The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 20th & Northampton Sts., Easton, Pa. Second-class postage paid at Easton, Pa., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in THIS JOURNAL are published on the authority of the writer over whose name they appear, and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N. W., Washington 7, D. C. Publication Offices: 20th & Northampton Streets, Easton, Pa.

Annual Subscription—United States and foreign, $15.00; single copies, $1.50; combined rate with the *Journal of the American Pharmaceutical Association*, $20.00. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $27.00 A.Ph.A. membership dues.

Claims—Missing numbers will not be supplied if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N. W., Washington 7, D. C., of any change of address

The Editor comments

DILUTING SCIENCE WITH POLITICS

We have become greatly disturbed in recent months by the increasing influence being exerted by political factors in what properly should be classified as strictly scientific considerations.

American ability in the field of science is recognized the world over, and no small part of the nation's more able and dedicated scientific personnel are affiliated with government agencies such as the Public Health Service, Food and Drug Administration, Department of Agriculture, National Bureau of Standards, and various others. Traditionally, the activities of these dedicated people have been of a noncontroversial nature and in fact have been the object of little, if any, fanfare. On the contrary, in the past, many commentators both outside and within government have been moved to decry that all too little notice or recognition has been accorded these scientists, their useful work, and often brilliant accomplishments.

Lately, however, a number of the more clever political tacticians have found that government scientific activities can provide a very fertile field from which they may derive much publicity, thereby drawing national attention and eventually swaying public opinion. Several such incidents, including the classic case of the 1962 drug amendments, attest to the success of maneuvers of this nature.

As noted above, this influence is most disturbing to us, because among other things, we regard such a climate as extremely unhealthy for the proper growth and further development of true science. The trend of the present environment is becoming less conducive to objective, unbiased decision-making on the part of our government scientists, and lends itself to unfortunate compromises on their part in drawing conclusions and taking actions which *should* be based entirely upon an accurate evaluation of the facts involved.

If the present movement is not soon checked, not only may our nation suffer from the immediate effects resulting from emotionally engendered legislation and enforcement, but even more seriously, it appears that the entire tenor of true objectivity within our scientific community might well be in jeopardy.

Review Article

Plastics in Pharmaceutical Practice and Related Fields. Part I

By JOHN AUTIAN

CONTENTS

[Contents for Part II will accompany the concluding part of Dr. Autian's Review Article next month.]

INTRODUCTION

No material has received so much attention, found so many useful applications, and presented so many challenges as a group of chemical agents making up a body of dissimilar substances collectively grouped under the generic term, plastics. No longer a laboratory curiosity of several decades ago, plastics have become an everyday way of life in our complex society. No item or product from the simple dish stand in the kitchen to the complexly engineered space capsules has escaped the touch of one or more plastic materials. The ingenuity of the polymer chemist and the skill of the product engineer make it possible for the plastic industry and all its related affiliates to create and produce products which to a previous generation either were made from the more conventional materials or could not be made at all. Plastics have had a profound effect upon our economy and no doubt will become an economic necessity in the future if our nation is to maintain its accustomed high standard of living.

Even though the use of plastic materials had reached large proportions in other areas, its introduction to pharmacy and medicine was of more recent times and in more limited applications. Natural reluctance by the various health professions and by those servicing these professions to introduce new, untried materials without careful analysis for potential harm prevented the same degree of expansion as seen in many other fields. This state of affairs, however, has changed and is continuing to change as may be witnessed by reviewing the number of items used in pharmacy and medicine made in part or whole of a plastic substance. The many advantages which can be fashioned from the proper plastic material will undoubtedly give further impetus to the use of plastics in the health professions.

The rapid introduction of plastic items, such as containers, syringes, tubings, sheetings, prosthetic devices both internal and external, and a host of other items, to the practice of pharmacy and medicine has not been without certain difficulties. It appears that a greater scientific body of knowledge must be accumulated to guide the manufacturer to produce a plastic item which will repeatedly behave in an identical manner under various conditions of storage and use and which will insure that no possible harm will directly or indirectly fall upon the patient. In recent years there has been some concern generated on the possible harmful effects on animals and humans in the use of plastics in medicine. No attempt will be made here to review the toxicity aspect of plastics. The reader if interested in this facet of the subject is encouraged to ferret out some of the references listed (1–8).

As the outline indicates, the review will cover a number of topics which the author felt would be pertinent to the overall presentation of plastics to a pharmaceutical group. Some topics have received more attention than others but this should not suggest that these other topics are of minor importance for it certainly is recognized that to certain individuals and groups these less emphasized topics may indeed be of paramount importance. The reader may also be distressed in not seeing certain facets on the subject of plastics covered at all in this review. Here the author has taken some liberty in the selection of the material in order to conserve space and to limit the discussion to those areas which would seem to be appropriate to pharmacy and medicine. No one review can cover adequately any subject and this is even more true of a subject which has so many applications and which is in a continual state of growth. It is hoped, however, that what will be presented here will serve as a source of useful information to all those interested in finding more and better uses of plastics while at the same time alerting others to the problems which may be created by the use of plastics if proper precautions are not taken.

History

The impetus to our present "world of plastics" can be directly and logically traced back to the years of the Second World War, when a sudden need developed in both the Allied and Axis camps to find and produce in sufficient volume suitable replacements for scarce war materials. Scientific and engineering talents met the challenge by the expanding use of well-established plastics as well as exploiting those polymeric materials which were hardly more than laboratory curiosities. It was natural that this pool of knowledge, personnel, and equipment would be directed to civilian needs after the war years and to the present. One must, however, go much further back in history than the Second World War to assign a time for the invention of the first plastic.

A lack of adequate supply in the 1860's of ivory for the production of billiard balls inspired a printer by the name of John Wesley Hyatt to experiment with pyroxylin. In 1868 he fashioned an ivorylike material which soon became known as Celluloid, a combination of pyroxylin and camphor (9). The new material became the

Received from the Drug-Plastic Research Laboratory, College of Pharmacy, University of Texas, Austin 12.

Editor's note: Additional considerations of plastics in pharmaceutical practice will be discussed in the concluding portion of this review, Part II, which will appear in the February issue of This Journal.

first commercial plastic and soon was being used as denture plates, parts of wearing apparel (wipe-clean collars, cuffs, etc.), windows, photographic film and in 1882, the first motion picture film.[1] Fraenkel (10) in 1890 recorded the first published information in the use of Celluloid in surgery as a replacement of bone in a portion of the skull of a human.

Celluloid reigned supreme as the only plastic material for a period of four decades until Dr. Leo Henrik Baekeland in the year 1909 developed a phenol-formaldehyde resin which was given the name of *Bakelite* for its creator (9). The '20's and '30's saw the introduction of other plastic materials which, in a real sense, gave rise to a new industry—the plastic industry. As a brief review of the chronological history of plastics development, the reader should see Table I.

TABLE I.—A CHRONOLOGICAL HISTORY OF PLASTICS DEVELOPMENT[a]

Date	Material
1868	Cellulose nitrate
1909	Phenol-formaldehyde
1909	Cold molded
1919	Casein
1926	Alkyds
1926	Aniline-formaldehyde
1927	Cellulose acetate
1928	Polyvinyl chloride
1929	Urea-formaldehyde
1935	Ethyl cellulose
1936	Acrylic
1936	Polyvinyl acetate
1938	Cellulose acetate butyrate
1938	Polystyrene or styrene
1938	Nylon
1939	Polyvinyl acetals
1939	Melamine-formaldehyde
1939	Polyvinylidiene chloride
1942	Polyester
1942	Polyethylene
1943	Silicones
1943	Fluorocarbons
1945	Cellulose propionate
1947	Epoxy
1948	Acrylonitrile-butadiene-styrene
1956	Acetal resin
1957	Polypropylene
1957	Polycarbonate resin
1959	Chlorinated polyether

[a] "Modern Plastics Encyclopedia"—Issue for 1962, New York, p. 18.

Each of the plastics has an interesting story and one must go to published texts on plastics to appreciate the scientific minds of individuals and groups who helped synthesize these materials. Swallow (11) gives a very revealing and at times amusing account of the developments leading up to the first isolation of polyethylene, which as the author points out really commenced in 1932 when he (Swallow) and Perrin, working for Alkali Division of I.C.I., England, recommended that studies on chemical reactions at high pressures should be conducted. Now that polyethylene was prepared, what possible market would be open to it? On this point Swallow writes:

> Much is written, today, on the way in which a new product should be developed with a view to shortening the time between its discovery and its large scale production and commercial availability. To use phraseology of today it would have been difficult at that time to have carried out a "Market Survey" which would have led to any profitable conclusion, but here again the role of chance played a part.

The chance Swallow refers to was the interest by those in the submarine cable field to find a material which would replace the insulation used for submarine telephone cables and in 1939 enough material was produced to insulate one nautical mile of submarine cable. The entry of England into the World War in the same year provided the coming of age for polyethylene and perhaps the saving of England during the early years of conflict. English scientists were working feverishly to develop a super-secret detection device (radar) for announcing the coming of enemy planes over their island. It became clear to the scientists that if radar was to be a practical success a new material must be found for insulating cables and other components of radar which could effectively handle high voltages needed in radar detection. The new material, it was soon to be found, was polyethylene. Perhaps no greater tribute could be paid to this plastic than by the inventor of radar, Sir Robert Watson Watt, who said: "And so polyethylene played an indispensable part in the long series of victories in the air, on the sea, and on land, which were made possible by radar" (12).

In the field of plastics one must recognize the contribution of many individuals from many countries but several deserve added attention, as for example W. H. Carothers (U. S. A.—nylon), Dr. K. Ziegler (Germany—low pressure method for producing plastics), and Professor Natta (Italy—isotactic plastics). It appears that the real history of plastics is yet to come. What has been recorded for the accomplishment of plastics in the past will be of small magnitude to what is to be expected in the future of the material called plastics.

Definitions

At the onset, one point must be made clear to the reader. Plastics cannot and should not be considered as one type of material but rather

[1] A point of reference should be made here. Polystyrene has been known for over a hundred years and, in fact, a German pharmacist, Simon, is credited with the discovery of the styrene monomer in 1839 but its commercial use had to wait until around 1938.

an unlimited number of substances. By far the most appropriate definition thus far given may be stated as follows (13):

> A large and varied group of materials which consist of, or contain as an essential ingredient, a substance of high molecular weight which, while solid in the finished state, at some state in its manufacture is soft enough to be formed into various shapes, usually through the application, either singly or together, of heat and pressure.

Plastics may further be divided into two general classes: (*a*) the *thermosets*, those substances which when heated to a melt and cooled will not regain their original identity, and (*b*) *thermoplastics*, those substances which will regain their original identity. There are instances where a plastic material can be made to behave as either one or the other but for the most part one may consider a plastic as either belonging to the one class or the other.

Because of the unusual versatility of thermoplastics, they have found a wider application than the thermosets especially in the medico-pharmaceutical field. For this reason the main emphasis will be placed on this group of plastics in the present review.

Often the term *resin* is used in plastics technology and indicates the polymer or polymers making up the plastic material. A number of plastics can be prepared for specific applications without the addition of any other ingredient to the resin but others may contain beside the resin, plasticizers, antioxidants, stabilizing agents, fillers, antistatic agents, colorants, or other specific agents, to impart a definite quality to the final plastic product. These other ingredients may vary in concentration from a few parts per million parts of resin up to as high as 60% of the total weight of the plastic.

In recent years new dimensions have been added to plastics by chemically combining different monomers to form polymers. These polymers can then be considered as being composed of two types of plastics. The term *copolymer* is used to distinguish these plastics from those which have been synthesized from one type of monomer.

Once the basic resin is manufactured in bulk quantities, one or more steps of processing are usually necessary to have the material in suitable form for actual use in making a specific item. Depending upon the specific plastic item, other steps may be necessary in fabricating and finishing the item before it is actually ready for market. Clearly, it is not a simple chain of events. Much scientific technology and art come into play with many groups adding their particular touch to the final product. It may thus be appreciated why there can be so many variations in a plastic product even though for all intents and purposes the product is designated with a specific generic name such as polyethylene, polypropylene, etc.

GENERAL INFORMATION ON A SELECTED NUMBER OF PLASTICS

To gain the most from plastics, one must have working knowledge of the various plastic materials which are currently being used in the medico-pharmaceutical field and, further, one must be cognizant that no one material can be selected which will give all the advantages without any disadvantages for a particular application. Each application is a special project and must be treated as such. The more information which is available to the user of the plastics, the less time and effort will be required in selecting the proper material or at least in setting a scheme which will permit proper evaluation of the plastic for the specific application. There is no doubt that the packaging department of a pharmaceutical firm must be highly concerned with such matters.

The following section will include a discussion of a number of plastics which are currently being used. It will be obvious that not all materials will be dealt with and that rather brief accounts will be made of the ones discussed. The variety of materials which could be discussed under the term plastics would be too staggering for one paper and probably would not serve to the best interest of the reader. Those plastics which have been included are, however, representative of materials which have or probably will have application to the pharmaceutical field and to the related medical sciences. Certain omissions and simplifications have also been necessary in order not to weight the contents of the discussion.

Polyethylene (14, 15, 16)

Polyethylene, as the name clearly indicates, is a long chain polymer prepared from ethylene. Depending upon the mode of synthesis and the presence of selective catalyst a variety of polyethylenes can be prepared. It is, however, possible to classify polyethylenes into three general classes by simply considering the density of the polymeric material. These classes are: (*a*) *low density* (may also be called conventional, regular, branched, or high pressure), (*b*) *medium density*, and (*c*) *high density* (may also be called linear, low pressure). The low density is the original polyethylene which is prepared at

extremely high pressures (15,000 to 30,000 p.s.i.) while high density can be synthesized at moderate pressures with suitable catalysts. Medium density polyethylene may be prepared by a modification of the high-pressure method or by combining portions of low and high-density polyethylene.

Little information can be revealed on the structure of polyethylene by simple chemical methods other than elucidating the empirical structure, $(CH_2)_n$ etc. Various physical methods of analysis have been used and are being used to describe the structure. It is known, for example, that the polymer molecule may have from 800 to 100,000 carbon atoms, primarily in a straight chain structure. In the early days of polyethylene it was believed that each molecule had one terminal ethylene group and one or two methyl groups in each molecule. With improvement in instrumental analysis, it was soon realized that the original model of the polymer (low density) was in error and that the polymer contained branched chains, a number of methyl groups (approximately two or three per 100 CH_2 groups), several types of unsaturations and several polar sites in the form of carbonyl or keto groups. A composite of these structures may be seen in Fig. 1 taken from Kresser (17).

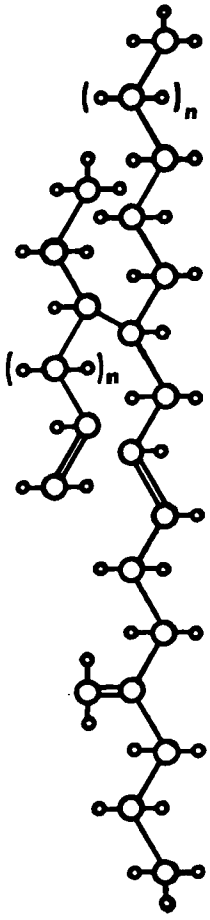

Fig. 1.—Polyethylene molecule showing some characteristic structures. Large circles represent carbon atoms; small circles, hydrogen atoms; double lines represent double bonds. [From Kressler, T. O. J., "Polyethylene," Reinhold Publishing Corp., New York, N. Y., 1961, p. 41.]

As with most polymers, the size of the polymer will play a very important role in imparting certain physical and mechanical properties to a finished plastic material. Unlike pure chemical compounds, polyethylene as well as other plastics, is not composed of an exact molecular size but rather that a distribution of molecular sizes are present. It is thus impossible to assign an exact molecular weight to a particular polyethylene and whatever value is assigned is some form of an average value. The determination of even these average molecular weights for high polymers is not a simple task and consequently highly refined physicochemical methods are used in an attempt to find a molecular weight. Since there are great technical problems associated with molecular weight determinations of high polymers, a number of methods for expressing molecular weight or size are evident in current practice and one must understand there may be considerable differences of values from one method to another. Techniques for these determinations are found in standard texts on plastics or polymers (18, 19).

One general method of expressing molecular weight of an unfractionated sample of polyethylene is to use the number-average molecular weight ($\bar{M}_n$) which may be depicted as

$$\bar{M}_n = \frac{\Sigma M_i n_i}{n_i} \qquad \text{(Eq. 1)}$$

where M_i is the molecular weight of molecules of a definite size i, and n_i, the number of that size. Measurement of colligative properties such as boiling point elevation, osmotic pressure, and freezing point depression of polymeric solutions will lead to the number average-molecular weight ($\bar{M}_n$).

A more convenient, but indirect, method for approximating $\bar{M}_n$ is through viscosity measurements. A number of equations have been developed connecting viscosity with molecular weight but in general they may be reduced to the empirical relation

$$\eta_0 = K\bar{M}_n^a \qquad \text{(Eq. 2)}$$

where η_0 is the intrinsic viscosity, K a constant,

and $\bar{M}_n^a$ the number-average molecular weight raised to a power, a. Often, rather than using molecular weight values, viscosities are used to convey molecular size and it can thus be understood why often comparison of data from one polyethylene to another becomes quite impractical.

Another expression of molecular weight, referred to as the weight-average molecular weight ($\bar{M}_w$) can be determined from light scattering experiments. This method actually measures a mean radius of a molecule in solution and not the molecular weight since two molecules having the same molecular weight may show different results if one has more branching in the chain than the other. The ratio $\bar{M}_w/\bar{M}_n$, however, helps to reveal the distribution of molecular weights in the same polymer, the larger the ratio, the broader the distribution.

Since it was early shown that polymers could be characterized by rheological properties, a standardized technique was devised to measure the viscosity of a polymer under specified conditions. The term *melt index* (*MI*) came into being and was defined as the number of grams of molten polymer which will flow through a standard orifice at a standard temperature and pressure (20). Unfortunately this method of measurement was soon found not to be very meaningful except for control purposes since two polymers produced by different manufactures but having the same melt index did not necessarily behave in the same manner during processing. The melt index, however, may be used as crude indication of molecular weight in an inverse fashion, *i.e.*, the higher the melt index the lower the molecular weight.

The various methods used to depict the size of polymers, as already stressed, is a form of an average. It would be extremely helpful if more information could be obtained on the exact distribution of the molecular sizes in a given polymer but technical difficulties which as yet have not been sufficiently overcome prevent reasonably accurate size frequency distributions to be charted. Attempts have been made, however, to fractionate polyethylene and thereby to reveal a molecular distribution with some limited success. In general the distribution has been found to be extremely broad. Important advantages may be gained by keeping the molecular weight distribution in a narrow range. For example, it has been found that such properties as tensile strength, stress cracking resistance, film impact strength, and low brittleness can be improved if the molecular weight distribution is narrowed.

It has now been clearly established that polyethylene as well as other plastics have in essence two zones of structure running through the material: a crystalline zone and an amorphous zone (see Fig. 2). Crystallization occurs when the polymer chains orient themselves side by side to form a more compact configuration. In a given polyethylene sample these compact zones of polymers, or crystallites, are dispersed throughout the amorphous zone of the material. The ratio of crystalline to amorphous structures in polyethylene impart various physical properties to the polyethylene. For example, the density of the crystalline zone by X-ray measurements indicates a density of 1.00, while for the amorphous zone, a density of 0.76 to 0.85 has been found. Conventional polyethylene has approximately 60 per cent of crystalline structure while high density polyethylene has a much greater content of crystallites.

Bunn (21) has made intensive studies on the crystalline zones of polyethylene and has found that the unit cell has an orthorhombic structure with $a = 7.40$Å, $b = 4.93$Å, and $c = 2.53$Å. The crystallites are not separate entities as may be found in metals but rather the chains composing the crystallites run through one or more amorphous zones as may be shown in the highly diagrammatic model in Fig. 2.

Thin samples of polyethylene show clarity while thicker samples display an opaque appearance. The opacity is due to the scattering of light which was thought to be due to the individual crystallites in the sample, but it is now known that the phenomenon of opacity is due to larger structural units than a crystallite. These larger units form a spherulite which comes about by proper arrangement of a number of small crystallites forming a nearly distinctive zone radiating outward from a central point (22).

A number of methods for evaluating the crystal structure of polymers have been devised (23, 24). Perhaps the most useful techniques are X-ray diffraction, infrared, density, nuclear magnetic resonance, and electron microscopy studies. It should be apparent that a number of factors will alter the ratio of crystalline to amorphous composition of a plastic material. Some of these factors are (*a*) structure of the molecule *i.e.*, chain length, degree of branching, length of chains in the various branches, degree of unsaturation, presence of other constituents, etc., (*b*) the temperatures, and (*c*) mechanical treatment (drawing or pulling the plastic material). An example of the effect of temperature on polyethylene may be noted by observing

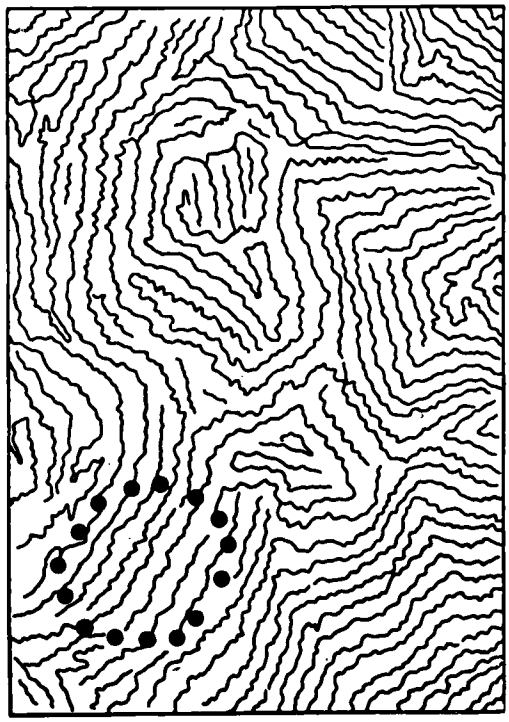

Fig. 2.—Plane projection of chains showing amorphous and crystalline (enclosed in dots) regions. [From Kinney, G. F., "Engineering Properties and Applications," John Wiley & Sons, Inc., New York, N. Y., 1957, p. 11.]

Table II where the degree of crystallinity is shown to decrease with an increase in temperature.

Mechanical treatment of a plastic sample such as pulling the material along one axis will help orient the polymers by straightening out the chains so that they become more parallel and closer to each other. This treatment favors crystalline structures in the plastic.

The degree of crystallinity in polyethylene will be a determinant for certain applications. For example, by experience it has been found that as the crystallinity of the material increases, stiffness increases, suface hardness increases, chemical resistance increases, permeability decreases, and film toughness decreases.

From what has been said it should be clear that the selection of a particular polyethylene for a specific application requires much care and it is wise not to succumb to the use of one or two parameters in defining the quality of the polyethylene. A prudent user should define his particular polyethylene by a number of parameters including important data such as density, melt index, molecular weight distribution, chain structure, and branching. The user should also have a complete background of the history of the plastic with pertinent and detailed information on additives which have been added directly or which have been introduced in the processing of the material.

The list of applications for polyethylene is in a sense unlimited. Production in 1962 amounted to 1.45 billion pounds (25). In medical and pharmaceutical practice much use is being made of this material for containers both as bottles and as film packaging materials, tubings, syringes, and other units for the administration of drugs and blood or for the collection of body fluids. Polyethylene coating on various surfaces has ushered in many new uses which could not be anticipated a few years ago.

Polypropylene (26)

In 1954 Professor Natta of the Institute di Chimica Industriale del Politenico, Milan, Italy, introduced a new plastic material which was synthesized by stereospecific polymerization. This new material was polypropylene which in a period of a few years has created a mild sensation for product designers because of certain advantages over the polyethylene line. Perhaps even more important than the introduction of a new plastic material was the sudden intense interest of polymer scientists in a new field of stereopolymers which may make possible newer plastic materials having superior properties over the conventional materials.

Commercial use of polypropylene started in 1958 and by 1961 had reached a production of approximately 80 million pounds which is estimated to increase to 425 million pounds by 1965 (25).

Polypropylene is colorless and odorless with a density of 0.90–0.91, which makes this material one of the lightest plastics known. The physical properties of polypropylene are in direct relationship to the molecular structure and to the geometry of the constituents in the chain.

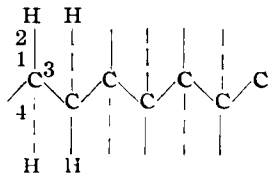
[a] Hunter, E., and Oakes, W. G., *Trans. Faraday Soc.*, **41**, 49 (1945).

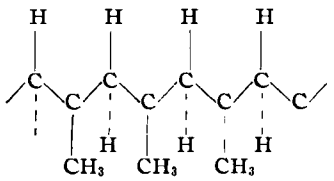
Two types of polypropylene are possible. The first of these will be called an *atactic* polymer while the second an *isotactic* polymer. First, however, it will be necessary to define or at least to visualize another term which will be designated as *tacticity*. If a polymer is composed of molecules whose basic units follow each other in the same spatial configuration, a tactic polymer is achieved. Depending upon the particular polymer, many possibilities arise for a variety of tacticities, even though only two will be discussed in this section.

The definition of atactic thus becomes a simple matter and indicates that no tacticity is present (no steric order present). Isotactic may be defined as a polymer in which parts of the molecule are oriented in space in the same manner for each unit of the polymer.

It will be helpful in understanding the term isotactic to compare the polymerization of ethylene and propylene to produce polyethylene and polypropylene, respectively. In the polymerization of ethylene, one molecule will join another by rupture of the double bonds forming, in an idealized fashion, a chain which may be depicted as



where lines 1 and 3 are in the plane of the paper, line 2 is from the paper toward the reader, and line 4 (dotted line) passes from the paper downward at the same angle as line 2. The structure depicted above is perfectly symmetrical and cannot be isotactic. Propylene on polymerization will follow the same addition steps to become a structure which might be visualized as



Here it will be noted that an unsymmetrical structure results with every other carbon being bonded to a methyl group. Since each methyl group is in the same spatial position (coming up from the paper) this molecule is isotactic. If the methyl groups were distributed in a random fashion (*i.e.*, some up and some down), the polymer would be referred to as an atactic polymer.

Another term now must be introduced, *syndiotactic* polymer. This refers to a structure whereby the methyl group alternates up and down in a regular pattern.

The above structure for polypropylene is for convenience and it should not be interpreted that in reality the chain would exist in this fashion. In fact it would be extremely difficult for several of these chains to approach each other since the methyl groups from two chains would repel each other. In an isotactic polypropylene, the chain forms a spiral, one spiral in three propylene units. The spiral formation permits the interlocking of two or more polymers into tight segments which in turn give rise to the crystal structure in polypropylene.

It is possible to prepare 100% isotactic polypropylene even though most commercial samples are never this high. In general, as the isotacticity increases, crystallinity increases in approximately the same order and often this relationship holds fairly well but it must be emphasized that there is no numercial correlation between the two. As with polyethylene, other factors will influence crystallinity, particularly time-heat treatment. This fact should caution one to be alert in designating polypropylene by only one or the other parameter (crystallinity and tacticity) if a specialized use is to be made of the polypropylene.

The degree of crystallinity, the size and shape of the individual crystallites, in any plastic material will affect both the physical and mechanical properties of the material. For example, it has been found that small and uniform crystallites will cause less stress points in the material. Crystallite size in polypropylene is approximately 150Å in diameter and 50–60Å thick. These crystallites form larger aggregates (spherulites) and it is necessary to control the growth of these spherulites since large sizes will invariably weaken points in the plastic which in turn lead to cracks or breaks (26).

Usual methods of molecular weight determination are used to characterize polypropylene but these values may be in gross error or may not really serve a useful purpose. Viscosity measurements appear to be the most used method of correlating molecular weight and it appears that such a factor as molecular weight distribution is an important consideration in designing a specific use for the plastic. Greater difficulties, however, are encountered in fractionating polypropylene than polyethylene in an attempt to collect size distribution data and newer techniques must be developed before reliable information can be accumulated.

As may be anticipated with a molecule containing a hydrogen attached to a tertiary carbon, polypropylene is more susceptible to oxidation than the polyethylenes and the inclusion of an antioxidant is a necessity for sustaining product life. Polypropylene is quite resistant to chemical attacks and products prepared from this plastic can be repeatedly autoclaved without any real harmful effect. Presently the material is being used for films, bottles, jars, household items, and industrial machinery to mention a few uses. In medicine and pharmacy the material is finding use as bottles, jars, syringes, cups, basins, sanitary ware, tubings, laboratory ware, and film packaging material. In completing this section, it is imperative to stress that varied properties, sometimes quite different, can exist between two or more polypropylenes. One should not surmise, therefore, the failing or success of a particular polypropylene product to mean that exact results will be duplicated when another polypropylene is used.

Polyvinyl Chloride (27, 28, 29)

One of the most versatile plastics is polyvinyl chloride (*PVC*) produced from the monomer vinyl chloride in a number of ways. Its present importance may be recognized by noting that approximately 950 million pounds of the homologous polymer and its copolymers were manufactured in this country in 1961 (25).

The simplest structure representing *PVC* may be shown with alternating (up and down) atoms of chlorine throughout the chain. If the chain is considered in its most extended form, repeating units occur at a distance of 5Å along the chain. Since the structure reveals asymmetric carbon atoms, isotactic polymers are conceivable but as yet practical realization of this type of material with *PVC* has not occurred. Viscosity measurements as well as other physicochemical studies reveal little indication that branching occurs in the polymer. Commercial samples of *PVC* vary in molecular weight from around 50,000 to 150,000 and most of these samples show a wide distribution of molecular weights.

Unmodified *PVC* is a hard, transparent plastic. In general, 60% of the material is in an amorphous state. On long standing in the presence of light, *PVC* shows a tendency to decompose by releasing hydrogen chloride. This reaction is accelerated with temperature and catalyzed by traces of zinc and iron. It is, therefore, necessary to include from one to two per cent of a suitable stabilizer to ensure an acceptable material. All types of *PVC* are susceptible to chemical attacks with organic materials such as ketones, esters, aromatic, and chlorinated hydrocarbons.

Polyvinyl chloride has unique properties which permit it to be modified in numerous ways giving a spectrum of end uses not seen with the other plastic materials. By far the most important modifying agent is the plasticizer. Often this ingredient may constitute up to 60% of the total weight of the finished material.

The use of plasticizers is not new, even though their economic impact is of more recent times. Early recorded history reveals that oil was added to pitch in order to make it pliable enough to squeeze between fittings in ships thus preventing leakage. Hyatt, as has already been mentioned, prepared flexible Celluloid by using camphor (a plasticizer) (9). The Second World War stimulated production of *PVC* for war needs and the years following the war saw a great many advancements in the use of plasticizers. Even though a great many studies have since been reported on various aspects of plasticizers, the selection of the proper plasticizer for a particular application is still considered an art.

A recent book by Mellan (29) is devoted exclusively to the behavior of plasticizers and should be consulted for quick references by those in need of authoritative information on the subject. Mellan points out in his text that "the term plasticizer means different things to different users, who apply it to those qualifications which lie within the limits sought by their particular industry." He, however, gives a definition for the term which appears to be adequate for this discussion:

> A plasticizer is generally defined as a substantially nonvolatile, highboiling, nonseparating substance which, when added to another material, changes certain physical and chemical properties of that material. (Ref. 29, p. 4).

One general behavior of the polyvinyl chloride, modified with the addition of the plasticizer, is flexibility and softness. Other physical properties are altered depending upon the particular plasticizer or plasticizers and the concentration present. It is the diversity of physical properties which can result by the proper use of a plasticizer which makes possible the broad range of end uses now seen for *PVC*.

Often two adjectives (internal and external) are used with plasticizers which should now be clarified. The term "internal plasticizer" should be relegated to the copolymers and implies that the ordinary polymer chain has been modified by the inclusion at repeating intervals, in the chain proper, another structural unit which, in

effect, reduces the bond strength between adjacent chains and imparts polymer mobility. "External plasticizers" are those modifying ingredients which are added to the polymer mass but which do not become an integral portion of the chain. These "external" ingredients are meant when one speaks about a plasticizer being added to a plastic material and it will be helpful to all concerned if the term "internal" is not used at all except in the specific instances where copolymers are discussed.

If one were to itemize all of the currently suggested plasticizers, he would assemble an imposing list of ingredients. This large number of ingredients has been extremely difficult to classify and for this reason many different classifications have been suggested. Boyer (30) has given a simple classification by dividing plasticizers into three distinct types: (*a*) the solvent type, (*b*) the nonsolvent type, and (*c*) the polymeric type. Each of these types behaves in a different manner but in effect all reduce the cohesive forces between two or more of the polymer chains thereby imparting chain mobility. Often commercial classifications of plasticizers are more conveniently divided under their chemical types as, for example, glycolates, sebacates, adipates, laurates, stearates, abietates, esters of polyhydric alcohols, etc.

Neither the art nor the growing science in the plasticizer field has produced the one universal plasticizer and it is doubtful if in fact this objective will ever be reached. Undoubtedly newer and better ones will come into being but more for particular applications.

In general, flexible *PVC* items are prepared from a specific formulation which includes a number of ingredients. For example, a common formula for a garden hose may be

Resin—100 parts 95 to 5 vinyl chloride-acetate copolymer
Plasticizer—50 parts dioctyl phthalate
Color—3 parts dye or pigment
Stabilizer—2 parts thermal stabilizer such as dibutyl tin laurate
Lubricant—1 part aluminum stearate
Filler—as required

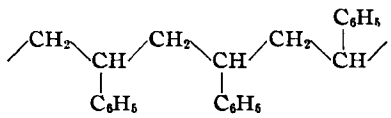
In any formulated plastic, there is always a propensity for one of the ingredients to migrate into the environment which has intimate contact with the material. This can become a serious problem, particularly when the material is used for foods or for drug products. Recent changes in the Food and Drug regulations in regard to foods require that only approved ingredients be included in packaging materials for food. At present there is no such regulation for devices for drug products or in general for plastic items used in medical practice. This point on migration will be discussed again in more detail in a later portion of the paper.

The primary use of the polyvinyl chlorides is in tubings for the administration of blood, drugs, nutritional fluids, and for the collection of blood and other body exudates. Other uses such as flexible containers for blood are in current practice.

Polystyrene (27, 31)

As was mentioned in an earlier portion of this review, polystyrene is one of the oldest plastics known but the real growth is a direct outcome of the Second World War. The sales of styrene-type polymers reached an impressive sales volume of 922 million pounds last year, placing it second to polyethylene in use (25). One of the main reasons for the high volume of use is the low cost per pound as compared to comparable resins to be used for the same application.

Polystyrene is formed from the monomer styrene in the presence of a catalyst and proper conditions to give a long chain configuration which may be represented in its simplest form as



When the term polystyrene is used it indicates that the plastic is composed of the homopolymers of styrene and often this material is referred to as *normal* or *conventional* polystyrene. Other types of polystyrene are also (modified and copolymers) produced, several of which will be alluded to presently.

Polystyrene (conventional) is a hard, amorphous solid, having transparent properties. The material is stable to distortion up to approximately 95° at which point it begins to become pliable, and as the temperature is further increased the material becomes soft and putty-like. Certain modifications in the structure of polystyrene will either increase or decrease the softening temperature. The brittle characteristic of conventional polystyrene may be overcome by combining various concentrations of rubber with the polymer producing the *impact* polystyrenes. Certain desired properties are lessened, however, with these impact plastics, as for example, lack of clarity and decrease of hardness. The shock resistance or toughness of impact polystyrene may be increased by increasing the content of rubber in the material

and often these materials may be further classified as (*a*) intermediate-impact, (*b*) high-impact, and (*c*) super-impact polystyrenes.

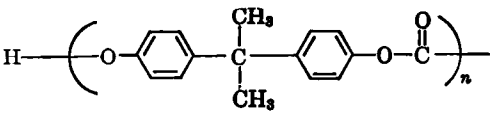
Crystalline polystyrene can be prepared by stereopolymerization following Natta's work and, as with the polypropylenes, isotactic polymers are possible. Commercial use of these stereopolymers is still in its infancy and little practical information is at present available to judge the merits of the material.

Added dimension has been achieved by copolymerization of the styrene monomer with other monomers. In particular, these copolymers are more stable to chemical agents and heat and are finding a long list of special applications. Combination of polystyrenes with fibrous glass makes possible other uses for this material. Finally polystyrene can be made into a foam which can take on any shape desired. The resultant light, porous material has numerous industrial and household applications.

Use in pharmacy and medicine may be listed (in part) as follows: syringes, parts of administration sets, containers, cups, plates, rigid glass-like tubings for various purposes, and other items where rigidity and clarity are desired.

Polycarbonate (32)

Polycarbonates represent a large group of esters of carbonic acid but the most successful material is prepared from the monomer, bisphenol-A [2,2-bis(4-hydroxyphenol)propane]. The structure formula for the bisphenol-A polycarbonate may be depicted as



Commercial production of polycarbonate began in Germany in 1959 and was followed by the United States in 1960. A number of important properties has stimulated a great interest in this material. Commercial polycarbonate has an extremely high molecular weight—weights up to one million have been produced. One of the outstanding characteristics of the polycarbonates is the resistance to physical changes in a broad range of temperatures (−215 to 250–275°). The plastic is known for its dimensional stability, high impact strength, resistance to stain, low water absorption, and transparency. Much of the characteristic properties of the polycarbonates can be directly attributed to the structural configuration of the chains which impart a great deal of rigidity to the molecules. This rigidity is probably due to the rather long monomer units anchored to the pivotal carbons (between two phenyl groups). If the pivotal carbon is replaced with an alkyl group, a definite increase in flexibility will occur. The rigidness of the chains can be further emphasized by comparing the glass transition temperature of this new plastic with several of the other well-known polymeric materials. For example, the glass transition temperature of polycarbonate is 145° to 147° for nylon 66, and −135° for polyethylene. Replacement of the methyl groups on the pivotal carbon with larger radicals increases the rigidity of the chain while substitution with hydrogens increases the flexibility.

Originally it was believed that all of the polycarbonates were completely amorphous but recent studies have indicated that various degrees of crystallinity can be produced. In those samples where crystallinity has been induced the crystallites are usually smaller than the visible wavelength of light and transparency is still maintained even for materials which may be several inches thick.

Polycarbonates are quite stable to degradation by oxygen because of the high degree of aromaticity. Further resistance to oxidation is enhanced due to the absence of secondary or tertiary carbons. The lack of reactive hydrogen atoms in the vicinity of the ester linkages helps stabilize the polymer and prevents degradation or cleavage of the chains. Most solvents do not attack the plastic material even after prolonged periods of time but solvents such as the chlorinated hydrocarbons, cyclic ethers, and tertiary amines will have solubilizing effect.

Polycarbonates have extremely large molecular weights, at times reaching a value of one million. Increase in molecular weight will offer certain advantages for a particular application but a molecular weight range may be reached where further increase in weight will serve no real advantage but, instead, may have a pronounced objectionable effect on several of the properties. As with all plastic substances, molecular weight distribution will influence a number of the properties but not enough experimental data are at hand to delineate the exact influence.

Much use is already being made of this material in both industrial applications and in household applications. The medical and pharmaceutical field is turning its attention to the polycarbonates for such devices as animal cages, parts of surgical equipment which require a window, and replacement of conventional materials where toughness, heat resistance, and transparency are needed.

Nylon (33, 34)

In the late 1920's, W. H. Carothers of Du Pont became interested in synthesizing various types of polyamides. It was, however, in 1938 that Du Pont announced the realization of a new material resembling in many ways wool and silk. This new plastic material was baptized with the generic name nylon and now includes a number of different types of polyamides and copolymers. Nylon has distinctive properties such as high melting point, toughness, resistance to chemical attack, and resistance to abrasion, as well as other qualities which are desired for a number of applications.

In general, polyamides are synthesized by two methods: (*a*) condensation of a diacid with a diamine or (*b*) self-condensation of amino acids. Common to all nylons is the repeating amide linkage running through the chain. At present there are a number of nylon plastics but only four types appear to be enjoying commerical success. These are: (*a*) nylon 6/6, (*b*) nylon 6/10, (*c*) nylon 6, and (*d*) nylon 11. The numbers following nylon indicate that both the acid and amine used for synthesis contain six carbons. Commercial samples of nylon must contain an antioxidant since there will be a tendency for degradation of the polymer in the presence of ultraviolet light and air. Nylons are quite stable to heat but degradation by hydrolysis in an acid medium at high temperature is possible.

The polar sites (referring to the amide groups) are responsible for many of the properties of the nylon. Strong forces of attraction become possible between two parallel chains by hydrogen bonding. In this case, hydrogen atoms from the nitrogens in one chain bond with the oxygen atoms in an adjacent chain. Clearly the more of these bonds per unit of polymer segment the greater will be the force of attraction. Table III lists a number of polyamides with their respective melting points and it can be seen that a great difference exists among the various melting points.

TABLE III.—APPROXIMATE MELTING POINTS (IN AIR) FOR VARIOUS NYLONS[a]

Diamine	Dibasic Acid	M.p. of Nylon, °C.
Ethylene	Sebacic	254
Tetramethylene	Adipic	278
Tetramethylene	Suberic	250
Tetramethylene	Azelaic	223
Tetramethylene	Sebacic	239
Pentamethylene	Glutaric	198
Pentamethylene	Adipic	223
Pentamethylene	Pimelic	183
Pentamethylene	Suberic	202
Pentamethylene	Azelaic	178
Hexamethylene	Sebacic	209
Octamethylene	Adipic	235
Octamethylene	Sebacic	197
Decamethylene	Carbonic	200
Decamethylene	Oxalic	229
Decamethylene	Sebacic	194
Piperazine	Sebacic	153

[a] Floyd, D. E., "Polyamide Resins," Reinhold Publishing Corp., New York, N. Y., 1958, p. 41.

A number of studies have been conducted on the effect that substituent groups have on the property of nylon. It has been shown, for example, that if the hydrogens from the amides are replaced with other groups, *i.e.*, methyl, ethyl, propyl, and amyl, a decrease in molecular weight will occur. These substituted groups not only prevent hydrogen bonding but also by steric effect prevent close approach of parallel chains. This results in nylon having a lower molecular weight, higher solubility, and more flexibility. The same type of alteration in properties may be observed by immersing samples of nylon in phenolic solutions. In this case molecules of the particular phenol will penetrate the plastic and compete for polar sites, thereby breaking existing hydrogen bonds (between two chains). If sufficient concentration of a particular phenol is present, the nylon will dissolve.

The intermolecular forces between the polar sites (of adjacent molecules), as has been stated, holds the polymer chains firmly together but secondary valence forces are also present to stabilize the interaction. It should be obvious that each chain, if highly bonded, will be parallel to its neighbor chain. This gives rise to an orientation of polymer molecules in such a manner that a high state of crystallization becomes possible. Even though other polymers can be drawn with or without addition of heat, the polyamides are a very good example of a plastic material which can be made more crystalline by simply pulling the material. In effect this straightens out the chains and orients the molecules in a parallel direction which permits close spatial contact of the polar sites (through hydrogen bonding) in one chain to polar sites in another. Nylon filament to be used for textile purposes is manufactured as an amorphous polyamide which on cold-drawing up to six or eight times its original length gives a highly crystalline material.

Many industrial uses have been found for nylon such as gears, machined parts which may have to withstand heavy mechanical shock and high temperatures, tires, tubings, instrument casings, and films for packaging oil products and food. In medical and pharmaceutical practice, nylon has been used for syringes, parts of administration kits, containers, and film

packaging of surgical items such as sutures or delicate and expensive surgical items. No doubt the polyamides will find wider use in medical practices as the cost of the material is reduced.

Cellulosics (35, 36)

Under this heading belong a number of thermoplastic products having considerable commercial value as packaging material, especially of the film type. For example, the following would fall under the so-called cellulosic-type plastics: cellulose acetate, cellulose acetate butyrate, cellulose propionate, cellulose nitrate, and cellophane. Each material may find advantages over the others for a specific application. These groups of materials have apparently reached a plateau in yearly consumption which should remain about constant for the next several years. Approximately 141 million pounds of cellulosics were consumed in 1962 (25).[2]

Cellulose nitrate, as has already been mentioned, is the oldest plastic material which has found successful commercial application. In an attempt to find a less flammable material than celluloid, cellulose acetate was developed in the early part of this century and as early as 1912 cellulose acetate was used in photographic film. True commercial success of this material, however, did not take place until around 1927. Since then, the other cellulose esters have been developed.

The various cellulosics are prepared from purified cotton linters or wood cellulose which contain high content of alpha cellulose. Each cellulose molecule has approximately 3000 glucosidic units, each unit having three available hydroxyl groups. It is the esterification of these hydroxyl groups with a particular agent which gives rise to a specified plastic.

Cellulose Acetate.—This cellulosic-type plastic has numerous uses today from such items as ladies' shoe heels to transparent windows in envelopes and cartons. The material is tough and has high impact strength. A clear transparent material can be prepared and a variety of colored items are possible with the use of cellulose acetate. The material has advantages over some of the other thermoplastics because of its dimensional stability. The flexible plastic must contain various proportions of plasticizers. In pharmacy and medicine the most use is being made of this material for one form or another of film packaging.

Cellulose Acetate Butyrate.—This material has many of the properties of cellulose acetate but appears to have improved dimensional stability. It tends to absorb less water than its close cousin and, because higher boiling plasticizers can be used, less plasticizer is needed in a cellulose acetate butyrate formula than for cellulose acetate. These two factors aid in producing a more stable material. It is imperative that cellulose acetate butyrate not be contaminated with other plastic materials since this may cause a diminution of the quality of the item being produced. A variety of uses have been found for this particular material, especially for items which will be exposed to various weather conditions. In the pharmaceutical field it is used as a packaging medium, particularly for blister and skin packaging.

Cellulose Propionate.—This is an extremely tough plastic and requires approximately half the quantity of plasticizer which must be added to cellulose acetate for a particular application. The use of this material for parts of equipment and instruments is due to its toughness and durability to shock.

Cellulose Nitrate.—This plastic is considered the toughest of the thermoplastic materials. A number of disadvantages, however, have decreased the use of this material with the advent of the other cellulosics and newer thermoplastics. The chief disadvantages are its flammability and tendency to become brittle and to discolor in the presence of light.

Regenerated Cellulose or Cellophane.—This substance is not considered as a plastic material even though, often for convenience, it is included as such. We will also include it here with the cellulosics since it has a very close relation to the other materials, being a product of cotton or wood. The use of cellophane as a film packaging material is well known and probably this material has had more applications for a variety of items than any other packaging material. In the late 1920's, a process was patented by Du Pont which made possible moisture-proof cellophane. It was this event which ushered in the transparent flexible packaging industry.

Silicones (37)

The silicone products came into commercial use during the Second World War even though they were known as laboratory curiosities in the last century. Properties such as stability to high and low temperatures, resistance to oxidation, water repellency, and unusual inertness have aided the growth of these materials for a number of special applications where use of other plastic materials is not always possible.

The silicones are a group of materials which

[2] Note that this does not include cellophane.

are composed of a molecular backbone of alternating atoms of silicon and oxygen. Organic groups are attached to this backbone in repeated intervals. The silicones can be produced to yield physical properties from various viscosities as a liquid to a solid material. They can be used as coating material for glass and other materials and as encapsulating agents. Other uses, too numerous to mention in this short résumé, have also been found which give great versatility to the silicones. The advent of silicone rubber has made it possible to expose tubing to very extreme temperatures without altering the physical or mechanical properties of the material. Many uses have been found for the silicones in pharmacy and medicine. The coating of glassware for water repellency is now widely used in most laboratories and by the pharmaceutical industry for bottles and ampuls. Surgeons are finding a great deal of success with the silicone rubbers as prosthesis for various segments of the body. No doubt more and varied uses will be found for this group of plastics in the near future.

Others[3]

Some consideration has been given to a number of plastics but it should be kept in mind that there are other important plastic materials which may have individual advantages for specific applications in both pharmacy and medicine. One would not be doing justice to plastics in general if mention were not made of the *acrylics* which have been employed for a great period of time in the field of dentistry. The *acetals* are of more recent vintage and should find favorable use as parts of equipment which previously were made from metals. A number of *fluorocarbons* have been introduced since 1943 when the first successful material was manufactured. These materials have good thermal and chemical resistance and are finding uses in medical practice as tubings, synthetic prosthetic devices, and replacement for rubber and metals where good wear is desired. The *isocyanates* or, perhaps more correctly, the *polyurethanes* are an interesting group of materials. Various shapes and sizes of flexible foams can be prepared from polyurethane which take on the characteristics of rubber or rigid foams can be produced for special applications. These materials are finding use in surgery as prosthesis and as packing material for certain pharmaceuticals or agents which need extreme care in shipment. *Polyvinyl alcohol* behaves quite differently from most of the other plastic materials. This particular material will dissolve when placed into hot water. Use is now being made of this unique property to design packets which will contain a product to be eventually dissolved in water. All that needs to be done is to place the packet into warm water and, in a brief interval of time, the container will dissolve, releasing its contents. Measured amounts of ingredients can thus be assured without the need of the user to do the measuring or even to come in direct contact with the product. A group of polymeric materials which range from brittle solids to low viscosity liquids are the *epoxies*. These compounds are used as coating materials and in cementing various types of materials with such adhesion that often the components will break before separation at the cement point.

[3] See "Modern Plastics Encyclopedia" (1962 issue) for further information on plastics.

DRUG-PLASTIC CONSIDERATIONS

Introduction

In the previous section devoted to general information, the reader had an opportunity to explore, in a mild manner, a number of insoluble polymeric materials collectively called plastics. Even though the discussion on the selected plastics was brief, it should be evident that a large number of materials exist which have properties quite different from each other. Furthermore, it has been pointed out that even a plastic material having the same generic name can be dramatically different from the same named material from another source. Added to this already complex picture are the numerous modifications which are possible in formulating a final plastic material. From this maze of materials, often not clearly defined as to specifications, the pharmaceutical scientist must select one or more materials for a specific application. In the same manner, the surgical house must, with the utmost caution, find the proper plastic material for the numerous devices presently entering the hospital field in part or whole of a polymeric material.

The task of selecting the "right" material for a specific application was at one time given little attention in the pharmacy and medical fields. A prior assumption was made that plastics were quite inert and no serious problems could develop. It soon became evident that this was not the case and interest and energies were directed to evaluate materials as to their pharmaceutical and medical acceptability. Information and guidance were solicited from the various segments of the plastic industry to help formulate materials and devices which would prove

of equal quality to those standard materials which have been used for countless decades. Even this approach, it was soon found, was not enough since applications to pharmacy and medicine required special studies which had not been conducted by the plastic industry and which, it appeared, would have to fall on the shoulders of both the pharmaceutical industry and the surgical houses manufacturing and distributing devices for medical practice. A number of firms, representing both groups, are now pursuing an active and conscientious research program to eliminate possible problems in the use of plastics or to at least circumvent these problems to the advantage of all.

The point has been reached to become more specific in this review and discuss those problems which have or may become of consequence to both the pharmaceutical worker and to those other individuals and groups who will, in one manner or another, be involved in the chain of events leading to the ultimate use of the plastic item. In particular, the attention of the reader will be directed toward drug-plastic problems. Since plastics are relatively new to the practice of pharmacy and medicine, it will be convenient to classify these considerations in a rather arbitrary manner to facilitate the presentation. For this reason drug-plastic consideration is subdivided into five parts: permeation, leaching, sorption (including adsorption and absorption), chemical reactivity, and alteration in the physical properties of the plastic. As will be noted in due time, certain aspects of the various problems will be common to more than one class or section.

Permeation

One of the chief advantages of glass containers, for pharmaceutical solutions, is the lack of penetration of molecules from the solution in and through the glass walls or, conversely, the entrance of gas molecules through the glass wall into the solution. With plastic materials, one is immediately confronted with the problem of permeation in two directions: (*a*) from solution through the plastic into the ambient environment or (*b*) from the ambient environment through the plastic into the solution. It should be obvious at this point that the permeation rate will depend primarily upon the particular plastic material used (see Table IV).

Theory.—When a gas or a vapor is placed on one side of a plastic film, molecules of the gas will tend to dissolve at the surface of the film and will diffuse under a concentration gradient through the film reaching the other side (or the low pressure side) of the film. After a short period of time a steady state will be reached whereby the gas will diffuse through the film at a constant rate, providing that a constant pressure difference is maintained across the film.

TABLE IV.—TYPICAL GAS TRANSMISSION RATES OF PLASTIC FILMS AT 23° C.[a]

Plastic Film	Gas Transmission Rates, ml./m²—24 hr.—1 atm.) O_2	N_2	CO_2
Cellulose acetate	350	1500	7,800
Methylcellulose	1300	450	6,800
Polyethylene			
0.917	2700		
0.950	1700		
0.960	1600	440	...
Polyethylene terephthalate	50	8.4	240
Polystyrene	4500	640	11,000
Polyvinyl chloride, plasticized	190–3100	58–810	430–19,000
Polyvinyl chloride, rigid	120	20	320
Polyvinyltoluene	5700	1200	17,000
Rubber HCl	390	62	1,100
Saran	16	2.5	50
Styrene-acrylonitrile (copolymer)	900	120	2,800

[a] Brown, W. E., and Sauber, W. J., *Mod. Plastics*, 36, 107 (Aug. 1959).

In order to develop the usual equations for diffusion, consider a film having a thickness of l cm. and of unit area (38). One side of the film will be a pressure P_1 (high pressure side) while on the other, a pressure of P_2 (low side) will exist. A schematic representation of this situation is shown in Fig. 3.

For simplicity at layer A of the film, a concentration of gas equal to c_1 will be present while in the last layer (at B) the concentration will be c_2. The letter x will designate a distance between

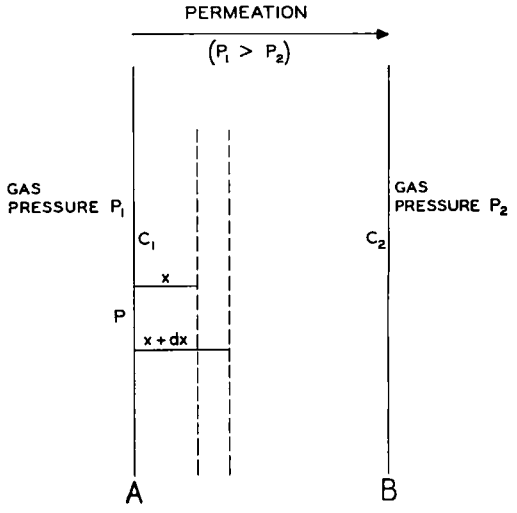


Fig. 3.—Representation of a gas entering and passing through a film from surface A to B.

two planes in the film, and $x + dx$ another distance between two planes. Designating the rate of gas permeation at x as q ml. per second and permeation at $x + dx$ as $q + (dq/dx)dx$, the amount retained per unit volume will equal $-(dq/dx)$ which can be equated to the rate of change of concentration c with time or

$$-\frac{dq}{dx} = \frac{dc}{dt} \qquad \text{(Eq. 3)}$$

When a steady-state condition is reached, $dc/dt = 0$ and q will become a constant.

No permeation will occur when the concentration gradient is zero and extremely high rates of permeation when the gradient is very large. The mathematical relationship between permeation and the gradient of concentration can be expressed by Fick's first law or

$$q = -D\frac{dc}{dx} \qquad \text{(Eq. 4)}$$

where D is defined as the diffusion coefficient or constant. Fick's second law as an equation may be developed by combining Eq. 3 with Eq. 4 to get

$$\frac{dc}{dt} = \frac{d}{dx}\left(D\frac{dc}{dx}\right) \qquad \text{(Eq. 5)}$$

If the diffusion constant, D, is independent of concentration, Eq. 5 reduces to

$$\frac{dc}{dt} = \frac{Dd^2c}{dx^2} \qquad \text{(Eq. 6)}$$

At a steady state of diffusion the rate of permeation, of q, will be constant and by integrating Eq. 4 between the two concentrations, c_1 and c_2, Eq. 7 will result

$$q\int_{x=0}^{x=l} dx = -D\int_{c_1}^{c_2} dc$$

or

$$ql = -D(c_2 - c_1) = D(c_1 - c_2)$$

$$q = \frac{D(c_1 - c_2)}{l} \qquad \text{(Eq. 7)}$$

Henry's law relates the concentration of gas at each surface in the film to the partial pressure of the gas or

$$c = S \cdot p \qquad \text{(Eq. 8)}$$

where S is the solubility coefficient of the gas in the film at equilibrium and p the partial pressure. Substituting $S \cdot p$ for the concentration terms in Eq. 7 will give Eq. 9

$$q = \frac{DS(p_1 - p_2)}{l} \qquad \text{(Eq. 9)}$$

The permeability constant, P, can now be defined as $P = D \cdot S$ or

$$P = \frac{q \cdot l}{(p_1 - p_2)} \qquad \text{(Eq. 10)}$$

If a plot is made of q *versus* time for a particular material, as appears in Fig. 4, it will be noted that a short time period must pass before a linear relation is reached. This portion of the curve indicates that a steady state of diffusion has been reached. The initial time period (non-linear portion of curve) is considered the non-steady state and Fick's second law applies (Eq. 5 or 6). No true solution for this equation for a finite solid has been developed, but for those cases where the diffusion coefficient is independent of concentrations and boundary requirements are stated, a number of mathematical approaches have been postulated. Of these, the works of Daynes (39) and Barrer (40) are perhaps the most widely accepted.

The equation which has found considerable use in the evaluation of D, P, and S is Barrer's equation (40), often referred to as the "time-lag" equation or method, which may be stated as

$$D = \frac{l^2}{6\tau} \qquad \text{(Eq. 11)}$$

where l is the thickness of the film and τ is referred to as the "time lag" which may be found by extrapolating the linear portion of the curve (see Fig. 4) to the time axis. This value, τ, may then be used to calculate D in the above equation. The permeability constant, P, can be evaluated from the slope of the linear portion of the line. Since D and P are known it is a simple matter to find S.[4]

As may be expected, temperature will have a direct effect on D, S, and P. Experimental data at various temperatures will follow the Arrhenius relationship and thus

$$\begin{aligned} D &= D_0 \exp.(-\Delta E_D/RT) \\ S &= S_0 \exp.(-\Delta H/RT) \\ P &= P_0 \exp.(-\Delta E_p/RT) \end{aligned} \qquad \text{(Eq. 12)}$$

where D_0, S_0, and P_0 are pre-exponential factors, ΔH is the heat of solution, ΔE_D the activation energy for the diffusion, and ΔE_p activation energy for permeation.

Studies of transmission of gases through permeable materials are not new. Graham, in the 1860's, had investigated the penetration of gases through rubber. Greater emphasis on these types of studies increased with the development of the synthetic materials for both theoretical and practical reasons.

[4] D = cm.²/sec.; P = ml.(S.T.P.)mm./cm.²/sec./cm. Hg; S = Gm./Gm./cm. Hg. It should be noted that other units have and may be used for these three terms.

Measurement of Permeation.—A variety of methods for studying gas permeability through plastics have appeared in the past decade (41–44). It is apparent that measurements of this type are not always quite as simple as may be thought. Major and Kammermeyer (45), in a recent publication, cite that they have finally reached the conclusion, after thousands of permeation measurements, "that they are anything but simple and often can lead to frustrating experiences." This perhaps is one reason why permeation data often do not agree when different laboratories have conducted studies on permeation on the same type of material. Keeping in mind that problems may arise in permeation studies, it is still possible to list a number of general methods which have been used. For this listing it is convenient to refer to the work of Brown and Sauber (46) who mention five methods of measuring permeation: thermal conductivity, refractive index, mass spectrometry, gas analysis by chemical means, and pressure-volume-temperature (*PVT*) methods. Of these, the last method appears to be the most practical and, in fact, is used as an *ASTM* test for gas transmission rate of plastic sheets (47).

In general, the *PVT* method employs a cell which contains two compartments separated by the particular sample of film to be studied. Gas is introduced to one side of the film and the pressure change on the other side recorded over a period of time. From these data the volume of gas transferring from the high pressure side to the low pressure side may be calculated, which in turn can be used to calculate the permeation rate or constant. Brown and Sauber (46) developed the type of instrument which is now included in the *ASTM* test, referred to above. This instrument lacks high accuracy if very exacting permeation data are needed, but serves to give acceptable data when rapid measurements are needed as might be the case for control work or for other industrial applications. The already mentioned authors, Major and Kammermeyer (45), suggest a new instrument which operates basically in the same manner as the *ASTM* instrument, but which seems to give greater accuracy without the loss of speed.

For more precise and accurate permeation data using a *PVT* method, it will be necessary to set up a more elaborate instrument such as used by Stannett and co-workers in their numerous permeation studies (48–51). Certain advantages, however, can be gained by the use of this latter instrument since the accumulated data can then be calculated to give both the solubility and the diffusion constants (see Fig. 4). The chief disadvantage of Stannett's instrument is the painstaking techniques which are needed for proper operation.

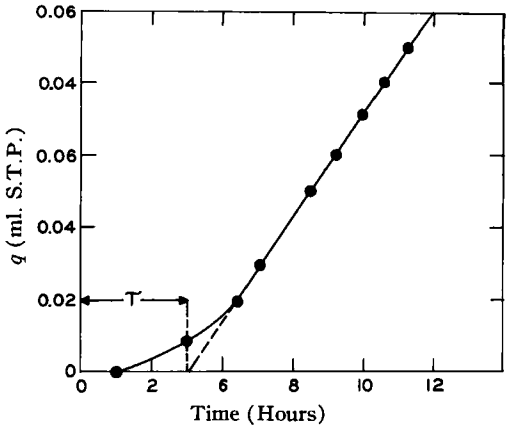

Fig. 4.—Plot of gas transmission *vs.* time through a plastic film.

Penetrant Molecules.—*Permanent Gases.*—The particular plastic material will influence the permeation rate of a gas as may be noted by referring to Table IV. Even for the same generically named plastic, the rate may differ due to such factors as molecular weight, molecular weight distribution, branching, degree of crystallinity, and the presence of other ingredients. Some of these factors have been investigated in some detail, but a great deal still has to be done to have a true indication of the influence a combination of these factors has on the penetration of gas molecules. One must be content to examine several of the factors individually, keeping in mind that other forces are also exerting an influence even though these may not be so apparent.

From simple theoretical considerations gas molecules must find "holes" in the plastic material to travel through the material. Any hindrance to this passage will of necessity tend to decrease the permeation rate. Polymeric materials, which have a great deal of crosslinking, will retard the movement of the gas molecules. Crystallite formation and the degree of crystallinity in the plastic material will have a very appreciable effect on permeation and it is now generally accepted that gas molecules probably travel through the amorphous zone. High crystalline materials would thus have low rates of permeation.

Considerable work has been done on the influence of crosslinking in rubber on permeation of various gases (52, 53). Less information is available on the crosslinking of plastics, but it

appears that permeation follows in somewhat the same general order as seen for rubber—the more crosslinking, the less permeation (54).

Table V is taken from the work of Rogers, Meyer, Stannett, and Szwarc, and indicates the influence of crosslinking on the permeability of unirradiated and irradiated polyethylene to three gases. The higher dosed plastic showed a reduction in the permeation rate revealing an appreciable increase in crosslinking, whereas the lower dosed material apparently had little change in the crosslinking, as may be surmised from the lack of a significant change in the permeation rate.

Many of the currently used plastic materials for packaging purposes have various degrees of crystallinity. As has been indicated, the greater the degree of crystallinity the less will be the permeation rate. This is an oversimplification of a rather complex phenomenon, but a number of authors have attempted to describe the influence of crystallinity on the permeation rate (55, 56). An example of the effect of crystallinity on permeation may be noted by observing Table VI. With both polyethylene and polychlorotrifluoroethylene with the three gases, a decrease in permeability takes place as the approximate crystallinity increases.

It has been theorized that a decrease in permeability of permanent gases in materials of high crystallinity is probably due to the decrease in the diffusion constant, since little change occurs in the solubility constant of the gas in the material. At one time, it was believed that the diffusion constant was related by simple proportion to the amorphous content of the plastic (57). This has since been proved as false (56). Other reasons influence the diffusion constant of the gas. Crystallite zones may have an effect on the geometric structure of the amorphous zones, giving rise to difference in diffusion and, of course, on permeability. Michaels and Parker clearly state that diffusion of a gas in polyethylene is not solely a function of the degrees of polymer crystallinity, even though it is highly dependent upon it (58). They point out that the crystallite shape has an influence in altering the diffusion which, in turn, alters the permeability.

Several investigators have indicated that polyethylene permeability can be related in a linear fashion to the density of the material (59, 60). This prediction seems not to have been verified by Brandt (61). Lasoski and Cobbs (62) postulate that permeation will be more apt to be related to the square of the density of the material. Alter (63) in a critical investigation of permeation and using the previous concepts of Myers, *et al.* (64), Klute (59), and Lasoski and Cobbs (62) developed the simple expression $P = K(1 - d)^n$, where K is a constant characteristic of each gas, n is an exponential value without further definition, and d is the density, for relating permeation to

TABLE V.—PERMEABILITY CONSTANTS FOR POLYETHYLENE (INFLUENCE OF CROSSLINKING)[a]

Gas	Temp., ° C.	Unirradiated	Irradiated	
			10^7/rad	10^8/rad
Nitrogen	0	2.59×10^{-10}	2.67×10^{-10}	1.46×10^{-10}
	15	7.84	7.72	4.36
	30	21.5	20.1	11.0
	45	54.6	50.6	27.4
Oxygen	0	11.0	...	5.91
	15	27.5	...	15.3
	30	69.4	...	34.8
	45	143	...	73.7
Carbon dioxide	0	54.7	54.6	29.7
	15	130	129	72.7
	30	280	277	152
	45	540	542	287

TABLE VI.—EFFECT OF CRYSTALLINITY ON GAS PERMEABILITY[a]

Polymer	Approximate Crystallinity, %	P, at 30° C.		
		N_2	O_2	CO_2
Polyethylene	60	1.9×10^{-9}	5.5×10^{-9}	25.2×10^{-9}
	69	0.66	2.1	7.4
	81	0.27	1.1	4.3
Polychlorotrifluorethylene	30	0.008	0.05	0.11
	80	0.004	0.013	0.03

[a] Myers, A. W., Rogers, C. E., Stannett, V., and Szwarc, M., "Permeability of Plastic Films and Coated Papers to Gases and Vapors," Tappi Monograph Series No. 23, New York, 1962, p. 53.

density. Experimental data for nitrogen, oxygen, and carbon dioxide in various film samples of polyethylene having different densities followed in general the mathematical expression shown above. Alter (63) believes that there is more justification in relating permeability to density of the material than to the usual degree of crystallinity or to the volume fraction of the amorphous zone.

Organic Vapors.—The solubility coefficient and the diffusion coefficient are constants at any given temperature for penetrant gas molecules. Since the permeation coefficient is a product of the solubility and diffusion, P will also be a constant. Large permeation constants for a specific gas are primarily dependent upon an increase in the diffusion constant while, in most instances, for organic vapors, an increase in the permeation rate is much more dependent upon an increase in the solubility of the vapor molecule. The ability of a polymer to attract and sorb (increase in solubility) penetrant vapor molecules will obviously be related to the physical and chemical properties of both the penetrant and the polymer. As a first approximation then, it can be assumed that as the chemical structure of the penetrant becomes more similar to the polymer, greater solubility will result and as a consequence greater permeability. This has in fact been found to be generally true. For example, Bent and Pinsky (65) found that permeation through polyethylene increased in the following order: alcohols, acids, nitroderivatives, aldehydes, ketones, esters, and hydrocarbons.

Since very little interaction occurs between the permanent gases and a particular polymer, the permeability rate is not concentration dependent. Quite different, however, is the case for most of the vapors since many of these will interact (sorb) with the polymer. Increases in concentration of the penetrant in the plastic will usually have a material effect upon the diffusion. Part of this effect may be due to the ability of the penetrant when sorbed to swell the plastic or to act as a plasticizing agent, thereby permitting greater degree of traversity or diffusion in the material. Often unusual or anomalous results are seen which become difficult to resolve on theoretical grounds.

There has been little success in relating, quantitatively, organic vapor permeation with crystallinity, amorphous content, or plastic density, but by indirect means, data have been accumulated at least to support the contention that certain vapors will follow a direct relationship with the amorphous content of the plastics. Perhaps the best example to illustrate this point is the correlation of the data on methyl bromide sorption (consider solubility and sorption as being nearly identical) with the amorphous content in several polyethylenes (51). The top portion of Fig. 5 represents the sorption isotherm in three polyethylenes, each having a different density. As may be noted from this figure, the sorption decreases as the density of the material increases. The single curve at the bottom of the same figure has been recalculated on the basis of the amorphous content of the samples and it will be noted that all the points now fall on the one line. Other molecules, especially those molecules which are considered as good solvents for the plastic, will not show the single curve after recalculation on the basis of the amorphous content (51).

Crosslinking in a plastic material usually will decrease the permeation rate, more probably due to hindering the travel of the penetrant (diffusion) than to decreasing solubility. For those penetrants which are better solvents for the plastic, both the solubility and diffusion will increase slightly at low temperatures, but at higher temperatures the crosslinks prevent the usual swelling and decrease the mobility of the chains and, in consequence, both solubility and diffusion decrease.

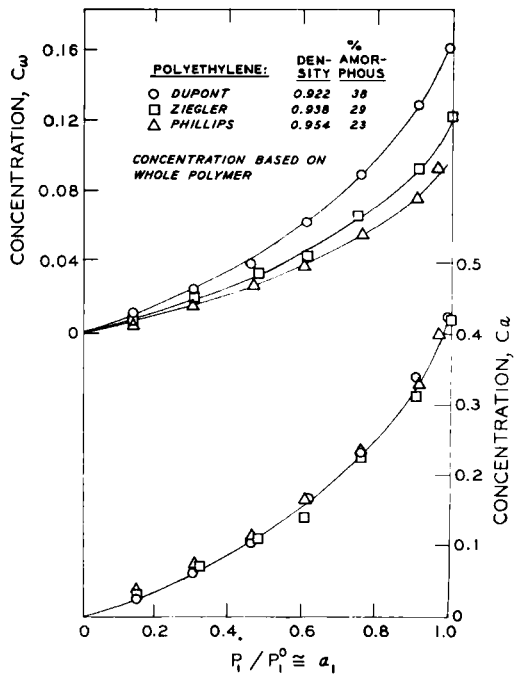

Fig. 5.—Sorption isotherm for polyethylenes and methyl bromide to 0°C. [From Rogers, C. E., Stannett, V., and Szwarc, M., *Tappi*, **44**, 715 (1961).]

As has already been noted on organic vapors, solubility plays an extremely important role in the permeation phenomenon. Reference has also been made that the chemical structure of the penetrant will either increase or decrease the solubility in a particular plastic. One other factor must now be brought to light in permeation of organic vapors: the geometry of the particular organic molecule. It has been found, for example, that as the size and the shape of the penetrant molecule increases, a similar increase in solubility will occur. Figure 6 illustrates a linear relationship between solubility and the molar volume of various penetrants. Solubility (at zero concentration of penetrant) appears also to increase as the cross-sectional area of the penetrant increases. The overall effect upon permeation is not as great as might be expected, since diffusion decreases as the volume and shape of the penetrant increases. Other factors, of course, are involved and for this reason it becomes quite difficult to predict the behavior of certain organic vapors in a particular plastic material.

In general, permeation will usually increase with an increase in temperatures. For the permanent gases, the permeability-temperature relationship follows the accepted Arrhenius relationship. With organic vapors, however, this may or may not be the case, depending upon the vapor pressure. For example, it has been found that certain vapors (at a definite vapor pressure) will show a gradual decrease in permeation as the temperature is lowered until a critical temperature is reached, at which point further decrease in temperature will reveal

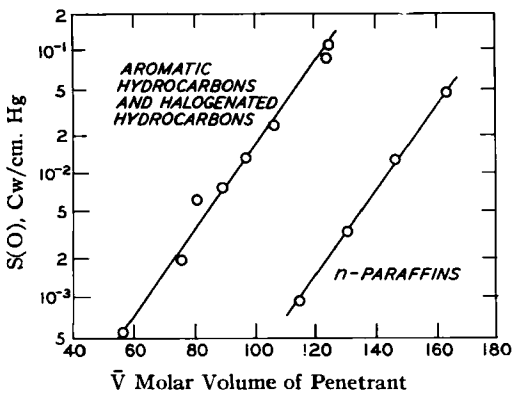

Fig. 6.—Effect of molar volume of penetrant on S(O); polyethylene density 0.922 Gm./ml. at 25°C. NOTE: S(O) is the intrinsic solubility coefficient for a penetrant of zero molar volume. [From Rogers, C. E., Stannett, V., and Szwarc, M., *Tappi*, **44**, 715(1961).]

an increase in permeation (51). From what has been discussed on vapor pressure permeability, it may be seen that the phenomenon is not a simple mechanism and will be altered by many factors, each having some part in the overall mechanism.

Water Vapor.—Water vapor transmission through plastic materials, like a number of the organic vapors, is quite complex and often the results are difficult to interpret. Earlier measurements on water vapor permeability have been found to be in error because of the presence of dissolved air in the vapor (66). The method of evaluating the diffusion constant by the time-lag method will also lead to serious errors (67). Myers, *et al.* (67), found it necessary to calculate the diffusion constant from sorption and permeation data. The rate of permeation is, as might be expected, dependent upon the physical and chemical properties of the particular plastic film. In general, it is possible to describe two general types of permeation: (*a*) those that are dependent on pressure and (*b*) those that are independent of pressure. Past experience has demonstrated that the pressure-dependent permeation follows for most of those polymeric materials which are hydrophilic in nature, such as cellophane, nylon, and polyvinyl alcohol. while the pressure-independent permeation is seen for the hydrophobic polymers, such as the polyethylenes (see Fig. 7).

Pressure dependent permeation (*i.e.*, with nylon) will show large rates of permeation as the vapor pressure increases. This result is due to the ability of the nylon to attract water vapor molecules which are then sorbed to the various polar sites. As the concentration of water in the nylon increases, a swelling and plasticizing effect takes place, which in turn aids the diffusion process. Since both the solubility and the diffusion constants are increasing, the final permeation constant will also be increased. An unusual effect may also be noted with nylon, which in a manner has already been mentioned with certain of the organic vapors (67). For example, an increase in temperature after a certain point will show a decrease in permeation (see Fig. 8). This may be explained in the following way. As the temperature is decreased at a fixed vapor pressure, the relative humidity increases. This increase in humidity is reflected by an increase in solubility in the nylon which accelerates the diffusion process to a much greater extent than the decrease in diffusion normally attributed to a reduction in temperature.

Permeation through the hydrophobic plastics (*i.e.*, polyethylenes) for the most part are

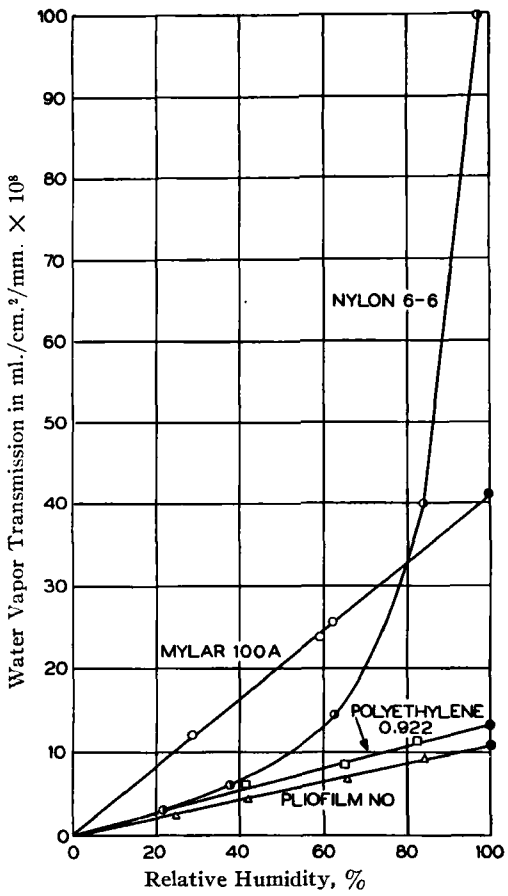

Fig. 7.—Water vapor transmission as a function of humidity for various plastic films. [From Myers, A. W., Meyer, J. A., Rogers, C. E., Stannett, V., and Szwarc, M., *Permeability of Plastic Films and Coated Paper to Gases and Vapors*, Tappi Monograph No. 23, 1962, p. 62.]

independent of the relative humidity. The mechanism for this type of permeation, as pointed out by Myers, *et al.* (67), is not quite as simple as it would at first appear. Strong experimental evidence is at hand to reveal that solubility increases with an increase in pressure, but that the diffusion decreases with an increase in concentration. One apparently compensates for the other, leading to a pressure-independent permeability constant.

Permeation Through Containers.—*Permanent Gases.*—In the discussion which has so far been presented on permeation of permanent gases, organic vapors, and water vapor, the plastic material has been in the form of a film which was then placed in an appropriate apparatus for the study of the penetration and transmission of the gaseous molecules. The parameters of the experiments were kept as simple and as constant as the experimental procedure warranted. Even in these instances, however, as has been demonstrated, a number of anomalous results occurred. For the most part, these data with proper assessment have been utilized by various investigators to give theoretical treatments for penetrant-polymer interactions. Even though this information can serve as a useful foundation for those interested in permeation, certain problems of a more practical nature must still be handled by more empirical means, since the science still has not caught up with the art of manufacture of certain types of plastic devices. This appears to be true for the present plastic containers used in pharmaceutical practice.

Studies of permeation in the intact container for various gases appear not to have been considered in too serious a vein by those presently manufacturing plastic containers. Often the complete formulation of the plastic material, the actual handling of the material, and the exact history of the manufacture of the containers are not really known by the one utilizing the containers. It is possible that any change in a procedure from the acquisition of the raw materials to the final ejection of a completed container will have an influence on the permeation rate of gases. More time and space

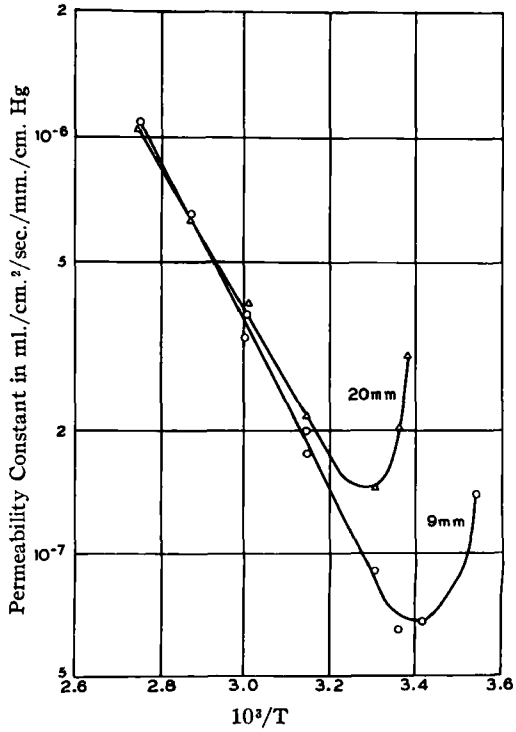

Fig. 8.—Temperature dependence of the permeability constant for water in nylon 66 at vapor pressures of 9 and 20 mm. Hg. [From Myers, A. W., Meyer, J. A., Stannett, V., and Szwarc, M., *Tappi*, **44**, 58(1961).]

than presently available would be needed to explore the various factors which might alter the container to permeation.

Let us for a moment consider some consequences of gas transmission through the walls of a plastic container into a particular drug system. For those agents which are prone to oxidation, a rapid degradation may take place before the useful shelf-life of the product has been reached. Various product development laboratories have noted this effect with one or more of their drug products. Often, even the product development groups have not properly assessed their product in a plastic container to the embarrassment of the company, since reports start arriving indicating that a change in color or a precipitate has formed when the pharmacist, medical practitioner, or patient is about to utilize the medication. Oxygen or air perhaps is the most serious offender in destroying the product, but at times the transmission of carbon dioxide alters the pH of the preparation enough to catalyze degradation by either an oxidation or hydrolysis mechanism. Other problems may be seen due to the transmission of ambient gases, either inside the container or outside. For example, distortion of the container, either collapsing or bulging of the bottle, may be attributed to the transmission of air either out of the container or into the container. Even though there may not be any adverse effect upon the therapeutic efficacy of the medication, the distorted appearance of the container will certainly not add prestige to the company's name.

Vapors and Liquids.—Since 1950 a number of investigators have directed their attention to studying advantages and disadvantages of plastic containers (68–75). Perhaps the most work has been done on regulation-size bottles composed of one of the polyethylenes. Invariably these studies include filling a bottle with a specific ingredient (liquid), stoppering, and exposing it to various temperatures for short and long periods of time, while noting the loss or gain in weight. Pinsky, Nielsen, and Parliman (68) have reported in one study the results of 67 typical chemicals which can be represented by one of the following groups: (*a*) inorganic acids, (*b*) alkalies, (*c*) organic acids, (*d*) alcohols, (*e*) polyhydric alcohols, (*f*) esters, (*g*) ethers, (*h*) aldehydes, (*i*) ketones, (*j*) anhydrides, (*k*) terpenes, (*l*) nitrogen-containing compounds, (*m*) aliphatic hydrocarbons, (*n*) aromatic hydrocarbons, (*o*) chlorinated hydrocarbons, and (*p*) miscellaneous. In studies of this type, it is usually found that for the same material, liquid permeability will invariably be higher than vapor permeability. Table VII will show this trend, taken from the work of Martinovich and Boeke (76). Even though theoretically it is assumed that permeability should vary inversely with the thickness of the plastic, in actual practice, using bottles, this may not be the case.

TABLE VII.—VAPOR AND LIQUID PERMEABILITY OF MARLEX 50[a] AT 80° F.[b]

Chemicals Used	Vapor Permeability[c]	Liquid Permeability[c]
Amyl alcohol	0.353	0.268
Ethylene glycol	0.669	0.873
Acetic acid	0.940	0.993
Aniline	1.09	1.27
Ethyl alcohol	1.26	1.77
Oil of peppermint	1.36	1.75
Butyric acid	1.54	3.61
Benzaldehyde	2.45	3.92
Methyl salicylate	3.39	3.92
Methyl ethyl ketone	4.12	8.05
Amyl acetate	5.54	6.75
Diethyl ketone	7.67	7.67
Ethyl valerate	8.11	9.69
Butyraldehyde	9.86	12.58
Ethyl acetate	13.7	13.7
n-Butyl ether	19.3	34.3
Butyl iodide	52.04	112.72
Heptane	54.0	69.7
Butyl chloride	69.63	86.05
Butyl bromide	76.15	113.19

[a] Trademarked name for Phillips' high density polyethylene. [b] Martinovich, R. J., and Boeke, P. J., "Technical Information on Marlex," Sales Service Lab., Phillips Petroleum Co., Bartlesville, Okla., Oct. 1957, p. 2. [c] Expressed in Gm., 24 hr., 100 in.^{2}, mil thickness.

Results of studies have also revealed that formulations containing volatile ingredients might change, when stored in plastic bottles, because one or more of the ingredients are passing through the walls of the container (77). Often the aroma of cosmetic products becomes objectionable due to preferential transmission of one of the ingredients, or the taste of medicinal products changes for the same reason (78). The plastic container may also have an influence upon the physical system making up the product. For example, certain water-in-oil emulsions cannot be stored in the hydrophobic plastic bottles, since there is a tendency for the oil phase to migrate and diffuse into the plastic.

Heise, Parliman, and Pinsky (73, 74) have done considerable noteworthy work on plastic containers and have made a number of suggestions on how to select a particular container for a general type of product. Even more noteworthy, however, is the series of tests their group has developed to help interested parties evaluate the merits of a container. They include the following tests (74): environmental stress-crack test, using Igepal CO-630 water solution,

impact test, leakage test, side-wall distortion test, and side-wall rigidity tests. Unfortunately, as stated earlier, there is little published information on drug products in plastic containers and it appears that one must study the specific product in each container before final evaluation of the container is possible.

One must not deal lightly with permeation in plastic containers. Some plastic materials will, of course, act as stronger barriers to permeation than others. It is now well known that the high density polyethylenes will give greater protection than the low density types. It has also been found that special types of coating can further prevent permeation. From all past and present indications, it appears that plastic containers for the pharmaceutical industry will have to be manufactured under very special and rigid conditions, a situation which at present, at least for the most part, is not true.

X-ray and Crystallographic Applications in Pharmaceutical Research II

Quantitative X-ray Diffraction

By JOHN W. SHELL†

In a comparison of quantitative methods, bioassays have an advantage of being specific for an intact molecule. Such assay methods, however, often lack a high degree of precision. Chemical methods usually offer high precision but are notoriously nonspecific. A general quantitative method which offers a combination of specificity and precision is highly desirable, particularly for use in describing pharmaceutical systems. This unique combination is found by the adaptation of quantitative X-ray diffraction to systems containing crystalline ingredients. This paper describes the general method and the procedures which have been found useful in the application of the method to the most commonly encountered situations. Illustrating the procedures are examples of the applications to specific drug systems.

ONE OF the most seldom used, and yet potentially powerful methods for describing some pharmaceutical systems is the method of quantitative X-ray diffraction. Of the numerous advantages of this method, the most striking is the offer of absolute specificity combined with a high degree of accuracy. This feature, which is particularly desirable for drug systems, is unique. Further, the method can often be applied directly to complex mixtures such as final drug formulations without the need for separations, is usually rapid, and does not necessarily require a knowledge of all of the ingredients of an unknown mixture. The method applies only to the determination of crystalline ingredients, but the system containing the ingredients may be in any physical state.

Some mention of the possibilities of quantitative diffraction was first made by Hull as early as 1919 (1), but the first work reported was by Clark and Reynolds on the analysis of mine dust in 1936 (2). This work, and other work following (3), was based upon microphotometric density measurements of X-ray film following exposure. This method of measuring the intensity of diffracted X-rays was highly inaccurate and it was not until the advent of the Geiger counter spectrometer (4) that truly quantitative diffraction became possible. Some early papers describing Geiger techniques were on the determination of quartz (5, 6) and heavy metal carbides (7).

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
† Present address: Allergan Pharmaceuticals, Inc., Santa Ana, Calif.

The mathematical relationships pertinent to quantitative diffraction analysis were derived and published in an important fundamental paper by Alexander and Klug appearing in 1948 (8). This paper described conditions under which standard curves alone could be used, and under which standard curves based on internal standards were required, depending upon absorption effects. Relationships permitting, in certain instances, quantitative analysis of differential absorption systems without the use of internal standards were described in 1953 (9). In 1958, Copeland and Bragg (10) described special conditions under which calibration curves could be sometimes eliminated and multiple components determined.

All of the above papers refer to investigations of inorganic systems. Published reports on quantitative diffraction applications to organic systems are almost nonexistent. A notable exception is the application to the determination of sodium penicillin G, by Christ, Barnes, and Williams (11).

It is the purpose of this paper to describe the application of quantitative diffraction methods to typical pharmaceutical systems. In making this application, several situations may be encountered and each situation requires a somewhat different procedure. The procedures found useful for each of the commonly encountered situations are described and illustrated by specific examples.

THEORY

The feasibility of quantitative X-ray diffraction stems from the fact that the intensity of a diffracted beam of X-rays is a function of the amount of

diffracting material. The linearity of this response, for a fixed set of experimental conditions, depends upon the difference in the amount of absorption of X-ray energy between the compound of interest and its surrounding matrix. The absorption of any material depends upon the mass absorption coefficients of its constitutive atoms, which in turn are generally a function of atomic number for a given wavelength of radiant energy. Thus, as a compound differs chemically from its matrix, so will it differ in absorption for the radiant energy. The result of a large difference is a very nonlinear relationship between the amount of diffracting material and the diffracted intensity.

It is significant that in inorganic systems the probability of wide variation in X-ray absorption between the compound of interest and its surrounding matrix is high, whereas with organic systems the variation is usually low. This feature of organic systems results in an advantageous gain in linearity of response and allows, in many instances, the use of a simple calibration curve for the quantitative analysis of complex organic systems.

The diffraction of X-rays by a crystal is a well-known phenomenon. It occurs because the wavelengths of X-rays are of the same order of magnitude as the spacings between planes of crystalline lattices. A fundamental relationship, the Bragg equation, is $N\lambda = 2d \sin \theta$. A monochromatic X-ray beam (wavelength λ) is diffracted by a set of parallel, equally spaced planes (spacing d) within a crystal. Diffraction occurs only in precise directions (the angle θ) with respect to the planes, for each of several orders of diffraction (N).

A single crystal has a number of sets of parallel planes, oriented differently from one another, each set having a constant d spacing between its parallel planes. Diffraction from any single set of parallel planes is possible when the crystal is properly oriented with respect to an X-ray beam. If a sample consists not of a single crystal but of a large number of small crystals packed together with random orientation, all possible orientations of single crystals will be presented to a fixed X-ray beam. Such an arrangement is found in the goniometer shown in Fig. 1 where S represents an edge view of a shallow tray containing a finely powdered crystalline sample with a planar surface. A proportional counter C rotates about S at an angle of 2θ, while the sample turns at θ, with respect to the fixed X-ray source. Whenever a crystal in the randomly packed powder sample falls into such a position that the Bragg equation is satisfied, diffraction will occur and the position (2θ) and intensity of the diffracted ray is measured by the scanning counter.

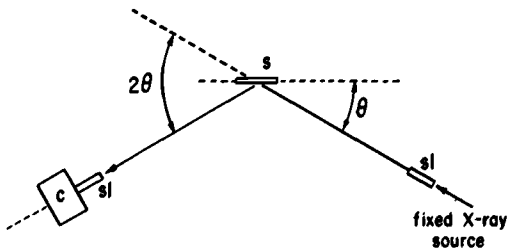

Fig. 1.—The sample (s) rotates through θ while the counter (c) scans through 2θ. An edge view of the planar-surface sample is shown. X-ray beam slits (sl) define the beam parallel to the sample surface.

Modern instrumentation permits this operation to be accomplished automatically. While the proportional counter is driven in its scanning operation at constant velocity, the sample is rotated at half this angular velocity, and a synchronized strip-chart recorder plots the diffracted intensity as a function of the angle, 2θ. For semiquantitative studies, strip-charts can be used directly but for truly quantitative work, scaler and timer circuits are employed, permitting the more accurate determination of the intensities of the diffracted rays.

When diffraction occurs at a given 2θ value, it does so because a sufficient number of crystals have the same set of planes, whose d spacings correspond to the 2θ value, properly oriented with respect to the X-ray beam. The intensity of the diffracted ray is a function of the amount of material so oriented. If truly random orientation is assured,[1] and except for absorption effects, the diffracted intensity becomes proportional to what may be termed the specific lattice volume. It is highly significant that when the intensity of a single diffraction peak is measured at a fixed 2θ value, both additive and constitutive effects are being measured. This unique fact is the basis for the specificity of quantitative diffraction analysis.

EXPERIMENTAL

For the experimental work reported, a General Electric XRD-5 unit and copper $K\alpha$ radiation were employed. The unit was equipped with a decade scaler and timer circuit, proportional counter, 1° beam slit, and 0.2° detector slit.

Simple Calibration Curves.—For the preparation of the standard curve for the determination of pamoic acid in a matrix of the pamoic acid salt of a basic antibiotic, use was made of synthetic mixtures containing known concentrations of pamoic acid in the antibiotic salt. Following thorough mixing and grinding in a mortar, each sample was poured into a standard 2-in. sample tray, which required about 200 mg. of material. In order to assure random crystal orientation, the excess powder was carefully removed by use of the edge of a glass microscope slide, and the sample surface finally packed slightly by use of the surface of a rough, low-grade blotting paper. This procedure eliminates large errors due to preferred orientation of the crystals.

The diffraction peak intensity of each sample was determined in the following manner. After placing the sample in the diffractometer, the goniometer was set for 26.25° 2θ and the instrument set to record the time required for the accumulation of 20,000 counts. This operation was followed by a setting of the goniometer at 26.80° 2θ and a second recording of the time required to accumulate 20,000 counts. The diffraction intensity at 26.25° (peak intensity) in counts-per-second was calculated, and the intensity at 26.80° (background intensity) in counts-per-second was also calculated. Since the statistical accuracy of a counting process is a function of the

[1] In all quantitative diffraction studies the effects of preferred orientation of the crystals must be minimized. Simple grinding, followed by careful packing in the sample tray, usually accomplishes this for organic compounds. In instances where an extreme of one crystal habit is represented, the advantageous use of 2% carbon black added to the mixture has been reported (11).

total number of counts taken, a preset count, rather than preset time, was used to determine the intensities in counts-per-second. This procedure allows all values, when compared later, to be of the same statistical accuracy.

The background intensity was subtracted from the peak intensity and the resulting value for each of the standard samples representing synthetic mixtures was plotted *vs.* the known concentration.

The calibration curve for the determination of novobiocin in mixtures of tetracycline and amorphous suspending agent was prepared from aqueous suspensions containing known amounts of novobiocin in mixtures of these ingredients. Solids were separated from suspension by centrifugation and air dried.

Use of an Internal Standard and Integrated Diffraction Peak Areas.—A method for the determination of a crystalline sulfonamide in aqueous suspension illustrates the use of integrated peak areas and an internal standard.

In this method, exactly 3.00 Gm. of powdered $CaSO_4 \cdot 2H_2O$, the internal standard, was added to 50.0 ml. of the sulfonamide suspension. As the suspension was too viscous to filter and too stable to separate with reasonable centrifuge times, it was diluted 1:4 with water which was freshly saturated with the pure sulfonamide. Centrifugation and decantation was followed by a second suspension in the dilution medium. A second centrifugation and decantation step freed the total solids from all water-soluble materials. The sulfonamide itself was virtually insoluble. The dried residue was mixed by grinding and packed into a standard diffraction sample tray. A portion of the diffraction pattern of the mixed solids from a 5% suspension of the sulfonamide is shown in Fig. 2. The doublet at 10° is from the sulfonamide diffraction, and the peak at 11.5° is from the internal standard.

The integrated intensity values were determined by the following procedure. With the scaler set for a preset time of 100 sec., the counting rate at 9° was determined in counts-per-second. This was repeated for positions at 11° and 13°. Diagrammatically these three values of background counting rates are represented in Fig. 2 by the lengths of the lines *AF*, *BE*, and *CD*.

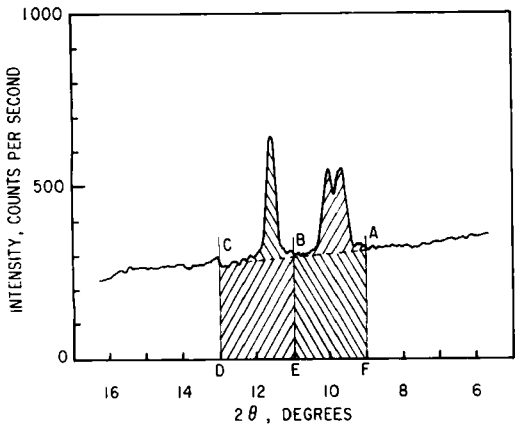

Fig. 2.—Partial diffraction pattern showing sulfonamide peaks (doublet at 10°) and internal standard peak (11½°).

With the goniometer set at somewhat less than 9°, an automatic scan was begun at 2° per minute. As the scan reached 9°, the counting switch was turned on, simultaneously starting the scaler and timer. As the scan crossed 11°, this switch was turned off. The total count and total elapsed time (approximately 60 sec.) were recorded. The elapsed time (in seconds) is represented by *EF* on the diagram and when multiplied by the average of background counting rates measured at 9° and 11° (in counts-per-second) gives the area of background under the the sulfonamide curve (*ABEF*) expressed in total count. This value was subtracted from the total count accumulated in the scan operation. The difference was the area of only the sulfonamide diffraction peak, expressed in total count. The operation was repeated between 11° and 13° to determine the area of the internal standard peak. The ratio of sulfonamide peak area to standard peak area was then computed.

RESULTS AND DISCUSSION

Use of Simple Calibration Curves.—No errors due to changing absorption effects occur with simple, two-component mixtures, or with multicomponent mixtures whose composition, except for the component being analyzed, remains constant. The determination of a crystalline ingredient in such systems may be based on calibration curves prepared from synthetic mixtures. An example is the determination of pamoic acid in a matrix of the pamoic acid salt of a basic antibiotic. The method was found useful in testing for completeness of the salt-forming reaction, and particularly in support of the long-term stability studies of a formulation of the antibiotic salt.

The diffraction pattern of pamoic acid is shown in Fig. 3. Although major diffraction peaks occur at 2Θ values of 9.50°, 11.20°, 15.60°, and 19.40°, all of these peaks are at least partially obscured when superposed on the pattern of the matrix materials. For this reason the peak at 26.25° 2Θ was chosen as a basis for the determination.[2] The results of a plot of intensity differences, peak minus background, for several known concentrations is shown in Fig. 4. The linearity shows the direct applicability to simple systems. The total counting time for each point was approximately 3 min.

Since organic molecules are large, organic crystals have large unit cells. Most interplanar spacings are, therefore, large. Such spacings give rise to diffraction peaks at small values of 2Θ which is the region of maximum response to scattering of the X-rays by the powdered sample. Thus it sometimes happens that a diffraction peak of interest occurs in an area of maximum background. This is particularly true when a sample contains a large amount of amorphous or scattering material.

Such a situation is illustrated by Fig. 5 which shows the superposition of diffraction peaks of novobiocin and tetracycline on a steep background slope. This diffraction pattern was measured using

[2] One has a choice of several possibilities upon which to base a proposed analysis. If the matrix is not obtainable in pure form, and there is doubt as to the freedom from interference of diffraction peaks, two simultaneous methods may be developed, each using a separate peak. Freedom from interfering peaks is assured when results of the determinations agree.

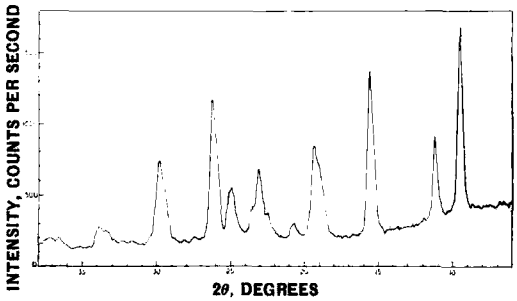

Fig. 3.—The pamoic acid diffraction pattern.

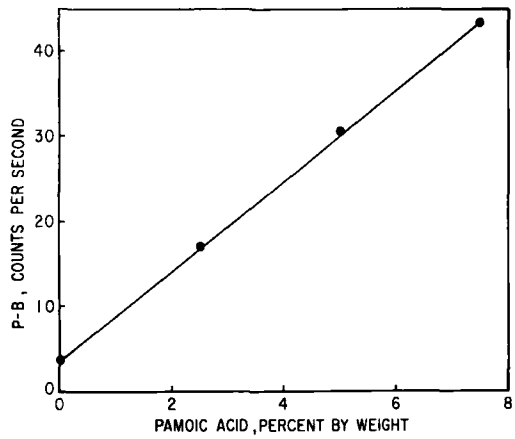

Fig. 4.—Intensity difference, peak minus background, as a function of pamoic acid concentration.

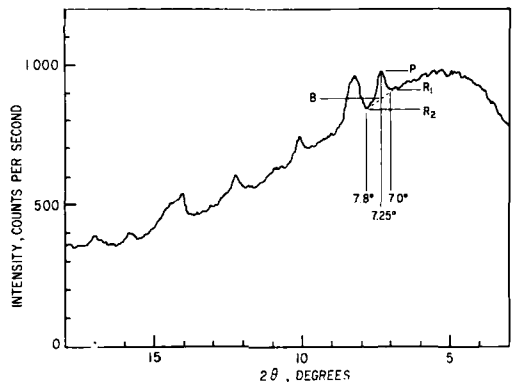

Fig. 5.—Partial diffraction pattern of an antibiotic mixture showing novobiocin peak at 7.25°.

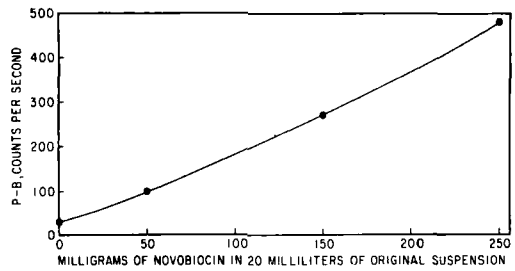

Fig. 6.—Intensity difference, peak minus background, as a function of novobiocin concentration.

the solids removed by centrifugation from a diluted aqueous suspension of calcium novobiocin, tetracycline, and an added known amount of crystalline novobiocin acid as a standard.

The diffraction peak at 7.25° 2θ (Fig. 5) is due to crystalline novobiocin acid. Its intensity is not influenced by the other peaks, which are due to tetracycline, but it is influenced by the unusually high background caused by the large percentage of amorphous suspending agent which was concentrated by the centrifugation.

A large part of the apparent novobiocin peak intensity is actually due to the background intensity. The true net peak intensity, upon which accuracy is based, is smaller. Moreover, reproducibility of the background intensity at the base of the peak is poor due to the steepness of the background slope.

Under these conditions it has been found advantageous to determine the net peak height by a different procedure in order to maintain accuracy. This procedure resulted in a close approach to linearity of response when the net peak intensity was plotted against concentration of crystalline novobiocin, for a series of prepared standard samples.[3] Using the scaler and synchronous timer circuits, the intensity P was measured at 7.25° 2θ (Fig. 4). The intensities at R_1 and R_2 were measured at 2θ values of 7.00° and 7.80°. The background B was calculated by interpolation

$$B = R_2 + \frac{7.80 - 7.25}{7.80 - 7.00}(R_1 - R_2) = R_2 + 0.688(R_1 - R_2)$$

The net peak height (P-B) was then calculated for each sample. These values were plotted against concentration of crystalline novobiocin. The results are shown in Fig. 6.

If all variables such as instrumental drift and the density of sample packing could be held constant, the background correction could be eliminated. Its use, however, permits day-to-day validity of the standard curve with good accuracy.

In the two previous examples, peak intensities were corrected by subtracting background intensities. It is just as valid to use a peak-to-background intensity ratio in place of the arithmetical difference. Moreover, the choice of position for the background measurement is not limited, an obvious advantage in instances of multiple peak overlapping. In the formation of a standard curve for the determination of mucic acid in mixtures of mucic acid and tetracycline,[3] peak-to-background ratios were used and the 2θ position for the background determination (29.00°) was necessarily some distance removed from the mucic acid peak of choice (19.48°). The resulting plot of intensity ratios *vs.* known concentration over the range to which interest was limited is shown in Fig. 7.

Use of an Internal Standard.—The most universally applicable method for quantitative diffraction involves the use of an internal standard. This method is free from all matrix effects as well as errors due to variations in sample packing density and variations in instrumental conditions. It is ideal for drug systems containing unknown mixtures, such as possible degradation products.

[3] The author is grateful to Drs. L. C. Schroeter and W. Morozowich, of The Upjohn Co., who prepared the samples for these standard curves.

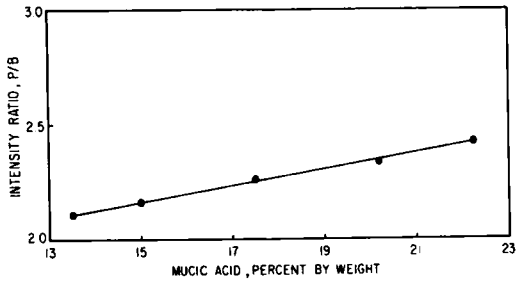

Fig. 7.—Intensity ratio, peak to background, as a function of per cent mucic acid in tetracycline.

The procedure involves examination of the diffraction patterns of the material to be assayed, and of the matrix in which it is found, and selecting a peak produced by the material which is free of interference from neighboring peaks. A suitable inert crystalline material, the internal standard, must then be found which has a peak in a clear region with respect to the system to be analyzed.

When a suitable internal standard has been found, a standard curve is prepared. Samples for the standard curve contain known but different concentrations of the compound to be analyzed and a fixed concentration of the internal standard. The proper concentration of internal standard to establish for use in all samples is one which is found to give a diffraction peak about equal in intensity to that of the material to be analyzed when the latter is present in the usually expected concentration.

The X-ray procedure then consists simply of determining the ratio of intensities of the diffraction peaks of the unknown and the internal standard, without regard for the background. The ratio is linearly proportional to the concentration of the unknown. Typical results of the use of an internal standard are shown in an example to follow.

Finding a suitable internal standard for each new system is often a problem. An ideal internal standard has several attributes: It must not have a diffraction peak which is obscured by matrix peaks, nor which will interfere with that of the material to be analyzed; the internal standard peak should be near the usable peak of the analyzed ingredient; it should be of high crystal symmetry, preferably isometric, so that strong but few diffraction peaks are produced and preferred orientation effects will be minimized by the more equant crystals; because of absorption effects, it should contain only elements of low atomic number; it should have a density not too far removed from those of the system ingredients for aid in maintaining homogeneity in mixing; and it should be chemically stable in the presence of the system. No one compound can qualify universally on all counts, but in addition to the compound used in an example to follow later, a material which has been found to have many of the above attributes is hexamethylenetetramine, one of the few organic compounds of isometric (cubic) symmetry. Another compound, beryllium acetate, has been proposed as an ideal standard since it meets most of the above specifications. Its extreme toxicity, however, would tend to disqualify it for use in pharmaceutical areas.

It is worth mentioning that in instances in which the system is of many variable components, and would therefore require an internal standard, but for which no suitable standard can be found, an alternative procedure exists. This consists of using known additions of the ingredient to be analyzed to the unknown system, plotting the peak intensity values as a function of the amount added, and extrapolating the curve. The intercept value gives a measure of the original amount of ingredient present.

Use of Integrated Diffraction Peak Areas.—Some organic compounds, when produced in successive batches over a period of time, tend to vary in the degree of crystallinity possessed at any one time. A decrease in the degree of crystallinity of a compound is accompanied by a drop in the apparent diffraction peak intensity as measured by the peak height. Such a drop in peak height, however, is accompanied by a peak broadening. It is significant that the area of the diffraction peak is relatively constant for a wide range of crystallinity. It is, therefore, sometimes of value to base a diffraction assay on peak areas rather than on peak heights. Further, the use of peak areas is advantageous when the particle size of the crystalline ingredient is very small due, again, to line broadening and a significant drop in peak height. Measurable line broadening occurs in the particle size range below 0.2 μ. Finally, the peak area method offers an advantage in being free from errors due to apparent shifts in peak maxima.

A standard curve for an assay based on the use of an internal standard and on integrated peak areas is always linear and intersects the origin.

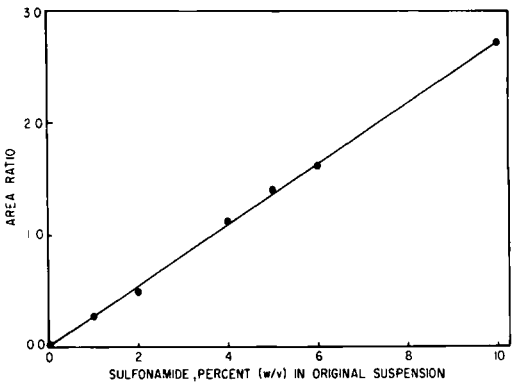

Fig. 8.—Ratio of peak areas, sulfonamide to internal standard, as a function of sulfonamide concentration.

A method for the determination of a sulfonamide in aqueous suspension illustrates the use of an internal standard, as well as integrated diffraction peak areas. Figure 8 shows a least squares plot of values for the ratios of sulfonamide peak areas to internal standard peak areas as a function of sulfonamide concentration. Following sample preparation, X-ray analysis required about 15 min. per sample. The values indicate an accuracy of $\pm 0.15\%$ of the amount present. The method is specific for the intact sulfonamide molecule in the crystalline state and, therefore, sensitive to any product degradation.

Dissolution Rate Studies I

Continuous Recording Technique for Following Rapid Reactions in Solution

By PAUL J. NIEBERGALL† and JERE E. GOYAN

An automatic recording apparatus was developed to follow the process of dissolution. Results were obtained as a recording of per cent transmittance *vs.* time. The recorder was equipped with various speed chart drive motors that permitted readings to be taken from the graph at intervals down to 0.375 sec. Several experiments were performed to demonstrate the applicability of this apparatus to the determination of dissolution rates, and constants obtained agreed well with those obtained by the usual method of removing samples with a pipet.

THE FIRST quantitative study of the dissolution process was made by Noyes and Whitney in 1897 (1). Since that time numerous workers have evaluated the effect of different variables on the dissolution rate constant. The majority of these studies have been done using a single large tablet or disk. In a few instances, particularly in attempts to obtain a measure of mixing efficiency, multiparticulate systems have been used.

Initial dissolution rates in multiparticulate systems are rapid, and previous studies have been handicapped by the lack of an accurate method for sampling the solution in the early stages of the process. Therefore, the object of this study was to develop an automatic recording technique which would furnish continuous data and obviate the need for hand sampling in studies of rapid reactions.

THEORY

Calculation of Dissolution Rate Constants.—Hixson and Crowell (2) derived an equation for the dissolution of a single particle in which the surface area was allowed to change with time, using the following form of the Noyes-Whitney equation

$$V\frac{dw}{dt} = -KS(w_s - w_o + w) \quad \text{(Eq. 1)}$$

in which w is the weight of the particle at time t, K is a rate constant, S is the surface area of the particle, w_s is the weight of solid needed to saturate the volume, V, of solvent at a given temperature, and w_o is the initial weight of the particle. Using the property of geometrically similar solids, Hixson and Crowell replaced the surface area by

$$S = kw^{2/3} \quad \text{(Eq. 2)}$$

in which k is a constant containing the shape factor and the density of the particle.[1]

The basic equation of Hixson and Crowell has been extended for use in multiparticulate systems by assuming a system of N equal-sized particles. The total surface area, A, would then be equal to $N \times S$ or

$$A = kNw^{2/3} \quad \text{(Eq. 3)}$$

The total weight, W, for a sample of N equal sized particles would be

$$W = Nw \quad \text{(Eq. 4)}$$

[1] The particles used in this study had a height, h, greater than the diameter, d, which may result in a change in the h/d ratio during the process of dissolution, and the Hixson-Crowell equations would theoretically not be applicable. However, the salicylamide crystals were followed for a total change in weight which was felt to represent a negligible change in the h/d ratio. The benzoic acid crystals were followed to a much greater change in weight. However, the Hixson-Crowell equations did yield straight lines, and it was felt that the apparent rate constants obtained from these equations would be suitable for use in a comparison study of this nature. Dissolution Rate Studies I

Continuous Recording Technique for Following Rapid Reactions in Solution

By PAUL J. NIEBERGALL† and JERE E. GOYAN

An automatic recording apparatus was developed to follow the process of dissolution. Results were obtained as a recording of per cent transmittance *vs.* time. The recorder was equipped with various speed chart drive motors that permitted readings to be taken from the graph at intervals down to 0.375 sec. Several experiments were performed to demonstrate the applicability of this apparatus to the determination of dissolution rates, and constants obtained agreed well with those obtained by the usual method of removing samples with a pipet.

THE FIRST quantitative study of the dissolution process was made by Noyes and Whitney in 1897 (1). Since that time numerous workers have evaluated the effect of different variables on the dissolution rate constant. The majority of these studies have been done using a single large tablet or disk. In a few instances, particularly in attempts to obtain a measure of mixing efficiency, multiparticulate systems have been used.

Initial dissolution rates in multiparticulate systems are rapid, and previous studies have been handicapped by the lack of an accurate method for sampling the solution in the early stages of the process. Therefore, the object of this study was to develop an automatic recording technique which would furnish continuous data and obviate the need for hand sampling in studies of rapid reactions.

THEORY

Calculation of Dissolution Rate Constants.—Hixson and Crowell (2) derived an equation for the dissolution of a single particle in which the surface area was allowed to change with time, using the following form of the Noyes-Whitney equation

$$V\frac{dw}{dt} = -KS(w_s - w_o + w) \quad \text{(Eq. 1)}$$

in which w is the weight of the particle at time t, K is a rate constant, S is the surface area of the particle, w_s is the weight of solid needed to saturate the volume, V, of solvent at a given temperature, and w_o is the initial weight of the particle. Using the property of geometrically similar solids, Hixson and Crowell replaced the surface area by

$$S = kw^{2/3} \quad \text{(Eq. 2)}$$

in which k is a constant containing the shape factor and the density of the particle.[1]

The basic equation of Hixson and Crowell has been extended for use in multiparticulate systems by assuming a system of N equal-sized particles. The total surface area, A, would then be equal to $N \times S$ or

$$A = kNw^{2/3} \quad \text{(Eq. 3)}$$

The total weight, W, for a sample of N equal sized particles would be

$$W = Nw \quad \text{(Eq. 4)}$$

[1] The particles used in this study had a height, h, greater than the diameter, d, which may result in a change in the h/d ratio during the process of dissolution, and the Hixson-Crowell equations would theoretically not be applicable. However, the salicylamide crystals were followed for a total change in weight which was felt to represent a negligible change in the h/d ratio. The benzoic acid crystals were followed to a much greater change in weight. However, the Hixson-Crowell equations did yield straight lines, and it was felt that the apparent rate constants obtained from these equations would be suitable for use in a comparison study of this nature. [See also the paper by Blumberg, *J. Phys. Chem.*, **63**, 1129(1959).]

Substitution of this into Eq. 3, with the condition that the number of particles remains constant, gives

$$A = k_1 W^{2/3} \quad \text{(Eq. 5)}$$

This result, when substituted into Eq. 1, with the weight of a single particle replaced by the total weight of N particles gives

$$V \frac{dW}{dt} = -K_1 W^{2/3} (W_s - W_o + W) \quad \text{(Eq. 6)}$$

Two sets of conditions can be utilized in order to simplify this equation. When the amount of sample used is equal to the amount needed to saturate the solution, W_s equal to W_o, the equation becomes

$$V \frac{dW}{dt} = -K_1 W^{5/3} \quad \text{(Eq. 7)}$$

which upon integration under the condition that W is equal to W_o at time zero, gives

$$W^{-2/3} - W_o^{-2/3} = K_2 t \quad \text{(Eq. 8)}$$

in which K_2 now contains V.

When the amount of solute needed to saturate a given volume of solvent is much greater than the concentration of material in solution, $C_s \gg C$, the equation becomes

$$\frac{dW}{dt} = -K_3 W^{2/3} \quad \text{(Eq. 9)}$$

in which K_3 contains V and W_s. This equation, when integrated under the condition that W is equal to W_o at time zero, gives

$$W_o^{1/3} - W^{1/3} = K_4 t \quad \text{(Eq. 10)}$$

where K_4 is equal to $K_3/3$.

EXPERIMENTAL

Apparatus.—A model 5800 Beckman energy recording adapter was attached to a Beckman model DU spectrophotometer. The adapter leads were connected to a Varian Associates model G-10 potentiometric recorder. A tube bent into a U shape was made from silica glass, 5-mm. internal diameter. This was fitted into two holes drilled into a cell-compartment cover for the spectrophotometer and the protruding ends painted with black paint. The solution could then be passed through the tube and a continuous tracing of per cent transmittance *vs.* time obtained.

The remainder of the system consisted of a 1-L. beaker equipped with four baffles, a Cenco variable-speed stirrer and a Gordon-Rupp model 1612 centrifugal pump. The width of the baffles represented 10% of the beaker diameter; they were set about 1/8 in. out from the wall and 1/8 in. up from the bottom to eliminate dead pockets. The impeller was a four-blade turbine, 2 1/2 in. in diameter.

The beaker was placed in a constant temperature water bath and the impeller centered by means of appropriately placed markings. A glass filter stick was clamped into the beaker and the open end connected with rubber tubing to one end of the U tube. The other end of the U tube was connected with rubber tubing to the pump and a tube led from the pump back to the beaker.

Assay Procedure.—In this system, the solution coming from the beaker is assayed directly without dilution. Dissolution rates in multiparticulate systems are rapid, and for materials having high absorptivities, concentrations at which large deviations from the Beer-Lambert law occur are reached rapidly. This can be circumvented in some instances by assaying at absorption minima.

A series of dilutions was made for the material to be assayed. The apparatus was assembled as described above and the recorder was balanced at 0% transmittance with the shutter of the spectrophotometer closed. The pump was started and the recorder was balanced at 100% transmittance with the solvent flowing through the system and the shutter open, thus blanking out the absorbance due to the solvent. When the 100% transmittance base line had held steady for 2 minutes, the rubber tubing was clamped shut, and the glass tube cleaned and placed into one of the dilutions. The tubing was released and the solution allowed to flow through the apparatus until a steady transmittance tracing was obtained. The rubber tubing was again clamped and the glass tube placed into the next dilution. When all of the dilutions had been recorded, pure solvent was again passed through the system. If the base line did not level off at 100% transmittance, the calibration was repeated.

The values for per cent transmittance were converted into units of absorbance and plotted in the usual manner to obtain a Beer-Lambert line. The slopes of the resulting lines were calculated using the method of least squares and were used in the usual manner to calculate concentrations. Results for benzoic acid U.S.P. and salicylamide C.P. appear in Table I.

[a] Calculated by least squares as the absorbance of a 0.001% solution.

Dissolution with Return Flow to the Beaker.—In order to determine any systematic error due to the apparatus, the rate constant for the dissolution of salicylamide in water was determined using both the apparatus and the conventional method of sampling.

The salicylamide was carefully screened through a 20-mesh sieve onto a 30-mesh sieve. The particles retained on the latter were used in the study. The solubility of the salicylamide was found to be 2.44 Gm./L. at 25°.

The dissolution apparatus was assembled as described previously, and the total volume of the

glass filter tube, rubber tubing, U tube, and pump was determined by filling the system with water. This was repeated five times with the average being 55 ml. This volume of water was added to 750 ml. of distilled water in the beaker, and the system filled by siphoning. The pump was started with the water being circulated back into the beaker.

The recorder was balanced at 0% and 100% transmittance. When the contents of the beaker had reached temperature equilibrium, the end of the rubber tubing through which the water was passing into the beaker was placed into a 100-ml. graduated cylinder. An accurately weighed sample of salicylamide was simultaneously poured into the beaker. When the volume of liquid needed to fill the system (55 ml.) had been removed, the end of the rubber tubing was again placed so the solution would be returned to the beaker keeping the volume constant at 750 ml. It was felt that by this time (15 sec.) the concentration of the solution in the beaker was great enough that the dilution due to the returning solution would be negligible. The total time for the run was 30 sec. The stirring rate was 500 r.p.m. and the flow rate 350 ml. per minute.

The amount of salicylamide used was just sufficient to saturate the 750 ml. of water; Eq. 8 was applicable. Therefore, $W^{-2/3} - W_0^{-2/3}$ was plotted against time, resulting in a straight line which is shown in Fig. 1. The positive intercept represents a lag of 1.2 sec. This lag is not a factor of circulation time since time zero was taken as being the instant before the recording pen started to move. This lag will be discussed further in a future publication. The rate constant was evaluated using the method of least squares on the data shown in Table II.

$K_1 = 1.79 \times 10^{-2}$ mg.$^{-2/3}$ sec.$^{-1}$ ml.

[a] Time zero point omitted in calculation of the rate constant due to the time lag.

Circulation time should have no effect on the rate constant since it corresponds to frequency of sampling in the hand sampling case. This was verified by running the previous experiment at two other flow rates and calculating the rate constants. The results are given in Table III.

The effect of the dilution resulting from the return of the solution to the beaker could not be determined since the solution was thoroughly mixed while passing through the pump. If it had been serious, however, a break in the line shown in Fig. 1 would have been expected at the point representing the elapsed time of 15 sec.

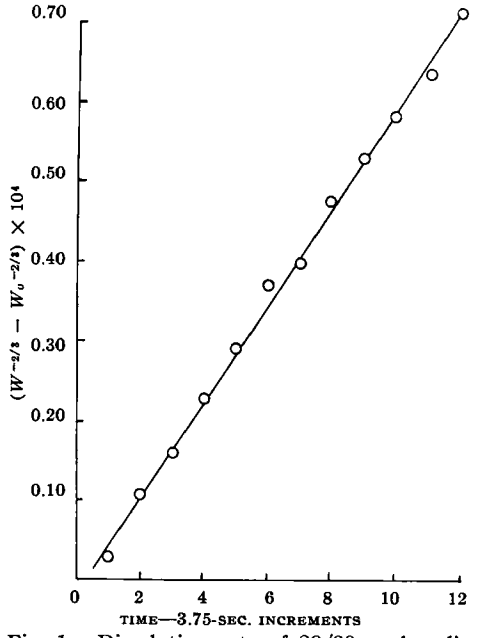

Fig. 1.—Dissolution rate of 20/30-mesh salicylamide in water at 25° using the automatic recording apparatus.

TABLE III. DISSOLUTION RATE CONSTANTS OF 20/30-MESH SALICYLAMIDE CRYSTALS WITH VARYING CIRCULATION TIMES

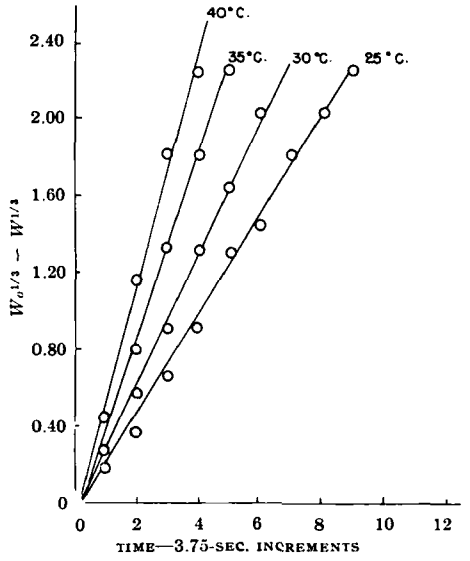

Fig. 3.—Dissolution rate of benzoic acid in water at various temperatures, using the automatic recording apparatus.

using the method described by Davies (3). The value of t was 0.945 with 16 degrees of freedom. The value of t necessary for the difference to be significant at the 95% level is 2.12. Therefore, there is no difference between the two values. It should also be noted that the standard deviation about the regression line was twice as large in the hand sampling case.

Dissolution Rate as a Function of Temperature.—One other experiment was performed to demonstrate the usefulness of the automatic recording apparatus. Reagent grade benzoic acid was screened to collect the 80/100-mesh fraction. The dissolution rate was obtained at four different temperatures using the automatic recording apparatus. In this study, however, the conditions met the requirements for the use of Eq. 10, C_s being much greater than C. The results are plotted in Fig. 3, and the rate constant K_4 was evaluated from the data shown in Table V.

[a] Time zero point omitted in calculation of the rate constants due to the time lag.

This constant contains W_s, the effect of which was canceled by dividing K_4 by the W_s values taken from Edwards' work (4), resulting in a new constant, K_5.

Values for log K_5 were plotted against $1/T$ as shown in Fig. 4. The energy of activation calculated from the data shown in Table VI was 5210 cal./mole. Edwards (4) reported a value of 5162 cal./mole for the dissolution of benzoic acid in water, using a method of sampling similar to the one used in the above study.

DISCUSSION

The good agreement between the dissolution rate constant obtained using the automatic recording technique and the conventional method of withdrawing samples with a pipet indicate that the recording technique is valid for following rapid reactions in solution.

Standard deviations were obtained on the

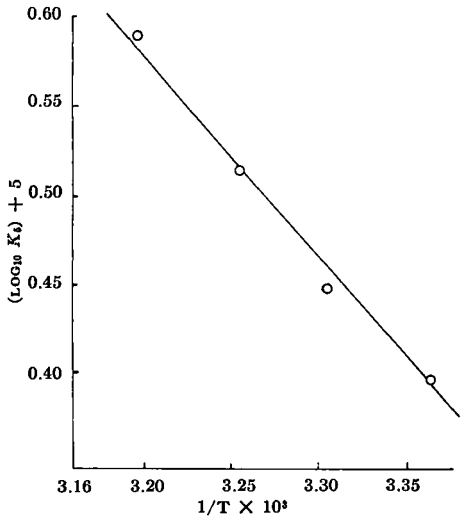

Fig. 4.—Arrhenius plot of the rate constants obtained for the dissolution of benzoic acid in water using the automatic recording apparatus.

values for the energy of dissolution as reported by Edwards' and those obtained in this study. The data from Edwards' paper give a standard deviation of 750 cal./mole, while the results obtained using the recording apparatus gave a standard deviation of 200 cal./mole. Thus, the apparatus appears to be particularly useful for working at elevated temperatures since it eliminates the problem of temperature change during the collection and subsequent handling of samples.

TABLE VI.—RATE CONSTANTS AS A FUNCTION OF TEMPERATURE FOR THE DISSOLUTION OF BENZOIC ACID IN WATER

Temp., °K.	K_4	Weight Needed for Saturation[a]	$K_5 \times 10^5$
298	0.07227	2565	2.818
303	0.09890	3075	3.216
308	0.13410	3623	3.701
313	0.18271	4163	4.389

[a] Taken from Edwards' data (4), and given as mg. needed to saturate 750 ml. of water.

One further advantage for the apparatus is that it can be cleaned and assembled for further use within 15 minutes after the completion of a run. This is a vast saving in time over that generally needed to clean volumetric glassware used in a kinetic study. This apparatus is therefore suggested for use in the study of rapid reactions in which one chemical species can be assayed spectrophotometrically with no interference from other species in solution.

Investigation of the Mechanism of Urea-Induced Hemolysis

By DALE E. WURSTER and PAUL H. SHAPIRO†

The hemolysis of mammalian erythrocytes in concentrated urea solutions and in isotonic sodium chloride and dextrose solutions containing thirty per cent urea was investigated. Increased concentrations of sodium chloride, dextrose, and other osmotic agents inhibited the urea-induced hemolysis. The existence of urea–dextrose complexes in water, methanol, and methanol–water systems containing high dextrose concentrations were demonstrated.

DURING the last decade, Javid and Settlage, *et al.*, developed a remarkably effective method for reducing elevated intracranial and intraocular pressures. The method involves the intravenous administration of 30 per cent urea solutions (1, 2). In preliminary work with animals they observed that the administration of concentrated solutions caused a hemolysis which was detectable by the resulting hemoglobinuria. This would be expected to happen since the erythrocyte is permeable to urea, and thus the urea solution can exert no osmotic pressure. However, it was found that hemolysis also occurred when the urea was dissolved in an isotonic solution of sodium chloride or dextrose. In experimenting with the addition of various con-

centrations and combinations of salts and sugars it was found that 10 per cent invert sugar was a suitable agent for preventing this hemolysis.

The purpose of this investigation was to obtain additional information on the mechanism of the urea-induced hemolysis. Equally important was a desire to study the effects produced by sugars in these systems and to determine in what manner they inhibited hemolysis. Since beef erythrocytes were used in this study, a quantitative transfer of the experimental data to a system containing human erythrocytes is not possible; however, it is reasonable to expect that the data would apply, qualitatively.

Hemolysis can be caused by two general methods, the lowering of the osmotic pressure of the medium in which the cells are suspended and by the direct action of a substance on the cell membrane. There are other means of causing hemolysis, but these methods are the most important.

In the early stages of the study it was suggested that urea might cause hemolysis by the latter method. Since the erythrocyte is permeable to urea, hemolysis occurs when erythrocytes are suspended in a solution containing any concentration of urea in water. Since hemolysis also occurred in a system containing 0.9 per cent sodium chloride plus 30 per cent urea, it seemed possible that the urea was attacking the cell membrane. Urea has previously been reported to complex with proteins and long chain fatty acids (3) and these substances are, of course, present in the cell membrane (4). Therefore, the possibility that such a complex was causing the disruption of the cell membrane was strongly considered. It was also possible that the sugars were adsorbed on the cell membrane and thereby protecting it from the urea or else forming a complex with the urea and thereby blocking its hemolytic action on the cell membrane. Several investigators have noted the inhibition of hemolysis by nonelectrolytes (5–9).

As the study progressed, however, there was reason to believe that urea caused hemolysis not by exerting any specific action on the cell membrane, but by the general action of a penetrating molecule. The study was then approached from this viewpoint.

EXPERIMENTAL

Source of the Blood.—The blood used in this study was obtained from beef cattle immediately after killing. The blood was collected in 125-ml. glass-stoppered Erlenmeyer flasks into which had previously been placed 0.25 ml. of heparin sodium injection U.S.P. After mixing, the flasks were immediately refrigerated.

Hemolysis Conditions.—The 100-ml. volumetric flasks containing 49 ml. of the particular solution were placed in a shaking apparatus in a 30° constant temperature bath. After allowing sufficient time for the solutions to reach 30°, 1 ml. of the whole blood was pipeted into each flask. The shaker was started and the flasks were maintained in the bath for 1 hour. Then, about 15 ml. of each suspension was poured into 15-ml. centrifuge tubes which were immediately centrifuged at 2000–2500 r.p.m. for about 15 minutes in a Servall type SP/X angle centrifuge.

Determination of Hemoglobin.—The analytical method for the determination of hemoglobin was a modification of that described by Finholt (10). Ten milliliters of the supernatant liquid from the centrifuge tubes was removed by pipet and placed in 25-ml. volumetric flasks. To these solutions was added 1 ml. of a 0.2% potassium cyanide–1% potassium ferricyanide solution. After waiting 15 minutes for the cyanomethemoglobin to form, the absorbance of the solutions was read at 545 mμ on a Cary model 11 recording spectrophotometer using 1-cm. silica cells.

Calculation of Per Cent Hemolysis.—The hemoglobin was assayed for the relative, not the absolute concentration. In each experiment one sample was included which contained 2% blood in water or in 30% urea, depending upon whether or not the other samples contained urea. The absorbance of this sample was taken as the 100% hemolysis reading. The per cent hemolysis of the samples was determined by dividing the absorbance of the sample by the 100% hemolysis reading.

Urea-Dextrose Complex in Methanol.—In the case of 100% methanol as the solvent, 2 Gm. of dextrose was placed in a series of 30-ml. vials along with varying amounts of urea and 20 ml. of methanol. The vials were placed in a shaker in a 30° constant temperature bath. After three days, 10 ml. was withdrawn from each vial and placed in tared containers. After the solvent was evaporated, the weight of dextrose was determined by subtracting the appropriate weight of urea. When 80 and 90% methanol were used as the solvent, 10 Gm. of dextrose was added and a 2-ml. aliquot was withdrawn.

Urea-Dextrose Complex in Water.—Varying amounts of urea were weighed into 4-dram vials. Into each vial was placed 3 Gm. of dextrose and 5 ml. of a saturated solution of dextrose. The vials were maintained with agitation in a 25° constant temperature bath for at least one week.

Upon removal from the bath, the entire contents of each vial was filtered through a 15-M sintered glass filter into a 100-ml. volumetric flask. Then the interior of the vial and the contents of the filter were washed repeatedly with 95% ethanol until the 100-ml. volumetric flask was filled. Three milliliters of this solution was diluted to 1,000 ml. with water. Two milliliters of this dilution was assayed for dextrose. In this case, the dextrose was determined according to the method of Nelson (11) and Somogyi's modification (12).

RESULTS AND DISCUSSION

Effect of 30 Per Cent Urea Plus Varying Sodium Chloride Concentration.—Since the erythrocyte is

TABLE I.—PER CENT HEMOLYSIS WITH 30% UREA AND VARYING SODIUM CHLORIDE CONCENTRATION

permeable to urea, if urea is the only dissolved substance in the suspension then hemolysis will occur regardless of the urea concentration. It was previously thought, however, that this permeability would not affect the cell adversely as long as the urea was dissolved in an isotonic solution of sodium chloride. Since hemolysis did occur under these conditions, it appeared possible that urea caused the hemolysis by attacking the cell membrane. However, it was found that when beef erythrocytes were suspended in medium containing 30% urea plus higher concentrations of sodium chloride, the per cent of hemolysis decreased with an increase in the sodium chloride concentration. The results of one such experiment are shown in Table I. Several of the earlier experiments were repeated on five consecutive days to determine what effects storing the blood in a refrigerator would have on the results.

On each day, the degree of hemolysis decreased as the sodium chloride concentration increased. As the sodium chloride concentration increased, increasing volumes of water necessarily left the erythrocyte. When the suspension medium contained 30% urea, a large volume of urea molecules diffused into the erythrocyte. When the sodium chloride concentration was low, the cell membrane was not able to accommodate the large increase in cellular content and it finally broke. Presumably, if the sodium chloride concentration was elevated sufficiently, a large enough quantity of water would leave the cell to enable the cell membrane to accommodate a large volume of urea without breaking.

For some of the intermediate concentrations of sodium chloride, the per cent hemolysis decreased daily for four days. This may be due to the constant leakage of potassium from the erythrocytes, as reported by Davson and Danielli (14). It is possible that the increased degree of hemolysis on the fifth day was due to some deterioration in the cell membrane.

Effect of Varying the Urea Concentration at a Constant Sodium Chloride Concentration.—The critical volume of the erythrocyte is about 1.6 times greater than the normal volume (15). If urea caused hemolysis as was described, there should be a minimum concentration below which no hemolysis should occur at any one concentration of sodium chloride. Table II shows the results of an experiment in which the urea concentration was varied, but the sodium chloride concentration was maintained constant at 0.9%.

The results indicated that when beef erythrocytes were suspended in 0.9% sodium chloride, the cells could accommodate approximately 20% urea before the critical volume was reached. As the concentration of urea was increased above 20 per cent, the degree of hemolysis increased rapidly.

Effect of Methylurea.—If urea caused hemolysis by the bulk of its molecules increasing the volume of the cell to the breaking point, then methylurea, having a greater molecular volume, should show a somewhat more pronounced effect. An experiment in which equal molar concentrations of the two compounds were compared showed that this was the case. The compilation of results from several experiments are given in Table III.

TABLE III.—A COMPARISON OF THE PER CENT HEMOLYSIS WITH UREA AND METHYLUREA

Molar Concentration	Per Cent Hemolysis	
	Urea	Methylurea
0.25	9	50
0.292	5	11
0.33	9	17
0.375	23	34
0.392	33	89
0.409	54	100
0.417	75	100

Effects of Dextrose.—It has been shown that urea-induced hemolysis can be inhibited by increasing the sodium chloride concentration in the medium. It was assumed that this effect could be produced by adding an osmotic equivalent of any nonpenetrating compound, but this assumption was not completely correct. Dextrose proved to be a far more effective agent in preventing hemolysis. Table IV shows a comparison of equal osmotic concentration of sodium chloride and dextrose.

It is interesting to note that the presence of urea affected the results only quantitatively. It was mentioned previously that erythrocytes are reported to have increased osmotic resistance when

TABLE IV.—COMPARISON OF HEMOLYSIS OF SODIUM CHLORIDE AND DEXTROSE WITH AND WITHOUT UREA

Concentration of Osmotic Agent		Per Cent Hemolysis	
		30% Urea	No Urea
Isotonic concn. 0.6	0.54% Sodium Chloride	100	71
	3.03% Dextrose	34	5
	0.585% Sodium Chloride	100	41
Isotonic concn. 0.65

	3.54% Dextrose	18	0

placed in a solution of a nonelectrolyte. These results with and without urea further indicate the similarity between osmotic hemolysis and urea-induced hemolysis.

The observation that erythrocytes behave abnormally when placed in a solution of a nonelectrolyte implies that it is the absence of electrolyte that causes the difference. To investigate this further, solutions were prepared which contained combinations of sodium chloride and dextrose such that the combination of the two compounds yielded a solution that was 0.6 isotonic. No urea was included. These results are given in Table V.

TABLE V.—PER CENT HEMOLYSIS WITH VARYING COMBINATIONS OF SODIUM CHLORIDE AND DEXTROSE

Concn. Sodium Chloride, %	Concn. Dextrose, %	Hemolysis, %
0.27	2.02	30
0.18	2.52	18
0.09	3.03	11
0	3.54	2

The increase in sodium chloride concentration from zero to 0.18 per cent caused a marked response even though this was only a 0.03 molar solution. This suggested that the dextrose did not affect the cell membrane directly, but acted only by allowing electrolyte to be excluded from the medium.

Effects of Other Sugars.—Dextrose was the primary sugar studied in this investigation. The results in Table VI show that hypotonic lactose and sucrose solutions cause an increased osmotic resistance similar to the effect produced by dextrose.

TABLE VI.—PER CENT HEMOLYSIS IN HYPOTONIC LACTOSE AND SUCROSE SOLUTIONS

Concentration of Osmotic Agent		Per Cent Hemolysis
Isotonic concn. 0.6	5.85% Lactose	7
	5.55% Sucrose	6
	6.34% Lactose	3
Isotonic concn. 0.65	6.01% Sucrose	3
	6.82% Lactose	2
Isotonic concn. 0.7	6.48% Sucrose	2

Blood in isotonic fructose (5.05%) plus 30% urea showed only 6% hemolysis. Thus, it is evident that all of these sugars gave very similar results. It is probable that all four sugars act simply by allowing electrolyte to be excluded from the medium.

Other Effects of Sugars.—On several occasions when blood was suspended in an isotonic solution of dextrose, lactose, sucrose, or inositol, within 15 minutes the red cells aggregated into large masses which immediately settled to the bottom of the flask. Upon the addition of very small quantities of one of several salts such as sodium chloride, sodium bromide, or potassium bromide, it was immediately possible to resuspend the red cells to form an apparently normal suspension. The addition of sufficient sodium chloride to give a concentration of only 0.18% was sufficient to bring about this reversal.

Effects of Other Electrolytes.—The only electrolyte reported on extensively thus far has been sodium chloride. Therefore, an attempt was made to compare the other electrolytes with sodium chloride to determine whether the erythrocyte reacted similarly to electrolytes in general. Table VII is a compilation of the results of several experiments on several different samples of blood.

The results showed that whenever the anion was divalent or trivalent, there was little or no hemolysis. There was a danger, of course, that in working with such a wide variety of salts in unbuffered solutions, that changes in the pH of the medium would become important. However, the results suggested that perhaps it was not the presence of

TABLE VII.—PER CENT HEMOLYSIS WITH HYPOTONIC CONCENTRATION OF VARIOUS SALTS

electrolyte *per se* which determined whether or not the erythrocyte behaved normally, but that the anion was the important moiety.

Urea-Dextrose Complex.—It was mentioned previously that a urea-dextrose complex could be a contributing factor to the ability of dextrose to inhibit urea-induced hemolysis. Since the erythrocyte is impermeable to dextrose, such a complex would serve to reduce the effective concentration of urea. The problem was to demonstrate the existence of such a complex. The small size of both molecules combined with their very high water solubility and low solubility in solvents made it very difficult to detect a complex. Because of the small molecular size, it was not possible to use a semipermeable membrane to follow the complex formation. The high water solubility also made it very difficult to measure changes in concentration in two immiscible solvents as the complex formed. However, it was possible to demonstrate the existence of urea-dextrose complex in water, methanol, and water-methanol mixtures by using the solubility method. Unfortunately, it was necessary to use saturated solutions of dextrose to do so. It would have been much more desirable to use the same concentrations of dextrose that were used in the hemolysis studies.

In the case where the complex was studied in water, a further complication was provided by the large variation in the volume of the various samples caused by the amount of urea included. This large fluctuation in volume made it extremely difficult to determine the concentrations of urea and dextrose in the solutions. Since it was necessary to remove the vials from the bath for the dextrose determination, the complex in water was thermostated at 25° instead of 30°. The former temperature being closer to room temperature made it less likely that a temperature change would disturb the complex.

Figure 1 shows that as urea was added to a saturated solution of dextrose in water, the quantity of dextrose in solution increased. Since the precise concentrations of urea and dextrose were difficult to determine, it was not possible to calculate the equilibrium constant of the complex. The plateau of the curve was used to calculate the stoichiometric ratio of the complex (16). The ratio of urea to dextrose was probably in the neighborhood of

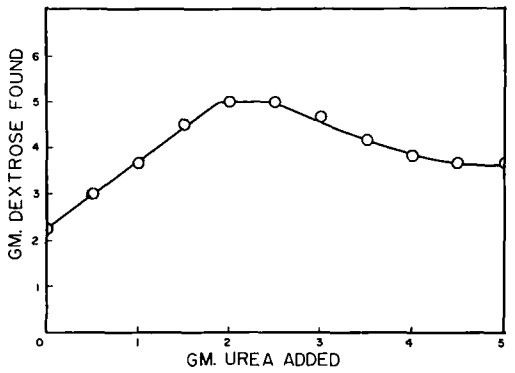

Fig. 1.—Phase diagram of dextrose–urea system in water at 25°.

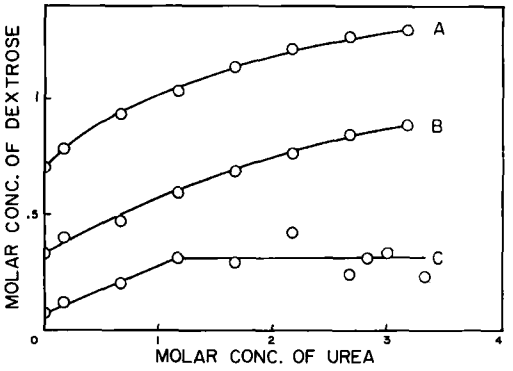

Fig. 2.—Phase diagrams of dextrose–urea systems in methanol–water and methanol at 30°. (Curve *A* is 80% methanol, curve *B* is 90% methanol, and curve *C* is 100% methanol.)

3:1 to 4:1. The uncertainty arose from the difficulty in ascertaining the exact length of the plateau.

The low solubility of dextrose in methanol made it easier to demonstrate the existence of a complex in this solvent. Figure 2 shows the results that were obtained with three concentrations of methanol. In curve A, 80% methanol was used as the solvent; curve B represents 90%; and pure methanol was employed as the solvent in curve C.

Thus, there was little doubt that under certain conditions a urea-dextrose complex did indeed exist. However, because of the aforementioned solubility problems, it was not possible to demonstrate the existence of this complex at low dextrose concentrations in water. If urea did complex with dextrose at low dextrose concentrations this would become a very important factor in the inhibition of urea-induced hemolysis.

SUMMARY

Various aspects of urea-induced hemolysis have been investigated. It was shown that high concentrations of urea cause hemolysis in the presence of isotonic concentrations of other compounds by a sufficient volume of urea molecules diffusing into the cell to cause it to rupture. Therefore, a sufficiently large concentration of any nonpenetrating compound in the medium will inhibit urea-induced hemolysis.

Experimental evidence was obtained which indicates that it is necessary for electrolyte to be present in the medium in order to maintain a normal suspension of the erythrocytes. There is also evidence that the anion may be the important ion of the electrolyte in maintaining the integrity of the cell.

The existence of a urea-dextrose complex has been demonstrated at high dextrose concentrations. If this complex forms at low dextrose concentrations it would be an important factor in the ability of dextrose to inhibit urea-induced hemolysis.

Softening and Liquefaction Temperature of Suppositories

By IVO SETNIKAR and SERGIO FANTELLI

A method is described for testing the softening and liquefaction temperature of suppositories. The data obtained yield the maximum environmental temperature at which suppositories retain sufficient firmness for handling and for ordinary storage. The physical properties of 44 bases were investigated by this new method. The melting point was determined by the open capillary method. Of 27 fatty bases, only 8 present properties which are as satisfactory as or better than those of theobroma oil. Most of the 17 water-soluble bases investigated have very satisfactory firmness, but their melting point is above body temperature so that, for liquefaction, they must dissolve in water drawn from the rectal mucosa.

RECTAL suppositories, if well formulated, should melt, soften, or dissolve when introduced into the rectum and yet retain their firmness and shape in ordinary storage conditions.

Melting, softening, or dissolving may be tested in an apparatus which reproduces the physical conditions of the rectum (1). This apparatus, however, does not give indications as to the firmness of the suppositories. The following characteristics may be examined in order to test firmness.

Melting temperature.—Melting temperature may be determined (*a*) by the open capillary method for fatty substances (*cf.* U.S.P. XVI, p. 926, class II) or by the sealed capillary method (2). Only suppository bases can be tested and the results are influenced by the technique used in the preparation of the capillary (2). (*b*) The suppository may be put in an aqueous environment whose temperature is raised until the suppository melts (3–6). In these conditions only strictly water-insoluble suppositories can be tested. Suppositories containing water-soluble substances soften or dissolve in the aqueous environment irrespective of temperature. (*c*) The temperature of the air surrounding the suppository may be gradually raised until melting. This method was followed by Erbe (7) who used an apparatus described by Bogs (8).

Hardness—Malangeau (3) molded a cylinder with a diameter of 9 mm. of the same composition of the suppository and determined the temperature at which the cylinder collapsed under a weight of 500 Gm. (8 Gm./-mm.^{2}). Münzel (9) and other authors (2, 10, 11) used the penetrometric method described in U.S.P. XIV, p. 693. Büchi and Oesch (12) stated that a suppository, at a temperature of 22°, should not be deformed by a weight of 500 Gm.

The first two methods cannot be used directly on suppositories while the method of Büchi and Oesch can, though it gives only limited information on the maximal temperature at which a suppository still shows sufficient mechanical stability. We describe here a method for determining the softening and melting temperatures directly on suppositories.

Softening and Liquefaction Temperature of Suppositories

By IVO SETNIKAR and SERGIO FANTELLI

A method is described for testing the softening and liquefaction temperature of suppositories. The data obtained yield the maximum environmental temperature at which suppositories retain sufficient firmness for handling and for ordinary storage. The physical properties of 44 bases were investigated by this new method. The melting point was determined by the open capillary method. Of 27 fatty bases, only 8 present properties which are as satisfactory as or better than those of theobroma oil. Most of the 17 water-soluble bases investigated have very satisfactory firmness, but their melting point is above body temperature so that, for liquefaction, they must dissolve in water drawn from the rectal mucosa.

RECTAL suppositories, if well formulated, should melt, soften, or dissolve when introduced into the rectum and yet retain their firmness and shape in ordinary storage conditions.

Melting, softening, or dissolving may be tested in an apparatus which reproduces the physical conditions of the rectum (1). This apparatus, however, does not give indications as to the firmness of the suppositories. The following characteristics may be examined in order to test firmness.

Melting temperature.—Melting temperature may be determined (*a*) by the open capillary method for fatty substances (*cf.* U.S.P. XVI, p. 926, class II) or by the sealed capillary method (2). Only suppository bases can be tested and the results are influenced by the technique used in the preparation of the capillary (2). (*b*) The suppository may be put in an aqueous environment whose temperature is raised until the suppository melts (3–6). In these conditions only strictly water-insoluble suppositories can be tested. Suppositories containing water-soluble substances soften or dissolve in the aqueous environment irrespective of temperature. (*c*) The temperature of the air surrounding the suppository may be gradually raised until melting. This method was followed by Erbe (7) who used an apparatus described by Bogs (8).

Hardness—Malangeau (3) molded a cylinder with a diameter of 9 mm. of the same composition of the suppository and determined the temperature at which the cylinder collapsed under a weight of 500 Gm. (8 Gm./-mm.^{2}). Münzel (9) and other authors (2, 10, 11) used the penetrometric method described in U.S.P. XIV, p. 693. Büchi and Oesch (12) stated that a suppository, at a temperature of 22°, should not be deformed by a weight of 500 Gm.

The first two methods cannot be used directly on suppositories while the method of Büchi and Oesch can, though it gives only limited information on the maximal temperature at which a suppository still shows sufficient mechanical stability. We describe here a method for determining the softening and melting temperatures directly on suppositories.

Received March 24, 1962, from Recordati S.p.A., Research Division, Milano, Italy.
Accepted for publication May 11, 1962.

METHODS

The apparatus (Fig. 1) consists of a 200-mm. long glass tube with an internal diameter 1–3 mm. larger than the maximal diameter of the suppository to be tested. The tube, in the middle part, has a constriction with an internal diameter of 3 mm. This constriction supports the suppository. The tube is surrounded by a glass mantle fitted with two connections through which water circulates. The temperature of the circulating water can be read on a thermometer.

The suppository is introduced into the upper part of the tube as shown in Fig. 1. Then a 120-mm. long glass rod, which has a diameter 2 mm. smaller than the internal diameter of the tube, is placed on the suppository. A short thick-walled rubber tube is slipped over the glass rod in such a way that, when the rod rests on the suppository, there is a distance of 14 mm. between the lower end of the rubber and the upper end of the glass tube. The rubber supports a lead cylinder which moves freely on the glass rod. The lead cylinder and glass rod with rubber have a weight of 500 Gm. when the test is performed on suppositories of a diameter of 9–10 mm. For thinner suppositories, the weight should be about 7 Gm./mm.^{2}. When the suppository collapses, the lead cyclinder sinks 5 mm., then it is stopped by a support which prevents any further sinking of the lead. We define the temperature at which this happens as the softening temperature (*ST*).

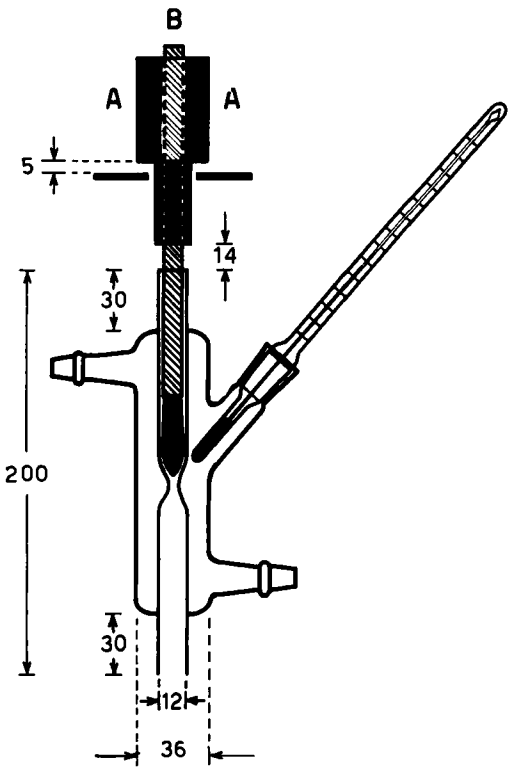

Fig. 1.—Apparatus described in the text for the determination of the softening and liquefaction temperatures. *A*, lead cylinder weighing 460 Gm.; *B*, glass rod, over which a rubber tube is fitted, supporting the lead cylinder. The glass rod and rubber tube have a weight of 40 Gm. The glass rod rests on the suppository. When the suppository collapses the glass rod sinks. After sinking 5 mm. the lead cylinder is supported by a rest and on the suppository there remains only the weight of the glass rod. All measures are in mm. The internal diameter of the glass tube may differ according to the diameter of the suppository. For suppositories of 9.5-mm. diameter, as those used in our experiments, an internal diameter of the tube of 12 mm. is satisfactory.

An alternative method consists in putting on the glass rod, and therefore on the suppository, increasing weights, *e.g.*, lead disks of 100 Gm. In this way the collapsing weight (CW_t) of a suppository may be determined at a given temperature.

When the suppository has collapsed so that it no longer supports the lead cylinder or disks, it bears the weight of the glass rod (30–40 Gm.) only. As the temperature of the water jacket rises, the suppository liquefies, and the glass rod can then sink for another 9 mm. until the rubber rests on the glass tube. We define the temperature at which this happens as the liquefaction temperature (*LT*).

The glass rod is very useful because, as pointed out by Reznek (6) and by Krowczynski (4), an objective measurement of the "melting" or rather of the liquefaction, can be performed only when the suppository is subjected to a light mechanical stress. In our opinion the term "liquefaction temperature" is more proper than that of "melting temperature," since very often suppositories contain drugs which do not melt together with the base and the base, too, may be a mixture of substances with different melting points.

When the suppository has liquefied it flows through the 3-mm. constriction of the glass tube of the apparatus. This usually happens at the liquefaction temperature as defined above. Only for very viscous mixtures is the flow temperature (*FT*) 0.5–1.0° higher than the *LT*.

As described in the result section, we found it convenient to raise the temperature in the apparatus at the rate of 0.1°/min. A simple method of doing this automatically is to drive the thermoregulation knob of a Tecam-Tempunit thermostat water pump with a synchronous motor at the rate of 0.1 angular degrees per minute. Furthermore the sinking of the lead weight or of the glass rod can switch off the current to the motor by means of a microswitch and thus the temperature remains constant when the *ST* or the *LT* is reached.

In order to verify the results obtained, the melting temperature of the bases was determined also by the capillary method for class II substances described in U.S.P. XVI, p. 926 (capillary melting temperature—*CMT*). For water-soluble bases, instead of a water bath, a liquid petrolatum bath was used. In both cases the temperature was raised at the rate of 0.5°/-min.

The melting temperature was controlled by putting the suppositories in a small metallic basket with 5-mm. meshes and keeping these suppositories in an incubator in which the temperature was raised 0.5° every 4 hours. We defined the incubator liquefaction temperature (*ILT*) as the temperature at which at least $^2/_3$ of the suppository had passed through the meshes of the basket.

RESULTS

A very important factor for correct use of the apparatus is the rate at which the temperature is raised in the water jacket. If this rate is too high, the temperature of the suppository remains below that of the water jacket and the temperature read on the thermometer at the moment of softening or of liquefying of the suppository does not correspond to the temperature within the suppository. It is therefore important to define the time necessary to reach thermal equilibrium between the suppository and the water jacket of the apparatus. For this determination we adopted the procedure previously described (1), *i.e.*, we inserted a thermocouple in the middle of a suppository of the shape represented in Fig. 2. The suppository so prepared was then kept for several hours at a temperature of 18 ± 0.2° and then put in the apparatus with the circulating water at 2–3° below the liquefaction temperature of the suppository.

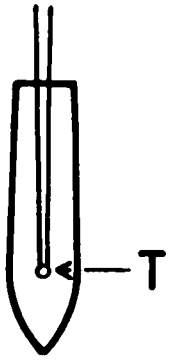

Fig. 2.—Shape and actual size of the suppositories used in our experiments. The position of the thermocouple (T) in the suppository is also shown.

The temperatures measured in the suppository were subjected to a quantitative treatment as previously described. The thermal equilibrium curves obtained on suppositories made with different bases (Fig. 3) show that a 90% thermal equilibrium is reached in 8.5 min. by Carbowax 6000 suppositories, in 12.0 min. by Imhausen H suppositories, in 15.5 min. by theobroma oil suppositories, in 21.5 min. by Neosuppostal suppositories, and in 33.5 min. by Imhausen E suppositories.

On the basis of these data, several procedures of raising the temperature in the apparatus were tried and the following was found convenient. The suppository was put in the apparatus kept at 28.0 ± 0.1° and left at this temperature for 1 hour. Then the temperature was raised at the rate of 0.1°/min. until the ST and the LT were reached. Table I shows the temperature read on the thermometer and the differences between this temperature and the one measured in the middle of the suppository. This difference is not more than 2.0° and, at liquefaction temperature, it becomes very small, probably because heat transmission is improved by the melted part of the suppository which fills the space between the glass tube and the suppository.

Table II gives the capillary melting temperature (CMT), the incubator liquefaction temperature (ILT), the liquefaction temperature (LT), the softening temperature (ST), and the collapsing weight at 25° (CW_{25}) observed in 44 bases or suppositories made with these bases and tested 1–6 months after their preparation.

Table III gives the CMT, the LT, and the ST determined during a 4-month observation on some suppository bases. The same data determined on Carbowax 4000 and on Tween 61 did not show significant changes.

DISCUSSION

Table II shows that there is usually a good agreement between the ILT and the LT, whereas the CMT may be up to 6° lower than the ILT. Since the actual storage conditions of the suppositories are certainly better reproduced by the incubator than by the capillary, the CMT must be considered critically, especially when it is determined on fatty bases and found close to 37°. Indeed, fatty base suppositories liquefy in the rectum only when their liquefaction temperature is below 37° (1). An error of 2–6° in the estimation of the melting temperature means that in some cases a suppository base, which really liquefies above 37° and therefore does not liquefy in the rectum may be accepted as

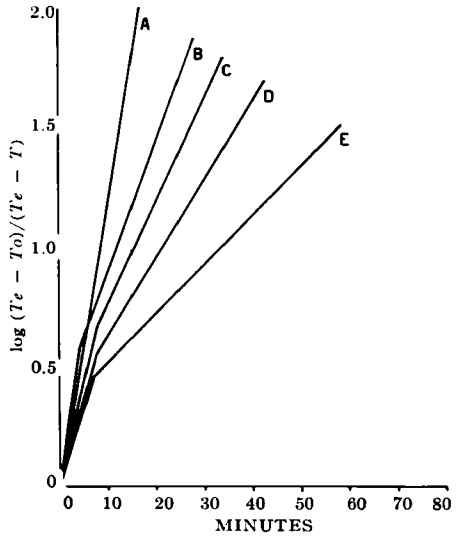

Fig. 3.—Thermal equilibrium curves determined on suppositories obtained with different bases. *Ordinate:* log $(Te - To)/(Te - T)$ (Te is the temperature measured in the suppository at equilibrium, To is the temperature measured at time zero, *i.e.*, at the beginning of the experiment, T is the temperature of the suppository measured at the time corresponding to the abscissa). *Abscissa:* time in minutes. The inclination of the curves expresses the thermal equilibrium rate constant k of the equation: $dT/dt = k(Te - T)$ where t is the time in minutes. A 90% thermal equilibrium is reached in correspondence with $\log (Te - To)/(Te - T) = 1$. A is the curve obtained with a Carbowax 6000 suppository ($k = 0.118$); B, an Imhausen H suppository, ($k = 0.055$); C, a theobroma oil suppository ($k = 0.044$); D, a Neosuppostal suppository ($k = 0.033$); E, an Imhausen E suppository ($k = 0.021$),

satisfactory on the basis of a *CMT* found below 37°. The capillary method has the further disadvantage that some formulations for suppositories, like those containing a large amount of insoluble drugs (*e.g.*, 0.5 Gm. aminophylline in theobroma oil suppositories), are difficult to test since the mixture can not be homogeneously introduced into the capillary. Finally, by this method, it is not possible to determine the melting temperature directly on suppositories, as is necessary, for example, after stability tests, *etc.* For the liquefaction temperature determination, the incubator method and the apparatus described in this paper seems therefore more suitable.

Before choosing the 500-Gm. weight for the determination of the softening temperature, suppositories made with mixtures of theobroma and almond oils were submitted for examination to pharmacists and physicians. The suppositories considered sufficiently firm for handling, storage, and for introduction into the rectum supported a weight between 500 and 700 Gm. (7–10 Gm./mm.^{2}). Since Büchi and Oesch (12) and Malangeau (3) proposed that suppositories of about the same diameter should not be deformed by a weight of 500 Gm., we finally adopted this weight for the determination of the *ST* on our suppositories.

The determination of the *ST* is particularly important for suppositories which must be handled and stored in warm or hot climates. An estimation of the *ST* through the collapsing weight at a given temperature (CW_t), as proposed by Büchi and Oesch (12), is possible only if the two values are very well correlated. The regression calculated on the data obtained on 27 fatty suppository bases is $ST = (24.1 \pm 0.5) + (2.4 \pm 0.33)\, CW_{25}$, from which *ST* can be estimated from the CW_{25} value with an error which may be as much as ±6.7° ($P = 0.05$).

The regression calculated on the data obtained on the 17 water-soluble bases is $ST = (25.88 \pm 1.51) + (5.53 \pm 0.90)\, CW_{25}$, from which *ST* can be estimated with an error which may be as much as ±13.3° ($P = 0.05$). In both cases the correlation of *ST* to CW_{25} is evidently so poor that the determination of the *ST* cannot be replaced by that of the CW_t.

Some comment on the physical qualities of the bases investigated is also relevant. Of the fatty bases, theobroma oil may still be considered as a standard, although it was criticized for its rather low melting temperature and for the comparatively low consistency. On the basis of the *LT* and the *ST* reported in Table II, however, it must be concluded that, of the fatty bases, only Estarinum A, BB, and Pi, Imhausen H, OG, and W, Suppocire A, and Vi-Tin 136, present properties which are as satisfactory as, or better than, those of theobroma oil. However, of the bases with an *LT* higher than 37°, many can be considered for correcting the *LT* of some particular formulations with an *LT* below 35°.

The water-soluble bases, with their high *ST* and *LT*, seem ideally suited for hot climates. But it must be emphasized that these bases liquefy only by a process of dehydrating the rectal mucosa, which is antiphysiological, sometimes irritant and painful, and very often so slow that the drugs vehicled are liberated after only some considerable time (1).

A disadvantage of theobroma oil is its unstable forms, with low melting temperature, which is particularly evident after a heating above 37–40° (13, 14). A consequence of this is that the suppositories remain liquid after pouring in the molds unless these are kept at fairly low temperature. Another consequence is that for the experimenter, it is impossible to know the final physical characteristics of the suppositories for some time after preparation.

In order to investigate the importance of the unstable forms from the analytical point of view, we performed the experiments summarized in Table III. The results show that not only theobroma oil, but also other fatty bases as Dehydag III, Estarinum A and BB, Imhausen H and W, and Suppocire A, reach a stable form not after a few days, as usually stated in the literature, but after 10–30 days. Theobroma oil heated beyond the transition temperature, however, does not reach a stable form even after 4 months. The changes in physical properties are particularly evident in the light of the *CMT* and

CONCLUSIONS

As already pointed out by Caldwell (13) the definitions of the suppositories reported in the pharmacopeias, in which it is stated that they should soften, melt, or dissolve at body temperature, are of little assistance unless the method of determining these characteristics is given. In point of fact, different methods give quite different results and sometimes suppositories may be accepted as satisfactory on the basis of the capillary melting temperature for example, even when they do not melt, soften, or dissolve in the rectal environment. Besides this, there should be an accepted method for finding out whether a suppository is sufficiently firm to be introduced in the rectum, handled and stored at ordinary room temperatures or in warm climates.

The method proposed in this paper supplies this information and, for suppositories with fatty bases, shows also whether the liquefaction temperature is sufficiently low to permit liberation of the contained drugs after introduction in the rectum. As a matter of fact all the fatty

Proposed Method of Assay for Diaphene

By SOBHI A. SOLIMAN and LOYD E. HARRIS

A rapid and convenient differential spectrophotometric assay is proposed for the assay of Diaphene in liquid soaps and hand creams.

DIAPHENE[1] is a mixture of 5,4′-dibromosalicylanilide and 3,5,4′-tribromosalicylanilide, and is used in toilet detergent formulations. It is reported to possess an unusually long-lasting germicidal effect.

Methods described in the literature for the determination of phenolic antiseptics in soaps employ colorimetric or spectrophotometric techniques. The method of Gottlieb and Marsh (1), depending on color formation by the reaction of a phenol with 4-aminoantipyrine in the presence of potassium ferricyanide as an oxidizing agent, was reported to give unreliable results since the color fades rapidly. Ettinger, *et al.* (2), in an attempt to stabilize the color, concentrated the reaction products by extraction with chloroform. This modification, however, does not stabilize the color produced to any degree of accuracy.

The colorimetric method of Johnson and Savidge (3) depends upon the measurement of the

color produced by the coupling of the phenol with 4-aminophenazone in the presence of an alkaline oxidizing agent. The method was reported to give unsatisfactory results with hexachlorophene and dichlorophene since the darkening characteristic of these substances in alkaline medium considerably changes the orange color.

The method of Larson (4), depending on the color determination of the phenol-ferric chloride salt, involves precipitation of the soap with barium bromide. The method was discussed by Childs and Parks (5) who found that the fleeting color produced in this method made it difficult to obtain reproducible results.

The rapid spectrophotometric method of Lord, *et al.* (6), is applied directly to the soap sample by dissolving it in 0.1 *N* potassium hydroxide solution and measuring its absorbance. Measurements were taken at three different wavelengths in the region of the peak of absorption. A correction for irrelevant absorption due to the soap base is made by application of the Morton-Stubbs three-point geometrical correction.

The spectrophotometric procedure of Clements and Newburger (7) is designed for the determination of hexachlorophene in all types of cosmetic formulations and involves several extractions which would appear to be unnecessary for the determination of its content in a liquid soap.

A differential rapid spectrophotometric method was developed by Childs and Parks (5) for the determination of hexachlorophene in the presence of liquid soap. The advantages of this method lie in the fact that the extraction of the phenolic antiseptic from the soap is not necessary; also, it does not depend upon color determination. The method depends on a substance of equal concentration in both the solute and solvent cells of the spectrophotometer when an absorption is obtained that is essentially the same as a cell blank curve. It appeared that such a technique might eliminate the error caused by absorption of the soap base by allowing the instrument to cancel out the irrelevant absorption.

Alkali increases the intensity of absorption of phenols by converting them from the molecular to the ion or salt form, and shifts their absorption peaks to longer wavelengths. Childs and Parks (5) showed that by determining the absorption of hexachlorophene in alkaline media in the solute cell against its absorption in the acid media in the solvent cell, an absorption curve could be obtained which is unique for the phenol and without interference from the soap base. This technique of determining the absorbance of the phenolic compound at an alkaline pH in the solute cell *versus* its same concentration at an acid pH in the solvent cell is known as the differential method.

The differential spectrophotometric procedure has been modified by Matuszak, *et al.* (8), in order to be applicable for the determination of bithionol in liquid soap.

Van Der Pol (9) modified the differential method of Childs and Parks (5) so that it may be used for a wide variety of preparations.

The ion exchange resin method of Suffis and Dean (10) for assaying chlorinated phenolic compounds in soaps depends on separating the antiseptic from the soap and then assaying spectrophotometrically. The separation is based upon the fact that chlorinated phenolics are stronger acids than nonchlorinated phenolics and carboxylic acids. Therefore, they may be separated by their differing adsorptive properties on a strongly basic anionic exchange resin. An empirical calibration must be made using soap preparations of known chlorophenolic content. Apparently resin hold-up prevents a quantitative elution, but a partial and reproducible recovery of chlorophenol is obtained.

The ion exchange resin method was later modified (11) to be applicable for the determination of Diaphene in soap.

EXPERIMENTAL

Apparatus and Reagents.—Beckman DU quartz spectrophotometer with matched 1.0-cm. silica cells; methanol, absolute, reagent grade; 90% methanol, prepared by mixing 100 ml. of distilled water with sufficient anhydrous methanol to make 1000 ml.; hydrochloric acid, approximately 0.1 *N* in distilled water; sodium hydroxide, approximately 0.1 *N* in distilled water.

Development of a Standard Diaphene Spectrophotometric Graph.—Differential absorption spectra of Diaphene (3 mg./100 ml.) in 90% methanol were prepared by measuring the differential absorbance (pH 3 *vs.* pH 8) at various wavelengths. The absorption peak was at 280 mμ. Ninety per cent methanolic solutions of Diaphene (not more than 5 mg./100 ml.) followed Beer's law at this wavelength. The differential absorption spectrum of Diaphene in the presence of soap exhibits a flat peak at 280, 281, and 282 mμ.

Diaphene[2] was assayed at 280 mμ, using the standard absorption graph, in the presence of soap.

A 0.3 *N* acetic acid solution in 90% methanol, was prepared by dissolving 18 Gm. glacial acetic acid in 90% methanol to produce 1000 ml. The solution was then adjusted to pH 3 with 0.1 *N* hydrochloric acid using the Beckman Zeromatic pH meter.

Ninty per cent methanol was adjusted to pH 8 with 0.1 *N* sodium hydroxide using the Beckman Zeromatic pH meter.

Proposed Spectrophotometric Assay for Diaphene.—The differential absorbance index of

[2] ASC-4 brand, marketed by Stecker Chemicals, Inc.

Diaphene in the presence of soap was determined in absorbance units per mg. per ml. as follows: dissolve 5 ml. of the soap base in 90% methanol to make exactly 100 ml.; dissolve a 0.1000-Gm. sample of Diaphene in absolute methanol to make exactly 100 ml.; and dilute a 50-ml. aliquot of this solution to exactly 100 ml. with 90% methanol (solution *A*).

Place 5 ml. of the soap base solution in each of four 100-ml. beakers. To each of the four beakers add 2.0, 3.0, 4.0, and 5.0 ml. of solution *A*. Then to each of the beakers add 20 ml. of 90% methanol and sufficient 0.1 *N* hydrochloric acid to bring the solution to pH 3 on the Beckman Zeromatic pH meter. Wash the electrodes with pH 3 acetic acid–methanol solution. Transfer the beaker contents quantitatively to a dry 50-ml. G. S. volumetric flask, adjust to volume with the acetic acid–methanol solution, and mix thoroughly. This gives a series of solutions containing 2.0, 3.0, 4.0, and 5.0 mg./100 ml. of Diaphene, respectively, at pH 3.

Prepare a second series of solutions of the same concentration as above at pH 8 as follows: Place 5 ml. of the soap base solution in each of four 100-ml. beakers, to each of which add 2.0, 3.0, 4.0, and 5.0 ml. of solution *A*, then 20 ml. of 90% methanol, adjust to pH 8 on a Beckman Zeromatic pH meter using 0.1 *N* sodium hydroxide or 0.1 *N* hydrochloric acid, in distilled water, as required. Wash the electrodes with 90% methanol at pH 8. Transfer the beaker contents quantitatively to a dry 50-ml. G.-S. volumetric flask, adjust to volume with 90% methanol at pH 8 and mix thoroughly. This gives a series of solutions containing 2.0, 3.0, 4.0, and 5.0 mg./100 ml. of Diaphene, respectively, at pH 8.

Arrange the two series of solutions in pairs of the same concentration. Place the pH 3 member of each pair in the solvent cell of the spectrophotometer and the pH 8 member in the solute cell.

Divide the observed absorbance by the number of mg. of Diaphene per ml. of solution to get the absorbance index, I.

The average absorbance index at 280 mμ and slit width of 1.62 mm., as determined by the differential method, should have a value of 10 absorbance units per mg. per ml. in the presence of soap.

TABLE I.—ABSORBANCE INDEX OF DIAPHENE IN 90% METHANOL CONTAINING SOAP SHAMPOO BASE pH 3 *vs.* pH 8[a]

Diaphene, mg. per 100 ml.	Absorbance		Absorbance Index	Av. Absorbance Index
2	0.204	0.204	10.20	
3	0.300	0.300	10.00	
4	0.398	0.400	9.97	
5	0.490	0.495	9.86	10.00

[a] Wavelength, 280 mμ; slit width, 1.62 mm.

Assay Procedure for Diaphene in Liquid Soap.—Dissolve 5 ml. of the soap sample to be assayed in 90% methanol to make exactly 100 ml. (solution *A*). The amount taken could be decreased or increased, but the final dilution should not contain more than 5 mg. Diaphene/100 ml.

Place 5 ml. of solution *A* in a 100-ml. beaker, add 20-ml. of 90% methanol and sufficient 0.1 *N* hydrochloric acid to bring the solution to pH 3 using the Beckman Zeromatic pH meter. Wash the electrodes with pH 3 acetic acid–methanol solution. Transfer the contents of the beaker quantitatively to a dry 50-ml. G.-S. volumetric flask, adjust to volume with acetic acid–methanol solution and mix thoroughly.

Place another 5 ml. of solution *A* in a 100-ml. beaker, add 20 ml. of 90% methanol, adjust to pH 8 on a Beckman Zeromatic pH meter. Wash the electrodes with 90% methanol at pH 8. Transfer the beaker contents quantitatively to a dry 50-ml. G.-S. volumetric flask, adjust to volume with 90% methanol at pH 8 and mix thoroughly.

Measure the absorbance at 280 mμ and slit width 1.62 mm. by placing the pH 3 solution in the solvent cell of the Beckman DU spectrophotometer, and the pH 8 solution in the solute cell.

The per cent of Diaphene was calculated using the following formula:

$$\text{per cent of Diaphene} = \frac{A \times 50 \times 100}{I \times V \times W \times 100}$$

where A = differential absorbance measured; I = differential absorbance index (10); V = volume of solution A in 50 ml. of the assayed solution; W = volume of the sample in ml. × 1000 or weight in mg.

Soap samples to which known amounts of Diaphene had been added were assayed by this method.

Results are given in Table II. The method was also used for the assay of Diaphene in hand cream[3] with results in the same Table.

TABLE II.—DIAPHENE ASSAY IN SOAPS AND CREAMS

	% Diaphene Found
Soap shampoo base plus 0.40% w/v added Diaphene[a]	0.408
Soap shampoo base plus 0.60% w/v added Diaphene	0.602
Soap shampoo base plus 0.80% w/v added Diaphene	0.790
Peck's antiseptic soap base plus 0.70% w/v added Diaphene	0.700
G. S. 40% soap base plus 0.50% w/v added Diaphene	0.502
Hand cream labeled to contain 0.05% w/v Diaphene	0.052
Hand cream labeled to contain 0.05% plus 0.20% added Diaphene	0.253

[a] Diaphene added to the 5-ml. aliquot of the final dilution of the sample.

The Effect of Light and Time on Diaphene.—The effect of sunlight, short ultraviolet, and long ultraviolet light on Diaphene has been studied. The absorbance of 2.5 mg./100 ml. of Diaphene in 90% methanol, containing G. S. 40% soap, at pH 8 was found to decrease gradually on exposure to sunlight for 10 minutes. After that period, the absorbance of the same solution did not show an appreciable change when the solution was exposed to sunlight for a total period of three hours. The solution assumed a distinct yellow color during the 10-minute exposure.

When an acidic solution at pH 3 containing the

[3] In Cuticura Laboratories.

same amount of Diaphene and soap was similarly treated, no significant change in absorbance or color took place.

On exposing a similar solution at pH 8 in a 1.00-cm. silica cell to short ultraviolet light (using a short-wave ultraviolet lamp, model SL 2537, with a short-wave ultraviolet filter, Model SL 2537[4]) a considerable decrease in absorbance took place in a period of 40 minutes after which a gradual change occurred through a total period of three hours. When a pH 3 solution was exposed to the short ultraviolet light, no significant change in absorbance took place in the same period of time.

A long-wave ultraviolet lamp, model SL 3660, with a long-wave ultraviolet filter, model SL 3660[4], was used to determine the effect of long ultraviolet light on Diaphene solutions of pH 8 and pH 3. Absorbances were determined in the same manner (using 90% methanol at pH 8 and pH 3, respectively, in the solvent cell). It was found that long ultraviolet light had more or less the same effect as sunlight on both solutions of Diaphene. No apparent color change took place in either solution after exposure to short or long ultraviolet light, as observed in the 1.0-cm. silica cell. It could be recommended that Diaphene containing preparations that are alkaline should be protected from sunlight as well as ultraviolet light.

DISCUSSION

The spectrophotometric method proposed by Childs and Parks (5) for assaying hexachlorophene in the presence of soap when used for Diaphene gave results that were lower than expected. When liquid soap bases were employed in constructing the standard curve, results were found to be more accurate.

The proposed method eliminates the necessity of the establishment of a standard graph. The method also does not necessitate the presence of the same soap sample free from Diaphene. The proposed spectrophotometric assay for Diaphene was used for assaying liquid soaps and hand creams with accuracy.

[4] Mineralight, marketed by Fisher Scientific Co.

SUMMARY

A rapid, convenient, and accurate differential method for the assay of Diaphene in liquid soaps and hand creams has been proposed. The method is based on the differential spectrophotometric assay for hexachlorophene in liquid soaps developed by Childs and Parks (5).

This proposed method does not necessitate the establishment of a standard graph as was necessary in the Childs and Parks procedure. The method also does not require the same soap base free from Diaphene.

The optical density of Diaphene in solutions at pH 8 is reduced by sunlight and ultraviolet light.

Use of 3-Azabicyclo[3.2.2]nonane in the Mannich Reaction II. Secondary γ-Amino Alcohols

By C. DEWITT BLANTON, Jr., and W. LEWIS NOBLES

The syntheses of a group of secondary γ-amino alcohols by reduction of the corresponding Mannich base with sodium borohydride are described. These alcohols are to be screened for possible pharmacodynamic activity.

IN THE FIRST paper of this series (1), a number of substituted β-amino ketones were synthesized for pharmacological evaluation employing the Mannich reaction and 3-azabicyclo[3.2.2]-nonane as the amine moiety. Previously, Denton (2) and his associates had similarly prepared certain amino ketones and converted them to the corresponding secondary and tertiary alcohols. In many cases, the conversion to the alcohol had a significant effect on the physiological activity. Therefore, it was considered that the transformation of the ketones previously reported by us (1), might possibly have a similar effect. In

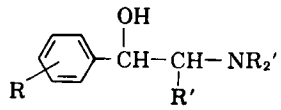
addition, the γ-amino alcohols are generally more stable than the corresponding ketones.

An examination of the ring system utilized in these studies will indicate a relationship to the complex heterocyclic systems which occur in certain natural products, such as cocaine and atropine. Thus, in every instance, caged structures are present in the molecule. Furthermore, it may be noted that the ring systems in cocaine may be regarded as a condensed piperidine-pyrollidine nucleus whereas the present amine component, 3-azabicyclo[3.2.2]nonane may be considered to be a cyclohexane ring condensed with a hexamethyleneimine moiety. Similarly, this system may be compared with many derivatives of the solanaceous alkaloids which also possess the condensed piperidine-pyrollidine nucleus.

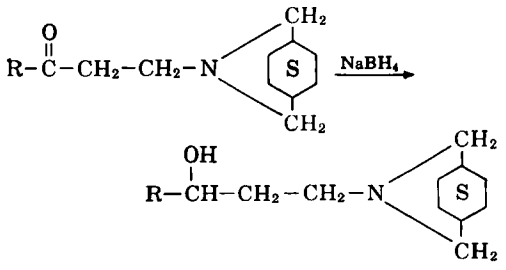
Lutz and co-workers (3) have reported the preparation and screening of 184 amino alcohols against avian malaria. The general structure of the secondary alcohols is represented as



These compounds included examples of 50 variations in the benzene nucleus and over 60 variations in the N,N-dialkyl groups on the nitrogen. Although most of these amino alcohols proved to be inactive, special mention should be made of the α-dichlorophenyl-β-dioctylaminoethanols which proved to be equal to or better than quinine in tests against avian malaria.

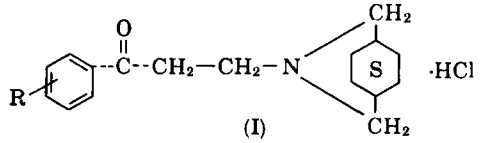
Denton and his associates (4) reported the preparation of a secondary alcohol, 3-(1-piperidyl)-1,2-diphenyl-1-propanol hydrochloride, and noted that it ranked higher in antispasmodic activity than did the seven tertiary alcohols with which it was compared. 3-Dimethylaminophenyl-1-propanol hydrochloride was prepared by Denton and co-workers (5) and was found to rank low in antispasmodic activity when compared with 15 tertiary alcohols.

We have prepared a series of secondary alcohols from the substituted β-amino ketones previously reported (1) according to the reaction

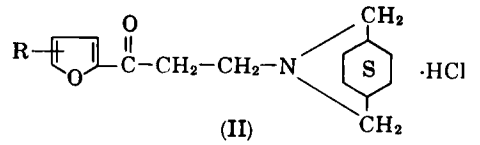


Our results are reported in Tables I and II.

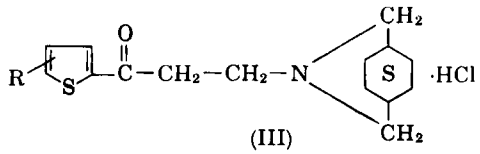
During the course of this work, compounds having the general structure of types I and III were converted to alcohols without difficulty. Under these conditions, treatment of compounds of type II did not give the expected secondary alcohol.



(I)



(II)



(III)

It is possible as Elderfield (6) reports that the furan ring is more easily reduced than the benzene ring to give the tetrahydrofurfuryl alcohol together with smaller amounts of the products of reductive ring opening: pentanediols-1,2, and -1,5, and pentanol-1.

PHARMACOLOGICAL RESULTS

Preliminary screening data (7) indicate a weak central nervous system activity for compound 16 (Table I). This activity was characterized by hypotonia, salivation, and fore-limb clonus. Compounds 1 and 2 of Table I and compound 1 of Table II failed to produce any overt activity when administered orally in doses of 300 mg./Kg. As other results become available, it is anticipated that they will be reported as an integral part of this overall study.

EXPERIMENTAL

The preparation of the γ-amino secondary alcohols was patterned after the method of Chaikin and Brown (8) as employed by Rogers and Nobles (9). These secondary alcohols were all prepared by one of the following two procedures. Basically, as will be evident from an inspection of the actual procedures, these methods differ only in regard to the manner in which the final product is isolated.

Procedure A.—The γ-amino secondary alcohols were prepared by the general procedure of suspending 0.05 mole of the β-amino ketone hydrochloride in 100 ml. of distilled water and making the solution basic to litmus with 10% sodium hydroxide solution. The free Mannich base was then collected. If this was a solid, it could be filtered off. If the free base was a liquid, it could be collected by extraction with ether. The Mannich base was dissolved in 100 ml. of methanol. This alcoholic solution was placed in a 300-ml. three-neck flask fitted with a dropping

[a] All secondary γ-amino alcohols were recrystallized from an ethanol-water or ethanol-acetone solution. [b] Melting points are uncorrected. [c] Carbon, hydrogen, and nitrogen analyses are through the courtesy of Dr. Paul Craig of Smith Kline & French Laboratories, Philadelphia, Pa.

funnel, thermometer, reflux condenser, and magnetic stirrer. To this was added 0.1 mole of sodium borohydride dissolved in 50 ml. of methanol. The addition was conducted at such a rate as to maintain the temperature between 20–40°. After the evolution of hydrogen had subsided somewhat, the methanol was removed under water-pump vacuum. The residue was suspended in 100 ml. of distilled water and extracted with three 100-ml. portions of ether. The ether was then removed under diminished pressure and the solid material recrystallized to analytical purity from an ethanol-water solution.

Procedure B.—This method was utilized only when the secondary alcohol obtained upon removal of the ether was an oil. The liquid alcohols obtained by Procedure A were dissolved in 100 ml. of anhydrous ether. This ether solution was treated with anhydrous hydrogen chloride and the ether decanted from the sticky mass which adhered to the sides of the flask. A few milliliters of acetone was added and shortly a white solid appeared. This solid material was recrystallized to analytical purity from an ethanol-acetone solution.

Compound number 19 from Table I was prepared from the corresponding ketonic Mannich base. This Mannich base was prepared from 1-acetonaphthone in a 31% yield according to procedures previously indicated (1). After recrystallization to analytical purity from an ethanol-acetone solution, a m.p. of 219–221° was observed.

Kinetics of Rapid Aggregation in Suspensions

Comparison of Experiments with the Smoluchowski Theory

By W. I. HIGUCHI, R. OKADA, G. A. STELTER, and A. P. LEMBERGER

Rates of aggregation of initially monodispersed 1.83-μ polystyrene latex particles in various electrolyte solutions at different electrolyte concentrations have been studied. The experiments involved the determination of the distribution of singlets, doublets, and triplets as a function of time with the Coulter Counter. In order to permit a comparison of the data with theory, theoretical calculations of the "bimolecular" rate constants were carried out for both the diffusion-controlled mechanism and the surface-controlled mechanism. These rate constants were employed to construct theoretical curves which were used to evaluate the data. Maximum rates observed approached the Smoluchowski rate to within about a factor of two. With the purified samples the rates were found to be relatively independent of electrolyte concentration and type. Rates observed with the unpurified samples in salt solutions were substantially lower than those for the purified suspension even at high salt concentrations.

MOST STUDIES (1–4) of aggregation in solid-liquid or liquid-liquid dispersed systems have involved methods based on observation of the sedimentation behavior. While in many instances the desired information may be or may best be obtained by these techniques, it is generally difficult to quantitate aggregation, *per se*, from such experiments.

With the introduction of a novel instrument, the Coulter Counter,[1] it has become possible to conveniently study aggregation without the complicating effects of sedimentation. Recently (5) the reversible aggregation in oil-in-water emulsions was studied with the aid of this instrument. Considerable insight into the problem was gained from this investigation.

In the present communication, results of a study of the kinetics of rapid aggregation of initially monodispersed polystyrene latex suspension particles are reported. The purposes of this work were to evaluate the validity of the existing theories as they apply to rapid aggrega-

tion of particles in the micron size range and to lay the groundwork for future studies on the role of additives in influencing the aggregation behavior in dispersed systems.

