)=|Q_n^C(|\psi\rangle)|$ has smaller level sets than

C_n itself. Moreover, it turns out that the normalized states within these level sets $[Q_n^C]^{-1}(\{z\}) = \{|\psi\rangle; Q_n^C(|\psi\rangle) = z\}$ are naturally orbits of the group K, which must then be false for C_n.

Suppose throughout $n=2p$ is an even number of qubits. For a vector $v \in \mathbb{C}^N$, put $Q_{\mathbf{AI}}(v) = v^T v$, noting that $Q_{\mathcal{C}}(E_0 v) = Q_{\mathbf{AI}}(v)$. Moreover, for $O \in SO(N)$, we have the following:

$$Q_{\mathbf{AI}}(O \cdot v) = Q_{\mathcal{C}}[E_0 O E_0^\dagger \cdot (E_0 v)]. \tag{B1}$$

Thus we may study level sets of $Q_{\mathbf{AI}}$ under $SO(N)$ rather than study level sets of $Q_{\mathcal{C}}$ under K. Now if $v = v_1 + iv_2$ is a decomposition into real and imaginary parts of a complex vector, note that $Q_{\mathbf{AI}}(v_1 + iv_2) = v^T v = (|v_1|^2 - |v_2|^2) + 2i(v_1 \cdot v_2)$.

Lemma B.1: Label $S^{2N-1} = \{|\psi\rangle; \langle\psi|\psi\rangle = 1\}$. *We have the following orbit decompositions of the level sets* $Q_{\mathbf{AI}}^{-1}(\alpha) \cap S^{2N-1}$ *for any fixed* $\alpha \in \mathbb{C}$.

(1) Let t *be real, and let* $v \in Q_{\mathbf{AI}}^{-1}(t) \cap S^{2N-1}$. *Then* $Q_{\mathbf{AI}}^{-1}(t) \cap S^{2N-1} = [SO(N) \cdot v]$.

(2) Let α *be complex, and let* $v \in Q_{\mathbf{AI}}^{-1}(\alpha) \cap S^{2N-1}$. *Then* $Q_{\mathbf{AI}}^{-1}(\alpha) \cap S^{2N-1} = [SO(N) \cdot v]$.

Proof: For the first item, write $v = v_1 + iv_2$. Then $v_1 \cdot v_2$ is zero as a set of real vectors. Consider the subset of $\mathbb{R}^{2N}$ given by $|v_1|^2 - |v_2|^2 = t$. Suppose now we have another pair of orthogonal vectors w_1, w_2 with $|w_1|^2 - |w_2|^2 = t$ and $|w_1|^2 + |w_2|^2 = 1$. Then $|w_1|^2 = |v_1|^2 = (1 - t)/2$, thus $|v_2|^2 = |w_2|^2$ so that there is some $O \in SO(N)$ with $O \cdot v_1 = w_1$, $O \cdot v_2 = w_2$.

For the second item, suppose $\alpha = e^{i\phi} t$ for some $t \in \mathbb{R}$. Now if $v \in Q_{\mathbf{AI}}^{-1}(\alpha)$, then note that we have $Q_{\mathbf{AI}}(e^{-i\phi/2} v) = e^{-i\phi} Q_{\mathbf{AI}}(v) = e^{-i\phi} \alpha = t$. Conversely, if $w \in Q_{\mathbf{AI}}^{-1}(t)$ we have $e^{i\phi/2} w \in Q_{\mathbf{AI}}^{-1}(\alpha)$. Having established bijective phase maps between the two level sets, it must also be the case that the level set of α forms a single $SO(N)$ orbit. □

Corollary B.2: The restricted action of K to the normalized kets in any concurrence level set is transitive. Specifically, suppose $\alpha \in \mathbb{C}$, *with* $|\psi\rangle$ *normalized with* $Q_{\mathcal{C}}(|\psi\rangle) = \alpha$. *Then label* $S^{2N-1} = \{\langle\phi|\phi\rangle = 1\}$ *the set of normalized kets. Per Eq. (B1), we have* $K \cdot |\psi\rangle = Q_{\mathcal{C}}^{-1}(\alpha) \cap S^{2N-1}$.

We restate the result colloquially. Should any two normalized states $|\phi\rangle$, $|\psi\rangle$ have the same concurrence, then there is some global phase $e^{i\theta}$ so that $|\phi\rangle = e^{i\theta} k |\psi\rangle$ for $k \in K = E_0 SO(N) E_0^\dagger$.

APPENDIX C: CONCURRENCE IS AN ENTANGLEMENT MONOTONE

The n-tangle, defined to be $\tau_n(|\psi\rangle) = C_n(|\psi\rangle)^2$ has been proposed[25] as a measure of an n-qubit entanglement for n even. The n-tangle of a state $|\psi\rangle$, like the n-concurrence, assumes real values in the range $0 \leqslant \tau_n \leqslant 1$ and has been shown to be an entanglement monotone, meaning τ_n is a convex function on density matrices and is nonincreasing under local operations and classical communication (LOCC). Most of our arguments focus on constructions more directly related to the concurrence C_n rather than the n-tangle $\tau_n = (C_n)^2$. Therefore, for completeness, we show that the n-concurrence is, in fact, a good measure of entanglement. The monotonicity property of a function is established by considering its action on mixtures of quantum states encoded within Hermitian density matrices ρ with tr $\rho = 1$. See, e.g., Ref. 18.

Definition C.:1 The n-concurrence can be defined on mixed states ρ using the convex roof extension:

$$C_n(\rho) = \min\left\{ \sum_k \lambda_k C_n(|\psi^k\rangle); \quad \rho = \sum_k \lambda_k |\psi^k\rangle\langle\psi^k|, |\psi\rangle^k \in \mathcal{H}_n, \quad \langle\psi^k|\psi^k\rangle = 1 \right\}. \tag{C1}$$

This minimization is over all pure state ensemble decompositions of the state $\rho = \Sigma_k \lambda_k |\psi^k\rangle\langle\psi^k|$.

This definition is quite intricate. We point out the following remarkable result, not used in the sequel.

Theorem C.2 (Uhlmann[22,25]): *We may express* $C_n(\rho)$ *in closed form as follows:*

$$C_n(\rho) = \max\{0, \lambda_0 - \lambda_1 \cdots - \lambda_{N-1}\}. \tag{C2}$$

Here, the λ_k are the square roots of the eigenvalues (in nonincreasing order) of the product $\rho\tilde{\rho}$ where $\tilde{\rho}=S\overline{\rho}S^{-1}$.

The necessary and sufficient conditions for a function on quantum states to be a entanglement monotone are delineated in Ref. 23. For the n-concurrence, they can be summarized as follows:

- $C_n \geqslant 0$, and $C_n(\rho)=0$ if ρ is fully separable.
- C_n is a convex function, i.e., $C_n(p\rho_1+(1-p)\rho_2)\leqslant pC_n(\rho_1)+(1-p)C_n(\rho_2), \forall p\in[0,1]$ and ρ_1,ρ_2 Hermitian matrices of trace one.
- C_n is nonincreasing under LOCC. Specifically, $C_n(\rho)\geqslant \Sigma_j p_j C_n(\rho_j)$, where $\rho_j=A_j\rho A_j^\dagger/p_j$ are the states conditioned on the outcome j of a positive operator valued measurement (POVM) which occurs with probability $p_j=\mathrm{Tr}[A_j^\dagger A_j\rho]$.

Before proving this, we first establish the useful fact that the n-concurrence is invariant under permutations of the qubits. Defining Π_n to be the set of unitary operators corresponding to permutations on n qubits, we have the following.

Proposition C.3: For n even, $C_n(P|\psi\rangle)=C_n(|\psi\rangle)\forall P\in\Pi_n$.

Proof: Any permutation P on n elements can be written as a finite composition of transpositions on pairs of elements. Hence it suffices to show invariance under a single swap operation. Writing the swap operator between qubits j and k as

$$S_{jk}=\frac{\mathbf{1}_j\otimes\mathbf{1}_k+\sigma_j^x\otimes\sigma_k^x+\sigma_j^y\otimes\sigma_k^y+\sigma_j^z\otimes\sigma_k^z}{2}, \tag{C3}$$

we have for any state $|\psi\rangle$,

$$C_n(S_{jk}|\psi\rangle)=|\overline{\langle\psi|S_{jk}^\dagger}SS_{jk}|\psi\rangle|=|\overline{\langle\psi|}S_{jk}SS_{jk}|\psi\rangle|=|\overline{\langle\psi|}SS_{jk}^2|\psi\rangle|=C_n(|\psi\rangle). \tag{C4}$$

Here we have used the fact that S_{jk} is real symmetric and unitary, and in the third equality we use the fact that $[\sigma_j^y\otimes\sigma_k^y,\sigma_j^l\otimes\sigma_k^l]=0$ for $\sigma^l\in\{\sigma^x,\sigma^y,\sigma^z\}$. This proposition necessarily implies that $\Pi_n^+\subsetneq K$, where Π_n^+ is the set of unitary permutation matrices on n objects with $+1$ determinant, i.e., permutations composed of an even number of transpositions. □

Lemma C.4: $C_n(\rho)$ is an entanglement monotone.

Sketch: For the first condition, one first checks that $0\leqslant C_n\leqslant 1$ using the eigenvalue decomposition of the matrix $S=(-i\sigma_1^y)(-i\sigma_2^y)\cdots(-i\sigma_n^y)$. Then any separable state can be realized by stochastic local unitaries acting on the fiducial separable state $|0\rangle_n=|0_1\cdots 0_n\rangle$. Now, $C_n(|0\rangle_n)=0$ and C_n is invariant under local unitaries per Proposition II.1 and Theorem I.3. To generalize from pure states to density matrices, recall Definition C.1.

The second condition is shown by writing the minimal ensemble decompositions for ρ_1 and ρ_2 separately as

$$p\min_{\{\lambda_k,|\psi^k\rangle\}|\Sigma\lambda_k|\psi^k\rangle\langle\psi^k|=\rho_1}\sum_k\lambda_k C_n(|\psi^k\rangle)+(1-p)\min_{\{\beta_k,|\phi^k\rangle\}|\Sigma\beta_k|\phi^k\rangle\langle\phi^k|=\rho_2}\sum_k\beta_k C_n(|\phi^k\rangle). \tag{C5}$$

These are not necessarily the minimal decompositions for the composite state $\rho=pp_1+(1-p)p_2$, therefore, $C_n(p\rho_1+(1-p)\rho_2)\leqslant pC_n(\rho_1)+(1-p)C_n(\rho_2)$.

Finally, we show that the n-concurrence is on average nonincreasing under LOCC. First, because of permutation symmetry of the concurrence we can consider operations on one particular qubit of the n qubit system, say the first. An arbitrary, trace perserving, completely positive map on a quantum system can written in the Krauss decompostion[12] as $S(\rho)=\Sigma_j A_j\rho A_j^\dagger$ where the positive Krauss operators satisfy the sum rule $\Sigma_j A_j^\dagger A_j=\mathbf{1}$. The map can be composed of multiple operations with two operators at a time so we consider only two operators A_0 and A_1 acting on the first qubit. By the polar decomposition theorem, the operators can be written as $A_j=u_j b_j$, where $b_j=\sqrt{A_j^\dagger A_j}$ is positive and u_j is defined to be $\mathbf{1}$ on the kernel $\mathcal{K}$ of A_j and $A_j|A_j|^{-1}$ on $\mathcal{K}^\perp$.

Physically, the map $S(\rho)$ corresponds to a generalized measurement on ρ followed by a unitary operation conditioned on the measurement. Because of the sum rule, which corresponds to trace preservation, we can write $A_0 = w_o \cos gX$ and $A_1 = w_1 \sin gX$ for $g \in \mathbb{R}$ and X a positive operator with unit trace. These operators are expressed in simpler form by diagonalizing X, viz., $A_0 = u_o d_o v$ and $A_1 = u_1 d_1 v$, where $u_j, v \in SU(2)$ and d_j are real diagonal matrices with elements (q,r) and $(\sqrt{1-q^2}, \sqrt{1-r^2})$. The average concurrence of a state ρ after the 2 outcome POVM is

$$p_0 C_n(\rho_0) + p_1 C_n(\rho_1) = p_0 \min_{\{\lambda_k, |\psi^k\rangle\} | \Sigma \lambda_k |\psi^k\rangle\langle\psi^k| = \rho} \sum_k \lambda_k C_n(A_0 |\psi^k\rangle / \sqrt{p_0}) + p_1 \min_{\{\beta_k, |\phi^k\rangle\} | \Sigma \beta_k |\phi^k\rangle\langle\phi^k| = \rho} \sum_k \beta_k C_n(A_1 |\phi^k\rangle / \sqrt{p_1}). \tag{C6}$$

States conditioned on the first outcome satisfy

$$C_n(A_0|\psi\rangle/\sqrt{p_0}) = |\overline{\langle\psi|} v^T d_0^T u_0^T S u_0 d_0 v |\psi\rangle| / p_0 = qr C_n(v|\psi\rangle)/p_0 = qr C_n(|\psi\rangle)/p_0, \tag{C7}$$

where in the second equality we have used $u_0^T(-i\sigma^y)u_0 = -i\sigma^y$, and the third equality follows by invariance of concurrence under local unitaries. Similarly, $C_n(A_1|\phi\rangle/\sqrt{p_1}) = \sqrt{(1-q^2)(1-r^2)} C_n(|\phi\rangle)/p_1$. The result is

$$\begin{aligned} p_0 C_n(\rho_0) + p_1 C_n(\rho_1) &= qr \min_{\{\lambda_k, |\psi^k\rangle\} | \Sigma \lambda_k |\psi^k\rangle\langle\psi^k| = \rho} \sum_k \lambda_k C_n(|\psi^k\rangle) \\ &\quad + \sqrt{(1-q^2)(1-r^2)} \min_{\{\beta_k, |\phi^k\rangle\} | \Sigma \beta_k |\phi^k\rangle\langle\phi^k| = \rho} \sum_k \beta_k C_n(|\phi^k\rangle) \\ &= (qr + \sqrt{(1-q^2)(1-r^2)}) C_n(\rho) \leqslant C_n(\rho), \end{aligned} \tag{C8}$$

with equality iff $q = r$. □

[27] It is not clear how to recover the celebrated 3-tangle from this construction. By this definition we will see that $\tau_n \equiv 0$ for all odd n, so references to τ_n in the present paper will suppose that is not the case.

JOURNAL OF MATHEMATICAL PHYSICS VOLUME 45, NUMBER 6 JUNE 2004

Properties of continuous Fourier extension of the discrete cosine transform and its multidimensional generalization

A. Atoyan[a] and J. Patera[b]
Centre de Recherches Mathématiques, Université de Montréal, C.P. 6128, Succ. Centre-ville, Montréal (QC) H3C 3J7, Canada

(Received 3 April 2003; accepted 5 March 2004; published online 17 May 2004)

A versatile method is described for the practical computation of the exact discrete Fourier transforms (DFT), both the direct and the inverse ones, of a continuous function g given by its values g_j at the points of a uniform grid F_N generated by conjugacy classes of elements of finite adjoint order N in the fundamental region F of compact semisimple Lie groups. The present implementation of the method is for the groups SU(2), when F is reduced to a one-dimensional segment, and for $\mathrm{SU}(2)\times\mathrm{SU}(2)\times\cdots\times\mathrm{SU}(2)$ in multidimensional cases. This simplest case turns out to be a version of the discrete cosine transform (DCT). Implementations, abbreviated as DGT for *Discrete Group Transform*, based on simple Lie groups of higher ranks, are to be considered separately. DCT is often taken to be simply a specific type of the standard DFT. Here we show that the DCT is very different from the standard DFT when the properties of the *continuous extensions* of the two inverse discrete transforms are studied. The following properties of the continuous extension of DCT (called CEDCT) from the discrete $t_j \in F_N$ to all $t \in \mathsf{F}$ are proven and exemplified. Like the standard DFT, the DCT also returns the exact values of $\{g_j\}$ on the $N+1$ points of the grid. However, unlike the continuous extension of the standard DFT:

(a) The CEDCT function $f_N(t)$ closely approximates $g(t)$ *between* the points of the grid as well;
(b) for increasing N, the derivative of $f_N(t)$ converges to the derivative of $g(t)$;
(c) for CEDCT the principle of locality is valid.

In this article we also use the continuous extension of the two-dimensional (2D) DCT, $\mathrm{SU}(2)\times\mathrm{SU}(2)$, to illustrate its potential for interpolation as well as for the data compression of 2D images. © *2004 American Institute of Physics.*

I. INTRODUCTION

The decomposition of functions integrable on a finite segment into Fourier series of trigonometric functions of one variable is a well known method (e.g., Refs. 1 and 2) whose theoretical and practical aspects have been thoroughly investigated during the last two centuries in connection with its numerous applications in science and engineering. It is natural to question whether any attempt to add something to it is not in fact a reinvention of what has been found before.

Our general goal, which goes beyond this paper, is to elaborate a new decomposition method of functions of n variables into Fourier series using orbit functions of compact semisimple Lie groups,[3,4] with the idea of (i) making it accessible to users who are not specialists in Lie theory, (ii) underlining the versatility of its practical implementations, and (iii) most importantly, demonstrating the fertility of the underlying theme of this approach. One can find complete answers to

[a]Electronic mail: atoyan@crm.umontreal.ca
[b]Electronic mail: jmp@indiana.edu

limited questions (like the values of a finite number of Fourier coefficients) replacing the Lie group by a suitably chosen set of its discrete elements. The choice of the discrete elements is clearly crucial.

In the context of our goal, the SU(2) case results in the simplest example of the new method, even though that is the case where the potential advantages of the method based on the symmetry groups could be most limited. Remarkably, however, in this low dimensional space the discrete Fourier transform on the SU(2) group results in one type of discrete cosine transforms discovered in 1974,[5] or more exactly the DCT-1 (see Refs. 6 and 7). Its comparison with the standard method is both misleading and revealing. It is misleading because of its apparent similarity (see Ref. 13) to the well known Discrete Fourier transform abbreviated as DFT (e.g., Refs. 8–10). Nevertheless it is revealing, since it can help to understand better the underlying reasons why for many practical applications the DCT is proven significantly more efficient than the DFT. In this paper we consider the concept of *continuous extension* of the discrete transform, and show that the convergence properties of the continuous extension of the inverse DCT, abbreviated here as CEDCT, match very closely the properties of the canonical (*continuous*) Fourier transform (CFT) of smooth functions. Meanwhile continuous extension of the inverse DFT (hereafter CEDFT) does not result in any reasonable function. Note that for the sake of simplicity, if the ''inverse'' is not explicitly used, we will henceforth adopt DFT and DCT (or DGT in a more general sense) abbreviations for both direct and inverse Fourier transforms.

In Sec. II we present some pertinent information on the Fourier analysis on the SU(2) group, which also demonstrates the general formalism used for the Fourier transforms on Lie groups. We show that in practice the Fourier transform of a class function of SU(2) is reduced to the decomposition of a discrete function $\{g_k | k=0,1,\ldots,N\}$ defined on a N-interval grid of variable $t \in [0,T_0]$ onto the series of $(N+1)$ cosine functions (including $\cos 0=1$) of harmonic order $n=j/2\leqslant N/2$. The basis for the DCT series is thus composed of the first N *half*-order harmonics of $\cos(2\pi t/T_0)$, i.e., $\cos(2\pi nt/T_0)=\cos(\pi jt/T_0)$ with $j=0,1,\ldots,N$. The harmonic order of these functions formally is either integer for j even, *or* half-integer for odd j. This approach is compared to the standard method of DFT where the given $\{g_k\}$ is decomposed into the trigonometric polynomials of $e^{(i\,2\pi\,nt/T_0)}$ of the *full* harmonic order $n\leqslant N$. In Sec. II we also define the continuous extension of a discrete transform onto the segment $[0,T_0]$. We then compare CEDCT and CEDFT, and show that although both DCT and DFT formally belong to the group of *exact* discrete transforms, rather surprisingly, only the CEDCT converges with increasing N to the continuous function $g(t\in[0,T_0])$ which originates the grid function $\{g_k\}$. We explain this difference comparing CEDCT and CEDFT from the point of view of Shannon sampling theorem.

In Sec. III we prove some important properties of CEDCT. These properties closely resemble those of the canonical CFT polynomials, such as the principle of *locality* of CEDCT. This property can ensure, in particular, that numerical computation errors or uncertainties in one segment of the interval $[0,T_0]$ would not dramatically affect the transform results in a distant segment. Another important property proven in Sec. III is that, similar to the CFT polynomials, the term-by-term derivative series of the continuous extension of an N-interval DCT converges to $g'(t)$ with the increase of N. Note that all these properties hold for any function $g(t)$ with bounded second derivative. In particular, they are also valid when $g_0\neq g_N$, which is not the case for standard DFT.

In Sec. IV we extend the formalism of one-dimensional DGT on SU(2), or the DCT, for decomposition of multidimensional functions. We bring examples of approximation of two-dimensional discrete functions/images by two-dimensional CEDCTs.

Finally, let us also point out that additional examples of exploitation of our method are found in the Proceedings of 3 recent meetings on the numerical methods.[11,12,34–36]

II. FOURIER ANALYSIS ON SU(2)

The Lie group SU(2) can be realized as a set of all 2×2 unitary matrices A, with $\det A=1$. A complex valued *class function* f on SU(2) is any map of SU(2) onto the complex number space $\mathbb{C}$

which is invariant under conjugation, i.e., $f:\mathrm{SU}(2)\to\mathbb{C}$, and $f(B^{-1}AB)=f(A)$ for all $A,B\in\mathrm{SU}(2)$. Since the defining two-dimensional representation of SU(2) is faithful, we can use it in order to describe the pertinent discrete elements of SU(2).

Any unitary matrix can be diagonalized by a unitary transformation. Therefore, every element of SU(2) is conjugate to at least one diagonal matrix in the defining two-dimensional representation. All the elements which can be simultaneously diagonalized form a maximal torus T of SU(2). Since all maximal tori are SU(2)-conjugate, we can write

$$\mathsf{T}=\left\{ x(\theta)=\begin{pmatrix} e^{2\pi i\theta} & 0 \\ 0 & e^{-2\pi i\theta}\end{pmatrix} \;\middle|\; 0\leqslant\theta\leqslant 1\right\}. \tag{1}$$

Furthermore, using $B=\left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right)\in\mathrm{SU}(2)$, we have $Bx(\theta)B^{-1}=x(-\theta)$. Therefore, every element of SU(2) is conjugate to just one element in the subset $F\subset T$, where

$$\mathsf{F}=\left\{ x(\theta)=\begin{pmatrix} e^{2\pi i\theta} & 0 \\ 0 & e^{-2\pi i\theta}\end{pmatrix} \;\middle|\; 0\leqslant\theta\leqslant \frac{1}{2}\right\}. \tag{2}$$

Trace functions, otherwise called *characters*, play an important role in SU(2). For any element $x(\theta)$ of (1) we have $\mathrm{tr}\,x(\theta)=2\cos(2\pi\theta)$. In general, $\mathrm{tr}\,x(\theta)$ is a class function because for all $B\in\mathrm{SU}(2)\Rightarrow\mathrm{tr}\{B^{-1}xB\}=\mathrm{tr}\,x$. Let $R=R(\mathrm{SU}(2))$ denote a complex algebra generated by the character functions of SU(2). It is well known that R has a linear basis consisting of characters of all finite dimensional irreducible representations of SU(2).

With each irreducible representation of a semisimple Lie group, in particular SU(2), one associates a set of weights (weight system) of the representation,[3,4] which is a union of orbits of weights under the action of the Weyl group, W. In physics the SU(2)-weights are known as projections of the angular momenta which have integer and half-integer eigenvalues. In mathematics one usually prefers to deal with the doubles of the angular momenta in order to avoid nonintegers.

The Weyl group of SU(2) is very simple. It is of order 2, its 2 elements being generated by reflection r. It acts on any element $m\in\mathbb{R}$ of the one-dimensional space $\mathbb{R}$ of the ''projections of angular momenta'' in the straightforward way: $r(m)=-m$. The finite dimensional irreducible representations of SU(2) and of its Lie algebra su(2) are well known. The ''angular momentum states,'' the basis vectors of representation spaces, are eigenvectors of the ''diagonal'' generator of SU(2). Unlike the common normalization of that generator in physics, we normalize it so that its eigenvalues are twice the usual projections of angular momenta. The set of the eigenvalues $\Omega(l)$ is the weight system of the representation l. The weight system of an irreducible representation consists of $l+1$ weights,

$$\Omega(l)=\{m\omega|m\in\{-l,-l+2,\ldots,l-2,l\}\},$$

where l is the highest weight (''twice the angular momentum'') of the representation;[31] l is used to specify the representation. Note that all the elements of $\Omega(l)$ have the same parity.

A W-orbit of a weight m thus consists of one or two elements:

$$Wm=\begin{cases}\{m,-m\} & \text{for } m\neq 0\\ \{0\} & \text{for } m=0.\end{cases}$$

The character $\chi(\theta)$ is a function of conjugacy classes of the elements of SU(2). Every class is represented by one value of θ within $0\leqslant\theta\leqslant\frac{1}{2}$. The values of the character of an irreducible representation l can be written as the sum of values of the orbit functions $\Phi_m(\theta)$,

$$\chi_l(\theta)=\sum_m^l \Phi_m(\theta)=\Phi_l(\theta)+\Phi_{l-2}(\theta)+\cdots+\begin{cases}\Phi_1(\theta), & l \text{ odd}\\ \Phi_0(\theta), & l \text{ even.}\end{cases} \tag{3}$$

$$\Phi_m(\theta)=\begin{cases} e^{2\pi i m\theta}+e^{-2\pi i m\theta} & \text{for } m>0 \\ 1 \quad \text{for } m=0 \end{cases}, \quad \text{and } 0\leqslant\theta\leqslant\frac{1}{2}. \tag{4}$$

Only for the one- and two-dimensional representations, $l=0$ and 1, respectively, the character consists of a single orbit function. Note that $\Phi_m(\theta)$ is symmetric (antisymmetric) with respect to the midpoint of its range of θ for m even (odd).

The decomposition of irreducible characters (3) into the sum of orbit functions is given by a triangular matrix. Hence it is invertible. Therefore, the orbit functions $\{\Phi_m(\theta),\ m=0,1,2,\ldots\}$ also form a basis in the space of class functions $f(\theta)$ of SU(2). Using (4), it implies that

$$f(\theta)=\sum_{m=0}^{\infty} a_m\,\Phi_m(\theta) \quad =a_0+2\sum_{m=1}^{\infty} a_m\cos(2\pi m\theta), \quad 0\leqslant\theta\leqslant\frac{1}{2}. \tag{5}$$

There are two properties of the expansion (5) which we want to underline:
(i) It can be reduced to the familiar case of the standard Fourier decomposition of $f(\theta)$ in the interval $\theta\in[-1/2,1/2]$, if one makes an even extension $f(\theta)=f(-\theta)$ for $t\in[-1/2,0]$.
(ii) Although $f(\theta)$ is being expanded into a series of functions which are periodic within the range $0\leqslant\theta\leqslant1$, the actual range of θ in (5) makes periodic only the cosines with even values of m, i.e., $m=2k$. Their arguments vary over the range $\{0,2k\pi\}$, i.e., over an integer multiple of 2π.

A. Discrete Fourier transform on SU(2)

The discrete Fourier transform differs from (5) by the fact that the independent variable θ takes only finite number of values within its range of variation. Fixing a rational value of θ, one fixes an element of finite order (EFO) belonging to the SU(2) torus T. Every conjugacy class of EFO in SU(2) is represented by an element of T with $0\leqslant\theta\leqslant\frac{1}{2}$. In SU(2) one can be explicit, see Refs. 14 or 15 (Sec. IV) for all other compact simple Lie groups.

Let T_N denote the set of all elements of T whose adjoint order divides N, where N is a positive integer. The adjoint order is the order of an element given by matrices of irreducible representations of SU(2) of odd dimensions (i.e., l even). There are exactly $(N+1)$ SU(2)-conjugacy classes of such elements. Taking the unique diagonal matrix as representative of each conjugacy class, in representations of dimensions 2 and 3 we have the following set of matrices

$$\mathsf{T}_N^{(2)}=\left\{ x_{N,k}=\begin{pmatrix} e^{2\pi ik/2N} & 0 \\ 0 & e^{-2\pi ik/2N} \end{pmatrix} \;\middle|\; k=0,1,\ldots,N \right\},$$

$$\mathsf{T}_N^{(3)}=\left\{ x_{N,k}=\begin{pmatrix} e^{2\pi ik/N} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & e^{-2\pi ik/N} \end{pmatrix} \;\middle|\; k=0,1,\ldots,N \right\}.$$

The trace functions of each of these matrices, of size $(l+1)\times(l+1)$, are the characters $\chi_l(\theta)$ of the representation l. The characters can be used for decomposition of the class functions on SU(2), and generally on compact simple Lie groups.

A more suitable basis for such a decomposition consists of orbit functions.[3,4] It makes possible (*practical*) decomposition of class functions on groups of high ranks, such as E_8.[16–18] In the case of SU(2), the orbit functions are also much closer to the familiar set of exponentials $\exp(2\pi im\theta)$ used in the standard Fourier analysis.

Note that the elements $x_{N,k}$ are equidistant in the fundamental region $\mathsf{F}=\{\theta\in[0,1/2]\}$ of the Weyl group W. The number of elements of the W-conjugacy class $m=k/N$ is denoted by $C_{N,k}$ and is given by

$$C_{N,k}=\begin{cases} 1 & \text{if } k=0,N \\ 2 & \text{otherwise.} \end{cases} \tag{6}$$

The following definition of a sesquilinear form $\langle f,g\rangle_N$ in the space R of class functions f and g on SU(2) is a crucial step for our method:

$$\langle f,g\rangle_N=\sum_{k=0}^{N} C_{N,k} f(x_{N,k})\,\overline{g(x_{N,k})}\,, \tag{7}$$

where the overline stands for complex conjugation. It is known,[3,15] and it can be verified by direct computation, that the set of orbit functions $\{\Phi_k|k=0,\ldots,N\}$ is orthogonal on the discrete equidistant N-interval grid with respect to this form. More precisely, we have

$$\frac{\langle \Phi_k,\Phi_m\rangle_N}{\langle \Phi_m,\Phi_m\rangle_N}=\delta_{km},\quad \text{for}\quad 0\leqslant k,m\leqslant N.$$

For further convenience and for comparison of the results with the conventional Fourier series, let us instead of orbit functions $\Phi_m(\theta)$ defined by (4) consider the functions $\psi_m(\theta)=\cos(2\pi m\theta)$ for all $m\geqslant 0$. Then one can easily verify that for $0\leqslant k,m\leqslant N$

$$\langle \psi_k,\psi_m\rangle_N=\sum_{j=0}^{N} C_{N,j}\cos\frac{\pi jk}{N}\cos\frac{\pi jm}{N}=\frac{2N}{C_{N,k}}\delta_{km}. \tag{8}$$

The method proposed here for decomposition of the class functions into series of orbit functions is based on the discrete orthogonality relation (8).

Let $f(\theta)\in R$ be a class function that can be decomposed into a *finite* series of orbit functions:

$$f(\theta)=\sum_{m=0}^{N} a_m\,\psi_m(\theta)\quad (0\leqslant\theta\leqslant\tfrac{1}{2})\,. \tag{9}$$

This can be compared with the general case of infinite series (5) and with the discrete Fourier transform (2) in Ref. 19.

Our goal now is to find the expansion coefficients $\{a_m\}$. In order to use the orthogonality property (8), we form a system of $(N+1)$ linear equations for $\{a_m\}$, restricting θ to the discrete set of its values $\{\theta_k=k\Delta\theta\,|k=0,\ldots,N\}$, with $\Delta\theta=1/2N$:

$$f_k\equiv f(\theta_k)=\sum_{m=0}^{N} a_m\psi_m(\theta_k)=\sum_{m=0}^{N} a_m\cos\frac{\pi mk}{N}. \tag{10}$$

After multiplication of (10) by $C_{N,k}\,\psi_{jk}$ and summing over k, we arrive at $\Sigma_{m=0}^{N} a_m\langle\psi_m,\psi_j\rangle_N$. Then, given (8), we find

$$a_j=\sum_{k=0}^{N} D_N^{jk} f_k\quad \text{for}\quad j=0,\ldots,N, \tag{11}$$

where

$$D_N^{jk}=\frac{C_{N,j}\,C_{N,k}}{2N}\cos\frac{\pi kj}{N}. \tag{12}$$

Here D_N^{jk} are the elements of $(N+1)\times(N+1)$ matrix D_N of the DGT on SU(2). It is easily reduced to the transform matrix of the discrete cosine transform of the type DCT-1 after renormalization by a factor $\sqrt{2C_{N,j}\,C_{N,k}/N}$. The matrix D_N is independent of the values $\{f_k\}$ of the class function which is being decomposed. It is therefore possible to compute D_N in advance for any predefined value of the positive integer N, and use it repeatedly whenever it is needed.

Examples of the transform matrices D_N for the lowest values of N are the following:

$$D_1=\begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} \end{pmatrix},\quad D_2=\frac{1}{2}\begin{pmatrix} \frac{1}{2} & 1 & \frac{1}{2} \\ 1 & 0 & -1 \\ \frac{1}{2} & -1 & \frac{1}{2} \end{pmatrix},\quad D_3=\frac{1}{3}\begin{pmatrix} \frac{1}{2} & 1 & 1 & \frac{1}{2} \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \\ \frac{1}{2} & -1 & 1 & -\frac{1}{2} \end{pmatrix},$$

$$D_4=\frac{1}{4}\begin{pmatrix} \frac{1}{2} & 1 & 1 & 1 & \frac{1}{2} \\ 1 & \sqrt{2} & 0 & -\sqrt{2} & -1 \\ 1 & 0 & -2 & 0 & 1 \\ 1 & -\sqrt{2} & 0 & \sqrt{2} & -1 \\ \frac{1}{2} & -1 & 1 & -1 & \frac{1}{2} \end{pmatrix}. \tag{13}$$

Introducing single-column matrices $A_N=\{a_j\}$ and $F_N=\{f_N(t_k)\}$, and a square matrix $\Psi_N=\{\cos(\pi jk/N)|j,k=0,\ldots,N\}$, Eqs. (10) and (11) can be written in the matrix form,

$$F_N=\Psi_N A_N \quad \text{and} \quad A_N=D_N F_N, \quad \text{where} \quad D_N=\Psi_N^{-1}. \tag{14}$$

The matrix D_N, being the inverse of Ψ_N, formally solves the problem of discrete Fourier transform on SU(2).

B. Continuous extension of the discrete Fourier transforms

Let a continuous function $g(t)$ be the origin for the discrete function $\{g_k=g(t_k)\}$ defined at the $(N+1)$ points $t_k=kT_0/N$, $k=0,1,\ldots,N$, of the interval $[0,T_0]$. The DCT of $\{g_k\}$ with the use of the transform matrix (12) results in the discrete function $\{a_j\}$ in the frequency space. This is an exact (''lossless'') discrete transform, since it allows unambiguous recovery of all $N+1$ values of $\{g_k\}$ by applying the inverse DCT in the form of (10). We recall that the standard discrete Fourier transform, i.e., DFT, has the same property.

It seems then natural to ask if it is possible to recover the originating function $g(t)$ by a Fourier series not only at the grid points $\{t_k\}$, but also on the entire continuous segment $[0,T_0]$. In order to answer this question, let us consider the continuous extension of the discrete transform between the grid points, which can be formulated as follows.

Proposition: Let $g(t)$ be a complex valued function of $t\in[0,T_0]$, taking values $g_k=g(t_k)$ on an equidistant point grid $\{t_k=kT_0/N\,|k=0,1,\ldots,N\}$. The function

$$f_N(t)=\sum_{j=0}^{N} a_j \cos(\pi jt/T_0), \qquad t\in[0,T_0], \tag{15}$$

with the discrete transform coefficients

$$a_j=\sum_{k=0}^{N} \frac{C_{N,j}C_{N,k}}{2N} g_k \cos\frac{\pi jk}{N}, \tag{16}$$

is the continuous Fourier extension of the inverse DCT of $\{g_k\}$. It is exact in the sense that $f(t_k)=g_k$ at all $N+1$ points of the grid.

