

as seen with decamethonium and hence belongs to the group of depolarizing neuromuscular blocking agents. The block seen with XII and XIII was similar to that observed with the antidepolarizer, (+)-tubocurarine.

Discussion.—Even the slightest modification of the decamethonium molecule usually either decreases the potency or changes it from a depolarizing drug to an antidepolarizer, or both.²¹ Thus the introduction of the halogen atoms and the double bond in the 5,6 positions of the decamethylene chain, as in III, caused a change in potency and therapeutic index. Furthermore, on the isolated preparations, the ability of III to produce the characteristic biphasic block and initial contracture, together with fasciculations normally seen with depolarizers, was less marked as compared with decamethonium. In particular this was the case for the isolated guinea pig diaphragm, as III produced only a slight phase I block. The slowly developing block seen with III on this preparation is not typical of either the depolarizers or antidepolarizers. Presumably, this block is characteristic of compounds which have a very weak ability to depolarize the motor end plate.

Recently, tritiated decamethonium has become available and has proved to be useful for *in vitro* studies.^{4e,22}

Revised Manuscript Received October 31, 1966

A series of ω -alkylaminoacyl derivatives of 4-aminosalicylic acid esters (methyl through hexyl, plus 2-diethylaminoethyl) were synthesized and their hydrochlorides were tested for local anesthetic activity. The synthesis of the diethylaminoethyl ester series was examined in some detail since these compounds easily undergo alcoholysis and aminolysis. These reactions were ascribed to an intramolecular *o*-hydroxy catalysis. Only derivatives of the methyl, ethyl, and diethylaminoethyl esters exhibited significant local anesthetic activity. Compared to lidocaine, these compounds were generally more irritating, less toxic, and less active. When the compounds exhibiting local anesthetic activity were quaternized with methyl iodide, local anesthetic activity was lost while the toxicity increased.

Although Drill³ states that, as a general rule, effective local anesthetics rarely contain either free carboxyl or hydroxy groups, Clinton and co-workers⁴ and

Ludueña and Hoppe⁵ have reported that a series of dialkylaminoalkyl 4-alkylaminosalicylates showed a high degree of infiltration and topical anesthetic activity. Keil and Rademacher⁶ also reported that some alkylaminoethyl 4-aminosalicylates possessed local anesthetic activity similar to the corresponding esters of 4-aminobenzoic acid. Oxycaïne, the 2-hydroxy analog of procaine synthesized by Grimme and Schmitz,⁷ has been shown by

Vinogradov⁸ to possess toxicity approximately equal to procaine but with considerably greater local anesthetic activity. In addition, Epstein and Kaminsky^{9,10} reported local anesthetic activity in a number of alkylaminoacylamino benzoates. Examination of these studies suggested that an exploration of the activity of alkylaminoacyl derivatives of 4-aminosalicylic acid esters, might result in the discovery of potentially useful local anesthetic agents.

Chemistry.—The derivatives synthesized were: methyl through hexyl 4-(2-alkylaminoacetyl amino)- and 4-(3-alkylaminopropionyl amino)salicylates as the hydrochloride and, in some cases, as the methiodide salts (Tables II and III). Their preparation consisted of treating an ester of 4-aminosalicylic acid with chloroacetyl or 3-chloropropionyl chloride and subsequent heating of the intermediate 4-(ω -chloroacylamino) derivative (Table I) with an excess of amine in ethanol.

Synthesis of the 2-diethylaminoethyl 4-(2-alkylaminoacetyl amino)salicylates was performed as outlined in Scheme I. 2-Diethylaminoethyl 4-aminosalicylic acid (I) was treated with chloroacetyl chloride to yield the intermediate chloroacetanilide hydrochloride II. Reaction of II with an excess of amine in a *polar* medium, *e.g.*, ethanol, gave the corresponding ethyl ester derivative III (R = C₂H₅)—equally obtained *via* the ethyl ester chloroacetanilide IV (R = C₂H₅)—instead of the desired diethylaminoethyl ester derivative V. Alcoholysis was found to occur in methanol, as well as in ethanol, irrespective of the amine used (Experimental Section and Table II) and was prevented by carrying out the reaction in a *nonpolar* solvent, such as benzene (Table III). Heating II with a low-boiling amine, in the *absence* of solvent, resulted in the formation of the corresponding diethylaminoethyl ester derivatives V. However, with high-boiling amines, salicylamide derivatives VI constituted the main product of the reaction (Table IV). Synthesis *via* the 4-chloroacetylaminosalicylic acid chloride (VII) proved the structure of the aminolysis products.

