Abstract The geometrical structures, energetics properties, and aromaticity of  $C_{36-n}Si_n$  ( $n \le 18$ ) fullerene-based clusters were studied using density functional theory calculations. The geometries of  $C_{36-n}Si_n$  clusters undergo strong structural deformation with the increase of Si substitution. For the most energy favorable structures of  $C_{36-n}Si_n$ , the silicon and carbon atoms form two distinct homogeneous segregations. Subsequently, the binding energy, HOMO–LUMO energy gap, vertical ionization potential, vertical electron affinity, and chemical hardness for the energetic favorable  $C_{36-n}Si_n$  geometries were computed and analyzed. In addition, the aromatic property of  $C_{36-n}Si_n$  cagelike clusters was investigated, and the result demonstrate that these  $C_{36-n}Si_n$  cagelike structures possess strong aromaticity.

## Introduction

Doping fullerene with various elements has attracted intense research efforts since the discovery of  $C_{60}$  [1, 2]. Interest in fullerene-based nanomaterials originates from the diverse dopants and capricious structures, which lead to exceptional physical, chemical and optoelectronic properties with potential applications in material science [3]. In recent years, several doped fullerenes have been produced successfully through introducing different dopants; examples include transitionmetal atoms [4], lanthanum and niobium [5], and nitrogen and boron [6-8]. Owing to the good performance of silicon carbide as a tunable bandgap semiconductor with high breakdown field strength, high thermal conductivity, and high saturation drift velocity [3, 9], many studies are searching for  $C_m Si_n$  fullerene-based nanostructures [9–13]. Silicon, which has the same kind of outer electronic structure as carbon, is an ideal candidate for C<sub>m</sub>Si<sub>n</sub> fullerene-like structures. However, Si prefers to form tetrahedral structures because of its  $sp^3$ -like bond features, and substitution of silicon will induce high instability. Therefore, with many Si atoms added, local strains increase in magnitude. Nevertheless, some experimental and theoretical studies have explicitly proved the existence of Sidoped heterofullerenes [14-23]. Ray et al. [10] acquired significant evidence of  $C_{2n-q}Si_q$  (2n=32–100; q <4) cage-type clusters via mass spectroscopy experiments. Moreover, a series of attempts was made to acquire  $C_{60-n}$ Si<sub>n</sub> ( $n \leq 30$ ) cagelike clusters [16-24]. Nevertheless, other than the experimental and theoretical studies on C60-nSin cagelike clusters, few works on silicon substituted small fullerenes have been reported [25-28]. The interesting issue with silicon heterofullerenes is to know to what extent carbon atoms can be substituted without destroying the cage framework, and to reveal the arrangement of silicon atoms in cagelike clusters, as well as the electronic and aromatic properties caused by Si substitution. However, due to the low chemical stability of small fullerenes, theoretical investigations on small  $C_m Si_n$  cagelike clusters are so far scarce.

Considering the absence of small  $C_m Si_n$  fullerene-like nanostructures, carbon fullerenes are usually considered as model structures. Among the numerous small carbon fullerenes, C<sub>36</sub> is one of the "magic-number" fullerenes that has gained special attention [29, 30]. Nevertheless, few experimental works have been reported on C<sub>36</sub> exclusively. Nuclear magnetic resonance spectra indicate that  $C_{36}$  fullerene has a  $D_{6h}$  point group [31]. Subsequent theoretical calculation showed that another  $D_{2d} C_{36}$ isomer exists that is almost isoenergetic to the  $D_{6h}$  structure [32, 33]. By virtue of the  $D_{6h}$  and  $D_{2d}$  isomers having a minimal number of adjacent pentagons, they are expected to be candidates for  $C_{36}$  fullerene. In the present work, we performed a density functional theory (DFT) study on the structural, energetic, and aromatic properties of  $C_{36-n}Si_n$  fullerene-based materials. Our results not only deepen understanding of the growth mechanism of C<sub>m</sub>Si<sub>n</sub>-based nanostructures and size-dependent evolution of physical properties, but will also inspire further experimental study to synthesize these novel fullerene-like materials.