The proof of this proposition is obvious if one recalls that (15) and (16) are reduced, respectively, to (10) and (11) after substitution $t=2\theta T_0$ with $\theta\in[0,\frac{1}{2}]$.

Similar to DCT, one can also continuously extend to all points of the segment $[0,T_0]$ any other types of discrete transforms, in particular the DFT, resulting in CEDFT.

Below we address two important questions. First, how well the CEDCT approximates any "reasonably behaved" (e.g., continuous) function $g(t)$ on the interval $[0,T_0]$ between the points of the grid. The second question is how it compares with the CEDFT. At last, we will also briefly address the question of the possible use of CEDCT in practical applications, in particular, for purposes of smooth representation of compressed images.

In order to provide a partial answer to the first question, we consider two examples.

Example 1: Let us take a Gaussian function

$$g(t)=\exp[-\tfrac{1}{2}(t/\sigma)^2], \quad t\in[0,1], \tag{17}$$

with the dispersion $\sigma=1/3$, and choose $N=3$. Thus we have chosen a rather coarse grid relative to the dispersion: The width of its intervals $1/N$ is equal to the dispersion. The coefficients (11) are readily calculated using D_3 from (13):

$$A_3=\begin{pmatrix} a_0\\ a_1\\ a_2\\ a_3\end{pmatrix}=\frac{1}{3}\begin{pmatrix} 0.5+e^{-0.5}+e^{-2}+0.5\,e^{-4.5}\\ 1+e^{-0.5}-e^{-2}-e^{-4.5}\\ 1-e^{-0.5}-e^{-2}+e^{-4.5}\\ 0.5+e^{-0.5}+e^{-2}+0.5\,e^{-4.5}\end{pmatrix}=\begin{pmatrix} 0.415\,807\\ 0.486\,695\\ 0.089\,748\\ 0.007\,750\end{pmatrix}. \tag{18}$$

The corresponding CEDCT function (15) reads

$$f_3(t)=a_0+a_1\cos(\pi t)+a_2\cos(2\pi t)+a_3\cos(3\pi t), \tag{19}$$

where the coefficients are given by (18).

Now we are in a position to compare (17) with (19). At the grid points $t_k=k/3$ the functions coincide, $f_3(t_k)=g(t_k)$ (which is easily verified). One may then expect large deviations of $f_3(t)$ from $g(t)$ around intermediate points of the grid, i.e., $t=1/6$, $1/2$, and $5/6$:

$$\begin{pmatrix} f_3(1/6)\\ f_3(1/2)\\ f_3(5/6)\end{pmatrix}=\begin{pmatrix} 0.882\,171\\ 0.326\,059\\ 0.039\,191\end{pmatrix} \quad\leftrightarrow\quad \begin{pmatrix} g(5/6)\\ g(1/2)\\ g(1/6)\end{pmatrix}=\begin{pmatrix} 0.882\,497\\ 0.324\,652\\ 0.043\,937\end{pmatrix}.$$

A good agreement between $f_3(t)$ and $g(t)$ is apparent even for $t=5/6$ where $g(t)$ becomes very small.

Example 2: DCT approximation for a more complicated function is found in Fig. 1, where we show $f_N(t)$, $N=10$ and 14, for the function $g(t)$ composed of two Gaussians,

$$g(t)=A_1e^{-((t-t_1)/\sigma_1)^2/2}+A_2e^{-((t-t_2)/\sigma_2)^2/2}, \tag{20}$$

with amplitudes $A_1=2$, $A_2=1.5$, narrow dispersions $\sigma_1=\sigma_2=0.05$, and centered at $t_1=0.42$, $t_2=0.56$.

For comparison, in Fig. 1 we show by dashed lines the approximations to $g(t)$ provided by the trigonometric CFT polynomials where the transform coefficients are calculated by exact integrations. Recall that for a real function $g\to\mathbb{R}$ the CFT polynomials of the harmonic order K are given by the series[32] (see, e.g., Ref. 2):

$$P_K(t)=\sum_{j=-K}^{K} c_j\,e^{i2\pi jt/T_0}=c_0+2\,\mathrm{Re}\sum_{j=1}^{K} c_j\,e^{i2\pi jt/T_0}, \tag{21}$$

where

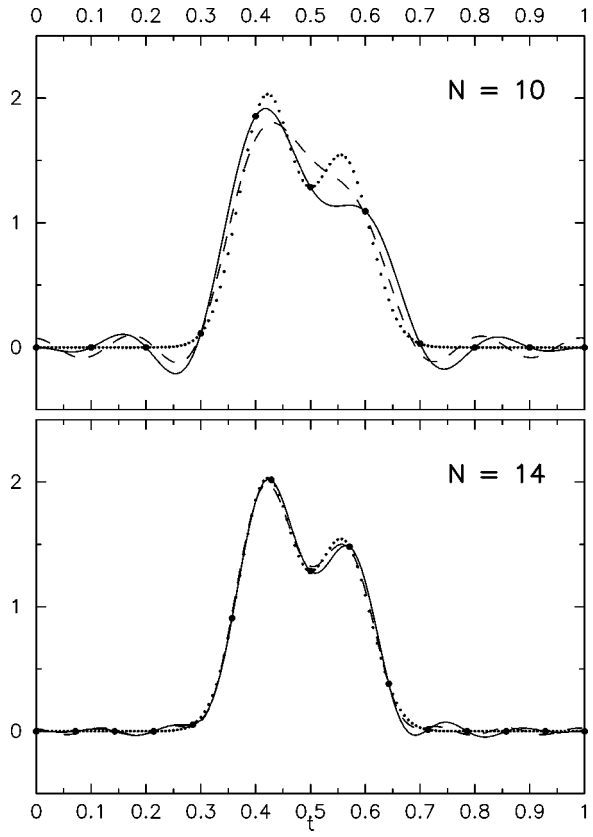

FIG. 1. Approximation of an analytic function (20), shown by the dotted lines, with the CEDCT function $f_N(t)$ (solid lines) for the discrete interval numbers $N=10$ and $N=14$. The big dots show the values of the grid function $\{g_k \equiv g(t_k)\}$ for $\{k=0,\ldots,N\}$. For comparison we also show by dashed lines the approximation of $g(t)$ by the exact CFT polynomials of (21) with $K=N/2$. It gives polynomials of the same harmonic maximum order as the ones in the DCT. The parameters in (20) are $A_1=2$, $A_2=1.5$, $\sigma_1=\sigma_2=0.05$, $t_1=0.42$, $t_2=0.56$.

$$c_j=\frac{1}{T_0}\int_0^{T_0} g(t)\, e^{-i2\pi jt/T_0}\, \mathrm{d}t. \tag{22}$$

In order to compare approximations to $g(t)$ that can be provided by series (15) and (21) of the same order for the highest harmonics, for the series $P_K(t)$ in Fig. 1 we put $K=N/2$.

Figure 1 illustrates that the DCT is really an exact discrete Fourier transform, i.e., that $f_N(t_j)=g(t_j)$ for all $0\leqslant j\leqslant N+1$. Remarkably, its continuous extension $f_N(t\in[0,T_0])$ approximates $g(t)$ practically as well as the accurate CFT trigonometric Fourier series $P_K(t)$ of the same harmonic order, i.e., $K=N/2$. In the case of Gaussian-type functions, CEDGT series approximates the original function $g(t)$ reasonably well even in the case of narrow structures with dispersions as small as $\sigma\approx T_0/1.5N$.

C. Comparing with standard DFT

First, let us recall some properties of the standard exploitation of the discrete Fourier transform. Further details can be found in many books (e.g., see Refs. 8–10).

The standard DFT is formally derived from an approximate calculation of the integral coefficients c_j for the trigonometric Fourier series, using a simple rule of rectangles for integration of c_j in (22) when the function g is given on the N-interval equidistant grid, $g(t)\rightarrow\{g_k|k=0,\ldots,N\}$. This leads to DFT coefficients

$$u_j = \frac{1}{N} \sum_{k=0}^{N-1} g_k e^{-i(2\pi/N)kj}, \tag{23}$$

where $1/N$ is the length of the sampling interval Δt (assuming for simplicity $T_0 = 1$).

A crucial feature of this definition of DFT consists in the fact that the system of Eqs. (23) for the first N coefficients $\{u_j | j = 0,\ldots,N-1\}$ can be inverted with respect to $\{g_k | k = 0,\ldots,N-1\}$. Such a possibility is based on the observation that the matrices with matrix elements

$$M_{jk} = \frac{1}{N} e^{-i(2\pi/N)kj} \quad \text{and} \quad (M^{-1})_{jk} = e^{i(2\pi/N)kj},$$

are inverse to each other. Therefore, the *inverse* DFT is

$$g_k = \sum_{j=0}^{N-1} u_j e^{i(2\pi/N)kj}. \tag{24}$$

Thus, the discrete sets $\{u_j\}$ and $\{g_k\}$ represent a pair of exact (*lossless*) direct and inverse transforms (e.g., see Ref. 10) in the form of Fourier series, which is generally treated as the exact *solution* to the problem of Fourier transform of discrete functions given on the equidistant grid.

We argue below, however, that there are significant reasons to suggest that the real (and not only formal) exact solution to the problem of discrete Fourier transform of a grid function is provided by the DCT transform pair given by (16) and (10). It retains all the ''good'' properties of the DFT:

(i) it is easy and fast to compute;

(ii) it is a lossless discrete transform, with the exact inverse DCT at all $(N+1)$ points of the grid (even if $g_0 \neq g_N$, unlike for DFT).

However, in addition to these properties, the continuous extension of DCT, $f_N(t)$ in (15), converges to the originating continuous function $g(t)$ with increasing N, as illustrated in the previous section, and as it is proved in the next Section. Only the continuous extension of the DCT, and not the DFT, reveals properties characteristic to the canonical continuous Fourier transform series.

It is worth noting here that the very good convergence properties seem to be a common feature for the discrete Lie group transforms, as we also demonstrate on the example of SU(3) group in our recent paper, Ref. 34. The basic mathematics of DGT has been formulated[15] for any dimension $n < \infty$. In fact there are as many different variants of the method one could use, as there are different semisimple compact Lie groups of rank n, and then within each variant the choice of the points of the grid is also far from unique, except for the lowest cases like SU(2). It then provides an opportunity to make a choice of appropriate DGT in situations where the choice of symmetry is dictated by the experimental data.

The absence of the convergence property for the continuous extension of the DFT given by (24) is not easy to anticipate because CEDFT looks like a Fourier polynomial, or a cutoff of an ''ordinary'' Fourier expansion:

$$h_N(t) = \sum_{j=0}^{N-1} u_j e^{2i\pi jt}. \tag{25}$$

Similar to CEDCT, it satisfies the equality $h_N(t_k) = g_k$ on the grid points $t_k = k/N$ for[33] all $k \leqslant N-1$. The fact that their continuous extensions CEDGT and CEDFT behave quite differently is illustrated in Example 3. It has rarely been emphasized that $h_N(t)$ *does not* approximate the initial function $g(t)$ between the grid points, and it does not converge at all to any continuous function (except for a trivial case of $g(t) = \text{const}$) with increasing N. It is worth citing in this regard Ref. 9, p. 87: ''The DFT is a Fourier representation of finite length sequence which is itself a sequence rather than a continuous function.''

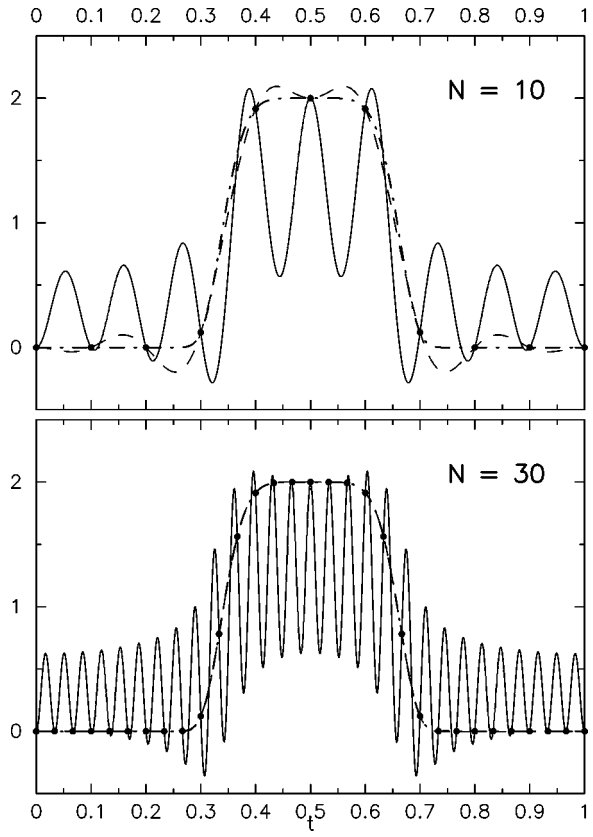

FIG. 2. Behaviors of the Fourier series $h_N(t)$ and $f_N(t)$, given by Eq. (25) and (15). Solid lines represent the CEDFT, and dashed lines show the CEDCT. Big dots show the values of the grid function $\{g_k|k=0,\ldots,N\}$ originated from an analytic function $g(t)$ which is given by Eq. (26), and is shown by the dot–dashed line.

Example 3: Let $h_N(t)$ be the CEDFT of N-interval grid function arising from a sampling of the continuous function

$$g(t)=Ae^{-(t-t_0)^6/a^6}, \tag{26}$$

with $A=2$ and parameter $a=0.15$. Here we have chosen a large value, 6, for the power in the exponent in order to illustrate a case with gradients significantly larger than in the case of Gaussian functions.

Solid lines in Fig. 2 correspond to continuous DFT extensions $h_N(t)$, and the dashed lines show the DCT extension $f_N(t)$. Although $h_N(t)$ passes through all g_k at $t=t_k$ (shown as full dots), similar to $f_N(t)$, its behavior in between shows profound oscillations due to the presence in (25) of high-frequency Fourier components, $\nu_j=j$ (for $T_0=1$), with values of $N/2\leqslant j\leqslant N-1$ comparable to N. These oscillations in CEDFT do not decrease with increasing N. But they quickly disappear in CEDCT series where the harmonic order of the maximum frequency mode does not exceed $J_{\mathrm{Ny}}\equiv N/2$. Note that this mode corresponds to the so called Nyquist frequency $N/2$ which plays a fundamental role in the digital signal processing theory.

D. Shannon sampling theorem and DCT and DFT

Nonconverging behavior of CEDFT appears puzzling especially in the light of Nyquist–Shannon sampling theorem[20,21] for a continuous band-limited signal which states

Every continuous band-limited analog signal $X(t)$ *can be reconstructed fully from its discrete samples* $X_n = X(n\Delta t)$, *provided the sampling rate* $1/\Delta t$ *exceeds twice the maximum frequency* ν_{max} *contained in* $X(t)$.

The sampling rate $1/\Delta t = 2\nu_{\max}$ corresponds to the sampling at the rate of 2 points per period $T_{\min} = 1/\nu_{\max}$, which is the Nyquist rate. Shannon formula[21] provides exact interpolation between the sampling points for unlimited time sequence:

$$X(t) = \sum_{n=-\infty}^{\infty} X_n \frac{\sin(t - n\Delta t)\pi/\Delta t}{(t - n\Delta t)\pi/\Delta t}. \tag{27}$$

It should be emphasized here that Shannon interpolation is *not* a Fourier-type interpolation, but is based on *sinc* function $\sin(t)/t$. In case of limited time interval $t \in [0,1]$, hence limited number of points $X_n \to g_n$ with $n = 0,\ldots,N$, the truncated version $X_N(t)$ of the sequence (27) provides an approximate interpolation to the original $g(t)$ converging in the limit of $N \gg J_{\mathrm{Ny}}$.

The reason for oscillatory behavior of CEDFT can be understood if we note that for any large N the harmonics $\exp(-2i\pi jt)$ with frequencies $j > N/2$ strongly vary and change the sign within any single narrow interval $\Delta t = 1/N$. The use of rectangular integration rule in (22) cannot provide any reasonable similarity between the canonical CFT coefficients c_j in (22) and their standard DFT ''approximations'' u_j in (23). Effectively, the ''fine tuning'' between the coefficients for high-order harmonics intrinsic to the continuous Fourier transform is lost. Moreover, the DFT coefficients (23) with harmonic order exceeding J_{Ny} are no more declining for higher j, which is a normal general trend for both DCT and CFT coefficients. In fact, the well known property of DFT coefficients at $j > J_{\mathrm{Ny}}$ is that they fully ''recover'' the low-order coefficients in complex conjugate form as

$$u_j = \overline{u}_{N-j}. \tag{28}$$

This notion allows us to understand different behaviors of continuous extensions of DFT and DCT in the view of Nyquist–Shannon sampling theorem. Indeed, for any N one can consider CEDCT as a continuous band-limited function with maximum frequency formally equal to frequency J_{Ny}/T_0. This function is formally sampled at the Nyquist rate. However, for large N the DCT coefficients $|a_j|$ for large order harmonics rapidly drop (see Ref. 13). It leaves the CEDCT with an effective bandwith of order of the bandwidth ν_g of the original function $g(t)$. Thus, we can say that at large N the set $\{g_j \mid j = 0,1,\ldots,N\}$ samples CEDCT with a rate much higher than the Nyquist rate. Therefore, one could also say that ''$g(t)$ provides a good reconstruction to CEDCT.''

Meanwhile, because of the relation (28), large frequency harmonics do not disappear from DFT at any large N. The maximum bandwidth of CEDFT is $\nu_{\max} = (N-1)$. Therefore the sampling rate of $\{g_j\}$ is 2 times less than the Nyquist rate which is needed to have sufficient information about the CEDFT function. In a definite sense, $g(t)$ represents an example of a ''low-frequency alias'' to CEDFT. In the next section we will see that elimination of high-order harmonics from the DFT sequence allows construction of a reasonable continuous interpolation for $g(t)$ based on DFT coefficients.

E. Comments on fast Fourier transform

There is a number of ways to make a more accurate approximation for the high-frequency Fourier transform coefficients c_j than the rectangular integration can provide. Despite this, the standard version of DFT defined by (23) and (24) for the direct and inverse discrete transforms has been widely used since the pioneering paper by Cooley and Tukey,[22] where the first algorithms for fast calculation of this DFT had been developed. Different algorithms for such *fast Fourier transform* (FFT) computations allow an increase of the speed of practical calculations of DFTs by one or two orders of magnitude. A direct ''head-on'' algorithm for calculations of $\{u_j \mid j = 0,\ldots,N$

$-1\}$ would require about N^2 multiplications and additions. Meanwhile, for special values of N, FFT algorithms significantly reduce the required number of elementary operations, e.g., down to $\sim N \log_2 N$ in case of $N=2^n$.

The discussion of various FFT algorithms, extensively developed by many authors (e.g., Refs. 23–26), is outside the scope of this article. Here we only note that the FFT methods are fundamentally exploiting the property of the standard DFT coefficients (23) that u_j can be reduced to a power-law series of a single complex element $W_N=\exp(-i2\pi/N)$ as $u_j=N^{-1}\Sigma g_k W_N^{jk}$. This would not be possible if more accurate integration methods for the high-order harmonics were used. It should be also noted, however, that the DCT does allow application of FFT methods since it can be formally reduced (with insignificant differences) to $2N$-point DFT of an even function $g(-t)=g(t)$ (see Ref. 13). A number of efficient FFT-based algorithms have been developed for DCT (e.g., Refs. 27–30) including algorithms competing with FFT but specific to DCT (see Ref. 13 for details).

A simple modification could significantly improve behaviors of continuous extensions of the discrete transforms based on the use of standard DFT coefficients (23), but not without a penalty. Because the reason for strong oscillations of CEDFT is the use of frequencies exceeding the Nyquist frequency J_{Ny}/T_0, one can try to eliminate first these terms from the discrete transform construction (24). Using (28), in the case of even $N=2K$, the sum in (24) is reduced to

$$g_k=u_0+\sum_{j=1}^{K-1}\left(u_j e^{i2\pi j\,k/N}+\overline{u}e^{-i2\pi j\,k/N}\right)\ +u_{N/2}(-1)^k. \tag{29}$$

In the case of odd $N=2K+1$ the last term disappears. However, the attractiveness of DFT retains mostly to the cases of even N $(=2^p)$, for which very effective FFT algorithms are developed. Meanwhile, it is impossible to ''continuously extend'' the modified DFT sequence (29) by substituting $k/N\rightarrow t/T_0$, unless one neglects the last term with flipping argument $(-1)^k$. The resulting function is similar to the series (21) truncated to harmonics of order $j\leqslant N/2$, but it uses the DFT coefficients u_j:

$$s_K(t)=u_0+2\ \mathrm{Re}\sum_{j=1}^{K} u_j e^{i2\pi jt/T}, \tag{30}$$

where the coefficients u_j are defined by (23). Here we use K equal to $J_{\mathrm{Ny}}=N/2$. But one also can take $K<N/2$, and still $s_K(t)$ will be converging to $g(t)$ for $K\rightarrow\infty$.

In Fig. 3 we show that the function $s_K(t)$ with $K=N/2$ (dashed curves) can indeed approximate $g(t)$ practically as well as the DCT extension $f_N(t)$. But in this case the penalty is a loss of the ''exactness'' property for such modified DFT sequence. Because we had to drop the last term in (29) out, $s_K(t)$ can be equal to g_k at the grid points $t=t_k$ only within the accuracy of the term $u_{N/2}$. Therefore, (30) cannot represent an exact solution to the problem of discrete Fourier transform. Meanwhile, the series $f_N(t)$ both satisfies that condition, and rapidly converges to $g(t)$ with increasing N.

For comparison, we also show in Fig. 3 (dot–dashed line) the function $s_K(t)$ calculated for $K=6<N/2=8$. In this case the approximation errors $[s_K(t)-g(t)]$ are larger than the ones when $K=8$, because the order of high frequency harmonics becomes important for the approximation of features with a dispersion $\sigma\leqslant T/2K$.

III. LOCALIZATION AND DIFFERENTIABILITY OF CEDCT

In this section we prove the properties *localization* and *differentiability* of the CEDCT which are analogous to the properties of the canonical CFT polynomials (21) (e.g., see Ref. 2).

Derive first a useful formula for an N-interval CEDGT (15) of a grid function $\{g_k\}$. Using (16), and assuming for simplicity $T_0=1$, i.e., $t\in[0,1]$, (15) is reduced to

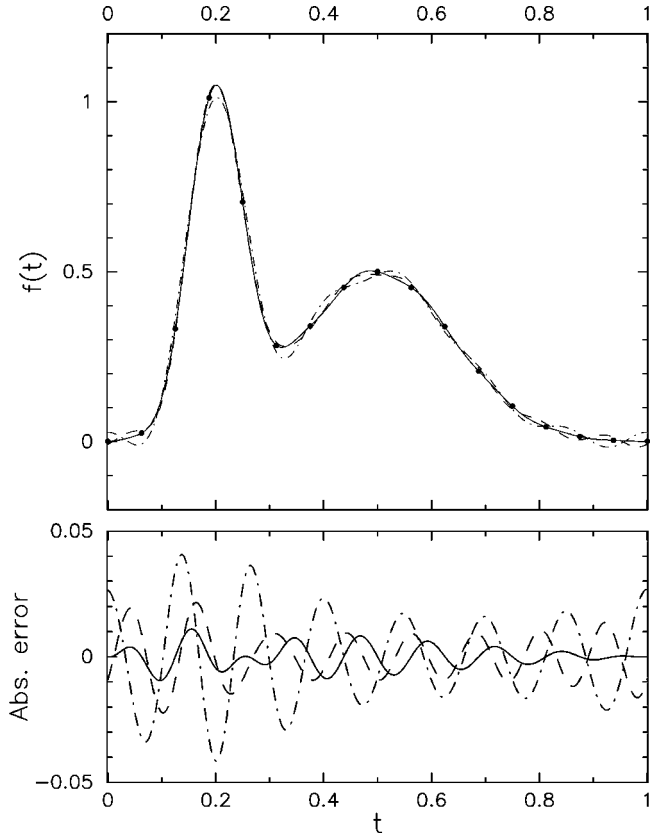

FIG. 3. Approximation of an analytic function $g(t)$ composed of two Gaussians, (20), with the CEDCT function $f_N(t)$ of (15) with $N=16$ (*solid lines*) and the Fourier series $s_K(t)$ of (30) that uses only the first $K\sim N/2$ coefficients $\{u_j|j\leqslant K\}$ of the standard DFT (23). The dashed line is for $K=N/2=8$, and the dot–dashed line corresponds to $K=6$. The full dots in the upper panel correspond to $\{g_k|k=0,\ldots,N\}$. The lower panel shows the corresponding errors of the approximation to $g(t)$ by these 3 types of discrete Fourier transforms. The dispersions in (20) are assumed to be $\sigma_1=0.07$ and $\sigma_2=0.2$.

$$f_N(t)=\frac{1}{2N}\sum_{j=0}^{N}\sum_{k=0}^{N} C_{N,k}C_{N,j}\cos(\pi jt)\cos(\pi jt_k)\,g_k, \tag{31}$$

where $t_k\equiv k/N$. Using $2\cos\alpha\cos\beta=\cos(\alpha+\beta)+\cos(\alpha-\beta)$, the terms containing index j can be re-written as a sum of two geometric series:

$$\sum_{j=0}^{N} C_{N,j}\cos(\pi jt)\cos(\pi jt_k)=(-1)^k\cos(\pi Nt)-1+\mathrm{Re}\left(\sum_{j=0}^{N-1} e^{i\pi(t+t_k)j}+\sum_{j=0}^{N-1} e^{i\pi(t-t_k)j}\right).$$

Summing up the series, one gets a compact expression for CEDGT:

$$f_N(t)=\sum_{k=0}^{N}\frac{(-1)^kC_{N,k}}{2N}\frac{\sin(\pi Nt)\sin(\pi t)}{\cos\pi t_k-\cos\pi t}g_k\equiv\sum_{k=0}^{N}A_{N,k}(t)\,g_k,\quad\text{for}\quad t\in[0,1]. \tag{32}$$

The values of $f_N(t)$ for any $t\to t_n=n/N$ are found by applying the Lipshitz rule for the ratio of infinitesimals of a smooth function. For (32) it results in $f_N(t_n)=g_n$ for all $n=0,\ldots,N$, as expected.

Using (32), below we prove that the *localization principle*, known (see Ref. 2) for the CFT series (21) also holds for the CEDCT. The localization lemma can be formulated as follows:

Localization Lemma: Let the set of N-interval grid functions $\{g_k\}$*, with various* N*, be originated from a smooth function* $g(t)$ *with a bounded derivative* $g'(t)$ *on the interval [0,1]. Then at any given* $t\in[0,1]$ *and for any small* $\Delta>0$ *and* $\epsilon>0$ *there exists* $N_{\epsilon,\Delta}$ *such that for all* $N>N_{\epsilon,\Delta}$ *the behavior of the continuous extension of the discrete group transform* $f_N(t)$ *is defined within the accuracy* ϵ *only by the values of* $g(t)$ *in the* Δ*-neighborhood of* t*, i.e.:*

for any $\epsilon,\Delta>0$ $\exists N_{\epsilon,\Delta}$ *such that for all* $N>N_{\epsilon,\Delta}\Rightarrow$

$$\left| f_N(t)-\sum_{\{k'\}} A_{N,k'}(t)g_{k'}\right|<\epsilon, \quad \text{with all } k' \text{ within} \quad t-\Delta<\frac{k'}{N}<t+\Delta.$$

Proof: From (16), using (8), it follows that the DGT coefficients of any constant function $g_1(t)=\text{const}$ are equal to $a_k^{(1)}=\delta_{k0}\times\text{const}$, i.e., that all coefficients except for $a_0^{(1)}=\text{const}$ are equal to 0. Thus the convergence properties of the CEDGT of any function $g(t)$ are the same as the properties of the function $g(t)+\text{const}$. So taking into account that the function is bounded, it is sufficient to prove the Lemma, while generally assuming that $g(t)$ is positive on the interval [0,1].

Let us split the sum in (32) into 3 parts corresponding to

$$\begin{aligned} S_-&=\sum_{k=0}^{K_t-K_\Delta-1} A_{N,k}\,g_k,\\ S_+&=\sum_{k=K_t+K_\Delta+1}^{N} A_{N,k}\,g_k,\\ S_\Delta&=\sum_{k=K_t-K_\Delta}^{K_t+K_\Delta} A_{N,k}\,g_k, \end{aligned} \tag{33}$$

where $K_t=[Nt]$ and $K_\Delta=[N\Delta]$ are the integer parts of the respective products. If any of the points $t\pm\Delta$ is outside the interval [0,1], then only 2 sub-series are left. In all cases, only S_Δ of these sub-sums is defined by $g(t)$ in the close neighborhood of t. The localization Lemma for (32) then implies that the *non-local* sums, S_+ and S_-, are reduced with increasing N to absolute values below any small ϵ.

Indeed, on the basis of (32), for any fixed Δ each of those non-local sums represents a series of bound-value elements with alternating signs, which can be then combined into pairs of consequetive elements of order $O(1/N^2)$ each. Considering for example the sum S_-, and using the Taylor series decomposition for $g_{k+1}\equiv g(t_{k+1})=g_k+g'(t_k)/N+o(1/N)$ each pair of elements $A_{N,k}g_k+A_{N,k+1}g_{k+1}$ starting with even $k\geqslant 2$ can be reduced to

$$\frac{\sin(\pi Nt)\sin(\pi t)}{N^2}\left[\frac{g'(t_k)}{\cos\pi t_k-\cos\pi t}-\frac{g_k\sin\pi t_k}{(\cos\pi t_k-\cos\pi t)^2}+o(1/N^2)\right].$$

The expression in the square brackets is bounded with some absolute value independent of N as far as g' is bounded and $|t_k-t|>\Delta$, therefore, $A_{N,k}g_k+A_{N,k+1}g_{k+1}\sim O(1/N^2)$. The number of such pairs in S_- or S_+ is increasing $\propto N$. Therefore taking also into account that in the sums S_- and S_+ each of the limited number of elements left out from such pairing process (e.g., in case of $C_{N,k}=1$ for $k=0,N$) is only of order $O(1/N)$, we conclude that both series S_- or S_+ tend to zero with the increase of N. This proves the localization Lemma. ■

A very important property of the CEDGT series $f_N(t)$ is the possibility of its term-by-term differentiation such that the resulting series converges with increasing N to the derivative $g'(t)$. Note that while being well-known for the CFT series (21), this property is not trivial for finite (N-)element discrete Fourier transforms. Recall that although in trigonometric polynomials in the form of (15) or (30) each individual term, being $\propto 1/N$, decreases to 0 at large N, their derivatives over t corresponding to a high-order harmonics, say $j>N/2$, become of order $j/N\sim 1$, and therefore, might not necessarily vanish with increasing N. Thus, a "fine tuning" of the entire discrete-

transform based series is needed in order to provide convergence of the series produced by its term-by-term differentiation.

Theorem: *Let $g(t)$ be a smooth function with bounded second derivative on the interval $t \in [0,T_0]$, which originates the N-interval grid function $\{g_k | k=0,1,\ldots,N\}$. Then the function $f'_N(t)$ produced by the term-by-term differentiation of the continuous extension of the discrete Fourier transform on SU(2), $f_N(t)$, converges with increasing N to $g'(t)$ at any $t \in (0,T_0)$.*

Proof: As earlier, we put $T_0=1$ for simplicity of the formulas below. Because the series $f_N(t)$ given by (31) contains a finite number of elements, it is obvious that its derivative f'_N can be summed up to the series produced by the term-by-term differentiation of (32).

Consider first the derivative $f'_N(t)$ at any *rational* t_0 in the open interval (0,1). In that case we can choose N such that $t_0=m/N$, and it then makes sense to choose all further subdivisions of the interval $[0,1]$ such that t_0 will be always kept as a knot of the grid, i.e., $t_0=m_1/N_1$ for all $N_1 > N$, i.e., choosing $N_1=aN$ with some integer $a>1$. Using the Lipshitz rule, the derivative of (32) at $t_0=m/N$ is reduced to

$$f'_N(t_0)=\frac{\pi}{2}\sin \pi t_0 \sum_{k=0}^{N\ (k\neq m)} (-1)^{k-m} C_{N,k}\, U_k(t_0) \quad + \quad \frac{\pi \cos \pi t_0}{2 \sin \pi t_0} g_m, \tag{34}$$

$$U_k(t_0)=\frac{g_k}{\cos \pi t_k - \cos \pi t_0}, \quad \text{where} \quad t_k=k/N. \tag{35}$$

Let us choose some small Δ, such that both $(t_0 \pm \Delta) \in (0,1)$, and then split the sum in (34) into 3 sub-series S'_+, S'_- and S'_Δ as in (33), where the number $K_t=m$ for $t=t_0=m/N$. It is convenient for further analysis to choose K_Δ as the maximum integer which satisfies the condition $K_\Delta/N \leqslant \Delta$ and is of the same parity as m. Then the indices of both the last element in the series S'_- and the first element in S'_+, $m-K_\Delta-1$ and $m+K_\Delta+1$, respectively, are odd.

Recall that for any smooth function $U(t)$ with a bounded second derivative on the equidistant grid we have

$$2U_k=U_{k-1}+U_{k+1}+U''_k N^{-2}+o(N^{-2}) \quad , \tag{36}$$

which follows from the familiar Taylor series decomposition $g(t+x)=g(t)+g'(t)\,x+0.5\,g''(t)\,x^2+o(x^2)$ in the $x=\pm 1/N$ vicinity of t. Applying (36) to $U(t)=g(t)/[\cos \pi t - \cos \pi t_0]$ at all $t=t_k$ in (34) and (35) with k odd (i.e., $k=2j-1 | 1 \leqslant j \leqslant (m-K_\Delta)/2$), and given (6), the series S'_- is reduced to

$$S'_-=(-1)^m \frac{\pi \sin \pi t_0}{2}\left(-U_{m-K_\Delta}+N^{-2} \sum_{j=1}^{(m-K_\Delta)/2} U''_{2j-1} \right)+o(N^{-1}). \tag{37}$$

The first term on the right-hand side is exactly one half of the first term in the localized sum S_Δ, but with a negative sign. The second term is of order $O(N^{-1})$. A more precise estimate of this term can be derived if we note that for large N the sum

$$\frac{2}{N} \sum_{j=1}^{(m-K_\Delta)/2} U_{2j-1} \to \int_0^{t_0-\Delta} U''(t)\mathrm{d}t = U'(t_0-\Delta)-U'(0) \tag{38}$$

is bounded for any given Δ, as far as $g''(t)$ is bounded. Note that the estimate of (38) implies only that $U''(t)$ is integrable. This suggests that in principle the conditions of the validity of the differentiation Theorem can be relaxed, requiring that $g''(t)$ be an integrable function on $[0,1]$, but not necessarily bounded.

