# Preferred Conformation of Prostaglandin $\mathrm{E}_{1}$ 

James R. Hoyland* and Lemont B. Kier<br>Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio. Received March 30, 1971

#### Abstract

Calculations on the conformational preference of prostaglandin $\mathrm{E}_{1}\left(\mathrm{PGE}_{1}\right)$ have been made using extended Hückel theory and interaction energy calculations, including dispersion bonding. The results predict the energetic preference for a few conformations in which the two side chains are intimately associated, in contrast to random chain arrangements. These results support the previously invoked conformation of $\mathrm{PGE}_{1}$ used to compare structural features in the potent $\beta$-adrenergic agents. It would appear that if structural modification is to be made on these molecules, retaining the basic prostaglandin structure, then the retention of major portions of both chains is essential for the interchain stabilization and presentation of structurally active features.

The prostaglandins are known to be widely distributed in the body, of very high potency, and responsible for a wide variety of pharmacological actions. ${ }^{1,2}$ The present state of our knowledge of mechanisms of action of the various prostaglandins does not permit detailed conclusions. It is known with some certainty, however, that prostaglandins have an intimate relationship with catecholamines and the adrenergic system, adenyl cyclase and cyclic AMP, and that they play a hormonal role in some processes such as reproduction. ${ }^{3}$
In a series of studies ${ }^{4,5}$ culminating in some theoretical considerations of $\alpha$-and $\beta$-adrenergic activity, ${ }^{6}$ we invoked a possible structural relationship between $\beta$-adrenergic agents and prostaglandin $\mathrm{E}_{1}$ to support our hypothesis of structure-activity relationships influencing $\beta$-adrenergic activity. We noted that if prostaglandin $\mathrm{E}_{1}$ was assigned a "reasonable" conformation in regard to the hydroxylated side chain, then a definite similarity of functional group positions with $N$-n-propylnorepinephrine, in its calculated preferred conformation, was evident. This relationship was based on the hypothesis that an onium group is nonessential for $\beta$-adrenergic activity. ${ }^{6}$
In spite of the large numbers of studies regularly appearing on the prostaglandins, very little attention has been devoted to their structure. Abrahamsson has reported on the conformation of prostaglandin $\mathrm{F}_{2-1}{ }^{7}$ They analyzed the tri-p-bromobenzoate methyl ester crystal using X-ray analysis. The proximity of the faces of two of the benzene rings is such that the side-chain conformations observed are likely a function of benzene-benzene interaction and not necessarily the conformation to be found in the natural prostaglandin.
The conformation prediction of prostaglandin $E_{1}$ was undertaken in this study to attempt to support our previously hypothesized relationship with $\beta$-adrenergic agonists and to provide structural information from which relationships with presently known and future biological activity data may be correlated.

## Experimental Data

A number of assumptions must necessarily be made in a calculation of this kind. We have attempted to utilize existing experimental data as intelligently as possible in order to keep such assumptions to a minimum.

We have assumed, first, on the basis of experimental investigations by Brutcher, et al., ${ }^{8}$ that the cyclopentanone ring is maintained in either of the 2 possible half-chair conformations. Extended Hückel (EHT) calcns using truncated side chains of 2-C atoms each were next carried out to determine conformational preferences of atoms close to the ring. These calcns indicated that the second side chain comes off the cyclopentanone ring such that the $\mathrm{H}^{\text {at }} \mathrm{C}_{12}$ eclipses the $\mathrm{C}_{13}-\mathrm{C}_{14}$ double bond, as expected. It was also predicted
that the first, or carboxyl-contg, side chain shows no preference between coming off the ring trans to the $\mathrm{C}_{8}-\mathrm{C}_{9}$ bond or trans to the $\mathrm{C}_{8}-\mathrm{C}_{12}$ bond. This result was assumed thereafter.

The total relative energy of a given conformation can now be assumed to be a sum of 2 parts: first, a conformational energy arising from the twisting of either side chain into a gauche conformation, and secondly, the interaction energy between the 2 chains through long-range forces. It was assumed that an energy increment of $0.6 \mathrm{kcal} / \mathrm{mole}^{9}$ is associated with the formation of a gauche conformation about a $\mathrm{CH}_{2} \mathrm{CH}_{2}$ fragment.