### **Computational methodology**

All calculations were performed with the Gaussian 09 quantum chemical package [34]. Geometry optimizations were carried out without any symmetry constraints using the B3LYP functional [35, 36] in combination with the 6-31G(d) basis set. The accuracy of the B3LYP/6-31G(d) method has been proved acceptable for geometry optimization of large molecules [37, 38]. To make sure that the obtained lowest-energy structures are real local minima, normal-mode vibrational analysis was applied. All the energy minima obtained for the lowest-energy  $C_{36-n}Si_n$  clusters were confirmed by the absence of an imaginary mode. The electronic properties of the  $C_{36-n}Si_n$  clusters were analyzed on geometrical structures obtained at the B3LYP/6-31G(d) level. Vertical ionization potentials (VIP) and vertical electron affinities (VEA) were calculated as the total energy differences between clusters and charged clusters with the assumption that the electron transfer occurred in a time too short for the cluster to respond. In addition, aromaticity of  $C_{36-n}$ Si<sub>n</sub> cagelike clusters was evaluated by calculating nucleus-independent chemical shifts (NICS) [39, 40] at the molecule's center using the gauge-including-atomic-orbital (GIAO) method at B3LYP/6-31G(d) level.

## **Results and discussion**

Geometrical structures of  $C_{36-n}Si_n$ 

In the book *An Atlas of Fullerenes* [41], among all the 15 mathematically possible conventional isomers for  $C_{36}$ 

fullerene, only the  $D_{6h}$  and  $D_{2d}$  isomers have the minimal count of 12 pentagon adjacencies. According to the pentagon adjacency penalty rule (PAPR) [42], the most stable structure should be the one with the smallest number of adjacent pentagons. Consequently, the  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> cages are predicted to be most stable, and their geometrical structures are presented in Fig. 1.  $D_{6h}$  C<sub>36</sub> has a geometrical structure of a highly symmetric spheroid, with six-membered cyclic polyacene, joined to hexagonal terminal caps. For  $D_{2d}$  C<sub>36</sub>, eight hexagons are divided into two separate tetracene-like subunits by a chain made up of 12 pentagons.

To study  $C_{36-n}Si_n$  cagelike clusters, the first challenge is to find the lowest energy favorable structures. On the basis of  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> cages, C<sub>36-n</sub>Si<sub>n</sub> clusters were obtained in the following way (as suggested by Huda et al. [9]). Firstly, a Si atom is placed arbitrarily at a substitutional site in  $D_{6h}$  C<sub>36</sub> fullerene and the energy favorable structure obtained through comparing different symmetry nonequivalent sites. Next, a second Si atom is introduced in all symmetrically distinguishable positions of the most stable C35Si structures to obtain a C<sub>34</sub>Si<sub>2</sub> cluster. From C<sub>34</sub>Si<sub>2</sub>, the other energetically favorable structures of  $C_{33}Si_3$ ,  $C_{32}Si_4$ , ... are achieved in a similar way. The methodology of Si substitution for D<sub>2d</sub> C<sub>36</sub> fullerene was similar. Previous studies have proved that  $C_m Si_n$  clusters with equal proportions of silicon and carbon atoms are particularly stable, and the substitutional  $C_m Si_n$  clusters become unstable as the number of silicon atoms increases [43].

The energy favorable structures of  $C_{36-n}Si_n$  (n=1-18) cagelike clusters proceeding from  $D_{6h}$  and  $D_{2d}$   $C_{36}$  fullerene are presented in Tables 1 and 2. In these systems, the structures of clusters are distorted and yet maintained, and structural deformation occurred mainly in the vicinity of Si atoms. In the clusters from  $D_{6h}$   $C_{36}$  fullerene, the  $C_{35}Si$  has a framework in which a Si atom locates at the fusion site of a pair of pentagons and hexagons. The distance from Si to the cage center is 3.572 Å, about 0.880 Å longer than that of carbon atoms at the equivalent site, thus the Si atom tends to emerge from the cage structure. Mulliken charge analysis shows that an evident charge transfer exists between Si and C atoms. The Si atom in  $C_{35}Si$  has a positive charge of 0.352 |e|, and, accordingly, a negative charge is distributed uniformly among its first carbon neighbor atoms, as can be expected from