THEORY

We shall concern ourselves with the problem of the rapid irreversible aggregation of an initially monodispersed suspension. It is assumed that stirring is not present and that the effects of sedimentation are negligible. The reactions which must be considered are given in the scheme in Table I. Here the A_1, A_2, *etc.*, refer to the singlet, doublet, *etc.*, and the k's are the rate constants for the reactions. The differential equations for this set of bimolecular reactions may be written

$$\frac{d(A_1)}{dt} = -(A_1)[k_{11}(A_1) + k_{12}(A_2) + k_{13}(A_3) + k_{14}(A_4) + \ldots]$$

$$\frac{d(A_2)}{dt} = {}^1/_2 k_{11}(A_1)^2 - (A_2)[k_{12}(A_1) + k_{22}(A_2) + k_{23}(A_3) + k_{24}(A_4) + \ldots]$$

$$\frac{d(A_3)}{dt} = k_{12}(A_1)(A_2) - (A_3)[k_{13}(A_3) + k_{23}(A_2) + k_{33}(A_3) + k_{34}(A_4) + \ldots]$$

$$\frac{d(A_4)}{dt} = k_{13}(A_1)(A_3) + k_{22}(A_2)^2 - (A_4)[k_{14}(A_1) + k_{24}(A_2) + k_{34}(A_3) + k_{44}(A_4) + k_{45}(A_5) + \ldots]$$

$$\vdots$$

etc. (Eq. 1)

In these equations (A_1), (A_2), *etc.*, are the concentrations of A_1, A_2, *etc.*, in number of particles per ml. and t is time in seconds. These equations cannot be analytically solved for the general case. However, for the special case in which a steady-state[2] diffusion is assumed and in which all of the rate constants, k's, are equal, the solutions may be easily obtained (6). Since, as we shall see later, the rate constants may not differ too greatly for the aggregate pairs under consideration in our experiments, the special case of all k's being equal is a useful approximation.

For cases in which the rate constants are different, the equations may be solved numerically by the usual methods (8). There are two of these cases which are of particular interest to our problem. One of these is the diffusion-controlled (no particle-particle repulsion) case and the other is the surface-barrier-controlled case. In the diffusion-controlled process, the rate is determined by how rapidly the aggregates can diffuse field-free to each other by Brownian motion. Thus this rate is the theoretical maximum rate.[3] The other case of interest is that in which aggregation occurs much more slowly. This may come about if a stabilizing agent acting at the particle surface is able to reduce the effectiveness of particle-particle sticking during collisions between the particles. In this instance the rate will be determined principally by not how quickly the particles can diffuse to each other, but by how rapidly they can overcome the barrier between them after they have nearly gotten together.

The rate constants, k's, for the surface-controlled process should be proportional to the interfacial contact area between the aggregates. For the diffusion-controlled rate constants this is not the case (6, 7). This difference is the reason for the difference in the aggregate size dependence upon the rate constants between the two processes.

TABLE II.—THEORETICAL RATE CONSTANTS FOR DIFFUSION-CONTROLLED AND SURFACE-CONTROLLED PROCESSES

Rate Constant	D. C.	S. C.
k_{11}	k_{11}	k_{11}
k_{12}	1.03 k_{11}	1.3 k_{11}
k_{13}	1.07 k_{11}	1.5 k_{11}
k_{14}	1.13 k_{11}	1.7 k_{11}
k_{15}	1.16 k_{11}	1.8 k_{11}
k_{22}	1.00 k_{11}	1.5 k_{11}
k_{23}	1.01 k_{11}	1.7 k_{11}
k_{24}	1.03 k_{11}	1.9 k_{11}
k_{33}	1.00 k_{11}	1.8 k_{11}
k_{34}	1.0 k_{11}	2.0 k_{11}
k_{44}	1.0 k_{11}	2.2 k_{11}

The results of the theoretical calculations[4] of the aggregate size dependence upon the rate constants for these two cases are given in Table II. For these calculations of the rate constants in the diffusion controlled case we started with Smoluchowski's relation (6, 7)

$$k_{ij} = 4\pi(D_i + D_j)(R_i + R_j) \quad \text{(Eq. 2)}$$

[2] See Overbeek, Reference 7, for the validity criterion for this assumption. This steady-state is not to be confused with "Steady-state" concentration of aggregates.

[3] Actually if the theory includes the effects of the attractive long-range London dispersion forces, calculations would predict greater (by the order of about 1 to 10%) maximum rates for particles in the micron size range. See Reference 9 for a discussion of these forces.

[4] Unpublished work. Because of the approximate nature of these calculations, only the outline of the method of computation is presented here.

where D_i and D_j are the diffusion coefficients for the i and j aggregates, and R_i and R_j are the respective "collision" radii. The sum, $D_i + D_j$, is the effective diffusion coefficient for the pair, and the sum, $R_i + R_j$, is the interparticle distance (center-to-center) at particle-particle contact. While Eq. 2 is well suited for calculations involving spheres only, it cannot be rigorously applied where nonspheres are involved. In the latter cases approximations become necessary. Thus the singlet-singlet rate constant, k_{11}, was directly obtained by combining Eq. 2 with the Stokes-Einstein relation for a sphere

$$D_1 = \frac{k_o T}{6\pi\eta a} \qquad \text{(Eq. 3)}$$

where k_o is Boltzmann's constant, T is the absolute temperature, η is the viscosity, and a is the radius of the primary particle. Thus

$$k_{11} = \frac{8k_o T}{3\eta} \qquad \text{(Eq. 4)}$$

for the diffusion-controlled case. For calculations involving doublets, the translational diffusion coefficient for the doublet was calculated with the assumption that the doublet is a prolate spheroid with an axial ratio of two with the minor axis equal to the diameter of the singlet sphere. Then the equations of Perrin (10) were used to estimate the D value assuming random orientation of the doublet. The effective collision radius, R, for the doublet was obtained using this spheroid model and finding the radius of the equivalent volume[5] sphere. For triplets and quadruplets and D and R values were estimated in the same manner but the various arrangements of the primary particles were weighted. For aggregates made up of more than four particles it was assumed that the aggregates were spheres with hydrodynamic radii equal to the radii of spheres of equal mass but with a porosity of 0.5. In all of these calculations the effects of rotational diffusion were neglected.

The rate constant calculations for the surface-controlled case involved primarily the estimation of the available areas of contact between the two aggregates involved. We may write

$$k_{ij} = (\text{Total Available Contact Area})(D_i + D_j)\,\alpha \qquad \text{(Eq. 5)}$$

where α is a constant for a given system in which the local curvature of the contacting surfaces are the same.[6] The factor includes the sticking probability determined by the barrier. As before the D's in Eq. 5 are the diffusion coefficient of the aggregates. These were calculated in the same manner as those for the diffusion-controlled process. The total contacting area for the singlet-singlet is simply $16\pi a^2$. Therefore

$$k_{11} = 32\pi a^2 D_1 \alpha \qquad \text{(Eq. 6)}$$

With Eq. 3 this becomes

$$k_{11} = \frac{16 k_o T a \alpha}{3\eta} \qquad \text{(Eq. 7)}$$

for the surface-controlled case. The contact areas for the multiplets were estimated by calculating the surface generated by the center of one aggregate around the other with aggregate-aggregate contact always present. Equivalent volume sphere approximations based on the spheroidal model were used as in the diffusion-controlled case for the calculations involving doublets and triplets. The larger aggregates were assumed as before to be spheres of equal mass with a porosity of 0.5. Again rotational diffusion of the aggregates was ignored.

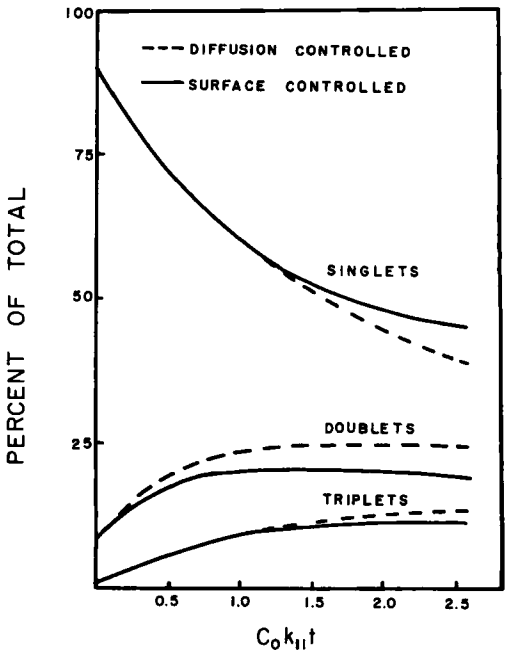

Fig. 1.—Theoretical curves for the per cent of various species as a function of time in a system composed of uniform-size primary particles undergoing irreversible aggregation at zero shear and zero sedimentation.

In Fig. 1 the results of the numerical integration of Eq. 1 employing the k values in Table II are presented. Where necessary the rate constants given in Table II were supplemented with k's involving larger (than four) aggregates calculated by the methods outlined above. For the calculations over the range of $C_o k_{11} t$ given in Fig. 1, only the rate constants involving small aggregates were of major importance. The particular boundary conditions selected for the integrations were at $t = o$

$$\begin{aligned}
\%\ \text{singlets} &= \frac{100\,(A_1)}{(A_T)} = 90 \\
\%\ \text{doublets} &= \frac{100\,(A_2)}{(A_T)} = 8 \qquad \text{(Eq. 8)} \\
\%\ \text{triplets} &= \frac{100\,(A_3)}{(A_T)} = 1 \\
\%\ \text{larger aggregates} &= \frac{100 \sum_4^\infty (A_i)}{(A_T)} = 1
\end{aligned}$$

where the total particle number concentration is

[5] This equivalent volume sphere calculation compares well with that employing rigorous equations obtained from electrostatic theory (11) with the spheroid model.

[6] This is generally expected for aggregates composed of uniform size spherical primary particles.

$$(A_T) = \sum_{i=1}^{\infty} (A_i) \text{ at any } t$$

and

$$C_o = (A_T) \text{ at } t = 0$$

This set of conditions was chosen because it approximately conforms to most of the experiments which will be discussed later.

It can be seen from Fig. 1 that according to theory the dependence of the number distribution of aggregate sizes upon $C_o k_{11} t$ does not differ too greatly for the two processes over the range considered. As expected, the initial portions of the two curves are identical. The singlet curve for the surface-controlled case tends to level off more rapidly than that for the diffusion-controlled case at large times. Also the doublet and triplet curves for the surface-controlled case do not reach as high as those for the diffusion-controlled case.

When data conform to the plots in Fig. 1, it is simply a matter of matching the data curve to the theoretical curves. Then the k_{11} may be determined directly if C_o is known. The experimental k_{11} values may be compared then with Eq. 4 to see whether the system obeys the Smoluchowski theory or, if not, to see how much stabilization (retardation of aggregation) is present.

Because of the near constancy of the k values for the diffusion-controlled case (see Table II), equating all of the k's to k_{11} results in a good approximation for this case at small times. As already mentioned, analytical solutions to Eq. 1 exist (6, 7) for this situation. If at time = 0 there are 100% singlets present, then for later times this approximation gives

$$\% \text{ singlets} = \frac{100}{1 + (1/2) C_o k_{11} t}$$

$$\% \text{ doublets} = \frac{50\, k_{11} C_o t}{[1 + (1/2) C_o k_{11} t]^2} \quad \text{(Eq. 9)}$$

$$\% \text{ triplets} = \frac{100\, [(1/2)\, k_{11} C_o t]^2}{[1 + (1/2)\, k_{11} C_o t]^3}$$

Plots of these equations are essentially identical with those for the diffusion-controlled case given in Fig. 1. The simplicity of Eq. 9 makes them useful when curves of the type given in Fig. 1 are not available.

EXPERIMENTAL

General Considerations.—While it is generally conceded (6, 7) that the Smoluchowski theory explains the data fairly well for the limiting coagulation rates of sols in the 0.01 to 0.1-μ size range, there appears to have been no examination of the applicability of the theory to particles in the micron-size range. Because particle sizes in most pharmaceutical suspensions range mainly in the micron region, mass-wise, a basic understanding of suspension aggregation behavior in this size region is important. To this end, the questions of whether and when the Smoluchowski theory applies are foremost and essential.

The system selected for this study was the suspension of monodispersed polystyrene latex particles[7] of 1.83-μ diameter. For this system the resolution of the Coulter Counter is sufficiently great as to permit the classification of the aggregates into singlets, doublets, triplets, and sometimes even quadruplets. This is illustrated for a typical case of a partially aggregated system in Fig. 2. The differences between the plateau values on the curve give the relative amounts of the different species. Thus it was possible to conveniently follow the time change in population of the various aggregates in the suspension.

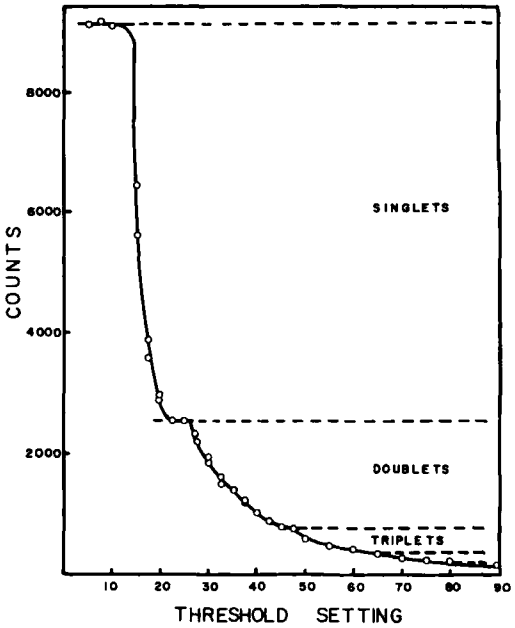

Fig. 2.—Coulter Counter data obtained with a system of partially aggregated suspension composed of 1.83-μ diameter primary particles.

It was decided to carry out the kinetic studies on both a purified suspension as well as on the unpurified sample in the presence of various electrolytes at different electrolyte concentrations. Since it was known (12) that the soluble impurity in the sample as received was a sulfonate type stabilizer, the limiting aggregation rates for the unpurified suspension were expected to also approach the theoretical Smoluchowski rate if the theory was to apply in this instance.

Procedure.—The sample of the latex suspension was diluted to about 1×10^8 particles per ml. A portion of this master suspension was purified by centrifugation in a clinical centrifuge followed by decantation of the liquid and ultrasonic[8] redispersion in the solvent. This was repeated three times in 70% aqueous ethanol and three times in redistilled water. The other portion of the master suspension was used directly without any purification.

For the runs the suspensions were further diluted and mixed with equal volumes of an aqueous electrolyte solution so that the initial total particle concentration, c_o, was always in the neighborhood of 1×10^7 to 7×10^7 particles per ml. These suspen-

sions were then allowed to stand without agitation[9] in 25-ml. volumetric flasks maintained at 25.0 ± 0.5°. Aliquots were taken periodically, diluted in 0.9% sodium chloride solution, and the distribution of aggregates were determined with the Coulter Counter employing the 50-μ aperture. The dilutions for counting were sufficiently great so that coincidence effects were negligible. Generally about 1 ml. of the suspension was added to 100 to 250 ml. of saline. The manner of pipeting and mixing the aliquot was found not to influence the results.

RESULTS AND DISCUSSION

Time Dependence.—The results of two of the kinetic runs are presented in Figs. 3 and 4. The data are plotted as per cent species *vs.* time to permit comparison with theory. For the particular experiment the theoretical curves were obtained by selecting a suitable single value for k_{11} and replotting the curves in Fig. 1 with the experimental C_o so that the singlet theoretical curve would give the best fit to the singlet data.

For these and for the other electrolyte systems the fit of the data was more often somewhat better for the surface-controlled theoretical case, but in some instances the fit was equally good for both theoretical cases. As we shall see later, the Smoluchowski rate constant for the singlet-singlet reaction as predicted by Eq. 4 was never reached in any of the experiments, although closely approached particularly by the runs with the purified suspension and by the runs in 1.0% hydrochloric acid with the unpurified suspension (Fig. 4). Thus it is reasonable that most of the data did fit the surface-controlled theory or fit somewhere in between the two. However, because in many cases the experimental uncertainty was not much less than the differences between the two theoretical predictions, no conclusions can be made regarding the correct mechanism on this basis alone. Up to this point, however, it can be said that the time-dependent behavior of the aggregate distribution was found to be in good agreement with theory.

Dependence of k_{11} on Electrolyte Concentration.—By means of the method described above for matching theoretical curve to data, values for k_{11} were determined for all of the runs. The results are presented in Figs. 5 and 6 for the purified and the unpurified suspensions, respectively.

It is first worthwhile to note from these results that the k_{11} value as predicted by the diffusion controlled theory of Smoluchowski (see Eq. 4), *viz.* $k_{11} = 1.2 \times 10^{-11}$, has been closely approached in most of these experiments. In particular, with the purified suspension, all salt systems gave maximum k_{11} values within about a factor of two of the theoretical value. Because it is believed that these latex particles are typically hydrophobic, similar maximum k_{11} values can be expected with most unprotected suspensions and emulsions. Thus a useful upper limit for rate of aggregation has been experimentally established.

The salt runs with the unpurified suspension consistently gave lower k_{11} values and showed greater concentration dependence in the range of study than the runs with the purified sample. While it was expected that the concentration dependence would

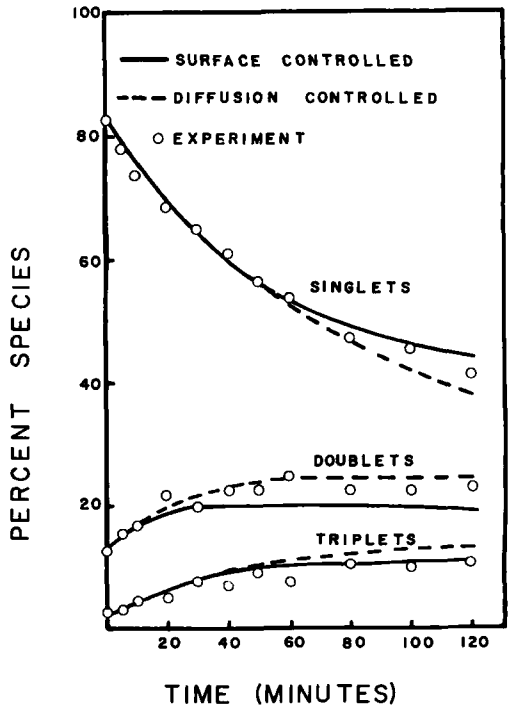

Fig. 4.—Experiment and theory showing aggregation of unpurified polystyrene latex suspension particles in 1% HCl. $C_o = 5.2 \times 10^7$ particles per ml.

[9] Both from Stokes' law consideration and actual experimental observations, sedimentation effects were judged to be negligible during the experiments.

be generally greater for the unpurified suspension because of the stabilizing action of the sulfonate additive at low salt concentration, it was somewhat surprising to find that maximum k_{11} values nearer to the theoretical k_{11} were not obtained in this series of runs. A sulfonate would normally be expected to operate as a charge-conferring agent. At such high salt concentrations (1 to 5%) the electrical double layer would be very thin and therefore should be completely canceled out at all interparticle distances by the attractive long-range London dispersion forces (7) between the primary particles. Thus it was expected that repulsive interactions would be entirely absent. The real situation is perhaps more complex than this simple picture. It may possibly involve aggregation of the sulfonate in a gel-like structure at the particle surface.

The effect of hydrochloric acid on the aggregation rate of the unpurified suspension was most interesting (see Fig. 6). The protective action of the stabilizer appeared to have been nearly completely destroyed in 1.0% hydrochloric acid. At this hydrochloric acid concentration the k_{11} was found to be approximately the same as those limiting values found with the purified suspension. The decrease in rate at higher hydrochloric acid concentrations has not been explained.

The dependences of k_{11} upon both the electrolyte type and the electrolyte concentration were relatively small with the purified suspension. This was not surprising since the few charge-producing ions present in these systems were not expected to

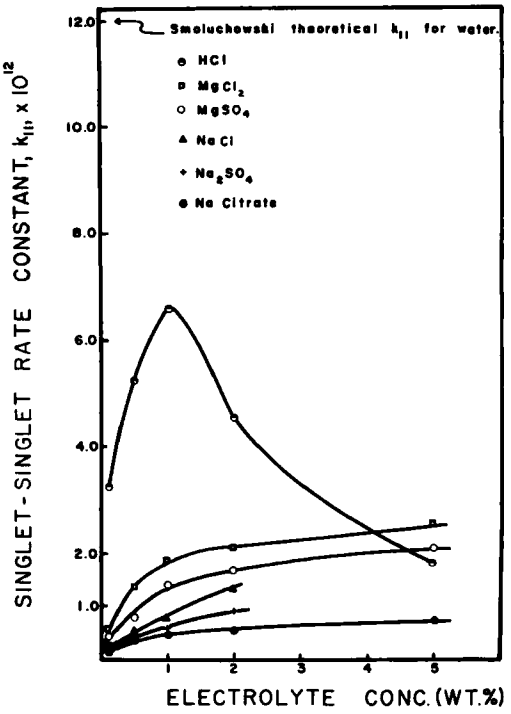

Fig. 6.—Experimental k_{11} values obtained with unpurified polystyrene latex suspension as function of electrolyte type and concentration. Theoretical $k_{11} = 1.2 \times 10^{-11}$.

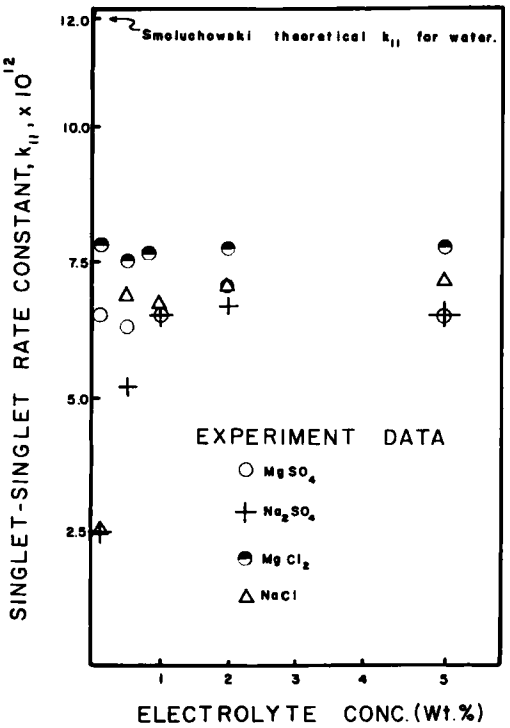

Fig. 5.—Experimental k_{11} values obtained with purified polystyrene suspension as function of electrolyte type and concentration. Note theoretical $k_{11} = 1.2 \times 10^{-11}$.

be very effective. To within about ±10%, the maximum k_{11} values observed in this series were found to be the same in all electrolyte systems studied.

While it may be purely academic, it is interesting to note that these experiments suggest that the correct diffusion-controlled rate is somewhat less than that predicted by the Smoluchowski theory. The correction factor appears to have a value somewhere between 0.5 and 0.8. It is reasonable that this might arise from the neglect of particle-particle hydrodynamic interactions which become important when the particles are near (order of a particle diameter) each other.

Polarographic Study of Iodothiophenes

By LEO WAYNE BROWN† and EDWARD KRUPSKI

Eight iodothiophenes were polarographed in two different solvents, N,N-dimethylformamide and 2-ethoxyethanol and the half-wave potential for each wave was calculated. The reduction of the iodothiophenes at the dropping mercury electrode was found to be essentially the same as reduction of the iodothiophenes by chemical methods. Reaction mixtures obtained in the preparation of some iodothiophenes were polarographed and the information obtained was found to be useful in determining the iodothiophenes present and their relative amounts. A study of the wave heights *vs.* concentration of 2-iodothiophene in N,N-dimethylformamide and in 2-ethoxyethanol was conducted and the diffusion current was shown to be proportional to the concentration.

THIOPHENE has been of interest in the field of organic synthesis because it possesses chemical characteristics similar to those of benzene and has been substituted for benzene and other aromatic nuclei in the synthesis of intermediates of pharmaceutical compounds and thiophene derivatives with therapeutic activity.

It was the intent of this project to make a polarographic study of iodothiophenes to provide additional information relative to the characteristics of the thiophene nucleus and to give an insight into the reactions taking place at the dropping mercury electrode.

Polarography has been used to compare the reactivities of the thiophene and benzene nucleus. Day and Blanchard (1) have studied the polarography of phenyl-2-thienyl ketone and 2,2′-dithienyl ketone in buffered solutions ranging from pH 1 to 13. Elving and Callahan (2) have studied the polarographic behavior of thenoyltrifluoroacetone and related compounds. Tirouflet and co-workers (3) have studied the polarographic behavior of thiophene derivatives and similarly substituted benzene derivatives. They compared 2-nitrothiophene, 2-iodothiophene, 2-thiophenealdehyde and other compounds with the corresponding benzene derivatives.

Since a direct correlation between the half-wave potential of corresponding benzene and thiophene derivatives had been shown, Tirouflet and Chane (4) studied the half-wave potential increments due to substituent X in the 5-position in 2- and 3-nitrothiophene and found them to be equal within experimental error with the corresponding increments in nitrobenzene with X-substituent in the *para* and *meta* position. The Hammett equation, which relates structure to both equilibrium constants and rate constants for the reactions of *meta*- and *para*-substituted benzene derivatives, was thus shown to hold for the thiophene series and sigma values were shown to be of the same order of magnitude. Further work by these same workers has shown that an extention of the Hammett equation to the thiophene series was possible in most cases, but must be carefully evaluated. Imoto and co-workers (5) have studied the effects of the benzene and thiophene nucleus on the polarographic half-wave potentials of the aromatic aldehydes and nitro compounds and concluded that Hammett's law is applicable to the half-wave potential of the thiophene derivatives.

EXPERIMENTAL

Polarographic Procedure.—A manual polarograph (Sargent polarograph model III) equipped with a standard mercury capillary electrode and a saturated calomel reference electrode in an H-type cell was used for the determinations. Nitrogen was passed through each solution of iodothiophene for 30 minutes to remove the oxygen from the solution before being polarographed.

All determinations were conducted in a constant temperature bath at 25 ± 0.5°. The current readings *vs.* voltage were plotted on graph paper and a smooth curve was drawn through the points. The half-wave potential was obtained from the graph by taking the mid-point of what appeared to be the most symmetrical curve.

The characteristics of the capillary in N,N-dimethylformamide with 0.05 M tetrabutylammonium iodide as the electrolyte were measured at 25 ± 0.5° with a mercury height of 60 cm. and are reported in Table I.

Purification of Solvents.—N,N-Dimethylformamide was dried over anhydrous potassium carbonate and distilled through a 90-cm. Fenske column. The fraction that distilled at 152–153° was collected.

Cellosolve (2-ethoxyethanol) was refluxed for 30 minutes with exsiccated ferrous sulfate and distilled through a 90-cm. Fenske column. The fraction that distilled at 135° was collected.

Tetrabutylammonium iodide was twice crystallized from ethyl acetate, suction filtered and 10-Gm. quantities placed in green glass containers. The containers were placed in a vacuum desiccator for 1 hour, then sealed and stored in a dark place.

Preparation of Iodothiophenes.—Tetraiodothiophene, 2-iodothiophene, 2,5-diiodothiophene, 3-iodothiophene, and 3,4-diiodothiophene were prepared essentially by the methods described in *Thiophene and its Derivatives* by Hartough (6). 2,3,4-Triiodothiophene, 2,3,5-triiodothiophene, and 2,3-diiodothiophene were prepared essentially by the methods described by Steinkopf (7).

Polarographic Results.—The eight iodothiophenes were polarographed in N,N-dimethylformamide and in 2-ethoxyethanol to obtain the half-wave potentials as shown in Tables III and IV.

The polarograms for all the prepared compounds, some mixtures of these compounds and several unknowns were plotted and analyzed but only a selected few of these polarograms are shown in this paper.

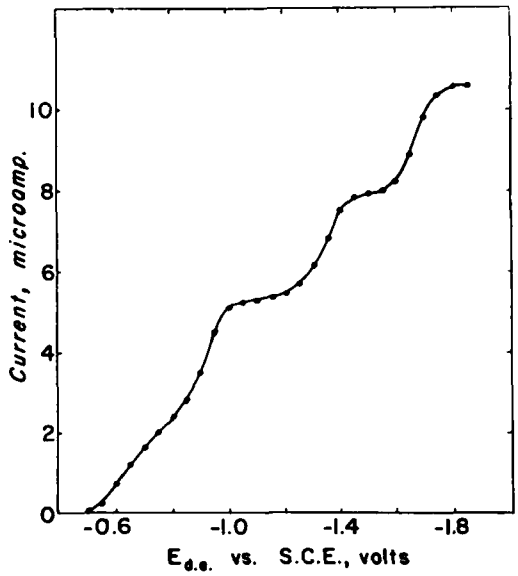

Fig. 1.—Polarogram of 1.0 millimolar tetraiodothiophene in N,N-dimethylformamide containing 0.05 *M* tetrabutylammonium iodide as electrolyte.

Four waves were obtained in the curve of the polarogram of tetraiodothiophene with the first two waves almost merging into one single large wave. The four waves were all of approximately the same height as shown in Fig. 1. 3-Iodothiophene, when polarographed, gave a single wave which corresponded to the last wave in tetraiodothiophene, consequently the last wave in tetraiodothiophene was judged to be caused by the iodine in the 3-position. To get a smooth wave from 3-iodothiophene, the concentration was maintained at about 0.5 millimolar because larger concentrations caused an inflection at the top of the wave as shown in Fig. 2. The polarogram of 2-iodothio-

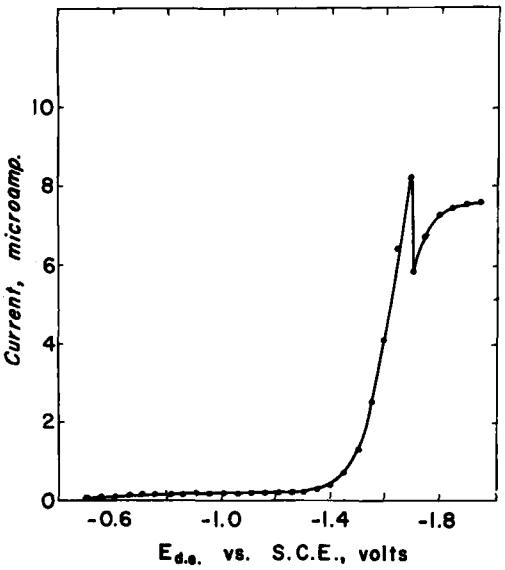

Fig. 2.—Polarogram of 1.78 millimolar 3-iodothiophene in 2-ethoxyethanol containing 0.05 *M* tetrabutylammonium iodide as electrolyte.

phene showed a single wave which corresponded with the second wave of tetraiodothiophene but it, too, gave an inflection when concentrations greater than 0.55 millimolar were used. Two maximum suppressors, Triton X-100 and methyl red, were added to the more concentrated solutions of 2-iodothiophene in an attempt to eliminate the inflections, but the suppressors had no effect on the inflections.

The curves of 2,3,5-triiodothiophene were similar to those of tetraiodothiophene except that the wave of the 4-position iodine was missing from the curves.

2,5-Diiodothiophene was polarographed to obtain a normal two-wave curve. In conjunction with this work a mixture of 2-iodothiophene and 2,5-diiodothiophene was polarographed and in the polarogram there was observed a short 5-position iodine wave and an extended 2-position iodine wave to indicate the ratio of these two substitutions. The polarograms of 3,4-diiodothiophene and 2,3-diiodothiophene were normal two-wave curves with the waves well distinguished from one another but with some shifting of the 2-position wave to a less negative potential in the case of the 2,3-diiodothiophene.

When 2,3,4-triiodothiophene was polarographed in N,N-dimethylformamide, four waves were produced but only the expected three waves were produced when polarographed in 2-ethoxyethanol. The sum of the wave heights of the first two waves of the curve of 2,3,4-triiodothiophene in N,N-dimethylformamide was equal to a single wave of the other two waves in the curve. Also, since only three waves were observed on the polarogram of 2,3,4-triiodothiophene in 2-ethoxyethanol, it was concluded that the first two waves of 2,3,4-triiodothiophene in N,N-dimethylformamide were caused by the single iodine in the 2-position. As the concentration of 2,3,4-triiodothiophene in N,N-dimethylformamide was decreased, the height of the first wave of the polarogram increased while the second wave decreased.

In one attempt to prepare 2,3,5-triiodothiophene by iodinating 3-iodothiophene in the 2 and 5 position, only an oil was obtained instead of solid 2,3,5-triiodothiophene. A polarogram was run with this oil and the curve in Fig. 3 was obtained. This curve showed that the reaction had not been run long enough since only a small amount of triiodothiophene was evident from the curve.

In the course of this study an experiment was conducted to determine the linearity of wave heights *vs.* concentration of 2-iodothiophene in N,N-dimethylformamide and in 2-ethoxyethanol. The results, shown in Fig. 4, indicated that the diffusion current was proportional to the concentration.

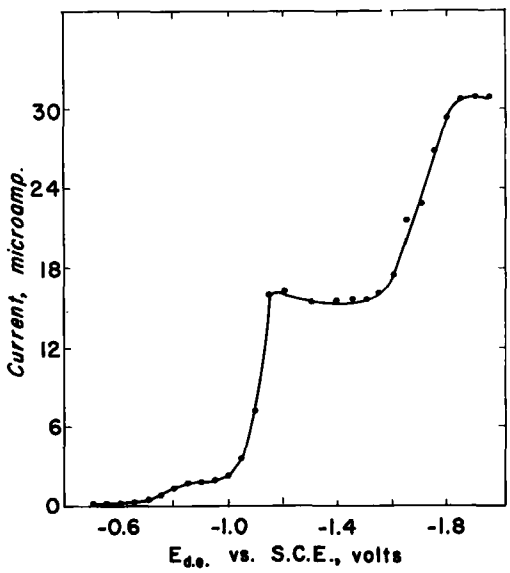

Fig. 3.—Polarogram of the oil obtained in preparing 2,3,5-triiodothiophene (3 drops per 50 ml. of N,N-dimethylformamide containing 0.5 *M* tetrabutylammonium iodide).

DISCUSSION

In order for data obtained from polarography to be of the utmost use to the chemist, a correlation between the normal chemical reaction and the reaction at the dropping mercury electrode should be obtained. Some researchers in this field suggest that the potential gradient near the surface of the mercury drop causes organic halides to approach the mercury surface with the halogen atom away from the drop and that this places the backside of the carbon holding the halogen in position to accept electrons, unless this is sterically interfered with by the presence of other groups. In addition, a large field effect should aid alkyl halide dissociation at all potentials. Lambert and Kobayashi (8) have studied the half-wave potentials of alkyl halides and cycloalkyl halides. They found good correlation between S_N2 reactivity and half-wave potential for many of these compounds which react by S_N2 reaction.

If the iodothiophenes approach the mercury surface with the iodine atoms away from the surface of the mercury, then it would seem that the polaro-

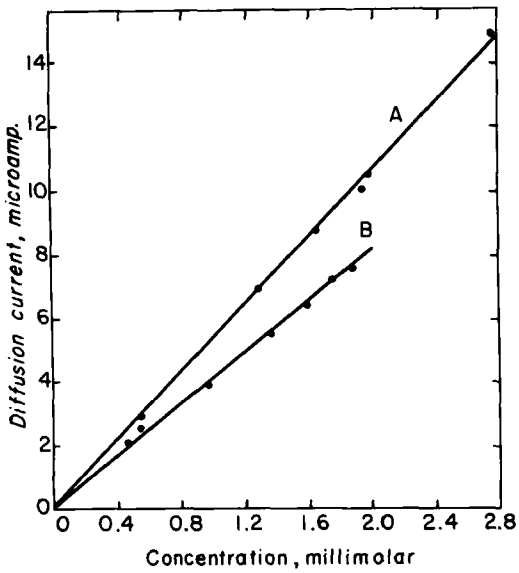

Fig. 4.—Plot of concentration *vs.* diffusion current of 2-iodothiophene in (*A*) N,N-dimethylformamide and (*B*) 2-ethoxyethanol.

gram of a compound such as 2,5-diiodothiophene would show a greater first wave height than second wave height since there are two identical carbons from which the removal of the first iodine atom can be made. In this study, the wave height produced by each iodine in a polyiodothiophene was approximately the same. Also, the position in which 2-iodothiophene approached the mercury surface would probably be different than the position in which 2,5-diiodothiophene approached the surface because they would have different dipole moments, yet in this study the half-wave potential of 2-iodothiophene corresponded fairly well with the 2-position iodine in 2,5-diiodothiophene. Levin and Fodiman (9) have shown earlier that a molecule such as the benzene nucleus containing *n* chlorine atoms was reduced at a potential independent of whether this molecule was introduced as such or was formed in the solution by reduction of a molecule richer in chlorine. It might be speculated then, in the case of the iodothiophenes, that the first electron could be added to the aromatic ring causing one of the ring electrons to shift to the iodine that is most easily reduced.

Marple, Hummelstedt, and Rogers (10) studied the polarographic reductions of benzyl halides. They proposed the following for the mechanism of reduction of benzyl halides at the dropping mercury electrode.

$$RX + e^- \rightarrow RX^- \quad \text{I}$$

$$RX^- \rightarrow R\cdot + X^- \quad \text{II}$$

$$R\cdot + e^- \rightarrow R^- \quad \text{III}$$

$$R^- + H_2O \rightarrow RH + OH^- \quad \text{IV}$$

$$2R\cdot \rightarrow R{-}R \quad \text{V}$$

$$RX + Hg \rightarrow RHgX \quad \text{VI}$$

It was generally assumed that addition of the first electron was the slow step and that reactions II, III, and IV were relatively rapid because only one wave was usually observed for each halogen atom replaced. Reactions V and VI were possible side reactions. They also found that benzyl iodide underwent two widely separated one-electron reduction steps at concentrations of less than 10^{-4} *M*. At higher concentrations, adsorption phenomena were encountered between the two waves due to the presence of bibenzyl, a by-product of the first reduction step. Judging from Marple and co-workers work, bithienyl might possibly have been formed as a side reaction and produced an adsorption wave causing the inflection observed in higher concentrations of 2-iodothiophene and 3-iodothiophene.

The behavior of 2,3,4-triiodothiophene in N,N-dimethylformamide in which a single iodine in the 2-position caused a double wave was probably an example of the kinetics of the reaction varying with the concentration.

The plot of concentration *vs.* diffusion current in Fig. 4 indicates that there exists a linear relationship between diffusion current and concentration of 2-iodothiophene in N,N-dimethylformamide and in 2-ethoxyethanol but that the diffusion current is higher in N,N-dimethylformamide than in 2-ethoxyethanol.

SUMMARY

Eight prepared iodothiophenes were reduced at a dropping mercury electrode of a manual polarograph in two different solvents, N,N-dimethylformamide and 2-ethoxyethanol, and their half-wave potentials were determined. The polarograms of the iodothiophenes in the two solvents were compared and discussed.

Polarograms were run on some of the reaction mixtures obtained in preparing the iodothiophenes in order to determine their composition. The information gained in these polarograms was of value in determining the length of time that the reaction should be run under the conditions used.

A study of the wave heights *vs.* concentration of 2-iodothiophene in N,N-dimethylformamide and in 2-ethoxyethanol was conducted and the diffusion current was shown to be proportional to the concentration; consequently a quantitative estimation of this compound could be obtained from its diffusion current.

Stabilization of Vitamin B_{12} I

Complex Cyanides

By DONALD A. ZUCK and JAMES W. CONINE

The destruction of cyanocobalamin in liquid multiple vitamin preparations can be greatly reduced by the addition of small amounts of complex cyanides or iron salts. Cyanocobalamin stabilization with iron salts is not as effective as with complex cyanides under conditions designed to exclude air. The superiority of complex cyanides over iron salts was also demonstrated in partly filled containers where a large volume of air overlaid the product. The complex cyanides were also effective in reducing the destruction of cyanocobalamin induced by ultraviolet irradiation.

THE PROBLEM of deterioration of vitamin B_{12} in aqueous and multiple vitamin preparations was recognized shortly after its isolation as a pure crystalline compound (1, 2). Mention of stabilizers was first made in 1952 by Rosenblum (3) who reported that ferrous and ferric ions showed definite stabilizing properties on vitamin B_{12} in a multiple vitamin capsule. Additives such as sodium bisulfite (4), saccharated iron oxide (5), and thiodipropionic acid (6) found use as stabilizers with some degree of success.

Analogs of cyanocobalamin have been recognized (2, 11) as less stable forms. Other factors contributing to the instability of vitamin B_{12} in the complex preparations were air volume above the liquid and/or the area of the liquid-air interface (7), presence of copper ions with ascorbic acid (12), exposure to sunlight, direct ultraviolet light, or incandescent light (13).

The use of cyanide as a stabilizer was first mentioned in 1953 (8, 9). The process involved addition of hydrogen cyanide to the vitamin solution. Excess hydrogen cyanide was then removed by vacuum.

The question of vitamin B_{12} stability in multiple vitamin preparations has continued to be of major concern. Campbell (10) pointed out from a survey on marketed products that vitamin B_{12} was below label in all liquid and tablet formulations which were tested by his group.

Sodium pyrosulfite and sodium nitrite reduced vitamin B_{12} decomposition by 50% in liver preparations which were exposed to diffused light. This rapid decomposition of vitamin B_{12} in liver preparations, when exposed to air and light, was also reversed by the addition of sodium cyanide. Screenivasamurthy (14) found that light favored the conversion of the cyanocobalamin to the hydroxo form. The decomposition was then due to the instability of the hydroxo form in the presence of oxygen.

Received March 26, 1962, from the Pharmaceutical Research Department, Eli Lilly and Co., Indianapolis, Ind.
Accepted for publication May 24, 1962.

More recently reported stabilizers were ammonium sulfite (15), iron compounds (16, 18, 19), organonitriles of the R—CH(OH)CN type (17), and metallocyanide complexes (20). This report deals with a comparative study of the iron salts and complex cyanide salts as stabilizers for vitamin B_{12} in a liquid multiple vitamin preparation in presence and absence of air. The effect of complex cyanides on the stability of an aqueous cyanocobalamin solution on exposure to ultraviolet light was also studied.

EXPERIMENTAL

A homogenized liquid multiple vitamin formulation was made up to 95% of the final volume of the preparation. Each milliliter of the finished preparation was to contain the following: vitamin A synthetic, 600 units; thiamine hydrochloride, 0.20 mg.; riboflavin, 0.24 mg.; pyridoxine hydrochloride, 0.20 mg.; nicotinamide, 2.0 mg.; ascorbic acid, 12.0 mg.; and vitamin D synthetic, 200 units.

The bulk preparation was stored under refrigeration. Cyanocobalamin, to give a final concentration of 1.0 mcg. per ml., and different stabilizers at predetermined amounts were dissolved in a minimum amount of purified water. This solution was then added to the bulk vitamin preparation which was then made up to 100% of volume with purified water. Such a multiple vitamin preparation was then filled under nitrogen cover into 4-oz. amber screw-capped bottles, and partly filled (40 oz.) under air cover into 1-gal. amber screw-capped bottles. These containers were stored at 26, 37, 46,[1] and 65° in constant temperature storage rooms or ovens. Assays were carried out by control laboratory using the U.S.P. microbiological method of assay for vitamin B_{12}.[2] The sampling schedule was based on results received in order to obtain the best distribution of data log-concentration-time plots.

For the ultraviolet irradiation study, solutions of 15 mcg. of cyanocobalamin containing potassium ferrocyanide 0.1 to 0.00005% and potassium ferricyanide 0.1 to 0.00001% were irradiated in a Fade-

[1] Upon completion of experiment it was found that the temperature in the 50° storage room was not uniform throughout. The area in which the bottles were stored was found to be 46°.

[2] The microbiological assays were performed by Mr. J. T. Stephenson and his associates of the Microbiological Testing Department, Eli Lilly and Co.

RESULTS AND DISCUSSION

Liquid Multiple Vitamin Product, Stabilization of Vitamin B_{12} in Presence of Vitamin C.—The results tabulated in Table I and Table II were from data obtained at the time and temperature indicated from full and partly filled containers for each of the stabilizers listed. Table I is a comparison of a number of stabilizers containing iron at 170 mcg. of iron per ml. Table II represents a study of ferrous gluconate and potassium ferrocyanide at four different concentrations. This was an attempt to determine the minimum effective concentration of stabilizer that could be used advantageously. Although the difference between the two stabilizers is quite striking, no appreciable change is observed in the effect of potassium ferrocyanide concentrations between 160 mcg. and 40 mcg. of iron per ml. Very little difference in stabilizing effect was noted with ferrous gluconate between the concentrations of 170 and 40 mcg. of iron per ml. It has been observed that potassium ferrocyanide and other metalocomplexes were effective at a metal-concentration as low as 10 mcg. per ml.

Because of amber glass containers which were used, light (13, 14) cannot be considered as a contributing factor in the conversion of the cyano-form to the relatively unstable hydroxo form in these experiments. It appears that a compound like potassium ferrocyanide, by furnishing cyanide ions, interferes with the transformation of the cyanocobalamin to the hydroxo or other less stable analogs of vitamin B_{12}. This action has been demonstrated in the study with ultraviolet irradiation. The analogs, once formed, were readily oxidized in presence of oxygen (14). A similar situation exists in the presence of ascorbic acid (1) where the cyano-form was found to be more stable than the other vitamin B_{12} analogs. Ferrous sulfate appears to inhibit the oxidation of vitamin B_{12}; however, this protection is reduced by an increase in air volume and/or surface area.

In Table III a comparison of six different metalocyanide complexes was made. The amounts added were such as to give 20 mcg. of metal per ml. of the vitamin preparation. There were no marked differences with respect to their stabilizing properties with the exception of $K_3Cu(CN)_4$. This complex exhibited a somewhat lesser stabilizing effect which became more evident in the partially filled containers at the higher temperatures. This behavior supports a previous observation (12) made with respect to copper ions, ascorbic acid, and vitamin B_{12}.

With the exception of $K_3Cu(CN)_4$ it would be difficult to select one of these complexes as a stabilizer for vitamin B_{12} on the basis of these results. But toxicity results show that potassium ferrocy-

anide and potassium ferricyanide are the least toxic of the compounds studied with an LD_{50} oral in mice greater than 2 Gm. per Kg. Potassium cobalticyanide had an LD_{50} of 1529 ± 196 mg. per Kg. The LD_{50} of potassium molybdocyanide was found to be approximately 1500 mg. per Kg. Potassium nickelocyanide and potassium manganocyanide and potassium zinc cyanide had an LD_{50} of less than 275 mg. per Kg. This large variation in degree of toxicity is directly related to the ease with which the complex salts dissociate in solution (21). For example, the double nickelocyanide ($K_2[Ni(CN)_4]$) gives a precipitate with ammonium sulfide whereas potassium ferrocyanide gives no precipitate with either ammonium sulfide or with sodium hydroxide.

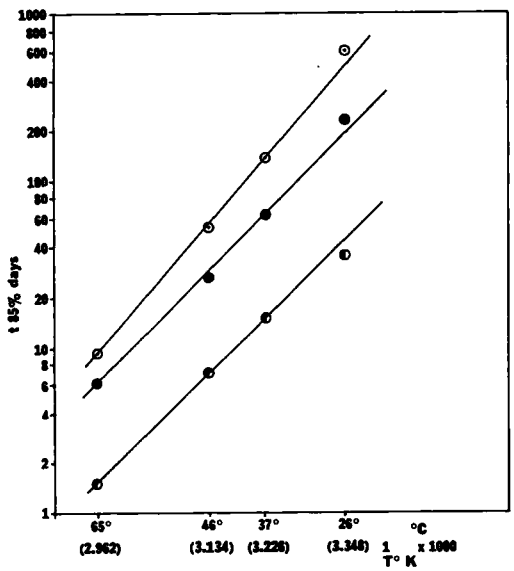

Fig. 1.—The relationship of $t_{85\%}$ (logarithmic scale) of vitamin B_{12} in a liquid multiple vitamin preparation and the reciprocal of the absolute temperature under nitrogen cover. ⊙, Potassium ferrocyanide; ●, ferrous gluconate; ◐, control.

The addition of iron at a concentration of 170 mcg. per ml. will stabilize vitamin B_{12} quite satisfactorily in both filled and partly filled containers. The superiority of potassium ferrocyanide as a stabilizer is not as pronounced in the full containers as it is in partly filled containers. This effect can be more readily seen in Fig. 1 and Fig. 2 in which the t_{85} (time for material to reach 85% of the initial concentration) was plotted against the reciprocal of the absolute temperature. The t_{85} values were obtained directly from the concentration-time plots at four different temperatures. Straight line plots indicated first-order reactions.[4]

There was no indication that changes in concentration of the stabilizer affected the decomposition rate for vitamin B_{12} between concentrations of potassium ferrocyanide at 20 to 170 mcg. of iron per ml. The t_{85} values for potassium ferrocyanide are averages of five separate experiments: 170, 40, 40, 20, and 20 mcg. of iron per ml. The t_{85} values representing ferrous gluconate are averages of three experiments: 170, 160, and 40 mcg. of iron per ml.

Figures 1 and 2 clearly demonstrate the superiority of potassium ferrocyanide over that of ferrous gluconate, particularly where contact with air is a factor. For example, under air cover, the time in days to reach 85% of initial at 26° was 320 days using potassium ferrocyanide *vs.* 90 days using ferrous gluconate (a ratio of 3.5:1.0); and under nitrogen cover the time was 560 days using potassium ferrocyanide *vs.* 230 days with ferrous gluconate (a ratio of 2.4:1.0).

Cyanocobalamin Solution, Effect of Cyanides on Decomposition Due to Ultraviolet Irradiation.—Results obtained from the ultraviolet degradation studies are tabulated in Tables IV and V.

A rapid destruction of vitamin B_{12} was observed at the higher concentrations of the complex. Over the limits of this particular study this decomposition

[4] The assay at 1 month for the control experiment at 26° in partly filled containers showed a greater drop than was expected. Thereafter, a first-order decomposition followed.

[a] Extrapolated value.

was proportional to the amount of cyanide added. The initial reaction appeared to be destruction of the vitamin B_{12} activity. After this, a stabilizing effect on the remaining vitamin B_{12} activity was observed. The optimum concentration for potassium ferricyanide was 0.001% and for potassium ferrocyanide it was from 0.001 to 0.005%. The stabilizing effect decreased rapidly below these concentrations. The optimum stabilizing effect of potassium cyanide under the same conditions was 0.001% (25). With concentrations greater than this, there was no improvement in the stabilizing effect. Tables IV and V give the per cent of initial concentration lost in the first 8 hours and the per cent of initial concentration lost in the remaining 88 hours. The total per cent loss is also given. Figure 3 illustrates the type of curve obtained when the logarithm of per cent of the initial vitamin B_{12} concentration was plotted against time. After 8 hours' exposure, a precipitate giving a positive test for iron was formed, the pH changed as listed in Tables IV and V, and a pronounced odor of cyanide was present in solutions.

At this time the reasons that the two complexes accelerate the degradation of vitamin B_{12} during their photochemical decomposition are not clear.

The photochemical degradation of potassium ferrocyanide has been studied previously (22–24). Although our work was done on less concentrated solutions, it confirms the previously reported results.

The reaction for potassium ferrocyanide in presence of air is believed to be

$$2Fe^{++} + 4OH^- + H_2O + {}^1/_2O_2 \rightarrow 2Fe(OH)_3$$

In the absence of air the reaction is

$$Fe(CN)_6^{----} + HOH \rightleftharpoons Fe(CN)_5 \cdot H_2O^{---} + CN^-$$

and then followed by

$$CN^- + HOH \rightleftharpoons HCN + OH^-$$

Since the glass-sealed ampuls had a limited supply of air, both reactions could have occurred.

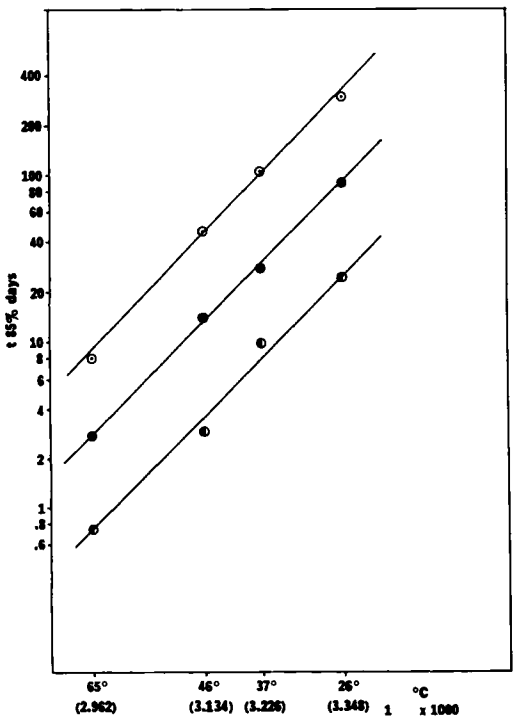

Fig. 2.—The relationship of $t_{85\%}$ (logarithmic scale) of vitamin B_{12} in a liquid multiple vitamin preparation and the reciprocal of the absolute temperature in presence of air. ⊙, Potassium ferrocyanide; ●, ferrous gluconate; ◐, control.

SUMMARY

1. A comparative study of the stabilizing effect of ferrous salts and complex cyanides on

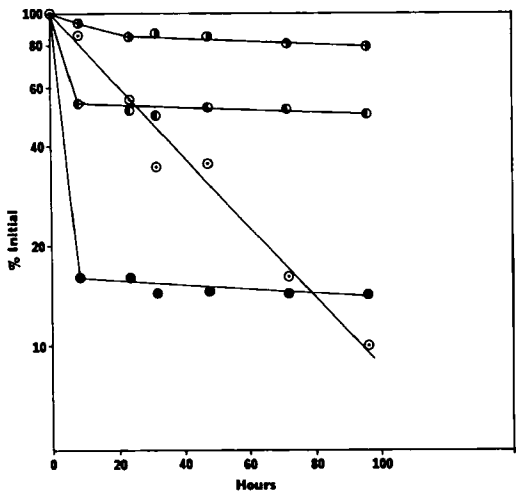

Fig. 3.—Decomposition of vitamin B_{12} in the presence of potassium ferricyanide following exposure to ultraviolet irradiation in the Fade-Ometer. ●, 0.02% potassium ferricyanide; ◐, 0.005% potassium ferricyanide; ◑, 0.001% potassium ferricyanide; ⊙, control.

vitamin B_{12} in multiple vitamin preparations in the presence and absence of air was made.

2. The superiority of potassium ferrocyanide over iron salts as a vitamin B_{12} stabilizer in multiple vitamin preparations was demonstrated.

3. The destruction of vitamin B_{12} by ultraviolet light was investigated. Under the conditions of the experiment it was found that the optimum stabilizing concentration of potassium ferrocyanide and potassium ferricyanide was 0.001 to 0.005% and 0.001%, respectively.

Stabilization of Vitamin B_{12} II

α-Hydroxynitriles

By JAMES W. CONINE and DONALD A. ZUCK

The destruction of vitamin B_{12} in liquid multiple vitamin products can be greatly reduced by the addition of α-hydroxynitriles or their esters. The stabilizing effect appears to be due to decomposition of the α-hydroxynitrile into hydrogen cyanide and the corresponding aldehyde. An initial stabilization of cyanocobalamin was seen in solutions which contained α-hydroxynitriles and were exposed to ultraviolet irradiation. However, upon long exposure to ultraviolet light, cyanocobalamin solutions containing α-hydroxynitriles eventually decomposed more than the control.

VITAMIN B_{12} has been shown to be extremely susceptible to decomposition in the presence of ascorbic acid (1, 2). A recent review (3) has covered a number of compounds which have been suggested as stabilizers to reduce the rate of decomposition of vitamin B_{12}. Some of these, such as nitrites or bisulfites, are not completely satisfactory because they have an adverse affect upon the stability of thiamine or some of the other vitamins. Hydrogen cyanide has been used successfully to stabilize vitamin B_{12} injections (4, 5), and cyanides have been utilized in the production of cyanocobalamin (6). α-Hydroxynitriles and their esters are potential sources of cyanide and as such have been shown to be effective stabilizers of vitamin B_{12} in pharmaceutical preparations (7). The effect of α-hydroxynitriles and their esters upon the rate of decomposition of vitamin B_{12} is the subject of the present study.

EXPERIMENTAL

Liquid Multiple Vitamin Preparation.—A homogenized liquid multiple vitamin formulation was made up to contain 95% of the final volume of the preparation. Each milliliter of the finished preparation was to contain: vitamin A, 600 units; vitamin B_1, 0.2 mg.; vitamin B_2, 0.24 mg.; vitamin B_6, 0.2 mg.; nicotinamide, 2.0 mg.; ascorbic acid, 12 mg.; and vitamin D synthetic, 200 units. To this preparation was added a triturate of crystalline cyanocobalamin in mannitol to give the preparation a concentration of 1 mcg. per ml. of vitamin B_{12}. The α-hydroxynitrile was dissolved in distilled water or aqueous alcohol and added in the appropriate concentration. The product was brought up to final volume with distilled water and stirred until uniform. The samples were filled into amber

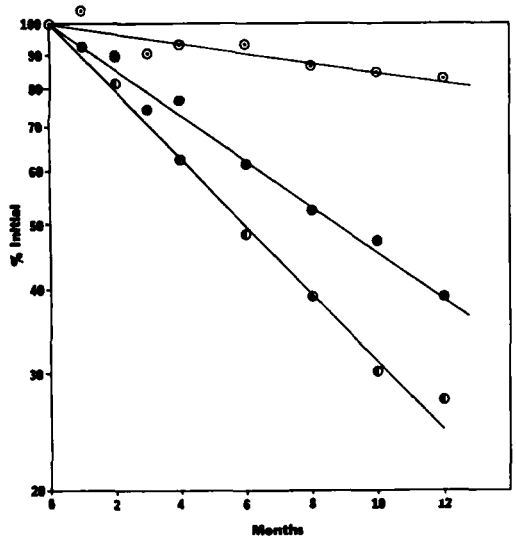

Fig. 1.—First-order decomposition of vitamin B_{12} at 26° in a liquid multiple vitamin preparation containing esters of mandelonitrile. ⊙, 0.1% acetylmandelonitrile; ●, 0.1% benzoylmandelonitrile; ◐, control.

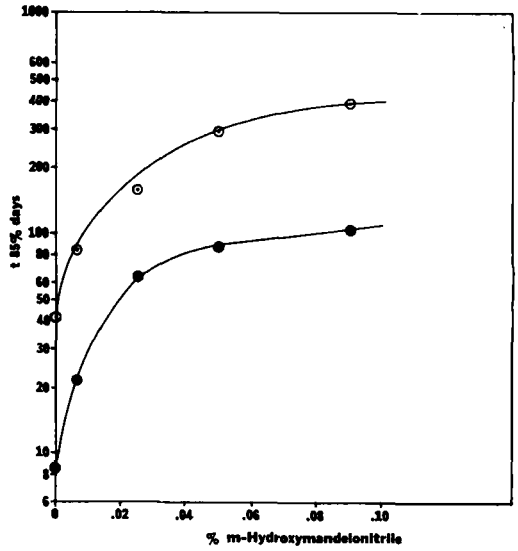

Fig. 2.—The relationship of $t_{85\%}$ of vitamin B_{12} in a liquid multiple vitamin preparation (logarithmic scale) and concentration of *m*-hydroxymandelonitrile. ⊙, at 26°; ● , at 37°.

1-pt. bottles and stored at 26 and 37° in controlled temperature rooms. Samples were removed periodically and assayed for vitamin B_{12} activity by the microbiological method of the U.S.P.[1]

Solution Cyanocobalamin.—Solutions of cyanocobalamin, 15 mcg. per ml., were prepared. Before the solution was made up to final volume the α-hydroxynitriles were added from a stock solution. Water was used to dissolve *m*-hydroxymandelonitrile. Ethanol, 95%, was used as a solvent for carbethoxymandelonitrile, and the solutions in this series were prepared at a final concentration of 5% ethanol. The solutions were filled into 5-ml. No. 1 flint glass ampuls and irradiated in the Fade-Ometer[2] at a temperature of 52° for periods of up to 96 hours. The ampuls were assayed for vitamin B_{12} activity by microbiological assay method of the U.S.P.[1]

The substituted mandelonitriles were prepared by the method of Buck (8). The esters of mandelonitrile were prepared by the method of Francis and Davis (9). Lactonitrile,[3] amygdalin, and aniline-free benzonitrile were also used in this study.

DISCUSSION AND RESULTS

The effect of five α-hydroxynitriles and four esters of mandelonitrile upon the stability of vitamin B_{12} in a liquid multiple vitamin preparation was studied and the results are listed in Table I.

The decomposition of vitamin B_{12} follows first-order kinetics as indicated by the straight line relationship obtained when the concentration of vitamin B_{12} was plotted on a logarithmic scale against the age of the sample (Fig. 1). In order to determine the effect of concentration of α-hydroxynitrile upon the rate of vitamin B_{12} decomposition, several concentrations of *m*-hydroxymandelonitrile were studied and these results are listed in Table II.

TABLE I.—PER CENT OF VITAMIN B_{12} REMAINING AFTER AGING SAMPLE

[3] American Cyanamid Co.

[a] The plot of the log concentration *vs.* storage time changes from one rate to another at 10–12 months; the more rapid reaction rate is given here.

Figure 2 is a graph of $t_{85\%}$ (the time required for vitamin B_{12} concentration to reach 85% of the initial assay value) plotted on a logarithmic scale against the concentration of *m*-hydroxymandelonitrile. The $t_{85\%}$ was calculated from *k* values obtained by drawing the best straight line through the points obtained by plotting log concentration of vitamin B_{12} against the sample age in days. The most rapid change in reaction rate occurred at the lowest concentrations of nitrile. As the amount of of *m*-hydroxymandelonitrile was increased up to 0.1%, successively less change was produced for each unit of α-hydroxynitrile added. This indicates that the reaction rate may be related to the equilibrium reaction between two forms of vitamin B_{12}, cyanocobalamin and a noncyano form.

$$\text{cyanocobalamin} \rightleftharpoons \text{noncyanocobalamin} + [CN^-]$$

$$k = \frac{[\text{noncyanocobalamin}]\,[CN^-]}{\text{cyanocobalamin}}$$

It has been reported that at pH 2.5–3.0 at room temperature pure cyanocobalamin decomposes at the rate of about 1.5% a day in the presence of ascorbic acid, compared with almost complete destruction of hydroxocobalamin (vitamin B_{12a}) in 1 day under similar conditions (2). In the presence of cyanide the equilibrium is shifted toward the more stable cyanocobalamin and away from the less stable compound.

Equilibrium constants have been reported for the dissociation of α-hydroxynitriles (10). These compounds dissociate to a greater extent in aqueous solutions than when water is absent (11). If the dissociation is sufficiently in favor of the formation of cyanide, this in turn will favor the formation of cyanocobalamin

$$\begin{array}{l} \text{RCH} - \text{CN} \rightleftharpoons \text{RCHO} + \text{HCN} \\ \quad\;\; | \qquad\qquad\qquad\quad \Uparrow \\ \quad\;\; \text{OH} \qquad\qquad\qquad\quad \Downarrow \end{array}$$

$$\text{cyanocobalamin} \rightleftharpoons \text{noncyanocobalamin} + \text{HCN}$$

All the compounds employed in this study demonstrated this stabilizing effect on vitamin B_{12} except amygdalin and benzonitrile. Amygdalin would be expected to undergo dissociation more slowly than either free α-hydroxynitriles or the esters. Benzonitrile should not dissociate to form cyanide. Benzoyl mandelonitrile was not as satisfactory a stabilizer as the other esters or free nitriles, possibly because of a slower rate of hydrolysis.

Aqueous cyanocobalamin solutions are stable for long periods of time under ordinary storage conditions, but decompose readily upon exposure to ultraviolet light (12). Solutions which contained 15 mcg. per ml. of cyanocobalamin and from 0.1 to 0.001% of *m*-hydroxymandelonitrile were exposed to ultraviolet irradiation on the Fade-Ometer for periods of up to 96 hours. The results were plotted in Fig. 3 as log per cent of the initial assay against time of exposure.

The rate of decomposition of cyanocobalamin in the presence of α-hydroxynitrile did not follow first-order kinetics as did the control sample. Plots of the decomposition of cyanocobalamin in the

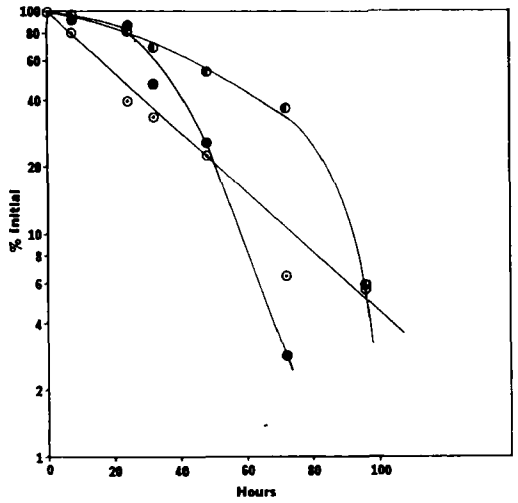

Fig. 5.—Decomposition of vitamin B_{12} in the presence of carbethoxymandelonitrile following exposure to ultraviolet irradiation in the Fade-Ometer. ●, 0.1% carbethoxymandelonitrile; ◐, 0.005% carbethoxymandelonitrile; ⊙, control.

presence of potassium cyanide and *m*-hydroxybenzaldehyde are illustrated in Fig. 4. The reactions in both of these cases follow first-order kinetics. The fact that solutions containing *m*-hydroxymandelonitrile do not follow first-order kinetics suggests that the rate at which equilibrium is reached in the dissociation of the nitrile to the aldehyde and hydrogen cyanide is the factor controlling the rate of decomposition of cyanocobalamin. In the cases where carbethoxymandelonitrile was used, the change in reaction rate was much slower (Fig. 5). This would be expected since hydrolysis of the ester precedes the dissociation of the mandelonitrile. The hydrolysis rate is the rate-controlling step in this reaction. The eventual reaction rate at which vitamin B_{12} decomposes should be that for the equilibrium mixture of aldehyde, hydrogen cyanide and α-hydroxynitrile.

Cyanocobalamin solutions containing α-hydroxynitriles after short periods of irradiation are more stable than the control solution of cyanocobalamin alone. After longer periods of irradiation they are less stable than the control. One explanation for this is that a competition exists between the cobalamin and the aldehyde for the cyanide in solution and that the ratio of cobalamin to free aldehyde is an important factor in the loss of vitamin B_{12} activity. If the effect of cyanide and aldehyde upon the rate of decomposition of cyanocobalamin were independent, the change from a rate slower than the control to one which is faster would not be expected to occur. Cyanide salts are much more effective in stabilizing cyanocobalamin in the presence of ultraviolet light than is cyanide in the form of an α-hydroxynitrile.

Acute oral toxicity in the mouse was obtained for two compounds (Table III). Although these

TABLE III.—ACUTE ORAL TOXICITY OF α-HYDROXYNITRILES IN MICE

	LD_{50}, mg. per Kg.
m-Hydroxymandelonitrile	25.40 ± 1.47
Carbethoxymandelonitrile	34.86 ± 2.34

compounds have a low LD_{50}, they may still be useful because of the low concentration required for vitamin B_{12} stabilization. The optimum concentration for *m*-hydroxynitrile based on both efficacy and toxicity is close to 0.05%. No toxicity studies have been made on pharmaceutical preparations.

SUMMARY

1. α-Hydroxynitriles and esters of mandelonitrile were shown to be effective stabilizers of vitamin B_{12} in a liquid multiple vitamin preparation.

2. *m*-Hydroxymandelonitrile and carbethoxymandelonitrile demonstrated some stabilizing action on vitamin B_{12} solutions which were exposed to ultraviolet irradiation. The initial stabilizing effect is reversed upon longer exposure and, at or before 96 hours, all the samples containing α-hydroxynitriles were decomposing at a greater rate than the control samples.

Dissolution Rates of Finely Divided Drug Powders I

Effect of a Distribution of Particle Sizes in a Diffusion-Controlled Process

By W. I. HIGUCHI† and E. N. HIESTAND

An equation is derived to describe the dissolution rate of a particle with time in a diffusion-controlled dissolution process. This is applied to a hypothetical powder whose particles are approximately log-normally distributed. The change in size distribution with time is shown. Also, the dissolution rate of such a powder is compared with that of a monosized powder whose radius equals the mass median radius of the powder.

THE dissolution rate of many finely divided powders is diffusion controlled. In addition to the diffusion rate constant, the effect of the size distribution must be included in order to calculate the dissolution rate. This paper discusses the use of equations suitable for making these calculations.

THEORY

The Dissolution of a Single Particle.—Several simplifying assumptions enable one to describe the dissolution of a single particle. These assumptions are: (*a*) The dissolution rate is diffusion controlled. (*b*) The diffusion layer thickness is always the same for all particles of the same size and is comparable to or greater than the particle radius. (*c*) The concentration change of dissolved solid in the bulk solution is negligible at all times. (*d*) The effective particle shape approximates a sphere.

From Fick's law of diffusion,

$$\frac{dm}{dt} = D4\pi r^2 \frac{dC}{dr} \qquad \text{(Eq. 1)}$$

where m is the weight of a solid particle, D is the diffusion rate constant, C is the concentration of dissolved solid, t is time, and r is the radius of an imaginary sphere through which the diffusion occurs.

If a is the radius of the particle at time t, then $r > a$. The second assumption, (*b*), implies a quasi-steady state condition in the diffusion layer. Hence, the time required to establish this steady state condition is neglected (see the Appendix). Therefore, one may write

$$\frac{dm}{dt}\int_a^\infty \frac{dr}{r^2} = 4\pi D \int_{C_s}^{C_o} dC$$

C_s is the saturation concentration and C_o is the concentration in the bulk of the solution. Upon integration one obtains

$$\frac{dm}{dt} = -4\pi D a \Delta C \qquad \text{(Eq. 2)}$$

where $\Delta C = C_s - C_o$.

Received March 29, 1962, from Product Research and Development, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication June 18, 1962.
† Present address: School of Pharmacy, University of Michigan, Ann Arbor.

Since it has been assumed that ΔC is independent of time, particle size, a, is the only variable with time. From the volume of the particle, v, and density, ρ

$$\frac{dm}{dt} = \frac{d(v\rho)}{dt} = 4\pi\rho a^2 \frac{da}{dt} \qquad \text{(Eq. 3)}$$

Equating 2 and 3

$$a\rho \frac{da}{dt} = -D\Delta C$$

Let $a = a_o$ at $t = o$, then

$$\int_{a_o}^{a} a\, da = -\frac{D\Delta C}{\rho}\int_o^t dt$$

$$a^2 = a_o^2 - \frac{2D\Delta C t}{\rho} \qquad \text{(Eq. 4)}$$

Equation 4 provides a means of calculating any particle diameter at time t if its radius at zero time is known.

The Total Dissolution Rate.—Let the particle size distribution at zero time be characterized by some function of a_o

$$n = n(a_o) \qquad \text{(Eq. 5)}$$

then the total number of particles, N, in any increment of sizes is

$$N = \int_{a_{so}}^{a_{lo}} n(a_o)\, da_o \qquad \text{(Eq. 6)}$$

where a_{lo} and a_{so} are the largest and smallest particles at zero time in the increment; and by defining a_{so} and a_{lo} as the extremes of the size distribution, N becomes the total number of particles in the entire sample.

The total mass of undissolved drug at

$$t \ll \frac{a_{so}^2 \rho}{2D\Delta C}$$

is

$$M = \int_{a_{so}}^{a_{lo}} 4/3\pi\rho a^3 n(a_o)\, da_o \qquad \text{(Eq. 7)}$$

where a in the integral is given by Eq. 4.

When

$$t > \frac{a_{so}^2 \rho}{2D\Delta C}$$

the lower limit of integration must be changed to correspond to the zero time radius of the particle that has just dissolved at time t, *viz.* a_{ot}

$$a_{ot} = \left(\frac{2D\Delta Ct}{\rho}\right)^{1/2} \qquad \text{(Eq. 8)}$$

Combining Eqs. 4 and 7, and using the lower limit defined in Eq. 8, the amount of undissolved drug at time t is

$$M = \int_{a_{ot}}^{a_{lo}} 4/3\pi\rho\left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o)\, da_o \qquad \text{(Eq. 9)}$$

so the fraction undissolved, Q, at time t is

$$Q = \frac{\int_{a_{ot}}^{a_{lo}} 4/3\pi\rho\left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o)\, da_o}{M_o} \qquad \text{(Eq. 10)}$$

or

$$Q = \frac{\int_{a_{ot}}^{a_{lo}} \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o)\, da_o}{\int_{a_{so}}^{a_{lo}} a_o^3 n(a_o)\, da_o}$$

where M_o is the total weight of solid at zero time.

The Cumulative Distribution Curve.—The use of the cumulative plot of per cent of sample above a given size *vs.* the size is most convenient, especially when the particles are approximately log-normally distributed as they usually are when produced by milling. The fraction larger than a_{io} is given by

$$f > a_{io} = \frac{\int_{a_{io}}^{a_{lo}} 4/3\pi\rho a_o^2 n(a_o)\, da_o}{M_o} \qquad \text{(Eq. 11)}$$

The Change in Size Distribution with Time.—It is possible to evaluate the size distribution at times after the dissolution has started. When

$$t \leqslant \frac{a_{so}^2\rho}{2D\Delta C}$$

$$f > a_i = \frac{\int_{a_{io}}^{a_{lo}} \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o)\, da_o}{\int_{a_{so}}^{a_{lo}} \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o) da_o} \qquad \text{(Eq. 12)}$$

or when

$$t > \frac{a_{so}^2\rho}{2D\Delta C}$$

$$> a_i = \frac{\int_{a_{io}}^{a_{lo}} \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o)\, da_o}{\int_{a_{ot}}^{a_{lo}} \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{3/2} n(a_o) da_o} \qquad \text{(Eq. 13)}$$

Obviously the integrals in Eqs. 12 and 13 are the same form as in Eq. 9 and may be evaluated if Eq. 9 may be evaluated.

The Size Distribution Function.—Equation 5 states that the size distribution is some function of a_o. Equation 9 is sufficiently complex that the integration becomes difficult if the distribution function is not simple. In practice, many materials have particle size distributions that correspond to a relatively simple function of a_o. Such a case will be described in a later publication which gives a test of the theory presented here.

Because many materials when milled produce a size distribution that approximates a log-normal distribution, it would be useful to substitute for $n(a_o)$ the log-normal distribution function. However, this becomes a somewhat complex case.

A log-normal distribution when plotted as n *vs.* a_o gives a skewed curve with the long tail toward the large diameters. In such a case the mass median diameter is much larger than the diameter corresponding to the mode of the histogram. Consequently, most of the mass is present in the region of the distribution where n is increasing as a_o is decreasing. Therefore, distributions approximately log-normal may also be approximately characterized over the region accounting for most of the mass by some inverse power of the radius. Figure 1 shows the reasonable correlation of such a case. This case corresponds to a distribution according to the equation

$$\frac{nv_o}{V_o} = \frac{K'}{a_o} \qquad \text{(Eq. 14)}$$

where $v_o = 4/3\ \pi\ a_o^3$; $V_o = \sum_{a_{so}}^{a_{lo}} nv_o$ and K' is a constant. Hence

$$n = \frac{K}{a_o^4} \qquad \text{(Eq. 15)}$$

where K is another constant.

Note that Fig. 1 was plotted on log-probability paper; a straight line represents a material that is log-normally distributed. A plot of values cal-

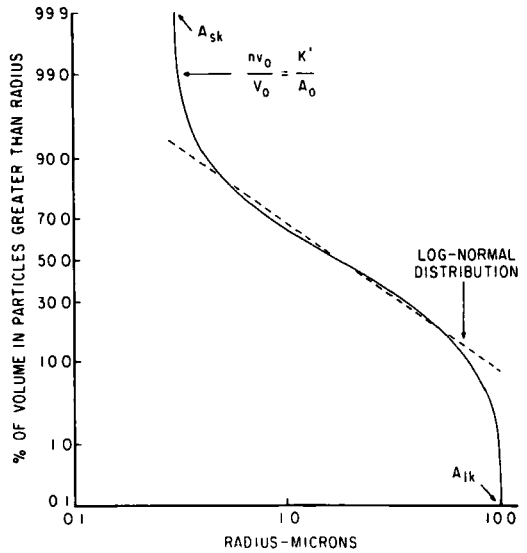

Fig. 1.—Comparison of the log-normal distribution with a simpler case, $n = \frac{K}{a_o^4}$.

culated using Eqs. 1 and 15 fits the log-normal line very closely except for the upper and lower 10% by volume. The contribution of the larger radius 10% to the dissolution will be small except at the very end of the dissolution process and the particles at the small end of the distribution will dissolve very rapidly. Consequently, after they have dissolved completely, these smallest particles will contribute nothing to the solution of Eq. 9. Therefore, deviations from the log-normal case resulting from the use of Eq. 15 are modest, and the general conclusions from its use may be considered to also be approximately true for the log-normally distributed case.

The Dissolution Rate of Powder when $n = K/a_o^4$.—Substituting from Eq. 15 into Eq. 10 and integrating gives

$$Q = \frac{4K\pi\rho}{3M_o}\left(ln\frac{a_{lo}+a_l}{a_{ot}} - \frac{a_l}{a_{lo}} - \frac{a_l^3}{3a_{lo}^3}\right) \quad \text{(Eq. 16)}$$

where

$$a_l = \sqrt{a_{lo}^2 - \frac{2D\Delta Ct}{\rho}}$$

In our hypothetical case we do not have an experimental value for M_o so we must use Eq. 7, which gives

$$M_o = 4/3\pi\rho K\, ln\frac{a_{lo}}{a_{so}} \quad \text{(Eq. 17)}$$

and

$$Q = \frac{1}{ln\left(\frac{a_{lo}}{a_{so}}\right)}\left(ln\frac{a_{lo}+a_l}{a_{ot}} - \frac{a_l}{a_{lo}} - \frac{a_l^3}{3a_{lo}^3}\right) \quad \text{(Eq. 18)}$$

In a real case it might be better to evaluate K to give the best fit to the real size distribution and use the experimental value of M_o in the equation. Of course this leads to some hypothetical values of the largest and smallest radii that correspond with the selected value of K. These we may designate a_{lK} and a_{sK}, respectively. It is necessary that $a_{lK} \geqslant a_{lo}$ and that $a_{sK} \leqslant a_{so}$ where a_{lo} and s_{so} now define the experimental largest and smallest particle in the real sample.

An Illustrative Example.—Figure 2 represents a plot of Eq. 18 when the following values are used: $a_{lo} = 10\mu$; $a_{so} = 0.3\mu$; $\rho = 1.3$ Gm/ml.; $\Delta C = 1 \times 10^{-4}$ Gm./ml.; $D = 5 \times 10^{-6}$ cm²./sec. Note that Q *vs.* log t gives a nearly linear plot over much of the dissolution time.

According to Eq. 4, a_{so} will dissolve completely when

$$t = \frac{(3 \times 10^{-5})^2\, 1.3}{2 \times 5 \times 10^{-6} \times 1 \times 10^{-4}} = 1.17 \text{ sec.}$$

and a_{lo} will dissolve completely when

$$t = \frac{(10 \times 10^{-4})^2\, 1.3}{2 \times 5 \times 10^{-6} \times 1 \times 10^{-4}} = 1300 \text{ sec.} = 21 \text{ min. and } 40 \text{ sec.}$$

Also, Fig. 2 shows the dissolution rate of a material if the entire material is assumed to have the radius of the mass median radius. Obviously, the results of a calculation based on a single particle size do not produce rates similar to those that include the entire size range.

Figure 3 shows the change of a_l and a_{ol} during the dissolution process.

Figure 4 represents the size distributions at the time when approximately half of the solid has dissolved. Obviously, the smallest particles are dissolving most rapidly and the size distribution changes accordingly.

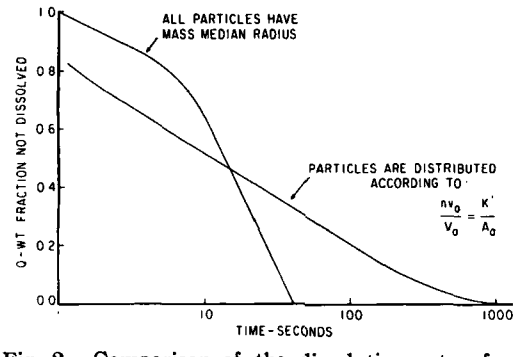

Fig. 2.—Comparison of the dissolution rate of a polydispersed powder with a monodispersed powder.

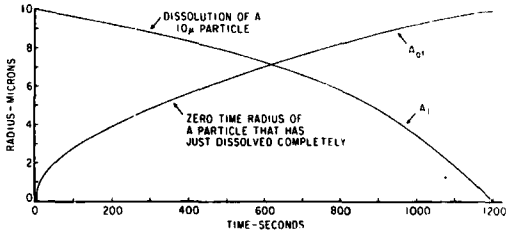

Fig. 3.—Changes in a_l and a_{ol} with time.

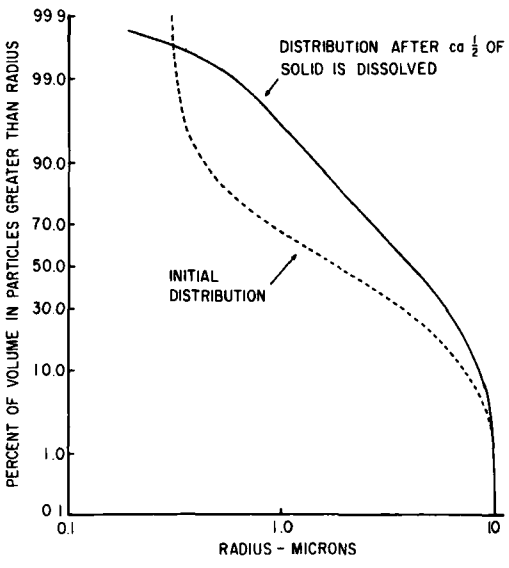

Fig. 4.—Illustration of size distribution changes during dissolution of powder.

Equations 13, 15, and 18 are combined to obtain Eq. 19.

$$> a = \frac{ln \frac{a_{lo} + a_l}{a_o + a} + \frac{a}{a_o} - \frac{a_l}{a_{lo}} + \frac{a^3}{3a_o^3} - \frac{a_l^3}{3a_{lo}^3}}{Q \, ln \frac{a_{lo}}{a_{so}}} \qquad \text{(Eq. 19)}$$

which was used to calculate this plot.

DISCUSSION

In the derivation of Eq. 18, ΔC was considered constant both with time and with particle size. The first requires that the liquid phase be large so that no significant change in concentration results from the dissolved solid. A later communication (1) describes a method of handling this problem when a correction is needed.

The particle size effect on solubility cannot be easily included since many sizes are present at any given time. If one assumes the interfacial tension to be about 50 ergs/cm.^{2}, then a 0.1 μ particle would have a solubility approximately 1.1 times that of a large particle. Usually this does not become significant except when dissolving in a nearly saturated vehicle. Such small particles dissolve so rapidly even when the change in ΔC is neglected that this effect cannot significantly alter the dissolution characteristics of the powder.

APPENDIX

Considerations on the Validity of Equation 2.— The use of the steady state equation to describe this case seems to be justified. The arguments used by Nielsen (2) for the case of crystal growth may be applied here since the growth and dissolution expressions are identical except for sign, as becomes evident in the following:

Fick's law of diffusion is

$$\frac{\partial C}{\partial t} = D\nabla^2 C \qquad \text{(Eq. 1a)}$$

When solved for the boundary conditions for growth it gives

$$C(r,t) = C_o \left[1 - \frac{a}{r} \, erfc \frac{r - a}{2\sqrt{Dt}}\right] \qquad \text{(Eq. 2a)}$$

where

$$erfc \, y = \frac{2}{\sqrt{\pi}} \int_y^\infty e^{-E^2} dE$$

and when solved for the boundary conditions for dissolution it gives

$$c(r,t) = C_o \left[\frac{a}{r} \, erfc \frac{r - a}{2\sqrt{Dt}}\right] \qquad \text{(Eq. 3a)}$$

and from Eq. 1 the gradient across the boundary sphere at $r = a$ is

$$\frac{dm}{dt} = 4\pi a^2 D \left(\frac{\partial C}{\partial r}\right)_{r=a}$$

Obviously, $\partial c/\partial r$ for the two cases differ only in sign.

Equation 2 may be written to include the time dependent term. It becomes

$$\frac{dm}{dt} = 4\pi D \Delta C a \left(1 + \frac{a}{\sqrt{\pi Dt}}\right) \qquad \text{(Eq. 4a)}$$

where the second term in the parenthesis represents the non-steady part, *i.e.*, the time dependent rate. If this term becomes much less than the first term before any significant material has dissolved then the steady state case is a very good approximation.

An estimate of the time, t', required for this term to be negligible is obtained when

$$\int_o^{t'} dt \gg \int_o^{t'} \frac{a dt}{\sqrt{\pi Dt}} \qquad \text{(Eq. 5a)}$$

which gives

$$t' \gg 2a \left(\frac{t'}{\pi D}\right)^{1/2}$$

or

$$t' \gg \frac{4a^2}{\pi D} \qquad \text{(Eq. 6a)}$$

When $a = 1 \times 10^{-4}$ cm. and $D = 5 \times 10^{-6}$ cm.^{2}/sec. as before, then

$$t' \gg 2 \times 10^{-3} \text{ sec.}$$

is the criterion of the time in which very little dissolution should occur if the steady state equation is to be sufficient.

Both Eqs. 4 and 6a involve a^2, so the time criterion changes with the radius in the inverse direction to the rate of change of radius by dissolution. Thus, the effects are compensating.

Equation 4a rigorously applies only when a is constant. Obviously a is constant only when $\Delta C = o$ and in a real case $\Delta C \neq o$. Therefore, one must determine how large ΔC may be before the change in a is important.

The steady state diffusion layer will have a thickness at least equal to a. A significant change in a might be set at level where the change in a is 1% or more of the diffusion layer thickness, *i.e.*, approximately 0.01 a. The change in a necessary to establish the diffusion layer may be estimated by estimating the amount of solid required to form the diffusion layer. Of course, this varies with the magnitude of ΔC. In the case considered here, values of $\Delta C < 1 \times 10^{-2}$ Gm./ml. seem to be sufficient for the constancy of a to be a good approximation for calculating t'.

DEFINITIONS OF SYMBOLS

a = radius of a particle at time t.
a_o = radius of a particle at zero time.
a_{lo} = radius of largest particle at zero time.
a_{so} = radius of smallest particle at zero time.
a_{ot} = zero time radius of largest particle that has completely dissolved at time t.
a_l = $\left(a_{lo}^2 - \frac{2D\Delta Ct}{\rho}\right)^{1/2}$
a_{lK} = hypothetical values of the largest particle corresponding to the value of K.
a_{sK} = hypothetical values of the smallest particle corresponding to the value of K.

a_i = any chosen value of a in the range present.
a_{io} = the zero time radius of a_i.
C = concentration.
C_s = saturation concentration.
C_o = concentration of bulk of solution.
D = diffusion coefficient.
$f>a_o$ = fraction larger than radius, a_o, at zero time.
$f>a$ = fraction larger than radius, a, at time t.
K = a proportionality constant.
$K' = \frac{4\pi K}{3V_o}$
m = mass of a single particle.
M = total mass of undissolved solid.
M_o = total mass of solid at zero time.
n = number of particles of a given size.
N = total number of particles.
Q = fraction of undissolved solid at time t; M/M_o.
r = radius of imaginary sphere through which diffusion occurs.
t = time.
v = volume of a single particle.
$V_o = \frac{M_o}{\rho}$
v_o = volume of a particle of a_o radius at zero time.
π = 3.1416.
ρ = density.

Hypotensive Activity of Certain Diquaternarized Ammonium Compounds as Influenced by Administration Route and Anesthesia

By DAVID W. COATES†, JOSEPH P. BUCKLEY, and WILLIAM J. KINNARD

A three-way crossover experimental design demonstrated that urethan anesthesia enhanced the hypotensive responses of certain diquaternarized ammonium compounds in normotensive rats. The test showed that cardiovascular responses were more significant in hypertensive than in normotensive rats. Barbiturate anesthesia potentiated the hypotensive responses of certain of the compounds in normotensive dogs. Intravenous infusion of two of the compounds into anesthetized normotensive dogs produced a maximum hypotensive effect in 2 minutes with no further lowering of the blood pressure as the infusion was continued.

THE INCOMPLETE absorption following the oral administration of bisquaternary ammonium compounds has long been considered one of the main factors contributing to the erratic results produced by these ganglionic blocking agents in the treatment of arterial hypertension, and strong support for this view was provided by the absorption studies of Levine, *et al.* (1), and Schanker, *et al.* (2). Maxwell, *et al.* (3), reported the relative ineffectiveness of chlorisondamine in lowering the blood pressure of unanesthetized normotensive rats and dogs following intravenous administration. Haas and Goldblatt (4) obtained slight pressor responses in mean femoral arterial blood pressure following the intravenous infusion of tetraethylammonium, hexamethonium, pentolinium, chlorisondamine, and mecamylamine in unanesthetized normotensive dogs. However, these same investigators demonstrated a depressor response with pentolinium during an intermediate period of renal hypertension in dogs (5).

This report deals with the attempt to evaluate several bisquaternary ammonium compounds (Fig. 1) for their oral hypotensive activity in unanesthetized normotensive rats and dogs and in unanesthetized renal hypertensive rats. The experiment was designed to allow comparisons between oral and parenteral administration of the compounds to unanesthetized animals and between parenteral administration to unanesthetized and anesthetized animals.

METHOD

Hypotensive Activity in Normotensive Rats.—Normotensive Wistar rats were trained for indirect systolic blood pressure determinations using the photoelectric tensometer.[1] These rats were then divided into five groups of eight animals each. One of the following compounds was assigned to each

Hypotensive Activity of Certain Diquaternarized Ammonium Compounds as Influenced by Administration Route and Anesthesia

By DAVID W. COATES†, JOSEPH P. BUCKLEY, and WILLIAM J. KINNARD

A three-way crossover experimental design demonstrated that urethan anesthesia enhanced the hypotensive responses of certain diquaternarized ammonium compounds in normotensive rats. The test showed that cardiovascular responses were more significant in hypertensive than in normotensive rats. Barbiturate anesthesia potentiated the hypotensive responses of certain of the compounds in normotensive dogs. Intravenous infusion of two of the compounds into anesthetized normotensive dogs produced a maximum hypotensive effect in 2 minutes with no further lowering of the blood pressure as the infusion was continued.

THE INCOMPLETE absorption following the oral administration of bisquaternary ammonium compounds has long been considered one of the main factors contributing to the erratic results produced by these ganglionic blocking agents in the treatment of arterial hypertension, and strong support for this view was provided by the absorption studies of Levine, *et al.* (1), and Schanker, *et al.* (2). Maxwell, *et al.* (3), reported the relative ineffectiveness of chlorisondamine in lowering the blood pressure of unanesthetized normotensive rats and dogs following intravenous administration. Haas and Goldblatt (4) obtained slight pressor responses in mean femoral arterial blood pressure following the intravenous infusion of tetraethylammonium, hexamethonium, pentolinium, chlorisondamine, and mecamylamine in unanesthetized normotensive dogs. However, these same investigators demonstrated a depressor response with pentolinium during an intermediate period of renal hypertension in dogs (5).

This report deals with the attempt to evaluate several bisquaternary ammonium compounds (Fig. 1) for their oral hypotensive activity in unanesthetized normotensive rats and dogs and in unanesthetized renal hypertensive rats. The experiment was designed to allow comparisons between oral and parenteral administration of the compounds to unanesthetized animals and between parenteral administration to unanesthetized and anesthetized animals.

METHOD

Hypotensive Activity in Normotensive Rats.—Normotensive Wistar rats were trained for indirect systolic blood pressure determinations using the photoelectric tensometer.[1] These rats were then divided into five groups of eight animals each. One of the following compounds was assigned to each

group: JB 654, JB 643, JB 591, JB 676, or chlorisondamine dimethochloride.[2] The compounds were first administered orally to 24-hr. fasted unanesthetized animals in a dose ten times the selected intraperitoneal dose for that particular compound (6). The oral doses selected were as follows: JB 654, 100 mg./Kg.; JB 643, 100 mg./Kg.; JB 591, 250 mg./Kg.; JB 676, 75 mg./Kg.; and chlorisondamine dimethochloride, 5 mg./Kg. Blood pressures were obtained prior to administration of the compounds and periodically as indicated in Table I. After a recovery period of from 3 to 5 days to allow for full elimination of the compounds, these same unanesthetized groups of rats received the compounds by intraperitoneal injection. Blood pressure determinations were again made over the noted period of time. Following the recovery period, these same groups of rats were anesthetized with urethan, 1.2 Gm./Kg. i.p., and control pressures obtained. The compounds were administered by intraperitoneal injection and the effects on systolic blood pressure determined.

All compounds were administered in the form of freshly prepared solutions in distilled water. The concentrations were held constant for each compound, since it has been shown that the concentration is an important factor in oral absorption (7, 8).

The data were grouped into three sections: results following oral administration, results following intraperitoneal administration in unanesthetized rats, and results following intraperitoneal administration in anesthetized rats. The data were then subjected to an analysis of variance (9) to determine any differences between the actions of the compounds within each of the three sections.[3] The analysis also made it possible to demonstrate any effect time had upon the results obtained.

The data were then regrouped and paired comparisons (10) made between the oral and the intraperitoneal unanesthetized results and the intraperitoneal unanesthetized and intraperitoneal anesthetized results for each compound.[4] The values for the comparisons were obtained by totaling the blood pressure responses, noted as the per cent of the control blood pressure, at each time interval following drug administration and dividing by the number of intervals for each of the eight rats in the groups. This can be termed: the Individual Overall Cardiovascular Response (IOCR). A single figure representative of the entire group was determined by

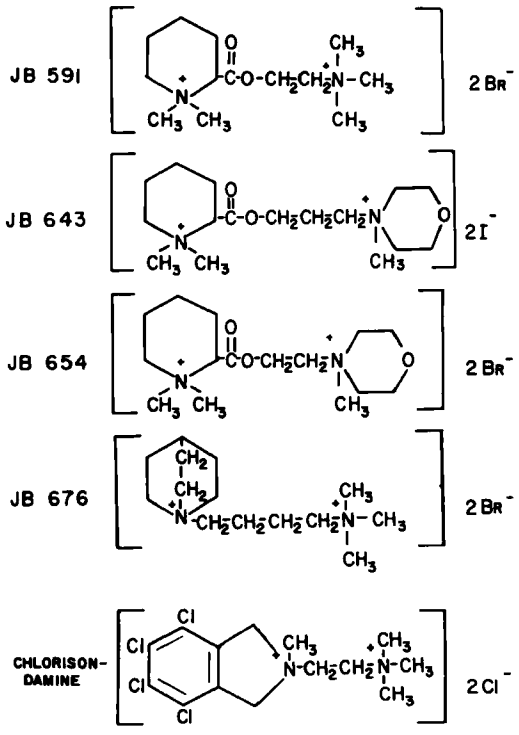

Fig. 1.—Structures of compounds investigated. [a] Each value in the table represents the mean responses of eight rats. [b] Rats anesthetized with urethan 1.2 Gm./Kg. i.p.

dividing the sum total of the IOCR's by the number of subjects in the group. This was termed: Overall Cardiovascular Response (OCR) for that particular compound and method of administration. An OCR less than 100 indicated hypotensive activity while a figure greater than 100 indicated pressor activity.

Hypotensive Activity in Hypertensive Rats.—Hypertensive rats were prepared using a modification of the method of Freed, *et al.* (11). Four to 6 weeks following the simultaneous unilateral nephrectomy and figure-of-eight ligature of the contralateral kidney, weekly injections of desoxycorticosterone trimethylacetate,[5] 0.25 ml. (6.25 mg.), were initiated. Simultaneously, 1% sodium chloride solution was substituted for drinking water. This regimen was continued until a marked and sustained hypertension was produced, as recorded by the photoelectric tensometer. The rats were divided into five groups of eight animals each, and the identical experimental design as that outlined for normotensive rats was employed.

Hypotensive Activity in Normotensive Dogs.—The systolic blood pressures of unanesthetized mongrel dogs were obtained by the method of Prioli and Winbury (12) using the Infratron unit.[6] The dogs were restrained in a specially constructed animal sling which limited movement but did not completely support the animals. The tail was shaved and the coccygeal artery, located on the ventral surface, used as the site of blood pressure determination. A digital cuff was placed at the base of the tail and the microphone of the Infratron unit secured to the tail beneath the coccygeal artery, distal to the cuff, and so adjusted to obtain the best pulse pattern that could be observed on an oscilloscope. Systolic blood pressure was determined by increasing the cuff pressure until the pulse waves disappeared and then slowly reducing this pressure until the pulse pattern was again evident on the oscilloscope. At this point, the cuff pressure in mm. of Hg was recorded as the systolic blood pressure. The experimental design was identical with that utilized in rats except that the number of animals per group was reduced to four, 35 mg./Kg. i.v. of pentobarbital sodium was utilized as the anesthetic, and the compounds were administered orally in capsule form or intravenously.

Intravenous Infusion of JB 591 and JB 676.—Mongrel dogs were anesthetized with 35 mg./Kg. i.v. of pentobarbital sodium and prepared for direct femoral blood pressure determinations in the usual manner. The contralateral femoral vein was isolated and freed of surrounding fascia. An intravenous drip system[7] was fitted with a 20-gauge hypodermic needle and adjusted to deliver 1 ml./min. of the drug solutions. Aqueous drug solutions were prepared in suitable concentrations so that a previously determined total intravenous dose of JB 676 (7.5 mg./Kg.) or JB 591 (25 mg./Kg.) could be delivered over a 20-min. period. Following a stabilization period of at least 30 minutes, the needle was inserted into the vein and the infusion started. Blood pressure recordings were obtained for the 20-min. infusion period.

RESULTS

Hypotensive Activity in Normotensive Rats.—The effects of the diquaternary ammonium compounds on the blood pressure of normotensive rats are summarized in Table I. The compounds did not produce significant hypotensive effects when administered orally or intraperitoneally to unanesthetized normotensive rats. There was no significant difference between any of the compounds when the IOCR data for oral and intraperitoneal activity were analyzed.

Urethan anesthesia enhanced the hypertensive activity of JB 654, JB 676, and chlorisondamine but did not significantly alter the depressor response to JB 591 and JB 643.

Hypotensive Activity in Hypertensive Rats.—The results obtained following the administration of the compounds to hypertensive rats are summarized in Table II. Most of the compounds were active in unanesthetized hypertensive rats in contrast to their relative inertness in unanesthetized normotensive rats. The analysis of variance demonstrated a difference between the activities of the compounds

[5] Supplied as Percorten by Ciba Pharmaceutical Products.
[6] Medical Electronics Development Co.

when administered orally. The OCR's, expressed in per cent of predrug control blood pressure, suggested the following order of decreasing potency: JB 643, 72%; JB 591, 79%; JB 676, 82%; JB 654, 88%; and chlorisondamine, 112%. The maximum hypotensive effects occurred in approximately 60 minutes with JB 591 and JB 676 and 150 minutes with JB 643. There was a marked difference in the response to certain of the compounds when they were administered intraperitoneally to unanesthetized hypertensive rats. The activities of JB 654, JB 643, and JB 591 were similar, their respective OCR's being 82%, 82%, and 79% of the control blood pressure. JB 676 and chlorisondamine produced slight pressor responses. The maximum mean hypotensive effects of the depressor compounds occurred 15 minutes following drug administration.

Analysis of the data obtained from the intraperitoneal administration of the compounds to anesthetized hypertensive rats showed a difference in the hypotensive activity of the compounds. All the agents were active and the following order of decreasing hypotensive activity was suggested: chlorisondamine and JB 654, 50% and 56% of the control; JB 591 and JB 643, 69% and 72%; and JB 676, 80%. Maximum hypotensive activity occurred within 15 minutes for all the compounds except JB 591, which required 30 minutes.

The results of the paired comparisons between the oral and intraperitoneal routes of administration in unanesthetized animals showed the oral route to be significantly more effective in lowering the blood pressure for JB 643 and JB 676. The intraperitoneal route was more active for JB 654 and chlorisondamine, and there was no significant difference between these two routes of administration with JB 591.

When the data obtained from the intraperitoneal administration of the drugs to unanesthetized and anesthetized rats were compared, urethan anesthesia was found to significantly enhance the hypotensive activity of all compounds in the hypertensive animals.

Hypotensive Activity in Normotensive Dogs.—All the compounds produced some degree of hypotension in normotensive dogs (Table III). However, the differences in activity were not significant regardless of the route of administration. The OCR's, reported in per cent of predrug blood pressure, following oral administration were: JB 654, 75%; JB 643, 83%; JB 591, 89%; JB 676, 88%; and chlorisondamine, 94%. The mean depressor responses were maximal at the termination of the experiment (240 minutes).

The intravenous administration of the compounds to unanesthetized dogs produced the following OCR's: JB 654, 79% of the control pressure; JB 643, 81% of the control; JB 591, 75%. The time at which the maximum mean hypotensive effects occurred varied from 15 minutes for JB 654 to 180 minutes for JB 643. The intravenous administration of the compounds to anesthetized normotensive dogs produced the following OCR's: JB 654, 64%; JB 591, 70%; JB 643, 74%; chlorisondamine, 81%; and JB 676, 84%. Time of maximum depressor activity varied from 15 minutes for JB 654 to 120 minutes for JB 643 and chlorisondamine.

The paired comparison of the data obtained with the compounds administered orally and intravenously to the unanesthetized dogs suggest that JB 676 and chlorisondamine were more effective intravenously and JB 654 more effective orally. No significant differences could be demonstrated between the intravenous or oral activities of JB 591 and JB 643.

Analysis of the data obtained when the compounds were administered intravenously to unanesthetized and anesthetized dogs indicated that the anesthetic augmented the hypotensive effects produced by JB 654, JB 591, and JB 676. The anesthetic did not significantly alter the depressor effect of JB 643 and chlorisondamine.

Intravenous Infusion of JB 591 and JB 676.—The results obtained from the intravenous infusion of JB 676 and JB 591 into anesthetized normotensive dogs are recorded in Table IV. JB 676 produced its maximum effect upon blood pressure within 2 minutes in each of the two dogs receiving this drug. The dose delivered at this time was one-tenth of the

total dose or 0.75 mg./Kg. No further decrease in blood pressure was produced over the 20-minute infusion period.

JB 591 produced similar effects in two dogs. The maximum depressor response occurred in less than 2 minutes. The dose delivered at this time was 2.5 mg./Kg. No further decrease in the blood pressure was realized over the remainder of the infusion period. Total dose given was 25 mg./Kg.

DISCUSSION

The results obtained from the administration of the experimental compounds to unanesthetized normotensive rats and dogs indicate that there is some mechanism present in the normotensive animal which is capable of offsetting the expected hypotensive effects of ganglionic blocking agents. Since these agents are all active in anesthetized animals, the nature of the compensatory mechanism would appear to be central in origin. Most of the compounds were active in unanesthetized hypertensive rats indicating that these restorative mechanisms were reduced in the hypertensive animals but not absent since the compounds were even more active in anesthetized hypertensive rats.

No explanation can be offered for the ineffectiveness of chlorisondamine in unanesthetized hypertensive rats. This finding is similar to the results obtained by Maxwell, *et al.* (3), in studies on unanesthetized normotensive rats. However, when chlorisondamine was administered to these animals under barbiturate anesthesia, the compound produced marked sustained falls in both systolic and diastolic blood pressure. Haas and Goldblatt also studied the effects of various ganglionic blocking agents in normotensive (4) and hypertensive (5) dogs. Infusion of tetramethylammonium, hexamethonium, pentolinium, chlorisondamine, and mecamylamine in unanesthetized normotensive dogs resulted in slight pressor responses in mean femoral blood pressure. Pentolinium infusion produced varying effects in renal hypertensive dogs. They noted that pressor responses were obtained following short (2 to 14 days) and long (50 to 103 weeks) periods of hypertension but a depressor response was obtained during an intermediate period (2 to 19 weeks) of hypertension. It is possible that this same pattern of response to ganglionic blocking agents occurs in hypertensive rats. The hypertensive rats used in this study were prepared at approximately the same time and were possibly tested during this intermediate period. An explanation for the hypotensive activity of the experimental compounds and the ineffectiveness of chlorisondamine may be the possible central hypotensive actions of the former compounds. Although JB 654, JB 643, and JB 676 have not been tested in the cross circulation preparation, they are structurally related to JB 591 (see Fig. 1), which has been reported to produce a centrally evoked depressor response (13).

The results obtained from the intravenous infusion of JB 591 and JB 676 in anesthetized normotensive dogs demonstrated a difficulty which might arise in attempting to estimate oral absorption on the basis of activity produced. One-tenth of the previously employed intravenous doses of these compounds produced a maximum hypotensive effect on blood pressure. The remainder of the dose must, therefore, contribute only to maintaining the duration of this maximum effect. If this is also true of oral absorption, then we cannot estimate oral absorption in excess of the amount necessary to produce maximum effects.

SUMMARY

1. The three-way crossover design in normotensive rats demonstrated no significant hypotensive activity following either oral or intraperitoneal administration of the drugs to unanesthetized animals. Urethan anesthesia enhanced the hypotensive responses of JB 654, JB 676, and chlorisondamine.

2. There was a statistically significant difference between the hypotensive activities of the experimental compounds investigated in a three-way crossover test in hypertensive rats. The order of decreasing hypotensive activity following oral administration was: JB 643, JB 591, JB 676, and JB 654. Chlorisondamine produced a pressor response. JB 654, JB 643, and JB 591 produced approximately equal depressor effects upon intraperitoneal administration to unanesthetized hypertensive rats, JB 676 and chlorisondamine produced pressor effects, JB 643 and JB 676 were more active orally, and JB 654 more effective *via* the intraperitoneal route. JB 591 appeared equally active by either route. Urethan anesthesia increased the hypotensive response of all compounds.

3. All the compounds lowered systolic blood pressure of the normotensive dog regardless of the method of administration. The oral route was more active for JB 654 and the intravenous route was more active for JB 676 and chlorisondamine in unanesthetized dogs. Barbiturate anesthesia enhanced the hypotensive responses of JB 654, JB 591, and JB 676 but not those of JB 643 and chlorisondamine.

4. The intravenous infusion of JB 591 and JB 676 in anesthetized normotensive dogs showed the

maximum hypotensive response to occur within 2 minutes and at a dose one-tenth that previously employed. Continued infusion only served to maintain the hypotensive effect.

Pharmaceutical Aspects of a *p*-Aminosalicylate Dialdehyde Starch Compound

By JAMES A. CAMPBELL

A compound resulting from the reaction between sodium *p*-aminosalicylate and dialdehyde starch was investigated. The bland taste and slow rate of dissolution of the compound appeared to offer certain advantages in the administration of NaPAS. The compound was subjected to certain *in vitro* and *in vivo* tests to demonstrate the availability of NaPAS.

THE EFFECT of *p*-aminosalicylic acid upon the tubercule bacillus has been known for a number of years. Bernheim (1) in 1941 observed that benzoic and salicylic acids increased the oxygen consumption of the bacillus. Lehmann (2) discovered that the increased oxygen consumption was accompanied by an inhibition in growth and multiplication, and subsequently found that *p*-aminosalicylic acid was the most effective of a group of related compounds.

A number of salts and other derivatives of the acid have been prepared and investigated (3, 4). Particularly well known are the sodium, potassium, and calcium salts. These salts have the advantage of being more soluble than the acid, and are reputed to be less irritating. Aqueous solutions of the sodium salt are more stable on heating than is a solution of the acid.

Foye and Duvall (5) made a comparative study of the *in vivo* antitubercular activity in mice of cupric and ferrous chelates of PAS. Both compounds were found to be active, but the cupric complex possessed a much higher activity than the ferrous complex.

Due to the large dosage level of PAS (2–4 Gm., with a daily average dose of 12–16 Gm.), the unpleasant taste, the irritant action, and other factors, the administration of PAS is sometimes beset with problems. Intolerance manifested by nausea and vomiting is common with average or large doses (6).

The objective in this effort was to prepare and study a derivative of PAS which might have certain advantages in overcoming the problems associated with the administration of PAS. Dialdehyde starch is known to react with amines and compounds containing the amino group, and the resulting compounds are sometimes noted for their unique properties (7). Dialdehyde starch was thus reacted with sodium PAS and the resulting compound was studied.

EXPERIMENTAL

Formation of the Compound.—A 27.4-Gm. quantity (0.141 mole) of dialdehyde starch (90.4% oxidized; 8.6% moisture) and 24.6 Gm. (0.116 mole) of sodium *p*-aminosalicylate dihydrate was slurried in 100 ml. of dry benzene in a 500-ml. three-necked flask equipped with a stirrer, Barret trap, and condenser. During the refluxing and stirring period of 5 hours, 5.0 ml. of water separated in the Barret trap. After cooling the mixture to room temperature, the pale yellow solid was collected, washed with dry benzene and dried to constant weight in a vacuum oven. Subsequent analysis including infrared spectra showed that a linkage between the compounds had taken place. Total nitrogen and free aldehyde content showed that NaPAS had added to half of the available aldehyde groups. Based upon the action of dialdehyde

Pharmaceutical Aspects of a *p*-Aminosalicylate Dialdehyde Starch Compound

By JAMES A. CAMPBELL

A compound resulting from the reaction between sodium *p*-aminosalicylate and dialdehyde starch was investigated. The bland taste and slow rate of dissolution of the compound appeared to offer certain advantages in the administration of NaPAS. The compound was subjected to certain *in vitro* and *in vivo* tests to demonstrate the availability of NaPAS.

THE EFFECT of *p*-aminosalicylic acid upon the tubercule bacillus has been known for a number of years. Bernheim (1) in 1941 observed that benzoic and salicylic acids increased the oxygen consumption of the bacillus. Lehmann (2) discovered that the increased oxygen consumption was accompanied by an inhibition in growth and multiplication, and subsequently found that *p*-aminosalicylic acid was the most effective of a group of related compounds.

A number of salts and other derivatives of the acid have been prepared and investigated (3, 4). Particularly well known are the sodium, potassium, and calcium salts. These salts have the advantage of being more soluble than the acid, and are reputed to be less irritating. Aqueous solutions of the sodium salt are more stable on heating than is a solution of the acid.

Foye and Duvall (5) made a comparative study of the *in vivo* antitubercular activity in mice of cupric and ferrous chelates of PAS. Both compounds were found to be active, but the cupric complex possessed a much higher activity than the ferrous complex.

Due to the large dosage level of PAS (2–4 Gm., with a daily average dose of 12–16 Gm.), the unpleasant taste, the irritant action, and other factors, the administration of PAS is sometimes beset with problems. Intolerance manifested by nausea and vomiting is common with average or large doses (6).

The objective in this effort was to prepare and study a derivative of PAS which might have certain advantages in overcoming the problems associated with the administration of PAS. Dialdehyde starch is known to react with amines and compounds containing the amino group, and the resulting compounds are sometimes noted for their unique properties (7). Dialdehyde starch was thus reacted with sodium PAS and the resulting compound was studied.

EXPERIMENTAL

Formation of the Compound.—A 27.4-Gm. quantity (0.141 mole) of dialdehyde starch (90.4% oxidized; 8.6% moisture) and 24.6 Gm. starch with other compounds similar to NaPAS (7), the linkage is believed to have occurred according to the equation shown in Fig. 1.

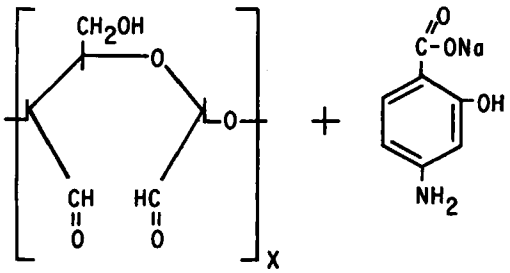
Description of the Compound.—The compound is a pale yellow to light tan powder, having a bland taste. One gram is soluble in 2.85 Gm. of water.



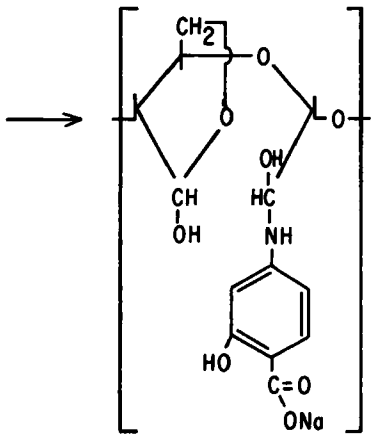


Fig. 1.—Reaction between dialdehyde starch and sodium *p*-aminosalicylate.

Prolonged-Release Experiments.—Accurately weighed, approximately 0.5 Gm., samples of the compound were sealed in small packets made of filter paper (Whatman #41). The packets were heat sealed after application of a heat sensitive adhesive. A packet was then placed in a 1-L. round-bottom flask containing 500 ml. of simulated gastric fluid, T.S. The fluid was stirred constantly with a mechanical stirrer which passed through the neck of the flask by means of a mercury seal. The flask was mounted in a water bath maintained at 37°. At the end of 1 hour and 20 minutes, half of the fluid was removed and replaced by an equal quantity of simulated intestinal fluid, T.S. At the end of 2 hours and 40 minutes, all the fluid was replaced by 500 ml. of fresh intestinal fluid, T.S. Small samples of the fluid were removed by means of a pipet at varying time intervals up to the end

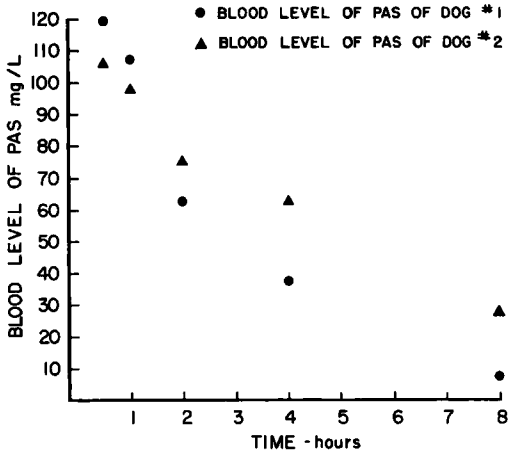

Fig. 3.—Blood levels of free PAS in dogs after oral administration of 100 mg./Kg. of free NaPAS.

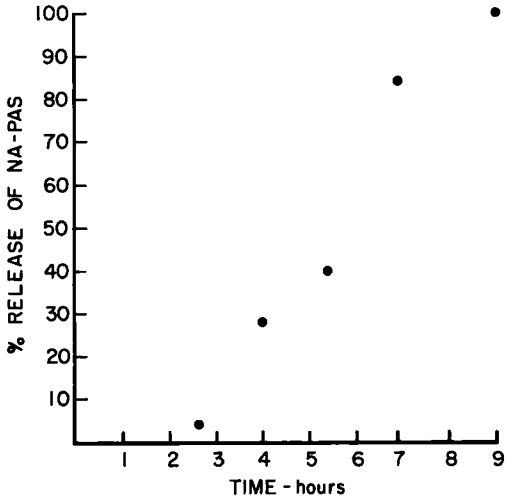

Fig. 2.—Rate of passage of NaPAS from a compound through a filter paper barrier when bathed in simulated gastrointestinal fluids.

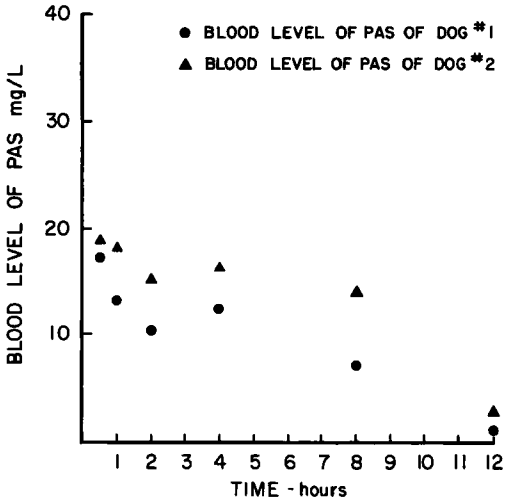

Fig. 4.—Blood levels of free PAS in dogs after oral administration of a quantity of a compound equivalent to 100 mg./Kg. of free NaPAS.

of a 9-hour period from the beginning of the experiment. Each time a sample was removed, an equal volume of fluid was placed back into the flask to maintain a constant volume.

The samples of fluid removed were used to assay for NaPAS content in the following manner. A 5-ml. quantity of the solution to be assayed was placed in a 250-ml. volumetric flask containing 12.5 ml. of concentrated pH 7 buffer (prepared by dissolving 34 Gm. of C.P. anhydrous KH_2PO_4 in 136 ml. of 1 *N* NaOH and diluting to 1000 ml. with distilled water). This was diluted to volume with distilled water and mixed well. A blank was prepared by diluting 5 ml. of concentrated pH 7 buffer to 100 ml. with distilled water. The absorbance of the sample solution was determined at 265 and 299 mμ in a 1.0-cm. quartz cell by means of a Beckman DU spectrophotometer using the blank solution (diluted pH 7 buffer) as the reference liquid.

Calculations

$X = A\text{-}265\ (136.1) = \%$ NaPAS based on absorbance at 265 mμ

$Y = A\text{-}299\ (208.8) = \%$ NaPAS based on absorbance at 299 mμ

$\frac{X + Y}{2} = \%\ C_7H_6NNaO_3$ on anhydrous basis

The rate of passage of NaPAS is shown in Fig. 2. When the free NaPAS was treated under identical conditions, all had passed out of the packet within 1 hour.

PAS Blood Level in Dogs.—Two dogs were administered NaPAS by intubation at a dosage level of 100 mg./Kg. Blood samples were taken at 0, 1/2, 1, 2, 4, and 8 hours. The free PAS content in whole blood was determined by a modified Bratton-Marshall method (8). The concentration of PAS found in the blood is given in Fig. 3. Approximately 10 days later, the compound was administered to the same dogs and with the dosage level being the same in regard to NaPAS content. Blood samples were taken on the same schedule as in the former experiment with additional samples being taken at 12 and 24 hours. The PAS blood levels found are shown in Fig. 4.

SUMMARY AND CONCLUSIONS

Sodium *p*-aminosalicylate was reacted with dialdehyde starch and the resulting compound was characterized. The compound was tested for the rate of passage of NaPAS through a filter paper barrier when bathed in gastrointestinal fluids ranging from all gastric fluid to all intestinal fluid. It was found that very little passed through in the presence of all gastric fluid, but the rate of passage began to increase as part of the fluid was changed to intestinal fluid. The rate of passage appeared to be proportional to the percentage of intestinal fluid. All was found to have passed through at the end of a 9-hour test period.

When the compound was administered to dogs, PAS was detected in the blood during a 12-hour period, but at a lower level than when the uncombined NaPAS was administered.

The bland taste of the compound provides a definite advantage in the problems associated with the administration of NaPAS; however, the lower rate of absorption in the bloodstream of the dog might possibly be considered a disadvantage. The question as to the efficacy of the compound in the *in vivo* control of tuberculosis is yet to be determined.

Synthesis and Local Anesthetic Activity of Several Dialkylaminoalkyl Esters of Indole Carboxylic Acids

By SAMUEL ELKIN† and FRANCIS M. MILLER

The largest number of compounds synthesized for local anesthetic purposes are the alkamine esters of aromatic acids. In this work, two indole carboxylic acids were incorporated as the acid portion of the ester. All the compounds were effective as topical anesthetics, but had no action on unbroken skin. Nitration of indole-3-carboxylic acid reduced the duration of activity of the esters. The esters of indole-2-carboxylic acid showed a marked decrease in duration of local anesthetic activity.

At present, most of the compounds synthesized for local anesthetic purposes are alkamine esters of aromatic acids. They furnish the preponderant number of marketable local anesthetics.

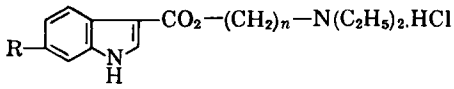
While procaine is relatively low in toxicity and very effective when given hypodermically (1), it requires the addition of a vasopressor substance to help localize the drug at the nerve and thereby prolong the period of anesthesia. Procaine is also only very slightly active as a topical anesthetic. Hence, many compounds of the same general type have been synthesized to improve these properties.

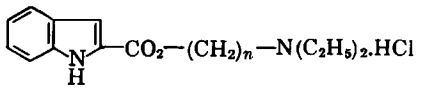
Among the modifications studied are included those which contain a heterocyclic aromatic ring in the acid portion of the molecule. Blicke and Jenner (2) prepared several dialkylaminoalkyl nicotinates, 2-alkyl acid quinolates, and 2-alkyl-3-dialkylaminoalkyl quinolates. They reported that none of these compounds possessed marked activity as local anesthetics.

Blicke and Blake (3) found that the local anesthetic action of a procaine-type compound can be retained by the substitution of a 2-pyrrolyl moiety for the benzoyl and 4-aminobenzoyl groups and by the replacement of dimethyl and diethylamino groupings by 1-pyrrolyl and 1-pyrollidinyl nuclei.

Burtner and Lehmann (4) investigated a series of alkylaminoalkyl esters of carbazole, dibenzfuran, and dibenzthiophene carboxylic acids. They prepared several effective local anesthetics. The best one of the series was β - diethylaminoethyl - 5 - ethylcarbazole - 3 - carboxylate hydrochloride. However, all of the foregoing were irritating and could not be regarded as useful anesthetics. An interesting conclusion which Burtner and Lehmann were able to derive from their investigations was that the activity of the compounds they prepared appeared to be predominantly a function of the carboxyl group rather than of other structural features. That is, equal concentrations of derivatives of carbazole-2- and carbazole-3-carboxylic acids were equally effective. However, the derivatives of carbazole-4-carboxylic acid showed no anesthetic activity.

In this investigation the following dialkylaminoalkyl esters of indole-3-carboxylic acid and indole-2-carboxylic acid have been prepared





I, R = H, n = 2; II, R = H, n = 3; III, R = NO_2, n = 2; IV, R = NO_2, n = 3; V, n = 2; VI, n = 3. The effectiveness of these compounds as local anesthetics has been determined. II showed the most pronounced activity followed by I.

The esters were prepared essentially according to the method of Burtner and Cusic (5). The indole carboxylic acids were dissolved in hot isopropanol and either 2-diethylaminoethyl chloride or 3-diethylamino-1-propyl chloride was added to the refluxing solution. The mixture was allowed to reflux for $2^1/_2$ hours and then cooled overnight. The method of isolation of the resulting compounds varied because of the difference in their solubility.

EXPERIMENTAL

Indole-3-carboxylic Acid (6, 7).—Into a thoroughly dried 1-L. flask equipped with stirrer, dropping funnel, and condenser (drying tube) were placed 12 Gm. (0.5 mole) of magnesium turnings, 100 ml. of anhydrous ether, and a small crystal of iodine as catalyst. Ethyl iodide, 5 Gm., was added all at

TABLE I.—COMPILED DATA ON THE ESTERS PREPARED

Ester	Yield, %	M.p., °C.	Formula	Analysis N Calcd.	Analysis N Found
I	25.0	174–175	$C_{15}H_{21}N_2O_2Cl$	9.44	9.27
II	21.8	165–167	$C_{16}H_{23}N_2O_2Cl$	9.01	8.80
III	15.6	210–212	$C_{15}H_{20}N_3O_4Cl$	12.30	12.62
IV	15.1	208–210	$C_{16}H_{22}N_3O_4Cl$	11.81	12.13
V	6.2	178–180	$C_{15}H_{21}N_2O_2Cl$	9.44	9.31
VI	17.5	170–171	$C_{16}H_{23}N_2O_2Cl$	9.01	9.06

once and, after a few moments, the yellow color of the iodine disappeared and the ether began to boil. The reaction was controlled by periodic cooling in an ice bath. An additional 75 Gm. (0.5 mole, total) of ethyl iodide was then added dropwise. Stirring was maintained after the addition of the ethyl iodide for about 1/2 hour or until the reaction mixture cooled to room temperature.

An ice-salt bath was applied and 29.5 Gm. (0.25 mole) of indole in 40 ml. of anhydrous ether was added gradually with vigorous stirring. Ethyl chlorocarbonate, 30 Gm. (0.28 mole), was then added dropwise to the cooled solution of indolylmagnesium iodide. The mixture was kept cold and stirring was maintained for an hour after the addition of the ethyl chlorocarbonate. Ice water was added very slowly and the resulting mixture was acidified with acetic acid and the ether layer separated. The ether solution was washed with sodium bicarbonate and dried over sodium sulfate.

Removal of the ether under reduced pressure left a red oily residue of the ethyl ester. This was not purified, but was hydrolyzed by refluxing for 2 1/2 hours with 100 ml. of 0.5 *N* potassium hydroxide. The aqueous solution was separated from a gummy residue that formed, acidified with acetic acid whereby indole-3-carboxylic acid precipitated. The product was transferred to a beaker and washed with a little ether and petroleum ether to remove any unreacted indole. The acid was filtered and recrystallized from a 40% aqueous ethanol solution. Yield, 19 Gm. (47.5%); m.p., 218–220°. Reported m.p., 218–220° (6); 220–224° (8).

6-Nitroindole-3-carboxylic Acid.—Ten grams (0.06 mole) of indole-3-carboxylic acid was suspended in 50 ml. of glacial acetic acid contained in a 600-ml. beaker. A 50-ml. quantity of concentrated nitric acid was added dropwise with stirring. During the addition of the nitric acid the mixture turned a deep red and began to boil. The reddish-brown residue was collected after cooling overnight. This was dissolved in hot ethanol and treated with charcoal. After filtering, water was added to the alcoholic solution and a bright yellow product precipitated. Yield, 4 Gm. (31.2%); darkened at 223° and decomposed at 275–280°. Reported, darkening at 227° and decomposing at 275–280° (7).

Indole-2-carboxylic Acid.—Prepared from *o*-nitrophenyl-pyruvic acid (9) upon boiling with ferrous sulfate in ammonium hydroxide (10). M.p. 197–200°. Reported m.p., 202–204° (10).

2-Diethylaminoethyl Chloride.—Prepared according to Shirley (11) from 2-diethylaminoethyl chloride hydrochloride by treatment with sodium hydroxide and extraction with ether; b.p., 146–148°/756 mm. Reported b.p., 146–147°/750 mm. (11).

3-Diethylamino-1-propyl Chloride.—Prepared in the same manner as indicated under 2-diethylaminoethyl chloride. The free base, a colorless oil distilled at 94–95°/42 mm. Reported b.p., 82°/28 mm. (12).

2-Diethylaminoethyl Indole-3-carboxylate Hydrochloride (I)[1].—Into a 300-ml. flask equipped with stirrer, dropping funnel, and condenser were placed 5 Gm. (0.031 mole) of indole-3-carboxylic acid and 80 ml. of isopropanol. The acid dissolved upon heating. The solution was allowed to reflux and 4.2 Gm. (0.03 mole) of 2-diethylaminoethyl chloride was added dropwise. The mixture was refluxed for 2 1/2 hours and allowed to cool overnight. A white precipitate formed which was filtered off and washed with anhydrous ether. Recrystallization from isopropanol gave a product which was very readily soluble in water.

3-Diethylaminopropyl Indole-3-carboxylate Hydrochloride (II).—Into a 300-ml. flask equipped with stirrer, dropping funnel, and condenser were placed 4.5 Gm. (0.028 mole) of indole-3-carboxylic acid and 75 ml. of isopropanol. The acid dissolved upon heating. The solution was allowed to reflux and 4.2 Gm. (0.028 mole) of 3-diethylamino-1-propyl chloride was added dropwise. The mixture was refluxed for 2 1/2 hours and allowed to cool overnight. No precipitation resulted. The solvent was removed under reduced pressure leaving a reddish oil. The oil was washed several times with anhydrous ether whereupon it became semisolid and almost white. The compound was then treated with isopropanol and a small amount of anhydrous ether, and a white solid precipitated upon scratching. The product was recrystallized from absolute ethanol and ether.

All esters were prepared in a manner described above. Pertinent data are presented in Table I.

Pharmacological Procedures.—The hair around the rabbit's eye was carefully clipped. The winking reflex was tested by gently touching the center of the cornea with a bluntly pointed glass rod. Four drops (equivalent to 1.4 mg.) of 1% aqueous test

TABLE II.—LOCAL ANESTHETIC ACTIVITY OF THE DIALKYLAMINOALKYL ESTERS PREPARED

Ester	Trials	Minimum Duration, min.	Maximum Duration, min.	Average
I	35	68	152	94.2
II	18	83	141	117.0

[1] *Note added in galley proof:* J. Büche, *et al.*, *Arch. Pharmazie*, **295**, 209(1962), report the preparation of 2-diethylaminoethyl indole-3-carboxylate hydrochloride and the corresponding 6-nitro derivative.

solution was instilled into the conjunctival sac of the left eye by means of a pipet (28 drops per ml.). The right eye was maintained as a control. The solution was allowed to remain in contact with the surface of the eyeball for 2 minutes by gently pressing the lids together. The time of abolishment of the wink reflex was noted and the duration of anesthesia was tested at 2-minute intervals.

RESULTS

None of the compounds gave any evidence of any deleterious action on the eye. The eyes were carefully checked for corneal pitting, excessive lacrimation, and hyperemia. None of these was present. Pharmacological data are presented in Table II.

SUMMARY

Several dialkylaminoalkyl esters of two indole carboxylic acids were prepared. All of the compounds were effective as topical anesthetics, but had no action on unbroken skin. Nitration of indole-3-carboxylic acid reduced the duration of activity of the esters. The esters of indole-2-carboxylic acid showed a marked decrease in duration of local anesthetic activity.

Synthesis of Some Hydrazono Derivatives of *p*-[N,N-Bis(β-chloroethyl)amino]benzaldehyde

By HENRY C. KOPPEL, ROBERT H. SPRINGER, G. DOYLE DAVES, Jr., and C. C. CHENG

THE CONDENSATION of *p*-[N,N-bis(β-chloroethyl)amino]benzaldehyde (1, 2) (I, benzaldehyde nitrogen mustard) with active methylene groups, (2, 3, 4) hydrazides (2) and amines (5, 6) have been reported. Recent discovery of the activity of some anil derivatives against Dunning leukemia in rats (6) and the inhibitory effect of 8-[bis(β-chloroethyl)triazeno]theophylline (II) (7) on spontaneous tumor (8) prompted the synthesis of some benzalhydrazone derivatives (III) for biological evaluation.

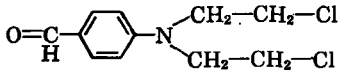
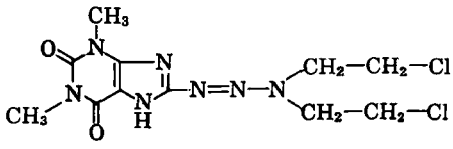
Synthesis of Some Hydrazono Derivatives of *p*-[N,N-Bis(β-chloroethyl)amino]benzaldehyde

By HENRY C. KOPPEL, ROBERT H. SPRINGER, G. DOYLE DAVES, Jr., and C. C. CHENG

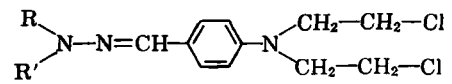
THE CONDENSATION of *p*-[N,N-bis(β-chloroethyl)amino]benzaldehyde (1, 2) (I, benzaldehyde nitrogen mustard) with active methylene groups, (2, 3, 4) hydrazides (2) and amines (5, 6) have been reported. Recent discovery of the activity of some anil derivatives against Dunning leukemia in rats (6) and the inhibitory effect of 8-[bis(β-chloroethyl)triazeno]theophylline (II) (7) on spontaneous tumor (8) prompted the synthesis of some benzalhydrazone derivatives (III) for biological evaluation.



I



II



III

The preparation of III, together with the starting materials used, is described in the experimental section.

EXPERIMENTAL[1]

Synthesis of Hydrazinopyrimidines.—To a mixture of 35 Gm. of chloropyrimidine in 70 ml. of absolute ethanol was added, with stirring, 35 ml. of anhydrous hydrazine at such a rate that the reaction temperature remained at 65–75° (occasional cooling in an ice bath may be necessary). After the addition was complete, the resulting solution was stirred at room temperature for 30 minutes, during

Received April 14, 1962, from Midwest Research Institute, 425 Volker Boulevard, Kansas City, Mo.
Accepted for publication May 21, 1962.
This investigation was supported by research contract SA-43-ph-3025 from the Cancer Chemotherapy National Service Center, National Cancer Institute of the National Institutes of Health, Public Health Service.
The authors wish to express their appreciation to Professor Roland K. Robins of Arizona State University for helpful suggestions, and to Mr. Hal P. Van Fossen, Mrs. Margaret L. Rounds, Mrs. Carol R. Tuttle, and Mrs. Phyllis G. Lewis for their valuable assistance in performing analytical and instrumental measurements.

[1] All melting points were taken on the Thomas-Hoover melting point apparatus.

which time crystallization took place. The reaction mixture was diluted with 200 ml. of ethanol and filtered. The solid product was washed well with ethanol and ether. The resulting hydrazinopyrimidine was of sufficient purity to be used for the preparation of hydrazones.

5-Bromo-4,6-di(hydrazino)pyrimidine was thus obtained from 5-bromo-4,6-dichloropyrimidine (9) in 46% yield, m.p. 150° dec.

Anal.—Calcd. for $C_4H_7BrN_6$: N, 38.3 Found: N, 38.5.

Similarly 5 - bromo - 4 - hydrazino - 2 - (methylthio) pyrimidine was prepared from 5-bromo-4-chloro-2-methylthiopyrimidine (10) in 35% yield, m.p. 148–150°.

Anal.—Calcd. for $C_5H_7BrN_4S$: N, 24.0. Found: N, 24.1.

2 - (Hydrazinomethyl)naphthimidazole.—To 75 ml. of anhydrous hydrazine was added, portionwise, 30 Gm. of 2-chloromethylnaphthimidazole [prepared by the method of Bloom and Day (11), using 2,3-naphthalenediamine rather than *o*-phenylenediamine] at such a rate that the reaction temperature remained below 80°. Crystallization began after the addition was complete. The reaction mixture was allowed to stand at room temperature for 20 minutes, diluted with 200 ml. of ethanol and filtered. The product was washed with ethanol and ether, and recrystallized from a mixture of dimethylformamide and water to give 14 Gm. of light yellow crystals, m.p. 245° dec.

Anal.—Calcd. for $C_{12}H_{12}N_4 \cdot H_2O$: N, 24.3. Found: N, 24.0.

5-Uracilcarbohydrazide was similarly prepared from 60 ml. of anhydrous hydrazine and 35 Gm. of 5-carbethoxyuracil (12) to yield, after recrystallization from dilute hydrochloric acid, 13 Gm. of white prisms, m.p. 245° dec.

Anal.—Calcd. for $C_5H_6N_4O_3 \cdot HCl$: N, 27.2. Found: N, 27.0.

General Method for the Preparation of *p*-[N,N-Bis(β - chloroethyl)amino]benzalhydrazone Derivatives (III).—To 250 ml. of absolute ethanol was added 0.04 mole of substituted hydrazine. The mixture was heated till solution took place (for those hydrazines that are insoluble in absolute ethanol, 80% aqueous ethanol was substituted). The solution was treated with charcoal and filtered. To the filtrate, heated at 60°, 0.04 mole of *p*-[N,N-bis(β - chloroethyl)amino]benzaldehyde (1, 2) dissolved in 250 ml. of absolute ethanol was added with stirring followed by two drops of concentrated hydrochloric acid. A precipitate appeared almost immediately. Stirring was continued for 5 minutes and the reaction mixture was filtered. The solid was washed with ethanol and ether, and dried *in vacuo* to give the desired product of analytical purity.

The following compounds were prepared:

2 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazono}pyrimidine, m.p. 187–188°, was prepared from 2-(hydrazino)pyrimidine (13) in 52% yield.

Anal.—Calcd. for $C_{15}H_{17}Cl_2N_5$: C, 53.2; H, 5.2; N, 20.7. Found: C, 53.5; H, 5.2; N, 20.4.

4 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazono} - 6 - chloropyrimidine, m.p. 295–297°, was prepared from 6-chloro-4-hydrazinopyrimidine (9) in 86% yield.

Anal.—Calcd. for $C_{15}H_{16}Cl_3N_5$: C, 48.3; H, 4.3; N, 18.7. Found: C, 48.5; H, 4.3; N, 18.9.

5 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazono}uracil, m.p. 225° dec., was prepared from 5-hydrazinouracil hydrochloride (14) in cold water in 74% yield.

Anal.—Calcd. for $C_{15}H_{17}Cl_2N_5O_2$; C, 48.4; H, 4.6; N, 18.8. Found: C, 48.8; H, 4.7; N, 18.7.

5 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazonocarbonyl}uracil, m.p. 290° dec., was prepared from 5-uracilcarbohydrazide hydrochloride in 56% yield.

Anal.—Calcd. for $C_{16}H_{17}Cl_2N_5O_3$: C, 48.2; H, 4.3; N, 17.6. Found: C, 48.3; H, 4.5; N, 17.6.

6 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazonocarbonyl}uracil, m.p. 182° dec., was prepared from orotic acid hydrazide (15), using dimethylformamide as solvent, in 79% yield.

Anal.—Calcd. for $C_{16}H_{17}Cl_2N_5O_3 \cdot H_2O$: C, 46.1; H, 4.6; N, 16.8. Found: C, 46.0; H, 4.7; N, 16.4.

2 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazono}benzothiazole, m.p. 197–199°, was prepared from 2-hydrazinobenzothiazole (16) in 43% yield as light yellow crystals.

Anal.—Calcd. for $C_{18}H_{18}Cl_2N_4S$: C, 55.0; H, 4.5; N, 14.2. Found: C, 55.3; H, 4.8; N, 13.9.

2 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazonomethyl}naphthimidazole, m.p. 225° dec., was prepared from 2-(hydrazinomethyl)-naphthimidazole in 56% yield as white crystals.

Anal.—Calcd. for $C_{23}H_{23}Cl_2N_5$: C, 62.7; H, 5.2; N, 15.9. Found: C, 62.3; N, 5.4; N, 16.3.

4 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazonosulfonyl}toluene, m.p. 179–181°, was prepared from *p*-toluenesulfonyl hydrazide (17) in 75% yield as light orange crystals.

Anal.—Calcd. for $C_{18}H_{21}Cl_2N_3O_2S$: C, 52.2; H, 5.2; N, 10.2. Found: C, 52.2; H, 5.2; N, 10.0.

Di - {*p* - (N,N - bis(β - chloroethyl)amino]benzal}oxalic carbohydrazone, m.p. 244–245°, was prepared from oxalyl hydrazide (18) in 77% yield as light yellow crystals.

Anal.—Calcd. for $C_{24}H_{28}Cl_4N_6O_2$: C, 50.2; H, 4.9; N, 14.6. Found: C, 50.3; H, 5.2; N, 14.2.

4 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzalhydrazono}benzoic acid, m.p. 226–228°, was prepared from *p*-(hydrazino)benzoic acid (19) in 74% yield.

Anal.—Calcd. for $C_{18}H_{19}Cl_2N_3O_2$: C, 56.9; H, 5.0; N, 11.0. Found: C, 57.1; H, 5.3; N, 10.8.

4 - {*p* - [N,N - Bis(β - chloroethyl)amino]benzal}thiosemicarbazone, m.p. 189–191°, from thiosemicarbazide in 63% yield as light yellow crystals.

Anal.—Calcd. for $C_{12}H_{16}Cl_2N_4S$: C, 45.2; H, 5.0; N, 17.5. Found: C, 45.4; H, 5.1; N, 17.2.

3- Methyl - 6(1′ - methyl - 2′ - {*p* - [N,N - bis(β-chloroethyl)amino]benzal}hydrazono) - 2 - (methylthio)-4(3H)pyrimidinone, m.p. 218°, was prepared from 3 - methyl - 6 - (1′ - methylhydrazino) - 2 - (methylthio) - 4(3H)-pyrimidinone (20) in 80% yield as light brown crystals.

Anal.—Calcd. for $C_{18}H_{23}Cl_2N_5OS$: C, 50.5; H, 5.4; N, 16.4 Found: C, 50.3; H, 5.6; N, 16.8.

3 - Methyl - 6 - (1′ - methyl - 2′ - {*p* - [N,N-bis(β - chloroethyl)amino]benzal}hydrazono)uracil, m.p. 239°, was prepared from 3-methyl-6-(1′-methylhydrazino)uracil (20) in 50% yield.

Anal.—Calcd. for $C_{17}H_{21}Cl_2N_5O_2$: C, 51.3; H, 5.3; N, 17.6. Found: C, 51.3; H, 5.5; N, 17.5.

3-Methyl-6-(1′-methyl-2′-{*p*-[N,N-bis(β-chloroethyl)amino]benzal} - hydrazino) - 5 - (phenylazo) uracil, m.p. 204°, was obtained from 3-methyl-6-(1′-methylhydrazino)-5-(phenylazo)uracil (20) in 48% yield.

Anal.—Calcd. for $C_{23}H_{25}Cl_2N_7O_2$: C, 55.0; H, 5.0; N, 19.5. Found: C, 54.8; H, 4.9; N, 19.7.

The following compounds were prepared by essentially the same procedure except that 5 ml., rather than two drops, of concentrated hydrochloric acid was added to the reaction mixture. As a result, the desired product was isolated as its hydrochloride.

4 - {*p* - [N,N - Bis(β - chloroethyl)amino] benzalhydrazono} - 5 - bromo - 2 - methylthiopyrimidine hydrochloride, m.p. 210–213° dec., was prepared from 5 - bromo - 4 - hydrazino - 2 - methylthiopyrimidine in 56% yield.

Anal.—Calcd. for $C_{16}H_{18}BrCl_2N_5S \cdot HCl$: C, 38.5; H, 3.8; N, 14.1. Found: C, 38.7; H, 4.0; N. 14.5.

2,4 - Di - {*p* - [N,N - bis(β - chloroethyl)amino]-benzalhydrazono}pyrimidine dihydrochloride, m.p. 180° dec., was prepared from 2,4-di(hydrazino)-pyrimidine (21) in 40% yield.

Anal.—Calcd. for $C_{26}H_{30}Cl_4N_8 \cdot 2HCl$: C, 46.8; H, 4.8; N, 16.8. Found: C, 46.5; H, 4.7; N, 16.7.

2,4 - Di - {*p* - [N,N - bis(β - chloroethyl)amino]-benzalhydrazono} - 6 - methylpyrimidine hydrochloride, m.p. 190° dec., was prepared from 2,4-di(hydrazino)-6-methylpyrimidine (22) in 67% yield.

Anal.—Calcd. for $C_{27}H_{32}Cl_4N_8 \cdot HCl$: C, 50.1; H, 5.1; N, 17.3. Found: C, 49.7; H, 5.4; N, 17.3.

5 - Bromo - 4,6 - di{*p* - [N,N - bis(β - chloroethyl)-amino]benzalhydrazono}pyrimidine hydrochloride, m.p. 207° dec. was prepared from 5-bromo-4,6-di-(hydrazino)pyrimidine in 79% yield.

Anal.—Calcd. for $C_{26}H_{29}BrCl_4N_8 \cdot HCl$: C, 43.8; H, 4.4; N, 15.8. Found: C, 43.4; H, 4.8; N, 15.8.

SUMMARY

A number of hydrazono derivatives of *p*-[N,N-bis(β-chloroethyl)amino]benzaldehyde have been synthesized. The compounds have been submitted for general screening at the Cancer Chemotherapy National Service Center.

Isolation of Acetyldigitoxin

By OLE GISVOLD

A method for the convenient isolation of acetyldigitoxin from *Digitalis mertonensis* and *D. siberica* is described. The former yielded acetyldigitoxin in approximately twice the amount of digitoxin that could be isolated from *D. purpurea*.

PREVIOUS reports (1) on the nature of the chief desglucoglycosides of *Digitalis mertonensis*[1] yielded somewhat inconclusive results. In these investigations both fresh and dried leaves were used together with a number of different extraction conditions and solvents to prepare the primary extracts. Both acetyldigitoxin and digitoxin, when combined, represented the major desglucoglycosides. In one case it was chiefly digitoxin, in another, it was chiefly acetyldigitoxin. It now has been demonstrated that when a primary extract of fresh leaves of *D. mertonensis* is made with 35 per cent methanol and the subsequent purification steps carried out with care, acetyldigitoxin is the chief desglucoglycoside that can be detected and subsequently isolated in good yield. The leaves must be in a healthy condition and free from damaged or partially damaged leaves. Where any amounts of the

[1] See *New Phytologist*, **31**, 225(1932).

latter were present, digitoxin also could be detected. Leaves that had been dried rapidly at 50° in 1958 and 1961 yielded chiefly acetyldigitoxin together with very small amounts of digitoxin. Leaves that had been dried less rapidly in 1958, 1959, and 1960 yielded larger amounts of digitoxin together with acetyldigitoxin. Leaves dried at 70° gave results comparable to those dried rapidly at 50°. Drying at 70° was prompted by the discovery (unpublished data) that when *D. siberica* was dried under these conditions the chief desglucoglycoside was digitoxin, while the chief native glycoside is lanatoside A. In the limited number of conditions used to dry the leaves of *D. mertonensis*, varying amounts of deacetylation occurred. As a continuation of this project other drying conditions shall be studied in order to determine if deacetylation can be completely avoided and also if complete deacetylation can be effected. In the latter case, this would lead to the convenient isolation of digitoxin which occurs in about twice the amount that occurs in *D. purpurea* grown in Minnesota.

The chief objective of this report is to describe the convenient isolation of acetyldigitoxin from *D. mertonensis* and *D. siberica*. These techniques also were applied to the isolation of digitoxin from *D. purpurea* with marked success. Aqueous methanol 35 per cent was chosen to prepare an initial (primary) extract in all cases. The desired desglucoglysides readily could be extracted from this initial extract with methyl isoamyl ketone (MIAK). The latter solvent was chosen also because it removed a minimum amount of undesirable substances, can be recovered in good yield, and is not as hazardous as some organic solvents. The initial extract from dried leaves of *D. mertonensis* that had been stored for several years contained degradation products of chlorophyll that carried over into the MIAK extracts and subsequently proved somewhat troublesome. This was not true with freshly dried leaves. Initial extraction of the dry leaves with benzene[2] did not prove advantageous. Extraction of the initial extract with isopropyl ether readily removed these troublesome pigments together with small amounts of acetyldigitoxin and digitoxin. This step may or may not prove advantageous, depending upon the amount of colored degradation products that might be encountered in the primary extract. In the case of carefully collected fresh leaves or carefully dried leaves that are soon used, the extraction with isopropyl ether is not necessary.

[2] With the hope that the benzene soluble degradation products of chlorophyll could be eliminated.

In an attempt to shorten the isolation procedure, the MIAK extract from the primary extract was extracted with aqueous alkali to remove certain yellow pigments. This modification did not lead to deacetylation of acetyldigitoxin if the aqueous alkaline phase was rapidly separated from the MIAK phase. However, fewer pigments were removed by this technique than when they were removed from a mixture of ether-methylene dichloride (3:1).

EXPERIMENTAL

The details of the paper chromatographic techniques used in these studies have been described previously (2). Both solvent systems I and II were used for the development of the paper chromatograms. The Raymond reagent, Kedde reagent, or Jensen's trichloroacetic acid reagent (3) were used to detect the position of the glycosides on the paper. The Raymond reagent readily detected digitoxin and acetyldigitoxin, however, gitoxin was difficult to detect by this reagent. This no doubt was due to the poor solubility of gitoxin. The Kedde reagent readily detected gitoxin and when equal amounts of digitoxin and gitoxin were spotted on paper and then treated with the Kedde reagent, the color intensities were comparable in both cases.

THE ISOLATION OF ACETYL DIGITOXIN

The leaves of *D. mertonensis* collected in the fall of 1961 were rapidly dried at 50° with aid of a fan. The powdered leaves, 250 Gm., were macerated overnight with 1 L. of 35% methanol. The next day they were packed in a percolator, percolated slowly with 35% methanol, and 1500 ml. of percolate was collected. This initial extract then was extracted with three successive portions of 200 ml. each of methylisoamyl ketone by means of a separatory funnel. Some emulsions were encountered that could be broken with anhydrous sodium sulfate. This was the only step that proved somewhat troublesome. Some of the yellow pigments could be extracted from this MIAK extract with aqueous sodium or potassium hydroxide 5%. The MIAK was removed under vacuum (water pump) at 38 to 45°. The dark-colored amorphous mass was digested with methylene chloride which partially dissolved in this solvent. The insoluble yellow-brown solid was removed either by filtration or by use of a centrifuge at 5000 r.p.m., using polypropylene test tubes. This colored insoluble material contained pigments (flavones) that have been partially characterized and will be the subject of a future report. The methylene chloride solution (40 ml.) was diluted with 120 ml. of ether and subsequently extracted with two 10-ml. portions of 5% aqueous potassium hydroxide in order to remove certain yellow flavones and related pigments. These pigments, together with the aforementioned methylene chloride insoluble pigments, which also are alkali soluble, are usually removed by lead acetate or basic lead acetate. We previously have shown that basic lead acetate can effect some deacetylation of the acetyl glycosides. Also, the

use of these reagents for clarification purposes, pigment removal, *etc.*, sometimes results in manipulative techniques that might better be replaced by simpler techniques that accomplish the same results. After washing once with water, the organic solution then was washed with 10 ml. of 20% of sodium phosphate monobasic and then once again with water. Sodium phosphate monobasic is an excellent way to remove the excess alkali in that it is much superior to acetic acid and permits the ready removal by washing of any excess of the acidifying agent. The removal of any excess acetic acid is most troublesome; for at this stage, if the ether methylene chloride solution is allowed to stand overnight, the separation of small amounts of glycosides takes place. However, the solvent was directly removed by distillation until a concentrate of about 20 ml. was obtained. The concentrate was impregnated on filter cell 4 Gm. and dried. The mixture was placed in a sintered-glass funnel and eluted slowly with 150 ml. of a mixture of 60 parts skellysolve B and 40 parts benzene. This solvent mixture removed some nonphenolic pigments and other resin-like substances that have not been characterized. The mixture then was eluted with 150–200 ml. of anhydrous ether. Upon concentration of the ether eluate to a small volume, acetyldigitoxin crystallized out directly in the distillation flask. The glycoside was collected by means of a sintered-glass filter. The filtrate was diluted with an equal volume of skellysolve B (hexane) and additional amounts of glycoside separated out that was collected by filtration. When the paper was examined chromatographically, the above two fractions contained chiefly acetyldigitoxin. The procedure in subsequent isolations was shortened by adding the skellysolve B directly to the ether concentrate and the total glycosides obtained by one filtration. Concentration of the ether–skellysolve filtrate to remove about half the ether caused the separation of further small quantities of acetyldigitoxin together with some green pigments. The filter cell finally was extracted with methylene dichloride to yield an additional small amount of glycosides which could have been extracted very slowly by additional quantities of ether. Of the solvents tested, ether gave the most satisfactory results and gave an initial glycoside preparation that had a very high glycoside concentration consisting almost entirely of acetyldigitoxin.

Acetyldigitoxin also can be eluted from the filter cell mixture by isopropyl ether, and upon concentration of this eluate the glycosides separated out as when ether was used.

When 250-Gm. samples of dry *D. mertonensis* were assayed by the above described techniques, values of the order of 0.55 Gm. of acetyldigitoxin were obtained, or 2.10 Gm. per Kg.

In the case of dried leaves in which some deacetylation had taken place during the drying, the same approximate weights of glycoside were obtained that were mixtures of digitoxin and acetyldigitoxin.

When fresh leaves of *D. mertonensis* were used, the only variation in the above techniques was the disintegration of the fresh with aqueous methanol of such a concentration that the final extract was 35%. With fresh leaves, as previously stated, one can be assured of very little or no deacetylation.

Although no effort was made to isolate or determine the acetylgitoxin or gitoxin fractions, all evidence obtained to date indicates that very small amounts of digilanide B are present in *D. mertonensis*. Contrast this with the large amounts of gitoxin (from purpurea glycoside B) that occur in *D. purpurea* grown in Minnesota.

The same techniques that were used for the isolation of acetyldigitoxin from *D. mertonensis* were applied to both the fresh and dried leaves of *D. siberica*. The results were essentially the same as those obtained with *D. mertonensis*, however, considerably fewer pigments were encountered, especially the flavone type. Quantitative studies will be carried out at a later date and reported.

The Isolation of Digitoxin from *D. purpurea*.—The isolation of digitoxin from *D. purpurea* was accomplished with ease by the same techniques used to isolate acetyldigitoxin from *D. mertonensis*. The gitoxin separated from the methylene dichloride ether solution both before and after concentration and very little gitoxin was encountered in the final digitoxin preparation.

When 250 Gm. samples of dry *D. purpurea* were assayed by the above described techniques, values of the order of 0.225 Gm. of digitoxin were obtained, or 0.90 Gm. per Kg. This is less than half of that obtainable from *D. mertonensis*.

Preliminary Report on the Comparative Stability of Certified Colorants with Lactose in Aqueous Solution

By CHARLES A. BROWNLEY, JR., and LEON LACHMAN

The influence of conventional lactose and spray-processed lactose and their primary hydrolysis products (*d*-glucose and *d*-galactose) on the stability of various certified colorants has been investigated. Spectrophotometric and paper partition chromatographic examination indicated that in aqueous buffered solutions (pH 6.6 to 6.8), FD&C Red No. 4, FD&C Yellow No. 5, FD&C Green No. 3, and FD&C Blue No. 1 are relatively stable when exposed to exaggerated lighting and temperature in the presence of these sugars. FD&C Blue No. 2 was found to be very unstable, particularly when exposed to light, and the sugars significantly accelerate the decomposition of this color. The decomposition of FD&C Blue No. 2 appears to proceed by reduction to a semiquinone followed by oxidation. There appears to be some evidence to indicate molecular changes in the lactose when stored at high temperature. These changes appear to interfere with the spectrophotometric analysis of colorants which absorb between 228 mμ and 284 mμ.

THE INTRODUCTION of spray-drying procedures for the manufacture of alpha lactose monohydrate and the subsequent acceptance of this sugar by the official compendia afforded the pharmaceutical tablet developer with a pharmaceutical excipient exhibiting a number of advantages. Among these are flow and compaction properties unknown with conventionally manufactured lactose. The use of spray-dried lactose permits the economical production of tablets by direct compaction, a process which consists of only two steps—powder blending and compression. Through this method of preparation it is possible to formulate tablets of heat and moisture-sensitive ingredients in a simple manner and with enhanced stability.

Efforts to produce colored tablets by direct compaction through the use of blended dye triturates, lakes, or precolored disintegrants or lubricants with spray-processed lactose were not completely successful and were rather costly. Through the use of colored spray-dried lactose (the lactose being colored during the spray-drying operation), the preparation of colored tablets by direct compaction was made possible. The colored spray-dried lactose exhibits similar flow and compaction properties as the uncolored material. The preparation of colored spray-dried lactose was initiated in 1958 by Brownley and Reger (1).

The initial batches were manufactured with certified FD&C Blue No. 1, FD&C Yellow No. 5, FD&C Green No. 3, FD&C Orange No. 3, and the formerly certified FD&C Red No. 1. The quantities of colorants used varied from 0.008 to 0.05%. Preliminary investigation indicated that fading and color changes occurred in some of these lactoses. As examples, the colored lactose containing 0.05% FD&C Yellow No. 5 changed during normal ambient storage from a golden yellow to a dull yellowish-tan. The product containing 0.008% FD&C Red No. 1 varied in color from light to dark pink within a particular batch of lactose. These adverse changes, however, were not evident in colored lactose granules prepared with conventional lactose. These granules had been prepared by customary wet granulating techniques in the same dye concentration as in the colored spray-dried lactoses.

A possible explanation for the difference in color stability for the spray-dried and conventional lactose can be the presence of higher concentrations of lactose's hydrolysis products in the spray-dried lactose, as compared to the conventional lactose. It has been shown by Jenness and Patton (2), Weisberg (3), and Whittier (4) that heat differences during manufacture can cause appreciable difference in the extent of lactose hydrolysis. When analyzing the two types of lactose for other sugars according to U.S.P. methods, results indicated that some batches of spray-dried lactose contained two to four times as much other sugars as found in conventional lactose. The other sugars were identified as being the primary hydrolysis products of lactose, namely, D-glucose and D-galactose. These monosaccharides possess 30% greater reducing power than pure lactose (5). Therefore, it would be expected for the spray-dried

Received March 29, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication June 11, 1962.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

lactose to have a more deleterious effect on colorants susceptible to reduction reactions than conventional lactose.

Although there has been an increase in recent years in the number of investigations concerned with stability of colorants used in pharmaceutical dosage forms (6–10), these studies did not consider the relative stability of spray-dried and conventionally processed lactose with certified dyes. Since the oxidation–reduction interreactions between dyes and pharmaceutical agents are a serious problem for the pharmaceutical industry, it seemed desirable to evaluate the relative stability of spray-dried lactose *vs.* conventional lactose with several commonly used certified colors. In addition, it was desirable to discern the exact influence of lactose's primary hydrolysis products on the stability of these colorants.

In this investigation, the chemical stability of dye-sugar mixtures was examined in aqueous solutions. Five dyes representing three of the major chemical categories were selected for study. The dyes and sugars were studied at 0.15 and 5% concentrations, respectively, in aqueous solutions buffered at pH 6.6 to 6.8. This buffer system was chosen in order to maintain a constant hydrogen ion concentration as well as to approximate the pH of a 0.15% aqueous solution of the majority of dyes.

EXPERIMENTAL

Materials Used.—Conventionally processed lactose U.S.P. (Avoset Co.); spray-processed lactose U.S.P. (Western Condensing Co.); dextrose U.S.P. (D-glucose); D-galactose (Matheson Coleman and Bell); FD&C Red No. 4 (monoazo); FD&C Blue No. 1 and FD&C Green No. 3 (triphenylmethane); FD&C Yellow No. 5 (pyrazolone); FD&C Blue No. 2 (indigoid) (H. Kohnstamn Co.); ethyl acetate and pyridine (Baker Chemical Co.); benzidine reagent (Matheson Coleman and Bell); Sorensen phosphate buffer solution at pH 6.6 to 6.8.

Equipment.—Beckman recording spectrophotometer, model DK-1; Beckman Zeromatic pH meter; light stability cabinet exhibiting intensified illumination as described in a previous publication (11); precision scientific oven maintained at 60° ± 1°; Whatman's No. 1 chromatographic paper supplied in sheets 18.25 inches × 22.5 inches; microliter pipets; chromatography jars, 18 inches high × 12 inches in diameter, including complete setup for descending development; spray bottles; ultraviolet lamp, long wave (3660 Å).

Procedure for Spectrophotometric Analysis.—Aqueous buffer solutions containing 0.15% dye, 0.15% dye + lactose, 0.15% dye + D-glucose and 0.15% dye + D-galactose were prepared and investigated for colorant stability. These solutions were filtered through sintered glass funnels and filled into 10-ml. clear neutraglas color-break ampuls. The ampuls were then sealed on the Popper HI laboratory ampul sealer. Each batch of ampuls was divided into three groups and stored as follows: Group one was stored at room temperature in light-resistant cardboard containers; group two was stored under intensified illumination in the light stability cabinet; group three was stored in light-resistant cardboard containers at 60° ± 1°. At designated time intervals, individual ampuls were removed and assayed spectrophotometrically by running a complete absorption spectra in the visible and ultraviolet regions. Absorbance was measured at the wavelengths indicated in Table I.

FD&C Blue No. 1	625	307	6.80
FD&C Blue No. 2	617	285	6.72

[a] Beckman recording spectrophotometer, model DK-1.
[b] Beckman Zeromatic pH meter.

Procedure for Paper Partition Chromatography.—The solvent system was prepared by mixing 400 ml. of ethylacetate, 200 ml. of pyridine, and 400 ml. of water in a separatory funnel, shaken and allowed to separate. The lower phase was used to saturate the chamber. The upper phase was used to develop the chromatograms.

The chromatographic jars, used for descending chromatography, were lined with filter paper. The lower phase was placed in the bottom of the chamber with the liner dipping into the solvent. The upper phase was placed in the solvent troughs. The chamber was then allowed to equilibrate for 16 hours.

Points for the application of the sample were marked 3 cm. apart on a line 6.5 cm. from the top of Whatman's No. 1 paper cut to 46-cm. lengths. The samples and standards were dissolved in an appropriate solvent and the samples were spotted on the chromatograms in concentrations of 100 to 500 mcg. The size of the spot should be approximately 5 mm. in diameter. This was accomplished by repeated spotting and drying of the solvent. The chromats were placed into the troughs and developed for approximately 7 hours. The developed chromats were then air dried and sprayed with a benzidine reagent prepared according to Bacon and Edelman (12).

The chromats were then heated in an oven for 15 min. at 90°. The reducing sugars appeared as

TABLE II.—R_f VALUES OF DYES AND SUGARS

Compound	R_f Values[a]
Lactose	0.25
D-Glucose	0.35
D-Galactose	0.35
FD&C Red No. 4	0.55
FD&C Yellow No. 5	0.20
FD&C Blue No. 1	0.60
FD&C Blue No. 2	0.50
FD&C Green No. 3	0.47

[a] Solvent: ethyl acetate-pyridine-water 2:1:2 v/v.

brown spots. The sensitivity was increased by viewing under an ultraviolet lamp. Table II shows the R_f values for the sugars and dyes used in this study.

The use of this ethyl acetate-pyridine-water system for paper partition chromatography of colorants and sugars has the advantage over other previously reported systems for use with carbohydrates (22) in that good separations can be obtained in a shorter period of time.

RESULTS AND DISCUSSION

The influence of conventional lactose and spray-processed lactose and their primary hydrolysis products (D-glucose and D-galactose) on the stability of FD&C Red No. 4, FD&C Yellow No. 5, FD&C Green No. 3 and FD&C Blue No. 1 and No. 2 in solution has been investigated at several storage conditions.

FD&C Red No. 4.—The data presented in Tables III and IV indicate that FD&C Red No. 4 is reasonably stable equally in the presence of spray-processed lactose, conventionally processed lactose and lactose's primary hydrolysis products, D-glucose and D-galactose, at these conditions of testing. A change occurred in the absorption maximum for the buffered dye solutions but no change was seen in the dye-sugar solutions. This change was more pronounced in the visible than the ultraviolet range. The presence of the reducing sugars showed an apparent stabilizing effect on the dye as evidenced particularly by the data showing the influence of light. This improved stability is believed to be due to preferential reduction of the lactose instead of the dye.

[a] Exaggerated lighting.

This apparent stability of the dye-sugar solution was further shown by paper partition chromatography examination of the FD&C Red No. 4–sugar solutions after storage, as evidenced by no development of R_f values different from those obtained initially.

These results are in keeping with the recent findings of Swartz, *et al.* (13), in which tablets buffered to pH 7 containing FD&C Red No. 4 exhibited excellent chemical stability after storage for 20 days at 80°.

FD&C Yellow No. 5.—The effect of various sugars on the thermal and light stability of FD&C Yellow No. 5 in solution is summarized in Tables V and VI. The absorbance values indicate apparent stability of FD&C Yellow No. 5 with spray-processed lactose, conventionally processed lactose, and the hydrolysis products, D-glucose and D-galactose.

[a] Exaggerated lighting.

A diminution in absorbance is seen for the dye-sugar solutions exposed to light. This is in keeping with the report by Lachman, *et al.* (14), who have shown that a flattening as well as a hypsochromic shift of the absorption maximum occurs for FD&C Yellow No. 5 when this colorant is exposed to exaggerated illumination in tablet formulations.

The dye-sugar solutions, after storage at 60°, failed to show the decrease in absorbance at 257 mμ as seen for the room temperature and light samples stored for the same period of time. This may be explained by the changes which take place in the sugar molecule when stored at 60° resulting in high absorption tendencies in the wavelength region of 228–284 mμ as shown in Fig. 1. Since the analysis for FD&C Yellow No. 5 was performed within this range, the results obtained would be expected to be higher than the true values because the absorbance due to the sugars is now playing a role. The tendency of the sugars to appear to develop absorption properties in this wavelength region is being further investigated.

Upon examining the paper chromatograms of the solutions of dye and dye-plus-sugars after storage, no change in R_f values was noticed. This further illustrates the apparent stability of FD&C Yellow No. 5 under the conditions of study. Exposure to exaggerated lighting, however, should be avoided.

FD&C Green No. 3.—The data presented in Tables VII and VIII show FD&C Green No. 3 to be essentially stable in the presence of lactose and its hydrolysis products. Paper partition chromatographic examination of these solutions stored for the same periods of time substantiated this effect. From the paper chromatograms shown in Fig. 2, it is indicated that four impurities (R_f values 0.15, 0.35, 0.65, and 0.75), initially present in the dye, subsequently disappeared upon storage. A possible explanation for this is that the impurities were over-

oxidized colors. This postulation is in keeping with the spectrophotometric and partition chromatographic findings of Jones, *et al.* (15). Their analysis of various samples of commercial triphenylmethane colors accounted for an average of 94% of the material as the sum of pure dye, leuco compound, volatile material, and inorganic salts. These investigators concluded that the remaining material was chiefly overoxidized color.

FD&C Blue No. 1.—Aqueous solutions of FD&C Blue No. 1 with the various sugars were stored similarly to the FD&C Green No. 3 and no change in absorbance value at 625 mμ was noticed to occur with this dye in the presence of the sugars stored at room temperature and 60° as presented in Table IX.

However, at 625 mμ, the spectrophotometric data indicated a decrease in absorbance for the FD&C Blue No. 1 in solution with spray-processed lactose, D-glucose, and D-galactose exposed to exaggerated lighting for 90 days. The data indicated that the effect on the absorbance was greatest with the D-galactose.

No absorbance at 307 mμ was observed for this dye in the presence of the sugars at 60° as illustrated in Table X. The absorption maximum was found to

shift from 307 to 280 mμ as shown in Fig. 3. This effect can possibly be explained by the sugar molecule being thermally degraded producing products which absorb at 280 mμ as previously shown in Fig. 1.

No changes were detected in the FD&C Blue No. 1 solutions stored at room temperature and 60° by paper partition chromatographic procedures. There was some indication of dye loss in the samples kept for 90 days in the light cabinet.

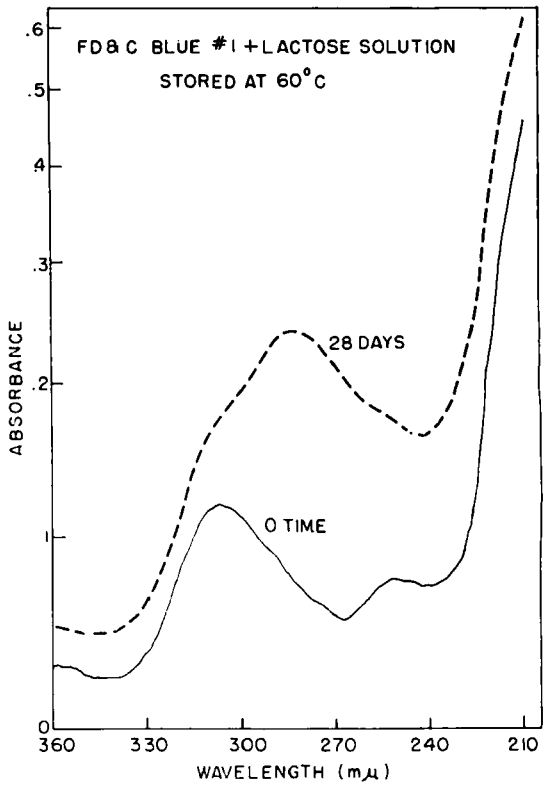

Fig. 3.—Plot showing the influence of lactose on the ultraviolet absorption maximum of FD&C Blue No. 1 after 28 days' storage at 60°.

FD&C Blue No. 2.—Although studies with the dye FD&C Blue No. 2 are still in progress, it is felt worth while to mention certain observations obtained thus far. The preliminary data indicated that lactose, D-glucose, and D-galactose were very deleterious to the stability of this colorant and that the monosaccharides were more destructive than the unhydrolyzed disaccharide. The absorption data obtained from these conditions of testing were very erratic and did not permit kinetic interpretation. Figure 4 shows the spectra changes for FD&C Blue No. 2 in the presence of D-glucose after 3, 6, and 10 days exposure to light. For the 10-day sample, two different spectra (A and B) were obtained for the same sample taken within minutes of one another. Paper partition chromatographic examination of the aqueous buffered solutions of FD&C Blue No. 1 and FD&C Blue No. 2 plus the sugars further substantiated the findings of instability for this colorant. The initial R_f values for FD&C Blue No. 2 at 0.50, and 0.60 for trace impurities, diminished rapidly until no dye was visible after 14 days of heat and light storage (Fig. 5). After 12 weeks, no dye was detected in the room temperature sample. It was observed that two new R_f values appeared at 0.16 and 0.35, which probably indicated the decomposition products of the dye.

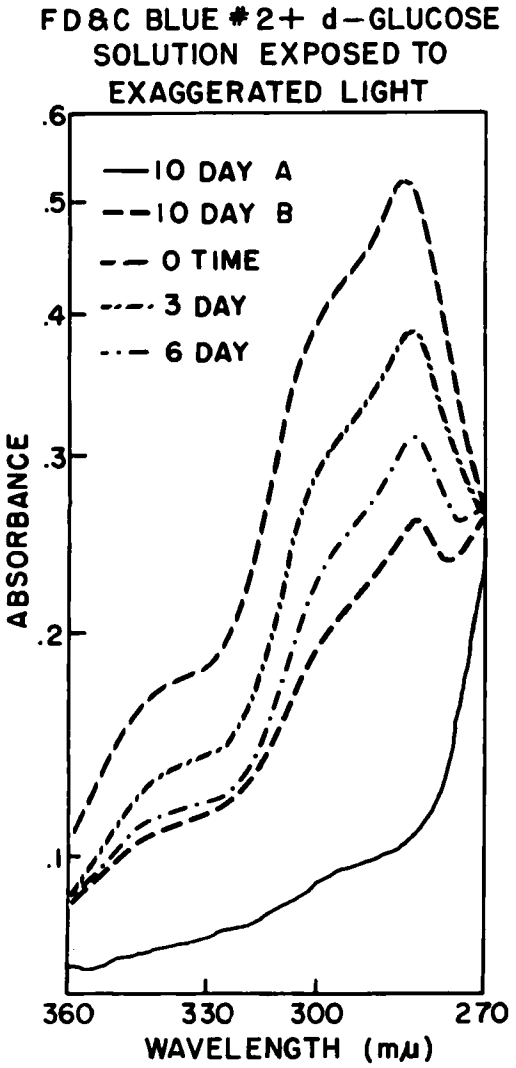

Fig. 4.—A plot of the ultraviolet absorption spectra of FD&C Blue No. 2 indicating changes in the presence of D-glucose after varying periods of storage at 60°.

The decomposition of this indigo disulfonate dye has been studied by several investigators. Scott, *et al.* (8), reporting on the accelerated color loss of certified dyes in the presence of nonionic surfactants, showed that the rate of fading of FD&C Blue No. 2 in the presence or absence of Pluronic F68 follows pseudo first-order kinetics. Kuramoto, *et al.* (7), evaluated the influence of several pharmaceutical materials on the rate of fading of FD&C Blue No. 2 in aqueous solution at pH 6.64 and found that sugars, such as dextrose, lactose, and sucrose, increased the rate of fading of this dye. These investigators postulated that the decomposition of FD&C Blue No. 2 took place by reduction *via* a semiquinone formation to a colorless leuco compound.

Preisler, *et al.* (16), investigated the oxidation–reduction potentials of the indigo sulfonates and their reduced forms and their absorption coefficients in alkaline buffers. These investigators observed that "when indigo in alkaline alcoholic solution or indigo disulfonate in aqueous buffers of about pH 11.0 to 12.5 are reduced by the gradual addition of reducing agent, a red intermediate color appears between the initial blue (or green) of the fully oxidized and the yellow of the reduced compound; on reoxidation the red color appears in the reverse color sequence. Outside this pH zone, the red color is not observed; in less alkaline solutions of the sulfonates, the color changes from blue, through the green of the mixture, to yellow; in more strongly alkaline solutions, the initial color is a yellow, which on reduction changes to a lighter yellow." The data collected by Preisler established conclusively that the red intermediate color was due to a semiquinone formation.

In the present study, a similar reduction pattern was observed. A red color developed after 6 days at 60° in the FD&C Blue No. 2—D-glucose solution between the initial blue and the final yellow color of the faded solution. This red color lasted for only a short period of time. The appearance of this red intermediate at the lower pH's of this study indicated that the semiquinone formation was possible under less alkaline conditions than those observed by Preisler and his co-workers. These data tended to support the postulation of Kuramoto, *et al.*, that reduction to a semiquinone formation occurred in the decomposition of this certified color.

Preliminary results in this investigation indicated that when the sealed ampuls of FD&C Blue No. 2 plus the sugar solutions were exposed to atmospheric conditions, the green-yellow color of the apparently reduced compound changed to a pale blue. On further exposure, the blue color of the solution faded to a pale yellow. The solution at this time was observed to be strongly fluorescent when viewed under ultraviolet light. These changes appeared to indicate that the decomposition of FD&C Blue No. 2 was not solely one of complete reduction to the leuco compounds, but that the mechanism of fading of this indigo disulfonate dye could possibly be reduction followed by oxidation. Inskeep and Kretlow (17)

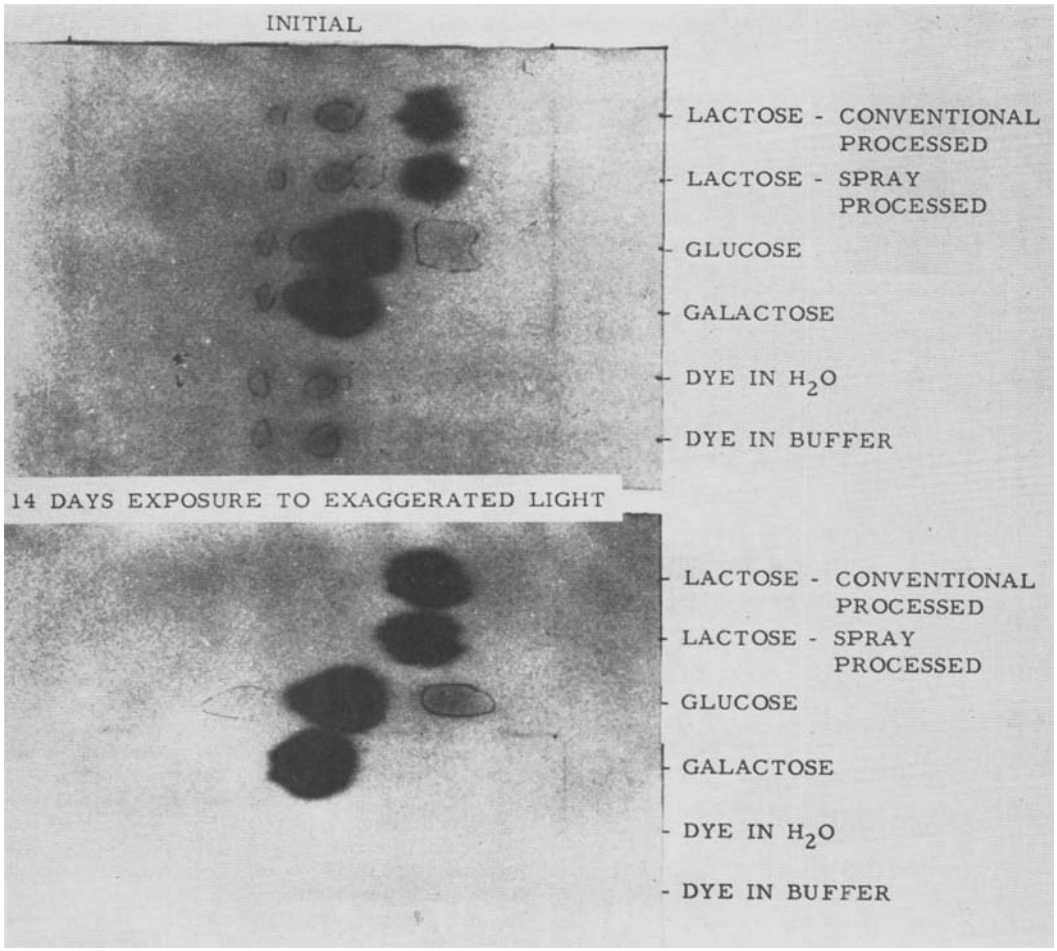

Fig. 5.—Chromatograms showing the R_f values for FD&C Blue No. 2 initially and their absence after 14 days' exposure to exaggerated lighting.

observed that although a common property of dyestuffs is their ability to take up hydrogen with the formation of colorless compounds, the leuco compounds so formed from indigo dyes were oxidized by air.

Jones, *et al.* (18), studied the photodecomposition of dilute solutions of FD&C Blue No. 2 exposed to ordinary and diffuse laboratory light. Spectrophotometric examination showed that the chief component was isatinsulfonic acid. When viewed under ultraviolet light, the faded solutions exhibited a bluish fluorescence characteristic of the sulfonated anthranilic acids. These experiments showed that the fading of solutions of FD&C Blue No. 2 was due almost entirely to the oxidation of the colorant to isatinsulfonic acid and finally to sulfonated anthranilic acid. In alkaline solution, these investigators observed that the indigo disulfonate is converted to disulfonated crysanilic acid which is oxidized by potassium persulfate in acid solution to approximately equal amounts of isatinsulfonic acid and sulfonated anthranilic acid.

That oxidative decomposition was more destructive to this colorant than reduction is stated in the review made by Desai and Giles (19). Hibbert (20) was able to isolate a small quantity of isatin from samples of indigo-dyed cotton cloth which had been faded by exposure to sunlight or to the light from a carbon arc. Zuckerman (21) also reported that FD&C Blue No. 2 had the poorest light resistance of all the certified colors and because of its structure exhibited the best resistance to reducing agents.

SUMMARY AND CONCLUSIONS

In this study the influence of lactose, D-glucose, and D-galactose on the stability of five certified dyes has been investigated. From the results obtained the following conclusions can be drawn.

1. In aqueous solutions buffered to pH 6.6 to 6.8, FD&C Red No. 4, FD&C Yellow No. 5, FD&C Green No. 3, and FD&C Blue No. 1 are relatively stable upon exposure to exaggerated lighting and temperature in the presence of spray-dried and conventional-processed lactose, D-glucose, and D-galactose.

2. FD&C Blue No. 2 is very unstable, particularly when exposed to light, and the sugars significantly accelerate the decomposition of this

colorant. The decomposition of FD&C Blue No. 2 appears to proceed by reduction to a semiquinone followed by oxidation.

3. There appears to be some evidence to indicate molecular changes in the lactose upon storage at high temperature. These changes seem to interfere with the spectra analysis in the ultraviolet range for colorants which absorb between 228 and 284 mμ.

As a result of this investigation, further studies are underway to thoroughly evaluate the thermal stability of lactose and lactose-and-colorants, both in aqueous solutions and in solid dosage forms. In addition studies are continuing to elucidate the degradation reaction for FD&C Blue No. 2.

Assay of Progesterone in Oil Injectables

By JACOB WOLFF

A method is presented for the quantitative determination of progesterone in oil solutions. The ketosteroid is isolated by partition chromatography using nitromethane on purified siliceous earth as the immobile phase and *n*-heptane as the eluent. The assay is based on the ultraviolet absorbance in ethanol solution at the maximum near 241 mμ. The identity of the separated progesterone is confirmed by determining the infrared spectrum in carbon disulfide solution.

THE U.S.P. XVI (1) assay procedure for progesterone injection is a welcome simplification of the method in the previous edition (2). However, the assay is still based on the reaction with 2,4-dinitrophenylhydrazine, a general reagent for aldehydes and ketones. The melting point of the resulting hydrazone is rather high, 267–275°, and no other purity criteria are specified. Monty (3) reports that some chromatographically inhomogeneous 2,4-dinitrophenylhydrazones exhibit melting points no lower than the accepted values for the pure compounds. Umberger (4) used the color reaction with isonicotinic acid hydrazide for the determination of progesterone and testosterone. This reaction is more specific since it depends on the presence of a conjugated carbonyl linkage as in Δ^4-3-ketosteroids. Touchstone and Murawec (5) used spectrofluorometric techniques for the determination of progesterone in biological fluids. It appeared that a procedure based on the physical separation of progesterone from oil solutions, with its subsequent assay and identification, would be a more desirable approach than any of these.

Column chromatographic techniques have been successfully applied to similar problems.

Assay of Progesterone in Oil Injectables

By JACOB WOLFF

A method is presented for the quantitative determination of progesterone in oil solutions. The ketosteroid is isolated by partition chromatography using nitromethane on purified siliceous earth as the immobile phase and *n*-heptane as the eluent. The assay is based on the ultraviolet absorbance in ethanol solution at the maximum near 241 mμ. The identity of the separated progesterone is confirmed by determining the infrared spectrum in carbon disulfide solution.

THE U.S.P. XVI (1) assay procedure for progesterone injection is a welcome simplification of the method in the previous edition (2). However, the assay is still based on the reaction with 2,4-dinitrophenylhydrazine, a general reagent for aldehydes and ketones. The melting point of the resulting hydrazone is rather high, 267–275°, and no other purity criteria are specified. Monty (3) reports that some chromatographically inhomogeneous 2,4-dinitrophenylhydrazones exhibit melting points no lower than the accepted values for the pure compounds. Umberger (4) used the color reaction with isonicotinic acid hydrazide for the determination of progesterone and testosterone. This reaction is more specific since it depends on the presence of a conjugated carbonyl linkage as in Δ^4-3-ketosteroids. Touchstone and Murawec (5) used spectrofluorometric techniques for the determination of progesterone in biological fluids. It appeared that a procedure based on the physical separation of progesterone from oil solutions, with its subsequent assay and identification, would be a more desirable approach than any of these.

Column chromatographic techniques have been successfully applied to similar problems.

Received May 15, 1962, from the Food and Drug Administration, Division of Pharmaceutical Chemistry, Washington 25, D. C.
Accepted for publication June 1, 1962.
The author is very grateful to the following members of the U. S. Food and Drug Administration: Jonas Carol and Joseph Levine, for their valuable suggestions on chromatographic procedures, and Mrs. Alma L. Hayden for her advice and guidance on infrared techniques.

Carol (6) separated progesterone and testosterone using alcohol on purified siliceous earth as the immobile phase and iso-octane as the mobile solvent. Wotherspoon and Bedoukian (7) determined oxygenated compounds in essential oils by stripping from silica gel with ether after eluting the oils with pentane. Pesticides may be separated from fats and oils by the acetonitrile-hydrocarbon partition of Jones and Riddick (8) followed by chromatography on Florisil,[1] magnesium oxide, or purified siliceous earth. Umberger (4) obtained separation of progesterone or testosterone from oil, adequate for his colorimetric assay procedure, using Florisil and eluting with 2:1 iso-octane-chloroform. Tappi and co-workers (9) separated a number of steroidal hormones from each other and from olive oil using Florisil with successively more polar solvent mixtures. Snair and Schwinghamer (10) obtained a partial separation of estradiol dipropionate from oil using a column of siliceous earth and iso-octane thickened with polyethylene glycol 600, hexane being used as the mobile solvent. Monty (3) separated the 2,4-dinitrophenylhydrazones of aliphatic aldehydes and ketones on a nitromethane-Kieselguhr column with petroleum ether as the mobile solvent.

The proposed method was chosen after rather extensive experimentation with immiscible solvent systems and adsorbants. While many other techniques separated the main portion of the oil in the control samples, there was a steroid-like fraction which tended to remain with the progesterone throughout the various manipulations. Only the proposed procedure reduced the background absorbance to negligible proportions.

PROCEDURE

Materials.—Infrared spectrophotometer, a double beam Perkin-Elmer model 21; adsorbant, purified siliceous earth,[2] immobile solvent, nitromethane C.P.;[3] eluent, redistilled *n*-heptane; chromatographic column.

Insert a plug of purified cotton at the constriction of a chromatographic tube about 200 mm. long and about 25 mm. in internal diameter. Mix 8.0 ml. of nitromethane with 7.0 Gm. of adsorbant in a 150-ml. beaker until uniformly moistened. Transfer to the chromatographic tube in three approximately equal portions, tamping down with a packing rod after each addition. Arrange a long-stemmed, glass-stoppered, 250-ml. separator to serve as a reservoir for maintaining a constant level of liquid in the tube.

Standard Preparation.—Dissolve in alcohol 20.0 mg. of U.S.P. Progesterone Reference Standard, previously dried in vacuum over silica gel for 4 hours, dilute with ethanol to exactly 100 ml., and mix. Dilute 5.0 ml. of the solution with ethanol to make exactly 100 ml. and mix.

Assay Preparation.—Transfer, by means of accurately calibrated hypodermic syringe, 1.00 ml. of oil solution to a suitable volumetric flask so that the final solution will contain about 1 mg. of progesterone per ml. Dissolve in redistilled *n*-heptane, make to volume, and mix.

