Abstract Artemisinin and some derivatives with activity against D-6 strains of *Plasmodium falciparum* were studied. Molecular electrostatic potential (MEP) maps were used in an attempt to identify key features of the compounds that are necessary for their activities, and then use those to propose new artemisinin derivatives. The partial least squares (PLS) method was then used to generate a predictive model. The PLS model with three latent variables explaining 88.9% of total variance, with $Q^2=0.839$ and $R^2=0.935$, was obtained for 15/6 compounds in the training/external validation set. For construction of the model, the most important descriptors were the highest occupied molecular orbital (HOMO) energy, atomic charges on the atoms O1 (Q_1) and C3 (Q_3), molecular volume (VOL), and hydrophilic index (HYF). From a set of 20 proposed artemisinin derivatives, one new compound (**39**) with higher antimalarial activity than the molecules initially studied was predicted. Synthesis of these new derivatives may follow the results of the MEP maps studied and the PLS modeling.

Introduction

Malaria is the major cause of death among the world's population in tropical regions of the planet. Most deaths are attributed to the parasite *Plasmodium falciparum*. The severity of the disease caused by this species results primarily from its ability to modify the surface of infected red blood cells by inserting proteins [1]. The enzymes in the parasite digestive vacuole (cysteine- and aspartic-proteinases) break down hemoglobin into amino acids and heme [2]. While all the amino acid content is used to build parasite proteins, only a small portion of the heme is incorporated into the parasite hemoproteins; the rest of the heme is detoxified (polymerized) by parasite enzymes [3]. A number of drugs have been investigated for their use in the treatment of malaria [4–7]. However, new strains of *Plasmodium falciparum* resistant to some of those drugs are causing substantial deterioration in clinical treatment [4–7]. This has motivated the search for new antimalarial drugs that are effective against this form of malaria, having thus a very high priority in antimalarial drug design [8–10]. This led to Chinese researchers introducing a new compound, qinghaosu (or artemisinin, as it is known in the West), present in extracts of Qinghao or *Artemisia annua* L. that have been used in China for thousands of years [11]. The structure of artemisinin was identified as an endoperoxide containing sesquiterpene lactone (Fig. 1, compound **1**) and the presence of the 1,2,4-trioxane-ring system seems to be essential for its antimalarial activity [12–16]. Studies on the mode of action of artemisinin and its derivatives have shown that free heme could be the molecule targeted by artemisinin in biological systems and that Fe^{+2} ions interact with the peroxide when artemisinins react with heme [8, 10, 17–20]. An initial step in the action of artemisinin includes heme-catalyzed artemisinin activation into a very reactive

radical, and the subsequent covalent binding of this radical to parasite proteins or heme [4, 10, 18–21], hemozoin [4, 18–22], reduced glutathione [4, 18–23] or other parasite molecules. On the other hand, experimental studies by Hynes and coworkers [24, 25] have demonstrated that the biological activity of artemisinin derivatives is not always related to their chemical reactivity.

In a systematic study of the structure of artemisinin and related molecules, Bernardinelli et al. [12] showed that active molecules have similar molecular electrostatic

potential (MEP) around the essential trioxane ring, and that this property is due to the peroxide linkage. Using the methodology of Bernardinelli et al., it is not possible to quantify the activities of the molecules studied, and so establish a quantitative comparison among those activities.

In a previous study, molecular graphics and modeling have supported partial least squares (PLS) results, revealing heme–ligand and protein–ligand stereoelectronic relationships as important factors in the antimalarial activity of artemisinin derivatives [26]. In this study, using an HF/3-

21G approach [27, 28], we built MEP maps to a training set of 21 active compounds (artemisinin and derivatives) against D-6 strains of *P. falciparum* from Sierra Leone that are resistant to mefloquine reported in the literature [29, 30] (Fig. 1), and 20 derivatives proposed by us (shown in Fig. 2, test set). The MEP maps were then evaluated and used in an attempt to identify key features of the derivatives that are necessary for their activities [12]. The PLS method [31–33] was then used to generate a predictive quantitative structure–activity relationship (QSAR) model.