electronegativity considerations [44]. As an inference, the C-Si bonds are partially ionic. With Si substitution, the structural transition from C35Si to C34Si2 is very symmetrical. Two Si atoms in the C<sub>34</sub>Si<sub>2</sub> cluster occupy the para position of the hexagon, and the Si–Si bond is 3.329 Å. Next, as with C<sub>33</sub>Si<sub>3</sub>, a contorted cage structure with Si atoms standing in line is proposed to be the most energetically favorable. The Si-Si bond is 2.334 Å, which is comparable to the bond distance in bulk silicon (2.345 Å). Starting from C<sub>32</sub>Si<sub>4</sub>, the Si atom show a tendency to assemble, and this evolutionary trend continues up to the C<sub>18</sub>Si<sub>18</sub> cluster. Considering that the Si atom prefers to be accommodated in  $sp^3$  bonding hybridization, another configuration corresponding to spatially separated sets will lead to a decrease in stability. As a consequence, not only is there a structural deformation in the vicinity of Si atoms but a segregation of Si and C atoms in C<sub>36-n</sub>Si<sub>n</sub> cluster also clearly stands out. Accordingly, the segregation pattern increases in extent as the silicon content increases.

For the lowest-lying C<sub>35</sub>Si configuration from  $D_{2d}$  C<sub>36</sub> fullerene, the Si atom sits at the junction between a pair of pentagons and a hexagon. The Si–C bonds range from 1.938 Å to 1.954 Å, compared to the bonds of Si<sub>n</sub>C<sub>n</sub> (n=10–15) clusters [28]. In the C<sub>34</sub>Si<sub>2</sub> cluster, two Si atoms present a symmetrical distribution, with a Si–Si distance of 3.316 Å, slightly shorter than that of replacing  $D_{6h}$  C<sub>36</sub> via Si substitution. For production of C<sub>33</sub>Si<sub>3</sub>, the third Si atom prefers to locate beside the existing Si atom, just as in C<sub>33</sub>Si<sub>3</sub> from the  $D_{6h}$  C<sub>36</sub> cage. Nevertheless, an obvious difference also exists between these two types of C<sub>36-n</sub>Si<sub>n</sub> cagelike clusters, viz., the Si atoms herd together from n=4 for Si substitutions in the  $D_{2d}$  C<sub>36</sub> cage rather than n=18 for the  $D_{6h}$  C<sub>36</sub> cage. Consequently, both C and Si atoms tend to form subunits spontaneously in the C<sub>31</sub>Si<sub>5</sub>–C<sub>18</sub>Si<sub>18</sub> cluster structures.

After presenting the low-lying structures, it is very interesting to discuss the structural properties of  $C_{36-n}Si_n$  (n=1-18) clusters. The average bond lengths, and Mayer bond orders of C-C, Si-C, and Si-Si bonds are given in Table 3. Along with the longer length in going from C-C to Si-Si bonds, the relative chemical bonds strength decreases in the order C-C>Si-C>Si-Si. The bond lengths show significant variation with respect to the type of C-C, Si-C, Si-Si bonds in C<sub>36-n</sub>Si<sub>n</sub> clusters. The corresponding average distances of C-C, Si-C, Si-Si bonds in the cagelike clusters from the  $D_{6h}$  C<sub>36</sub> cage vary in the range of 1.434-1.455 Å, 1.821-1.914 Å, and 2.334-2.418 Å, respectively; and the counterparts of cagelike clusters from  $D_{2d}$  C<sub>36</sub> cage range from 1.433–1.442 Å for C–C bonds, 1.852–2.015 Å for Si-C bonds, and 2.344-2.458 Å for Si-Si bonds, respectively. By virtue of the structural distortion caused by C-C, Si-C, and Si-Si bonds, there is a tendency to maximize the number of C-C and Si-C bonds to relieve the strain energy. As a consequence, the Si atoms prefer to "pop out" in all  $C_{36-n}Si_n$ (n=1-18) clusters, similar to the case of small nonstoichiometric  $C_m Si_n$  clusters [19–23].