The observed facile alcoholysis and aminolysis of the diethylaminoethyl ester series may be compared to the intramolecular *o*-hydroxy catalysis in the hydrolysis of *p*-nitrophenyl salicylates studied by Bender and co-workers.¹¹ The reported reactions of 2-diethylaminoethyl 4-chloroacetylaminobenzoate with an excess of amine, either in ethanol¹² or in the absence of solvent,³ resulting only in substitution of the chlorine atom, agree with such a description. On the other hand, no comparable large rate enhancement of the *o*-hydroxy group could be detected in the case of the ethyl salicylate series.¹¹ This might account equally well for the isolation of the ethyl ester derivatives III as products of alcoholysis, as well as for the observed lack of alcoholysis in the alkyl ester series (IV-III, R = methyl through hexyl), the reaction with the amine being run in ethanol solution.

Experimental Section¹³

The **N-alkylaminoacylanilines** obtained by the various methods described below were transformed to their salts, hydrochlorides and methiodides, without further purification. Accordingly, the free bases reported in the tables correspond to non-purified products. Salts were purified by recrystallization from absolute ethanol or from absolute ethanol-ether. Hydrochlorides were prepared in absolute alcohol (and ether, where necessary). Quaternary ammonium salts were prepared by heating a solution of the amine in absolute ethanol or anhydrous acetone with an excess (2-4 moles) of methyl iodide under reflux for 2 hr. In most cases the salt crystallized upon cooling; otherwise, it was precipitated by adding anhydrous ether. Colors, ranging from intense yellow to orange, were formed by adding 1% FeCl₃ solution.

Esters of 4-Aminosalicylic Acid.—The alkyl esters, methyl through *n*-amyl, were prepared by standard methods.¹⁴ The *n*-hexyl ester, not previously reported in the literature, was obtained by direct esterification of the acid as follows. A mixture of 4-aminosalicylic acid (25 g, 0.18 mole), 125 ml of purified *n*-hexyl alcohol, and 50 ml of concentrated H₂SO₄ was heated on a water bath for 8 hr. After standing overnight, the mixture was

diluted with an equal volume of cold water and the precipitate which formed was filtered and washed successively (cold H_2O , 20% NH_4OH , cold water) yielding 20 g (52%) of a colorless product, mp 62° . Upon recrystallization from absolute ethanol, a crystalline solid, mp 64° , was obtained.

Anal. Calcd for $\text{C}_{13}\text{H}_{19}\text{NO}_3$: C, 65.80; H, 8.07; N, 5.90. Found: C, 66.00; H, 8.10; N, 6.07.

This procedure may be applied to the preparation of the alkyl esters, methyl through *n*-butyl, with yields ranging from 65 (*n*-butyl) to 80% (methyl). The 2-diethylaminoethyl ester hydrochloride was obtained in 84% yield according to details given in a patent.¹⁵

Alkyl 4-(ω -Chloroacylamino)salicylates.—Alkyl 4-aminosalicylate (0.15 mole) was dissolved in 300 ml of glacial acetic acid and 0.165 mole of the corresponding chloride (chloroacetyl or 3-chloropropionyl) was added in small portions with continuous stirring. Generally, a voluminous, colorless precipitate formed immediately. The mixture was then diluted with 150 ml of glacial acetic acid and stirred for 1 hr; water (500 ml) was added and the stirring continued for an additional hour. Yields of crude product, melting point, and analytical data, after recrystallization from ethanol, for the chloroanilides prepared are given in Table I.