Materials and methods

Computers, software, and compounds

The molecular calculations for this work were performed on an IBM-RISC-6000 machine and the statistical treatment was carried out on a PC Pentium IV computer.

In the molecular modeling step, the starting point was the construction of the structure of artemisinin (1) with the aid of GasussView software [34]. Complete geometry

optimization was carried out with the HF/3-21G method (in this work). In order to check the reliability of the geometry obtained, we compared the structural parameters of the artemisinin 1,2,4-trioxane ring with theoretical [35] and experimental [36, 37] values from the literature. All calculations reproduced most of the structural parameters of the artemisinin 1, 2, 4-trioxane ring seen in X-ray structures (Table 1). This applies especially to the bond length of the endoperoxide bridge which, as mentioned before, seems to be responsible for the antimalarial activity [12–16]. All the other structures (Figs. 1, 2) were built with the optimized geometry of the artemisinin, also using GaussView software. Complete geometry optimizations of these molecules were carried out using the Gaussian 98 program and the DIRECT-SCF method [38].

According to the literature, when we compare artemisinin with its derivatives, the MEP maps of active compounds are similar in form to that of artemisinin in the region of the 1,2,4-trioxane ring [12]. Figure 3 shows that compounds 1–21 have a region of negative electrostatic potential of similar form near the trioxane ring, which indicates that all the compounds in the training set are active. This evidence is supported by the experimentally determined activity values shown in Table 2 (see below). Using this premise, and chemical intuition, we introduced substitutes in the artemisinin derivatives of the training set

(Fig. 1) designed to maintain the antimalarial activity in the new derivatives shown in Fig. 2. The compounds in Fig. 1 were obtained from the literature [29, 30] and those which had a small methyl group substituted at the α -methylene carbon (*C) showed weaker activity than compounds with a larger carbethoxyalkyl substituent, indicating that steric effects of these molecule plays an important role in their antimalarial activity. However, we can infer that compounds (3 – 14) are 2- to 10-times more potent than artemisinin. In general, compounds containing chloride atoms (Cl) or bromide (Br) are more potent than analogous ones containing fluoride (F) or a methoxyl group (OCH₃), thus indicating that electronic effects may play an important role in the efficacy of these compounds. Compounds (15–21) are 3- to 9-times more potent than artemisinin; compounds containing electron-withdrawing groups such as O₂CH₃ and NO₂ substituted in the aromatic ring are more potent than analogous compounds in which the NO₂ group is absent. All the activities used in this article are logarithms of relative activity (RA) (RA = IC₅₀ of artemisinin/IC₅₀ of analogue). For each new derivative we built a corresponding MEP map and compared its form with those of compounds 1–21 in the region near the trioxane ring.

The MEP maps were computed from the electronic density and displayed using MOLEKEL software [39]. The

Molecular descriptors

In the descriptions of the structural characteristics of compounds **1** to **41** used to obtain valuable information about the influence of electronic, steric and hydrophobic features that allow us to quantify the biological activity of the molecules studied, we considered quantum descriptors [bond distances, bond and torsion angles, total energy, highest occupied molecular orbital (HOMO) energy, lowest unoccupied molecular orbital (LUMO) energy, Mulliken's electronegativity, molecular hardness, etc.]. With the pur-

pose of representing different sources of chemical information in terms of molecular size and shape, symmetry and atom distribution in the molecule, we also included holistic molecular descriptors. Molecular volume (VOL), molecular refractivity, and octanol–water partition coefficient descriptors were also considered.

The quantum descriptors were obtained with the Gaussian 98 program. The holistic descriptors were generated with the WHIM-3D program [40] and the other descriptors were obtained with the ChemPlus module [41].

Multivariate analysis

All multivariate analyses were performed with the Pirouette program [42].

Principal components analysis

The underlying purpose of principal components analysis (PCA) is dimension reduction. The use of this method produces a new set of variables called principal components (PCs), which is a linear combination of all the initial variables so that the first new variable (PC1) describes the largest variance in the data set, the second new variable (PC2) chosen must be orthogonal (uncorrelated) to the first, and in a direction such that it describes as many variances left as possible, and so on [31, 32].

