We investigated the site selectivity switch in $\mathrm{BF}_{3}$-catalyzed dual skeletal rearrangements of cyclobutene-fused diarylhomobenzoquinones by changing the stoichiometric amount of acid concentration. From the lower to the higher equivalency of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$, the branching product ratios (path $\mathrm{A} /$ path B) obeyed nonlinear sigmoid curves against the equivalency of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$. The observed selectivity profiles were simulated to elucidate factors that govern thermodynamic aspects (binding affinity $K$ of each carbonyl function with acid) and kinetic aspects (rate constants $k$ for the cyclobutene-ring cleavage).

Lewis acids (LAs) are versatile catalysts in a variety of organic reactions, including additions, substitutions, isomerizations, and rearrangements. Continuous effort has been exerted to attain high chemo-, regio-, and stereoselectivity through modification of the catalyst. ${ }^{1}$ If the substrate of interest possesses several acid-binding sites (i.e., basic lone-pair electrons) showing different reaction features, the preferential occurrence of the desired pathway requires appropriate control of the reaction conditions. However, such site selectivity control has been explored less than other selectivities. ${ }^{2}$

[^0]

FIGURE 1. Plots of product ratios (\%) of path B (open symbols) and path A (filled symbols) vs the equivalency of $\mathrm{BF}_{3}$. $\mathrm{Et}_{2} \mathrm{O}$ relative to substrate $\mathbf{1}(30 \mathrm{mM})$ on the rearrangement of $\mathbf{1 a}$ (circles) and $\mathbf{1 b}$ (triangles) catalyzed by $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ at $25^{\circ} \mathrm{C}$ in $\mathrm{CDCl}_{3}$.

In previous papers, we have reported that the cy-clobutene-fused homoquinone 1a, which has two basic carbonyl sites and high strain energy, undergoes a twoway tandem skeletal rearrangement upon treatment with various Lewis acids to give several polycyclic ketones quantitatively ${ }^{3}$ (Scheme 1). The kinetic substituent effects and solvent effects indicated that the reaction proceeds through a concerted $\mathrm{S}_{\mathrm{N}} 2$-like mechanism involving a unique endo-aryl-assisted transition state. ${ }^{4}$ In this paper, we wish to report interesting stoichiometric effects of the catalyst on site selectivity (selectivity switch) in the rearrangement of homoquinones 1a and 1b. Simulation of the observed selectivity profile also allows evaluation of the factors governing acid binding ability as well as the rate of the cyclobutene-ring cleavage.

Reaction of 1,5 -dimethyl-substituted $1 \mathbf{1 a}(30 \mathrm{mM}$ ) was carried out using various amounts of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ in $\mathrm{CDCl}_{3}$ at $25^{\circ} \mathrm{C}\left( \pm 1^{\circ} \mathrm{C}\right)$ for $1-100 \mathrm{~h}$. Interestingly, however, the product branching ratio of $\mathbf{2}$ to $\mathbf{3}+\mathbf{4}+\mathbf{5}$ (path A/B) increased gradually with the increase of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ but decreased concomitant with a decrease in the catalyst, demonstrating a selectivity switch at ca. 2.5 equiv excess of the catalyst (solid lines, Figure 1). A similar selectivity change was also observed for 1,3-dimethyl-substituted 1b (dotted lines), but the crossing (switching) point moved to the higher catalyst concentration (ca. 12.5 equiv). According to the mechanism depicted in Scheme 1, path B is kinetically preferred to path A because of the involvement of the tertiary carbocation intermediate $\mathbf{I}$. However, the less hindered path A carbonyl benefits from stronger complexation with $\mathrm{BF}_{3}$ as compared to the carbonyl of the hindered path $B .{ }^{3 b}$ Actually, the progress of each path can be related to the product of the

[^1]SCHEME 1. Lewis Acid Catalyzed Dual Skeletal Rearrangement of the Cyclobutene-Fused Homoquinone 1

## SCHEME 2. Kinetic and Thermodynamic Scheme for the $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$-Catalyzed Skeletal Rearrangement of 1

complexation affinity $K$ of each carbonyl group and the rate constant $k$ for the initial vinyl migration. ${ }^{5}$ The observed selectivity switch can only be explained by formation of the carbonyl-bound 1:2 complex $\mathbf{1}_{\mathrm{AB}} \cdot(\mathrm{LA})_{2}$ on increasing LA ( $=\mathrm{BF}_{3}$ ).