Assay.—Transfer 4.0 ml. of the assay preparation to the prepared chromatographic column. Pass 135 ml. of redistilled *n*-heptane through the column and discard the eluate.[4] Place a 200-ml. volumetric flask under the column as a receiver, add an additional 175 ml. of *n*-heptane to the column, and collect the entire eluate. Fill to the mark with *n*-heptane, and mix.

Transfer a 50-ml. aliquot to a 150-ml. beaker and save the remainder for the Identification Test. Evaporate to dryness under a gentle current of air on a steam bath. Remove the last traces of heptane by adding 1 ml. of methanol and redrying. Dissolve the progesterone by warming a few minutes in about 10 ml. of ethanol. Cool and dilute to exactly 100 ml. with ethanol.

Determine the absorbances of the sample and standard solutions relative to an alcohol blank at the peak near 241 mμ and at 300 mμ in a suitable spectrophotometer using matched 1-cm. cells. Calculate the quantity of progesterone in mg. in the aliquot taken from the formula $4\ A_u/A_s$, where A_u is the absorbance of the sample at 241 mμ minus the absorbance of the sample at 300 mμ, and A_s is the corresponding value for the standard.

Identification Test.—Evaporate the remainder of the eluate to dryness as discussed, starting with a 400-ml. beaker and transferring to a 5- or 10-ml. glass-stopper Erlenmeyer flask for the final evaporation. Dissolve the residue in 1.0 ml. of carbon disulfide, and determine the infrared absorption spectrum between 2 and 15 μ in a 1-mm. sodium chloride cell, using carbon disulfide in a matched cell as the blank. The resulting spectrogram should show all the significant absorption bands—and no others—that are found on a spectrogram similarly obtained with 3 mg. of U.S.P. Progesterone Reference Standard in 1.0 ml. of carbon disulfide.

DISCUSSION

In most chromatographic procedures, 1 ml. or less of immobile solvent is used per gram of adsorbant.

TABLE I.—ANALYSIS OF SYNTHETIC SOLUTIONS

Progesterone, mg./ml.	Adjuncts	% Recovered	
10.00	None	98.6	100.8
25.11	None	100.0	101.0
99.96	8% Benzyl alcohol 2% Ethanol	98.2	98.2

[1] Marketed by Floridin Co., Tallahassee, Fla.
[2] Acid-washed Celite 545, Johns-Manville Corp.
[3] Certified reagent grade from Fisher Scientific Co. was found to be satisfactory without further purification.

[4] The optimal volume of fore-run may vary by about 10 ml. with different batches of *n*-heptane or nitromethane. When new bottles of these reagents are used, determine the proper fore-run by the following procedure: Collect the last 25 ml. of the fore-run separately, and collect a tail cut of 25 ml. by passing through more eluant after collecting the main fraction in the 200-ml. flask. Evaporate these fractions as in the assay and make up to 25 ml. with ethanol. Determine the absorbance at 220, 241, and 300 mμ. An absorbance at 241 mμ exceeding that at 220 mμ indicates the presence of progesterone in the fraction involved, and the volume of the fore-run should be adjusted accordingly.

TABLE II.—ANALYSIS OF COMMERCIAL PROGESTERONE INJECTABLES

Sample	Declared mg./ml.	Adjuncts	Suggested Procedure % of Declared	Suggested Procedure Average	U.S.P. Assay % of Declared
1	100	8% Benzyl alcohol	86.2		
		2% Ethanol	87.0		
			86.8

			92.9		
			92.0	93.0	91.3
7	25	1:4000 Benzethonium octylacetate,	75.8		
		in peanut oil	75.4	75.6	75.3

[a] Determined m.p. at 260–264° (267–275° in U.S.P. XVI).

Here it was found that a relative excess of immobile solvent gave more consistent results. Evaporation to dryness and redissolving in alcohol are necessary to remove not only the heptane, but also the nitromethane which absorbs strongly in the ultraviolet region.

The progesterone recovered from oil injectables is usually slightly contaminated with ultraviolet absorbing substances. Consequently, the absorption spectra of samples and standards of equal concentration do not coincide exactly. While this difference may be appreciable at 220 mμ, it was never greater than 2% at 241 mμ. Prewashing the column with heptane did not reduce the background. Equilibrating the mobile and immobile solvents with each other increased the background, possibly by increasing the amount of nitromethane in the eluate. The interference, in any case, does not seem to affect the assay results. The absorbance of progesterone at 300 mμ is very low. On the samples, however, it ranged from 1–5% of the absorbance at the maximum around 241 mμ. It was found empirically on the samples of known concentration that subtracting this absorbance from that at the peak gave better results.

RESULTS

The recovery of progesterone from oil solutions was determined on solutions of known concentration. Weighed samples of U.S.P. Progesterone Reference Standard were dissolved by warming in 1 ml. of ethanol. About 4 ml. of sesame oil was added and the ethanol removed by heating on a steam bath for several hours. The solution was cooled and diluted to the desired volume. To check the reliability of the procedure under adverse conditions, the sesame oil used was from an old, somewhat oxidized sample. Duplicate determinations on three such samples are given in Table I and indicate that the recoveries are accurate within a 2% range.

In Table II, the results of the analysis of seven commercial preparations by the proposed method are compared with the results by the U.S.P. XVI (1) procedure. Except for samples 1 and 3, the results of the two procedures are in fair agreement. In sample 1, the difference may be explained in part by the impurities present in the hydrazone obtained in the U.S.P. procedure as indicated by the low melting point. Only two of the seven samples, 2 and 6, meet the requirements of the U.S.P. by either method of analysis.

The infrared absorption spectra of the progesterone recovered in the samples examined were indistinguishable from those of the reference standard.

SUMMARY

A method has been proposed for the assay of progesterone in oil solution, based on the isolation of the active ingredient by partition chromatography. The method is more specific than the current U.S.P. method and yields comparable results.

Synthesis of Pyridine-2-aldoxime-C^{14} Methiodide (2-PAM-C^{14} Iodide)

By LEON CLARK and LLOYD J. ROTH

A procedure is described for the synthesis of C-14 oxime-labeled pyridine-2-aldoxime methiodide. Picolinamide-C^{14} is prepared from 2-bromo-pyridine and potassium cyanide-C^{14}. This amide is used in the synthesis of 2-picolinyl-C^{14}-benzenesulfonyl hydrazide which, upon decomposition with heat and alkali, yields pyridine-2-aldehyde-C^{14}. Pyridine-2-aldoxime-C^{14} is readily obtained from the aldehyde. Treatment of the oxime with methyl iodide in benzyl alcohol yields the desired 2-PAM iodide.

INTEREST in 1-methyl-2-pyridinium aldoxime iodide or pyridine-2-aldoxime methiodide (2-PAM iodide) is largely a result of its effectiveness as an antidote for organic phosphate poisoning. The ever-increasing use of highly toxic organophosphorus compounds as agricultural insecticides as well as potential military nerve gases makes it a drug of importance. In addition, 2-PAM iodide has found important research application in the study of enzyme systems involving cholinesterase inhibitors.

2-PAM iodide labeled with C-14 makes possible the study of this drug and/or its metabolites within brain and other body tissues. Studies utilizing oxime-labeled as well as methyl-labeled PAM iodide are desirable. The lack of any published procedure for the synthesis of oxime-labeled 2-PAM, and the potential usefulness of this compound as a research tool, led us to develop the synthesis herein reported.

EXPERIMENTAL

Picolinamide-C^{14}.—Two major considerations entered into the choice of this compound as a starting point in the synthesis of C^{14}-labeled pyridine-2-aldehyde. First, because it can be prepared from cyanide-C^{14}, it affords a convenient means for the introduction of a labeled atom. Secondly, the amide can be used directly in the synthesis of the required hydrazide thus circumventing the problem of esterification of picolinic acid.

The preparation of picolinamide from 2-bromopyridine and potassium cyanide has been reported by Brode and Bremer (1). Inasmuch as these workers were concerned with optimum yield based upon bromopyridine, the procedure had to be redesigned with a view toward the achievement of optimum yield based upon cyanide.

A solution of potassium cyanide-C^{14} (390 mg., 6m*M*, 10 mc.) in water (1 ml.) was prepared in a heavy-walled Pyrex reaction tube. The tube and contents were kept cold by means of an ice water bath as cuprous chloride (250 mg.), added in small portions, was brought into solution with shaking and swirling. To the solution thus prepared were added, in order, 790 mg. (5 m*M*) of 2-bromopyridine dissolved in 1 ml. of ethanol, and 100 mg. of potassium carbonate. The tube was then sealed and heated for 40 hours at 180 to 200°.

The tube was allowed to cool to room temperature, chilled in an ice bath, then opened and the contents evaporated to dryness under reduced pressure. The residue was redissolved in hot dilute ammonium hydroxide. This ammoniacal solution was then made slightly acidic with hydrochloric acid and treated with hydrogen sulfide. Copper sulfide was filtered off, and the filtrate evaporated to dryness *in vacuo*. The residue was dissolved in a minimum volume of water, neutralized with potassium carbonate, and submitted to continuous extraction with ether for 2 hours. Crude picolinamide-C^{14} was obtained upon evaporation of the solvent. The product was purified by sublimation *in vacuo*, m.p. 105–106° [reported m.p., 106.3 to 106.8° (1)]. Yield: 182 mg. (25%), based on cyanide.

During the course of preliminary research with unlabeled materials, the product was further characterized by hydrolysis to the corresponding acid, isolated as the copper salt. The acid obtained by regeneration from the copper salt was chemically indistinguishable from an authentic purified specimen of picolinic acid.

Picolinic-C^{14} Acid Hydrazide.—The amide from the previous step was dissolved in absolute alcohol (5 ml.) and treated with 0.5 ml. of hydrazine hydrate (99–100%). This solution was heated under reflux for 48 hours on a steam bath. Solvent was then removed under reduced pressure. The product was purified by recrystallization from benzene. Yield: 169 mg. (82%), m.p. 98–99° [reported m.p. 100° (2)].

2-Picolinyl-C^{14}-benzenesulfonylhydrazide.—The above product in pyridine solution was treated with benzenesulfonyl chloride in accordance with the method of Niemann, Lewis, and Hays (3). The resultant benzenesulfonylhydrazide was purified by recrystallization from boiling alcohol. Yield: 230 mg. (68%), m.p. 202–203° [reported m.p. 202–203.5° (3)].

Pyridine-2-aldoxime-C^{14}.—Use was made of the reaction of McFadyen and Stevens (4) in the production of pyridine-2-aldehyde-C^{14} from the above benzenesulfonylhydrazide. Inasmuch as this reaction imposes rather severe conditions of temperature and alkalinity upon the relatively unstable aldehyde, it was deemed imperative that the

Received March 6, 1962, from the Department of Pharmacology, University of Chicago, Chicago, Ill.

This work was aided by United States Army Chemical Research Contract No. DA-CML-18-108-61-G-8, and United States Public Health Service Grant No. B-2331.

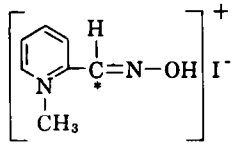
product be isolated from the reaction mixture as rapidly as possible. Accordingly, the reaction was carried out under vacuum, using an all-glass apparatus with appropriate ground glass, Apiezon (N) lubricated fittings. In essence, this apparatus consisted of a vacuum trap with a separable receiver and a side arm to accommodate a ground glass-jointed reaction tube.

With a mixture of the above benzenesulfonylhydrazide, anhydrous sodium carbonate (200 mg.) and glycerol (2 ml.) in the reaction tube, the system was evacuated to 10^{-5} mm. of Hg. The lower portion of the receiver-trap was surrounded by a liquid nitrogen bath while the reaction tube was gently heated with a micro burner. The reaction proceeded with a vigorous evolution of gas. The condensable fraction of the gas collected as an ice in the cold trap. The noncondensable portion was pumped into the exhaust system of an efficient hood which was equipped with a high-efficiency filter.[1]

When the evolution of gas had practically ceased, the evacuated trap was closed off and permitted to warm to room temperature. The separable receiver (a 1 × 10 in. test tube with ⅋ 24/40 outer joint) was used as a reaction vessel in the next operation.

To the water-clear liquid in the receiver tube was added hydroxylamine hydrochloride (20 mg.), sodium bicarbonate (25 mg.), and water (1 ml.). The resultant mixture was heated for 10 minutes on a steam bath. The oxime was isolated by continuous extraction with ether and purified by recrystallization from benzene-petroleum ether. Yield 20.2 mg (20%), m.p. 112–113° [reported m.p. 113.5° (5)].

Radiochemical purity of the pyridine-2-aldoxime-C^{14} was determined by means of paper chromatography, using a water-saturated benzene system and a water-saturated chloroform system. In each instance, an autoradiogram of the chromatographic strip showed a single band of radioactivity.



Pyridine-2-aldoxime-C^{14} Methiodide

Pyridine-2-aldoxime-C^{14} Methiodide.—Whereas pyridine-2-aldoxime methiodide has been prepared by heating the oxime with methyl iodide in a suitable solvent (6), this procedure proved unsatisfactory when applied to production of the radiochemically pure compound on a millimole scale. Thus, a scheme of synthesis was sought whereby side reactions could be minimized or eliminated by conducting the reaction at a lower temperature. The use of benzyl alcohol as a catalytic solvent (7) proved a satisfactory solution to the problem.

The oxime from the previous step was thoroughly mixed with 0.25 ml. of freshly distilled benzyl alcohol in a glass-stoppered test tube. To it was added 0.25 ml. of freshly distilled methyl iodide. The tube was securely stoppered and set aside for 1 week at room temperature. An additional 0.25-ml. portion of methyl iodide was then added and the mixture set aside for 4 or 5 days. In the meantime, bright yellow crystals of the methiodide had formed in the reaction mixture. This mixture was added, dropwise with stirring, to 100 ml. of anhydrous ether. The precipitate was collected on a sintered-glass filter, washed thoroughly with anhydrous ether, and dried in air. A sample for microanalysis was dried for several days *in vacuo*, at room temperature. Yield: 39.3 mg. (90%); m.p. 225–226° (decompn.) [reported m.p. 225–226° (decompn.) (8)].

Anal.—Calcd. for $C_7H_9IN_2O$: C, 31.8; H, 3.41; N, 10.6; I, 48.1. Found: C, 32.1; H, 3.45; I, 47.96; N, 10.5. I, 47.96.

Radiochemical purity of the pyridine-2-aldoxime-C^{14} methiodide was determined by means of paper chromatography, using a *n*-butanol:acetic acid:water (5:1:3) system, and a water-saturated *n*-butanol system. In each case an autoradiogram of the chromatographic strip showed a single band of radioactivity. Radiochemical yield 0.232 millicuries (2.3% based on potassium cyanide).

SUMMARY

1. Pyridine-2-aldoxime-C^{14} has been synthesized and used in the preparation of the corresponding methiodide.

Relationship of *in Vitro* Release to Urinary Recovery in Man of a Sustained-Release Preparation of S^{35} Prochlorperazine

By EARL ROSEN

A sustained-release preparation of S^{35}-labeled prochlorperazine prepared with different *in vitro* release patterns as determined by the rotating bottle method was administered to human subjects. Urinary recovery of S^{35} was determined by liquid scintillation counting. Previously published data on sustained-release preparations of phenylpropanolamine and trimeprazine, treated in the same fashion as the prochlorperazine data, are included. For the specific dosage form of each drug, a direct rank relationship was found to exist between *in vitro* data and the respective *in vivo* data.

EARLY IN the development of sustained-release products it was recognized that a laboratory test method could not be expected to duplicate the *in vivo* release of a product, but should provide an artificial means of assuring batch-to-batch reproducibility of a product proved to be clinically effective on the basis of controlled studies in humans (1, 2). Though numerous sustained-release products have been developed in the past, little objective human data have been reported which correlates differences in *in vitro* release patterns with *in vivo* response. Or, to put it another way, few data have been published to directly correlate the *in vitro* release pattern with clinically satisfactory material of a specific formulation.

This study was undertaken to establish that, for various dosage regimens of sustained-release formulations of S^{35}-labeled prochlorperazine, a relationship exists between *in vitro* release by the Souder and Ellenbogen technique (2) and human *in vivo* response. In addition, the experiment was designed to provide data to verify that the *in vitro* release limits used for *in vitro* control of lot-to-lot reproducibility are realistic.

The procedure utilized in this study is one previously described (3) for preparing radiochemically labeled formulations of pelleted sustained-release medication. The basic approach involves the preparation of "fast," "normal," and "slow" releasing S^{35}-labeled prochlorperazine formulations and the measurement of the radioactivity appearing in the urine after administration to human subjects.

It was recognized that this plan involved certain assumptions, namely, that the human body metabolizes prochlorperazine from any of the three formulations in the same manner, and, secondly, that the observed radioactivity measures only the phenothiazine moiety. In order to validate the treatment of experimental data and to support the conclusions, previously published data by Heimlich, *et al.* (4, 5), were subjected to a method of analysis permitting direct comparison of *in vitro* and *in vivo* results.

EXPERIMENTAL

***Preparation* of Dosage Forms.**—Chemical and radiochemical purity of S^{35} prochlorperazine dimaleate were established by spectrophotometric analysis, infrared analysis, chloride determination, half-life determination, and chromatographic analysis. The labeled compound was synthesized with a specific activity requiring no dilution with unlabeled chemical prior to formulation.

The general procedure used for preparation of sustained-release pellets was the same as previously reported by Rosen and Swintosky (3). The various sustained-release groups thus prepared were combined in varying proportions into three different pellet mixtures each of which had a different *in vitro* release pattern. Each mixture was formulated as capsules containing 15 mg. of prochlorperazine as the dimaleate salt, with an activity of 3 μc./mg. at the time of administration.

The *in vitro* release patterns of prochlorperazine were determined using the apparatus and general method reported by Souder and Ellenbogen (2). The percentage of drug released at specified intervals was obtained by difference after spectro-

The author wishes to acknowledge the technical contributions of colleagues T. Flanagan, A. Post, and D. Blackburn without whose cooperation this work could not have been conducted.

photometrically determining the amount of drug in the undisintegrated residual pellets at each test interval. The *in vitro* release patterns of the three S^{35}-labeled prochlorperazine formulations are given in Fig. 1.

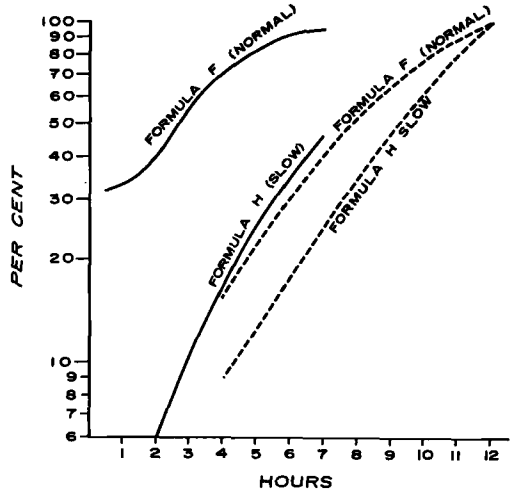

Fig. 2.—Comparison of *in vitro* release and *in vivo* measurements. Solids lines ——— represent per cent *in vitro* release of Formula "F" ("normal") and Formula "H" ("slow") pellet-type trimeprazine sustained-release formulations (4). Broken lines - - - - - - represent per cent average cumulative 12-hr. urinary recovery from adult human subjects after administration of Formula "F" ("normal") and Formula "H" ("slow") (4).

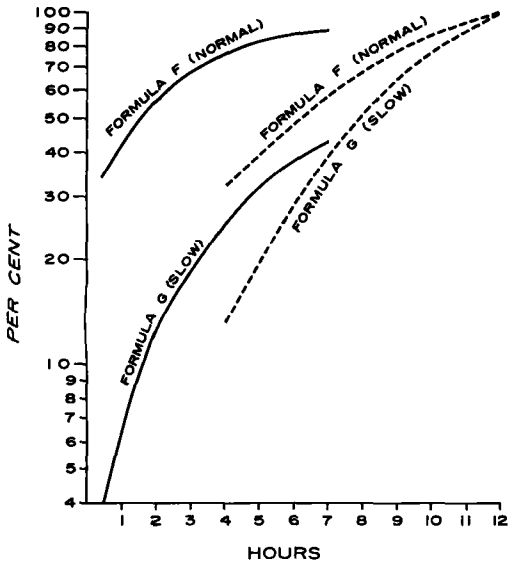

Fig. 3.—Comparison of *in vitro* release and *in vivo* measurements. Solid lines ——— represent per cent *in vitro* release of Formula "F" ("normal") and Formula "G" ("slow") pellet-type phenylpropanolamine sustained-release formulations (5). Broken lines - - - - - - represent per cent average cumulative 12-hr. urinary recovery from adult human subjects after administration of Formula "F" ("normal") and Formula "G" ("slow") (5).

Analysis of Specimens.—Urine samples were counted in a liquid scintillation counting solution adapted from one devised by Kinard (6). This solution consists of dioxane, 400 ml.; naphthalene, 80 Gm.; PPO,[1] 5 Gm.; and POPOP,[2] 50 mg. A sample of urine (0.4 ml. or less) is added to 10 ml. of liquid phosphor contained in a sample vial and, after mixing, this solution is counted in a model 314 Tri-Carb[3] liquid scintillation spectrometer. An internal standard is then added, the sample is again counted and, after proper corrections are made for quench, the counting rate of the urine sample is obtained.

Decay corrections were employed to permit a direct comparison of all experimental results.

Human Studies.—A total of 16 healthy adult subjects were given one or more of the sustained-release formulations. Of these, seven received a second formulation after a lapse of 2 weeks. Seven individuals received the "fast" formulation, nine the "normal" formulation, and seven the "slow" formulation, for a total of 23 observations. All subjects were given the drug in the morning, and urine samples were collected in 3-hr. increments over a 12-hr. period.

RESULTS AND DISCUSSION

In order to provide a basis for direct comparisons of the experimental *in vitro* and *in vivo* data, the per cent of the cumulative 12-hr. S^{35} to be excreted (Fig. 1) was plotted. The *in vitro* and *in vivo* data of Heimlich, *et al.*, on "normal" and "slow" formulations of trimeprazine (4) and "normal" and "slow" formulations of phenylpropanolamine (5) are treated in the same manner in Fig. 3.

Inspection of Figs. 1, 2, and 3 shows a direct rank relationship of the *in vivo* and *in vitro* data, indicating that "slow" or "fast" *in vitro* release patterns correlate with respective *in vivo* measurements. The data also show that formulations outside of the *in vitro* control limits can be differentiated *in vivo*.

For the formulations studied, differences in release are more demonstrable by the *in vitro* test than by *in vivo* response. This feature of the rotating bottle technique provides a measure of assurance that in the cited instances the test is sufficiently sensitive to discriminate between materials which might and those which might not produce a satisfactory clinical effect.

In vitro control specifications of 20–40% at 0.5 hour, 40–60% at 2 hours, 65–85% at 4.5 hours, and not less than 85% at 7 hours are rational and meaningful for control of this particular sustained-release prochlorperazine formulation.

It is apparent from this study that when biochemical measurements of a drug and its metabolites in humans are available in conjunction with objective and subjective clinical studies, there exists a scientific basis for evaluating the effectiveness of sustained-release formulations and for establishment of a realistic *in vitro* procedure to assure lot-to-lot reproducibility of the specific formulation prepared in the specific manner.

X-ray and Crystallographic Applications in Pharmaceutical Research III. Crystal Habit Quantitation

By JOHN W. SHELL†

It is customary practice when describing the crystal habit of a given compound to make use of qualitative terms, such as "needles" or "plates." These terms are useful in describing crystal habit as it relates to some important pharmaceutical characteristics, such as suspension stability and syringeability, but inadequate for the more involved processes in which crystal habit affects tableting ability. In this paper a method is presented for describing the crystal habit of a given compound in quantitative terms which may be used, in some instances, to predict tableting behavior and to serve as specifications for tableting materials.

THE SYMMETRY of a crystal is fixed by the crystal system and class to which it belongs. Its relative dimensions, however, are independent of its symmetry. As a crystal grows from solution, a variety of factors, notably crystallization rate and the presence of impurities, tend to influence the amount of growth on each of the possible faces. Extremes of the possible conditions result in acicular, or needle-shaped crystals as a consequence of unidimensional growth (bidimensional retardation) and tabular, or plate-shaped crystals, as a consequence of bidimensional growth (unidimensional retardation). Terms such as acicular, equant, and tabular describe crystal habit in a qualitative manner.

Crystal habit often exerts a dominant influence on some important pharmaceutical characteristics, such as suspension stability, suspension syringeability, and the behavior of powder mixes during a tablet-compressing process. In the case of suspension syringeability, the influence is mostly mechanical. A suspension of plate-shaped crystals, for instance, may be injected through a small needle with greater ease than one with needle-shaped crystals of the same overall dimensions.

In the case of tableting behavior, however, the influence of the crystal habit of the active ingredient is more involved. The mechanical influence of crystal shape just mentioned is one factor, but there is another, sometimes dominant one, which results from the anisotropy of cohesion and of hardness which is possessed by organic (low symmetry) crystals and, therefore, of most pharmaceutically important compounds. It is significant that this anisotropy bears a fixed relation to the fundamental crystallographic directions. Therefore, as crystal habit varies, the dominant faces may vary in their relation to this anisotropy, and it is the influence of the dominant faces which tends to orient the crystals during a packing or compression process. Thus, major habit variations of an active ingredient can influence greatly the ease or the difficulty of making satisfactory compressed tablets. This is particularly true when the active ingredient makes up a large portion of the total tablet mass.

In order to evaluate tableting behavior as influenced by crystal habit, the habit must be expressed in quantitative terms which reflect some relationship between the dominant faces and the principal crystallographic directions. Qualitative terms describing shape are, in some instances, not sufficient.

Relating the Dominant Faces to the Crystallographic Directions.—An ideal situation exists when the crystals are less than about 0.2 μ in size, for in this range there is measurable "line-broadening" in the X-ray powder diffraction pattern, and the average crystal sizes in each of the crystallographic directions can be measured directly. Thus, needle-shaped crystals elongated along the c axis show sharp (001) reflections, and broadened (hk0) reflections. The actual dimensions can be measured from the width of each of the appropriate peaks at half maximum height. However, most crystalline preparations for pharmaceutical use are out of the X-ray line-broadening range, being larger, usually, than one micron, and this procedure cannot be applied.

For a typical pharmaceutical composition, it has been found that a quantitative description of crystal habit as it affects tableting behavior can be based upon measurements of preferred orientation. After relating habit extremes to tableting behavior by experimentation, optical and X-ray crystallographic studies on representative single crystals allow the designation of the dominant faces by their Miller indexes. An X-ray powder diffraction

X-ray and Crystallographic Applications in Pharmaceutical Research III. Crystal Habit Quantitation

By JOHN W. SHELL†

It is customary practice when describing the crystal habit of a given compound to make use of qualitative terms, such as "needles" or "plates." These terms are useful in describing crystal habit as it relates to some important pharmaceutical characteristics, such as suspension stability and syringeability, but inadequate for the more involved processes in which crystal habit affects tableting ability. In this paper a method is presented for describing the crystal habit of a given compound in quantitative terms which may be used, in some instances, to predict tableting behavior and to serve as specifications for tableting materials.

THE SYMMETRY of a crystal is fixed by the crystal system and class to which it belongs. Its relative dimensions, however, are independent of its symmetry. As a crystal grows from solution, a variety of factors, notably crystallization rate and the presence of impurities, tend to influence the amount of growth on each of the possible faces. Extremes of the possible conditions result in acicular, or needle-shaped crystals as a consequence of unidimensional growth (bidimensional retardation) and tabular, or plate-shaped crystals, as a consequence of bidimensional growth (unidimensional retardation). Terms such as acicular, equant, and tabular describe crystal habit in a qualitative manner.

Crystal habit often exerts a dominant influence on some important pharmaceutical characteristics, such as suspension stability, suspension syringeability, and the behavior of powder mixes during a tablet-compressing process. In the case of suspension syringeability, the influence is mostly mechanical. A suspension of plate-shaped crystals, for instance, may be injected through a small needle with greater ease than one with needle-shaped crystals of the same overall dimensions.

In the case of tableting behavior, however, the influence of the crystal habit of the active ingredient is more involved. The mechanical influence of crystal shape just mentioned is one factor, but there is another, sometimes dominant one, which results from the anisotropy of cohesion and of hardness which is possessed by organic (low symmetry) crystals and, therefore, of most pharmaceutically important compounds. It is significant that this anisotropy bears a fixed relation to the fundamental crystallographic directions. Therefore, as crystal habit varies, the dominant faces may vary in their relation to this anisotropy, and it is the influence of the dominant faces which tends to orient the crystals during a packing or compression process. Thus, major habit variations of an active ingredient can influence greatly the ease or the difficulty of making satisfactory compressed tablets. This is particularly true when the active ingredient makes up a large portion of the total tablet mass.

In order to evaluate tableting behavior as influenced by crystal habit, the habit must be expressed in quantitative terms which reflect some relationship between the dominant faces and the principal crystallographic directions. Qualitative terms describing shape are, in some instances, not sufficient.

Relating the Dominant Faces to the Crystallographic Directions.—An ideal situation exists when the crystals are less than about 0.2 μ in size, for in this range there is measurable "line-broadening" in the X-ray powder diffraction pattern, and the average crystal sizes in each of the crystallographic directions can be measured directly. Thus, needle-shaped crystals elongated along the c axis show sharp (001) reflections, and broadened (hk0) reflections. The actual dimensions can be measured from the width of each of the appropriate peaks at half maximum height. However, most crystalline preparations for pharmaceutical use are out of the X-ray line-broadening range, being larger, usually, than one micron, and this procedure cannot be applied.

For a typical pharmaceutical composition, it has been found that a quantitative description of crystal habit as it affects tableting behavior can be based upon measurements of preferred orientation. After relating habit extremes to tableting behavior by experimentation, optical and X-ray crystallographic studies on representative single crystals allow the designation of the dominant faces by their Miller indexes. An X-ray powder diffraction

pattern is then measured for crystals of each habit extreme on specially prepared samples. The samples are prepared in such a manner that preferred orientation effects are maximized. A ratio of the relative peak intensities of critical lines in this diffraction pattern serves to indicate the average habit of the crystals. The ratio is useful in predicting tableting behavior, as well as serving, when desired, as a manufacturing specification.

General Illustrative Example.—In the preparation of compressed tablets of a specific drug, it has been found that some lots of bulk material vary in their ability to compress readily into satisfactory tablets. Although the pure crystalline drug in the various lots displayed no variation in measurable physical constants, examination with a petrographic microscope has disclosed a crystal habit variation. Crystals from lots with histories of good tableting behavior exhibited an acute bisectrix interference figure as the most common orientation, and crystals from lots with bad tableting behavior histories exhibited obtuse bisectrix figures most commonly. A consideration of the optic orientation (a = Y, b = X) and optic sign (positive) of single crystals indicated that the c crystallographic axis was coincident with the acute bisectrix direction, and the b axis with the obtuse bisectrix direction. Thus, it followed that "poor lot" crystals tended to lie on their 010 face, and "good lot" crystals tended to lie on their 001 face. Figure 1 shows orthogonal and clinographic projections of the crystal. The projections do not show the 001 face, although this face sometimes is present from growth, and often from cleavage, resulting in crystals with favorable tableting ability.

Using single crystal X-ray data,[1] an X-ray powder diffraction pattern was partially indexed. This allowed the choosing of powder pattern peaks whose intensities would most likely be influenced by crystals changing from 001 orientation to 010 orientation. These peaks were found in the diffraction pattern at 2 θ values of 8.72° (intensity indicates 010 orientation) and 12.09° (intensity indicates close to 001 orientation). (The 001 reflection itself is extinct.[2])

Samples for analysis were prepared so that all crystals had the best chance to orient preferentially on their most prominent faces. To accomplish this the sample was dusted onto a petrolatum-smeared glass microscope slide, and the excess shaken off. The essentially monolayered sample was placed directly in a diffractometer (General Electric XRD-5) and the intensities of the peaks at 8.72 and 12.09° were determined from the recorder tracing.

TABLE I.—CORRELATION OF TABLETING ABILITY OF VARIOUS LOTS OF BULK DRUG WITH CRYSTAL HABITS

Order of Tableting Ability of Lots		Intensity at 12.09°/Intensity at 8.72°
A		3.60
B		2.36
C		2.43
D	decreasing	1.50
E	tableting	2.00
F	ability	1.40
G		1.25
H		1.15
I	↓	1.12

[1] The orthorhombic unit cell dimensions are: a = 9.07 A; b = 20.14 A; c = 7.78 A.

[2] Corresponding d spacings for these 2 θ values are: 10.13 A for 8.72°; 7.31 A for 12.09°.

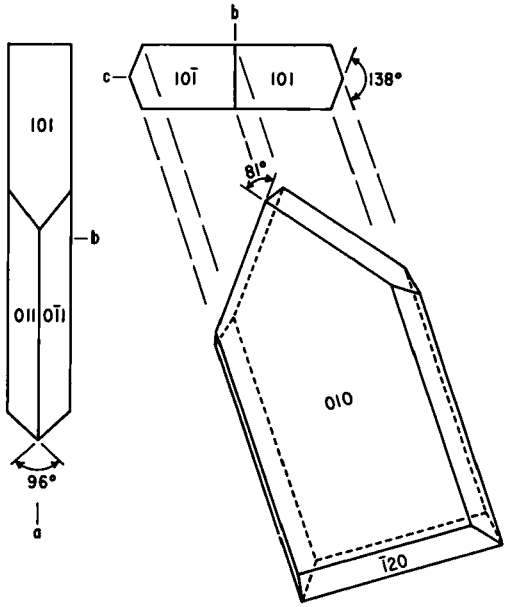

Fig. 1.—Orthogonal and clinographic crystal projections.

Since the intensity of the 12.09° peak is proportional to the mass of crystalline material with 001 orientation (good tableting ability) and that of the 8.72° peak proportional to the mass with 010 orientation (poor tableting ability), the ratio of intensities of these two peaks is a very sensitive measure of the average crystal habit represented, as it relates to tableting ability.

Table I shows a comparison of nine sample lots of bulk drug. In the left-hand column the designations are listed in decreasing order of acceptability, as determined by actual observation during the tableting process by experienced personnel. In the right-hand column are listed the intensity ratios for each sample designation as determined by the method described above. Although the averaging of multiple samplings of each lot gives better correlation, the measured values of Table I, representing single determinations, show good correlation with observed tableting behavior and indicate the validity of the method. The results reported are from a blind study.

As the method employs the use of measured ratios, it is independent of the total amount of sample taken for each determination. The validity is increased, however, by taking as large a sample as is practical and, for this reason, it has been found advisable to employ large X-ray beam and detector slits in order to scan larger sample areas. The attendant loss of resolution when large slit values are employed is not important for these studies.

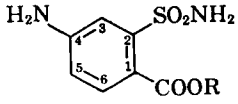
A total time of approximately 5 minutes is required for sample preparation, X-ray scanning, and ratio calculations.

Synthesis of Alkyl Esters of 4-Amino-2-sulfamoylbenzoic Acid

By GLENN H. HAMOR and MEHDI JANFAZA

Nine esters of 4-nitro-2-sulfamoylbenzoic acid were prepared by the alcoholysis reaction of passing hydrogen chloride into a refluxing solution of 6-nitrosaccharin in the appropriate alcohol. Reduction of these alkyl 4-nitro-2-sulfamoylbenzoates using hydrogen and palladium-on-carbon catalyst gave the following alkyl 4-amino-2-sulfamoylbenzoates: methyl; ethyl; *n*-propyl; isopropyl; *n*-butyl; *sec*-butyl; *n*-pentyl; 1-ethylpropyl; and *n*-hexyl. Also synthesized was isopropyl 6-amino-2-sulfamoylbenzoate. Many of these compounds possessed marked anticonvulsant activity as indicated by their prevention of the effect of strychnine or maximal electric shock in mice.

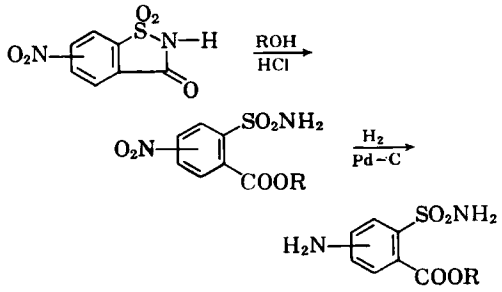
A NUMBER of alkyl esters of 4 (or 6)-amino-2-sulfamoylbenzoic acid were prepared for pharmacological screening. The ten compounds synthesized are listed and their properties given in Table I, and have the following formula



A

R = CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, i-C_3H_7(6-NH_2), n-C_4H_9, s-C_4H_9, n-C_5H_{11}, $CH(C_2H_5)_2$, n-C_6H_{13}

Nine esters of 4-nitro-2-sulfamoylbenzoic acid (Table II) were prepared by the alcoholysis reaction of passing hydrogen chloride into a refluxing solution of 6-nitrosaccharin in the appropriate alcohol (1). The 6-nitrosaccharin was prepared by the permanganate oxidation of 4-nitro-2-sulfamoyltoluene (2). Isopropyl 6-nitro-2-sulfamoylbenzoate was synthesized by refluxing 4-nitrosaccharin in acidified 2-propanol. The 4-nitrosaccharin was prepared by nitration of 2-sulfobenzoic acid, followed by reaction with phosphorus pentachloride to form the diacid chloride, and then treatment with anhydrous ammonia (3). Reduction of these 4 (or 6)-nitro-2-sulfamoylbenzoates using hydrogen and palladium-on-carbon catalyst gave the desired amino esters. The reaction sequence is



Pharmacological testing has shown several of the alkyl 4-amino-2-sulfamoylbenzoates to possess marked anticonvulsant activity.[1] The most potent anticonvulsant compound in this series, as indicated by potency in preventing the effect of strychnine or maximal electric shock in mice, was the isopropyl ester. The methyl and ethyl esters were much less potent.[2]

EXPERIMENTAL

4-Nitro-2-sulfamoylbenzoic Acid Esters.—These esters were prepared by acidic alcoholysis of 6-nitrosaccharin (prepared according to Noyes) (2) in the appropriate alcohol. The compounds are listed and their properties given in Table II. The procedure used will be illustrated by the following account of the synthesis of ethyl 4-nitro-2-sulfamoylbenzoate. Two and one-half grams (0.01 mole) of 6-nitrosaccharin was dissolved in 25 ml. of absolute ethanol and poured into a dry 50-ml. two-neck flask. The solution was heated under reflux for 2 hours, with continuous passage of dry hydrogen chloride gas through the solution. The current of hydrogen chloride gas was discontinued and the reflux condenser removed; the solution was then heated for several minutes to expel hydrogen chloride. At the beginning of the reflux period it was noted that the color of the solution of 6-nitrosaccharin in ethanol was yellow, but as the reaction proceeded, it gradually became lighter, thus showing the progress of the reaction. On cooling and slow evaporation, the hot solution yielded crystals. Recrystallization from absolute ethanol gave 2.7 Gm. (90%) of crystalline solid, m.p. 139–141°.

Isopropyl 6 - Nitro - 2 - sulfamoylbenzoate.—Four and one-half grams (0.02 mole) of 4-nitrosaccharin (prepared according to Hamor) (3) was dissolved in 50 ml. of warm dry 2-propanol in a 100-ml. round-bottom flask fitted with a gas inlet tube and a reflux condenser topped by a calcium chloride drying tube. The solution was refluxed for 2 hours, with hydrogen chloride gas being passed in for 46 minutes of this time. Evaporation of the solvent and recrystallization of the resulting solid from 2-propanol, followed by washing with cold 2-propanol gave 2.8 Gm. (50%) of white crystalline compound, m.p. 130–133°.

4 - Amino - 2 - sulfamoylbenzoic Acid Esters.—These esters were prepared by reduction of the corresponding nitro compounds, using hydrogen and palladium-on-carbon catalyst. The compounds thus synthesized are listed and their properties given in Table I. The procedure used will be shown by the following account of the synthesis of ethyl

[a] Analyses were performed by Elek Micro Analytical Laboratories, Los Angeles, Calif. [b] Melting points were taken either with a Fisher-Johns melting point apparatus or by the capillary tube method, and are uncorrected. [c] Reported m.p. 191° (5).

4-amino-2-sulfamoylbenzoate. Ethyl 4-nitro-2-sulfamoylbenzaote (3.4 Gm., 0.012 mole) in 75 ml. of ethyl acetate was reduced with hydrogen at about 3 Atm. pressure with 1.5 Gm. of 5% palladium-on-carbon catalyst. Filtration of the mixture, using a small amount of a filter aid, and evaporation of the filtrate followed by recrystallization of the resultant solid from absolute ethanol gave 2.0 Gm. (66%) of ethyl 4-amino-2-sulfamoylbenzoate, m.p. 152–153°.

Isopropyl 6 - Amino - 2 - sulfamoylbenzoate.—This compound was synthesized by reduction of isopropyl 6-nitro-2-sulfamoylbenzoate in a manner similar to that used for preparation of the 4-amino-2-sulfamoylbenzoic acid esters. Its properties are listed in Table I.

Formation of an Insoluble Condensation Product from Sulfamethizole and Formaldehyde

Sir:

Zinsser, *et al.* (1), recently reported on the composition of the sediment found in human urine after the ingestion of a combination of sulfamethizole, methenamine, and mandelic acid. Using the Bratton and Marshall assay procedure (2), more than 50% of the sediment was shown to be sulfonamide. In agreement with previous investigators (3), the sediment was also stated to contain ammonium salts and urates.

In vitro, we have investigated the compatibility of sulfamethizole, methenamine, and mandelic acid in the pH range of 4.5 to 6.0. It was found that precipitation quickly followed the addition of methenamine to solutions of the sulfonamide. Since methenamine is hydrolyzed to formaldehyde in acidic solution, the aldehyde was tested in the same manner. Formaldehyde precipitated sulfamethizole from solution.

Table I summarizes an experiment involving the addition of formaldehyde, methenamine, and mandelic acid to saturated aqueous solutions of sulfamethizole at pH 5.0 and pH 6.0. The buffer systems employed were 0.1 *M* acetate (pH 5.0) and 0.1 *M* phosphate (pH 6.0). A saturated solution of the sulfonamide was prepared in each buffer at room temperature and the actual concentrations of sulfamethizole were determined by assay (2). [Using a Coleman Junior spectrophotometer and selected round cells as described previously (4), the optical density value corresponding to 1 mcg. of sulfamethizole per milliliter was 0.098.] Ten-milliliter aliquots of each sulfonamide solution were treated with stoichiometric quantities of mandelic acid and methenamine and with 6 molar equivalents of formaldehyde. Each mixture was filtered at the end of 1 hour and the filtrates were analyzed for sulfamethizole. At both pH levels, sulfamethizole was precipitated quantitatively by formaldehyde in 1 hour. Methenamine caused the precipitation of 22–33% of the sulfamethizole in 1 hour. In a similar experiment conducted at pH 6.0, methenamine was found to precipitate 65–80% of the sulfamethizole in 20 hours.

Druey (5) and Basu (6) independently discovered that sulfathiazole formed the same insoluble condensation product with either formaldehyde or methenamine. From elemental analyses, both workers suggested possible chemical structures for the product. Later, however, new and polymeric structures were advanced for formosulfathiazole (7, 8). An investigation of the nature of the insoluble sulfamethizole-formaldehyde product is in progress at this laboratory. Another area of interest is the determination of the site of formation of the condensation product (kidney, ureter, bladder).

The Editor Comments

FOR A SOPHISTICATED PUBLIC

The pharmaceutical industry can be rightly proud of the extensive steps it takes in testing new drugs to assess their degree of safety or lack of toxicity. While much of this information or testing has been required under the new drug requirements of the federal law, nevertheless, many firms have generally exceeded the minimum testing required in order to provide as much assurance as possible that a particular drug is adequately safe for use in the treatment of a particular illness.

Unfortunately, however, on the basis of the above experimentation many pharmaceutical firms will refer to their drugs as "*safe*" in promotion campaigns to physicians, pharmacists, and even to the public. In our opinion, this is most unfortunate and ill-advised, since no drug is completely "safe" and without some possible risk associated with its use or misuse.

Other industries, such as the automobile manufacturers and the electrical appliance producers, have long ago recognized that under certain conditions their products might result in injury to the public using them. This realistic attitude has been reflected in their advertising which rarely, if ever, refers to the safety or complete lack of hazard in using their products.

Why is it, then, that the pharmaceutical industry feels that its products must be held out as being completely safe before those products will gain acceptance and use by the health professions or the public? It appears to us that the pharmaceutical industry might well consider directing more of its advertising and promotion resources toward education of the public to the fact that any drug—like everything else we use in everyday life—of necessity has a degree of fundamental hazard connected with it. The sooner that this basic fact is brought home to all those using drugs, the sooner we will have a sophisticated public utilizing the benefits of drugs with a proper realization of the cautions which must be exercised and the potential dangers which cannot be completely divorced from any drug therapy.

Leaching

A CONSTITUENT which migrates from a plastic material into a drug system or into a biological system may, for our purposes, be headed under the term *leaching*. In a résumé of this subject, it might be convenient to consider plastic devices or items in two categories. The first of these are plastic materials which can be shaped or composed into a device without the addition of other ingredients. These may be referred to as *pure* plastics, keeping in mind that pure will mean a material composed of only the polymer or copolymer. The second class or category can be called *compounded plastics*, and these materials will be composed

Received from the Drug-Plastic Research Laboratory, College of Pharmacy, University of Texas, Austin 12.
Editor's note: Part I of this review appeared in the January issue; THIS JOURNAL, 52, 1(1963).

of the polymer or copolymer with the addition of other ingredients.

Pure Plastics.—The pure plastics should present few problems to the pharmaceutical or medical practitioners in regard to leaching. That there never may be problems, however, is too much to expect even from the so-called pure plastics. The reason will become obvious when it is mentioned that often ingredients are added in very small quantities to stabilize or impart a specific property to the plastic. Since these ingredients are in very small quantities, they often are not revealed as being in the plastic. Other ingredients, such as mold release agents, or even contaminants, can become part of the plastic during the history of manufacture of the particular item. For example, it has been found that when used plastics are reground in a worn-out machine, trace metal contaminants can appear in the final plastic item. On occasions, there may be the possibility of using several pure plastic materials from different sources. Usually, these plastics are formed in pellet or powder form for convenience of use to the manufacturer of the plastic item. One supplier may add a stabilizer to his pellets or powder, which is not added to the material from the second supplier. Other situations could be revealed which would strongly suggest that the pure plastic is not in reality as pure as is believed. These trace amounts of other ingredients could cause some problems to either a drug system, to blood, or to a biological system. In the past few years reports, unfortunately not well documented, showed certain unusual results when plastic Petri dishes were employed in a laboratory (79). A change to another plastic dish, from another company, produced results which were more in keeping with the behavior of the organism.

Untoward problems may arise with the pure plastics when colorants are added to the formula. Even though these colorants might be in relatively small concentrations, the particular dye might migrate into a solution and cause a toxic effect. An example of this was seen by Autian and Brewer (80) in the development of new plastic-hubbed hypodermic needles. They noted that certain of the formulations would release a constituent to saline solution which, when injected into the mice, would cause death. Further investigation of this problem revealed that certain of the colorants could cause the toxic response.

Compounded Plastics.—As has been indicated in the first portion of this review, certain advantages may be gained by the addition of other ingredients to a polymer material. Perhaps the most important property to be gained is flexibility which, of course, would seem to be requisite for tubings which are to be used either to collect body fluids or to transfer drug solutions, blood, and other liquids into the body. The plastic which has found the most use as tubing material is polyvinyl chloride. A properly formulated polyvinyl chloride contains a plasticizer, stabilizing agent, antioxidant, and perhaps other ingredients such as a colorant. Often the final material is composed of 40 to 60% of the other ingredients, primarily of the plasticizer. The presently used polyvinyl chloride tubings for various purposes in medical practice may represent a great many formulas, without the actual formulation being revealed. This, of course, is regrettable since information of this type would prove exceedingly helpful to those who are interested in evaluating the merits of a particular polyvinyl chloride device.

One wonders how much thought was given to the use of compounded plastic materials for those devices which are to have contact with various drug systems or body tissues. The very prospect of migration of one or more ingredients from the material to a solution or tissue would seem to preclude the use of these materials until satisfactory tests are first performed. It is to the credit of several responsible firms that proper evaluations were first conducted prior to the introduction of these items to medical practice. One must, however, always be alert to the possibility of untoward reactions or problems when compounded plastics are employed.

Autian and Kapadia (81) noted that various polyvinyl chloride tubings used for medical purposes would release a constituent to several solvent systems employed in parenteral preparations. A revealing study was made by Thomas and Lagrange (82) on the leaching characteristics of several plastic materials. They exposed these materials to sodium chloride injection and to dextrose injection for a period of time and found that the polyvinyl chloride released a significant quantity of one or more ingredients to the solution. On further analysis, they found that a plasticizer and a stabilizer were the leached constituents. Hemolytic studies revealed that an organo-tin compound, used as the stabilizer, caused the reaction while the plasticizer showed no ill effect on the cells. The question of toxicity due to leaching from plastics was brought to the attention of Meyler, Willebrands, and Durrer (83), who observed

an unusual reaction during a heart perfusion study. The event was noticed directly after plastic tubings were substituted for the conventional glass. In this particular instance, the plastic tubing was a brand of polyvinyl chloride which released a constituent to a perfusion liquid, which in turn caused a cardiotoxic response to an animal heart. Further study of the problem led to the conclusion that the plasticizer was not the culprit, but rather a stabilizer used in the formulation of the plastic tubing.

A recent study in the author's own laboratory should be of interest to the reader for it does demonstrate that even several of the present tubings might cause a toxic effect, if not properly used. In this particular study, a number of unit packaged tubings (most were of the vinyl type) used for various purposes in hospitals were obtained. Many of these tubings were labeled as sterile, pyrogen free, and several indicated that they had been animal tested. Samples of these tubings were implanted into the muscles of rabbits, as suggested by Brewer and Bryant (84), and after from 3 to 7 days they were sacrificed and the area of the implants morphologically examined for any tissue response. Several of these tubings revealed a striking effect upon the tissue which could not be easily overlooked. Gas chromatographic techniques indicated that a number of components would be released to a solvent system composed of alcohol-water systems. Up to this writing, the actual component causing the toxic effect has not been found, but it appears that it may be due to one of the stabilizers. There appears to be little published information on intravenous, subcutaneous, and intramuscular toxicity of the various plasticizers, stabilizers, and antioxidants currently being used in the formulation of polyvinyl chloride tubings. It should be mentioned, however, that most of these ingredients have passed the requirements under the new food additive amendment and are considered nontoxic compounds. But, one should keep in mind that these tests include oral feeding tests and not tissue study tests. This last statement should perhaps be taken with some seriousness since it should dispel the idea that "FDA Approved," at the present time, means that the particular plastic device has been approved by the FDA. Rather, it should be noted that the ingredients used in the device have been approved for a food packaging application, not for a medical application.

From what has been said on leaching, it will be obvious that the solvent can have an appreciable influence on the migration of an ingredient from the plastic to the liquid phase. Further complications can develop when one or more solutes are present in the solvent. One example may illustrate this point. A polyvinyl chloride sheet was exposed to various concentrations of benzalkonium chloride (85). The results indicated that the cationic agent was sorbed by the sheet, but during the sorption process an ingredient or ingredients was being released to the solution. Some thought should also be given to the pH of the solution since experimental evidence has demonstrated that the rate of release might be somewhat dependent upon the hydrogen ion concentration of the surrounding liquid.

Sorption

Introduction.—When a solution is in contact with a solid phase, both the solvent and solute molecules will be striking the solid surface. If the conditions are optimum, both types of molecules may be adsorbed to the surface of the solid. Normally with "nonreactive" materials the quantity of molecules, either solvent or solute, will be negligible and for all practical purposes it may be assumed that no adsorption has taken place. On the other hand, if the chemical structures of the components making up the solid phase are of such a nature that they can electrically attract a molecule in the solution with comparative ease, a situation may exist (depending upon the total surface area of the solid phase exposed to the solution) where a significant quantity of the solute might be removed from the solution. With plastic materials there is usually not only surface attachment, but actual penetration of the solute molecules which in turn come into contact with particular attraction sites in the polymer. In fact, it may be assumed that the greatest extent of uptake of the solute from a solution would be a consequence of the solute penetrating and diffusing into the plastic. This of course, without describing any mechanism of interaction, is exactly what occurs with most dyes in both the natural and synthetic yarns. Drug uptake or binding to a particular plastic can be considered as following one of the many postulated mechanisms for dye-yarn interaction. In general, the interaction is a physicochemical phenomenon, directly related to the chemical structure of the drug and the particular physical and chemical properties of the plastic. A number of other factors will materially affect the uptake and it is well to mention the more important ones:

concentration of solution, particular solvent system, other agents in the solution, pH of the solution, temperature, time of contact, quantity of plastic exposed to solution, purity of plastic, and possible changes in the plastic material after exposure to solution.

To prevent confusion, the term *sorption* will be used in this section to indicate that both adsorption and absorption are taking place, even though one may predominate. The terms *uptake* and *binding* will be used with the understanding that both terms may refer to either equilibrium or nonequilibrium conditions.

It has already been demonstrated that plastic materials are composed of crystalline regions, dispersed throughout amorphous regions. Under the discussion on permeation of gases, the point was clearly emphasized that the penetrant molecule probably could not travel through the crystalline region, but must find passageway in the amorphous zone. Solute molecules in a solution differ not from the picture given for the gas molecules and it may be assumed, except in unusual instances, that these molecules (solute) can travel or diffuse only through the amorphous zone where they become affixed to a particular site in the polymer.

One general method of studying solute-plastic interactions is by the measurement of the quantity of solute taken up at equilibrium by a plastic material at a constant temperature and pressure. The resultant data may then be fitted to one of two basic expressions. The first of these is the empirical relationship of Freundlich (86), which may for this purpose be written as

$$\log q = \log k + 1/n \log C \qquad \text{(Eq. 13)}$$

where q is the quantity of drug or other chemical agents sorbed by a specified quantity of plastic, k and n are constants, and C the equilibrium concentration of the agent in the solution. The second, based upon kinetic considerations by Langmuir (87), may be depicted as shown below

$$\frac{1}{q} = \frac{1}{kSC} + \frac{1}{S} \qquad \text{(Eq. 14)}$$

where k is constant and S may be considered as the theoretical saturation value of solute which will be sorbed by the plastic. A plot of $1/q$ *vs.* $1/C$ will produce a straight line from which the intercept, $1/S$, may be found (see Fig. 9).

Often it is highly desirable to express in a quantitative manner the affinity of a particular drug or agent for a plastic material. In this

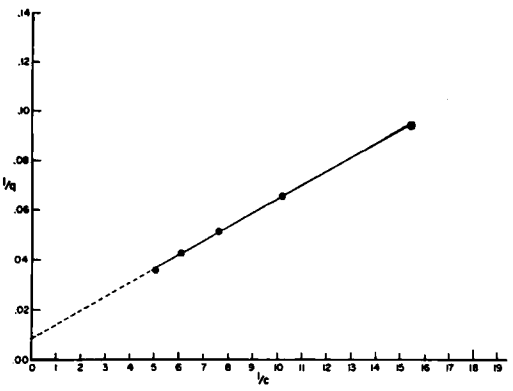

Fig. 9.—A Langmuir plot of sorption data of salicylic acid by nylon at 41.5° C. [From: Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published].

instance recourse has been made to the partial molar-free energy or chemical potential (μ). For example, it should be clear that if the chemical potential of a solute in one phase is greater than the potential in a second phase, there will be a driving force moving the solute molecules from the higher to the lower phase. At equilibrium, both chemical potentials would be equal and the driving force would be reduced to zero. It is possible to express the chemical potential of solute as (88)

$$\mu = A + RT \ln a \qquad \text{(Eq. 15)}$$

where A is a constant, dependent upon the temperature and pressure but independent of composition, R and T the usual symbols for the gas constant and absolute temperature, while a is the activity of the solute. By comparing the chemical potential in any given state to that in a standard state, represented as follows

$$\mu^o = A + RT \ln a^o \qquad \text{(Eq. 16)}$$

and subtracting this last equation from the previous one will give

$$\mu - \mu^o = RT \ln a/a^o \qquad \text{(Eq. 17)}$$

Now if in the standard state a^0 is given the value of unity, Eq. 17 will reduce to

$$\mu = \mu^o + RT \ln a$$

If we now consider a drug or solute distributed between a liquid phase (in solution) and a solid phase (plastic), we can write the expression depicting the conditions in both phases as

$$\mu_l = \mu_l^o + RT \ln a_l \quad \text{(for liquid phase)} \qquad \text{(Eq. 18)}$$
$$\mu_s = \mu_s^o + RT \ln a_s \quad \text{(solid phase)}$$

but at equilibrium

$$\mu_1 = \mu_s$$

or

$$-\Delta\mu^o = RT \ln a_s/a_1 \qquad \text{(Eq. 19)}$$

If it is assumed that the solute forms an ideal solution in both phases, activities may be replaced by concentration or

$$-\Delta\mu^o = RT \ln C_s/C_1 \qquad \text{(Eq. 20)}$$

The difference in standard chemical potential ($\Delta\mu^o$) may now be considered as the quantitative measure of the tendency of a drug or solute to move from its standard state in a liquid to its standard state in the plastic. Furthermore, this standard chemical potential may be taken as the affinity of the drug or other agent toward a particular plastic.

Equation 20 is based upon ideal conditions, a state which is often difficult to attain in practice and for this reason other more complex expressions have been developed for the evaluation of the affinity. It also appears that each particular plastic material might require a separate equation. Gilbert and Rideal (89) were one of the first to formulate a mathematical expression which could be applied to a practical situation; in this case the interaction of mineral acids with insoluble fibrous materials. Others have since used the Gilbert and Rideal equation directly, or have modified it, to fit their particular needs. Vickerstaff reviews a number of these expressions, based upon the postulated mechanism of interaction, and the reader should refer to his text for further information (90).

Little, if any, data have been published on the affinities of various agents to plastic materials, but considerable data exist for various dyes and textile material (90). Unfortunately, some of these data are in error due to the collection of results at conditions other than at equilibrium. It would seem, however, that the standard chemical potential could be used to indicate the affinity of a drug to a specific plastic material if and when such information becomes of sufficient interest to those in the pharmaceutical or research field.

Negligible uptake or sorption will be noted, at least by conventional analytical means, for a number of drugs and plastic materials. For example, with our present information it can be assumed that little sorption will occur with those plastic materials which do not have polar sites, the possibility of high uptake or sorption are minimal and often not easily discerned unless very large surface areas are exposed to the solution. Significant sorption will, however, be seen for those hydrophilic plastic materials (nylon, cellulose, acetates, etc.) which will permit the diffusion of the solute. As might be anticipated, the physical and chemical properties of the solute will also be a determinant for sorption for it appears likely that the interaction between a solute molecule and the polymer is one of an electrical nature, whether it be one of ion-ion type, dipole-dipole, ion-dipole or through secondary valence forces, such as Van der Waals' forces, or perhaps a combination of these.

In order to represent the sorption process in a simple manner, Fig. 10 is presented. Here it may be seen that a drug molecule, D, is in solution in contact with a polar plastic material. The parallel lines in the plastic material represent the crystalline zone or region, while the lower lines attempt to portray an amorphous region in the same plastic. Sites for possible interaction in the polymers are shown by the dots. When the solute molecules are placed into the solvent, one or more will diffuse toward the surface of the plastic and become adsorbed. When most of these surface sites are filled, there will be sufficient energy to permit these solute molecules to penetrate the surface and to travel or diffuse into the amorphous zone of the plastic where new binding sites become available. When all available sites are filled, equilibrium has been reached and sorption attained at one specific temperature and pressure. In most instances it will be correct to assume that the rate determining step of the sorption process is the diffusion of the drug in the matrix of the plastic and if this is the case, then special emphasis must be placed upon the diffusion constant or coefficient.

Diffusion.—In reviewing, even briefly, aspects of diffusion in insoluble materials such as plastics, it will be necessary once again to allude to some of the work of dyers and colorants in the textile industry, since this group by far has been concerned to a greater degree and depth in this facet of research than perhaps any other single group.

The usual experiments which have been utilized for the study of diffusion of solute molecules in insoluble polymeric materials may be divided into two general types: studies under a steady-state condition, and studies under nonsteady-state conditions.

Perhaps the simplest method of evaluating the diffusion coefficient of a solute in a plastic is to set up an experiment under the steady-state condition. In one compartment a known

solution of the particular solute is placed, while in the other an equal quantity of water. At repeated intervals, the water compartment is measured for solute which has permeated through the film. The data are then plotted as concentration of drug or agent appearing in the water compartment against time. The curve will initially curve, but after a steady-state condition is reached, a linear relationship will be observed from which the diffusion coefficient may be calculated using the familiar time-lag equation already given under permeation

$$D = \frac{l^2}{6\tau} \qquad \text{(Eq. 21)}$$

where l is the thickness of the film and τ the time lag or the point where the straight portion of the curve crosses the time axis (see Fig. 4).

Even though the steady-state condition has much to be desired in evaluating diffusion coefficients, often it becomes impossible to use this method and one must therefore turn his attention to experiments where nonsteady-state conditions exist. Under the nonsteady-state conditions, where the concentration of the solute in the plastic is continually changing, Fick's second law is applicable or

$$\frac{dC}{dt} = D\frac{d^2C}{dx^2} \qquad \text{(Eq. 22)}$$

where C is the concentration, D, t, and x are terms already defined. It is not, however, possible to solve for D in the above equation directly and hence recourse must be made to other mathematical expressions which are in themselves special cases dependent upon the experimental design. These special cases, for convenience, may be divided into two broad categories: for "finite solutions" (or where the concentration of the drug in the solution does not appreciably decrease over the time period of the experiment), and for "infinite solutions" (or where the concentration of the drug in the solution does decrease over the time period of the experiment). Each of these categories may be further divided into the particular geometry of the plastic (*i.e.*, plane sheet, cylinder, or sphere) and whether the diffusion coefficient is constant or varied over various concentration ranges of the solute in the plastic. Representa-

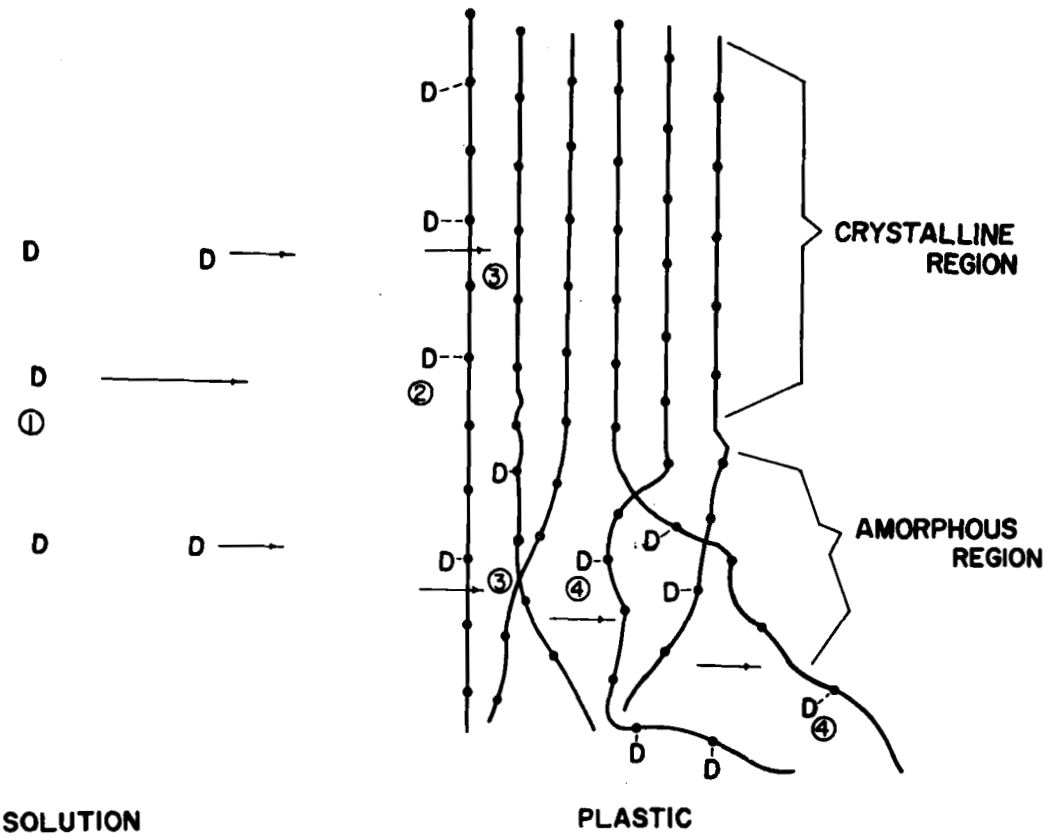

Fig. 10.—A schematic model showing sorption of a drug by nylon. D = drug molecule; -- = polymer chain; and • = binding sites in polymer.

tive mathematical expressions will be given for several of these special cases in the section to follow, but for more details the reader should become familiar with several texts on the subject of diffusion, in particular the books of Barrer (91), Jost (92), and Crank (93).

Perhaps the most work in the past for the calculation of diffusion coefficients has been based upon the "infinite solution" and a diffusion coefficient which may be considered as constant, an assumption which may not be correct, as we will learn later. For simplicity also, the plane sheet has most often been employed, even though the cylinder and sphere have received attention. For the most part, the mathematical expressions or methods have been derived for use with data collected from sorption studies.

McBain (94), as early as 1909, used an expression which apparently was borrowed from previous investigators on heat transfer problems to evaluate D from adsorption data. The equation may be stated as

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2}\left(e^{-\pi^2 Dt/l^2} + \frac{1}{9}e^{-9\pi^2 Dt/l^2} + \frac{1}{25}e^{-25\pi^2 Dt/l^2} + \ldots\right) \quad \text{(Eq. 23)}$$

where M_t is the concentration of drug or agent taken up by a sheet in time t, M_∞ is amount of the drug or agent taken up at equilibrium, and l is the thickness of the sheet. Hill in 1928 (95) used a nearly similar equation to calculate the diffusion of oxygen into muscle tissue and this particular equation has since been suggested for calculation of diffusion into cylinders.

Neal and Stringfellow (96) used Eq. 23 for the first time to calculate the diffusion coefficient of a dye in cellulose from absorption-time data. Crank and Henry (97) presented an expression following an infinite series as shown above for calculating D. This expression follows

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \times e^{-D_o\pi^2(n+1/2)^2 t/l^2}, \ldots \quad \text{(Eq. 24)}$$

For simplicity it is best to find a suitable value for t/l^2 for which $M_t/M_\infty = 1/2$ or

$$\left(\frac{t}{l^2}\right)_{1/2} = -\frac{1}{\pi^2 D_o} \ln\left\{\frac{\pi^2}{16} - \frac{1}{9}\left(\frac{\pi^2}{16}\right)^9\right\}, \ldots \quad \text{(Eq. 25)}$$

which may be reduced to

$$D_o = 0.04939/(t/l^2)_{1/2} \ldots \quad \text{(Eq. 26)}$$

Equation 26 can be used rather conveniently to find D. A sorption-time experiment is run from which t at 50% sorption is found. Since t and l (thickness) are known, D may be calculated. Up to this point it has been assumed that the diffusion coefficient was a constant and not dependent upon concentration in the plastic. Recently this has been found not to be the case for many systems and it has been surmised that (97, 98) values for D using the above equations are actually average values and should be indicated as such or designated as apparent diffusion coefficients. Crank and Park (99), using Eq. 26 as a starting point, developed a method of evaluating D as a function of concentration. These same authors have also found that desorption studies may also be used for the calculation of D and that if both are considered, a better approximation for D (than by either sorption or desorption) is possible.

In the past also, it has usually been necessary to run sorption experiments in such a manner that the concentration of the drug or agent in the solution would remain nearly constant. This problem has now been overcome by the development of newer mathematical expressions for "finite solutions" or for those cases where there is a decrease in the concentration of solution over the time period for equilibrium to be reached. Crank (93) gives full treatment to these methods in his excellent text on the mathematics of diffusion.

Since McBain's equation, a great many other equations of the same general type have evolved for both "infinite" and "finite" solutions. These usually have followed an infinite series which might be represented by the general expression (100)

$$\frac{M_t}{M_\infty} = 1 - A.e^{-BK} - C.e^{-FK} - G.e^{-HK} \ldots \quad \text{(Eq. 27)}$$

where A, B, C, etc., are numerical constants of known values and K is equal to Dt/l^2 for a plane sheet (or if for a cylinder l can be considered as the radius). The task of solving equations of this type are rather formidable and quite time consuming. Fortunately, the task has been simplified by preparing theoretical values of M_t/M_∞ for various values of K. From these tables it becomes an easy task to evaluate the apparent diffusion coefficients, as is now described. First, a sorption experiment is run at a specified temperature and the data plotted as M_t/M_∞ *vs.* the square root of time. If the diffusion is of a Fickian nature, a straight line relation will result.

Now a theoretical plot is made of M_t/M_∞ *vs.* the square root of K from data taken from

the appropriate table. This relationship will also result in a straight line. From the experimental curve at a definite M_t/M_∞ value, the appropriate t is found. In an identical manner and at the same M_t/M_∞ value, K is deduced. Since $K = Dt/l^2$ and since the values for K, t, and l are now known, it is a simple calculation to find the diffusion coefficient.

This graphical method using appropriate tables has had great use, particularly in evaluating the diffusion of dyes in textiles. Since very little published work is available for the diffusion of drugs in plastics, only one example will be cited to demonstrate the ease with which these tables can be used. The particular case will be the work of Kapadia, *et al.* (101), who studied the diffusion of salicylic acid in nylon. Their particular experiment was of the "finite solution" type, using a plane sheet.

Sorption studies were conducted at various temperatures and a plot was made of M_t/M_∞ *vs.* $\sqrt{t}$ as shown in Fig. 11. For each temperature the total amount of drug removed from the solution at equilibrium was found and equated to a per cent value. From Bertheir's table (see Fig. 12) and at the appropriate total per cent uptake

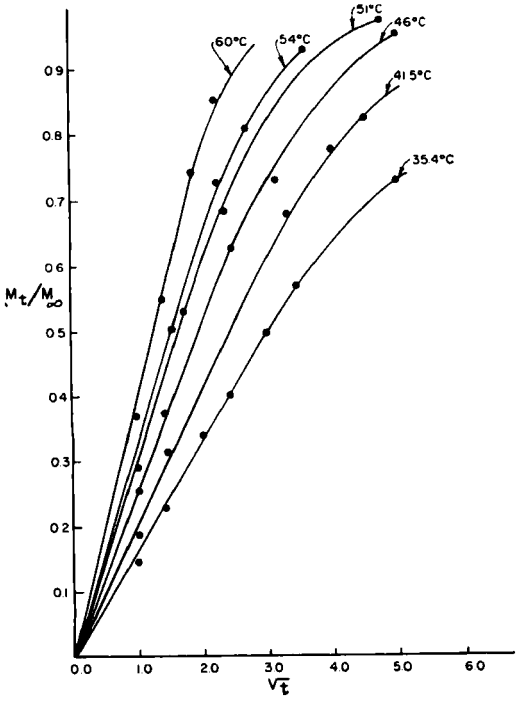

Fig. 11.—Fractional uptake of salicylic acid *vs.* square root of time at various temperatures. [From Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published.]

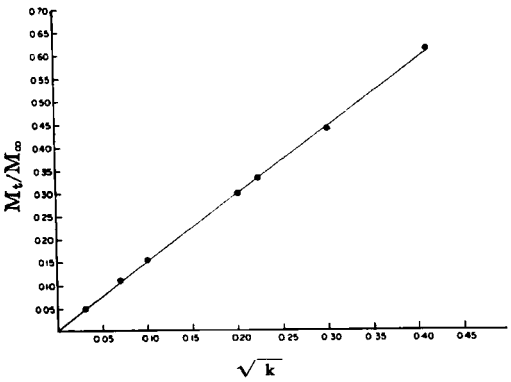

Fig. 12.—Theoretical plot of fractional uptake *vs.* the square root of K at a total per cent uptake of 45.8. K is taken from Berthier's table for a plane sheet. [Berthier, G., *J. Chim. Phys.*, **49**, 527(1952).]

TABLE VIII.—APPARENT DIFFUSION COEFFICIENT OF SALICYLIC ACID IN NYLON AT VARIOUS TEMPERATURES[a]

Temperature, °C.	D, cm.²/sec.
35.4	8.97×10^{-10}
41.5	1.26×10^{-9}
46.0	2.08×10^{-9}
51.0	2.73×10^{-9}
54.0	3.86×10^{-9}
60.0	5.91×10^{-9}

[a] Kapadia, A. J., Guess, W. L., and Autian, J., to be published.

(at equilibrium), corresponding K values for each M_t/M_∞ were used to draw a theoretical curve as shown in Fig. 12. In the manner already described, or by the method of slopes, the apparent diffusion for each temperature was calculated. These values are included in Table VIII.

Some remarks should be made in regards to the variable diffusion coefficients. Even though expressions have been developed for calculating these values as a function of concentration in the plastic, it becomes a bit more complex to arrange the experiment where accurate values of the concentration in a particular point of the plastic can be measured. McGregor, Peters, and Petropoulos in recent publications point out some of the fallacies inherent with previously used methods for studying the variable diffusion coefficients and recommend a microdensitometric technique for more accurate values of these constants (102–104). For extremely accurate work and where fundamental knowledge may be needed in regards to the diffusion of a drug into a solid material, the method of McGregor, *et al.* (102), may hold great promise. The exact technique, however,

will undoubtedly pose some problems which may be difficult to overcome in certain laboratories.

Mention might also be made of the advantage of using radiotracer techniques in diffusion studies. For example, Hayashi (105) has found this method as a very fast method for determining the diffusion of surface-active agents in nylon. Briner, *et al.* (106), have employed a liquid scintillation method for measuring the diffusion of certain agents in plastics. The radiotracer method makes possible the evaluation of diffusion in a substrate, which might not be feasible by the use of conventional analytical methods and it undoubtedly is a method which will receive greater attention in the very near future.

Mechanism for Sorption and Factors Influencing the Process.—*General.*—It has been pointed out in this review, and demonstrated experimentally in many instances, that diffusion of the solute in the matrix of the plastic is the rate determining step in the overall process of sorption. Here it should not be implied that little importance is attached to those instances when only surface adsorption occurs, but rather to indicate that when both adsorption (at surface) and absorption are taking place, most likely the quantity of solute adsorbed is insignificant to the amount absorbed. That serious consequences might arise when a very potent drug or an extremely active biological agent is adsorbed on the surface of a plastic, even in microquantities, is certainly not to be minimized and good pharmaceutical practice demands an appreciation of this fact.

The question now arises as to how best depict a mechanism for sorption of an agent by a plastic material. This task has presented a formidable obstacle to numerous conscientious investigators and it appears now that no one mechanism can describe all of the sorption process for all the varieties of plastic materials. In fact, often a number of theories can be used to describe the same interaction between a solute and a plastic. With our present knowledge, one must be content to accept certain, rather broad, generalities on the mechanism of sorption and then to turn his attention to a number of factors which may influence the sorption process.

Even though the uptake of a solute from a solution onto and into a plastic material is a sorption phenomenon, it should be clear that the chemical structure of both the solute and the polymer (making up the plastic) are the determining factors for sorption to occur. A second consideration, which can play a rather large role in the sorption process, is the physical condition of the particular plastic material. Here reference is made to the available regions in the plastic which will permit entrance and travel to the solute molecules, for without these passageways the solute will react only at the surface of the material. All other factors, such as pH, solvent systems, concentration of solute, presence of other ingredients in both the solution and plastic, and temperature only diminish or accent the magnitude of sorption.

Effect of Structure.—In considering structural relationship and uptake of drugs by plastic, one soon recognizes that little available literature has been compiled on this subject by the pharmaceutical and medical professions, the obvious reason being that sorption of a drug is highly undesired, and all efforts will be expended to prevent such an incident from occurring. One must, therefore, dip into the literature of other disciplines, in particular the textile group, to learn of the influence of the structure on uptake of chemical agents, primarily those which are used for dying of yarns (90). Other related data may be sifted from extensive work in the biological field on the binding of various agents to proteins (107–110) and protein-like compounds and recent contributions from the physical pharmacists on binding of drugs with macromolecules used in pharmaceutical systems (111–114). Data from the textile industry seem to be most closely related to our particular interest because textiles both chemically and physically resemble the plastic materials which are used in pharmacy and medicine and because textiles are solid materials, whereas the polymeric materials of the biochemists and the physical pharmacist have been primarily of the water-soluble type.

The greatest bulk of substrates investigated by the textile group has been those yarns which can be either of the cellulosic type (cotton, cellophane, cellulose acetate) or the polyamide type (silk, wool, and nylon). From these two types of materials and with the addition of other information, an attempt will be made to view certain structure features of the solute molecules which give rise to the interaction (and of sorption) between an agent and a polymeric material.

One important feature of a dye molecule is its ionic charge which can arise from such functional groups as the sulfo and carboxyl radicals for acidic dyes and from cationic quaternary

ammonium groups in basic dyes (115). The presence of this electrical charge, positive or negative, can cause either an interaction to take place or conversely can prevent an interaction. Other forces beside the ionic type for attracting and binding solute molecules to a polymer have also been recognized and it appears that the particular substrate will have a further influence on which force or combination of forces will support the interaction. For example, wool (a polyamide-like material) seems to have the ability of attracting any type of solute molecule, which will ionize in solution, while for substrates such as cellulose acetates or certain of the polyesters (Orlon), little uptake will be noted for those solute molecules which are in ionic form (115).

It seems to be well established that for cellulose fibers, the charge on the solute is of secondary importance and the particular structure and the geometric arrangement in the molecule are the most critical points in the dyeing or sorption process. A number of investigators have indicated that the dye molecule must be linear so that it can lie parallel to the polymer chain and further, that the molecule (dye) should contain polar groups spaced at critical intervals to interact with specific sites in the cellulose polymers (116–118). Vickerstaff points out that the dye-cellulose interaction seems to favor a "lock and key" process (115).

From the great number of studies on the dyeing of cellulose, Vickerstaff has been able to set down a number of requirements which a dye should meet in order to be considered for dyeing of cellulose material. These may be stated as follows (119):

1. The molecule should be capable of assuming a linear configuration.
2. The aromatic nuclei should be capable of assuming a coplanar arrangement.
3. The molecule should contain groups capable of forming hydrogen bonds.
4. The presence of a conjugated system of double bonds, which by resonance promotes coplanarity of the molecule and probably favors hydrogen bond formation by the groups at the ends of the conjugated chain.

Favorable, but not essential, conditions are (again from Vickerstaff).

5. Widely spaced hydrogen bond-forming groups.
6. The presence of the minimum number of solubilizing groups necessary for solubility.
7. The disposition of the solubilizing groups along one side of the dye molecule and of hydrogen bonding groups along the other side.

Until recently, little work of a physical chemical nature was conducted on the uptake of surface-active agents by cellulose materials. White and associates (120–122) made an intensive investigation of the absorption of certain cationic surface-active agents by cellulosic substrates (such as cotton). They theorized that the uptake was due to two processes, namely a cationic exchange between the surface-active agent and the polymer followed by an ion-pair absorption.

The acetylation of the hydroxyl groups in cellulose gives rise to commercially important materials such as cellophane and rayon. Alteration in the structure of the original material (cellulose) by the presence of acetyl groups produces a marked difference in the sorption of various solute materials. For example, most anionic dyes will not produce good coloring of rayon material as they will on cotton (123). Several reasons have been given for the inability of cellulose acetate to behave like cellulose (124). For one reason, the hydrophilic characteristic of cellulose acetate is decreased, which in turn prevents swelling (in water) in comparison to cellulose. This affords less opportunity for certain molecules to find passage through the material. A second reason for less uptake of a solute such as the acidic dyes (or anions) is the high negative surface potential on the cellulose acetate which repels the anionic molecules. Conversely, however, the cationic molecules become easily sorbed. Giles (125) has presented an interesting discussion on effects of structure on the dyeing of cellulose acetate. In his paper, he points out that a review of studies on adsorption (including absorption) gives rise to three general mechanisms of interaction: solid solution, polar forces, and nonpolar forces. Rather than coming to the conclusion that these mechanisms are conflicting, Giles gives recognition that all three types may be true, under certain circumstances. Several other interesting points are revealed in Giles' work. For example, as the number of hydrogen donating groups increase in a particular molecule, a general increase in uptake will be noted. There are instances, however, where this rule is not followed, but these exceptions might be explainable on the internal bonding of these functional groups, preventing the hydrogen from the solute molecule to bind with a negative site in the cellulose acetate. Steric hindrance may also block hydrogen donating groups (in the solute molecule) from interacting with the polymer. Forces of attraction may also be set up between hydrogen molecules of the cellulose acetate and negative sites in the solute molecule, forming the usual

hydrogen bond. Well-documented evidence is at hand to demonstrate the effect which the hydrophobic portion of the solute molecule will have on sorption of solute molecules by cellulose acetate and, in fact, with most types of substrates (125). In general, it will follow that in a related series of solute molecules, uptake of the solute will increase with an increase in an aliphatic chain.

Very little published information, if any, has appeared in which the objective of the investigator was to study sorption of drugs by cellulose acetate. Saski (126), however, has recently undertaken such a study and has demonstrated that sorbic acid will be bound to various degrees to the plastic, both from an aqueous and from a hydroalcoholic solution. It would be reasonable to assume that other similar agents would also be sorbed by the cellulose acetate, and it will be interesting to see how structural changes in the solute molecule will alter the overall uptake.

The protein fibers (silk and wool) and the polyamide fibers and plastics (nylon) present a very old substrate (silk and wool) and a relatively new substrate (nylon). In general, the uptake of certain agents on the above mentioned substrates follow to various degrees the same pathways but since nylon is a synthetic material and since more experimental work has been conducted on this substrate, the remaining portion of the section will be devoted to nylon.

Nylon has three polar sites in the molecule. On one end of the molecule there is a carboxylic acid group while on the other there is an amine group. Dispersed throughout the chain there are a number of amide linkages. These polar sites for the main part determine the binding phenomenon. Acidic dyes (salts of the various acid dyes are actually used) will interact with the terminal amino group in the following manner (127, 128). In a pH above 3.0 the end amino group will become positively charged. This positive charge will then bind the anion of the dye. In the stated pH range (above 3.0) there appears to be little interaction at the amide linkages. The carboxylic group seems to contribute little to binding of these acidic dyes. On the other hand, weak organic acids may be bound to both the terminal amino group and to the amide linkages (in this case by hydrogen bonding). Phenol appears to be bound only through hydrogen bonding to the amide linkages since acetylation of the amino group blocks completely the binding (129). As will be seen shortly, the pH of the solution will have a great effect on the uptake of acidic compounds.

Studies in the author's own laboratory have indicated that a great many weak organic acids will be sorbed by nylon (130–132). Those already studied include phenol, salicylic acid, the parabens, sorbic acid, benzoic acid, and derivatives of benzoic acid. Not all weak organic acids are bound, however, as may be witnessed by the work of Briner, Autian, and Skolaut (133) who found that no significant amounts of acetic acid, glycine, or tyrosine were sorbed by nylon. These results give further support to the already well-emphasized fact that with our present knowledge predictions of binding or uptake can only be considered as a hazardous guess—at least with the polyamides.

Cationic agents have been studied as to uptake by nylon and it appears that these interact at the negative sites in the polymer, but the exact mechanism has not been clearly defined. Guess and group (134) noted the uptake of both dicyclomine hydrochloride and benzalkonium chloride. Others have investigated the uptake of surface-active agents of the cationic type and found these also to be sorbed (105, 135).

Steric effects and internal bond formation may reduce the uptake of a particular solute molecule by nylon (as well as other substrates). For example, it has been found that salicylic acid will be bound to nylon in very large quantities, but that acetylsalicylic acid under identical experimental conditions revealed little or no binding (13).

One cannot ignore the influence of van der Waals' forces on the overall interaction between a solute and a polyamide (125, 129, 136). Many examples may be cited to demonstrate that in those molecules which are bound to various substrates, an increase in the hydrophobic characteristic will usually increase the uptake. Practical and theoretical work must still be pursued in regard to nylon as well as to other plastic materials in regard to the influence of the structure of the solute on uptake, in particular, those molecules which resemble or are considered as drugs.

Effect of pH.—Sorption of a particular solute by a plastic material will not only depend upon the structure of the polymer and the solute, but may also depend upon the hydrogen ion concentration of the solution. This of course is true of those agents which might be classified as weak organic acids or weak organic bases. The polyamides (nylon) are a good substrate to illustrate an example where pH influences the

uptake of weak organic acids. A number of textile investigators have observed that acid dyes will have less tendency to be sorbed by nylon as the pH of the dye bath is increased (127, 128). Opinions have been offered as to the mode of interaction and even though there is some difference in opinion among the investigators, Peters' explanation for a number of dyes seems to be fairly well supported by experimental data.

An analysis of an actual nylon molecule would reveal that there are many more amide groups than either of the terminal end groups (carboxylic or amino). At very high pH values, the uptake of an acid dye is quite low, but as the pH decreases a sharp increase in uptake is noted which quickly reaches a fairly constant value. At a pH around 3.0–2.5, another sudden upsurge is noted which continues with further increase in uptake. This S-type of uptake curve appears to be true of most acidic dyes and weak organic acids. Peters (127) has postulated the following mechanism for the pH effect. At the high pH values the interaction of the dye (as an ion) takes place on terminal amino groups which are positively charged forming a salt-type of binding (ion-ion). This type of combination between a dye and a substrate has already been reported for wool (137). Proof that the amino groups are taking part in the interaction may be demonstrated by acetylating these groups in nylon, whereby the uptake at the high pH is decreased. As the pH is decreased, binding or uptake is increased but does reach a limiting value which is interpreted to mean that all of the amino groups have become saturated with the dye. At the lowest pH range 3.0 and below, the nitrogen of the amide group has taken on a positive charge and attracts the dye (which is still in an ionic form even at low pH values).

Some investigators have indicated that the high rate of uptake at low pH values for the acidic dyes are in reality due to the hydrolysis of the main chain which creates new sites for interaction (138, 139). Others (127, 140) have disputed this thesis in the past but the work of O'Briain and Peters (141) sheds considerable light on the actual mechanism of high uptake at low pH values. These latter workers reveal that the acidic dyes are bound to the amide linkages either as free acids or by adsorption of the hydrogen ions to the amides followed by the dye anion. Simultaneously but much slower binding takes place with new terminal amino groups due to hydrolysis of the polymer.

Kapadia, Guess, and Autian (101) have also noted the S-type of sorption curve for salicylic acid. Figure 13 is taken from their study and illustrates the influence pH has on salicylic acid in nylon. Their postulated mechanism at the lower pH is binding of the acid to the amide linkages by hydrogen bonding since at the low pH values the salicylic acid is completely in the unionized form.

Effect of Solvents.—The solvent system may have an appreciable influence on the uptake of solute molecules. Several reasons have been stated for the effect of the solvent on sorption. Perhaps the most important influence the solvent can have is to swell and plasticize the plastic

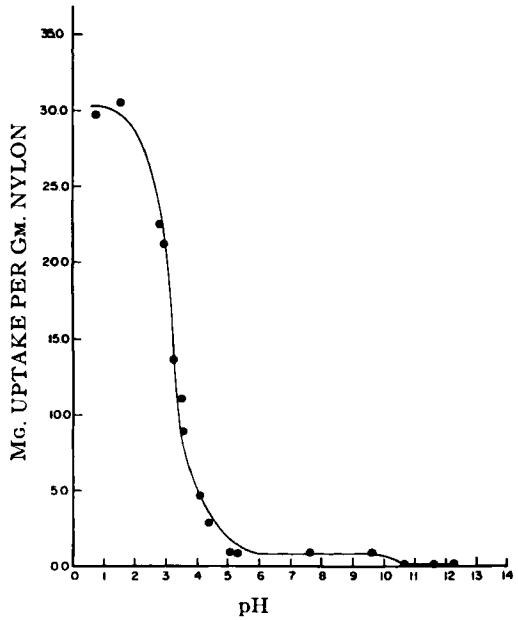

Fig. 13.—Uptake of salicylic acid by nylon at different pH values. [From Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published.]

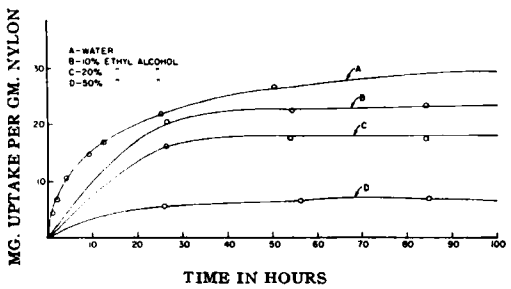

Fig. 14.—Effect of ethyl alcohol on the sorption of salicylic acid (0.15%) by nylon (41.5°C). [From Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published.]

permitting more passageways to open up for the solute molecules (142). A less polar solvent system will have less tendency to swell a hydrophilic plastic material, which in turn should decrease the uptake of a solute. One example of this may be seen in Fig. 14 where various concentrations of water-alcohol systems have been used as a solvent for salicylic acid. As the concentration of alcohol increases, there is a general drop in the quantity of drug sorbed at equilibrium by the nylon. This trend may not always be followed. For example, Teulings and White (143) noted that certain dyes (dispersed dyes) would show a decrease in uptake at equilibrium in cellulose acetate up to a specific concentration and then an increase in uptake with an increase in butanol concentration. One should of course keep in mind that certain organic solvent systems may alter the structure of the particular plastic material in a manner which increases the amorphous content of the plastic. This structural change would then make available new sites for the binding of solute molecules.

Effect of Concentration.—Certain unusual features may be met with in regard to the concentration of a particular solute in a solution. As an illustration of this point reference is made to Figs. 15 and 16. In this particular study, the investigators were observing the uptake of several acidic drugs by nylon syringes. Figure 15 demonstrates the usual uptake curve at various concentrations when the data are plotted as bound *vs.* unbound drug (in this case sorbic acid). In like manner, the data for phenol are plotted as appears in Fig. 16. It is evident that phenol, up to a certain concentration, deviates markedly from sorbic acid. In the case of phenol, the uptake increases in a linear fashion but at a specific concentration there is a sudden increase in the uptake. This result may be attributed to the swelling and plasticizing effect which phenol will have on nylon, but apparently this influence is not felt until a critical concentration is approached (130). Other effects due to concentration, which are not as dramatic as phenol, have been observed in careful experiments of certain acidic drugs in nylon. In one particular study it was noted that the Langmuir relation would hold true for a certain concentration range, but an inflection would be seen if all the points were plotted on the curve (101). Much more information will be needed to interpret these results, but it is important to recognize that concentration effects should not be ignored in practical applications, since even slight effects might cause, on long storage conditions, unexplainable results.

Another group of compounds, which have shown unusual behavior in regard to the influence of concentration, are the surface-active compounds on solid substrates. In general, as the concentration of the solution is increased, adsorption or sorption increases in a regular manner until the critical micelle concentration is reached and a sudden increase in uptake is noted. With further increase in the concentration of the surface-active agent, the uptake

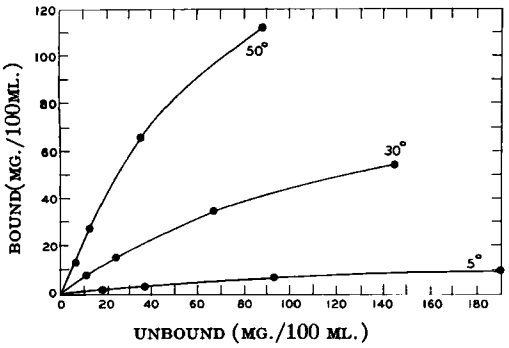

Fig. 15.—Uptake of sorbic acid by nylon syringes. [From Marcus, E., Kim, H. K., and Autian, J., THIS JOURNAL, 48, 457(1959).]

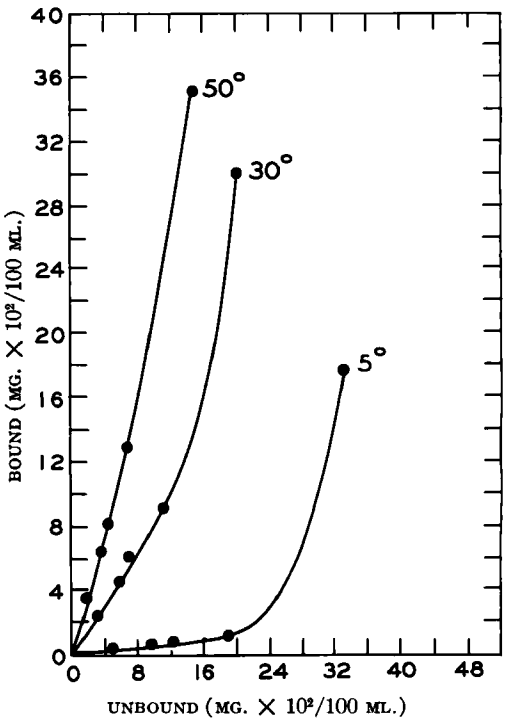

Fig. 16.—Uptake of phenol by nylon syringes. [From Marcus, E., Kim, H. K., and Autian, J., THIS JOURNAL, 48, 457(1959).]

continues until a limiting value is reached. Aickin (144) is believed to have been one of the first to note this type of behavior with surface-active agents, but since then, a great many other investigators have observed the same phenomenon on a number of unrelated substrates. Vold and Sivaramakrishnan (145) explained the sharp increase at the critical micelle concentration of surface-active agents on carbon black as being due to the binding of the surface-active agent as micelles on the substrate, rather than individual molecules. Hayashi (105), in one of his studies on nylon, postulated that below the c.m.c., the uptake was probably due to a chemical adsorption of the surface-active agent on the nylon, but at or above the c.m.c. the agent was adsorbed as micelles.

Effect of Other Ingredients in Solution.—Most practical systems, especially those which might be considered as drug systems, are composed of usually more than one solute and it becomes necessary to establish the influence of these other ingredients on the sorption process. It is known, for example, in the dyeing industry that inclusion of electrolytes will aid in the sorption process (90). Other solute molecules, which may structurally resemble the main ingredient in a solution, are apt to compete for sites in the plastic and in these instances a knowledge of the affinities would be of help in predicting which ingredient would be sorbed to the greatest extent. Possibility of interaction between the same molecules and with other molecules in the solution forming a complex or micelle will undoubtedly have an influence on the uptake, which would be extremely difficult to predict without a thorough study of the problem experimentally.

Effect of Temperature.—Temperature may have two effects on the sorption process. As the temperature is increased, the rate of uptake is increased, but the uptake at equilibrium is decreased. This statement is illustrated in Fig. 17 showing the effect of temperature on the uptake of salicylic acid by nylon. The fast rate of uptake at the higher temperatures is directly related to the increase in the diffusion rate. The lower equilibrium uptake is a consequence of several factors of which the increase in kinetic energy of both the solute molecules and polymer molecules plays the most decisive role. This energy appears to be sufficient to break bond formations between the solute and the polymer which were stable at lower temperatures and also appears to prevent, statistically, adequate solute orientation to the binding sites due to the increase in mobility of both the solute and the polymer. Certain anomalous results have been obtained with cationic agents and nylon. In these cases there was an increase of uptake with an increase of temperature. These values indicate another mechanism for the interaction (134) or a degradation of the polymer.

A great many of the investigated solute-polymer uptake data may be plotted to the Arrhenius equation with considerable success. Since diffusion is considered as the rate determining step, the influence of temperature on diffusion is usually employed as

$$\log D = \log D_o - \Delta E/2.303\ RT$$

where D is the apparent diffusion coefficient

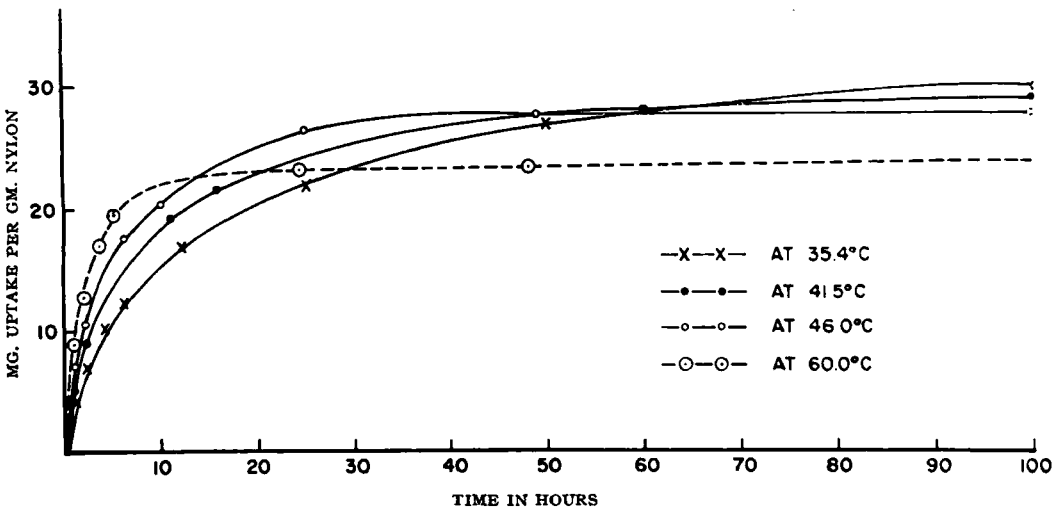

Fig. 17.—Effect of temperature on the sorption of salicylic acid by nylon. [From Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published.]

D_o is a pre-exponential factor indicating the value of D at infinite temperature, ΔE the activation energy for diffusion, R and T the appropriate gas constant and absolute temperature, respectively. A plot of log D *vs.* $1/T$ for salicylic acid is shown in Fig. 18 from which the activation energy for diffusion may be calculated and in this case ΔE is 20.5 Kcal./mole.

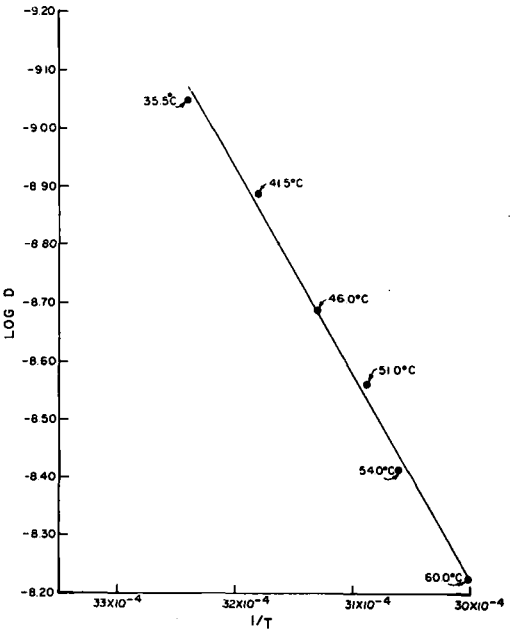

Fig. 18.—A plot of the log of D *vs.* the reciprocal of the absolute temperature for salicylic acid in nylon. [From Kapadia, A. J., Guess, W. L., and Autian, J., "Sorption and Diffusion Studies of Salicylic Acid in a Nylon Sheet," to be published.]

Effect of Other Ingredients in Plastics.—The discussion on sorption has dealt with a plastic which is considered composed of only the polymer, but it is known that many of the commercially available materials have various ingredients added for securing certain advantages. Sorption in these compounded plastics raised the question as to the possibility that the solute has interacted with one of the other ingredients, rather than the polymer. Reference may be made to an experiment conducted by Guess, Worrell, and Autian (85) on polyvinyl chloride used in medical practice. Benzalkonium chloride was found to be sorbed by the plastic to a significant degree, as may be noted by referring to Fig. 19. Even though no direct proof was obtained on the mechanism, it was believed that the benzalkonium chloride reacted with one of the other ingredients in the plastic formulation, since the structure of polyvinyl chloride would not suggest that this relatively nonpolar polymer would interact with a charged molecule to any appreciable extent.

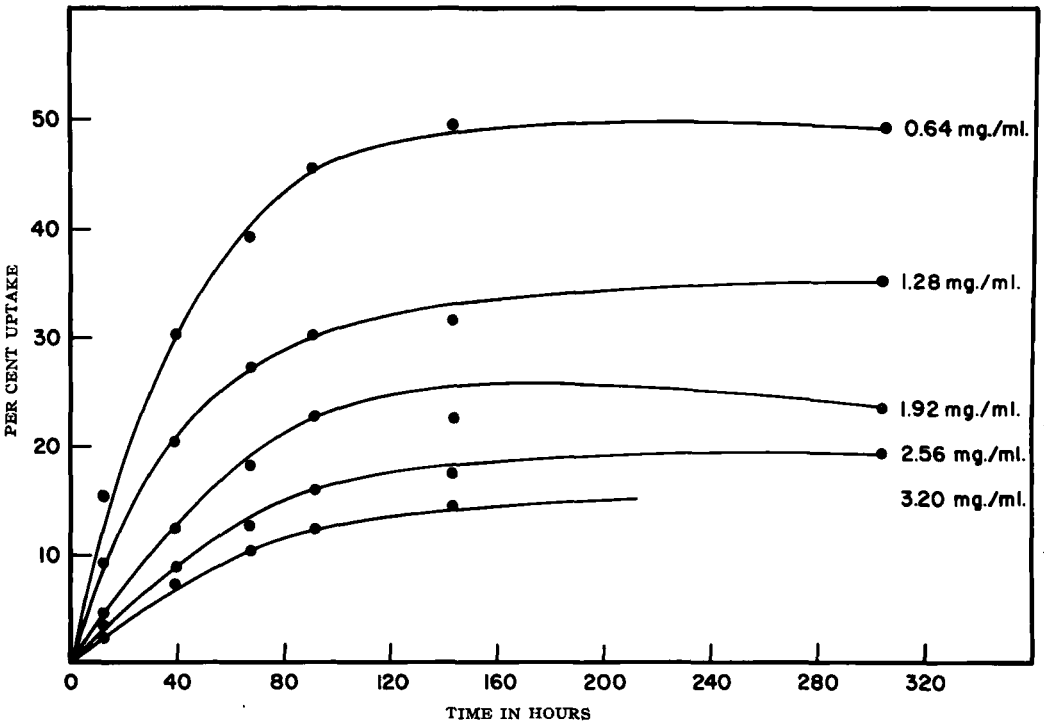

Fig. 19.—Effect of concentration on uptake of benzalkonium chloride by PVC. [From Guess, W. L., Worrell, L. F., and Autian, J., *Am. J. Hosp. Pharm.*, 19, 370(1962).]

Chemical Reactivity

The term *chemical reactivity* perhaps is not the best selection of a title for a discussion of plastics, since it appears that true chemical reactions between a polymer and a specific drug or similar agent are indeed far and few between. This does not, however, exclude the effect of oxygen under certain conditions of temperature and environment in reacting with a particular polymer, leading to eventual degradation of the plastic. Chemical reactivity here will refer to visible evidence that a particular plastic material is altered, or that a change has taken place in the physical characteristic of the solution. More of this type of information is available to the product development and packaging groups, rather than available in the literature and for this reason only a few selected instances will be cited which have been seen in the author's laboratory or have been brought to his attention.

Hartop has found that certain colorations in a plastic material are probably a result of one of the additives in the plastic, rather than due to the polymer itself (146). Since even the pure plastic materials usually have an antioxidant or a stabilizer there may always be the possibility for a stain developing on the plastic with certain ingredients in a drug product. This stain may also pass into the solution, adding a color or changing the color of the product. In a series of tests on various formulations of polyvinyl chloride with a number of parenteral products, several incompatibilities were observed. No further investigation as to the causative agent was pursued, but it was noted that in several cases, even though the exact material was employed, one drug product induced a color, while a second, having the same generic title, did not (2). The results of these studies do lend support to the contention that it will be quite difficult to predict performance in a plastic package until exacting testing programs are conducted on the whole drug product.

Since there are a variety of drugs and a variety of other ingredients used in pharmaceutical systems, one must expect occasional incompatibilities in which an agent or solvent has either etched or dissolved the plastic. This problem has already been touched upon under the section on leaching, but again, deserves some comments here.

Certain ingredients in parenteral products (as for example, paraldehyde, diethyl carbonate, benzyl alcohol, and benzaldehyde) will etch and dissolve polystyrene (147). Products of an oily nature may have a dissolving or softening effect upon polyethylene. The fluorinated hydrocarbons have been found to attack polystyrene, polyethylene, and most vinyl products. Brown has stated that the attack on plastics by the fluorinated hydrocarbons decreases as the number of fluorine atoms increase in the molecule (148).

When a chemical reaction occurs and it is easily evident, the product can be removed, thereby producing no harm to the patient or embarrassment to the manufacturer. What effect minor changes may have on the plastic or solution is a question which cannot be rightly answered. These changes usually take place after the product is out in the market or in the hands of the physician or patient. It will be interesting to see what results will turn up in the near future concerning plastic containers which have had long contact with drug systems under a variety of environmental conditions.

Alteration in the Physical Properties of Plastics

Such incidents as permeation, leaching, sorption, and chemical reactivity in regards to plastics will undoubtedly have an effect on one or more physical properties of the plastic. One of the more common observations with polyethylene bottles is the "bulging" or partial "collapse" of the container depending upon the direction of migration of a particular gas or vapor. Often this can be minimized by proper design of the container. A test which is frequently used to detect changes in physical characteristics is tensile strength measurements which may be defined as the force required to break by simple tension. As an example of the effect various liquids may have on the tensile strength of two plastic materials (polyethylene and polypropylene), Table IX is given. It will be noted that the linear polyethylene has the least ability to withstand these liquids. Surface-active agents, such as Igepal have a dramatic effect on polyethylene and, as has been stated in a previous portion of this review, Igepal is a recommended ingredient for testing of bottles. No real information is presently available as to the influence of drug systems on the tensile strength of plastics but it is suspected that certain combinations of ingredients might alter this physical property.

Temperature and changes of temperature can cause certain plastic objects to become distorted or, if the material contains plasticizers, the material may become brittle. Treatment of plastic items to various types of sterilization may alter

TABLE IX.—CHANGE IN TENSILE STRENGTH OF POLYETHYLENE AND POLYPROPYLENE ON LONG IMMERSION IN SELECTED LIQUIDS; 4 MONTHS OR MORE[a]

Liquid	Polyethylene		Polypropylene % Crystallinity	
	Low Density	Linear	63	56
Water	1.8	0	−1.1	−8.6
Isopropyl alcohol	1.1	−7.1	−7.1	−11.3
Primol D	−8.1	−78.0	10.1	−20.0
Silicone oil	−1.5	−11.0	13.8	−7.1
Methylethylketone	−5.2	−42.7	0	−6.0
Sodium hydroxide, 10%	−1.6	−14.0	3.2	−4.5
Common salt, 10%	2.6	−6.5	0	−9.1
Acetic acid, 10%	−8.1	9.8	13.2	−4.7
Dioctyl phthalate	−6.5	−2.3	5.9	−3.6
Linseed oil	−5.6	−60.5	1.1	−3.4
Corn oil	0	−50.5	16.0	−19.8
Methanol	2.2	2.5	2.3	−7.2
Igepal	−100	−100	9.8	−1.8

the physical properties of the material to such a point that the device is no longer worthy of use. Preliminary reports on electron sterilization of plastic items have revealed that certain polypropylenes will take on a color while others will become brittle and break on touch (79). Ethylene oxide sterilization with certain Freons will disintegrate a number of plastic items which are used in hospitals (79).

Since pharmaceutical products are to be in contact with containers for long periods of time prediction of the behavior of the container over the history of the product will be extremely difficult without suitable testing programs. Even this approach may fail if a complete history of the container is not known. Plastic materials are also finding use in surgery where implants for the replacement of body organs or vessels are becoming more frequent. Exactly what effects the biological system will have on these plastic materials over long periods of time is a question which still needs to be answered.

SUMMARY

Plastics are no longer a curiosity item in the practice of pharmacy and medicine. Each year which passes finds more, and often better, uses for these polymeric materials. Since at the present time there are no real controls or standards for plastic items in the medical field, each group must select their plastic material with the greatest of care. This selection must be based upon thorough testing procedures to suit the needs of the product and the market. Problems can arise from improper use of plastics and public health responsibility requires that all in the chain of distributing the plastic article, be what it may, are morally liable for any adverse consequence.

This review was an attempt to acquaint those in the pharmaceutical and closely allied fields with the opportunities which plastics offer while at the same time exposing a number of present and possible future problems. If this paper contributes in some small way to eliminating or circumventing the problems which may be associated with plastics, while kindling greater interest in developing better uses for plastics in pharmacy and medicine, the author's efforts in composing the review will be justly rewarded.

Methyl-Substituted Tyrosines and Related Compounds as Potential Anticancer Agents

By EUGENE C. JORGENSEN and ROBERT A. WILEY†

3,5-Dimethyl-DL-tyrosine, 3-methyl-DL-tyrosine, 3-methyl-5-iodo-DL-tyrosine, as well as synthetic intermediates and derivatives of these, have been prepared for study of anticancer activity. Preliminary tests on two members of the series against experimental tumors in mice showed a slight inhibition of tumor growth.

THE SYNTHESIS and antitumor activity of a number of derivatives of phenylalanine, N-acetylphenylalanine, and diethyl α-acetamido-α-benzylmalonate have been reported (1, 2). The most active members of this series were diethyl α-acetamido-α-(4-methylbenzyl) malonate (I) and N-acetyl-3-methyl-DL-phenylalanine (II). Studies relative to the synthesis of analogs of thy-

TABLE I.—SCREENING TEST FOR ANTICANCER ACTIVITY AGAINST ASCITES TUMORS IN MICE

Compound	Dose mg. per Kg. Body Weight	Gardner (ED) Lymphosarcoma TPCV,[a] %	Gardner (ED) Lymphosarcoma Survival,[b] days	Erhlich (E2) Carcinoma TPCV,[a] %	Erhlich (E2) Carcinoma Survival,[b] days	L4946 (C1) Leukemia TPCV,[a] %	L4946 (C1) Leukemia Survival,[b] days
V	500	126	+2.0	82	...	48	−1.5
VII	500	137	+2.0	65	...	77	−1.5

[a] TPCV = (Total packed cell volume treated/total packed cell volume controls). [b] Survival = (Median survival treated)-(median survival controls).

roxine involved the preparation of methyl-substituted derivatives of DL-tyrosine, and synthetic intermediates closely related to I. From these, a series of derivatives has been prepared for study as antitumor agents.

The chloromethylation procedure of Bielig (3) was adapted in the preparation of 3,5-dimethyl-4-methoxybenzyl chloride (III) and of 3-methyl-4-methoxybenzyl chloride (IV) from the corresponding methyl-substituted anisoles. 3,5-Dimethyl-4-methoxybenzyl chloride was condensed with ethyl acetamidocyanoacetate, and the resulting α-substituted cyanoacetic ester (V) converted into 3,5-dimethyl-DL-tyrosine (VI) by prolonged heating with hydriodic acid. Following the completion of this work, Dibbo, *et al.* (4), have reported a similar synthesis of 3,5-dimethyl-DL-tyrosine proceeding through the α-substituted diethyl acetamidomalonate (VII), which was also prepared in this study. This intermediate was used to prepare derivatives retaining the O-methyl group by selective hydrolysis to the acetamidomalonic acid (VIII), decarboxylation to the acetamido acid (IX), and further hydrolysis to form 3,5-dimethyl-4-methoxy-DL-phenylalanine (X).

3-Methyl-DL-tyrosine (XII) was obtained by the condensation of 3-methyl-4-methoxybenzyl chloride with diethyl acetamidomalonate, followed by hydrolysis of the ester (XI) with hydriodic acid. Iodination of XII in aqueous ethylamine yielded 3-methyl-5-iodo-DL-tyrosine (XIII).

The amino acids (VI, XII, XIII) were converted into their N-acetyl (XIV–XVI) and N-acetyl ethyl ester (XVII–XIX) derivatives.

Two of the intermediates, ethyl α-acetamido-α-cyano-β-(3,5-dimethyl-4-methoxyphenyl)-propionate (V) and diethyl α-acetamido-α-(3,5-dimethyl-4-methoxybenzyl)malonate (VII) were submitted for preliminary antitumor screening against lymphosarcoma, carcinoma, and leukemia tumors in mice[1] by the method of Costa, Blumenthal, and Greenberg (5). As shown in Table I, the compounds were inactive against the lymphosarcoma, but showed slight activity against the carcinoma (18 and 35% inhibition) and leukemia (52 and 23% inhibition). The remaining compounds herein reported will be submitted for antitumor screening.

EXPERIMENTAL[2]

3,5-Dimethyl-4-methoxybenzyl Chloride (III).—A mixture of 2,6-dimethylanisole (71 Gm., 0.5 mole), glacial acetic acid (500 ml.), and paraformaldehyde (20 Gm., 0.65 mole) was stirred and cooled in an ice bath until the temperature reached 10°. Concentrated hydrochloric acid (60 ml.) was added, and hydrogen chloride was passed into the stirred mixture for 11 hours. The temperature was held below 10° for the first 2 hours and at room temperature thereafter. The mixture was poured into 2 L. of ice water, and extracted with chloroform. The chloroform extract was washed successively with water, 1 *N* sodium bicarbonate solution, and water, and dried over anhydrous sodium sulfate. The chloroform was removed under reduced pressure, and the residual oil flash-distilled under nitrogen at reduced pressure. There was obtained 66.4 Gm. (68.6%) of an almost colorless liquid, n_D^{20} 1.5294, b.p. 124–128° (4 mm.) [Lit. (4), n_D^{20} 1.5375, b.p. 83–85° (1 mm.)].

Anal.—Calcd. for $C_{10}H_{13}ClO$: Cl, 19.25. Found: Cl, 18.89.

3-Methyl-4-methoxybenzyl Chloride (IV).—Prepared[3] from 2-methylanisole as described above, b.p. 125° (5 mm.), n_D^{20} 1.539.

Ethyl α-Acetamido-α-cyano-β-(3,5-dimethyl-4-methoxyphenyl)propionate (V).—To sodium (0.58 Gm., 0.025 mole) in absolute ethanol (10 ml.) was added in one portion ethyl acetamidocyanoacetate (4.25 Gm., 0.025 mole). 3,5-Dimethyl-4-methoxybenzyl chloride (III, 4.61 Gm., 0.025 mole) was added dropwise over 20 minutes to the stirred solution. The reaction mixture was heated under reflux for 1 hour, then poured into ice water. The yellow oil which separated solidified on standing to yield 6.99 Gm. (88%); recrystallization from methanol gave colorless plates, m.p. 139–140°.

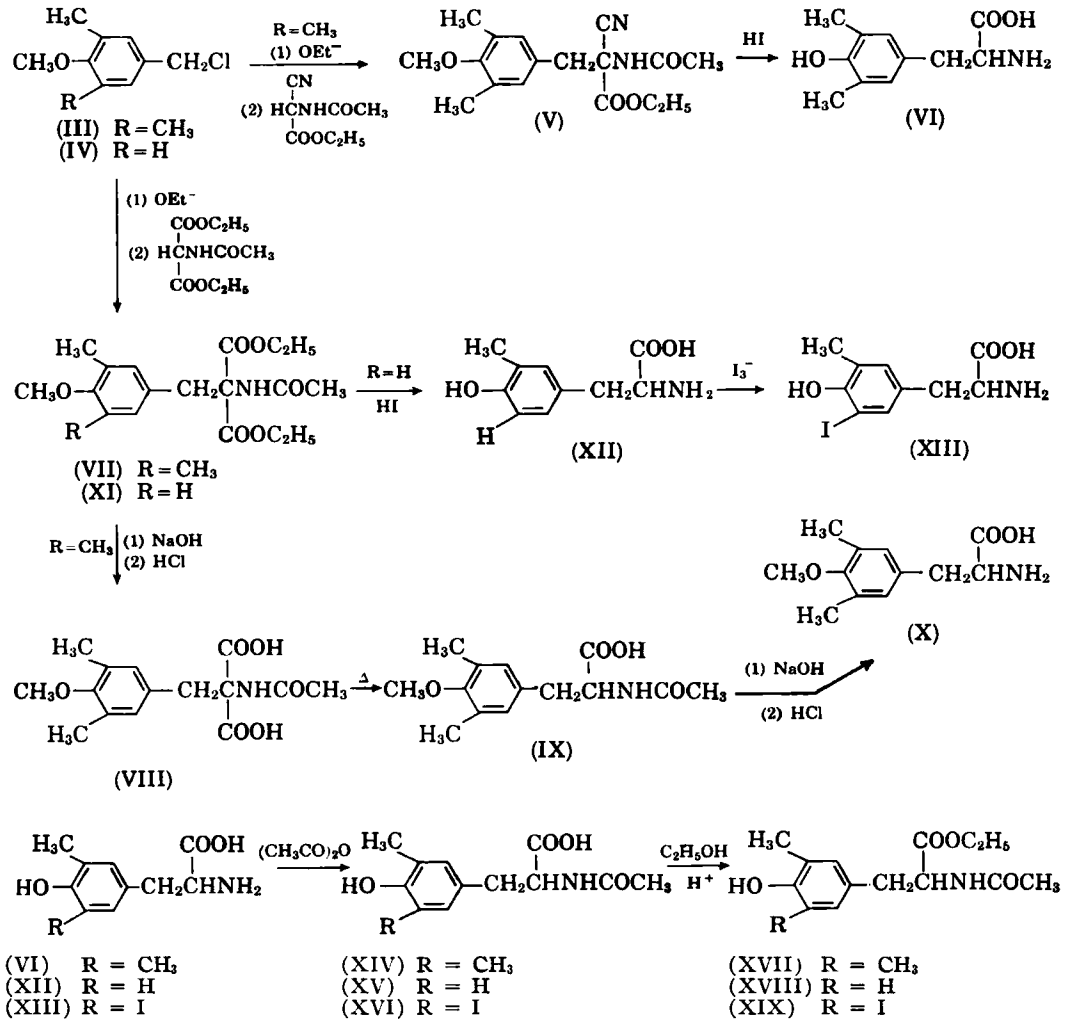
Anal.—Calcd. for $C_{17}H_{22}N_2O_4$: N, 8.81. Found: N, 8.66.

3,5-Dimethyl-DL-tyrosine (VI).—The preceding ester (V, 5.0 Gm., 15.4 mmoles) was heated under reflux for 4 hours with a mixture of glacial acetic acid (25 ml.) and 48% hydriodic acid (25 ml.). The reaction mixture was evaporated to dryness

[1] The authors are indebted to Dr. D. M. Greenberg for the biological results.

[2] Melting points obtained on a Fisher-Johns melting point apparatus and are uncorrected. Microanalyses by the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley.

[3] Prepared by Mr. Menlo Kawakami, to whom we express our gratitude.



in vacuo, and the light pink residue dissolved in hot water (5 ml.). Concentrated sodium acetate solution was added to pH 5; after overnight refrigeration, 3.03 Gm. (92%) of yellowish powder was collected. An analytical sample was prepared by iso-electric precipitation at pH 5, m.p. 240–243° (decompn.) [Lit. (4), 242–248° (decompn.)].

Anal.—Calcd. for $C_{11}H_{15}NO_3$: C, 63.16; H, 7.23. Found: C, 62.88; H, 7.13.

Ethyl α-Acetamido-α-(3,5-dimethyl-4-methoxybenzyl)malonate (VII).—To sodium (1.15 Gm., 0.05 mole) dissolved in absolute ethanol (125 ml.) was added in one portion ethyl acetamidomalonate (10.85 Gm., 0.05 mole). 3,5-Dimethyl-4-methoxybenzyl chloride (III, 9.22 Gm., 0.05 mole) was added dropwise over 20 minutes to the stirred solution. The reaction mixture was heated under reflux for 1 hour, then poured into ice water. The oil which separated soon solidified, affording 11.6 Gm. (64%) of colorless prisms. Recrystallized from hexane it had m.p. 94–95° [Lit. (4), 97–99°].

Anal.—Calcd. for $C_{19}H_{27}NO_6$: C, 62.44; H, 7.45. Found: C, 62.59; H, 7.39.

Ethyl α-Acetamido-α-(3-methyl-4-methoxybenzyl)malonate (XI).—Prepared[3] from 3-methyl-4-methoxybenzyl chloride (IV) as described above in 83.5% yield, m.p. 106–107°. An unstable polymorphic form melting at 113° was also observed, which reverted to the lower melting, more stable form on standing.

Anal.—Calcd. for $C_{18}H_{25}NO_6$: C, 61.51; H, 7.17. Found: C, 61.77; H, 6.99.

α - Acetamido - α - (3,5 - dimethyl - 4 - methoxybenzyl)malonic Acid (VIII).—The malonate ester (VII, 2.0 Gm., 5.47 mmoles) was dissolved in a solution of sodium hydroxide (5 Gm.) in 50% ethanol (50 ml.) and stirred at room temperature for 24 hours. Most of the alcohol was evaporated *in vacuo*, and the unreacted ester removed from the aqueous residue by extraction with chloroform. The solution was cooled to 10° and acidified with concentrated hydrochloric acid, whereupon 1.0 Gm. (59%) of white precipitate separated. This was crystallized from acetone-water, and from acetone-hexane, m.p. 143–144°.

Anal.—Calcd. for $C_{15}H_{19}NO_6$: C, 58.28; H, 6.19. Found: C, 58.49; H, 6.26.

N - Acetyl - 3,5-dimethyl - 4 - methoxy - DL-

phenylalanine (IX).—The preceding acetamido acid (VIII, 0.8 Gm., 2.6 mmoles) was heated at a bath temperature of 180° for 30 minutes. The resulting yellow oil was taken up in chloroform, extracted with 2% sodium hydroxide, the aqueous extract acidified, and extracted with ether. The ether solution was dried over anhydrous sodium sulfate, filtered, and allowed to evaporate in the air, affording 0.3 Gm. (44%) of colorless prisms. Crystallized from ethanol-water, it had m.p. 151.5–152°.

Anal.—Calcd. for $C_{14}H_{19}NO_4$: C, 63.39; H, 7.22. Found: C, 63.31; H, 7.20.

3,5-Dimethyl-4-methoxy-DL-phenylalanine (X).—The preceding N-acetyl derivative (IX, 3.4 Gm., 12.8 mmoles) was heated under reflux with 100 ml. of 10% aqueous sodium hydroxide for 24 hours. Acidification with concentrated hydrochloric acid resulted in a white inorganic precipitate which was removed by filtration, and the filtrate evaporated to dryness *in vacuo*. The residue was extracted with 250 ml. of boiling absolute ethanol which, on evaporation, yielded 0.7 Gm. (25%), m.p. 250° (decompn.). Purification was effected by isoelectric precipitation at pH 5.

Anal.—Calcd. for $C_{12}H_{17}NO_3$: C, 64.50; H, 7.67. Found: C, 64.22; H, 7.76.

3-Methyl-DL-tyrosine (XII).—The acetamidomalonic ester (XI, 25 Gm., 0.071 mole), 47% hydriodic acid (100 ml.), and glacial acetic acid (100 ml.) were heated under reflux for 7 hours. Additional hydriodic acid (60 ml.) was added and heating was continued overnight. The acids were removed by distillation *in vacuo*, the residue taken up in water, and the pH of the solution adjusted to 5 with 40% aqueous sodium hydroxide, affording 21.6 Gm. of white solid. One isoelectric precipitation at pH 5 yielded 12 Gm. (86%) of white amorphous powder, m.p. 285° (decompn.) [Lit. (6), 276°].

3-Methyl-5-iodo-DL-tyrosine (XIII).—To a well-stirred solution of 3-methyl-DL-tyrosine (XII, 10 Gm., 0.051 mole) in 33% aqueous ethylamine (100 ml.), a solution of iodine (15.5 Gm., 0.061 mole) and potassium iodide (20 Gm.) in water (100 ml.) was added dropwise at room temperature. After the addition was complete, stirring was continued for 30 minutes, excess iodine was reduced with aqueous sodium bisulfite, and the pH of the solution was adjusted to 5 with acetic acid. The resulting precipitate was removed by filtration and purified by isoelectric precipitation at pH 5, yielding 12.2 Gm. (74.5%), m.p. 213–214° (decompn.). The compound was not obtained analytically pure.

N-Acetyl-3,5-dimethyl-DL-tyrosine (XIV).—To 3,5-Dimethyl-DL-tyrosine (VI, 1.5 Gm., 7.18 mmoles) dissolved in 2 *N* sodium hydroxide (31 ml.) and maintained at 5–10°, acetic anhydride (3.45 ml.) was added over a period of 1.5 hours. After standing overnight at room temperature, the solution was cooled to 10° and a solution of sodium hydroxide (1.49 Gm.) in water (3.8 ml.) was added, followed by ethanol (18 ml.), and concentrated hydrochloric acid to pH 1.5. Upon partial evaporation, 1.42 Gm. of brownish crystals was deposited. Crystallization from ethanol-water yielded 1.0 Gm. (55%) of colorless crystals, m.p. 182–183° [Lit. (4), 183–185°].

Anal.—Calcd. for $C_{12}H_{17}NO_4$: C, 62.12; H, 6.82. Found: C, 62.51; H, 7.19.

N-Acetyl-3-methyl-DL-tyrosine (XV).—3-Methyl-DL-tyrosine (XII) was acetylated as described above. The resulting oil resisted crystallization, but was identified by conversion to the N-acetyl ethyl ester (XVIII).

N-Acetyl-3-methyl-5-iodo-DL-tyrosine (XVI).—The N-acetyl derivative was prepared in 80% yield from 3-methyl-5-iodo-DL-tyrosine (XIII) as previously described, m.p. 180–181°.

Anal.—Calcd. for $C_{12}H_{14}INO_4$: C, 39.68; H, 3.89. Found: C, 39.87; H, 4.03.

N-Acetyl-3,5-dimethyl-DL-tyrosine Ethyl Ester (XVII).—N-Acetyl-3,5-dimethyl-DL-tyrosine (XIV, 4.7 Gm., 18.7 mmoles), *p*-toluenesulfonic acid (0.6 Gm.), absolute ethanol (6 ml.), and chloroform (60 ml.) were heated together under reflux for 8 hours, during which the azeotropic mixture of water, ethanol, and chloroform was removed by distillation. Additional chloroform was added as needed to maintain a minimum volume of 60 ml. After 4 hours an additional 5 ml. of absolute ethanol was added. The reaction mixture was washed with 5% aqueous sodium bicarbonate and with water, dried over anhydrous calcium chloride, and the chloroform removed by distillation under reduced pressure. The residual brown oil solidified upon standing, and was crystallized from ethanol-water and from ethyl acetate-hexane, yielding 3.8 Gm. (72%), m.p. 96–97° [Lit. (4), 101–102°].

Anal.—Calcd. for $C_{15}H_{21}NO_4$: C, 64.48; H, 7.58. Found: C, 64.20; H, 7.33.

N-Acetyl-3-methyl-DL-tyrosine Ethyl Ester (XVIII).—The oily N-acetyl derivative (XV) was esterified as described above, yielding a crystalline compound, m.p. 133–134°. The overall yield from 3-methyl-DL-tyrosine was 56%.

Anal.—Calcd. for $C_{14}H_{19}NO_4$: C, 63.38; H, 7.22. Found: C, 63.57; H, 7.11.

N-Acetyl-3-methyl-5-iodo-DL-tyrosine Ethyl Ester (XIX).—The N-acetyl derivative (XVI) was esterified as described above, yielding (66%) a crystalline compound, m.p. 126–127°.

Anal.—Calcd. for $C_{14}H_{18}INO_4$: C, 42.98; H, 4.64. Found: C, 43.03; H, 4.50.

Studies on the Mechanism of Action of Phenolic Disinfectants II

Patterns of Release of Radioactivity from *Escherichia coli* Labeled by Growth on Various Compounds

By JOSEPH JUDIS

Previous studies on the leakage of radioactivity from glutamate-C^{14} labeled *Escherichia coli* cells in the presence of phenolic disinfectants were extended to involve cells labeled by growth on glucose-U-C^{14}, acetate-C^{14}, adenine-C^{14}, sulfate-S^{35}, and phosphate-P^{32}. In general, the phenolic disinfectants considered caused varying amounts of radioactivity to be released from the labeled cells. The phenol derivatives did not cause leakage of significant amounts of radioactivity from heat-treated cells, and cells exposed to *n*-butanol (which breaks the osmotic barrier) did release additional radioactivity when treated with *p*-chloro-*m*-xylenol or phenol, but the total counts released under the experimental conditions did not exceed that with further butanol treatment. Cells labeled with P^{32}, once treated with *p*-chloro-*m*-xylenol, continued to release radioactivity in saline buffer but glucose-C^{14}-labeled cells did not. The amount of radioactivity released from variously labeled cells in the presence of phenol, *p*-chloro-*m*-xylenol, or *n*-butanol was affected by temperature.

In previous studies (1), it was shown that *Escherichia coli*, when labeled by incubation with glutamate-C^{14}, would lose radioactivity when exposed to phenolic disinfectants. This loss of radioactivity was proportional to the concentration of the phenol derivative and was caused by all of the phenols tested. It was assumed that the radioactivity lost could be due to extrusion of cell contents through a damaged cell membrane. This hypothesis was further investigated by studying the release of radioactivity in the presence of phenol derivatives from *E. coli* labeled by growth on a number of radioactive compounds.

METHODS AND MATERIALS

Materials.—Only reagent grade chemicals were used and biochemicals were obtained from Nutritional Biochemicals Corp. or the California Corp. for Biochemical Research. The radioactive compounds were obtained either from the California Corp. for Biochemical Research, New England Nuclear Corp., or Abbott Laboratories. The labeled organic compounds had the following specific activities (mc./mmole): glucose-U-C^{14}, 4; sodium acetate-1,2-C^{14}, 10.5; adenine-8-C^{14}, 14.4; sodium glutamate-3,4-C^{14}, 2.3. Phosphorus^{32} was purchased as NaH_2PO_4 in solution with an activity of 10 μc./5 ml., and sodium sulfate-S^{35} was obtained with an activity of 50 μc./5 ml. The organic compounds were dissolved in distilled water to give a concentration of 2 μc./ml. A number of the phenol derivatives were a gift of the Ottawa Chemical Co., Toledo, Ohio.

Labeling of Bacteria.—The procedure for labeling *Escherichia coli* ATCC 11229 (the strain used throughout) with glutamate-C^{14} has been previously described (1). The synthetic medium (C) of Roberts, *et al.* (2), was used for growth as previously. Glucose-C^{14}, sodium sulfate-S^{35}, or sodium phosphate-P^{32} were added to the medium at the time of inoculation. In the case of P^{32}, the total phosphate content of the medium was reduced to one-fourth of the usual to permit a greater uptake of P^{32}. Approximately 1–2 μc. of glucose-C^{14} or sodium phosphate-P^{32}, or 10–20 μc. of sodium sulfate-S^{35} were added to 200 ml. of medium in a 500-ml. Erlenmeyer flask. The culture flasks were incubated on a Burrell wrist action shaker for 24 hours at 37° and harvested by centrifugation, followed by three washes with cold saline to remove any medium constituents. In the case of adenine-C^{14} and sodium acetate-C^{14}, normally two flasks (200 ml. of medium per flask) were grown for 24 hours, as above, without the addition of the labeled compounds. The cells were harvested by centrifugation and resuspended in one flask of fresh medium containing 2 μc. of radioactive acetate or adenine. The flask was shaken for an additional 3 hours at 37°, after which the cells were harvested and washed as above. During growth on labeled organic compounds, the flasks were attached to a U-tube containing soda lime to trap $C^{14}O_2$.

The washed, labeled cells were suspended in saline to give a concentration of 4×10^{10} cells/ml., as determined by turbidity readings previously calibrated with plate counts.

Measurement of Release of Radioactivity.—Basically, the previously described procedures (1) were used throughout. Phenol derivatives (except phenol) were dissolved in 25% v/v ethanol. Reaction mixtures contained, in a total volume of 3.0 ml., 2.4×10^{10} cells, pH 7.2 phosphate buffer in a final concentration of 0.02 *M*, the phenol derivative in a volume of 0.5 ml. (or made up to 0.5 ml. with 25% v/v ethanol) and enough saline

to bring to volume. The reaction mixtures were incubated at 22 ± 2° for a total of 10 minutes and centrifuged for 20 minutes. Aliquots of the supernatant and the cells were dried on 1¼ inch, concentric ring stainless steel planchets, and radioactivity was assayed in a Nuclear-Chicago thin window gas flow counter.

In the experiments in which the amount of radioactivity released was measured at time intervals, a number of replicate reaction mixtures were prepared and removed at the indicated times for centrifugation (5 minutes at 14,000 r.p.m.).

RESULTS AND DISCUSSION

A bactericidal substance may act by a number of possible mechanisms which could be roughly categorized as either metabolic or physical-chemical (structural damage). Undoubtedly, a given substance may combine these mechanisms. In the case of phenolic disinfectants, there has been relatively little work on metabolic effects. Recently published data (1, 3–10) stress the effects of phenol derivatives on permeability mechanisms and suggest that damage to the latter are responsible ultimately for their killing effect. The results shown in Table I would tend to indicate that in the concentrations used, phenol derivatives do cause leakage of radioactivity from *Escherichia coli* labeled by growth on a number of compounds. The highest concentration used of each phenol derivative was adequate to cause at least 99% killing or more under the experimental conditions (1) except 2,4,6-trichlorophenol which caused 32% killing and 2,4-dichloro-*m*-xylenol, 97% killing.

Roberts, *et al.* (2), labeled *E. coli* by growth on a number of radioactive compounds (such as glucose, acetate, purines, sulfate-S^{35}, and phosphate-P^{32}) and fractionated the cells to determine into which type of compounds the label was incorporated. For example, inorganic sulfate was incorporated primarily into protein; phosphate into nucleic acids primarily but also phospholipids and metabolic intermediates; acetate equally into lipids and protein; and glucose, primarily into protein but also nucleic acids, lipids, and some metabolic intermediates. It was hoped that if phenol derivatives would cause release of radioactivity from cells labeled by growth on specific compounds to a much greater degree than when labeled with other compounds, some insight might be obtained as to what the substrate, in general terms, might be for phenols.

The data in Table I would seem to suggest that phenol derivatives cause release of the highest per cent of radioactivity of cells labeled by growth on adenine-C^{14} or phosphate-P^{35}, both of which are reported as being incorporated primarily into nucleic acids. Both DNA and RNA have been detected in isolated membranes (11, 12) although nucleic acids, nucleotides, and other phosphorus compounds could also originate from within the cell. Joswick (10) has reported the release of 260 mμ-absorbing substances (purines and pyrimidines) from bacteria in the presence of hexachlorophene, and the release of 260 mμ-absorbing substances is generally taken as an index of damage to the mechanisms which control permeability of the cell.

The substantial amounts of radioactivity released from cells labeled by growth on sulfate-S^{35}, which is incorporated primarily into protein, could also originate in the cell membrane which is known to contain considerable protein (13). Radioactivity from acetate-C^{14} cells, which is reported to be incorporated about equally into

[a] The cell concentrations in the reaction mixtures were 8 × 10^9 cells/ml., with the exception of the cells labeled with glutamate-C^{14} which was 3.8 × 10^9 cells/ml. The labeled cells had approximately the following activities (c.p.m./10^9 cells): glucose-C^{14}, 300; acetate-C^{14}, 300; adenine-C^{14}, 2600; sulfate-S^{35}, 1500; phosphate-P^{32}, 40 to 186; glutamate-C^{14}, 520. [b] The radioactivity released in the appropriate control (ethanol-buffer for phenolic disinfectants except phenol and saline-buffer for others) was subtracted to obtain the net leakage. [c] Alkyl (C_{12}–C_{16}) dimethyl benzyl ammonium chloride, Rohm and Haas Co., Philadelphia, Pa.

lipids and proteins (2) of *E. coli*, is also released. The greatest release was found with glutamate-C^{14}-labeled cells and, although it is not clear as to what the glutamate is incorporated into, it is rapidly incorporated into nondiffusible compounds (2) and would not be simply adsorbed to the cells. While it cannot be said that the data in Table I indicate damage to the cell membrane as the basis for the lethal action of phenols, they are compatible with this hypothesis.

It would seem that the source of the radioactivity released from labeled cells must be due either to weakening or destruction of the permeability barrier of the cell, or "uncoupling" of protoplasmic constituents, or a combination of the two. If phenolic disinfectants act by affecting the permeability barriers, they should not cause release of additional radioactivity from cells whose permeability barrier has been destroyed. This can be accomplished by heating the cells, which causes a rapid release of the cellular pool and a certain amount of cytoplasmic degradation (14), or treatment with *n*-butanol, which breaks the osmotic barrier (15).

In Tables II, III, and IV, it can be seen that neither phenol, *p*-chloro-*m*-xylenol (PCMX), or butanol caused significant additional release of radioactivity from heated cells, thus indicating little or no additional cytoplasmic degradation. These results are in agreement with Beckett, *et al.* (14), who studied the release of 260 mμ-absorbing exudate in heat-treated *E. coli*, followed by hexylresorcinol. When labeled cells were first treated with butanol, and then retreated with phenol, *p*-chloro-*m*-xylenol, or butanol, the total counts released never exceeded that obtained with butanol, although the rate of release varied. Beckett, *et al.* (14), concluded from their data that hexylresorcinol caused extensive intracellular uncoupling because much more exudate was released from *E. coli* after preliminary treatment with butanol (which broke the osmotic barrier) than without preliminary treatment of the cells. The data in Tables II, III, and IV seem to be more compatible with the contention that the phenol derivatives considered, like butanol, act by breaking the permeability barrier.

It is interesting to speculate as to whether the alleged damage caused to the cell membrane is quantitatively related to the amount of phenol derivative to which the cell is exposed or whether the effect is such that once small damages are caused, they rapidly enlarge and leakage proceeds continuously. Experimentally, this was approached by treating cells with *p*-chloro-*m*-xylenol, and then exposing these cells to either saline-buffer, butanol, or additional treatments with *p*-chloro-*m*-xylenol. The results obtained are given in Tables V and VI. It would seem that phosphate-P^{32}-labeled cells continued to release some radioactivity once treated with *p*-chloro-*m*-xylenol, and additional exposure to the latter did not markedly affect the release of

[a] The cells had an activity of 2049 c.p.m./10^9 cells.

radioactivity. However, glucose-C^{14}-labeled, *p*-chloro-*m*-xylenol-treated cells did not release additional radioactivity when extracted with saline-buffer or ethanol-buffer. Also additional treatment with *p*-chloro-*m*-xylenol did not cause release of much additional radioactivity.

It is generally assumed that the antimicrobial activity of phenol increases with temperature (16, 17) and one would presume that phenomena associated with killing of bacteria by phenol derivatives should respond similarly. Table VII presents the per cent of radioactivity released from variously labeled cells in the presence of phenol, *p*-chloro-*m*-xylenol, and *n*-butanol at three temperatures. In general, an increase in temperature caused an increase in release of radioactivity. The only exception occurred with sulfate-S^{35}-labeled cells. It would seem that the latter observation coupled with the low release of radioactivity caused in sulfate-S^{35}-labeled cells by butanol would suggest an origin of the radioactivity which might be different from that obtained from cells labeled in other ways. Perhaps the fact that phenol derivatives cause the release of more counts from sulfate-S^{35}-labeled cells than butanol may indicate that some of the counts are coming from surface layers rather than low molecular weight compounds which would be released simply by breaking the osmotic barrier. Joswick (10) described a biphasic release of cell exudate caused by hexachlorophene which is also known to occur with other surface-active detergents (18) and polymyxin (19). He considers the leakage at 0° to be related to membrane damage, and at higher temperatures to be related to autolysis.

[a] The cells had an activity of 368 c.p.m./10^9 cells.

However, in the experiment for which results are presented in Table VII, insufficient time would have elapsed for significant autolysis.

Figures 1 and 2 indicate the rates of release of radioactivity from either phosphate-P^{32} or sulfate-S^{35}-labeled cells in constant contact with *p*-chloro-*m*-xylenol. The difference in the shapes of these two curves also suggest the mechanism of release and/or the origin or identity of the radioactive compounds released may be different. The control curves indicate a greater tendency for leakage after 1 to 2 hours, of P^{32}-labeled compounds than of S^{35}-labeled compounds.

In general, the observations presented above and others would suggest that phenols exert their lethal action by physical damage to the permeability barriers. It is quite reasonable to expect that a relatively minor amount of physical damage, such as alteration in permeability without lysis, could be lethal. For example, Strauss (20) reported the formation of a lethal permeability defect in *E. coli* by a mutagenic alkylating agent, ethyl sulfate. On the other hand, Nathan (21) described a permeability change in *Lactobacillus plantarum* caused by chlorpromazine which was nonlethal. It must still be recognized that evidence regarding permeability damage and lethal effects of phenols is circumstantial and, as has been shown by Stedman, *et al.* (22), and Kravitz, *et al.* (23), the total effect of a germicide (a quaternary ammonium compound in their studies) may involve, to different extents, leakage of cellular materials and inhibition of energy yielding reactions. The contribution of each of these effects may depend upon a number of conditions, and varying the latter will vary the influence of a given effect. There are a number of additional approaches to examining the mechanism of the lethal effects of phenolic disinfectants, such as determining the cytological site of uptake of these compounds. If the cell membrane is the site of action of phenolic disinfectants, one should be able to assume that the latter would be bound to the membrane and concentrate there, at least until the integrity of the latter is destroyed and the germicide penetrates into the cell. It would be useful to determine the relative distribution of labeled phenolic disinfectants in the usual fractions obtained in cell fractionation, or even better, among the basic structural fractions, such as the cell wall, cell membrane, and cytoplasm. Beckett, *et al.* (4, 5), have already shown that cell walls from *E. coli* do not bind hexylresorcinol although the whole cell does.

More precise knowledge of the identity of the substances which leak from the cell would be useful for determining to what extent phenol derivatives

cause cytoplasmic degradation following membrane disruption. Bean and Walters (24) have shown that benzylchlorophenol-induced cell exudate from *E. coli* influenced survival in a bactericidal system and interpreted their data to indicate that the last survivors utilize the released cell constituents as nutrients. Also to be explored are the effects on metabolism of the germicidal derivatives of phenol, and even more challenging, the biochemical and biophysical basis for the relative nontoxicity to animals (25) of certain potent phenolic disinfectants such as *p*-chloro-*m*-xylenol and 2,4-dichloro-*m*-xylenol.

Interaction of Pharmaceuticals with Schardinger Dextrins I

Interaction with Hydroxybenzoic Acids and *p*-Hydroxybenzoates

By JACK COHEN† and JOHN L. LACH

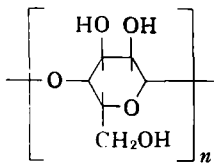
By means of the solubility method of analysis, the Schardinger dextrins were shown to interact in aqueous solution with benzoic acid derivatives. A definite interaction occurred with all compounds tested. Some stoichiometric data are presented and several formation constants calculated. It is postulated that both hydrogen bonding and inclusion formation are responsible for the main interaction observed.

SCHLENK (1) defines inclusion compounds as addition compounds in which one entity fits into and is surrounded by the crystal lattice of the other. These inclusion compounds may be called "no bond" complexes and are characterized by the lack of adhesive forces between the components of the complex. It is not a chemical interaction which causes an inclusion compound to form, although this may be a factor in the net complexation observed.

The steric configurations of the molecules are such that the enclosing, or "host," molecule can spatially enclose the included, or "guest," molecule, leaving unaffected the bonding systems of the components. Geometrical rather than chemical characteristics of the molecules are limiting factors in the interaction.

The chief forces involved in an inclusion compound are those holding host molecules to each other forming the space which encloses the guest molecule. Such is not the case with monomolecular inclusion compounds formed by one molecule of host enclosing one or more molecules of guest. This type of inclusion formation is typified by the Schardinger dextrins.

The Schardinger dextrins are a series of homologous oligosaccharides obtained from the breakdown of starch by the action of *Bacillus macerans* amylase. They are also known (2) as the cycloamyloses, cyclodextrins, and cycloglucans. They are homogeneous cyclic molecules composed of six or more alpha-D-glucopyranose units linked 1-4 as in amylose (3). Their structure is



where n is 6, 7, or 8, known as the alpha, beta, and gamma cyclodextrins, respectively.

The cyclic structure of the Schardinger dextrins confers upon the compound the ability to form monomolecular inclusion compounds where the guest is enclosed within the cyclodextrin void. These inclusion compounds may be grouped within the class of clathrate compounds where the host assumes a cagelike shape. Because of their cyclic structures, and the relatively large open space within each molecule (6 Å. for alpha, 8 Å. for beta, and 10–11 Å. for gamma), they have been reported to form complexes with crystal violet (4), carbon dioxide (5), 1-isopropyl azulene, cinnamaldehyde, hexachlorocyclohexane, pentamethylene tetrazole, and diethylaminoethyl-*p*-amino benzoate (6), ethylene (7), methyl orange (8), tetrachlorosalicylate, butter yellow, and adrenaline (9), and various gases (10).

Because of their different internal ring sizes, the cyclodextrins show different degrees of inclusion formation with different sized molecules. For example (11), alpha has been shown to form adducts with chlorine, bromine, iodine, hydrocarbons, and benzene derivatives with small substituents. Beta interacts with bromine, iodine, and almost any organic molecule. Gamma interacts with iodine and only large organic molecules. Alpha forms an inclusion compound with ethylene (7), while beta does not.

The clathrate forming power of the cyclodextrins has been utilized in various applications. They have been shown (12) to retard the cleavage of glycosides by inclusion. Cramer

(13) has carried out basic catalyses with the cyclodextrins. They have been used as indicators (14) in paper chromatography. By means of the cyclodextrins (15), optically active compounds have been separated and solutions of labile compounds have been stabilized. They have been used for the resolution of racemates (16). The cyclodextrins form clathrates with many labile drugs such as unsaturated fatty acids and vitamin A (17). Since the drug included is, in essence, shielded by the host from its surroundings, stability of the drug can be greatly increased.

In view of the properties of these dextrins, this study was undertaken as a preliminary investigation into the possible utilization of the Schardinger dextrins in pharmaceutical systems.

EXPERIMENTAL

Reagents.—Benzoic acid, recrystallized, m.p. 119–121°; *o*-hydroxybenzoic acid, recrystallized, m.p. 155–157°; *m*-hydroxybenzoic acid, recrystallized, m.p. 198–200°; *p*-hydroxybenzoic acid, recrystallized, m.p. 212–214°; methylparaben, m.p. 124–126°; ethylparaben, recrystallized, m.p. 112–115°; propylparaben, recrystallized, m.p. 95–97°; butyl paraben, recrystallized, m.p. 67–69°; alpha cyclodextrin; beta cyclodextrin; *Bacillus macerans*, strain 7069, American Type Culture Collection; agar; dextrose; nutrient broth; Quaker oats; calcium carbonate, reagent grade; potato starch; trichloroethylene; bromobenzene; and *n*-propanol were used as reagents.

Apparatus.—A constant temperature water bath, set at 30°, ±1/2°, with rotating spindle; 20-ml. capacity vials with gum rubber stoppers and aluminum caps; Beckman DU spectrophotometer; 1-cm. and 5-cm. silica cells comprised the necessary apparatus.

PROCEDURE

Preparation of the Schardinger Dextrins.—The Schardinger dextrins are prepared by the action of *Bacillus macerans* amylase on one or another of the common starches.

Our method of preparation was based on the experiences of others, notably French and his group (18) and Tilden and Hudson (19). The complete process is quite involved and time consuming and need not be gone into in detail, although the basic procedure will be summarized.

Bacillus macerans was grown on a rolled oats medium, buffered with calcium carbonate, at 40° for 2 to 3 weeks to permit production of the amylase enzyme. This enzyme-containing solution was then decanted into 4% starch (potato) paste and stored, with intermittent agitation, at 40° for 24 hours. At the end of this period, marked by a noticeable decrease in the viscosity of the starch paste, the production of the Schardinger dextrins was completed.

The Schardinger dextrins were precipitated out of solution as trichloroethylene complexes. The alpha, beta, and gamma cyclodextrins were then separated by taking advantage of their differing solubilities in water and in the presence of bromobenzene. The individual cyclodextrins were then purified by repeated crystallizations from water and 60% *n*-propanol.

The greatest yields obtained were of beta, with lesser but satisfactory yields of alpha. Gamma was produced in such small quantities that no experimentation with this cyclodextrin was possible.

The cyclodextrins were checked for purity by the microscopic method of French (18) and by carbon-hydrogen analysis (Table I). These were then dried in an oven at 70° and kept in a desiccator until used.

TABLE I.—CARBON-HYDROGEN ANALYSIS OF THE CYCLODEXTRINS

Cyclodextrin	% C Calcd.	% C Det.	% H Calcd.	% H Det.
Alpha	44.44	43.79	6.22	6.16
Beta	44.44	43.84	6.22	6.46

Solutions of the cyclodextrins were freshly prepared, with the aid of heat, before each run because of the tendency toward mold growth in these solutions.

Solubility Studies.—The procedure used in this study was the solubility method of Higuchi and Lach (20).

Quantities in excess of the normal solubilities of the drugs studied were weighed into 20-ml. vials. Quantities of 3% alpha or 1% beta cyclodextrin were accurately measured in, and water added to make a volume of 5 ml. of solution in each vial. A more concentrated solution of beta was not used because of its limited solubility in water. The vials were sealed with gum-rubber stoppers and aluminum caps and rotated on a mechanical shaker in a constant temperature water bath at 30° for 24–48 hours until the system reached equilibrium.

At the end of the equilibration time, 1- or 2-ml. aliquots of the supernatant solutions were removed, diluted with water, and analyzed for total drug concentration by ultraviolet spectrophotometry. Since several of the vials showed solid material present, a cotton plug was used as a filter on the pipet tips.

Absorptivities had previously been determined for each of the drugs studied at the following wavelengths: benzoic acid, 272.5 mμ; *o*-hydroxybenzoic acid, 298 mμ; *m*-hydroxybenzoic acid, 290 mμ; *p*-hydroxybenzoic acid, 251 mμ; methyl *p*-hydroxybenzoate, 256 mμ; ethyl *p*-hydroxybenzoate, 256 mμ; propyl *p*-hydroxybenzoate, 255 mμ; and butyl *p*-hydroxybenzoate, 256 mμ. It was determined that the cyclodextrins did not interfere with the spectrophotometric measurements at the concentrations employed.

RESULTS AND DISCUSSION

In order that some insight be gained into the mechanism of interaction of organic compounds with the Schardinger dextrins, two homologous series of acid derivatives, the hydroxybenzoic acids and the *p*-hydroxybenzoates, were tested for complexing activity with the cyclodextrins.

A definite interaction occurred with each of these eight compounds with both alpha and beta cyclodextrins. The straight-line plots obtained show that the increase in solubility of the drug is a function of the concentration of the cyclodextrin. All of the isotherms show a positive slope and several show a plateau. Plots showing this plateau are indicative of a relatively insoluble complex being formed. Phase diagrams of this type, with calculation of stoichiometries and formation constants, have been explained by Higuchi and Lach (20).

The Hydroxybenzoic Acids.—Figures 1 and 2 represent interactions of the hydroxybenzoic acids with the cyclodextrins. Table II represents the slopes of these plots. Several conclusions can be drawn from these data.

TABLE II.—SLOPES OF ISOTHERMS OF INTERACTIONS OF THE HYDROXYBENZOIC ACIDS WITH THE SCHARDINGER DEXTRINS

	Alpha	Beta
o-Hydroxybenzoic acid	0.305	0.885
p-Hydroxybenzoic acid	0.813	1.044
Benzoic acid	1.004	1.135
m-Hydroxybenzoic acid	1.085	1.192

Data for these interactions indicate no clear cut mechanism of complexation. If these interactions were pure, that is classic, inclusion formation, the smallest molecule, unsubstituted benzoic acid, would show the greatest degree of inclusion and therefore the greatest slope. Since it does not, other forces are probably involved. This is reasonable in view of the multiplicity of hydroxyl groups on the cyclodextrin molecule and the likelihood of hydrogen bonding between the cyclodextrin and the hydroxybenzoic acids in the aqueous system employed. This is further substantiated by the lowest complexing activity, as evidenced by the lowest slope, being a property of the *ortho*-hydroxy acid in the case of both alpha and beta interaction. *ortho*-Hydroxybenzoic acid possesses intramolecular hydrogen bonds, thus decreasing the number of hydroxyl and carboxyl groups available for hydrogen bonding with the cyclodextrin. Hydrogen bonding therefore would seem to be a factor of importance in the cyclodextrin-hydroxybenzoic acid interaction, especially since we note that the *meta*- and *para*-hydroxy acids interact to approximately the same degree as benzoic acid itself. Since these substituted acids are larger than the parent acid, we would expect them to show less tendency towards inclusion formation. However, they possess an extra hydroxyl group, causing greater intermolecular hydrogen bonding with the cyclodextrins, and a greater degree of interaction than expected is observed.

It would seem, therefore, that the interactions observed are not true inclusion formation. Inclusion formation as such involves molecules associated by spatial relationships only, while in the interactions observed, hydrogen bonding seems to play a significant role. Thus the interaction data must be considered from a semiquantitative standpoint since the interaction is probably a result of more than one mechanism; attempts to interpret the data assuming inclusion formation only would not be wholly successful.

Results of Schlenk and Sand (21) support this conclusion. Their work on the association of the Schardinger dextrins with organic acids showed that the mole ratio of the cyclodextrins to certain benzoic acid derivatives was a function of the physical state of the complex. The stoichiometry of

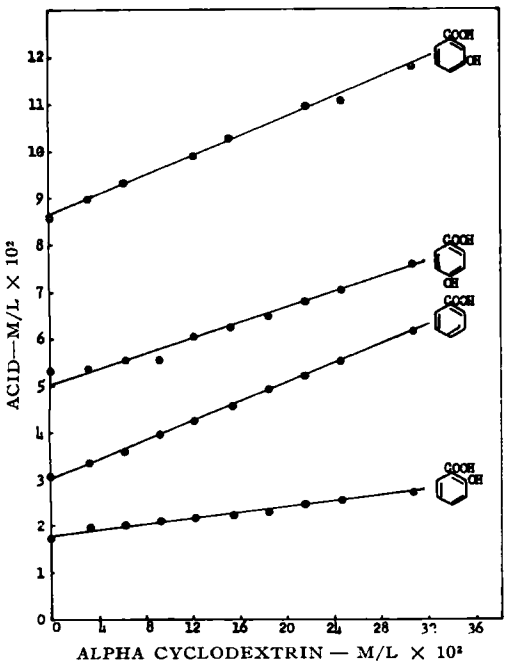

Fig. 1.—Interaction of the hydroxybenzoic acids with alpha cyclodextrin at 30°.

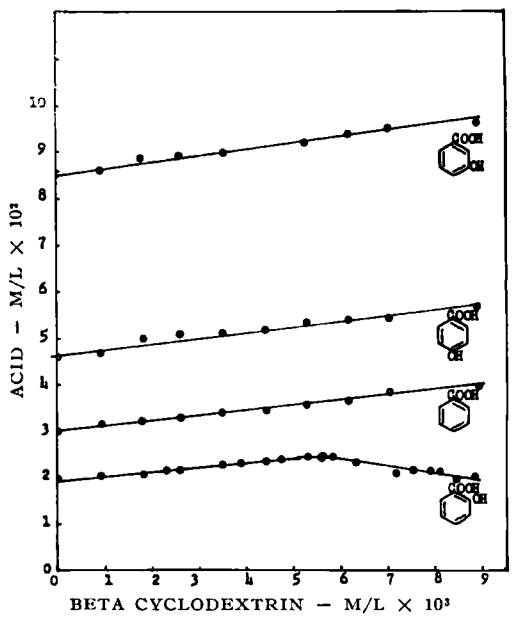

Fig. 2.—Interaction of the hydroxybenzoic acids with beta cyclodextrin at 30°.

the crystallized solid complex was not the same as that of the associated compound in solution. This indicates a complex mechanism of interaction in the aqueous system studied. It should be emphasized here that this study was conducted in aqueous solution where conditions for hydrogen bonding are favorable. In nonpolar systems, hydrogen bonding would not be as significant a factor in the net interaction.

Certain plots obtained through solubility data provide information concerning both stoichiometry and formation constant of the complex formed.

Where no plateau region is obtained, stoichiometry cannot be determined because the concentration of free drug present in solution is an invariant. However, linear dependence of the complexation upon cyclodextrin concentration is indicative of a first order dependency of the interaction upon cyclodextrin concentration. In cases such as this, stoichiometry with respect to the drug molecule is difficult to calculate since the data were obtained at constant drug activity because of the drug excess present.

Of the hydroxybenzoic acids, only the salicylic acid-beta cyclodextrin plots shows a plateau region which is indicative of formation of a relatively insoluble complex. From the plateau region of a phase diagram of this type, the stoichiometry of the complex can be determined and its formation constant calculated (20). Analysis of this region indicates three salicylic acid to one beta cyclodextrin complex, with a formation constant on the order of 5×10^4. This value is accepted with reservation because of the probable complexity of the interaction. The magnitude of this formation constant does indicate, however, the existence of a complex of great stability. In other studies of interactions of the hydroxybenzoic acids (22–25), calculated formation constants were all on the order of 1–100, calculated on the basis of a 1:1 interaction. Since the cyclodextrin interaction constant is much higher, an interaction of greater stability than the previously reported intermolecular attractive forces is indicated. This is reasonable in view of the complexity of these interactions and the probability of more than one interaction mechanism being involved.

The *p*-Hydroxybenzoates.—In the study of the interactions of the cyclodextrins with esters of *p*-hydroxybenzoic acid, strong interactions are also observed (Figs. 3 and 4).

Alpha forms soluble complexes with the parabens while the beta isomer forms complexes of limited solubility. The complexes formed with alpha are all soluble due to the greater solubility of alpha over beta. For the beta interactions, the data indicate that the less the solubility of the paraben, the less the solubility of the complex. Thus, methyl forms a soluble complex while butyl forms a relatively insoluble complex. The ethylparaben and propylparaben complexes show intermediate stages of solubility.

For both alpha and beta interactions with the parabens, a decrease in slope with increasing molecular weight is observed, except for the propyl and butyl esters (Table III). This latter phenomenon

TABLE III.—SLOPES OF ISOTHERMS OF INTERACTIONS OF THE *p*-HYDROXYBENZOATES WITH THE SCHARDINGER DEXTRINS

	Alpha	Beta
Methylparaben	0.911	1.044
Ethylparaben	0.510	0.896
Propylparaben	0.295	0.687
Butylparaben	0.357	0.747

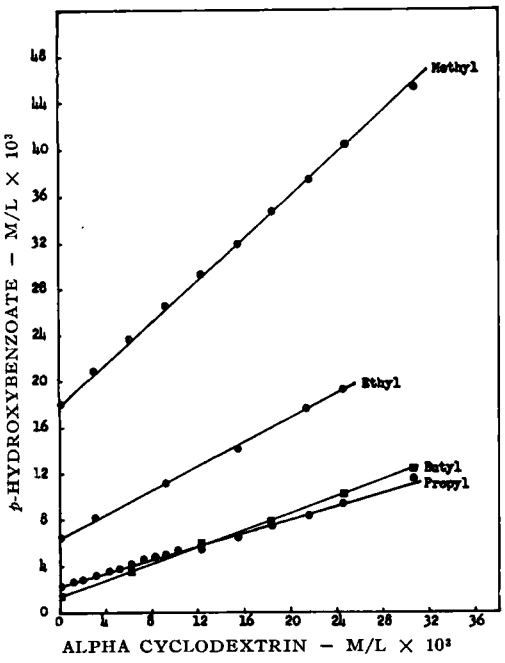

Fig. 3.—Interaction of the *p*-hydroxybenzoates with alpha cyclodextrin at 30°.

requires further elucidation of the mechanism of interaction before any explanations can be attempted. The overall tendency towards generally decreasing slope can be attributed to spatial filling; as the ester chain becomes longer and the molecule therefore larger, less inclusion of the ester takes place.

Calculation of stoichiometry along the propyl-beta and butyl-beta plateaus shows a molecular ratio in each case of 1:1. On this basis, stoichiometries of the methyl-beta and ethyl-beta complexes are tacitly assumed to be 1:1, and formation constants calculated (Table IV).

TABLE IV.—FORMATION CONSTANTS OF THE PARABEN-BETA COMPLEXES

Compound	K_f
Methylparaben	"infinite"
Ethylparaben	1.38×10^3
Propylparaben	9.23×10^2
Butylparaben	2.04×10^3

These formation constants are quite high compared to those previously reported in pharmaceutical interaction studies. Stability constants reported for paraben complexes at 30° are on the order of 50 for complexes with caffeine (21), and are generally below 50 for complexes of drugs with other complex-

ing agents when studied by the solubility method (26). The work of Poole and Higuchi (27) with sarcosine anhydride shows very low formation constants, with some values approaching the magnitude of our results but usually falling below 100.

Formation constants of the magnitude reported here indicate formation of a complex of increased stability. Thus an interaction involving more than hydrogen bonding or dipole-dipole attraction is likely involved and a combination of these plus inclusion formation is a distinct probability.

Unpublished results of Pauli (28) indicate that alpha cyclodextrin has a greater stabilizing effect on the stability of benzocaine to alkaline hydrolysis than any other complexing agent reported. This too is indicative of a stable complex and lends additional support to the above conclusions.

CONCLUSION

Molecular complexes exist where there are forces of an electrostatic nature drawing molecules together. Inclusion formation involves molecules held together by virtue of their spatial configurations; these compounds have been defined as being chemically inert toward each other since true inclusion formation involves no attractive forces between guest and host.

This criterion for inclusion formation may be valid for crystalline and solid complexes, but when the complex exists in aqueous solution, as in this study, attractive forces such as hydrogen bonds come into play. Evidence for this is provided by the hydroxybenzoic acid interactions where hydrogen bonding appears to play a significant role in the net interaction observed. Therefore, in these interactions of the cyclodextrins with organic molecules, we assume that hydrogen or other attractive bonds act to bring the molecules together in solution and play a part in holding them together.

The net interaction observed in this study is believed to be a combination of attractive forces and inclusion formation. No distinctions as to the relative contributions of the two forces can be obtained from the data presented. Since X-ray examination of solid compositions is the only method known by which unequivocal identification of inclusion compounds can be made (29), this question is deferred for further study.

High formation constants observed in this study indicate a more stable complex than is usually observed in pharmaceutical studies of this type. Since, undoubtedly, some attractive forces are to be considered in this study, we feel that the interaction of the Schardinger dextrins with organic molecules is probably a combination of hydrogen bonding, inclusion formation, or other forces acting as factors in the net observed interaction.

Interaction of Pharmaceuticals with Schardinger Dextrins II

Interaction with Selected Compounds

By JOHN L. LACH and JACK COHEN†

Data for the interaction of the Schardinger dextrins with 19 pharmaceuticals in aqueous solution are presented. All the compounds interact with both alpha and beta cyclodextrin. Data are presented to show that the less soluble the drug is in water, the greater is its per cent increase in solubility as a function of cyclodextrin concentration. Comparison of the isothermal slopes of the interactions shows that the largest molecules show the smallest slopes and therefore the smallest degree of interaction with the cyclodextrins. Molecular structure is a very important factor in the interaction which is believed to be a combination of inclusion formation and other intermolecular attractive forces.

THE PHENOMENON of complexation has become a very active area of pharmaceutical research. Only during this past decade has its importance in pharmaceutical formulations been fully realized. Many varied types of molecules and macromolecules have been found to interact with drug molecules of widely differing structures. Beginning with the work of Higuchi and Zuck (1), pharmaceutical researchers have devoted a good deal of time to elucidation of the nature of these phenomena.

Solubility changes have been observed as a function of these interactions and substantial increases in drug stability have been reported (2–6). Of particular importance in pharmacy and medicine is the relationship of complexation to the absorption and distribution of a drug in the body and the way that complexation influences the onset and duration of drug action (7).

In Part I of this series (8) it was observed that the Schardinger dextrins form complexes with the hydroxybenzoic acids and the *p*-hydroxybenzoates. This work was an attempt to extend the study to a variety of pharmaceutical compounds to obtain additional information concerning this interaction.

EXPERIMENTAL

The apparatus and reagents used in this study were those reported in Part I of this series, except that the following drugs were tested for complexing activity; benzocaine, m.p. 87–88°; aspirin, m.p. 134–135°; tetracycline, m.p. 170–173°; *p*-aminobenzoic acid, m.p. 185–186°; sulfadiazine, m.p. 255–256°; morphine, m.p. 250°; vanillin, m.p. 78–81°; N-acetyl-*p*-aminophenol, m.p. 169–170°; *p*-aminosalicylic acid, m.p. 150–151°; ephedrine, m.p. 34°; and sorbic acid, m.p. 134–138°.

The Schardinger dextrins were prepared by accepted methods (9, 10) and the interactions studied by the solubility method of Higuchi and Lach (11). The drugs were analyzed spectrophotometrically at the following wavelengths: benzocaine, 285 mμ; aspirin, 275 mμ; tetracycline, 357 mμ; *p*-aminobenzoic acid, 278 mμ; sulfadiazine, 266 mμ; morphine, 285 mμ; vanillin, 279 mμ; N-acetyl-*p*-aminophenol, 244 mμ; *p*-aminosalicylic acid, 267 mμ; ephedrine, 257 mμ; and sorbic acid, 259 mμ.

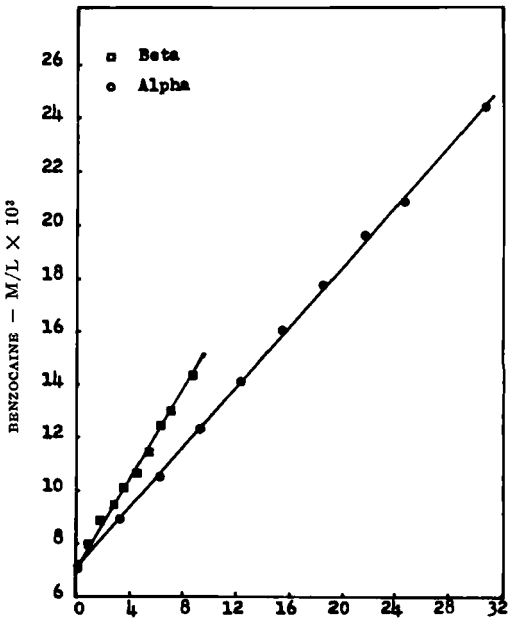

Fig. 1.—Interaction of benzocaine with the cyclodextrins at 30°.

Received May 5, 1962, from the College of Pharmacy, State University of Iowa, Iowa City.
Accepted for publication May 17, 1962.
Abstracted in part from the dissertation presented to the Graduate College of the State University of Iowa by Jack Cohen in partial fulfillment of the requirements for the degree of Doctor of Philosophy.
This investigation was supported in part by a research grant GM 06607-02, Division of General Medical Sciences, National Institutes of Health.
† Present address: Chas. Pfizer & Co., Inc., Groton, Conn.

Aspirin was run in 10^{-3} *M* sulfuric acid to decrease its rate of hydrolysis.

RESULTS AND DISCUSSION

Figures 1–11 represent solubility isotherms of the interactions of 11 drugs with the alpha and beta cyclodextrins. The Schardinger dextrins interact with all compounds tested. Linear plots are obtained with most drugs and both cyclodextrins, demonstrating first order dependence of the inter-

action upon cyclodextrin concentration. The morphine-beta and tetracycline-beta plots show a curvature, probably due to the nature of the complex (which prevented complete filtration) or to unperceived complexities in the interaction. The tables and figures presented also include some data from Part I of this series (8), for comparative purposes.

All the compounds studied, except morphine, tetracycline, sulfadiazine, and sorbic acid, are substituted benzene rings. Benzene rings will fit into the voids of both alpha and beta cyclodextrins since the dextrin voids are 6 and 8 Å. in diameter, respectively, while the phenyl structure occupies a space measuring approximately 7 × 7 × 3.4 Å. (12, 13).

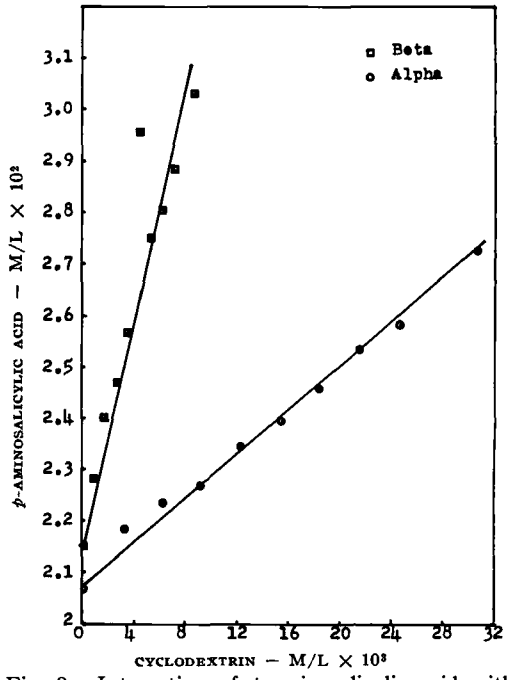

Fig. 9.—Interaction of *p*-aminosalicylic acid with the cyclodextrins at 30°.

Allowing for slight molecular structural changes caused by inclusion formation and other distorting forces, it is apparent that these molecules would be prone to inclusion by the alpha and beta cyclodextrins.

Morphine, tetracycline, and sulfadiazine, being polynuclear ring systems, are quite large compared to the phenyl group and fit into the voids with difficulty. If we assume that the others are complexed, in part, by inclusion formation, we can see that these three, being too large for inclusion, cannot interact in this way to any significant degree.

It is possible, however, that side chains and substituent groups may fit into the dextrin void and that the complexation is actually a matter of these groups being included in the void, thereby forming the inclusion complex. Since questions of this sort concern exact structural conformation of the complex, which can be determined only by X-ray diffraction, elucidation of this mechanism is postponed until further study.

Several methods have been used to compare relative complexing tendencies using data obtained from solubility studies. Comparison of the per cent increase in solubility has been used (14) as a comparison of relative complexing tendencies with the assumption being made that a higher per cent increase in solubility involves a greater degree of interaction. In this study it was felt that a truer picture of relative complexing tendencies could be obtained by comparing the slopes of the interaction isotherms.

In phase diagrams showing a plateau region, stoichiometries and formation constants can be calculated and overall complexing tendencies compared by interpretation of these constants. Since, in this study, no plateau regions were observed, slopes of the interaction isotherms are used as indications of relative complexing tendencies (Table I).

Ethylparaben	0.510	0.885	Salicylic acid
Benzocaine	0.567	0.896	Ethylparaben
Vanillin	0.567	1.010	Vanillin
p-Hydroxybenzoic acid	0.813	1.044	Benzoic acid
p-Aminobenzoic acid	0.891	1.044	Methylparaben
Methylparaben	0.911	1.100	N-Acetyl-*p*-aminophenol
Sorbic acid	0.911	1.111	*p*-Aminosalicylic acid
Benzoic acid	1.004	1.135	*p*-Hydroxybenzoic acid
m-Hydroxybenzoic acid	1.085	1.192	*m*-Hydroxybenzoic acid
Ephedrine	1.101	1.588	Ephedrine

However, it must be realized that this comparison of slopes is an approximation. If complexes show the same stoichiometries, comparison of their slopes directly relates stability constants of the interactions. Since these stoichiometries are unknown, due to the nature of the phase diagram, comparison of slopes of interactions of different stoichiometries can lead to errors in interpretation. Thus, the correlation is accepted as an approximation and is used because of the lack of exact stoichiometric data.

Inspection of Table I shows that the largest molecules show the smallest slopes. Their solubilization by the cyclodextrins, relative to their initial solubilities, is great but the extent of complex formation with these compounds is small.

In general, the smallest and most soluble drugs show the highest slopes. Since compounds of lower molecular weight are usually more water soluble, one is a corollary of the other. A plot of log slope *vs.* log S_o (solubility in absence of dextrin), Fig. 12, shows fair regularity of this trend. In view of the part played by inclusion formation in this interaction, we feel that the smaller molecules show a greater inclusion tendency because of greater ease of fitting into the dextrin voids. Morphine, tetracycline, and sulfadiazine show deviation from this linearity, presumably caused by the decrease in inclusion formation tendency because of their large sizes. These large molecules show interaction with the cyclodextrins even though they are too large to be guests in the dextrin ring. Hydrogen bonding, due to the multiplicity of hydroxyl and carboxyl groups on the cyclodextrin ring, occurring in aqueous solution, is probably the chief interaction mechanism here and is responsible for solubilization of the larger molecules.

Most of the compounds tested show a greater slope for beta interaction than for alpha interaction with a few compounds showing the same slope for both. This greater interaction with beta is reasonable in that the beta void is larger than the alpha void and can include molecules to a greater degree. The compounds studied, being phenyl derivatives, fit more easily into the beta void than the alpha void since the alpha void is of approximately the same size as the diameter of the benzene ring.

Sorbic acid was the only straight chain compound studied. This is the only compound studied where the complexing activity with alpha is greater than that with beta. Here the chain molecule fits into the alpha void with ease, unlike compounds containing one benzene ring where some strain is necessarily involved by inclusion formation with alpha. It is also possible that the chain molecule is too small in diameter to form a stable complex with beta cyclodextrin since a minimum size of guest is necessary for stable inclusion formation. If a guest is too small, forces holding it within the void are too weak to form a stable complex. This reverse of previous observations by sorbic acid is logical evidence of the existence of strong inclusion formation by the compounds studied.

Most studies of inclusion formation have been carried out in nonaqueous media. It is felt that a study of this type conducted in nonaqueous media would yield additional information as to the mechanism of interaction and estimates of the relative contributions of molecular complexing and inclusion formation could be made. A study of this type is currently under way in our laboratories.

CONCLUSION

The data in this study indicate that the Schardinger dextrins form complexes with a variety of pharmaceutical compounds. It was observed that those drugs which are least soluble in water showed the greatest per cent increase in solubility as a function of quantity of cyclodextrin present. In general, the smallest drug molecules showed the greatest complexing activity with the cyclodextrins. Interaction with sorbic acid demonstrates the importance

of the structure of the guest molecule to the degree of interaction where inclusion formation is a major contributing mechanism.

Molecules which are too large to be included within the cyclodextrin voids interact with the cyclodextrins indicating an interaction mechanism other than inclusion formation. The literature dealing with inclusion formation by various host molecules usually considers only inclusion formation as a mechanism of interaction for these compounds. However, in this aqueous system, we believe that other intermolecular attractive forces, particularly hydrogen bonds, seem to play a part in the net observed interaction.

Synthesis of Several Derivatives of Phenyl(2-hydroxy-3-pyrazyl)carbinol

By VINCENT S. VENTURELLA†, J. A. BIANCULLI, and R. W. SAGER‡

Several derivatives of 2-hydroxypyrazine were prepared containing a phenylcarbinol moiety in the 3-position. A method was developed to prepare these compounds in order to test the efficacy of the basic cyclization reaction between a bifunctional α-amino amide and several 1,2-dicarbonyls. The synthetic method used necessitated some study of the chemistry of threo-β-phenylserine and its amide. After many unsuccessful experiments, it was found that the amide of this acid is best prepared through the use of the N-carbobenzoxy methyl ester.

THE PURPOSE of this investigation was to prepare several compounds of general structure, I, which might be useful as psychopharmacological agents.

In the event that two nitrogen functions (as present in serotonin) and added hydroxyl functions (1) are necessary for antimetabolite activity, these compounds should exhibit some activity toward blocking or reversing the physiological activity of excess serotonin (2, 3).

DISCUSSION

Several methods have previously been used for the preparation of substituted hydroxypyrazines (4, 5), but none of these methods was applicable to the introduction of the phenylcarbinol group into the 3-position of the pyrazine ring.

The most promising methods available were those developed by Sharp and Spring (6) and by Jones (7). The Jones method was chosen for the synthesis of the cyclized product because the former method would require the use of the nitrile of β-phenylserine as an intermediate. The preparation of this compound, although possible, was expected to result in a great deal of difficulty because of the presence of the β-hydroxy group. The Jones method for the final step in the synthesis is represented in Eq. 1

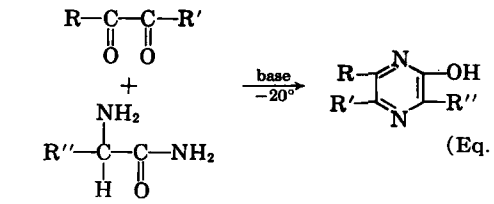
In the event that two nitrogen functions (as present in serotonin) and added hydroxyl functions (1) are necessary for antimetabolite activity, these compounds should exhibit some activity toward blocking or reversing the physiological activity of excess serotonin (2, 3).

DISCUSSION

Several methods have previously been used for the preparation of substituted hydroxypyrazines (4, 5), but none of these methods was applicable to the introduction of the phenylcarbinol group into the 3-position of the pyrazine ring.

The most promising methods available were those developed by Sharp and Spring (6) and by Jones (7). The Jones method was chosen for the synthesis of the cyclized product because the former method would require the use of the nitrile of β-phenylserine as an intermediate. The preparation of this compound, although possible, was expected to result in a great deal of difficulty because of the presence of the β-hydroxy group. The Jones method for the final step in the synthesis is represented in Eq. 1



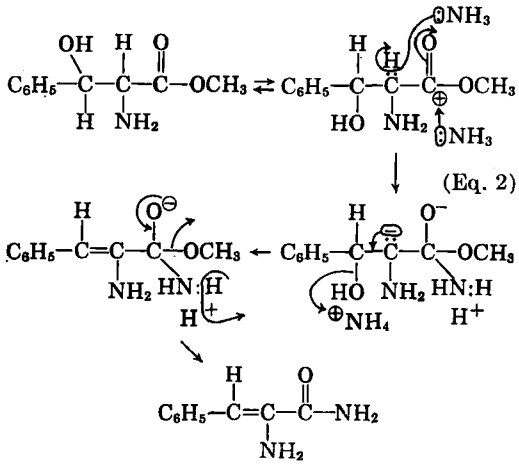
(Eq. 1)

The use of this method for the final step therefore required the use of one of the isomers of phenylserine due to R″ = $C_6H_5CH(OH)$—. The threo isomer was used throughout the experiments due to the possible steric interference that might result from the use of the erythro compound in the Jones sequence.

The isomerically pure acid was prepared by a modification of the procedure of Shaw and Fox (8) and its isomeric purity ascertained chromatographically (9) by comparison with authentic samples of the acids.[1]

The lower esters of the acid resisted ammonolysis using standard procedures, and treatment of the ethyl ester hydrochloride with liquid ammonia yielded only the erythro amide which gave an R_f value of 0.82 when chromatographed in a manner similar to the acid. The stereochemistry of this compound was demonstrated by infrared analysis which showed an absorption in the 11.9 to 12.1 μ range, which is indicative of the erythro isomers of this general series of compounds (10, 11). The absence of bands at 6.2 and 11 μ precludes the possibility that this compound was recovered β-phenylserine, which was suggested by the proximity of melting points.

When the ammonolysis of the methyl ester was attempted under pressure with continuous agitation over extended periods of time, a compound was isolated which was shown to be α-aminocinnamamide. The formation of this compound may be explained by the sequence of reactions in Eq. 2



(Eq. 2)

The infrared spectrum of this compound showed strong bands in the $—NH_2$ and $—CONH_2$ regions, presence of monophenyl substitution, absence of —CH(OH)—, and a conjugated carbonyl system, as evidenced by the shift in the carbonyl absorption followed by a doublet (12, 13).

Since previous attempts to prepare the threo amide were unsuccessful or resulted in isomerization, the electromeric carbobenzoxy group (14) was used to reverse the inductive effect of the amino group. This reversal permitted an easier discharge of the $—OCH_3$ group due to activation of the ester group followed by an unhindered attack of $:NH_3$, according to the inductomeric mechanism (15). The carbobenzoxy group prevents neighboring group neutralization of the carbonyl carbon as well as providing activation of the ester group.

The relationship of stability of isomers to favored formation of amide can be related to configuration versus reaction specificity. The erythro form is less stable, but its formation is favored due to the possibility of hydrogen bonding between the α-amino and the β-hydroxy groups. The relatively more stable threo isomer is made to form by the presence of the bulky carbobenzoxy group which sterically removes the possibility of inversion and electronically removes the possibility for hydrogen bonding.

Condensation Reactions.—Threo-β-phenylserine amide was reacted with the 1,2-dicarbonyls studied using a modification of the Jones procedure for the reaction of tyrosine amide (7). An excess of the dicarbonyl was used in the reaction in all cases except pyruvic aldehyde condensation. With this compound it was found that using an excess of the amide resulted in greater yield, purer product, and easier isolation of product.

Derivative Formation.—It has been shown (16) that compounds of this type exist in tautomeric equilibrium with the corresponding pyrazone structures. This phenomenon was further demonstrated during this study by the strong infrared absorption bands in the carbonyl region of the prepared compounds. The presence of this group along with the coexistence of the functional nuclear hydroxyl group and the side chain hydroxyl group suggested the possibility of hydroxylic and ketonic derivatives.

However, it was found that steric crowding prevented the formation of hydroxylic derivatives, phenylhydrazide and semicarbazide. In contrast to this, the compounds reacted in low yield in aqueous dimethylsulfate to form the corresponding methyl ethers of the nuclear hydroxyl groups.

EXPERIMENTAL[2]

Threo-β-phenylserine Monohydrate.—The procedure of Shaw and Fox (8) was followed for the preparation of this compound, with minor variations. Twenty-five Gm. (0.33 mole) of glycine in 100 ml. of 6 *N* sodium hydroxide was cooled to 10° and stirred vigorously while 70 Gm. (0.66 mole) of benzaldehyde was added slowly. When the resultant slurry thickened, 20 ml. of water was added and the thick edges were broken up. At this point the benzaldehyde addition was stopped and the slurry was stirred very vigorously until it was homogeneous. The benzaldehyde addition was then completed. The mixture was stirred for a half hour at 10°, and finally at room temperature until pasty. After standing at room temperature for 22 hours, the resultant condensation cake was fragmented and acidified with 49 ml. of concentrated hydrochloric acid, added slowly. The resultant yellow suspension was refrigerated at 5° for 40 hours.

[1] Kindly supplied by Dr. James M. Sprague, Merck Sharp & Dohme, Rahway, N. J.

[2] All melting points were taken on a Fisher-Johns apparatus and are uncorrected.

Filtration, followed by washing with three 250-ml. portions of boiling ethanol gave 46.2 Gm. (76.6%) of microcrystals, m.p. 197–200° [Erlenmeyer (17) reported 192–193°, Shaw and Fox (8) reported 185–200°].

Calcd. for neut. equiv. (formol): 199. Found: 203.

Anhydrous Threo-β-phenylserine (9).—Forty-five grams of the monohydrate in 300 ml. of boiling water recrystallized as layered plates after dilution with 300 ml. of boiling methanol and refrigeration overnight. The plates were suction dried and placed in a vacuum desiccator at 50–60° and dried over calcium chloride for 3 hours. The product melted at 196–196.5° [lit. (17) m.p. 195–196°]. Calcd. for neut. equiv. (formol): 181. Found: 182, 183. R_f, 0.47, 0.46 [lit. (9) 0.43].

Preparation of Threo-β-phenylserine Methyl Ester Hydrochloride (18, 19).—Fifteen grams (0.085 mole) of the anhydrous threo acid was suspended in 150 ml. of absolute methanol in a 500-ml. three-neck flask equipped with a water condenser and drying tube, and the mixture was stirred magnetically. A steady stream of dry hydrogen chloride was passed into the suspension at a rate sufficient to promote gentle refluxing. The solid dissolved immediately, and after 2.5 hours the yellow solution had cooled to room temperature. The solution was filtered after standing overnight to remove any erythro isomer formed and evaporated to dryness to give a light yellow solid. The solid was dissolved in a minimum amount of hot methanol and crystallized by the addition of 6 volumes of anhydrous ether. Recrystallization was effected from methanol-ether (1:6) at −15° as glistening white flakes, m.p. 162–163.5° (decompn.), 13.4 Gm., (70.5%). Shaw and Fox (8) reported 160° (decompn.), Bergmann, *et al.* (18), 161° (decompn.), Carrara and Weibnauer (19), 156° (decompn.).

Erythro-β-phenylserine Amide.—Seven grams (0.036 mole) of the threo methyl ester was dissolved in 300 ml. of absolute ethanolic ammonia at 0° contained in a 1-L. thick-walled round-bottom flask. The flask was stoppered and wired shut in a cage while at 0° and allowed to stand at room temperature for 72 hours.

