## Abstract

The role of the metal during the reduction of NO<sub>2</sub> by propylene in oxygen over alumina and silica-supported gold, rhodium and platinum was studied. It was found that three parallel reactions take place, i.e., reduction of NO<sub>2</sub> to N<sub>2</sub> and N<sub>2</sub>O, reduction of NO<sub>2</sub> to NO, and oxidation of propylene. It was also found that in the case of rhodium and platinum catalysts, the reaction may proceed entirely on metallic sites and that the alumina and silica supports do not play a critical role in determining the catalytic activity for NO<sub>2</sub> reduction. For gold catalysts, the reaction seems to involve a combination of metal and support catalyzed processes. It was noted that the selectivity toward N<sub>2</sub> formation seems to be primarily influenced by the nature of the metal. © 1997 Elsevier Science B.V.

*Keywords:* NO<sub>2</sub> reduction; Propylene; Rhodium; Platinum; Gold; Alumina; Silica supported catalyst

## 1. Introduction

The reduction of NO<sub>x</sub> to N<sub>2</sub> is a subject of great interest, from both theoretical and practical aspects, as attempts are being made to get more insight into the nature of the active sites and to find catalysts and reaction conditions which would maximize the catalytic activity for the reduction of nitrogen oxides.

In the literature, the role played by different constituents of the catalysts in the reaction mechanism of NO<sub>x</sub> reduction is still not clear because it seems to vary depending on the type of the reactant and the catalytic systems used. Another complicating factor is that it seems that

different mechanisms may be operable with different catalysts [1–5].

In an attempt to address the fundamental question concerning the role of the metal in the mechanism of the selective catalytic reduction (SCR) of NO<sub>x</sub>, we studied the reduction of NO<sub>2</sub> over alumina and silica-supported gold, rhodium, and platinum catalysts so as to gain insight into the possible role of metals during this process.

## 2. Experimental

### 2.1. Catalyst preparation

The gold, rhodium and platinum catalysts were prepared by impregnation of γ-Al<sub>2</sub>O<sub>3</sub> (KHS-24 from Sumitomo Chemical, initially

<sup>\*</sup> Corresponding author. Fax: +81-298-588259.

calcined in air at 600°C for 5 h, area 208 g m<sup>-2</sup>) and silica (70–230 mesh, Merck) with aqueous solutions of H<sub>2</sub>AuCl<sub>4</sub> · 4H<sub>2</sub>O, RhCl<sub>3</sub> · 3H<sub>2</sub>O and H<sub>2</sub>PtCl<sub>6</sub> · 6H<sub>2</sub>O, so as to yield 3 wt% metal loading. After impregnation, the slurries were freeze dried overnight at 15 Pa, then calcined in flowing air at 500°C for 5 h and finally reduced at 400°C under 1 vol% H<sub>2</sub> for 15 h. The resulting powders were sieved to give a 60–100 mesh fraction.

## 2.2. Catalyst characterization

The BET surface areas were determined using N<sub>2</sub> physisorption and a Niskso 4232 analyzer. The dispersion of Pt and Rh were measured after activity tests by adsorption of CO using the pulse adsorption technique and the Ohkura R6015 system. The dispersion of Au particles was not determined due to the lack of an appropriate adsorbate.

Transmission electron micrographs (TEM) of the catalyst samples were obtained with a JOEL JEM-2000EX electron microscope. The metal particle size distributions were obtained from diameter measurements of up to 500 particles per catalyst sample from TEM photographic print enlargements, in a procedure similar to that we have reported previously [6]. The physicochemical properties of alumina supported catalysts are summarized in Table 1.

Table 1  
Physicochemical properties of the catalysts

Catalyst	Surface area <sup>a</sup> (m <sup>2</sup> /g)	Dispersion <sup>b</sup> (%)	<i>d</i> <sub>metal</sub> <sup>c</sup> (nm)
γ-Al <sub>2</sub> O <sub>3</sub>	208	—	—
3% Au/Al <sub>2</sub> O <sub>3</sub>	177	n.d. <sup>d</sup>	54
3% Rh/Al <sub>2</sub> O <sub>3</sub>	172	75	0.9
3% Pt/Al <sub>2</sub> O <sub>3</sub>	164	34	1.0

<sup>b</sup> Determined by CO adsorption.

<sup>c</sup> Mean diameter of metal crystallites, determined from TEM micrographs (magnification: 400 000–2 000 000) by counting 100–500 particles for each sample.