Applying the same approach to S'_+, we find

$$S'_- + S'_+ = \frac{\pi \sin \pi t_0}{2}(-1)^{m+1}(U_{m-K_\Delta} + U_{m+K_\Delta}) + O_1, \tag{39}$$

with $O_1 \sim O(N^{-1})$. Note that in the case of an odd N, the residual O_1 also includes the difference between the last term, $k=N$, and one *half* of the $k=(N-1)$-th term, which is of order $U'_N \sin(\pi t_0)/N$. Here we take into account that $C_{N,N-1} = 2\, C_{N,N}$ from (6). Thus, for any ϵ we can choose N_ϵ such that for all $N > N_\epsilon$ the residual in (39) is $O_1 < \epsilon/2$. Then (34) is reduced with accuracy $< \epsilon/2$ to a summation of elements localized around, and symmetric with respect to, the point $t_0 = m/N$:

$$f'_N(t_0) = \pi \sin \pi t_0 \sum_{j=1}^{K_\Delta - 1} (-1)^j (U_{m-j} + U_{m+j}) + \frac{\pi \sin \pi t_0}{2}(-1)^{K_\Delta}(U_{m-K_\Delta} + U_{m+K_\Delta})$$

$$+ \frac{\pi \cos \pi t_0}{2 \sin \pi t_0} g_m + O_1(\epsilon/2). \tag{40}$$

Here we take into account that K_Δ is chosen to be of the same parity with m. Introducing now $r_j = j/N$ which is $\leqslant \Delta$ for $j \leqslant K_\Delta$, we have

$$\sin \pi t_0 (U_{m-j} + U_{m+j}) = g_m \frac{\cos \pi t_0}{\sin \pi t_0} - \frac{2}{\pi} g'_m + O_{2,j} \quad ,$$

where, keeping the largest order terms, the residual $O_{2,j}$ is reduced to

$$O_{2,j} \simeq \left(g_m - \frac{2}{\pi} g'_m + \frac{2 \sin^2 \pi t_0}{\pi^2} g''_m \right) \left(\frac{\pi r_j}{2 \sin \pi t_0} \right)^2 \quad . \tag{41}$$

Substituting these 2 relations into (40), and recalling that $g'_m \equiv g'(t_0 = m/N)$, it is easily shown that for both even and odd m and K_Δ one has

$$f'_N(t_0) = g'(t_0) + O_1(\epsilon/2) + O_2(\Delta^2), \tag{42}$$

where the residual O_2 represents the sum of residuals $O_{2,j}$, i.e., $O_2 \Sigma_{\{j\}} O_{2,j}$. Because of the sign alteration term $(-1)^j$ in (40), this sum does not increase with increasing N beyond the absolute value of $O_{2,j}$ at $r_j = \Delta$ in (41). It follows then that for any small $\epsilon > 0$ we can first choose an interval Δ proportional to $\sqrt{\epsilon} \sin \pi t_0$ (depending also on g, g', g'') such that $|O_2| < \epsilon/2$. Then we can choose a number N_ϵ such that $|O_1| < \epsilon/2$. Hence $|O_1 + O_2| < \epsilon$ for all $N > N_\epsilon$. This proves the differentiation Theorem. ■

Note that in the derivation of (38) which has allowed principal clipping of both end-terms in the localized (40) exactly by one half, the symmetry properties of the SU(2) DGT series expressed in the term $C_{N,k}$ have been fully exploited.

Another notice is that, along with the continuous DGT extension of $\{g_k\}$, the *localization Lemma is also valid for its term-by-term derivative* $f'_N(t)$. This property is actually proven by the localized structure of the sum in the construction (40).

Example 4: In Fig. 4 we show interpolations which are provided by the CEDCT series (15) (dashed curves) for the function

$$g(t) = e^{-3t} + \tfrac{1}{2} e^{-((t-0.5)/0.1)^2}, \tag{43}$$

and its first derivative $g'(t)$ (bottom panels). For comparison, we also show approximations provided by the continuous extension of the truncated DFT series (30) with $K = N/2$ (thin solid curves), and by the Shannon's interpolation formula (27) (heavy 3-dot–dashed curves). Recall that the use of the standard CEDFT series (25) for calculations of derivatives does not make any sense as far as CEDFT does not converge (see Fig. 2). Although both the truncated DFT series $s_N(t)$ and the Shannon's interpolation series $X(t)$ do converge to $g(t)$ with increasing N, as shown on the

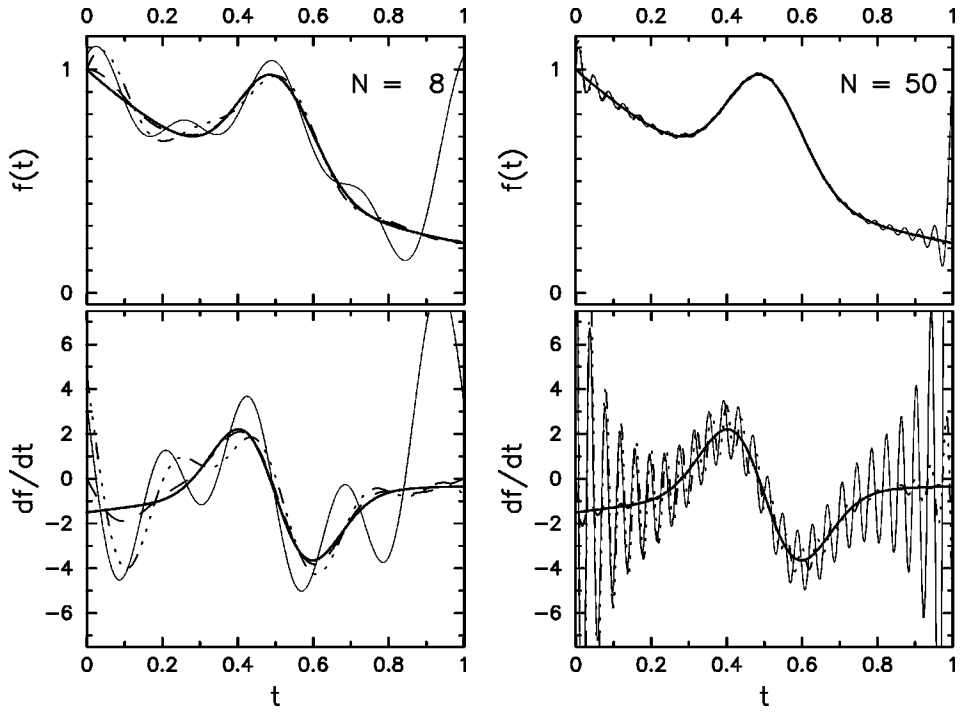

FIG. 4. The CEDCT series $f_N(t)$ (*dashed curves, top panels*) and the derivatives $f'_N(t)$ (*dashed curves, bottom panels*) for an analytic function $g(t)$ of Eq. (43) and its derivative $g'(t)$ (*heavy solid curves*) in the case of $N=8$ and $N=50$. For comparison, we also show the approximations provided by Shannon interpolation formula (27) with $N+1$ points (3-dot–dashed curves), and by truncated DFT series $s_K(t)$ of Eq. (30) and its derivative $s'_K(t)$ with $K=N/2$ (thin solid curves). Note that both $s_K(t)$ and $X_N(t)$ converge with $N\to\infty$ at all $t\in(0,1)$, but their derivatives do not.

top right-side panel, their derivatives reveal profound oscillations at any large N. Meanwhile, $f'_N(t)$ shown by solid lines on the two bottom panels of Fig. 4 already provides a rather good approximation to $g'(t)$ at rather small values of N.

At the end of this section we would like to note, albeit without any proof or demonstration in this paper, that our numerical calculations show that the second derivative of CEDGT also appears to converge to $g''(t)$ if the derivatives $g'(0)=g'(T_0)=0$ is satisfied.

IV. MULTIDIMENSIONAL FOURIER TRANSFORM

Being a transform with separable variables, the multidimensional DCT is easily reduced to the product of one-dimensional DCTs, which is widely used, for example, for effective 2D-image processing (e.g., see Refs. 7 and 13). Although the multidimensional DCT is well known, in this section we will first formulate it in terms of discrete Fourier transform on the $\mathrm{SU}(2)\times\cdots\times\mathrm{SU}(2)$ group. Then we will briefly discuss the convergence properties of the continuous extension of 2D discrete cosine transforms.

The generalization of the transform formulas for decomposition of functions of n variables, $G(x_1,\ldots,x_n)$, into the Fourier series of orbit functions of $[\mathrm{SU}(2)]^n$ group is straightforward. Let us consider first the case of $n=2$, i.e., when a function $G\to G(x,y)$ defined in the region $\mathsf{F}_\mathsf{n}=\{0\leqslant x\leqslant 1,\ 0\leqslant y\leqslant 1\}$ (i.e., assuming normalized variables $x\to x/X_0$, $y\to y/Y_0$) is to be decomposed into the series of the orbit functions $\Phi_{mn}(x,y)$ of the symmetry group $\mathrm{SU}(2)\times\mathrm{SU}(2)$. In this case $\Phi_{mn}(x,y)=\Phi_m(x)\,\Phi_n(y)$. Using for convenience again the functions $\psi_m(x)=\cos(\pi m x)$ instead of $\Phi_m(x)$, we can write

$$\Psi_{mn}(x,y)=\psi_m(x)\,\psi_n(y)=\cos(\pi m x)\cos(\pi n y)\,, \tag{44}$$

where $(x,y)\in F$. For a uniform rectangular grid $\{x_j,y_k\}$ defined in the region F such that

$$\{x_j = j/M,\ \ y_k = k/N \ \ | j = 0,1,\ldots,M;\quad k = 0,1,\ldots,N\},$$

the functions Ψ_{mn} are orthogonal in the following bilinear form

$$\langle \Psi_{mn}, \Psi_{pq} \rangle_{M,N} = \sum_{j=0}^{M} \sum_{k=0}^{N} C_{M,j} C_{N,k} \Psi_{m,n}(x_j, y_k) \Psi_{pq}(x_j, y_k) = \frac{4MN}{C_{M,j}\, C_{N,k}} \delta_{mp}\, \delta_{nq}, \tag{45}$$

which follows directly from (8).

Let $G(x,y) \to \mathbb{R}$ be a continuous function originating a two-dimensional grid function $G_{jk} = G(x_j, y_k)$ on the grid $\{x_j, y_k\}$. Then the decomposition of G into the Fourier series on SU(2) $\times$ SU(2) group corresponds to solving the system of equations

$$G_{jk} = \sum_{m=0}^{M} \sum_{n=0}^{N} A_{mn}\, \Psi_{mn}(x_j, y_k) \equiv \sum_{m=0}^{M} \sum_{n=0}^{N} A_{mn} \cos\frac{\pi m j}{M} \cos\frac{\pi n k}{N}, \tag{46}$$

with $\{0 \leqslant j \leqslant M,\, 0 \leqslant k \leqslant N\}$, with respect to the coefficients A_{mn}. This can be easily achieved using the orthogonality relation (45), if we multiply (46) by $C_{M,j} C_{N,k} \Psi_{pq}(x_j, y_k)$ and take the sum over $\{j,k\}$. Thus we find the coefficients A_{mn} of the discrete Fourier transform (46),

$$A_{mn} = \sum_{j=0}^{M} \sum_{k=0}^{N} D_M^{mj} D_N^{nk} G_{jk}. \tag{47}$$

The matrix D_N is defined as before by (12),

$$D_N^{ab} = \frac{C_{N,a} C_{N,b}}{2N} \cos\frac{\pi a b}{N}, \quad N, a, b \in \mathbb{Z},$$

with the weights $C_{N,a}$, $C_{N,b}$ given by (6).

In this way the coefficients A_{mn} of the two-dimensional DGT are found for any grid function $\{G_{jk}\}$ with bounded values at the grid points $(x_j, y_k) \in \mathsf{F}$. Thus we can formulate the following proposition:

Proposition: Let $G_{jk} = G(x_j, y_k)$ be values of a bounded function $G(x,y)$ on the rectangular grid points

$$x_j = jX_0/M, \quad y_k = kY_0/N; \quad j \in \{0,1,\ldots,M\}, \quad k \in \{0,1,\ldots,N\}.$$

A trigonometric function given by finite Fourier series

$$F_{MN}(x,y) = \sum_{m=0}^{M} \sum_{n=0}^{N} A_{mn} \cos\frac{\pi m x}{X_0} \cos\frac{\pi n y}{Y_0}, \tag{48}$$

with

$$A_{mn} = \sum_{j=0}^{M} \sum_{k=0}^{N} \frac{C_{M,m} C_{M,j} C_{N,n} C_{N,k}}{4MN} G_{jk} \cos\frac{\pi m j}{M} \cos\frac{\pi n k}{N}, \tag{49}$$

continuously extends the discrete inverse Fourier transform of the grid function $\{G_{jk}\}$ onto the entire rectangular area $(x \in [0,X_0], y \in [0,Y_0])$, and satisfies the equality

$$F_{MN}(x_j, y_k) = G_{jk} \quad \textit{for all} \quad j \in \{0,1,\ldots,M\}, \quad k \in \{0,1,\ldots,N\}.$$

Furthermore, if $G(x,y)$ is continuous, then $F_{MN}(x,y)$ converges to $G(x,y)$ for $M,N \to \infty$.

Since for any fixed $y_0 \in [0,Y_0]$ or $x_0 \in [0,X_0]$ the series $F_{MN}(x,y_0)$ or $F_{MN}(x_0,y)$, respectively, are reduced to one-dimensional CEDCT/CEDGT series along the x or y axes considered in

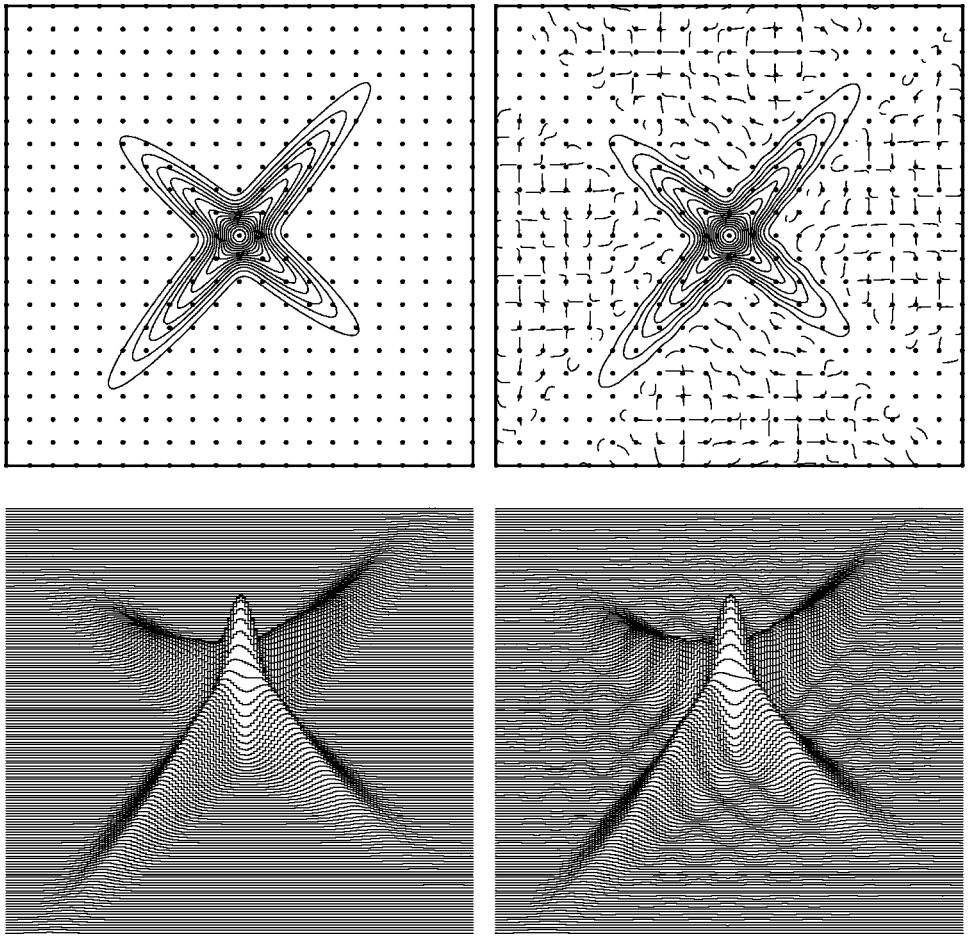

FIG. 5. Contour plots (upper panels) and visual "3D" images (lower panels) of an analytic function $G(x,y)$ (right side) and its approximation by two-dimensional SU(2)×SU(2) CEDGT/DCT series $F_{MN}(x,y)$ (left side) with $M=N=20$. $G(x,y)$ is composed of a sum of 2 two-dimensional Gaussian ellipsoids, each in the form of (50), and with dispersions $\sigma_{\perp,1}=\sigma_{\perp,2}=0.025=1/2N$. The dashed lines on the left bottom panel show the contour level $F_{MN}(x,y)=-0.001$.

the previous section, it is obvious that the continuous extension $F_{MN}(x,y)$ of 2D DGT on the SU(2)×SU(2) group (i.e., the two-dimensional DCT) not only converges with increasing (M,N) to $G(x,y)$, but also that it has properties of *locality* and *differentiability* similar to the one-dimensional CEDGT on ordinary SU(2) group.

Example 5: The upper panels in Fig. 5 show the contour plots of a function $G(x,y)$ defined in the square region $F=[0,1]\times[0,1]$ and composed of two two-dimensional Gaussian functions, each of type

$$e^{-(x'-x_0)^2/2\sigma_\parallel^2-(y'-y_0)^2/2\sigma_\perp^2}, \tag{50}$$

where $\sigma_\parallel \geqslant \sigma_\perp$, but with directions of the major axes x_1' and x_2' perpendicular to each other. For both Gaussians we have taken the transverse dispersions to be $\sigma_{1,\perp}=\sigma_{2,\perp}=0.025$, which is exactly 2 times smaller than the grid's cell size $\Delta x=\Delta y=1/20$ for the chosen $M=N=20$. The contour plots shown on the upper panels in Fig. 5 illustrate that even in the case of a grid with cell size this large compared with $\sigma_\perp$, the continuous extension of the two-dimensional DGT series reconstructs Gaussian-fast smooth structures reasonably well.

This is also apparent on the bottom panels of Fig. 5 where we show the three-dimensional images for the same analytic function $G(x,y)$ (left panel) and its approximation in the form of

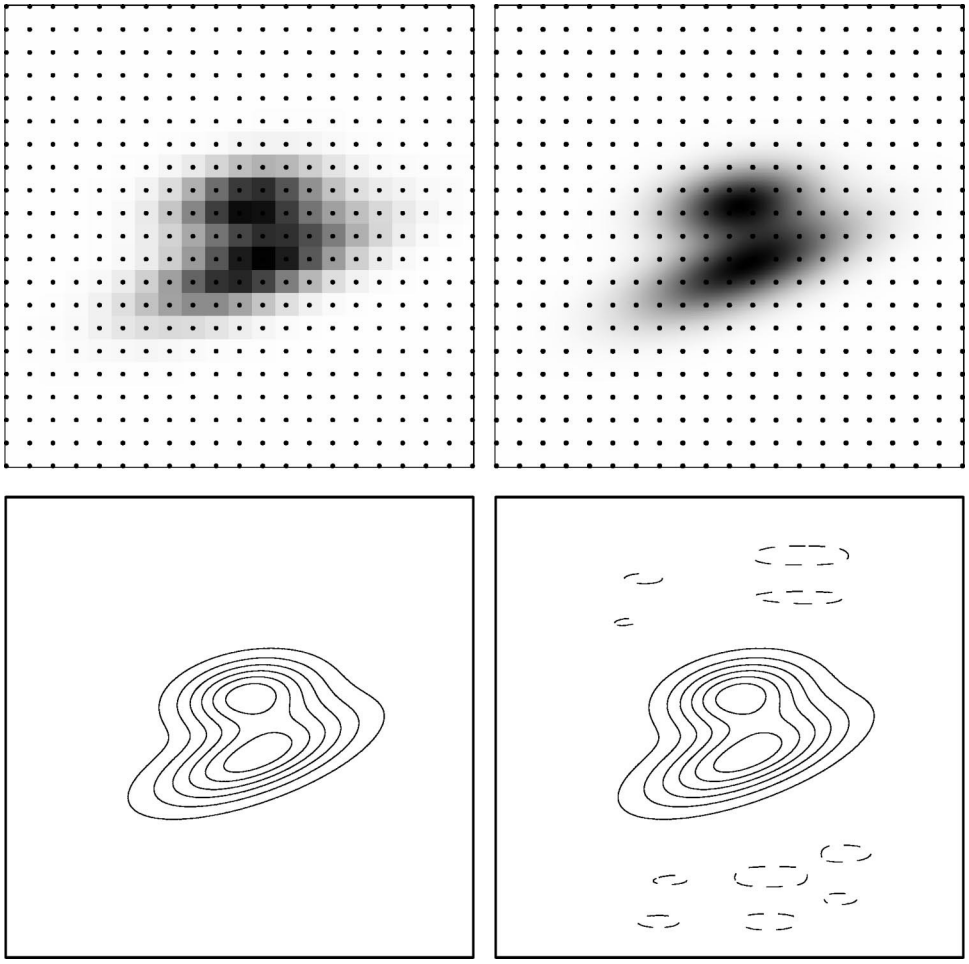

FIG. 6. **Upper panels**: The images, in terms of brightness distributions, corresponding to the grid function $\{G_{j,k}\}$ given on $M=N=20$ square grid (on the left), and its reconstruction by two-dimensional CEDCT series $F_{M,N}(x,y)$ (on the right). **Lower panels**: Contour plots of the analytic function $G(x,y)$ originating $\{G_{j,k}\}$ (on the left), and of its approximation by $F_{M,N}(x,y)$ (on the right). The original function $G(x,y)$ is composed of two-dimensional Gaussian distributions with transverse dispersions for both $\sigma_\perp = 1/N = 0.05$, an angle between long axes of the ellipsoids equal to 20°, and a small separation between their peak positions.

two-dimensional continuous DGT extension $F_{MN}(x,y)$ (right panel). Note that any waviness that can be seen in the approximated function would disappear from the images had we taken $N, M \geqslant 1/\sigma_\perp$ for the same functions.

Example 6: The latter case is chosen in Fig. 6 where the upper panels show, in terms of brightness distribution, the original grid function produced by 2 Gaussians with $\sigma_{1,\perp}=\sigma_{2,\perp} = 0.05 = 1/N$, for $N=M=20$, and its reconstruction in the form of two-dimensional continuous DGT extension (on the right). The major axes of the ellipsoids are inclined at a small angle (20°) to each other. For comparison, on the bottom left panel we show the contour plot of the exact (i.e., originating) function $G(x,y)$, and the bottom right panel shows its approximation by two-dimensional CEDGT. It is obvious that the reconstructed CEDGT image not only recovers the directions of the ellipsoids and their maxima, but it practically coincides with the exact image. Note that the dashed contours on both Figs. 5 and 6 show a level slightly below zero, $F_{MN} = -0.001$.

Generalization of the proposition for an n-dimensional DGT of a function $G(x_1,\ldots,x_n)$ on $[\mathbf{SU}(2)]^n$ group is straightforward:

Proposition: Let $G_{j_1\cdots j_n}=G(x_{1,j_1},\ldots,x_{n,j_n})$ *be values of a bounded function* $G(x^{(1)},\ldots,x^{(n)})$ *given on the rectangular* $(M_1,\ldots,M_n)$*-interval grid points*

$$\{x^{1,j_1}=j_1X_1/M_1,\ldots,x^{n,j_n}=j_nX_n/M_n,\quad j_k=0,1,\ldots,M_k:\quad k=0,1,\ldots,n\}.$$

A continuous function given by finite Fourier series

$$F_{M_1\cdots M_n}(x_1,\ldots,x_n)=\sum_{m_1=0}^{M_1}\cdots\sum_{m_n=0}^{M_n}A_{m_1\cdots m_n}\cos\frac{\pi m_1x_1}{X_1}\cdot\cdots\cdot\cos\frac{\pi m_nx_n}{X_n},\tag{51}$$

where

$$A_{m_1\cdots m_n}=\sum_{j_1=0}^{M_1}\cdots\sum_{j_n=0}^{M_n}\frac{C_{M_1,m_1}C_{M_1,j_1}\cdot\cdots\cdot C_{M_n,m_n}C_{M_n,j_n}}{2^nM_1\cdot\cdots\cdot M_n}\times G_{j_1\cdots j_n}\cos\frac{\pi m_1j_1}{M_1}\cdot\cdots\cdot\cos\frac{\pi m_nj_n}{M_n},\tag{52}$$

satisfies the equality

$$F_{M_1\cdots M_n}(x_{j_1},\ldots,x_{j_n})=G_{j_1\cdots j_n}\quad\text{,for all}\quad j_k\in\{0,1,\ldots,M_k\}\quad\text{and}\quad k\in\{0,1,\ldots,n\}.$$

Furthermore, if $G(x_1,\ldots,x_n)$ *is continuous, then* $F_{M_1\cdots M_n}(x_1,\ldots,x_n)$ *converges to* $G(x_1,\ldots,x_n)$ *with* $M_1,\ldots,M_n\to\infty$.

The proof of this proposition is readily obtained by the method of induction on the SU(2) factors of the group.

A. An example of CEDCT application to real images

In order to demonstrate the potential of the above suggested approach of *continuous extension* of the inverse multidimensional discrete group transforms for purposes of natural interpolation of discrete images between the grid points, as well as for the possibility of data compression and smooth representation of the compressed images, we have chosen a 56×140 pixel fragment of the well known image "Lena." The original fragment shown on Fig. 7(a) is strongly enlarged ("zoomed") in order to make visible the granularity of the image at its resolution limits. The grayscale color coding of the fragment contains all 256 intensity levels, from $g=0$ (*black*) to $g=255$ (*white*).

In Fig. 7(b) we show the continuous extension of the original image. It is constructed by subdividing each of the initial intervals Δx and Δy into 3 subintervals. This procedure increases the density of the grid points (pixels) by a factor $3\times3=9$. Calculations are done dividing first the initial 56×140 pixel fragment into ten 28×28 pixel subfragments, then calculating the CEDCT for each of these sub-fragments. It allows us to demonstrate, on the next two panels, the effects of CEDCT image reconstruction at the block edges after some image compression is done. Because the continuous extension of the inverse DCT can formally extend the values of the initial intensity distribution function to values $F_{MN}(x,y)$ beyond the limits $[0,255]$ used for the intensity coding, we have linearly renormalized the values of $F_{NN}\to\widetilde{F}_{NN}\in[0,255]$. The positive impact of the higher resolution achieved by the use of CEDCT in Fig. 7(b), as compared with the original image in Fig. 7(a), is apparent.

Note that the harmonic order of the cosine functions $\cos(\pi nx/X_0)$ and $\cos(\pi my/Y_0)$ used in CEDCT corresponds to the modes $0\leqslant m,n\leqslant50$. In Fig. 7(c) we show the continuous extension of the image obtained after application of the simplest "low-pass compression" procedure (see, e.g., Ref. 13), putting the DCT coefficients $A_{mn}\to0$ for all high-order modes with either m or n exceeding $n_{\max}=19$. This procedure generally removes the high-frequency "noise" from the image, and compresses the image by a factor $(29/20)^2\approx2$. No visual degradation of the CEDCT image is apparent. It is noteworthy that although the exactness property of the transform in Fig. 7(c) is lost, the edges of the 10 individual blocks, or the sub-fragments, cannot be visually

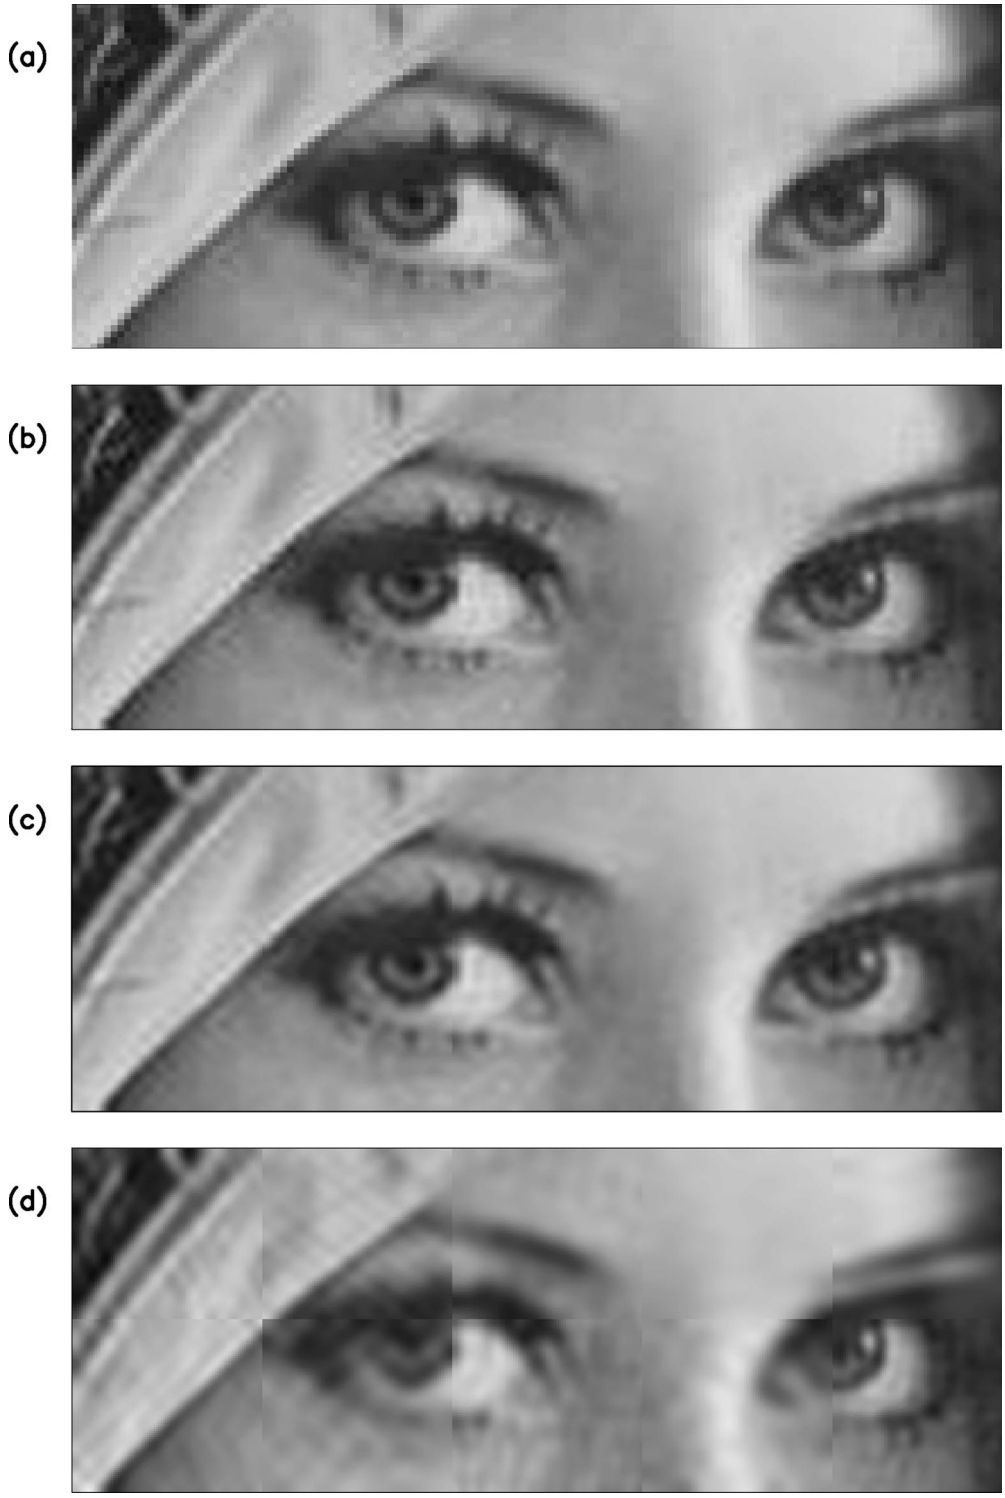

FIG. 7. **(a)** Zoomed 56×140-pixel fragment of the original image ''Lena''; **(b)** CEDCT image calculated with the 3×3 higher resolution, i.e., corresponding to 168×420 pixels; For our calculations the image was first subdivided into 10 square blocks of 28×28 size. **(c)** The picture in the same 168×420 pixel representation compressed by a factor of 2. The compression is reached by retaining in (48) only the first $0 \leqslant m,n \leqslant 19$ DCT coefficients A_{mn}, and discarding all higher-order terms. **(d)** The picture compressed by a factor of 10; the compression is achieved by discarding all cosine terms with $|A_{mn}| \leqslant 0.05\, A_{\max}$ (see text).

distinguished. The block edges become noticeable only in Fig. 7(d), where we have applied again the CEDCT approach for visualization of the image compressed now by a factor of 10. The compression in Fig. 7(d) is effectively reached by keeping in CEDCT series only 10% of the cosine terms with the large-value coefficients A_{mn}, and discarding all terms with small-value A_{mn}. For Fig. 7(b) it has corresponded to the assumption $A_{mn}\to 0$ if $|A_{mn}|\leqslant 0.05\,A_{\max}$, where $A_{\max}$ is the maximum absolute value of the coefficients $\{A_{mn}|\}$ (*excluding* A_{00}). Obviously, the image in Fig. 7(d) still remains smooth and quite recognizable.

We would like to note here that it has not been our aim in this paper to reach the goal of the best possible image compression. We believe, however, that through this paper our examples demonstrate the high potential of the developed approach of *continuous extensions* of DCT, and of the DGTs generally, as considered in the next Paper II for the SU(3) group (in preparation), for purposes of practical applications, and in particular for image processing and compression.

V. SUMMARY

We have shown that:

1. A discrete Fourier transform of a grid function $\{g_k|k=0,1,\ldots,N\}$ on the orbit functions of Lie groups, abbreviated DGT, in the case of SU(2) is reduced to the well known discrete cosine transform, namely, to DCT-I, which is a known type of exact discrete transforms, like the standard DFT sequence.
2. The principal difference between these 2 types of discrete Fourier transforms consists in the fact that DCT is based on the functions $\cos(k\pi t/T_0)$ corresponding to $k\leqslant N$ trigonometric harmonics of both integer and half-integer orders, $n=k/2\leqslant N/2$, whereas the DFT utilizes trigonometric functions of integer n only, but extending to orders $n\leqslant N$. This results in vital differences in the subsequent properties of DFT and DCT (or DGT generally).
3. If the function $g(t)$ originating $\{g_k\}$ is a continuous function of $t\in[0,T_0]$, then the continuous extension of the (*inverse*) DCT sequence results in the function $f_N(t)$ which converges to the original $g(t)$ with increasing N at all t. This property does not hold for the continuous extension of the standard DFT sequence, which shows profound oscillations between the points of the grid. Note that potentially this feature implies significantly smaller vulnerability of DCT to the truncation/approximation errors in the process of filtering as compared with the standard DFT. Therefore, it could be the reason for the superior general performance of the DCT compared with the DFT (see Ref. 5).
4. Similar to canonical *continuous* Fourier transform polynomials with coefficients calculated by exact integrations, the CEDCT series satisfies the principle of *locality*. This property insures, in particular, that the computation errors connected, e.g., with noise or uncertainties in one segment of the data will not significantly affect the reconstructed CEDCT image on the distant segment of data. This property of DCT may become important especially in the process of lossy data compression when the property of exactness of the *discrete* transform is not necessarily preserved.
5. Similar to the canonical CFT, the CEDCT series $f_N(t)$ can be differentiated term by term, so that for the (*first*) derivative series $\lim_{N\to\infty} f'_N(t)\to g'(t)$ for all $t\in(0,T_0)$ provided that the second derivative of $g(t)$ is a continuous (or just an integrable) function on the interval $[0,T_0]$. For CEDCT this property is valid both when $g(0)=g(T_0)$ and $g(0)\neq g(T_0)$. It does not necessarily hold for continuous extensions of other types of discrete transforms, which might be converging, like $s_k(t)$ in (30) or Shannon interpolation $X_N(t)$, but which produce nonconverging derivative series, as demonstrated in Fig. 4.

The derivative series $f'_N(t)$ satisfies the localization principle along with $f_N(t)$.

6. In the case of an n-dimensional function defined on the knots of a rectangular n-dimensional grid, the DGT Fourier decomposition can be performed using the orbit functions of $[\mathrm{SU}(2)]^n$ group. Such Fourier series are effectively reduced to the n-fold convolution of one-dimensional DGT on SU(2) alongside n independent (rectangular) axes. Therefore they have nice properties of *convergence*, *localization*, and *differentiability* of their continuous DGT extensions similar to the one-dimensional CEDCT.

Superconformal primary fields on a graded Riemann sphere

Jasbir Nagi[a)]

(Received 13 October 2003; accepted 16 March 2004; published online 17 May 2004)

Primary superfields for a two-dimensional Euclidean superconformal field theory are constructed as sections of a sheaf over a graded Riemann sphere. The transformation law is found to be the same as that of an O(N) extended primary field. The construction is then applied to the $N=3$ Neveu–Schwarz case. Various quantities in the $N=3$ theory are calculated, such as elements of the super-Möbius group, and the two-point function. Applications of the construction to calculate three-point functions and fusion rules in a manifestly supersymmetric fashion are discussed. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1739295]

I. INTRODUCTION

Two-dimensional conformal field theory has many applications in statistical mechanics and string theory. It also has a very rich algebraic nature, in a sense due to the symmetry algebra being infinite-dimensional. Exactly how this works in the bosonic case is extremely well understood.[13]

The supersymmetrization of two-dimensional conformal field theory is something that has been studied heavily from a string theory approach.[16] The string is described by a two-dimensional conformal field theory, and the supersymmetrization of the conformal field theory essentially admits fermions onto the string. This has mostly been studied from a Lagrangian point of view, where the Lagrangian exhibits the classical symmetries. Canonical quantization can then be used to then obtain the quantum algebra.