After standing, the flask was cooled to 0° and reopened. Evaporation of the solution under reduced pressure gave a yellow solid which was taken up in absolute ethanol, and the evaporation was repeated. This procedure was repeated twice more to remove all traces of ammonia. The yellow solid was recrystallized from hot absolute methanol yielding 2.2 Gm. (36%) of white fluffy needles, m.p. 191–193°.

Anal.—Calcd. for $C_9H_{12}N_2O_2$: N, 15.55. Found: N, 15.25, 15.27, 15.05.

Isolation of α-Aminocinnamamide from Ammonolysis Experiment.—A 15-Gm. quantity (0.08 mole) of the methyl ester was dissolved in 300 ml. of absolute methanolic ammonia at 0° and the flask was sealed as previously described. The solution was shaken continuously for 60 hours at room temperature. The flask was then cooled to 0° and opened. The excess ammonia and methanol were removed at reduced pressure to yield a yellow residue which dissolved in 75 ml. of hot methanol. Refrigeration of the solution at 5° for 3 hours gave 2.2 Gm. of a tan powder, m.p. 186–190°. Evaporation of the filtrate under reduced pressure to dryness gave a red solid which partially dissolved in 100 ml. of hot benzene. Refrigeration of the filtrate at 5° for 12 hours gave 1.5 Gm. of yellowish-white needles, m.p. 122-123°. An additional 1.5 Gm. of product was obtained by concentration of the filtrate and refrigeration.

Anal.—Calcd. for $C_9H_{10}N_2O$: N, 17.28. Found: N, 17.27, 17.36, 17.56.

N - Carbobenzoxy - threo - β - phenylserine Methyl Ester.—Five grams (0.022 moles) of the threo methyl ester hydrochloride was treated with an excess of potassium bicarbonate solution. The solution was extracted, portionwise, with 300 ml. of ethyl acetate. The ethyl acetate layers were dried over sodium sulfate and placed in a 1-L. 3-neck flask equipped with a stirrer and a drying tube. The solution was cooled in an ice-salt bath and treated with 5 Gm. of solid potassium bicarbonate. To the vigorously stirred solution, 3.0 Gm. of carbobenzoxy chloride was added in two portions. The cloudy mixture was stirred in the cold for 4 hours, at which time no more carbon dioxide was evolved. Fifteen milliliters of dry pyridine was added. The resulting mixture was alternately washed with 100-ml. portions of water, dilute hydrochloric acid, and water. The organic layer was dried over sodium sulfate and evaporated under reduced pressure to one-half the original volume. Refrigeration overnight gave a white slurry which yielded 2.0 Gm. of amorphous material when suction filtered and dried. Concentration of the filtrate and similar treatment gave an additional 2.5 Gm. Total yield was 73.5%. Crystallization from hot ethyl acetate gave white fluffy plates, m.p. 91.5–93°.

Anal.—Calcd. for $C_{18}H_{19}NO_3$: N, 4.26. Found: N, 4.64.

N - Carbobenzoxy - threo - β - Phenylserine Amide.—A 2.5-Gm. quantity (0.0076 mole) of the carbobenzoxy methyl ester was dissolved in 100 ml. of absolute methanolic ammonia according to previous procedures and allowed to stand at room temperature for 40 hours. Processing gave a white solid, weighing 2.1 Gm., m.p. 152–153° (88%). Recrystallization from methanol-water and vacuum drying gave fine white needles, m.p. 159–160°.

Anal.—Calcd. for $C_{17}H_{18}N_2O_4$: C, 64.96; H, 5.73; N, 8.91. Found: C, 64.35; H, 5.84; N 8.55.

Preparation of the Threo-amide.—Two grams (0.0063 moles) of the carbobenzoxyamide was dissolved in 100 ml. of methanol in a 300-ml. long-neck round-bottom flask, palladium catalyst was added, and the flask was fitted with a gas delivery adapter. The mixture was then shaken continuously while being flushed with a stream of dry nitrogen for 10 minutes. The amide was then reduced with a constant stream of hydrogen until the exit gases failed to precipitate barium carbonate in a saturated solution of barium hydroxide. The flask was again flushed with dry nitrogen for 10 minutes. The catalyst was removed by filtration through a Celite mat, washed with three small portions of methanol, and the filtrate was evaporated under reduced pressure to a semisolid mass. Drying in a vacuum desiccator over calcium chloride gave 1.1 Gm. of solid material (90.5%). The solid was washed with 10 ml. of ice-cold ether and recrystallized from methanol-petroleum benzin (cold). The final product was a white microcrystalline solid, m.p. 144–145°.

Anal.—Calcd. for $C_9H_{12}N_2O_2$: C, 60.00; H,

6.66; N, 15.55. *Found:* C, 60.54; H, 6.46; N, 15.34.

Phenyl(2 - hydroxy - 3 - pyrazyl)carbinol Hydrochloride.—Five grams (0.028 mole) of the threo amide was placed in a 100-ml. 3-neck flask equipped with a stirrer and dropping funnel and suspended in 50 ml. of absolute methanol. The flask was immersed in a dry ice bath and the contents stirred until the internal temperature reached −20°. Seven grams (0.035 moles) of 30% glyoxal was added all at once and 6 ml. (0.07 mole) of sodium hydroxide (12 *N* solution) was added dropwise over 15 minutes.

The tan suspension was stirred for 3 hours at −20°, 2 hours at room temprature, then acidified with 7 ml. of concentrated hydrochloric acid at 15°. A tan material precipitated which redissolved upon the addition of 10 ml. of water. Refrigeration at −20° for 40 hours gave 2.2 Gm. of a tan powder (39.4%), m.p. 199–203° (decompn.). Washing with ice-cold ether and crystallization from warm ether gave a tan microcrystalline powder, m.p. 199–201° (decompn.). Recrystallization from ethanol (charcoal)-ether (cold) gave fluffy plates, m.p. 203–204.5° (decompn.).

Anal.—Calcd. for $C_{11}H_{11}ClN_2O_2$: C, 55.50; H, 4.63; N, 11.79. Found: C, 56.35; H, 5.06; N, 12.34.

Phenyl(2 - hydroxy - 5 - methyl - 3 - pyrazyl)carbinol.—Six grams (0.034 moles) of the threo amide was suspended in 35 ml. of absolute methanol in a manner similar to above and treated with 7.0 Gm. (0.032 mole) of pyruvic aldehyde added in three portions over a 5-minute period. An equimolar amount (amide) of 12 *N* sodium hydroxide was added in 10 minutes over a 15-minute period. The suspension was stirred at −20 to −30° for 4 hours then at room temperature for 1 hour. The solution was acidified with concentrated hydrochloric acid to pH 6.8, treated with a small amount of solid sodium bicarbonate, and stirred for 10 minutes. Suction filtration gave 5.5 Gm. of a tan residue. The residue was washed with three 50-ml. portions of ice water and crystallized from hot acetone to give 3.2 Gm. (46.5%) of fluffy white needles, m.p. 174–176° (decompn.).

Anal.—Calcd. for $C_{12}H_{12}N_2O_2$: C, 65.60; H, 5.56; N, 12.95. Found: C, 64.99; H, 5.99; N, 12.91.

Phenyl(2 - hydroxy - 5,6 - dimethyl - 3 - pyrazyl)carbinol.—A suspension of 3.6 Gm. (0.02 mole) of the threo amide in 40 ml. of absolute methanol was treated with 2.58 Gm. (0.03 mole) of butanedione at −20°. While stirring, 4.5 ml. of 12 *N* sodium hydroxide was added over 20 minutes. The mixture was stirred for 4 hours and then for 1 hour at 0°. The dark brown solution was then acidified with concentrated hydrochloric acid to pH 7, diluted with 5 ml. of water, and allowed to come to room temperature. Tarry material present was precipitated by the addition of 15 ml. of water and the filtrate refrigerated to yield a tan granular material. Crystallization from 20% aqueous methanol gave 1.3 Gm. (33%) of light tan flakes, m.p. 181.5–183° (decompn.).

Anal.—Calcd. for $C_{13}H_{14}N_2O_2$: C, 67.82; H, 6.09; N, 12.17. Found: C, 67.20; H, 6.05; N, 11.80.

Phenyl(2 - hydroxy - 5,6 - diphenyl - 3 - pyrazyl)carbinol.—To 5 Gm. (0.028 mole) of the threo amide, suspended in 50 ml. of absolute methanol contained in a 3-neck flask equipped with a stirrer, water condenser, and dropping funnel, was added 5.9 Gm. (0.028 mole) of benzil. The mixture was stirred and heated to reflux, after which 4.85 ml. of 12 *N* sodium hydroxide was added slowly. The solution was refluxed for 30 minutes, cooled to room temperature, and then acidified with concentrated hydrochloric acid, dropwise. One gram of solid potassium bicarbonate was added during a 10-minute stirring period. The suspension was cooled to 0° and filtered. The yellow residue was washed twice with 500 ml. of water. Air drying overnight gave 6.5 Gm. (65.8%) of yellow powder which recrystallized from hot butanol in yellow flakes, m.p. 213–216° (decompn.).

Anal.—Calcd. for $C_{23}H_{18}N_2O_2$: C, 77.96; H, 5.07. Found: C, 77.78; H, 5.41.

Methyl Ether of the Prepared Compounds.—The methyl ethers of the hydroxypyrazines were formed by treatment with dimethylsulfate (equimolar) in dilute aqueous base. Isolation procedures and analytical data for the compounds follow. All reactants were mixed at 0°, followed by reflux for at least 1 hour.

Phenyl(2-methoxy-3-pyrazyl)carbinol.—The reaction filtrate was cooled to room temperature and filtered to remove a crop of tan microcrystals. Refrigeration at 5° overnight gave an additional crop of crystals. From 0.5 Gm. of pyrazyl compound, 0.185 Gm. (34%) was obtained. Recrystallization from hot water gave fluffy tan microcrystals, m.p. 140–142°.

Anal.—Calcd. for $C_{12}H_{12}N_2O_2$: N, 12.96. Found: N, 12.53.

Phenyl(2 - methoxy - 5 - methyl - 3 - pyrazyl)carbinol.—Refrigeration of the reaction filtrate for 30 hours gave a precipitate of yellowish-white rods. Filtration and recrystallization from hot water gave 0.115 Gm. of white rhombs, m.p. 134.5–136.5°, from 2.0 Gm. of starting material.

Anal.—Calcd. for $C_{13}H_{14}N_2O_2$: N, 12.17. Found: N, 11.85.

Phenyl(2 - methoxy - 5,6 - dimethyl - 3 - pyrazyl)carbinol.—The reaction mixture from 0.4 Gm. of reactant was cooled to room temperature and filtered to give a soft gummy residue which was air-dried. The residue was dissolved in a minimum amount of hot acetone and cooled to 5° for 30 hours, giving 0.048 Gm. of tan flakes which were recrystallized from ether-petroleum benzin, m.p. 110–111.5°.

Anal.—Calcd. for $C_{14}H_{16}N_2O_2$: N, 11.47. Found: N, 11.08.

Phenyl(2 - methoxy - 5,6 - diphenyl - 3 - pyrazyl)carbinol.—When the reaction mixture from 2.0 Gm. of reactant was cooled to room temperature, a small amount of insoluble gum was filtered off. After 2 hours at room temperature, the cloudy solution was treated with methanol until clear, an equal volume of water was added, and the mixture was refrigerated at 5° for 10 hours. A greenish-yellow solid precipitated. Recrystallization from cold aqueous methanol gave 0.035 Gm. of a yellow amorphous solid, m.p. 94.5–96° (decompn.).

Anal.—Calcd. for $C_{24}H_{20}N_2O_2$: N, 7.60. Found: N, 7.48.

SUMMARY

1. A series of hydroxypyrazines, with a phenylcarbinol moiety in the 3-position, was prepared. The prepared compounds were unobtainable by any other existing method.

2. A study of β-phenylserine indicated that the amide of this acid is more stable in the threo form than in the erythro form. The erythro form is preferentially obtained by reaction mechanism due to the excess pressure required in the reaction. The inversion during the formation of the amide from the ester is minimized by the use of the bulky carbobenzoxy group.

3. It was shown, by infrared analysis and low yield of methoxy compound from reaction with dimethylsulfate, that the compounds exist in predominantly the keto or pyrazone form. In addition, it was shown that sufficient crowding of the 2-position is present to prevent normal hydroxylic and ketonic reactions due to preventing sterically the formation of the necessary transition states required for these compounds.

4. The steric crowding has little effect on the formation of the methyl ethers because of the size and the linearity of the entering group.

Influence of Excipients on the Analysis of Tablets and Capsules by Nonaqueous Titrimetry

By L. G. CHATTEN and C. A. MAINVILLE

Investigation of the effect of twenty-seven tablet and capsule excipients on the titration of medicinal organic acids and bases has shown that a careful choice of solvents can limit interference to a very small percentage of the excipients. Certain of these excipients which are titratable when dissolved alone in common nonaqueous solvents do not always consume titrant when combined with strong organic acids and bases. Polyvinylpyrrolidone and stearic acids cause the most difficulty in the titration of medicinal organic bases and acids, respectively.

ALTHOUGH the scientific literature of the past decade is filled with reports on the application of nonaqueous titrimetry to the analysis of drugs and chemicals, only a relatively few workers, by comparison, have adapted this technique to the analysis of pharmaceuticals. This situation can be attributed in part to the extensive use made of glacial acetic acid as a solvent, both by numerous investigators in the field as well as by such authoritative compendia as the British and United States pharmacopoeias (1, 2). While the wide solubilizing properties of glacial acetic acid enhance its utility, it is this very factor that limits its application in the analyses of pharmaceuticals. A second contributing cause to the reluctance of some workers in the field to accept nonaqueous titrations as a practical means of assaying pharmaceuticals has been the lack of investigations into the effect of excipients on the quantitative determination of active components of pharmaceutical forms.

The purpose of this report is to assess the influence of a number of excipients and to investigate means of obviating interference by altering the solvent system. The effect of the presence of drugs on interfering excipients is also within the scope of this work.

Received February 12, 1962, from the University of Alberta Faculty of Pharmacy, Edmonton.

EXPERIMENTAL

Apparatus

A microburet graduated to 0.01 ml.; electromagnetic stirrers; a precision Shell titrometer fitted with Beckman glass electrode No. 1190–80, and Beckman sleeve-type calomel electrode No. 1170–71.

Reagents

Perchloric acid in dioxane 0.05 *N;* potassium hydroxide in anhydrous methanol 0.1 *N;* and 6% mercuric acetate in glacial acetic acid. Solvents: acetone, A.C.S.; acetonitrile A.C.S. redistilled at 81.6° prior to use; benzene A.C.S.; chlorobenzene A.C.S., redistilled at 131–132° prior to use; chloroform A.C.S.; dimethylformamide, practical, redistilled at 150° prior to use; ethylene glycol A.C.S.; technical *n*-hexane; isopropanol A.C.S.; anhydrous methanol A.C.S.; practical nitromethane redistilled at 101.2°; propylene glycol A.C.S.

Indicators

Bromocresol purple 0.5% in anhydrous methanol; crystal violet 0.5% in glacial acetic acid; methyl red 0.1% in glacial acetic acid; methyl red 0.5% in anhydrous methanol; methylene blue 0.1% and quinaldine red 0.2% in anhydrous methanol; thymol blue 0.5% in anhydrous methanol.

Excipients

Acacia, 1; beeswax, 2; calcium carbonate, 3; calcium phosphate, 4; calcium phosphate tribasic, 5; calcium sulfate, 6; carnauba wax, 7; cetyl alcohol, 8; gelatin, 9; lactose, 10; magnesium carbonate, 11; magnesium hydroxide, 12; magnesium stearate, 13; magnesium sulfate, 14; methylcellulose, 15; polyethylene glycol 4000, 16; polyvinyl pyrrolidone, 17; sodium alginate, 18; sodium benzoate, 19; sodium carboxymethylcellulose, 20; sodium silicate, 21; sodium sulfate, 22; starch, potato, 23; stearic acid, 24; sucrose, 25; talcum, 26; tragacanth, 27.

PROCEDURE

General.—An excess amount of excipient was placed in a 150-ml. beaker, 50 ml. of solvent added, and stirring was then carried out for 15 to 20 minutes. The undissolved excipient was removed by filtration through a fine sintered-glass funnel. The appropriate indicator was added, and the filtrate was then titrated with 0.05 *N* perchloric acid in dioxane in order to determine those excipients which consume this titrant. A second set of filtrates was titrated with 0.1 *N* potassium hydroxide in methanol in the presence of the indicator of choice, in order to determine which excipients behave as acids.

All titrations with potassium hydroxide in methanol were performed in a closed system to prevent contamination by atmosphere. A blank was carried out on each solvent system and in all cases was found to be within reasonable limits.

Special procedures.—In the phenol-chloroform-acetonitrile system, a stock solution of 25% phenol in chloroform was prepared. The excipients were stirred with 25 ml. of this solution for the prescribed time, filtration was carried out and 25 ml. of acetonitrile was added to facilitate the visual titration.

In the glycols-isopropanol systems (25:25), because these solvent systems were viscous, filtration was carried out through a sintered-glass funnel of medium porosity. Using *n*-hexane, excipients were dissolved in 30 ml. of hexane, filtration was carried out, and 20 ml. of acetone added to facilitate the titration.

Testing the Effect of Interfering Excipients in the Presence of Drugs.—A quantity of drug sufficient to give a 3 to 4 ml. titration was accurately weighed and dissolved in the solvent of choice by stirring electromagnetically for 15 minutes. The appropriate indicator was added and the titration performed with 0.05 *N* perchloric acid in dioxane for bases. In the presence of a halide salt, 2 ml. of mercuric acetate solution was added to the titration. Organic acids were titrated by 0.1 *N* potassium hydroxide in methanol. All assays were carried out in duplicate. In certain instances, the visual end points was verified potentiometrically.

A similar quantity of active ingredients was accurately weighed and dissolved in 50 ml. of the solvent of choice. Varying amounts of excipients were added. The solution was stirred for 15 minutes and then filtered through a sintered-glass funnel of medium porosity to remove undissolved excipients. Two ml. of mercuric acetate solution was used when necessary. The indicator of choice was added and the titration performed with the appropriate titrant. Blanks were subtracted.

For perchloric acid titrations, 0.1% methyl red in glacial acetic acid was used as the indicator in every instance except for isopropanol where 0.5% thymol blue in methanol was used.

When potassium hydroxide was the titrant, 0.5% bromothymol blue was the indicator of choice for the solvent anhydrous methanol. For all other solvents, 0.5% thymol blue in methanol was the most suitable indicator.

TABLE I.—EXCIPIENTS TITRATABLE WITH 0.05 *N* PERCHLORIC ACID

Solvent	Indicator	Interfering Excipients
Acetone	Methyl red (CH_3COOH)	17, 19, 23
Acetonitrile	Methyl red (CH_3COOH)	17, 19
Benzene	Crystal violet	16, 17
Chlorobenzene	Crystal violet	16, 17
Ethylene glycol	Methyl red (CH_3OH)	13, 19, 21
n-Hexane	Methyl red (CH_3COOH)	None
Isopropyl alcohol	Methyl red (CH_3COOH)	17, 19
Methanol	Thymol blue	12, 13, 14, 17, 18, 19, 20, 21, 22, 27
Nitromethane	Methylene blue & quinaldine red	16, 17, 18, 19, 20, 21, 22
Phenol-chloroform-acetonitrile	Methyl red (CH_3COOH)	15, 19
Propylene glycol	Thymol blue	12, 13, 14, 17, 18, 19, 21, 22

RESULTS AND DISCUSSION

Although suitable indicators were known for some of the solvent systems, it was necessary to find indicators for others. This was accomplished by checking the color changes against a potentiometer which was equipped with a glass-calomel electrode system.

Twenty-seven excipients which occur most commonly in tablets and capsules were titrated in the manner outlined under Experimental, and those which consumed the amount of titrant in excess of the blank are reported in Tables I and II. Titration of these same excipients in chloroform and glacial acetic acid have been reported in a previous publication (3).

Table I shows that acetone, acetonitrile, benzene, chlorobenzene, *n*-hexane, isopropanol, and phenol-chloroform-acetonitrile are highly satisfactory solvents for the titration of medicinal compounds in tablets and capsules by perchloric acid, as very few excipients consume titrant in these solvents. Interference by polyvinylpyrrolidone and sodium benzoate seems to be widespread. It was found that in *n*-hexane no excipient consumed titrant. The utility of this solvent will be investigated and results published in a later report.

Table II shows that acetone, acetonitrile, benzene, chlorobenzene, and *n*-hexane are highly desirable solvents for the titration of acidic medicinal agents which are found in pharmaceuticals. Beeswax, polyvinylpyrrolidone, and stearic acid, however, are the common interfering agents.

From the results reported here, it is apparent that a careful choice of solvent system can markedly reduce and may even virtually eliminate interference by excipients in the nonaqueous titration of tablets and capsules.

The recoveries of the organic bases and acids are given in Tables III and IV, respectively. It can be seen from these tables that interfering excipients do not always cause overestimation when in the presence of some drugs and in certain solvents. It must be remembered that excipients were present in an amount far in excess of their normal occurrence in tablets. This produced, in certain instances, end points which were difficult to detect because they were seriously obscured by the formation of precipitates.

TABLE II.—EXCIPIENTS TITRATABLE WITH 0.1*N* POTASSIUM HYDROXIDE

Solvent	Indicator	Interfering Excipients
Acetone	Thymol blue	2, 19, 24
Acetonitrile	Thymol blue	17, 24
Benzene	Thymol blue	2, 24
Chlorobenzene	Thymol blue	2, 24
Chloroform	Thymol blue	2, 13, 17, 24
Dimethylformamide	Thymol blue	2, 7, 13, 14, 17, 19, 24
Ethylene glycol	Methyl red (CH_3OH)	24
Hexane	Thymol blue	2, 24
Isopropyl alcohol	Thymol blue	2, 17, 24
Methanol	Bromocresol purple	17, 24
Propylene glycol	Bromocresol purple	17, 18, 24

TABLE III.—TITRATION OF DRUGS AND EXCIPIENTS WITH PERCHLORIC ACID IN DIOXANE

Solvent	Active Ingredient	Excipient	Recovery, %

TABLE IV.—TITRATION OF DRUGS AND EXCIPIENTS WITH POTASSIUM HYDROXIDE IN METHANOL

Solvent	Active Ingredient	Excipient	Recovery, %
Acetone	Acetylsalicylic acid	...	100.1
	Acetylsalicylic acid	Beeswax	101.1
	Acetylsalicylic acid	Sodium benzoate	99.8
	Phenobarbital	...	99.3
	Phenobarbital	Beeswax	100.8
	Phenobarbital	Sodium benzoate	99.8
Acetonitrile	Acetylsalicylic acid	...	99.8
	Acetylsalicylic acid	Cetyl alcohol	100.1
	Acetylsalicylic acid	Polyvinylpyrrolidone	100.2
	Phenobarbital	...	99.6
	Phenobarbital	Cetyl alcohol	99.7
	Phenobarbital	Polyvinylpyrrolidone	97.8
Chloroform	Acetylsalicylic acid	...	100.3
	Acetylsalicylic acid	Beeswax	105.2
	Acetylsalicylic acid	Magnesium stearate	111.1
	Acetylsalicylic acid	Polyvinylpyrrolidone	100.6
	Phenobarbital	...	99.7
	Phenobarbital	Beeswax	104.9
	Phenobarbital	Magnesium stearate	99.9
	Phenobarbital	Polyvinylpyrrolidone	100.8
Isopropyl alcohol	Acetylsalicylic acid	...	99.7
	Acetylsalicylic acid	Beeswax	100.2
	Acetylsalicylic acid	Polyvinylpyrrolidone	100.2
	Phenobarbital	...	99.8
	Phenobarbital	Beeswax	100.6
	Phenobarbital	Polyvinylpyrrolidone	100.4
Methanol	Acetylsalicylic acid	...	99.3
	Acetylsalicylic acid	Polyvinylpyrrolidone	99.9
	Benzoic acid	...	100.1
	Benzoic acid	Polyvinylpyrrolidone	100.8

As predicted, stearic acid readily consumed titrant in the presence of other organic acids and hence created a gross error in every solvent system. Beeswax, polyvinylpyrrolidone, and sodium benzoate were also major interfering agents but did not always consume titrant.

CONCLUSION

It has long been the feeling by some critics that the effect which excipients might exert on the quantitative analysis of tablets and capsules by nonaqueous titrimetry is probably so great as to limit its usefulness to the assay of the basic materials alone, or at best, to the products of those manufacturers where the control laboratory might be able to exert its influence in the formulation. The findings reported herein show that the careful choice of solvent systems can greatly minimize or even eliminate the possibility of interference by excipients.

It has been shown also that the nonaqueous titration of organic medicinal acids and bases suffers from very limited interference by tablet excipients, even when the excipients themselves are titratable. Sodium benzoate and polyvinylpyrrolidone appear to cause the major concern in the titration of bases. Only stearic acid causes serious and consistent interference in the titration of acids. This could be overcome by pharmaceutical manufacturers using magnesium stearate as a lubricant.

Polymorphism and Drug Availability

Solubility Relationships in the Methylprednisolone System

By W. I. HIGUCHI†, P. K. LAU, T. HIGUCHI, and J. W. SHELL

The thermodynamic relationships involving polymorphism and solubility were examined in some detail and applied to experimental results with the methylprednisolone system. The solubilities of the two crystal forms of this steroid were determined in water, decyl alcohol, and dodecyl alcohol at various temperatures. The solubility ratios for the two forms were generally found to be independent of the solvent in accordance with theory. At room temperatures the activity of the more energetic form of the drug was found to be the order of 80% greater than that of the more stable form. The heat, entropy, and temperature of transition were calculated from the data, and the possible molecular factors involved in polymorphism were considered. Further work of exploratory nature involving cloudpoint determinations indicate that much more energetic crystal forms are probable.

AMONG THE numerous ways (1) of altering drug availability to the patient, methods involving changing the crystal form of the drug appear to have received proportionately the least detailed examination. Thus it appeared to us that an investigation of this problem would be worthwhile. This report represents the initial phase of a program aimed toward the understanding of factors determining activity, physical stability, and frequency of occurrence (or preparation) of polymorphs.

THERMODYNAMIC THEORY

For simplicity let us assume that a particular drug exhibits only two crystalline forms depending on the conditions of preparation. Let these be form I and form II, the former designating the more thermodynamically stable one at room temperatures.

We may then write

$$F_I^\circ = H_I^\circ - T^\circ S_I \qquad \text{(Eq. 1a)}$$

and

$$F_{II}^\circ = H_{II}^\circ - TS_{II}^\circ \qquad \text{(Eq. 1b)}$$

where F°, H°, and S° are the usual standard state Gibbs free energy, enthalpy, and entropy, respectively, for the two forms, and T is the absolute temperature in °K. For completeness we may also write the corresponding equation for the supercooled liquid

$$F_I^\circ = H_I^\circ - TS_I^\circ \qquad \text{(Eq. 1c)}$$

If now f_I and f_{II} are the drug fugacities (2) or escaping tendencies for the two phases in their standard states, we have then

$$RT \ln f_I/f_{II} = \Delta F_{I.II} = F_I^\circ - F_{II}^\circ \qquad \text{(Eq. 2)}$$

where R is the gas constant. Since fugacities may be equated to the vapor pressures in the limit of low pressures (gas ideality) and since vapor imperfection is generally negligible in our system, we may regard the fugacity ratio expressed in Eq. 2 as simply the vapor pressure ratio for the two forms.

By combining Eq. 1 and Eq. 2 we obtain the following relation

$$RT \ln f_I/f_{II} = \Delta F_{I.II}^\circ = \Delta H_{I.II}^\circ - T\Delta S_{I.II}^\circ \qquad \text{(Eq. 3)}$$

which relates the fugacities with the standard entropy, enthalpy, and free energy changes for the I to II phase transformation. Equation 3 is particularly useful in discussing the relationship between molecular arrangements in the crystals and fugacity of polymorphs.

As our interests are associated with drug availability with respect to solid-solution behavior we must introduce solubility into the theory. Adopting the convention that the activity becomes equal to molality at infinite solute dilution we can write (3)

$$\frac{\partial \ln (\gamma m)}{\partial T} = \frac{H^\infty - H^S}{RT^2} \qquad \text{(Eq. 4)}$$

Here m is the solubility in molal units, γ is the activity coefficient defined by

$$\gamma \to 1 \text{ as } m \to 0$$

H^∞ is the partial molar enthalpy of the solute at infinite dilution and H^S is the mola' enthalpy of the crystal. The difference

$$\Delta H = H^\infty - H^S$$

is the heat of dissolution at infinite dilution per mole of crystal.

Now when Henry's law is obeyed, *i.e.*, for dilute solutions in which solute association is negligible, solute fugacity of the solution will be proportional to the solute concentration. Thus under these conditions $\gamma = 1$ and $f_I/f_{II} = m_I/m_{II}$. Since most systems of interest to us involve dilute solutions, this case is of practical importance. Assuming Henry's law we may write from Eq. 4

$$\frac{\partial \ln m_I}{\partial T} = \frac{H^\infty - H_I^\circ}{RT^2} = \frac{\Delta H_I^\circ}{RT^2} \qquad \text{(Eq. 5a)}$$

and

$$\frac{\partial \ln m_{II}}{\partial T} = \frac{H^{\infty} - H_{II}^{\circ}}{RT^2} = \frac{\Delta H_{II}^{\circ}}{RT^2} \quad \text{(Eq. 5b)}$$

for each of the two forms in their standard states. Here the ΔH°'s are the heats of solution at infinite dilution.

Equations 5a and 5b may be combined to give

$$\frac{\partial \ln (m_I/m_{II})}{\partial T} = \frac{\Delta H_{I,II}^{\circ}}{RT^2} \quad \text{(Eq. 6)}$$

Equation 6 relates the solubility (or fugacity) ratio to the enthalpy of phase change. It can be seen that

$$\frac{\partial \ln (m_I/m_{II})}{\partial T}$$

should be independent of the solvent as long as Henry's law is obeyed.

At some temperature, T_t, known as the transition temperature the fugacities of the two forms will be equal, *i.e.*, $f_I = f_{II}$ or $m_I = m_{II}$. From Eq. 3 we have the condition

$$\Delta H_{I,II}^{\circ} = T_t \Delta S_{I,II}^{\circ} \quad \text{(Eq. 7)}$$

at $T = T_t$.

It is apparent that the above thermodynamic relationships, if judiciously applied, should be helpful in the characterization and the evaluation of polymorphic systems. In particular, it is noteworthy that by means of solubility measurements alone it is possible to obtain the enthalpy and entropy differences between polymorphic forms of crystals. These thermodynamic quantities are useful in the understanding of the inter- and intramolecular crystalline factors determining the frequencies of occurrence and differences in activities among polymorphs.

EXPERIMENTAL

General Considerations.—Methylprednisolone was selected for this study because only two crystalline forms of this compound are known to exist. Furthermore, these can be easily prepared and characterized by X-ray or infrared methods.

Polymorph I was prepared by recrystallization from acetone and polymorph II by sublimation at 190°. Table I gives the X-ray powder diffraction data for the two forms. The infrared mull spectra (mineral oil) are presented in Fig. 1. Either of these two methods serve to characterize the two forms.

TABLE I.—METHYLPREDNISOLONE, INTERPLANAR SPACINGS, A

2.85	...	3.38	...

To permit a test of the solvent independence of f_I/f_{II} (or m_I/m_{II}), three solvents—water, decyl alcohol, and dodecyl alcohol—were selected. The solubilities of methylprednisolone in these solvents are all low enough so that Henry's law is likely to be obeyed by these solutions.

Procedure.—For determinations of solubilities in

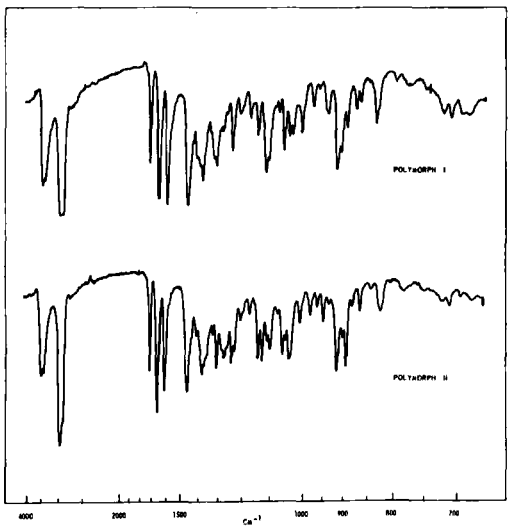

Fig. 1.—Infrared mull spectra of methylprednisolone, polymorphs I and II.

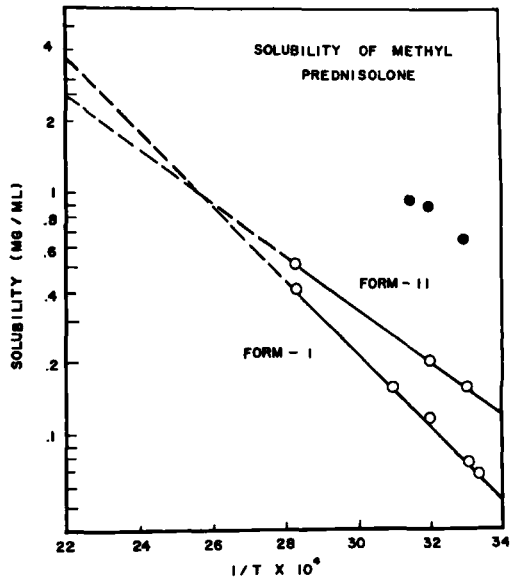

Fig. 2.—Water solubilities of methylprednisolone as a function of temperature: ○ refers to data for form I and Form II; ● is cloudpoint data (see text).

water, 15-ml. vials containing water and excess amounts of the particular form were slowly rotated in a water bath thermostated to ±0.05°. Periodically 5-ml. aliquots of the solution were withdrawn with a pipet fitted with a glass wool plug, diluted with 95% ethanol, and assayed spectrophotometrically. After several days the steroid concentrations in the solution phase were found to be constant.

For determinations in the alcohols, excess amounts of the particular form of the drug were placed with the solvent in a stoppered flask which was water jacketed to maintain a constant temperature within ±0.05°. The mixture was vigorously agitated with a magnetic stirrer. Aliquots of the solution were withdrawn and filtered by a syringe fitted with a hypodermic adapter for Millipore[1] filter paper. Then the solutions were diluted appropriately in 95% ethanol and assayed spectrophotometrically.

In the water system with both forms I and II the steroid concentration always increased with time to a constant value. This was also the general behavior with the alcohol systems at the lower temperatures. However, beyond 50° in the decyl alcohol case involving form II, the steroid concentrations initially increased with time, then reached a maximum value, and then decreased steadily. This can be explained on the basis of relatively rapid conversion of the drug to another form at the higher temperatures in decyl alcohol. Thus for form II in decyl alcohol, data were obtained only up to 60°.

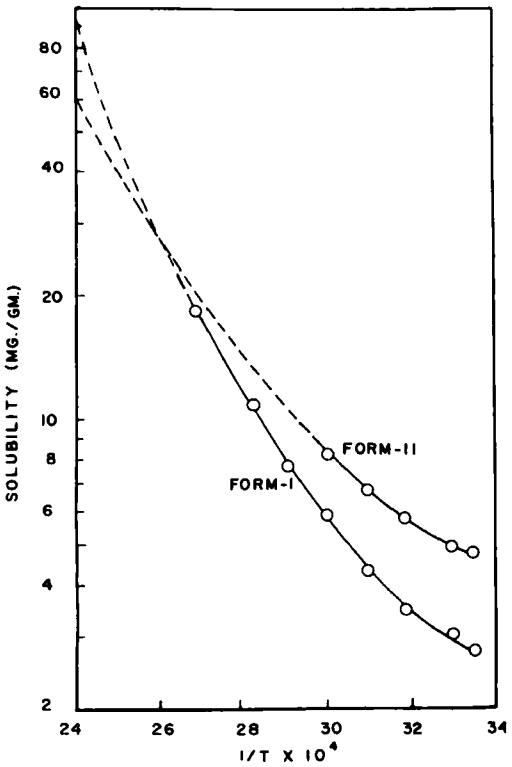

Fig. 3.—Solubility of the two forms of methylprednisolone in decyl alcohol as a function of temperature.

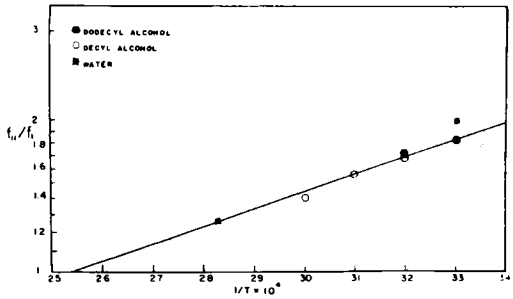

Fig. 4.—A plot of the fugacity or solubility ratio for the two forms of methylprednisolone as a function of solvent and temperature.

RESULTS AND DISCUSSION

The results of the determinations in water and decyl alcohol are shown in Figs. 2 (open circles) and 3, respectively. The data are plotted as log solubility *vs.* $1/T$ rather than *vs.* T. This method of plotting follows from rearranging Eq. 5 to give

$$\frac{\partial \ln m_I}{\partial (1/T)} = \frac{-\Delta H_I^\circ}{R} \qquad \text{(Eq. 8a)}$$

and

$$\frac{\partial \ln m_{II}}{\partial (1/T)} = \frac{-\Delta H_{II}^\circ}{R} \qquad \text{(Eq. 8b)}$$

In Fig. 4, these data and the data for the dodecyl alcohol system are all plotted as log solubility ratio *vs.* $1/T$. This type of plot is suggested by Eq. 6. Except for the results at the lowest temperatures, the solubility ratios appear to be independent of the solvent in accordance with theory. While it appears unlikely, the deviations at the low temperatures are possibly attributable to the deviations from Henry's law.

From the slope of the best straight line drawn through the points in Fig. 4 we may calculate a value for $\Delta H_{I,II}^\circ$. The transition temperature, T_t, may be obtained by extrapolating the curve to

$$\frac{f_I}{f_{II}} = \frac{m_I}{m_{II}} = 1$$

For these quantities we obtain $\Delta H_{I,II}^\circ = 1600$ cal. mole^{-1} and $T_t = 118°$. Then by application of Eq. 7 we obtain $\Delta S_{I,II}^\circ = 4.1$ e.u.

Paucity of data in the literature on entropies of transition and the lack of structural information on the methylprednisolone system preclude a single interpretation of the $\Delta S_{I,II}^\circ$ value in terms of molecular arrangement in the crystals. It appears likely, however, that the entropy difference is a result of greater localization of the functional groups in the side chain in form I resulting either from intermolecular or intramolecular interactions. It is well known (4) that lack of freedom of rotation about the carbon-carbon bond contributes about $R\ln 3$ per methylene group to the entropy of fusion for long chain paraffins. Thus the effects of two or more linkages in the side chain may account for the observed $\Delta S^\circ_{I,II}$.

[1] Millipore Filter Corporation, Bedford, Mass.

These results with form I and form II of methylprednisolone demonstrate that significant differences in solubilities may exist among polymorphs. In the present example the unstable form, II, exhibits a solubility the order of 80% greater than that for the more stable form, I, at room temperature. In order to obtain an idea as to the order of magnitude of the solubility of amorphous methylprednisolone, exploratory studies[2] involving cloudpoint determinations were carried out. The results of these are presented in Fig. 2 (darkened circles). These "solubility" values represent the concentrations of the steroid in aqueous solutions necessary for rapid appearance of turbidity when a concentrated dimethylformamide solution of the steroid was added dropwise to water. If it can be assumed that appreciable supersaturation is unnecessary for nucleation of the supercooled liquid phase, it is reasonable to presume that these values represent a lower limit for the solubility of the supercooled liquid or the amorphous solid. It is noteworthy that these correspond to almost 20 times the solubility of form I. It is hoped that future studies on this problem would lead to preparable crystal forms exhibiting such large differences in solubilities.

X-Ray and Crystallographic Applications in Pharmaceutical Research IV

Modified Procedures for Molecular Weight Determinations

By JOHN W. SHELL†

The modified procedures described in this paper for the determination of molecular weights of crystalline organic compounds differ from conventional procedures in the replacement of film recording by proportional counter recording and by the use of fractional-cell, rather than true unit-cell volumes. These procedures allow the routine determination of molecular weights with relatively small investments of time, yet with errors usually no greater than one hydrogen atom. The general method is presented and detailed procedures for lower symmetry crystal systems, in which most organic compounds fall, are described. The procedures are illustrated by specific examples.

FOR THE precise determination of molecular weights of crystalline compounds, the X-ray diffraction method has long been the method of choice. If one invests sufficient time and all the necessary care, the accuracy of this method need be limited only by errors due to crystal imperfections, which are often of the order of 0.04% if due to void spaces and often less if due in part to inclusions.

The strong relationship between time investment and accuracy appears, for practical purposes, to have a point of diminishing returns. Experience has shown that somewhat less than absolute, but yet fairly accurate determinations can be made with reasonable time investments.

In these laboratories an attempt has been made to develop procedures which assure an acceptable level of accuracy (the error usually approximating one hydrogen atom) with a minimum investment of operator time. This has required differing procedures for crystals of different symmetry, as noted below. It has also required the replacement of film techniques with direct recorder techniques.

GENERAL METHOD

The feasibility of the X-ray method for molecular weight determinations derives from the fact that an exact and determinable numbe; of molecules occupies a *unit cell* which, by three-dimensional repetition, generates the space lattice of the crystal. As the repeat spacings are of the same order of magnitude as X-ray wavelengths, diffraction of X-rays is possible and oriented diffraction procedures permit the measurement of the unit cell volume. An experimentally determined unit-cell density (crystal density) permits then the simple calculation of the unit-cell weight. This is either the molecular weight or some

multiple of it, depending upon the number of molecules per cell. The number of molecules per cell is determinable.

The conventional approach to the measurement of the unit-cell volume has been by the use of X-ray film cameras and oriented crystal procedures producing values for the true cell edge lengths and the angular relationship between the true cell edges. A modified approach is by use of proportional counter detection and the measurement of fractional cells, rather than true cells, resulting in a more rapid accumulation of accurate information.

In the sections which follow, two crystal density determination methods are described, followed by modified procedures for the determination of unit-cell volumes for the various crystal symmetries encountered most often with organic compounds. The methods are illustrated by specific examples.

Determination of the Crystal Density

Two methods of crystal density determination have been found to be highly reliable. The first, which is more rapid, is less accurate and tends to limit the molecular weight determination to the density error, usually about 2×10^{-3} Gm./ml. The second method requires more time but allows the accuracy of the molecular weight determination to be limited to either that of the X-ray measurements or to the crystal imperfections.

Method 1.—This less accurate, but more rapid method is an adaptation of the flotation method of Bernal and Crowfoot (1), and consists essentially of immersing a few crystals in a light liquid, followed by addition of a miscible heavy liquid until the crystals tend to rise in the mixture. At this point the heavy liquid is added dropwise to the mixture with stirring. Each addition is followed by a short period of centrifugation. This is continued until complete dispersion is maintained even after prolonged centrifugation. The temperature of the suspension is noted, using the same thermometer which is later to be used as part of a standard pycnometer, and the suspension cooled to a few degrees below this temperature. The suspension is then used to fill the pycnometer and the volume adjusted when the temperature reaches the original suspension temperature. The density is then computed from the weight of the known volume.

The centrifuge should be of the clinical type, which permits the tubes to swing to a horizontal position. A convenient volume to use is 10 to 12 ml. so that standard centrifuge tubes and a 10-ml. pycnometer may be used.

When only a few crystals are available, it is convenient to do all mixing in a small (25-ml.) beaker, adding each new liquid mixture to the few crystals in a 3-ml. test tube for centrifuging. If, in the early stages of the determination, density equilibration is approached by adding the heavy liquid to the light liquid, centrifugation after each addition will pack the few crystals to the bottom of the tube and the liquid can be poured into the breaker for the next addition and mixing. This confines the crystals to the small volume of the tube and conserves them even during a large number of liquid additions and a large total volume increase.

The liquids used for flotation must obviously be nonsolvents for the crystals of interest. Both an aqueous system and a series of organic liquids have been used with good success, depending upon the solubility of the crystals. The aqueous system is comprised of various concentrations of zinc chloride which allow increases in density from 1.0 up to about 2.0 and covers the density range of most organic compounds. The addition of a slight trace of Aerosol OT, or other wetting agent, to aqueous flotation liquids has been found to be advantageous. The organic series comprises the miscible liquids benzene (d = 0.879), α-chloronaphthalene (d = 1.194), α-bromonaphthalene (d = 1.487), s-tetrabromoethane (d = 2.964), and methylene iodide (d = 3.3). With either flotation system it has been found helpful to place the container with the lighter liquid and immersed crystals into some evacuable chamber so that the crystals may be freed from occluded air within a few minutes at reduced pressure.

During centrifugation, the flotation suspension undergoes a temperature rise; this is the source of the chief error of this method. For this reason, short centrifugation time and larger volumes are advantageous. A crystal density may be determined by this method in about 1 hour.

Method 2.—The most precise crystal density determination method is that of Straumanis. Since it has been previously described (2), it will receive only brief mention here.

Use is made of a special tube-shaped pycnometer constricted at the neck with a calibration mark in the area of constriction. A flotation liquid nearly equal in density to that of the suspended crystal is added past the mark and the filled pycnometer immersed in a water bath adapted for temperature control. The temperature is adjusted until suspension is achieved, at which time the volume is adjusted to the mark and the pycnometer and contents weighed. Knowing by previous calibration the pycnometer volume over a range of temperatures, the density of the crystal is calculated. The use of a cathetometer to observe the suspended crystals in the final stages of equilibration has been found advantageous. The accuracy of the method depends upon the difference in cubical expansion of the liquid and the crystal, which is usually quite large. The accuracy reported by Straumanis (2) was at least 3×10^{-4} Gm./ml. The time required for a determination is from 2 to 3 hours.

Measurement of the Unit Cell Volume and Calculation of the Molecular Weight

Many alloys, minerals, and other inorganic compounds crystallize in high symmetry systems. The measurement of their unit-cell dimensions can often be made directly from easily obtained powder-diffraction patterns. The organic compounds of pharmaceutical interest, however, almost invariably crystallize in lower symmetry systems and their powder-diffraction patterns are too complicated for the direct determination of unit cell dimensions. This is always true for triclinic and monoclinic crystals; indirect graphical methods have been extended with with some success, particularly to orthorhombic powder patterns, but only when each powder line is known to a high degree of accuracy, and accompanied by an extremely large investment of time. It has, therefore, become standard procedure to utilize single-crystal studies in place of the more easily acquired, but less meaningful, powder patterns.

Several types of single-crystal X-ray cameras are

well known. Most of them are designed for use in total structure determination, only the first step of which involves unit-cell measurements. Most all of these cameras use film for the detection of diffracted X-rays. The recently developed General Electric single crystal orienter, however, utilizes direct recording by a proportional or scintillation counter instead of film. Its use permits accurate measurements with a saving of much of the time otherwise required for the exposure, developing, drying, and measuring of the film for determination of each dimension. Moreover, unlike the procedures required in the use of most film cameras, all measurements may be made from a single mounting of the crystal. The attachment, mounted on a G. E. XRD-5 diffractometer, is shown in Fig. 1.

For unit-cell measurements, a single crystal is selected on the basis of size, shape and the freedom from small, adhering crystals. A polarizing microscope is ideal for the purpose of crystal selection. Crystal habit varies considerably within most crops of organic crystals. It is often convenient to select a crystal with an elongated prism axis. Compared to the optimum size for inorganic crystals (about 0.2 mm.), the low mass absorption coefficients of elements comprising organic compounds permits use of fairly large crystals (up to 1 mm., if properly positioned).

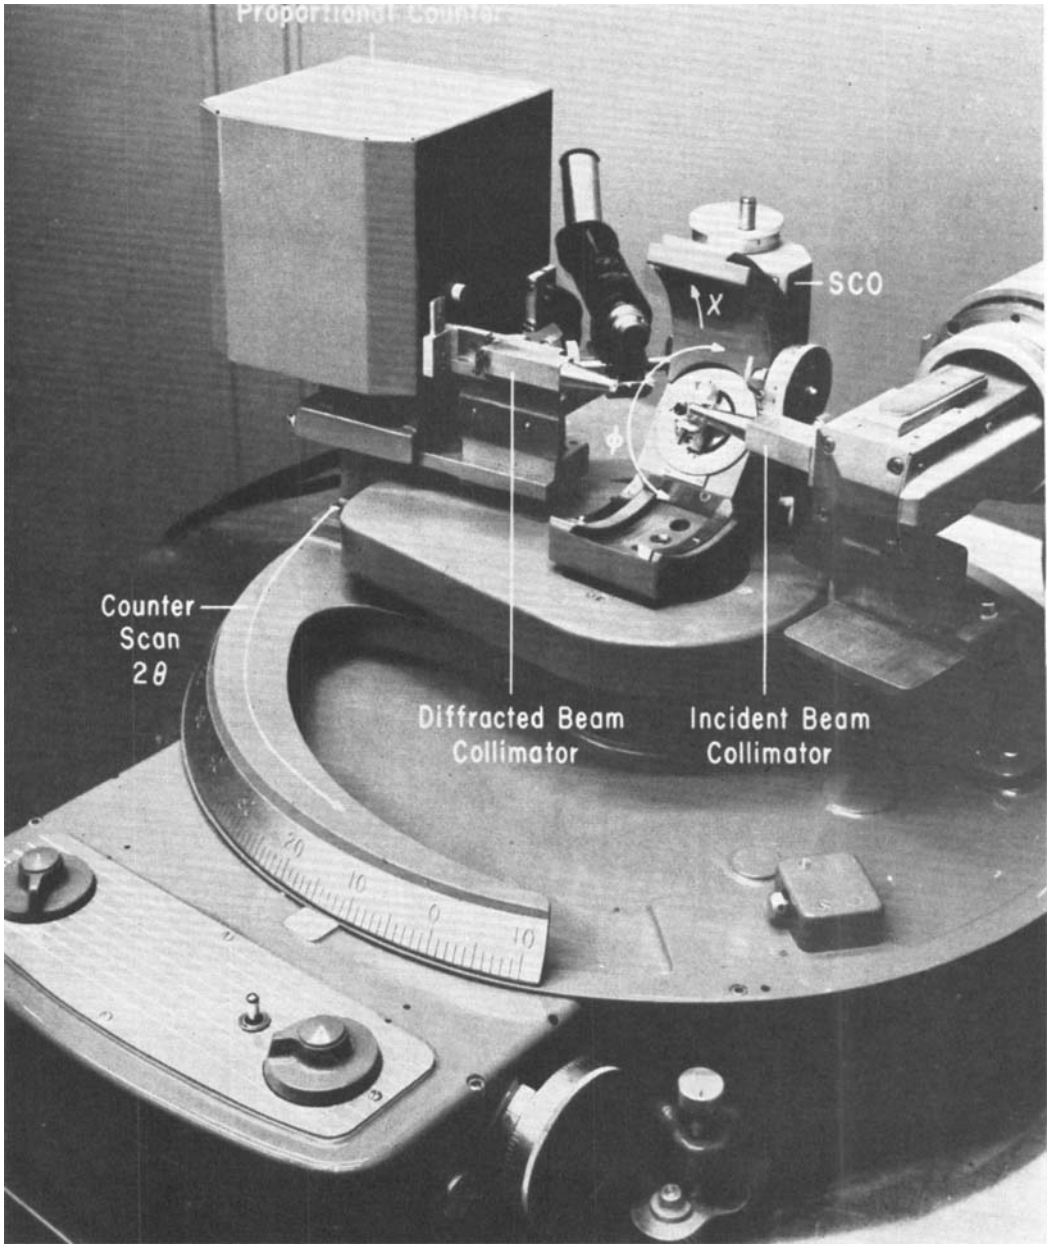

Fig. 1.—X-ray diffractometer and single-crystal orienter (SCO). Crystal rotation directions ϕ and χ are shown (radiation shields removed).

With the aid of a microscope, the crystal is cemented to the end of a fine glass fiber in such a manner that the fiber is approximately coincident with one of the crystallographic axes. The fiber is then attached to the goniometer head of the single crystal orienter (SCO) by the use of beeswax, plasticine, or other suitable medium. With the aid of the microscope shown in Fig. 1, the goniometer head permits orientation of the crystal at a point in space such that there is no departure of the crystal from this point, regardless of rotation about the various SCO axes. The principal SCO axes are phi (ϕ), about which the originally chosen crystal axis may be rotated, and chi (χ), about which this crystal axis may be inclined. The ϕ axis is rotatable through 360° and calibrated to 0.02°. The χ axis may be rotated from $-10°$ to $+100°$ and is calibrated to 0.01°. The ϕ axis is vertical when χ is set at 0°. All orientations of the crystal with respect to the X-ray beam are possible from a single mounting of the crystal. From a properly oriented crystal, the diffractometer measures the Bragg angle, 2θ, directly.

As the proportional counter shown in Fig. 1 scans in a counterclockwise direction, the SCO also rotates in this direction, but at half the angular velocity of the counter. The Bragg equation, $N\lambda = 2d \sin \theta$, relates the X-ray wavelength (λ), the diffraction angle between the diffracted and projected incident beams (2θ), and the crystal interplanar spacings (d), all for various orders of diffraction (N). Thus, when a diffraction "signal" is found at a certain 2θ position, solution of the Bragg equation gives the spacing within the crystal of parallel planes which are normal to the bisector of the angle between the incident and diffracted beams.

Since most pharmaceutically important compounds are organic, and most crystalline organic compounds are of either orthorhombic, monoclinic, or triclinic symmetry, these lower symmetry systems will be considered in detail. The higher symmetry systems, isometric, tetragonal, and hexagonal, can be treated as special, simplified cases of the lower symmetry systems described. For instance, a tetragonal crystal may be treated as an orthorhombic crystal which has two of its axes equal in length.

A. Crystals of Orthorhombic Symmetry.—Orthorhombic crystals are referred to three mutually perpendicular, unequal axes. The volume of an orthorhombic unit cell is simply the product of the three axial lengths or, in other words, the product of the dimensions of the repeat lattice in each of the three perpendicular directions.

The orthorhombic cell volume is measured by mounting the crystal with one of the crystallographic axes vertical, and coincident with ϕ, while $\chi = 0°$. With ϕ rotated until a major crystal face is parallel to the X-ray beam when $2\theta = 0°$, a scan of 2θ will generally give a first diffraction signal. Solution of the Bragg equation for the 2θ value thus obtained gives one of the cell dimensions or some submultiple of it. Repeating this operation after a rotation of 90° in ϕ produces the second cell dimension. The third cell dimension is obtained from a 2θ scan following a 90° rotation of χ. Orthorhombic axes are designated such that $c<a<b$.

The recording of 2θ data for each signal should be made only after the signal is maximized by slight adjustments of all three variables, χ, ϕ, and 2θ. Further, it should be noted that each diffraction position of the crystal may give rise to several signals at different 2θ values, each representing a different diffraction order. As certain errors diminish with increasing values of θ, higher order diffractions are advantageously used for the cell-dimension determination. Finally, this procedure sometimes results in a cell-dimension value which is one-half that of the true cell dimension, due to certain diffraction extinctions. A fractional, rather than true cell volume is thus obtained. For the purpose of molecular weight determination this is of no consequence as the error will result in only a different whole number value for the number of molecules determined per unit cell and not in a different value for the molecular weight itself.

When the crystal density and the unit-cell axes, a, b, c, (or possibly semiaxes) have been determined, the cell volume ($v = abc$ for orthorhombic crystals) and the molecular weight, M, of the compound are calculated (3)

$$M = \frac{dv}{1.6604\ n}$$

where d = density, v = cell volume, and, n = number of molecules per cell.

Although more involved methods exist for determining n, the number of molecules per cell, the simplest method which is invariably applicable consists of substituting for M in the above equation an approximate molecular weight value obtained from chemical evidence and solving for n. Knowing that the only possibilities for n in this crystal system are 1, 2, 4, 8, etc., the proper choice becomes obvious and the exact value of n may be used to calculate M.

Sometimes a significant gain in accuracy can be accomplished by the combined use of single-crystal data and powder-diffraction data. This can often be accomplished at an overall saving of time, since when this procedure is followed, the single-crystal data need not be so precise and can, therefore, be collected more rapidly.

The procedure involves rapid measurement of unit cell dimensions by the SCO operation described above and the use of these approximate values to partially index a powder diffraction pattern.[1] By a slow scan of only the three appropriate powder diffraction lines, using standard diffractometer techniques for high resolution,[2] the cell dimensions can be measured with extreme accuracy.

Examples of the results of the use of combined single-crystal and powder-diffraction data are shown

---

[1] For orthorhombic crystals,

$$d = \frac{1}{\sqrt{\frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2}}}$$

This reduces greatly for the determination of d for $h00$, $0k0$ and $00l$, usually found, with organic crystals, in the first few powder lines. Occasionally $hk0$, $h0l$, or $0kl$ will have to be calculated also, if one of the first series is absent.

[2] It has been found useful to mix a small amount of sodium chloride with the unknown material before measuring the powder diffraction pattern. The 2θ positions of all measured lines may then be corrected by the measured position of a sodium chloride line, and errors due to instrumental misalignment, temperature, etc. are compensated. Sodium chloride has a d spacing (100) of 5.64009Å. at 25°.

TABLE I.—RESULTS OF THE USE OF PRECISE POWDER DIFFRACTION DATA TO REFINE APPROXIMATE SINGLE-CRYSTAL DATA FOR UNIT-CELL MEASUREMENTS

	Crystal Density	Cell Dimensions, Å.		Molecular Weight					
				Approximate			Refined		
		Approximate	Refined	Found	True	% Error	Found	True	% Error
Example 1	1.255	a = 9.30	9.50						
		b = 11.01	11.00						
		c = 5.10	5.08	394.70	401.49	1.7	401.25	401.49	0.06
Example 2	1.197	a = 8.46	8.34						
		b = 12.86	12.93						
		c = 3.99	3.99	312.94	309.39	1.1	310.18	309.39	0.26

in Table I, as applied to two different crystalline steroids of orthorhombic symmetry. Approximately 1 day was required for each example.

The modified method described here usually results in a gain in both time saved and accuracy. A comparison of these variables for the modified and the conventional film methods is presented in Table II using the orthorhombic crystal tolbutamide for an example. The molecular weight values were calculated using an experimentally determined density value of 1.245.

TABLE II.—COMPARISON OF MODIFIED METHOD AND CONVENTIONAL-FILM METHOD FOR THE ORTHORHOMBIC CRYSTAL TOLBUTAMIDE, MOL. WT. = 270.34

	Conventional Film Method (4)	Modified Method
Unit cell dimensions, Å.	a = 9.07	a = 9.116
	b = 20.14	b = 20.32
	c = 7.78	c = 7.770
Cell volume, Å.^{3}	1421.2	1439.3
Molecular weight, calculated	266.4	269.3
Per cent error in molecular weight	1.45%	0.20%
Time required for result:		
Operator hours	6	4
Total hours	17	8

B. Crystals of Monoclinic Symmetry.—Monoclinic crystals are referred to three unequal axes, two of which, a and c, intersect at an oblique angle, β, and with the b axis normal to the plane of a and c.

The SCO procedure found most useful for the rapid but accurate determination of a monoclinic cell, which again is not necessarily the true unit cell, is as follows.

The crystal is mounted so that the ϕ rotation is about the b crystallographic axis. The procedure is similar to that used for orthorhombic crystals, except that the angular measurement of β (measured in ϕ) is required. Using crystal faces as a guide for a first diffraction signal with χ at 0°, the ϕ and 2θ values are recorded and signals at other ϕ positions sought by scanning both ϕ and 2θ. Only fortuitously would a second signal be found with a ϕ setting 90° from the ϕ setting of the first signal, as would be found with orthorhombic crystals. Several signals at different settings will usually be found, and two ϕ values should be selected for use which are as close to 90° apart as possible. The difference between these ϕ settings is the β angle. The 2θ values at each ϕ setting, when converted to interplanar spacings, may be used to compute the area of a monoclinic cell in the ac plane. Rotation of χ to 90° permits determination of a 2θ value which, when converted, is the cell length along b.

Conventional procedures result in values for a, b, and c, representing true cell edge lengths, and the angle β. The SCO procedure described here measures interplanar spacings which are not necessarily the same as cell edge lengths.

Appropriate interplanar spacings are the same as cell edge lengths in orthorhombic crystals, and one set of interplanar spacings is the same as one cell length in monoclinic crystals (the 90° χ position gives true b). Figure 2 shows a planar section (normal to b) through a monoclinic crystal; a and c are true cell edge lengths; a' and c' are the values obtained from the SCO procedure. The area of the section is $ac \sin \beta$, or $a'c'/\sin \beta$ and the cell volume is $abc \sin \beta$ as conventionally determined, or $a'bc'/\sin \beta$ as determined by the SCO procedure.

Exemplifying the method are the results of the application to the determination of the cell size and the molecular weight of methylprednisolone. This compound crystallizes under normal conditions in the monoclinic system with the true unit-cell constants shown in Table III.

TABLE III.—TRUE UNIT-CELL CONSTANTS FOR THE MONOCLINIC CRYSTAL METHYLPREDNISOLONE

a = 21.78 Å.	Cell volume—1979 Å.^{3}
b = 9.183	n = 4
c = 10.88	Density—1.2544
β = 65° 26.1′	

With the crystal mounted so that the ϕ rotation was about the b axis, and with χ = 0°, signals were found at ϕ settings 65° 26.1′ apart. The 2θ values for these settings gave interplanar spacing values of

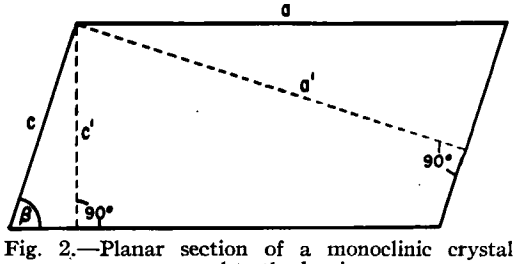

Fig. 2.—Planar section of a monoclinic crystal normal to the b axis.

9.904 Å. and 9.895 Å. Following rotation of χ to 90°, conversion of the measured 2θ value gave a result of 4.591 Å. These values gave a calculated cell volume of 494.69 Å.^{3} which, together with the measured density value of 1.2544, allowed the calculation of the molecular weight, 373.8. (True molecular weight, 374.46.)

The volume of the subcell measured by the SCO procedure is one-fourth that of the true unit cell, as two of the measurements were of hemiaxes. Again, the fact that the modified method measures a fractional cell is of no consequence when used for molecular weight determinations. In fact, the method quite often gives the molecular weight directly, as in the example just cited, rather than some multiple of it.

As with the determination of orthorhombic cell volumes, a gain in accuracy can sometimes be achieved with monoclinic cells by combining SCO data and at least partial powder-diffraction data. The probability of doing so at a saving of time is not so great as with orthorhombic crystals, however, due to the greater complexity of the indexing problem. This is so when the indexing is done manually. With the aid of machine methods, however, the gain in accuracy can be made with no time loss. By programming a digital computer[3] to solve the following equation[4] for all values of h, k, and l,

$$d = \frac{1}{\sqrt{\frac{\frac{h^2}{a^2} + \frac{l^2}{c^2} - \frac{2hl}{ac}\cos\beta}{\sin^2\beta} + \frac{k^2}{b^2}}}$$

given a, b, c, and β, a list of d spacings can be produced. This list is essentially a synthetic powder pattern whose d values are of no greater accuracy than the SCO data but which is accurately indexed. Comparison with the experimental powder pattern (accurate d values, but not indexed) results in accurate indexing of the accurate d values, which may then be used to compute the cell volume.

C. Crystals of Triclinic Symmetry.—Triclinic crystals are referred to three unequal axes, all intersecting at oblique angles. Such crystals have undergone such an extreme decrease in symmetry when compared to monoclinic crystals that the cell volume calculation is highly involved. Further, measurements of three oblique angles give rise to major sources or error. When using conventional film techniques, one almost invariably gains in both time and accuracy of the cell-volume determination when time is invested in converting the organic crystal to one of higher symmetry through either a polymorphic change, solvation (the degree to be later determined), or derivativization.

Although the SCO is ideally suited for the determination of the true unit cell edge lengths and true interaxial angles, for purposes of molecular weight determinations the true cell constants need not be found. As pointed out by Bunn as early as 1945 (4), the volume of a triclinic cell is one axis length multiplied by the area of that axis projection. Using film techniques, one could measure the layer-line spacings, achieving the axis length, and theoretically, from equatorial spacings, the dimensions of the axis projection. Finding the axis projection required the determination of an oblique angle, however, as well as several reflection orders of two different dimensions, all from one row of superimposed spots. With film techniques, then, the axis projection method is still quite complicated.

The availability of the SCO allows easy application of the axis-projection method to triclinic cells. Errors are significantly reduced by the reduction in the number of required angles measured from three to one and even when the SCO method is combined with a partial film method (to measure one axis length) there is a great saving of time. As mentioned above, the SCO is capable of measuring all triclinic cell constants. Experience in these laboratories has shown, however, that the most rapid procedure with acceptable accuracy involves a combination of SCO and film techniques. This procedure is described below.

With the crystal mounted in the SCO ($\chi = 0°$) so that one crystal axis is coincident with ϕ, scans of ϕ and 2θ are made until signals corresponding to two different settings of ϕ are found. The 2θ values are converted to interplanar spacings and recorded along with the angle between the two ϕ settings. The product of these spacings, divided by the sine of this angle, is the area of the axis projection. The goniometer head, together with the undisturbed mounted crystal, can then be transferred to a film camera for a standard rotation photograph. The layer-line spacings of the rotation photograph allow the calculation by standard techniques of the axis length. The product of this length and the area of the axis projection is the volume of the cell. The cell measured in this manner is not necessarily the true unit cell but bears some whole number relation to it so that an accurate molecular weight value can be found.

In order to compare the conventional and the modified techniques, as applied to a triclinic crystal, cholesterol may be used as an example. The true unit cell constants of cholesterol (5) are shown in Table IV. The volume of a triclinic cell is $v = abc$

TABLE IV.—TRUE UNIT-CELL CONSTANTS FOR THE TRICLINIC CRYSTAL CHOLESTEROL

$a = 14.10$	$\alpha = 94.60°$
$b = 33.75$	$\beta = 90.00°$
$c = 10.46$	$\gamma = 95.72°$

$\sin\beta \sin\gamma \sin\delta$ where

$$\sin\frac{\delta}{2} = \sqrt{\sin\frac{(\alpha - \beta + \gamma)}{2}\sin\frac{(\alpha + \beta - \gamma)}{2}}$$

The calculated volume of the cholesterol unit cell is 4939.7 Å.^{3}. All six constants listed above were required to calculate this value.

Applying the modified method with the crystal mounted with c and ϕ coincident, values of 33.60 Å. and 13.97 Å. are recorded from two separate ϕ settings, which are 95°42′ apart. These correspond to the 010 and 100 reflections. After determining

[3] The author is grateful to Dr. O. S. Carpenter of The Upjohn Co. for programming and operation supervising of the Burroughs E-102 digital computer.

[4] It may be noted that for orthorhombic crystals, where $\beta = 90°$, this equation reduces to that presented in the previous section, footnote 1. The same computer program may therefore be used to index powder patterns of both orthorhombic and monoclinic symmetry.

the c axis length, 10.46 Å., from a single rotation photograph, a simple calculation gives v'

$$v' = \frac{33.60 \text{ Å.} \times 13.97 \text{ Å.} \times 10.46 \text{ Å.}}{\sin 95°42'} = 4934.2 \text{ Å.}^3$$

This value agrees well with the previously calculated v for the true unit cell, 4939.7 Å.^{3}. It should be noted that v' was obtained by a simpler procedure which is usually more rapid and, as noted above, the requirement of measuring only one, instead of three angles, usually results in a significant gain in accuracy.

Effect of Drugs on Survival Time from Scorpion Envenomation

By LEO GREENBERG and JAMES W. INGALLS

Androctonus australis **venom at various dilutions was administered to matched groups of mice and the effects on survival time and number determined for various classes of therapeutic agents. Meperidine and other narcotics were consistently deleterious to envenomed animals as were alcohol and calcium acetylsalicylate carbamide. Neither corticosteroids nor muscle relaxants were beneficial. With tranquilizing agents, meprobamate tended to increase survival time, while reserpine markedly curtailed survival.**

In previous papers from our laboratories, we have investigated the interaction of tranquilizing drugs and various toxic agents in laboratory animals. These challenges have included curare (1), bacterial exotoxins (2–4), bacterial endotoxins (3, 4) and septicemias (2, 3). Presently, reports are in preparation on amoebiasis and trichinosis. It was of interest therefore to determine if the profound alterations in survival time evinced with tranquilizer treatment in the previous conditions could be demonstrated with arthropod venom. Moreover, it was felt that such a study might have more than academic interest since scorpion envenomation represents a major hazard to man and animals throughout much of the tropical and semitropical areas of the earth's surface. In some areas, principally North Africa, the danger from scorpions is greater than from venomous snakes (5).

It is known that the pharmacological actions of scorpion venom from a great variety of genera and species are quite similar (6) and that species widely separated by geography contain venom components in common (7). Symptoms of envenomation include muscular contractions, salivation, respiratory paralysis, and vasoconstriction. It is suggested that these indicate the existence of a substance or substances with strong parasympathetic activity acting in a similar manner to serotonin (8).

In the present study, in addition to tranquilizing drugs, other agents of real or imagined therapeutic significance in the envenomed state were included for comparison. The narcotics meperidine,[1] cocaine, codeine, and morphine were tested in light of the findings of Stahnke (9, 10) that both morphine and meperidine are undesirable therapeutic agents for use in envenomation from the Arizona scorpion, *Centruroides sculpturatus*. The analgesics calcium acetylsalicylate carbamide[2] and dextropropoxyphene hydrochloride[3] were included as possible substitutes for the narcotic agents in controlling pain. Methocarbamol[4] was tested on the basis of its reported value in cases of black widow spider bites (11), and two other muscle relaxants, carisoprodol[5] and phenyramidol hydrochloride,[6] were included for comparison. In view of the reported parasympathomimetic action of scorpion venoms, the antiparasympathetic scopolamine was included in this study. Alcohol was used in keeping with the long standing proscription against whisky in snake bite, and the barbi-

turates phenobarbital and hexobarbital were tested as possible substitutes for the narcotics as sedating agents. Finally, the corticosteroids were included in keeping with their role in the stress state, and in light of recent reports on the relation of cortisone and the effects of Egyptian scorpion venom (12) and protection against cobra venom by hydrocortisone (13).

MATERIALS AND METHODS

The animals used in this study were 20–25-Gm. CF1 male mice (Carworth Farms), caged in small groups and kept in the thermostatically controlled animal house for several days prior to use. In all experiments food was withheld after the venom challenge for at least 12 hours but water was allowed *ad libitum*.

Lyophilized venom of the North African scorpion, *Androctonus australis*[7] was diluted with sterile, isotonic saline immediately prior to each experimental series. Preliminary evaluation of this venom indicated an intraperitoneal LD_{50} of approximately 0.05 mg. for mice, which compares favorably with the published intramuscular LD_{50} of 0.091 mg. (5). In all experiments, 0.2 ml. of diluted venom was injected intraperitoneally.

All drugs were purchased locally or supplied through the courtesy of their manufacturers, diluted with sterile, isotonic saline, and injected intraperitoneally in a volume of 0.2 ml. approximately 30 minutes prior to venom challenge. Insoluble substances, such as meprobamate, were first suspended in a small volume of 5% acacia solution. Preliminary experiments established that at the doses employed none of the drugs were markedly deleterious to mice of the weight and strain used in these tests. In all experiments, matched groups of ten or more animals were used; experimental and control animals in any given series were inoculated within a few minutes of one another. Control animals all received 0.2 ml. of sterile saline solution. Death times were recorded at the cessation of respiration and heart beat.

RESULTS AND DISCUSSION

Following the establishment of an approximate LD_{50} for the venom sample at 0.2 ml. of 1:20,000 dilution, fifteen therapeutic agents were tested for their ability to alter survival time and number, the results being plotted in Fig. 1. From these data, several distinct patterns of response are evident. One group of agents, including the barbiturates, corticosteroids, the antiparasympathetic scopolamine, and the muscle relaxant methocarbamol, showed no evident difference from the control animals at the dose employed. Five of the drugs used, carisoprodol, ethanol, calcium acetylsalicylate carbamide, phenyramidol hydrochloride, and dextropropoxyphene hydrochloride markedly shortened survival time compared to control animals. Still more marked, both in shortening of survival time and in increase in mortality, were chlorpromazine, meperidine, and reserpine. On the other hand, of all of the agents tested, only meprobamate evidenced a moderate increase in survival time over control animals.

A similar group of drugs, in some cases at different dose levels, was then evaluated using an overwhelmingly lethal dilution of venom. These data are summarized in Table I. A general agreement with the previous figure is evident. Of all the agents tested, reserpine most sharply reduced survival time while increasing doses of meprobamate significantly increased survival time in the envenomed animals. At a dose of 50 mg./Kg., meperidine again shortened survival time as did calcium acetylsalicylate carbamide and ethanol while corticosteroid therapy again showed no significant alteration in survival time.

On the basis of these data, further studies were conducted with meprobamate and reserpine. With meprobamate treatment at various dose levels, time of administration and venom dilutions, a general trend toward increased survival was noted. However, this was neither of such magnitude nor consistency as to merit serious clinical consideration. With reserpine, however, a marked and consistent pattern of decreased survival time was demonstrated. Table II indicates the effect of a single dose of reserpine on the survival time and number in matched groups of animals inoculated with eight dilutions of scorpion venom. At all dilutions, mean survival time was decreased with reserpine treatment, and at or near the LD_{50}, mortality was increased.

In speculating on the mode of action by which reserpine exerts its deleterious effect in these experiments, it is tempting to implicate serotonin. Mention has already been made of the similarity in action between scorpion venom and serotonin (8).

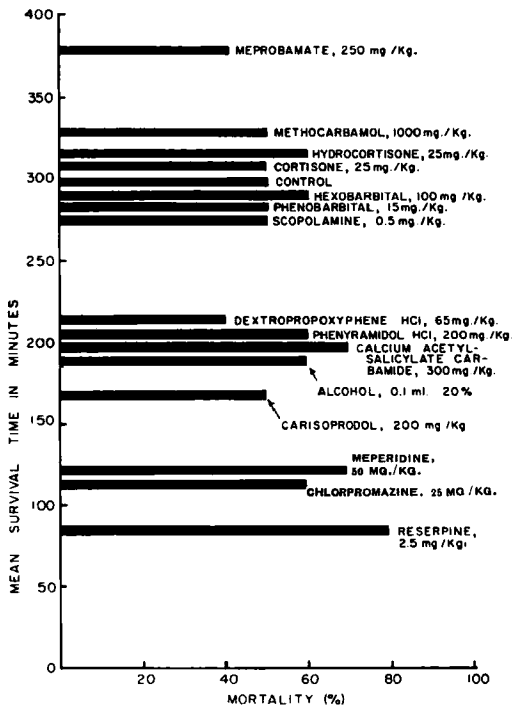

Fig. 1.—Effect of various drugs on matched groups of mice inoculated with 0.2 ml. of 1:20,000 venom (LD_{50}).

[a] Mean survival time of those animals which died.

More recently, it has been reported that serotonin is present in the venom of all species of scorpions studied, and that this ubiquitous finding cannot be fortuitous (14). Since it is well known that reserpine administration results in the release of considerable serotonin into the circulation, it is indeed possible that the overwhelming combination of exogenous serotonin in scorpion venom and endogenous serotonin from reserpine injection sharply curtails the survival time of such animals.

SUMMARY AND CONCLUSIONS

1. Venom of the North African scorpion, *Androctonus australis* was administered intraperitoneally to mice in dilutions ranging from the LD_{50} to the overwhelmingly lethal. Numerous drugs of possible significance in scorpion envenomation were tested to determine their effect on survival time.

2. Of the drugs tested, only meprobamate evidenced a trend toward increased survival in envenomed animals although this was not of sufficient magnitude to merit clinical trial.

3. Our results support previous studies demonstrating the profoundly deleterious effects of meperidine in scorpion envenomation and indicate a similar response, although not as marked, with other narcotic drugs.

4. Ethanol and calcium acetylsalicylate carbamide consistently reduced survival time while corticosteroid and barbiturate treatment showed little effect. Antiparasympathetic and muscle relaxant drugs proved of little significance or were deleterious.

5. Reserpine treatment consistently and markedly reduced survival time at all venom dilutions tested, and the likelihood that this effect is related to serotonin release has been discussed.

Dissolution Rates of Finely Divided Drug Powders II

Micronized Methylprednisolone

By W. I. HIGUCHI†, E. L. ROWE, and E. N. HIESTAND

The dissolution rate of micronized methylprednisolone in aqueous solutions was measured. Also, the particle size distribution was measured and an approximate distribution function was found. This function was incorporated into the theory for the diffusion-controlled dissolution of finely divided heterodisperse powders. The reasonably good agreement between experiment and theory suggests that the rate-determining step, in this instance, is diffusion of the drug in the aqueous phase. The possible effects of agitation, sedimentation, particle shapes, and the variation of solubility with particle size have been considered. The composite effects of these may account for the deviations between experiment and theory.

RECENTLY (1), the theoretical aspects of the liquid phase diffusion-controlled release characteristics of finely divided drug powders were examined in detail. The effects of particle size, size distribution, and drug solubility were considered in the formulation of a procedure for predicting the release *versus* time curves for powders in the region of particle size $\lesssim 25\,\mu$.

In this report, experimental studies of the dissolution rates of micronized methylprednisolone[1] in water are presented. The agreement of the data with theory is very satisfactory and demonstrates the usefulness of the theoretical procedure.

EXPERIMENTAL

Dissolution Rate Studies.—About 2.20 mg. of micronized methylprednisolone was added at zero time to 100 ml. of water in bottles which were rotated at 6 r.p.m. in a constant temperature bath maintained at 25°. The bottles were held in fixed positions on rotating wheels. Thus, mild agitation by tumbling action was achieved. Pure water was used in one set of experiments. In the other runs, the water was partially saturated with methylprednisolone to the extent of 30, 50, 70, and 90% of saturation so that a more rigorous test of the theory would be possible. At predetermined times bottles were removed and filtered rapidly, and then the filtrates were assayed spectrophotometrically.

Particle Size Analysis.—The Coulter counter[2] with the 100-μ aperture was used to determine the distribution of sizes. A 1% sodium chloride solution saturated with methylprednisolone was employed as the vehicle.

THEORETICAL CALCULATIONS

As before (1), we may write

$$a = \left(a_o^2 - \frac{2D\Delta Ct}{\rho}\right)^{1/2} \qquad \text{(Eq. 1)}$$

where a_o is the initial particle radius, a is the particle radius at time t, D is the diffusion coefficient of the drug molecule in water, ρ is the solid drug density, and $\Delta C = C_s - C_o$ where C_s is the solubility of the drug and C_o is the drug concentration in solution. While Eq. 1 applies strictly to the case where ΔC remains constant, it is easy to correct for the effects of the variation in ΔC, as will be shown later.

As most milled materials follow the log-normal distribution of sizes, Eq. 1 may be combined with a suitable function which approximates the log-normal function to give the expression for the dissolution rate of powders. This was done in the previous paper (1) and represents a generalization of the present treatment. Since in this study the initial size distribution of the methylprednisolone powder was determined with the Coulter counter, the present analysis utilizes the measured particle size distribution and constitutes a test of the applicability of the theory.

Equation 1 describes the dissolution of a single particle of initial size a_o. Consider now the situation in which there is initially a *distribution* of sizes. Let

$$n = n(a_o) \qquad \text{(Eq. 2)}$$

represent the measured distribution function. The quantity n is the initial ($t = 0$) number of particles between the sizes a_o and $a_o + da_o$. The total number of particles in the system at $t = 0$ is then

$$N = \int_{a_{so}}^{a_{lo}} n(a_o)da_o \qquad \text{(Eq. 3)}$$

where a_{lo} and a_{so} are the radii of the smallest and the largest particles, respectively, at $t = 0$.

The total mass of undissolved drug at $t = 0$ is

$$M_o = \int_{a_{so}}^{a_{lo}} \frac{4}{3}\pi a_o^3 \rho n(a_o)da_o \qquad \text{(Eq. 4)}$$

Now at any $t > \frac{a_{so}^2\rho}{2D\Delta C}$, the total amount of undissolved drug will be

$$M = \int_{a_{ot}}^{a_{lo}} \frac{4}{3}\pi\rho a^3 n(a_o)da_o \qquad \text{(Eq. 5)}$$

Here a is given by Eq. 1 and the lower limit of the integral, a_{ot}, is given by

Received March 29, 1962 from Product Research and Development, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication June 18, 1962.
† Present address: School of Pharmacy, University of Michigan, Ann Arbor.
[1] Medrol, from The Upjohn Co.
[2] Marketed by Coulter Industrial Sales, Elmhurst, Ill.

$$a_{ot} = \left(\frac{2Dt\Delta C}{\rho}\right)^{1/2} \quad \text{(Eq. 6)}$$

This limit a_{ot} is the initial ($t = 0$) size of the particle which dissolves completely at time t.

Inserting the expression for a from Eq. 1 into Eq. 5 gives

$$M = \int_{a_{ot}}^{a_{lo}} \frac{4}{3}\pi\rho\left(a_o^2 - \frac{2Dt\Delta C}{\rho}\right)^{3/2} n(a_o)da_o \quad \text{(Eq. 7)}$$

So the fraction, Q, of drug undissolved at time t is

$$Q = \frac{M}{M_o} = \frac{\int_{a_{ot}}^{a_{lo}} \left(a_o^2 - \frac{2Dt\Delta C}{\rho}\right)^{3/2} n(a_o)da_o}{\int_{a_{so}}^{a_{lo}} a_o^3 n(a_o)da_o} \quad \text{(Eq. 8)}$$

and hence the per cent release, R, is given by

$$R = 100\,(1 - Q) \quad \text{(Eq. 9)}$$

APPLICATION

Release Rate Data on Micronized Methylprednisolone.—In Fig. 1 we have the Coulter counter data for micronized methylprednisolone for which the dissolution rate studies were carried out. In the figure the smooth curve corresponds to the following empirical equation for the distribution function

$$n(a_o) = \frac{K}{a_o^2} \quad \text{(Eq. 10)}$$

where K is a constant. For a_{lo} and a_{so} the values of 0.5 μ and 9.0 μ were chosen respectively to give the good fit shown in Fig. 1. These limits correspond to a size range of 1–18 μ diameter and agree with microscopic sizing of micronized methylprednisolone.

We may now substitute Eq. 10 into Eq. 8 to get

$$Q = \frac{\int_{a_{ot}}^{a_{lo}} \frac{1}{a_o^2}\left(a_o^2 - \frac{2Dt\Delta C}{\rho}\right)^{3/2} da_o}{\int_{a_{so}}^{a_{lo}} a_o da_n} \quad \text{(Eq. 11)}$$

Integrating over the limits for both integrals in Eq. 11 and substituting for a_{ot} from Eq. 6, we obtain

$$Q = \frac{2}{(a_{lo}^2 - a_{so}^2)}\left[\left(\frac{a_{lo}}{2} + \frac{2Dt\Delta C}{\rho a_{lo}}\right)\left(a_{lo}^2 - \frac{2Dt\Delta C}{\rho}\right)^{1/2} + \frac{3Dt\Delta C}{\rho} ln\left\{\frac{\left(\frac{2Dt\Delta C}{\rho}\right)^{1/2}}{a_{lo} + \left(a_{lo}^2 - \frac{2Dt\Delta C}{\rho}\right)^{1/2}}\right\}\right] \quad \text{(Eq. 12)}$$

Now we have the following information on methylprednisolone: ρ = density = 1.28 Gm./ml.;[3] MW = molecular weight = 374; C_s = solubility = 7.4×10^{-5} Gm./ml. at 25°. We may calculate the diffusion coefficient, D, by means of the Stokes-Einstein relation

$$D = \frac{kT}{6\pi vs} \quad \text{(Eq. 13)}$$

where k = Boltzmann's constant = 1.37×10^{-16}; T = 300° Kelvin; v = viscosity $\simeq$ 0.01 poise for water; s = molecular diffusion radius for methylprednisolone, calculated from density and molecular weight = 4.7×10^{-8} cm. ±10%. Equation 13 then gives $D = 4.7 \times 10^{-6}$ cm.^{2} sec.$^{-1}$.

Inserting all of these values into Eq. 12 and combining with Eq. 9 gives the per cent released, R,

$$R = 100\left[1 - (1.12 \times 10^3 + 2.02 \times 10^4\, t\Delta C)(8.1 \times 10^{-7} - 7.34 \times 10^{-6}\, t\Delta C)^{1/2} - 62t\Delta C \log_{10}\left\{\frac{2.71 \times 10^{-3}\,(t\Delta C)^{1/2}}{9 \times 10^{-4} + (8.1 \times 10^{-7} - 7.34 \times 10^{-6}\, t\Delta C)^{1/2}}\right\}\right] \quad \text{(Eq. 14)}$$

Now in the derivation of Eq. 1 it was necessary to assume that ΔC was constant with time. Hence, Eq. 14 strictly applies only to the case of large undersaturation, *i.e.*, for $\Delta C \simeq C_s \gg C_o$. In order to apply Eq. 14 to the present release data (for which ΔC decreases with time), an approximation procedure was employed. The procedure may be carried out in the following manner: First, make a plot of R *vs.* $t\Delta C$ by means of Eq. 14. Then select R values from 0 to 100 so that ΔC does not change too greatly from one R value to the next (*i.e.*, changes in ΔC from one R value to the next must be small compared to ΔC itself). From the release rate experiments we know $\Delta C = C_s - C_o$ for any R value. Hence $\Delta t = t_{n+1} - t_n$ corresponding to R_{n+1} and R_n may be determined. Then finally, the sum of Δt values may be plotted against R to give the R *vs.* time curves.

Figure 2 shows the theoretical curves obtained by means of Eq. 14 and the approximation procedure just outlined. The experimental data are represented by the points in the figure. Because no empirical factor was used in the theoretical calculations, the agreement between the experiments and theory must be regarded as highly satisfactory

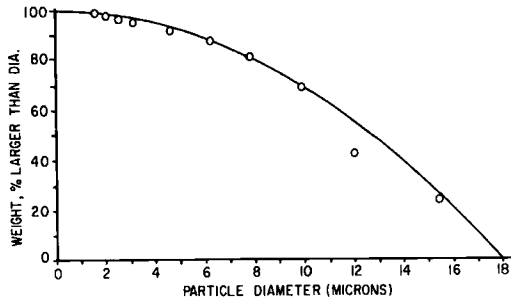

Fig. 1.—Distribution of particle sizes for micronized methylprednisolone obtained with the Coulter counter. Smooth curve is in accordance with $n = \frac{K}{a_0^2}$.

despite some deviations. Clearly, the most likely rate-determining step is the rate of diffusion of methylprednisolone in water. It is possible that other processes such as surface nucleation or surface orientation might contribute to the dissolution rate, but certainly, even if they do, they are not very important for micronized methylprednisolone.

It is apparent that the experimental release rates are always somewhat greater than theory at small values, and always somewhat less at large t. Several possible reasons may be put forward to explain these deviations.

Firstly, it is worthwhile to mention that if a particle size-distribution function corresponding to a somewhat broader distribution were employed in the theoretical calculations, an almost perfect agreement would be obtained for cases A through D. It is possible that the distribution curve (Fig. 1) determined with the Coulter counter does not exactly represent the true initial size distribution, particularly for the smaller sizes. This might be attributed to the tendency for small particles to be more soluble than the larger ones. Thus, if the vehicle were saturated with a sample of methylprednisolone, it might have been undersaturated with respect to the small particles of a subsequently added sample. In case E (see Fig. 2), for which the dissolution medium was initially 90% saturated, the final concentration of methylprednisolone exceeded the solubility (7.40 mg. per 100 ml.) of prednisolone by about 3 or 4%.[4] This might also be explained by the greater solubility of the smaller particles. It was furthermore noted that in the determination of the methylprednisolone solubility, which was found by adding a three-fold excess of methylprednisolone to water and following the methylprednisolone concentration as a function of time, a maximum value several per cent greater than the final constant value was observed. This is consistent with the behavior in case E and with the possibility that the Coulter counter did not give correct weighting to the small particles.

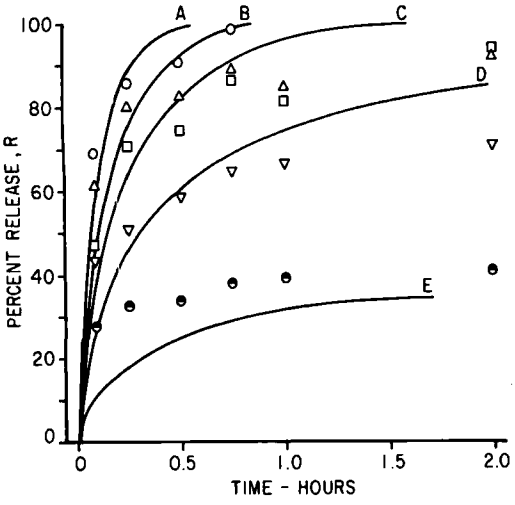

Fig. 2.—Experimental and theoretical release of drug from micronized methylprednisolone. Theory A, pure water, experiment ○; theory B, 30% presaturation, experiment △; theory C, 50% presaturation, experiment □; theory D, 70% presaturation, experiment ▽; theory E, 90% presaturation, experiment ●.

The theory assumes that the particles are spheres. The influence of shape variations may be estimated from the electrostatic theory (2) of conducting ellipsoids. Ellipsoids with axial ratios of two or so will dissolve at about a 5% greater rate than spheres of the same volume. Since the micronized methylprednisolone particles were found to be relatively isometric under the microscope, the shape effects were probably unimportant.

Occasionally, clumping of some of the particles was observed during the dissolution experiments. Some of the scatter as well as the low rates at large t values may be explained on this basis. In general, however, the methylprednisolone samples dispersed readily.

Another factor contributing to the deviations is the Stokes law calculated value for the diffusion coefficient. The uncertainty here is estimated to be around 10–20%. If a smaller value for D were used, the theoretical curves in Fig. 2 would be expanded in proportion to t along the t-axis, or if a larger D value were employed, the curves would be linearly contracted.

Finally, the effects of stirring and the sedimentation of particles will affect the dissolution rate to a certain extent. Recent studies by Nielsen (3) show that for methylprednisolone particles in the size range $\lesssim 25\ \mu$, the hydrodynamic effects arising from sedimentation should be small, the order of a few per cent, insofar as the dissolution rate is concerned. Furthermore, the effects due to moderate stirring should have been also small for these particle sizes since the local accelerations and decelerations in the medium probably were at most only comparable to that due to gravity, and since velocity gradients were probably $\lesssim 1.0\ \text{sec.}^{-1}$.

Thus, the composite effect of these uncertainties may very well account for the deviations. Future experiments will dwell upon these factors more thoroughly.

Permeability of Excised Human Keratin to Lipid-Soluble Substances II

By ROBERT E. DEMPSKI†, DALE E. WURSTER, and STANLEY L. BECKER

Data are presented which compare the rate of penetration through keratin tissue of 2-hydroxystearic acid and three mixtures composed mainly of lipid-soluble esters, with oleyl alcohol. The hydroxy acid which was strongly adsorbed by keratin had a very slow rate of penetration. The ester mixture with the lowest acid number showed rapid penetration. The mathematical interpretation of the data indicated that the transport occurred by a diffusional process.

A PREVIOUS study has shown that certain lipid-soluble substances were able to penetrate sections of excised human callous tissue (1). It was also observed that substances such as linolenic and linoleic acids which were adsorbed by human keratin from *n*-heptane solutions manifested relatively slow permeability rates in sections of this tissue. This paper is a continuation of that study, and contains permeability data on a hydroxy fatty acid and three different lipid-soluble mixtures containing esters as the primary component.

Since it can be shown that the distribution coefficient (2) can affect the rate of penetration, the influence of this factor was also investigated.

EXPERIMENTAL

Procedure.—The apparatus, including the diffusion cells and the method employed to follow the permeability rate of the various lipid-soluble substances in human keratin tissue, were essentially the same as described in a previous paper (1). The preparation of the keratin tissue sections and the assay for oleyl alcohol were also the same.

The 2-hydroxystearic acid concentration in each side of the diffusion cell was determined by titrating with a standard solution of 0.001 *N* sodium hydroxide in *n*-butanol with a microburet under an atmosphere of nitrogen using *p*-naphtholbenzein as the indicator. The initial concentration of the acid was 1.0×10^{-6} moles per ml. Use of this low concentration was necessitated due to the low solubility of the acid in *n*-heptane. The reference penetrant, oleyl alcohol, was used in the same concentration in this case.

The lipid-soluble mixtures (liquid lanolin Nos. 1, 2, and 3), consisting mainly of esters (3, 4), were assayed as previously described (1) by the hydroxylamine test using 2 ml. of the *n*-heptane solution and 3 ml. of ether. The concentration of the mixtures and the oleyl alcohol in this case was based on mg./ml. (from 5.26 to 6.29 mg./ml.) rather than on a molar basis. This, of course, was necessary since these penetrants were composed mainly of a mixture of esters rather than a pure component. Naturally, minor concentrations of other components such as acids and alcohols were also present in the mixtures.

Distribution coefficients were determined according to the following method: Five grams of powdered (200 mesh) ether-extracted keratin tissue was placed in a glass-stoppered vessel; a measured volume (100 ml.) of a *n*-heptane solution of the lipid-soluble test substance was then added, and the mixture was continuously agitated and allowed to reach equilibrium at 25°. Samples of the clear *n*-heptane solution were subsequently removed and assayed according to the described procedure for each agent.

Acid numbers were determined for each lipid-soluble mixture according to the U.S.P. XVI procedure.

RESULTS AND DISCUSSION

The results of the permeability studies again showed a wide variation in the permeability coefficients for the callous tissue from different individuals to a specific penetrant. Therefore, as previously explained, each penetrant and oleyl alcohol was tested against alternate layers from the same piece of tissue (1). The permeability coefficients, K, are average values and were calculated according to the equation (5),

$$\log (C_o - 2C_b) = (-2K/2.303)t + \log C_o \quad \text{(Eq. 1)}$$

where C_o is the initial concentration of solution to which the keratin barrier was exposed and C_b is the concentration at the time, t, on the other side of the barrier in the diffusion cell.

This paper is based in part on a dissertation submitted by Robert E. Dempski to the Graduate School of the University of Wisconsin in partial fulfillment of the requirements for the degree of Doctor of Philosophy.
This study was supported by a grant from Malmstrom Chemical Corp., Newark, N. J.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
† Present address: Merck Sharp and Dohme, West Point, Pa.

Since biological variation makes it impossible to directly compare permeability constants of various penetrants tested on different tissue sections, oleyl alcohol was again used as a reference. By calculating the ratio of the permeability coefficient for the test penetrant to that obtained for oleyl alcohol on the alternate tissue layers, the values obtained for each agent were reduced to a common basis. In Table I the ratios for various agents investigated previously (1) and those included in this study are shown.

Obviously, those substances in the table having the larger values have greater permeability coefficients as a result of their more rapid penetration rates in keratin tissue. It can also be observed, as previously reported (1), that some substances which are strongly adsorbed by keratin have low penetration rates. Thus, 2-hydroxystearic acid was the most strongly adsorbed of all the substances tested (6) and had the lowest permeability rate.

In the case of the various liquid lanolin preparations tested, these, too, appear to follow the same pattern. The liquid lanolin No. 1 sample had an acid number of 1.69. The No. 2 liquid lanolin sample was characterized by its low hydroxyl content and an acid number of 1.17, whereas the No. 3 liquid lanolin had an acid number of 6.79. Since wool fat contains both unsaturated and 2-hydroxy acids (7), it is reasonable to expect that the No. 2 liquid lanolin would have the greatest, and No. 3 the smallest, permeability coefficient of these three mixtures.

Although the relative position of each of the three mixtures is no doubt correct, an additional theoretical point should be mentioned. It was necessary, for reasons already given, to follow the change in concentration of the lanolin mixtures on a weight per unit volume basis and thus, the Beer's plot which was employed to follow the change in concentration with time was constructed on a similar basis. However, the material diffusing through the keratin membrane could differ from the composition of the mixture. Since the intensity of the color produced in the assay is directly proportional to the ester concentration, the results could be misleading. For example, if the material diffusing through the membrane contained a higher concentration of esters or a larger fraction of the lower molecular weight esters than an equivalent weight of the entire mixture, the absorbance would be greater. This would then show an apparent fast rate of penetration for the mixture.

In the derivation of the previous equation, the permeability coefficient is shown to be equal to several constants

$$K = \frac{AD\,(DC)}{VL} \qquad \text{(Eq. 2)}$$

where K is the permeability coefficient, A is the cross-sectional area, D is the diffusion coefficient, DC is the distribution coefficient, V is the volume, and L is the length of the diffusional pathway. Thus, if the quantity, AD/VL is constant, the permeability coefficient should vary directly with the distribution coefficient. In Table II, the apparent distribution coefficients between powdered keratin and n-heptane for several lipid-soluble substances are shown.

In the case where the penetrating molecule is soluble in a liquid or semisolid medium in contact with a similar medium it can be shown that the permeability coefficient is directly proportional to the distribution coefficient (2). However, in the case where a liquid is in contact with a solid and the solute is strongly adsorbed by the solid, such as in the case of the powdered keratin-n-heptane systems employed in this study, the above relationship was not found to exist.

Microscopic examination of the sections of callous tissue showed them to be free of orifices through which the penetrant could stream (8). Also, the two sides of the permeability cell did not reach equilibrium even after being agitated for 10 days. Thus, the experiment and the mathematical interpretation of the data indicated that a true diffusional process occurred. This lends support to the theory that transepidermal penetration, at least through the stratum corneum, can occur.

TABLE II.—DISTRIBUTION COEFFICIENTS OF VARIOUS AGENTS BETWEEN POWDERED EXCISED HUMAN KERATIN AND NORMAL HEPTANE

Test Agent	Distribution Coefficient
Oleyl alcohol	0.40
Cholesteryl acetate	0.63
Cholesteryl oleate	0.64
Oleic acid	1.72
Linolenic acid	1.19
Linoleic acid	0.58
2-Hydroxystearic acid	36.00
Liquid lanolin No. 1	0.53

SUMMARY

The penetration rates in excised human callous tissue of 2-hydroxystearic acid and three liquid lanolin preparations were determined.

The 2-hydroxystearic acid which was strongly adsorbed by human keratin showed the lowest permeability coefficient of all the substances tested.

The acid numbers of the three liquid lanolin preparations were also determined. The liquid lanolin characterized by the lowest acid number and low hydroxyl content showed the most rapid penetration rate. The preparation having the highest acid number showed the slowest penetration rate of the three mixtures.

The apparent distribution coefficients for several lipid-soluble substances in a powdered keratin-n-heptane system were determined.

Spectrophotometric Determination of Chloramphenicol and Tetracycline Hydrochloride in Mixtures

By R. C. SHAH, P. V. RAMAN, and B. M. SHAH

A rapid method for the spectrophotometric determination of chloramphenicol and tetracycline hydrochloride in binary mixtures without prior separation is described. Chloramphenicol is determined by the measurement of difference in (extinction) values (ΔE) at 282 mμ and 233 mμ, and tetracycline hydrochloride is determined by measurement of absorbance at 380 mμ, using 0.1 *N* ammonium hydroxide as the solvent.

With the extensive use of antibiotics, and the increased prevalence of mixed antibiotic therapy, the pharmaceutical analyst is faced with the problem of developing quick and reliable methods for the assay of individual components in mixtures. Spectrophotometric and other physicochemical methods are now finding increased acceptance over the bioassay methods (1, 2). Marzys (3) has described the application of spectrophotometric procedures for the determination of individual components in mixtures where the results are computed by solving simultaneous equations. Pernarowski, *et al.* (4), have described the application of spectrophotometric assay for the components of binary mixtures based on the location of isoabsorptive points. Elvidge and Peutrell (5) have described a (ΔE) spectrophotometric method which is based on a single wavelength and two solvents at different pH. The present paper describes a (ΔE) spectrophotometric method based on two wavelengths and one solvent for the determination, without prior separation, of chloramphenicol and tetracycline hydrochloride present in binary mixtures.

EXPERIMENTAL

Materials and Equipment.—Chloramphenicol U.S.P. (99.5%) from Carlo Erba, S.p.A., Milan, Italy, tetracycline hydrochloride U.S.P. (99.6%) from Messrs. Eigenmann & Veronelli, S.p.A., Milano, 0.1 *N* ammonium hydroxide, a Beckman spectrophotometer model G 2400 with DU photomultiplier combination G 4700 using hydrogen discharge tube, and 1-cm. silica cells were the materials and equipment employed in this study.

From a study of the spectral characteristic curves of chloramphenicol and tetracycline hydrochloride using water as the solvent, it was observed that by determining the absorptivities ($E^{1\%}_{1cm.}$) at 278 mμ and 360 mμ and using simultaneous equations, the composition of the binary mixture could be determined. However, this procedure involves relatively long calculations.

Received April 12, 1962, from Mac Laboratories Private Ltd., Kirol, Bombay-77, Iudia.
Accepted for publication May 25, 1962.

Experiments were performed to determine the isoabsorptive wavelength using various solvents. Water was found unsuitable as a solvent for this purpose, and the use of 0.1 *N* acetic acid gave two isoabsorptive wavelengths, *viz.*, 282.5 mμ and 297.5 mμ. The slopes of curves at the former wavelength were more steep than those at the latter wavelength. Various mixtures of chloramphenicol and tetracycline hydrochloride were assayed by this method by measuring absorbances at 278 mμ, 297.5 mμ, and 360 mμ but the method lacked precision. The use of 0.1 *N* sodium hydroxide gave some interesting results. Chloramphenicol gave almost the same spectral characteristics as with 0.1 *N* acetic acid except for a slight depression of absorbance at the maxima. Tetracycline hydrochloride gave almost constant values of absorptivity in the spectral range of 230 mμ to 280 mμ. In this range, $E^{1\%}_{1\,cm.}$ for chloramphenicol registered a steep continuous increase up to 275 mμ, whereas those for tetracycline hydrochloride remained almost the same.

It was thus evident that chloramphenicol could be determined in the presence of tetracycline hydrochloride by making use of the "difference in absorptivity values" (ΔE) at two suitable wavelengths. The use of 0.1 *N* sodium hydroxide was found to be critical as regards time for ΔE measurements. Higher concentrations of alkali, such as 0.25 *N*

14	6	13.8	5.9	98.6	98.3
16	4	15.9	4	99.4	100
18	2	17.6	2.25	112.5	97.7

sodium hydroxide, were not critical in the determination of ΔE values for chloramphenicol. However, with this strength of sodium hydroxide the determination of tetracycline hydrochloride spectrophotometrically at 380 mμ requires strict adherence to time (6, 7). The use of 0.1 *N* ammonium hydroxide satisfied all requirements. The spectral characteristics of both chloramphenicol and tetracycline hydrochloride were almost the same as with 0.1 *N* sodium hydroxide. Furthermore, with ammonia, the normality of the solution and time for taking readings were not critical. The absorbance values remained almost the same for 3 hours.

Determination of ($\Delta E^{1\%}_{1cm.}$) for Chloramphenicol and $E^{1\%}_{1cm.}$ for Tetracycline Hydrochloride.—Solutions containing 20 mcg./ml. of tetracycline hydrochloride and chloramphenicol were prepared in 0.1 *N* ammonium hydroxide and spectrophotometric readings were taken in the ultraviolet range of 220 mμ to 400 mμ using 0.1 *N* ammonium hydroxide as blank (Fig. 1). For the determination of chloramphenicol, the most suitable wavelengths were 233 mμ and 282 mμ, and $\Delta E^{1\%}_{1cm.}$ was found to be 190 (Table I). For tetracycline hydrochloride, the most suitable wavelength was 380 mμ and $E^{1\%}_{1cm.}$ was 355.

Recovery Experiments.—Various mixtures containing a total of 20 mcg./ml. of chloramphenicol and tetracycline hydrochloride were prepared in 0.1 *N* ammonium hydroxide. Absorbances were measured at 233 mμ, 282 mμ, and 380 mμ using 0.1 *N* ammonium hydroxide as blank. Chloramphenicol was determined from the difference in absorptivities at 282 mμ and 233 mμ taking $\Delta E^{1\%}_{1cm.}$ as 190. Tetracycline hydrochloride was determined from the absorptivity at 380 mμ taking $E^{1\%}_{1cm.}$ as 355. The results are tabulated in Table II and show that the method gives very satisfactory results except at the two extremes.

Results.—The method was satisfactorily applied for the assay of commercial capsules of chloramphenicol 200 mg. and tetracycline hydrochloride 100 mg.[1] The usual excipients like lactose, amylum, and talcum were not found to interfere in the assay. The results compared very well with those of the usual method of determining chloramphenicol and tetracycline hydrochloride, after resolving the mixture into its components, by selective solvent extraction with ethyl acetate.

DISCUSSION

From Table II, it is evident that the method can safely be applied to the mixtures containing 20% and 80%. In practice, the majority of preparations will contain these two antibiotics within this range and hence the method is of great practical value. Again the method offers an advantage over the official spectrophotometric method for the determination of tetracycline hydrochloride (7) because strict adherence to time is not necessary when 0.1 *N* ammonium hydroxide is used as a solvent. The normality of ammonium hydroxide is not critical as it may range from 0.07 *N* to 0.13 *N* without affecting the results. Finally the ΔE value for chloramphenicol and $E^{1\%}_{1cm.}$ at 380 mμ value for tetracycline hydrochloride may vary slightly from instrument to instrument; hence these values must be ascertained on the individual instrument.

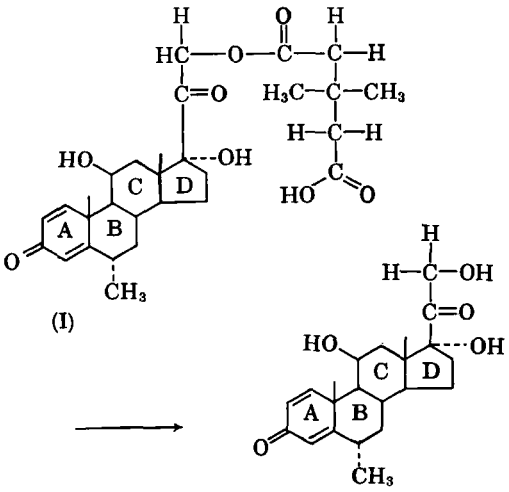
Colorimetric Procedure for Determination of Methylprednisolone Hemi-ββ′-dimethylglutarate and Methylprednisolone in Aqueous Solutions

By THOMAS CHULSKI and DONALD J. LAMB

An analytical procedure for the determination of methylprednisolone hemi-ββ′-dimethylglutarate and its hydrolysis product, methylprednisolone, was developed. The method involves separation of the steroids by extraction, followed by their colorimetric assay.

ONE APPROACH to the production of an aqueous pharmaceutical preparation of a cortical steriod is the use of the hemiesters of dicarboxylic acids. Of particular interest is the hemiester of methylprednisolone[1] and ββ′-dimethylglutarate (DMG).

The hydrolysis of methylprednisolone DMG (I) yields methylprednisolone (II) which is also physiologically active. Upon degradation of the dihydroxyacetone side chain, methylprednisolone would yield one or more neutral and acidic compounds which absorb radiation in the ultraviolet region of the spectrum (1).



(I)

(II)

Although ring A is photolabile (2), this mode of degradation is not important in pharmaceutical preparations if suitable precautions are taken to provide for protection from light (3).

Thus, in the stability testing of an aqueous pharmaceutical preparation of methylprednisolone DMG, assay methods are required that would be specific for I and II in the presence of each other and in the presence of degradation products. Ultraviolet absorption spectroscopy is not applicable, even in the absence of extraneous ultraviolet absorbing materials, as both active species have the same ultraviolet chromophore, *i.e.*, the A ring. Partitioning between water at a high pH and an immiscible solvent followed by ultraviolet spectroscopy is not applicable, as the neutral and acidic degradation products would interfere when present (1).

An assay procedure was developed that separated the two active compounds by extracting an aqueous solution at a high pH with chloroform. The chloroform phase was assayed for methylprednisolone using the blue tetrazolium procedure (4, 5). The aqueous phase was assayed for methylprednisolone DMG by acidifying, extracting with chloroform, and applying the method of Porter and Silber (6). Neither of the methods is affected by the presence of degradation products (4, 7).

EXPERIMENTAL

Determination of Partition Coefficient vs. pH.—Aqueous solutions containing 500 mcg. of methylprednisolone DMG per ml. were prepared using 0.5 *M* phosphate buffers. Two-milliliter volumes of these solutions were equilibrated with 25 ml. of water-saturated chloroform at room temperature. The layers were separated and the amount of steroid in each phase was determined by ultraviolet spectroscopy. Hydrolysis of the ester was assumed to be negligible during the equilibration period. The results listed in Table I indicate that essentially all of the hemiester remains in the aqueous layer at pH 10.0.

Color Development of Methylprednisolone Hemi-ββ′-dimethylglutarate and the Porter-Silber Re-

agent.—To our knowledge, the applicability of the Porter-Silber reagent to steroidal hemiesters such as the ββ′-dimethylglutarate has not been reported in the literature. Hence, the formation of color by methylprednisolone DMG in the Porter-Silber procedure was studied as a function of time, and compared to methylprednisolone.

Two-milliliter volumes of a 1.43×10^{-4} *M* 3A alcoholic solution of methylprednisolone DMG were mixed with 4-ml. volumes of a dilute sulfuric acid solution of phenylhydrazine hydrochloride (see Reagents, below), and with 4 ml. of the dilute acid only. In the same manner, 2-ml. volumes of 3A alcohol were mixed with the two reagents to serve as blanks. The reaction mixtures were heated for various times, 20–60 minutes, in a water bath at 60°, and then cooled rapidly in cold water. The absorbance was measured at 415 mμ in a 10-mm. cell with the appropriate 3A alcohol blank in the reference cell in each instance. The Porter-Silber color was determined by difference, *i.e.*, $A_{steroid} = A_{reagent\ sample} - A_{acid\ sample}$. A 1.43×10^{-4} *M* solution of methylprednisolone was handled in the same manner.

The data are presented graphically in Fig. 1 Although the color development with methylprednisolone DMG is not complete after 60 minutes at 60°, the rate of change is small enough, about 4%, that heating at 60° for 60 minutes would be satisfactory as an analytical procedure.

METHOD

Reagents.—*pH 10.0 buffer.* Seventy-one grams of anhydrous sodium dibasic phosphate, Mallinckrodt A.R. grade, was dissolved in 1000 ml. of water. The pH was adjusted to 10.0 with 1.0 *M* sodium hydroxide solution; *ca.* 30 ml. was required.

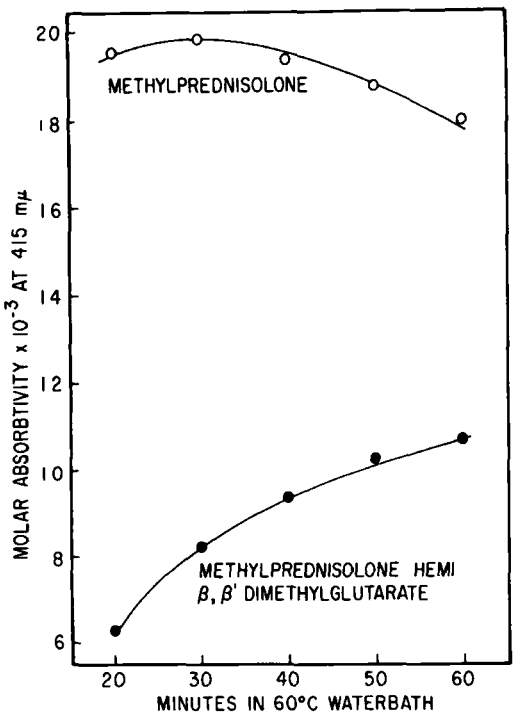

Fig. 1.—Development of the Porter-Silber color with methylprednisolone and with methylprednisolone hemi-ββ′-dimethylglutarate.

Blue tetrazolium solution. One hundred twenty-five milligrams of blue tetrazolium[2] was dissolved in 3A alcohol and diluted to 50 ml.

Tetramethylammonium hydroxide solution. Five milliliters of a 10% aqueous solution[3] was diluted to 50 ml. with 3A alcohol. These two solutions were usable for three days if refrigerated when not in use.

Sulfuric acid solution. Three hundred and ten milliliters of concentrated sulfuric acid and 190 ml. of water were mixed.

Phenylhydrazine hydrochloride solution. Phenylhydrazine hydrochloride[3] was recrystallized twice from 3A alcohol. One hundred fifty milligrams of the pure white material was dissolved in the dilute sulfuric acid and diluted to 100 ml. This reagent was prepared fresh daily.

Chloroform. Reagent grade.

Procedure.—Two-milliliter aliquots of aqueous samples containing 50–500 mcg./ml. of sodium methylprednisolone DMG and also of a standard solution were diluted with 3 ml. of pH 10 buffer and extracted with two 25-ml. portions of chloroform. The solvent was removed from the combined chloroform extracts under reduced pressure at room temperature. The dry residue was dissolved in 4 ml. of 3A alcohol. One milliliter of blue tetrazolium solution was added, followed by 0.5 ml. of tetramethylammonium hydroxide solution, and timing started. Forty-five ± 1 minutes later, the color development was quenched and the color was stabilized by adding 0.5 ml. of glacial acetic acid (8). The absorbance was measured at 525 mμ in a 10-mm. cell with 3A alcohol in the reference cell. A chloroform extract of 2 ml. of water treated in the same manner as the sample extract served as a reagent blank. Its absorbance was subtracted from that of the sample.

Beer's law was followed up to 12.5 mcg. methylprednisolone per ml. final volume.

The sample, after the removal of the methylprednisolone, and the water blank were acidified with 1 ml. of 6 *M* hydrochloric acid and extracted with 25 ml. of chloroform. A 10-ml. aliquot of the chloroform extract was taken to dryness. The residue was dissolved in 5 ml. of 3A alcohol. Two 2-ml. aliquots were transferred to glass-stoppered test tubes. To one of the aliquots was added 4 ml. of the phenylhydrazine solution; to the other was added 4 ml. of the dilute sulfuric acid. Both were heated for 60 minutes in a water bath at 60° and then cooled rapidly in cold water. The absorbance was measured at 415 mμ with the appropriate blank in the reference cell. The absorbance, due to the steroid, was obtained by difference, *i.e.*, $A_{steroid} = A_{reagent\ sample} - A_{acid\ sample}$.

The molar absorptivity for methylprednisolone ββ′-dimethylglutarate sodium was found to be approximately 10,000. Beer's law followed up to 53 mcg. per ml. final volume.

DISCUSSION

The results of the partition study indicate that a small amount of hemiester accompanies the extrac-

[2] Certified reagent marketed by Fisher Scientific Co.
[3] Marketed by Eastman Organic Chemicals.

tion of methylprednisolone. The molar absorptivity of the hemiester in the blue tetrazolium procedure is 513, while that of the steroid alcohol is 29,190. Therefore, the effect of minor amounts of the hemiester on the assay of methylprednisolone would be negligible.

From Fig. 1 it is seen that on a molar basis methylprednisolone DMG is 61% as chromogenic as methylprednisolone. It is interesting to note that the chromogenicities of hydrocortisone acetate and cyclopentylpropionate in the Porter-Silber reaction are equal to that of hydrocortisone (9).

Marcus (10) determined hydrocortisone phosphate with the Porter-Silber procedure by heating for 2 hours at 60°. He did not state the chromogenicity of the phosphate ester relative to hydrocortisone under the same conditions.

The sample of steroid ester used in this investigation was found by papergram analysis to contain approximately 2% of the steroid alcohol. The necessity of purifying the material was circumvented by a synthetic sample approach. Known amounts of methylprednisolone were added to the chloroform used to extract a standard volume of hemiester solution, and the samples were assayed using the procedure described. The results of these assays are listed in Table II. A plot of micrograms of methylprednisolone added *vs.* micrograms found yielded a straight line, as shown in Fig. 2. The intercept of the line indicates that 2.63 ± 0.04% steroid alcohol was present in the sample of hemiester.

The average variation of individual results from the average of duplicate results was 2.5% for the methylprednisolone DMG in simple systems. The standard deviation for the methylprednisolone assay was ±1.3%.

The procedure was applied successfully to pharmaceutical formulations.

TABLE II.—THE ADDITION OF KNOWN AMOUNTS OF METHYLPREDNISOLONE TO METHYLPREDNISOLONE ββ′-DIMETHYLGLUTARATE KNOWN TO CONTAIN SOME METHYLPREDNISOLONE[a]

[a] Slope of the least squares line = 1.001 ± 0.013 (S.D.). Intercept 26.26 ± 0.42. Since 1000 mcg. of hemiester was taken, % of methylprednisolone present = 2.63 ± 0.04.

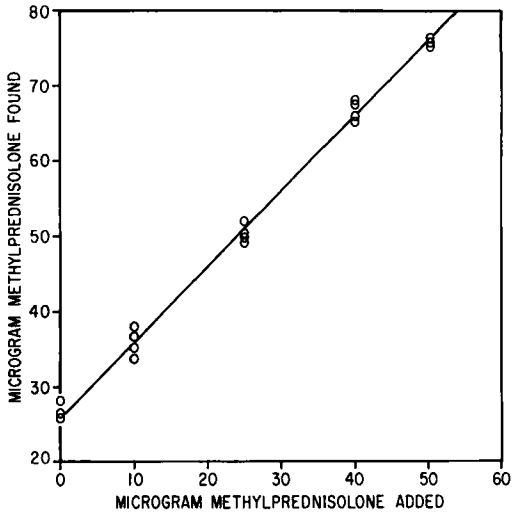

Fig. 2.—The addition of known amounts of methylprednisolone to methylprednisolone ββ′-dimethylglutarate known to contain some methylprednisolone.

SUMMARY AND CONCLUSIONS

A colorimetric method is described for determining methylprednisolone ββ′-dimethylglutarate and methylprednisolone in aqueous solution in the presence of each other and in the presence of degradation products.

Effect of Monoamino Oxidase Inhibitors on Audiogenic Seizures

By N. PLOTNIKOFF, J. HUANG, and P. HAVENS

This study attempts to demonstrate that monoamino oxidase inhibitors possess anticonvulsant activity as evaluated by their effects on audiogenic seizures in mice.

A RECENT STUDY of iproniazid and pheniprazine in rats indicated that the two agents inhibit the tonic extensor component of convulsions induced by electroshock (1). The present study is concerned with the effects of several inhibitors on audiogenic seizures in mice.

EXPERIMENTAL

Methods.—The apparatus employed in the study has been described in earlier reports by Plotnikoff (2, 3). Essentially, the apparatus consisted of a metal auditory-test chamber placed inside a sound-deadened plywood box. The sound source consisted of two common doorbells attached to the inner wall of the metal test chamber. The test procedure consisted of placing a single animal inside the metal chamber and exposing it to auditory stimulation for 1 minute. The sole criterion used to measure protection in this study was the presence or absence of tonic extension. Each drug was tested at three or more dose levels with ten mice tested per dose. The dose that reduced tonic extension responses to 50% of the control values (PD_{50}) and its standard error were estimated by the technique of Miller and Tainter (4). The drugs were administered by the intraperitoneal route. The animals used for this study were random bred male Swiss mice susceptible to audiogenic seizures.[1]

Studies on convulsions induced by electroshock were based on the maximal electroshock seizure test (M.E.S.) in mice reported by Swinyard, *et al.* (5), for maximal electroshock (50 *mA*). Normal albino Swiss mice (18–22 Gm.) nonsusceptible to audiogenic seizures were used for the M.E.S. test.

Results.—The anticonvulsant effects of several monoamino oxidase inhibitors are shown in Table I. The first agent to be reported upon is iproniazid which was shown to have an anticonvulsant effect (inhibition of both tonus and clonus) 30 minutes after administration in a dose range from 130 to 200 mg./Kg. The protective dose in 50% of the animals (PD_{50}) was found to be 163 ± 8.5 mg./Kg.

The second agent, tranylcypromine, was found to have anticonvulsant activity (inhibition of tonic extension) 1 hour after administration in a dose range from 10 to 40 mg./Kg. The protective dose in 50% of the animals was found to be 16.5 ± 2.2 mg./Kg.

The third agent, pheniprazine, was found to be active (inhibition of tonic extension) 16 hours after administration in a dose range from 5 to 20 mg./Kg. The protective dose in 50% of the animals was found to be 11.0 ± 1.6 mg./Kg.

Etryptamine was found to be the most active agent against audiogenic seizures (inhibition of tonic extension), with a PD_{50} of 4.1 ± 0.6 mg./Kg. It was tested in a range from 1.25 to 20.0 mg./Kg. 2 hours after being administered.

Phenelzine also prevented tonic extension with a PD_{50} dose of 19.0 ± 3.0 mg./Kg., and was tested in a range from 15 to 60 mg./Kg.

Nialamide exerted protection against tonic extension and was found to have a PD_{50} dose of 8.7 ± 1.1 mg./Kg. and was tested in a range from 5 to 40 mg./Kg.

Comparative anticonvulsant studies were carried out in normal mice (not susceptible to audiogenic seizures) by maximal electroshock. The results are shown in Table II. Iproniazid was evaluated over a time period of 15 minutes to 8 hours after injection and found to be ineffective in preventing tonic extension. Tranylcypromine and pheniprazine exerted partial protection against tonic extension only at high doses. Phenelzine and nialamide were also found to be ineffective in preventing tonic extension. Mortality following maximal electroshock was not significantly different from that found in controls. Etryptamine exterted significant protection against tonic extension in a dose range from 5 to 40 mg./Kg. The PD_{50} was estimated to be 13.5 ± 1.8 mg./Kg.

DISCUSSION

The present study raises several questions regarding the efficacy of comparing anticonvulsant effects of drugs on seizures induced by audiogenic stimuli and electroshock. Most of the animals susceptible to audiogenic seizures are between 21 and 25 days of age, whereas mice used for electroshock are between 25 and 30 days of age. Thus, audiogenic-seizure-susceptible mice may be more sensitive to the effects of various drugs because of their age. A similar observation with known anticonvulsants was recently

reported by Swinyard (6). Although both stimuli (electroshock and auditory) produce the very same kind of convulsion (clonic-tonic), there may be a difference in stimulus spread in the central nervous system. Thus, the anticonvulsant effects of monoamino oxidase inhibitors in mice with audiogenic seizures and on normal animals may vary considerably. The latter were employed for evaluation of agents against convulsions induced by maximal electroshock. Nevertheless, such comparisons are useful for studying anticonvulsant drug responses. In the present study, the monoamino oxidase inhibitors did not exert significant anticonvulsant effects in mice experiencing convulsions induced by maximal electroshock. An exception was etryptamine which protected animals from tonic extension. The anticonvulsant mechanisms involved may be related to levels of central amines, although recently Lehmann (7) reported that there was not a complete parallelism between anticonvulsant effects and serotonin brain levels. Perhaps a more complete correlation can be established between other central intermediates such as norepinephrine, pyridoxal 5-phosphate, dihydroxyphenylalanine, or dopadecarboxylase.

SUMMARY

Mice susceptible to audiogenic seizures and normal mice were employed to evaluate the anticonvulsant activity of monoamino oxidase inhibitors. This study has demonstrated that tranylcypromine, pheniprazine, etryptamine, phenelzine, and nialamide inhibit the tonic extensor component of audiogenic seizures in mice. Iproniazid was found to inhibit both the tonic and clonic components of audiogenic seizures in mice. With the exception of etryptamine, all of the inhibitors were inactive in preventing convulsions induced by electroshock (M.E.S. test).

Spectrophotometric Determination of Cholesterol in Wool Fat Using the Zak Reaction

By BLAKE F. PUTNEY and ANTHONY N. PARUTA

In an effort to overcome some of the shortcomings of previous methods for determination of cholesterol in wool fat, the Zak reaction has been studied. A procedure is presented in which cholesterol is separated as its digitonide with subsequent development of color by the addition of ferric ammonium chloride and sulfuric acid. The method is reproducible and appears to be superior to other methods now in use.

THE spectrophotometric methods currently in use for the determination of cholesterol in wool fat are for the most part based on the Liebermann-Burchard reaction (1–3). The use of this reaction as a quantitative measure of cholesterol, however, leaves much to be desired due to the dependence of the reaction on temperature, time of color development, and stability of the reagent. The ferric chloride reaction proposed by Zlatkis, Zak, and Boyle (4) for the determination of cholesterol has been shown to be a reliable method for determination of blood cholesterol. Later publications by Zak (5–7) have set forth improvements in the original procedure.

The color produced by the Zak reagent with cholesterol has been found to be reproducible without the necessity for temperature control. The color reaches a maximum in about 10 minutes and is sufficiently stable to be read in the period of 10–50 minutes after mixing. The reagent, composed of ferric ammonium chloride ($FeCl_3 \cdot 2NH_4Cl \cdot H_2O$) in 80% acetic acid is stable for periods up to six months. This new method has, therefore, overcome most of the troublesome aspects of the procedure in which the Liebermann-Burchard reaction is used.

It was the purpose of this research to determine if the Zak reaction could be utilized in the analysis of wool fat and wool fat-containing products for cholesterol content. It appears to the authors that the reaction can be used for this purpose.

EXPERIMENTAL

Equipment.—The Beckman DK-2 recording spectrophotometer was used for determination of the various spectra. The routine colorimetric analyses were run on a Coleman Universal spectrophotometer, using square cuvettes of 1.3 cm. light path.

Materials.—Cholesterol U.S.P.,[1] after crystallization from alcohol-water and drying at 80°, had m.p. 148–149°, $[\alpha]_{25}^{D}$ ($CHCl_3$) −38.4°. The lanosterol[2] used had a m.p. of 137-138°. Wool fat U.S.P., wool fat unsaponifiable, and a liquid wool fat fraction were used in the sample analyses.[3] All other materials used were analytical reagent grade, except ethanol and potassium hydroxide, which were U.S.P., and acetone and aluminum chloride, which were N.F.

Preparation of Solutions.—Stock solutions for use in the experimental procedures were accurately prepared as shown in Table I.

TABLE I.—PREPARATION OF SOLUTIONS

Solute	Gm./100 ml.	Solvent
Ferric ammon. chlor.	2.12	80% Acetic acid
Digitonin	1.00	50% Ethanol
Cholesterol	0.20–0.30	Ethanol
Lanosterol	0.10	Ethanol
Wool fat unsaponifiable	0.20	Ethanol
Wool fat solution I[a]	0.15–0.40	20% Dioxane, 20% acetone in ethanol
Wool fat solution II[a]	0.050	Acetic acid

[a] *Wool fat or liquid wool fat fraction. Heat was necessary to bring about solution. Solution I was used for saponification and precipitation; solution II was used for direct color analysis.*

Procedure: Preliminary Saponification.—An amount of wool fat solution I (Table I) equivalent to 8–12 mg. of wool fat was placed in a 15-ml. centrifuge tube and ethanol added to make 5 ml. (if necessary). To the tube was added 0.2 ml. of 50% aqueous potassium hydroxide and one drop of phenolphthalein T.S. The tube was boiled in a water bath for 5 minutes, loosely stoppered, and heated on a sand bath in an oven at 65° for 3 hours. At the end of the heating period, 0.5 ml. of water was added and the mixture was neutralized by dropwise addition of 10% hydrochloric acid. This solution was then treated with digitonin as further described.

Digitonin Precipitation.—The digitonin precipitation was carried out on the neutralized solution resulting from the saponification contained in a 15-ml. centrifuge tube. Where saponification was not necessary, an amount of stock solution (Table I) equivalent to 2–3 mg. of cholesterol or 6–8 mg. of wool fat unsaponifiable was placed in 15-ml. centrifuge tubes and ethanol added to make 5 ml. (if needed).

Received March 29, 1962, from Rutgers · The State University, College of Pharmacy, Newark 4, N. J.
Accepted for publication June 11, 1962.
Grateful acknowledgment is made to the Research Council, Rutgers · The State University and the Malmstrom Chemical Corp., Newark, N. J., for financial support of this project.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

[3] Obtained from the Malmstrom Chemical Corp., Newark, N. J.

Two drops of 30% aqueous aluminum chloride and 1 ml. of 1% digitonin solution were added to each tube. The tube was gently boiled in a water bath for 5 minutes and then allowed to stand at 20° for 2 hours. The mixture was centrifuged at 2,800 r.p.m. for 5 minutes and the supernatant liquid decanted. The precipitate was washed twice with 5 ml. of acetone, the precipitate being broken up each time with a fine glass rod, and then centrifuged. After the final spinning, the supernatant liquid was decanted and the precipitate allowed to dry. The residue was then dissolved in warm acetic acid and brought to volume in a 10-ml. volumetric flask.

Colorimetric Analysis.—For colorimetric analysis, 1 ml. of the acetic acid solution of the digitonide was used. The stock solutions (Table I) were diluted with acetic acid so that they contained 0.2–0.3 mg. of cholesterol or lanosterol or 0.4–0.6 mg. of wool fat unsaponifiable per ml.; 1 ml. of each was used for colorimetric analysis. Three milliliters of wool fat solution II (Table I) was used for analysis.

The specified quantity of the respective solutions was pipetted into 18 × 150-mm. tubes and acetic acid added from a buret to make 6 ml.; 0.40 ml. of ferric ammonium chloride solution was added, and the contents mixed. Four milliliters of concentrated sulfuric acid was added slowly down the side of the tube to form a layer under the acetic acid solution. The contents were then mixed thoroughly on a Vortex Jr. mixer and allowed to cool for at least 10 minutes. The absorbance of the solution at 560 mμ was taken in the period of 10–25 minutes after adding sulfuric acid. The blank consisted of 6 ml. of acetic acid, 0.4 ml. of ferric ammonium chloride, and 4 ml. of sulfuric acid, which had been mixed as before.

DISCUSSION

Ideally, it would be desirable to determine the amount of cholesterol directly, without prior treatment or separation of the cholesterol from wool fat. This would necessitate the determination of the effect of the reagent on the other constituents of wool fat which might give a color with the reagent. Lanosterol, which is the chief component of the triterpene fraction of wool fat and reported to be present in wool fat to the extent of about 15% (3), was used as a measure of this effect. On determination of the spectra of lanosterol and cholesterol (Fig. 1), it was found that a maximum of absorbance occurs for lanosterol at 490 mμ. From this plot of the absorptivities it is seen that there would be considerable interference of one constituent with the other at that wavelength. This is a situation which was found to make precise analysis of 1:1 mixtures of these components difficult to obtain.

Since in wool fat most of the cholesterol is present as fatty acid esters, the effect of this esterification would also have to be considered. Assous and Girard (8) have shown that the fatty acid esters of cholesterol do not exhibit the same rate of color development as does free cholesterol. These workers added the samples for analysis and the reagent to previously mixed and cooled acids, and allowed the reaction to take place at room temperature. Under these conditions the fatty acid esters of cholesterol did not develop any appreciable color in 1 hour, while the color developed by free cholesterol became constant after about 30 minutes.

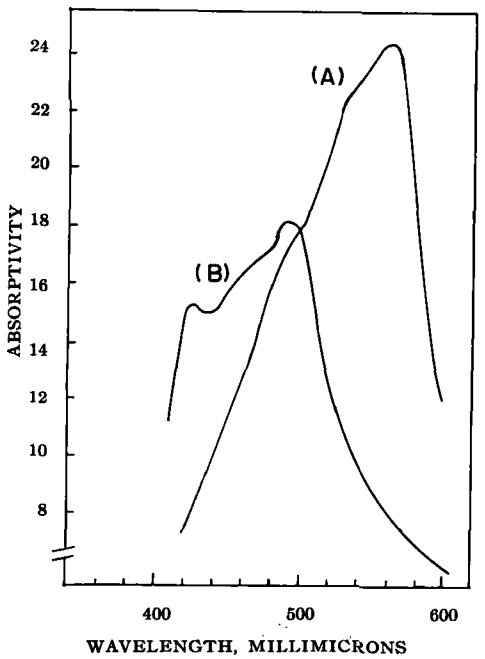

Fig. 1.—The spectra of cholesterol and lanosterol on treatment with the Zak reagent. *A*, cholesterol; *B*, lanosterol.

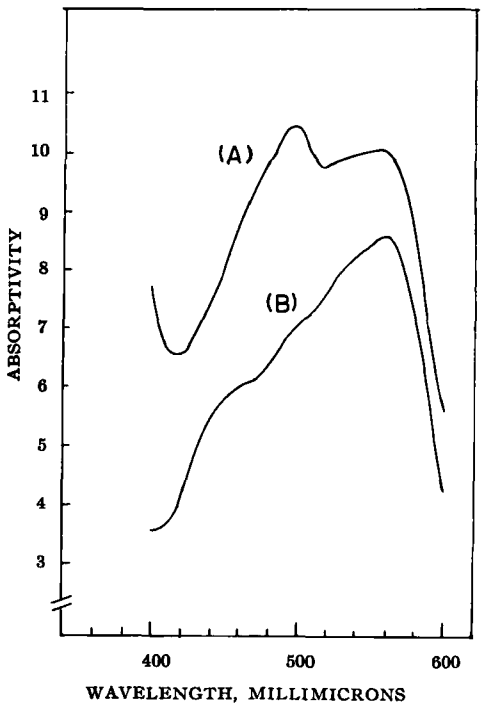

Fig. 2.—The spectra of wool fat unsaponifiable reacted directly with Zak reagent and after precipitation, with digitonin. The absorptivities were calculated using the concentration of wool fat unsaponifiable in the color solutions. *A*, reacted directly; *B*, after digitonin precipitation.

In the procedure used in the present work, elevation of temperature takes place on mixing the acetic acid solution of the cholesterol and reagent with sulfuric acid. On studying the stability of the color complex under the conditions used here, it was found that the absorbance of the color complex of untreated wool fat (containing the fatty acid esters) reached a maximum in about 60–70 minutes, while the color complex of cholesterol or cholesterol digitonide reached a maximum in about 10 minutes and remained the same or decreased slightly during the period of 1 hour after addition of the acid. This indicates that the fatty acid esters of cholesterol also react more slowly under the present conditions than does cholesterol. This is contrary to the situation with the Liebermann-Burchard reaction, in which the esters of cholesterol react more rapidly.

In sample analyses carried out on wool fat directly, the amount of cholesterol found was somewhat less than that found when wool fat was first saponified and the free cholesterol precipitated by digitonin before color development (Table II). This may be partially explained by the difference in the rate of reaction of the fatty acid esters of cholesterol, since more compatible results were obtained when the wool fat unsaponifiable fraction was analyzed by direct color analysis or by the precipitation technique (Table II).

From a practical standpoint also, it would be desirable to have a technique which would be useful in the determination of the amount of wool fat in pharmaceutical and cosmetic products. It was concluded that the best way to separate the color-producing moiety from such mixtures was by saponification and precipitation of the free cholesterol with digitonin, before color development. The saponification procedure suggested by Luddy, *et al.* (1), was used and the saponified mixture was treated directly with digitonin to precipitate the cholesterol.

It was found that lanosterol did not give a precipitate with digitonin under the conditions utilized here and so it was not necessary to calculate for lanosterol in this procedure. From an examination of the spectra of wool fat unsaponifiable, treated and untreated with digitonin (Fig. 2) it appears that there is no appreciable increase in the absorption of the treated sample at 490 mμ where a peak would be expected if there were lanosterol present.

Cholesterol digitonide was shown to have a slightly higher absorptivity than free cholesterol when treated with the iron reagent (Fig. 3). This difference can probably be accounted for by the absorbance of digitonin when treated with the reagent, since as shown by the spectrum of digitonin, there is a small amount of absorbance at the primary wavelength of cholesterol, 560 mμ.

The optimum ratio of sulfuric acid to acetic acid (2:3) in the reaction mixtures was determined by Zak (9). This ratio appears to be necessary for the proper formation of the color complex due to the amount of heat liberated on dilution of the sulfuric acid. Immediately after mixing the solutions, an amber color is observed, which changes through violet to a reddish-violet color after about 5 minutes. In time studies on the color complexes of both cholesterol and its digitonide, there was noted a decrease in absorbance of from 2–3% during the period of 10–50 minutes after mixing the solutions.

Brown and co-workers (10) have investigated the use of several agents to facilitate the flocculation of cholesterol digitonide in blood serum studies. These workers reported that aluminum chloride was very effective for this purpose. In the studies on wool fat, it was found that separation and washing of the digitonide precipitate was more easily carried out in the presence of aluminum chloride.

The viscosity of the solution resulting from the mixture of sulfuric acid and acetic acid was a source of some difficulty, particularly with respect to adequate mixing of the two acids. The use of the Vortex Jr. mixer seemed to solve this problem to a considerable extent. Occasionally in the mixing process air bubbles would become entrapped in the solution, which would usually be dissipated by the time the solution had cooled.

TABLE II.—COMPARISON OF RESULTS OBTAINED ON DETERMINATION OF CHOLESTEROL BY DIRECT TREATMENT WITH THE ZAK REAGENT AND AFTER SAPONIFICATION AND PRECIPITATION WITH DIGITONIN

Sample	Direct Method[a]	Sapon. and Pptn. Method[b]
IIIb-L	13.5[c]	19.1[c]
IVb-W	11.6	20.7
W.F. unsap.	32.5	35.4

[a] Acetic acid solutions of wool fat or wool fat unsaponifiable were analyzed colorimetrically. [b] Acetic acid solutions of the digitonide obtained from wool fat unsaponifiable or wool fat after saponification and precipitation were analyzed. [c] Gm. of cholesterol found per 100 Gm. of wool fat or wool fat unsaponifiable taken for analysis.

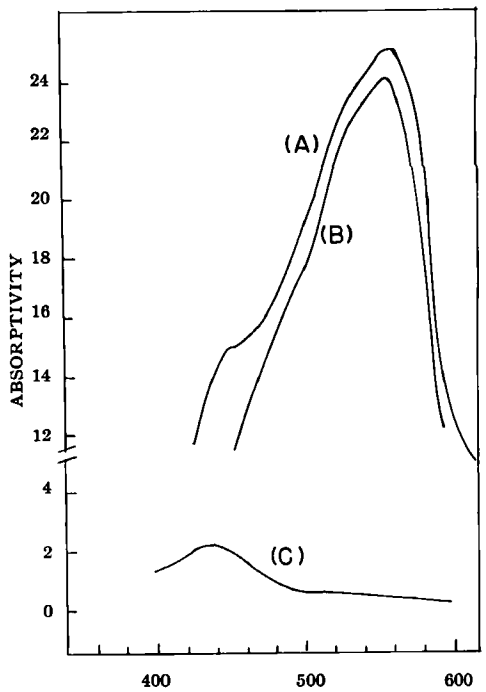

Fig. 3.—The spectra of cholesterol, cholesterol digitonide, and digitonin after treatment with the Zak reagent. The absorptivities were calculated using the concentration of the respective substances in the color solutions. *A*, cholesterol digitonide; *B*, cholesterol; *C*, digitonin.

RESULTS

The preliminary tests performed showed that the color complex formed with both cholesterol and its digitonide obeyed Beer's law (Fig. 4). This shows also the slightly greater absorbance of cholesterol digitonide than free cholesterol, as mentioned earlier.

The precision of the whole analytical procedure for determination of cholesterol in wool fat and its derivatives is shown in Table III. The difference of cholesterol content for different lots of wool fat or wool fat derivatives is also shown. However, within each lot of wool fat tested, good reproducibility was obtained with a maximum deviation from the mean of 6.8%. The average difference from the mean of all lots tested was 2.7% with a standard deviation from the mean of 3.3%. The calculations for the determination of cholesterol content were done by the use of the absorptivity of cholesterol digitonide, which had previously been determined.

The procedure as described requires some 6–7 hours to run, but does not require constant attention during the entire period. The periods of time given are for the most part minimum periods which were found to be necessary for completion of the respective reactions. The lapse of time between the addition of the sulfuric acid and the reading of the absorbance of the solution is not critical, since the readings in the analyses are taken in the period of 10–25 minutes after mixing the solutions.

[a] Gm. cholesterol found per 100 Gm. of wool fat taken for analysis. [b] Each number represents the average obtained from color analysis of duplicate samples of acetic acid solutions of the digitonide after saponification and precipitation.

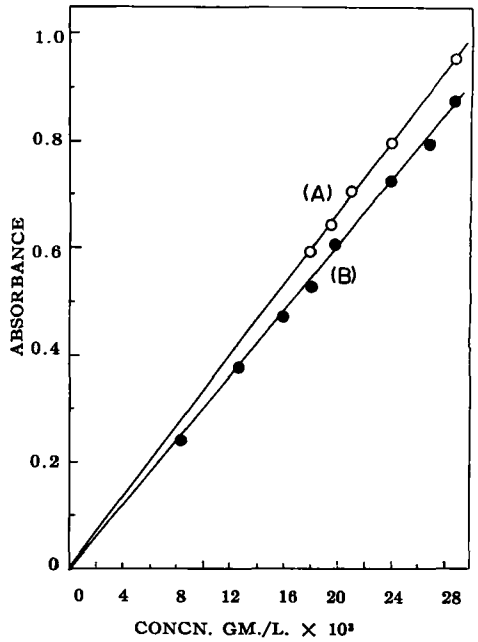

Fig. 4.—Beer's law plot of cholesterol and its digitonide using the Coleman spectrophotometer with 1.3-cm. cuvettes. *A*, cholesterol digitonide; *B*, cholesterol.

SUMMARY

A procedure is presented which is reproducible, which requires a minimum of control of conditions, and which constitutes a great improvement over previous methods in use. The reaction is quite sensitive; the analysis can be carried out using as little as 5 ml. of a mixture containing as little as 0.2% of wool fat. The reagent in use is stable for extended periods and no elaborate equipment is necessary. The method should lend itself to the analysis of many different types of pharmaceutical and cosmetic products containing wool fat or the many wool fat derivatives presently on the market.

Comparative Evaluation of Tablet Formulations Prepared from Conventionally-Processed and Spray-Dried Lactose

By WILLIAM C. GUNSEL and LEON LACHMAN

Four tablet formulations made from two types of lactose were studied. The granulations were compared for particle size distribution, flow properties, and moisture content. The tablets made from them were evaluated for hardness, friability, disintegration time, weight control, and color development at room temperature, 40°, 50°, and 60° for 12 weeks. In general, it was found that spray-dried lactose produced harder, less friable tablets which, however, were more susceptible to color development following storage at elevated temperatures.

SINCE 1956, lactose suitable for use in tablets has been available in two types, depending upon the final manufacturing step. In the manufacture of lactose, the whey of milk is placed in vats where it is heated with dilute hydrochloric acid to coagulate the protein. The acidity is then neutralized with lime and the protein removed by filtration. The liquid portion is evaporated to produce a thick syrup containing 60–70% solids. Upon standing, the syrup crystallizes. After centrifuging the crystals are washed with water. This is crude lactose. The crude is dissolved in tap water at 180 to 200°F. and treated with carbon to decolorize it. It is again filtered and then sterilized by maintaining it at 210°F. for 25 to 35 minutes. It is reconcentrated to 60% solids in vats which then contain 10,000 to 14,000 pounds dry weight. It is at this point that the method of manufacture differentiates the two kinds of lactose discussed in this paper (1, 2). That which will be called conventionally-processed lactose is obtained by centrifuging first and then drying; the second kind is pumped into a spray dryer and becomes spray-dried lactose.

Spray-dried lactose contains about 8% of amorphous material; this is actually dried syrup which has not crystallized. Because the mother liquor becomes a part of the final material, spray-dried lactose contains larger amounts of impurities than the centrifuged product. Thus, it has about five times as much ash and protein, twice the heavy metals and "other sugars," and ten times the lipids (3).

In mesh size, spray-dried lactose has a small portion less than 100; over 94% passes through 100 mesh and 27 to 44% is finer than 200. Conventionally-processed lactose may be obtained in several mesh sizes. This article is mainly concerned with the fine material all of which passes through 100 and 40–50% through 200 mesh. The spray-dried lactose flows readily while the conventionally-processed has poor flow, except in the coarser mesh sizes.

Although spray-dried lactose is now also widely used in tablet formulations, literature about its tableting properties has not appeared in scientific journals. Accordingly, this study was undertaken to determine how the two kinds of lactose compared with each other as the major excipient in several representative tablet formulations.

The following aspects were evaluated: (*a*) particle size distribution in the granulations; (*b*) flow rate and angle of repose of the granulations; (*c*) changes in disintegration time, hardness, friability, and color, for several representative tablet formulations after storage at room temperature, 40°, 50°, and 60° (tests were made at 0, 4, 8, and 12 weeks); and (*d*) uniformity of tablet weight.

EXPERIMENTAL

Formulations

The first formulation (4) examined had the following composition

FORMULATION I

Lactose U.S.P.	88.5%
Tragacanth U.S.P.	2.0%
Polyethylene glycol 6000	4.0%
Confectioners sugar	2.0%
Talcum U.S.P.	3.0%
Magnesium stearate U.S.P.	0.5%
3A Alcohol 50%	*q.s.*

The polyethylene glycol was dissolved in the 50% alcohol and added to the mixture of the other components. The moist mass was passed through a No. 10 hand screen and dried with circulating, dehumidified air for a minimum of 16 hours. The granules were broken on a No. 16 hand screen and were then ready for compression.

Received March 26, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication June 25, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

FORMULATION II

Lactose U.S.P.	94.5%
Cornstarch (dried)	4.5%
Stearic acid powder U.S.P.	1.0%
Purified water	*q.s.*

The lactose, stearic acid, and part of the starch were mixed together; the rest of the starch was converted to a paste with the water and used to wet down the powders. The moist mass was forced through a No. 8 hand screen and dried on trays at 100° F. for 16 hours. The material was then broken on a No. 16 hand screen.

FORMULATION III

Lactose U.S.P.	89.5%
Tragacanth U.S.P.	2.0%
Cornstarch	5.0%
Talcum U.S.P.	3.0%
Magnesium stearate U.S.P.	0.5%
3A Alcohol 50%	*q.s.*

The lactose and tragacanth were mixed and then moistened with the alcohol solution. The moist mass was screened through a 10-mesh sieve and dried with circulating dehumidified air for 16 hours. The dried material was then broken on a No. 16 hand screen and mixed with the cornstarch, talcum, and magnesium stearate.

The fourth formula is a simple mixture of the ingredients which are

FORMULATION IV

Lactose U.S.P.	94.5%
Cornstarch	5.0%
Magnesium stearate U.S.P.	0.5%

These materials were passed through a 20-mesh screen and then mixed.

Granulations were prepared in batches of 20,000 tablets, ten batches with conventionally-processed lactose, ten batches with spray-dried lactose. They were manufactured in a model A-200 Hobart planetary mixer. For each series, the mixing time, mixing speed, and amount of granulating liquid were the same. The granulations were compressed into 150-mg. tablets on a single rotary, 16-station press set to operate at 27,000 tablets per hour. The punches were $^{9}/_{32}$ in. diameter standard concave, uppers bisected and lowers monogrammed. Plain steel dies were used.

The results of the various tests to be described are the average of ten determinations.

Test Methods

Moisture Content.—Moisture content of the granulations was determined on a Cenco moisture balance operating at 120 v. with a 125-w. infrared lamp. The test was continued until the granulation changed color or until three consecutive readings at 1-min. intervals were the same.

Hardness.—Hardness was read on the hardness tester manufactured by the Strong-Cobb Arner Company. This unit was modified to operate from a compressed air line.

Friability.—Friability was measured with a Roche Friabilitor using a 4-min. cycle.

Disintegration Time.—Disintegration times were taken on the U.S.P. apparatus; no disks or holders were used.

Particle Size Analysis.—Sieve sizing was done on a Ro-Tap testing sieve shaker using stainless steel U.S. Standard sieve series in 20, 30, 40, 50, 60, and 80 mesh sizes and operating for 15 minutes. Each sample tested weighed 100 Gm.

Angle of Repose.—Angle of repose was measured by the cone method using a cathetometer and a 4-in. diameter tripod.

Flow Rate.—Flow rate was determined by timing the passage of 250 Gm. of granulation through a stainless steel funnel with a 1-in. orifice.

[a] A conventionally-processed lactose; B, spray-dried lactose.

RESULTS AND DISCUSSION

Formulation I.—As is evident from the data in Tables I, II, and III, the tablets were physically satisfactory. At the end of the 12-week test period, disintegration times were lower than initially at all temperatures. The tablets of spray-dried lactose disintegrated a little more rapidly except at 60°. Times for both types of tablets were well within U.S.P. limits.

Both sets of tablets exhibited good hardnesses with the conventional lactose always associated with the lower results. With time and temperature, there were changes downward from the initial figures but all the tablets were satisfactory except those of conventional lactose at 60°.

In friability the tablets containing spray-dried lactose suffered losses approximately one-half those of the conventional lactose regardless of time or temperature. The results for both sets of tablets remained quite constant under all storage conditions. It may be noted from the tables that even for those tablets which had a relatively poor hardness, the friability was not adversely affected.

A visible color change appeared in the spray-dried lactose tablets at 50° and 60°, a change confirmed by reflectance readings. However, the set of tablets from conventionally-processed lactose retained its original whiteness. The flow rates of the two granulations were very much alike, a fact confirmed by the similarities in the angles of repose. Spray-dried lactose gave slightly better results. On sieve analysis, both granulations contained mostly fine material, 78% of the conventional type and 89% of the spray-dried passing through a No. 60 sieve. Moisture content ranged between 3.3% and 5.3% but a correlation between moisture content and other physical characteristics was not apparent.

Formulation II.—Table IV shows that disintegration times were very rapid at room temperature throughout the test period. They rose gradually with storage at 40° and 50° with a severe increase at 60°. At this temperature, the tablets of spray-dried lactose disintegrated more rapidly than those of conventionally-processed lactose. Melting of the stearic acid or some change in the starch may have produced this effect.

Both types of tablets behaved similarly in the hardness test as evidenced by the data in Table V. At room temperature, there was a progressive softening of the tablets; this did not occur at the other temperatures. The tablets of conventionally-processed lactose were generally harder than those of spray-dried lactose.

Friability results shown in Table VI indicated tnat the conventionally-processed lactose produced better tablets initially but the losses became almost identical in all the later tests except the one at 60° for 12 weeks. These losses represented a large increase over the initial levels.

In flow rate and angle of repose, the conventional lactose averaged slightly better than the spray-dried. Moisture content averaged 0.7% higher in the granulations made from conventionally-processed lactose. A comparison of individual batch results gave no apparent correlation of moisture with hardness, with friability, or with disintegration time.

On sieve analysis, the granulations from spray-dried lactose had almost equal amounts caught on all screens with the No. 20 having the least. On the other hand, the granulations from the conventionally-processed lactose had a 43% cut passing through the 80-mesh screen with the second largest (19%) caught on the No. 80. Nevertheless, tableting characteristics of the two were very similar.

12 Weeks	0.52	0.55	0.48	0.49	0.57	0.62	0.60	0.73

[a] A, conventionally-processed lactose; B, spray-dried lactose.

By reflectance measurement, the tablets of spray-dried lactose were darker even when freshly made and became more so at 60°, the change being 7.3% whereas the tablets of conventionally-processed lactose changed only 2%. The difference between the two initially was 8.4% and increased to 13.7%.

Formulation III.—From Table VII it may be seen that both sets of tablets were almost identical in disintegration time at each storage condition. There were decreases with time and with temperature. All test results were low.

On the average, the spray-dried lactose produced the superior hardnesses as is indicated by the data in Table VIII. These increased from the fourth to the twelfth week at all temperatures with the room temperature samples increasing about half a unit while the 40°, 50°, and 60° samples ended up almost equal with each other and slightly below the initial level. The conventionally-processed lactose tablets softened under all conditions with the room temperature samples falling one unit and the other temperature results dropping slightly less.

In the friability tests, the conventionally-processed lactose tablets were very poor, two of the batches capping in the initial test and continuing to do so under the various storage conditions as shown in Table IX. Most of the other batches capped also but in a random pattern. Only two batches did not cap at all. As a consequence at all times and conditions, average friabilities were 0.9% or worse. On the other hand, the spray-dried lactose gave very good results at room temperature and satisfactory results at 50°, but rather poor at 40° and at 60°.

Tablets of spray-dried lactose darkened slightly more than those of conventionally-processed lactose at the accelerated conditions. There were small differences in flow rate and angle of repose. Both granulations contained many fines, the spray-dried lactose having more—93.6% passing through a No. 80 screen as against 81.7% for the conventional.

Formulation IV.—It was impossible to make adequate tablets from conventionally-processed lactose even when it was in the form of coarse (60–80 mesh) free-flowing granules. The tablets would not hold together. Therefore, the following data refer only to spray-dried lactose.

Disintegration times decreased with time at room temperature and reached their lowest points after 4 weeks at the other three storage conditions. These

latter then rose during the next 8 weeks until the 60° samples approached the initial result at room temperature (Table X).

Table XI indicates that all hardness results were greater than the initial one. For room temperature, 50°, and 60° they reached a peak at 4 weeks and then declined. Although the hardness readings decreased at 50° and 60° during the last 8 weeks, the disintegration times increased.

Friability was remarkably low at the beginning of the study but it increased with time, the highest level being at room temperature (See Table XII). All results were satisfactory however. Color change was very strong, being 13.5% darker after 12 weeks at 60° than initially.

An inconvenience with spray-dried lactose is that on aging it darkens appreciably more than the conventionally-processed material. This fact has been indicated in the discussion of each formulation. Table XIII compares the reflectance values of the tablets at the beginning and the end of the study along with the values for samples of the two types of lactose.

TABLE XIII.—EFFECT OF STORAGE ON COLOR STABILITY OF LACTOSE AND LACTOSE TABLETS ACCORDING TO REFLECTANCE MEASUREMENTS

B	88.0	88.0	62.0	63.0	38.0

[a] A, conventionally-processed lactose; B, spray-dried lactose.

Why spray-dried lactose discolors more than conventionally-processed lactose has not been specifically elucidated. However, it does contain larger amounts of impurities because the mother liquor is included in it. It is exposed to high heat while passing through the spray dryer but, theoretically, the evaporation of the moisture cools the crystals and prevents them from overheating. However, the other ingredients in the formulation afford some protection and indicate one method of attack on the problem.

A seeming paradox occurred between the data on flow and on weight control of the tablets (Table XIV).

The formulation with the slowest flow rate (Formulation III) produced the tablets with the most accurate weight control while the formulation with the most rapid flow (Formulation II) had the greatest weight variance.

Reference has been made several times to sieve sizing. The complete results are available in Table XV.

SUMMARY AND CONCLUSIONS

1. In three out of four formulations examined, tablets made from spray-dried lactose exhibited better physical qualities than those made from conventionally-processed lactose.

2. Spray-dried lactose is particularly useful because tablets can be made from it without wet granulating or slugging.

3. Spray-dried lactose darkens much more readily than conventionally-processed lactose.

Stability of Antibacterial Preservatives in Parenteral Solutions II

Microbiological Turbidimetric Assay Method for Preservative Content

By P. C. EISMAN, E. EBERSOLD, J. WEERTS, and L. LACHMAN

An accurate and rapid microbiological method for assaying chemical preservatives of nonantibiotic nature has been developed which employs a time-tested, proven procedure. Preservative concentration is measured by a turbidimetric procedure using *Escherichia coli* as the test organism. The method has been applied to chlorobutanol, phenol, and -chloro-beta-phenylethyl alcohol and compares favorably with chemical analytical methods.

IN CARRYING out stability studies on chemical preservatives in pharmaceutical solutions, it is essential that the methods employed accurately establish the preservative content. Analytical methods invariably have involved chemical procedures of varying degrees of complexity. Although regarded as possessing reliability, such assays may require chemical manipulation and equipment which are not always readily available. From a theoretical standpoint it is conceivable that while a chemical analysis may indicate appreciable loss of preservative content because of degradation, the breakdown products *per se* may possess intrinsic antibacterial activity.

In view of the generally accepted concept that preservative as well as antibiotic content is best expressed on the basis of antimicrobial activity, an attempt was made to develop an accurate and rapid turbidimetric assay similar to those generally employed for antibiotics. An extensive search of the literature has revealed no reports on the existence of a bioassay for chemical preservatives of nonantibiotic nature.

Initial attempts on our part (1) to arrive at a bioassay method involved the addition to the sample being assayed of a standardized number of *E. coli* organisms. At intervals, 1-ml. portions were removed, which were immediately plated for survivor count. Curves were then plotted of per cent survivors *vs.* time for each concentration of preservative. The time required to produce 50% killing was obtained from the plots. A standard curve was then drawn of the time required to destroy 50% of the organisms *vs.* the corresponding concentrations of preservative. Using the 50% killing time value of a sample of preservative solution under test and placing it on the standard curve, an estimate of the concentration of preservative was obtained. However, this procedure proved too cumbersome and time-consuming and, moreover, yielded poorly reproducible results.

As presently applied, the assay has proved to be rapid and reliable for the determination of chlorobutanol, phenol, and *p*-chlorophenylethyl alcohol, the only preservatives investigated thus far. With minor modifications, the procedure is similar to that of the turbidimetric assay employed in our laboratory for viomycin as described by Kersey (2).

In essence, the method consists of the addition graded concentrations of the preservative to a series of test tubes containing nutrient broth seeded with *E. coli*. After an incubation of approximately 3.5 hours the turbidity of each tube is measured for graded response by means of a photoelectric colorimeter fitted with a color filter. The potency of the sample is established by comparing the response of the test organism to the preservative under test with that observed in the standard reference series. Because of the rapidity of the test and the relatively heavy *E. coli* inoculum, strictly sterile techniques need not be necessarily observed.

EXPERIMENTAL

Culture and Medium.—Stock cultures of *E. coli*, strain Su 2, are maintained on BBL trypticase soy agar slants. Prior to the assay, the culture is transferred to two fresh agar slants which are incubated overnight at 37°. The growth from these slants are suspended in sufficient sterile 0.9 per cent sodium chloride solution to yield a light transmission reading of 10–12% (equivalent to an optical density of approximately 1.0 at a wavelength of 580 mμ in a Bausch and Lomb Spectronic 20 colorimeter). One milliliter of this suspension is added to 100-ml.

Received March 29, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication July 10, 1962.
The authors are indebted to Mrs. H. Sylwestrowicz of the Research Department, Ciba Pharmaceutical Co., for her evaluation of the statistical data presented in this paper.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

[a] All values based upon microbiological assay values for each different preservative were obtained from a single standard slope.

amounts of BBL trypticase soy broth. This inoculated broth is now ready for use in the assay.

Standard Solutions.—The following standard reference solutions are prepared in pH 4.0 (0.275 *M*) citric acid–sodium phosphate buffer: chlorobutanol, 0.5, 0.4, 0.3, 0.2, 0.1, and 0.05%; phenol, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, and 0.2%; and *p*-chloro-beta-phenylethyl alcohol, 0.262, 0.225, 0.187, 0.15, 0.112, and 0.075%.

Samples.—All samples for assay are diluted to contain not more than the maximum concentration of preservative employed in the standard reference series.

Assay Procedure: One-milliliter amounts of each standard reference concentration and of each unknown solution are added to test tubes in quadruplicate. As controls, 1.0 ml. of buffer solution containing no preservative is included in each assay. Nine milliliters of inoculated broth is then added to each tube. A syringe pipetting assembly (Cornwall type) fitted with a two-inch cannula is used for the rapid dispensing of the broth. Each tube is thoroughly shaken and placed in a water bath uniformly maintained at 37° until the control tubes have an optical density reading of approximately 0.35 (usually 3.5 hours of incubation). Further growth of the test organism is immediately stopped by the addition of 0.5-ml. amounts of formalin, diluted 1:3, employing the syringe pipet for this purpose.[1] The optical density of each tube of broth is obtained with the colorimeter at a wavelength of 530 mμ.

[1] The use of buffers with pH values greater than 4.0 will result in short periods of incubation.

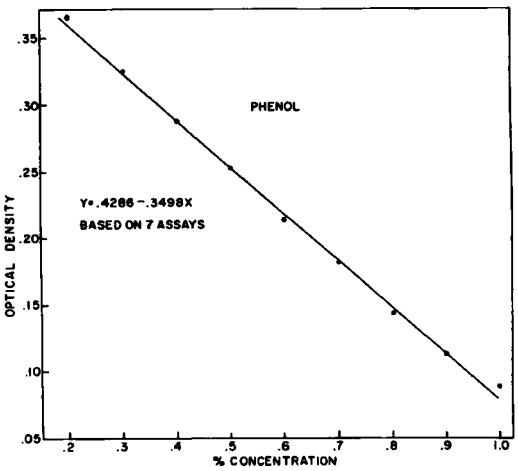

Fig. 1.—Computed line based on the values obtained from 7 assays.

The colorimeter is adjusted with clear, sterile broth to a reading of *O* optical density (*i.e.*, 100% light transmission). For each turbidity reading, the contents of the tube are transferred to a 3/4 in. × 6 in. test tube made expressly for the Spectronic 20 colorimeter by Bausch and Lomb.[2] After each reading, the broth is removed by suction. The values obtained for each set of quadrupli-

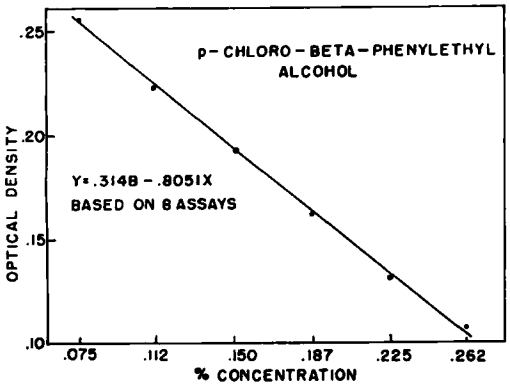

Fig. 2.—Computed line based on the values obtained from 8 assays.

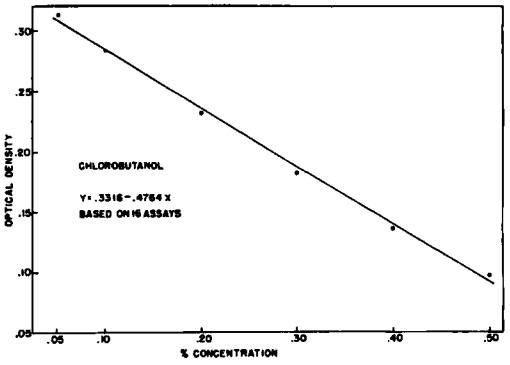

Fig. 3.—Computed line based on the values obtained from 16 assays.

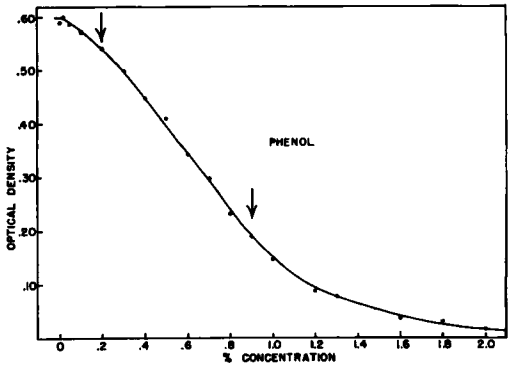

Fig. 4.—A typical sigmoid curve obtained when % concentration is plotted against optical density. The zone of straight line relationship is indicated by the arrows.

cate tubes are averaged. The average optical density values obtained for the standard reference concentrations are plotted on arithmetic paper against the corresponding preservative concentrations, and a straight line is drawn. Potencies of samples being assayed are then determined from the standard slope. Figures 1, 2, and 3 represent computed lines for phenol, *p*-chloro-beta-phenylethyl alcohol, and chlorobutanol based on 7, 8, and 16 assays, respectively, each assay being performed on different days. A straight line relationship was proved by the analysis of variance. Figure 4 shows the typical sigmoid curve for phenol. For our potency estimations only the linear zone, as indicated by the arrows, was used.

RESULTS

Since the relationship between the variables (*i.e.*, the per cent concentration of preservative and the corresponding observed optical density) is linear, we have compared the standard dose-response line as drawn by inspection with one drawn by the method of least squares. In almost all instances these two drawn lines, with respect to each of the three preservatives studied, were virtually superimposable.

As indicated in Table I, there is excellent agreement between the values derived for the three preservatives by chemical analysis and those obtained by the turbidimetric bioassay with *E. coli*.

That assay values of unknown samples calculated from different portions of the standard reference slope agree with corresponding values obtained by chemical analysis is shown in Table II.

SUMMARY

1. An accurate method is described for the turbidimetric assay of chlorobutanol, phenol, and *p*-chloro-beta-phenylethyl alcohol, employing *E. coli* as the test organism and requiring a $3^1/_2$-hour incubation period. The method is essentially the same as that currently used for viomycin and other antibiotics.

2. The procedure for establishing standard reference slopes for these preservatives is described.

Evaluation of Antispasmodic Activity in the Intact Dog

By STUART A. TURKANIS and HOWARD J. JENKINS

Results of a method developed to determine the comparative effectiveness of the active components of an antispasmodic formula and their combination in the surgically intact animal are presented. These confirm established relative potencies of the compounds involved and indicate that the combination of the formula under investigation represents a potentiating union.

THE QUALITATIVE and quantitative effects of atropine and chemically related cholinergic blocking agents have been demonstrated by numerous investigators using both *in vivo* and *in vitro* pharmacologic procedures. In most instances, some sort of surgical intervention of the gastrointestinal tract has been involved in the *in vivo* studies to date. Excellent *in vitro* biological assays such as those reported by Luduena and Lands are available (1). Using ileal strips, these investigators have achieved procedures of general acceptance in the pharmacologic screening of cholinergic blocking agents.

One of the problems confronting *in vivo* methods has been that involved with the tachyphylactic response to the more potent cholinergic blocking agents, evidenced in the progressive depression of gastrointestinal sensitivity and described by Seevers, *et al.* (2), in 1954 and by Quigley, *et al.* (3), in 1937. Since the reliability of a biological assay is known to be dependent upon the stability of the dose-response relationship, the tachyphylactic response here encountered constitutes a barrier to the successful development of a biological assay method for the aforementioned agents.

The quantitative determination of the cholinolytic activity of atropine and its belladonna relatives individually and in combination *in vivo* constitutes the basis of this investigation.

EXPERIMENTAL

Pressure changes occurring in the sensing element, a rubber sheath, in response to gastrointestinal movements were transmitted by means of its partially encased Cantor tube (D-111, 12, French) to a sensitive Sanborn transducer where these changes were converted to electrical impulses. The electrical impulses were then, after amplification, conveyed to a Sanborn two-channel recorder.

Along with measurement of gastrointestinal tract activity of the test animal, the respiratory activity was recorded concomitantly by means of a pneumograph, a second Sanborn transducer and Sanborn strain gauge amplifier being employed for this recording.

The test animals were mongrel dogs of either sex ranging in weight from 11.85 to 18.0 Kg. During the study they were fed once daily and supplied with water *ad libitum*. Each dog was anesthetized before each test with 30 mg./Kg. of pentobarbital sodium administered intravenously. The level of anesthesia that was achieved was just insufficient to abolish the swallowing reflex. No dog was used more often than every 48 hours for the testing of these compounds.

In all the tests, the Cantor tube reached approximately the same level in the gastrointestinal tract. At the completion of this series of tests a dog was sacrificed to reveal that the rubber sheath was located in the pyloric portion of the stomach.

All drugs were administered intravenously by means of an in-dwelling 18-gauge hypodermic needle, which was attached by a rubber tube to a 50-ml. buret containing 0.9% saline solution.

In the series of tests involving the response of the gastrointestinal tract to methacholine chloride, tachyphylaxis was not observed.

In view of the possibility of achieving a complete block with atropine sulfate and the chemically related cholinergic blocking agents of belladonna, the range values of the blocking dose of atropine sulfate were determined experimentally prior to the study to be 0.067 to 0.10 mg./Kg. Ten minutes after the intravenous administration of 0.10 mg./Kg. of atropine sulfate, no increase in gastrointestinal activity was achieved with an indefinitely large dose of methacholine chloride, although profuse salivation was evidenced.

In preliminary experiments, it was noted that the greater the dose of the spasmogen, methacholine chloride, the greater the response and the greater the duration of the response. Termination of the response was assumed when the base line of the recording returned approximately to its predose level. The mean average duration of the response to methacholine chloride, according to the above criterion, was 8 minutes, with a range of 4–10 minutes. To allow a margin of safety, the spasmogen was administered at 15-minute intervals throughout the entire series of the tests. Thus, cumulative effects of methacholine chloride were avoided.

The onset of atropine and hyoscyamine activity, which was indicated by a fall in the base line of the graph, was shown to occur within 5 minutes of the

Presented to the Scientific Section, A.PH.A., Washington meeting, August 1960.

intravenous administration of these cholinergic blocking agents. The establishment of the atropine or the hyoscyamine partial cholinergic block of the gastrointestinal tract was demonstrated in every instance within 10 minutes following the intravenous administration of these agents. The onset of hyoscine activity was more variable than that of atropine or hyoscyamine, and the establishment of the partial cholinergic block of hyoscine required at least 30 minutes following the intravenous administration of the drug.

From the preliminary studies, it became evident that the antispasmodic activity of atropine and related belladonna alkaloids is sufficiently enduring that cumulative effects would almost certainly occur if several doses of antispasmodic were administered during the course of one determination. This would, of course, make difficult or impossible the evaluation of the effectiveness of a single dose of antispasmodic. Consequently, the individual alkaloids and their combinations were given in this method only one dose per determination.

Methacholine chloride, the spasmogen, was administered in varying doses with the intent of obtaining a methacholine chloride$_{50}$, or Me$_{50}$, a dose of methacholine chloride the response to which is reduced by the antispasmodic to 50% of that to a preantispasmodic dose of this drug. The extent of the inhibition of methacholine chloride was determined and expressed as per cent of the preantispasmodic response.

A minimum of three doses was employed in order to obtain a Me$_{50}$: a high dose with an inhibition of less than 50%, a low dose with an inhibition of more than 50%, and a middle dose with an inhibition of approximately 50%. Each postantispasmodic dose of methacholine chloride in mcg./Kg. was plotted against the corresponding per cent reduction of the preantispasmodic response to methacholine chloride on logarithmic probability paper. The line to fit these data was drawn by inspection and the Chi^2 test was applied to determine the goodness of fit. From this line of the plotted data the Me$_{50}$ was read directly.

Throughout a particular determination, only one preantispasmodic dose of methacholine chloride was used, and the per cent reduction of the postantispasmodic methacholine responses was determined from this value.

The Me$_{50}$ of atropine sulfate at 0.030 mg./Kg. was calculated to be 9.25 mcg./Kg. To assess a relative activity with respect to the other antispasmodics and a combination of belladonna alkaloids[1] (CBA) the Me$_{50}$ 9.25 of each of these agents was determined. A minimum of three doses of antispasmodic was employed in order to obtain an antispasmodic dose with an Me$_{50}$ 9.25: a dose with an Me$_{50}$ above 9.25, a dose with an Me$_{50}$ below 9.25, and a dose with an Me$_{50}$ between these values. The log of each Me$_{50}$ was plotted against the log of the corresponding dose of the antispasmodic. From the resulting linear relationship, the Me$_{50}$ 9.25 of that particular antispasmodic or combination of antispasmodics was read directly from the graph and was calculated from the regression equation.

Each antispasmodic was assigned a relative potency value which was based on the reciprocal of its Me$_{50}$ 9.25 value multiplied by the Me$_{50}$ 9.25 of atropine sulfate, 0.030 mg./Kg. Thus atropine was given a value of unity and the other agents, including CBA, were listed according to their relative potencies as multiples of this number.

The individual Me$_{50}$ 9.25 doses of the three active components were weighted according to the relative concentrations of each in the combination, CBA. The sum of these weighted means was then divided by the sum of the relative concentrations of the components and the quotient obtained was considered to represent the calculated Me$_{50}$ 9.25 of CBA. The actual or the experimental Me$_{50}$ 9.25 value of CBA was obtained as were the component values. Comparison of the calculated and the experimental values for CBA effectiveness indicates that the combination constitutes an activity greater than the summed activity of the components.

DISCUSSION

This investigation has produced a method for evaluating the antispasmodic effectiveness of anti-

CBA	0.01120	2.68

cholinergic agents generally. The potency of such agents may be assessed in the procedure on the basis of comparison with an established standard. The advantage claimed for the method is that it is carried out in the intact dog without the necessity for surgical intervention in the placement of the sensing element. Thus, the same group of animals can be used repeatedly and without lengthy preparation in the determination involved.

The method developed has made possible a comparison of the relative effectiveness of the individual components of the combination CBA with the relative effectiveness of the combination. The results obtained have indicated potentiation of action in the combination.

Although atropine, hyoscyamine, and hyoscine were administered intravenously, it is very likely that similar results would be produced by oral administration, since these alkaloids are well absorbed from the gastrointestinal tract. Synthetic blockers should be studied, to be sure, by several routes of administration, since an agent which shows considerable cholinergic blocking activity parenterally could fail to achieve clinical usefulness because of poor absorption from the gastrointestinal tract.

Another possibility for further application of the method involves the direction of the alteration of the concentrations of the various alkaloids in such combinations as CBA in order to achieve an optimum combination of the component alkaloids, *i.e.*, one providing the greatest potentiation of the therapeutic benefits of the components consistent with the lowest incidence and least severity of untoward side effects.

SUMMARY

A biological assay employing the surgically intact dog is used to determine the relative activity of atropine sulfate, hyoscyamine sulfate, and hyoscine hydrobromide both alone and in combination on the gastrointestinal tract.

Indication of potentiation in the antispasmodic activity of CBA is provided by a comparison of the experimentally determined activity with the activity calculated from the activities of the components.

Solubilization of Salicylic Acid by Polysorbate 80 as Determined by Solubility Titration

By NATHAN A. HALL

A solubility titration has been used to study the solubilization of salicylic acid in water by polysorbate 80 since a liquid phase separates from supersaturated solutions to give a distinct turbidity end point. The ratio of solubilizate to solubilizer necessary for complete water-miscibility was also determined. The method should be of general applicability in studying phenols solubilized by polyoxyethylene surface-active agents. The effect on the system of including a fixed weight fraction of certain additives in the polysorbate 80 was investigated. The additives included a series of monohydroxy alcohols of decreasing dielectric constants, a group of polyhydroxy alcohols, polyethylene glycol 400, and Tween 20. Added monohydroxy alcohols increased or decreased the solubilizing power of polysorbate 80 in order of their polarity. Added polyhydroxy alcohols and polyethylene glycol 400 showed little effect. Added Tween 20 decreased the solubilizing power of polysorbate 80 in a linear fashion.

In the preparation of solubilized systems the formulator is faced with the problem of selecting the proper amount of solubilizing substance to prepare stable isotropic liquids for a specific purpose. Studies on micellular solubilization conducted near the critical micelle concentration of the surface-active agent are valuable in elucidating mechanisms of solubilization, but because they deal with low concentrations of both solubilizer and solubilizate they are of limited utility in designing a suitable formula where relatively large amounts of each may be required.

For a rapid means of determining the amount of solubilizer needed for a given solubilizate, titration with water has been recommended as a simple procedure (1–3). Results can be tabulated or plotted as a phase diagram from which the relative quantities of solubilizer and solubilizate can be determined for each situation. Titrations where the solubilizate is a liquid, such as a volatile oil, give good end points easily detected by formation of an opaque emulsion. The end point is not always readily discernible if the solubilizate is a solid, however. Guttman and Higuchi (4) have reported complex formation between a number of phenols and macromolecules including polyethylene glycols. Complexes separated as oily liquids. Mulley and Metcalf (5) studied the complex form between chloroxylenol and cetomacrogol, a surface-active polyethylene glycol ether, and observed a similar separation of an oily liquid. These observations suggested that a solubility titration procedure could be used to examine solubilization in water of the salicylic acid complex by polysorbate 80, and preliminary experiments showed the system to give a suitable turbidity end point. Practically, the solubilization of the polyethylene glycol derivative-salicylic acid complex reflects the solubilization of salicylic acid by polysorbate 80. Pharmaceutically the use of polysorbate 80 could be criticized since its ester linkage is susceptible to hydrolysis in aqueous salicylic acid solutions, but it served to illustrate the general applicability of the method and presented no problems in the short term experiments of this study.

This investigation revealed that there was a critical ratio of solubilizate to surface-active agent which gave maximum complete solubilization, namely, a ratio which was miscible with water in all proportions. Coles (6) has shown that glycerol could be used to lower the amount of polysorbate 80 needed to produce a water-miscible solution of vitamin A palmitate, and has studied the glycerol:polysorbate 80:vitamin A:-water system in some detail (8). It was decided, therefore, to examine the effect of some added alcohols and Tween 20 upon critical miscibility ratios of salicylic acid and polysorbate 80.

EXPERIMENTAL

Materials.—Commercial samples of polysorbate 80 and Tween 20 (Honeywill-Atlas Ltd., London, England) were used without purification. The same samples were used in all experiments. Salicylic acid B.P. was recrystallized from 70% ethanol, dried under vacuum, and reduced to a fine powder in an agate mortar. All monohydric alcohols were dehydrated, redistilled, and stored under anhydrous conditions. Ethylene glycol, propylene glycol, and glycerin were dehydrated by heating to 180°, cooled and stored in a desiccator charged with sulfuric acid. Polyethylene glycol 400 U.S.P. was used as supplied by Government Medical Stores, Singapore. Mixtures of polysorbate 80 and added substances were prepared by weight. Dehydrated glycerin was not miscible with polysorbate 80; there-

fore the mixture was shaken vigorously to assure homogeneity just prior to withdrawing the sample.

Solubility Titration.—The method was adapted from that of O'Malley, *et al.* (1). Five-gram samples of the solubilizer were weighed into 50-ml. beakers containing a weighed quantity of salicylic acid and a magnetic stirring bar. Beakers were placed in a shallow water bath on the platform of a magnetic stirrer and stirred until complete solution resulted. The titration was carried out in an air-conditioned room and the water bath was maintained at 25 ±1° by the application of heat at irregular intervals. A strong light was used to illuminate the beaker during the addition of purified water from a buret mounted so that the tip was just above the surface of the stirring liquid. Turbidity which remained for 2 minutes was taken as the end point. Titrations were accomplished with polysorbate 80 alone and containing various additives listed in Table I.

At the turbidity end point the ratio of salicylic acid to polysorbate 80 and the per cent water by weight was calculated for each sample. The ratio was based upon only the polysorbate 80 present without the additive; thus it expressed the weight of salicylic acid solubilized in the presence of 1 Gm. of polysorbate 80 in the system studied. The solubility of salicylic acid at the concentrations examined in the system excluding the surface-active agent was not large enough to significantly affect the results. Figure 1 shows several titration curves for polysorbate 80 alone and containing 20% by weight of various alcohols. The 20% concentration was selected as being a convenient concentration showing a well-defined behavior by preliminary experiments.

Determination of the Critical Miscibility Ratio (CMR).—The ratio (salicylic acid:polysorbate 80) at which complete miscibility with water was observed was termed the "Critical Miscibility Ratio" (*CMR*). Ratios of salicylic acid to polysorbate 80 above the *CMR* would not form an isotropic system with all proportions of water and any ratio below the *CMR* would. Systems containing low concentrations of salicylic acid where its solubility in the dispersion medium significantly affects the ratio must be excluded from the definition. For salicylic acid the *CMR* was found applicable to solutions containing 5% or more of polysorbate 80 (*ca.* 0.75% salicylic acid). An indication of the probable *CMR* was obtained from the titration curve.

A more exact determination of the *CMR* was made by adding to the weighed solubilizing mixture known weights of salicylic acid calculated to give the desired ratio to three figures. Each sample was quantitatively transferred to 50-ml. ground glass-

stoppered tubes with water and mixed. Each tube contained at least 90% water. The tubes containing the samples were suspended in a thermostatically controlled water bath at 25 ±0.1° for 24 hours. The tubes were then removed and turbidity was readily observable under a strong light. The highest ratio which showed no evidence of instability was taken as the *CMR*. Determinations were made in duplicate. Table I shows the effect on the *CMR* of various additives to polysorbate 80 and Table II shows the effect of mixtures of polysorbate 80 and Tween 20 on the *CMR*.

DISCUSSION

The titration curves of Fig. 1 are essentially phase diagrams. For systems containing percentages of water indicated, ratios of salicylic acid to polysorbate 80 above the line will not produce clear solutions; those below will. The titration curves can be used to calculate the amount of salicylic acid solubilized by a given weight of polysorbate 80 at known water concentrations and the reciprocal of the ratio can be used to calculate the amount of polysorbate 80 needed for a given weight of salicylic acid. The data may also be plotted as a three-component phase diagram if desired; however, as plotted for Fig. 1 the data are especially valuable to reflect comparative effects of added substances on solubilizing ability of polysorbate 80 for salicylic acid. Thus it is seen that ethanol assists considerably in the solubilization below 50% water but at high water concentrations it has little effect; propylene glycol has some power to increase solubilization at very low water concentrations but generally neither promotes nor inhibits the solubilization; *n*-pentanol generally depresses the solubilization.

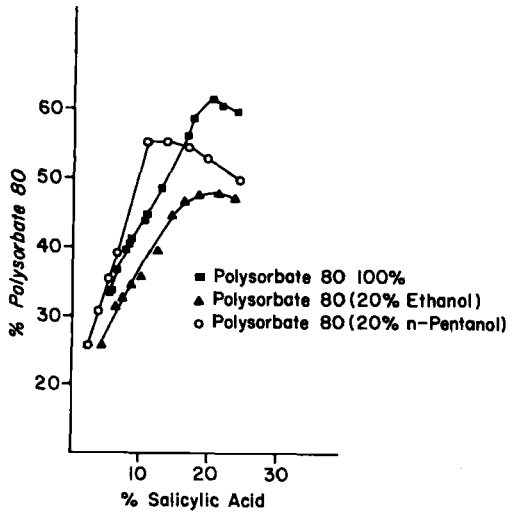

Fig. 2.—Titration data showing salicylic acid concentration at the turbidity end point as a function of polysorbate 80 concentration.

Another plot of the titration data in which the composition at the turbidity end point is used to determine the percentage of salicylic acid in the system as a function of the percentage of Tween 80 (all % by weight) is shown in Fig. 2. This shows in another fashion the solubilizing activity of polysorbate 80 and the maximum amount of salicylic acid which can be solubilized. The solubility of salicylic acid in the additives at the concentrations used does not significantly affect the plot. The solubilizing power of polysorbate 80 appears to follow increasing percentages until higher concentrations are reached. At higher concentrations the system becomes lipophilic in nature and the titration reflects the solubilization of water rather than salicylic acid. This explanation is borne out by the pronounced decrease in apparent solubilizing power shown with the less polar additives (*n*-pentanol curve, Fig. 2). These phenomena correlate well with Winsor's theory of intermicellular equilibria (9) which explains phase changes observed in proceeding from a lipophilic to a hydrophilic dispersion medium.

As the ratio of salicylic acid to polysorbate 80 is reduced, greater amounts of water can be tolerated by the system until a ratio is obtained which is completely water miscible. The highest ratio at which this occurs is termed the critical miscibility ratio (*CMR*). This ratio is not meaningful at very low salicylic acid concentrations approaching the limit of water solubility of salicylic acid; however it gives a good indication of the minimum amount of solubilizer needed for water-miscible combinations. Table I which records the *CMR* values for a series of added alcohols reveals that, although alcohols such as ethanol may assist in solubilization at the lower concentrations of water (Fig. 1), the effect disappears at the *CMR*. In the series of monohydric alcohols, the decrease in *CMR* follows their polarity, the decrease paralleling the decrease in dielectric constant. The constancy of the *CMR* for the polyhydric alcohols is remarkable in the light of the report by Coles (6) that glycerin markedly increases the solubilizing power of polysorbate 80 for vitamin A palmitate in the formulation of water-miscible vitamin A preparations. Possibly the different results observed in this study for salicylic acid could be due to its semipolar nature while vitamin A palmitate is of much lower polarity. For mixtures of polysorbate 80 and Tween 20 (Table II) the change in *CMR* parallels the relative concentration of the two micelle-forming agents.