<sup>d</sup> Not determined due to the lack of an appropriate adsorbate.

## 2.3. Catalytic measurements

The catalytic experiments were performed in a continuous flow tubular, quartz reactor (8 mm I.D.) operated at atmospheric pressure. The catalyst (200 mg) was packed into a 7–8 mm long bed between plugs of quartz wool. The feed consisted of the mixtures of ca. 1000 ppm NO<sub>2</sub>, 1000 ppm C<sub>3</sub>H<sub>6</sub>, and 5% O<sub>2</sub>, with a He (UHP) balance. The gas flow rates were controlled with mass flow controllers, and the total flow rate was maintained at 160 cm<sup>3</sup>/min (STP), corresponding to a space velocity of ca. 27 000 h<sup>-1</sup>. The feed gases was passed downward through the catalyst layer. After activity measurements at a given temperature, by bypassing the catalyst bed a background spectrum was measured to determine initial concentrations of NO, NO + NO<sub>2</sub>, N<sub>2</sub>O, CO and CO<sub>2</sub>. The equilibrium for the reaction NO<sub>2</sub> = NO + 1/2O<sub>2</sub> is such that a small amount of NO and O<sub>2</sub> are always present in NO<sub>2</sub> at room temperature (*K*<sub>298 K</sub> = 7.23 × 10<sup>-7</sup>) [7]. Thus in the NO<sub>2</sub> feed, NO was initially present as a 0.6–1% impurity. The temperature was monitored by a thermocouple placed below the catalyst bed. The activity data were acquired at steady state, in an ascending temperature sequence followed by a descending temperature sequence. The obtained data had fairly good reproducibility.

## 2.4. Analysis

Total NO<sub>x</sub> (NO + NO<sub>2</sub>) in the feed and product streams was analyzed with a chemiluminescent NO<sub>x</sub> analyzer (Yanagimoto, ECL-77A). The NO concentration was analyzed with a Horiba CLA-510SS analyzer. In repeated experiments, the product concentrations of nitrogen oxides were reproducible within ±5%.

The N<sub>2</sub>, O<sub>2</sub> and CO in the effluent was sampled and analyzed by gas chromatography (GC) (Shimadzu, 14A) with a thermal conductivity detector (TCD), using 40 cm<sup>3</sup> min<sup>-1</sup> He

as a carrier gas and a 2 m molecular sieve 13X column at 70°C. The outlet N<sub>2</sub>O was analyzed both with a Horiba VIA-510 analyzer and by GC (Shimadzu GC-14B) equipped with a TCD detector and a 2 m stainless steel column packed with molecular sieves 13 × at 70°C. Carbon dioxide and CO in the products were analyzed with a non-dispersive infrared spectroscopic gas analyzer (Shimadzu, URA 106). The identification of the minor products was performed using a Hewlett Packard HP5970B GC-MS.

The following expressions will be used in the text. The conversion of NO<sub>2</sub> is defined as:

$$X_{\text{NO}_x} = \frac{([\text{NO}_2]_r + [\text{NO}]_r - [\text{NO}_2]_p - [\text{NO}]_p)}{[\text{NO}_2]_r} \times 100$$

Selectivity to N<sub>2</sub> =  $[\text{N}_2]/([\text{N}_2] + [\text{N}_2\text{O}]) \times 100$ .

Amount of carbon in C<sub>3</sub>H<sub>6</sub> converted to CO<sub>2</sub> and CO: e.g.,

$$\text{CO}_2 = [\text{CO}_2]_p \times 100/3[\text{C}_3\text{H}_6]_r.$$

where [NO<sub>2</sub>]<sub>r</sub> and [NO<sub>2</sub>]<sub>p</sub> are reactor inlet and exit NO<sub>x</sub> concentrations, respectively, and [N<sub>2</sub>] and [N<sub>2</sub>O] are the exit N<sub>2</sub> and N<sub>2</sub>O concentrations, respectively.