In bosonic conformal field theory there is a way, using the high degree of symmetry, to obtain the quantum algebra by algebraic means, rather than from a Lagrangian. Extending this to a theory with one or two Grassmann variables has been covered extensively in the literature. Adding more supersymmetry to the theory has been studied, e.g., Refs. 29, 8, 9, but in nowhere near as much depth as the $N=1,2$ theories.

In two-dimensional conformal field theory, it is found that one can always find a conformal transformation that maps the two-dimensional theory to a two dimensional theory that is flat. In the Euclidean case, the conformal transformations that map the plane to itself are precisely the holomorphic and antiholomorphic transformations of the plane to itself. One can therefore build Euclidean two-dimensional conformal field theory on a complex plane.[17] To get a more ''global'' picture of what is going on, the theory can then be conformally mapped to the Riemann sphere. Many of the properties of the conformal field theory can then be described by the properties of the Riemann sphere. The question then becomes how to build a theory on a ''super-Riemann sphere,''[14,15] and how the properties of this object can be related to the properties of a superconformal field theory. In this note, the question is addressed, with particular attention payed to the $N=3$ case.

Superconformal algebras in the classical case look like derivations on a polynomial ring in $\{z,z^{-1},\theta_i\}$, where the θ_i are anticommuting ''coordinates,'' that preserve a differential form. This can be combined with the theory of extended graded manifolds, with the manifold in question being the Riemann sphere, to give a suitable setting for superconformal field theory (Secs. II–IV).

a)Electronic mail: J.S.Nagi@damtp.cam.ac.uk

One can then use this setting to construct and calculate various quantities in the field theory. The $N=3$ Neveu–Schwarz case is studied in detail (Secs. V–X).

II. THE GRADED RIEMANN SPHERE

In this section, a Riemann sphere is considered, and how one can generalize it to the superconformal case. It should be mentioned that there are strictly speaking two approaches, which give rise to the same structure.[28,5,4] Here, the algebraic structure,[23,24] known as a Graded Manifold (of the extended type) will mostly be used. In some instances, it will become necessary to transfer to the analytic point of view, namely Supermanifolds.[26]

First consider an ordinary Riemann sphere. Rather than consider it as a geometric object, one could consider it as a collection of open sets, U_i, and consider the functions $f:U_i\to\mathbb{C}$ that are holomorphic in each open set, denoted $f(U_i)$. Each $f(U_i)$ is a ring under addition in $\mathbb{C}$, and pointwise multiplication. Given an open subset $V\subseteq U$, one can construct a nonsingular ring homomorphism $\rho_{UV}:f(U)\to f(V)$. These ring homomorphisms become the fundamental tools to work with. They give a way of comparing $f(U_i)|_{U_i\cap U_j}$ and $f(U_j)|_{U_i\cap U_j}$ and allow one to construct a sheaf of rings over the Riemann sphere, denoted $\mathcal{A}_0$.[23,18] One can see that each $f(U_i)$ will be a subring of $\mathbb{C}[z,z^{-1}]$. One can then consider derivations on each $f(U_i)$, denoted $\mathrm{Der}(U_i)$ which are $\mathbb{C}$-linear maps from $f(U_i)$ to $f(U_i)$ that obey the Leibniz rule. $\mathrm{Der}(U_i)$ then forms a rank one module over $f(U_i)$. The map ρ_{UV} induces a map $\rho_{UV*}^{-1}:\mathrm{Der}(U)\to\mathrm{Der}(V)$. One can use these ρ_{UV*} to construct a sheaf of abelian groups, namely the tangent sheaf, denoted $\mathcal{D}^1\mathcal{A}_0$. It is, locally, a rank one $\mathcal{A}_0$-module. A section of it can be written locally as $g(z)(\partial/\partial z)$. On each U_i, one can also consider the $\mathcal{A}_0$ linear maps of $\mathrm{Der}(U_i)$ into $\mathcal{A}_0$, denoted $\Omega^1(U_i)$. This is also a rank one $f(U_i)$-module, and the ρ_{UV*} induce a map $\rho_{UV}^*:\Omega^1(U)\to\Omega^1(V)$. Once again, the ρ_{UV}^* can be used to construct a sheaf, denoted $\mathcal{D}_1\mathcal{A}_0$. It is locally a rank one $\mathcal{A}_0$-module. Locally, a section can be written as $dzg(z)$. One can define the conformal condition as demanding that $\rho_{UV}:z'\mapsto z$, for z',z local coordinates in U,V respectively, as having the property $\rho_{UV}^*dz'=dz\kappa(z)$ for some $\kappa\in\mathcal{A}_0$. Given this construction, a basis of infinitesimal transformations can be written down, namely $z'=z+az^{n+1}$ corresponding to a space of vector fields, which gives rise to the Witt algebra. Phrasing the structure of a Riemann sphere in this way gives the most natural generalization to a graded Riemann sphere.

Similarly, an extended graded manifold can be defined, where each ring associated to each open set is no longer a subring of $\mathbb{C}[z,z^{-1}]$, but a larger ring containing Grassmann generators. The ring is no longer over $\mathbb{C}$, but over a complex, finitely generated unital Grassmann algebra, $B_{L'}$. Each ring associated to each open set is now a subring of

$$B_{L'}[z,z^{-1},\theta_1,\ldots,\theta_N]. \tag{1}$$

It is worth noting that this is a slightly more general requirement than that of a graded manifold. In the graded manifold case, the ring is often still taken to be over $\mathbb{C}$, and so would look like

$$\mathbb{C}[z,z^{-1},\theta_1,\ldots,\theta_N], \tag{2}$$

which, as a ring, is contained in (1). This can be seen by constructing a map $\pi:B_{L'}\mapsto\mathbb{C}$ by projecting onto the unital element in $B_{L'}$. The map defines an important quantity, namely the "body" of an element of a grassmann algebra. The approach of looking at an algebra over $B_{L'}$ rather than $\mathbb{C}$, as far as the author is aware, was first introduced in Ref. 28. The ring (1) is the Neveu–Schwarz ring. This gives rise to a sheaf, denoted by $\mathcal{A}_N$ for some positive integer N. The only condition on the ring associated to each open set, is that it be "holomorphic in z." This is, in fact, quite a subtle analytic condition, a discussion of which will be postponed for a few paragraphs. Derivations are now replaced by the sheaf of graded derivations, $\mathcal{D}^1\mathcal{A}_N$ which is a left $\mathcal{A}_N$ module. Accordingly, there is the sheaf of graded one-forms, $\mathcal{D}_1\mathcal{A}_N$, which are $\mathcal{A}_N$ linear maps of $\mathcal{D}^1\mathcal{A}_N$ into $\mathcal{A}_N$. $\mathcal{D}_1\mathcal{A}_N$ is a right $\mathcal{A}_N$ module. For full details of this construction of derivations and one-forms, see Ref. 23.

There is now a question of a preserved one-form. The basis of differentials is now given by $(dz, d\theta_i)$. Rather than the one-form coming for free, it must now be defined. This one-form will define a generalized conformal structure.[19] Define the one form[9] $\omega = dz - \Sigma_i d\theta_i \theta_i$. A transformation $(z, \theta_i) \mapsto (z', \theta_i')$ is superconformal iff it is invertible and $\omega' = \omega\kappa(z, \theta_i)$ for $\kappa \in \mathcal{A}_N$. All homomorphisms between open sets with intersection are demanded to be superconformal. An alternative basis for $\mathcal{D}_1\mathcal{A}_N$ is $(\omega, d\theta_i)$, which gives a corresponding dual basis of $\mathcal{D}^1\mathcal{A}_N$, namely (∂, D_i). Here, $\partial = \partial/\partial z$, and $D_i = (\partial/\partial\theta_i) + \theta_i(\partial/\partial z)$. This is a convenient basis to work with. It can be readily shown from the superconformal condition, that

$$D_i z' - \sum_j \theta_j' D_i \theta_j' = 0, \tag{3}$$

$$\kappa = \partial z' + \sum_j \theta_j' \partial \theta_j'. \tag{4}$$

From here on summations are dropped, and summation convention should be assumed. In particular, considering infinitesimal transformations, once the z' transformation is known, all the θ_i' transformations can almost be deduced. In the $N=1$ case, there is a $\mathbb{Z}_2$ ambiguity. For higher N this ambiguity becomes a continuous group, often interpreted as a gauge group in the physics literature.[1,2] κ can also be given by a slightly different expression. The relation $[D_i, D_k] = 2\delta_{ik}\partial$, where the commutator is graded, and (3), are useful in showing that $\det(D_i\theta_j')^2 = (\partial z' + \theta_i' \partial\theta_i')^N = \kappa^N$. This is an expression in a Grassmann ring over $\mathbb{C}$, so it is not obvious that one can divide or take Nth roots. If the coordinate transformation on the intersection of two open neighborhoods $(z, \theta_i) \mapsto (z', \theta_i')$ involves a scale factor κ, the inverse transformation will induce a scale factor κ', with $\kappa\kappa' = \kappa'\kappa = 1$. Thus, κ has a unique[32] inverse, and both κ and κ' have a component that is pure complex number, i.e., they have a nonzero "body." Since an extended graded manifold framework is being used, this is not as trivial a fact as it might seem. Nth roots of κ can now be defined, as the binomial expansion around the "body," $\epsilon(\kappa)$. This expansion is finite due to the nilpotency of $\kappa - \epsilon(\kappa)$. One finds that $\omega' = \omega(\det(D_i\theta_j'))^{2/N}\zeta^2$, where ζ is an Nth root of unity. Calculating the corresponding transformation on the basis of $\mathcal{D}^1\mathcal{A}_N$, one finds that $D_i' = (D_i'\theta_j)D_j$, and that $(D_i\theta_j')^{-1} = (D_i'\theta_j)$.

There is a subtle point about the superconformal transformation. The map

$$z' = z, \quad \theta_i' = -\theta_i \tag{5}$$

is superconformal. If one restricts to transformations $z' = z'(z)$ and uses the superconformal condition to deduce how the θ_i can transform, the choice of possible minus manifests itself as a choice of spin structure. Considering the transformation (5), one can ask what functions of (1) are invariant under it. A basis can be chosen for this ring, namely $\{z^n, z^n\theta_i, \ldots, z^n\theta_1\theta_2, \ldots, \theta_N\}$, for $n \in \mathbb{Z}$. Without the minus sign, all these basis elements are transformed to themselves. With the minus sign, one finds that those elements with an odd number of θ_i obtain a minus sign. Thus, only a subring is invariant. One can enlarge the invariant subring by introducing square roots and choosing the minus sign in the square root whenever one has an odd number of θ_i in a basis element. Consider now a subring of

$$B_{L'}[z^{1/2}, z^{-(1/2)}, \theta_1, \ldots, \theta_N], \tag{6}$$

which has as a basis $\{z^n, z^{n+(1/2)}\theta_i, z^n\theta_i\theta_j, z^{n+(1/2)}\theta_i\theta_j\theta_k, \ldots\}$ $n \in \mathbb{Z}$ and choose the negative square root under a superconformal transformation. Now all the basis elements are mapped to themselves under a superconformal transformation. This is the Ramond ring. It should be noted that with the analytic definition of functions that are "holomorphic in z" that will be used here

(see below), the Ramond ring introduces a branch cut. It should also be noted that this construction can easily be extended to the case when some of the θ_i have a minus sign in the transformation, and some do not.

Already the need for a more analytic idea of what is going on is apparent. This will be particularly important when the question of contour integration arises. Full details of this approach can be found in Refs. 28, 26. Many details are not mentioned here. Consider now a Grassmann algebra generated by L generators, B_L. This algebra can be given a Banach algebra structure, with the resulting topology being Hausdorff. This splits into an even and odd part, $B_L = B_{L0} \oplus B_{L1}$ as a vector space over $\mathbb{C}$. Now the θ coordinates take values in B_{L1} and z in B_{L0}. In particular, z can now have a nilpotent even part $s(z)$ (the soul), but must have a proper complex number part $\epsilon(z)$ (the body). Using the fact that a body exists, a "superdifferentiable" [26] function can be constructed. For $L' = \{\text{the smallest integer not smaller than } L/2\}$, a continuation can be specified, namely a continuation $Z_{L',L} : C^\infty(\epsilon(U), B_{L'}) \to G^\infty(U, B_L)$ for U open in B_L. The algebra $B_{L'}$ can be associated to the algebra B_L by the inclusion map $\iota_{L',L} : B_{L'} \to B_L$ which is the algebra homomorphism that maps the generators β_i to L' of the generators in B_L, and the unit in $B_{L'}$ to the unit in B_L. Note, $f(z)$ may be even or odd,

$$Z_{L',L}(f)(z) = \sum_{i=0}^{L} \frac{1}{i!} \iota_{L',L}(f^{(i)}(\epsilon(z))) \times s(z)^i, \tag{7}$$

where $f^{(i)}$ denotes the ith derivative. Now consider functions of the variables (z, θ_i) that can be written as

$$F(z, \theta_i) = Z_{L',L}(f_0)(z) + \sum_{i=1}^{N} Z_{L',L}(f_i)(z)\,\theta_i + \cdots = \sum_{\mu=0}^{2^L - 1} Z_{L',L}(f_\mu)(z)\,\theta_\mu . \tag{8}$$

The statement that $F(z, \theta_i)$ is holomorphic in z is the statement all the $f_\mu(w)$, are holomorphic in the complex variable w. These are examples of GH^∞ functions. For a sheaf to be GH^∞, its restriction maps, ρ_{UV}, must also be GH^∞.

An interesting sheaf to look at is that formed by the one-form ω. It shares similar properties to the one-form dz on an ordinary Riemann sphere. Call the sections of this line bundle on the Riemann sphere $\mathcal{O}_0(1)$. If the change of coordinates on an intersection from one open set to another is $z \mapsto f(z)$, then the transition function for an element of $\mathcal{O}_0(1)$ is $f'(z)$. In conformal field theory, a primary field of weight h can be thought of as a section of $\mathcal{O}_0(h) = \mathcal{O}_0(1)^{\otimes h}$, where h is a positive integer. In the super case, this gives something similar. It should be pointed out that ω will not give a line bundle. This would require the typical fiber to be a free $B_{L'}$ module of rank one, rather than a line. As a result, it must be regarded as a sheaf. This gives rise to a sheaf of sections, $\mathcal{O}_N(1)$. On an intersection, the function $(\det D_i \theta'_j)^{2/N} \zeta^2$ is the sheaf's homomorphism. This should be compared to the transition functions on a line bundle. "Uncharged" primary superfields[12] can then be thought of as sections of $\mathcal{O}_N(h) = \mathcal{O}_N(1)^{\otimes h}$. It should be noted that now tensor products are taken over a graded ring, $\mathcal{A}_N$, so care must be taken with signs in the tensor product. For example, consider a tensor product between two graded left-$\mathcal{A}_N$ modules. Then

$$f_1 \otimes p f_2 = (-1)^{p f_1} p f_1 \otimes f_2 ,$$

where $p \in \mathcal{A}_N$, and exponents of (-1) give the parity of the associated element. Similar formulas should be used if one of the two modules, or both are right-$\mathcal{A}_N$ modules, with the obvious modifications in the exponent of (-1).

There are other interesting sheaves also present. If one accepts the Berezin prescription for integration, then the integration "measure" on the graded Riemann sphere is $\omega \otimes_i D_i$, which has a transformation rule $(\det D_i \theta'_j)^{((2/N)-1)} \zeta^2$. As was first noticed in Ref. 29, there is also a O(N) group present. This can be regarded as a sheaf in the following way. Since the $\{D_i\}$, $i = 1,\ldots,N$, transform amongst themselves, one can consider the sheaf of supercovariant derivatives. Then the

transformation law on intersections of open sets is $D_i' = (D_i' \theta_j) D_j$. Since the superderivatives transform into one another, one can consider the sheaf of supercovariant derivatives. Call the sections of this sheaf $\mathcal{C}_N$. The matrices $D_i \theta_j'$ enjoy the following property:

$$(D_i \theta_j')(D_k \theta_j') = \delta_{ik}(\partial z' + \theta_j' \partial \theta_j') = \delta_{ik} \kappa = \delta_{ik} (\det D_i \theta_j')^{2/N} \zeta^2. \tag{9}$$

The right-hand side can be though of as an $N \times N$ identity matrix multiplying the scale factor of the superconformal transformation. Consider now a sheaf whose sections are $\mathcal{O}(-\frac{1}{2}) \otimes \mathcal{C}_N$. Constructing $\mathcal{O}(-\frac{1}{2})$ requires taking a square root, and is very analogous to taking the square root of a line bundle. Hence, the choice of sign can be thought of as choosing a spin structure. The group homomorphisms on an intersection of open sets in this sheaf are given by

$$M_{ij} = \frac{(D_i \theta_j')}{\sqrt{\kappa}} \tag{10}$$

and the sheaf itself is an $\mathcal{A}_N$-module of rank N. Recall that on intersections, κ has an inverse κ', and so $\kappa^{-(1/2)}$ is well defined on this intersection. There is still a question of a sign. Keeping in mind that $\theta_j' = \pm \theta_j$ is a superconformal transformation, it is really the θ_j that one would want to account for different spin structures, rather than $\mathcal{O}(-\frac{1}{2})$. Therefore, it seems reasonable to choose a plus sign for $\kappa^{-(1/2)}$. Regarding the new homomorphism M_{ij} as a matrix acting on a free module of rank N, it can be thought of as an element of $\mathrm{O}(N)$, with the entries being even Grassmann elements. The new sheaf then gives rise to a fundamental representation of $\mathrm{O}(N)$, and the M_{ij} the coefficients of a matrix with basis E^{ij}. Call this sheaf $\mathcal{G}_N$. This can give rise to other sheaves which are also $\mathrm{O}(N)$ representations.

The manner in which this is done parallels what is often done for vector bundles, in particular frame bundles and spin bundles. The reason this treatment can be applied is that $\mathcal{G}_N$ almost looks like a vector bundle, the only hinderance being that the ''typical fiber'' would be a $B_{L'}$ module rather than a vector space. Rather than an Abelian group of rank N being associated to each open set, one can instead associate a group element of $\mathrm{O}(N)$, just as is done with frame bundles with principal bundles, and retain the same M_{ij}. This gives rise to a sheaf $\tilde{\mathcal{G}}_N$. Considering, now a different representation ρ of $\mathrm{O}(N)$ gives rise to a sheaf homomorphism (albeit of non-Abelian groups)

$$\sigma: (\mathbb{P}_1, \tilde{\mathcal{G}}_N) \to (\mathbb{P}_1, \tilde{\mathcal{G}}_N^{\rho}), \tag{11}$$

where the group homomorphisms are now given by $M_{ij} \rho(E^{ij})$. Since the representation ρ has a vector space V associated to it, one can consider the sheaf which has the group homomorphisms given by $M_{ij} \rho(E^{ij})$, and stalk V, and denote the sections of this sheaf by $\mathcal{R}(G_N)$. An $\mathrm{O}(N)$-extended primary superfield, first introduced in Ref. 29, can then be defined as a section of $\mathcal{O}_N(h) \otimes \mathcal{R}(G_N)$.

III. CONTOUR INTEGRATION

Since one wishes to do conformal field theory in the setting presented above, a sensible question to ask is what closed contour integrals will look like, given the set of analytic functions (7). All functions on a given open set look like

$$f(z) = Z_{L',L}(f_0)(z) = \sum_{i=0}^{L} \frac{1}{i!} \iota_{L',L}(f_0^{(i)}(\epsilon(z))) s(z)^i, \tag{12}$$

where $f_0 \in C^{\infty}(\mathcal{U}, B_{L'})$. This should be compared to the usual notion of a Taylor expansion, around $\epsilon(z)$. Note that if $L' = 0$, $B_{L'} = \mathbb{C}$, and H^{∞} functions are retrieved. In the following, the $\iota_{L',L}$ will

be suppressed (for clarity). It is a linear map, so one can see that the following workings are unaffected. The contour integral $\oint_{C_z} f(z)dz$ needs to be considered. By the definition above, if z is an ordinary complex number (i.e., has no soul), one finds

$$f(z)=\sum_{i=0}^{L}\frac{1}{i!}f_0^{(i)}(\epsilon(z))s(z)^i=f_0(z). \tag{13}$$

If the even coordinate, w, were to have soul as well as body, it would give an element of an even Grassmann algebra over a complex field, when evaluated at a point. Hence one can consider w itself as being parametrized by a complex number z. Now consider a parametrization $w=g(z)=b(z)+u(z)$, where $\epsilon(w)=b(z)$, $s(w)=u(z)$,

$$f(w)=\sum_{i=0}^{L}\frac{1}{i!}f_0^{(i)}(\epsilon(w))s(w)^i=\sum_{i=0}^{p}\frac{1}{i!}(f_0^{(i)}\circ b)(z)u(z)^i=(f\circ g)(z), \tag{14}$$

where $p<L$ is the integer such that $u(z)^p\neq 0$, $u(z)^{p+1}=0$. Using the definition of a contour integral given in Ref. 27, with $C_w=g(C_z)$,

$$\begin{aligned}\oint_{C_w} f(w)dw &= \oint_{C_z}(f\circ g)(z)g'(z)dz\\ &= \oint_{C_z}\left(\sum_{i=0}^{p}\frac{1}{i!}(f_0^{(i)}\circ b)(z)u(z)^i\right)\left(\frac{d}{dz}b(z)+\frac{d}{dz}u(z)\right)dz\\ &= \oint_{C_z}\left(\frac{d}{dz}b(z)\right)(f_0\circ b)(z)+\sum_{i=1}^{p}\frac{1}{i!}\left(\frac{d}{dz}b(z)\right)(f^{(i)}\circ b)(z)u(z)^i\\ &\quad+\sum_{i=0}^{p}\frac{1}{i!}(f^{(i)}\circ b)(z)u(z)^i\left(\frac{d}{dz}u(z)\right)dz.\end{aligned} \tag{15}$$

All that has be done above is put all the definitions in and split up some summations. Note in the first summation, the chain rule can be used on the function $b(z)$, and in the second summation, the chain rule can be used on $u(z)$, giving

$$\begin{aligned}\oint_{C_w} f(w)dw &= \oint_{C_z}\left(\frac{d}{dz}b(z)\right)(f_0\circ b)(z)+\sum_{i=1}^{p}\frac{1}{i!}\left(\frac{d}{dz}(f^{(i-1)}\circ b)(z)\right)u(z)^i\\ &\quad+\sum_{i=0}^{p}\frac{1}{(i+1)!}(f^{(i)}\circ b)(z)\frac{d}{dz}(u(z)^{i+1})\quad dz\\ &= \oint_{C_z}\left(\frac{d}{dz}b(z)\right)(f_0\circ b)(z)+\sum_{i=1}^{p}\frac{1}{i!}\frac{d}{dz}((f^{(i-1)}\circ b)(z)\cdot u(z)^i)\\ &\quad+\frac{1}{(p+1)!}(f^{(p)}\circ b)(z)\frac{d}{dz}(u(z)^{p+1})\quad dz.\end{aligned} \tag{16}$$

The last term is in fact zero, due to the nilpotency of $u(z)$. The term under the summation is a total derivative. As such, integrated around a closed contour, it vanishes identically. All that remains is

$$\oint_{C_w} f(w)dw = \oint_{C_z} (f_0 \circ b)(z) b'(z) dz. \tag{17}$$

Thus, the contour integral can formally be treated as an integral in a normal complex number. It should be noted that all that has been used in this calculation is the chain rule and product rule over C^∞ functions.

IV. THE PRESERVED ONE-FORM AND RAMOND FIELDS

Whilst generalizing the bosonic setting in the previous sections, it was found that rather than a preserved one-form coming for free, it had to be specified. One could ask, what happens if another one-form is specified. In Ref. 21, other one-forms were considered. It was found that if one wanted a $\mathbb{Z}$-graded algebra, a one-form of the form $dz - d\theta_i f(z)\theta_i$ had to have $f(z) = z^n$. By making a change of variables,[21] then shows that one only need consider the cases $n = 0,1$.

Consider, now, a different preserved one-form, namely $\omega = dz - d\theta_i z \theta_i$. The dual derivations to (ω, θ_i) are (∂, D_i), where $D_i = (\partial/\partial\theta_i) + z\theta_i(\partial/\partial z)$. Now one finds that $[D_i, D_j] = 2\delta_{ij} z\partial$. Requiring that under a transformation, $\omega' = \omega\kappa(z, \theta_i)$ yields

$$D_j z' - z' \theta_i' D_j \theta_i' = 0, \tag{18}$$

$$\kappa = \partial z' + z' \theta_i' \partial \theta_i' = \left(\frac{z'}{z}\right) (\det D_i \theta_j')^{2/N} \zeta^2, \tag{19}$$

$$D_i' = (D_i' \theta_j) D_j, \tag{20}$$

$$(D_i \theta_j')(D_k \theta_j') = \delta_{ik} (\det D_i \theta_j')^{2/N} \zeta^2. \tag{21}$$

One can ask what an element of $\mathcal{O}_N(h)$ may transform like, and what is the algebra of infinitesimal transformations associated to it. Consider the case $N = 1$. The field has a transformation rule under $(z, \theta) \mapsto g(z, \theta) = (z', \theta')$,

$$(U_g^{-1} \Phi U_g)(z', \theta') = \Phi'(z', \theta') = \Phi(z, \theta) \left(\left(\frac{z'}{z}\right) (D\theta')^2 \right)^{-h}. \tag{22}$$

The superconformal condition, namely preserving the new one-form w, imposes two types of transformation, a bosonic and a fermionic one. On the coordinates, (z, θ), the infinitesimal transformations are given by

$$\begin{gathered} (z, \theta) \mapsto \left(z + a z^{n+1}, \theta + a \frac{n}{2} z^n \theta \right) \quad \text{and} \\ (z, \theta) \mapsto (z + \epsilon \theta z^{r+1}, \theta - \epsilon z^r), \end{gathered} \tag{23}$$

where $r, n \in \mathbb{Z}$. These provide a basis for all infinitesimal transformations. Each one induces a transformation on the field, (22), with $a(n) = a z^{n+1}$, $\epsilon(r) = \epsilon \theta z^{r+1}$,

$$\begin{aligned} \delta_{a(n)} \Phi(z, \theta) &= -a \left(z^{n+1} \partial_z + \frac{n}{2} z^n \theta \partial_\theta + h(n+1) z^n \right) \Phi(z, \theta), \\ \delta_{\epsilon(r)} \Phi(z, \theta) &= -\epsilon (\theta z^{r+1} \partial_z - z^r \partial_\theta + h(2r+1) \theta z^r) \Phi(z, \theta), \end{aligned} \tag{24}$$

where $n, r \in \mathbb{Z}$. These differential operators give rise to commutation relations

$$[\delta_{a_1(m)},\delta_{a_2(n)}]=(m-n)\delta_{a_2a_1(m+n)},$$

$$[\delta_{\epsilon_1(r)},\delta_{\epsilon_2(s)}]=2\delta_{\epsilon_2\epsilon_1(r+s)}, \tag{25}$$

$$[\delta_{a(m)},\delta_{\epsilon(r)}]=\left(\frac{m}{2}-r\right)\delta_{\epsilon a(m+r)}.$$

This gives a representation of the Ramond algebra. Note that no branch cut has been introduced. Another thing to note is that $\delta_{a(0)}$ gives a l_0 operator, which says that θ scales like a field of weight zero, rather than a field of weight half. As a result, the expansion of $\Phi(z,\theta)$ is now taken to be

$$\Phi(z,\theta)=\phi_0(z)+\theta\phi_1(z)=\sum_{m\in\mathbb{Z}}\phi_{0m}z^{-m-h}+\theta\sum_{m\in\mathbb{Z}}\phi_{1m}z^{-m-h}.$$

Using this expansion, and writing the transformation of a field as

$$(U_g\Phi U_g^{-1})(z,\theta)=\Phi(z',\theta')\left(\left(\frac{z'}{z}\right)(D\theta')^2\right)^h \qquad U_g=\exp(a_nL_n+\epsilon_rG_r) \tag{26}$$

one can find the action of the algebra on the modes of Φ as[33]

$$[L_n,\phi_{0m}]=((h-1)n-m)\phi_{0m+n},\quad [L_n,\phi_{1m}]=((h-\tfrac{1}{2})n-m)\phi_{1m+n},$$

$$[G_r,\phi_{0m}]=\phi_{1m+r},\quad [G_r,\phi_{1m}]=((2h-1)r-m)\phi_{0m+r}.$$

These are precisely the commutation relations one obtains from the $N=1$ Ramond OPEs from the usual method of introducing a branch cut.[25] Rewriting the commutation relations (25) in a more familiar way, and inserting the unique central extension,[21] the algebra can be written down

$$\begin{aligned}[L_m,L_n]&=(m-n)L_{m+n}+\frac{C}{6}m(m^2-1)\delta_{m+n,0},\\ [L_m,G_r]&=\left(\frac{m}{2}-r\right)G_{m+r},\quad [G_r,G_s]=2L_{r+s}+\frac{2C}{3}\left(r^2-\frac{1}{4}\right)\delta_{r+s,0}.\end{aligned} \tag{27}$$

Influenced by the form of the infinitesimal changes (24), OPEs can be postulated that give the above commutation relations, which read as

$$L(w)\phi_0(z)\sim\left(\frac{\partial}{(w-z)}+\frac{h}{(w-z)^2}\right)\phi_0(z),$$

$$L(w)\phi_1(z)\sim\left(\frac{\partial}{(w-z)}+\frac{h+\frac{1}{2}}{(w-z)^2}-\frac{1}{2z(w-z)}\right)\phi_0(z),$$

$$G(w)\phi_0(z)\sim\frac{1}{z(w-z)}\phi_1(z),$$

$$G(w)\phi_1(z)\sim\left(\frac{\partial}{(w-z)}+\frac{2h}{(w-z)^2}-\frac{h}{z(w-z)}\right)\phi_0(z), \tag{28}$$

$$L(w)L(z)\sim\frac{C}{(w-z)^4}+\frac{2L(z)}{(w-z)^2}+\frac{\partial L(z)}{(w-z)},$$

$$L(w)G(z)\sim\frac{\partial G(z)}{(w-z)}+\frac{3G(z)}{2(w-z)^2}-\frac{G(z)}{2z(w-z)},$$

$$G(w)G(z)\sim\frac{2zL(z)}{(w-z)}+\frac{2C}{3}\left(\frac{2z}{(w-z)^3}+\frac{1}{(w-z)^2}-\frac{1}{4z(w-z)}\right), \tag{29}$$

where $L(z)=\Sigma_n L_n z^{-n-2}$, $G(z)=\Sigma_r G_r z^{-r-1}$, $z,r\in\mathbb{Z}$. This final set of OPEs demonstrate the drawbacks of the more abstract construction used in this paper of a Conformal Field Theory (namely via a section of a sheaf over some manifold), compared to the more usual approach of a free field realization. One can calculate the infinitesimal transformations of the field (the section obtained), and show the transformations close as a Lie algebra. One then has to ''work backwards'' and try and construct OPEs and central charge terms that agree with the transformations and lie algebras calculated. It would be interesting to see if the Ramond field (22) could be realized via a free field realization where usually one finds central terms and OPEs are explicitly calculable.

V. CLASSICAL $N=3$ ALGEBRA

Consider now that case of preserving the usual one-form, $dz-d\theta_i\theta_i$, with three Grassmann variables. The superconformal condition is then (3). Using a notation of $Z=(z,\theta_i)$, and writing a superconformal transformation as $Z\mapsto g(Z)$, a representation of the group can be constructed via $\mathcal{A}_3$, namely $U_g f(Z)=(f\circ g^{-1})(Z)$. The infinitesimal transformations can be calculated, and a Lie superalgebra constructed. The infinitesimal transformations take the form of vector fields acting on functions.

The most general infinitesimal transformation on the z coordinate is

$$z\mapsto z+af(z,\theta_1,\theta_2,\theta_3)+\epsilon h(z,\theta_1,\theta_2,\theta_3)$$

for f (h) some even (odd) function, and a (ϵ) infinitesimal and of even (odd) parity. The functions f have analogs for transformations in the θ_i coordinates. Breaking up f into superfield components gives eight different types of transformation.

$$z\mapsto z+a(z)+\alpha_i(z)\theta_i+\tfrac{1}{2}a_{ij}(z)\theta_i\theta_j+\alpha_{123}(z)\theta_1\theta_2\theta_3. \tag{30}$$

The possible transformations are forced into only these eight types, and not some mix between them, by the superconformal condition.

An infinitesimal transformation most generally reads

$$z'=z+\delta z,\quad \theta_j'=\theta_j+\delta\theta_j. \tag{31}$$

On substituting into (3), one finds that the superconformal condition reads

$$D_i\delta z=\delta\theta_i+\sum_{j=1}^{3}\theta_j D_i\delta\theta_j, \tag{32}$$

i.e., three equations, with three unknowns once δz has been specified. A basis for the infinitesimal z transformations is easily found, which is $\delta z=\epsilon\theta_1\theta_2\theta_3 z^{n+(1/2)}$, $\delta z=a\theta_i\theta_j z^{n+1}$ for $i<j$, $\delta z=\epsilon\theta_i z^{n+(1/2)}$, and $\delta z=az^{n+1}$. Given these eight types of transformation, precisely what the corresponding $\delta\theta_i$ are, modulo possible $\delta\theta_i$ if $\delta z=0$, can be calculated explicitly. The case when $\delta z=0$ is taken care of by the t_n^i generators below. Using this procedure, the infinitesimal genera-

tors of the $N=3$ algebra can be calculated. The results are quite hefty, but the actual transformations give an intuitive idea of what each element of the algebra actually does. Summation convention is used in the following:

$$z\mapsto z+az^{n+1},$$

$$\theta_i\mapsto\theta_i+a\tfrac{1}{2}(n+1)\theta_i z^n, \tag{33}$$

$$\Rightarrow l_m=-z^m\left(z\frac{\partial}{\partial z}+\frac{1}{2}(m+1)\theta_i\frac{\partial}{\partial\theta_i}\right)$$

gives a vector field corresponding to an infinitesimal transformation when only $a(z)$ is nonzero in (30). There are then the three single θ terms, which can be found by considering the case when only one $\alpha_i(z)$ is nonzero,

$$z\mapsto z-\epsilon\theta_1 z^{r+(1/2)},$$

$$\theta_1\mapsto\theta_1+\epsilon z^{r+(1/2)},$$

$$\theta_2\mapsto\theta_2-\epsilon(r+\tfrac{1}{2})\theta_1\theta_2 z^{r-(1/2)},$$

$$\theta_3\mapsto\theta_3-\epsilon(r+\tfrac{1}{2})\theta_1\theta_3 z^{r-(1/2)}$$

gives rise to the vector field

$$g_r^1=z^{r-(1/2)}\left(z\theta_1\frac{\partial}{\partial z}-z\frac{\partial}{\partial\theta_1}+\left(r+\frac{1}{2}\right)\theta_1\theta_2\frac{\partial}{\partial\theta_2}+\left(r+\frac{1}{2}\right)\theta_1\theta_3\frac{\partial}{\partial\theta_3}\right).$$

Similarly

$$g_r^i=z^{r-(1/2)}\left(z\theta_i\frac{\partial}{\partial z}-z\frac{\partial}{\partial\theta_i}+\left(r+\frac{1}{2}\right)\theta_i\theta_j\frac{\partial}{\partial\theta_j}\right).$$

It is worth noting that if one were not working on an extended graded manifold, but on a graded manifold (cf. (1), (2)), then one would not be able to obtain the above vector field. The same statement holds for ψ_r below.