Scheme 2 shows that because the $1: 2$ complex $\mathbf{1}_{\mathrm{AB}} \cdot(\mathrm{LA})_{2}$ participates in the rearrangement of $\mathbf{1}$, the proportion of the kinetically favored path B is raised, where $K, k$, and P respectively indicate the binding constants with $\mathrm{BF}_{3}$, the rate constants for the initial 1,2-vinyl migration, and the products. Subscripts A and B refer respectively to paths A and B.

[^2]The formation rate for $\mathrm{P}_{\mathrm{A}}(\mathbf{2})$ can be expressed as eq 1:

$$
\begin{equation*}
\frac{\mathrm{dP}_{\mathrm{A}}}{\mathrm{~d} t}=k_{\mathrm{A}}\left[\mathbf{1}_{\mathrm{A}} \cdot \mathrm{LA}\right]+k_{\mathrm{A}}^{\prime}\left[\mathbf{1}_{\mathrm{AB}} \cdot(\mathrm{LA})_{2}\right] \tag{1}
\end{equation*}
$$

Using $K_{\mathrm{A}}$ and $K_{\mathrm{B}}{ }^{\prime}$, eq 1 can be rewritten as eq 2 :

$$
\begin{equation*}
\frac{\mathrm{dP}_{\mathrm{A}}}{\mathrm{~d} t}=K_{\mathrm{A}}[\mathbf{1}][\mathrm{LA}]\left(k_{\mathrm{A}}+k_{\mathrm{A}}^{\prime} K_{\mathrm{B}}^{\prime}[\mathrm{LA}]\right) \tag{2}
\end{equation*}
$$

With a similar equation for formation of $\mathrm{P}_{\mathrm{B}}(\mathbf{3}-\mathbf{5})$, the product ratio of path $A / B$ is expressed as eq 3:

$$
\begin{equation*}
\frac{\mathrm{P}_{\mathrm{A}}}{\mathrm{P}_{\mathrm{B}}}=\frac{K_{\mathrm{A}}\left(k_{\mathrm{A}}+k_{\mathrm{A}}{ }^{\prime} K_{\mathrm{B}}{ }^{\prime}[\mathrm{LA}]\right)}{K_{\mathrm{B}}\left(k_{\mathrm{B}}+k_{\mathrm{B}}{ }^{\prime} K_{\mathrm{A}}{ }^{\prime}[\mathrm{LA}]\right)} \tag{3}
\end{equation*}
$$

Assuming that the rate constants $k$ and binding constants $K$ are almost identical for each pathway irrespective of the stoichiometric difference of $\mathrm{BF}_{3}$ complexes, i.e., $k_{\mathrm{A}} \cong k_{\mathrm{A}}{ }^{\prime}, k_{\mathrm{B}} \cong k_{\mathrm{B}}{ }^{\prime}, K_{\mathrm{A}} \cong K_{\mathrm{A}}{ }^{\prime}$, and $K_{\mathrm{B}} \cong K_{\mathrm{B}}{ }^{\prime}$, eq 3 may be simplified as eq 4:

$$
\begin{equation*}
\frac{\mathrm{P}_{\mathrm{A}}}{\mathrm{P}_{\mathrm{B}}}=\frac{k_{\mathrm{A}} K_{\mathrm{A}}\left(1+K_{\mathrm{B}}[\mathrm{LA}]\right)}{k_{\mathrm{B}} K_{\mathrm{B}}\left(1+K_{\mathrm{A}}[\mathrm{LA}]\right)} \tag{4}
\end{equation*}
$$

Apparently, the product ratio $\mathrm{P}_{\mathrm{A}} / \mathrm{P}_{\mathrm{B}}$ converges asymptotically to the ratio of $k_{\mathrm{A}} K_{\mathrm{A}} / k_{\mathrm{B}} K_{\mathrm{B}}$ at lower catalyst concentration ( $1 \gg K[\mathrm{LA}]$ ) and oppositely to the rate ratio $k_{\mathrm{A}} / k_{\mathrm{B}}$ at higher concentration ( $1 \ll K[\mathrm{LA}]$ ). Actually, the product ratios obtained in a wide range of practical catalyst concentration ( $0.02-264$ equiv (neat)) showed characteristic sigmoid curves for both 1a and 1b, consistent with the previous argument (Figure 2).