Hierarchical cluster analysis

The primary purpose of hierarchical cluster analysis (HCA) is to display the data set in such a way as to emphasize its natural clusters and patterns in two-dimensional space. The distances between samples or variables that appear in the dendrograms are calculated and compared through the similarity index, which ranges from 0 (i.e., no similarity

and large distance among samples) to 1, for identical samples [31, 32].

Partial least squares analysis

In PLS analysis, a regression model was built between the X block of independent variables (given by the descriptors) and the Y vector (given by the activities). PLS is a projection method that uses projection of the matrix X onto a lower dimensional orthogonal basis, or at least a linear independent set [31–33].

Validation of the PLS model

The PLS model is validated through a cross-validation procedure (the leave-one-out technique) in order to verify the accuracy of the model in future predictions. The usefulness of the model is checked by SEP (Standard Error of Prediction), R² (correlation between the estimated values found by the model built with the full data set and actual values of y), Q² (crossvalidated correlation coefficient), and PRESS (predicted residual error sum of squares) parameters as well as the F-test.

Autoscaling

The purpose of autoscaling is to allow variables to be compared to each other on the same scale. In applying autoscaling, the data matrix was mean-centered followed by division by the standard deviation (autoscaling to unit variance).

Results and discussion

MEP maps

The MEP maps of artemisinin and artemisinin derivatives (1–21) are shown in Fig. 3. From this figure we can see that compounds (2–21) have similar MEP to artemisinin (1) around the essential trioxane ring.

To obtain the new artemisinins (22–41), we used the information reported by Lin et al. [30], and then considered the fact that a small methyl group substituted at the α -methylene carbon (*C) shows weaker activity than compounds with a larger carbethoxyalkyl substituent, which would increase the steric effect of the molecules and, concomitantly, their antimalarial activity. Compounds with electron-withdrawing function also substantially increase antimalarial activity.

The MEP maps to the new artemisinins (22–41) are shown in Fig. 4. In this figure, one can see that, around the essential 1,2,4-trioxane ring, the proposed compounds also present similar MEP to artemisinin (1).