### 3. Results

#### 3.1. The NO<sub>2</sub> = NO + 1/2O<sub>2</sub> reaction in the absence of propylene

Fig. 1a shows the activities of the catalysts for NO<sub>2</sub> decomposition into NO. Nitrogen and N<sub>2</sub>O were not detected in the product stream. For Rh and Pt catalysts, the conversion of NO<sub>2</sub> to NO increased with temperature and quickly attained equilibrium conversion levels at ca. 350°C and 400°C, respectively. At temperatures > 400°C, the thermodynamic equilibrium strongly favors the partial decomposition of NO<sub>2</sub> into NO and oxygen. This reaction was slow on Au and γ-Al<sub>2</sub>O<sub>3</sub>, and the conversions were always some distance from equilibrium. For

Au/Al<sub>2</sub>O<sub>3</sub>, the temperatures required for the onset of NO<sub>2</sub> conversion to NO was > 350°C. Also, pure γ-Al<sub>2</sub>O<sub>3</sub> significantly converted NO<sub>2</sub> to NO at temperatures > 400°C. The same results were obtained in repeated experiments with another batches of γ-Al<sub>2</sub>O<sub>3</sub> and new reactors.

When the feed was a mixture of NO and O<sub>2</sub> (Fig. 1b), the oxidation of NO to NO<sub>2</sub> over Rh/Al<sub>2</sub>O<sub>3</sub> and Pt/Al<sub>2</sub>O<sub>3</sub> increased progressively with temperature passing over a maximum of 58 and 45% at ~ 350°C before declining to near equilibrium conversions of 44 and 42% at ca. 400°C, respectively. Only a slight oxidation of NO was observed on Au, peaking at about at 450°C. The γ-Al<sub>2</sub>O<sub>3</sub> showed only a marginal activity in NO<sub>2</sub> formation and it was practically independent of temperature in the tested range.

It follows from Fig. 1 that in large excess of oxygen the equilibrium between NO<sub>2</sub> and NO is approached rapidly on Rh/Al<sub>2</sub>O<sub>3</sub> and Pt/Al<sub>2</sub>O<sub>3</sub> in the temperature range between 350–400°C, but Au/Al<sub>2</sub>O<sub>3</sub> moves the reactants to equilibrium at temperatures > 500°C. The observed differences in the relative effectiveness of the catalysts for the NO<sub>2</sub> = NO + 1/2O<sub>2</sub> and its reverse reaction may possibly be ascribed to kinetic factors e.g., the differences in the dissociative adsorption rates of nitrogen oxides and oxygen, and the differences in the bonding strengths of the species formed on the catalysts surfaces. Finally, the results obtained in Fig. 1 suggest that the NO<sub>2</sub> = NO + 1/2O<sub>2</sub> forward and reverse reactions proceed on the same sites.

#### 3.2. The NO<sub>2</sub> + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction on alumina and silica-supported catalysts

The principal products from the NO<sub>2</sub> + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction on both alumina and silica-supported catalysts were nitrogen, nitrous oxide, nitric oxide, carbon dioxide and carbon monoxide, and water. A variety of minor side-products such as cyanides, oxygenated products such as HCHO, CH<sub>3</sub>CHO, C<sub>2</sub>H<sub>3</sub>CHO, (CH<sub>3</sub>)<sub>2</sub>C=O,

Fig. 1. Temperature dependence for (a) the  $\text{NO}_2$  conversion to  $\text{NO}$  and (b) oxidation of  $\text{NO}$  to  $\text{NO}_2$ . Feed: (a)  $\text{NO}_2 = 1000$  ppm,  $\text{O}_2 = 5\%$ ; (b)  $\text{NO} = 1000$  ppm,  $\text{O}_2 = 5\%$ , balance He. Flow rate,  $160 \text{ cm}^3/\text{min}$ ; catalyst,  $0.2 \text{ g}$ . The dashed line is the equilibrium conversion.

and small amounts of cracked products such  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_6$  were also present. A more detailed analysis of the minor products, and the variation of product distribution with temperature will be published elsewhere [8].

The catalytic effects on the selective reduction of  $\text{NO}_2$  over alumina (solid lines) and silica (dashed lines)-supported catalysts are summarized in Figs. 2–5. The conversion of  $\text{NO}_2$  over Pt and Rh supported on silica and alumina increased with temperature, reached a maximum at 250 and  $300^\circ\text{C}$ , respectively, and then declined sharply with increasing reaction tempera-

Fig. 2. Catalytic activities of silica (dashed line, closed symbol) and alumina (solid lines, open symbol)-supported 3 wt% Au, Rh and Pt for reduction of  $\text{NO}_2$ . Conditions:  $\text{NO}_2 = 970$  ppm,  $\text{C}_3\text{H}_6 = 1000$  ppm,  $\text{O}_2 = 5\%$ , balance He. GHSV =  $27000 \text{ h}^{-1}$ .