Table 3 also lists the average Mayer bond orders of C-C. Si-C, Si-Si bonds, which are proportional to the bond strength between different atoms [45]. For  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> cages, the average bond orders for C-C bonds are 1.226 and 1.229, which is comparable to the predicted bond order (1.250) of C-C bonds in C<sub>60</sub>. These results also lie between the values of the single bond in ethane (1.02) and the double bond in ethene (1.75) [46]. For Si-C bonds, the bond orders range from 0.882 to1.122 for cagelike clusters deriving from  $D_{6h}$  C<sub>36</sub> cage, and 0.840–1.075 for those cagelike clusters from  $D_{2d}$  C<sub>36</sub> cage, respectively, approaching 0.953 in silacyclobutane [47]. Due to the large distances in Si-Si bonds, a variety of average bond orders with considerably smaller values are observed. The smallest value reaches 0.733 for the  $C_{32}Si_4$  cluster from the  $D_{6h}C_{36}$  cage and 0.702 for the  $C_{33}Si_3$  cluster from the  $D_{2d}$   $C_{36}$  cage.

Stabilities and energetic properties

The stability of  $C_{36-n}Si_n$  cagelike clusters is still an intractable issue since no experimental confirmation has been reported. The binding energy ( $E_b$ ) is known to be an important quantity for estimating stability and possibility for experimental synthesis of  $C_{36-n}Si_n$  cagelike clusters;  $E_b$  can be calculated according to following equation:

$$E_b(C_{36-n}Si_n) = \frac{1}{36} [(36-n)E(C) + nE(Si) - E(C_{36-n}Si_n)]$$
(1)

where E(X) is the total energy of the corresponding X system. The binding energies for the lowest-energy structures of  $C_{36-n}Si_n$  clusters are also tabulated in Tables 1 and 2. The  $E_b$  for  $C_{36-n}Si_n$  clusters decreases with silicon substitution. Accordingly, a structure with one Si substitution is the most energetically favorable, and isomers where the C–Si proportion equals 1:1 are found to be less stable energetically. The  $E_b$  values of the  $C_{35}Si$  system are 8.43 and 8.44 eV/atom, respectively, i.e., about 0.12 eV and 0.13 eV/atom smaller than those of pristine  $D_{6h}$  and  $D_{2d}$   $C_{36}$  fullerene. Furthermore, a monotonically decreasing relationship between binding energy and the concentration of silicon is also observed from Tables 1 and 2; therefore, silicon substitution costs almost the same amount of energy (about 0.12 eV) despite the number of carbon atoms that have been replaced before.

Additionally, the energy gap  $(E_{gap})$  between the highest occupied molecular orbital (HOMO) and the lowest molecular orbital (LUMO) is also an important factor influencing the structural stability. The  $E_{gap}$  values for  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> fullerene are 1.09 and 1.39 eV, respectively, i.e., about 38.7 % and 21.9 % smaller than that of C<sub>60</sub> [48]. Looking at Fig. 2a, a significant oscillation is observed in the evolution trend of the  $E_{gap}$  with respect to silicon content. For clusters from  $D_{6h}$  C<sub>36</sub> fullerene, the  $E_{gap}$  of C<sub>28</sub>Si<sub>8</sub> is particularly

Table 3 Average bond lengths (Å) and average Mayer bond order (in parenthesis) of Si–Si, Si–C, and C–C bonds

large, whereas  $C_{25}Si_{11}$  has the smallest value of 0.83 eV. As for clusters from  $D_{6h}$   $C_{36}$  fullerene, the  $C_{21}Si_{15}$  and  $C_{34}Si_2$ clusters have the largest and smallest value of  $E_{gap}$ , respectively. Nevertheless, the  $E_{gap}$  for all  $C_{36-n}Si_n$  cagelike clusters is not very large, and varies from 0.83 to 1.35 eV for clusters from the  $D_{6h}$   $C_{36}$  cage, and 1.07 to 1.60 eV for those from the  $D_{2d}$   $C_{36}$  cage, respectively. Thus, these clusters are expected to be very reactive. Figure 2a also shows that  $E_{gap}$  for clusters from the  $D_{2d}$  cage are notably larger than those values of  $C_{36-n}Si_n$  $Si_n$  clusters from the  $D_{6h}$  cage overall, except in the case of  $C_{34}Si_2$  and  $C_{28}Si_8$  clusters. Consequently, the  $C_{36-n}Si_n$ cagelike clusters from the  $D_{2d}$  cage are more stable in energy.

