# Empirical Method for Consideration of Solvent Effect on the Dissociation Constants of Carboxylic Acids 

Yu. E. Zevatskii and D. V. Samoilov<br>St. Petersburg State Institute of Technology, Moskovskii pr. 26, St. Petersburg, 190013 Russia<br>e-mail: samoylov@newchem.ru

Received February 15, 2007

#### Abstract

An empirical method was used to calculate 363 dissociation constants of 33 benzoic and acetic acid derivatives in 11 solvents. The relative error in the calculations did not exceed $9.5 \%$, and the average error was no higher than $3 \%$. The calculated values were compared with those obtained by quantum-chemical and other methods for determination of acid dissociation constants in different solvents.

DOI: 10.1134/S1070428008010065

Solvent exerts a considerable effect on properties of organic molecules dissolved therein [1-3], which is clearly illustrated by variations in their UV, IR, and NMR spectra [1, 4, 5]. As a result, solvent inevitably affects the kinetic [6-9] and equilibrium parameters of chemical [10-15], biochemical [16, 17], and photochemical processes [17, 18]. Up to now, numerous parameters have been proposed to characterize solvent effect on properties of organic compounds. These parameters include physical constants (such as dielectric permittivity, dipole moment, refractive index, polarizability, etc.), parameters derived from physical constants, and empirical parameters [1,3]. The latter become more and more popular in the recent years [3, 19]; they are related mainly to spectral parameters of solvatochromic indicators. The set of empirical parameters continuously broadens due to efforts made to build up a universal scale taking into account all specific features of solvents $[3,19,20]$. The problem concerning solvent effect in all the above aspects attracts growing researchers' interest, as follows from a large number of publications appeared in the past decade [2-22] and recent monographs [1, 23, 24].

Solvent effect on protonation-deprotonation equilibria, i.e., variation of basicity (acidity) constants in going from one solvent to another, remains so far an important problem. In the recent years, considerable progress was achieved in the calculations of acidity parameters (such as proton affinity $\Delta H_{\mathrm{H}}$ and basicity $\Delta G$ ) of molecules of many organic compounds in the gas phase [21, 25-29, 50-73]. Modern calculation methods are based on quantum-chemical approaches,
including newest modifications of Hartree-Fock approximation and density functional theory with continuously extending basis sets. In the past 5 years, the error in the calculation of the above acidity parameters for the gas phase was smaller than $1 \%[25,30,41,44]$. Therefore, it became possible to draw reliable relations between $\Delta H_{\mathrm{H}}$ and structural parameters [31-33, 36] or other properties [27, 28, 30-37] and describe competing protonation processes involving multicenter molecules $[27,28,34,35]$ and gas-phase tautomeric protontransfer equilibria $[34,37]$.

In order to pass from gas-phase acidities to $\mathrm{p} K_{\mathrm{a}}$ in solution and estimate solvent effect on a quantitative level, a thermodynamic cycle (i.e., a set of elementary steps that characterize most appropriately the dissociation process in solution and species involved therein) is selected preliminarily. Energies corresponding to each elementary step are then calculated [38]. Here, an important problem is the calculation of the energies of solvation of undissociated and dissociated substrate, $\Delta G_{\mathrm{s}}$ [39-49]. During the past decade, these quantities were usually calculated using various modifications of the polarizable dielectric continuum solvation model (PCM) [38-73] in combination with other methods, e.g., statistical thermodynamics [50] and electrostatic models [22]. Methods for determination of $\Delta G_{\mathrm{s}}$ with account taken of solvent molecules in the explicit form were used only in [61, 64, 71]. The history of development, current state, and scope of application of the PCM were considered in [39, 40]. The most recent modification of this approach is conductor-like polarizable continuum model (CPCM) [41] which was used to
calculate $\mathrm{p} K_{\mathrm{a}}$ values in [50-58]. The energies of deprotonation of molecules in solution are calculated from $\Delta G_{\mathrm{s}}$ values in accordance with the selected thermodynamic cycle, and $\mathrm{p} K_{\mathrm{a}}$ values are then determined using van't Hoff equation or its analogs with empirical coefficients [50, 56, 59-63]. For example, in the calculations of energies for a series of 50 compounds in water, the right part of the van't Hoff equation should be multiplied by a factor of 0.49 [50].