Complex Formation Between Hydrocolloids and Tranquilizers and Hypotensive Agents

By HORACE D. GRAHAM, YEDE MARIE BAKER, and A. N. NJOKU-OBI†

Highly insoluble complexes are formed between hydrocolloids such as carrageenan and sodium carboxymethylcellulose and sodium alginate, and tranquilizers and hypotensive agents such as promazine hydrochloride, chlorpromazine hydrochloride, and reserpine. Meprobamate and hexamethonium chloride form much weaker complexes as evidenced by their failure to produce turbidity with several hydrocolloids tested. Using the promazine hydrochloride–carrageenan (Seakem type 5) interaction as the experimental system, it was shown that maximum interaction occurred at 45° and at a pH of 4.95 in a buffered medium. After intramuscular injection of the carrageenan–promazine hydrochloride complex into rabbits, free promazine was detected in the blood up to six days after administration as contrasted to the disappearance of the free form, similarly administered, after only 24 hours.

RECENTLY, chlorpromazine has gained much attention, not only because of its tranquilizing effect but also because of its interaction with sulfated mucopolysaccharides such as chondroitin sulfate and other biochemical compounds (1–4). Since chondroitin sulfate occurs in dentin and enamel and is produced in excessive quantities in abnormal calcification of the arteries and bone (5, 6), such interactions are important pathologically. In one specific study, Sobel and Burger (6) exploited it to study the mechanism of dentin formation. DeLuca and Kostenbauder (7) mentioned that drugs such as chlorpromazine, promethazine, and tetracaine hydrochlorides are bound by nonionic surfactants but, as far as can be ascertained, a comprehensive study of the binding of tranquilizers and hypotensive agents by hydrocolloids has apparently not been made.

Many tranquilizers, when given in large doses, may cause several undesirable side effects. On the other hand, if small compatible doses are given, the treatment must be repeated at frequent intervals. For these reasons, sustained release dosage forms of many medicinals have become of primary importance.

Chemically, sulfated hydrocolloids like carrageenan, furcellaran, fucoidan, etc., are similar to chondroitin sulfate, are readily available, and are very reactive. Therefore, it was decided to study the interactions of these natural compounds with tranquilizers and hypotensive agents. It was considered that if highly insoluble complexes could be obtained, these studies would provide some basis for the use of some of these hydrocolloids in the development of sustained release forms of the drugs. Since the hydrocolloids are natural, readily available, and highly innocuous products, their introduction into biological systems would present no medico-legal problems.

Received March 29, 1962, from The George Washington Carver Foundation, Tuskegee Institute, Ala.

Accepted for publication August 8, 1962.

The authors are grateful to the Ciba Pharmaceutical Products Inc., Summit, N. J., Wyeth Institute for Medical Research, and Smith, Kline and French Laboratories, Philadelphia, Pa., for samples of tranquilizers and hypotensive agents. The technical assistance of Misses Carolyn Sue Kemper, Linnie B. Thomas, and Patricia Smith, and the cooperation of the School of Veterinary Medicine are appreciated.

This research was supported by NIH grant Nos. EF-173 (C 2) and E-4025, Carver Foundation, and the School of Veterinary Medicine, respectively, of Tuskegee Institute, Ala.

† Present address: School of Veterinary Medicine, Tuskegee Institute, Ala.

EXPERIMENTAL

Reagents

Hydrocolloids.—These are listed in Table I. Unless otherwise stated, all dispersions were prepared as described by Graham and Thomas (8). All calculations were made on a dry weight basis.

Tranquilizers and Hypotensive Agents.—Promazine hydrochloride, 0.5% in distilled water; chlorpromazine hydrochloride, 0.5% in distilled water; Serpasil phosphate (reserpine), 0.1% in distilled water; veratrine sulfate, 0.5% in distilled water; Veriloid, 0.1% in dilute acetic acid; and veratrine alkaloid, 0.1% in dilute acetic acid.

Equipment

The following were used: a Coleman Universal spectrophotometer, model 14; a Beckman pH meter, model G; Pyrex glass-stoppered test tubes; and dialysis membrane, 27/32 dialysis tubing, seamless cellulose.[1]

Procedure

General Survey of the Interaction of Hydrocolloids with Tranquilizers and Hypotensive Agents.—In order to obtain some idea of the reaction of a broad spectrum of hydrocolloids with several tranquilizers and hypotensive agents, a screening program was undertaken. For this, 1–5 ml. of each hydrocolloid suspension was mixed with 2 ml. of the stock solution of each tranquilizer or hypotensive agent and the development or nondevelopment of turbidity noted. The results of this study are summarized in Table I.

Relative Reactivity of Hydrocolloids with Tranquilizers and Hypotensive Agents.—Since in some

[1] From Fisher Scientific Co

cases only slight precipitation was observed in the screening program, more information was sought on the relative reactivity of the hydrocolloids with tranquilizers and hypotensive agents. The sulfated hydrocolloids were previously observed to be precipitated most readily by the drugs in question. Moreover, the turbidity developed was shown to be proportional to the amount of hydrocolloid present. Based on this premise, a scheme was developed for comparing the reactivities of the hydrocolloids.

One to five ml. containing 1–10 mg. of the particular hydrocolloid was mixed with 2 ml. of the stock solution of the particular tranquilizer or hypotensive agent at 45°. The total volume in all cases was 10 ml., attained by adding distilled water where necessary. The reaction was allowed to proceed for 15 minutes, the tubes were cooled to room temperature and the turbidity developed measured at 400 mμ, with a Coleman Universal spectrophotometer, model 14. Since some solutions were appreciably viscous, accompanying control tubes were included by substituting 2 ml. of distilled water for the solution of tranquilizer or hypotensive agent. The actual turbidity (optical density) developed, therefore, was calculated as "the turbidity measured minus the turbidity (if any) of the accompanying control."

In order to compare the reactivities of the hydrocolloids, the turbidity produced by 1 ml. of carrageenan (Seakem type 5) with a particular tranquilizer or hypotensive agent was assigned an arbitrary value of 10. The turbidity produced by 1 mg. of any other hydrocolloid through interaction with the same tranquilizer or hypotensive agent was then compared with the value obtained for carrageenan (Seakem type 5) to give values recorded in Table II.

Influence of Variables on the Interaction.—Several variables such as temperature, pH, buffer normality, interaction time, and the presence of inorganic salts could possibly influence the binding of the drugs by the hydrocolloids. Therefore, these variables were systematically investigated. Unless otherwise stated, the carrageenan (Seakem type 5)-promazine hydrochloride system was used throughout the investigations on variables.

The influence of temperature was assessed by reacting 10 mg. of the hydrocolloid with 2 ml. of the drug solution at 30, 45, and 65° in a total volume of 10 ml. (Where reactions were done at 45 and 65°, the tubes were immediately cooled in an ice water bath after the desired reaction time.) After adjusting to room temperature, the turbidity (optical density) developed was measured at 400 mμ with the Coleman Universal spectrophotometer, model 14. For the establishment of the optimum

interaction time at 45°, mixtures of the hydrocolloid and the drug in a total volume of 10 ml. were allowed to interact for the periods shown in Table III and the optical density measured as described above. Studies on the effects of pH were done by adding 2 ml. of 0.1 *M* phosphate buffers of varying pH levels to test tubes containing a suspension of 10 ml. of the hydrocolloid and 2 ml. of the drug solution. The total volume was always 10 ml. The mixtures were incubated at 45° for 15 minutes and, after cooling to room temperature, the turbidity that developed was measured at 400 mμ. The final pH of each system was checked with a Beckman model G pH meter. Since the drugs gave precipitates with buffer salts in the alkaline range, all experimentation was restricted to the acid range. Any influence of buffer molarity was ascertained by adding varying amounts of 1.0 *M* phosphate buffer, pH 4.95, to test tubes containing 1 ml. of the hydrocolloid suspension and 2 ml. of the drug solution. After making the volume 10 ml., the turbidity developed at 45° for 15 minutes was measured as described above.

Since pharmaceutical formulations may contain certain salts, the influence of some of the more common salts on the intensity of the interaction was

assessed. This was done by adding varying amounts of each salt solution to the reaction tubes and measuring the optical density as described above. Duplicate control tubes containing no added salt were included in each experiment. The tolerance level of each salt was established in a manner similar to that employed by Graham and Thomas (8). It was taken as "That maximum final concentration (the concentration of salt in the 10 ml. of reaction medium) of salt which did not cause a significant difference (in this case ±1%) in the absorbance as compared to a control tube to which no salt was added." The results are summarized in Table IV.

Maximum Binding Capacity of Hydrocolloids for the Tranquilizers and Hypotensive Agents.—More detailed quantitative data on the binding process were obtained by determining the maximum binding capacity of representative hydrocolloids for promazine hydrochloride and reserpine. For this, 5 ml. of the suspension containing 50 mg. of the particular hydrocolloid was allowed to react at 45° for 15 minutes with increasing quantities of the tranquilizer or hypotensive agent, in a centrifuge tube, and with a total volume of 10 ml. After cooling to room temperature, the reaction mixture was centrifuged at 1500 r.p.m. for 10 minutes. One milliliter of the supernatant was placed in 9 ml. of methyl alcohol and this alcohol mixture again centrifuged as above. One milliliter of this supernatant was then used for the colorimetric determination of the particular tranquilizer or hypotensive agent. The amount of the drug bound was calculated as "the amount added minus the amount found free in the supernatant."

Colorimetric Methods for Determination of Tranquilizers and Hypotensive Agents. Promazine was determined according to the method of Leach and Crimmin (9). Reserpine was determined by the method of Indemans, *et al.* (10).

Calculation of the Maximum Binding Capacity.—The maximum amount of promazine hydrochloride and reserpine bound per gram of three representative hydrocolloids was established from a Langmuir type plot as employed by Kennon and Higuchi (11) and Patel and Kostenbauder (12). By plotting the reciprocal of the amount of drug bound per unit of hydrocolloid on the Y axis *vs.* the reciprocal of the amount of free drug in the system, and extrapolating to zero concentration of the drug, a line which cuts the Y axis was obtained. The Y intercept gives a measure of the maximum binding capacity (13). The results are summarized in Table V and representative graphs are shown in Figure 1.

Solubility of the Promazine Hydrochloride–Hydrocolloid Complexes.—Since the promazine hydrochloride–carrageenan complex was so readily formed and seemed highly insoluble, it was deemed useful to study its solubility in solutions of sodium chloride and of hydrochloric acid. The method used was similar to that employed by Antonopoulous, *et al.* (14), in studying detergent complexes and Bridger, *et al.* (15), in studying metal ammonium phosphate complexes. For this, 5 ml. of a dispersion containing 50 mg. of carrageenan (Seakem type 5) and 5 ml. of a 0.5% solution of promazine hydrochloride were allowed to react at 45° for 30 minutes in 15-ml. graduated centrifuge tubes. After cooling, the mixture was centrifuged at 2500 r.p.m. for 10 minutes and the supernatant carefully poured off. The precipitate was washed five times with distilled water and centrifuged after each washing. The precipitate from the centrifuge tubes was added to consecutive 200 × 15 Kimax test tubes and quantities of 4 M sodium chloride or 2 N hydrogen chloride added to give the final normalities shown in Table VI. The final volume was 20 ml. in all cases attained by adding distilled water where necessary. The tubes were shaken on a Burrell wrist action shaker at 27° and, at the intervals shown, 3 ml. of the

mixture centrifuged and one ml. of the supernatant assayed for promazine released from the complex. The results are shown in Tables VI and VII. For comparison, the promazine hydrochloride–sodium carboxymethylcellulose complex was also studied.

Experiments on the Promazine Hydrochloride–Carrageenan Complex.—Batch quantities were prepared by using a 200-ml. suspension containing 200 mg. of carrageenan (Seakem type 5), preincubated at 45° for 30 minutes. One hundred milliliters of a solution containing 2 Gm. of promazine hydrochloride was similarly preincubated. At the end of the preincubation period, both the hydrocolloid suspension and the promazine hydrochloride solution were mixed in a 1000-ml. Erlenmeyer flask and allowed to interact for 30 minutes at 45°. The mixture was placed in a cold room at 4° overnight and filtered. The filtrate was collected and carrageenan added to precipitate any promazine in it. If precipitation occurred, the cooling and filtration processes were repeated. The precipitates were pooled and washed with distilled water to remove any unreacted hydrocolloid. This was then followed by washing 5 times with absolute methyl alcohol. The precipitate was then collected, placed in a Petri dish and dried overnight in a vacuum oven at 75°. After this, the mass was pulverized in a mortar and stored in a vial.

Titration of the Complex.—In order to determine the promazine content of the complex 10 mg. was placed in a 25-ml. volumetric flask and enough concentrated sulfuric acid added to dissolve it. Water was added to make it up to volume. From this, 1 ml. was taken, further appropriately diluted with distilled water and the promazine content determined colorimetrically by the method of Leach and Crimmin (9).

Sustained Release of the Promazine from the Complex *in vivo*.—In order to ascertain if sustained release of the promazine from the carrageenan (Seakem type 5)–promazine complex could be achieved, free promazine, and the suspending medium, respectively, was injected intramuscularly into individual rabbits. Sterile physiological saline and a 1:5:4 mixture of ethyl alcohol, glycerin, and water were used as suspending media in the separate experiments. Samples of blood were drawn at intervals from 4 hours to 6 days and analyzed for promazine by the method of Leach and Crimmin (9). Simultaneously, changes in the picture of the white blood cells were followed. The results are summarized in Table VIII.

RESULTS AND DISCUSSION

From Tables I and II it is clear that the sulfated polysaccharides are the most reactive hydrocolloids. The low reactivity of agar may be partly explained by the fact that its sulfation is still not well established (16, 17). The carboxylic acid type polysaccharides are next in order of reactivity. Of these, sodium carboxymethylcellulose is one of the more reactive. In the experiments with sodium carboxymethylcellulose, all reagents were dissolved in distilled water to avoid precipitation of the hydrocolloid itself at low pH levels of the medium (17). The neutral polysaccharides were the least reactive.

Of the several variables which affect the interaction of promazine hydrochloride with carrageenan (Seakem type 5), the pH of the interaction medium is the most important. In the alkaline range, the tranquilizer will precipitate in the absence of the hydrocolloid, hence only the acid range was investigated. Maximum interaction occurs at pH 4.95, and as the pH decreases the amount of promazine bound per mg. of the hydrocolloid decreases. At a final pH of 2.25, binding of the drug by the hydrocolloid was still appreciable since ionization of the sulfate group is not drastically impeded even at this low final pH. A similar pattern would be expected for the other sulfated hydrocolloids. However, the carboxylic acid type hydrocolloids would be more severely influenced since at pH levels of 2.5–3.0, sodium carboxymethylcellulose, in particular, would precipitate in the absence of the tranquilizer.

The temperature has a great influence on the interaction as exemplified by the promazine hydrochloride–carrageenan (Seakem type 5) interaction. In the acid range (pH 4.95) turbidity is a good measure of the intensity of the interaction and it was used to assess this influence. At 30°, the turbidity developed was lower than at 45° or at 65°. Apparently, at this temperature (30°) ionization of both interactants may not be complete. The great sensitivity of the system to temperature as indicated

by the measurements made immediately (before cooling) and those made after cooling to room temperature indicate that, apparently, forces other than the ionic type can participate in the binding process. Since the turbidity developed at 45° was essentially the same as that at 65° (after cooling), 45° was chosen for all later experiments.

Under the experimental conditions employed, at 45° the maximum interaction occurred after 30 minutes. Despite this, a heating time of 15 minutes was selected to avoid any possibility of hydrolysis of the hydrocolloid due to prolonged heating, and to facilitate rapidity of experimentation when many samples were involved. The degree of interaction at 45° for 15 minutes remained constant for as long as 4 hours, hence comparisons based on the time–temperature selection are not invalid.

Final buffer molarities of 0.01–0.10 resulted in no drastic change in the interaction as evidenced by the turbidity measurements. Therefore, where buffers were used, a final molarity of 0.01 was selected.

Table IV summarizes the influence of salts on the promazine hydrochloride–carrageenan (Seakem type 5) interaction. On a molar basis, the order of tolerance of the added salts was found to be monovalent > divalent > trivalent. Severe interference of the salts is due to competition for the binding sites of the hydrocolloids. The trivalent cations will actually precipitate carrageenan and other hydrocolloids, even at relatively low concentrations.

Although only the promazine hydrochloride–carrageenan (Seakem type 5) system was investigated in detail, it is to be expected that the other systems would be similarly affected by the variables listed. As noted with the precipitation with alkaloids (8), lambda carrageenan was always more reactive than kappa carrageenan. This is in line with chemical data which show that the lambda fraction is much richer in ester sulfate content than the kappa fraction (17).

The solubility data recorded in Tables VI and VII indicate that the promazine hydrochloride complexes of carrageenan (Seakem type 5) and sodium carboxymethylcellulose are highly insoluble in sodium chloride and hydrochloric acid. Relatively, the sodium carboxymethylcellulose complex is more soluble than the carrageenan complex in both sodium chloride and hydrochloric acid. This insolubility renders them potentially suitable as sustained release forms of this and possibly other drugs. The need for complexing agents for the development of such depot forms of drugs has recently been clearly emphasized by Hirscher and Miller (18).

Analysis of the data recorded in Table VIII indicate that the promazine hydrochloride–carrageenan (Seakem type 5) complex can serve as a depot form of the drug. The prolonged presence of the drug in the blood of the rabbit leads to the conclusion that the drug was released from the complex. Contrastingly, the disappearance of drug administered as the "free form," after 24 hours, indicates the further superiority of the complex where sustained release is desired. Le Blanc (19) reported that a single injection of chlorpromazine caused a drop in the eosinophils, leucocytes, and platelets in the blood of male albino rats. This effect, in their opinion, was not a direct result of hypothermia. Korst (20) has reviewed several cases of agranulocytosis caused by phenothiazine derivatives including chlorpromazine and promazine. It was noted that in some cases the neutrophils decreased drastically or even vanished and that the total leucocyte count severely decreased. Since promazine hydrochloride is very closely related to chlorpromazine hydrochloride, it was decided to investigate the blood picture changes, if any. The variations in the blood cell picture shown in Table IX, may be considered as further evidence that the promazine was being released from its hydrocolloid complex. Besides the possibility of their use for development of sustained release forms of drugs, the effect of these hydrocolloids on the availability of drugs and other chemicals in pharmaceutical preparations must also be emphasized. It has been shown that gums (hydrocolloids) will lower the availability of tetracycline antibiotics.

Technique of Implanting Permanent Electrodes in Cats for Chronic Stimulation and Observation of EEG and Behavioral Effects

By ZOLA P. HOROVITZ and MAY-I CHOW

A procedure for preparing cats with permanently implanted electrodes is described. This technique, which has been used to successfully prepare over 50 of these animals, employs fixation with dental cement and the use of a direct contact connection on the top of the head. The procedure is quick, inexpensive, and very productive. This makes it quite useful in both industrial and academic pharmacological, physiological, and psychological research.

SINCE Hess' pioneer work on stimulation of the unrestrained, unanesthetized cat (1), techniques for stimulating and lesioning or for recording of electrical and behavioral phenomena in the active animal have become useful to the pharmacologist, physiologist, and psychologist. Bradley and Elkes (2), Horovitz and Chow (3), and many others, have used cats with permanently implanted electrodes (P.I.E. cat) for correlating the effects of drugs upon electrical and behavioral responses. This type of preparation has also been used for various types of chronic stimulation by Killam and Killam (4), Doty (5), and Horovitz, *et al.* (6).

The literature, unfortunately, reveals only a few complete descriptions of the techniques involved in preparing these P.I.E. animals. The techniques used by Hess, ingenious for his time, have been outdated by technical advancements. Knowles (7) in 1951 described a method of implantation that employed a base-plate assembly. This technique requires a large craniotomy and the building of a complicated base-plate head assembly for each cat. Bradley and Elkes (8) in 1953 described an excellent procedure for implanting deep and cortical electrodes but the leads were threaded under the skin of the neck and out the animal's back. This required the animal to carry a bulky harness on its back. Delgado (9) has described a method of implanting multipolar needle electrodes; unfortunately his technique also requires a bulky harness. Delgado (10) has expertly reviewed various implantation procedures and the effects of long term stimulation and recording in animal brains.

Our laboratory has explored various aspects of many techniques for preparing the P.I.E. cat. We feel that the procedure described below is the quickest, easiest, and most productive we have tested. It requires very little laboratory preparation; every item is commercially available, and the animal requires very little maintenance care. We have successfully used this procedure to prepare over 50 P.I.E. cats within the past two years.

MATERIALS

Deep Electrodes.—The deep electrodes (Fig. 1-B) are of the bipolar concentric type and consist of insulated 0.0117 in. platinum-tungsten wire inserted into 23-gauge stainless steel hypodermic tubing. The inter-polar distance varies between 0.6–0.8 mm. Each tip exposure is approximately 0.3 mm. A patch wire is soldered onto the tubing about 5 mm. from the top. The length from the tip to the patch solder joint varies, depending upon the electrode placement. Generally, the length is equal to 5 mm. plus the distance between electrode tip and surface of cortex, as determined from the cat brain atlas (11). This allows enough extra length on the electrode for cementing to the skull surface. The tubing is insulated with three or four coats of BC-341 Dolphon epoxy resin varnish and the wire with two coats of Formvar insulation.[1]

Surface Corticals.—The surface cortical electrodes are 5-mm. long stainless steel rivets with the heads removed. Flexible lead wires are soldered onto the top of the rivets. The rivets are 1.5 mm. thick and insulated with Insl-X varnish,[2] except at the tip (Fig. 1-C).

Ground and Support Screws.—The ground wire is usually three or four entwined strands of platinum wire forced into one of the temporal muscles or wound around one of the support screws. These screws are No. 4-36 × 1/4 in. machine screws.

Electrode Connectors.—The electrode connector is an Amphenol Blue Ribbon 14 pin connector #57-40140 (Fig. 1-A). This connector was found to be the easiest to handle and solder of all the connectors tested.

Cement.—All electrodes and the connector are fixed to the skull with Caulk Grip dental cement. This cement is a quick drying powder-liquid resin that has proved to be very easy to handle. To increase the gripping effect, Caulk dental primer is painted on the skull surface prior to cementing.

METHOD

Most of our cats have been adult female cats of more than 2.0 Kg., deprived of their ovaries and uteri. We have successfully used six male cats, but in general find the spayed female a much more stable and tractable animal. At least two weeks prior to implantation, the cats were immunized against feline pneumonitis and feline infectious enteritis (distemper).

The cats are anesthetized intraperitoneally with 35 mg./Kg. of pentobarbital sodium. Sterile operating procedures have been found to be unnecessary but the electrodes are sterilized overnight under ultraviolet light and all the instruments are soaked in iodine solution[3] prior to use. The head and neck are shaved and painted with antiseptic solution. The animal is placed into the stereotaxic instrument and a midline incision is made in the scalp. The incision is approximately 5 cm. in length and ends just behind the occipital protuberance. The temporal muscles are reflected to give the desired skull exposure. Small pock marks

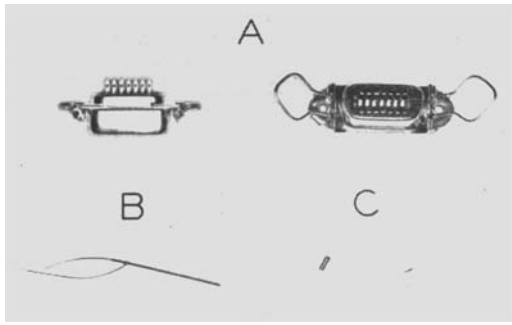

Fig. 1.—*A* = electrode connector; *B* = deep bipolar electrode; *C* = cortical electrode.

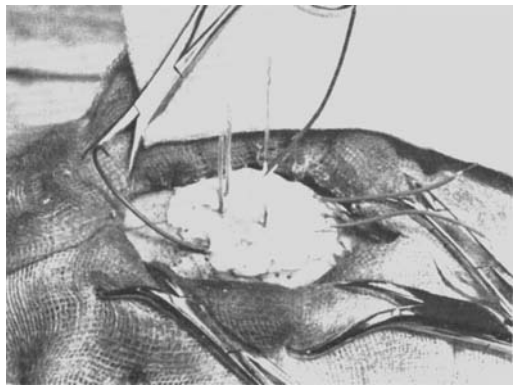

Fig. 2.—Deep and cortical electrodes cemented onto top of skull.

are made on the skull with a No. 1/2 burr on a dental drill. These marks serve as additional gripping points for dental cement and help to hold the electrodes in place. The previously zeroed electrodes[4] are then placed into the holders and moved to the appropriate lateral and anterior-posterior positions prior to insertion. The electrodes are then lowered to a point just above the surface of the skull and the skull is marked with pencil just below the electrodes. After all the electrode skull-entry points have been marked, they are drilled with a No. 4 burr. Care is taken not to damage the dura. After drilling, any bleeding between the bone plates is stopped by plugging the hole for a few minutes with Gelfoam. After each deep electrode has been inserted into the brain, the skull surface around it is carefully dried with cotton swabs and primer and a small amount of cement applied. About 5 minutes is allowed for the cement to dry before the electrode holder is removed (Fig. 2).

The holes for the corticals are drilled with a No. 5 burr and those for the supporting screws with a No. 8 burr. After these are in place they are also cemented to the skull (Fig. 2). Using an Oryx miniature soldering iron, the previously tinned ends of the electrodes are then soldered onto the appropriate connector pins (Fig. 3). All soldered joints are tested for mechanical strength and elec-

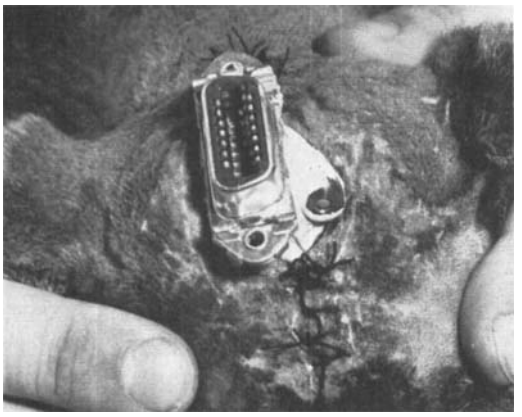

Fig. 4.—Finished preparation with venous cannula.

trical conductivity. The wires are then carefully coiled to avoid shorting and the connector is placed as close to the skull surface as possible. The connector and wires are then cemented to the skull. Care must be taken at all times not to abrade the insulation on the lead wires. The incision is then closed with No. 2-0 surgical silk thread and the animal removed from the stereotaxic instrument. The cat is usually placed in a warm cage overnight and is, in most cases, alert and hungry the following morning. Figure 4 illustrates a completed preparation. The rubber diaphragm on the right is cemented to the skull and attached on the inside to polyethylene tubing which is brought down under the skin and inserted into the jugular vein for subsequent intravenous injections. Figure 5 is an X-ray of another P.I.E. cat.

After a few preliminary scratchings, the cats do not disturb the plug. Any infection that develops under the skin surrounding the connector can be kept under control by cleaning and washing with iodine solution. More severe infections have been successfully treated with a triamcinolone-antibiotic combination ointment.[5]

To record or stimulate, an amphenol male connector No. 57-30140, attached by cable to the stimulator and electroencephalograph apparatus, is connected to the female connector on the animal's head. The connectors are durable, and since the contact is a wiping one there is always a clean contact surface.

It has been our experience that this technique of fixation with dental cement and the use of a direct contact connection on the top of the head is more practical and less bulky, has a longer duration and is better tolerated than any other procedure presently described in the literature.

Spectrophotometric Determination of Three Sulfa Drugs in Combination

By S. M. MODY and R. N. NAIK

The principle of simultaneous equations has been applied to a tertiary mixture containing three sulfa drugs. A rapid procedure for the spectrophotometric determination, without prior separation, of sulfacetamide, N^1-benzoylsulfanilamide, and sulfathiazole in combination has been developed.

WHERE the individual amounts of three sulfa drugs appearing in combination with each other in a product are to be estimated, the official procedures (1, 2) utilize paper strip chromatography to first separate each drug and then colorimetric procedures to estimate the individual amounts of the components. The official procedures are quite time-consuming and not so accurate. There is a need, therefore, for a method which will permit the quick and accurate estimation of sulfacetamide, N^1-benzoylsulfanilamide, and sulfathiazole in combination with each other in a water-dispersible cream base.

Marzys (3) has developed a procedure for the individual estimation of the components of sulfathiazole, sulfamerazine, and sulfadiazine mixtures utilizing a combination of colorimetric and spectrophotometric procedures. Since no specific color reaction was known for any of the three sulfas studied, their ultraviolet absorption spectra in 0.1 *N* hydrochloric acid were used to determine whether or not the amounts of the individual sulfas could be estimated from the absorption at three wavelengths and solving simultaneous equations with three unknowns (4).

EXPERIMENTAL

Apparatus: Beckman spectrophotometer model DU 4700 with 1-cm. matched quartz cells was used. Cell correction was applied where necessary. Unless otherwise mentioned the measurements were done against 0.1 *N* hydrochloric acid as blank.

Reagents: Hydrochloric acid, A.R. grade, solvent ether, reagent grade, sulfacetamide U.S.P. XV (5), sulfathiozole N.F. X (6), N^1-benzoyl sulfanilamide, supplied by Bengal Immunity Co. Ltd., conforming to the specifications of Basu & Sikdar (7).

The absorption spectra for the three sulfas were determined at 220, 235, and 280 mμ (see Fig. 1). They conformed to Beer's law between 5 and 25 mcg./ml.; the absorption being additive. The absorptivities of the three compounds, determined using 1-cm. quartz cells and 0.2-mm. slit width, are given in Table I.

By solving the following three simultaneous equations from the absorbances at the indicated wavelengths, one obtains the concentrations of the three ingredients:

$$460\ a + 465\ b + 345\ c = 1000 \times A_{220}$$

$$56.5\ a + 584\ b + 106.5\ c = 1000 \times A_{235}$$

$$167.5\ a + 189\ b + 489\ c = 1000 \times A_{280}$$

where a = concentration of sulfacetamide, b = N^1-benzoylsulfanilamide, and c = sulfathiazole, expressed as mg. per 100 ml. of solution.

Analysis of Known Synthetic Mixtures.—Known mixtures were prepared by taking suitable aliquots of solutions of individual components. The acidity in the final solution was maintained at 0.1*N*. The absorbances were measured at 220, 235, and 280 mμ and the content of each component calculated using simultaneous equations. The results are given in Table II.

Analysis of the Cream Containing Sulfacetamide, N^1-Benzoylsulfanilamide, and Sulfathiazole.—About 1 Gm. of the cream (containing about 100 mg. of total sulfonamides) was mixed with a little solvent ether to get a good dispersion and transferred to a 250-ml. separator with the aid of about 50 ml. of

solvent ether. The suspension was extracted with four 50-ml. portions of 1 *N* hydrochloric acid. The combined acid extracts were washed in a 500-ml. separator with 25 ml. of solvent ether and filtered through a Whatman No. 41 filter paper into a 500-ml. volumetric flask. The filter was washed and the volume made up with 1 *N* hydrochloric acid. A 10-ml. aliquot was pipetted into a 100-ml. volumetric flask and the volume made up with distilled water. A 200-ml. portion of 1 *N* acid was similarly treated to prepare the blank.

The absorbances of the sample solution at 220, 235, and 280 mμ, measured against the blank, were used in the calculations as above to obtain the results in Table III.

CONCLUSION

A spectrophotometric procedure has been developed for rapid and fairly accurate determination of three individual sulfa drugs in combination with each other without prior separation. Though the combination is not the one very frequently used, the procedure could, perhaps, be extended to other combinations as well.

Synthesis of Methylglyoxal-bis-guanylhydrazone-C^{14}

By VINCENT T. OLIVERIO and CHARLENE DENHAM

Methylglyoxal-bis-guanylhydrazone (methyl GAG), an antitumor agent in current animal and clinical trials, has been synthesized with isotopic carbon (C^{14}) in excellent yield and radiochemical purity for pharmacological studies.

NUMEROUS reports have recently appeared relating the inhibitory effects of guanylhydrazones, particularly methylglyoxal - bis - guanylhydrazone (methyl GAG), on various animal and human neoplasms (1–7). To facilitate studies on the metabolic fate and mechanism of action of these agents in man and animals, we have synthesized radioactive methyl GAG-C^{14} (I) in excellent yield and radiochemical purity.

Methyl GAG may be prepared by the reduction of nitroguanidine with zinc dust in acetic acid to aminoguanidine (8), followed by condensation with pyruvaldehyde (9). The aminoguanidine may also be prepared, alternatively, as originally described for pilot plant production (8), by methylation of thiourea with dimethyl sulfate followed by hydrazinolysis of the S-methylisothiuronium sulfate.

For the preparation of methyl GAG-C^{14} on the milligram scale, the latter procedure was chosen because: (*a*) appreciable quantitites of zinc salts were coprecipitated with addition of sodium bicarbonate after reduction of nitroguanidine, even in the presence of ammonium chloride, resulting in an impure product; (*b*) the specific activity (mc./mmole) of the commercially available C^{14}-guanidine nitrate was only one-fourth as high as the less expensive C^{14}-thiourea; and finally; (*c*) the overall reaction yield (30%) of the first procedure was appreciably lower than the yield (70%) of the alternate

solvent ether. The suspension was extracted with four 50-ml. portions of 1 *N* hydrochloric acid. The combined acid extracts were washed in a 500-ml. separator with 25 ml. of solvent ether and filtered through a Whatman No. 41 filter paper into a 500-ml. volumetric flask. The filter was washed and the volume made up with 1 *N* hydrochloric acid. A 10-ml. aliquot was pipetted into a 100-ml. volumetric flask and the volume made up with distilled water. A 200-ml. portion of 1 *N* acid was similarly treated to prepare the blank.

The absorbances of the sample solution at 220, 235, and 280 mμ, measured against the blank, were used in the calculations as above to obtain the results in Table III.

CONCLUSION

A spectrophotometric procedure has been developed for rapid and fairly accurate determination of three individual sulfa drugs in combination with each other without prior separation. Though the combination is not the one very frequently used, the procedure could, perhaps, be extended to other combinations as well.

Synthesis of Methylglyoxal-bis-guanylhydrazone-C^{14}

By VINCENT T. OLIVERIO and CHARLENE DENHAM

Methylglyoxal-bis-guanylhydrazone (methyl GAG), an antitumor agent in current animal and clinical trials, has been synthesized with isotopic carbon (C^{14}) in excellent yield and radiochemical purity for pharmacological studies.

NUMEROUS reports have recently appeared relating the inhibitory effects of guanylhydrazones, particularly methylglyoxal - bis - guanylhydrazone (methyl GAG), on various animal and human neoplasms (1–7). To facilitate studies on the metabolic fate and mechanism of action of these agents in man and animals, we have synthesized radioactive methyl GAG-C^{14} (I) in excellent yield and radiochemical purity.

Methyl GAG may be prepared by the reduction of nitroguanidine with zinc dust in acetic acid to aminoguanidine (8), followed by condensation with pyruvaldehyde (9). The aminoguanidine may also be prepared, alternatively, as originally described for pilot plant production (8), by methylation of thiourea with dimethyl sulfate followed by hydrazinolysis of the S-methylisothiuronium sulfate.

For the preparation of methyl GAG-C^{14} on the milligram scale, the latter procedure was chosen because: (*a*) appreciable quantitites of zinc salts were coprecipitated with addition of sodium bicarbonate after reduction of nitroguanidine, even in the presence of ammonium chloride, resulting in an impure product; (*b*) the specific activity (mc./mmole) of the commercially available C^{14}-guanidine nitrate was only one-fourth as high as the less expensive C^{14}-thiourea; and finally; (*c*) the overall reaction yield (30%) of the first procedure was appreciably lower than the yield (70%) of the alternate

Guanidine-C^{14}, 1,1′-(methylethanedilidenedinitrilo)dihydrochloride monohydrate, is the full chemical name. The abbreviated name, methyl GAG-C^{14}, is employed throughout the text.
The thiourea-C^{14} was obtained from New England Nuclear Corp., Boston, Mass.
Pyruvaldehyde (43%) was obtained through the courtesy of Union Carbide Chemicals Co., New York, N. Y.

method. Thus, in combination with several minor modifications in manipulation and apparatus for adaptation to the semimicro scale, the dihydrochloride salt of methyl GAG-C^{14} was prepared in 99% radiochemical purity with a specific activity of 1.95 mc./mmole.

PROCEDURE

S-Methylisothiuronium-C^{14} Sulfate.—The method was adapted from "Organic Syntheses" (10). In a 20-ml. round bottom flask fitted with a condenser and a soda-lime trap were mixed 10 mmoles of thiourea-C^{14} [50.6 mg. of thiourea-C^{14} (15 mc./mmoles) and 710 mg. of unlabeled thiourea] and 1 ml. of water. To this was added, dropwise, 1 ml. (10 mmoles) of freshly distilled dimethyl sulfate and the mixture was gently refluxed for 1 hour. The reaction mixture was concentrated on a steam bath in a stream of nitrogen to approximately one-half the original volume. Upon cooling, the solidified contents were triturated with several milliliters of ethanol, filtered, and washed with ether. The white solid material was suspended in 10 ml. of a warm mixture of 95% ethanol and ether (1:1), filtered, and washed with ether. The first crop of crystals weighed 406 mg. and melted, with decomposition, at 242°. Concentration of subsequent filtrates to an oil, precipitation with ether, and recrystallization from a mixture of 95% ethanol and either (1:1) yielded an additional 783 mg. of product melting at 242–244°, with decomposition. The total yield was 1.188 Gm. (85%).

Aminoguanidine-C^{14} Bicarbonate.—The procedure was an adaptation of a pilot plant scale reaction in "Organic Syntheses" (8). Hydrazine sulfate (1.095 Gm., 8.4 mmoles) suspended in 3 ml. of water was solubilized by the measured, dropwise, addition of 12 *N* sodium hydroxide solution until neutral to congo red. A second equal volume of sodium hydroxide solution was then added. This hydrazine solution was rapidly added through a reflex condenser to a solution of 1.188 Gm. (4.2 mmoles) of S-methylisothiouronium-C^{14} sulfate and 1 ml. of water in a 20-ml. round-bottom flask. The reaction mixture was stirred magnetically for 1 hour at room temperature. Evaporation of the solution *in vacuo* on a steam bath to one-half the original volume yielded a negligible amount of hydrated sodium sulfate crystals which were removed by filtration. The filtrate was warmed to 30° and glacial acetic acid was added to pH 5. Approximately 1 Gm. of sodium bicarbonate was added to the solution which was stirred at room temperature for 1 hour or until precipitation was complete. The white aminoguanidine bicarbonate salt was filtered, washed with cold water, and dried *in vacuo* at room temperature. The product weighed 1.043 Gm. (90.5%) and melted, with decomposition, at 175°.

Methylglyoxal-bis-guanylhydrazone-C^{14}.—The procedure of Thiele (9) was adapted. A mixture of 1.043 Gm. (7.6 mmoles) of aminoguanidine-C^{14} bicarbonate, 1 ml. of 12 *N* hydrochloric acid, and 0.5 ml. of 95% ethanol was refluxed 30 minutes in a 20-ml. round-bottom flask to give white needles of the hydrochloride salt. To the cooled reaction mixture were added, dropwise, 0.85 ml. (6 mmoles) of 43.2% pyruvaldehyde (partially decolorized by treatment with Darco-G60) and 2 ml. of 95% ethanol. The mixture was stirred 45 minutes at ice-bath temperature. The reaction mixture was poured into 50 ml. of acetone to give a white flocculent precipitate of the bis-guanyldhydrazone dihydrochloride monohydrate. The product was filtered and washed with cold acetone and ether. After drying *in vacuo* at room temperature, the pure compound weighed 982 mg. (3.57 mmoles, 93%) and melted at 256–257°, with decomposition.

The specific activity of the pure radioactive product (1.95 mc./mmoles) was determined by liquid scintillation counting of 0.2-ml. aliquots of a standard aqueous solution (100 mcg./ml.) dissolved in 18 ml. of 30% methanol in toluene containing 0.3% of 2,5-diphenyloxazole and 0.01% of 1,4-bis[2-(5-phenyloxazolyl)]benzene. An absolute counting efficiency of 63% was obtained when samples were counted in plastic bottles. When glass counting bottles were used there was a rapid loss of counts in the samples due to the absorption of the methyl GAG on the surface of the glass container (11).

The radiopurity of the product was assayed by high voltage paper electrophoresis and by paper chromatography in two solvent systems, followed by autoradiography of papers and counting of radioactivity in all spots (12). High voltage electrophoresis (40 v./cm.) of the drug on Whatman No. 3MM paper at pH 3.5 in 0.05 *M* ammonium formate buffer, resulted in a single spot migrating toward the cathode and containing more than 99% of the radioactivity of the load. No radioactive contaminant was detected. In a descending system of *n*-propanol, 1 *N* hydrochloric acid, and water (3:1:1) methyl GAG-C^{14} had an R_f of 0.36 and contained more than 99% of the total load radioactivity. In butanol, 95% ethanol, and water (4:1:1), the compound had an R_f of 0.15 and no radioactive contaminent. In both systems the R_f values for the radioactive compound were identical with those of authentic methyl GAG as located by ferricyanide nitroprusside reagent (13). Lastly, the ultraviolet absorption spectrum at pH 6 of the radioactive methyl GAG was in agreement with authentic methyl GAG.

Occurrence of a Weak Anti-inflammatory Substance in *Simaba cedron* Seed

By E. ROY HAMMARLUND

Ethanol and aqueous extracts of *Simaba cedron* seeds contain a weak, nonspecific, and relatively toxic anti-inflammatory substance.

It was suggested that *Simaba cedron* seed, *Simaroubaceae*, possibly contained an anti-inflammatory or antiarthritic agent because a 5% extract of the powdered seeds in 70% ethanol had been used orally in Denmark for rheumatoid arthritis with some apparent success (1).

Previous investigations on the plant have been few and the results have been contradictory. Nauck and Picado (2) reported limited success with injections of an alcoholic extract of cedron seed as a treatment for malaria, whereas Spencer, *et al.* (3), found no antimalarial activity present. Gauckler (4) described the use of the cotyledons as a remedy for snakebite and fever, whereas Bonsmann (5) reported that an extract of cedron had no antisnakebite activity. Krebs and Rüber (6) isolated cedrin, a nonalkaloid or glycosidal bitter principle, and reported that it is probably a partially hydrated naphthalene derivative similar to santonin. However, no tests were made for any biological activity. Polonsky (7) isolated two nonalkaloidal cedron fractions, cedronine and cedronyline, but likewise did not test for biological activity. Moreover, Wall, *et al.* (8), in their numerous surveys of plants for the presence of steroidal sapogenins did not investigate *Simaba cedron*.

The object of this initial investigation was to make several crude extracts of the powdered dried cedron seeds by employing various solvents and to biologically screen these extracts on rats for the possible presence of any anti-inflammatory principle. The finding of any appreciable amount of activity would then have been followed by an intensive search for, and the isolation of, the particular biologically active ingredient. However, none of the extracts yielded a substance sufficiently active to warrant further and more complete investigation. Nevertheless, because there may be some value in an essentially negative report, the experimental procedures and findings of this study are here reported very briefly.

EXPERIMENTAL

Extraction Procedure.—Dried seeds which had been collected in South America were verified by botanists of S. B. Penick and Co. and E. R. Squibb and Co. The seeds were finely powdered in a grinder and this powder was used for all extractions. Approximately 500 Gm. of the powdered seeds were used for each of the individual extractions by the following solvents: petroleum ether, anhydrous ethyl ether, ethanol, and water. Three or four repeated extractions were made with each solvent on a separate batch of seeds using a high-speed blender at room temperature. No attempt was made to obtain a complete extraction with any solvent. The solvents were evaporated in a rotary film evaporator without heat and the following amounts of extractives were obtained: with petroleum ether, 500 Gm. of powdered seeds yielded 36.6 Gm. of a yellow oil; with anhydrous ethyl ether, 500 Gm. of powdered seeds yielded 48.8 Gm. of a viscous yellow oil which contained a small amount of white solids; with ethanol, 500 Gm. of powdered seeds yielded 27.1 Gm. of a sticky dark yellow solid; with distilled water, 400 Gm. of powdered seeds yielded 37.8 Gm. of a dried yellow solid which could be powdered.

These extracts were dried in a vacuum desiccator and the vials were tightly stoppered under nitrogen. The samples were sent to the Squibb Institute for Medical Research for routine screening for the presence of anti-inflammatory activity.

Biological Screening Tests and Results.—The four extracts were assayed in both intact and adrenalectomized male rats implanted with cotton pellets. Results of these studies indicate that the petroleum ether soluble and anhydrous ethyl ether soluble extracts were inactive even at daily subcutaneous doses of 10 mg. per animal. The ethanol soluble extract was lethal at 10 mg. in the adrenalectomized animal. This ethanol extract induced a slight anti-inflammatory effect in the intact rat at daily doses of 0.4 mg. and 2 mg. The water soluble extract was lethal in the intact rat at a 10-mg. dose and had a weak anti-inflammatory effect at a 4-mg. daily dose, but was inactive at lower doses. In additional studies in intact animals the water soluble extract partially prevented (28%) the hind limb edema induced by the parenteral administration of dextran.

DISCUSSION

The results indicate that the extracts of the seeds are highly toxic and have only a weak, nonspecific anti-inflammatory activity. A large number of toxic or irritating substances such as turpentine could produce similar effects in these same tests. Therefore, there is little justification for continuing the search for an anti-inflammatory agent in this plant. No attempt was made to identify the slightly active substance.

Since the aqueous solutions of the powdered seeds foamed so copiously during the extraction and evaporation, it was suspected that there were probably saponins, sapogenins, or protein material present. Using a DuNouy tensiometer, a 1% aqueous solution of the aqueous extract was found to lower the surface tension of distilled water a total of 28.1 dynes/cm. at room temperature. Furthermore, in order to find out if this aqueous solution was strongly hemolytic to red blood cells, two drops of fresh human capillary blood were added to flasks containing 25 ml. of 0.1%, 1.0%, and 5.0% aqueous solutions of the extract each in 0.6%, 0.75%, and 0.9% sodium chloride solutions. The solutions were stoppered,

The author is indebted to the Squibb Institute for Medical Research for carrying out the biological screening tests.

mixed by inversion, and allowed to stand one hour at room temperature and for an additional 24 hours at approximately 5°. None of the solutions caused any hemolysis of the erythrocytes by the end of the 25 hours. This indicates that the saponin content is not great and the extract is not strongly hemolytic.

The powdered seeds were further investigated for the presence of alkaloids by employing the routine acidic-aqueous and alkaline-chloroform partition extraction procedure twice and then testing the aqueous solution with Mayer's reagent and, likewise, the chloroform solution on a spot plate with Erdmann's, Froehde's, and Mandelin's reagents. All tests were negative, which indicates the absence of alkaloids in cedron seeds.

SUMMARY

1. *Simaba cedron* seeds contain a weak, nonspecific, and relatively toxic anti-inflammatory substance.

2. An aqueous extract of the seeds is nonhemolytic to erythrocytes and does not contain alkaloids.

Application of Solvent Extraction and Anion-Exchange Chromatography to the Determination of Sodium Pantothenate in Pharmaceutical Products

By T. PANALAKS

A spectrophotometric method, developed for calcium *d*-pantothenate, was demonstrated to be equally applicable to the sodium salt.

A CHEMICAL method for the determination of calcium *d*-pantothenate in pharmaceutical products was recently developed in this laboratory (1). The method was based in part on an extraction with benzyl alcohol in the presence of a salting-out agent and on an anion exchange chromatography. Since different salts were shown to affect the partition coefficient of the pantothenate in the solvent extraction, it was necessary to investigate the applicability of the method to sodium *d*-pantothenate which is used in some pharmaceutical products. The possibility of using the calcium salt as a reference standard in the determination of the sodium form was also studied by comparing the relative absorbance produced by the reaction product of the two salts.

EXPERIMENTAL

Preparation of Sodium Pantothenate.—A 5.0-Gm. quantity of calcium *d*-pantothenate was dissolved in a minimum volume of distilled water and 21.5 ml. of a 5% solution of sodium carbonate was added with stirring. The solution was let stand overnight in a refrigerator, then filtered on a No. 1 Whatman. The precipitate was washed with about 350 ml. distilled water. The combined filtrate and washings was adjusted to pH 6.0, and made up to 500 ml. with distilled water.

Received June 11, 1962, from the Food and Drug Laboratories, Department of National Health and Welfare, Ottawa, Canada.
Accepted for publication June 26, 1962.
Helpful discussions concerning this paper by Dr. J. A. Campbell and statistical assistance of Mr. J. Malcolm Airth are gratefully acknowledged.

Recovery Test.—Amounts of 1.235, 2.470, and 4.940 ml. of the prepared solution were each added to 25 ml. of a liquid multivitamin preparation. These amounts were equivalent to 0.5, 1.0, and 2.0 mg. of sodium *d*-pantothenate per ml. of the liquid sample. The determinations were made in duplicate on aliquots of 10 ml. of the solutions after being diluted to a 100 ml. with distilled water. Calcium *d*-pantothenate was the reference standard and a factor of 1.0124 was used for the conversion of calcium *d*-pantothenate to its equivalent of the sodium salt.

RESULTS AND DISCUSSION

To compare the behavior of the two salts, 5 mg. of the calcium salt and an equivalent weight of the prepared sodium salt were subjected to the procedure (1). The assays were conducted in three replicates on different days. The results, presented in Table I, indicated that although there was significant variation between assays for the sodium salt there was no significant difference on the average between the absorbance of the reaction products of the two salts. No apparent destruction of the pantothenate radical due to hydrolysis was observed. Since it was shown previously that the presence of amino acids did not significantly affect the final absorbance readings (1), and that an equal response of both forms of the pantothenate was obtained in this experiment, it was concluded that β-alanine was not formed before the pantothenate was subjected to the complete analytical procedure.

The results of the recovery test of sodium *d*-

0.50	0.83	0.58
1.00	1.38	1.13
2.00	2.20	1.95

pantothenate added to a liquid elixir containing a mixture of the B vitamins and yeast extracts, as shown in Table II, indicated a recovery of 97–116%.

Samples of typical multivitamin preparations containing sodium *d*-pantothenate were analyzed, using calcium *d*-pantothenate as a reference standard. Three of these samples were in a lyophilized form. The results, shown in Table III, indicated a reasonable mean overage of 20% of the declared potency.

It may be concluded that the spectrophotometric method developed for calcium *d*-pantothenate is equally applicable to the determination of its sodium salt in pharmaceutical products, and that calcium *d*-pantothenate may be used as a reference standard.

TABLE III.—SODIUM *d*-PANTOTHENATE CONTENT OF MULTIVITAMIN PREPARATIONS

Sample	Mg. per ml. or Vial — Label Claim	Found
1. Injectable, lyophilized, B vitamins,[a] C, gentisic acid ethanolamide	20	22.7
2. Injectable, lyophilized, B vitamins,[a] C	5	7.13
3. Injectable, lyophilized, B vitamins,[a] C	5	5.20
4. Liquid drops, B vitamins,[a] A, C, D	8.33	10.2

[a] Including thiamine hydrochloride, riboflavin, pyridoxine hydrochloride, niacinamide, vitamin B_{12}, and sodium *d*-pantothenate.

Thin-Layer Chromatographic Identity Test for Steroids in Sesame Oil Preparations

By B. P. KORZUN and S. BRODY

A thin-layer chromatographic method is described as a rapid identity test for methandrostenolone,[1] estradiol dipropionate,[2] testosterone propionate,[3] desoxycorticosterone acetate,[4] and aldosterone acetate in sesame oil preparations. Preliminary extractions are not necessary to obtain desired results.

IT WAS desirable to obtain a rapid method for identifying steroids and decomposition products in sesame oil preparations. Attempts to apply paper chromatography failed because the sesame oil interfered, and the low concentration of steroid present did not give discernible spots with the usual reagents. Thin-layer chromatography, a technique described by Stahl (1, 2), using silica gel G as the adsorbent gave good results. The steroid is well separated from the oil and is easily detected with a modified Le Rosen reagent (3). The time required to complete the test is one to two hours.

Received August 1, 1962, from the Research Department, CIBA Pharmaceutical Co., Summit, N. J.
Accepted for publication August 21, 1962.

[1] Marketed as Dianabol by CIBA Pharmaceutical Co.
[2] Marketed as Ovocylin by CIBA Pharmaceutical Co.
[3] Marketed as Perandren by CIBA Pharmaceutical Co.
[4] Marketed as Percorten by CIBA Pharmaceutical Co.

EXPERIMENTAL

Apparatus.—The apparatus for coating the glass plates and other accessories is commercially available from Research Specialties Co., Richmond, Calif.; Arthur H. Thomas Co., Philadelphia, Pa.; and Desaga, Heidelberg, Germany. The adsorbent used is silica gel G.[5]

Preparation of Plates.—A slurry of 30 Gm. of silica gel G and 60 ml. of water is prepared and poured into applicator and spread over the plates.

[5] Manufactured according to specifications of E. Stahl by Merck, A. G., Darmstadt, Germany, and available through Research Specialties Co. and Terra Chemicals, Inc., New York.

Accepted for publication August 21, 1962.

[1] Marketed as Dianabol by CIBA Pharmaceutical Co.
[2] Marketed as Ovocylin by CIBA Pharmaceutical Co.
[3] Marketed as Perandren by CIBA Pharmaceutical Co.
[4] Marketed as Percorten by CIBA Pharmaceutical Co.

EXPERIMENTAL

Apparatus.—The apparatus for coating the glass plates and other accessories is commercially available from Research Specialties Co., Richmond, Calif.; Arthur H. Thomas Co., Philadelphia, Pa.; and Desaga, Heidelberg, Germany. The adsorbent used is silica gel G.[5]

Preparation of Plates.—A slurry of 30 Gm. of silica gel G and 60 ml. of water is prepared and poured into applicator and spread over the plates.

[5] Manufactured according to specifications of E. Stahl by Merck, A. G., Darmstadt, Germany, and available through Research Specialties Co. and Terra Chemicals, Inc., New York.

The plates are then activated in an oven at 80° for 2 hours, and stored over a desiccant in an air-tight container.

Sample Application.—The samples are applied as a streak 2.5 cm. wide, 2.5 cm. apart, and 1.5 cm. from the bottom of the plate. This is accomplished with a micropipet just above the point of application and allowing the solution to be deposited uniformly as the pipet is passed along the 2.5 cm. length. The sample is applied in a volume sufficient to deposit 100 mcg. of the steroid on the plate. An equal volume of sesame oil used to prepare the sample is run as a reference and a 100 mcg. steroid reference sample is also applied. The concentration of steroid in the sesame oil preparation ranges from 0.5 mg./ml. to 50 mg./ml. Therefore, the reference samples of sesame oil must be applied at a volume equal to the volume required to apply 100 mcg. of steroid in the sample preparation.

Solvent Systems.—The developing chambers are lined with filter paper to saturate the chambers. The solvent for testosterone propionate and desoxycorticosterone acetate is chloroform. The solvent for estradiol dipropionate is benzene-methylene chloride (4:6); for aldosterone acetate the solvent is chloroform-ethyl acetate (7:3); and for methandrostenolone the solvent is chloroform-methanol (98:2). The length of development is 15 cm. from the point of application for all solvent systems. After the first development the solvent is dried and developed again.

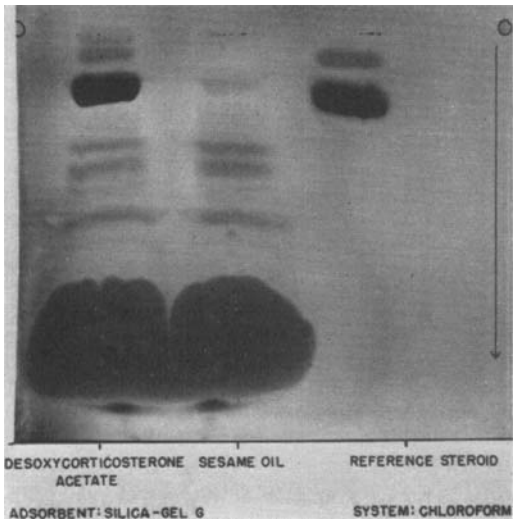

Fig. 1.

Detection.—The steroids are revealed by spraying the plate with a modified Le Rosen reagent (3). The reagent is prepared by dissolving 0.8 ml. formaldehyde (37%) in 10 ml. sulfuric acid and diluted with 3 ml. water. After being sprayed, the plate is heated in an oven at 80° for 5 to 10 minutes. The steroids produce visible colored spots and also produce fluorescent spots under an ultraviolet lamp (3660 Å.).

RESULTS

Figure 1 shows a typical separation of the steroid in sesame oil. The reference steroid shows another slower moving band which can be detected in the oil preparation. Also, another band is detected at the origin in the sample which is not detected in the sesame oil or the reference steroid and which could be a decomposition product of the steroid. Therefore, it is necessary to run a sesame oil reference sample to determine which bands are due to the steroid. Table I lists the R_f values and the colors produced after spraying with formalin reagent. The identity test can be accomplished in one to two hours.

TABLE I.

Steroid	R_f Value[a]	Color	
		Visible	Fluorescent
Methandrostenolone	0.40	Brown	Salmon pink
Estradiol dipropionate	0.45	Red	Orange
Testosterone propionate	0.40	Dark green	Pale pink
Desoxycorticosterone acetate	0.15	Blue	Red
Aldosterone acetate	0.30	Dark yellow	Yellowish green

[a] Value for steroid in solvent described.

Book Notices

Pharmazeutisches Taschenbuch. 5th ed. Wissenschatliche Verlagsgesellschaft MBH., Postfach 40, Stuttgart, Germany, 1962. vii + 1158 pp. 17 × 11.5 cm. Price DM 58.

For persons working in the pharmaceutical and related sciences, this handbook (in German) collects a considerable amount of information, mainly in tabular form, on drugs. Much of the information available in this book can be obtained by consulting other reference sources; its chief contribution would seem to be as a ready, compact, reference source. Sections on formulas frequently used in German hospitals, formulas for reagents, preparation of ointments, practical information derived from the German pharmacopeia, and an extensive section on solubilities, incompatibilities, largest permissible single and daily doses of numerous drugs are included. In addition, there are sections devoted to analytical methods, instruments and apparatus, and an index of nonproprietary names giving the corresponding chemical name in English.

Rapid Microchemical Identification Methods in Pharmacy and Toxicology. By Felix Amelink. Publisher in U. S.: John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. vi + 121 pp. 13.5 × 19 cm. Price $9.

The volume deals with rapid microchemical identification techniques for sulfonamides, sulfones, barbiturates, thiobarbiturates, and hydantoins. It was originally published in the Netherlands and translated from the Dutch manuscript for publication in this country. The procedures described require few reagents and little equipment; nine reagents suffice for the sulfonamides and sulfones and five are sufficient for the barbiturates, thiobarbiturates, and hydantoins. Detailed information for the identification of the substances is provided, including color reactions with the various reagents, optical characteristics, and melting points. The book discusses first the microchemical method and utensils, the polarizing microscope, reagents, and extraction methods. The substances are treated as two main groups, sulfas and barbiturates. Under each section a table of melting point information, a list of synonyms for each substance, and then a section listing the reactions and results of reagents with the particular substance involved is included. Also included is a separate pamphlet of drawings showing the characteristic crystal formations of the substances with the various reagents. This book should provide invaluable assistance to those working with microchemical identification techniques.

Trees and Shrubs of Mexico. By P. C. Standley. Reprinted by the Smithsonian Institution, Washington 25, D. C., 1961. 15.5 × 24 cm. Price $20.

The Smithsonian Institution has reprinted Paul C. Standley's Trees and Shrubs of Mexico, Contr. U. S. National Herbarium, Vol. 23, 1920–26, Part 1 (pp. xvii +1–170) Part 2 (pp. xviii +171–515) 3 (pp. xxviii + 517–848), and 5 (ii + 1313–1721), in 2 paper-bound volumes containing pts. 1–3 and pt. 5, respectvely. The price of these 4 parts is $20, postpaid. Part 4 (pp. xxxix + 849–1312), which is available in the original 1924 edition published by the U. S. National Museum, will be enclosed free of charge to complete the set of 5 parts unless specific instructions to the contrary are received. Orders should be accompanied by check and addressed to Publications Distribution Section, Smithsonian Institution, Washington 25, D. C.

Annual Review of Biochemistry. Vol. 31. Edited by J. M. Luck. Annual Reviews, Inc., 231 Grant Ave., Palo Alto, Calif., 1962. vii + 731 pp. 15 × 22 cm. Price $7.

The current volume, like its predecessors, is an annual review of the principal advances in the field of biochemistry. Topics covered in this volume include Biological oxidations, Oxidative phosphorylation, Chemistry of the carbohydrates, Chemistry of the lipids, Chemistry of peptides and proteins, Amino acid metabolism, Chemistry and function of polypeptide hormones, Nucleic acids; molecular biology of DNA, Metabolism of nucleic acids, Protein biosynthesis, Lipid metabolism, Carbohydrate metabolism, Biochemistry of the water-soluble vitamins, Fat-soluble vitamins, Nutrition—germfree animal research, Biochemistry of cancer (immunological aspects), Inborn errors of metabolism, Biochemistry of fungi, Immunochemistry, and Insect nutrition. Author and subject indexes for Vol. 31 as well as cumulative author and chapter title indexes for Vols. 27–31 are appended.

Pharmacogenetics, Heredity and the Response to Drugs. By Werner Kalow. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. vi + 231 pp. 18 × 26 cm.

This volume, apparently a pioneer effort in its field, deals with pharmacologic responses and their modification by hereditary influences, *i.e.*, pharmacogenetics. The book stresses genetic factors which cause an alteration of drug response but the book can only be said to point out illustrative examples of genetic influence on therapeutic response to certain drugs. However, it appears to be an excellent starting point for those interested in this newer field of pharmacogenetics. An adequate index is appended for ready reference and lists of source materials, both genetic and pharmacologic, follow each section to facilitate further study of the topic discussed. Unfortunately, the text is set in "cold type" which reduces its readability.

Book Notices

Pharmazeutisches Taschenbuch. 5th ed. Wissenschatliche Verlagsgesellschaft MBH., Postfach 40, Stuttgart, Germany, 1962. vii + 1158 pp. 17 × 11.5 cm. Price DM 58.

For persons working in the pharmaceutical and related sciences, this handbook (in German) collects a considerable amount of information, mainly in tabular form, on drugs. Much of the information available in this book can be obtained by consulting other reference sources; its chief contribution would seem to be as a ready, compact, reference source. Sections on formulas frequently used in German hospitals, formulas for reagents, preparation of ointments, practical information derived from the German pharmacopeia, and an extensive section on solubilities, incompatibilities, largest permissible single and daily doses of numerous drugs are included. In addition, there are sections devoted to analytical methods, instruments and apparatus, and an index of nonproprietary names giving the corresponding chemical name in English.

Rapid Microchemical Identification Methods in Pharmacy and Toxicology. By Felix Amelink. Publisher in U. S.: John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. vi + 121 pp. 13.5 × 19 cm. Price $9.

The volume deals with rapid microchemical identification techniques for sulfonamides, sulfones, barbiturates, thiobarbiturates, and hydantoins. It was originally published in the Netherlands and translated from the Dutch manuscript for publication in this country. The procedures described require few reagents and little equipment; nine reagents suffice for the sulfonamides and sulfones and five are sufficient for the barbiturates, thiobarbiturates, and hydantoins. Detailed information for the identification of the substances is provided, including color reactions with the various reagents, optical characteristics, and melting points. The book discusses first the microchemical method and utensils, the polarizing microscope, reagents, and extraction methods. The substances are treated as two main groups, sulfas and barbiturates. Under each section a table of melting point information, a list of synonyms for each substance, and then a section listing the reactions and results of reagents with the particular substance involved is included. Also included is a separate pamphlet of drawings showing the characteristic crystal formations of the substances with the various reagents. This book should provide invaluable assistance to those working with microchemical identification techniques.

Trees and Shrubs of Mexico. By P. C. Standley. Reprinted by the Smithsonian Institution, Washington 25, D. C., 1961. 15.5 × 24 cm. Price $20.

The Smithsonian Institution has reprinted Paul C. Standley's Trees and Shrubs of Mexico, Contr. U. S. National Herbarium, Vol. 23, 1920–26, Part 1 (pp. xvii +1–170) Part 2 (pp. xviii +171–515) 3 (pp. xxviii + 517–848), and 5 (ii + 1313–1721), in 2 paper-bound volumes containing pts. 1–3 and pt. 5, respectvely. The price of these 4 parts is $20, postpaid. Part 4 (pp. xxxix + 849–1312), which is available in the original 1924 edition published by the U. S. National Museum, will be enclosed free of charge to complete the set of 5 parts unless specific instructions to the contrary are received. Orders should be accompanied by check and addressed to Publications Distribution Section, Smithsonian Institution, Washington 25, D. C.

Annual Review of Biochemistry. Vol. 31. Edited by J. M. Luck. Annual Reviews, Inc., 231 Grant Ave., Palo Alto, Calif., 1962. vii + 731 pp. 15 × 22 cm. Price $7.

The current volume, like its predecessors, is an annual review of the principal advances in the field of biochemistry. Topics covered in this volume include Biological oxidations, Oxidative phosphorylation, Chemistry of the carbohydrates, Chemistry of the lipids, Chemistry of peptides and proteins, Amino acid metabolism, Chemistry and function of polypeptide hormones, Nucleic acids; molecular biology of DNA, Metabolism of nucleic acids, Protein biosynthesis, Lipid metabolism, Carbohydrate metabolism, Biochemistry of the water-soluble vitamins, Fat-soluble vitamins, Nutrition—germfree animal research, Biochemistry of cancer (immunological aspects), Inborn errors of metabolism, Biochemistry of fungi, Immunochemistry, and Insect nutrition. Author and subject indexes for Vol. 31 as well as cumulative author and chapter title indexes for Vols. 27–31 are appended.

Pharmacogenetics, Heredity and the Response to Drugs. By Werner Kalow. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. vi + 231 pp. 18 × 26 cm.

This volume, apparently a pioneer effort in its field, deals with pharmacologic responses and their modification by hereditary influences, *i.e.*, pharmacogenetics. The book stresses genetic factors which cause an alteration of drug response but the book can only be said to point out illustrative examples of genetic influence on therapeutic response to certain drugs. However, it appears to be an excellent starting point for those interested in this newer field of pharmacogenetics. An adequate index is appended for ready reference and lists of source materials, both genetic and pharmacologic, follow each section to facilitate further study of the topic discussed. Unfortunately, the text is set in "cold type" which reduces its readability.

COMPROMISING PHARMACEUTICAL EDUCATION

Numerous speakers and writers have devoted an almost endless stream of attention in recent years to the changes which have taken place in the field of pharmacy. However, recent developments affecting the orientation of pharmaceutical education make it appear that certain new concepts are now being advanced which seem to call for specific comment.

A few so-called "foreward-looking" pharmacy schools have announced and widely publicized the introduction of revised or new curricula designed to produce pharmacy graduates who will be "better businessmen, better salesmen, and better merchandisers." In some cases abbreviated programs of study are offered for specialized groups, such as prospective medical service representatives. While the specific programs at these schools differ somewhat, they all have one thing in common—commercial courses are being added at the expense of courses in the pharmaceutical sciences.

It remains our firm conviction that it is the primary responsibility of pharmaceutical educators to lead the way in assuring a proper professional-oriented education for tomorrow's pharmacists. These educators must not permit themselves to be led astray into the same pitfalls from which many of today's pharmacists are desperately trying to extricate themselves!

Fortunately, other schools are wisely resisting ill-advised suggestions that they adopt similar programs and philosophies. And although they are implementing well-considered changes in their curricula, which will add to the professional competence and abilities of their graduates, these latter schools are standing by the traditional proposition that it is properly the function of the educational institution to determine what the student should be taught to equip him suitably for his professional pursuits. Consequently, it is particularly offensive that the pressures to reorient educational pursuits toward the commercial aspects are often coming from vocal sources outside the schools of pharmacy, but which nevertheless wish to influence the intended goals of a pharmaceutical education.

Review Article

X-ray Emission Spectroscopy in Pharmaceutical Analysis

By G. J. PAPARIELLO and W. J. MADER

X-RAY EMISSION spectroscopy (also called X-ray fluorescent spectroscopy) is a rapid, nondestructive, highly sensitive, and precise technique amenable to and applicable to the pharmaceutical control laboratory.

A concise consideration of X-ray fundamentals is presented as an introduction and orientation for those readers with only a superficial knowledge of X-ray methods. The advanced reader is referred to two excellent and very comprehensive books on the subject by Birks (1) and by Liebhafsky and co-workers (2).

FUNDAMENTALS

The Origin of X-rays.—X-rays are produced when fast-moving electrons impinge on matter. The phenomena resulting from the deceleration of such electrons are very complex, and X-rays result from two general types of interaction of the electrons with the atoms of the target material. A high-speed electron may strike and displace a tightly bound electron deep in the atom near the nucleus, thereby ionizing the atom. When a certain inner shell of an atom has been ionized in this manner, an electron from an outer shell may fall into the vacant place, with the resulting emission of an X-ray characteristic of the atom involved. This process produces the characteristic line spectrum of the target element. This production of X-rays is a quantum process similar to the origin of the optical spectra; however, there is a second process in which the high-speed electron is simply slowed down in passing through the strong electric field near the nucleus of an atom. X-radiation produced in this manner is independent of the nature of the atoms being bombarded, and appears as a band of continuously varying wavelength whose lower limit is a function of the maximum energy of the bombarding electrons as shown in Fig. 1.

Continuous Spectrum.—The short-wavelength limit of the continuous spectrum, as seen for tungsten in Fig. 1, is clearly a quantum phenomenon. This short-wavelength limit discovered by Duane and Hunt (3) obeys the relationship

$$\lambda \text{ min.} = \frac{12{,}350}{V} \qquad \text{(Eq. 1)}$$

where λ min. is the minimum wavelength in Ångströms and V is the voltage in volts. This

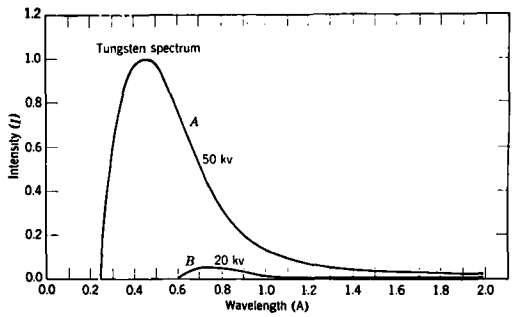

Fig. 1.—The continuous X-ray spectrum. [Reprinted with permission from Liebhafsky, Pfeiffer, Winslow, and Zemany, "X-Ray Absorption and Emission in Analytical Chemistry," Wiley, 1960.]

Received from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.

equation is merely the standard equation relating quantum energy to frequency and is expressed in convenient units. Although the minimum wavelength is independent of the target element, the overall intensity of the spectrum does depend upon the atomic number, Z. This dependency is usually expressed in terms of the frequency, ν, rather than as a function of the wavelength, λ. This relationship is

$$I = AZ(\nu_{max.} - \nu) + BZ^2 \qquad \text{(Eq. 2)}$$

where I is the intensity obtained at a frequency, υ, when $\upsilon_{max.}$ is the maximum frequency (minimum wavelength) obtainable and A and B are constants. One can see from the above expression that the heavier elements will yield more intense primary radiation at all the wavelengths considered.

Characteristic Radiation.—Characteristic radiation from the target element is produced when the high-voltage electrons from a filament have sufficient energy to knock out the inner electrons of the target atoms. Moseley made the first systematic investigation into the production of characteristic radiation (4, 5). He studied the K and L series spectra of 38 different elements by using them successively as the target element and observed that the same type of lines occurred for all of these elements but that they occurred at different wavelengths. From this work Moseley derived the relationship between the atomic number of an element, Z, and the wavelength, λ, at which the characteristic lines of the element occur, or

$$\frac{1}{\lambda} \propto Z^2 \qquad \text{(Eq. 3)}$$

The proportionality constant needed in the above expression is dependent upon which series is being considered. Figure 2 is an illustration of characteristic line dependency on atomic number.

When the applied voltage is sufficient, the filament electrons knock out the inner electrons of the target atoms, and the characteristic lines of the target element will then be superimposed on the continuous radiation curve as in Fig. 3 for molybdenum.

For any element, there is more than one characteristic line because an electron can be ejected from more than one electron shell, and this shell vacancy can be filled by an electron from more than one energy level. Thus the lines of the K series occur if an electron is ejected from a K shell and an electron, in accordance with certain selection rules, from an outer shell fills the vacancy in the K shell. If an L-shell electron fills the K-shell vacancy, the emitted line will be K_α radiation; and if a K-shell vacancy is filled by an M-shell electron, the K_β line is emitted. Similarly, such electronic transitions from outer shells to vacancies in the L shell of atoms lead to the production of the lines of the L series. Figure 4 is a schematic representation of the energy levels for an iron atom showing the transitions that correspond to the four lines of the K spectrum.

BASIC X-RAY EMISSION SPECTROSCOPY SYSTEM

Arrangement and Method of Use.—A brief description of the arrangement of the components of an X-ray emission spectrograph and the manner in which it functions is now in order. It should be noted that although many of the

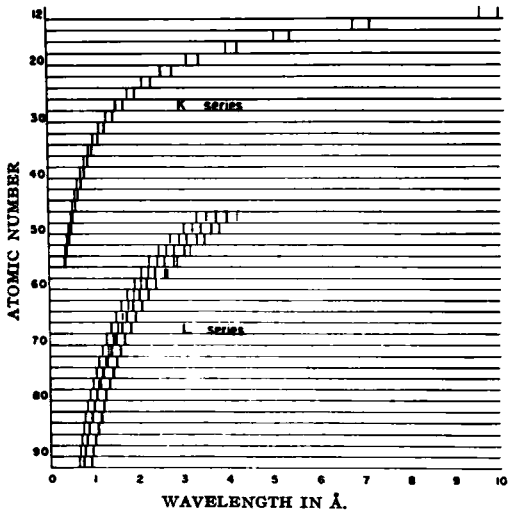

Fig. 2.—The K and L series X-ray lines that are commonly used for X-ray spectrochemical analysis. [Reprinted with permission from Birks, "X-Ray Spectrochemical Analysis," Interscience, 1959.]

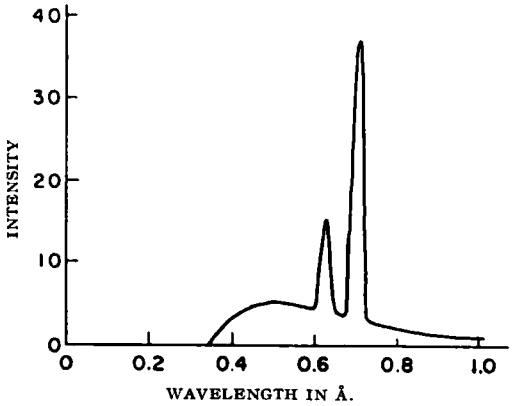

Fig. 3.—The characteristic K series lines of molybdenum superimposed on the continuous spectrum. [Reprinted with permission from Birks, "X-Ray Spectrochemical Analysis," Interscience, 1959.]

components are similar, the arrangement described here for X-ray fluorescent work is different from that used in other X-ray techniques such as diffraction and absorption.

A schematic representation of the arrangement used for fluorescent X-ray spectroscopy is shown in Fig. 5. The main components are *A*, the primary X-ray tube; *B*, the sample; C, the collimator; *D*, the analyzing crystal; and *E*, the detector. The functioning of these components as a unit can best be described by a consideration of the sequence of events which occur when a sample is analyzed. This sequence is as follows:

1. The target material within the X-ray tube is excited, causing the emission of primary radiation. This emitted radiation will consist of characteristic radiation of the target material as well as continuous radiation.

2. This primary radiation strikes the sample with sufficient energy to cause the excitation of the sample. (The foregoing consideration of electron excitation of a primary target and the resulting characteristic lines is applicable to the X-ray photon excitation of the sample as well.) Hence the generation of the characteristic radiation of the elements present in the sample occurs.

3. This characteristic radiation which is emitted in all directions is collected into a parallel bundle by use of the collimator. The collimator is nothing more than a tube filled with parallel metal blades evenly spaced. Thus the radiation emerges from the collimator as a parallel bundle of radiation.

4. This parallel bundle of radiation is polychromatic since each of the elements present in the sample has a different characteristic line. Thus it is necessary to separate this polychromatic radiation into its component parts. This is done by applying the Bragg equation to an analyzing crystal

$$n\lambda = 2d \sin \theta \qquad \text{(Eq. 4)}$$

where n is the order of diffraction, λ is the wavelength of the radiation in Ångströms, d is the interplanar spacing of the analyzing crystal in Ångströms, and θ is the angle formed by the incident radiation and the crystal surface. Rotation of the crystal will change θ, the angle of incidence, and therefore the wavelength of the diffracted radiation will be changed. In this manner the incident polychromatic radiation is separated into its component parts since any one

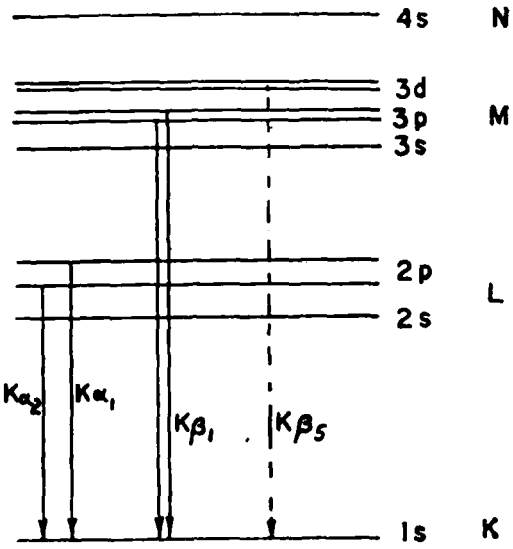

Fig. 4.—Schematic representation of the energy levels for an iron atom showing the transitions that correspond to the four lines of the *K* spectrum. [Reprinted with permission from Birks, "X-Ray Spectrochemical Analysis," Interscience, 1959.]

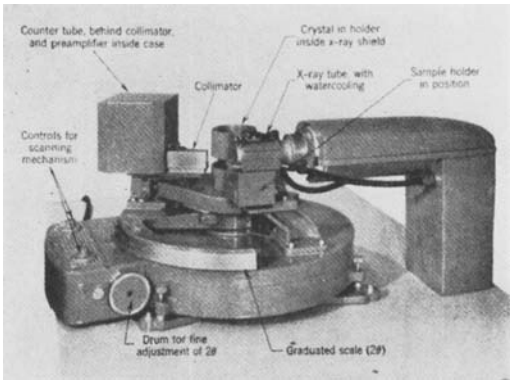

Fig. 6.—XRD-5 D/S spectrogoniometer arranged for X-ray emission work. [Reprinted with permission from Liebhafsky, Pfeiffer, Winslow, and Zemany, "X-Ray Absorption and Emission in Analytical Chemistry," Wiley, 1960.]

crystal rotation position will yield radiation of only one wavelength.

5. The diffracted radiation emerges at an angle of 2 θ with respect to the incident beam and is measured by means of a radiation detector. As stated above, the crystal is rotated, from $\theta = 0°$ to $\theta = 90°$, while the detector is rotated at twice the speed of the crystal so it will always be in position to intercept the diffracted radiation. The goniometer is that part of the equipment which indicates the 2 θ position of the detector. The crystal and detector move as the goniometer moves. The wavelengths of the intercepted X-ray lines indicate the elements that are present in the sample, and the intensities of these lines are an indication of the concentration of each element within the sample.

The actual physical appearance of the instrumentation which performs the above function is depicted in Figs. 6 and 7.

Components.—A more detailed description of several of the components, mentioned just briefly above, is necessary in order for the reader to obtain a more complete understanding of the operation of the X-ray emission spectrograph.

X-ray Tube.—The X-ray tube commonly used in X-ray fluorescent analysis is the hot-cathode or Coolidge tube. These tubes are thoroughly evacuated and sealed. The electrons for excitation are supplied by application of the Edison effect, that is, by emission from a heated filament. A schematic representation of a Coolidge tube is shown in Fig. 8. Two serious drawbacks of this tube are target contamination and the absence of target interchangeability.

Analyzing Crystals.—Crystals which are used as analyzing crystals are not truly perfect crystals but are what are referred to as ideally imperfect crystals. Perfect crystals would give very low diffracted intensities because of primary extinction. Crystals such as lithium fluoride and sodium chloride are ideally imperfect crystals and are commonly used as analyzing crystals.

By inspection of Bragg's equation, Eq. 4, it will be seen that the maximum wavelength that may be diffracted is equal to $2d$, that is, twice the interplanar spacing of the analyzing crystal. Consequently, the wavelengths of the characteristic radiation of the lighter elements become too great for the commonly used crystals. For example, lithium fluoride, $2d = 4.02$ Å, may only be used effectively down to the K lines of potassium, which are at 3.7 Å. Obviously in considering the analysis of lower atomic number elements it is necessary to find suitable crystals with greater d spacings. An example of such a crystal is ethylenediamine ditartrate, $2d = 8.76$ Å, which enables one to work with

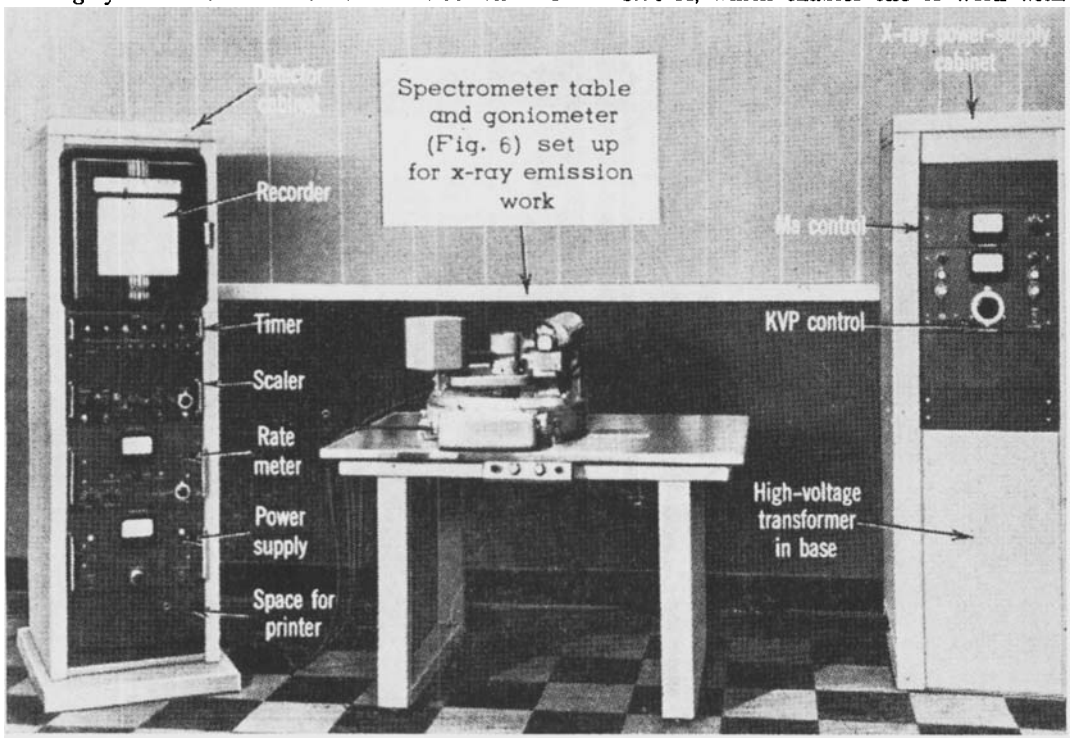

Fig. 7.—XRD-5 D/S spectrometer arranged for X-ray emission work. [Reprinted with permission from Liebhafsky, Pfeiffer, Winslow, and Zemany, "X-Ray Absorption and Emission in Analytical Chemistry," Wiley, 1960.]

aluminum, which has a characteristic line at 8.3 Å.

Detectors.—The detectors in common use for X-ray spectrochemical analysis are the Geiger, proportional, and scintillation counters. These three detectors all operate on the principle of electronic amplification of the energy pulse generated when an X-ray quantum is absorbed. In this way, signals strong enough to operate scaling or integrating circuits are obtained.

It should be noted that photographic film as a means of detection has wide use in X-ray diffraction work but is of little use in emission work.

LIMITING FACTORS OF X-RAY FLUORESCENT ANALYSIS

Fluorescent Yield.—The X-ray fluorescent analysis of all elements is not possible at the present time; however, the analysis of those elements with an atomic number of 23 or above can be performed quite simply and without any special equipment adaptations. On the other hand, the analysis of those elements with an atomic number of 11 or below cannot be assayed by X-ray fluorescent methods. The "light elements," elements with an atomic number of 12 to 22, represent the intermediate range where analysis is possible only after certain difficulties are overcome.

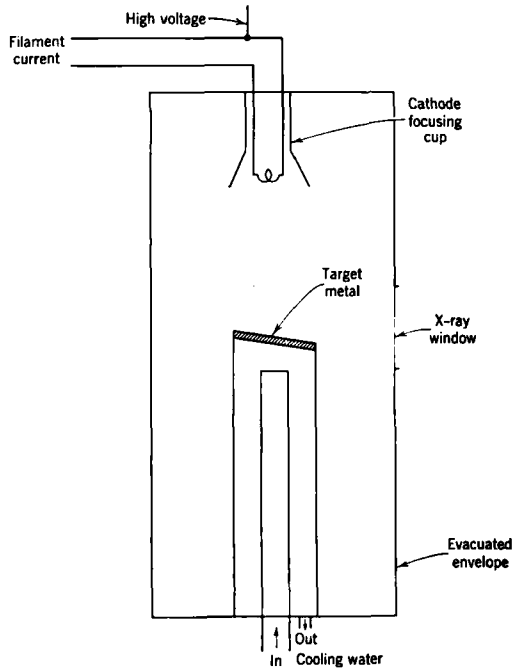

Fig 8.—Schematic diagram of a Coolidge X-ray tube. [Reprinted with permission from Liebhafsky, Pfeiffer, Winslow, and Zemany, "X-Ray Absorption and Emission in Analytical Chemistry," Wiley, 1960.]

The main reason that an elemental distinction must be made, according to atomic number, is that the fluorescent yield of the elements is less than unity, and as the atomic number decreases so does the fluorescent yield as illustrated in Fig. 9. It has been shown that 70% of the K radiation escapes from the atoms with an atomic number of 55, but only 10% escapes from atoms with atomic numbers less than twenty (6). The Auger effect is responsible for this difference in fluorescent yield. Normally when a K electron is knocked out of an atom, another electron will replace it, giving rise to one of the K series emission lines. The Auger effect occurs when the K emission radiation does not leave the atom but instead knocks out an L electron to generate an L series. The probability of the Auger effect occurring increases with a decrease in atomic number.

There are other factors besides the Auger effect which limit the applicability of X-ray fluorescence to the determination of the lower atomic number elements. One of these factors is the air absorption of the X-ray radiation as it travels through this medium. The weaker radiations of the lower atomic number elements are, of course, more easily absorbed. It is for this reason that a helium atmosphere or a vacuum path is necessary in order to determine the "light elements."

Background Radiation.—As in other spectroscopic methods of analysis, the line-to-background ratio is critical when considering the lower limits of detection of a method. Hence some mention should be made of the processes which produce the background radiation in X-ray fluorescence and therefore limit the range of detection. There are two scattering processes, coherent and Compton, which increase the background intensity.

Coherent scattering or unmodified scattering occurs when a photon undergoes an elastic collision with the sample. In this process the primary radiation is not absorbed nor does it cause fluorescence. It is merely reflected unchanged off the sample. Thus continuous background and weak characteristic primary radiation lines are always found superimposed on the fluorescent spectrum of a sample.

Compton or incoherent scattering occurs when an X-ray photon strikes an atom, especially the lower atomic number atoms such as oxygen, carbon, or hydrogen, and it is inelastically scattered, losing part of its energy. This loss of energy results in an increase in wavelength of the scattered X-ray photons. For a sample containing a high percentage of hydro-

carbons or other light elements, the Compton scattering will increase relative to the coherent scattering and may even be stronger than the coherent scattering.

Background scattering has a decided influence on the line-to-background ratio and therefore on the limit of detectability. The limit of detection of an element by X-ray fluorescence has been related to the background intensity by Birks (1). Birks states that the minimum composition detectable by X-ray fluorescence is that concentration that yields an intensity equal to three standard deviations of the background intensity. Thus to be detectable, a line must be at least three standard deviations above the background. Using this criterion, some typical orders of magnitude values for the minimum detectable limit, in parts per million, are shown in Table I.

METHODS OF ANALYSIS

Qualitative Analysis.—In order to determine which X-ray detectable elements are present in a sample, one merely has to scan through a wide 2 θ degree range recording the reflected intensities. That is, with the present-day commercial X-ray equipment it is possible to automatically scan and record, obtaining a plot of intensity *versus* 2 θ angle as shown in Fig. 10. From a chart recording of this kind, one obtains information as to what elements are

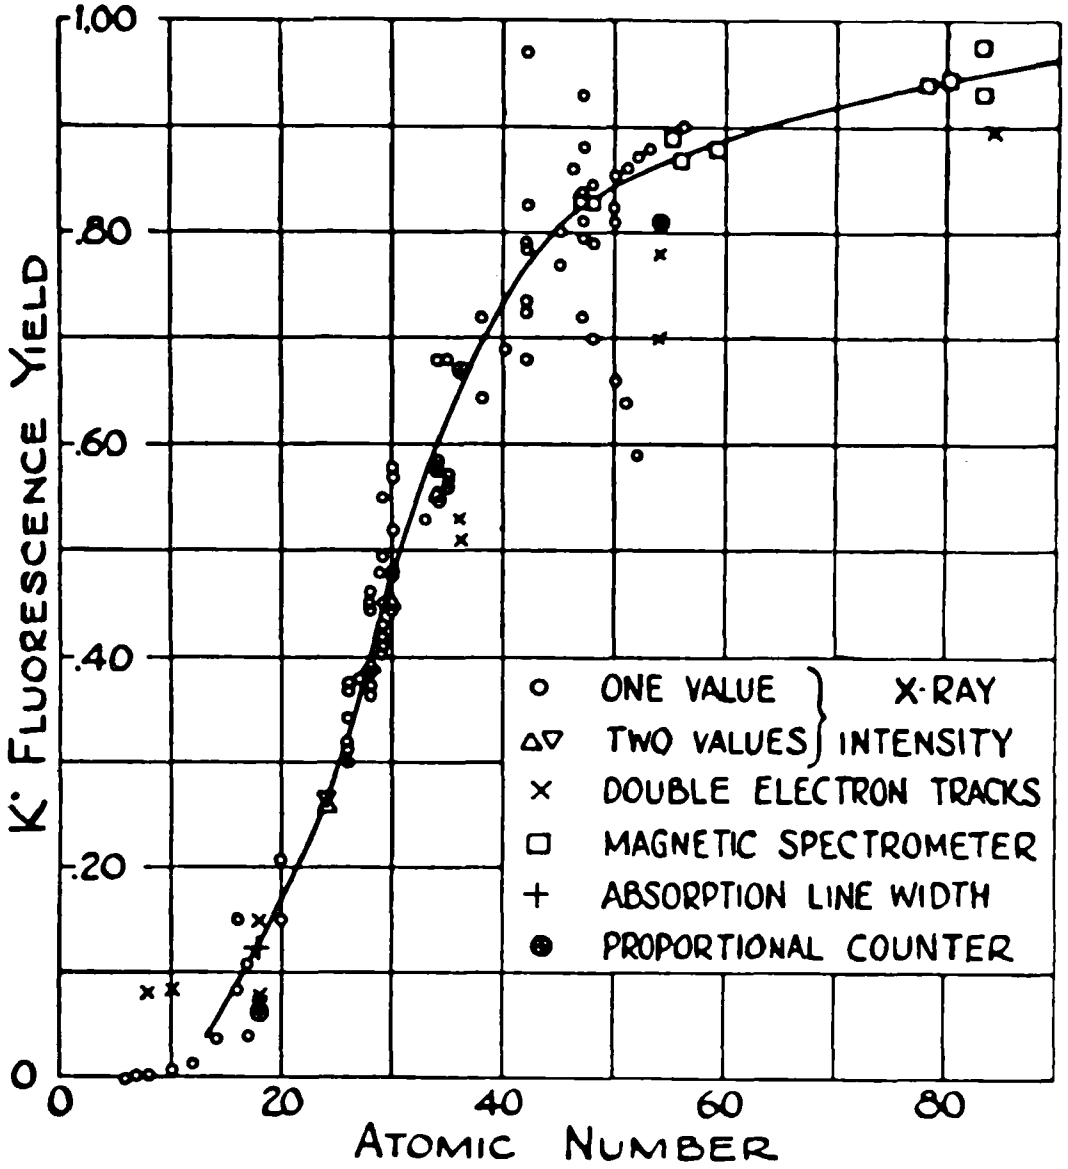

Fig. 9.—Fluorescent yield as a function of atomic number. [Reprinted with permission from Birks, "X-Ray Spectrochemical Analysis," Interscience, 1959.]

TABLE I.—MINIMUM DETECTABLE LIMIT

Nonconcentrated	Concentrated
10 p.p.m.	0.01 p.p.m.[a]
100 p.p.m. for light element in heavy matrix	
1 p.p.m. for medium element in light matrix	

[a] There is, of course, no absolute lower limit if large enough starting quantities are used. There are, however, practical limitations on both quantity and preparation time. The value listed represents a limit actually achieved in what is considered a practical analytical procedure (1).

present and their relative concentrations. It should be borne in mind that a great variety of sample forms can be analyzed both qualitatively and quantitatively by means of X-ray fluorescence (7). For example, analyses of rocks, powders, metal plates, wires and bars, briquets, solutions, films, evaporated residues, and massive solids are all possible with only slight if any instrumental modifications.

Quantitative Analysis—To quantitatively determine the concentration of a particular element in a sample, the goniometer must be positioned at a 2 θ angle peculiar to the element in question. Usually this 2 θ angle is the angle corresponding to the wavelength at which the $K\alpha$ first-order line of the sample element is reflected by the analyzing crystal. The counter is then allowed to accumulate either a fixed number of counts, the time for such a count being recorded, or to count for a fixed period of time. It is necessary to relate this intensity measurement to a per cent composition value for this element in the sample.

The relationship between measured intensity and elemental content of sample is controlled by what is known as the matrix effect. The matrix is everything which is present in the sample with the exception of the element of interest. Thus the matrix effect, which consists of both absorption and enhancement effects, is the effect which the elemental composition or matrix of the sample has upon the incident and diffracted radiation. Figure 11 is an illustration of the effect that the matrix has on the intensity-composition relationship. The matrix effect must be corrected for either by computation or physical methods. The computation methods are rather involved and are less popular than the physical methods.

The three principal physical methods are use of calibration standards, use of an internal standard, and the dilution technique.

In the calibration standard method, a series of standards is prepared with varying concentrations of the element in question but with a matrix identical to that of the sample. From this standard series a calibration curve of concentration *versus* intensity can be made. Thus, once the intensity from the unknown sample is obtained, the elemental concentration can be found by use of the calibration curve. In this method the matrix effect is eliminated by duplicating the sample matrix in the prepared standards.

When it is difficult or impossible to reproduce the matrix of the sample, one often resorts to the use of the internal standard. In this procedure the internal standard is added to the sample matrix and the prepared standard matrix. In this case the sample and standard matrix do not have to be identical. What actually is plotted in order to obtain the concentration of the element in the sample is the ratio of the internal standard intensity to the desired element intensity *versus* the desired element composition.

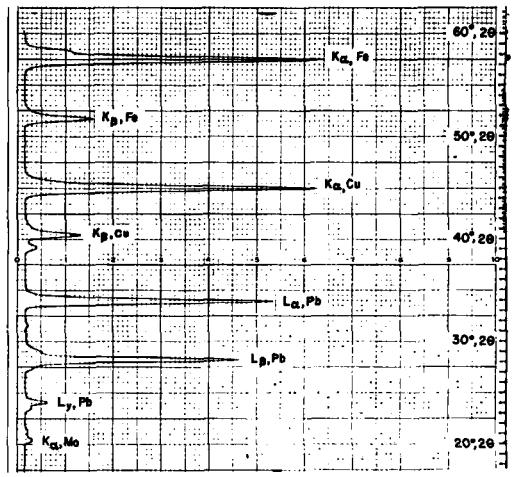

Fig. 10.—X-ray fluorescent chart recording of a sample consisting of copper, lead, and iron.

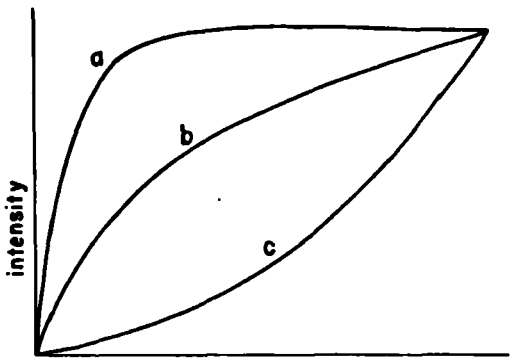

Fig. 11.—Variation of the intensity *vs.* composition curve with matrix effect. Curve *a*, a heavy element in a light-element matrix; in curve *b*, the absorption of the matrix is only slightly less than the self-absorption of the desired element; in curve *c*, the matrix absorption is slightly greater than the self-absorption of the desired element. [Reprinted with permission from Birks, "X-Ray Spectrochemical Analysis," Interscience, 1959.]

It is important that the internal standard chosen have an atomic number close to that of the element in question so that the absorption and enhancement effects of the matrix will be similar for the two elements.

The third physical method, the dilution technique, is simply a method whereby the samples' absorption and enhancement effects are reduced to a negligible amount by a physical dilution of the sample in a relatively transparent material. Materials often used for this purpose are water, organic solvents, starch, alumina, and borate glass.

APPLICATIONS

The use of X-ray fluorescent analysis in the pharmaceutical industry is certainly not extensive, and, consequently, there are not a great many published applications; however, the authors will supplement the published works of others with some of their own unpublished experiences in order to give the reader a full appreciation of the usefulness of X-ray fluorescence.

Qualitative Inspection.—X-ray spectroscopy is often utilized for the qualitative inspection of raw materials, intermediates, and final products. The reason for this is that a quick X-ray fluorescent scan will immediately reveal whether or not metal contamination has occurred or whether or not the concentration of a metal in a product has varied. Thus fluorescent scans are routinely taken of certain raw materials to assure the chemist that the same quality of material is being received.

Routine Quantitative Procedures.—There are several good examples of quantitative X-ray methods that have been adopted as routine control procedures. In almost all of these cases the analysis by any other method was either impossible or prohibitively time consuming.

R. B. Scott developed an X-ray method of analysis for the alkaloid hyoscine hydrobromide in a tablet formulation which contained one hundred times as much diphenhydramine hydrochloride (8). It was possible to analyze for halide conventionally, but the predominance of chloride was so great that the assay was meaningless for the small percentage of bromide. The X-ray fluorescent method using the $K\alpha$ line of bromine was found to be precise, convenient, fast, and unhampered by the presence of chloride.

The analysis of most of the minerals in vitamin-mineral supplement products is one of the most outstanding applications of X-ray fluorescence in this indusitry. Manganse, iron, potassium, zinc, calcume, and copper have been quantitatively assayed in a vitamin-mineral preparation by use of an internal standard technique (9). A wet chemical method of analysis of the minerals in such a product is at least ten times more time consuming than the X-ray method.

The arsenic content of arsenosobenzene, a coccidiostat used in veterinary food products is determined by an X-ray spectrographic method (9). The wet chemical method for arsenic in this product took 2 to 3 days to complete, whereas the X-ray method requires only 1 hour.

The analysis of merthiolate, a mercurial preservative, at the fifty parts per million level in pharmaceutical preparations is a relatively simple task if one assays for the mercury present by X-ray fluorescence (10).

The use of selenium dioxide and selenium dioxide in the presence of mercury as dehydrogenation catalysts in the chemical manufacture of certain steroids necessitated the analysis of selenium and mercury in the final product. Olson and Shell developed an X-ray fluorescent method of analysis for the determination of selenium and selenium and mercury in the presence of each other at the parts per million range (11, 12). This method has an accuracy of ± 1 p.p.m. in the range of 2 to 40 p.p.m. for both selenium and mercury.

Special Problems.—X-ray fluorescence has been quite useful as a tool in the solution of certain perplexing problems. The following are some examples of these problems.

A large pharmaceutical firm was confronted with the problem of a precipitate appearing in their diphtheria-tetanus toxoid preparation after the material had been packaged (8). An X-ray fluorescent scan of the precipitate revealed that zinc was present. This discovery led to an investigation of the rubber stoppers of the container since zinc is often used in rubber compounding. An X-ray examination of the rubber closures revealed zinc to be present. Obviously, the precipitation in the preparation was caused by zinc that was leached out of the rubber stoppers. The problem was quickly eliminated by changing closure specifications with respect to zinc content.

Another firm was faced with the problem of reporting to the Federal Food and Drug Administration the amount of ink present on an imprinted capsule (9). This problem was solved by an X-ray fluorescent determination of the titanium content in the ink itself and on the capsule. Calculations revealed that each capsule bore 13 mcg. of ink.

Trace Analysis.—Possibly one of the most dramatic applications of X-ray emission spec-

troscopy in the pharmaceutical industry has been in the determination of trace quantities of metallic elements either present as impurities or intentionally added in pharmaceutical formulations. X-ray emission spectroscopy acts as a a fingerprint of the formulation and has been used to positively identify the source of manufacture of the product. This technique, due to its high sensitivity, quantitative aspects, and nondestructive nature, has proven infallible to date.

Organic Analysis Through Inorganic Association.—As previously mentioned, those elements with an atomic number of 11 or below cannot be assayed by X-ray fluorescent methods because of the minimal fluorescent yield of these elements. Thus, the direct analysis of organic compounds by X-ray fluorescent methods is impossible at the present time. This is a great advantage when considering the analysis of a heavy element in an organic matrix, but it is also a serious limitation on a fine tool. Consequently, work has been done in this laboratory to illustrate the feasibility of determining organic substances indirectly through their association with an X-ray detectable element (13). Three different methods of associating an X-ray detectable element with an organic compound and assaying for this element have already been explored. They are the determination of phenolic and unsaturated compounds by bromination, the determination of 5-chloro-7-iodo-8-quinolinol by chelation, and the determination of ammonium acetate by salt formation. These methods provide specificity, selectivity, and sensitivity. Specificity and selectivity are obtained by the proper choice of the inorganic association reaction. Thus in many cases lengthy, time-consuming, error-introducing separation procedures may be eliminated. Such methods also have the potential of assaying, without isolation, microgram quantities in highly colored, many component solutions. This method should be quite useful in the analysis of drugs and metabolites in body fluids. In support of this statement, it might be mentioned that Natelson and Bender have already determined the calcium, chlorine, sulfur, and potassium content of a 20-μl. sample of serum by X-ray fluorescence (14, 15).

CONCLUDING REMARKS

Advantages and Disadvantages.—A consideration of the advantages and disadvantages of X-ray emission methods will emphasize the major points presented in the main body of this text.

The advantages of X-ray emission spectroscopy can be listed as follows:

1. Rapid.
2. Nondestructive.
3. Trace determinations possible.
4. Many sample forms are acceptable; *e.g.*, solutions, powders, intact tablets, *etc.*
5. Organic compounds do not interfere in the analysis of heavy atoms.
6. Equipment can easily and rather inexpensively be modified for diffraction use as well.
7. Once methods are developed, they can easily be performed by a technician.

The principal disadvantages are the initial cost of the equipment, which is \$15,000 to \$20,000, and the fact that direct analysis of organic compounds and elements with an atomic number less than 12 is not possible at the present time.

Future.—A number of uses for X-ray emission spectroscopy in pharmaceutical analysis have already been cited; however, as more investigators become involved in its use, one can be sure that many more applications will be uncovered.

As a matter of fact, it has already been shown that X-ray emission lends itself quite nicely to automation for the analysis of large numbers of samples as well as to the analysis of dynamic systems (1). It is highly probable that in the near future extensive use will be made of X-ray emission as an automatic analyzer in quality control laboratories. Also, greater use will be made of X-ray fluorescence in dynamic systems studies such as rate of solution, rate of precipitation, *etc.*

The vast amount of research that is now in progress on analyzing crystals, detectors, and X-ray tubes will someday make it possible to determine some, if not all, of the lower atomic number elements by X-ray emission methods.

Resolution of Binary Mixtures by Partial Extraction and Specialized Spectrophotometric Techniques

By M. PERNAROWSKI and V. A. PADVAL†

One of the most common procedures in analytical chemistry is the separation of two substances by solvent–solvent extraction. Complete separation of the two ingredients in the binary mixture is, however, unnecessary for quantitative assay purposes. Simultaneous analysis of the ingredients is possible by using the relationship that exists between measured partition coefficients and the relative concentration of one of the substances in the binary mixture. The method is based on the distribution of the pure substances between two immiscible solvents and on specialized spectrophotometric techniques.

ONE OF THE FIRST steps in the analysis of a pharmaceutical is the separation of one or more of the ingredients from the bulk form of the dosage unit. This is most often carried out by the solvent–solvent extraction process based on the distribution law. Analytical conditions are usually so fixed that at the completion of the extraction process only one of the ingredients is present in one of the phases of the two-phase system. If these conditions are altered in such a way that both ingredients in a binary system are present in both phases, then a relationship is established between the measured partition coefficient of the mixture and the relative concentration of one of the ingredients in such a mixture. Furthermore, simultaneous analysis does not require the total separation of the ingredients but only partial separation under controlled conditions. This technique is thus analogous to the absorbancy ratio method of analysis described in previous publications (1, 2). The principles of controlled partial extraction are outlined in the literature (3, 4) but the procedures described therein differ from those in this paper in the types of measurements used to evaluate total concentrations and in the mathematical manipulations required in the analysis.

It is not the intention of the authors to discuss or elaborate on the subject of partition coefficients. The fundamentals inherent in the distribution law and the pitfalls associated with the determination of partition coefficients are set forth in textbooks on physical pharmacy (5) or physical chemistry (6). Factors such as temperature, phase volumes, association, dissociation, or chemical reaction of the component with one or both of the solvents must be considered in any investigation involving distribution between two immiscible solvents.

The spectrophotometric terminology and symbology used in this paper shall be that suggested by the National Bureau of Standards (7). Thus, absorbancy (A_s) is equal to the product of the absorbancy index (a_s), the cell length (b), and the concentration (c).

THEORY

When component X is distributed between two immiscible phases, the equilibrium state may be expressed mathematically in the following way

$$K_x = \frac{C_{xu}}{C_{xl}} \qquad \text{(Eq. 1)}$$

K_x, the partition coefficient, is thus equal to the ratio of the concentration of the X component in the upper layer (C_{xu}) to that in the lower layer (C_{xl}). Similarly, the partition coefficient for component Y, K_y, distributed between the same two solvents under similar experimental conditions, is defined as

$$K_y = \frac{C_{yu}}{C_{yl}} \qquad \text{(Eq. 2)}$$

The concentrations of Y in the upper and lower phases are equal to C_{yu} and C_{yl}, respectively. If the distribution of X is not influenced by Y and vice versa, the partition coefficient for the mixture (K_m) containing X and Y may be defined as

$$K_m = \frac{C_{xu} + C_{yu}}{C_{xl} + C_{yl}} \qquad \text{(Eq. 3)}$$

Received April 10, 1962, from the Pharmaceutical Chemistry Section, Food and Drug Directorate, Ottawa, Canada.
Accepted for publication June 7, 1962.
† Present address: New Custom House, Ballard Estate Bombay 1, India.

However, the sum of the concentrations in the two layers is equal to the total concentration of X, C_x, and Y, C_y, in the binary mixture. The concentration of X in the upper layer is thus equal to $C_x - C_{xl}$. This latter value is now substituted for C_{xu} in Eq. 1

$$K_x = \frac{C_x - C_{xl}}{C_{xl}} \qquad \text{(Eq. 4)}$$

Eq. 4 is rearranged

$$C_{xl} = \frac{C_x}{K_x + 1} \qquad \text{(Eq. 5)}$$

Using similar mathematical manipulations, Eq. 1 is defined in terms of C_x and C_{xu}

$$C_{xu} = \frac{K_x C_x}{K_x + 1} \qquad \text{(Eq. 6)}$$

In exactly the same way as shown in Eqs. 5 and 6, C_{yu} and C_{yl} are defined in terms of C_y. All of these quantities are substituted into Eq. 3

$$K_m = \frac{\frac{K_x C_x}{K_x + 1} + \frac{K_y C_y}{K_y + 1}}{\frac{C_x}{K_x + 1} + \frac{C_y}{K_y + 1}} \qquad \text{(Eq. 7)}$$

K_1 is equal to $K_x/(K_x+1)$, K_2 to $K_y/(K_y+1)$, K_3 to $1/(K_x+1)$, and K_4 to $1/(K_y+1)$. Each term in Eq. 7 is divided by $C_x + C_y$. $C_x/(C_x + C_y)$ is now equal to F_x, the fraction of X component in the binary mixture, and $C_y/(C_x + C_y)$ is equal to F_y, the fraction of Y component in the binary mixture

$$K_m = \frac{K_1 F_x + K_2 F_y}{K_3 F_x + K_4 F_y} \qquad \text{(Eq. 8)}$$

However, the sum of F_x and F_y is equal to 1. F_y is, therefore, equal to $1 - F_x$. This latter quantity is substituted for F_y above and the equation is rearranged

$$K_m = \frac{F_x (K_1 - K_2) + K_2}{F_x (K_3 - K_4) + K_4} \qquad \text{(Eq. 9)}$$

A plot of K_m *vs.* the fraction of X in the binary mixture is thus a curve, the extremities of which are equal to the partition coefficients of X, K_x, and Y, K_y. To use this equation K_m, K_x, and K_y must be assigned numerical values during the course of an analysis. This can be conveniently carried out by using the appropriate spectrophotometric techniques.

The determination of partition coefficients by carrying out absorbancy measurements on the two phases of the system has been previously described in the literature (8). Such measurements are usually carried out at those wavelengths at which the pure substance exhibits maximum absorption. Such a technique cannot be used to determine K_m since the phases contain two substances. The total concentration in any one phase can, however, be determined by carrying out absorbancy measurements at an isoabsorptive point, that is, that wavelength at which the two substances have the same absorbancy index value. Methods for locating such a point have been described in a previous publication (2).

At the isoabsorptive point, the following equations are valid

$$C_{xu} + C_{yu} = A_u/a \qquad \text{(Eq. 10)}$$

$$C_{xl} + C_{yl} = A_l/a \qquad \text{(Eq. 11)}$$

The absorbancy index value at the isoabsorptive point is equal to a. A_u is equal to the *total* absorbancy at the isoabsorptive point in the upper phase and A_l is equal to the *total* absorbancy at the isoabsorptive point in the lower phase.

The right-hand members of Eqs. 10 and 11 may now be substituted for K_m in Eq. 3

$$K_m = \frac{A_u/a}{A_l/a} = \frac{A_v}{A_l} \qquad \text{(Eq. 12)}$$

Therefore, a plot of A_u/A_l *vs.* F_x, the fraction of X in the binary mixture, is a curve, the extremities of which are equal to K_x and K_y. A binary mixture may now be analyzed by distributing the pure substances and the binary mixture between two immiscible solvents under controlled conditions.

Eq. 9 can yield only relative quantities but absolute analysis can be carried out by utilizing the above mathematical principles in a slightly different form. From Eqs. 1 and 2, C_{xu} is equal to $K_x C_{xl}$ and C_{yu} to $K_y C_{yl}$. The appropriate terms are substituted for C_{xu} and C_{yu} in Eq. 3

$$K_m = \frac{K_x C_{xl} + K_y C_{yl}}{C_{xl} + C_{yl}} \qquad \text{(Eq. 13)}$$

K_m is, however, equal to A_u/A_l and $C_{xl} + C_{yl}$ to A_l/a. C_{yl} is thus equal to $A_l/a - C_{xl}$. These quantities are substituted into Eq. 13

$$\frac{A_u}{A_l} = \frac{K_x C_{xl} + K_y (A_l/a - C_{xl})}{C_{xl} + (A_l/a - C_{xl})} \qquad \text{(Eq. 14)}$$

The equation is rearranged, each term is multiplied by a and divided by A_l

$$\frac{A_u}{A_l} = \frac{C_{xl}}{A_l}(aK_x - aK_y) + K_y \qquad \text{(Eq. 15)}$$

However, the total concentration of X, C_x, in the binary mixture is equal to $C_{xu} + C_{xl}$. Therefore, C_{xu} is equal to $C_x - C_{xl}$. This latter quantity is substituted into Eq. 1

$$C_{xl} = \frac{C_x}{K_x + 1} \qquad \text{(Eq. 16)}$$

The right-hand member of the above equation is substituted for C_{xl} in Eq. 15

$$\frac{A_u}{A_l} = \frac{C_x}{A_l} \cdot \frac{aK_x - aK_y}{K_x + 1} + K_y \qquad \text{(Eq. 17)}$$

A plot of A_u/A_l *vs.* C_x/A_l results in a straight line with a slope value of

$$\frac{aK_x - aK_y}{K_x + 1}$$

and an intercept value of K_y. Eq. 17 may now be used to determine the quantity of X component in the binary mixture.

An acetophenetidin-caffeine system was investigated to illustrate the method described herein.

EXPERIMENTAL

Apparatus.—(*a*) Beckman model DU spectro-

photometer; (*b*) Eberbach automatic shaker; (*c*) Thomas-Hoover capillary melting point apparatus.

Reagents and Solutions.—(*a*) Acetophenetidin, recrystallized from ethanol, the sample melted between 134.5 and 135.5°; (*b*) caffeine, recrystallized from ethanol, the melting point of the substance was 235.0–236.0°; (*c*) water, saturated with *n*-butanol: add 100 ml. of reagent grade *n*-butanol to 250 ml. of water, shake well, and allow to stand at room temperature for 30 min., filter the aqueous layer through Whatman No. 1 filter paper; (*d*) *n*-butanol, saturated with water: add 100 ml. of water to 250 ml. of reagent grade *n*-butanol, shake well, and allow to stand at room temperature for 30 min., filter the butanol layer through Watman No. 1 filter paper.

Spectral Characteristics of Acetophenetidin and Caffeine.—In water, acetophenetidin absorbs ultraviolet radiant energy most strongly at 245 mμ. Caffeine exhibits maximum absorption at 273 mμ. An isoabsorptive point occurs at 261.5 mμ. Methods for locating isoabsorptive points were described in a previous publication (2).

Solutions were prepared by dissolving the substance in 25.00 ml. of ethanol and diluting to 1 L. with water. Aliquots of such stock solutions were diluted with water to give final concentrations of approximately 8–10 mg. of substance per liter of solution.

Determination of Partition Coefficients.—To a weighed sample of either acetophenetidin or caffeine, add 25.00 ml. of *n*-butanol and 50.00 ml. of water. (References to *n*-butanol and water in the text of this paper imply the solutions described in the second part of this section.) Shake for 1 hour at room temperature. Allow the layers to separate, withdraw suitable aliquots, dilute to 1 L. with water, and determine absorbancy values. The *total* absorbancy in the butanol phase divided by the *total* absorbancy in the aqueous phase is equal to the partition coefficient for the substance.

The partition coefficient for caffeine was found to be 0.83 ±0.01. This value represents six determinations on samples ranging in weight from 0.1990 to 0.2136 Gm. Two-milliliter aliquots of the butanol phase and 4.00-ml. aliquots of the aqueous phase were taken for the determinations. The partition coefficient for acetophenetidin was equal to 16.40 ±0.09. Six samples, ranging in weight from 0.1274 to 0.2078 Gm., were processed in the manner described above. Aliquots of 1.00-ml. (butanol phase) and 25.00-ml. (aqueous phase) were used in the determinations.

Relative Analysis of Mixtures Containing Acetophenetidin and Caffeine.—A 200-mg. sample of the mixture was accurately weighed and transferred to a 125-ml. Erlenmeyer flask. Twenty-five milliliters of butanol and 50.00 ml. of water were added to the flask. The flask was continuously agitated for 1 hour at room temperature. Suitable aliquots were then taken for absorbancy measurements. For commercial preparations containing $2^1/_2$ grains of acetophenetidin and $^1/_2$ grain of caffeine, 2.00 ml. of the butanol phase and 20.00 ml. of the aqueous phase, diluted to 1 L., will give suitable absorbancy readings. All absorbancies were determined at 261.5 mμ. The total absorbancy in the butanol phase divided by the total absorbancy in the aqueous phase is equal to K_m. Eq. 9 may now be used in the analysis of the binary mixture. The numerical form of this equation is

$$K_m = \frac{0.489\ F_x + 0.545}{-0.489\ F_x + 0.546}$$

F_x is equal to the relative concentration of acetophenetidin in the binary mixture. The relative contration of caffeine in the mixture may be determined by subtracting F_x from 1, or by using an equation similar to that above but defined in terms of caffeine. The results of the analysis of 10 mixtures of acetophenetidin and caffeine are reported in Table I.

Table I.—Results of the Analysis of Mixtures Containing Acetophenetidin and Caffeine

Mixture	Acetophenetidin Present, %	Acetophenetidin Found, %	Caffeine Present, %	Caffeine Found, %
1	90.9	90.9	9.1	9.1
2	87.7	87.7	12.3	12.3
3	85.0	84.9	15.0	15.1
4	80.0	80.2	20.0	19.8
5	78.9	79.4	21.1	20.6
6	75.1	75.5	24.9	24.5
7	69.4	68.9	30.6	31.1
8	60.0	60.3	40.0	39.7
9	50.7	51.2	49.3	48.8
10	39.4	40.4	60.6	59.6

Absolute Determination of Acetophenetidin in Mixtures.—The analytical manipulations are identical to those described above. Eq. 17 must be put in its numerical form in order to complete the analysis. This was done by preparing 10 synthetic mixtures containing known quantities of acetophenetidin and caffeine, subjecting the mixtures to the above procedure, and substituting the appropriate numbers for A_u and A_l in Eq. 17. The data were plotted as shown in Fig. 1 and subjected to the method of least squares (9). The numerical form of Eq. 17 is

$$K_m = A_u/A_l = \frac{30.99\ C_p}{A_l} + 0.88$$

In the analysis of unknown mixtures, the total

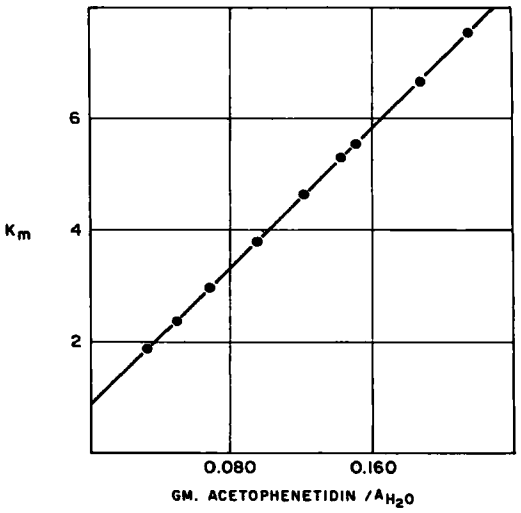

Fig. 1.—Calibration curve for the determination of acetophenetidin in the presence of caffeine.

absorbancy in the butanol phase (A_u) and the total absorbancy in the aqueous phase (A_l) are knowns. C_p, the concentration of acetophenetidin in the sample taken in the analysis, can then be calculated from the above equation. The results of the analysis of acetophenetidin in synthetic mixtures are shown in Table II.

TABLE II.—RECOVERY OF ACETOPHENETIDIN FROM MIXTURES CONTAINING ACETYLSALICYLIC ACID, ACETOPHENETIDIN, AND CAFFEINE

Acetophenetidin Present, Gm.	Acetophenetidin Recovered, Gm.	Recovery, Per Cent

Determination of Acetophenetidin in APC Tablets.—Add 50 ml. of chloroform to an amount of sample equivalent to one tablet. Shake to dissolve as much of the powdered material as possible and then add 10 ml. of 5% sodium bicarbonate solution. Shake, draw off the chloroform layer, and wash with 15 ml. of distilled water. Extract the combined bicarbonate and wash solutions with 2 × 15-ml. portions of chloroform. Wash the chloroform with 10 ml. of water, combine the chloroform extracts, filter through a pledget of cotton wool, wash the cotton wool with a few ml. of chloroform, and evaporate the organic solvent. To the residue, add water and butanol and continue as indicated above. The results of the analysis of a number of commercial preparations are shown in Table III.

DISCUSSION

This method of analysis is based on a single but controlled extraction and on specialized spectrophotometric measurements. Although this confers a degree of specificity to the technique, it also limits its applicability to those binary mixtures which meet the conditions implied by the mathematical derivations. These limitations are mostly those associated with the distribution law and with the spectrophotometric measurements required by the assay.

Eq. 9 yields relative concentrations but places no limitations on the procedures used to determine K_m, K_x, and K_y. Eq. 12, on the other hand, specifies absorbancy measurements at an isoabsorptive point. Consequently, the two components in the binary mixture must characteristically absorb ultraviolet radiant energy and, more important, must show the presence of an isoabsorptive point when the absorbancy index–wavelength curves are superimposed. The exact nature of the spectrophotometric curves is not too important but if the spectrophotometric differences between the two substances are optimal, then some other method of analysis may prove to be faster and more accurate. This method of analysis is, therefore, applicable to those substances which have essentially similar spectral characteristics.

Eq. 9 implies that a plot of K_m *vs.* the relative concentration of one of the substances in the binary mixture should result in a curve. This was found to be experimentally true and such a curve is shown in Fig. 2. This curve is based on the data obtained by subjecting known mixtures of acetophenetidin and caffeine to the procedure described in the previous section. An examination of this figure indicates one of the limitations of this method of analysis. Even though the partition coefficients of the pure substances differ significantly, the rate of change of K_m with relative concentration is small in the 0 to 60% acetophenetidin region. Mixtures having concentrations defined by the above limits will not lend themselves to accurate analysis and consequently this method becomes inoperative. The reason for choosing the binary mixture containing acetophenetidin and caffeine to illustrate the applicability of this technique is thus almost self-evident.

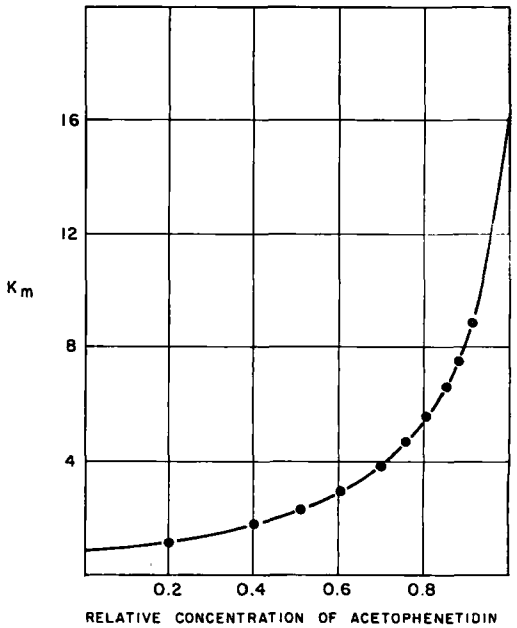

Fig. 2.—Partition curve for acetophenetidin and caffeine.

Commercial preparations usually contain 85 parts of acetophenetidin and 15 parts of caffeine. Fig. 2 shows that mixtures containing 85% acetophenetidin can be analyzed with good accuracy because the rate of change of K_m with respect to relative concentration is now considerably greater than that for lesser concentrations. A curve such as that shown in Fig. 2 must, therefore, be constructed in order to assess the relative accuracy of the method. If the particular mixture under investigation does not fall in an optimal range then some other method of analysis must be used.

The equations derived in the previous section imply that no spectrophotometric constants or partition values are required prior to analysis. Necessary data can be accumulated by analyzing synthetic mixtures or mixtures in which the absolute concentration of only one of the two substances is known. For example, the calibration curve illustrated in Fig. 1 can be constructed from data obtained by subjecting weighed quantities of acetophenetidin and unknown quantities of caffeine to the distribution process described in the previous section. The direct approach is to determine K_x, K_y, and a separately and then substitute the appropriate values into Eq. 17. This was done for the mixture investigated herein. When the determined partition and absorbancy index values at 261.5 mμ were substituted into Eq. 17, certain discrepancies between the numerical form so calculated and that reported in the previous section were observed. The slope value was found to be 31.59 and the intercept value 0.83. The latter value differs from that reported in the previous section by approximately 2%, a not unacceptable error. The discrepancy between intercept values is somewhat greater (that is, 0.83 as compared to 0.88). This discrepancy is not too significant provided the relative concentration of acetophenetidin is 60% or more and is probably due to the factors cited in the previous paragraph. It is preferable, therefore, to obtain the numerical form of Eq. 17 by the method of least squares from data obtained by analyzing actual mixtures of the two substances. This not only avoids a tedious, direct determination of constants but also serves as a check on the validity of Eq. 17.

The general shape of Fig. 2 is governed by the partition coefficient values of the two components and these, in turn, are governed by the volumes of the two phases used in the first step of the determination. By changing the ratio of one solvent to the other, the partition coefficient values will change and hence alter the accuracy of the method. For example, initial investigations on the acetophenetidin-caffeine mixture were carried out by using 50.00 ml. of *n*-butanol and 50.00 ml. of water. The results obtained under such circumstances were not as satisfactory as those shown in Table 1. The volumes were then changed to 25.00 ml. of *n*-butanol and 50.00 ml. of water in order to provide a more favorable distribution of the two components between the two immiscible solvents. This might be considered as one of the advantages of the method, that is, by altering volumes, the conditions of assay and hence the accuracy can be easily changed. On the other hand, it is somewhat difficult to determine optimal conditions for the most accurate analysis of the binary mixture. As a general rule, conditions should be so fixed that there is a maximal difference between the partition coefficient values of the pure substances. Substance solubility and ease of handling of smaller quantities of solvent will limit the applicability of this rule.

Any two immiscible solvents can be used in this type of analysis provided the two components of the mixture show complete solubility when subjected to the distribution procedure. The limitation here is the temperature coefficients of the particular solvents used in the analysis. All the determinations described in this paper were carried out at room temperature and because this temperature varied only slightly from day to day, the accuracy of the method was found to be excellent. This, of course, may not always occur (and, in fact, certain solvents are more susceptible to slight varations in temperature) and, consequently, a more accurate control of temperature would be necessary. This in itself is a disadvantage and implies a criticism of the method. There is yet a second factor to consider. Partition coefficient values depend not only on the volumes of the two phases but also on the inherent characteristics of the solvents. Although this was not investigated, changes in pH, for example, will alter the solubility of a particular substance in one of the phases and thus change the numerical value of the partition coefficient.

If the total weight of the mixture being analyzed is known, then relative concentrations can be easily converted to absolute quantities. Even though most methods of analysis begin with a weighing, the sample often contains substances other than those being analyzed. There is thus no way of determining the total weight of the active ingredients unless some secondary step is introduced into the method. The simplest approach is to carry out a complete isolation of the two components, determine the total weight, and then subject the mixture to the procedure described in the previous section. Another possible approach is to determine the absorbancy index value at the isoabsorptive point. The total absorbancy in both phases divided by the absorbancy index value is equal to total quantity of mixture present. The absolute concentrations of the two components can then be calculated. Both approaches suffer from a number of inherent errors. The gravimetric approach is tedious and does not guarantee that the isolated material being weighed is actually composed of only two substances. The spectrophotometric approach involves the determination of absorbancy index values at an isoabsorptive point. While this is feasible (2), the necessary manipulations are sufficiently involved to make this approach undesirable.

Eq. 17 provides an alternative approach. Since this is the equation of a straight line, it can be used in its numerical form, a form that can be easily calculated from data obtained on a restricted number of synthetic mixtures. Concentrations are now in absolute terms and are more meaningful when comparing the analytical result with the quantity claimed on a label or manufacturing ticket.

This method of analysis has an accuracy of approximately one per cent under ideal conditions. If secondary steps are introduced into the procedure in order to isolate the two substances being analyzed, the precision and accuracy of the method will be somewhat less than that shown in Tables I and II. There is no indication, however, that such

errors become excessive since the agreement between duplicate analyses of commercial preparation containing acetophenetidin is generally satisfactory.

CONCLUSION

Eq. 9 is fundamental to this general type of analysis. All the basic advantages and disadvantages associated with this method are found therein. It is important, therefore, to prepare a plot of K_m *vs.* relative concentration before attempting an analysis based on controlled partial separation. The importance of this is evident from Fig. 2. If such a curve shows that a simultaneous analysis of the components of a particular binary mixture is possible, then the method commends itself to the analyst. This method is particularly useful in those cases where the usual spectrophotometric methods of simultaneous analysis are not possible because of the similarity of the spectrophotometric curves of the components and where the usual solvent–solvent extraction techniques are not capable of completely separating the two components. Table I shows that the method is accurate and precise. The method, therefore, provides another approach to the basic problem of the analysis of complex pharmaceuticals.

Investigation of the Sedimentation Behavior of Dispersions

By AMY MOORE† and A. P. LEMBERGER

Using a modification of the method of Greiner and Vold, suspension isotherms were obtained for dispersions of zinc oxide, calcium carbonate, and bismuth subcarbonate in sodium lauryl sulfate, dioctyl sodium sulfosuccinate and sodium-salts of polymerized alkylnaphthalenesulfonic acids (Daxad 11) solutions. For zinc oxide and bismuth subcarbonate systems maximum suspendability was reached at surfactant concentrations somewhat beyond the critical micelle concentration and extended over a relatively short concentration range. In the case of calcium carbonate, limited suspendability was observed with all three surfactants. Previous workers attribute the reduction in suspendability at higher surfactant concentrations to a reduction in zeta potential, thus permitting increased aggregation. Suspension isotherms obtained at constant and varying ionic strengths of sodium chloride indicate that aggregation is facilitated by the presence of excess surfactant through some additional mechanism.

THE SEDIMENTATION behavior exhibited by a dispersion has long been recognized as being of interest and importance pharmaceutically. Separation of phases in a polyphase pharmaceutical product can result in failure to provide uniform doses of the drug or drugs suspended.

One phenomenon which may occur and contribute to increased rates of sedimentation in these dispersions is aggregation (1). Thus, a number of investigations of sedimentation or creaming rates have been made and aggregation behavior deduced in a qualitative or semiquantitative fashion (1–5).

Further interest in the phenomenon of aggregation arises from the observation that in addition to the effect on physical stability, aggregation may also contribute to the flow properties exhibited by emulsions and suspensions (6). Recently, W. I. Higuchi, Okada, and Lemberger (7) reported on the reversible aggregation-deaggregation of hexadecane-in-water emulsions containing dioctyl sodium sulfosuccinate (AOT). In this study a procedure involving rapid counting and sizing of droplets as a function of time was employed, thus permitting direct determination of aggregation in the system.

Sedimentation studies in which ionic surface-active agents have been employed reveal that in a given system, suspendability of the dispersed phase passes through a maximum at a given concentration of surface-active agent something in excess of its critical micelle concentration (2, 3, 5, 8). Increasing suspendability to the maximum is generally accepted as being due to selective adsorption of the anion (2, 3, 5, 8, 9). As the anion is adsorbed, the zeta potential of the particles increases which leads to deflocculation of aggregates. As a result of deflocculation, effective particle size is decreased and the rate of sedimentation under gravitational effects is reduced.

Two possible explanations for the observed decrease in suspendability beyond the maximum have been offered. Greiner and Vold (2) and Vold and Konecny (3) propose that the decrease in suspendability at higher concentrations of surface-active agent results from a decrease in zeta potential caused by the increased concentration of counter ions. However, Doscher, in his sedimentation studies (5), showed that sedimentation rates increased markedly at a concentration in excess of the critical micelle concentrations, while zeta potential decreased only slightly. Both he and Cockbain, reporting on the creaming of emulsions systems (1), suggest that adsorption of polymolecular aggregates occurs at higher concentrations, and that interaction of hydrophobic surfaces results in bridging between particles leading to aggregation. Higuchi, Okada, and Lemberger (7) recognized that both London dispersion forces, rendered more effective by decreased zeta potential, and film to film interactions may be important in aggregation phenomena. It is the purpose of this study to lend further support to this position.

EXPERIMENTAL

Materials.—The insoluble powders employed were zinc oxide U.S.P., calcium carbonate, reagent grade, and bismuth subcarbonate U.S.P. (light powder). These particular powders were chosen because of their widespread use in pharmaceutical suspensions.

The anionic surfactants used were sodium lauryl sulfate (NaLS), Aerosol OT (100% pure sodium dioctyl sulfosuccinate from American Cynamid), and Daxad 11 (sodium salts of polymerized alkyl naphthalene sulfonic acids from Dewey and Almy). The AOT and Daxad 11 were used without alteration. The NaLS was recrystallized twice with hot 95 per cent ethanol before use.

Sodium chloride U.S.P. was used in the experiments concerning electrolytes.

The distilled water used in the dispersions was decarbonated by vigorous boiling for fifteen minutes and cooling in a flask stoppered with a soda-lime tube apparatus.

Procedure.—The procedure employed was a modification of the method outlined by Greiner and Vold (2). Surfactant solutions of the desired concentrations were prepared in 250-ml. quantities at specific time intervals before use (3 hours for the AOT solutions and 24 hours for the Daxad 11 and NaLS solutions). The necessity for using solutions of uniform age was demonstrated by Greiner and Vold in their studies of the suspending powers of aged AOT solutions.

A small portion of this solution and 2 Gm. of the insoluble powder were placed in a ground-glass homogenizer and levigated vigorously for 2 minutes. The concentrated suspension was then transferred quantitatively to a graduated 12-in. test tube, using portions of the remaining surfactant solution. All test tubes were calibrated at the 50-ml. and 250-ml. levels. Both the diameter (3.7 cm.) and the distance between calibrations (23 cm.) were identical in every case. The liquid was brought up to volume (250 ml.) with the remaining surfactant solution and the tube clamped on the stirring apparatus. This consisted of an elongated glass spiral terminated with a soft rubber propeller fitted onto a small reduction motor. The suspension was stirred for 18 minutes, effecting a total stirring time of 20 minutes. The tube was then removed from the stirrer, stoppered, inverted slowly by hand several times, clamped in a vertical position, and allowed to stand undisturbed for a 2-hour period. At the end of this time the liquid was withdrawn to the 50-ml. mark, and assayed for the amount of powder which had remained suspended. A special J-tipped siphon and a slow withdrawal rate were employed to minimize the disturbance of the sediment.

The zinc oxide suspensions were assayed according to a modified U.S.P. XVI procedure in which the zinc oxide was dissolved in an excess of 1.0 *N* sulfuric acid in the presence of ammonium chloride, and the resulting solution back-titrated with 1.0 *N* sodium hydroxide.

The 1932 British Pharmacopoeia assay method was employed for calcium carbonate. The calcium carbonate was dissolved in an excess of 1.0 *N* hydrochloric acid, and back-titrated with 1.0 *N* sodium hydroxide. Methyl orange test solution (U.S.P. XVI) was used as an indicator in both of the above cases.

A gravimetric procedure was used for bismuth subcarbonate, whereby the 200 ml. of suspension were centrifuged approximately 20 minutes, or until the supernatant liquid was clear. The liquid was decanted, and the residue was transferred quantitatively to a tared crucible and dried to constant weight.

In the experiments demonstrating the influence of electrolytes on the suspending ability of the surfactants, the salt was dissolved in the surfactant solution before levigation was begun.

Suspension isotherms were obtained by plotting the milligrams per milliliter of insoluble powder remaining suspended after the 2 hours *vs.* the concentration of surfactant solution used.

It has been established that the effects of stirring time (10) and precontact[1] time (2) are critical factors in sedimentation analysis, and, therefore, were carefully controlled. Inasmuch as the suspending power

[1] Precontact time is the length of time which the powder and surfactant are allowed to remain in contact before the actual sedimentation period begins (2).

of detergents is generally independent of temperature (11), no effort was made to maintain a constant temperature experimental environment; all work was done at room temperature.

RESULTS AND DISCUSSION

The suspension isotherms obtained for the various insoluble powder–anionic surface-active agent combinations employed are given in Figs. 1–5. In accordance with results of previous workers, a maximum suspendability which extended over a relatively short concentration range was observed at a point somewhat beyond the critical micelle concentration of the surfactant.

An exception to the normal pattern was observed in the case of calcium carbonate. With all three anionic surface-active agents employed in this study only a slight increase in suspendability was noted

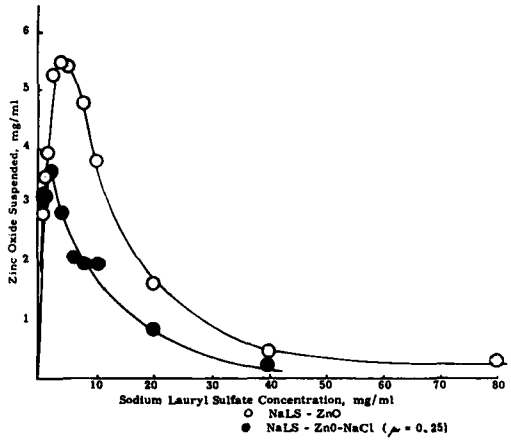

Fig. 1.—Suspension isotherms for zinc oxide–NaLS systems.

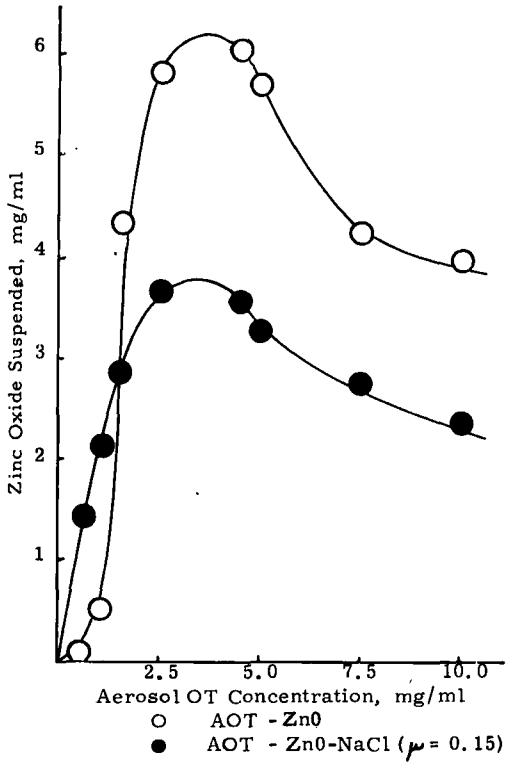

Fig. 2.—Suspension isotherms for zinc oxide–AOT systems.

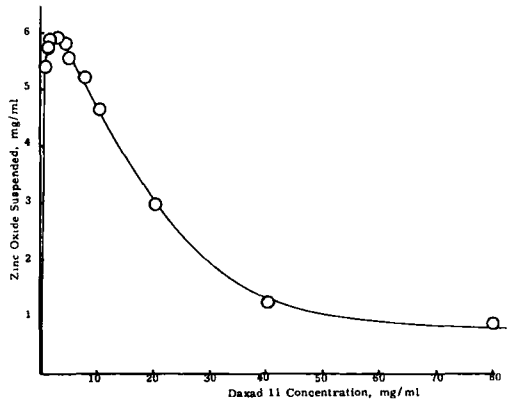

Fig. 3.—Suspension isotherm for zinc oxide–Daxad 11 system.

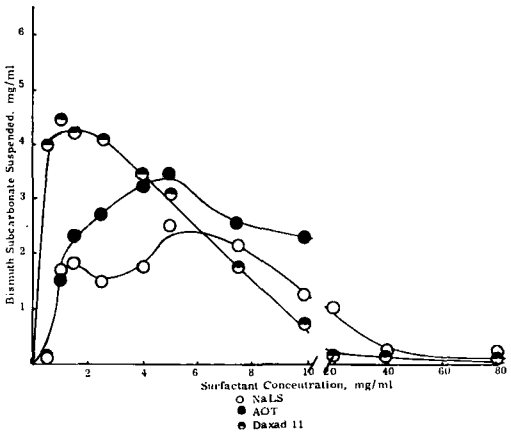

Fig. 4.—Suspension isotherms for bismuth subcarbonate with various anionic surface active agents.

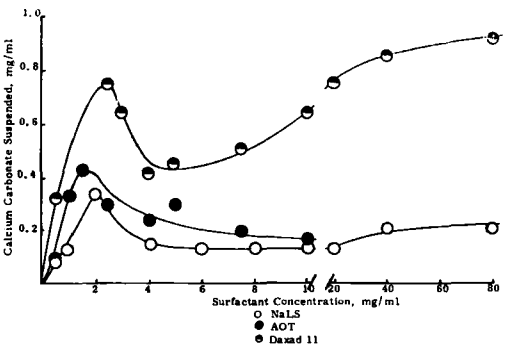

Fig. 5.—Suspension isotherms for calcium carbonate with various anionic surface-active agents.

in the initial portion of the suspension isotherm. With both Daxad 11 and NaLS, whose greater water solubility permitted determination of suspendability at higher concentrations, suspendability was observed to increase once again in the higher concentration range. Qualitative evidence for a high degree of aggregation in these systems which might in part account for their low order of suspendability is furnished by the observation that calcium carbonate sediments were more loosely packed than the other powder sediments.

A further objective of this study was to show experimentally that the zeta potential of the particles exerts a significant influence on the sedimentation characteristics of a dispersion. Since zeta potential is reduced or lost in the presence of high concentrations of electrolyte, suspension isotherms were obtained for zinc oxide–NaLS and zinc oxide–AOT systems in the presence of swamping electrolyte. For the zinc oxide–NaLS system, ionic strength was maintained at 0.25 and for the AOT system, at 0.15 with sodium chloride. For calculation of ionic strength, 100% dissociation of the surface-active agent was assumed. Although at higher concentrations the ionic strength would be somewhat less, it was felt that electrolyte concentration was sufficient to assure flooding of the system. Results of these experiments are given in Figs. 1 and 2.

In both instances maximum suspendability of the zinc oxide was significantly decreased indicating that zeta potential plays an important role in the suspendability of insoluble powders by contributing to the formation of a deaggregated system. It seems reasonable to expect the appearance of maxima in the suspension isotherms even though zeta potential is minimal because the NaLS and AOT could act as weakly ionic or nonionic surface-active agents in these systems. For the zinc oxide-NaLS system, the position of the maximum was shifted to a slightly lower concentration of NaLS and the width of the peak reduced. A possible explanation of this observation would be the greater ionic strength and/or an increased sensitivity to the presence of electrolyte in the case of NaLS.

Also of interest in suspendability behavior is the decrease observed beyond the maximum. At higherconcentrations of anionic surfactant, the concentr ation of counter ions increases and results in a decreased zeta potential. If the aggregation responsible for the increased sedimentation rates observed in this portion of the suspension isotherm is entirely due to London dispersion forces, rendered more effective because of the closer approach of particles under a decreased zeta potential, any source of counter ions should produce equivalent behavior in the system. For this reason suspension isotherms were obtained where the concentration of surface-active agent at which maximum suspendability was observed held constant (4 mg./ml.) and varying amounts of sodium chloride were added. The resulting suspension isotherms are shown in Fig. 6, where zinc oxide suspended is plotted as a function of total ionic strength of the system. Dotted and broken lines represent the suspension isotherms for zinc oxide–

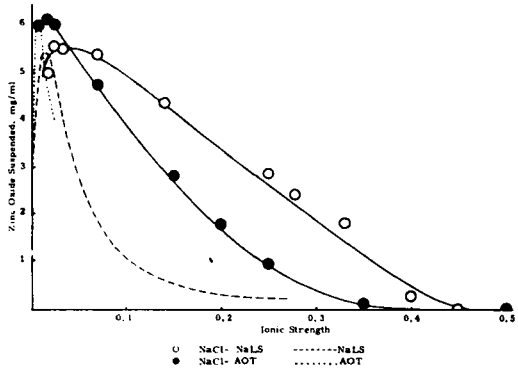

Fig. 6.—Influence of ionic strength on the suspendability of zinc oxide in NaLS and AOT solutions.

AOT and zinc oxide–NaLS, respectively, in the absence of sodium chloride. In order to plot these curves 100% dissociation of the surface-active agent was assumed for the calculation of ionic strength, thus these curves are displaced slightly to the right along the ionic strength axis.

It is seen that although suspendability decreased upon addition of increasing amounts of electrolyte, it did not fall off as rapidly as in the case of addition of excess surface-active agent. The major effect brought about by the presence of electrolyte would be the reduction in zeta potential and, perhaps at higher ionic strength, some dehydration of the interfacial film. It would thus appear that excess anionic surface-active agent in the system facilitates aggregation by some mechanism in addition to reduction of zeta potential. It seems reasonable to expect this mechanism to be film to film interactions enhanced by multilayer adsorption of surface-active agent at concentrations in excess of the critical micelle concentration.

As a result of these studies it may be deduced that both reduction in zeta potential and the presence of excess surface-active agent contribute to the deaggregation and aggregation of suspended particles. The relative significance of each in the total behavior shown can only be determined through direct measurement of aggregation in these systems under controlled environmental conditions.

Effect of Neostigmine on the Tissue Concentration of Antibiotic in Streptomycin Treated Rats

By VERNON A. GREEN†

Increased streptomycin levels in rat skeletal muscle tissue were observed after the administration of neostigmine methylsulfate alone and in combination with atropine. Acetylcholine and methacholine bromide were administered to determine if the increase in antibiotic concentration was due to vasodilation or to some other action of the anticholinesterase.

THIS AUTHOR (1–3) has reported both a potentiation of activity and an increase in the rate of tissue penetration of some agents which have been administered after cholinesterase inhibitors. Similarly, Greig (4) has noted an increased barbital concentration in mouse brain when the barbiturate was administered shortly after an anticholinesterase agent. The purpose of this investigation was to ascertain the concentration of streptomycin in skeletal muscle and blood serum of rats which received the antibiotic after the administration of either neostigmine methylsulfate alone and in combination with atropine sulfate or the choline esters—acetylcholine and methacholine bromide.

Streptomycin levels in muscle extracts and blood serum were determined by a bacteriological cup method. A standard curve was obtained after the method of Grove and Randall (5), with reference standards from 0.1 to 10 mcg. The curve was then used to determine the streptomycin level in the rat tissue.

EXPERIMENTAL

Procedure for Determining the Streptomycin Level in Rat Tissue (I).—Albino rats used in this study were selected without regard for age, weight, or sex. Control and experimental animals were studied concurrently in each procedure.

The experimental animals were administered 0.0004 mg./Gm. neostigmine subcutaneously. Thirty minutes after the injection of the cholinesterase inhibitor into the experimental animals, 40 mg./Kg. of streptomycin was administered intramuscularly into the right rear thighs of both the control and experimental animals.

Three hours after the administration of the streptomycin, the animals were etherized and sacrificed by severance of both common carotid arteries, whereupon the blood was collected in centrifuge tubes and refrigerated. The skin was then removed from the left rear leg and the muscle tissue removed. After washing the tissue to remove any remaining blood,[1] the fascia and fat were removed and 20 Gm. of the remaining muscle tissue added to 100 ml. of the cold phosphate buffer,[2] and homogenized for 15 minutes at high speed in a Waring Blendor. The homogenate was then diluted to 200 ml. with cold phosphate buffer to be used for testing.

Three cups on each of three agar plates to be used in the test were filled with 0.2 ml. of the homogenate and the other 3 cups filled with 0.2 ml. of a known concentration of streptomycin, 1 mcg./ml. of tissue extract, as a control. The plates were covered and incubated for 18 hours at 37° at which time the diameters[3] of the inhibitory zone for each cup of the homogenate and control were noted. The readings were then corrected to the 1 mcg./ml. reference point by the same procedure used in establishing the standard curve and the corrected zone measurements compared to the standard curve in order to interpret the number of micrograms of streptomycin per milliliter in the experimental test tissue homogenates. Because a dilution factor of the tissue was involved, 20 Gm. in 200 ml., the figures obtained from the standard curve were multiplied by 10 and the milligram concentration of streptomycin per gram of tissue was reported.

The Determination of the Effects of the Cholinesterase Inhibitor on the Serum Levels of Streptomycin in Rats (II).—The blood collected was allowed to clot in the refrigerator; the clot was then loosened with a sterile loop and the tube centrifuged at high speed about 25,000 r.p.m. for 7 minutes. After centrifuging, the serum was pipetted off and diluted from 1 part serum up to 4 parts with phosphate buffer. The streptomycin concentration of the serum was then determined by the same method as the antibiotic concentration of the muscle tissue, using 0.2 ml. of 10 mcg./ml. solution of streptomycin in the control cups as the control. The readings of the zones of inhibition and corrections were made after the same method used in part I, but using the 10 mcg./ml. reference point as the correction standard.

The Determination of the Effects of Atropine on

Received March 29, 1962, from the College of Pharmacy, Ohio Northern University, Ada.
Accepted for publication July 12, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
Part of this study was made at the College of Pharmacy, Pharmacology Division, The University of Texas, Austin.
† Present address: School of Pharmacy, The University of Kansas City, Kansas City, Mo.

[1] The wash liquid was the same phosphate buffer that was used for the dilution of the extract—dibasic potassium phosphate, 16.73 Gm. and monobasic potassium phosphate, 0.523 Gm. per 1000 ml. adjusted to pH 8.

[2] Cold phosphate buffer was used since the liquid in the blender had a tendency to heat up, thereby destroying part of the streptomycin activity.

[3] Since the zones of inhibition were irregular, six different measurements of the diameter for each zone were made and the average recorded as the diameter of the inhibitory zone.

the Streptomycin Levels in Neostigmine-treated and Untreated Rats (III).—Experimental and control animals were prepared and medicated in the same manner as in part I, except that the controls received 8 mg. of atropine sulfate subcutaneously 30 minutes prior to streptomycin and the experimental animals received 8 mg. of atropine sulfate subcutaneously with the neostigmine prior to streptomycin. Three hours after the administration of streptomycin, the animals were sacrificed and the muscle tissue and blood serum used for the determination of the streptomycin level as in parts I and II. The readings of the zones of bacterial inhibition, and corrections, were made as in parts I and II.

The Determination of the Effects of Methacholine and Acetylcholine on the Streptomycin Level in Rat Tissue (IV).—A vasodilator, methacholine bromide 0.05 mg./Kg. intramuscularly, was given to albino rats 15 minutes prior to 40 mg./Kg. of streptomycin. After 3 hours, the animals were sacrificed and the blood serum and muscle tissue collected and tested as in parts I and II above. Streptomycin tissue levels were determined and corrected for reporting as described above.

When acetylcholine was administered with neostigmine at a dose level of 0.05 mg./Kg., all animals succumbed, but by decreasing the acetylcholine dose to 0.01 mg./Kg. with neostigmine prior to streptomycin, the animals survived. The muscle tissue and blood serum in this group were checked as above.

RESULTS AND DISCUSSION

Streptomycin Concentration in Rat Tissue-Controls.—Six rats were given streptomycin 40 mg./Kg. intramuscularly; after 3 hours the animals were sacrificed and the blood and muscle tissue checked for antibiotic activity by the cup method.

The homogenate of the muscle tissue, 1:10 dilution, gave no inhibitory zones, indicating that the concentration of streptomycin was less than 0.005 mg. per gram of tissue by this method. Blood serum levels were checked and found to be, for the average of the six animals, 0.0402 mg./ml. These findings were recorded to be used as the basis of comparison for animals receiving prior medications.

Streptomycin Concentration in Tissue and Blood Serum of Rats Pretreated with Neostigmine.—Neostigmine 0.4 mg./Kg. was given subcutaneously to six rats 30 minutes prior to 40 mg./Kg. of intramuscular streptomycin. Three hours after streptomycin administration the animals were sacrificed; the blood and tissue were collected and tested for antibiotic activity as described above.

The muscle tissue showed streptomycin activity equal to 0.0159 mg./Gm. which was more than the controls, since the controls showed less than 0.005 mg. per gram. The serum level of streptomycin as determined in these tests showed only 0.0245 mg./ml., a 0.0157 mg./ml. decrease from that of the control animals.

Streptomycin Concentration in Rats Premedicated with Atropine and Neostigmine.—Eight milligrams of atropine sulfate plus neostigmine methylsulfate were administered 30 minutes prior to 40 mg./Kg of intramuscular streptomycin to six rats. Three hours after the streptomycin administration, the animals were sacrificed, the blood and muscle tissue collected and tested as above to determine the antibiotic activity.

One group of plates with muscle tissue of one animal showed no inhibition beyond the cups, but in the other five there were clearly defined zones of inhibition which gave an average reading of 0.0123 mg. of streptomycin per gram of muscle tissue. The blood serum level gave an average of 0.0299 mg. per ml for the six animals tested. These findings were similar to those for neostigmine alone.

Atropine 8 mg. per animal is a dose of atropine that should prevent the vasodilating effects of neostigmine, even though the rat is quite tolerant to the belladonna alkaloids. Because the administration of atropine did not change appreciably the tissue levels of streptomycin in the above animals, it appears evident that the increase in tissue levels of the antibiotic in neostigmine pretreated rats is not primarily due to vasodilation.

Streptomycin Concentration in Tissue of Rats Pretreated with Atropine Sulfate.—Six rats of varying ages, weights, and sex were administered subcutaneously 8 mg. of atropine sulfate 30 minutes before streptomycin 40 mg./Kg. intramuscularly. Three hours after the streptomycin injections, the animals were sacrificed and the blood and tissue collected for testing.

Five of the animals showed concentrations of streptomycin too small to read by this method, *i.e.*, less than 0.005 mg. per gram of tissue. One animal, however, showed slight inhibitory zones about the test cups, but the 1 mcg./ml. reference cups were much below the average which increased the corrected reading to a point that it could be estimated by extending the slope of the standard curve. However, the concentration of the antibiotic was still below 0.005 mg./Gm.

The blood serum level of streptomycin in the atropinized animals was 0.0216 mg./ml., which was less than the control but near that for animals pretreated with neostigmine alone or neostigmine and atropine combined.

Streptomycin Concentration in Rats Pretreated with Methacholine and Acetylcholine.—Methacholine bromide 0.05 mg./Kg. was administered to 4 rats subcutaneously and followed immediately by streptomycin 40 mg./Kg. intramuscularly. After 3 hours, the tissue and blood serum were collected from the sacrificed animals, as above, and tested for streptomycin activity.

The muscle tissue in methacholine pretreated rats showed a tissue level of 0.0076 mg./Gm. and the blood serum 0.02727 mg./ml. The muscle tissue antibiotic level was slightly more than the controls, and the blood serum level was much less than the serum level of the controls, but about the same as that of neostigmine treated and atropinized animals in this study.

Acetylcholine bromide 0.05 mg./Kg. was administered to four rats subcutaneously, followed immediately by streptomycin 40 mg./Kg. After 3 hours the animals were sacrificed; the tissue and blood serum collected and tested as above to determine the antibiotic level.

The muscle tissue showed a tissue level of streptomycin of 0.0068 mg./Gm. and the serum 0.0328 mg./ml. which was about the same as metha-

STREPTOMYCIN IN RAT TISSUE[a]

Streptomycin, neostigmine, and atropine	0.0299	0.0123
Streptomycin and atropine	0.0216	Less than 0.005
Streptomycin and methacholine	0.0272	0.0076
Streptomycin and acetylcholine	0.0328	0.0068

[a] The above was determined from tissue obtained from animals three hours after administration of 40 mg./Kg. of the antibiotic.

choline for the tissue, but a higher level for the serum.

This study of the effects of methacholine and acetylcholine on the tissue levels of streptomycin indicates that vasodilation produced by these agents did not cause as appreciable a rise in the tissue level of the antibiotic as does neostigmine alone, or in combination with atropine. If vasodilation were the only factor involved in the increase in the tissue level of streptomycin brought about by the neostigmine, methacholine and acetylcholine should have given an increase in the tissue level of the antibiotic equal to that produced by neostigmine.

SUMMARY AND CONCLUSION

The cup method using agar plates seeded with *B. subtilis* was used to determine the streptomycin concentration of the tissue and blood serum of rats receiving 40 mg./Kg. of streptomycin. Additional tissue and blood levels of streptomycin were determined on rats premedicated with neostigmine, neostigmine and atropine combined, atropine, methacholine, or acetylcholine.

Animals premedicated with neostigmine and neostigmine plus atropine, showed tissue levels of 0.0159 mg./Gm. and 0.0123 mg./Gm., respectively, which represented increases over the controls (streptomycin level less than 0.005 mg./Gm.). Also with the increased tissue level there was a decrease in the blood serum level.

Attempts to increase the rat tissue levels of antibiotic by the use of the vasodilators, methacholine and acetylcholine 0.05 mg./Kg., resulted in tissue levels of 0.0076 mg./Gm. and 0.0068 mg./Gm., respectively.[4] These tissue levels were slightly greater than the controls, but much less than the levels in neostigmine, or neostigmine and atropine combined, pretreated animals.

Atropine, 8 mg. per animal, failed to block the tissue level increases of streptomycin produced by neostigmine, although this dose of atropine should have blocked any vasodilating activity of neostigmine.

The observed increases in the rat muscle tissue level of streptomycin must be some action other than that of producing vasodilation by the action of the endogenous acetylcholine that accumulates with neostigmine administration.

From this investigation and previous studies by other authors,[5] it appears that some of the inhibitors of cholinesterase (6) increase the absorption and penetration of certain agents into tissue. Because neostigmine affected increases in the tissue levels of streptomycin, it would appear that it increases the permeability of the skeletal muscle to the antibiotic.

Quantitative Spectrophotometric Papergram Assays I

Tubercidin

By T. F. BRODASKY and W. L. LUMMIS

The paper chromatographic characteristics of the cytotoxic agent tubercidin in a number of solvents is reported. The technique for the production of bioautographs on Eagle's KB carcinoma cells is described. A study of the quantitation of tubercidin on KB cells and on papergrams by ultraviolet analysis was undertaken. Using the same chromatograms, ultraviolet analysis followed by bioautographic assay allowed the compilation of data which were statistically analyzed by the pairing technique. This indicated that the two methods were equivalent; however, the ultraviolet assay is the method of choice inasmuch as it requires only half the time required for the biological method.

BECAUSE of the inherent nature of pharmaceutical compounds, laboratories rely upon biological methods to detect, identify, and assay new drug candidates. This often requires handling pathogenic materials or systems requiring lengthy procedures for quantitative evaluation. It would be advantageous, once biological activity has been established, to use a more direct method, one not based on a biological process but which compared favorably with the biological procedure in regard to quantitative features. In this regard, a series of papers (1, 2) has been written concerning the statistical comparison of biological and spectrophotometric assay methods. The principal aim of the work is to establish the usefulness of existing nonbiological techniques in quantitating biological materials and to point out, in a limited way, the nature of these techniques with regard to accuracy, precision, and time comsumption. Three compounds, each presented in a separate paper, have been chosen because of their dissimilar biological nature and response to light absorption techniques.

Considerable work has been done on quantitating papergrams by ultraviolet spectroscopy (3) and a number of unique devices for scanning papergrams has been developed (4). This paper describes the use of spectrophotometry to follow a biologically active compound. Since paper chromatography is a basic tool in the study of pharmaceuticals, the quantitative absorption of ultraviolet radiation by tubercidin (5) on chromatographic paper was studied. Tubercidin was chosen because it represents a class of compounds principally active on carcinoma tissue culture. The use of this system entails some difficulty, and the ability to detect tubercidin by a physical method would to some extent alleviate this problem. The technique of producing bioautograms of this antibiotic with human carcinoma cells in tissue culture and subsequent development of a quantitative papergram assay are also described. An ultraviolet quantitative papergram assay was developed using the 272 mμ absorption peak of tubercidin.

A statistical comparison of the two assays was made to determine if the absorption and scattering errors inherent in the spectrophotometric papergram assay would limit the usefulness of this method.

EXPERIMENTAL

Bioautograms and Quantitative Papergram Assay.—Whatman No. 1 sheets, 15 × 44 cm., were spotted with 100-μl. samples of fermentation liquor containing tubercidin. The papergrams were developed 16 hours (5 hours, for V and VI) descending in the six solvent systems listed in Table I in a sealed chromatographic chamber. After development, the strips were air-dried (System III strips were neutralized in an ammonia atmosphere for 10 min.), then plated on 19 × 50 cm. trays containing 125 ml. of modified Miyamura agar seeded with 0.2 mg. Eagle's KB epidermoid carcinoma cell protein per ml. (6). The trays were incubated at 37° for 16 hours with the strips in contact with the agar. The zones of activities on the trays were detected by spraying the agar with an 0.4% solution of 2,5-dichlorophenol-

TABLE I.—PAPERGRAM SOLVENT SYSTEMS

System	Composition
I	1-butanol:water::84:16 (v/v)
II	1-butanol:water::84:16 (v/v) plus 0.25% *p*-toluenesulfonic acid (w/v)
III	1-butanol:acetic acid:water::2:1:1 (v/v/v)
IV	1-butanol:water::84:16 (v/v) plus 0.2% (v) piperidine
V	1-butanol:water::4:96 (v/v)
VI	1-butanol:water::4:96 plus 0.25% *p*-toluenesulfonic acid (w/v)

indophenol in methanol-saline (1:20 by volume). Within 1 hour, during which time the unaffected cells reduced the blue dye, the zones of activity appeared dark blue against a colorless or light blue background. None of the solvents resulted in inhibition of KB cells as shown by plating strips washed in each of the mobile phases.

The KB cell assay was developed using essentially the procedure described above. The crystalline standard (purity >95%) was spotted at 10, 20, 40, and 60 mcg. per 0.5 in. strip of Whatman No. 1 paper and developed in solvent system IV. A set of standard strips were developed for each assay tray. The maximum width of the zones of activity were plotted against the log of the dose per strip to construct a standard assay curve.

Ultraviolet Quantitative Papergram Assay.— Using measured volumes of a 10 mcg./ml. dimethylformamide solution, a 0.5 in. strip of Whatman No. 1 paper was spotted with 50 mcg. of tubercidin (purity >95%) and developed descending in system IV for 16 hours. After drying, the strip was placed on an ultraviolet scanning box and the center of the tubercidin zone marked. This zone was then scanned on a Cary spectrophotometer from 365 to 210 mμ with a sheet of Whatman No. 1 paper in the reference beam. Two maxima were noted, 238 and 272 mμ.

Strips spotted with 10, 20, 40, and 60 mcg. per strip of tubercidin were developed descending in system IV for 16 hours. After scanning the strips at 272 mμ using a strip scanner, the areas under the response peaks were calculated by the height times the half band width method and plotted against log dose per strip to construct a standard curve.

RESULTS AND DISCUSSION

The chromatographic pattern for tubercidin in six solvent systems on Eagle's KB cells is shown in Fig. 1. This pattern correlates with the patterns on *Bacillus subtilis* and *Proteus vulgaris*. The activity on the latter organisms was considerably weaker than on KB tissue culture and for this reason the bioassay was developed on KB cells. The 272 mμ peak of tubercidin was chosen for the ultraviolet papergram assay for several reasons. The 272 mμ peak was more intense than the 238 mμ peak, $a_{272} = 33$, $a_{238} = 8$. The 238 mμ peak failed to give a linear relationship between log dose per strip and either optical density or area of response peaks.

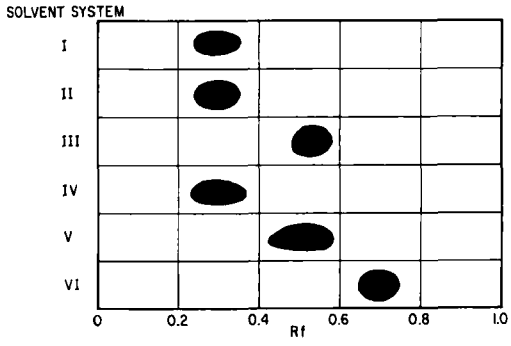

Fig. 1.—KB tissue culture papergram pattern of crystalline tubercidin.

The 238 mμ peak also showed an intensity variation depending upon the pH of the solvent system used in development. The 272 mμ peak did not display any of these variations.

The standard assay curves for the biological and ultraviolet method appear in Figs. 2 and 3, respectively. The points represent the average of 7 determinations and the indices of precision (S/b) of the curves for the biological and ultraviolet method are 0.22 and 0.06. The 95% confidence limits about the points are indicated. Data have been obtained for a limited number of runs indicating the accuracy of the assay methods. Tubercidin was chromatographed in system IV at known doses in the presence of compounds which are coproduced with this antibiotic. Strips were first analyzed by ultraviolet spectroscopy and subsequently assayed by the tissue culture process. The errors were -6.4 ± 5.3 and $25 \pm 34\%$, respectively. The large errors incurred in the tissue culture procedure can be traced to variable sensitivity of the assay organism

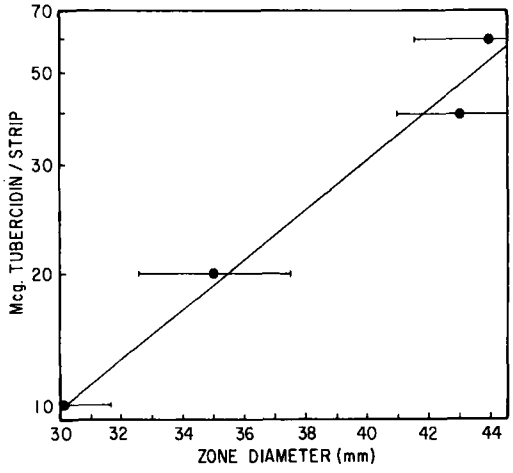

Fig. 2.—Tissue culture assay standard curve for tubercidin.

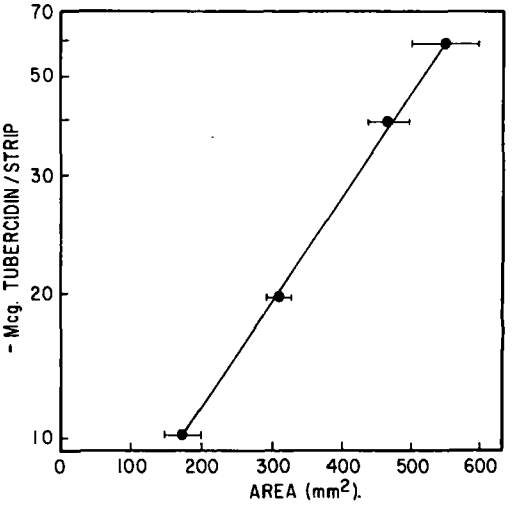

Fig. 3.—Ultraviolet assay standard curve for tubercidin at 272 mμ.

in this early stage of development. A great deal of care must be taken in preparing the trays since such factors as agar thickness can result in a large day-to-day variation in response.

The precision of the assay procedures is given in Table II. This data was accumulated from assays of

TABLE II.—PRECISION OF ASSAY METHODS

[a] d = differences between paired assay values.

crystalline tubercidin (purity >95%) performed first by ultraviolet analysis and then, using the same strips, by the tissue culture method. This was done to allow testing of the equality of the means of the population samples by the pairing technique (7). The difference between paired values of each set of assay results represents a random sample of a population of unknown variance. The population is assumed to have a normal distribution. The pairing procedure allows testing of the mean of the differences for zero and therefore whether the procedures are equivalent. The mean is tested using the t distribution statistic, $t = [\bar{d} - (\mu_1 - \mu_2)]/(Sd/\sqrt{N})$. Assuming that $\mu_1 = \mu_2$, the value of t equals 0.41 and one rejects the hypothesis that $\mu_1 = \mu_2$ only if t is greater than +2.36 or less than −2.36 at a 5% level of significance. The 95% confidence limits shown in Table II were obtained using the statistics for a t distribution $(\bar{x} + (t_{\alpha/2}S)/\sqrt{N}; \bar{x} + (t_{1-\alpha/2}S/\sqrt{N})$ (8). The data indicate a favorable agreement between the two methods. Since the incubation of biological trays is eliminated in the spectrophotometric method, the time necessary for assays is reduced by one-half.

The use of Whatman No. 1 paper in the reference beam of the spectrophotometer during the recording of the response curves does not eliminate the errors due to scattering and absorption by the paper but the inherent advantages of the method offset in part the lack of ultimate quantitation. The spectrophotometric method has been successfully used to estimate the amount of tubercidin in fermentation cultures down to 38 mcg./ml. of culture. In the assay of crystalline preparations the ultraviolet method is capable of detecting biologically inactive materials. This eliminates the inherent error in the biological assay of basing assays on materials which appear pure by biological standards but may actually contain biologically inactive material. For this reason, preparative samples can be selected by the ultraviolet method for standards which are of the highest purity.

SUMMARY

Tubercidin has been chromatographed in a number of solvents to obtain a pattern of Eagle's carcinoma cells. The chromatographic pattern was found to correlate with the *B. subtilis* and *P. vulgaris* patterns although the latter were considerably weaker.

Quantitative papergram assays were developed on carcinoma tissue culture and by using spectrophotometric techniques on papergrams. A statistical analysis of both methods indicates that the assays are essentially equal. However, the spectrophotometric method is more accurate and reduces the assay time by one half.

GLOSSARY OF TERMS

μ_1—Mean of the population values for the ultraviolet assay.
μ_2—Mean of the population values for the biological assay.
$\bar{d}$—Mean of the differences between the paired values (assays).
S_d—Standard deviation of the differences between the paired values (assays).
α—Probability of rejecting true hypotheses; level of significance.
N—The number of samples (assays).
S—Standard deviation of the samples (assays).
$\bar{x}$—The mean of the samples (assay).
$t_{\alpha/2}$; $t_{1-\alpha/2}$—Limits of the critical region for a t distribution as determined by α.
b—Slope of standard curves.

Quantitative Spectrophotometric Papergram Assays II

Sparsomycin, A New Antitumor Antibiotic

By T. F. BRODASKY

The paper chromatographic characteristics of a new cytotoxic agent, sparsomycin, on a variety of solvent systems are reported. The chromatographic pattern of this antibiotic on Eagle's KB human epidermoid carcinoma cells in agar was found to correlate with the pattern on *Bacillus subtilis* UC-564. A quantitative papergram assay was developed on agar seeded with *B. subtilis* and compared statistically with a quantitative papergram assay based on the ultraviolet absorption of sparsomycin. The equivalence of the assay methods was determined by testing the equality of the means of the population of assay values using the pairing technique. The effect of the edges of the papergram on the chromatographic zone and its influence on the ultraviolet assay curve are described. There is a favorable agreement between the assays; however, the ultraviolet method reduces the assay time by 50% in comparison to the biological method.

A NEW cytotoxic agent, sparsomycin,[1] has been isolated from *Streptomyces sparsogenes* culture. This paper describes the paper chromatographic characteristics of sparsomycin and the development of a biological and physical quantitative papergram assay. Fermentation, isolation, and characterization studies are described in other papers (1, 2).

Since sparsomycin is coproduced with three other biologically active components, a disk plate assay is not feasible except as a measure of total bioactivity. Paper chromatography in suitable solvent systems yields resolved zones and allows quantitative evaluation of doses of individual components on the papergram. A statistical comparison between the two assays was made to determine the most rapid and reliable means of estimating yields in culture media and purity of preparative samples.

EXPERIMENTAL

Whatman No. 1 paper strips, 15 × 44 cm., containing 10 mcg. of sparsomycin per strip were developed descending for 16 hours (5 hours, in the case of V and VI), using the solvent systems listed in Table I. After a one-hour drying period, the strips were plated on 19 × 50 cm. trays containing 0.2 mg. of Eagle's KB cell protein per ml. of modified Miyamura agar (3). The trays were incubated for 16 hours at 37° with the strips remaining in contact with the agar. Upon removal of the strips, the agar was sprayed with a 0.4% solution of 2,6-dichlorophenol-indophenol in methanol-saline (1:20 by volume). One hour was allowed for dye reduction, during which zones of activity appeared blue against a colorless or very light blue background.

Received July 27, 1962, from the Research Laboratories, The Upjohn Co., Kalamazoo, Mich.

Accepted for publication September 28, 1962.

This work was supported by contract No. SA-43-ph-1933, Cancer Chemotherapy National Service Center, National Cancer Institutes, National Institutes of Health, Bethesda, Md.

[1] Sparsomycin was formerly called sparsogenin.

The biological assay was established on agar seeded with *Bacillus subtilis* UC-564. The agar was inoculated with 0.3 ml. per liter of a suspension containing 1.3 × 10^{10} spores/ml. The $^1/_2$-inch Whatman No. 1 paper strips containing 60, 40, 20, and 10 mcg. of sparsomycin per strip (used in both assays) were developed descending for 16 hours in solvent system IV. This system was found to yield the greatest resolution of the various components in the sparsomycin fermentation broths. After one-hour drying, the strips were plated on *B. subtilis* seeded trays and incubated for 16 hours at 30°. Three strips containing assay samples and two strips containing standard (purity > 95%) were plated on each tray. On removal of the strips,

TABLE I.—PAPERGRAM SOLVENT SYSTEMS

System	Composition
I	1-butanol:water::84:16 (v/v)
II	1-butanol:water::84:16 (v/v) plus 0.25 % *p*-toluenesulfonic acid (w/v)
III	1-butanol:acetic acid:water::2:1:1 (v/v/v)
IV	1-butanol:water::84:16 (v/v) plus 0.2% (v) piperidine
V	1-butanol:water::4:96 (v/v)
VI	1-butanol:water::4:96 plus 0.25% *p*-toluenesulfonic acid (w/v)

the diameter of the zones in the R_f 0.1 region were measured. These values were plotted against the log dose per strip to obtain a standard assay curve.

An ultraviolet papergram assay was established on $^1/_2$-inch Whatman No. 1 paper strips using a strip scanner (4) in conjunction with a Cary spectrophotometer. The strips were developed in system IV as before. After drying, the strips were scanned from the origin at 302 mμ with a blank of Whatman No. 1 paper in the reference beam of the spectrophotometer. A set of strips containing standard was run for each group of three unknown samples. Only one peak in the pertinent R_f region appeared and the area under this peak was calculated by the peak height times the half-band width method. The areas were plotted against the log dose per strip to obtain a standard assay curve.

RESULTS AND DISCUSSION

Figure 1 shows the typical six solvent system pattern of sparsomycin against Eagle's KB epidermoid carcinoma cells in agar. A similar pattern was obtained against *B. subtilis* and *Proteus vulgaris*.

Standard curves for the biological and ultraviolet assays appear in Figs. 2 and 3. The points represent an average of 11 determinations and the indices of precision (S/b) of the curves for the biological and ultraviolet methods are 0.047 and 0.072, respectively. The 95% confidence limits for each point are indicated. The 10 mcg. point was not included in the biological curve because of the poor sensitivity of *B. subtilis* to sparsomycin at this level. There was considerably more variation in the higher dose responses in the ultraviolet assay curve than in the biological assay curve and this can be accounted for by irregularities in the chromatographic zone. At high doses on 1/2-inch strips, there is a tendency for some materials to give broad zones exhibiting an effect of the edge of the paper strip. This effect is manifested as a variation in the density of the material across the width of the strip. When the strips are plated on agar, diffusion tends to mask the true density gradient in the zone. When a spectrophotometric determination is made, only the central portion of the strip is scanned because of geometric considerations. Under these conditions, the variation in density of a zone across the width of a strip is manifested as a variation in the area of the response peak. Figure 4 shows an ultraviolet curve indicating the density gradient across a 1/2-inch zone of sparsomycin perpendicular to the direction of development.

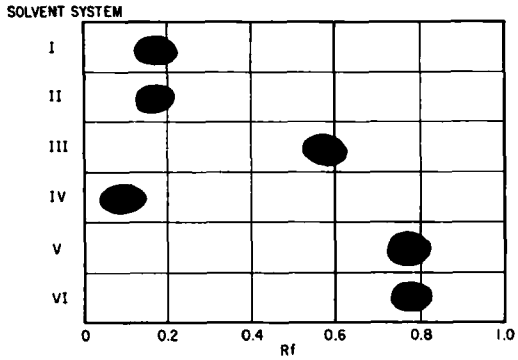

Fig. 1.—Six solvent system patterns of sparsomycin on KB cells.

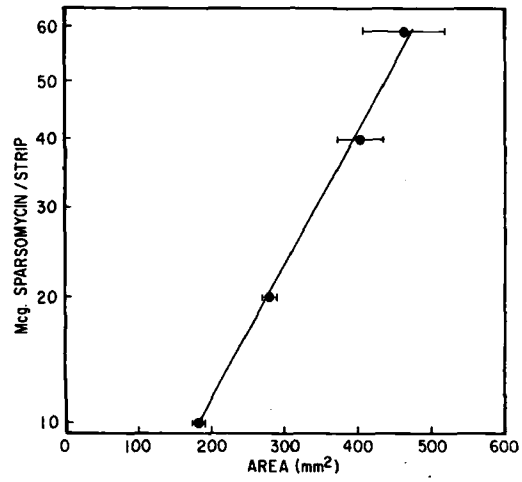

Fig. 2.—Standard *B. subtilis* assay curve for sparsomycin.

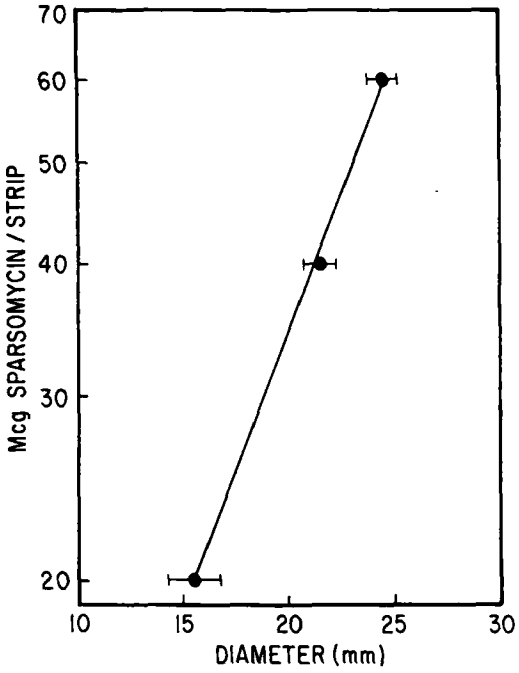

Fig. 3.—Standard ultraviolet assay curve for sparsomycin at 302 mμ.

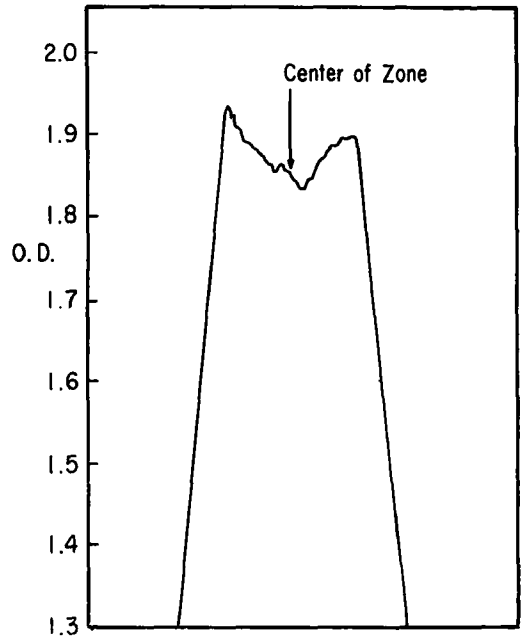

Fig. 4.—Density gradient of sparsomycin zone perpendicular to solvent flow.

Table II summarizes the variation between assay methods. The fact that the mean per cent variation is positive (bioassay with respect to ultraviolet assay) indicates that the ultraviolet assay did not include extraneous material during the recording of the sparsomycin peaks. Large variations in some assay results cannot be explained at this time.

TABLE II.—VARIATION IN UV AND BIOASSAY OF SPARSOMYCIN

Mcg. Sparsomycin/mg. Sample		Variation, %
a UV	*b* Bio	100 (*b* − *a*)/*a*
743	875	+17.8

940	934	− 0.6
	Mean	+14.2
	S. D.	22.9

Table III was prepared from data recorded during the evaluation of a crystalline preparation of sparsomycin. The assay results were obtained over a 3-day period using a set of standards for each group of three samples. The 95% confidence limits, determined using a *t* distribution [$\bar{x} + (t_{\alpha/2}\ S)/\sqrt{N}$; $\bar{x} + (t_{1-\alpha/2}\ S)/\sqrt{N}$] (5), indicate considerably greater precision for the ultraviolet assay procedure. The values obtained from ultraviolet assays were consistent with values expected on the basis of ultraviolet and melting point data for sparsomycin. The accuracy of the UV assay was not determined directly. In a previous paper (6), the accuracy of the UV assay for one of the components of a sparsomycin culture in the presence of sparsomycin was found to be −6.3 ± 5.3% at 95% confidence. It is assumed that the sparsomycin assay will be as accurate. Testing for the

TABLE III.—PRECISION OF ASSAY METHODS

Mean 911	5.5	906
S. D. 33	21	66
95% Confidence Limits ± 27 γ/mg.		± 53 γ/mg.

[a] *d* = Difference of paired values of assays.

equality of the mean of the population of values for both assays by the pairing technique indicated that the procedures were equivalent. This is done by determining the value of $t = [\bar{d} - (\mu_1 - \mu_2)]/(S_d/\sqrt{N})$ (7) assuming $\mu_1 - \mu_2$, and comparing it with values obtained from a table giving percentiles for a *t* distribution. The value of *t* was 0.73 and one rejects the hypothesis that μ_1 is equal to μ_2 only if *t* is greater than 2.26 or less than −2.26 at a 5% level of significance.

The data lead to the conclusion that the UV assay compares favorably with the biological method. The UV assay is more rapid than the biological method and eliminates the need for handling biological systems routinely, although it is important to periodically check the ultraviolet method biologically to ascertain that the original bioactivity is being followed.

SUMMARY

Paper chromatographic characteristics of a new cytotoxic agent, sparsomycin, against KB epidermoid carcinoma cells in agar and *B. subtilis* UC-564 are reported.

An ultraviolet assay has been developed and compared statistically with a biological assay. The methods are statistically equivalent with respect to the mean values, but the ultraviolet method is preferred because of greater precision and a reduction in assay time.

GLOSSARY OF TERMS

μ_1–Mean of the population values for the ultraviolet assay.

μ_2–Mean of the population values for the biological assay.

$\bar{d}$–Mean of the differences between the paired values (assays).

S_d–Standard deviation of the differences between the paired values (assays).

α–Probability of rejecting true hypotheses; level of significance.

N–The number of samples (assays).

$t_{\alpha/2}$ − $t_{1-\alpha/2}$–The limits for the critical region, of a *t* distribution, as determined by α.

b–Slope of the standard curve.

Dissolution Rate Studies II

Dissolution of Particles Under Conditions of Rapid Agitation.

By P. J. NIEBERGALL,† G. MILOSOVICH, and J. E. GOYAN

Dissolution data for sized fractions of three different compounds were obtained using the method of Niebergall and Goyan. The Hixon-Crowell "cube root law" did not describe the data. Deviation from this law was accounted for by deriving a rate expression assuming that the thickness of the diffusion layer was proportional to the square root of the mean volume diameter. Experiments were performed to verify the applicability of the equation so derived.

NOYES AND WHITNEY (1) were the first to report a differential equation relating the rate of dissolution of solid solute to concentration of dissolved solute in the surrounding solvent

$$\frac{dC}{dt} = K(C_s - C) \qquad \text{(Eq. 1)}$$

The rate constant, K, contains several variables which have been the subject of study by succeeding workers. While Noyes and Whitney assumed that the rate would be proportional to surface, it was Brunner and St. Tolloczko (2–5) who showed this dependence and also that K depended upon temperature and rate of stirring. Nernst (6) considered dissolution as a special case of heterogeneous reaction and suggested that Eq. 1 could be written

$$\frac{dC}{dt} = \frac{DA}{V\delta}(C_s - C) \qquad \text{(Eq. 2)}$$

where: D = diffusion coefficient; A = area of the interface; V = volume of solvent; and δ = thickness of a stagnant film of solvent on the solid surface. Brunner (7) showed this rate dependence on the diffusion constant and presented data to show that K was also proportional to (stirring rate)$^{2/3}$.

The Nernst-Brunner layer has been the subject of controversy over the years but, as pointed out by King (8), it is not necessary to the theory that the layer be stagnant on the solid surface. Perhaps the Nernst-Brunner layer may be identical with a hydrodynamic boundary which, rather than being stagnant, merely reflects a velocity gradient between the bulk fluid and the surface of the solid.