ture. Note that the maximum  $\text{NO}_x$  conversions are attained at lower temperatures than the temperature of maximum  $\text{NO}$  oxidation to  $\text{NO}_2$ , and the temperature where  $\text{NO}_2$  decomposition into  $\text{NO}$  reaches equilibrium (see Fig. 1). The activity curve of the Au catalyst was markedly different from those of Rh and Pt. The  $\text{NO}_2$  conversion increased steadily with temperature reaching conversions up to 52% at  $400^\circ\text{C}$  before gradually falling off with temperature [9]. The  $\text{NO}_2$  conversion over  $\gamma\text{-Al}_2\text{O}_3$  increased steadily with temperature and remained near 100% at temperatures  $> 400^\circ\text{C}$  [10]. It is worth noting that although  $\text{NO}_2$  conversion curves of  $\gamma\text{-Al}_2\text{O}_3$  and  $\text{Au}/\gamma\text{-Al}_2\text{O}_3$  are somewhat similar,  $\gamma\text{-Al}_2\text{O}_3$  is far more effective than the  $\text{Au}/\text{Al}_2\text{O}_3$  catalyst in the investigated temperature range. We will come back to this further in the text. In an empty reactor, not shown, there was practically no measurable  $\text{NO}_2$  conversion below  $500^\circ\text{C}$ .

The selectivity of  $\text{N}_2$  and the undesirable  $\text{N}_2\text{O}$  production from  $\text{NO}_2$  reduction are presented in Fig. 3. Platinum exhibited a poor selectivity to  $\text{N}_2$ , giving  $\text{N}_2\text{O}$  as a predominant product. The Au and Rh catalysts showed a good  $\text{N}_2$  selectivity, while  $\gamma\text{-Al}_2\text{O}_3$  reached  $\text{N}_2$  selectivities ca. 90% at temperatures  $> 350^\circ\text{C}$ . Overall,  $\gamma\text{-Al}_2\text{O}_3$  and  $\text{Au}/\gamma\text{-Al}_2\text{O}_3$  are more selective towards  $\text{N}_2$  with a lower formation of  $\text{N}_2\text{O}$ .

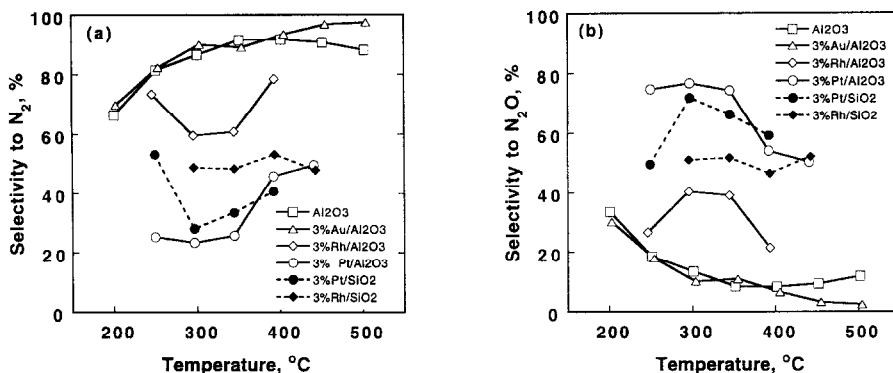

Fig. 3. Selectivity of NO<sub>2</sub> conversion to N<sub>2</sub> and N<sub>2</sub>O. Conditions as in Fig. 2.

Fig. 4 depicts the yield of CO and CO<sub>2</sub> from the conversion of C<sub>3</sub>H<sub>6</sub> during the reduction of NO<sub>2</sub>. It is seen that on Au, Rh and Pt catalysts, at temperatures greater than the optimum temperature, the combustion of C<sub>3</sub>H<sub>6</sub> becomes a predominant route. A notable feature here is the simultaneous enhanced evolution of the C<sub>3</sub>H<sub>6</sub> oxidation products CO<sub>2</sub> and CO, and the onset of the NO<sub>2</sub> conversion (see Fig. 2). Although  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> was able to convert NO<sub>2</sub> to N<sub>2</sub> it gave mainly CO in the process. A careful examination of Figs. 2 and 4 reveals that the low NO<sub>2</sub> conversion over Au/Al<sub>2</sub>O<sub>3</sub> in comparison with bare Al<sub>2</sub>O<sub>3</sub> can be attributed to the fact that at a substantial amount of propylene is burned over Au/Al<sub>2</sub>O<sub>3</sub> before it can selectively reduce NO<sub>x</sub>, and this leads to the suppression of its activity.