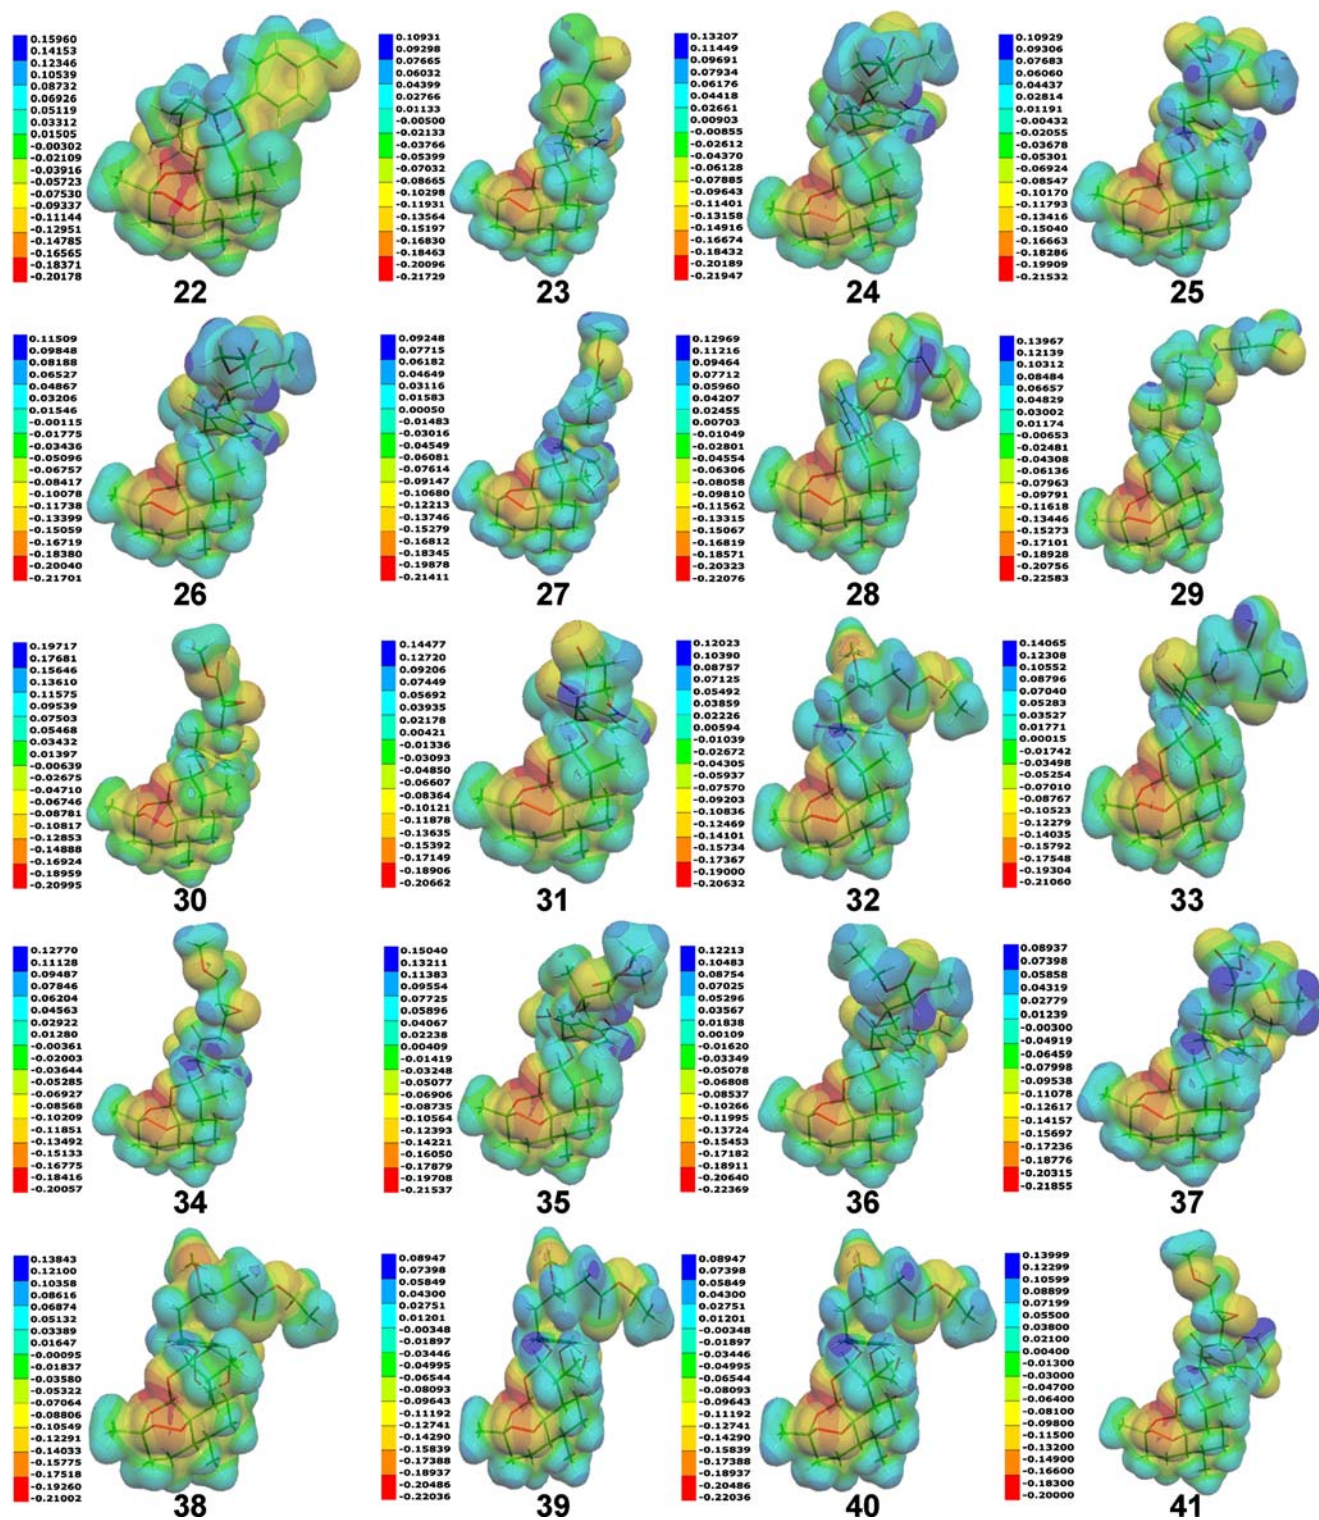

Fig. 4 MEP (au) maps to new proposed artemisinin derivatives with unknown antimalarial against D-6 strains of *P. falciparum*

Principle components and hierarchical cluster analysis

The analysis was started with 200 molecular descriptors and, in order to give each variable an equal weight in the analysis before applying the PCA, HCA, and PLS methods, each variable was auto-scaled. The selection

of descriptors was done by PCA through matrix correlation of the variables, and those that showed little correlation with activity (<0.20, exception Q₁) were discarded. The PLS model was then built with descriptors that in general supply larger regression vectors (>0.20, exception Q₁ and Q₃).

Analysis of the data facilitated the selection of five descriptors. Table 2 shows the descriptors (HOMO, Q_1 , Q_3 , VOL, and HYF), the activity values of the antimalarial artemisinin derivatives, and correlations—including all data for 21 compounds. For the descriptors the correlation is less than 0.84, as can be seen in Table 2. The results of the selection for the first three PCs explained 91.7% of the total variance for the first 21 molecules from the training set. Figures 5 and 6 show the PC1–PC2 scores and loadings plots. From Fig. 5, one can see that PC2 discriminates between the most active (3–9, 10, 15–21) and the least active (1, 2, 11–14) compounds. According to Fig. 6, the most active compounds have the main contribution of HOMO, Q_1 , Q_3 , and VOL in the first principal component, while the least active compounds have a major contribution of the HYF descriptor in PC2.