Only in [41,54-58, 63-66] the calculations of $\mathrm{p} K_{\mathrm{a}}$ were performed with account taken of variation of the substrate geometry in solution relative to the geometry of isolated molecule, while in $[51,54,60,67]$ the effect of solvent on the substrate geometry was considered only partially. In some cases, the substrate geometry was optimized with no account taken of solvent effect [40, 50, 52-54, 58, 59, 61, 62, 68-73]. Optimization of geometric parameters of carboxylic acid molecules in solution considerably enhances the accuracy of $\mathrm{p} K_{\mathrm{a}}$ calculations [66]. For instance, the absolute error in the calculation of ionization constants $\left(\Delta \mathrm{p} K_{\mathrm{a}}\right)$ using geometric parameters of isolated molecules ranged from 0.4 to 0.97 log units, and the relative error $\left(\varepsilon p K_{\mathrm{a}}\right)$, from 11 to $47 \%$. After optimization of the substrate geometry for solution, the $\varepsilon \mathrm{p} K_{\mathrm{a}}$ values were less than $10 \%$ for a half of the examined substrates.

By contrast, Tran and Colvin [54] showed that geometry optimization for solution gives no essential gain in the calculation accuracy. A combination of the Langevin dipole model and PCM in 6 versions was used to calculate $\mathrm{p} K_{\mathrm{a}}$ values of acetic, orthophosphoric, and mono-, di-, and trifluoroacetic acids and 4 nucleobases. Although $\varepsilon \mathrm{p} K_{a}$ for all 9 substrates exceeded $30 \%$ (the lowest relative accuracy among the data published in the past decade), an acceptable correlation ( $r=0.92$ ) between the experimental and calculated $\mathrm{p} K_{\mathrm{a}}$ values was obtained for all substrates.

An alternative approach to calculation of $\mathrm{p} K_{\mathrm{a}}$ values with account taken of solvation is based on the use of cluster models involving molecules in the nearest solvate shell in the explicit form $[56,61,62,70-72]$ and geometric parameters of such clusters [61, 71, 72]. These models were applied both in combination with $\operatorname{PCM}[56,70]$ and without the latter [61, 62, 71, 72].

Calculations of $\mathrm{p} K_{\mathrm{a}}$ values were performed for both chemically different $[50,54,62,68-70,72,73]$ and structurally related compounds $[40,51,52,53,55,57-$ $61,63,64,66,67]$. Some series were isolated from a large group [52, 54, 56, 61, 65, 71, 73]. While studying complex structures, conformational behavior and
tautomerism were taken into account [41, 51, 53, 57, $58,60,69]$ by averaging tautomer energies in different ways or excluding structures that were shown to be energetically unfavorable by preliminary calculations. The relative deviation of the calculated energies of solvation from the experimental values ( $\varepsilon \Delta G_{\mathrm{s}}$ ) ranges from 10 to $40 \%$. As a result, the relative error in the calculation of $\mathrm{p} K_{\mathrm{a}}$ is 5 to $40 \%$. The errors did not exceed $10 \%$ for more than half of the calculated $\mathrm{p} K_{\mathrm{a}}$ values (sometimes calculated by different methods for the same substrate) only in $[50,51,55,56,61,63$, 67, 71, 73].

A good accuracy in the calculation of $\mathrm{p} K_{\mathrm{a}}$ values was achieved due to joint application of quantumchemical methods and QSPR approach implying calculated or experimental parameters as descriptors $\left(\Delta G_{\mathrm{s}}\right.$ for molecules, anions, or a proton, $\Delta H_{\mathrm{H}}$ ) or their combinations [50, 56, 61, 63].