Fig. 5 shows the conversion of NO<sub>2</sub> to NO from the NO<sub>2</sub> + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction as a function of temperature. At low temperatures, a high conversion of NO<sub>2</sub> to NO, above equilibrium NO<sub>2</sub> → NO + 1/2O<sub>2</sub> conversion, was noted on Au, Rh and Pt catalysts. With increase in reaction temperature, the NO composition eventually approached the equilibrium between 350–400 °C on alumina-supported catalysts and, at ca. 400 °C over silica-supported catalysts. On Au/Al<sub>2</sub>O<sub>3</sub>, the NO yield fell below equilibrium concentrations at temperatures greater than the temperature of maximum NO<sub>2</sub> conversion (see Fig. 2). Over pure Al<sub>2</sub>O<sub>3</sub>, the NO yield was far below equilibrium and it remained more or less constant before declining at temperatures > 350 °C. Nearly the same conversions to NO

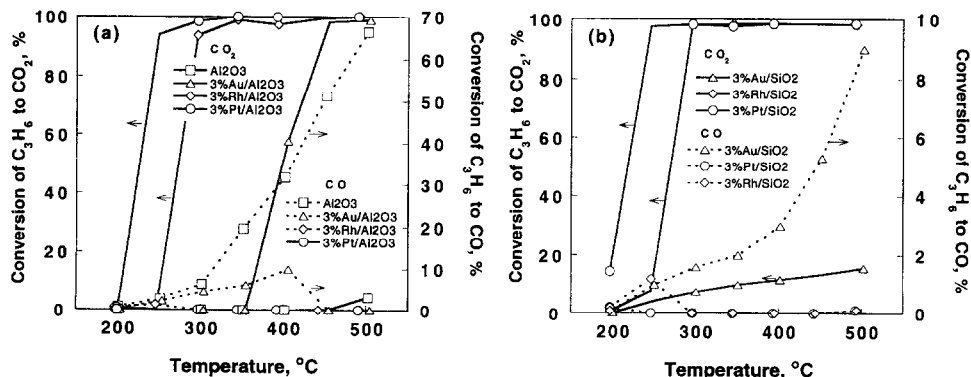

Fig. 4. Conversion of C<sub>3</sub>H<sub>6</sub> to CO and CO<sub>2</sub> as a function of temperature. Conditions as in Fig. 2.

Fig. 5. Conversion of  $\text{NO}_2$  to  $\text{NO}$  during the SCR of  $\text{NO}_2$ . Conditions as in Fig. 2.

were obtained in runs in which the reaction temperature was raised to  $500^\circ\text{C}$  and lowered again to  $200^\circ\text{C}$ .

It is evident from Figs. 2–5 that the temperature-dependent behavior, the percentage conversions of  $\text{NO}_2$  reduction to  $\text{N}_2$  for alumina- and silica-supported Rh and Pt catalysts are qualitatively quite similar; the most notable differences are that the measurable conversion set in at lower temperatures on alumina-supported catalysts than on silica-supported catalysts, and the disparity in the selectivity toward  $\text{N}_2$  formation; Rh catalysts exhibiting higher  $\text{N}_2$  yields. Thus,

it appears that alumina and silica has little, if any, direct effect on the  $\text{NO}_2$  reduction process over these catalysts. Surprisingly, only a minute activity was observed over  $\text{Au}/\text{SiO}_2$  and none on bare  $\text{SiO}_2$  at temperatures up to  $500^\circ\text{C}$ .

### 3.3. The $\text{NO} + \text{C}_3\text{H}_6 + \text{O}_2$ reaction

In order to get the full picture on the reduction of nitrogen oxides over these catalysts, we studied the  $\text{NO} + \text{C}_3\text{H}_6 + \text{O}_2$  reaction under identical reaction conditions, and the results are summarized in Table 2. In the case of Rh and Pt catalysts, the qualitative comparison between the  $\text{NO} + \text{C}_3\text{H}_6 + \text{O}_2$  and  $\text{NO}_2 + \text{C}_3\text{H}_6 + \text{O}_2$  systems indicates similar behaviors from the point of view of both products observed and the temperature of maximum activity. For  $\text{Au}/\text{Al}_2\text{O}_3$  and unsupported  $\text{Al}_2\text{O}_3$ , the conversion levels were lower than when the feed stream was  $\text{NO}_2 + \text{C}_3\text{H}_6 + \text{O}_2$ , but here the conversion levels of  $\text{NO}$  on  $\text{Au}/\text{Al}_2\text{O}_3$  was significantly higher than that of bare  $\text{Al}_2\text{O}_3$ . This result partially indicates that over bare alumina and  $\text{Au}/\text{Al}_2\text{O}_3$ ,  $\text{NO}_2$  plays a certain role in the reduction of  $\text{NO}$ . The results presented in Fig. 3 and Table 2 also suggest that the selectivity with respect to  $\text{N}_2$  seems to be primarily influenced by the nature of the metal used.