There are three double θ terms, e.g., $\theta_1\theta_2$ gives t_n^3,

$$z\mapsto z,$$

$$\theta_1\mapsto\theta_1+a\theta_2 z^{n+1},$$

$$\theta_2\mapsto\theta_2-a\theta_1 z^{n+1},$$

$$\theta_3\mapsto\theta_3+a(n+1)\theta_1\theta_2\theta_3 z^n.$$

A similar calculation applies to t_n^1 and t_n^2,

$$t_m^i=z^{m-1}\left(z\epsilon_{ijk}\theta_j\frac{\partial}{\partial\theta_k}-m\theta_1\theta_2\theta_3\frac{\partial}{\partial\theta_i}\right).$$

These transformations leave the z component unaltered, and as such have sometimes been interpreted in the physics literature[2] as a gauge group. The final term is similarly calculated, and is the three θ transformation

$$\psi_r=-z^{r-(1/2)}\left(\theta_1\theta_2\theta_3\frac{\partial}{\partial z}+\frac{1}{2}\epsilon_{ijk}\theta_i\theta_j\frac{\partial}{\partial\theta_k}\right).$$

These vector fields, similarly calculated in Refs. 20, 7 then give rise to the commutation relations for the $N=3$ algebra without central extension,

$$[t^i_m,t^j_n]=-\epsilon_{ijk}t^k_{m+n},\quad [t^i_m,\psi_s]=0,\quad [t^i_m,g^j_r]=\delta_{ij}m\psi_{r+m}-\epsilon_{ijk}g^k_{r+m},$$

$$[l_m,\psi_s]=-\left(\frac{m}{2}+s\right)\psi_{m+s},\quad [l_m,t^i_n]=-nt^i_{m+n},\quad [g^i_r,\psi_s]=t^i_{r+s},$$

$$[l_m,g^i_r]=\left(\frac{m}{2}-r\right)g^i_{r+m},\quad [g^i_r,g^j_s]=2\delta_{ij}l_{r+s}+\epsilon_{ijk}(r-s)t^k_{r+s},$$

$$[l_m,l_n]=(m-n)l_{m+n},\quad [\psi_m,\psi_n]=0. \tag{34}$$

Note in particular that the t^i_n form an su(2) loop algebra, which will be enhanced by a central extension in the quantum case to give an affine su(2) algebra. One implication of this is that the representation theory will have to be very different to that of the $N=2$ case, where a u(1) loop algebra appeared. The highest weight state must also be an su(2) highest weight state. Since U(1) is Abelian, all its irreducible representations are one dimensional. The upshot of this is that the OPE can be easily adapted by including one more quantum number. Since SU(2) is non-Abelian, it will be seen that su(2) generators will appear in the OPE.

VI. QUANTUM $N=3$ ALGEBRA

The quantum $N=3$ algebra was calculated from a Lagrangian approach, and canonically quantized in Refs. 1 and 2. Whilst this section may look very technical, it should be stressed that essentially the same procedure is being used as in the well documented bosonic case, where the starting point is a section of a sheaf, namely $\mathcal{O}_0(h)$. One plays the same game, but now uses the section $\mathcal{O}_N(h)\otimes\mathcal{R}(G_N)$. Since it is defined covariantly, one can then write down how it transforms. This then gives rise to infinitesimal transformations $\delta\Phi$, which close as a Lie algebra. These relations can be written in terms of an operator $\mathbb{T}$ acting on Φ, giving an OPE. From the $\delta\Phi$, an ansatz for the OPE of $\mathbb{T}$ with itself can be inferred. The action of the quantum algebras on primary fields is inherent in the $\mathbb{T}\Phi$ OPE. The commutation relations of the quantum algebra are then inherent in the $\mathbb{T}\mathbb{T}$ OPE as the modes. What must be checked from the first OPE, is that the primary superfield does indeed yield a highest weight vector.

Recall that for a primary field in the bosonic case, one performs a diffeomorphism from the Riemann sphere to itself that obeys the conformal condition, and looks at how the primary field transforms. More precisely, one considers, a diffeomorphism f,

$$\begin{aligned} f&:\mathbb{P}_1\to\mathbb{P}_1\\ z&\mapsto f(z)=z' \end{aligned} \tag{35}$$

with the conformal condition

$$(f^*dz)=dz\,\kappa(z). \tag{36}$$

One then calculates how $\phi\in\mathcal{O}(h)$ transforms under a pullback, where ϕ in local coordinates is $\phi(z)dz^{\otimes h}$,

$$(f^*\phi)(z)=\kappa^h(\phi\circ f)(z)dz^{\otimes h}=\left(\frac{dz'}{dz}\right)^h\phi(z')dz^{\otimes h}=:\phi'(z)dz^{\otimes h} \tag{37}$$

yielding the transformation law

$$(U_g \phi U_g^{-1})(z) = \left(\frac{dz'}{dz}\right)^h \phi(z') = \phi'(z). \tag{38}$$

For the graded case, one has to consider an invertible sheaf morphism

$$\begin{aligned} f&:(\mathbb{P}_1, \mathcal{A}_N) \to (\mathbb{P}_1, \mathcal{A}_N), \\ Z = (z, \theta_i) &\mapsto Z' = (z', \theta_i'), \end{aligned} \tag{39}$$

such that f (as well as f^{-1}) has a GH^∞ action on the functions $\mathcal{A}_N$, and obeys the conformal condition

$$(f^* \omega) = \omega \kappa(Z). \tag{40}$$

The transformation rule for the components of $\Phi \in \mathcal{O}_N(h) \otimes \mathcal{R}(G_N)$ under a pullback are then given by

$$\Phi'(Z) = \kappa^h \frac{(D_i \theta_j')}{\sqrt{\kappa}} g^{ij} (\Phi \circ f)(Z). \tag{41}$$

The g^{ij} are, up to a discrete subgroup, a representation of the Lie group O(N). The g^{ij} explicitly realize the map (11). This formula matches that found in Ref. 29 for how a primary superfield transforms. One now writes down the transformation law as

$$(U_g \Phi U_g^{-1})(Z) = \kappa^h \frac{(D_i \theta_j')}{\sqrt{\kappa}} g^{ij} \Phi(Z') \tag{42}$$

and parametrize the group action infinitesimally by

$$\begin{aligned} U_g &= \exp(a_n L_n + \alpha_r^i G_r^i + b_n^i T_n^i + \beta_r \psi_r), \\ Z' &= \exp(a_n l_n + \alpha_r^i g_r^i + b_n^i t_n^i + \beta_r \psi_r) Z, \end{aligned}$$

in a completely analogous way to (26), to obtain the commutators of the super-Virasoro operators on a primary field. For the $N=3$ case this yields (45). One must now work backward to try and construct an OPE between a stress-energy tensor and primary superfield that yield these commutators.

For the $N=3$ case, the stress-energy tensor will be weight $\frac{1}{2}$, and have superfield decomposition[34]

$$\mathbb{T}(Z) = \theta_1 \theta_2 \theta_3 L(z) + \tfrac{1}{2} \epsilon_{ijk} \theta_i \theta_j G^k(z) + \theta_i T^i(z) + \psi(z). \tag{43}$$

An OPE for $N=3$ is found in Ref. 8, that, on contour integration, gives rise to the infinitesimal transformations of a primary superfield.[29] With $Z_1 = (w, \chi_i)$, $Z_2 = (z, \theta_i)$, this reads

$$\begin{aligned} \mathbb{T}(Z_1)\Phi(Z_2) \sim{}& \frac{h \theta_{12,1} \theta_{12,2} \theta_{12,3}}{Z_{12}^2} \Phi(Z_2) + \frac{\theta_{12,1} \theta_{12,2} \theta_{12,3}}{Z_{12}} \partial_w \Phi(Z_2) + \frac{\epsilon_{ijk} \theta_{12,i} \theta_{12,j} D_{2,k}}{4 Z_{12}} \Phi(Z_2) \\ &+ \frac{\theta_{12,i} J_i}{Z_{12}} \Phi(Z_2), \end{aligned} \tag{44}$$

where

$$D_{2,i} = \frac{\partial}{\partial \theta_i} + \theta_i \frac{\partial}{\partial z}, \quad Z_{12} = (w - z - \chi_i \theta_i), \quad \theta_{12,i} = (\chi_i - \theta_i),$$

where the J_i form an su(2) algebra.[35] The field, $\Phi(Z)$, now also lives in an su(2) representation, say $\mathcal{V}$. It is in fact an su(2) highest weight. $\mathbb{T}$ can then be thought of as being an endomorphism of $\mathcal{V}$, e.g., explicitly with su(2) indices $\mathbb{T}(Z_1)^a{}_b\Phi(Z_2)^b$. This OPE is effectively a non-abelian version of the q term appearing in the $N=2$ case. In its place, another quantum number appears, which is the J_3 eigenvalue. On the representation space, the action of T_0^i on a highest weight state is identified with that of J_i. The OPE can be split up into θ components, according to (43), and modes be taken of each of the operators, $L(z), G^i(z), T^i(z), \psi(z)$, giving the formulas (45), as required. Note in particular, how the classical algebra appears in the relations again. The extra terms are the h terms, which will give the L_0 eigenvalue h. The other extra terms, the J_i, will give an action of su(2) on the primary field, and hence on the highest weight, which we know must be required from the classical analysis (34), where an su(2) loop algebra appeared,

$$
\begin{aligned}
[L_m,\Phi(Z)] &= z^m\left(h(m+1)+z\partial_z+\frac{1}{2}(m+1)\theta_i\partial_{\theta_i}+\frac{1}{2z}m(m+1)\epsilon_{ijk}\theta_i\theta_jJ_k\right)\Phi(Z),\\
[G_s^i,\Phi(Z)] &= -z^{(s-(1/2))}\left(h\left(s+\frac{1}{2}\right)\theta_i+\frac{1}{2}\theta_iz\partial_z-\frac{1}{2}z\partial_{\theta_i}+\frac{1}{2}\left(s+\frac{1}{2}\right)\theta_i\theta_j\partial_{\theta_j}+\left(s+\frac{1}{2}\right)(\epsilon_{ijk}\theta_jJ_k)\right.\\
&\quad\left.-\frac{1}{z}\left(s^2-\frac{1}{4}\right)\theta_1\theta_2\theta_3J_i\right)\Phi(Z),\\
[T_m^i,\Phi(Z)] &= z^{(m-1)}\left(\frac{mh}{2}\epsilon_{ijk}\theta_j\theta_k-\epsilon_{ijk}\frac{1}{2}z\theta_j\partial_{\theta_k}+\frac{1}{2}m\theta_1\theta_2\theta_3\partial_{\theta_i}+zJ_i-m(\theta_i\theta_kJ_k)\right)\Phi(Z),\\
[\psi_s,\Phi(Z)] &= z^{(s-(1/2))}\left(-\frac{h}{z}\left(s-\frac{1}{2}\right)\theta_1\theta_2\theta_3+\frac{1}{2}\theta_1\theta_2\theta_3\partial_z+\frac{1}{4}\epsilon_{ijk}(\theta_i\theta_j\partial_{\theta_k}-\theta_iJ_i)\right)\Phi(Z).
\end{aligned}
\tag{45}
$$

Note that

$$
[L_{-1},\Phi(Z)]=\partial_z\Phi(Z),\quad [G^i_{-(1/2)},\Phi(Z)]=\tfrac{1}{2}(\partial_{\theta_i}-\theta_i\partial_z)\Phi(Z). \tag{46}
$$

In particular, L_{-1} acts as a translation in z and $G^i_{-(1/2)}$ as a supertranslation in the respective θ_i direction. This allows vertex operators to be used, and an operator-state mapping employed.[22,36,17] In the bosonic theory, vertex operators are characterized uniquely by their action on a vacuum $|0\rangle$, which is annihilated by the raising operators, $\{L_n : n\geqslant -1\}$. The vacuum cannot be invariant under the whole symmetry algebra without implying vanishing of the central extension. This generalizes to $N=3$, so that now $|0\rangle$ is annihilated by $\{L_n, G^i_r, T^i_m, \psi_s : n\geqslant -1, r\geqslant -\frac{1}{2}, m\geqslant 0, s\geqslant \frac{1}{2}\}$. To get the state associated to any vertex operator $\Phi(Z)$, one looks at $\lim_{Z\to 0}\Phi(Z)|0\rangle$. Given this, it can be seen from the relations (45) that the action of the raising operators on $|\Phi\rangle$ is zero, e.g., for $\{L_m : m>0\}$

$$
\lim_{Z\to 0}[L_m,\Phi(Z)]|0\rangle=0.
$$

The action of L_0 is given by

$$
[L_0,\Phi(Z)]=(h+z\partial_z+\tfrac{1}{2}(\theta_1\partial_{\theta_1}+\theta_2\partial_{\theta_2}+\theta_3\partial_{\theta_3}))\Phi(Z)\Rightarrow\lim_{Z\to 0}[L_0,\Phi(Z)]|0\rangle=h|\Phi\rangle=L_0|\Phi\rangle. \tag{47}
$$

The action of T_0^i is given by

$$
\begin{aligned}
[T_0^1,\Phi(Z)] &= (\tfrac{1}{2}\theta_3\partial_{\theta_2} - \tfrac{1}{2}\theta_2\partial_{\theta_3} + J_1)\Phi(Z),\\
[T_0^2,\Phi(Z)] &= (\tfrac{1}{2}\theta_1\partial_{\theta_3} - \tfrac{1}{2}\theta_3\partial_{\theta_1} + J_2)\Phi(Z),\\
[T_0^3,\Phi(Z)] &= (\tfrac{1}{2}\theta_2\partial_{\theta_1} - \tfrac{1}{2}\theta_1\partial_{\theta_2} + J_3)\Phi(Z),\\
\Rightarrow \lim_{Z\to 0}[T_0^i,\Phi(Z)]|0\rangle &= \lim_{Z\to 0}(J_i\Phi)(Z)|0\rangle = J_i|\Phi\rangle = T_0^i|\Phi\rangle,
\end{aligned}
\tag{48}
$$

where the vacuum is T_0^i invariant.

Hence, on the highest weight state, the T_0^i can be identified with the J_i, so that T_0^3 gives rise to the q eigenvalue, and $J^+ = J_0^1 + iJ_0^2$ annihilates $|\Phi\rangle$. As can be seen, $\Phi(Z)$ is associated to a vector $|\Phi\rangle$, which is a highest weight of the $N=3$ field.

Rather than work explicitly with (45), one could simply consider what the infinitesimal transformations of the field are under an infinitesimal superconformal map

$$(z,\theta_i)\mapsto(z+\delta z,\theta_i+\delta\theta_i). \tag{49}$$

This is useful to check closure as a Lie algebra. It is useful to introduce the quantity $\nu(z)=\delta z + \theta_i\delta\theta_i$. The transformation reads

$$
\begin{aligned}
\delta\Phi(Z) &= h(\partial_z\nu(Z))\Phi(Z) + \nu(Z)\partial_z\Phi(Z) + \frac{1}{2}\sum_{j=1}^{3}(D_j\nu(Z))(D_j\Phi(Z))\\
&\quad + ((J_3D_1D_2 + J_1D_2D_3 + J_2D_3D_1)(\nu(Z)))\Phi(Z)\\
&= \frac{2h}{3}(D_1\delta\theta_1 + D_2\delta\theta_2 + D_3\delta\theta_3)\Phi(Z) + (\delta z)\partial_z\Phi(Z) + \sum_{j=1}^{3}(\delta\theta_j)\partial_{\theta_j}\Phi(Z)\\
&\quad + ((D_1\delta\theta_2 - D_2\delta\theta_1)J_3 + (D_2\delta\theta_3 - D_3\delta\theta_2)J_1 + (D_3\delta\theta_1 - D_1\delta\theta_3)J_2)\Phi(Z).
\end{aligned}
\tag{50}
$$

The infinitesimal transformations form a Lie algebra, which can be calculated explicitly from (50),

$$
\begin{aligned}
[\delta_{\nu_1},\delta_{\nu_2}]\Phi(Z) &= \delta_{\nu_3}\Phi(Z),\\
\nu_3 &= \nu_2(\partial_z\nu_1) - \nu_1(\partial_z\nu_2) + \frac{1}{2}\sum_{i=1}^{3}(D_i\nu_2)(D_i\nu_1).
\end{aligned}
\tag{51}
$$

It is worth noting that the algebra closes if and only if the J_i satisfy the commutation relations $[J_i,J_j] = -\frac{1}{2}\epsilon_{ijk}J_k$.

This can then be used to construct an ansatz for an OPE of $\mathbb{T}(Z_1)\mathbb{T}(Z_2)$ (52), and then the modes calculated to give the commutators of the quantum theory (53),

$$\mathbb{T}(Z_1)\mathbb{T}(Z_2) = \frac{c}{Z_{12}} + \frac{\theta_{12,1}\theta_{12,2}\theta_{12,3}}{2Z_{12}^2}\mathbb{T}(Z_2) + \frac{\theta_{12,1}\theta_{12,2}\theta_{12,3}}{Z_{12}}\partial_w\mathbb{T}(Z_2) + \frac{\epsilon_{ijk}\theta_{12,i}\theta_{12,j}D_{2,k}}{4Z_{12}}\mathbb{T}(Z_2). \tag{52}$$

The first term gives rise to the central extension in the algebra, and arises in precisely the same way as the bosonic case. This OPE shows explicitly that $\mathbb{T}(Z)$ is a weight $\frac{1}{2}$ field, although not primary. Since the central charge does not appear for the super-Möbius subalgebra, $\mathbb{T}$ can be thought of as a quasiprimary superfield, in the trivial representation of su(2). The modes of this

can then be calculated to give the $N=3$ algebra. Note that when the classical algebra expressions appear in (45), there are extra factors of $\frac{1}{2}$ appearing in (45). This corresponds to the extra factors of $\frac{1}{2}$ appearing in (53) when compared to the classical algebra,

$$[T^i_m,T^j_n]=-\tfrac{1}{2}\epsilon_{ijk}T^k_{m+n}+mc\,\delta_{ij}\delta_{m+n,0},\quad [T^i_m,\psi_s]=0,$$

$$[T^i_m,G^j_r]=\tfrac{1}{2}(\delta_{ij}m\psi_{r+m}-\epsilon_{ijk}G^k_{r+m}),\quad [L_m,\psi_s]=-\left(\frac{m}{2}+s\right)\psi_{m+s},$$

$$[L_m,T^i_n]=-nT^i_{m+n},\quad [G^i_r,\psi_s]=\tfrac{1}{2}T^i_{r+s},\quad [L_m,G^i_r]=\left(\frac{m}{2}-r\right)G^i_{r+m}, \tag{53}$$

$$[G^i_r,G^j_s]=\tfrac{1}{2}\delta_{ij}L_{r+s}+\tfrac{1}{2}\epsilon_{ijk}(r-s)T^k_{r+s}-c(r^2-\tfrac{1}{4})\delta_{r+s,0}\delta_{ij},$$

$$[L_m,L_n]=(m-n)L_{m+n}-cm(m^2-1)\delta_{m+n,0},\ [\psi_r,\psi_s]=c\,\delta_{r+s,0},$$

which agrees with Ref. 2.

VII. THE NEVEU–SCHWARZ ALGEBRA AND ITS VERMA MODULE

The $N=3$ Neveu–Schwarz algebra is given by the above commutation relations where $m\in\mathbb{Z}$, $r\in\mathbb{Z}+\frac{1}{2}$. The basis can be changed so that the above relations are more useful for representation theory. Consider a change of variables

$$\begin{gathered}T^+_m=2(iT^1_m-T^2_m),\quad T^-_m=2(iT^1_m+T^2_m),\quad T^H_m=-2iT^3_m,\\ G^+_r=4(G^2_r-iG^1_r),\quad G^-_r=4(G^2_r+iG^1_r),\quad G^H_r=8iG^3_r,\quad k=-4c.\end{gathered} \tag{54}$$

Then, the commutation relations become, for $x\in\{H,\pm\}$,[37]

$$[T^+_m,T^-_n]=2T^H_{m+n}+2km\,\delta_{m+n,0},\quad [T^H_m,T^\pm_n]=\pm T^\pm_{m+n},\quad [T^\pm_m,T^\pm_n]=0,$$

$$[T^H_m,T^H_n]=km\,\delta_{m+n,0},\quad [T^\pm_m,G^\pm_r]=0,\quad [T^\mp_m,G^\pm_r]=-G^H_{r+m}\pm 8m\psi_{r+m},$$

$$[T^\pm_m,G^H_r]=-2G^\pm_{m+r},\quad [T^H_m,G^H_r]=8m\psi_{m+r},\quad [T^H_m,G^\pm_r]=\pm G^\pm_{r+m},$$

$$[\psi_s,G^\pm_r]=\mp T^\pm_{r+s},\quad [\psi_s,G^H_r]=-2T^H_{r+s},\quad [G^\pm_r,G^\pm_s]=0,\quad [T^x_m,\psi_s]=0,$$

$$[G^H_r,G^H_s]=-32L_{r+s}-16k(r^2-\tfrac{1}{4})\delta_{r+s,0},\quad [G^\pm_r,G^H_s]=8(r-s)T^\pm_{r+s}, \tag{55}$$

$$[G^+_r,G^-_s]=16L_{r+s}+8k(r^2-\tfrac{1}{4})\delta_{r+s,0}+8(r-s)T^H_{r+s},$$

$$[L_m,\psi_s]=-\left(\frac{m}{2}+s\right)\psi_{m+s},\quad [L_m,T^x_n]=-nT^x_{m+n},\quad [\psi_r,\psi_s]=-\frac{k}{4}\delta_{r+s,0},$$

$$[L_m,G^x_r]=\left(\frac{m}{2}-r\right)G^x_{r+m},$$

$$[L_m,L_n]=(m-n)L_{m+n}+\frac{k}{4}m(m^2-1)\delta_{m+n,0}.$$

On the representations considered here, the algebra obeys hermiticity conditions[38]

$$(\psi_r)^\dagger = -\psi_{-r}, \quad (T_m^+)^\dagger = T_{-m}^-, \quad (T_m^-)^\dagger = T_{-m}^+, \quad (T_m^H)^\dagger = T_{-m}^H,$$
$$(G_r^H)^\dagger = -G_{-r}^H, \quad (L_n)^\dagger = L_{-n}, \quad (G_r^+)^\dagger = G_{-r}^-, \quad (G_r^-)^\dagger = G_{-r}^+. \tag{56}$$

The highest weight conditions on a vector $|\phi\rangle$ are then

$$T_m^x|\phi\rangle = 0, \quad G_r^x|\phi\rangle = 0, \quad L_m|\phi\rangle = 0, \quad \psi_r|\phi\rangle = 0, \quad T_0^+|\phi\rangle = 0 \tag{57}$$

for $m,r>0$. The Cartan subalgebra is spanned by the elements L_0, T_0^H, such that $L_0|\phi\rangle = h|\phi\rangle$, $T_0^H|\phi\rangle = q|\phi\rangle$. The algebra of raising operators, i.e., the algebra spanned by the elements giving the highest weight conditions, is generated by T_0^+, $G_{1/2}^-$, $\psi_{1/2}$. Thus, a vector $|\chi\rangle$ with the properties $T_0^+|\chi\rangle = 0$, $G_{1/2}^-|\chi\rangle = 0$ and $\psi_{1/2}|\chi\rangle = 0$ will obey the highest weight conditions. Consider the Verma module $V(h,q)$ for a highest weight $|\phi\rangle$, with $L_0|\phi\rangle = h|\phi\rangle$, $T_0^H|\phi\rangle = q|\phi\rangle$. A vector $|\chi\rangle \neq |\phi\rangle$ in the module defines a singular vector. The module itself admits a decomposition

$$V(h,q) = \bigoplus_{(m\geqslant 0)} \bigoplus_{(n\leqslant m/2)} V_{m,n}, \tag{58}$$

where $m \in \mathbb{Z}$ and $n \in \mathbb{Z}/2$. This can be seen from the root structure (55), and the highest weight conditions. An example of a singular vector occurs when $(h,q,k) = (-\frac{1}{2}, -1, k)$. Under such conditions, a singular vector exists in $V_{1/2,0}$,

$$|\chi\rangle = T_0^- G_{-(1/2)}^+ |\phi\rangle. \tag{59}$$

VIII. THE SUPER MÖBIUS GROUP

One might ask how exactly does the theory of the Möbius group generalize. In the bosonic case, the lie algebra of the group can be obtained by finding the globally defined vector fields on the Riemann sphere. The Riemann sphere can be considered as a pair of complex planes with transition function $w = \frac{1}{z}$ between them. In the graded Riemann sphere case, one can choose a homomorphism between rings of functions given by $(w, \chi_i) = (1/z, \theta_i\sqrt{-1}/z)$. The South pole is $Z_s = (z, \theta_i) = (0,0,0,0)$, and the North pole given by $Z_n = (1/z, \theta_i\sqrt{-1}/z) = (0,0,0,0)$. One can then ask what are the globally defined graded vector fields. A basis of vector fields was calculated in Sec. V. It can be seen that many of them are divergent at the origin, or South pole. One must then check which vector fields are well behaved at both poles. As an example, consider the vector field (33). This is clearly divergent for $m<-1$ at the south pole. To find out what l_n looks like at the north pole, one uses the techniques of graded one-forms and vector fields[23] to find

$$l_m = w^{-m+1}\frac{\partial}{\partial w} - \frac{1}{2}(m-1)w^{-m}\chi_j\frac{\partial}{\partial \chi_j}, \tag{60}$$

which is divergent for $m>1$ at the North pole. Thus, one can conclude that $\{l_1, l_0, l_{-1}\}$ are globally defined. Similarly, one finds that the only other globally defined vector fields are $\{g_{1/2}^r, g_{-(1/2)}^r, t_0^i\}$. From the commutation relations, (34) it can be seen that the vector fields form a closed subalgebra, namely osp(3,2). One can then write down formal group elements by exponentiation.

$$
\begin{gathered}
\exp(\lambda l_1):(z,\theta_i)\mapsto \frac{1}{1-\lambda z}(z,\theta_i),\\
\exp(\lambda l_0):(z,\theta_i)\mapsto (e^{\lambda}z,e^{\lambda/2}\theta_i),\\
\exp(\lambda l_{-1}):(z,\theta_i)\mapsto (z+\lambda,\theta_i),\\
\exp(\epsilon g^j_{-(1/2)}):(z,\theta_i)\mapsto (z-\epsilon\theta_j,\theta_i,\theta_j+\epsilon),\quad i\neq j,\\
\exp(\epsilon g^j_{1/2}):(z,\theta_i)\mapsto \frac{1}{1+\epsilon\theta_j}(z,\theta_i,\theta_j+\epsilon z),\quad i\neq j,\\
\exp(\lambda_i t^i_0):(z,\theta_i)\mapsto (z,M_{ij}(\lambda)\theta_j),\quad M_{ij}(\lambda)\in \mathrm{SO}(3).
\end{gathered}
\tag{61}
$$

In particular, the $g^i_{-(1/2)}$ give supersymmetry generators, the $g^i_{1/2}$ give special superconformal transformations, and the t^i_0 give an R-symmetry. Writing these transformations as $Z\mapsto Z'$, the corresponding transformations on the field become

$$
\begin{gathered}
e^{\lambda L_0}\Phi(Z)e^{-\lambda L_0}=e^{\lambda h}\Phi(Z'),\quad e^{\lambda L_{-1}}\Phi(Z)e^{-\lambda L_{-1}}=\Phi(Z'),\\
e^{\epsilon G^i_{-1/2}}\Phi(Z)e^{-\epsilon G^i_{-1/2}}=\Phi(Z'),\\
e^{\rho G^i_{1/2}}\Phi(Z)e^{-\rho G^i_{1/2}}=\frac{1}{(1+\epsilon\theta_i)^h}e^{-2\rho\epsilon_{ijk}\theta_j J_k}\Phi(Z'),\\
e^{\lambda T^i_0}\Phi(Z)e^{-\lambda T^i_0}=e^{\lambda J_i}\Phi(Z'),\\
e^{\lambda L_1}\Phi(Z)e^{-\lambda L_1}=\frac{1}{(1-\lambda z)^h}e^{(\lambda/(1-\lambda z)\,\epsilon_{ijk}\theta_i\theta_j J_k)}\Phi\left(\frac{z}{(1-\lambda z)},\frac{\theta_i}{(1-\lambda z)}\right).
\end{gathered}
\tag{62}
$$

Using these formal group elements, any two points, $V=(v,\beta_i)$ and $U=(u,\alpha_i)$ say, can be mapped to the North and South poles, respectively. In a conformal field theory formalism, usually the South pole is where the ''in vacuum'' sits, and the North pole where the ''out vacuum'' sits. The formal group element corresponding to this map is given by

$$
(z,\theta_i)\mapsto(z',\theta'_i)=\frac{\left(z-u,\theta_i-\alpha_i+\left(\frac{\alpha_i-\beta_i}{v-u}\right)(z-u)\right)}{\left(1+\frac{(\alpha-\beta)\cdot\theta}{v-u}\right)-\left(1+\frac{\alpha\cdot\beta}{v-u}\right)\left(\frac{z-u}{v-u}\right)},
\tag{63}
$$

where $\alpha\cdot\beta=\Sigma_{i=1}^3\alpha_i\beta_i$.

To obtain this transformation, one can use $g^i_{-(1/2)}$ to send α^i to 0, l_{-1} to move u to 0, $g_{1/2}$ to send β_i to 0 when $z=v$, and l_1 to send v to ∞. It is worth noting, that the only operators that have not been used are the t^i_0 and l_0. This degree of freedom is essentially a (complex) scale factor, and an SO(3) action on the θs. Thus, the even ''coordinate'' of the third point can be sent anywhere one wishes, but one cannot quite do the same with the odd ''coordinates'' of the third point. It should also be noted, that this construction should generalize to osp(N,2), i.e., with an arbitrary number of odd coordinates.

The formal group element found (63) implies that a correlation function of the form

$$
\langle 0|\Phi_1(V)\Phi_2(Z)\Phi_3(U)0\rangle
\tag{64}
$$

can be superconformally mapped to a more typical presentation of the three-point function in conformal field theory,

$$\langle 0|\Phi_1(\infty)\Phi_2(Z')\Phi_3(0)0\rangle=\langle \phi_1|\Phi_2(Z')\phi_3\rangle. \tag{65}$$

IX. THE TWO-POINT FUNCTION

In conformal field theory it is known that global conformal invariance is sufficient to solve for the two point function. This is indeed also the case for $N=1,2$.[31] In this section, global $N=3$ invariance is used to solve for the two-point function. This becomes quite a bit more complicated than $N\leqslant 2$, calculationally, due to the presence of non-Abelian R-symmetry, manifested by the presence of su(2) generators in the theory. More precisely, the primary fields are $\mathcal{A}_N\otimes \mathrm{End}\mathcal{H}\otimes\mathcal{V}$ valued, where $\mathcal{V}$ is an su(2) representation and $\mathcal{H}$ is the Hilbert space that $|0\rangle$ belongs to. The super-Virasoro operators are valued in $\mathrm{End}\mathcal{H}\otimes\mathrm{End}\mathcal{V}$.

The most convenient basis to work in is a ''charged'' basis, where elements can be classified by their su(2) charge, namely their T_0^3 eigenvalue. The basis is given by

$$\begin{gathered}\theta^+=2(i\theta_1-\theta_2),\quad J^+=2(iJ_1-J_2),\\ \theta^-=2(i\theta_1+\theta_2),\quad J^-=2(iJ_1+J_2),\\ \theta^H=i\theta_3,\quad J^H=-2iJ_3.\end{gathered} \tag{66}$$

The primary field Φ itself is the highest weight in an su(2) representation, i.e., carries an su(2) representation index, so that

$$\begin{gathered}J^+\Phi(Z)=(J^+)^A{}_B\Phi^B(Z)=0,\\ J^H\Phi(Z)=(J^H)^A{}_B\Phi^B(Z)=q\Phi^A(Z).\end{gathered} \tag{67}$$

In the following, $\Phi_i(Z)$ has conformal weight h_i and spin q_i. The action of the twelve globally defined generators on $\Phi(Z)$ can then be given in Lie algebra form. The infinitesimal transformations are

$$\begin{gathered}[L_{-1},\Phi]=\partial_z\Phi,\quad [G^{\pm}_{-(1/2)},\Phi]=\pm(\theta^{\pm}\partial_z+8\partial_{\theta^{\mp}})\Phi,\\ [G^H_{-(1/2)},\Phi]=-4(\theta^H\partial_z+\partial_{\theta^H})\Phi,\quad [T_0^H,\Phi]=(\theta^-\partial_{\theta^-}-\theta^+\partial_{\theta^+}+J^H)\Phi,\\ [L_0,\Phi]=(h+z\partial_z+\tfrac{1}{2}(\theta^+\partial_{\theta^+}+\theta^-\partial_{\theta^-}+\theta^H\partial_{\theta^H}))\Phi,\\ [T_0^{\pm},\Phi]=(\mp\tfrac{1}{2}\theta^{\pm}\partial_{\theta_H}\pm 4\theta^H\partial_{\theta^{\mp}}+J^{\pm})\Phi,\\ [L_1,\Phi]=(2hz+z(z\partial_z+\theta^+\partial_{\theta^+}+\theta^-\partial_{\theta^-}+\theta^H\partial_{\theta^H})+\tfrac{1}{8}\theta^+\theta^-J^H+\tfrac{1}{4}\theta^+\theta^HJ^--\tfrac{1}{4}\theta^-\theta^HJ^+)\Phi,\\ [G^{\pm}_{1/2},\Phi]=(\pm 2h\theta^{\pm}\pm\theta^{\pm}z\partial_z\pm 8z\partial_{\theta^{\mp}}\pm\theta^{\pm}\theta^H\partial_{\theta^H}+\theta^+\theta^-\partial_{\theta^{\mp}}+2\theta^HJ^{\pm}+\theta^{\pm}J^H)\Phi,\\ [G^H_{1/2},\Phi]=(-8h\theta^H-4\theta^Hz\partial_z-4z\partial_{\theta^H}-4\theta^H\theta^-\partial_{\theta^-}-4\theta^H\theta^+\partial_{\theta^+}+\theta^-J^+-\theta^+J^-)\Phi.\end{gathered} \tag{68}$$

Note that under the T_0^H operator, θ^+ and θ^- are ''charged,'' i.e., they possess a nonzero T_0^H eigenvalue. The two point function, $\langle 0|\Phi_1(Z_1)\Phi_2(Z_2)0\rangle=\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle$ is, as a function, a function of $Z_1=(z,\theta_i)$ and $Z_2=(w,\chi_i)$. Since the Φ_i are also highest weight vectors of su(2) representations, $\mathcal{V}_i$, the two point function is an element of $\mathcal{V}_1\otimes\mathcal{V}_2$. The L_{-1} condition on the two-point function reads

$$\mathcal{L}_{-1}\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle=(\partial_z+\partial_w)\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle=0 \tag{69}$$

implying that $\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle$ is a function of $(z-w)$ and θ_i,χ_i. Applying the $G^x_{-(1/2)}$ conditions yields similar equations to (69). These conditions show that $\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle$ is a function of

$$\begin{gathered}(\theta^- - \chi^-),\quad (\theta^H - \chi^H),\quad (\theta^+ - \chi^+),\\ s = (z-w+\tfrac{1}{8}(\theta^-\chi^+ + \theta^+\chi^-) + \theta^H\chi^H).\end{gathered} \tag{70}$$

The L_0 condition gives a scaling condition, from which the most general form of the two point function can be seen to be

$$\begin{aligned}\langle\Phi_1(Z_1)\Phi_2(Z_2)\rangle = \frac{a}{s^{h_1+h_2}} + \frac{\epsilon_+(\theta^+ - \chi^+)}{s^{h_1+h_2+1/2}} + (\text{two similar terms}) + \frac{b_{+H}(\theta^+ - \chi^+)(\theta^H - \chi^H)}{s^{h_1+h_2+1}}\\ + (\text{two similar terms}) + \frac{\eta(\theta^+ - \chi^+)(\theta^- - \chi^-)(\theta^H - \chi^H)}{s^{h_1+h_2+3/2}}.\end{aligned} \tag{71}$$

The T_0^H condition includes su(2) elements. It is worth writing this condition out explicitly, to illustrate the action of the elements. Putting in all the tensor products between su(2) representations explicitly, the condition reads

$$((\mathbb{I}\otimes\mathbb{I})(\theta^-\partial_{\theta^-} - \theta^+\partial_{\theta^+} + \chi^-\partial_{\chi^-} - \chi^+\partial_{\chi^+}) + J^H\otimes\mathbb{I} + \mathbb{I}\otimes J^H)\langle\Phi_1(Z_1)\otimes\Phi_2(Z_2)\rangle = 0, \tag{72}$$

where

$$\begin{aligned}(J^H\otimes\mathbb{I} + \mathbb{I}\otimes J^H)\langle\Phi_1(Z_1)\otimes\Phi_2(Z_2)\rangle &= \langle(J^H\Phi_1)(Z_1)\otimes\Phi_2(Z_2)\rangle + \langle\Phi_1(Z_1)\otimes(J^H\Phi_2)(Z_2)\rangle\\ &= (q_1+q_2)\langle\Phi_1(Z_1)\otimes\Phi_2(Z_2)\rangle.\end{aligned} \tag{73}$$

This condition gives three possible cases

$$\begin{gathered}q_1+q_2 = 0 \Rightarrow \text{only } (a, \epsilon_H, b_{+-}, \eta) \text{ nonzero},\\ q_1+q_2 = 1 \Rightarrow \text{only } (\epsilon_+, b_{+H}) \text{ nonzero},\\ q_1+q_2 = -1 \Rightarrow \text{only } (\epsilon_-, b_{-H}) \text{ nonzero}.\end{gathered} \tag{74}$$

Replacing H with $+$ in (73), it can be seen that $J^+\otimes\mathbb{I} + \mathbb{I}\otimes J^+$ annihilates $\langle\Phi_1(Z_1)\otimes\Phi_2(Z_2)\rangle$. The T_0^+ condition then gives—if $q_1+q_2=-1$, then $\epsilon_-, b_{-H}=0$—if $q_1+q_2=0$, then $\epsilon_+, b_{+H}=0$—and gives no extra conditions if $q_1+q_2=1$. Thus, the $q_1+q_2=-1$ case is irrelevant. J^- is an operator that can cause calculational difficulties. The T_0^- condition can be used to relate $\langle(J^-\Phi_1)\Phi_2\rangle$ and $\langle\Phi_1(J^-\Phi_2)\rangle$.