Since no experimental information is available concerning internal rotation about the $\mathrm{C}_{14}-\mathrm{C}_{15}$ and $\mathrm{C}_{15}-\mathrm{C}_{16}$ bonds, extended Hückel calons were carried out on isolated chains. These calcns indicated that the $\mathrm{C}_{15}-\mathrm{H}$ bond eclipses the double bond. Although no good estimate of the energy of the other conformations involving the $\mathrm{C}_{15}-\mathrm{O}$ or $\mathrm{C}_{15}-\mathrm{C}_{16}$ bonds eclipsing the double bond can be made since the EHT calcns exaggerate steric effects, these lie significantly higher in energy and also lead to decreased chain-chain interaction energy. For this reason, the $\mathrm{C}_{15}-\mathrm{H}$ bond was held eclipsed to the $\mathrm{C}_{13}-\mathrm{C}_{14}$ bond in all calcns. Finally, the EHT results, coupled with studies on $2-\mathrm{BuOH}$ (for which some experimental conformational data are known ${ }^{10}$ ) predict that the $\mathrm{C}_{15}-\mathrm{C}_{16}$ bond will prefer a trans orientation to the $\mathrm{C}_{14}-\mathrm{C}_{15}$ bond, and that $\mathrm{C}_{15}-\mathrm{C}_{16}$ trans to the $\mathrm{C}_{15}-\mathrm{O}$ or $\mathrm{C}_{15}$ - H bonds will result in approximate energy increments of 0.4 and $0.8 \mathrm{kcal} / \mathrm{mole}$, respectively. It should be emphasized that all EHT calcns described in this paragraph were carried out on isolated chain fragments so that no perturbation by the second chain has been included.

The interaction energy between the 2 chains can be written approximately as a sum of first- and second-order perturbation terms. The monopole-bond polarizabilities method of Claverie and Rein, ${ }^{11}$ elaborated by Huron and Claverie, ${ }^{12}$ was utilized for the actual numerical calculations. Within this approximation, the interaction energy can be written in terms of the charge distributions of the 2 chains approximated by point charges centered at the nuclei and the polarizabilities of the bonds, together with an algorithm for computing the repulsive energy component as the charge distribution begin to overlap. The actual working equations are given below.

For convenience we designate the 2 chains by subscripts 1 and 2 and let $N_{\mathrm{i}}$ and $B_{\mathrm{i}}$ be the number of atoms and bonds, respectively, in chain i. Then the long-range interaction energy can be written as a sum of electrostatic ( $E_{\mathrm{e}}$ ), polarization ( $E_{\mathrm{p}}$ ), and a dispersion $\left(E_{\mathrm{d}}\right)$ components. The explicit formulas are as follows.

$$
\begin{align*}
& E_{\mathrm{e}}=\sum_{\mathrm{i}=1}^{N_{1}} \sum_{\mathrm{j}=1}^{N_{2}} \frac{q_{\mathrm{i}} q_{\mathrm{j}}}{R_{\mathrm{ij}}} \\
& E_{\mathrm{p}}=-\frac{1}{2} \sum_{\mathrm{k}=1}^{B_{1}} \varepsilon_{\mathrm{k}} \overline{\bar{A}}_{\mathrm{k}} \varepsilon_{\mathrm{k}}-\frac{1}{2} \sum_{\mathrm{l}=1}^{B_{2}} \varepsilon_{1} \overline{\overline{\mathrm{~A}}}_{1} \varepsilon_{\mathrm{l}}  \tag{2}\\
& E_{\mathrm{d}}=-\frac{1}{4} \times \frac{I_{1} I_{2}}{I_{1}+I_{2}} \sum_{\mathrm{k}=1}^{B_{1}} \sum_{\mathrm{l}=1}^{B_{2}} R_{\mathrm{k} 1}^{-6} \operatorname{Tr}\left[\overline{\bar{T}}_{\mathrm{k} 1} \overline{\overline{\mathrm{~A}}}_{\mathrm{k}} \overline{\overline{\mathrm{~T}}}_{\mathrm{k} 1} \overline{\overline{\mathrm{~A}}_{1}}\right] \tag{3}
\end{align*}
$$

In eq $1, q_{\mathrm{i}}$ is the charge at nucleus i and $R_{\mathrm{ij}}$ is the distance between the nuclei $i$ and $j$. The quantity $\varepsilon_{k}$ in eq 2 is the electric field at the center of bond k (in chain 1 ) due to the monopole charges $q_{\mathrm{j}}$ of molecule 2
$\varepsilon_{\mathrm{k}}=\sum_{\mathrm{j}=1}^{N_{2}} q_{\mathrm{j}} \mathbf{R}_{\mathrm{jk}} R_{\mathrm{jk}}^{-3}$
where $R_{\mathrm{jk}}$ is the distance from nucleus j to the mid point of bond k , and $R_{\mathrm{jk}}$ is the vector of magnitude $R_{\mathrm{jk}}$ pointing from center j to the bond midpoint k . The quantity $\overline{\overline{\mathrm{A}}}_{\mathrm{k}}$ is the polarizability tensor for bond $k$.