Table 2  
Catalytic activities and products from the  $\text{NO} + \text{C}_3\text{H}_6 + \text{O}_2$  reaction

Catalyst	$T_{\text{max}}^a$ ( $^\circ\text{C}$ )	Conversion (%)		Selectivity (%)		Yield of $\text{NO}_2$ (%)
		$\text{NO}$	$\text{C}_3\text{H}_6$	$\text{N}_2$	$\text{N}_2\text{O}$

No measurable activity was detected on bare silica.

## 4. Discussion

The purpose of this study was to obtain information concerning the catalytic reduction of  $\text{NO}_2$  and to investigate the role played by the metal during the SCR process.

From the results presented above, the tested catalysts can be divided into catalysts that are active at low temperatures ( $\text{Pt}/\text{Al}_2\text{O}_3$  and  $\text{Rh}/\text{Al}_2\text{O}_3$ ) and those active at relatively high temperatures ( $\text{Al}_2\text{O}_3$ ,  $\text{Au}/\text{Al}_2\text{O}_3$ ).

### 4.1. Pure $\text{Al}_2\text{O}_3$

During the SCR of  $\text{NO}_2$ ,  $\gamma$ -alumina has exhibited a significant activity towards  $\text{NO}_2$  reduction to  $\text{N}_2$ , and  $\text{NO}_2$  partial decomposition into  $\text{NO}$ . This may be rationalized in the terms of the following considerations: The surface of  $\gamma\text{-Al}_2\text{O}_3$  possesses both Lewis acid and basic sites which have been confirmed by strong adsorption of basic and acidic molecules [11]. Propylene can be activated on  $\gamma\text{-Al}_2\text{O}_3$  through the interaction with Lewis acid sites and/or by the concerted action of the basic and acidic sites to form allyl complexes [12,13]. The interaction of these adspecies with gas phase or adsorbed  $\text{NO}$  and  $\text{NO}_2$  complexes may lead to the formation of active intermediates which may eventually lead to the formation of the observed products. Recently, Sadykov et al. [14] provided experimental evidence that stable nitrates, as  $\text{M-NO}_3$  or  $\text{M-ONO}_2$ , were adsorbed on  $\gamma\text{-Al}_2\text{O}_3$  and suggested that the interaction of these strongly bound nitrogen oxides species with activated hydrocarbons provide the selective reduction route observed on  $\gamma\text{-Al}_2\text{O}_3$ .

### 4.2. Pt supported on $\gamma\text{-Al}_2\text{O}_3$ and $\text{SiO}_2$

The remarkable feature of the data from platinum catalysts is the great similarity in the  $\text{NO}_2$  conversion results over Pt supported on alumina and on inactive silica. The peak  $\text{NO}_2$  conver-

sion and kinetic behavior of  $\text{Pt}/\text{Al}_2\text{O}_3$  are very similar to those of  $\text{Pt}/\text{SiO}_2$ ; it seems that, on Pt-based catalysts, the SCR reaction may proceed predominantly on active centers of platinum crystallites of the catalysts. In other words, the support component contributes little to the SCR of  $\text{NO}_2$ . The high  $\text{NO}$  yields observed from the SCR of  $\text{NO}_2$  at lower temperatures may be ascribed to the fact that, apart from the direct decomposition of  $\text{NO}_2$  shown in Fig. 1a,  $\text{NO}$  is additionally produced from the interaction between adsorbed propylene and  $\text{NO}_2$ . Nitrogen dioxide has an unpaired electron. It is known that  $\text{NO}_2$  radicals can remove hydrogen from saturated hydrocarbons, e.g., during the nitration of  $\text{CH}_4$  to form nitromethane via a gas phase  $\text{NO}_2 + \text{CH}_4$  reaction [15,16]. Thus, it seems reasonable to speculate that during  $\text{NO}_2$  reduction,  $\text{NO}_2$  can abstract an allylic hydrogen from propylene to form  $\text{NO}$ ,  $\text{OH}$ , propenyl and/or allyl radicals, which may eventually take part directly or indirectly in subsequent  $\text{NO}_2$  reduction reactions.