Apart from water, the most popular medium for assay of methods involving solvent effects is dimethyl sulfoxide (DMSO) [44, 68, 72, 73].

Thus the existing methods for the calculation of $\mathrm{p} K_{\mathrm{a}}$ values with account taken of solvent effect are based on complex and resource-consuming quantum-chemical procedures that are characterized by appreciable errors.

In this paper we demonstrate the possibility of using the empirical procedure proposed by us previously [74-76] for the calculation of dissociation constants of some organic compounds in various solvents on the basis of experimental parameters of the substrates and solvents. The use of exclusively experimental data is the main difference between our procedure and empirical QSPR method which relates experimental molecular parameters to other parameters of molecules or molecular fragments, calculated by quan-tum-chemical methods (mostly semiempirical), via multiparameter equations. In particular, QSPR calculations of dissociation constants involved charges on the carbonyl oxygen atoms of an acid and its anion and differences in their HOMO energies, calculated by the AM1 method [77]. The correlation coefficient was as poor as 0.88 ; it corresponded to an average relative error of about $10-15 \%$.

Our method is based on the linear Gibbs energy relationship principle [78] with account taken of atomic contributions to a given molecular parameter. Refinement of that principle originates from the assumption that any molecular parameter may be represented as the sum of contributions of atoms consti-
tuting the given molecule. Obviously, unlike other parameters (such as electronic, rotational, and vibrational quantum numbers, configuration, etc.), just the formula of a molecule, ion, or radical can be determined experimentally before any chemical reaction.

As in [74-76], the sought quantity (in the given case, $\mathrm{p} K_{\mathrm{a}}^{j k}$ value of some acid denoted as $k$ in some solvent denoted as $j$ ) was determined using the linear form of Eq. (1):

$$
\begin{equation*}
\delta \mathrm{p} K_{\mathrm{a}}^{j k}=a \delta X_{j k}+b, \tag{1}
\end{equation*}
$$

where $a$ and $b$ are constants. The quantity $\delta \mathrm{p} K_{\mathrm{a}}^{j k}$ is linearly related to the dissociation constant through the parameter $Y_{j}$ :

$$
\begin{equation*}
\delta \mathrm{p} K_{\mathrm{a}}^{j k}=\mathrm{p} K_{\mathrm{a}}^{j k}-Y j . \tag{2}
\end{equation*}
$$

The experimental solvent parameter ( $X_{\text {exp. } j}$ ) minus atomic contributions was determined using Eq. (3):

$$
\begin{equation*}
\delta X_{\mathrm{exp}, j}=X_{\mathrm{exp}, j}-X_{k} \sum_{i} g_{i j} X_{i} . \tag{3}
\end{equation*}
$$

Here, $g_{i j}$ is the number of $i$ th atoms in a $j$ th solvent molecule, $X_{i}$ is the contribution of $i$ th atom to the molecular solvent parameter, and $X_{k}$ is a dimensionless coefficient. The principal difference from the procedure described in [74-76] is that Eqs. (1)-(3) relate to each other similar molecular parameters of different compounds rather than different molecular parameters of the same compound. Therefore, Eqs. (2) and (3) were reduced to bilinear form as follows: the coefficient $Y_{j}$ was assumed to be a constant of $j$ th solvent, and the coefficient $X_{k}$ at atomic contributions to the