In many dissolution studies conditions are chosen such that $DA/V\delta$ remains essentially constant during the experiment. This is accomplished by using single large particles such as compressed tablets or crystal masses grown from the melt. The fraction of the particle which dissolves is so small that surface can be assumed constant as long as the particle remains intact. The thickness of the Nernst-Brunner layer is kept constant by maintaining the position of the particle with respect to the stirrer. When dissolution from powders is studied these conditions may not be obtained. Thus, both surface area and rate of shear on the particles may be expected to change during an experiment.

Hixon and Crowell (9) considered the change in surface as small particles dissolve. They pointed out that the surface area of a particle was proportional to its weight to the $^2/_3$ power, the proportionality constant being composed of density and volume shape factor. If the shape factor remains constant as the particle dissolves the substitution of $W^{2/3}$ for A in Eq. 2 can be made. Then, under the condition that $C_s >> C$ and D, V and δ are constant, the equation can be integrated to give

$$W_o^{1/3} - W_t^{1/3} = kt \qquad \text{(Eq. 3)}$$

where: W_o is the initial weight of solute, W_t is the weight at time t. Equation 3 may also be written

$$W_o^{1/3} - W_t^{1/3} = \frac{k'N^{1/3}DC_st}{\delta} \qquad \text{(Eq. 4)}$$

for N particles, where k' is a constant containing surface and volume shape factors and particle density. The validity of Eqs. 3 and 4 depend on the constancy of k and k'. Shape factors for cubic or spherical particles will remain constant as long as the particles dissolve equally from all sides. This is not true for other particle shapes, and the equations would not be expected to hold for nonequant habits after dissolution has occurred.

Received March 29, 1962, from the University of Michigan College of Pharmacy, Ann Arbor.
Accepted for publication July 2, 1962.
Abstracted from a thesis submitted by Paul J. Niebergall to the Horace H. Rackman School of Graduate Studies in partial fulfillment of the requirements for the degree of Doctor of Philosophy.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
† Present address: Philadelphia College of Pharmacy and Science, Philadelphia, Pa.

While δ was ignored or assumed constant by Hixon and Crowell, inspection of their data (10) shows that their rate constants increased as dissolution proceeded. Since they were working with cubic salt crystals, this drift probably was not due to shape-factor effects. It could be due, however, to a δ dependence on particle size.

Wilhelm, *et al.* (11), reported an empirical relationship between δ and particle size

$$\frac{D}{\delta} = f(d^{1/4})$$

where the symbols have their usual meaning. Their results, however, predict that the Hixon-Crowell rate constant would decrease with dissolution.

This effect has also been reported in studies on crystal growth (12) under diffusion control. McCabe and Stevens (13) verified that the cube root law applies for growth of various sized crystals under conditions of constant shear. On this basis they postulated that larger crystals grow faster because of a thinner Nernst-Brunner layer due to greater shear imposed on the larger particles in a slowly stirred system. This leads to the analogous situation of dissolution, *i.e.*, larger particles dissolving faster because of thinner diffusion layer.

Thus, a review of the literature indicates that the dissolution process for small particles is still not theoretically well defined. It is most apparent that the influence of agitation is important, yet the effect of various degrees of agitation is still unanswered. Certainly, if larger particles dissolve faster under conditions of agitation present in the intestinal tract, one must question the practice of reducing size to effect faster dissolution of drug particles for oral dosage.

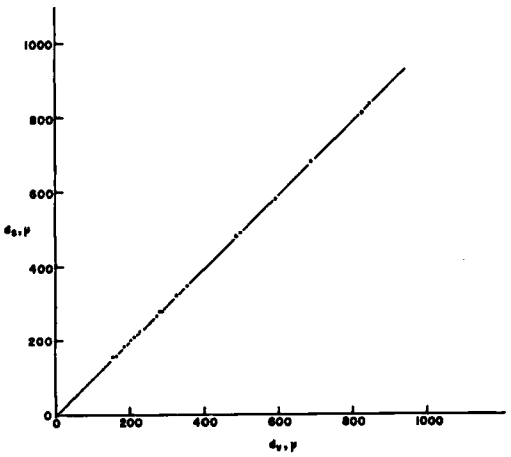

Fig. 1.—Plot of mean surface diameter *vs.* mean volume diameter for all sized fractions used in this study. Slope = 0.99.

This paper reports the initial investigation on the effect of stirring on the dissolution process for small particles. It was the objective of this study to test the applicability of the cube root law to dissolution of particles moving freely in rapidly stirred systems.

EXPERIMENTAL[1]

The continuous recording spectrophotometric procedure described by Niebergall and Goyan (14) was used in this study with one modification. The pump introduced a considerable amount of heat into the solution and made temperature control in the dissolution vessel inadequate. It was decided, therefore, to collect the returning solution in a graduated cylinder. It was then necessary to make corrections for volume changes and loss of solute to the cylinder. These corrections were simplified by the fact that the concentration in the dissolution

[1] Equation 5 is more correctly written

$$W_o - W_t = C_t [V_o - ft] + \int_o^t \frac{dC_t}{dt} ft\, dt \quad \text{(Eq. 6)}$$

which is equivalent to

$$CV_o = C_t [V_o - ft] + f \int_o^t \frac{dC_t}{dt} t\, dt \quad \text{(Eq. 7)}$$

Differentiating Eq. 7 with respect to time

$$V_o \frac{dC}{dt} = [V_o - ft] \frac{dC_t}{dt} - f C_t + f t \frac{dC_t}{dt}$$

$$= V_o \frac{dC_t}{dt} - C_t$$

and

$$\frac{dC_t}{dt} = \frac{dC}{dt} + \frac{fC_t}{V_o} \quad \text{(Eq. 8)}$$

Now, squaring Eq. 14 and rearranging gives

$$W_o - W_t = 2 W_o^{1/2} k'' N^{1/2} t - (k'')^2 N t^2$$

or

$$C V_o = 2 W_o^{1/2} k'' N^{1/2} t - (k'')^2 N t^2$$

Thus,

$$\frac{dC}{dt} = \frac{2 W_o^{1/2} k'' N^{1/2}}{V_o} - \frac{2(k'')^2 N t}{V_o} \quad \text{(Eq. 9)}$$

Combining Eqs. 8 and 9 gives

$$\frac{dC_t}{dt} = \frac{2 W_o^{1/2} k'' N^{1/2}}{V_o} - \frac{2(k'')^2 N t}{V_o} + \frac{fC_t}{V_o} \quad \text{(Eq. 10)}$$

Under the experimental condition that

$$2 (k'')^2 N t = f C_t$$

dC_t/dt would be constant and a plot of C_t *versus* time would be linear. If f is approximately constant as was the case in these experiments, a linear plot would be expected only in the case where

$$\left(\text{Since } C_t = \int_0^t \frac{2 W_o^{1/2} k'' N^{1/2}}{V_o}\right)$$

However, at the relatively small t and C_t values and the average flow rate used in this study, the deviation from linearity is negligible. Nonlinear plots were evident only with the smallest size materials and in these cases the corrections were made using Eq. 7 and graphical integration.

Note that data giving a linear C_t *vs.* t plot may not necessarily be described by Eq. 14, nor will data fitting Eq. 14 necessarily give linear C_t *vs.* t plots. The results reported in this paper were obtained under a fortuitous choice of experimental conditions which gave good correlation between Eqs. 5 and 14.

vessel increased linearly with time. The amount of solute dissolved in time, t, is then given as

$$W_o - W_t = C_t(V_o - ft) + {}^1/_2kft^2 \quad \text{(Eq. 5)}$$

where: C_t = concentration in the vessel at time, t; V_o = initial volume in the vessel; f = flow rate determined by timing the flow into the cylinder; and $k = dC_t/dt$, obtained by plotting concentration against time.

After this modification was made, continuous temperature recording using a thermistor in a wheatstone bridge circuit and a Varian strip-chart recorder showed a maximum temperature variation of $-0.1°$.

The three materials used in this study were selected on the basis of solid state, particle shape, and suitable spectral curves. Potassium dichromate (absorption minimum 317.5 mμ) reagent grade was obtained as equant triclinic prisms. Salicylamide U.S.P. (absorption minimum 262.5 mμ) was spray-congealed to obtain spherical aggregates of microcrystals. Potassium ferricyanide (absorption minimum 418 mμ) reagent grade was obtained as equant rectangular prisms (maximum length to width ratio of about 1.5) with rounded edges. While the latter particles were not as symmetrical as the others it was felt that for the size ranges used the amount of dissolution required for a determination would not significantly alter the shape factor. These materials were sieved three times to obtain sized fractions in which particle sizes were then determined microscopically. Figure 1 is a plot of d_s against d_v, and shows by its slope (0.99) that these fractions were essentially monodisperse (monodisperse slope = 1.00). Size data is presented in Table I.

The solvent selected for these three materials was 50% v/v aqueous ethanol, 750 ml. being used in each run. This solvent was chosen because it wetted the particles and was not a "good" solvent for these compounds (solubility ~2–4%). One-gram samples of each size fraction were used and the stirrer was operated at 500 r.p.m. This speed was chosen as being rapid enough to insure complete suspension of the particles, instantaneous mixing, and representative sampling, yet slow enough that the dissolution process was diffusion controlled. This is seen in the plot of rate constant against r.p.m. in Fig. 2.

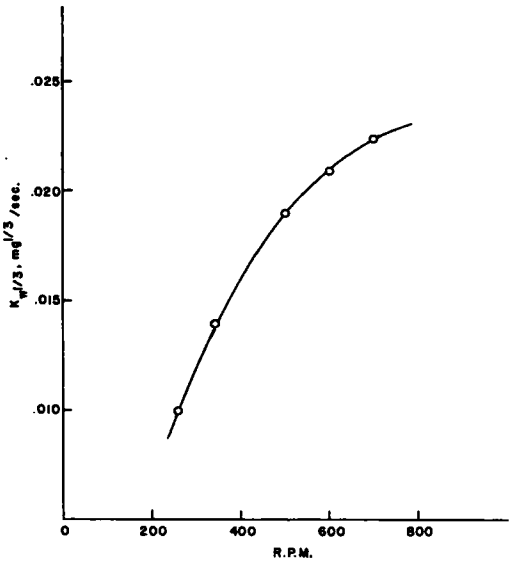

Fig. 2.—Effect of stirrer r.p.m. on the Hixon-Crowell rate constant for dissolution of 681μ potassium dichromate. Complete suspension of particles at 400 r.p.m. T = 24.8°.

The data were plotted initially as $\Delta W^{1/3}$ *vs.* t and good straight lines were obtained in all cases. The slopes of these lines would then be equal to $(k'N^{1/3}\cdot DC_s)/\delta$ as seen from Eq. 4 and are given as $k_W^{1/3}$ in Table I. Since linear plots were obtained, even though particle size changed with time, it would appear that δ does not depend on size. To test this further, the rate constants for different sized fractions were plotted against the reciprocal of the respective mean volume diameters. The expected linear relationship was not obtained. A logarithmic plot of rate constant *vs.* d_v showed for all the materials that the rate constant depended on $d_v^{-3/2}$, Fig. 3.

One way that this relationship may be obtained from Eq. 4 is to set δ proportional to $d_v^{1/2}$. Equation 4 can then be modified as follows:

Table I.—Size Data and Dissolution Rate Constants for the Three Materials Used in this Study

Material	Screen Size	d_s, μ	d_v	$K_W^{1/3}$, mg.$^{1/3}$/sec.	$K_W^{1/2}$, mg.$^{1/2}$/sec.

$$-\frac{dW}{dt} = \frac{3k'N^{1/3}DC_sW^{2/3}}{\delta} \quad \text{(Eq. 11)}$$

since $d_v^3 = \frac{W}{\alpha_v N}$, α_v being the volume shape factor

$$\delta = k\,d_v^{1/3} = \frac{k\,W^{1/6}}{\alpha_v^{1/6}N^{1/6}} \quad \text{(Eq. 12)}$$

combining Eqs. 11 and 12

$$-\frac{dW}{dt} = \frac{3k'\alpha_v^{1/6}N^{1/2}DC_sW^{1/2}}{k} \quad \text{(Eq. 13)}$$

which upon integration gives

$$W_o^{1/2} - W_t^{1/2} = k''N^{1/2}t \quad \text{(Eq. 14)}$$

where

$$k'' = \frac{3k'\alpha_v^{1/6}DC_s}{2k}$$

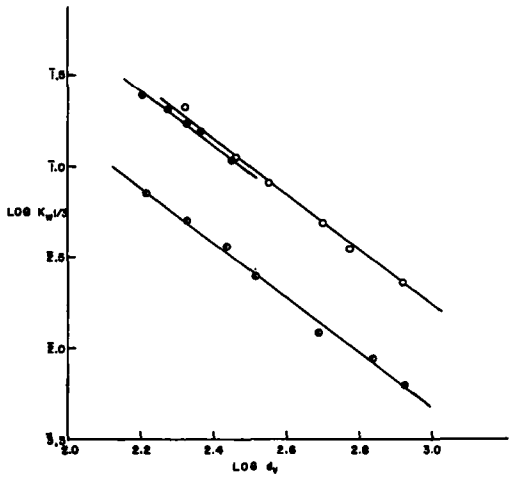

Fig. 3.—Dependency of log initial Hixon-Crowell rate constants on log initial mean volume diameter. Lines have slope of −1.5. —O—O— potassium ferricyanide, 23.4°; —●—● spray-congealed salicylamide, 24.8°; —◐—◐— potassium dichromate, 23.4°.

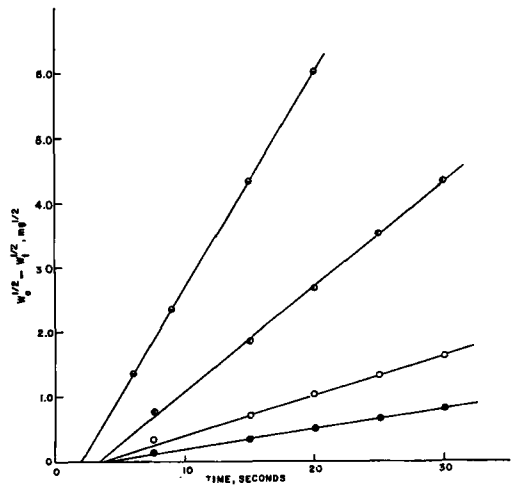

Fig. 4.—Typical dissolution data for potassium dichromate plotted according to Eq. 14. T = 23.4°. ◒—164μ, ◐—272μ, O—489μ, ●—846μ.

All of the data were replotted as $\Delta W^{1/2}$ *vs.* t according to Eq. 14 and were found to be described by this equation even better than by Eq. 4. Figure 4 shows typical data plots of Eq. 14. These rate constants are listed in Table I as $K_w^{1/2}$.

Figure 5 is a model plot of fraction initial diameter against time calculated from Eqs. 4 and 14. It is seen from Fig. 5 that appreciable deviation from the cube root law is not encountered until dissolution has progressed to a region where $d_t \sim 0.6\,d_v$ or 80% of the particle has dissolved. This explains why Eq. 4 described the data within a run but did not correlate data between runs of sufficiently different size material.

As additional tests of Eq. 14, two experiments were run. From Eq. 14 it may be seen that the rate constant depends on the square root of the total number of particles. Since N is proportional to weight, aqueous dissolution rate constants were determined for different initial weights of a single size fraction of crystalline salicylamide (needle habit). Figure 6 shows a plot of $k_w^{1/2}$ against $W_o^{1/2}$ and shows by its linearity that Eq. 14 is valid.

The number of particles can be kept constant for different size fractions by calculating equivalent weights from the size data. When this is done the rate constant given by Eq. 14 should be independent of size while the constant given by Eq. 4 would be independent of size only if δ were constant. Table II gives data obtained from dissolution runs on samples of potassium dichromate in which the number of particles was kept constant.

It can be seen from the data in Table II that $k_w^{1/2}$ is constant but that $k_w^{1/3}$ increases as particle size is decreased. The most exacting test of the experimental method and Eq. 14 would be their ability to describe the complete dissolution curve. One run was made using 0.1000 Gm. of 140–200 mesh potassium dichromate in the previous experiment. In this system the particles completely dissolved to give a solution which could still be assayed directly in the instrument. Figure 7 compares the experimental data using the Hixon-Crowell $\Delta W^{1/3}$ plot and the $\Delta W^{1/2}$ plot derived above.

As seen in Fig. 7 neither equation exactly described the data over the complete run. While the results from the $\Delta W^{1/3}$ plot cannot be explained at this time unless the δ dependency is accepted, there is a valid reason for the deviation in the $\Delta W^{1/2}$ plot. At the point where deviation first occurs, 96% of the material has dissolved and it is not unreasonable to expect that the smaller particles are disappearing. Thus, N would no longer be constant and the curve would be expected to fall off as shown. It was also of interest to note in this run that the final three data points showed that exactly 0.100 Gm. of potassium dichromate had dissolved. This indicates the accuracy of dissolution data obtained with the apparatus.

DISCUSSION

The data obtained in this study clearly show that the cube root law does not describe dissolution of particles under the degree of agitation used. The data were described by an equation derived by making the assumption that δ was proportional to $d_v^{1/2}$. It might be expected that such a simple relationship between δ and d_v should be derivable on a theoretical basis. This type of mathematical treatment has been well developed for flow past a flat surface, but it is generally conceded that flow past a sphere is so complicated that mathematical handling is impossible (15). Solving the Prandtl boundary layer equations for flow past a flat surface result in the relationship (16)

$$\delta = k \frac{L^{1/2}}{v^{1/2}} \qquad \text{(Eq. 15)}$$

where L = the length of the surface in the direction of flow, v = the approach velocity of the flowing liquid. Thus, in the system studied one might expect that the larger particles would be subjected to greater flow velocities as postulated by McCabe and Stevens, but, on the other hand, that their surface dimensions would be larger. These two effects are in opposition as seen from Eq. 15. Certainly, direct measurement of the diffusion layer and correlation of factors affecting it would contribute significantly to the complete understanding of particle dissolution. Until such information is available the possible nonconstancy of δ as dissolution proceeds must be considered in the treatment of particle dissolution data.

SUMMARY

1. Dissolution data for different size fractions of three different compounds were obtained.

2. The data were described by an equation derived on the assumption that the thickness of the diffusion layer was proportional to the square root of the mean volume diameter.

3. Experiments designed to test the equation showed that it was valid under the conditions of study.

4. The applicability of the method of Niebergall and Goyan to dissolution studies was demonstrated.

Stability of Antibacterial Preservatives in Parenteral Solutions III

Relationship Between Chemical Loss and Microbiological Activity in Multiple-Dose Vials

By L. LACHMAN, S. WEINSTEIN, T. URBANYI, E. EBERSOLD, and J. COOPER

The loss of preservative content due to degradation in solution and absorption by rubber stoppers was studied by chemical and microbiological analytical methods. The preservatives investigated were chlorobutanol and *p*-chloro-β-phenylethyl alcohol in conjunction with neoprene rubber stoppers. The contribution of rubber extractives and preservative degradation products towards enhanced antimicrobial activity is discussed.

THE LOSS of preservatives from solution due to degradation or absorption by rubber stoppers has been determined by chemical (1–4) and microbiological (4–6) methods. However, there are no reports in the literature quantitatively comparing the loss of preservative as determined chemically and microbiologically. This lack of information can be ascribed to two major factors: (*a*) the time consuming and cumbersome characteristics of microbiological procedures and (*b*) the fact that existing microbiological assay methods have not been of sufficient accuracy or precision to permit valid comparisons.

In a previous investigation (7) a turbidimetric microbiological assay method was described for chlorobutanol and *p*-chloro-β-phenylethyl alcohol. This would now permit a valid correlation between chemical and microbiological determinations of preservative content.

Because of the techniques employed in the manufacture of rubber stock to be used for molding rubber stoppers, it is not uncommon for the rubber to contain appreciable amounts of unreacted accelerators, activators, and antioxidants. It has been recognized that these unreacted materials, as well as certain reaction products (8–12), can be extracted by solutions coming in contact with the stopper. These materials have been shown to exert deleterious effects on active ingredients (13) and antibacterial agents (10) in injectable solutions.

In this study the influence of rubber closure extractives on the microbiological activity of the preservatives chlorobutanol and *p*-chloro-β-phenylethyl alcohol in vial solutions buffered to a pH 4 and stoppered with neoprene closures was determined. In addition, the contribution of preservative degradation products to antibacterial activity was ascertained. These two preservatives were chosen for study because chlorobutanol is representative of one which degrades in solution as well as being absorbed by the closure, whereas *p*-chloro-β-phenylethyl alcohol is representative of a preservative which essentially undergoes no degradation for the duration of study but which is lost from solution by absorption into the closure. Analyses for residual preservative content were performed both chemically and microbiologically and the results compared to determine whether rubber extractives or preservative degradation products influence the microbiological determinations.

mer closure No. 704, West Co.; U.S.P. type I, 10-ml. amber ampuls and vials, Kimble Glass Co.; and three-piece aluminum caps for vials Nos. 13–30, West Co.

Equipment.—Bausch & Lomb Spectronic 20 colorimeter; Beckman spectrophotometer model DU; Beckman pH meter model G; and Cary recording spectrophotometer model No. 11.

Preparation of Ampuls and Vials of Preservative Solution.—The rubber closures, vials, and ampuls used in this study were prepared in accordance with the procedures described in a previous publication of this series (14). Solutions of 0.3% *p*-chloro-*β*-phenylethyl alcohol and 0.5% chlorobutanol were prepared on a w/v basis with water for injection buffered to a pH of 4.0. The preservative solutions were then filtered through medium porosity sintered-glass filters. Each preservative solution was filled into 10-ml. amber ampuls and vials. The ampuls were closed by normal pull sealing techniques under an oxygen-gas flame. The vials of each preservative solution were stoppered with the neoprene closures. The stoppered vials were then sealed at a constant head pressure of 60 p.s.i. with a Westcapper. The preservative solutions in ampuls and vials were placed into a constant temperature oven regulated at 60° ± 1.5°. Half of the vials were stored in an upright position and half inverted. At prescribed time intervals, samples were withdrawn and tested chemically for residual preservative content, and microbiologically for residual antibacterial activity.

Analytical Methods.—*Chemical:* The assay methods employed for chlorobutanol and *p*-chloro-*β*-phenylethyl alcohol have been described in an earlier publication of this series (14).

Microbiological: A complete description of the method used for quantitatively determining the residual antibacterial activity of chlorobutanol and *p*-chloro-*β*-phenylethyl alcohol has been presented in the previous paper of this series (7).

RESULTS AND DISCUSSION

The loss of preservative content and its related antibacterial activity was determined by chemical and microbiological methods. Converting the antibacterial activity to preservative concentration permitted a comparison with the residual preservative content measured chemically. This then enabled a valid evaluation of the influence of closure extractives and preservative degradation on antibacterial activity.

TABLE I.—NEOPRENE CLOSURE COMPOSITION AND PHYSICAL PROPERTIES

Composition	Physical Properties
Neoprene polymer[a]	Specific gravity = 1.490
Sulfonated oil	Thickness[b] = 0.125 inch
Calcined clay	Weight[c] = 548 mg.
Barium sulfate

	Vials inverted	35.7	32.1

The neoprene closures were chosen for this study as a result of earlier data (14) showing that these preservatives exhibited the greatest loss from solution when in contact with these closures. The composition, per cent rubber content, and the physical properties of these closures are given in Table I.

Chemical and Microbiological Results

***p*-Chloro-*β*-phenylethyl Alcohol.**—The data summarized in Table II show the amount of *p*-chloro-*β*-phenylethyl alcohol absorbed by the rubber when the vials are stored at 60° in inverted and upright positions. When plotting these data rectilinearly, as shown in Fig. 1, it is evident from these graphs that at about 21 days the curves develop a plateau. This would indicate that the time required for the absorption to reach an equilibrium concentration is the same for the vials stored in an inverted or upright position. However, the equilibrium concentration of the preservative in the closure is higher for the vials stored in the inverted position as compared with those stored upright.

From the equilibrium portions of the curves it is apparent that the per cent preservative absorbed as determined microbiologically is less than that found chemically. This difference can be attributed to extractives being leached from the rubber stopper and exhibiting antimicrobial activity. When the preservative solutions are assayed microbiologically, the antibacterial activity found is a measure of the biological activity of the residual preservative plus that due to extractives. Therefore, when the microbiological assay data are converted from activity to concentration, it would suggest that less preservative was absorbed. Berry (10) has shown that the presence of tetramethylthiuram disulfide used as an accelerator in rubber compositions exerts a bactericidal effect. The present investigation indicates that the accelerator contained in the neoprene closures, namely 2-mercaptoimidazoline ethylene thiourea, also possesses antibacterial activity.

Since the total concentration of preservative in solution would be expected to be significantly greater than that in the vapor above the solution, there should occur less preservative absorption when the vials are stored upright. That this is the case is shown by comparing the difference between the equilibrium absorption concentrations for the vials stored upright and inverted. As measured

chemically, the difference is about 7% as compared to 11% when measured microbiologically. The 4% difference that exists between these two assay methods must be attributed to extractives being leached from the closure and exerting antibacterial activity. This is confirmed by comparing the equilibrium concentration of preservative absorbed for the vials stored in an inverted position and determined both chemically and microbiologically. The microbiological assay shows about 4% less preservative absorbed when compared with the chemical assay.

Chlorobutanol.—A comparison between chemical and microbiological assays measuring chlorobutanol loss in vial solutions stoppered with neoprene closures and stored at 60° in inverted and upright positions is presented in Table III. It is evident from the degradation data obtained for the ampul solutions that the microbiological assay does not indicate any loss of preservative until there is about a 6% reduction in concentration as measured chemically. It is postulated that this difference is due to the degradation products exerting antibacterial activity. These degradation products were identified by Nair and Lach (15) to be acetone, carbon monoxide, chloride ion, and alpha-hydroxybutyric acid.

It would appear from the data for the vial solutions that the difference between the residual concentration of preservative measured chemically and microbiologically can be mainly ascribed to the antimicrobial activity of the rubber extractives leached from the rubber and to a lesser degree to the antibacterial activity of the degradation products of the preservative.

SUMMARY

This study was undertaken in an effort to determine whether chemical analysis for residual preservative in vial solutions stoppered with rubber closures is a true indication of residual preservative activity. The preservatives evaluated were chlorobutanol which degrades in solution and is absorbed by the rubber and *p*-chloro-β-phenylethyl alcohol which is apparently lost from solution entirely by absorption into the rubber stopper. The data may be summarized as follows:

1. The extractives leached from the neoprene stoppers were found to exhibit demonstrable antimicrobial activity causing the microbiological analysis for residual preservative to be higher than that determined chemically.

2. Although the degradation products of chlorobutanol showed some antibacterial activity, it was substantially less than the extractives leached from the rubber closure.

3. In order to properly determine the influence of rubber closures on preservatives in parenteral solutions, it is important to study the preservative systems both chemically and microbiologically.

Stability of Antibacterial Preservatives in Parenteral Solutions IV

Contribution of Rubber Closure Composition on Preservative Loss

By LEON LACHMAN, TIBOR URBANYI, and SEYMOUR WEINSTEIN

The loss of benzyl alcohol, phenylethyl alcohol, and methylparaben from solution in the presence of natural, neoprene, and butyl rubber stoppers was studied. The influence of closure extractives on the analysis for residual preservative was evaluated. To insure valid determinations of preservative loss, techniques for eliminating the interference of extractives in the analysis were investigated. Partition studies were performed on the preservatives to determine their relative preference for each rubber composition studied.

THE USE of rubber closures for parenteral solutions in multiple-dose vials has resulted in many compatability problems (1–3). This can be attributed to the complexity of most rubber closure formulations which contain about 40–50% rubber, plus at least seven other components (4). These include vulcanizing agents, activators, accelerators, fillers, pigments, antioxidants, and softeners, all of which are reported to be essential if the stoppers are to possess the desirable physical and chemical properties.

In order to insure complete vulcanization of various type rubbers, excess quantities of accelerators, activators, and other additives are generally used. It has been shown that some of these unreacted agents and reaction products of the vulcanization process can be leached from the closure by parenteral solutions. These materials exert toxic and pyrogenic effects (5, 6) as well as deleterious effects on the stability of the injectable solution (7–10).

In previous investigations conducted at this laboratory (11, 12), rubber closures and rubber extractives were found to significantly influence preservative loss from solution and antimicrobial activity, respectively. In this study an attempt was made to determine (*a*) the effect of neoprene, natural, and butyl rubber closures on the loss of benzyl alcohol, methylparaben, and phenylethyl alcohol from vial solutions, (*b*) the manner in which rubber extractives interfere with the assay methods for residual preservative, and (*c*) the distribution tendencies of the above three preservatives between water buffered to a pH of 4 and each composition rubber stopper.

Received March 29, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication July 10, 1962.

EXPERIMENTAL

Materials.—Benzyl alcohol, reagent grade, Fisher Scientific Co., methylparaben, U.S.P.; phenylethyl alcohol, Eastman Organic Chemicals; heptaldehyde aniline reaction product, tetramethyl thiuram monosulfide, and zinc dimethyl dithiocarbamate, West Co.; 0.275 *M* citric acid–sodium phosphate buffer of pH 4.0; natural crepe, neoprene polymer, and butyl polymer rubber stoppers, West Co.; 10-ml. amber ampuls and vials, U. S. P. type I; and three-piece aluminum caps for vials, West Co., No. 13–30.

Equipment.—Beckman spectrophotometer model DU; Cary recording spectrophotometer model No. 11; and Beckman pH meter model G.

Preparation of Ampuls and Vials of Preservative Solutions.—The ampuls, vials, and stoppers were washed in a manner described in a previous study (11). Solutions of 1.0% benzyl alcohol, 0.2% methylparaben, and 0.5% phenylethyl alcohol were prepared on a w/v basis with water for injection buffered to a pH of 4.0. The solutions were filtered through a medium porosity sintered-glass filter. Each preservative solution was filled into 10-ml. ampuls and vials. The ampuls were closed by customary pull sealing procedures with an oxygen-gas flame. The vials of each preservative solution were stoppered with three different composition rubber closures and then sealed with three-piece aluminum caps at a constant sealing head pressure of 60 p.s.i. with a Westcapper. The preservative solutions in ampuls and vials were placed in constant temperature ovens regulated at 25, 40, 50, and 60° ± 1.5°. Half of the vials were stored upright and half inverted. At designated time intervals, samples were withdrawn and tested for residual preservative content, pH, and physical change.

Apparent Distribution of Preservative Between Buffer Solution and Rubber.—The procedure employed has been described in detail in a previous publication (11). This evaluation was done for the three stoppers: neoprene, natural, and butyl rubber, and the preservatives: benzyl alcohol, phenylethyl alcohol, and methylparaben.

Analytical Methods

Benzyl Alcohol.—The concentration of preserva-

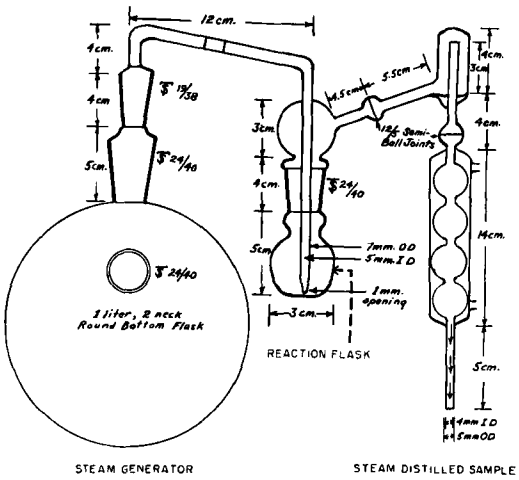

Fig. 1.—Microsteam-distillation apparatus.

tive was determined by pipetting 1 ml. of solution into a microsteam-distillation apparatus (Fig. 1) and the sample distilled to 25 ml. Absorbance was measured at 257 mμ where the $A(1\%, 1\text{ cm.}) = 18$.

Phenylethyl Alcohol.—The concentration of preservative was determined by pipetting 3 ml. of solution into a microsteam-distillation apparatus and the sample steam distilled to 30 ml. The distillate was brought up to volume in a 50-ml. volumetric flask with distilled water. Absorbance was measured at 257 mμ where $A(1\%, 1\text{ cm.}) = 18$.

Methylparaben.—A 3-ml. aliquot was pipetted into a 50-ml. volumetric flask and brought up to volume with methanol. Five milliliters of this solution was transferred to a 100-ml. volumetric flask and brought up to volume with methanol. Absorbance was measured at 256 mμ where $A(1\%, 1\text{ cm.}) = 1115$.

TABLE I.—BUTYL RUBBER COMPOSITION AND PHYSICAL PROPERTIES

Composition	Physical Properties
Butyl polymer[a]	Specific Gravity = 1.609
Barium sulfate	Thickness[b] = 0.125 inches

Titanium dioxide	
Zinc oxide	
Stearic acid	
Paraffin wax	
Sulfur	
Thiuram combined with aniline reaction product	

[a] Rubber content is 36.8% of total composition. [b] Measured microscopically, and the value is an average of five measurements from different stoppers. [c] Value is an average of ten stoppers.

RESULTS AND DISCUSSION

The stability of several bacteriological preservatives in aqueous buffered solutions stored in multiple-dose vials was studied. The rubber stoppers used in this investigation are representative of three closure compositions frequently employed for multiple-dose vials. The composition, per cent rubber, and physical properties for the neoprene and natural rubber stoppers were presented in a previous paper (11). However, a different butyl stopper was used in place of the one used earlier because there was an obvious physical incompatability with the preservative solutions used. The composition and physical properties for this closure are presented in Table I.

Benzyl Alcohol

The influence of neoprene, natural, and butyl rubber stoppers on the stability of benzyl alcohol in aqueous solution buffered to a pH of 4.0 was investigated. The results obtained from ampul and vial solutions are summarized in Table II. It is evident from the data in this table that for the vials stoppered with butyl rubber closures, there appears to be a substantial increase in benzyl alcohol concentration with time instead of the expected loss or maintenance of concentration. This also seems to occur for the vial solutions stoppered with neoprene closures, but to a lesser degree. However, for the vials stoppered with the natural rubber closures, this effect was not observed.

As a result of this unexpected finding, investigations were initiated to determine whether extractives from the rubber stopper were responsible for the apparent increase in benzyl alcohol content. After reviewing the composition of the butyl rubber closure (Table I), it was presumed that the presence of unreacted accelerators or their reaction products would most likely be the causative agents for the difficulties being encountered. If these agents were leached from the closure by the benzyl alcohol solution they could interfere with the analysis for residual preservative content by exhibiting high absorptivity in the wavelength region of benzyl alcohol.

In order to verify this assumption, samples of the primary (heptaldehyde aniline reaction product) and secondary (tetramethyl thiuram monosulfide) accelerators and the reaction product of the accelerators (zinc dimethyl dithiocarbamate) were obtained from the rubber closure manufacturer and analyzed according to the procedure used for the preservative solution. For the heptaldehyde aniline reaction product, 1 ml. was steam distilled in a manner similar to that used for benzyl alcohol, while for the secondary accelerator and the reaction product of the accelerators, separate saturated solutions were prepared in pH 4 buffer and a 3-ml.

TABLE II.—PER CENT RESIDUAL BENZYL ALCOHOL AFTER STORAGE AT 60° C.

12	103	124	131	102	102	87	88

aliquot removed and steam distilled. The absorption curves in the ultraviolet region for the distilled samples are shown in Fig. 2. It is evident from these curves that a volatile component of the heptaldehyde aniline reaction product exhibits strong absorption in the region of 257 mμ, the wavelength where measurements are made for benzyl alcohol. The other two components, namely tetramethyl thiuram monosulfide and zinc dimethyl dithiocarbamate, show very low absorption at 280 mμ and no absorption at 257 mμ.

The influence of the closure extractives on the absorption characteristics of benzyl alcohol stored as a buffered solution in vials stoppered with the butyl rubber closure is illustrated in Fig. 3. By studying the curve for the zero time sample, it is apparent that the absorbance values for the minimum at 253 mμ and the maximum at 263 mμ are equal.

However, the curve for the sample stored for 12 weeks at 60° shows a large difference between the absorbance at 253 mμ and 263 mμ. This difference can be ascribed to the influence of the absorption characteristic of the volatile component of the primary accelerator which is leached into the benzyl alcohol solution from the rubber stopper. The effect at 253 mμ and 263 mμ causes a concurrent effect at 257 mμ, the absorption maximum used for benzyl alcohol analysis.

In order to correct the absorption readings for benzyl alcohol to deduct the amount due to extractives, two procedures were evaluated.

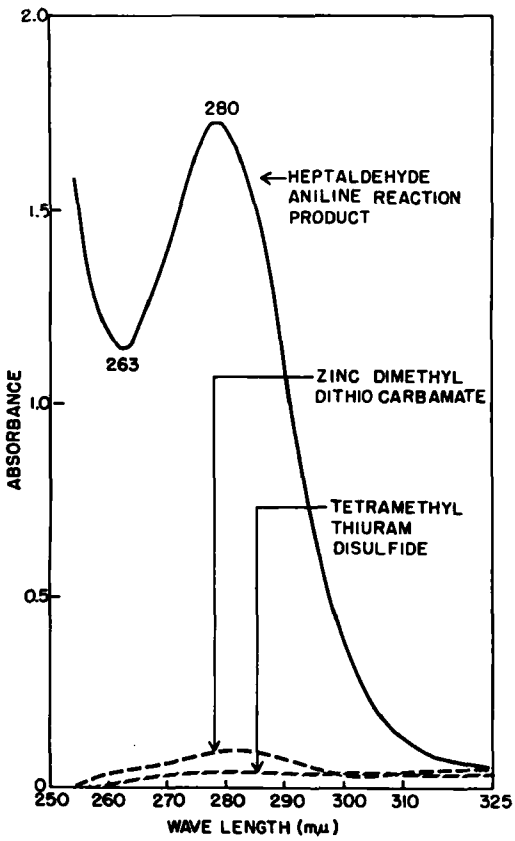

Fig. 2.—The ultraviolet absorption spectra of the accelerators and a reaction product found in the butyl rubber stoppers.

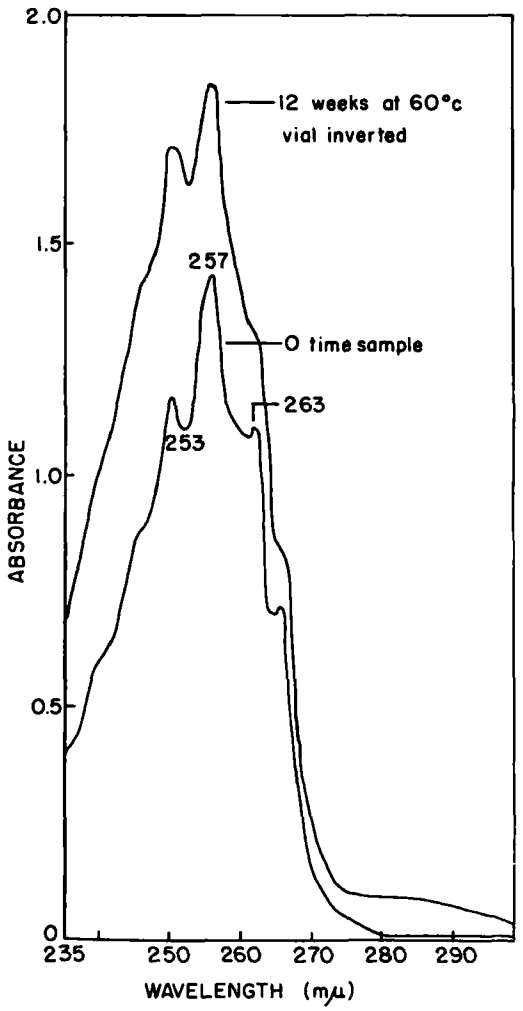

Fig. 3.—Plots showing the influence of butyl rubber closure extractives on the absorption characteristics of benzyl alcohol.

Method I.—The following equation was developed to correct for the absorbance due to extractive and thus give the true absorbance at 257 mμ for benzyl alcohol: $A = B - (C - D)$ where A = corrected absorbance at 257 mμ; B = observed absorbance at 257 mμ; C = observed absorbance at 253 mμ; D = observed absorbance at 263 mμ.

Using this equation, the uncorrected data in Table II for the vials stoppered with butyl rubber stoppers were recalculated and are presented in Table III. It is evident from this table that the corrected values are still higher than the original concentration in most instances. However, if the data are now further corrected for benzaldehyde development measured at 280 mμ, the results presented in the last two columns of Table III are obtained. These data now show that no absorption of benzyl alcohol by the butyl rubber stopper results when the vials are stored in an inverted or upright position.

Method II.—An alternate method used to correct

TABLE III.—CORRECTED PER CENT RESIDUAL BENZYL ALCOHOL IN VIALS STOPPERED WITH BUTYL RUBBER AFTER STORAGE AT 60° C.

Time, weeks	Uncorrected		Corrected			
			Extractives		Extractives and Benzaldehyde	
	Upright	Inverted	Upright	Inverted	Upright	Inverted
2	105	110	100	101	100	100
4	106	124	101	105	99	101
8	115	127	105	107	101	100
12	124	131	103	108	100	102

for the absorbance at 257 mμ due to extractives was a modification of the Morton-Stubb technique (13). A model is presented in Fig. 4 representing pure benzyl alcohol and benzyl alcohol containing extractives which influence the characteristics of the absorption curve. Points *A* and *B* in Fig. 4 are representative of the equal absorbance at the minimum of 253 mμ and maximum of 263 mμ shown in Fig. 3 for pure benzyl alcohol. These wavelengths in the model are represented by λ_2 and λ_3. The wavelength of 257 mμ used in the analysis for benzyl alcohol is represented in the model by λ_1. Using the curves in Fig. 4 as simplified models of the benzyl alcohol absorption curves shown in Fig. 3, an equation was derived which corrects for the absorbance due to extractives.

CE = increase in absorbance at 257 mμ due to extractives; $CD = \frac{DG}{FG} \times HF$ by trigonometry; where HF represents the difference between the observed absorbance at λ_2 and λ_3. $DG = \lambda_3 - \lambda_1$ and $FG = \lambda_3 - \lambda_2$.

If DE is denoted by X, then the corrected value for the absorbance at λ_1 is $A\lambda_1$ corrected $= A\lambda_1$ observed $- CD - X$ and at λ_2 is $A\lambda_2$ corrected $= A\lambda_3$ observed $- X$. Therefore, the ratio of these must be equal to the known ratio for the pure substance designated as K

$$K = \frac{A\lambda_1 \text{ observed} - CD - X}{A\lambda_3 \text{ observed} - X} = 1.31$$

for pure benzyl alcohol.

Since DG = 263 mμ − 257 mμ = 6 mμ and FG = 263 mμ − 253 mμ = 10 mμ then $\frac{DG}{FG} = 0.6$

$$K = \frac{A^{1\%}_{257} - (A^{1\%}_{253} - A^{1\%}_{263})\,0.6 - X}{A^{1\%}_{263} - X}$$

Solving for X

$$A^{1\%}_{257} - (A^{1\%}_{253} - A^{1\%}_{263})\,0.6 - X =$$
$$(A^{1\%}_{263} - X)\,1.31 - X + 1.31\,X =$$
$$[(A^{1\%}_{263})\,1.31] - [A^{1\%}_{257} - (A^{1\%}_{253} - A^{1\%}_{263})\,0.6]$$
$$X = \frac{[(A^{1\%}_{263})\,1.31] - [A^{1\%}_{257} - (A^{1\%}_{253} - A^{1\%}_{263})\,0.6]}{0.31}$$
$$CD = (A^{1\%}_{253} - A^{1\%}_{263})\,0.6$$
$$A^{1\%}_{257} \text{ corrected} = A^{1\%}_{257} \text{ observed} - (X + CD)$$

The data for the vials stoppered with the butyl rubber closures were corrected according to this equation and the corrected data were found to be in agreement with the data obtained from the equation in Method I. This indicates that either Method I or II satisfactorily corrects for the absorbance due to extractives. However, since Method I is simpler than Method II, it was used to correct the data for the vials stoppered with the neoprene closures.

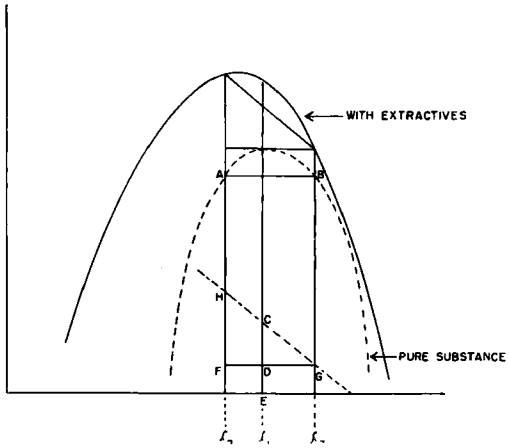

Fig. 4.—Model curves developed from the absorption plots shown in Fig. 3 for use in developing the modified Morton-Stubbs correction for benzyl alcohol assay.

The results in Table IV show the corrected and uncorrected values for the per cent preservative

TABLE IV.—CORRECTED AND UNCORRECTED PER CENT RESIDUAL BENZYL ALCOHOL IN VIALS STOPPERED WITH NEOPRENE RUBBER AFTER STORAGE AT 60°C.

Time, weeks	Uncorrected		Corrected	
	Upright	Inverted	Upright	Inverted
2	96	98	94	95
4	96	97	92	92
8	99	107	90	92
12	102	102	91	90

absorbed by the neoprene rubber stoppers. These stoppers behave differently from the butyl rubber, in that they absorb preservative from solution as well as leach out extractives. This is particularly apparent from the data for the vials stored in an inverted position. The decrease in apparent benzyl alcohol concentration after 12 weeks storage indicates that the benzyl alcohol is continuing to be absorbed by the closure while the amount of extractives being leached from the closure has apparently reached an equilibrium concentration somewhere between 8 and 12 weeks.

In Table V is presented the corrected per cent residual benzyl alcohol for the ampul and vial solutions stoppered with the three closures. It can be seen from this table that the natural rubber

TABLE V.—THE CORRECT PER CENT RESIDUAL BENZYL ALCOHOL AFTER STORAGE AT 60° C.

Time, weeks	Ampul	Butyl Rubber		Neoprene Rubber		Natural Rubber	
		Upright	Inverted	Upright	Inverted	Upright	Inverted
2	100	100	100	94	95	96	98
4	100	99	101	92	92	95	95
8	101	101	100	90	92	89	92
12	100	100	102	91	90	87	88

absorbs slightly more benzyl alcohol than the neoprene rubber. However, it is interesting to note that for both stoppers the amount of preservative absorbed is the same for the vials stored in an upright and inverted position.

From the data presented above, it is apparent that extractives leached from closures may have a significant effect on the assay for residual preservatives. Consequently, when assay results for preservative content appear to be irregular or show an increase with storage, consideration should not only be given to the assay method but also to the possibility that extractives are being leached from the rubber stoppers and interfering with the assay. If the assay method is a spectrophotometric one, it is necessary to run the complete absorption curves in order to adequately demonstrate the interfering characteristics of the extractives.

Methylparaben

The stability of a 0.2% solution of methylparaben (pH 4.0) in vials stoppered with natural, neoprene, and butyl rubber closures and stored at 60° was investigated. According to the data presented in Table VI, methylparaben appears to exhibit good stability in the presence of butyl rubber and fair stability with natural and neoprene rubber, with the latter causing the greater deleterious effect. As in the case of benzyl alcohol, the amount of methylparaben lost from solution was the same in vials stored upright or inverted.

It is interesting to note that although residual methylparaben was assayed spectrophotometrically at 256 mμ which is extremely close to the 257 mμ used for benzyl alcohol, no interference was observed due to extractives. This may be explained as follows: (*a*) since methylparaben is a solid, it does not exert any solublizing effect on the unreacted accelerator in the rubber, (*b*) the steam distilling of the benzyl alcohol solution before assaying could concentrate the volatile component responsible for interfering with the assay for benzyl alcohol, and (*c*) the high $A^{1\%}_{1cm.}$ of 1115 for methylparaben compared to 18 for benzyl alcohol could diminish any effect due to the absorptivity of the extractives.

Phenylethyl Alcohol

The influence of neoprene, natural, and butyl rubber stoppers on the preservative content of a 0.5% aqueous buffered solution of phenylethyl alcohol (pH 4.0) stored in vials at 60° was studied. It became evident early in the study that the solutions in the vials as well as in the ampuls developed a very fine precipitate which remained fairly well distributed throughout the solution. This precipitate was found to interfere with the spectrophotometric assay for residual preservative since it appeared to distill over from the aliquot of phenylethyl alcohol solution taken for assay, causing high assays for phenylethyl alcohol. In fact, after 12 weeks storage at 60°, the ampuls assayed 112% phenylethyl alcohol. Because of the interfering properties of the precipitate on the assay results, it was felt that the data were not adequate for presentation in this report.

It is believed that the precipitate is due to oxidation products of phenylethyl alcohol, namely, phenylacetaldehyde and phenylacetic acid. Further information will be presented on this preservative at a later date when the studies presently underway to elucidate the responsible factors for the precipitate development are completed.

Apparent Distribution of Preservative Between Rubber and Solution.—In an earlier report (11) data were presented on the distribution of *p*-chloro-β-phenylethyl alcohol and phenylethyl alcohol between rubber and water buffered to a pH of 4.0. These tests were performed with neoprene and natural rubber stoppers.

Similar studies were performed in this investigation for the preservatives chlorobutanol, benzyl alcohol, and methylparaben. The apparent partition coefficients for these three preservatives, as well as for the two studied in the earlier investigation, are summarized in Table VII. These data indicate that of the five preservatives, benzyl alcohol exhibits the least tendency to distribute into either the natural or neoprene rubber of the five preservatives tested. For each preservative the neoprene stoppers absorb to a greater degree than the natural rubber.

From the distribution data in this table, the natural rubber stoppers show the following order of absorption of preservative: benzyl alcohol < methylparaben < phenylethyl alcohol < *p*-chloro-β-phenylethyl alcohol < chlorobutanol. The results for the neoprene stoppers are as follows: benzyl alcohol < phenylethyl alcohol < methylparaben < chlorobutanol < *p*-chloro-β-phenylethyl alcohol. It is interesting to note that the order of absorption is not the same for the two composition closures. The preservative being most absorbed by the natural

TABLE VI.—PER CENT RESIDUAL METHYLPARABEN AFTER STORAGE AT 60° C.

	Neoprene	7.27	8.40

[a] Solutions buffered to a pH of 4.0.

rubber is chlorobutanol while for the neoprene rubber it is *p*-chloro-β-phenylethyl alcohol.

It is common practice for rubber closure manufacturers to use an excess of accelerators and additives in rubber closure formulations. As a result, there exists at the completion of the manufacturing process certain unreacted components in the rubber stock. The quantity of unreacted accelerators present in synthetic rubbers would be expected to be greater than in natural rubber. This is due to the fact that the synthetic rubber, such as butyl and neoprene, is generally more inert than natural rubber, thus making the vulcanization process more difficult. In order to minimize this difficulty, higher dosages of accelerator are used (14).

The results obtained in this investigation, as well as those reported by other investigators, show that the unreacted components of the closure could be extracted by the solution in the vials. These extractives could be extremely dangerous in that they can (*a*) affect the toxicity of the injectable solution, (*b*) interact with components in the solution and cause physical and chemical instability, (*c*) influence bactericidal activity, and (*d*) as illustrated in this investigation, seriously interfere with the analysis of the solution. Consequently, it is essential that rubber stopper manufacturers use more precise formulations and adequate quality standards in the manufacture of rubber closures.

SUMMARY

The interaction between several composition rubber stoppers and three preservatives was evaluated. Aqueous buffered solutions of the preservatives benzyl alcohol, methylparaben, and phenylethyl alcohol were filled into multiple-dose vials and stoppered with natural, neoprene, and butyl rubber closures. These vials were then stored at several temperatures and tested at designated time intervals for the effect of closure on preservative content. The data from this study may be summarized as follows:

1. Two methods were developed to correct for the interference of rubber closure extractives on the analytical procedure used for benzyl alcohol.

2. The butyl rubber closures, although leaching extractives into the preservative solutions, exhibited the least absorbing tendencies toward benzyl alcohol and methylparaben.

3. The amount of benzyl alcohol and methylparaben lost from vial solutions was not significantly influenced by storage of the vials in an upright or inverted position.

4. Distribution studies have shown that both the natural and neoprene rubber stoppers absorbed preservative from solution with the latter closure exhibiting greater absorbing tendencies.

5. From the distribution data in this and a previous study, the natural rubber stoppers exhibit the following order of preservative absorption: benzyl alcohol < methylparaben < phenylethyl alcohol < *p*-chloro-β-phenylethyl alcohol < chlorobutanol. For the neoprene stoppers the following order exists: benzyl alcohol < phenylethyl alcohol < methylparaben < chlorobutanol < *p*-chloro-β-phenylethyl alcohol.

Some 2-Substituted Derivatives of 2-Dimethylamino-1,2,3,4-tetrahydronaphthalene

By WILLIAM H. SHELVER† and ALFRED BURGER

The synthesis and pharmacological examination of several 2-dimethylamino-1,2,3,4-tetrahydronaphthalene 2-alcohols, 2-esters, and 2-ketones is described.

IT HAS BEEN postulated that potent morphine-type analgetics must contain a rigid structure in which the position of the basic nitrogen relative to an aromatic ring is fixed within narrow limits (1). In morphinan the 1,3-fused ring system serves to hold the nitrogen in the axial conformation. Since morphinan contains the 2-amino-1,2,3,4-tetrahydronaphthalene moiety, properly designed derivatives of this structural segment could be candidates for analgetic tests. In simple derivatives of 2-amino-1,2,3,4- tetrahydronaphthalene, the nitrogen will tend to assume the more stable equatorial position, and means other than ring fusion have now been considered to produce axial amino derivatives. Bulky groups in the 2-position with some degree of polarity, whose solvation may further increase their bulk, may cause a dimethylamino group at position 2 to assume an axial conformation. This article describes the synthesis of such compounds. Because bulky groups, on the other hand, may interfere with receptor fit, several compounds containing smaller ester and keto groups in position 2 were also prepared for pharmacological evaluation.

Starting with 2-amino-2-carboxy-1,2,3,4-tetrahydronaphthalene (2), the amino group was methylated by an adaptation of the method of Clarke, *et al.* (3), and the carboxyl function was esterified. The synthesis of alkyl and aryl ketones proceeded from 2-carboxy-2-dimethylamino-1,2,3,4-tetrahydronaphthalene (I), or better from its methyl ester (II). Treatment of I with methyllithium at 25° gave small yields of 2-acetyl-2-dimethylamino-1,2,3,4-tetrahydronaphthalene (III) besides nonbasic decomposition products. Phenyllithium led to a mixture from which 2-benzoyl-2-dimethylamino- (IV) and 2-dimethylamino-2-(α-hydroxybenzhydryl)-1,2,3,4-tetrahydronaphthalene (V) could be separated. Compound V was also obtained from the reaction of phenyllithium and II at 25°, no ketone being isolated in this case. By contrast, the action of methyllithium on II furnished a mixture which on chromatography yielded 55% of 2-acetyl-2-dimethylamino-1,2,3,4-tetrahydronaphthalene (III) and 22% of 2-dimethylamino-2-(2-hydroxy-2-propyl)-1,2,3,4-tetrahydronaphthalene (VI). Reaction of II with ethyllithium furnished a mixture from which only a small amount of 2-dimethylamino-2-propionyl-1,2,3,4-tetrahydronaphthalene (VII) could be elaborated.

Reduction of I with lithium aluminum hydride gave 2-dimethylamino-2-hydroxymethyl-1,2,3,4-tetrahydronaphthalene whose benzoate ester (VIII) was prepared for pharmacological tests.

Compounds II, III, V, and VIII were screened pharmacologically.[1] None of them exhibited analgetic properties in mice at doses up to 200 mg./Kg.; the substances gave no indication of central nervous system depression or excitation, and did not produce hypoglycemia three hours after oral administration of 100 mg./Kg. to 18-hour fasted guinea pigs.

EXPERIMENTAL[2]

2 - Carboxy - 2 - dimethylamino - 1,2,3,4 - tetrahydronaphthalene (I).—A mixture of 2-amino-2-carboxy-1,2,3,4-tetrahydronaphthalene(2)(140 Gm., 0.73 mole), formaldehyde solution U.S.P. (1 L.), and 98% formic acid (1 L.) was refluxed for 10 hours; 100 ml. of concentrated hydrochloric acid was added, and volatile materials were removed by distillation. To the oily residue was added ethanol (750 ml.), and the solid which separated was filtered and washed with ether. Yield, 110 Gm. (70%). Recrystallization from ethanol gave a colorless material, m.p. 223–227° (decompn.). The infrared spectrum was compatible with an amino acid hydrochloride.

Anal.—Calcd. for $C_{13}H_{17}NO_2 \cdot HCl$: C, 61.29; H, 7.12. Found: C, 61.19; H, 6.94.

2 - Carbomethoxy - 2 - dimethylamino - 1,2,3,4-tetrahydronaphthalene (II).—A solution of I (50 Gm., 0.2 mole) in methanol (300 ml.) was treated slowly with a solution of diazomethane, prepared from 110 Gm. of N-methyl-N-nitrosourea, in 2 L. of ether at 0°. After standing overnight, most of the solvents were distilled off, the residue was taken up in ether, washed with potassium hydroxide solution, dried over sodium sulfate, and the ether was evaporated. The residual oil (34 Gm., 71%; b.p. 137°/0.3 mm.; n_D^{25} 1.5310) gave a hydrobromide salt which was recrystallized from isopropyl alcohol-isopropyl ether, m.p. 180°. The infrared spectrum had bands at 3.4, 3.6, 5.8, 6.3, 6.7, 6.9, 7.3, 8–8.5, 9.0, 9.3, 9.7, 9.9, 10.1, 11.0, 11.5, 12.0, 12.6, 12.8, 13.4, 14.2, and 14.8μ.

Anal.—Calcd. for $C_{14}H_{19}NO_2 \cdot HBr$: C, 53.34; H, 6.40. Found: C, 53.54; H, 6.54.

A small yield of the same methyl ester was obtained by refluxing I with equal weights of methanol and sulfuric acid.

2 - Carbethoxy - 2 - diethylamino - 1,2,3,4 -tetrahydronaphthalene.—Prepared in the same manner as the methyl ester, using diazoethane or ethanol and sulfuric acid. Yield 50%, based on weight of oil. Infrared bands of the base were at 3.4, 3.6, 5.8, 6.7, 6.9, 7.3, 8.3, 9.0, 9.75, 10.1, 11.0, 11.4, 12.4, 13.5, and 14.1μ. The hydrobromide, prepared in ether solution, was recrystallized from isopropyl alcohol-isopropyl ether, m.p. 160°.

Anal.—Calcd. for $C_{15}H_{21}NO_2 \cdot HBr$: C, 54.71; H, 6.74. Found: C, 54.44; H, 6.65.

Reaction of I with Phenyllithium.—To a stirred solution of 0.3 mole of phenyllithium in 300 ml. of ether was added, under nitrogen, 10 Gm. (0.04 mole) of I-hydrochloride in quantities of about 0.5 Gm., with sufficient time between additions to allow vigorous refluxing to cease. After 3 hours at 25° the mixture was poured on ice and the ether layer washed with dilute hydrochloric acid to dissolve all basic materials. The acid extracts were made basic with potassium hydroxide solution and extracted with ether. The combined ether extracts were dried and evaporated. The solid residue was crystallized fractionally from ethanol. The more soluble product (18%) melted at 82–83°; its infrared spectrum showed bands at 5.95μ (C=O), and 13.3 and 13.9μ (monosubstituted phenyl); there was no OH band. It represented the phenyl ketone IV.

Anal.—Calcd. for $C_{19}H_{21}NO$: C, 81.68; H, 7.57. Found: C, 81.75; H, 7.25.

The colorless hydrobromide crystallized from isopropyl alcohol-isopropyl ether, m.p. 175–176°.

Anal.—Calcd. for $C_{19}H_{21}NO \cdot HBr$: C, 63.33; H, 6.16. Found: C, 63.37; H, 6.28.

The less soluble compound (28%), m.p. 155–157°, was identical with V and obtained in better yield as described in the next experiment.

2 - Dimethylamino - 2 - (α - hydroxybenzhydryl)-1,2,3,4-tetrahydronaphthalene (V).—To 0.3 mole of phenyllithium in 300 ml. of ether was added 10 Gm. (0.04 mole) of II. The mixture was stirred under nitrogen at 25° for 6 hours, decomposed with ice, and the ether layer was dried over sodium sulfate and evaporated. The solid residue (60% yield) was recrystallized from ethanol, m.p. 155–157°. The material was identical (mixture m.p. and infrared spectra) with the less soluble substance described in the preceding experiment.

Anal.—Calcd. for $C_{25}H_{27}NO$: C, 83.99; H, 7.61. Found: C, 83.58; H, 7.59.

Reaction of 2-Carbomethoxy-2-dimethylamino-1,2,3,4-tetrahydronaphthalene (II) with Methyllithium.—A mixture of 0.3 mole of methyllithium and 10 Gm. of II in 300 ml. of ether was stirred for 3 hours, poured on ice, and the ether layer was extracted well with dilute hydrochloric acid The acid solution was made alkaline and re-extracted with ether. The oily residue from the dried ether extracts exhibited a large C=O band in the infrared, and a small OH band, and the latter did not increase when, in another experiment, the reaction time was extended to 9 hours. Chromatography in ether on Alcoa F-20 alumina furnished 5 Gm. (55%) of a solid, m.p. 52–53°; infrared peaks at 3.4, 3.6, 5.8, 6.75, 6.85, 7.4, 7.9, 8.4, 8.7, 8.9, 9.3, 9.5, 9.9, 10.75, 11.2, 11.9, and 13.3μ. This material represented 2-acetyl-2-dimethylamino-1,2,3,4-tetrahydronaphthalene (III) and was identical with a substance obtained in low yield from I and methyllithium.

Anal.—Calcd. for $C_{14}H_{19}NO$: C, 77.37; H, 8.81. Found: C, 77.04; H, 8.71.

The hydrobromide crystallized from isopropyl alcohol-isopropyl ether, m.p. 173–175°.

Anal.—Calcd. for $C_{14}H_{19}NO \cdot HBr$: C, 56.37; H, 6.75. Found: C, 55.91; H, 6.72.

A second, oily, fraction from the alumina column weighed 2 Gm. (22%) and represented the alcohol VI; infrared bands at 2.8, 3.4, 3.6, 6.3, 6.7, 6.9, 7.3, 7.7, 7.9, 8.1, 8.4, 9.0, 9.3, 9.6, 10.0, 10.6, 10.9, 11.1, 11.5, 11.8, 12.1, 12.4, 13.4, and 14.8 μ.

2 - Dimethylamino - 2 - propionyl - 1,2,3,4 - tetrahydronaphthalene (VIII).—This ethyl ketone was prepared as described for the lower homolog (III), using ethyllithium. The oily reaction product (6 Gm., 58%) exhibited both carbonyl and hydroxyl peaks in the infrared; only after chromatography could a solid salt be obtained from the ketonic fraction. The hydrobromide crystallized from isopropyl alcohol-isopropyl ether, m.p. 161–164°.

Anal.—Calcd. for $C_{15}H_{21}NO \cdot HBr$: C, 57.69; H, 7.10. Found: C, 57.90; H, 6.90.

2 - Benzoyloxymethyl - 2 - dimethylamino - 1,2,3,4-tetrahydronaphthalene (VIII).—To a filtered and stirred solution of 10 Gm. (1.25 moles) of lithium aluminum hydride was added, under nitrogen and in

[2] All melting points are corrected, boiling points uncorrected. Microanalyses by Mrs. Margaret Logan and Mrs. Dorothy Ellis.

small portions, 10 Gm. (0.04 mole) of I-hydrochloride. The mixture was refluxed for 2 hours, allowed to stand at 26° for 6 hours, decomposed with water and worked up as usual. The oily yellow material (6.5 Gm., 82%) had a strong OH peak in its infrared spectrum. It was benzoylated directly with 20 ml. of benzoyl chloride and 150 ml. of 10% sodium hydroxide solution for 15 minutes, the mixture was decomposed with ice, extracted with dilute hydrochloric acid, the acid solutions were made alkaline and re-extracted with ether. The oily product from the dried ether extract weighed 5 Gm. (50%) and exhibited an ester band in its infrared spectrum. Its hydrobromide crystallized from ethyl formate-isopropyl ether, m.p. 194–197°.

Anal.—Calcd. for $C_{20}H_{23}NO_2 \cdot HBr$: C, 61.54; H, 5.94. Found: C, 61.00; H, 6.10.

Analysis of the Volatile Components of Ylang-Ylang Oil by Gas Chromatography

By DAVID B. KATAGUE and ERNST R. KIRCH

Five samples of commercially available ylang-ylang oil were analyzed by gas chromatography. Of the various stationary liquid phases used, a 20% Ucon on Chromosorb P(w/w) gave consistently the best separation. The composition of extra, first, second, and third quality fractions and pure oil No. 123 was determined on the basis of relative retention times.

Most essential oils are complex mixtures of individual organic compounds that contain varied functional groups which make complete and detailed analysis relatively difficult or at times impossible using conventional procedures.

Thus, prior to the advent of gas chromatography, the analyses of essential oils were tedious and time consuming. Furthermore, in certain instances in which other methods were used, the analyses were not considered complete (1). The availability and development of gas chromatography as an analytical tool has not only greatly facilitated the separation, and at times the identification, of the constituents of a number of essential oils, but also reduced the time required for analyses (2, 3).

One of the important ingredients in a number of perfumes and other cosmetic products is ylang-ylang oil. This is obtained from the flowers of the ylang-ylang tree (*Cananga odorata*, Hook *f et* Thomson), which is probably a native of the Philippines (1). The important commercial sources of this oil for use in the United States today are the Nossi-Be and Comoro Islands. The oil is available in four different quality fractions, based on the respective boiling points, and is classified commercially as extra, first, second, and third quality fractions. The extra fraction exhibited the highest specific gravity and the lowest refractive index when compared to the other fractions. The samples labeled extra and first quality possess the strongest and finest odors.

That the chemical composition of the oil may be related to the manner in which the oil is extracted from the flowers has been shown by Glitchitch and Naves (4). They found that when the flowers were initially extracted with petroleum ether and the extract concentrated and distilled, the product was almost free of sesquiterpenes (5). On the other hand, if the flowers were steam distilled, a relatively high concentration of sesquiterpenes was found. This was interpreted by some authors to mean that the sesquiterpenes are formed during distillation from compounds insoluble in petroleum ether and should not be considered true natural products in the strict sense (1).

The chemical composition of ylang-ylang oil was cursorily investigated as early as 1873 working with samples obtained in the Philippines (6–8). In 1932, Glitchitch and Naves (4) using a classical separation identified certain constituents of the extra oil and reported a semiquantita-

Analysis of the Volatile Components of Ylang-Ylang Oil by Gas Chromatography

By DAVID B. KATAGUE and ERNST R. KIRCH

Five samples of commercially available ylang-ylang oil were analyzed by gas chromatography. Of the various stationary liquid phases used, a 20% Ucon on Chromosorb P(w/w) gave consistently the best separation. The composition of extra, first, second, and third quality fractions and pure oil No. 123 was determined on the basis of relative retention times.

Most essential oils are complex mixtures of individual organic compounds that contain varied functional groups which make complete and detailed analysis relatively difficult or at times impossible using conventional procedures.

Thus, prior to the advent of gas chromatography, the analyses of essential oils were tedious and time consuming. Furthermore, in certain instances in which other methods were used, the analyses were not considered complete (1). The availability and development of gas chromatography as an analytical tool has not only greatly facilitated the separation, and at times the identification, of the constituents of a number of essential oils, but also reduced the time required for analyses (2, 3).

One of the important ingredients in a number of perfumes and other cosmetic products is ylang-ylang oil. This is obtained from the flowers of the ylang-ylang tree (*Cananga odorata*, Hook *f et* Thomson), which is probably a native of the Philippines (1). The important commercial sources of this oil for use in the United States today are the Nossi-Be and Comoro Islands. The oil is available in four different quality fractions, based on the respective boiling points, and is classified commercially as extra, first, second, and third quality fractions. The extra fraction exhibited the highest specific gravity and the lowest refractive index when compared to the other fractions. The samples labeled extra and first quality possess the strongest and finest odors.

That the chemical composition of the oil may be related to the manner in which the oil is extracted from the flowers has been shown by Glitchitch and Naves (4). They found that when the flowers were initially extracted with petroleum ether and the extract concentrated and distilled, the product was almost free of sesquiterpenes (5). On the other hand, if the flowers were steam distilled, a relatively high concentration of sesquiterpenes was found. This was interpreted by some authors to mean that the sesquiterpenes are formed during distillation from compounds insoluble in petroleum ether and should not be considered true natural products in the strict sense (1).

The chemical composition of ylang-ylang oil was cursorily investigated as early as 1873 working with samples obtained in the Philippines (6–8). In 1932, Glitchitch and Naves (4) using a classical separation identified certain constituents of the extra oil and reported a semiquantita-

tive estimate of some of the group components.

A more detailed composition of an absolute ylang-ylang oil was reported by Naves in 1959 (9). This particular oil which was prepared by solvent extraction consisted of the following: *p*-cresylmethylether, 5.7–6.6%; linalool, 6.5–8.1%; methylbenzoate, 6.9–7.4%; benzyl acetate, 19.6–26.5%; and benzyl benzoate, 6.2–9.9%.

Because of the interest in this oil, it was thought advisable to undertake a more detailed analysis of the various commercial samples commonly available in this country. This report deals with the analyses of five samples of ylang-ylang oil by gas chromatography.

EXPERIMENTAL

Apparatus.—The apparatus used in this investigation was the Beckman GC-2 gas chromatograph equipped with a thermal conductivity cell and connected to a Sargent SR recorder with a K-4 disk integrator. The carrier gas was helium. The column used consisted of 6 ft. of copper tubing with a diameter of 1/4 inch.

Column Preparation.—The following stationary liquid phases were used: (*a*) Tide detergent extract (alkyl aryl sulfonates); a commercial sample (20 Gm.) of Tide detergent was extracted in a soxhlet with methanol (200 ml.) and the extract concentrated to a semisolid consistency; (*b*) Apiezon L;[1] diethyleneglycol succinate (DEGS); LAC-R-446 (the adipate polyester of diethyleneglycol partially cross-linked with pentaerythritol); Carbowax 4000;[2] and Ucon 50.[3]

As a solid support, acid-washed Johns-Manville Chromosorb P, 30/60 mesh size, was used. Approximately 20 Gm. of Chromosorb P was required to fill the 6-ft. column employed. In general, a certain weight of a particular liquid phase was dissolved in a minimum amount of an appropriate solvent. To this solution, the proper amount of solid support was added gradually with constant stirring to insure uniform mixing. The mixture was then spread on a large evaporating dish, air-dried at first, and then oven-dried until all the solvent was evaporated. The packing thus prepared was poured slowly into the copper tubing at a uniform rate with persistent tapping to insure uniform packing. Pyrex glass wool was used to plug both ends of the column.

It was determined that 30 ml. of methylene chloride was sufficient to dissolve and deposit 2.0 Gm. of Ucon and 1.0 Gm. of Carbowax on the 20 Gm. of Chromosorb P, while 40 ml. was needed when 2.5 Gm. of Carbowax was used. Thirty milliliters of benzene was used to deposit 1.8 Gm. of DEGS and 1.5 Gm. of LAC-R-446. The same amount of benzene was sufficient to deposit 2.1 Gm. of Apiezon L and 3.0 Gm. of Tide detergent "extract." All solvents employed were of AR grade.

[a] Flow rate, 40 ml./min.; filament current, 200 ma.; maximum attenuation; linalool, 1.00. [b] Nerol, nerolidol, farnesol, terpenyl acetate, and benzyl benzoate were not eluted even after 70 minutes at the conditions of the experiment. [c] At 756 mm.

Procedure.—The carrier gas flow rate was maintained at 40 ml./min. The temperature ranged from 160 to 190°. The chart speed used was one inch per minute and a filament current of 200 ma. was maintained.

Unless otherwise specified, 0.01 ml. of oil samples were used at maximum sensitivity under the ideal conditions stated above.

For purposes of identification, the comparison of retention times and relative retention times[4] of an unknown with known pure standards were employed. Twenty-nine known compounds were analyzed under conditions identical to that at which the unknown was analyzed. Each peak was then confirmed by the enrichment method. In some cases, infrared spectra were run for confirmation.

The quantitative amount of each peak was measured based on the integrated area under each peak. Computation was based on the integrator. All the percentages as calculated were based on the total eluted.

Samples[5] and Standard Compounds.—The following quality fractions of ylang-ylang oil were analyzed. Their respective refractive indexes at 28° and specific gravities at 24° as determined are listed

[4] The relative retention time is the ratio of the retention time of an unknown constituent to that of a standard constituent.

[5] The authors wish to express their thanks to Fritzsche Brothers Inc., New York, for supplying the five samples of ylang-ylang oil.

Samples	$n_D^{28°}$	Sp. Gr.$^{24°}$
Extra	1.5008	0.963
First quality	1.5041	0.946
Second quality	1.5063	0.936
Third quality	1.5091	0.933
Pure oil No. 123	1.5089	0.915

In addition to the above oils, a number of known pure compounds were analyzed under exactly the same operating conditions as those used for the oils. Table I lists both retention times and relative retention times based on linalool. The corresponding boiling points at 760 mm., unless otherwise stated, are also listed. The compounds are arranged according to their increasing retention and relative retention times. A number of compounds not eluted after 50 to 70 minutes at experimental conditions mentioned are also listed.

RESULTS AND DISCUSSION

Five samples of ylang-ylang oil were analyzed, using various liquid phases in different concentrations with respect to the solid support. The samples analyzed were the extra, first, second, and third quality fraction and pure oil No. 123.

With the extra fraction oil and a 25% w/w Apiezon L on Chromosorb P at 190°, four peaks were obtained, the first two of which only showed good resolution. A change in the column temperature to below or above 190° or a reduction in the amount of Apiezon L to as low as 10% w/w did not improve the resolution. Four peaks at best could be observed at 190° with either a 10% or 25% LAC-R-446, while with DEGS only two broad peaks were obtained. An extract of a detergent (Tide) as the liquid phase was found to decompose at the same temperature and gave incomplete separations.

Carbowax or Ucon gave better resolutions. Both of these liquid phases were investigated in various proportions and at different operating temperatures.

It should be noted that with the extra and first fraction oils at least nine distinct peaks were obtained at 160° and eight peaks at 190° with Carbowax in 10% proportions. Figures 1 and 2 show the typical chromatogram of the extra oil at two temperatures.

Only four, or at best five, peaks (Figs. 3–5) were obtained with the second and third quality fractions and pure oil No. 123, either at 160° or 190°. The results may be due to the absence of the same components as found in the extra and first quality oils, or they may be different components that could not be separated using Carbowax as the liquid phase. It was thought desirable to use another liquid phase.

One of these liquid phases is Ucon (a polyalkylene glycol and its aliphatic diesters). It is reported (10, 11) to be an efficient liquid phase for the separation of components of some volatile oils. With this material in a 20% w/w on Chromosorb P, we were successful in obtaining consistent and better separation of all the oil samples investigated. Figures 6 and 7 represent typical chromatograms obtained with the extra and first quality oils at 190°.

Comparing the results obtained for all the oil samples investigated, it should be noted that the second and third quality as well as the pure oil

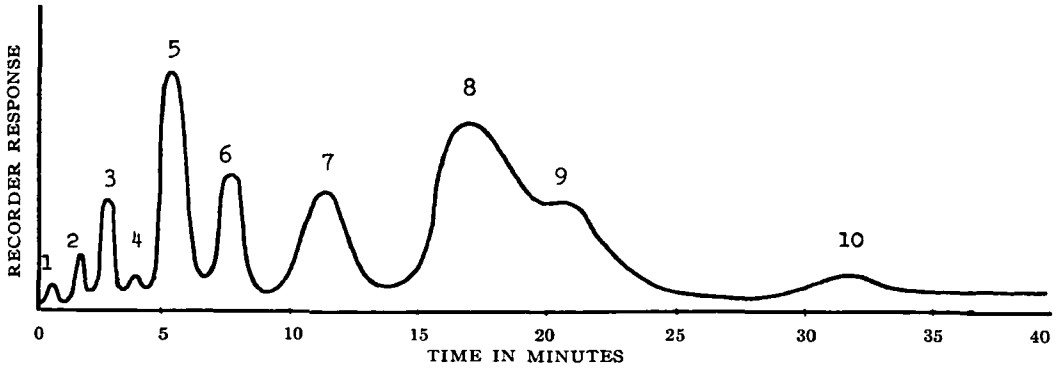

Fig. 1.—Typical chromatogram of extra fraction on 10% Carbowax at 160°.

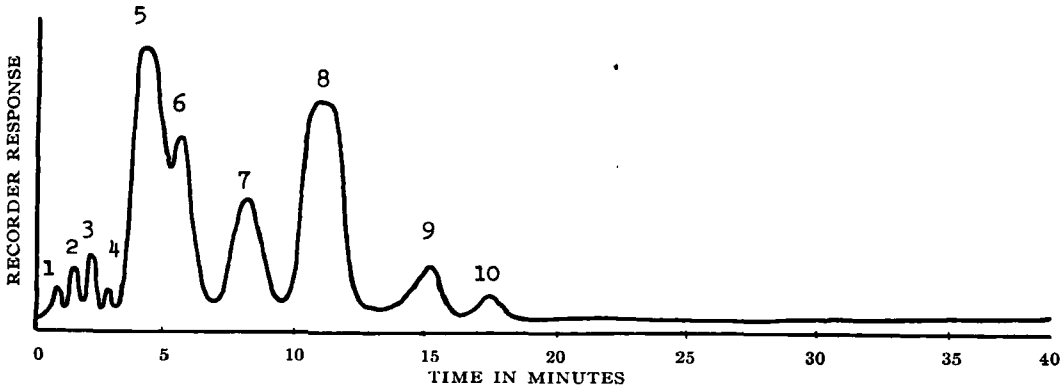

Fig. 2.—Typical chromatogram of extra fraction on 10% Carbowax at 190°.

No. 123 (Figs. 8–10) gave fewer number of peaks. Similar results were obtained at 160° with every one of these oils with the exception that the time required for complete elution was about twice as long.

The primary volatile components of all the oils investigated are listed in Tables II and III giving relative retention times of the peaks and the per cent composition. A particular peak number in a table corresponds to the same number in the various figures. The identity of peaks 2, 4, 5, 6, and 7 was confirmed by the enrichment method using one standard at a time. Peaks 3, 8, and 9 were collected and infrared spectra were run. Peaks 1 and 10, corresponding to low and high boiling components, respectively, were too small

10	Geranyl acetate	2.99	3.08	68.8	86.9	73.9

[a] Liquid phase Ucon; temperature 190°; flow rate, 40 ml./min.; linalool, 1.00 (8.1 min.).

and indistinct for practical confirmation. The retention times for peaks 5, 9, and 10 are within the allowable range as described by James and Bernhard (12, 13).

Alpha-pinene (peak 2) was found to be present both in the extra and first fraction oil. A phenol (peak 3) as indicated by the frequencies of the infrared spectrum as shown in Table IV was also observed in the same two oils. Peak 4 was increased when furfural was added to either one of these oils. *p*-Cresyl methyl ether (peak 5) was present in a higher concentration in the extra as compared to the first fraction, while the amount of linalool (peak 6) was about the same in the two oils. Methyl benzoate as shown by peak 7 is present in slightly higher amounts in the extra fraction.

Terpineol has been reported present in the oil (1). When chromatographed individually under identical conditions used for the oils, a retention time of 15.5 minutes was observed. Peak 8, with a retention time of 14.7 minutes, was not completely enriched. An overlapping, however, was evident. Infrared spectra of peak 8 and standard terpineol were not identical, but indicate an aromatic ester grouping. Infrared spectrum of benzyl acetate compared to peak 8 was similar (Table V).

The constituent represented by peak 9 has a retention time of 24.5 minutes. Two reported components were found to have retention times close to this peak. Geranyl acetate and benzyl acetate were observed to elute after 25 and 24 minutes, respectively. Only geranyl acetate showed

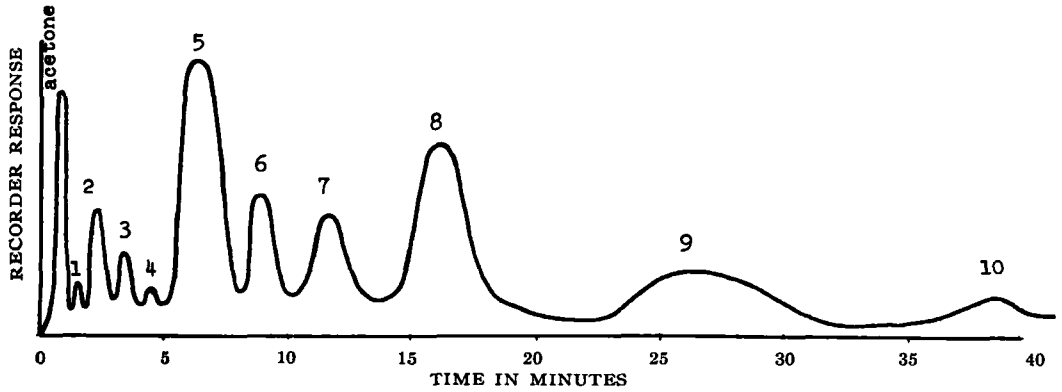

Fig. 6.—Typical chromatogram of extra fraction on 20% Ucon at 190°.

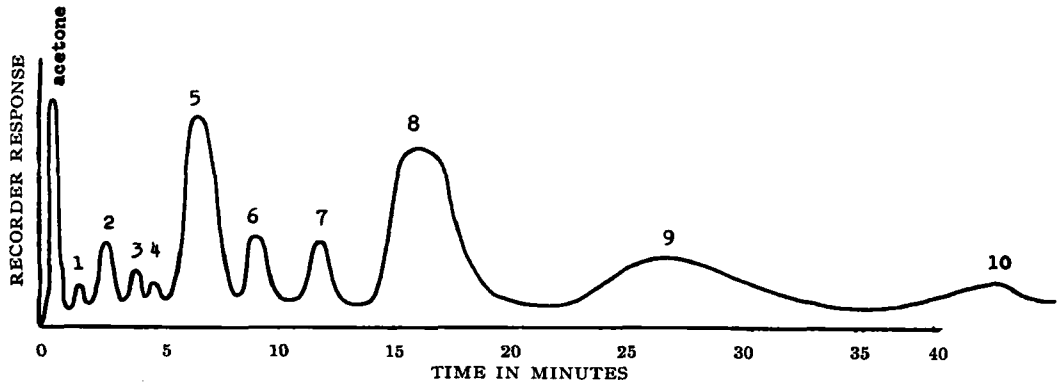

Fig. 7.—Typical chromatogram of first fraction on 20% Ucon at 190°.

an increase in the peak when added to the oil. The infrared spectra of peak 9 and standard geranyl acetate were identical. Table VI shows the infrared frequencies and intensities of peak 9.

Comparing the components of the extra and first fraction oils with the other oils, it should be mentioned that the first four peaks were not observed in the second, third, and pure oil No. 123. The first peak observed (peak 5) was *p*-cresyl methyl ether which was present to the extent of about 2.5% in both the second fraction and pure oil No. 123 samples, but was present only in a concentra-

[a] Identical to standard geranyl acetate.

tion of 0.7% in the third fraction. Linalool (peak 6) was slightly higher in concentration in the second fraction than in the pure oil. Again, the amount of this alcohol in the third fraction was almost negligible. Methyl benzoate (peak 7) represents about 2.9% of the second fraction and 1.5% of the pure oil, while only a trace of it was found in the third fraction. An aromatic ester (benzyl acetate), as represented by peak 8, was found to be present in greater amounts in both pure oil No. 123 and the second fraction, as compared to the third fraction.

Caryophyllene has been reported to be one of the sesquiterpenes present in the oil (1). The addition of caryophyllene to the above fraction oils increased peak 9 which eluted at 19.3 minutes. It should be noted that this was not observed in the first or extra oils.

The last peak (peak 10) obtained with second and third quality and pure oil No. 123 represents geranyl acetate and was found to be present in these oils in a relatively high percentage, 68.8 to 86.9%. This amount is about three times as high as was found in the extra or first fraction oils.

It had been mentioned earlier that the literature reports a whole series of compounds present in ylang-ylang oil (1). In practically all cases, the analytical work was carried out on the extra fraction only. The percentages reported by these authors represent several classes of compounds rather than individual compounds. For example, Glitchitch and Naves (4) reported the presence of 0.1 to 0.2% of aldehydes and ketones including benzaldehyde. The latter compound was not found in any of the oils investigated by us. The terpene content reported by the same authors ranged from 0.3 to 0.6%, while we found that the alpha-pinene content of the extra fraction oil as analyzed was in the neighborhood of 1.3%. Some of the samples analyzed in our laboratory showed a concentration of *p*-cresyl methyl ether as high as 18% and a concentration of a phenol as high as 1.9%, while Glitchitch, *et al.*, reported only 3% of phenols and phenol ethers including *p*-cresyl methyl ether. A range of 52 to 64% of alcohols and esters were reported to be present in the extra fraction by the same authors. It was established in this investigation that 10.8% linalool, 13.3% methyl benzoate, 25.1% geranyl acetate, and 26.7% of an aromatic ester (benzyl acetate) were present in the same quality fraction analyzed. Furthermore, Glitchitch, *et al.*, reported about 35% sesquiterpenes to be present in the extra fraction oil. No sesquiterpenes were detected in the extra oil analyzed by us, but caryophyllene was definitely found in the second, third, and pure oil No. 123 in concentration of about 10% (Table III).

SUMMARY

Ylang-ylang oil obtained commercially by distillation of the flowers of *Cananga odorata*, Hook *f et* Thomson, *forma genuina* was analyzed by gas chromatography, using 20% Ucon on Chromosorb P (w/w). The composition of the extra, first, second, and third quality fractions and the pure oil No. 123 was determined on the basis of relative retention times.

The following natural components were identified in ylang-ylang oil: *d*-alpha-pinene, *p*-cresyl methyl ether, linalool, methyl benzoate, geranyl acetate, caryophyllene, and a phenol and an aromatic ester (benzyl acetate). Identification was confirmed by the enrichment method and in certain instances by use of infrared spectra.

On a qualitative basis, the extra and first fractions were similar in that all the components listed above were present except caryophyllene. The second, third, and pure oil 123 oils were similar in that all components listed above were present in significant quantities except *d*-alpha-pinene and a phenol. These two compounds were present in trace amounts in the second and pure oil fractions and were absent in the third fraction.

On a quantitative basis, all five fraction oils analyzed differed in the relative concentration of the components present.

Some Studies of a Sustained Release Principle

By C. J CAVALLITO, LESTER CHAFETZ, and LOWELL D. MILLER

Urinary excretion of drug after oral dosage of chlorpheniramine as maleate salt and in an oral sustained release formulation was studied, and the urinary excretion and plasma levels of tritium radioactivity obtained after crossover administration of tritium-tagged phenylephrine as hydrochloride and in sustained release formulation were compared. The urinary excretion of both drugs varied widely among individuals, indicating that this parameter is limited in value as a reflection of oral absorption. No relation between blood level and excretion of tritiated phenylephrine was apparent.

THE DEVELOPMENT of oral sustained release forms of medication, which was receiving but scant attention about ten years ago, became a subject of increasing interest following successful introduction of the early products in this field. The increased awareness of the potentials of oral sustained release products has not only led to the development of additional techniques for providing the desired effects, but has also attracted the attention of academic investigators as well as of regulatory agencies. Lazarus and Cooper (1) have provided timely reviews of the subject.

A sustained release product should provide improved performance of a drug as well as the added convenience of fewer doses. Such a product should prevent too rapid a release rate of an absorbable form of drug and permit its gradual availability for absorption over a prolonged period of time. Ideally, these rates of absorption should be tailored as closely as possible to meet the drug requirements of the body without eliciting undesirable effects. There are drugs which obviously have no need for or do not benefit from sustained release formulations.

The interest in our laboratories in oral sustained release products evolved from some simple studies about ten years ago which showed that *Veratrum* alkaloids were relatively well-tolerated orally when utilized as the tannate salt complexes. Investigations showed that a variety of drugs which are organic amines can be converted to stoichiometrically homogeneous pentaamine gallotannates, which are stable, tasteless substances of limited aqueous solubility and which, in the presence of aqueous solutions of electrolytes, provide a gradual release of soluble therapeutic amine salt (2). Since the goal was to provide drug which would be available over a prolonged period of time without initial overdosage, and since stomach acid could lead to too rapid a release of amine from its tannate, it was determined that intimate combination with a polymeric, polyanionic agent, such as polygalacturonic acid, could protect the tannate from too rapid solution in acids. Using as a guide the responses in humans administered a variety of dosage preparations, there was developed an oral sustained release principle which utilizes amine tannates and polygalacturonic acid in such proportions that rate of release and absorption of the amine drug can occur gradually over a wide range of pH values.[1] The polygalacturonic acid, which prevents too rapid a solubilization of amine from the tannate in the acid media, itself becomes more soluble as the gut becomes less acid. Ultimately, all components may become individually dissolved. Since the specially prepared solid and liquid dosage forms disperse to a colloidal state in aqueous media, they should tend to empty from the stomach gradually and continue to be available at intestinal sites of absorption over an extended period of time. [Wagner (3) has critically reviewed the effect of particle number and size as related to gastric emptying and the onset of therapeutic effect of sustained release drugs.]

A variety of therapeutic and chemical categories of amine drugs have been converted to this type of sustained release product and evaluated largely on the basis of their clinical performance relative to that of the usual, nonsustained release forms of the drugs (4–16). Following demonstrated performance in man, ancillary studies were carried out with these preparations in an attempt to obtain more quantitative measures of drug action. Some of these *in vivo* studies are reported and their uses and limitations discussed.

EXPERIMENTAL

Urinary Excretion of Chlorpheniramine.—Urinary excretion of chlorpheniramine was measured after the administration of the drug in nonsustained re-

Received June 18, 1962, from the Research Laboratories, Irwin, Neisler & Co., Decatur, Ill.
Accepted for publication September 13, 1962.
Presented in part to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

[1] This type of sustained release product is referred to by the trade name of Durabond by Irwin, Neisler & Co.

lease and in sustained release forms. The sustained release form utilized the tannate salt[2] of chlorpheniramine, and chlorpheniramine maleate served as the more rapidly absorbable form of the drug. Each subject was given, at weekly intervals, unit doses of 10.2 mg. of chlorpheniramine maleate (7.17 mg. base) in small gelatin capsules and 30 mg. of chlorpheniramine tannate (13.4 mg. base). Following ingestion of drug, urine samples were voided at specified intervals corresponding to times at which urine blanks were obtained on each subject. Urine samples were made alkaline with sodium hydroxide, and the drug was extracted into chloroform. The chloroform was washed with pH 10 borate buffer to reduce the blank readings, then extracted with dilute aqueous acid. The concentration of chlorpheniramine was estimated from the absorbance of the acid solution at 265 mμ determined with a Beckman model DU spectrophotometer. The isolation procedure gave satisfactory recoveries (98.4%) of chlorpheniramine four hours after its addition to urine.

Plasma Levels and Urinary Excretion Rate of Tritium-Labeled Phenylephrine.—Several years ago, a study in humans was initiated for the purpose of determining the rates of appearance of a radioactive drug component in blood following its oral administration in conventional and in Durabond-type preparations. Phenylephrine with random tritium tagging was used as the test drug. The investigation was conducted in cooperation with the Nuclear Science and Engineering Corporation, and the technique used in the pilot study was described by Bogner and Walsh (17). A more extensive study was completed more recently in which both blood levels and urinary excretion of drug were measured.

Twelve adult male subjects with no known disorders of absorption or excretion were used in the study. They were given doses of tritiated phenylephrine as hydrochloride and as tannate in similar appearing tablets at intervals of a week. Six subjects (age range: 23–39 years; weight range: 150–206 lbs.) were given doses of phenylephrine tannate equivalent to 15.68 mg. base, and phenylephrine hydrochloride corresponding to 7.4 mg. base was selected for comparison. These were doses which in practice provided comparable initial therapeutic responses and which in earlier pilot studies yielded initially comparable drug blood levels.[3] In another six subjects administered half these doses, the lower radioactivity levels showed relatively large standard deviations and were of questionable quantitative significance. Even with the higher doses, the standard deviations were appreciable.

All doses were given after an overnight fast, and the subject was allowed four ounces of water immediately after taking each tablet. Identical light meals were ingested by each subject 1 hour after dose administration. Blood samples (15 ml.) were obtained at indicated intervals from the antecubital veins. Plasma was immediately separated by centrifugation and frozen until analyzed. Total urine collections were made as voided at five interval periods up to 48 hours. Details of the analytical procedures used for determination of tritium radioactivity in plasma and urine samples are described elsewhere (17).

RESULTS AND DISCUSSION

Chlorpheniramine Urinary Excretion.—The quantities of chlorpheniramine found in the urine of four subjects after oral dosage of chlorpheniramine maleate and of three of the same four (one subject became unavailable) after oral dosage of the drug in the tannate form are shown in Table I.

Table I.—Interval Excretions of Chlorpheniramine[a] in Urine After Oral Dose

Hours	Subject I	Subject II	Subject III	Subject IV
	Chlorpheniramine Maleate[b]

[a] As mg. base. [b] 7.17 mg. base. [c] 13.4 mg. base.

The doses of each form selected were those which represented equivalents in terms of initially induced therapeutic response. The data for the rapidly absorbable form show a considerable difference and irregularity among subjects in their period of maximum excretion and in the total amount of drug excreted. These differences appear to be less after dosage of the sustained release form of the drug.

Variations in Urinary Excretions.—The wide variation among individual excretions of chlorpheniramine with these few subjects raised questions as to the significance of such measurements as reflections of rate of absorption of this antihistaminic and possibly of other drugs. A review of the published literature purporting to relate urinary excretion to drug absorption rates showed that wide individual variations also were evident from the data of others but that usually little if any note was made of this in plotting cumulative averaged values. Following oral administration of a drug, wide variations are evident among individual excretions, particularly during the first few hours, and as cumulative values are shown with time, the interval excretion variations tend to cancel one another to provide more uniform total recoveries. Wide variations in excretion (of drug or metabolite) following oral administration of single doses of

[2] Reference to tannates throughout this report denotes their incorporation with polygalacturonic acid in Durabond formulations.

[3] From a practical use basis, we were interested in the relative duration of action of dosage forms producing an adequate therapeutic response without undesirable side reactions.

drugs, particularly during the earlier intervals, may be illustrated by published data (Table IV) (18–26). All of these reports (except reference 26) measured only urinary excretion of drug or metabolites and not drug blood concentrations. A more comprehensive study utilizing sulfaethylthiadiazole was reported by Swintosky, *et al.* (26–28), in which both blood and urine drug levels were measured. This drug, which is virtually all excreted in 72 hours, also showed considerable individual variations in excretion levels in the first 3-hour period even with parenteral administration of the drug and these variations tended to decrease with increase in administered dosage.

Phenylephrine Plasma Levels and Urinary Excretion Rates.—The tritiation tagging technique was used to measure blood concentrations and urinary excretions of drug following administration of soluble and tannate forms of phenylephrine in that there was not available a sufficiently sensitive chemical method at the time of the study. [Since the completion of this study a fluorometric method for the determination of phenylephrine in blood has been reported (29).] Although there is no absolute evidence that the tritium level represents unchanged phenylephrine, nevertheless the measure of tritium radioactivity does directly reflect phenylephrine which has been absorbed and does permit comparison of the dosage forms. The tritium-labeled phenylephrine had been recrystallized under conditions which removed labile tritium (17) and minimized the possible influence of tritium exchange during the experimental period. The tritium activity values, expressed in terms of micrograms of phenylephrine base per 100 ml. of plasma, are given in Table II for phenylephrine hydrochloride and for the tannate. The mean values are graphically represented in Fig. 1. Trit-

ium levels expressed as phenylephrine base recovered in urine during intervals following ingestion of the hydrochloride and tannate forms are presented in Table III for these subjects, and the mean cumulative amount of radioactivity expressed as phenylephrine base is plotted for both dosage forms in Fig. 2. The plotting of mean cumulative values is a rather conventional procedure but, as noted earlier, this can leave a misleading impression of uniformity or consistency of excretion patterns.

Fairly similar mean tritium blood levels are provided (Fig. 1) at the first hour by the doses utilized of rapidly soluble and sustained release forms of phenylephrine. The blood levels are definitely maintained closer to this initial value for a considerably greater time from the sustained release than from the rapidly soluble drug form. Drug blood concentrations may not necessarily be directly related to therapeutic responses but the results are at least consistent with the clinical reports on the sustained effects of the principle.

If one compares tritium interval excretion with average blood levels during that interval (the shorter the interval the more valid the comparison, however, physical limitations should be recognized), there is observed a rather poor correlation. Particularly puzzling is the much greater difference in urinary excretion than in the blood levels from the two drug forms in the first 4 hours. Thus, although the two drug forms show no great dif-

ference in mean blood levels during the first 4 hours, the mean urinary excretion values are in the ratio of 2.48 to 0.87 (hydrochloride to tannate) for this interval. From 4–48 hours the mean urinary excretion ratio was 1.15 to 2.21 (hydrochloride to tannate) and this more closely reflected the blood level patterns.

The question arose as to whether a peak blood level might have been provided by the rapidly soluble drug form in less than 1 hour and that this led to the large excretion. To determine this, several of the same subjects were again given the hydrochloride form of the drug about 3 months later, and blood levels were measured after one-half hour as well as 1 hour. In four of five repeated subjects the blood levels were considerably lower in the half-hour reading than after 1 hour; in subject III blood levels were negligible at both periods; whereas in the previous test the same subject gave a 1-hour level near the mean for the group. The higher urinary excretion in the comparative study would thus be difficult to explain on a basis of very high blood levels within a half hour or less after drug administration.

The new data reported here and most of that previously published by others show that urinary excretion of drugs and their metabolites varies very widely among individuals, particularly with lower dosage of drugs and during the first few hours after administration. In those few instances in which both drug blood concentrations and urinary excretions are measured, there is found to be rather inconsistent correlation among individuals. The use of drug excretion rate measurements as reflections of oral absorption from sustained release formulations is of questionable value.

SUMMARY AND CONCLUSIONS

With the drugs, chlorpheniramine and phenylephrine, urinary excretion in man shows wide individual variations and is indicated to be an unreliable reflection of rate of oral absorption. This also is evident from published data with other drugs, particularly as pertains to the first few hours after drug administration. Plotting of cumulative excretion values tends to obscure interval variations.

Rapidly absorbable and sustained release formulations containing tritiated phenylephrine were administered in doses which provided similar early blood levels. There is little relation between urinary excretion and blood concentrations of tritiated drug during the first few hours. The sustained release form maintained blood levels at near the first hour's value for a considerably longer period of time than did the rapidly soluble drug form.

More information is needed with regard to interrelationships of absorption, blood concentrations, and urinary excretion of rapidly soluble forms of drugs before one can assume that urinary excretion profiles are true reflections of rates of absorption of drugs from oral sustained release preparations. The wide variations among these parameters in the first few hours after drug administration particularly merits more attention.

Adsorption of Sorbic Acid by Plastic Cellulose Acetates

By WITOLD SASKI

The adsorption of sorbic acid from aqueous solutions by plastic cellulose acetate and cellulose triacetate was studied. Adsorption isotherms at 25 ± 0.2° were determined and Langmuir constants were calculated. The method presented is recommended as satisfactory for use in comparative studies of adsorption of drugs, fungistatic and bacteriostatic agents by plastic materials. Adsorption of sorbic acid as a function of pH was studied and was shown to decline to zero in the vicinity of the point of maximum ionization of sorbic acid.

PLASTICS have been rapidly replacing the conventional materials for the manufacture of containers and various devices used in pharmaceutical and medical practice. The common belief that plastics are inert and, therefore, safe for any use is unjustified. It has been demonstrated that they may cause a tissue sensitivity or toxic response when used as surgical implants. A constituent may be released from the plastic to the solution which is to be injected into the patient when plastic devices such as syringes and tubings are used. A plastic device or container may bind or adsorb a significant quantity of the drug, bacteriostatic or fungistatic agent present in the formulation and affect the potency and perhaps even the stability of the product. A review of the literature on the subject was published by Autian (1).

Plastics, by definition (2), are a large and varied group of materials which consist of, or contain as an essential ingredient, a substance of high molecular weight which while solid in the finished state, at some stage in its manufacture is soft enough to be formed into various shapes, usually through the application, either singly or together, of heat and pressure. The thermosets are plastics which harden and form a permanent shape upon heating. On reheating and cooling, these thermosets will no longer have the same characteristics they originally had. In contrast to the thermosets, the thermoplastics can be reheated and cooled a number of times without materially altering their original characteristics. Fluorocarbons, polyethylenes, vinyls, nylons, styrenes, acrylics, and cellulosics are examples of thermoplastics.

To attain the desirable properties of plastic materials, various additives are needed. They may consist of plasticizers, fillers, and stabilizers. In cellulose plastics (3), the plasticizers most frequently used are the phthalates—diethyl, dibutyl, dioctyl, and methoxyethyl phthalate. Although triphenyl phosphate is a relatively poor plasticizer when compared with the phthalates, it is frequently used in order to produce a more rigid sheet or to reduce the flammability of the product. The proportions of the above plasticizers used may vary widely, frequently running from as low as 8 to as high as 40 parts per 100 parts of cellulose ester, depending upon the physical properties desired in the finished sheet. In addition to plasticizers, coloring agents, ultraviolet light absorbers, and various types of surface coatings to improve slip characteristics may also be employed (4).

The present study set out to determine the extent of possible adsorption of the fungistatic agent, 2,4-hexadienoic (sorbic) acid, by plastic cellulose acetates, and to develop a method suitable for comparative evaluation of the adsorptive capacities of different plastic materials.

EXPERIMENTAL

Apparatus and Materials.—The following apparatus was used: Beckman DU spectrophotometer, Photovolt model 110 electronic pH meter, Christian Becker analytical balance, constant temperature water bath, and the Burrell wrist-action model DD shaker. The following materials were used: plastic cellulose acetate sheets, 0.01 in. thick;[1] plastic cellulose triacetate sheets, 0.01 in. thick;[2] sorbic acid;[3] alcohol U.S.P.; 1 *N* hydrochloric acid, and 1 *N* sodium hydroxide.

Methods of Analysis.—Sorbic acid was recrystallized and the melting point determined according to standard procedures. The quantitative determinations of sorbic acid in solutions were performed using standard spectrophotometric techniques. A 256 mμ wavelength of maximum absorption was used (5). In all instances, the solutions to be assayed were adjusted to contain 3 mcg. or less of sorbic acid per ml.

Adsorption as a Function of Time.—Strips of

plastic cellulose acetate sheet, 0.01 in. thick and approximately 1 in. × 7 in. in size, were weighed on the analytical balance and placed into glass-stoppered cylinders containing exactly 100 ml. of a 0.150% (w/v) sorbic acid solution in distilled water. Seven cylinders were used: six with plastic strips, and one as a control and to check on possible sorbic acid degradation. The cylinders were placed in the constant temperature bath adjusted to 25 ± 0.2° and subjected to constant and uniform shaking by means of the Burrell wrist-action model DD shaker set in position 1.

The procedure developed in this investigation was as follows. One-milliliter portions of the solution were withdrawn from each cylinder and diluted to 500 ml. in a volumetric flask to obtain the desired sorbic acid concentration. The adsorbance of the samples was then determined, using quartz 1-cm. cells in the Beckman DU spectrophotometer. The results are shown in Table I and Fig. 1. It became apparent that the equilibrium concentration of sorbic acid in aqueous solution in the presence of plastic cellulose acetate is reached within 14 days. This finding has been utilized in the subsequent experiments.

Adsorption as a Function of Concentration.— Following the procedure described, strips of cellulose acetate were placed into cylinders containing 100 ml. of aqueous solutions of sorbic acid. Triplicate samples of each of five concentrations, 0.050, 0.075, 0.100, 0.125, and 0.150% (w/v), were used. This experiment was carried out as before in the constant temperature water bath at 25 ± 0.2° and with the shaker set at the same speed. Since the previous experiment determined that the equilibrium concentration of sorbic acid was reached within 14 days, no samples were tested until this time had elapsed. Following the identical procedure, strips of plastic cellulose triacetate were subjected to the same treatment. The results are reported in Table II. Figure 2 shows the adsorption iso-

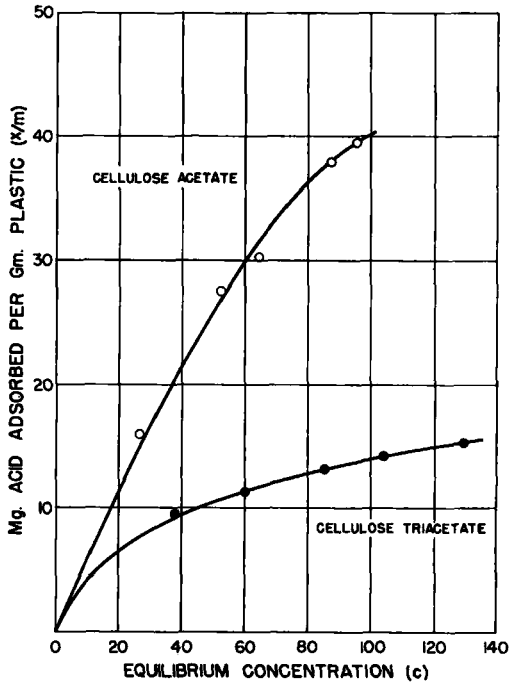

Fig. 2.—Langmuir adsorption isotherms for plastic cellulose acetate and cellulose triacetate.

therms for both plastic materials. Figure 3 shows the linear form of the Langmuir adsorption isotherms for both plastics.

Adsorption as a Function of pH.—Following essentially the same procedure, strips of plastic cellulose acetate were placed into glass cylinders containing 100 ml. of a 0.150% (w/v) sorbic acid aqueous solution adjusted to various pH levels by the addition of 1 *N* solution of hydrochloric acid or 1 *N* solution of sodium hydroxide, all in triplicate. The solutions were not buffered, in order to avoid the possibility of interference with adsorption by the buffer salts. The pH of each solution was determined with the Photovolt model 110 electronic pH meter, both at the outset of the experiment and at the end of the apparent equilibration period of 14 days. The results are reported in Table III and graphically presented in Fig. 4, which represents the pH data obtained after contact with the plastic. Sorbic acid percentage ionization values were calculated and shown in Table III.

Adsorption as a Function of Solvent System.—The effect of ethyl alcohol concentration on sorbic acid adsorption by plastic cellulose acetate was determined. The concentration of sorbic acid in all samples was 0.150% (w/v) and the concentrations of the alcohol were 0, 9.5, 19.0, 38.0, and 76.0 (v/v), respectively, with triplicate samples of each concentration being tested, together with an appropriate number of controls. The procedure followed was that previously described. The results are graphically presented in Fig. 5.

RESULTS AND DISCUSSION

After having determined the time necessary to attain equilibrium, the effect of sorbic acid concentration on adsorption by plastic cellulose acetate and cellulose triacetate was studied. This is presented in two ways. First, by plotting the equilibrium concentration of sorbic acid in mg. per 100 ml. of solution (c) as abscissa against the number of mg. of sorbic acid adsorbed by one Gm. of plastic, as shown in Fig. 2.

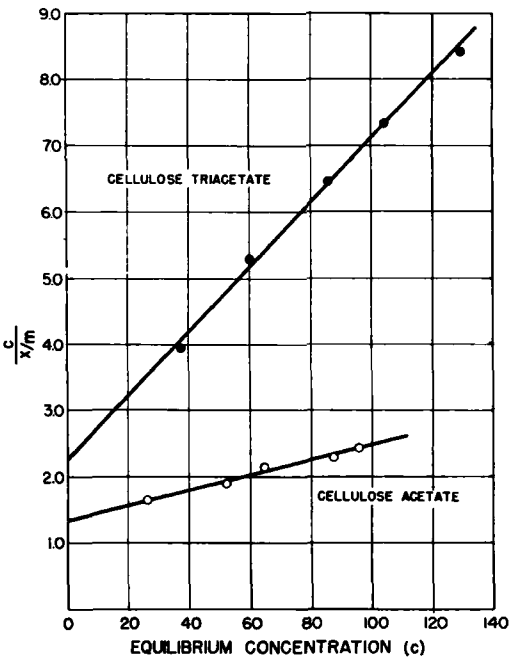

Fig. 3.—Linear form of the Langmuir adsorption isotherms for plastic cellulose acetate and cellulose triacetate.

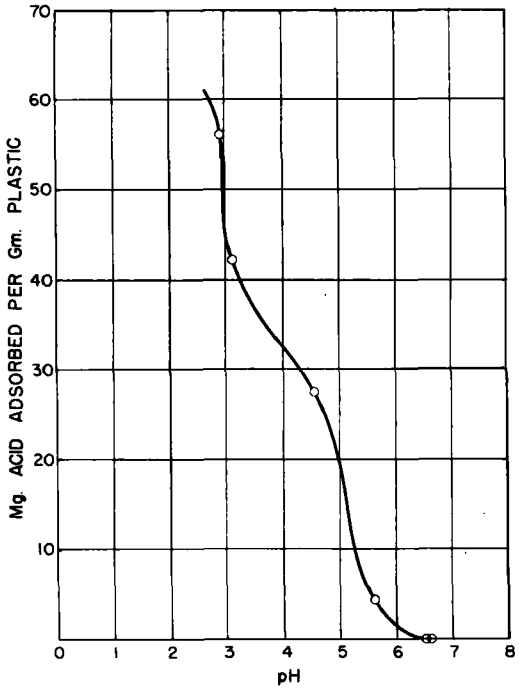

Fig. 4.—Adsorption of sorbic acid by plastic cellulose acetate at various pH levels.

[a] From a 0.150% (w/v) solution. Temperature 25 ± 0.2°. [b] Calculated from the equation (6):

$$\text{Percentage ionization} = \frac{100}{1 + \text{Antilog (pKa} - \text{pH)}}$$; pKa of sorbic acid is 4.76.

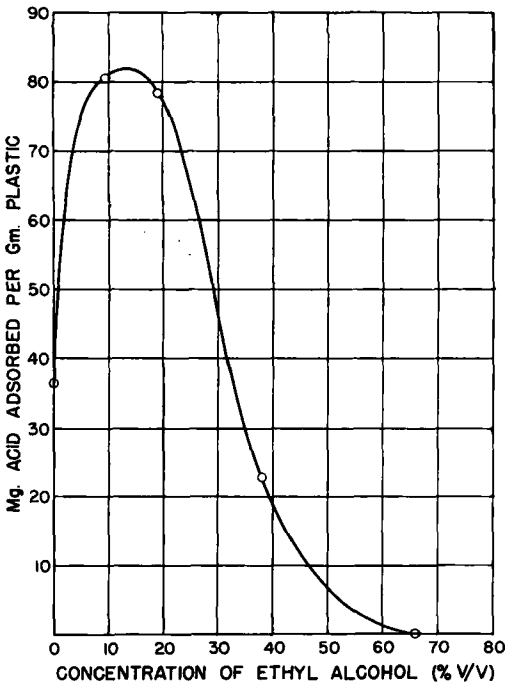

Fig. 5.—Effect of ethyl alcohol on the adsorption of sorbic acid (0.150% w/v) by plastic cellulose acetate.

The second method of presenting these data is by plotting the equilibrium concentration against the ratio of the equilibrium concentration to the number of mg. of sorbic acid adsorbed by one Gm. of plastic, as shown in Fig. 3. This type of graph, which represents the linear form of the Langmuir equation (7), is particularly useful. Derived from the equation

$$\frac{x}{m} = \frac{abc}{1 + a\,c}$$

where x/m = mg. of sorbic acid adsorbed per Gm. of plastic, c = equilibrium concentration in mg. sorbic acid per 100 ml., and a and b are constants, the linear form of the Langmuir equation is

$$\frac{c}{x/m} = \frac{1}{b}\,c + \frac{1}{a\,b}$$

In this form, the slope is $1/b$ and the intercept is $1/ab$. By plotting $\frac{c}{x/m}$ against c, linear curves are obtained from which may be found the slopes and intercepts. The closer the line is to paralleling c, the greater adsorptive power of the plastic. The slope of the line may be determined, as well as the values of the constants, a and b.

The described procedure provides a satisfactory quantitative method for the evaluation of different plastic materials with respect to their relative adsorptive capacities in contact with various drugs and bacteriostatic and fungistatic agents. Langmuir adsorption isotherms have been employed by Barr, *et al.*, in adsorption studies on clays (8, 9).

The adsorptive avidity of plastic cellulose acetate has been compared with that manifested by plastic cellulose triacetate. As Fig. 3 shows, such avidity with respect to sorbic acid is much higher in case of cellulose acetate. The slopes of the two linear curves for the two respective plastics were calculated and so were the constants a and b. They are shown in Table IV.

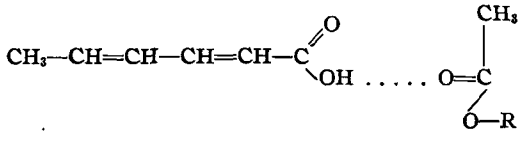
TABLE IV.—CONSTANTS OF LANGMUIR EQUATION FOR SORBIC ACID

Plastic	a	b
Cellulose acetate	0.0085	87.0
Cellulose triacetate	0.0218	20.4

It can be seen that the b value for plastic cellulose acetate is more than four times as high as for cellulose triacetate.

The anhydroglucose units of cellulose each contain three hydroxyl groups, one primary alcohol group and two secondary alcohol groups, which can be acetylated. Study of the distribution of the acetyl groups along the cellulose chain indicates that the esterification is fairly uniform, so that most of the anhydroglucose units will contain at least two acetyl groups. Acetylation obviously alters the surface characteristics of cellulose. The extent of acetylation of cellulose apparently influences the adsorption of weak acidic substances. Vickerstaff suggested that as a consequence of the alteration of the cellulose structure by acetylation, the negative surface potential of cellulose acetate in water is much higher than that of cellulose, and this will assist the repulsion of anionic dyes (10). This theory should extend to cellulose triacetate and sorbic acid. Cellulose triacetate results from the replacement of all or most of the hydroxyl units on the cellulose chain with acetyl groups (11). The much lesser adsorptive capacity of plastic cellulose triacetate as compared with cellulose acetate is in agreement with Vickerstaff's theory.

As has been demonstrated in the experiment with sorbic acid at different pH levels, upon approaching neutrality from the acid side, and nearly complete ionization of the acid, adsorption becomes reduced to zero. The undissociated sorbic acid may be adsorbed on the ester groupings by the formation of the hydrogen bond



The decrease of adsorption upon the increase of the percentage of ionization is not surprising since it seems to have been generally found that ionization of an adsorptive decreases its surface activity. It has been suggested (12) that this may be so because the ion, with its envelope of solvent, is much more soluble than the undissociated molecule, and so shows less tendency to escape from the solution. As is shown in Table III, considerable change in pH occurred at the higher pH values at the end of the experiment. Assays of the controls revealed that no decomposition of the sorbic acid at these high pH levels had occurred. This would indicate that possibly a plasticizer was the cause

of the decrease in pH. The term "apparent equilibration" with reference to the pH data is used advisedly since the data clearly show that the true equilibrium with the original plastic will never be reached. Since the plastic is leaching one or more constituents into the solution, the material is continually being altered and it is improbable that a true equilibrium is attained.

Although the adsorption of acids and bases has been found in some cases to be proportional to the concentration of undissociated molecules, many highly ionized surface-active substances are known so that the extent of ionization itself cannot be a sole controlling factor. As a matter of fact, the experiments conducted with hydroalcoholic solvents have demonstrated the maximum sorbic acid adsorption from the solution containing about 10% (v/v) of ethyl alcohol. This finding had not been anticipated. Autian and Shaikh, in their study on adsorption of sorbic acid by nylon (13), noted that as the water is replaced with a less polar solvent, the binding of sorbic acid decreased. The experiments described, which were carried out three times, show that plastic cellulose acetate behaves differently with respect to sorbic acid. No explanation can be given by this author for the reason or reasons why the adsorption increases and then sharply decreases with increase in alcohol concentration.

The effect of temperature has not been studied because of the instability of sorbic acid at somewhat elevated temperatures (14).

SUMMARY AND CONCLUSIONS

The adsorption of sorbic acid by plastic cellulose acetate and cellulose triacetate has been studied and a method for its determination has been developed. Langmuir adsorption isotherms were determined and the constants calculated. The main significance of this paper is that the applicability of the Langmuir equation to the comparative study of different plastic materials with respect to adsorption has been demonstrated. The method suggested is just one parameter which may be helpful in studying drug–plastic interactions but many other tests and procedures might be necessary to establish useful standards for a particular plastic.

Multiple Dose Excretion Kinetics

By R. G. WIEGAND, J. D. BUDDENHAGEN, and C. J. ENDICOTT

General mathematical equations describing expected blood and urine drug concentrations were derived to analyze riboflavin excretion data after a single large oral dose followed by multiple smaller but equal doses at equal time intervals. The urinary excretion equation was applied to the riboflavin data to obtain the least squares fit using the IBM digital computer, and by this means the absorption and excretion rates were determined. Such calculations can be applied to find the optimum dosage regimen of other drugs for which the kinetic constants are known. The general expressions reduce to all simpler cases already reported in the literature.

THE FITTING of equations to experimental data on blood and urine concentrations of drug has found wide application in determining the kinetics of the processes involved and in measuring the rates of these processes. Considering absorption and elimination of drug to be apparent first order processes, equations describing blood drug levels (1–4) and urine levels (2, 5) after a single oral dose of drug have been reported. The general equation for blood levels after multiple oral administration of drug at equal doses and time intervals was derived by Dost (4). Boxer, *et al.* (6), had earlier used a simplified form of this equation to obtain the expected maximum and minimum blood levels

Multiple Dose Excretion Kinetics

By R. G. WIEGAND, J. D. BUDDENHAGEN, and C. J. ENDICOTT

General mathematical equations describing expected blood and urine drug concentrations were derived to analyze riboflavin excretion data after a single large oral dose followed by multiple smaller but equal doses at equal time intervals. The urinary excretion equation was applied to the riboflavin data to obtain the least squares fit using the IBM digital computer, and by this means the absorption and excretion rates were determined. Such calculations can be applied to find the optimum dosage regimen of other drugs for which the kinetic constants are known. The general expressions reduce to all simpler cases already reported in the literature.

THE FITTING of equations to experimental data on blood and urine concentrations of drug has found wide application in determining the kinetics of the processes involved and in measuring the rates of these processes. Considering absorption and elimination of drug to be apparent first order processes, equations describing blood drug levels (1–4) and urine levels (2, 5) after a single oral dose of drug have been reported. The general equation for blood levels after multiple oral administration of drug at equal doses and time intervals was derived by Dost (4). Boxer, *et al.* (6), had earlier used a simplified form of this equation to obtain the expected maximum and minimum blood levels

Received July 26, 1962, from the Chemical Pharmacology Section and Pharmaceutical Research Department, Abbott Laboratories, North Chicago, Ill.
Accepted for publication September 10, 1962.

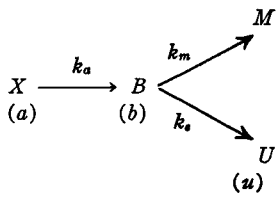
after intravenous administration. For the dosage regimen of an initial large dose and subsequent smaller equal doses at equal time intervals Swintosky, *et al.* (7), have given an approximation for the maximum and minimum blood levels expected, and Krüger-Thiemer (8, 9) has derived the equation giving the ratio of initial to sustaining doses such that the blood level at the time of the first sustaining dose will be maintained.

The general equations describing blood or urine drug levels after administration of an initial dose different in size from successive equal doses at equal time intervals have not been published. Such an equation for blood levels should reduce as time approaches infinity to the expression given by Swintosky, *et al.* (7), for maximum and minimum blood levels, and by appropriate substitutions the dose ratio should be obtained. It should also reduce to the general equations for blood concentration after multiple equal doses or after a single dose. Similarly, the equation for urine levels should reduce to the expression for use with data collected after all equal doses as well as to the equation describing urine drug levels after a single dose. In the process of reducing the general expressions to the simpler forms the assumptions on which the simpler equations are based become apparent and the expected errors resulting from their use can be calculated.

After a large dose and successive smaller doses, the general form of the equations will also make possible calculation of the complete curves for blood or urine levels. This will allow fitting the curves to actual data collected after this dosage regimen, confirming the kinetic order and obtaining a measure of the rates involved. The work with riboflavin reported here was started to find the amount of vitamin necessary in divided doses to maintain the circulating level. The equations were derived to analyze the urinary riboflavin data in terms of the rates of absorption and excretion plus the parameters of dosage.

MATHEMATICAL DERIVATION

After oral administration of a drug, it and its metabolites will pass through a series of compartments according to the flow diagram



where X is the gastrointestinal tract, B is the body exclusive of the gastrointestinal tract and urine, U is the urine, and M indicates the metabolite pool. Apparent first order rate constants are assigned for absorption, k_a, metabolism, k_m, and excretion, k_e. Since when working with blood levels of drug the relative contribution to disappearance of drug by metabolism or excretion is usually not known, the apparent first order disappearance constant, k_d, is defined as the sum of k_e and k_m. The fractional amounts of the total dose in a compartment at any time will be given by the lower case letters in parentheses in the diagram.

Following an initial dose A_o, the amount of drug in the gastrointestinal tract, body, and urine at time τ is given by substitution of $t = \tau$ in previously published equations (5) as

$$a = A_o e^{-k_a \tau} \qquad \text{(Eq. 1)}$$

$$b = \frac{A_o k_a}{k_d - k_a} (e^{-k_a \tau} - e^{-k_d \tau}) \qquad \text{(Eq. 2)}$$

$$u = A_o \frac{k_e}{k_d} \left(1 - \frac{(k_d e^{-k_a \tau} - k_a e^{-k_d \tau})}{(k_d - k_a)}\right) \qquad \text{(Eq. 3)}$$

If a second oral dose, a_o, (different in size from the initial dose) is administered at time τ, the amounts of drug in the compartments a, b, and u can be derived by solving the differential equations

$$-\frac{da}{dt} = k_a a \qquad \text{(Eq. 4)}$$

$$\frac{db}{dt} = k_a a - k_d b \qquad \text{(Eq. 5)}$$

$$\frac{du}{dt} = k_e b \qquad \text{(Eq. 6)}$$

where time, t, is calculated from the time of administration of the last dose. Using Eqs. 1, 2, and 3 for the values of a, b, and u at $t = O$, the equations giving the amount of drug in each compartment as a function of time are

$$a = (a_o + A_o e^{-k_a \tau}) e^{-k_a t} \qquad \text{(Eq. 7)}$$

$$b = \frac{k_a}{k_d - k_a} [(a_o + A_o e^{-k_a \tau}) e^{-k_a t} - (a_o + A_o e^{-k_d \tau}) e^{-k_d t}] \qquad \text{(Eq. 8)}$$

$$u = \frac{k_e}{k_d} \left[A_o + a_o - \frac{k_d(a_o + A_o e^{-k_a \tau})}{k_d - k_a} e^{-k_a t} + \frac{k_a(a_o + A_o e^{-k_d \tau})}{k_d - k_a} e^{-k_d t}\right] \qquad \text{(Eq. 9)}$$

Similar extension of Eqs. 7, 8, and 9 can be made for successive oral doses equal to the second (a_o), administered at the same time interval τ. Under these conditions the term within the parentheses in Eq. 7 becomes $(a_o + a_o e^{-k_a \tau} + a_o e^{-2k_a \tau} + \ldots + a_o e^{-(n-1)k_a \tau} + A_o e^{-nk_a \tau})$. Because the sum of all but the last term in this expression equals $a_o(1 - e^{-nk_a \tau})/(1 - e^{-k_a \tau})$, the expression for a after an initial dose A_o and successive doses a_o given at time intervals τ becomes

$$a = \left(A_o e^{-nk_a \tau} + a_o \frac{1 - e^{-nk_a \tau}}{1 - e^{-k_a \tau}}\right) e^{-k_a t} \qquad \text{(Eq. 10)}$$

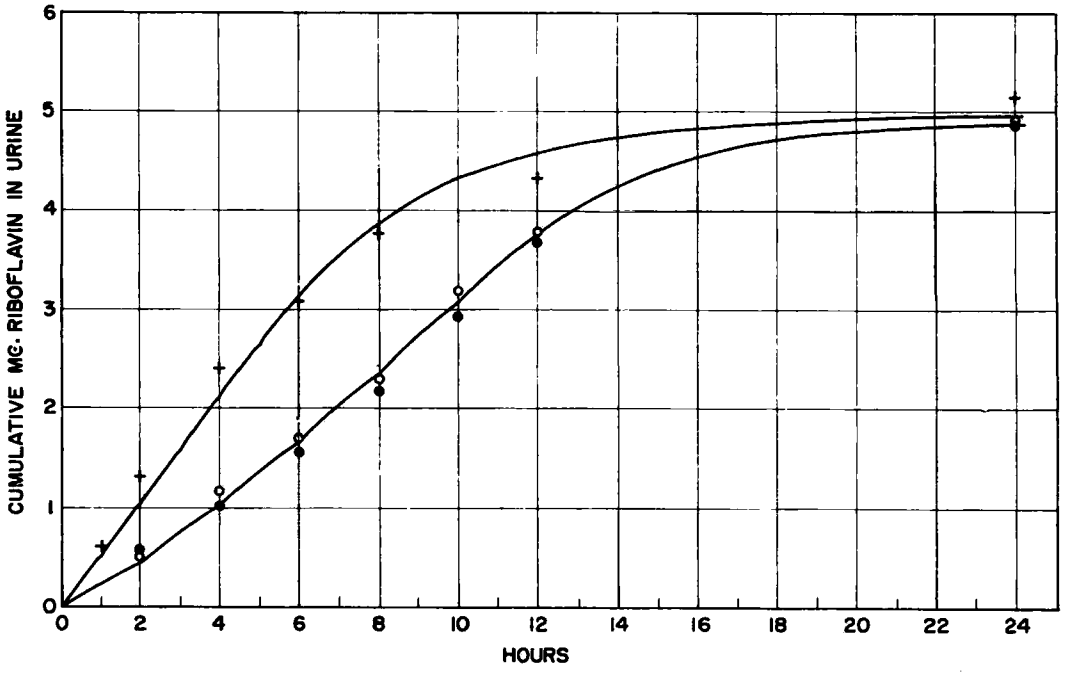


Fig. 1.—Mean cumulative riboflavin urine levels from 10 adults after 5 mg. riboflavin orally at zero time and 5 doses of 1 mg. every hour (+, experiment 800) or after 2.4 mg. at zero time and 5 doses of 1.5 mg. every 2 hours, (○, experiment 801; ●, experiment 996). Curves are calculated according to equation 12 with $k_e = .123$ hr.$^{-1}$, $k_d = .246$ hr.$^{-1}$, $k_a = 30$ hr.$^{-1}$, and appropriate values of A_0, a_0, τ, n, and t.

where n is the number of doses of size a_o. By similar derivations the equations describing b and u in this general case become

$$b = \frac{k_a}{k_d - k_a}\left[\left(A_o e^{-nk_a\tau} + a_o\frac{1 - e^{-nk_a\tau}}{1 - e^{-k_a\tau}}\right)e^{-k_a t} - \left(A_o e^{-nk_d\tau} + a_o\frac{1 - e^{-nk_d\tau}}{1 - e^{-k_d\tau}}\right)e^{-k_d t}\right] \quad \text{(Eq. 11)}$$

$$u = \frac{k_e}{k_d}\left[A_o + na_o - \frac{k_d}{k_d - k_a}\left(A_o e^{-nk_a\tau} + a_o\frac{1 - e^{-nk_a\tau}}{1 - e^{-k_a\tau}}\right)e^{-k_a t} + \frac{k_a}{k_d - k_a}\left(A_o e^{-nk_d\tau} + a_o\frac{1 - e^{-nk_d\tau}}{1 - e^{-k_d\tau}}\right)e^{-k_d t}\right] \quad \text{(Eq. 12)}$$

If the initial dose was the same as all successive doses ($A_o = a_o$) Eq. 11 reduces to the form given by Dost (4) for the case of equal doses administered at equal time intervals

$$b = \frac{a_o k_a}{k_d - k_a}\left[\left(\frac{1 - e^{-n'k_a\tau}}{1 - e^{-k_a\tau}}\right)e^{-k_a t} - \left(\frac{1 - e^{-n'k_d\tau}}{1 - e^{-k_d\tau}}\right)e^{-k_d t}\right] \quad \text{(Eq. 13)}$$

where n' is the number of doses given ($n' = n + 1$). Similar reduction of Eq. 12 can be made, giving

Equation 11 reduces to $b = 0$ at infinite time, which would be expected since the drug is no longer in the body. Equation 12 reduces at infinite time to $u = \frac{k_e}{k_d}(A_o + na_o)$, which indicates that the fraction of the total dosage administered which appears in the urine is a function of the rate of excretion compared to the sum of the excretion and metabolism rates.

According to the nomenclature used above, the fraction of drug in compartment b at the time of administration of the first dose of size a_o is given by substitution of $n = 0, t = \tau$ in Eq. 11. Substitution of $n = \infty, t = \tau$ in the same equation gives the minimum value of b after sufficient doses of size a_o such that the effect of the initial dose A_o is negligible. From these two equations the ratio A_o/a_o can be obtained as

$$\frac{A_o}{a_o} = \frac{1}{(1 - e^{-k_a\tau})(1 - e^{-k_d\tau})} \quad \text{(Eq. 15)}$$

This is the same form as given by Krüger-Thiemer (8) for the ratio of initial dose to supporting dose such that the blood drug levels obtained at time τ after the initial dose will be maintained. The blood levels at any time can be calculated from the expression $c = b/V_d'$, where c = drug concentration in blood (mg./L.) and V_d' = specific volume of distribution (L./Kg.) if dose is in units of mg./Kg., and substituting b from Eq. 11 to give

$$u = a_o\frac{k_e}{k_d}\left[n' - \frac{\{k_d[(1 - e^{-n'k_a\tau})/(1 - e^{-k_a\tau})]e^{-k_a t} - k_a[(1 - e^{-n'k_d\tau})/(1 - e^{-k_d\tau})]e^{-k_d t}\}}{k_d - k_a}\right] \quad \text{(Eq. 14)}$$

$$c = \frac{k_a}{V_d'(k_d - k_a)}\left[\left(A_o e^{-nk_a\tau} + a_o\frac{1 - e^{-nk_a\tau}}{1 - e^{-k_a\tau}}\right)e^{-k_a t} - \left(A_o e^{-nk_d\tau} + a_o\frac{1 - e^{-nk_d\tau}}{1 - e^{-k_d\tau}}\right)e^{-k_d t}\right] \quad \text{(Eq. 16)}$$

METHODS AND RESULTS

Riboflavin U.S.P. in finely divided form was used in this study. Suspensions were freshly prepared in deionized water at a concentration of 10 mg. riboflavin per 50 ml. Each subject drank the appropriate amount of suspension at the indicated interval, rinsing the container with several smaller portions of water to insure consumption of the total dose.

Ten apparently healthy adults were used as subjects. The subjects were placed on a semi-restricted diet, refraining from eggs, liver, and vitamin supplements for one day preceding the test and the two-day test period. On test 996 the diet was more closely controlled. No food, other than a 200-ml. portion of vegetable puree at 2-hour intervals, was consumed during the critical 12-hour Wednesday test period. This test was included to check the effect of diet in the first two experiments where the subjects were allowed to consume the foods of their choice with the exceptions previously mentioned. A 9.9-mg. or 10-mg. dose of riboflavin, divided as outlined in Table I, was used in the study.

The test periods began Tuesday morning at 8:15 and lasted through 8:15 on Thursday morning. On the first day, all the urine accumulated up to 8 hours and from 8 to 24 hours after the start of the test was collected and used to obtain the base riboflavin excretion level for each individual. Wednesday morning at 8:15 a.m. the first dose of the test series was taken. Subsequent doses were taken as indicated in Table I. Urine was collected at the time intervals shown in Table I during each experiment. The urine was collected in amber glass bottles, the volume measured, and aliquots stored at 4° until assayed.

The urine was assayed for riboflavin by the U.S.P. fluorometric method (10). The base value for each individual was subtracted from the riboflavin levels obtained after the ingestion of the test preparation to determine the net amount of riboflavin excreted. The excretion data obtained are presented in Table I.

The data in Table I were analyzed using Eq. 12. In this equation for total amount of drug in urine the parameters A_o, a_o, n, τ, and t are known for any single value of u reported. Because the average fraction of the total dose excreted within 24 hours in the three experiments was 0.50, this value of the ratio k_e/k_d was used. Thus, only k_a and k_e remained to be determined. This was done by assuming values for these constants and evaluating Eq. 12 at each time a urine sample was collected. The sum of the squares of the differences between the observed and calculated values of u was obtained. An IBM 1620 digital computer was used for the calculations. The constants k_a and k_e which minimized this sum of squares were $k_e = 0.123$ hr.$^{-1}$ and $k_a > 30$ hr.$^{-1}$. Values of k_a as great or greater than 30 hr.$^{-1}$ are not meaningful in this application because they indicate that absorption is 95% complete in a tenth of an hour or less.

The mean cumulative urinary riboflavin levels are shown in Fig. 1 for each of the three experiments with the curves calculated according to Eq. 12 with $k_a = 30$ hr.$^{-1}$, $k_e = 0.123$ hr.$^{-1}$, $k_d = 0.246$ hr.$^{-1}$ and other constants as given by Table I.

The theoretical levels of drug in compartment b during the 24-hour duration of the experiment can be calculated from Eq. 11 without further assumptions, and are shown in Fig. 2.

DISCUSSION

The applicability of Eq. 12 to the riboflavin excretion data depends primarily on the assumption of apparent first order kinetics of riboflavin excretion. This kinetic order is substantiated by the riboflavin excretion data of Axelrod, *et al.* (11), and Najjar and Holt (12), obtained after single doses of the drug. First order excretion is also consistent with the finding of Morrison and Campbell (13) that the per cent of dose excreted is constant over the 1 to 20 mg. range of oral doses.

The fraction of the total dose excreted appears from our data to be independent of how the total dose is divided or at what interval the individual doses are administered. This is similar to the findings of Chapman and Campbell (14) and Morrison and Campbell (13), who reported equal recovery of riboflavin in urine after single or divided oral dosage.

TABLE I.—URINARY RIBOFLAVIN EXCRETION IN HUMAN SUBJECTS

Time Interval, hr.	Total Riboflavin (mg.) Excreted During Indicated Interval (Mean ± S.D.)[a] Test 800: 5.0 mg. at $t = o$ and 1.0 mg. every hour for 5 doses	Test 801: 2.4 mg. at $t = o$ and 1.5 mg. every 2 hours for 5 doses	Test 996: 2.4 mg. at $t = o$ and 1.5 mg. every 2 hours for 5 doses
0–1	0.62 ± 0.34		
1–2	0.68 ± 0.20		
0–2		0.53 ± 0.13	0.58 ± 0.13
2–4	1.11 ± 0.31	0.66 ± 0.17	0.45 ± 0.07
4–6	0.70 ± 0.32	0.51 ± 0.19	0.53 ± 0.19
6–8	0.68 ± 0.28	0.61 ± 0.12	0.61 ± 0.14
8–10		0.89 ± 0.18	0.77 ± 0.16
10–12		0.65 ± 0.29	0.73 ± 0.18
8–12	0.56 ± 0.18		
12–24	0.60 ± 0.11	1.13 ± 0.36	1.23 ± 0.33

[a] Each value is based on the mean of 10 subjects.

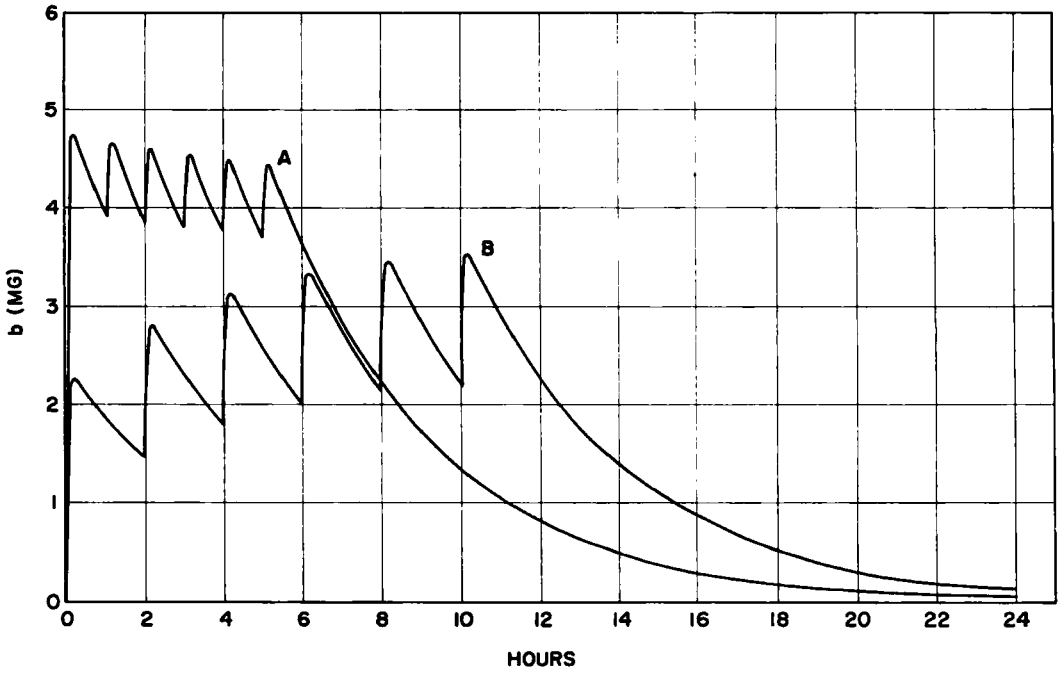

Fig. 2.—Amount of riboflavin in the body (b) as calculated from Eq. 11 with k_d = .246 hr.$^{-1}$ and k_a = 30 hr.$^{-1}$. In curve A, A_0 = 5 mg., a_0 = 1 mg., τ = 1 hr., and $n_{max.}$ = 5. In curve B, A_0 = 2.4 mg., a_0 = 1.5 mg., τ = 2 hr., and $n_{max.}$ = 5.

The shape of the excretion curve calculated from Eq. 12 during any time period τ is convex, rising more rapidly during the first part of the period than later. This is because riboflavin appears to be rapidly absorbed, causing higher blood levels early in the period (see Fig. 2), and thus more rapid excretion than occurs toward the end of the interval. For drugs which are slowly absorbed the shape of the excretion curve would be sigmoid, with the inflection occurring at the time of peak blood concentration.

More apparent in this type experiment than the shape of the excretion curve in the interval τ is the shape over the period of the whole experiment. If blood levels of drug are higher after each successive dose (due to a low dose ratio, A_0/a_0) the general shape of the excretion curve will be concave, rising more steeply during each successive interval. This is the shape of the lower curve in Fig. 1 where the dose ratio was 1.6. If blood levels of drug are lower after each successive dose due to a high dose ratio, a generally convex excretion curve will result. This is the case in test 800 in which the dose ratio was 5.0.

Absorption rate, as well as kinetic order, is best determined by the shape of the curve in the time period in which absorption is occurring. In these experiments urine samples over the period of drug administration were emphasized rather than consecutive samples after a single administration. Thus, the shape of the curves obtained from the data in Table I are primarily determined by the dose ratio and the time interval between doses. This does not mean that absorption rate cannot be calculated from this type experiment. In theory it can be calculated under any combination of dosage variables, but in practice a precise measure is best obtained using Eq. 12 when absorption is not essentially complete in the interval between doses.

The equations derived for blood and urine drug levels after an initial dose different from the remaining doses reduce to the forms given in the literature for more specific cases. Equation 13, which gives the values of b after all equal doses at equal time intervals, is the same as that of Dost (4) except for nomenclature. This equation, for the case of intravenous administration ($k_a = \infty$) considered by Boxer, *et al.* (6), simplifies to $b = a_0(1 - e^{-n'k_d\tau})\, e^{-k_d t}/(1 - e^{-k_d\tau})$. Neglecting distribution of drug immediately after injection, the ratio of the value of b when equilibrium is established, b_∞, ($n' = \infty$), to its value in the first period, b_1, ($n' = 1$), is $b_\infty/b_1 = 1/(1 - e^{-k_d\tau})$. This is the expression given by Boxer, *et al.*

Considering the more cymplicated case in which the initial dose is different than successive doses and in which drug is administered orally, the blood levels (c in Eq. 16) or fraction of drug in the body (b in Eq. 11) after a large number of doses such that equilibrium is established can be calculated from the equations after substitution on $n = \infty$ and simplifying. Thus, Eq. 16 simplifies to the form of Eq. 13 and is similar to the treatment of Boxer, *et al.* (6), except that k_a is not large enough to make the exponential terms containing it zero. Maximum and minimum values of blood concentration are then given by the equations

$$c_{max.} = \frac{a_0 k_a}{V_d'(k_d - k_a)} \left[\frac{e^{-k_a t_{max.}}}{1 - e^{-k_a\tau}} - \frac{e^{-k_d t_{max.}}}{1 - e^{-k_d\tau}} \right] \quad \text{(Eq. 17)}$$

where

$$t_{max.} = ln \frac{\left[\frac{k_d(1 - e^{-k_a\tau})}{k_a(1 - e^{-k_d\tau})}\right]}{k_d - k_a} \quad \text{(Eq. 18)}$$

and

$$c_{min.} = \frac{a_o k_a}{V_d'(k_d - k_a)} \left[\frac{e^{-k_a\tau}}{1 - e^{-k_a\tau}} - \frac{e^{-k_d\tau}}{1 - e^{-k_d\tau}}\right] \quad \text{(Eq. 19)}$$

Equations 17 and 18 are identical to the equations derived by Dost (4) for all equal doses because as n approaches infinity the effect of the initial dose on equilibrium blood levels disappears. Equation 19 differs from the equation given by Dost for minimum blood levels only by the exponential factors in the numerators, and reduces directly to the form given by Dost. Equation 19 also reduces to a form similar to the expression given by Swintosky, *et al.* (7), for minimum blood levels when k_a is large. However, Swintosky uses one extrapolated value for $a_o k_a / V_d'(k_d - k_a)$ into which he also combines the absorption terms. Swintosky arrives at his equation for $c_{max.}$ by similar means.

The dose ratio, A_o/a_o, which will maintain a minimum blood level equal to that existing at time τ after the first dose, A_o, is given in Eq. 15. This has been given by a different derivation by Krüger-Thiemer (8), who suggested its clinical application for cases in which k_a is large and $\tau = t_{1/2}$, the half-life of drug disappearance, whereby the dose ratio becomes 2. When k_a is large such that absorption is complete in the interval τ, the equilibrium minimum blood level obtained after many doses is also obtained after the first dose, resulting in a plateau effect (15). From Eq. 16 the effect of repeated doses before absorption of the previous dose is complete is found to be an increase in both maximum and minimum blood levels above the equilibrium values. These higher blood concentrations decrease to the equilibrium values when n becomes large. Thus the dose ratio given by Krüger-Thiemer will not give the plateau effect desired if the product $k_a\tau$ is not large, although minimum drug concentrations will be maintained.

The equations given above should be useful in the interpretation of blood drug concentration or cumulative drug urine level data obtained after the common dosage regimen of one large dose and subsequent equal smaller doses at equal time intervals. Such experiments are useful in determining that the calculated dosage regimen is optimal, and the analysis of the results according to the appropriate equation should allow an assessment of what actually occurred. The equations in their general form are also useful for the derivation of simpler forms by substitution of the appropriate limiting assumptions.

SUMMARY

1. General mathematical equations have been derived to analyze plasma concentration or urinary excretion data obtained when a drug is given as one large dose followed by successive equal small doses at equal time intervals.

2. The validity of the urinary excretion equation has been demonstrated by fitting the equation to urinary excretion data from human subjects. Assuming first-order kinetics, the absorption, disappearance, and excretion constants of riboflavin were found to be: $k_a = 30$ hr.$^{-1}$, $k_d = 0.25$ hr.$^{-1}$, and $k_e = 0.12$ hr.$^{-1}$.

3. The disappearance rate was found to be the controlling factor for sustaining riboflavin levels. In the case of riboflavin, absorption is almost immediate and an accurate measure of the absorption rate was not made.

4. Expected maximum and minimum blood levels can be calculated when the necessary rate constants and volume of distribution are known.

5. The equations presented reduce to simpler expressions found in the literature by substituting appropriate limiting functions.

6. These equations allow calculation of the ratio of the initial dose to subsequent smaller doses given at equal time intervals which will maintain a relatively constant blood level. Such calculations can be applied to find the optimum dosage regimen of any drug for which the absorption, excretion, and disappearance constants are known.

Spectrophotometric Analysis of Phenobarbital and Pentobarbital in Pharmaceuticals

By THEODORE L. BROWN

An analytical procedure has been developed for measuring the concentration of phenobarbital and pentobarbital in mixtures of these substances, *e.g.*, in pharmaceuticals. This new method is a spectrophotometric procedure based upon the shift in ultraviolet absorbance of pentobarbital subsequent to dealkylation in sulfuric acid.

IN THE COURSE of their investigation of the structure of the metabolites of pentobarbital, Maynert and Washburn (1) found that certain dialkyl barbituric acids are subject to dealkylation in sulfuric acid. These workers reported that 5,5-dialkyl barbituric acids containing a secondary group lost this group in sulfuric acid. For example, 5-ethyl-5-(1-methylbutyl)-barbituric acid was dealkylated to 5-ethyl barbituric acid. Monoalkyl derivatives, such as 5-(1-methylbutyl)-barbituric acid, were found to be stable in this menstruum, as were 5,5-disubstituted barbituric acids containing two primary alkyl groups or a phenyl and a primary alkyl group.

Brooker (2) found this reaction mechanism could be utilized in the analysis of mixed barbiturates by paper chromatography. He demonstrated that the chromatographic resolution of amylobarbital and pentobarbital could be markedly improved by selectively converting the pentobarbital to 5-ethyl barbituric acid with hot sulfuric acid.

Curry (3) reported that the ultraviolet absorbance maximum of pentobarbital shifts from 240 to 268 millimicrons as a consequence of dealkylation. He found that phenobarbital under these conditions was completely destroyed and the ultraviolet absorbance of this substance became zero as a consequence of this hot acid treatment.

Work in this laboratory has confirmed the shift in the ultraviolet absorbance maximum of pentobarbital. However, we found that the absorbance of phenobarbital is essentially unchanged by hot sulfuric acid treatment (see Fig. 1). These results are consistent with Maynert and Washburn's observations concerning the stability of 5,5-disubstituted barbituric acids in sulfuric acid solution

These data suggested the possibility of using this technique for measuring the concentration of both phenobarbital and pentobarbital in pharmaceuticals containing both of these substances.

Received June 19, 1962, from the Research Division of Cutter Laboratories, Berkeley, Calif.
Accepted for publication August 10, 1962.
The author would like to thank Mr. Joel Benjamin for technical assistance in this work.

EXPERIMENTAL

In order to define the necessary conditions for the proposed analytical technique, the following experiments were performed:

Effect of Heating Time On Dealkylation of Pentobarbital.—An aqueous solution was prepared by dissolving 25.0 mg. of pentobarbital in 5.0 ml. of 0.13 *N* sodium hydroxide. One-milliliter aliquots were mixed with 9.0 ml. of concentrated sulfuric acid and heated at 100° for increments of time. Subsequent to cooling, these samples were diluted to 50.0 ml. with distilled water. Five-milliliter aliquots were mixed with 5.00 ml. of 22.5% ammonium hydroxide and then diluted to 100.0 ml. with distilled water. The absorbance of these solutions at 240 and 268 mμ was then measured, using a Beckman DU spectrophotometer. The results are recorded in Table I. It would seem from these data that timing of the acid treatment step is not critical. Thirty minutes at 100° was used for all subsequent work.

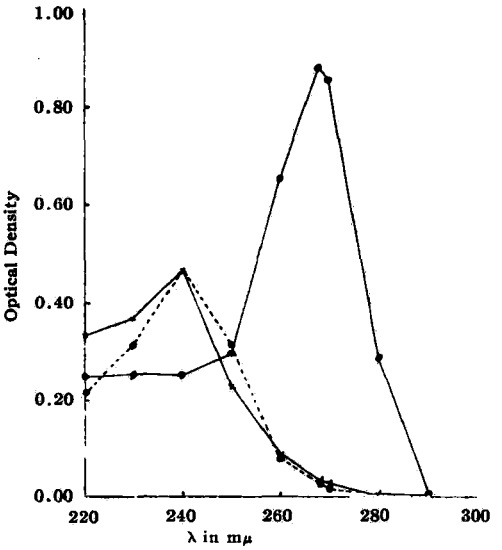

Fig. 1.—U.V. absorbance of phenobarbital and pentobarbital before and after treatment with hot sulfuric acid: ⊙-⊙-⊙ 10 mcg. pentobarbital/ml. before hot sulfuric acid treatment; ⊙—⊙—⊙ 10 mcg. pentobarbital/1 ml. after hot sulfuric acid treatment; ×—×—× 10 mcg. phenobarbital/ml. before and after hot sulfuric acid treatment.

TABLE I.—EFFECT OF HEATING TIME ON PENTOBARBITAL DEALKYLATION

Time of Heating, min.	Absorbance 240mμ	Absorbance 268mμ
0	0.466	0.022
15	0.269	0.846
30	0.252	0.880
60	0.252	0.880

Effect of Sulfuric Acid Concentration on Rate of Dealkylation of Pentobarbital.—An aqueous solution was prepared by dissolving 25.0 mg. of pentobarbital in 5.0 ml. of 0.13 *N* sodium hydroxide. One-milliliter aliquots were mixed with 9.0 ml. of sulfuric acid of varying strengths. Subsequent to cooling, these samples were diluted to 50.0 ml. with distilled water. Five-milliliter aliquots were mixed with 5.0 ml. of 22.5% ammonium hydroxide and then diluted to 100.0 ml. with distilled water. The absorbances were then measured at 240 and 268 mμ. The results are recorded in Table II.

TABLE II.—EFFECT OF ACID CONCENTRATION ON PENTOBARBITAL DEALKYLATION

Concentration of Acid Added	Absorbance 240mμ	Absorbance 268mμ
21 *N*	0.445	0.018
30 *N*	0.431	0.102
36 *N*	0.252	0.880

It is apparent from these data that acid concentration is critical and must be carefully controlled. In all of the subsequent work, 36 *N* sulfuric acid was used in the analysis.

Interfering Substances.—Only those substances present in the pharmaceutical preparation of interest in this laboratory were evaluated with respect to their effect on the proposed analytical technique. It was found that preliminary purification by filtration and solvent extraction eliminated most of these substances prior to acid treatment. Thus, lactose, calcium stearate, procaine hydrochloride, and N-ethyl-3-piperidyl benzilate methobromide were found to be without significant effect on the proposed barbiturate analysis.

Effect of pH on Ultraviolet Absorbance of Phenobarbital, Pentobarbital, and Ethyl Barbituric Acid.—It is known that pH has significant effect on ultraviolet absorbance of barbiturates and their derivatives. However, it is extremely simple to prepare samples of exactly reproducible pH by mixing measured volumes of reagents of known concentration. Our experience indicated that if ordinary quantitative techniques are observed in measuring the standardized reagents employed, the variation in absorbance on a given sample will be negligible.

Summation of Experimental Procedure—Ten milliliters of an ethereal extract containing 2.5–5.0 mg. each of phenobarbital and pentobarbital was transferred to a 2.2 × 24 cm. test tube. The ether was carefully evaporated off with the aid of a warm water bath. The residual barbiturates were then dissolved in 1.0 ml. of 0.13 *N* sodium hydroxide and mixed with 9.0 ml. of 36 *N* sulfuric acid. This mixture was heated at 100° for 30 minutes and then cooled to RT. The sample was then placed in an ice bath and diluted to 50.0 ml. with distilled water. Five milliliters of this solution was mixed with 5.0 ml. of 22.5% ammonium hydroxide and then diluted to 100.0 ml. with distilled water. The absorbance was then measured against a reagent blank at 240 and 268 mμ.

TABLE III.—EFFECT OF HOT SULFURIC ACID TREATMENT UPON ULTRAVIOLET ABSORBANCE OF PHENOBARBITAL AND PENTOBARBITAL

Wavelength, mμ	Absorbance of Phenobarbital[a] Heated	Absorbance of Phenobarbital[a] Unheated	Absorbance of Pentobarbital[a] Heated	Absorbance of Pentobarbital[a] Unheated
220	0.336	0.336	0.244	0.216
230	0.366	0.366	0.254	0.309
240	0.465	0.466	0.252	0.466
250	0.220	0.222	0.296	0.308
260	0.082	0.083	0.656	0.078
268	0.032	0.031	0.880	0.022
270	0.022	0.021	0.856	0.015
280	0.003	0.003	0.282	0.001
290	0.000	0.000	0.006	0.000

[a] Concentration of each barbiturate is 10.0 mcg./ml.

Pure samples of phenobarbital and pentobarbital were analyzed by this technique and the absorbances were measured at intervals throughout the ultraviolet spectrum. Similar samples were prepared and the absorbances similarly measured after addition of the acid but prior to heat treatment. These data are recorded in Table III. These data were then used to calculate the concentration in unknown sample mixtures as follows: Let X = mcg. of pentobarbital/ml., and Y = mcg. of phenobarbital/ml. Then, $0.465\ Y/10 + 0.252\ X/10$ = absorbance at 240 mμ and $0.032\ Y/10 + 0.880\ X/10$ = absorbance at 268 mμ.

Substituting in the absorbance values observed on a given sample and then solving simultaneously, one can determine the concentration of each of the barbiturates in the dilute ammoniacal solution. Back calculating by substituting in the appropriate dilution factors, one can determine the concentration of each of the barbiturates in the original sample.

RECOVERY EXPERIMENT

Mixtures were prepared containing varying proportions of phenobarbital and pentobarbital. Aliquots of the resultant solutions were analyzed in the proposed manner. The results obtained are recorded in Table IV.

TABLE IV.—PER CENT RECOVERY OF PHENOBARBITAL AND PENTOBARBITAL IN KNOWN MIXTURES

Sample	Phenobarbital, mcg./ml. Theor.	Found	% Recovery	Pentobarbital, mcg./ml. Theor.	Found	% Recovery
1	6.04	6.01	99.7	4.02	4.08	101.3
2	5.04	5.04	100.0	5.02	5.04	100.1
3	4.03	4.09	101.4	6.02	6.11	101.3

Chemistry of Guareschi Imides I

Lithium Aluminum Hydride Reduction of Some Bicyclo Guareschi Imides

By ARNOLD A. LIEBMAN† and FRANK E. DiGANGI

In the course of the synthesis of some 3,5-disubstituted piperidine compounds which would also contain the essential requirements for analgesic activity, some Guareschi imides were prepared and their subsequent reduction with lithium aluminum hydride was studied.

IN AN EFFORT to prepare compounds of types I, II, and III as potential analgesics, Guareschi imides (IV) were synthesized as model compound intermediates. If lithium aluminum hydride would selectively reduce the imide grouping, then the intermediate dicyanopiperidines (V) could be converted into the desired compounds (I, II) and total reduction of these imides should yield III. A review of the literature shows no attempted selective reduction of cyanoimides. Avison and Morrison (1) have successfully reduced ethyl-5-chloro-2-cyano-2-phenylvalerate (VI) to 5-chloro-2-cyano-2-phenyl-1-pentanol (VII) but the lactam (VIII) derived from VII yielded only a mixture of basic products when selective reduction was attempted.

The model β,β-dialkyldicyanoimides (IV) were prepared using the modified procedure of Benica and Wilson (2) for the Guareschi reaction (3). It was noted that the Guareschi imides are insoluble in diethyl ether and other solvents commonly used in lithium aluminum hydride reductions, being only slightly soluble in tetrahydrofuran. Therefore, this solvent was used exclusively in the reduction studies. Selective reduction of the Guareschi imides was attempted under various conditions. Dissolving the imide in the minimum amount of peroxide-free tetrahydrofuran and adding a calculated amount of lithium aluminum hydride dissolved in tetrahydrofuran resulted in an immediate precipitate. For example, treating α,α'-dicyano-β,β-dimethyl-N-methylglutarimide (IX) with a molecular equivalent of lithium aluminum hydride resulted in the formation of a precipitate. The mixture was not heated but decomposed by adding water until refluxing had ceased. The solid material obtained by filtering the mixture was dissolved in hydrochloric acid and after extraction with ether, the solution alkalinized with sodium carbonate. After filtering the

resulting suspension followed by extraction with ether, evaporation of the ether left a small amount of solid material. This material melted higher than starting material and an infrared spectrum showed the retention of carbonyl and cyano functions. The organic solution from the reaction mixture deposited only starting material when evaporated. The original aqueous layer was evaporated to a small amount of impure semisolid, the quality of which precluded any attempts at characterization.

In addition, selective reduction was attempted allowing the reaction mixture to reflux for periods of from 2–24 hours and the complex being decomposed with either acid or alkali, extracting the organic material with suitable solvents. Also, increasing amounts of lithium aluminum hydride were used. In each instance, however, evaporation of the solvent left a small amount of hygroscopic semisolid but no pure reduction product could be isolated. Regardless of the compound or the experimental conditions, similar results were encountered.

It became apparent that the lithium aluminum hydride easily complexed with the acidic hydrogen atoms of the Guareschi imides and the resulting tetrahydrofuran insoluble material does not undergo the desired reduction. The preparation of XII[1] represents a compound having no acidic hydrogen. This compound was prepared by first synthesizing the Guareschi imide (X) from cyclohexanone, ethylcyanoacetate, and alcoholic ammonia. The bicyclo compound (XI) was prepared by the method of Kerr (4) and Paul (5), using sodium methoxide and methylene iodide. Methylation of the imide nitrogen was effected with sodium hydride and methyl iodide. Attempted selective reduction of this compound (XII) proceeded in a manner similar to the monocyclic compounds and gave similar results in that no pure reduction product could be identified.

Total reduction of the β,β-dialkyldicyanoglutarimides was attempted by adding a solution of the imide in tetrahydrofuran to an excess of lithium aluminum hydride contained in an ether-tetrahydrofuran mixture. Again, a precipitate formed, and regardless of the conditions used, no appreciable amounts of reduced material could be obtained.

Total reduction of a bicyclo Guareschi imide was attempted under the same conditions with the expected diaminomethylpiperidine being obtained. The Guareschi imide derived from acetone was converted into a bicyclo compound (XIII) with methylene iodide and subsequent reduction yielded 20% of the expected product (XIV). The N-methyl analog (XV) yielded 38% of the diaminomethyl-N-methylpiperidine (XVI) upon reduction.

Two unsymmetrical Guareschi imides were prepared to determine their susceptibility toward bicyclization with methylene iodide and subsequent reduction with lithium aluminum hydride. The Guareschi imide derived from 2-butanone was readily prepared. Due to the extremely low yield of Guareschi imide derived from 4-1 ethyl-2-pentanone in the Guareschi synthesis (6), this compound was prepared in an overall yield of 54% using the two step procedure for the preparation of β-alkyl-β-aryl Guareschi-like imides (7–9). These two Guareschi imides along with the two previously mentioned readily underwent bicyclization with methylene iodide yielding the products shown in Table I, Nos. 1–4. The sodio derivatives of the various bicyclo Guareschi imides were prepared with sodium hydride in tetrahydrofuran and each underwent N-methylation with methyl iodide (Table I, Nos. 5–8).

The general procedure for reduction of the bicyclo imides was patterned after the successful

[1] Named according to the Ring Index, compound XII is: spiro-(3-aza-1,5-dicyano-2,4-dioxo-3-methyl-bicyclo-(3.1.1)-heptane-6,1′-cyclohexane).

reduction of 3-aza-1,5-dicyano-2,4-dioxo-6,6-dimethyl-bicyclo-(3.1.1)-heptane and its N-methyl analog (Nos. 1 and 5, Table I). It was found that a 30% excess of lithium aluminum hydride over the theoretical amount and a reflux time of 9 hours gave the best yields (Table II). The N-methyl-bicyclo-glutarimides gave slightly higher yields on reduction than those possessing the somewhat acidic free imide. The resulting compounds were extremely hygroscopic as were derivatives prepared from them. The purity of these compounds was established by elemental analysis of the base or of its picrate derivative and gas chromatograms. Compounds 11 and 15 (Table II) analyzed for tripicrate derivatives while compound 14 (Table II) appears to have formed a mixture of di- and tripicrate derivatives.

EXPERIMENTAL

General procedure for preparation of Guareschi Imides (2).—The appropriate ketone (0.5 mole), 1.1 mole of freshly distilled ethyl cyanoacetate, and 225 ml. of alcoholic ammonia were mixed and refrigerated for 3 days in a well-stoppered flask. The precipitated ammonium salt was collected and, after washing with ether, dissolved in approximately 350 ml. of warm water. Sufficient concentrated hydrochloric acid was added to insure complete precipitation and the imide then recrystallized from dilute alcohol.

The ketones used in this procedure were acetone, 2-butanone, and cyclohexanone.

Ethyl - (1 - isobutylethylidene) - cyanoacetate.—A mixture of 79.1 Gm. (0.07 mole) of ethyl cyanoacetate, 70.0 Gm. (0.7 mole) of 4-methyl-2-pentanone, 33.6 Gm. (0.56 mole) of glacial acetic acid, 10.8 Gm. (0.14 mole) of ammonium acetate, and 140 ml. of anhydrous benzene were placed in a flask fitted with a Dean-Stark water separator and

[a] All reported boiling points are uncorrected. [b] Melts with decomposition.

treated according to the procedure of Cope (7). Distillation yielded 101.6 Gm. (72%) of the product boiling between 90–95°/0.6 mm.

α,α′ - Dicyano - β - isobutyl - β - methylglutarimide.—According to the procedure of McElvain and Clemens (8, 9), 0.5 mole of sodium cyanoacetamide was treated with 0.5 mole of ethyl-(1-isobutylethylidene)-cyanoacetate. The product was dried to a constant weight of 87.3 Gm. (75%) and melted at 237–239°. Reported (6) m.p. 239–240°.

Selective Reduction Studies.—In a 1-L., three necked, round-bottom flask fitted with a stirrer, dropping funnel, condenser, and drying tube was placed a solution of 10.3 Gm. (0.05 mole) of α,α′-dicyano - β,β - dimethyl - N - methylglutarimide dissolved in 100 ml. of absolute tetrahydrofuran. The flask was cooled in an ice bath and a solution of 1.9 Gm. (0.05 mole) of lithium aluminum hydride dissolved in tetrahydrofuran[2] was added with stirring over a period of 1 hour. A solid began to separate after approximately one-half of the hydride solution was added. After the addition was completed, stirring was continued for 15 minutes at room temperature and then 100 ml. of water was cautiously added. The solid material was filtered with suction and washed with water. Five hundred milliliters of ether was added to the filtrate and the two layers separated. Evaporation of the aqueous layer under reduced pressure yielded a small amount of highly colored semisolid which could not be purified. The organic layer, when evaporated, left starting material only.

The solid obtained during the decomposition of the reaction mixture was dissolved in an excess of 6 *N* hydrochloric acid and the resulting solution extracted with ether. Upon evaporation of the ether, an additional small amount of starting material was obtained. The acidic solution was neutralized with sodium bicarbonate and the precipitated aluminum compounds filtered with suction. The filter cake was washed with ether and these washings were then used to extract the now alkaline solution. After drying the ethereal extract with anhydrous sodium sulfate, the solvent was evaporated under reduced pressure, leaving approximately 0.5 Gm. of a white solid. This material was recrystallized several times from 50% ethanol and melted at 206°. The infrared spectrum of this compound showed retention of carbonyl and nitrile functions.

Selective reduction was also attempted under the experimental conditions of increasing reflux periods up to 24 hours and/or decomposing the hydride complex with 10% sulfuric acid (10). In addition, increasing amounts of lithium aluminum hydride, up to 100% excess, were used. In each instance, the apparent reduction product(s) consisted of highly colored, ether-insoluble semisolid material. Typical amine salts such as methiodide, hydrochloride, citrate, etc., were prepared from tetrahydrofuran solution, but were of such a hygroscopic nature that purification could not be effected. Attempts to purify the reduced material by microdistillation *in vacuo* were unsuccessful in that the material resinified.

The imides used in these studies were α,α′-dicyano-β,β-dimethylglutarimide, α,α′-dicyano-β,β-dimethyl-N-methylglutarimide, and spiro-(3-aza-1,5-dicyano-2,4-dioxo-3-methyl-bicyclo-(3.1.1)-heptane-6,1′-cyclohexane).

Total Reduction Studies.—A suspension of 15.5 Gm. of 95% lithium aluminum hydride (0.39 mole) in a mixture of 150 ml. of absolute ether and 50 ml. of absolute tetrahydrofuran was heated under reflux for 1 hour to effect solution of the hydride. After cooling, 15.3 Gm. (0.08 mole) of α,α′-dicyano-β,β-dimethylglutarimide dissolved in 350 ml. of absolute tetrahydrofuran was added dropwise with stirring. When the addition was completed, the reaction mixture was stirred and heated under reflux for 7 hours during which time a thick, dark yellow precipitate appeared. The mixture was cooled and decomposed by cautiously adding 16 ml. of water, 16 ml. of 15% sodium hydroxide solution, and 48 ml. of water. The gelatinous precipitated material was removed by filtration and washed with two 50-ml. portions of tetrahydrofuran. The combined filtrates, which had a yellow color, were dried (anhydrous sodium sulfate) and then evaporated under reduced pressure. The residue consisted of 3.6 Gm. of starting material and approximately 100 mg. of a dark yellow oil having amine characteristics. A stable solid derivative could not be prepared from this oil.

This reduction was also attempted using 50% excess lithium aluminum hydride in addition to the theoretical amount required to reduce the imide and two nitrile groups. The reflux time was increased to 24 hours but no change in the results was noted. Similar results were obtained in the attempted total reduction of α,α′-dicyano-β,β-dimethyl-N-methylglutarimide.

3-Aza-1,5-dicyano-6,6-dimethyl-2,4-dioxo-bicyclo-(3.1.1)-heptane.[3]—Following the procedure of Kerr (4) and Paul (5), 61.2 Gm. (0.32 mole) of α,α′-dicyano-β,β-dimethylglutarimide was converted into its trisodium salt and treated with 129.0 Gm. (0.048 mole) of methylene iodide. The crude product recovered from aqueous acid weighed 30.0 Gm. (46%) and melted between 305–315° (decompn.). When recrystallized from methanol and acetone, the melting point was raised to 319° (decompn.). Reported (4) m.p. of the product recrystallized from glacial acetic acid is 305–306° (decompn.).

3-Aza-1,5-dicyano-2,4-dioxo-3,6,6-trimethyl-bicyclo-(3.1.1)-heptane.—Sodium hydride, 6.6 Gm. of a 54.5% dispersion (0.15 mole), was suspended in 100 ml. of absolute tetrahydrofuran contained in a 1-L., three-necked, round-bottom flask equipped with a stirrer, dropping funnel, reflux condenser, and drying tube. To the suspension, 30.0 Gm. (0.15 mole) of 3-aza-1,5-dicyano-6,6-dimethyl-2,4-dioxo-bicyclo-(3.1.1)-heptane dissolved in 300 ml. of absolute tetrahydrofuran was added dropwise with stirring. The reaction mixture was refluxed for 1 hour, cooled, and 24.0 Gm. (0.17 mole) of methyl iodide added. Stirring and reflux were continued for 2½ hours and after cooling, 20 ml. of water was added. The solution was evaporated under reduced pressure leaving 28.8 Gm. (85%) of the crude product melting at 222–226°. The product was recrystallized from ethanol and melted at 229–231°.

3-Aza-1,5-diaminomethyl-6,6-dimethyl-bicyclo-(3.1.1)-heptane.—Lithium aluminum hydride, 8.4

[2] Prepared according to directions given by Rapoport and Payne (10).

[3] This and the following procedures are typical of those used for the preparation of compounds listed in Tables I and II.

Gm. of 95% purity (0.21 mole), was crushed and suspended in a mixture of 150 ml. of absolute ether and 50 ml. of absolute tetrahydrofuran contained in a 2-L., three-necked, round-bottom flask fitted with a dropping funnel, stirrer, condenser, and drying tube. The suspension was heated under reflux for 1 hour, cooled and 10.2 Gm. (0.05 mole) of 3-aza-1,5-dicyano-6, 6-dimethyl-2, 4-dioxo-bicyclo-(3.1.1)-heptane dissolved in 350 ml. of absolute tetrahydrofuran was added with stirring. After the addition was completed, stirring and reflux were continued for 9 hours. The reaction mixture was cooled and the complex decomposed by the cautious addition of 9 ml. of water, 9 ml. of 15% sodium hydroxide solution, and 27 ml. of water. The granular precipitate that had formed was filtered and washed with ether, the washings being added to the previous filtrate which was then dried with anhydrous sodium sulfate. The solvent was removed under reduced pressure and the residue of 3.4 Gm. distilled. The fraction boiling between 109–110°/0.16 mm. was collected and weighed 1.8 Gm. (20%).

The distilled material solidified at room temperature and attempts to prepare solid derivatives from it resulted in hygroscopic compounds which could not be purified.

3-Aza-1,5-diaminomethyl-6-ethyl-6-methyl-bicyclo-(3.1.1)-heptane Tripicrate.—Reduction of the bicyclo Guareschi imide derived from 2-butanone yielded 16% of the product. However, the material was too hygroscopic to have analyzed. A picrate derivative was readily formed but decomposed into picric acid and the triamine when recrystallization from conventional solvents was attempted. A stable tripicrate was prepared by dissolving 0.5 Gm. of the triamine in 1 ml. of absolute ethanol and slowly adding 22 ml. of a saturated solution of picric acid in absolute ethanol. The precipitated derivative was collected and purified by washing it with chloroform and decanting the solvent. This process was repeated six times using ethanol as the washing medium and finally the solid derivative was dried in a vacuum, m.p. 245–248° (decompn.).

SUMMARY

1. Five Guareschi imides were prepared by known procedures.

2. Selective reduction of the imide grouping of the Guareschi imides with lithium aluminum hydride uniformly resulted in ether-insoluble semisolids from which no pure product could be isolated or characterized.

3. Total reduction of the imide grouping and the nitrile groups of the Guareschi imides gave similarly poor results.

4. A series of four bicyclo Guareschi imides was prepared from the monocyclic Guareschi imides.

5. The four bicyclo Guareschi imides prepared readily underwent N-methylation.

6. Lithium aluminum hydride reduction of the four bicyclo Guareschi imides and their N-methyl analogs yielded the expected totally reduced products.

Stability of Certified Dyes in Tablets I

Fading of FD&C Red No. 3 in Tablets as a Function of Concentration, Time, and Light Intensity

By MARTIN E. EVERHARD and FRANK W. GOODHART

The effect of concentration, time, and light intensity on the rate of fading of FD&C Red No. 3 in tablets has been examined. By modification of the Nolan and Foote equation relating the Kubelka-Munk function, θ, to dye concentration, a linear relation between the concentration of dye in the tablet and the θ calculated from the reflectance was found. A first-order rate equation for fading is given. This equation allows the fading which occurs under normal light intensity to be calculated from the fading which occurs at high light intensity.

One of the recurrent pharmaceutical problems is the instability of certified dyes in tablet formulations. The problem has historically been solved by selecting dyes which exhibit good stability in similar formulations. Within the last few years, several investigators have undertaken studies to determine the color stability by measuring the reflectance properties of the formulation.

Reflectance measurements of creams, powders, granulations, and coated tablets were made by McKeehan and Christian (1) using a modified Beckman DU spectrophotometer. This type of study was made quantitative by Lachman, *et al.* (2–5), who observed the changes in reflectance of tablets with time when exposed to visible radiation. In this latter case, the fading of the dyes was accelerated by using a high intensity light cabinet (6, 7). A plot of log (−log reflectance) *vs.* time demonstrated the fading rates of the dyes to be apparent first order.

It is necessary, however, to develop equations for relating dye fading as a function of time and light intensity so that more fundamental aspects of color degradation can be studied. Qualitative studies in our laboratory have shown that certain drug-dye incompatibilities alter fading and that, furthermore, tablet diluents, binders, lubricants, and processing methods may also do the same. Whether these factors are significant has not been determined. The dye concentration is also an important factor since apparent increased stability can sometimes be gained by increasing concentration. Therefore, we have conducted a series of experiments to determine the effect of dye concentration on the stability of FD&C Red No. 3[1] in tablets, and have discovered certain time-intensity relationships which are of significant importance to the research pharmacist.

Received March 26, 1962, from the Squibb Institute for Medical Research, New Brunswick, N. J.
Accepted for publication May 23, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

EXPERIMENTAL

Materials.—Lactose U.S.P., acacia U.S.P., magnesium stearate U.S.P., and FD&C Red No. 3.

Equipment.—Light sources were a bank of G.E. F4OCW fluorescent tubes, an incandescent lamp of 25 watts, and a light cabinet similar to that previously described (6, 7). The cabinet was equipped with a G.E. No. 6G1020-150 watts ballast and No. F40CW-3 fluorescent tubes. The tubes were 1.5 in. in diameter and 48 in. long, slant line cool white. They were G.E. rated at 3250 lumens per each 40 watt tube.

The temperature of the tablets was about 22 to 24°, except for the tablets stored in the light cabinet. The temperature of the tablets in the light cabinet was 2 to 3° higher than room temperature.

A Bausch and Lomb Spectronic 505 spectrophotometer with a reflectance attachment was used to obtain tablet reflectances. Magnesium carbonate was used as a white standard. A Gossen Tri-Lux foot-candle meter employing a microgalvanometer connected to the photoelectric cell by a 3-ft. extension cord was utilized to determine incident flux.

Preparation of Tablets.—Tablets were prepared according to the following three formulas

	L	M	N
Lactose U.S.P., %	93.940	93.970	93.985
Acacia U.S.P., %	5.000	5.000	5.000
Magnesium stearate U.S.P., %	1.000	1.000	1.000
FD&C Red No. 3, %	0.060	0.030	0.015
Distilled water, ml.	50	50	50

Lactose and acacia were mixed together and pulverized. The dye, dissolved in 50 ml. of distilled water, was poured onto the powder mixture while mixing. The wet powder was dried at 75° F. and 40% relative humidity for 16 hours, and then in an oven at 100° F. for 2 hours. The dyed powder was pulverized and the magnesium stearate added and

[1] Disodium salt of 9-o-carboxyphenyl-6-hydroxy-2,4,5,7-tetraiodo-3-isoxanthone (erythrosine).

blended with the powder. Uniformly colored, flat-faced pink slugs were produced on the Stokes F-4 tablet press using 1-in. punches and die. The tablets were run at uniform weights and pressures in order to produce tablets having consistent surface properties. The free moisture content of the tablets was about 1%.

Preparation of Tablet Samples.—Tablets were glued on large, black rubber stoppers.[2] The stoppers were marked so that the geometry could be reproduced when returning the sample to the reflectance sample holder.

Storage of Tablets.—Prepared tablet samples were exposed under the following conditions: (*a*) in the light stability cabinet at a flux of 655 foot-candles, (*b*) under a bank of fluorescent lights at 80 foot-candles, (*c*) under fluorescent lights and amber glass (0.120 in.) at 11 foot-candles, and (*d*) under incandescent light at 50 foot-candles.

DISCUSSION AND RESULTS

Previous workers have plotted the logarithm of the function log $1/R$ *vs.* time, where R is the fraction of the light reflected at a specified wavelength. They interpreted the results in terms of apparent first-order reactions (3). Although they did not explicitly state that log $1/R$ is a linear function of dye concentration, just as log transmission is a linear function of concentration in transmission work, this is inferred because they interpret their results in kinetic terms (8). However, when this assumption was tested at different dye concentrations, a new "kinetic" constant, k, was found for the rate equation at each concentration, although the results for any one concentration were linear and reproducible. Since k is different for each concentration, the reaction is either not first order or an incorrect rate equation was used. In the present work, doubling the dye concentration resulted in a 20% change in k when plots of log R *vs.* time were made. Similar results were obtained by using R *vs.* time, that is, zero-order plots. Since the reflectance value is not proportional to concentration, an expression relating these two quantities is needed.

From theoretical consideration Kubelka and Munk (9, 10) derived a series of differential equations describing the behavior of light when it strikes a diffusing surface. These equations can be combined and integrated to give one simple equation if certain assumptions are met

$$\theta = (1 - R)^2/2R \qquad \text{(Eq. 1)}$$

Where θ is the ratio of absorbed light to scattered light at a given wavelength. The most important assumptions are that the material is homogeneous, that it has sufficient thickness to be opaque, and that the reflectance is diffuse. These assumptions are easily met by using uniformly dyed tablets with a dull surface.

Nolan (11) and Foote (12), in working with the Kubelka-Munk function, found that if the scattering coefficient is assumed to be very small, zero, or constant, θ is proportional to concentration. The scattering coefficient is the fraction of incident light lost due to scattering. If this is assumed, then

$$\theta_d = AC \qquad \text{(Eq. 2)}$$

where θ_d is the Kubelka-Munk function for the dye, A is a constant of proportionality, and C is the concentration of dye in weight per cent. The observed reflectance, however, is due to the dye and the inert, background materials in the formulation. Nolan showed that the Kubelka-Munk function of a mixture is the sum of the individual Kubelka-Munk functions. Therefore

$$\theta_t = \theta_d + \theta_b \qquad \text{(Eq. 3)}$$

where θ_t is the Kubelka-Munk function of the tablet and θ_b of the background. Substituting Eqs. 1 and 2 into 3 gives

$$\theta_t = (1 - R_t)^2/2\,R_t = AC + \theta_b \qquad \text{(Eq. 4)}$$

where R_t is the measured reflectance of the tablet at the minimum in the reflectance-wavelength curve, 543 mμ.

Since the concentration of inert material, mostly lactose, is essentially constant, θ_b is a constant. Therefore, a plot of θ_t *vs.* C, Eq. 4, should be a straight line. By using the smoothed values of θ_t at zero time from Fig. 1, a straight line is obtained. The value of A is 8.2 and θ_o is 0.146, within 2%. This shows that θ_t is linearly related to the concentration and suitable for use in kinetic plots.

Previous attempts to correlate the fading of tablets at different intensities of the incident light have not been satisfactory. Each intensity was considered a separate case and different kinetic constants were calculated for each intensity (3, 4). However, since fading is proportional to the product of time, t, and intensity, I (13), plots of θ_t *vs.* the product of time and intensity were made. The plots are shown in Fig. 1. The consistency of the k value at the three different concentrations shows that the decomposition of the dye is indeed first order. By using the product of time and intensity, each intensity condition was found to lie on the same straight line for any given concentration.

The general first-order rate equation is

$$\ln \theta_t = -ktI + \ln \theta_t' \qquad \text{(Eq. 5)}$$

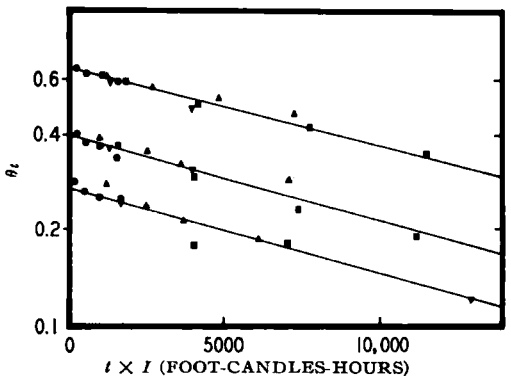

Fig. 1.—Plots of θ_t *vs.* the product of time and intensity. ●, 11 foot-candles; Δ, 50 foot-candles; □, 80 foot-candles; ▽, 655 foot-candles. Top line, 0.06% dye; middle line, 0.03% dye; bottom line, 0.015% dye.

[2] Our thanks to Mr. D. Dickcius for devising this easy method of mounting the samples and for taking many of the reflectance measurements.

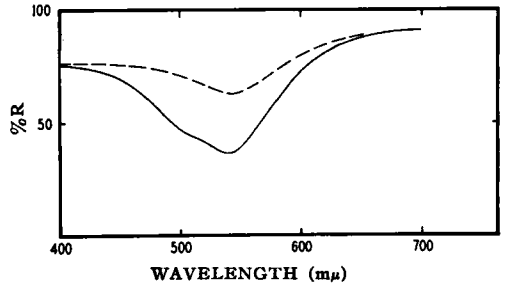

Fig. 2.—Reflectance curves for 0.06% dye. Solid line, initial; dashed line, after 140 hours at 80 foot-candles.

where θ_t is the θ calculated at time t, θ_t' is the θ_t at $t = 0$, and the other symbols have the meanings explained above. The rate constant was calculated to be $6.1 \pm 0.3 \times 10^{-5}$ hr.$^{-1}$ foot-candles^{-1}.

Figure 2 shows the 543 mμ absorbance peak and the shape of the reflectance curve before and after fading. Since the rate of fading is the same for incandescent and fluorescent illumination, as well as for samples protected by amber glass, the decomposition must be due largely to absorption at wavelengths greater than 500 mμ.

The times at which objectionable fading under high light intensity occurred for this dye, in the opinion of the authors, at all three concentrations are shown in Table I. From these time-intensity values, the time for objectionable fading at lower intensities was calculated using Eq. 5. The advantage of using high intensity lighting conditions is obvious from this table.

TABLE I.—TIME REQUIRED FOR OBJECTIONABLE FADING AT LOW LIGHT INTENSITIES AS CALCULATED FROM ACCELERATED LIGHT CONDITIONS

Concentration of Dye, % w/w	Hours at 540 f.-c.	Calcd. Hours at 50 f.-c.	Calcd. Hours at 10 f.-c.
0.060	17	180	920
0.030	7	75	380
0.015	2	20	110

Examination of the cross section of the tablets showed that fading proceeds to a given depth into the tablet and a fairly sharp demarcation can be seen between the white faded portion and the unchanged dye. The fading occurs first at the surface and gradually progresses into the tablet. When the tablet is viewed from above, the pink color seems to fade uniformly, indicating that the lower layers of dye are responsible for some of the surface color.

When the fading had penetrated to about 0.3 mm. into the tablet, the tablet surface appeared white and no further increase in the thickness of the white layer occurred.

The faded top layer did not interfere with the measurements of the reflectance until about 15,000 foot-candle-hours. After that, the fading rate slowed, probably because the upper layers of faded dye were thick enough to offer some protection to the lower, visible layers. The lower fading rate was obtained only in the light cabinet and is not shown in Fig. 1.

This work will be continued by measuring rate constants for other dyes using the equations developed above. It is hoped that when enough experience is obtained, it will be possible to predict the rate of fading for various combinations of dyes in the same tablet or tablets of different composition. By use of the present data, it is now possible to predict the amount of fading of FD&C Red No. 3 in the formulation studied at any specified time under any light intensity.

Drying as a Unit Operation in the Pharmaceutical Industry I

Drying of Tablet Granulations in Fluidized Beds

By M. W. SCOTT, H. A. LIEBERMAN, A. S. RANKELL, F. S. CHOW, and G. W. JOHNSTON

The results of drying tests in a fluidized bed and a tray dryer are reported for typical tablet granulations. The data are analyzed to give estimates of total drying times, rates of drying, and overall heat transfer coefficients in each unit. It is concluded that fluidized bed drying of tablet granulations is at least 15 times faster than tray drying procedures. Additional factors, such as capacities per unit floor space, operating costs and thermal efficiencies are reviewed and illustrate other advantages of the fluidization technique.

DRYING procedures, like other important unit operations in pharmacy, such as size reduction, solids blending and liquid agitation, have received little attention in pharmaceutical literature. Within recent years, however, growing interest in these pharmaceutical engineering areas has become apparent. This report on fluidized bed drying is one in a series by the authors in this new investigative field of pharmacy.

Fluidization operations, although relatively unexplored in pharmacy, have been firmly established on a broad scale in other industries. Textbooks and other extensive references on fluidization have been published during the past 20 years (1–5). However, relatively few reports have appeared on the applications of fluidized beds to materials of pharmaceutical interest (6–10).

Fluidized bed drying of coal, sand, plastics, and numerous other materials have been discussed in technical literature (11–14). These studies show that high heat transfer, mass transfer and drying rates are obtainable in fluidization systems. As a result of turbulence and excellent interphase contact, uniform bed temperatures are readily achieved. Product temperatures also are controllable over narrow limits within the fluidized bed. These reported advantages would appear to have particular importance in processing pharmaceuticals. It is surprising to note, therefore, that no studies on fluidized bed drying have appeared in pharmaceutical literature.