As is evident from Figs. 2 and 4, the  $\text{NO}_2$  reduction activity over platinum-based catalysts passed through the maximum as the conversion of  $\text{C}_3\text{H}_6$  to  $\text{CO}_x$  increased and approached a 100% level. This demonstrates that part of the  $\text{C}_3\text{H}_6$  conversion process is initiated by the interaction between  $\text{NO}_2$  and  $\text{C}_3\text{H}_6$  species, as described above. After passing the peak activity, the  $\text{NO}_2$  reduction activity falls with increasing reaction temperature. The following explanations can be sought for this behavior. At temperatures higher than optimum temperature, the fall in activity of Pt catalysts is related to the decrease in surface coverage by nitrogen oxides or its complexes, i.e., nitrites and/or nitrates, and a decrease in organic adspecies due to desorption and/or decomposition. These factors decrease the  $\text{NO}_2$  reduction rate, as we have observed previously from in situ DRIFT spectroscopy studies [17,18]. Another explanation is the competition for propylene between oxygen (combustion process) and  $\text{NO}_x$  species. A higher temperature favors the  $\text{C}_3\text{H}_6$  combustion.

### 4.3. Rh supported on $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub>

The trend and performance of Rh/Al<sub>2</sub>O<sub>3</sub> were similar to that observed for Rh/SiO<sub>2</sub>. The NO<sub>2</sub> SCR reaction profile for rhodium catalysts was much the same to that observed in the case of alumina and silica supported-platinum catalysts. A notable exception is that Rh catalysts displayed a slightly wide activity window with a temperature of maximum NO<sub>2</sub> reduction ca. 50°C higher than that of Pt catalysts, and they provided a better N<sub>2</sub> selectivity in the whole temperature range examined. Similar activity trends were noted in the NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction (not shown). Therefore, the observed catalytic behavior of Rh catalysts can be explained on the similar basis as that discussed above for Pt catalysts.

When considering the commercial application of Rh and Pt catalysts, it would be important to minimize the formation of N<sub>2</sub>O which contributes to both stratospheric ozone destruction and greenhouse warming [19,20].

At the temperature of maximum NO<sub>2</sub> conversion, the N<sub>2</sub>/N<sub>2</sub>O concentration ratio in the exit stream was about 0.3 and 1.6 for Pt and Rh catalysts, respectively. In the NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction, the N<sub>2</sub>/N<sub>2</sub>O ratio was 0.6 and 1.6, for Pt and Rh catalysts, respectively (Table 2). Thus, for Rh catalysts, the selectivity to N<sub>2</sub> was nearly identical for the NO<sub>2</sub> + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> and NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> systems, whereas over Pt catalysts it was slightly better in the NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> system. The better selectivity to N<sub>2</sub> observed on Rh catalysts can be attributed to the fact that Rh catalysts have a good activity for N<sub>2</sub>O decomposition to dinitrogen. When we used the same Pt and Rh catalysts, to investigate the N<sub>2</sub>O (0.1%) + O<sub>2</sub> (5%)/He reaction, the steady-state rates for N<sub>2</sub>O decomposition were 3.6 and 5.7 × 10<sup>3</sup> μmol(N<sub>2</sub>O) g<sup>-1</sup> h<sup>-1</sup> for 3% Pt/Al<sub>2</sub>O<sub>3</sub> and 3% Rh/Al<sub>2</sub>O<sub>3</sub> at 300°C, respectively. At 400°C, the N<sub>2</sub>O decomposition rates were 20 and 24.4 × 10<sup>3</sup> μmol g<sup>-1</sup> h<sup>-1</sup> for 3% Pt/Al<sub>2</sub>O<sub>3</sub> and 3% Rh/Al<sub>2</sub>O<sub>3</sub>, respectively. On 3% Rh/Al<sub>2</sub>O<sub>3</sub>, the temperature of 50% (T<sub>50</sub>) de-

composition of N<sub>2</sub>O for the N<sub>2</sub>O + O<sub>2</sub> reaction was ca. 400°C [21,22]. Thus, the N<sub>2</sub>O decomposition performance of Pt/Al<sub>2</sub>O<sub>3</sub> is negligible in comparison to that of Rh/Al<sub>2</sub>O<sub>3</sub>. Therefore, the observed differences in the N<sub>2</sub>/N<sub>2</sub>O ratio between Pt and Rh catalysts during the SCR of NO<sub>2</sub> may be interpreted on the basis of the fact that Rh exhibits a significantly higher activity for the decomposition of N<sub>2</sub>O to N<sub>2</sub> than Pt catalysts.