The dispersion equation, eq 3 , contains the average excitation energies, $I_{1}$ and $I_{2}$ approximated by the ionization potentials and a factor $x$ which corrects for the fact that the usual London equation ( $x=1$ ) gives a result which is too small. The quantity $R_{\mathrm{kl}}$ is the distance between the midpoints of bond k and 1 , and the tensor $\mathrm{T}_{\mathrm{kl}}$ is defined as

$$
\begin{equation*}
\overline{\bar{T}}_{\mathrm{k} 1}=3 \frac{\mathbf{R}_{\mathrm{k} 1} \cdot \mathbf{R}_{\mathrm{k} 1}}{R_{\mathrm{k} 1}^{2}}-\mathbf{1} \tag{5}
\end{equation*}
$$

where 1 is the unit matrix. The symbol $\operatorname{Tr}$ in eq 3 indicates the trace of the quantity in parenthesis.

The final contribution which must be considered is the repulsion resulting from overlap of the charge distributions of the 2 chains, which we designate as $E_{\mathrm{r}}$. We use the Kitaygorodsky repulsion ${ }^{13}$ derived empirically from crystal energies of hydrocarbons, but slightly modified by Huron and Claverie. This relation is
$E_{\mathrm{r}}=30,000 \sum_{\mathrm{i}=1}^{N_{1}} \sum_{\mathrm{j}=1}^{N_{2}} \exp \left[-5.5 R_{\mathrm{ij}}\left(V_{\mathrm{i}} V_{\mathrm{j}}\right)^{-1 / 2}\right]$
where $V_{i}$ is the van der Waals radius of atom $i$.
Standard bond lengths and angles are assumed for the 2 side chains. The ionization potentials in eq 3 are taken as 0.4 and 0.37 atomic units, the bond polarizabilities are taken from Denbigh ${ }^{14}$ or le Fevre ${ }^{15}$ and the van der Waals radii are $1.1,1.6$, and $1.4 \AA$, respectively, for $\mathrm{H}, \mathrm{C}$, and O . The monopole charge distribution is derived from iterative extended Hückel calcns ${ }^{16}$ on isolated chains followed by a Mulliken population analysis. ${ }^{17}$ The IEHT method was not utilized for conformational calcns since it requires a good deal more computer time with no promise of producing significantly better results. The charges are given in Table I.

## Results

The results of the numerical calculations are given in Table II. The notations utilized are summarized below.
The 2 possible half-chair conformations of the cyclopentanone ring are denoted by $D$ and $U$, the former indicating the conformation in which the angle between the bond vectors $\mathrm{C}_{8}-\mathrm{C}_{7}$ and $\mathrm{C}_{12}-\mathrm{C}_{13}$ is a maximum. This angle is a minimum for the conformations labeled $U$.
The basic conformation to which all others are referred is that for which the alkyl parts of the side chains are in an all-

trans configuration, with the carboxyl chain trans to the $\mathrm{C}_{8}-\mathrm{C}_{9}$ bond. The $\mathrm{C}_{13}-\mathrm{C}_{14}$ double bond eclipses the $\mathrm{C}_{12}-\mathrm{H}$ and $\mathrm{C}_{15}-\mathrm{H}$ bonds, and the pentyl group $\left(\mathrm{C}_{16}-\mathrm{C}_{20}\right)$ is taken to be trans to the $\mathrm{C}_{14}-\mathrm{C}_{15}$ bond. Gauche conformations arising from this basic structure are listed in Table I by clockwise or counterclockwise ( c or cc ), indicating rotation about the denoted bond. To carry out these rotations properly, the molecule is assumed oriented such that the cyclopentanone ring is at a maximum distance from an observer, and the side chains are directed toward him, with the carboxyl chain on the left, as shown in Figure 1.
The energies $E_{\mathrm{e}}, E_{\mathrm{p}}, E_{\mathrm{d}}$, and $E_{\mathrm{r}}$ are the components of the chain-chain interaction energy as discussed in the previous section, $E_{\mathrm{c}}$ is the conformational correction due to formation of gauche structures, and $E_{\mathrm{t}}$ is the total of these five values. All results are given in kilocalories per mole.
The values given in Table II are the predicted results for the lowest lying 12 conformations. These were selected from a study in which over 400 conformations were examined. It is felt that this table includes all the low lying configurations for prostaglandin $\mathbf{E}_{1}$. It should be noted that we have not found any conformation lying within at least $3 \mathrm{kcal} /$ mole of the preferred mode in which there is any evidence of H bonding.
It is evident from the results that the role of intramolecular forces is a very important one in determining the favorable conformations. This is strikingly illustrated by considering the basic structure and the two gauche configurations arising from clockwise or counterclockwise rotation about the $\mathrm{C}_{17}-\mathrm{C}_{18}$ bond. Clockwise rotation leads to a much more favorable positioning of the chains which is manifested by a large increase (in absolute magnitude) in dispersion energy. This is partially compensated by a concomitant increase in the repulsion, the net effect being a more favorable chainchain interaction energy of $1.55 \mathrm{kcal} /$ mole. Subtracting 0.6 $\mathrm{kcal} / \mathrm{mole}$ due to the formation of a gauche structure leads to a net gain of $0.95 \mathrm{kcal} /$ mole, making this conformation the most favorable of all those examined. Counterclockwise rotation, on the other hand, leads to a net gain in chain-chain interaction energy of only $0.30 \mathrm{kcal} / \mathrm{mole}$, so that this configuration is actually less favorable than the basic one when the conformational component is added. These two gauche conformations are essentially degenerate in the absence of chain-chain interactions, so that the latter effect has led to a splitting of $1.25 \mathrm{kcal} /$ mole.