The object of the work conducted in the present report was to investigate the applications, advantages, and limitations of fluidization techniques in drying pharmaceutical tablet granulations. A representative, commercially available, fluidized bed dryer was used for these studies. Comparative data were obtained from drying tests with a conventional tray dryer.

EXPERIMENTAL

Materials.—Two tablet granulations were used in this study. The first was a lactose placebo made with a solution of methylcellulose as the binding agent. This granulation was prepared also with added color (FD&C No. 1 Red). The second test granulation was an antacid consisting primarily of magnesium trisilicate with syrup as the binding agent. These granulations were prepared by conventional techniques and screened through a standard No. 4 sieve before drying.

Equipment.—The fluidized bed dryer used in this work was the Glatt dryer, laboratory model TR-5.[1] Figure 1 gives an illustration of the equipment, which consists of a fan, a drying chamber fitted with a wire mesh support for the granulation, a bag dust collector, an air filter, and electrical heating elements. Controls are provided for adjustment of air flow (by damper settings) and inlet air temperatures.

The instrument operates by forcing, by induced draft, heated air through the drying chamber at

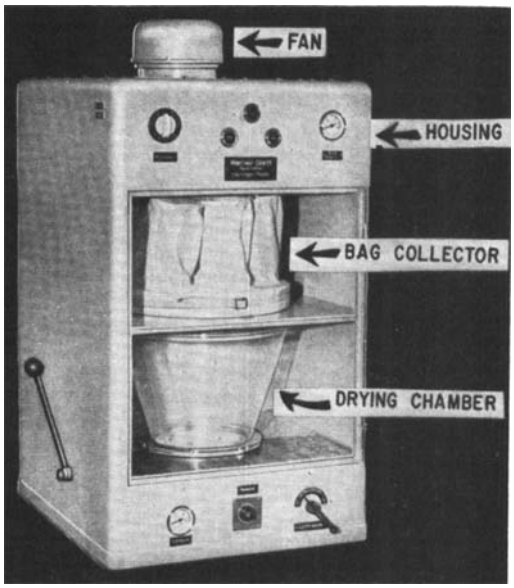

Fig. 1.—Glatt TR-5 dryer.

velocities which are sufficient to fluidize the granulation charged in the chamber. The air escapes through the bag collectors and is vented through an exit port. Granulation is quickly charged and discharged from the drying chamber by dumping. The Glatt dryer was modified for this study by attaching auxiliary thermometers within the drying chamber and immediately outside the dust collector bag.

The tray dryer used in these experiments was a Stokes dryer, model 38A, fitted with 16 shelves and automatic thermostat controls. Damper positions for air recirculation were set in accordance with the manufacturer's recommended operating directions. Air temperatures were measured with auxiliary thermometers installed within the inlet and outlet air ducts. Bed temperatures were obtained from thermometers inserted into the granulation on the bottom, middle, and top trays.

Drying Methods.—All experiments were performed in an air conditioned, temperature-controlled area. Readings of relative humidity were taken throughout each run and found to be relatively constant at 40 to 45%.

Equilibrium inlet air conditions were established at the start of each fluidized bed run. All experiments were conducted with a 5-Kg. charge of wet granulation except where the load was the variable. In these latter experiments, loads of 1, 3, 5, and 7 Kg. were employed. Inlet air temperatures (3 levels) and air velocities (2 levels) were the other experimental variables studied.

Tray dryer experiments were run, using 40 Kg. of placebo granulation (full dryer capacity) as the charge. This was equally distributed by weight over each tray to give a uniform bed thickness of approximately one inch. Inlet air temperatures were varied (5 levels) in these experiments. In one drying experiment the same colored placebo test granulation was used that had been studied by the fluidized bed technique.

Product Evaluation Techniques.—Aliquots of granulation were obtained by combining at least 10 random spot samples from representative locations within each drying unit. Samples and instrument measurements were taken at 5- or 10-minute intervals in fluidized bed experiments and at hourly intervals in the tray dryer studies. Moisture analyses were performed on each sample, using a Cenco moisture balance set at 90 volts for 6 minutes. Replicate determinations established the levels of reproducibility at ±0.2%. Screen analyses were performed on 100-Gm. coned and quartered aliquots of the total dried product collected in each run. Portions of the dry granulations then were mixed with lubricant and compressed into tablets. Compression characteristics were noted for each test granulation. Tablets made from the colored placebo granulations were inspected further for mottling and overall color uniformity.

DISCUSSION OF RESULTS

Engineering Analysis of Fluidized Bed Drying.—Figure 2 presents typical data for drying the placebo and antacid granulations in the fluidized bed. Moisture contents are expressed here on a wet basis in terms of the weight loss on drying or L.O.D. values. This method of expressing moisture has been employed in the pharmaceutical industry and is defined by Eq. 1

$$\% \text{ L.O.D.} = (100)\ \frac{x}{y + x} \qquad \text{(Eq. 1)}$$

where x = weight of water, y = weight of dry solid.

L.O.D. values were obtained directly by analysis with the Cenco moisture balance. Equilibrium L.O.D. values for each drying run were obtained by inspection of the plots of L.O.D. *vs.* time. In Fig. 2, for example, the equilibrium L.O.D. for the dried placebo and antacid granulation were found to be 0.9 and 3.0%, respectively. Over the range of inlet air conditions studied, equilibrium values were found to fall in the range of 1.1 ± 0.2% for all

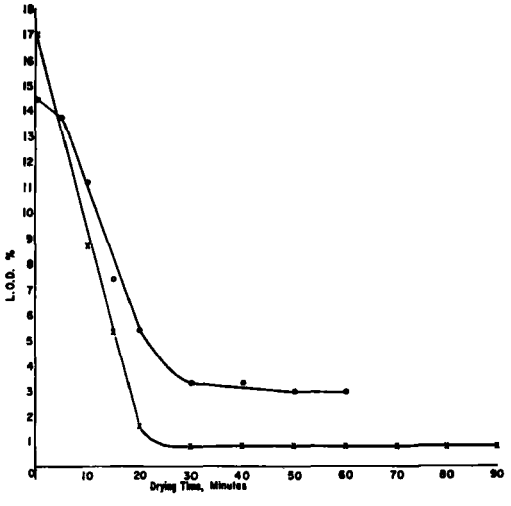

Fig. 2.—Loss on drying *versus* time for placebo and antacid granulation in fluidized beds. ×— Placebo, run 2; O— antacid, run 13.

placebo runs and 3.2 ± 0.2% for all antacid tests. These moisture levels were consistent with those desired for good compression characteristics of each granulation.

The total processing time required to dry the test granulations to their equilibrium L.O.D. values also were obtained from drying curves of the type illustrated in Fig. 2. The drying times for runs 2 and 13 were 24 and 30 minutes, respectively. For other runs in the fluidized bed, total drying times ranged from approximately 10 to 62 minutes. Table I reviews the conditions employed in these experiments and summarizes the data for fluidized bed drying. The rapidity of the fluidized bed drying technique is demonstrated by drying time results shown in Table I.

Inspection of drying data on the basis of L.O.D. values serves as a convenient starting point for comparison of drying operations. For a more detailed analysis, however, it is generally preferable to express moisture contents on a dry basis, *i.e.*, % M.C., defined by Eq. 2

$$\% \text{ M.C.} = (100)\,\frac{x}{y} \qquad \text{(Eq. 2)}$$

where x = weight of water, y = weight of dry solid.

The conversion of % L.O.D. to % M.C. is expressed by Eq. 3

$$\% \text{ M.C.} = \frac{\% \text{ L.O.D.}}{100\% - \% \text{ L.O.D.}} \qquad \text{(Eq. 3)}$$

Figure 3 gives the moisture content (% M.C.) histories for runs 2 and 13 and is representative of the other fluidized bed experiments. Estimates of drying rates were obtained from these curves by graphic determinations of slope values. Next, rates of drying were plotted as a function of drying time, as illustrated in Fig. 4. A semilogarithmic graph was employed here for better visualization of the slower drying rates. In passing, it should be noted that L.O.D. values as such cannot be used for calculation of drying rates. The basis for these values (wet basis) changes continuously as drying proceeds, thereby introducing significant errors into the rate determinations.

Data presented in Fig. 4 for run 13 (antacid) exhibit the typical rate patterns observed in drying studies (15, 16). Three major drying rate periods are apparent. The first is a period of initial rate adjustment which lasts approximately 5 minutes. This is followed by a constant drying rate period of about 15 minutes duration. Continued drying then occurs at falling rates. This last interval is referred to as the falling rate period. Similar constant and falling rate periods are seen with the placebo granulation (run 2). In this case, however, experimental demonstration of an initial rate adjustment period was not obtained.

Rate data were also examined as a function of granulation moisture content, as illustrated in Fig. 5. The various rate periods and the critical moisture content values (defined as the moisture content which terminates the constant rate period) are readily identified. For experiments 2 and 13,

critical moisture contents were estimated at 1.7 and 4.9%, respectively. Critical moisture content values for other drying runs are listed in Table I.[2]

Theoretical mechanisms for moisture movement during each rate-of-drying period have been reviewed elsewhere (15, 16). In general, constant drying rates occur during the period when the surface of the solid is completely wet with a thin film of unbound moisture. Water that is evaporated from the surface during this interval is immediately replaced by moisture diffusing out from within the solid. Constant rates of drying are maintained so long as the rate of internal moisture diffusion equals the rate of surface evaporation. As drying proceeds, a condition eventually is reached at which the surface film of moisture can no longer be replenished completely by internal moisture diffusion. At this point (critical moisture content), the surface of the solid becomes partially dry and the rate of drying decreases. This initiates the period of falling drying rate. During the falling rate period, mass transfer (diffusion) effects within the solid control the course of drying. During the constant rate periods, external factors which influence heat transfer to the surface and mass transfer from the surface govern the operation.

Each drying period may be analyzed separately to simplify mathematical treatments and correlations of the drying variables. If the bulk of the moisture is evaporated during constant rate periods, analysis of this period alone will be sufficient for definition of the drying operation. For the experiments reported in this study, inspection of the curves of the rate of drying *vs.* moisture content, as illustrated in Fig. 5, indicated that evaporation occurred predominantly under constant rate conditions. Major emphasis, therefore, was placed on analysis of this drying period.

Data for the constant rate periods of drying are given in Table I for all fluidization runs. Rate of drying is defined by Eq. 4.

$$R = \frac{\text{M.C.}_s - \text{M.C.}_e}{\theta} \qquad \text{(Eq. 4)}$$

where R = rate of drying—Kg. (H_2O)/min./Kg. (dry solid); M.C.$_e$ = moisture content at end of constant rate period (critical moisture content)—Kg. (H_2O)/Kg. (dry solid); M.C.$_s$ = moisture content at the start of constant rate period—Kg. (H_2O)/Kg. (dry solid); θ = duration of constant rate period (minutes). All values in Eq. 4 are obtainable directly from the plots of rates of drying *vs.* drying time (Fig. 4) and rates of drying *vs.* moisture content (Fig. 5).

Constant rate values for fluidized bed drying of the placebo granulation using 5-Kg. loads ranged between 3.4 and 14 × 10^{-3} Kg. of water evaporated per minute per Kg. of dry product, as shown in Table I. Drying rates for the antacid were of the same order of magnitude. Comparison of rates of drying at approximately equal inlet air temperatures shows, however, that the placebo generally was easier to dry than the antacid granulation. This conclusion is supported further by the data for drying times listed in Table I.

As expected, increasing the bed load in the fluidization runs was found to have an adverse effect on the drying rate. This is shown in Fig. 6. The derivation of the semilogarithmic correlation obtained here is not fully understood at present. It is believed to result in part from the influence of the conical geometry of the Glatt drying chamber on the height of the bed at different charge weights.

Although drying rates decreased with increased loads, overall processing rates were shown to be highest when 5 and 7 Kg. of granulation was used as charge. In the present experiments, loading and emptying of the fluidized bed was accomplished in less than 2 minutes. This handling time was added to the drying time data listed in Table I to give

[2] Critical moisture contents are not constants, but vary from material to material and with the drying conditions employed. In general, the values are expected to be higher at increasing drying rates (15). No correlations in this direction could be established, however, in the present study.

estimates of the total cycle times. Processing rates per unit weight of product (throughput) were obtained from these values and found to reach a maximum with 5 Kg. of charge. This is in line with the manufacturer's statement of optimum load for the model TR-5 dryer.

Figure 7 shows the relationship between the duration of the constant rate period and bed load. Extrapolation of the data to 0 Kg. was used to give an estimate of the duration of the initial rate adjustment period, *i.e.*, the time when constant rate begins. An intercept value of 2.5 minutes was obtained under the inlet air conditions employed for these load experiments. The duration of this period was expected (15) and observed to change with varying inlet air temperatures.

During constant rate periods, rates of drying can be based on heat transfer relationships as shown in Eq. 5

$$R = \frac{h_t(\Delta T)}{DL\lambda} = K(\Delta T) \qquad \text{(Eq. 5)}$$

where R = rate of drying—Kg. (H_2O)/min./Kg. (dry solid); D = density of dry solid—Kg./meter^3; L = thicknes of drying solid—meter; λ = latent heat of vaporizaton—B.t.u./Kg.; h_t = total heat transfer coefficient—B.t.u./min./meter^2/° F.; K = overall transfer coefficient—Kg. (H_2O)/min./Kg. dry solid/° F; ΔT = temperature gradient between drying air and product—° F. Plots of rates of drying *vs.* ΔT are expected to give linear relationships which pass through the origin as indicated by Eq. 5. The slope of the line is numerically equal to K, the overall transfer coefficient.

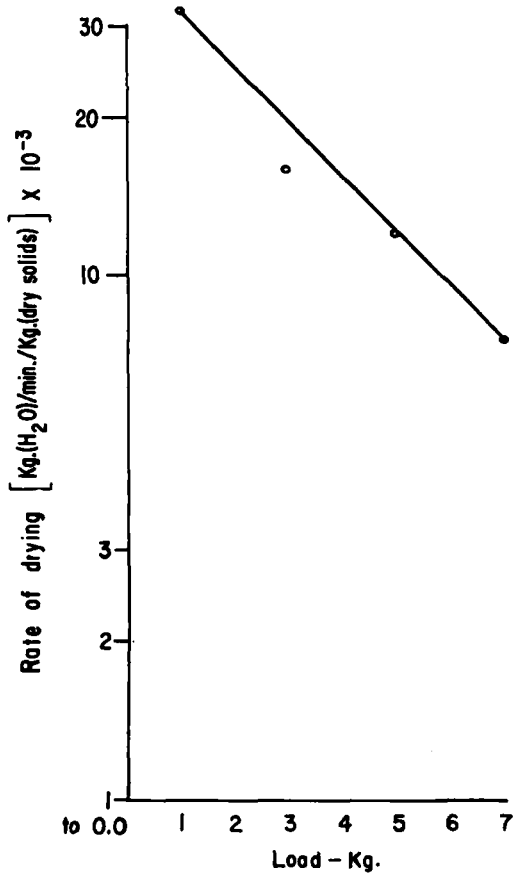

Fig. 6.—Plot of rate of fluidized bed drying *versus* bed load.

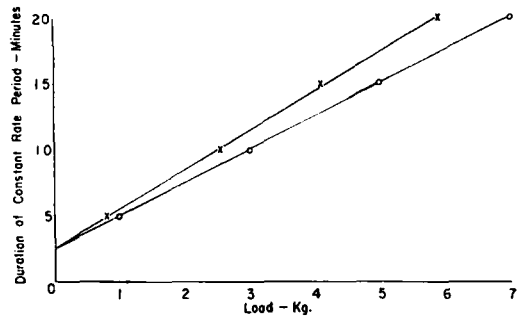

Fig. 7.—Plot of duration of constant drying rate *versus* bed load. X— Bed load expressed on dry basis; O— bed load expressed on wet basis.

Rate data for fluidized bed drying under two different inlet air velocity settings are plotted in Fig. 8. The temperature gradients used here were calculated from averaged inlet air temperatures and bed temperatures which existed during the constant rate period of drying. The linear relationship in Fig. 8 is considered satisfactory, particularly in view of the averaging procedures used in obtaining ΔT values. Results obtained for the two air velocity settings appear to follow identical relationships. This suggests that the transfer coefficient, K, is independent of air velocity settings over the range studied. Therefore, little or no increase in drying rates can be expected at the higher setting, setting 6.

The numerical value of the overall transfer coefficient obtained from the slope of the line in Fig. 8 is 2.8 × 10^{-4} Kg. of water evaporated per minute per Kg. of dry solid per ° F. This value does not compare favorably with published transfer coefficients for fluidized bed drying when all are expressed in common units (17, 18). Undoubtedly, the low Glatt value arises because the bed did not fluidize completely during all of the drying cycle. Efficient fluidization of the granulation occurred only after considerable drying had taken place. This lack of complete fluidization throughout the

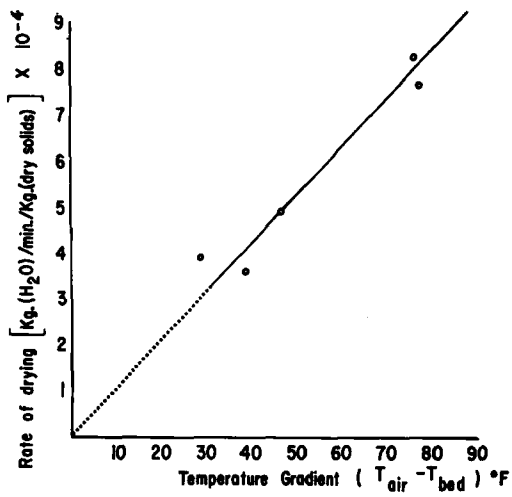

Fig. 10.—Rate of drying *versus* thermal gradient in tray dryer.

entire drying cycle represents an area for needed improvement in the Glatt equipment.

Comparison of Tray Drying and Fluidized Bed Drying.—Data collected for drying the placebo granulation in tray dryers was subjected to the same analysis techniques used above. Figure 9 illustrates moisture content histories for two typical runs. Pertinent operating and performance data for all tray experiments are summarized in Table II. Results of the present study show that drying times ranging from about 330 to 720 minutes are required in tray drying operations. These values are significantly higher (by a factor of about 20) than those observed in fluidized bed drying. Direct comparisons of the two operations on the basis of drying times alone are not completely valid, however, because different loads are handled in each unit.

Meaningful comparisons of tray and fluidized bed drying can be obtained using rate data which have been expressed on a common weight basis as listed in Tables I and II. Rates of tray drying during the constant rate period were found to be in the range of 3.6–8.2 $\times 10^{-4}$ Kg. of water evaporated per minute per Kg. of dry solid (Table II). These rates are approximately 15 times lower than those obtained in the fluidized bed drying and again indicate the comparative rapidity of the fluidization technique.

Rates of tray drying noted above are equal to 0.02–0.05 when expressed in units of lb. of water evaporated per hour per lb. of dry solid. These constant rate values fall toward the lower side of the range (0.1–2.0 lb. per hour per lb.) previously reported for tray drying (19). Overall rates of tray drying have been reported also (15), and fall between 0.03–0.30 lb. of water evaporated per hour per ft.^{2} of tray surface. When calculated on this basis, the present data indicate a rate of approximately 0.02 lb. per hour per ft.^{2} which is slightly lower than expected. These results suggest, therefore, that areas for improved performance also may exist with the particular tray drying unit used here.

Figure 10 presents the plot of rate of drying *vs.* temperature gradient for the tray dryer studies. The agreement of the experimental data with the relationship expressed by Eq. 5 is satisfactory. The overall transfer coefficient determined from the slope of the line in Fig. 10 is equal to 1×10^{-5} Kg. of water evaporated per minute per Kg. dry solid per ° F. This value has the correct order of magnitude. It is lower, however, by at least a factor of 2 to 5 than the values previously reported in the literature for transfer coefficients (15).

It will be recognized that K values are independent of temperature gradient and weight of feed charge. Therefore, these coefficients also are useful indices for comparative evaluation of different drying procedures. Comparison of the transfer coefficients for the two drying operations studied in the present report shows that heat transfer is at least 28 times more effective in the fluidized bed than in the tray dryer. This is fully in accord with theoretical considerations and results from the very favorable interphase contact obtainable in fluidized beds. Relative thermal efficiencies between fluidized bed and tray drying pointed to other advantages of the fluidization technique in this study.

TABLE II.—ANALYSIS OF DATA FOR TRAY DRYING OF PLACEBO GRANULATION[a]

Run	Average Inlet Air Temperature, ° F.	Drying Time to Reach Equilibrium L.O.D., min.	Duration of Constant Rate Period, min.	Critical Moisture Content, Per Cent	Rate of Drying During Constant Rate Period Kg. (H_2O)/min./Kg. Dry Solid
15	131	720	420	5.3	3.6×10^{-4}
16	140	420	270[c]	3.3	4.5×10^{-4}
17	160	480	240[c]	3.2	4.9×10^{-4}
18	177	430	180	6.8	7.6×10^{-4}
19	191	330	216	3.2	8.2×10^{-4}

[a] Data for 40 Kg. charge to dryer. [b] Equilibrium L.O.D. values for all runs were found equal to 1.1 ± 0.2%. [c] Constant rate period began after 60-minute interval initial of rate adjustment.

Thermal efficiency was defined as the ratio of the minimum thermal energy theoretically required to dry the solid to the actual thermal energy used in the drying unit.[3] For the present experiments, a 2–6 fold advantage in thermal efficiency was determined for the fluidized bed operation. This can be related directly to potential fuel cost savings obtainable with the fluid bed.

Other Considerations.—Several additional advantages of fluidization techniques which have direct importance in the drying of tablet granulations were apparent in this study. Firstly, fluidized beds are turbulent systems which give rise to good mixing effects. As a consequence, uniform bed temperatures (product temperatures) are readily achieved and easily controlled. With a properly designed unit, local areas of overheating can be completely eliminated. In tray drying procedures, however, nonuniform tray and product temperatures are the rule rather than the exception. For example, in the present study it was observed that tray temperatures varied as much as ±7° from location to location within the dryer. The close control of product temperature in fluidized bed drying suggests that the operation will be particularly suited for processing heat-sensitive materials and granulations which tend to case harden.

Tablets made from granulations dried in the fluidized bed compared favorably in all respects to those made from tray dried granulations. Visual inspection of tablets made from the colored granulations showed further that improved color uniformity is obtained with the fluidized bed granulation.

Agitation and product turnover are inherent in fluidization. As a consequence, opportunities appeared to exist for blending lubricants and other materials with the dry granulation within the fluidized bed itself. The use of the fluidized bed for the blending of solids has been reported previously (20, 21), and this aspect was not explored further in the present study.

For tray drying procedures, it is generally agreed that the labor involved in loading and unloading represents about one-third of the total operating costs (15). About one man-hour was required for these steps in the present experiments. In comparison charging and emptying the fluidized bed dryer was completed in less than two minutes. On this basis, therefore, fluidized bed drying offers significant opportunities for reductions in labor costs.

Caking of the granulation was observed at the start of several of the fluidization runs. In one experiment (not reported in Table I), severe caking was noted when using a slightly overwet granulation. This decreased drying rates significantly and led to the development of many oversized granules. The results of this single experiment suggest, therefore, that tacky granulations may pose special difficulties in fluidized bed drying. Friable and dusty granulations also may be troublesome because of their tendency to clog the bag collectors.

In the majority of the fluidization experiments reported here, only small amounts of oversize granules (larger than 10 mesh) were present in the final dried product. The bulk of the granulation was suitably sized for compression without additional grinding operations. The elimination of this post-drying grinding step represents an important advantage of the fluidized bed technique.

The present experiments indicate that fluidized drying of tablet granulations may require special control of drying times. Turbulence in the fluidized bed was found to give varying degrees of particle attrition. These attrition effects became particularly significant when fluidization was continued for extended time intervals with dry granulations. The degree of attrition also was found to increase at the higher air velocity, damper setting 6. For example, in run 1 at damper setting 2, the final dry granulation contained 9.3% fines (less than 60 mesh) with 15% of the granulation larger than 10 mesh. At damper setting 6 (run 3), no particles larger than 10 mesh were present while fines increased to 15%. Under usual operating conditions, however, good reproducibility of granulation size distribution was readily obtainable.

A Glatt fluidized bed dryer of about 30 Kg. wet load capacity occupies slightly less floor space than the 40 Kg. tray dryer. It is reasonable to assume that with proper scale-up, drying times in the larger fluidized bed can be maintained at one-half hour. Production rates per unit floor space will be expected, therefore, to be at least 15 times higher than those obtainable by tray dryers.

CONCLUSIONS

The results of this study show that the fluidized bed dryer offers significant advantages over the conventional tray dryer commonly used in the pharmaceutical industry. These advantages are not limited to the particular commercial unit tested in this report but rather arise from the inherent qualities and characteristics of the fluidization process itself. These advantages include:

1. Increased rates of drying and product throughput, accompanied by significant improvements in thermal efficiency.
2. Increased drying capacities per unit floor space.
3. Increased ability to control product tem-

---

[3] Thermal efficiency $= (100)\dfrac{E_T}{E_A}$ (Eq. 6)

E_T = minimum energy input theoretically required to dry the solid in B.t.u./min., while E_A = actual energy input used by the unit in drying the solid in B.t.u./min. E_T values for Eq. 6 were obtained from Eq. 7

$$E_T = (W)(\lambda) \quad \text{(Eq. 7)}$$

where W = water evaporated per minute in drying solid to equilibrium M.C.—Kg./min., λ = latent heat of vaporization for water—B.t.u./Kg. The values of E_A required for Eq. 6 were calculated from Eq. 8.

$$E_A = (C_p)V\rho\Delta T \quad \text{(Eq. 8)}$$

where C_p = heat capacity of air—$\dfrac{\text{B.t.u.}}{\text{lb.}\,^\circ\text{F.}}$,

V = air velocity through dryer—C.F.M. $\dfrac{(\text{ft.}^3)}{(\text{minute})}$ (air velocities can be approximated from the manufacturer's stated operating values); ρ = density of air—$\dfrac{\text{lb.}}{\text{ft.}^3}$; ΔT = temperature gradient between ambient air temperature and averaged temperature of heated air at inlet to drying compartment—°F.

perature during drying, thereby reducing color bleeding and case hardening effects, and facilitating the handling of heat sensitive materials.

4. Decreased handling costs resulting from simplified loading and unloading operations.

5. Simplification of tablet manufacturing procedures by the possible elimination of grinding steps. Opportunities may also exist for blending lubricants and other materials into dry granulations directly in the fluidized bed.

Fluidized drying beds of small capacity appear to have further significant usefulness in research operations for routine testing of new tablet formulas on a rapid basis.

Because of the extensive application in other industries of the fluidized bed drying technique, it is reasonable to assume that the conclusions of this report are not limited to the prototype granulations actually tested. The Glatt dryer used in this study represents a significant improvement over conventional tray dryers. The present data suggest, however, that the drying performance of this unit is not as high as that which can be expected from fluidized bed dryers.

Psychophysical Concept of Color

By ALLAN M. RAFF

Color has been defined as a psychophysical concept by the Committee on Colorimetry of the Optical Society of America. The concept of the Commission Internationale de l'Eclairage (C.I.E.) standard human observer is discussed, which illustrates the color sensitivity curves on which the C.I.E. color triangle is based. Examples are given which show the variance in results that occur in color stability studies when a "standard observer" is used as opposed to an evaluation made solely on the basis of spectrophotometric data. Several standard techniques for evaluating small color differences are reviewed.

WITHIN the last several years the stability studies of pharmaceutical products have become increasingly more sophisticated. The use of kinetics, cyclization of temperatures, and more advanced forms of instrumentation are just a few of the things that have brought the study of the chemical stability of pharmaceutical products to a very high level.

This same high level has yet to be reached in the matter of color stability studies. This deficiency may be due to two causes. The first cause has been a lack of the need for such studies until recent times. Until the FDA decertified some dyes and indicated a prospect for the decertification of several more, the pharmaceutical formulator had a relatively easy task. He had only to choose the most stable dye from a long list of dyes and color his product. Today he has the task of determining which of several very photosensitive dyes is the most stable. He must also make matches of colors heretofore achieved with one dye (perhaps now decertified), now with different colorants. The second cause of the deficiency noted is due in a very large part to a complete misunderstanding of the concept of color as it should be used in pharmaceutical stability studies.

Psychophysical Concept of Color

By ALLAN M. RAFF

Color has been defined as a psychophysical concept by the Committee on Colorimetry of the Optical Society of America. The concept of the Commission Internationale de l'Eclairage (C.I.E.) standard human observer is discussed, which illustrates the color sensitivity curves on which the C.I.E. color triangle is based. Examples are given which show the variance in results that occur in color stability studies when a "standard observer" is used as opposed to an evaluation made solely on the basis of spectrophotometric data. Several standard techniques for evaluating small color differences are reviewed.

WITHIN the last several years the stability studies of pharmaceutical products have become increasingly more sophisticated. The use of kinetics, cyclization of temperatures, and more advanced forms of instrumentation are just a few of the things that have brought the study of the chemical stability of pharmaceutical products to a very high level.

This same high level has yet to be reached in the matter of color stability studies. This deficiency may be due to two causes. The first cause has been a lack of the need for such studies until recent times. Until the FDA decertified some dyes and indicated a prospect for the decertification of several more, the pharmaceutical formulator had a relatively easy task. He had only to choose the most stable dye from a long list of dyes and color his product. Today he has the task of determining which of several very photosensitive dyes is the most stable. He must also make matches of colors heretofore achieved with one dye (perhaps now decertified), now with different colorants. The second cause of the deficiency noted is due in a very large part to a complete misunderstanding of the concept of color as it should be used in pharmaceutical stability studies.

METHODOLOGY

The increased need of color stability studies has brought about a corresponding increase in the application of scientific methodology to this field. There have been several studies (1–6) reported which utilize such techniques as kinetics, advanced instrumentation, and reproducible methods of fading pharmaceutical dosage samples. Investigations such as these have alleviated one of the causes of unsophisticated color stability studies. However, even these investigations may be inconclusive because none of them have treated color as a psychophysical concept.

If we stop short of this concept, *i.e.*, if we confine all of our color studies to an instrumental level, then we have not, in reality, made a study of color stability.

Concepts of Color.—As defined by the Optical Society of America (7), "Color consists of the characteristics of light other than spatial and temporal inhomogeneities; light being that aspect of radiant energy of which a human observer is aware through the visual sensations which arise from the stimulation of the retina of the eye." This concept is reiterated in one form or another in other references in the field of color measurement (8–13).

Nickerson (14) states that: "It is true that a spectral distribution curve may serve to define unambiguously the *stimulus* for the color of a light source, but the spectral-reflectance or spectral-transmittance curve of an object is not sufficient to define even the stimulus for its color. Its spectral properties must be combined with those of the light source under which it is to be viewed before even the stimulus for the object's color is defined. To define its *color* the concept of an observer must also be introduced."

The *Ciba Review* (15) expresses this concept: "Measurement of the spectral reflection curves of typical colored surfaces shows, as we should expect, that a red surface has a high reflection at the red end of the spectrum, but a low reflection in the green and blue. A green surface has its maximum reflection in the green, and a blue surface in the blue. Consideration of the reflection curve for a yellow surface, however, shows that *this correlation is of limited application*, since a yellow surface is nearly as efficient in reflecting the green and red wavelengths as it is the narrow band of yellow wavelengths around 0.58 μ. *Clearly, an adequate interpretation must take account of the combined effect in the eye of all the wavelengths reflected by the surface.*"[1]

This consideration of color as a psychophysical concept is of more than academic interest in pharmaceutical formulating and in the resultant color stability studies of these products. Colorants are added to various pharmaceutical dosage forms, unlike the active ingredients, primarily for their esthetic effect and as a means of identification. When one assays for the active constituent in a product and it is found to be only 50% of theory then this may be, with a fair degree of certainty, interpreted to mean that there will only be 50% of the desired therapeutic response. However, if one determines by a spectrophotometric assay that a green colorant has decreased in concentration by a numerical value of 10% and a yellow colorant has also decreased by an equal amount, one cannot say without performing certain mathematical transformations that these two colorants will *appear* to a *human observer* to have faded equal amounts. Since the relationship between the visual appearance of colors is what one is really attempting to establish when color stability studies are done, it is of the utmost importance that the concept of the human observer be brought into consideration.

EXPERIMENTAL

In order to illustrate the errors that may occur when we attempt to evaluate color solely on the basis of spectrophotometric data, the following study is presented.[2] Test panels containing pigments were exposed to sunlight, and after several months exposed and unexposed panels were measured on a G.E. recording spectrophotometer equipped with a Librascope automatic integrator. Color differences were calculated using the Godlove formula (16) and the results expressed in N.B.S. units (10, 17, 18, appendix of this article[3]).

Figures 1–5 illustrate the reflectance measurements on control and exposed panels of violet, green, yellow, orange, and red pigment colorants, respectively. Figures 6 and 7 are the reflectance curves of Figs. 2 and 3, respectively, mathematically transformed into "absorbance" units.

It may be seen from these figures and the compilation in Table I that no correlation can be made,

TABLE I.—REFLECTANCE AND "ABSORBANCE" DIFFERENCES *vs.* COLOR CHANGE

Color	Color Change N.B.S. Units	Per Cent Difference in Reflectance[a] at Max.	at Min.	Difference in Absorbance[a] at Max.
Violet	5	1	1	
Green	5	0	5	0.068[b]
Yellow	6	6	1	−0.028[b]
Orange	4	5	1	
Red	5	1	1	

[a] Value of control minus that of exposed. [b] Absorbance units.

by a visual inspection of the curves, between a change in reflectance (or so-called absorbance) and the change in color that one will perceive.

All five of these colorants have changed to different degrees, but their appearances are essentially the same in terms of visual perception.

The pigments chosen yielded relatively simple curves. Other colorants and mixtures of colorants that display more than one maximum or exhibit metamerism would be even more illustrative of this lack of correlation.

In view of this demonstrated lack of correlation between reflectance curves and the color perceived by a human observer, the author believes that it is the responsibility of the investigator reporting on

[2] These test panels and the evaluation of their color differences in N.B.S. units were a part of a study made by Vincent C. Vesce, while technical director of Harmon Colors, National Aniline Division, Allied Chemical Corp. (19). I wish to thank Mr. Max Saltzman of National Aniline Division of Allied Chemical Corp. for allowing the use of these data and his very generous giving of his time and assistance to the author.

[3] A brief review of the techniques useful to those engaged in color studies is presented in an appendix to this article and is available from the author.

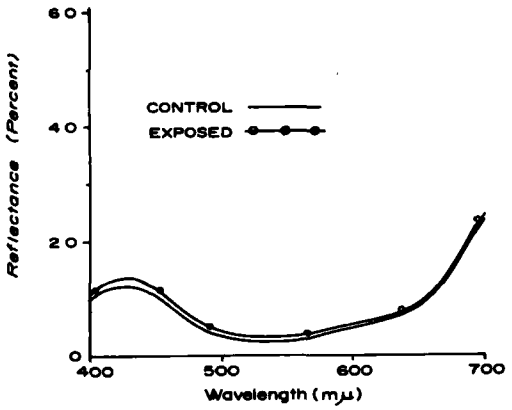

Fig. 1—Reflectance measurement of a violet pigment; Color Index No. 60016; color change is 5 N.B.S. units.

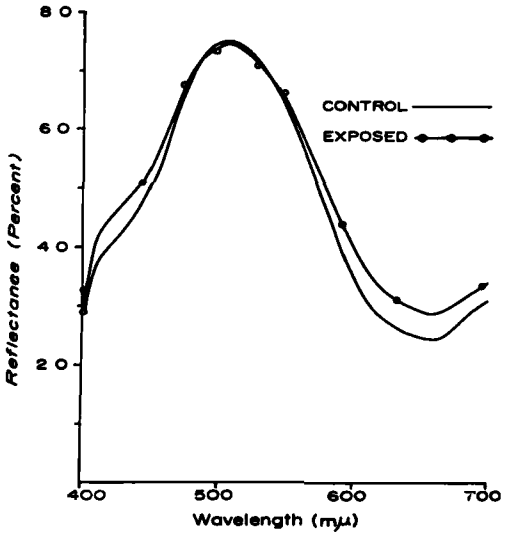

Fig. 2.—Reflectance measurement of a green pigment; Color Index No. 74120; color change is 5 N.B.S. units.

color studies to prove that where it is utilized, a single wavelength determination is valid in each and every case studied. This is not to say that a single wavelength cannot be utilized to follow the course of a colorant change, but it must be substantiated by sufficient data to prove its validity. This method of using a single wavelength determination has been used, for example, by McLaren (20). He states, however, "This method of determining the degree of fading is only very rough; greater accuracy could have been achieved if the Kubelka-Munk equation or the best of the American colour difference formulas had been used. Such methods would have taken very much longer, however, and did not appear essential in view of the elementary nature of the investigation."

A failure to transform spectrophotometric data into some system which takes into account the sensitivity of the eye in conjunction with a specific light source will also, in some instances, invalidate those studies that attempt to rank different colorants with regards to their resistance to fading.

Other Experiments.—Urbanyi, *et al.* (3), measure the reflectance of opaque objects in terms of absorbance, yet absorbance is, by definition, the negative log of transmittance.

In dealing with transmission data the values of the various concentrations follow Beer's law. Absorbance ($-\log T$) is directly proportional to concentration. For reflectance work, two ordinate scales are in use. The linear scale is the most common, but has the same limitations as the linear scale in transmittance work. Reflectance data at various concentrations follow an entirely different scheme which may be termed the K/S rule. Kubelka and Munk

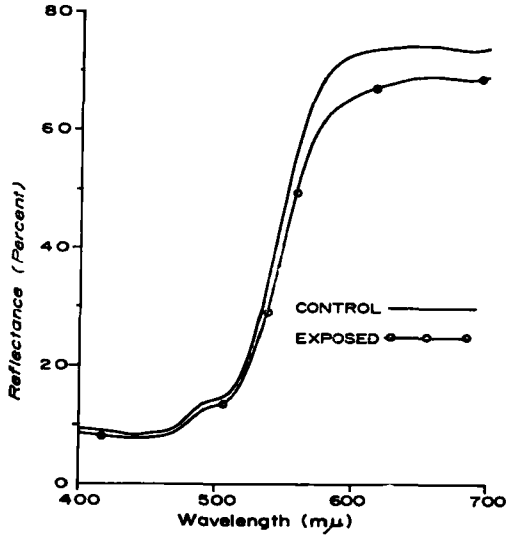

Fig. 3.—Reflectance measurement of a yellow pigment; Color Index No. 70600; color change is 6 N.B.S. units.

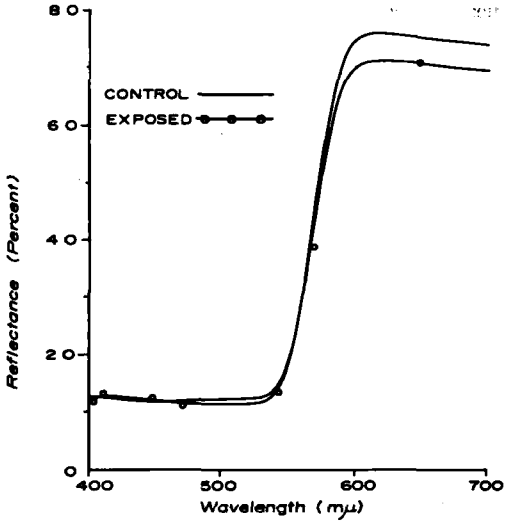

Fig. 4.—Reflectance measurement of an orange pigment; Color Index No. 11725; color change is 4 N.B.S. units.

(10, 21, 22) defined monochromatic reflectivity as

$$K/S = \frac{(1 - R_\infty)^2}{2R_\infty}$$

where:

$$R_\infty = 1 + (K/S) - [(K/S)^2 + 2(K/S)]^{1/2}$$

K = absorption coefficient or fraction of the incident energy lost by absorption per unit thickness of material, while S = scattering coefficient or fraction of the incident energy lost due to scattering per unit thickness of material.

This theory has been extended by others, showing that within limits, the dye and a matrix material absorb and scatter light independently of one another and that the ratio K/S for the dye (as distinct from K/S for the matrix material) bears a proportionality to the amount of dye present.

Urbanyi further utilizes a tristimulus technique measuring the color of opaque objects at only three wavelengths. The tristimulus values are normally computed by integrating the product of the ordinates

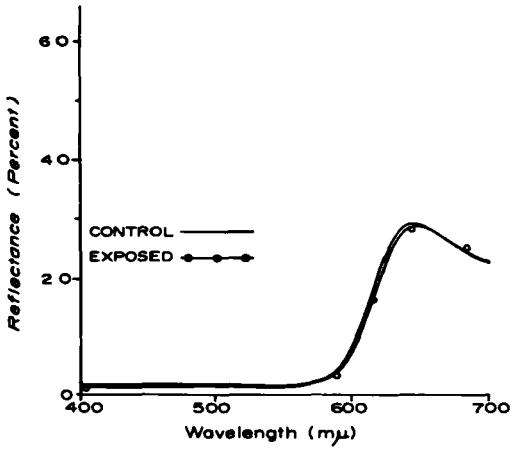

Fig. 5.—Reflectance measurement of a red pigment; Color Index No. 15865; color change is 5 N.B.S. units.

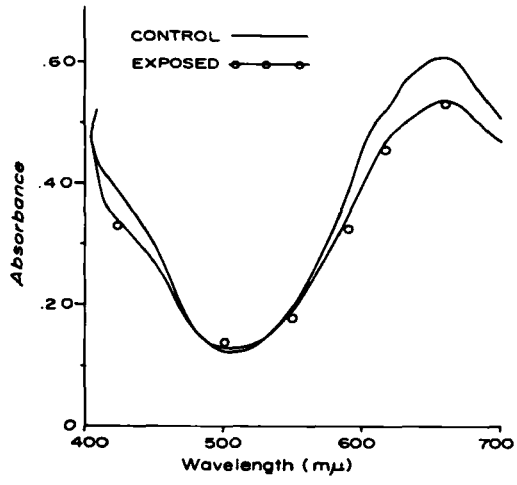

Fig. 6.—Reflectance data of Fig. 2 mathematically transformed into "absorbance" units and replotted.

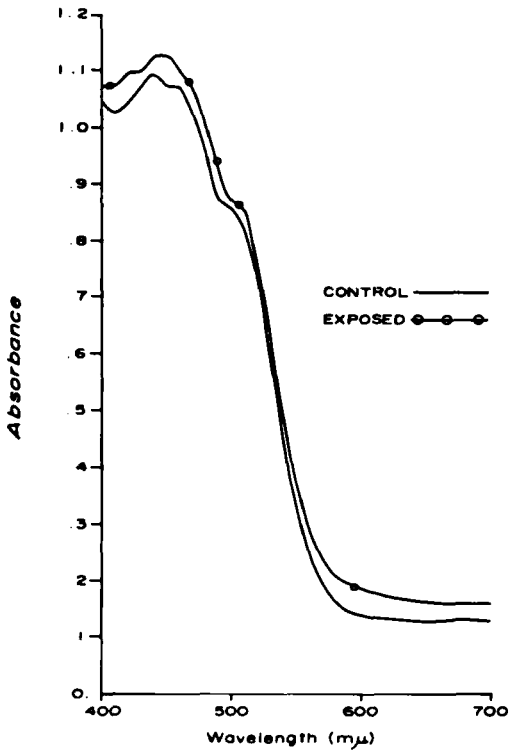

Fig. 7.—Reflectance data of Fig. 3 mathematically transformed into "absorbance" units and replotted.

of one of the standard color mixture curves multiplied by the energy in the corresponding wavelength regions of the spectrum of the sample of radiant energy. If the sample of radiant energy is that reflected from a surface, the spectral composition of the reflected energy is given by the products at each wavelength of the spectral composition of the incident energy and the corresponding radiant reflectance of the surface. This product can be employed as the spectral composition of the reflected energy in the calculation of the tristimulus values of the color of the light reflected from the surface. The integration may be carried out by use of any convenient method of numerical integration (consult appendix).

Lachman, *et al.* (4), ranked dyes in the order of decreasing light stability by improperly using an inadequate abridged selected-ordinate method and the results were stated in "absorbance" units. Furthermore, they failed to establish the validity of the single wavelength type of measurement and their basis of ranking did not take into account the sensitivity of the human eye.

Garrett and Carper (1) determined the color stability of a multisulfa preparation by decanting the clear liquid containing the dye and determining the spectrophotometric absorbance of the dye. While their results and conclusions drawn may be perfectly correct, they nevertheless failed to show that there was a correlation between the dye content *in vitro* and the color of the multisulfa preparation. Since in pharmacy the primary purpose in coloring a product is its total visual effect, then it would seem to be most important to measure color as

perceived, not some other attribute that may or may not correlate with it unless the correlation has been previously rigorously established.

Vickerstaff and Tough (23) discussed the uncertainties of equating fading with the destruction of the dyes involved. They stated that a 50% fade need not involve the destruction of 50% of the dye. The only type of substrate to which such a criterion could be applied with justification is the dyed transparent film, where dye concentrations can be estimated from transmission measurements, and the true reduction in concentration on fading determined.

In another publication of Lachman, *et al.* (5), the comparative light fastness of several water-soluble dyes and their corresponding lakes were evaluated. To make a comparative light stability study of tablets colored with water-soluble dyes and lakes of the same dyes, the concentration of dye in the amount of lake used for the tablets was calculated, and the same quantity of dye was used for the tablets colored with the water-soluble dye. The results of this study indicated that the photostability of the lakes was less than in those of the dyes in the systems studied.

While these results may be correct it should be pointed out that the lakes and dyes were in the tablet formulas in equal dye contents, not equal tinctorial content. The color of the tablets, both before and after fading, is the significant matter, and not the dye contents. Perhaps a more valuable study could have been achieved by starting with the lakes and dyes having the same appearance and then noting their fading with time and light. The *Ciba Review* (15) states, "Perhaps the greatest emphasis should be placed on the recognition that colour is subjective and that colour appearance is not just a matter of spectral absorption and reflection."

Some of the anomalies that have been discussed in the pharmaceutical literature with regard to the light fastness of dyes and lakes varying in different formulations can be, in part, resolved by the following concepts.

Smith and Stead (24) contend that the light fastness of a pigment has no significance and that it is only the light fastness of a pigmentation that can be measured and has any value. In their study they went on to describe the wide differences in light fastness shown by using the same pigment at the same concentration in different media. They further stated: "All that can fairly be said of pigments is that Pigment A used according to Formulation B at Concentration C in Medium D exposed to Light Source E for Time F under Humidity G and Atmospheric Conditions H at Temperature I has a Fastness X relative to an arbitrary standard. This is a *reductio ad absurdum* mode of presenting the idea, but the absurd in this case is strictly true."

Schwen and Schmidt (25) substantiated this in their study. They said: "In the light of present knowledge it is now quite clear that the system comprising dye and fibre together—or, rather, dye, fibre, and further components—is necessary to define the light fastness of a particular dyeing. One cannot quote the light fastness of a dye alone."

SUMMARY

If those working in the field of pharmacy will realize that it is not the colorants but the color that is the primary objective in coloring pharmaceutical products, then they will be able to take advantage of a vast amount of research that has been done by workers in the fields of textiles, plastics, pigments, dyes, ceramics, films, and paints. The government, through the Bureau of Standards and the Department of Agriculture, has made very basic and rewarding contributions to the science of color. The Optical Society of America and the Inter Society Color Council are just two of the many organizations whose research, when utilized by pharmacy, could put us far ahead of where we are today with regards to the study of color in all of its facets.

To date there has been no study conducted in the pharmaceutical field which treats color as the psychophysical phenomenon that it is. Until this is done all results and conclusions will be open to question.

Adaptation of Commercial Viscometers for Special Applications in Pharmaceutical Rheology I

The Brookfield Viscometer

By JOHN H. WOOD, GREGORY CATACALOS, and S. V. LIEBERMAN†

The adaptation of the Brookfield LVT and RVT viscometers to absolute rheometers by the use of a fixed cup and bob system is described. The resultant instruments, providing shear rates in the 0.1 to 15 seconds^{-1} range, supplement the Drage Epprecht rheometer in the next two lower decades of shear. The converted LVT was used to evaluate the apparent shears found with the conventional disk spindles of the Brookfield RVF. It is shown that the resultant shear is an integration of the Newtonian and non-Newtonian components. Thus, although the use of several speeds with such spindles does give indications of pseudoplastic behavior, the shear dependency is not fully characterized.

ONE OF THE most widely available viscometers for general control use has been the Brookfield Synchro-Electric viscometer in one of its several models. For routine control measurement, it is frequently customary to use only the most suitable speed for measurement with a given spindle. Most spindles are of the disk type rather than the bob or rod. As a result of this general type of usage, the instrument has tended to be somewhat in disrepute among practicing rheologists. There have been several attempts (1–3) to apply the use of the several available speeds of the instrument, four in the F models and eight in the T models, to the study of non-Newtonian systems. However, these have been confined to the use of the normally supplied Brookfield disk spindles, and hence have been limited by the nondefinable shear-rates used.

Since this instrument in the T model has very slow speeds available, it seemed desirable to attempt to fit it with a series of cups and bobs such that reasonably absolute shear measurements might be made in the low shear-rate range.

EXPERIMENTAL

Initially a Brookfield model LVT viscometer was equipped with cups *A* and *B* of internal diameters 2.54 and 0.852 cm., respectively, attached rigidly to the viscometer by a twist plate identical to that normally used to mount the guard ring. (See Fig. 1.) The Nos. 1 and 4 spindles as normally supplied are straight geometric cylinders. Similar geometric spindles are available for Nos. 2 and 3 on order from Brookfield Engineering Corporation, Stoughton, Mass. The pertinent dimensions are given in Table I. All are flat bottomed and have a shaft diameter of 3.0 mm.

It was intended that the use of this instrument would be primarily to complement the Drage Epprecht rheometer by supplying the lower shear-rate range. For this reason Newtonian shear rates were calculated in accordance with the standard

TABLE I.—DIMENSIONS OF CYLINDRICAL BROOKFIELD LVT SPINDLES

Dimension	Brookfield Spindle Number 1	2	3	4

practice for that instrument (4). The torque factor was calibrated experimentally from the slope of the plot of the scale reading of the instrument *vs.* calculated shear rates for all suitable National Bureau of Standards calibration oils. These oils are all Newtonian in the range of shears used here, so that straight line plots were obtained for each bob for each oil used. This method previously had provided torque factors for the Drage identical to those cited by the manufacturer.

Since the spindle mounting of the Brookfield is not rigid but quite free-floating, close cup-to-bob clearances are not practical. In types of non-Newtonians with which the instrument has been used for the last 3 years, the use of the *A* cup with spindles 1 and 2, occasionally 3, has been the general rule. For those systems for which the two thinnest bobs, 3 and 4, are needed it is often not practical to fill the smaller cup without the use of excessive disturbing shear of the sample. We intend to extend our usage of the smaller bobs by the insertion into the filled *A* cup of sleeves similar in design to those now available with the Drage Epprecht rheometer. These reduce the cup-to-bob ratio, and incidentally raise the shear rate used. These sleeves can be inserted into filled cups with very little shear disturbance.

Most applications of this instrument, as with the Drage, involve direct comparisons between samples measured in identical manners. This is particularly true of its use in routine aging comparisons.

For heavier consistency systems we have similarly adapted a Brookfield model RVT using the same bobs and the large cup only. Here the cup is mounted by an adapter plate which connects by the mounting screws normally used to bolt on the guard ring. The relative spring moments of the LVT and RVT models as given by the manufacturer are 6.737 and 71.97 dyne cm./division, respectively.

Apparent Shear with Regular Brookfield RVF Spindles.—Frequently it has been desirable to know under what equivalent shear routine control type Brookfield RVF readings were being taken. Accordingly six pseudoplastic materials were chosen of varying viscosity characteristics as shown in Table II.

TABLE II.—VISCOSITY CHARACTERISTIC OF TEST SUBSTANCES AS FUNCTION OF SHEAR RATE

Test Substance	Apparent Viscosity (Point to Origin) D = 0.1 sec.$^{-1}$	D = 1 sec.$^{-1}$	Cps. D = 10 sec.$^{-1}$
1	36,000	14,000	2,200
2	42,000	17,000	3,700
3	30,000	5,000	940
4	22,000	3,900	870
5	13,000	4,400	920
6	66,000	14,000	3,500

All RVF spindles which would give readings were also used with each lotion. The multiplying factors appropriate to each spindle as supplied by the manufacturer were used to calculate apparent viscosities. Plots were then made for each liquid against the relative Newtonian apparent shear rate. An example is shown in Fig. 2. The reference point chosen was the No. 7 spindle at 2 r.p.m. This has the highest multiplying factor, 20,000. This was given a relative Brookfield shear rate of 1*X*. The relative shear rates were assumed to vary with the multiplying factor. Thus spindle No. 3 at 20 r.p.m. with a multiplying factor of 50 was given a relative shear of 20,000/50 or 4000*X*. The shear rate from the rheogram necessary to give an apparent viscosity equivalent to that observed using the Brookfield multiplying factor was taken as the Spindle Equivalent Shear Rate for that operating condition.

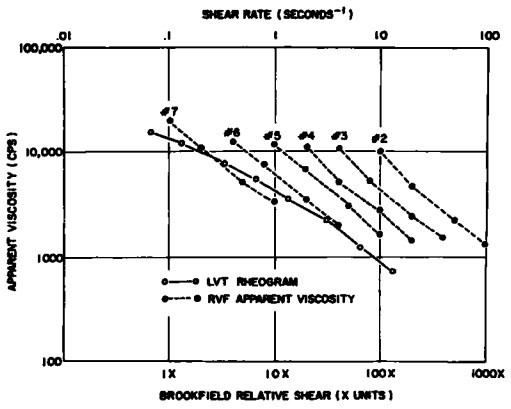

Fig. 2.—Comparison between conventional Brookfield RVF readings at each speed for the various spindles and a rheogram from the modified LVT for the same pseudoplastic lotion.

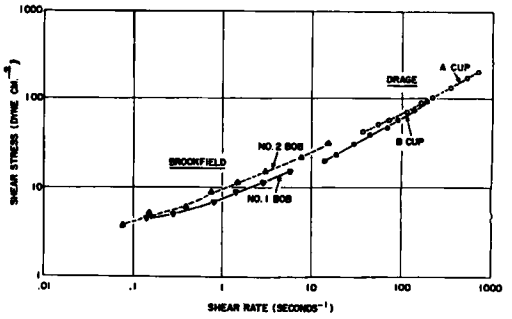

Fig. 3.—Rheograms run with the modified Brookfield LVT and with the Drage Epprecht viscometer for a pseudoplastic lotion.

RESULTS AND DISCUSSION

Rheology.—In the calculation of shear rates for cup-and-bob combinations where the radius ratio departs significantly from unity, the choice of the method of calculation is a major problem. Fischer (5) and Andrade (6) have tried different approaches to the integration of the average shear rate. Since the Newtonian viscosity is independent of the integration procedure used, the shear stress term must bear the same averaging method. It was therefore decided to take the direct approach, namely, to use the simple Newtonian shear-rate formula and, by the empirical calibration, include any necessary correction factor into the torque term.

This is justified because a multispeed instrument is of no value for Newtonian systems, but is of particular need for pseudoplastic ones. In such systems, having as they do exponential torque-shear rate dependencies, it is no longer possible to simply relate the shear gradient to the system geometry since the nature of the shear dependency enters into

TABLE III.—APPARENT SPINDLE EQUIVALENT SHEAR RATES FOR BROOKFIELD RVF SEC.$^{-1}$

Spindle Speed, r.p.m.	Brookfield Spindle Number					
	7	6	5	4	3	2
2	0.03–0.22	0.11–0.33	0.09–0.50	0.10–0.50	0.11–0.54	0.19–0.60
4	0.12–0.40	0.09–0.70	0.5 –1.1	0.5 –1.1	0.7 –1.2	0.8 –1.2
10	0.6 –1.4	1.3 –2.5	1.9 –2.9	2.1 –2.8	2.6 –3.2	3.2 –3.6
20	1.5 –3.8	3.7 –4.8	4.3 –5.3	4.3 –5.6	4.4 –6.2	6.0 –7.4

the observed gradient. In this case, for absolute measurements, all calculations must be reduced to the walls of the measuring system (7). In the extrapolated limit, any equations should lead to the same values for apparent shear rate and torque at the wall. It is intended that such a treatment be the subject of a later paper.

Figure 3 shows the results obtained for the measurement of an antiperspirant lotion at 25° using the Nos. 1 and 2 bobs of the Brookfield and the *A* and *B* cups of the Drage rheometer. It is apparent that this is a pseudoplastic system. The variety of cup and bob ratios used here partially justifies Fischer's statement (5) that "For non-Newtonian liquids . . . the mean value of η is found experimentally to be approximately the same for large and small clearances, so that the effect of variable rate of shear apparently balances out."

The Brookfield LVT modified in the manner shown compliments the Drage Epprecht viscometer by providing for the two to three decades of shear lower than otherwise available. This modification thus provides an economical low-shear rheometer suitable for measurements in the range normally found for tipping and slow pouring from a bottle of rather heavy lotions (8). Thus the rheological study of their aging in a useful shear rate range is facilitated. The use of this instrument in the study of Veegum suspensions is given elsewhere (9).

Apparent Shear of Brookfield RVF Spindles.—Table III gives the ranges found for the Equivalent Shear Rates for the various spindles in use with the Brookfield RVF. It will be noted in Fig. 2, that with the exception of the No. 7 spindle (which has no disk) the apparent viscosity at each speed was surprisingly independent of the bob used to measure it. (Note the correspondence of the serial spots for each bob.)

The slopes of the bob lines are relatively parallel, but do not in all cases parallel the shear-dependency line of the rheogram. No absolute correlation can be made between apparent Brookfield readings for a given speed and the viscosity of a non-Newtonian. Nevertheless, the ranges of apparent shear rate are narrow enough that we consider we can predict satisfactorily from the rheogram of a given system what its apparent Brookfield viscosity will be.

Thus readings obtained by a conventional Brookfield RVF can be empirically equated to the values found from a conventional rheogram. However, the apparent viscosity value does depend on the spindle used, as does the apparent shear dependency. The fact that such correlation is possible obviously follows from the reasonable success the instrument has had in process monitoring.

With such a low-shear rheometer, equivalent types of calibrations may be made of shear rates of other nondefinable measuring systems.

SUMMARY

A readily constructed attachment to convert a Brookfield viscometer of the T type to an absolute rheometer is described. Its application in the case of the Brookfield model LVT to give a rheometer of shear rate range 0.1 to 15 sec.$^{-1}$ is described.

The equivalent shear rate obtained by conventional Brookfield RVF with disk spindles was determined by equating the viscosities obtained to the rheogram. It is found that, since the spindle integrates the non-Newtonian with the Newtonian component, the use of the multispeed determination, as described in the literature, gives a useful but an incomplete idea of the non-Newtonian character.

Effect of Surface-Active Agents on the Extraction of Belladonna Herb

By G. P. SRIVASTAVA and T. N. CHADHA

The effect of two surface-active agents, Tween 20 and Tween 80, on the extraction of belladonna herb (*Atropa belladonna*) by percolation and mechanical agitation processes using 70% alcohol and water as solvents has been studied. The concentration of the surfactants in the solvents was uniformly 0.2%. These surfactants have been shown to potentiate the solvents leading to a more complete and expedient extraction of the drug. Seventy per cent alcohol and water containing 0.2% Tween 20 extracted the drug better than the unpotentiated solvents. Tween 80 gave better results than Tween 20 when used in the extraction by mechanical agitation. In the percolation process only Tween 20 was used.

In recent years some novel methods of drug extraction have been suggested. Bay and Gisvold (1) worked out a method for extracting digitalis leaves by disintegrating them in a Waring Blendor in presence of water as menstruum. Greco and Dumez (2) used a pressure cooker for extracting vegetable drugs like nux vomica, belladonna, hyoscyamus, stramonium, cascara, and wild cherry. Changes in the use of solvents have also been suggested. Carkhuff and Gramling (3) used various furans for the extraction of belladonna. Campo and Gramling (4, 5) extended the use of furans to the extraction of defatted ergot and cinchona. Dean, *et al.* (6), made use of a colloid mill for preparing tinctures of belladonna and stramonium. Head, *et al.* (7), worked on the ultrasonic extraction of *Cinchona succirubra* using various solvents. Bose, *et al.* (8), also employed this method in the extraction of *Rauwolfia serpentina*. Different workers have shown advantages of their respective methods.

The use of surface-active agents in the extraction of vegetable drugs was suggested by Butler and Wiese (9), who successfully employed such agents for extracting belladonna, hyoscyamus, cinchona, and ipecac. They used several surfactants and extracted the drugs by the official percolation method. Brochmann-Hanssen (10) followed the use of surfactants for the extraction of cinchona and ipecac. These investigations induced the present authors to undertake the inquiry of the effect of two surface-active agents, Tween 20 (polyoxyethylene sorbitan monolaurate) and Tween 80 (polyoxyethylene sorbitan mono-oleate), not so far studied by the previous workers, on the extraction of belladonna herb (*Atropa belladonna*), an important drug of the Indian Pharmacopoeia. The above two surfactants belong to the nonionic group and are practically nontoxic (11, 12).

A surfactant concentration of 0.2%, usually employed in pharmaceutical formulations, was used in 70% alcohol and in water. Extractions were done by percolation and mechanical agitation. Throughout this study we employed 70% alcohol where alcohol was utilized and maintained the concentration of the surfactants at 0.2%.

Received June 4, 1962, from the Department of Pharmaceutics, Banaras Hindu University, Varanasi 5, India.
Accepted for publication July 10, 1962.

EXPERIMENTAL

A sample of belladonna herb (*A. belladonna*) powdered to No. 40 and assayed by the method of the Indian Pharmacopoeia of 1955 (13), was used all through the present work. The average result of six readings of assay was 0.08782% w/w of alkaloids calculated as hyoscyamine.

Extraction by Percolation.—In the first series of experiments 100 Gm. of the drug powder (No. 40) was extracted by the percolation process in the following ways: (*a*) simple percolation using alcohol as menstruum (control for comparison); (*b*) percolation without 24-hour maceration using alcohol containing Tween 20 for moistening only and alcohol for the rest of the process; (*c*) simple precolation using alcohol containing Tween 20 for moistening as well as for maceration and alcohol for the rest of the process; and (*d*) percolation without 24-hour maceration using alcohol containing Tween 20 for the entire process.

In every case the same size percolator was used and the rate of percolation was maintained at 30 drops per minute. A 700-ml. quantity of the percolate was collected in five fractions—three 100 ml. and two 200 ml. Each fraction was assayed for its alkaloidal content and from the data thus obtained the progressive percentage of alkaloids extracted from 100 Gm. of the drug was calculated. Three sets of experiments were done in each case and the average values are recorded in Table I. The total solids (T.S.) extracted from 100 Gm. of drug was determined and the solvent selectivity index (s.s.i. = alkaloids × 100/total solids) was calculated therefrom. These values are also noted in Table I.

Table I.—Results of the Extraction of Belladonna Herb by the Percolation Process

Fraction No.	Progressive Percentage of Alkaloid Extracted (a)	(b)	(c)	(d)
1	55.7	47.3	51.3	53.2
2	83.8	74.4	80.5	81.2
3	93.2	84.6	89.0	92.1
4	97.7	89.6	94.4	98.3
5	100.4	91.4	96.6	100.6
s.s.i.	0.662	0.625	0.570	0.632

It is clear that complete extraction of alkaloids from belladonna herb is effected by percolation without 24-hour maceration when Tween 20 is incorporated in the total volume of alcohol used as menstruum. The efficiency of extraction procedure *d* is similar to simple percolation with 24-hour maceration, and plain alcohol procedure *a*. The solvent selectivity, however, is slightly reduced in this case. The other modifications adopted, *b* and *c*, have not proved successful.

Extraction by Mechanical Agitation.—In order to have more controllable conditions and obtain comparable results, extraction by mechanical agitation with or without maceration was used in the following series of experiments. For this purpose 20 Gm. of drug powder (No. 40) was taken with 150 ml. of menstruum in a well-closed 250-ml. bottle and agitated in a mechanical shaker at the rate of 200 strokes per minute. At the end of the specified time the clear extract was decanted off. Duplicate samples were prepared in each case and each sample was assayed twice for alkaloids taking 50 ml. of extract each time; total solids were also determined. Total alkaloids and solids present in the total volume of menstruum added (150 ml.) were calculated. This was done to find out the percentage of the alkaloids in 20 Gm. of drug (calculated value = 0.0176 Gm.) taken up by the total volume of the menstruum at the end of the process. In this way the results obtained were rendered comparable.

The effect of the duration of time of agitation was first determined; 20 Gm. of the drug and 150 ml. of alcohol containing Tween 20 were first macerated for 24 hours and then shaken for 5, 10, 20, and 30 minutes. As a control for comparison, 20 Gm. of the drug was also extracted with plain alcohol and agitated for 30 minutes by this method. The results are recorded in Table II.

TABLE II.—RESULTS OF EXTRACTION OF BELLADONNA HERB BY MECHANICAL AGITATION AFTER 24-HOUR MACERATION

Agitation, Minutes	Menstruum Used	Alkaloid Extracted, %	s.s.i.
5	Alcohol with Tween 20	67.9	0.420
10	Alcohol with Tween 20	71.7	0.442
20	Alcohol with Tween 20	83.2	0.510
30	Alcohol with Tween 20	90.9	0.535
30	Alcohol (control)	46.1	0.294

The results in Table II show evidence of the superiority of the extraction of alkaloids from belladonna herb with alcohol containing Tween 20 over the extraction with plain alcohol; the extraction with agitation for 30 minutes in the former case is nearly double (90.9%) of that in the latter (46.1%). Even agitation for 5 minutes with the potentiated menstruum extracts nearly one and a half times more alkaloids than in the control. It is interesting to note that the solvent selectivity index is also higher in the case of the potentiated menstruum.

In the following experiments the 24-hour maceration before agitation was eliminated and 20 Gm. of the drug was agitated with 150 ml. of solvent. The time of shaking was increased as shown in Table III. Three types of solvents were used: (i) plain alcohol as control for comparison, (ii) alcohol containing Tween 20, and (iii) purified water containing Tween 20. The results obtained are given in Table III.

TABLE III.—RESULTS OF EXTRACTION OF BELLADONNA HERB BY MECHANICAL AGITATION WITHOUT MACERATION

Agitation, Minutes	Menstruum Used	Alkaloid Extracted, %	s.s.i.
30	Alcohol with Tween 20	26.4	0.296
60	Alcohol with Tween 20	34.4	0.377
90	Alcohol with Tween 20	73.9	0.480
120	Alcohol with Tween 20	97.6	0.595
60	Water with Tween 20	53.1	0.143
120	Water with Tween 20	66.4	0.187
120	Alcohol (control)	42.5	0.313

It is clear that 2 hours of agitation of the drug with alcohol containing Tween 20, without maceration, extracts it almost completely (97.6%), purified water containing Tween 20 extracts 66.4% of the alkaloids, while plain alcohol under similar conditions extracts only 42.5% of the alkaloids. It is also significant to note that Tween 20 in alcohol gives a much higher value for the solvent selectivity index than the value obtained in the case of water.

Having examined the effect of Tween 20, some experiments were also done with Tween 80, both in alcohol and water. Extraction of 20 Gm. of the drug was done by mechanical agitation without maceration in 150 ml. of the menstruum. Duplicate samples were prepared and each sample was assayed twice. The results are given in Table IV. For the sake of ready comparison, the values of per cent alkaloids extracted by alcohol and water both potentiated separately and severally with Tween 20 and Tween 80 are tabulated in Table V.

TABLE IV.—RESULTS OF EXTRACTION OF BELLADONNA HERB BY MECHANICAL AGITATION WITHOUT MACERATION

Agitation, Minutes	Menstruum Used	Alkaloid Extracted, %	s.s.i.
30	Alcohol with Tween 80	72.7	0.519
60	Alcohol with Tween 80	83.87	0.555
90	Alcohol with Tween 80	92.2	0.592
120	Alcohol with Tween 80	100.7	0.640
60	Water with Tween 80	61.5	0.159
120	Water with Tween 80	69.9	0.181

TABLE V.—RESULTS OF EXTRACTION OF BELLADONNA HERB BY MECHANICAL AGITATION WITHOUT MACERATION

Agitation, Minutes	Alkaloid Extracted, %: Alcohol, 70% — Tween 20	Alcohol, 70% — Tween 80	Water — Tween 20	Water — Tween 80
30	26.4	72.7	...	...
60	34.3	83.9	53.1	61.5
90	73.9	92.2	...	...
120	97.6	100.7	66.4	69.9

Tween 80 in the same concentration potentiates both alcohol and water more than Tween 20 does;

and, it also acts better in alcohol than in water. It may be noted that the alcohol incorporating either Tween 20 or Tween 80 extracts the drug almost equally. However, the solvent potentiated with Tween 80 acts more quickly in the beginning as evidenced by the values of per cent alkaloids extracted within short durations. Further, alcohol incorporating Tween 80 acts as a more selective solvent than that containing Tween 20 as indicated by the respective s.s.i. values (0.640 and 0.594).

DISCUSSION

The effect of two surfactants, Tween 20 and Tween 80, on the extraction of belladonna herb has been studied first by the percolation process (Tween 20 only) and then by the mechanical agitation process. It has been found, in both the processes, the solvent (alcohol) is potentiated by adding Tween 20 and permits the preliminary maceration for 24 hours to be eliminated. The purpose of maceration is to allow the drug to imbibe the solvent to facilitate the subsequent extraction. The most apparent effect of the use of the two Tweens in the solvent is that imbibition takes place so quickly that day-long maceration becomes unnecessary and the whole process is expedited.

Though both the surfactants were shown to be effective in potentiating the solvents, Tween 80 was superior to Tween 20 in the mechanical agitation process. This, probably, is due to the presence of the oleate radical, an 18-carbon chain, in the molecule of Tween 80. The laurate radical present in Tween 20 is only a 10-carbon group.

In the percolation process the potentiation of alcohol by Tween 20 has been found not to improve its solvent selectivity, but in the mechanical agitation process there is a marked enhancement. Both Tween 20 and Tween 80 have definitely higher s.s.i. values. The higher the value of this index, the higher will be the selectivity of the solvent, meaning that it extracts the active principles more than it does the other inert constituents.

CONCLUSIONS

Polyoxyethylene sorbitan monolaurate (Tween 20) and polyoxyethylene sorbitan mono-oleate (Tween 80) have been found to potentiate 70% alcohol and water as solvents in the extraction of belladonna herb (*A. belladonna*) by percolation and mechanical agitation processes. Tween 80 acts better than Tween 20 in the latter process. Both these surfactants act better in 70% alcohol than they do in water. In the percolation process the selectivity of the solvent (70% alcohol) is not improved but in the mechanical agitation process it is appreciably enhanced.

Absorption and Excretion of Sulfadiazine After Subcutaneous Implantation of Disks in Rats

By BERTON E. BALLARD and EINO NELSON†

Thin, cylindrical disk-shaped pellets of sulfadiazine were subcutaneously implanted in rats and free and total urinary sulfadiazine excretion followed. It was possible to relate the mean pellet absorption rate per unit area to the mean excretion rate per unit area and to the fraction of a dose of the drug eventually excreted in the urine.

ABSORPTION of drugs from implants may be studied by following urinary excretion of the unchanged drug, its metabolite(s), or both, by determination of drug blood level, by following excretion of substances such as electrolytes that reflect the drug's action in the body, by studying drug action on a target organ, or by following the decrease in weight of the implants themselves. In previous work it has been shown that the rate-limiting step in absorption after subcutaneous implantation of a number of drugs was the dissolution process at the absorption site (1). The work reported now gives the results of experiments which were conducted to determine the relationship between cumulative urinary excretion of sulfadiazine and acetylated sulfadiazine and change in surface area of thin, cylindrical disks of this material after subcutaneous implantation in rats. A study of this type has not been previously conducted using cylindrical implants; sulfadiazine serves as a readily available and assayable model compound.

PROCEDURE

Thin, cylindrical disks of compressed drug grade sulfadiazine were prepared and subcutaneously implanted in a manner and site described before (1). Four weighed disks were implanted into each of three Sprague-Dawley rats of both sexes designated as A, B, and C, having weights of 210, 335, and 410 Gm., respectively. They were placed in separate glass metabolism cages from which the urine was collected twice daily for 5 days. The urine was assayed for free and total sulfadiazine

Received May 10, 1962, from the School of Pharmacy, University of California Medical Center, San Francisco.

and, it also acts better in alcohol than in water. It may be noted that the alcohol incorporating either Tween 20 or Tween 80 extracts the drug almost equally. However, the solvent potentiated with Tween 80 acts more quickly in the beginning as evidenced by the values of per cent alkaloids extracted within short durations. Further, alcohol incorporating Tween 80 acts as a more selective solvent than that containing Tween 20 as indicated by the respective s.s.i. values (0.640 and 0.594).

DISCUSSION

The effect of two surfactants, Tween 20 and Tween 80, on the extraction of belladonna herb has been studied first by the percolation process (Tween 20 only) and then by the mechanical agitation process. It has been found, in both the processes, the solvent (alcohol) is potentiated by adding Tween 20 and permits the preliminary maceration for 24 hours to be eliminated. The purpose of maceration is to allow the drug to imbibe the solvent to facilitate the subsequent extraction. The most apparent effect of the use of the two Tweens in the solvent is that imbibition takes place so quickly that day-long maceration becomes unnecessary and the whole process is expedited.

Though both the surfactants were shown to be effective in potentiating the solvents, Tween 80 was superior to Tween 20 in the mechanical agitation process. This, probably, is due to the presence of the oleate radical, an 18-carbon chain, in the molecule of Tween 80. The laurate radical present in Tween 20 is only a 10-carbon group.

In the percolation process the potentiation of alcohol by Tween 20 has been found not to improve its solvent selectivity, but in the mechanical agitation process there is a marked enhancement. Both Tween 20 and Tween 80 have definitely higher s.s.i. values. The higher the value of this index, the higher will be the selectivity of the solvent, meaning that it extracts the active principles more than it does the other inert constituents.

CONCLUSIONS

Polyoxyethylene sorbitan monolaurate (Tween 20) and polyoxyethylene sorbitan mono-oleate (Tween 80) have been found to potentiate 70% alcohol and water as solvents in the extraction of belladonna herb (*A. belladonna*) by percolation and mechanical agitation processes. Tween 80 acts better than Tween 20 in the latter process. Both these surfactants act better in 70% alcohol than they do in water. In the percolation process the selectivity of the solvent (70% alcohol) is not improved but in the mechanical agitation process it is appreciably enhanced.

Absorption and Excretion of Sulfadiazine After Subcutaneous Implantation of Disks in Rats

By BERTON E. BALLARD and EINO NELSON†

Thin, cylindrical disk-shaped pellets of sulfadiazine were subcutaneously implanted in rats and free and total urinary sulfadiazine excretion followed. It was possible to relate the mean pellet absorption rate per unit area to the mean excretion rate per unit area and to the fraction of a dose of the drug eventually excreted in the urine.

ABSORPTION of drugs from implants may be studied by following urinary excretion of the unchanged drug, its metabolite(s), or both, by determination of drug blood level, by following excretion of substances such as electrolytes that reflect the drug's action in the body, by studying drug action on a target organ, or by following the decrease in weight of the implants themselves. In previous work it has been shown that the rate-limiting step in absorption after subcutaneous implantation of a number of drugs was the dissolution process at the absorption site (1). The work reported now gives the results of experiments which were conducted to determine the relationship between cumulative urinary excretion of sulfadiazine and acetylated sulfadiazine and change in surface area of thin, cylindrical disks of this material after subcutaneous implantation in rats. A study of this type has not been previously conducted using cylindrical implants; sulfadiazine serves as a readily available and assayable model compound.

PROCEDURE

Thin, cylindrical disks of compressed drug grade sulfadiazine were prepared and subcutaneously implanted in a manner and site described before (1). Four weighed disks were implanted into each of three Sprague-Dawley rats of both sexes designated as A, B, and C, having weights of 210, 335, and 410 Gm., respectively. They were placed in separate glass metabolism cages from which the urine was collected twice daily for 5 days. The urine was assayed for free and total sulfadiazine

† Present address: School of Pharmacy, State University of New York, Buffalo, N. Y.

by the Bratton and Marshall method (2). A Bausch and Lomb Spectronic 20 colorimeter was used in the application of the method.

The final mean weights of the disks were corrected for the weight of the proteinaceous "ghost" described by Folley (3) in the following way. A 0.4190-Gm. sample of most of the remains of disks removed from rats A, B, and C was dissolved in dilute ammonium hydroxide. The clear solution was decanted from the "ghost" residues and several portions of distilled water were added and decanted. The small amount of water remaining containing the "ghost" was then evaporated to dryness at room temperature. The residue weighed 3 mg. Thus, the final weight of the disks as yet uncorrected for "ghost" weight was heavy by slightly more than 0.71%. The observed final mean weights in Table I were corrected for the weight of the "ghost."

RESULTS

Table I shows for rats A to C data on the properties and dimensions of the disk-shaped pellets before and after implantation. The initial and final mean disk areas were graphically estimated by a method described previously which used for illustration some of the data given here for rat A (4). The cumulative amounts of free and total sulfadiazine excreted in the urine for the three animals appear in Table II, along with the fraction, f, of total drug recovered in a time infinite in terms of the experiment which was about 147 hours. The nature of the type of cumulative drug excretion curves obtained is shown in Fig. 1 which was constructed from data obtained from rat A. It should be noted that on the cumulative excretion curve only the high points should be considered in the plot, because low points may be due to collection time not corresponding to the last voiding time.

DISCUSSION

There are only a few reports in the literature where the urinary excretion of drug or metabolite(s) have been followed subsequent to drug implantation (5–11). However, except in one of these studies, no attempts were made to relate the absorption rate of implants to urinary excretion rate of drug or metabolite(s) (5).

Theoretically, if the cumulative amount of drug and its metabolite(s) excreted in the urine is plotted against time, one should note a line with a progressively decreasing slope, indicating that the ex-

cretion rate diminishes with time. This decrease in excretion rate should parallel the decrease in absorption rate of the implant because of area changes which occur during absorption. When such a plot is made from the data presented in Table I of Latven and Welch (9), a decrease in excretion rate with time is observed. However, it cannot be determined from their data the values of the initial and final areas of the implants. Further, it should be possible to equate implant absorption rate to the urinary excretion rate of free and metabolized drug when implant surface area and fraction of the total dose recovered are considered and when absorption is solution rate limited.

An animal implanted with a drug pellet of a geometric form such that only small decreases in area occur with absorption may be likened to one given a continuous infusion of a drug when absorption from implant is solution rate limited. For the infused animal the relationship

$$Ri = Re/f \qquad \text{(Eq. 1)}$$

should apply after equilibrium is established, assuming drug removal processes are first order which is the usual case, where Ri is the constant rate of infusion, Re is the rate of urinary excretion, and f is the fraction of the total dose excreted in the urine in a time infinite in terms of the experiment. A similar relationship should hold in the case of implants after surface area corrections are made. Then the mean absorption rate per mean area, $\bar{R}/\bar{A}$, should equal the mean excretion rate per mean area, $\overline{Re}/\bar{A}$, divided by the fraction, f

$$\bar{R}/\bar{A} = (\overline{Re}/\bar{A})/f \qquad \text{(Eq. 2)}$$

assuming that no deposition of drug occurs at another site (*i.e.*, the kidney) (12, 13).

$$\bar{R}/\bar{A} \text{ per pellet} = \frac{(W_i - W_f)/t_i}{(A_i + A_f)/2} \qquad \text{(Eq. 3)}$$

$$\overline{Re}/\bar{A} \text{ per pellet} = \frac{(W_e/N)/t_e}{(A_i + A_f)/2} \qquad \text{(Eq. 4)}$$

where W_i and W_f are the initial and final mean pellet weights, t_i is the time of implantation, A_i and A_f are the initial and final areas of the implant, W_e is the weight of total drug recovered in the urine in time t_e, N is the number of pellets used, and t_e is the time of excretion.

TABLE III.—MATERIAL BALANCE: SHOWING THAT $\bar{R}/\bar{A} \cong (\overline{Re}/\bar{A})/f$

Rat	$\bar{R}/\bar{A}$ Gm./hr./cm.²	$(\overline{Re}/\bar{A})/f$ Gm./hr./cm.²
A	1.74×10^{-4}[a]	1.66×10^{-4}[b]
B	1.57×10^{-4}	1.47×10^{-4}
C	1.49×10^{-4}	1.40×10^{-4}

[a] $\bar{R}/\bar{A}$ per pellet $= \dfrac{(Wi - Wf)/ti}{(Ai + Af)/2} = \dfrac{(0.0508 - 0.0342)/119.2}{(0.864 + 0.740)/2} = 1.74 \times 10^{-4}$

[b] $(\overline{Re}/\bar{A})/f$ per pellet $= \dfrac{(We/N)/te}{(Ai + Af)/2}/f = \dfrac{(1/4 \times 0.0528)/118.9}{(0.864 + 0.740)/2}/0.837 = 1.66 \times 10^{-4}$

Table III shows the agreement between the experimental values of $\bar{R}/\bar{A}$ and $(\overline{Re}/\bar{A})/f$. Similar agreement was also observed when a different method of calculating $\overline{Re}/\bar{A}$ was used (13). The value of the $(\overline{Re}/\bar{A})/f$ is slightly smaller than that for $\bar{R}/\bar{A}$. This is expected since time in the beginning of the experiment is required for the establishment of equilibrium in drug absorption, distribution, metabolism, or excretion of drug; *i.e.*, t_e by this method is slightly larger than it should be.

A Field Method for Alkaloid Screening of Plants

By C. C. J. CULVENOR and J. S. FITZGERALD

An alkaloid screening procedure is described which is suitable for use in the field with fresh plant material and can be carried out in a sufficiently short time to enable a chemist to keep pace with a collecting botanist.

IN VIEW of a strong world-wide interest in the discovery and isolation of new plant alkaloids, the following observations on a simple screen test suitable for field use may be of value. The method was designed for use by a botanist-chemist team collecting in remote and sparsely settled areas not previously explored for alkaloid-bearing plants. In making a test in the field under these circumstances there are great advantages: only positive samples need be collected, thus avoiding drying and despatch of most of the new species encountered; and samples giving strongly positive tests can be collected in bulk immediately, eliminating the need to revisit the area for this purpose. To achieve these advantages, a species should be tested when first encountered rather than collecting and keeping it until camp is set up in the evening. Thus, speed of operation and simplicity of procedure are essential. The

Accepted for publication June 11, 1962.

method described allows a plant to be tested in about six minutes, and the full requirements of chemicals and apparatus for one or two days' operations to be housed in a small carrying-case.

EXPERIMENTAL

About 2–4 Gm. of fresh plant material, preferably leaf and soft stems, is ground in a 3 in. unglazed porcelain mortar with a small amount of clean sand and sufficient chloroform to yield a thick slurry. Fine grinding to break down cell structure is important for rapid extraction. Ammoniacal chloroform (10 ml., *N*/20 with respect to ammonia) is added and the mixture stirred for about one minute before filtering the chloroform into a 5 × 1/2 in. test tube. Sufficient recovery of extract is obtained by pressing the material in the filter with a finger. Dilute sulfuric acid (2 *N*, 0.5 ml.) is added, the test tube shaken with a finger closing the end, and the phases allowed to separate (one minute or less is usually sufficient). The aqueous layer, or portion thereof, is removed with a dropper whose tip is fitted with a cotton wool plug for filtering and breaking emulsions. After removing the cotton wool and any chloroform in the dropper, two or three drops of the aqueous solution are placed in two 1 in. × 1/4 in. test tubes for testing with Mayers reagent or silicotungstic acid. The density of precipitate formed is assessed on a + to ++++ basis. Mortar, pestle, and filter funnel are wiped immediately with paper tissue but not washed after a negative test. Test tubes (5 × 1/2 in.) and droppers are emptied and re-used without washing after a negative test. After a positive result, mortar, pestle, and funnel are rinsed with chloroform and re-wiped, and test tube and dropper are rinsed with water from a wash-bottle. These precautions are sufficient to avoid contamination of a sample by the preceding one, while keeping the time required and usage of water at a minimum.

Fig. 1.—Alkaloid testing kit. At rear: Water wash bottle (100 ml.); chloroform containing *N*/20 ammonia (250 ml.); chloroform (250 ml.); 2 *N* sulphuric acid with calibrated dropper (100 ml.); Mayers reagent (50 ml.); silicotungstic acid solution (50 ml.); Center: Droppers with cotton wool filter plug (30); 2 in. funnel; 5 in. × 1/2 in. test tubes (24); 1 in. × 1/4 in. test tubes (several dozen). Front: Folded 11 cm. filter papers (24), 3 in. × 3/4 in. test tube calibrated to measure 10 ml.; 3 1/2 in. mortar; pestle; scissors; sand (250 ml. bottle).

The carrying case is illustrated in Fig. 1. All items are well embedded in balsa wood to prevent breakage or spillage under rough conditions. Polystyrene foam, although lighter in weight, is not satisfactory in place of balsa wood since it collapses wherever chloroform is spilled. Under field conditions, restocking is carried out each evening.

RESULTS

Results of the field test have been compared with those of a laboratory method which employs extraction of 20 Gm. dried milled plant with hot ethanol, removal of the ethanol, partitioning of the residue between ether and aqueous ammonia, and recovery of base from the ether with aqueous acid. The initial comparison was of results obtained in the field on fresh leaf material, with those obtained by the laboratory procedure on the same samples after drying and storing for up to three months. A limitation of the field method is that it misses all quaternary alkaloids, and the following comparisons are based only on the test for tertiary bases. The two methods gave identical results on 114 samples out of 147, 104 being negative, 4 weakly positive, and 6 strongly positive. The field test gave negative results for 14 species which were weakly positive by the laboratory method. The field test gave positive results (7 weak, 12 medium to strong) with 19 species for which the laboratory method gave only doubtful positives.

In view of the different condition of the samples, this comparison is useful only as evidence that the field method is a reliable screening procedure. Since our experience is that a weakly positive result (1+) in the laboratory test indicates that a plant is rarely worth further examination, the negative field result for 14 species in this category would not lead to any useful material being lost. The 12 species giving medium or strong field tests but weak laboratory tests may contain amines of very low molecular weight or suffer decomposition of alkaloid during drying of the plant material.

In order to compare the two methods more closely, a second group of 49 species was examined with both tests made from the same sample of fresh leaf material. Forty-four species gave the same result in both tests, 30 being negative, 10 strongly positive, and 4 weakly positive. Five species were strongly positive in the field test but only weakly positive by the laboratory method.

Our conclusion is that the field method with fresh material is a reliable screening procedure in so far as no species are missed which would have attracted further attention on the basis of the laboratory method. Since the field test is much simpler and can be performed more rapidly than the other, it may find application in circumstances other than that for which it was designed.

Gas Chromatographic Analysis of Acetylsalicylic Acid, Acetophenetidin, and Caffeine Mixture in Pharmaceutical Tablet Formulations

By ALLAN J. HOFFMAN and H. I. MITCHELL

THE WIDESPREAD use of APC mixtures suggested the possibility that the technique of gas chromatography might be useful as an analytical method. Although it was felt that the chemically dissimilar natures of the ingredients and the widely differing quantities of drug mixtures in tablet formulations might present a problem, a single-run type of analysis was attempted. The results are reported below.

EXPERIMENTAL

Equipment.—A linear programed-temperature gas chromatograph, F & M Scientific Corp. model 609, equipped with a flame ionization detector, was used for the experimental work. The detector signal was supplied to a model Y153 Minneapolis-Honeywell 1-mv. recorder, with a 1-second full scale response and a chart speed of 20 inches per hour. A Disc Chart Integrator model No. 201B (Disc Instrument, Inc., Santa Ana, California) accessory to the recorder was also used. For injection a 10-μl.-capacity Hamilton syringe was employed.

Materials.—Helium (Matheson Co.) was used as carrier gas. Haloport F 60–80 mesh (a dispersion polymer of a tetrafluoroethylene obtainable from F & M Scientific Corp., Avondale, Pa.) was coated with 2% by weight of Dow Corning 200 Fluid, and packed into a 6-ft. stainless-steel column, 4 mm. I.D., with the aid of a vibrating motor shaft. The chemical materials used in the investigation were purchased from commercial sources.

Operating Conditions.—The column temperature was programed, in all cases, from 75 to 200°. The heating rate found optimal was 9° per minute. The flow rate of helium was maintained at 50 ml./min. ±3% when the inlet pressure was kept at 50 psig. This constancy was essential for quantitative results. The sample injection port was maintained at 325°, and the detector block at 275° was employed for all experiments. Division of the peaks was performed vertically at the minima or by the inside tangent method, and peak areas were estimated by use of the automatic integrator. Two-microliter injections of chloroformic solutions were used throughout.

Quantitative Analysis.—Internal normalization, using correction factors for the conversion of peak areas to weight composition, was employed. Synthetic APC mixtures of the same percentage composition found in commercial tablets were prepared (see Table I). Correction factors were obtained by dividing the calculated weight per cent of each component of interest by its corresponding peak area per cent. Sample mixtures were then analyzed by multiplying the peak area of each component by the corresponding correction factor. The corrected peak areas were then normalized in the usual procedure. A sample of the procedure is given in Table I (top).

Tablet A consisted of a commercial APC tablet, uncoated, containing no other active ingredients, and of the composition indicated. The ground equivalent of four tablets was placed into a 100-ml. volumetric flask and diluted to the mark with chloroform. The mixture was then stirred magnetically for 1 hour and filtered through a No. 42 Whatman paper. Ten milliliters of the filtrate was evaporated to dryness in a current of dry air at about 40 to 45°. The residue was taken up in exactly 2 ml. of chloroform. Two microliters of this solution was injected to yield a chromatogram of the form shown in Fig. 1.

Tablet B consisted of a commercial APC tablet that also contained chlorpheniramine maleate. Results are shown in Table I (lower portion).

A commercial tablet, containing 8.1 mg. of codeine phosphate per tablet in addition to an APC mixture of the same weight per cent composition as Tablets A and B, was analyzed by this procedure. The chromatograms were in every way identical to those of the other tablets and to the synthetic mixture, indicating that codeine does not interfere under the conditions employed. Some quantitative results are shown in Table I under Tablet C.

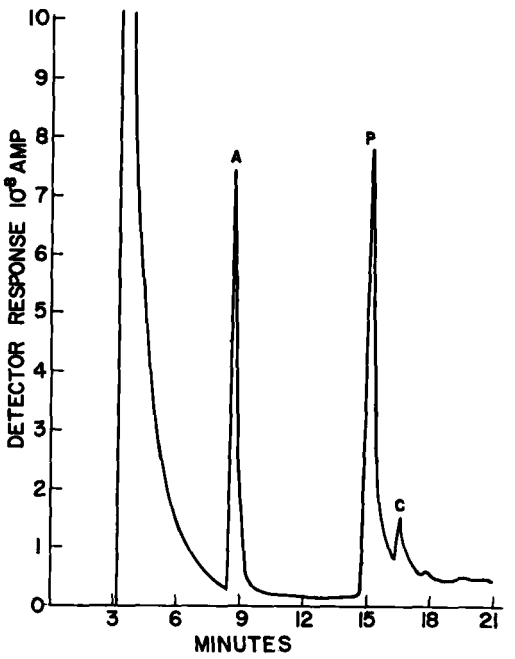

Fig. 1.—Typical gas chromatographic recording obtained for acetylsalicylic acid, acetophenetidin, and caffeine mixture with Dow Corning 200 fluid on Haloport F. Range 1000. Attenuation × 4.

Received July 16, 1962, from the Quality Control Department, White Laboratories, Inc., Kenilworth, N. J.
Accepted for publication August 22, 1962.

TABLE I.—PRECISION AND ACCURACY ANALYSIS OF A SYNTHETIC APC MIXTURE

SUMMARY AND DISCUSSION

GLC has been investigated with respect to its applicability to dosage forms containing APC mixture. It was felt that (*vis-a-vis* the N.F. column chromatographic technique) a method might be developed that would permit a greater number of replicate samples to be assayed, obviate the need for daily preparation of uniform columns, and release spectrophotometric facilities for other use.

This paper reports preliminary findings *via* a single-run type of assay. The results indicate that while the reliability of a single assay is less than in the official method, the means of the runs performed yielded results close to either labeled claim or composition by synthesis.

Efforts are being made to increase the precision of the technique and results will be reported in a future paper.

Communications

Possible Error in the Use of Polynomial Approximations in Urinary Excretion Rate Studies

Sir:

The utilization of urinary excretion data for the estimation of absorption rates has been employed in several reported studies (1–3). These papers indicate the method has certain advantages over one which bases its calculations on the concentration of the drug in blood plasma. Even though direct determination of plasma concentration of drug is recognized as a more accurate procedure, urinary excretion data are frequently employed since samples may be obtained at greater frequencies with a minimum of inconvenience to the subject, and drug concentration is such as to preclude assay difficulties.

Theoretical considerations of urinary excretion kinetics as related to absorption rate are reflected in the equation

$$dAe/dt = KfA_b$$

where dAe/dt is the rate of drug excretion; $K = 0.693/t_{1/2}$ where $t_{1/2}$ is the half-life of the drug in the body; f is the fraction of drug which is excreted in the urine unchanged; and A_b is the amount of drug in the body fluids. This equation is valid when the drug in the plasma is in equilibrium with other tissues and fluids of distribution. On the basis of this direct proportionality between excretion rate and the amount of drug in the body fluids, it is apparent that measurements of excretion rates plotted against time are far more indicative of rate of drug absorption than are plots of cumulative amounts of drug in the urine *vs.* time.

Excretion rates are defined as the instantaneous rate of change, at any given time, of cumulative

Possible Error in the Use of Polynomial Approximations in Urinary Excretion Rate Studies

Sir:

The utilization of urinary excretion data for the estimation of absorption rates has been employed in several reported studies (1–3). These papers indicate the method has certain advantages over one which bases its calculations on the concentration of the drug in blood plasma. Even though direct determination of plasma concentration of drug is recognized as a more accurate procedure, urinary excretion data are frequently employed since samples may be obtained at greater frequencies with a minimum of inconvenience to the subject, and drug concentration is such as to preclude assay difficulties.

Theoretical considerations of urinary excretion kinetics as related to absorption rate are reflected in the equation

$$dAe/dt = KfA_b$$

where dAe/dt is the rate of drug excretion; $K = 0.693/t_{1/2}$ where $t_{1/2}$ is the half-life of the drug in the body; f is the fraction of drug which is excreted in the urine unchanged; and A_b is the amount of drug in the body fluids. This equation is valid when the drug in the plasma is in equilibrium with other tissues and fluids of distribution. On the basis of this direct proportionality between excretion rate and the amount of drug in the body fluids, it is apparent that measurements of excretion rates plotted against time are far more indicative of rate of drug absorption than are plots of cumulative amounts of drug in the urine *vs.* time.

Excretion rates are defined as the instantaneous rate of change, at any given time, of cumulative

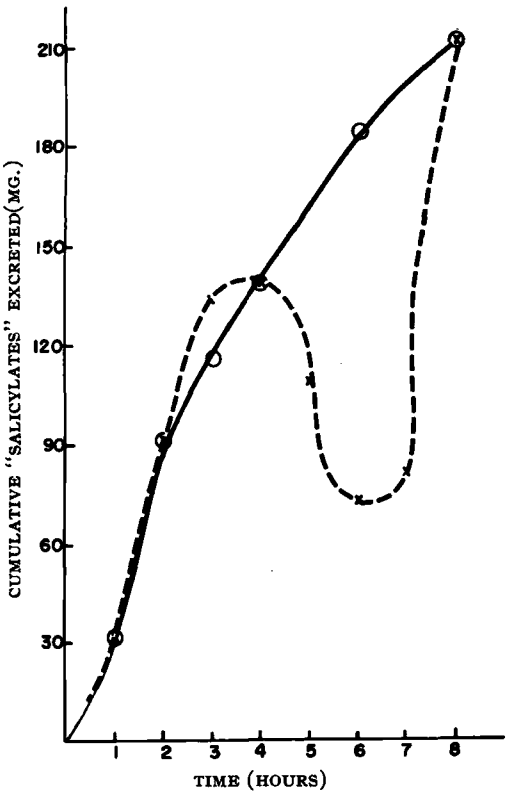

Fig. 1.—Comparison of actual and polynomial approximation curves. O, cumulative "salicylates" in urine in human subjects; X, polynomial approximations derived from 1, 2, 4, and 8 hour cumulative salicylate data.

amount of drug in the urine. Two basic methods may be used for their evaluation: graphical determination, or mathematical approximation of the Cumulative Amount *vs.* Time Curve with subsequent differentiation of the formula obtained.

The former method is tedious and requires a multiplicity of data for accurate determinations. The latter method, with the aid of a calculator, is to be favored both for rapidity and accuracy.

It has recently been proposed (2, 4, 5) that polynomial equations of fourth-order magnitude may be utilized to approximate the Cumulative Drug *vs.* Time Curve. The subsequent differentiation of the derived equations would directly yield the excretion rate at any time where the polynomial gives a good fit to the observed data.

The current literature in this area contains no reference to validation of reported data by a comparison of the instantaneous rates determined by polynomial approximation with either another approximation, or with graphical estimates. In addition, no graphical comparisons have been reported between experimental data and the polynomial approximation of these data.

Studies on excretion rates of salicylate currently being conducted in our laboratories indicate errors of rather large magnitude may be introduced in the mathematical treatment of data when using polynomial equations. The comparative plots in Fig. 1 indicate a possible degree of error which may be encountered in such approximations. The polynomial curve was derived from the actual cumulative salicylate levels of 30.5 mg. at the first hour, 90.3 mg. at the second, 138.9 mg. at the fourth, and 212.6 mg. at the eighth hour after ingestion. These data, obtained from one human subject, are typical of results obtained with other subjects in the study.

These results yielded the equation

$$x = -5.556t + 48.801t^2 - 13.766t^3 + 1.021t^4$$

where t is the time in hours and x equals the approximated cumulative milligrams of salicylate in urine.

In an effort to determine whether the range of the curve exercised any control on the accuracy of the approximation, a shorter plot covering the first 4 hours was calculated. The cumulative milligrams of salicylate at the third hour was 116.4 and this point, together with those for the first, second, and fourth hours, were utilized to derive

$$x = -28.43t + 88.83t^2 - 33.78t^3 + 3.88t^4$$

The fourth hour comparative curves in Fig. 2

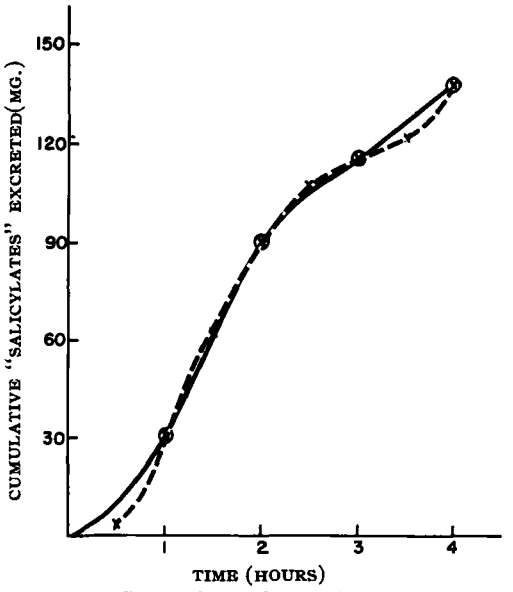

Fig. 2.—Comparison of actual and polynomial approximation curves. O, cumulative "salicylates" in urine in human subjects; X, polynomial approximations derived from 1, 2, 3, and 4 hour cumulative salicylate data.

indicate the degree of error is decreased, but it is evident that the deviations are such as to preclude the use of polynomials in this case.

The actual extent of error in the determination of excretion rate is more apparent when a comparison is made between rates obtained by graphical methods with those of the 4-hour polynomial equation. The graphical determination at the first hour is 63 mg.-hr.$^{-1}$, 43 at the second hour, and 22 at the third. The differentiated polynomial yielded values of 63, 46, and 11 mg.-hr.$^{-1}$, respectively. Good approximation is evident only up to the 2-hour level.

Polynomials are valid only when the curve being approximated tends to be parabolic either in its entirety or in the segments which compose it. The approximating equation to be used for a particular curve, or sets of curves, will depend on the nature of the curve and must be selected with consideration of its shape.

Based on these observations, we suggest that polynomial approximations be utilized with caution in excretion rate determinations.

Book Notices

A Survey of Cardiac Glycosides and Genins. By J. HAMPTON HOCH. University of South Carolina Press, Columbia 1, S. C., 1961. 94 pp. 20.5 × 26 cm.

An exceptional reference source in a special field, this book includes tabulated information on plant sources of cardiac glycosides and genins, hydrolytic products of natural glycosides, and animal assay doses of natural and semisynthetic compounds. Structural features of compounds are grouped, and a discussion on structure-activity relationships is included.

General Pharmacology. By JEAN SICÉ. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. ix + 593 pp. 16 × 25 cm.

This textbook on general pharmacology covers the pragmatic, biochemical and pharmacodynamic properties of the major classifications of drugs. General topic headings include: Physicochemical basis of pharmacodynamics, The ions, Cholinergic agents, Cardiac drugs, Smooth muscle relaxants, Conduction anesthetics, Histamine and antagonists, Adrenergic agents, The cerebral stimulants, The Cerebral depressants, Hormonal analogs and antagonists, Anticoagulants and inhibitors, Hematopoietic agents, Radioprotective agents, Antirheumatic analgesics, Antimicrobial agents, Anthelmintics, and Insecticides. Specific and general references of varying scope are provided at the end of each chapter. The book will probably prove most useful to the beginning pharmacology student.

Curare and Curare-like Agents. Edited by A. V. S. DE REUCK. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 103 pp. 12 × 18.5 cm. Price $2.95.

This book reports the papers presented and discussions of the Ciba Foundation Study Group No. 12. The contents includes: The fate of curare during curarization, Influence of curare on uptake and release of neuromuscular blocking agent labeled with ^{131}I, Drug-receptor interactions at the neuromuscular junction, Structure-action relations throwing light on the receptor; and Experimental hazards and artefacts in the study of neuromuscular blocking drugs. The discussions following each presentation as well as a general group discussion which concluded the session are reported.

Pulmonary Structure and Function. Edited by A. V. A. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xv + 403 pp. 14 × 20 cm. Price $11.50.

This is another volume in the Ciba Foundation General Symposia series covering the various ways normal pulmonary ventilation is disturbed by disease and the effects in the alveoli. Paper topics include: Recent advances in pulmonary anatomy, Bronchial gas flow, Cellular structure and mucus activity in the bronchial tree and alveoli, Ventilation-perfusion relationship, Pulmonary gas exchange measurements using radioactive gases, Pulmonary capillary blood flow and gas exchange, Techniques used in the study of lung pathology: the anatomy of emphysema, and The degree of variation of blood perfusion and of ventilation within the emphysematous lung and some related considerations. Papers on other topics and discussions are included in the book. Author and subject indexes are appended.

Specific and general references of varying scope are provided at the end of each chapter. The book will probably prove most useful to the beginning pharmacology student.

Curare and Curare-like Agents. Edited by A. V. S. DE REUCK. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 103 pp. 12 × 18.5 cm. Price $2.95.

This book reports the papers presented and discussions of the Ciba Foundation Study Group No. 12. The contents includes: The fate of curare during curarization, Influence of curare on uptake and release of neuromuscular blocking agent labeled with ^{131}I, Drug-receptor interactions at the neuromuscular junction, Structure-action relations throwing light on the receptor; and Experimental hazards and artefacts in the study of neuromuscular blocking drugs. The discussions following each presentation as well as a general group discussion which concluded the session are reported.

Pulmonary Structure and Function. Edited by A. V. A. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xv + 403 pp. 14 × 20 cm. Price $11.50.

This is another volume in the Ciba Foundation General Symposia series covering the various ways normal pulmonary ventilation is disturbed by disease and the effects in the alveoli. Paper topics include: Recent advances in pulmonary anatomy, Bronchial gas flow, Cellular structure and mucus activity in the bronchial tree and alveoli, Ventilation-perfusion relationship, Pulmonary gas exchange measurements using radioactive gases, Pulmonary capillary blood flow and gas exchange, Techniques used in the study of lung pathology: the anatomy of emphysema, and The degree of variation of blood perfusion and of ventilation within the emphysematous lung and some related considerations. Papers on other topics and discussions are included in the book. Author and subject indexes are appended.

indicate the degree of error is decreased, but it is evident that the deviations are such as to preclude the use of polynomials in this case.

The actual extent of error in the determination of excretion rate is more apparent when a comparison is made between rates obtained by graphical methods with those of the 4-hour polynomial equation. The graphical determination at the first hour is 63 mg.-hr.$^{-1}$, 43 at the second hour, and 22 at the third. The differentiated polynomial yielded values of 63, 46, and 11 mg.-hr.$^{-1}$, respectively. Good approximation is evident only up to the 2-hour level.

Polynomials are valid only when the curve being approximated tends to be parabolic either in its entirety or in the segments which compose it. The approximating equation to be used for a particular curve, or sets of curves, will depend on the nature of the curve and must be selected with consideration of its shape.

Based on these observations, we suggest that polynomial approximations be utilized with caution in excretion rate determinations.

Book Notices

A Survey of Cardiac Glycosides and Genins. By J. HAMPTON HOCH. University of South Carolina Press, Columbia 1, S. C., 1961. 94 pp. 20.5 × 26 cm.

An exceptional reference source in a special field, this book includes tabulated information on plant sources of cardiac glycosides and genins, hydrolytic products of natural glycosides, and animal assay doses of natural and semisynthetic compounds. Structural features of compounds are grouped, and a discussion on structure-activity relationships is included.

General Pharmacology. By JEAN SICÉ. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. ix + 593 pp. 16 × 25 cm.

This textbook on general pharmacology covers the pragmatic, biochemical and pharmacodynamic properties of the major classifications of drugs. General topic headings include: Physicochemical basis of pharmacodynamics, The ions, Cholinergic agents, Cardiac drugs, Smooth muscle relaxants, Conduction anesthetics, Histamine and antagonists, Adrenergic agents, The cerebral stimulants, The Cerebral depressants, Hormonal analogs and antagonists, Anticoagulants and inhibitors, Hematopoietic agents, Radioprotective agents, Antirheumatic analgesics, Antimicrobial agents, Anthelmintics, and Insecticides. Specific and general references of varying scope are provided at the end of each chapter. The book will probably prove most useful to the beginning pharmacology student.

Curare and Curare-like Agents. Edited by A. V. S. DE REUCK. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 103 pp. 12 × 18.5 cm. Price $2.95.

The Editor comments

POSTGRADUATE READING— THE HALLMARK OF A PROFESSIONAL

Some months ago a report came to our attention which struck us as reflecting a considerable degree of professional motivation in a particular group of pharmacy students. The report briefly and factually described a project which has been under way at Columbia University College of Pharmacy since late 1961.

Under the guidance of faculty advisor Dr. Gilbert Hite, the A.PH.A. Student Chapter decided to undertake a project which they aptly titled, *Postgraduate Reading is the Hallmark of a Professional.* A committee of three students then conducted a vigorous campaign using posters and displays, and sending a personal letter, together with a sample copy of THIS JOURNAL, to each student at the College. Their main goal was to interest the students in the monthly review articles, and various ideas were employed to publicize the review articles as well as the change in journal format, and to indicate the courses in which the journal articles would be most useful.

The purpose of the campaign was stated by the students as follows: "To stimulate postgraduate reading as a means of learning the new, recalling the useful, and dispossessing the old; and to stimulate interest in postgraduate studies." The committee also pointed out various secondary benefits, such as the building up of a useful personal library.

During the first year, 125 students (35 per cent) of the undergraduate student body subscribed to THIS JOURNAL. The campaign was renewed during the current year with even more spectacular results, the number of subscribers having increased to over 70 per cent of the undergraduate enrollment. Clifford Restler, the student committee chairman, states that the goal for next year is 100 per cent participation, and adds that the student chapters at other pharmacy schools should consider similar programs.

We wish to take this occasion to congratulate both the student chapter and the cooperative faculty at Columbia. The completely *voluntary and spontaneous* nature of this entire project is a real tribute to the professional attitude of the students and reflects their sincere dedication to develop themselves into knowledgeable pharmaceutical experts.

Review Article

Synthesis of Tetracycline Analogs

By G. C. BARRETT

NATURAL PRODUCTS possessing valuable physiological activity almost invariably have complicated structures; but simpler analogs representing part or parts of a natural product molecule may possess comparable activity, and the synthesis and testing of possible analogs has yielded useful new pharmaceuticals. This empirical approach to the synthesis of new drugs and antibiotics will eventually be replaced by more direct routes as soon as the mode of action of each family of compounds is fully understood. But while such knowledge is being slowly accumulated, useful advances have often accompanied the patterns of physiological activity shown by numerous analogs.

This article reviews the contributions of the study of analogs to the present understanding of the structural features essential for the characteristic activity of the tetracycline antibiotics. Large numbers of tetracycline analogs have been prepared by chemical modification of the natural products, and by modified fermentation techniques, and a comparative assessment of "tetracycline activity" in this series has revealed some of the basic structural requirements, variation of which may further yield simpler, highly active analogs. Physiologically active degradation products of the antibiotics are available by total synthesis, and other linearly fused tetracyclic, tricyclic, and bicyclic compounds have been prepared as potentially useful substitutes.

Received from the Department of Chemistry, University of Exeter, Devonshire, England.

The author thanks Dr. J. A. Barltrop, University of Oxford, for his introduction to and stimulating guidance in the field of tetracycline chemistry.

The objective of the present review may thus be fulfilled by a sequence of subsections describing the properties of the known tetracyclines and of the closely related compounds obtained from them; a critical discussion of the theory of the mode of action of the tetracyclines, and experimental facts relating to this theory; and the results of the synthesis and testing of analogs. Other reviews of the tetracyclines have appeared, stressing either their chemistry (1–4) or their general pharmacological properties and use (5, 6). General reviews are available (7, 8); that by Professor Shemyakin and his colleagues is a particularly complete account—both of the chemical and pharmacological aspects of the subject—of work published to mid-1960. The Russian treatise is to be published in English translation (9); the present review, therefore, aims at a complete literature coverage of the chemistry and pharmacological activity of the antibiotics and their analogs for the period 1960 to mid-1962. All known tetracycline analogs and reported pharmacological properties are listed in this review (Tables I and II), but the primary literature references quoted in (8) are not repeated here. However, the section describing *Totally Synthetic Tetracycline Analogs* aims at a complete coverage of the literature.

NATURALLY OCCURRING TETRACYCLINES

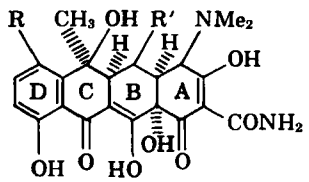
A strain of *Streptomyces*, uncataloged in 1948, was found to produce a remarkably effective antibiotic (10) which has since proved to be the first-discovered tetracycline. The pure active princi-

TABLE I.—TETRACYCLINES PRODUCED BY *Streptomycetes*

Name	Activity	References
Tetracycline	Highly active (8)	(8, 16, 17, 156)
7-Chlorotetracycline	Three to four times as active as tetracycline (8, 22, 60)	(8, 10, 11)
5-Hydroxytetracycline	Same activity as tetracycline (8, 22, 36, 60)	(8)
7-Bromotetracycline	Similar to chlortetracycline (8)	(19, 20, 21)
6-Demethyltetracycline	Same activity as tetracycline (8, 22, 60)	(22)
6-Demethyl-7-chlorotetracycline	Slightly less active than chlortetracycline (8, 22, 60)	(22)
5a,11a-(5,5a-?)[a] Dehydro-7-chlorotetracycline	Inactive (60). More than 50 times less active than tetracycline against *S. aureus* (8, 23)	(23)
2-Acetyl-2-decarboxamidotetracycline	Only 10% of the activity of tetracycline	(25)
2-Acetyl-2-decarboxamido-7-chlorotetracycline	Only 30% of the activity of tetracycline	(26)
2-Acetyl-2-decarboxamido-5-hydroxytetracycline	Only 10% of the activity of tetracycline	(26)

[a] Scott and Bedford (24) have suggested that the infrared spectrum of the dehydro-7-chlorotetracycline is more compatible with the 5,5a-location of the double bond.

ple was isolated as an orange-yellow hydrochloride (11); it was consequently named Aureomycin,[1] and its source was named *Streptomyces aureofaciens*. Degradative studies (12, 13) pointed to structural similarities with Terramycin,[2] a broad-spectrum antibiotic discovered in 1950 as a metabolite of *Streptomyces rimosus* (14). The brilliantly conducted study of the chemistry of Terramycin had progressed rapidly, and its structure and probable stereochemistry was published in 1953 (15); the name "tetracycline" was proposed (12) for a structure (I; R = R' = H) to which Aureomycin and Terramycin were simply related. Convenient to this nomen-

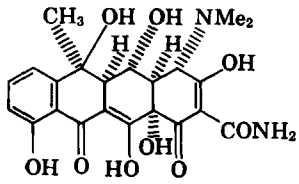


I

R = R' = H, tetracycline
R = Cl, R' = H, Aureomycin[1]
R = H, R' = OH, Terramycin[2]

clature was the later discovery that tetracycline itself is a highly active antibiotic which can be obtained by hydrogenolysis of chlortetracycline (16, 17), and is also produced by *S. aureofaciens* and by other *Streptomycetes* (18). Modifications to the environment in which the antibiotics are produced and the use of mutant *Streptomycetes* have since yielded a range of differently substituted tetracyclines. The members of this family available by biosynthesis are listed in Table I.

Results of the X-ray structural analysis (28) of oxytetracycline suggest that the molecule should be depicted as II.



II

Chemical evidence has been accumulated in support of both the α-orientation II (51, 157) and of the β-orientation I (15) of the dimethylamino-substituent at the 4-position in oxytetracycline; but the ease of epimerisation at this position must be responsible for these conflicting results (51), and it might be wisest now to picture naturally occurring 4- and 5-substituted tetracyclines as possessing the α-orientation at these positions, as shown in II. Recent papers (24, 29) are, indeed, adopting the relative stereochemistry indicated by the X-ray method. Independent X-ray studies (27, 163) have shown further that chlortetracycline and oxytetracycline possess the same configurations at all common asymmetric centers, and it is probable that all other naturally occurring tetracyclines may be assigned to this same configurational family.

CHEMICAL MODIFICATION OF NATURALLY OCCURRING TETRACYCLINES

Extension of the available totally synthetic routes to yield new tetracyclines cannot be an economic proposition, since the natural products are now relatively cheap and may be converted into a range of differently substituted tetracyclines by simple procedures. The variety of functional groupings, while conferring on the

[1] Subsequently the trade name of Lederle Laboratories for chlortetracycline hydrochloride.
[2] Subsequently the trade name of Chas. Pfizer and Co. for oxytetracycline hydrochloride.

molecule a bewildering complexity, makes it possible to envisage a host of small, feasible modifications; some modifications have been performed and, in general, the resulting compounds retain antibiotic activity if the natural configuration of the intact framework of the molecule is unaltered. Epimerisation at positions 4 and 5a results in almost complete loss of activity,[3] and the natural stereochemistry of the molecule is thus shown to be an essential prerequisite of physiological activity (105). Even though the inversion at C_6 which occurs (29) during the removal of the 6-hydroxy group by catalytic hydrogenolysis does not significantly reduce the antibiotic activity of the molecule, 6-deoxytetracyclines with the natural configuration of the 6-methyl group are appreciably more active than their C_6-epimers (29).

Methods are available for the selective removal and for the alteration of some existing substituents, and for the introduction of new functional groupings. New tetracyclines thus obtained from the natural products are listed in Table II, and their reported activities are quoted. A place is found in the Table for any particular modified tetracycline by checking its formula through the following sequence:

(*A*) 6-Deoxytetracyclines
  (*a*) 6-Deoxytetracyclines (excepting 5a,-6-anhydrotetracyclines)
  (*b*) 6-Demethyl-6-deoxytetracyclines
  (*c*) 6-Methylene-6-demethyl-6-deoxytetracyclines
  (*d*) 5a,6-Anhydrotetracyclines
  (*e*) Dedimethylamino-5a,6-anhydrotetracyclines
(*B*) 2-Carboxamide-modified tetracyclines
(*C*) Dimethylamino-modified tetracyclines
(*D*) Dedimethylamino-tetracyclines
(*E*) O-Acylated- and O-alkylated-tetracyclines
(*F*) Other modified tetracyclines

Comparative figures are available for many of the more active naturally occurring and chemically modified tetracyclines, and these figures are listed in Table III. The commonly used assay methods (57, 58) yield some inconsistent results, and activities are therefore quoted in Table II in qualitative terms, either in the words used in the reference cited or as implied by the figures in Table III.

Although a useful variety of transformations has been achieved in this series, it should be emphasized that the methods now available lead only to certain classes of analogs. Thus, D-ring substituents cannot be introduced by electrophilic substitution reactions into the parent tetracyclines, but may be introduced into more stable 6-deoxy- and 5a,6-anhydrotetracyclines.

Many analogs are thus potentially accessible only by total synthesis; but the development of methods which can augment the range of modified tetracyclines may now be expected. The new methods may involve ever more circuitous routes, and the general pattern is likely to involve the conversion of the natural products into their more stable anhydro-derivatives, followed by specific substitution and reconversion into the substituted tetracycline by oxygenation. The 6-hydroxy-group can be introduced into anhydroaureomycin by microbiological agents (59), or *via* the 6-hydroperoxy-compound (obtained by bubbling oxygen through an irradiated benzene solution of the anhydro-compound) (24), and these procedures, which yield the tetracycline with the natural C_6 configuration, are likely to be widely used. Oxygenation of certain 12a-deoxytetracyclines is also a simple matter by a microbiological method (*Circularia lunata*) (62, 63), by means of perbenzoic acid (64) [not applicable to 12a-deoxytetracycline (65, 51)], or with oxygen in the presence of sodium nitrite (61, 63) or in the presence of a noble metal (66). Other inorganic oxidizing agents can be used for 12a-hydroxylation (150).

The range of modified tetracyclines listed in Table II includes derivatives (for example, the halogen-substituted and diazonium modifications) suitable for further elaboration into antibiotics with novel substituents; particularly, the 6-methylenetetracyclines offer an entry into a new family of 6-substituted 6-deoxytetracyclines likely to possess high activity.

MODE OF ACTION OF THE TETRACYCLINES

The tetracycline molecule clearly depends more for useful activity upon the presence of the sequence of oxygen functions, from the phenolic hydroxyl at C_{10} and the groups at C_{11} and C_{12} through to the ring A 1,3-diketone grouping, than upon the presence of substituents at carbons 4–9. Other essential structural requirements also may be deduced from the relative activities of the various classes of modified tetracyclines; first, that the 2-carboxamide substituent also seems to have an essential role, since its replacement by a cyano- or acetyl-grouping greatly reduces antibiotic activity in this series. 2-Carboxamide-N-mono-substituted tetracyclines retain full activity, and this may indicate that the —CO—NH— grouping at the 2-position is a minimum requirement for activity. This conclusion suggests that the 2-substituent should be capable of forming the chelated structure III

[3] 4-Epi-tetracyclines are active *in vivo* but are almost devoid of activity against the standard assay organisms; conversion into the natural isomer might occur in the tissues of the laboratory animals, resulting in the observed *in vivo* activity.

TABLE II.—SUBSTITUENT-MODIFIED TETRACYCLINES

-tetracycline	Activity	Refs.
-6-Deoxytetracyclines		
6-Deoxytetracycline	Slightly less active than tetracycline	(29)
6-epi-methyl-	Half as active as tetracycline (29); similar activity to tetracycline (8).	(8, 30, 38)
5-Hydroxy-	More active than oxytetracycline	(29)

involving the oxygen functions at positions 1 and 3. Second, the removal of the 12a-hydroxyl group deprives tetracycline of its activity, but O^{12a}-esters are highly active (49); the presence of a substituent larger than hydrogen may be the simple requirement at this position. Thus, replacement of the 12a-hydroxyl group of dedimethylamino-5-hydroxy-5a,6-anhydrotetracycline by methyl with simultaneous inversion of configuration yields an active antibiotic, though the very different antibacterial spectrum of 5a,6-anhydrotetracyclines (suggesting that a different mode of antibacterial action applies to this class (130, 131)) reduces the validity of this comparison. The presence of a 9-nitro-substituent greatly reduces antibiotic activity, whereas 7-chloro-tetracyclines are invariably more active than their unsubstituted analogs. The phe-

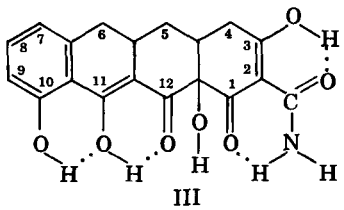
[a] Pelcak and Dornbush's method (58) was modified for this set of results by the addition of 10% normal horse serum to the test medium. This modification yields results more closely paralleling those of *in vivo* tests. [b] *In vitro* against *S. aureus*.

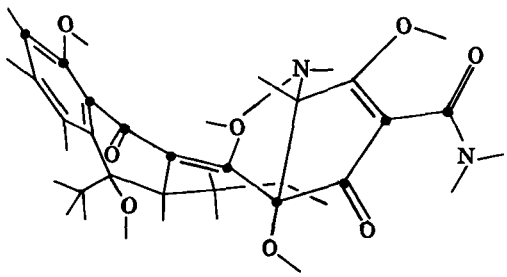
nolic hydroxyl group at position 10 is assumed to have an important role (*vide infra*), and its effective performance may be impaired by hydrogen-bonding with the nitro-group (34). The opposite effect of the 7-chloro-substituent is consistent with its capability (67) of electron-release to the para-position.



III

The deduction (138) that the 11 and 12 oxygen functions, augmented by the effect of the phenolic hydroxyl at C_{10}, are primarily responsible for holding metal ions with which tetracyclines form strong chelates (68–70) does not satisfactorily explain the function of the A-ring substituents, if the antibiotic activity of the tetracyclines is accepted to be due to the disturbance of certain enzyme systems by chelation of vital trace metals (68). Ferric ions are strongly held by the tetracyclines (68, 69); also by 8-hydroxyquinoline, which is a potent antibacterial (71–73). The tetracyclines may inhibit protein synthesis by chelation of essential metals, resulting in the production of unstable, small molecular weight RNA (74), but no experimental evidence is yet available in support of this theory. It is known, however, that chlortetracycline inhibits the action of an aromatic nitro-reductase by combining with manganese ions essential to the function of this enzyme (75); also that oxidative phosphorylation in liver mitochondria preparations, inhibited by the presence of chlortetracycline (76, 77), again proceeds normally when an excess of magnesium ions is added to the nutrient medium (77). Significantly, it has been found that the antibacterial action of chlortetracycline and of oxytetracycline is inhibited in the presence of magnesium ions (78). The conclusion, drawn from studies of *E. coli* extracts, that chlortetracycline exerts its antibiotic action by inhibiting electron-transport in sensitive organisms (79) takes account of the fact that the electron-transport enzymes and nitro-reductases of *Neurospora crassa* (80) and of *E. coli* (81, 82) are known to be metalloflavins. Chlortetracycline-sensitive nitro-reductase concentrates contain easily dissociable flavin, whereas the flavin is firmly bound in resistant species (83); the point of inhibition by the antibiotic is concluded to be the stage of reoxidation of conjugated flavoproteins (79).

It has been pointed out that epimerisation at positions 4 and 5a results in almost complete loss of antibiotic activity, and that the 6-epimer is significantly less active. As can be visualized from the scale drawing IV, the spatial relationships between parts of the molecule must be affected by epimerisation, but it is not obvious that the consequent changes in the shape of the molecule would limit the chelating ability of the sequence of oxygen functions involved—though interaction between the 4-dimethylamino-group and the oxygen functions at carbons 10, 11, and 12 is a distinct possibility in 4-epi-tetracyclines. Unless the varying antibiotic activities shown by modified tetracyclines can be directly related to their ability to form more or less strong metal chelates, then other factors must also be essential to the activity of this group of antibiotics.



IV

BIOSYNTHESIS

An exact understanding of the stepwise synthesis of tetracyclines *in vivo* can suggest ways by which new tetracyclines may be obtained from normal and mutant *Streptomycetes*, utilizing nutrient media in which new substrates replace the "building blocks" essential to the normal biosynthetic route.

The production of 7-chlorotetracycline by *S. aureofaciens* is dependent upon the presence of ionic chlorine in the nutrient medium, but the total yield of tetracyclines produced under conditions of low halide concentration is unchanged since tetracycline itself then forms in increased amount (21). Thiocyanate, added to the usual *S. aureofaciens* nutrient medium, also inhibits 7-chlorotetracycline synthesis but the total yield of tetracyclines is again unchanged (146, 21). The same organism can be induced to synthesize 6-demethyl-7-chlorotetracycline in addition to 7-chlorotetracycline by contamination of the nutrient medium with sulfonamides (84); the proportion of the 6-demethyl compound formed under these conditions can be made smaller by the addition of methionine to the medium. Halogenation and methylation are thus shown to be

late steps in the biosynthetic sequence. Mutant strains of the tetracycline-producing organisms can produce only modifications of the normal product of their earlier generations in some cases because they cannot complete the biosynthetic route; thus, the 7-chloro-5a,11a-(5,5a-?)dehydrotetracycline produced by *S. aureofaciens* "S 1308" (23, 59) is converted into 7-chlorotetracycline by the normal strain of the organism (59), also by other mutants (146). The 6-demethyl- and the 2-acetyl-2-decarboxamido-tetracyclines listed in Table I are also produced by mutant *Streptomycetes*.

The "head-to-tail" linkage of acetate units (86), predicted by Robinson (85), has been demonstrated to be the route by which the skeleton is largely built up, the 6-methyl substituent and the dimethylamino methyl groups being derived from methionine (87). Glutamic acid is probably the basis of the larger part of ring A(87).

Incorporation of isotopically-labeled acetic acid (both carboxyl-^{14}C- and methyl-^{14}C- labeled forms) (87, 88), glycine-2-^{14}C (88), and methionine-$^{14}CH_3$ (87) has been separately demonstrated. The dimethylamino group in chloro-

V

tetracycline contains 40% of the total radioactivity when glycine-2-^{14}C is used as substrate for *S. aureofaciens*, but carboxyl-^{14}C-glycine is not significantly utilized (88).

The use of mutant strains (59) to oxygenate anhydrotetracyclines has been mentioned, and current investigation of precursor activity possessed by other tetracycline degradation products might be extended to make available new biosynthetic tetracyclines from modified precursors, and from new mutant *Streptomycetes*.

of oxytetracycline and chlortetracycline were announced between 1951 and 1959 (89–96, 148, 152), and papers describing syntheses of simple model compounds date from 1956. Initial stages in projected total syntheses of tetracyclines were announced in 1957 by several research groups, and their continued efforts during later years were augmented by work in other laboratories; the objective has recently been realized by the total synthesis of (±)-6-demethyl-6-deoxytetracycline (97).

The complex stereochemistry and substitution of the tetracycline molecule has inspired many different conceptions of its total synthesis, each route representing a particular approach to the solution of problems of stereochemistry and synthesis. The most successful approach follows, in broad outline, the probable biogenetic route; various forms of the Claisen condensation are employed in the stepwise fusion of rings C, B, and A to a benzene derivative carrying the ring D substituents and a basis for the construction of ring C. The approach is exemplified by each of the syntheses outlined in Figs. 1–6; the products obtained by the routes in Figs. 2, 3, 4, and 5 were proved to be identical to the appropriate tetracycline degradation products. Although an adaptation of Woodward's synthesis (Fig. 5) has not yet been announced which leads to a naturally occurring 6-substituted tetracycline, and Muxfeldt's and Boothe's earlier routes (Figs. 2 and 3, respectively) yield dedimethylamino-anhydrotetracyclines, the major problems in this approach to the total synthesis have been overcome. Other research groups have reported initial stages in related syntheses, *e.g.*, synthesis of VI (92) (see also (95)), VII (98), and stereoisomers of VIII (99) (see also (161)), and model reactions have supplied useful guidance to crucial steps—the introduction of the N,N-dimethylglycine residue in Woodward's synthesis was earlier worked out, in principle, by Shemyakin's

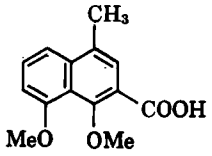
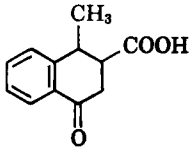
VI



VII

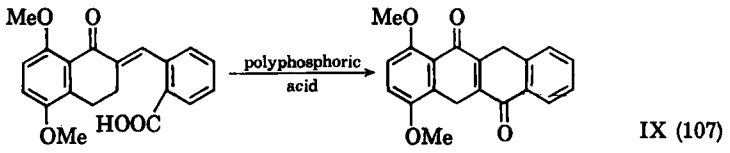


VIII

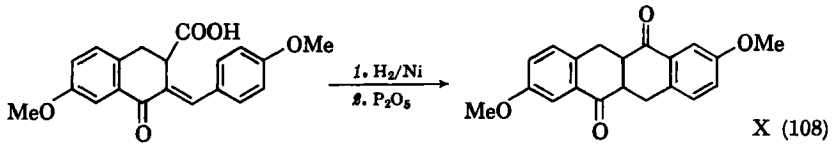
group (100), starting from cyclohexanone as a model.

Modification of each of the syntheses outlined above is easily visualized to yield many differently substituted tetracyclines, possibly with improved medical properties; and the outcome of other approaches to the total synthesis may provide alternative routes to modified tetracyclines.

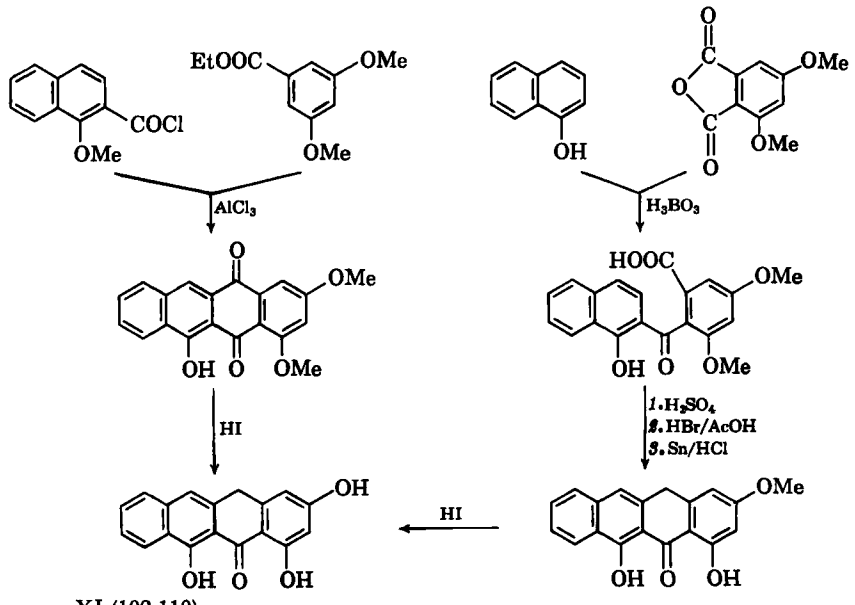
Naphthacene derivatives IX, X, and XI have been synthesized as more or less distant relatives of the antibiotics; compounds XI and XII of this group are closely similar to dedimethylamino-terrarubein, a degradation product of oxytetracycline (15). The naphthacene derivative XIII was found to possess less than 0.1% of the antimicrobial activity of chlortetracycline



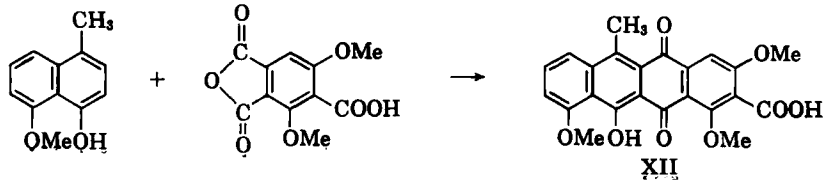
IX (107)



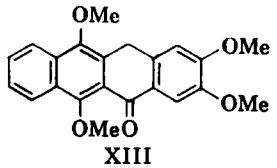
X (108)



XI (109,110)



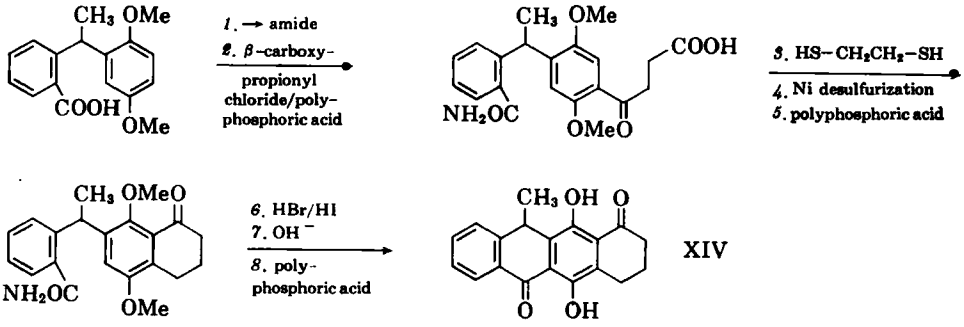
XII



XIII

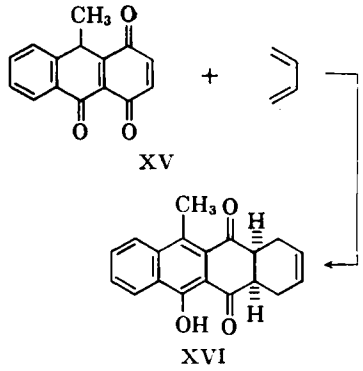
(111, 161); it is the only compound of this class whose antibiotic activity has been reported. The dark orange tetracycline analog XIV was built up as shown (112).

The more successful analogs are likely to be those which incorporate features of the stereo-



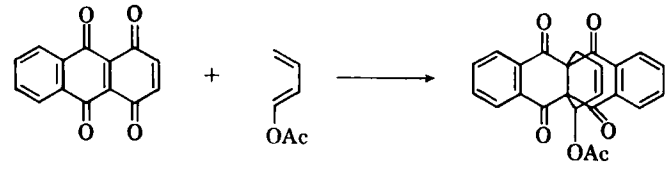
XIV

chemistry of the natural tetracyclines, and the Diels-Alder reaction has been used for the synthesis of a variety of compounds containing *cis*-fused rings corresponding to rings A and B. The tricyclic quinone XV has been reported (109, 113) to yield with butadiene the expected adduct XVI, although the same quinone was earlier (112) found to be unstable to Diels-Alder reaction conditions with butadiene.

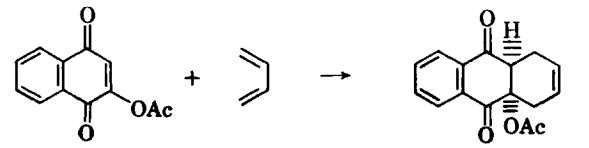


XV XVI

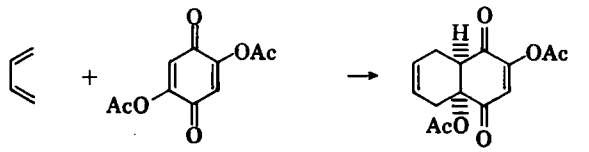
Quinazarinquinone XVII failed to yield the expected tetracycline analog with 1-acetoxybutadiene, but *cis-trans*-1,4-diacetoxybutadiene added



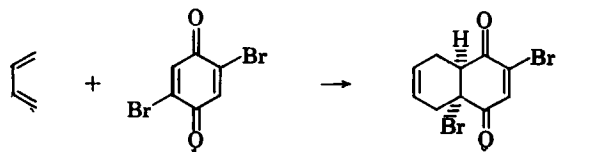
XVII



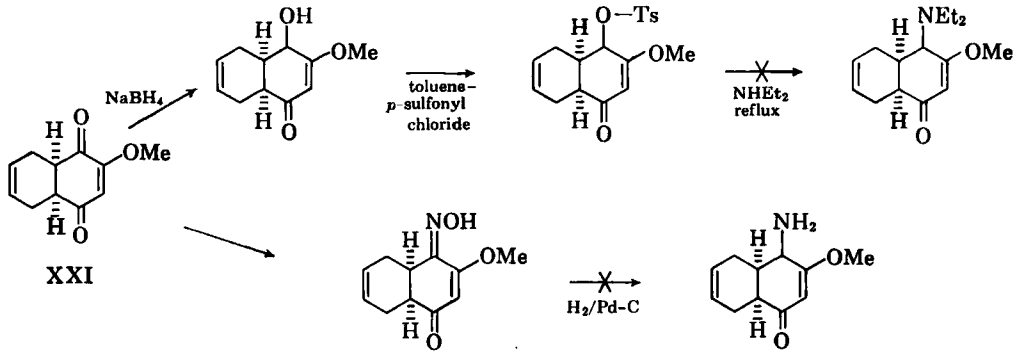
XVIII (115)



XIX (115)



XX (96)



normally (114). Related two- and three-ring model compounds have been prepared, some (XVIII, XIX) carrying an oxygen function at the ring junction. The unstable adduct XX could not be converted into XIX by treatment with silver acetate (96). One carbonyl group in the adduct XXI from butadiene and 2-methoxybenzoquinone can be selectively reduced, and the adduct can be converted into its mono-oxime; but efforts to introduce a nitrogen function corresponding to the ring A dimethylamino-substituent were not successful (116).

Nakamichi (117) has prepared adducts from *p*-toluquinol and a series of symmetrical and unsymmetrical dienes, and has reported that the adducts with isoprene and with cyclohexadiene showed marked *in vitro* activity.

The model compound XXII carries five oxygen functions, disposed in almost the same spatial arrangement as those of rings A and B of oxytetracycline, and may possess useful activity, in confirmation of the role played by the A- and B-ring substituents in conferring activity on the tetracycline molecule, when converted into its 2-carboxamide (118).

The Diels-Alder reaction has been applied also to the incorporation of the B-C ring-junction into intermediates potentially suitable for total synthesis of tetracyclines. Derivatives of juglone XXIII yield adducts XXIV with 1-acetoxybutadiene (119), with *cis-trans*-1,4-diacetoxybutadiene (120), and with 2- and 3-substituted butadienes (121), and one of the carbonyl groups in some of the various products is selectively

XXIII XXIV XXV XXVI

attacked during their reaction with one equivalent of methyl magnesium iodide (121, 122), yielding the useful intermediate XXV from the adduct XXIV (R = OMe, R_1, R_2, R_3, R_4 = H). Further elaboration (123) of XXV has yielded the chloroketone XXVI (for the synthesis of a tetracycline from an analog of XXV see Fig. 6), which appears suitable for use in the route developed for the synthesis, from 2-chlorocyclohexanone, of a model compound carrying the ring A substituents with the exception of the dimethylamino group (124, 125, 164).

The overall route should thus yield (±)-dedimethylamino-12-deoxy-tetracyclines with the natural stereochemistry. New routes to XXVII have been reported recently (126) by the Moscow workers, who have also achieved the synthesis

of its 4-dimethylamino-analog XXVIII. The synthesis of a tetracycline, outlined in Fig 6, also involves the cyanohydrin-lactone sequence exemplified in the syntheses of the model compounds XXVII and XXVIII.

The possibility that the naphthoquinone-butadiene adducts XXIV might be selectively reduced, to yield tricyclic intermediates suitable for the synthesis of 6-demethyltetracyclines, has also been investigated (126). 1,4,4a,9a-Tetrahydroanthraquinone (XXIX) yields the ketol XXX with one equivalent of $LiAlH_4$, and further elaboration has yielded the epoxide XXXI suitable for the route outlined in Fig. 6.

XXIX XXX XXXI

Several model compounds, XXXII–XXXIV, containing the chelating carbonyl and enolic oxygen functions of the tetracycline molecule have been synthesized; no activities have been reported. The tetrahydroanthracene XXXV possesses appreciable activity (30 oxytetracycline units per milligram) (130, 131, 132); its mono-, di-, and tri-chloro- and bromo-derivatives

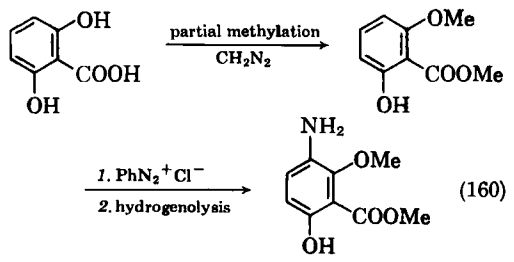
valent metal ions (134); dioxo-octahydroanthracene acetic acid derivatives are similarly effective (135), and tetraloneacetaldehyde derivatives (*e.g.*, XXXIX) possess fungicidal properties (149).

The model compound XL incorporates the main features of rings A, C, and D of 7-chloro-6-demethyl-6-deoxy-tetracycline, and of rings A, B, and D of chlortetracycline, but it is quite inactive (139). It is structurally related to the active tetrahydroanthracene XXXV, and the reason for the differing activities of these two compounds possibly lies in the differing potential chelation sites presented by them to metal ions.

Several ring A analogs are available, compounds XLII (b, c, and e) possessing weak tetracycline activity.

Appropriately substituted benzene and naphthalene models for ring A have been synthesized.

The minimum requirements for activity (discussed in the section of this review devoted to *The Mode of Action of the Tetracyclines*) revealed by antibiotic assays of tetracyclines derived from the natural products are a useful guide to future syntheses of simpler analogs. However, few of the available totally synthetic tetracycline analogs appear to have been tested; those bearing structural similarities with the



(160)

A-ring analogs, XLII, the BCD-rings analog, XXXV, and the *p*-toluquinol-isoprene and *p*-toluquinol-cyclohexadiene adducts (117) may possess similar activity.

Esters of Bicyclic Aminoalcohols as Potential Anticholinergics III

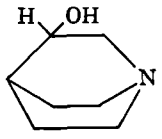
Synthesis of Some Isomeric Hydroxy-1-azabicyclononanes and Certain of Their Esters†

By MICHAEL J. MARTELL, JR.‡ and TAITO O. SOINE

Attempts to improve upon the literature preparation of 3-oxo-1-azabicyclo[3.2.2]-nonane failed. The previously unknown aminoalcohol 3-hydroxy-1-azabicyclo-[3.3.1]nonane (VI) was synthesized in good yield. The described synthesis of 8-hydroxy-1-azabicyclo[4.3.0]nonane (VII) was improved considerably and a series of nineteen esters of VI and VII was prepared using five acids. The pharmacological testing of the esters is reported.

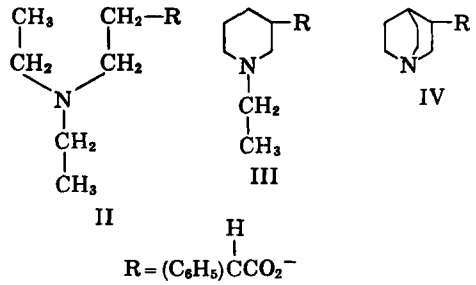
THESE laboratories have been engaged for some time (1) in the synthesis of esters of bicyclic aminoalcohols as potential spasmolytics. The paucity of information in this area has been discussed in the earlier papers.

Referring to the work of Sternbach and Kaiser (2), one can see from models that 3-quinuclidinol is arranged in a compact, rigid cage-type structure, the piperidine ring of which exists in the boat form (I).



I

The inflexibility of the molecule may have some bearing on the marked spasmolytic activity of its esters when one considers the differences in activity between 2-diethylaminoethyl diphenylacetate[1] (II), piperidolate[2] (III), and the diphenylacetate of 3-quinuclidinol (IV). 2-Diethylaminoethyl diphenylacetate has roughly the same order of activity as piperidolate (3), and is about 1/4 as active as atropine (4). However, racemic IV is equal in activity to atropine and the (−) enantiomorph is twice as active.



II III IV

R = $(C_6H_5)CCO_2^-$

To further explore the subtle effects of molecular flexibility on spasmolytic activity, it was decided to synthesize the aminoalcohols V, VI, and VII, if possible, and to prepare a representative selection of esters from them to be tested for anticholinergic activity. These isomeric bicyclic aminoalcohols are all β-aminoalcohols, esters of which have been shown to be the most active, particularly in the bicyclic series (5).

Received June 20, 1962, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Minnesota, Minneapolis.

Accepted for publication August 9, 1962.

Taken from the Ph.D. dissertation of Michael J. Martell, Jr., presented to the College of Pharmacy, University of Minnesota, Minneapolis.

The authors wish to express their deep gratitude to Dr. T. M. Lin and Mr. C. E. Powell and their assistants of the Division of Pharmacology, The Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, Ind., for the pharmacological screening of the esters.

Presented to the Scientific Section, A.PH.A., Washington, D. C., meeting, August 1960.

† Paper II in this series, Counsell, R. E., and Soine, T. O., THIS JOURNAL, 49, 289(1960).

‡ Samuel W. Melendy Fellow, 1956–1958. Present address: Organic Chemical Research Section, Lederle Laboratories, American Cyanamid Co., Pearl River, N. Y.

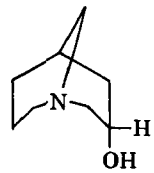
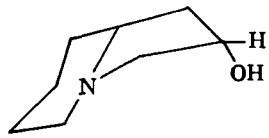
V



VI



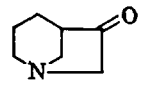
VII

The stereochemistry of 3-hydroxy-1-azabicyclo-[3.2.2]nonane (V) [and quinuclidine (6)], as well as 3-hydroxy-1-azabicyclo[3.3.1]nonane[3] (7, 8) (VI), and 8-hydroxy-1-azabicyclo[4.3.0]nonane[4] (VII) (as a special azahydrindane (9)) has been adequately discussed in the literature. Suffice it to say that, as one passes from V to VII, the molecular flexibility is increased among these isomers.

The aminoalcohols in this study were prepared by the Dieckmann synthesis for aminoketones possessing a bridgehead nitrogen (10, 11). It was found impractical, according to this method, to prepare suitable quantities of V and esters of this aminoalcohol were not prepared. The other two aminoalcohols, VI and VII, were prepared in good yield, however.

For these aminoalcohols the three isomeric pyridylacetic esters were required as key intermediates in good quantity.[5]

Although VII had been prepared previously (12), the synthesis was impracticable in part. Ethyl 2-pyridylacetate was best prepared by the method of Winterfeld and Flick (13). Reduction of the pyridine ring was carried out as described (1), followed by alkylation with ethyl chloroacetate in the presence of anhydrous potassium carbonate (12). The diester thus obtained was best cyclized to the aminoketone using high dilution methods and employing potassium *tert*-butylate in a nitrogen atmosphere (14, 15). Reduction of the aminoketone to the alcohol in water by sodium borohydride was accomplished in nearly quantitative yield. Although the aminoketone was rapidly air-oxidized, the aminoalcohol was quite stable. The reduction product appears identical with the product prepared by Clemo and Metcalf (12) by sodium and alcohol reduction.[6]



i

Although several syntheses of 3-pyridylacetic ester are published in the literature, none appeared to be suitable without modification as an intermediate to VI. A sample of 3-pyridylthioacetmorpholide (16, 17) prepared from 3-acetylpyridine (18, 19) was converted directly to ethyl 3-pyridylacetate. Refluxing the thiomorpholide with concentrated hydrochloric acid (18) and replacement of the acid with alcohol and sulfuric acid gave good yields of the desired ester. Quaternization of the ester with ethylbromoacetate proceeded smoothly as did the subsequent reduction to the diester. Cyclization with potassium *tert*-butylate as described (14) gave the desired aminoketone in 74% yield. Sodium borohydride reduction in water afforded only one isomer.[7]

The preparation of the aminoketone corresponding to V according to the procedure of Leonard and co-workers (14) failed to give better yields than the 0.7% conversion reported in the Dieckmann reaction. Attempts to improve the yield by employing other catalysts or changing reaction conditions were fruitless. It would seem that perhaps the three carbon atom bridge increases greatly the extent of nonbonded interactions in the piperidine ring over that of quinuclidine (6).

Substantial improvements in the published methods for the preparation of ethyl 4-pyridylacetate were developed and 4-pyridylthioacetmorpholide was conveniently prepared by the reaction of 4-vinylpyridine, sulfur, and morpholine in the presence of hydroquinone. The thiomorpholide was converted directly to the ester by simply refluxing with equal weights of

[3] Although *Chemical Abstracts* catalogs this nucleus under the name 1-isogranatanine, in accordance with the nomenclature suggested by McElvain and Adams, *J. Am. Chem. Soc.*, **45**, 2744(1923), the authors prefer the 1-azabicyclo terminology to maintain consistency and to demonstrate the correlation among isomers.

[4] *Chemical Abstracts* prefers the name octahydropyrrocoline for this nucleus (see above). Other trivial names include piperolidine, indolizidine, and δ-coniceine.

[5] The 2, 3, and 4-pyridylacetic acids are now commercially available (Aldrich Chemical Co.). For a review of methods of synthesizing the isomeric pyridylacetic acids and their derivatives see M. J. Martell, Jr., Ph.D. thesis (University of Minnesota, 1958).

[6] These authors also reported the isolation of another "isomeric aminoalcohol" as a by-product of the Clemmensen reduction of the aminoketone. However, such a product seems unlikely, and, although no reinvestigation of this result was undertaken, it would seem that cleavage during reduction had taken place, probably to 2-piperidylacetone, isomeric with the aminoalcohol. Leonard and co-workers (14) have shown that *i* is cleaved during Clemmensen reduction to 3-acetylpiperidine.

[7] The reduction of bicyclic aminoketones of the bicyclo-[3.3.1]type has been investigated recently and excellently reviewed [Zirkle, C. L., Gerno, F. R., Pavloff, A. M., and Burger, A., *J. Org. Chem.*, **26**, 395(1961)] and shows that attack with large reducing groups is from the unhindered side giving the less thermodynamically stable axial conformer, which indeed VI may well be. Reduction with sodium and amyl alcohol gives the more stable equatorial conformer. We are presently investigating this reduction in greater detail.

absolute alcohol and sulfuric acid (23). Formation of the quaternary salt and subsequent reactions followed those described by Leonard, *et al.* (14).

The acid chloride method, as described by Counsell and Soine, was used for the preparation of the esters of diphenylacetic and xanthene-9-carboxylic acids. Transesterification in *n*-heptane, using a trace of sodium hydride as catalyst, conveniently transformed the methyl esters of benzilic, phenyl-2-thienylglycolic, and 9-hydroxyfluorene-9-carboxylic acids to the corresponding esters of the respective aminoalcohols.

Published methods (20, 21) for the synthesis of phenyl-2-thienylglycolic acid were unsatisfactory for our purposes and therefore a direct synthesis of its methyl ester was developed. Thus, the action of 2-thienyl magnesium bromide on methyl phenylglyoxylate gave fair yields of methyl phenyl-2-thienylglycolate.

Examination of the pharmacological data presented in Tables I and II readily reveals that whatever differences in activity exist between corresponding esters of VI and VII are small indeed, and lie well within the errors presented by the testing methods. The compounds, however, are quite potent anticholinergic agents.

All of the esters were tested in Shay (pyloric ligated) rats (22) and their effects on gastric secretion noted. Only five esters were either sufficiently active or well absorbed orally to demonstrate significant activity. The benzilate and xanthene-9-carboxylate methobromides of VII showed minimal action on gastric acid and no effect on gastric secretion volume at 40 mg./Kg. The phenyl-2-thienylglycolate methobromide of VII had minimal action on both acid and volume at 20 mg./Kg. The phenyl-2-thienylglycolates of VI showed unusually high activity. The methobromide was effective at only 40 mg./Kg. but the hydrochloride was active at 10 mg./Kg. These last two compounds were tested in Heidenhain denervated and Thomas innervated chronic fistula dogs, and the effect on the gastric secretion observed. The methobromide in oral doses of 0.1–0.25 mg./Kg. produced slightly delayed onset of acid secretion. However 0.5 mg./Kg. caused suppression of gastric acid output by at least 50% in two dogs. At 0.05–0.1 mg./Kg., taken intravenously, the acid secretion was completely suppressed in two dogs. The hydrochloride in dogs was very potent. Oral doses of 0.5 mg./Kg. completely inhibited secretion of acid for 5 hours in 4 dogs (3 denervated, 1 innervated), but serious side effects probably resulting from central stimulation (5) were observed. At doses of 0.1 mg./Kg., side effects were reduced and the gastric secretion was still abolished for at least 5 hours. In this type of test, atropine abolishes gastric secretion at about 0.065 mg./Kg.[8]

EXPERIMENTAL[9]

4-Pyridylthioacetmorpholide.—A mixture of redistilled morpholine (45.7 Gm., 0.525 mole), freshly distilled 4-vinylpyridine[10] (50.0 Gm., 0.475 mole) containing 1% of hydroquinone, and sulfur (31.0 Gm., 0.95 Gm. atom) were placed in a 200-ml. flask equipped with a reflux condenser. The sulfur dissolved and the temperature of the solution rose to 110°. The solution was then heated at 160° for 2 hours, during which time hydrogen sulfide evolved. The solution was poured into cracked ice, stirred until solid, filtered, pressed as dry as possible, washed with ice water, dried and recrystallized from absolute ethanol. This procedure gave 56.0 Gm. (53%) of slightly impure material, m.p. 103–106° [m.p. 104–105.5° lit. (17)].

Ethyl 3-Pyridylacetate.—3-Pyridylthioacetmorpholide (195 Gm., 0.88 mole) (16, 17) was dissolved in concentrated hydrochloric acid (200 ml.) and the solution refluxed for 2.5 hours. The solution was cooled, filtered until clear, and evaporated to dryness *in vacuo*. The residue was dissolved in absolute ethanol (400 ml.) and the solvent distilled under reduced pressure to remove traces of water. The solid was again dissolved in absolute ethanol (500 ml.) and concentrated sulfuric acid (200 ml.) was added with cooling. The solution was allowed to stand for 24 hours at room temperature, after which it was refluxed for 1 hour. The cooled solution was poured slowly with stirring into 600 ml. of ice-cold concentrated ammonium hydroxide solution in an ice bath and the ester extracted with five 150-ml. portions of ether. The ether extracts were dried over anhydrous sodium sulfate and the solvent removed *in vacuo*. The product was distilled to give 92.5 Gm. (64%) of a light greenish liquid, b.p. 65° (0.1 mm.), n_D^{20} 1.5000 [b.p. 121–122° (10 mm.), lit. (17)].

Diethyl Pyridinium-1,3-diacetate Bromide.—Ethyl 3-pyridyl acetate (92.5 Gm., 0.56 mole), ethyl bromoacetate (94.0 Gm., 0.56 mole), and absolute ether (200 ml.) containing absolute ethanol (10 ml.) were mixed, briefly stirred, and left at room temperature for 24 hours. The oil that separated solidified upon scratching. The solid was separated by filtration, washed well with anhydrous ether, and dried to give 176 Gm. (94.5%) of product suitable for reduction. A sample was crystallized

[8] Dr. T. M. Lin, Eli Lilly and Co., personal communication.

[9] All melting points were determined on a calibrated Kofler micro hot stage apparatus unless otherwise specified, in which case they are uncorrected as are the boiling points. The microanalyses were performed by Wm. Kuryla and Mrs. Olga Hamerston of the Microanalytical Laboratories, School of Chemistry, University of Minnesota, or by Drs. Weiler and Strauss, Microanalytical Laboratories, Oxford, England. The infrared spectra were determined by the Spectroscopy Laboratory, School of Chemistry, University of Minnesota, on a Perkin-Elmer model 21 doublebeam spectrophotometer using sodium chloride optics.

several times from butanone to give hygroscopic colorless prisms, m.p. 81–82°.

Anal.—Calcd. for $C_{13}H_{18}BrNO_4$: C, 47.00; H, 5.46. Found: C, 47.27; H, 5.49.

Diethyl Piperidyl-1,3-diacetate.—Crude diethyl pyridinium-1,3-diacetate bromide (50 Gm., 0.15 mole) in glacial acetic acid (150 ml.) and water (50 ml.) was hydrogenated at 2–3 Atm. at room temperature, using 0.7 Gm. of platinum oxide catalyst. After uptake of hydrogen had ceased, the catalyst was removed by filtration and the solution evaporated to a syrup *in vacuo*. The syrup was neutralized with 25% aqueous sodium hydroxide solution and the diester extracted with five 50-ml. portions of ether. The ether extracts were dried over anhydrous sodium sulfate and the ether removed under reduced pressure. The residue was distilled to give 33.6 Gm. (87% yield) of product as a colorless oil, b.p. 110–111° (0.15 mm.), n_D^{25} 1.4607.

Anal.—Calcd. for $C_{13}H_{23}NO_4$: C, 60.67; H, 9.01. Found: C, 60.65; H, 8.97.

The picrate was formed in and recrystallized from absolute ethanol, m.p. 92–93°.

Anal.—Calcd. for $C_{19}H_{26}N_4O_{11}$: C, 46.92; H, 5.39. Found: C, 46.90; H, 5.53.

3 - Oxo - 1 - azabicyclo[3.3.1]nonane. — Anhydrous xylene (2500 ml.) and freshly trimmed potassium (45.6 Gm., 1.17 Gm. atoms) were placed in a 5-L. three-neck flask, equipped with a mechanical stirrer, reflux condenser fitted with a drying tube, and a dropping funnel. The xylene was heated and the potassium pulverized with vigorous stirring under a stream of dry nitrogen, which was maintained throughout the reaction. The heat was removed and *tert*-butyl alcohol (freshly distilled from calcium hydride) (325 ml., 3.5 moles) was added at such a rate as to maintain a gentle reflux. The mixture was then stirred and refluxed until all the potassium had reacted. The excess alcohol was removed by collecting 1200 ml. of azeotrope by means of a Dean-Stark trap. A solution of diethyl piperidyl-1,3-diacetate (120 Gm., 0.47 mole) in anhydrous xylene (800 ml.) was added over a period of 10 hours with vigorous stirring followed by a period of 20 hours of refluxing and stirring, the ethanol-xylene azeotrope being removed the entire time. The mixture, which by now was reduced in volume to about 1 L. was cooled in ice, and 400 ml. of 6 *N* hydrochloric acid was added with vigorous stirring. The xylene layer was extracted twice more with 200-ml. portions of 6 *N* acid, and the combined acid extracts refluxed for 8 hours. The cooled solution was basified to pH 9 with 50% aqueous potassium hydroxide, with cooling, saturated with solid potassium carbonate, and extracted with six 200-ml. portions of benzene. The combined benzene extracts were dried and the solvent removed at slightly reduced pressure. The solid residue was sublimed at 70° and 0.1 mm. pressure to give 47.7 Gm. (73.5%) of product as tiny colorless prisms. A sample was recrystallized twice from Skellysolve B and sublimed for analysis, m.p. 123–125° (capillary with slight decompn.). The infrared spectrum (potassium bromide) showed carbonyl absorption at 1705 cm.$^{-1}$.

Anal.—Calcd. for $C_8H_{13}NO$: C, 69.03; H, 9.41. Found: C, 68.79; H, 9.40.

The hydrochloride salt melted at 292–293° (decompn. and sublimation, capillary) after several recrystallizations from *iso*propyl alcohol.

Anal.—Calcd. for $C_8H_{14}ClNO$: C, 54.70; H, 8.00. Found: C, 54.91; H, 7.93.

[a] Expressed as percentage of activity of atropine sulfate. [b] Alleviation due to blocking spasm, induced by 1:10,000,000 dilutions of methacholine, on an isolated guinea pig ileum. [c] Alleviation due to blocking depressor response to 1 mcg./Kg. intravenously of methacholine on the blood pressure of an anesthetized cat. [d] The free base was ether insoluble, so methylene chloride was added following hydrolysis and the salts were prepared in methylene chloride. [e] With decomposition. [f] Recrystallized from ethyl acetate–absolute alcohol–*iso*propyl ether. [g] Slowly soluble in absolute alcohol so the solution was concentrated after filtration. [h] Recrystallized from acetone–absolute alcohol–*iso*propyl ether. [i] Capillary. [j] The melting point is dependent on the rate of heating. The temperature must be raised very slowly over the range 190–250°. [k] Air-dried sample. [l] Recrystallized from ethyl acetate–tetrahydrofuran–*iso*propyl ether. [m] Was an oil which resisted crystallization. Other salts were equally as unsuitable.

A solution of the aminoketone (22.5 Gm., 0.162 mole) in water (50 ml.) was slowly added to a solution of sodium borohydride (1.68 Gm., 0.0445 mole) in water (50 ml.). The solution was allowed to stand at room temperature overnight. Concentrated ammonium hydroxide (50 ml.) (24) was added and the solution allowed to stand for 1.5 hours, after which it was saturated with sodium chloride. The aminoalcohol was extracted with seven 50-ml. portions of benzene. The extracts were dried over anhydrous sodium sulfate and the benzene was removed under slightly reduced pressure to give 20.0 Gm. (87.5%) of product. A sample was recrystallized twice from Skellysolve B and sublimed for analysis at 100° and 0.1 mm. The material was very hygroscopic and a good analysis could not be obtained, m.p. 148–151° (capillary). An infrared spectrum (potassium bromide) showed hydroxyl bands at 3400 cm.$^{-1}$ and 3150 cm.$^{-1}$.

Anal.—Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71. Found: C, 67.43; H, 10.69.

8 - Oxo - 1 - azabicyclo[4.3.0]nonane. — Diethyl piperidyl-1,2-diacetate (12) was subjected to the Dieckmann conditions in a manner essentially like that of the 1,3-diacetate except that higher dilutions (2 times the volumes of xylene) were employed. The product was obtained in 60% yield as a colorless liquid that quickly turned to a brown tar upon exposure to air, b.p. 64° (1.25 mm.), n_D^{25} 1.4786 [b.p. 61° (1 mm.) lit. (12)]. The picrate was formed in absolute ethanol and recrystallized from water, m.p. 189° (capillary, with decompn.) [m.p. 187° (decompn.) lit. (12)]. The infrared spectrum (film) showed carbonyl absorption at 1756 cm.$^{-1}$.

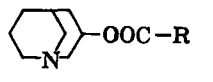
8 - Hydroxy - 1 - azabicyclo[4.3.0]nonane.— The aminoketone was reduced with sodium borohydride as was described for the preparation of 3-hydroxy-1-azabicyclo[3.3.1]nonane, in 89% yield, b.p. 73–74° (0.15 mm.), n_D^{25} 1.4950 [b.p. 95° (14 mm.), lit. (12)].

The picrate was formed in and recrystallized from absolute ethanol, m.p. 175–176° [m.p. 175° (reduction by sodium and alcohol), lit. (12)].

An infrared spectrum (film) showed broad hydroxyl absorption centering at 3400 cm.$^{-1}$.

Methyl Phenyl-2-thienylglycolate.—Methyl phenylglyoxylate (104 Gm., 0.635 mole) [prepared from methyl mandelate as described for the ethyl ester (25) in 97% yield] and anhydrous ether (400 ml.) were placed in a flask equipped with a mechanical stirrer and dropping funnel. The flask was cooled in an ice-salt mixture and a solution of 2-thienyl magnesium bromide [made from 2-bromothiophene (113.8 Gm., 0.7 mole) and magnesium (16.7 Gm., 0.7 Gm. atom)] in anhydrous ether (500 ml.) was siphoned into the dropping funnel and was added to the flask with stirring over a period of 2 hours. The mixture was stirred in the ice-salt bath for an additional hour and then for 3 hours at room temperature. The magnesium addition product was filtered off, washed well with anhydrous ether, and hydrolyzed by stirring it in ether (500 ml.) and cautiously adding a saturated aqueous solution of ammonium chloride (100 ml.) with ice cooling. The ether layer was decanted, washed with water (two 100-ml. portions), 2.5% hydrochloric acid (100 ml.), 5% sodium carbonate solution (two 100-ml. portions), and finally with water (two 100-ml. portions). The ether layer was treated, with charcoal, filtered, and dried over anhydrous sodium sulfate. The ether was removed *in vacuo* and the residue soldified upon scratching and cooling. This was dissolved in 3.5 liters of warm Skellysolve B and carefully cooled to room temperature, additional solvent being added if necessary to prevent oiling. Upon cooling to 10°,

TABLE II.—ESTERS OF 3-HYDROXY-1-AZABICYCLO[3.3.1]NONANE (VI)



Acid (R-COOH) Used for the Esterification	M.p.,° C.	Molecular Formulas	Salt	Analyses, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found	Activity[a] Muscle Strip[b]	Cat Blood Pressure[c]

	203–204		CH_3Br[g]	64.18	64.41	6.56	6.73	<10	0

[a] Expressed as a percentage of atropine sulfate. [b] Alleviation due to blocking spasm induced by 1:10,000,000 dilutions of methacholine on an isolated guinea pig ileum. [c] Alleviation due to blocking depressor response to 1 mcg./Kg. intravenously of methacholine on the blood pressure of an anesthetized cat. [d] With decomposition. [e] Capillary. [f] Recrystallized from ethyl acetate–absolute alcohol–*iso*propyl ether. [g] Recrystallized from acetone–absolute alcohol–*iso*propyl ether. [h] Release of ethanol and resolidification at 130–140°. [i] Air-dried sample.

there was deposited 47.5 Gm. of crude ester. Further cooling of the mother liquor gave an additional 17.0 Gm. for a total of 64.7 Gm. (41% yield) of crude ester. This material was recrystallized from warm cyclohexane to give 44.0 Gm. of pure ester, m.p. 62–63°. This material was identical to a sample of the methyl ester of phenyl-2-thienylglycolic acid (21, 26) which had been distilled and had solidified and been recrystallized, m.p. 61.5–62.5°.

Methyl 9-Hydroxyfluorene-9-carboxylate.—9-Hydroxyfluorene-9-carboxylic acid (27, 28) was converted to its methyl ester by the method of Clinton and Laskowski (29), m.p. 165° [m.p. 160° lit. (30)].

1-Azabicyclo[4.3.0]nonan-8-yl Benzilate Hydrochloride and Methobromide.—In a 250-ml. three-neck flask fitted with a mercury sealed stirrer, reflux condenser with drying tube, and a Dean-Stark trap, was placed 8-hydroxy-1-azabicyclo-[4.3.0]nonane (1.0 Gm., 7.1 mmoles), methyl benzilate (1.75 Gm., 7.1 mmoles) and Skellysolve C (freshly distilled from calcium hydride) (75 ml.). A trace of a 46% dispersion of sodium hydride in mineral oil (Metal Hydrides) was added to the refluxing solution with stirring and the mixture refluxed and stirred for 10 hours. Most of the solvent was removed *via* the trap, the mixture cooled, and water (25 ml.) and ether (25 ml.) added with stirring. The organic layer was extracted four times with water (20-ml. portions), and finally dried over anhydrous sodium sulfate. The solvent was removed *in vacuo*, and the residue was taken up in 25 ml. of anhydrous ether. The hydrochloride was prepared by adding ethereal hydrogen chloride. The methobromide was formed by adding methyl bromide, stoppering the flask tightly, and allowing it to remain at room temperature for several days. The salts, in this case and in general, were recrystallized by the solvent mixtures listed in Tables I and II.

1-Azabicyclo[3.3.1]nonan-3-yl Xanthene-9-carboxylate Hydrochloride and Methobromide.—Xanthene-9-carboxylic acid[11] was converted to its acid chloride by refluxing the acid (1.6 Gm., 7.1 mmoles) in thionyl chloride (10 ml.) for 2 hours. The excess thionyl chloride was removed *in vacuo*, and the residue dissolved in dry benzene (15 ml.) and the solvent removed under reduced pressure. A solution was made of freshly sublimed 3-hydroxy-1-azabicyclo[3.3.1]nonane (1.0 Gm., 7.1 mmoles), anhydrous benzene (50 ml.) and triethylamine (1.0 ml.). A solution of the acid chloride in dry benzene (25 ml.) was added dropwise over a period of 1/2 hour, with stirring. The mixture was heated at 70° and stirred for 2 1/2 hours. The mixture was cooled, and the triethylamine hydrochloride filtered off (*ca.* 1 Gm.). The benzene solution of the free base was washed with four 20-ml. portions of water, dried over anhydrous sodium sulfate, and the solvent removed *in vacuo*. The residue was dissolved in 25 ml. of dry ether and the hydrochloride or methobromide formed and recrystallized as outlined in the previous preparation.

[11] The authors wish to express their appreciation to Dr. R. M. Dodson of G. D. Searle and Co. for a generous gift of xanthene-9-carboxylic acid.

SUMMARY

1. The literature preparation of 3-oxo-1-azabicyclo[3.2.2]nonane could not be improved upon. Its isomers and their respective alcohols (3-hydroxy-1-azabicyclo[3.3.1]nonane and 8-hydroxy-1-azabicyclo[4.3.0]nonane) were synthesized in good yield.

2. A series of 19 esters of the named amino-alcohols using five acids was prepared.

3. The pharmacological testing of these esters show several to be potent anticholinergic agents.

Effects of *dl*-, *d*-, and *l*-Amphetamine on Levarterenol Tachyphylaxis in the Isolated Heart of *Venus mercenaria*

By RAYMOND F. ORZECHOWSKI and DAVID E. MANN, JR.

The comparative potencies of *dl*-, *d*-, and *l*-amphetamine in completely blocking the onset of levarterenol tachyphylaxis (characterized by diminished negative inotropic responses) in the isolated heart of *Venus mercenaria* were as follows: *d*-amphetamine was the most potent; *dl*-amphetamine and *l*-amphetamine were equally active, and less potent than the *d*-isomer. The observance of positive inotropic responses, occurring with higher doses of amphetamine isomers, indicated that both agents may act at the same receptor site. Furthermore, it is speculated that amphetamine may possibly block the inhibitory cardiac sites upon which levarterenol acts, thereby allowing the latter agent to exert a stimulatory action.

THE TERM tachyphylaxis or skeptophylaxis is used to denote a diminution in the response to successive equal doses of a pharmacological agent within a limited time interval. The diminished pressor responses which occur after consecutive doses of ephedrine (1), and the inability of repeated administrations of atropine to depress intestinal motility (2), are well-known examples of this phenomenon.

In 1953 Welsh (3), while evaluating the effects of various drugs on the isolated heart of the quahog—*Venus mercenaria*—observed the development of acute tolerance to repeated administrations of epinephrine. Fujita and Mann (4) reported that tachyphylaxis, characterized by diminished negative inotropic responses, occurred in the *Venus* heart after three or four successive doses of levarterenol. Further studies (5) showed that this response could be partially or completely blocked by ephedrine hydrochloride, *l*-ephedrine being more potent than either the *d*-isomer or the racemic mixture in this respect.

Amphetamine, a sympathomimetic agent chemically related to ephedrine, is believed to exert its peripheral actions in a manner similar to that of ephedrine, *i.e.*, adrenergic blockade (6). Because it had been noted that *l*-amphetamine was more potent than *d*-amphetamine in pressor activity (7), it was the purpose of this investigation to determine whether or not amphetamine would act as ephedrine in this situation and which isomer was the more potent.

Received June 11, 1962, from Temple University, School of Pharmacy, Philadelphia, Pa.

Accepted for publication July 20, 1962.

Abstracted from a thesis presented to the Graduate School of Temple University, School of Pharmacy, by Raymond F. Orzechowski, in partial fulfillment of the requirements for the degree of Master of Science.

This investigation was supported by research grant H-4283 (C2) from the National Heart Institute of the National Institutes of Health, Bethesda, Md.

EXPERIMENTAL

The bathing chamber for the isolated heart preparation was constructed of plexiglas and consisted of a section of tubing 4.5 cm. in diameter and 5 cm. in length with a circular base enclosing one end. A hole in the center of the base provided for the insertion of a hypodermic syringe sleeve through which was passed a ground-glass syringe plunger. A small fish hook was fused into the upper end of the plunger. By raising the glass rod vertically until it protruded above the lip of the chamber, the heart could easily be attached to the hook, while lowering the rod immersed the heart in the bathing medium (filtered sea water), thereby minimizing handling and stretching. Inflow and outflow of sea water were accomplished by means of tubes, one of which provided for aeration, inserted through the base of the chamber which was graduated at a volume of 40 ml.

The heart of *Venus mercenaria* was isolated according to the methods of Welsh and Taub (8), and Wait (9). Contractions were recorded on a Livingston long-paper kymograph. The specific gravity of the sea water was maintained at 1.025 and the temperature was kept at 24–26°.

The tabulation of results was done in accordance with the method of Ciuchta and Mann (5). The figures in Table I, representing per cent inhibition, were derived by dividing the lowest amplitude value (in millimeters) recorded within three minutes after the administration of levarterenol, by the amplitude value preceding the administration of the drug. The terms trial I, trial II, and trial III pertain to the three types of treatment that each *Venus* heart underwent. Trial I refers to the administration of three successive doses of levarterenol to establish a tachyphylactic response in a fresh heart; trial II designates that the same heart, after washing, was pretreated with the appropriate isomer and dose of amphetamine sulfate (0.1%) before the subsequent injection of three doses of levarterenol; and trial III refers to the re-establishment of tachyphylaxis by the administration of three successive doses of levarterenol to the heart after washing at the completion of trial II.

Effect of *dl*-Amphetamine Sulfate on Levarterenol Tachyphylaxis.—With the *Venus* heart suspended in the bathing chamber containing 40 ml. of sea

water, normal contractions were recorded, whereupon the ventricle was challenged with three 0.40-ml. doses of levarterenol[1] administered at 6-minute intervals to elicit tachyphylaxis. The majority of hearts were unresponsive to the third dose of levarterenol, while several preparations reacted slightly. Nevertheless, the pattern of diminishing responses to the three successive injections indicated that tachyphylaxis had occurred. The concentrations of levarterenol in 40 ml. of sea water after each dose were as follows: 0.4 mg. (1×10^{-5}) after the initial dose, 0.8 mg. (2×10^{-5}) after the second, and 1.2 mg. (3×10^{-5}) after the third. Following the development of the tachyphylactic pattern, the ventricle was allowed to beat for three minutes, then it was washed and rewashed with fresh sea water for one-minute periods. This procedure terminated trial I.

After the wash, the heart was again permitted to beat for approximately three minutes, or until it had resumed normal contractions. It was next treated with a dose of *dl*-amphetamine sulfate (0.40, 0.50, 0.70, or 0.80 mg.) so that when injected into 40 ml. of sea water the concentrations were respectively: 1.0×10^{-5}, 1.25×10^{-5}, 1.75×10^{-5}, or 2.0×10^{-5}. Approximately four minutes later, the heart was treated with three 0.40-ml. doses of levarterenol. This phase of the experiment was referred to as trial II.

Trial III consisted of the administration of three 0.40-ml. doses of levarterenol for the purpose of re-establishing tachyphylaxis in the same heart subsequent to final washing after trial II, and after normal contractions had been obtained.

Pretreatment with the lowest dose (0.4 mg.) of *dl*-amphetamine caused a complete blockage to subsequent doses of levarterenol in 4 out of 10 cases; 0.5 mg. completely blocked only 1 out of 10 cases; 0.7 mg. inhibited tachyphylaxis in 5 out of 8 cases; 0.8 mg. caused a complete blockage of the negative inotropic response in 12 out of 13 determinations (Table I).

Effect of *d*-Amphetamine Sulfate on Levarterenol Tachyphylaxis.—The heart was treated as in the previous part, with the exception of trial II which consisted of pretreatment with a dose of *d*-amphetamine sulfate (0.40, 0.50, 0.60, 0.70, or 0.80 mg.) so that the bath concentrations attained were: 1.0×10^{-5}, 1.25×10^{-5}, 1.50×10^{-5}, 1.75×10^{-5}, or 2.0×10^{-5}.

[1] Levophed bitartrate, 0.1% base, Winthrop Laboratories.

Pretreatment with the 0.40-mg. dose of *d*-amphetamine caused a complete blockage to the negative inotropic response of levarterenol in 3 out of 8 cases. The five remaining hearts were partially blocked as shown by a great diminution of response as compared to trial I. A dose of 0.5 mg. caused 7 out of 8 hearts to be unresponsive to all doses of levarterenol. Nine hearts were treated with either 0.60, 0.70, or 0.80 mg. of *d*-amphetamine (3 at each dose) with the following results: all 9 hearts showed a complete blockage to subsequent doses of levarterenol; in trial III, after thorough washing, 6 of the 9 hearts remained either completely refractory to all doses of levarterenol or partially responsive to only one dose.

Effect of *l*-Amphetamine Sulfate on Levarterenol Tachyphylaxis.—The heart was treated as previously described with the exception of trial II which consisted of pretreatment with a dose of *l*-amphetamine sulfate (0.40, 0.60, 0.70, or 0.80 mg.) to attain bath concentrations of 1.0×10^{-5}, 1.5×10^{-5}, 1.75×10^{-5}, or 2.0×10^{-5}. The 0.40 and 0.60 mg. doses produced complete blockage of levarterenol tachyphylaxis in 1 out of 5 and 1 out of 6 cases, respectively; 2 out of 7 hearts were blocked by 0.70 mg.; and complete blockage of 13 out of 15 hearts occurred at the 0.80 mg. dosage level.

DISCUSSION

The results of trial I have reconfirmed the published observations of Fujita and Mann (4) that tachyphylaxis to the negative inotropic response of levarterenol occurs in the isolated *Venus* heart. In trial II, pretreatment with the isomers of amphetamine sulfate partially or completely blocked this effect in a manner similar to that produced by the isomers of ephedrine hydrochloride (5). The latter study revealed that *l*-ephedrine was the most potent inhibitor of the tachyphylactic response. This investigation has shown that *d*-amphetamine possesses the greatest blocking activity, while *l*-amphetamine and the racemic mixture are approximately equal in their ability to block the tachyphylactic response. The comparative potencies of these isomers are recorded in Table II. From these results, it is reasonable to assume that the spatial configurations of the amphetamine and ephedrine molecules are implicated in the antagonism of levarterenol.

The theory of Gaddum and Kwiatowski (10), which attempted to explain the mechanism of action of ephedrine, has also been applied to amphetamine and offers a possible explanation for the observed effects in the *Venus* heart. Accordingly, amphetamine might exert its antagonistic actions upon the same receptor mechanism which levarterenol activates, *i.e.*, by combining with levarterenol receptors in a manner comparable to substrate competition, thus preventing the onset of acute tolerance. Another similarity between amphetamine and ephedrine was noted particularly at higher dosage levels. When the hearts were pretreated with amphetamine in trial II, positive inotropic effects were frequently seen which were potentiated by subsequent doses of levarterenol, perhaps indicating that both agents may act at mutual receptor sites. Consequently, large doses of amphetamine might block the inhibitory sites and allow levarterenol to produce its positive inotropic action upon excitatory receptors.

The pretreatment of *Venus* hearts with large doses (0.5 mg. plus) of *d*-amphetamine in trial II frequently resulted in a failure to re-establish the tachyphylactic response in trial III, despite several thorough washings. This effect was seldom encountered when *l*-amphetamine was used, but occasionally occurred after large doses of the racemic mixture. It may be due to a binding of the *d*-isomer at the receptor site to prevent the characteristic levarterenol response, a phenomenon which further supports the contention that *d*-amphetamine is the most potent isomer in abolishing levarterenol tachyphylaxis.

SUMMARY

Pretreatment of the isolated *Venus* heart in trial II with various concentrations of the *dl*-, *d*-, and *l*-isomers of amphetamine has indicated that *d*-amphetamine is the most potent inhibitor of levarterenol tachyphylaxis, while *dl*-amphetamine and *l*-amphetamine, although equally active, are less potent than the *d*-isomer.

It is postulated that amphetamine could block levarterenol responses by acting on the same receptor sites which levarterenol affects.

Observance of a positive inotropic effect with higher doses of amphetamine isomers, which is proportional to their relative blocking abilities, and the potentiation of this response with subsequent administrations of levarterenol indicated that both agents may act at the same receptor site. Furthermore, it is presumed that amphetamine may block the inhibitory sites, thereby allowing levarterenol to exert a stimulatory action.

Effect of Ultrasonic Waves on the Stability of Selected Surface-Active Agents, Sulfonamides, and *p*-Aminobenzoic Acid

By G. D. FENN† and P. F. BELCASTRO

Data are presented showing the effect of ultrasonic waves on the stability of certain surface-active agents, sulfonamides, and *p*-aminobenzoic acid. Under the experimental conditions employed, the surface-active agents were stable and the breakdown of the sulfonamides and *p*-aminobenzoic acid was greater than could be accounted for on the basis of peroxide formation.

BEAL and Skauen have reported that the viscosity of several surface-active agents is reduced upon exposure to ultrasonic waves (1). This suggests the possibility of a decrease in molecular weight of these agents as a result of depolymerization or some other type of chemical decomposition. Similar breakdown of large molecules has been reported by several authors (2–5). Araujo has reported the decomposition of procaine penicillin G and sulfathiazole in an ultrasonic field (6). The authors have noted similar decomposition of procaine and buteth-amine hydrochlorides. This decomposition was apparently of an oxidative nature and was prevented by the use of sodium bisulfite as an antioxidant (7). A number of authors have reported the formation of peroxides in aqueous solutions as a result of treatment with ultrasonic waves (8–11). In view of these investigations, it was deemed to be of value to determine if surface-active agents are stable in an ultrasonic field and if peroxide formation is responsible for the breakdown of sulfonamides and similar compounds. This communication reports the effect of ultrasonic waves at a frequency of 400 kilocycles per second upon the stability of selected surface-active agents. This should give an indication as to the advisability of using these agents when preparing emulsions or suspensions by ultrasonics. The amount of peroxides formed as a result of exposure to ultrasonic waves of this frequency was determined. The effect of similar amounts of peroxide alone on the stability of one of the sulfonamides was compared with the effect of ultrasonic waves upon stability. This should indicate if the breakdown due to ultrasonic waves is caused primarily by the formation of peroxides.

EXPERIMENTAL

Calibration of the Generator.—The ultrasonic generator employed in this study was constructed at Purdue University and was designed for use with a barium titanate transducer. The generator is rated at 250 watts with a variable frequency range. A Hypersonic Transducer, model BU-305,[1] with a focused bowl of barium titanate was employed. The generator was calibrated by determining the wattage produced at various rheostat settings by multiplying the power amplifier voltage and the power amplifier current as shown by appropriate meters on the generator. All of the experiments involving insonation were conducted at a frequency of 400 kilocycles per second and an energy level of approximately 150 watts.

Stability of Selected Surface-Active Agents.—The surface-active agents chosen for this part of the study were Myrj 45,[2] G-2159,[2] Aerosol AY,[3] Tween 80,[2] Span 80,[2] and Triton X-200.[4] Solutions of these surfactants were insonated for extended periods of time. values of both insonated and noninsonated samples were determined. Hydroxyl values were determined by the method of Ogg, Porter, and Willits (12), while the saponification values were determined by the official method of the American Oil Chemists' Society (13). A decrease in the saponification value would indicate that ester hydrolysis had occurred while an increased hydroxyl value would indicate either ester or ether hydrolysis, or both, had occurred. The temperature was held at 25° ± 0.5° by circulating cold water through the transducer cooling coil. Table I shows the values obtained for these agents under these conditions.

Stability of Selected Sulfonamides and *p*-Aminobenzoic Acid.—The drugs selected for this portion of the study were sulfanilamide, sulfapyridine sodium, sulfathiazole sodium, and *p*-aminobenzoic acid. Solutions of 0.050 *M* concentration were prepared. To each 0.050 mole of sulfanilamide 0.025 mole of sodium hydroxide was added to give a salt to acid ratio of 1:1, and to each 0.050 mole of *p*-aminobenzoic acid, 0.050 mole of sodium hydroxide was added to form the sodium salt. The solutions were prepared using a pH 10.43 phosphate buffer of such composition that the resulting solutions had ionic strengths of 1.0. The buffer was composed of 11.40 Gm./L. of $Na_3PO_4 \cdot 12\ H_2O$ and 74.28 Gm./L. of $Na_2HPO_4 \cdot 7\ H_2O$. Sample volumes of 30 ml. were exposed to ultrasonic irradiation for time periods of from one to six hours at a temperature of 25° ± 0.5°, maintained by circulating the transducer coupling fluid from a constant temperature bath. Noninsonated control samples were held at the same temperature for equal time periods. For sulfanilamide, control samples were also run at 75° and 100° ± 0.5°. A 25.0-ml. sample of each of the insonated and control samples was then analyzed for remaining drug by the potentiometric titration of LaRocca and Waters (14). The amount of drug present in the samples before treatment was also determined by this method. Table II and Fig. 1 show typical results, while Table III summarizes the findings.

insonated at a temperature of 25° ± 0.5° for varying periods of time. The buffer was composed of 11.29 Gm./L. of $Na_3PO_4 \cdot 12H_2O$ and 73.43 Gm./L. of $Na_2HPO_4 \cdot 7\ H_2O$. One-milliliter portions were withdrawn and analyzed for hydrogen peroxide, using a Beckman model B spectrophotometer, by the method of Patrick and Wagner (15). Table IV shows the results of this segment of the study.