2-Diethylaminoethyl 4-Chloroacetylaminosalicylate.—A stirred solution of 2-diethylaminoethyl salicylate hydrochloride (65 g, 0.23 mole) in 260 ml of glacial acetic acid was treated with a solution of chloroacetyl chloride (28 g, 0.25 mole) in 30 ml of glacial acetic acid, added in small portions. Stirring was continued for 1 hr after the last addition of chloride and the excess of acetic acid was evaporated *in vacuo*. The residual acetic acid was then just neutralized by adding a saturated NaHCO_3 solution to the heavy syrupy residue. The crystalline hydrochloride which formed weighed 60.1 g (73%), mp 99 – 103° . After recrystallization from ethanol, mp 105 – 106° .

Anal. Calcd for $\text{C}_{15}\text{H}_{22}\text{Cl}_2\text{N}_2\text{O}_4$: Cl, 19.42; N, 7.67; mol wt, 365.25. Found: Cl, 19.27; N, 7.85; mol wt, 363.0 (acidimetry).

If the addition of bicarbonate solution is continued until the medium is strongly alkaline, the hydrochloride initially formed is transformed to the free base; this is extracted with ether and obtained as an amorphous solid in a 60% yield, mp 75 – 80° . After crystallization from ligroin, it is obtained in a crystalline form, mp 81 – 82° . When the crystalline material is allowed to stand for a few hours in the air or even under vacuum, it transforms into a glutinous mass,¹⁶ melting in a wide range over 160° . However, the free base gives the same reactions as its stable hydrochloride if used immediately after its isolation.

(15) Dr. A. Wander A.-G., British Patent 739,210 (1955); *Chem. Abstr.*, **50**, 10779f (1956).

Alkyl 4-(ω -Alkylaminoacylamino)salicylates.—A suspension of the chloroamide (0.05 mole) in 200 ml of absolute ethanol was refluxed for 2 hr with an excess of amine (0.15 mole). In two cases the aminoacylaniline crystallized after cooling and was filtered, washed with water, and dried (method A). Otherwise, the ethanol was removed by distillation, and the residue was treated with 50 ml of a saturated NaHCO_3 solution and 50 ml of water; the aminoacylaniline separated either as a solid, or as an oil. In the first case it was filtered, washed, and dried (method B); in the second, it was extracted with ether (method C). Following this same procedure, reaction of 2-diethylaminoethyl 4-chloroacetylaminosalicylate hydrochloride with different amines in methanol or ethanol, gave the corresponding methyl or ethyl esters (methods A', B', and C', respectively). Mixtures of the products obtained by the two methods described showed no melting point depression. The constants of the aminoacylanilines prepared and their salts are given in Table II.

2-Diethylaminoethyl 4-Alkylaminoacylamino)salicylates.—A suspension of 2-diethylaminoethyl 4-chloroacetylaminosalicylate hydrochloride (0.025 mole) in 100 ml of anhydrous benzene was refluxed for 4 hr with an excess of amine (0.125 mole). The benzene was then distilled, the residue was treated with 80 ml of a saturated NaHCO_3 solution, and the aminoacylaniline was extracted with ether (method D). The diethylamino and isopropylamino derivatives were also prepared by method E (*vide infra*). The constants of the derivatives and their salts are given in Table III.

4-Alkylaminoacylamino)salicylamides.—A mixture of 2-diethylaminoethyl 4-chloroacetylaminosalicylate hydrochloride and an excess of amine (*ca.* 5 moles) was heated on a steam bath for 4 hr. After cooling, the excess amine was removed under vacuum, and the residue was extracted with ether to remove the diethylaminoethyl ester derivative and then with chloroform which dissolves the amide derivative (method E). The reaction with diethylamine and isopropylamine resulted in the corresponding ester derivatives (Table III), while all other amines gave the corresponding amides (Table IV); in these cases a low yield (10–15%) of the corresponding ester derivative could be isolated from the ether extracts.

Starting with 4-chloroacetylaminosalicylic acid¹⁷ the same amide derivatives were obtained as follows. The acid (0.02 mole) was transformed to its chloride by refluxing with excess SOCl_2 . After elimination of the excess reagent under vacuum,

(16) W. A. Jacobs and M. Heidelberger, *J. Biol. Chem.*, **21**, 139 (1915), reported that in a similar manner the 2-(diethylaminoethyl) ester of 4-chloroacetylaminobenzoic acid was unstable and did not keep well in the crude state.

(17) A. J. Quick and R. Adams, *J. Am. Chem. Soc.*, **44**, 816 (1922).