Consider now the L_1 condition. This contains a term like

$$\theta^+\theta^H\langle(J^-\Phi_1)\Phi_2\rangle + \chi^+\chi^H\langle\Phi_1(J^-\Phi_2)\rangle.$$

The T_0^- condition can be used to relate this to a term of the form

$$(\theta^+\theta^H - \chi^+\chi^H)\langle(J^-\Phi_1)\Phi_2\rangle.$$

Thus the condition implies that all those terms that cannot be factored by $(\theta^+\theta^H - \chi^+\chi^H)$ are zero. A similar condition arises for the $G^x_{1/2}$ conditions. After much tedious algebra, one finds that

$$\langle \Phi_1(Z_1)\Phi_2(Z_2)\rangle = \begin{cases} \dfrac{a}{s^{h_1+h_2}} & \text{if} \quad h_1=h_2, \quad q_1=q_2=0, \\ \dfrac{b_{+H}(\theta^+-\chi^+)(\theta^H-\chi^H)}{s^{h_1+h_2+1}} & \text{if} \quad h_1=h_2, \quad q_1+q_2=1, \\ \qquad q_1,q_2\neq 0 & \\ 0 \quad \text{otherwise.} & \end{cases} \tag{75}$$

This has important applications to fusion. Considering the three-point function

$$\mathcal{F}_{123}=\langle \Phi_1(Z_1)\Phi_2(Z_2)\Phi_3(Z_3)\rangle,$$

where $\Phi_1(Z_1)$ is a "probe field," i.e., one can choose its (h,q) parameters, call them (h_1,q_1). $\Phi_2(Z_2)$ and $\Phi_3(Z_3)$ will have an OPE, which schematically looks like (i.e., omitting pole structure and other factors)

$$\Phi_2(Z_2)\Phi_3(Z_3)\sim\sum_n \Psi_n(Z_3) \tag{76}$$

that may be unknown, namely one may not know the (h,q) of the Ψ_n. One can ask if the OPE between $\Phi_2(Z_2)$ and $\Phi_3(Z_3)$ can be deduced if one knows the values of $\mathcal{F}_{123}$, for all h_1 and q_1. From (75), one can see that for $\langle \Phi_1(Z_1),\Psi_n(Z_3)\rangle$ to be nonzero, a unique (h_1,q_1) must be chosen. This choice determines the (h,q) of $\Psi_n(Z_3)$. Thus one can make the statement that knowing when the three point function $\mathcal{F}_{123}$ vanishes is equivalent to knowing what $\Psi_n(Z_3)$ are in (76). These then give rise to the fusion rules.

One should note that global conformal invariance of the theory almost fixes three super coordinates, as can be seen from (63). In the mapping from (64) to (65) one can map V and U to the North and South poles. One can also map z' from $Z'=(z',\theta_i')$ in (65), to wherever desired, using L_0. There is not enough freedom to move the θ_i' wherever desired. Thus, one would expect that the three-point function could also be computed, up to an arbitrary function in θ_i'. After expanding this function into components, this can be seen as being computable up to some arbitrary constants.

X. OTHER APPLICATIONS

This section is strictly speaking a list of things that could be done, in the $N=3$ theory. Since most of these things are very calculationally intensive, the author has not checked the details.

An interesting question is analyzing the constraints that singular vectors give on three-point functions. If $|\chi\rangle$ is a singular vector in a module with highest weight $|\phi_1\rangle$, then what does the requirement that

$$\langle \phi_3|\Phi(Z)\chi\rangle$$

vanish imply about

$$\langle \phi_3|\Phi(Z)\phi_1\rangle.$$

Algebraically, this is in fact quite difficult, and the author has not managed to accomplish this. The main complication is that the composition between primary fields in the correlator are a tensor product between su(2) representations $\mathcal{V}$ and $\mathcal{V}'$ and an End$\mathcal{H}$ composition. This means that the only super-Virasoro operators that can be transferred across the tensor product are those that have End$\mathcal{V}$ part proportional to the identity. The most obvious case where this applies is where all the

fields have $q=0$, i.e., they are all su(2) singlets. Following Refs. 11 and 30, the lowering operators acting appearing in $|\chi\rangle$ can be rewritten in terms of operators that have commutator with a primary field in (z,θ_i) given by a polynomial in (z,θ_i), namely

$$\begin{aligned}
\mathcal{L}_m &= -L_m + \frac{1}{z}L_{m+1} + \frac{1}{16z}(\theta^+ G^-_{m+(1/2)} - \theta^- G^+_{m+(1/2)} + 2\theta^H G^H_{m+(1/2)}) \\
&\quad + \frac{m+1}{4z}(\theta^-\theta^H T^+_m - \theta^+\theta^H T^-_m - \theta^+\theta^- T^H_m), \\
\mathcal{G}^\pm_r &= -G^\pm_r + \frac{1}{z}G^\pm_{r+1} - \frac{2\theta^H}{z}T^\pm_{r+(1/2)} - \frac{\theta^\pm}{z}T^H_{r+(1/2)}, \\
\mathcal{G}^H_r &= -G^H_r + \frac{1}{z}G^H_{r+1} - \frac{\theta^-}{z}T^+_{r+(1/2)} + \frac{\theta^+}{z}T^-_{r+(1/2)}, \\
\mathcal{T}^\pm_m &= -T^\pm_m + \frac{1}{z}T^\pm_{m+1} - \frac{\theta^\pm}{z}\psi_{m+(1/2)}, \\
\mathcal{T}^H_m &= -T^H_m + \frac{1}{z}T^H_{m+1} + \frac{2\theta^H}{z}\psi_{m+(1/2)}, \\
\mathcal{P}_r &= -\psi_r + \frac{1}{z}\psi_{r+1}.
\end{aligned} \tag{77}$$

One then finds

$$\begin{aligned}
&[\mathcal{L}_m,\Phi(Z)] = hz^m, \quad [\mathcal{G}^\pm_r,\Phi(Z)] = \pm 2h\theta^\pm z^{r-(1/2)}, \\
&[\mathcal{G}^H_r,\Phi(Z)] = -8h\theta^H z^{r-(1/2)}, \quad [\mathcal{T}^\pm_m,\Phi(Z)] = \pm h\theta^\pm\theta^H z^{m-1}, \\
&[\mathcal{T}^H_m,\Phi(Z)] = -\tfrac{1}{4}h\theta^+\theta^- z^{m-1}, \quad [\mathcal{P}_r,\Phi(Z)] = \tfrac{1}{8}h\theta^+\theta^-\theta^H z^{r-(3/2)}.
\end{aligned} \tag{78}$$

Now one can commute the operators from $|\chi\rangle$ past Φ without introducing differential operators. The operators $\mathcal{L}_m$, etc., may now be re-expanded in terms of L_m, etc. Some of these operators will annihilate $\langle\phi_3|$. Those that do not, and are not diagonal, must be processed using the descent equations on $|\Phi(Z)\phi_1\rangle$.[6] This then yields a set of polynomial equations giving conditions on the weights of the primary fields.

From a differential equation point of view, the question of singular vectors may not be such a difficult problem. As in Ref. 6, the lowering operators can be written as contour integrals, e.g.,

$$\begin{aligned}
L_{-k}(z) &= \frac{1}{2\pi i}\oint dw L(z)(w-z)^{1-k}, \\
G_{-r}(z) &= \frac{1}{2\pi i}\oint dw G(z)(w-z)^{(1/2)-r}, \quad \text{etc.}
\end{aligned} \tag{79}$$

The condition of a singular vector, $\mathcal{N}|\phi_3\rangle$, where $\mathcal{N}$ are some lowering operators, can be written as

$$\langle\Phi_1(Z_1)\Phi_2(Z_2)(\mathcal{N}\Phi_3)(Z_3)\rangle = 0.$$

This then gives rise, via (79) and the OPE, to a differential equation on the three point function. One would expect the three point function to look like a product of powers of differences, as in the

case of the two point function, e.g., $s,(\theta^+-\chi^+)$. As in the bosonic case, this should give rise to a polynomial in the h_i,q_i of the fields concerned. The difference now, is that the presence of J^- operators will give independent equations, e.g., $\mathcal{F}_{123}\in\mathcal{V}_1\otimes\mathcal{V}_2\otimes\mathcal{V}_3$, hence $(\mathbb{I}\otimes\mathbb{I}\otimes J^-)\mathcal{F}$ is linearly independent of $(\mathbb{I}\otimes\mathbb{I}\otimes\mathbb{I})\mathcal{F}$. Other than this, the calculations should proceed precisely as in the bosonic case.

XI. CONCLUSIONS

Starting from a graded Riemann sphere, a superconformal field theory was constructed. The construction roughly parallels that of the bosonic case, namely defining sections of a line bundle on a Riemann sphere, and rewriting the infinitesimal transformations of these sections as operator product expansions. Two ways were used to introduce a Ramond field, one by introducing a branch cut, the other by altering the preserved one-form. This suggests that looking at various sheaves on a graded Riemann sphere may be a potentially useful way of realizing fields in a superconformal field theory.

The super OPEs, together with an understanding of how the symmetries act on the graded Riemann sphere, were sufficient to compute the $N=3$ two-point function, up to multiplicative constants. In addition, it was illustrated how, in principle, the $N=3$ three point function and conditions given by singular vectors on the three point function could be calculated. It should be pointed out that the method of calculation was entirely in superfield formalism, and hence manifestly supersymmetric.

The only case that has really been studied here is the $N=3$ case, based on a Riemann surface of genus zero. How this generalizes to higher genus is an interesting question. An even more interesting question, is the $N=4$ case. Processing the $N=4$ theory through this machinery, does not produce the full OPE of the theory. There is a log term missing from the OPE corresponding to a U(1) charge. A question then arises, how to extend the framework of a graded Riemann sphere to incorporate this log term. Many parts of the $N=4$ theory will in fact look like the $N=3$ theory,[3] since the $N=4$ currents arising from R-symmetry are a pair of commuting su(2) currents.

[32] Assume otherwise, so that $\kappa\kappa'=1=\kappa'\kappa$, and $\kappa\kappa''=1=\kappa''\kappa$. Subtracting and factorizing gives $(\kappa'-\kappa'')\kappa=0=\kappa(\kappa'-\kappa'')$. Using either inverse on these equations shows $\kappa'-\kappa''=0$.
[33] The commutators are graded, i.e., $[A,B]=AB-(-1)^{p(A)p(B)}BA$.
[34] $\epsilon_{123}=1$ and ϵ is antisymmetric in all its indices. Summation convention is used over repeated indices.
[35] The commutation relations are $[J_i,J_j]=-\frac{1}{2}\epsilon_{ijk}J_k$. These are precisely the commutation relations of the subalgebra formed by the $\frac{1}{2}t_0^i$.
[36] In the bosonic case, a vertex operator is characterized uniquely by its action on a vacuum, and can be defined by $\phi(z)|0\rangle=\exp(zL_{-1})|\phi\rangle$. On a supercomplex plane, this can be generalized to $\Phi(Z)|0\rangle=\exp(zL_{-1})\exp(\theta_1 G^1_{-(1/2)})\cdots\exp(\theta_N G^N_{-(1/2)})|\Phi\rangle$, giving the operator associated with a state.
[37] The author thanks M. Dörrzapf for checking these relations.
[38] More precisely, these come from an ungraded involution on the algebra. On any representation of the algebra that admits a Hermitian contragredient form, this involution then gives the adjoint with respect to that form.

Cyclic statistics in three dimensions

Sumati Surya[a)]

(Received 7 October 2003; accepted 10 March 2004; published online 18 May 2004)

The existence of anyons in two-dimensional systems is a well-known example of nonpermutation group statistics. In higher dimensions, however, it is expected that statistics is dictated solely by representations of the permutation group. Using basic elements from representation theory we show that this expectation is false in three-dimensions for a certain nongravitational system. Namely, we demonstrate the existence of "cyclic," or $\mathbb{Z}_n$, *nonpermutation group* statistics for a system of $n>2$ identical, unknotted rings embedded in $\mathbb{R}^3$. We make crucial use of a theorem due to Goldsmith in conjunction with the Fuchs–Rabinovitch relations for the automorphisms of the free product group on n elements. © *2004 American Institute of Physics.* [DOI: 10.1063/1.1738189]

I. INTRODUCTION

It is a well-established fact that the topology of the configuration space of a classical system can have a nontrivial effect on its quantization. A simple illustration of this is found in the sum-over-histories quantization of a particle on a circle wherein the set of paths with fixed initial and final positions fall into classes labeled by the winding number m.[1] The full partition function is expressed as a sum of partitions over these different classes of paths, each multiplied by an overall phase $e^{im\theta}$, where $\theta\in[0,2\pi]$ labels the unitary irreducible representations of the fundamental group $\mathbb{Z}$ of the circle. Each choice of θ thus leads to an inequivalent quantization of the system. In general, inequivalent quantizations of a classical system are labeled by the unitary irreducible representations of the fundamental group of the configuration space. Indeed, several phenomena of physical interest ranging from the quantum statistics of point particles, to a Hamiltonian interpretation of the QCD theta angle, to spinorial states in quantum gravity, can be attributed to such inequivalent quantizations.[2–6]

The particular phenomenon of interest to us in this paper is the emergence of quantum statistics in systems of n identical objects. For spatial dimensions $d>2$, the fundamental group of the configuration space of such systems contains the permutation group on n elements S_n as a subgroup. For typical systems, the unitary irreducible representations of S_n and its permutation subgroups are sufficient to determine quantum statistics. For $n=2$, $d>2$, for example, the permutation group S_2 generated by the exchange operation $\mathcal{E}$ has two inequivalent unitary irreducible representations: The trivial one ($\mathcal{E}\rightarrow 1$) corresponds to bose statistics and the nontrivial one ($\mathcal{E}\rightarrow -1$) corresponds to fermi statistics. For $n>2$, $d>2$, S_n has nonabelian unitary irreducible representations which give rise to parastatistics. In dimension $d=2$, however, statistics is dictated by a nonpermutation infinite discrete group called the braid group B_n, rather than the finite group S_n. The resulting statistics is referred to as "anyonic" and plays a central role in the study of two-dimensional systems.[5,6]

Since the permutation group S_n is always a subset of the fundamental group of the configuration space for $d>2$, it is generally believed that quantum statistics is dictated by a nonpermutation group only in two-dimensions. However, for $d>2$ quantum statistics does not merely depend on the existence of the permutation group S_n as a subgroup of the fundamental group

a)Electronic mail: ssurya@rri.res.in

$\pi_1(\mathcal{Q}_n)$ of the configuration space $\mathcal{Q}_n$, but more crucially on how it "sits" in $\pi_1(\mathcal{Q}_n)$.[7] Typically, for a system of n identical objects, $\pi_1(\mathcal{Q}_n)$ has the semidirect product structure $P \ltimes S_n$, with $\ltimes$ the semidirect product and P a normal subgroup. Standard representation theory[7,8] then tells us that quantum statistics is determined not by unitary irreducible representations of S_n, but rather those of the little groups (or stability subgroups) $\mathcal{R} \subseteq S_n$ with respect to the action of S_n on the space of representations of P.

For most systems the little groups are themselves permutation subgroups S_m of S_n, with $m \leqslant n$. This can be traced to the fact that the normal subgroup P is generated only by the "internal" symmetry groups K of each object and is simply the product of n copies of K. Representation theory then tells us that the little group $\mathcal{R}$ must be a permutation subgroup of S_n.[7,8] For example, consider a system of 3 identical extended solitons which are allowed to possess spin, i.e., a 2π rotation of the soliton is nontrivial (see Ref. 9 for an example). The permutation group on 3 elements, S_3 is a subgroup of $\pi_1(\mathcal{Q}_3) = P \ltimes S_3$, where for concreteness, P can be identified with the spin subgroup $\mathbb{Z}_2 \times \mathbb{Z}_2 \times \mathbb{Z}_2$, each $\mathbb{Z}_2$ factor representing the spin subgroup of a single soliton. Even though the solitons are classically identical, one can construct the representation $\{1/2,1/2,0\}$ of P in which two of the solitons are spin half and the third one is spin zero, thus rendering it quantum mechanically distinguishable from the others. As one might expect, the little group $\mathcal{R} \subseteq S_3$ associated with P is S_2 and not S_3, thus implying 2 rather than 3 particle quantum statistics.

In this paper, we will explicitly construct a nongravitational example in which the normal subgroup P does not have a simple product structure, and thus does indeed admit nonpermutation little groups $\mathcal{R} \subset S_n$. Namely, we will construct quantum sectors for a system of n closed, identical unknotted rings embedded in $\mathbb{R}^3$, for which $\mathcal{R}$ is a cyclic group, so that the associated quantum statistics is *cyclic*. An analogy was made between this system and that of n $\mathbb{R}P^3$ geons in $3+1$ canonical quantum gravity by the authors of Ref. 10; drawing on earlier results of Ref. 2 they demonstrated the existence of quantum sectors exhibiting indeterminate statistics when $n=2$. [A reanalysis of these sectors for 2 $\mathbb{R}P^3$ geons shows that this ambiguity is due to the lack of a canonical exchange operator (Ref. 7). Such indeterminate statistics have also been found for a system of two particles on $\mathbb{R}P^3$.] In Ref. 7 a rigorous analysis of the quantum sectors for a system of n topological geons in $3+1$ canonical quantum gravity was carried out and the existence of sectors obeying cyclic, or $\mathbb{Z}_n$ statistics was demonstrated for a system of n $\mathbb{R}P^3$ geons. Here, we will employ techniques developed in Ref. 7 to demonstrate the existence of cyclic statistics (an analogue of cyclic statistics in five-dimensions has been constructed in Ref. 12) for the system of $n \geqslant 3$ closed rings embedded in $\mathbb{R}^3$. Rings can appear in a wide class of physical systems, ranging from closed string theory, to cosmic strings, to closed superconducting flux tubes, to name a few. Recently, the existence of ring-like solitons was shown for certain nonlinear sigma models.[11] The existence of kinematical sectors exhibiting novel statistics in such systems may therefore have nontrivial physical implications.

The inequivalent quantizations for this system of rings are determined by the unitary irreducible representations of the so-called *motion group* $\mathcal{G}$ which we present in Sec. II. Using a theorem due to Goldsmith,[13] combined with the Fuchs–Rabinovitch relations for the automorphisms of the free product group on n elements,[14] we show that $\mathcal{G}$ has a nested semidirect product structure. In Sec. III, using Mackey's theory of induced representations,[8] we construct quantum sectors which exhibit cyclic statistics in a system of $n > 2$ rings. We end with some brief remarks in Sec. IV on the question of modeling cyclic statistics using string Lagrangians with topological terms.

Since the spin of the rings we consider is trivial, the sectors obeying cyclic statistics clearly violate the spin-statistics connection. In Ref. 15 a spin-statistics correlation was shown to hold when the configuration space is expanded to allow the creation and annihilation of rings, thus excluding nonpermutation group statistics. However, first quantized systems with ring-like structures could very well occur in condensed matter systems; as suggested in Ref. 10, the rings can be stabilized against creation and annihilation by carrying conserved charges. Whether sectors obeying cyclic statistics are physically realized or not is, of course, ultimately a question for experiment to decide.

II. THE MOTION GROUP FOR A SYSTEM OF *n* RINGS

We consider the system of n identical, nonintersecting, infinitely thin, unknotted, unlinked, unoriented rings, $C=C_1\cup C_2\cup\cdots\cup C_n$ in $\mathbb{R}^3$, which cannot be destroyed or created. The configuration space $\mathcal{Q}_n$ for this system of rings is the space of embeddings of C in $\mathbb{R}^3$ quotiented by an appropriate group of symmetries called the *motion group* $\mathcal{G}$ which we will define below. An obvious example of a symmetry is the exchange of a pair of identical rings. The fundamental group of $\mathcal{Q}_n$ for this system is isomorphic to the motion group $\mathcal{G}$. This group is nontrivial for all $n\geqslant 1$, and has been extensively studied by Dahm and Goldsmith.[13]

Since the configuration space $\mathcal{Q}_n$ is multiply connected, on quantization, the Hilbert space splits into inequivalent quantum sectors. A systematic study of such quantum sectors can be found in Ref. 4. The wave functions $\psi:\tilde{\mathcal{Q}}_n\rightarrow\mathbb{C}$, where $\tilde{\mathcal{Q}}_n$ is the universal cover of $\mathcal{Q}_n$, so that $\pi_1(\mathcal{Q}_n)$ acts nontrivially on ψ. Since physically measurable quantities like inner products should only be functions on the classical configuration space $\mathcal{Q}_n$, the action of $\pi_1(\mathcal{Q}_n)$ on ψ must be represented as a "phase," which can be nonabelian for $n\geqslant 2$. Thus, at every point $q\in\mathcal{Q}_n$, ψ is valued in the carrier spaces of the unitary irreducible representations of $\pi_1(\mathcal{Q}_n)$. The inequivalent unitary irreducible representations of $\pi_1(\mathcal{Q}_n)$ then correspond to inequivalent quantum sectors.

The motion group $\mathcal{G}$ for this system of rings is defined as follows.[13] Let $H(\mathbb{R}^3)$ denote the space of continuous maps or homeomorphisms of $\mathbb{R}^3$ into itself and $H(\mathbb{R}^3,C)$ the subspace of homeomorphisms which leave C invariant. Let $H_\infty(\mathbb{R}^3)$ and $H_\infty(\mathbb{R}^3,C)$ be subspaces of $H(\mathbb{R}^3)$ and $H(\mathbb{R}^3,C)$, respectively, consisting of homeomorphisms with compact support. A *motion* is then defined as a path h_t in $H_\infty(\mathbb{R}^3)$ such that h_0 is the identity map from $\mathbb{R}^3$ to itself and $h_1=H_\infty(\mathbb{R}^3,C)$. The product of two motions can then be defined and the inverse g^{-1} of the motion g is the path $g_{(1-t)}\circ g_1^{-1}$.[13] Two motions h,h' are taken to be equivalent if $h'^{-1}h$ is homotopic to a path which lies entirely in $H_\infty(\mathbb{R}^3,C)$. The motion group $\mathcal{G}$ is then the set of equivalence classes of motions of C in $\mathbb{R}^3$ with multiplication induced by "$\circ$" (for brevity of expression we will henceforth refer to an equivalence class of motions as a motion).

We will use Hendricks' definition of a rotation[16] to describe the generators of the motion group. A 3-ball $\mathbb{B}^3\subset\mathbb{R}^3$ will be said to be rotated by an angle α in the following sense: take a collar neighborhood $S^2\times[0,1]$ of $\partial\mathbb{B}^3\approx S^2$ and let the S^2's be differentially rotated from 0 to α with $S^2\times\{0\}=\partial\mathbb{B}^3$ rotated by α and $S^2\times\{1\}$ not rotated at all. The rotation by an angle α of a solid torus $U=\mathbb{B}^2\times S^1$ in the direction of its noncontractible circle S^1 is similarly defined as a differential rotation of a collar neighborhood $T^2\times[0,1]$ of $\partial U\approx T^2$, with $T^2\times\{0\}=\partial U$ rotated by α and $T^2\times\{1\}$ not rotated at all.

$\mathcal{G}$ is generated by three types of motions which are quite easily visualized.[13] The first is the flip motion f_i which corresponds to "flipping" the ith ring (in the case of oriented rings, this motion yields a configuration distinct from the first and is not a symmetry). This motion corresponds to a rotation by π of an open ball in $\mathbb{R}^3$ containing C_i, about an axis lying in the plane of C_i. Since the rings are embedded in three dimensions, $f_i^2=e$, so that each flip generates a $\mathbb{Z}_2$ subgroup. Next is the exchange motion e_i which exchanges the ith ring with the $(i+1)$th ring. This can be thought of as a π rotation of a solid torus in $\mathbb{R}^3$ containing both C_i and C_{i+1} (but no others). These motions generate the permutation group S_n. Finally, one has the slide motion s_{ij} which requires a slightly more detailed description. A point in the configuration space (i.e., $\mathbb{R}^3-C$ modulo the action of the motion group) is itself a multiply connected space with $\pi_1(\mathbb{R}^3-C)$ isomorphic to the free product group on n generators $F(x_1,x_2\ldots,x_n)\approx\mathbb{Z}*\mathbb{Z}*\cdots*\mathbb{Z}$, each factor of $\mathbb{Z}$ isomorphic to the fundamental group of a single ring in $\mathbb{R}^3$. s_{ij} is then the motion of C_i along one of these $\mathbb{Z}$ factors, specifically, the generator of $\mathbb{Z}\subset\pi_1(\mathbb{R}^3-C)$ passing through C_j. Again, one can define the slide using a rotation: Consider a solid torus containing C_i and "threading" C_j, without intersecting it. A slide is then a 2π rotation of this solid torus. The existence of slide motions is key to the present analysis, and is what makes the analogy with the system of topological geons explicit.

We denote the three subgroups generated by the flips, the exchanges and the slides as $\mathcal{F}$, S_n and $\mathcal{S}$, respectively. We will also need to identify the subgroup $\tilde{\mathrm{G}}$ generated by only the flips and

the exchanges. The structure of S_n is known: It is simply the permutation group on n elements. However, the structures of $\mathcal{F}$ and $\mathcal{S}$ need to be deduced, as does information on how these groups sit in $\mathcal{G}$. While the generators of $\mathcal{G}$ have been known for some years, its explicit structure in terms of these subgroups has not been obtained until now.

Definition: A group G is said to be a semidirect group $P \ltimes K$ if (a) $\forall g \in G$, $\exists p \in P$ and $k \in K$ such that $g = pk$ (b) P is normal in G and (c) $P \cap K = e$. For every fixed $k \in K$, $p \to kpk^{-1}$ generates an automorphism α_k of P. G is said to have a nested semidirect product structure if further, either K or P or both, themselves are semidirect product groups.

We now show that $\mathcal{G}$ has the nested semidirect product structure

$$\mathcal{G} = \mathcal{S} \ltimes (\mathcal{F} \ltimes S_n). \tag{1}$$

We also show that $\mathcal{S}$ is the nonabelian group made up of the free product group on $n(n-1)$ generators

$$\underbrace{\mathbb{Z} * \mathbb{Z} * \cdots * \mathbb{Z}}_{n(n-1)}, \tag{2}$$

subject to the conditions

$$s_{ij} s_{kl} = s_{kl} s_{ij}, \quad s_{ij} s_{kj} = s_{kj} s_{ij}, \quad s_{ik} s_{jk} s_{ij} = s_{ij} s_{ik} s_{jk}. \tag{3}$$

$\mathcal{F}$, on the other hand, can be shown to be the abelian group isomorphic to the direct product group of the $\mathbb{Z}_2$ flips of each ring

$$\mathcal{F} = \underbrace{\mathbb{Z}_2 \times \mathbb{Z}_2 \times \cdots \times \mathbb{Z}_2}_{n}. \tag{4}$$

For brevity of notation we define the exchange action π_i on the set of n integers labeling the n rings as follows: For $1 \leqslant j \leqslant n$, $\pi_i : j \to \pi_i(j)$ where $\pi_i(j) = j$ for $j \neq i, i+1$, $\pi_i(i) = i+1$ and $\pi_i(i+1) = i$. Here when $i = n$, $i+1$ is identified with 1.

Lemma: $\mathcal{G}$ has the nested semidirect product structure (1). Thus, $\mathcal{S}$ is normal in $\mathcal{G}$ and $\mathcal{F}$ is normal in the subgroup $\tilde{\mathrm{G}} \subset \mathcal{G}$ generated by the flips and the permutations. The automorphisms of $\mathcal{S}$ generated by $\tilde{\mathrm{G}}$ and those of $\mathcal{F}$ generated by S_n are given by the Fuchs–Rabinovitch relations, induced by the Dahm isomorphism $D : \mathcal{G} \to \overline{\mathcal{G}} \subseteq Aut(F(x_1, \ldots, x_n))$ where $Aut(F(x_1, \ldots, x_n))$ is the group of automorphisms of $F(x_1, \ldots, x_n)$. Moreover, $\mathcal{S}$ is isomorphic to the group (2) subject to the conditions (3), and $\mathcal{F}$ is isomorphic to the group (4).

Proof: The induced action of the motion group on $\pi_1(\mathbb{R}^3 - C)$ has been examined by Goldsmith,[13] and provides us with a crucial step in deducing the structure of $\mathcal{G}$. As noted earlier, $\pi_1(\mathbb{R}^3 - C)$ is isomorphic to $F(x_1, \ldots, x_n)$, the free product group on n-generators, x_i, $i = 1, \ldots, n$. In Ref. 13 the "Dahm" homomorphism $D : \mathcal{G} \to Aut(F(x_1, \ldots, x_n))$ is defined where $Aut(F(x_1, \ldots, x_n))$ is the group of automorphisms of $F(x_1, \ldots, x_n)$. For each motion $g \in \mathcal{G}$, D induces an automorphism of $F(x_1, \ldots, x_n)$. The following theorem then states:

Goldsmith's Theorem:[13] The group of motions $\mathcal{G}$ of the trivial n-component link C in $\mathbb{R}^3$ is generated by the following types of motions:

(1) f_i or flips. Turn the ith ring over. This induces the automorphism $\phi_i : x_i \to x_i^{-1}$, $x_k \to x_k$, $k \neq i$, of $F(x_1, \ldots, x_n)$.
(2) e_i or exchange. Interchange the ith and the $(i+1)$th rings. The induced automorphism of $F(x_1, \ldots, x_n)$ is $\epsilon_i : x_i \to x_{i+1}, x_{i+1} \to x_i$ and $x_k = x_k$ for $k \neq i, i+1$.
(3) s_{ij} or slides. Pull the ith ring through the jth ring. This induces the automorphism $\sigma_{ij} : x_i \to x_j x_i x_j^{-1}$, $x_k \to x_k$, $k \neq i$, of $F(x_1, \ldots, x_n)$.

Moreover, the Dahm homomorphism, $D : \mathcal{G} \to Aut(F(x_1, \ldots, x_n))$ is an isomorphism onto the subgroup $\overline{\mathcal{G}}$ of $Aut(F(x_1, \ldots, x_n))$ generated by ϕ_i, ϵ_i and σ_{ij}, where $1 \leqslant i, j \leqslant n, i \neq j$.

Let us denote the subgroups of $\overline{\mathcal{G}}$ generated by the automorphisms σ_{ij}, ϕ_i and ϵ_i as $\overline{\mathcal{S}}$, $\overline{\mathcal{F}}$ and $\overline{\mathrm{S}_n}$, respectively. We may now employ the Fuchs–Rabinovitch relations for $Aut(F(x_1,\ldots,x_n))$ which provides a complete set of relations for the generators of $\overline{\mathcal{G}}$.[14] For $\pi_1(\mathbb{R}^3-C)=\mathbb{Z}*\mathbb{Z}*\cdots*\mathbb{Z}$, in particular, these relations are simple and imply that $\overline{\mathcal{G}}\subset Aut(F(x_1,\ldots,x_n))$ has the nested semidirect product structure

$$\overline{\mathcal{G}}=\overline{\mathcal{S}}\ltimes(\overline{\mathcal{F}}\ltimes\overline{\mathrm{S}_n})=\overline{\mathcal{S}}\ltimes\bar{\bar{\mathrm{G}}}, \tag{5}$$

where $\bar{\bar{\mathrm{G}}}=\overline{\mathcal{F}}\ltimes\overline{\mathrm{S}_n}$. In particular, the generators ϵ_i of $\overline{\mathrm{S}_n}$ generate the following automorphisms of $\overline{\mathcal{F}}$:

$$\epsilon_i\phi_j\epsilon_i^{-1}=\phi_{\pi_i(j)}, \tag{6}$$

and the generators ϵ_i and ϕ_i of $\bar{\bar{\mathrm{G}}}$ generate the following automorphisms of $\overline{\mathcal{S}}$:

$$\begin{aligned}\epsilon_i\sigma_{jk}\epsilon_i^{-1}&=\sigma_{\pi_i(j)\pi_i(k)},\\ \phi_i\sigma_{jk}\phi_i^{-1}&=\sigma_{jk},\forall k\neq i,\\ \phi_i\sigma_{ji}\phi_i^{-1}&=\sigma_{ji}^{-1}.\end{aligned} \tag{7}$$

Moreover, these relations imply that $\overline{\mathcal{S}}$ is the free product group on $n(n-1)$ generators $\mathbb{Z}*\mathbb{Z}*\cdots*\mathbb{Z}$ subject to the conditions $\sigma_{ij}\sigma_{kl}=\sigma_{kl}\sigma_{ij}$, $\sigma_{ij}\sigma_{kj}=\sigma_{kj}\sigma_{ij}$, and $\sigma_{ik}\sigma_{jk}\sigma_{ij}=\sigma_{ij}\sigma_{ik}\sigma_{jk}$ while $\overline{\mathcal{F}}$ is the abelian direct product group made up of n factors of $\mathbb{Z}_2$, $\overline{\mathcal{F}}=\mathbb{Z}_2\times\mathbb{Z}_2\times\cdots\times\mathbb{Z}_2$. Since D is an isomorphism with $D(\mathcal{S})\subseteq\overline{\mathcal{S}}$, $D(\mathcal{F})\subseteq\overline{\mathcal{F}}$ and $D(S_n)\subseteq\overline{\mathrm{S}_n}$, this means that $\mathcal{S}\approx\overline{\mathcal{S}}$, $\mathcal{F}\approx\overline{\mathcal{F}}$ and $S_n\approx\overline{\mathrm{S}_n}$. From (5), it is then obvious that $\mathcal{G}$ itself has the nested semidirect product structure (1). The automorphisms of S_n on $\mathcal{F}$ and of $\tilde{\mathrm{G}}$ on $\mathcal{S}$, respectively, are given by (6) and (7) and induced by the isomorphism $D:\mathcal{G}\rightarrow\overline{\mathcal{G}}$. Moreover, $\mathcal{S}$ is the free product group on $n(n-1)$ generators $\mathbb{Z}*\mathbb{Z}*\cdots*\mathbb{Z}$ subject to the relations (3) and $\mathcal{F}$ is given by (4). □

While the structure of the motion group can be completely deduced from the Dahm homomorphism and the Fuchs–Rabinovitch relations, it is instructive to examine this group without recourse to $Aut(F(x_1,\ldots,x_n))$. Using just the definition of the motion group we now illustrate the following properties of $\mathcal{G}$: (a) $\mathcal{S}$ is normal in $\mathcal{G}$ and satisfies the relations (3) and (b) that $\mathcal{F}$ is normal in $\tilde{\mathrm{G}}$.