The vertical electron affinity (VEA, energy difference between the neutral and mono-anionic molecules on the basis of the same neutral geometry) and vertical ionization potential (VIP, energy difference between the monocationic and the neutral molecule based on the same neutral geometry) are also important parameters for estimating the stability of  $C_{36-n}Si_n$ clusters. Figure 2b and c present VIPs and VEAs of  $C_{36-n}Si_n$ cagelike structures. The VIP value of  $D_{6h}$   $C_{36}$  fullerene is 6.61 eV, about 2.1 % greater than those of  $D_{2d}$   $C_{36}$  cage. Nevertheless, these two  $C_{36}$  isomers possess smaller VIPs in comparison with  $C_{60}$  (7.05 V) and, consequently,  $D_{6h}$  and  $D_{2d}$   $C_{36}$  fullerenes are liable to lose electrons. In view of the overall situation, the evolutionary trend of VIPs is quite similar to the case of the HOMO–LUMO gap. This downward trend gives an indication that the reactivity of pure  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> fullerene increases as the silicon increases. Except for C<sub>34</sub>Si<sub>2</sub>, clusters from the  $D_{2d}$  C<sub>36</sub> cage have a larger VIP with respect to the VIP of  $D_{6h}$  C<sub>36</sub> fullerene, implying that it is difficult to remove electrons from these clusters. For VEA values, there is no notable separation region between the cagelike clusters from  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> fullerene. The C<sub>36-n</sub>Si<sub>n</sub> cagelike structures have higher VEA values than the  $D_{2d}$  and  $D_{6h}$  cage on the whole (the VEA for  $D_{2d}$  and  $D_{6h}$  fullerene are 2.16 and 2.57 eV, respectively), and therefore these clusters have a slightly more reactive nature. Hence, this may be one reason that the C<sub>36-n</sub>Si<sub>n</sub> clusters have not been observed in experimental studies until now.

On the basis of the VIP and the VEA, the global chemical hardness ( $\eta$ ) [49] can be approximated by following formula:

$$\eta \approx \frac{1}{2} (\text{VIP} - \text{VEA}) \tag{2}$$

As is well known, cluster structures with large hardness values are often considered to be hard, and thus less reactive or more stable. Figure 2d offers a graphic definition of chemical hardness for all  $C_{36-n}Si_n$  cagelike clusters. The  $C_{33}Si_3$  clusters in both  $D_{2d}$  and  $D_{6h}$  fullerene have the highest values of chemical inertness (2.13 and 1.96 eV, respectively), implying that these two clusters are relatively stable among  $C_{36-n}Si_n$  clusters. Other clusters with apparent low values of chemical hardness may present an obstacle to finding these

**< Fig. 2** Size dependence of **a** the HOMO–LUMO energy gap, **b** vertical ionization potential (VIP), (**c**) vertical electron affinity (VEA), and (**d**) chemical hardness (η) of  $C_{36-n}Si_n$  clusters (*n*=1−18). The characteristic values of clusters from  $D_{2d}$  and  $D_{6h}$   $C_{36}$  fullerene are represented by a *dashed line/open circles* and *solid line/filled circles*, respectively

experimentally. The evolutionary tendency of chemical hardness is in good agreement with the HOMO–LUMO gap, and accordingly, an empirical correlation between the chemical hardness and HOMO–LUMO gap can be established qualitatively, viz., a hard molecule usually has a large HOMO– LUMO gap, and a soft molecule possesses a small HOMO– LUMO gap.

#### Aromatic stabilization energies

With respect to the stability of cagelike compounds, aromatic stabilization energies can provide some useful hints. The nucleus independent chemical shift (NICS) technique is the most common magnetic index of aromaticity in cage structure despite the existence of some flaws and limitations [50-54]. Previous study shows that aromatic molecules are chemically more stable than less aromatic or antiaromatic molecules [49]. In general, aromaticity and antiaromaticity are characterized by negative and positive NICS values, respectively. The NICS values of the  $C_{36-n}Si_n$  clusters are presented in Fig. 3. The NICS values of pristine  $D_{6h}$  and  $D_{2d}$  C<sub>36</sub> fullerene obtained at B3LYP/6-31G(d) level are -27.08 and -11.20 ppm, respectively, i.e., more negative than that of  $C_{60}$  [-4.25 ppm at B3LYP/6-311G(d) level]; these cages therefore present a strong aromatic character. With silicon substitution, the delocalized  $\pi$  electrons of the carbon cage are broken and then rebuilt on the remaining carbon subunit of the cage. In  $C_{36-n}Si_n$  clusters, the Si has a stronger preference for  $sp^3$ hybridization, and therefore Si substitution leads to a severe change of delocalized  $\pi$  electrons, as evidenced by the NICS