Work is underway in our laboratory to develop catalysts for N<sub>2</sub>O decomposition after a NO<sub>x</sub> reduction stage. Preliminary results show that hydrotalcit derived catalysts, e.g., ZnAlRh-HTlc (0.8 wt% Rh) with a T<sub>50</sub> = 350°C, are prospective candidates for practical application even in the presence of water [22]. With such a catalyst, the overall conversion of NO<sub>x</sub> to N<sub>2</sub> can be improved and catalytic efficiencies of industrial relevance can be obtained.

### 4.4. Au supported on $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub>

The impregnation of gold on alumina slightly enhanced the activity for oxidation of NO to NO<sub>2</sub> (Fig. 1b), and led to the formation of a relatively large amount of NO during the SCR of NO<sub>2</sub> than that noted over bare alumina (Fig. 5). Over Au/SiO<sub>2</sub>, mainly a non-selective interaction between C<sub>3</sub>H<sub>6</sub> and NO<sub>2</sub> leading to the formation of NO and O<sub>2</sub> was noted; only a negligible NO<sub>2</sub> reduction activity to N<sub>2</sub> was observed. The fact that the activity of Au/Al<sub>2</sub>O<sub>3</sub> towards NO<sub>2</sub> reduction was lower than that observed over bare Al<sub>2</sub>O<sub>3</sub> implies that gold on the alumina masks some of the sites on the alumina and makes them inactive for reduction of NO<sub>2</sub>. On the other hand, Au/Al<sub>2</sub>O<sub>3</sub> displayed a better activity in the NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reaction. In this case, it appears reasonable to assume that, the reaction may involve a combination of metal and support catalyzed processes, where Au assists Al<sub>2</sub>O<sub>3</sub> in the formation of NO<sub>2</sub>, which is then mostly reduced to N<sub>2</sub> and small amounts of N<sub>2</sub>O on active sites of Al<sub>2</sub>O<sub>3</sub>. It may be added here that, the fact that the SCR

of NO<sub>2</sub> proceeds at such reasonable rate in spite of much of the NO<sub>2</sub> being converted to NO suggests that the propagation of the NO<sub>x</sub> reduction may take place via an interaction between activated C<sub>3</sub>H<sub>6</sub> species and either NO or NO<sub>2</sub>.

## 5. Summary

The Rh and Pt catalysts showed a relatively high NO<sub>2</sub> reduction activity in the 250–300°C temperature range but with a narrow temperature window over which the catalysts are effective. Gold and alumina showed a low activity towards NO<sub>2</sub> decomposition in the absence of propylene, moderate SCR activities at high temperatures with a broad temperature window, and a remarkably high NO<sub>2</sub> conversion selectivity to N<sub>2</sub> as compared with N<sub>2</sub>O.

The kinetic behavior and performances of Rh/Al<sub>2</sub>O<sub>3</sub> and Pt/Al<sub>2</sub>O<sub>3</sub> are very similar to that of Rh/SiO<sub>2</sub> and Pt/SiO<sub>2</sub> indicating that, in the case of Rh and Pt catalysts, the supports Al<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub>, contribute little to the catalytic activity for NO<sub>2</sub> reduction. The important factor appears to be the reaction dynamics between competing reactions, e.g., between the reduction of NO<sub>2</sub> to N<sub>2</sub> and N<sub>2</sub>O, NO<sub>2</sub> partial decomposition to NO and, combustion of propylene on the surfaces of rhodium and platinum or their oxides. In the case of gold catalysts, the reaction may involve a combination of metal and support catalyzed processes.

Since the both NO<sub>2</sub> + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> and NO + C<sub>3</sub>H<sub>6</sub> + O<sub>2</sub> reactions proceed at comparable rates over Rh and Pt, this suggests that the oxidation of NO to NO<sub>2</sub> is not a prerequisite for the SCR reaction to proceed over Pt and Rh metals. Such an initial NO pre-oxidation step seems to be necessary on catalysts like alumina or alumina-supported gold.

Finally, the present results also suggest that the selectivity with respect to N<sub>2</sub> seems to be

primarily influenced by the nature of the metal used.