By definition, an element of the motion group is a homotopy equivalence class of paths in the space of homeomorphisms with compact support. Two homeomorphisms h_1 and h_2 with compact support on the regions U_1 and U_2 commute if $U_1\cap U_2=\phi$ and hence so do the corresponding motions. It is, therefore, useful to isolate the "minimal" neighborhoods in which homeomorphisms representing the generators of the motion group act so as to determine which two motions commute.

Let U_i denote an open ball neighborhood of C_i in $\mathbb{R}^3$ which contains no other C_j, $j\neq i$, and let U_{ij} denote an open ball neighborhood of $C_i\cup C_j$ containing no other C_k, $k\neq i,j$, etc. We will refer to the U_i as "exclusive" neighborhoods and the $U_{ij}, U_{ijk},\ldots$, etc. as "common" neighborhoods. The flip motion f_i is then defined by a homotopy equivalence class of paths in $H_\infty(\mathbb{R}^3)$ which include a "model" path made up of homeomorphisms with support only on U_i, i.e., a path in $H_\infty(\mathbb{R}^3)$ along which C_i is flipped without disturbing any of the other rings. Next, the exchange motion e_i is defined by a homotopy equivalence class of paths including a model path made up of homeomorphisms with support only on $U_{i(i+1)}$, i.e., the ith and the $(i+1)$th ring are exchanged without disturbing the other rings. Finally, the slides s_{ij} are defined by a homotopy equivalence class of paths including a model path with support only on U_{ij}, i.e., a path in which the other rings are not disturbed.

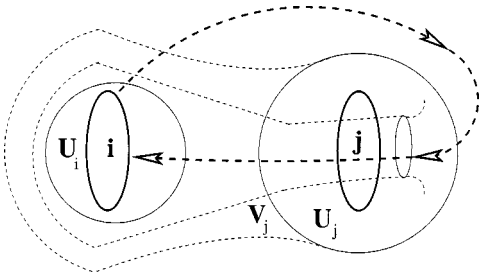

FIG. 1. Under the slide s_{ij} C_i "tunnels" through the neighborhood U_j of C_j and maps it onto the region V_j, shown by dashed lines. V_j, therefore, "encloses" C_i without containing it, i.e., $U_i \cap V_j = \phi$.

Now, the set of exclusive neighborhoods $\{U_i\}$ remains invariant when acted upon by the subgroup $\tilde{\mathrm{G}}$ generated by the flips and by the exchanges. This is obvious for $\mathcal{F}$, since each flip f_i acts within an exclusive neighborhood. For S_n, while the exchange e_i has compact support on $U_{i(i+1)}$, its action can be considered as a pure exchange of U_i with U_{i+1}. Thus, one can consider as a model path for the exchange, a localized π rotation in $U_{i(i+1)}$ which exchanges U_i with U_{i+1}. This, however, is not the case with the slides s_{ij}. While the set $\{U_k\}$ for $k \neq j$ remains invariant under the slide s_{ij} of C_i through C_j, the exclusive neighborhood U_j does not. The nonlocal action of the slide takes U_j into a set V_j which "encloses" C_i even though it does not contain it, i.e., there exists a U_i such that $U_i \cap V_j = \phi$ (see Fig. 1). Thus, V_j is not an exclusive neighborhood of C_j. This feature leads to subtleties in what follows.

Since the exchanges and the flips leave the set $\{U_i\}$ invariant, model paths are sufficient to see that $\mathcal{F}$ is normal in $\tilde{\mathrm{G}}$, i.e., for all $\tilde{g} \in \tilde{\mathrm{G}}$, $i \leqslant n$, $\tilde{g} f_i \tilde{g}^{-1} \in \mathcal{F}$. To show this, it is sufficient to take $\tilde{g}$ to be an exchange. For the motion $e_i f_j e_i^{-1}$ with $j \neq i, i+1$, the model paths for e_i and f_j have compact support on $U_{i(i+1)}$ and U_j, respectively, where $U_{i(i+1)} \cap U_j = \phi$. Hence the motions commute, so that $e_i f_j e_i^{-1} = f_j$. Now consider the motion $e_i f_i e_i^{-1}$. The model paths for e_i^{-1} exchange U_i with U_{i+1}. One can then use a model path for the motion f_i which acts on some $U'_{i+1} \subset U_{i+1}$ so that the final exchange e_i which exchanges U_{i+1} with U_i does not disturb the action of f_i on U'_{i+1}. Thus, $e_i f_i e_i^{-1} = f_{i+1}$. Similarly, $e_i f_{i+1} e_i^{-1} = f_i$.

However, model paths are insufficient when one wants to deal with the slides. Let us consider a motion whose model path involves homeomorphisms with support only on the compact region U. The homotopy class of paths defining this motion also includes the nonmodel, or "gregarious" paths, which involve homeomorphisms with nontrivial compact support on $\mathbb{R}^3 - U$. In other words, gregarious paths *can* disturb the other rings; they can contain homeomorphisms with nontrivial support on neighborhoods of rings left undisturbed by the model path. Consider the motion f_i for simplicity. A model path for f_i has support only on U_i and corresponds to a π rotation about an axis in the plane of C_i. A gregarious path on the other hand can be constructed piecewise as follows: (a) Rotate C_i by $\pi/3$, about an axis $\hat{x}$ in its plane; (b) flip another C_j, $j \neq i$; (c) rotate C_i by a further $\pi/3$ about $\hat{x}$ in the same sense as before; (d) flip C_j again; (e) and complete with a further $\pi/3$ rotation of C_i about $\hat{x}$ in the same sense as before. Such a path clearly corresponds to the motion f_i, but involves homeomorphisms of $\mathbb{R}^3$ in $H_\infty(\mathbb{R}^3)$ which have nontrivial support on the ring C_j, $j \neq i$.

Both model and gregarious paths are necessary to demonstrate that $\mathcal{S}$ is normal in $\mathcal{G}$. $\mathcal{S}$ is a normal subgroup of $\mathcal{G}$ if $\forall g \in \mathcal{G}$ and $\forall i,j \leqslant n$ $g s_{ij} g^{-1} \in \mathcal{S}$. It is sufficient to take g to be a generator of S_n or $\mathcal{F}$.

We begin with the exchanges. Let us examine the motion $e_k s_{ij} e_k^{-1}$ by considering only model paths in the appropriate homotopy class. For $k \neq i,j$ $e_k s_{ij} e_k^{-1} = s_{ij}$, since the homeomorphisms that make up model paths for e_k and s_{ij} have compact supports on U_k and U_{ij} with $U_k \cap U_{ij} = \phi$. Model paths are, however, insufficient to show that $e_k s_{ij} e_k^{-1}$ is also a slide for $k = i$, $i-1$, j or $j-1$. Consider the motion $e_j s_{ij} e_j^{-1}$ with $k = j$, $i \neq j, j+1$. e_j^{-1} swaps U_j with U_{j+1} by a π rotation of a torus containing both U_j and U_{j+1}. Next, s_{ij} rotates by 2π a solid torus containing

C_i and threading C_{j+1}, thus mapping U_{j+1} into a nonexclusive neighborhood V_{j+1}. A model path for the final exchange e_j would rotate by π a solid torus containing new exclusive neighborhood U'_{j+1} of C_{j+1} and U_i. $U_{i(j+1)}$ in which the slide acts, is not left invariant by this final exchange, making the resultant motion difficult to unravel. Instead, we use the following gregarious path to perform the final exchange: consider a path in $H_\infty(\mathbb{R}^3)$ where $U_{i(j+1)}$ and U_j are swapped by performing an appropriate π rotation in the common neighborhood $U_{ij(j+1)}$ of C_i, C_j and C_{j+1}. The final exchange motion is then completed by merely moving C_i back to its original position. $U_{i(j+1)}$ is thus left undisturbed so that the full motion is the slide $s_{i(j+1)}$. A use of a similar gregarious path for the final exchange shows that $e_{(j-1)}s_{ij}e^{-1}_{(j-1)}=s_{i(j-1)}$, $e_i s_{ij} e_i^{-1} = s_{(i+1)j}$ and $e_{(i-1)}s_{ij}e^{-1}_{(i-1)}=s_{(i-1)j}$.

Next, consider the flips. The motion $f_k s_{ij} f_k^{-1}$ can again be examined using only model paths for $k\neq j$, and we can see that it is s_{ij}. This is because the model path for f_k has compact support only on U_k which is undisturbed by the slide even when $k=i$. However, the use of model paths is insufficient to examine the motion $f_j s_{ij} f_j^{-1}$: not only does U_j not remain an exclusive neighborhood under the slide s_{ij}, but the f_j moves the points in U_j relative to each other. Rather than consider just a single gregarious path, following Ref. 7, we use a particular set of homotopy equivalent paths. Let κ be the generator of $\pi_1(\mathbb{R}^3-C)$ through C_j about which the slide s_{ij} takes C_i. We define the paths γ_α as follows: (a) perform a "part" inverse flip corresponding to a $(\pi-\alpha)$ rotation of C_j about $\hat{x}$ (b) slide C_i through C_j along κ^{-1} (c) finish the inverse flip f_j^{-1} of C_j by a rotation α about $\hat{x}$ and (d) finally, perform the flip f_j of C_j about $\hat{x}$. γ_0 then corresponds to the model path for the motion $f_j s_{ij} f_j^{-1}$ while the path γ_π corresponds to the slide s_{ij}^{-1}. Since α is a continuous parameter $\alpha\in[0,\pi]$, the γ_α provide a homotopy map from γ_0 to γ_π, which implies that $f_j s_{ij} f_j^{-1}=s_{ij}^{-1}$ (it is perhaps a useful exercise for the reader to see why a similar argument cannot be used to find a set of homotopic paths between $s_{ij}f_j s_{ij}^{-1}$ and an element of $\mathcal{F}$).

Thus, the slide subgroup $\mathcal{S}$ is a normal subgroup of $\mathcal{G}$.

We can also demonstrate that the relations (3) are satisfied by $\mathcal{S}$, using just the definition of the motion group. The first of these relations is clearly satisfied by the generators of $\mathcal{S}$, since the model paths corresponding to the slides s_{ij} and s_{kl} involve homeomorphisms with compact support only on U_{ij} and U_{kl} where $U_{ij}\cap U_{kl}=\phi$. It takes a little more work to show that the other two relations are also satisfied by the generators of $\mathcal{S}$.

Consider the motion $s_{ij}s_{kj}s_{ij}^{-1}$. s_{ij} and s_{kj} are slides of the two rings C_i and C_k through a third ring C_j. These slides are obtained by 2π rotations of the solid tori $V_{ij}\approx B^2\times S^1$ and $V_{kj}\approx B^2\times S^1$ which thread through C_j, with $V_{ij}\cap V_{kj}=\phi$. Define the paths γ_α as follows: (a) A rotation by $-\alpha$ of V_{ij}; (b) a 2π rotation of V_{kj}; (c) a $-(2\pi-\alpha)$ rotation of V_{ij} and finally; (d) a 2π rotation of V_{ij}. γ_0 then defines a model path for the motion $s_{ij}s_{kj}s_{ij}^{-1}$, and $\gamma_{2\pi}$ corresponds to the slide s_{kj}. Since α is a continuous parameter, γ_0 is homotopic to $\gamma_{2\pi}$ and hence also corresponds to s_{kj}. Notice that by keeping $V_{ij}\cap V_{kj}=\phi$ we prevent a mixing of their rotations and hence the deformations of the neighborhood U_j by s_{ij} and by s_{kj}.

Next, consider the motion $s_{ij}s_{ik}s_{jk}s_{ij}^{-1}$. Although this looks considerably more complicated than the previous motion, the two elements of $\mathcal{S}$ involved, $s_{ik}s_{jk}$ and s_{ij}, have compact supports on nonintersecting neighborhoods. Namely, the element $s_{ik}s_{jk}$ corresponds to sliding C_j through a generator ρ of π_1 of C_k and then sliding C_i through the same generator. Under this action, $U_j\rightarrow U_j$ and $U_i\rightarrow U_i$, while U_k is now mapped to a region V_k which now "encloses" both C_i and C_j. Thus, there exists a path in $H_\infty(\mathbb{R}^3)$ corresponding to the motion $s_{ik}s_{jk}$ made up of homeomorphisms which leave the common neighborhood U_{ij} undisturbed. Since there is a model path corresponding to the slide s_{ij} which has compact support only on U_{ij}, this means that the two motions $s_{ik}s_{jk}$ and s_{ij} indeed commute. Thus, the generators of $\mathcal{S}$ satisfy all the relations (3).

Remark: In Ref. 10 a set of relations for the generators in the $n=2$ case was given: $f_i^2=\mathcal{E}^2=(f_i\mathcal{E})^4=(f_i\mathcal{E}s_j\mathcal{E})^2=e$ where $i=1,2$ and the slides s_i generate $\mathcal{S}$, the flips f_i generate $\mathcal{F}$ and the exchange $\mathcal{E}$ generates S_2. These follow in a straightforward manner from the relations presented above.

III. CYCLIC STATISTICS

The inequivalent quantum sectors for our system of n identical rings are labeled by the unitary irreducible representations of $\pi_1(\mathcal{Q}_n)\approx\mathcal{G}$. The group $\mathcal{G}$ represents a "gauge" symmetry and the action of the individual motions $g\in\mathcal{G}$ on $\mathbb{R}^3-C$ can be used to interpret the associated quantum phases.

Let us begin by considering the simplest case, namely a single ring for which the motion group $\pi_1(\mathcal{Q})$ is simply $\mathcal{F}=\mathbb{Z}_2$. Let ψ_1 be a wave function on $\tilde{\mathcal{Q}}$ with localized support along the fibre $\{\tilde{q}_1,\tilde{q}_2\}$ at $q\in\mathcal{Q}$, generated by the action of the flip f, i.e., $\tilde{q}_1\rightarrow\tilde{q}_2=f\circ\tilde{q}_1$. Under the action of f, $\psi_1\rightarrow\psi_2$, which is also localized on the fibre at q. Since wave functions take values in the carrier spaces of the irreducible representations of $\pi_1(\mathcal{Q})$, $\psi_2=\Delta(f)\circ\psi_1$, where Δ is a unitary irreducible representation of $\mathcal{F}=\mathbb{Z}_2$. Δ can be either the trivial representation $\Delta(f)=1$ or the nontrivial one with $\Delta(f)=-1$, the associated quantum sectors corresponding to either an "unoriented" quantum ring in which $\psi_2=\psi_1$ or an "oriented" quantum ring in which $\psi_2=-\psi_1$. (Recall that classically, the rings are unoriented, since flips are a symmetry of the classical configuration space.) When there are two rings, i.e., $n=2$, the motion group includes the permutation group $S_2=\mathbb{Z}_2$ which gives rise to nontrivial quantum statistics. Consider a wave function ψ which is localized along the fibre of a configuration where the two rings are well-separated and identical: Under an exchange operation ψ, therefore, picks up a phase of ±1 corresponding to bosonic/fermionic quantum statistics (see Refs. 2, 4, and 7 for a more detailed discussion of quantum phases and statistics for extended objects). As we will presently demonstrate, for $n>2$ the existence of the slide subgroup in $\pi_1(\mathcal{Q}_n)$ gives rise to an unexpected complexity in the structure of the phases acquired by the wave function under the action of the permutation group.

As mentioned in the introduction, the quantum statistics of a system is not solely determined by S_n, but rather by the unitary irreducible representations of its stability subgroup $\mathcal{R}\subseteq S_N$ associated with its action on the unitary irreducible representations of the normal subgroup $\mathcal{S}\ltimes\mathcal{F}$ of $\mathcal{G}$. This follows from Mackey's theory of induced representations for semidirect product groups $P\ltimes K$.[8] In this construction, one begins with the space of unitary irreducible representations $\hat{P}$ of the normal subgroup P. The subgroup K has the (not necessarily free) action on $\hat{P}$

$$\Delta(p)\rightarrow\tilde{\Delta}(p)=\Delta(kpk^{-1}), \tag{8}$$

where $\Delta\in\hat{P}$, $p\in P$ and $k\in K$. Starting with a particular $\Delta_1\in\hat{P}$ one obtains an orbit $\mathcal{O}=\{\Delta_1,\Delta_2,\ldots,\Delta_r\}$ of the K action on $\hat{P}$, and the little group $\mathcal{R}$ associated with $\mathcal{O}$. The full unitary irreducible representation of $P\ltimes K$ is then built up by taking the direct product of (a) $[\Delta_1\oplus\Delta_2\oplus\cdots\oplus\Delta_r]$ with (b) a unitary irreducible representation of $\mathcal{R}$. For example, if one starts with the trivial representation of P, then the orbit consists of a single point and $\mathcal{R}=K$. The unitary irreducible representations of $P\ltimes K$ that can be constructed from this orbit are just the unitary irreducible representations of K. On the other hand, one may find an orbit of K in $\hat{P}$ with $\mathcal{R}=e$. The full unitary irreducible representation is then simply the sum of the unitary irreducible representations in the orbit, $\oplus_i\Delta_i$. The action of the subgroup K is then reduced to a canonical map which permutes the carrier spaces $\mathbb{H}_i$ of Δ_i[7] (as discussed in Ref. 7 for $n\geqslant4$ the possibility of projective statistics exists when $\pi_1(Q)$ has a semidirect product structure).

We now illustrate the importance of the little group in determining quantum statistics with a simple example. Because of the nested semidirect product structure of the motion group, we may begin by first representing the slides trivially. We thus need to find only the unitary irreducible representations of the subgroup $\tilde{\mathrm{G}}=\mathcal{F}\ltimes S_n$. Since $\mathcal{F}\approx\mathbb{Z}_2\times\mathbb{Z}_2\times\cdots\times\mathbb{Z}_2$ with n $\mathbb{Z}_2$ factors, it is trivial to list its unitary irreducible representations, i.e., $\Delta\equiv(k_1,k_2,\ldots,k_n)$, with $k_i=\pm1$. For example, for $n=3$, let us start with the unitary irreducible representation $\Delta_1=(-,-,+)$ of the normal subgroup $\mathcal{F}$ of $\tilde{\mathrm{G}}$. This choice corresponds to two of the rings being identical and oriented, while the third is unoriented and hence distinguishable from the others. The action of S_3 on Δ_1

generates the orbit $\{\Delta_1,\Delta_2,\Delta_3\}\equiv\{(-,-,+),(+,-,-),(-,+,-)\}$ in $\hat{\mathcal{F}}$ whose associated little group is S_2. The resulting unitary irreducible representation of $\tilde{\mathrm{G}}$ is then $\{\Delta_1\oplus\Delta_2\oplus\Delta_3\}\otimes\Gamma$, where Γ is a unitary irreducible representation of S_2. Under a two particle exchange Γ provides either a bosonic $(+1)$ or a fermionic (-1) phase. Since one of the three rings has been rendered quantum mechanically distinguishable from the other two, one obtains an appropriate two ring statistics. The action of the remaining elements of S_3, namely the cyclic elements, is canonical: They merely permute the carrier spaces $\mathbb{H}_i$ of the Δ_i. This general structure continues to hold for all n, and is illustrative for the case of primary interest here when the slides are nontrivially represented.

Before proceeding to construct a quantum sector exhibiting cyclic statistics for $n\geqslant 3$, let us consider the simplest case with the slides nontrivially represented, namely when $n=2$. For $n=2$, the slide subgroup is generated by the two slides s_1,s_2, the flip subgroup $\mathcal{F}$ by the two flips f_1,f_2 and the permutation group S_2 by the exchange $\mathcal{E}$. The following example demonstrates a peculiar feature which will reappear for $n>2$, whereby slides render a pair of ''locally identical'' rings distinguishable. Let us start with the abelian unitary irreducible representation of $\mathcal{S}$, $\Omega_1(s_1)=1,\Omega_1(s_2)=-1$. The action of f_j on Ω_1 is $\Omega_1(s_i)\rightarrow\tilde{\Omega}_1(s_i)=\Omega_1(f_j s_i f_j^{-1})=\Omega_1(s_i)$ and is hence contained in the little group $\mathcal{R}$ of $\tilde{\mathrm{G}}$. Under the action of $\mathcal{E}$, $\Omega_1(s_i)\rightarrow\tilde{\Omega}_1(s_i)=\Omega_1(\mathcal{E}s_i\mathcal{E}^{-1})=\Omega_1(s_j)\neq\Omega_1(s_i)$ where $j\neq i$, so that $S_2\subseteq\mathcal{R}$. Thus, the two rings are quantum mechanically distinguishable even if $\mathcal{F}$ is trivially represented. This is very unusual, since indistinguishability of a collection of objects is often thought of as a local, intrinsic property of each object. However, in this representation, it is the nonlocal action of slides which renders the two rings distinguishable: The rings slide through each other differently. Thus, there exists a wave function ψ localized along the fibre of a configuration of two well-separated identical rings such that under the action of s_1, $\psi\rightarrow\psi$ and under that of s_2, $\psi\rightarrow-\psi$. This quantum lifting of indistinguishability by slides is key to the existence of nonpermutation group statistics for $n>2$.

We are now ready to demonstrate cyclic statistics for the case of $n=3$ rings. The slide subgroup $\mathcal{S}$ is generated by the six generators s_{ij}, $i,j=1,2,3$, $i\neq j$, the flip subgroup $\mathcal{F}$ is generated by the 3 elements f_1,f_2,f_3, and the permutations form the nonabelian subgroup S_3. We start with the following abelian unitary irreducible representation Ω_1 of $\mathcal{S}$:

$$\Omega_1(s_{12})=\Omega_1(s_{23})=\Omega_1(s_{31})=-1,\quad \Omega_1(s_{21})=\Omega_1(s_{32})=\Omega_1(s_{13})=1. \tag{9}$$

Consider the action of $\tilde{\mathrm{G}}$ on Ω_1. The action of a flip f_k on Ω_1 for $k=i$ or j is: $\Omega_1(s_{ij})\rightarrow\Omega_1(f_k s_{ij} f_k^{-1})=\Omega_1^{-1}(s_{ij})=\Omega_1(s_{ij})$, while the action of f_k, $k\neq i,j$ is trivial. Thus, $\mathcal{F}$ lies in the stability subgroup of $\tilde{\mathrm{G}}$. Single exchanges e_i however, do not leave Ω_1 invariant: For example, $\Omega_1(s_{i(i+1)})\rightarrow\Omega_1(e_i s_{i(i+1)}e_i^{-1})=\Omega_1(s_{(i+1)i})=-\Omega_1(s_{i(i+1)})$ (where $(i+1)$ is defined mod 3). However, a pair of exchanges does leave Ω_1 invariant! A pair of exchanges, say $z=e_2e_3$, generates the cyclic subgroup Z_3 of S_3. Under the action of e_2e_3 the slides $\{s_{12},s_{23},s_{31}\}\rightarrow\{s_{23},s_{31},s_{12}\}$, and $\{s_{21},s_{32},s_{13}\}\rightarrow\{s_{32},s_{13},s_{21}\}$, thus leaving Ω_1 invariant. Therefore, the stability subgroup associated to Ω_1 is $\mathcal{F}\ltimes\mathbb{Z}_3$. The remaining elements of $\mathcal{F}\ltimes S_3$, namely e_1,e_2, and e_3 generate the two element orbit $\mathcal{O}\equiv\{\Omega_1,\Omega_2\}$ in $\hat{\mathcal{S}}$ the space of unitary irreducible representations of $\mathcal{S}$, where

$$\Omega_2(s_{12})=\Omega_2(s_{23})=\Omega_2(s_{31})=1,\quad \Omega_2(s_{21})=\Omega_2(s_{32})=\Omega_2(s_{13})=-1. \tag{10}$$

The associated unitary irreducible representation of $\mathcal{G}$ is therefore nonabelian, and can be symbolically expressed as

$$(\Omega_1\oplus\Omega_2)\otimes\mathcal{T}, \tag{11}$$

where $\mathcal{T}$ is a unitary irreducible representation of the stability subgroup $\mathcal{F}\ltimes\mathbb{Z}_3$.

Let us for simplicity consider the case when $\mathcal{F}$ is trivially represented in $\mathcal{T}$, so that $\mathcal{T}$ is a unitary irreducible representation of $\mathbb{Z}_3$. $\mathbb{Z}_3$ has two nontrivial inequivalent unitary irreducible

representations (a) $z \to e^{2\pi i/3}$ and (b) $z \to e^{4\pi i/3}$. Thus, wave functions ψ_a, ψ_b on $\tilde{\mathcal{Q}}_3$ take values in the (two-dimensional) carrier spaces $\mathbb{H}_a$ and $\mathbb{H}_b$ of the corresponding quantum sectors. If $\psi_{a,b}$ are localized along the fibre of a configuration of well separated identical rings, under the action of the cyclic permutations they pick up the respective phases $\psi_a \to e^{2\pi i/3}\psi_a$ and $\psi_b \to e^{4\pi i/3}\psi_b$. Thus, these sectors exhibit a cyclic, nonpermutation group, statistics: the rings are identical *only* when permuted by a cyclic combination, and *not* under pair-wise exchange! This is indeed a very curious behavior and is again linked to the nonlocality of slide motions: even though the flips are all trivially represented the slides render the rings pair-wise distinguishable but cyclically indistinguishable. We say that the rings obey $\mathbb{Z}_3$ *cyclic statistics*.

The case for arbitrary $n>2$ follows in a straightforward manner. Namely, we can always isolate a pair of nontrivial subsets from the set of slide generators $\{s_A\}$ and $\{s_B\}$ which are invariant under $\mathbb{Z}_n$. There is a small difference in the construction in the even $n=2m$ and odd $n=2m+1$ cases. For $n=2m$, $\mathbb{Z}_{2m}$ contains the subgroup $\mathbb{Z}_2$; if z is the generator of $\mathbb{Z}_{2m}$ with $z^{2m}=e$, then z^m generates a $\mathbb{Z}_2$ subgroup corresponding to m commuting exchanges. One can then see that the two sets of generators $\{s_A\}$ and $\{s_B\}$ which are invariant under $\mathbb{Z}_{2m}$ have cardinality $2m(m-1)$ and $2m^2$, respectively. For $n=2m+1$, Z_2 is not a subgroup of $\mathbb{Z}_{2m+1}$. Hence the two sets of generators $\{s_A\}$ and $\{s_B\}$ each have cardinality $m(2m+1)$. One can thus obtain $\mathbb{Z}_n$ cyclic statistics for arbitrary $n>2$.

We end this section by commenting on the possibility that sectors with more complicated nonpermutation group statistics may exist. To construct the above cyclic statistics sectors we started with very simple abelian unitary irreducible representations of the slide subgroup. It is conceivable that if one instead started with a nonabelian unitary irreducible representation of $\mathcal{S}$ (with certain symmetries) that the stability subgroup $\mathcal{F}\ltimes K$ associated with it is such that K is nonabelian and a nonpermutation subgroup of S_n. Such a sector would then exhibit a *nonabelian, nonpermutation* group statistics. Our current work provides a framework in which to probe such questions.

IV. REMARKS

Anyonic statistics in $2+1$ dimensions can be modeled by adding a Chern Simon's term to the n particle Lagrangian.[17] In Ref. 10 a stringy generalization of this was developed to obtain nontrivial phases from the action of the motion group, namely a $B\wedge F$ topological term made up of an abelian gauge field and an axion field was added to the n string Lagrangian along with an interaction term. Similar systems have subsequently been studied in Ref. 18. In Ref. 10 it was shown that even though the statistical phases are trivial (i.e., bosonic) the action of the slide subgroup is nontrivial, giving rise to fractional quantum phases. Since slides involve the motion of one ring through a nontrivial generator of the fundamental group of another ring, these fractional phases correspond to Aharnov–Bohm phases rather than to fractional quantum statistics. Indeed, slides can occur between nonidentical particles as well and hence the interpretation of such phases as statistics in Ref. 18 seems questionable. Since cyclic statistics occur in nonabelian sectors of the system, it would be interesting to construct appropriate nonabelian generalizations of Ref. 10 which exhibit this behavior. We leave this problem to future investigations.

We characterize all position and momentum observables on $\mathbb{R}$ and on $\mathbb{R}^3$. We study some of their operational properties and discuss their covariant joint observables.
 [DOI: 10.1063/1.1739296]

I. INTRODUCTION

In the traditional presentation of quantum mechanics, observables are represented by self-adjoint operators or, equivalently, by spectral measures. It is widely recognized that this concept is too narrow. Indeed, spectral measures correspond to measurements with perfect accuracy, never found in real experiments. A less restrictive mathematical formulation of a quantum mechanical observable is a normalized positive operator measure. This generalization allows one, among many other things, to describe measurements with limited accuracy. (For a review of positive operator measures in quantum mechanics, see Refs. 4, 10, 15.)

In this paper we take covariance and invariance with respect to suitable symmetry groups as the defining properties of an observable. For example, a position observable on $\mathbb{R}$ is defined to be an observable which is covariant under space translations and invariant under momentum boosts. We characterize all position and momentum observables on $\mathbb{R}$ and on $\mathbb{R}^3$.

In Sec. II we study position and momentum observables on $\mathbb{R}$. In Sec. II A the definitions are given and in Sec. II B we characterize the structure of position and momentum observables. In Sec. II C we investigate the ability of a position observable to discriminate states, that is, the state distinction power. Another relevant property, the limit of resolution, is studied in Sec. II D. In Sec. II E we consider a covariant joint observable of position and momentum in phase space and derive a lower bound for the product of their limits of resolution. Section III is devoted to studying position and momentum observables in $\mathbb{R}^3$. The corresponding definitions are formulated in Sec. III A, and a complete classification of position and momentum observables in $\mathbb{R}^3$ is given in Sec. III B.

Concluding this section we fix some notations. Let $\mathcal{H}$ be a complex separable Hilbert space and $\mathcal{L}(\mathcal{H})$ the set of bounded operators on $\mathcal{H}$. A positive operator $T \in \mathcal{L}(\mathcal{H})$ of trace one is called a *state* and the set of all states is denoted by $\mathcal{S}(\mathcal{H})$. A positive operator A bounded from above by the unit operator I is called an *effect* and the set of all effects is denoted by $\mathcal{E}(\mathcal{H})$. We say that the null operator O and the unit operator I are *trivial effects*. Let Ω be a nonempty set and $\mathcal{A}$ a σ-algebra of subsets of Ω. A set function $E:\mathcal{A}\to\mathcal{L}(\mathcal{H})$ is an *operator measure*, if it is σ-additive with respect to the strong (or Ref. 12, p. 318, equivalently, weak) operator topology.

We call an operator valued measure E an *observable* if $E(X) \in \mathcal{E}(\mathcal{H})$ for all $X \in \mathcal{A}$ and

[a)]Electronic mail: carmeli@ge.infn.it
[b)]Electronic mail: teiko.heinonen@utu.fi
[c)]Electronic mail: toigo@ge.infn.it

$E(\Omega)=I$. If an observable E has projections as its values, that is, $E(X)^*=E(X)=E(X)^2$ for all $X\in\mathcal{A}$, it is called a *sharp observable*. For an observable $E:\mathcal{A}\to\mathcal{L}(\mathcal{H})$ and a state $T\in\mathcal{S}(\mathcal{H})$, we let p_T^E denote the probability measure on Ω defined by

$$p_T^E(X)=\mathrm{tr}[TE(X)],\quad X\in\mathcal{A}.$$

The number $p_T^E(X)$ is interpreted as the probability of having an outcome in X when the system is in the state T and the observable E is measured.

We denote by $\mathcal{B}(\mathbb{R}^n)$ the Borel σ-algebra of $\mathbb{R}^n$. The Fourier transform of any $f\in L^1(\mathbb{R}^n)$ is denoted by $\hat{f}$. We set also $\hat{f}=\mathcal{F}(f)$ to denote the Fourier–Plancherel transform of any $f\in L^2(\mathbb{R}^n)$ and $\hat{\mu}=\mathcal{F}(\mu)$ is the Fourier–Stieltjes transform of any complex Borel measure μ on $\mathbb{R}^n$.

II. POSITION AND MOMENTUM OBSERVABLES ON $\mathbb{R}$

A. Definitions

Let us consider a nonrelativistic particle living in the one-dimensional space $\mathbb{R}$ and fix $\mathcal{H}=L^2(\mathbb{R})$. Let U and V be the one-parameter unitary representations on $\mathcal{H}$ related to the groups of space translations and momentum boosts. They act on $\varphi\in\mathcal{H}$ as

$$[U(q)\varphi](x)=\varphi(x-q),$$

$$[V(p)\varphi](x)=e^{ipx}\varphi(x).$$

Let P and Q be the self-adjoint operators generating U and V, that is, $U(q)=e^{-iqP}$ and $V(p)=e^{ipQ}$ for every $q,p\in\mathbb{R}$. We denote by Π_P and Π_Q the spectral decompositions of the operators P and Q, respectively. They have the form

$$[\Pi_Q(X)\varphi](x)=\chi_X(x)\varphi(x),$$

$$\Pi_P(X)=\mathcal{F}^{-1}\Pi_Q(X)\mathcal{F}.$$

The sharp observable Π_Q has the property that, for all $q,p\in\mathbb{R}$ and $X\in\mathcal{B}(\mathbb{R})$,

$$U(q)\Pi_Q(X)U(q)^*=\Pi_Q(X+q), \tag{1}$$

$$V(p)\Pi_Q(X)V(p)^*=\Pi_Q(X). \tag{2}$$

Equation (1) means that Π_Q is covariant under translations, whereas (2) shows that Π_Q is invariant under momentum boosts. Hence, these relations suggest to call Π_Q a position observable. As the kinematical meaning of the observable Π_Q is solely in the relations (1) and (2), we take these symmetry properties as the definition of a general position observable. The observable Π_Q is called the *canonical position observable*.

Definition 1: An observable $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ is a *position observable on* $\mathbb{R}$ if, for all $q,p\in\mathbb{R}$ and $X\in\mathcal{B}(\mathbb{R})$,

$$U(q)E(X)U(q)^*=E(X+q), \tag{3}$$

$$V(p)E(X)V(p)^*=E(X). \tag{4}$$

We will denote by $\mathcal{POS}_{\mathbb{R}}$ the set of all position observables on $\mathbb{R}$.

In an analogous way we define a momentum observable to be an observable which is covariant under momentum boosts and invariant under translations.

Definition 2: An observable $F:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ is a *momentum observable on* $\mathbb{R}$ if, for all $q,p\in\mathbb{R}$ and $X\in\mathcal{B}(\mathbb{R})$,

$$U(q)F(X)U(q)^*=F(X), \tag{5}$$

$$V(p)F(X)V(p)^*=F(X+p). \tag{6}$$

Since $\mathcal{F}U(q)=V(-q)\mathcal{F}$ and $\mathcal{F}V(p)=U(p)\mathcal{F}$, the sharp observable $\Pi_P=\mathcal{F}^{-1}\Pi_Q\mathcal{F}$ satisfies (5) and (6). It is called the *canonical momentum observable*. Moreover, an observable E is a position observable if and only if $\mathcal{F}^{-1}E\mathcal{F}$ is a momentum observable. Therefore, in the following we will restrict ourselves to the study of position observables, the results of Secs. II B, II C, and II D being easily converted to the case of momentum observables.

Remark 1: In some articles an observable $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ satisfying the covariance condition (1) (and not necessarily the invariance condition (2)) is called a (generalized) position observable. In this paper we say that such an observable is a *localization observable*. These are characterized in Refs. 7 and 16. In Sec. II B it is shown, especially, that every position observable is commutative. However, there exist noncommutative localization observables. Hence, the set $\mathcal{POS}_{\mathbb{R}}$ is a proper subset of all localization observables.