## Discussion

In carrying out the calculations described in this paper, we have attempted to make use of available experimental data and to make all assumptions as reasonable as possible. This does not leave the present study free of criticism. It is unfortunate that the number of assumptions made must necessarily be so large, but if the results reported here are viewed as preliminary and suggestive only, we feel they should be of significant aid in interpreting the pharmacological properties of prostaglandin $\mathrm{E}_{1}$.
It should be pointed out at this time that one assumption which has been made is considerably less valid than the others This is the assumption that the 2 possible half-chair conformations of the cyclopentanone ring have equal energies, aside from chain-chain interaction. It is probable that the U conformations are somewhat more favored in that such configurations bring $\mathrm{C}_{7}$ more closely into a cis-type arrangement with respect to the carbonyl group. The cis conformation of propionaldehyde is more stabile than the gauche by about $0.9 \mathrm{kcal} /$ mole,${ }^{18}$ so that the U conformations may be further favored in this study by perhaps $0.2-0.3 \mathrm{kcal} / \mathrm{mole}$. Therefore, the exact nature of the second lowest lying conformation may be somewhat doubtful.
The results of this study indicate that the U-type conformations of prostaglandin $E_{1}$ show a distance between the ring and unsaturated chain hydroxyl oxygen atoms of about 5.1 $\AA$, which is the same as the $O-O$ separation in active $\beta$ adrenergic agonists. These 2 O's are considered vital in binding the $\beta$-adrenergic agent to the receptor site, so that the activity of prostaglandin $E_{1}$ is not surprising, in that we have previously speculated that the presence of an onium group does not appear to be essential for efficacious $\beta$-adrenergic agents. ${ }^{6}$ These results then support our hypothesis concerning $\beta$-adrenergic activity.
The calculations indicate that a definite pattern or patterns of atoms involving the chains and the rings prevails by virtue of the dispersion interactions between chains, molding each other into a few fairly rigid arrangements. If dispersion bonding between chains was not significant, then the chains would assume isolated independent arrangements.

In this case the energetic ease of formation of gauche conformations of each chain would not permit either chain to present to a receptor a prominent or dependable pattern of atoms. The molecule would likely resemble a fatty acid or long-chain alcohol as far as nonspecific biological activity. It is also possible now to explain why chain modifications found in the prostaglandin series can have such a profound effect on activities. These changes likely influence interchain dispersion, hence conformation.
Two observations can be made upon consideration of these results. First, in addition to defining what we have predicted to be the $\beta$-adrenergic pattern in the ring and alcohol side chain, another pattern emerges involving the ring and carboxyl side chain. In most of the prominent conformers predicted, the distance separating the ring carbonyl O atom and an O atom of $\mathrm{CO}_{2} \mathrm{H}$ is about $10.5 \AA$. This is identical with the interoxygen distance previously predicted for several active 3,20 -keto steroids. ${ }^{19}$ The significance of this predicted congruence and possible common biological activities remains to be demonstrated.
The second observation concerns a rationale for the design of compounds with $\mathrm{PGE}_{1}$ activity of a more potent or more selective nature. It is proposed from these studies that the 2 chains stabilize each other through dispersion interaction. Therefore, if the features of the ring and the alcohol chain are presumed essential for the $\beta$-adrenergic-like activity, molecular refinements of the molecule must retain enough of the other chain to permit the interchain conformation stabilizing influence. It might be possible, however, to remove or modify $\mathrm{CO}_{2} \mathrm{H}$, thereby removing an alternate receptor feature and eliminating a particular biological response. It would appear, however, that significant portions of each chain are necessary in minor modifications of $\mathrm{PGE}_{1}$ in order to retain any of the existing activities.

    ${ }^{b}$ This conformation involves gauche configurations in two consecutive $\mathrm{C}-\mathrm{C}$ bonds and is considered less favorable than a random double gauche configuration. We have arbitrarily assigned a conformational contribution of $1.5 \mathrm{kcal} / \mathrm{mole}$ to this configuration.