Fig. 3 Nucleus-independent chemical shift (NICS) values versus Si content in  $C_{36-n}Si_n$  (n=0-18) clusters

value at the cage center. The NICS values range from -9.37 to -30.95 ppm for clusters from the  $D_{6h}$  C<sub>36</sub> cage and -5.92 to -22.77 ppm for those from the  $D_{2d}$  C<sub>36</sub> cage, respectively. As to the set of clusters deriving from the  $D_{6h}$  C<sub>36</sub> cage, only C30Si6, C29Si7, and C28Si8 clusters present more negative values than their parent C<sub>36</sub> fullerene, and therefore these clusters shows an increase in aromaticity. Furthermore, it is also interesting to compare the NICS of cagelike clusters from the  $D_{2d}$  C<sub>36</sub> cage with the corresponding values from the  $D_{6h}$ C<sub>36</sub> cage. As Fig. 3 shows, compared to the NICS of cagelike clusters from the  $D_{6h}$  C<sub>36</sub> cage, the C<sub>35</sub>Si, C<sub>34</sub>Si<sub>2</sub>, and C<sub>33</sub>Si<sub>3</sub> from D<sub>2d</sub> C<sub>36</sub> cage have more negative NICS values, indicating stronger aromatic properties. The NICS values become less negative with further Si substitution, especially for  $C_{24}Si_{12}$  (NICS: -5.92 ppm), presenting weak aromaticity. The reason may be attributed to fact that, in the  $C_{36-n}Si_n$ clusters, carbon atoms preserve the conjugated pattern of fullerene while Si-Si bonds create a perturbing network capping the cluster. Consequently, these  $C_{36-n}Si_n$  heterofullerenes yield less negative NICS values at their cage centers. In addition, it is very interesting to compare the evolutionary trend of aromaticity with that of chemical hardness. As showed in Fig. 2d and Fig. 3, a parallel exists between aromaticity and chemical hardness in  $C_{36-n}Si_n$  heterofullerenes, i.e., the  $C_{36-n}Si_n$  cluster with the more negative NICS value is often a hard molecule, while counterparts with less negative or positive NICS values are soft molecules. For instance, the  $C_{28}Si_8$  cluster derived from the  $D_{6h}$   $C_{36}$  cage shows the most negative NICS value and a relatively high value of hardness. Therefore, chemical hardness can be served as a qualitative technique to measure aromaticity of  $C_{36-n}$ Si<sub>n</sub> heterofullerenes, which accords well with the argument of Zhou and Parr [55].

#### Conclusions

DFT calculations were performed on the low-energy structures of  $C_{36-n}Si_n$  ( $n \le 18$ ) clusters to investigate the effect of silicon doping on the structural relaxation, energetics properties, and aromatic character of  $C_{36}$  ( $D_{6h}$  and  $D_{2d}$ ) fullerene. Si substitution brings a new family of  $C_{36-n}Si_n$  ( $n \le 18$ ) clusters. Regarding structural features, a distinct segregation between the silicon and carbon atoms develops as a consequence of aggregation of Si atoms. A significant electron transfer from silicon to carbon atoms was seen in all C<sub>36-n</sub>Si<sub>n</sub> clusters, rendering a partially ionic character to the Si-C bonds. The stability of  $C_{36-n}Si_n$  clusters was found to be associated with the silicon content, and binding energies decreased gradually in a linear trend. The cagelike structures from  $D_{2d}$  fullerene were more energetically favourable than those from the  $D_{6h}$ cage. The  $E_{gap}$ , VIP and VEA showed strong variation with respect to Si substitution, and the magnitude of the energy gaps varied from 0.83 to 1.60 eV. Si substitution leads to negative NICS in  $C_{36-n}Si_n$  ( $n \le 18$ ) clusters, providing an indication of strong aromatic character.