B. The structure of position observables

Let $\rho:\mathcal{B}(\mathbb{R})\to[0,1]$ be a probability measure. For any $X\in\mathcal{B}(\mathbb{R})$, the map $q\mapsto\rho(X-q)$ is bounded and measurable, and hence the equation

$$E_\rho(X)=\int \rho(X-q)\ \ d\Pi_Q(q) \tag{7}$$

defines a bounded positive operator. The map

$$\mathcal{B}(\mathbb{R})\ni X\mapsto E_\rho(X)\in\mathcal{L}(\mathcal{H})$$

is an observable. It is straightforward to verify that the observable E_ρ satisfies the covariance condition (3) and the invariance condition (4), hence it is a position observable on $\mathbb{R}$. Denote by δ_t the Dirac measure concentrated at t. The observable E_{δ_0} is the canonical position observable Π_Q. We may also write

$$\Pi_Q(X)=\int \delta_0(X-q)\ \ d\Pi_Q(q) \tag{8}$$

and comparing (7) to (8) we note that E_ρ is obtained when the sharply concentrated Dirac measure δ_0 is replaced by the probability measure ρ. The observable E_ρ admits an interpretation as an imprecise, or fuzzy, version of the canonical position observable Π_Q. (See Refs. 1–3 for further details.)

Proposition 1: Any position observable E on $\mathbb{R}$ is of the form $E=E_\rho$ for some probability measure $\rho:\mathcal{B}(\mathbb{R})\to[0,1]$.

The proof of Proposition 1 is given in Appendix A.

Besides covariance (1) and invariance (2), the canonical position observable Π_Q has still more symmetry properties. Namely, let $\mathbb{R}_+$ be the set of positive real numbers regarded as a multiplicative group. It has a family of unitary representations $\{A_t|t\in\mathbb{R}\}$ acting on $\mathcal{H}$, and given by

$$[A_t(a)f](x)=\frac{1}{\sqrt{a}}f(a^{-1}(x-t)+t).$$

It is a direct calculation to verify that for all $a\in\mathbb{R}_+$, $X\in\mathcal{B}(\mathbb{R})$,

$$A_0(a)\Pi_Q(X)A_0(a)^*=\Pi_Q(aX).$$

We adopt the following terminology.

Definition 3: We say that an observable $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ is *covariant under dilations* if there exists a unitary representation A of $\mathbb{R}_+$ such that for all $a\in\mathbb{R}_+$ and $X\in\mathcal{B}(\mathbb{R})$,

$$A(a)E(X)A(a)^*=E(aX). \tag{9}$$

The canonical position observable Π_Q is not the only position observable which is covariant under dilations. An observable $E_{\delta_t}, t\in\mathbb{R}$, is a translated version of Π_Q, namely, for any $X\in\mathcal{B}(\mathbb{R})$,

$$E_{\delta_t}(X)=\Pi_Q(X-t)=U(t)^*\Pi_Q(X)U(t).$$

Since $A_{-t}(a)=U(t)^*A_0(a)U(t)$, the observable E_{δ_t} is covariant under dilations, with, for example, $A=A_{-t}$.

Proposition 2: Let E be a position observable on $\mathbb{R}$. The following conditions are equivalent:

(a) *E is covariant under dilations;*
(b) *$\|E(U)\|=1$ for every nonempty open set $U\subset\mathbb{R}$;*
(c) *$E=E_{\delta_t}$ for some $t\in\mathbb{R}$;*
(d) *E is a sharp observable.*

Proof: Let E be covariant under dilations. In a similar way as in Ref. 8, Lemma 3, it can be shown that $\|E(U)\|=1$ for all nonempty open sets U, and so, (a) implies (b). Assume then that (b) holds. For any nonempty open set U we get

$$1=\|E(U)\|=\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(x+U). \tag{10}$$

It follows that $\operatorname{supp}(\rho)$ contains only one point. Indeed, assume on the contrary that $\operatorname{supp}(\rho)$ contains two points $x_1\neq x_2$ and denote $U=\{x\in\mathbb{R}\,|\,|x|<\frac{1}{4}|x_1-x_2|\}$. Since x_1+U and x_2+U are neighborhoods of x_1 and x_2, respectively, we have $m_i:=\rho(x_i+U)>0$ for $i=1,2$. Then, for any $x\in\mathbb{R}$, $\rho(x+U)\leqslant 1-\min(m_1,m_2)$. This is in contradiction with (10). Hence, (b) implies (c). As previously mentioned, (c) implies (a). Clearly, (c) also implies (d). Since (d) implies (b) the proof is complete. □

The dilation covariance means that the observable in question has no scale dependence. A realistic position measurement apparatus has a limited accuracy and hence it cannot define a position observable which is covariant under dilations. Thus, sharp position observables are not suitable to describe nonideal situations.

Remark 2: If A is a unitary representation of $\mathbb{R}_+$ satisfying Eq. (9) with $E=E_{\delta_t}$, then there exists a measurable function $\beta:\mathbb{R}\to\mathbb{T}$ ($\mathbb{T}=$ the complex numbers of modulus 1) such that

$$[A(a)f](x)=\frac{1}{\sqrt{a}}\beta(x+t)\overline{\beta(a^{-1}(x+t))}f(a^{-1}(x+t)-t).$$

In particular, A is equivalent to A_{-t}. See Appendix B for more details.

C. State distinction power of a position observable

Definition 4: Let E_1 and E_2 be observables on $\mathbb{R}$. The *state distinction power* of E_2 is greater than or equal to E_1 if for all $T,T'\in\mathcal{S}(\mathcal{H})$,

$$p_T^{E_2}=p_{T'}^{E_2}\Rightarrow p_T^{E_1}=p_{T'}^{E_1}.$$

In this case we denote $E_1\sqsubseteq E_2$. If $E_1\sqsubseteq E_2\sqsubseteq E_1$ we say that E_1 and E_2 are *informationally equivalent* and denote $E_1\sim E_2$. If $E_1\sqsubseteq E_2$ and $E_2\not\sqsubseteq E_1$, we write $E_1\sqsubset E_2$.

Example 1: An observable $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ is *trivial* if $p_T^E=p_{T'}^E$ for all states $T,T'\in\mathcal{S}(\mathcal{H})$. This implies that a trivial observable E is of the form $E(X)=\lambda(X)I, X\in\mathcal{B}(\mathbb{R})$, for some probability measure λ. The state distinction power of any observable E' is greater than or equal to that of the trivial observable E. Clearly there is no trivial position observable on $\mathbb{R}$.

Example 2: An observable $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ is called *informationally complete* if $p_T^E\neq p_{T'}^E$ whenever $T\neq T'$. The state distinction power of an informationally complete observable is greater than or equal to that of any other observable E_1 on $\mathbb{R}$. It is easy to see that there is no informationally complete position observable. Namely, let ψ be a unit vector, $p\neq 0$ a real number, and denote $\psi'=V(p)\psi$. Then the states $T=|\psi\rangle\langle\psi|$ and $T'=|\psi'\rangle\langle\psi'|$ are different but for any position observable E_ρ, $p_T^{E_\rho}=p_{T'}^{E_\rho}$ since $V(p)$ commutes with all the effects $E_\rho(X), X\in\mathcal{B}(\mathbb{R})$.

We will next think of $\sim$ as a relation on the set $\mathcal{POS}_\mathbb{R}$. The relation $\sim$ is clearly reflexive, symmetric and transitive, and hence it is an equivalence relation. We denote the equivalence class of a position observable E by $[E]$ and the space of equivalence classes as $\mathcal{POS}_\mathbb{R}/\sim$. The relation $\sqsubseteq$ induces a partial order in the set $\mathcal{POS}_\mathbb{R}/\sim$ in a natural way.

Let E_ρ be a position observable and T a state. The probability measure $p_T^{E_\rho}$ is the convolution of the probability measures $p_T^{\Pi_Q}$ and ρ,

$$p_T^{E_\rho}=p_T^{\Pi_Q}*\rho. \tag{11}$$

It is clear from (11) that for all $T,T'\in\mathcal{S}(\mathcal{H})$,

$$p_T^{\Pi_Q}=p_{T'}^{\Pi_Q}\Rightarrow p_T^{E_\rho}=p_{T'}^{E_\rho},$$

and hence $E_\rho\sqsubseteq\Pi_Q$. We conclude that $[\Pi_Q]$ is the only maximal element of the partially ordered set $\mathcal{POS}_\mathbb{R}/\sim$.

It is shown in Ref. 14, Proposition 5, that a position observable E_ρ belongs to the maximal equivalence class $[\Pi_Q]$ if and only if $\mathrm{supp}(\hat{\rho})=\mathbb{R}$. The following proposition characterizes the equivalence classes completely.

Proposition 3: Let ρ_1,ρ_2 be probability measures on $\mathbb{R}$ and E_{ρ_1},E_{ρ_2} the corresponding position observables. Then

$$E_{\rho_1}\sqsubseteq E_{\rho_2}\Leftrightarrow\mathrm{supp}(\hat{\rho}_1)\subseteq\mathrm{supp}(\hat{\rho}_2). \tag{12}$$

Proof: Taking the Fourier transform of Eq. (11), we get

$$\mathcal{F}(p_T^{E_\rho})=\mathcal{F}(p_T^{\Pi_Q})\mathcal{F}(\rho). \tag{13}$$

Since the Fourier transform is injective, it is clear from the above relation that $\mathrm{supp}(\hat{\rho}_1)\subseteq\mathrm{supp}(\hat{\rho}_2)$ implies $E_{\rho_1}\sqsubseteq E_{\rho_2}$.

Conversely, suppose $\mathrm{supp}(\hat{\rho}_1)\nsubseteq\mathrm{supp}\,(\hat{\rho}_2)$. As $\hat{\rho}_i$, $i=1,2$, are continuous functions and $\hat{\rho}_i(\xi)=\overline{\hat{\rho}_i(-\xi)}$, there exists a closed interval $[2a,2b]$, with $0\leqslant a<b$, such that $[2a,2b]\cup[-2b,-2a]\subseteq\mathrm{supp}\,(\widehat{\rho}_1)$ and $([2a,2b]\cup[-2b,-2a])\cap\mathrm{supp}(\hat{\rho}_2)=\varnothing$. Define the functions

$$h_1=\frac{1}{\sqrt{2(b-a)}}(\chi_{[a,b]}-\chi_{[-b,-a]}),$$

$$h_2=\frac{1}{\sqrt{2(b-a)}}(\chi_{[a,b]}+\chi_{[-b,-a]}),$$

and for $i=1,2$, denote

$$h_i^*(\xi) := \overline{h_i(-\xi)}.$$

Define

$$f_i = \mathcal{F}^{-1}(h_i),$$

and let T_i be the one-dimensional projection $|f_i\rangle\langle f_i|$. We then have

$$dp^{\Pi_Q}_{T_i}(x) = |f_i(x)|^2 dx = |(\mathcal{F}^{-1}h_i)(x)|^2 dx = \mathcal{F}^{-1}(h_i * h_i^*)(x)dx,$$

and

$$\begin{aligned}\mathcal{F}(p^{\Pi_Q}_{T_i}) &= \mathcal{F}\mathcal{F}^{-1}(h_i * h_i^*) \\ &= h_i * h_i^* \\ &= \frac{1}{2(b-a)}(2\chi_{[a,b]} * \chi_{[-b,-a]} + (-1)^i \chi_{[-b,-a]} * \chi_{[-b,-a]} + (-1)^i \chi_{[a,b]} * \chi_{[a,b]}).\end{aligned}$$

Since

$$\operatorname{supp}(\chi_{[a,b]} * \chi_{[-b,-a]}) = [a-b, b-a],$$

$$\operatorname{supp}(\chi_{[a,b]} * \chi_{[a,b]}) = [2a, 2b],$$

$$\operatorname{supp}(\chi_{[-b,-a]} * \chi_{[-b,-a]}) = [-2b, -2a],$$

an application of (13) shows that

$$\mathcal{F}(p^{E_{\rho_1}}_{T_1}) \neq \mathcal{F}(p^{E_{\rho_1}}_{T_2}),$$

$$\mathcal{F}(p^{E_{\rho_2}}_{T_1}) = \mathcal{F}(p^{E_{\rho_2}}_{T_2}),$$

or in other words, $E_{\rho_1} \not\sqsubseteq E_{\rho_2}$. □

Remark 3: It follows from the above proposition that $E_1 \sqsubset E_2 \Leftrightarrow \operatorname{supp}(\hat{\rho}_1) \subset \operatorname{supp}(\hat{\rho}_2)$, and hence the set $\mathcal{POS}_{\mathbb{R}}/\sim$ has no minimal element. Indeed, if ρ_2 is a probability measure, there always exists a probability measure ρ_1 such that $\operatorname{supp}(\hat{\rho}_1) \subset \operatorname{supp}(\hat{\rho}_2)$. In fact, since $\hat{\rho}_2$ is continuous, $\hat{\rho}_2(\xi) = \overline{\hat{\rho}_2(-\xi)}$ and $\hat{\rho}_2(0) = \rho_2(\mathbb{R}) \neq 0$, there exists $a > 0$ such that the closed interval $[-a, a]$ is strictly contained in $\operatorname{supp}(\hat{\rho}_2)$. If we define $h = (1/\sqrt{a})\,\chi_{[-(a/2),(a/2)]}$, $f = \mathcal{F}^{-1}h$, then $d\rho_1(x) := |f(x)|^2 dx$ is a probability measure, and $\operatorname{supp}(\hat{\rho}_1) = \operatorname{supp}(h * h) = [-a, a]$.

D. Limit of resolution of a position observable

Let $\Pi : \mathcal{B}(\mathbb{R}) \to \mathcal{L}(\mathcal{H})$ be a sharp observable. For any nontrivial projection $\Pi(X)$, there exist states $T, T' \in \mathcal{S}(\mathcal{H})$ such that $p^{\Pi}_T(X) = 1$ and $p^{\Pi}_{T'}(X) = 0$. We may say that $\Pi(X)$ is a *sharp property* and it is *real* in the state T.

In general, an observable E has effects as its values which are not projections and, hence, not sharp properties. An effect $B \in \mathcal{E}(\mathcal{H})$ is called *regular* if its spectrum extends both above and below $\frac{1}{2}$. This means that there exist states $T, T' \in \mathcal{S}(\mathcal{H})$ such that $\operatorname{tr}[TB] > \frac{1}{2}$ and $\operatorname{tr}[T'B] < \frac{1}{2}$. In this sense regular effects can be seen as *approximately realizable properties*, see Ref. 4, Sec. II.2.1. The observable E is called regular if all the nontrivial effects $E(X)$ are regular.

It is shown in Ref. 14, Proposition 4 that if a probability measure ρ is absolutely continuous with respect to the Lebesgue measure, then the position observable E_ρ is not regular. Here we modify the notion of regularity to get a quantification of sharpness, or resolution, of position observables.

For any $x\in\mathbb{R}, r\in\mathbb{R}_+$, we denote the interval $[x-(r/2), x+(r/2)]$ by $I_{x;r}$. We also denote $I_r=I_{0;r}$. Let $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ be an observable and $\alpha>0$. We say that E is *α-regular* if all the nontrivial effects $E(I_{x;r})$, $x\in\mathbb{R}$, $r\geqslant\alpha$, are regular.

Definition 5: Let $E:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ be an observable. We denote

$$\gamma_E=\inf\{\alpha>0|E \text{ is } \alpha\text{-regular}\}$$

and say that γ_E is the *limit of resolution of E*.

It follows directly from definitions that the limit of resolution of a regular observable is 0. Especially, the limit of resolution of canonical position observables is 0.

Example 3: Let E be a trivial observable (see Example 1). For any $X\in\mathcal{B}(\mathbb{R})$, we have either $E(X)\geqslant\frac{1}{2}I$ or $E(X)\leqslant\frac{1}{2}I$. Hence, $\gamma_E=\infty$.

Proposition 4: A position observable E_ρ is α-regular if and only if

$$\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(I_{x,\alpha})>\tfrac{1}{2}. \tag{14}$$

Proof: An effect $E_\rho(X)$ is regular if and only if $\|E_\rho(X)\|>\frac{1}{2}$ and $\|E_\rho(\mathbb{R}\backslash X)\|>\frac{1}{2}$. Since the norm of the multiplicative operator $E_\rho(X)$ is $\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(X-x)$, we conclude that $E_\rho(X)$ is regular if and only if

$$\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(X-x)>\tfrac{1}{2} \quad\text{and}\quad \operatorname{ess\,inf}_{x\in\mathbb{R}}\rho(X-x)<\tfrac{1}{2}.$$

Thus, E_ρ is α-regular if and only if, for all $r\geqslant\alpha$,

$$\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(I_{x;r})>\tfrac{1}{2} \quad\text{and}\quad \operatorname{ess\,inf}_{x\in\mathbb{R}}\rho(I_{x;r})<\tfrac{1}{2}.$$

The second condition is always satisfied and the first is equivalent to (14). □

Corollary 1: A position observable E_ρ has a finite limit of resolution and

$$\gamma_{E_\rho}=\inf\{\alpha>0|\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(I_{x;\alpha})>\tfrac{1}{2}\}. \tag{15}$$

Example 4: Let us consider the case in which the probability measure has Gaussian distribution, that is,

$$d\rho(x)=\frac{1}{\sigma\sqrt{2\pi}}e^{-[(x-\bar{x})^2/2\sigma^2]}dx.$$

By Proposition 4 the position observable E_ρ is α-regular if, for each $r\geqslant\alpha$,

$$\frac{1}{2}<\int_{I_{\bar{x};r}}\frac{1}{\sigma\sqrt{2\pi}}e^{-[(x-\bar{x})^2/2\sigma^2]}dx=\frac{1}{\sqrt{2\pi}}\int_{-r/2\sigma}^{r/2\sigma}e^{-(x^2/2)}dx.$$

It follows that the limit of resolution γ_{E_ρ} is proportional to the standard deviation σ and $\gamma_{E_\rho}\approx 1.36\sigma$.

E. Covariant joint observables of position and momentum observables

Let $E_1, E_2:\mathcal{B}(\mathbb{R})\to\mathcal{L}(\mathcal{H})$ be two observables. An observable $G:\mathcal{B}(\mathbb{R}^2)\to\mathcal{L}(\mathcal{H})$ is their *joint observable* if for all $X,Y\in\mathcal{B}(\mathbb{R})$,

$$E_1(X)=G(X\times\mathbb{R}),$$

$$E_2(Y)=G(\mathbb{R}\times Y).$$

In this case E_1 and E_2 are the *margins* of G.

For all $(q,p)\in\mathbb{R}^2$, we denote

$$W(q,p)=e^{-iqP+ipQ}=e^{iqp/2}U(q)V(p).$$

The mapping $W:(q,p)\mapsto W(q,p)$ is an irreducible projective representation of the phase space translation group $\mathbb{R}^2$ in $\mathcal{H}$. An observable $G:\mathcal{B}(\mathbb{R}^2)\to\mathcal{L}(\mathcal{H})$ is called a *covariant phase space observable* if for all $(q,p)\in\mathbb{R}^2$ and $Z\in\mathcal{B}(\mathbb{R}^2)$,

$$W(q,p)G(Z)W(q,p)^*=G(Z+(q,p)).$$

It is proved in Ref. 6, Sec. III A that all covariant phase space observables are of the form

$$G_T(Z)=\frac{1}{2\pi}\int_Z W(q,p)TW(q,p)^*\ dqdp \tag{16}$$

for some $T\in\mathcal{S}(\mathcal{H})$.

The margins of a covariant phase space observable G_T are position and momentum observables. Indeed, let $\Sigma_i\lambda_i|\varphi_i\rangle\langle\varphi_i|$ be the spectral decomposition of T. A straightforward calculation shows that

$$G_T(X\times\mathbb{R})=\int \rho(X-q)\ d\Pi_Q(q)=E_\rho(X), \tag{17}$$

where $d\rho(q)=e(q)dq$ and $e(q)=\Sigma_i\lambda_i|\varphi_i(-q)|^2$. Similarly,

$$G_T(\mathbb{R}\times Y)=\int \nu(Y-p)\ d\Pi_P(p)=F_\nu(Y), \tag{18}$$

where $d\nu(p)=f(p)dp$ and $f(p)=\Sigma_i\lambda_i|\hat{\varphi}_i(-p)|^2$.

The following proposition is a direct consequence of the previously mentioned results.

Proposition 5: A position observable E_ρ [a momentum observable F_ν] is a margin of a phase space observable if and only if the probability measure ρ [prob. measure ν] is absolutely continuous with respect to the Lebesgue measure.

As noted in Example 4, the limit of resolution of a position observable E_ρ with ρ having Gaussian distribution is proportional to the standard deviation σ of ρ. This shows, in particular, that there exists a position observable which is a margin of a phase space observable and which has an arbitrary small positive limit of resolution. However, we next show that if position and momentum observables have a covariant phase space observable as their joint observable, then the product of limit of resolutions has a lower bound.

Proposition 6: Let E_ρ be a position observable and F_ν a momentum observable. If E_ρ and F_ν have a covariant phase space observable as their joint observable, then

$$\gamma_{E_\rho}\cdot\gamma_{F_\nu}\geqslant 3-2\sqrt{2}. \tag{19}$$

Proof: Since E_ρ and F_ν have a covariant phase space observable as a joint observable there is a vector valued function $\theta\in L^2(\mathbb{R},\mathcal{H})$ such that $d\rho(q)=\|\theta(q)\|^2_{\mathcal{H}}dq$ and $d\nu(p)=\|\hat{\theta}(p)\|^2_{\mathcal{H}}dp$.

By Proposition 4 the observable E_ρ is α-regular if and only if

$$\operatorname{ess\,sup}_{x\in\mathbb{R}}\rho(I_{x;\alpha})>1/2.$$

Since the map $x\mapsto\rho(I_{x;\alpha})$ is continuous, this is equivalent to

$$\sup_{x\in\mathbb{R}}\rho(I_{x;\alpha})=\sup_{x\in\mathbb{R}}\int_{I_{x;\alpha}}\|\theta(x)\|_{\mathcal{H}}^2 dx>1/2.$$

By the same argument, F_ν is β-regular if and only if

$$\sup_{\xi\in\mathbb{R}}\nu(I_{\xi;\beta})=\sup_{\xi\in\mathbb{R}}\int_{I_{\xi;\beta}}\|\hat{\theta}(\xi)\|_{\mathcal{H}}^2 d\xi>1/2.$$

Using Ref. 11, Theorem 2 extended to the case of vector valued functions, we find

$$\alpha\cdot\beta\geqslant 3-2\sqrt{2},$$

and hence (19) follows. □

III. POSITION AND MOMENTUM OBSERVABLES ON $\mathbb{R}^3$

A. Definitions

In this section $\mathcal{H}=L^2(\mathbb{R}^3)$. Let $Q_i, i=1,2,3$, denote the multiplication operator on $\mathcal{H}$ given by $[Q_i f](\mathbf{x})=x_i f(\mathbf{x})$, where x_i is the ith component of $\mathbf{x}$. By P_i we mean the operator $\mathcal{F}^{-1}Q_i\mathcal{F}$ and we denote $\mathbf{Q}=(Q_1,Q_2,Q_3)$, $\mathbf{P}=(P_1,P_2,P_3)$. The space translation group $\mathbb{R}^3$ has a unitary representation $U(\mathbf{q})=e^{-i\mathbf{q}\cdot\mathbf{P}}$ and similarly, the momentum boost group has a representation $V(\mathbf{p})=e^{i\mathbf{p}\cdot\mathbf{Q}}$. It is an immediate observation that the sharp observables $\Pi_{\mathbf{Q}}$ and $\Pi_{\mathbf{P}}$ on $\mathbb{R}^3$, associated with the representations V and U, respectively, satisfy the obvious covariance and invariance conditions, analogous to (3)–(6). Let D be the representation of the rotation group SO(3) in $\mathcal{H}$ defined as

$$[D(R)f](\mathbf{x})=f(R^{-1}\mathbf{x}).$$

It is straightforward to verify that the sharp observables $\Pi_{\mathbf{Q}}$ and $\Pi_{\mathbf{P}}$ are covariant under rotations, that is, for all $R\in\mathrm{SO}(3)$ and $X\in\mathcal{B}(\mathbb{R}^3)$,

$$D(R)\Pi_{\mathbf{Q}}(X)D(R)^*=\Pi_{\mathbf{Q}}(RX),$$

$$D(R)\Pi_{\mathbf{P}}(X)D(R)^*=\Pi_{\mathbf{P}}(RX).$$

These observations motivate the following definitions:

Definition 6: An observable $E:\mathcal{B}(\mathbb{R}^3)\to\mathcal{L}(\mathcal{H})$ is a *position observable on* $\mathbb{R}^3$ if, for all $\mathbf{q},\mathbf{p}\in\mathbb{R}^3$, $R\in\mathrm{SO}(3)$ and $X\in\mathcal{B}(\mathbb{R}^3)$,

$$U(\mathbf{q})E(X)U(\mathbf{q})^*=E(X+\mathbf{q}), \tag{20}$$

$$V(\mathbf{p})E(X)V(\mathbf{p})^*=E(X), \tag{21}$$

$$D(R)E(X)D(R)^*=E(RX). \tag{22}$$

We will denote by $\mathcal{POS}_{\mathbb{R}^3}$ the set of all position observables on $\mathbb{R}^3$.

Definition 7: An observable $F:\mathcal{B}(\mathbb{R}^3)\to\mathcal{L}(\mathcal{H})$ is a *momentum observable on* $\mathbb{R}^3$ if, for all $\mathbf{q},\mathbf{p}\in\mathbb{R}^3$, $R\in\mathrm{SO}(3)$ and $X\in\mathcal{B}(\mathbb{R}^3)$,

$$U(\mathbf{q})F(X)U(\mathbf{q})^*=F(X),$$

$$V(\mathbf{p})F(X)V(\mathbf{p})^*=F(X+\mathbf{p}),$$

$$D(R)F(X)D(R)^*=F(RX).$$

B. Structure of position observables on $\mathbb{R}^3$

We say that a probability measure ρ on $\mathbb{R}^3$ is rotation invariant if for all $X \in \mathcal{B}(\mathbb{R}^3)$ and $R \in \mathrm{SO}(3)$,

$$(R \cdot \rho)(X) := \rho(R^{-1}X) \equiv \rho(X).$$

The set of rotation invariant probability measures on $\mathbb{R}^3$ is denoted by $M(\mathbb{R}^3)^+_{1,\mathrm{inv}}$. Using the isomorphism $\mathbb{R}^3\backslash\{0\} \simeq \mathbb{R}_+ \times S^2$ and the disintegration of measures, the restriction of any measure $\rho \in M(\mathbb{R}^3)^+_{1,\mathrm{inv}}$ to the subset $\mathbb{R}^3\backslash\{0\}$ can be written in the form

$$d\rho|_{\mathbb{R}^3\backslash\{0\}}(\mathbf{r}) = d\rho_{\mathrm{rad}}(r)\, d\rho_{\mathrm{ang}}(\Omega),$$

where ρ_{rad} is a finite measure on $\mathbb{R}_+$ with $\rho_{\mathrm{rad}}(\mathbb{R}_+) = 1 - \rho(\{0\})$, and ρ_{ang} is the SO(3)-invariant measure on the sphere S^2 normalized to 1.

Given a rotation invariant probability measure ρ, the formula

$$E_\rho(X) = \int \rho(X - \mathbf{q})\; d\Pi_{\mathbf{Q}}(\mathbf{q}), \quad X \in \mathcal{B}(\mathbb{R}^3), \tag{23}$$

defines a position observable on $\mathbb{R}^3$.

Proposition 7: Any position observable E on $\mathbb{R}^3$ is of the form $E = E_\rho$ for some $\rho \in M(\mathbb{R}^3)^+_{1,\mathrm{inv}}$.

Proof: It is shown in Appendix A that if E satisfies Eqs. (20), (21), then E is given by Eq. (23) for some probability measure ρ in $\mathbb{R}^3$. If $\varphi \in C_c(\mathbb{R}^3)$, let

$$E(\varphi) = \int_{\mathbb{R}^3} \varphi(\mathbf{x})\, dE(\mathbf{x}).$$

For all $f \in L^2(\mathbb{R}^3)$, define the measure

$$d\mu_f(\mathbf{x}) = |f(\mathbf{x})|^2 d\mathbf{x}.$$

We then have

$$\langle f \,|\, E(\varphi) f \rangle = (\mu_f * \rho)(\varphi).$$

From (22) it then follows

$$(\mu_{D(R)f} * \rho)(\varphi) = (\mu_f * \rho)(R^{-1} \cdot \varphi), \tag{24}$$

where $(R^{-1} \cdot \varphi)(\mathbf{x}) = \varphi(R\mathbf{x})\ \forall \mathbf{x} \in \mathbb{R}^3$. Rewriting explicitly (24), we then find

$$\int_{\mathbb{R}^3 \times \mathbb{R}^3} \varphi(\mathbf{x}+\mathbf{y}) |f(R^{-1}\mathbf{x})|^2 d\mathbf{x} d\rho(\mathbf{y}) = \int_{\mathbb{R}^3 \times \mathbb{R}^3} (R^{-1} \cdot \varphi)(\mathbf{x}+\mathbf{y}) |f(\mathbf{x})|^2 d\mathbf{x} d\rho(\mathbf{y}).$$

With some computations, setting $\psi(\mathbf{x}) = (R^{-1} \cdot \varphi)(-\mathbf{x})$, this gives

$$\int_{\mathbb{R}^3} (\psi * |f|^2)(-\mathbf{y}) d(R^{-1} \cdot \rho)(\mathbf{y}) = \int_{\mathbb{R}^3} (\psi * |f|^2)(-\mathbf{y}) d\rho(\mathbf{y}). \tag{25}$$

Letting ψ and f vary in $C_c(\mathbb{R}^3)$, the functions $\psi * |f|^2$ span a dense subset of $C_0(\mathbb{R}^3)$. From Eq. (25), it then follows that $R^{-1} \cdot \rho = \rho$. □

Proposition 8: Let E be a position observable on $\mathbb{R}^3$. The following facts are equivalent:

(a) $\|E(U)\|=1$ *for every nonempty open set* $U\subset\mathbb{R}$*;*
(b) E *is a sharp observable;*
(c) $E=\Pi_{\mathbf{Q}}$.

Proof: It is clear that (c)⇒(b)⇒(a). Hence, it is enough to show that (a) implies (c). As in the proof of Proposition 2, it follows from (a) that $\rho=\delta_{\mathbf{t}}$ for some $\mathbf{t}\in\mathbb{R}^3$. However, the probability measure $\delta_{\mathbf{t}}$ is rotation invariant if and only if $\mathbf{t}=\mathbf{0}$. This means that $E=\Pi_{\mathbf{Q}}$. □

APPENDIX A: TRANSLATION COVARIANT AND BOOST INVARIANT OBSERVABLES IN DIMENSION *n*

Let $N=\mathbb{R}^{n+1}$ and $H=\mathbb{R}^n$, with the usual structure of additive Abelian groups. Denote with (p,t), $p\in\mathbb{R}^n$, $t\in\mathbb{R}$, an element of N. Let H act on N as

$$\alpha_q(p,t)=(p,t+q\cdot p),\quad q\in H,(p,t)\in N.$$

The Heisenberg group is the semidirect product $G=N\times_{\alpha}H$ (see Ref. 13). We will denote an element $nq\in G$, with $n=(p,t)\in N$ and $q\in H$, as $((p,t),q)$.

Let W be the following irreducible unitary representation of G acting in $L^2(\mathbb{R}^n)$

$$[W((p,t),q)f](x)=e^{-i(t-p\cdot x)}f(x-q).$$

Clearly, $W((0,0),q)=U(q)$, $W((p,0),0)=V(p)$, and $W((0,t),0)=e^{-it}$. The groups H and G/N are naturally identified. With such an identification, the canonical projection $\pi:G\to G/N$ is

$$\pi((p,t),q)=q,$$

and an element $((p,t),q)\in G$ acts on $q_0\in H$ as

$$((p,t),q)[q_0]=\pi(((p,t),q)((0,0),q_0))=q+q_0.$$

An observable E based on $\mathbb{R}^n$ and acting in $L^2(\mathbb{R}^n)$ then satisfies the analogs of Eqs. (3), (4) in dimension n if, and only if, for all $X\in\mathcal{B}(\mathbb{R})$ and $((p,t),q)\in G$,

$$W((p,t),q)E(X)W((p,t),q)^*=E(X+q),\tag{A1}$$

i.e., if and only if E is a W-covariant observable based on G/N. By virtue of the Generalized Imprimitivity Theorem (see Refs. 5 and 9), E is W-covariant if and only if there exists a representation σ of N and an isometry L intertwining W with the induced representation $\mathrm{ind}_N^G(\sigma)$ such that

$$E(X)=L^*P(X)L$$

for all $X\in\mathcal{B}(\mathbb{R}^n)$, where P is the canonical projection valued measure of the induced representation. Since $\mathrm{ind}_N^G(\sigma)\subset\mathrm{ind}_N^G(\sigma')$ (as imprimitivity systems) if $\sigma\subset\sigma'$ (as representations), it is not restrictive to assume that such σ has constant infinite multiplicity, so that there exists a positive Borel measure μ_σ on $\hat{N}=\mathbb{R}^{n+1}$ and an infinite dimensional Hilbert space $\mathcal{H}$ such that σ is the diagonal representation acting in $L^2(\mathbb{R}^{n+1},\mu_\sigma;\mathcal{H})$, i.e.,

$$[\sigma(p,t)\phi](h,k)=e^{ih\cdot p}e^{ikt}\phi(h,k).$$

Denote with $\gamma_{h,k}$, $h\in\mathbb{R}^n$, $k\in\mathbb{R}$ the following character of N:

$$\gamma_{h,k}(p,t)=e^{ih\cdot p}e^{ikt}.$$

The action of H on $\hat{N}$ is given by

$$(q\cdot\gamma_{h,k})(p,t)=\gamma_{h,k}(\alpha_{-q}(p,t))=e^{i(h-kq)\cdot p}e^{ikt},$$

or in other words

$$q\cdot\gamma_{h,k}=\gamma_{h-kq,k}.$$

If $k\neq 0$, the orbit passing through $\gamma_{h,k}$ is

$$\mathcal{O}_{\gamma_{h,k}}=\mathbb{R}^n\times\{k\}$$

and the corresponding stability subgroup is

$$H_{\gamma_{h,k}}=\{0\}.$$

From the Mackey Machine it follows that the representations

$$\rho_{h,k}:=\mathrm{ind}_N^G(\gamma_{h,k})$$

are irreducible if $k\neq 0$, $\rho_{h,k}$ and $\rho_{h',k'}$ are inequivalent if $k\neq k'$ and, fixed $k\neq 0$, $\rho_{h,k}$ and $\rho_{h',k}$ are equivalent.

The representation $\rho:=\mathrm{ind}_N^G(\sigma)$ acts on $L^2(\mathbb{R}^n,dx;L^2(\mathbb{R}^{n+1},\mu_\sigma;\mathcal{H}))$ according to

$$[\rho((p,t),q)f](x)=\sigma(p,t-p\cdot x)f(x-q).$$

Using the fact that σ acts diagonally in $L^2(\mathbb{R}^{n+1},\mu_\sigma;\mathcal{H})$ and the identification $L^2(\mathbb{R}^n,dx;L^2(\mathbb{R}^{n+1},\mu_\sigma;\mathcal{H}))\cong L^2(\mathbb{R}^n\times\mathbb{R}^{n+1},dx\otimes d\mu_\sigma(x);\mathcal{H})$, we find that ρ acts on $L^2(\mathbb{R}^n\times\mathbb{R}^{n+1},dx\otimes d\mu_\sigma(x);\mathcal{H})$ as

$$[\rho((p,t),q)f](x,h,k)=e^{ih\cdot p}e^{ik(t-p\cdot x)}f(x-q,h,k).$$

Write $\mu_\sigma=\mu_{\sigma_1}+\mu_{\sigma_2}$, where $\mu_{\sigma_1}\perp\mu_{\sigma_2}$ and $\mu_{\sigma_2}(\mathcal{O}_{\gamma_{0,-1}})=0$, and let $\sigma=\sigma_1\oplus\sigma_2$ be the corresponding decomposition of σ. We then have

$$\mathrm{ind}_N^G(\sigma)=\mathrm{ind}_N^G(\sigma_1)\oplus\mathrm{ind}_N^G(\sigma_2),$$