Table 1. Empirical solvent parameters $Y_{j}$ for $\Delta H_{\mathrm{H}}$ and $E_{\mathrm{T}}^{30}$ selected as experimental solvent parameters

| 11 | Ethanol | 9.60 | 27.2 |  |

solvent parameter was assumed to be a constant of $k$ th acid. As molecular parameters of solvent we preliminarily tested molecular volume, dipole moment, reciprocal dielectric permittivity, polarizability, DimrothReichardt solvatochromic parameter $E_{\mathrm{T}}^{30}$, and molecular proton affinity (gas-phase enthalpy of protonation $\left.\Delta H_{\mathrm{H}}\right)$. Rough calculations showed that better results were obtained with the use of the two latter parameters. In these cases, the physical sense of atomic contributions $X_{i}$, in contrast to [74-76], becomes unobvious. For example, a contribution of an atom to nonadditive solvent parameter $E_{\mathrm{T}}^{30}$ a fortiori makes no sense. Therefore, atomic contributions to solvent parameters were fitted empirically. The experimental $\Delta H_{\mathrm{H}}$ values for atoms and molecules were taken from the NIST database [79], and $E_{\mathrm{T}}^{30}$ values, from [1, 80].

Although numerous experimental $\mathrm{p} K_{\mathrm{a}}$ values of structurally different compounds (carboxylic acids, amines, phenols, CH acids, NH acids) in various solvents are available [81-113], combination of the data obtained in different studies into a single set for further processing and analysis is not appropriate for the following reasons:
(1) Different methods were used to determine $\mathrm{p} K_{\mathrm{a}}$ values (spectrophotometry, potentiometry, conductometry). The two latter cannot be applied to determination of $\mathrm{p} K_{\mathrm{a}}$ values in weakly polar media [85];
(2) Different mathematical models were used in the calculation of $\mathrm{p} K_{\mathrm{a}}$ values from the data of experimental measurements and in data processing;
(3) Experimental studies were generally performed on large series of substrates and a limited number of solvents, and the substrate series were specific in each case;
(4) The acid dissociation constant in weakly polar aprotic solvents makes no rigorous physical sense, while constants for formation of ion pairs with proton transfer (that are measured experimentally) depend on the selected base [93, 100, 106-111].

As a result, $\mathrm{p} K_{\mathrm{a}}$ values for the same substrate in the same solvent, determined by different authors, may differ by 5 log units. Therefore, as basis experimental data set we selected $\mathrm{p} K_{\mathrm{a}}$ values of substituted benzoic [81] and acetic acids [82] in 12 and 5 polar solvents, respectively, which were supplemented by recent data [83]. In addition, $\mathrm{p} K_{\mathrm{a}}$ values for methanol and ethanol [97] were used. All measurements were performed by the potentiometric method, and the results were processed uniformly.

Table 2. Coefficients for the calculation of $\mathrm{p} K_{\mathrm{a}}$ using $\Delta H_{\mathrm{H}}$ and $E_{\mathrm{T}}^{30}$ as experimental solvent parameter, numbers of solvents $N$, and maximal relative errors $\max \left(\varepsilon \mathrm{p} K_{\mathrm{a}}\right)$

The coefficients $a_{k}, b_{k}, X_{k}$, and $Y_{j}$ were determined by minimization of the sum of the squared relative deviations of the calculated values from the experimental (denoted with superscript "exp") ionization constants of $k$ th acid in the selected solvent series:

$$
\begin{equation*}
E_{k}=\sum_{j}\left[\frac{\mathrm{p} K_{\mathrm{a}}^{\text {exp.jk }}-\mathrm{p} K_{\mathrm{a}}^{j k}}{\mathrm{p} K_{\mathrm{a}}^{\exp . j k}}\right]^{2} . \tag{4}
\end{equation*}
$$

Analysis of the results performed in [76] showed that a high correlation coefficient $r$ for two parameters does not necessarily ensure low error in the calculation of one parameter from the other. For example, at $r=$ 0.9 , the relative deviation of calculated values from the experimental ones can attain $30 \%$, which makes the correlation unsuitable for practical use.