Table 1 presents a summary of the estimated values of $k$ and $K$ from the curve-fitting simulation ${ }^{6}$ along with the observed second-order rate constant $k_{\text {obs }}$ at the lower catalyst concentration. Values of $k_{\mathrm{A}} K_{\mathrm{A}}$ and $k_{\mathrm{B}} K_{\mathrm{B}}$ are calculated ${ }^{7,8}$ using curve-fitting methods from experi-

[^3]

FIGURE 2. Plots of path B product ratios (\%) for rearrangement of $\mathbf{1 a}$ (circles) and $\mathbf{1 b}$ (triangles) vs $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ concentration (on a logarithmic scale). Each calculated fitting curve is shown as a solid line. Dotted lines show asymptotes corresponding to the extreme case of only the presence of a $1: 1$ or 1:2 complex.

${ }^{a}$ Values obtained from experimental data of $\mathrm{P}_{\mathrm{A}} / \mathrm{P}_{\mathrm{B}} .{ }^{b}$ The ratio in parentheses is $\mathrm{P}_{\mathrm{A}}: \mathrm{P}_{\mathrm{B}}$ at 264 equiv of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ (neat). ${ }^{c} \mathrm{P}_{\mathrm{A}}: \mathrm{P}_{\mathrm{B}}$ at 0.5 equiv of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O} .{ }^{d}$ Obtained by dividing the pseudo-firstorder rate constant with $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ concentration that was used (3 equiv).
mental values of $k_{\mathrm{A}} / k_{\mathrm{B}}$ and $k_{\mathrm{A}} K_{\mathrm{A}} / k_{\mathrm{B}} K_{\mathrm{B}}$. The simulation validity is demonstrated by the reasonable agreement of $k_{\text {obs }}$ with $k_{\mathrm{A}} K_{\mathrm{A}}+k_{\mathrm{B}} K_{\mathrm{B}}$ (Table 1 ).

Moreover, the estimated values were in good agreement with the switching profile of experimental results. Rate constants $k_{\mathrm{A}}$ in both 1a and 1b are $1 / 30$ - to $1 / 20$ fold smaller than $k_{\mathrm{B}}$, reflecting the stability difference between intermediates I and II. However, the binding constants $K_{\mathrm{A}}$ are 70-90 times larger than $K_{\mathrm{B}}$. Thus, at lower concentration of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$, in which the $1: 1$ complex dominates the kinetics, the binding constant is so important that the reaction rate is proportional to the product of $k$ and $K$. On the other hand, for higher concentrations of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$, in which the $1: 2$ complex dominates the kinetics, the binding constant is less important and the rate is only proportional to the rate constant $k$. The site selectivity switch is thus explained reasonably by assuming that path B is favored by the higher rate constant $k_{\mathrm{B}}$ but has the disadvantage of the reduced binding constant $K_{\mathrm{B}}$ caused by steric hindrance of the adjacent methyl groups. The value of $K_{\mathrm{A}} / K_{\mathrm{B}}>1$ in

[^4]both $\mathbf{1 a}$ and $\mathbf{1 b}$ indicates that steric hindrance from the methyl group is more serious in the cyclobutene-side methyl group than in the cyclopropane-side one. ${ }^{9}$ The larger value of $K_{\mathrm{A}} / K_{\mathrm{B}}$ for $\mathbf{1 b}$ (87.1) as compared to that for 1a (72.0) is reasonable, because path B of $\mathbf{1 b}$ engenders greater steric hindrance with both two methyl groups. Therefore, the shift of the crossing point of $\mathbf{1 b}$ to the higher $\mathrm{BF}_{3}$ concentration is attributable to the more enhanced steric hindrance around the C2 carbonyl site as compared to that of the C6 carbonyl.

In conclusion, we found the site selectivity switch in the Lewis acid catalyzed dual rearrangement of cy-clobutene-fused homoquinones 1 because of the higher order complexation. Consequently, thermodynamic and kinetic balances on each reaction pathway explained nonlinear stoichiometric effects of the catalyst on product distributions. These findings provide useful insights into the fields of synthetic and theoretical organic chemistry.