TABLE IV.—PEROXIDE FORMATION IN PHOSPHATE BUFFER AS A RESULT OF ULTRASONIC IRRADIATION

Time, Hr.	Absorbance	Moles/L. × 10^5
0.5	0.029	0.15
1.0	0.085	0.4
1.5	0.164	0.8
2.0	0.505	2.5
2.5	1.08	5.3
3.0	1.35	6.6

Effect of Hydrogen Peroxide on the Stability of Sulfanilamide.—Dilutions of varying concentrations of hydrogen peroxide in a pH 10.43 phosphate buffer which, when used to prepare 0.050 *M* sulfanilamide solution, gave an ionic strength of 1.0 were prepared. The hydrogen peroxide concentration ranged from 2×10^{-5} moles/L. to 2×10^{-3} moles/L., or up to about 40 times the amount shown to be produced by ultrasonic waves. These concentrations of hydrogen peroxide had no measurable effect on the stability of sulfanilamide.

DISCUSSION

These data would indicate that the surface-active agents chosen were stable, in terms of ether and ester hydrolysis, to prolonged periods of ultrasonic irradiation. No danger of breakdown would be anticipated if these agents were employed in emulsions or suspensions prepared by ultrasonics.

The stability of the sulfonamides and the *p*-aminobenzoic acid is decreased by exposure to ultrasonic waves. The amount of peroxides formed, however, is not sufficient to account for the observed decomposition of these drugs. It would also appear that very high temperatures would be required to produce a similar degree of decomposition. It seems reasonable to state that other factors must be involved in the ultrasonic decomposition of these drugs. Possible local heating effects or mechanical effects may be partially responsible.

SUMMARY AND CONCLUSIONS

1. The purposes of this study were to determine if selected surface-active agents are subject to ester or ether hydrolysis in an ultrasonic field and if the amount of peroxide formed by ultrasonic irradiation is sufficient to account for the observed decomposition of certain sulfonamides and *p*-aminobenzoic acid.

2. No ester or ether hydrolysis of selected surface-active agents was induced by exposure to ultrasonic waves, as noted by determination of hydroxyl and saponification values.

3. The amount of hydrogen peroxide shown to be formed by ultrasonics is not sufficient to account for the observed decomposition of selected sulfonamides and *p*-aminobenzoic acid. The decreased stability of the sulfonamides and *p*-aminobenzoic acid as well as the amount of hydrogen peroxide formed as a result of ultrasonic irradiation was noted. No decrease in the stability of sulfanilamide with up to 40 times this amount of hydrogen peroxide was noted without insonation.

4. Under the experimental conditions described in this paper, the stability of the surface-active agents investigated was not affected by ultrasonic waves. The effect on the stability of the sulfonamides and *p*-aminobenzoic acid cannot be accounted for by the amounts of hydrogen peroxide shown to be formed by ultrasonic irradiation. Local thermal or mechanical effects, or some other factors must be involved.

Stability of Ascorbic Acid in a Liquid Multivitamin Emulsion Containing Sodium Fluoride

By JAMES E. TINGSTAD, LEE H. MACDONALD, and PETER D. MEISTER

The kinetics of the thermal oxidative nonphotolytic degradation of ascorbic acid in a liquid multivitamin emulsion containing sodium fluoride have been studied. The vitamin appears to degrade initially by a pseudo zero-order reaction, but other evidence indicates that the true order of the reaction is closer to one. The reaction rate increases rapidly as the pH rises from 3.2 to 3.8, and it is this pH effect which probably causes the reaction to appear zero-order in its initial stages. By use of the Arrhenius equation, data obtained from high temperature studies have been used to predict shelf life at room temperature. Factors affecting the accuracy of the predictions are discussed. Sodium fluoride does not appreciably affect the stability of ascorbic acid in this preparation, but a reaction between sodium fluoride and glass, producing a precipitate (Na_2SiF_6), has been observed.

IN THE development of new pharmaceutical products, investigators are often asked to pass judgment on the shelf life of a product long before complete room temperature stability data are available. It then becomes necessary to predict the room temperature shelf life using data obtained from accelerated kinetic studies of degradation rates at elevated temperatures. The theory and mechanics of such predictions have been well outlined by E. R. Garrett of these laboratories (1–3). In order to make the best use of these methods, it is necessary to give careful consideration to all factors that might affect the accuracy of the predictions.

The present investigation was undertaken to determine the shelf life of a liquid o/w multivitamin emulsion containing, as active ingredients, sodium fluoride and vitamins A, B_6, D, and C. Results of preliminary experiments indicated that the stability of ascorbic acid would be the limiting factor in the shelf life of this product; consequently, only the stability of that vitamin was followed during the accelerated kinetic studies. Although Garrett (2) had already studied the stability of ascorbic acid in this type of system, it had been shown that many additives significantly affect the stability of ascorbic acid (4–6) and that the reactions by which ascorbic acid degrades are many and complex (7–9). Consequently, it was necessary to conduct kinetic studies on the new product before reasonably accurate stability predictions could be made. The effect of pH and sodium fluoride on the ascorbic acid stability and the nature of the reaction between sodium fluoride and glass were also studied to a limited extent.

Received May 22, 1962, from The Upjohn Co., Kalamazoo, Mich.

Accepted for publication July 18, 1962.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

The authors are indebted to Dr. R. E. Booth and his associates in the Control Division of The Upjohn Co. for the ascorbic acid and sodium fluoride assays, to Dr. J. W. Shell and W. A. Struck for the isolation and identification of sodium fluosilicate, and to Mr. J. I. Northam for his invaluable help with the statistical interpretation of the data.

EXPERIMENTAL

Composition of the Product.—The product is a water-polyol based o/w emulsion labeled to contain, in each 0.6 ml., 1.105 mg. sodium fluoride, 1.5 mg. vitamin A palmitate in oil, 1.0 mg. pyridoxine hydrochloride U. S. P., 25 mcg. vitamin D_3 in oil, 50 mg. ascorbic acid U.S.P., and various sweetening agents, preservatives, emulsifiers, *etc.* When necessary, the pH of the product is adjusted to the desired level with 0.1 *N* sodium hydroxide. The pH of this product is very erratic and can vary as much as ±0.2 unit from lot to lot and can vary with time within the same lot. This makes it difficult (*a*) to set up experiments studying variables other than pH, and (*b*) to evaluate results of these experiments.

As usual, the overage on the labeled amounts of the vitamins is that required to attain acceptable room temperature shelf life. However, since this report is concerned with the stability of ascorbic acid only, it will suffice to say that the theoretical initial concentration of ascorbic acid is 82.5 mg./0.6 ml. in one formula (Preparation I, pH adjusted to 3.35) and 70.0 mg./0.6 ml. in the other (Preparation II, pH adjusted to 3.20).

Kinetic Studies on the Effect of Temperature on Ascorbic Acid Stability.—After determining (by careful gross visual examination) that the emulsion was stable over the temperature range of the kinetic study, 30 ml. of the preparation was filled into 38-ml. capacity high-density polyethylene bottles; the bottles were then loosely capped and placed in amber 1-lb. ointment jars. When the bottles were tightly capped, the CO_2 pressure buildup, caused by the degradation of ascorbic acid and by the elevated temperatures, ruptured the plastic containers. Glass containers could not be used here because of a reaction between sodium fluoride and glass. The loss of water (through vaporization) from the loosely capped bottles was found to be negligible. Amber jars were used because the product would be stored in opaque cardboard containers; therefore, only the nonphotolytic degradation was of interest.

The jars were then sealed and immersed in constant temperature baths set at 70.0, 60.0, 47.0, and

40.0 (±0.1°). Samples were periodically removed from the baths and immediately refrigerated. Just prior to being assayed (by the U.S.P. iodometric titration method) the samples were allowed to equilibrate at room temperature. Both Preparation I and Preparation II (see previous section) were subjected to this treatment.

Kinetic Studies on the Effect of pH, Initial Ascorbic Acid Concentration and Sodium Fluoride on Ascorbic Acid Stability.—To determine the effect of pH on ascorbic acid stability, one lot of the product was divided into three parts, and the pH of each part was adjusted to a different level (3.15, 3.40, and 3.80).[1] The samples were stored as outlined above, this time at 70.0° only, and the stability was determined in the usual manner.

To help determine the apparent order of the reaction, the effect of initial ascorbic acid concentration on the apparent degradation rate was studied. One lot of the product was made with an initial ascorbic acid concentration of 40.0 mg./0.6 ml. (Preparation III, pH adjusted to 3.50).[2] Again the samples were stored at 70.0° only, and the stability was followed in the usual way.

In order to study the effect of sodium fluoride on the ascorbic acid stability in this product, part of Preparation III was processed without sodium fluoride (Preparation IV, pH adjusted to 3.30).[2] These samples were stored at 70.0° and the stability was determined in the usual manner.

Studies on the Effect of Sodium Fluoride on Glass.—Initially, it was planned to package this product in glass, the standard container for this type of preparation. However, after only 24 hours storage in ordinary soft glass or in U.S.P. Type I glass, the product developed a precipitate. To determine the nature of this material, it was separated from the emulsion by centrifugation and subjected to X-ray diffraction analysis using a General Electric XRD-5 diffraction unit.

To further elucidate the conditions under which this precipitate would form, sodium fluoride A.R. (1.105 mg./0.6 ml.) and ascorbic acid (50.0 mg./0.6 ml.) were dissolved in deionized water; and the pH was adjusted to various levels (2.78, 3.25, 4.10, 4.79, 5.80, and 6.35) with 0.1 *N* sodium hydroxide. The solutions were stored in ordinary soft glass and in high-density polyethylene bottles. They were observed for 1 week at room temperature, after which they were assayed for sodium fluoride. When a precipitate was present in the bottle the clear supernatant was used for the assay sample.

RESULTS AND DISCUSSION

The reactions by which ascorbic acid degrades are many and complex (7–9). It is not the intent here to present a complete discussion of the subject, but rather to briefly summarize the more important details so that the data presented herein will be more meaningful. A more complete account may be found in the literature.

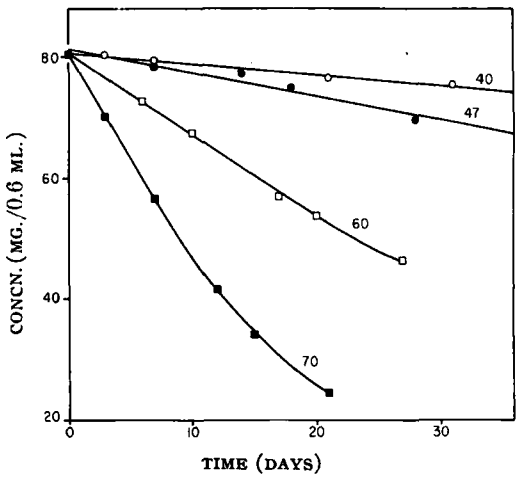

Fig. 1.—Zero-order plots of the thermal oxidative degradation of ascorbic acid in Preparation I; concentration (mg./0.6 ml.) against time (days).

In aqueous solution, ascorbic acid undergoes both a reversible (oxidative) and an irreversible (nonoxidative) degradation. The nonoxidative reaction rate, apparently first-order, decreases with an increase in pH in the 2.2 to 6.0 range; it then increases as the pH rises to 7.0 and above. The products of this anaerobic degradation are furfural, carbon dioxide, and numerous uncharacterized compounds (7). This reaction has not been studied as extensively as the oxidative one.

The oxidative reaction, catalyzed by copper and other trace substances, is 100–1000 times faster than the nonoxidative (7). The aerobic reaction rate increases rapidly as the pH rises from 2.0 to 5.0, then decreases slightly from pH 5.0 to 9.0, then increases rapidly again above pH 9.0. The irregularity of the pH-stability curve seems to be due to the differences in concentrations of the three species of ascorbic acid (undissociated, singly ionized, and doubly ionized) that can exist in aqueous solution at various pH's, and to the different reaction rate constants associated with each of these species (8).

The first step of the oxidation process, in which dehydroascorbic acid is produced, is reversible.[3] However, subsequent oxidation of dehydroascorbic acid is irreversible, and leads to the production of oxalic and threonic acids, carbon dioxide, hydrogen peroxide, and numerous uncharacterized compounds

[1] The pH of the emulsion rises about 0.20 units at room temperature the first one or two days after it is processed; from then on it remains relatively constant at room temperature. The recorded pH's are those measured after the pH has reached this "constant" value. However, at elevated temperatures, the pH continues to rise (0.15 to 0.20 units) during the first part of the kinetic study (how fast it rises depends on the temperature); after that it remains relatively constant. All pH determinations were made on a Beckman Zeromatic pH meter.

[2] In order to eliminate the pH effect on the degradation rate, it was necessary to adjust the pH of these formulas to about the same level as the pH of Preparation I. But since it is extremely difficult to attain the exact desired pH in these systems, there is a measurable pH difference between Preparations I, III, and IV. These differences should be kept in mind when evaluating the data.

[3] The term "reversible," as used here, means that by using appropriate reducing agents, dehydroascorbic acid can be reconverted to ascorbic acid (8). There is a great deal of disagreement as to the optimum pH for the ascorbic acid-dehydroascorbic acid interconversion reaction. Ball (10) says the reaction takes place only below pH 5.0, while Fruton (11) states that it takes place between 5.5 and 7.5. Ghosh and Char (12) have shown that it is possible to reduce dehydroascorbic acid to ascorbic acid in the 2.5 to 7.5 pH range. Levenson (13) says that the irreversible oxidation rate is slowest at pH 3.5. This illustrates that ascorbic acid degradation is extremely complex, and that different results can be obtained by making relatively small changes in the system.

[a] For a plot of concentration *vs.* time, the slope = the zero-order rate constant (k_0).

(8, 9). Some of the oxidation products act as catalysts for the degradation of more ascorbic acid; the drug thus undergoes autoxidation (9).

The literature is in general agreement on the fact that ascorbic acid undergoes apparent first-order degradation in simple drug-buffer systems (8, 9). However, in a more complex pharmaceutical system (containing other vitamins, flavors, sugars, etc.), Garrett (2) found that the degradation of ascorbic acid was pseudo zero-order during the initial phase of the reaction. In the later stages apparent first-order kinetics prevailed.

Effect of Temperature.—The effect of temperature on the degradation rate of ascorbic acid is shown in Figs. 1 and 2 where concentration of ascorbic acid is plotted against time at four different temperatures for Preparations I and II, respectively. The behavior of the points (a straight line can be drawn through the points above 45 mg./0.6 ml.; below that concentration the line is curved) at each temperature indicates that the reaction is pseudo zero-order during its initial stages; however, as the reaction proceeds, first-order kinetics become apparent. These results agree essentially with those of Garrett (2). A summary of the statistical treatment of the zero-order data obtained from Figs. 1 and 2 is given in Table I.

[a] For a plot of logarithm *vs.* time, the slope = k_1 = the first-order rate constant/2.303 = k_1'/2.303.

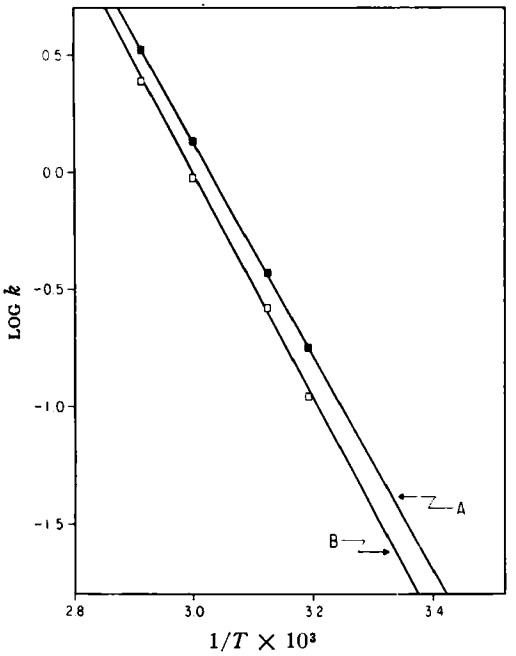

Fig. 5.—Arrhenius plots of log k (zero-order rate constants from Figs. 1 and 2; mg./0.6 ml./day) against the reciprocal of the absolute temperature for Preparation I (plot A) and Preparation II (plot B).

In making predictions of shelf life it is essential to consider the possibility that the reaction might be pseudo first-order from the beginning, and then to consider what the difference is between predictions based on zero-order kinetics and those based on first-order kinetics. Therefore, the logarithm of ascorbic acid concentration was plotted against time (Figs. 3 and 4) for Preparations I and II, respectively. For convenience and ease of calculation, the numerical value of the slopes (k_1) of the lines in Figs. 3 and 4 were used in the Arrhenius plots, calculations of shelf life, etc., rather than the actual first-order rate constant (k_1'). The first-order rate constants could be obtained by plotting logarithm *vs.* time, or by using the following equation: $2.303\ k_1 = k_1'$. A summary of the statistical treatment of these first-order data is given in Table II.

Arrhenius Plots.—In order to best predict the shelf life of this product, Arrhenius plots were made using data obtained from both the zero-order and first-order plots. In Fig. 5 the logarithm of the zero-order rate constants for both preparations (obtained from Figs. 1 and 2) are plotted against the reciprocal of the absolute temperature, while in Fig. 6 the same thing is done for the "first-order" slopes obtained from Figs. 3 and 4. A summary of the statistical treatment of the Arrhenius plot data is given in Table III. It should be noted that the apparent heats of activation for the reaction [these agree very well with those obtained by Garrett (2)] are very similar in all four cases, but that the shelf lives are considerably different, depending on which order is assumed for the reaction. This is due, in part, to the fact that a first-order reaction will slow down as substrate concentration decreases, whereas a zero-order reaction will continue at a constant rate.

Effect of pH.—The effect of pH on the degradation rate of ascorbic acid can be seen in Fig. 7 where a zero-order plot is made for the degradation of ascorbic acid at 70° at three different pH's, and in Fig. 8 where the same data are plotted as first order. The pH dependence of the reaction rate can better be seen in Figs. 9 and 10, where zero-order reaction rates (Fig. 9) and "first-order" slopes (Fig. 10) are plotted against pH. The values for the k's at pH 3.20 and 3.35 were obtained from the slopes of the 70° plots in Figs. 1 and 2. Since

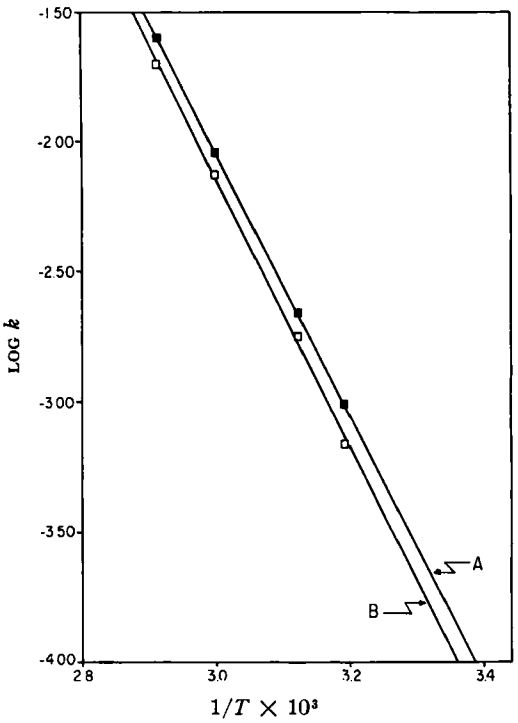

Fig. 6.—Arrhenius plots of log k (slopes of first-order plots from Figs. 3 and 4; day^{-1}) against the reciprocal of the absolute temperature for Preparation I (plot A) and Preparation II (plot B).

TABLE III.—TABULATION OF ARRHENIUS EQUATIONS OF BEST FIT, APPARENT HEATS OF ACTIVATION (ΔH_a), k_0 AND k_1 AT ROOM TEMPERATURE, SHELF LIFE (t_{90})[a] AND 95% CONFIDENCE LIMITS OF SHELF LIFE

Preparation	Equation of Best Fit	ΔH_a (Kcal/mole)	Predicted k_0 and k_1 (25° C.)[b]	t_{90}, Years	95% Confidence Limits of t_{90}
I—Zero-Order	$\log k_o = -4599/T + 13.94$	21.0	0.0326	3.15	2.79–3.56
II—Zero-Order	$\log k_o = -4809/T + 14.43$	22.0	0.0200	3.43	1.90–6.00
I—First-Order	$\log k_1 = -5077/T + 13.20$	23.2	0.000148	4.89	4.29–5.57
II—First-Order	$\log k_1 = -5216/T + 13.52$	23.9	0.000106	4.95	3.16–7.72

[a] The shelf life is defined as the time it takes for the ascorbic acid to degrade to 90% of the labeled potency. Since the labeled potency is 50 mg./0.6 ml., t_{90} for Preparation I is the time it takes for the ascorbic acid concentration to drop from 82.5 mg./0.6 ml. (initial) to 45.0 mg./0.6 ml. (90% of label); and t_{90} for Preparation II is the time it takes for the ascorbic acid concentration to drop from 70.0 mg./0.6 ml. (initial) to 45.0 mg./0.6 ml. (90% of label). [b] Units for k_0 are mg./0.6 ml./day and the units for k_1 are day^{-1}.

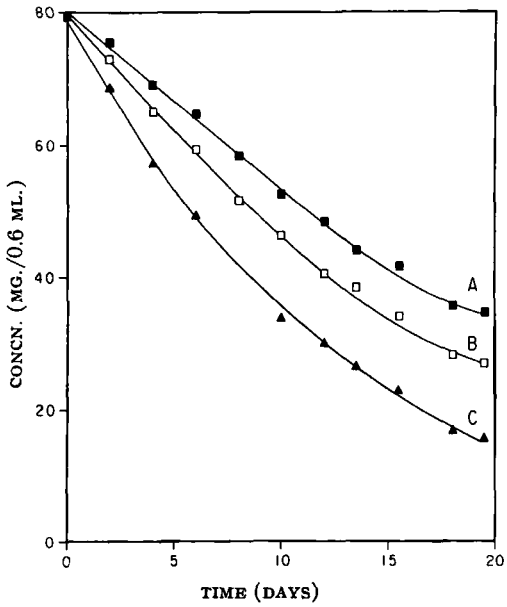

Fig. 7.—Zero-order plot showing the effect of pH on the degradation rate of ascorbic acid; *A*—pH 3.15, *B*—pH 3.40, *C*—pH 3.80; concentration (mg./0.6 ml.) against time (days). Temperature was 70°.

Preparation I and Preparation II have slightly different initial ascorbic acid concentrations, the zero-order reaction rate constants associated with each of these formulas will be slightly different, regardless of pH (see next section). This has not been taken into account in Figs. 9 and 10.

The straight lines in Figs. 9 and 10 are not meant to imply that there is a strict linear relationship between pH and reaction rate in this pH range; rather they are meant to illustrate the significant effect of pH on ascorbic acid stability. Csuros and Petro (8) have represented the pH profile of the reaction as being slightly curved in this pH region. They showed the same significant pH dependence of the reaction rate that is reported here.

Effect of Initial Ascorbic Acid Concentration.—The effect of initial ascorbic acid concentration on its degradation rate is shown in Table IV, where the k's (70°) for Preparation I (82.5 mg./0.6 ml.) are compared with those for Preparation III (40.0 mg./0.6 ml.). The k's for Preparation III were obtained from the *A* plot in Fig. 11 (zero-order) and Fig. 12 (first-order). Note that the pH of Preparation I is lower than that of Preparation III. Considering the pH effects only, a faster rate for Preparation III would be expected. However, the comparison shows that a drop in initial ascorbic acid concentration overcomes the pH effect and slows the rate. The apparent zero-order rate constant is affected much more than is the "first-order" slope; and by using appropriate equations, it can be shown that the true reaction is closer to first-order than to zero-order (14). The cause(s) of the apparent drop in the value of the first-order rate constant when the initial concentration was reduced, even though the pH difference favored a change in the opposite direction, was (were) not investigated.

A possible explanation for the apparent zero-order character of the first part of the reaction is that the initial rise in pH at elevated temperatures (see footnote 3) causes an increase in the reaction rate which offsets the tendency of the first-order reaction to slow down as the substrate concentration decreases. As soon as the pH reaches a constant value, no further deviations from first-order kinetics

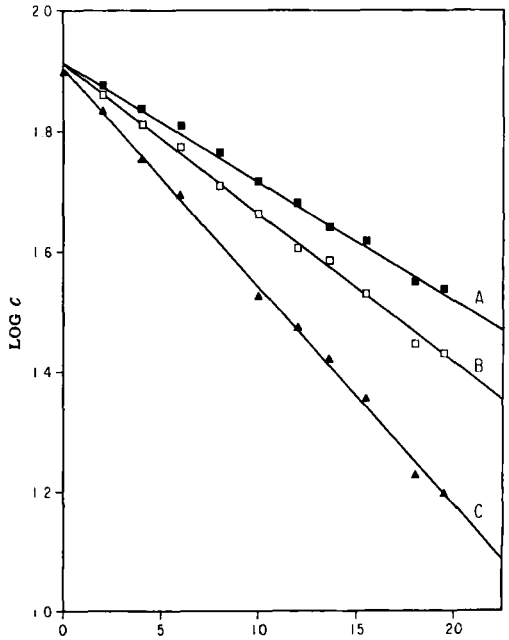

Fig. 8.—First-order plot showing the effect of pH on the degradation rate of ascorbic acid; *A*—pH 3.15, *B*—pH 3.40, *C*—pH 3.80, log concentration (mg./0.6 ml.) against time (days). Temperature was 70°.

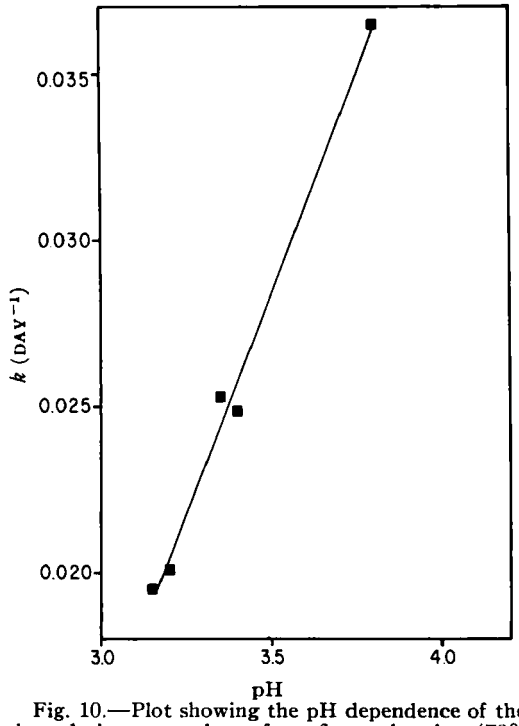

Fig. 10.—Plot showing the pH dependence of the degradation rate; slopes from first-order plots (70°; day^{-1}) against pH.

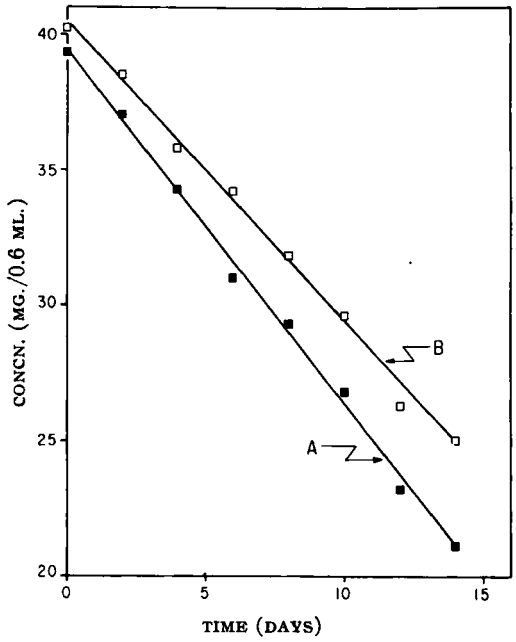

Fig. 11.—Zero-order plot showing the effect of sodium fluoride on ascorbic acid stability at 70°; *A*—Preparation III (with sodium fluoride), *B*—Preparation IV (without sodium fluoride); concentration (mg./0.6 ml.) against time (days).

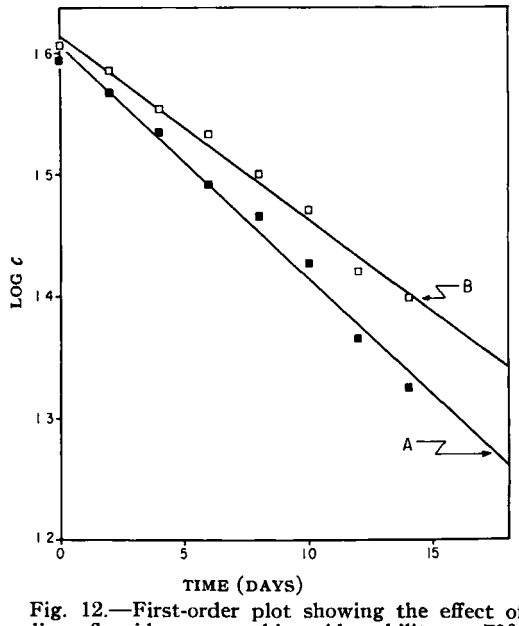

Fig. 12.—First-order plot showing the effect of sodium fluoride on ascorbic acid stability at 70°; *A*—Preparation III (with sodium fluoride), *B*—Preparation IV (without sodium fluoride); log concentration (mg./0.6 ml.) against time (days).

Table IV.—Comparison of Zero-Order Rate Constants (k_0) and "First-Order" Slopes (k_1) for Preparation I (82.5 mg./0.6 ml.) and Preparation III (40.0 mg./0.6 ml.) at 70°C.

Preparation	pH	k_0 (mg./0.6 ml./day)	k_1 (× 10^2 day^{-1})	k_0 (I)/k_0 (III)	k_1 (I)/k_1 (III)
I	3.35	3.411	2.532	2.60	1.31
III	3.50	1.310	1.930		

TABLE V.—COMPARISON OF ZERO-ORDER RATE CONSTANTS (k_0) AND "FIRST-ORDER" SLOPES (k_1) FOR PREPARATION III (WITH SODIUM FLUORIDE) AND PREPARATION IV (WITHOUT SODIUM FLUORIDE)

Preparation	pH	k_0 (mg./0.6 ml./day)	k_1 ($\times 10^2$ day^{-1})	k_0 (III)/k_0 (IV)	k_1 (III)/k_1 (IV)
III	3.5	1.310	1.930	1.17	1.27
IV	3.3	1.120	1.514		

are apparent. The fact that (*a*) the period of pH change corresponds closely with the period during which zero-order kinetics are apparent, and (*b*) the magnitude of the deviations from the first-order character of the reaction is compatible with the magnitude of the pH effect on the degradation rate, supports this explanation.

Effect of Sodium Fluoride.—The effect of sodium fluoride on the stability of ascorbic acid is shown in Figs. 11 and 12. Plot *A* in each figure is the plot of the kinetic data obtained at 70° for Preparation III, while plot *B* is the plot of the kinetic data obtained at 70° for Preparation IV (identical to III except that it contains no fluoride). It can be seen (Table V) that sodium fluoride does not significantly affect the stability of ascorbic acid. The small increase in reaction rate seen with Preparation III can be explained on the basis of its slightly higher pH.

Effect of Sodium Fluoride on Glass.—The precipitate which was isolated from the preparations stored in glass was identified by X-ray diffraction analysis as sodium fluosilicate, Na_2SiF_6 (15). Further studies on the effect of pH on precipitate formation showed that the precipitate forms between pH 2.4 and 4.3 overnight at room temperature, but not between pH 4.8 and 6.5, after 7 days' storage at room temperature. Assays showed no detectable loss of fluoride ion from the system in those preparations in which a precipitate formed. It is possible that a small amount of hydrogen fluoride is liberated at the more acid pH's and that this material attacks the glass. Longer term studies were not carried out because the tests showed that the precipitate forms at the pH's (2.8–3.4) which, because of stability and taste considerations, are optimum for the product. Therefore, it was necessary to package the product in plastic bottles.

Correlation of Predictions with Actual Room Temperature Stability.—The problem in this study was not so much one of predicting shelf life for a product containing a definite amount of ascorbic acid and having a certain pH; rather it was one of deciding what initial ascorbic acid concentration and what pH would allow a shelf life of 2 years for the product. On the basis of the results of this study it was decided to market the product at pH 3.4 or slightly lower with an initial ascorbic acid concentration of 82.5 mg./0.6 ml. These predictions are based on zero-order kinetics because (*a*) the reaction is pseudo zero-order in the concentration range of interest, and (*b*) predictions based on zero-order kinetics give the shortest shelf life; therefore predictions based on zero-order kinetics will err on the safe side, if at all. The first-order treatment of the data has been included for informational purposes. The usefulness of this general approach is demonstrated by the fact that preliminary (6 months) room temperature stability data on the above formulation indicate a shelf life of 2.2–2.8 years.

General Considerations.—An attempt has been made to investigate those problems which could be solved in a reasonable length of time and whose solution might lead to a better product or to a significantly more accurate prediction of shelf life. No attempt has been made to ascertain (*a*) the effect of the polyol concentration and of temperature on the thermodynamic activity of the hydrogen ions and on the dissociation constants of ascorbic acid, (*b*) the effect of ionic strength on the degradation rate, (*c*) the effect of loosening the caps of the polyethylene bottles on the diffusion of oxygen, or (*d*) the effect of temperature on the diffusion rates of oxygen, carbon dioxide, and water vapor through the walls of the polyethylene bottles. These problems were not investigated because (*a*) the system is too complex, and (*b*) the answers to these questions are not likely to lead to a better product or to a significantly more accurate prediction of shelf life. The effect of antioxidants on the ascorbic acid stability was not studied because previous experience had shown that antioxidants are not particularly effective in stabilizing ascorbic acid in this type of system.

SUMMARY

1. The degradation rates of ascorbic acid at elevated temperatures in a liquid, o/w emulsion-type multivitamin preparation have been determined. Arrhenius plots have been made using these kinetic data, and room temperature shelf life has been predicted. Preliminary room temperature studies indicate that these predictions are accurate.

2. The reaction appears to be pseudo zero-order during the initial stages of the reaction; in the latter phases it assumes first-order characteristics. Studies on the effect of initial ascorbic acid concentration on the apparent degradation rate indicate that the true reaction rate is probably closer to first-order than to zero-order.

3. The reaction rate increases rapidly as the pH increases from 3.2 to 3.8. This effect of pH is postulated to be the reason for the zero-order nature of the initial phases of the reaction.

4. Sodium fluoride does not appreciably affect the stability of ascorbic acid in this product.

5. Storing the product in glass results in a precipitate (Na_2SiF_6, sodium fluosilicate) which forms at room temperature within 24 hours between pH 2.4 and 4.3 but not between pH 4.8 and 6.5 after seven days.

Problems in Chemotaxonomy I

Alkaloids of *Peschiera affinis*

By JERRY A. WEISBACH, ROBERT F. RAFFAUF, OSCAR RIBEIRO,† EDWARD MACKO, and BRYCE DOUGLAS

A phytochemical study of this plant has yielded three indole alkaloids, two of them being of the α-ketoindole type and the third containing a simple nonconjugated indole moiety. One of the α-ketoindole alkaloids has been identified as vobasine, whose recently described structure is found compatible with NMR spectral data. The isolation procedures are described for the second α-ketoindole alkaloid, affinine, and for the indole alkaloid, affinisine.

THE HISTORY of the genus *Tabernaemontana* L. (family *Apocynaceae*) is exceedingly complex. At various times, botanists have split other genera from it (*e.g.*, *Voacanga*, *Ervatamia*, *Gabunia*, *Conopharyngia*) leaving a residue of synonymy of genera and/or species within the group. With regard to South American representatives, botanical opinion concerning their classification has varied widely. Markgraf has separated and readjusted the genus *Tabernaemontana* L. into nine genera, preserving that name for species found in the Antilles, Central America, and parts of northwestern South America, while maintaining *Peschiera* A. DC. for those found in Brazil (1). Woodson does not share this opinion (2).

There is reason to believe that even in closely related genera sufficient differences in alkaloid composition exist to serve as a basis for chemotaxonomic distinctions. In Farnsworth's excellent review of the periwinkles (3) one notes that of the 48 characterized alkaloids isolated from *Vinca* and *Catharanthus* species, only one, akuammine (vincamajoridine) is common to both genera. Obviously, it will be necessary to know more about the actual structures before detailed comparisons can be made between the chemical types found in each genus. As of now, however, it can be stated that the dimeric C_{46} bases have been found only in the genus *Catharanthus*.

From the chemical point of view, the genera in the subtribe Tabernaemontainae have been found to contain two major structural types of alkaloids: the predominant ibogaine, I, type (4, 5) and the tabernaemontanine,[1] II, type (6, 7).

In the course of a broad screening program, about thirty plants which were identified as either *Tabernaemontana* or *Peschiera* species by South American botanists have been encountered. In order to detect any chemical differences which may exist between, and perhaps thus differentiate, these closely related genera, we have chosen a number of them for detailed study. The first of these, reported here, is *Peschiera affinis* (Meull.-Arg.) Miers.

DISCUSSION

A 5.8-Kg. sample of *P. affinis*[2] collected in northeastern Brazil was extracted with alcohol until removal of alkaloidal material was complete (Mayer's reagent). The extract was concentrated under reduced pressure and the residue was treated with dilute phosphoric acid. The filtered, aqueous

Problems in Chemotaxonomy I

Alkaloids of *Peschiera affinis*

By JERRY A. WEISBACH, ROBERT F. RAFFAUF, OSCAR RIBEIRO,† EDWARD MACKO, and BRYCE DOUGLAS

A phytochemical study of this plant has yielded three indole alkaloids, two of them being of the α-ketoindole type and the third containing a simple nonconjugated indole moiety. One of the α-ketoindole alkaloids has been identified as vobasine, whose recently described structure is found compatible with NMR spectral data. The isolation procedures are described for the second α-ketoindole alkaloid, affinine, and for the indole alkaloid, affinisine.

THE HISTORY of the genus *Tabernaemontana* L. (family *Apocynaceae*) is exceedingly complex. At various times, botanists have split other genera from it (*e.g.*, *Voacanga*, *Ervatamia*, *Gabunia*, *Conopharyngia*) leaving a residue of synonymy of genera and/or species within the group. With regard to South American representatives, botanical opinion concerning their classification has varied widely. Markgraf has separated and readjusted the genus *Tabernaemontana* L. into nine genera, preserving that name for species found in the Antilles, Central America, and parts of northwestern South America, while maintaining *Peschiera* A. DC. for those found in Brazil (1). Woodson does not share this opinion (2).

There is reason to believe that even in closely related genera sufficient differences in alkaloid composition exist to serve as a basis for chemotaxonomic distinctions. In Farnsworth's excellent review of the periwinkles (3) one notes that of the 48 characterized alkaloids isolated from *Vinca* and *Catharanthus* species, only one, akuammine (vincamajoridine) is common to both genera. Obviously, it will be necessary to know more about the actual structures before detailed comparisons can be made between the chemical types found in each genus. As of now, however, it can be stated that the dimeric C_{46} bases have been found only in the genus *Catharanthus*.

From the chemical point of view, the genera in the subtribe Tabernaemontainae have been found to contain two major structural types of alkaloids: the predominant ibogaine, I, type (4, 5) and the tabernaemontanine,[1] II, type (6, 7).

In the course of a broad screening program, about thirty plants which were identified as either *Tabernaemontana* or *Peschiera* species by South American botanists have been encountered. In order to detect any chemical differences which may exist between, and perhaps thus differentiate, these closely related genera, we have chosen a number of them for detailed study. The first of these, reported here, is *Peschiera affinis* (Meull.-Arg.) Miers.

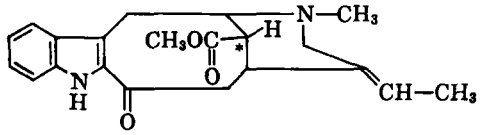
II

solution (pH 1) was subjected to continuous exhaustive extraction with ether. The pH of the aqueous phase was adjusted to 7 and exhaustive extraction with ether was repeated. Finally, extraction with chloroform, after further adjustment of pH to 10, removed residual non-quaternary alkaloidal materials. The quaternary constituents of the aqueous solution were investigated separately and will be the subject of a future communication. The bulk of the crude alkaloids was obtained in the ether extract made at pH 7. Much smaller amounts were found in the chloroform fraction, and the ether extract made at pH 1 was devoid of materials giving a positive alkaloid test.

The ether (pH 7) fraction was chromatographed on 100–200 mesh Florisil. Elution with chloroform gave (in the early fractions) a viscous oil which yielded a crystalline hydrochloride on treatment with ethyl acetate-ethereal hydrogen chloride solution. The regenerated base, obtained in *ca.* 0.45% overall yield, was found identical to the known alkaloid vobasine, III (6, 9, 10), by a mixed melting point determination, and by a comparison of its infrared spectrum and X-ray diffraction pattern with those of an authentic sample.[3]

The nuclear magnetic resonance spectrum[4] of vobasine was found to be in good accord with the elegant structure III, arrived at by Renner and Prins (6) on the basis of chemical as well as electronic and vibrational spectral results. The NMR data are described and interpreted as



III

δ (11)	Assignment
1.70	Vinyl-CH_3 split into doublet by adjacent proton
2.58, 2.65	Ester OCH_3 and NCH_3
3.50	A two-proton singlet from methylene adjacent to the basic nitrogen
5.43	Vinyl proton split into quartet by adjacent methyl
~7.3	Aromatic protons
9.37	N—H hydrogen bonded to carbonyl

[3] We are grateful to Dr. U. Renner, Geigy A. G., Basel, Switzerland, for an authentic sample of vobasine.

[4] The NMR spectrum was determined and interpreted by Dr. G. O. Dudek, Chemistry Department, Harvard University.

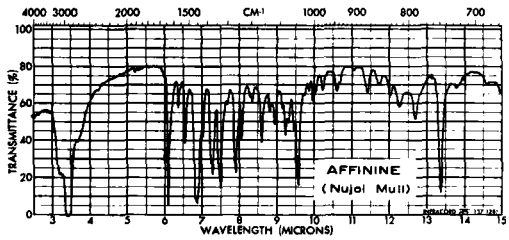


Fig. 1

Some commentary is required with regard to the signals assigned to methoxyl and tertiary aliphatic N-methyl. The expected shifts (as compared to tetramethyl silane) for the two groups are *ca.* 3.7–3.8 and 2.2–2.6 p.p.m., respectively (11, 12, 13). Thus, either signal may be assigned to the N-methyl. The striking shift of O-methyl to higher fields can be explained on the basis of the stereochemistry at C* (as written in III) by an interaction with the diamagnetic portion of the induced field from the aromatic π electrons leading to the observed increased shielding effects (14). If the alternative stereochemistry does in fact

obtain, an $N:\rightarrow C(=O)-OCH_3$ interaction would be expected which also leads to increased shielding of methoxyl, but this time accompanied by a diminished shielding of the N-methyl. In either event there will be a small (~0.2–0.3 p.p.m.) diamagnetic effect from the adjacent double bond on the latter grouping. This situation is also compatible with the observed signals. The resolution of this point is presently under investigation and will be the subject of a future communication.

The above bands represent the majority of the substituents of the molecule and are located and spin-spin coupled in conformity with III. The remaining signals from protons located in the fused ring system cannot be assigned with any certainty as the expected signals cover a small portion of the spectrum. In addition, both their position and spin-spin couplings are dependent upon ring geometry and conformation.

Further elution of the column yielded two new alkaloids, affinisine, $C_{19}H_{24}N_2O$, (5.5 Gm., 0.095%, isolated as hydrochloride) and affinine, $C_{20}H_{24}N_2O_2$ (0.85 Gm.[5]).

Affinisine has an ultraviolet absorption spectrum indicating the presence of a simple nonconjugated indole. Its infrared spectrum (Nujol mull) shows no bands in the 5.5 to 6.5 μ region corresponding to a carbonyl function and did not afford a decision as to the presence or absence of a hydroxyl group on the basis of the 3 μ region. A negative methoxyl determination requires that the single oxygen be present as in either an internal ether or a hydrogen bonded hydroxyl group.

The ultraviolet spectrum of affinine in 95% ethanol indicates the presence of an α-keto indole moiety similar to that found in tabernaemontanine, II, vobasine, III, dregamine (7, 10, 15), voacafrine (16), voacafricine (16), and perivine (17). The infrared spectra of these alkaloids are all reported to

[5] Additional affinine was isolated from the chloroform extract at pH 10 to bring the total yield to *ca.* 0.07%.

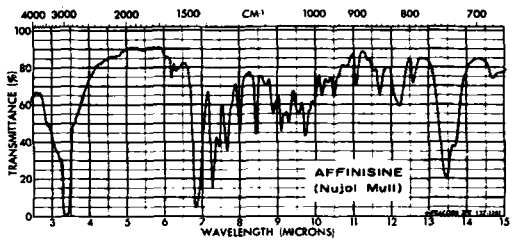

Fig. 2

contain a band at *ca.* 6.06–6.08 μ ascribable to the keto indole grouping, accompanied by a band at 5.79–5.80 μ, probably due to an ester grouping. The infrared spectrum of affinine contains only one band, at 6.08 μ, making it the first example of an alkaloid of this type with a single carbonyl functionality. Its empirical formula, $C_{20}H_{24}N_2O_2$, corresponds to a des-carbomethoxylated voacafrine ($C_{22}H_{26}N_2O_4$) to which it may be directly related.

Isolation of two α-keto indole alkaloids as well as a third containing a simple indole chromophore is in good accord with the predicted general botanical-chemical relationship with *Tabernaemontana*, *Ervatamia*, *Voacanga*, etc. The absence of any of the known alkaloids of the ibogaine type is suggestive of differences between *Peschiera* and the other genera. However, the structure determination of affinisine as well as additional chemical studies in this area are necessary before a firm generalization can be made.

PHARMACOLOGY OF VOBASINE, AFFININE, AND AFFINISINE

Vobasine hydrochloride exhibited weak, but significant, central nervous system depression and ataxia after oral doses of 200 mg./Kg. in mice. Doses of 300 mg./Kg. caused lacrimation, mydriasis, and respiratory depression as well as a progressive increase in the central depressant activity. This compound failed to produce overt effects in cats receiving doses of 15 mg./Kg. intraperitoneally, but was found to produce vocalization, mydriasis, and short-lived, tonic-clonic convulsions following doses of 35 mg./Kg. intraperitoneally. When injected intravenously into the ether-chloralose anesthetized cat at doses ranging from 0.5 to 5.0 mg./Kg. it produced transient depressor activity. A dose of 10 mg./Kg. proved lethal as a result of respiratory depression. No significant changes were observed in the standard test agents (epinephrine, norepinephrine, DMPP, or furfuryl trimethyl ammonium iodide) which measure alterations in the autonomic nervous system after drug treatment. No diuretic activity was observed in the saline hydrated rat receiving doses of 25 mg./Kg. of vobasine orally. Utilizing a modification of the method of Randall and Selitto (18) as presumptive evidence for anti-inflammatory action, we found that vobasine in doses of 25 mg./Kg. orally produced very weak analgesia and moderate antipyretic action, but failed to reduce edema in the rat paw. In the rat, doses of 100 mg./Kg. orally produced signs of toxicity.

Affinine produced gross behavioral changes in the mouse similar to those observed with vobasine. Orally, doses of 200 mg./Kg. caused only slight CNS depressant action, whereas doses of 300 mg./Kg. produced delayed intention tremors, marked CNS depressant activity, ataxia, hypothermia, and bradypnea. No overt effects were observed in the unanesthetized cat receiving 25 mg./Kg. of the compound intraperitoneally. In the anesthetized cat, affinine produced only transient lowering of the mean arterial blood pressure after a cumulative dose as high as 19 mg./Kg. intravenously. Some evidence of toxicity was uncovered since bradycardia, respiratory depression, and cardiac arrhythmias were observed as the dose levels were increased. Affinine was practically inactive when tested for analgetic, antipyretic, or antiedema activity in the Randall and Selitto anti-inflammatory test. No diuretic action was produced in the saline hydrated rat.

Affinisine produced central nervous system depression, lacrimation, and tremors after doses of 50 mg./Kg. orally in the mouse. However, no side effects were observed in the unanesthetized cat following a dose of 10 mg./Kg. intraperitoneally. In the ether-chloralose anesthetized cat, affinisine caused respiratory toxicity after a dose of 1.0 mg./Kg. and proved lethal after an acute dose of 10 mg./Kg. intravenously. Affinisine possesses moderate analgetic activity in the rat after doses as low as 25 mg./Kg. orally. On the other hand, this activity was not accompanied by an effect on skin temperature or on edema. There was no evidence of diuretic activity when affinisine was tested in doses of 25 mg./Kg. orally in the saline-loaded rat.

EXPERIMENTAL[6, 7]

Isolation

The ground whole plant of *P. affinis* (5.8 Kg.) was extracted in a Soxhlet type apparatus with hot 95% ethanol until the marc gave a negative alkaloid test (Mayer's reagent). The extract was concentrated *in vacuo* to a syrupy consistency and the residual solvent was removed at 25° in a stream of air.

The residue was extracted with phosphoric acid (0.2 *M*, total of 14 L.) and the resultant mixture was filtered with Celite. The aqueous solution was treated with ether in a liquid-liquid continuous extractor to yield *ca.* 7 Gm. of nonalkaloidal material. An aliquot (*ca.* two-thirds) of the aqueous layer was neutralized (pH 7) with concentrated sodium bicarbonate solution and extracted to completion with ether. The organic layer yielded 43 Gm. of alkaloid as a brown, crispy foam, which was further processed as described below. The aqueous phase was made alkaline with ammonia and extracted with chloroform to yield an additional 2.3 Gm. of an alkaloidal precipitate and *ca.* 3.5 Gm. of viscous bases.

Forty grams of the alkaloids, extracted at pH 7,

[6] Melting points were determined on a Thomas-Hoover Uni-Melt apparatus. Ultraviolet absorption spectra were obtained using a Cary model 14 spectrometer, and infrared spectra were obtained using a Perkin-Elmer model 173B.

[7] We are indebted to Mr. Irving Eisdorfer of our laboratories for the following paper chromatographic procedure used throughout this study. The mixture *iso*-amyl alcohol: *tert*-amyl alcohol:water:88% formic acid–5:5:10:2 was shaken well. The separated lower layer was used as standing phase and the upper layer as the moving phase on 3 mm. Whatman paper (12 in. × 18 in. sheet) arranged for circular development. The spray reagent used was potassium iodoplatinate.

was dissolved in chloroform and chromatographed on a Florisil column (1 Kg. adsorbent, 3 in. diameter) made up with chloroform. The initial chloroform eluate (*ca.* 3 L.) on combination and evaporation yielded a pale yellow, viscous liquid. Treatment with ethyl acetate-ethereal hydrogen chloride yielded a white crystalline product (17.9 Gm.). Recrystallization from ethyl acetate-methanol gave an analytical sample, m.p. 247° (decompn.), R_f 0.65.

Anal.—Calcd. for $C_{21}H_{24}N_2O_3 \cdot HCl$: C, 64.84; H, 6.48; N, 7.21; Cl, 9.12; O—CH_3, 8.05; N—CH_3 (calcd. CH_3), 3.89; C—CH_3, 6.98. Found: C, 64.42; H, 6.37; N, 7.10; Cl, 8.84, O—CH_3, 8.06; N—CH_3, 3.48; C—CH_3, 5.01.

The free base was obtained by treatment of the hydrochloride with ammoniacal chloroform and isolation of the alkaloid in the usual manner. Recrystallization from ether yielded an analytical sample, m.p. 112.5–115°.

Anal.—Calcd. for $C_{21}H_{24}N_2O_3$: C, 71.57; H, 6.86; N, 7.85. Found: C, 71.32; H, 6.98; N, 7.94.

A mixed melting point determination with authentic vobasine,[3] m.p. 112.5–115° gave m.p. 112.5–115°. The infrared spectra (Nujol mull) of this base and of authentic vobasine were essentially identical and their X-ray diffraction patterns were superimposable.

Affinisine

Further elution with chloroform (9 L.) gave an eluate which on combination and evaporation yielded a viscous oil. On treatment with ethereal hydrogen chloride-ethyl acetate a white crystalline product (5.55 Gm.) was obtained. Recrystallization from methanol gave fine needles, m.p. 287° (decompn.) $[\alpha]_D^{25}$ +40.3 (C = 0.5, MeOH), R_f 0.76.

Anal.—Calcd. for $C_{19}H_{24}N_2O \cdot HCl$: C, 68.57; H, 7.52; N, 8.42; Cl, 10.65; O—CH_3, 9.31; N—CH_3 (calcd. CH_3), 4.50; C—CH_3, 8.11. Found: C, 68.78; H, 7.36; N, 8.30; Cl, 10.44; O—CH_3, negligible; N—CH_3, 3.53; C—CH_3, 3.58. $\lambda_{max.}^{EtOH}$ 224 mμ (log ε 4.65), 282 mμ (log ε 3.92), 292 mμ (log ε 3.82).

The free base was obtained in the usual manner and was recrystallized from methylene chloride-petroleum ether, m.p. 115–118° (insertion at 100°).

Anal.—Calcd. for $C_{19}H_{24}N_2O$: C, 76.99; H, 7.53; N, 9.45. Found: C, 77.07; H, 7.79; N, 9.05, negligible O—CH_3.

Affinine

Elution of the chromatographic column with 15% methanol in chloroform (2 L.) yielded a viscous oil which readily crystallized (0.85 Gm.) from ethyl acetate. Recrystallization from methanol-ethyl acetate yielded an analytical sample as a white crystalline powder, m.p. 265° (decompn.), R_f 0.60.

Anal.—Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.04; H, 7.46; N, 8.64. Found: C, 74.19; H, 7.49; N, 8.64. $\lambda_{max.}^{EtOH}$ 238 mμ (log ε 4.18), 318 mμ (log ε 4.34).

The hydrochloride salt was prepared by solution in methanol, addition of ethereal hydrogen chloride, and removal of solvent *in vacuo*. An analytical sample, m.p. 267–269° (decompn.) was obtained by recrystallization from methanol-ethyl acetate $[\alpha]_D^{25}$ −105.4 (C = 0.5, MeOH).

Anal.—Calcd. for $C_{20}H_{24}N_2O_2 \cdot HCl$: C, 66.56; H, 6.98; N, 7.76. Found: C, 66.21; H, 7.03; N, 7.88, negligible O—CH_3.

Further elution of the column with 15% methanol in chloroform (5 L.) yielded only dark viscous oils (9.9 Gm.), which were not further characterized.

Infrared examination of the alkaloidal precipitate obtained at pH 10 with chloroform showed it to be essentially pure affinine.

No additional non-quaternary crystalline compounds were obtained upon chromatography of any other materials from this plant.

A Rheological Study of the Aging of Veegum Suspensions

By JOHN H. WOOD, GREGORY CATACALOS, and S. V. LIEBERMAN†

Veegum HV and Veegum F suspensions, 2 per cent by weight in water, were found to be pseudoplastic at all ages for all temperatures of preparation and storage. The study is reported over the time range of a few hours to several months for temperatures from 6 to 88°. The logarithm of the apparent viscosity at any shear rate was found to be a linear function of the logarithm of time, and also to be a function of the reciprocal of temperature, obeying an Arrhenius type relation. The apparent activation energy for Veegum hydration was found to be 8000 calories per mole. A general equation is empirically derived to relate viscosity at any given shear rate with the temperature of storage and the age of the suspension.

TODAY VEEGUM[1] has become one of the more commonly used clay-type suspending agents for the whole range of pharmaceutical and cosmetic formulation. Probably the most popular is Veegum HV but a processed variant, Veegum F, has also a wide acceptability in certain special applications. Veegum is a complex magnesium aluminum silicate containing small amounts of other metal oxides. In composition it is intermediate between aluminum silicate (montmorillonite or bentonite) and magnesium silicate (saponite); these are platy and rod-like, respectively (1). The Veegum lattice tends to the rod form but is alleged to be the form most readily swollen by water. The extensive literature on application of this colloid as a thickening, suspending, or stabilizing agent in diverse products for human use, both internal and external, has been summarized elsewhere (2).

Veegum hydrates more completely as temperature is elevated and held during the suspension period. This hydration leads to the growth of a strong gel, the gel strength increasing with the increased temperature used to make it. Presumably this is due to the particles tending to disperse down to their ultimate structure as water penetrates and swells the lattice. Eventually the medium is a semicontinuous silicate-water complex.

Only limited literature (1, 3, 4) discusses the properties of Veegum suspensions in water alone. The temperature used to make the gel affects the resultant properties (2). The time of hydration for a given procedure as well as the method of mixing have been shown to be critical to the properties of the resultant gel (3, 4). In the most recent study (4), "the processed suspensions were stored . . . for a minimum of sixty days to allow system equilibrium to be established."

It was, therefore, of interest to consider in a single study, for a given arbitrary method of preparation, the rheological aging characteristics of Veegum suspensions prepared and stored at different temperatures.

EXPERIMENTAL

Sample Preparation.—All suspensions, 2% by weight, were prepared in a Waring Blendor, model CB-3, in lots of 1 Kg. by the addition of the Veegum to the water. Mixing was 2 minutes at the slowest of the 5 speeds, followed by 5 minutes at the highest speed. The procedure chosen was quite arbitrary and no attempt was made to evaluate effects introduced by deviations from it.

The following temperatures were used for hydration and subsequent storage: Run 1, room temperature, 40, 73, and 88°; Run 2, 6.5°, room temperature, 32, 40, 50, and 60°. The initial water temperature was chosen so that the final hydration temperature did not exceed the values given. Suspensions were made for both Veegum HV and Veegum F. All samples, except for 6.5°, room temperature, and 40° were stored in forced draft air ovens. The 6.5° sample was in a laboratory refrigerator, the room temperature was ambient, and the 40° in a constant temperature room.

Rheological Examination.—All evaluations were made at 25° immediately upon attainment of that temperature. The rheometer was the modified Brookfield LVT described elsewhere (5), permitting shear rates up to 20 sec.$^{-1}$. Only in the last stages of the study was the similarly modified RVT available. Because of its higher speeds, shear rates to 45 sec.$^{-1}$ were available for samples in the appropriate viscosity range. All rheological measurements were made on aliquots removed as required from bulk storage. No samples were ever reused.

The time intervals for measurement were chosen as convenient for measurement rather than at fixed intervals since the logarithm of time plot was being used to follow changes. Thus samples are compared at corresponding times by graphical interpolation. All interpolations were from plots with point to point joining, rather than from smoothed lines.

Since the sample rheology was time dependent, it

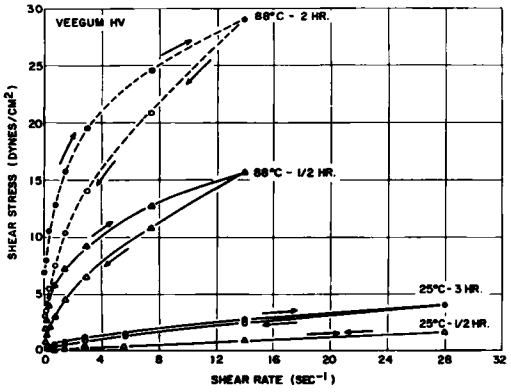

Fig. 1.—Typical rheograms for newly formed Veegum HV mucilages.

was not possible to replicate rheograms in the early hours. At later times, since each rheogram fitted satisfactorily into the pattern of all those preceding it, no attempt was made at replication, except for the example shown in Fig. 2. This is at a period of maximum thixotropy and hence of greatest difficulty in duplication.

With the modified Brookfield in use here, the time constant is such that, in viscous Newtonian systems at very low shear rates, several revolutions of the bob are necessary to reach the steady state reading. Generally, two or three rotations at the low speeds were all that was necessary to attain maximum torque in this study. Immediately upon attaining this value, the speed was increased to the next increment, thus minimizing thixotropic breakdown during the ascending curve. This is the accepted best procedure for systems of this type. All points shown in this study are from the ascending shears only. In Figs. 1 and 2 are shown the gambit of typical rheograms in the initial hours after preparation and after extensive aging, respectively.

Intrinsic Viscosity Comparison.—Suspensions of Veegum HV in 0.5*M* sodium chloride were made for 11 concentrations of Veegum in the range 0.01 to 0.4 wt. per cent, using the Waring Blendor as before. These suspensions were made at room temperature, split into two fractions, and were held in tightly sealed bottles at room temperature and 95° for 1 week. A further 2 days were allowed for the 95° sample to cool. The bottles were checked for any weight loss. Viscosity measurements at 25° were run both for ascending and descending speeds using the "O" cup and bob of the Epprecht (Drage) viscometer. The measuring system is ideal for intrinsic viscosity studies on systems where the normal capillary methods are subject to blockage (6). Shear readings were taken over the full range of speeds for both ascending and descending rates of shear. Limiting slopes of shear stress against shear rate extrapolated to zero shear rate were taken as the viscosity of the sample.

RESULTS AND DISCUSSION

General Rheology and Aging Characteristics.—As initially prepared, the suspensions were very thin. They showed limited thixotropy and were typically pseudoplastic in both ascending and descending shear curves (see Fig. 1). As aging continued, the yield value character already evident in Fig. 1 became more pronounced; both static and dynamic yield values are evident in Fig. 2. This phenomena and this typical rheogram shape has been discussed elsewhere (7). It should be noted that extensive aging introduced a mild rheopectic behavior into the low shear rheogram replacing the earlier minor thixotropy. More severe shear would have probably shown sufficient thixotropy to mask the very low shear rheopexy. Veegum F exhibited similar properties throughout to Veegum HV but, as is clearly evident from Fig. 2, did not show anywhere near as much build-up of plastic body, by a factor of over 10 in viscosity or shear stress units. This difference is also exhibited in comparing the 10 sec.$^{-1}$ curve for HV in Fig. 4 with the 50° isotherm for F in Fig. 5.

In the shear rate permitted by the modified Brookfield LVT rheometer, approximately 0.1 to 20 sec.$^{-1}$, all the 2% Veegum suspensions behaved in this study as almost ideal pseudoplastic systems. Thus a plot of the log of the shear stress, T, against the log of the shear rate, D (log T *vs.* log D), gave essentially straight line plots, an example of which is given in Fig. 3. The slope, or Power law index, ranged from 0.70 to 0.33 for the time interval shown in Fig. 1. Characteristics to be noted are the increase in shear stress required with time, and the marked decrease in the slope of the line with increasing sample age. It is more convenient to deal with apparent viscosity, η_D, defined as T/D, for various given values of the shear rate. The resultant plot, Fig. 4, shows clearly that with age the apparent viscosity becomes increasingly dependent on the shear rate of measurement used.

Recently the application of log viscosity-log time plots for the following of the aging of systems which develop viscous body with time was discussed (8) for use with lotion products. This type of plot was applicable for all the samples studies. Within a set

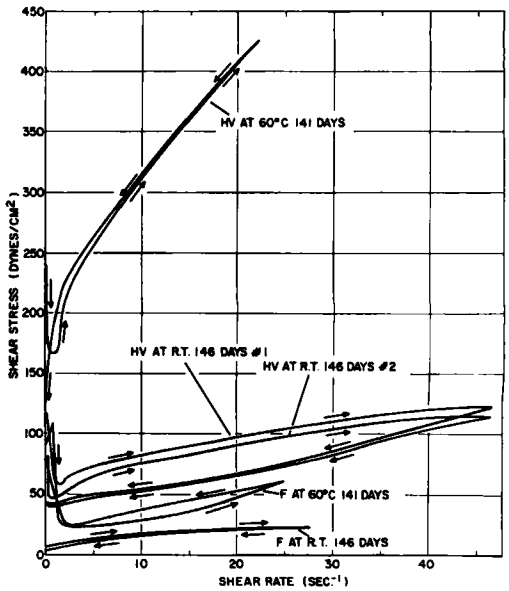

Fig. 2.—Typical rheograms for aged Veegum suspensions.

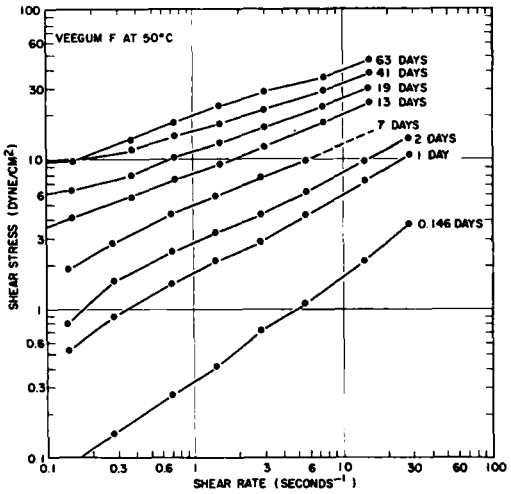

Fig. 3.—Shear stress *vs.* shear rate curves for a 2% Veegum F suspension prepared and held at 50° for varying periods of time.

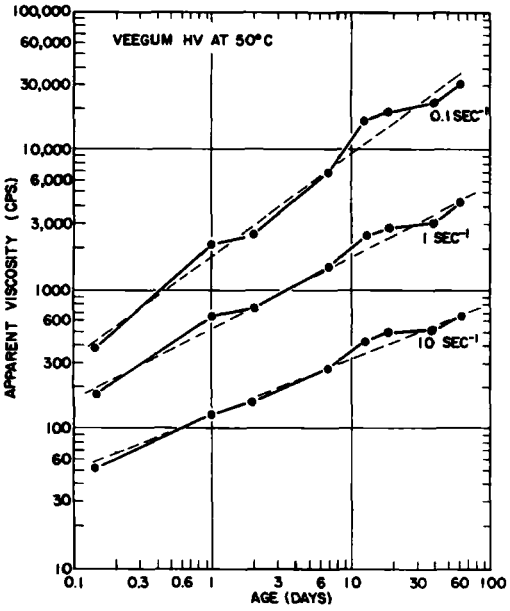

Fig. 4.—Variation of apparent viscosity at different shear rates with time for 2% Veegum HV suspensions prepared at 50°.

of samples prepared at the same time, a series of almost parallel lines for different temperatures of preparation and storage was obtained. An example is shown in Fig. 5. Arbitrarily the apparent viscosity may be compared for any desired shear rate. The general utility of this plot means that

$$\log \eta_D = a \log t + b \qquad \text{(Eq. 1)}$$

or

$$\eta_D = ct^a \qquad \text{(Eq. 2)}$$

where η_D is the apparent viscosity at shear rate D as measured at time t, a is the slope of the line from the plot, and b or c are constants which are dependent on the shear of making, temperature, and sample age.

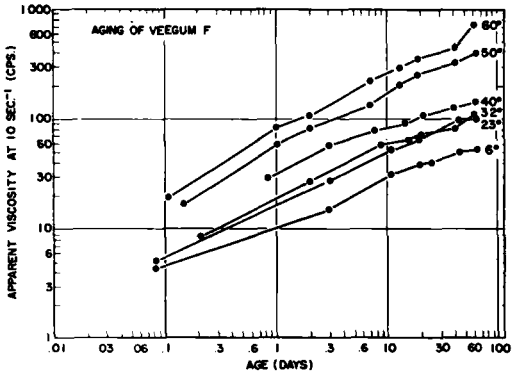

Fig. 5.—Variation of apparent viscosity at 10 sec.$^{-1}$ with time for 2% Veegum F suspensions prepared and held at various temperatures.

We have found that this equation is general for age dependent systems (9) and has been applicable over the time range of fractions of an hour to almost 2 years.

In Table I are given values of the constant a for both Veegums when viscosity is in centipoises and time in days.

It is felt that the values of a are temperature independent over the range examined, and in all probability the values are identical for the two Veegums. Because of the narrow range of a values it is impossible to tell the nature of the dependency on the logarithm of shear rate, since both plots of a directly and of log a are linear with log D over the range of data.

It is of interest to realize that the shear dependency of a does imply that a static yield value builds with time at a faster rate than does the dynamic viscosity.

Although every effort was made to duplicate making procedures, it was found that, in general, samples made over a year and a half apart tended not to duplicate but rather to yield their own set of parallel lines. This is probably due to minor variations in technique of initial hydration. This, however, did not affect the degree of temperature dependence reported in the next section.

Since the constants b or c are so history dependent, they are not reported here. Since the literature (3, 4) so emphasizes the critical dependence of mucilage viscosity upon the making procedure, it is evident that each method of preparation will generate its own set of b or c constants.

Samples stored at temperatures at 50° or higher tended to show slight syneresis after prolonged storage although they continued to yield viscosity determinations reasonably in line with the projection from earlier points.

Temperature Dependence.—Initially only four temperatures of preparation and storage were used: room temperature, 40, 73, and 88°. Somewhat later, when it was noted that, for any age, the log of the viscosities might obey an inverse temperature law, further samples were prepared. The samples prepared at different times yielded parallel lines for all plots, regardless of the age of the samples. Figure 6 shows for Veegum HV the dependence of the logarithm of the viscosity (at 10 sec.$^{-1}$) on the reciprocal of the absolute temperature for agings of

TABLE I.—DEPENDENCE OF a OF EQUATION 1 ON SHEAR RATE OF MEASUREMENT AND VEEGUM TYPE USED

Average	0.69	0.52	0.37	0.74	0.57	0.43

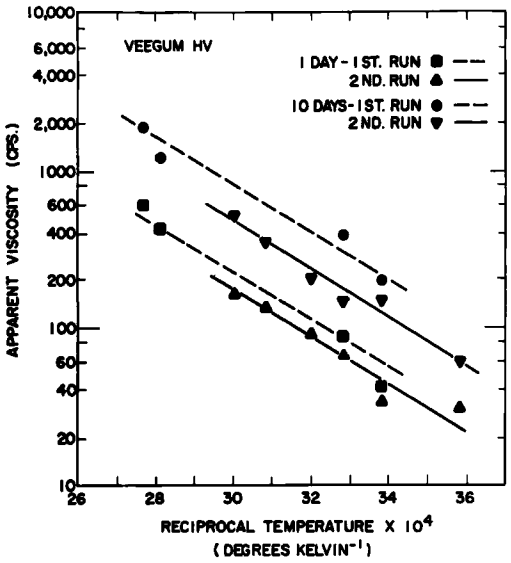

Fig. 6.—Variation of apparent viscosity at 10 sec.$^{-1}$ with reciprocal of absolute temperature for 2% Veegum HV suspensions for two different periods of aging.

both 1 and 10 days. The best fits are lines of similar slope through all points of a given set. The same slope was found for Veegum F.

Thus it is apparent that Veegum viscosity build-up follows an Arrhenius activation law relationship

$$2.303 \log \eta = -\frac{E}{RT} + d \qquad \text{(Eq. 3)}$$

and

$$\eta = fe^{-E/RT} \qquad \text{(Eq. 4)}$$

where η is in appropriate units, T is the absolute temperature, e is the base of natural logarithms, d and f are fit constants which are dependent on the units used for η and obviously upon the whole sample history, E is the apparent activation energy, and R the gas constant. It is apparent that torque at any shear rate, or similar units of gel measurement can be used for η and would affect only the fit constants d and f.

E is then found to have the magnitude of 8000 calories/mole. This would be the activation energy for process of opening up the crystal lattice to water. Since Veegum is slowly hydratable without heat, this is a plausible value for activation.

The normal temperature dependency of viscosity has been the subject of considerable work especially in the polymer field (10). Typical is the simple Andrade equation (11) which has a positive exponential since all polymer variants normally decrease in viscosity with increasing temperature. In contrast, this system shows a viscous build-up with temperature, the viscosity being a measure of the degree of hydration that has occurred.

Intrinsic Viscosity.—All samples in the range of concentration used showed slight thixotropic structure which was lost during the course of the full cycle of measurement. However, within the range of experimental determination, no significant difference between the heated and unheated samples could be detected at the low concentrations. This implies that in the very dilute stage all lattice structures are apparently swollen equally, within the week, or carry equivalent hydration shells, regardless of the temperature of storage during hydration.

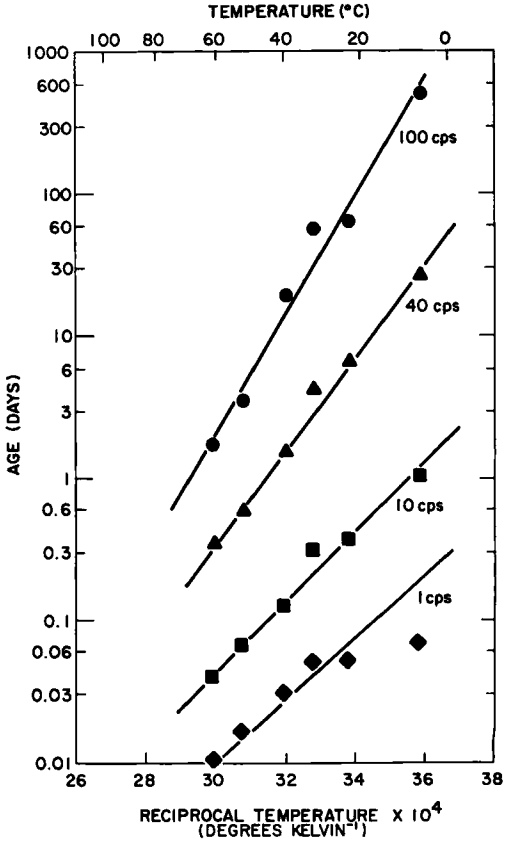

Fig. 7.—Variation of the time required to attain a given viscosity at 10 sec.$^{-1}$ as a function of the reciprocal of absolute temperature for 2% Veegum F suspensions.

General.—We may combine the equations for the viscosity dependence on aging at constant temperature and on temperature at equal ages into the form

$$2.303 \log \eta_D = 2.303\, a \log t - E/RT + g \quad \text{(Eq. 5)}$$

or

$$\eta_D = ht^a e^{-E/RT} \quad \text{(Eq. 6)}$$

where g and h are fit constants which are dependent upon units used and upon preparative history of the sample.

Equation 5 implies that, for any given viscosity level attained during aging, a plot of the reciprocal of temperature and the logarithm of the time required to attain that viscosity will be a straight line. In Fig. 7 are shown such plots for four viscosity levels of Veegum F. The lines are reasonably parallel as is required by the equation. Thus the times required to attain a given level of viscous build-up by varying temperature may be compared.

Equation 5 or 6 or their precursors imply an infinite viscosity with infinite time. This seems to have no practical likelihood of substantiation. Syneresis appears to be the phenomenon which dictates the boundaries within which Eqs. 5 and 6 are valid.

SUMMARY

The exponential aging relation has been found to hold for 2% Veegum HV and 2% Veegum F suspensions in water, so that the logarithm of the viscosity is a linear function of the logarithm of time over a time interval from a few hours to several months.

For samples of equivalent age, an Arrhenius-type relation holds to relate the viscosity with the temperature of preparation and storage. The apparent activation energy for both Veegum HV and Veegum F is about 8000 calories/mole.

The temperature and time relationship may be combined to one general equation which permits time to reach a given viscosity for a given temperature to be determined.

One constant of any of the above relationships is critically dependent on the method of mucilage preparation.

Benzoic Acid as an Absorbance Standard in Infrared Spectrophotometry in Pharmaceutical Analyses

By J. P. COMER and A. M. RIBLEY

A solution of benzoic acid in chloroform measured at 5.91 μ was used to establish absorbance ratios for several drug substances. The ratios were used with daily measurements of benzoic acid as absorbance standards. The precision and accuracy of the technique was found to be equal to the customary method of using the drug substance as a reference standard.

THE PREDICTION of Carol (1) that the use of infrared spectrophotometry in pharmaceutical analyses would increase has certainly been correct. The maintenance of the multitude of chemical standards for infrared spectrophotometry has created many problems. The pharmaceutical laboratories must store and maintain in the original state these standard compounds and also supply governmental agencies with the proper standards. Many analysts (2–6) have reported on various methods for the standardization of instruments. Most of the work concerning the standardization of wavelength and possible use of solid standards does not consider some of the variables encountered in routine control of pharmaceuticals. Variable cell paths, temperature changes, and instrumental responses are corrected normally by performing standard readings of the known compound in solution. The purpose of this investigation was to attempt to find a suitable standard that could be used for quantitative analyses to replace the ever increasing number of individual standards that are encountered in pharmaceutical research programs.

Benzoic acid being readily available in high purity was selected as a trial substance since it has

distinct absorption maxima scattered through the 3–10 μ range. The carboxylic acid absorption at 5.91 μ was the most desirable reference wavelength since it represents the carbonyl region characteristic of so many drug substances and because it exhibits maximum sensitivity for benzoic acid. The results of the initial work with benzoic acid was so encouraging that studies of other potential standards were not undertaken.

EXPERIMENTAL

The Beckman IR 2 instrument was used for all the measurements unless noted otherwise. The benzoic acid solutions were prepared fresh daily to avoid concentration by loss of chloroform. A solution of *d*-propoxyphene hydrogen chloride (130 mg.) was made alkaline and extracted with chloroform. The chloroform was evaporated and the residue dissolved in 4 ml. of chloroform. Another solution was prepared containing acetylsalicylic acid (908 mg.), caffeine (640 mg.), and acetophenetidin (130 mg.) in 50 ml. of chloroform. Benzoic acid solutions were prepared containing 100 mg. (BA) and 600 mg. (BAII) in 10 ml. chloroform. The absorbances of these solutions were measured and ratios calculated. Accurate location of the absorption maxima was required for each determination made through the study.

Sufficient materials were obtained so that the same lot numbers could be used for the preparation of the solutions for the complete wavelengths studies. The solutions were prepared immediately before use.

RESULTS AND DISCUSSION

The use of a single standard would not be practical unless the absorption ratios of compound to standard would be constant in respect to time and changes of absorption cells thickness. Wichers (7) reported the use of benzoic acid as a thermometric standard but indicated possible instability problems. It was found that chloroform solutions of benzoic acid were stable. (Zero time A = 0.394, 1 hr. A = 0.392, 5 hr. A = 0.393, and 48 hr. A = 0.396.) The maxima of benzoic acid in chloroform solutions observed on a Beckman IR 2 instrument are shown in Table I.

The *d*-propoxyphene hydrogen chloride and the acetylsalicylic acid, caffeine, and acetophenetidin solutions were prepared at an interval of 30 months and the ratios of absorbances were calculated. Table II lists the comparative results. The changes in the ratios were not considered significant for the number of observations so a study was started for the selection of the optimum standard wavelengths to be used for a series of compounds. Table III shows the concentration, wavelength, cell path, etc. The calculated ratios from the absorb-

ance data are shown in Table IV. Precision is expressed as coefficient of variation (100 × S.D./Av.) since the ratios differ in magnitude.

General observations indicated that a single benzoic acid solution (BAI) at 0.3 slit and 5.91 μ could be used as a suitable standard. Precision and accuracy studies were started based on these observations.

The precisions of ratios derived from absorbance of acetylsalicylic acid and benzoic acid (BAI) were obtained over a three-month span. The ratios in Table V were calculated from the average absorbance of three solutions. There is no statistically significant difference (F-test) in the precision of the ratios calculated by using benzoic acid as the reference or by using acetylsalicylic acid as reference.

Another cell having 80% of the cell path of the one used for data in Table V was used for obtaining absorbances and ratios for four averages of three solutions each. The ratios found for ASA/BA were 0.995, 1.007, 1.006, 1.012, illustrating that cell path changes occurring in practical use will not significantly change the ratios.

After the ratios were established by numerous replicate determinations between BAI and each of the several compounds previously mentioned, a measure of the accuracy of this system for its proposed use was made. Observed absorbance values at weekly intervals for the individual standard materials were compared to absorbance values calculated by multiplying the current BAI absorbance by the previously established ratios.

Observation of the data from this experiment shown in Table VI indicates an accuracy and precision equivalent to that expected in customary standardization techniques.

Since the manually operated Beckman IR 2 was used for the preceding experiments, the precision of the technique was evaluated on the Perkin-Elmer model 21 recording instrument. Ratios of the five drugs *vs.* BAI were determined on three different days using an average of three replicates for benzoic acid and a single observation of the samples. An extensive realignment of the instrument was made between the first and second series. The data in Table VII show that satisfactory precision may be obtained using benzoic acid as a standard on a recording instrument if careful control of instrument parameters (recording speed, pen sensitivity, slit width, etc.) is maintained.

SUMMARY

Chloroform solutions of benzoic acid (BAI) were shown to be stable over two-day periods, but were prepared fresh daily to avoid concentration by evaporation. Ratios of *d*-propoxyphene, caffeine, and acetophenetidin solutions were found to be constant over a 30-month period (Table II). The precision of ratios calculated from maxima of benzoic acid nearest the maxima of various drug substances were compared to those ratios calculated from benzoic acid at 5.91 μ and the maxima of the drug substances (Table IV). Statistical analysis showed a significant difference for acetophenetidin and ethanol but not for aniline, phenaglycodol, or isopropanol. For acetophenetidin the best precision was by the ratio calculated from the 5.91 μ BA solution.

TABLE VI.—ACCURACY STUDY

Solution[a]	Absorbance Observed	Absorbance Calcd.	Absorbance Diff.	% Error

[a] See Table III for identification of solutions.

TABLE VII.—PRECISION OF RATIOS WITH A RECORDING INSTRUMENT

Time Elapsed, Months	Salicylic Acid[a] BAI	Caffeine[a] BAI	Acetophenetidin[a] II BAI	Acetylsalicylic[a] Acid BAI	Phenaglycodol[a] BAI
0	0.609	0.849	1.21	0.895	1.16
1	0.621	0.962	1.19	0.920	1.16
2	0.622	0.848	1.21	0.904	1.18
$\frac{\text{S.D.}}{\text{Av.}} \times 100$	1.17	0.916	0.962	1.40	0.987

[a] Ratio of absorbance.

The difference for ethanol is not considered practically significant for the coefficient of variation for the ethanol/BAI is only 0.92%. It was concluded from this study that the absorbance of BAI at 5.91 μ could be used for a reference standard for all drugs listed in this experiment.

The ratios for acetylsalicylic acid/BAI and acetylsalicylic acid/acetylsalicylic acid were measured during a three-month period (Table V). No statistically significant difference (F-test) was observed, and the coefficient of variation was less than 1%. Cell path changes occurring in practical use did not change the ratios.

Accuracy studies (Table VI) showed an average difference between customary standardization techniques and the ratio method of +0.16% with a pooled standard deviation of ±0.9%.

Ratios must be established for each instrument, for changes in slit width, optics, or measuring systems of various instruments will change the ratios. For example the ratio found for acetylsalicylic acid/BAI for single beam Beckman IR 2 was 1.01 and the ratio found for double beam Perkin-Elmer No. 21 was 0.907.

Noticeable changes in ratios on a single instrument can be used as an indication of needed maintenance or instrumental calibration by techniques described in references (2–6).

CONCLUSION

The accuracy and precision of the use of benzoic acid solutions in chloroform as secondary reference standards for quantitative infrared spectrophotometry was found to be for practical purposes equivalent to the use of individual standards of the drugs being measured. The successful use of the technique of using the secondary reference depends upon the establishment of accurate ratios on a single instrument by suitable replication and careful control of slit width and instrument calibration.

The technique would be useful to laboratories doing large numbers of measurements on a variety of drug substances that require the preparation of individual standards.

Spectrophotometric Determination of Sodium 2,6-Dimethoxyphenyl Penicillin Monohydrate (Methicillin)

By W. J. WEAVER and R. F. RESCHKE

Sodium 2,6-dimethoxyphenyl penicillin in pH 3.8 acetate buffer shows no absorbance in the region 290 mμ to 360 mμ. When heated in this buffer an absorption maximum appears at 330 mμ. The increase in absorption is directly proportional to the penicillin concentration. This procedure has been used to determine potencies in finished products. Results are compared with the iodimetric and microbiological methods.

HERRIOTT (1) investigated the degradation of salts of penicillin G, X, K, and F under controlled acidic conditions. Procedures are given for the determination of high and low potency material, in which solutions are diluted in 0.4 *M* acetic acid-sodium acetate buffer, pH 4.6, and heated for 15 minutes at 100°. The difference in absorbance at 322 mμ between heated and unheated buffered solutions provides a means of measuring total penicillin present. The results are within 5.0% of theoretical values. Herriott noted in his work that the change in absorbance did not increase linearly with concentration.

Stock (2) modified the method proposed by Herriott. His work demonstrates the importance of the presence of trace amounts of copper in the penicillin-penicillenic acid reaction. When copper is added to the buffer solution, reproducible results are obtained in the determination of benzylpenicillins in penicillin oral tablets. Stock demonstrated the effects of variable conditions such as time of immersion in water bath, volume of penicillin buffer mixture, and concentration of copper. By adding a small amount of copper, not only is the reproducibility improved, but the sensitivity is increased approximately ten per cent.

More recently Holbrook (3) investigated the experimental conditions and expanded the original method to include determination of various salts of benzylpenicillin in ointments, lozenges, oily injections, and suspensions. Penicillin potencies obtained by the spectrophotometric method are compared with those obtained by microbiological methods.

We have studied the application of these methods to one of the new synthetic penicillins, methicillin,[1] for the purpose of developing a routine analytical procedure. The main advantages of the proposed method are simplicity, speed, and sensitivity. The procedure has been successfully employed for analyzing large numbers of samples.

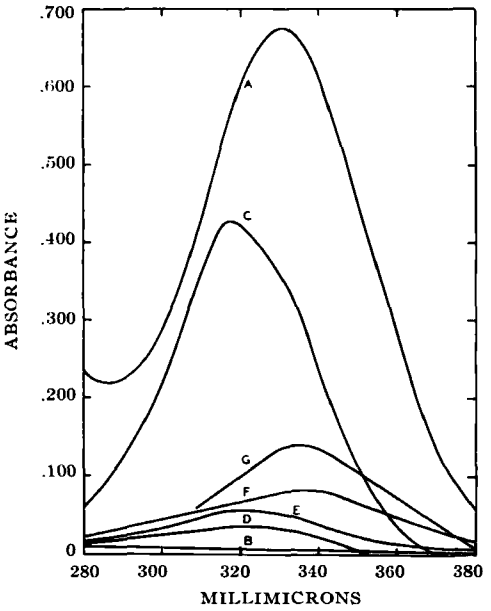

Fig. 1—Absorption spectra of penicillins: 4.76×10^{-5} moles per ml., 0.2 *M* buffer, pH 3.8, 30 min., 70°C. A, methicillin; B, 6-aminopenicillanic acid; C, benzylpenicillin potassium; D, potassium phenoxyethylpenicillin; E, potassium phenoxyethylpenicillin; F, D(-)α-aminobenzylpenicillin (free acid); and G, potassium methylphenylisoxazolylpenicillin.

EXPERIMENTAL

Reagents.—*Dilute Copper Sulfate Solution:* Dissolve 0.392 Gm. of copper sulfate pentahydrate in 100 ml. of distilled water. This solution contains 1 mg. of copper per ml.

Buffer Solution, pH 3.8: Mix 13 ml. of 2 *M* sodium acetate and 87 ml. of 2 *M* acetic acid. Add 0.5 ml. of the dilute copper sulfate solution and dilute to 1 L. with distilled water. The resulting solution is 0.2 *M* in respect to acetate and

Received April 13, 1962, from Bristol Laboratories, a division of Bristol-Myers Co., Syracuse, N. Y.
Accepted for publication July 5, 1962.
The authors are indebted to Mr. J. P. Messerly of Bristol Laboratories and Dr. W. D. Cooke of Cornell University for their suggestions and encouragement.

[1] Marketed as Staphcillin by Bristol-Myers Co.

contains 0.5 mcg. of copper per ml. Adjust the pH within the range 3.7–3.9 with sodium acetate or acetic acid, as required.

Preparation of Standard Curve.—Prepare an aqueous solution containing 500 mcg. of standard methicillin per ml. Transfer a 2.0-ml. aliquot to each of two 100-ml. volumetric flasks. Dilute the contents of one flask to volume with the buffer solution. Dilute the other to volume with distilled water. Transfer 10 ml. of the buffer dilution to a 16 mm. × 150 mm. test tube and place in a 70° water bath for 30 minutes. Remove and cool immediately in an ice bath to quench the reaction. Determine the absorbance within 1 hour in a 1-cm. cell at 330 mμ, using the water dilution as reference. Establish additional points on the calibration curve by using 3.0- and 4.0-ml. aliquots of the methicillin standard solution. Plot absorbance *versus* mcg. per ml.

Procedure.—Prepare an aqueous solution containing approximately 500 mcg. methicillin per ml. Dilute 3.0 ml. of the solution to 100 ml. with the buffer solution. Prepare a similar 3.0 to 100 dilution with water, which serves as the reference solution. Proceed as directed in preparation of the standard curve, and determine the concentration from the prepared graph.

RESULTS AND DISCUSSION

Figure 1-A illustrates the change that occurs when methicillin is heated under optimum conditions of pH, time, and temperature. Equivalent amounts of other natural and synthetic penicillins heated under these conditions produce absorption spectra shown in Fig. 1, B-G. Note that methicillin develops an absorption maximum at 330 mμ, whereas maxima of the other penicillins appear at different wavelengths in the 310–340 mμ range. Table I contains the absorptivities at the absorption maximum for each penicillin.

TABLE I.—ABSORPTIVITIES AND ABSORPTION MAXIMA OF VARIOUS PENICILLINS IN 0.2 *M* ACETATE BUFFER, pH 3.8, AFTER HEATING FOR 30 MIN. AT 70°C.

	Wavelengths at Absorption Maximum in 310–340 mμ Range	Absorptivities at λ Max.
2,6-Dimethoxyphenylpenicillin, sodium salt	330 mμ	330
6-Aminopenicillanic acid	None	...
Benzylpenicillin, potassium salt	317 mμ	240
Phenoxymethylpenicillin, potassium salt	320 mμ	11
Phenoxyethylpenicillin, potassium salt	320 mμ	21
D(−) α-Aminobenzylpenicillin (free acid)	335 mμ	44
Methylphenylisoxazolylpenicillin, potassium salt	334 mμ	64

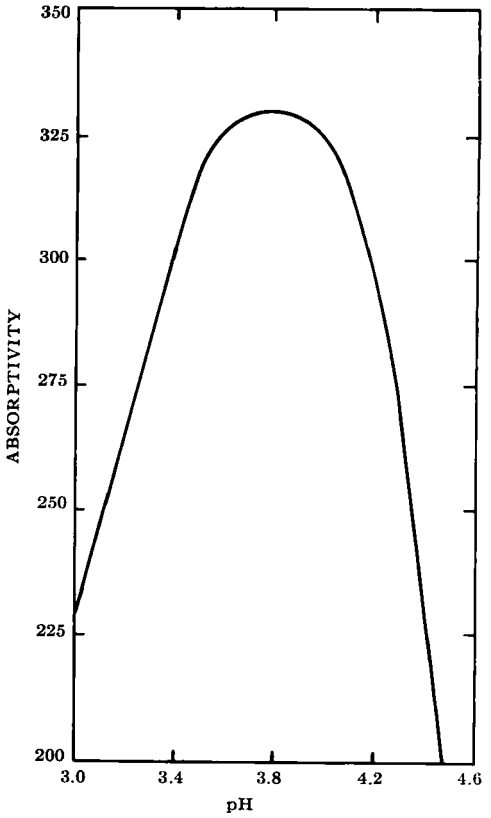

Fig. 2.—Effect of pH: 0.2 *M* buffer, 30 min., 70°C.

The conditions necessary to produce maximum sensitivity and reproducibility for methicillin were found to be 30 minutes heating at 70° in 0.2 *M* acetate buffer, pH 3.8, containing 0.5 mcg. copper

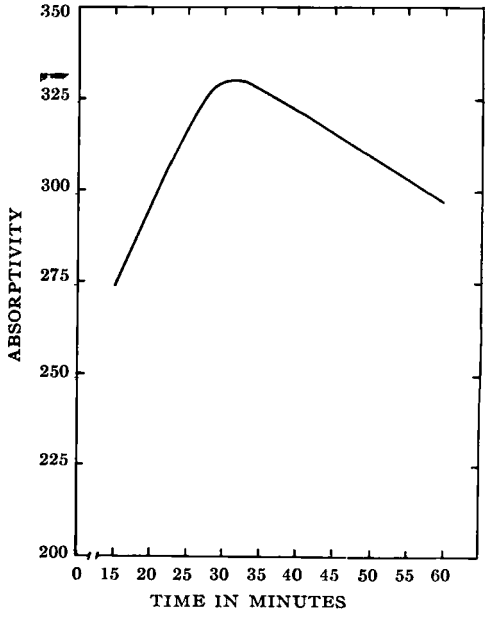

Fig. 3.—Effect of heating time: 0.2 *M* buffer pH 3.8, 70°C.

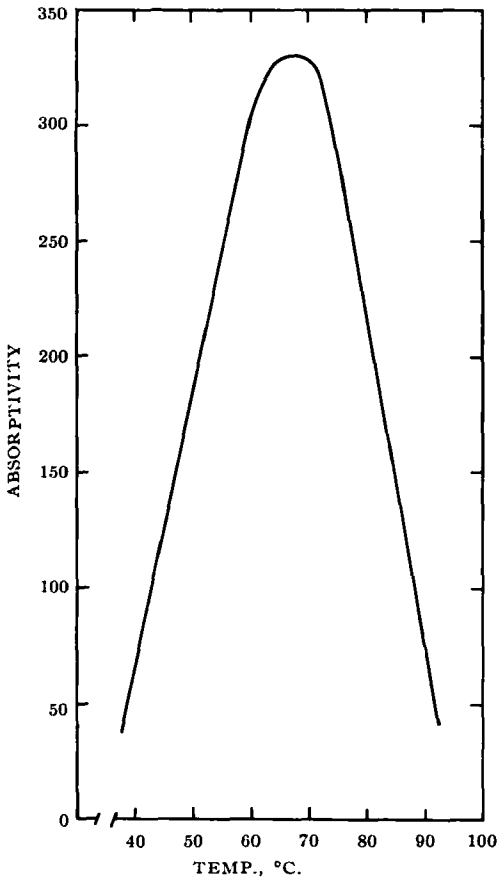

Fig. 4.—Effect of temperature: 0.2 *M* buffer, pH 3.8, 30 min.

per ml. The effect of acetate buffers over a pH range of 3.0 to 4.6 was studied, the results being shown in Fig. 2. Figure 3 shows the effect of time of heating at 70° in 0.2 *M* acetate buffer, pH 3.8. The maximum absorptivity develops after 30 minutes. Between 28 and 40 minutes the range of variation in the absorptivity is approximately 1.3%. Figure 4 indicates the effect on the absorptivity at 330 mμ when methicillin is heated in pH 3.8 buffer at various temperatures for 30 minutes. Heating at 25°, 50°, and 100° at other pH levels produces lower absorptivities.

The effect on absorptivity using buffers ranging from 0.1 to 1.0 molar is illustrated in Fig. 5.

The method was also applied to buffered methicillin containing 5% sodium citrate. The results are compared with iodimetric and biological assays

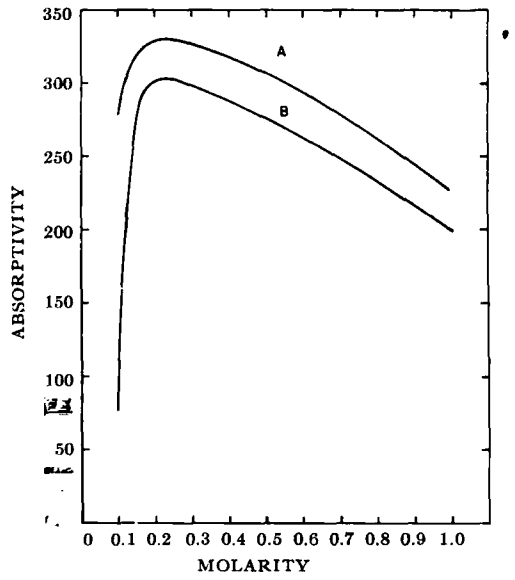

Fig. 5.—Effect of buffer molarity: pH 3.8, 30 min., 70°C. *A*, 0.5 mcg. copper per ml. added; *B*, without copper.

in Table II. It can be seen that sodium citrate causes no interference.

TABLE II.—COMPARISON OF THE RESULTS BY THE SPECTROPHOTOMETRIC METHOD WITH THOSE BY IODIMETRIC AND BIOASSAY

Sample	Spectrophotometric, mcg./mg.	Iodimetric, mcg./mg.	Bioassay, mcg./mg.
Buffered methicillin	850	854	850
Buffered methicillin	834	830	860
Buffered methicillin	847	837	830
Unbuffered methicillin[a]	877	880	870

[a] Theoretical potency of methicillin (sodium salt, monohydrate) is 905 mcg./mg.

Precision.—A statistical study of the recommended procedure was made by assaying eight samples ranging from 10 to 20 mcg. methicillin per ml. The apparent relative standard deviation(s) calculated as percentage of average absorptivity is ±1.8%.

Identification and Differentiation of Some Phenothiazine-Type Tranquilizers

By D. K. YUNG and M. PERNAROWSKI

Methods are described for the identification and differentiation of the 13 phenothiazine-type tranquilizers listed in Schedule F of the Canadian Food and Drugs Act. These tranquilizers may be identified by observing the colors formed with certain reagents and by determining the melting points and infrared spectral characteristics of either the picrate or reineckate derivatives.

Most of the substituted phenothiazines possess tranquilizing properties and, consequently, are subject to controls in the market place. The pharmaceutical analyst, particularly if he is employed by an enforcing agency, is often called on to identify substances such as those listed herein. The methods available to the analyst depend mostly on the formation of a characteristic color with a selected reagent.

Feigl (1) described two spot tests for the base material, phenothiazine. Deviller (2) developed methods for the identification of thirteen substituted phenothiazines. Filho and Aichinger (3) showed that phenothiazine, promethazine, diethazine, isothiazine, chlorpromazine, and neozine could be identified by reacting these compounds with a series of reagents. Identification procedures for chlorpromazine hydrochloride, based on color formation, are described in the "British Pharmacopoeia 1958" (4) and the "United States Pharmacopeia XVI" (5). Because of the similarity in chemical structure, many substituted phenothiazines have been included in studies on the identification of antihistamines by color formation (6, 7). Rajeswaran and Kirk (8, 9) reported the identification of 50 tranquilizing and related drugs by means of color reactions and microscopic crystal tests.

Little systematic work has been carried out on the identification of substituted phenothiazines by derivative formation. The preparation of picrate and reineckate derivatives of some of the substituted phenothiazines has been reported (10, 11). Some picrates (12) and reineckates (11) were prepared and used in quantitative procedures involving the colorimetric determination of selected substituted phenothiazines.

Received July 9, 1962, from the Pharmaceutical Chemistry Section, Food and Drug Directorate, Ottawa, Canada.

Accepted for publication August 13, 1962.

The authors wish to thank the following manufacturers for supplying some of the phenothiazine derivatives used in this investigation: Ayerst, McKenna & Harrison Ltd.; G. D. Searle & Company of Canada Ltd.; Poulenc Ltd.; Sandoz (Canada) Ltd.; Schering Corp. Ltd.; Smith Kline and French Inter-American Corporation; E. R. Squibb & Sons of Canada Ltd.; Warner-Chilcott Laboratories Co. Ltd.; John Wyeth & Brother (Canada) Ltd. The authors also wish to thank G. Morris for drafting the spectra illustrated in this paper.

A number of procedures are described in this paper that will aid the analyst in the rapid identification of a restricted group of phenothiazines possessing tranquilizing properties.

EXPERIMENTAL

The following substituted phenothiazines were investigated: acepromazine hydrochloride, chlorpromazine hydrochloride, fluphenazine, levomepromazine maleate, mepazine acetate, perphenazine, prochlorperazine dimaleate, promazine hydrochloride, thiopropazate dihydrochloride, thioridazine hydrochloride, trifluoperazine dihydrochloride, triflupromazine hydrochloride, and trimeprazine tartrate. A Thomas-Hoover capillary melting point apparatus was used to determine the melting points of these compounds. The values so obtained are shown in Table I and are in good agreement with those supplied by the manufacturers or reported in the "Merck Index" (13). The chemical names of these substances may be found in the latter reference.

Reagents for Identification by Color Formation.—(*a*) Reagent I: Add 10 drops of 10% w/w hydrochloric acid to 30 ml. of a 1% aqueous ferric chloride solution; (*b*) Reagent II: 1% aqueous cobalt acetate solution; 10% isopropylamine in acetone; (*c*) Reagent III: 10% aqueous chloramine-T solution; (*d*) Reagent IV: add 1 ml. of hydrochloric acid U.S.P. to 50 ml. of a 0.1% aqueous palladium chloride solution; (*e*) Reagent V: nitric acid; (*f*) Reagent VI: add three ml. of concentrated sulfuric acid to 17 ml. of a 6% solution of uranium nitrate in 95% ethanol. This reagent will not form the desired colors unless it is freshly prepared. (*g*) Reagent VII: 0.5% w/w ammonium vanadate in concentrated sulfuric acid; (*h*) Reagent VIII: Add five drops of 0.1 *N* sulfuric acid to 20 ml. of a 4% aqueous silver nitrate solution.

Identification by Color Formation.—Prepare a 0.15% aqueous solution of the substituted phenothiazine. Heat gently, if necessary, to completely solubilize the phenothiazine. Transfer five drops of this solution to a depression in a white spot plate and add one drop of reagent. Observe the color immediately after mixing. (For the purposes of this paper, one drop is equal to approximately 0.05 ml.)

For reactions involving Reagent II, add one drop of the cobalt acetate solution and then one drop of the 10% isopropylamine in acetone to five drops of the test solution.

For reactions involving silver nitrate, transfer ten drops of the phenothiazine solution to a semimicro

TABLE I.—MELTING POINTS OF THE SALTS, PICRATES, AND REINECKATES OF SOME SUBSTITUTED PHENOTHIAZINES

	M.p., °C. (uncor.)		
	Salt[a]	Picrate	Reineckate
Acepromazine	135.0–136.0	69.0–73.0	154.0–156.0[b]

Triflupromazine	173.0–174.0	152.0–153.0	194.5–195.0[b]
Trimeprazine	162.0–163.0	130.0	168.5–170.0[b]

[a] See first paragraph under *Experimental*. [b] Melt with decomposition.

test tube and add two drops of the reagent. Heat the solution in boiling water for 5 minutes and observe the color.

The colors formed with seven of the eight reagents are reported in Table II. The results obtained for Reagent I are shown in Fig. 1.

Identification by Picrate Formation.—Dissolve 500 mg. of the substituted phenothiazine in 50 ml. of distilled water. If the substance is not completely soluble, stir for 10 minutes and filter. Add slowly, with stirring, 50 ml. of a saturated solution of picric acid in water. Allow the mixture to stand for ten minutes, filter using a sintered-glass filter of medium porosity, and wash the precipitate with a small quantity of distilled water. Recrystallize twice from 95% ethanol and dry the crystals in a desiccator over phosphorous pentoxide.

If recrystallization is not possible, wash the recovered substance thoroughly with distilled water, then with 95% ethanol, and dry as indicated above.

The melting points of the 13 picrate derivatives are listed in Table I.

Purity Criterion for Picrate Derivatives.—Carbon, hydrogen, and nitrogen determinations were carried out on the 13 picrate derivatives. Experimental values agreed satisfactorily with the calculated theoretical values.

The equivalent weights of the picrate derivatives were determined in the following way: (*a*) Method for monopicrates: Dissolve 30 mg., accurately weighed, in 15 ml. of glacial acetic acid and 15 ml. of chloroform. Titrate the solution with 0.02 *N* acetous perchloric acid using four drops of a 0.5% solution of crystal violet in glacial acetic acid as indicator. The color change, from purple to blue, was checked potentiometrically using a Precision-Shell dual titrometer equipped with glass and sleeve-type calomel electrodes. Carry out a blank determination and make any necessary corrections in the calculation. (*b*) Method for dipicrates: Dissolve 50 mg., accurately weighed, in 30 ml. of dimethylformamide. Titrate the solution with 0.1 *N* potassium hydroxide in methanol using four drops of a freshly prepared 0.5% solution of thymol blue in methanol as indicator. The color change, from greenish yellow to green, was checked potentiometrically as indicated above. Protect the contents of the flask from atmospheric conditions. Carry out a blank determination and make any necessary corrections in the calculation.

The equivalent weight is equal to the weight of the sample in grams divided by the product of the volume and normality of the titrant. The equivalent weight of each picrate was determined by using the appropriate method and the experimental and theoretical values compared. All results were found to be satisfactory.

Identification by Reineckate Formation.—Dissolve 150 mg. of the substituted phenothiazine in 50 ml. of 0.1 *N* hydrochloric acid. If the substance is not completely soluble, stir for 10 minutes, and then filter. Add slowly, with stirring, 50 ml. of a saturated solution of ammonium reineckate in water. Refrigerate for 10 minutes, filter through

a sintered-glass filter of medium porosity, wash the precipitate with distilled water, and recrystallize twice from 70% ethanol at 55°. Dry the crystals in a desiccator over phosphorous pentoxide.

The decomposition points of the 13 reineckate derivatives are listed in Table I.

Purity Criterion for Reineckate Derivatives.—The chromium content of each of the reineckates was determined by ashing the sample at 800° for 3 hours. The per cent chromium in the derivatives (calculated from the weight of ash) compared favorably with theoretical values.

Procedure for the Preparation of Infrared Spectrum.—Mix 15 mg. of the picrate or reineckate with 285 mg. of previously dried A.C S. grade potassium bromide in a Wig-L-Bug amalgamator. Transfer the sample to a Beckman rectangular pellet die, evacuate, and subject the mixture for 10 minutes to a pressure of 20,000 lb./sq. in. using a Carver laboratory press. Record the spectrum of the pellet on a Beckman IR 5 infrared spectrophotometer.

The infrared spectra of promazine picrate and trifluoperazine reineckate are shown in Fig. 2. Portions of other spectra are illustrated in Figs. 3 and 4.

DISCUSSION

One of the easiest ways to identify an organic

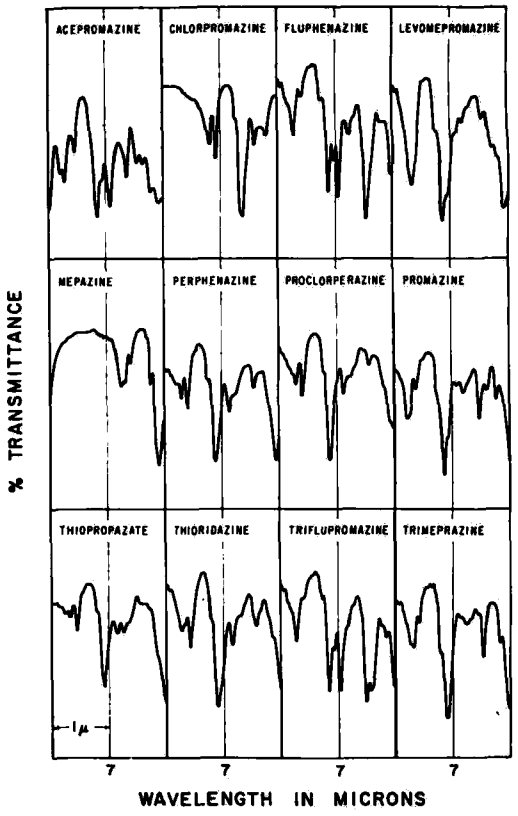

Fig. 4.—Infrared spectra of the reineckates of some substituted phenothiazines.

compound is to carry out a reaction which yields a characteristically colored product. The rationale in most of these tests is that the particular reaction is specific but, unfortunately, such specificity is limited to the conditions outlined by the researcher. Moreover, reaction to color is largely a matter of opinion and, consequently, what is red to one chemist might be orange to another. Tests in sequence are thus better since there is less chance of error in interpretation.

Two sets of data are presented herein. The first set (See Fig. 1) outlines a sequence of color tests that are useful in the identification and differentiation of the substituted phenothiazines listed in this paper. Only some of the reagents listed in the previous section are required for this testing sequence. The second set (See Table II) is a tabulation of the colors formed with seven of the eight reagents and may be useful to the control chemist in setting up a different sequence of tests to cover particular problems involving a more restricted group of phenothiazines.

Tests based on color formation depend upon the amount of material available and on the degree of dilution. In order to standardize conditions, tests were carried out on solutions containing 0.15% of active ingredient. This concentration value was derived from the solubility of the least soluble phenothiazine, prochlorperazine dimaleate. On this basis, reactions were carried out on solutions containing approximately 0.5 to 1.0 mg. of sample. Some of the reagents will detect much smaller quantities of material but some change in color will occur and, consequently, control samples should be run at the same time. A total of approximately 15 mg. of ingredient is generally sufficient to carry out the color tests indicated in Fig. 1.

Levomepromazine gave a violet color with all reagents except chloramine-T. This latter reagent did, however, produce an initial light violet color which then turned to the light yellow color indicated in Table II. Similarly, thioridazine gave a blue color with all reagents except palladium chloride. These two substituted phenothiazines can, therefore, be quickly and fairly accurately characterized on the basis of these particular color tests.

Fluorescent solutions resulted when the substituted phenothiazines were reacted with Reagent II and then exposed to ultraviolet radiant energy. Solutions containing acepromazine yield a bright yellow fluorescence and, on this basis, can be readily differentiated from the other 12 phenothiazines. This technique is of no further value in the identification of any single phenothiazine. It does, however, divide the remaining 12 phenothiazines into two groups, the first yielding a green fluorescence with fluphenazine, trifluoperazine, and triflupromazine and the second giving a basically blue color with the remaining substances. These observations are useful in the differentiation scheme outlined in Fig. 1. It was also observed that aqueous solutions of these substituted phenothiazines fluoresced when exposed to ultraviolet

radiant energy but this did not appear to be useful for identification purposes because the colors formed were not characteristic. Prolonged exposure to ultraviolet radiant energy will result in colored solutions but, again, this does not particularly aid the analyst in the identification of these substances. This color formation is probably due to oxidation reactions caused by the radiant energy.

Color reactions cannot be considered as final criterion in the identification of drugs and, for this reason, picrate and reineckate derivatives of the substituted phenothiazines were prepared. As expected, the monobasic phenothiazines, that is, acepromazine, chlorpromazine, levomepromazine, mepazine, promazine, thioridazine, triflupromazine, and trimeprazine formed monopicrates. The dibasic phenothiazines formed dipicrates. These derivatives can usually be purified by recrystallization from 95% ethanol. Difficulty was experienced, however, in the purification of acepromazine, levomepromazine, perphenazine, prochlorperazine, and thioridazine picrates. These derivatives were washed with water, and then with 95% ethanol, to remove undesired impurities. Levomepromazine picrate is soluble in 95% ethanol and cannot be washed with this solvent. Elementary analyses and equivalent weight determinations indicated that such washings were sufficient for purification purposes.

Dipicrates are insoluble in the glacial acetic acid-chloroform solvent system used in the determination of equivalent weight values. It was, therefore, necessary to develop a secondary technique involving the use of dimethylformamide as solvent and potassium hydroxide in methanol as titrant. The latter technique involves a titration of the picric acid portion of the molecule whereas the acetous perchloric acid method implies a determination of the phenothiazine itself. Both methods gave satisfactory results.

All reineckate derivatives were prepared in acidic medium. It has been reported that high temperatures will decompose some reineckates (14, 15) and, consequently, recrystallizations were carried out at 55°. After two recrystallizations, all derivatives were obtained as the monoreineckates. Chromium determinations on the crude materials indicated that five of the dibasic substituted phenothiazines, namely fluphenazine, perphenazine, prochlorperazine, thiopropazate, and trifluoperazine, first formed direineckates. Trifluoperazine, a dibasic compound, initially formed a monoreineckate. Recrystallization converted the direineckates described above to monoreineckates. Such conversion was also observed by Lee (15) in his study on the use of ammonium reineckate in the identification of nitrogenous organic bases.

Although the melting points of these derivatives are useful in the identification of these substances, overlapping of values does occur and, consequently, creates difficulties but only if such values are viewed alone. The analyst may turn to color formation or to infrared spectroscopy in order to resolve these difficulties. In one case, at least, crystal color aids in differentiating one picrate from another. Mepazine forms a bright yellow picrate, whereas the promazine derivative has a rusty red color.

Infrared spectra are useful in further identifying these derivatives. For the most part, the spectra of these compounds are similar and, consequently, only those of promazine picrate and trifluoperazine reineckate are illustrated over the full 2–16 μ region. It was observed, however, that the spectra of the picrates and reineckates were sufficiently different in the 8–10 and 6–8 μ regions, respectively, to permit identification of the parent substance. Figures 3 and 4 illustrate the significant portions of these spectra.

Certain bands are common to all of the picrates of the substituted phenothiazines. Strong bands occur throughout the 3.00 (OH stretching), 3.30 to 4.00 (CH stretching), 5.90 to 6.26 (C—C stretching), 6.42 (nitro stretching), 6.62 to 7.00 (benzene ring frequency), 7.35 (nitro stretching), and 13.40 to 14.10 (benzene ring frequency) μ regions. It is probable that all of these bands arise from the picric acid portion of the molecule since they are all present in the spectrum of this acid alone. In spite of all of this, special characteristics in the 8–10 μ region makes identification possible. Thus, promazine picrate can be differentiated from fluphenazine picrate by the appearance of bands of weak and medium intensity at 8.85 and 9.50 μ, respectively. Similarly, trimeprazine picrate yields a spectrum which shows two weak bands at 8.10 and 8.40 μ, bands which are not present in the spectrum of promazine picrate.

The spectra of the reineckates of the substituted phenothiazines have certain bands in common. Strong bands occur in the 4.86 and 8.00 to 8.10 (nitrile stretching) μ regions. Broad, intense bands, due to an NH stretching vibration, may be observed in the 2.96 to 3.50 μ region. As in the case of the picrates, differentiation must be based on special features in a restricted portion of the spectra. Even though heavy atoms have a damping effect on the spectrum (16), there is sufficient detail in the 6–8 μ region to permit identification of these substances. For example, fluphenazine reineckate has a band of medium intensity of 6.96 μ whereas trifluoperazine reineckate shows no such absorption. It is difficult to distinguish between perphenazine and prochlorperazine reineckates on the basis of the features in this particular region. However, a weak band does occur at 8.11 μ in the spectrum of perphenazine reineckate. No problems should occur with the evaluation of the other spectra of the derivatives of these substituted phenothiazines.

Several of the substituted phenothiazines deserve special mention. Thus, fluphenazine, trifluoperazine, and trifluopromazine possess a $-CF_3$ group within their molecules. The presence of this particular functional group is indicated in the infrared spectrum by a band at approximately 7.50 μ. Similarly, the presence of the carbonyl groups of acepromazine and thiopropazate may be established on the basis of sharp, intense bands near 5.90 μ. All of these bands occur in the spectra of either the picrate or the reineckate derivatives.

The techniques developed herein were applied to 12 commercial preparations containing various substituted phenothiazines. One of these prepara tions contained fluphenazine in concentrations equal to 0.25 mg. per tablet. This preparation could not be identified by using the techniques described herein because of the difficulties encountered in extracting this quantity of active ingredient

from the tablet mass. No difficulties were encountered with the remainder of the preparations.

CONCLUSION

Several methods are described for the identification of 13 substituted phenothiazines with tranquilizing properties. The methods are rapid and the manipulative techniques are simple.

Stability Assays of Pharmaceutical Preparations by Quantitative Paper Chromatography II

Quantitation by Spectrophotofluorometry

By HENRY R. ROBERTS and MARIA RITA SIINO

A quantitative paper chromatographic method has been developed which is routinely used as a stability assay for estrogenic hormones in castor oil and tablet formulations. The method involves: (*a*) A separation of the estrogenic hormone from interfering degradation products. (*b*) The location of the estrogenic hormone on the chromatogram by the guide strip technique employing a chromogenic agent. (*c*) The elution of the estrogenic hormone from the chromatogram. (*d*) A quantitative spectrophotofluorometric analysis of the eluate. Recoveries in excess of 95% are obtained by simultaneously chromatographing replicates of standard and sample solutions on the same chromatogram. A detailed account of the procedure is presented using as examples the assay of estradiol valerate in castor oil formulations and ethinyl estradiol in tablets.

RECENTLY we have described methods for the quantitative determination of hormone preparations using paper chromatographic separations followed by spectrophotometric analysis (1). In this paper we wish to report on techniques which permit the quantitation of estrogens in ethanol eluates by spectrophotofluorometry. The examples chosen are the quantitative determination of two estradiol derivatives, estradiol valerate in castor oil and ethinyl estradiol in tablets.

The sensitivity of the method permits the chromatography and quantitation of 10 and 20 mcg. quantities. This is important since estrogens, because of their physiological potency, are generally compounded in low concentrations, for example, 0.5% in oil formulations and 0.05% in tablets.

Fluorometric methods may be classified according to whether the fluorescence measured is that of the compound in its native state or is induced by chemical transformations. Most accepted procedures for the quantitation of estrogens fall in this second category. The fluorescence is developed in sulfuric acid and measured in the visible range (2).

The development of the spectrophotofluorometer, capable of activating and measuring fluorescence throughout the visible and ultraviolet regions, has revealed the presence of useful ultraviolet fluorescence in many compounds not previously known to fluoresce in solution.

TABLE I.—PAPER CHROMATOGRAPHIC CONDITIONS FOR ASSAY OF ESTROGENIC HORMONES

Compound	Paper Impregnating Solution	Developing Solvent	Time, hr.
Estradiol Valerate	20% Carbitol in Chloroform	Methylcyclohexane saturated with Carbitol	3
Ethinyl Estradiol	25% Propylene Glycol in Chloroform	Toluene saturated with Propylene Glycol	16

cal interest found that estradiol fluoresced in the ultraviolet region in the absence of sulfuric acid.

Based on this observation, a sensitive quantitative paper chromatographic assay has been developed which is used routinely for the analyses of estradiol derivatives in castor oil and tablet formulations.

EXPERIMENTAL

The paper chromatographic procedure involves essentially four steps: (*a*) The separation of the intact estrogenic hormone from interfering degradation products. (*b*) The location of the intact estrogenic hormone on the chromatogram by the guide strip technique employing a chromogenic agent. (*c*) The elution of the intact estrogenic hormone from the chromatogram. (*d*) A quantitative spectrophotofluorometric analysis of the eluate.

Preparation of Standard

The reference standard solution should contain 0.2 mg. of the estrogenic hormone per ml. of solution. In a volumetric flask, the appropriate amount of steroid is dissolved in the smallest volume of N,N-dimethylformamide. Then methyl isobutyl ketone is added to the mark. The reference standard material should be from the same lot as the formulation undergoing analysis.

Preparation of Sample

Oil Preparations.—For the assay of estradiol valerate in castor oil, the amount of sample which will yield, based on theory, 0.2 mg. of the hormone per ml. of solution is weighed into a volumetric flask, dissolved and diluted to the mark with methyl isobutyl ketone.

Tablet Preparations.—For the assay of ethinyl estradiol in tablets containing ethinyl estradiol and norethindrone acetate,[1] 10 tablets are reduced to a fine powder using a mortar and pestle and an amount of the powdered tablet mix which contains, based on theory, 250 mcg. of the steroid are transferred to a 60 ml. glass-stoppered bottle. Two ml. of N,N-dimethylformamide are added, the bottle stoppered, and shaken mechanically for 10 minutes, after which 3 ml. of methyl isobutyl ketone are added and the bottle shaken mechanically for an additional 10 minutes. The extract is then filtered under reduced pressure through a 15 ml. Buchner funnel (fine porosity fritted disk). If the filtrate is not clear, an asbestos pad should be used with the filter.

The filter paper used is the same as described previously (1). Methylcyclohexane saturated with Carbitol [2-(2-ethoxyethoxy) ethanol] (4) and toluene saturated with propylene glycol (5) are the two developing solvents used. Any conventional chamber used for descending paper chromatography is suitable. The chromogenic agent is made up of one part of Folin-Ciocalteu phenol reagent plus 4 parts of water (6). The eluting solvent used was 95% ethanol.

Paper Chromatographic Procedure.—Two chromatograms are run per sample. The slotted filter paper, which has been described previously (1), contains six 3/4 in. strips which are spotted for the estradiol valerate assay at 1-in. intervals along the line of origin as follows:

ORIGIN 1 2 3 4 5 6

No. 1 Chromatogram	No. 2 Chromatogram
1 = Sample, 0.05 ml.	Sample, 0.10 ml.
2 = Standard, 0.05 ml.	Standard, 0.05 ml.
3 = Standard, 0.10 ml.	Standard, 0.10 ml.
4 = Sample, 0.05 ml.	Sample, 0.10 ml.
5 = Sample, 0.05 ml.	Sample, 0.10 ml.
6 = Paper blank	Paper blank

For the ethinyl estradiol assay, both strips are spotted as follows:

ORIGIN 1 2 3 4 5 6

1 = Sample, 0.20 ml.; 2 = Standard, 0.05 ml.; 3 = Standard, 0.10 ml.; 4 = Sample, 0.20 ml.; 5 = Sample, 0.20 ml.; 6 = Paper blank.

Blow-out pipets, of 1- and 2-ml. capacity, graduated in 0.01 ml., are used to apply the standards and the sample to the paper. The spotted strips are impregnated with the stationary phase by dipping them into the appropriate chloroform solution (Table I). The procedure has been described in detail previously (1). Following solvent development (Table I), the strips are removed from the chamber and dried in a mechanical convection oven for 20 minutes at 90°.

The positions of the estrogens on the chromatogram are located by employing the guide strip technique. The strip corresponding to the No. 1 spot on each chromatogram is cut out, dipped into the diluted phenol reagent, and then exposed to

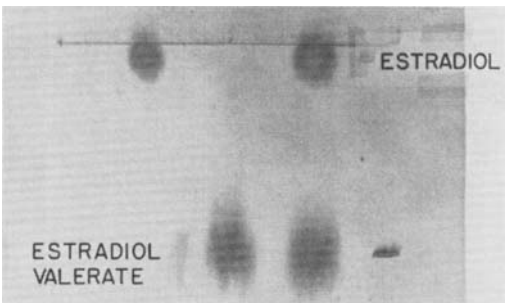

Fig. 1.—Chromatogram showing the separation achieved between estradiol valerate and estradiol in the solvent system methylcyclohexane saturated with Carbitol. Folin-Ciocalteau phenol reagent was used as the color reagent.

[1] Marketed as Gestest by E. R. Squibb & Sons.

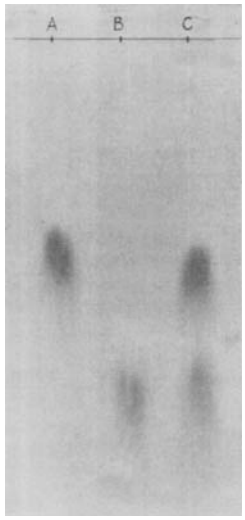

Fig. 2.—Chromatogram showing the separation achieved between ethinyl estradiol and estradiol in the solvent system toluene saturated with propylene glycol. Folin-Ciocalteau phenol reagent was used as the color reagent. A = estradiol, B = ethinyl estradiol, and C = mixture of the two.

ammonia vapors for 5 minutes by placing them into a chamber containing concentrated ammonium hydroxide. Estrogens appear on the chromatogram as blue spots against a light gray background (Figs. 1 and 2). This color development procedure is a slight modification of the procedure for the detection of estrogens on chromatograms described by Mitchell (6).

The color developed guide strip is air dried and then realigned with the untreated portion of the chromatogram. The positions of the estrogens are marked off with a solder pencil, cut out and folded, and placed in 50 ml. Erlenmeyer flasks. A paper blank, equal in area to the standard and sample segments, is included for each chromatogram. Ten milliliters of 95% ethanol are added to each flask and the estrogens are eluted off the filter paper segment by shaking on a reciprocating shaker for 30 minutes (1).

The amount of estrogens present in the eluates is determined by spectrophotofluorometry. An Aminco-Bowman spectrophotofluorometer (Cat. No. 4-8100) is used under the following conditions: clear silica cells, 10 mm. light path; 1P28 photomultiplier tube; No. 3 slit arrangement; and activation at 280 mμ and measurement of the resulting fluorescence at 310 mμ for estradiol valerate and 305 mμ for ethinyl estradiol.

The instrument is adjusted to a scale reading (on the photomultiplier-microphotometer) of 90–95, using the maximum standard eluate. The intensity of fluorescence is measured on an arbitrary 0–100 scale, using the photometer.

Calculation of Estradiol Valerate in Castor Oil Formulations.—The photometer readings are recorded on a data sheet which contains all the information necessary to calculate the concentration of estradiol valerate in the sample. Table II gives the data obtained in typical analyses.

For each of the two chromatograms, readings are obtained for the standard at two levels and for the sample at one level in duplicate. The readings of the two standards for each of the chromatograms are converted to the equivalent reading for the 0.1 ml. standard concentration and averaged. The two photometer readings of the sample are converted to 0.1 ml. readings and averaged.

The concentration of estradiol valerate in the sample is calculated from the following equation

$$\text{mg. estradiol valerate per ml. formulation} = \frac{A \times B \times C \times D}{E \times F \times G}$$

where: A = average photometer reading of 10 ml. eluate of 0.1 ml. chromatographed sample; B = weight in mg. of chromotographed 0.1 ml. standard; C = volume in ml. of sample dilution; D = specific gravity of formulation; E = average photometer reading of 10 ml. eluate of 0.1 ml. chromatographed standard; F = weight in Gm. of sample; and G = volume (0.1 ml.) of chromatographed sample.

The final concentration of estradiol valerate in the sample is obtained by averaging the values obtained for each of the two chromatograms.

Sample Calculation.—In Table II, chromatogram No. 1:

Spectrophotofluorometer specifications: Aminco-Bowman instrument, Cat. No. 4-8100; 10 mm. silica cells; 1P28 tube: No. 3 slit; activate, 280 mμ; fluorescence, 305 mμ. [b] Average: 0.051.

mg. estradiol valerate per ml. =

$$\frac{54.0 \times 0.020 \times 250 \times 1.0295}{57.75 \times 1.190 \times 0.1} = 40.5$$

Calculation of Ethinyl Estradiol in Gestest Tablets.—For each of the two chromatograms, photometer readings are obtained for the standard at two levels and for the sample at one level in duplicate. The readings of the two standards for each of the chromatograms are converted to the equivalent reading for the 0.05 ml. (or 10 γ) standard concentration and averaged. The two readings of the sample are also averaged.

The concentration of ethinyl estradiol per tablet is calculated from the following equation

$$\text{mg. ethinyl estradiol/tablet} = \frac{A \times B \times C \times D}{E \times F \times G}$$

where: A = average photometer reading of 10 ml. eluate of 0.2 ml. chromatographed sample extract; B = weight in mg. of chromatographed 0.05 ml. standard; C = theoretical weight in mg. of 1 tablet; D = volume in ml. of sample extract; E = average photometer reading of 10 ml. eluate of 0.05 ml. chromatographed standard; F = weight in mg. of sample; and G = volume (0.2 ml.) of chromatographed sample extract.

The final concentration of ethinyl estradiol per tablet is obtained by averaging the values obtained for each of the two chromatograms.

Sample Calculation.—In Table III, chromatogram No. 1

mg. ethinyl estradiol per tablet =

$$\frac{33 \times 0.0101 \times 100 \times 5}{32.5 \times 499.5 \times 0.2} = 0.052$$

The reported value, 0.051 mg. per tablet (see Table III), is the average of the values obtained for each of the chromatograms.

RESULTS AND DISCUSSION

In general, the fluorescent peak-height, as measured on the microphotometer, will be a linear function of concentration. This is true for the range of concentrations employed in the assays described here. This was demonstrated by preparing two chromatograms, each containing 10, 20, 30, 40, and 50 mcg. of ethinyl estradiol, and carrying them through the complete assay procedure. The two corrected readings were averaged for each concentration and plotted against the concentration, yielding the resulting straight line, as seen in Fig. 3.

(280–310 mμ for estradiol valerate and 280–305 mμ for ethinyl estradiol) are only apparent wavelengths. No corrections (7) have been made to provide true activation and fluorescence spectra. The apparent activation and fluorescence maxima may, therefore, vary slightly from instrument to instrument and should be determined by each investigator for his instrument.

The sensitivity of fluorescent measurement results in accurate analysis at eluate concentration ranges of 1 and 2 mcg. per ml. This, in turn, eliminates the need of any elaborate extraction procedure and permits the dilution of the oil formulation and the subsequent chromatography and resolution of estradiol valerate without interference from the oil base (which occurs at higher applications of diluted formulations to the filter paper).

While estradiol valerate in castor oil formulations is chromatographed at 10 and 20 mcg. levels, the sample extracts of ethinyl estradiol are chromatographed only at 10 mcg. levels. Ethinyl estradiol is present in Gestest at a concentration of 50 mcg. per tablet. Five hundred milligrams of powdered tablet (equivalent to 5 tablets) extracted with 5 ml. of solvent yields 50 mcg. of ethinyl estradiol per ml. of extract. Therefore, in order to chromatograph 10 mcg. of steroid, 200 μl. are spotted. To spot 20 mcg. would require 400 μl. of solution to be spotted. For this reason, the sample extract is spotted in duplicate at the 10 mcg. level.

As discussed previously (1), recoveries in excess of 95% must be obtained if any analytical method is to serve as an effective stability assay. The assay procedure described here yields results having an error less than ±5% and can accurately differentiate between preparations differing by 10%.

This was demonstrated by preparing two known estradiol valerate solutions, one at 25.2 mg./ml. and the other, 10% less, at 22.5 mg./ml. The analysis of the first solution, Table IV, gave a result of 24.65 mg. of estradiol valerate, a deviation of 2.2% from the theoretical concentration of 25.2 mg. The second solution assayed 22.75 mg. or 1.1% deviation from the theoretical concentration of 22.5 mg.

Accuracies of this magnitude are obtained since the standards and sample are run on the same chromatogram in replicate and both are exposed simultaneously to the same chromatographic and assay conditions. Table V contains additional data indicating that assays with recoveries in excess of 95% are obtained with consistency. The data also show that estradiol valerate in castor oil formulations at various concentrations is extremely stable and no breakdowns have been observed upon prolonged storage at elevated temperatures.

The stability of ethinyl estradiol in Gestest tablets plus the sensitivity and accuracy of the technique is illustrated in the data presented in Table VI. The reliability of the assay is assured when 50 mcg. of ethinyl estradiol can be measured with an accuracy of ±5% or ±2.5 mcg.

TABLE VI.—PAPER CHROMATOGRAPHIC ANALYSES OF ETHINYL ESTRADIOL IN TABLETS UNDERGOING STABILITY STUDIES

3	0.051	5	0.048	0.049
4	0.049	6	0.048	0.050
5	0.049	12	0.050	0.049
6	0.049	12	0.051	0.048

Not only does the procedure provide for an accurate analysis of ethinyl estradiol in tablets, but it achieves this without the need of any elaborate extraction. The extraction with N,N-dimethylformamide followed by dilution with methyl isobutyl ketone is all the sample preparation required.

The spectrophotofluorometric procedure for the assay of estrogenic hormones has not been applicable to those preparations which contain sesame oil. Some component or components present in the oil interfere in the spectrophotofluorometric measurement, resulting in assay figures greatly in excess of theory.

SUMMARY

1. A quantitative paper chromatographic spectrophotofluorometric procedure has been developed for the assay of estrogenic hormones.

2. The procedure is used routinely to measure the stability of a number of estrogenic hormones in castor oil and tablet formulations. The assay of estradiol valerate in castor oil and ethinyl estradiol in tablets are described in detail.

3. No extraction of the estrogenic hormones

in castor oil is required. A simple dilution with methyl isobutyl ketone is the only sample preparation required.

4. Estrogenic hormones in tablets are extracted simply with N,N-dimethylformamide followed by dilution with methyl isobutyl ketone and filtration.

5. Accuracies in excess of 95% are obtained by simultaneously chromatographing replicates of standard and sample solutions on the same chromatogram.

Adaptation of Commercial Viscometers for Special Applications in Pharmaceutical Rheology II

Severs Extrusion Rheometer

By JOHN H. WOOD, GREGORY CATACALOS, and S. V. LIEBERMAN†

The Severs rheometer has been slightly modified to provide greater flexibility of use. Besides its normal use as a rheometer, it may be used to accept samples in collapsible tubes. Such samples undergo no change in thixotropic set before actual measurement. The apparatus can also be used to shear samples of up to 700-ml. volume in a manner comparable to a high-speed filler. The method of calibrating the filler shears is outlined. Commercial fillers show shears from slightly in excess of 10,000 seconds^{-1} to 100,000 seconds^{-1}. It is demonstrated that the combination of nozzle, piston, and filler geometry is such that each can become the point of critical shear, depending on the relative dimensions of the other parts.

IN THE pharmaceutical field, couette-type instrument rheology has been largely the standard of usage because any instrument with either a range of cups and/or bobs or of springs could be adapted to take the wide range of consistencies so characteristic of this discipline. The engineering profession and the polymer, plastics, and petroleum industries tended to adapt the classical Poiseuille capillary to their special needs by increasing the radius to tubes, and even pipes, and by using pressure to increase the driving force over that of gravity alone. Such an instrument, designed by Severs (1), is commercially available. Its use with pressurized dentifrice has been described elsewhere (2). This paper is intended to show some other possible adaptations for this useful and relatively inexpensive instrument.

As a rheometer alone it is flexible and covers a wide shear-rate range but this alone does not justify special note. It is, however, readily adaptable to give useful information in two fields where the couette instrument is not directly utilizable. The first of these is the study of thixotropic systems of slow recovery in which the mere process of loading the instrument with sample partially destroys the set. Many creams, pastes, and other semisolid systems fall into this category. Two types of measurement on such

systems are then possible, conventional stress-shear rate determinations and the relative extrudibility of different formulations under constant stress. In this respect it becomes comparable to the modified De Waale plastometer described by Adler (3).

The second application, of considerable importance in industrial technology, is the application of the rheometer as a shear device to prepare samples of a known shear history for aging study. The properties of a thixotropic system of low recovery rate can be drastically changed by a subsequent shear hours or even days after original preparation. This generally is the commercial manufacturing and packaging procedure. Lotions and semisolid systems may be filled at varying times after manufacture. The filling shear will depend upon the type of equipment used, the rate of filling, and also for a given container rate, the container size filled. The calibration of a laboratory pseudofiller capable of encompassing such variables is then of practical value.

EXPERIMENTAL

The Rheometer.—The Castor-Severs extrusion rheometer, model A-100[1] was modified by the manufacturer to permit use over the range 0 to 200 p.s.i. A special sample tube of 700-ml. volume was supplied. It is 57 cm. long and 4 cm. internal diameter. This is approximately twice the length and volume of the usual rheometer. It has been found desirable to tee into the gauge line a manifold with a series of gauges for lower pressure ranges. Each is protected by a manual cut-off valve. (See Fig. 1.) Appropriate gauge calibrations were made primarily for internal self-consistency between gauges but also for absolute values. The instrument is supplied with nitrogen gas at 300 p.s.i. from cylinders. Flow times are measured with a foot pedal activated digital electric clock reading to 0.1 second. Density determinations are made in vessels suitable to the consistency of the material under investigation, fluid or semisolid. Three capillaries, 5.0 cm. long, are supplied. These have diameters of 0.6283, 0.3141, and 0.1556 cm.

Rheology of Thixotropes.—Because of the wide internal bore of the sample holder, paste-type samples can be examined if shears lower than those employed in loading can be ignored. Since such loading can be of quite low shear, this is frequently possible. More elegant, however, is the procedure of loading the sample upon preparation into conventional collapsible tubes of composition of lining compatible with the sample to be studied. Adapter plates were made by drilling a $^3/_8$-in. hole through an aluminum plate of the same dimensions as the capillary socket plate. The threaded portion of a tube cap was coaxially cemented over this hole with epoxy resin. For sample study, a tube was then uncapped, screwed into the plate, the end cut open, and the whole assembled into the rheometer with

[1] Burrell Corporation, Pittsburgh 19, Pa.

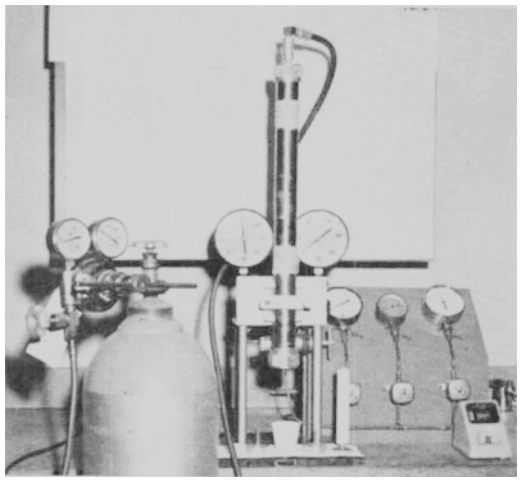

Fig. 1.—The modified Severs rheometer showing assembly and collapsible tube adapter.

the adapter plate immediately above the capillary plate. A light coat of vacuum grease is used between the two plates to prevent gas leakage. Conventional extrusion rheometry then follows. Alternately, by only using the adapter plate without the capillary, the pressure required for paste extrusion from a given sized tube may be determined for any desired delivery rates.

It has been found desirable, because of the large void space in the barrel, to prepressurize it while holding a finger over the end of the capillary. The timer is then foot activated as the finger is withdrawn. This is practical for pressures up to 100 p.s.i. The run is terminated instantly by releasing manually the extrusion pressure with the pressure release lever built into the apparatus. At the same time the timer is pedally stopped. The extrudate is caught and weighed in a tared container of suitable dimensions.

Rate of shear, D, is calculated from the equation

$$D = \frac{4Q}{\pi r^3} = \frac{4W}{\pi d r^3}$$

where Q is volume delivery per unit time, W the weight delivery per second, r is the radius of the capillary, and d the density of the extrudate.

The shearing stress, T, is given by

$$T = \frac{Pr}{2L}$$

where P is the driving pressure, and L is the length of capillary used.

Comparison values are shown in Fig. 2 for the measurement of a commercial dentifrice using each of the three capillaries in the extrusion rheometer. In addition, data were obtained from the Hercules Hi-Shear rheometer and from the D cup of the Drage Epprecht rheometer. In the latter case, the D cup was used alone and with each of the five sleeves available for it. The dentifrice system is highly thixotropic and is also pseudoplastic in rheology.

Pseudofilling.—The barrel is first charged with the sample. If the material under investigation is fluid, then the capillary is capped with a rubber plug; if the sample is semisolid then the bottom end is

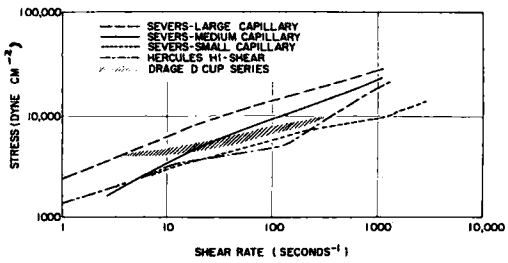

Fig. 2.—Rheograms run on an aged, strongly thixotropic, pseudoplastic dentifrice system with the Severs extrusion rheometer, the Hercules Hi-Shear rheometer, and the Drage Epprecht rheometer (D cup with sleeves).

capped with an end plate for loading and tamping, and the capillary is then put in place. Prepressurizing, as previously described, leads to the most consistent results. The appropriate volume, up to 700 ml. per charge, is then extruded at the desired rate, time of delivery and weight of extrudate being as before. For high rates of delivery, it is desirable to use two operators, one of whom notes the gauge pressure used and maintains its constancy. Under high flow rates, the diaphragm reducing system cannot deliver at sufficient rate to maintain the pressure preset at zero flow rate. If a series of points are obtained, then the resultant data also represent a high shear-rate rheogram. The samples made in this fashion are stored and monitored with passing time by low-shear measurements using our modified Brookfield system (4).

For the calibration of the equivalent shear of a filler, a full shear range set of samples are obtained by delayed filling of a thixotropic material whose "set" is partially broken by any shear at a time, days or hours, subsequent to making. Samples are simultaneously obtained from the filler. By using the exponential plot of aging behavior (5, 6), points of corresponding age and shear are compared directly for the rheometer prepared and the conventional filler samples (see Fig. 3). Equivalent shears of the filler are then noted as indicated in the graph by the solid triangles for points of identical rheological behavior. Usually the average of at least two periods of delayed fill and several periods of post-filling aging are obtained. Laboratory samples, pseudofilled equivalent to high-speed production filling, may thus be obtained for a wide range of shears to examine the effect of filling shears on subsequent rheological properties as part of a laboratory process study.

With a Colton 175–63 single nozzle filler, a study was made in the above manner of the resultant equivalent shear for two different operating speeds, two delivery piston sizes, and three filling nozzles, to permit an evaluation of whether the primary shear zone was in the piston or the orifice. Similarly two high-speed production fillers were also examined under their normal operating conditions.

RESULTS AND DISCUSSION

Rheology.—In the rheologic examination of highly thixotropic pseudoplastic systems, it is generally of sufficient utility to consider comparisons between samples made with only one measuring system. However, when two or more measuring systems are used, especially in a conventional couette system where the cup and bob ratios are changed, nonsuperimposable rheograms are obtained. Two phenomena, acting in opposition, are responsible for this. The first of these is the relaxation time of the thixotrope. The longer the time of applied shear, the greater the thinning that occurs. In a couette instrument the shear thinning at any shear rate is an integrated history of all the shear that has preceded. The measurement of a thixotropic index by the fall in torque with time is always complicated by the inability to measure the zero time value. In the capillary method, the length of the capillary sets the duration of the shear time for a given shear rate; therefore, a similar problem exists. However, the capillary is continuously using new sample so that a rheogram becomes independent of the rate at which increasing shear-rate points are taken.

The second consideration is correction for slippage either at the wall or internally. For the pseudoplastic system, which is not time dependent, Wilkinson (7) and others have outlined methods of calculation where data for various cup and bob ratios or different capillary radii are extrapolated to give measurements of torque and shear rate at the wall as the limiting case. From these extrapolations, true equations of flow may be derived.

However, for the thixotrope, the dimensions enter in a consideration of relaxation. The higher the shear-rate gradient, the greater the shear dependent thinning that occurs during a measurement. This is clearly shown in Fig. 2 for both types of measuring systems. In the couette type, as the Drage cup-to-bob ratio approached unity by the use of closer sleeves, the torque decreased for any given shear rate. For the Hercules, in which the

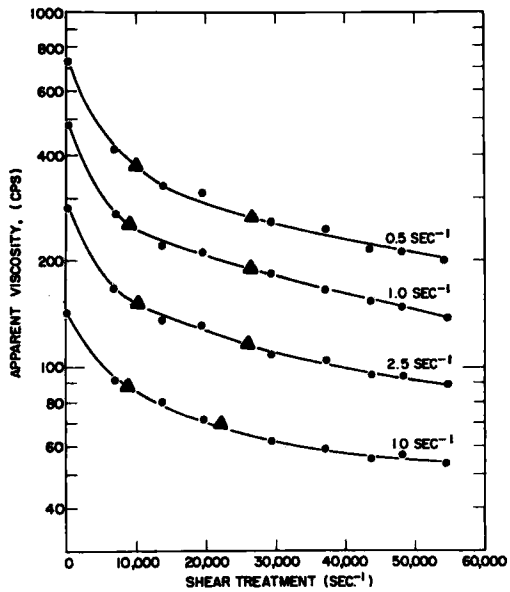

Fig. 3.—Apparent viscosities at different shear rates of a thixotropic lotion pseudofilled at various rates of shear, 2 days after manufacture. (Measurements were made after 7 days.) The triangular points represent equivalent behavior of material filled on two commercial fillers.

ratio is 0.95, the torque is even lower. Similarly decreasing radius of capillary resulted in lower torque for any given shear rate.

That the large capillary is capable of giving readings with minimal thixotropic breakdown is then evident from Fig. 2. Extrapolation procedures would indicate that the truly undisturbed readings are in excess of those found even with the large capillary.

The capillary type of measurement has another virtue. Most couettes are confined optimally to slightly over two decades of shear. In practice a given capillary is useful for almost four decades of shear rate.

Using the collapsible tube system, one restriction is necessary. The neck size must be such that a negligible portion of the shear occurs there relative to the measuring capillary.

The case shown here, the highly thixotropic dentifrice system, shows the worst possible disagreement between instruments. Normally the agreement is much more consistent and the dependency on dimensions far less critical. For nonthixotropic pseudoplastic substances, excellent agreement between measuring systems of the capillary and couette type is the general rule.

Pseudofilling.—In Fig. 3, for a cosmetic antiperspirant lotion, we see the agreement obtainable for four shear rates of measurement for the apparent shear exerted by a filler as determined by the rheological properties measured at a later date. Similar agreement was obtained between other test situations of different ages before filling and also different ages for post examination. In this way we concluded that one production filler filling 1-oz. bottles exerted a shear equivalent to approximately 25,000 seconds^{-1} while another filling 1$^1/_2$-oz. bottles gave only 12,000 seconds^{-1}, thus emphasizing the role played by filler dimensions. This was subsequently shown in detail with the Colton filler.

An examination of the equivalent shear of the Colton filler operating at full speed with full and partial stroke is given in Table I. For reduced speeds, for those nozzle, stroke, piston combinations examined the apparent shear was proportional to the delivery rate. Using the small piston, with either full or partial stroke, the primary shear zone appears to be in the region from the piston to the orifice for the large and medium orifices. The small orifice, however, either contributes to or becomes the most significant shear zone. With the large piston, it is evident that the medium orifice now contributes significantly to the shear imposed, and it is not clear whether this applied to the large orifice too. Admittedly full speed, full stroke, filling is not a commercial practicality, but these data do demonstrate the role filler shear can play in subsequently important rheological properties. The data of Table I also emphasize that filling conditions set what part of the machine becomes the source of primary shear.

TABLE I.—EFFECT OF MACHINE VARIABLES ON APPARENT SHEAR OF A COLTON FILLER

		Small Piston Delivery		Large Piston Delivery	
Stroke	Nozzle	Rate, Gm./sec.	Shear, sec.$^{-1}$	Rate, Gm./sec.	Shear, sec.$^{-1}$
Full	Large	58	37,000	143[a]	53,000
	Medium	58	37,000	171[a]	105,000
	Small	58	47,000	142[a]	112,000
Partial	Large	36	29,000	93	16,000
	Medium	37	28,000	92	54,000
	Small	38	36,000	85	78,000

[a] Possible sample loss due to splashing at such high flow rates.

Only an extrusion type rheometer is practically capable of applying shears in the range found for commercial fillers. Being able to collect samples that have been subjected to known shear rates in quantities suitable for study is a distinct advantage to the modified Severs described here.

SUMMARY

The commercially available Severs rheometer is shown to be applicable directly, and by minor adaptation, to rheological problems of concern in the properties of lotions and semisolids. By the use of samples stored in collapsible tubes of suitable composition almost "undisturbed" rheological measurements of thixotropes may be made.

The bulk preparation of samples prepared under various known rates of shear permits calibration of the apparent shear of commercial filling equipment and the study of shear dependency in the laboratory. The shear rates for filling may range from 10,000 sec.$^{-1}$ to 100,000 sec.$^{-1}$. The critical dimensions to shear in a commercial piston filler vary with the piston and orifice tube sizes used.

Compressed Coated Tablets I

Measurement and Factors Influencing Core Centration

By LEON LACHMAN, PETER P. SPEISER†, and HANNA D. SYLWESTROWICZ

A novel and accurate procedure for measuring the horizontal and vertical centration of tablet core in compressed coated tablets is described. This method of measurement permits the determination of core dislocation along and across the axis of turntable movement. The influence of size distribution of the coating granulation on core expansion and centration was studied. Results are presented for compressed coated tablets processed under similar operating characteristics on the Manesty and Kilian machines. A statistical treatment of the data was performed to permit a more meaningful interpretation and comparison of the results within one machine as well as between machines. This method for measuring core centration permits the determination of the size distribution of granulation necessary to give optimal centration.

THE PAST several years have seen the principle of coating tablets by compression meet with wide acceptance and enthusiasm in the pharmaceutical industry. This is evidenced by the numerous compressed coated tablets on the market today.

Literature reports relative to dry coating also began to appear during this time. Linde (1) and Windheuser and Cooper (2) reported on the physical properties required for core and coating granulations to give suitable compressed coated tablets. Wolff (3) presented coating and core formulations adequate for use in compression coating. Klump, *et al.* (4), have shown that the process of dry coating can be used to hide the bitter taste of active medicaments, to eliminate discoloration, and to improve the stability of active ingredients. Core formulations intended for sustained action dry coated tablets have been described by Cooper and Windheuser (5). Several reports have recently appeared in the literature pertaining to the application of an enteric coating to a core by compression methods (6–9).

It is evident from the above that considerable research has gone into the development of suitable formulas for compression coating. On the other hand, there appears to be little work reported relative to accurate methods for measuring horizontal and vertical centration of cores in compressed coated tablets. Weinstein (10) made an attempt in this direction by employing a roentgenographic technique. This consisted of including a small concentration of elemental iron in the core formulation and subsequently developing a radiographic plate showing the contrast between core and coating. Using this method the author was only able to present a general picture of core dislocation in the horizontal plane and cocking in the vertical plane.

In this report an accurate procedure for measuring horizontal and vertical centration of tablet cores in compressed coated tablets will be described. The method to be illustrated permits the determination of core dislocation in the horizontal plane, both parallel and at right angles to turntable movement, as well as maximum dislocation. In addition, it is possible to determine cocking in the vertical plane along the same three vectors and also core displacement up or down along the vertical axis. The utility of this method for determining the optimal size distribution of a coating granulation to give the most satisfactory core centration is demonstrated. This was done for the Manesty and Kilian dry coating machines using one formula granulation which was fractionated to give four granulations, each having a different size granule as its major component.

EXPERIMENTAL

Core Tablets

The core tablets were prepared according to the following formula and procedure:

Material and Formula.—Lactose U.S.P., 10.000 Kg.; wheat starch, 2.750 Kg.; Aerosil Compositum,[1] 0.750 Kg.; gelatin U.S.P., 0.250 Kg.; stearic acid, spray dried, 0.625 Kg.; charcoal, 0.125 Kg.; talcum U.S.P., 0.500 Kg.; and purified water, *q.s.*

Procedure.—The granulation was prepared according to customary wet granulating techniques using gelatin solution as the granulating agent. The wet granulation was dried at 40° in a circulating

Received March 23, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J., and Ciba Ltd., Basle, Switzerland.

Accepted for publication July 12, 1962.

The authors would like to express their sincere appreciation to Mrs. Dorothy Chen for her assistance with the statistical computations and to Miss Sarah Bassett for her aid with the measurements of core dislocation.

Presented to the Scientific Section of the A.PH.A., Las Vegas meeting, March 1962.

† Present Address: Pharmacy School, Swiss Federal Institute of Technology, Zurich, Switzerland.

[1] Aerosil Compositum is composed of 85% colloidal silica and 15% hydrolyzed starch.

air oven to a moisture content of 1.5%. The dried granulation was screened through a No. 12 mesh screen in a Fitzpatrick model D comminuting machine. Into this granulation were mixed the charcoal and stearic acid, which were previously passed through a No. 40 mesh screen.

Table I shows the sieve analysis for a representative sample of this granulation.

TABLE I.—SIEVE ANALYSIS OF CORE GRANULATION

50	0.5

Coating Granulation

Material and Formula.—This granulation was prepared according to the procedure described under the core tablets. The following was the formula used: lactose U.S.P., 16.000 Kg.; Aerosil Compositum, 1.500 Kg.; gelatin U.S.P., 0.500 Kg.; wheat starch, 2.500 Kg.; arrowroot starch, 2.500 Kg.; talcum U.S.P., 1.000 Kg.; stearic acid, spray dried, 1.000 Kg.; and purified water, *q.s.*

The granulation was then divided into four parts and each part sieved through different size screens to give granulations of different size distribution. The sieve analysis data for these four batches of granulation are presented in Table II.

TABLE II.—SIEVE ANALYSIS OF THE FOUR COATING GRANULATIONS

Preparation of Compressed Coated Tablets on Manesty DryCota and Kilian Prescoter.—The core tablets used for both machines were compressed on the core side of the Manesty DryCota model 350 at a rate of 18,000 tablets per hour. They weighed 150 mg., were 7 mm. in diameter (0.276 inch), and had a radius of curvature of 13 mm. The dry coated tablets produced weighed 400 mg., were 10 mm. in diameter (0.394 inch), and had a radius of curvature of 18 mm.

The Manesty machine is a 16-station press, while the Kilian machine has 20 stations. The die table of the Manesty machine traveled at 18.7 r.p.m. to produce 18,000 tablets per hour, while the die table on the Kilian machine traveled at a rate of 15 r.p.m. to produce the same number of tablets per hour.

Influence of Coating Size Distribution on Core Centration.—In order to determine the influence of particle size on the centering of the core in the finished compressed coated tablets, the particle size distribution of the core granulation was kept constant, while that of the coating granulation varied. Compressed coated tablets were prepared on the Manesty and Kilian machines using the four coating granulation fractions previously described. After the machine was regulated with regard to weight uniformity for each coating granulation, samples of 100 tablets were taken initially and then every 10 minutes for an hour without adjusting the machine during the hour's run. From each of these 100 compressed coated tablets, 10 were taken at random for determining horizontal centration and 20 were taken at random for vertical centration measurements. Of these 20 tablets, 10 tablets were cut crosswise to and the other ten tablets were cut along the axis of die table movement.

Core Centration Measurements

Horizontal Centration.—Figure 1 shows a schematic diagram of a die table and gives the direction of rotation of the die table used for compressing the coating granulation around the core for both the Manesty and Kilian machines. As the coated tablet begins to leave the bore of the die it is marked on the outside of the tablet cylinder with a special marking pen attached to the machine. This takes place just before the take-off point. Marking the tablets in this manner identifies the tablet position with regard to the direction of die table movement. It is then possible to measure the core dislocation along and across the axis of die table movement as illustrated in Fig. 1. In addition, by further calculation it is also possible to estimate the maximum dislocation of the core within the tablet.

In order to permit an accurate measure of core dislocation, tablets were cut along the horizontal surface to a definite depth with the device shown in Fig. 2. Then fivefold magnification photographs were taken, an example of which is shown in Fig. 3. Centration measurements were made using these photographs.

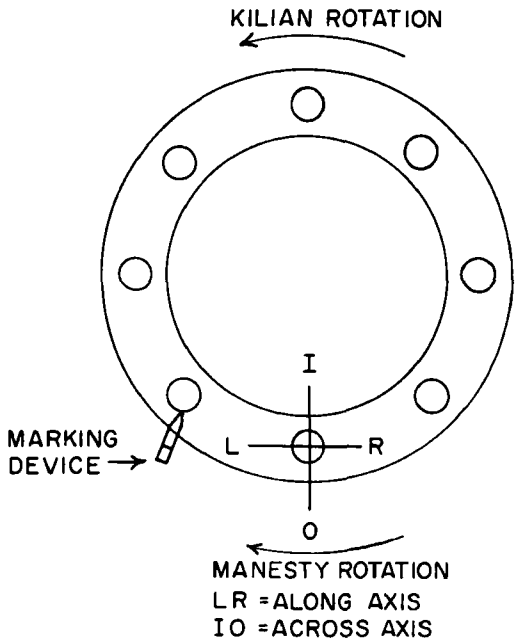

Fig. 1.—Schematic diagram of die table showing marking device attachment and direction of rotation for Manesty and Kilian machines.

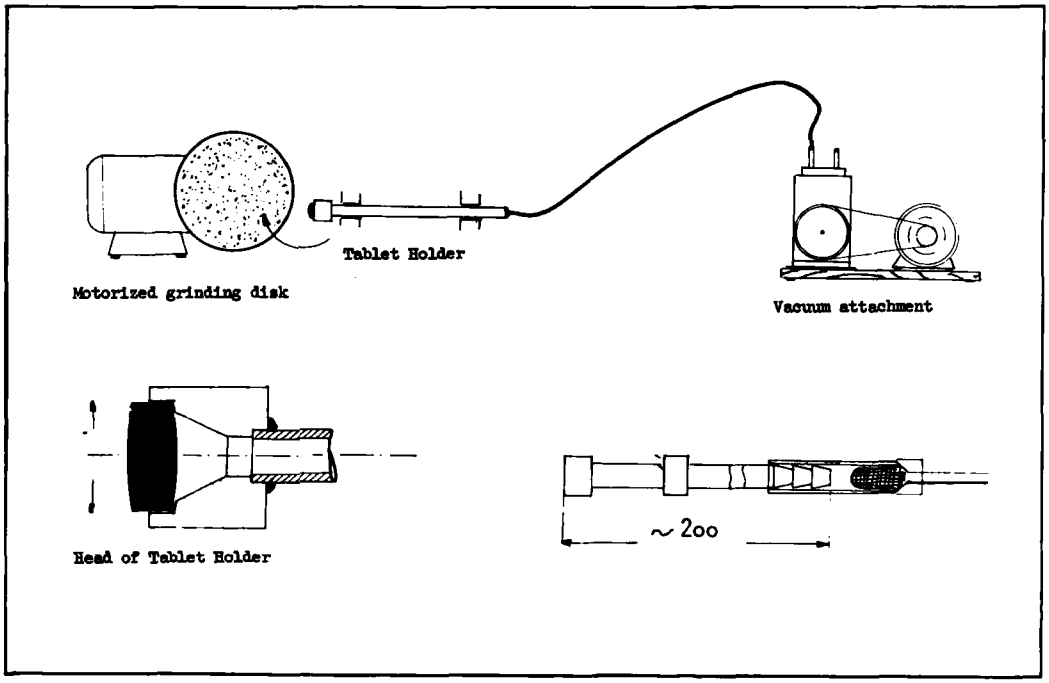

Fig. 2—Tablet cutting device.

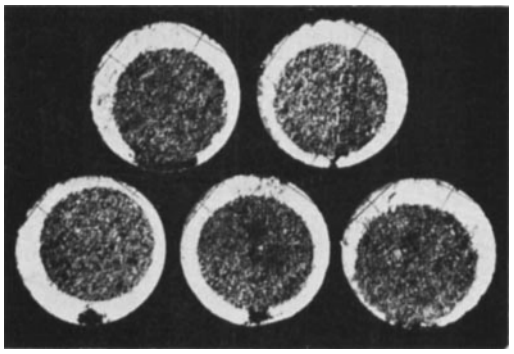

Fig. 3.—A five-fold magnification photograph of horizontal cut tablets.

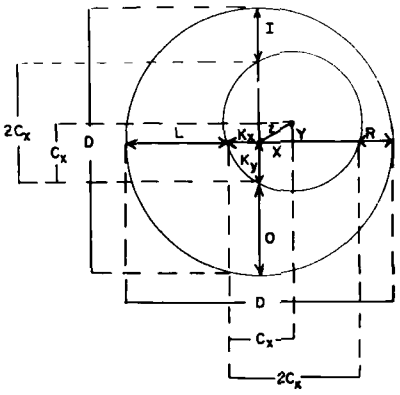
In the past, attempts to measure core centration consisted at best of determining the maximum dislocation of the core in the tablet. Only in the ideal situation, where core dislocation has taken place on the diameter of the tablet along the axis of die table movement, can direct measurements be made of core dislocation by determining the difference between the distance at the left and right between the core and coating along the diameter of the tablet. This ideal situation is seldom observed. Instead, the center of the core is dislocated from the diameter of the tablet along and across the axis of die table movement or in both directions. In this situation if any attempt is made to use the difference between the left and right side of the core edge to the coating edge, incorrect results would be obtained in the estimation of core dislocation. To accurately measure core dislocation along the horizontal plane, the geometry of the tablet was taken into consideration and equations derived to accurately determine centration "along axis" and "across axis" of die table movement and the maximum dislocation. Figure 4 represents a graphic model of the core dislocated from the center of the tablet along and across the horizontal plane. The resulting right triangle having the sides X, Y, and Z, drawn from the center of the tablet to the center of the core, was used to derive the equations needed to measure core dislocation. The equations needed to determine "along axis" dislocation of center of core from center of tablet (X), "across axis" dislocation of center of core from center of tablet (Y), and maximum dislocation of center of core from center of tablet (Z) are as follows:

$$X = \frac{L - R}{2} \qquad Y = \frac{O - I}{2} \qquad Z = \sqrt{X^2 + Y^2}$$

The symbols used in the derivation of the equations from Fig. 4 are defined as follows: D = diameter of tablet; R = distance between core and coating on the right side; L = distance between core and coating on the left side; and R and L are measurements for dislocation along the axis of turntable movement. O = distance between core and coating on the outside; I = distance between core and coating on the inside; and O and I are measurements for dislocation across the axis of turntable movement.

Now if: $X = 0$, the core is not dislocated along axis of turntable movement; $X > 0$, the core is dislocated to the right; $X < 0$, the core is dislocated to the left; $Y = 0$, the core is not dislocated across axis of turntable movement; $Y < 0$, the core is dislocated toward the outside, and if $Y > 0$, the core is dislocated toward the inside.

It is evident from the above equations that it is only necessary to know the values for L, R, I, and O to be able to determine core dislocation in the three directions X, Y, and Z. In order to measure



Derivation of Formulas for x, y and z

x	y	z
Since $x = C_x - K_x$	Since $y = C_y - K_y$	Since $z^2 = x^2 + y^2$
$K_x = \frac{D}{2} - L$	$K_y = \frac{D}{2} - O$	$z = \sqrt{x^2 + y^2}$
$2C_x = D-(R+L)$	$2C_y = D - (O+I)$	
$C_x = \frac{D-(R+L)}{2}$	$C_y = \frac{D - (O+I)}{2}$	
Then	Then	
$x = \frac{D-R-L}{2} - \frac{D}{2} + L$	$y = \frac{D-O-I}{2} - \frac{D}{2} + O$	
$x = -\frac{R}{2} - \frac{L}{2} + L$	$y = \frac{O}{2} - \frac{I}{2} + O$	
$x = \frac{L-R}{2}$	$y = \frac{O-I}{2}$	

Fig. 4.—A graphic illustration of core dislocation along horizontal plane and derivation of equations for "along axis," "across axis," and maximum dislocation of center of core from center of tablet.

these values the exact center of the tablet was determined by drawing two cords along the edge of the coating and taking the intersection of the perpendicular bisectors of these cords as the center.

Horizontal core centration was determined by measuring *R*, *L*, *I*, and *O* on 70 tablets taken from each of the four coating granulations after compression on both the Manesty and Kilian machines.

Vertical Centration.—Since the tablets were marked as they came out of the die cavity before the takeoff point, it was possible to measure core off-centering "along" and "across" the axis of die table movement by cutting the tablets along *L*, *R*, *I*, or *O*, respectively, as shown in Fig. 1. This is more adequately illustrated in Fig. 5, where the A portion shows the cutting of the tablet "across" die table movement and the B, "along" the axis of die table movement. Tablets so cut were photographed under fivefold magnification as shown in Fig. 6 and measurements for core centration were made from these photographs.

Off-centering of the core in the vertical plane can take place either by (*a*) tilting or (*b*) displacement of the center of the core up or down along the center axis of the tablet as illustrated by portions B and C, respectively, of Fig. 7. If the distances *AB* and *CD* as shown in portion A of Fig. 7 were measured, incorrect data would result. This is due to the fact that if the core shifted to the left or right of the center axis it would show up by this method of measurement. Since this dislocation is representative of off-centering in the horizontal plane, it was measured earlier. However, by measuring the dislocation along *HG* and *EF* a true indication could be obtained of core off-centering in the vertical plane, thus eliminating the interference in measurement due to horizontal dislocation. Accordingly, this technique of measuring was used to determine tilting, as illustrated by portion *B* of Fig. 7 and up and down displacement, as shown by portion C of Fig. 7.

By measuring the distances *L* and *L'* and *R* and *R'*, *O* and *O'*, and *I* and *I'*, as illustrated in portion B of Fig. 7, it is possible to determine tilt "along axis" (T), tilt "across axis" (T_l), maximum tilt (T_m), displacement "along axis" (D), and displacement "across axis" (D_l). The equations used to determine T and T_l are as follows

$$T = \frac{(R - L) + (L' - R')}{2}$$

$$T_l = \frac{(O - I) + (I' - O')}{2}$$

T and T_l could be determined from $R - L$ and $O - I$ alone, but by using the means of $(R - L)$ and $(L' - R')$ or $(O - I)$ and $(I' - O')$ more precise data are obtained by minimizing the error of measurements.

Now if: $T = 0$, no tilt takes place along axis of turntable movement; $T < 0$, the left edge of the core is tilted up; $T > 0$, the right edge of the core is tilted up; $T_l = 0$, no tilt takes place across axis of turntable movement; $T_l < 0$, the inside edge of

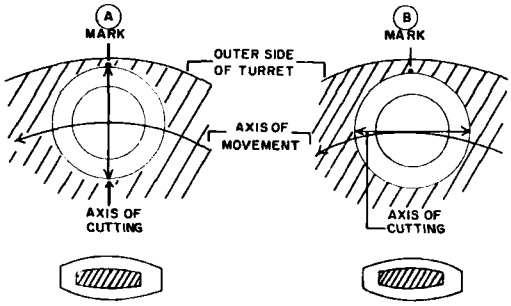


Fig. 5.—A schematic diagram showing the cutting of tablets vertically along and across the axis of die table movement.

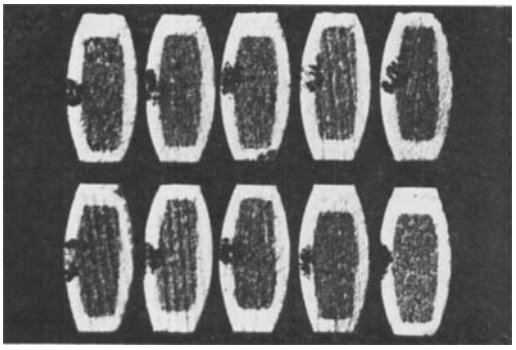

Fig. 6.—A five-fold magnification photograph of tablets cut along vertical plane.

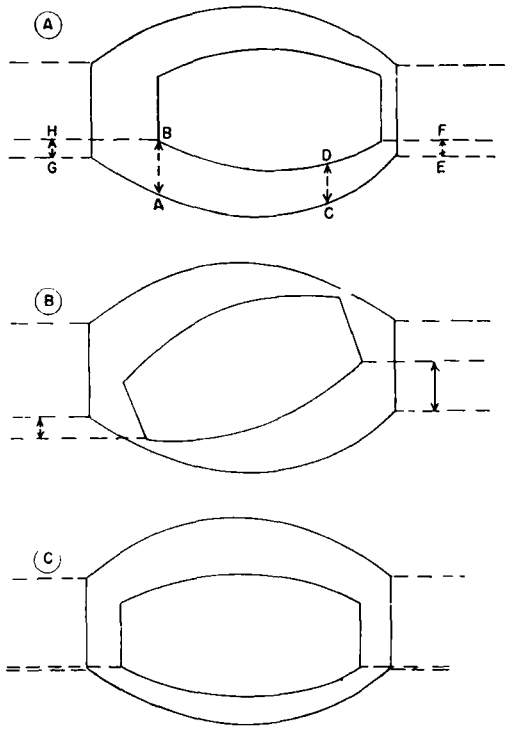

Fig. 7.—A graphical illustration indicating off-centering of core in the vertical plane of the tablet. (A) = horizontal dislocation, B = tilting, C = displacement along vertical plane. Lines AB and CD indicate improper distances to measure, while HG and EF are the correct distances to determine tilt and displacement in vertical plane.

core is tilted up; and if $T_l > 0$, the outside edge of core is tilted up.

To assist in the derivation of Tm, a spatial view of a tilted core is presented in Fig. 8. The solid line shows the tilted core and the dotted line its projection in space. The angle α is between the tilted core and its projection and opposite to T, Tl, and Tm. The triangles are right triangles. The letter ρ is equal to the radius of the core. From this figure it would appear that the values of ρ are different along the various radii, but this is only an optical illusion.

Side views of the right triangles in the spatial diagram give the projection shown by portion A of Fig. 9, and an imaginary top surface view of the tilted core is shown in portion B of Fig. 9.

From the right triangles in portion A of Fig. 9, the following equations can be derived

$$\frac{Tm}{Km} = \frac{T}{K} = \frac{T_l}{K_l} \qquad \text{(Eq. 1)}$$

or

$$\begin{aligned} TmK &= TKm \\ TmK_l &= T_lKm \end{aligned} \qquad \text{(Eq. 2)}$$

In portion B of Fig. 9, β is the same angle for both triangles because they are right triangles and the line across axis is perpendicular to the line along axis. Therefore

$$Km = \rho \qquad \text{(Eq. 3)}$$

$$K_l = \rho \cdot \cos\beta \qquad \text{(Eq. 4)}$$

$$K = \rho \cdot \sin\beta \qquad \text{(Eq. 5)}$$

By substituting Eqs. 3, 4, and 5 into Eqs. 1 and 2, we obtain the derivation for the formula to be used to measure maximum tilt (Tm)

$$\begin{aligned} Tm\,\rho \sin\beta &= T\,\rho & Tm\,\rho\cos\beta &= T_l\,\rho \\ T &= Tm \sin\beta & T_l &= Tm\cos\beta \\ T^2 &= Tm^2\sin^2\beta & T_l^2 &= Tm^2\cos^2\beta \\ T^2 + T_l^2 &= T^2m\,(\sin^2\beta + \cos^2\beta) \end{aligned}$$

since $\sin^2\beta + \cos^2\beta = 1$, then $T^2 + T_l^2 = Tm^2$ and $Tm = \sqrt{T^2 + T_l^2}$.

In the case where $T \neq 0$ and $T_l \pm 0$, Tm should be determined from the above formula. Such a situation means that the axis of maximum tilt is located somewhere between the "along axis" and the "across axis" of tablet. If the axis of maximum tilt lies on the "along axis" of tablet, then $T = 0$ and $Tm = T_l$. In the case where the maximum tilt lies on the "across axis" of tablet, $T_l = O$ and $Tm = T$.

The equations used to determine core displacement "along axis," D, and core displacement "across axis," D_l, are

$$D = \frac{(R + L) - (R' + L')}{4}$$

$$D_l = \frac{(O + I) - (O' + I')}{4}$$

These equations were derived in the following manner: If the core is displaced by the amount D upward

$$\left.\begin{matrix} R \text{ is increased by } D \\ L \text{ is increased by } D \\ R' \text{ is decreased by } D \\ L' \text{ is decreased by } D \end{matrix}\right\} (R + L) - (R' + L') = 4D$$

Therefore

$$D = \frac{(R + L) - (R' + L')}{4}$$

The derivation for D_l is analogous to D. Now if: $D = 0$, no displacement takes place along the axis; $D < 0$, downward displacement takes place along the axis; $D > 0$, upward displacement takes place along the axis; $D_l = 0$, no displacement takes place across the axis; $D_l < 0$, downward displacement takes place across the axis; and if $D_l > 0$, upward displacement takes place across the axis.

In measuring core tilting and displacement in the

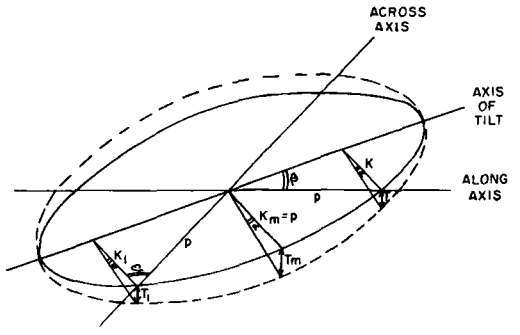

Fig. 8.—A spatial view of tilted core.

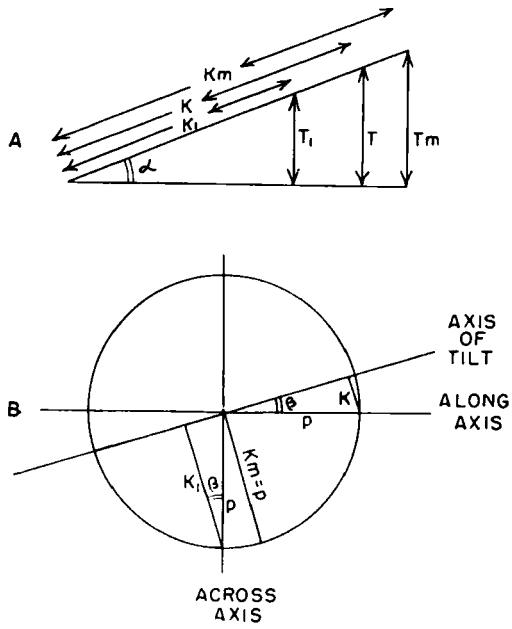

Fig. 9.—Side views of triangles of the spatial diagram A and top view of core shown in spatial diagram B.

vertical plane, measurements for R, R', L, L', O, O', and I, I' were taken for each of the four coating granulations on 70 tablets (10 tablets per each of seven time intervals) for both the Manesty and Kilian machines.

Core Expansion.—Since experience has indicated that the core tablet undergoes expansion in the lateral direction when compressed a second time in the bed of coating granulation, measurements were made of core diameter for tablets produced with the four coating granulations on each machine. The center of the core was obtained in the same manner as was described for determining the center of the tablet. Once the center of the core was obtained, the diameter measurements were readily made. These were done on the fivefold magnification photographs of the horizontally cut tablets.

Statistical Analysis of Data.—The Manesty and Kilian machines were analyzed separately and then compared for each of the following nine parameters for core centration: *1.* dislocation along axis (X), *2.* dislocation across axis (Y), *3.* maximum dislocation (Z), *4.* tilt along axis (T), *5.* tilt across axis (T_i), *6.* maximum tilt (Tm), *7.* displacement along axis (D), *8.* displacement across axis (D_i); and *9.* core expansion (E).

The purpose of this analysis was to determine whether the dislocations, tilts, and displacements were significant (comparison with the theoretical value of zero) and if they differed significantly among themselves. Additional evaluations were performed to determine if there were significant differences between the "along axis" and "across axis" dislocations and tilts.

As methods of analysis, the F test and analysis of variance were employed. In order to specify which of the means are significantly different from one another and from the theoretical zero value, a test suggested by Professor A. P. Dempster of Harvard University (11) was employed. This test is an alternative to the D. B. Duncan multiple range test (12) and is based on tables of F distribution and on the so-called 95% simultaneous confidence statement about true (unknown) means.

For the evaluation of maximum dislocation (Z) and maximum tilt (Tm) it was necessary to estimate and subtract the variance due to bias of measurement because the formulas for Z and Tm contain squared units of measurement. This bias correction was done for each granulation on each of the parameters Tm and Z.

RESULTS AND DISCUSSION

Horizontal Centration

The results obtained from the analysis of core dislocation of tablets prepared on the Manesty and Kilian machines are summarized in Tables III and

IV, respectively. The significant dislocations shown in both tables are graphically illustrated in Fig. 10.

Manesty Machine.—The tablets prepared with all four different size distribution granulations show the core to be significantly dislocated toward the right ($+X$) and to the outside ($-Y$) of the compressed coated tablet. The tablets prepared with granulation fraction 100 exhibit cores that are significantly more dislocated than the cores in the tablets prepared from the other three granulation fractions, which do not differ in dislocation among themselves.

Kilian Machine.—For this machine only the tablets prepared with granulation fractions 35 and 50 show cores that are dislocated toward the left ($-X$) and to the outside ($-Y$) of the compressed coated tablets and these dislocations differ significantly from the tablets prepared with the other two granulation fractions.

The difference between the absolute mean values for "across axis" and "along axis" core dislocations

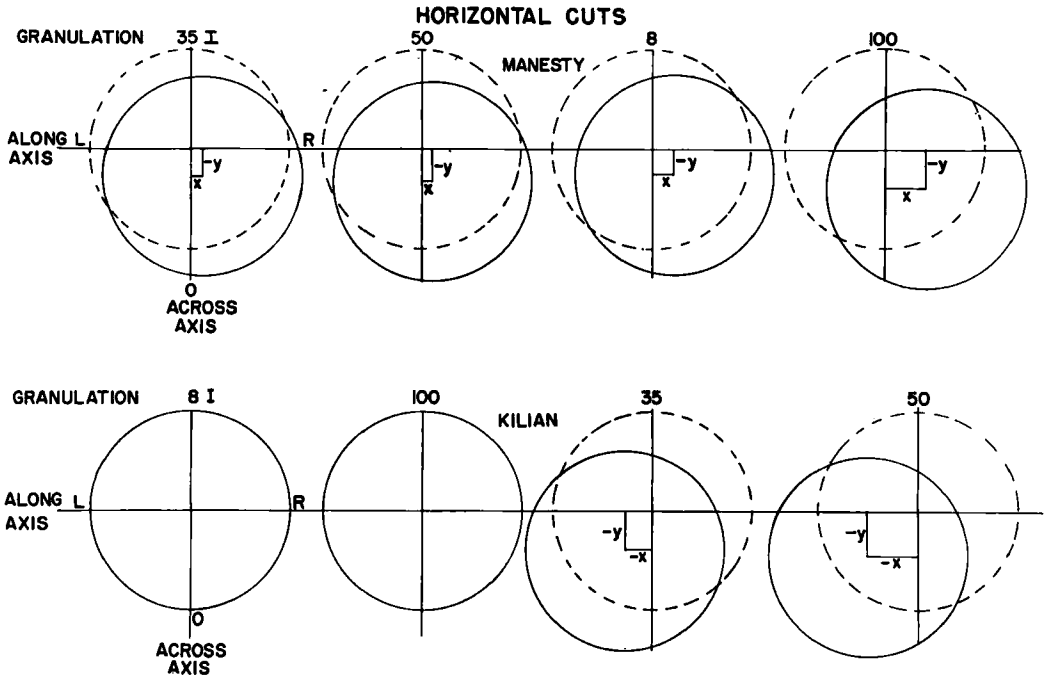

Fig. 10.—A graphic illustration of the influence of coating granulation size on core dislocation along the horizontal plane for tablets produced on the Manesty and Kilian machines. Only statistically significant dislocations are shown.

[a] Any two means not underscored by the same line are significantly different while those underscored by the same line do not differ significantly.

was proved significant only for the tablets prepared with granulation fraction 50 for the Manesty machine. This would mean that the cores are more dislocated toward the outside than toward the right position in the compressed coated tablet.

In analyzing the core dislocations of tablets prepared on the Manesty and Kilian machines, it was found that no conclusions could be drawn simultaneously for both machines. Consequently, the results for each machine must be reported separately.

Core Expansion

The results obtained for the Manesty and Kilian machines are presented in Table V. For both machines the core expansion in the tablets prepared with granulation fraction 100 is significantly smaller than that obtained with the other three granulation fractions.

Since the data for both machines, when analyzed simultaneously, showed significant interaction between machine and granulation fraction, the conclusions concerning core expansion for the granulation fractions must be drawn independently for each machine.

Vertical Centration

The data obtained from the analysis of tilt and displacement of core for the tablets prepared on the Manesty machine are summarized in Tables VI and VII and those for the Kilian machine in Tables VIII and IX. In Figs. 11 and 12 the tilt and displacement data found to be statistically significant are graphically presented for the Manesty and Kilian machines, respectively.

Manesty Machine.—From the mean values of tilt in the three directions, it seems that the tablets prepared with coating granulation fraction 8 show a consistent tendency for least tilting of core. On the other hand, the mean values of core displacement "along" and "across axis" show that the tablets prepared with granulation fraction 100 give the least displacement "along axis" and those prepared with granulation fraction 35 give the least displacement "across axis." But in each case, granulation fraction 8 results in tablets having cores exhibiting the most significant displacement. Where the displacement is significant, it is always in the upward direction for both "along" and "across axis."

Kilian Machine.—It is apparent from the data that the tilting of core has the tendency to take place in the upward direction at the left side of the tablet for the "along axis" and in the upward direction at the inside of the tablet for the "across axis" cuts. From the mean values of tilt in the three directions it is evident that the tablets prepared with granulation fractions 8 and 100 show the least tilting of core. However, for core displacement, "along" and "across" die table movement, the mean values obtained indicate that the tablets

prepared with granulation fraction 35 exhibit the best overall results.

A statistical evaluation of the difference between the absolute mean values of core tilt "across" and "along axis" of die table movement for each tablet press indicated no significant difference of tilt for "along" or "across axis."

Since the results obtained for tilt and displacement of core in the tablets produced on the Manesty and Kilian were so different, it was unreasonable to attempt a pooled analysis of the data for both machines.

GENERAL DISCUSSION

From the data presented under horizontal and

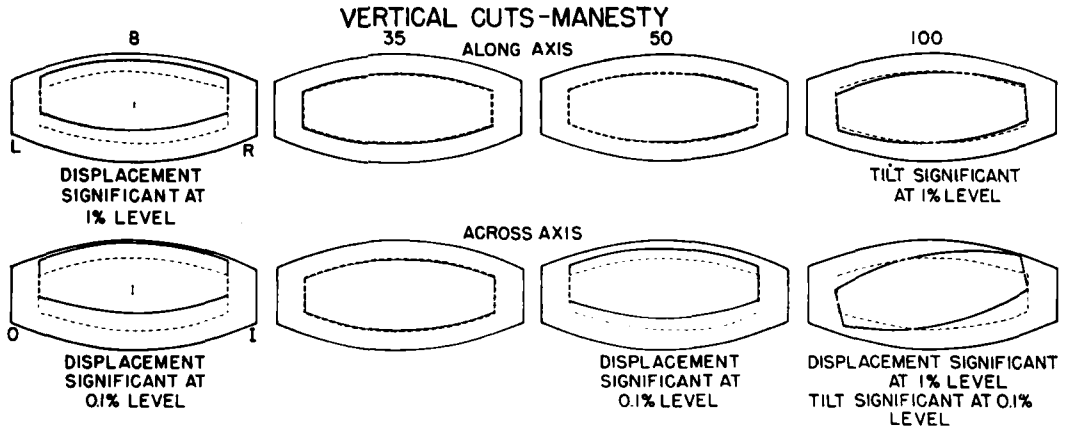

Fig. 11.—A graphic illustration indicating the influence of coating granulation size on core tilt and displacement "along" and "across" axis of die table movement for vertical cuts of tablets produced on the Manesty machine.

vertical core off-centering, it became evident that the cause for core dislocation in the horizontal cuts and core tilting and displacement in the vertical cuts could be explained by certain basic laws of physics. It seems that there are two major forces which are responsible for core dislocation, and these will be discussed in the subsequent paragraphs of this section.

As a result of the die table rotation, two forces are exerted on the tablets, one being centrifugal and the other tangential. Since the density of the core is greater than that of the coating granulation in the die, these two forces will tend to displace the core in the coating bed before the final compression step in the formation of the compressed coated tablets. The centrifugal force will tend to displace the core in the radial direction while the other force, which is tangential to the movement of the die table, will cause core displacement in the direction opposite to the rotation of die table. This effect is graphically illustrated in Fig. 13. The tangential force is dependent upon the direction of die table movement, while the centrifugal force is in the same direction for both machines. This effect is illustrated in Fig. 10, where the core is dislocated to the right and outside for the Manesty and toward the left and outside for the Kilian machine.

In the vertical plane, "across the axis" of die table movement, centrifugal force is active in causing the core to tilt toward the more stable vertical position. Because of the constraining properties of the coating granulation bed on the core, the only possible movement toward the vertical position is the lifting of the inside edge of the core in the upward direction. The core is also displaced in the upward direction along the vertical axis of the tablet. This is illustrated in Fig. 11.

For the vertical "along axis" core centration measurements, the tablets produced on the Manesty machine showed lifting of the right edge of the core and for those produced on the Kilian machine lifting of the left edge. This tilting of the core can be caused if the bottom bed of coating granulation onto which the core is deposited lies at a slant, instead of in a flat position in the die. The rotational movement of the die table would be expected to cause the bottom bed of coating granulation in the die to accumulate to a larger amount at the rear

edge of the die wall which is on the right for the Manesty and on the left for the Kilian. This larger amount of coating granulation at edge of the die would cause the coating bed to take on a tilted position in the die cavity. Subsequently, when the core tablet is deposited, it will take the tilted position of the coating bed. In the Kilian machine, where the core is imbedded into the coating bed by the free fall of the upper punch before the upper layer of coating granulation is added, the "along axis" tilt would be expected to be less due to the overall flattening out of the coating bed by the free fall of the upper punch. This was found to be the case and can be seen from the drawings in Figs. 11 and 12.