As in [76], the minimum condition was written as

$$
\begin{equation*}
\frac{\partial \sum_{k} E_{k}}{\partial a_{k}}=\frac{\partial \sum_{k} E_{k}}{\partial b_{k}}=\frac{\partial \sum_{k} E_{k}}{\partial X_{k}}=\frac{\partial \sum_{k} E_{k}}{\partial Y_{k}}=0 \tag{5}
\end{equation*}
$$

for any $j$ and $k$. However, numerical solution of a system consisting of 110 equations was unsuccessful, and the number of equations was reduced by exclusion of the solvent parameters $Y_{j}$. The condition implying minimal sum of the squared relative deviations of
the calculated dissociation constants from the experimental values for $k$ th acid in all solvents became as follows:

$$
\begin{equation*}
\frac{\partial \sum_{k} E_{k}}{\partial a_{k}}=\frac{\partial \sum_{k} E_{k}}{\partial b_{k}}=\frac{\partial \sum_{k} E_{k}}{\partial X_{k}}=0 . \tag{6}
\end{equation*}
$$

Using Eq. (6), all coefficients $X_{k}, a_{k}$, and $b_{k}$ were determined. The program for the calculation of $X_{k}, a_{k}$,

${ }^{\text {a }}$ Single value per cell.
${ }^{\text {b }}$ Two values separated by slash per cell; the first corresponds to $\Delta H_{\mathrm{H}}$ as solvent parameter, and the second, to $E_{\mathrm{T}}^{30}$.
and $b_{k}$ from known values of $X_{i}$ and $Y_{j}$ was given in [114]. The optimal atomic contributions $X_{i}$ to any of the two selected molecular solvent parameters were found by random search within the range from -5 to +5 . The solvent parameters $Y_{j}$ were found in parallel in a similar way (within the range from -100 to +100 ) until several their combinations were obtained for
which the maximal value of $\varepsilon \mathrm{p} K_{\mathrm{a}}$ was lower than $50 \%$. One of the sets of $X_{i}$ thus obtained was assumed to be constant, and $Y_{j}$ values were varied in such a way that $E_{k}$ be minimal. If this condition was not met, a new set of $X_{i}$ was selected. The contributions $X_{i}$ of $\mathrm{C}, \mathrm{H}, \mathrm{O}, \mathrm{N}$, and S atoms are $-1.97,1.75,-2.30,-2.85$, and -0.76 , respectively. The optimal solvent parameters $Y_{j}$ are

[^0]listed in Table 1. The coefficients $X_{k}, a_{k}$, and $b_{k}$ for $X_{\text {exp }}$ $=\Delta H_{\mathrm{H}}$ and $X_{\mathrm{exp}}=E_{\mathrm{T}}^{30}$ are given in Table 2.

The different numbers of solvents for different acids is explained by the available experimental data. The set of acids was selected taking into account that five or more experimental dissociation constant in different solvents be available for each acid. A large dis-
persion of $Y_{j}$ values for $X_{\text {exp }}=\Delta H_{\mathrm{H}}$ as compared to $X_{\text {exp }}=E_{\mathrm{T}}^{30}$ corresponds to more significant correlation between $\mathrm{p} K_{\mathrm{a}}$ and $E_{\mathrm{T}}^{30}$, while no correlation between $\mathrm{p} K_{\mathrm{a}}$ and $\Delta H_{\mathrm{H}}$ exists.

The solvent parameter $Y_{j}$ and oxygen contribution $X_{\mathrm{O}}$ were found to affect $\varepsilon \mathrm{p} K_{\mathrm{a}}$ most strongly. Although the coefficients $a$ and $b$ are not similar for all 33 acids
(as might be expected; Table 2), they have comparable values and the ratio $a_{k} / b_{k}$ is relatively constant.