## Experimental Section

Cyclobutene-fused homobenzoquinones 1a,b were synthesized by the $[2+2]$ photocycloaddition of the corresponding homobenzoquinone with alkynes as previously described. ${ }^{10}$ The rearrangement products were isolated by HPLC equipped with a semifractionation ODS column and recrystallized from hexanebenzene. The compounds 1a, 2a, 4a, and 5a were already reported ( $\mathbf{3 a}$ was not formed). ${ }^{3}$ The new compounds $\mathbf{1 b}, \mathbf{2 b}, \mathbf{3 b}$, and $\mathbf{5 b}$ were identified by ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ NMR as well as IR spectra as follows ( $\mathbf{4 b}$ was not formed), and also the structures of $\mathbf{3 b}$ (CCDC 279749) and 5b (CCDC 279750) were confirmed by X-ray crystallographic analysis.

General Procedure for $\mathrm{BF}_{3} \cdot \mathbf{E t}_{2} \mathbf{O}$-Catalyzed Reactions of $1 . \mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}(7.6 \mu \mathrm{~L}, 0.06 \mathrm{mmol})$ was added into a $\mathrm{CDCl}_{3}$ solution $(670 \mu \mathrm{~L})$ of $\mathbf{1 a}(8.36 \mathrm{mg}, 0.02 \mathrm{mmol})$ in a NMR tube using a microsyringe at room temperature. The progress of the reaction was monitored by ${ }^{1} \mathrm{H}$ NMR. After a requisite period of time, the reaction solution was transferred into a separate funnel, diluted with chloroform $(10 \mathrm{~mL})$, and then washed with water ( $3 \mathrm{~mL} \times 3$ ). The aqueous layer was extracted with chloroform $(5 \mathrm{~mL} \times 2)$. The combined organic layers were washed with water ( $3 \mathrm{~mL} \times 3$ ) and then dried over calcium chloride. After the evaporation of the solvent, the residue was submitted for a ${ }^{1} \mathrm{H}$ NMR analysis to determine the product distribution.

X-ray Crystal Structure Determination of 3b: $\mathrm{C}_{30} \mathrm{H}_{26} \mathrm{O}_{2}$, $M_{\mathrm{r}}=418.53$, monoclinic, space group $P 2_{1} / c$, with $a=12.752(7)$ $\AA, b=13.44(1) \AA, c=14.274(4) \AA, \beta=115.22(3)^{\circ}, V=2213.46$ $\AA^{3}, Z=4, D_{\mathrm{c}}=1.256 \mathrm{~g} / \mathrm{cm}^{3}, R=0.079$ and $R_{\mathrm{w}}=0.079$ for 3380 reflections with $I>3.00 \sigma(I)$.

X-ray Crystal Structure Determination of 5b: $\mathrm{C}_{30} \mathrm{H}_{26} \mathrm{O}_{2}$, $M_{\mathrm{r}}=418.53$, monoclinic, space group $P 2_{1} / c$, with $a=15.503(5)$ $\AA, b=8.505(2) \AA, c=16.954(3) \AA, \beta=100.37(2)^{\circ}, V=2199.0-$ (9) $\AA^{3}, Z=4, D_{\mathrm{c}}=1.264 \mathrm{~g} / \mathrm{cm}^{3}, R=0.070$ and $R_{\mathrm{w}}=0.054$ for 2657 reflections with $I>3.00 \sigma(I)$.

Kinetic Simulation for $\mathrm{BF}_{3} \cdot \mathbf{E t}_{2} \mathbf{O}$-Catalyzed Reactions of 1. The theoretical product ratio $\mathrm{P}_{\mathrm{A}} / \mathrm{P}_{\mathrm{B}}$ for each concentration of $\mathrm{BF}_{3} \cdot \mathrm{Et}_{2} \mathrm{O}$ was calculated by eq 4 . The estimated kinetic parameters were obtained by using the program Solver in Microsoft Excel software, reducing the difference between calculated and experimental values of $\mathrm{P}_{\mathrm{A}} / \mathrm{P}_{\mathrm{B}}$ on the basis of the least-squares method.