^{a-d} As in Table II. ^e Corresponding to dihydrochlorides and bismethiodides. ^f These compounds were not submitted for pharmacological evaluation.

the residue was heated with 0.2 mole of the amine for 2 hr and the amide was isolated according to method E (method F) (Table IV). Mixtures of the amides prepared by methods E and F showed no melting point depression.

Pharmacology. Local Anesthetic Screening.—Preliminary qualitative screening was done by subcutaneous injection of the test compounds into the mouse tail according to the method described by Bianchi.¹⁸ A 2% solution of each compound was prepared in distilled water. Five mice were injected subcutaneously with 0.1 ml of test solution in the tail about 1 cm from the base and an artery clip was applied periodically for about 15 min. Untreated mice attempted to remove the artery clip within 5-6 sec. The end point of the procedure indicating local anesthesia was the failure of the mouse to attempt to dislodge the clip within 30 sec. The compounds which exhibited local anesthetic activity using the Bianchi method were in addition quantitatively evaluated for local anesthetic potency in guinea pigs using the Bulbring and Wajida¹⁹ method. All of the compounds were tested at 1% concentration and the relative potency on a molar basis was compared with 1% lidocaine. A minimum of six guinea pigs was used for each compound shown in Table V. No more than two compounds were tested on any single guinea pig. The tissue irritancy of the compounds was determined in rabbits by the trypan blue method of Hoppe, *et al.*²⁰ The numerical estimation of TIC (tissue irritant concentration) was made according to the scoring system described by these authors.

Toxicity in Mice.—Male CF strain mice weighing between 20 and 30 g were used for acute toxicity determination. An approximate intravenous LD₅₀ was determined in five groups of mice (five mice per dose level). Water-insoluble compounds were suspended in 1% tragacanth and given orally to obtain approximate oral LD₅₀'s. The acute intraperitoneal toxicity (24 hr) of the selected compounds presented in Table V was conducted with five groups of mice (ten animals per dose level). The median lethal dose (LD₅₀ ± SE) with 95% confidence limits was estimated according to the method of Litchfield and Wilcoxon.²¹

Results and Discussion

In Tables II-IV, 58 compounds are listed which were tested for local anesthetic activity and toxicity as described under Methods. The following correlations between local anesthetic activity, acute toxicity, and chemical structure can be made.

(1) Of the various esters tested, only the methyl, ethyl, and diethylaminomethyl derivatives exhibited

local anesthetic activity. The propyl, butyl, amyl, and hexyl esters were generally more toxic and did not show local anesthetic activity.

(2) In the acyl-substituted portion of the molecule, the benzylamino, isopropylamino, and cyclohexylamino derivatives were very insoluble and could not be tested for local anesthetic activity by the procedure of Bianchi.¹⁸ The oral toxicity of these compounds was quite low which may be due, in part, to their low solubility. The dimethylamino, diethylamino-, piperidino-, and morpholinoacyl derivatives of the methyl and ethyl esters generally showed local anesthetic activity and, with the exception of the dimethylaminoacyl derivatives of the ethyl ester, were also appreciably soluble in water. These compounds apparently possess the balance which, as Quevauviller²² has pointed out, must exist between the lipophilic and hydrophilic portions of a molecule in order to have a local anesthetic effect. The acute toxicities of the methyl and ethyl esters containing these four groups were in the same range varying from 80 to 150 mg/kg.

(3) The number of methylene groups (*n*) in the acyl chain was either one or two. In general, the compounds with two methylene groups exhibit a higher local anesthetic activity but also show increased toxicity and irritancy.

In Table II, 17 compounds are listed which were synthesized as the methiodide salts. The quaternization of the tertiary amine by the methyl group destroyed the local anesthetic activity of compounds which were active as the hydrochlorides. This is in agreement with the findings of Nador, *et al.*,²³ and Löfgren and Fischer²⁴ who reported a similar loss of activity after the methyl quaternization of active compounds. In addition, these compounds are much more toxic than the corresponding hydrochlorides.

In Table V, the toxicity (intraperitoneal), irritancy, and local anesthetic potency of ten of the derivatives which exhibited significant activity are compared to lidocaine. Although 19 compounds of the series showed a qualitative local anesthetic response, only