The results of the HCA are displayed in the dendrogram in Fig. 7 and are similar to those of PCA. The compounds are fairly well grouped according to their activity. From Fig. 7 one can see that the two clusters (+ and –) mirror the same two classes determined by PCA (Fig. 5).

PLS modeling

To build the PLS model, 15 compounds ($n=15$, calibration set) were used. Three latent variables (LVs) proved significant: the explained variance (%EV) is 88.9% of the total variance, the correlation coefficient (R) is 0.967, and $F(5,10)=25.892$. Figure 8 shows the plot of the correlation between the measured and predicted logRA for the three LVs model, with the highly active compounds located in its lower part. The quality of the PLS model can be seen by numerical comparison between the measured and predicted activities listed in Table 3 and by Q^2 , R^2 , and SEP. From Table 3, it can be seen that the agreement between measured and predicted values is quite satisfactory; taking

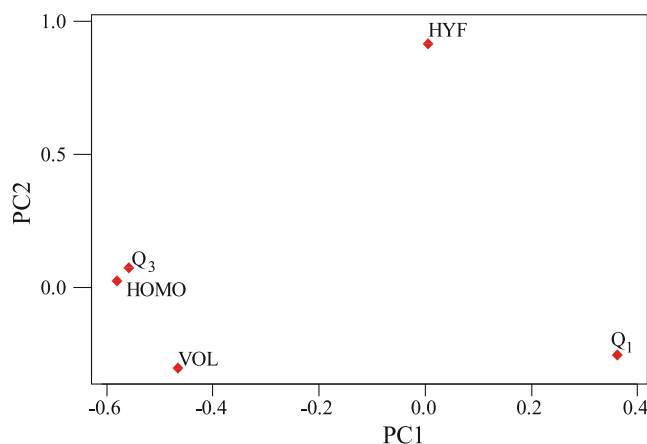

Fig. 6 Plot of the PC1–PC2 loadings obtained with the four descriptors selected to build the PLS model of artemisinin and derivatives with activity against D-6 strains of *P. falciparum*

into account the complex molecular structure of artemisinin. The parameters considered as criteria for explaining the performance of the PLS model are quite meaningful ($Q^2=0.839$, $R^2=0.935$).

$$\log RA = 0.2105HOMO + 0.024Q_1 + 0.1976Q_3 + 0.261VOL - 0.7006HYF$$

$$n = 15 \quad \%EV = 88.9 \quad R^2 = 0.935 \quad F_{(5,10)} = 25.8926 \\ Q^2 = 0.839 \quad SEP = 0.152 \quad PRESS = 0.347$$

Table 4 shows the predicted activities against D-6 strains of *P. falciparum* resulting from application of the regression model.