The $\mathrm{p} K_{\mathrm{a}}$ values were calculated by Eq. (7) that directly follows from Eqs. (1)-(3):

$$
\begin{equation*}
\mathrm{p} K_{\mathrm{a}}^{j k}=a_{k}\left[X_{\text {exp }, j}-X_{k} \sum_{i} g_{i j} X i\right]+Y_{j}+b_{k} . \tag{7}
\end{equation*}
$$

The calculated $\mathrm{p} K_{\mathrm{a}}$ values are given in [114] together with the experimental data. Table 3 compares the $\mathrm{p} K_{\mathrm{a}}$ values calculated by Eq. (7) with the experimental values for three benzoic acids. We calculated $\mathrm{p} K_{\mathrm{a}}$ values of acids in solvents for which no experimental data were given in [81-83, 97] (Table 4). The $\mathrm{p} K_{\mathrm{a}}$ values of all 33 acids in acetonitrile $(j=1)$, acetone $(j=2)$, and dimethylformamide $(j=3)$ were reported in [81-83, 97].

Comparison with the results of quantum-chemical calculations. In the present work we calculated $530 \mathrm{p} K_{\mathrm{a}}$ values, and the relative deviation from the corresponding experimental data [81-83, 97] did not exceed $9.5 \%$. Our results allowed us to define the accuracy criterion for calculation methods at a level of $10 \%$ relative error $\left(\Delta \mathrm{p} K_{\mathrm{a}}\right)$. Among the results of quan-tum-chemical calculations of $\mathrm{p} K_{\mathrm{a}}$ values of organic compounds in different solvents, published in the past decade, the best agreement with the experimental data was achieved in [55]. The above criterion was met for 36 of $40 \mathrm{p} K_{\mathrm{a}}$ values calculated for 20 substituted phenols in water. The use of a combination of different methods gave the best results in [61]: 61 of 62 calculated values for 35 halogen-substituted phenols in water matched the proposed criterion. Different calculation methods are compared in Table 5. It is seen that, among $173 \mathrm{p} K_{\mathrm{a}}$ values calculated in [50-73], deviation from the experimental data for only four values is lower than that obtained in the present work.

Although the average error in the calculation of $\mathrm{p} K_{\mathrm{a}}$ from the enthalpies of protonation of solvents is slightly greater than in the calculations from the parameter $E_{\mathrm{T}}^{30}$ (3.0 against $2.8 \%$ ), we cannot still prefer the latter. The numerical part of the proposed empirical method should be updated with a view to eliminate random search for atomic contributions $X_{i}$ and solvent parameters $Y_{j}$. For example, the fact that $X_{i}$ values are similar regardless of the solvent parameter used in the calculations ( $\Delta H_{\mathrm{H}}$ or $E_{\mathrm{T}}{ }^{30}$ ) is likely to indicate wide potential of the calculation procedure rather than physical relation between these parameters.

The authors are grateful to Prof. I.V. Tselinskii for helpful discussion.

[^0]:    ${ }^{\text {a }}$ PCM stands for polarizable continuum model, CPCM stands for conductor-like polarizable continuum model, cluster denotes the model taking into account geometric parameters of the solvate-solvent complex, and QSPR stands for the quantitative structure-property relationship.
    ${ }^{\mathrm{b}}$ The number of $\mathrm{p} K_{\mathrm{a}}$ values calculated by different methods is given in parentheses.
    ${ }^{c}$ The number of acids for which $\mathrm{p} K_{\mathrm{a}}$ values were calculated in the present work and in the corresponding referenced study; the total number of $\mathrm{p} K_{\mathrm{a}}$ values calculated for these acids by different methods is given in parentheses.
    ${ }^{\mathrm{d}}$ The number of $\mathrm{p} K_{\mathrm{a}}$ values (see note ${ }^{\mathrm{c}}$ ) for which the relative error was lower than in the present work.
    ${ }^{\mathrm{e}}$ The number of $\mathrm{p} K_{\mathrm{a}}$ values matching the condition $\varepsilon \mathrm{p} K_{\mathrm{a}}<10 \%$, which exceeds the half of the total number of calculated values.