For the compounds in the test set, the results showed that the increase in the steric effect in the α -methylene carbon (*C) characterized by the introduction of substituents in this carbon or in the benzene ring in the position ortho to the methylene group reflects the increase in antimalarial activity predicted by the PLS model.

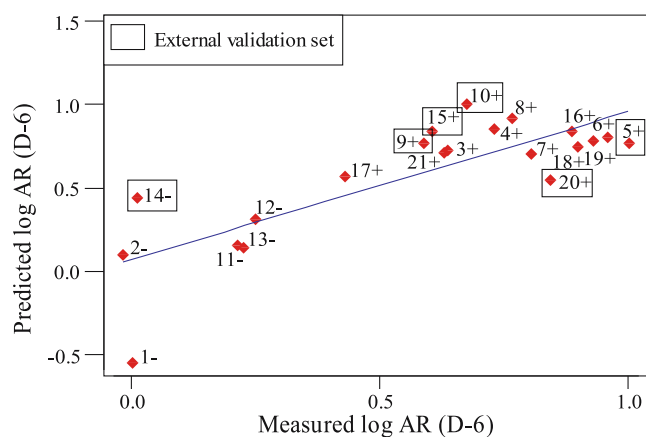

Fig. 8 Measured versus predicted log RA by PLS model using three latent variables (LVs). Symbols as in Fig. 5

For compounds in the test set predicted as less active (**22**, **23**, **28**, **30**, **33**), small substituent groups in R_3 and R_6 did not contribute to the increase in the molecular volume, thereby diminishing the antimalarial activity. However, for compounds (**27**, **37–41**) with large substituent groups in R_6 , we noticed an increase in the molecular volume and, consequently, an increase in antimalarial activity. The results of predictions for compounds in the test set reveal

that compounds (**25**, **27**, **37**, **38** and **40**) have predicted activities greater than that of artemisinin and some of the most potent derivatives in the training set (**3**, **4**, **7**, **8** and **21**).

Thus, information from QSAR models in combination with MEP maps can provide valuable insight into the experimental processes of syntheses and biological evaluation of the studied compounds.

Conclusions

MEP maps were built for 21 compounds reported in the literature with antimalarial activity against D-6 strains of *Plasmodium falciparum*. Key features of the molecules that are necessary for their antimalarial activity together with chemical intuition allowed the introduction of substituents in derivatives of artemisinin to obtain 20 new artemisinins active against the malaria *falciparum*.

For the antimalarials reported in the literature, a significant regression model was obtained using the PLS method, based on the HOMO energy, charge Q_1 (O1), charge Q_3 (C3), molecular volume (VOL), and hydrophilic index (HYF). The regression model showed statistical significance and revealed that higher values for the HOMO energy combined with lower negative charge on the atom O1 (Q_1), higher positive charge on the atom C3 (Q_3), higher values for the VOL, and generally lower values for the HYF, increase antimalarial activity against *P. falciparum*. The use of the QSAR model along with MEP maps can provide valuable insights during

the experimental processes of syntheses and biological evaluation of the studied compounds.

Acknowledgments We gratefully acknowledge the financial support of the Brazilian agencies Conselho Nacional de Desenvolvimento Científico e Tecnológico and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior. The authors would like to thank the Instituto de Química-Araraquara for the use of the GaussView software, and the Swiss Center for Scientific Computing for the use of the MOLEKEL software. We employed computing facilities at the Centro Nacional de Processamento de Alto Desempenho-Universidade Estadual de Campinas and at the Laboratório de Química Teórica e Computacional-Universidade Federal do Pará.
